$$\begin{pmatrix} b_{21}b_{12} - g_1g_2 + \mu R_1 h_2 & -(b_{21}g_1 + b_{11}g_2) & b_{11}b_{22} - g_1g_2 + \frac{R_2h_1}{\mu} & b_{21}g_1 + b_{11}g_2 \\ b_{22}g_1 + b_{12}g_2 & b_{22}b_{11} - g_1g_2 + \mu R_1 h_2 & -(b_{22}g_1 + b_{12}g_2) & b_{12}b_{21} - g_1g_2 + \frac{R_2h_1}{\mu} \\ -\frac{d_2}{\mu} & \frac{e}{\mu} & \frac{d_2}{\mu} & -\frac{e}{\mu} \\ -\frac{e}{\mu} & -\frac{d_1}{\mu} & \frac{e}{\mu} & \frac{d_1}{\mu} \end{pmatrix},$$

with the Rayleigh functions $R_j(\xi)$, b_{ij}, g_j, $i,j=1,2$, and the Stoneley function $S(\xi)$ defined in Appendix C; and

$$\begin{aligned} d_j(\xi) &= R_2(\xi)b_{1j}(\xi) + \mu R_1(\xi)b_{2j}(\xi), \\ e(\xi) &= R_2(\xi)g_1(\xi) - \mu R_1(\xi)g_2(\xi), \quad j=1,2. \end{aligned} \tag{3.19}$$

In the case under consideration, the equation $|\widehat{A}^-(\xi)|=0$ has no solutions (see Appendix C), and therefore the matrix $B^+(\xi)$ is bounded. Equation (3.16) is a vector functional equation, which has no known analytical solution and is difficult to solve numerically.

4. The functional equations for nonsingular unknowns. Let us reformulate (3.16) as a vector functional equation for nonsingular components of the displacements and stresses in the crack plane. We start by introducing two new unknown vector functions, the crack opening displacement (COD) $\mathbf{u}^{COD}(y_1)$ and $\mathbf{t}(y_1)$, as

$$\begin{aligned} \mathbf{u}^{COD}(y_1) &= \mathbf{u}^{(1)}(y_1,0) - \mathbf{u}^{(2)}(y_1,0), \\ \mathbf{t}(y_1) &= \frac{1}{k_1^{(1)}\mu^{(1)}}\sigma_{2i}^{(1)}(y_1,0). \end{aligned} \tag{4.1}$$

Then using the definition (3.2), their Fourier transforms $\widehat{\mathbf{u}}^{COD}(\xi)$ and $\widehat{\mathbf{t}}(\xi)$ may be expressed in terms of components of the old half unknowns $\mathbf{v}^{\pm}(\xi)$ as

$$\begin{aligned} \widehat{u}_l^{COD}(\xi) &= \widehat{v}_l^+(\xi) - \widehat{v}_{2+l}^+(\xi), \\ \widehat{t}_l(\xi) &= i\widehat{v}_{l+2}^-(\xi), \quad l=1,2. \end{aligned} \tag{4.2}$$

The last two equations in (3.16) can be rewritten in terms of the new unknowns $\widehat{\mathbf{u}}^{COD}(\xi)$ and $\widehat{\mathbf{t}}(\xi)$ as

$$-i\widehat{\mathbf{t}}(\xi) + \tilde{B}^+(\xi)\widehat{\mathbf{u}}^{COD}(\xi) = p(\xi)\tilde{\mathbf{T}}^{inc}, \tag{4.3}$$

where $p(\xi)$ is defined in (3.10); the matrix $\tilde{B}^+(\xi)$ and vector $\tilde{\mathbf{T}}^{inc}$ are bounded and are

$$\tilde{B}^+(\xi) = \frac{1}{S(\xi)}\begin{pmatrix} -d_2(\xi) & e(\xi) \\ -e(\xi) & -d_1(\xi) \end{pmatrix}, \qquad \tilde{\mathbf{T}}^{inc} = (T_3^{inc}, T_4^{inc})^T. \tag{4.4}$$

The right-hand side of the above equation has two poles, $\xi^{inc}+i0$ and $\xi^{inc}-i0$, which lie infinitely close to each other. Let us isolate one of them by introducing

$$\widehat{\mathbf{s}}(\xi) = -i\widehat{\mathbf{t}}(\xi) - \frac{1}{\xi-\xi^{inc}-i0}\tilde{\mathbf{T}}^{inc}. \tag{4.5}$$

Then the second pole $\xi^{inc}-i0$ can be shifted back to the real axis. For this reason, everywhere below we use ξ^{inc} to mean $\xi^{inc}-i0$. Using (4.5), the functional equation (4.3) can be rewritten as

$$\widehat{\mathbf{s}}(\xi) + \tilde{B}^+(\xi)\widehat{\mathbf{u}}^{COD}(\xi) = -\frac{1}{\xi-\xi^{inc}}\tilde{\mathbf{T}}^{inc}. \tag{4.6}$$

The function $\widehat{\mathbf{u}}^{COD}(\xi)$ is analytic in the upper half plane. Therefore, its domain contains both Rayleigh poles $-\xi^{R(j)}$, $j=1,2$, the incident pole $\xi=\xi^{inc}$, and also

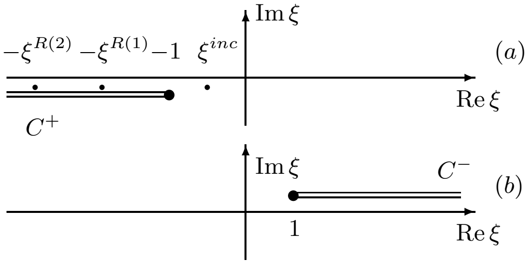

FIG. 4.1. *The poles and branch cuts of* (a) $\widehat{\mathbf{u}}^{COD}(\xi)$ *and* (b) $\widehat{\mathbf{s}}(\xi)$.

the branch cut C^+ (see Figure 4.1(a) and Appendix C). This means that we can decompose $\widehat{\mathbf{u}}^{COD}(\xi)$ as follows:

$$\widehat{\mathbf{u}}^{COD}(\xi) = \frac{G(\xi^{inc})}{G(\xi)}\widehat{\mathbf{w}}^{ge+}(\xi) + \frac{G(\xi)}{[\xi+\xi^{R(1)}][\xi+\xi^{R(2)}]}\widehat{\mathbf{w}}^{+}(\xi), \tag{4.7}$$

where $G(\xi)$ is defined in Appendix D, $\widehat{\mathbf{w}}^{ge+}(\xi)$ has the pole at $\xi = \xi^{inc}$, and $\widehat{\mathbf{w}}^{+}(\xi)$ is a new unknown vector describing the edge diffracted body and surface waves. Note that as $\xi \to \infty$, the function $G(\xi) \sim \xi$, and therefore $\widehat{\mathbf{w}}^{+}(\xi)$ behaves as $\xi\widehat{\mathbf{u}}^{COD}(\xi)$.

The function $\widehat{\mathbf{w}}^{ge+}(\xi)$ can be chosen to be

$$\begin{aligned}\widehat{\mathbf{w}}^{ge+}(\xi) = &-\frac{1}{\xi-\xi^{inc}}\tilde{B}^{-}(\xi^{inc})\tilde{\mathbf{T}}^{inc}\\ &+\frac{1}{\xi-\xi^{inc}}\frac{1}{G(\xi^{inc})}\sum_{k=1}^{4}F_k^{+}(\xi,\xi^{inc})\Delta_k^{+}[G(\xi)\tilde{B}^{-}(\xi)]\big|_{\xi=\xi^{inc}}\tilde{\mathbf{T}}^{inc},\end{aligned} \tag{4.8}$$

where the auxiliary functions $F_k^{+}(\xi,\zeta)$, $k = 1,\dots,4$, are defined in Appendix D; we have

$$\tilde{B}^{-}(\xi) = \frac{1}{R_1(\xi)R_2(\xi)}\begin{pmatrix} -d_1(\xi) & -e(\xi) \\ e(\xi) & -d_2(\xi) \end{pmatrix}, \tag{4.9}$$

and for any function $\Phi(\xi)$ we denote by $\Delta_k^{+}\Phi(\xi)$ the jump of $\Phi(\xi)$ over the branch cut C_k^{+} defined in (D.4) of Appendix D.

Analogously, the function $\widehat{\mathbf{s}}(\xi)$ is analytic in the lower half plane, and we can write the decomposition

$$\widehat{\mathbf{s}}(\xi) = \widehat{\mathbf{w}}^{ge-}(\xi) + \widehat{\mathbf{w}}^{-}(\xi), \tag{4.10}$$

where $\widehat{\mathbf{w}}^{ge-}(\xi)$ is introduced to cancel the extraneous incident pole appearing on the negative side of the branch cut C^- (see Figure 4.1(b)) and $\widehat{\mathbf{w}}^{-}(\xi)$ is a new unknown vector. The function $\widehat{\mathbf{w}}^{ge-}(\xi)$ can be chosen to be

$$\widehat{\mathbf{w}}^{ge-}(\xi) = -\frac{1}{\xi-\xi^{inc}}\sum_{k=1}^{4}F_k^{-}(\xi,\xi^{inc})\Delta_k^{-}[\tilde{B}^{+}(\xi)]\big|_{\xi=\xi^{inc}}\tilde{B}^{-}(\xi^{inc})\tilde{\mathbf{T}}^{inc}, \tag{4.11}$$

where the auxiliary functions $F_k^{-}(\xi,\zeta)$ are defined in Appendix D and $\Delta_k^{-}\Phi(\xi)$ denotes a jump of a function $\Phi(\xi)$ over the branch cut C_k^{-} defined in (D.4). It can be shown that whether or not $\xi = \xi^{inc}$ lies close to the branch cut C^-, we can always use the definition (4.11).

Let us substitute decompositions (4.7) and (4.10) into the functional equation (4.6) to obtain a functional equation for the new unknowns $\widehat{\mathbf{w}}^+(\xi)$ and $\widehat{\mathbf{w}}^-(\xi)$,

$$\widehat{\mathbf{w}}^-(\xi) + M^+(\xi)\widehat{\mathbf{w}}^+(\xi) = \mathbf{V}^{inc-}(\xi), \tag{4.12}$$

where the matrix $M^+(\xi)$ is given by

$$M^+(\xi) = \frac{G(\xi)}{(\xi^{R(1)} + \xi)(\xi^{R(2)} + \xi)}\tilde{B}^+(\xi) \tag{4.13}$$

and the vector $\mathbf{V}^{inc-}(\xi)$ on the right-hand side of (4.12) can be written as

$$\mathbf{V}^{inc-}(\xi) = -\frac{1}{\xi - \xi^{inc}}\tilde{\mathbf{T}}^{inc} - \frac{G(\xi^{inc})}{G(\xi)}\tilde{B}^+(\xi)\widehat{\mathbf{w}}^{ge+}(\xi) - \widehat{\mathbf{w}}^{ge-}(\xi). \tag{4.14}$$

Multiplying (4.12) by the inverse matrix $[M^+(\xi)]^{-1}$, we obtain the functional equation

$$\widehat{\mathbf{w}}^+(\xi) + M^-(\xi)\widehat{\mathbf{w}}^-(\xi) = \mathbf{V}^{inc+}(\xi), \tag{4.15}$$

where $M^-(\xi) = [M^+(\xi)]^{-1}$, so that we have

$$M^-(\xi) = \frac{(\xi^{R(1)} + \xi)(\xi^{R(2)} + \xi)}{G(\xi)R_1(\xi)R_2(\xi)}\begin{pmatrix} -d_1(\xi) & -e(\xi) \\ e(\xi) & -d_2(\xi) \end{pmatrix}, \tag{4.16}$$

and the vector $\mathbf{V}^{inc+}(\xi)$ is

$$\mathbf{V}^{inc+}(\xi) = M^-(\xi)\mathbf{V}^{inc-}(\xi). \tag{4.17}$$

The functional vector equations (4.12) and (4.15) form a system of four functional equations in four unknowns.

5. The system of integral equations. Since the vector $\widehat{\mathbf{w}}^+(\xi)$ introduced in the decomposition (4.7) has no poles and vanishes at infinity, it can be represented as a Hilbert transform

$$\widehat{\mathbf{w}}^+(\xi) = -\frac{1}{2\pi i}\int_1^\infty \frac{\Delta\mathbf{w}^+(\xi')}{\xi' + \xi}d\xi', \tag{5.1}$$

where $\Delta\mathbf{w}^+(\xi)$ is a jump of $\widehat{\mathbf{w}}^+(\xi)$ over the branch cut C^+ (see Figure 4.1(a)); i.e., we have

$$\Delta\mathbf{w}^+(\xi) = \widehat{\mathbf{w}}^+(-\xi + i0) - \widehat{\mathbf{w}}^+(-\xi - i0), \quad \xi > 1. \tag{5.2}$$

Also, the vector $\widehat{\mathbf{w}}^-(\xi)$ introduced in (4.10) can be represented as

$$\widehat{\mathbf{w}}^-(\xi) = -\frac{1}{2\pi i}\int_1^\infty \frac{\Delta\mathbf{w}^-(\xi')}{\xi' - \xi}d\xi', \tag{5.3}$$

where, for $\xi \in C^-$, $\Delta\mathbf{w}^-(\xi)$ is a jump of $\widehat{\mathbf{w}}^-(\xi)$ over the branch cut C^-(see Figure 4.1(b)); i.e., we have

$$\Delta\mathbf{w}^-(\xi) = \widehat{\mathbf{w}}^-(\xi - i0) - \widehat{\mathbf{w}}^-(\xi + i0), \quad \xi > 1. \tag{5.4}$$

Note that $\widehat{\mathbf{w}}^{+}(\xi)$ and $\widehat{\mathbf{w}}^{-}(\xi)$ have the same branches as $\widehat{\mathbf{v}}^{+}(\xi)$ and $\widehat{\mathbf{v}}^{-}(\xi)$, respectively (see, e.g., [9]).

Let us now substitute (5.1) into (4.15), (5.3) into (4.12), and calculate the jumps in the resulting equations across the branch cuts C^+ and C^-, respectively. Then for $\xi > 1$ we have

$$\begin{aligned} &\Delta\mathbf{w}^{+}(\xi) + \Delta M^{-}(-\xi)\widehat{\mathbf{w}}^{-}(-\xi) = \Delta\mathbf{V}^{inc+}(\xi),\\ &\Delta\mathbf{w}^{-}(\xi) + \Delta M^{+}(\xi)\widehat{\mathbf{w}}^{+}(\xi) = \Delta\mathbf{V}^{inc-}(\xi), \end{aligned} \tag{5.5}$$

where Δ denotes the jump over the cut, $\xi \in C^-$, and we use the notation

$$\Delta M^{\pm}(\pm\xi) = 2i\,\mathrm{Im}\,M^{\pm}(\pm\xi), \quad \xi \geq 1. \tag{5.6}$$

In view of (3.10), (4.16), (5.2), (5.4), and the definitions of the functions $F_k^{\pm}(\xi, a)$, $k = 1, \dots, 4$ (see Appendix D), the apparent poles $\xi = \xi^{R(j)}$ and $\xi = \pm\xi^{inc}$ in (5.5) are in fact absent (their residues are zero). Decompositions (4.8) and (4.11) have been chosen in order to achieve this regularization.

Equation (5.5) can be rewritten as the system of coupled integral equations

$$\begin{aligned} &\Delta\mathbf{w}^{+}(\xi) - \frac{1}{\pi}\mathrm{Im}\,[M^{-}(-\xi)]\int_1^\infty \frac{\Delta\mathbf{w}^{-}(\xi')}{\xi+\xi'}d\xi' = \Delta\mathbf{V}^{inc+}(\xi),\\ &\Delta\mathbf{w}^{-}(\xi) - \frac{1}{\pi}\mathrm{Im}\,[M^{+}(\xi)]\int_1^\infty \frac{\Delta\mathbf{w}^{+}(\xi')}{\xi+\xi'}d\xi' = \Delta\mathbf{V}^{inc-}(\xi). \end{aligned} \tag{5.7}$$

6. The numerical scheme. As mentioned above, we seek the solution of (5.7) that allows the tip condition (2.8) to be satisfied, that is, exhibit the asymptotic behavior

$$\Delta\mathbf{w}(\xi) \to \xi^{-1/2}[\mathbf{D}^{+}\cos(\nu_0 \ln\xi) + \mathbf{D}^{-}\sin(\nu_0\ln\xi)], \quad \xi \to \infty, \tag{6.1}$$

where ν_0 is a bimaterial constant; $\mathbf{D}^{\pm}$ are unknown four dimensional constant vectors, and $\Delta\mathbf{w}(\xi) = (\Delta w_1^{+}(\xi), \Delta w_2^{+}(\xi), \Delta w_1^{-}(\xi), \Delta w_2^{-}(\xi))$ is the unknown four dimensional vector function.

Let us rewrite the system of (5.7) as one vector integral equation,

$$\Delta\mathbf{w}(\xi) - \frac{1}{\pi}M(\xi)\int_1^\infty \frac{\Delta\mathbf{w}(\xi')}{\xi'+\xi}d\xi' = \Delta\mathbf{V}^{inc}(\xi), \tag{6.2}$$

where we use the notation

$$\Delta\mathbf{V}^{inc}(\xi) = (\Delta {V_1}^{inc+}(\xi), \Delta {V_2}^{inc+}(\xi), \Delta {V_1}^{inc-}(\xi), \Delta {V_2}^{inc-}(\xi))^T,$$

with $\Delta {V_i}^{inc\pm}(\xi),\ i = 1, 2$, being the right-hand side of (5.5) and $M(\xi)$ being the 4×4 matrix that can be written as

$$M(\xi) = \begin{pmatrix} 0_2 & \mathrm{Im}\,[M^{-}(-\xi)] \\ \mathrm{Im}\,[M^{+}(\xi)] & 0_2 \end{pmatrix}. \tag{6.3}$$

Then there exists a constant L_2 such that for $\xi \geq L_2$ the solution $\Delta\mathbf{w}(\xi)$ exhibits the behavior (6.1) and we can rewrite (6.2) as

$$\Delta\mathbf{w}(\xi) - \frac{1}{\pi}M(\xi)\int_1^{L_2} \frac{\Delta\mathbf{w}(\xi')}{\xi'+\xi}d\xi' - \frac{1}{\pi}M(\xi)[\mathbf{D}^{+}I^{+}(\xi) + \mathbf{D}^{-}I^{-}(\xi)] = \Delta\mathbf{V}^{inc}(\xi), \tag{6.4}$$

where we use the notation

$$
\begin{aligned}
I^+(\xi) &= \frac{1}{2}\left(\int_{L_2}^{\infty} \frac{x^{-1/2+i\nu_0}}{x+\xi}dx + \int_{L_2}^{\infty} \frac{x^{-1/2-i\nu_0}}{x+\xi}dx\right),\\
I^-(\xi) &= \frac{1}{2i}\left(\int_{L_2}^{\infty} \frac{x^{-1/2+i\nu_0}}{x+\xi}dx - \int_{L_2}^{\infty} \frac{x^{-1/2-i\nu_0}}{x+\xi}dx\right).
\end{aligned}
\tag{6.5}
$$

The integral in (6.4) can be approximated using N collocation points $\xi_i,\ i = 1, N$, and weights $W_i,\ i = 1, N$, so that (6.4) may be approximated by

$$
\Delta\mathbf{w}(\xi) - \frac{1}{\pi}M(\xi)\sum_{i=1}^{N}\frac{\Delta\mathbf{w}(\xi_i)}{\xi_i+\xi}W_i - \frac{1}{\pi}M(\xi)[\mathbf{D}^+I^+(\xi) + \mathbf{D}^-I^-(\xi)] = \Delta\mathbf{V}^{inc}(\xi),
\tag{6.6}
$$

which at $\xi = \xi_j,\ j = 1, N$, becomes

$$
\Delta\mathbf{w}(\xi_j) - \frac{1}{\pi}M(\xi_j)\sum_{i=1}^{N}\frac{\Delta\mathbf{w}(\xi_i)}{\xi_i+\xi_j}W_i - \frac{1}{\pi}M(\xi_j)[\mathbf{D}^+I^+(\xi_j) + \mathbf{D}^-I^-(\xi_j)] = \Delta\mathbf{V}^{inc}(\xi_j),
\quad j = 1, \dots, N.
\tag{6.7}
$$

System (6.7) contains $4N$ equations with $4N+8$ unknowns $\Delta w_i(\xi_j),\ i = 1, 4,\ j = 1, N$, and $D_i^{\pm},\ i = 1, 4$, and is thus underdetermined. Four extra equations are provided by the continuity of the solution at the point $\xi_N = L_2$ and can be written as

$$
\Delta\mathbf{w}(\xi_N) = \xi_N^{-1/2}\left[\mathbf{D}^+\cos(\nu_0\ln\xi_N) + \mathbf{D}^-\sin(\nu_0\ln\xi_N)\right].
\tag{6.8}
$$

Four more can be supplied by the relation (E.15) (see Appendix E). The resulting algebraic system of $4N+8$ equations in $4N+8$ unknowns can be written as

$$
M\Delta\mathbf{w} = \mathbf{f},
\tag{6.9}
$$

where the $4N+8$ dimensional vectors are

$$
\begin{aligned}
&\Delta\mathbf{w} = (\Delta w_1(\xi_1), \Delta w_2(\xi_1), \Delta w_3(\xi_1), \Delta w_4(\xi_1), w_1(\xi_2), \dots,\\
&\qquad\qquad \Delta w_4(\xi_N), D_1^+, \dots, D_4^+, D_1^-, \dots, D_4^-),\\
&\mathbf{f} = (\Delta V_1^{inc}(\xi_1), \dots, \Delta V_4^{inc}(\xi_1), \Delta V_1^{inc}(\xi_2), \dots, \Delta V_4^{inc}(\xi_N), 0, 0, 0, 0, 0, 0, 0, 0),
\end{aligned}
\tag{6.10}
$$

and matrix M may be given in a block form as

$$
M =
\begin{pmatrix}
I_4 - \frac{M(\xi_1)W_1}{2\pi\xi_1} & -\frac{M(\xi_1)W_2}{\pi(\xi_1+\xi_2)} & \cdots & -\frac{M(\xi_1)W_{N-1}}{\pi(\xi_1+\xi_{N-1})} & -\frac{M(\xi_1)W_N}{\pi(\xi_1+\xi_N)} & M^D(\xi_1)\\
-\frac{M(\xi_2)W_1}{\pi(\xi_1+\xi_2)} & I_4 - \frac{M(\xi_2)W_2}{2\pi\xi_2} & \cdots & -\frac{M(\xi_2)W_{N-1}}{\pi(\xi_2+\xi_{N-1})} & -\frac{M(\xi_2)W_N}{\pi(\xi_2+\xi_N)} & M^D(\xi_2)\\
\vdots & \vdots & \vdots & \vdots & \vdots & \vdots\\
-\frac{M(\xi_N)W_1}{\pi(\xi_1+\xi_N)} & -\frac{M(\xi_N)W_2}{\pi(\xi_2+\xi_N)} & \cdots & -\frac{M(\xi_N)W_{N-1}}{\pi(\xi_N+\xi_{N-1})} & I_4 - \frac{M(\xi_N)W_N}{2\pi\xi_N} & M^D(\xi_N)\\
0_4 & 0_4 & \cdots & 0_4 & I_4 & M^{V1}\\
0_4 & 0_4 & \cdots & 0_4 & 0_4 & M^{V2}
\end{pmatrix},
\tag{6.11}
$$

where we use the notation

$$\begin{aligned} &M^D(\xi) = -\frac{1}{\pi} M(\xi) J\left(I^+(\xi), I^-(\xi)\right), \\ &M^{V1} = -J\left(\xi_N^{-1/2}\cos(\nu_0 \ln \xi_N), \xi_N^{-1/2}\sin(\nu_0 \ln \xi_N)\xi_N)\right), \end{aligned} \tag{6.12}$$

with matrix $J\left(f_1(\xi), f_2(\xi)\right)$ given by

$$J\left(f_1(\xi), f_2(\xi)\right) = \begin{pmatrix} f_1(\xi) & f_2(\xi) & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & f_1(\xi) & f_2(\xi) & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & f_1(\xi) & f_2(\xi) & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & f_1(\xi) & f_2(\xi) \end{pmatrix}, \tag{6.13}$$

and

$$M^{V2} = \begin{pmatrix} I_2 & -\sqrt{\frac{m_\infty^-}{m_\infty^+}} I_2 & 0_2 & 0_2 \\ 0_2 & 0_2 & I_2 & -\sqrt{\frac{m_\infty^-}{m_\infty^+}} I_2 \end{pmatrix}. \tag{6.14}$$

To evaluate integrals $I^{\pm}(\xi)$ in (6.5), we consider two cases:

- Case 1: $\xi \le L_2$. It is easy to see that we can write

  $$\frac{x}{x+\xi} = \sum_{k=0}^{\infty} (-1)^k \left(\frac{\xi}{x}\right)^k, \tag{6.15}$$

  where the right-hand side is the geometric series with the common ratio $-\xi/x$ such that $|\xi/x| < 1$. Therefore, we have

  $$\int_{L_2}^{\infty} \frac{x^{-1/2 \pm i\nu_0}}{x+\xi} dx = \int_{L_2}^{\infty} x^{-3/2 \pm i\nu_0} \sum_{k=0}^{\infty} (-1)^k \left(\frac{\xi}{x}\right)^k dx. \tag{6.16}$$

  Exchanging in the right-hand side the order of summation and integration and evaluating the resulting integrals, we obtain

  $$\int_{L_2}^{\infty} \frac{x^{-1/2 \pm i\nu_0}}{x+\xi} dx = (L_2)^{-1/2 \pm i\nu_0} \sum_{k=0}^{\infty} \frac{(-1)^k}{0.5 + k \mp i\nu_0} \left(\frac{\xi}{L_2}\right)^k. \tag{6.17}$$

  Substituting (6.17) into (6.5) gives us

  $$\begin{aligned} I^+(\xi) &= \frac{1}{\sqrt{L_2}} \left\{ S_1\left(\frac{\xi}{L_2}\right) \cos(\nu_0 \ln L_2) - \nu_0 S_2\left(\frac{\xi}{L_2}\right) \sin(\nu_0 \ln L_2) \right\}, \\ I^-(\xi) &= \frac{1}{\sqrt{L_2}} \left\{ S_1\left(\frac{\xi}{L_2}\right) \sin(\nu_0 \ln L_2) + \nu_0 S_2\left(\frac{\xi}{L_2}\right) \cos(\nu_0 \ln L_2) \right\}, \end{aligned} \tag{6.18}$$

  where we use the notation

  $$S_1(\xi) = \sum_{k=0}^{\infty} \frac{(-1)^k (0.5+k)}{(0.5+k)^2 + \nu_0^2} \xi^k, \qquad S_2(\xi) = \sum_{k=0}^{\infty} \frac{(-1)^k}{(0.5+k)^2 + \nu_0^2} \xi^k. \tag{6.19}$$

Note that, according to the Leibnitz theorem, the alternating series $S_i(\xi/L_2)$, $i = 1, 2$, converge. The difference between the infinite series and partial sum $S_{iN}(\xi/L_2)$ does not exceed the $(N + 1)$th term. This property can be used to establish the number of terms necessary to achieve the required accuracy. The latter can be improved further if instead of a partial sum S_{iN} we use S_{iN} plus one half of the $(N + 1)$th term. Then the error in $S_i(\xi/L_2)$, $i = 1, 2$, is $O(k^{-i-1})$ rather than $O(k^{-i})$.

- Case 2: $\xi > L_2$. Let us rewrite each term in (6.5) as

$$\int_{L_2}^{\infty} \frac{x^{-1/2\pm i\nu_0}}{x+\xi}dx = \int_{0}^{\infty} \frac{x^{-1/2\pm i\nu_0}}{x+\xi}dx - \int_{0}^{L_2} \frac{x^{-1/2\pm i\nu_0}}{x+\xi}dx. \tag{6.20}$$

The first integral can be evaluated to give

$$\int_{0}^{\infty} \frac{x^{-1/2\pm i\nu_0}}{x+\xi}dx = \frac{\pi}{\cosh \pi\nu_o}\xi^{-1/2\pm i\nu_0} \tag{6.21}$$

(see, e.g., [20]). The integrand of the second term in (6.20) can be represented as

$$\frac{x^{-1/2\pm i\nu_0}}{x+\xi} = \sum_{k=0}^{\infty} \frac{x^{-1/2+k\pm i\nu_0}}{\xi^{k+1}}. \tag{6.22}$$

Integrating both sides of (6.22) over $\xi \in [0, L_2]$ and using (6.21), the integral (6.20) can be represented as

(6.23)
$$\int_{L_2}^{\infty} \frac{x^{-1/2\pm i\nu_0}}{x+\xi}dx = \frac{\pi}{\cosh \pi\nu_o}\xi^{-1/2\pm i\nu_0} - \frac{(L_2)^{0.5\pm i\nu_0}}{\xi}\sum_{k=0}^{\infty} \frac{(-1)^k}{0.5+k\pm i\nu_0}\left(\frac{L_2}{\xi}\right)^k.$$

Therefore, (6.5) becomes

$$\begin{aligned} I^+(\xi) &= -\frac{\sqrt{L_2}}{\xi}\left\{S_1\left(\frac{L_2}{\xi}\right)\cos(\nu_0 \ln L_2) + \nu_0 S_2\left(\frac{L_2}{\xi}\right)\sin(\nu_0 \ln L_2)\right\} \\ &\quad + \frac{\pi}{\sqrt{\xi}\cosh \pi\nu_0}\cos(\nu_0 \ln \xi), \\ I^-(\xi) &= -\frac{\sqrt{L_2}}{\xi}\left\{S_1\left(\frac{L_2}{\xi}\right)\sin(\nu_0 \ln L_2) - \nu_0 S_2\left(\frac{L_2}{\xi}\right)\cos(\nu_0 \ln L_2)\right\} \\ &\quad + \frac{\pi}{\sqrt{\xi}\cosh \pi\nu_0}\sin(\nu_0 \ln \xi). \end{aligned} \tag{6.24}$$

Note that, similarly to the previous case, according to the Leibnitz theorem, the alternating series $S_i(L_2/\xi)$, $i = 1, 2$, converge, and instead of the partial sum S_{iN}, we can utilize S_{iN} plus one half of the $(N + 1)$th term.

The resulting linear system (6.9) can be solved numerically using the LU decomposition subroutines from the LAPACK library. After the unknowns are evaluated at the nodes, system (6.6) can be used to extrapolate the solution for any $\xi \geq 1$. Note that in system (6.9) the integrals $I^{\pm}(\xi)$ are calculated at $\xi \leq L_2$, and therefore when solving this system we utilize only (6.18). When extrapolating, (6.24) is used instead. It is easy to see that, whatever the case, the integrals $I^{\pm}(\xi)$ are real valued.

7. The diffraction coefficients.

7.1. The diffraction coefficients for bulk waves. Let us first define the function

$$E(k_i^{(j)}r) = \sqrt{\frac{i}{8\pi}}\frac{e^{ik_i^{(j)}r}}{\sqrt{k_i^{(j)}r}}e^{-ik_i^{(j)}y_1p_1}, \tag{7.1}$$

where $\mathbf{p} = (\cos\theta, \sin\theta)$ is a unit vector in the direction of the diffracted wave, with the angle θ such that $\cos\theta = x_1/r$ and r is the distance to the origin. Let $\mathbf{p}^\perp$ be another unit vector, which is orthogonal to $\mathbf{p}$. It then can be chosen to be $\mathbf{p}^\perp = (-p_2, p_1) = (-\sin\theta, \cos\theta)$. It is easy to check that as $k_i^{(j)}r \to \infty$, the leading term in the expansion of the argument gives

$$\begin{aligned} H_0\left(k_i^{(j)}\sqrt{(x_1-y_1)^2+x_2^2}\right) &= H_0\left(k_i^{(j)}\left[r - y_1\cos\theta + O\left(\frac{1}{r}\right)\right]\right) \\ &\approx H_0(k_i^{(j)}r) \approx -4iE(k_i^{(j)}r). \end{aligned} \tag{7.2}$$

In the far field, the Green's tensor and Green's stress can be decomposed as

$$\begin{aligned} u_{ik}^{G(j)}(x_1-y_1,x_2) &= u_{ik}^{G1(j)}(x_1-y_1,x_2) + u_{ik}^{G2(j)}(x_1-y_1,x_2), \\ \sigma_{2ik}^{G(j)}(x_1-y_1,x_2) &= \sigma_{2ik}^{G1(j)}(x_1-y_1,x_2) + \sigma_{2ik}^{G2(j)}(x_1-y_1,x_2), \end{aligned} \tag{7.3}$$

where the superscript $i(j)$ refers to longitudinal ($i = 1$) or transverse ($i = 2$) wave in the medium $I^{(j)}$, and in the far field, as $k_i^{(j)}r \to \infty$, we can use approximations

$$\begin{aligned} u_{ik}^{G1(j)}(x_1-y_1,x_2) &\approx \left[\frac{1}{\mu^{(j)}}(\kappa^{(j)})^{-2}p_iE(k_1^{(j)}r)\right]p_k, \\ \sigma_{2ik}^{G1(j)}(x_1-y_1,x_2) &\approx ik_1^{(j)}\left[(\delta_{i2} - 2(\kappa^{(j)})^{-2}p_1p_i^\perp)E(k_1^{(j)}r)\right]p_k, \\ u_{ik}^{G2(j)}(x_1-y_1,x_2) &\approx \left[\frac{1}{\mu^{(j)}}p_i^\perp E(k_2^{(j)}r)\right]p_k^\perp, \\ \sigma_{2ik}^{G2(j)}(x_1-y_1,x_2) &\approx ik_2^{(j)}\left[(p_2p_i^\perp + p_1p_i)E(k_2^{(j)}r)\right]p_k^\perp \end{aligned} \tag{7.4}$$

(see [11], [21], or Appendix A).

To continue, for the scattered field $\mathbf{u}^{sc(j)}(\mathbf{x})$, the integral representation (2.1) can be rewritten as

$$\begin{aligned} H[(-1)^{j+1}x_2]u_k^{sc(j)}(\mathbf{x}) = (-1)^j\sum_{i=1}^{2}\int_{-\infty}^{\infty}&[\sigma_{2ik}^{G(j)}(x_1-y_1,x_2)u_i^{sc(j)}(y_1,0) \\ &+ u_{ik}^{G(j)}(x_1-y_1,x_2)\sigma_{2i}^{(j)sc}(y_1,0)]dy_1 \end{aligned} \tag{7.5}$$

(see, e.g., [11]). Substituting (7.4) into (7.3) and the result into the version of (2.1) applicable to the scattered field, for $0 < \theta < 2\pi$ we can write

$$H(\pi-\theta)u_k^{tip(j)} \approx D^{1(j)}(\theta)\frac{e^{ik_1^{(j)}r}}{\sqrt{k_1^{(j)}r}}p_k + D^{2(j)}(\theta)\frac{e^{ik_2^{(j)}r}}{\sqrt{k_2^{(j)}r}}p_k^\perp,$$

where the diffraction coefficients for diffracted body waves can be expressed in terms of the displacement vectors $\widehat{\mathbf{u}}^{(j)}(\xi),\ j=1,2$, and traction vector $\widehat{\mathbf{t}}(\xi)$ in the following manner:

$$\begin{aligned}
D^{1(1)}(\theta) &= -\sqrt{\frac{-i}{8\pi}}(\kappa^{(1)})^{-2}\Big\{2p_1p_2\widehat{u}_1^{(1)}(-p_1)+[(\kappa^{(1)})^2-2p_1^2]\widehat{u}_2^{(1)}(-p_1)\\
&\qquad\qquad +p_1\widehat{t}_1(-p_1)+p_2\widehat{t}_2(-p_1)\Big\},\\
D^{1(2)}(\theta) &= \sqrt{\frac{-i}{8\pi}}\Big[\kappa_1^{(2)}\{2(\kappa^{(2)})^{-2}p_1p_2\widehat{u}_1^{(2)}(-\kappa_1^{(2)}p_1)+[1-2(\kappa^{(2)})^{-2}p_1^2]\widehat{u}_2^{(2)}(-\kappa_1^{(2)}p_1)\}\\
&\qquad +\mu(\kappa^{(2)})^{-2}\{p_1\widehat{t}_1(-\kappa_1^{(2)}p_1)+p_2\widehat{t}_2(-\kappa_1^{(2)}p_1)\}\Big],\\
D^{2(1)}(\theta) &= -\sqrt{\frac{-i}{8\pi}}\Big[\kappa^{(1)}\{[p_1^2-p_2^2]\widehat{u}_1^{(1)}(-\kappa_2^{(1)}p_1)+2p_1p_2\widehat{u}_2^{(1)}(-\kappa_2^{(1)}p_1)\}\\
&\qquad -p_2\widehat{v}_3^-(-\kappa_2^{(1)}p_1)+p_1\widehat{v}_4^-(-\kappa_2^{(1)}p_1)\Big],\\
D^{2(2)}(\theta) &= \sqrt{\frac{-i}{8\pi}}\Big[\kappa_2^{(2)}\{[p_1^2-p_2^2]\widehat{u}_1^{(2)}(-\kappa_2^{(2)}p_1)+2p_1p_2\widehat{u}_2^{(2)}(-\kappa_2^{(2)}p_1)\}\\
&\qquad +\mu\{-p_2\widehat{v}_3^-(-\kappa_2^{(2)}p_1)+p_1\widehat{v}_4^-(-\kappa_2^{(2)}p_1)\}\Big],
\end{aligned}\tag{7.6}$$

where if $\widehat{\mathbf{s}}(\xi)$ is known, $\widehat{\mathbf{t}}(\xi)$ can be found using (4.5). An additional difficulty is presented by the fact that, for $\xi>1$, $\widehat{\mathbf{s}}(\xi)$ as defined in (4.10) contains a singular integral (5.3). Since in (7.6) the arguments of all $\widehat{\mathbf{t}}$ components are given in the form $\xi=-\kappa_i^{(j)}p_1$, the function that needs evaluating is $\widehat{\mathbf{s}}(-\kappa_i^{(j)}p_1)$. When $p_1\geq 0$ the evaluation can be carried out using (4.10), and when $p_1\leq 0$ the combination of (4.7) and (4.6) should be used instead. To calculate the displacement vectors $\widehat{\mathbf{u}}^{(j)}(\xi),\ j=1,2$, we note that the system (3.11) can be rewritten in terms of $\widehat{\mathbf{u}}^{(j)}(\xi),\ j=1,2$, and $\widehat{\mathbf{t}}(\xi)$ as

$$p(\xi)\mathbf{v}^{(j)inc}=\widehat{A}^{(j)+}(\xi)\widehat{\mathbf{u}}^{(j)}(\xi)+\widehat{A}^{(j)-}(\xi)\widehat{\mathbf{t}}(\xi),\quad j=1,2,\tag{7.7}$$

where $\widehat{A}^{(j)\pm}(\xi)$ are 2×2 matrices, which form matrices $\widehat{A}^{\pm}(\xi)$ in (3.11), so that we have

$$\widehat{A}^{+}(\xi)=\begin{pmatrix}\widehat{A}^{(1)+}(\xi) & 0\\ 0 & \widehat{A}^{(2)+}(\xi)\end{pmatrix},\qquad A^{-}(\xi)=\begin{pmatrix}\widehat{A}^{(1)+}(\xi) & \widehat{A}^{(1)-}(\xi)\\ \widehat{A}^{(2)+}(\xi) & \widehat{A}^{(2)-}(\xi)\end{pmatrix},\tag{7.8}$$

and vectors $\mathbf{v}^{(j)inc}(\xi)$ are

$$\mathbf{v}^{(1)inc}(\xi)=\begin{pmatrix}v_1^{inc}(\xi)\\ v_2^{inc}(\xi)\end{pmatrix},\quad \mathbf{v}^{(2)inc}(\xi)=\begin{pmatrix}v_3^{inc}(\xi)\\ v_4^{inc}(\xi)\end{pmatrix}.\tag{7.9}$$

Therefore, after $\widehat{\mathbf{t}}(\xi)$ is found, vectors $\widehat{\mathbf{u}}^{(j)}(\xi),\ j=1,2$, can be calculated using (7.7). Note that since $|\kappa_i^{(j)}p_1|\leq\max\{\kappa_i^{(j)}\}<\xi^{R(j)}$, matrices $\widehat{A}^{(j)+}(-\kappa_i^{(j)}p_1)$ are regular.

7.2. The Rayleigh diffraction coefficients. On each of the traction-free surfaces $(x_2=0,x_1>0)$ the Rayleigh wave can be defined as

$$\mathbf{u}^{R(j)}(y_1,0)=D^{(j)R}\mathbf{v}^{(j)R}e^{ik^{R(j)}y_1},\qquad y_1>0,\tag{7.10}$$

where the so-called Rayleigh diffraction coefficient $D^{(j)R}$ is its amplitude, $k^{R(j)} = k_1^{(1)}\xi^{R(j)}$, and the unit vector $\mathbf{v}^{(j)R}$ is a nonzero solution of the homogeneous equation

$$\widehat{A}^{+}(-\xi^{R(j)})\mathbf{v}^{(j)R} = \mathbf{0}. \tag{7.11}$$

It can be shown that the unit vector $\mathbf{v}^{(j)R}$ is

$$\mathbf{v}^{(j)R} = \left(-\frac{2\xi^{R(j)}\gamma_2^{(j)}(\xi^{R(j)})}{[\kappa_2^{(j)}]^2}, (-1)^{j+1}\frac{a_j(\xi^{R(j)})}{[\kappa_2^{(j)}]^2}\right)^T. \tag{7.12}$$

Applying the Fourier transform to (7.10), we obtain

$$\widehat{\mathbf{u}}^{R(j)}(\xi) = \frac{iD^{(j)R}\mathbf{v}^{(j)R}}{\xi + \xi^{R(j)}}. \tag{7.13}$$

Multiplying (7.7) by $[\widehat{A}^{(j)+}(\xi)]^{-1}$ gives us

$$p(\xi)[\widehat{A}^{(j)+}(\xi)]^{-1}\mathbf{v}^{(j)inc} = \widehat{\mathbf{u}}^{(j)}(\xi) + \frac{1}{R_j}\widehat{B}^{(j)-}(\xi)\widehat{\mathbf{t}}(\xi), \quad j = 1, 2, \tag{7.14}$$

with a finite matrix

$$\widehat{B}^{(j)-}(\xi) = \mu_j \begin{pmatrix} (-1)^j b_{j1}(\xi) & -g_j(\xi) \\ g_j(\xi) & (-1)^j b_{j2}(\xi) \end{pmatrix}, \quad j = 1, 2. \tag{7.15}$$

Let us now evaluate the residue of both sides of (7.14) at $\xi = -\xi^{R(j)}$. This can be done by multiplying them by $\xi + \xi^{R(j)}$ and finding the limits when $\xi \to -\xi^{R(j)}$. By definition of $p(\xi)$, the left-hand side of the resulting equation is zero. The residue of the displacement vector at the Rayleigh pole $\xi = -\xi^{R(j)}$ is

$$\operatorname*{Res}_{\xi=-\xi^{R(j)}} \widehat{\mathbf{u}}^{(j)}(\xi) = \lim_{\xi\to-\xi^{R(j)}} (\xi + \xi^{R(j)})\widehat{\mathbf{u}}^{R(j)}(\xi) = iD^{(j)R}\mathbf{v}^{(j)R}, \quad j = 1, 2. \tag{7.16}$$

Therefore, (7.14) leads to

$$iD^{(j)R}\mathbf{v}^{(j)R} + \frac{1}{R_j'(-\xi^{R(j)})}\widehat{B}^{(j)-}(-\xi^{R(j)})\widehat{\mathbf{t}}(-\xi^{R(j)}) = \mathbf{0}, \quad j = 1, 2, \tag{7.17}$$

where $R_j'(\xi)$ is the derivative of the Rayleigh function $R_j(\xi)$. It follows that, for each medium $I^{(j)}$, $j = 1, 2$, the respective Rayleigh diffraction coefficient can be expressed via $\widehat{\mathbf{t}}(\xi)$ as

$$D^{(j)R} = \frac{i[\widehat{B}_{11}^{(j)-}(-\xi^{R(j)})\widehat{t}_1(-\xi^{R(j)}) + \widehat{B}_{12}^{(j)-}(-\xi^{R(j)})\widehat{t}_2(-\xi^{R(j)})]}{R_j'(-\xi^{R(j)})v_1^{(j)R}}, \quad j = 1, 2. \tag{7.18}$$

8. Numerical results. We have developed a FORTRAN90 program for computing the diffraction coefficient $D^{i(j)}(\theta)$ using (7.6), where the displacements and tractions are evaluated at $\xi = -\kappa_i^{(j)}\cos\theta$, with θ being an observation angle.

As has been discussed above, $\widehat{\mathbf{u}}^{(j)}(\xi)$ and $\widehat{\mathbf{t}}(\xi)$ are both singular at the GE pole $\xi = \xi^{inc}$. At the real angles $\theta = \theta^{sh}$, which satisfy the equation

$$\kappa_i^{(j)}\cos(\theta^{sh}) = -\kappa_n^{(m)}\cos(\theta^{inc}), \tag{8.1}$$

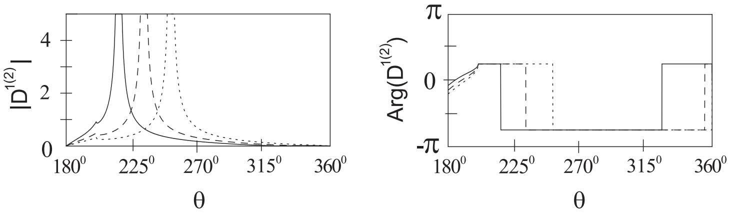

FIG. 8.1. *The longitudinal diffraction coefficient in the lower medium. The solid line corresponds to the angle of incidence of $\theta^{inc} = 30^o$, the dashed line to 50^o, and the dotted line to 70^o.*

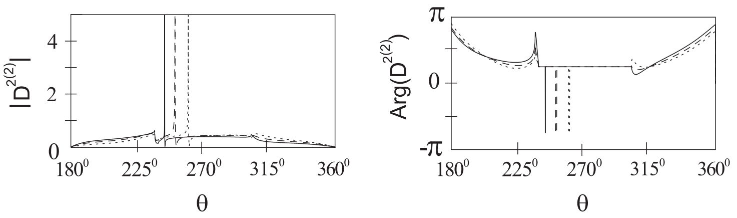

FIG. 8.2. *The transverse diffraction coefficient in the lower medium. The key is as above.*

the estimates of $|D^{i(j)}(\theta)|$ (incorrect near these angles) are infinite and the estimates of $\mathrm{Arg}[D^{i(j)}(\theta^{sh})]$ experience a π jump. When $|\kappa_n^{(m)}\cos(\theta^{inc})/\kappa_i^{(j)}| > 1$, (8.1) has no real valued solutions and $D^{i(j)}(\theta)$ are correct estimates, continuous at all observation angles. The solution of (8.1) is

$$\theta^{sh} = \pi + (-1)^j \arccos\left(\frac{\kappa_n^{(m)}}{\kappa_i^{(j)}}\cos(\theta^{inc})\right). \tag{8.2}$$

When (8.2) defines a real valued angle, it is the shadow boundary of either the reflected or refracted wave in the incident medium, or either the transmitted longitudinal or transverse wave in the other medium.

Other special angles, which can be seen on the graphs in this section, are the so-called critical angles θ^{cr}. They describe the boundaries of the regions that support head waves and correspond to the branch points, that is, satisfy the equation

$$\pm\kappa_k^{(l)} = -\kappa_i^{(j)}\cos\theta^{cr}, \qquad l, k = 1, 2. \tag{8.3}$$

These critical angles do not depend on the angle of incidence. Again, the approximation method used in section 7.1 fails in their vicinity, and they show up on the graphs as small blips.

As an illustration, Figures 8.1–8.4 present diffraction coefficients for a semi-infinite crack, which is sandwiched between aluminum and steel.

The incident plane wave is a longitudinal wave, incoming from the aluminum half plane. The amplitudes of the diffraction coefficients are presented on the left and phases on the right. The model parameters are as follows. In medium 1 (aluminum), density $\rho^{(1)} = 2700$ kg/m^3, longitudinal speed $c_1^{(1)} = 6300$ m/s, and shear speed $c_2^{(1)} = 3100$ m/s. In medium 2 (steel), density $\rho^{(2)} = 7800$ kg/m^3, longitudinal speed $c_1^{(2)} = 5900$ m/s, and shear speed $c_2^{(2)} = 3200$ m/s. We can see the geometrical shadow boundaries described by (8.2), where the amplitude of the formally evaluated

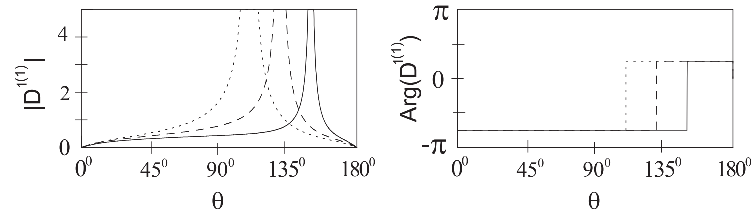

FIG. 8.3. *The longitudinal diffraction coefficient in the upper medium. The key is as in Figure* 8.1.

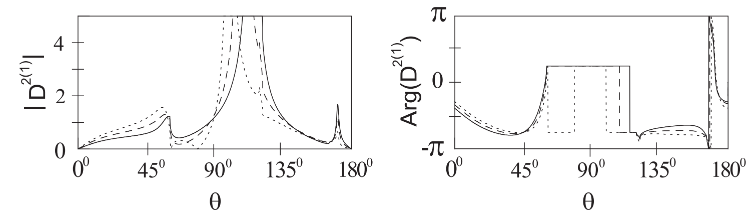

FIG. 8.4. *The transverse diffraction coefficient in the upper medium. The key is as in Figure* 8.1.

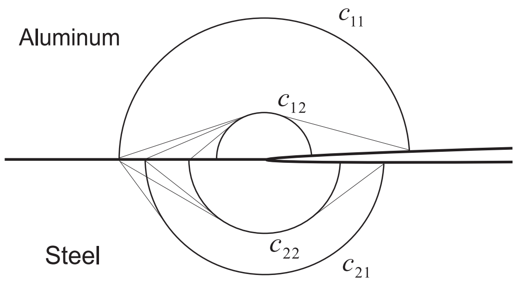

FIG. 8.5. *Head wave fronts.*

diffraction coefficient is infinite and the phase experiences a π jump. Since the critical angles do not depend on the angle of incidence, the corresponding blips appear at the same place for all three curves. The corresponding head wave fronts are shown in Figure 8.5. It can be seen that in the upper medium, the diffracted longitudinal wave is not affected by head waves. This is due to the fact that in aluminum the longitudinal speed is greater than in steel.

In Figure 8.1 the critical angle is $\theta \approx 200^o$. The head wave affects $D^{2(2)}$ at $\theta \approx 237.2^o$, $\theta \approx 239.5^o$, and $\theta \approx 328^o$. In Figure 8.2 only two blips are seen at about $\theta \approx 237^o$ and $\theta \approx 303.6^o$. This is due to the small difference between the first two critical angles $\theta \approx 237.2^o$ and $\theta \approx 239.5^o$. By decreasing both the discretization step and the interval of observation angles, the critical angles separate. The head wave affects $D^{2(1)}$ at $\theta \approx 60.5^o$, $\theta \approx 119.5$, $\theta \approx 121.7^o$, and $\theta \approx 165.6^o$. Again, in Figure 8.4 the critical angles $\theta \approx 119.5^o$ and $\theta \approx 121.7^o$ lie too close to each other. The overall conclusion is that for, say, the 30^o incidence, the longitudinal tip diffracted waves, which propagate in the upper medium, can be best detected at observation angles between 40^o and 130^o. As the angle of incidence increases, the range of advantageous observation angles shortens (see Figure 8.3).

The Rayleigh diffraction coefficients do not depend on the observation angle and are calculated using (7.18). Note that the Rayleigh speeds for aluminum and steel are $c_{Al} = 2894$ m/s and $c_{St} = 2964$ m/s, respectively, and the bimaterial constant is $\nu_0 = 0.0330434$. For the angle of incidence $\theta^{inc} = 30^{\text{o}}$, in aluminum $D^{(1)R} = -0.1208 - 0.206i$, and in steel $D^{(2)R} = 0.1428{-}0.2128i$; for $\theta^{inc} = 50^{\text{o}}$, $D^{(1)R} = -0.1004{-}0.3094i$ and $D^{(2)R} = 0.1285 - 0.3272i$; and for $\theta^{inc} = 70^{\text{o}}$, $D^{(1)R} = -0.0517 - 0.4005i$ and $D^{(2)R} = 0.0784 - 0.4285i$.

We finish this section by discussing the code testing. As already mentioned, the critical angles and positions of the shadow boundaries of reflected and refracted waves, when calculated independently, agree with the above graphs. We also know the phase (either $\pi/4$ or $-3\pi/4$) on those portions of the wave front which are not occupied by the head waves—these are correct. Another stringent internal test is to evaluate the left-hand side of (4.6) on the interval $\xi \,\epsilon\, [-1, 1]$. The right-hand side of this equation is known. The left-hand side has been computed using our code. The maximum relative error of each component has been found to be 2%, which is satisfactory. Finally, one could make another check by considering the limiting case of the two identical half planes: In this case, the off-diagonal terms in (4.4) become zero, and (4.3) reduces to the equivalent of the decoupled Wiener–Hopf equations for the crack opening displacements as found in the studies of the isotropic case, e.g., [11]. However, no numerical check of this nature has been conducted, because, when both half planes are the same, (4.7) contains a dipole instead of a pole, and although one could use this representation, it would require additional careful programming: In (4.7) one would have to use the sum of the two poles instead of the product. Even then, numerical difficulties would still arise for nearly identical top and bottom media.

9. Conclusions.

We have developed a semianalytical approach to calculating diffraction coefficients for a semi-infinite crack sandwiched between two different isotropic media. We have introduced a stable numerical scheme for solving the resulting system of integral equations, (5.7). Our main achievement has been to produce a fast computer code, which is applicable to any pair of (sufficiently different) isotropic materials which do not support the Stoneley wave and are irradiated by a plane wave incident from either medium. The incident wave can be longitudinal or transverse and incoming at an arbitrary angle. The absence of the Stoneley wave does not constitute a serious restriction, since this case is ubiquitous in applications. Nevertheless, we plan to publish another paper modeling materials where the Stoneley wave is present too. As an illustration, we have presented plots of diffraction coefficients for a crack sandwiched between aluminum and steel.

Appendix A. The two dimensional Green's tensor and Green's stress tensor.

Since the incident wave can be considered as radiated by a line load, both the two dimensional Green's tensor and Green's stress tensor can be represented in terms of the Hankel function of the first kind of the zeroth order, $H_0 \equiv H_0^{(1)}$, and its derivatives (see [11], [21]), so that at any observation point $\mathbf{x}$ we have

$$-4i\mu^{(j)} u_{ik}^{G(j)}(\mathbf{x}) = \frac{1}{[k_2^{(j)}]^2}\left[-H_0(k_1^{(j)}r) + H_0(k_2^{(j)}r)\right]_{,ik} + H_0(k_2^{(j)}r)\delta_{ik},$$

$$\begin{aligned}-4i\sigma_{2ik}^{G(j)}(\mathbf{x}) &= \left\{1 - 2\left[\frac{c_2^{(j)}}{c_1^{(j)}}\right]^2\right\}\left[H_0(k_1^{(j)}r)\right]_{,k}\delta_{2i} - \frac{2}{(k_2^{(j)})^2}\left[H_0(k_1^{(j)}r) - H_0(k_2^{(j)}r)\right]_{,2ik} \\ &\quad + \left[H_0(k_2^{(j)}r)\right]_{,2}\delta_{ik} + \left[H_0(k_2^{(j)}r)\right]_{,i}\delta_{2k}, \qquad \text{(A.1)}\end{aligned}$$

where $\mu^{(j)},\ j=1,2$, is the shear modulus in medium $I^{(j)}$; r is the distance to the origin; and an index, say k, after the comma refers to differentiation with respect to the corresponding spatial variable x_k. Applying operations of dilatation and rotation to both sides of (A.1) gives us

$$\begin{aligned}
4i\mu^{(j)}u_i^{G(j)1}(\mathbf{x}) &= \left[\frac{c_2^{(j)}}{c_1^{(j)}}\right]^2 \left[H_0(k_1^{(j)}r)\right]_{,i}\,,\\
-4i\sigma_i^{G(j)1}(\mathbf{x}) &= (k_1^{(j)})^2\left\{\left[2\left(\frac{c_2^{(j)}}{c_1^{(j)}}\right)^2-1\right]H_0(k_1^{(j)}r)\delta_{2i}+\frac{2}{(k_2^{(j)})^2}\left[H_0(k_1^{(j)}r)\right]_{,2i}\right\},\\
-4i\mu^{(j)}u_i^{G(j)2}(\mathbf{x}) &= \left[H_0(k_2^{(j)}r)\right]_{,1}\delta_{2i}-\left[H_0(k_2^{(j)}r)\right]_{,2}\delta_{1i},\\
-4i\sigma_i^{G(j)2}(\mathbf{x}) &= \left[H_0(k_2^{(j)}r)\right]_{,12}\delta_{2i}-\left[H_0(k_2^{(j)}r)\right]_{,22}\delta_{1i}+\left[H_0(k_2^{(j)}r)\right]_{,1i}\,.
\end{aligned}\tag{A.2}$$

Appendix B. The extinction theorem. The extinction theorems are easily proved for finite sources and obstacles using Green's theorem. Difficulties arise when the incident waves are plane and obstacles infinite. One approach to dealing with this complication is to develop methods such as those offered in [22] and references therein (also see [23]). Below we offer an alternative justification.

Let us focus on the scattered field in the upper plane. Any identity involving the incident field can be established by direct integration. For simplicity of presentation, we omit the superscript $^{(1)}$. Then solving the Fourier transform of the equations of motion for the elastic solid gives

$$\widehat{\mathbf{u}}^{sc}(\xi,x_2)=A(\xi)(-\xi,\gamma_1)^Te^{ik_1\gamma_1x_2}+B(\xi)(\gamma_2,\xi)^T\mathrm{e}^{ik_1\gamma_2x_2},\quad x_2>0,\tag{B.1}$$

where $A(\xi)$ and $B(\xi)$ are unknown. The solutions proportional to $\exp[-ik_1\gamma_ix_2]$, $i=1,2$, are rejected because they do not satisfy the radiation conditions: Either they are incoming from infinity or else, when we move the branches off the real axis (see Figure C.1 below) as $x_2\to\infty$, they become unbounded. It follows that on the top face of the crack, $x_2=0^+$, we have

$$\widehat{\mathbf{u}}^{sc}(\xi,0^+)=A(\xi)(-\xi,\gamma_1)^T+B(\xi)(\gamma_2,\xi)^T.\tag{B.2}$$

It can easily be verified that a similar formula holds for the traction related vector $\widehat{\mathbf{t}}^{sc}$ (see (4.1)),

$$\widehat{\mathbf{t}}^{sc}(\xi,0^+)=-i[A(\xi)(2\xi\gamma_1,2\xi^2-\kappa_2^2)^T+B(\xi)(2\xi^2-\kappa_2^2,-2\xi\gamma_2)^T].\tag{B.3}$$

The solution to the Fourier transform of the equations of motion, which is valid in both half planes, is

$$\widehat{\mathbf{u}}^{sc}(\xi,x_2)=A_1(\xi)(-\xi,\gamma_1\mathrm{sgn}(x_2))^Te^{ik_1\gamma_1|x_2|}+B_1(\xi)(\gamma_2\mathrm{sgn}(x_2),\xi)^T\mathrm{e}^{ik_1\gamma_2|x_2|},\ x_2>0,\tag{B.4}$$

where we have

$$\begin{aligned}
2\kappa_2^2\gamma_1A_1(\xi) &= -2\xi\gamma_1\mathrm{sgn}(x_2)\widehat{u}_1^{sc}(\xi,0^+)+(\kappa_2^2-2\xi^2)\widehat{u}_2^{sc}(\xi,0^+)\\
&\quad+i[\xi\widehat{t}_1^{sc}(\xi,0^+)-\gamma_1\mathrm{sgn}(x_2)\widehat{t}_2^{sc}(\xi,0^+)],\\
2\kappa_2^2\gamma_2B_1(\xi) &= (\kappa_2^2-2\xi^2)\widehat{u}_1^{sc}(\xi,0^+)+2\xi\gamma_2\mathrm{sgn}(x_2)\widehat{u}_2^{sc}(\xi,0^+)\\
&\quad-i[\gamma_2\mathrm{sgn}(x_2)\widehat{t}_1^{sc}(\xi,0^+)+\xi\widehat{t}_2^{sc}(\xi,0^+)].
\end{aligned}\tag{B.5}$$

Substituting (B.2) and (B.3) into (B.5) yields

$$(A_1(\xi), B_1(\xi)) = (A(\xi), B(\xi))H(x_2). \tag{B.6}$$

Thus, the scattered field defined by (B.4) agrees with (B.1) in the upper half plane and is identically zero in the fictitious half plane $x_2 < 0$. The inverse transform of (B.4) leads to the extinction theorem (2.1) for the scattered field.

Appendix C. Singularities in (3.11). Let us describe all singularities of functions that appear in (3.11). First, in view of (3.10), the left-hand side of (3.11) has simple poles at $\xi = \xi^{inc} + i0$ and $\xi = \xi^{inc} - i0$, which correspond to the incident and reflected bulk waves, respectively. They give rise to GE bulk waves.

Second, it is easy to check that the determinant of the matrix $\widehat{A}^{+}(\xi)$, $|\widehat{A}^{+}(\xi)|$ is a product of two Rayleigh functions, $R_1(\xi)$ and $R_2(\xi)$,

$$R_j(\xi) = a_j^2(\xi) + 4\xi^2\gamma_1^{(j)}(\xi)\gamma_2^{(j)}(\xi), \tag{C.1}$$

where the subscript $j = 1, 2$ refers to medium $I^{(j)}$ (see, e.g., [21]). Thus, the solutions $\xi = \pm\xi^{R(j)}$ of the equation $|\widehat{A}^{+}(\xi)| = 0$ are zeros of $R_1(\xi)$ and $R_2(\xi)$ and can be shown to be simple (distinct). The zeros $\xi = -\xi^{R(j)}$ are known to give rise to the outgoing Rayleigh surface waves.

It is equally easy to check that $|\widehat{A}^{-}(\xi)|$ is the well-known Stoneley function

$$S(\xi) = \mu^2 R_1(\xi)h_2(\xi) + R_2(\xi)h_1(\xi) + \mu[b_{11}(\xi)b_{22}(\xi) + b_{21}(\xi)b_{12}(\xi) - 2g_1(\xi)g_2(\xi)] \tag{C.2}$$

(see, e.g., [24]), where we use the notation

$$\begin{aligned} &b_{j1}(\xi) = [\kappa_2^{(j)}]^2\gamma_2^{(j)}(\xi), \qquad b_{j2}(\xi) = [\kappa_2^{(j)}]^2\gamma_1^{(j)}(\xi), \\ &g_j(\xi) = \xi[2\gamma_1^{(j)}(\xi)\gamma_2^{(j)}(\xi) - a_j(\xi)], \qquad h_j(\xi) = \gamma_1^{(j)}(\xi)\gamma_2^{(j)}(\xi) + \xi^2, \quad j = 1, 2. \end{aligned} \tag{C.3}$$

In general, the zero of $S(\xi) = 0$ (which is also simple) can give rise to an outgoing Stoneley wave. Using Cagniard's method (see [24]) we have established that for the set of parameters used in this paper such a solution does not exist, and therefore no Stoneley surface wave runs between materials under study. We remark in passing that this situation is common, and Cagniard [24] refers to the Stoneley wave as "a rather special phenomenon," meaning that it exists only in narrow ranges of material parameters.

To continue, both matrices $\widehat{A}^{\pm}(\xi)$ involve multivalued radicals $\gamma_i^{(j)}(\xi)$ defined below (3.14). In order to render the matrices single valued we introduce the branch cuts $C_i^{(j)\mp}$, $i, j = 1, 2$, which run between branch points $\pm\kappa_i^{(j)}$, defined below (3.9), and $\pm\infty$, respectively. Let us apply the limiting absorption principle and replace $\kappa_i^{(j)}$ by $\kappa_i^{(j)} + i\epsilon_1$, $\epsilon_1 > 0$. This shifts the branch cuts away from the real axis as indicated in Figure C.1, and when performing the inverse Fourier transform, the corresponding singularities give rise to the waves, which satisfy the radiation condition, that is, are outgoing to infinity.

The radicals $\gamma_i^{(j)}(\xi)$ can be factorized so that we have

$$\gamma_i^{(j)}(\xi) = \gamma_i^{(j)+}(\xi)\gamma_i^{(j)-}(\xi), \tag{C.4}$$

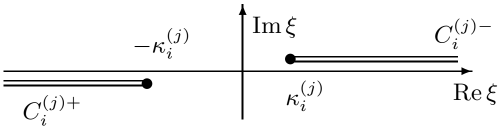

FIG. C.1. *The branch cuts of* $\gamma_i^{(j)}(\xi)$.

where we use the notation

$$\gamma_i^{(j)+}(\xi) = \sqrt{\kappa_i^{(j)} + \xi}, \quad \gamma_i^{(j)-}(\xi) = \gamma_i^{(j)+}(-\xi), \tag{C.5}$$

and only the cut $C_i^{(j)+}$ is required to render $\gamma_i^{(j)+}(\xi)$ single-valued. The radical $\gamma_i^{(j)-}(\xi)$ is rendered single-valued by $C_i^{(j)-}$. Note that if $\xi = -\zeta$ lies on the branch cut $C_i^{(j)+}$, the definition implies that ξ lies on the upper side of the cut, so that $\xi = -\zeta + i0$. It follows that $\gamma_i^{(j)+}(-\zeta)$ is well defined. As ξ tends to $-\zeta$ from below the branch cut, we have

$$\gamma_i^{(j)+}(\xi) \to -\gamma_i^{(j)+}(-\zeta) \equiv \gamma_i^{(j)+}(-\zeta - i0). \tag{C.6}$$

Note that in the main text we drop a combination of subscript and superscript ${}_1^{(1)}$ in the symbol for the longest branch cut $C_1^{(1)\pm}$. To summarize, the known functions in (3.11) involve two GE poles $\xi^{inc} \pm i0$, two Rayleigh poles $-\xi^{R(1)}$ and $-\xi^{R(2)}$, as well as two branch cuts $C^{\pm}$.

Appendix D. Auxiliary functions and vectors. Let us now describe auxiliary functions used in the main text. Let four branch points be sorted in order of the descending moduli, with $\kappa_1 = \min\{\kappa_i^{(j)}\}$ and $\kappa_4 = \max\{\kappa_i^{(j)}\}$, $i, j = 1, 2$, denoting the corresponding radicals $\gamma_i^{\pm}(\xi) = \sqrt{\kappa_i \pm \xi}$ and the respective branch cuts $C_i^+ = \{\xi : \xi \leq -\kappa_i\}$ and $C_i^- = \{\xi : \xi \geq \kappa_i\}$, $i = 1, 2, 3, 4$.

For each pair of numbers $a \neq -\kappa_i$ and ξ, let us introduce the auxiliary functions $H_i^{\pm}(\xi, a)$,

$$H_i^+(\xi, a) = \frac{\gamma_i^+(a) - \gamma_i^+(\xi)}{2\gamma_i^+(a)} \left[\frac{a_0 - \gamma_i^+(a)}{a_0 + \gamma_i^+(\xi)}\right]^{2n+1}, \qquad H_i^-(\xi, a) = H_i^+(-\xi, -a), \tag{D.1}$$

where $n \geq 3$ and a_0 lies far away from the branch cut C_i^+. To be specific, let $a_0 = 1+i$. Then the function H_i^+ has the following properties:

- It has no poles in ξ.
- The branch cut C^+ renders it single-valued.
- For any $\xi \in C_i^+$ we have

  $$H_i^+(\xi + i0, \xi) = 0 \quad \text{and} \quad H_i^+(\xi - i0, \xi) = 1, \tag{D.2}$$

  where, as the above notation suggests, $H_i^+(\xi + i0, a)$ and $H_i^+(\xi - i0, a)$ are values of $H_i^+(\xi, a)$ evaluated on the upper and lower sides of C_i^+, respectively. (We recall that, unless stated otherwise, ξ lies on the positive side of the cut.)
- For any $\xi \in C_i^-$ such that Re $\zeta \gg 1$ we have

  $$H_i^+(-\xi + i0, a) - H_i^+(-\xi - i0, a) \sim \frac{\text{constant}}{[\gamma_i^+(-\xi)]^{2n}}. \tag{D.3}$$

Let us now define branch cuts

$$\begin{aligned} &C^-_{ii+1} = \{\xi : \kappa_i \le \xi \le \kappa_{i+1}\}, \quad i = 1, 2, 3,\\ &C^-_{45} = \{\xi : \xi \ge \kappa_4\},\\ &C^+_{ii+1} = \{\xi : -\kappa_{i+1} \le \xi \le -\kappa_i\}, \quad i = 1, 2, 3,\\ &C^+_{45} = \{\xi : \xi \le -\kappa_4\}, \end{aligned} \tag{D.4}$$

and introduce the auxiliary functions

$$\begin{aligned} &F^{\pm}_i(\xi, a) = H^{\pm}_i(\xi, a) - H^{\pm}_{i+1}(\xi, a), \quad i = 1, 2, 3,\\ &F^{\pm}_4(\xi, a) = H^{\pm}_4(\xi, a). \end{aligned} \tag{D.5}$$

It is easy to see that each function $F^{\pm}_i(\xi, a)$ has a branch cut $C^{\pm}_{ii+1}$, $i = 1, 2, 3, 4$, and $F^{\pm}_i(\xi, \xi) = 1$ on the negative side of its branch cut and 0 everywhere else. Let us introduce a function $G(\xi)$ as

$$G(\xi) = \left(\sqrt{1+\xi} + \sqrt{\kappa^{(1)}_2 + \xi}\,\right)^2, \tag{D.6}$$

which is real outside the interval $(-\kappa^{(1)}_2, -1)$ and $O(\xi)$ at infinity.

Appendix E. Auxiliary relationships. Let us determine eight scalar constants $D^{\pm}_i$, $i = 1, 2, 3, 4$, introduced in (6.1). Let us show that they are linearly dependent, and therefore that the total number of unknowns can be decreased by four. Let us do this by analyzing the asymptotic behavior of both sides of (6.2). As $\xi \to \infty$, matrix $M(\xi) \to M_\infty$,

$$M_\infty = \begin{pmatrix} 0_2 & m^-_\infty I_2 \\ m^+_\infty I_2 & 0_2 \end{pmatrix}, \tag{E.1}$$

where matrices 0_2 and I_2 denote the zero and identity 2×2 matrices, respectively; $m^{\pm}_\infty$ are known constants,

$$\begin{aligned} m^-_\infty &= -\frac{1}{8}\left\{ \frac{[\kappa^{(1)}_2]^2}{[\kappa^{(1)}_2]^2 - [\kappa^{(1)}_1]^2} + \mu \frac{[\kappa^{(2)}_2]^2}{[\kappa^{(2)}_2]^2 - [\kappa^{(2)}_1]^2} \right\},\\ m^+_\infty &= -8[S_\infty]^{-1}\left([\kappa^{(1)}_2]^2\{[\kappa^{(2)}_2]^2 - [\kappa^{(2)}_1]^2\} + \mu[\kappa^{(2)}_2]^2\{[\kappa^{(1)}_2]^2 - [\kappa^{(1)}_1]^2\} \right); \end{aligned} \tag{E.2}$$

and we use the notation $S_\infty = \lim_{\xi\to\infty} S(\xi)/\xi^2$. Using the Stoneley function $S(\xi)$ defined in (C.2), we find

$$\begin{aligned} S_\infty = \mu^2&\{[\kappa^{(1)}_2]^2 - [\kappa^{(1)}_1]^2\}\{[\kappa^{(2)}_2]^2 + [\kappa^{(2)}_1]^2\} + \{[\kappa^{(1)}_2]^2 + [\kappa^{(1)}_1]^2\}\{[\kappa^{(2)}_2]^2 - [\kappa^{(2)}_1]^2\}\\ &+ 2\mu\{[\kappa^{(1)}_2]^2[\kappa^{(2)}_2]^2 + [\kappa^{(1)}_1]^2[\kappa^{(2)}_1]^2\}. \end{aligned} \tag{E.3}$$

The right-hand side of (6.2) decays faster than the left-hand side. It can be shown that it has the asymptotic behavior

$$\Delta\mathbf{V}^{inc}(\xi) \to \frac{1}{\xi}, \qquad \xi \to \infty. \tag{E.4}$$

The asymptotic solution of (6.2) can be rewritten using (6.1) as

$$\Delta\mathbf{w}(\xi) = \xi^{-\nu}\mathbf{W}, \quad \nu = \frac{1}{2} \pm i\nu_0. \tag{E.5}$$

Then the Cauchy integral of the latter can be found in [20] to behave as

$$\frac{1}{\pi}\int_1^\infty \frac{\mathbf{W}d\zeta}{\zeta^\nu(\xi+\zeta)} \to \frac{\beta}{\xi^\nu}\mathbf{W}, \quad \xi \to \infty, \tag{E.6}$$

where $\beta = 1/\sin\nu\pi$. Therefore, using (E.1) and (E.4), as $\xi \to \infty$, the system (6.2) becomes

$$\frac{1}{\xi^\nu}(I_4 - \beta M_\infty)\mathbf{W} = \mathbf{0}. \tag{E.7}$$

The matrix in the above equation must have a zero determinant,

$$\det(I_4 - \beta M_\infty) = \begin{vmatrix} I_2 & -\beta m_\infty^- I_2 \\ -\beta m_\infty^+ I_2 & I_2 \end{vmatrix} = 1 - \beta^2 m_\infty^+ m_\infty^-. \tag{E.8}$$

This determines β, and hence, by its definition, the parameter ν_0:

$$\beta = \frac{1}{\sin\left(\frac{1}{2}\pm i\nu_0\right)\pi} = \frac{1}{\cosh(\pi\nu_0)} = \frac{1}{\sqrt{m_\infty^+ m_\infty^-}}. \tag{E.9}$$

Using one of the Dundurs parameters, which can be represented as

$$\beta_D = \frac{1 - [\kappa^{(2)}]^2 + \mu([\kappa^{(1)}]^2 + 1)}{\mu[\kappa^{(2)}]^2([\kappa^{(1)}]^2 - 1) + [\kappa^{(1)}]^2([\kappa^{(2)}]^2 - 1)} \tag{E.10}$$

(see [25]), as well as expressions (E.2) for $m_\infty^\pm$, we can write

$$\tanh(\pi\nu_0) = \beta_D. \tag{E.11}$$

Now it can be shown that there are two linearly independent vectors $\mathbf{W}^{(1)}$ and $\mathbf{W}^{(2)}$ such that $(I_4 - \beta M_\infty)\mathbf{W} = \mathbf{0}$. They are

$$\mathbf{W}^{(1)} = \begin{pmatrix} m \\ 0 \\ 1 \\ 0 \end{pmatrix}, \quad \mathbf{W}^{(2)} = \begin{pmatrix} 0 \\ m \\ 0 \\ 1 \end{pmatrix}, \quad m = \sqrt{\frac{m_\infty^-}{m_\infty^+}}. \tag{E.12}$$

It follows that as $\xi \to \infty$, the vector $\Delta\mathbf{w}$ behaves as

$$\Delta\mathbf{w}(\xi) \to \xi^{-1/2}\left[\left(\frac{A^+}{\xi^{i\nu_0}} + \frac{A^-}{\xi^{-i\nu_0}}\right)\mathbf{W}^{(1)} + \left(\frac{B^+}{\xi^{i\nu_0}} + \frac{B^-}{\xi^{-i\nu_0}}\right)\mathbf{W}^{(2)}\right], \qquad \xi \to \infty. \tag{E.13}$$

Rewriting the above equation in the form of (6.1) leads us to the following relationship:

$$\begin{aligned} \mathbf{D}^+ &= (A^+ + A^-)\mathbf{W}^{(1)} + (B^+ + B^-)\mathbf{W}^{(2)}, \\ \mathbf{D}^- &= -i[(A^+ - A^-)\mathbf{W}^{(1)} + (B^+ - B^-)\mathbf{W}^{(2)}]. \end{aligned} \tag{E.14}$$

Substituting (E.12) into (E.14) gives us a simple relationship between the components of $\mathbf{D}^\pm$,

$$D_1^\pm = \sqrt{\frac{m_\infty^-}{m_\infty^+}} D_3^\pm, \qquad D_2^\pm = \sqrt{\frac{m_\infty^-}{m_\infty^+}} D_4^\pm. \tag{E.15}$$

Acknowledgments. We are indebted to Profs. V. A. Borovikov and G. Mishuris for numerous enlightening discussions, and to an anonymous referee for insightful comments on the extinction theorems.

ON CENTER SUBSPACE BEHAVIOR IN THIN FILM EQUATIONS[*]

V. A. GALAKTIONOV[†] AND P. J. HARWIN[†]

Abstract. The large-time behavior of weak nonnegative solutions of the thin film equation (TFE) with absorption $u_t = -\nabla \cdot (|u|^n \nabla \Delta u) - |u|^{p-1}u$, with parameters $n \in (0,3)$ and $p > 1$, is studied. The standard free-boundary problem (FBP) with zero height, zero contact angle, and zero-flux conditions at the interface and bounded compactly supported initial data is considered. It is shown that there exists the *critical* absorption exponent $p_0 = 1 + n + \frac{4}{N}$ such that, for $p = p_0$, the asymptotic behavior of solutions $u(x,t)$ for $t \gg 1$ is represented by the well-known source-type solution of the pure TFE absorption, $u_s(x,t) = t^{-\beta N} F(y)$, $y = x/t^\beta$, with the exponent $\beta = \frac{1}{4+nN}$, which is perturbed by a couple of $\ln t$-factors. For $n = 1$, this behavior is associated with the center subspace for the rescaled linearized thin film operator and is given by $u(x,t) \sim (t \ln t)^{-\beta N} F(x/t^\beta (\ln t)^{-\beta N/4})$, with $\beta = \frac{1}{4+N}$, where $F(y) = \frac{1}{8(N+2)(N+4)}(a_*^2 - |y|^2)^2$ and the constant $a_* > 0$ depends on dimension N only. The $2m$th-order generalization of such TFEs with critical absorption is considered, and some local and asymptotic features of changing sign similarity solutions of the Cauchy problem are described. Our study is motivated by the phenomenon of logarithmically perturbed source-type behavior for the second-order porous medium equation (PME) with critical absorption $u_t = \nabla \cdot (u^n \nabla u) - u^p$ in $\mathbb{R}^N \times \mathbb{R}_+$, $p_0 = 1 + n + \frac{2}{N}$, $n \geq 0$, which has been known since the 1980s.

Key words. quasilinear thin film equation, critical absorption exponent, similarity solutions, asymptotic behavior

DOI. 10.1137/060666275

1. Introduction: The model, motivation, and results.

Our goal is to describe some unusual asymptotic phenomena for *higher-order quasilinear* degenerate parabolic equations, in which the nonlinear interaction between operators involved deforms the scaling-invariant structure of solutions for large times. These delicate cases of asymptotic phenomena, such as *logarithmic perturbations* of fundamental or source-type solutions, have been known since the 1980s for quasilinear second-order reaction-diffusion equations. For *semilinear* higher-order parabolic equations, those phenomena can be detected by using spectral theory of non–self-adjoint operators and semigroup approaches. For *quasilinear* models, similar asymptotic patterns were unknown.

In the present paper, we introduce a new quasilinear parabolic model by adding to the standard thin film operator an extra absorption term. This creates a nonconservative evolution PDE, which enjoys a variety of logarithmically perturbed nonscaling asymptotics in both the free-boundary and the Cauchy problems. We then fix several similarities with simpler second-order diffusion-absorption models.

We begin with some physical motivation of such models.

1.1. On general thin film models: A class of conservative and nonconservative PDEs.

For a long time, modern thin film theory and application dealt with rather complicated nonlinear models. Typically, such models include the principal quasilinear fourth-order operator and several lower-order terms. For instance,

[*] Received by the editors July 28, 2006; accepted for publication (in revised form) November 6, 2008; published electronically February 19, 2009.
http://www.siam.org/journals/siap/69-5/66627.html

[†] Department of Math. Sci., University of Bath, Bath, BA2 7AY UK (vag@maths.bath.ac.uk, P.J.Harwin@maths.bath.ac.uk).

the *Benney equation* (1966) describes the nonlinear dynamics of the interface of two-dimensional liquid films flowing on a fixed inclined plane [2],

$$u_t + \tfrac{2\mathrm{Re}}{3}(u^3)_x + \varepsilon\big[\big(\tfrac{8\mathrm{Re}^2}{15}\,u^6 - \tfrac{2\mathrm{Re}}{3}\cot\theta\, u^3\big)u_x + \Sigma\, u^3 u_{xxx}\big]_x = 0, \tag{1.1}$$

where Re is the unit-order *Reynolds number* of the flow driven by gravity, σ is the rescaled *Weber number* (related to surface tension σ), θ is the angle of plane inclination to the horizontal, and $\varepsilon = \frac{d}{\lambda} \ll 1$, with d being the average thickness of the film and λ the wavelength of the characteristic interfacial disturbances. See [40].

Thin film equations (TFEs) can include nonpower nonlinearities. For instance, in multidimensional geometry, a typical example is

$$u_t + \nabla\cdot\big[\big(-G\,u^3 + \tfrac{BM\,u^2}{2P(1+B\,u)^2}\big)\nabla u\big] + S\,\nabla\cdot(u^3\nabla\Delta u) = 0, \tag{1.2}$$

which describes, in dimensionless form, the dynamics of a film in $\mathbb{R}^3$ subject to the actions of thermocapillary, capillary, and gravity forces. Here, G, M, P, B, and S are the gravity, Marangoni, Prandtl, Biot, and inverse capillary numbers, respectively. For more on Marangoni instability in such TFE models, see [38].

The above conservative PDEs preserve the finite mass of thin films. Nonconservative TFEs occur for evaporating/condensing films and via other effects [39, 28]. Actually, the first study of the vapor thrust effects in the Rayleigh–Taylor instability of an evaporating liquid-vapor interface above a hot horizontal wall was performed by Bankoff in 1961. His stability analysis in 1971 of an evaporating thin liquid film on a hot inclined wall extended earlier results of Yih (1955, 1963) and Benjamin (1957). The history and detailed derivation of models of (a) an evaporating thin film and (b) a condensing thin film can be found in [39, pp. 946–949]. A typical TFE of that type in one dimension is as follows [39, p. 949]:

$$u_t + \tfrac{\bar{E}}{u+K} + \tfrac{1}{3}\tfrac{1}{C}\big(u^3 u_{xxx}\big)_x + \big\{\big[\tfrac{A}{u} + \tfrac{\bar{E}^2}{D}\big(\tfrac{u}{u+K}\big)^3 + \tfrac{KM}{\mathrm{Pr}}\big(\tfrac{u}{u+K}\big)^2\big]u_x\big\}_x = 0. \tag{1.3}$$

Here, the six terms represent, respectively, the rate of volumetric accumulation, the mass loss, the stabilization capillary, van der Waals, vapor thrust, and thermocapillary effects. In the second absorption-like term, $\bar{E}$ is the scaled evaporation number and K is the scaled interfacial thermal resistance that physically represents a temperature jump from the liquid surface temperature to the uniform temperature of the saturated vapor. D is a unit-order scaled ratio between the vapor and liquid densities.

Another origin of nonconservative TFEs with more complicated nondivergent operators is the study of flows on a rotating disc (centrifugal spinning as an efficient mean of coating planar solids with thin films). This gives extra absorption-like, spatially nonautonomous terms in the equations written in radial geometry, e.g., [39, p. 955]

$$\begin{aligned} &u_t + \tfrac{2}{3}E + \tfrac{1}{3r}\big[r^2u^3 + \varepsilon\mathrm{Re}\big(\tfrac{5}{12}Er^2u^4 - \tfrac{34}{105}r^2u^7\big)\big] \\ &+ \tfrac{\varepsilon}{3}\big\{\mathrm{Re}\big(\tfrac{2}{5}r^3u^6 - r\tfrac{1}{F^2}u^3\big)u_r + r\tfrac{1}{C}u^3\big[\tfrac{1}{r}(ru_r)_r\big]_r\big\}_r = 0. \end{aligned} \tag{1.4}$$

Here E is again the evaporation number, F is the Froude number, and $\varepsilon = \frac{h_0}{L}$ is a small parameter. Observe a rather complicated combination of various absorption- and reaction-like nondivergent terms (with different nonlinear powers u^3, u^4, and u^7) in the first line of (1.4). Various exact solutions of nonconservative TFEs can be found in [25, Ch. 3], where more references and a survey on TFE theory are given.

Modern nonlinear parabolic theory and application to thin film models demand better understanding of the interaction of various nonlinear terms and operators of different orders that can create rather complicated spatiotemporal patterns and dissipative structures. We chose one particular but special case of center subspace behavior that will be shown to have rather robust mathematical significance.

1.2. Basic limit model: The TFE with absorption. We study the large-time asymptotic behavior of nonnegative solutions of the *thin film equation* (TFE) *with absorption* (for convenience, we also examine solutions of changing sign)

$$u_t = -\nabla \cdot (|u|^n \nabla \Delta u) - |u|^{p-1} u, \tag{1.5}$$

where $n > 0$ and $p > 1$ are fixed exponents. Here we use the simplest second term which is not a differential operator but is represented by just a power function. Our main goal is to justify that in the critical case

$$p_0 = 1 + n + \tfrac{4}{N} \tag{1.6}$$

various solutions of (1.5) exhibit a complicated asymptotic behavior with some logarithmic corrections $\ln t$ for $t \gg 1$.

We have chosen the nonconservative equation (1.5) for simplicity and for better presentation of our mathematical tools. We claim that similar phenomena are quite general and appear also in various conservative models. Actually, the logarithmic correction $\sim (\ln \frac{1}{t})^{-1/7}$ in the behavior for large enough t was rigorously observed [27] for the relaxed conservative thin film model consisting of two operators,

$$u_t + (u^3 u_{xxx})_x + (u^n u_{xxx})_x = 0, \quad \text{with} \quad 0 < n < 3 \quad (u \geq 0), \tag{1.7}$$

where the first term with u^3 corresponds to Reynolds's equation from lubrication theory. It was shown that, for concentrated enough initial data, in a certain intermediate time-range, the propagation rate is as follows:

$$\text{meas}\,\{u(x,t) > 1\} \sim \big(\tfrac{t}{\ln \frac{1}{t}}\big)^{\frac{1}{7}}, \tag{1.8}$$

where the usual scaling-invariant factor $t^{\frac{1}{7}}$ is associated with a standard dimensional analysis. Here, the log-correction is a result of a delicate interaction of two scaling invariant operators in (1.7). We believe that (1.8), proved in [27] rigorously, can be put into a framework of a center manifold calculus (though a justification can be extremely hard).

Log-corrections were observed for the limit stable Cahn–Hilliard equation [20, section 5.4]

$$u_t = -\Delta^2 u + \Delta(|u|^{p-1} u), \quad \text{with} \quad p = 1 + \tfrac{2}{N}. \tag{1.9}$$

For the semilinear case $n = 0$ in the TFE (1.5), such logarithmically perturbed asymptotic are also well known and admit a rigorous mathematical treatment [22].

Thus, we consider for (1.5) the standard free-boundary problem (FBP) with *zero height*, *zero contact angle*, and *zero-flux* (conservation of mass) conditions

$$u = \nabla u = \nu \cdot (u^n \nabla \Delta u) = 0 \tag{1.10}$$

at the singularity surface (interface) $\Gamma_0[u]$, which is the lateral boundary of $\operatorname{supp} u$ with the outward unit normal ν. Bounded, smooth, and compactly supported initial data

$$u(x,0) = u_0(x) \quad \text{in } \Gamma_0[u] \cap \{t=0\} \tag{1.11}$$

are added to complete a suitable functional setting of the FBP. As usual, we assume that these three free-boundary conditions give a correctly specified problem for the fourth-order parabolic equation, at least for sufficiently smooth and bell-shaped initial data, e.g., in the radial setting.

Returning to basics of thin film theory, earlier references on derivation of the pure fourth-order TFE

$$u_t = -\nabla \cdot (|u|^n \nabla \Delta u) \tag{1.12}$$

and related models can be found in [29, 42], where the first analysis of some self-similar solutions for $n=1$ was performed. Source-type similarity solutions of (1.12) for arbitrary n were studied in [7] for $N=1$ and in [21] for the equation in $\mathbb{R}^N$. More information on similarity and other solutions can be found in [5, 4, 11]. In general, the TFEs are known to admit nonnegative solutions constructed by special "singular" parabolic approximations of the degenerate nonlinear coefficients; see the pioneering paper [3], various extensions in [30, 15, 16, 34, 45], and the references therein. In what follows we study the asymptotic behavior of sufficiently "strong" weak solutions of the TFEs, which satisfy necessary regularity and other assumptions; see also the survey paper [1]. Notice that regularity theory for the TFEs is not fully developed, especially in the nonradial N-dimensional geometry and for solutions of changing sign, so we will need to impose extra formal requirements, which are necessary for justifying our asymptotic approaches.

Let us mention other well-established and related conservative thin film models with extra lower-order terms describing the dynamics of thin films of viscous fluids in the presence of two competing forces; see [9]. For $N=1$, typical *quasilinear* TFEs are

$$u_t = -(uu_{xxx} + u^3 u_x)_x \quad (u \geq 0), \tag{1.13}$$

and the general equation with power nonlinearities is

$$u_t = -(u^n u_{xxx})_x - (u^m u_x)_x \quad (u \geq 0). \tag{1.14}$$

We refer the reader to papers [17, 18] and the book [25, Ch. 3] as sources of a large number of further references and results of TFE theory and application.

In addition, our extra motivation of the TFE model like (1.5) is mathematical and is associated with the previous investigations of the quasilinear diffusion-absorption PDEs.

1.3. A mathematical motivation: The PME with critical absorption. Second-order quasilinear parabolic equations with absorption are well known in combustion theory. A key model is the *porous medium equation* (PME) *with absorption*

$$u_t = \nabla \cdot (u^n \nabla u) - u^p \quad \text{in } \mathbb{R}^N \times \mathbb{R}_+ \quad (u \geq 0), \tag{1.15}$$

where $n > 0$ and p are fixed exponents. A special interest to such equations was motivated by localized similarity solutions introduced by L.K. Martinson and K.B. Pavlov at the beginning of the 1970s. Mathematical theory of such PDEs was developed by A.S. Kalashnikov a few years later; see his survey [31] for the full history. Besides new phenomena of localization and interface propagation, for more than twenty years, the PME with absorption (1.15) became a crucial model for determining various asymptotic patterns, which can occur for large times $t \gg 1$ or close to finite-time extinction as $t \to T^-$ (for $p < 1$). For (1.15), there are a few parameter ranges with different asymptotics:

$$p > p_0 = 1 + n + \tfrac{2}{N}, \quad p = p_0, \quad 1 + n < p < p_0, \quad p = 1 + n,$$
$$1 < p < 1 + n, \quad p = 1, \quad 1 - n < p < 1, \quad p = 1 - n, \quad p < 1 - n,$$

etc.; see references and details in [26, Chs. 5, 6].

The most interesting and unusual transitional behavior for (1.15) occurs at the first *critical* (or *Fujita*) absorption exponent

$$p_0 = 1 + n + \tfrac{2}{N}. \tag{1.16}$$

In this case (see details and references in [26, p. 83]), the asymptotic behavior as $t \to \infty$ of nonnegative compactly supported solutions of (1.15) is described by the logarithmically perturbed source-type solution of the pure PME,

$$u(x,t) = (t \ln t)^{-\beta N}[F(x/t^{\beta}(\ln t)^{-\beta n/2}) + o(1)], \quad \text{where } \beta = \tfrac{1}{2+nN}. \tag{1.17}$$

Without the logarithmic factors and the $o(1)$-term, the right-hand side is indeed the famous *Zel'dovich–Kompaneetz–Barenblatt* (ZKB) similarity source-type solution of the pure PME $u_t = \nabla \cdot (u^n \nabla u)$, which has the form

$$u_s(x,t) = t^{-\beta N} F(y), \;\; y = x/t^{\beta}, \quad \text{with } F(y) = \left[\tfrac{n\beta}{2}(a^2 - |y|^2)_+\right]^{\frac{1}{n}}, \tag{1.18}$$

where $a > 0$ is an arbitrary scaling parameter. This explicit solution dates back to the 1950s. In the class of solutions of changing sign, (1.15) admits a countable sequence of critical exponents, where the patterns contain similar logarithmic time-factors [23].

1.4. Outline of the paper: Logarithmically perturbed patterns for the TFE with absorption. In section 2 we show that similar logarithmically perturbed source-type patterns exist for the TFE with absorption (1.5), with the critical exponent (1.6). In this case, the source-type solutions of the TFE (1.12) take the form

$$u_s(x,t) = t^{-\beta N} F(y), \quad y = x/t^{\beta}, \quad \text{with } \beta = \tfrac{1}{4+nN}, \tag{1.19}$$

where $F(y) \geq 0$ is a radially symmetric compactly supported solution of the PDE [7, 21]

$$\mathbf{A}(F) \equiv -\nabla \cdot (F^n \nabla \Delta F) + \beta \nabla F \cdot y + \beta N F = 0. \tag{1.20}$$

In the case $n = 1$, the similarity profile for the FBP is given explicitly,

$$F(y) = c_0(a^2 - |y|^2)^2, \quad c_0 = \tfrac{1}{8(N+2)(N+4)}, \quad a > 0, \tag{1.21}$$

and was first constructed in [42]. Figure 1 shows profiles $F(y)$ for $N = 1$ in four cases $n = \frac{1}{4}, \frac{1}{2}, \frac{3}{4}$, and 1. The profiles are normalized by their values at $y = 0$, so $F(0) = 1$.

First, for $n = 1$, relying on the explicit representation (1.21) and good spectral properties of the corresponding self-adjoint linearized rescaled operator, we show that,

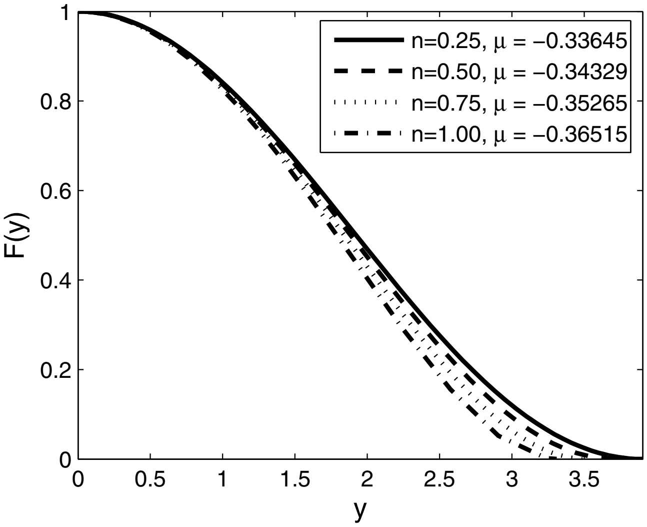

FIG. 1. *The similarity profiles $F(y)$ of* (1.20) *for $N = 1$ in four cases $n = \frac{1}{4}$, $\frac{1}{2}$, $\frac{3}{4}$, and* 1*; $F(0) = 1$, $\mu = F''(0)$.*

for $p = p_0 = 2 + \frac{4}{N}$, the TFE with absorption (1.5) admits asymptotic patterns of the following form:

$$u(x,t) \sim (t \ln t)^{-\beta N} F_*(x/t^{\beta}(\ln t)^{-\beta N/4}) \quad \left(\beta = \tfrac{1}{4+N}\right). \tag{1.22}$$

Here F_* is a fixed rescaled profile from the family (1.21) with a uniquely chosen parameter $a = a_* > 0$ that depends on N only. We also present evidence that similar logarithmic factors can occur for arbitrary $n > 0$, but this does not lead to self-adjoint linearized operators and explicit mathematics. On the other hand, for the semilinear case $n = 0$, i.e., for the fourth-order parabolic equation written for solutions of changing sign

$$u_t = -\Delta^2 u - |u|^{p-1} u, \tag{1.23}$$

the critical behavior like (1.22) is known to occur at the critical exponent $p = 1 + \frac{4}{N}$ [22], which is precisely (1.6) with $n = 0$. In this case, the center manifold analysis also uses spectral properties of a non–self-adjoint linear operator studied in [13, section 2].

In section 3 we briefly describe the essence of the easier supercritical case $p > p_0$. Very singular similarity solutions (VSSs) in the subcritical one $p \in (n+1, p_0)$ will be studied in a forthcoming paper.

In section 4, we explain how the critical asymptotic behavior occurs for the $2m$th-order TFE with absorption

$$u_t = (-1)^{m+1} \nabla \cdot (u^n \nabla \Delta^{m-1} u) - u^p, \quad m \geq 2, \tag{1.24}$$

where the critical absorption exponent is

$$p_0 = 1 + n + \tfrac{2m}{N}, \tag{1.25}$$

and again $n = 1$ leads to a simpler self-adjoint case.

In section 5 we discuss similar local and global asymptotics for the Cauchy problem admitting *maximal regularity* solutions of changing sign.

Finally, let us note that (1.6) (and (1.25) for equation (1.24)) is the critical *Fujita* exponent of the TFE with source

$$u_t = -\nabla \cdot (|u|^n \nabla \Delta u) + |u|^p \quad (n > 0,\ p > 1);$$

i.e., for $p \in (n+1, p_0]$, all solutions with arbitrarily small initial data $u_0(x)$, where $\int u_0 > 0$, blow up in finite time [24].

2. Rescaled equation and center subspace behavior.

2.1. To the style of the analysis. For convenience of the reader, we must emphasize from the beginning that all our final conclusions on center subspace behaviors detected below are *mathematically formal* when we deal with the quasilinear case $n > 0$. The semilinear case $n = 0$ is easier and admits a rigorous treatment by invariant manifold theory [22]. It is then worth mentioning that there is no hope that such asymptotics can admit a reasonably simple rigorous treatment. We recall that even for the second-order model (1.15) with $n > 0$, there is no full center manifold justification of the main results that were proved by essential use of the maximum principle and comparison-barrier techniques; see [26, Ch. 4]. Some of the asymptotic patterns for (1.15) of center subspace type turned out to be very complicated [23]. As we will show, the main difficulty is not a proper spectral theory of linearized operators (this is justified in many cases) but a justification of the center subspace behavior associated with such singular operators. On the other hand, we always clearly indicate the rigorous steps and split the whole approach into a sequence of standard steps. We would be very pleased if some of our formal results and discussions would attract the attention of experts in these areas of differential equations.

Thus, in what follows, we use by implication the following rule:

(i) all conclusions concerning spectral and other properties of self-adjoint singular elliptic and ordinary differential operators are *rigorous* (or can be made rigorous after sometimes technical manipulations; for non–self-adjoint cases we are not certain, and extra analysis is necessary); and

(ii) further extensions via the above spectral properties to describe the behavior for TFEs close to center subspaces and various matching procedures are mathematically *formal*.

2.2. Rescaled equation. We begin with rescaling the PDE (1.5) with the critical exponent (1.6) according to the time-factors of the source-type solution (1.19), i.e., by setting

$$u(x,t) = (1+t)^{-\beta N} v(y,\tau), \quad y = x/(1+t)^{\beta}, \quad \tau = \ln(1+t), \tag{2.1}$$

which leads to the following autonomous rescaled equation in $\mathbb{R}^N \times \mathbb{R}_+$:

$$v_\tau = \mathbf{A}(v) - v^p, \tag{2.2}$$

where $\mathbf{A}$ is the operator specified in (1.20). We first need to check that a simple stabilization as $\tau \to +\infty$ to a nontrivial stationary solution in (2.2) is not possible.

Proposition 2.1. *The stationary equation*

$$\mathbf{A}(g) - g^p = 0 \tag{2.3}$$

does not have a nontrivial compactly supported nonnegative solution of the FBP.

Proof. Indeed, integrating (2.3) over $\operatorname{supp} g$ yields $\int g^p(y)\,\mathrm{d}y = 0$. □

This means that the only bounded nonnegative equilibrium for the dynamical system (2.2) is trivial:

$$g(y) \equiv 0 \quad \text{in } \mathbb{R}^N. \tag{2.4}$$

In order to detect the actual nonstationary asymptotic behavior, we next perform a second rescaling by introducing the as yet unknown positive function $b(\tau)$,

$$v(y,\tau) = b(\tau)w(\zeta,\tau), \quad \zeta = y/b^{\frac{n}{4}}(\tau), \tag{2.5}$$

to get the following perturbed equation:

$$w_\tau = \mathbf{A}(w) + \tfrac{b'}{b}\,\mathbf{C}w - b^{p-1}w^p, \quad \text{where } \mathbf{C}w \equiv \tfrac{n}{4}\,\nabla w \cdot \zeta - w. \tag{2.6}$$

2.3. Linearization. Roughly speaking, in order to detect the asymptotic behavior according to (2.5), we can use the estimate

$$b(\tau) \approx \|v(\cdot,\tau)\|_\infty \to 0 \quad \text{as } \tau \to \infty, \tag{2.7}$$

so that $\|w(\cdot,\tau)\|_\infty \approx 1$ for $\tau \gg 1$. On the other hand, in the radial setting, it is convenient to use $b(\tau)$ for the scaling of the support of the solution $w(\zeta,\tau)$ to get that it approaches the unit ball B_1 as $\tau \to \infty$; see below.

We next perform the linearization by setting

$$w(\zeta,\tau) = F(\zeta) + Y(\zeta,\tau), \tag{2.8}$$

where F is a rescaled similarity profile from the family (1.21). Then Y solves the following rescaled equation:

$$Y_\tau = \mathbf{A}'(F)Y + \tfrac{b'}{b}\,\mathbf{C}F - b^{p-1}F^p + \mathbf{D}(Y) - b^{p-1}[(F+Y)^p - F^p], \tag{2.9}$$

where $\mathbf{A}'(F)Y$ is the formal Fréchet derivative of $\mathbf{A}$ at F,

$$\mathbf{A}'(F)Y = -\nabla \cdot (F^n \nabla \Delta Y) - \nabla \cdot (nF^{n-1}Y\nabla\Delta F) + \beta\nabla Y \cdot y + \beta N Y, \tag{2.10}$$

and $\mathbf{D}(Y)$ is a higher-order perturbation, which is quadratic in $Y \to 0$ on smooth functions. Using the elliptic equation (1.20) for F, on integration,

$$F^n\nabla\Delta F = \beta F y \quad \Longrightarrow \quad \mathbf{A}'(F)Y = -\nabla \cdot (F^n\nabla\Delta Y) + (1-n)\beta\nabla \cdot (Y\zeta). \tag{2.11}$$

2.4. The self-adjoint case $n = 1$. It follows from (2.11) that $n = 1$ is a special case, where the last term vanishes. We fix $a = 1$ in (1.21), so that the linearized operator is

$$\mathbf{A}'(F)Y = -\nabla \cdot (F\nabla\Delta Y) \equiv -c_0\nabla \cdot ((1-|\zeta|^2)\nabla\Delta Y), \quad y \in B_1 = \{|\zeta| < 1\}. \tag{2.12}$$

One can see that it can be written in the form

$$\mathbf{A}'(F)Y = -c_0\,\tfrac{1}{\rho(|\zeta|)}\,[\Delta(a(|\zeta|)\Delta Y) + 2N\Delta Y], \quad \text{where } a(|\zeta|) = 1 - |\zeta|^2 = \tfrac{1}{\rho(|\zeta|)}, \tag{2.13}$$

so, in the topology of $L^2_\rho(B_1)$, operator (2.12) is symmetric in $C_0^\infty(B_1)$ with good coefficients and hence admits self-adjoint extensions. Next, using classical theory

[10], we specify properties of its unique Friedrichs self-adjoint extension. Its domain is constructed by completing $C_0^\infty(B_1)$ in the norm induced by its positive quadratic form (corresponding to the operator $-\mathbf{A}'(F) - c_0\Delta > 0$)

$$\langle Y, W\rangle_* \equiv c_0 \textstyle\int_{B_1} [a\Delta Y \Delta W - (2N-1)\nabla Y \cdot \nabla W].$$

The intersection of this Hilbert space with the domain of the maximal adjoint operator $D((\mathbf{A}'(F))^*) = \{v \in L^2_\rho : \ \mathbf{A}'(F)v \in L^2_\rho\}$ defines the domain of the self-adjoint extension, which we denote by $D(\mathbf{A}'(F)) = H^4_{\rho,0}$. In particular, for any $v \in H^4_{\rho,0}$, there holds

$$v = 0 \quad \text{on } \partial B_1, \quad \text{and} \quad \textstyle\int_{B_1} a(\Delta v)^2 < \infty,$$

so that $H^4_{\rho,0} \subset H^2_{\rho,0}$. Consider the corresponding eigenvalue problem written in the form

$$-c_0[\Delta(a(|\zeta|)\Delta\psi) + 2N\Delta\psi] = \rho\lambda\psi \quad \text{in } H^4_{\rho,0}. \tag{2.14}$$

Since the embeddings of the corresponding functional spaces $H^2_{a,0}$ and H^1_0 into L^2_ρ are compact [36, p. 63], we have that the spectrum $\sigma(\mathbf{A}'(F))$ is real and discrete.

For our purposes, it suffices to detect the eigenvalues and eigenfunctions in the radial (ODE) setting with the single spatial variable $r = |\zeta| > 0$. The extension to the elliptic setting is performed by using the polar coordinates $\zeta = (r, \sigma)$ in B_1,

$$\Delta = \Delta_r + \tfrac{1}{r^2}\,\Delta_\sigma, \tag{2.15}$$

where Δ_σ is the Laplace–Beltrami operator on the unit sphere $S^{N-1} = \partial B_1$ in $\mathbb{R}^N$. Δ_σ is a regular operator with a discrete spectrum in $L^2(S^{N-1})$ (each eigenvalue repeated as many times as its multiplicity),

$$\sigma(-\Delta_\sigma) = \{\nu_k = k(k+N-2), \ k \geq 0\}, \tag{2.16}$$

and an orthonormal, complete, closed subset $\{V_k(\sigma)\}$ of eigenfunctions, which are homogeneous harmonic kth order polynomials restricted to S^{N-1}. We plug (2.15) into (2.13), where all the coefficients are radial functions, and use the separation of variables

$$\psi(r, \sigma) = R(r)V_k(\sigma) \tag{2.17}$$

to solve the eigenvalue problem (2.14). For each fixed ν_k, we then arrive at a radial eigenvalue problem for R, which is similar to that discussed below.

Thus we take $k = 0$ in (2.17) and consider the radially symmetric eigenvalue problem (2.14). For $N = 1$, this problem was studied in [8], where further references are given. It is not difficult to check that the radial operator $\mathbf{A}'(F)$ has the discrete spectrum

$$\sigma(\mathbf{A}'(F)) = \{\lambda_k = c_0 k(k+2)(k+N)(k+N+2), \ k = 0, 2, 4, \ldots\}, \tag{2.18}$$

where each eigenfunction ψ is a $(k{+}2)$th-order polynomial,

$$\psi_k(r) = b_k(r^{k+2} + \cdots + d_k) \quad (\psi_k(1) = 0), \tag{2.19}$$

where $\{b_k\}$ are normalization constants, so that the eigenfunction subset $\{\psi_k\}$ is orthonormal in L^2_ρ. In particular,

$$\psi_0(r) = b_0(r^2-1) > 0, \quad b_0 = -\sqrt{\tfrac{N+2}{2\omega_N}} \quad (\lambda_0 = 0), \tag{2.20}$$

where $\omega_N = \frac{2\pi^{N/2}}{N\Gamma(N/2)}$ is the volume of the unit ball in $\mathbb{R}^N$. Such polynomials are complete and closed in typical weighted L^p-spaces (a standard functional analysis result; see [13, section 2.3] for details), and this justifies the equality in (2.18). Moreover, we then can use the eigenfunction expansion with the orthonormal eigenfunction subset $\{\psi_k\}$ to deal with solutions of the corresponding PDE.

We next consider the rescaled equation (2.9), which for $n = 1$ takes the form

$$Y_\tau = \mathbf{A}'(F)Y + \tfrac{b'}{b}\,\mathbf{C}F - b^{p-1}F^p - \nabla\cdot(Y\nabla\Delta Y) - b^{p-1}[(F+Y)^p - F^p]. \tag{2.21}$$

We deal with strong radially symmetric solutions of (2.21), where we now choose the normalization function $b(\tau)$ in (2.5) such that

$$\operatorname{supp} w(\cdot,\tau) = B_1 \quad \text{for } \tau \gg 1. \tag{2.22}$$

According to (2.21), we then need to assume that $b(\tau)$ is smooth, at least for large τ, though this requirement can be weaken by using a weak (integral) form of the PDE. We now use the converging (in L^2_ρ and in the corresponding Sobolev class) eigenfunction expansion of the radial solution

$$Y(\zeta,\tau) = \textstyle\sum_{k\ge 0} a_k(\tau)\psi_k(\zeta) \tag{2.23}$$

to study the corresponding center subspace behavior for the nonlinear operator $\mathbf{A}$. This part of our asymptotic analysis is formal.

Thus substituting (2.23) into (2.21) and projecting onto ψ_0 in L^2_ρ, we have that the first coefficient satisfies the following perturbed ODE:

$$a_0' = -\gamma_1\tfrac{b'}{b} - \gamma_2 b^{p-1} + \dots, \ \text{ where } \ \gamma_1 = -\langle \mathbf{C}F, \psi_0\rangle_\rho > 0, \ \gamma_2 = \langle F^p, \psi_0\rangle_\rho > 0. \tag{2.24}$$

We omit in (2.24) the higher-order terms, assuming that, for this type of behavior, the nonautonomous perturbations are the leading ones. The signs of the coefficients $\gamma_{1,2}$ in (2.24) are essential and are easily checked by integration.

It follows from (2.4) and (2.22) that $b(\tau) \to 0$ as $\tau \to \infty$, so

$$\tfrac{b'(\tau)}{b(\tau)} \quad \text{is not integrable at } \tau = \infty.$$

Therefore, in order to have a uniformly bounded expansion coefficient $a_0(\tau)$, we need to suppose that two terms on the right-hand side of (2.24) annul each other asymptotically, so that, up to an integrable perturbation,

$$\tfrac{b'}{b} = -\tfrac{\gamma_2}{\gamma_1}\,b^{p-1} + \dots \quad \text{for } \tau \gg 1. \tag{2.25}$$

This gives the following necessary condition for the existence of such behavior:

$$b(\tau) = \gamma_*\tau^{-\frac{1}{p-1}} + \dots, \quad \text{where } \gamma_* = \left[\tfrac{(p-1)\gamma_2}{\gamma_1}\right]^{-\frac{1}{p-1}}. \tag{2.26}$$

Returning to the original variables $\{x,t,u\}$, from (2.26) we obtain the asymptotic pattern (1.22). The rescaled profile F_* is uniquely determined from (1.21) with $a_* = \gamma_*^{n/4}$.

2.5. Arbitrary $n \in (0, \frac{3}{2})$. This non–self-adjoint case is more difficult. Consider the linearized operator (2.11) for $n \neq 1$, where $F > 0$ is the radial solution of the ODE (1.20) in B_1; see [21] for existence, uniqueness, and asymptotics. Then, for $n < \frac{3}{2}$ [21],

$$F(\zeta) \sim (1 - |\zeta|)^2 \quad \text{as } |\zeta| \to 1^-. \tag{2.27}$$

Notice that there exists a one-parameter family of the solutions given by

$$F_a(\zeta) = a^{\frac{4}{n}} F(\tfrac{\zeta}{a}), \quad a > 0. \tag{2.28}$$

First, we claim that, for $n \neq 1$, operator (2.11) is not symmetric in L^2_ρ for any positive weight ρ in B_1; see the appendix. Second, we have that

$$\psi_0(\zeta) = \tfrac{\mathrm{d}}{\mathrm{d}a} F_a(\zeta)|_{a=1} \equiv \tfrac{4}{n} F - \nabla F \cdot \zeta \tag{2.29}$$

is a positive eigenfunction of (2.11) corresponding to $\lambda_0 = 0$. Observe that, with respect to the regularity, this eigenfunction well corresponds to that for $n = 1$; cf. (2.20). Moreover, it follows that, close to the singular point $|\zeta| = 1$, the radial part of (2.11) is governed by the singular (at ∂B_1) higher-order operator

$$L_4 Y = -(s^{2n} Y''')', \quad s = 1 - |\zeta|, \tag{2.30}$$

which is symmetric in a weighted H^{-1} topology (but we need a result in L^2). Solving the problem $L_4 Y = g$ with natural conditions at the point $s = 1$, which is assumed to be regular, we obtain, up to compact perturbations, that

$$L_2 Y \equiv -Y'' \sim \int^s s^{-2n} \int^s g \equiv L_* g \quad \Longrightarrow \quad Y \sim L_2^{-1} L_* g, \tag{2.31}$$

where L_2^{-1} is a compact operator in L^2. It is easy to check that the integral operator L_* is bounded in L^2 for

$$n < \tfrac{3}{4}, \tag{2.32}$$

and then $L_2^{-1} L_*$ is compact in L^2 as the product of a compact and a bounded operator. Therefore, $\mathbf{A}'(F)$ has discrete spectrum in the parameter range (2.32). This is not an optimal result since, as we have seen, the discreteness of the spectrum remains valid for $n = 1$. We use this analysis as a simple illustration of the fact that the spectrum is usually discrete in the nonsymmetric case.

Thus $0 \in \sigma(\mathbf{A}'(F))$ is an isolated eigenvalue. There is numerical evidence that the spectrum is discrete for all $n \in (0, \frac{3}{2})$; see [8], where, moreover, the first six eigenvalues turned out to be *real* for $N = 1$. Possibly this might mean that in a special topology of sequences as l^2 (not related to any of L^2_ρ) the linearized operator can be treated as symmetric and self-adjoint; cf. an example in [13]. For $n = 0$ in any dimension $N \geq 1$, the whole spectrum is proved to be real. We refer the reader to [13, section 2], where this and other $2m$th-order operators were studied in $L^2_\rho(\mathbb{R}^N)$, i.e., for the Cauchy (not a free-boundary) problem.

The rest of our study is formal. Once in the radial setting there exists the center subspace of $\mathbf{A}'(F)$; we are looking for a (formal) center subspace patterns for (2.9)

$$Y(\zeta, \tau) = a_0(\tau) \psi_0(\zeta) + \dots . \tag{2.33}$$

We assume center subspace dominance in the behavior, so, as usual, other terms in this expansion are assumed to be negligible for $\tau \gg 1$. Substituting (2.33) into (2.9), we next find the projection onto the corresponding adjoint eigenfunction ψ_0^*. In general, such an analysis becomes rigorous if we establish existence of complete, closed, and biorthonormal eigenfunction subsets $\{\psi_k\}$ and $\{\psi_k^*\}$. This is an open problem except for the case $n = 1$ above and $n = 0$ studied in [13]. We do not deal with the adjoint operator $\mathbf{A}'^*(F)$ in this formal asymptotic analysis. The projection onto ψ_0^* yields the perturbed ODE (2.24), where the same coefficients $\gamma_{1,2}$ are determined via the standard dual L^2 product, where ψ_0 is replaced by ψ_0^*. This formally leads to the same asymptotics (2.26).

The range $n \in [\frac{3}{2}, 3)$. The center subspace analysis applies also for larger n's. The asymptotics of similarity profiles change at $n = \frac{3}{2}$, where, instead of (2.27),

$$F(\zeta) \sim (1-|\zeta|)^2 \big[\tfrac{3}{4}\,\beta|\ln(1-|\zeta|)|\big]^{\frac{2}{3}} \quad \text{as } |\zeta| \to 1; \tag{2.34}$$

see [21]. On the other hand, for $n \in (\frac{3}{2}, 3)$,

$$F(\zeta) \sim (1-|\zeta|)^{\frac{3}{n}} \quad \text{as } |\zeta| \to 1. \tag{2.35}$$

This regularity is sufficient for determining the corresponding eigenfunction and the logarithmic behavior.

For $n \geq 3$, the zero contact angle FBP does not provide us with a proper interesting evolution; see [21].

3. On the supercritical parameter range $p > p_0$.

3.1. Exponentially perturbed dynamical system for $p > p_0$. Let us explain what we expect for $p > p_0$ in (1.5). In terms of the rescaled function

$$u(x,t) = (1+t)^{-\frac{N}{4+nN}}\, v(y,\tau), \quad \tau = \ln(1+t), \tag{3.1}$$

the equation takes the form

$$v_\tau = -\nabla \cdot (v^n \nabla \Delta v) + \tfrac{1}{4+nN}\, y \cdot \nabla v + \tfrac{N}{4+nN}\, v - \mathrm{e}^{-\gamma\tau} v^p, \tag{3.2}$$

where $\gamma = \frac{N(p-p_0)}{4+nN} > 0$ if $p > p_0$. Therefore, the absorption term $-u^p$ in (1.5) generates an exponentially small perturbation in the rescaled equation (3.2). Hence one can expect the convergence as $\tau \to \infty$ to the rescaled similarity profile F in (1.19) of the limit mass, though the passage to the limit in (3.2) generates a number of technical difficulties. Here (3.2) is formally an exponentially small perturbation of the autonomous rescaled TFE

$$v_\tau = \mathbf{A}(v) \equiv -\nabla \cdot (v^n \nabla \Delta v) + \tfrac{1}{4+nN}\, y \cdot \nabla v + \tfrac{N}{4+nN}\, v. \tag{3.3}$$

As usual, we gain an extra advantage in the case $n = 1$.

3.2. The gradient case $n = 1$. It is known that, for $n = N = 1$, the rescaled TFE (3.3) is a gradient system [12]. Let us construct an "approximate" Lyapunov function for strong solutions of the FBP in $\mathbb{R}^N$. Namely, we write down (3.2) in the form

$$v_\tau = \nabla \cdot \big[v \nabla \big(-\Delta v + \tfrac{1}{2(4+N)}\, |y|^2\big)\big] + \mathrm{e}^{-\gamma\tau} v^p \tag{3.4}$$

and multiply in $L^2(\mathbb{R}^N)$ by $(-\Delta_v)^{-1} v_\tau$, where, by definition,

$$(-\Delta_v)^{-1} w = g \quad \text{if } \Delta_v g \equiv \nabla \cdot (v \nabla g) = -w,$$

and $g = 0$ at the free boundary of v. Then integrating by parts yields the identity

$$\int v|\nabla(-\Delta_v)^{-1}v_\tau|^2 = \tfrac{\mathrm{d}}{\mathrm{d}\tau}\left[-\tfrac{1}{2}\int|\nabla v|^2 - \tfrac{1}{2(4+N)}\int v|y|^2\right] + J, \tag{3.5}$$

where J corresponds to the exponentially small term,

$$J = \mathrm{e}^{-\gamma\tau}\int v^p(-\Delta_v)^{-1}v_\tau. \tag{3.6}$$

Integrating (3.5) over $(0, T)$ yields

$$\int_0^T\int v|\nabla(-\Delta_v)^{-1}v_\tau|^2 + \tfrac{1}{2}\int|\nabla v(T)|^2 + \tfrac{1}{2(4+N)}\int v(T)|y|^2 \le C + \int_0^T J,$$

so that, if the exponential term (3.6) $J \in L^1(\mathbb{R}_+)$, this yields extra uniform estimates,

$$\sqrt{v}\,\nabla(-\Delta_v)^{-1}v_\tau \in L^2(\mathbb{R}\times\mathbb{R}_+) \;\text{ and }\; \nabla v,\ \sqrt{v}|y| \in L^\infty(\mathbb{R}_+; L^2).$$

Note that, obviously, (3.5) does not imply existence of a Lyapunov function (the nonautonomous PDE (3.4) is not a gradient system). Anyway, since (3.5) gives a rather strong estimate of v_τ for $\tau \gg 1$, this makes it possible to pass to the limit $\tau \to \infty$ and establish stabilization to an equilibrium point (see the technique in [26, pp. 116–117]), which is unique by the obvious mass-monotonicity with time of the solution.

The symmetry of the Fréchet derivative (2.12) at F looks like a certain "remnant" of the fact that the original PDE is a gradient system.

4. Center subspace patterns for the $2m$th-order TFE.

We consider the $2m$th-order TFE with absorption (1.24) with the critical absorption (Fujita) exponent (1.25). The proper setting of a standard "zero contact angle" FBP for the TFE includes $m + 1$ free boundary conditions at the free boundary $\Gamma_0 = \partial\Omega(t)\times\mathbb{R}_+$ ($\Omega(t)$ is the support of $u(\cdot, t)$ at time $t > 0$),

$$u = \nabla u = \cdots = \tfrac{\partial^{m-1}u}{\partial\nu^{m-1}} = \nu\cdot\nabla(u^n\Delta^{m-1}u) = 0, \tag{4.1}$$

where ν is the unit outward normal to $\partial\Omega(t)$ that is assumed to be sufficiently smooth.

4.1. Similarity solutions.

The similarity solutions of the pure TFE

$$u_t = (-1)^{m+1}\nabla\cdot(u^n\nabla\Delta^{m-1}u) \tag{4.2}$$

take the standard form (1.19) with

$$\beta = \tfrac{1}{2m+nN}. \tag{4.3}$$

One can see that the critical exponent (1.25) is precisely the one for which the PDE (1.24) possesses the same group of scaling transformations. Then the rescaled profile F satisfies the radial restriction of the $2m$th-order elliptic equation

$$\mathbf{A}(F) = (-1)^{m+1}\nabla\cdot(F^n\nabla\Delta^{m-1}F) + \beta\nabla F\cdot y + \beta NF = 0. \tag{4.4}$$

It seems that, for any $m \ge 3$, the questions of existence and uniqueness of a solution $F(y) > 0$ in B_1 remain open. It is clear that, for large m, a standard approach to existence based on a multiparametric shooting leads to a complicated geometric analysis (though some general conclusions in this geometry are likely). We expect that the approach based on the n-branching (or a continuous homotopy connection with

$n=0$) via the classical theory [43] makes it possible to explain properties solutions, at least, for small $n>0$ by branching from the linear case $n=0$ (but, surely, a standard approach to smooth branching does not apply). For the Cauchy problem, the spectral and other properties of the corresponding linear operator (4.4) for $n=0$ are given in [13] and can be used to clarify the behavior for small $n>0$. For the FBP (4.1), an extra analysis of the linearized elliptic PDE is necessary.

As usual, the case $n=1$ provides us with the explicit solution. Writing the ODE (4.4) in the radial divergent form (here y is actually $|y|$)

$$(y^{N-1}F(\Delta^{m-1}F)')' = (-1)^m\beta(y^N F)',$$

on integration we obtain $\Delta^{m-1}F = (-1)^m \frac{1}{2}\beta y^2$. Integrating this linear ODE $2m-2$ times yields the positive solution in B_1

$$F(y) = c_0(1-|y|^2)^m, \quad \text{where } c_0 = \tfrac{1}{2}\,\tfrac{N!!}{(2m)!!(2m+N)!!}. \tag{4.5}$$

4.2. Linearized operator. We next follow the same scheme of the asymptotic analysis as in section 2. Similar to (2.10), we introduce the linearized operator

$$\begin{aligned}\mathbf{A}'(F)Y &= (-1)^{m+1}\nabla\cdot(F^n\nabla\Delta^{m-1}Y)\\ &\quad + (-1)^{m+1}\nabla\cdot(nF^{n-1}Y\nabla\Delta^{m-1}F) + \beta\nabla Y\cdot y + \beta NY.\end{aligned} \tag{4.6}$$

Using the ODE (4.4), we have that

$$(-1)^{m+1}\nabla\cdot(nF^{n-1}\nabla\Delta^{m-1}F) = -\beta nN, \;\; (-1)^{m+1}nF^{n-1}\nabla\Delta^{m-1}F = -\beta ny,$$

so (4.6) can be written in the form

$$\mathbf{A}'(F)Y = (-1)^{m+1}\nabla\cdot(F^n\nabla\Delta^{m-1}Y) + \beta N(1-n)y\cdot\nabla Y + \beta N(1-n)Y, \tag{4.7}$$

and we again observe that $n=1$ is a special case.

4.3. The self-adjoint case $n=1$. Plugging the profile (4.5) into (4.7) yields the following symmetric form of the operator:

$$\begin{aligned}\mathbf{A}'(F)Y &= c_0(-1)^{m+1}\nabla\cdot((1-|y|^2)^m\nabla\Delta^{m-1}Y)\\ &\equiv c_0(-1)^{m+1}[D^m((1-|y|^2)D^mY) + m(m-1)N\Delta^{m-1}Y],\end{aligned} \tag{4.8}$$

where D^m denotes $\Delta^{m/2}$ for m even and $\nabla\Delta^{(m-1)/2}$ for m odd. For instance, for $N=1$ and $m=3$, we have

$$\mathbf{A}'(F)Y = c_0(1-y^2)^2[((1-y^2)Y''')''' + 6Y^{(4)}].$$

Having the symmetric operator (4.8) in C_0^∞, we next determine its self-adjoint extensions [10]. In particular, there exists the extension with discrete spectrum and polynomial eigenfunctions in the radial setting (the nonradial case is covered by using the spherical polynomials as in (2.17)). The eigenvalues λ_k for the polynomials $\psi_k(y)$ given in (2.19) are calculated by using (4.8),

$$\lambda_k = -c_0(k+2)k\ldots[k+2-2(m-2)](k+N+2)(k+N)\ldots[k+N-2(m-2)] \tag{4.9}$$

for $k=2(m-3), 2(m-2), \ldots$. Using the eigenfunction expansion in terms of a complete and closed subset of polynomials $\{\psi_k\}$ partially justifies the asymptotic center subspace analysis of the corresponding rescaled equation (2.9), which yields the same ODE (2.24) and hence the asymptotics (2.26). Here in the critical case (1.25) we still have $\frac{1}{p-1} = \beta N$ with β given by (4.3). Finally, we arrive at the asymptotic pattern (1.22), where 4 is replaced by $2m$.

4.4. The general case $n \neq 1$. We do not have such a self-adjoint operator, but anyway, once $F > 0$ in B_1 is determined, we obtain the radial eigenfunction ψ_0 for $\lambda_0 = 0$ from the scaling symmetry group (2.28) (the exponent $\frac{4}{n}$ is replaced by $\frac{2m}{n}$) of (4.4). We can also guarantee that (4.7) has compact resolvent provided that $n > 0$ is not large, so $\lambda_0 = 0$ is an isolated eigenvalue. The rest of the center subspace behavior via the expansion (2.33) remains unchanged and leads to similar logarithmically perturbed asymptotic patterns. A rigorous justification is a hard open problem.

5. Logarithmically perturbed patterns in the Cauchy problem.

The asymptotic behavior and similarity solutions for the TFE (1.12) or (1.24) posed in the whole space $\mathbb{R}^N \times \mathbb{R}_+$ are less studied in the literature. For $n \in (0, \frac{3}{2})$, in the Cauchy problem, the solutions exhibiting the "maximal regularity" at the interfaces are oscillatory and of changing sign. See [17, 18] and the book [25, Ch. 1] for the correct meaning of the Cauchy problem for TFEs and further examples. For such solutions, we need to assume that u^n in (4.1) is replaced by $|u|^n$. Therefore, from now on, in all the expressions and equations we use the convention that

$$\begin{gathered} u^n, f^n, v^n, w^n, \dots \text{ are replaced by } |u|^n, |f|^n, |v|^n, |w|^n, \dots \text{ and} \\ u^p, f^p, v^p, w^p, \dots \text{ are replaced by } |u|^{p-1}u, |f|^{p-1}f, |v|^{p-1}v, |w|^{p-1}w, \dots . \end{gathered} \tag{5.1}$$

We must admit that solutions of changing sign are less relevant for many known physical applications of TFEs. Nevertheless, for general PDE theory, it is key and of principal importance to include the Cauchy problem and to show that the basic techniques developed above apply to these much more complicated oscillatory solutions.

The idea of sign changing solutions of TFEs is straightforward. Indeed, the oscillatory properties of such solutions are a manifestation of the fact that TFEs (4.2) are "homotopic," i.e., can be continuously deformed (e.g., as $n \to 0$) via nonsingular uniformly parabolic PDEs with analytic coefficients (for details see [18, section 14]) to the linear *polyharmonic equation*

$$u_t = (-1)^{m+1}\Delta^m u \quad \text{in } \mathbb{R}^N \times \mathbb{R}_+. \tag{5.2}$$

By classical parabolic theory (see, e.g., Èĭdel'man [14]), given initial data $u_0 \in L^1$, there exists the unique solution of the Cauchy problem for (5.2) defined by the convolution

$$u(x,t) = b(x,t) * u_0, \quad b(x,t) = t^{-\frac{N}{2m}} F(y), \;\; y = x/t^{\frac{1}{2m}}, \tag{5.3}$$

where $b(x,t)$ is the fundamental solution of the operator $D_t - (-1)^{m+1}\Delta^m$. For any $m \geq 2$, the rescaled kernel $F = F(|y|)$ is oscillatory as $y \to \infty$, so this property of changing sign is inherited by L^1 solutions of (5.2). Assuming a continuous (homotopic) deformation of a class of solutions of (1.12) as $n \to 0^+$, this confirms that the TFE admits oscillatory solutions of changing sign at least for not very large $n > 0$. Continuity and homotopy concepts are effective for treating the Cauchy problem for higher-order TFEs; see other examples in [18].

Then the source-type solutions of the TFE take the same form (1.19), where the radial function F of changing sign solves the ODE (1.20) with the convention (5.1). We begin with the linear case $n = 0$, which by continuity is going to describe some properties of source-type solutions for sufficiently small $n > 0$.

5.1. Properties of the rescaled fundamental solution for $n = 0$. The linear ODE

$$\mathbf{A}(F) \equiv -\Delta^2 F + \tfrac{1}{4}\nabla F \cdot y + \tfrac{N}{4} F = 0 \quad \text{in } \mathbb{R}^N \tag{5.4}$$

is precisely the elliptic equation for the rescaled kernel F of the fundamental solution in (5.3). Therefore, the similarity profile $F(y)$ exists and is unique under the assumption

$$\textstyle\int F(y)\,\mathrm{d}y = 1 \tag{5.5}$$

(in view of existence-uniqueness of the fundamental solution).

Let us next describe an important relation between similarity profiles for the FBP and the Cauchy problem. Without loss of generality, we consider the case $N = 1$, where on integration once (5.4) takes the form

$$F''' = \tfrac{1}{4} F y. \tag{5.6}$$

It is easy to find all decaying profiles corresponding to the Cauchy problem with the exponential WKBJ asymptotics as $y \to +\infty$,

$$F(y) \sim y^{-\frac{1}{3}} \mathrm{e}^{a y^{4/3}}, \quad \text{with } a \text{ satisfying } a^3 = \tfrac{1}{4}\left(\tfrac{3}{4}\right)^3. \tag{5.7}$$

There exist two complex conjugate roots for exponentially decaying profiles

$$a_\pm = -\tfrac{3}{8}\, 4^{-\frac{1}{3}}(1 \pm \mathrm{i}\sqrt{3}) \equiv -c_1 \pm \mathrm{i} c_2. \tag{5.8}$$

This yields a *two-dimensional* bundle of oscillatory solutions with the behavior

$$F(y) \sim y^{-\frac{1}{3}} \mathrm{e}^{-c_1 y^{4/3}} \left[A_1 \cos\left(c_2 y^{\frac{4}{3}}\right) + A_2 \sin\left(c_2 y^{\frac{4}{3}}\right)\right] \quad \text{as } y \to \infty, \tag{5.9}$$

where A_1 and A_2 are arbitrary constants. The algebraic factor $y^{-1/3}$ is obtained by a standard asymptotic WKBJ method. We observe here the periodic behavior with a *single* fundamental frequency (a result we will refer to in the TFE analysis below).

PROPOSITION 5.1. *For $N = 1$, the rescaled profile of the Cauchy problem $F = F_\infty$ given by* (5.4), (5.5) *is the limit of FBP similarity profiles on bounded intervals,*

$$F_\infty = \lim F_k, \tag{5.10}$$

where each $F_k(y)$ is defined on interval $(-y_k, y_k)$,

$$F_k(\pm y_k) = F_k'(\pm y_k) = 0, \quad \textit{and} \tag{5.11}$$

$$y_k = \left(\tfrac{\pi}{c_2}\, k\right)^{\frac{3}{4}} (1 + o(1)) \quad \textit{as } k \to \infty. \tag{5.12}$$

Proof. The geometric aspect of such a property is obvious in view of the oscillatory behavior in (5.9). The convergence as $k \to \infty$ follows from straightforward computations related to the whole exponential bundle including (5.9) and the growing counterpart

$$F(y) = y^{-\frac{1}{3}} \mathrm{e}^{a_0 y^{4/3}} + \cdots, \quad \text{with } a_0 = \frac{3}{4}\, 4^{-\frac{1}{3}}.$$

Then solving the FBP problem (5.11) yields the asymptotic equality $\cos(c_2 y_k^{4/3} + \text{const}) = 0$, whence the asymptotics (5.12). □

We also expect the following *Sturm property* be valid:

$$F_k(y) \quad \text{has precisely } k \text{ zeros on } (0, y_k). \tag{5.13}$$

Such a zero-number property is easily seen for $k \gg 1$ but is not obvious for smaller k's.

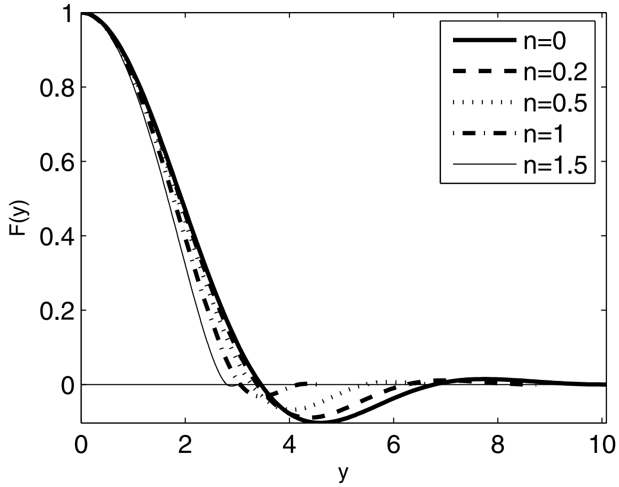

FIG. 2. *The oscillatory Cauchy problem profiles satisfying* (5.14). *Parameters of shooting are* $F''(0) = -0.3379890$ *(*$n = 0$*)*, -0.3414702 *(*$n = 0.2$*)*, -0.3490986 *(*$n = 0.5$*)*, -0.3697143 *(*$n = 1$*)*, *and* -0.4052680 *(*$n = 1.5$*)*.

5.2. Similarity profiles for $n > 0$: Existence and uniqueness.

PROPOSITION 5.2. *For* $N = 1$ *and* $n \in (0,1)$*, the ODE* (1.20), (5.1) *in* $\mathbb{R}$ *admits a unique solution* $F \in C^3$ *of unit mass. The solution* $F(y)$ *is symmetric, compactly supported, and oscillatory near finite interfaces at* $y = \pm y_0$.

Proof. For $N = 1$ the ODE (1.20) has the form

$$|F|^n F''' = \beta F y, \quad y \in \mathbb{R}. \tag{5.14}$$

Dividing by $|F|^n$ and setting $|F|^{-n}F = g$ yields

$$(|g|^\alpha g)''' = \beta g y, \quad y \in \mathbb{R}, \quad \alpha = \tfrac{n}{1-n}. \tag{5.15}$$

Then existence and uniqueness of a compactly supported solution $F \in C^3$ for any $n \in (0,1)$ follow from the results in Bernis and McLeod [6]. □

For $n \in [1, \frac{3}{2})$ solutions of (5.14) are less regular (see below), so the techniques in [6] do not apply directly, but we expect that the existence-uniqueness result remains valid and can be extended further to some interval $n \in [\frac{3}{2}, n_{\rm h})$; see below.

In Figure 2 we have shown these similarity profiles for some $n > 0$ including the linear case $n = 0$ leading to the ODE (5.6) for the fundamental rescaled profile. Here we observe convergence of the fundamental profiles as $n \to 0^+$, which is justified rigorously if all the zeros are "transversal" and isolated except the last one; see below.

5.3. Oscillatory properties via periodic orbits. We next describe the oscillatory properties of such sign changing profiles $F(y)$ near interfaces. We rescale F to have that

$$\operatorname{supp} F = [-1, 1].$$

It was shown in [17] that the asymptotic behavior of $F(y)$ satisfying (5.14) near the interface point $y \to 1^-$ is given by the expansion

$$F(y) = (1-y)^\mu \phi(s), \quad s = \ln(1-y), \quad \mu = \tfrac{3}{n}, \tag{5.16}$$

where, after scaling $\phi \mapsto \beta^{\frac{1}{n}}\phi$, the oscillatory component ϕ satisfies the following autonomous ODE (we omit exponentially small terms):

$$\phi''' + 3(\mu-1)\phi'' + (3\mu^2 - 6\mu + 2)\phi' + \mu(\mu-1)(\mu-2)\phi + \tfrac{\phi}{|\phi|^n} = 0. \tag{5.17}$$

Oscillatory periodic orbits: Existence. We are now interested in periodic solutions $\phi_*(s)$ of (5.17), which, according to (5.16), can determine the simplest typical (and possibly stable and generic) oscillatory behavior of solutions near interfaces when $s = \ln(1-y) \to -\infty$ as $y \to 1^-$. There are several classic methods of ODE theory for establishing existence and multiplicity of periodic solutions of finite-dimensional dynamical systems. These are various topological techniques, such as rotations of vector fields, index, and degree theory; see [33, sections 13, 14]. Another approach is based on branching theory [43, Ch. 6]. In our case, such an n-branching approach is especially effective since for $n = 0$ the unique solution F is the rescaled kernel of the fundamental solution (a rigorous justification of some aspects of branching for such degenerate equations can be a hard problem). We also mention papers [44, 35, 32] containing further related references and methods concerning modern theory of periodic solutions of higher-order nonlinear ODEs. In general, equations like (5.17) are difficult to study; particularly, the main difficulty is proving *uniqueness* of such periodic orbits. Therefore, later on, together with analytic techniques, we will need also to rely on careful numerical evidence on existence, uniqueness, and stability of periodic solutions.

It is curious that for $n = 1$, the unique periodic solution can be detected by a direct algebraic approach; see [17, section 7.4].

Proposition 5.3. *For $n = 1$, the ODE* (5.17) *has a unique T-periodic solution, with*

$$T = -2\ln s > \theta = 1.9248\ldots, \tag{5.18}$$

where $\theta = 0.381966\ldots$ is the unique root on the interval $(0, 1)$ *of the cubic equation*

$$\theta^3 - 2\theta^2 - 2\theta + 1 = 0. \tag{5.19}$$

Indeed, for $n = 1$, the nonlinearity in (5.17) is $\operatorname{sign}\phi$ and the ODE is linear in the positivity and negativity domain of solutions,

$$\phi''' + 6\phi'' + 11\phi' + 6\phi \pm 1 = 0,$$

and so can be solved explicitly. Matching positive and negative branches leads to the result.

Let us now state the main result concerning periodic orbits of the ODE (5.17).

Theorem 5.4. *The ODE* (5.17) *admits a nontrivial stable periodic solution $\phi_*(s)$ of changing sign for all*

$$0 < n < n_{\rm h} \in (\tfrac{3}{2}, n_+), \quad \textit{where} \quad n_+ = \tfrac{9}{3+\sqrt{3}} = 1.9019238\ldots. \tag{5.20}$$

Uniqueness of such periodic $\phi_*(s)$ in the interval (5.20) is still open.

Proof. For the interval

$$0 < n < \tfrac{3}{2}, \tag{5.21}$$

the proof of existence is performed in [17, p. 292] by a shooting argument. Numerical representation of periodic solutions is given therein on page 294; see also [25, p. 143]. We need to point out the main two ingredients of the proof in [17]:

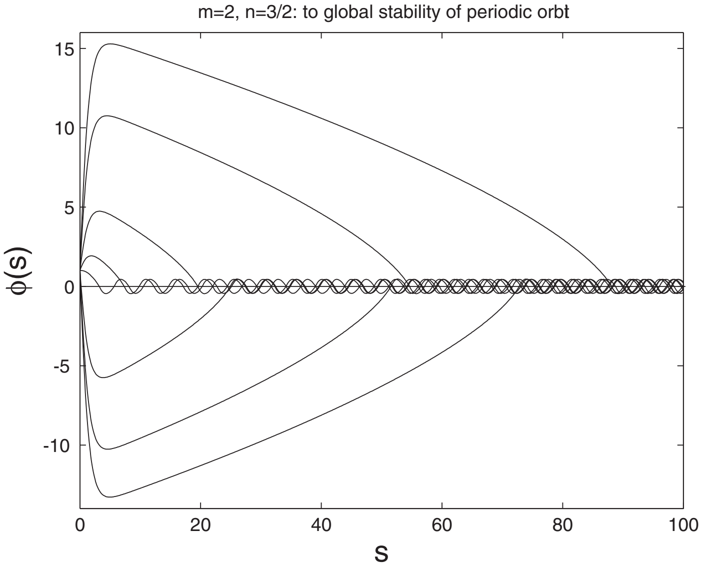

FIG. 3. *Convergence to the stable periodic solutions of* (5.17) *for* $n = \frac{3}{2}$ *for various Cauchy data posed at* $s = 0$.

(i) it is shown that for exponents (5.21) no orbits of the dynamical system (5.17) are attracted to infinity as $s \to +\infty$; i.e., all orbits stay uniformly bounded; and

(ii) as a consequence, then (5.17) is a dissipative dynamical system having a bounded absorbing set.

Dissipative dynamical systems are known to admit periodic solutions in a rather general setting [33, section 39] provided these are nonautonomous (so the period is fixed). For the autonomous system (5.17), the proof in [17, section 7.1] was completed by shooting. Note that, in view of the last term, (5.17) is not a smooth dynamical system and solutions are not locally C^3-smooth. Nevertheless, as local analysis shows [17, p. 291], at least for $n \in (0, 2)$, the nonlinearity is integrable to guarantee local extensions of solutions through generic “transversal” zeros. This means that the equivalent integral equation is well-posed and is composed from compact operators in a certain topology (this is necessary for application of classic methods of branching in Banach spaces [43, Ch. 7]). We continue to deal with the differential equation, where the justification of calculus is done by local analysis.

It turns out that both properties (i) and (ii) also remain valid for $n = \frac{3}{2}$, so that a periodic solution ϕ_* also exists and is stable; see Figure 3. For the extension of ϕ_* to $n > \frac{3}{2}$, we will use the following crucial stability result.

PROPOSITION 5.5. *If the periodic solution* $\phi_*(s)$ *of* (5.17) *persists for all* $\frac{3}{2} \le n_{\rm h} < 3$, *then it is stable and hyperbolic on this interval.*

Proof. Note that, for $n \in (\frac{3}{2}, 3)$, there exist two unstable constant equilibria of equation (5.17),

$$\phi_\pm = \pm \big[-\tfrac{1}{\mu(\mu-1)(\mu-2)} \big]^{\frac{1}{n}} \quad \text{for } \ n \in (\tfrac{3}{2}, 3), \tag{5.22}$$

and we expect a stable periodic motion in between. Consider the eigenvalue problem for the ODE (5.17) linearized about the T-periodic solution ϕ_* by setting $\phi = \phi_* + Y$,

$$Y''' + 3(\mu-1)Y'' + (3\mu^2 - 6\mu + 2)Y' + \mu(\mu-1)(\mu-2)Y + (1-n)|\phi_*|^{-n}Y = \lambda Y.$$

As usual, assuming that $\lambda \in \mathbb{C}$, multiplying this by the complex conjugate $\overline{Y}$ in $L^2(0,T)$, taking the conjugate and multiplying by Y, and summing up both yields (5.23)

$$-3(\mu-1)\int |Y'|^2 + \mu(\mu-1)(\mu-2)\int |Y|^2 + (1-n)\int |\phi_*|^{-n}|Y|^2 = \tfrac{\lambda+\bar{\lambda}}{2}\int |Y|^2.$$

Since all three terms on the left-hand side of (5.23) are negative for any $\frac{3}{2} < n < 3$, the result follows. The case $n = \frac{3}{2}$ is similar since just the second term vanishes. □

Thus, by classic branching theory [43, Ch. 6], stable hyperbolic periodic solutions are locally extensible relative to the parameter $n \ge \frac{3}{2}$. In particular, using the hyperbolicity of ϕ_* for $n = \frac{3}{2}$, we conclude that the periodic solution exists in an interval $n \in [\frac{3}{2}, \frac{3}{2} + \delta)$ with some $\delta > 0$, and the interval of existence must be open from the right-hand side.

Finally, let us justify the estimate in (5.20). To this end, we multiply (5.17) by ϕ_*' and integrate over $(0,T)$ to get for any $n \in (0,2)$

$$-\int (\phi_*'')^2 + (3\mu^2 - 6\mu + 2)\int (\phi_*')^2 = 0,$$

so that one needs

$$3\mu^2 - 6\mu + 2 > 0 \quad \Longrightarrow \quad \mu = \tfrac{3}{n} > \mu_+ = \tfrac{3}{n_+} = \tfrac{3+\sqrt{3}}{3}.$$

This completes the proof of Theorem 5.4. □

On heteroclinic bifurcation. Since the periodic orbit $\phi_*(s)$ remains stable and hyperbolic in the whole interval of existence (5.20), the end point $n = n_{\rm h}$ cannot be any kind of subcritical saddle-node bifurcation, at which two branches meet each other. Classic bifurcation and branching theory [33, 43] then suggests that at $n = n_{\rm h}^-$ the dynamical system (5.17) undergoes a *heteroclinic bifurcation* when the period increases without bound (this claim needs further study and a full analytical justification); see standard scenarios in Perko [41, Ch. 4]. Note that, by Proposition 5.5, the heteroclinic orbit that occurred remains stable and hyperbolic.

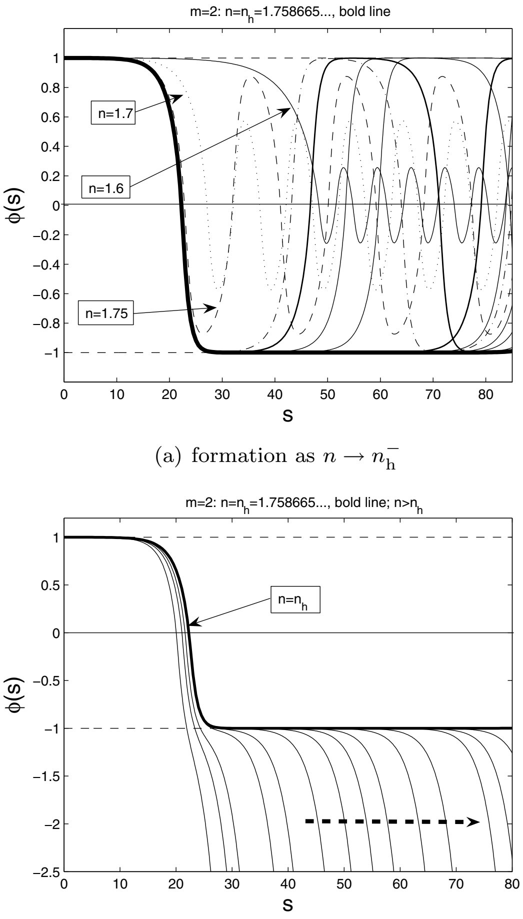
Numerically, $n_{\rm h}$ is given by

$$n_{\rm h} = 1.7598665026\ldots. \tag{5.24}$$

Figure 4 shows the formation of the heteroclinic orbit in both limits: as $n \to n_{\rm h}^-$ (a) and $n \to n_{\rm h}^+$ (b). This bifurcation exponent $n_{\rm h}$ plays an important role and shows the parameter range of n's, for which many ODE profiles near interfaces are *oscillatory*, except those that approach the interface point $s = -\infty$, the stable manifold of the constant equilibrium (5.22). In the interval (5.21), this manifold of orbits of constant sign is empty, so that all the orbits near $s = -\infty$ are oscillatory and coincide with the periodic one $\phi_*(s + s_0)$, where $s_0 \in \mathbb{R}$ is a parameter of shifting. Indeed, this also characterizes important oscillatory features of the PDE. Note that some kind of a "heteroclinic bifurcation" phenomenon also exists for the sixth-order ($m = 3$) and higher-order TFEs with more difficult mathematics involved; see [18, section 13] and [25, pp. 142–147].

On one-dimensional shooting for $n \in (1, n_{\rm h})$. As a key application of the above oscillation analysis, we have that, according to (5.16), for all $n \in (0, n_{\rm h})$, there exists a one-dimensional bundle of oscillatory orbits of changing sign

$$F(y) = (1-y)^{\frac{3}{n}}\phi_*(\ln(1-y) + s_0) + \ldots, \tag{5.25}$$



(a) formation as $n \to n_{\mathrm{h}}^-$

(b) formation as $n \to n_{\mathrm{h}}^+$

FIG. 4. *Formation of a heteroclinic orbit as $n \to n_{\mathrm{h}}$.*

where $s_0 \in \mathbb{R}$ is an arbitrary parameter of phase shift in the periodic orbit $\phi_*(s)$. Recall that, for the ODE (5.14), we need to shoot just a single symmetry condition at the origin,

$$F'(0) = 0 \quad (F(0) \neq 0), \tag{5.26}$$

so the one-dimensional bundle (5.25) is well suited for this. In view of oscillatory character of the behavior in (5.25), it is not difficult to prove the existence of such an s_0 to satisfy (5.26), while uniqueness (as expected) remains open.

Further comments about n_{h}. For any $n > n_{\mathrm{h}}$, the behavior in the ODE (5.17) becomes exponentially unstable, and we did not observe oscillatory or changing sign patterns. This suggests that precisely above $n = n_{\mathrm{h}}$, the ODE (and the corresponding PDE) loses its natural similarities with the linear one for $n = 0$ (though a continuous homotopic connection is expected to be still available; i.e., some local properties of solutions dramatically change at n_{h}).

Thus, in the range $n \in (\frac{3}{2}, 3)$, (5.17) possesses the positive constant solution $\phi(s) \equiv \phi_+$ given in (5.22). This gives the behavior (2.35), so that, for such solutions, formally, the FBP and the Cauchy problem may coincide in the ODE setting. But this is not the case for all the solutions since for $n \in (\frac{3}{2}, n_{\rm h})$ there are other oscillatory profiles with a similar (actually, a bit less) regularity at the interfaces, so that the Cauchy problem demands oscillatory solutions, while the FBP can admit positive solutions; for more details see [17, section 9]. In the parameter range $n \geq n_{\rm h}$, the oscillatory behavior is no longer generic, so we expect a certain improvement of the positivity preserving properties of the TFE, where the Cauchy problem and the FBP may coincide; see further discussion in [17, section 9.4].

5.4. The TFE with critical absorption $\boldsymbol{p = p_0}$. The formal asymptotics for the TFE (1.5), (1.6) is now calculated similarly using the center subspace spanned by the eigenfunction (2.29). Of course, we then do not gain any explicit mathematics or symmetric operators as for $n = 1$ in the case of the FBP.

The main ideas of the analysis can be extended to the $2m$th-order case, where many aspects of source-type and general solutions of the Cauchy problem for the TFEs remain mathematically open. The oscillatory character of solutions near the interface for $m = 3$ was studied in [18, section 13]; see also [25, section 3.7] for further examples for $m \geq 3$ and other oscillatory PDEs.

5.5. Supercritical range $\boldsymbol{p > p_0}$. We use the same scaling (3.1) and obtain the exponentially perturbed rescaled PDE (3.2), which suggests that the solutions behave as $t \to \infty$ as the source-type solution with a finite positive mass attained at $\tau = +\infty$ (no proof is yet available).

Appendix. The linearized operator is not symmetric when $\boldsymbol{n \neq 1}$. We prove that, in the FBP setting, the linearized operator (2.11) admits a self-adjoint extension only when $n = 1$. Without loss of generality we consider the one-dimensional case, and we formulate first the following results we are already familiar with.

Proposition A.1. *The linearized operator* (2.11) *in* $\mathbb{R}$ *is symmetric in some weighted space* L^2_ρ *when* $n = 1$.

Proof. For $N = n = 1$, the linearized operator is given by

$$\mathbf{A}'(f)Y = -(fY''')' - (Yf''')' + \tfrac{1}{5}\,(Yy)'. \tag{A.1}$$

For this to be symmetric in L^2_ρ with some weight $\rho \geq 0$, we require that [37, section 1]

$$\mathbf{A}'(f)Y \equiv \tfrac{1}{\rho}\,\left[(p_0Y'')'' - (p_1Y')' + p_2Y\right]. \tag{A.2}$$

Expanding the right-hand sides of these equations and comparing coefficients yields the following system:

$$Y'''' : \ -f = \tfrac{p_0}{\rho}, \tag{A.3}$$

$$Y''' : \ -f' = \tfrac{2p_0'}{\rho}, \tag{A.4}$$

$$Y'' : \ 0 = \tfrac{p_0''-p_1}{\rho}, \tag{A.5}$$

$$Y' : \ -f''' + \tfrac{1}{5}y = -\tfrac{p_1'}{\rho}, \tag{A.6}$$

$$Y : \ -f'''' + \tfrac{1}{5} = \tfrac{p_2}{\rho}. \tag{A.7}$$

We know the exact solution of the ODE for f when $n = 1$ (see (1.21)):

$$f(y) = \tfrac{1}{120}\,(a^2 - y^2)^2 \ \text{ for } y \in (-a, a). \tag{A.8}$$

Substituting this into (A.7) yields $p_2 = 0$. Equation (A.6) yields $p_1 = C$, where C is a constant. Equations (A.3) and (A.4) yield $p_0^2 = f$ and $\rho = -f^{-1/2}$. Equation (A.5) is thus the consistency condition and is satisfied since it yields $p_1 = C$ (since $p_0'' = p_1 = C$). Thus the linearized operator for the TFE is symmetric if $n = 1$. □

THEOREM A.2. *For $N = 1$ and $n \neq 1$, operator* (2.11) *is not symmetric in L^2_ρ for any weight $\rho > 0$.*

Proof. The ODE for $f > 0$ for any $n > 0$ is

$$-(f^n f''')' + \tfrac{1}{n+4}\,(fy)' = 0. \tag{A.9}$$

The linearized operator (2.11) is given by

$$\mathbf{A}'(f)Y = -(f^n Y''')' - n(f^{n-1} Y f''')' + \tfrac{1}{n+4}\,(Yy)'. \tag{A.10}$$

For this to be symmetric, we require identity (A.2) to hold. Comparing coefficients yields

$$Y'''' : \quad -f^n = \tfrac{p_0}{\rho}, \tag{A.11}$$

$$Y''' \;:\quad -nf^{n-1}f' = \tfrac{2p_0'}{\rho}, \tag{A.12}$$

$$Y'' \;:\quad 0 = \tfrac{p_0''-p_1}{\rho}, \tag{A.13}$$

$$Y' \;:\quad -nf^{n-1}f''' + \tfrac{y}{n+4} = -\tfrac{p_1'}{\rho}, \tag{A.14}$$

$$Y \;:\quad -n(n-1)f^{n-2}f''' - nf^{n-1}f'''' + \tfrac{1}{n+4}. \tag{A.15}$$

From this

$$p_0^2 = f^n,\;\; p_1 = p_0'',\;\; \rho = -f^{-n/2},\;\; p_2 = \rho\big[-n(n-1)f^{n-2}f''' - nf^{n-1}f'''' + \tfrac{1}{n+4}\big],$$

and the consistency condition is

$$f^{\frac{n}{2}}(f^{\frac{n}{2}})''' = -nf^{n-1}f''' + \tfrac{1}{n+4}\,y. \tag{A.16}$$

To see if this coincides with (A.9) for some f, we use a Taylor expansion of $f(y)$ and check if (A.16) and (A.9) produce the same coefficients for f. To do this we set $f(0) = 1,\; f'(0) = f'''(0) = 0$, and $f''(0) = b \in \mathbb{R} \setminus \{0\}$, differentiate (A.16) and (A.9) the required number of times, and set $y = 0$. The expansions coincide up to the coefficient of y^3, but the coefficients of y^4 coincide only if

$$b = \pm \tfrac{\sqrt{-6n(n^2+2n-8)(3n-2)}}{3n^3+6n^2-24n}. \tag{A.17}$$

Since we require $b \in \mathbb{R} \setminus \{0\}$, we must have $n \in (-4, 0) \cup (\frac{2}{3}, 2)$. This gives us a range of values of n, for which the linearized operator may be symmetric. To check whether it is, we examine the coefficient of y^6 for (A.16) and (A.9). If the operator is symmetric, then the same value of b should be obtained as in the coefficients of y^4 for both equations. For the coefficients of y^6 to coincide, we require

$$b = 0, \;\text{ or }\; b = \pm \tfrac{2\sqrt{2}\sqrt{n(9n^3-40n^2-188n+464)(3n-2)}}{9n^4-40n^3-188n^2+464n}\,, \tag{A.18}$$

and since we require $b \in \mathbb{R} \setminus \{0\}$, we discard $b = 0$. For this b to coincide with (A.17), we require $n = \frac{2}{3}$. This contradicts the fact that we must have $n \in (-4, 0) \cup (\frac{2}{3}, 2)$ for the linearized operator (2.11) to have a chance of being symmetric and admit a suitable (Friedrichs) self-adjoint extension. Hence the linearized operator is not symmetric if $n \neq 1$. □

BURSTING OSCILLATIONS INDUCED BY SMALL NOISE*

PAWEL HITCZENKO† AND GEORGI S. MEDVEDEV†

Abstract. We consider a model of a square-wave bursting neuron residing in the regime of tonic spiking. Upon introduction of small stochastic forcing, the model generates irregular bursting. The statistical properties of the emergent bursting patterns are studied in the present work. In particular, we identify two principal statistical regimes associated with the noise-induced bursting. In the first case, type I, bursting oscillations are created mainly due to the fluctuations in the fast subsystem. In the alternative scenario, type II bursting, the random perturbations in the slow dynamics play a dominant role. We propose two classes of randomly perturbed slow-fast systems that realize type I and type II scenarios. For these models, we derive the Poincaré maps. The analysis of the linearized Poincaré maps of the randomly perturbed systems explains the distributions of the number of spikes within one burst and reveals their dependence on the small and control parameters present in the models. The mathematical analysis of the model problems is complemented by the numerical experiments with a generic Hodgkin–Huxley-type model of a bursting neuron.

Key words. neuronal dynamics, bursting, Hodgkin–Huxley model, slow-fast system, noise, Poincaré map

1. Introduction.

Differential equation models of excitable cells often include small random terms to reflect the unresolved or poorly understood aspects of the problem or to account for intrinsically stochastic factors [1, 8, 9, 10, 15, 16, 32, 41, 39, 43, 46]. In addition, many neuronal models also exhibit multistability [38, 26]. In systems with multiple stable states, noise may induce transitions between different attractors in the system dynamics, thus creating qualitatively new dynamical regimes that are not present in the deterministic system. In the present paper, we study this situation for a class of square-wave bursting models of excitable cell membranes. This class includes many conductance-based models of excitable cell membranes. Here we just mention the model of a pancreatic β-cell [6, 7], models of neurons in various central pattern generators such as those involved in insect locomotion [20], control of the heartbeat in a leech [25], and respiration in mammals [4, 5], to name a few. These models, as well as the underlying biological systems, exhibit characteristic bursting patterns of the voltage time series: clusters of fast spikes alternating with pronounced periods of quiescence (Figure 1a). For introduction to bursting, examples, and bibliography, we refer the reader to [26, 31, 37, 38, 44]. The dynamical patterns generated by the conductance-based models typically depend sensitively on parameters. For example, models of square-wave bursting neurons often exhibit both bursting and spiking behaviors for different values of parameters (see Figure 1a,b). In many relevant experiments, the transition from spiking to bursting is achieved by changing the injected current. In the present paper, we consider a model of a square-wave bursting neuron in the regime of tonic spiking (Figure 1b). We show that a small noise

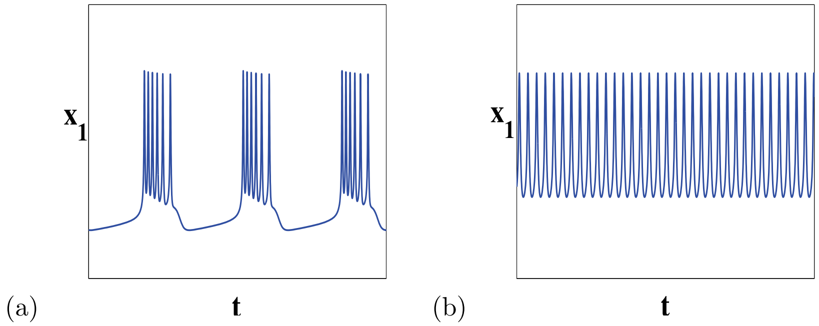

FIG. 1. *The dynamical patterns generated by a model of of a square-wave bursting neuron* (1.1) *and* (1.2)*:* (a) *periodic bursting and* (b) *tonic spiking.*

can transform spiking patterns into irregular (noise-induced) bursting patterns and describe two distinct mechanisms for generating noise-induced bursting. In the first scenario, bursting oscillations are triggered by the fluctuations in the fast subsystem. We refer to this mechanism as type I bursting. In contrast, the bursting dynamics in the type II scenario are driven by the random motion along the slow manifold. For each of these cases, we describe the statistical properties of the emergent bursting patterns and characterize them in terms of the small and control parameters present in the model.

Noise-induced phenomena have received considerable attention in the context of neuronal modeling (see, e.g., [1, 8, 9, 32, 39, 41, 43, 46]). A representative example is given by a two-dimensional (2D) excitable system perturbed by the white noise of small intensity [1]. In the presence of noise and under certain general conditions, a typical trajectory occasionally leaves the basin of attraction (BA) of the stable equilibrium and makes a large excursion in the phase plane of the deterministic system before returning to a small neighborhood of the stable fixed point (Figure 2a). This gives rise to irregular spiking (Figure 2b). The properties of the noise-induced spiking and stochastic resonance-type effects arising in the context of the perturbed FitzHugh–Nagumo model have been considered in [1, 8, 9, 10] (see also [3, 17, 18, 19] for the mathematical analysis of more general classes of related phenomena in randomly perturbed slow-fast systems). In the present paper, we study a related mechanism for irregular bursting. Specifically, we consider a class of models of square-wave bursting neurons:

$$\dot{x} = f(x, y), \tag{1.1}$$

$$\dot{y} = \epsilon g(x, y), \quad x = (x^1, x^2)^T \in \mathbb{R}^2,\ y \in \mathbb{R}^1, \tag{1.2}$$

where f and g are smooth functions and $0 < \epsilon \ll 1$ is a small parameter. We refer to (1.1), where y is treated as a parameter, as a fast subsystem. It is formally obtained from (1.1) and (1.2) by setting $\epsilon = 0$. We assume that the fast subsystem has a family of stable limit cycles and of stable equilibria for y in a certain interval $y \in (y_{sn}, y_{bp})$ (see Figure 3a). The additional assumptions on (1.1) and (1.2), which are explained in section 2, imply that for small $\epsilon > 0$, system (1.1) and (1.2) has a stable limit cycle, as shown in Figure 3c. In the presence of noise, a typical trajectory of the randomly perturbed system will occasionally leave the BA of the limit cycle of the deterministic system to make an excursion along the curve of equilibria of the degenerate system, E (see Figure 4a). Thus, in analogy to the 2D FitzHugh–Nagumo model (Figure 2a),

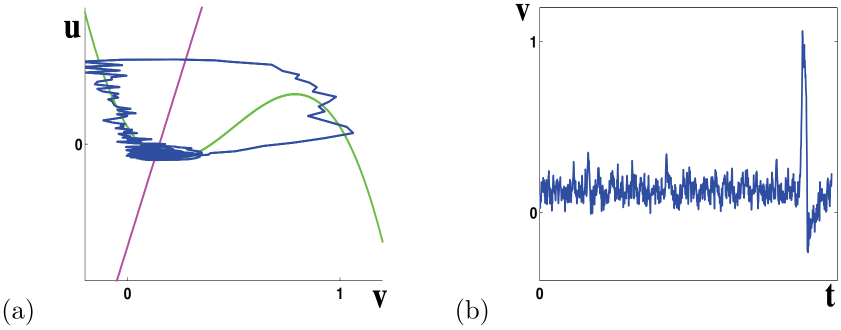

Fig. 2. (a) *A phase-plane trajectory of the randomly perturbed FitzHugh–Nagumo model in an excitable regime (see* [1] *for the model description and the parameter values).* (b) *The time series corresponding to the phase plot in* (a).

noise transforms spiking dynamics into irregular bursting. We refer to the latter as noise-induced bursting. In both examples above, irregular spiking (Figure 2a) or bursting patterns (Figure 4a,b) are created due to the escape of a trajectory of the randomly perturbed system from the BA of a stable fixed point in the case of spiking or of that of the stable limit cycle in the case of bursting. The statistics of the first exit times can then be related to the properties of the emergent firing patterns such as the frequency of spiking or the distribution of the number of spikes within one burst. Compared to the analysis of the irregular spiking in the randomly perturbed FitzHugh–Nagumo model (Figure 2), the analysis of the noise-induced bursting faces several additional challenges due to the fact that in the latter case one has to consider the exit problem for the trajectories near a stable limit cycle as opposed to those near a stable equilibrium in the former case. The structure of the BA of the limit cycle combined with the slow-fast character of the vector field determines the main features of the resultant bursting patterns. The description of the principal statistical regimes associated with the noise-induced bursting is the focus of the present paper.

There are general mathematical approaches for analyzing exit problems for stochastic processes generated by randomly perturbed differential equations such as (1.1) and (1.2): the Wentzell–Freidlin theory of large deviations [19] and the geometric theory for randomly perturbed slow-fast systems due to Berglund and Gentz [3]. In this paper we study the vector fields arising in the context of bursting. The specialized structure of this class of problems allows us to keep the analysis of the present paper self-contained and avoid using more technical methods, which are necessary for analyzing more general situations. Our analytical approach is based on the reduction of a randomly perturbed differential equation model to the Poincaré map and studying the exit problems for the trajectories of the discrete system. Using maps is quite natural in the context of bursting due to the intrinsic discreteness of bursting patterns imposed by the presence of spikes. Reductions to maps have been very useful for analyzing bursting dynamics in a variety of deterministic models [6, 33, 34, 35, 40]. As follows from the results of the present paper, the first return maps also provide a very convenient and visual representation for the mechanism underlying noise-induced bursting. In particular, we show that the distributions of spikes in one burst in many cases are effectively determined by one-dimensional (1D) linear randomly perturbed maps. We develop a set of probabilistic techniques for analyzing the dynamics of randomly perturbed 1D and 2D linear maps such as those arising in the analysis of bursting. The special structure of this class of problems, which is motivated by the applications to bursting, affords a more direct and simpler analysis than the treatment of more general classes of random linear maps found in the literature [29, 21, 28, 45].

The outline of the paper is as follows. In section 2, we formulate our assumptions on the deterministic system. We then present the preliminary numerical results, motivating our formulation of the randomly perturbed models at the end of this section. Specifically, we distinguish two types of the noise-induced bursting. *Type I* bursting is generated due to the fluctuations predominantly in the fast subsystem, while *type II* bursting is induced by variability mainly in the slow variable. Accordingly, we introduce two types of models that generate type I and type II bursting patterns. Section 3 develops a set of probabilistic techniques, which will be needed for the analysis of the first return maps for the randomly perturbed differential equation models. We first analyze a simple linear map with an attracting slope and small additive Gaussian perturbations in section 3.2. Due to the simple structure of the map, we obtain very explicit characterization of the first exit times for this problem. The analysis of this first relatively simple example provides the guidelines for the more complex cases dealt with in sections 3.3–3.5. Section 4 contains the definition and the construction of the Poincaré map for the type I randomly perturbed model introduced in section 2. The 2D Poincaré map is decomposed into two 1D maps for the fast and slow subsystems, which are constructed in sections 4.2 and 4.3, respectively. In section 4.4, we apply the results of section 3 to the linearization of the Poincaré map to derive the distributions of the first exit times. The latter are interpreted as the distributions of the number of spikes in one burst. In sections 4.5, we outline the modifications necessary to cover type II models. Since the analysis for type II models closely follows the lines of that for type I models, we omit most of the details. Finally, the numerical experiments in section 5 are designed to illustrate our theory.

2. The model.

In the present section, we introduce the model to be studied in the remainder of this paper. We start by formulating our assumptions on the deterministic model and then describe the random perturbation.

2.1. The deterministic model.

We consider slow-fast system (1.1) and (1.2) in $\mathbb{R}^3$ with one *slow* variable. The *fast* subsystem associated with (1.1) and (1.2) is obtained by sending $\epsilon \to 0$ in (1.2) and treating y as a parameter:

$$\dot{x} = f(x, y). \tag{2.1}$$

Under the variation of y, the fast subsystem has the bifurcation structure as shown schematically in Figure 3a. Specifically, we rely on the following assumptions:

(PO) There exists $y_{bp} \in \mathbb{R}$ such that for each $y < y_{bp}$, (2.1) has an exponentially stable limit cycle of period $\mathcal{T}(y)$:

$$L(y) = \{x = \phi(s, y) : \ 0 \leq s < \mathcal{T}(y)\}. \tag{2.2}$$

The family of the limit cycles, $L = \bigcup_{y<y_{bp}} L(y)$, forms a cylinder in $\mathbb{R}^3$ (Figure 3a).

(EQ) There is a branch of asymptotically stable equilibria of (2.1), $E = \{x = \psi(y) : y > y_{sn}\}$, which terminates at a saddle-node bifurcation at $y = y_{sn} < y_{bp}$ (Figure 3a).

(LS) For each $y \in \mathbb{R}$, the ω-limit set of almost all trajectories of (2.1) belongs to $L(y) \bigcup \{\psi(y)\}$.

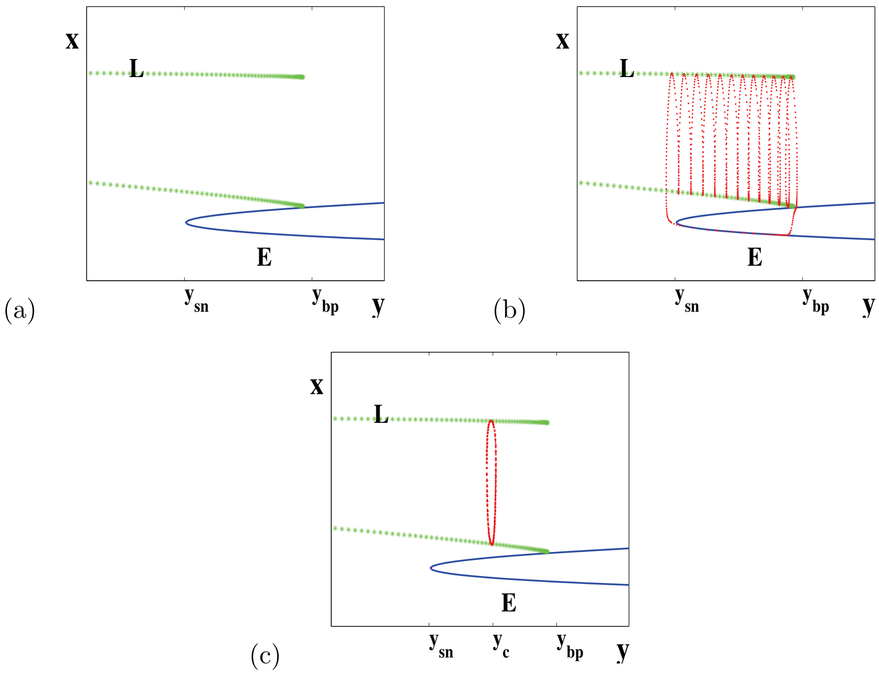

FIG. 3. (a) *The bifurcation diagram of the fast subsystem* (2.1). *L denotes a cylinder foliated by the stable periodic orbits. The lower branch of the parabolic curve E is composed of stable equilibria of the fast subsystem (see Figure* 6b *for the plot of a representative phase plane of the fast subsystem for $y \in (y_{sn}, y_{bp})$).* (b), (c) *Periodic trajectories of the full system* (1.1) *and* (1.2) *are superimposed on the bifurcation diagram of the fast subsystem. Assumptions* (SE) *and* (SB) *(see the text) result in a bursting limit cycle* (b), *while* (SS) *yields spiking* (c).

Remark 2.1. At $y = y_{bp}$, either L terminates or $L(y_{bp} + 0)$ loses stability. We do not specify the type of the bifurcation at $y = y_{bp}$. It may be, for instance, a homoclinic bifurcation as shown in Figure 3a, or a saddle-node bifurcation of limit cycles [22]. Having specified the assumptions on the bifurcation structure of the fast subsystem, we turn to the slow dynamics. The geometric theory for singularly perturbed systems implies the existence of the exponentially stable locally invariant manifolds E_ϵ and L_ϵ, which are $O(\epsilon)$ close to $E \bigcap \{(x, y) : y > y_{sn} + \delta\}$ and $L \bigcap \{(x, y) : y < y_{bp} - \delta\}$, respectively, for arbitrary fixed $\delta > 0$ and sufficiently small $\epsilon > 0$ [14, 27]. Manifolds E_ϵ and L_ϵ are called *slow manifolds*. For small $\epsilon > 0$, the dynamics of (1.1) and (1.2) on the slow manifolds is approximated by

$$L_\epsilon : \quad \dot{y} = \epsilon G(y), \quad y < y_{bp} - \delta, \tag{2.3}$$

$$E_\epsilon : \quad \dot{y} = \epsilon g(\psi(y), y), \quad y > y_{sn} + \delta, \tag{2.4}$$

where

$$G(y) = \frac{1}{\mathcal{T}(y)} \int_0^{\mathcal{T}(y)} g\left(\phi(s), y\right) ds. \tag{2.5}$$

We distinguish two types of the asymptotic behavior of solutions of (1.1) and (1.2): *bursting* and *spiking* (see Figure 1). The following conditions on the slow subsystem yield bursting.

For some $c > 0$ independent of ϵ,

(SE)

$$g(\psi(y), y) < -c \quad \text{for} \quad y > y_{sn}, \tag{2.6}$$

(SB)

$$G(y) > c \quad \text{for} \quad y < y_{bp}. \tag{2.7}$$

Under these assumptions, for sufficiently small $\epsilon > 0$ a typical trajectory of (1.1) and (1.2) consists of the alternating segments closely following L_ϵ and E_ϵ and fast transitions between them (see Figure 3b). For detailed discussions of the geometric construction of "bursting" periodic orbits, we refer the reader to [31, 37]. To obtain spiking, we substitute (SB) with

(SS) $G(y)$ has a unique simple zero at $y = y_c \in (y_{sn}, y_{bp})$:

$$G(y_c) = 0 \quad \text{and} \quad G'(y_c) < 0. \tag{2.8}$$

In this case, the asymptotic behavior of solutions follows from the following theorem due to Pontryagin and Rodygin.

Theorem 2.2 (see [36]). *If $\epsilon > 0$ is sufficiently small, system* (1.1) *and* (1.2) *has a unique exponentially stable limit cycle $L_\epsilon(y_c)$ of period $\mathcal{T}(y_c) + O(\epsilon)$ lying in an $O(\epsilon)$ neighborhood of $L(y_c)$, provided* (SS) *holds.*

Almost all trajectories of (1.1) and (1.2) are attracted by the limit cycle lying in an $O(\epsilon)$ neighborhood of $L(y_c)$. This mode of behavior is called spiking (see Figures 3c and 3b). In the remainder of this paper we assume (SS), in addition to (PO), (EQ), (LS), and (SE).

2.2. The randomly perturbed models.

In this subsection, we provide a heuristic description of the effects of the random perturbations on the dynamics of (1.1) and (1.2). To study these effects quantitatively, at the end of this section we propose two randomly perturbed models.

Suppose the trajectories of (1.1) and (1.2) experience weak stochastic forcing, such that the perturbed trajectories represent well-defined stochastic processes and are close to the trajectories of (1.1) and (1.2) on finite intervals of time. Since the trajectories of the unperturbed system remain in a small neighborhood of $L(y_c)$ (possibly after short transients), we expect that in the presence of noise the trajectories will occasionally leave the BA of $L(y_c)$ and after making a brief excursion along E will return back to the vicinity of $L(y_c)$. Therefore, under random perturbation the system can exhibit bursting dynamics, while the underlying deterministic system is in the spiking regime. We refer to this mode of behavior as *noise-induced* bursting. Our goal is to describe typical statistical regimes associated with the noise-induced bursting and to relate them to the structure of (1.1) and (1.2) and to the properties of the stochastic forcing. To illustrate the implications of the structure of the deterministic vector field for the bursting patterns that it produces under random perturbations, we refer to the following numerical examples. Note that the BA of $L(y_c)$ naturally extends along the cylinder of periodic orbits L (Figure 3c). The escape from the BA of $L(y_c)$ can be dominated by the fluctuations along L or by those in the transverse plane. These two possibilities are shown in Figure 4. The trajectory shown in Figure 4a spends most of the time near $L(y_c)$ and leaves its BA due to the fluctuations in the fast subsystem. We refer to this scenario as *type I* escape. Alternatively, the trajectory shown in Figure 4b travels a good deal along L before the escape and exits

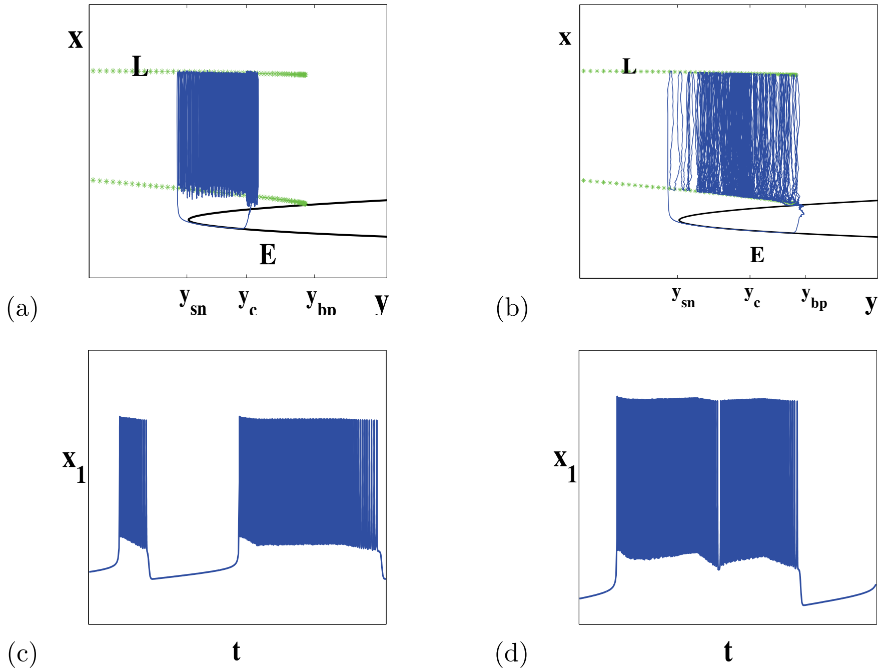

Fig. 4. *Noise-induced bursting.* (a) *A trajectory of the randomly perturbed system is shown in the phase space of the frozen system* (1.1), (1.2) *with* $\epsilon = 0$. *The trajectory leaves the basin of* $L(y_c)$ *mainly due to the fluctuations in the fast plane. This is characteristic to type I bursting. An alternative type II scenario is shown in plot* (b), *where the fluctuations in the slow direction dominate in the mechanism of escape from the basin of the stable limit cycle. The trajectory in* (b) *samples a wide region of* L *and leaves a neighborhood of* L *near the right boundary,* $y \approx y_{bp}$, *while that in* (a) *remains near* $L(y_c)$ *most of the time and jumps down near* $y \approx y_c$. *The differences translate into the distinctive features of the generic time series of the bursting patterns generated via type I or type II mechanisms shown in plots* (c) *and* (d), *respectively. Note that the longer burst in* (c) *has a typical square-wave form (roughly determined by* $L(y_c)$*), while the burst shown in* (d) *exhibits more variability due to the drifting of the trajectory along* L.

from the BA near $y = y_{bp}$. This mechanism is dominated by the slow dynamics. We refer to this scenario as *type II* escape. These mechanisms of escape translate into distinct features of the resultant bursting patterns. First, note that since in type I and type II scenarios the transition from spiking to quiescence typically takes place at $y \approx y_c$ and $y \approx y_{bp}$, respectively, by (1.2) and (EQ), the corresponding interburst intervals are approximately equal to

$$IBI \approx \epsilon^{-1} \int_{\hat{y}}^{y_{sn}} \frac{dy}{g\left(\psi(y), y\right)}, \quad \text{where} \quad \begin{cases} \hat{y} = y_c, & \text{type I,} \\ \hat{y} = y_{bp}, & \text{type II.} \end{cases}$$

In addition, we expect that the interspike intervals (ISIs) within one burst in type I scenarios are localized about $\mathcal{T}(y_c)$, since the trajectory of the randomly perturbed system in the active phase of bursting spends most of the time near $L(y_c)$. In type II bursting patterns, ISIs are expected to have more variability, since the trajectories sample a wider range of ISIs during their excursions along L. Perhaps, a more pronounced distinction between these two types of bursting patterns lies in the degree of the variability of the spikes in one burst. Most of the spikes forming a burst in type I pattern are generated by (2.1) with $y \approx y_c$ and, therefore, are similar in shape

(Figure 4c). In contrast, spikes in type II scenarios are subject to more variability and the bursting patterns typically have a ragged shape (Figure 4d).

To study type I and type II noise-induced bursting patterns it is convenient to consider two types of models. The *type I model* incorporates random forcing in the fast subsystem:

$$\dot{x}_t = f\left(x_t, y_t\right) + \sigma p \dot{w}_t, \tag{2.9}$$

$$\dot{y}_t = \epsilon g(x_t, y_t), \tag{2.10}$$

while in the *type II model* the slow subsystem is forced:

$$\dot{x}_t = f\left(x_t, y_t\right), \tag{2.11}$$

$$\dot{y}_t = \epsilon\left(g(x_t, y_t) + \sigma q \dot{w}_t\right). \tag{2.12}$$

Here, $0 < \sigma \ll 1$, $p(x,y) = \left(p^1(x,y), p^2(x,y)\right)^T$ and $q(x,y)$ are differentiable functions; $\dot{w}_t$ stands for the white noise, i.e., a generalized derivative of the Wiener process.

3. The randomly perturbed maps.

In this section, we develop probabilistic tools needed for the analysis of randomly perturbed systems (2.9)–(2.12). The number of spikes in one burst is a natural random variable associated with the noise-induced bursting. It is commonly used in the experimental studies of bursting, and we shall adopt it for characterizing irregular bursting patterns in this work. In section 4, we will show that the number of spikes in one burst is represented by a stopping time (more precisely, the level exceedance time) of a discrete random process, the Poincaré map of the randomly perturbed system (2.9)–(2.12). In preparation for the analysis of the linearized Poincaré map in section 4, in the present section we study certain stochastic linear difference equations. Equations of this form have been considered in the literature before. The study was initiated by Kesten [29], who considered the multidimensional case (in which the coefficients of the stochastic equations are random matrices). Subsequent work focused mostly on the 1D case. We refer the reader to the papers [21, 45], which contain representative results, examples of applications, and further references. There is also a review paper [12], unfortunately not easily accessible. The convergence properties of the solutions that we will need could be deduced from a general theory of stochastic difference equations. However, the results in the literature are often stated in the most general form and some of the proofs are rather involved. We will be dealing with special cases that are much easier to justify. For this reason, and also to keep the paper self-contained, we will include the proofs of the needed results.

3.1. Geometric random variables.

We begin by recalling the necessary properties of geometric random variables (RVs). Recall that Y is a geometric RV with parameter p, $0 < p < 1$, if

$$\mathbb{P}\left(Y = k\right) = p(1-p)^{k-1}, \quad k \geq 1. \tag{3.1}$$

We refer the reader to [28, Chapter 5] for the review of the properties of geometric distributions and their applications. In particular, the following characterization of geometric RVs is classical.

LEMMA 3.1. *Let Y be an RV with values in the set of positive integers. Y is a geometric with parameter p, $0 < p < 1$, iff*

$$\mathbb{P}(Y = n) = p\mathbb{P}(Y \geq n), \quad n \geq 1. \tag{3.2}$$

Lemma 3.1 motivates the following definition.

Definition 3.2. *Let Y be a random variable with values in the set of positive integers and let $0 < p < 1$. We say that Y is asymptotically geometric with parameter p if*

$$\lim_{n\to\infty} \frac{\mathbb{P}\,(Y = n)}{\mathbb{P}(Y \geq n)} = p. \tag{3.3}$$

3.2. The randomly perturbed map: Additive perturbation. Consider

$$Y_n = \lambda Y_{n-1} + \varsigma r_n, \quad n \geq 1, \tag{3.4}$$

where $r_1, r_2, \dots$ are independent identically distributed (IID) copies of the standard normal RV, and Y_0 is a real number. We will use $N(\mu, \eta^2)$ notation for a normal RV with mean μ, variance η^2, and probability density function given by

$$\frac{1}{\sqrt{2\pi}\eta} \exp\left\{-\frac{(x-\mu)^2}{2\eta^2}\right\}, \quad -\infty < x < \infty.$$

We will also let Z denote a generic $N(0,1)$ RV and write

$$\Phi(x) := \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{x} e^{-t^2/2} dt$$

for its distribution function. For a given $h > 0$, let

$$\tau = \inf\{k \geq 1 : \ Y_k > h\}.$$

Theorem 3.3. *Let*

$$\varepsilon \in (0,1), \quad \lambda = 1 - \varepsilon, \quad \beta^2 = \frac{\varsigma^2}{\varepsilon(2-\varepsilon)}, \quad \textit{and} \quad h - Y_0 > 0. \tag{3.5}$$

Then for sufficiently small $\varsigma > 0$, τ is asymptotically geometric RV with parameter

$$p = \frac{1}{\sqrt{2\pi}} \frac{\beta}{h\Phi(h/\beta)} \exp\left\{-\frac{h^2}{2\beta^2}\right\} \left(1 + O\left(\frac{\varsigma}{\varepsilon}\right)^2\right). \tag{3.6}$$

We precede the proof of the theorem with the following auxiliary.

Lemma 3.4. *For $n \geq 1$, Y_n is a normal RV with*

$$\mathbb{E}\ Y_n = \lambda^n Y_0 \quad \textit{and} \quad \operatorname{var} Y_n = \frac{\varsigma^2\left(1 - \lambda^{2n}\right)}{1 - \lambda^2} =: \beta_n^2. \tag{3.7}$$

In particular,

$$Y_n \xrightarrow{d} Y \overset{d}{=} N(0, \beta^2),$$

where $\xrightarrow{d}$ (and $\overset{d}{=}$) denote the convergence (equality) in distribution.

Proof of Lemma 3.4. The statements in (3.7) are verified by a straightforward calculation. The rest follows, because $\mathbb{E}\ Y_n \to 0$ and $\beta_n \to \beta$.

Proof of Theorem 3.3. Let $Y_k^* = \max\{Y_j : \ 1 \leq j \leq k\}$, $k \geq 1$. Then

$$\begin{aligned}\mathbb{P}(\tau = n+1) &= \mathbb{P}(Y_{n+1} > h, Y_n^* \leq h) = \mathbb{P}(Y_{n+1} > h | Y_n^* \leq h)\mathbb{P}(Y_n^* \leq h)\\ &= \mathbb{P}(Y_{n+1} > h | Y_n \leq h, Y_{n-1} \leq h, \dots, Y_0 \leq h)\mathbb{P}(\tau \geq n+1)\\ &= \mathbb{P}(Y_{n+1} > h | Y_n \leq h)\mathbb{P}(\tau \geq n+1). \end{aligned} \tag{3.8}$$

In the last equality, we used the fact that $\{Y_n\}$ is a Markov process which is clear from (3.4). By (3.8),

$$p_n := \frac{\mathbb{P}(\tau = n+1)}{\mathbb{P}(\tau \geq n+1)} = \mathbb{P}\left(Y_{n+1} > h \,|Y_n \leq h\,\right) = \frac{\mathbb{P}\left(Y_{n+1} > h, Y_n \leq h\right)}{\mathbb{P}\left(Y_n \leq h\right)}. \tag{3.9}$$

In accordance with Definition 3.2, we need to show that $\{p_n\}$ converges and to estimate the limit. By Lemma 3.4,

$$\mathbb{P}\left(Y_n \leq h\right) \longrightarrow \Phi(h/\beta), \text{ as } n \to \infty.$$

Next, we turn to estimating the numerator in (3.9). We have

$$\begin{aligned} Q_n &:= \mathbb{P}\left(Y_{n+1} > h, Y_n \leq h\right) = \mathbb{P}\left(\lambda Y_n + \varsigma r_{n+1} > h, Y_n \leq h\right) \\ &\to \mathbb{P}\left(\lambda Y + \varsigma Z > h, Y \leq h\right) =: Q, \end{aligned}$$

where Z is standard normal, Y is $N(0,\beta^2)$, and both are independent. This follows from Lemma 3.4 and the fact that r_{n+1} is $N(0,1)$ and is independent of Y_n. Q is the probability that a 2D Gaussian vector is in the region $[h,\infty) \times (-\infty, h]$. There are several ways of estimating this probability. We take the following, elementary approach. Let $X = h - Y$ so that X is $N\left(h,\beta^2\right)$ and is independent of Z. Then

$$Q = \mathbb{P}\left(Z > \frac{\varepsilon}{\varsigma}h + \frac{1-\varepsilon}{\varsigma}X, X \geq 0\right) = \frac{1}{\sqrt{2\pi}\beta}\int_0^\infty \mathbb{P}\left(Z > \frac{\varepsilon h + (1-\varepsilon)s}{\varsigma}\right) e^{\frac{-(s-h)^2}{2\beta^2}}\, ds.$$

By the well-known asymptotics (see [13, Chapter VII, Lemma 2 and section 7, Problem 1])

$$\mathbb{P}(Z > u) = 1 - \Phi(u) = \frac{1}{\sqrt{2\pi}}\frac{e^{-\frac{u^2}{2}}}{u}\left(1 + O\left(\frac{1}{u^2}\right)\right), \quad u > 0. \tag{3.10}$$

Hence, for sufficiently small $\varsigma > 0$ ($\varsigma \ll \varepsilon$), we have

$$Q \approx \frac{1}{2\pi}\frac{\varsigma}{\beta}\int_0^\infty \frac{\exp\left\{-\frac{1}{2}\left(\frac{(\varepsilon h + (1-\varepsilon)s)^2}{\varsigma^2} + \frac{(s-h)^2}{\beta^2}\right)\right\}}{\varepsilon h + (1-\varepsilon)s}\, ds. \tag{3.11}$$

Since

$$\frac{(\varepsilon h + (1-\varepsilon)s)^2}{\varsigma^2} + \frac{(s-h)^2}{\beta^2} = \frac{(s-\varepsilon h)^2}{\varsigma^2} + \frac{h^2}{\beta^2},$$

we obtain

$$Q \approx \frac{\varsigma}{2\pi\beta}\exp\left\{-\frac{h^2}{2\beta^2}\right\}\int_0^\infty \frac{\exp\left\{-\frac{(s-h\varepsilon)^2}{2\varsigma^2}\right\}}{\varepsilon h + (1-\varepsilon)s}\, ds.$$

By Laplace's method [47], for sufficiently small $\varsigma > 0$ ($\varsigma \ll \varepsilon$), the last integral is asymptotic to

$$\frac{\sqrt{2\pi}}{(h\varepsilon + (1-\varepsilon)\varepsilon h)\sqrt{1/\varsigma^2}} = \frac{\sqrt{2\pi}\varsigma}{h\varepsilon(2-\varepsilon)}.$$

Hence,

$$Q \approx \frac{\varsigma}{2\pi\beta} \frac{\sqrt{2\pi}\varsigma}{h\varepsilon(2-\varepsilon)} \exp\left\{-\frac{h^2}{2\beta^2}\right\} = \frac{\beta}{\sqrt{2\pi}h} \exp\left\{-\frac{h^2}{2\beta^2}\right\}.$$

By the same reasoning the error term from (3.10) is of order

$$\exp\left\{-\frac{h^2}{2\beta^2}\right\} \times O\left(\frac{1}{\varepsilon}\left(\frac{\beta}{h}\right)^3\right),$$

which gives (3.6). □

3.3. The randomly perturbed map: Random slope. Consider a process

$$Y_n = \mu(1+\sigma r_{1,n})Y_{n-1} + \sigma r_{2,n}, \quad n \geq 1, \tag{3.12}$$

where $(r_{1,n}, r_{2,n})_{n=1}^{\infty}$ are IID copies of a 2D random vector (r_1, r_2). Here, we assume that (r_1, r_2) has bivariate normal distribution with mean vector 0 and covariance matrix $\Sigma_2 = [\sigma_{i,j}]$, where $\sigma_{i,j} = \mathrm{cov}(r_i, r_j)$, $1 \leq i, j \leq 2$. We assume that the entries $\sigma_{i,j}$ are of order 1 in a sense that they do not depend on other parameters. Recall that the probability density function of a multivariate normal random vector $(r_1, \ldots, r_d)$ with mean vector 0 and covariance matrix Σ is given by

$$\frac{1}{\sqrt{(2\pi)^d \det(\Sigma)}} \exp\left\{-\frac{1}{2}x^T\Sigma^{-1}x\right\}, \quad x = (x_1, \ldots, x_d)^T,$$

and we denote such vectors by $N(0, \Sigma)$.

For a given $h > 0$, let

$$\tau = \inf\{k \geq 1 : \ Y_k > h\}.$$

THEOREM 3.5. *Suppose that h and $\mu \in (0,1)$ are both of order 1 and $\sigma \ll 1$ so that the following condition holds:*

$$\gamma := \mu\mathbb{E}|1+\sigma r_1| < 1. \tag{3.13}$$

Then τ is asymptotically geometric RV with parameter

$$p = \frac{\sigma}{c\sqrt{2\pi}} e^{-\frac{c^2}{2\sigma^2}}\Big(1 + O(\sigma^2)\Big), \tag{3.14}$$

where a positive constant c depends on h, μ, and Σ_2, but not on σ.

As before, we first establish convergence of $\{Y_n\}$ and characterize the limit. Iteration of (3.12) yields

$$\begin{aligned} Y_n &= \mu(1+\sigma r_{1,n})Y_{n-1} + \sigma r_{2,n} = \mu(1+\sigma r_{1,n})\left(\mu(1+\sigma r_{1,n-1})Y_{n-2} + \sigma r_{2,n-1}\right) + \sigma r_{2,n} \\ &= \cdots = \mu^n Y_0 \prod_{j=1}^{n}(1+\sigma r_{1,j}) + \sigma \sum_{j=0}^{n-1} \mu^j r_{2,n-j} \prod_{\ell=n-j+1}^{n} (1+\sigma r_{1,\ell}), \end{aligned} \tag{3.15}$$

where as usual $\prod_{j=k}^{m}(\ *\ ) = 1$ if $k > m$.

Lemma 3.6.

$$Y_n \xrightarrow{d} Y \overset{d}{=} \sigma \sum_{j=0}^{\infty} \mu^j g_{2,j} \prod_{\ell=0}^{j-1} (1+\sigma g_{1,\ell}),\ n\to\infty, \tag{3.16}$$

where $(g_{1,j}, g_{2,j}),\ j = 0, 1, 2, \ldots,$ *are IID copies of a* 2D *random vector, which is equal in distribution to* (r_1, r_2)*.*

Proof of Lemma 3.6. First, we show that Y is well-defined as the series in (3.16) converges almost surely. To see this, note that the summands

$$g_{2,j} \prod_{\ell=0}^{j-1} (1+\sigma g_{1,\ell})$$

are martingale differences with respect to the natural filtration. By triangle inequality, independence, and (3.13),

$$\begin{aligned}\mathbb{E}\left|\sigma \sum_{j=0}^{m} \mu^j g_{2,j} \prod_{\ell=0}^{j-1}(1+\sigma g_{1,\ell})\right| &\le \sigma \mathbb{E}|g_2| \sum_{j=0}^{m} \mu^j \mathbb{E}\left|\prod_{\ell=0}^{j-1}(1+\sigma g_{1,\ell})\right| \\ &= \sigma\mathbb{E}|g_2| \sum_{j=0}^{m} \mu^j \left(\mathbb{E}|1+\sigma r_1|\right)^j = \frac{\sigma\mathbb{E}|g_2|}{1-\gamma}(1-\gamma^{(m+1)}) \le \frac{\sigma \mathbb{E}|g_2|}{1-\gamma}.\end{aligned}$$

Hence, the partial sums of the right-hand side of (3.16) form an L_1-bounded martingale which converges almost surely by the martingale convergence theorem (see, e.g., [42]). For every $n \ge 1$

$$\sigma \sum_{j=0}^{n-1} \mu^j r_{2,n-j} \prod_{\ell=n-j+1}^{n} (1+\sigma r_{1,\ell}) \overset{d}{=} \sigma \sum_{j=0}^{n-1} \mu^j g_{2,j} \prod_{\ell=0}^{j-1} (1+\sigma g_{1,\ell}).$$

Since the sequence on the right converges almost surely and the almost sure convergence implies convergence in distribution, we infer that the sequence on the left converges in distribution. To conclude that $Y_n \xrightarrow{d} Y$ it is enough to show that the first term on the right-hand side of (3.15) converges to 0 in probability. But that is clear since we have

$$\mathbb{E}\left|Y_0 \mu^n \prod_{j=1}^{n}(1+\sigma r_{1,j})\right| = |Y_0|\mu^n \prod_{j=1}^{n} \mathbb{E}|1+\sigma r_{1,j}| = |Y_0|\gamma^n.$$

Hence, by Markov inequality it goes to 0 in probability. □

Proof of Theorem 3.5. The proof follows along the lines of the proof of Theorem 3.3. The main complication in treating the present case is that we know less about the distribution of Y_n than before. Nonetheless, we will argue that for large n

$$p_n := \frac{\mathbb{P}(\tau = n)}{\mathbb{P}(\tau \ge n)} = \mathbb{P}(\mu(1+\sigma r_{1,n})Y_{n-1} + \sigma r_{2,n} > h | Y_{n-1} \le h) \tag{3.17}$$

is approximately constant. For this, we rewrite the right-hand side of (3.17) as

$$\frac{\mathbb{P}(\mu(1+\sigma r_{1,n})Y_{n-1} + \sigma r_{2,n} > h, Y_{n-1} \le h)}{\mathbb{P}(Y_{n-1} \le h)},$$

and since the denominator converges to $\mathbb{P}(Y \le h)$ we focus on the numerator. Let (r_1, r_2) be a generic vector distributed like $(r_{1,n}, r_{2,n})$ and independent of Y. Since for every $n \ge 1$, $(r_{1,n}, r_{2,n})$ is independent of Y_{n-1}, as $n \to \infty$, we have

$$(r_{1,n}, r_{2,n}, Y_{n-1}) \xrightarrow{d} (r_1, r_2, Y).$$

Thus,

$$\mathbb{P}(\mu(1+\sigma r_1)Y_{n-1} + \sigma r_2 > h, Y_{n-1} \le h) \longrightarrow \mathbb{P}(\mu(1+\sigma r_1)Y + \sigma r_2 > h, Y \le h),$$

which establishes the existence of $p = \lim_{n\to\infty} p_n$.

To estimate p, we first recall that (r_1, r_2) is bivariate normal iff every linear combination of r_1 and r_2 is a normal RV. Hence, conditionally on $Y = y$, $\sigma(\mu y r_1 + r_2)$ is $N(0, \sigma^2\sigma_y^2)$ RV, where

$$\sigma_y^2 = \sigma_{22}^2 + \mu^2 y^2 \sigma_{11}^2 + 2\mu y \sigma_{12}. \tag{3.18}$$

Therefore,

$$\begin{aligned}
&\mathbb{P}(\mu(1+\sigma r_1)Y + \sigma r_2 > h,\ Y \le h) = \mathbb{P}(\sigma(\mu Y r_1 + r_2) > h - \mu Y, Y \le h) \\
&\quad = \int_{-\infty}^{h} \mathbb{P}\left(Z > \frac{h-\mu y}{\sigma\sigma_y}\right) dF_Y(y) = \int_{-\infty}^{h} \left(1 - \Phi\left(\frac{h-\mu y}{\sigma\sigma_y}\right)\right) dF_Y(y) \\
&\quad = \left(1 - \Phi\left(\frac{h-\mu y_0}{\sigma\sigma_{y_0}}\right)\right) \mathbb{P}(Y \le h),
\end{aligned}$$

where $-\infty < y_0 < h$ by the mean value theorem. Hence,

$$p = \frac{\mathbb{P}(\mu(1+\sigma r_1)Y + \sigma r_2 > h,\ Y \le h)}{\mathbb{P}(Y \le h)} = 1 - \Phi\left(\frac{h-\mu y_0}{\sigma\sigma_{y_0}}\right).$$

Let $c := c(y_0)$, where

$$c(x) = c_{h,\mu,\Sigma_2}(x) := \frac{h-\mu x}{\sigma_x} = \frac{h-\mu x}{\sqrt{\mu^2\sigma_{11}^2 x^2 + 2\mu\sigma_{12}x + \sigma_{22}^2}}.$$

Then, by (3.10),

$$p = 1 - \Phi\left(\frac{c}{\sigma}\right) = \frac{\sigma}{c\sqrt{2\pi}} e^{-\frac{c^2}{2\sigma^2}} \left(1 + O\left(\frac{\sigma^2}{c^2}\right)\right).$$

Furthermore, by elementary analysis we see that

- $c(x)$ is increasing on $x \in (-\infty, x^*)$ and decreasing on $x \in (x^*, \infty)$, where
$$x^* = -\frac{\sigma_{11}^2 + h\sigma_{12}}{\mu(h\sigma_{22}^2 + \sigma_{12})};$$
- $c(-\infty) = \sigma_{11}^{-1}$, $c(h) = \frac{(1-\mu)h}{((\mu h\sigma_{11})^2 + 2\mu\sigma_{12}h + \sigma_{22})^{1/2}} = \frac{(1-\mu)h}{((\mu h\sigma_{11} + \sigma_{22})^2 - 2\mu h(\sigma_{11}\sigma_{22} - \sigma_{12}))^{1/2}}$, and $c(x^*)$ is given by a quite unwieldy expression that depends on h and Σ_2 but not on μ.

In particular, c is bounded away from 0 and ∞, provided μ and h are positive and $\mu < 1$. This proves (3.14). □

3.4. A 2D randomly perturbed map.

In this subsection we consider the following 2D model:

$$\xi_{n+1} = \mu\xi_n \left(1 + \sigma r_{1,n+1}\right) + \sigma r_{2,n+1}, \tag{3.19}$$

$$\eta_{n+1} = \lambda\eta_n + \epsilon\sigma r_{3,n+1} + \epsilon a_2 \xi_n, \tag{3.20}$$

where $(r_{1,n}, r_{2,n}, r_{3,n})$, $n \geq 1$, is a sequence of IID copies of (r_1, r_2, r_3) which, as follows from a discussion at the beginning of section 4.4, is assumed to be a trivariate normal random vector $N(0, \Sigma_3)$, with $\Sigma_3 = [\sigma_{i,j}]$, $1 \leq i, j \leq 3$, where $\sigma_{i,j} = \operatorname{cov}(r_i, r_j)$ do not depend on any parameters in (4.44) and (4.45). For positive $h_1, h_2 = O(1)$, we define

$$\tau_\xi = \inf_{k \geq 1}\{\xi_k > h_1\}, \qquad \tau_\eta = \inf_{k \geq 1}\{\eta_k > h_2\}.$$

We are interested in $\tau = \min\{\tau_\xi, \tau_\eta\}$. We know the distribution of τ_ξ from Theorem 3.5. As we will show below, under suitable conditions the distribution of τ is again asymptotically geometric. Moreover, if $\epsilon > 0$ is small, then τ_η has practically no effect on the distribution of τ.

In order to be more precise, let us define

$$A_n = \begin{bmatrix} \mu(1 + \sigma r_{1,n}) & 0 \\ \epsilon a_2 & \lambda \end{bmatrix}, \quad G_n = \begin{bmatrix} r_{2,n} \\ \epsilon r_{3,n} \end{bmatrix}, \quad \text{and} \quad \Theta_n = \begin{bmatrix} \xi_n \\ \eta_n \end{bmatrix}. \tag{3.21}$$

Then (3.19) and (3.20) are described by

$$\Theta_{n+1} = A_{n+1}\Theta_n + \sigma G_{n+1}, \quad n \geq 1. \tag{3.22}$$

Theorem 3.7. *Let $\mu, \sigma, \epsilon \in (0, 1)$ be such that μ is of order 1 and $\sigma \ll 1$ so that condition (3.13) holds. Assume $\epsilon \ll 1$ and set $\lambda = 1 - \epsilon$. Suppose further that h_1 and h_2 are of order 1. Then τ is an approximately geometric RV with parameter p satisfying*

$$p \approx \frac{\sigma}{c\sqrt{2\pi}} e^{-\frac{c^2}{2\sigma^2}}, \tag{3.23}$$

and where the constant c depends on h_1, μ, and Σ_3 but not on σ.

The following lemma shows that $\{\Theta_n\}$ converges in distribution and describes the limit.

Lemma 3.8.

$$\Theta_n \xrightarrow{d} X \overset{d}{=} \sigma \sum_{k=1}^{\infty} \left(\prod_{j=1}^{k-1} A_j\right) G_k, \; n \to \infty, \tag{3.24}$$

where A_n and $G_n, n = 1, 2, \ldots,$ are defined in (3.21). Furthermore, this random vector X satisfies the distributional equation

$$X \overset{d}{=} AX + \sigma G, \tag{3.25}$$

where

$$A = \begin{bmatrix} \mu(1 + \sigma r_1) & 0 \\ \epsilon a_2 & \lambda \end{bmatrix} \quad \text{and} \quad G = \begin{bmatrix} r_2 \\ \epsilon r_3 \end{bmatrix}, \tag{3.26}$$

(r_1, r_2, r_3) is $N(0, \Sigma_3)$, and X on the right-hand side of (3.25) *is independent of* (A, G).

Proof of Lemma 3.8. Note first that each of the sequences (A_n) and (G_n) consists of IID random elements. By iterating (3.22), we obtain

$$\Theta_n = A_n(A_{n-1}\Theta_{n-2}+\sigma G_{n-1})+\sigma G_n = \cdots = \left(\prod_{k=0}^{n-1} A_{n-k}\right)\Theta_0+\sigma\sum_{k=1}^{n}\left(\prod_{j=0}^{n-k-1} A_{n-j}\right) G_k,$$

where, as usual, the product is set to be 1 if its index range is empty. We have

$$\prod_{k=0}^{n-1} A_{n-k} = \begin{bmatrix} \mu^n \prod_{k=1}^{n}(1+\sigma r_{1,k}) & 0 \\ T_n & \lambda^n \end{bmatrix},$$

where

$$T_n = \epsilon a_2 \sum_{j=1}^{n} \lambda^{n-j} \prod_{k=1}^{j-1}(\mu(1+\sigma r_{1,k})).$$

Set $\delta = \max\{\lambda, \mu\mathbb{E}|1+\sigma r_1|\}$ and note that by (3.13) $\delta < 1$. By triangle inequality and independence of $r_{1,k}$'s

$$\mathbb{E}|T_n| \le \epsilon a_2 \sum_{j=1}^{n} \lambda^{n-j}\mathbb{E}\left|\prod_{k=1}^{j-1}(\mu(1+\sigma r_{1,k}))\right| = \epsilon a_2 \sum_{j=1}^{n} \lambda^{n-j}\left(\mu\mathbb{E}|1+\sigma r_1|\right)^{j-1} \le \epsilon a_2 n\delta^{n-1}.$$

Similarly,

$$\mu^n\mathbb{E}\left|\prod_{k=1}^{n}(1+\sigma r_{1,k})\right| = \left(\mu\mathbb{E}|1+\sigma r_1|\right)^n \le \delta^n.$$

It follows that both components of $\big(\prod_{k=0}^{n-1} A_{n-k}\big)\Theta_0$ converge to 0 in probability, and thus this term is negligible.

Since the sequences (A_n) and (G_n) are IID, for every $n \ge 1$ we have

$$\sum_{k=1}^{n}\left(\prod_{j=0}^{n-k-1} A_{n-j}\right) G_k \overset{d}{=} \sum_{k=1}^{n}\left(\prod_{j=1}^{k-1} A_j\right) G_k.$$

By the same argument as above we verify that both components of the sequence of partial sums on the right-hand side are Cauchy in L_1. Hence, the components of the series

$$\sum_{k=1}^{\infty}\left(\prod_{j=1}^{k-1} A_j\right) G_k$$

converge in probability (and thus in distribution). Therefore, the sequence (Θ_n) defined by (3.22) converges in distribution to a random vector X defined in (3.24). Furthermore, X satisfies the distributional equation (3.25). □

Proof of Theorem 3.7. For $h = (h_1, h_2)$ set $B_h := (-\infty, h_1] \times (-\infty, h_2]$. Then

$$\{\tau = n\} = \{\Theta_j \in B_h,\ j < n,\ \Theta_n \notin B_h\},$$

so that

$$\begin{aligned}\mathbb{P}(\tau = n) &= \mathbb{P}(\Theta_n \notin B_h | \Theta_j \in B_h,\ j < n)\mathbb{P}(\Theta_j \in B_h,\ j < n)\\ &= \mathbb{P}(A_n\Theta_{n-1} + \sigma G_n \notin B_h | \Theta_{n-1} \in B_h)\mathbb{P}(\tau \geq n).\end{aligned}$$

Since Θ_n converge in distribution to X, we have

$$\begin{aligned}p_n := \mathbb{P}(A_n\Theta_{n-1} + \sigma G_n \notin B_h | \Theta_{n-1} \in B_h) &= \frac{\mathbb{P}(A_n\Theta_{n-1} + \sigma G_n \notin B_h, \Theta_{n-1} \in B_h)}{\mathbb{P}(\Theta_{n-1} \in B_h)}\\ \longrightarrow p := \frac{\mathbb{P}(AX + \sigma G \notin B_h, X \in B_h)}{\mathbb{P}(X \in B_h)}, &\quad \text{as} \quad n \to \infty. \qquad (3.27)\end{aligned}$$

It follows from (3.24) that X is symmetric, so since both h_1 and h_2 are positive the denominator is at least $1/2$ and does not affect the asymptotics.

To handle the numerator, using (3.26), denoting the components of X by X_1 and X_2, and using the notation adopted in (3.18), we see that it is equal to

$$\begin{aligned}&\mathbb{P}((\mu(1+\sigma r_1)X_1 + \sigma r_2, \epsilon a_2 X_1 + \lambda X_2 + \epsilon\sigma r_3) \notin B_h, (X_1, X_2) \in B_h)\\ &\quad = \mathbb{P}(\mu(1+\sigma r_1)X_1 + \sigma r_2 > h_1, (X_1, X_2) \in B_h)\\ &\qquad + \mathbb{P}(\epsilon a_2 X_1 + \lambda X_2 + \epsilon\sigma r_3 > h_2, (X_1, X_2) \in B_h)\\ &\qquad - \mathbb{P}(\mu(1+\sigma r_1)X_1 + \sigma r_2 > h_1, \epsilon a_2 X_1 + \lambda X_2 + \epsilon\sigma r_3 > h_2, (X_1, X_2) \in B_h)\\ &\quad = \mathbb{P}\left(\frac{\mu X_1 r_1 + r_2}{\sigma_{X_1}} > \frac{h_1 - \mu X_1}{\sigma\sigma_{X_1}}, (X_1, X_2) \in B_h\right)\\ &\qquad + \mathbb{P}\left(r_3 > \frac{h_2 - \epsilon a_2 X_1 - \lambda X_2}{\epsilon\sigma}, (X_1, X_2) \in B_h\right)\\ &\qquad - \mathbb{P}\left(\frac{\mu X_1 r_1 + r_2}{\sigma_{X_1}} > \frac{h_1 - \mu X_1}{\sigma\sigma_{X_1}}, r_3 > \frac{h_2 - \epsilon a_2 X_1 - \lambda X_2}{\epsilon\sigma}, (X_1, X_2) \in B_h\right). \qquad (3.28)\end{aligned}$$

Conditionally on $(X_1, X_2) = (x_1, x_2)$,

$$Z_1 := \frac{\mu x_1 r_1 + r_2}{\sigma_{x_1}} \quad \text{and} \quad Z_2 := \frac{r_3}{\sigma_{33}}$$

are $N(0,1)$ RVs. Hence by letting $F_X(x_1, x_2)$ denote the distribution function of (X_1, X_2), we see that the first of the last three probabilities is

$$\int_{-\infty}^{h_2}\int_{-\infty}^{h_1}\left(1 - \Phi\left(\frac{h_1 - \mu x_1}{\sigma\sigma_{x_1}}\right)\right) dF_X(x_1, x_2). \qquad (3.29)$$

Likewise, for the second of these probabilities we get

$$\int_{-\infty}^{h_2}\int_{-\infty}^{h_1}\left(1 - \Phi\left(\frac{h_2 - \epsilon a_2 x_1 - \lambda x_2}{\epsilon\sigma\sigma_{33}}\right)\right) dF_X(x_1, x_2). \qquad (3.30)$$

We now note that if ϵ is of a smaller order than all other parameters (except possibly σ), then (3.10) implies that (3.30) (and hence also (3.28)) are negligible when compared to (3.29). To analyze the behavior of (3.29) as a function of its parameters, note that by the mean value theorem the quantity in (3.29) is equal to

$$\left(1 - \Phi\left(\frac{h_1 - \mu x_0}{\sigma\sigma_{x_0}}\right)\right)\int_{-\infty}^{h_2}\int_{-\infty}^{h_1} dF_X(x_1, x_2) = \left(1 - \Phi\left(\frac{h_1 - \mu x_0}{\sigma\sigma_{x_0}}\right)\right)\mathbb{P}(X \in B_h)$$

for some $-\infty < x_0 < h$. Substituting this into (3.27) (and neglecting the terms that depend on ϵ) we see that

$$p = \frac{\mathbb{P}(AX + \sigma G \notin B_h, X \in B_h)}{\mathbb{P}(X \in B_h)} \sim 1 - \Phi\left(\frac{h_1 - \mu x_0}{\sigma \sigma_{x_0}}\right).$$

If both $0 < \mu < 1$ and h_1 are of order 1, we are in the same situation as with (3.14). This shows (3.23). $\square$

3.5. Diffusive escape. The exit problems for the stochastic difference equations analyzed in the previous subsections all feature the geometric escape mechanism. In the simplest case when the evolution is given by (3.4), the geometric distribution characterizes the statistics of the times of exit of the trajectories of (3.4) from a certain neighborhood of the attracting fixed point. In this subsection, we study another statistical regime associated with the exit problem for (3.4) that is important in applications: the diffusive regime. The role of the diffusive regime in characterizing the statistics of the exit times for the trajectories of (3.4) is twofold. First, the geometric distribution approximates the distribution of the exit times only for sufficiently large times, i.e., for large n. In this subsection, we show that in the intermediate range of n, i.e., when n is neither too large nor too small, Y_n's are approximated by the sums of the IID RVs, and therefore the level exceedance times are distributed as those for random walks. We refer to this situation as the diffusive regime. Second, we recall that to justify the geometric distribution in the proof of Theorem 3.3, we implicitly assumed that the rate of attraction of the fixed point is stronger than the noise intensity. Specifically, it is easy to see from the proof of Theorem 3.3 that ς is required to be $o(\epsilon)$, $\epsilon = 1 - \lambda$. The analysis in this subsection does not use this assumption. We show that when the noise is stronger than the attraction of the fixed point (though both are sufficiently small), the mechanism of escape of the trajectories from the BA of the fixed point changes from geometric to diffusive. Therefore, we conclude this section by pointing out some features intrinsic to the diffusive escape. Specifically, we consider (3.4), for which we define, as before,

$$\tau = \inf\{k \geq 1 : \; Y_k > h\} \tag{3.31}$$

for given $h > 0$. In contrast to the case considered in section 3.2, here we assume

$$\varepsilon = O(\varsigma^{\alpha}), \quad \alpha > 0. \tag{3.32}$$

In Theorem 3.9 below, we show that in the present situation in the intermediate range of n, $Y_n's$ behave as sums of IID normal RVs. The behavior of the latter is well known (cf. Lemma 3.11).

Recall that $\Phi(x)$ stands for the distribution function of an $N(0,1)$ RV and denote

$$\Psi_a(x) = 2\left(1 - \Phi\left(\frac{a}{\sqrt{x}}\right)\right), \quad a > 0. \tag{3.33}$$

Note that $\Psi_a(x)$ is a probability distribution function on $\mathbb{R}^+$ (see Figure 5).

THEOREM 3.9. *Let the evolution of* Y_n, $n = 0, 1, 2, \ldots$, *be given by* (3.4). *Suppose that* $\lambda = 1 - \varepsilon$ *with* $\varepsilon = O(\varsigma^{\alpha})$, $\alpha > 0$. *Then for arbitrary positive* β_1 *and* β_2 *such that* $\beta_1 + \beta_2 < 2\alpha/3$, *for sufficiently small* $\varsigma > 0$,

$$\mathbb{P}(\tau \leq n) = \Psi_a(n)\Big(1 + o(1)\Big), \quad a = \frac{h}{\varsigma}, \tag{3.34}$$

in the range $\varsigma^{-\beta_1} \ll n \ll \varsigma^{\frac{-2\alpha}{3} + \beta_2}$.

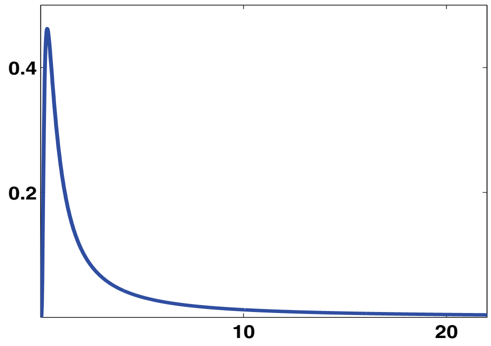

FIG. 5. *Probability density function corresponding to the distribution $\Psi_a(y), a = 1$. With a suitable $a > 0$, $\Psi_a(y)$ approximates the distribution of the exit times in the diffusive escape.*

Remark 3.10. Since $\beta_{1,2} > 0$ are arbitrary, $\Psi_a(n)$ practically approximates $\mathbb{P}(\tau \leq n)$ in the range $1 \ll n \ll \varepsilon^{-2/3}$.

We will need the following auxiliary lemma [11, Theorem 2.2, Chapter III]. It may be viewed as a quantified version of a reflection principle for random walk (see, e.g., [42, sections 5.3, 5.4]).

LEMMA 3.11. *Let $X_1, X_2, \dots$ be a sequence of independent, symmetric RVs and set*

$$S_k = \sum_{j=1}^{k} X_j \quad \textit{and} \quad S_k^* = \max_{1\leq j\leq k} S_j, \quad j \geq 1.$$

Then for any $t, u > 0$ the following inequalities hold:

$$2\mathbb{P}(S_n \geq t + 2u) - 2\sum_{k=1}^{n} \mathbb{P}(X_k \geq u) \leq \mathbb{P}(S_n^* \geq t) \leq 2\mathbb{P}(S_n \geq t). \tag{3.35}$$

Remark 3.12. As was noticed by Kwapień, a bit stronger version of the first inequality in (3.35) follows from a slight modification of the proof of Proposition 1.3.1 in [30].

Proof of Theorem 3.9. Without loss of generality, we assume that $Y_0 = 0$ (otherwise, apply the same argument to $Y_k - Y_0$). Note that the distributions of τ and Y_k^* are linked by the following relation:

$$\mathbb{P}(\tau \leq n) = \mathbb{P}(Y_n^* \geq h).$$

Unwinding (3.4) and using $Y_0 = 0$ gives

$$Y_k = \varsigma(\lambda^{k-1} r_1 + \lambda^{k-2} r_2 + \cdots + \lambda r_{k-1} + r_k),$$

which we write as $S_k + W_k$, where

$$S_k := \varsigma \sum_{j=1}^{k} r_j, \qquad W_k := \varsigma \sum_{j=1}^{k-1} r_j(\lambda^{k-j} - 1). \tag{3.36}$$

We will first show that the main contribution to Y_n^* is from the S_n^*. First, by subadditivity of maxima, for any $0 < h_1 < h$,

$$\begin{aligned}\mathbb{P}(Y_n^* \geq h) \leq \mathbb{P}(S_n^* + W_n^* \geq h) &\leq \mathbb{P}(S_n^* \geq h - h_1) + \mathbb{P}(W_n^* \geq h_1) \\ &\leq \mathbb{P}(S_n^* \leq h - h_1) + \mathbb{P}\left(|W_n|^* \geq h_1\right).\end{aligned} \tag{3.37}$$

Further, $Y_k \geq S_k - |W_k|$ so that

$$\begin{aligned}\mathbb{P}(S_n^* \geq h + h_1) &\leq \mathbb{P}(S_n^* \geq h + h_1, |W_n|^* < h_1) + \mathbb{P}(|W_n|^* \geq h_1) \\ &\leq \mathbb{P}(Y_n^* \geq h) + \mathbb{P}(|W_n|^* \geq h_1),\end{aligned}$$

which, when combined with (3.37), means that

$$\mathbb{P}(S_n^* \geq h + h_1) - \mathbb{P}(|W_n|^* \geq h_1) \leq \mathbb{P}(Y_n^* \geq h) \leq \mathbb{P}(S_n^* \geq h - h_1) + \mathbb{P}(|W_n|^* \geq h_1). \tag{3.38}$$

First, we estimate $\mathbb{P}(|W_n|^* \geq h_1)$ in (3.38). To this end, we use $1-\lambda^j = 1-(1-\varepsilon)^j \leq j\varepsilon$ to obtain

$$\operatorname{var}(W_n) = \varsigma^2 \sum_{j=1}^{n-1} (1-\lambda^j)^2 \leq \varsigma^2 \varepsilon^2 \frac{n^3}{3} = \varsigma^2 n \frac{\varepsilon^2 n^2}{3}.$$

Consequently, by (3.35) and (3.36), we have

$$\begin{aligned}\mathbb{P}(|W_n|^* \geq h_1) \leq 2\mathbb{P}(|W_n| \geq h_1) \leq 4\mathbb{P}(W_n \geq h_1) &= 4\mathbb{P}\left(Z \geq \frac{h_1}{\sqrt{\operatorname{var}(W_n)}}\right) \\ &\leq 4\mathbb{P}\left(Z \geq \frac{h_1}{\varsigma\sqrt{n}} \cdot \frac{\sqrt{3}}{\varepsilon n}\right).\end{aligned}$$

Next, we turn to estimating the probabilities involving S_n^* in (3.38). By the second inequality in (3.35), for every $u > 0$, we have

$$\mathbb{P}(S_n^* \geq h - h_1) \leq 2\mathbb{P}(S_n \geq h - h_1) = 2\mathbb{P}\left(Z \geq \frac{h - h_1}{\varsigma\sqrt{n}}\right), \tag{3.39}$$

while the first one yields

$$\begin{aligned}\mathbb{P}(S_n^* \geq h + h_1) &\geq 2\mathbb{P}\left(S_n \geq h + h_1 + 2u\right) - 2\sum_{k=1}^{n} \mathbb{P}(\varsigma r_k \geq u) \\ &= 2\mathbb{P}\left(Z \geq \frac{h + h_1 + 2u}{\varsigma\sqrt{n}}\right) - 2n\mathbb{P}\left(Z \geq \frac{u}{\varsigma}\right).\end{aligned} \tag{3.40}$$

The combination of (3.38), (3.39), and (3.40) yields

$$\mathbb{P}(Y_n^* \geq h) \geq 2\mathbb{P}\left(Z \geq \frac{h + h_1 + 2u}{\varsigma\sqrt{n}}\right) - 2n\mathbb{P}\left(Z \geq \frac{u}{\varsigma}\right) - 4\mathbb{P}\left(Z \geq \frac{h_1}{\varsigma\sqrt{n}} \cdot \frac{\sqrt{3}}{\varepsilon n}\right), \tag{3.41}$$

$$\mathbb{P}(Y_n^* \geq h) \leq 2\mathbb{P}\left(Z \geq \frac{h - h_1}{\varsigma\sqrt{n}}\right) + 4\mathbb{P}\left(Z \geq \frac{h_1}{\varsigma\sqrt{n}} \cdot \frac{\sqrt{3}}{\varepsilon n}\right). \tag{3.42}$$

To complete the proof, we need to choose h_1 and u such that

$$\frac{h_1}{\varsigma\sqrt{n}} = o(1), \quad \frac{u}{\varsigma\sqrt{n}} = o(1), \quad \frac{\varsigma}{u} = o(1), \quad \text{and} \quad h_1^{-1}\varsigma\varepsilon n^{3/2} = o(1). \tag{3.43}$$

It is straightforward to verify that relations in (3.43) hold with $h_1 = \varsigma^{1+\frac{3\beta}{2}}$ and $u = \varsigma^{1-\frac{\beta_1}{2}}$, $\beta_{1,2} > 0$, $\beta_1 + \beta_2 < 2\alpha/3$, and n as in (3.34). □

4. The Poincaré map. In the present section, we consider the type I model, i.e., the randomly perturbed system with the stochastic forcing acting via the fast subsystem (see (2.9) and (2.10)). In the active phase of bursting (when the system undergoes spiking), the trajectory of the randomly perturbed system remains in the vicinity of the cylinder foliated by the periodic orbits of the fast subsystems (see Figure 6a). The time that the trajectory spends near L determines the duration of the active phase. The goal of this section is to describe the slow dynamics near L. In particular, we will estimate the distribution of the number of spikes in one burst. To this end, we introduce a transverse to L cross-section Σ (see Figure 6a) and construct the first return map. Specifically, we estimate the change in the state of the system after one cycle of rotation of the trajectory around L. The construction of the first return map for (2.9) and (2.10) is done in analogy to that for the deterministic models of bursting (see [34, 31]). However, the treatment of the randomly perturbed system requires certain modifications. First, we have to resolve the ambiguity in the notion of the first return time. The latter is due to the fact that generically a trajectory of the randomly perturbed system makes multiple crossings with Σ during each cycle around L. We refer the reader to the comments following Theorem 2.3 in [19] for an explicit example illustrating this effect. For the randomly perturbed system, we define the time of the first return so that it approaches the first return time of the underlying deterministic system in the limit of vanishing random perturbation. The definition of the first return time motivates the definition of the Poincaré map (see Definition 4.2). In sections 4.1 and 4.2, we use asymptotic expansions to construct the linear approximation for the Poincaré map of the fast subsystem. Here, we use an obvious observation that on finite time intervals and for sufficiently small $\epsilon > 0$, the slow variable typically remains in an $O(\epsilon)$ neighborhood of its initial value. Therefore, for finite times the Poincaré map of the fast subsystem captures the dynamics of the full system. Since we are interested in long-term behavior of the system, to complete the description of the first return map we also need to track the (small) changes in the slow variable after each cycle of oscillations. This is done in section 4.3, where we derive a 1D map for the slow variable. The combination of the 1D Poincaré map for the fast subsystem and that for the slow variable provides the first return map for the full problem (2.9) and (2.10). The linear approximation of the 2D map is used in section 4.4 to estimate the distribution of the number of spikes in one burst for the type I model. Effectively, the problem is reduced to the exit problem for a 1D linear randomly perturbed map. For the latter problem, we have already developed necessary analytical tools in section 3. Finally, in section 4.5, we comment on the straightforward modifications necessary to extend the analysis of this section to cover type II models.

4.1. Preliminary transformations. Recall that Σ stands for the transverse section located as shown schematically in Figure 6a. Let $y_0 < y_{bp}$ be outside an $O(\sigma)$ neighborhood of y_{bp}, and let $x_0 = \left(x_0^1, x_0^2\right)^T \in \Sigma$ be from an $O(\sigma)$ neighborhood of L. Consider an initial value problem (IVP) for (2.9) and (2.10) with initial data (x_0, y_0).

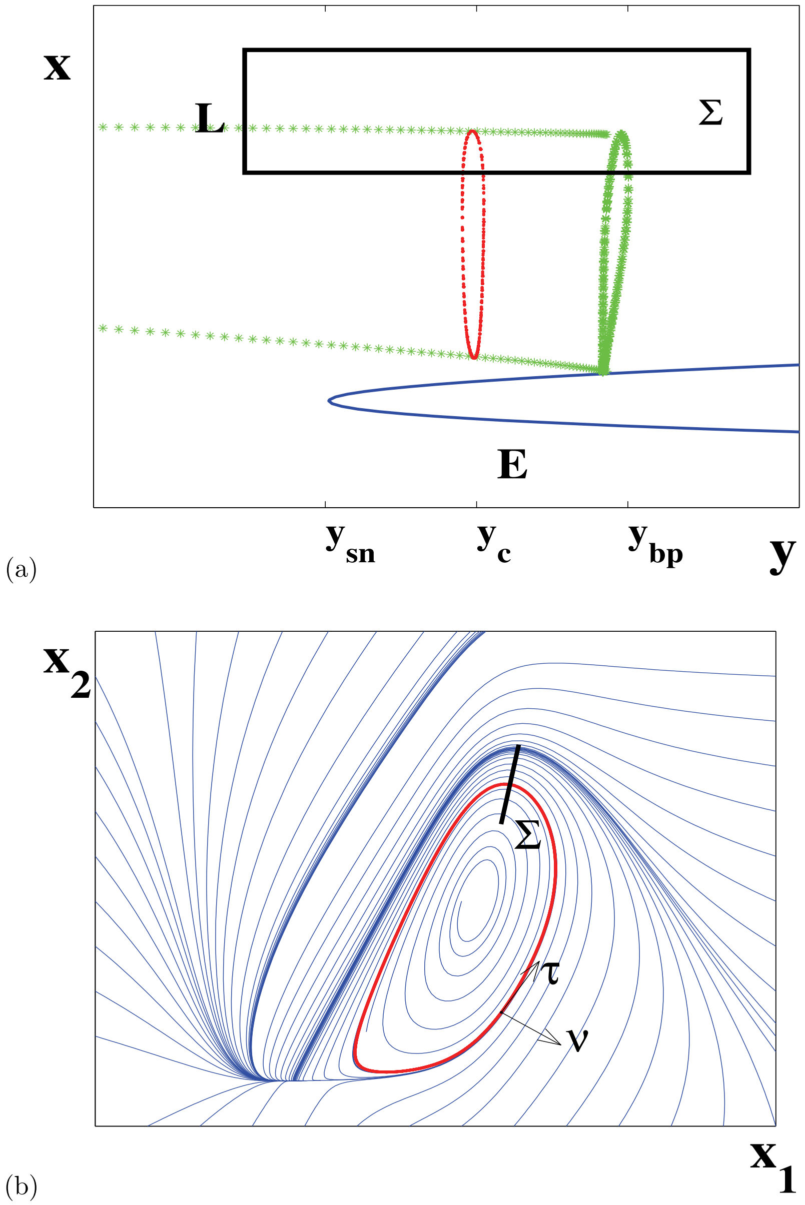

FIG. 6. (a) *Cross-section* Σ *is used in the construction of the first return map.* (b) *The phase plane of the fast subsystem* (2.1) *for* $y \in (y_{sn}, y_{bp})$.

By standard results from the asymptotic theory for randomly perturbed systems [19], we have the estimate

$$y_t = y_0 + O(\epsilon), \tag{4.1}$$

valid on a finite interval of time $t \in [0, \bar{t}]$. Here and below, for a small parameter $\epsilon > 0$, the symbols $O(\epsilon)$ and $o(\epsilon)$ in the asymptotic expansions of the random functions mean that the corresponding relations hold almost surely (a.s.). Specifically, $\psi_t(\epsilon) = O(\epsilon)$

for $t \in [t_1, t_2]$ means that there exists $\epsilon_0 > 0$ such that

$$\sup_{\substack{t \,\in\, [t_1,\, t_2] \\ \epsilon \,\in\, [0,\, \epsilon_0]}} \left|\epsilon^{-1}\psi_t(\epsilon)\right| < \infty \quad \text{a.s.}$$

In a similar fashion, we interpret $\psi_t(\epsilon) = o(\epsilon)$ when $\psi_t(\epsilon)$ is a random function.

By plugging (4.1) into (2.9), we obtain the following stochastic ODE:

$$dx_t = f\,(x_t)\,dt + \sigma p(x_t) dw_t + O(\epsilon), \tag{4.2}$$

where $f\,(x) := f\,(x, y_0)$, $p(x) := p\,(x, y_0)$, and y_0 is fixed. Equation (4.2) with $\epsilon = \sigma = 0$ has an exponentially orbitally stable periodic solution $x = \phi(t, y_0)$ of period $\mathcal{T}(y_0)$:

$$L(y_0) = \{x = \phi(\theta, y_0) :\ \theta \in [0, \mathcal{T}(y_0))\} \qquad \text{(cf. (2.2))}.$$

To simplify the notation, throughout the analysis of the fast subsystem, we will not explicitly indicate the dependence on y_0 when referring to L, ϕ, and $\mathcal{T}$. At each point $x = \phi(\theta) \in L$, we define vectors

$$\tau(\theta) = \left(f^1(x), f^2(x)\right)^T \quad \text{and} \quad \nu(\theta) = Jf(x), \ \text{ where } J = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}, \tag{4.3}$$

pointing in the tangential and normal directions, respectively. To study the trajectories of (4.2) in a small neighborhood of L, it is convenient to rewrite (4.2) in normal coordinates (θ, ξ) [23]:

$$x = \phi(\theta) + \xi\nu(\theta), \quad \theta \in [0, \mathcal{T}). \tag{4.4}$$

Lemma 4.1. *For sufficiently small $\delta > 0$, (4.4) defines a smooth change of coordinates in*

$$B_\delta = \{x = \phi(\theta) + \xi\nu(\theta) :\ |\xi| < \delta,\ \theta \in [0, \mathcal{T})\}. \tag{4.5}$$

In new coordinates, (4.2) has the form

$$d\theta_t = (1 + b_1(\theta_t)\xi_t)dt + \sigma h_1(\theta_t, \xi_t)\,(1 + b_2(\theta_t)\xi_t)\,dw_t + O(\epsilon, \delta^2, \sigma^2), \tag{4.6}$$

$$d\xi_t = a(\theta_t)\xi_t dt + \sigma h_2(\theta_t, \xi_t) dw_t + O(\epsilon, \delta^2, \sigma^2), \tag{4.7}$$

where smooth functions $a(\theta), b_1(\theta)$, and $b_2(\theta)$ are $\mathcal{T}$-periodic and

$$0 < \mu := \exp\left(\int_0^{\mathcal{T}} a(\theta) d\theta\right) = \exp\left(\int_0^{\mathcal{T}} \operatorname{div} f\,(\phi(\theta))\right) < 1, \tag{4.8}$$

$$h_1(\theta, \xi) = \frac{\langle p, \tau\rangle}{\langle \tau, \tau\rangle} = \frac{p^1 f^1 + p^2 f^2}{|f|^2},\ \ h_2(\theta, \xi) = \frac{\langle p, \nu\rangle}{\langle \tau, \tau\rangle} = \frac{p^2 f^1 - p^1 f^2}{|f|^2}. \tag{4.9}$$

Proof. The proof of the lemma follows along the lines of the proof of Theorem VI.1.2 in [23]. Let $z = (z^1, z^2)^T := (\theta, \xi)^T$ and denote the transformation in (4.4) by

$$x = v(z),\ z \in B_\delta. \tag{4.10}$$

Note

$$|Dv(\theta, 0)| = \begin{vmatrix} {\phi^1}'(\theta) & -f^2\,(\phi(\theta)) \\ {\phi^2}'(\theta) & f^1\,(\phi(\theta)) \end{vmatrix} = |f\,(\phi(\theta))|^2 \neq 0,\ \theta \in [0, \mathcal{T}).$$

Therefore, for sufficiently small $\delta > 0$, (4.10) defines a smooth invertible transformation in B_δ. Denote the inverse of v by $z = u(x)$, $x \in v(B_\delta)$, and note that

$$[Du(x)]^{-1} = Dv(z),\ x \in v(B_\delta). \tag{4.11}$$

By Itô's formula, we have

$$dz_t = Du(x_t)dx_t + O(\sigma^2)dt \tag{4.12}$$

and, therefore,

$$Dv(z_t)dz_t = dx_t + O(\sigma^2)dt. \tag{4.13}$$

By recalling that $z = (\theta, \xi)$ and after plugging (4.2) into (4.13), we obtain

$$\begin{aligned}\left[\frac{d\phi(\theta_t)}{d\theta} + \frac{d\nu(\theta_t)}{d\theta}\xi_t\right] d\theta_t + \nu(\theta_t)d\xi_t = \left(f\left(\phi(\theta_t)\right) + Df\left(\phi(\theta_t)\right)\nu(\theta_t)\xi_t + Q(\theta_t, \xi_t)\right) dt \\ + \sigma p dw_t + O(\epsilon, \sigma^2),\end{aligned} \tag{4.14}$$

where

$$Q(\theta, \xi) = f\left(\phi(\theta) + \xi\nu(\theta)\right) - f\left(\phi(\theta)\right) - Df\left(\phi(\theta)\right)\nu(\theta)\xi = O\left(\xi^2\right), \quad |\xi| < \delta.$$

Note that

$$\frac{d\phi(\theta)}{d\theta} = f\left(\phi(\theta)\right) = \tau(\theta), \quad \tau^T(\theta)\tau(\theta) = \nu(\theta)^T\nu(\theta) = \left|f\left(\phi(\theta)\right)\right|^2, \tag{4.15}$$

$$\frac{d\nu(\theta)}{d\theta} = \frac{d}{d\theta}Jf\left(\phi(\theta)\right) = JDf\left(\phi(\theta)\right)f\left(\phi(\theta)\right). \tag{4.16}$$

Taking into account (4.15) and (4.16), we project (4.14) onto the subspace spanned by $\tau(\theta_t)$ and after some algebra obtain

$$\dot{\theta}_t = 1 + \frac{f^TQ + f^T\left[DfJ - JDf\right]f\xi_t + \sigma f^Tp\dot{w}_t + O(\epsilon)}{f^Tf + f^TJDff\xi_t}. \tag{4.17}$$

Here and for the rest of the proof, for brevity we use the following notation:

$$f := f\left(\phi(\theta_t)\right), \quad Q := Q(\theta_t, \xi_t), \quad \text{and} \quad \nu := \nu(\theta_t).$$

Equation (4.17) can be rewritten as (4.6) with

$$\begin{aligned} b_1(\theta_t) &= \frac{1}{|f|^2}f^T\left[DfJ - JDf\right]f, \\ b_2(\theta_t) &= \frac{1}{|f|^2}f^TJDff. \end{aligned}$$

Similarly, by projecting (4.14) onto the subspace spanned by $\nu(\theta)$ and using (4.15) and (4.14), we derive

$$\dot{\xi}_t = a(\theta_t)\xi_t + \sigma h_2(\theta_t)\dot{w}_t + O\left(\delta^2\right),$$

where

$$a(\theta_t) = \frac{1}{|\nu|^2}\nu^T\left[Df\nu + \frac{d\nu}{d\theta}\right] - \frac{2\nu^T}{|\nu|^2}\frac{d\nu}{d\theta}.$$

The expression in the square brackets can be simplified as follows:

$$\nu^T \left[Df\nu + \frac{d\nu}{d\theta} \right] = f^T \left[J^T Df J + Df \right] = \mathrm{div} f\left(\phi(\theta)\right) |f|^2 .$$

Also,

$$\frac{2\nu^T}{|\nu|^2} \frac{d\nu}{d\theta} = \frac{2}{|f|^2} f^T J^T \frac{d}{d\theta} J f = \frac{2}{|f|^2} f^T \frac{d}{d\theta} f = \frac{1}{|f|^2} \frac{d}{d\theta} |f|^2 = \frac{d}{d\theta} \ln |f\left(\phi(\theta)\right)|^2 .$$

Therefore,

$$a(\theta) = \mathrm{div} f\left(\phi(\theta)\right) - \frac{d}{d\theta} \ln |f\left(\phi(\theta)\right)|^2 . \tag{4.18}$$

Equation (4.18) implies (4.8), since the integral over $[0, \mathcal{T}]$ of the last term on the right-hand side of (4.18) is zero. □

4.2. The Poincaré map for the fast subsystem. In the present subsection, we analyze the trajectories of the randomly perturbed system (4.2) lying close to the limit cycle $L(y_0)$, $y_0 < y_{bp}$. To this end, we consider an IVP for (4.6) and (4.7) subject to the initial condition

$$\theta_0 = 0 \quad \text{and} \quad |\xi_0| < \delta. \tag{4.19}$$

Throughout this section, we assume (even when it is not stated explicitly) that $\delta > 0$ is sufficiently small. It will be convenient to view the range of θ_t as $\mathbb{R}^1$ rather than a circle. Equation (4.4) provides the transformation of (θ_t, ξ_t) to the Cartesian coordinates even when θ_t exceeds $\mathcal{T}$.

We now turn to the construction of the Poincaré map. Condition $\theta = 0$ defines a transverse cross-section of $L(y_0)$, Σ. The trajectory of the deterministic system (4.6) and (4.7) with $\sigma = 0$ returns to Σ in time $\mathcal{T} + O(\xi_0)$. To define the Poincaré map for the randomly perturbed system, we also use another transverse cross-section $\tilde{\Sigma}$, which is located at an $O(1)$ distance away from Σ. Let (θ_t, ξ_t) be the solution of the IVP (4.6), (4.7), and (4.19) and

$$\tilde{T} = \inf\{t > 0 : \ (\theta_t, \xi_t) \in \tilde{\Sigma}\}.$$

Definition 4.2. *By the time of the first return of the trajectory* (4.6), (4.7), *and* (4.19) *to* Σ, *we call stopping time* T *such that*

$$T = \inf\{t > \tilde{T} : \ \theta_t = \mathcal{T}\}. \tag{4.20}$$

The first return map for (4.6), (4.7), *and* (4.19) *is defined as*

$$\bar{\xi} = P(\xi_0), \quad \textit{where} \quad \bar{\xi} = \xi_T.$$

In the remainder of this subsection, we compute the linear part of the Poincaré map. In the asymptotic expansions below, we do not indicate the dependence of the remainder terms on $\epsilon > 0$. The latter is assumed to be sufficiently small so that it has no effect on the leading order approximation of the Poincaré map.

The following notation is reserved for four functions, which will appear frequently in the asymptotic expansions below:

$$A(t,s) = \exp\left\{ \int_s^t a(u) du \right\}, \quad A(t) = A(t,0),$$
$$B(t,s) = \int_s^t A(u,s) b_1(u) du, \quad B(t) = B(t,0).$$

LEMMA 4.3. *On a finite time interval* $t \in [0, \bar{t}]$, $0 < \bar{t} < \infty$, *the solution of the IVP* (4.6), (4.7), *and* (4.19) *admits the asymptotic expansion*

$$\theta_t = \theta_t^{(0)} + \sigma\theta_t^{(1)} + O(\sigma^2, \xi_0^2), \tag{4.21}$$

$$\xi_t = \xi_t^{(0)} + \sigma\xi_t^{(1)} + O(\sigma^2, \xi_0^2). \tag{4.22}$$

The leading order coefficients are given by

$$\theta_t^{(0)} = t + \xi_0 B(t) + O(\xi_0^2), \tag{4.23}$$

$$\xi_t^{(0)} = \xi_0 A(t) + O(\xi_0^2). \tag{4.24}$$

The first order terms are given by the Gaussian diffusion process $z_t = (\theta_t^{(1)}, \xi_t^{(1)})^T$*:*

$$z_t = \int_0^t U(t,s)h(s)dw_s + O(\xi_0), \tag{4.25}$$

where

$$U(t,s) = \begin{pmatrix} 1 & B(t,s) \\ 0 & A(t,s) \end{pmatrix}, \quad h(t) := h(t,0) = (h_1(t,0), h_2(t,0))^T. \tag{4.26}$$

Proof. The procedure for constructing asymptotic expansions of solutions for a class of IVP, which includes (4.6), (4.7) and (4.19), can be found in [2, 19]. These sources also contain the estimates controlling the remainder terms. The coefficients $\theta_t^{(0,1)}$ and $\xi_t^{(0,1)}$ are determined as follows. By plugging (4.21) and (4.22) into (4.6) and (4.7) and extracting the coefficients multiplying different powers of σ, one obtains IVPs for the functions on the right-hand sides of (4.21) and (4.22). Specifically, for the leading order terms we have the following IVP:

$$\dot{\theta}_t^{(0)} = 1 + b_1\left(\theta_t^{(0)}\right)\xi_t^{(0)}, \tag{4.27}$$

$$\dot{\xi}_t^{(0)} = a\left(\theta_t^{(0)}\right)\xi_t^{(0)}, \tag{4.28}$$

$$\xi_0^{(0)} = \xi_0, \ \theta_0^{(0)} = 0. \tag{4.29}$$

To the next order,

$$\dot{z}_t = \Lambda(t, \xi_0)z_t + h\left(\theta_t^{(0)}, \xi_t^{(0)}\right)\dot{w}_s, \tag{4.30}$$

$$z_0 = 0, \tag{4.31}$$

where $z_t = \left(\theta_t^{(0)}, \xi_t^{(1)}\right)^T$, $h = (h_1, h_2)^T$, and

$$\Lambda(t, \xi_0) = \begin{pmatrix} b_1'\left(\theta_t^{(0)}(\xi_0)\right)\xi_t^{(0)}(\xi_0) & b_1\left(\theta_t^{(0)}(\xi_0)\right) \\ a'\left(\theta_t^{(0)}(\xi_0)\right)\xi_t^{(0)}(\xi_0) & a\left(\theta_t^{(0)}(\xi_0)\right) \end{pmatrix}. \tag{4.32}$$

Here, we explicitly indicated the dependence of the leading order coefficients on ξ_0 and used a prime to denote the differentiation with respect to θ. Formulae (4.23)–(4.26) in the statement of the lemma follow from (4.27)–(4.32). The details can be found in the appendix to this paper. ☐

Next, we calculate the time of the first return.

Lemma 4.4. *The time of the first return is given by*

$$T = T^{(0)} + \sigma T^{(1)} + o(\sigma) + O(\xi_0^2), \tag{4.33}$$

where

$$T^{(0)} = \mathcal{T} - \xi_0 B(\mathcal{T}) + O(\xi_0^2), \tag{4.34}$$

$$T^{(1)} = -\sigma\theta^{(1)}_{\mathcal{T}} = -\sigma \int_0^{\mathcal{T}} \left[h_1(u) + B(\mathcal{T}, u) h_2(u)\right] dw_u. \tag{4.35}$$

Proof. From the definition of the first return time, (4.21), and (4.23), we have

$$T + \xi_0 B(T) + \sigma\theta^{(1)}_T + O(\sigma^2, \xi_0^2) = \mathcal{T} \text{ a.s.} \tag{4.36}$$

Thus,

$$\lim_{\sigma\to 0} T = T^{(0)}(\xi_0) \text{ a.s.}, \tag{4.37}$$

where $T^{(0)}(\xi_0)$ is found from the following equation:

$$T^{(0)}(\xi_0) + \xi_0 B\left(T^{(0)}(\xi_0)\right) + O(\xi_0^2) = \mathcal{T}. \tag{4.38}$$

Equation (4.38) implies (4.34). Furthermore, the combination of (4.34), (4.36), and (4.37) yields (4.35). □

Lemma 4.5. *The first return map is given by the*

$$\bar{\xi} = \mu\xi\left(1 + \sigma r_1\right) + \sigma r_2 + o(\sigma) + O(\xi_0^2), \tag{4.39}$$

where Gaussian RVs $r_{1,2}$ are given by

$$r_1 = -a(0) \int_0^{\mathcal{T}} \left[h_1(u) + B(\mathcal{T}, u) h_2(u)\right] dw_u, \quad r_2 = \int_0^{\mathcal{T}} A(\mathcal{T}, u) h_2(u) dw_u. \tag{4.40}$$

Proof. From (4.22), (4.24)–(4.26), and (4.33), we have

$$\begin{aligned} \bar{\xi} = \xi_T &= \xi_0 A(T) + \sigma \int_0^T A(T, s) h_2(s) dw_s + O(\sigma^2, \xi_0^2) \\ &= \xi_0 A(T) + \sigma r_2 + O(\sigma^2, \xi_0^2), \end{aligned} \tag{4.41}$$

where r_2 is defined in (4.40). The first term on the right-hand side of (4.41) can be rewritten as follows:

$$\begin{aligned} A(T) = A(\mathcal{T}) A(\mathcal{T} + \sigma T^{(1)}, \mathcal{T}) + o(\sigma) + O(\xi_0) &= \mu \exp\left(\sigma a(0) T^{(1)}\right) + o(\sigma) \\ = \mu\left(1 - \sigma a(0)\theta^{(1)}_{\mathcal{T}}\right) + o(\sigma) + O(\xi_0). \end{aligned} \tag{4.42}$$

Finally, we extract the expression for $\theta^{(1)}_{\mathcal{T}}$ from (4.25) and (4.26):

$$\theta^{(1)}_{\mathcal{T}} = \int_0^{\mathcal{T}} \left[h_1(u) + B(\mathcal{T}, u) h_2(u)\right] dw_u. \tag{4.43}$$

Equations (4.41)–(4.43) yield (4.39) and (4.40). □

Remark 4.6. We close this section by observing that, as follows from (4.40), RVs r_1 and r_2 are stochastic integrals of different deterministic functions, say $f(t)$ and $g(t)$, with respect to the same Brownian motion over the interval $[0, \mathcal{T}]$. Consequently, their joint distribution is bivariate normal with 0 mean vector and a covariance matrix whose diagonal entries are

$$\int_0^{\mathcal{T}} f^2(t)dt \quad \text{and} \quad \int_0^{\mathcal{T}} g^2(t)dt,$$

and whose off-diagonal entry is

$$\int_0^{\mathcal{T}} f(t)g(t)dt.$$

This is perhaps easiest to see by using Riemann representation of a stochastic integral (see, e.g., [42, Proposition 7.6]), basic properties of Brownian motion, and the fact that a random vector is multivariate normal iff any linear combination of its components is a normal RV.

4.3. The first return map for the slow variable.

Our next goal is to estimate the change of the slow variable, y_t, after one cycle of oscillations of the fast subsystem for the following initial conditions:

$$0 < y_{bp} - y_0 = O(1),\ x_0 = \phi(0) + \xi_0\nu(0) \in \Sigma, \ \text{ and } |\xi_0| < \delta. \tag{4.44}$$

We denote the first return map for y by

$$\bar{y} = P(y, \xi_0), \quad \text{where} \quad P(y_0, \xi_0) = y_T,$$

and T is the first return time of the fast subsystem (see Definition 4.2).

LEMMA 4.7. *The first return map for* y *has the following form:*

$$P(y, \xi) = y + \epsilon G(y) + \epsilon\sigma r_3 + \epsilon a\xi + o(\epsilon\sigma), \tag{4.45}$$

where

$$G(y) = \int_0^{\mathcal{T}} g\left(\phi(s), y\right) ds \tag{4.46}$$

and $r_3 = N\left(0, O(1)\right)$ *and* a *is a constant independent of* σ *and* ϵ.

Remark 4.8. Recall that $\mathcal{T}$ and $\phi(\cdot)$ are functions of slow variable y (see (2.2)). To avoid using cumbersome notation we continue to suppress the dependence on y.

Proof of Lemma 4.7. By (2.10),

$$y_T = y_0 + \epsilon \int_0^T g(x_s, y_0)ds + O(\epsilon^2), \tag{4.47}$$

where x_s satisfies IVP (4.6), (4.7), and (4.19). Let $x = \phi(\theta) + \xi\nu(\theta)$ and denote

$$\tilde{g}(\theta, \xi, y) := g(x, y),\ g_0(s) = \tilde{g}(s, 0),\ g_1(s) = \frac{\partial \tilde{g}}{\partial \theta}(s, 0), \text{ and } g_2(s) = \frac{\partial \tilde{g}}{\partial \xi}(s, 0). \tag{4.48}$$

Using (4.48), we rewrite (4.47) as

$$y_T = y_0 + \epsilon \int_0^T \tilde{g}(\theta_s^{(0)} + \sigma\theta_s^{(1)}, \xi_s^{(0)} + \sigma\xi^{(1)}) + O(\epsilon\sigma^2). \tag{4.49}$$

Using the Taylor expansion for $\tilde{g}$ in (4.49) and (4.21), (4.22) and (4.33), from (4.49) we derive

$$y_T = y_0 + \epsilon \int_0^{\mathcal{T}} \left\{ g_0(s) + g_1(s) \left[\xi_0 B(s) + \sigma \theta_s^{(1)} \right] + g_2(s) \left[\xi_0 A(s) + \sigma \xi_s^{(1)} \right] \right\} ds$$

$$+ \int_{\mathcal{T}}^{\mathcal{T} - \xi_0 B(\mathcal{T}) - \sigma \theta_{\mathcal{T}}^{(1)}} g_0(s) ds + o(\epsilon\sigma) + O(\epsilon \xi_0^2). \tag{4.50}$$

We approximate the last integral on the right-hand side of (4.50) by

$$\int_{\mathcal{T}}^{\mathcal{T} - \xi_0 B(\mathcal{T}) - \sigma \theta_{\mathcal{T}}^{(1)}} g_0(s) ds = -g_0(0) \left[\xi_0 B(\mathcal{T}) + \sigma \theta^{(1)} \right] + o(\sigma, \xi_0). \tag{4.51}$$

The combination of (4.50) and (4.51) implies (4.45) with

$$a = \int_0^{\mathcal{T}} \left[g_1(s) B(s) + g_2(s) A(s) \right] ds - g_0(0) B(\mathcal{T}), \tag{4.52}$$

$$r_3 = \int_0^{\mathcal{T}} \left[g_1(s) \theta_s^{(1)} + g_2(s) \xi_s^{(1)} \right] ds. \qquad \square \tag{4.53}$$

4.4. The exit problem. In this subsection, we first combine the return maps derived for the slow and fast subsystems to obtain the Poincaré map for the full 3D system. Next, we approximate the Poincaré map and the BA of the limit cycle $L(y_c)$ and characterize the distribution of the exit times for the approximate problem. This distribution is then related to the distribution of the number of spikes within bursting episodes. To approximate the Poincaré map we linearize it around the stable fixed point of the deterministic map corresponding to the limit cycle $L(y_c)$. Aside from the systematic derivation of the Poincaré map in the previous subsections, we offer no rigorous justification for substituting the nonlinear Poincaré map with its linear part in the analysis of the exit problem. While in general such approximation may not be accurate, we believe that for the present problem the analysis of the linearized system captures the statistics of the first exit times well for the following reason. In models of square-wave bursting the limit cycle generating spiking is often located close to the boundary of its BA (see Figure 6b for a representative example). Therefore, before the trajectories leave the BA, they remain in a small neighborhood of the limit cycle, where the linear part of the vector field governs the dynamics. After these preliminary remarks, we turn to the derivation of the approximate problem and its analysis.

Lemmas 4.5 and 4.7 yield the asymptotic formulae for the first return map of the randomly perturbed system (2.9) and (2.10) in the normal coordinates (4.4):

$$\xi_{n+1} = \mu \xi_n \left(1 + \sigma r_{1,n}\right) + \sigma r_{2,n} + o(\sigma), \tag{4.54}$$

$$y_{n+1} = y_n + \epsilon G(y_n) + \epsilon \sigma r_{3,n} + \epsilon a \xi_n + o(\epsilon\sigma),\ n = 0, 1, 2, \ldots, \tag{4.55}$$

where (ξ_0, y_0) are given in (4.44) and the expressions for a and $r_{i,n},\ i = 1, 2, 3$, are are given in (4.40), (4.52), and (4.53). Recall that by (SS) (see section 2), $G(y)$ has a simple zero at $y = y_c$ and $\lambda := -G'(y_c) > 0$. Thus, $(0, y_c)$ is an attracting fixed point of the unperturbed map (4.54) and (4.55) with $\sigma = 0$. The linearization of (4.54) and (4.55) about $(0, y_c)$ yields

$$\xi_{n+1} = \mu \xi_n \left(1 + \sigma \tilde{r}_{1,n}\right) + \sigma \tilde{r}_{2,n}, \tag{4.56}$$

$$\eta_{n+1} = \lambda \eta_n + \epsilon \sigma \tilde{r}_{3,n} + \epsilon a_2 \xi_n, \quad n = 0, 1, 2, \ldots, \tag{4.57}$$

where $\eta = y - y_c$, $0 < \lambda = 1 - \epsilon a_1$, and $0 < \mu < 1$. The distributions of the RVs $r_{i,n},\ i = 1,2,3$, depend on y_n, as both the upper bound of integration $\mathcal{T}$ and the integrands in (4.40) and (4.53) are smooth functions of y. The stochastic terms $\tilde{r}_{i,n},\ i = 1,2,3$, in the linearized system are obtained by evaluating the expressions for $\tilde{r}_{i,n},\ i = 1,2,3$, in (4.40) and (4.53) at $y = y_c$. Thus, $(\tilde{r}_{1,n}, \tilde{r}_{2,n}, \tilde{r}_{3,n})$ are IID copies of an $N(0, \Sigma_3)$, where the entries of Σ_3 are $O(1)$ in a sense that they do not depend on any other parameters. Further, we approximate the BA of $L(y_c)$ by a cylindrical shell, so that in the (ξ, η) coordinate plane, it projects to $\Pi := \left[-\tilde{h}_\xi, h_\xi\right] \times \left[-\tilde{h}_\eta, h_\eta\right]$ for some $\tilde{h}_{\xi,\eta} > h_{\xi,\eta} > 0$ independent of $\sigma > 0$. Each iteration of the Poincaré map corresponds to a spike within a burst. The burst terminates when the trajectory leaves the BA of $L(y_c)$. Assuming that the linearization (4.56) and (4.57) and Π provide suitable approximations for the Poincaré map and the BA of $L(y_c)$, respectively, the distribution of the number of spikes in one burst can be approximated by the distribution of the first exit times for the trajectories of (4.56) and (4.57) from Π:

$$\tau = \min\{\tau_\xi, \tau_\eta\}, \tag{4.58}$$

where

$$\tau_\xi = \inf_{n>0}\{\xi_n > h_\xi\} \quad \text{and} \quad \tau_\eta = \inf_{n>0}\{\eta_n > h_\eta\}.$$

We are now in a position to apply the results of section 3 to describe the distribution of (4.58). By Theorem 3.7, the distribution of τ is asymptotically geometric with parameter

$$p \approx \frac{\sigma}{C\sqrt{2\pi}} e^{-\frac{C}{\sigma^2}} \tag{4.59}$$

for some $C > 0$ independent of ϵ and σ. In the proof of Theorem 3.7, we studied a class of 2D randomly perturbed maps that includes (4.56) and (4.57). However, the distribution of τ is effectively determined by the first equation (4.56), i.e., by the 1D first return map of the fast subsystem. This can be seen by observing that according to the approximations given at the end of the proof of Theorem 3.7 (see the arguments following (3.30)) if $\epsilon > 0$ is sufficiently small, then $\tau_\xi \ll \tau_\eta$ and $\tau \sim \tau_\xi$. Thus, in type I models the distribution of spikes in one burst is effectively determined by the 1D first return map for the fast subsystem (4.56). In particular, the statistics of the number of spikes in one burst does not depend on the relaxation parameter $\epsilon > 0$, provided the latter is sufficiently small.

4.5. Type II model. The derivation of the Poincaré map for the type II models differs from the analysis in sections 4.1–4.4 for type I models only in some minor details. In this subsection, we comment on the necessary modifications and state the final result. Recall that in contrast to type I models, in (2.11) and (2.12), stochastic forcing enters the slow equation. As before, the initial condition is given by (4.44). On finite time intervals, solutions of the IVP for (2.11) and (2.12) admit the following asymptotic expansions:

$$x_t = x_t^{(0)} + \epsilon\sigma x_t^{(1)} + O\left((\epsilon\sigma)^2\right), \tag{4.60}$$

$$y_t = y_t^{(0)} + \epsilon\sigma y_t^{(1)} + O\left((\epsilon\sigma)^2\right), \tag{4.61}$$

where the first order corrections $x_t^{(1)}$ and $y_t^{(1)}$ are Gaussian processes (cf. Theorem 2.2 in [19]). Using (4.60) and (4.61), we obtain the leading order approximation of the fast subsystem:

$$\dot{x}_t = f(x_t, y_0) + \epsilon\sigma \frac{\partial f(x_t^{(0)}, y_0)}{\partial y} y_t^{(1)} + o(\epsilon\sigma). \tag{4.62}$$

From this point, the derivation of the Poincaré map follows along the same lines as described in detail for type I models in sections 4.1–4.4. We omit any further details and state the final result, the linear approximation of the Poincaré map for the present case:

$$\xi_{n+1} = \mu\xi_n \left(1 + \epsilon\sigma\tilde{r}_{1,n}\right) + \epsilon\sigma\tilde{r}_{2,n}, \tag{4.63}$$

$$\eta_{n+1} = \lambda\eta_n + \epsilon\sigma\tilde{r}_{3,n} + \epsilon a_2\xi_n, \quad n = 0, 1, 2, \dots. \tag{4.64}$$

As in the previous case, we are interested in the distribution of the first exit time τ (see (4.58)). To estimate the latter, we use the same argument as in the previous subsection. This time the system is described by

$$\Theta_{n+1} = A_{n+1}\Theta_n + \sigma\epsilon G_{n+1}, \quad n \geq 1, \tag{4.65}$$

where A_n is as before and $G_n = \left[\begin{smallmatrix} r_{2,n} \\ r_{3,n} \end{smallmatrix}\right]$. The presence of the factor ϵ in both components of G_n leads to the following expression for the numerator of p (see (3.27)):

$$\mathbb{P}\left(\frac{\mu X_1 r_1 + r_2}{\sigma_{X_1}} > \frac{h_1 - \mu X_1}{\epsilon\sigma\sigma_{X_1}}, r_3 > \frac{h_2 - a_2 X_1}{\sigma} + \frac{\lambda(h_2 - X_2)}{\epsilon\sigma}, (X_1, X_2) \in B_h \right).$$

This expression decays very fast as a function of $h_2 - X_2$, and since X_2 has heavy tails it is approximated (up to inessential polynomial factors) by

$$\mathbb{P}\left(\frac{\mu X_1 r_1 + r_2}{\sigma_{X_1}} > \frac{h_1 - \mu X_1}{\epsilon\sigma\sigma_{X_1}}, r_3 > \frac{h_2 - a_2 X_1}{\sigma}, (X_1, X_2) \in B_h \right).$$

We are now in the analogous situation to that encountered in (3.28), except that the small parameter $\epsilon > 0$ appears in the denominator of the other variable. As a consequence, this time we obtain that $\tau_\xi \ll \tau_\eta$ for small $\epsilon > 0$. Therefore, in contrast to type I models, the escape of a trajectory of (2.11) and (2.12) from $\mathcal{A}$ is dominated by the slow subsystem, i.e., $\tau = \tau_\eta$.

5. Numerical example. In the present section, we illustrate the statistical regimes identified in this study with numerical simulations of a conductance-based model of a neuron in the presence of noise. To this end, we use a three-variable model of a bursting neuron introduced by Izhikevich [26]. The model dynamics is driven by the interplay of the three ionic currents: persistent sodium, I_{NaP}, the delayed rectifier, I_K, a slow potassium M-current, I_{KM}, and a passive leak current, I_L. The following system of three differential equations describes the dynamics of the membrane potential, v, and two gating variables, n and y:

$$C\dot{v} = F(v, n, y), \tag{5.1}$$

$$\tau_n \dot{n} = n_\infty(v) - n, \tag{5.2}$$

$$\tau_y \dot{y} = y_\infty(v) - y, \tag{5.3}$$

where $F(v, n, y) = -g_{NaP} m_\infty(v)(v - E_{NaP}) - g_K n(v - E_K) - g_{KM} y(v - E_K) - g_L(v - E_L) + I$; g_s and E_s, are the maximal conductance and the reversal potential

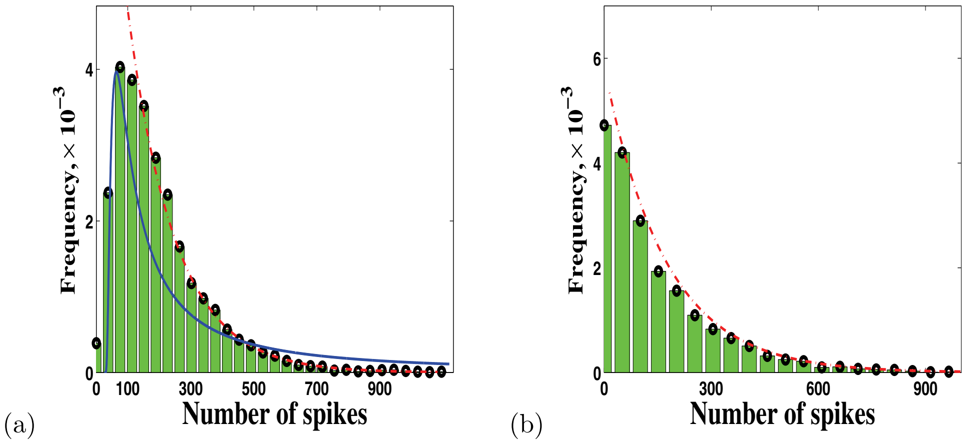

FIG. 7. *The histograms for the number of spikes in one burst. The histograms computed for the type I model in* (a) *and type II in* (b) *are normalized to approximate the corresponding PDFs. The tails of both functions are well approximated by the exponential densities with parameters* 0.0067 *and* 0.0125*, respectively. In* (b) *the exponential distribution already gives a very good approximation for the number of spikes exceeding* 10*. The region of exponential behavior in* (a) *starts around* $n \sim 100$*. In* (a)*, we also plotted in solid line the shifted diffusive density* $\Psi_a(x-25), a \approx 10.8$*. Although it is hard to claim a quantitative fit of the diffusive density and the data, the qualitative similarity between the diffusive pdf* $\Psi_a(x)$ *and the peak in the data in the range* $n \sim 50-100$ *is apparent. The values of parameters are* $C = 1$ $\left(\mu F cm^{-2}\right)$; $g_{NA} = 20$, $g_K = 10$, $g_{KM} = 5$, $g_L = 8$ $\left(mS cm^{-2}\right)$; $E_{Na} = 60$, $E_K = -90$, $E_L = -80$ (mV); $a_m = -20$, $a_n = -25$, $a_y = -10$ (mV); $b_m = 15$, $b_n = 5$, $b_y = 5$; $\tau_n = 0.152$, $\tau_y = 20$ $\left(ms^{-1}\right)$, $I = 5pA$*, and* $\sigma = 1$.

of I_s, $s \in \{NaP, K, KM, L\}$, respectively; and I is the applied current. The time constants τ_n and τ_y determine the rates of activation in the populations of K and KM channels. The steady-state functions are defined by $s_\infty(v) = \left(1 + \exp(\frac{a_s - v}{b_s})\right)^{-1}$, $s \in \{m, n, y\}$. The parameter values are given in the caption of Figure 7. This completes the description of the deterministic model. The random perturbation is used in the form of white noise, $\sigma \dot{w}_t$, and is added to the first equation (5.1) for the type I model or to the third one (5.3) for the type II model. After suitable rescaling, these models can be put in the nondimensional form (2.9), (2.10) or (2.11), (2.12). The separation of the timescales in the nondimesional models (i.e., small $\epsilon > 0$) is the result of the presence of the disparate time constants $\tau_h \gg \tau_n$ in the original model (see caption of Figure 7).

The parameters of the deterministic system are chosen so that it has a limit cycle located as shown in Figure 3c. In the presence of small noise the system generates bursting. In each numerical experiment, we integrated the randomly perturbed system using the Euler–Maruyama method [24] until it generated 5,000 bursts. We used these data to estimate the probability density for the number of spikes within one burst. In Figure 7, we plot the histograms for the number of spikes in one burst for type I and type II models. The histograms in Figure 7 are scaled to approximate the probability density function (PDF) for the number of spikes in one burst. Both PDFs shown in Figure 7a,b have distinct exponential tails as expected for the asymptotically geometric RVs. Note that the distribution in Figure 7a fits well with the geometric distribution for $N > 100$, while in Figure 7b the geometric distribution fits the data almost on the entire domain $N > 10$. In addition, the peak in the histogram in Figure 7a is reminiscent of the PDF characteristic for the diffusive escape (see Figure 5). For comparison, we plotted a slightly shifted diffusive PDF, $\Psi_a(x),\ a = 10.8$, in Figure 7a. Matching the data and Ψ_a is a delicate matter, because it is not clear how wide the range of n is, to which the estimates of Theorem 3.9 apply. Nonetheless, the qualitative similarity of the peak in the histogram in the range $n \sim 50 - 100$ and the diffusive PDF is apparent. We repeated these numerical experiments for a few other sets of parameters and found qualitatively similar results.

Collecting the statistical data shown in Figure 7 requires integrating the system over very long intervals of time, for which it would be hard to justify the accuracy of the Euler–Maruyama method. However, capturing the statistical features of the dynamical patterns does not require having an accurate solution on the entire interval of time, because they are determined by the discrete dynamics of the first return map. The iterations of the latter are expected to be insensitive to the numerical noise, as suggested by the analysis of the randomly perturbed maps in section 3. Therefore, we only need to have accurate numerical solutions on the time intervals comparable with the typical periods of the fast oscillations. This is easy to achieve with the Euler–Maruyama method. We repeated these numerical experiments using the second order Runge–Kutta method and obtained very similar results. These informal arguments form the rationale for using the above numerical scheme. The rigorous justification of the numerics is beyond the scope of this paper.

Appendix. In this appendix, we provide the details of the derivation of (4.23)–(4.26), which were omitted in the main part of the paper.

To derive (4.23) and (4.24), we first note that $\theta_t^{(0)}$ is a monotonic function on $[0,\bar{t}]$, provided $\delta > 0$ is sufficiently small. Thus,

$$\frac{d\xi^{(0)}}{d\theta^{(0)}} = a(\theta^{(0)})\xi^{(0)} + O(\xi_0^2)$$

and

$$\xi^{(0)}(\theta^{(0)}) = \xi_0 A(\theta^{(0)}) + O(\xi_0^2). \tag{A.1}$$

By plugging (A.1) into (4.27), we have

$$\dot{\theta}_t^{(0)} = 1 + b_1(\theta_t^{(0)})\xi_0 A(\theta^{(0)}). \tag{A.2}$$

By Gronwall's inequality,

$$\theta_t^{(0)} = \psi_t + O(\xi_0^2),\ t \in [0,\bar{t}], \tag{A.3}$$

where ψ_t solves

$$\dot{\psi}_t^{(0)} = 1 + \xi_0 b_1(t) A(t),\ \psi_0 = 0. \tag{A.4}$$

The combination of (A.1), (A.3), and (A.4) implies (4.24).

We next turn to IVP (4.30), (4.31), and (4.24). Let $U(t,\xi_0)$ denote the principal matrix solution of the homogeneous system

$$\dot{z}_t = \Lambda(t,\xi_0) z_t. \tag{A.5}$$

Then the solution of (4.30) and (4.31) is given by

$$z_t = \int_0^t U(t,s,\xi_0) h\left(\theta_s^{(0)}, \xi_s^{(0)}\right) dw_s = \int_0^t U(t,s) h\,(s,0)\, dw_s + O(\xi_0),\ t \in [0,\bar{t}], \tag{A.6}$$

where

$$U(t,s,\xi_0)=U(t,\xi_0)U^{-1}(s,\xi_0) \quad \text{and} \quad U(t,s)=U(t,s,0). \tag{A.7}$$

Finally, by integrating (A.5) with $\xi_0 = 0$ and appropriate initial conditions, one computes

$$U(t,0)=\begin{pmatrix} 1 & B(t) \\ 0 & A(t) \end{pmatrix}. \tag{A.8}$$

The expression for $U(t,s)$ in (4.26) follows from (A.7) and (A.8).

DERIVATION OF A CONTINUUM MODEL FOR THE LONG-RANGE ELASTIC INTERACTION ON STEPPED EPITAXIAL SURFACES IN $2+1$ DIMENSIONS[*]

HAOYUN XU[†] AND YANG XIANG[†]

Abstract. In heteroepitaxy, the mismatch of lattice constants in the crystal film and the substrate causes a misfit stress in the bulk of the film, driving the self-organization of the film surface into various nanostructures. Below roughening transition temperature, the epitaxial surface consists of terraces separated by atomic-height steps, and the misfit results in a long-range elastic interaction between surface steps. In this case, the surface morphology is determined by the motion of the steps, and the widely used continuum models for surface evolution above the roughening transition temperature do not apply directly. In this paper, we present a continuum model for this long-range elastic interaction on a stepped heteroepitaxial surface in $2+1$ dimensions. The continuum model is derived rigorously by taking the continuum limit from the discrete model for the interaction between steps, thus incorporating the discrete features of the stepped surface.

Key words. epitaxial growth, misfit, steps, continuum model, elasticity

1. Introduction.

The study of stress-driven morphological evolution of surfaces in epitaxial growth has attracted extensive interest recently. These stress-driven self-assembled nanostructures exhibit novel electronic and optical properties, which have various potential applications in semiconductor industry [33, 9, 10, 29]. Many continuum models can be found in the literature on surface morphological evolution under elastic effects [2, 11, 43, 42, 8, 52, 4, 53, 41, 10, 54, 50]. In these models, the surfaces are modeled as continuously changed profiles without discrete structures, and thus they work only for surfaces above the roughening transition temperature.

Below the roughening transition temperature, a crystal surface forms facets and steps, thus the continuum approaches mentioned above do not apply directly. In the step-flow model, a stepped surface changes its morphology by lateral motion of steps [3, 33, 29, 24, 1]. For an unstrained film, a step can be viewed as a force dipole on the film surface. The elastic dipole interaction force decays as $1/r^3$ for two parallel straight steps with distance r. A step on the surface of a strained film (in heteroepitaxy) can be approximated by a force monopole. The elastic monopole interaction force decays as $1/r$ for two parallel straight steps with distance r. Expansions with higher order terms for the elastic effects of surface steps were obtained in [37, 44, 20].

The force dipole effect between steps on unstrained epitaxial surfaces is relatively well modeled in the frameworks of both the discrete step dynamics and the continuum theory [24, 21, 31, 35, 33, 16, 32, 29, 26, 27, 28, 25]. In the framework of the continuum theory, it is well known that the elastic effect on such a stepped surface is quite different from that on a surface above roughening transition temperature, due to the discrete structures on the stepped surface.

Several models can be found in the literature on the long-range force monopole interaction on heteroepitaxial surfaces with straight and parallel steps (1+1 dimensional models). Alerhand et al. [1] studied the spontaneous formation of stress domains on crystal surfaces. Tersoff et al. [47, 23] described the step bunching phenomenon by a step dynamics model accounting for the attractive force monopole interaction due to misfit stress and the repulsive force dipole interaction. Duport et al. [5, 6] proposed models that take into account the force monopole and force dipole interactions as well as the elastic interaction between adatoms and steps and the effect of the Schwoebel barrier. Kaganer and Ploog [18] studied the energy of a strained stepped surface including the force dipole and force monopole effects of the steps and the interaction between them. Shenoy and Freund [39] obtained a continuum model based on continuum variational principles. Besides the force dipole and force monopole effects of the steps, they also showed that the dependence of the step line energy on the sign of the misfit strain may lead to nucleation of steps without energy barrier. Even though the discrete features of the step line energy and force dipole interaction between steps were included in these continuum models [18, 39], for the long-range elastic interaction due to misfit, the traditional expression above the roughening transition temperature was directly used. Xiang [49] and Xiang and E [51] derived a continuum model rigorously by taking the continuum limit of the discrete step dynamics models of Tersoff et al. [47, 23] and Duport et al. [5, 6]. For the misfit elastic effect, in addition to the widely used integral expression above the roughening transition temperature, there is another term incorporating the discrete features of the stepped surface in their continuum model. This additional term is crucial in modeling the step bunching instability on stepped surfaces [51].

A few models for crystal surfaces in $2 + 1$ dimensions accounting for the force monopole elastic effect of curved steps have also been proposed. Tersoff and Pehlke [46] analyzed step undulation instability of a stepped Si(001) surface which is subject to a force monopole effect at the steps, and their results agree well with the experimental observations obtained by Tromp and Reuter [48]. Houchmandzadeh and Misbah [15] studied the force dipole and force monopole elastic interactions between modulated steps. Kukta and Bhattacharya [19] proposed a $2 + 1$ step-flow model that accounts for both the elastic effects and terrace diffusion. Léonard and Tersoff [22] compared the different instability modes of a stepped surface under stress for both permeable and impermeable steps. Shenoy [38] studied the growth of epitaxial nanowires by controlled coarsening of strained islands. Haußer, Jabbour, and Voigt [12] proposed a step-flow model for the heteroepitaxial growth of strained, substitutional, binary alloy films with phase segregation. These models are all within the framework of discrete step dynamics. Within the continuum framework, Kaganer and Ploog [18] investigated the energetics of strained axially symmetric cone-shaped stepped surfaces; Ramasubramaniam and Shenoy [36] generalized the $1 + 1$ dimensional continuum model of Shenoy and Freund [39] to $2 + 1$ dimensions. However, continuum expressions above the roughening transition temperature were directly used in these continuum models. Still lacking is a continuum theory that accounts for the long-range elastic effect and the discrete features for a strained epitaxial film with a stepped surface in $2 + 1$ dimensions, as the continuum equation proposed in [49, 51] for a surface with straight steps in $1 + 1$ dimensions.

In this paper, we present such a continuum model for the long-range elastic interaction on the stepped surface of a strained film in $2 + 1$ dimensions. The continuum model is derived from the discrete model based on the BCF theory [3] that incorporates the processes of adatom diffusion on the terraces and attachment-detachment of adatoms to the steps [3, 33]. The continuum model is derived under the condition that the lattice constant and the average distance between adjacent steps are very small compared with the length unit of the continuum model, and thus there are many steps contained in a unit area of the domain of the continuum model. The derived continuum model contains new terms representing the contribution to the step line energy from this long-range elastic interaction, in addition to the traditional continuum expression for the surface above the roughening transition temperature. We focus on derivation in this paper. Validation of the model and simulation results using the model will be presented elsewhere [55].

The rest of this paper is organized as follows. In section 2, we briefly review the elastic effects on epitaxial surfaces and currently available continuum models for them. In section 3, we give the discrete model for the long-range elastic interaction on the stepped surface of a strained film. In section 4, we present the details of the derivation of the continuum model for the long-range elastic interaction on a stepped surface by taking the continuum limit from the discrete model. The results are summarized and discussion is made in section 5.

2. Currently available continuum models for epitaxial surfaces under elastic effects.

In this section, we briefly review the elastic effects on epitaxial surfaces and currently available continuum models for them. More details can be found in the books and reviews [33, 10, 9, 29] and other references in this section.

In heteroepitaxial growth, the misfit of the lattice constants is defined by

$$\varepsilon_0 = \frac{a_f - a}{a}, \tag{2.1}$$

where a_f and a are the lattice constants of the film and the substrate, respectively. This misfit results in strain and stress fields in the film and the substrate. For an isotropic film with flat surface and infinite substrate, there is a constant stress field in the bulk of the film. When the height of the film is in the z direction, the nonzero components of the stress tensor in the film are

$$\sigma_{xx} = \sigma_{yy} = \sigma_0 = \frac{2G(1+\nu)\varepsilon_0}{1-\nu}, \tag{2.2}$$

when the film and the substrate have the same shear modulus G and Poisson's ratio ν.

Above the roughening transition temperature, the surface can be modeled as a continuously changed profile without discrete structures on it; see Figure 2.1. Without the deposition flux, the surface morphological evolution due to surface diffusion is given by [30]

$$\frac{\partial h}{\partial t} = (1 + |\nabla h|^2)^{\frac{1}{2}} \nabla_s \cdot (D_s \nabla_s \mu), \tag{2.3}$$

where $h = h(x, y)$ is the height of the surface, ∇_s is the surface gradient operator, D_s is the surface diffusion coefficient, μ is the total chemical potential,

$$\mu = \mu_0 + \mu_m, \tag{2.4}$$

μ_0 is the chemical potential due to the surface energy, and μ_m is the chemical potential due to the elastic energy.

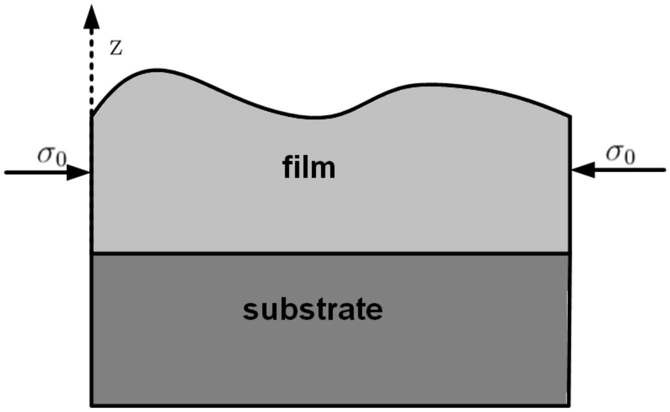

FIG. 2.1. *The film undergoes a stress due to the misfit in heteroepitaxy.*

The chemical potential due to the surface energy μ_0 is given by [30, 13]

$$\mu_0 = \gamma\kappa, \tag{2.5}$$

where γ is the surface energy density, $\kappa = \kappa_1 + \kappa_2$, κ_1 and κ_2 are the two principal values of the curvature of the surface.

The chemical potential due to the elastic energy μ_m is given by the elastic energy density on the surface [2, 11, 43]. For a nonflat surface, the chemical potential μ_m has to be obtained by solving an elasticity system in the film and the substrate. For a film with slightly modulated surface subject to the misfit stress, the elasticity system is approximately equivalent to that in a film with flat surface and subject to a traction [2, 11, 43, 42, 8, 33, 10, 9]

$$\mathbf{T} = \sigma_0(h_x, h_y, 0) \tag{2.6}$$

on its surface. In this case, μ_m is given by [17]

$$\mu_m(x,y) = -\frac{(1-\nu)\sigma_0^2}{2\pi G}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\frac{(x-\xi)h_x(\xi,\eta)+(y-\eta)h_y(\xi,\eta)}{[(x-\xi)^2+(y-\eta)^2]^{3/2}}\,d\xi d\eta, \tag{2.7}$$

when the surface $h(x,y)$ is defined in the whole two-dimensional space.

Below the roughening transition temperature, an epitaxial surface consists of atomic-height steps and atomic flat terraces; see Figure 2.2. The surface changes its morphology by motion, nucleation, and annihilation of steps. The evolution equation is given by [21, 31, 35, 16, 18, 49, 39, 51, 36, 38, 26, 27, 28, 25]

$$\frac{\partial h}{\partial t} = \nabla\cdot(D_0\nabla\mu), \tag{2.8}$$

where D_0 is the mobility. The mobility D_0 depends on the adatom diffusion on the terraces and attachment-detachment of adatoms along the steps. Derivations of this mobility from the BCF models [3] can be found for surfaces with straight steps in [49, 51], for conical surfaces with circular steps in [16, 18, 27], and for general stepped surfaces in $2+1$ dimensions in [25].

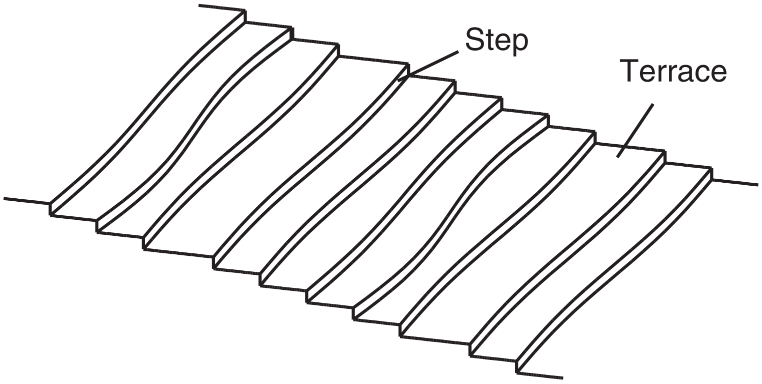

FIG. 2.2. *A stepped epitaxial surface.*

The total chemical potential μ on a misfit-strained stepped surface can be written as

$$\mu = \mu_s + \mu_d + \widehat{\mu}_m. \tag{2.9}$$

The first term μ_s is the chemical potential due to the step line energy

$$\mu_s = -\nabla \cdot \left(g_1 \frac{\nabla h}{|\nabla h|} \right) = \frac{\delta E_{\text{line}}}{\delta h}, \tag{2.10}$$

where

$$E_{\text{line}} = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} g_1 |\nabla h| dx dy \tag{2.11}$$

is the step line energy, and g_1 is the step line energy density. The second term μ_d is the chemical potential due to the interaction between steps in unstrained films which can be approximated by force dipole interaction

$$\mu_d = -\nabla \cdot (g_3 |\nabla h| \nabla h) = \frac{\delta E_{\text{dipole}}}{\delta h}, \tag{2.12}$$

where

$$E_{\text{dipole}} = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \frac{g_3}{3} |\nabla h|^3 dx dy \tag{2.13}$$

is the energy due to the force dipole interaction, and g_3 is the strength of this interaction.

The last term, $\widehat{\mu}_m$, in the above total chemical potential expression is the contribution of the long-range elastic interaction due to the misfit. The chemical potential for this long-range elastic interaction above the roughening transition temperature given in (2.7) was directly used for a surface with straight steps in [39], for a conical surface with circular steps in [18], and for a stepped surface in 2+1 dimensions in [36].

Xiang [49] and Xiang and E [51] derived a continuum model for epitaxial surfaces with straight steps rigorously by taking the continuum limit of the discrete models of steps [47, 23, 5, 6]. Their result for the force monopole and dipole elastic effects of steps is

$$\widehat{\mu}(x) = -\frac{(1-\nu)\sigma_0^2}{\pi G} \int_{-\infty}^{\infty} \frac{h'(\xi)}{x-\xi} d\xi - \frac{(1-\nu)\sigma_0^2 a}{2\pi G} \frac{h_{xx}(x)}{|h_x(x)|} \tag{2.14}$$

for a monotonic surface. The first term in (2.14) is the same as the chemical potential above the roughening transition temperature given in (2.7) in $1+1$ dimensions. The second term is the correction due to the discrete step-terrace structure of the surface. This continuum model of the chemical potential is also the variation of an elastic energy:

$$E_{\text{misfit}} = -\frac{(1-\nu)\sigma_0^2}{2\pi G}\int_{-\infty}^{\infty}\left(h(x)\int_{-\infty}^{\infty}\frac{h'(\xi)}{x-\xi}d\xi + a|h_x|\log|h_x|\right)dx. \tag{2.15}$$

In this paper, we shall generalize this work to epitaxial surfaces with curved steps in $2+1$ dimensions.

3. Discrete model for the elastic interaction between steps due to misfit.

In this section, we give the discrete model for the chemical potential of a stepped surface due to the misfit-induced long-range elastic interaction in $2+1$ dimensions. Following [1, 46, 5, 6, 15, 47, 23, 33, 19, 18, 22, 29, 38], this chemical potential can be obtained by considering the surface height $h(x,y)$ as a mathematical step function whose jump at a step is the lattice constant a in the continuum model (2.7). We assume that the steps $\{\gamma_j\}$, $j=\dots,-2,-1,0,1,2,\dots$, are smooth plane curves. Using the relation

$$\nabla h = -a\sum_j \delta(\gamma_j)\mathbf{n}_j \tag{3.1}$$

in (2.7), where $\delta(\gamma_j)$ is the one-dimensional Dirac delta function in the normal direction $\mathbf{n}_j$ of γ_j, the chemical potential at a point $\mathbf{X}$ on step γ_n is

$$\widehat{\mu}_m(\mathbf{X}) = \widehat{\mu}_m^{\text{int}}(\mathbf{X}) + \widehat{\mu}_m^{\text{self}}(\mathbf{X}), \tag{3.2}$$

with

$$\widehat{\mu}_m^{\text{int}}(\mathbf{X}) = \frac{(1-\nu)\sigma_0^2 a}{2\pi G}\left(\sum_{j\neq n}\int_{\gamma_j}\frac{(\mathbf{X}-\mathbf{X}_1)\cdot\mathbf{n}_j(\mathbf{X}_1)}{\|\mathbf{X}-\mathbf{X}_1\|^3}\,dl\right) \tag{3.3}$$

and

$$\widehat{\mu}_m^{\text{self}}(\mathbf{X}) = \frac{(1-\nu)\sigma_0^2 a}{2\pi G}\left(\int_{-\infty}^{\infty}\delta(\omega)\,d\omega\int_{\gamma_\omega}\frac{(\mathbf{X}-\mathbf{X}_1)\cdot\mathbf{n}_\omega(\mathbf{X}_1)}{\|\mathbf{X}-\mathbf{X}_1\|^3}\,dl\right), \tag{3.4}$$

where $\mathbf{X}_1$ is a point that varies along the curves in these line integrals, the curve $\gamma_\omega = \{\mathbf{X}_0 + \omega\mathbf{n}_n(\mathbf{X}_0) : \mathbf{X}_0 \in \gamma_n\}$, and $\mathbf{n}_\omega$ is its unit normal vector. Note that there are two possible directions for the normal vector of a step. In (3.1) and throughout this paper, we choose the normal direction of a step to be the direction in which the surface height h is decreasing.

The delta function $\delta(\omega)$ in the chemical potential due to the self-interaction $\widehat{\mu}_m^{\text{self}}(\mathbf{X})$ has to be regularized to avoid nonphysical singularity. (The same notation is used for simplicity.) The width of the regularization of $\delta(\omega)$, which reflects the detailed structure of the step and can be determined from atomistic calculations, is of the order of the lattice constant a. The regularization or cut-off is commonly used to remove nonphysical singularities in the models of steps [1, 19, 22, 29, 38] or other line defects such as dislocations [14]. We also assume that the regularized delta function $\delta(\omega)$ has compact support and $\delta(-\omega)=\delta(\omega)$.

Suppose that the step γ_n is parameterized by its arclength s, and the unit normal vector at a point $\mathbf{X}_1(s) \in \gamma_n$

$$\mathbf{n}_n(\mathbf{X}_1) = (-y'(s), x'(s)) \tag{3.5}$$

is in the direction in which the surface is decreasing. The curve γ_ω can also be parameterized by s (no longer arclength) as

$$(x_\omega(s)\,, y_\omega(s)) = (x(s) - \omega y'(s)\,, y(s) + \omega x'(s)), \tag{3.6}$$

and its tangent vector and normal vector (not normalized) are

$$(x'_\omega(s)\,, y'_\omega(s)) = (1 - \kappa(s)\omega)(x'(s)\,, y'(s)) \tag{3.7}$$

and

$$(-y'_\omega(s)\,, x'_\omega(s)) = (1 - \kappa(s)\omega)(-y'(s)\,, x'(s)), \tag{3.8}$$

respectively, where $\kappa(s)$ is the curvature of γ_n at point $\mathbf{X}_1(s)$. Note that $(x''(s)\,, y''(s)) = \kappa(s)(-y'(s)\,, x'(s))$. Thus we can rewrite the chemical potential due to the self-interaction in (3.4) as

$$\widehat{\mu}_m^{\text{self}}(\mathbf{X}) = \frac{(1-\nu)\sigma_0^2 a}{2\pi G} \int_{-\infty}^{\infty} \delta(\omega)\, d\omega \int_{\gamma_n} (1 - \kappa(\mathbf{X}_1)\omega) \frac{(\mathbf{X} - \mathbf{X}_1 - \omega \mathbf{n}_n(\mathbf{X}_1)) \cdot \mathbf{n}_n(\mathbf{X}_1)}{\|\mathbf{X} - \mathbf{X}_1 - \omega \mathbf{n}_n(\mathbf{X}_1)\|^3}\, dl. \tag{3.9}$$

4. Derivation of the continuum model. Although (3.2)–(3.4) give an exact expression for the misfit-induced long-range elastic interaction on a stepped surface, in the framework of a continuum model, the stepped surface is often described by a smooth profile without resolving the details of the steps; see the surfaces $z = h(x, y)$ in Figure 4.1. In this section, we will derive a continuum model for the long-range elastic interaction on such a surface from the discrete model given by (3.2)–(3.4) by letting the lattice constant $a \to 0$. Similarly to the derivation for surfaces with straight steps in [49, 51], we will find the continuum approximation by considering the difference between this discrete model and the continuum expression on a surface without steps given by (2.7).

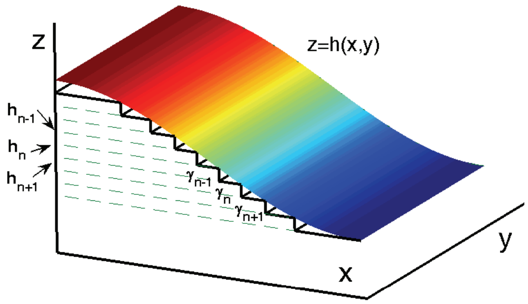

FIG. 4.1. *A stepped surface described by a smooth profile $z = h(x, y)$.*

4.1. Assumptions. We assume that in the length unit of the continuum model, the lattice constant $a \ll 1$, which means that there are many steps in a unit area of the domain of the continuum model, and the curvature radius of the steps is $O(1)$. The surface in the continuum model is a smooth profile $h(x, y)$, and a step γ_n with height h_n is described by the contour line $\gamma_n = \{(x, y)|h(x, y) = h_n\}$; see Figure 4.1. We assume that $h(x, y)$ has up to fourth order bounded partial derivatives, and $|\nabla h(x, y)| > c_0$, where $c_0 > 0$ is a constant. When the domain size is infinity, we assume that the integral expression in (2.7) converges, the line integrals in the discrete model in (3.3) and (3.4) converge absolutely, and the summation in the discrete model in (3.3) converges. Without loss of generality, the whole xy plane is used as the domain in our derivation.

4.2. Integral expression reformulated. In this subsection, we rewrite the integral expression given by (2.7) using parameter z and the parameter of the contour line

$$\gamma_z = \{(x, y)|h(x, y) = z\} \tag{4.1}$$

for the surface $z = h(x, y)$. From the assumptions of $h(x, y)$ given above, the contour line γ_z is smooth, with unit normal vector

$$\mathbf{n}_z(x, y) = -\frac{\nabla h(x, y)}{|\nabla h(x, y)|} \tag{4.2}$$

and bounded curvature

$$\kappa(x, y) = \nabla \cdot \left(\frac{\nabla h(x, y)}{|\nabla h(x, y)|} \right) \tag{4.3}$$

for $(x, y) \in \gamma_z$.

Using the new parameters, the integral expression (2.7) for the chemical potential at a point (x, y) on step γ_n, i.e., $h(x, y) = h_n$, can be rewritten as

$$\begin{aligned} \mu_m(x, y) &= -\frac{(1-\nu)\sigma_0^2}{2\pi G} \int_{-\infty}^{\infty} dz \int_{\gamma_z} \frac{(x-\xi)h_x(\xi, \eta) + (y-\eta)h_y(\xi, \eta)}{[(x-\xi)^2 + (y-\eta)^2]^{3/2}} \frac{1}{\sqrt{h_x^2(\xi, \eta) + h_y^2(\xi, \eta)}}\, dl \\ &= \frac{(1-\nu)\sigma_0^2}{2\pi G} \int_{-\infty}^{\infty} dz \int_{\gamma_z} \frac{(\mathbf{X} - \mathbf{X}_1) \cdot \mathbf{n}_z(\mathbf{X}_1)}{\rho^3}\, dl, \end{aligned} \tag{4.4}$$

where $\rho = \sqrt{(x-\xi)^2 + (y-\eta)^2}$, $\mathbf{X}_1 = (\xi, \eta)$ varies along γ_z, and $\mathbf{X} = (x, y)$.

Using the above formulation for the integral expression, the discrete formulation (3.2)–(3.4) can be roughly considered as a numerical discretization for the outer integral with respect to z of the integral expression. Since the inner integral in (4.4),

$$J(z) = \int_{\gamma_z} \frac{(\mathbf{X} - \mathbf{X}_1) \cdot \mathbf{n}_z(\mathbf{X}_1)}{\rho^3}\, dl, \tag{4.5}$$

is singular when $z = h_n = h(x, y)$, here we derive the asymptotic behavior of this singularity as $z \to h_n$, which will be used later to find the difference between the discrete and integral expressions accurately. The derivation method is similar to that for the asymptotic behavior of vortices in the Ginzburg–Landau equation [7, 34].

Suppose that $\mathbf{X}_0$ is the point on γ_z such that the point $\mathbf{X}$ lies on the normal direction (positive or negative) of γ_z at $\mathbf{X}_0$. Let $(\mathbf{t}_z, \mathbf{n}_z)$ be the Frenet coordinates at $\mathbf{X}_0$, where $\mathbf{t}_z$ is the unit tangent vector of γ_z, and $\mathbf{n}_z$ is the unit normal vector of γ_z defined in (4.2). Let s be a shifted arclength of γ_z such that $\mathbf{X}_0 = \gamma_z(0)$, and let $\kappa_z(s)$ be the curvature along γ_z. If $\kappa_z = \kappa_z(0)$ is the curvature of γ_z at $\mathbf{X}_0$ and $\kappa_z' = \kappa_z'(0)$, a point $\mathbf{X}_1$ on γ_z near $\mathbf{X}_0$ has the representation $\mathbf{X}_1 = \alpha(s)\mathbf{t}_z + \beta(s)\mathbf{n}_z$, where $\alpha(s) = s - \frac{1}{6}\kappa_z^2 s^3 + \cdots$ and $\beta(s) = \frac{1}{2}\kappa_z^2 s^2 + \frac{1}{6}\kappa_z' s^3 + \cdots$, and $\mathbf{X} = d\mathbf{n}_z$. Thus d is the signed distance from point $\mathbf{X}$ to the curve γ_z. We will find the asymptotic behavior of the integral $J(z)$ in (4.5) as $d \to 0$. Note that the signed distance d can be expressed in terms of z near h_n:

$$d = -\frac{z - h_n}{\sqrt{h_x^2(\mathbf{X}_0) + h_y^2(\mathbf{X}_0)}} + O((z - h_n)^2),\ z \to h_n, \tag{4.6}$$

whose proof can be found in Appendix A. (Note that the notation is different in Appendix A. The points $\mathbf{X}_0$ and $\mathbf{X}$ here are the points $\mathbf{X}$ and $\mathbf{P}$ in Appendix A, respectively. See Figure A.1.)

We first divide the integral in (4.5) into two parts: $J(z) = J_1(z) + J_2(z)$ with

$$J_1(z) = \int_{\gamma_z^1} \frac{(\mathbf{X} - \mathbf{X}_1) \cdot \mathbf{n}_z(\mathbf{X}_1)}{\rho^3}\, dl, \quad J_2(z) = \int_{\gamma_z^2} \frac{(\mathbf{X} - \mathbf{X}_1) \cdot \mathbf{n}_z(\mathbf{X}_1)}{\rho^3}\, dl, \tag{4.7}$$

where γ_z^1 is the segment of γ_z for $s \in [-1, 1]$, $\gamma_z^2 = \gamma_z - \gamma_z^1$, and $\mathbf{n}_z(\mathbf{X}_1) = -\beta'(s)\mathbf{t}_z + \alpha'(s)\mathbf{n}_z$. Using the expansions of $\alpha(s)$ and $\beta(s)$ and change of variable $s = \lambda|d|$ [34], we have

$$\begin{aligned}
J_1(z) &= \int_{-1}^{1} \frac{\alpha(s)\beta'(s) - \alpha'(s)\beta(s) + \alpha'(s)d}{[\alpha^2(s) + (\beta(s) - d)^2]^{3/2}}\, ds \\
&= \int_{-1}^{1} \frac{d + \frac{1}{2}\kappa_z s^2 + O(s^3 + s^2 d)}{(s^2 + d^2 - d\kappa_z s^2)^{3/2}[1 + O(s^2 + sd)]}\, ds \\
&= \int_{-1}^{1} \frac{d + \frac{1}{2}\kappa_z s^2 + O(s^2 d + s d^2)}{(s^2 + d^2 - d\kappa_z s^2)^{3/2}}\, ds + O(1) \\
&= \int_{-|d|^{-1}}^{|d|^{-1}} \frac{d|d| + \frac{1}{2}d^2|d|\kappa_z\lambda^2 + O(\lambda^2 d^4 + \lambda d^4)}{(\lambda^2 d^2 + d^2 - d^3\kappa_z\lambda^2)^{3/2}}\, d\lambda + O(1) \\
&= \int_{-|d|^{-1}}^{|d|^{-1}} \frac{1 + \frac{1}{2}d\kappa_z\lambda^2 + O(\lambda^2 d^2 + \lambda d^2)}{d(\lambda^2 + 1 - d\kappa_z\lambda^2)^{3/2}}\, d\lambda + O(1) \\
&= -\kappa_z \log|d| + \frac{2}{d} + O(1) \\
&= -\kappa \log|d| + \frac{2}{d} + O(1), \qquad (4.8)
\end{aligned}$$

as $d \to 0$, where κ is the curvature of the step γ_n at $\mathbf{X}$. Since $J_2(z) = O(1)$, we have

$$J(z) = -\kappa \log|d| + \frac{2}{d} + O(1),\ d \to 0. \tag{4.9}$$

This asymptotic behavior holds uniformly when $z \to h_n$ due to the smoothness assumption of the surface $h(x, y)$ and the convergence of the line integral.

Using (4.6) and (4.9), and $\mathbf{X}=\mathbf{X}_0+O(z-h_n)$, we have the asymptotic approximation of line integral in (4.5):

$$J(z)=-\kappa\log|z-h_n|-\frac{2\sqrt{h_x^2(\mathbf{X})+h_y^2(\mathbf{X})}}{z-h_n}+O(1),\ z\to h_n. \tag{4.10}$$

4.3. Difference between the discrete model and the continuum expression. When the continuum expression $\mu_m(x,y)$ is written in the form in (4.4), the discrete model $\widehat{\mu}_m(x,y)$ given by (3.2)–(3.4) can be regarded as a numerical scheme of this continuum expression. Thus, the continuum expression with the leading order error terms of this numerical scheme will give an accurate continuum approximation of the discrete model. The error of this numerical scheme can be found using the following theorem, whose proof is given in Appendix B.

THEOREM 4.1. *Suppose that interval $[a,b]$ is divided into m subintervals with $\Delta x=(b-a)/m$, $x_j=a+(j-1)\Delta x$, $j=1,\dots,m+1$. Let $G(x)=g_1(x)\log|x-t|+g_2(x)/(x-t)+g_3(x)$ with $t=x_{j_0}$ for some j_0, where $g_1(x)$, $g_2(x)$, and $g_3(x)$ are twice continuously differentiable functions. Then*

$$\begin{aligned}\int_a^b G(x)\,dx&=\Delta x\left(\frac{G(a)+G(b)}{2}+\sum_{2\le j\le m,j\ne j_0}G(x_j)\right)\\&\quad+\int_{t-\frac{\Delta x}{2}}^{t+\frac{\Delta x}{2}}G(x)\,dx-(\log\pi-1)g_1(t)\Delta x+O(\Delta x^2).\end{aligned} \tag{4.11}$$

Using this theorem for $G(z)=\frac{(1-\nu)\sigma_0^2}{2\pi G}J(z)$, where $J(z)$ is given by (4.5) with the asymptotic behavior as $z\to h_n$ given by (4.10), and the discretization $z=h_j$, $j=\dots,-1,0,1,2,\dots$, we have, as $a\to 0$,

$$\begin{aligned}\mu_m(x,y)&=\widehat{\mu}_m^{\text{int}}(x,y)\\&\quad+\frac{(1-\nu)\sigma_0^2}{2\pi G}\left(\int_{h_n-\frac{a}{2}}^{h_n+\frac{a}{2}}\left(\int_{\gamma_z}\frac{(\mathbf{X}-\mathbf{X}_1)\cdot\mathbf{n}_z(\mathbf{X}_1)}{\rho^3}dl\right)dz+(\log\pi-1)\kappa a\right)\\&\quad+O(a^2),\end{aligned} \tag{4.12}$$

or

$$\begin{aligned}\widehat{\mu}_m(x,y)&=\widehat{\mu}_m^{\text{int}}(x,y)+\widehat{\mu}_m^{\text{self}}(x,y)\\&=\mu_m(x,y)+\widehat{\mu}_m^{\text{self}}(x,y)-\mu_m^{\text{self}}(x,y)-\frac{(1-\nu)\sigma_0^2}{2\pi G}(\log\pi-1)\kappa a+O(a^2),\end{aligned} \tag{4.13}$$

where

$$\mu_m^{\text{self}}(x,y)=\frac{(1-\nu)\sigma_0^2}{2\pi G}\int_{h_n-\frac{a}{2}}^{h_n+\frac{a}{2}}\left(\int_{\gamma_z}\frac{(\mathbf{X}-\mathbf{X}_1)\cdot\mathbf{n}_z(\mathbf{X}_1)}{\rho^3}dl\right)dz. \tag{4.14}$$

Now, to find the continuum approximation of $\widehat{\mu}_m(x,y)$, it remains to find the difference between the self-interaction in the discrete model $\widehat{\mu}_m^{\text{self}}(x,y)$, given by (3.4), and $\mu_m^{\text{self}}(x,y)$, given by (4.14), which can be explained as the self-interaction in the continuum model.

In order to find the difference between $\widehat{\mu}_m^{\text{self}}(x,y)$ and $\mu_m^{\text{self}}(x,y)$, similar to $\widehat{\mu}_m^{\text{self}}(x,y)$ given by (3.9), we also rewrite the inner integral in $\mu_m^{\text{self}}(x,y)$ as an integral along γ_n.

When the lattice constant a is very small compared with the minimum radius of curvature of contour lines of h, which exists due to the uniform boundedness of the curvature, the contour line γ_z when $z \in [h_n - \frac{a}{2}, h_n + \frac{a}{2}]$ can be written as

$$\gamma_z = \{\mathbf{X}_1 + d(\mathbf{X}_1, \omega)\mathbf{n}_n(\mathbf{X}_1) : \mathbf{X}_1 \in \gamma_n\}, \tag{4.15}$$

where $\omega = z - h_n$, $\mathbf{n}_n(\mathbf{X}_1)$ is the unit normal vector of γ_n at the point $\mathbf{X}_1$ on γ_n, and $d(\mathbf{X}_1, \omega)$ is the signed distance between a point $\mathbf{X}_1$ on γ_n and a point $\mathbf{P}$ on the nearby contour line γ_z such that $\mathbf{PX}_1$ is parallel to the normal direction of γ_n at $\mathbf{X}_1$.

Suppose that γ_n is parameterized by its arclength s: $\mathbf{X}_1 = (x(s), y(s)) \in \gamma_n$, with unit tangent vector $\mathbf{t}_n(\mathbf{X}_1) = (x'(s), y'(s))$ and unit normal vector $\mathbf{n}_n(\mathbf{X}_1) = (-y'(s), x'(s))$. Then γ_z can also be parameterized by s (no longer arclength) as

$$(\widehat{x}_\omega(s), \widehat{y}_\omega(s)) = (x(s) - d(s, \omega)y'(s)\,, y(s) + d(s, \omega)x'(s)), \tag{4.16}$$

where $d(s, \omega) = d(\mathbf{X}_1, \omega)|_{\mathbf{X}_1=(x(s),y(s))}$ is the signed distance from the point $\mathbf{P}$ to the point $\mathbf{X}_1$ which is positive in the direction of $\mathbf{n}_n(\mathbf{X}_1)$. The tangent and normal vectors of γ_z (not normalized) are

$$(\widehat{x}'_\omega(s), \widehat{y}'_\omega(s)) = (1 - \kappa(s)d(s, \omega))(x'(s)\,, y'(s)) + d_s(s, \omega)(-y'(s)\,, x'(s)) \tag{4.17}$$

and

$$(-\widehat{y}'_\omega(s), \widehat{x}'_\omega(s)) = (1 - \kappa(s)d(s, \omega))(-y'(s)\,, x'(s)) - d_s(s, \omega)(x'(s)\,, y'(s)), \tag{4.18}$$

respectively, where $\kappa(s)$ is curvature of γ_n at $(x(s), y(s))$, and $d_s(s, \omega) = \frac{\partial}{\partial s} d(s, \omega)$. Hence, $\mu_m^{\text{self}}(x, y)$ defined in (4.14) can be written as

$$\mu_m^{\text{self}}(x, y) = \frac{(1 - \nu)\sigma_0^2}{2\pi G} \int_{-\frac{a}{2}}^{\frac{a}{2}} \left(\int_{\gamma_n} \frac{(\mathbf{X} - \mathbf{X}_1 - d(\mathbf{X}_1, \omega)\mathbf{n}_n(\mathbf{X}_1)) \cdot \widetilde{\mathbf{n}_n}(\mathbf{X}_1)}{\|\mathbf{X} - \mathbf{X}_1 - d(\mathbf{X}_1, \omega)\mathbf{n}_n(\mathbf{X}_1)\|^3} dl \right) d\omega, \tag{4.19}$$

where

$$\widetilde{\mathbf{n}}_n(\mathbf{X}_1) = (1 - \kappa(\mathbf{X}_1)d(\mathbf{X}_1, \omega))\mathbf{n}_n(\mathbf{X}_1) - d_s(\mathbf{X}_1, \omega)\mathbf{t}_n(\mathbf{X}_1). \tag{4.20}$$

4.4. Difference between $\widehat{\mu}_m^{\text{self}}(x, y)$ and $\mu_m^{\text{self}}(x, y)$. Now we want to find the asymptotic approximation, up to $O(a)$, of the difference between $\widehat{\mu}_m^{\text{self}}(x, y)$ given by (3.9) and $\mu_m^{\text{self}}(x, y)$ given by (4.19). We use a shifted arclength parameter s for γ_n with $\mathbf{X} = \gamma_n(0)$. When $\mathbf{X}_1 \in \gamma_n$ is close to $\mathbf{X}$,

$$\mathbf{X}_1 = \mathbf{X} + \left(s - \frac{\kappa^2 s^3}{6} \right) \mathbf{t} + \left(\frac{\kappa s^2}{2} + \frac{\kappa' s^3}{6} \right) \mathbf{n} + O(s^4), \tag{4.21}$$

where $\mathbf{t}$ and $\mathbf{n}$ are unit tangent and normal vectors of γ_n at $\mathbf{X}$, respectively, $\kappa = \kappa(s)|_{s=0}$ is the curvature of γ_n at $\mathbf{X}$, and $\kappa' = \frac{d\kappa(s)}{ds}|_{s=0}$.

Let γ_n^A be the segment of γ_n with $s \in [-a^{\frac{1}{4}}, a^{\frac{1}{4}}]$ and $\gamma_n^B = \gamma_n - \gamma_n^A$. Due to the smoothness assumptions of h, we have

$$\|\mathbf{X} - \mathbf{X}_1\|^2 \geq \frac{1}{2} a^{\frac{1}{2}}, \quad \mathbf{X}_1 \in \gamma_n^B, \tag{4.22}$$

when a is small enough compared with the minimum radius of the curvature of γ_n. Thus when $\omega = O(a)$, for $\mathbf{X}_1 \in \gamma_n^B$, we have

$$\begin{aligned} &\|\mathbf{X}-\mathbf{X}_1-\omega\mathbf{n}_n(\mathbf{X}_1)\|^3 \\ &= (\|\mathbf{X}-\mathbf{X}_1\|^2 - 2\,\omega(\mathbf{X}-\mathbf{X}_1)\cdot\mathbf{n}_n(\mathbf{X}_1)+\omega^2)^{3/2} \\ &= \|\mathbf{X}-\mathbf{X}_1\|^3\left(1-2\,\omega\frac{(\mathbf{X}-\mathbf{X}_1)\cdot\mathbf{n}_n(\mathbf{X}_1)}{\|\mathbf{X}-\mathbf{X}_1\|^2}+\frac{\omega^2}{\|\mathbf{X}-\mathbf{X}_1\|^2}\right)^{3/2} \\ &= \|\mathbf{X}-\mathbf{X}_1\|^3(1+O(a^{\frac{3}{4}})). \end{aligned} \tag{4.23}$$

Using (4.22) and (4.23), when $\omega = O(a)$, we have

$$\int_{\gamma_n^B}(1-\kappa(\mathbf{X}_1)\omega)\frac{(\mathbf{X}-\mathbf{X}_1-\omega\mathbf{n}_n(\mathbf{X}_1))\cdot\mathbf{n}_n(\mathbf{X}_1)}{\|\mathbf{X}-\mathbf{X}_1-\omega\mathbf{n}_n(\mathbf{X}_1)\|^3}\,dl = \int_{\gamma_n^B}\frac{(\mathbf{X}-\mathbf{X}_1)\cdot\mathbf{n}_n(\mathbf{X}_1)}{\|\mathbf{X}-\mathbf{X}_1\|^3}\,dl + O(a^{\frac{1}{4}}), \tag{4.24}$$

which implies that when the inner line integral is along γ_n^B in $\widehat{\mu}_m^{\mathrm{self}}(x,y)$ given by (3.9), we have

$$\begin{aligned} &a\int_{-\infty}^{\infty}\delta(\omega)d\omega\int_{\gamma_n^B}(1-\kappa(\mathbf{X}_1)\omega)\frac{(\mathbf{X}-\mathbf{X}_1-\omega\mathbf{n}_n(\mathbf{X}_1))\cdot\mathbf{n}_n(\mathbf{X}_1)}{\|\mathbf{X}-\mathbf{X}_1-\omega\mathbf{n}_n(\mathbf{X}_1)\|^3}\,dl \\ &= a\int_{\gamma_n^B}\frac{(\mathbf{X}-\mathbf{X}_1)\cdot\mathbf{n}_n(\mathbf{X}_1)}{\|\mathbf{X}-\mathbf{X}_1\|^3}\,dl + O(a^{\frac{5}{4}}), \end{aligned} \tag{4.25}$$

when the delta function $\delta(\omega)$ has compact support with a width of $O(a)$.

Now we consider $\mu_m^{\mathrm{self}}(x,y)$ given by (4.19) when the inner line integral is along γ_n^B. First, it is shown in Appendix A that when ω is small,

$$d(\mathbf{X}_1,\omega) = \left. -\frac{\omega}{(h_x^2+h_y^2)^{1/2}} + \frac{h_x^2h_{xx}+2h_xh_yh_{xy}+h_y^2h_{yy}}{2\,(h_x^2+h_y^2)^{5/2}}\omega^2\right|_{\mathbf{X}_1=(x(s),y(s))} + O(\omega^3). \tag{4.26}$$

Thus we have

$$d_s(\mathbf{X}_1,\omega) = \left.\frac{h_x(x'h_{xx}+y'h_{xy})+h_y(x'h_{xy}+y'h_{yy})}{(h_x^2+h_y^2)^{3/2}}\omega\right|_{\mathbf{X}_1=(x(s),y(s))} + O(\omega^2) \tag{4.27}$$

and

$$\|\widetilde{\mathbf{n}}_n(\mathbf{X}_1)\| = 1 + O(\omega), \tag{4.28}$$

where $\widetilde{\mathbf{n}}_n(\mathbf{X}_1)$ is given by (4.20).

Using (4.22) and (4.26), when $\omega = O(a)$, for $\mathbf{X}_1 \in \gamma_n^B$, we have

$$\|\mathbf{X}-\mathbf{X}_1-d(\mathbf{X}_1,\omega)\mathbf{n}_n(\mathbf{X}_1)\|^3 = \|\mathbf{X}-\mathbf{X}_1\|^3(1+O(a^{\frac{3}{4}})). \tag{4.29}$$

Thus when $\omega = O(a)$, for $\mathbf{X}_1 \in \gamma_n^B$, using (4.28) and (4.29), we have

$$\int_{\gamma_n^B}\frac{(\mathbf{X}-\mathbf{X}_1-d(\mathbf{X}_1,\omega)\mathbf{n}_n(\mathbf{X}_1))\cdot\widetilde{\mathbf{n}_n}(\mathbf{X}_1)}{\|\mathbf{X}-\mathbf{X}_1-d(\mathbf{X}_1,\omega)\mathbf{n}_n(\mathbf{X}_1)\|^3}\,dl = \int_{\gamma_n^B}\frac{(\mathbf{X}-\mathbf{X}_1)\cdot\mathbf{n}_n(\mathbf{X}_1)}{\|\mathbf{X}-\mathbf{X}_1\|^3}\,dl + O(a^{\frac{1}{4}}), \tag{4.30}$$

which implies

$$\int_{-\frac{a}{2}}^{\frac{a}{2}} d\omega \int_{\gamma_n^B} \frac{(\mathbf{X}-\mathbf{X}_1-d(\mathbf{X}_1,\omega)\mathbf{n}_n(\mathbf{X}_1))\cdot\widetilde{\mathbf{n}_n}(\mathbf{X}_1)}{\|\mathbf{X}-\mathbf{X}_1-d(\mathbf{X}_1,\omega)\mathbf{n}_n(\mathbf{X}_1)\|^3}\,dl$$
$$= a\int_{\gamma_n^B} \frac{(\mathbf{X}-\mathbf{X}_1)\cdot\mathbf{n}_n(\mathbf{X}_1)}{\|\mathbf{X}-\mathbf{X}_1\|^3}\,dl + O(a^{\frac{5}{4}}). \tag{4.31}$$

Next, we consider $\widehat{\mu}_m^{\rm self}(x,y)$ in (3.9) and $\mu_m^{\rm self}(x,y)$ in (4.19) when the inner line integrals are along γ_n^A. When $\mathbf{X}_1 \in \gamma_n^A$, $\mathbf{X}_1$ can be written as (4.21), and the unit tangent vector, unit normal vector, and curvature at $\mathbf{X}_1$ are

$$\mathbf{t}_n(\mathbf{X}_1) = \left(1-\frac{\kappa^2 s^2}{2}\right)\mathbf{t} + \left(\kappa s + \frac{\kappa' s^2}{2}\right)\mathbf{n} + O(s^3), \tag{4.32}$$

$$\mathbf{n}_n(\mathbf{X}_1) = \left(-\kappa s - \frac{\kappa' s^2}{2}\right)\mathbf{t} + \left(1-\frac{\kappa^2 s^2}{2}\right)\mathbf{n} + O(s^3), \tag{4.33}$$

and

$$\kappa(\mathbf{X}_1) = \kappa + O(s), \tag{4.34}$$

respectively, for $s \in [-a^{\frac{1}{4}}, a^{\frac{1}{4}}]$.

When $s \in [-a^{\frac{1}{4}}, a^{\frac{1}{4}}]$, $\omega = O(a)$, and a is small enough, using (4.21), (4.32)–(4.34), the integrand in (3.9) can be written as

$$(1-\kappa(\mathbf{X}_1)\omega)\frac{(\mathbf{X}-\mathbf{X}_1-\omega\mathbf{n}_n(\mathbf{X}_1))\cdot\mathbf{n}_n(\mathbf{X}_1)}{\|\mathbf{X}-\mathbf{X}_1-\omega\mathbf{n}_n(\mathbf{X}_1)\|^3}$$
$$= \frac{\kappa s^2/2-\omega+\kappa\omega^2+O(s^3+\omega s^2+\omega^2 s)}{[s^2+\omega^2-\kappa\omega s^2+O(s^4+\omega s^3)]^{3/2}}$$
$$= \frac{\kappa s^2/2-\omega+\kappa\omega^2}{(s^2+\omega^2)^{3/2}} - \frac{\frac{3}{2}\kappa\omega^2 s^2}{(s^2+\omega^2)^{5/2}} + O(1). \tag{4.35}$$

Hence, when $\mathbf{X}_1 \in \gamma_n^A$, the integral in $\widehat{\mu}_m^{\rm self}(x,y)$ given by (3.9) can be written as

$$\frac{(1-\nu)\sigma_0^2 a}{2\pi G}\int_{-\infty}^{\infty}\delta(\omega)\,d\omega\int_{\gamma_n^A}(1-\kappa(\mathbf{X}_1)\omega)\frac{(\mathbf{X}-\mathbf{X}_1-\omega\mathbf{n}_n(\mathbf{X}_1))\cdot\mathbf{n}_n(\mathbf{X}_1)}{\|\mathbf{X}-\mathbf{X}_1-\omega\mathbf{n}_n(\mathbf{X}_1)\|^3}dl \tag{4.36}$$
$$= \frac{(1-\nu)\sigma_0^2 a}{2\pi G}\int_{-\infty}^{\infty}\delta(\omega)d\omega\int_{-a^{\frac{1}{4}}}^{a^{\frac{1}{4}}}\left[\frac{\kappa s^2/2-\omega+\kappa\omega^2}{(s^2+\omega^2)^{3/2}} - \frac{\frac{3}{2}\kappa\omega^2 s^2}{(s^2+\omega^2)^{5/2}}\right]ds + O(a^{\frac{5}{4}})$$
$$= \frac{(1-\nu)\sigma_0^2 a}{2\pi G}\int_{-\infty}^{\infty}\kappa\delta(\omega)(\log a^{\frac{1}{4}} + \log 2 - \log|\omega|)d\omega + O(a^{\frac{5}{4}})$$
$$= \frac{(1-\nu)\sigma_0^2 a}{2\pi G}\kappa(\log 2a^{\frac{1}{4}} - \log r_c) + O(a^{\frac{5}{4}}),$$

when the regularized delta function $\delta(\omega)$ has compact support with a width of $O(a)$ and $\delta(-\omega) = \delta(\omega)$, where r_c is a parameter depending on the core of the step represented by the regularized delta function $\delta(\omega)$:

$$\log r_c = \int_{-\infty}^{\infty}\delta(\omega)\log|\omega|\,d\omega. \tag{4.37}$$

The inner integral with respect to s in (4.36) is calculated using change of variable $s = |\omega|\lambda$.

Now we consider $\mu_m^{\text{self}}(x, y)$ given by (4.19) when the inner line integral is along γ_n^A. First, from (4.26) and (4.27), we have

$$d(\mathbf{X}_1, \omega) = \beta_1\omega + \beta_2\omega^2 + \beta_3\omega s + O(\omega(s^2 + \omega^2)), \tag{4.38}$$

$$d_s(\mathbf{X}_1, \omega) = \beta_3\omega + O(\omega^2 + \omega s), \tag{4.39}$$

where

$$\beta_1 = -\frac{1}{(h_x^2 + h_y^2)^{1/2}}, \tag{4.40}$$

$$\beta_2 = \frac{h_x^2 h_{xx} + 2h_x h_y h_{xy} + h_y^2 h_{yy}}{2\,(h_x^2 + h_y^2)^{5/2}}, \tag{4.41}$$

$$\beta_3 = \frac{h_x(x' h_{xx} + y' h_{xy}) + h_y(x' h_{xy} + y' h_{yy})}{(h_x^2 + h_y^2)^{3/2}}, \tag{4.42}$$

in which all partial derivatives are values at $\mathbf{X} = (x, y)$.

Hence, when $s \in [-a^{\frac{1}{4}}, a^{\frac{1}{4}}]$, $\omega = O(a)$, and a is small enough, using (4.20), (4.21), (4.32)–(4.34), (4.38), and (4.39), the integrand in (4.19) can be written as

$$\begin{aligned}
&\frac{(\mathbf{X} - \mathbf{X}_1 - d(\mathbf{X}_1, \omega)\mathbf{n}_n(\mathbf{X}_1)) \cdot \widetilde{\mathbf{n}}_n(\mathbf{X}_1)}{\|\mathbf{X} - \mathbf{X}_1 - d(\mathbf{X}_1, \omega)\mathbf{n}_n(\mathbf{X}_1)\|^3} \\
&= \frac{-\beta_1\omega + (\kappa\beta_1^2 - \beta_2)\omega^2 + \kappa s^2/2}{(s^2 + \beta_1^2\omega^2)^{3/2}} + \frac{\frac{3}{2}\beta_1\omega(-\beta_1\kappa\omega s^2 + 2\beta_1\beta_3\omega^2 s + 2\beta_1\beta_2\omega^3)}{(s^2 + \beta_1^2\omega^2)^{5/2}} + O(1).
\end{aligned} \tag{4.43}$$

Using this expansion and change of variable $s = |\beta_1\omega|\lambda$, when $\mathbf{X}_1 \in \gamma_n^A$, the integral in $\mu_m^{\text{self}}(x, y)$ given by (4.19) can be written as

$$\begin{aligned}
&\frac{(1-\nu)\sigma_0^2}{2\pi G} \int_{-\frac{a}{2}}^{\frac{a}{2}} d\omega \int_{\gamma_n^A} \frac{(\mathbf{X} - \mathbf{X}_1 - d(\mathbf{X}_1, \omega)\mathbf{n}_n(\mathbf{X}_1)) \cdot \widetilde{\mathbf{n}_n}(\mathbf{X}_1)}{\|\mathbf{X} - \mathbf{X}_1 - d(\mathbf{X}_1, \omega)\mathbf{n}_n(\mathbf{X}_1)\|^3} dl \\
&= \frac{(1-\nu)\sigma_0^2}{2\pi G} \int_{-\frac{a}{2}}^{\frac{a}{2}} d\omega \int_{-a^{\frac{1}{4}}}^{a^{\frac{1}{4}}} \left[\frac{-\beta_1\omega + (\kappa\beta_1^2 - \beta_2)\omega^2 + \kappa s^2/2}{(s^2 + \beta_1^2\omega^2)^{3/2}} \right. \\
&\qquad \left. + \frac{\frac{3}{2}\beta_1\omega(-\beta_1\kappa\omega s^2 + 2\beta_1\beta_3\omega^2 s + 2\beta_1\beta_2\omega^3)}{(s^2 + \beta_1^2\omega^2)^{5/2}} \right] ds + O(a^{\frac{5}{4}}) \\
&= \frac{(1-\nu)\sigma_0^2 a}{2\pi G} \left[\kappa \left(\log 2a^{\frac{1}{4}} + 1 + \log \frac{2\sqrt{h_x^2 + h_y^2}}{a} \right) \right. \\
&\qquad \left. + \frac{h_x^2 h_{xx} + 2h_x h_y h_{xy} + h_y^2 h_{yy}}{(h_x^2 + h_y^2)^{3/2}} \right] + O(a^{\frac{5}{4}}).
\end{aligned} \tag{4.44}$$

Using (4.25), (4.31), (4.36), and (4.44), we have

$$\begin{aligned}
&\widehat{\mu}_m^{\text{self}}(x, y) - \mu_m^{\text{self}}(x, y) \\
&= \frac{(1-\nu)\sigma_0^2 a}{2\pi G} \left[\kappa \left(-1 + \log \frac{a}{2r_c\sqrt{h_x^2 + h_y^2}} \right) - \frac{h_x^2 h_{xx} + 2h_x h_y h_{xy} + h_y^2 h_{yy}}{(h_x^2 + h_y^2)^{3/2}} \right] + O(a^{\frac{5}{4}}).
\end{aligned} \tag{4.45}$$

4.5. The continuum model for a stepped surface. Using (2.7), (4.3), (4.13), and (4.45), we have the continuum model for the long-range elastic interaction on a stepped surface in heteroepitaxy:

(4.46)

$$\begin{aligned}
&\widehat{\mu}_m(x,y)\\
&= \mu_m(x,y) + \frac{(1-\nu)\sigma_0^2 a}{2\pi G}\left(\kappa\log\frac{a}{2\pi r_c\sqrt{h_x^2+h_y^2}} - \frac{h_x^2h_{xx}+2h_xh_yh_{xy}+h_y^2h_{yy}}{(h_x^2+h_y^2)^{3/2}}\right)\\
&\quad + O(a^{\frac{5}{4}})\\
&\approx -\frac{(1-\nu)\sigma_0^2}{2\pi G}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\frac{(x-\xi)h_x(\xi,\eta)+(y-\eta)h_y(\xi,\eta)}{[(x-\xi)^2+(y-\eta)^2]^{3/2}}d\xi d\eta\\
&\quad -\frac{(1-\nu)\sigma_0^2 a}{2\pi G}\left[\nabla\cdot\left(\frac{\nabla h}{|\nabla h|}\right)\log\frac{2\pi r_c|\nabla h|}{a} + \frac{\nabla h\, D^2h\,\nabla^T h}{|\nabla h|^3}\right],
\end{aligned}$$

where D^2h is the Hessian matrix of $h(x,y)$, and $\nabla h\, D^2 h\,\nabla^T h = h_x^2h_{xx}+2h_xh_yh_{xy}+h_y^2h_{yy}$. In this continuum expression, the integral term over the whole domain of the surface is the same as the expression of the misfit-induced elastic interaction above the roughening transition temperature, and the two additional terms incorporate the discrete feature of the stepped surface. It is easy to verify that this continuum model is reduced to the $1+1$ dimensional model for a surface with straight steps given by (2.14) [49, 51].

In particular, for an axisymmetric conical mound-like stepped surface $h(r)$ with $h'(r)<0$, where r is the radial coordinate, the result becomes

$$\begin{aligned}
\widehat{\mu_m}(r) &= \frac{(1-\nu)\sigma_0^2}{\pi G}\int_0^{\infty}\left(\frac{E(m)}{\hat{r}-r}+\frac{K(m)}{\hat{r}+r}\right)h'(\hat{r})\,d\hat{r}\\
&\quad + \frac{(1-\nu)\sigma_0^2 a}{2\pi G}\left(\frac{1}{r}\log\frac{2\pi r_c|h'(r)|}{a}+\frac{h''(r)}{h'(r)}\right)+O(a^2), \qquad (4.47)
\end{aligned}$$

where $K(m) = \int_0^{\frac{\pi}{2}}\frac{d\theta}{\sqrt{1-m\sin^2\theta}}$ and $E(m) = \int_0^{\frac{\pi}{2}}\sqrt{1-m\sin^2\theta}\,d\theta$ are the complete elliptic integrals of the first and second kind, respectively, with $m = \frac{4\hat{r}r}{(\hat{r}+r)^2}$.

The derived continuum expression of chemical potential given by (4.46) can be written as the variation of an elastic energy

$$\widehat{\mu}_m(x,y) = \frac{\delta E_{\text{misfit}}}{\delta h}, \qquad (4.48)$$

where

$$\begin{aligned}
E_{\text{misfit}} = &-\frac{(1-\nu)\sigma_0^2}{4\pi G}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}h(x,y)\\
&\cdot\left[\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\frac{(x-\xi)h_x(\xi,\eta)+(y-\eta)h_y(\xi,\eta)}{[(x-\xi)^2+(y-\eta)^2]^{3/2}}d\xi d\eta\right]dxdy\\
&+\frac{(1-\nu)\sigma_0^2 a}{2\pi G}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}|\nabla h|\log\frac{2\pi r_c|\nabla h|}{ea}dxdy. \qquad (4.49)
\end{aligned}$$

The first term in this expression is the traditional expression of the misfit elastic energy above the roughening transition temperature on surfaces with small amplitude modulation. The second term is new, which is the contribution to the step line energy from the force monopole interaction, and which gives the two local terms in the chemical potential in (4.46).

It is easy to verify that this misfit elastic energy is reduced to that in the $1+1$ dimensional continuum model for surfaces with straight steps given by (2.15) [49, 51]. Note that in the $1+1$ model, the term of $|h_x|$ with constant coefficient in the total energy, i.e., the step line energy with constant density, plays no role in the surface morphology evolution when the surface is monotonic; thus this kind of term does not appear in the $1+1$ model in (2.15).

The total misfit elastic energy of a surface consisting of a uniform step train has also been calculated using the discrete model [1], whose density is

$$e_{\text{misfit}} = -\frac{(1-\nu)\sigma_0^2 a^2}{2\pi G l}\log\frac{l}{\pi r_0}, \tag{4.50}$$

where l is the distance between two adjacent steps, and r_0 is a cut-off distance. In this case, using the relation $|h'(x)| = a/l$, our model (4.49) gives the misfit elastic energy density

$$e_{\text{misfit}} = -\frac{(1-\nu)\sigma_0^2 a^2}{2\pi G l}\log\frac{el}{2\pi r_c}, \tag{4.51}$$

which agrees with the result of the discrete model. (Note that the values of the cut-off distance are different in these two models.)

Finally, using (2.8), (2.9), (2.10), (2.12), and (4.46), we have the morphological evolution equation of a stepped surface:

$$\begin{aligned}\frac{\partial h}{\partial t} = \nabla\cdot\Bigg\{ D_0\nabla\Bigg[& -\nabla\cdot\left(g_1\frac{\nabla h}{|\nabla h|} + g_3|\nabla h|\nabla h\right) \\ & -\frac{(1-\nu)\sigma_0^2}{2\pi G}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\frac{(x-\xi)h_x(\xi,\eta)+(y-\eta)h_y(\xi,\eta)}{[(x-\xi)^2+(y-\eta)^2]^{3/2}}d\xi d\eta \\ & -\frac{(1-\nu)\sigma_0^2 a}{2\pi G}\nabla\cdot\left(\frac{\nabla h}{|\nabla h|}\right)\log\left(\frac{2\pi r_c|\nabla h|}{a}\right) - \frac{(1-\nu)\sigma_0^2 a}{2\pi G}\frac{\nabla h\, D^2 h\,\nabla^T h}{|\nabla h|^3}\Bigg]\Bigg\}.\end{aligned} \tag{4.52}$$

The first two terms in this equation containing parameters g_1 and g_3 are due to the step line energy without misfit and the force dipole interaction between steps, respectively. The last three terms come from the long-range force monopole interaction due to the misfit stress.

For the special case of an axisymmetric conical stepped surface $h(r)$ with $h'(r) < 0$, the equation can be written as

$$\begin{aligned}\frac{\partial h}{\partial t} = \nabla\cdot\Bigg\{ D_0\nabla\Bigg[& \frac{g_1}{r} + \frac{g_3 {h'}^2}{r} + 2g_3 h'h'' + \frac{(1-\nu)\sigma_0^2}{\pi G}\int_0^{\infty}\left(\frac{E(m)}{\hat{r}-r} + \frac{K(m)}{\hat{r}+r}\right)h'(\hat{r})\,d\hat{r} \\ & + \frac{(1-\nu)\sigma_0^2 a}{2\pi G\, r}\log\frac{2\pi r_c|h'|}{a} + \frac{(1-\nu)\sigma_0^2 a}{2\pi G}\,\frac{h''}{h'}\Bigg]\Bigg\}.\end{aligned} \tag{4.53}$$

5. Conclusion and discussion. In this paper, we have presented a continuum model for the long-range elastic interaction on a stepped heteroepitaxial surface in $2+1$ dimensions. The continuum model is derived rigorously by taking the continuum limit from the discrete model for the interaction between steps. Compared with the integral expression above the roughening transition temperature, our model has additional terms that incorporate the discrete features of the stepped surface.

Our continuum model has a singularity when $|\nabla h(x,y)|=0$, which happens at a place where there is no step such as the top of a mound or a valley. This is consistent with our assumption in the derivation that $|\nabla h(x,y)|>c_0$, where $c_0>0$ is a constant. In fact, any continuum model containing step line energy becomes singular when $|\nabla h(x,y)|=0$ [21, 31, 35, 16, 39, 36, 26, 27, 28, 25] and may not describe the physics accurately at such places [35]. A continuum model that addresses this problem was given in [28]. A numerical treatment for this singularity can be found in [45, 39, 36].

Our continuum model is reduced to the $1+1$ dimensional continuum model in [49, 51] for a surface with straight steps. The energy for a surface with straight steps obtained using our model, which comes entirely from the two new terms, agrees with the result using the discrete model [1], which indicates the importance of these terms. Our model can be used to study the morphological instabilities of stepped surfaces under elastic effects. Such results, including linear instability analysis and numerical simulations in the nonlinear regime, as well as comparisons of our results with those of the discrete model, will be reported in a forthcoming paper [55].

Future work may also include the incorporation of the anisotropic mobility [25], the stress-dependent step line energy [39], the step line energy due to the interaction between the force monopole and dipole effects [18], or multispecies epitaxy [12].

Appendix A. Distance in the normal direction of a contour line of the surface *h*. Suppose that $\mathbf{X}=(x,y)$ is a point on the contour line of the surface h: $\gamma=\{(\xi,\eta):h(\xi,\eta)=h_n\}$. Let $\mathbf{P}=(u,v)$ be a point such that $\mathbf{XP}$ is parallel to the normal direction of γ at $\mathbf{X}$ and $h(u,v)=z$; see Figure A.1. We want to find the signed distance between points $\mathbf{P}$ and $\mathbf{X}$, which is positive in the direction of $-\nabla h(x,y)$, when z is close to h_n.

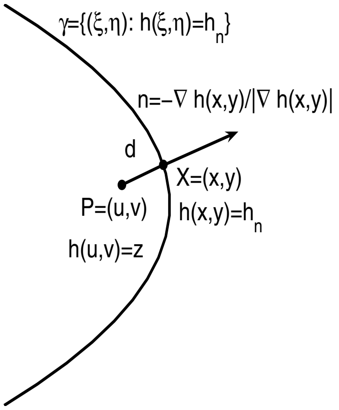

FIG. A.1. *Distance in the xy plane in the normal direction of a contour line of the surface h.*

Considering (u,v) as a function of z, we have

$$h(u(z),v(z))=z. \tag{A.1}$$

Since $\mathbf{XP}$ is parallel to the normal direction of γ at $\mathbf{X}$, we have

$$\frac{u(z)-x}{v(z)-y}=\frac{h_x^0}{h_y^0}. \tag{A.2}$$

Here and throughout Appendix A, for simplicity of notation, we use the notation h_x^0 for $h_x(x,y)$ and h_x for $h_x(u,v)$, and the same applies for other partial derivatives of h.

Differentiating these two equations with respect to z, we can solve for $u_z(z)$ and $v_z(z)$:

$$u_z(z)=\frac{h_x^0}{h_x^0h_x+h_y^0h_y}, \tag{A.3}$$

$$v_z(z)=\frac{h_y^0}{h_x^0h_x+h_y^0h_y}. \tag{A.4}$$

Differentiating these derivatives with respect to z, we have

$$u_{zz}(z)=-\frac{(h_x^0)^2[h_{xx}u_z(z)+h_{xy}v_z(z)]+h_x^0h_y^0[h_{xy}u_z(z)+h_{yy}v_z(z)]}{(h_x^0h_x+h_y^0h_y)^2}, \tag{A.5}$$

$$v_{zz}(z)=-\frac{h_x^0h_y^0[h_{xx}u_z(z)+h_{xy}v_z(z)]+(h_y^0)^2[h_{xy}u_z(z)+h_{yy}v_z(z)]}{(h_x^0h_x+h_y^0h_y)^2}. \tag{A.6}$$

Since $(u,v)\to(x,y)$ as $z\to h_n$, we have

$$u_z(h_n)=\frac{h_x^0}{(h_x^0)^2+(h_y^0)^2}, \tag{A.7}$$

$$v_z(h_n)=\frac{h_y^0}{(h_x^0)^2+(h_y^0)^2}, \tag{A.8}$$

and

$$u_{zz}(h_n)=-\frac{h_x^0[(h_x^0)^2h_{xx}^0+2h_x^0h_y^0h_{xy}^0+(h_y^0)^2h_{yy}^0]}{[(h_x^0)^2+(h_y^0)^2]^3}, \tag{A.9}$$

$$v_{zz}(h_n)=-\frac{h_y^0[(h_x^0)^2h_{xx}^0+2h_x^0h_y^0h_{xy}^0+(h_y^0)^2h_{yy}^0]}{[(h_x^0)^2+(h_y^0)^2]^3}. \tag{A.10}$$

The signed distance from the point $\mathbf{P}$ to the point $\mathbf{X}$, which is positive (or negative) if $\mathbf{XP}$ is in the positive (or negative) direction of $-\nabla h(x,y)$, is given by

$$d=-\frac{(u-x)h_x^0+(v-y)h_y^0}{\sqrt{(h_x^0)^2+(h_y^0)^2}}. \tag{A.11}$$

Using (A.7)–(A.10) and Taylor expansions of u at x and v at y up to second order of $z - h_n$, we have

$$d = -\frac{z-h_n}{[(h_x^0)^2+(h_y^0)^2]^{1/2}} + \frac{(h_x^0)^2 h_{xx}^0 + 2h_x^0 h_y^0 h_{xy}^0 + (h_y^0)^2 h_{yy}^0}{2[(h_x^0)^2+(h_y^0)^2]^{5/2}}(z-h_n)^2 + O((z-h_n)^3) \tag{A.12}$$

as $z \to h_n$.

Appendix B. Proof of Theorem 4.1. In this appendix, we give the proof of Theorem 4.1 on the error estimate of the trapezoidal rule for the integral of some singular function. We will use the following theorems, whose proofs can be found in Sidi and Israeli [40] or the references therein.

In the theorems below, interval $[a,b]$ is divided into m subintervals with $\Delta x = (b-a)/m$, $x_j = a + (j-1)\Delta x$, $j = 1, \ldots, m+1$. It is assumed that $g(x)$ is $2N$ times continuously differentiable on $[a,b]$ throughout Appendix B.

THEOREM B.1 (Euler–Maclaurin formula).

$$\begin{aligned}\int_a^b g(x)\,dx = \Delta x \left(\frac{g(a)+g(b)}{2} + \sum_{j=2}^{m} g(x_j) \right)\\ + \sum_{k=1}^{N-1} \frac{B_{2k}}{(2k)!}[g^{(2k-1)}(a) - g^{(2k-1)}(b)]\Delta x^{2k} + O(\Delta x^{2N}),\end{aligned} \tag{B.1}$$

where B_k's are the Bernoulli numbers.

THEOREM B.2 (Sidi and Israeli [40]). *Let $G(x) = g(x)/(x-t)$ with $t = x_{j_0}$ for some j_0. Then*

$$\begin{aligned}\int_a^b G(x)\,dx = \Delta x \left(\frac{G(a)+G(b)}{2} + \sum_{2\le j\le m, j\ne j_0} G(x_j) \right) + \Delta x g'(t)\\ + \sum_{k=1}^{N-1} \frac{B_{2k}}{(2k)!}[G^{(2k-1)}(a) - G^{(2k-1)}(b)]\Delta x^{2k} + O(\Delta x^{2N}),\end{aligned} \tag{B.2}$$

where B_k's are the Bernoulli numbers.

THEOREM B.3 (Sidi and Israeli [40]). *Let $G(x) = g(x)\log|x-t|$ with $t = x_{j_0}$ for some j_0. Then*

$$\begin{aligned}\int_a^b G(x)\,dx = \Delta x \left(\frac{G(a)+G(b)}{2} + \sum_{2\le j\le m, j\ne j_0} G(x_j) \right) + g(t)\log(\Delta x)\Delta x\\ + \sum_{k=1}^{N-1} \frac{B_{2k}}{(2k)!}[G^{(2k-1)}(a) - G^{(2k-1)}(b)]\Delta x^{2k}\\ +2\sum_{k=0}^{N-1} \frac{\zeta'(-2k)}{(2k)!} g^{(2k)}(t)\Delta x^{2k+1} + O(\Delta x^{2N}),\end{aligned} \tag{B.3}$$

where B_k's are the Bernoulli numbers and $\zeta(\tau)$ is the Riemann zeta function.

Proof of Theorem 4.1. Using the above theorems, we have

$$\int_a^b G(x)\,dx - \Delta x\left(\frac{G(a)+G(b)}{2} + \sum_{2\le j\le m, j\ne j_0} G(x_j)\right)$$

$$= g_1(t)\Delta x\log(\Delta x) - \log(2\pi)g_1(t)\Delta x + g_2'(t)\Delta x + g_3(t)\Delta x + O(\Delta x^2). \tag{B.4}$$

On the other hand,

$$\begin{aligned}
&\int_{t-\frac{\Delta x}{2}}^{t+\frac{\Delta x}{2}} G(x)\,dx\\
&= \int_{t-\frac{\Delta x}{2}}^{t+\frac{\Delta x}{2}} \left[g_1(x)\log|x-t| + \frac{g_2(x)}{x-t} + g_3(x)\right] dx\\
&= \int_{t-\frac{\Delta x}{2}}^{t+\frac{\Delta x}{2}} \Bigg[(g_1(t)+g_1'(t)(x-t)+O((x-t)^2))\log|x-t|\\
&\qquad + \frac{g_2(t)+g_2'(t)(x-t)+O((x-t)^2)}{x-t} + g_3(t) + O(x-t)\Bigg] dx\\
&= \int_{t-\frac{\Delta x}{2}}^{t+\frac{\Delta x}{2}} [g_1(t)\log|x-t| + g_2'(t) + g_3(t)]\,dx + O(\Delta x^2)
\end{aligned}$$

$$= g_1(t)\Delta x\log(\Delta x) - (1+\log 2)g_1(t)\Delta x + g_2'(t)\Delta x + g_3(t)\Delta x + O(\Delta x^2). \tag{B.5}$$

A combination of these two equations gives the theorem.

VOLTAGE AND CURRENT SPECTRA FOR MATRIX POWER CONVERTERS*

STEPHEN M. COX† AND STEPHEN C. CREAGH†

Abstract. Matrix power converters are used for transforming one alternating-current power supply to another, with different peak voltage and frequency. There are three input lines, with sinusoidally varying voltages which are 120° out of phase one from another, and the output is to be delivered as a similar three-phase supply. The matrix converter switches rapidly, to connect each output line in sequence to each of the input lines in an attempt to synthesize the prescribed output voltages. The switching is carried out at high frequency and it is of practical importance to know the frequency spectra of the output voltages and of the input and output currents. We determine in this paper these spectra using a new method, which has significant advantages over the prior default method (a multiple Fourier series technique), leading to a considerably more direct calculation. In particular, the determination of the input current spectrum is feasible here, whereas it would be a significantly more daunting procedure using the prior method instead.

Key words. matrix power converter, power electronics, Fourier spectrum

1. Introduction.

In electrical and electronic engineering, there are many applications in which it is necessary to convert a power supply from one voltage and frequency to another. Particular examples arise in aeronautical and marine applications, since there are increasingly many electrically powered devices aboard aircraft and ships, all with separate demands in terms of power supplies. The field of power conversion, while of great economic importance, thus poses particular technological challenges in aircraft in particular, where it is clearly highly desirable that power conversion be achieved without recourse to heavy bulk energy storage elements.

In modern solid-state power converters, the need for intermediate energy storage is avoided, because the output voltage is generated by rapidly switching between multiple input voltages (see, for example, [7]). The aim is that the low-frequency components of the output synthesize a prescribed waveform, while the high-frequency components related to the switching are ultimately filtered out.

In this paper, we describe a compact means of determining the voltage and current spectra for one such application of particular technological significance: the matrix power converter [12]. This is a device which aims to convert an alternating-current power supply at one voltage and frequency to a second at a different voltage and frequency. Applications of matrix converters include adjustable-speed drives, where the speed of the motor is governed by the frequency of its power supply. A significant benefit of the approach outlined in this paper is that we are able to give explicit and detailed descriptions of input currents, which are considerably more complex and difficult to determine than the output voltages and currents which have been predominantly studied in the past.

The matrix converter switching frequency greatly exceeds the input and output frequencies. The way in which its switching takes place is termed its modulation strategy here, and there are many such strategies adopted in practice, of which a comparatively simple variant is comprehensively analyzed in this paper. The matrix converter successively connects, via switches, each output line to each of the input lines, according to the modulation strategy. Thus the voltage on any given output line comprises short segments of the three input sinusoidal waveforms; it contains both low-frequency contributions (from the input voltages) and high-frequency contributions (from the switching). It is the spectrum of the output voltages and currents that we compute here, along with the more involved calculation for the corresponding currents drawn from the input lines.

In digital implementations, the input voltages are measured (sampled) at high frequency, at the start of each switching period. Then after each sample a calculation must be done to determine the corresponding switching times to achieve the desired output. This leads to so-called *regular* or *uniform* sampling of the input to determine the modulation strategy. The delay between sampling and switching results in undesirable distortion in the form of unintended low-frequency components in the output [5]; it also affects the high-frequency part of the spectrum, but this is not so serious provided that the low-pass filtering still effectively removes such components.

Although less relevant to the power converter application, an alternative sampling technique is also analyzed here: so-called *natural* sampling, which is widely used in, for example, audio applications [3, 6, 8]. In natural sampling, an analogue device compares one of the input voltages with some reference waveform and switches whenever the two become (instantaneously) equal. The lack of delays in natural sampling leads to a more accurate spectrum for the audio component of the output [7]; a comparison between the spectra for regular and natural sampling allows us to determine what aspects of the former spectrum are due to associated digital implementation effects.

In the engineering literature, spectra for switching devices are generally computed by a multiple Fourier series method usually ascribed to Black [3], but acknowledged to go at least as far back as Bennett [2] (see, for example, [4]). The method involves introducing separate independent variables representing time scaled by each of the input, output, and switching frequencies, then writing the required quantities as multiple Fourier series, in terms of each of these variables separately. The corresponding Fourier coefficients are then computed. Finally, the answer is specialized to the physical case, in which the separate time variables are recognized to be constant multiples of one another. The method is simplest for natural sampling, but can be modified for regular sampling, although it is more algebraically involved in that case.

The major content of this paper is the development of more direct methods than Black's for determining the output voltage, output current, and input current spectra. The methods contained herein can be used for regular and natural sampling, although the order in which various steps are applied is different in the two cases if the greatest efficiency is to be achieved. However, in contrast to Black's method, neither calculation is intrinsically more algebraically cumbersome than the other. Furthermore, our analysis, although presented here for the matrix converter problem, is in fact readily adaptable to any other switching problem for which Black's method is the usual default, for example the modeling of class-D audio amplifiers [6].

In section 2 we outline some notation and describe model calculations (given for both regular and natural sampling), which form the building blocks for many of the subsequent calculations. The output voltages are then computed, using these building-block solutions, for both types of sampling. In section 3 we introduce further notation and calculate the output and input currents, for general output impedances, illustrating our results in section 4. In section 5 we show how to derive more rapidly convergent solutions when the form of the output impedances is known (it is often the case that the output loads may be approximated by a resistor and an inductor in series, for example), considerably reducing the computation time. Our conclusions are given in section 6. In the appendix, we illustrate how the results in this paper may be extended to a more complicated modulation strategy.

2. Calculation of output voltages. We begin by calculating the spectra of output voltages in a matrix converter. Some of the main ideas of this simpler calculation recur in the more involved calculation for input currents and it is useful to set out the main features and establish notation in the simpler context.

2.1. Notation for voltages. In an idealized matrix converter [12] (see Figure 2.1), there are three input voltages, which we label

$$v^A(t) = \mathrm{e}^{\mathrm{i}\omega_0 t}, \qquad v^B(t) = \mathrm{e}^{\mathrm{i}(\omega_0 t + 2\pi/3)}, \qquad v^C(t) = \mathrm{e}^{\mathrm{i}(\omega_0 t + 4\pi/3)}, \tag{2.1}$$

where ω_0 is the input frequency and voltages are scaled to give unit peak input voltages. Of course, the physical voltages are the real parts of the expressions given in (2.1). It will be convenient to write these collectively as a vector

$$\mathbf{v}^{\mathrm{in}}(t) = \begin{pmatrix} v^A(t) \\ v^B(t) \\ v^C(t) \end{pmatrix} = \mathrm{e}^{\mathrm{i}\omega_0 t} \begin{pmatrix} 1 \\ p \\ p^2 \end{pmatrix}, \qquad \text{where} \quad p = \mathrm{e}^{2\pi\mathrm{i}/3}.$$

Three output voltages, denoted $v^a(t)$, $v^b(t)$, and $v^c(t)$ and written in the vector form,

$$\mathbf{v}^{\mathrm{out}}(t) = \begin{pmatrix} v^a(t) \\ v^b(t) \\ v^c(t) \end{pmatrix},$$

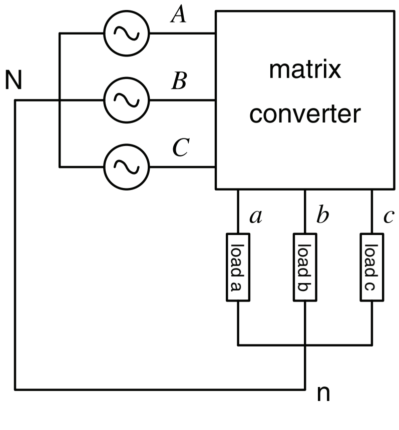

FIG. 2.1. *Diagram of a matrix converter. Three input lines (A, B, and C) each supply sinusoidal voltages, each* 120° *out of phase with any other. There are loads on each of the output lines (a, b, and c). The neutral point of the input lines is denoted by* N *and that of the output lines by* n*; these neutral points are assumed to be connected to one another, and to be at a nominal zero volts.*

are obtained by sampling the input voltages during intervals which repeat quasiperiodically, according to the modulation strategy. We scale time so that the switching period is unity (hence the switching frequency is 2π), and consider a simple form of switching pattern such that each output, labeled $o = a, b, c$, is of the form [9]

$$v^o(t) = \begin{cases} v^A(t) & \text{for } n < t < n + \alpha_n^o, \\ v^B(t) & \text{for } n + \alpha_n^o < t < n + \beta_n^o, \\ v^C(t) & \text{for } n + \beta_n^o < t < n + 1 \end{cases} \tag{2.2}$$

(more sophisticated switching strategies can also be analyzed using the methods described in this paper; these are discussed briefly in the appendix). An important assumption in our analysis will be that the switching frequency is much larger than the input frequency: $2\pi \gg \omega_0$. This is certainly the case in practical implementations, to allow the high-frequency switching components to be filtered without affecting the desired low-frequency components.

We encode the relationships in (2.2) using a switching matrix

$$M(t) = \begin{pmatrix} F^{aA}(t) & F^{aB}(t) & F^{aC}(t) \\ F^{bA}(t) & F^{bB}(t) & F^{bC}(t) \\ F^{cA}(t) & F^{cB}(t) & F^{cC}(t) \end{pmatrix},$$

whose elements are either 0 or 1 at any given instant, according to which input and output lines are connected. Then

$$\mathbf{v}^{\text{out}}(t) = M(t)\mathbf{v}^{\text{in}}(t). \tag{2.3}$$

For example,

$$F^{aA}(t) = \sum_{n=-\infty}^{\infty} \psi_{n,n+\alpha_n^a}(t), \tag{2.4}$$

where the step function ψ_{t_1,t_2} is defined by

$$\psi_{t_1,t_2}(t) = \begin{cases} 1 & \text{if } t_1 < t < t_2, \\ 0 & \text{otherwise,} \end{cases}$$

and similar expressions can be written for the other elements of $M(t)$, using (2.2).

2.2. A model calculation for the case of uniform sampling. Before describing the full calculation of the three-phase output voltages it is useful to outline a model calculation which illustrates the essence of our approach in a somewhat simpler setting. We consider a function,

$$F(t) = \sum_{n=-\infty}^{\infty} \psi_{n+\alpha_n,n+\beta_n}(t), \tag{2.5}$$

which samples a unit input voltage over the quasiperiodically repeating intervals

$$n + \alpha_n < t < n + \beta_n.$$

In the case of *uniform sampling*, we assume that the switching times are determined by sampling the continuous functions

$$\alpha(\tau) = \mu_\alpha + \lambda_\alpha \cos(\Omega\tau + \delta_0) \quad \text{and} \quad \beta(\tau) = \mu_\beta + \lambda_\beta \cos(\Omega\tau + \delta_0 + \delta_1) \tag{2.6}$$

at the evenly spaced times $\tau = n$ [1, 9, 10]. In other words,

$$\alpha_n = \alpha(n) \qquad \text{and} \qquad \beta_n = \beta(n). \tag{2.7}$$

Note that the matrix product in (2.3) consists of sums of functions of the form (2.5), modulated by the harmonic function $\mathrm{e}^{\mathrm{i}\omega_0 t}$.

Adopting the convention that the Fourier transform is written as

$$\hat{F}(\omega) = \int_{-\infty}^{\infty} \mathrm{e}^{-\mathrm{i}\omega t} F(t)\,\mathrm{d}t,$$

and noting that the Fourier transform of the step function $\psi_{t_1,t_2}(t)$ is

$$\hat{\psi}_{t_1,t_2}(\omega) = \frac{\mathrm{e}^{-\mathrm{i}\omega t_2} - \mathrm{e}^{-\mathrm{i}\omega t_1}}{-\mathrm{i}\omega},$$

we find

$$\hat{F}(\omega) = \sum_{n=-\infty}^{\infty} \mathrm{e}^{-in\omega} \hat{\psi}_{\alpha_n,\beta_n}(\omega) = \sum_{n=-\infty}^{\infty} \mathrm{e}^{-in\omega} \frac{\mathrm{e}^{-\mathrm{i}\omega\beta_n} - \mathrm{e}^{-\mathrm{i}\omega\alpha_n}}{-\mathrm{i}\omega}.$$

We now make use of the identity [11]

$$\mathrm{e}^{-\mathrm{i}z\cos\theta} = \sum_{m=-\infty}^{\infty} \mathrm{J}_m(z)(-\mathrm{i})^m \mathrm{e}^{\mathrm{i}m\theta}, \tag{2.8}$$

so that

$$\frac{\mathrm{e}^{-\mathrm{i}\omega\beta_n} - \mathrm{e}^{-\mathrm{i}\omega\alpha_n}}{-\mathrm{i}\omega} = \sum_{m=-\infty}^{\infty} X_m(\omega) \mathrm{e}^{\mathrm{i}nm\Omega + \mathrm{i}m\delta_0},$$

where, using (2.6), we find

$$X_m(\omega) = \frac{(-\mathrm{i})^m}{-\mathrm{i}\omega} \left(\mathrm{e}^{-\mathrm{i}\omega\mu_\beta + \mathrm{i}m\delta_1} \mathrm{J}_m(\omega\lambda_\beta) - \mathrm{e}^{-\mathrm{i}\omega\mu_\alpha} \mathrm{J}_m(\omega\lambda_\alpha) \right). \tag{2.9}$$

It is useful to record the following limiting values:

$$X_m(0) = \begin{cases} \mu_\beta - \mu_\alpha & \text{when } m = 0, \\ \frac{1}{2}\left(\mathrm{e}^{m\mathrm{i}\delta_1}\lambda_\beta - \lambda_\alpha\right) & \text{when } m = \pm 1, \\ 0 & \text{otherwise.} \end{cases} \tag{2.10}$$

Then, using the Poisson summation formula in the form

$$\sum_{n=-\infty}^{\infty} \mathrm{e}^{\mathrm{i}n(\omega - m\Omega)} = 2\pi \sum_{n=-\infty}^{\infty} \delta(\omega - m\Omega - 2\pi n),$$

we find that

$$\begin{aligned} \hat{F}(\omega) &= \sum_{n=-\infty}^{\infty} \sum_{m=-\infty}^{\infty} X_m(\omega)\, \mathrm{e}^{-\mathrm{i}n(\omega - m\Omega) + \mathrm{i}m\delta_0} \\ &= 2\pi \sum_{n=-\infty}^{\infty} \sum_{m=-\infty}^{\infty} X_m(\omega_{nm}) \mathrm{e}^{m\mathrm{i}\delta_0} \delta(\omega - \omega_{nm}), \end{aligned} \tag{2.11}$$

where we denote

$$\omega_{nm} = 2\pi n + m\Omega. \tag{2.12}$$

The result (2.11) can alternatively be written in the time domain as

$$F(t) = \sum_{n=-\infty}^{\infty} \sum_{m=-\infty}^{\infty} X_m(\omega_{nm}) \mathrm{e}^{\mathrm{i}\omega_{nm}t + \mathrm{i}m\delta_0}. \tag{2.13}$$

We therefore find that the spectrum of the function $F(t)$ is confined to integer combinations of the switching frequency 2π and the modulation frequency Ω (cf. [3]). Furthermore, the frequencies of particular practical interest are those with $n = 0$ (those with $n \neq 0$ will be filtered out), and it is easily verified that in the limit $\Omega \ll 2\pi$ the dominant frequencies with $n = 0$ are $\omega_{00} = 0$ and $\omega_{0\pm1} = \pm\Omega$. It will later prove useful to denote by $F_0(t)$ the terms in (2.13) for $n = 0$; summing over m the contributions to $F(t)$ with $n = 0$ is then easily seen to give

$$F_0(t) \equiv \sum_{m=-\infty}^{\infty} X_m(\omega_{0m}) \mathrm{e}^{\mathrm{i}\omega_{0m}t + \mathrm{i}m\delta_0} = \beta(t) - \alpha(t) + O(\Omega). \tag{2.14}$$

By comparing (2.14) with (2.6), we see that the $n = 0$ contribution $F_0(t)$ is thus, with errors of order Ω, a sinusoidal signal with frequency Ω, plus a constant signal.

2.3. Output voltages in the case of uniform sampling. The model calculation in section 2.2 can now be used as the basis for a more complete description of the output voltages. We begin by describing more explicitly the switching conventions in (2.2). These are designed to generate output voltages

$$\mathbf{v}_{\mathrm{ref}}^{\mathrm{out}}(t) = \begin{pmatrix} v_{\mathrm{ref}}^a(t) \\ v_{\mathrm{ref}}^b(t) \\ v_{\mathrm{ref}}^c(t) \end{pmatrix} = q\mathrm{e}^{\mathrm{i}\omega_1 t} \begin{pmatrix} 1 \\ p \\ p^2 \end{pmatrix}, \tag{2.15}$$

where ω_1 is the output frequency and q is the output amplitude. The subscript "ref" indicates that the corresponding quantity is the intended, reference state; the actual output voltage will generally approximate this reference value in its low-frequency spectrum, but also contain slight low-frequency distortion terms and significant high-frequency components. The matching of the low-frequency terms in $\mathbf{v}^{\mathrm{out}}(t)$ and $\mathbf{v}_{\mathrm{ref}}^{\mathrm{out}}(t)$ is achieved by letting α_n^o and β_n^o in (2.2) oscillate with an appropriate frequency that is much smaller than the switching frequency.

We focus on the simplest Venturini switching [1, 9, 10], in which, for each output $o = a$, b, or c, the times α_n^o and β_n^o are obtained by sampling smooth functions as in (2.6) and (2.7), with

$$\alpha^o(\tau) = \tfrac{1}{3} + \tfrac{2}{3}q\cos(\Omega\tau + \delta^o), \qquad \beta^o(\tau) = \tfrac{2}{3} + \tfrac{2}{3}q\cos(\Omega\tau + \delta^o - \tfrac{\pi}{3}). \tag{2.16}$$

Here,

$$\Omega \equiv \omega_1 - \omega_0$$

is the difference between output and input frequencies and

$$\delta^a = 0, \quad \delta^b = \tfrac{2}{3}\pi, \quad \text{and} \quad \delta^c = \tfrac{4}{3}\pi.$$

The coefficients in (2.16) were originally derived by attempting to generate the correct low-frequency components in the output voltages, in the limit $\Omega \to 0$.

We now adapt the model calculation in section 2.2 to describe the output voltages. Note that (2.3) indicates that any given output voltage can be written as

$$\begin{aligned} v^o(t) &= \mathrm{e}^{\mathrm{i}\omega_0 t} \sum_{n=-\infty}^{\infty} \psi_{n,n+\alpha_n^o}(t) + p\psi_{n+\alpha_n^o,n+\beta_n^o}(t) + p^2\psi_{n+\beta_n^o,n+1}(t) \\ &= \left(F^{oA}(t) + pF^{oB}(t) + p^2F^{oC}(t)\right)\mathrm{e}^{\mathrm{i}\omega_0 t}, \qquad o = a, b, c, \end{aligned}$$

where

$$\begin{aligned} F^{oA}(t) &= \sum_{n=-\infty}^{\infty} \psi_{n,n+\alpha_n^o}(t), \\ F^{oB}(t) &= \sum_{n=-\infty}^{\infty} \psi_{n+\alpha_n^o,n+\beta_n^o}(t), \qquad (2.17) \\ F^{oC}(t) &= \sum_{n=-\infty}^{\infty} \psi_{n+\beta_n^o,n+1}(t) \end{aligned}$$

are all particular cases of the function $F(t)$ described in section 2.2. Repeating the calculations there, we find that $F^{oA}(t)$, $F^{oB}(t)$, and $F^{oC}(t)$ have Fourier transforms

$$(2.18) \qquad \hat{F}^{oi}(\omega) = 2\pi \sum_{n=-\infty}^{\infty} \sum_{m=-\infty}^{\infty} X_m^i(\omega_{nm})\mathrm{e}^{m\mathrm{i}\delta^o}\delta(\omega - \omega_{nm}), \qquad i = A, B, C,$$

where

$$\begin{aligned} X_m^A(\omega) &= \frac{(-\mathrm{i})^m}{-\mathrm{i}\omega}\left[\mathrm{e}^{-\mathrm{i}\omega/3}\mathrm{J}_m\left(\tfrac{2}{3}q\omega\right) - \delta_{m0}\right], \\ X_m^B(\omega) &= \frac{(-\mathrm{i})^m}{-\mathrm{i}\omega}\left[\mathrm{e}^{-2\mathrm{i}\omega/3-\mathrm{i}m\pi/3} - \mathrm{e}^{-\mathrm{i}\omega/3}\right]\mathrm{J}_m\left(\tfrac{2}{3}q\omega\right), \qquad (2.19) \\ X_m^C(\omega) &= \frac{(-\mathrm{i})^m}{-\mathrm{i}\omega}\left[\mathrm{e}^{-\mathrm{i}\omega}\delta_{m0} - \mathrm{e}^{-2\mathrm{i}\omega/3-\mathrm{i}m\pi/3}\mathrm{J}_m\left(\tfrac{2}{3}q\omega\right)\right]; \end{aligned}$$

here δ_{0m} is the Kronecker δ. Note that the quantities $X_m^i(\omega)$ do not depend on the output line.

The transformed output voltages are given by

$$\hat{v}^o(\omega) = \hat{F}^{oA}(\omega - \omega_0) + p\hat{F}^{oB}(\omega - \omega_0) + p^2\hat{F}^{oC}(\omega - \omega_0),$$

which can then be written as

$$\hat{v}^o(\omega) = 2\pi \sum_{n=-\infty}^{\infty} \sum_{m=-\infty}^{\infty} \mathrm{e}^{\mathrm{i}m\delta^o} V_{nm}\delta(\omega - \Omega_{nm}),$$

where we denote

$$V_{nm} = X_m^A(\omega_{nm}) + pX_m^B(\omega_{nm}) + p^2X_m^C(\omega_{nm})$$

and

$$\Omega_{nm} = \omega_0 + \omega_{nm} = \omega_0 + 2\pi n + m\Omega.$$

The corresponding expression in the time domain gives us the key result of this section, that the output voltages may be written as

$$v^o(t) = \sum_{n=-\infty}^{\infty} \sum_{m=-\infty}^{\infty} V_{nm} \mathrm{e}^{\mathrm{i}\Omega_{nm} t + \mathrm{i} m \delta^o}. \tag{2.20}$$

Note that the amplitudes V_{nm} are common to all three output lines; the differences between the three output voltages result from the different values of δ^o for $o = a, b, c$ in (2.20).

The most physically interesting part of the result is

$$v_0^o(t) \equiv \sum_{m=-\infty}^{\infty} V_{0m} \mathrm{e}^{i\Omega_{0m} t + \mathrm{i} m \delta^o} = \sum_{m=-1}^{1} V_{0m} \mathrm{e}^{i\Omega_{0m} t + \mathrm{i} m \delta^o} + O(\Omega). \tag{2.21}$$

In analogy with (2.10), we find the limiting cases

$$X_0^i(0) = \tfrac{1}{3}, \qquad i = A, B, C$$

and

$$X_{\pm 1}^A(0) = \tfrac{1}{3} q, \qquad X_{\pm 1}^B(0) = \tfrac{1}{3} q (\mathrm{e}^{\mp \mathrm{i}\pi/3} - 1), \qquad X_{\pm 1}^C(0) = -\tfrac{1}{3} q \mathrm{e}^{\mp \mathrm{i}\pi/3}, \tag{2.22}$$

and these can be used to show that the rightmost sum in (2.21) approximately returns the voltages required in (2.15), so that

$$v_0^o(t) = v_{\mathrm{ref}}^o(t) + O(\Omega). \tag{2.23}$$

The $O(\Omega)$ error results from the discrete sampling of the input voltages used to compute the modulation strategy with regular sampling. It can be eliminated by changing the modulation strategy to natural sampling, which is now described.

2.4. A model calculation for the case of natural sampling. We now turn to the case of natural sampling. Here, in contrast to regular sampling, the input voltages are monitored continuously, and switching takes place at the instants when these voltages become equal to some other reference voltage. Because of the need to continuously monitor the input voltages, such sampling is generally implemented using analogue electronics. The key additional algebraic complication associated with natural sampling is that the switching times satisfy *implicit* equations. To analyze *natural sampling*, then, we consider once again the model sum in (2.5) except that the switching times are chosen to satisfy conditions

$$\alpha_n = A(n + \alpha_n) \qquad \text{and} \qquad \beta_n = B(n + \beta_n), \tag{2.24}$$

where $A(t) = \mu_\alpha + \lambda_\alpha \cos(\Omega t + \delta_0)$ and $B(t) = \mu_\beta + \lambda_\beta \cos(\Omega t + \delta_0 + \delta_1)$.

We note that, according to (2.24), we may consider α_n and β_n to be *irregular* samples of the continuous functions $A(t)$ and $B(t)$. However, to make analytical headway with our approach, it is preferable instead to regard α_n and β_n as being obtained by *regularly* sampling continuous functions $\alpha(\tau)$ and $\beta(\tau)$ as in (2.7). Now, however, it is the functions $A(t)$ and $B(t)$ that are prescribed explicitly while the functions $\alpha(\tau)$ and $\beta(\tau)$ are determined implicitly by

$$\alpha(\tau) = A(\tau + \alpha(\tau)) \qquad \text{and} \qquad \beta(\tau) = B(\tau + \beta(\tau)),$$

which are continuous versions of (2.24).

In the case of natural sampling, the output spectrum is best calculated by performing Poisson resummation *before* taking the Fourier transform of the function $F(t)$. Using the version

$$\sum_{n=-\infty}^{\infty} f(n) = \sum_{n=-\infty}^{\infty} \int_{-\infty}^{\infty} \mathrm{e}^{2\pi n \mathrm{i}\tau} f(\tau)\,\mathrm{d}\tau \tag{2.25}$$

of Poisson resummation on expression (2.5) for $F(t)$, we find that

$$F(t) = \sum_{n=-\infty}^{\infty} \int_{-\infty}^{\infty} \mathrm{e}^{2\pi n \mathrm{i}\tau} \psi_{\tau+\alpha(\tau),\tau+\beta(\tau)}(t)\,\mathrm{d}\tau = \sum_{n=-\infty}^{\infty} \int_{\tau_B(t)}^{\tau_A(t)} \mathrm{e}^{2\pi n \mathrm{i}\tau}\,\mathrm{d}\tau, \tag{2.26}$$

where $\tau_B(t)$ and $\tau_A(t)$ are, respectively, the values of τ at which the step function $\psi_{\tau+\alpha(\tau),\tau+\beta(\tau)}(t)$ switches on and then off again for fixed t. These switching times satisfy the conditions $t = \tau_A + \alpha(\tau_A)$ and $t = \tau_B + \beta(\tau_B)$, which can be rearranged to give

$$\tau_A(t) = t - \alpha(\tau_A) = t - A(t) \qquad \text{and} \qquad \tau_B(t) = t - \beta(\tau_B) = t - B(t).$$

We therefore have

$$F(t) = \sum_{n=-\infty}^{\infty} \int_{t-B(t)}^{t-A(t)} \mathrm{e}^{2\pi n \mathrm{i}\tau}\,\mathrm{d}\tau = \sum_{n=-\infty}^{\infty} \mathrm{e}^{2\pi n \mathrm{i}t} F_n(t), \tag{2.27}$$

where

$$F_n(t) = \int_{-B(t)}^{-A(t)} \mathrm{e}^{2\pi n \mathrm{i}\tau}\,\mathrm{d}\tau = \begin{cases} B(t) - A(t) & \text{if } n = 0, \\ \dfrac{\mathrm{e}^{-2\pi n \mathrm{i} B(t)} - \mathrm{e}^{-2\pi n \mathrm{i} A(t)}}{-2\pi n \mathrm{i}} & \text{otherwise.} \end{cases} \tag{2.28}$$

Equation (2.8) now gives

$$F(t) = \sum_{n=-\infty}^{\infty} \sum_{m=-\infty}^{\infty} X_m(2\pi n)\,\mathrm{e}^{\mathrm{i}\omega_{nm}t + \mathrm{i}m\delta^o},$$

where $X_m(\omega)$ has been defined in (2.9) and, in the special case $n = 0$, we may use (2.10); ω_{nm} has been defined in (2.12). The Fourier transform is

$$\hat{F}(\omega) = 2\pi \sum_{n=-\infty}^{\infty} \sum_{m=-\infty}^{\infty} X_m(2\pi n)\,\mathrm{e}^{m\mathrm{i}\delta^o} \delta(\omega - \omega_{nm}). \tag{2.29}$$

These results are similar to those given in section 2.2 for the case of uniform sampling, except that the amplitude functions X_m are evaluated at different values of the argument ($2\pi n$ here, rather than ω_{nm} for uniform sampling). This difference has a dramatic effect on the terms with $n = 0$, however, which collectively contribute

$$F_0(t) = \sum_{m=-\infty}^{\infty} X_m(0)\,\mathrm{e}^{\mathrm{i}\omega_{0m}t + \mathrm{i}m\delta^o} = B(t) - A(t)$$

to the sum (see also (2.28)). This is the natural-sampling analogue of (2.14) and it is *exact*, which means that the *only* low frequencies present in $F(t)$ are those present in the prescribed functions $A(t)$ and $B(t)$ (cf. [3, 6, 8]).

2.5. Output voltages in the case of natural sampling. We now adapt the model calculation in section 2.4 to the case of three-phase output voltages produced by naturally sampling input voltages as in (2.2). The difference from the calculation in section 2.3 is that here the switching times are determined implicitly by equations of the form

$$\alpha_n^o = A^o(n+\alpha_n^o) \qquad \text{and} \qquad \beta_n^o = B^o(n+\beta_n^o),$$

where

$$A^o(\tau) = \tfrac{1}{3} + \tfrac{2}{3}q\cos(\Omega\tau+\delta^o), \qquad B^o(\tau) = \tfrac{2}{3} + \tfrac{2}{3}q\cos(\Omega\tau+\delta^o-\tfrac{\pi}{3}), \tag{2.30}$$

rather than being given directly as in (2.16).

There is nothing fundamentally new in the calculation here that has not already been covered in sections 2.3 and 2.4 so we simply present the main results. The output voltages can be given in the form

$$v^o(t) = \sum_{n=-\infty}^{\infty}\sum_{m=-\infty}^{\infty} \tilde{V}_{nm}\mathrm{e}^{i\Omega_{nm}t+\mathrm{i}m\delta^o}, \tag{2.31}$$

which is similar to (2.20), except that in the expression

$$\tilde{V}_{nm} = X_m^A(2\pi n) + pX_m^B(2\pi n) + p^2X_m^C(2\pi n),$$

the arguments of the functions X_m^i (which are once again given by (2.19)) are $2\pi n$ instead of ω_{nm}. The part of $v^o(t)$ of most physical interest is the contribution from terms with $n=0$; this contribution can be written, using (2.10),

$$v_0^o(t) = \sum_{m=-1}^{1}\left(X_m^A(0) + pX_m^B(0) + p^2X_m^C(0)\right)\mathrm{e}^{i\Omega_{0m}t+\mathrm{i}m\delta^o} = q\mathrm{e}^{\mathrm{i}\omega_1 t+\mathrm{i}\delta^o}. \tag{2.32}$$

Remarkably, this result coincides exactly with the desired form in (2.15). We emphasize that the result $v_0^o(t) = v_{\mathrm{ref}}^o(t)$ is *exact* for natural sampling (cf. the corresponding result (2.23) for uniform sampling, where there are errors of order Ω). In other contexts, this exact capture of some reference output is well known [3, 6, 7, 8].

3. Input and output currents. We now turn our attention to the currents in the system. The *output* currents are readily determined from the output voltages, provided that the output impedances are known (for simplicity, we suppose that the output neutral is connected to the supply neutral—see Figure 2.1). In order to construct the *input* currents, however, we must examine how the modulation strategy assigns the output currents to each input line; we are thus led to consider *two* separate discrete sampling processes, and the Fourier transform is as a result more complex to analyze. We note that in practice the input currents are monitored to provide a diagnostic of the system, and thus a knowledge of their spectrum is of particular practical utility.

The general discussion below applies equally to either regular or natural sampling. In section 3.4 below, we specialize the analysis to the two cases separately.

3.1. Notation for currents. We begin by setting out notation, building on the discussion in section 2.1. We adopt similar conventions for the input and output currents, writing

$$\mathbf{i}^{\text{in}}(t) = (i^A, i^B, i^C)^T \quad \text{and} \quad \mathbf{i}^{\text{out}}(t) = (i^a, i^b, i^c)^T,$$

where the superscript T denotes the transpose, and we note that current conservation means that these are connected by the transpose of the switching matrix [12], according to

$$\mathbf{i}^{\text{in}}(t) = M(t)^T \mathbf{i}^{\text{out}}(t). \tag{3.1}$$

A central goal in this paper is to compute the spectrum of the input currents in terms of the input voltages, and there are two elements to this calculation: summing over the windows of time in which the input voltage is sampled as a simple harmonic, and calculating the contributions from individual windows within that sum.

The summation is a double sum arising from the combined matrix products in (2.3) and (3.1) and is described explicitly below. We first describe in general terms the contribution of an individual element in this sum.

3.2. Loading the output: Currents associated with individual input pulses. Let

$$v_{t_3,t_4}(t) = \psi_{t_3,t_4}(t)\mathrm{e}^{i\omega_0 t} \tag{3.2}$$

represent an output voltage obtained by sampling a harmonic input voltage $\mathrm{e}^{i\omega_0 t}$ over the window $t_3 < t < t_4$. Let the output be connected to a load described by the impedance $Z(\omega)$, so that in the frequency domain the output current is

$$\hat{\imath}_{t_3,t_4}(\omega) = \frac{1}{Z(\omega)}\hat{v}_{t_3,t_4}(\omega) = \frac{1}{Z(\omega)}\hat{\psi}_{t_3,t_4}(\omega - \omega_0).$$

We describe the corresponding relation in the time domain using an admittance operator Y, such that $i_{t_3,t_4}(t) = Yv_{t_3,t_4}(t)$. This will describe an output current that switches on at $t = t_3$, is driven harmonically in the window $t_3 < t < t_4$, and decays as a transient thereafter, when $t_4 < t < \infty$. If a given input line connects to the output in question during the window $t_1 < t < t_2$, then we denote the corresponding contribution to that input current by

$$i_{t_1,t_2,t_3,t_4}(t) = \psi_{t_1,t_2}(t) i_{t_3,t_4}(t) = \psi_{t_1,t_2}(t) Y v_{t_3,t_4}(t). \tag{3.3}$$

The corresponding relation in the frequency domain is

$$\hat{\imath}_{t_1,t_2,t_3,t_4}(\omega) = \frac{1}{2\pi}\hat{\psi}_{t_1,t_2}(\omega) * \hat{\imath}_{t_3,t_4}(\omega) = \frac{1}{2\pi}\hat{\psi}_{t_1,t_2}(\omega) * \left[\frac{1}{Z(\omega)}\hat{v}_{t_3,t_4}(\omega)\right], \tag{3.4}$$

where $*$ denotes convolution.

3.3. Loading the output: Total currents. Net input currents are obtained by summing individual contributions of the form (3.4), as governed by the matrix products in (2.3) and (3.1). We now outline details and notation for this process. Let the output voltages and currents be related by

$$\mathbf{i}^{\text{out}}(t) = \mathcal{Y}\mathbf{v}^{\text{out}}(t), \tag{3.5}$$

where $\mathcal{Y}$ is the diagonal matrix of admittance operators

$$\mathcal{Y} = \begin{pmatrix} Y^a & 0 & 0 \\ 0 & Y^b & 0 \\ 0 & 0 & Y^c \end{pmatrix} \equiv \operatorname{diag}(Y^a, Y^b, Y^c),$$

and where the diagonal elements are specific to each output. In Fourier representation, the admittance operator is represented by the simple diagonal matrix

$$\mathcal{Y}(\omega) = \mathrm{diag}(Z^a(\omega)^{-1}, Z^b(\omega)^{-1}, Z^c(\omega)^{-1})$$

of output-specific admittances. Combining (3.5) with (2.3) and (3.1), we may write

$$\mathbf{i}^{\mathrm{in}}(t) = M(t)^T \mathcal{Y} M(t) \mathbf{v}^{\mathrm{in}}(t).$$

Let us denote by

$$Q(t) = M(t)^T \mathcal{Y} M(t) \mathrm{e}^{i\omega_0 t}$$

the combined operator relating the input currents to the (known) input voltages, so that

$$\mathbf{i}^{\mathrm{in}}(t) = Q(t) \begin{pmatrix} 1 \\ p \\ p^2 \end{pmatrix}. \tag{3.6}$$

A typical element of $Q(t)$ can be written as a simple sum over outputs. Specifically,

$$Q^{ij}(t) = \sum_{o=a,b,c} F^{oi}(t) Y^o F^{oj}(t) \mathrm{e}^{i\omega_0 t}, \tag{3.7}$$

where the row index $i = A, B, C$ and the column index $j = A, B, C$ are labels of inputs. Each switching element $F^{oi}(t)$ is, in fact, a train of step-functions, as illustrated in (2.4). This allows us to write more explicitly, for example,

$$Q^{BB}(t) = \sum_{o=a,b,c} \sum_{m=-\infty}^{\infty} \sum_{n=-\infty}^{\infty} \psi_{m+\alpha_m^o, m+\beta_m^o}(t) Y^o \psi_{n+\alpha_n^o, n+\beta_n^o}(t) \mathrm{e}^{i\omega_0 t}. \tag{3.8}$$

Note that the individual terms in this sum are of the form given in (3.3), with $t_1 = m + \alpha_m^o$, $t_2 = m + \beta_m^o$, $t_3 = n + \alpha_n^o$, and $t_4 = n + \beta_n^o$. Other entries in the matrix $Q(t)$ can be written similarly, except that alternative combinations of switching times are substituted for t_1, t_2, t_3, and t_4.

In the frequency domain, a typical element of the matrix $\hat{Q}(\omega)$ can be written, in analogy with (3.7),

$$\hat{Q}^{ij}(\omega) = \frac{1}{2\pi} \sum_{o=a,b,c} \hat{F}^{oi}(\omega) * \left[\frac{1}{Z^o(\omega)} \hat{F}^{oj}(\omega - \omega_0) \right]. \tag{3.9}$$

3.4. Direct calculation of input currents. We now outline a direct calculation of the input currents, for regular or natural sampling, using (3.8) and (3.9), respectively, as a basis. Nothing is assumed here about the form of the output impedances and the method is very general. More efficient, but less general, methods are described later, for specific forms of the output impedances. The difference between the two sets of calculations derives from whether we perform the convolution integral in (3.9) before or after the double sum over switching times. In this section, the sum is performed first and the convolution after.

3.4.1. Regular sampling. We first describe the calculation for regular sampling. For the contribution $\hat{Q}^{ij}(\omega)$, as described by (3.9), we first write

$$\hat{Q}^{ij}(\omega) = \sum_{o=a,b,c} \hat{Q}^{o,ij}(\omega),$$

where

$$\hat{Q}^{o,ij}(\omega) = \frac{1}{2\pi}\hat{F}^{oi}(\omega) * \left[\frac{1}{Z^o(\omega)}\hat{F}^{oj}(\omega - \omega_0)\right], \tag{3.10}$$

and the function $\hat{F}^{oi}(\omega)$ has been defined in (2.17). In this expression the function

$$\hat{F}^{oi}(\omega) = 2\pi \sum_{n=-\infty}^{\infty}\sum_{m=-\infty}^{\infty} X_m^i(\omega_{nm})\mathrm{e}^{m\mathrm{i}\delta^o}\delta(\omega - \omega_{mn})$$

is convolved with

$$\frac{1}{Z^o(\omega)}\hat{F}^{oj}(\omega - \omega_0) = 2\pi \sum_{n=-\infty}^{\infty}\sum_{m=-\infty}^{\infty} \frac{X_m^j(\omega_{nm})\mathrm{e}^{m\mathrm{i}\delta^o}}{Z^o(\omega_0 + \omega_{mn})}\delta(\omega - \omega_0 - \omega_{mn}),$$

and the result is a quadruple sum

$$\hat{Q}^{o,ij}(\omega) = 2\pi \sum_{klnm} W_{klnm}^{o,ij}\delta(\omega - \omega_0 - \omega_{kl} - \omega_{nm}),$$

where

$$W_{klnm}^{o,ij} = X_l^i(\omega_{kl})X_m^j(\omega_{nm})\left[\frac{\mathrm{e}^{\mathrm{i}(l+m)\delta^o}}{Z^o(\omega_0 + \omega_{nm})}\right]$$

and, in the sum, the indices k, l, n, and m run independently from $-\infty$ to ∞. The output-dependent parts (to be summed over later) have been isolated within square brackets in this expression. Using the fact that $\omega_{kl} + \omega_{nm} = \omega_{k+n,l+m}$, this result can alternatively be stated in the time domain as

$$Q^{o,ij}(t) = \sum_{klnm} W_{klnm}^{o,ij}\mathrm{e}^{\mathrm{i}(\omega_0 + \omega_{k+n,l+m})t}.$$

It is convenient to group terms in this sum with a common frequency, giving

$$Q^{o,ij}(t) = \sum_{NM} \mathcal{Q}_{NM}^{o,ij}\mathrm{e}^{\mathrm{i}\Omega_{NM}t}, \tag{3.11}$$

where $\Omega_{NM} = \omega_0 + \omega_{NM} = \omega_0 + 2\pi N + M\Omega$ and

$$\mathcal{Q}_{NM}^{o,ij} = \sum_{nm} W_{N-n,M-m,n,m}^{o,ij}. \tag{3.12}$$

In this result, the amplitude $\mathcal{Q}_{NM}^{o,ij}$ of a term with a given frequency Ω_{NM} is expressed as a double sum. Finally, we note that, according to (3.6), the total current in an input labeled by the superscript i can be obtained from the results above using

$$i^i(t) = \sum_{o=a,b,c} Q^{o,iA}(t) + pQ^{o,iB}(t) + p^2Q^{o,iC}(t). \tag{3.13}$$

Although these formulas for the input currents seem rather unwieldy, we may already note the potentially diagnostically useful result that, if all outputs have equal impedance, then the sum over outputs produces a factor $\sum_o \mathrm{e}^{M\mathrm{i}\delta^o} = 1 + \mathrm{e}^{2\pi M\mathrm{i}/3} + \mathrm{e}^{4\pi M\mathrm{i}/3}$, which vanishes unless M is a multiple of 3. Hence, in this special case, the frequencies $\Omega_{NM} = \omega_0 + 2\pi N + M\Omega$ appear only where M is a multiple of 3.

3.4.2. Natural sampling. We may readily adapt the expressions derived in the previous section to the case of natural sampling, without repeating the entire calculation. To do so, we simply note, from (2.18) and (2.29), that the only material difference in the natural sampling case lies in the arguments of the functions X_m^i used in the definitions of $\hat{F}^{oi}(\omega)$. Hence the input currents are still given by an expression of the form (3.13), with $Q^{o,ij}$ given by (3.11); however, $\mathcal{Q}_{NM}^{o,ij}$ is now given by

$$\mathcal{Q}_{NM}^{o,ij} = \sum_{nm} X_{M-m}^i(2\pi(N-n))X_m^j(2\pi n)\left[\frac{\mathrm{e}^{\mathrm{i}M\delta^o}}{Z^o(\omega_0+\omega_{nm})}\right], \tag{3.14}$$

rather than by (3.12). It is interesting to note that in the case of input currents, unlike in the cases of output voltages and currents, natural sampling does not produce a clean single harmonic when the high-frequency terms with $N \neq 0$ are filtered out.

4. Results for the voltage and current spectra. In this section we illustrate the results above for the output voltage and input current spectra. Recalling that the switching frequency has been scaled to 2π, we choose parameter values as follows:

$$\omega_0 = \tfrac{1}{20} \times 2\pi, \qquad \omega_1 = \tfrac{1}{25} \times 2\pi, \qquad q = 0.4. \tag{4.1}$$

The corresponding output voltage spectrum is independent of the output loads, and is shown in Figure 4.1, for regular and natural sampling. The primary feature of note is the exact reproduction of the low-frequency ($n = 0$) part of the voltage spectrum for natural sampling and, in contrast, the significant low-frequency distortion introduced by regular sampling.

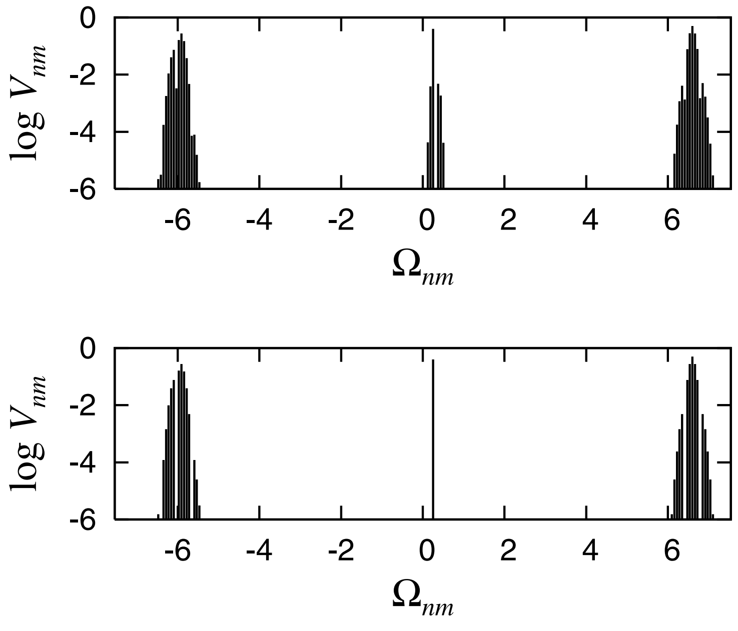

FIG. 4.1. *Spectrum of the output voltages, for parameter values* (4.1). *Upper plot: regular sampling. Lower plot: natural sampling. Note the significant low-frequency distortion of the regularly sampled case.*

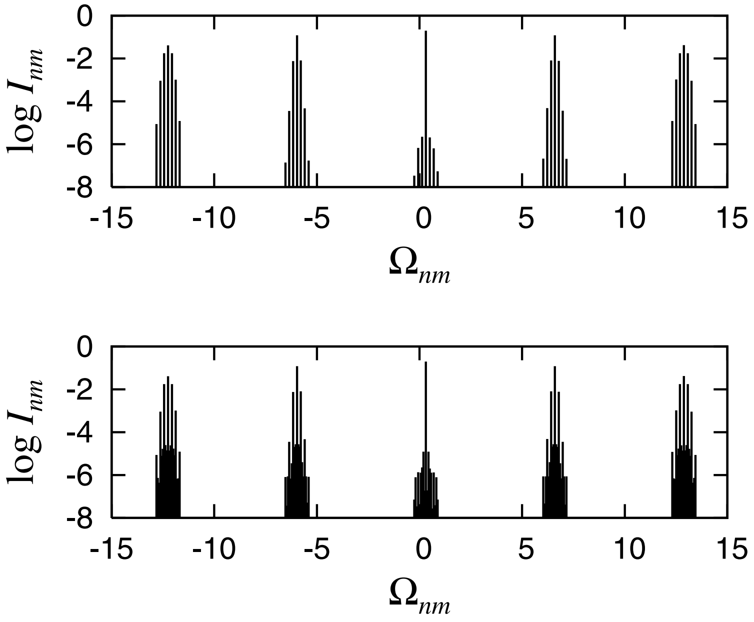

FIG. 4.2. *Spectrum of the input currents in line A with regular sampling, for parameter values* (4.1). *Upper plot: balanced loads, with* (4.3). *Lower plot: unbalanced loads, with* (4.4). *Spectra for input lines B and C are similar.*

To determine the input currents, we must specify the output loads, which will each comprise a resistor and an inductor in series, so that

$$Z^o(\omega) = R^o + \mathrm{i}\omega L^o, \quad o = a,\, b, \text{ or } c. \tag{4.2}$$

We consider two cases. In the first, all output lines offer equal impedance, with

$$R^a = R^b = R^c = 5\Omega, \qquad L^a = L^b = L^c = 5\text{mH}; \tag{4.3}$$

in the second, the output impedances are unbalanced, and we take

$$R^a = R^b = R^c = 5\Omega, \qquad L^a = L^b = 5\text{mH}, \quad L^c = 0\text{mH}. \tag{4.4}$$

From Figure 4.2 we see that the frequency spectrum for the input current is sparser for the balanced load. In fact, as argued above, the spectrum is confined to frequencies of the form $\omega_0 + 2\pi n + m\Omega$, where m is a multiple of 3; for the unbalanced load, by contrast, all frequencies of the form $\omega_0 + 2\pi n + m\Omega$ are present.

5. More efficient calculation of the input spectrum. The results of section 3 provide expressions for the input and output currents, and thus solve the problem posed at the start of this paper. However, each coefficient in the input current spectrum requires the evaluation of a doubly infinite sum, as in (3.12) and (3.14). Furthermore, these sums converge rather slowly. So we now describe a more efficient means of obtaining the input current spectrum for specific output impedances. It differs from the calculation in section 3 by taking advantage of the known impedances to perform the convolution integrals in (3.9) before the sum over switching times is evaluated. A consequence is that each Fourier coefficient will then require calculation of only a single infinite sum.

The explicit calculations outlined are for the case where each output load takes the form of a resistor and an inductor in series, so that the corresponding impedances are given by (4.2). The various complex impedances need not be equal between outputs a, b, and c. We shall discuss later how this method may be extended to the case of more general forms for the output impedances.

5.1. Illustration of transfer matrix calculation for purely resistive loads. We begin by considering purely resistive loads, with $L^o = 0$. Although such loads are of limited practical interest, they are nevertheless useful to illustrate the following transfer matrix method. For a purely resistive load, the admittances of the three output lines are simply the constants $Y^o = 1/R^o$. This case is thus considerably easier to analyze than that of general impedance because a step output voltage of the sort described in section 3.2 produces an output current only while the voltage is switched on. Then, for example, the terms in the sum (3.7) vanish unless $n = m$ and we find that the diagonal terms in Q take the form

$$Q^{ii}(t) = \sum_{o=a,b,c} \frac{1}{R^o} F^{oi}(t) \mathrm{e}^{\mathrm{i}\omega_0 t}, \quad i = A,\, B, \text{ or } C. \tag{5.1}$$

Note that the functions $F^{oi}(t)$ have been defined in (2.17). The off-diagonal terms in Q necessarily vanish for resistive loads. To see this, consider, for example,

$$Q^{AB}(t) = \sum_{o=a,b,c} \sum_{m,n} \frac{1}{R^o} \psi_{m,m+\alpha_m^o}(t) \psi_{n+\alpha_n^o, n+\beta_n^o}(t). \tag{5.2}$$

It is clear that the intervals $(m, m+\alpha_m^o)$ and $(n+\alpha_n^o,\, n+\beta_n^o)$ never overlap and hence $Q^{AB} = 0$. A similar consideration shows that all other off-diagonal terms are zero.

The three input currents are then, using the results and notation of sections 2.3 and 2.5,

$$\begin{aligned} i^A(t) = Q^{AA}(t) \quad &= \sum_{nm} Y_m X_m^A(x_{nm}) \mathrm{e}^{\mathrm{i}\Omega_{nm} t}, \\ i^B(t) = pQ^{BB}(t) \quad &= \sum_{nm} pY_m X_m^B(x_{nm}) \mathrm{e}^{\mathrm{i}\Omega_{nm} t}, \\ i^C(t) = p^2 Q^{CC}(t) &= \sum_{nm} p^2 Y_m X_m^C(x_{nm}) \mathrm{e}^{\mathrm{i}\Omega_{nm} t}, \end{aligned}$$

where $x_{nm} = \omega_{nm}$ for regular sampling, and $x_{nm} = 2\pi n$ for natural sampling. Here

$$Y_m = \sum_{o=a,b,c} \frac{\mathrm{e}^{\mathrm{i}m\delta^o}}{R^o}$$

is an effective total output admittance, common to all three inputs.

These two simplifying elements of the matrix Q (namely that Q is a *diagonal* matrix, and that the diagonal elements are given by a *single* sum, as in (5.1)) follow from there being a purely resistive load. The key points are that an output voltage pulse produces a proportional output current pulse, and that after the voltage pulse the corresponding current drops immediately to zero.

5.2. Frequency domain calculation for series resistor/inductor loads. We now consider the case of more general loads, with inductive as well as resistive elements, with output impedances given by (4.2). In this case, the double sum in (3.9) does not collapse to a single sum as it did in the purely resistive case and the calculation is more complex.

Before summing the series, let us consider in more detail the structure of the summand, whose general form is given in (3.4). For an inductive load with impedance $Z = R + i\omega L = iL(\omega - i\gamma)$, where $\gamma = R/L$ is the decay rate of transients in the current, we can write (3.4) more explicitly as

$$\hat{\imath}_{t_1,t_2,t_3,t_4}(\omega) = \frac{1}{2\pi \mathrm{i}} \int_{-\infty}^{\infty} \frac{(\mathrm{e}^{-\mathrm{i}(\omega-\omega')t_2} - \mathrm{e}^{-\mathrm{i}(\omega-\omega')t_1})(\mathrm{e}^{-\mathrm{i}(\omega'-\omega_0)t_4} - \mathrm{e}^{-\mathrm{i}(\omega'-\omega_0)t_3})}{L(\omega'-\omega)(\omega'-\mathrm{i}\gamma)(\omega'-\omega_0)}\, \mathrm{d}\omega',$$

having substituted the explicit forms for $\hat{\psi}_{t_1,t_2}(\omega)$ and $\hat{\psi}_{t_3,t_4}(\omega)$ in the convolution integral. This is conveniently evaluated using the residue calculus. The denominator in the integrand has three zeroes, two on the real axis and one on the positive imaginary axis. The zeroes on the real axis are canceled by zeroes in the numerator and do not lead to poles in the total integrand. Since the integrand is analytic on the real axis, we may move the contour slightly off the real axis before beginning the calculation proper and the manner in which we do this will not affect the final result. This observation is relevant because we will evaluate the integral by expanding the numerator and considering terms individually. Although these individual terms have poles on the real axis, if we have deformed the contour away from these poles beforehand, the individual integrals are well defined. Furthermore, any contributions made by the poles on the real axis through the residue calculus must combine consistently and be independent of the initial contour deformation. The integral is therefore controlled by the pole at $\omega' = i\gamma$. There are three cases to consider.

Case 1. *Window t_1, t_2 precedes window t_3, t_4.*
In this case, where $t_1 < t_2 < t_3 < t_4$, every term in the expanded numerator

$$\begin{aligned}(\mathrm{e}^{-\mathrm{i}(\omega-\omega')t_2} - \mathrm{e}^{-\mathrm{i}(\omega-\omega')t_1})&(\mathrm{e}^{-\mathrm{i}(\omega'-\omega_0)t_4} - \mathrm{e}^{-\mathrm{i}(\omega'-\omega_0)t_3}) \\ &= \mathrm{e}^{-\mathrm{i}\omega t_2 + \mathrm{i}\omega_0 t_4 + \mathrm{i}\omega'(t_2-t_4)} - \mathrm{e}^{-\mathrm{i}\omega t_2 + \mathrm{i}\omega_0 t_3 + \mathrm{i}\omega'(t_2-t_3)} \\ &\quad - \mathrm{e}^{-\mathrm{i}\omega t_1 + \mathrm{i}\omega_0 t_4 + \mathrm{i}\omega'(t_1-t_4)} + \mathrm{e}^{-\mathrm{i}\omega t_1 + \mathrm{i}\omega_0 t_3 + \mathrm{i}\omega'(t_1-t_3)}\end{aligned} \tag{5.3}$$

decays exponentially as ω' descends into the lower-half plane. The contour of integration can therefore be pushed downwards and, because there are no poles in the lower-half plane, the integral must vanish. We therefore necessarily have

$$\hat{\imath}_{t_1,t_2,t_3,t_4}(\omega) = 0 \tag{5.4}$$

in this case. Note that in the case of more complicated load impedances, causality demands that all of the zeroes of $Z(\omega')$ lie in the upper-half plane and the result (5.4) still holds. The result is obvious in the time domain because a driving voltage confined to the window (t_3, t_4) produces no current for $t < t_3$, and any sampling window confined to this range must produce a null result.

Case 2. *Window t_1, t_2 follows window t_3, t_4.*
In this case, $t_3 < t_4 < t_1 < t_2$. Let us assume that the integration contour has been moved slightly above the real axis before the calculation for individual terms in expansion (5.3) begins. Then, all of the terms on the right of (5.3) are exponentially

decaying into the upper-half plane and we push the contour upwards, picking up a contribution only from the pole at $\omega' = \mathrm{i}\gamma$. This yields

$$\begin{aligned}\hat{\imath}_{t_1,t_2,t_3,t_4}(\omega) &= \frac{(\mathrm{e}^{-\mathrm{i}(\omega-\mathrm{i}\gamma)t_2} - \mathrm{e}^{-\mathrm{i}(\omega-\mathrm{i}\gamma)t_1})(\mathrm{e}^{\mathrm{i}(\omega_0-\mathrm{i}\gamma)t_4} - \mathrm{e}^{\mathrm{i}(\omega_0-\mathrm{i}\gamma)t_3})}{L(\omega-\mathrm{i}\gamma)(\omega_0-\mathrm{i}\gamma)}\\ &= \frac{1}{L}\left(\frac{\mathrm{e}^{-\mathrm{i}(\omega-\mathrm{i}\gamma)t_2} - \mathrm{e}^{-\mathrm{i}(\omega-\mathrm{i}\gamma)t_1}}{-\mathrm{i}(\omega-\mathrm{i}\gamma)}\right)\left(\frac{\mathrm{e}^{\mathrm{i}(\omega_0-\mathrm{i}\gamma)t_4} - \mathrm{e}^{\mathrm{i}(\omega_0-\mathrm{i}\gamma)t_3}}{\mathrm{i}(\omega_0-\mathrm{i}\gamma)}\right)\\ &= \frac{1}{L}\hat{\psi}_{t_1,t_2}(\omega-\mathrm{i}\gamma)\hat{\psi}_{t_3,t_4}(-\omega_0+\mathrm{i}\gamma). \qquad (5.5)\end{aligned}$$

For more general load impedances, there would be a sum of such contributions, each term corresponding to a zero of $Z(\omega')$, or equivalently a decay rate of the system, weighted by residues of $1/Z(\omega')$.

Case 3. *Window t_1, t_2 coincides with window t_3, t_4.*
In this case, $t_1 = t_3 < t_2 = t_4$. The calculation here is somewhat more complicated and requires a more careful consideration of the poles on the real axis. We forgo the details here and simply quote the result:

$$\begin{aligned}\hat{\imath}_{t_1,t_2,t_3,t_4}(\omega) &= \frac{1}{\mathrm{i}L(\omega_0-\mathrm{i}\gamma)}\left(\frac{\mathrm{e}^{-\mathrm{i}(\omega-\omega_0)t_2} - \mathrm{e}^{-\mathrm{i}(\omega-\omega_0)t_1}}{-\mathrm{i}(\omega-\omega_0)}\right)\\ &\qquad - \frac{\mathrm{e}^{\mathrm{i}(\omega_0-\mathrm{i}\gamma)t_1}}{\mathrm{i}L(\omega_0-\mathrm{i}\gamma)}\left(\frac{\mathrm{e}^{-\mathrm{i}(\omega-\mathrm{i}\gamma)t_2} - \mathrm{e}^{-\mathrm{i}(\omega-\mathrm{i}\gamma)t_1}}{-\mathrm{i}(\omega-\mathrm{i}\gamma)}\right)\\ &= \frac{1}{Z(\omega_0)}\left[\hat{\psi}_{t_1,t_2}(\omega-\omega_0) - \mathrm{e}^{\mathrm{i}(\omega_0-\mathrm{i}\gamma)t_1}\hat{\psi}_{t_1,t_2}(\omega-\mathrm{i}\gamma)\right], \qquad (5.6)\end{aligned}$$

which is obtained by summing the contributions from the various poles for each of the terms in (5.3) and following some further algebraic manipulation.

So far we have established the forms of the individual terms in (3.9). It remains to perform the double sum over switching times in that equation. Once again we concentrate initially on the element $\hat{Q}^{BB}(\omega)$ and indicate later how the calculation is altered for other elements. In this case, the summands in (3.9) are of the form $\hat{\imath}_{t_1,t_2,t_3,t_4}(\omega)$, as calculated above, with $t_1 = m + \alpha^o_m$, $t_2 = m + \beta^o_m$, $t_3 = n + \alpha^o_n$, $t_4 = n + \beta^o_n$, and with loads that are output-specific. Let us denote by

$$\gamma^o = R^o/L^o \qquad (5.7)$$

the decay rate of transients associated with output o. In view of (5.4), the summands vanish if $n < m$, so let us set $n = m + r$ for $r = 0, 1, 2, \ldots$, and separate (3.9) into "diagonal" and "off-diagonal" contributions:

$$\hat{Q}^{BB}(\omega) = \hat{Q}^{BB}_{\mathrm{diag}}(\omega) + \hat{Q}^{BB}_{\mathrm{offdiag}}(\omega),$$

where

$$\hat{Q}^{BB}_{\mathrm{diag}}(\omega) = \sum_{o=a,b,c}\sum_{n=-\infty}^{\infty}\hat{\imath}_{n+\alpha^o_n,n+\beta^o_n,n+\alpha^o_n,n+\beta^o_n}(\omega)$$

and

$$\hat{Q}^{BB}_{\mathrm{offdiag}}(\omega) = \sum_{o=a,b,c}\sum_{r=1}^{\infty}\sum_{n=-\infty}^{\infty}\hat{\imath}_{n+r+\alpha^o_{n+r},n+r+\beta^o_{n+r},n+\alpha^o_n,n+\beta^o_n}(\omega).$$

The diagonal contribution accounts for the terms with $r = 0$ and corresponds to the case of coinciding windows given in (5.6). We expect these terms to dominate the total sum and so describe them first. We start with regular sampling (natural sampling is discussed at the end of this section). Then using the notation of section 2.3, we write

$$\begin{aligned}\sum_{n=-\infty}^{\infty} \hat{\psi}_{t_1,t_2}(\omega-\omega_0) &= \sum_{n=-\infty}^{\infty} \hat{\psi}_{n+\alpha_n^o,n+\beta_n^o}(\omega-\omega_0) = \hat{F}^{oB}(\omega-\omega_0)\\ &= 2\pi \sum_{nm} X_m^B(\omega_{nm}) \mathrm{e}^{mi\delta^o} \delta(\omega-\Omega_{nm}),\end{aligned}$$

recalling that $\Omega_{nm} = \omega_0 + \omega_{nm} = \omega_0 + 2\pi n + m\Omega$. A similar calculation shows that

$$\begin{aligned}\sum_{n=-\infty}^{\infty} \mathrm{e}^{\mathrm{i}(\omega_0-\mathrm{i}\gamma^o)t_1} \hat{\psi}_{t_1,t_2}(\omega-\mathrm{i}\gamma^o) &= \sum_{n=-\infty}^{\infty} \mathrm{e}^{\mathrm{i}(\omega_0-\mathrm{i}\gamma^o)(n+\alpha_n^o)} \hat{\psi}_{n+\alpha_n^o,n+\beta_n^o}(\omega-\mathrm{i}\gamma^o)\\ &= \sum_{n=-\infty}^{\infty} \mathrm{e}^{-\mathrm{i}n(\omega-\omega_0)}\, \mathrm{e}^{\mathrm{i}(\omega_0-\mathrm{i}\gamma^o)\alpha_n^o}\, \hat{\psi}_{\alpha_n^o,\beta_n^o}(\omega-\mathrm{i}\gamma^o)\\ &= 2\pi \sum_{nm} Y_m^B(\omega_{nm}, -\omega_0+\mathrm{i}\gamma^o) \mathrm{e}^{\mathrm{i}m\delta^o} \delta(\omega-\Omega_{nm}),\end{aligned}$$

where

$$Y_m^B(\omega,\omega') \equiv \sum_{k=-\infty}^{\infty} X_k^B(\omega-\omega') C_{m-k}^B(\omega') \tag{5.8}$$

and

$$C_m^B(\omega) = \mathrm{e}^{-\mathrm{i}\omega/3}(-\mathrm{i})^m \mathrm{J}_m\left(\tfrac{2}{3}q\omega\right).$$

Note that the expression defining $Y_m^B(\omega,\omega')$ can be summed using Graf's theorem [11]. However, leaving the definition of $Y_m^B(\omega,\omega')$ as a sum, as done here, has the advantage of admitting easier generalization to other diagonal terms and being simpler to write. We can therefore write

$$\hat{Q}^{BB}_{\mathrm{diag}}(\omega) = 2\pi \sum_{o=a,b,c} D_{nm}^{o,B} \mathrm{e}^{\mathrm{i}m\delta^o} \delta(\omega-\Omega_{nm}),$$

where

$$D_{nm}^{o,B} = \frac{1}{Z^o(\omega_0)} \left(X_m^B(\omega_{nm}) - Y_m^B(\omega_{nm}, -\omega_0+\mathrm{i}\gamma^o)\right).$$

There are similar diagonal contributions to $\hat{Q}^{AA}$ and $\hat{Q}^{CC}$, except that $C_k^A(\omega)$ and $C_k^C(\omega)$ have the alternative forms

$$C_m^A(\omega) = \delta_{m0}, \qquad C_m^C(\omega) = \mathrm{e}^{-2\mathrm{i}\omega/3-\mathrm{i}m\pi/3}(-\mathrm{i})^m \mathrm{J}_m\left(\tfrac{2}{3}q\omega\right).$$

We next discuss off-diagonal contributions. In this case the summands are of the form given in (5.5) and

$$
\begin{aligned}
\hat{Q}^{BB}_{\text{nondiag}}(\omega) &= \sum_{o=a,b,c} \sum_{r=1}^{\infty} \sum_{n=-\infty}^{\infty} \frac{1}{L^o} \hat{\psi}_{t_1,t_2}(\omega - \mathrm{i}\gamma^o) \hat{\psi}_{t_3,t_4}(-\omega_0 + \mathrm{i}\gamma^o) \\
&= \sum_{o=a,b,c} \sum_{r=1}^{\infty} \sum_{n=-\infty}^{\infty} \frac{1}{L^o} \mathrm{e}^{-\mathrm{i}n(\omega-\omega_0) - \mathrm{i}r(\omega - \mathrm{i}\gamma^o)} \\
&\qquad\qquad\qquad \times \hat{\psi}_{\alpha^o_{n+r},\beta^o_{n+r}}(\omega - \mathrm{i}\gamma^o) \hat{\psi}_{\alpha^o_n,\beta^o_n}(-\omega_0 + \mathrm{i}\gamma^o) \\
&= 2\pi \sum_{o=a,b,c} \sum_{nm} A^{o,BB}_{nm} \mathrm{e}^{\mathrm{i}m\delta^o} \delta(\omega - \Omega_{nm}), \qquad (5.9)
\end{aligned}
$$

where (after some manipulation)

$$
A^{o,BB}_{nm} = \frac{1}{L^o} U^{BB}_m(\omega_{nm}, -\omega_0 + \mathrm{i}\gamma^o)
$$

and

$$
U^{BB}_m(\omega, \omega') = \sum_{k=-\infty}^{\infty} G_1(\omega - \omega' - k\Omega) X^B_k(\omega - \omega') X^B_{m-k}(\omega')
$$

and

$$
G_1(\omega) = \sum_{r=1}^{\infty} \mathrm{e}^{-\mathrm{i}r\omega} = \frac{1}{\mathrm{e}^{\mathrm{i}\omega} - 1}.
$$

The off-diagonal contributions to $\hat{Q}^{AA}$ and $\hat{Q}^{CC}$ are of the same form, with appropriate replacements for X^B_m.

If we now consider elements $\hat{Q}^{ij}(\omega)$ with $i \neq j$, we find that the appropriate intervals (t_1, t_2) and (t_3, t_4) never overlap and all summands are of the form given in (5.5). The calculation is very similar to that for $\hat{Q}^{BB}_{\text{offdiag}}(\omega)$ except that, when $i > j$, the sum over r starts from $r = 0$ rather than $r = 1$ (here we adopt the convention that $C > B > A$). The result is the following generalization of (5.9):

$$
\hat{Q}^{ij}(\omega) = 2\pi \sum_{o=a,b,c} \sum_{nm} A^{o,ij}_{nm} \mathrm{e}^{\mathrm{i}m\delta^o} \delta(\omega - \Omega_{nm}), \qquad (5.10)
$$

where

$$
A^{o,ij}_{nm} = \frac{1}{L^o} U^{ij}_m(\omega_{nm}, -\omega_0 + \mathrm{i}\gamma^o)
$$

and

$$
U^{ij}_m(\omega, \omega') = \sum_{k=-\infty}^{\infty} G^{ij}(\omega - \omega' - k\Omega) X^i_k(\omega - \omega') X^j_{m-k}(\omega') \qquad (5.11)
$$

and

$$
G^{ij}(\omega) = \begin{cases} \mathrm{e}^{\mathrm{i}\omega} G_1(\omega) & \text{if } i > j, \\ G_1(\omega) & \text{if } i < j. \end{cases}
$$

Again, the sum defining $U^{ij}_m(\omega, \omega')$ can be expressed alternatively using Graf's theorem but the form given is simpler to write. Note that if we set $i = j$, then (5.10) also describes the off-diagonal part of $\hat{Q}^{ii}$, if we take $G^{ii}(\omega) = G_1(\omega)$.

The current in the input labeled by the subscript i is (cf. (3.13))

$$i^i(t) = Q^{iA}(t) + pQ^{iB}(t) + p^2 Q^{iC}(t), \tag{5.12}$$

where

$$Q^{ij}(t) = \sum_{o=a,b,c} \sum_{nm} \left(D^{o,i}_{nm} \delta_{ij} + A^{o,ij}_{nm} \right) \mathrm{e}^{\mathrm{i}m\delta^o} \mathrm{e}^{\mathrm{i}\Omega_{nm} t}.$$

Thus, from (5.12), the coefficient of each frequency component in the input current $i^i(t)$ requires (aside from sums over the three output lines) only a *single* infinite sum for computing each of the the terms $D^{o,i}_{nm}$ and $A^{o,ij}_{nm}$, as in (5.8) and (5.11).

Finally, we note also that a similar calculation is possible in the case of natural sampling. The answer in that case is similar, the main difference being that the functions X^i_m, Y^i_m, and U^{ij}_m take different arguments when they are used in the calculation of the amplitudes $D^{o,i}_{nm}$ and $A^{o,ij}_{nm}$ (compare (2.20) with (2.31), for example).

6. Conclusions. We have shown how to compute the output voltage spectrum, and the output and input current spectra for an idealized matrix power converter, for general output loads. Our method provides a rather more direct alternative to the usual approach of Black's multiple Fourier series [2, 3], and appears to be the first published calculation of the full spectrum. The mathematical expressions involved in the present calculations are considerably more compact than would be the equivalent expressions using Black's method. Despite its greater directness, however, our method still requires calculations that are rather algebraically involved. We have shown how reasonable assumptions about the form of the output loads—for example, if they are all series resistor-inductor loads—can be used for deriving more rapidly convergent expressions for the input currents (which are of particular significance since they provide an easily monitored diagnostic of the system). We note that the calculation in this paper can be adapted relatively easily to more general output impedances.

One potential practical upshot of our work is the following. In applications such as aeronautics, there are strict regulations regarding acceptable levels of the electromagnetic interference generated by high-frequency switching applications such as matrix converters. This paper provides, apparently for the first time, analytical expressions for the full frequency spectrum of voltages and currents. We therefore expect the formulas derived herein, and appropriate extensions of the methodology to more general cases (for example, a wider range of output impedances) to allow engineers to design matrix converters to satisfy mandatory restrictions on power quality without wasteful overspecification of the associated filters.

In the appendix, we illustrate how similar techniques can be adapted to more general switching protocols for the matrix converter. However, these introduce new frequencies into the spectrum, so the calculation is more involved.

The Fourier transform/Poisson resummation techniques applied here (with a judicious choice of the order in which the elements of the technique are applied, according to whether regular or natural sampling is used) may also be applied to other switching problems. Notable examples are the class-D audio amplifier, for which an analysis such as that given in this paper would lead to considerably more compact derivations of the spectrum than previously given [3, 8], and DC–AC converters (inverters) [7].

Appendix. The modulation strategies considered in the main text are the simplest possible; in practice, more complicated strategies are used. Many of these will be amenable to a treatment similar to that described in this paper, but with increased algebraic complexity. In this appendix we illustrate some of the necessary modifications by calculating the output voltage spectrum for natural sampling using a hybrid Venturini modulation strategy. In this case, the switching times are determined by

$$\begin{aligned}
A^o(\tau) &= \tfrac{1}{3} + \tfrac{2}{3}q\left[\theta\cos((\omega_1-\omega_0)\tau+\delta^o) + (1-\theta)\cos((\omega_1+\omega_0)\tau+\delta^o)\right],\\
B^o(\tau) &= \tfrac{2}{3} + \tfrac{2}{3}q\left[\theta\cos((\omega_1-\omega_0)\tau+\delta^o-\tfrac{\pi}{3}) + (1-\theta)\cos((\omega_1+\omega_0)\tau+\delta^o+\tfrac{\pi}{3})\right],
\end{aligned}$$

where $0 \le \theta \le 1$, rather than by (2.30). Notice that the case $\theta = 1$ recovers (2.30). The case $\theta = 1/2$ proves particularly straightforward to implement in practice [12].

The calculation of $F^{oi}(t)$ is now rather more involved, since

$$\mathrm{e}^{-2\pi n\mathrm{i}A^o(t)} = \mathrm{e}^{-2\pi n\mathrm{i}/3}\sum_{m=-\infty}^{\infty}\sum_{m'=-\infty}^{\infty}\mathcal{C}_{mm'}\mathrm{e}^{\mathrm{i}(m(\omega_1-\omega_0)+m'(\omega_1+\omega_0))t}$$

and

$$\mathrm{e}^{-2\pi n\mathrm{i}B^o(t)} = \mathrm{e}^{-4\pi n\mathrm{i}/3}\sum_{m=-\infty}^{\infty}\sum_{m'=-\infty}^{\infty}\mathcal{C}_{mm'}\mathrm{e}^{\mathrm{i}(m(\omega_1-\omega_0)+m'(\omega_1+\omega_0))t}\mathrm{e}^{\mathrm{i}(m'-m)\pi/3},$$

where

$$\mathcal{C}_{mm'} = (-\mathrm{i})^{m+m'}\mathrm{J}_m(\tfrac{4}{3}n\pi q\theta)\mathrm{J}_{m'}(\tfrac{4}{3}n\pi q(1-\theta))\mathrm{e}^{\mathrm{i}(m+m')\delta^o}.$$

Thus, in general, these quantities now involve additional frequencies beyond those present for the simpler case $\theta = 1$.

Writing the output voltages as

$$v^o(t) = \sum_{nmm'}\tilde{V}_{nmm'}\mathrm{e}^{\mathrm{i}(2\pi n+\omega_0+m(\omega_1-\omega_0)+m'(\omega_1+\omega_0))t}\mathrm{e}^{\mathrm{i}(m+m')\delta^o},$$

we have

$$\text{(A.1)}\qquad \tilde{V}_{nmm'} = X^A_{mm'}(2\pi n) + pX^B_{mm'}(2\pi n) + p^2X^C_{mm'}(2\pi n),$$

where

$$\begin{aligned}
X^A_{mm'}(\omega) &= \frac{(-\mathrm{i})^{m+m'}}{-\mathrm{i}\omega}\left[\mathrm{e}^{-\mathrm{i}\omega/3}\mathrm{J}_m(\tfrac{2}{3}q\omega\theta)\mathrm{J}_{m'}(\tfrac{2}{3}q\omega(1-\theta)) - \delta_{m0}\delta_{m'0}\right],\\
X^B_{mm'}(\omega) &= \frac{(-\mathrm{i})^{m+m'}}{-\mathrm{i}\omega}\left[\mathrm{e}^{-2\mathrm{i}\omega/3+\mathrm{i}(m'-m)\pi/3} - \mathrm{e}^{-\mathrm{i}\omega/3}\right]\mathrm{J}_m(\tfrac{2}{3}q\omega\theta)\mathrm{J}_{m'}(\tfrac{2}{3}q\omega(1-\theta)),\\
X^C_{mm'}(\omega) &= \frac{(-\mathrm{i})^{m+m'}}{-\mathrm{i}\omega}\left[\mathrm{e}^{-\mathrm{i}\omega}\delta_{m0}\delta_{m'0} - \mathrm{e}^{-2\mathrm{i}\omega/3+\mathrm{i}(m'-m)\pi/3}\mathrm{J}_m(\tfrac{2}{3}q\omega\theta)\mathrm{J}_{m'}(\tfrac{2}{3}q\omega(1-\theta))\right].
\end{aligned}$$

Special consideration needs to be given to the values of $X^i_{mm'}(0)$. We find that $X^i_{mm'}(0) = 0$ for $i = A$, B, or C, except in the following cases:

$$X^i_{00}(0) = \tfrac{1}{3}, \qquad i = A,\ B,\ \text{or}\ C$$

and

$$X^A_{0\pm1}(0) = \tfrac{1}{3}q(1-\theta), \quad X^B_{0\pm1}(0) = \tfrac{1}{3}q(1-\theta)(\mathrm{e}^{\pm\mathrm{i}\pi/3}-1), \quad X^C_{0\pm1}(0) = -\tfrac{1}{3}q(1-\theta)\mathrm{e}^{\pm\mathrm{i}\pi/3}$$

and

$$X^A_{\pm 10}(0) = \tfrac{1}{3}q\theta, \qquad X^B_{\pm 10}(0) = \tfrac{1}{3}q\theta(\mathrm{e}^{\mp \mathrm{i}\pi/3} - 1), \qquad X^C_{\pm 10}(0) = -\tfrac{1}{3}q\theta\mathrm{e}^{\mp \mathrm{i}\pi/3}.$$

It then follows from (A.1) that for the contribution to the output voltages with $n = 0$ we have $\tilde{V}_{00-1} = q(1-\theta)$ and $\tilde{V}_{010} = q\theta$, with $\tilde{V}_{0mm'} = 0$ for all other choices of m and m'. Thus the corresponding contribution to the output voltages is

$$v^o_0(t) = q\theta\mathrm{e}^{\mathrm{i}\omega_1 t + \mathrm{i}\delta^o} + q(1-\theta)\mathrm{e}^{-\mathrm{i}\omega_1 t - \mathrm{i}\delta^o}.$$

Hence the physical output voltage, given by the real part of this expression, is, as for the simpler modulation strategy of section 2.5, *exactly* the intended reference voltage $v^o_{\mathrm{ref}}(t)$. A similar calculation can be undertaken for uniform sampling but is not described here.

A DOUBLE LAYER SURFACE TRACTION FREE GREEN'S TENSOR[*]

DARKO VOLKOV[†]

Abstract. A double layer Green's tensor for linear elasticity in half space is computed. Traction free conditions on the surface are imposed making this Green's tensor relevant in geophysics for modeling displacements caused by slips on faults. Past attempts at computing related Green's tensors are discussed. Applications to computing displacement fields by integration over fault regions or by use of asymptotic estimates are presented.

Key words. linear elasticity, Green's tensors in half space, traction free surface, cracks in half space, slip along cracks

1. Introduction.

Inside a linear elastic region Ω with Lamé coefficients $\lambda > 0$ and $\mu > 0$, a displacement field u satisfies the equation

$$\mu\Delta u + (\lambda+\mu)\nabla \operatorname{div} u = 0 \text{ in } \Omega \tag{1}$$

or alternatively

$$\operatorname{div} \sigma = 0 \text{ in } \Omega, \tag{2}$$

where the stress tensor is given by

$$\sigma_{ij}(u) = \lambda \operatorname{div} u\, \delta_{ij} + \mu(\partial_i u_j + \partial_j u_i).$$

We will use the following notation for stress vectors in the normal direction n throughout this paper:

$$T_n u = \sigma(u)n.$$

The natural basis for $\mathbb{R}^3$ will be denoted by (e_1, e_2, e_3). If Ω is unbounded, a finite energy condition for displacements is required:

$$\int_\Omega \sigma(u) : \epsilon(u) < \infty, \tag{3}$$

where we have used the strain tensor $\epsilon_{ij}(u) = \frac{1}{2}(\partial_i u_j + \partial_j u_i)$ and the dot product between two 3×3 matrices A and B defined by $A : B = \operatorname{tr}(A^T B)$. If Ω is the whole space $\mathbb{R}^3$, it is known since Kelvin that the tensor

$$G_{ij}(x,y) = \frac{1}{8\pi\mu(\lambda+2\mu)}((\lambda+\mu)\partial_{x_i} r \partial_{x_j} r + (\lambda+3\mu)\delta_{ij})\frac{1}{r}, \tag{4}$$

where $r = \sqrt{(x_1 - y_1)^2 + (x_2 - y_2)^2 + (x_3 - y_3)^2}$, satisfies Green's problem

$$\mu \Delta G + (\lambda + \mu) \nabla \operatorname{div} G = -I_3 \delta_y \text{ in } \mathbb{R}^3, \tag{5}$$

where I_3 is the 3×3 identity matrix. In addition G decays at infinity and has finite energy away from the singularity at $x = y$,

$$\int_{\mathbb{R}^3 \setminus B(y,1)} \sigma(G(x,y)) : \epsilon(G(x,y)) dx < \infty. \tag{6}$$

Let Γ be a bounded fault or cut in the space $\mathbb{R}^3$. It is possible to use tensor G to find an integral representation for displacement fields in $\mathbb{R}^3$ that are continuous across Γ and whose stress vector has a given discontinuity (sometimes called jump) across Γ; see [5].

We are interested in this paper in elastic displacement fields in the half space $x_3 < 0$, denoted by $\mathbb{R}^{3-}$, that are traction free on the surface $x_3 = 0$, satisfy some discontinuity condition across a bounded surface Γ in $\mathbb{R}^{3-}$, and decay at infinity while having finite energy. Such displacement fields u can be expressed as integrals on Γ involving Green's tensor M which satisfies

$$\mu \Delta M + (\lambda + \mu) \nabla \operatorname{div} M = -I_3 \delta_y \text{ in } \mathbb{R}^{3-}, \tag{7}$$

$$T_{e_3} M = 0 \text{ on the surface } x_3 = 0, \tag{8}$$

$$M \text{ decays at infinity and } \int_{\mathbb{R}^{3-} \setminus B(y,1)} \sigma(M(x,y)) : \epsilon(M(x,y)) dx < \infty. \tag{9}$$

Mindlin was the first to compute a tensor of this type; see [4]. Sheu performed an analogous computation in the anisotropic case; see [7]. In that same paper he was able to reconstruct displacement fields produced by the 1999 Jiji, Taiwan earthquake using his new Green's tensor.

If u is a finite energy elastic displacement field in the half space $\mathbb{R}^{3-}$ that has zero traction on the surface $x_3 = 0$ and satisfies some discontinuity condition across a bounded surface Γ in $\mathbb{R}^{3-}$, then u can be expressed as the integral over Γ of M against some density which solves an adequate boundary integral equation. These equations on Γ were studied by Martin, Päivärinta, and Rempel in [3].

It might be costly and nontrivial to solve the boundary integral equations discussed in [3]. However, this can be avoided altogether in some cases. Assume that we want to solve for a (finite energy, decaying at infinity) displacement field u such that

$$\mu \Delta u + (\lambda + \mu) \nabla \operatorname{div} u = 0 \text{ in } \mathbb{R}^{3-} \setminus \Gamma, \tag{10}$$

$$T_{e_3} u = 0 \text{ on the surface } x_3 = 0, \tag{11}$$

$$u \text{ is continuous across } \Gamma, \tag{12}$$

$$[T_n u] = f \text{ is a given jump across } \Gamma; \tag{13}$$

then u is given by the integral formula

$$u = \frac{1}{2} \int_\Gamma M f. \tag{14}$$

Note that the free space analogue of problem (10), (12), and (13) is given by the field $u = \frac{1}{2} \int_\Gamma G f$ (see [5]), and from there integral formula (14) is easily conceived in half space. Let us now examine the adjoint problem to (10)–(13), namely, solving for a (finite energy, decaying at infinity) displacement field u such that

$$\mu\Delta u + (\lambda+\mu)\nabla \operatorname{div} u = 0 \text{ in } \mathbb{R}^{3-} \setminus \Gamma, \tag{15}$$

$$T_{e_3} u = 0 \text{ on the surface } x_3 = 0, \tag{16}$$

$$T_n u \text{ is continuous across } \Gamma, \tag{17}$$

$$[u] = g \text{ is a given jump across } \Gamma. \tag{18}$$

We know from [5] that the free space analogue of this problem has the solution $u = \frac{1}{2}\int_\Gamma (T_{n(y)}G)^T g$, where, as previously, G is Kelvin's Green's tensor and $T_{n(y)}$ is the stress vector in the y dependent normal direction $n(y)$. The main result of this paper is to find Green's tensor H such that problem (15)–(18) has the solution $u = \frac{1}{2}\int_\Gamma Hg$ for any smooth tangential vector field on Γ, g. Note that some authors have incorrectly thought that H could be simply given by $(T_{n(y)}M)^T$; this is not true for the operators $T_{e_3(x)}$ and $(T_{n(y)}\cdot)^T$ do not commute when applied to Mindlin's Green's tensor M. We verified this using a symbolic computer software. Actually, this lack of a commutativity property can be understood on simple examples. We discuss three such simple examples in this paper. Steketee was the first author to offer a correct approach on how to compute Green's tensor H; see [6]. Interestingly, he was able to give a full solution only in Fourier space, and he was able to complete his computation in section 7 of his paper [6] in only one particular case.

We now outline the contents of this paper. In section 2 we present our method for computing Green's tensor H. We do not provide any explicit calculations. They are a good order of magnitude more complex than those of Mindlin's because we have to start from the derivative of Kelvin's tensor. It was actually possible for us to perform this calculation thanks to the use of a symbolic calculus software. We indicate the form of the final solution in the appendix. In effect, we are able to provide relatively concise formulas for H only on the surface $x_3 = 0$. For $x_3 < 0$, the simplest form for H is too lengthy to appear in this paper. Note, however, that this formula for H is still malleable using a symbolic calculus software, and it can then be turned into any computer language code. We also demonstrate in section 2 how our Green's tensor relates to two-dimensional (2D) linear elasticity in a half plane. Assuming that displacements occur only in one direction, we are able to recover Green's scalar function in the lower half plane with zero Neumann condition on the surface. In section 3 we explain why under some decay and growth condition, at infinity and near singular points, our Green's tensor is unique, and we use this uniqueness result to verify our (long!) calculation for H. We also include in section 3 a paragraph aimed at understanding why past attempts at computing Green's tensor H were erroneous and why discrepancies were not picked up on numerical data. In section 4 we use our tensor H for the explicit numerical computation of surface displacement fields due to a slip on a crack, or fault, beneath the surface. We note that the exact solution given by $u = \frac{1}{2}\int_\Gamma Hg$ might require a costly computation, which is undesirable in applications where such a direct computation would have to be iterated a large number of times. We found a way to obtain an approximate field $u(x_1, x_2, 0)$ based on asymptotics that just assume that (x_1, x_2) is some distance away from the fault Γ. We also evaluate in section 4 the error incurred in making that approximation. We then discuss in that same section an interesting symmetry property, valid for deep faults.

2. Assembling Green's tensor *H*.

We start from the well-known Kelvin Green's tensor G given by (4). Let $n(y)$ be a y dependent normal direction. We define a double layer potential by setting

$$\tilde{G}(x,y,n) = (T_{n(y)}G(x,y))^T. \tag{19}$$

2.1. The image method. The image method consists of combining $\tilde{G}(x,y,n)$ with terms from

$$(T_{\overline{n}(y)}G(x,\overline{y}))^T,$$

where $\overline{n} = (n_1, n_2, -n_3)$ and $\overline{y} = (y_1, y_2, -y_3)$, in such a way to obtain vanishing traction on the plane $x_3 = 0$, along the x_1 and x_2 directions. More precisely, set

$$\begin{aligned}\tilde{\tilde{G}}_{ij}(x,y) &= \tilde{G}_{ij}(x,y,n) + \tilde{G}_{ij}(x,\overline{y},\overline{n}) \text{ for } 1 \le i \le 3, \quad 1 \le j \le 2,\\ \tilde{\tilde{G}}_{i3}(x,y) &= \tilde{G}_{i3}(x,y,n) - \tilde{G}_{i3}(x,\overline{y},\overline{n}) \text{ for } 1 \le i \le 3.\end{aligned}$$

If g is a smooth vector field on Γ, then $u(x) = \frac{1}{2}\int_\Gamma \tilde{\tilde{G}}(x,y)g(y)$ satisfies (15), (17), and (18), has finite elastic energy, and decays at infinity. However, (16) is only partially satisfied; only the first two components of $T_{e_3}u$ are zero at $x_3 = 0$. Consequently, to find Green's function H, we need to solve three Boussinesq problems with data

$$-F_j := T_{e_3(x)}\tilde{\tilde{G}}_{3j}(x,y)|_{x_3=0}, \quad j = 1,2,3, \tag{20}$$

to compensate for the nonzero $T_{e_3}u \cdot e_3$ term on the surface $x_3 = 0$.

2.2. A Fourier method for solving Boussinesq problems. We find it most efficient to follow the method outlined by Steketee [6]. Recall the definition of Boussinesq half space elasticity problems: find v of finite elastic energy in $\mathbb{R}^{3-}$ such that

$$\mu\Delta v + (\lambda+\mu)\nabla \operatorname{div} v = 0 \text{ in } \mathbb{R}^{3-}, \tag{21}$$

$$T_{e_3}u \cdot e_i = 0 \text{ on the surface } x_3 = 0, \quad i = 1,2, \tag{22}$$

$$T_{e_3}u \cdot e_3 = -F \text{ on the surface } x_3 = 0. \tag{23}$$

The solution to (21)–(23) can be sought in terms of a Galerkin vector $(0,0,\gamma)$, where γ is biharmonic in the lower plane $x_3 < 0$. Indeed, if a displacement field v is in the form

$$v = \left(-\alpha\partial_1\partial_3\gamma,\ -\alpha\partial_2\partial_3\gamma,\ \left[(1-\alpha)\partial_3\partial_3 + \partial_1^2 + \partial_2^2\right]\gamma\right), \text{ where } \alpha = \frac{\lambda+\mu}{\lambda+2\mu}, \tag{24}$$

then it satisfies (21). Note that $\frac{1}{2} < \alpha < 1$. The stress vector $T_{e_3}v$ simplifies as

$$\begin{aligned}\sigma_{13}(v) &= \mu\partial_1(\Delta - 2\alpha\partial_3\partial_3)\gamma,\\ \sigma_{23}(v) &= \mu\partial_2(\Delta - 2\alpha\partial_3\partial_3)\gamma,\\ \sigma_{33}(v) &= \partial_3((\lambda(1-\alpha)+2\mu)\Delta - 2\alpha\mu\partial_3\partial_3)\gamma.\end{aligned}$$

Starting from the problem

$$\Delta^2\gamma = 0 \text{ in } x_3 < 0, \tag{25}$$

$$\sigma_{13}(v) = \sigma_{23}(v) = 0 \text{ on } x_3 = 0, \tag{26}$$

$$\sigma_{33}(v) = -F \text{ on } x_3 = 0, \tag{27}$$

$$\gamma \text{ is bounded as } x_3 \to -\infty, \tag{28}$$

we perform a Fourier transform of γ in the first two variables only. A long calculation leads to

$$\hat{\gamma}(\xi, x_3) = \left(-\frac{1}{2}\,\frac{(-1+2\,\alpha)}{|\xi|^3 \alpha\,\pi^3} + \frac{x_3}{\pi^2 |\xi|^2} \right) \hat{F} \frac{1}{8\,(\mu+\lambda)\,(\alpha-1)} e^{2\,\pi\,|\xi| x_3}, \tag{29}$$

where Fourier transforms are given by

$$\hat{F}(\xi_1, \xi_2) = \iint e^{2\pi i (x_1 \xi_1 + x_2 \xi_2)} F(x_1, x_2) dx_1 dx_2.$$

$\hat{v}$ can be now found according to formula (24). Finally, applying an inverse Fourier transform to $\hat{v}$ will give a finite energy, decaying at infinity, vector field v which satisfies the elasticity equations in $\mathbb{R}^{3-}$ and whose stress vector at the surface $x_3 = 0$ satisfies (26) and (27).

2.3. The Boussinesq solution in our case. Can the vector field v defined in the previous paragraph be given in a closed form? The answer is yes if F is the force coming from adding to Kelvin's tensor its image above the plane $x_3 = 0$ and computing, for each column, the resulting vertical traction at $x_3 = 0$; this will yield Mindlin's tensor. In our case the forcing term F is given by (20); this case involves more terms, of higher degree, compared to those appearing in the derivation of Mindlin's solution. Steketee was able to carry out such a computation in section 7 of his paper [6] in only one particular case. At the time of his work, symbolic algebra software was not available, and this greatly limited investigators' ability to manipulate large expressions. Going back to our work, let us give, for illustration, the expression of F_1, the forcing term for the first Boussinesq problem that we need to solve. F_1 is the ratio of

$$\begin{aligned} \big((2\,\mu+\lambda)\,\mu^2 {x_1}^4 + \left((\mu+2\,\lambda)\,\mu^2 {x_2}^2 - {y_3}^2\,(13\,\lambda+11\,\mu)\,\mu^2 \right) {x_1}^2 + (\lambda-\mu)\,\mu^2 {x_2}^4 \\ + {y_3}^2\,(\mu+2\,\lambda)\,\mu^2 {x_2}^2 + {y_3}^4\,(2\,\mu+\lambda)\,\mu^2 \big) n_1 \\ + \left(3\,\mu^3 x_2 {x_1}^3 + \left(3\,\mu^3 {x_2}^3 - 3\,{y_3}^2\,(4\,\mu+5\,\lambda)\,\mu^2 x_2 \right) x_1 \right) n_2 \\ + \left(-3\,y_3\,(\mu+\lambda)\,\mu^2 {x_1}^3 + \left(-3\,y_3\,(\mu+\lambda)\,\mu^2 {x_2}^2 + 12\,{y_3}^3\,(\mu+\lambda)\,\mu^2 \right) x_1 \right) n_3 \end{aligned}$$

to

$$\left({x_1}^2 + {x_2}^2 + {y_3}^2 \right)^{7/2} \pi\,\mu\,(2\,\mu+\lambda)\,.$$

To compute v given by (24)–(29), for $F = F_j$, $j = 1, 2, 3$, we first computed the Fourier transform $\hat{F}$, which we multiplied by adequate terms to find $\hat{\gamma}$ according to formula (29). We then proceeded to compute the inverse Fourier transform of $\hat{\gamma}$, from which the expression for v, solution to (21)–(23), follows from (24). Corresponding double integrals were evaluated in polar coordinates. A symbolic calculation software had to be used due to the length and complexity of the expressions involved. Of particular importance for polar angle integration was the use of the following integrals:

$$\int_0^{2\pi} e^{iz\cos\theta} \cos p\theta d\theta = (i)^p 2\pi J_p(z), \tag{30}$$

where p is an integer and J_p is the Bessel function of the first kind of order p. This formula can be derived from formula (9.1.21) in [1]. As to integration in radius, a formula for

$$\int_0^\infty \frac{J_q(2\pi\rho r)\rho^p}{(\rho^2 + y_3^2)^{\frac{7}{2}}} d\rho, \quad p = 1, \dots, 5, \quad q = 0, \dots, 4 \quad y_3 < 0, \quad r > 0, \tag{31}$$

was needed. For compuation of inverse Fourier transforms the following was also needed

$$\int_0^\infty e^{2\pi r x_3} J_p(2\pi\rho r) r^q dr \quad p = 0, \dots, 4 \quad q = 0, \dots, 2, \quad x_3 < 0, \quad \rho > 0, \tag{32}$$

Closed forms for (31), (32), albeit intricate, can be computed. The final expression for H is intricate and involves many terms. We discuss it in the appendix.

2.4. Symmetry properties. We first notice that Green's tensor H depends on x_1, y_1, x_2, and y_2 only through $x_1 - y_1$ and $x_2 - y_2$.

2.4.1. Switching the first two coordinates. Let (t_1, t_2, t_3) be a vector in $\mathbb{R}^3$. Denote by $u = (u_1, u_2, u_3)$ the vector $H(t_1, t_2, t_3)$. (u_1, u_2, u_3) is a function of $x_1 - y_1$, $x_2 - y_2$, $x_3 \leq 0$, $y_3 \leq 0$, (n_1, n_2, n_3), (t_1, t_2, t_3), $\lambda > 0$, and $\mu > 0$. The following relations hold:

$$u_1(x_1 - y_1, x_2 - y_2, n_1, n_2, t_1, t_2) = u_2(x_2 - y_2, x_1 - y_1, n_2, n_1, t_2, t_1), \tag{33}$$

$$u_3(x_1 - y_1, x_2 - y_2, n_1, n_2, t_1, t_2) = u_3(x_2 - y_2, x_1 - y_1, n_2, n_1, t_2, t_1). \tag{34}$$

Physically, they express that the first and the second coordinate play the same role for the displacement vector Ht.

2.4.2. Switching the normal vector *n* and the source vector *t*. Computations indicate that the coordinates of Ht depend on the normal vector n and on t only through

$$n_1 t_1, \quad n_2 t_2, \quad n_3 t_3, \quad n_1 t_2 + n_2 t_1, \quad n_1 t_3 + n_3 t_1, \quad n_2 t_3 + n_3 t_2,$$

and, consequently,

$$u(n, t) = u(-n, -t), \tag{35}$$

and

$$u(n, t) = u\left(\frac{t}{|t|}, n|t|\right). \tag{36}$$

Symmetry property (35) corresponds to reversing the orientation on the fault Γ. Symmetry property (36) expresses that the displacements caused by a concentrated slip of vector t, on an infinitesimal fault of normal vector n, are the same as the displacements caused by a concentrated slip of vector $n|t|$, on an infinitesimal fault of normal vector $t/|t|$. We will give in a subsequent section another interpretation of this symmetry property valid for deeper faults of finite size.

2.5. Relation to 2D elasticity. Two dimensional scalar elasticity is the limit model of general elasticity as boundary conditions are constant along a given direction, say, x_2, and displacements take place only in the x_2 direction. We assume here that the fault Γ introduced earlier is linear and infinite in the x_2 direction; thus, a normal vector to Γ satisfies $n_2 = 0$. We then integrate the vector He_2 in x_2 in the range $(-\infty, \infty)$. A long computation leads, after simplification, to the vector

$$\left(0, \frac{(x_1 - y_1)\left({x_3}^2 + {y_3}^2 + (x_1 - y_1)^2\right) n_1 + y_3\left({x_3}^2 - {y_3}^2 - (x_1 - y_1)^2\right) n_3}{\pi\left((x_1 - y_1)^2 + (x_3 - y_3)^2\right)\left((x_1 - y_1)^2 + (x_3 + y_3)^2\right)}, 0\right). \tag{37}$$

Next, we show that this is in agreement with the 2D model. It is known that

$$g(x_1,y_1,x_3,y_3) = -\frac{1}{4}\,\frac{\ln\left((x_1-y_1)^2+(x_3-y_3)^2\right)}{\pi} - \frac{1}{4}\,\frac{\ln\left((x_1-y_1)^2+(x_3+y_3)^2\right)}{\pi}$$

is the half plane $x_3<0$ Green's function for the 2D Laplacian in the x_1, x_3 coordinates that satisfies the zero Neumann condition $\partial_{x_3} g = 0$ at $x_3 = 0$. Note that $\partial_{x_3}\partial_{y_1} g$ and $\partial_{x_3}\partial_{y_3} g$ are also zero at $x_3 = 0$. Computing

$$\partial_{y_1} g\, n_1 + \partial_{y_3} g\, n_3,$$

we find exactly the second coordinate of the vector given in (37).

Remark. The scalar operators ∂_{x_3}, ∂_{y_1}, and ∂_{y_3} do commute. However, we wish to emphasize that, in 3D elasticity, the argument cannot be as simple since the traction operators $T_{e_3(x)}$ and $(T_{e_j(y)}\cdot)^T$ are not commutative.

3. Verification.

We were able to devise a way of verifying our long computation resulting in a closed form for the tensor H.

3.1. A uniqueness theorem.

THEOREM 3.1. *There is a unique tensor $A(x,y)$, for x and y in $\mathbb{R}^{3-}$, whose entries are measurable functions in (x,y) and which satisfies the following equations:*

$$\mu\Delta_x A(x,y) + (\lambda+\mu)\nabla_x \mathrm{div}_x A(x,y) = 0 \text{ in } \mathbb{R}^{3-} \text{ if } x \neq y, \tag{38}$$

$$T_{e_3(x)} A(x,y) = 0 \text{ on the surface } x_3 = 0 \text{ if } y_3 < 0, \tag{39}$$

$$|A(x,y)| \leq \frac{C}{|x|} \text{ as } y \text{ is fixed and } |x| \to \infty, \tag{40}$$

$$|\nabla_x A(x,y)| \leq \frac{C}{|x|^2} \text{ as } y \text{ is fixed and } |x| \to \infty, \tag{41}$$

$$|A(x,y) - \tilde{G}(x,y,n)| \leq C \text{ as } y \text{ is fixed and } x \to y, \tag{42}$$

$$|\nabla_x (A(x,y) - \tilde{G}(x,y,n))| \leq C \text{ as } y \text{ is fixed and } x \to y, \tag{43}$$

where C is a constant independent of x and $\tilde{G}$ is defined by (19).

Proof. It is clear that our Green's tensor $H(x,y)$ satisfies conditions (38)–(43). To show uniqueness, assume that A_1 and A_2 satisfy (38)–(43) and set $\overline{A} = A_1 - A_2$. Then as $\overline{A}(x,y)$ and $\nabla_x \overline{A}(x,y)$ are bounded for x and y, $x \neq y$, in $\mathbb{R}^{3-}$, $\overline{A}$ satisfies the elasticity equations everywhere in $\mathbb{R}^{3-}$. Next, if $\overline{A}_j$ is the jth column of $\overline{A}$, let B_R be the subset of $\mathbb{R}^3$ defined by $\{x : |x| \leq R \text{ and } x_3 \leq 0\}$. Applying conditions (38)–(41) and integrating by parts,

$$\int_{B_R} \varepsilon\left(\overline{A}_j\right) : \sigma\left(\overline{A}_j\right) = \int_{\partial B_R} T_n\left(\overline{A}_j\right)\overline{A}_j.$$

Applying boundary condition (39) and decay at infinity (40)–(41), we find that

$$\int_{\mathbb{R}^{3-}} \varepsilon\left(\overline{A}_j\right) : \sigma\left(\overline{A}_j\right) = 0.$$

$\overline{A}_j$ is then a rigid displacement which, due to the imposed decay at infinity, must be zero. ◻

3.2. Application to verifying our calculation for the tensor $\boldsymbol{H}$. Equations (38) and (39) were verified directly. Conditions (40) and (41) are satisfied with an additional order of magnitude for H, that is,

$$|H(x,y)| \leq \frac{C}{|x|^2} \text{ as } y \text{ is fixed and } |x| \to \infty,$$
$$|\nabla_x H(x,y)| \leq \frac{C}{|x|^3} \text{ as } y \text{ is fixed and } |x| \to \infty.$$

More precisely, each entry of $H(x,y)$ is asymptotically equivalent as $|x| \to \infty$, to the ratio of some homogeneous polynomial of degree 11 in $x_1, x_2, x_3, \sqrt{x_1^2+x_2^2}$, and $\sqrt{x_1^2+x_2^2+x_3^2}$ to $(x_1^2+x_2^2)^3(x_1^2+x_2^2+x_3^2)^{\frac{7}{2}}$.

H also satisfies conditions (42) and (43); they express that $H(x,y)$ and $\tilde{G}(x,y,n)$ have the same type of singularity as y approaches x.

3.3. The problem with past attempts at finding Green's tensor $\boldsymbol{H}$. Some authors have incorrectly thought that H could be simply given by $(T_{n(y)}M)^T$; this is not true for the operators $T_{e_3(x)}$ and $(T_{n(y)}\cdot)^T$ do not commute when applied to Mindlin's Green's tensor M. We verified this fact using a symbolic computer software; note, however, that this lack of a commutativity property can be understood on simple examples. We discuss such simple examples below.

Example 1. For the vector $v(x,y) = (0,0,x_1y_3)$, $T_{e_3(x)}v = (\mu y_3, 0, 0)$. Let A be the 3×3 matrix (v,v,v); that is, each column of A is v. The first column of $(T_{e_3(y)}T_{e_3(x)}A)^T$ is computed to be equal to (μ^2,μ^2,μ^2), while the first column of $T_{e_3(x)}(T_{e_3(y)}A)^T$ is $(0,0,0)$.

Example 2. The following vector field has zero traction derivative in x at the surface $x_3 = 0$:

$$v(x,y) = \left(-\frac{(2\,\mu+\lambda)\,(x_1-y_1)^2}{\lambda}, 0, (x_1-y_1)\,(x_3-y_3) + (x_1-y_1)\,(x_3+y_3)\right).$$

In other words, calculations indicate that $T_{e_3(x)}v = (0,0,0)$ at $x_3 = 0$. Let A be the 3×3 matrix (v,v,v). A computation indicates that $T_{e_3(x)}A$ does not depend on y. Accordingly, $(T_{e_3(y)}T_{e_3(x)}A)^T$ is zero. The first column of $(T_{e_3(y)}A)^T$ is $(-2\mu x_3, -2\mu x_3, -2\mu x_3)$, and, thus, the first column of $T_{e_3(x)}(T_{e_3(y)}A)^T$ is $(-2\mu^2, -2\mu^2, -2\mu(2\mu+\lambda))$.

Example 3. We computed Mindlin's tensor, following a method that proceeds along the same lines as those sketched earlier in this present paper for the calculation of our Green's tensor H: we started from Kelvin's tensor G, which we reflected about the plane $x_3 = 0$, and finally three Boussinesq problems had to be solved. The case of Mindlin's tensor is computationally less intensive, as it involves terms of smaller degree than that of terms involved in the computation of Green's tensor H. Nevertheless, we found it worthwhile to utilize a symbolic computation software for two reasons: first, this certainly reduces chances of obtaining a wrong result; and, second, it makes it more convenient for verifying the final answer. Verification was made by validating elasticity equations, and decay at infinity, and order of growth near singularities and checking traction free boundary conditions.

In the end we found that although $T_{e_3(x)}M(x,y)$ is zero at $x_3 = 0$, $T_{e_3(x)}$ $(T_{e_3(y)}M(x,y))^T$ is not zero at $x_3 = 0$, whereas previously $M(x,y)$ was Mindlin's tensor. The reason why this was not picked up in previous studies in natural sciences may lie in the following observation: $M(x,y)$ is homogeneous in (x,y) of degree -1, and, consequently, $T_{e3(x)}(T_{e3(y)}M(x,y))^T$ is homogeneous in (x,y) of degree -3. If this tensor is evaluated for y_3 at some depth d beneath the surface $x_3=0$, the error in surface traction $T_{e3(x)}(T_{e3(y)}M(x,y))^T$ decays as d^{-3}, which is one order of magnitude smaller than displacements on the surface. In other words, using $T_{e3(y)}M(x,y)$ for computing surface displacements due to a slip on a fault may lead to gross discrepancies, only if that fault is shallow and for those surface points close enough to the fault.

4. Application: Computations of displacement fields caused by a slip along a fault. In this section we use Green's tensor H introduced in this paper to compute displacement fields u due to a slip on a fault Γ, in the half space $x_3<0$, with traction free conditions on the surface $x_3=0$. In other words, u satisfies (15)–(18). This equation for u plays an important role in geophysics models. It may be used in the study of quasi-static displacements near a fault during a "silent earthquake" episode. Accounts of silent earthquakes in subduction zones near Japan [12] and New Zealand, Alaska, and Mexico [13, 11] were recently reported in the literature. This equation for u may also be used to study the nucleation phase (occurring after destabilization of faults and before the onset of seismic waves) for dynamically active faults. The earthquake nucleation phase, which precedes dynamic rupture, was uncovered by detailed seismological observations [14, 16] and identified in laboratory experiments [15, 17].

Typical length scales attached to faults observed in nature range from 0 to 100 kilometers for depth and 1 to 100 kilometers for length. During destabilization, slip on faults are on the order of 1 to 100 meters. Accordingly, in all numerical simulations in this section, we choose one kilometer to be the unit length for spatial coordinates, while surface displacements are given in meters. The Lamé coefficients are set to be $\lambda=\mu=1$, a common choice in geophysics. This choice of λ and μ is not necessary for our computations to run faster or more accurately. It was rather made in order to facilitate comparisons to other pieces of work.

4.1. Exact field in two numerical examples. Recall that the displacement field u due to a slip g on a fault Γ, in the half space $x_3<0$, with traction free conditions on the surface $x_3=0$, that is, the solution to problem (15)–(18), can be expressed as $u=\frac{1}{2}\int_\Gamma Hg$. We compute in this section the displacement u on the surface $x_3=0$ using this integral formula in two examples.

These two examples involve the same fault geometry: Γ is contained in the plane normal to the vector $(1,0,1)$ and is bounded by an ellipse centered at $(0,0,-2)$. In local coordinates the ellipse has the equation $\tilde{y_1}^2+(\tilde{y_2}/5)^2=1$, where local coordinates are related to the original coordinates by

$$(44)\qquad y=\begin{pmatrix} s & 0 & s \\ 0 & 1 & 0 \\ -s & 0 & s \end{pmatrix}\tilde{y}+\begin{pmatrix} 0 \\ 0 \\ -2 \end{pmatrix}, \quad s=\frac{1}{\sqrt{2}}.$$

A sketch of this cross section appears in Figure 1.

In the first example slip occurs only in the e_2 direction. In local coordinates the slip was picked to be $g=C_1\sqrt{1-\tilde{y_1}^2-(\tilde{y_2}/5)^2}e_2$, where the constant C_1 was adjusted in such a way that the total slip $\int_\Gamma g$ be of norm 1; see Figure 2 for a plot of resulting surface displacements. We wish to emphasize that this choice of slip g is not arbitrary; it corresponds to the expected dominant profile of slip occurring

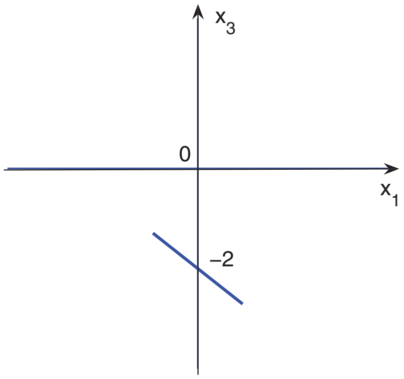

FIG. 1. *A cross section of the fault Γ involved in the first two numerical examples. The cross section is in the plane $x_2 = 0$. The small axis of the ellipse appears as the line segment in the cross section plane.*

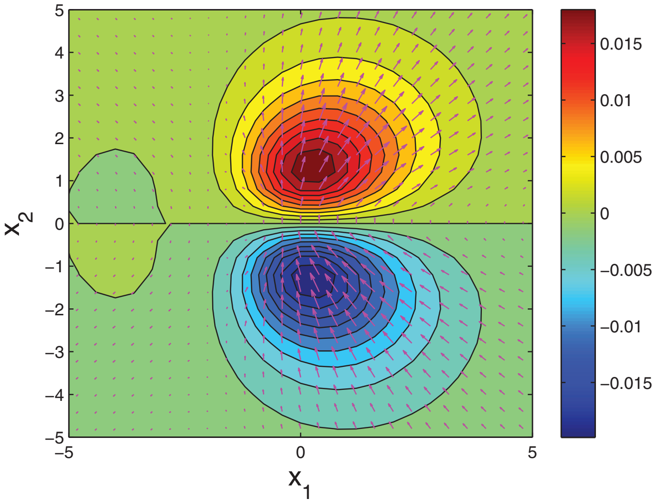

FIG. 2. *Computed surface displacement for the elliptic geometry and slip in the e_2 direction considered in the first example. In local coordinates the slip was picked to be $g = C_1\sqrt{1 - \tilde{y_1}^2 - (\tilde{y_2}/5)^2}e_2$, where the constant C_1 was adjusted in such a way that the total slip $\int_\Gamma g$ be of norm 1. The e_1 and e_2 components of $u(x_1, x_2)$ are represented as a planar vector field using arrows, while the e_3 component is sketched on the same graph using a color contour map.*

during the destabilization process of a fault. A complete theory for that process has been studied in the 2D case; see [2], [8], [9]. In the 3D case a complete theory is still being investigated, but analysis of relevant hypersingular operators suggests that slip occurring during the destabilization process of a fault decays toward the edge of the fault as the square root of the distance to this edge.

In the second example the slip does not have constant direction and is picked to be, in local coordinates, $g = C_2(-2m^{3/2}, m^{1/2}, 2m^{3/2})$, where $m = 1 - \tilde{y_1}^2 - (\tilde{y_2}/5)^2$ and the constant C_2 was adjusted, as previously, in such a way that the total slip $\int_\Gamma g$ still be of norm 1; see Figure 3 for a plot of resulting surface displacements.

4.2. Approximate field. Solving (15)–(18) by integrating $u = \frac{1}{2}\int_\Gamma Hg$ might be costly in number of operations, which is undesirable in applications where such a

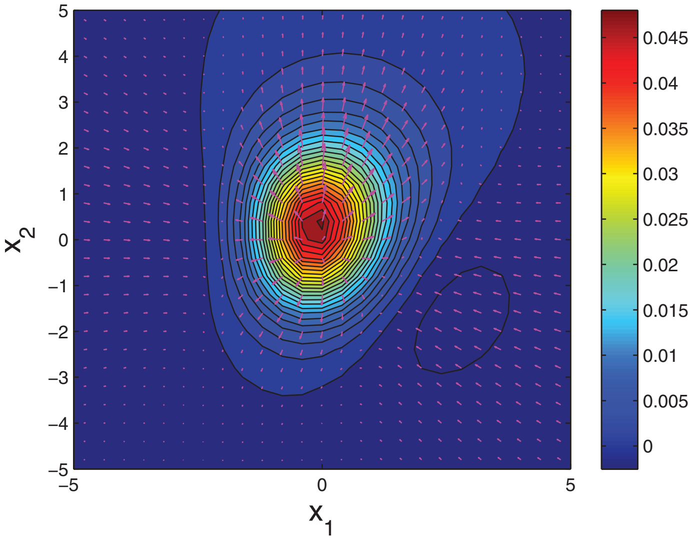

FIG. 3. *Computed surface displacements in the second example. The geometry of the fault is the same as in the first example; however, the slip does not in this case have constant direction and is picked to be, in local coordinates,* $g = C_2(-2m^{3/2}, m^{1/2}, 2m^{3/2})$*, where* $m = 1 - (\tilde{y_1}/5)^2 - \tilde{y_2}^2$ *and the constant* C_2 *was adjusted in such a way that the total slip* $\int_\Gamma g$ *be of norm* 1.

direct computation would have to be iterated a large number of times. We found a way to obtain a reasonable approximation to the field $u(x_1, x_2, 0)$ based on asymptotics that just assume that (x_1, x_2) is some distance away from the fault Γ. Suppose that the fault Γ is centered at the point (a, b, c) where $c < 0$. To obtain a simpler formula for the surface displacement $u(x_1, x_2, 0)$ we now assume that either the surface point (x_1, x_2) is far enough from (a, b) or $|c|$ is large enough. Thus, we may write

$$\begin{aligned} H(x_1, x_2, 0, y_1, y_2, y_3) &= H(x_1 - y_1, x_2 - y_2, 0, 0, 0, y_3) \\ &= H(x_1 - a, x_2 - b, 0, 0, 0, c) + O\left(\frac{1}{(x_1^2 + x_2^2 + c^2)^{3/2}}\right) \end{aligned}$$

as long as (y_1, y_2, y_3) remains on the fault Γ. From there, integrating over Γ,

$$u(x_1, x_2, 0) \simeq H(x_1 - a, x_2 - b, 0, 0, 0, c)\frac{1}{2}\int_\Gamma g(y_1, y_2, y_3)dy. \tag{45}$$

Setting $(t_1, t_2, t_3) = \frac{1}{2}\int_\Gamma g(y_1, y_2, y_3)dy$, we obtain

$$u(x_1, x_2, 0) \simeq H(x_1 - a, x_2 - b, 0, 0, 0, c)(t_1, t_2, t_3). \tag{46}$$

The vector $t := (t_1, t_2, t_3)$ can be interpreted as half the average slip on Γ times the area of Γ. We will call $2t$ the total slip on Γ.

We now proceed to demonstrate numerically the accuracy of approximation (46). We plot the relative L^2 error incurred in making the approximation (46) against depth for three different geometries in Figure 4. The L^2 error was computed on the surface $x_3 = 0$ in a square $[-10, 10] \times [-10, 10]$. In each case the fault was contained in the plane normal to the vector $(1, 0, 1)$ and passing through the center $(0, 0, c)$, where $|c|$ is the depth. Depth ranged from 2 to 20 in these numerical runs. Slip

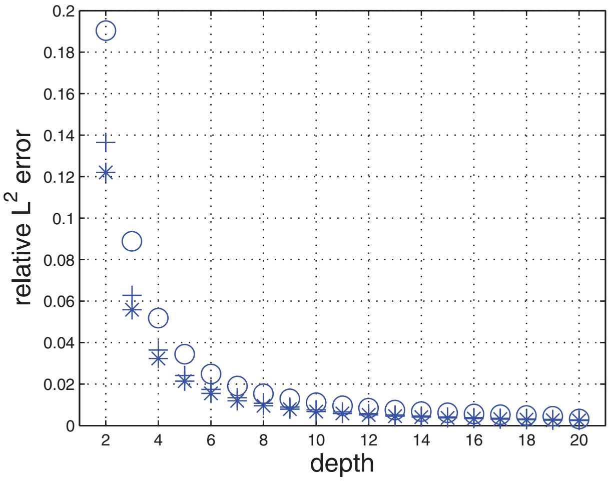

FIG. 4. *The relative L^2 error incurred by making the approximation* (46) *plotted against depth for the three different fault geometries discussed in section* 4.2.

was set to occur in the e_2 direction. Total slip was computed in order to apply formula (46). The plus markers correspond to a square geometry for Γ with edges of length 2. In local coordinates $(\tilde{y_1}, \tilde{y_2})$ centered on the fault, the slip was picked to be $\sqrt{(1-|\tilde{y_1}|)(1-|\tilde{y_2}|)}$. Local coordinates are now related to the original coordinates by

$$y = \begin{pmatrix} s & 0 & s \\ 0 & 1 & 0 \\ -s & 0 & s \end{pmatrix} \tilde{y} + \begin{pmatrix} 0 \\ 0 \\ c \end{pmatrix}, \quad s = \frac{1}{\sqrt{2}}.$$

The star markers correspond to Γ being a circle of radius 1. In local coordinates the slip was picked to be $\sqrt{1-\tilde{y_1}^2-\tilde{y_2}^2}$. The circular markers correspond to an elliptic geometry for Γ. The equation of the ellipse was picked to be, in local coordinates, $\tilde{y_1}^2+(\tilde{y_2}/5)^2=1$. In local coordinates the slip was picked to be $\sqrt{1-\tilde{y_1}^2-(\tilde{y_2}/5)^2}$. The largest error is found for the most shallow faults, that is, for $|c|=2$, and ranges from 12 to 19%, depending on geometry. We sketched the exact and approximated fields for faults at depth 2 in the elliptic geometry case in Figures 2 and 5. It appears that even at that shallow depth the exact and approximated profiles exhibit very similar patterns.

4.3. A symmetry property for deeper faults.

Denote by $\tilde{u}$ the approximate surface displacement obtained by application of asymptotic formula (46). Accordingly, $\tilde{u} = Ht$. The coordinates of Ht are given in the appendix. Recall that symmetry property (35) corresponds to reversing the orientation on the fault Γ. A consequence of symmetry property (36) is that, for deeper faults, a total slip t on a planar fault Γ of normal vector n produces approximately the same surface displacements as in the "reversed case" of a total slip $n|t|$ on a planar fault Γ of normal vector $t/|t|$. Of course, this equivalence does not hold for shallow faults at surface points close to the fault.

Due to the expression for $H(x_1-a, x_2-b, 0, 0, 0, c)$ it turns out that $u(x_1, x_2)$ is

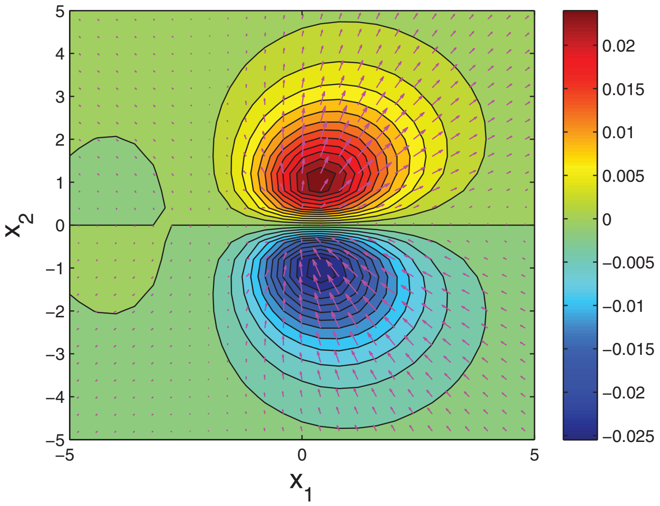

FIG. 5. *Approximate surface displacement for the elliptic geometry from Figure* 4 *at depth* 2. *The approximation was obtained by applying formula* (46). *The computed exact field is sketched in Figure* 2.

a function that depends on n and t only through s_0, s_1, s_2, s_3, and s_4 defined by

$$s_0 := n_1t_1 + n_2t_2, \tag{47}$$

$$s_1 := n_2t_3 + n_3t_2, \tag{48}$$

$$s_2 := n_1t_3 + n_3t_1, \tag{49}$$

$$s_3 := n_1t_2 + n_2t_1, \tag{50}$$

$$s_4 := n_1t_1 - n_2t_2. \tag{51}$$

Thus, one might wonder whether additional symmetries akin to (36) hold. The following proposition explains in detail how s_0, s_1, s_2, s_3, and s_4 relate to n and t if n and t are perpendicular. Note that, in the destabilization process of faults, previous studies have shown that the slip is tangential to the fault, so n and t are indeed perpendicular in that case.

PROPOSITION 4.1. *Assume that* $n = (n_1, n_2, n_3)$ *and* $t = (t_1, t_2, t_3)$ *are two orthogonal vectors in space such that* $|n| = 1$ *and* $|t| \neq 0$. *Given* s_0, s_1, s_2, s_3, *and* s_4 *defined by* (47)–(51) *exactly four different pairs* (n, t) *can be reconstructed. If* $(\tilde{n}, \tilde{t})$ *is one reconstructed pair, the other three are* $(-\tilde{n}, -\tilde{t})$, $(\frac{\tilde{t}}{|\tilde{t}|}, \tilde{n}|\tilde{t}|)$, *and* $(-\frac{\tilde{t}}{|\tilde{t}|}, -\tilde{n}|\tilde{t}|)$.

Proof. Form the matrix

$$D = \begin{pmatrix} 2n_1t_1 & s_3 & s_2 \\ s_3 & 2n_2t_2 & s_1 \\ s_2 & s_1 & 2n_3t_3 \end{pmatrix},$$

and notice that $D = nt^T + tn^T$. Denote $t' = t/|t|$ and $D' = D/|t| = nt'^T + t'n^T$. Since n and t' are orthogonal of norm 1, we have that $D't' = n$ and $D'n = t'$ from where it follows that $D'(n - t') = -(n - t')$ and $D'(n + t') = n + t'$. We conclude that $n - t'$ and $n + t'$ are eigenvectors for D for the respective eigenvalues $-|t|$ and $|t|$. Notice also that $n \times t$ is an eigenvector for the eigenvalue 0.

To reconstruct n and t, as D is real symmetric and has zero trace and determinant, we may denote by $-\alpha, 0, \alpha$ (with $\alpha > 0$) the eigenvalues of D.

To find a pair (n, t) from the symmetric matrix D we have to find two vectors v_1 and v_2 of norm $\sqrt{2}$ such that $Dv_1 = -\alpha v_1$ and $Dv_2 = \alpha v_2$. As D is symmetric v_1 and v_2 are orthogonal. If we then set $n = \frac{v_1 - v_2}{2}, t' = \frac{v_1 + v_2}{2}$, and $t = \alpha t'$, it is clear that the coordinates of (n, t) will satisfy (47)–(51) and so will the coordinates of the other pairs $(-n, -t), (\frac{t}{|t|}, n|t|)$, and $(-\frac{t}{|t|}, -n|t|)$.

Finally, we show that these are the only four solutions. This is because a basis for the eigenspace attached to the eigenvalue $-\alpha$ containing vectors of length $\sqrt{2}$ can only be given by either v_1 or $-v_1$, and a basis for the eigenspace attached to the eigenvalue α containing vectors of length $\sqrt{2}$ can only be given by either v_2 or $-v_2$; this gives a total number of four combinations. □

Remark. Assume that s_0, s_1, s_2, s_3, and s_4 are any five real numbers. Can we find two orthogonal vectors n and t such that $|n| = 1$ and (47)–(51) are satisfied? Forming the matrix

$$E = \begin{pmatrix} s_0 + s_4 & s_3 & s_2 \\ s_3 & s_0 - s_4 & s_1 \\ s_2 & s_1 & -2s_0 \end{pmatrix}$$

this is possible if and only if $\det(E) = 0$. Indeed, the condition $\det(E) = 0$ is necessary since $E(n \times t) = 0$. Conversely, as E is real and symmetric and its trace is zero, if $\det(E) = 0$, the eigenvalues of E must be $-\alpha, 0, \alpha$ for some $\alpha > 0$ unless $s_0 = s_1 = s_2 = s_3 = s_4 = 0$, in which case $E = 0$. The assertion then follows from the previous proposition.

To illustrate numerically the symmetry property, we computed the surface displacements $u(x_1, x_2)$ arising from the slip on the fault Γ of equation $\tilde{y_1}^2 + (\tilde{y_2}/5)^2 = 1$, in local coordinates, at depth $c = -2$ and normal to the vector $(\frac{1}{\sqrt{2}}, 0, \frac{1}{\sqrt{2}})$, where new and original coordinates are again related by (44). We imposed on that fault the slip $C_1(-2m^{3/2}, m^{1/2}, 2m^{3/2})$, where $m = 1 - \tilde{y_1}^2 - (\tilde{y_2}/5)^2$, in local coordinates, and the constant C_1 was computed such that the norm of the total slip $2t$ was 1. The computed profile appears in Figure 3.

Next, we proceeded to find the surface displacements for a reversed geometry, that is, the surface displacements $u'(x_1, x_2)$ arising from the slip on the fault Γ of equation $\tilde{y_1}^2 + (\tilde{y_2}/5)^2 = 1$, in local coordinates, at depth $c = -2$ and normal to the vector t with imposed slip $C_2((m/2)^{1/2} + 2m^{3/2})(1, 0, 1)$, where $m = 1 - \tilde{y_1}^2 - (\tilde{y_2}/5)^2$, in local coordinates, and the constant C_2 was computed such that the norm of the total slip was 1. The computed profile for $u'(x_1, x_2)$ appears in Figure 6.

We also computed the surface displacements $u''(x_1, x_2)$ obtained by application of asymptotic formula (46). The computed profile for $u''(x_1, x_2)$ appears in Figure 7.

Finally, we compared relative differences in the L^2 norm for u, u', and u'' where the surface domain of integration is $[-10, 10] \times [-10, 10]$. For example, the relative difference of u to u' is $\sqrt{\int |u - u'|^2 / \int |u|^2}$, where all integrals are over $[-10, 10] \times [-10, 10]$. We computed these relative differences for two depths $c = -2$ and $c = -20$, and we placed them in Table 1.

5. Conclusion. We have computed in this paper a double layer Green's tensor for linear elasticity in half space, with traction free conditions on the surface. Our approach starts from Kelvin's free space tensor: we first took a traction derivative, and then we made a long calculation whose goal was to derive additional terms accounting for the traction free boundary condition. We indicated the form of the final solution in the appendix. In effect, we are able to provide relatively concise formulas for H

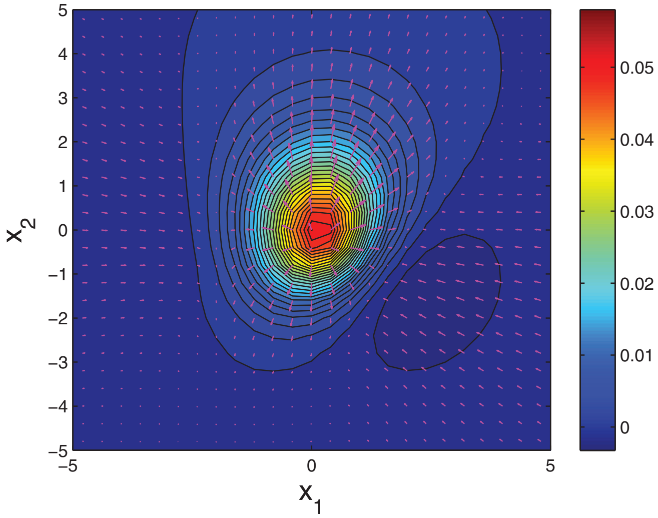

FIG. 6. *Surface displacements $u'(x_1, x_2)$ arising from the slip on the fault* Γ *of equation* $\tilde{y_1}^2 + (\tilde{y_2}/5)^2 = 1$*, in local coordinates, at depth* $c = -2$ *and normal to the vector* t *with imposed slip* $C_2((m/2)^{1/2} + 2m^{3/2})(1, 0, 1)$*, where* $m = 1 - (\tilde{y_1}/5)^2 - \tilde{y_2}^2$*, in local coordinates, and the constant* C_2 *is a computed constant ensuring that the norm of the total slip be* 1*. We observe that the displacement pattern is similar to the one plotted in Figure* 3*.*

only on the surface $x_3 = 0$. For $x_3 < 0$, the simplest form for H is too lengthy, but still manageable on a computer system.

We also showed that simply starting from Mindlin's half space tensor and then taking a traction derivative leads to an incorrect result: the traction free condition on the surface is lost. This is due to the fact that traction operators do not commute. We illustrated this lack of commutativity on simple examples.

We demonstrated how our Green's tensor relates to 2D linear elasticity in a half

Table 1

Relative differences in the L^2 norm for u, u', and u'' where the domain of integration is $[-10,10] \times [-10,10]$. For example, the relative difference of u to u' is $\sqrt{\int |u-u'|^2 / \int |u|^2}$, where all integrals are over $[-10,10] \times [-10,10]$. We computed these relative differences for two depths $c=-2$ and $c=-20$.

	u to u'	u to u''	u' to u''
$c=-2$	.1814	.1741	.1738
$c=-20$	.002265	.002103	.001984

plane. That case reduces to recovering Green's scalar function in the lower half plane with zero Neumann condition on the surface. We also explained why under some decay and growth condition our Green's tensor is unique, and we use this uniqueness result to verify our calculation for H. Finally, we used our tensor H for the explicit numerical computation of surface displacement fields due to a slip on a crack, or fault, beneath the surface. As the exact solution might require an intensive computation, we found a way to obtain an approximate field $u(x_1, x_2, 0)$ based on asymptotics assuming only that (x_1, x_2) is some distance away from the fault Γ. This led to a discussion on an interesting symmetry property, valid for deeper faults.

The half space setting considered in this paper plays an important role in geophysics, where the traction free plane at the boundary models the surface of the Earth. This geometry may also be helpful in material science at adequate length scales. We have shown in this paper the expression in closed form for H on the surface and its use for efficiently approximating surface fields due to a slip on the fault. In another paper we will demonstrate how one can take advantage of those approximate closed form expressions for surface displacements, in order to solve the fault inverse problem: given a surface displacement field u, can one recover the fault and the slip that gave rise to u? We provide a positive answer to a regularized version of that problem. Our recovery method combines algebraic manipulations on the approximate closed form expressions for surface displacements to minimization techniques; see [10].

6. Appendix.

Instead of giving formulas for each entry of the matrix H, it is advantageous to write out formulas for the coordinates $H\,t$, where t is the vector (t_1, t_2, t_3). We only present in this appendix formulas at $x_3 = 0$; the idea is to give a feel for the different terms involved. The complete formula for $x_3 < 0$ is best left within a computer code.

It proves convenient to introduce polar surface coordinates.

6.1. If $(x_1 - y_1)^2 + (x_2 - y_2)^2 = 0$.

The three coordinates of $H\,t$ are then, respectively,

$$0,$$

$$0,$$

$$\frac{-\mu(n_1 t_1 + n_2 t_2) + 6(\lambda+\mu) n_3 t_3}{4\pi {y_3}^2 (\lambda+\mu)}.$$

6.2. If $(x_1 - y_1)^2 + (x_2 - y_2)^2 > 0$.

We set

$$\rho = \sqrt{(x_1-y_1)^2 + (x_2-y_2)^2},$$
$$d = \sqrt{\rho^2 + y_3^2},$$

$$\begin{aligned} c &= \frac{x_1 - y_1}{\rho}, \\ s &= \frac{x_2 - y_2}{\rho}. \end{aligned}$$

The first coordinate of $H\,t$ is the ratio of

$$\alpha n_1 t_1 + \beta n_2 t_2 + \gamma n_3 t_3 + \delta(n_1 t_2 + n_2 t_1) + \epsilon(n_1 t_3 + n_3 t_1) + \zeta(n_2 t_3 + n_3 t_2) \tag{52}$$

to

$$(\lambda + \mu)\pi\, \rho^3 d^5, \tag{53}$$

where, setting

$$A = \left(y_3 d \rho^4 + \left(\frac{5}{2}\, {y_3}^4 + 2\, {y_3}^3 d \right) \rho^2 + {y_3}^6 + {y_3}^5 d \right) \mu\,,$$

$\alpha, \beta, \gamma, \delta, \gamma, \epsilon$, and ζ are given by

$$\begin{aligned} \frac{\alpha}{c} &= -A\left(4\,c^2 - 3\right) + \left(\frac{3}{2}\,\lambda\, c^2 + \mu \right) \rho^6 - \frac{1}{2}\,\mu\, \left(15\,c^2 - 11\right) {y_3}^2 \rho^4, \\ \frac{\beta}{c} &= A\left(4\,c^2 - 3\right) - \frac{3}{2}\,\lambda\, \left(c^2 - 1\right) \rho^6 + \frac{3}{2}\,\mu\, \left(5\,c^2 - 4\right) {y_3}^2 \rho^4, \\ \frac{\gamma}{c} &= \frac{3}{2}\,(\lambda + \mu) {y_3}^2 \rho^4, \\ \frac{\delta}{s} &= -A\left(4\,c^2 - 1\right) + \left(\frac{3}{2}\,\lambda\, c^2 + \frac{1}{2}\,\mu \right) \rho^6 - \frac{1}{2}\,\mu\, \left(15\,c^2 - 4\right) {y_3}^2 \rho^4, \\ \epsilon &= -\frac{3}{2}\,\rho^5 y_3 c^2 (\lambda + \mu), \\ \zeta &= -\frac{3}{2}\,(\lambda + \mu) c s y_3 \rho^5. \end{aligned}$$

The second coordinate of $H\,t$ is also in the form of a ratio of (52) to (53), where this time $\alpha, \beta, \gamma, \delta, \gamma, \epsilon$, and ζ are given by

$$\begin{aligned} \frac{\alpha}{s} &= -A\left(4\,c^2 - 1\right) + \frac{3}{2}\,\lambda\, c^2 \rho^6 - \frac{3}{2}\, \left(5\,c^2 - 1\right) \mu\, {y_3}^2 \rho^4, \\ \frac{\beta}{s} &= A\left(4\,c^2 - 1\right) + \left(\frac{3}{2}\,\lambda + \mu - \frac{3}{2}\,\lambda\, c^2 \right) \rho^6 + \frac{1}{2}\,\mu\, \left(-4 + 15\,c^2\right) {y_3}^2 \rho^4, \\ \frac{\gamma}{s} &= \frac{3}{2}\,(\lambda + \mu) {y_3}^2 \rho^4, \\ \frac{\delta}{c} &= A\left(4\,c^2 - 3\right) + \left(\frac{3}{2}\,\lambda + \frac{1}{2}\,\mu - \frac{3}{2}\,\lambda\, c^2 \right) \rho^6 + \frac{1}{2}\,\mu\, \left(15\,c^2 - 11\right) {y_3}^2 \rho^4, \\ \epsilon &= -\frac{3}{2}\,(\lambda + \mu) c s y_3 \rho^5, \\ \zeta &= \frac{3}{2}\,\rho^5 y_3 \left(c^2 - 1\right) (\lambda + \mu). \end{aligned}$$

Setting

$$B = \left(\frac{1}{2}\, d\rho^5 + dy_3{}^2\rho^3 + \left(\frac{1}{2}\, y_3{}^5 + \frac{1}{2}\, y_3{}^4 d\right)\rho\right)\mu\,,$$

the third coordinate of $H\,t$ is also in the form of a ratio of (52) to (53), where this time $\alpha, \beta, \gamma, \delta, \gamma, \epsilon$, and ζ are given by

$$\alpha = -B\left(-1 + 2\,c^2\right) + \left(-3\,\mu\,c^2 - \frac{3}{2}\,\lambda\,c^2 + \mu\right) y_3\rho^5 - \frac{1}{2}\,\mu\,\left(5\,c^2 - 3\right) y_3{}^3\rho^3,$$
$$\beta = B\left(-1 + 2\,c^2\right) + \left(-2\,\mu + \frac{3}{2}\,\lambda\,c^2 - \frac{3}{2}\,\lambda + 3\,\mu\,c^2\right) y_3\rho^5 + \frac{1}{2}\,\mu\,\left(-2 + 5\,c^2\right) y_3{}^3\rho^3,$$
$$\gamma = -\frac{3}{2}\,(\lambda + \mu) y_3{}^3\rho^3,$$
$$\frac{\delta}{sc} = \left(\left(-\frac{3}{2}\,\lambda - 3\,\mu\right) y_3 - d\mu\right)\rho^5 + \left(-\frac{5}{2}\,\mu\,y_3{}^3 - 2\,d\mu\,y_3{}^2\right)\rho^3 + \left(-d\mu\,y_3{}^4 - \mu\,y_3{}^5\right)\rho,$$
$$\frac{\epsilon}{c} = \frac{3}{2}\,(\lambda + \mu) y_3{}^2\rho^4,$$
$$\frac{\zeta}{s} = \frac{3}{2}\,(\lambda + \mu) y_3{}^2\rho^4.$$

Remark. Denote by (u_1, u_2, u_3) the coordinates of Ht, whose expressions were given above. From (33) and (34) the following symmetry properties must hold:

$$u_1(s, c, n_1, n_2, t_1, t_2) = u_2(c, s, n_2, n_1, t_2, t_1),$$
$$u_3(s, c, n_1, n_2, t_1, t_2) = u_3(c, s, n_2, n_1, t_2, t_1).$$

These symmetry properties can be directly verified from the previous formulas using that $s^2 + c^2 = 1$.

Acknowledgments. The author wishes to thank Prof. I. R. Ionescu for his offering of important suggestions and helpful comments.

A TWO-DIMENSIONAL DIFFUSION APPROXIMATION FOR A LOSS MODEL WITH TRUNK RESERVATION*

CHARLES KNESSL[†] AND JOHN A. MORRISON[‡]

Abstract. We consider a loss model with C servers, and arriving customers are split into two classes. Of the C servers, R may be used only by the high priority class. Thus if a high priority customer sees all C servers occupied, then that customer is lost, while a low priority customer is lost if $\geq C - R$ servers are occupied. Assuming Poisson arrivals of both customer types and exponential service, we study the problem asymptotically, with $C \to \infty$ and the arrival rates comparably large. We assume that the total load is roughly equal to the number of servers, and we obtain a two-dimensional diffusion equation satisfied by the joint steady state probability distribution of the numbers of servers occupied by the two customer classes. We analyze this equation by a combination of analytic and numerical methods. Our singular perturbation analysis makes certain assumptions about not only the forms of various asymptotic expansions but also the asymptotic matching between different scales.

Key words. asymptotics, diffusion, trunk reservation

1. Introduction.

We consider the following queueing model. There are C servers and two customer types. The high (resp., low) priority customers arrive according to a Poisson process of rate λ (resp., ν). The service times for the high and low priority customers are all exponentially distributed, with respective means 1 and $1/\kappa$. Of the C servers, R are reserved for the high priority customers. If a high priority customer arrives to see all C servers occupied, that customer is lost (or blocked). If a low priority customer arrives to see at least $C - R$ servers occupied, then that customer is lost.

This model is referred to as "trunk reservation." The concept of trunk reservation is of fundamental importance in circuit-switched networks. On any link of the network, which has a fixed number of circuits, some of the circuits may be reserved for the primary traffic, which is offered directly to the link. Secondary traffic, which is rerouted because of a busy link on its direct route, is accepted on an alternate link only if there is an unreserved link available.

In our notation, the servers are circuits, high priority customers are primary calls, and low priority customers are secondary calls. A circuit is held for the duration of the call. An arriving call is blocked and lost if a circuit is not available on any of the links on its route.

This model is a priority queue and a loss model. Variants and various aspects of trunk reservation models have been investigated by many authors, including Mitra, Gibbens, and Huang [8], [9], Mitra and Gibbens [7], Hunt and Laws [2], and Roberts [14], [15]. In [7], [8], [9] the authors considered symmetric loss networks with trunk

reservation and dynamic routing. They analyze in detail the case of a single queue (or link) and use the results to obtain approximations for more complicated loss networks. Optimization and control policies for related models are considered in [2]. In [14] and [15] the author obtains analytical approximations to the blocking probabilities for the two customer types, based on a certain approximate recurrence. Having a thorough understanding of a single queue is important since then fixed point approximations can be used to study more general loss networks; see Kelly [3], [4].

The total load from the two customer types is defined as $\lambda+\nu/\kappa$. This represents the number of customers that would, on average, be in the system if the number of servers were *infinite*. If the total load exceeds the number of servers ($\lambda+\nu/\kappa > C$), then we are in the "overloaded" case, while if $\lambda+\nu/\kappa < C$, we are in the "underloaded" case. Important in applications is the case of "critical loading" where $\lambda+\nu/\kappa \approx C$. Here the system's capacity is roughly equal to the load.

We consider the asymptotic limit where $C \to \infty$ and the arrival rates λ and $\nu \to \infty$, at the same rate as C. Furthermore we assume that the number R of reserved trunks is $O(1)$ and that $C-(\lambda+\nu/\kappa) = O(\sqrt{C})$, so we are in the critical loading case.

We will pay particular attention to computing the blocking probabilities for both the primary and secondary traffic. In a loss model such as this, these give the probability that a phone call is lost on the link.

Previous asymptotic analyses of this model are due to Morrison [10] and the present authors [5], [12], [13]. However, in [10], [12], and [13] the analyses assume that the arrival rate of one traffic type is asymptotically greater than the other traffic type. This leads to some mathematical simplifications, namely, that one needs to solve parabolic rather than elliptic PDEs in the heavy traffic limit. Here we treat the more difficult case where the arrival rates of the two traffic types are comparably large. In [5] we considered the same model as in the present paper, with arrival rates of the same order, but for underloaded and overloaded links rather than a critically loaded one. This again led to much simpler mathematical problems.

We assume that both arrival rates and both service rates are of comparable magnitude, and we obtain a two-dimensional diffusion equation satisfied by the joint steady state probability distribution in this asymptotic limit. We derive this by using singular perturbation methods, and obtaining the appropriate boundary condition for this diffusion equation involves the analysis of the two different scales, i.e., ranges of (n_1, n_2). The analysis makes certain assumptions about not only the forms of various asymptotic expansions but also the asymptotic matching between the two scales. We then analyze the diffusion equation by a semi-analytic, seminumerical approach. This employs the classic technique of separation of variables, but satisfying the boundary condition is done numerically.

The paper is organized as follows. In section 2 we formulate the mathematical problem and introduce the asymptotic limit. In section 3 we obtain the diffusion equation and the boundary condition. We use analytic methods in section 4 to convert the problem into determining an infinite sequence of constants, and these we obtain numerically in section 5. In section 6 we give a brief summary.

2. Statement of the problem.

We let $N_1(t)$ (resp., $N_2(t)$) denote the number of servers occupied by primary (resp., secondary) customers. The steady state distribution will be denoted by

$$p(n_1, n_2) = \lim_{t\to\infty} \mathrm{Prob}[N_1(t) = n_1, N_2(t) = n_2]. \tag{2.1}$$

It satisfies the difference equation

$$\begin{aligned}[\lambda I\{n_1+n_2+1\leqslant C\}+\nu I\{n_1+n_2+1\leqslant C-R\}+n_1+\kappa n_2]p(n_1,n_2)\\ = \lambda I\{n_1\geqslant 1\}p(n_1-1,n_2)\\ +\nu I\{n_1+n_2\leqslant C-R\}I\{n_2\geqslant 1\}p(n_1,n_2-1)\\ +I\{n_1+n_2+1\leqslant C\}(n_1+1)p(n_1+1,n_2)\\ +\kappa I\{n_1+n_2+1\leqslant C\}I\{n_2+1\leqslant C-R\}(n_2+1)p(n_1,n_2+1)\end{aligned} \tag{2.2}$$

for $n_1 \geqslant 0$, $0 \leqslant n_2 \leqslant C-R$, $n_1+n_2 \leqslant C$. Here $I\{\mathcal{A}\}$ is the indicator function on the event $\mathcal{A}$.

We also have the normalization condition

$$\sum_{n_2=0}^{C-R}\sum_{n_1=0}^{C-n_2} p(n_1,n_2) = 1. \tag{2.3}$$

Of particular interest are the blocking probabilities, defined by

$$B_1 = \sum_{n_1=R}^{C} p(n_1, C-n_1), \quad B_2 = \sum_{\ell=0}^{R}\sum_{n_1=\ell}^{C-R+\ell} p(n_1, C-R+\ell-n_1). \tag{2.4}$$

The use of indicator functions allows us to write the problem as the single equation (2.2), and this form is useful for programming the numerical or symbolic solutions. But, the form (2.2) somewhat obscures the structure of the equation(s). We note that

$$\begin{aligned}(\lambda+n_1+\kappa n_2)p(n_1,n_2) = \lambda p(n_1-1,n_2)\\ +(n_1+1)p(n_1+1,n_2)\\ +\kappa(n_2+1)p(n_1,n_2+1)\end{aligned} \tag{2.5}$$

in the discrete oblique strip where $0 < n_2 < C-R$ and $C-R < n_1+n_2 < C$, and

$$\begin{aligned}(\lambda+\nu+n_1+\kappa n_2)p(n_1,n_2) = \lambda p(n_1-1,n_2)+\nu p(n_1,n_2-1)\\ +(n_1+1)p(n_1+1,n_2)\\ +\kappa(n_2+1)p(n_1,n_2+1)\end{aligned} \tag{2.6}$$

in the discrete triangle $0 < n_1+n_2 < C-R$. By analogy to PDEs we can view (2.5) as a parabolic problem (since the equation involves only first order differences in n_2), coupled to an elliptic problem (2.6), with an interface along $n_1+n_2 = C-R$. If $n_1+n_2 = C$, we have $(n_1+\kappa n_2)p(n_1,n_2) = \lambda p(n_1-1,n_2)$ which expresses the loss of primary customers. The loss of secondary customers is evident in (2.5) due to the absence of the term $\nu p(n_1,n_2-1)$.

We consider the asymptotic limit where $C,\lambda,\nu \to \infty$ with $R,\kappa = O(1)$. We introduce the new parameters σ and ρ, with

$$C-R = \frac{\lambda}{\kappa}\sigma, \quad \nu+\kappa\lambda = \rho\lambda. \tag{2.7}$$

Note that σ and ρ are to be $O(1)$. We consider only $p(n_1,n_2)$ for those ranges of n_1 and n_2, where most of the probability mass accumulates, in this asymptotic limit.

Now we introduce the heavy traffic assumption that $\rho \sim \sigma$, with δ defined by

$$\rho-\sigma = \frac{\delta}{\sqrt{\lambda}}, \tag{2.8}$$

where $\delta = O(1)$ and $-\infty < \delta < \infty$. Note that with (2.8) $C - R - (\lambda + \nu/\kappa) = O(\sqrt{\lambda})$ so that the total load $(\lambda + \nu/\kappa)$ is roughly balanced by the total number of servers. Most of the mass will occur where $n_1 \sim \lambda$ and $n_1 + n_2 \sim C$. More precisely, we introduce (x, y) with

$$n_1 = \lambda + x\sqrt{\lambda}, \quad n_2 = \left(\frac{\sigma}{\kappa} - 1\right)\lambda - (x + y)\sqrt{\lambda} \tag{2.9}$$

and note also that $n_1 + n_2 = C - R - y\sqrt{\lambda}$.

On the (x, y) scale we define

$$p(n_1, n_2) = \mathcal{P}(x, y; \lambda) \tag{2.10}$$

and for $y > 0$ we obtain from (2.2) or (2.6)

$$\begin{aligned}\Big\{\lambda(2 + 2\sigma - 2\kappa) + \sqrt{\lambda}\,[(1-\kappa)x - \kappa y + \delta]\Big\}&\mathcal{P}(x, y; \lambda)\\ = \lambda\mathcal{P}\left(x - \frac{1}{\sqrt{\lambda}}, y + \frac{1}{\sqrt{\lambda}}; \lambda\right)&\\ + \Big[(\sigma-\kappa)\lambda + \sqrt{\lambda}\delta\Big]\,\mathcal{P}\left(x, y + \frac{1}{\sqrt{\lambda}}; \lambda\right)&\\ + \Big(\lambda + \sqrt{\lambda}x + 1\Big)\,\mathcal{P}\left(x + \frac{1}{\sqrt{\lambda}}, y - \frac{1}{\sqrt{\lambda}}; \lambda\right)&\\ + \Big[(\sigma-\kappa)\lambda - \kappa\sqrt{\lambda}(x+y) + \kappa\Big]\,\mathcal{P}\left(x, y - \frac{1}{\sqrt{\lambda}}; \lambda\right).&\end{aligned} \tag{2.11}$$

In order to understand the boundary behavior of $\mathcal{P}$ near $y = 0$, we must also analyze (2.2) on another scale, namely, on the (x, ℓ) scale, where

$$n_1 + n_2 - (C - R) = \ell, \quad -\infty < \ell \leqslant R. \tag{2.12}$$

Note that the expansion for $y > 0$ may cease to be valid when y becomes small, and thus we include $\ell < 0$ in (2.12).

Then we set

$$p(n_1, n_2) = p_\ell(x) = \mathcal{P}(x, y; \lambda) \tag{2.13}$$

and from (2.2) we obtain

$$\begin{aligned}\Big[\lambda I\{\ell \leqslant R-1\} + [\lambda(\sigma-\kappa) + \delta\sqrt{\lambda}]I\{\ell \leqslant -1\}&\\ + \lambda - \lambda\kappa + \lambda\sigma + \sqrt{\lambda}(1-\kappa)x + \ell\kappa\Big]&p_\ell(x)\\ = \lambda p_{\ell-1}\left(x - \frac{1}{\sqrt{\lambda}}\right) + [\lambda(\sigma-\kappa) + \sqrt{\lambda}\delta]I\{\ell \leqslant 0\}p_{\ell-1}(x)&\\ + I\{\ell \leqslant R-1\}(\lambda + x\sqrt{\lambda} + 1)p_{\ell+1}\left(x + \frac{1}{\sqrt{\lambda}}\right)&\\ + I\{\ell \leqslant R-1\}\Big[\lambda(\sigma-\kappa) - \sqrt{\lambda}\kappa x + \kappa(\ell+1)\Big]\,p_{\ell+1}(x).&\end{aligned} \tag{2.14}$$

Here $\ell \leqslant R$ and we note that

$$\ell = -y\sqrt{\lambda}. \tag{2.15}$$

Note that some of the indicator functions in (2.2) were replaced by 1, since the local scaling (2.9) corresponds to $(n_1, n_2) \approx (\lambda, C-\lambda)$. However, the boundary $n_1+n_2 = C$ $(\ell = R)$ and interface $n_1+n_2 = C-R$ $(\ell = 0)$ do play key roles in the analysis. In the next section we analyze (2.11) and (2.14) asymptotically, ultimately obtaining a two-dimensional diffusion equation, with an appropriate boundary condition along $y = 0$.

3. Diffusion approximation. We rewrite (2.11) as

$$\begin{aligned}(3.1)\quad & \lambda\left[\mathcal{P}(x-\varepsilon, y+\varepsilon;\lambda) - \mathcal{P}(x,y;\lambda)\right] \\ &\qquad + \left[(\sigma-\kappa)\lambda + \delta\sqrt{\lambda}\right]\left[\mathcal{P}(x,y+\varepsilon;\lambda) - \mathcal{P}(x,y;\lambda)\right] \\ &+ \left(\lambda + \sqrt{\lambda}x\right)\left[\mathcal{P}(x+\varepsilon,y-\varepsilon;\lambda) - \mathcal{P}(x,y;\lambda)\right] + \mathcal{P}(x+\varepsilon,y-\varepsilon;\lambda) \\ &\quad + \left[(\sigma-\kappa)\lambda - \kappa(x+y)\sqrt{\lambda}\right]\left[\mathcal{P}(x,y-\varepsilon;\lambda) - \mathcal{P}(x,y;\lambda)\right] \\ &\qquad\qquad + \kappa\mathcal{P}(x,y-\varepsilon;\lambda) = 0,\end{aligned}$$

where $\varepsilon = 1/\sqrt{\lambda} \to 0^+$ and $y > 0$. We assume an expansion of the form

$$(3.2)\qquad \mathcal{P}(x,y;\lambda) = \frac{1}{\lambda}\left[\mathcal{P}(x,y) + \frac{1}{\sqrt{\lambda}}\mathcal{P}^{(1)}(x,y) + O\left(\lambda^{-1}\right)\right].$$

Here the first factor of $1/\lambda$ is suggested by the scaling (2.9), with which we expect that the normalizing sum (2.3) will be replaced asymptotically by a double integral over x and y.

Expanding (3.1) for $\varepsilon \to 0$ and using (3.2) we find that to leading order ($O(\varepsilon) = O(1/\sqrt{\lambda})$) the equation holds automatically, and at $O(\varepsilon^2) = O(1/\lambda)$ we obtain

$$(3.3)\quad \mathcal{P}_{xx} - 2\mathcal{P}_{xy} + (1+\sigma-\kappa)\mathcal{P}_{yy} + x\mathcal{P}_x + [\delta - x + \kappa(x+y)]\mathcal{P}_y + (\kappa+1)\mathcal{P} = 0.$$

This is a second order elliptic PDE that applies over the half-plane $y > 0, -\infty < x < \infty$. We note that $\sigma > \kappa$, since $\sigma \sim \rho$ and $\rho = \kappa + \nu/\lambda > \kappa$. If we change variables from (x, y) to (ξ, η) with

$$(3.4)\qquad x = \xi, \quad x + y = \eta, \quad \mathcal{P}(x,y) = P(\xi,\eta),$$

we obtain from (3.3)

$$(3.5)\qquad P_{\xi\xi} + (\sigma-\kappa)P_{\eta\eta} + \xi P_\xi + (\delta + \kappa\eta)P_\eta + (\kappa+1)P = 0,$$

which applies for $\eta > \xi$ and $-\infty < \xi < \infty$. Now, (3.5) is a separable PDE, but it applies over an oblique half-plane. At certain times we will use (3.5), while at other times (3.3) will prove more convenient.

We need a boundary condition along $y = 0$ for (3.3), or along $\xi = \eta$ for (3.5). To this end we must carefully consider the problem on the (x, ℓ) scale, where the interface condition(s) ($\ell = 0$ in (2.14)) play a role. We assume that on this scale we have the expansion

$$(3.6)\qquad p_\ell(x) = \frac{1}{\lambda}\left[p_\ell^{(0)}(x) + \frac{1}{\sqrt{\lambda}}p_\ell^{(1)}(x) + O(\lambda^{-1})\right].$$

For $R \geqslant 2$ and $1 \leqslant \ell \leqslant R-1$ we use (3.6) in (2.14). In this range $I\{\ell \leqslant -1\} = 0$ and $I\{\ell \leqslant R-1\} = 1$, and to leading order (2.14) gives

$$(3.7)\qquad (2+\sigma-\kappa)p_\ell^{(0)}(x) = p_{\ell-1}^{(0)}(x) + (1+\sigma-\kappa)p_{\ell+1}^{(0)}(x), \quad 1 \leqslant \ell \leqslant R-1.$$

When $\ell = R$, using (3.6) in (2.14) leads to

$$(1+\sigma-\kappa)p_R^{(0)}(x) = p_{R-1}^{(0)}(x). \tag{3.8}$$

Setting

$$a = \frac{1}{1+\sigma-\kappa} < 1, \tag{3.9}$$

the most general solution to (3.7) and (3.8) is

$$p_\ell^{(0)}(x) = a^\ell F_0(x), \quad 0 \leqslant \ell \leqslant R, \tag{3.10}$$

where F_0 is at this point undetermined.

At the next order of the expansion of (2.14) using (3.6) we obtain, for $1 \leqslant \ell \leqslant R-1$,

$$\begin{aligned}(2+\sigma-\kappa)p_\ell^{(1)}(x) &+ (1-\kappa)xp_\ell^{(0)}(x) \\ &= p_{\ell-1}^{(1)}(x) - \frac{d}{dx}p_{\ell-1}^{(0)}(x) + p_{\ell+1}^{(1)}(x) + \frac{d}{dx}p_{\ell+1}^{(0)}(x) + xp_{\ell+1}^{(0)}(x) \\ &\qquad + (\sigma-\kappa)p_{\ell+1}^{(1)}(x) - \kappa x p_{\ell+1}^{(0)}(x).\end{aligned} \tag{3.11}$$

By using (3.10) we can rearrange (3.11) to

$$\begin{aligned}p_{\ell-1}^{(1)}(x) - (2+\sigma-\kappa)p_\ell^{(1)}(x) &+ (1+\sigma-\kappa)p_{\ell+1}^{(1)}(x) \\ &= a^{\ell-1}(1-a)\left[a(1-\kappa)xF_0(x) + (1+a)F_0'(x)\right].\end{aligned} \tag{3.12}$$

The most general solution to the difference equation (3.12) is of the form

$$\begin{aligned}p_\ell^{(1)}(x) = a^\ell &\left\{p_0^{(1)}(x) - \ell\left[a(1-\kappa)xF_0(x) + (1+a)F_0'(x)\right]\right\} \\ &+ (a^\ell - 1)H_1(x), \quad 0 \leqslant \ell \leqslant R.\end{aligned} \tag{3.13}$$

Here we used $a(1+\sigma-\kappa) = 1$. When $\ell = R$, (2.14) with (3.6) yields at the second order

$$(1+\sigma-\kappa)p_R^{(1)}(x) + (1-\kappa)xp_R^{(0)}(x) = p_{R-1}^{(1)}(x) - \frac{d}{dx}p_{R-1}^{(0)}(x). \tag{3.14}$$

Using (3.10) and (3.13) in (3.14), we obtain

$$H_1(x) = -\frac{a^{R+1}}{1-a}F_0'(x). \tag{3.15}$$

We have thus obtained two terms in the expansion (3.6) for $\ell \geqslant 0$, up to the functions $F_0(x) = p_0^{(0)}(x)$ and $p_0^{(1)}(x)$. We have thus far assumed that $R \geqslant 2$, but we shall show that (3.10) holds if $R = 1$ also.

Now consider (2.14) for $R \geqslant 1$ and $\ell \leqslant 0$. In this case the expansion (3.6) leads to

$$\begin{aligned}\left[2+\sigma-\kappa+(\sigma-\kappa)I\{\ell \leqslant -1\}\right]&p_\ell^{(0)}(x) \\ &= (1+\sigma-\kappa)\left[p_{\ell-1}^{(0)}(x) + p_{\ell+1}^{(0)}(x)\right], \quad \ell \leqslant 0,\end{aligned} \tag{3.16}$$

so that

$$2p_\ell^{(0)}(x) = p_{\ell-1}^{(0)}(x) + p_{\ell+1}^{(0)}(x), \quad \ell \leqslant -1, \tag{3.17}$$

and

$$(2+\sigma-\kappa)p_0^{(0)}(x) = (1+\sigma-\kappa)\left[p_{-1}^{(0)}(x) + p_1^{(0)}(x)\right]. \tag{3.18}$$

The general solution to (3.17) is $F_0(x) + \ell G_0(x)$, where F_0 is as in (3.10). But then (3.18), with $p_1^{(0)} = aF_0$, shows that

$$p_{-1}^{(0)} = [(2+\sigma-\kappa)F_0 - F_0]\, a = F_0,$$

so that $G_0 = 0$ and hence

$$p_\ell^{(0)}(x) = F_0(x), \quad \ell \leqslant 0. \tag{3.19}$$

At the next order in using (3.6) in (2.14) we obtain, for $\ell \leqslant -1$,

$$\begin{aligned}(1+\sigma-\kappa)&\left[2p_\ell^{(1)}(x) - p_{\ell-1}^{(1)}(x) - p_{\ell+1}^{(1)}(x)\right] \\ &= \delta\left[p_{\ell-1}^{(0)}(x) - p_\ell^{(0)}(x)\right] + (1-\kappa)x\left[p_{\ell+1}^{(0)}(x) - p_\ell^{(0)}(x)\right] \\ &\qquad + \frac{d}{dx}\left[p_{\ell+1}^{(0)}(x) - p_{\ell-1}^{(0)}(x)\right],\end{aligned} \tag{3.20}$$

and $\ell = 0$ leads to

$$\begin{aligned}(2+\sigma-\kappa)p_0^{(1)}(x)&-(1+\sigma-\kappa)\left[p_{-1}^{(1)}(x)+p_1^{(1)}(x)\right] \\ &= (1-\kappa)x\left[p_1^{(0)}(x)-p_0^{(0)}(x)\right] + \delta p_{-1}^{(0)}(x) + \frac{d}{dx}\left[p_1^{(0)}(x)-p_{-1}^{(0)}(x)\right].\end{aligned} \tag{3.21}$$

In view of (3.19), the right-hand side of (3.20) vanishes so that

$$p_\ell^{(1)}(x) = F_1(x) + \ell G_1(x), \quad \ell \leqslant 0. \tag{3.22}$$

We use (3.10) and (3.13) with $\ell = 1$, (3.15), and $p_0^{(0)} = p_{-1}^{(0)} = F_0$ in (3.21). With (3.22), after some calculation this yields, for $R \geqslant 2$,

$$(1+\sigma-\kappa)G_1(x) = [\delta - (1-\kappa)x]F_0(x) - \left(2 - a^R\right)F_0'(x). \tag{3.23}$$

If $R = 1$ and $\ell = 1$, (2.14) yields to leading order

$$(1+\sigma-\kappa)p_1^{(0)}(x) = p_0^{(0)}(x) \tag{3.24}$$

and at the next order

$$(1+\sigma-\kappa)p_1^{(1)}(x) + (1-\kappa)xp_1^{(0)}(x) = p_0^{(1)}(x) - \frac{d}{dx}p_0^{(0)}(x). \tag{3.25}$$

But (3.24) shows that $p_1^{(0)}(x) = ap_0^{(0)}(x)$ so that (3.10) remains valid when $R = 1$, and (3.25) becomes

$$(1+\sigma-\kappa)p_1^{(1)}(x) = p_0^{(1)}(x) - F_0'(x) - a(1-\kappa)xF_0(x). \tag{3.26}$$

Using (3.13) and (3.15) we see that (3.26) is the same as (3.13) with $\ell = 1$, so (3.13) remains valid also when $R = 1$. It follows that (3.23) is also true if $R = 1$.

We now compare expansions (3.2) and (3.6). Setting $y = -\ell/\sqrt{\lambda}$ in (3.2) leads to

$$\frac{1}{\lambda}\left\{\mathcal{P}(x,0) + \frac{1}{\sqrt{\lambda}}\left[\mathcal{P}^{(1)}(x,0) - \ell\mathcal{P}_y(x,0)\right] + O(\lambda^{-1})\right\}. \tag{3.27}$$

If this is to agree with (3.6) for $\ell < 0$, we must have, in view of (3.19) and (3.22),

$$\mathcal{P}(x,0) = F_0(x), \tag{3.28}$$

$$\mathcal{P}^{(1)}(x,0) = F_1(x), \tag{3.29}$$

and

$$G_1(x) = -\mathcal{P}_y(x,0). \tag{3.30}$$

But then (3.23), (3.28), and (3.30) yield

$$(1+\sigma-\kappa)\mathcal{P}_y(x,0) = \left(2 - a^R\right)\mathcal{P}_x(x,0) + [(1-\kappa)x - \delta]\mathcal{P}(x,0). \tag{3.31}$$

This is the boundary condition that we sought for the leading term in (3.2). Calculating F_1 and $\mathcal{P}^{(1)}$ would require computing further terms in the expansions. In terms of (ξ, η), (3.31) becomes

$$(1+\sigma-\kappa)P_\eta(\xi,\xi) + \left(a^R - 2\right)[P_\xi(\xi,\xi) + P_\eta(\xi,\xi)] = [(1-\kappa)\xi - \delta]P(\xi,\xi). \tag{3.32}$$

To summarize, we have formulated the problem for the leading term in (3.2) as the PDE (3.3) and the boundary condition (BC) (3.31). Alternately, in terms of ξ and η we have the PDE (3.5) and BC (3.32). Using the Euler–MacLaurin formula we can show that the normalization condition in (2.3) becomes, to leading order,

$$\int_{-\infty}^{\infty}\int_{0}^{\infty}\mathcal{P}(x,y)\,dy\,dx = 1 \tag{3.33}$$

or

$$\int_{-\infty}^{\infty}\int_{\xi}^{\infty}P(\xi,\eta)\,d\eta\,d\xi = 1. \tag{3.34}$$

We note that the fact that $p(n_1, n_2)$ has a different form on the (x, ℓ) scale for $\ell > 0$ would affect the $O(1/\sqrt{\lambda})$ correction to the normalization.

Finally, we briefly discuss the cases $R = 0$ and $R \to \infty$. When $R = 0$ there are no reserved trunks, and then we have the exact product form solution

$$p(n_1,n_2) = C_0\frac{\lambda^{n_1}(\nu/\kappa)^{n_2}}{n_1!n_2!}, \tag{3.35}$$

where C_0 is a normalizing constant. By using in (3.35) the heavy traffic scaling in (2.8), and also using (2.7) and (2.9), we obtain after some calculation

$$p(n_1,n_2) \sim (\text{const.})e^{-x^2/2}\exp\left[-\frac{(\kappa(x+y)+\delta)^2}{2\kappa(\sigma-\kappa)}\right]. \tag{3.36}$$

While our derivation of (3.3) and (3.31) assumed that $R \geqslant 1$, a similar analysis shows that in fact the diffusion approximation holds also if $R = 0$. In this case we replace the coefficient $2 - a^R$ in (3.31) by 1. Then we can easily verify that (3.36) satisfies the PDE (3.3) and the BC (3.31). Thus our analysis is certainly consistent with the exact product form solution if $R = 0$.

Now consider $R \to \infty$ with σ and κ fixed, so that a is fixed and $C \to \infty$. If $R \to \infty$, we can replace $2 - a^R$ in (3.31) by 2, and (3.32) becomes

$$2P_\xi + \left(2 - \frac{1}{a}\right) P_\eta + [\xi(1-\kappa) - \delta]P = 0, \quad \xi = \eta. \tag{3.37}$$

We define

$$\widetilde{P}(\xi) = \int_\xi^\infty P(\xi, \eta)\, d\eta = \int_0^\infty \mathcal{P}(\xi, y)\, dy. \tag{3.38}$$

By integrating (3.3) from $y = 0$ to $y = \infty$, setting $x = \xi$, and using (3.31), we get

$$\widetilde{P}''(\xi) + \xi \widetilde{P}'(\xi) + \widetilde{P}(\xi) = 0 \tag{3.39}$$

so that

$$\widetilde{P}(\xi) = \frac{1}{\sqrt{2\pi}} e^{-\xi^2/2}. \tag{3.40}$$

Here we also used (3.34) for $R = \infty$. This shows that if $R = \infty$, the lowest order asymptotic approximation to the marginal density is exactly Gaussian. But, the structure of the two-dimensional density $P(\xi, \eta)$ seems much more complicated. The explicit solutions for $R = 0$ and $R = \infty$ can be used as useful checks on any numerical method for solving this boundary value problem.

4. Modal expansions. We consider (3.5) and (3.32). The PDE (3.5) admits solutions of the separable form

$$P(\xi, \eta) = f(\xi) g(\eta). \tag{4.1}$$

Using (4.1) in (3.5), dividing by fg, and rearranging terms yields

$$-\left[\frac{f''(\xi)}{f(\xi)} + \xi \frac{f'(\xi)}{f(\xi)} + 1\right] = (\sigma - \kappa)\frac{g''(\eta)}{g(\eta)} + (\delta + \kappa\eta)\frac{g'(\eta)}{g(\eta)} + \kappa. \tag{4.2}$$

Since the left-hand side of (4.2) depends only on ξ and the right-hand side only on η, both must be constant. We call this separation constant μ, and then

$$f''(\xi) + \xi f'(\xi) + (\mu + 1) f(\xi) = 0, \tag{4.3}$$

$$(\sigma - \kappa) g''(\eta) + (\delta + \kappa\eta) g'(\eta) + (\kappa - \mu) g(\eta) = 0. \tag{4.4}$$

Both of these ODEs are parabolic cylinder equations [6].

We expect P to have rapid decay as $|\xi|$ and/or $|\eta| \to \infty$ with $\eta \geqslant \xi$. By choosing $\mu = r = 0, 1, 2, \dots$ the solution to (4.3) has Gaussian decay as $\xi \to \pm\infty$, with

$$f(\xi) = e^{-\xi^2/4} D_r(\xi) = e^{-\xi^2/2} \mathrm{He}_r(\xi), \tag{4.5}$$

where He is the Hermite polynomial [6]. With $\mu = r$ we can require the solution of (4.4) to decay as $\eta \to +\infty$, and then

$$g(\eta) = \exp\left[-\frac{(\delta+\kappa\eta)^2}{4\kappa(\sigma-\kappa)}\right] D_{-r/\kappa}\left(\frac{\delta+\kappa\eta}{\sqrt{\kappa(\sigma-\kappa)}}\right). \tag{4.6}$$

We note that, since $\eta \geqslant \xi$, we have $\xi \to -\infty$ whenever $\eta \to -\infty$. By linear superposition and the completeness of the Hermite polynomials we argue that a general solution to (3.5) is

$$P(\xi,\eta) = e^{-\xi^2/4} \exp\left[-\frac{(\delta+\kappa\eta)^2}{4\kappa(\sigma-\kappa)}\right] \sum_{r=0}^{\infty} A(r) D_r(\xi) D_{-r/\kappa}\left(\frac{\delta+\kappa\eta}{\sqrt{\kappa(\sigma-\kappa)}}\right). \tag{4.7}$$

The constants $A(r)$ must be determined by the boundary condition (3.32). A crude but effective numerical method is to truncate the sum in (4.7) at some $r = N_{\max}$ and require that (3.32) hold at $\xi = \eta$ for some discrete set of points ξ_j. The totality of these points should suffice to determine $A(r)$ for $0 \leqslant r \leqslant N_{\max}$. We employ such a method in section 5.

Our choice of having $f(\xi)$ decay as $\xi \to \pm\infty$ was somewhat arbitrary, as we could also require that $g(\eta)$ have Gaussian decay as $\eta \to \pm\infty$. Then $g(\eta)$ would involve Hermite polynomials, which forces $\mu = -p\kappa$ for $p = 0, 1, 2, \ldots$, and thus

$$g(\eta) = \exp\left[-\frac{(\delta+\kappa\eta)^2}{4\kappa(\sigma-\kappa)}\right] D_p\left(\frac{\delta+\kappa\eta}{\sqrt{\kappa(\sigma-\kappa)}}\right). \tag{4.8}$$

The solution to (4.3) that decays as $\xi \to -\infty$ is

$$f(\xi) = e^{-\xi^2/4} D_{-p\kappa}(-\xi). \tag{4.9}$$

Again using linear superposition we argue that another form of the general solution to (3.5) is

$$P(\xi,\eta) = e^{-\xi^2/4} \exp\left[-\frac{(\delta+\kappa\eta)^2}{4\kappa(\sigma-\kappa)}\right] \sum_{p=0}^{\infty} C(p) D_{-p\kappa}(-\xi) D_p\left(\frac{\delta+\kappa\eta}{\sqrt{\kappa(\sigma-\kappa)}}\right). \tag{4.10}$$

Here $C(p)$ must be determined by the BC in (3.32).

We next discuss the normalization (3.34) and the blocking probabilities in (2.4). Let us define

$$\omega_0(y) = \int_{-\infty}^{\infty} \mathcal{P}(x,y)\,dx = \int_{-\infty}^{\infty} P(\xi, y+\xi)\,d\xi \tag{4.11}$$

so that the normalization (3.33) or (3.34) yields

$$\int_0^{\infty} \omega_0(y)\,dy = 1. \tag{4.12}$$

Using (2.4) with the scaling in (2.9) and (2.15), and also using (3.6), (3.10), and (3.28), we find that the blocking probabilities are, to leading order, given by

$$\begin{aligned} B_1 \sim \frac{1}{\sqrt{\lambda}} \int_{-\infty}^{\infty} p_R^{(0)}(x)\,dx &= \frac{a^R}{\sqrt{\lambda}} \int_{-\infty}^{\infty} \mathcal{P}(x,0)\,dx \\ &= \frac{1}{\sqrt{\lambda}} a^R \omega_0(0) \end{aligned} \tag{4.13}$$

and

$$B_2 \sim \frac{1}{\sqrt{\lambda}} \int_{-\infty}^{\infty} \sum_{\ell=0}^{R} p_\ell^{(0)}(x)\, dx = \frac{1-a^{R+1}}{\sqrt{\lambda}(1-a)} \int_{-\infty}^{\infty} \mathcal{P}(x,0)\, dx \tag{4.14}$$

$$= \frac{1}{\sqrt{\lambda}} \frac{1-a^{R+1}}{1-a} \omega_0(0).$$

Using properties of parabolic cylinder functions in [6], we show in the appendix that, for $r \geqslant 0$,

$$\int_0^\infty \!\! \int_{-\infty}^{\infty} e^{-x^2/4} D_r(x) \exp\left[-\frac{(\delta+\kappa(x+y))^2}{4\kappa(\sigma-\kappa)}\right] D_{-r/\kappa}\left(\frac{\delta+\kappa(x+y)}{\sqrt{\kappa(\sigma-\kappa)}}\right) dx\, dy \tag{4.15}$$

$$= \sqrt{2\pi}(-1)^r \left(\sqrt{\frac{\kappa}{\sigma}}\right)^{r-1} \left(\sqrt{1-\frac{\kappa}{\sigma}}\right)^{1-r/\kappa} \exp\left(-\frac{\delta^2}{4\sigma\kappa}\right) D_{r-1-r/k}\left(\frac{\delta}{\sqrt{\sigma\kappa}}\right).$$

Then if we define $\alpha(r)$ from

$$\alpha(r) = \sqrt{2\pi}(-1)^r \left(\sqrt{\frac{\kappa}{\sigma}}\right)^{r} \left(\sqrt{1-\frac{\kappa}{\sigma}}\right)^{1-r/\kappa} \exp\left(-\frac{\delta^2}{4\sigma\kappa}\right) A(r) \tag{4.16}$$

and use the expansion (4.7) for $P(\xi,\eta) = \mathcal{P}(x, x+y)$, the normalization (4.12) becomes

$$\sqrt{\frac{\kappa}{\sigma}} = \sum_{r=0}^{\infty} \alpha(r) D_{r-1-r/\kappa}\left(\frac{\delta}{\sqrt{\sigma\kappa}}\right). \tag{4.17}$$

Similarly we show in the appendix that

$$\omega_0(0) = \sum_{r=0}^{\infty} \alpha(r) D_{r-r/\kappa}\left(\frac{\delta}{\sqrt{\sigma\kappa}}\right). \tag{4.18}$$

If instead of using (4.7) we use (4.10), then the analogous results are

$$\sqrt{\frac{\kappa}{\sigma}} = \sum_{p=0}^{\infty} \gamma(p) D_{p-1-p\kappa}\left(\frac{\delta}{\sqrt{\sigma\kappa}}\right), \tag{4.19}$$

where

$$\gamma(p) = \sqrt{2\pi} \left(\sqrt{\frac{\sigma}{\kappa}}\right)^{p\kappa} \left(\sqrt{1-\frac{\kappa}{\sigma}}\right)^{p+1} \exp\left(-\frac{\delta^2}{4\sigma\kappa}\right) C(p) \tag{4.20}$$

and

$$\omega_0(0) = \sum_{p=0}^{\infty} \gamma(p) D_{p-p\kappa}\left(\frac{\delta}{\sqrt{\sigma\kappa}}\right). \tag{4.21}$$

We comment that if $R = 0$, retaining only the $r = 0$ term in (4.7) or the $p = 0$ term in (4.10) regains the exact solution in (3.36).

5. Numerical studies. We consider now the numerical solution of (3.5), with (3.32) and (3.34). We use the C-mode expansion in (4.10), which proved numerically superior to the A-mode expansion in (4.7).

The basic method is as follows. We impose on (4.10) (or (4.7)) the boundary condition (3.32). First, we truncate the sum in (4.10) at $p = N_{\max}$ (or (4.7) at $r = N_{\max}$) so we approximate $P(\xi, \eta)$ using the first $N_{\max} + 1$ modes. Then we require (3.32) to hold along $\eta = \xi = u$ for certain discrete points ξ_j. For example, we choose some interval $[u_0 - AA, u_0 + AA]$ centered at u_0 and require (3.32) to hold at the points

$$u = u_0 + AA\frac{N}{N_0}; \quad N = -N_0, -N_0 + 1, \ldots, -2, -1, 1, 2, \ldots, N_0 - 1, N_0. \tag{5.1}$$

Here we omit $u = u_0$ and instead impose the normalization (3.34) in the form (4.20) (or (4.17)), with the sum again truncated at $p = N_{\max}$ (or $r = N_{\max}$). Using (5.1) yields $2N_0$ equations, and thus the $N_{\max} + 1$ coefficients in (4.10) satisfy $2N_0 + 1$ equations. If $N_{\max} = 2N_0$, we obtain an inhomogeneous linear system that should uniquely determine (an approximation to) the $C(p)$ for $0 \leqslant p \leqslant N_{\max}$. But, we have found that this approach leads to numerical instabilities. Instead we use an approach similar to that in [11] based on the method of least squares. Here we take a relatively small $N_{\max}$ and a much larger N_0, so that the points in (5.1) densely fill the interval $u \in [u_0 - AA, u_0 + AA]$, and obtain the least squares approximate solution to the linear system. Then we increase N_0 to get convergence of the first few $C(p)$ as $N_0 \to \infty$ for this fixed value of $N_{\max}$. We increase $N_{\max}$ and repeat the procedure. Thus if we write $C(p) = C(p; N_0, N_{\max})$, we first get convergence as $N_0 \to \infty$, and then as $N_{\max} \to \infty$, for the first few coefficients in (4.10).

Our studies show that $P(u, u)$ is a unimodal function with very thin tails, which corresponds to the boundary values of the two-dimensional density $P(\xi, \eta)$. We choose u_0 to be close to where $P(u, u)$ is peaked, and we have found that taking $AA = 5$ is more than sufficient to capture the left and right tails of $P(u, u)$. We have found that a good way of checking the numerical convergence of our method is to plot $P(u, u)$ for a given $N_{\max}$, and then for $N_{\max} + 5$ (using 5 additional modes), and see if the graphs coincide.

To illustrate the numerical method we first take $a = .5$, $\kappa = 2$, $\delta = .01$, and $R = 3$ (thus $\sigma = 3$). In Table 1 we used $u_0 = 1$ and $AA = 5$, and we give the first three coefficients $(C(0), C(1), C(2))$ in (4.10) for various values of $N_{\max}$. We start with $N_{\max} = 4$ (5 modes) and increase this in increments of 5. We also give the values of B_1^0 and B_2^0, where

$$B_1^0 = a^R \omega_0(0), \quad B_2^0 = \frac{1 - a^{R+1}}{1 - a}\omega_0(0), \tag{5.2}$$

and $\omega_0(0)$ is computed using (4.21) and (4.20), with the sum truncated at $p = N_{\max}$. It follows that $B_j^0/\sqrt{\lambda}$ should be an approximation to the blocking probabilities B_j for $j = 1, 2$. For each $N_{\max}$ we increased N_0 until we got convergence of $C(p)$ and B_j^0. We started with $N_{\max} = 4$ and $N_0 = 35$, so we used a least squares approximation to a system of 71 equations in 5 unknowns.

In Table 1 we consider 5, 10, 15, 20, and 25 modes. We see that the convergence of $C(0)$ with increasing $N_{\max}$ is quite rapid, but the coefficient $C(2)$ of the third mode is converging much more slowly. However, the B_j^0 converge very rapidly. In Figure 1 we plot the curve $P(u, u)$ for $-4 \leqslant u \leqslant 6$. Here we used $N_{\max} + 1$ modes in (4.10)

Table 1

$\delta = .01$, $a = .5$, $\kappa = 2$, $R = 3$.

$N_{\max}$	$C(0)$	$C(1)$	$C(2)$	B_1^0	B_2^0
4	.261	.272	$-.0328$	.102	1.53
9	.248	.301	$-.115$	.103	1.55
14	.246	.311	$-.164$	.103	1.55
19	.246	.315	$-.189$	.103	1.55
24	.245	.316	$-.201$	.103	1.55

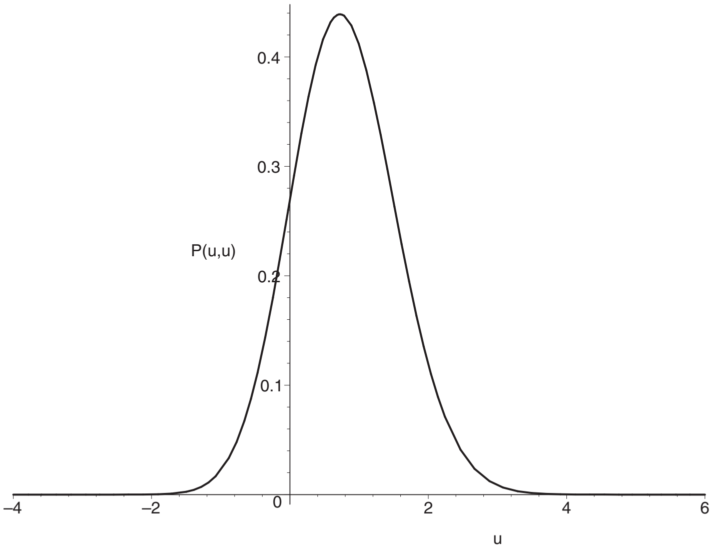

Fig. 1. *A sketch of the curve $P(u,u)$ for $-4 \leq u \leq 6$ when $\delta = .01$.*

and set $\xi = \eta = u$. Like the B_j^0 the graph converges quite rapidly with $N_{\max}$, and we get indistinguishable curves using 15 or 25 modes. The graph shows that $P(u,u)$ has very thin tails. Our results also show that the maximum value of $P(u,u)$ is about .438 and this occurs at $u \cong .723$. In Figures 2 and 3 we plot the "surface" $P(u,v)$ obtained from (4.10) with the sum truncated at $p = N_{\max}$. This also is quite robust and does not change much with increasing $N_{\max}$. In Figure 2 we view the surface from the direction $u = v > 0$ in the (u,v) plane, while Figure 3 uses $\Theta = -15°$, where $u = \sqrt{u^2+v^2}\cos(\Theta)$, $v = \sqrt{u^2+v^2}\sin(\Theta)$.

In Table 2, and Figures 4, 5, and 6 we use $\delta = -3.5$, retaining the other parameter values. Note that as $\delta \to -\infty$ we are moving out of the critically loaded case into the underloaded case (we have, by (2.7) and (2.8), $C - R = \lambda + \nu/\kappa - \sqrt{\lambda}\delta/\kappa$). We use $u_0 = 2$ and plot $P(u,u)$ for $u \in (-3,7)$. Figure 4 shows that decreasing δ from .01 to -3.5 tends to make the maximum of $P(u,u)$ much smaller ($< .09$) and shifts the peak to the right. The surface $P(u,v)$ is given in Figures 5 and 6, from the same two perspectives as in Figures 2 and 3. We see that now $P(u,v)$ has an interior maximum in the range $v > u$. From Table 2 we see that the blocking coefficients B_j^0 are now smaller, which is related to the fact that there is less mass near the boundary $u = v$. Table 2 also shows that the coefficient $C(0)$ associated with the first C-mode has a much larger numerical value than $C(1)$ or $C(2)$, suggesting that retaining only the $p = 0$ term in (4.10) may yield a reasonable approximation. For $\delta \to -\infty$ we can give an asymptotic argument, by using asymptotic matching to the underloaded case, that the solution to (3.5) should be a product of two Gaussians, as in (3.36).

Table 2

$\delta = -3.5$, $a = .5$, $\kappa = 2$, $R = 3$.

70	44.66	44.73	.0926	.103	1.29	1.55

Next we consider a fairly large positive value of δ. Table 3 and Figures 7, 8, and 9, have $\delta = +3.5$ (again with $a = .5$, $\kappa = 2$, $R = 3$). Compared to the other two cases, now the coefficients $C(p)$ increase in value with p. The convergence as $N_{\max}$ increases is similar to the other cases, and the blocking coefficients B_j^0 converge quickly. In the figures we use $u_0 = 0$ and $-5 \leqslant u, v \leqslant 5$. Now $P(u,u)$ has the maximum value of about .994 at $u \cong .227$. Figures 8 and 9 show that the two-dimensional density is now quite concentrated near the boundary $u = v$. Note that $\delta \to +\infty$ corresponds to going from the critically loaded case to the overloaded case. For the latter we showed in [5] that $p(n_1, n_2)$ is concentrated, where $\ell = n_1 + n_2 - (C - R) = O(1)$.

Up to now we have discussed the numerical solution of the diffusion equation, but not how accurate an approximation it is for the original discrete model. In Table 4 we consider the exact numerical values of the blocking probabilities, as computed by solving (2.2) and (2.3), and compare these to those obtained from the diffusion approximation. We compare $\sqrt{\lambda}B_j$ (cf. (2.4)) to B_j^0 (cf. (5.2)). To compute B_j^0 we need to input the parameters a, κ, R, and δ. From these we can get λ and ν from

$$\lambda = \frac{\kappa}{\sigma}(C - R) = \frac{\kappa}{a^{-1} - 1 + \kappa}(C - R), \tag{5.3}$$

$$\rho = \sigma + \frac{\delta}{\sqrt{\lambda}}, \tag{5.4}$$

and

$$\nu = (\rho - \kappa)\lambda = \frac{a^{-1} - 1 + \delta/\sqrt{\lambda}}{a^{-1} - 1 + \kappa}\kappa(C - R). \tag{5.5}$$

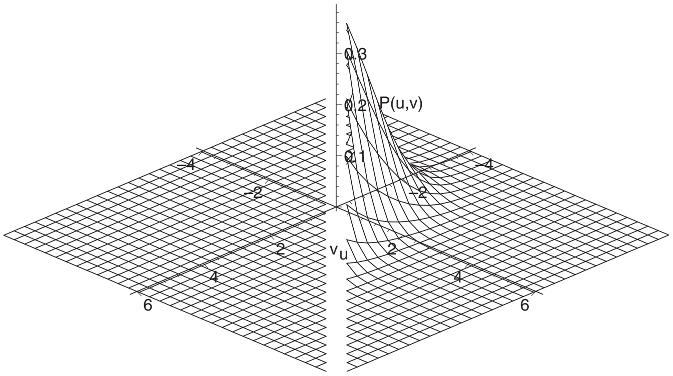

Fig. 2. *A sketch of the surface $P(u,v)$ from the direction $u = v$ when $\delta = .01$.*

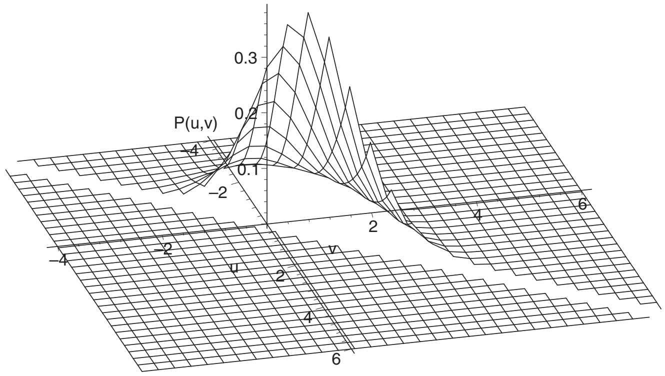

Fig. 3. *A sketch of the surface $P(u,v)$ from a different perspective when $\delta = .01$.*

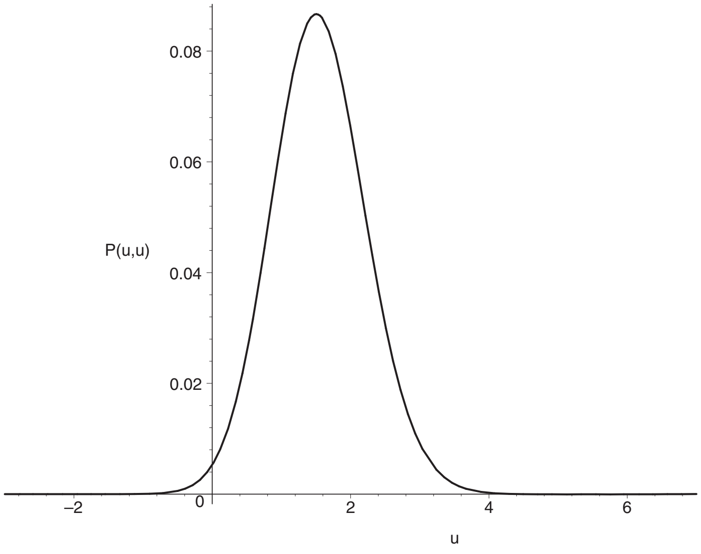

Fig. 4. *A sketch of the curve $P(u,u)$ for $-3 \leq u \leq 7$ when $\delta = -3.5$.*

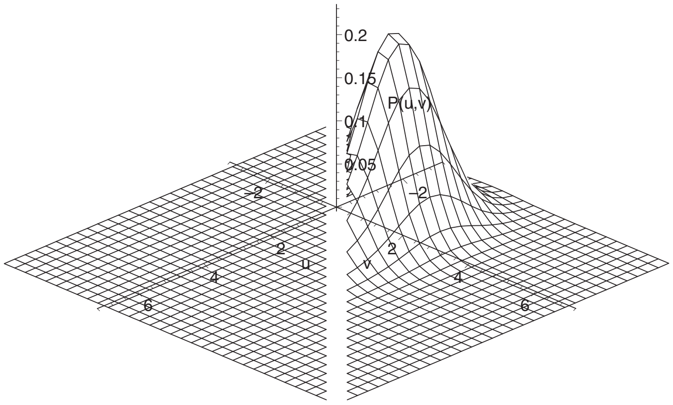

FIG. 5. *A sketch of the surface $P(u,v)$ from the direction $u = v$ when $\delta = -3.5$.*

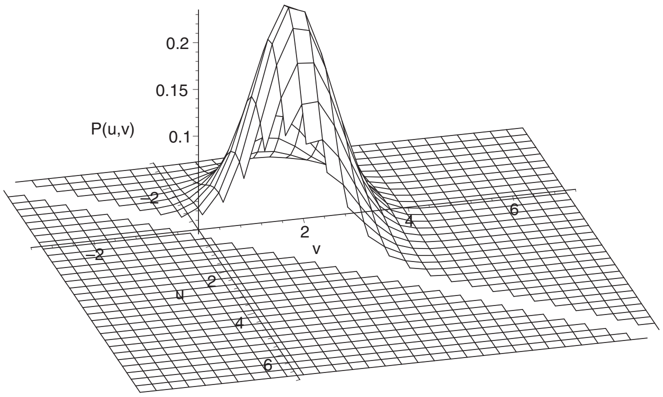

FIG. 6. *A sketch of the surface $P(u,v)$ from a different perspective when $\delta = -3.5$.*

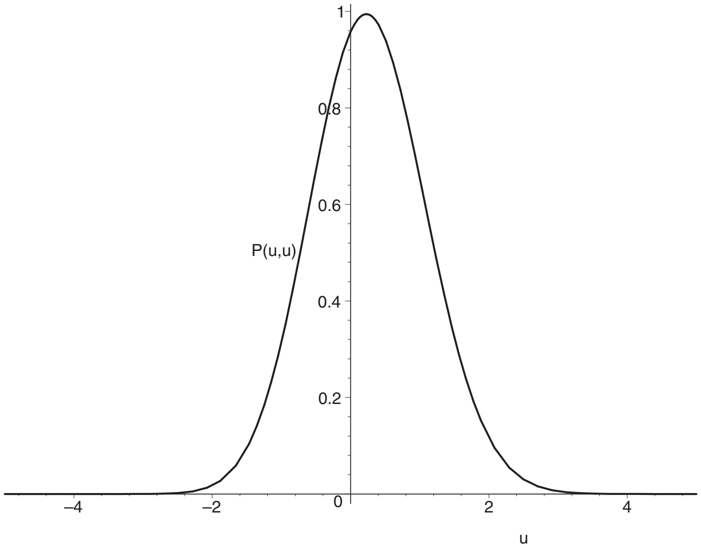

FIG. 7. *A sketch of the curve $P(u,u)$ for $-5 \leq u \leq 5$ when $\delta = 3.5$.*

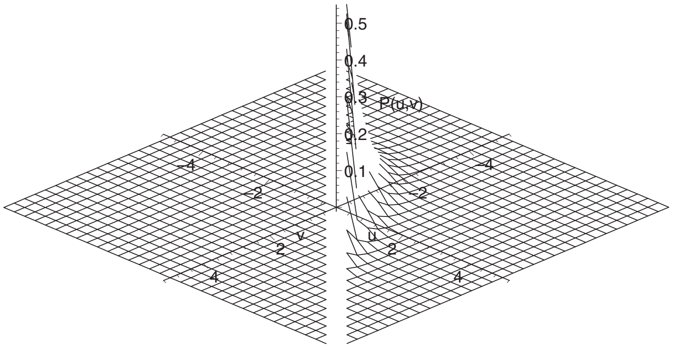

FIG. 8. *A sketch of the surface $P(u,v)$ from the direction $u=v$ when $\delta=3.5$.*

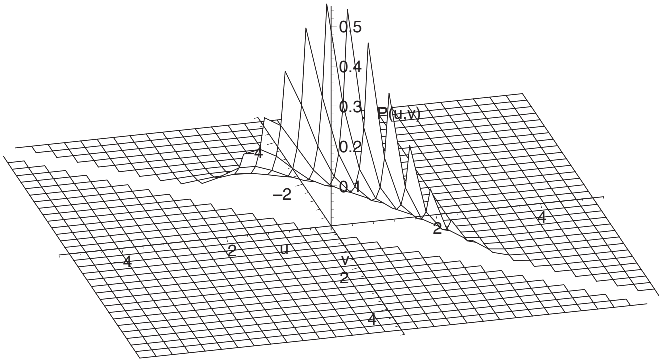

FIG. 9. *A sketch of the surface $P(u,v)$ from a different perspective when $\delta=3.5$.*

Then we input κ, R, C and λ,ν to solve the discrete linear system (2.2) numerically. Table 4 compares, for various C, the numerical values of $\sqrt{\lambda}B_j$ to B_j^0 (which are independent of C and λ). We see that $\sqrt{\lambda}B_j$ do appear to be converging as $C\to\infty$, but fairly slowly. The results are certainly consistent with the $O(1/\sqrt{\lambda})$ correction terms in, e.g., (3.2). We could in theory obtain the problem satisfied by the correction term to the diffusion approximation and analyze it numerically.

To summarize, the numerical method based on the C-modes does efficiently yield the blocking coefficients B_j^0, and determines the density $P(u,v)$, including $P(u,u)$, for ranges where there is significant mass. The method does have some problems with the tails, but here an asymptotic approach may be more appropriate.

6. Conclusion.

To summarize, we have analyzed a trunk reservation model in the limit of rapid arrivals for both high and low priority customer classes, a large number of servers or circuits, and a critical load condition in which the arrivals are roughly balanced by the number of circuits. Using a semi-analytic and seminumerical approach we derived and analyzed a two-dimensional PDE that describes the joint distribution of the numbers of circuits in use by both the high and low priority customers. Particular attention was paid to the blocking probabilities, which are both $O(1/\sqrt{\lambda})$ in this asymptotic limit.

This model may represent a single node in a circuit-switched network. However, the analysis of such a network depends on its topology, the capacities of its links and the offered traffic rates, and holding times between different pairs of origin and destination nodes. Consequently, it is not possible to say what our asymptotic results imply about the behavior of the network without a numerical analysis using fixed point approximations. This is beyond the scope of our paper.

Appendix. We will derive (4.17)–(4.19), using properties of the parabolic cylinder functions [6]. First, we use the property

$$e^{-z^2/4}D_\mu(z) = -\frac{d}{dz}\left[e^{-z^2/4}D_{\mu-1}(z)\right], \tag{A.1}$$

and note that $D_\nu(z) \to 0$ as $z \to \infty$, to obtain

$$\begin{aligned}\int_0^\infty \exp\left[-\frac{(\delta+\kappa(x+y))^2}{4\kappa(\sigma-\kappa)}\right] D_\mu\left(\frac{\delta+\kappa(x+y)}{\sqrt{\kappa(\sigma-\kappa)}}\right) dy \\ = \sqrt{\frac{\sigma}{\kappa}-1}\exp\left[-\frac{(\delta+\kappa x)^2}{4\kappa(\sigma-\kappa)}\right] D_{\mu-1}\left(\frac{\delta+\kappa x}{\sqrt{\kappa(\sigma-\kappa)}}\right).\end{aligned} \tag{A.2}$$

To evaluate $\omega_0(0)$ and the normalization condition (4.12) from (4.7) and (4.11), it will suffice, in view of (A.2), to consider the definite integral

$$I_m = \int_{-\infty}^\infty e^{-x^2/4}D_m(x)\exp\left[-\frac{1}{4}(a+bx)^2\right] D_{-\rho}(a+bx)\,dx \tag{A.3}$$

for $b > 0$ and m a nonnegative integer.

The term corresponding to $p = 0$ in the expansion (4.10) is equivalent to the term corresponding to $r = 0$ in (4.7). Hence we may restrict our attention to $p > 0$ in (4.10). If we let $a + bx = -\xi$ in (A.3), we obtain

$$\int_{-\infty}^\infty e^{-\xi^2/4}D_{-\rho}(-\xi)\exp\left[-\frac{(a+\xi)^2}{4b^2}\right] D_m\left(\frac{a+\xi}{b}\right) d\xi = (-1)^m bI_m. \tag{A.4}$$

Hence it will suffice to consider I_m for the expansion (4.10) also. But,

$$e^{-z^2/4}\sum_{m=0}^\infty D_m(z)\frac{t^m}{m!} = \exp\left[-\frac{1}{2}(z-t)^2\right]. \tag{A.5}$$

Hence, from (A.4), after some algebra, it follows that

$$\begin{aligned}\sum_{m=0}^\infty (-1)^m I_m\frac{t^m}{m!} = \frac{1}{b}\exp\left[-\frac{(a-bt)^2}{2(1+b^2)}\right] \\ \cdot\int_{-\infty}^\infty e^{\xi^2/4}D_{-\rho}(\xi)\exp\left\{-\frac{1+b^2}{2b^2}\left[\xi-\frac{a-bt}{1+b^2}\right]^2\right\} d\xi,\end{aligned} \tag{A.6}$$

where we have replaced ξ by $-\xi$.

Now by page 886 in [1],

$$\begin{aligned}\int_{-\infty}^\infty \exp\left[-\frac{(x-y)^2}{2\mu}\right] e^{x^2/4}D_\nu(x)\,dx \\ = \sqrt{2\pi\mu}(\sqrt{1-\mu})^\nu \exp\left[\frac{y^2}{4(1-\mu)}\right] D_\nu\left(\frac{y}{\sqrt{1-\mu}}\right), \quad 0 < \mu < 1.\end{aligned} \tag{A.7}$$

(There is a factor $\sqrt{2\pi\lambda}$ missing from the corresponding result in [6].) From (A.6) and (A.7), with $\mu = b^2/(1+b^2)$ and $y = (a-bt)/(1+b^2)$, we obtain

$$\text{(A.8)} \qquad \sum_{m=0}^{\infty}(-1)^m I_m \frac{t^m}{m!} = \frac{\sqrt{2\pi}}{(\sqrt{1+b^2})^{1-\rho}} \exp\left[-\frac{(a-bt)^2}{4(1+b^2)}\right] D_{-\rho}\left(\frac{a-bt}{\sqrt{1+b^2}}\right).$$

But,

$$\text{(A.9)} \qquad D_\nu(x+y) = \exp\left(\frac{xy}{2}+\frac{y^2}{4}\right)\sum_{m=0}^{\infty}\frac{(-y)^m}{m!}D_{m+\nu}(x).$$

It follows from (A.8) and (A.9) that

$$\text{(A.10)} \qquad I_m = \frac{\sqrt{2\pi}(-b)^m}{(\sqrt{1+b^2})^{m+1-\rho}} \exp\left[-\frac{a^2}{4(1+b^2)}\right] D_{m-\rho}\left(\frac{a}{\sqrt{1+b^2}}\right).$$

In (A.3), for the expansion (4.7), we take $a = \delta/\sqrt{\kappa(\sigma-\kappa)}$, $b = \sqrt{\kappa/(\sigma-\kappa)}$, and $m = r \geqslant 0$, and we take $\rho = 1 + r/\kappa$ for the evaluation of the normalization condition (4.12) and $\rho = r/\kappa$ for the evaluation of $\omega_0(0)$. The former choice of ρ, with the help of (A.2) and (A.10), leads to (4.15), and hence to (4.17), where $\alpha(r)$ is defined by (4.16). The latter choice of ρ leads to (4.18). For the expansion (4.10) we use (A.4), and in (A.3) we take $a = \delta/\kappa$, $b = \sqrt{(\sigma-\kappa)/\kappa}$, and $\rho = p\kappa$, and we take $m = p-1$, $p > 0$ for the evaluation of the normalization condition (4.12) and $m = p \geqslant 0$ for the evaluation of $\omega_0(0)$. The former choice of m, with the help of (A.2) and (A.10), leads to (4.19), where $\gamma(p)$ is defined by (4.20). The term corresponding to $p = 0$ in (4.10) is equivalent to that corresponding to $r = 0$ in (4.7), as pointed out previously. The latter choice of m leads to (4.21).

NUMERICAL MODELING OF ELECTROWETTING BY A SHAPE INVERSE APPROACH*

JÉRÔME MONNIER†, PATRICK WITOMSKI†, PATRICK CHOW-WING-BOM†, AND CLAIRE SCHEID†

Abstract. We model an electrified droplet spreading on a solid surface. The model aims to seek a drop shape that minimizes its total energy (capillary, electrostatic, and gravitational). We derive the equations and the shape gradient; then we detail the shape optimization algorithm and present some numerical results. Up to a critical applied voltage value, the computed angles fit the predictions of Lippman's equation (plane capacitor approximation). Then, when increasing the voltage, we observe an overestimate of the Lippman prediction. Numerical computations of the curvature show that it remains constant everywhere except in the vicinity of the contact point, where it increases sharply.

1. Introduction.

Electrowetting can be defined as a tool for spreading liquid droplets (e.g., water) on hydrophobic solid surfaces (e.g., polymer film). This is quite a recent technique (see [1]) which holds very attractive properties for manipulation of tiny liquid volumes, as is done, for example, in biotechnologies. The principle of electrowetting is to apply an electric field between the conductor liquid droplet and the solid surface in order to change the droplet spreading on the surface. Given the liquid volume, the main feature for describing the droplet is the wetting angle.

Several articles discuss the experimental aspects of electrowetting and present some analytical analysis; see, e.g., [1], [21], [2], and the references therein. One property of electrowetting still poorly understood by physicists is the contact angle saturation. Several mechanisms for explaining it were proposed in [21], [22], [17], [20]. When increasing the applied electric voltage, the liquid droplet spreads onto the solid and the wetting angle decreases. Nevertheless, this is true only if the value of the applied voltage is less than a certain critical value. Up to this critical value, the contact angle can be derived from the Lippman equation using the plane capacitor approximation. For higher values, one observes a saturation of the wetting angle and for even higher values, instabilities of the contact line liquid-solid-gas can appear. A few hypotheses have been made to explain the saturation phenomenon. Let us cite, for example, the air ionization (see [21]) or electrostatic effects near the wetting line (see [4]). This limiting phenomenon is still under investigation and the full modeling of electrowetting remains an open problem. In other respects, the authors of [5] show that the contact angle does not depend on the potential. It remains equal to the static Young angle (obtained when the potential is null). Also, they observe that the curvature near the contact line increases while the potential increases.

In this study, we present a mathematical approach for modeling and numerically computing the drop shape, given an applied voltage. The model is based on the shape optimal design methods; see, e.g., [6], [11]. We seek the drop shape (a free surface) such that it minimizes its total energy. The total energy is the sum of the capillary energy, the gravitational energy, and the electrostatic energy. Our numerical modeling is general in the sense that we do not make any assumption on the drop shape. The equations are fully solved and the shape is defined in a general family of surfaces. We assume that the drop shape is steady state and remains two-dimensional (2D) axisymmetric but the method remains valid for three-dimensional (3D) shapes as well. Of course, in the 3D case, the implementation is much more complex and time-consuming than in the present 2D axisymmetric case. This 2D axisymmetric assumption is valid for applied voltages up to the value leading to the instabilities mentioned above.

We obtain numerical results which are consistent with the plane capacitor approximation (Lippman's equation) only for low voltages. For higher voltages, we observe an overestimate of the Lippman predictions. Nevertheless, with the present model, we do not retrieve the wetting angle saturation but instead a deviation from Lippman's predictions of the shape of the drop. In other respects, we focus on the curvature values of the droplet interface. The computed curvature is constant everywhere except in the vicinity of the contact point. If we refine the surface representation near the contact line, we will observe an increase of the curvature—we noticed this behavior for all potentials applied.

The paper is organized as follows. In section 2, we present the electrowetting process and the plane capacitor approximation. In section 3, we derive our mathematical model. It is a shape inverse problem—we seek the drop shape such that it minimizes its total energy. The energy depends on the electric field, which is the solution of the external partial differential equation. The liquid volume is given and constant; it is considered an equality constraint. Finally, the problem consists in finding a min-max solution (saddle point) of an augmented Lagrangian (see [8]). Numerically, the solution is computed using Uzawa's algorithm and a quasi Newton optimization algorithm (BFGS). In section 4, we define the mathematical framework of shape optimization, and we derive the shape derivative of the augmented Lagrangian (the continuous gradient; see Theorem 4.1). In section 5, we detail the discretization of the equations and the shape derivative. The partial differential equation is solved using a standard linear P_1-Lagrange finite element method. The shape parameters and the shape deformation basis are defined; then the shape gradient and the optimization parameters are deduced from section 4. The full optimization process is presented in section 6. It has been implemented in C++. The code uses a public finite element library and a public mesh generator with automatic mesh refinement. In section 7, we present the algorithm we use to compute the droplet curvatures. It is based on a local least square approximation of the control points (second order Bezier approximation). In section 8, we present the numerical results.

2. Electrowetting process.

Let us consider the electrowetting process presented in Figure 2.1. We denote by σ_{LS}, σ_{SG}, and σ_{LG} the surface tension coefficients of the liquid-solid interface, solid-gas interface, and liquid-gas interface, respectively. We denote by θ the wetting angle.

When the applied electrical potential u_0 is null, Young's equation gives

$$\cos(\theta_0) = \frac{\sigma_{SG} - \sigma_{LS}}{\sigma_{LG}},$$

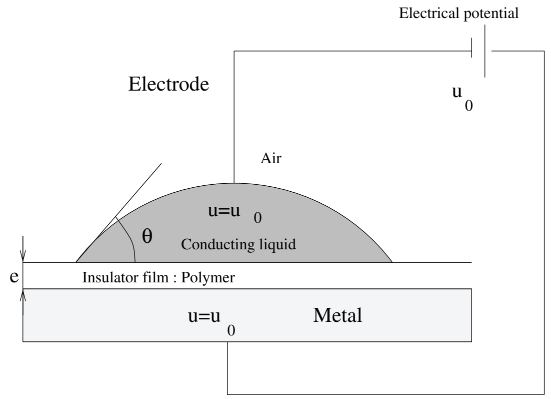

FIG. 2.1. *Electrowetting process.*

where θ_0 is the wetting angle at $u_0 = 0$.

Under the assumption that the system behaves as a plane capacitor with negligible boundary effects, the drop shape obeys the Young equation with the surface tension coefficient modified as follows (see [1]):

$$\sigma_{LS}(u_0) = \sigma_{LS} - \frac{\varepsilon_0 \varepsilon_1}{2e} u_0^2,$$

where e is the insulator thickness and ε_0 and ε_1 are the dielectric constants.

Also, we have (see [1])

$$\cos(\theta) = \cos(\theta_0) + \frac{\varepsilon_0 \varepsilon_1}{2\sigma_{LG}\ e} u_0^2.$$

This last equation is also called Lippman's equation.

Let us note that this law predicts total spreading when the potential increases. However, if u_0 is greater than a critical value u_{cr}, physicists observe a locking phenomenon limiting the spreading of the droplet on the polymer film. Such experiments are studied in [1], [21], [2].

The aim of the present study is to model and numerically compute the liquid drop shape for u_0 lower than the critical value u_{cr}. These computations include the wetting angle θ and the curvature κ of the liquid surface.

3. Mathematical modeling.

We model the electrowetting process described in the previous section as a shape inverse problem.

Assumptions.

(i) The applied electrical potential u_0 is continuous.

(ii) The liquid drop is a perfect conductor.

(iii) The drop geometry is 2D axisymmetric.

(iv) Electrostatic effects are negligible far away from the drop.

(v) For $u_0 = 0$, the liquid partially wets the polymer (the spreading coefficient is negative).

Notation (see Figure 3.1). We denote by $u(x)$ the electrical potential at point x, ω_0 the liquid drop, ω_1 the polymer domain, ω_2 the artificially bounded gas domain, and γ_{ext} its external boundary. The external boundary γ_{ext} is supposed to be located far enough from the liquid drop.

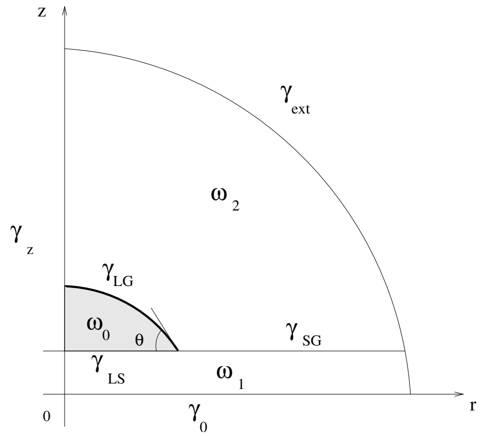

FIG. 3.1. *2D axisymmetric droplet (shaded gray). Domains and boundaries notations.*

We denote by γ_{LS}, γ_{SG}, and γ_{LG} the liquid-solid interface, solid-gas interface, and liquid-gas interface, respectively. We set $\omega = \omega_1 \cup \omega_2 \cup \gamma_{SG}$. We have $\partial\omega_0 = \gamma_{Lz} \cup \gamma_{LG} \cup \gamma_{LS}$ and $\partial\omega = \gamma_0 \cup \gamma_{Sz} \cup \gamma_{LG} \cup \gamma_{Gz} \cup \gamma_{ext}$, with $\gamma_z = \gamma_{Gz} \cup \gamma_{Lz} \cup \gamma_{Sz}$. We set $B = \omega_0 \cup \omega \cup \gamma_{LG} \cup \gamma_{LS}$. The liquid domain ω_0 will be variable; on the other hand, the domain B is given and fixed.

The questions we will answer numerically are the following. Given the electrical potential u_0,

- What is the drop shape?
- What is the wetting angle value θ?
- What is the curvature κ value of the drop surface?

The shape inverse formulation. We model this steady-state free surface problem as a shape inverse problem. We follow the approach presented in [4].

The total energy $\mathcal{E}$ is the sum of the gravitational energy, the capillary energy, and the electrostatic energy. In the 3D case, its expression is the following (see, e.g., [2]):

$$\mathcal{E}_{\omega_0} = \mathcal{E}_{\omega_0}^{grav} + \mathcal{E}_{\omega_0}^{cap} + \mathcal{E}_{\omega_0}^{elec};$$

with the gravitational energy:

$$\mathcal{E}^{grav} = \rho\ g \int_{\omega} z dx;$$

with the capillary balance energy:

$$\mathcal{E}^{cap} = \int_{\gamma_{LS}} (\sigma_{LS} - \sigma_{GS}) ds + \int_{\gamma_{LG}} \sigma_{LG} ds;$$

and the electrostatic energy:

$$\mathcal{E}^{elec} = -\frac{1}{2} \int_{\omega} \varepsilon |\nabla u|^2 dx,$$

where ρ is the liquid density, g is the gravity constant, $\varepsilon = \varepsilon_i$ in ω_i, $i = 1, 2$, and ε_i is the relative dielectric permittivity of ω_i; i.e., $\varepsilon_0\varepsilon_i$, $i = 1, 2$ is the polymer and the gas permittivity, respectively.

The shape inverse formulation is as follows:

$$\left\{\begin{array}{l} \text{Find } \omega_0^\star \text{ such that} \\ \mathcal{E}_{\omega_0^\star} \;=\; \displaystyle\min_{(\omega_0;\ \int_{\omega_0} dx = vol)} \mathcal{E}_{\omega_0}, \end{array}\right.$$

where *vol* is the given drop volume.

We set $u_i = u|_{\omega_i}$, $i = 1, 2$. Then, the potential u_i is the solution of the equation

$$-\mathrm{div}(\varepsilon_i \nabla u_i) \;=\; 0 \quad \text{in } \omega_i,\ i = 1, 2, \tag{3.1}$$

with the following Dirichlet boundary conditions:

$$\left\{\begin{array}{lcll} u_1 & = & u_0 & \text{on } \gamma_{LG}, \\ u_2 & = & u_0 & \text{on } \gamma_{LS}, \\ u_2 & = & 0 & \text{on } \gamma_0. \end{array}\right. \tag{3.2}$$

On the solid-gas interface, we have the transmission boundary conditions

$$\left\{\begin{array}{ccll} u_1 & = & u_2 & \text{on } \gamma_{SG}, \\ \varepsilon_1 \nabla u_1 n_1 & = & -\varepsilon_2 \nabla u_2 n_2 & \text{on } \gamma_{SG}. \end{array}\right. \tag{3.3}$$

On the artificial boundary $\gamma_{ext} = \gamma_{ext}^1 \cup \gamma_{ext}^2$, we impose

$$\varepsilon_i \nabla u_i n_i \;=\; 0 \qquad \text{on } \gamma_{ext}^i,\ i = 1, 2. \tag{3.4}$$

Therefore, the present mathematical problem is a shape optimal control problem for a system governed by a linear steady-state partial differential equation.

2*D axisymmetric equations.* As mentioned previously, we assume that the drop shape is 2D axisymmetric. We present below the weak formulation of the model. We set

$$X_0(\omega) = \{v \in H^1(\omega);\ v = 0 \text{ on } \gamma_0 \cup \gamma_{LS} \cup \gamma_{LG}\},$$

$$X_t(\omega) = \{v \in H^1(\omega);\ v = 0 \text{ on } \gamma_0;\ v = u_0 \text{ on } \gamma_{LS} \cup \gamma_{LG}\}.$$

The weak formulation of (3.1)–(3.4) in the 2D axisymmetric case is

$$\left\{\begin{array}{l} \text{Find } u^\omega \in X_t(\omega) \text{ such that} \\ \forall v \in X_0(\omega),\ a_\omega(u^\omega, v) = 0, \end{array}\right. \tag{3.5}$$

where

$$a_\omega(u, v) = \int_\omega \varepsilon r \langle \nabla u, \nabla v \rangle dx,$$

$x = (r, z)$, and $\langle .,. \rangle$ is the inner product of $\mathbb{R}^2$.

It follows from the Lax–Milgram theorem that state equation (3.5) has only one solution for $u^\omega \in X_t(\omega)$.

The shape inverse problem. In its dimensionless form, the drop energy is

$$\mathcal{E}_{\omega_0}(u^\omega) \;=\; \alpha \int_\omega z dx + \int_{\gamma_{LG}} r ds + \mu \int_{\gamma_{LS}} r dr - \delta \int_\omega \varepsilon r |\nabla u^\omega|^2 dx, \tag{3.6}$$

where u^ω is the unique solution of (3.5), $\alpha = \frac{\rho g (L^*)^2}{\sigma_{LG}}$, $\mu = -cos(\theta_0) = \frac{\sigma_{LS}-\sigma_{GS}}{\sigma_{LG}}$, $\delta = \frac{1}{2\sigma_{LG}L^*}$, and L^* is a characteristic length (typically $L^* \approx 10^{-4} - 10^{-3}$ m).

We set the cost function by

$$j(\omega) = \mathcal{E}_{\omega_0}(u^\omega). \tag{3.7}$$

We denote by $\mathcal{D}$ the admissible domain space. (The definition of $\mathcal{D}$ is detailed in the next section.) The shape optimal inverse problem is

$$\left\{ \begin{array}{l} \text{Find } \omega^\star \in \mathcal{D} \text{ such that} \\ j(\omega^\star) = \displaystyle\min_{(\omega; \int_{\omega_0} r dx = vol/2\pi)} j(\omega). \end{array} \right. \tag{3.8}$$

Let us point out that the variable is not the whole domain ω, but more precisely, the liquid-gas interface γ_{LG}; see Figure 3.1. We assume that the inverse shape problem (3.8) admits at least one solution. The existence of an optimal shape is not addressed in the present paper.

The augmented Lagrangian. Problem (3.8) is an optimization problem under an equality constraint. Thus, classically, we introduce the augmented Lagrangian $L_\tau : \mathcal{D} \times \mathbb{R} \longrightarrow \mathbb{R}$, defined by the following (see, e.g., [8]):

$$L_\tau(\omega, \lambda) = j(\omega) + \lambda c(\omega) + \tau c(\omega)^2, \tag{3.9}$$

where $c(\omega)$ is the volume constraint,

$$c(\omega) = \int_{\omega_0} r dx - \frac{vol}{2\pi} = \int_B r dx - \int_\omega r dx - \frac{vol}{2\pi}, \tag{3.10}$$

λ is the Lagrange multiplier, and τ is a penalty parameter.

Then, the shape optimal inverse problem (3.8) is formulated as the saddle-point problem:

$$\left\{ \begin{array}{l} \text{Find } (\omega^\star, \lambda^\star) \in \mathcal{D} \times \mathbb{R} \text{ such that} \\ L_\tau(\omega^\star, \lambda^\star) = \displaystyle\min_\omega \max_\lambda L_\tau(\omega, \lambda). \end{array} \right. \tag{3.11}$$

We will solve (3.11) using the classical Uzawa algorithm; see, e.g., [8]. This algorithm uses a gradient-type algorithm (BFGS), which requires us to compute the shape derivative of the cost function $\frac{dj}{d\omega}(\Omega)$ and the shape derivative of the constraint $\frac{dc}{d\omega}(\Omega)$. The expressions of these shape derivatives are presented in the next section.

4. Shape derivatives. As mentioned above, we need to compute the shape derivative of the cost function $\frac{dj}{d\omega}(\Omega)$ and the shape derivative of the constraint $\frac{dc}{d\omega}(\Omega)$. This is done using the optimal shape design method (see [15], [6], [11]; definitions of [7], [12] are used). Three approaches are possible: (i) we differentiate the equations and then we discretize them, thus obtaining the discretized continuous gradient; (ii) we discretize the equations and then we differentiate them, thus obtaining the discrete gradient; (iii) we directly differentiate the direct code (typically, using automatic differentiation). In the present study, we follow approach (i). This requires some extra mathematical definitions and tools, but this approach is rigorous; it leads to synthetic expressions of derivatives and it allows us to prove all the differentiabilities required. These derivatives are discretized in the next section, leading to shape gradients. The family of shapes considered is large enough in the sense that it includes those observed in the experiments.

This section is organized as follows. We define the admissible domain space $\mathcal{D}$ (Lipschitz domains); then we use the classical definition of shape derivatives based on domain deformations (a method of transport with $\mathcal{C}^1$ transformations). We prove the differentiability of the cost function j and the constraint function c with respect to the domain ω. Then, by introducing the adjoint state equation (in our case the adjoint state vanishes), we obtain the differential of j and c (Theorem 4.1). The shape derivative of the augmented Lagrangian L_τ follows (Corollary 4.2).

4.1. Mathematical framework: Domain variations and shape derivatives. We consider a family of Lipschitz domains. We define the space of admissible domains and the derivative with respect to the domain in a classical manner. The domain space is the set of domains homeomorphic to a reference domain. The transformations are $\mathcal{C}^1$ homeomorphisms. This regularity is necessary for all transported integrals to be well defined. The shape derivative of a real valued function is the derivative of the transported function with respect to the transformation. We refer to [15], [6], and we follow the definitions and properties presented in [7], [12].

Admissible domain space. Let $\hat{\Omega}$, a bounded open subset of $\mathbb{R}^2$ with a Lipschitz boundary, be the reference domain $\hat{\Omega} = \Omega_1 \cup \hat{\Omega}_2 \cup \hat{\Gamma}_{SG}$. Ω_1 represents the solid part and $\hat{\Omega}_2$ the gas part. We distinguish the variable part of $\hat{\Omega}$ from its fixed part; see Figure 4.1. We set $\partial\hat{\Omega} = \hat{\Gamma}_{Var} \cup \Gamma_{Fix}$, where $\hat{\Gamma}_{Var} = \hat{\Gamma}_{LG} \cup \hat{\Gamma}_{LS}$ is the variable boundary and Γ_{Fix} is the fixed boundary. We denote by B_{int} a neighborhood of $\hat{\Gamma}_{Var}$, B_{int} large enough; see Figure 4.1.

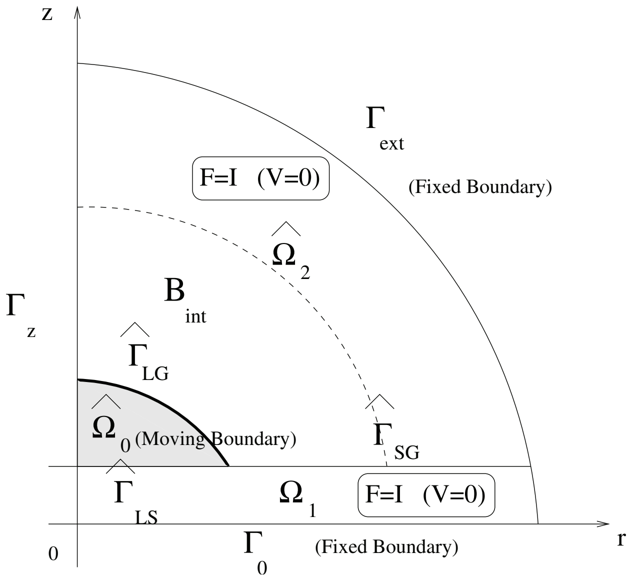

FIG. 4.1. *The reference domain $\hat{\Omega}$.*

We set the function space

$$\hat{\mathcal{F}} = \{\hat{F},\ \hat{F} \text{ bijection of } \hat{\Omega} \text{ onto } \hat{F}(\hat{\Omega});\ \hat{F} \in \mathcal{C}^1(\bar{\hat{\Omega}}, \mathbb{R}^d),\ \hat{F}^{-1} \in \mathcal{C}^1(\bar{\hat{F}}(\hat{\Omega}), \mathbb{R}^d)\} \tag{4.1}$$

and its affine subspace $\hat{\mathcal{F}}_0 = \{\hat{F} \in \hat{\mathcal{F}}; \hat{F} = I \text{ in } \hat{\Omega} \setminus B_{int}\}$, where I denotes the identity of $\mathbb{R}^d$. Then, we define the admissible domain space $\mathcal{D}$ as follows:

$$\mathcal{D} = \{\omega = \hat{F}_0(\hat{\Omega});\ \hat{F}_0 \in \hat{\mathcal{F}}_0\}. \tag{4.2}$$

One knows that if $\hat{F}$ is close enough to I in $\hat{\mathcal{F}}_0$ ($(\hat{F} - I)$ small enough), then $\hat{F}(\hat{\Omega})$ is an open set of $\mathbb{R}^2$ with a Lipschitz boundary and $F(\hat{\Gamma}_{Var}) \subset B_{int}$.

Shape derivative of a real valued function. For $\hat{F}_0 \in \hat{\mathcal{F}}_0$, $(\hat{F}_0 - I)$ small enough, we define the domain Ω by $\Omega = \hat{F}_0(\hat{\Omega})$ and $\Gamma_{Var} = \hat{F}_0(\hat{\Gamma}_{Var})$. We set the homeomorphism space defined in Ω (see Figure 4.2) as $\mathcal{F} = \{F,\ F = \hat{F} \circ \hat{F}_0^{-1},\ \hat{F} \in \hat{\mathcal{F}}\}$, and its affine subspace as $\mathcal{F}_0 = \{F,\ F = \hat{F} \circ \hat{F}_0^{-1},\ \hat{F} \in \hat{\mathcal{F}}_0\}$.

Let $F \in \mathcal{F}_0$; we define $\omega = F(\Omega)$ and $V \in \mathcal{C}^1(\bar{\Omega}, \mathbb{R}^d)$ by $V = F - I$. We have $V = 0$ in $\hat{\Omega} \setminus B_{int}$.

$$\begin{tikzcd}
\hat{\Omega} \arrow[r, "\hat{F}_0"] \arrow[dr, "\hat{F}"'] & \Omega \arrow[d, "F= I+ V"] \\
& \omega
\end{tikzcd}
\qquad
\begin{tikzcd}
\Omega \arrow[rr, shift left, "F= I+ V"] \arrow[dr, "\bar{v}"'] & & \omega \arrow[ll, shift left, "F^{-1}"] \arrow[dl, "v"] \\
& R &
\end{tikzcd}$$

FIG. 4.2. *Change of variables.*

For a given cost function j, $j : \omega \in \mathcal{D} \mapsto j(\omega) \in \mathbb{R}$, we define the "transported" cost function $\bar{\jmath}$ by $\bar{\jmath} : \mathcal{F}_0 \to \mathbb{R}\ :\ F \mapsto \bar{\jmath}(F) = j(F(\Omega)) = j(\omega)$. Then, the derivative with respect to the domain is defined as follows (see, e.g., [15], [7] for more details):

$$\frac{dj}{d\omega}\ (\Omega) \cdot V = \frac{d\bar{\jmath}}{dF}\ (I) \cdot V \quad \forall V \in \mathcal{C}^1(\bar{\Omega}, \mathbb{R}^d). \tag{4.3}$$

4.2. Shape derivatives. We present below the expressions of the exact differentials with respect to the shape ω.

THEOREM 4.1. *There exists $\mathcal{V}_I$, a neighborhood of I in $\mathcal{F}_0$, such that*

(i) *the cost function $j : \mathcal{D} \to \mathbb{R}$; $\omega \mapsto j(\omega) = \mathcal{E}_{\omega_0}(u^\omega)$ belongs to $\mathcal{C}^1$ for all $\omega = F(\Omega)$, $F \in \mathcal{V}_I$. Additionally, for all $V \in \mathcal{C}^1(\bar{\Omega}, \mathbb{R}^2)$, we have*

$$\frac{dj}{d\omega}(\Omega).V = \frac{\partial \mathcal{E}_{\Omega_0}}{\partial \omega}(u^\Omega).V, \tag{4.4}$$

with u^Ω the solution of the state equation (3.5) *posed in Ω and*

$$\begin{aligned}
\frac{\partial \mathcal{E}_{\Omega_0}}{\partial \omega}(u^\Omega).V = {} & \alpha \int_\Omega z \circ V\ dx + \alpha \int_\Omega z \operatorname{div}(V)\ dx \\
& + \int_{\Gamma_{LG}} r \circ V\ ds + \int_{\Gamma_{LG}} r\ \operatorname{div}_\Gamma V\ ds \\
& + \mu \int_{\Gamma_{LS}} r \circ V\ dr + \mu \int_{\Gamma_{LS}} r\ \operatorname{div}_\Gamma V\ dr \\
& - \delta \int_\Omega \varepsilon\ (r \circ V)\ |\nabla u^\Omega|^2\ dx - \delta \int_\Omega \varepsilon r |\nabla u^\Omega|^2\ \operatorname{div}(V)\ dx \\
& + \delta \int_\Omega \varepsilon r < (\ {}^T DV + DV) \nabla u^\Omega, \nabla u^\Omega > dx,
\end{aligned}$$

with $\operatorname{div}_\Gamma V = (\operatorname{div}(V) - \langle n,\ {}^T DVn \rangle)$, *$n$ the external normal, and $x = (r, z)$.*

(ii) *The volume constraint $c(\omega)$ belongs to $\mathcal{C}^1$ for all $\omega = F(\Omega)$, $F \in \mathcal{V}_I$ and, for all $V \in \mathcal{C}^1(\bar{\Omega}, \mathbb{R}^2)$,*

$$\frac{dc}{d\omega}(\Omega).V = -\int_\Omega r \circ V dx - \int_\Omega r\mathrm{div}(V)dx. \tag{4.5}$$

Proof. The proof follows with three steps: 1. transport of equations; 2. differentiability with respect to ω; 3. use of the adjoint technique leading to the expression of the exact differential.

Step 1. *Transport of equations.* As noted previously, we need to transport the cost function j in order to compute its shape derivative. To this end, we need to transport all the equations on the reference domain $\Omega = F^{-1}(\omega)$.

For any $u, v \in X_0(\omega)$, we let

$$\bar{a}(F;\bar{u},\bar{v}) = a_{F(\Omega)}(\bar{u} \circ F^{-1}, \bar{v} \circ F^{-1}) = a_\omega(u,v)$$
$$= \int_\Omega \bar{\varepsilon}\bar{r} <^T (DF^{-1} \circ F)\nabla\bar{u},^T (DF^{-1} \circ F)\nabla\bar{v} > |\mathrm{det}DF| d\bar{x},$$

with $\bar{u} = u \circ F$, $\bar{v} = v \circ F$, $\bar{x} = x \circ F$, and $\bar{\varepsilon} = \varepsilon \circ F$; see Figure 4.2.

The mapping $v \in X_0(F(\Omega)) \mapsto v \circ F \in X_0(\Omega)$ is an isomorphism for $F \in \mathcal{F}_0$. In other respects, the Dirichlet data u_0 is constant; hence $u_0 = u_0 \circ F$. Then, since state equation (3.5) has a unique solution u^ω, the transported state equation

$$\text{Find } \bar{u}^F \in X_t(\Omega): \ \bar{a}(F;\bar{u},\bar{v}) = 0 \quad \forall \bar{v} \in X_0(\Omega)$$

has a unique solution $\bar{u}^F = u^\omega \circ F$.

Similarly, for any $u \in X_0(\omega)$, we let $\bar{\mathcal{E}}(F;\bar{u}) = \mathcal{E}_{F(\Omega_0)}(\bar{u} \circ F^{-1}) = \mathcal{E}_{\omega_0}(u)$. We have $\bar{\jmath}(F) = \bar{\mathcal{E}}(F;\bar{u}^F)$,

$$\begin{aligned} \bar{\jmath}(F) = \alpha &\int_\Omega \bar{z}\ |\mathrm{det}DF|\ d\bar{x} \\ &+ \int_{\Gamma_{LG}} \bar{r}\ Jac(F)\ d\bar{s} + \mu \int_{\Gamma_{LS}} \bar{r}\ Jac(F)\ d\bar{r} \\ &- \delta \int_\Omega \bar{\varepsilon}\ \bar{r}\ |\ ^T(DF^{-1} \circ F)\nabla\bar{u}^F|^2\ |\mathrm{det}DF|\ d\bar{x}, \end{aligned} \tag{4.6}$$

with $Jac(F) = |\mathrm{det}DF|\ \|\ ^T DF^{-1}.n\|_{\mathbb{R}^2}$.

Also, we define

$$\bar{c}(F) = \int_B r dx - \int_\Omega \bar{r}\ |\mathrm{det}DF|\ d\bar{x} - \frac{vol}{2\pi}. \tag{4.7}$$

Step 2. *Differentiability with respect to ω.* The mapping $\bar{a}(F;\bar{u},\bar{v})$ is C^1 with respect to $(F;\bar{u})$. It follows from the implicit function theorem that the transported state equation defines a C^1-mapping $F \mapsto \bar{u}^F : \mathcal{F}_0 \to X_t(\Omega)$ in a neighborhood $\mathcal{V}_I$ of I.

Then, since the mapping $\bar{\mathcal{E}}$ is of class $\mathcal{C}^1(\mathcal{F} \times X_0(\Omega))$, the cost function j is continuously differentiable. Also, the constraint function c is continuously differentiable.

Step 3. *Expression of the exact differential.* By definition, we have $\frac{dj}{d\omega}(\Omega) \cdot V = \frac{d\bar{\jmath}}{dF}(I) \cdot V$ for all $V \in \mathcal{C}^1(\bar{\Omega}, \mathbb{R}^2)$.

Then, using the classical adjoint technique, we have

$$\frac{d\bar{\jmath}}{dF}(I).V = \frac{\partial \bar{\mathcal{E}}}{\partial F}(I;u^{\Omega}).V - \frac{\partial \bar{a}}{\partial F}(I;u^{\Omega},p^{\Omega}).V \quad \forall V \in \mathcal{C}^1(\bar{\Omega},\mathbb{R}^2),$$

where u^{Ω} is the solution of the state equation posed in Ω and $p^{\Omega} \in X_0(\Omega)$ is the adjoint state, unique solution of the following adjoint equation:

$$\frac{\partial \bar{a}}{\partial u}(I;u^{\Omega},p^{\Omega}).v = \frac{\partial \bar{\mathcal{E}}}{\partial u}(I;u^{\Omega}).v \quad \forall v \in X_0(\Omega).$$

We have

$$\frac{\partial \bar{a}}{\partial u}(I;u^{\Omega},p^{\Omega}).v = a_{\Omega}(p^{\Omega},v) \quad \text{and} \quad \frac{\partial \bar{\mathcal{E}}}{\partial u}(I;u^{\Omega}).v = -2\delta a_{\Omega}(u^{\Omega},v) = 0 \ \ \forall v \in X_0(\Omega).$$

Hence, $p^{\Omega} \in X_0(\Omega)$ and $a_{\Omega}(p^{\Omega},v) = 0$ for all $v \in X_0(\Omega)$. Therefore, $p^{\Omega} = 0$.

Hence,

$$\frac{dj}{d\omega}(\Omega).V = \frac{\partial \bar{\mathcal{E}}}{\partial F}(I;u^{\Omega}).V \quad \forall V \in C^1(\bar{\Omega},\mathbb{R}^2).$$

Using (4.7) and the classical expression of the derivatives of $|\det(DF)|$, $(DF^{-1} \circ F)$, and $(\| {}^{T}DF^{-1}.n\|_{\mathbb{R}^2})$ (see, e.g., [15, Chap. IV]), we obtain the result (i).

The result (ii) follows from (4.7) and the expression of the derivative of $|\det(DF)|$. □

Then, we have straightforwardly the following result.

COROLLARY 4.2. *At (λ,τ) given in $\mathbb{R} \times \mathbb{R}^+$, the augmented Lagrangian L_τ is locally and continuously differentiable with respect to ω. And for all $V \in \mathcal{C}^1(\bar{\Omega},\mathbb{R}^2)$,*

$$\frac{\partial L_\tau}{\partial \omega}(\Omega,\lambda).V = \frac{dj}{d\omega}(\Omega).V + \lambda\frac{dc}{d\omega}(\Omega).V + 2\tau c(\Omega)\frac{dc}{d\omega}(\Omega).V, \tag{4.8}$$

where $\frac{dj}{d\omega}(\Omega).V$ and $\frac{dc}{d\omega}(\Omega).V$ are defined by (4.4) *and* (4.5)*, respectively.*

5. Discretization.

In this section, we discretize the shape derivative of the augmented Lagrangian L_τ defined by (4.8); then we define the shape parameters and obtain the shape gradient. Then, we detail the full optimization process. We follow [7], [12]; see also [13].

Let us recall that the expression $\frac{\partial L_\tau}{\partial \omega}(\Omega,\lambda).V$ depends on u, the unique solution of (3.5).

Let $(\mathcal{T}_h)$ be a regular family of triangulation, where $\omega = \cup_{T\in\mathcal{T}_h} T$. We compute an approximation of u using the classical piecewise linear conforming finite element method (P_1-Lagrange). This finite element approximation is denoted by u_h, where the parameter h denotes a characteristic mesh size.

Discretization of the boundary and the shape parameters. Let $\hat{\Omega}$ be an open set of reference; typically $\hat{\Omega}$ is a quarter of a disk; see Figure 4.1. The domain of reference $\hat{\Omega}$ is defined using a parametric function:

$$s_{\hat{\Omega}}(t) = \sum_{i=0}^{N-1} \hat{P}_i \, s_i(t)\,,\ t \in [0,1],$$

where $\{s_i(t)\}_{i=0,\ldots,N-1}$ are piecewise linear functions, $s_i(\frac{j}{N-1}) = \delta_{ij}$; δ_{ij} denotes the Kronecker symbol, and $\hat{P}_i = ((\hat{P}_r)_i,(\hat{P}_z)_i)^T$ are the control points. We set $(\hat{P}_z)_1 = (\hat{P}_z)_0$.

We have $\Omega = \hat{F}_0(\hat{\Omega})$ with $\hat{F}_0 \in \hat{\mathcal{F}}_0$. Similarly, we define the variable boundary Γ_{LG} (the unknown of the problem) by

$$s_\Omega(t) = \sum_{i=0}^{N-1} P_i\, s_i(t)\,,\ t \in [0,1].$$

Hence, the boundary Γ_{LG} is defined by N control points $P_i, i = 0, \ldots, N-1$.

Initially, these points define $\hat{\Gamma}_{LG}$ as follows (see Figure 5.1):

$$\hat{P}_i = (0, R)^T,$$

$$\hat{P}_i = \left(R \cos\left(\frac{(N-1-i)\pi}{2(N-1)}\right),\ R \sin\left(\frac{(N-1-i)\pi}{2(N-1)}\right)\right)^T, \quad i = 2, \ldots, N-1,$$

$$\hat{P}_1 = \left(R \cos\left(\frac{(N-2)\pi}{2(N-1)}\right)/2, R\right)^T.$$

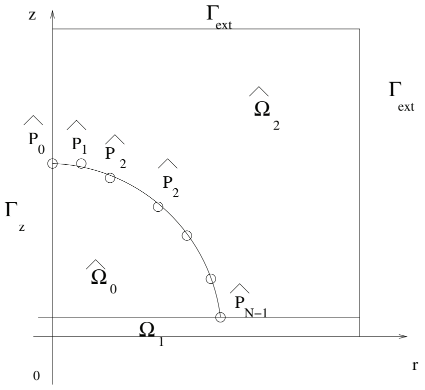

FIG. 5.1. *Reference domain. Parametrization.*

Therefore, during the optimization process, we compute a new domain that requires computing new control points P_i, $i = 0, \ldots, N-1$.

The shape deformation space. Let us discretize the shape deformation V, $V \in \mathcal{C}^1(\bar{\Omega}, \mathbb{R}^2)$. We have $\Omega = \hat{F}_0(\hat{\Omega})$ with $\hat{F}_0 \in \hat{\mathcal{F}}_0$. We set $V = \hat{V} \circ \hat{F}_0^{-1}$. V is defined in Ω, while $\hat{V}$ is defined in $\hat{\Omega}$.

We approximate $C^1(\bar{\hat{\Omega}}, \mathbb{R}^2)$ by $\hat{S}_H$, the vectorial space spanned by $\{\hat{V}_i\}_{i=0,\ldots,N-1}$:

$$\hat{S}_H = Span\{\hat{V}_i\}_{i=0,\ldots,N-1},$$

where the set of vectors $\{\hat{V}_i\}_{i=0,\ldots,N-1}$ is detailed below.

We set $H = \frac{1}{N-1}$. The parameter H denotes a characteristic size of the shape deformation space.

Then, the deformation field V is approximated by

$$V_H = \sum_{i=0}^{N-1} \eta_i V_i, \tag{5.1}$$

where $V_i = \hat{V}_i \circ \hat{F}_0^{-1}$ and η_i, $i = 0, \ldots, N-1$ are real coefficients.

We have $V_H = (\hat{V}_H \circ \hat{F}_0^{-1})$ with

$$\hat{V}_H = \sum_{i=0}^{N-1} \eta_i \hat{V}_i. \tag{5.2}$$

Finally, $C^1(\bar{\Omega}, \mathbb{R}^2)$ is approximated by $S_H = Span\{V_i = \hat{V}_i \circ \hat{F}_0^{-1}\}_{i=0,\dots,N-1}$.

The shape deformation basis. We have $\hat{F}_0 = (I + \hat{V})$, and $\hat{V}$ is approximated by $\hat{V}_H$, which was defined by (5.2).

The basis $\{\hat{V}_i\}_{i=0,\dots,N-1}$, is defined in $\hat{\Omega}$ as follows. For $i = 0, \dots, N-1$, we solve

$$\left\{ \begin{array}{ccll} \Delta(\hat{V}_r)_i & = & 0 & \text{in } \hat{\Omega} \cap Bint, \\ (\hat{V}_r)_i & = & 0 & \text{in } \hat{\Omega}/Bint, \\ (\hat{V}_r)_i & = & 0 & \text{on } \Gamma_{Gz} \cup \Gamma_{Sz}, \\ (\hat{V}_r)_i & = & \frac{(\hat{P}_r)_i}{||\hat{P}_i||}\, s_i & \text{on } \hat{\Gamma}_{LG}, \end{array} \right. \tag{5.3}$$

$$\left\{ \begin{array}{ccll} \Delta(\hat{V}_z)_i & = & 0 & \text{in } \hat{\Omega} \cap Bint, \\ (\hat{V}_z)_i & = & 0 & \text{in } \hat{\Omega}/Bint, \\ (\hat{V}_z)_i & = & 0 & \text{on } \Gamma_0 \cup \hat{\Gamma}_{LS} \cup \hat{\Gamma}_{SG}, \\ (\hat{V}_z)_i & = & \frac{(\hat{P}_z)_i}{||\hat{P}_i||}\, s_i & \text{on } \hat{\Gamma}_{LG}, \end{array} \right. \tag{5.4}$$

where $\hat{V}_i = ((\hat{V}_r)_i, (\hat{V}_z)_i)^T$, $\hat{P}_i = ((\hat{P}_r)_i, (\hat{P}_z)_i)^T$, and $\|\hat{P}_i\| = [(\hat{P}_r)_i^2 + (\hat{P}_z)_i^2]^{\frac{1}{2}}$.

Let us note that we could have extended this vector field over the whole domain by solving a linear elasticity system.

The shape gradient. We approximate V by V_H (see (5.1)), and we have

$$\frac{\partial L_\tau}{\partial \omega}(\Omega, \lambda).V \approx \frac{\partial L_\tau}{\partial \omega}(\Omega, \lambda).V_H = \sum_{i=0}^{N-1} \eta_i \frac{\partial L_\tau}{\partial \omega}(\Omega, \lambda).V_i.$$

Then, the shape gradient denoted by G^H is the vector

$$\begin{aligned} G^H = (G_i^H)_{i=0,\dots,N-1} &= \left(\left[\frac{\partial L_\tau}{\partial \omega}(\Omega, \lambda).V_i \right] \right)_{i=0,\dots,N-1} \\ &= \left(\left[\frac{\partial L_\tau}{\partial \omega}(\Omega, \lambda).(\hat{V}_i \circ \hat{F}_0^{-1}) \right] \right)_{i=0,\dots,N-1}, \end{aligned}$$

where $\Omega = \hat{F}_0(\hat{\Omega})$.

Finally, we have for all $i = 0, \dots, N-1$ (see Corollary 4.2),

$$G_i^H = \frac{dj}{d\omega}(\Omega).(\hat{V}_i \circ \hat{F}_0^{-1}) + \lambda \frac{dc}{d\omega}(\Omega).(\hat{V}_i \circ \hat{F}_0^{-1}) + 2\tau c(\Omega) \frac{dc}{d\omega}(\Omega).(\hat{V}_i \circ \hat{F}_0^{-1}). \tag{5.5}$$

Variables of optimization. Since $\Omega = \hat{F}_0(\hat{\Omega}) = (I + \hat{V})(\hat{\Omega}) \approx (I + \hat{V}_H)(\hat{\Omega})$ with $\hat{V}_H$ defined by (5.2), and $\hat{V}_i$ defined by (5.3), (5.4), the variables of optimization are the N coefficients η_i, $i = 0, \dots, N-1$.

6. Optimization process. As mentioned previously, we solve (3.11), an optimization problem with constraint, using Uzawa's algorithm; see, e.g., [8]. This algorithm requires a descent algorithm which is in the present case BFGS (the quasi Newton method). This gives the following:

- Initially, we set $\eta_i^0 = 0$, $i = 0, \dots, N-1$; $\lambda_0 = 0$.
- We compute the volume constraint $c(\eta^0)$.
- While the volume constraint ($|c(\eta^{k+1})| > eps1$) is not satisfied,
  - set $\lambda_{k+1} = \lambda_k + \rho\, c(\eta^k)$,
  - compute η_i^{k+1} $i = 0, \dots, N-1$ such that $L_\tau(\eta^{k+1}, \lambda_{k+1}) < L_\tau(\eta^k, \lambda_{k+1})$ using the BFGS algorithm, and
  - compute the volume constraint $c(\eta^{k+1})$.

Classically, we set $\rho = \tau$; see [8].

The BFGS algorithm is implemented with bounding constraints. The linear search is done using a dichotomic process.

We stop the BFGS algorithm either if $\frac{|j(\eta^{k+2}) - j(\eta^{k+1})|}{j(\eta^{k+1})} < eps2$ or if $\|(G^H)^{k+2}\| < eps3$.

As usual, each call of the algorithm BFGS implies a few calls to the simulator.

The simulator does the following:

- It computes the new shape and the new mesh defined by

$$\Omega = \left(I + \sum_{i=0}^{N-1} \eta_i \hat{V}_i \right) (\hat{\Omega}).$$

- It solves the state equation (3.5) posed in Ω by a P_1-Lagrange finite element method (with or without automatic mesh refinement).
- It computes the augmented Lagrangian L_τ defined by (3.9), with its gradient G^H defined by (5.5), and the volume constraint c defined by (3.10).

The full optimization process is represented in Figure 6.1.

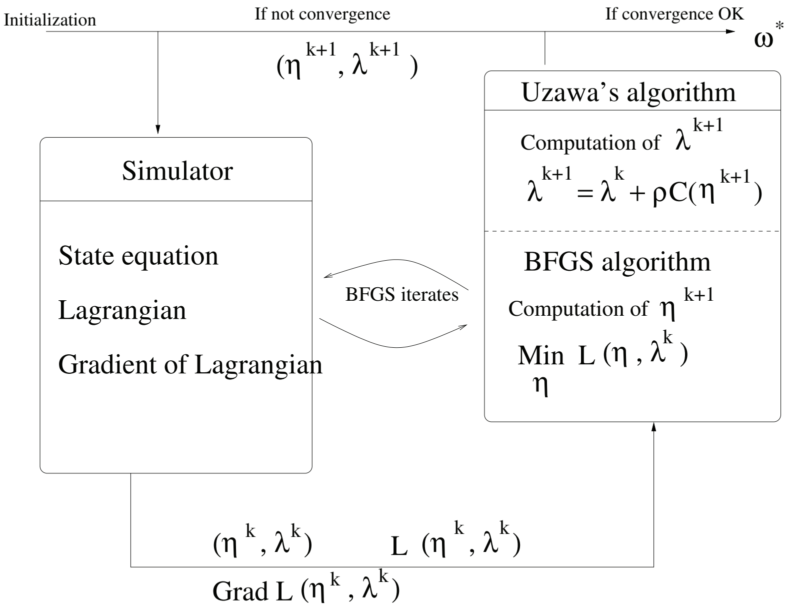

FIG. 6.1. *The optimization process.*

7. Curvature computation. In the next section, we consider the evaluation of the droplet curvature, particularly near the contact line. It was shown in [5] that the contact angle approaches Young's angle, independently of the applied electrical potential value. Observations show that the curvature is not constant. Then, it would be interesting to see if the present modeling approach allows us to observe such changes of curvature values near the triple point.

Accurately computing the droplet curvature is a difficult task since its interface is a piecewise linear curve, and hence is not C^2 differentiable. In addition, points defining this piecewise linear curve result from the full shape optimal design process and hence may comprise some nonnegligible numerical errors. Thus, we seek to estimate the curvature of an underlying smooth surface.

Computing a discrete surface curvature is a classical (and difficult) problem. Usually in the computer aided geometric design context, surfaces are 3D and triangularized, and the objectives are to smooth the mesh and simplify it, but not to quantify a local variation of curvature; see, e.g., [10].

We are facing the following dilemma. We seek to get rid of numerical errors on the points defining the curve while we try to detect as accurately as possible a local significant variation of curvature.

We do not consider a direct computation by a finite difference method since it is very sensitive to data error. We do not consider a polynomial reconstruction of the underlying smooth surface and then evaluate its curvature, since this leads to inaccurate results and unexpected behavior. Following [9], [14], we consider a local least square approximation and then we evaluate the curvature. In the present algorithm, we consider a second order local Bezier approximation; see [14]. As the numerical tests presented below show, this method filters noise reasonably.

7.1. The algorithm. Given N points $X_i = (r_i, z_i)^T$, $i = 1, \ldots, N$ defining the liquid-gas interface, the basic idea is to approximate these data using a local least square approximation by a Bezier curve.

The Bezier curve $\mathcal{C}(t)$ is given by

$$\mathcal{C}(t) = (r(t), z(t))^T = \sum_{j=1}^{M} P_j B_{j-1}^{M-1}(t) \qquad \text{for } t \in [0,1],$$

where $P_j = (\alpha_j, \beta_j)^T \in \mathbb{R}^2$ are the control points and $\{B_j^m(t)\}_{0 \le j \le M-1}$ is the classical Bernstein basis, with $B_j^m \in P_m$, $B_j^m(t) = C_j^m (1-t)^{m-j} t^j$, C_j^m being the binomial coefficients.

We set $M = 3$; hence we consider three points of control P_j and second degree curves.

For an inner point X_i (see Figure 7.1), we compute the least square approximation of the four points $\{X_{i-2}, \ldots, X_{i+2}\}$ by Bezier's curve as follows. We minimize

$$J(P_1, P_2, P_3) = \sum_{l=i-2}^{i+2} \left\| \sum_{j=1}^{3} P_j B_{j-1}^2(t_l) - X_l \right\|^2,$$

where $\{t_{i-2} = 0, \ldots, t_{i+2} = 1\}$ is a uniform subdivision of $[0,1]$. The unique minimum is computed by solving the corresponding normal equations.

For the extremal point X_1, we consider a Bezier curve approximating the points X_i for $i = 1, \ldots, 4$. For X_2, we consider a Bezier curve approximating the points X_i for $i = 1, \ldots, 5$.

For the extremal points X_{N-1} and X_N, the principle is similar.

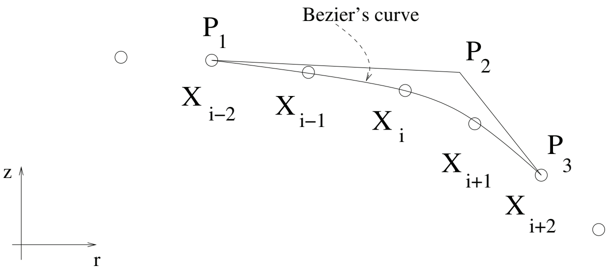

FIG. 7.1. *Inner point X_i. Local least square approximation using Bezier's curve.*

Curvature expression. Once a Bezier curve $\mathcal{C}(t) = (r(t), z(t))^T$ is computed for each point X_i, we evaluate the curvature as follows:

$$\kappa_i \;\equiv\; \kappa(t_i) = \frac{r'z" - r"z'}{(r'^2 + z'^2)^{\frac{3}{2}}}(t_i),$$

where (r', z') and (r'', z'') are computed using de Casteljau's algorithm, with t_i being the parameter value related to X_i.

Sensitivity to random noise. Since the control points defining the (optimal) droplet shape result from the full optimization process, they are perturbed by some nonnegligible numerical errors. Hence, we test the robustness of our algorithm to data perturbation below.

We set $N(r, z) = (r'z" - r"z')$ and $D(r, z) = (r'^2 + z'^2)^{\frac{3}{2}}$; hence $\kappa(r, z)(t) = \frac{N(r,z)}{D(r,z)}(t)$. Let δz be a perturbation on the z-coordinate of data X_i, $i = 1, \ldots, N$; then we have

$$\frac{\partial \kappa}{\partial z}(r, z).\delta z = \frac{N(r, \delta z)}{D(r, z)} - 3\ \frac{\kappa(r, z)}{(r'^2 + z'^2)} z'\delta z.$$

This formula expresses the curvature sensitivity to perturbation on z-coordinates. Noise introduced below is a random perturbation on the z-coordinate of data X_i, $i = 1, \ldots, N$. It is a normal distribution with mean zero and variance one.

7.2. Numerical tests. The numerical tests presented below are useful for (i) validating the present algorithm on explicit curves knowing their curvature value (the "exact" curves); and (ii) measuring the computed curvature sensitivity to random perturbation on data.

To this end, we consider an "oscillating curve" (see Figure 7.2), defined by N points as follows:

$$r(s) = (R + \epsilon\cos(a.s))\cos\left(\frac{\pi}{2}s\right), \quad z(s) = (R + \epsilon\cos(a.s))\sin\left(\frac{\pi}{2}s\right),$$

with $s \in [0, 1]$, s discretized by N points similarly to η and $\epsilon = \frac{R}{10}$, $a = 10$, $R = 1$.

The exact curvature of the "oscillating circle" is straightforwardly obtained. This curve presents smooth variations of curvature with changes of sign. If we compare the curvature values computed by the present algorithm and those computed by the second order finite difference scheme directly applied to the N data $X_i = (r_i, z_i)^T$, $i = 1, \ldots, N$, then without noise both lead to similar accuracy—the two methods give a very precise approximation.

However, in the presence of noise, the direct approximation does not give any good approximation. On the contrary, the present algorithm, based on a local least square approximation of the surface by Bezier's curve, leads to a good approximation of the curvature value of the nonperturbed curve.

We present in Figure 7.2 the curvature values obtained with the present algorithm when some noise is introduced. As mentioned above, the noise is defined as a perturbation on the z-coordinate of data X_i, $i = 1, \dots, N$. Its magnitude is about 0.5%.

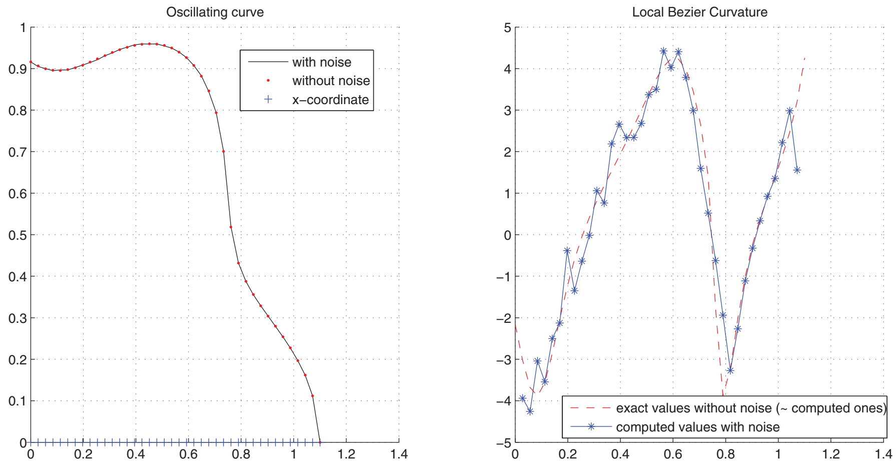

FIG. 7.2. *Left: Oscillating curve. Right: Computed curvature value when noise is introduced.*

8. Numerical results.

The full optimization process described in the previous section was implemented in C++. Our software, *ElectroCap* (see [13]), is based on the public C++ finite element library Rheolef [19] and an in-house BFGS algorithm. The mesh generator used is Bamg. For each simulator call, an automatic mesh refinement is used. This mesh refinement is based on the classical a posteriori estimates. We present in Figure 8.2 a typical mesh with the adaptive mesh in the edge.

Numerical data. The numerical data considered are the following:

- the surface tension coefficients (in N/m): $\sigma_{LS} = 2.7\ 10^{-2}$, $\sigma_{LG} = 5\ 10^{-2}$;
- the wetting angle at $u_0 = 0$ (in radians): $\theta_0 = \frac{\pi}{2}$ (hence $\mu = 0$);
- the insulator thickness (in m): $e = 200\ 10^{-6}$;
- the electrical permitivities: $\varepsilon_1 = 2 \times 8.85\ 10^{-12}$ and $\varepsilon_2 = 8.85\ 10^{-12}$;
- the drop volume (in L): $vol = 40\ 10^{-9}$.

We assume that the Bond number α is small; i.e., we neglect the gravitational term. Then, the cost function is (see (3.6), (3.7))

$$j(\omega) = j_{cap}(\omega) - j_{elec}(\omega), \tag{8.1}$$

with

$$j_{cap}(\omega) = \int_{\gamma_{LG}} r ds \quad \text{and} \quad j_{elec}(\omega) = \delta \int_{\omega} \varepsilon r |\nabla u^{\omega}|^2 \, dx,$$

where $j_{cap}(\omega)$ and $j_{elec}(\omega)$ are positive cost functions. The numerical parameters are the following:

- the penalty parameter: $\tau = \rho = 10^{-3}$;
- the convergence parameter of Uzawa's algorithm: $eps1 = 10^{-3}$;
- the convergence parameter of the BFGS algorithm: $eps2 = eps3 = 10^{-3}$;
- the number of control points: $NCP = 50$.

The NCP is defined as follows. If we consider the polar coordinates in the plane, for a droplet of radius R, the N points are equidistributed in θ. Their positions are indicated in Figure 8.4.

Code validation. All components of the code have been validated—the direct problem, the transport of the mesh, and the shape gradient.

The computed shape gradient has been compared with values obtained by a finite difference method using the following approach. For each shape parameter, a finite difference shape derivative is computed using a domain perturbation of magnitude 10^{-4}. The order of magnitude of the relative error obtained between the two approaches is between 10^{-4} and 10^{-6}, depending on the imposed electrical field value u_0.

In order to validate the entire code, we simulate the Lippman approximation by using the code with $u_0 = 0$ V but changing σ_{LS} for each value of u_0 using the formula given by the approximation of the plane capacitor:

$$\sigma_{LS}(u_0) = \sigma_{LS} - \frac{\varepsilon_0 \varepsilon_1}{2e} u_0^2.$$

Thus, theoretically, the contact angle should also be given by the Lippman equation. Numerically we observe a good agreement with the theory. Figure 8.1 shows the value of the contact angle found numerically (the angle of the last mesh triangle) and the theoretical value given by the Lippman equation.

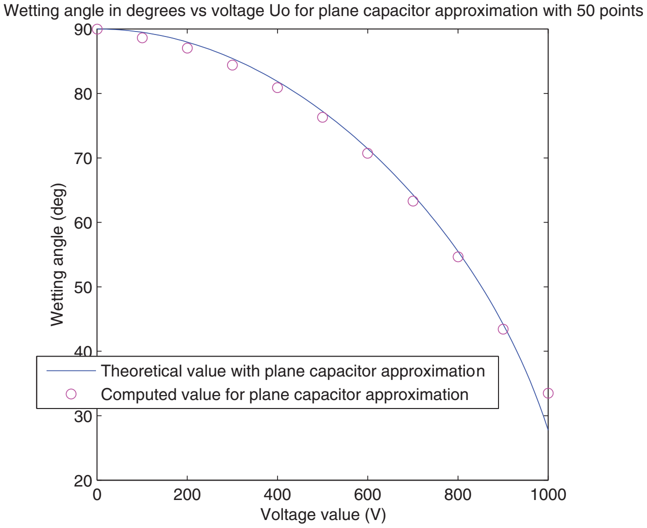

FIG. 8.1. *Plane capacitor approximation.*

Moreover, we compute the curvature for each value of σ_{LS} (which corresponds to a value of u_0). Given a value of u_0 and thus a value of σ_{LS}, we notice that the numerically computed curvature remains constant for each point of the drop. We also obtain for this case a very good agreement with the theory, which contributes to validating the code.

Now we compute the drop shape with the initial model, i.e., by considering σ_{LS} as a constant and by changing values of u_0.

Drop shape and wetting angle. We present in Figure 8.2 the drop shape (with mesh) obtained for $u_0 = 400$ V (left) and a zoom of the refined mesh near the edge (right). As a matter of fact, we use an adaptive mesh refinement near the contact point based on a posteriori estimates. All meshes contain approximately 4000 elements and 2000 vertices. For each computation, the volume constraint is satisfied at less than 0.1%.

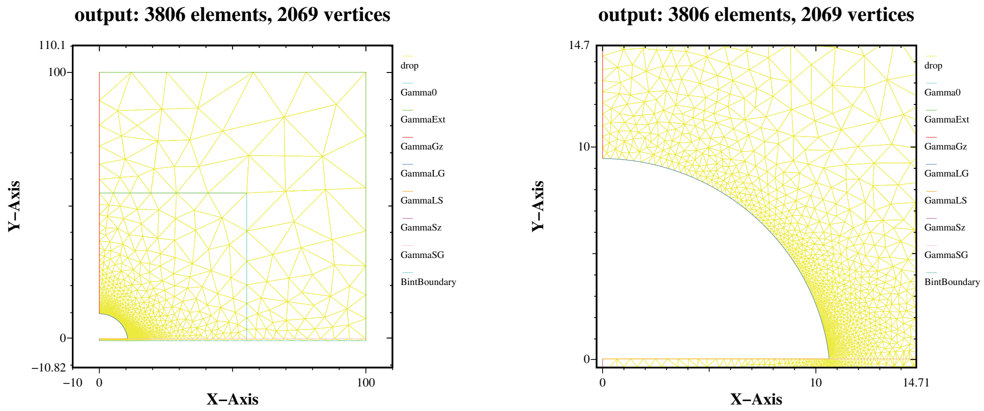

FIG. 8.2. *Left: Shape and mesh for* $u_0 = 400$ *V. Right: Zoom near the drop.*

We present the cost function, the augmented Lagrangian, and its gradient as a function of the iteration number for $u_0 = 400$ V in Figure 8.3. The behavior of the algorithm for other values of u_0 is similar.

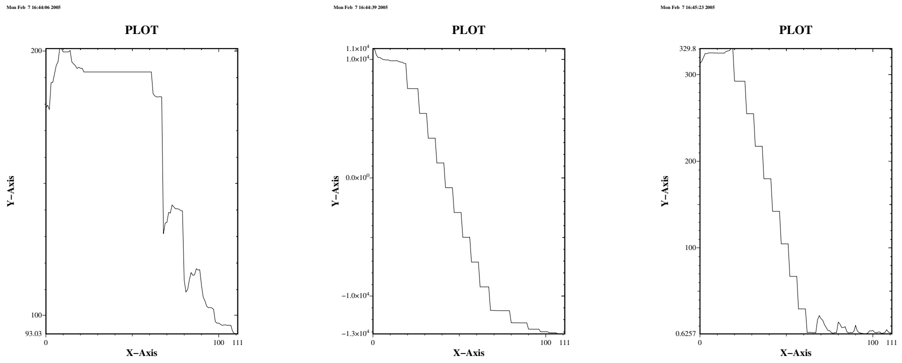

FIG. 8.3. $u_0 = 400$ *V. Left. Cost function* j *versus iterations. Middle. Augmented Lagrangian* L_τ*. Right. Gradient of* L_τ*.*

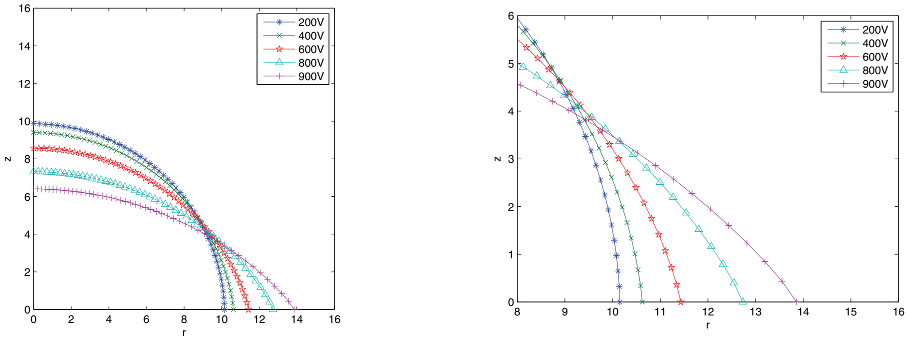

FIG. 8.4. *Droplet surfaces for different u_0 values. At right: zoom near the triple point.*

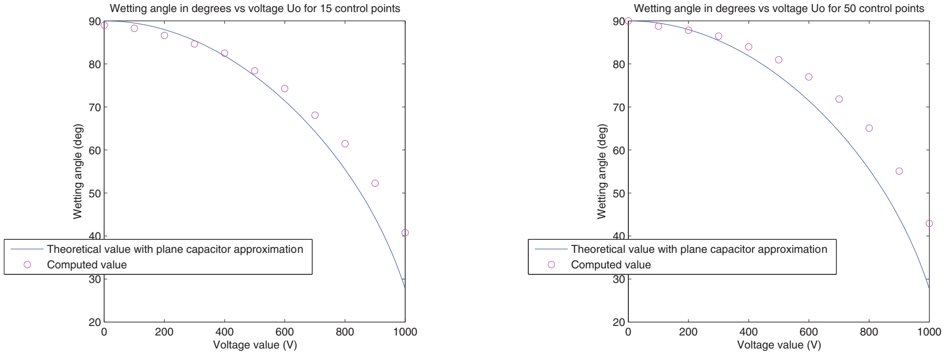

FIG. 8.5. *Wetting angle. Computed values and Lippman's equation predictions. Left. With $NCP = 15$. Right. With $NCP = 50$.*

We present in Figure 8.4 the drop shapes obtained in the function of u_0.

We present in Figure 8.5 (left and right) the wetting angle values in the function of u_0. In both figures (left and right), we plot the computed values (the angle of the last mesh triangle) and values predicted by the Lippman equation. On the left, plotted values are obtained using 15 control points ($NCP = 15$); on the right, plotted values are obtained using 50 control points ($NCP = 50$) (both with similar finite element meshes).

Let us recall that experimental results correspond to the Lippman equation up to a critical electrical potential u_{cr} (for the present case, the observed critical value $u_{cr} \approx 700$ V). For $u_0 > u_{cr}$, experimental results show a saturation of the wetting angle (locking phenomenon); see, e.g., [21]. As mentioned previously, the explanation of this locking phenomenon is still poorly understood by physicists. For $u_0 \approx 1050$ V, the Lippman equation predicts a total spreading of the drop on the substrate (the wetting angle vanishes).

With the present numerical model and with $NCP = 15$, we obtain a good agreement with the Lippman equation for $u_0 < 500$ V. For higher u_0 values, we do not model the angle saturation, but we observe that the contact angle is higher than the predicted value for the plane capacitor approximation.

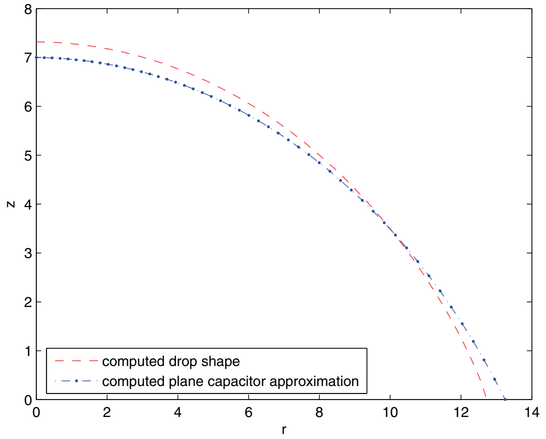

FIG. 8.6. *Computed shape compared to plane capacitor approximation shape for* $u_0 = 800$ *V.*

When increasing the number of control points to $NCP = 50$, we still obtain a good agreement with the Lippman equation for $u_0 < 400$ V. As with 15 points, we notice that the computed values are higher than the predicted values for the plane capacitor approximation. Moreover, the angle values computed with 50 points are higher than those obtained for 15 points for $u_0 > 500$ V.

Also, we compare the drop shape obtained to those obtained using the software but "forcing" the Lippman approximation (i.e., by changing σ_{LS} for each u_0 value). In Figure 8.6 the result for a drop at 400 V is presented. We again find that the wetting angle of the computed shape is higher than the Lippman predicted value.

Let us clarify that we did not manage to increase the NCP because of the well-known instability of the shape optimal design algorithms. As a matter of fact, shape optimal design algorithms become unstable when the control point density becomes similar to the finite element point density.

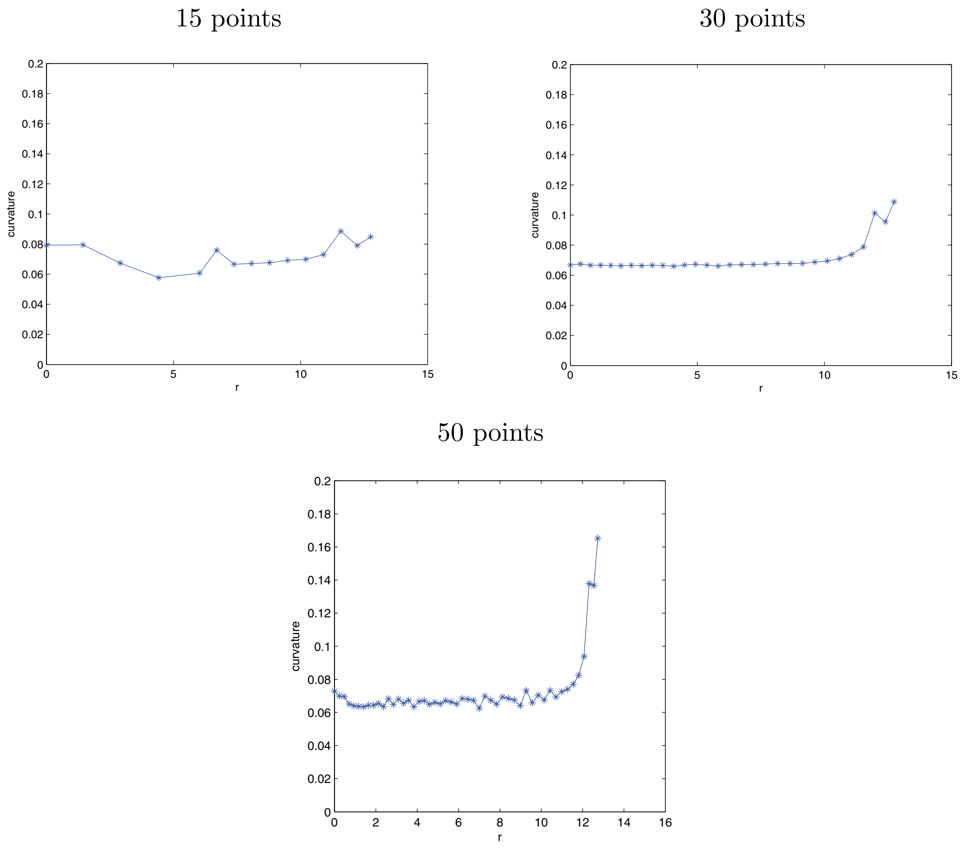
In summary, with the present model, we do not manage to properly simulate the locking phenomenon, but we do observe an overestimate of the Lippman predictions; this overestimate becomes more important when using a higher control point density.

Curvature. We use the algorithm described in the previous section; see also [14]. For all the computations we performed, the droplet shapes obtained had a constant curvature everywhere but in the vicinity of the triple point. In Figure 8.7, we present as an example (here $u_0 = 800$ V) the computed curvature at each control point. The results are presented with 15, 30, and 50 points, respectively.

In Figure 8.8, we present the curvature values for different electrical potential u_0 values with 50 control points (with curvature values corresponding to those in Figure 8.7, but for different u_0 values). In Figure 8.9, we present the gradient of the solution, i.e., the electric field.

For all computations we performed, the curvatures behave as those shown in Figure 8.8. Thus, we can make the following three main remarks:

- For the curvature, the results are more accurate with 50 points than with 15 or 30 points. With 15 or 30 points, the behavior of the curvature near the triple point appears to be less clear than with 50 points. This is due to the too small number of points near the triple line.



15 points

30 points

50 points

Fig. 8.7. *Curvature values at $u_0 = 800\,V$ for 15, 30, and 50 points, respectively.*

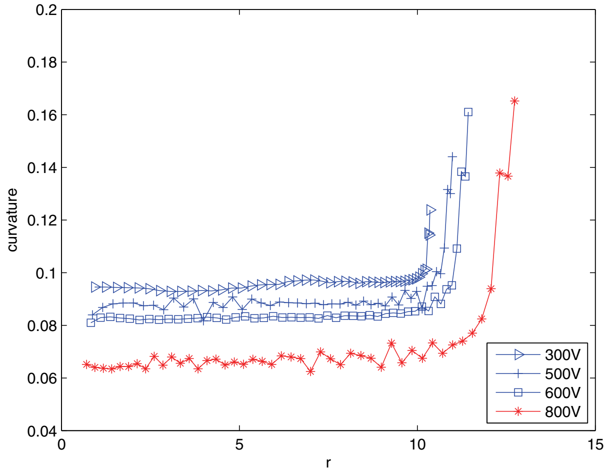


Fig. 8.8. *Curvature of the drop for several u_0 values with 50 control points.*

- For a given potential u_0, the curvature remains constant until we approach the triple line, where the curvature increases. We can see that the curvature is higher near the triple point than it is further away from it. (See Figure 8.7 for the case at 800 V. For other voltage the curvature has the same behavior; see Figure 8.8.)
- If we look at the evolution of the curvature for an increasing potential u_0, we notice the following:
  - The value of the curvature far from the triple line is constant and decreases when u_0 increases.
  - The curvature near the triple point increases, when u_0 increases. The fact that, with an increasing u_0, the curvature far from the triple point decreases is in accordance with the fact that, globally, the drop should be a portion of a sphere with an increasing radius as u_0 increases. We note that the curvature increases near the triple line; this is in accordance with the fact that the contact angle is higher than the Lippman predicted value.

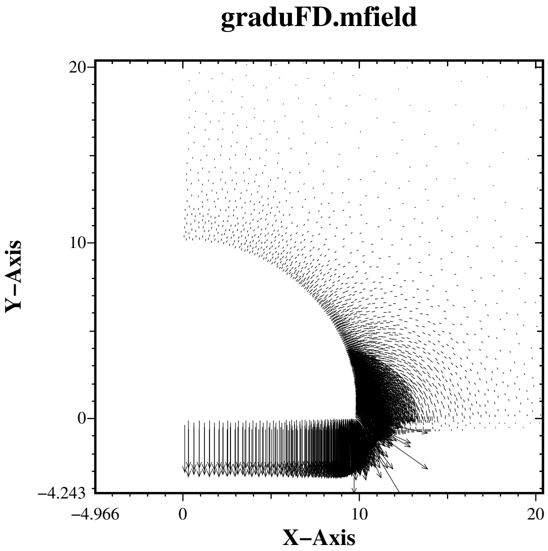

FIG. 8.9. *External electric field $\vec{E} = \vec{\nabla} u$ at $u_0 = 400$ V (zoom around the droplet).*

9. Conclusion. We have detailed and implemented a general approach for modeling the electrowetting process. The drop shape is computed as a minimum of the total energy. Our model is based on the shape optimal design methods. We test our model and software by including in the model the plane capacitor approximation (i.e., using the software with $u_0 = 0$ V and changing the value of σ_{LS} for each value of the potential). We obtain in this case an excellent agreement with the plane capacitor approximation, which contributes to validating the approach. Then, we compare numerical results obtained classically, that is to say, by changing the value of u_0, with the theoretical values for the plane capacitor approximation. In this case, the computed shapes and angles are not in agreement with this theory for a voltage higher than 300 V.

Although we did not properly obtain the locking phenomenon, the drop shape obtained deviates from the predicted shape as in [16]. Also, we did not manage to observe that the contact angle remains constant; instead, the computed contact angle values are higher than those predicted by Lippman's equation. Moreover, this overestimate becomes more important when using a higher control point density.

In other respects, we compute the curvature of the droplets. These values are globally constant except in the vicinity of the contact point where the computed curvature increases sharply. These results are in accordance with experimental results obtained in [3] and [5], which noted this increase of the curvature near the triple line.

Finally, in order to properly obtain the locking phenomenon and Young's angle at the triple line as in [5], [16], [3], further investigations based on extra singular basis functions to the finite element spaces are in progress.

Acknowledgments. The authors would like to thank C. Quilliet and M. Bienia from the Laboratory of Spectrometry Physics (LSP) in Grenoble, France, for the numerous and fruitful discussions; also, the referees for their constructive comments.

THE RIEMANN PROBLEM FOR A NONISENTROPIC FLUID IN A NOZZLE WITH DISCONTINUOUS CROSS-SECTIONAL AREA[*]

MAI DUC THANH[†]

Abstract. We present a full investigation of the Riemann problem for a nonisentropic polytropic fluid in a nozzle with piecewise constant cross-section. First, we introduce the concept of elementary waves which turn out to make up Riemann solutions. Second, we study a procedure to select admissible stationary waves relying on the monotone criterion. By projecting all the wave curves in the (p, u)-plane, we construct Riemann solutions. Existence of Riemann solutions can be obtained for large initial data. Furthermore, we establish the uniqueness of Riemann solutions in strictly hyperbolic domains. Our argument can lead to estimate regions where the Riemann problem admits a unique solution.

Key words. gas dynamics equations, Riemann problem, conservation law, shock wave, source term, nozzle

1. Introduction.

In this paper we provide a full investigation of the Riemann problem for the evolution of a fluid inside a nozzle with piecewise constant cross-section. The governing equations are given by

$$\begin{aligned}&\partial_t(a\rho) + \partial_x(a\rho u) = 0,\\ &\partial_t(a\rho u) + \partial_x(a(\rho u^2 + p)) = p(\rho)\partial_x a,\\ &\partial_t(a\rho e) + \partial_x(au(\rho e + p)) = 0, \quad x \in \mathbb{R},\, t > 0.\end{aligned} \tag{1.1}$$

Here, ρ, ε, T, S, and p denote the thermodynamical variables: density, internal energy, absolute temperature, entropy, and the pressure, respectively; u is the velocity, and $e = \varepsilon + u^2/2$ is the total energy. The function $a = a(x) > 0, x \in \mathbb{R}$, is the cross-sectional area. The expression of the source term on the right-hand side of (1.1) could be understood in the sense of *nonconservative product*; see [9, 26]. To begin with, we supplement the system (1.1) with the trivial equation (see [25, 29])

$$\partial_t a = 0, \quad x \in \mathbb{R},\, t > 0. \tag{1.2}$$

That step would remove the obstacle of the source term in producing a linearly degenerate characteristic field. However, the resulting system is not strictly hyperbolic as characteristic fields coincide on certain surfaces. Therefore we will deal with the question of constructing Riemann solutions for a nonstrictly hyperbolic system. For simplicity, we assume that the fluid is polytropic ideal so that the equation of state is given by

$$p = (\gamma - 1)\rho\varepsilon, \quad 1 < \gamma \le 5/3. \tag{1.3}$$

Nevertheless, our argument can be applied for a more general class of fluids.

This paper provides the constructions of all Riemann solutions of the system (1.1) for nonisentropic fluids in a nozzle with piecewise constant cross-sections for large initial data under the admissibility criterion on stationary waves. In particular, we establish the existence for large data and uniqueness in strictly hyperbolic domains. Moreover, our argument can lead to the estimates of regions where the Riemann problem admits a unique solution. This result is compatible with the uniqueness for the Cauchy problem in [16].

Recently, LeFloch and Thanh [27, 28] constructed Riemann solutions for the model of isentropic flows in a nozzle with variable cross-section and shallow water equations for arbitrary data. The Riemann problem for (1.1) was also considered by a different approach by Andrianov and Warnecke [2], where the authors introduced a new concept of solutions. For earlier work on resonant systems, see also [29, 18, 17, 11]. A careful investigation into a two-fluid model was obtained in [21]. These are typical examples of systems of balanced laws with source terms. Practically, these source terms often cause lots of inconveniences in their numerical discretization. The discretization of source terms therefore plays an important role in numerical approximations. The subject has been attracting attention of many authors for various classes of systems of balanced laws with source terms from a single conservation law, shallow water equations, or in the model of fluid flows in a nozzle with variable cross-section, to multiphase flow models; see [14, 23, 22, 15, 7, 13, 5, 6, 3, 20, 19, 32, 4, 8, 1, 10, 24, 31, 30] and the references therein. Since the system (1.1) may serve as a simple example of multiphase flow models, explicit constructions of Riemann solutions for (1.1) are interesting not only for the study of the Riemann problem itself, but also for the possibility of using these explicit solutions as references for testing various numerical schemes for multiphase flows.

The organization of this paper is as follows. In section 2 we provide general discussions and an argument for the establishment of stationary waves as elementary waves, and then we define elementary waves and determine all wave curves. Section 3 is devoted to the selection of admissible stationary waves. In section 4 we will construct Riemann solutions and establish the existence as well as the uniqueness of Riemann solutions.

2. Basic properties and elementary waves. In this section we recall basic properties of system (1.1)–(1.2) and draw elementary conclusions for stationary waves which will be used in the next sections. In particular, we derive formulas for all wave curves consisting of elementary waves.

2.1. Nonstrict hyperbolicity. To deal with the nonconservativeness of the system (1.1), we supplement it with the trivial equation (1.2). We therefore have the following system of balanced laws:

$$\begin{aligned}
&\partial_t(a\rho) + \partial_x(a\rho u) \;=\; 0,\\
&\partial_t(a\rho u) + \partial_x(a(\rho u^2 + p)) \;=\; p\partial_x a,\\
&\partial_t(a\rho e) + \partial_x(au(\rho e + p)) = 0,\\
&\partial_t a = 0, \quad x \in \mathbb{R},\, t > 0.
\end{aligned} \tag{2.1}$$

Let us take (p, S) as two independent thermodynamic variables. Then, the polytropic ideal gas equation of state can be represented by

$$\rho = \rho(p, S) = \left(\frac{p}{\gamma - 1}\mathrm{epx}\left(\frac{S_* - S}{C_v}\right)\right)^{1/\gamma}, \tag{2.2}$$

where $C_v = R/(\gamma - 1)$ and R is the specific gas constant.

A smooth solution $U = U(x,t) = (p(x,t), u(x,t), S(x,t), a(x))$ satisfies the following system of conservation laws in nonconservative form:

$$\partial_t U + A(U)\partial_x U = 0,$$

where

$$A(U) = \begin{pmatrix} u & \dfrac{\rho}{\rho_p} & 0 & \dfrac{u\rho}{a\rho_p} \\ \dfrac{1}{\rho} & u & 0 & 0 \\ 0 & 0 & u & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}. \tag{2.3}$$

The characteristic equation is given by

$$\lambda(u-\lambda)\Big((u-\lambda)^2 - \frac{1}{\rho_p}\Big) = 0.$$

Thus, we obtain four real eigenvalues

$$\lambda_1(U) = u - c, \quad \lambda_2(U) = u, \quad \lambda_3(U) = u + c, \quad \lambda_4(U) = 0, \tag{2.4}$$

where

$$c = \frac{1}{\sqrt{\rho_p(p,S)}}, \quad \rho_p(p,S) = \frac{p^{\frac{1-\gamma}{\gamma}}}{\gamma(\gamma-1)^{\frac{1}{\gamma}}}\exp\Big(\frac{S_* - S}{\gamma C_v}\Big) > 0.$$

Obviously, we have

$$\lambda_1(U) < \lambda_2(U) < \lambda_3(U) \quad \forall U.$$

However, any of $\lambda_1(U)$, $\lambda_2(U)$, $\lambda_3(U)$ can coincide with $\lambda_4(U)$. Consequently, the system is hyperbolic but *not strictly hyperbolic*. The corresponding eigenvectors can be chosen as

$$\begin{aligned} r_1 &= \big(\rho, -\sqrt{\rho_p(p,S)}, 0, 0\big)^T, \quad r_2 = (0,0,1,0)^T, \\ r_3 &= \big(\rho, \sqrt{\rho_p(p,S)}, 0, 0\big)^T, \qquad r_4 = \Big(-\frac{2\rho(p,S)}{\rho_p(p,S)}, \frac{2}{\rho_p(p,S)}, 0, 1\Big)^T. \end{aligned}$$

Since all the eigenvalues and eigenvectors are independent of the fourth component a, investigating properties of these quantities can be reduced to the three-dimensional subspace of the coordinates (p,u,S), which is referred to as the *phase domain* of the coordinates (p,u,S). In the (p,u,S)-space, there are three surfaces, denoted by Σ_1, Σ_2, and Σ_3, on which the system fails to be strictly hyperbolic:

$$\begin{aligned} \Sigma_1 &= \{U = (p,u,S) : \lambda_4(U) = \lambda_1(U)\} = \Big\{(p,u,S) : u = \frac{1}{\sqrt{\rho_p(p,S)}}\Big\} \\ &= \Big\{(p,u,S) : u = \gamma^{\frac{1}{2}}(\gamma-1)^{\frac{1}{2\gamma}}p^{\frac{\gamma-1}{2\gamma}}\exp\Big(\frac{S_*-S}{2\gamma C_v}\Big)\Big\}, \\ \Sigma_2 &= \{U = (p,u,S) : \lambda_4(U) = \lambda_2(U)\} = \{(p,0,S)\}, \\ \Sigma_3 &= \{U = (p,u,S) : \lambda_4(U) = \lambda_3(U)\} = \Big\{(p,u,S) : u = -\frac{1}{\sqrt{\rho_p(p,S)}}\Big\} \\ &= \Big\{(p,u,S) : u = -\gamma^{\frac{1}{2}}(\gamma-1)^{\frac{1}{2\gamma}}p^{\frac{\gamma-1}{2\gamma}}\exp\Big(\frac{S_*-S}{2\gamma C_v}\Big)\Big\}. \end{aligned} \tag{2.5}$$

These surfaces, referred to as *strictly hyperbolic boundaries*, separate the phase domain into four subdomains, denoted by $\mathcal{G}_1, \mathcal{G}_2, \mathcal{G}_3$, and $\mathcal{G}_4$, in which the system is strictly hyperbolic:

$$\begin{aligned}
&\mathcal{G}_1 = \{U = (p,u,S) : \lambda_4(U) < \lambda_1(U)\},\\
&\mathcal{G}_2 = \{U = (p,u,S) : \lambda_1(U) < \lambda_4(U) < \lambda_2(U)\},\\
&\mathcal{G}_3 = \{U = (p,u,S) : \lambda_2(U) < \lambda_4(U) < \lambda_3(U)\},\\
&\mathcal{G}_4 = \{U = (p,u,S) : \lambda_4(U) > \lambda_3(U)\}.
\end{aligned} \tag{2.6}$$

Clearly, the 2- and the 4-characteristic fields are linearly degenerate. On the other hand,

$$-\nabla\lambda_1(U)\cdot r_1(U) = \nabla\lambda_3(U)\cdot r_3(U) = \frac{\gamma+1}{2}\sqrt{\rho_p} > 0 \quad \forall U, \tag{2.7}$$

which implies that the 1- and the 3-characteristic fields are genuinely nonlinear.

2.2. Stationary smooth solutions. *A stationary smooth solution* U of (1.1) is a time-independent smooth solution. Thus, the derivative with respect to t in (1.1) can be omitted. Stationary solutions of the initial value problem for (1.1) are, therefore, the ones for the following ordinary differential equations:

$$\begin{aligned}
&(a\rho u)' = 0,\\
&(a(\rho u^2 + p))' = pa',\\
&(au(\rho e + p))' = 0,
\end{aligned} \tag{2.8}$$

where $(.)'$ stands for $d(.)/dx$.

We will show that the specific entropy is conserved across stationary waves. Therefore, for those concerning stationary waves, the choices of thermodynamic independent variables (ρ, S) or (p, S) are equivalent, since $p = p(\rho, S_0)$ implies $\rho = \rho(p, S_0)$, and vice versa. To make calculations simpler, let us, however, choose the thermodynamic independent variables in this subsection to be (ρ, S). Solutions of (2.8) are subject to the initial condition

$$(\rho, u, S, a)(x_0) = (\rho_0, u_0, S_0, a_0). \tag{2.9}$$

The *specific enthalpy* is given by

$$h \,=\, \varepsilon + pv, \tag{2.10}$$

which satisfies

$$dh \,=\, T\,dS + v\,dp.$$

The following lemma enables us to calculate stationary waves.

Lemma 2.1. *For smooth solutions, the system* (2.8) *is equivalent to*

$$\begin{aligned}
&(a\rho u)' = 0,\\
&\Big(\frac{u^2}{2} + h(\rho, S)\Big)' = 0,\\
&S' = 0.
\end{aligned} \tag{2.11}$$

Proof. The first equation of (2.11) can be expressed as

$$a\rho u = a_0\rho_0 u_0 = C,$$

where C is a constant. Thus, the second equation can be written as

$$(C \cdot u + a \cdot p)' = p \cdot a'$$

or

$$C \cdot u' + a \cdot p' = 0.$$

This yields

$$uu' + \frac{p'}{\rho} = uu' + p'v = 0, \quad v = \frac{1}{\rho}. \tag{2.12}$$

Now, provided $C \neq 0$, the third equation of (2.8) can be written as

$$\varepsilon' + uu' + (pv)' = 0. \tag{2.13}$$

Recall the thermodynamic identity that

$$TdS = d\varepsilon + pdv.$$

Since we are considering stationary waves, i.e., solutions independent of time, the thermodynamic identity applied to this kind of wave gives

$$\varepsilon' = TS' - pv'.$$

Substituting this into (2.13), we get

$$TS' + p'v + uu' = 0,$$

or, from (2.12), it holds that

$$S' = 0.$$

Since $S' = 0$, we have

$$p'v = h'(\rho, S),$$

and from (2.12), this yields the second line of (2.11). Lemma 2.1 is completely proved. ▯

2.3. Stationary contact waves. Suppose now we have a discontinuity with propagation speed λ. Then, the Rankine–Hugoniot relation associated with (1.2) gives

$$-\lambda[a] = 0, \tag{2.14}$$

where $[a] := a_+ - a_-$ is the jump of the cross-section a. Thus, (2.14) implies that there are two possibilities:

(i) either $\lambda = 0$: the shock speed vanishes,

(ii) or $[a] = 0$: the component a remains constant across the shock.

First, suppose (i) that the component a is discontinuous and, therefore, the shock speed vanishes. The solution is independent of time, and it is natural to search for a solution as the limit of a sequence of time-independent smooth solutions, or stationary solutions of (1.1)–(1.2), which are given by (2.11). The integral curve of (2.11) passing through each point (ρ_0, u_0, S_0, a_0) can be parameterized by ρ, say

$$\rho \mapsto (\rho, u(\rho), S_0, a(\rho)),$$

and satisfies

$$\begin{aligned}
&a\rho u = a_0\rho_0 u_0,\\
&\frac{u^2}{2} + h(\rho, S) = \frac{u_0^2}{2} + h(\rho_0, S_0),\\
&S = S_0.
\end{aligned}$$

Letting $\rho \to \rho_1$ and setting $u_1 = u(\rho_1), a_1 = a(\rho_1)$, we see that the states (ρ_0, u_0, S_0, a_0), (ρ_1, u_1, S_0, a_1) satisfy the Rankine–Hugoniot relations

$$\begin{aligned}
&[a\rho u] = 0,\\
&\left[\frac{u^2}{2} + h(\rho, S_0)\right] = 0,\\
&[S] = 0.
\end{aligned}$$

So

$$\begin{aligned}
&u = \frac{a_0\rho_0 u_0}{a\rho},\\
&\frac{u^2}{2} + h(\rho, S_0) = \frac{u_0^2}{2} + h(\rho_0, S_0),\\
&S = S_0.
\end{aligned} \tag{2.15}$$

Set $h_0 := h(\rho_0, S_0)$; then the relations (2.15) define a curve $\mathcal{W}_4(U_0)$ in the phase domain. Precisely, $\mathcal{W}_4(U_0)$ is the intersection of the two surfaces defined by the first and the second equations in (2.15) in the (ρ, u, a)-space (entropy is constant). Since the mapping $\rho \mapsto p(\rho, S_0)$ is monotone increasing, in the (p, u)-plane this curve can be parameterized as $p \mapsto u(p)$, which is monotone decreasing for $u_0 > 0$ and monotone increasing for $u_0 < 0$.

The system (2.15) defines a function $a \mapsto (\rho = \rho(a; U_0), p = p(a; U_0), u = u(a; U_0))$, where $\rho = \rho(a; U_0)$ is determined by

$$\Phi(\rho, a; U_0) := -\frac{2\kappa\gamma}{\gamma - 1}\rho^{\gamma+1} + \Big(u_0^2 + \frac{2\kappa\gamma}{\gamma - 1}\rho_0^{\gamma-1}\Big)\rho^2 - \Big(\frac{a_0 u_0 \rho_0}{a}\Big)^2 = 0, \tag{2.16}$$

where

$$\kappa = A(S_0), \quad A(S) = (\gamma - 1)\exp\Big(\frac{S - S_*}{C_v}\Big), \tag{2.17}$$

and then u is given by the first equation of (2.15), $S = S_0$, and $p = p(\rho, S_0)$.

2.4. Shocks, rarefaction waves, and contact discontinuities. Let us now suppose (ii) that the component a remains constant on both sides of the discontinuity. Eliminating a from (1.1), we obtain the usual gas dynamics equations

$$\begin{aligned}&\partial_t\rho+\partial_x(\rho u)=0,\\&\partial_t(\rho u)+\partial_x(\rho u^2+p)=0,\\&\partial_t(\rho e)+\partial_x(u(\rho e+p))=0.\end{aligned}\tag{2.18}$$

Thus, all elementary waves of the system (2.18) are obtained in a usual way which can be found in any standard material on gas dynamics equations. In particular, the reader is referred to [12]. However, it is convenient to brief basic facts of these waves here.

The Rankine–Hugoniot relations corresponding to (2.18) are given by

$$\begin{aligned}&-\lambda[\rho]+[\rho u]=0,\\&-\lambda[\rho u]+[\rho u^2+p(\rho)]=0,\\&-\lambda[\rho e]+[u(\rho e+p)]=0,\end{aligned}\tag{2.19}$$

where $[\rho]=\rho_1-\rho_0$, $[\rho u]=\rho_1u_1-\rho_0u_0$, etc., and λ is the speed of propagation of the discontinuity connecting the states U_0 and U_1.

Then the Hugoniot set issuing from a given state U_0 consisting of all states U that can be connected to U_0 by a discontinuity satisfying the Rankine–Hugoniot relations is determined by

$$\begin{aligned}&M:=\rho_0(u_0-\lambda)=\rho_1(u_1-\lambda),\\&\rho_0(u_0-\lambda)^2+p_0=\rho_1(u_1-\lambda)^2+p_1,\\&\left(\rho_0\left(\varepsilon_0+\frac{(u_0-\lambda)^2}{2}\right)+p_0\right)=\left(\rho_1\left(\varepsilon_1+\frac{(u_1-\lambda)^2}{2}\right)+p_1\right).\end{aligned}\tag{2.20}$$

If $M=0$, then

$$\begin{aligned}&u_0=\lambda=u_1,\\&p_0=p_1.\end{aligned}\tag{2.21}$$

Thus, the discontinuity is exactly the 2-contact discontinuity corresponding to $\lambda=\lambda_2=u$. When $M\neq 0$, we obtain a 1-shock if $M>0$, and a 3-shock if $M<0$.

Next, all discontinuities of (2.19) associated with nonlinear characteristic fields are required to satisfy the *Lax shock inequalities*

$$\lambda_i(U_0)>\lambda(U_0,U)>\lambda_i(U),\quad i=1,3,\tag{2.22}$$

where $\lambda(U_0,U)$ is the shock speed of the shock connecting the left-hand state U_0 to the right-hand state U belonging to the Hugoniot set issuing from U_0.

For polytropic ideal gas (1.3), the Lax shock inequalities (2.22) yield the following:

(a) For a 1-shock, the Lax shock inequalities are equivalent to

$$\rho_1\geq\rho_0,\quad p_1\geq p_0,\quad S_1\geq S_0,\quad u_1\leq u_0.\tag{2.23}$$

(b) For a 3-shock, the Lax shock inequalities are equivalent to

$$\rho_1\leq\rho_0,\quad p_1\leq p_0,\quad S_1\leq S_0,\quad u_1\geq u_0.\tag{2.24}$$

From (2.20) and (2.23), we obtain the first *forward* shock curve $\mathcal{S}_1(U_0)$ issuing from U_0 consisting of all right-hand states that can be connected to a given left-hand state U_0 as

$$\begin{aligned}\mathcal{S}_1(U_0): \qquad & v = v_1(U_0,p) = \frac{v_0(\mu p + p_0)}{p+\mu p_0}, \qquad \text{where} \quad \mu = \frac{\gamma-1}{\gamma+1},\\ & u = u_1(U_0,p) = u_0 - (p-p_0)\sqrt{\frac{(1-\mu)v_0}{p+\mu p_0}}, \quad p \geq p_0.\end{aligned} \tag{2.25}$$

From (2.20) and (2.24), we also obtain the third *backward* shock curve $\mathcal{S}_3(U_0)$ issuing from U_0 consisting of all left-hand states that can be connected to a given right-hand state U_0. Then, the inequalities in (2.24) must be reversed. So $\mathcal{S}_3(U_0)$ is given by

$$\begin{aligned}\mathcal{S}_3(U_0): \qquad & v = v_3(U_0,p) = \frac{v_0(\mu p + p_0)}{p+\mu p_0},\\ & u = u_3(U_0,p) = u_0 + (p-p_0)\sqrt{\frac{(1-\mu)v_0}{p+\mu p_0}}, \quad p \geq p_0.\end{aligned} \tag{2.26}$$

Next, rarefaction waves in genuinely nonlinear characteristic fields corresponding to λ_1 and λ_3 are continuous piecewise smooth self-similar solutions of (1.1) of the form

$$U(x,t) = V(\xi), \quad \xi = x/t.$$

Recall that the *forward* 1-rarefaction curve $\mathcal{R}_1(U_0)$ consisting of all right-hand states U that can be connected to the left-hand state U_0 by a 1-rarefaction wave is given by

$$\begin{aligned}\mathcal{R}_1(U_0): \qquad u = u_1(U_0,p) &= u_0 - \int_{p_0}^{p} \frac{\sqrt{\rho_p(z,S_0)}}{\rho(z,S_0)}dz,\\ &= u_0 - \frac{2\gamma^{1/2}}{(\gamma-1)^{1-1/2\gamma}}\exp\Big(\frac{S_0-S_*}{2C_v\gamma}\Big)(p^{(\gamma-1)/2\gamma} - p_0^{(\gamma-1)/2\gamma}).\end{aligned} \tag{2.27}$$

Similarly, the *backward* 3-rarefaction curve $\mathcal{R}_3(U_0)$ consisting of all left-hand states U that can be connected to the right-hand state U_0 by a 1-rarefaction wave is given by

$$\begin{aligned}\mathcal{R}_3(U_0): \qquad u = u_3(U_0,p) &= u_0 + \int_{p_0}^{p} \frac{\sqrt{\rho_p(z,S_0)}}{\rho(z,S_0)}dz,\\ &= u_0 + \frac{2\gamma^{1/2}}{(\gamma-1)^{1-1/2\gamma}}\exp\Big(\frac{S_0-S_*}{2C_v\gamma}\Big)(p^{(\gamma-1)/2\gamma} - p_0^{(\gamma-1)/2\gamma}).\end{aligned} \tag{2.28}$$

The wave curves associated with the genuinely nonlinear characteristic fields are then defined as

$$\mathcal{W}_i(U_0) := \mathcal{S}_i(U_0) \cup \mathcal{R}_i(U_0), \quad i = 1,3.$$

It is not difficult to check that the wave curve $\mathcal{W}_1(U_0)$ projected in (p,u)-plane, as a function $p \mapsto u$, is continuous, monotone decreasing, and the wave curve $\mathcal{W}_3(U_0)$ projected in (p,u)-plane, as a function $p \mapsto u$, is continuous, monotone increasing. In conclusion, we obtain the same waves associated with the first, second, and the third characteristic fields as in the usual gas dynamics equations.

The above arguments allow us to define elementary waves of the system (1.1) which form Riemann solutions.

Definition 2.2. *Elementary waves for the system* (3.1) *are the following ones:*

- *Lax shocks, rarefaction waves, and contact discontinuities of the usual gas dynamics equations corresponding to the case a is constant in* (1.1)*.*
- Stationary contacts *with zero propagation speed are given by* (2.15)*.*

3. Selection of admissible stationary waves. As seen in the previous section, the density ρ across a stationary wave with a given state U_0 is determined as zeros depending on the parameter a of the function

$$\Phi(\rho, a; U_0) := -\frac{2\kappa\gamma}{\gamma-1}\rho^{\gamma+1} + \Big(u_0^2 + \frac{2\kappa\gamma}{\gamma-1}\rho_0^{\gamma-1}\Big)\rho^2 - \Big(\frac{a_0u_0\rho_0}{a}\Big)^2, \tag{3.1}$$

where

$$\kappa = A(S_0), \quad A(S) = (\gamma-1)\text{exp}\Big(\frac{S-S_*}{C_v}\Big).$$

If $u_0 = 0$, then the equation $\Phi(\rho, a; U_0) = 0$ gives three roots; therefore there are three states $(\rho_0, 0, S_0), (0, \pm\sqrt{(2\kappa\gamma)/(\gamma-1)}\rho_0^{(\gamma-1)/2}, S_0)$ that can be connected to U_0 by a stationary wave. Assume $u_0 \neq 0$. First, observe that since we look for zeros of the function, we just consider those values ρ such that

$$-\frac{2\kappa\gamma}{\gamma-1}\rho^{\gamma+1} + \Big(u_0^2 + \frac{2\kappa\gamma}{\gamma-1}\rho_0^{\gamma-1}\Big)\rho^2 \geq 0,$$

which requires

$$\rho \leq \bar{\rho}(U_0) := \Big(\frac{\gamma-1}{2\kappa\gamma}u_0^2 + \rho_0^{\gamma-1}\Big)^{\frac{1}{\gamma-1}}. \tag{3.2}$$

Thus, we need to investigate the function Φ on the interval $[0, \bar{\rho}(U_0)]$ only. We have

$$\frac{d\Phi(U_0, \rho; a)}{d\rho} = -2\kappa\gamma\frac{\gamma+1}{\gamma-1}\rho^{\gamma} + 2\Big(u_0^2 + \frac{2\kappa\gamma}{\gamma-1}\rho_0^{\gamma-1}\Big)\rho$$

so that

$$\begin{aligned} &\frac{d\Phi(\rho; a, U_0)}{d\rho} > 0, \quad \rho < \rho_{\max}(U_0),\\ &\frac{d\Phi(U_0, \rho; a)}{d\rho} < 0, \quad \rho > \rho_{\max}(U_0), \end{aligned} \tag{3.3}$$

where

$$\rho_{\max}(U_0) := \Big(\frac{\gamma-1}{\kappa\gamma(\gamma+1)}u_0^2 + \frac{2}{\gamma+1}\rho_0^{\gamma-1}\Big)^{\frac{1}{\gamma-1}}. \tag{3.4}$$

Moreover,

$$\Phi(\rho = 0; a, U_0) = \Phi(\rho = \bar{\rho}; a, U_0) = -\Big(\frac{a_0u_0\rho_0}{a}\Big)^2 < 0, \quad u_0 \neq 0. \tag{3.5}$$

From (3.4) and (3.5), we can see that Φ admits a zero if and only if

$$\Phi(\rho = \rho_{\max}; a, U_0) \geq 0.$$

Equivalently

$$a \geq a_{\min}(U_0) := \frac{a_0 \rho_0 |u_0|}{\sqrt{\kappa\gamma}\rho_{\max}^{\frac{\gamma+1}{2}}(\rho_0, u_0)}. \tag{3.6}$$

If $a > a_{\min}(U_0)$, then there are exactly two values $\rho_*(U_0, a) < \rho_{\max}(U_0) < \rho^*(U_0, a)$ such that

$$\Phi(\rho_*(U_0, a); a, U_0) = \Phi(\rho^*(U_0, a); a, U_0) = 0.$$

By considering (p, S) as the two independent thermodynamic variables and phase domain in the (p, u, S, a) space, we have the following lemma.

Lemma 3.1 (stationary waves). *There exists a stationary contact from a given state $U_0 = (p_0, u_0, S_0, a_0)$ connecting to some state $U = (p, u, S = S_0, a)$ if and only if $a \geq a_{\min}(U_0)$. More precisely, we have the following:*

(i) *If $a < a_{\min}(U_0)$, there are no stationary contacts.*

(ii) *If $a \geq a_{\min}(U_0)$ along the curve $\mathcal{W}_4(U_0)$, there are exactly two points $U_* := (p = p(\rho_*(U_0, a), S_0), u = a_0\rho_0 u_0/(a\rho_*(U_0, a)), S = S_0, a)$, and $U^* := (p = p(\rho^*(U_0, a), S_0), u = a_0\rho_0 u_0/(a\rho^*(U_0, a)), S = S_0, a)$, where $\rho_*(U_0, a) < \rho_{\max}(U_0) < \rho^*(U_0, a)$ satisfying*

$$\Phi(\rho_*(U_0, a); a, U_0) = \Phi(\rho^*(U_0, a); a, U_0) = 0. \tag{3.7}$$

These two states U_*, U^* coincide only if $a = a_{\min}(U_0)$.

Since the function $\rho \mapsto p(\rho, S_0)$ is monotone, the following lemma can be obtained directly from Lemma 2.3 [27], which provides some useful properties of the above quantities. Setting

$$p_{\max} = p(\rho_{\max}, S_0), \quad p_* = p(\rho_*, S_0), \quad p^* = p(\rho^*, S_0),$$

and using notation in Lemma 3.1, we have the following lemma.

Lemma 3.2. *Given a state $U_0 = (p_0, u_0, S_0, a_0)$, we have the following.*

(a) *It holds that*

$$\begin{aligned} p_{\max}(U_0) &< p_0, \quad U_0 \in \mathcal{G}_2 \cup \mathcal{G}_3, \\ p_{\max}(U_0) &> p_0, \quad U_0 \in \mathcal{G}_1 \cup \mathcal{G}_4. \end{aligned}$$

(b) *The state $U_* = (p = p(\rho_*(U_0, a), S_0), u = a_0\rho_0 u_0/(a\rho_*(U_0, a)), S = S_0, a) \in \mathcal{G}_1$ if $u_0 < 0$, and $U_* \in \mathcal{G}_4$ if $u_0 > 0$. The state $U^* := (p = p(\rho^*(U_0, a), S_0), u = a_0\rho_0 u_0/(a\rho^*(U_0, a)), S = S_0, a) \in \mathcal{G}_2$ if $u_0 < 0$, and $U^* \in \mathcal{G}_3$ if $u_0 > 0$. In addition, we have the following:*

- *If $a > a_0$, then*

$$p_*(U_0, a) < p_0 < p^*(U_0, a).$$

- *If $a < a_0$, then*

$$\begin{aligned} p_0 &< p_*(U_0, a) \quad \textit{for} \quad U_0 \in \mathcal{G}_1 \cup \mathcal{G}_4, \\ p_0 &> p^*(U_0, a) \quad \textit{for} \quad U_0 \in \mathcal{G}_2 \cup \mathcal{G}_3. \end{aligned}$$

(c)

$$\begin{aligned} &a_{\min}(U,a) < a, \quad U \in \mathcal{G}_i,\ i=1,2,3,4,\\ &a_{\min}(U,a) = a, \quad U \in \Sigma_1 \cup \Sigma_3,\\ &a_{\min}(U,a) = 0, \quad p=0 \quad \textit{or} \quad u=0. \end{aligned}$$

In combining waves, we must know when the order of wave speeds associated with different characteristic fields changes. Precisely, we want to know when the shock speeds in the nonlinear characteristic fields equal zero. From (2.20), for polytropic gas (1.3), we can calculate the shock speeds as

$$\begin{aligned} \lambda = \lambda(U_0,U) &= \frac{\rho u - \rho_0 u_0}{\rho - \rho_0}\\ &= \frac{\rho(u-u_0) + u_0(\rho-\rho_0)}{\rho-\rho_0}\\ &= u_0 - v_0\frac{u-u_0}{v-v_0}\\ &= \begin{cases} u_0 - v_0\sqrt{\frac{p+\mu p_0}{(1-\mu)v_0}} & \text{for } 1-\text{(forward) shocks},\\ u_0 + v_0\sqrt{\frac{p+\mu p_0}{(1-\mu)v_0}} & \text{for } 3-\text{(forward) shocks}. \end{cases} \end{aligned}$$

Thus, the 1-shock speed $\lambda = \bar{\lambda}_1(U_0,U)$ from a given left-hand state U_0 to a right-hand state U on the Hugoniot set issuing from U_0 vanishes if

$$\begin{aligned} &u_0 > 0,\\ &p = \tilde{p}_0 := \frac{(1-\mu)u_0^2}{v_0} - \mu p_0. \end{aligned}$$

Besides, the Lax shock inequalities require that $\tilde{p}_0 > p_0$. This means

$$\frac{(1-\mu)u_0^2}{v_0} - \mu p_0 > p_0$$

or

$$u_0^2 > \frac{1+\mu}{1-\mu}p_0 v_0 = \gamma p_0 v_0 = \frac{1}{\rho_p(p_0,S_0)} = c^2.$$

Since $u_0 > 0$, this is equivalent to

$$\bar{\lambda}_1(U_0,U) = u_0 - c > 0,$$

which says that $U_0 \in \mathcal{G}_1$. Similarly, the backward 3-shock speed $\bar{\lambda}_3(U_0,U)$ from a given right-hand state U_0 to a left-hand state U vanishes if $U_0 \in \mathcal{G}_4$ and $p = \frac{(1-\mu)u_0^2}{v_0} - \mu p_0$. We therefore arrive at the following proposition.

PROPOSITION 3.3. (a) *The* 1-*shock speed* $\bar{\lambda}_1(U_0,U)$, *(for* $p > p_0$*) may change sign along the forward* 1-*shock curve* $\mathcal{S}_1(U_0)$. *More precisely, we have the following:*

(i) *If* $U_0 \in \mathcal{G}_2 \cup \mathcal{G}_3 \cup \mathcal{G}_4$, *then* $\bar{\lambda}_1(U_0,U)$ *remains negative:*

$$\bar{\lambda}_1(U_0,U) < 0, \quad U \in \mathcal{S}_1(U_0).$$

(ii) *If* $U_0 \in \mathcal{G}_1$*, then* $\bar\lambda_1(U_0, U)$ *vanishes once at some point* $U = \tilde U_0 \in \mathcal{G}_2$ *corresponding to a value* $p = \tilde p_0 = \frac{(1-\mu)u_0^2}{v_0} - \mu p_0$ *on the* 1*-shock curve* $\mathcal{S}_1(U_0)$ *such that*

$$\begin{aligned}&\bar\lambda_1(U_0, \tilde U_0) = 0,\\ &\bar\lambda_1(U_0, U) > 0, \quad p \in (p_0, \tilde p_0),\\ &\bar\lambda_1(U_0, U) < 0, \quad p \in (\tilde p_0, +\infty).\end{aligned} \tag{3.8}$$

(b) *The* 3*-shock speed* $\bar\lambda_3(U_0, U)$ *may change sign along the backward* 3*-shock curve* $\mathcal{S}_3(U_0)$ $(p > p_0)$*. More precisely,*

(i) *If* $U_0 \in \mathcal{G}_1 \cup \mathcal{G}_2 \cup \mathcal{G}_3$*, then* $\bar\lambda_1(U_0, U)$ *remains positive:*

$$\bar\lambda_3(U_0, U) > 0, \quad U \in \mathcal{S}_3(U_0).$$

(ii) *If* $U_0 \in \mathcal{G}_4$*, then* $\bar\lambda_3(U_0, U)$ *vanishes once at some point* $U = \tilde U_0 \in \mathcal{G}_3$ *corresponding to a value* $p = \tilde p_0 = \frac{(1-\mu)u_0^2}{v_0} - \mu p_0$ *on the backward* 3*-shock curve* $\mathcal{S}_3(U_0)$ *such that*

$$\begin{aligned}&\bar\lambda_3(U_0, \tilde U_0) = 0,\\ &\bar\lambda_3(U_0, U) < 0, \quad p \in (p_0, \tilde p_0),\\ &\bar\lambda_3(U_0, U) > 0, \quad p \in (\tilde p_0, +\infty).\end{aligned} \tag{3.9}$$

As shown in [27], the Riemann problem for (1.1)–(1.2) may admit up to a one-parameter family of solutions. This phenomenon can be avoided by requiring Riemann solutions to satisfy a monotone condition on the component a. Motivated by [27], we impose the following criterion on stationary waves of (1.1).

Admissibility Criterion 3.1. *Along the stationary curve in the* (ρ, u)*-plan between left- and right-hand states of any stationary wave, the component* a *obtained from* (2.15) *and expressed as a function of* ρ *has to be monotone in* ρ*.*

Since the specific entropy is constant along stationary curves, the following lemma can be established as in the case of isentropic gases (see [27]); therefore, we omit the proof.

Lemma 3.4. *Admissibility Criterion* 3.1 *is equivalent to the statement that any stationary wave has to remain in the closure of only one domain* $\mathcal{G}_i$*,* $i = 1, 2, 3, 4$*.*

Lemma 3.4 implies that if $U_0 \in \mathcal{G}_1 \cup \mathcal{G}_4$, then $p_*(U_0, a)$ is used, while $p^*(U_0, a)$ is used when $U_0 \in \mathcal{G}_2 \cup \mathcal{G}_3$.

4. Existence and uniqueness of the Riemann problem. In this section we will establish global existence and uniqueness of the Riemann problem for (1.1)–(1.2). Without loss of generality (by changing coordinates $x \mapsto -x, \quad u \mapsto -u$, if necessary), we can assume for definitiveness in this section that

$$a_L < a_R.$$

To construct Riemann solutions of (1.1)–(1.2), we project all the wave curves on the (p, u)-plane. Moreover, we will use the following notation:

(i) $W_k(U_i, U_j)$ $(S_k(U_i, U_j), R_k(U_i, U_j))$ denotes the kth-wave (kth-shock, kth-rarefaction wave, respectively) connecting the left-hand state U_i to the right-hand state U_j.

(ii) $W_m(U_i, U_j) \oplus W_n(U_j, U_k)$ indicates that there is an mth-wave from the left-hand state U_i to the right-hand state U_j, followed by an nth-wave from the left-hand state U_j to the right-hand state U_k.

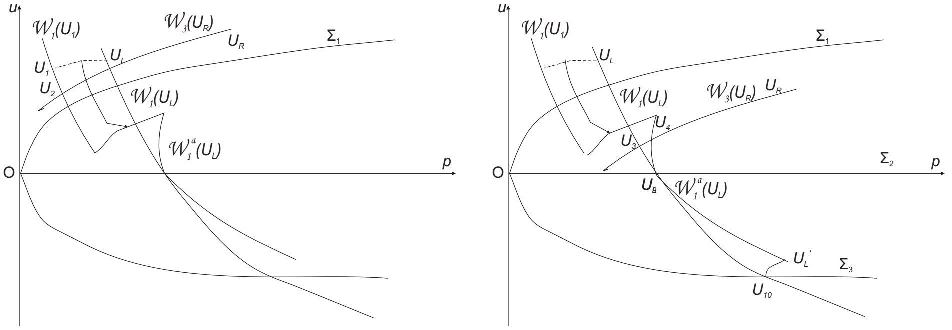

FIG. 4.1. *Riemann solution with structures* (4.1) *(left) and* (4.4) *(right).*

(iii) $\bar{U}$ denotes the right-hand state resulted by a contact discontinuity from a left-hand state U associated with the second characteristic field $\lambda_2 = u$. Observe that in the (p, u)-plane, U and $\bar{U}$ share the same location.

(iv) $\hat{U}$ denotes the right-hand state resulted by a contact discontinuity from a left-hand state U associated with the fourth characteristic field $\lambda_4 = 0$.

4.1. Explicit solutions and uniqueness for $\boldsymbol{U_L \in \mathcal{G}_1}$.

Construction N1. This construction holds for U_R, belongs to $\mathcal{G}_1 \cup \Sigma_1$, and belongs to some part of $\mathcal{G}_2$. Let U_1 be the state obtained by jumping from U_L by a stationary contact from the level a_L to the level a_R. Whenever $\mathcal{W}_1(U_1) \cap \mathcal{W}_3(U_R) \neq \emptyset$, there is a solution defined as follows. Let

$$\{U_2\} = \mathcal{W}_1(U_1) \cap \mathcal{W}_3(U_R).$$

Then the solution is

$$W_4(U_L, U_1) \oplus W_1(U_1, U_2) \oplus W_2(U_2, \bar{U}_2) \oplus W_3(\bar{U}_2, U_R). \tag{4.1}$$

The construction makes sense if $\lambda_1(U_1, U_2) \geq 0$. See Figure 4.1(left).

If $\mathcal{W}_1(U_1) \cap \mathcal{W}_3(U_R) = \emptyset$, then there is a vacuum. In fact, let $\{M\} = \mathcal{W}_1(U_1) \cap \{p = 0\}$, $\{N\} = \mathcal{W}_3(U_R) \cap \{p = 0\}$. The solution is

$$W_4(U_L, U_1) \oplus W_1(U_1, M) \oplus W_1(M, N) \oplus W_3(M, U_R). \tag{4.2}$$

Construction N2. This construction holds for U_R in $\mathcal{G}_2 \cup G_3 \cup \Sigma_1 \cup \Sigma_2$ and some part of $\mathcal{G}_1$. Consider the wave curve $\mathcal{W}_1(U_L)$. Let $\tilde{U}_L \in \mathcal{W}_1(U_L) \cap \mathcal{G}_2$ be the state at which the shock speed vanishes, i.e., $\lambda_1(U_L, \tilde{U}_L) = 0$, in view of Proposition 3.3. Let $\tilde{U}_L = (\tilde{p}_L, \tilde{u}_L)$. Then, from any point $U = (p, u) \in \mathcal{W}_1(U_L), p \geq \tilde{p}_L$, which means U is positioned "lower" than $\tilde{U}_L$, a stationary wave jumps from U from $a = a_L$ to $a = a_R$ to some state $\bar{U}$ using $W_4(U, \bar{U})$. These states $\bar{U}$ form a curve U which varies along $\mathcal{W}_1(U_L)$ "downward" from $\tilde{U}_L$. Precisely, set the "composite" curve

$$\mathcal{W}_1^a(U_L) := \{\bar{U} : \exists W_4(U, \bar{U}) \quad \text{from } a_L \quad \text{to } a_R, U = (p, u) \in \mathcal{W}_1(U_L), p \geq \tilde{p}_L\}. \tag{4.3}$$

Whenever $\mathcal{W}_3(U_R) \cap \mathcal{W}_1^a \neq \emptyset$, there will be a Riemann solution. In fact, let $\mathcal{W}_3(U_R) \cap \mathcal{W}_1^a = \{U_4\}$ and U_3 be the point on $\mathcal{W}_1(U_L)$ that corresponds to the stationary wave $W_4(U_3, U_4)$ or $W_4(\bar{U}_3, U_4)$. Then, the solution can be

$$S_1(U_L, U_3) \oplus W_4(U_3, U_4) \oplus W_2(U_4, \bar{U}_4) \oplus W_3(\bar{U}_4, U_R) \tag{4.4}$$

if $u_3 \geq 0$, and

$$S_1(U_L, U_3) \oplus W_2(U_3, \bar{U}_3) \oplus W_4(\bar{U}_3, U_4) \oplus W_3(U_4, U_R) \tag{4.5}$$

if $u_3 < 0$ and $\lambda_3(U_4, U_R) \geq 0$. See Figure 4.1(right).

Construction N3. This construction shows a connection between Constructions N1 and N2. Here, we meet an interesting phenomenon when wave speeds associated with different characteristic fields coincide. Precisely, there are solutions containing three waves with the same zero speed. This can be seen as follows. From U_L, the solution jumps by a stationary wave $W_4(U_L, A := \hat{U}_L(a))$ with an intermediate value of cross-section $a \in [a_L, a_R]$. Then, from A, the solution jumps to some state $B := \tilde{A} \in \mathcal{G}_2$ using $S_1(A, B)$ with $\lambda_1(A, B) = 0$. Next, the solution jumps from B to some state $C = U(a) := \hat{B}$ using a stationary wave $W_4(B, U(a))$ to shift the cross-section a to a_R. It is not difficult to check that the mapping

$$[a_L, a_R] \ni a \mapsto U(a) \tag{4.6}$$

is locally Lipschitz with a deterministic Lipschitz constant K on any compact neighborhood of U_L. Set

$$\mathcal{L}(U_L, a_R) = \{U(a) | a \in [a_L, a_R]\}.$$

Whenever

$$\mathcal{W}_3(U_R) \cap \mathcal{L}(U_L; a_R) \neq \emptyset$$

there is a solution containing three discontinuities having the same speed zero. Precisely, the solution begins with a stationary 4-wave from U_L to A, followed by a 1-shock with zero speed from A to B, then followed by a stationary 4-wave from B to $U(a)$, since $u(a) > 0$. The solution continues with a 2-wave from $U(a)$ to some state $D := \bar{U}(a)$, and then it arrives at U_R using a 3-wave. We therefore have a solution of the form

$$W_4(U_L, A) \oplus S_1(A, B) \oplus W_4(B, U(a)) \oplus W_2(U(a), \bar{U}(a)) \oplus W_3(\bar{U}(a), U_R). \tag{4.7}$$

See Figure 4.2(left).

Construction N4: $\boldsymbol{U_R \in \mathcal{G}_4}$. This construction can be applied for arbitrary U_L. For $U_R \in \mathcal{G}_4$, there is a stationary wave from U_R with $a = a_R$ to some state $U_8 \in \mathcal{G}_4$ with $a = a_L$. Let U_7 be the intersection point of $\mathcal{W}_3(U_8)$ and $\mathcal{W}_1(U_L)$. If $U_7 \in \mathcal{G}_4$, then there is a Riemann solution of the form

$$S_1(U_L, U_7) \oplus W_2(U_7, \bar{U}_7) \oplus W_3(\bar{U}_7, U_8) \oplus W_4(U_8, U_R). \tag{4.8}$$

See Figure 4.2 (right).

Construction N5: This construction conditionally holds for $\boldsymbol{U_R \in \mathcal{G}_4}$. This construction also holds for $\mathcal{W}_1(U_L) \cap \mathcal{G}_3 \neq \emptyset$. There is some set Δ in $\mathcal{G}_4$ so that if U_R belongs to Δ, the Riemann problem may also admit a solution containing three waves with the same zero speed. Let

$$\{U_9\} = \mathcal{W}_1(U_L) \cap \{u = 0\}, \quad U_{10} = \mathcal{W}_1(U_L) \cap \Sigma_3.$$

The solution can be a 1-shock from U_L to some state $E \in \mathcal{G}_3$, followed by a stationary wave using p^* with level $a \in [a_L, a_R]$ that remains in $\mathcal{G}_3$ to some point F, then followed

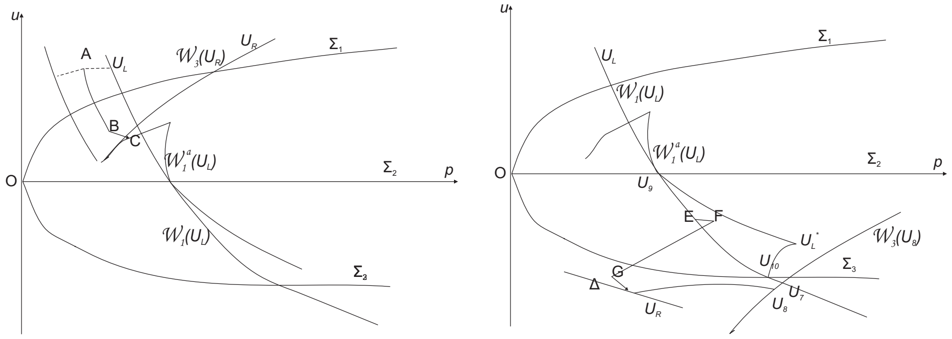

FIG. 4.2. *Riemann solution with structures* (4.7) *(left) and* (4.8) *(right).*

by a 3-shock with zero speed from F to some point $G \in \mathcal{G}_4$, and then followed by a stationary wave from G with level a to U_R with level a_R. For a varies in $[a_L, a_R]$, this procedure forms a set Δ in $\mathcal{G}_4$ so that if $U_R \in \Delta$, then a solution containing three waves with the same zeros speed exists, as just discussed above. See Figure 4.2 (right).

Thus, we can see from Constructions N4 and N5 that multiple solutions may exist.

Existence of Riemann problem. It is interesting to see that the curve $\mathcal{L}(U_L, a_R)$ meets $\mathcal{W}_1(U_1)$ when $a = a_R$, and $\mathcal{L}(U_R, a_R)$ meets $\mathcal{W}_1^a(U_L)$ when $a = a_L$. These patterns form a locally Lipschitz continuous curve in the (p, u)-plane. The Riemann problem admits a solution whenever $\mathcal{W}_3(U_R)$ intersects this curve in Constructions N1–N3, and $U_7 \in \mathcal{G}_4$ in Construction N4. Denote $U_L^* \in \mathcal{G}_3$ to be the state in which a stationary jump from U_{10} is available. Then, a sufficient condition for the Riemann problem to possess a solution is the following:

- U_L^* lies below the curve $\mathcal{W}_3(U_R)$, and U_R is above Σ_3, or $U_R \in \mathcal{G}_4$ and the configuration (4.5) makes sense. In this case, $\mathcal{W}_3(U_R)$ always intersects the curve $\mathcal{W}_1(U_1) \cup \mathcal{L}(U_L, a_R) \cup W_1^a(U_L)$ and the corresponding configuration of solutions makes sense.
- $U_7 \in \mathcal{G}_4$ for U_R is below Σ_3.

Evidently, the Riemann problem admits a solution for a large domain containing U_L.

Uniqueness of Riemann problem. If the right-hand side U_R is chosen so that only Construction N1 makes sense, then we get the *unique* solution. Geometrically, we can see that this can be done if $\mathcal{W}_3(U_R)$ does not meet $\mathcal{W}_1^a(U_L) \cup \mathcal{L}(U_L, a_R)$. Since the mapping $a \mapsto U(a), a \in [a_L, a_R]$ in (4.6) is locally Lipschitz, we can choose $|a_R - a_L|$ not too large so that $\mathcal{L}(U_L, a_R)$ is not far away from $\tilde{U}_L$. An alternative priori estimate for large $|a_R - a_L|$ is that $\mathcal{W}_3(U_R)$ lies entirely in $\mathcal{G}_1$, and this is the case if the intersection of this curve with the axis $\{p = 0\}$ is at a point with nonnegative velocity. Setting $p = 0$ in (2.28), we require

$$u_R - \frac{2\gamma^{1/2}}{(\gamma-1)^{1-1/2\gamma}} \exp\Big(\frac{S_R - S_*}{2C_v\gamma}\Big) p_R^{(\gamma-1)/2\gamma} \geq 0$$

or

$$u_R \geq \frac{2\gamma^{1/2}}{(\gamma-1)^{1-1/2\gamma}} \exp\Big(\frac{S_R - S_*}{2C_v\gamma}\Big) p_R^{(\gamma-1)/2\gamma}. \tag{4.9}$$

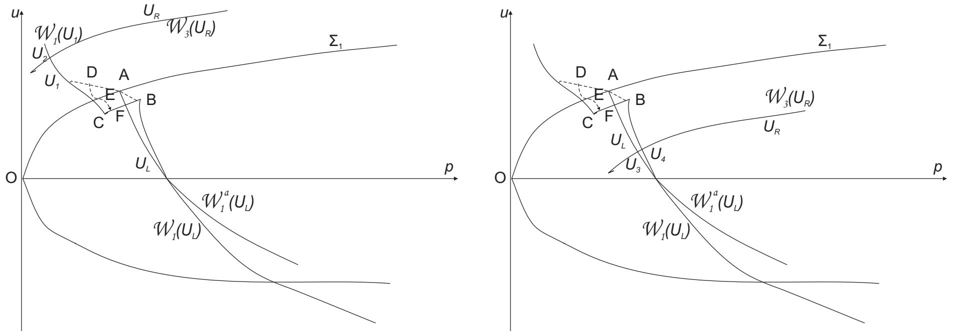

FIG. 4.3. *Riemann solution with structures* (4.10) *(left) and* (4.11)*(right).*

Therefore, we arrive at the following theorem.

THEOREM 4.1 (existence and uniqueness). *Given $U_L \in \mathcal{G}_1$, let $\{U_{10}\} = \mathcal{W}_1(U_L) \cap \Sigma_3$, and let $U_L^* \in \mathcal{G}_3$ be the state resulted by a stationary wave from U_{10} using p^*. The Riemann problem for* (1.1)–(1.2) *always has a solution if U_L^* lies below the curve $\mathcal{W}_3(U_R)$, and U_R is above Σ_3, or $U_R \in \mathcal{G}_4$ and the configuration* (4.5) *makes sense. Moreover, if* (4.9) *holds, or if $|a_R - a_L|$ is sufficiently small, then the Riemann problem for* (1.1)–(1.2) *has* (4.1) *or* (4.2) *as the unique solution.*

4.2. Explicit solutions and uniqueness for $U_L \in \mathcal{G}_2 \cup \mathcal{G}_3 \cup \mathcal{G}_4 \cup \Sigma_1 \cup \Sigma_2 \cup \Sigma_3$.

Construction N6. This construction holds for U_R belongs in $\mathcal{G}_1 \cup \Sigma_1$ and some part of $\mathcal{G}_2$. The solution begins with a 1-rarefaction wave $R_1(\bar{U}_L, A)$, where $\{A\} = \mathcal{W}_1(U_L) \cap \Sigma_1$; followed by a stationary jump $W_4(A, U_1)$, where $U_1 \in \mathcal{G}_1$, using p^* at A. Let $\{U_2\} = \mathcal{W}_1(U_1) \cap \mathcal{W}_3(U_R)$. The solution is then continued by a 1-wave from U_1 to U_2, followed by a 2-wave $W_2(U_2, \bar{U}_2)$, and finally followed by a 3-wave from $\bar{U}_2$ to U_R. Thus, the solution is

$$R_1(U_L, A) \oplus W_4(A, U_1) \oplus W_1(U_1, U_2) \oplus W_2(U_2, \bar{U}_2) \oplus W_3(\bar{U}_2, U_R). \tag{4.10}$$

The construction makes sense if $\lambda_1(U_1, U_2) \geq 0$. This construction is similar to Construction N1. See Figure 4.3(left).

Construction N7. This construction holds for U_R in $\mathcal{G}_2 \cup G_3 \cup \Sigma_1 \cup \Sigma_2$ and some part of $\mathcal{G}_1$. Let $\{A\} = \mathcal{W}_1(U_L) \cap \Sigma_1$ as in Construction 5, and let $B \in \mathcal{G}_2$ be the point resulted by a stationary wave $W_4(A, B)$ using p^*. Define the "composite" curve

$$\mathcal{W}_1^a(U_L) := \{\bar{U} : \exists W_4(U, \bar{U}) \quad \text{from } a_L \quad \text{to } a_R, U = (p, u) \in \mathcal{W}_1(U_L), p \geq \tilde{p}_A\}. \tag{4.11}$$

Whenever $\mathcal{W}_3(U_R) \cap \mathcal{W}_1^a \neq \emptyset$, there will be a Riemann solution. In fact, let $\mathcal{W}_3(U_R) \cap \mathcal{W}_1^a = \{U_4\}$ and U_3 be the point on $\mathcal{W}_1(U_L)$ that corresponds to the stationary wave $W_4(U_3, U_4)$ or $W_4(\bar{U}_3, U_4)$. Then, the solution can be

$$W_1(U_L, U_3) \oplus W_4(U_3, U_4) \oplus W_2(U_4, \bar{U}_4) \oplus W_3(\bar{U}_4, U_R) \tag{4.12}$$

if $u_3 \geq 0$, and

$$W_1(U_L, U_3) \oplus W_2(U_3, \bar{U}_3) \oplus W_4(\bar{U}_3, U_4) \oplus W_3(U_4, U_R) \tag{4.13}$$

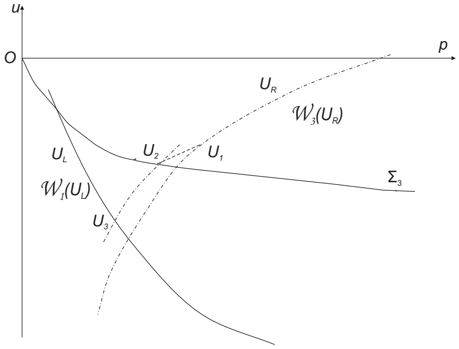

FIG. 4.4. *Riemann solution with structure* (4.14).

if $u_3 < 0$ and $U\lambda_3(U_4, U_R) \geq 0$. This construction is similar to Construction N2. This construction makes sense whenever $U_3 \in \mathcal{G}_2 \cup \mathcal{G}_3 \cup \cup\Sigma_1 \cup \Sigma_2 \cup \Sigma_3$. See Figure 4.3(right).

Construction N8. This construction shows a connection between Constructions N6 and N7. Here, we also meet an interesting phenomenon when wave speeds associated with different characteristic fields coincide; therefore there are solutions containing three waves with the same zero speed. This can be seen as follows. Look at Construction N6; the solution can jump to $\mathcal{G}_2$ as far as $C := \tilde{U}_1$ with a 1-shock with zero speed. Now, instead of jumping from A to U_1 using a $W_4(A, U_1)$ to shift the level a from a_L to a_R, the solution can use a stationary wave from A to some state $D \in \mathcal{G}_1$ with a shift in a from a_L to any value $a \in [a_L, a_R]$, then followed by a 1-shock $S_1(D, E)$ with zero speed, where $E \in \mathcal{G}_2$, and then followed by another stationary wave from E to $F = F(a) \in \mathcal{G}_2$ with a shift in a from $a \in [a_L, a_R]$ to a_R. As a varies continuously on $[a_L, a_R]$, the set of $F(a)$ forms a curve with $F(a_L) = B$ and $F(a_R) = C$, and we have an arc $\widehat{BC} \subset \mathcal{G}_2$. If $G \in \mathcal{W}_3(U_R) \cap \widehat{BC}$, then the Riemann solution admits a solution. This is similar to Construction N3. See Figure 4.3(right).

The arc $\widehat{BC}$ connects the 1-wave curve $\mathcal{W}_1(U_1)$ in Construction N6 and the composite wave curve $\mathcal{W}_1^a(U_L)$ in Construction N7. Therefore, the existence and uniqueness of the Riemann problem can be argued similarly as in the case $U_L \in \mathcal{G}_1$.

Construction N9. This construction holds for $U_L \in \mathcal{G}_4$ and some part of $\mathcal{G}_3 \cup \Sigma_3$; $U_R \in \mathcal{G}_2 \cup \mathcal{G}_3$; see Figure 4.4.

There are $U_1 \in \mathcal{W}_3(U_R)$ and $U_2 \in \Sigma_3$ that correspond to a stationary jump from the left-hand state U_2 with $a = a_L$ to the right-hand state U_1 with $a = a_R$. The state U_1 can be defined in one of the following ways:

(i) We use a backward composite wave curve defined by using a 3-wave from U_R to any $U \in \mathcal{W}_3(U_R)$ followed by a stationary contact from U to some $\hat{U}$ using p^* in the backward way. This curve intersects with Σ_3 at U_2.

(ii) We define a curve going along with Σ_3 by taking all the resulting states $\hat{U}$ of stationary contacts jumping from every point of Σ_3 using p^*. This curve intersects $\mathcal{W}_3(U_R)$ at U_1.

Whenever $\mathcal{W}_1(U_L) \cap \mathcal{W}_3(U_2) \neq \emptyset$, there is a solution defined as follows. Let

$$\{U_3\} = \mathcal{W}_1(U_L) \cap \mathcal{W}_3(U_2).$$

The solution is then

$$W_1(U_L, U_3) \oplus W_2(U_3, \bar{U}_3) \oplus W_3(\bar{U}_3, U_2) \oplus W_4(U_2, U_1) \oplus W_3(U_1, U_R). \tag{4.14}$$

In fact, this construction makes sense for a larger domain of U_R: U_R may belong to $\mathcal{G}_1$ provided the shock speed $\lambda_3(U_1, U_R) \geq 0$.

The above constructions list all possible configurations of Riemann solutions. So we now discuss the existence and uniqueness. Observe that in Construction N7, if $|a_R - a_L|$ is small, then the arc $\widehat{BC}$ is closed to the point A. Therefore, $\mathcal{W}_3(U_R)$ does not meet $\widehat{BC} \cup \mathcal{W}_1(U_1)$ if $|U_R - U_L| + |a_R - a_L|$ is small. Consequently, the Riemann problem admits a unique solution of the form (4.12) or (4.13). In Construction N4, we also have the unique solution if $|U_R - U_L| + |a_R - a_L|$ is small. So we arrive at the following theorem.

THEOREM 4.2 (existence and uniqueness). *Given* $U_L \in \mathcal{G}_2 \cup \mathcal{G}_3 \cup \mathcal{G}_4 \cup \Sigma_1 \cup \Sigma_2 \cup \Sigma_3$, *let* $\{U_{10}\} = \mathcal{W}_1(U_L) \cap \Sigma_3$, *and let* $U_L^* \in \mathcal{G}_3$ *be the state resulted by a stationary wave from* U_{10} *using* p^*. *The Riemann problem for* (1.1)–(1.2) *always has a solution if* U_L^* *lies below the curve* $\mathcal{W}_3(U_R)$, *and* U_R *is above* Σ_3, *or* $U_R \in \mathcal{G}_4$ *and the configurations* (4.8) *or* (4.13) *make sense. Moreover, we have the following:*

(i) *If* $U_L, U_R \in \mathcal{G}_2 \cup \mathcal{G}_3$ *and* $|U_R - U_L| + |a_R - a_L|$ *is sufficiently small, then the Riemann problem for* (1.1)–(1.2) *has* (4.12) *or* (4.13) *as the unique solution.*

(ii) *If* $U_L, U_R \in \mathcal{G}_4$ *and* $|U_R - U_L| + |a_R - a_L|$ *is sufficiently small, then the Riemann problem for* (1.1)–(1.2) *has* (4.8) *as the unique solution.*

Acknowledgments. The author would like to express his sincere thanks to the referees for their very constructive comments and helpful suggestions.

SCATTERING OF SURFACE WATER WAVES BY A FLOATING ELASTIC PLATE IN TWO DIMENSIONS*

RUPANWITA GAYEN† AND B. N. MANDAL‡

Abstract. A new method is developed to study the problem of water wave scattering by a thin elastic plate of arbitrary width floating in deep water assuming linear theory. Using Havelock's expansion of water wave potentials, the boundary value problem describing the potentials is reduced to solving singular integral equations of Carleman type. With the introduction of some integral operators the problem is further reduced to twelve Fredholm integral equations of second kind with regular kernels, and the numerical solutions of these integral equations are used to compute the reflection and transmission coefficients. The numerical estimates for the reflection coefficient are presented in a number of figures given varying different physical parameters. It is shown that the present analysis produces known results for the reflection coefficient.

Key words. water waves, scattering, elastic plate, reflection coefficient

1. Introduction.

The problems of water wave scattering by thin elastic plates of either semi-infinite or of finite width have been investigated by a number of researchers using a variety of mathematical techniques. The interest behind investigating this class of problems arises due to their applications in several practical areas. One of these is associated with understanding the behavior of the waves while interacting with the sea ice in the Marginal Ice Zone (MIZ) in Antarctica. Examples of such studies can be found in Fox and Squire (1990), (1994), Meylan and Squire (1994), Squire et al. (1995), and Williams and Squire (2006). The effect of surface wave interaction with floating elastic plates is also important in modeling floating breakwaters and very large floating structures (VLFS) like floating runways, offshore pleasure cities, floating oil-storage bases, etc. Problems dealing with wave-VLFS interaction have been considered by Kagemoto, Masataka, and Motohika (1998), Namba and Okhusu (1999), Kashiwagi (2000), Khapasheva and Korobkin (2002), Okhusu and Namba (2004), and others. An extensive review of ice-wave interaction problems and related methods to solve them are given by Squire (2007).

Evans and Davies (1968) derived the explicit solution of the scattering problem involving a semi-infinite thin elastic plate in finite depth water using the Wiener–Hopf technique (cf. Noble (1958)); however, no numerical calculation could be carried out due to the complicated nature of the solution. Later this problem was also attacked by Balmforth and Craster (1999) and Chung and Fox (2002) using the Wiener–Hopf technique by incorporating some modifications to determine simpler expressions for the reflection coefficient. Gol'dshtein and Marchenko (1989) and Tkacheva (2001), (2003) also employed the Wiener–Hopf technique to study various problems related to floating elastic plates.

A variety of different techniques can be found in the water wave literature for studying scattering problems involving two-dimensional models of elastic plates floating on the surface of either finite or infinite depth water. Newman (1994) presented a methodology for treating the interaction of water waves with arbitrary deformable bodies. His idea was to represent the displacement of the bodies in terms of sets of appropriate model functions and orthogonal polynomials. This theory was generalized by Wu, Watanabe, and Utsunomiya (1995) to a single floating elastic plate. Sahoo, Yip, and Chwang (2001) investigated the interaction of surface waves with a semi-infinite elastic plate floating on the surface of finite depth water. They used the method of eigenfunction expansions in the mathematical analysis. A mode matching principle was used by Meylan and Squire (1993) to find the reflection and transmission coefficients of ocean waves by a semi-infinite ice floe (thin elastic plate). In another paper Meylan and Squire (1994) considered a single ice floe of finite width as well as a pair of ice floes of the same width and the related problem was reduced to solving a Fredholm integral equation of second kind with logarithmic kernel by the application of Green's function technique. The problem of scattering of water waves by multiple floating plates of variable properties floating on water of uniform finite depth was considered by Kohout et al. (2007) using the principle of matching of eigenfunction expansions at the boundaries of the plates. Also they compared their solution with experimental results. Andrianov and Hermans (2003) and Hermans (2004) considered a single strip or multiple strips of floating elastic platforms employing integrodifferential equations along the platforms preceded by application of Green's integral theorem. The diffraction of surface waves by a semi-infinite ice sheet modeled as a thin elastic plate and by a gap of finite width between two semi-infinite elastic plates floating on water of finite depth were studied by Linton and Chung (2003) and Chung and Linton (2005), respectively, by the residue calculus technique.

On the other hand, very few papers can be found in the literature involving three-dimensional models of floating elastic plates, as the computations associated with these problems require much rigorous effort compared to two-dimensional problems. Even if the geometry of the plate and the boundary is three-dimensional, for simplicity, some restrictions are imposed on the shape of the plate and/or the boundary to reduce the dimension of the problem to two (cf. Porter and Porter (2004)). A fully developed theory for three-dimensional models can be found in Masson and LeBlond (1989) in connection with wave propagation through rigid circular ice floes in MIZ. They used a multiple scattering theory. Meylan, Squire, and Fox (1997) and Meylan and Masson (2006) studied the wave interaction with flexible ice floes in MIZ for arbitrary floe geometry. Both papers are based on a linear Boltzmann equation formulation. In a recent paper Porter and Evans (2007) considered the three-dimensional problem of scattering of flexural gravity waves through a finite number of cracks of finite length. The method is based on solving hypersingular integral equations by Galerkin technique.

Chakrabarti (2000a) solved explicitly the two-dimensional problem of water wave scattering by a semi-infinite ice-cover floating on the surface of deep water by reducing the problem to solving a Carleman-type singular integral equation. This technique was also employed by Chakrabarti (2000b) to study wave scattering by the discontinuity on the surface of water arising due to the presence of two types of semi-infinite inertial surfaces. A somewhat similar type of problem wherein a single semi-infinite inertial surface is present on the surface of deep water was earlier treated by Kanoria, Mandal, and Chakrabarti (1999) by the Wiener–Hopf technique. They also considered a finite strip of inertial surface floating on the surface of open water.

A Carleman singular integral equation is of the following form (cf. Spence (1965), Varley and Walker (1989)):

$$a(\xi)u(\xi)+\frac{b(\xi)}{\pi}\,⨍_{0}^{\infty}\frac{u(t)}{t-\xi}\mathrm{d}t=c(\xi),\ \ \xi>0, \tag{1.1}$$

where $a(\xi), b(\xi), c(\xi)$ are known rational functions of suitable order and the integral is in the sense of Cauchy principle value. In order to solve (1.1), an appropriate sectionally analytic function in terms of the unknown function $u(\xi)$ is introduced. Then, using Plemelj's formulae, it is reduced to a Riemann–Hilbert problem which is solved in the usual manner (cf. Muskhelishvili (1953), Gakhov (1966)).

Gayen, Mandal, and Chakrabarti (2005), (2006) generalized the problems of Chakrabarti (2000a), (2000b) to solve the problems of water wave scattering by a finite strip of ice-cover and by a strip of inertial surface floating sandwiched between another kind of inertial surface. Both boundary value problems were reduced to two Carleman singular integral equations of the forms

$$a_1(\xi)p_1(\xi)+\frac{1}{\pi}⨍_{0}^{\infty}\frac{p_1(u)}{\xi-u}\mathrm{d}u+\frac{1}{\pi}\int_{0}^{\infty}\frac{p_2(u)\mathrm{e}^{-ul}}{\xi+u}\mathrm{d}u=r_1(\xi), \tag{1.2}$$

$$a_2(\xi)p_2(\xi)+\frac{1}{\pi}⨍_{0}^{\infty}\frac{p_2(u)}{\xi-u}\mathrm{d}u+\frac{1}{\pi}\int_{0}^{\infty}\frac{p_1(u)\mathrm{e}^{-ul}}{\xi+u}\mathrm{d}u=r_2(\xi) \tag{1.3}$$

for determining the unknown functions $p_1(\xi)$ and $p_2(\xi)$, where l is the width of the strip and $a_i(\xi), r_i(\xi)$ $(i=1,2)$ are known functions. Due to the presence of the second integrals in (1.2) and (1.3), it was not possible to reduce the equations to Riemann–Hilbert problems directly, thereby solving the equations explicitly. This difficulty had been overcome by assuming the strip width l to be sufficiently large. Then the third terms on the left-hand sides of (1.2) and (1.3) became exponentially small and the two equations could be solved approximately by reducing them to Riemann–Hilbert problems.

Recently Gayen, Mandal, and Chakrabarti (2007) reinvestigated the finite strip problem considered earlier by Gayen et al. (2006) and solved it for any arbitrary width of strip. The idea was to introduce some integral operators and, with the help of these operators, express the solutions of the Carleman singular integral equations of the forms (1.2) and (1.3) in terms of solutions of four Fredholm integral equations of the second kind, and then compute the solutions numerically.

Keeping in mind the increasing interest in the study of wave interaction problems involving a floating plate due to their immense practical applications, our aim in the present work is to examine the applicability of the aforementioned Carleman singular integral equation method in solving the physical problem of wave scattering by a thin elastic plate floating freely on deep water. The physical problem leads to solving a boundary value problem for a second order partial differential equation involving fifth order partial derivative in the boundary condition. The occurrence of a fifth order derivative makes the problem somewhat difficult to handle compared to the surface strip problem, which involved first order derivative in the boundary condition (cf. Gayen et al. (2007)). As mentioned earlier, this problem was solved by Gayen et al. (2005) for elastic plates of large width. However, for practical purposes the strip width need not always be large. The problem would be more realistic if it could be solved for arbitrary strip widths, as was considered by Meylan and Squire (1994). This motivated us to employ the present analysis. The problem is formulated in terms of reduced velocity potentials in three different fluid regions, two below the semi-infinite free surfaces on either side of the floating plate and one below the finite plate. The conditions of continuity of the velocity potential and velocity across the vertical lines below the end points of the plate followed by Havelock's inversion theorem produce two Carleman-type singular integral equations. We then introduce a singular and a nonsingular integral operator and, after some algebraic manipulations, the entire problem is reduced to solving twelve Fredholm integral equations of the second kind. These are solved numerically by Nystrom's method, and in terms of these solutions the unknown functions that satisfy the Carleman singular integral equations are determined. The reflection and transmission coefficients and the other unknown constants appearing in the boundary value problem are also computed numerically for arbitrary strip width. The numerical estimates of the reflection coefficient ($|R|$) are represented graphically for large as well as moderate strip widths against the wave number. $|R|$ is also depicted against the length of the plate for its different thickness, where the data have been taken to be the same as were used by Meylan and Squire (1994). We obtain almost identical results as those in Meylan and Squire (1994) following a completely different method. Also the results for large width completely agree with those in Gayen et al. (2005). For wider plates, it has been observed that there is an infinite number of frequencies at which complete transmission takes place below the plate, resulting in rapid oscillation in the nature of the curve for $|R|$. This oscillatory nature reduces noticeably with a decrease in the plate width, and when the plate is sufficiently small we cannot find any zero of the reflection coefficient.

In solving problems of different branches of applied mathematics and engineering, Carleman singular integral equations are frequently used. However, to our knowledge no work prior to that of Chakrabarti (2000b) has been done in the field of linear water wave theory using this method. He showed in his two successive papers (Chakrabarti (2000a), (2000b)) how to reduce two particular scattering problems to a single Carleman singular integral equation. We generalized his works in our papers Gayen et al. (2005), (2006) for finite strip problems. Due to the asymptotic nature of the results, the scheme was not applicable for moderate values of strip width. So we were in search of a general method which would work for arbitrary strip widths. We first applied it to a strip of an inertial surface floating between another inertial surface (cf. Gayen et al. (2007)). There we studied the effect of wave propagation by a finite strip of inertial surface lying sandwiched between two other semi-infinite inertial surfaces. The successful implementation of the procedure impelled us to apply it to solve a more complicated boundary value problem involving higher order derivatives in the boundary conditions.

2. Mathematical formulation.

Cartesian coordinates are chosen in which the (x, z)-plane corresponds to the undisturbed upper surface and y-axis pointing vertically downwards. We consider the scattering of a normally incident surface wave train by an elastic plate which occupies the position $y = 0$, $0 \leq x \leq l$, $-\infty < z < \infty$ in deep water. The plate is composed of an elastic material having Young's modulus E and Poisson's ratio ν and is of very small thickness h_0 so that the draft is negligible. Since the plate is infinitely long along the z-direction, we can consider the problem to be two-dimensional in (x, y)-coordinates only. We assume that the motion in the fluid is irrotational, time-harmonic with time dependence $\mathrm{e}^{-\mathrm{i}\sigma t}$, σ being the angular frequency, and that the fluid is inviscid and incompressible. Within the framework of linearized theory, the mathematical problem can be described by a velocity potential $\Phi(x, y; t) = Re\{\phi(x, y)\mathrm{e}^{-\mathrm{i}\sigma t}\}$, where $\phi(x, y)$ is a time-independent complex valued function. It satisfies the Laplace equation

$$\frac{\partial^2\phi}{\partial x^2}+\frac{\partial^2\phi}{\partial y^2}=0 \quad \text{in the fluid region;} \tag{2.1}$$

the free surface condition

$$K\phi+\phi_y=0 \quad \text{on } y=0,\, (-\infty<x<0)\bigcup(l<x<\infty); \tag{2.2}$$

the plate condition

$$D\frac{\partial^5\phi}{\partial^4 x\partial y}+K\phi+\phi_y=0 \quad \text{on } y=0,\, 0<x<l, \tag{2.3}$$

D being proportional to flexural rigidity of the plate and given by $D=\frac{Eh_0^3}{12(1-\nu^2)\rho g}$, g being the acceleration due to gravity, and $K=\frac{\sigma^2}{g}$; and the bottom condition

$$\nabla\phi\to 0 \quad \text{as } y\to\infty. \tag{2.4}$$

The conditions of no bending moment and no shearing stress at the two ends of the plate are

$$\begin{aligned}&\phi_{xxy}\to 0 \quad \text{as } x\to 0^+, l^- \text{ on } y=0,\\ &\phi_{xxxy}\to 0 \quad \text{as } x\to 0^+, l^- \text{ on } y=0,\end{aligned} \tag{2.5}$$

and the requirements at infinity are

$$\phi\to\begin{cases} \mathrm{e}^{-Ky+\mathrm{i}Kx}+R\mathrm{e}^{-Ky-\mathrm{i}Kx} & \text{as } x\to-\infty,\\ T\mathrm{e}^{-Ky+\mathrm{i}K(x-l)} & \text{as } x\to\infty,\end{cases} \tag{2.6}$$

where R and T are the unknown amplitudes (complex) of the reflected and transmitted waves. Determination of these two quantities is the principal concern here.

It may be noticed that the ice-cover condition given in (2.3) is derived under the assumption that the waves are long compared to the thickness of the ice; i.e., the inertia term is nearly equal to zero. However, if we don't make this assumption, then the boundary condition would have been

$$D\frac{\partial^5\phi}{\partial^4 x\partial y}+(1-\epsilon K)\phi+\phi_y=0 \quad \text{on } y=0,\, 0<x<l.$$

Unless the frequency of the incident wave is very large, for most of the physical problems we can take $(1-\epsilon K)>0$. Now if we divide the above equation by $(1-\epsilon K)$, then it reduces to

$$D'\frac{\partial^5\phi}{\partial^4 x\partial y}+K'\phi+\phi_y=0 \quad \text{on } y=0,\, 0<x<l,$$

where $(D',K')=\frac{(D,K)}{1-\epsilon K}$, which has a form similar to (2.3).

In the next section we reduce the above boundary value problem to two Carleman-type singular integral equations.

3. Reduction to singular integral equations. We first observe that if we solve the Laplace equation (2.1) subject to the plate condition (2.3) by the method of separation of variables, we obtain the following solutions (cf. Chakrabarti, Ahluwalia, and Manam (2003)):

$$\mathrm{e}^{-\lambda Ky\pm \mathrm{i}\lambda Kx},\ \mathrm{e}^{-\lambda_1 Ky\pm \mathrm{i}\lambda_1 Kx},\ \mathrm{e}^{-\bar\lambda_1 Ky\pm \mathrm{i}\bar\lambda_1 Kx},\ \mathrm{e}^{-\lambda_2 Ky\pm \mathrm{i}\lambda_2 Kx},\ \mathrm{e}^{-\bar\lambda_2 Ky\pm \mathrm{i}\bar\lambda_2 Kx}$$

and $\{\xi(D\xi^4+1)\cos\xi y - K\sin\xi y\}\mathrm{e}^{\pm\xi x}$, $\xi\in(0,\infty)$, where λK is the real positive root of the equation

$$Dk^5+k-K=0, \tag{3.1}$$

whose other roots are $(\lambda_1 K,\bar\lambda_1 K),(\lambda_2 K,\bar\lambda_2 K)$ with $\mathrm{Re}(\lambda_1)>0, \mathrm{Re}(\lambda_2)<0, \mathrm{Im}(\lambda_1,\lambda_2)>0$.

Thus in the region below the strip, $\phi(x,y)$ has the form

$$\phi(x,y)=\alpha\mathrm{e}^{-\lambda Ky+\mathrm{i}\lambda Kx}+\beta\mathrm{e}^{-\lambda Ky-\mathrm{i}\lambda K(x-l)}+\chi(x,y),\ 0<x<l. \tag{3.2}$$

Here it may be observed that we have not taken the solutions involving λ_2 and $\bar\lambda_2$ for expressing $\phi(x,y)$ in $0<x<l$, as these do not satisfy the infinite bottom condition (2.4). The first two terms in (3.2) represent the propagating waves with α and β being unknown constants which can be identified with the reflection and transmission coefficients, respectively, through the points $(l,0)$ and $(0,0)$. The function $\chi(x,y)$ is a combination of the solutions $\mathrm{e}^{-\lambda_1 Ky\pm\mathrm{i}\lambda_1 Kx}, \mathrm{e}^{-\bar\lambda_1 Ky\pm\mathrm{i}\bar\lambda_1 Kx}$ and $\{\xi(D\xi^4+1)\cos\xi y-K\sin\xi y\}\mathrm{e}^{\pm\xi x}$, $\xi\in(0,\infty)$. We introduce a reduced potential $\psi(x,y)$ defined by $\phi=\frac{\partial^2\psi}{\partial x^2}$ and express this function in the three regions $x<0$, $0<x<l$, $x>l$ $(y>0)$. The basic reason to set $\phi=\frac{\partial^2\psi}{\partial x^2}$ is to ensure the convergence of the various integrals appearing in the mathematical analysis. Working with ψ ensures avoiding divergent integrals altogether, which is not possible if we work with ϕ.

We now employ Havelock's expansion of water wave potential (cf. Havelock (1929)) to represent $\psi(x,y)$ as

(3.3)
$$\psi(x,y)=-\frac{1}{K^2}\mathrm{e}^{-Ky+\mathrm{i}Kx}-\frac{R}{K^2}\mathrm{e}^{-Ky-\mathrm{i}Kx}+\frac{2}{\pi}\int_0^\infty\frac{A(\xi)}{\xi^2+K^2}L(\xi,y)\mathrm{e}^{\xi x}\mathrm{d}\xi,\ x<0,\ y>0,$$

$$\begin{aligned}\psi(x,y)=&-\frac{1}{\lambda^2K^2}\left\{\alpha\mathrm{e}^{-\lambda Ky+\mathrm{i}\lambda Kx}+\beta\mathrm{e}^{-\lambda Ky-\mathrm{i}\lambda K(x-l)}\right\}\\&-\frac{1}{\lambda_1^2K^2}\left\{A_1\mathrm{e}^{-\lambda_1 Ky+\mathrm{i}\lambda_1 Kx}+A_2\mathrm{e}^{-\lambda_1 Ky-\mathrm{i}\lambda_1 K(x-l)}\right\}\\&-\frac{1}{\bar\lambda_1^2K^2}\left\{A_3\mathrm{e}^{-\bar\lambda_1 Ky+\mathrm{i}\bar\lambda_1 K(x-l)}+A_4\mathrm{e}^{-\bar\lambda_1 Ky-\mathrm{i}\bar\lambda_1 Kx}\right\}\\&+\frac{2}{\pi}\int_0^\infty\frac{B(\xi)\mathrm{e}^{\xi(x-l)}+C(\xi)\mathrm{e}^{-\xi x}}{P(\xi)}M(\xi,y)\mathrm{d}\xi,\ 0<x<l,\ y>0,\end{aligned} \tag{3.4}$$

(3.5)
$$\psi(x,y)=-\frac{T}{K^2}\mathrm{e}^{-Ky+\mathrm{i}K(x-l)}+\frac{2}{\pi}\int_0^\infty\frac{G(\xi)}{\xi^2+K^2}L(\xi,y)\mathrm{e}^{-\xi(x-l)}\mathrm{d}\xi,\ x>l,\ y>0,$$

where A_1, A_2, A_3, A_4 are unknown constants and $A(\xi)$, $B(\xi)$, $C(\xi)$, and $G(\xi)$ are unknown functions of ξ and are such that the integrals in (3.3) to (3.5) are convergent, and

$$L(\xi, y) = \xi \cos \xi y - K \sin \xi y,$$

$$M(\xi, y) = D\xi^5 \cos \xi y + L(\xi, y),$$

and

$$P(\xi) = \xi^2 (D\xi^4 + 1)^2 + K^2.$$

From the representation of the function $\psi(x, y)$ it may be noted that the domain of the variable ξ is $(0, \infty)$, and so whenever ξ appears in the rest of the paper it will be assumed that $\xi > 0$.

Before we proceed further, we would like to state the following theorem, known as Havelock's inversion theorem (cf. Havelock (1929), Ursell (1947)).

THEOREM 3.1. *If a function $H(t)$ defined for $t > 0$ is of class $C^1(0, \infty)$, is absolutely integrable over $(0, \infty)$, and has the integral representation*

$$H(t) = H_0 \mathrm{e}^{-Ky} + \int_0^\infty \widehat{H}(\xi) L(\xi, t) \mathrm{d}\xi, \;\; t > 0,$$

then the constant H_0 and the function $\widehat{H}$ are given by

$$H_0 = 2K \int_0^\infty H(u) \mathrm{e}^{-Ku} \mathrm{d}u$$

and

$$\widehat{H}(\xi) = \frac{2}{\pi} \frac{1}{\xi^2 + K^2} \int_0^\infty H(u) L(\xi, u) \mathrm{d}u.$$

This theorem plays a crucial role in the further development of our method.

After obtaining the expansions of $\psi(x, y)$ given in (3.3)–(3.5) in the open water region and in the plate covered region, we employ the continuity of ψ and $\frac{\partial \psi}{\partial x}$ across the lines $x = 0$ and $x = l$ $(y > 0)$. This gives rise to four relations involving the eight unknown constants and the four unknown functions. To these relations we apply the above theorem and obtain two pairs of representations for the functions $A(\xi)$ and $G(\xi)$ (for details see Gayen et al. (2005)). Elimination of $A(\xi)$ and $G(\xi)$ from their dual representations produces the following Carleman-type singular integral equations for solving the unknown functions $B(\xi)$ and $C(\xi)$:

$$\mu(\xi) B_1(\xi) + \frac{1}{\pi} \fint_0^\infty \frac{B_1(u)}{u - \xi} \mathrm{d}u - \frac{1}{\pi} \int_0^\infty \frac{C_1(u)}{u + \xi} \mathrm{e}^{-ul} \mathrm{d}u = F_B(\xi), \;\; \xi > 0, \tag{3.6}$$

and

$$\mu(\xi) C_1(\xi) + \frac{1}{\pi} \fint_0^\infty \frac{C_1(u)}{u - \xi} \mathrm{d}u - \frac{1}{\pi} \int_0^\infty \frac{B_1(u)}{u + \xi} \mathrm{e}^{-ul} \mathrm{d}u = F_C(\xi), \;\; \xi > 0, \tag{3.7}$$

where

$$(B_1(\xi), C_1(\xi)) = \frac{DK\xi^5}{P(\xi)} \left(B(\xi), C(\xi) \right), \tag{3.8}$$

$$\mu(\xi) = \frac{\xi^2 (D\xi^4 + 1) + K^2}{DK\xi^5} \tag{3.9}$$

and

$$F_B(\xi) = \frac{\lambda-1}{2\lambda^2 K}\left\{\frac{\alpha \mathrm{e}^{\mathrm{i}\lambda Kl}}{\xi-\mathrm{i}\lambda K} + \frac{\beta}{\xi+\mathrm{i}\lambda K}\right\} + \frac{\lambda_1-1}{2\lambda_1^2 K}\left\{\frac{A_1\mathrm{e}^{\mathrm{i}\lambda_1 Kl}}{\xi-\mathrm{i}\lambda_1 K} + \frac{A_2}{\xi+\mathrm{i}\lambda_1 K}\right\}$$

$$+ \frac{\bar{\lambda}_1-1}{2\bar{\lambda}_1^2 K}\left\{\frac{A_3}{\xi-\mathrm{i}\bar{\lambda}_1 K} + \frac{A_4\mathrm{e}^{-\mathrm{i}\bar{\lambda}_1 Kl}}{\xi+\mathrm{i}\bar{\lambda}_1 K}\right\}, \tag{3.10}$$

$$F_C(\xi) = \frac{\lambda-1}{2\lambda^2 K}\left\{\frac{\alpha}{\xi+\mathrm{i}\lambda K} + \frac{\beta \mathrm{e}^{\mathrm{i}\lambda Kl}}{\xi-\mathrm{i}\lambda K}\right\} + \frac{\lambda_1-1}{2\lambda_1^2 K}\left\{\frac{A_1}{\xi+\mathrm{i}\lambda_1 K} + \frac{A_2\mathrm{e}^{\mathrm{i}\lambda_1 Kl}}{\xi-\mathrm{i}\lambda_1 K}\right\}$$

$$+ \frac{\bar{\lambda}_1-1}{2\bar{\lambda}_1^2 K}\left\{\frac{A_3\mathrm{e}^{-\mathrm{i}\bar{\lambda}_1 Kl}}{\xi+\mathrm{i}\bar{\lambda}_1 K} + \frac{A_4}{\xi-\mathrm{i}\bar{\lambda}_1 K}\right\}. \tag{3.11}$$

Here it may be mentioned that due to the presence of the second integrals involving $\exp(-ul)$ in (3.6) and (3.7), it is not possible to solve them in a straightforward manner. To get rid of these two terms, Gayen et al. (2005) eliminated them by assuming the strip width to be sufficiently large and, after employing the technique of the Riemann–Hilbert problem, solved the two equations by a sort of iteration process. Here the assumption of largeness of the strip width is not made, and a new method is introduced which is somewhat similar to Gayen et al. (2007). This is explained in section 4.

It will be found in what follows that the solutions of the integral equations (3.6) and (3.7) can be expressed as linear combinations of some known functions multiplied by six unknown constants $\alpha, \beta, A_1, A_2, A_3, A_4$. Once these expressions are obtained they are substituted into the following eight equations for determining the eight unknown constants $R, T, \alpha, \beta, A_1, A_2, A_3, A_4$:

(3.12)
$$\frac{1+R}{2} = \frac{\alpha+\beta\mathrm{e}^{\mathrm{i}\lambda Kl}}{\lambda^2(\lambda+1)} + \frac{A_1+A_2\mathrm{e}^{\mathrm{i}\lambda_1 Kl}}{\lambda_1^2(\lambda_1+1)} + \frac{A_3\mathrm{e}^{-\mathrm{i}\bar{\lambda}_1 Kl}+A_4}{\bar{\lambda}_1^2(\bar{\lambda}_1+1)} - \frac{2K^3}{\pi}\int_0^\infty \frac{B_1(\xi)\mathrm{e}^{-\xi l}+C_1(\xi)}{\xi^2+K^2}\mathrm{d}\xi,$$

(3.13)
$$\frac{1-R}{2} = \frac{\alpha-\beta\mathrm{e}^{\mathrm{i}\lambda Kl}}{\lambda(\lambda+1)} + \frac{A_1-A_2\mathrm{e}^{\mathrm{i}\lambda_1 Kl}}{\lambda_1(\lambda_1+1)} + \frac{A_3\mathrm{e}^{-\mathrm{i}\bar{\lambda}_1 Kl}-A_4}{\bar{\lambda}_1(\bar{\lambda}_1+1)} + \frac{2K^2\mathrm{i}}{\pi}\int_0^\infty \frac{B_1(\xi)\mathrm{e}^{-\xi l}-C_1(\xi)}{\xi^2+K^2}\xi\mathrm{d}\xi,$$

(3.14)
$$\frac{T}{2} = \frac{\alpha\mathrm{e}^{\mathrm{i}\lambda Kl}+\beta}{\lambda^2(\lambda+1)} + \frac{A_1\mathrm{e}^{\mathrm{i}\lambda_1 Kl}+A_2}{\lambda_1^2(\lambda_1+1)} + \frac{A_3+A_4\mathrm{e}^{-\mathrm{i}\bar{\lambda}_1 Kl}}{\bar{\lambda}_1^2(\bar{\lambda}_1+1)} - \frac{2K^3}{\pi}\int_0^\infty \frac{B_1(\xi)+C_1(\xi)\mathrm{e}^{-\xi l}}{\xi^2+K^2}\mathrm{d}\xi,$$

(3.15)
$$\frac{T}{2} = \frac{\alpha\mathrm{e}^{\mathrm{i}\lambda Kl}-\beta}{\lambda(\lambda+1)} + \frac{A_1\mathrm{e}^{\mathrm{i}\lambda_1 Kl}-A_2}{\lambda_1(\lambda_1+1)} + \frac{A_3-A_4\mathrm{e}^{-\mathrm{i}\bar{\lambda}_1 Kl}}{\bar{\lambda}_1(\bar{\lambda}_1+1)} + \frac{2K^2\mathrm{i}}{\pi}\int_0^\infty \frac{B_1(\xi)-C_1(\xi)\mathrm{e}^{-\xi l}}{\xi^2+K^2}\xi\mathrm{d}\xi,$$

$$(\lambda K)^3(\alpha+\beta\mathrm{e}^{\mathrm{i}\lambda Kl}) + (\lambda_1 K)^3(A_1+A_2\mathrm{e}^{\mathrm{i}\lambda_1 Kl}) + (\bar{\lambda}_1 K)^3(A_3\mathrm{e}^{-\mathrm{i}\bar{\lambda}_1 Kl}+A_4)$$

$$-\frac{2}{D\pi}\int_0^\infty \{B_1(\xi)\mathrm{e}^{-\xi l}+C_1(\xi)\}\mathrm{d}\xi = 0, \tag{3.16}$$

$$(\lambda K)^4(\alpha-\beta\mathrm{e}^{\mathrm{i}\lambda Kl}) + (\lambda_1 K)^4(A_1-A_2\mathrm{e}^{\mathrm{i}\lambda_1 Kl}) + (\bar{\lambda}_1 K)^4(A_3\mathrm{e}^{-\mathrm{i}\bar{\lambda}_1 Kl}-A_4)$$

$$+\frac{2\mathrm{i}}{D\pi}\int_0^\infty \{B_1(\xi)\mathrm{e}^{-\xi l}-C_1(\xi)\}\xi\mathrm{d}\xi = 0, \tag{3.17}$$

$$(\lambda K)^3(\alpha \mathrm{e}^{\mathrm{i}\lambda K l}+\beta)+(\lambda_1 K)^3(A_1\mathrm{e}^{\mathrm{i}\lambda_1 K l}+A_2)+(\bar{\lambda}_1 K)^3(A_3+A_4\mathrm{e}^{-\mathrm{i}\bar{\lambda}_1 K l}) \\ -\frac{2}{D\pi}\int_0^\infty \{B_1(\xi)+C_1(\xi)\mathrm{e}^{-\xi l}\}\mathrm{d}\xi=0, \tag{3.18}$$

$$(\lambda K)^4(\alpha \mathrm{e}^{\mathrm{i}\lambda K l}-\beta)+(\lambda_1 K)^4(A_1\mathrm{e}^{\mathrm{i}\lambda_1 K l}-A_2)+(\bar{\lambda}_1 K)^4(A_3-A_4\mathrm{e}^{-\mathrm{i}\bar{\lambda}_1 K l}) \\ +\frac{2\mathrm{i}}{D\pi}\int_0^\infty \{B_1(\xi)-C_1(\xi)\mathrm{e}^{-\xi l}\}\xi\mathrm{d}\xi=0. \tag{3.19}$$

The first four equations, (3.12)–(3.15), are obtained by application of Havelock's inversion theorem on the relations derived from the continuity of the functions ψ and $\frac{\partial\psi}{\partial x}$ across the lines $x=0$ and $x=l$ $(y>0)$, whereas (3.16)–(3.19) are the consequence of the conditions (2.4) at the end points of the plate.

4. Solution for arbitrary width of the plate. In this section we solve the two singular integral equations (3.6) and (3.7) for any plate width. For this we first introduce a singular integral operator

$$\mathcal{S}: L^2(0,\infty)\to L^2(0,\infty)$$

and a nonsingular integral operator

$$\mathcal{S}': C^\infty(0,\infty)\to C^\infty(0,\infty)$$

defined by

$$\mathcal{S}f(\xi)=\mu(\xi)f(\xi)+\frac{1}{\pi}\fint_0^\infty \frac{f(u)}{u-\xi}\mathrm{d}u \tag{4.1}$$

and

$$\mathcal{S}'f(\xi)=-\frac{1}{\pi}\int_0^\infty \frac{f(u)\mathrm{e}^{-ul}}{u+\xi}\mathrm{d}u. \tag{4.2}$$

Then (3.6) and (3.7) reduce to the following forms:

$$\mathcal{S}B_1(\xi)+\mathcal{S}'C_1(\xi)=F_B(\xi) \tag{4.3}$$

and

$$\mathcal{S}C_1(\xi)+\mathcal{S}'B_1(\xi)=F_C(\xi). \tag{4.4}$$

It may be observed that the analytical form of the inverse operator $\mathcal{S}^{-1}$ of $\mathcal{S}$ can be determined as follows:

Consider the singular integral equation

$$\mathcal{S}f(\xi)=h(\xi). \tag{4.5}$$

Assuming that the right-hand side is known, (4.5) can be reduced to a Riemann–Hilbert problem (see Muskhelishvili (1953, p. 123), Gakhov (1966, p. 148)),

$$(\mu(\xi)+\mathrm{i})\,\Lambda^+(\xi)-(\mu(\xi)-\mathrm{i})\,\Lambda^-(\xi)=h(\xi), \tag{4.6}$$

after introducing a sectionally analytic function associated with the unknown function $f(\xi)$ satisfying (4.5) as

$$\Lambda(\zeta)=\frac{1}{2\pi\mathrm{i}}\int_0^\infty \frac{f(u)}{u-\zeta}\mathrm{d}u, \quad \zeta=\xi+\mathrm{i}\eta. \tag{4.7}$$

$\Lambda(\zeta)$ is defined in the entire complex ζ-plane cut along the real axis from 0 to ∞. One can solve the Riemann–Hilbert problem given in (4.6) by methods of complex variable theory (see England (1971), Estrada and Kanwal (2000)). Plemelj's formulae corresponding to equation (4.7) are

$$\Lambda^{\pm}(\xi) = \pm\frac{1}{2}f(\xi) + \frac{1}{2\pi\mathrm{i}}\fint_0^\infty \frac{f(u)}{u-\xi}\mathrm{d}u$$

so that

$$\Lambda^{+}(\xi) - \Lambda^{-}(\xi) = f(\xi) \quad \text{and} \quad \Lambda^{+}(\xi) + \Lambda^{-}(\xi) = \frac{1}{\pi\mathrm{i}}\fint_0^\infty \frac{f(u)}{u-\xi}\mathrm{d}u = 2\Lambda(\xi).$$

Thus the function $f(\xi)$ is found to be

$$\begin{aligned} f(\xi) &= \mathcal{S}^{-1}h(\xi) = \Lambda^{+}(\xi) - \Lambda^{-}(\xi) \\ &= \frac{\Lambda_0^{+}(\xi)}{\mu(\xi)-\mathrm{i}}\hat{\mathcal{S}}\left[\frac{h(\xi)}{\Lambda_0^{+}(\xi)(\mu(\xi)+\mathrm{i})}\right], \end{aligned} \tag{4.8}$$

where the operator $\hat{\mathcal{S}}$ is defined by

$$\hat{\mathcal{S}}g(\xi) = \mu(\xi)g(\xi) - \frac{1}{\pi}\fint_0^\infty \frac{g(u)}{u-\xi}\mathrm{d}u \tag{4.9}$$

and

$$\Lambda_0^{+}(\xi) = \lim_{\eta\to 0^+}\Lambda_0(\zeta); \tag{4.10}$$

$\Lambda_0(\zeta)$ is a solution of the homogeneous problem corresponding to the Riemann–Hilbert problem (4.6) and its explicit form is found to be

$$\Lambda_0(\zeta) = \exp\left[\frac{1}{2\pi\mathrm{i}}\int_0^\infty \frac{\log\left(\frac{\mu(t)-\mathrm{i}}{\mu(t)+\mathrm{i}}\right) - \lim_{t\to\infty}\log\left(\frac{\mu(t)-\mathrm{i}}{\mu(t)+\mathrm{i}}\right)}{t-\zeta}\mathrm{d}t\right] \quad (\zeta \notin (0,\infty)). \tag{4.11}$$

It may be noted that the limiting term inside the integral is zero. We now apply the operator $\mathcal{S}^{-1}$ to (4.3) to obtain $B_1(\xi)$ in terms of $C_1(\xi)$ as

$$B_1(\xi) = \mathcal{S}^{-1}\left[F_B(\xi) - \mathcal{S}'C_1(\xi)\right] \tag{4.12}$$

and then substitute $B_1(\xi)$ into (4.4). This yields

$$\mathcal{S}C_1(\xi) + \mathcal{S}'\left[\mathcal{S}^{-1}(F_B - \mathcal{S}'C_1)\right](\xi) = F_C(\xi). \tag{4.13}$$

Applying the operator $\mathcal{S}^{-1}$ to the above equation, we find

$$\left[I - \mathcal{L}^2\right]C_1(\xi) = r(\xi), \tag{4.14}$$

where the operator $\mathcal{L} = \mathcal{S}^{-1}\mathcal{S}'$ is noncommutative and its analytical form is determined as

$$\mathcal{L}m(\xi) = -\frac{1}{\pi}\frac{\Lambda_0^{+}(\xi)}{\mu(\xi)-\mathrm{i}}\int_0^\infty \frac{m(u)\mathrm{e}^{-ul}}{(u+\xi)\Lambda_0(-u)}\mathrm{d}u. \tag{4.15}$$

The explicit derivation of the above expression is outlined in the appendix. The right-hand side of (4.14) is

$$r(\xi) = \mathcal{S}^{-1}\left[F_C - S' S^{-1} F_B\right](\xi) \tag{4.16}$$

and can be simplified as

$$r(\xi) = \alpha r_\alpha(\xi) + \beta r_\beta(\xi) + A_1 r_{A_1}(\xi) + A_2 r_{A_2}(\xi) + A_3 r_{A_3}(\xi) + A_4 r_{A_4}(\xi), \tag{4.17}$$

where the functions $r_\alpha(\xi), r_\beta(\xi), r_{A_1}(\xi), r_{A_2}(\xi), r_{A_3}(\xi), r_{A_4}(\xi)$ are given by

$$r_\alpha(\xi) = C_\alpha M(\xi)\left[\frac{1}{\Lambda_0(-\mathrm{i}K\lambda)(\xi + \mathrm{i}K\lambda)} + \frac{\mathrm{e}^{\mathrm{i}\lambda K l}}{\Lambda_0(\mathrm{i}K\lambda)}\int_0^\infty \frac{M_1(\xi,u)}{u - \mathrm{i}K\lambda}\mathrm{d}u\right], \tag{4.18}$$

$$r_\beta(\xi) = C_\beta M(\xi)\left[\frac{\mathrm{e}^{\mathrm{i}\lambda K l}}{\Lambda_0(\mathrm{i}K\lambda)(\xi - \mathrm{i}K\lambda)} + \frac{1}{\Lambda_0(-\mathrm{i}K\lambda)}\int_0^\infty \frac{M_1(\xi,u)}{u + \mathrm{i}K\lambda}\mathrm{d}u\right], \tag{4.19}$$

$$r_{A_1}(\xi) = C_{A_1} M(\xi)\left[\frac{1}{\Lambda_0(-\mathrm{i}K\lambda_1)(\xi + \mathrm{i}K\lambda_1)} + \frac{\mathrm{e}^{\mathrm{i}\lambda_1 K l}}{\Lambda_0(\mathrm{i}K\lambda_1)}\int_0^\infty \frac{M_1(\xi,u)}{u - \mathrm{i}K\lambda_1}\mathrm{d}u\right], \tag{4.20}$$

$$r_{A_2}(\xi) = C_{A_2} M(\xi)\left[\frac{\mathrm{e}^{\mathrm{i}\lambda_1 K l}}{\Lambda_0(\mathrm{i}K\lambda_1)(\xi - \mathrm{i}K\lambda_1)} + \frac{1}{\Lambda_0(-\mathrm{i}K\lambda_1)}\int_0^\infty \frac{M_1(\xi,u)}{u + \mathrm{i}K\lambda_1}\mathrm{d}u\right], \tag{4.21}$$

$$r_{A_3}(\xi) = C_{A_3} M(\xi)\left[\frac{\mathrm{e}^{-\mathrm{i}\bar{\lambda}_1 K l}}{\Lambda_0(-\mathrm{i}K\bar{\lambda}_1)(\xi + \mathrm{i}K\bar{\lambda}_1)} + \frac{1}{\Lambda_0(\mathrm{i}K\bar{\lambda}_1)}\int_0^\infty \frac{M_1(\xi,u)}{u - \mathrm{i}K\bar{\lambda}_1}\mathrm{d}u\right], \tag{4.22}$$

$$r_{A_4}(\xi) = C_{A_4} M(\xi)\left[\frac{1}{\Lambda_0(\mathrm{i}K\bar{\lambda}_1)(\xi - \mathrm{i}K\bar{\lambda}_1)} + \frac{\mathrm{e}^{-\mathrm{i}\bar{\lambda}_1 K l}}{\Lambda_0(-\mathrm{i}K\bar{\lambda}_1)}\int_0^\infty \frac{M_1(\xi,u)}{u + \mathrm{i}K\bar{\lambda}_1}\mathrm{d}u\right], \tag{4.23}$$

with

$$\begin{gathered} M(\xi) = \frac{\Lambda_0^+(\xi)}{\mu(\xi) - \mathrm{i}}, \quad M_1(\xi,u) = \frac{M(u)\mathrm{e}^{-ul}}{\pi(u+\xi)\Lambda_0(-u)}, \quad C_\alpha = C_\beta = \frac{\lambda - 1}{2\lambda^2 K}, \\ C_{A_1} = C_{A_2} = \frac{\lambda_1 - 1}{2\lambda_1^2 K}, \quad C_{A_3} = C_{A_4} = \frac{\bar{\lambda}_1 - 1}{2\bar{\lambda}_1^2 K}. \end{gathered} \tag{4.24}$$

In order to determine the functions $r_j(\xi)$ given in (4.18)–(4.23) we have utilized the definition of $\mathcal{S}^{-1}$ given in (4.8) together with (4.9). It may be observed that

$$\mathcal{S}^{-1}\left(\frac{1}{\xi + \xi_0}\right) = \frac{M(\xi)}{(\xi + \xi_0)\Lambda_0(-\xi_0)},$$

where ξ_0 is a positive constant.

Equation (4.14) can be regarded as an ordinary integral equation (involving no singular kernel) for solving $C_1(\xi)$. However, since the forcing function $r(\xi)$ is unknown in the sense that it contains the unknown constants α, β, etc., (4.14) cannot be solved directly. In order to overcome this difficulty we introduce two new functions, $U(\xi)$ and $V(\xi)$, in terms of the function $C_1(\xi)$ as

$$[I + \mathcal{L}]C_1(\xi) = U(\xi), \quad [I - \mathcal{L}]C_1(\xi) = V(\xi) \tag{4.25}$$

so that

$$C_1(\xi) = \frac{1}{2}[U(\xi) + V(\xi)] \quad \text{and} \quad \mathcal{L}C_1(\xi) = \frac{1}{2}[U(\xi) - V(\xi)]. \tag{4.26}$$

Then (4.14) can be written in terms of either $U(\xi)$ or $V(\xi)$ as

$$[I-\mathcal{L}]U(\xi)=r(\xi) \tag{4.27}$$

or

$$[I+\mathcal{L}]V(\xi)=r(\xi). \tag{4.28}$$

Because of (4.17) we may express $U(\xi)$ and $V(\xi)$ as

$$U(\xi)=[I-\mathcal{L}]^{-1}r(\xi)=\alpha u_\alpha(\xi)+\beta u_\beta(\xi)+A_1u_{A_1}(\xi)+A_2u_{A_2}(\xi)+A_3u_{A_3}(\xi)+A_4u_{A_4}(\xi) \tag{4.29}$$

and

$$V(\xi)=[I+\mathcal{L}]^{-1}r(\xi)=\alpha v_\alpha(\xi)+\beta v_\beta(\xi)+A_1v_{A_1}(\xi)+A_2v_{A_2}(\xi)+A_3v_{A_3}(\xi)+A_4v_{A_4}(\xi), \tag{4.30}$$

where $u_j(\xi), v_j(\xi)$ (with subscript j denoting $\alpha, \beta, A_1, A_2, A_3, A_4$) are unknown functions. These are determined by incorporating the fact that the integral equation (4.27), along with the relation (4.29), and the integral equation (4.28), along with the relation (4.30), are satisfied simultaneously if $u_j(\xi), v_j(\xi)$ satisfy the following Fredholm integral equations of the second kind:

$$[I-\mathcal{L}]u_j(\xi)=r_j(\xi) \tag{4.31}$$

and

$$[I+\mathcal{L}]v_j(\xi)=r_j(\xi), \tag{4.32}$$

where the subscript j stands for $\alpha, \beta, A_1, A_2, A_3, A_4$. The kernels of the equations and the right-hand sides can be computed from (4.15) and the set of relations (4.18)–(4.23), respectively. We solve the integral equations (4.31) and (4.32) by Nystrom's method to derive the functions $u_j(\xi), v_j(\xi)$ numerically.

In order to solve (4.31) and (4.32), we first need to simplify the forms of the operator $\mathcal{L}$ and the functions $\Lambda_0^+(\xi)$, $\Lambda_0(-\xi)$, and $M(\xi)$. The detailed procedure is given in the appendix.

Now, the solutions $B_1(\xi)$ and $C_1(\xi)$ of the Carleman integral equations (3.6) and (3.7) are determined in a straightforward manner as

$$\begin{aligned} B_1(\xi) &= (\mathcal{S}^{-1}F_B)(\xi)-\mathcal{L}C_1(\xi)=(\mathcal{S}^{-1}F_B)(\xi)-\frac{1}{2}\{U(\xi)-V(\xi)\} \\ &= \alpha B_1^\alpha(\xi)+\beta B_1^\beta(\xi)+A_1B_1^{A_1}(\xi)+A_2B_1^{A_2}(\xi)+A_3B_1^{A_3}(\xi)+A_4B_1^{A_4}(\xi) \end{aligned} \tag{4.33}$$

and

$$\begin{aligned} C_1(\xi) &= \frac{1}{2}\{U(\xi)+V(\xi)\} \\ &= \alpha C_1^\alpha(\xi)+\beta C_1^\beta(\xi)+A_1C_1^{A_1}(\xi)+A_2C_1^{A_2}(\xi)+A_3C_1^{A_3}(\xi)+A_4C_1^{A_4}(\xi). \end{aligned} \tag{4.34}$$

The functions $B_1^j(\xi), C_1^j(\xi)$ (the superscript j having obvious meanings) can be computed from the following relations involving the functions $u_j(\xi)$ and $v_j(\xi)$:

$$B_1^{\alpha}(\xi) = \frac{C_\alpha M(\xi)\mathrm{e}^{\mathrm{i}\lambda K l}}{\Lambda_0(\mathrm{i}K\lambda)(\xi - \mathrm{i}K\lambda)} - \frac{1}{2}\left\{u_\alpha(\xi) - v_\alpha(\xi)\right\},$$

$$B_1^{\beta}(\xi) = \frac{C_\beta M(\xi)}{\Lambda_0(-\mathrm{i}K\lambda)(\xi + \mathrm{i}K\lambda)} - \frac{1}{2}\left\{u_\beta(\xi) - v_\beta(\xi)\right\},$$

$$B_1^{A_1}(\xi) = \frac{C_{A_1} M(\xi)\mathrm{e}^{\mathrm{i}\lambda_1 K l}}{\Lambda_0(\mathrm{i}K\lambda_1)(\xi - \mathrm{i}K\lambda_1)} - \frac{1}{2}\left\{u_{A_1}(\xi) - v_{A_1}(\xi)\right\},$$

$$B_1^{A_2}(\xi) = \frac{C_{A_2} M(\xi)}{\Lambda_0(-\mathrm{i}K\lambda_1)(\xi + \mathrm{i}K\lambda_1)} - \frac{1}{2}\left\{u_{A_2}(\xi) - v_{A_2}(\xi)\right\},$$

$$B_1^{A_3}(\xi) = \frac{C_{A_3} M(\xi)}{\Lambda_0(\mathrm{i}K\bar{\lambda}_1)(\xi - \mathrm{i}K\bar{\lambda}_1)} - \frac{1}{2}\left\{u_{A_3}(\xi) - v_{A_3}(\xi)\right\},$$

$$B_1^{A_4}(\xi) = \frac{C_{A_4} M(\xi)\mathrm{e}^{-\mathrm{i}\bar{\lambda}_1 K l}}{\Lambda_0(-\mathrm{i}K\bar{\lambda}_1)(\xi + \mathrm{i}K\bar{\lambda}_1)} - \frac{1}{2}\left\{u_{A_3}(\xi) - v_{A_3}(\xi)\right\}, \tag{4.35}$$

and

$$C_1^{j}(\xi) = \frac{1}{2}\left\{u_j(\xi) + v_j(\xi)\right\}. \tag{4.36}$$

Thus the functions $B_1(\xi)$ and $C_1(\xi)$ are now derived as linear combinations of unknown constants $\alpha, \beta, A_1, A_2, A_3, A_4$. We then replace $B_1(\xi)$ and $C_1(\xi)$ appearing in (3.12)–(3.19) by their forms in (4.35) and (4.36). This yields a set of eight linear equations for determining the eight unknown constants including R, T. These equations are solved numerically to compute the numerical estimates for the unknown constants. In the next section the numerical results for the reflection coefficient for different parameters are discussed.

5. Numerical results. For numerical computations (except for Figure 1) a characteristic length L proportional to the wavelength is introduced in order to make the different parameters nondimensional. Thus KL, l/L, and D/L^4 represent dimensionless wave number, plate width, and ice-cover parameter, respectively. Because of the energy identity $|R|^2 + |T|^2 = 1$, it is sufficient to present the graphs of $|R|$ only.

In order to establish the correctness of the numerical results obtained by the present analysis, we have compared $|R|$ with the results given in Meylan and Squire (1994). Choosing the same values of various physical quantities such as Young's modulus ($E = 6$ GPa), Poisson's ratio ($\nu = 0.3$), densities of water ($1025\,\mathrm{kgm}^{-3}$) and ice ($922.5\,\mathrm{kgm}^{-3}$), wavelength $100\,\mathrm{m}$, and $g = 9.81\,\mathrm{ms}^{-2}$ as given in Meylan and Squire (1994), $|R|$ is depicted in Figure 1 for different values of thickness of the ice sheet ($h_0 = 1\mathrm{m}$, $2\mathrm{m}$, $5\mathrm{m}$) against its width (floe-length in meters). If Figure 1 is compared with the corresponding figure (Figure 2) of Meylan and Squire (1994), it is obvious that these are almost identical.

Figure 2 shows $|R|$ for plate width $\frac{l}{L} = 10$, ice-cover parameter $\frac{D}{L^4} = 0.001$. Here we notice that when $KL < 0.7$, $|R|$ is almost zero, implying that there occurs total transmission for incident waves with sufficiently smaller frequencies. The continuous line in this figure is drawn on the basis of our present approach, while the triangles represent corresponding data in Gayen, Mandal, and Chakrabarti (2005), wherein the mathematical analysis was based on the assumption of largeness of the plate width. It is evident that the present results completely match the previous ones, which establishes the validity of the theory presented in this paper.

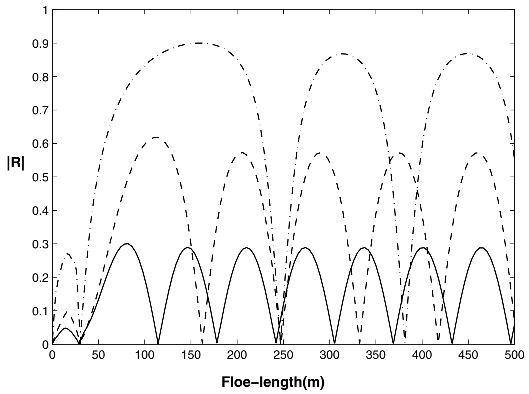

FIG. 1. *$|R|$ for different thickness: $h_0 = 1\mathrm{m}$ (solid curve), $2\mathrm{m}$ (dashed curve), $5\mathrm{m}$ (dash-dot curve).*

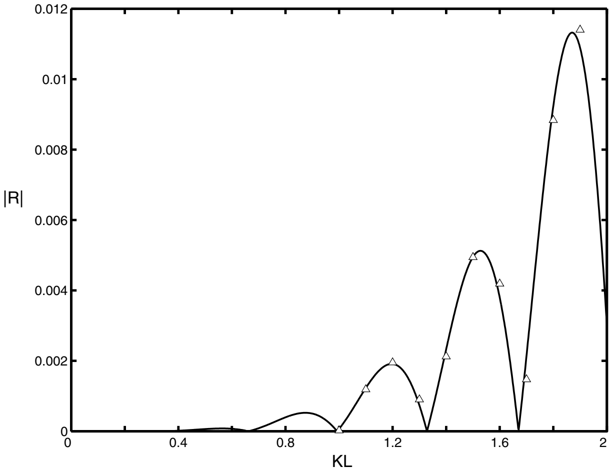

FIG. 2. *$|R|$ for plate width $l/L = 10$, $D/L^4 = 0.001$. Triangles denote data obtained by Gayen, Mandal, and Chakrabarti* (2005). *The line denotes $|R|$ computed by the present method.*

In Figures 3 and 4 the reflection coefficient is plotted against $\frac{D}{L^4}$ for two different wave numbers, $KL = 2$ and $KL = 4$, taking the strip width $\frac{l}{L} = 10$. It is observed that the overall amount of reflection increases with an increase in the wave number. Also the number of zeros of $|R|$ increases for larger frequency.

The effect of frequency is again compared in Figures 5 and 6 by choosing a larger strip width, i.e., $\frac{l}{L} = 100$ for $KL = 2, 4$. From these two figures it is obvious that maximum values of $|R|$ as well as number of zeros of $|R|$ increase with increase of wave number.

Now comparing Figures 3 and 5 or Figures 4 and 6, it is observed that $|R|$ becomes more oscillatory in nature for a wider strip. A similar feature was observed by Chung and Linton (2005) and Williams and Squire (2006) for a gap of finite width between two floating plates where the number of zeros of $|R|$ was found to be greater with larger gap width.

The effect of the thickness of the plate can be examined by varying the parameter

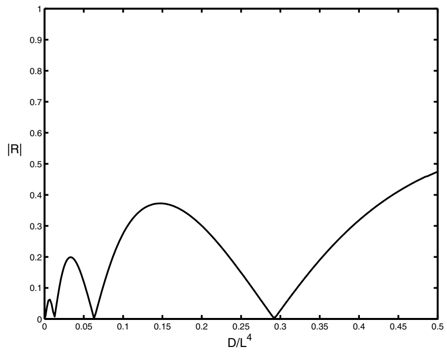

Fig. 3. $|R|$ *for* $l/L = 10,\ KL = 2$.

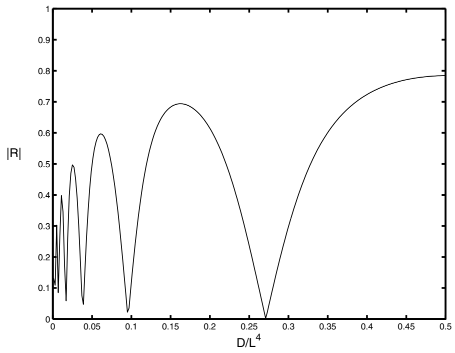

Fig. 4. $|R|$ *for* $l/L = 10,\ KL = 4$.

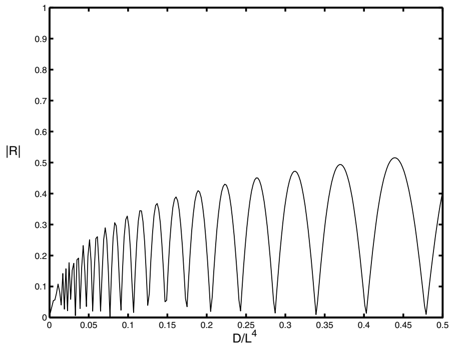

Fig. 5. $|R|$ *for* $l/L = 100,\ KL = 2$.

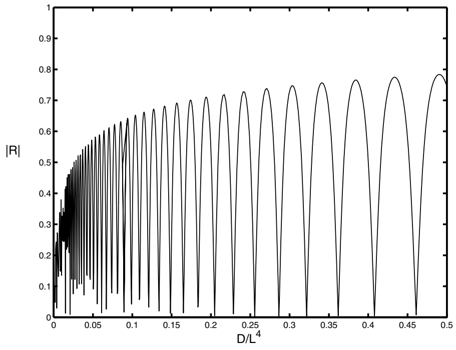

Fig. 6. $|R|$ *for* $l/L = 100,\ KL = 4$.

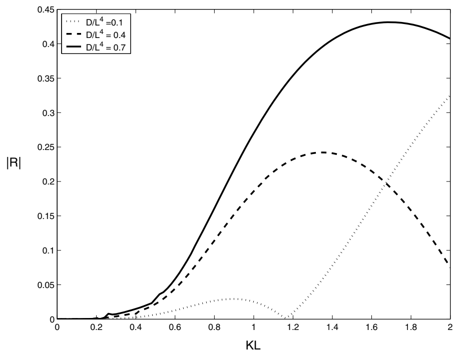

Fig. 7. $|R|$ *for* $l/L = 5$.

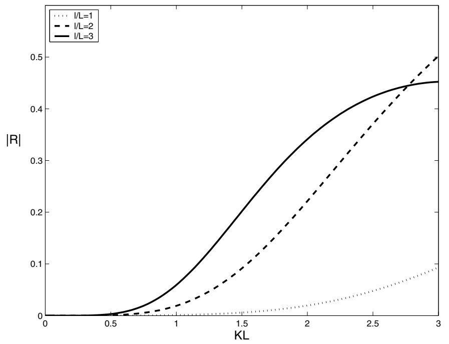

Fig. 8. $|R|$ *for* $D/L^4 = 0.1$.

D if we assume that Young's modulus and Poisson's ratio are kept fixed. This has been shown in Figure 7 by taking $\frac{l}{L} = 5$ and $\frac{D}{L^4} = 0.1, 0.4, 0.7$. The curves in Figure 7 reveal that $|R|$ increases with an increase of $\frac{D}{L^4}$. Thus for plates with the same elastic parameters, the amount of reflected wave energy is increased for thicker plates. This is also evident from Figure 1.

In Figure 8 we have again considered the effect of the plate width on $|R|$ for fixed value 0.1 of D/L^4. Here we have taken moderate plate widths, i.e., $\frac{l}{L} = 1, 2, 3$.

Here also $|R|$ increases with an increase in the plate width, but the phenomenon of multiple reflection does not occur for moderate widths, unlike Figures 3–6, where the plate width was taken to be sufficiently large. It may also be noticed from Figures 7 and 8 that total transmission occurs for smaller frequencies, as was found in Figure 2.

6. Conclusion. In this paper a new method for solving the problem of scattering of a normally incident wave train by the edges of a thin elastic plate of finite width has been described. The boundary value problem is first reduced to singular integral equations of Carleman type and then ultimately to Fredholm integral equations of the second kind. Mathematically it can be claimed that a technique has been developed to study a special type of coupled Carleman singular integral equations of the forms (1.2) and (1.3) wherein the solutions of two complicated singular integral equations have been derived in terms of solutions of integral equations having sufficiently smooth kernels. In this connection, it may be mentioned that Meylan and Squire's (1994) method appears to be somewhat straightforward compared to the method presented here since the solution of a single Fredholm integral equation of the second kind with weakly singular kernel was required. However, the solution method presented here is also somewhat straightforward, and ultimately it involves solving second kind Fredholm integral equations with *regular* kernels. Although our method appears to be cumbersome due to the occurrence of twelve Fredholm integral equations, these equations are solved numerically by using Nystrom's method. A single FORTRAN subroutine served the purpose for solving *all* twelve integral equations. Thus the present method is not really computationally demanding and is perhaps no more difficult than the previous method where a single integral equation is needed to be solved.

A wide range of problems can be handled by the technique presented in this paper. It can be used to investigate wave propagation along strips of floating elastic plates having different thickness or elastic properties, the edges of which are either disjoint (free) or welded together. An identical problem was recently considered by Williams and Squire (2006) using the Wiener–Hopf technique as well as the residue calculus technique. If there are strips of inertial surface surrounded by strips of elastic plates, or vice versa, then our method also can be implemented effectively. This is an ideal situation found in MIZ, where there are continuous sheets of ice and in between them there is broken ice. The former can be modeled as thin elastic plates, whereas the latter can be considered as strips of inertial surface.

The problem of scattering of flexural gravity waves by the edges of two semi-infinite floating elastic plates separated by a finite strip of free surface and present in water of uniform finite depth was investigated by Chung and Linton (2005) employing the residue calculus technique, and the limiting case of this, that is, wave scattering by a narrow crack, was considered by Williams and Squire (2002) and Evans and Porter (2003) using Green's function technique and the mode matching principle. The deep water version of these problems can be studied using the technique of this paper.

One of the classical problems in the literature of water waves is associated with water wave scattering by a semi-infinite or a finite dock (see Friedrichs and Lewy (1948), Holford (1964a), (1964b), Linton (2001), Hermans (2003), Chakrabarti, Mandal, and Gayen (2005)). The effect of wave propagation along a finite dock situated on the surface of deep water with appropriate behaviors at the edges of the dock can be examined by using the present analysis.

Appendix. The operator $\mathcal{L}$. Using the definitions of integral operators $\mathcal{S}'$ and $\mathcal{S}^{-1}$ as given in (4.2), (4.8), and (4.9), we find that

$$\mathcal{L}m(\xi) = (\mathcal{S}^{-1}\mathcal{S}')m(\xi)$$

$$= \frac{\Lambda_0^+(\xi)}{\mu(\xi)-\mathrm{i}}\left[\frac{\mu(\xi)}{\Lambda_0^+(\xi)\,(\mu(\xi)+\mathrm{i})}\left(-\frac{1}{\pi}\int_0^\infty \frac{m(u)\mathrm{e}^{-ul}}{u+\xi}\mathrm{d}u\right)\right.$$

$$\left. + \frac{1}{\pi^2}\int_0^\infty m(u)\mathrm{e}^{-ul}\mathrm{d}u\left(\fint_0^\infty \frac{\mathrm{d}t}{\Lambda_0^+(t)\,(\mu(t)+\mathrm{i})\,(t+u)(t-\xi)}\right)\right]. \tag{A.1}$$

To evaluate the inner integral in the second term of (A.1), we consider the integral

$$\int_\Gamma \frac{\mathrm{d}\tau}{\Lambda_0(\tau)(\tau+u)(\tau-\zeta)}, \quad \zeta \notin \Gamma, \tag{A.2}$$

where $\Lambda_0(\tau)$ satisfies the homogeneous Riemann–Hilbert problem

$$[\mu(\xi)+\mathrm{i}]\,\Lambda^+(\xi) - [\mu(\xi)-\mathrm{i}]\,\Lambda^-(\xi) = 0 \tag{A.3}$$

in the complex τ-plane cut along the positive real axis. The contour Γ is sketched in Figure 9.

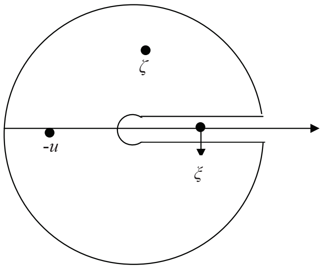

FIG. 9. *The contour* Γ.

Now the integral in (A.2) can be manipulated as

$$\int_\Gamma \frac{\mathrm{d}\tau}{\Lambda_0(\tau)(\tau+u)(\tau-\zeta)} = \int_0^\infty \left(\frac{1}{\Lambda_0^+(t)} - \frac{1}{\Lambda_0^-(t)}\right)\frac{\mathrm{d}t}{(t+u)(t-\zeta)}$$

$$= 2\mathrm{i}\int_0^\infty \frac{\mathrm{d}t}{\Lambda_0^+(t)(\mu(t)+\mathrm{i})(t+u)(t-\zeta)} \tag{A.4}$$

after using (A.3).

Also from the residue calculus theorem,

$$\int_\Gamma \frac{\mathrm{d}\tau}{\Lambda_0(\tau)(\tau+u)(\tau-\zeta)} = \frac{2\pi\mathrm{i}}{u+\zeta}\left(\frac{1}{\Lambda_0(\zeta)} - \frac{1}{\Lambda_0(-u)}\right). \tag{A.5}$$

Comparison of (A.4) and (A.5) gives

$$\frac{1}{u+\zeta}\left(\frac{1}{\Lambda_0(\zeta)} - \frac{1}{\Lambda_0(-u)}\right) = \frac{1}{2\pi\mathrm{i}}\int_0^\infty \frac{2\mathrm{i}\mathrm{d}t}{\Lambda_0^+(t)(\mu(\xi)+\mathrm{i})(t+u)(t-\zeta)}. \tag{A.6}$$

Applying Plemelj's formulae to (A.6) the inner integral in the second term on the right-hand side of (A.1) is evaluated as

$$\fint_0^\infty \frac{\mathrm{d}t}{\Lambda_0^+(t)(\mu(t)+\mathrm{i})(t+u)(t-\xi)} = \frac{\pi}{u+\xi}\left(\frac{\mu(\xi)}{(\mu(\xi)+\mathrm{i})\,\Lambda_0^+(\xi)} - \frac{1}{\Lambda_0(-u)}\right).$$

The above relation is substituted into (A.1) and the simplified form of the operator $\mathcal{L}$ is determined as

$$\mathcal{L}m(\xi) = -\frac{1}{\pi}\frac{\Lambda_0^+(\xi)}{\mu(\xi)-\mathrm{i}}\int_0^\infty \frac{m(u)\mathrm{e}^{-ul}}{(u+\xi)\Lambda_0(-u)}\mathrm{d}u.$$

Evaluation of the functions $\boldsymbol{\Lambda_0^+(\xi)}$, $\boldsymbol{\Lambda_0(-\xi)}$, and $\boldsymbol{\mathcal{M}(\xi)}$. We have

$$\Lambda_0(\zeta) = \exp\left[\frac{1}{2\pi\mathrm{i}}\int_0^\infty \frac{\log\left[\frac{\mu(t)-\mathrm{i}}{\mu(t)+\mathrm{i}}\right]}{t-\zeta}\mathrm{d}t\right], \quad \zeta \notin (0,\infty), \tag{A.7}$$

where

$$\mu(\xi) \mp \mathrm{i} = \frac{1}{K\xi^5}(\xi \mp \mathrm{i}K)(\xi \pm \mathrm{i}K\lambda)(\xi \pm \mathrm{i}K\lambda_1)(\xi \pm \mathrm{i}K\overline{\lambda}_1)(\xi \pm \mathrm{i}K\lambda_2)(\xi \pm \mathrm{i}K\overline{\lambda}_2). \tag{A.8}$$

If we define

$$\Gamma_0(\zeta) = \log\Lambda_0(\zeta),$$

then

$$\Gamma_0(\zeta) = \frac{1}{2\pi\mathrm{i}}\int_0^\infty \frac{\log\left[\frac{\mu(t)-\mathrm{i}}{\mu(t)+\mathrm{i}}\right]}{t-\zeta}\mathrm{d}t \tag{A.9}$$

and

$$\Gamma_0^+(\xi) = \frac{1}{2}\log\left[\frac{\mu(\xi)-\mathrm{i}}{\mu(\xi)+\mathrm{i}}\right] + \frac{1}{2\pi\mathrm{i}}\fint_0^\infty \frac{\log\left[\frac{\mu(t)-\mathrm{i}}{\mu(t)+\mathrm{i}}\right]}{t-\xi}\mathrm{d}t, \tag{A.10}$$

so that

$$\Lambda_0^+(\xi) = \left[\frac{\mu(\xi)-\mathrm{i}}{\mu(\xi)+\mathrm{i}}\right]^{\frac{1}{2}}\exp[Y(\xi)] \tag{A.11}$$

and

$$M(\xi) = \frac{\Lambda_0^+(\xi)}{\mu(\xi)-\mathrm{i}} = \frac{1}{[1+\mu^2(\xi)]^{\frac{1}{2}}}\exp[Y(\xi)] \tag{A.12}$$

with

$$Y(\xi) = \frac{1}{2\pi\mathrm{i}}\int_0^\infty \frac{\log\left[\frac{\mu(t)-\mathrm{i}}{\mu(t)+\mathrm{i}}\right]}{t-\xi}\mathrm{d}t. \tag{A.13}$$

Also it can be shown that

$$\Lambda_0(-u) = \exp[Y(-u)],$$

so that

$$[\Lambda_0(-u)]^{-1}=\exp[-Y(-u)]. \tag{A.14}$$

In the following we proceed to simplify the term $\exp[Y(\xi)]$ only.

Let

$$Y_1(\xi)=\frac{1}{2\pi\mathrm{i}}\fint_0^\infty \frac{\log\frac{t-\mathrm{i}K}{t+\mathrm{i}K}}{t-\xi}\mathrm{d}t,\quad Y_2(\xi)=\frac{1}{2\pi\mathrm{i}}\fint_0^\infty \frac{\log\frac{t-\mathrm{i}K\lambda}{t+\mathrm{i}K\lambda}}{t-\xi}\mathrm{d}t, \tag{A.15}$$

$$Y_3(\xi)=\frac{1}{2\pi\mathrm{i}}\fint_0^\infty \frac{\log\frac{t-\mathrm{i}K\bar{\lambda}_1}{t+\mathrm{i}K\lambda_1}}{t-\xi}\mathrm{d}t,\quad Y_4(\xi)=\frac{1}{2\pi\mathrm{i}}\fint_0^\infty \frac{\log\frac{t-\mathrm{i}K\lambda_1}{t+\mathrm{i}K\bar{\lambda}_1}}{t-\xi}\mathrm{d}t,$$

$$Y_5(\xi)=\frac{1}{2\pi\mathrm{i}}\fint_0^\infty \frac{\log\frac{t+\mathrm{i}K\lambda_2}{t-\mathrm{i}K\bar{\lambda}_2}}{t-\xi}\mathrm{d}t,\quad Y_6(\xi)=\frac{1}{2\pi\mathrm{i}}\fint_0^\infty \frac{\log\frac{t+\mathrm{i}K\bar{\lambda}_2}{t-\mathrm{i}K\lambda_2}}{t-\xi}\mathrm{d}t.$$

Hence

$$Y(\xi)=Y_1(\xi)-Y_2(\xi)-Y_3(\xi)-Y_4(\xi)+Y_5(\xi)+Y_6(\xi). \tag{A.16}$$

In order to simplify the integrals $Y_j(\xi)$ $(j=1,2,\ldots,6)$, we apply the following result of Varley and Walker (1989):

(A.17)

$$\begin{aligned}V(\xi)&=\frac{1}{2\pi\mathrm{i}}\int_0^\infty \frac{\log\frac{t-\lambda}{t+\lambda}}{t-\xi}\mathrm{d}t\\ &=-\frac{\sin\theta}{\pi}\fint_0^{\frac{\xi}{|\lambda|}}\frac{\ln t}{t^2-2t\cos\theta+1}\mathrm{d}t+\left(1-\frac{\theta}{2\pi}\right)\log\frac{\xi}{\xi-\bar{\lambda}}-\frac{\theta}{2\pi}\log\frac{\xi}{\xi-\lambda},\end{aligned}$$

where $\lambda=|\lambda|\mathrm{e}^{\mathrm{i}\theta}$.

By virtue of the above result, $Y_j(\xi)$'s $(j=1,2,\ldots,6)$ are determined as

$$Y_1(\xi)=-\frac{1}{\pi}\int_0^{\frac{K}{\xi}}\frac{\ln t}{1+t^2}\mathrm{d}t-\mathrm{i}\theta_1+\frac{1}{4}\log\frac{\xi^2}{\xi^2+K^2}, \tag{A.18}$$

$$Y_2(\xi)=-\frac{1}{\pi}\int_0^{\frac{K\lambda}{\xi}}\frac{\ln t}{1+t^2}\mathrm{d}t-\mathrm{i}\theta_2+\frac{1}{4}\log\frac{\xi^2}{\xi^2+\lambda^2K^2}, \tag{A.19}$$

$$\begin{aligned}Y_3(\xi)=&-\frac{\sin\hat{\theta}_3}{\pi}\int_0^{\frac{|\lambda_1|}{\xi}}\frac{\ln t}{t^2-2t\cos\hat{\theta}_3+1}\mathrm{d}t-\frac{\hat{\theta}_3}{2\pi}\log\frac{\xi}{\xi-K(\omega+\mathrm{i}\nu)}\\ &+\left(1-\frac{\hat{\theta}_3}{2\pi}\right)\log\frac{\xi}{\xi-K(\omega-\mathrm{i}\nu)},\end{aligned} \tag{A.20}$$

$$\begin{aligned}Y_4(\xi)=&-\frac{\sin\hat{\theta}_4}{\pi}\int_0^{\frac{|\lambda_1|}{\xi}}\frac{\ln t}{t^2-2t\cos\hat{\theta}_4+1}\mathrm{d}t-\frac{\hat{\theta}_4}{2\pi}\log\frac{\xi}{\xi+K(\omega-\mathrm{i}\nu)}\\ &+\left(1-\frac{\hat{\theta}_4}{2\pi}\right)\log\frac{\xi}{\xi+K(\omega+\mathrm{i}\nu)},\end{aligned} \tag{A.21}$$

$$\begin{aligned}Y_5(\xi)=&-\frac{\sin\hat{\theta}_5}{\pi}\int_0^{\frac{|\lambda_2|}{\xi}}\frac{\ln t}{t^2-2t\cos\hat{\theta}_5+1}\mathrm{d}t-\frac{\hat{\theta}_5}{2\pi}\log\frac{\xi}{\xi-K(\delta+\mathrm{i}\gamma)}\\ &+\left(1-\frac{\hat{\theta}_5}{2\pi}\right)\log\frac{\xi}{\xi-K(\delta-\mathrm{i}\gamma)},\end{aligned} \tag{A.22}$$

$$\begin{aligned} Y_6(\xi) = &-\frac{\sin\hat{\theta}_6}{\pi}\int_0^{\frac{|\lambda_2|}{\xi}}\frac{\ln t}{t^2-2t\cos\hat{\theta}_6+1}\mathrm{d}t-\frac{\hat{\theta}_6}{2\pi}\log\frac{\xi}{\xi+K(\delta-\mathrm{i}\gamma)} \\ &+\left(1-\frac{\hat{\theta}_6}{2\pi}\right)\log\frac{\xi}{\xi+K(\delta+\mathrm{i}\gamma)}, \end{aligned} \tag{A.23}$$

where

$$\begin{aligned} &\theta_1=\tan^{-1}\frac{K}{\xi}, \quad \theta_2=\tan^{-1}\frac{K\lambda}{\xi}, \quad \hat{\theta}_3=\tan^{-1}\frac{\nu}{\omega}, \\ &\hat{\theta}_4=\pi-\hat{\theta}_3, \quad \hat{\theta}_5=\tan^{-1}\frac{\gamma}{\delta}, \quad \hat{\theta}_6=\pi-\hat{\theta}_5, \end{aligned}$$

$\lambda_1=\nu+\mathrm{i}\omega$ and $\lambda_2=-\gamma+\mathrm{i}\delta$; $\nu,\omega,\gamma,\delta>0$.

Substituting the explicit forms of $Y_j(\xi)$ $(j=1,2,\dots,6)$ into (A.16), we ultimately find

$$\begin{aligned} \exp[Y(\xi)] = &\exp[V_{12}(\xi)-V_{34}(\xi)+V_{56}(\xi)]\mathrm{e}^{-\mathrm{i}(\theta_1-\theta_2-\theta_3-\theta_4+\theta_5+\theta_6)} \\ &\times\left|\frac{\xi^2+K^2\lambda^2}{\xi^2+K^2}\right|^{1/4}\left|(\xi-K\omega)^2+K^2\lambda^2\right|^{\frac{1}{2}-\frac{\hat{\theta}_3}{2\pi}}\times\left|(\xi+K\omega)^2+K^2\lambda^2\right|^{\frac{\hat{\theta}_3}{2\pi}} \\ &\times\left|(\xi-K\delta)^2+K^2\gamma^2\right|^{-\frac{1}{2}+\frac{\hat{\theta}_5}{2\pi}}\left|(\xi+K\delta)^2+K^2\gamma^2\right|^{-\frac{\hat{\theta}_5}{2\pi}}, \end{aligned} \tag{A.24}$$

where

$$\begin{aligned} V_{12} &= \frac{1}{\pi}\int_{\frac{K}{\xi}}^{\frac{K\lambda}{\xi}}\frac{\ln t}{1+t^2}\mathrm{d}t, \\ V_{34} &= -\frac{2\sin\hat{\theta}_3}{\pi}\int_0^{\frac{|\lambda_1|}{\xi}}\frac{(t^2+1)\ln t}{(t^2+1)^2-4t^2\cos^2\hat{\theta}_3}\mathrm{d}t, \\ V_{56} &= -\frac{2\sin\hat{\theta}_5}{\pi}\int_0^{\frac{|\lambda_2|}{\xi}}\frac{(t^2+1)\ln t}{(t^2+1)^2-4t^2\cos^2\hat{\theta}_5}\mathrm{d}t, \\ \theta_3,\theta_4 &= \tan^{-1}\frac{K\nu}{\xi\mp K\omega}, \quad \theta_5,\theta_6=\tan^{-1}\frac{K\gamma}{\xi\mp K\delta}. \end{aligned} \tag{A.25}$$

In deriving (A.23) we have used the following results:

$$\xi\mp K\omega+\mathrm{i}K\nu=\left\{(\xi\mp K\omega)^2+K^2\nu^2\right\}^{1/2}\mathrm{e}^{\mathrm{i}(\theta_3,\theta_4)}$$

and

$$\xi\mp K\delta+\mathrm{i}K\gamma=\left\{(\xi\mp K\delta)^2+K^2\gamma^2\right\}^{1/2}\mathrm{e}^{\mathrm{i}(\theta_5,\theta_6)}.$$

Acknowledgments. The authors thank the referees for their comments and suggestions to improve earlier versions of this paper. They also thank Prof. V. A. Squire for providing them with copies of the papers Meylan and Squire (1993), (1994).

INTERACTIONS OF ELEMENTARY WAVES FOR THE AW–RASCLE MODEL*

MEINA SUN†

Abstract. In this paper, we study the interactions of elementary waves for the traffic flow model proposed by Aw and Rascle in [*SIAM J. Appl. Math.*, 60 (2000), pp. 916–938]. The solutions are obtained constructively when the initial data are three piecewise constant states. In particular, a new wave SJ in which a shock wave S and a contact discontinuity J coincide with each other is obtained during the process of interaction. Moreover, by studying the limits of the solutions as the perturbed parameter ε tends to zero, it can be found that the Riemann solutions are stable for such perturbations with the initial data.

Key words. interaction of elementary waves, vacuum state, Aw–Rascle model, Riemann problem, traffic flow, hyperbolic conservation laws

1. Introduction.

The Aw–Rascle (AR) macroscopic model of traffic flow in the conservative form [2] is given by

$$\begin{cases} \rho_t + (\rho u)_x = 0, \\ (\rho(u + p(\rho)))_t + (\rho u(u + p(\rho)))_x = 0, \end{cases} \tag{1.1}$$

where ρ, u represent the density and the velocity, respectively; the velocity offset p takes the form $p(\rho) = \rho^\gamma$ with $\gamma > 0$. The AR model describes a traffic flow model on a unidirectional roadway. The basic assumptions of the model are the density $\rho(x,t) \geq 0$ and velocity $u(x,t) \geq 0$ of cars located at position x at time t.

The AR model was proposed in order to remedy the deficiencies of second order models of car traffic pointed out by Daganzo [6] and has been independently derived by Zhang [20]. The derivation of the model from a microscopic follow-the-leader (FL) model through a scaling limit was also given in [1]. The AR model resolves all the obvious inconsistencies and explains instabilities in the car traffic flow, especially near the vacuum, i.e., for very light traffic with few slow drivers [2, 11].

The AR model is one of the main fluid dynamic models for traffic flow and is appropriate for describing traffic phenomena, such as congestion and stop-and-go waves [10]. It is now widely used to study the formation and dynamics of traffic jams and is endowed with desirable stability properties. It is also the basis for the multilane traffic flow model [8, 9], the model for a road network with unidirectional flow [7, 10], and the hybrid traffic flow model [13].

In [3], the limit behavior was investigated by changing p into εp and taking $p(\rho) = (\frac{1}{\rho} - \frac{1}{\rho^*})^{-\gamma}$ with the density constraint $\rho \leq \rho^*$, where the maximal density ρ^* corresponds to a total traffic jam and is assumed to a fixed constant although

†School of Mathematics and Information, Ludong University, Yantai, Shandong 264025, People's Republic of China, and Laboratory of Mathematics Physics, Wuhan Institute of Physics and Mathematics, The Chinese Academy of Sciences, Wuhan 430071, People's Republic of China (smnwhy0350@163.com).

it should depend on the velocity in practice. They discovered that the pressure term becomes active so as to preserve the constraint $\rho \leq \rho^*$ when ρ reaches ρ^*. Recently, Shen and Sun [15] have considered the limit behavior without the constraint of the maximal density, i.e., $p(\rho)$ is not singular at $\rho = \rho^*$. The delta-shock wave was obtained through perturbing the pressure $p(\rho)$ suitably.

For convenience and conciseness, we replace $\rho p(\rho)$ with $p(\rho)$ in (1.1) and take $p(\rho) = \rho^\gamma$ for $\gamma > 1$; then the AR model can be rewritten in the following form:

$$(1.2) \qquad \begin{cases} \rho_t + (\rho u)_x = 0, \\ (\rho u + \rho^\gamma)_t + (\rho u^2 + \rho^\gamma u)_x = 0. \end{cases}$$

In the above equations, $p(\rho) = \rho^\gamma$ can be regarded as the traffic pressure term and γ is analogous with the adiabatic gas constant in gas dynamics.

In this paper, our main purpose is to investigate various possible interactions of elementary waves for the AR model (1.2). To include all kinds of interactions, it suffices to consider the AR model (1.2) with the following perturbed initial data:

$$(1.3) \qquad (u,\rho)(x,0) = \begin{cases} (u_-, \rho_-), & -\infty < x < -\varepsilon, \\ (u_m, \rho_m), & -\varepsilon < x < \varepsilon, \\ (u_+, \rho_+), & \varepsilon < x < +\infty, \end{cases}$$

where $\varepsilon > 0$ is arbitrarily small. We notice that (1.3) is a local perturbation of the Riemann data and we still call it a small perturbation here for ε is sufficiently small.

Aw and Rascle have investigated the Riemann problem of (1.1) in detail. With these results in mind, one would naturally like to study the interactions of elementary waves because they embody the internal mechanism of the AR model. Another motivation of this study comes from the fact that small changes in traffic flow will propagate and lead to the occurrence of wave interaction. Finally, the stability of the Riemann solutions of (1.2) can be analyzed if we take the initial data (1.3) and then let $\varepsilon \to 0$.

By definition, a vacuum state is any portion of the (x,t) plane in which $\rho = 0$. From [2], we know that the Riemann solutions do involve the vacuum state for certain Riemann data. In order to cover all the cases completely, we divide our work into two parts according to the presence of vacuum or not. When the vacuum is not involved, the problem about the interactions of elementary waves is classical and will not be addressed here. On the other hand, the AR model suitably explains instabilities near the vacuum. Therefore, we especially pay attention to the vacuum problem and consider the interactions of elementary waves in full detail when the vacuum is involved. Dealing with the vacuum problem, we adopt the idea proposed by Liu and Smoller [12] when they considered it for the isentropic gas dynamic equations, where they made a distinction between two vacuum states with different (fake) velocities.

With the method of characteristic analysis, the interactions are widely investigated and the global solutions are completely constructed. Furthermore, we find that the solutions of the perturbed initial value problem (1.2) and (1.3) converge to the solutions of the corresponding Riemann problem (1.2) and (2.1) as $\varepsilon \to 0$, which shows the stability of the Riemann solutions for certain perturbations of the initial data. Especially, when the vacuum is involved, the interesting feature in the solutions is that a new wave SJ is discovered during the interaction of a contact discontinuity J and a shock S in a particular situation. Here SJ is the superposition of a contact discontinuity and a shock. The reason for the generation of the wave SJ is due to the fact that the newly formed waves S and J after interaction propagate with the same speed and coincide with each other.

For basic references on nonlinear hyperbolic systems of conservation laws and the interactions of elementary waves, we refer the readers to the book of Smoller [17] and the monograph of Chang and Hsiao [4]. Furthermore, one can see the books written by Dafermos [5] and Serre [14] for a comprehensive survey. Also see [16, 18] for the recent work about the interactions of elementary waves.

This paper is organized as follows. In section 2, we restate the Riemann problem to the AR model (1.2) for readers' convenience. In section 3, we mainly discuss the interactions of elementary waves when the vacuum is involved. In section 4, we consider the stability of the Riemann solutions under the small perturbations and compare our results with those of Aw and Rascle before our conclusion in section 5.

2. Preliminaries. In this section, we briefly review the Riemann solutions of (1.2) with the initial data

$$(u,\rho)(x,0)=(u_\pm,\rho_\pm),\qquad \pm x>0, \tag{2.1}$$

where $u_\pm, \rho_\pm > 0$, and the detailed study can be found in [2].

The characteristic roots of system (1.2) are

$$\lambda_1=u-(\gamma-1)\rho^{\gamma-1},\qquad \lambda_2=u; \tag{2.2}$$

therefore (1.2) is strictly hyperbolic except for $\rho = 0$.

The corresponding right characteristic vector of $\lambda_i (i = 1, 2)$ is

$$\overrightarrow{r_1}=((1-\gamma)\rho^{\gamma-2},1)^T,\qquad \overrightarrow{r_2}=(0,1)^T. \tag{2.3}$$

It is easy to see that $\nabla\lambda_1\cdot\overrightarrow{r_1}\neq 0$ for $\rho\neq 0$ and $\nabla\lambda_2\cdot\overrightarrow{r_2}\equiv 0$ in which ∇ denotes the gradient with respect to (u,ρ); namely, λ_1 is genuinely nonlinear for $\rho\neq 0$ and λ_2 is always linearly degenerate. Therefore, the associated waves are rarefaction waves or shocks for the first family and contact discontinuities for the second family.

The Riemann invariants along the characteristic fields are

$$w=u+\rho^{\gamma-1},\qquad z=u. \tag{2.4}$$

Since (1.2) and the Riemann data (2.1) are invariant under stretching of coordinates: $(x,t)\to(\alpha x,\alpha t)$ (α is constant), we seek the self-similar solution

$$(u,\rho)(x,t)=(u,\rho)(\xi),\qquad \xi=x/t. \tag{2.5}$$

Then the Riemann problem is reduced to the boundary value problem of the ordinary differential equations:

$$\begin{cases} -\xi\rho_\xi+(\rho u)_\xi=0,\\ -\xi(\rho u+\rho^\gamma)_\xi+(\rho u^2+\rho^\gamma u)_\xi=0, \end{cases} \tag{2.6}$$

with $(u,\rho)(\pm\infty)=(u_\pm,\rho_\pm)$.

For smooth solutions, setting $U=(u,\rho)^T$, (2.6) can then be rewritten as

$$A(U)U_\xi=0, \tag{2.7}$$

where

$$A(u,\rho) = \begin{pmatrix} \rho & u-\xi \\ -\xi\rho + 2\rho u + \rho^\gamma & -\xi u - \gamma\xi\rho^{\gamma-1} + u^2 + \gamma\rho^{\gamma-1}u \end{pmatrix}.$$

Besides the constant state solution, it provides a rarefaction wave which is a continuous solution of (2.7) in the form $(u,\rho)(\xi)$. Then, for a given left state (u_-,ρ_-), the rarefaction wave curves in the phase plane, which are the sets of states that can be connected on the right by a 1-rarefaction wave, are as follows:

$$R(u_-,\rho_-) : \begin{cases} \xi = \lambda_1 = u - (\gamma-1)\rho^{\gamma-1}, \\ u - u_- = -\rho^{\gamma-1} + \rho_-^{\gamma-1}, \\ \rho < \rho_-, \qquad u > u_-. \end{cases} \tag{2.8}$$

Through differentiating u with respect to ρ in the second equation in (2.8), we get

$$u_\rho = -(\gamma-1)\rho^{\gamma-2}, \qquad u_{\rho\rho} = -(\gamma-1)(\gamma-2)\rho^{\gamma-3}. \tag{2.9}$$

Thus the 1-rarefaction wave curve is convex for $1 < \gamma < 2$ and concave for $\gamma > 2$ in the (u,ρ) plane.

For a bounded discontinuity at $\xi = \sigma$, the Rankine–Hugoniot condition holds:

$$\begin{cases} -\sigma[\rho] + [\rho u] = 0, \\ -\sigma[\rho u + \rho^\gamma] + [\rho u^2 + \rho^\gamma u] = 0, \end{cases} \tag{2.10}$$

where $[\rho] = \rho_r - \rho_l$, $\rho_l = \rho(\sigma - 0)$, and $\rho_r = \rho(\sigma + 0)$, etc.

From the first equation in (2.10), we obtain

$$\rho_r(u_r - \sigma) = \rho_l(u_l - \sigma). \tag{2.11}$$

Simplifying the second equation in (2.10) and noting (2.11), it yields

$$\rho_r(u_r - \sigma)(u_r + \rho_r^{\gamma-1} - u_l - \rho_l^{\gamma-1}) = 0. \tag{2.12}$$

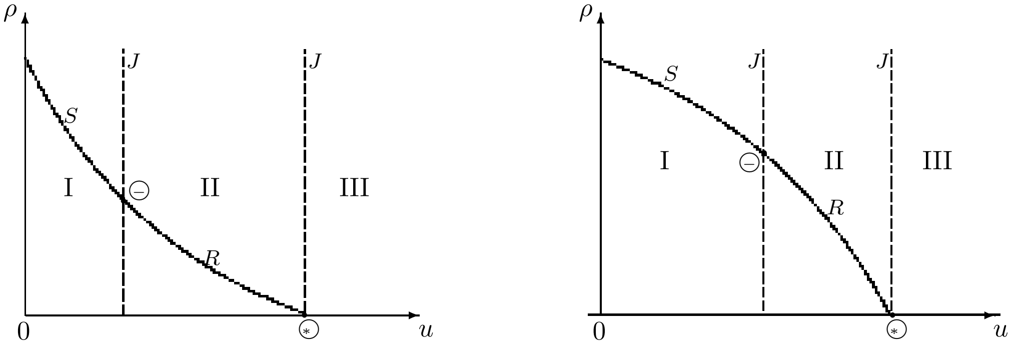
If $\rho_r(u_r - \sigma) \neq 0$, we have $u_r + \rho_r^{\gamma-1} = u_l + \rho_l^{\gamma-1}$, and the Lax entropy conditions imply that $\rho_l < \rho_r$. So for a given left state (u_-,ρ_-), the sets of states which can be connected to (u_-,ρ_-) by a 1-shock wave on the right are as follows:

$$S(u_-,\rho_-) : \begin{cases} \sigma = u - \dfrac{\rho_-(\rho^{\gamma-1} - \rho_-^{\gamma-1})}{\rho - \rho_-}, \\ u - u_- = -\rho^{\gamma-1} + \rho_-^{\gamma-1}, \\ \rho > \rho_-, \qquad u < u_-. \end{cases} \tag{2.13}$$

It is noted that the shock curves coincide with the rarefaction curves in the phase plane, due to the special form of (1.2), which can be written as $Y_t + (uY)_x = 0$ [19].

If $\rho_r(u_r - \sigma) = 0$, we can conclude that $u_r = u_l = \sigma$ except for $\rho_r = 0$ or $\rho_l = 0$, which corresponds to a contact discontinuity of the second family. Since λ_2 is linearly degenerate, the sets of states can be connected to a given left state (u_-,ρ_-) by a contact discontinuity on the right if and only if

$$J : \xi = u = u_-. \tag{2.14}$$



$1 < \gamma < 2$ $\gamma > 2$

FIG. 2.1.

We note that these waves travel at exactly the same speed as the corresponding cars, which means no information travels faster than the vehicle velocity and the drivers do not react to the traffic situation behind him.

Through the above analysis, we summarize that the sets of states connected on the right consist of the 1-rarefaction wave curve $R(u_-, \rho_-)$, the 1-shock wave curve $S(u_-, \rho_-)$, and the 2-contact discontinuity $J(u_-, \rho_-)$ for a given left state (u_-, ρ_-). These curves divide the quarter phase plane $(u, \rho \geq 0)$ into three regions, $\mathrm{I} = \{(u, \rho)|u < u_-\}$, $\mathrm{II} = \{(u, \rho)|u_- < u < u_*\}$, and $\mathrm{III} = \{(u, \rho)|u > u_*\}$, where $u_* = u_- + \rho_-^{\gamma-1}$ (see Figure 2.1). According to the right state (u_+, ρ_+) in the different region, one can construct the unique global Riemann solution connecting two constant states $(u_\pm, \rho_\pm)$.

Obviously, the Riemann solution contains a 1-shock wave, an intermediate nonvacuum constant state, and a 2-contact discontinuity when $(u_+, \rho_+) \in \mathrm{I}$; it contains a 1-rarefaction wave, an intermediate nonvacuum constant state, and a 2-contact discontinuity when $(u_+, \rho_+) \in \mathrm{II}$; it contains a 1-rarefaction wave, an intermediate vacuum state, and a 2-contact discontinuity when $(u_+, \rho_+) \in \mathrm{III}$.

All of the rarefaction waves R, the shock waves S, and the contact discontinuities J obtained in solving the Riemann problem are called the elementary waves for the AR model (1.2).

3. Interactions of elementary waves. We begin by considering the initial value problem (1.2) with three pieces of constant initial data (1.3). The data (1.3) is a perturbation of the Riemann initial data (2.1). We face the interesting question of determining whether the Riemann solutions of (1.2) and (2.1) are the limits of $(u_\varepsilon, \rho_\varepsilon)(x, t)$ as $\varepsilon \to 0$, where $(u_\varepsilon, \rho_\varepsilon)(x, t)$ are the solutions of (1.2) and (1.3). We will deal with this problem case by case along with constructing the solutions.

We notice that the Riemann solutions of (1.2) and (2.1) may contain the vacuum, so in order to cover all the cases, our discussion should be divided into two parts according to the appearance of vacuum or not. About the interactions of elementary waves not involving the vacuum, we have four cases according to the different combinations of elementary waves from $(-\varepsilon, 0)$ and $(\varepsilon, 0)$ as follows:

1. $R + J$ and $S + J$,
2. $S + J$ and $S + J$,
3. $S + J$ and $R + J$,
4. $R + J$ and $R + J$.

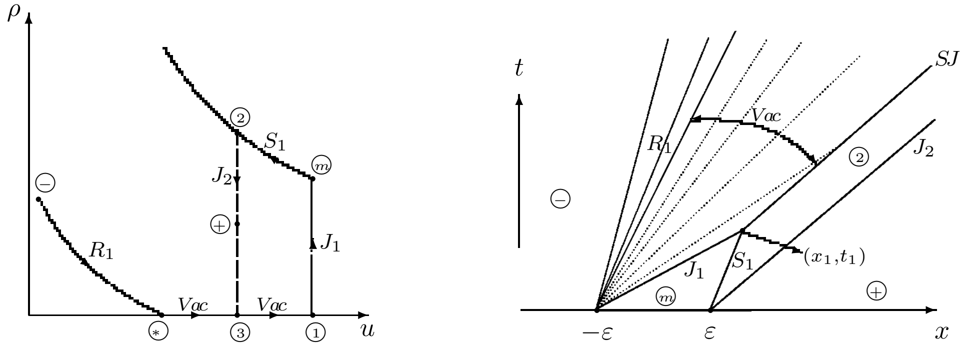


FIG. 3.1.

All the above interactions are classical and well known; hence they will not be pursued here.

In this section, we mainly consider the interactions of elementary waves when at least one of the Riemann solutions at $(-\varepsilon, 0)$ and $(\varepsilon, 0)$ involves the vacuum state. When the Riemann solution contains the vacuum, the AR model (1.2) becomes degenerate in the vacuum region and the two characteristics coincide. In this work, we can study this problem in the (u, ρ) plane, i.e., make a distinction between two vacuum states with different (fake) velocities, like for the method introduced by Liu and Smoller [12] for compressible gas dynamics.

Also, our discussion is divided into the following five cases according to the different combinations of elementary waves from $(-\varepsilon, 0)$ and $(\varepsilon, 0)$:

1. $R + Vac + J$ and $S + J$,
2. $R + Vac + J$ and $R + J$,
3. $R + Vac + J$ and $R + Vac + J$,
4. $R + J$ and $R + Vac + J$,
5. $S + J$ and $R + Vac + J$.

Case 3.1. $R + Vac + J$ and $S + J$.

In this case, when t is small, the solution of the initial value problem (1.2) and (1.3) can be expressed briefly as follows (see Figures 3.1 and 3.2):

$$(u_-, \rho_-) + R_1 + Vac + J_1 + (u_m, \rho_m) + S_1 + (u_2, \rho_2) + J_2 + (u_+, \rho_+),$$

where "+" means "followed by." This case happens if and only if $u_\pm < u_m$ and $u_* = u_- + \rho_-^{\gamma-1} < u_m$.

In the following figures, we just depict the convex situation, i.e., $1 < \gamma < 2$, for the reason that the concave situation is similar.

The propagating speed of J_1 is $\tau_1 = u_m$, and the propagating speed of S_1 is given by

$$\sigma_1 = u_m - \frac{\rho_2(\rho_2^{\gamma-1} - \rho_m^{\gamma-1})}{\rho_2 - \rho_m};$$

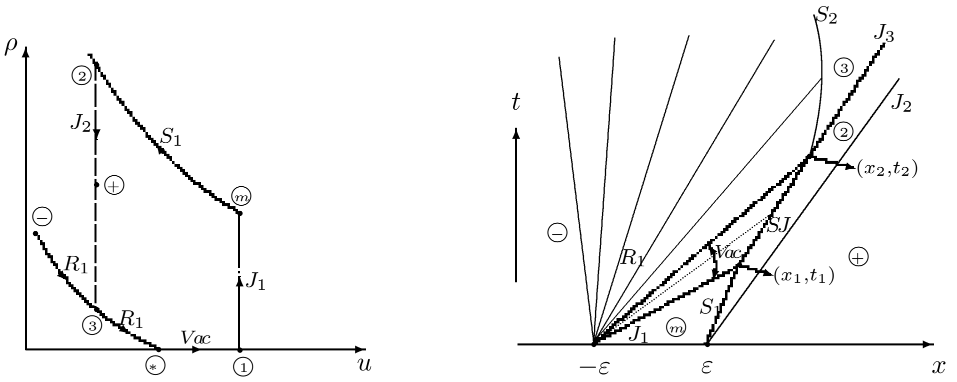

FIG. 3.2.

thus $\tau_1 > \sigma_1$ and the contact discontinuity J_1 will overtake the shock wave S_1 in finite time. The intersection (x_1, t_1) is determined by

$$(3.1)\qquad \begin{cases} x_1 + \varepsilon = u_m t_1, \\ x_1 - \varepsilon = \left(u_m - \dfrac{\rho_2(\rho_2^{\gamma-1} - \rho_m^{\gamma-1})}{\rho_2 - \rho_m} \right) t_1. \end{cases}$$

An easy calculation leads to

$$(3.2)\qquad (x_1, t_1) = \left(\frac{2\varepsilon(\rho_2 - \rho_m)u_m}{\rho_2(\rho_2^{\gamma-1} - \rho_m^{\gamma-1})} - \varepsilon, \frac{2\varepsilon(\rho_2 - \rho_m)}{\rho_2(\rho_2^{\gamma-1} - \rho_m^{\gamma-1})} \right).$$

It is clear that two elementary waves intersect at a finite time when a new Riemann problem is formed. At the time $t = t_1$, we again have a Riemann problem with data $(u_l, \rho_l) = (u_1, \rho_1)$, $(u_r, \rho_r) = (u_2, \rho_2)$, which is resolved by a new shock S and a new contact discontinuity J. Here we notice that at the left-hand side of S is the vacuum state; thus it is not difficult to see that the propagating speeds of S and J are both equal to u_2; i.e., S and J coincide with each other and form a new wave, which we denote by SJ.

Now, we turn our attention to the interaction of SJ and R_1. It is easy to see that $u_2 = u_+$ and the wave front in R_1 propagates with speed u_*. Our claim is that R_1 and SJ cannot intersect if $u_* \leq u_+$ (see Figure 3.1), while for $u_* > u_+$ they must intersect with each other (see Figure 3.2).

If $u_* > u_+$, SJ will cancel the vacuum region and then intersect with R_1 at the point (x_2, t_2), which can be given by

$$(3.3)\qquad \begin{cases} x_2 + \varepsilon = u_* t_2 = (u_- + \rho_-^{\gamma-1})t_2, \\ x_2 - x_1 = u_2(t_2 - t_1). \end{cases}$$

Solving the Riemann problem at (x_2, t_2), we can see the appearance of a shock wave S_2 and a contact discontinuity J_3. Namely, when $t > t_2$, SJ decomposes and the state (u_3, ρ_3) lies between S_2 and J_3. At the same time, the shock wave S_2 begins to penetrate R_1 with a varying speed of propagation during the process of penetration;

that is, the shock $S_2 : x = x(t)$ is no longer a straight line at $t > t_2$. The varying speed of S_2 can be determined by

$$\begin{cases} \dfrac{dx}{dt} = u - \dfrac{\rho_3(\rho_3^{\gamma-1} - \rho^{\gamma-1})}{\rho_3 - \rho}, \\ x + \varepsilon = (u - (\gamma-1)\rho^{\gamma-1})t, \\ u - u_- = \rho_-^{\gamma-1} - \rho^{\gamma-1}, \\ x(t_2) = x_2, \quad 0 \le \rho < \rho_3. \end{cases} \tag{3.4}$$

Differentiating the second equation in (3.4) with respect to t, we obtain

$$\frac{dx}{dt} = u - (\gamma-1)\rho^{\gamma-1} + t\Big(\frac{du}{dt} - (\gamma-1)^2\rho^{\gamma-2}\frac{d\rho}{dt}\Big). \tag{3.5}$$

Combining (3.5) with the first equation in (3.4), it is easy to get

$$\frac{(\gamma-1)\rho^\gamma - \gamma\rho_3\rho^{\gamma-1} + \rho_3^\gamma}{\rho - \rho_3} = t\Big(\frac{du}{dt} - (\gamma-1)^2\rho^{\gamma-2}\frac{d\rho}{dt}\Big). \tag{3.6}$$

It follows from the third equation in (3.4) that

$$\frac{du}{dt} = -(\gamma-1)\rho^{\gamma-2}\frac{d\rho}{dt}. \tag{3.7}$$

Substituting (3.7) into (3.6), it yields

$$\frac{d\rho}{dt} = \frac{(\gamma-1)\rho^\gamma - \gamma\rho_3\rho^{\gamma-1} + \rho_3^\gamma}{(\gamma-1)\gamma\rho^{\gamma-2}(\rho_3 - \rho)t}. \tag{3.8}$$

Differentiating the first equation in (3.4), in view of (3.7), (3.8), we have

$$\frac{d^2x}{dt^2} = \frac{((\gamma-1)\rho^\gamma - \gamma\rho_3\rho^{\gamma-1} + \rho_3^\gamma)^2}{(\gamma-1)\gamma\rho^{\gamma-2}(\rho - \rho_3)^3 t}, \tag{3.9}$$

which gives $\frac{d^2x}{dt^2} < 0$ for $\rho < \rho_3$, i.e., S_2 decelerates during the process of penetration.

Integrating (3.8) leads to

$$\ln\frac{t}{t_2} = \int_0^\rho \frac{(\gamma-1)\gamma\rho^{\gamma-2}(\rho_3 - \rho)}{(\gamma-1)\rho^\gamma - \gamma\rho_3\rho^{\gamma-1} + \rho_3^\gamma}d\rho. \tag{3.10}$$

It is clear that $t \to \infty$ as $\rho \to \rho_3$. Therefore, S_2 cannot penetrate over R_1 forever if $\rho_3 \le \rho_-$; otherwise S_2 will cross the whole of R_1 at the finite time

$$t_3 = t_2 \exp\left(\int_0^{\rho_-} \frac{(\gamma-1)\gamma\rho^{\gamma-2}(\rho_3 - \rho)}{(\gamma-1)\rho^\gamma - \gamma\rho_3\rho^{\gamma-1} + \rho_3^\gamma}d\rho\right).$$

Thus we conclude that S_2 is able to cross the whole of R_1 for $\rho_3 > \rho_-$ (i.e., $u_+ < u_-$), whereas it cannot for $\rho_3 \le \rho_-$ (i.e., $u_+ \ge u_-$) and ultimately has $x + \varepsilon = (u_3 - (\gamma-1)\rho_3^{\gamma-1})t$ as its asymptote.

In brief, if $u_+ \ge u_*$, when $t > t_1$, the solution can be expressed as

$$(u_-, \rho_-) + R_1 + Vac + SJ + (u_2, \rho_2) + J_2 + (u_+, \rho_+).$$

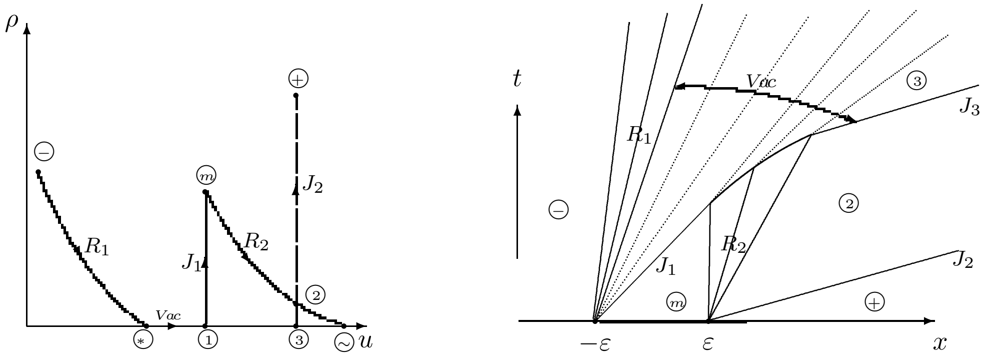

FIG. 3.3.

If $u_+ < u_*$, when $t \to \infty$, the solution can be expressed as

$$(u_-, \rho_-) + R + (u_3, \rho_3) + J_3 + (u_2, \rho_2) + J_2 + (u_+, \rho_+) \quad \text{for } u_+ \geq u_-,$$

$$(u_-, \rho_-) + S + (u_3, \rho_3) + J_3 + (u_2, \rho_2) + J_2 + (u_+, \rho_+) \quad \text{for } u_+ < u_-.$$

Case 3.2. $R + Vac + J$ and $R + J$.

In this case, when t is small, the solution of the initial value problem (1.2) and (1.3) can be expressed briefly as follows (see Figure 3.3):

$$(u_-, \rho_-) + R_1 + Vac + J_1 + (u_m, \rho_m) + R_2 + (u_2, \rho_2) + J_2 + (u_+, \rho_+).$$

This case occurs when $u_* < u_m < u_+ < u_\sim = u_m + \rho_m^{\gamma-1}$ is satisfied.

Obviously, the contact discontinuity J_1 will overtake the rarefaction wave R_2, and they begin to interact with each other at (x_1, t_1), which satisfies

$$\begin{cases} x_1 + \varepsilon = u_m t_1, \\ x_1 - \varepsilon = (u_m - (\gamma - 1)\rho_m^{\gamma-1}) t_1. \end{cases} \tag{3.11}$$

This gives

$$(x_1, t_1) = \left(\frac{2\varepsilon u_m - \varepsilon(\gamma-1)\rho_m^{\gamma-1}}{(\gamma-1)\rho_m^{\gamma-1}}, \frac{2\varepsilon}{(\gamma-1)\rho_m^{\gamma-1}} \right). \tag{3.12}$$

Then J_1 goes on to penetrate R_2, and the contact discontinuity $x = x(t)$ during the process of penetration is determined by

$$\begin{cases} \dfrac{dx}{dt} = u, \\ x - \varepsilon = (u - (\gamma - 1)\rho^{\gamma-1}) t, \\ u - u_m = \rho_m^{\gamma-1} - \rho^{\gamma-1}, \\ x(t_1) = x_1, \quad \rho_2 \leq \rho \leq \rho_m. \end{cases} \tag{3.13}$$

Differentiating (3.13) with respect to t along $x = x(t)$, we obtain

$$\frac{d^2 x}{dt^2} = \frac{du}{dt}, \tag{3.14}$$

$$\frac{dx}{dt} = u - (\gamma-1)\rho^{\gamma-1} + \Big(\frac{du}{dt} - (\gamma-1)^2\rho^{\gamma-2}\frac{d\rho}{dt}\Big)t, \tag{3.15}$$

$$\frac{du}{dt} = -(\gamma-1)\rho^{\gamma-2}\frac{d\rho}{dt}. \tag{3.16}$$

Substituting $\frac{dx}{dt} = u$ into the above expressions, it yields

$$\frac{d^2x}{dt^2} = \frac{(\gamma-1)\rho^{\gamma-1}}{\gamma t} > 0,$$

which means that the contact discontinuity accelerates during the process of penetration.

It follows from (3.13) that

$$\frac{dx}{dt} = \frac{x-\varepsilon}{t} + (\gamma-1)\rho^{\gamma-1} = \frac{x-\varepsilon}{t} + (\gamma-1)\Big(\rho_m^{\gamma-1} + u_m - \frac{dx}{dt}\Big).$$

So (3.13) can be simplified as

$$\begin{cases} \dfrac{dx}{dt} = \dfrac{x-\varepsilon}{\gamma t} + \dfrac{\gamma-1}{\gamma}(u_m + \rho_m^{\gamma-1}), \\ x(t_1) = x_1. \end{cases} \tag{3.17}$$

By applying the method of variation of constant, we obtain

$$x = \varepsilon + (u_m + \rho_m^{\gamma-1})t - \gamma\Big(\frac{2\varepsilon\rho_m}{\gamma-1}\Big)^{1-\frac{1}{\gamma}} t^{\frac{1}{\gamma}}, \tag{3.18}$$

which, together with

$$x - \varepsilon = (u_2 - (\gamma-1)\rho_2^{\gamma-1})t, \tag{3.19}$$

determines the ending point (x_2, t_2) of the penetration. A direct calculation leads to

$$(x_2, t_2) = \Big(\varepsilon + \frac{2\varepsilon\rho_m u_2}{(\gamma-1)\rho_2^{\gamma}} - \frac{2\varepsilon\rho_m}{\rho_2}, \frac{2\varepsilon\rho_m}{(\gamma-1)\rho_2^{\gamma}}\Big). \tag{3.20}$$

It turns out that the contact discontinuity J_1 crosses the rarefaction wave R_2 completely in finite time and R_2 becomes the vacuum state after penetration.

For large time, the solution can be expressed as

$$(u_-, \rho_-) + R_1 + Vac + J_3 + (u_2, \rho_2) + J_2 + (u_+, \rho_+).$$

Case 3.3. $R + Vac + J$ and $R + Vac + J$.

In this case, when t is small, the solutions of the initial value problems (1.2) and (1.3) can be expressed briefly as follows (see Figure 3.4):

$$(u_-, \rho_-) + R_1 + Vac + J_1 + (u_m, \rho_m) + R_2 + Vac + J_2 + (u_+, \rho_+).$$

The occurrence of this case depends on the condition $u_* < u_m < u_\sim < u_+$.

Indeed, this case is similar to Case 3.2 except that the vacuum states appear in front of R_2 at the beginning. In the same way as before, we can see that the

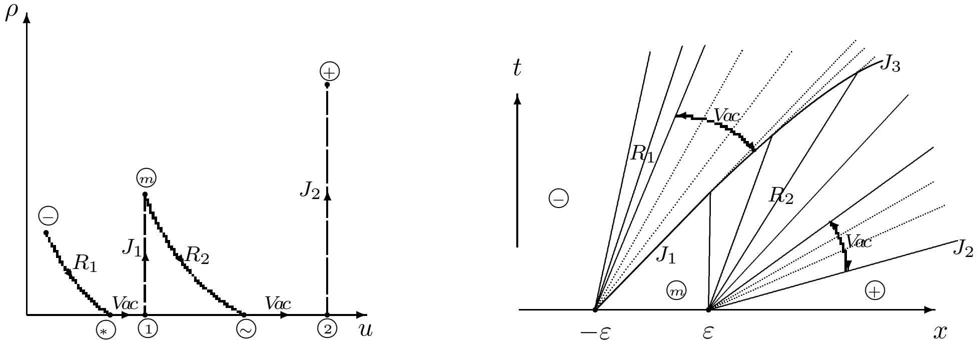

FIG. 3.4.

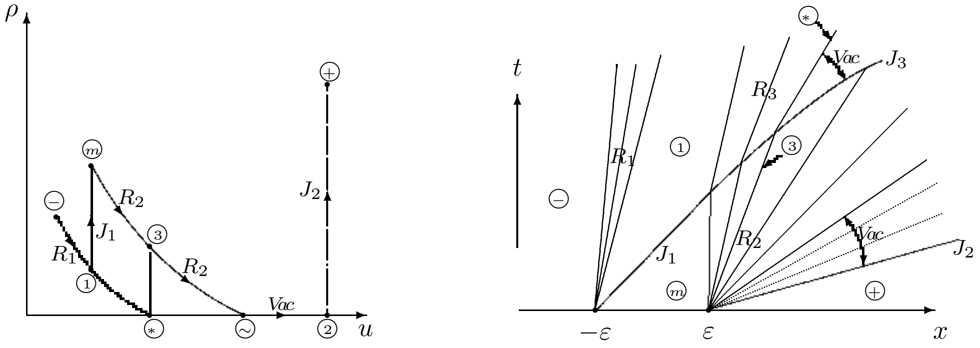

FIG. 3.5.

propagating speed of J_3 tends to $u_\sim$ as $t \to \infty$; i.e., J_3 has the wave front in R_2 as its asymptote.

As $t \to \infty$, the time-asymptotic solution can be described as

$$(u_-, \rho_-) + R_1 + Vac + J_2 + (u_+, \rho_+).$$

Case 3.4. $R + J$ and $R + Vac + J$.

In this case, when t is small, the solutions of the initial value problems (1.2) and (1.3) can be expressed briefly as follows (see Figure 3.5):

$$(u_-, \rho_-) + R_1 + (u_1, \rho_1) + J_1 + (u_m, \rho_m) + R_2 + Vac + J_2 + (u_+, \rho_+).$$

This case happens when $u_- < u_m < u_*$ and $u_+ > u_\sim$ are satisfied.

This case can be discussed similarly to Case 3.3. Moreover, it can be shown that the vacuum states form ahead of R_3 at the time when one of the states in R_2 becomes (u_3, ρ_3). Then, J_3 continues to penetrate R_2 and finally disappears in the vacuum as $t \to \infty$.

For large time, the solution can be expressed as

$$(u_-, \rho_-) + R_1 + (u_1, \rho_1) + R_3 + Vac + J_2 + (u_+, \rho_+).$$

Case 3.5. $S + J$ and $R + Vac + J$.

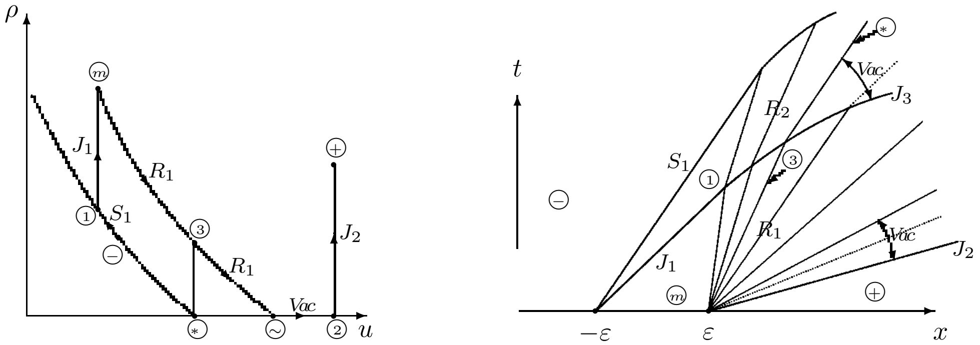

FIG. 3.6.

In this case, when t is small, the solutions of the initial value problems (1.2) and (1.3) can be expressed briefly as follows (see Figure 3.6):

$$(u_-, \rho_-) + S_1 + (u_1, \rho_1) + J_1 + (u_m, \rho_m) + R_1 + Vac + J_2 + (u_+, \rho_+).$$

The appearance of this case depends on the conditions $u_m < u_-$ and $u_\sim < u_+$.

Like for Case 3.4, the interaction of J_1 and R_1 results in a new contact discontinuity J_3 and a new rarefaction wave R_2. Similarly, the vacuum states present ahead of R_2 at the time when one of the states in R_1 turns to be (u_3, ρ_3). The propagating speed of J_3 tends to $u_\sim$ as $t \to \infty$; i.e., J_3 has the wave front in R_1 as its asymptote.

Now we mainly consider the interaction of the shock wave S_1 and the rarefaction wave R_2. The propagating speed of S_1 is

$$\sigma_1 = u_- - \frac{\rho_1(\rho_1^{\gamma-1} - \rho_-^{\gamma-1})}{\rho_1 - \rho_-},$$

and the propagating speed of the wave back in R_2 is $\omega_2 = u_1 - (\gamma-1)\rho_1^{\gamma-1}$. Noting $u_1 - u_- = \rho_-^{\gamma-1} - \rho_1^{\gamma-1}$, it is easy to get

$$\sigma_1 - \omega_2 = \frac{(\gamma-1)\rho_1^\gamma - \gamma\rho_-\rho_1^{\gamma-1} + \rho_-^\gamma}{\rho_1 - \rho_-}. \tag{3.21}$$

Define $x = \frac{\rho_1}{\rho_-} > 1$ and introduce $f(x) = (\gamma-1)x^\gamma - \gamma x^{\gamma-1} + 1$; then one can easily see that

$$\sigma_1 - \omega_2 = \frac{\rho_-^\gamma}{\rho_1 - \rho_-} f(x).$$

Obviously, we have $f'(x) = (\gamma-1)\gamma x^{\gamma-2}(x-1) > 0$ for $x > 1$, which gives $f(x) > f(1) = 0$ and then $\sigma_1 > \omega_2$. Thus S_1 will overtake R_2 in finite time and the intersection (x_2, t_2) can be calculated by

$$\begin{cases} x_2 + \varepsilon = \Big(u_- - \dfrac{\rho_1(\rho_1^{\gamma-1} - \rho_-^{\gamma-1})}{\rho_1 - \rho_-}\Big)t_2, \\ x_2 - x_1 = (u_1 - (\gamma-1)\rho_1^{\gamma-1})(t_2 - t_1), \end{cases} \tag{3.22}$$

in which (x_1, t_1) has the same representation as (3.12).

Hence, (x_2,t_2) can be expressed as

$$(x_2,t_2)=\left(\frac{2\varepsilon[\rho_1^{\gamma-1}(\rho_1-\rho_-)-\rho_1^{\gamma}(\rho_1^{\gamma-1}-\rho_-^{\gamma-1})]}{\rho_m^{\gamma-1}[(\gamma-1)\rho_1^{\gamma}-\gamma\rho_-\rho_1^{\gamma-1}+\rho_-^{\gamma}]}-\varepsilon,\frac{2\varepsilon\rho_1^{\gamma-1}(\rho_1-\rho_-)}{\rho_m^{\gamma-1}[(\gamma-1)\rho_1^{\gamma}-\gamma\rho_-\rho_1^{\gamma-1}+\rho_-^{\gamma}]}\right).$$

When $t>t_2$, S_1 begins to penetrate R_2, and the shock wave $x=x(t)$ during the process of penetration satisfies

$$\begin{cases}\dfrac{dx}{dt}=u_--\dfrac{\rho(\rho^{\gamma-1}-\rho_-^{\gamma-1})}{\rho-\rho_-},\\ x-\hat{x}=(u-(\gamma-1)\rho^{\gamma-1})(t-\hat{t}),\\ u-u_1=\rho_1^{\gamma-1}-\rho^{\gamma-1},\\ x(t_2)=x_2,\quad 0\le\rho\le\rho_1,\end{cases}\tag{3.23}$$

in which $(\hat{x},\hat{t})$ are the translation points from R_1 to R_2 and can be calculated by (3.13), but here $\rho_3\le\rho\le\rho_m$.

Similarly, by differentiating (3.23) with respect to t along $x=x(t)$ and noting that $u-u_-=-\rho^{\gamma-1}+\rho_-^{\gamma-1}$, we finally obtain, for $\rho>\rho_-$,

$$\frac{d\rho}{dt}=-\frac{(\gamma-1)\rho^{\gamma}-\gamma\rho_-\rho^{\gamma-1}+\rho_-^{\gamma}}{(\gamma-1)\gamma\rho^{\gamma-2}(\rho-\rho_-)(t-\hat{t})}<0,\tag{3.24}$$

$$\begin{aligned}\frac{d^2x}{dt^2}&=-\frac{(\gamma-1)\rho^{\gamma}-\gamma\rho_-\rho^{\gamma-1}+\rho_-^{\gamma}}{(\rho-\rho_-)^2}\cdot\frac{d\rho}{dt}\\&=\frac{((\gamma-1)\rho^{\gamma}-\gamma\rho_-\rho^{\gamma-1}+\rho_-^{\gamma})^2}{(\gamma-1)\gamma\rho^{\gamma-2}(\rho-\rho_-)^3(t-\hat{t})}>0,\end{aligned}\tag{3.25}$$

which means that the shock wave accelerates during the process of penetration.

Integrating (3.24) yields

$$\ln\frac{t-\hat{t}}{t_2-\hat{t}}=-\int_{\rho_1}^{\rho}\frac{(\gamma-1)\gamma\rho^{\gamma-2}(\rho-\rho_-)}{(\gamma-1)\rho^{\gamma}-\gamma\rho_-\rho^{\gamma-1}+\rho_-^{\gamma}}d\rho,\tag{3.26}$$

and we see that $t\to\infty$ as $\rho\to\rho_-$. Therefore, S_1 cannot penetrate over R_2 forever and the propagating speed of the shock wave will tend to $u_--(\gamma-1)\rho_-^{\gamma-1}$ as $t\to\infty$.

In brief, when $t\to\infty$, the solution can be expressed as

$$(u_-,\rho_-)+R+Vac+J_2+(u_+,\rho_+).$$

Remark 1. The curve passing through (u_-,ρ_-) is below the one passing through (u_m,ρ_m) if $u_-+\rho_-^{\gamma-1}<u_m+\rho_m^{\gamma-1}$ (i.e., $u_*<u_\sim$) in the (u,ρ) plane; otherwise the situation is opposite. Here we select the situation $u_*<u_\sim$ to discuss, and the other can be dealt with similarly.

4. Stability analysis and comparison. In this section, let us first consider whether the limits of the perturbed solutions of (1.2) and (1.3) are the corresponding Riemann solutions of (1.2) and (2.1). It is obviously true when the vacuum is not involved. On the other hand, if the vacuum is involved, let us take Case 3.1 as an example to study the limit situations of the above perturbed solutions for details.

In Case 3.1, it can be easily derived from (3.2) that $(x_1, t_1) \to (0, 0)$ as $\varepsilon \to 0$; thus the three points $(-\varepsilon, 0)$, $(\varepsilon, 0)$, and (x_1, t_1) coincide with each other in the limit situation. If $u_+ \geq u_* > u_-$ (see Figure 3.1), as $\varepsilon \to 0$, the intermediate state (u_2, ρ_2) disappears while SJ and J_2 unify into one contact discontinuity J since SJ and J_2 propagate with the same speed u_+. So the structure of the solution tends to $(u_-, \rho_-) + R + Vac + J + (u_+, \rho_+)$ as $\varepsilon \to 0$. Otherwise, if $u_+ < u_*$ (see Figure 3.2), we can also see that $(x_2, t_2) \to (0, 0)$ as $\varepsilon \to 0$ from (3.3) and the vacuum state disappears in the limit situation. Furthermore, S_2 cannot penetrate over R_1 for $u_- \leq u_+$, and the limit of the perturbed solution is $(u_-, \rho_-) + R + (u_3, \rho_3) + J + (u_+, \rho_+)$. Otherwise, S_2 is able to penetrate the whole of R_1 for $u_+ < u_-$, and the limit situation is $(u_-, \rho_-) + S + (u_3, \rho_3) + J + (u_+, \rho_+)$.

Therefore, in Case 3.1 the Riemann solutions are claimed to be stable for such perturbations with the Riemann data (2.1). The other cases can be analyzed similarly. Hence, we can see that the limits of the solutions of the perturbed Riemann problems (1.2) and (1.3) are exactly the solutions of the corresponding Riemann problems (1.2) and (2.1), which shows the stability of the Riemann solutions with respect to the small perturbations of the initial data in this particular situation.

In [2], Aw and Rascle considered the Riemann problem when the left (or right) state is the vacuum state and they fixed the right (or left) state and slightly perturbed the left (or right) state so that $0 < \rho_- \ll 1$ (or $0 < \rho_+ \ll 1$). They discovered that a big oscillation appeared and the solution dramatically changed under their small perturbations in some cases. Thus, the Riemann solution displays the instability when one of the Riemann data is near the vacuum under their perturbations. In [11], Lebacque, Mammer, and Haj-Salem extended properly the fundamental diagram (equilibrium speed-density relationship) in a suitable fashion to solve the Riemann problem for all initial conditions and to avoid irregular behavior at the low densities pointed out by Aw and Rascle.

If we adopt the perturbation such as (1.3), the stability of the Riemann solution can be obtained under the assumption $\rho_\pm > 0$ in section 3. Indeed, this stability can also be arrived at when one of the Riemann data is the vacuum state. Now, in order to compare with the results in [2], let us reconsider two interesting and typical examples: the perturbation (iv) of case 5 and the perturbation (vii) of case 4 (both in [2]).

Case 4.1. Let us first consider the perturbation (iv) of case 5 in [2]. In this case, the Riemann problem has no traffic on the left: $\rho_- = 0$, and the initial data on the right satisfies $u_+ < u_- < u_\star = u_+ + \rho_+^{\gamma-1}$. According to [2], for $\rho_- = 0$, the Riemann problem can be connected by a 2-contact discontinuity directly and the wave of the first family disappears. The shock with the large amplitude presents, and the Riemann solution is obviously unstable under the perturbation proposed by Aw and Rascle. But we can see that the Riemann solution is still stable if we take the perturbation (u_m, ρ_m) in the interval $(-\varepsilon, \varepsilon)$. According to the value of u_m, we divide our discussion into the following two subcases.

Subcase 4.1.1. If $u_+ < u_m$, then J_1 emerges from $(-\varepsilon, 0)$ and S_1 and J_2 start from $(\varepsilon, 0)$ (see Figure 4.1). Like in Case 3.1, J_1 must overtake S_1 in finite time and they unify into a contact discontinuity J_3 with the velocity u_+.

Subcase 4.1.2. If $u_+ > u_m$, then J_1 emerges from $(-\varepsilon, 0)$ and R_1 and J_2 emanate from $(\varepsilon, 0)$ (see Figure 4.2). Similarly to Case 3.2, J_1 will penetrate R_1 completely in finite time and then be denoted by J_3 with the velocity u_+, and R_1 will become the vacuum state at the same time.

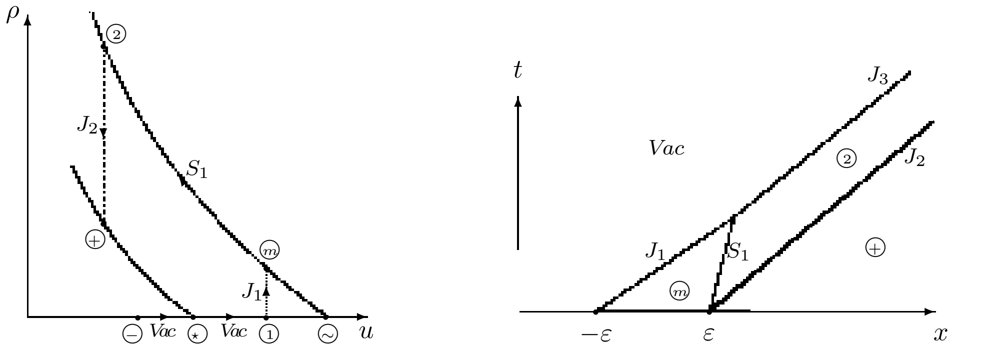

FIG. 4.1.

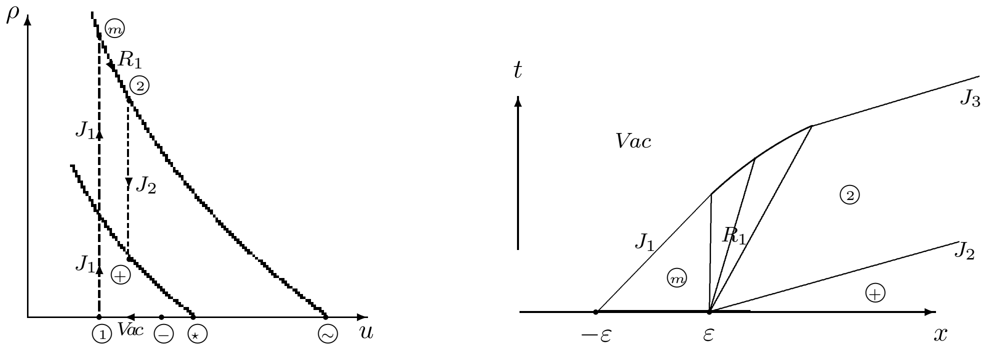

FIG. 4.2.

Remark 2. If $\rho_- = 0$ and $u_+ < u_-$, we can also believe that the Riemann solution consists of a 1-shock S connecting $(u_-, 0)$ and $(u_+, \sqrt[\gamma-1]{u_- - u_+})$, followed by a 2-contact discontinuity J connecting $(u_+, \sqrt[\gamma-1]{u_- - u_+})$ and (u_+, ρ_+). But S and J propagate at the same speed u_+; thus they coalesce into a new wave SJ and the intermediate state $(u_+, \sqrt[\gamma-1]{u_- - u_+})$ disappears in the (x, t) plane. The new wave SJ has the same properties as J and can also be regarded as J. Otherwise, if $\rho_- = 0$ and $u_+ > u_-$, it can also be believed that the Riemann solution consists of a fake vacuum wave connecting the two vacuum states $(u_-, 0)$ and $(u_+, 0)$ and then followed by a contact discontinuity J connecting $(u_+, 0)$ and (u_+, ρ_+).

Case 4.2. Let us now come back to the perturbation (vii) of case 4 in [2]. In this case, the Riemann data satisfies $\rho_+ = 0$ and $u_+ < u_-$. Based on [2], for $\rho_+ = 0$, the Riemann solution consists only of a rarefaction wave and there is no need to add a contact discontinuity. If we employ the perturbation in [2], the perturbed solution is still more dramatically different from the original one in that a (possible large) shock wave and a large contact discontinuity appear. However, we can see that the Riemann solution is still stable if we adopt the perturbation (1.3). Our discussion is also divided into the following two subcases according to the value of u_m.

Subcase 4.2.1. If $u_- < u_m$, then R_1 and J_1 generate from $(-\varepsilon, 0)$ and R_2 emanates from $(\varepsilon, 0)$. If $u_m \leq u_*$, as in Case 3.4, the vacuum state will form ahead of R_3 when one of the states in R_2 becomes (u_2, ρ_2). J_1 penetrates R_2 and has $x - \varepsilon = u_\sim t$ as its

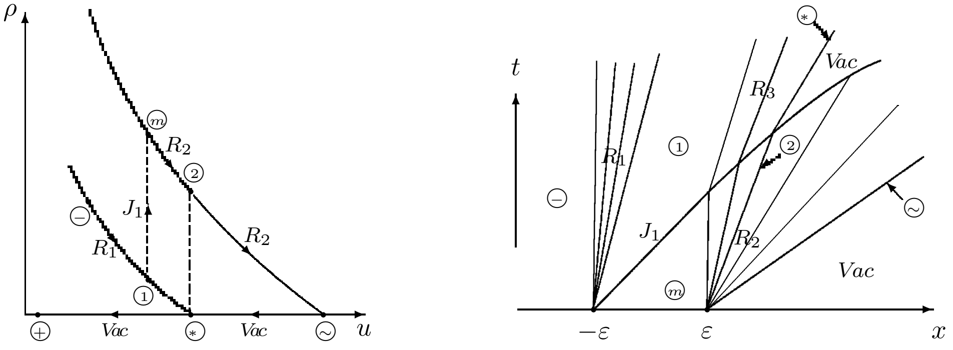

FIG. 4.3. $(u_+ <)u_- < u_m \leq u_*$.

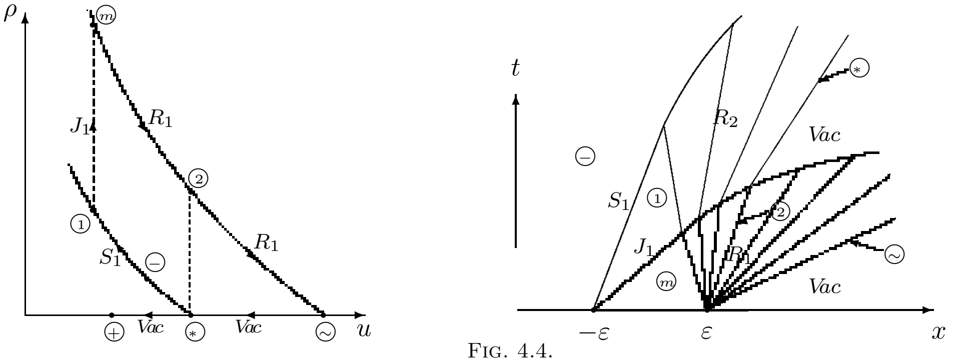

FIG. 4.4.

asymptote, which finally disappears at infinity for both sides are the vacuum states (see Figure 4.3). For the remaining case $u_m > u_*$, the conclusion is analogous and the difference lies in that R_3 disappears and the intermediate state between R_1 and J_1 becomes the vacuum state.

Subcase 4.2.2. If $u_- > u_m$, then S_1 and J_1 generate from $(-\varepsilon, 0)$ and R_1 emits from $(\varepsilon, 0)$. With the same reasoning as before, J_1 penetrates R_1 and has the wave front in R_1 as its asymptote; eventually it disappears in the vacuum as $t \to \infty$. For S_1, it cannot penetrate R_2 completely and its speed tends to $u_- - (\gamma - 1)\rho_-^{\gamma-1}$ in the end (see Figure 4.4).

Remark 3. If $\rho_+ = 0$ and $u_+ < u_-$ (or $u_- < u_+ < u_*$), we can also believe the Riemann solution consists of a 1-shock wave S (or a 1-rarefaction wave R) connecting (u_-, ρ_-) and $(u_+, \sqrt[\gamma-1]{u_- + \rho_-^{\gamma-1} - u_+})$ and then followed by a 2-contact discontinuity J connecting $(u_+, \sqrt[\gamma-1]{u_- + \rho_-^{\gamma-1} - u_+})$ and $(u_+, 0)$. Otherwise, if $\rho_+ = 0$ and $u_+ > u_*$, we can believe that the Riemann solution consists of a 1-rarefaction wave R connecting (u_-, ρ_-) and $(u_*, 0)$ and then followed by a fake vacuum wave connecting the two vacuum states $(u_*, 0)$ and $(u_+, 0)$.

By letting $\varepsilon \to 0$, it is easy to see that the Riemann solutions are stable under the perturbations (1.3) in the above two cases. The other cases in [2] can be treated in the same way, and the results are also identical with our assertions. It should be pointed out that the perturbations adopted in this paper are local perturbations, which are obviously different from the perturbations proposed by Aw and Rascle. This may be used to explain the following traffic situation: the perturbation of traffic status in a small range will come back soon.

5. Conclusion. So far, the discussion for all kinds of interactions has been completed. We have globally constructed the solutions for the perturbed initial value problem (1.2) and (1.3). From the above analysis, we can find that the asymptotic behavior of the perturbed solutions is governed completely by the states $(u_\pm, \rho_\pm)$. That is, the elementary waves in the time-asymptotic solutions consist of R and J for $u_+ > u_-$, or S and J for $u_+ < u_-$. Particularly, for $u_- < u_* < u_+$, the vacuum states are involved as the intermediate states between R and J in the time-asymptotic solutions. Thus we can draw the conclusion that the Riemann solutions of (1.2) and (2.1) are stable with respect to the small perturbations of the initial data in this particular situation.

DRIFT-DIFFUSION PAST A CIRCLE: SHADOW REGION ASYMPTOTICS[*]

SEAN LYNCH[†] AND CHARLES KNESSL[†]

Abstract. We consider the steady state concentration of some diffusing substance, subject to a uniform drift field, past a circular obstacle. We obtain some exact representations of the concentration profile of the substance exterior to the obstacle. These representations are particularly useful for studying the solution in ranges of space where the concentration is very small (the "shadow" regions). We assume then that the drift dominates diffusion and obtain various asymptotic expansions in the shadow regions.

Key words. convection, diffusion, shadow, asymptotics

1. Introduction.

A very basic problem in classical mathematical physics is the study of a diffusing substance drifting past an obstacle. Such problems occur in many applications, including chromatography, groundwater flow, electrophoresis, and sedimentation. We will briefly discuss several applications in the paragraphs below.

Perhaps the simplest geometry to consider for such problems is that of a circle in $\mathbf{R}^2$ (or circular cylinder in $\mathbf{R}^3$). The problem of steady state linear drift-diffusion past a circle was analyzed exactly by Philip, Knight, and Waechter in [1], where it was used to model unsaturated seepage of groundwater past a circular cylindrical impermeable obstacle such as a rock, tunnel, or for their purposes a subterranean hole. The air contained in a subterranean hole is at a greater pressure than that of seeping water originating from the soil's surface (see [5]). Thus water may enter subterranean holes only under circumstances that allow water pressure on the surface of the hole to sufficiently increase. Factors contributing to these circumstances include the seepage velocity and the size and shape of the hole.

We note that the drift is caused by gravity in this application, which of course exists throughout the spatial region (including the inside of the circular obstacle). Capillarity provides the diffusive effects, and $\alpha L/2$, which we call c, measures the relative strength of the drift to the diffusion, where L is a characteristic length and α is the sorptive number from hydrogeology (which measures the capacity of a porous medium for capillary uptake of a fluid). The concentration of groundwater, which we call p, is the quantity of interest.

Similar mathematical models were used in connection with the Brazil nut effect [11], [12], [13]. Here a container of different sized particles subjected to shaking becomes segregated, with larger particles rising to the top of the container. We can view the larger nut as the obstacle, the smaller nuts as the diffusing substance, gravity as the drift, and shaking as diffusion. In [13] qualitative comparisons were drawn between the Brazil nut problem and the groundwater seepage problem in [1].

We can also imagine other applications of this model. For example, we can consider a sea of charged particles subject to a uniform electromagnetic field in the presence of a fixed circular obstacle. The uniform electromagnetic field causes the drift, local particle interactions cause the diffusive effects, and the quantity of interest, p, now gives the concentration of particles. Another physical situation that could correspond to our model is the concentration of Brownian particles in still air, such as dust particles, subject to gravity and with the collection of particles modeled as a continuum.

Considering the original application, the solution obtained in [1] gave the steady state concentration of groundwater as a Fourier series, with the Fourier coefficients characterized as infinite series involving the modified Bessel functions $I_\nu(\cdot)$ and $K_\nu(\cdot)$. Due to the complexity of the solution and the resulting numerical difficulties which are exacerbated when c is large, an asymptotic solution for $c \gg 1$ is desirable, and this is the topic of this paper. The asymptotic solution will also provide qualitative information about the concentration, such as the manner in which it transitions from being constant in the far field to being small directly beneath the obstacle.

In [2] we obtained another form of the solution given in [1] and studied various asymptotic properties. The asymptotic analysis assumes that c is large. We assume that (i) the drift field is of uniform strength, (ii) the field exists in all of $\mathbf{R}^2$ (including inside the circular obstacle), (iii) there is a uniform concentration of particles infinitely far from the obstacle, and (iv) the normal component of the flux of particles vanishes on the obstacle's exterior boundary. With these assumptions we can divide the exterior of the obstacle into an "illuminated region" ($\{r = \sqrt{x^2+y^2} > 1,\ |y| > 1\} \cup \{r > 1,\ -1 \le y \le 1,\ x < 0\}$) and a complementary "shadow region" $\Omega_s = \{(x,y) \mid r > 1,\ -1 < y < 1,\ x > 0\}$. We note that this definition excludes the shadow side of the obstacle, where $r \approx 1$ and $x > 0$. Here we scale the spatial variables so that the obstacle is inside the unit circle $r = 1$, and the uniform concentration at $r = \infty$ is taken as unity. For large c the concentration inside the illuminated region will be asymptotically equal to one, while that in the shadow region will be exponentially small. These definitions of shadow and illuminated regions are useful qualitatively even for moderate c.

In [2] we gave asymptotic results for the illuminated region and also where the shadow boundaries (defined by $y = \pm 1,\ x > 0$) meet the obstacle. This corresponds to $(x, y) = (0, \pm 1)$, and in this range the particle concentration is asymptotically large, of the order $O(c^{2/3})$. In this paper we shall obtain detailed asymptotic results in the shadow region, including the shadow boundaries and the shadow side of the obstacle (where $r \approx 1$ and $0 < x < 1$).

In particular we shall obtain the exponentially small concentration profile in the shadow region, Ω_s. Then we will construct "boundary layer" expansions near the obstacle's shadow side, where $r - 1 = O(c^{-1})$ and $r - 1 = O(c^{-2/3})$. Thus, two nested layers are needed. In the shadow boundary we will consider the two scales $y - 1 = O(c^{-1/3})$ and $y - 1 = O(c^{-1/2})$. On the latter scale the concentration of particles is large, of the order $O(\sqrt{c})$, and follows a Gaussian profile in the similarity variable $\sqrt{c}(y-1)/\sqrt{x}$.

In studying the shadow region asymptotically it proves necessary to have a representation that is different from that of the Fourier series in [1] and [2], and we shall obtain such a representation. It does not seem possible to obtain the shadow region asymptotics from the Fourier series.

There has been much previous work on related problems, and we do not make any attempt to survey it here. Some related papers are those of Chapman, Lawry, and

Ockendon [3] and Cherepanov [4]. In [3] the authors analyzed temperature exterior to a slit, with a convecting fluid velocity field that avoids the slit. Thus in this case the field is not a constant drift field as it exists only exterior to the obstacle. The authors also use conformal mapping to treat more complicated obstacle geometries. In [4] the author obtained exact solutions for the case of a slit, in terms of Mathieu and modified Mathieu functions. Other exact solutions for simple geometries were obtained by Knight and Philip [6] for spherical obstacles and by Philip [7], [8], [9], [10].

This work assumes that the drift field is constant and exists everywhere in space. Thus the mathematical model would be appropriate when the drift is due to gravity or electromagnetic fields, but not for, say, a diffusing substance in a liquid (such as water) flowing past an obstacle. For the latter the convection field would be some given potential or viscous flow that would itself satisfy a boundary condition on the surface of the obstacle.

We mention that the asymptotic structure of drift-diffusion problems for large c has some similarities to scattering problems in the high frequency limit. However, there are important differences. For example, the scattering problem for a plane wave hitting a circle in $\mathbf{R}^2$ would have the shadow boundary correspond to the disappearance of the incoming plane wave via a Fresnel integral. But the drift-diffusion problems in this spatial range have to leading order a Gaussian behavior. A good survey of exact and asymptotic results for scattering by simple geometries can be found in [14].

The remainder of the paper is organized as follows. In section 2 we summarize our results, both exact and asymptotic. The exact results are derived in section 3 and the asymptotic ones in sections 4–6. Concluding remarks are given in section 7.

2. Summary of results.

We let $p(x, y)$ be the concentration of some substance that undergoes diffusion exterior to the unit circle $r = \sqrt{x^2 + y^2} = 1$ and is subject to a constant drift field in the $+x$ direction. Then the steady state concentration, p, satisfies the following linear PDE:

$$p_{xx} + p_{yy} - 2cp_x = \Delta p - 2cp_x = 0, \ r > 1. \tag{1}$$

Here $c > 0$ is a parameter measuring the ratio of drift to diffusion. We assume that the substance cannot penetrate the obstacle, which leads to a boundary condition at $r = 1$. The flux vector of the substance is $\mathbf{J} = (2cp - p_x, -p_y)$. The component of $\mathbf{J}$ normal to the obstacle must vanish, which leads to

$$(\cos\theta)p_x + (\sin\theta)p_y - 2c(\cos\theta)p = p_r - 2c\cos\theta p = 0, \ r = 1. \tag{2}$$

The other boundary condition we impose is far away from the obstacle. We assume that the concentration approaches a constant value, which we take to be one; hence

$$p(x, y) \to 1 \ , \ r = \sqrt{x^2 + y^2} \to \infty. \tag{3}$$

For convenience we define $q(x, y)$ via

$$p(x, y) = 1 + e^{cx} q(x, y). \tag{4}$$

Upon changing variables in (1)–(3) we see that q satisfies the Helmholtz equation

$$q_{xx} + q_{yy} = c^2 q, \ r > 1, \tag{5}$$

with the boundary conditions

$$(\cos\theta)q_x + (\sin\theta)q_y - c(\cos\theta)q = 2c(\cos\theta)e^{-cx},\ r = 1, \tag{6}$$

and

$$q(x,y) \to 0\ ,\ r = \sqrt{x^2+y^2} \to \infty. \tag{7}$$

In polar coordinates (6) becomes

$$q_r - c(\cos\theta)q = 2c(\cos\theta)e^{-c(\cos\theta)},\ r = 1. \tag{8}$$

The problem (1)–(3) was explicitly solved by Philip, Knight, and Waechter [1], and a different representation of the solution is given in [2], where it was shown that q in (4) is given by

$$q(r,\theta) = -\int_r^\infty e^{c(\cos\theta)(r-s)}\tilde{q}(s,\theta)ds, \tag{9}$$

where

$$\tilde{q}(s,\theta) = 2c(\cos\theta)Q_1(s,\theta) - Q_2(s,\theta) \tag{10}$$

with

$$\begin{aligned} Q_1(s,\theta) &= \sum_{m=-\infty}^{\infty}\int_{-\infty}^{\infty}\frac{K_\nu(cs)}{K_\nu(c)}I_{|\nu|}(c)e^{i\nu(\theta+(2m+1)\pi)}d\nu \\ &= 2\mathrm{Re}\left[\sum_{m=-\infty}^{\infty}\int_0^\infty \frac{K_\nu(cs)}{K_\nu(c)}I_\nu(c)e^{i\nu(\theta+(2m+1)\pi)}d\nu\right] \end{aligned} \tag{11}$$

and

$$Q_2(s,\theta) = \sum_{m=-\infty}^{\infty}\int_{-\infty}^{\infty}\frac{\nu}{K_\nu(c)}e^{i\nu(\theta+(2m+1)\pi)}\left[\frac{K_{\nu+1}(cs)}{K_{\nu+1}(c)} - \frac{K_{\nu-1}(cs)}{K_{\nu-1}(c)}\right]d\nu. \tag{12}$$

Here K and I are modified Bessel functions.

We give below an alternate form for p, which will prove useful for calculations in the "shadow region," $\Omega_s = \{(x,y)\mid r>1,\ -1<y<1,\ x>0\}$.

THEOREM 2.1. *The solution $p(x,y)$ to (1)–(3) is given by*

$$\begin{aligned} p = \mathrm{Im}\Bigg\{\int_r^\infty e^{c(\cos\theta)(2r-s)}\sum_{k=0}^{\infty}\frac{-4\pi\mathrm{csch}(\omega_k\pi)}{\dot{K}_{i\omega_k}(c)K_{i\omega_k+1}(c)}\Big[i\omega_k\cosh(\omega_k\theta)K_{i\omega_k+1}(cs) \\ + \left(\omega_k\sin\theta\sinh(\omega_k\theta) + i\omega_k\cos\theta\cosh(\omega_k\theta) - i\sin\theta\sinh(\omega_k\theta)\right)K_{i\omega_k}(cs)\Big]\Bigg\}ds. \end{aligned} \tag{13}$$

Here $\dot{K}$ is used to denote the derivative of K with respect to order, and the ω_k are real positive solutions to $K_{i\omega_k}(c) = 0$, ordered as $0<\omega_0<\omega_1<\cdots$.

Another form of the solution is given by

$$\begin{aligned} p = \mathrm{Im}\Bigg\{\int_{-\infty}^{\infty}\sum_{k=0}^{\infty}\frac{-2\pi c^{-1}\exp\left[i\omega_k t\right]\exp\left[cr\left(\cos\theta - \cosh t\right)\right]}{(\cos\theta+\cosh t)\sinh(\omega_k\pi)\dot{K}_{i\omega_k}(c)K_{i\omega_k+1}(c)} \\ \times\left[i\omega_k\cosh(\omega_k\theta)e^t + i\omega_k\cos\theta\cosh(\omega_k\theta) + (\omega_k - i)\sin\theta\sinh(\omega_k\theta)\right]dt\Bigg\}. \end{aligned} \tag{14}$$

While (13) and (14) are exact forms of the solution, their usefulness is still numerically constrained to situations involving moderate values of c, as are the forms given in [1] and by (4), (9)–(12). Also, their complexity is such that they do not yield qualitative insights into the solution.

We next give various asymptotic approximations to $p(x, y)$ for $c \to \infty$. The results apply in the shadow region with the following scaling:

(A)	Shadow region, Ω_s^+:	$r > 1,\ x > 0,\ 0 < y < 1.$
(B)	Intermediate shadow boundary:	$y - 1 = O(c^{-1/3}),$
	Inner shadow boundary:	$y - 1 = O(c^{-1/2}).$
(C)	Intermediate layer near obstacle:	$r - 1 = O(c^{-2/3}),\ 0 < y < 1,$
	Inner layer near obstacle:	$r - 1 = O(c^{-1}),\ 0 < y < 1.$

We summarize our results in Theorems 2.2–2.4 below. In view of the symmetry $p(x, y) = p(x, -y)$ it suffices to consider $y \geq 0$.

THEOREM 2.2. *In the domain Ω_s^+, we have*

$$\begin{aligned} p = {} & c^{5/6}\, \frac{2^{1/6} T(r,\theta)}{\sqrt{\pi}\left[\mathrm{Ai}'(r_0)\right]^2}\ \exp\left[c\left(r\cos\theta + \theta - \sin^{-1}\left(\frac{1}{r}\right) - \sqrt{r^2-1}\right)\right] \\ & \times\ \left(r^2-1\right)^{-1/4} \exp\left[c^{1/3} 2^{-1/3} |r_0| \left(\theta - \sin^{-1}\left(\frac{1}{r}\right)\right)\right] \\ & \times\ \left\{1 + c^{-1/3}\left[\gamma_0\left(\theta - \sin^{-1}\left(\frac{1}{r}\right)\right) - \frac{15\gamma_0}{\sqrt{r^2-1}}\right] + O(c^{-2/3})\right\}, \end{aligned} \tag{15}$$

where

$$T(r,\theta) = \frac{1 - r\sin\theta}{r\cos\theta + \sqrt{r^2-1}}, \qquad \gamma_0 = \frac{2^{-2/3} r_0^2}{30}, \tag{16}$$

and $r_0 = \max\{z : \mathrm{Ai}(z) = 0\} = -2.33811\ldots$.

If $-1 < y < 0$, we should replace θ by $-\theta$. If y is small, specifically $y = O(c^{-1})$ (thus $\theta = O(c^{-1})$), we must *add* the results with θ and $-\theta$.

THEOREM 2.3. *For the shadow boundary intermediate layer, where $y - 1 = O(c^{-1/3})$ and $x > 0$, we set $y - 1 = c^{-1/3} Y$ with $Y = O(1)$. For $Y < 0$ we obtain*

$$\begin{aligned} p = {} & c^{1/2} \frac{2^{-5/6}}{\sqrt{\pi}} \exp\left[-c^{1/3}\frac{Y^2}{2x}\right] \exp\left[\frac{Y^3}{6x^3}\right] \sum_{k=0}^{\infty} \frac{e^{A_k Y/x}}{\left[\mathrm{Ai}'(r_k)\right]^2} \\ & \times \left\{R_0(x,Y,k) + c^{-1/3} R_1(x,Y,k) + c^{-2/3} R_2(x,Y,k) + O(c^{-1})\right\}, \end{aligned} \tag{17}$$

where

$$R_0 = -\frac{Y}{x^{3/2}}, \tag{18}$$

$$R_1 = \left(\frac{Y}{x}\right)^5 \frac{1-x^2}{8x^{3/2}} + \left(\frac{Y}{x}\right)^3 \frac{A_k}{2x^{3/2}} + \left(\frac{Y}{x}\right)^2 \frac{1}{x^{3/2}} + \left(\frac{Y}{x}\right) \frac{A_k^2}{2x^{3/2}} + \frac{A_k}{x^{3/2}}, \tag{19}$$

$$\begin{aligned} R_2 = {} & \left(\frac{Y}{x}\right)^9 \frac{-(x^2-1)^2}{128x^{5/2}} + \left(\frac{Y}{x}\right)^7 \frac{A_k(x^2-1)}{16x^{5/2}} + \left(\frac{Y}{x}\right)^6 \frac{6x^2-5}{20x^{5/2}} \\ & + \left(\frac{Y}{x}\right)^5 \frac{A_k^2(x^2-3)}{16x^{5/2}} + \left(\frac{Y}{x}\right)^4 \frac{A_k(11x^2-27)}{24x^{5/2}} + \left(\frac{Y}{x}\right)^3 \frac{4x^2-11-2A_k^2}{8x^{5/2}} \\ & + \left(\frac{Y}{x}\right)^2 \frac{-A_k^2(x^2+45)}{30x^{5/2}} + \left(\frac{Y}{x}\right)\left(\frac{-A_k^4}{8x^{5/2}} - \frac{A_k(16x^2+30)}{15x^{5/2}}\right) - \frac{A_k^3+1}{2x^{5/2}}, \end{aligned} \tag{20}$$

and $A_k = 2^{-1/3}|r_k|$. *The* r_k *are the real negative zeros of the Airy function (thus* $\mathrm{Ai}(r_k) = 0$*) such that* $|r_0| < |r_1| < |r_2| < \cdots$. *We can also write* (17)–(20) *in an alternate integral form that will apply also for* $Y > 0$. *We have*

$$p = c^{1/2}2^{-1/6}\pi^{-1/2}\exp\left[-c^{1/3}\frac{Y^2}{2x}\right]\exp\left[\frac{Y^3}{6x^3}\right] \\ \times\left\{\mathcal{F}_0 + c^{-1/3}\mathcal{F}_1 + c^{-2/3}\mathcal{F}_2 + O(c^{-1})\right\}, \tag{21}$$

where

$$\mathcal{F}_0 = \frac{x^{-1/2}}{2\pi i}\int_C e^{-zY/x}\frac{dz}{\mathrm{Ai}^2(2^{1/3}z)}, \tag{22}$$

$$\begin{aligned}\mathcal{F}_1 = {} & \frac{x^{1/2}}{2\pi i}\int_C\left(\frac{Y^4}{8x^4}\right)e^{-zY/x}\frac{dz}{\mathrm{Ai}^2(2^{1/3}z)} \\ & - \frac{x^{-3/2}}{2\pi i}\int_C\left(\frac{Y^4}{8x^4} + \frac{Y}{2x} - z\frac{Y^2}{2x^2} + z^2\frac{1}{2}\right)e^{-zY/x}\frac{dz}{\mathrm{Ai}^2(2^{1/3}z)},\end{aligned} \tag{23}$$

$$\begin{aligned}\mathcal{F}_2 = {} & \frac{1}{2^{2/3}x^{1/2}}\sum_{k=0}^{\infty}\frac{e^{A_kY/x}}{\left[\mathrm{Ai}'(r_k)\right]^2} + \frac{x^{3/2}}{2\pi i}\int_C\left(\frac{Y^8}{128x^8}\right)e^{-zY/x}\frac{dz}{\mathrm{Ai}^2(2^{1/3}z)} \\ & + \frac{x^{-1/2}}{2\pi i}\int_C\left[\frac{-Y^8}{64x^8} - \frac{19Y^5}{80x^5} - \frac{Y^2}{6x^2} + z\left(\frac{Y^6}{16x^6} + \frac{Y^3}{3x^3} - 1\right)\right. \\ & \qquad \left. + z^2\left(\frac{-Y^4}{16x^4} + \frac{Y}{30x}\right)\right]e^{-zY/x}\frac{dz}{\mathrm{Ai}^2(2^{1/3}z)} \\ & + \frac{x^{-5/2}}{2\pi i}\int_C\left[\frac{Y^8}{128x^8} + \frac{3Y^5}{16x^5} + \frac{5Y^2}{8x^2} + z\left(\frac{-Y^6}{16x^6} - \frac{3Y^3}{4x^3} - \frac{1}{2}\right)\right. \\ & \qquad \left. + z^2\left(\frac{3Y^4}{16x^4} + \frac{3Y}{4x}\right) - z^3\frac{Y^2}{4x^2} + z^4\frac{1}{8}\right]e^{-zY/x}\frac{dz}{\mathrm{Ai}^2(2^{1/3}z)}.\end{aligned} \tag{24}$$

The integration contour C *is the imaginary axis (*z *goes from* $-i\infty$ *to* $i\infty$*). Expressions* (21)–(24) *give a three-term approximation to* p *for* $Y < 0$ *and a two-term approximation to* $p - 1$ *for* $Y > 0$ *(here we use only* (21)–(23)*). However, for* $Y \approx 0$ *a different expansion is needed, which is given below.*

For the shadow boundary inner layer, where $y - 1 = O(c^{-1/2})$, *and* $x > 0$, *we set* $\Delta = c^{1/2}\,(y - 1)$ *and obtain*

$$p = c^{1/2}p^{(0)} + c^{1/3}p^{(1/3)} + c^{1/6}p^{(2/3)} + p^{(1)} + O(c^{-1/6}), \tag{25}$$

where

$$p^{(0)} = \frac{1}{\sqrt{2\pi x}}e^{-\Delta^2/(2x)}, \tag{26}$$

$$p^{(1/3)} = \left(\frac{\Delta}{x}\right)\frac{-2^{-1/3}C_1}{\sqrt{2\pi x}}e^{-\Delta^2/(2x)}, \tag{27}$$

$$p^{(2/3)} = \left(\frac{\Delta^2}{2x^2} - \frac{1}{2x}\right) \frac{2^{-2/3}C_2}{\sqrt{2\pi x}} e^{-\Delta^2/(2x)}, \tag{28}$$

$$\begin{aligned} p^{(1)} = {} & \left(\frac{\Delta^3}{6x^3} - \frac{\Delta}{2x^2}\right) \frac{1 - 2^{-1}C_3}{\sqrt{2\pi x}} e^{-\Delta^2/(2x)} \\ & + 1 - 2^{-1/2}\pi^{-1/2} e^{-\Delta^2/(2x)} \int_0^\infty \exp\left[-\frac{z\Delta}{\sqrt{x}} - \frac{z^2}{2}\right] dz. \end{aligned} \tag{29}$$

The constants C_j above are defined as

$$C_j = \frac{1}{2\pi i} \int_{-i\infty}^{i\infty} \frac{z^j}{[\mathrm{Ai}(z)]^2} dz, \tag{30}$$

and their approximate numerical values are $C_0 = 1$, $C_1 \approx -1.25512$, $C_2 \approx 1.06458$, $C_3 \approx 0.20315$.

We note that as $\Delta \to +\infty$ the expressions in (26)–(28) have Gaussian decay while $p^{(1)} \to 1$. Thus as we leave the inner shadow boundary we begin to see the uniform concentration at infinity as given in (3).

Next we give results that apply where the shadow region meets the obstacle's boundary. There are again two scales to consider.

Theorem 2.4. *For the intermediate layer near the obstacle, where $r - 1 = O(c^{-2/3})$, $0 < y < 1$, and $x > 0$, we set $\eta = c^{2/3}(r-1)$ and obtain*

$$\begin{aligned} p = c \; & \exp\Big[c\left(\cos\theta + \theta - \frac{\pi}{2}\right) + c^{1/3}2^{-1/3}|r_0|\left(\theta - \frac{\pi}{2}\right)\Big] \exp\left[c^{1/3}\eta\cos\theta\right] \\ & \times \left\{F(\theta)\mathrm{Ai}(\widehat{\eta}) + c^{-1/3}\Big[-2^{1/3}F'(\theta)\mathrm{Ai}'(\widehat{\eta}) + \gamma_0\left(\theta - \frac{\pi}{2}\right)F(\theta)\mathrm{Ai}(\widehat{\eta})\Big] + O(c^{-2/3})\right\}, \end{aligned} \tag{31}$$

where

$$F(\theta) = \frac{2\cos\theta}{\left[\mathrm{Ai}'(r_0)\right]^2 (1 + \sin\theta)} \tag{32}$$

and $\widehat{\eta} = 2^{1/3}(\eta - 2^{-1/3}|r_0|) = 2^{1/3}\eta + r_0$.

For the inner layer near the obstacle, where $r - 1 = O(c^{-1})$, $0 < y < 1$, and $x > 0$, we set $\xi = c(r-1)$ and obtain

$$\begin{aligned} p = {} & c^{2/3}\frac{2^{4/3}(1 + \xi\cos\theta)}{\mathrm{Ai}'(r_0)(1 + \sin\theta)} \exp\Big[c\left(\cos\theta + \theta - \frac{\pi}{2}\right) + c^{1/3}2^{-1/3}|r_0|\left(\theta - \frac{\pi}{2}\right)\Big] \\ & \times \exp\left[\xi\cos\theta\right]\left\{1 + c^{-1/3}\frac{2^{-2/3}}{30}r_0^2\left(\theta - \frac{\pi}{2}\right) + O(c^{-2/3})\right\}. \end{aligned} \tag{33}$$

If $-1 < y < 0$, we should replace θ by $-\theta$. If y is small, specifically $y = O(c^{-1})$ (thus $\theta = O(c^{-1})$), we must add the results with θ and $-\theta$.

3. The exact representation.

The main steps in deriving the alternate form of p given in Theorem 2.1 will be to write the integrals in (11) and (12) as residue series and explicitly evaluate the m-sums.

First consider (12). To transform the integral into a residue series we recall that the zeros of $K_\nu(c)$ all lie on the imaginary axis in the ν-plane, and that $K_\nu(c) = K_{-\nu}(c)$ for all $\nu \in \mathbf{C}$. Allowing ν to take on complex values, we see that

$$\mathrm{Re}\left[i\nu\left(\theta + (2m+1)\pi\right)\right] = -\mathrm{Im}(\nu)\left[\theta + (2m+1)\pi\right],$$

which is negative when $m < 0$ and $\mathrm{Im}(\nu) < 0$, or when $m \geq 0$ and $\mathrm{Im}(\nu) > 0$ since $|\theta| < \pi$. Thus for $m < 0$ we will close in the lower half-plane, where $\mathrm{Im}(\nu) < 0$, and for $m \geq 0$ we will close in the upper half-plane, where $\mathrm{Im}(\nu) > 0$. This yields

$$\begin{aligned} Q_2(s,\theta) = &-\sum_{m=-\infty}^{-1} \sum \mathrm{Res}\left\{ \frac{2\pi i\nu}{K_\nu(c)} e^{i\nu(\theta+(2m+1)\pi)} \left[\frac{K_{\nu+1}(cs)}{K_{\nu+1}(c)} - \frac{K_{\nu-1}(cs)}{K_{\nu-1}(c)} \right] \right\} \\ &+ \sum_{m=0}^{\infty} \sum \mathrm{Res}\left\{ \frac{2\pi i\nu}{K_\nu(c)} e^{i\nu(\theta+(2m+1)\pi)} \left[\frac{K_{\nu+1}(cs)}{K_{\nu+1}(c)} - \frac{K_{\nu-1}(cs)}{K_{\nu-1}(c)} \right] \right\}, \end{aligned} \tag{34}$$

where the two inner sums are over all singularities in the lower and upper half-planes, respectively. Here Res denotes residue. The singularities of (34) are the zeros of K_ν and $K_{\nu\pm1}$ which are located at $i\omega_k$ and $i\omega_k \pm 1$, $k = 0, 1, 2, \ldots$, in the upper half-plane and at $-i\omega_k$ and $-i\omega_k \pm 1$, $k = 0, 1, 2, \ldots$, in the lower half-plane. We will also simplify (34) by recognizing

$$\frac{K_{\nu+1}(cs)}{K_{\nu+1}(c)} - \frac{K_{\nu-1}(cs)}{K_{\nu-1}(c)} \tag{35}$$

as the difference between a function and its complex conjugate, for purely imaginary ν. Evaluating the residues leads to

$$\begin{aligned} Q_2(s,\theta) = &-2\pi i \sum_{m=1}^{\infty} \sum_{k=0}^{\infty} \left\{ \frac{2\omega_k}{\dot{K}_{i\omega_k}(c)} e^{\omega_k[\theta+(1-2m)\pi]} \mathrm{Im}\left[\frac{K_{i\omega_k+1}(cs)}{K_{i\omega_k+1}(c)} \right] \right. \\ &\left. + \frac{K_{i\omega_k}(cs)}{\dot{K}_{i\omega_k}(c)} e^{\omega_k[\theta+(1-2m)\pi]} 2\mathrm{Re}\left[e^{-i[\theta+(1-2m)\pi]} \frac{i\omega_k+1}{K_{i\omega_k+1}(c)} \right] \right\} \\ &+ 2\pi i \sum_{m=0}^{\infty} \sum_{k=0}^{\infty} \left\{ \frac{-2\omega_k}{\dot{K}_{i\omega_k}(c)} e^{-\omega_k[\theta+(1+2m)\pi]} \mathrm{Im}\left[\frac{K_{i\omega_k+1}(cs)}{K_{i\omega_k+1}(c)} \right] \right. \\ &\left. + \frac{K_{i\omega_k}(cs)}{\dot{K}_{i\omega_k}(c)} e^{-\omega_k[\theta+(1+2m)\pi]} 2\mathrm{Re}\left[e^{i[\theta+(1+2m)\pi]} \frac{-i\omega_k-1}{K_{i\omega_k+1}(c)} \right] \right\}. \end{aligned} \tag{36}$$

The m-sums above are simply geometric series which we can evaluate, and after some rearrangement (36) becomes

$$\begin{aligned} Q_2(s,\theta) = 2\pi i \sum_{k=0}^{\infty} &\left\{ \frac{-2\omega_k \cosh(\omega_k\theta)}{\sinh(\omega_k\pi)\dot{K}_{i\omega_k}(c)} \mathrm{Im}\left(\frac{K_{i\omega_k+1}(cs)}{K_{i\omega_k+1}(c)} \right) \right. \\ &\left. + \frac{K_{i\omega_k}(cs)}{\sinh(\omega_k\pi)\dot{K}_{i\omega_k}(c)} \mathrm{Re}\left(e^{\omega_k\theta} e^{-i\theta} \frac{1+i\omega_k}{K_{i\omega_k+1}(c)} + e^{-\omega_k\theta} e^{i\theta} \frac{1+i\omega_k}{K_{i\omega_k+1}(c)} \right) \right\}. \end{aligned} \tag{37}$$

We will now rewrite the expression inside $\mathrm{Re}(\cdot)$, replace $\mathrm{Re}(\cdot)$ by $\mathrm{Im}(i\cdot)$, and finally move the rest of the expression inside the Im which we can do since $(\dot{K}_{i\omega_k}(c))^{-1}$ and $2\pi i$ are purely imaginary; thus their product is real. We obtain

$$\begin{aligned} Q_2(s,\theta) = \mathrm{Im}&\left\{ \sum_{k=0}^{\infty} \frac{-4\pi \mathrm{csch}(\omega_k\pi)}{\dot{K}_{i\omega_k}(c) K_{i\omega_k+1}(c)} \left[i\omega_k \cosh(\omega_k\theta) K_{i\omega_k+1}(cs) \right. \right. \\ &\left. \left. + (1+i\omega_k)\left(\cos\theta\cosh(\omega_k\theta) - i\sin\theta\sinh(\omega_k\theta)\right) K_{i\omega_k}(cs) \right] \right\}. \end{aligned} \tag{38}$$

Now we turn our attention to Q_1 given by (11). Similarly to how we approached Q_2, for $m \geq 0$ we will rotate the contour by $+90°$, to a contour C_1, that goes from $\nu = 0$ to $\nu = i\infty$ with indentations to the right of all poles which lie at $\nu = i\omega_k$, $\omega_k > 0$. For $m \leq -1$ we rotate by $-90°$ to a contour C_2, that goes from $\nu = 0$ to $\nu = -i\infty$, again indented to the right of the poles which lie at $\nu = -i\omega_k$, $\omega_k > 0$. We thus obtain

$$\begin{aligned} Q_1(s,\theta) = 2\mathrm{Re}\Bigg\{ &\sum_{m=0}^{\infty} \int_{C_1} \frac{K_\nu(cs)}{K_\nu(c)} I_\nu(c) \exp\Big[i\nu\left(\theta + (2m+1)\pi\right)\Big]\, d\nu \\ &+ \sum_{m=1}^{\infty} \int_{C_2} \frac{K_\nu(cs)}{K_\nu(c)} I_\nu(c) \exp\Big[i\nu\left(\theta + (1-2m)\pi\right)\Big]\, d\nu \Bigg\}. \end{aligned} \tag{39}$$

At this point we can evaluate the geometric m-sums since $\mathrm{Im}(\nu)$ is positive in the first integral and negative in the second. We also write the integral over C_1 as a singular integral plus the half-residues at the poles (since the poles are traversed counterclockwise). The integral over C_2 is written as a singular integral minus the half-residues at the poles, and thus

$$\begin{aligned} Q_1(s,\theta) = -2\mathrm{Re}\Bigg\{ &\int_0^{i\infty} \frac{K_\nu(cs)}{K_\nu(c)} I_\nu(c) \frac{e^{i\nu\theta}}{2i\sin(\nu\pi)} d\nu \\ &- \int_0^{-i\infty} \frac{K_\nu(cs)}{K_\nu(c)} I_\nu(c) \frac{e^{i\nu\theta}}{2i\sin(\nu\pi)} d\nu + \pi i \sum \mathrm{Res}\left[\frac{K_\nu(cs)}{K_\nu(c)} I_\nu(c) \frac{e^{i\nu\theta}}{2i\sin(\nu\pi)}\right] \\ &+ \pi i \sum \mathrm{Res}\left[\frac{K_\nu(cs)}{K_\nu(c)} I_\nu(c) \frac{e^{i\nu\theta}}{2i\sin(\nu\pi)}\right] \Bigg\}. \end{aligned} \tag{40}$$

The first residue series above is over all singularities on the negative imaginary axis, and the second residue series is over all singularities on the positive imaginary axis. We can simplify (40) by making the change of variables $\nu = i\omega$ in the integrals and combining the two sums; hence

$$\begin{aligned} Q_1(s,\theta) = -2\mathrm{Re}\Bigg\{ &\int_{-\infty}^{\infty} \frac{K_{i\omega}(cs)}{K_{i\omega}(c)} I_{i\omega}(c) \frac{-ie^{-\omega\theta}}{2\sinh(\omega\pi)} d\omega \\ &+ \pi i \sum_{\nu=\pm i\omega_k} \left(\mathrm{Res}\left[\frac{K_\nu(cs)}{K_\nu(c)} I_\nu(c) \frac{e^{i\nu\theta}}{2i\sin(\nu\pi)}\right]\right) \Bigg\}. \end{aligned} \tag{41}$$

Next we will explicitly evaluate the singular integral in (41). Using $I_\nu(z) = I_{-\nu}(z) - (2/\pi)\sin(\pi\nu)K_\nu(z)$ (from [15]) with $\nu = i\omega$ yields

$$\begin{aligned} &\int_{-\infty}^{\infty} \frac{K_{i\omega}(cs)}{K_{i\omega}(c)} I_{i\omega}(c) \frac{-ie^{-\omega\theta}}{2\sinh(\omega\pi)} d\omega \\ &= -\frac{1}{2\pi}\int_{-\infty}^{\infty} K_{i\omega}(cs) e^{-\omega\theta} d\omega + \int_{-\infty}^{\infty} \frac{K_{i\omega}(cs)}{K_{i\omega}(c)} \left[I_{-i\omega}(c) + I_{i\omega}(c)\right] \frac{-ie^{-\omega\theta} d\omega}{4\sinh(\omega\pi)}. \end{aligned} \tag{42}$$

In the first integral in the right-hand side of (42) we can replace $\exp(-\omega\theta)$ by $\cosh(\omega\theta)$ and use the identities from [17],

$$\int_0^{\infty} \cos(bx)\cosh\left(\frac{x\pi}{2}\right) K_{ix}(a) dx = \frac{\pi\cos\left(a\sinh(b)\right)}{2}, \tag{43}$$

$$\int_0^\infty \sin(bx)\sinh\left(\frac{x\pi}{2}\right)K_{ix}(a)dx = \frac{\pi\sin\left(a\sinh(b)\right)}{2}, \tag{44}$$

with $a = cs,\ b = i\left(\frac{\pi}{2} - \theta\right)$, to obtain

$$\begin{aligned} &\int_{-\infty}^\infty \frac{K_{i\omega}(cs)}{K_{i\omega}(c)} I_{i\omega}(c)\frac{-ie^{-\omega\theta}}{2\sinh(\omega\pi)}d\omega \\ &= -\frac{1}{2}e^{-cs\cos\theta} + \int_{-\infty}^\infty \frac{K_{i\omega}(cs)}{K_{i\omega}(c)}\left[I_{-i\omega}(c) + I_{i\omega}(c)\right]\frac{-ie^{-\omega\theta}}{4\sinh(\omega\pi)}d\omega. \end{aligned} \tag{45}$$

Now we recall that we are interested in only the real part of (45). Since $K_{i\omega}(c)$ is real for real ω and $I_{i\omega}(c) + I_{-i\omega}(c)$ is real by the reflection principle, the integral in the right-hand side of (45) is purely imaginary, and (45) thus gives

$$\text{Re}\left\{\int_{-\infty}^\infty \frac{K_{i\omega}(cs)}{K_{i\omega}(c)} I_{i\omega}(c)\frac{-ie^{-\omega\theta}}{2\sinh(\omega\pi)}d\omega\right\} = -\frac{1}{2}e^{-cs\cos\theta}, \tag{46}$$

which when put back into (41) yields

$$Q_1(s,\theta) = e^{-cs\cos\theta} - \text{Re}\left\{2\pi i \sum_{\nu=\pm i\omega_k}\left(\text{Res}\left[\frac{K_\nu(cs)}{K_\nu(c)}I_\nu(c)\frac{e^{i\nu\theta}}{2i\sin(\nu\pi)}\right]\right)\right\}. \tag{47}$$

To compute the residues we first use the identity [15]

$$I_\nu(c)K_{\nu+1}(c) + I_{\nu+1}(c)K_\nu(c) = \frac{1}{c} \tag{48}$$

evaluated at $\nu = i\omega_k$ to replace I_ν with $(cK_{\nu+1})^{-1}$. Then computing the residues at $\nu = i\omega_k$ and $\nu = -i\omega_k$ separately, we obtain

$$\begin{aligned} Q_1(s,\theta) &= e^{-cs\cos\theta} \\ &\quad + \text{Re}\left\{\frac{\pi i}{c}\sum_{k=0}^\infty \frac{K_{i\omega_k}(cs)}{\sinh(\omega_k\pi)\dot{K}_{i\omega_k}(c)}\left(\frac{e^{-\omega_k\theta}}{K_{i\omega_k+1}(c)} + \frac{e^{\omega_k\theta}}{K_{i\omega_k-1}(c)}\right)\right\}. \end{aligned} \tag{49}$$

Now, $i \times (\dot{K}_{i\omega_k}(c))^{-1}$ is real, and thus

$$\begin{aligned} Q_1(s,\theta) &= e^{-cs\cos\theta} + \frac{\pi i}{c}\sum_{k=0}^\infty \frac{K_{i\omega_k}(cs)}{\sinh(\omega_k\pi)\dot{K}_{i\omega_k}(c)}\text{Re}\left(\frac{e^{-\omega_k\theta}}{K_{i\omega_k+1}(c)} + \frac{e^{\omega_k\theta}}{K_{i\omega_k-1}(c)}\right) \\ &= e^{-cs\cos\theta} + \frac{\pi i}{c}\sum_{k=0}^\infty \frac{K_{i\omega_k}(cs)}{\sinh(\omega_k\pi)\dot{K}_{i\omega_k}(c)}\text{Re}\left(\frac{2\cosh(\omega_k\theta)}{K_{i\omega_k+1}(c)}\right) \\ &= e^{-cs\cos\theta} + \text{Re}\left\{\frac{\pi i}{c}\sum_{k=0}^\infty \frac{2\cosh(\omega_k\theta)K_{i\omega_k}(cs)}{\sinh(\omega_k\pi)\dot{K}_{i\omega_k}(c)K_{i\omega_k+1}(c)}\right\}. \end{aligned} \tag{50}$$

Finally we combine (50), (38), (10), and (9) and use $q = (p-1)\exp(-cx)$ to obtain (13) in Theorem 2.1.

The expression in (14) follows upon using the integral representation

$$K_\nu(z) = \frac{1}{2}\int_{-\infty}^\infty e^{\nu t}e^{-z\cosh t}dt \tag{51}$$

to evaluate the integral over s as

$$\int_r^\infty e^{c(2r-s)\cos\theta}K_\nu(cs)ds = \frac{1}{2c}\int_{-\infty}^\infty \frac{e^{\nu t}e^{cr(\cos\theta-\cosh t)}}{\cos\theta+\cosh t}dt. \tag{52}$$

We mention that while (13) and (14) are exact forms of the solution, their usefulness is still numerically constrained to situations involving moderate values of c, as are the forms given in [1] and by (4), (9)–(12).

4. Shadow region asymptotics. We begin the derivation by obtaining an asymptotic formula for the roots ω_k of $K_{i\omega}(c) = 0$. We then use that formula to obtain the asymptotics for the various modified Bessel functions appearing in (13). After substituting everything into (13) we drop all but the first term of the k-series and use Laplace's method to expand the s-integral. The terms with $k \geq 1$ in (13) lead to exponentially small errors in the shadow region.

To obtain the asymptotics of ω_k we first apply the saddle point method to (51). We set $\nu = i\omega_k = ic\beta$ and obtain the following for $0 < \beta < 1$:

$$K_{ic\beta}(c) \sim \sqrt{\frac{\pi}{2c}}\left(1-\beta^2\right)^{-1/4}\exp\left[-c\left(\beta\sin^{-1}(\beta)+\sqrt{1-\beta^2}\right)\right]. \tag{53}$$

For $\beta \approx 1$, specifically $\beta = 1+O(c^{-2/3})$, (53) becomes invalid. This range corresponds to two saddles coalescing, and then we need to approximate $K_{i\beta c}(c)$ by Airy functions as follows:

$$\begin{aligned} K_{i\left(c+c^{1/3}\alpha\right)}(c) &\sim \pi\left(\frac{2}{c}\right)^{1/3}\exp\left[-\frac{\pi}{2}\left(c+c^{1/3}\alpha\right)\right]\Bigg\{\mathrm{Ai}(-2^{1/3}\alpha) \\ &+ c^{-2/3}\left[\frac{-2\alpha}{15}\mathrm{Ai}(-2^{1/3}\alpha)+\frac{2^{1/3}\alpha^2}{30}\mathrm{Ai}'(-2^{1/3}\alpha)\right] \\ &+ c^{-4/3}\left[2^{1/3}\left(-\frac{\alpha^3}{105}+\frac{1}{70}\right)\mathrm{Ai}'(-2^{1/3}\alpha)+\left(-\frac{\alpha^5}{1800}+\frac{\alpha^2}{25}\right)\mathrm{Ai}(-2^{1/3}\alpha)\right]\Bigg\}. \end{aligned} \tag{54}$$

If the right-hand side of (54) is to vanish, we need $\alpha \sim -2^{-1/3}r_k$ so that $\omega_k \sim c + c^{1/3}2^{-1/3}|r_k|$. To find the next term we expand the Airy functions in (54) near $\alpha = -2^{-1/3}r_k$ and set $\alpha - 2^{-1/3}|r_k| \sim c^{-2/3}\gamma_k$ to find that $\gamma_k = 2^{-2/3}r_k^2/30$. We then repeat the process with $\alpha - 2^{-1/3}|r_k| \sim c^{-2/3}\gamma_k + c^{-4/3}\beta_k$ to find that $\beta_k = (r_k^3+10)/700$; thus

$$\omega_k = c + c^{1/3}2^{-1/3}|r_k| + c^{-1/3}\frac{2^{-2/3}r_k^2}{30} + c^{-1}\frac{r_k^3+10}{700} + O\left(c^{-5/3}\right). \tag{55}$$

Now that we have the expansion of ω_k we can derive the expansions for the modified Bessel functions in (13). We use (55) in (51) with $z = c$ and $\nu = i\omega_k$ or $\nu = i\omega_k + 1$ and expand the integral by the saddle point method, noting that there are two saddles near $t = i\pi/2$ and using also the derivatives of the Airy function, in the form

$$\mathrm{Ai}^{(n)}(z) = \frac{1}{2\pi i}\int_C v^n e^{zv-v^3/3}dv. \tag{56}$$

Here the integration contour runs from $\infty e^{-2\pi i/3}$ to the origin and then to $\infty e^{2\pi i/3}$ (C could also be taken as the imaginary axis in the ν-plane). After some calculation we obtain

$$\begin{aligned}\dot{K}_{i\omega_k}(c) = c^{-2/3}2^{2/3}\pi i\mathrm{Ai}'(r_k)\exp\left[-\frac{\pi}{2}\left(c+c^{-1/3}A_k\right)\right]\\ \times\left[1-c^{-1/3}\frac{\pi\gamma_k}{2}+c^{-2/3}\left(\frac{\pi^2\gamma_k^2}{8}-\frac{A_k}{5}\right)+O\left(c^{-1}\right)\right]\end{aligned}\tag{57}$$

and

$$\begin{aligned}K_{i\omega_k+1}(c) \sim -c^{-2/3}2^{2/3}\pi\mathrm{Ai}'(r_k)\exp\left[-\frac{\pi}{2}\left(c+c^{-1/3}A_k\right)\right]\\ \times\left[1-c^{-1/3}\frac{\pi\gamma_k}{2}+c^{-2/3}\left(\frac{\pi^2\gamma_k^2}{8}-\frac{2A_k}{15}\right)+c^{-1}\left(-\frac{A_k\gamma_k\pi}{15}-\frac{\beta_k\pi}{2}-\frac{\gamma_k^3\pi^3}{48}\right)\right].\end{aligned}\tag{58}$$

Here $A_k = 2^{-1/3}|r_k|$, where r_k satisfy $\mathrm{Ai}(r_k) = 0$ with $0 > r_0 > r_1 > r_2 > \cdots$.

Next we consider (51) with $z = cs$ and note that $s > r$ in the s-integral in (13), and that $r > 1$ in the shadow region. Then we obtain approximations to $K_{i\omega_k}(cs)$ and $K_{i\omega_k+1}(cs)$ by again using the saddle point method on (51), but now a single saddle at $t = i\sin^{-1}(1/s)$ (thus $|t| < \pi/2$) determines the asymptotic behavior of the integral(s). After a lengthy calculation we obtain

$$\begin{aligned}K_{i\omega_k}(cs) = c^{-1/2}\sqrt{\frac{\pi}{2}}\left(s^2-1\right)^{-1/4}\exp\left[-\sin^{-1}\left(\frac{1}{s}\right)\left(c+c^{-1/3}A_k\right)\right]\\ \times\exp\left[-c\sqrt{s^2-1}\right]\left\{1+c^{-1/3}\left[\frac{-A_k^2}{2\left(s^2-1\right)^{1/2}}-\gamma_k\sin^{-1}\left(\frac{1}{s}\right)\right]\right.\\ +c^{-2/3}\left[\frac{\gamma_k^2\left(\sin^{-1}\left(1/s\right)\right)^2}{2}+\frac{A_k^4+4A_k}{8\left(s^2-1\right)}+\frac{\gamma_kA_k^2\sin^{-1}\left(1/s\right)}{2\left(s^2-1\right)^{\frac{1}{2}}}\right]\\ +c^{-1}\left[\frac{-\gamma_k^3\left(\sin^{-1}\left(1/s\right)\right)^3}{6}-\frac{A_k\gamma_k\sin^{-1}\left(1/s\right)}{5}-\frac{A_k^6}{48\left(s^2-1\right)^{3/2}}\right.\\ -\frac{5}{24\left(s^2-1\right)^{3/2}}-\frac{1}{8\left(s^2-1\right)^{1/2}}-\frac{A_k\gamma_k}{\left(s^2-1\right)^{1/2}}-\frac{5A_k^3}{12\left(s^2-1\right)^{3/2}}\\ \left.\left.-\frac{\left(A_k^4+4A_k\right)\gamma_k\sin^{-1}\left(1/s\right)}{8\left(s^2-1\right)}-\frac{A_k^2\gamma_k^2\left(\sin^{-1}\left(1/s\right)\right)^2}{4\left(s^2-1\right)^{1/2}}\right]+O\left(c^{-4/3}\right)\right\}\end{aligned}\tag{59}$$

and

$$\begin{aligned}K_{i\omega_k+1}(cs) = c^{-1/2}\sqrt{\frac{\pi}{2}}\left(s^2-1\right)^{-\frac{1}{4}}\exp\left[-\sin^{-1}\left(\frac{1}{s}\right)\left(c+c^{-1/3}A_k-i\right)\right]\\ \times\exp\left[-c\sqrt{s^2-1}\right]\left\{1+c^{-1/3}\left[\frac{-A_k^2}{2\left(s^2-1\right)^{1/2}}-\gamma_k\sin^{-1}\left(\frac{1}{s}\right)\right]\right.\\ +c^{-2/3}\left[\frac{\gamma_k^2\left(\sin^{-1}\left(1/s\right)\right)^2}{2}+\frac{A_k^4+4A_k}{8\left(s^2-1\right)}+\frac{\gamma_kA_k^2\sin^{-1}\left(1/s\right)}{2\left(s^2-1\right)^{1/2}}+\frac{iA_k}{\sqrt{s^2-1}}\right]\\ +c^{-1}\left[\frac{-i\left(A_k^3+1\right)}{2\left(s^2-1\right)}-\frac{iA_k\gamma_k\sin^{-1}\left(1/s\right)}{\left(s^2-1\right)^{1/2}}\right.\end{aligned}$$

$$
\begin{aligned}
&- \frac{\gamma_k^3\left(\sin^{-1}(1/s)\right)^3}{6} - \frac{A_k\gamma_k\sin^{-1}(1/s)}{5} - \frac{A_k^6}{48\left(s^2-1\right)^{3/2}} \\
&- \frac{5}{24\left(s^2-1\right)^{3/2}} + \frac{3}{8\left(s^2-1\right)^{1/2}} - \frac{A_k\gamma_k}{\left(s^2-1\right)^{1/2}} - \frac{5A_k^3}{12\left(s^2-1\right)^{3/2}} \\
&\left. - \frac{\left(A_k^4+4A_k\right)\gamma_k\sin^{-1}(1/s)}{8\left(s^2-1\right)} - \frac{A_k^2\gamma_k^2\left(\sin^{-1}(1/s)\right)^2}{4\left(s^2-1\right)^{1/2}}\right] + O\left(c^{-4/3}\right)\left.\vphantom{\frac{1}{1}}\right\}. \qquad (60)
\end{aligned}
$$

Computing the reciprocals of (57) and (58) and using these along with (59) and (60) in (13), we obtain

$$
\begin{aligned}
p = c^{11/6}&\int_r^\infty e^{c(\cos\theta)(2r-s)}\sum_{k=0}^\infty \exp\left[\left(\theta-\sin^{-1}\left(\frac{1}{s}\right)\right)\left(c+c^{1/3}A_k\right)\right] \\
&\times \frac{2^{1/6}\left(1-s\sin\theta\right)}{\sqrt{\pi}\left[\mathrm{Ai}'(r_k)\right]^2 s\left(s^2-1\right)^{1/4}}\exp\left[-c\sqrt{s^2-1}\right] \qquad (61)\\
&\times\left\{1+c^{-1/3}\left[\gamma_k\left(\theta-\sin^{-1}\left(\frac{1}{s}\right)-\frac{A_k^2}{2\left(s^2-1\right)^{1/2}}\right)\right]+O(c^{-2/3})\right\}ds.
\end{aligned}
$$

We approximate (61) by retaining only the $k=0$ term, since it is exponentially larger (by a factor $\exp[O(c^{1/3})]$) than the terms with $k\geq 1$. The result (15) follows upon using Laplace's method to expand the integral. The main contribution comes from near the lower limit of integration $s=r$.

5. Shadow boundary asymptotics. For the intermediate shadow boundary region, where $y-1=O(c^{-1/3})$ and $x>0$, we begin similarly to the derivation of Theorem 2.2. But now we will keep the entire k-series in (13), not just the $k=0$ term. After substituting (59) and (60) and the reciprocals of (57) and (58) into (13) and determining several terms in the expansion of the resulting s-integral using Laplace's method, we are led to

$$
\begin{aligned}
p = \sum_{k=0}^\infty &\frac{c^{5/6}2^{1/6}}{\sqrt{\pi}\left[\mathrm{Ai}'(r_k)\right]^2}\exp\left[c\left(r\cos\theta-\sqrt{r^2-1}+\theta-\sin^{-1}\left(\frac{1}{r}\right)\right)\right] \\
&\times\left(r^2-1\right)^{-1/4}\frac{1-r\sin\theta}{r\cos\theta+\sqrt{r^2-1}}\exp\left[c^{1/3}A_k\left(\theta-\sin^{-1}\left(\frac{1}{r}\right)\right)\right] \\
&\times\left\{1+c^{-1/3}\left[\gamma_k\left(\theta-\sin^{-1}\left(\frac{1}{r}\right)\right)-\frac{A_k^2}{2\sqrt{r^2-1}}\right]\right. \\
&+c^{-2/3}\left[\frac{A_k\left(r^2-1\right)^{-1/2}}{r\cos\theta+\sqrt{r^2-1}}+\frac{16A_k}{15}+\frac{A_k^4+4A_k}{8\left(r^2-1\right)}+\frac{A_k}{1-r\sin\theta}\right. \\
&\qquad\left.+\frac{\gamma_k^2\left[\theta-\sin^{-1}(1/r)\right]^2}{2}+\frac{\gamma_kA_k^2\left[\theta-\sin^{-1}(1/r)\right]}{2\sqrt{r^2-1}}\right] \\
&+c^{-1}\frac{1}{1-r\sin\theta}\left[A_k\gamma_k\left[\theta-\sin^{-1}\left(\frac{1}{r}\right)\right]-\frac{A_k^3}{2\sqrt{r^2-1}}\right. \\
&\qquad\left.\left.-\frac{1}{r\cos\theta+\sqrt{r^2-1}}\right]+O(c^{-1})\right\}. \qquad (62)
\end{aligned}
$$

Note that we have written in (62) only a part of the $O(c^{-1})$ term inside the $\{\cdot\}$. This is the part that contains the factor $(1 - r\sin\theta)^{-1} = (1-y)^{-1}$, which becomes large as $y \to 1$.

In the shadow boundary we have $1 - r\sin\theta = 1 - y = c^{-1/3}Y$ and we rewrite (62) in terms of the variables (x, Y), also using the expansions

$$\sqrt{r^2-1} = x + c^{-1/3}\frac{Y}{x} + c^{-2/3}Y^2\frac{x^2-1}{2x^3} + c^{-1}Y^3\frac{1-x^2}{2x^5} + O(c^{-4/3}), \tag{63}$$

$$\theta - \sin^{-1}\left(\frac{1}{r}\right) = c^{-1/3}\frac{Y}{x} - c^{-2/3}\frac{Y^2}{2x^3} + c^{-1}Y^3\frac{3-2x^2}{6x^5} + O(c^{-4/3}), \tag{64}$$

$$\frac{1 - r\sin\theta}{r\cos\theta + \sqrt{r^2-1}} = -c^{-1/3}\frac{Y}{2x} + c^{-2/3}\frac{Y^2}{4x^3} + c^{-1}Y^3\frac{x^2-2}{8x^5} + O(c^{-4/3}). \tag{65}$$

After substituting (63)–(65) into (62) and simplifying, we obtain (17)–(20). But, this formula is valid only for $Y < 0$ since the series in (17) will not converge for $Y > 0$.

To transform (17)–(20) into the integral expressions in (21)–(24) we first observe that the residues at $z = -A_k$ are

$$\operatorname{Res}\left[e^{-zY/x}\frac{z^n}{\left(\operatorname{Ai}(2^{1/3}z)\right)^2}\right]_{z=-A_k} = \frac{2^{-2/3}}{\left[\operatorname{Ai}'(r_k)\right]^2}e^{A_kY/x}\left[n\left(-A_k\right)^{n-1} - \left(-A_k\right)^n\frac{Y}{x}\right], \tag{66}$$

which we use to obtain the identity

$$\begin{aligned}&\frac{2^{2/3}}{2\pi i}\int_C \left(a_0 + a_1z + a_2z^2 + a_3z^3 + a_4z^4\right)e^{-zY/x}\frac{dz}{\left[\operatorname{Ai}(2^{1/3}z)\right]^2}\\ &= \sum_{k=0}^{\infty}\frac{e^{A_kY/x}}{\left[\operatorname{Ai}'(r_k)\right]^2}\left[a_1 - a_0\frac{Y}{x} - A_k\left(2a_2 - a_1\frac{Y}{x}\right)\right.\\ &\qquad \left. + A_k^2\left(3a_3 - a_2\frac{Y}{x}\right) - A_k^3\left(4a_4 - a_3\frac{Y}{x}\right) - A_k^4a_4\frac{Y}{x}\right],\end{aligned} \tag{67}$$

where $a_i \in \mathbf{R}$ and the integration contour is the imaginary axis.

Using (67) with $a_0 = x^{-1/2}$ and $a_1 = a_2 = a_3 = a_4 = 0$, we see the equivalence of the leading terms in (17) and (21) (with (18) and (22)). A similar calculation shows the equivalence of the second terms in (17) and (21) (with (19) and (23)). In view of the rapid decay of $\operatorname{Ai}^{-2}(2^{1/3}z)$ in the imaginary directions ($z \to \pm i\infty$), the integrals in (22) and (23) converge for all real Y and give the continuation of the sums in (17) to the range $Y > 0$ ($y > 1$).

We next attempt to write R_2 in (20) as a similar integral and show that this is not quite possible. Since (20) is quartic in the A_k, we would need a fourth order polynomial in z as in (67). By examining (20) and writing it in the form of the right-hand side of (67), we would need

$$a_0 = \frac{Y^8}{x^8}\frac{\left(x^2-1\right)^2}{128x^{5/2}} + \frac{Y^5}{x^5}\frac{15-19x^2}{80x^{5/2}} + \frac{Y^2}{x^2}\frac{15-4x^2}{24x^{5/2}} - \frac{x^{1/2}}{Y}. \tag{68}$$

The last $x^{1/2}/Y$ term in (68) is problematic and occurs as a consequence of a "missing" term in (20). From the derivation of (17)–(20), we see that all terms appearing in (18)–(20) arise from the Q_2 contribution to (13) (cf. (38)). Had we considered only the Q_2 contribution in the derivation of (18)–(20), one other term, $-x^{-1/2}$, would also appear in (20). It is absent because it cancels with a contribution from Q_1 (the only other contribution of Q_1 to (17)–(20) is the cancellation of the -1 in $p-1$). The part of (20) that arises from Q_2 (including the "missing" term, $-x^{-1/2}$) can be represented in integral form, using (67) with

$$a_0 = \frac{Y^8}{x^8}\frac{\left(x^2-1\right)^2}{128x^{5/2}} + \frac{Y^5}{x^5}\frac{15-19x^2}{80x^{5/2}} + \frac{Y^2}{x^2}\frac{15-4x^2}{24x^{5/2}}, \tag{69}$$

$$a_1 = \frac{Y^6}{x^6}\frac{x^2-1}{16x^{5/2}} + \frac{Y^3}{x^3}\frac{4x^2-9}{12x^{5/2}} - \frac{1+2x^2}{2x^{5/2}}, \tag{70}$$

$$a_2 = \frac{Y^4}{x^4}\frac{3-x^2}{16x^{5/2}} + \frac{Y}{x}\frac{2x^2+45}{60x^{5/2}}, \tag{71}$$

$$a_3 = -\frac{Y^2}{x^2}\frac{1}{4x^{5/2}}, \tag{72}$$

$$a_4 = \frac{1}{8x^{5/2}}, \tag{73}$$

which gives us the integral portion of (24). Adding to it the contribution from Q_1 (which is $c^{-2/3}x^{-1/2}$ times the leading multiplicative factors in (17)) produces (24).

The first two terms in (21) can be extended for $Y > 0$, and when expanded for $Y \to +\infty$ they match to the asymptotic results for $p-1$ in the illuminated region in [2] when the latter are expanded for $y \downarrow 1$. They also asymptotically match to the results for $p-1$ at the birth of the shadow boundary where $x \approx 0$ and $y \approx 1$, which are also given in [2].

To see the appearance of the uniform concentration at infinity ($= 1$), we need to consider $Y \approx 0$ or, more precisely, $y - 1 = O(c^{-1/2})$, which corresponds to $Y = O(c^{-1/6})$. We thus set $y - 1 = c^{-1/2}\Delta$ or $Y = c^{-1/6}\Delta$ and examine $p-1$ as given by (4) with (9)–(12). We will examine separately the contributions from Q_1 in (11) and Q_2 in (12). We define $Q1$ and $Q2$, which are functions of (r,θ) or (x,y), by

$$Q1 = -2c\cos\theta \int_r^\infty e^{c(2r-s)\cos\theta} Q_1(s,\theta)ds \tag{74}$$

and

$$Q2 = \int_r^\infty e^{c(2r-s)\cos\theta} Q_2(s,\theta)ds \tag{75}$$

and note that $p-1$ is equal to the sum of (74) and (75).

The expansion of $Q2$ on the Δ-scale can be obtained as a limiting form of the integral expressions in (22)–(24), to four orders in $c^{-1/6}$. We begin by noting that $\mathcal{F}_0$ in (22) and $\mathcal{F}_1$ in (23) are smooth functions of Y and can be expanded as $Y =$

$c^{-1/6}\Delta \to 0$ using the Taylor expansion of $\exp[-zY/x] = \exp[-c^{-1/6}\Delta z/x]$. This leads to

$$\begin{aligned}\mathcal{F}_0 = 2^{-1/3}x^{-1/2}\Bigg[&1 - c^{-1/6}2^{-1/3}C_1\frac{\Delta}{x}\\ &+ c^{-1/3}2^{-2/3}C_2\frac{\Delta^2}{2x^2} - c^{-1/2}C_3\frac{\Delta^3}{12x^3} + O(c^{-2/3})\Bigg]\end{aligned} \tag{76}$$

and

$$\mathcal{F}_1 = -x^{-3/2}\left[\frac{C_2}{4} + c^{-1/6}2^{-1/3}\frac{\Delta\,(2-C_3)}{4x} + O(c^{-1/3})\right]. \tag{77}$$

The constants C_i above are defined in (30). The integral portion of (24) (which arose from $Q2$) remains $O(1)$ as $Y \to 0$ and will not contribute to (25) until the fifth order. We now change variables in (21) from Y to Δ and expand the exponential $\exp\left[c^{-1/2}\Delta^3/(6x^3)\right]$. Using (76) and (77), we thus obtain

$$\begin{aligned}Q2 &\sim c^{1/2}2^{-1/6}\pi^{-1/2}\exp\left[-c^{1/3}\frac{Y^2}{2x}\right]\exp\left[\frac{Y^3}{6x^3}\right]\left\{\mathcal{F}_0 + c^{-1/3}\mathcal{F}_1\right\}\\ &= \frac{c^{1/2}}{\sqrt{2\pi x}}\exp\left(-\frac{\Delta^2}{2x}\right)\Bigg\{1 - c^{-1/6}\left(\frac{2^{-1/3}C_1}{\sqrt{x}}\right)\frac{\Delta}{\sqrt{x}}\\ &\quad + c^{-1/3}\left(\frac{2^{-2/3}C_2}{2x}\right)\left[\left(\frac{\Delta}{\sqrt{x}}\right)^2 - 1\right]\\ &\quad + c^{-1/2}\left(\frac{2-C_3}{12x\sqrt{x}}\right)\left[\left(\frac{\Delta}{\sqrt{x}}\right)^3 - 3\frac{\Delta}{\sqrt{x}}\right] + O(c^{-2/3})\Bigg\}.\end{aligned} \tag{78}$$

We see that the expansion of $Q2$ involves the Hermite polynomials in the similarity variable $\Delta/\sqrt{x}$.

Next we consider $Q1$ on the Δ-scale. Substituting (50) into (74) yields

$$Q1 = -1 + \mathrm{Im}\left[\int_r^\infty e^{c(2r-s)\cos\theta}\sum_{k=0}^{\infty}\frac{4\pi\cos\theta\cosh(\omega_k\theta)K_{i\omega_k}(cs)}{\sinh(\omega_k\pi)\dot{K}_{i\omega_k}(c)K_{i\omega_k+1}(c)}ds\right]. \tag{79}$$

In the derivation of the shadow region asymptotics we needed to consider only the $k = 0$ term of the series. In the shadow boundary intermediate region (cf. (17)) we needed to keep all terms of the series, and this led to the first term in the right-hand side of (24) for $Y < 0$. On the Δ-scale, not only will we have to keep all terms of the k-series, but the terms with k large will actually play a larger role. Our previous expansions of the modified Bessel functions in (57)–(59) were derived under the assumption $r_k = O(1)$ and break down when $r_k = O(c^{1/6})$, since then the second terms become of the same order as the first terms. Since $r_k = O(k^{2/3})$ for $k \to \infty$ [15], this occurs when $k = O(c^{1/4})$, so our previous expansions are valid only for the $k \ll c^{1/4}$ terms of the series. We redo the saddle point analysis used to obtain (57)–(59), this time considering $r_k = O(c^{1/6})$. This yields to leading order

$$\dot{K}_{i\omega_k}(c) \sim c^{-2/3}2^{2/3}\pi i\mathrm{Ai}'(r_k)\exp\left[-\frac{\pi}{2}\left(c + c^{1/3}A_k + c^{-1/3}\gamma_k\right)\right], \tag{80}$$

$$K_{i\omega_k+1}(c) \sim -c^{-2/3}2^{2/3}\pi\mathrm{Ai}'(r_k)\exp\left[-\frac{\pi}{2}\left(c+c^{1/3}A_k+c^{-1/3}\gamma_k\right)\right], \tag{81}$$

and

$$\begin{aligned} K_{i\omega_k}(cs) &\sim c^{-1/2}\left(s^2-1\right)^{-1/4}\sqrt{\frac{\pi}{2}}\exp\left[-2^{-5/3}\left(s^2-1\right)^{-1/2}\frac{r_k^2}{c^{1/3}}\right] \\ &\times\exp\left[-c\sqrt{s^2-1}\right]\exp\left[-\sin^{-1}\left(\frac{1}{s}\right)\left(c+c^{1/3}A_k+c^{-1/3}\gamma_k\right)\right]. \end{aligned} \tag{82}$$

Note that $\gamma_k = O(c^{1/3})$ for $r_k = O(c^{1/6})$. Substituting (80)–(82) into (79) gives

$$\begin{aligned} Q1 \sim -1 &+ \int_r^\infty \exp\left[c\left((2r-s)\cos\theta-\sqrt{s^2-1}+\theta-\sin^{-1}\left(\frac{1}{s}\right)\right)\right] \\ &\times\frac{c^{5/6}2^{1/6}\cos\theta}{\sqrt{\pi}\left(s^2-1\right)^{1/4}}\sum_{k=0}^{\infty}\left\{\exp\left[-c^{1/3}2^{-1/3}r_k\left(\theta-\sin^{-1}\left(\frac{1}{s}\right)\right)\right]\right. \\ &\left.\times\exp\left[-\frac{r_k^2}{4}\left(c^{-1/3}2^{1/3}\left(s^2-1\right)^{-1/2}\right)\right]\left[\mathrm{Ai}'(r_k)\right]^{-2}\right\}ds. \end{aligned} \tag{83}$$

We now replace the k-series with an integral. To do so, we will utilize an identity derived in [16],

$$\begin{aligned} &\int_0^\infty \mathrm{Ai}(\tau+M)e^{N\tau}d\tau + 2\mathrm{Re}\left[\int_0^\infty\frac{\mathrm{Ai}(\omega\tau+M)}{\mathrm{Ai}(\omega\tau)}\mathrm{Ai}(\tau)e^{\omega N\tau}d\tau\right] \\ &= e^{-MN}e^{N^3/3}-\sum_{k=0}^{\infty}e^{Nr_k}\frac{\mathrm{Ai}(r_k+M)}{\left[\mathrm{Ai}'(r_k)\right]^2}, \end{aligned} \tag{84}$$

where $\omega = \exp[2\pi i/3]$. Note that the series in the right-hand side of (84) converges only for $N > 0$, but the integrals in the left-hand side converge for all N. First we expand the Airy functions for large M using the well-known expansion [15]

$$\mathrm{Ai}(\tau+M) \sim \frac{1}{2\sqrt{\pi}}M^{-1/4}\exp\left[-\frac{2}{3}M^{3/2}\right]\exp\left[-\tau\sqrt{M}-\frac{\tau^2}{4\sqrt{M}}\right]. \tag{85}$$

For $M \to \infty$ the second integral in (84) will be asymptotically negligible compared to the first. After replacing the Airy functions with their expansions we use the exact relationship $-MN + N^3/3 = -2M^{3/2}/3 + M^{1/2}(N-M^{1/2})^2 + (N-M^{1/2})^3/3$ and make the change of variables $\tau = 2^{1/4}M^{1/4}q$ in the first integral in (84). We then cancel the common factors $\exp\left[-2M^{3/2}/3\right]$ and rearrange terms to obtain

$$\begin{aligned} &\frac{2^{1/4}}{2\sqrt{\pi}}\int_0^\infty \exp\left[2^{1/4}M^{1/4}\left(N-M^{1/2}\right)q\right]\exp\left[-\frac{q^2}{2\sqrt{2}}\right]dq \\ &\qquad -\exp\left[M^{1/2}\left(N-M^{1/2}\right)^2+\frac{1}{3}\left(N-M^{1/2}\right)^3\right] \\ &\sim -\frac{M^{-1/4}}{2\sqrt{\pi}}\sum_{k=0}^{\infty}\frac{\exp\left[r_k\left(N-M^{1/2}\right)\right]\exp\left[-\frac{r_k^2}{4}M^{-1/2}\right]}{\left[\mathrm{Ai}'(r_k)\right]^2}. \end{aligned} \tag{86}$$

This result applies for $N,\ M \to \infty$ with $M^{1/4}\left(N-M^{1/2}\right) = O(1)$. To apply (86) to the k-sum in (83), we set $M = 2^{-2/3}c^{2/3}\left(s^2-1\right)$ and $N = 2^{-1/3}c^{1/3}[\left(s^2-1\right)^{1/2} -$

$\left(\theta - \sin^{-1}(1/s)\right)]$, which yields

$$\begin{aligned}
&\sum_{k=0}^{\infty} \frac{\exp\left[-r_k\left(2^{-1/3}c^{1/3}\right)\left(\theta-\sin^{-1}(1/s)\right)\right]\exp\left[-c^{-1/3}2^{-5/3}r_k^2\left(s^2-1\right)^{-1/2}\right]}{\left[\mathrm{Ai}'(r_k)\right]^2} \\
&\quad\sim\; c^{1/6}2^{5/6}\sqrt{\pi}\left(s^2-1\right)^{1/4}\exp\left[\frac{c}{2}\sqrt{s^2-1}\left(\theta-\sin^{-1}\left(\frac{1}{s}\right)\right)^2\right] \\
&\times\exp\left[-\frac{c}{6}\left(\theta-\sin^{-1}\left(\frac{1}{s}\right)\right)^3\right]-c^{1/6}2^{1/12}\left(s^2-1\right)^{1/4}\int_0^{\infty}\exp\left[-\frac{q^2}{2\sqrt{2}}\right] \\
&\qquad\times\exp\left[-c^{1/2}2^{-1/4}\left(s^2-1\right)^{1/4}\left(\theta-\sin^{-1}\left(\frac{1}{s}\right)\right)q\right]dq.
\end{aligned}\tag{87}$$

After substituting (87) into (83) and asymptotically evaluating the integral over s, we have

$$\begin{aligned}
Q1 \sim\; &-1+\frac{2r\cos\theta}{r\cos\theta+\sqrt{r^2-1}}\exp\!\left[c\left(r\cos\theta-\sqrt{r^2-1}+\theta-\sin^{-1}\left(\frac{1}{r}\right)\right)\right] \\
&\times\left\{\exp\left[\frac{c}{2}\sqrt{r^2-1}\left(\theta-\sin^{-1}\left(\frac{1}{r}\right)\right)^2-\frac{c}{6}\left(\theta-\sin^{-1}\left(\frac{1}{r}\right)\right)^3\right]\right. \\
&\left.-\frac{2^{1/4}}{2\sqrt{\pi}}\int_0^{\infty}\exp\left[-c^{1/2}2^{-1/4}\left(r^2-1\right)^{1/4}\left(\theta-\sin^{-1}\left(\frac{1}{r}\right)\right)q-\frac{q^2}{2\sqrt{2}}\right]dq\right\}.
\end{aligned}\tag{88}$$

Finally we set $Y = c^{-1/6}\Delta$ in (63) and (64) and rewrite (88) in terms of (x, Δ). To leading order this yields

$$Q1 \sim -\frac{2^{1/4}}{2\sqrt{\pi}}\exp\left[-\frac{\Delta^2}{2x}\right]\int_0^{\infty}\exp\left[-2^{-1/4}q\frac{\Delta}{\sqrt{x}}-\frac{q^2}{2\sqrt{2}}\right]dq.\tag{89}$$

Substituting (89) and (78) into $p = 1 + Q1 + Q2$ gives the result in (25)–(29). The error function in (89) reveals how the concentration p transitions from being small in the shadow region to being approximately unity in the illuminated region.

6. Shadow part of obstacle boundary. The derivation of the asymptotics for the nested layers close to the obstacle on the shadow side is similar to the derivation of the outer shadow region from Theorem 2.2. The main difference is that we will have to reexamine the expansions of the modified Bessel functions involving s. Our previous expansions (59) and (60) break down as $s \to 1$.

For the intermediate layer near the obstacle we again use (51) but make the change of variables

$$s = 1 + c^{-2/3}\rho\tag{90}$$

and approximate the Bessel functions by Airy functions, as

$$\begin{aligned}
K_{i\omega_k}(cs) = c^{-1/3}2^{1/3}\pi\mathrm{Ai}\left(\widehat{\rho}_k\right)\exp\left[-\frac{\pi}{2}\left(c+c^{-1/3}A_k\right)\right] \\
\times\left\{1-c^{-1/3}\frac{\pi\gamma_k}{2}+O\left(c^{-2/3}\right)\right\}
\end{aligned}\tag{91}$$

and

$$\begin{aligned} K_{i\omega_k+1}(cs) &= c^{-1/3}2^{1/3}\pi i \ \exp\left[-\frac{\pi}{2}\left(c+c^{-1/3}A_k\right)\right] \\ &\times\left\{\mathrm{Ai}\left(\widehat{\rho}_k\right)+c^{-1/3}\left(2^{1/3}i\mathrm{Ai}'\left(\widehat{\rho}_k\right)-\frac{\pi\gamma_k}{2}\mathrm{Ai}\left(\widehat{\rho}_k\right)\right)+O(c^{-2/3})\right\}, \end{aligned}\tag{92}$$

where $\widehat{\rho}_k = 2^{1/3}(\rho - A_k)$. We use (91), (92) and the reciprocals of (57) and (58) in (13). Only the $k = 0$ term in the series contributes, and after simplification we get

$$\begin{aligned} p &= c^{4/3}\frac{2\left(1-\sin\theta\right)}{\left[\mathrm{Ai}'(r_0)\right]^2}\exp\left[c\left(2r-1\right)\left(\cos\theta\right)+\left(c+c^{1/3}A_0\right)\left(\theta-\frac{\pi}{2}\right)\right] \\ &\times\int_{c^{2/3}(r-1)}^{\infty}e^{-c^{1/3}\rho\cos\theta}\mathrm{Ai}\left[2^{1/3}\left(\rho-A_0\right)\right]\left\{1+c^{-1/3}\gamma_0\left(\theta-\frac{\pi}{2}\right)+O(c^{-2/3})\right\}d\rho. \end{aligned}\tag{93}$$

We use Laplace's method to expand the integral in (93). We set $\eta = c^{2/3}\left(r-1\right) = O(1)$ (thus $r - 1 = O(c^{-2/3})$), and then the major contribution comes from the lower limit $\rho = \eta$. Setting $u = \rho - \eta$ and expanding for $u \to 0$ gives

$$\begin{aligned} p = c^{4/3}&\exp\left[c\left(2r-1\right)\cos\theta+\left(c+c^{1/3}A_0\right)\left(\theta-\frac{\pi}{2}\right)-c^{1/3}\eta\cos\theta\right] \\ &\times\ \frac{2\left(1-\sin\theta\right)}{\left[\mathrm{Ai}'(r_0)\right]^2}\int_0^{\infty}\exp\left[-c^{1/3}u\cos\theta\right] \\ &\times\ \left\{\mathrm{Ai}\left[2^{1/3}\left(\eta-A_0\right)\right]+2^{1/3}\mathrm{Ai}'\left[2^{1/3}\left(\eta-A_0\right)\right]u+O(u^2)\right\} \\ &\times\ \left[1+c^{-1/3}\gamma_0\left(\theta-\frac{\pi}{2}\right)+O(c^{-2/3})\right]du, \end{aligned}\tag{94}$$

and this leads to (31).

For the inner layer near the obstacle we use (51) with the change of variables

$$s = 1 + c^{-1}\sigma\tag{95}$$

to obtain

$$\begin{aligned} K_{i\omega_k}(cs) &= c^{-2/3}2^{2/3}\pi\sigma\mathrm{Ai}'\left(r_k\right)\exp\left[-\frac{\pi}{2}\left(c+c^{-1/3}A_k\right)\right] \\ &\times\left\{1-c^{-1/3}\frac{\pi\gamma_k}{2}+O\left(c^{-2/3}\right)\right\} \end{aligned}\tag{96}$$

and

$$\begin{aligned} K_{i\omega_k+1}(cs) &= c^{-2/3}2^{2/3}\pi i\left(\sigma+i\right)\mathrm{Ai}'\left(r_k\right)\exp\left[-\frac{\pi}{2}\left(c+c^{-1/3}A_k\right)\right] \\ &\times\left\{1-c^{-1/3}\frac{\pi\gamma_k}{2}+O\left(c^{-2/3}\right)\right\}. \end{aligned}\tag{97}$$

We use (96), (97) and the reciprocals of (57) and (58) in (13), retain only the $k = 0$ term, and set $\xi = c\left(r-1\right) = O(1)$ to obtain

$$\begin{aligned} p &= c^{2/3}\frac{2^{4/3}\left(1-\sin\theta\right)}{\mathrm{Ai}'(r_0)}\exp\left[c\left(2r-1\right)\cos\theta+\left(c+c^{1/3}A_0\right)\left(\theta-\frac{\pi}{2}\right)\right] \\ &\times\int_{\xi}^{\infty}\sigma e^{-\sigma\cos\theta}\left[1+c^{-1/3}\gamma_0\left(\theta-\frac{\pi}{2}\right)+O(c^{-2/3})\right]d\sigma. \end{aligned}\tag{98}$$

Evaluating the integral leads to (33).

7. Conclusion. To summarize, we have obtained alternate representations (cf. (13) and (14)) of the concentration profile of some substance that undergoes drift–diffusion past a circular obstacle. From the new formulas we obtained detailed asymptotic results for the concentration in the shadow region, including the shadow boundary and the shadow side of the obstacle. These asymptotic results do not seem to be obtainable from the previous forms of the solution in [1] and [2]. They show that in the shadow region the concentration is exponentially small in c, the parameter measuring the ratio of drift to diffusion, with additional factors that vary exponentially in $c^{1/3}$ and algebraically in c. The smallness is due mainly to the term $r\cos\theta + \theta - \arcsin(1/r) - \sqrt{r^2-1} < 0$ in the exponent in (15). The concentration remains small if $r \approx 1$ (cf. Theorem 2.4) as long as $|\theta| < \pi/2$. In the shadow boundaries, where $y \approx \pm 1$ with $x > 0$, the concentration profile undergoes the transition from $p \approx 1$ to $p \approx 0$. This is governed by the two nested layers in Theorem 2.3. For the coarser spatial scale $y - (\pm 1) = O(c^{-1/3})$ the transition has already taken place and the solution involves Airy functions. For the finer spatial scale $y - (\pm 1) = O(c^{-1/2})$ the transition from $p \approx 1$ to $p \approx 0$ occurs via the error function that arises as a part of the fourth term in the asymptotic expansion. The leading term on this scale shows (cf. (26)) a Gaussian particle profile and a large $O(\sqrt{c})$ concentration, with the profile diffusing further with increasing x. For sufficiently large x the shadow region disappears, as we must have $p \to 1$ as $r \to \infty$ in any direction.

The structure of the shadow boundary is much different from corresponding scattering problems, where an incoming plane wave disappears in the region Ω_s via a Fresnel integral at the leading asymptotic order.

While exact solutions can be obtained only for simple geometries such as circles or spheres, we are currently analyzing such problems directly, via singular perturbation techniques such as geometrical optics and asymptotic matching. Preliminary results show that Theorems 2.2–2.4 can be obtained, though less rigorously, directly from the PDE problem (1)–(3). With the direct methods we are also currently investigating more complex geometries such as ellipses and general convex obstacles.

NEW CONDITIONS ON THE EXISTENCE AND STABILITY OF PERIODIC SOLUTION IN LOTKA–VOLTERRA'S POPULATION SYSTEM[*]

YONGHUI XIA[†] AND MAOAN HAN[‡]

Abstract. In this paper, we revisit the famous periodic Lotka–Volterra competitive system. Some new and interesting sufficient conditions are obtained to guarantee the existence and global asymptotic stability of the periodic solution in the Lotka–Volterra competitive system. Our method is based on Mawhin's coincidence degree, matrix's spectral theory, and some new estimation techniques for the priori bounds of unknown solutions to the equation $Lx = \lambda Nx$. Due to this new method, our new results are much different from the known results in the previous literature. Finally, some examples and their simulations show the feasibility of our results.

Key words. global asymptotic stability, Lotka–Volterra system, periodic solution

1. Introduction.

In recent years, the application of theories of functional differential equations in mathematical ecology has developed rapidly. Various mathematical models have been proposed in the study of population dynamics, ecology, and epidemiology (see, e.g., [1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40, 41]). One of the famous models for dynamics of population is the Lotka–Volterra system. Due to its theoretical and practical significance, the Lotka–Volterra systems have been studied extensively (see, e.g., [1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 27, 28, 29, 30, 31, 32, 33, 34]). A basic model is the two-species competitive system which takes the form of

$$\left\{\begin{array}{rcl} \dot{y}_1(t) & = & y_1(t)[b_1 - a_{11}y_1(t) - a_{12}y_2(t)], \\ \dot{y}_2(t) & = & y_2(t)[b_2 - a_{21}y_1(t) - a_{22}y_2(t)]. \end{array}\right. \tag{1}$$

Gopalsamy [8] has studied system (1) and obtained that if $a_{11}b_1 > a_{12}b_2$, $a_{22}b_2 > a_{21}b_1$, $a_{11} > a_{21}$, and $a_{22} > a_{12}$, then system (1) has a unique equilibrium which is globally asymptotically stable.

Then Gopalsamy generalized the results to an n-species competitive system in [9, 10]. The autonomous n-species competitive model can be represented as follows:

$$\dot{y}_i(t) = y_i(t)\left[b_i - \sum_{j=1}^{n} a_{ij}y_j(t)\right], \qquad i = 1, 2, \ldots, n. \tag{2}$$

Recently, Xia, Han, and Ding [19] studied systems (1) and (2). By combining matrix's spectral theory with the Lyapunov function, some new sufficient conditions were obtained to guarantee the global asymptotic stability of a unique equilibrium for the Lotka–Volterra system. Their results generalize and significantly improve the known results in [8, 9, 10].

However, most of the literature mentioned above requires the coefficients of the system to be constants. As we know, the variation of the environment plays an important role in many biological and ecological dynamical systems. In particular, the effects of a periodically varying environment are important for evolutionary theory as the selective forces on a system in a fluctuating environment differ from those in a stable environment. If we consider the effects of the environmental factors, the assumption of periodicity of parameters is realistic and important (e.g., seasonal effects of weather, food supplies, mating habits, harvesting, etc.). To incorporate the varying properties of the parameters into the model, many authors considered the nonautonomous n-species competitive system (see, e.g., [2, 3, 4, 5, 7, 9, 11])

$$\dot{y}_i(t) = y_i(t)\left[b_i(t) - \sum_{j=1}^{n} a_{ij}(t)y_j(t)\right], \qquad i = 1, 2, \ldots, n, \tag{3}$$

where the coefficients are assumed to be continuous ω-periodic functions, i.e., $b_i(t+\omega) = b_i(t)$ and $a_{ij}(t+\omega) = a_{ij}(t)$, $i, j = 1, 2, \ldots, n$. For the biological point of view, it is always assumed that the parameters b_i, a_{ij}, $i, j = 1, 2, \ldots, n$, are nonnegative and a_{ii} is strictly positive. System (3) is supplemented with the initial condition

$$y_i(t_0) = y_i^0, \quad y_i^0 > 0, \qquad i = 1, 2, \ldots, n. \tag{4}$$

It is easy to see that for every given positive initial value condition (4), the corresponding solution of (3) remains positive for all $t \geq 0$. That is, the positive cones of R^n are positive invariant with respect to system (3).

To study the existence and global asymptotic stability of periodic solution for system (3), many approaches are employed, such as Brower fixed point, Lyapunov function, comparison theorem, Mawhin's coincidence degree, and so on. In particular, Mawhin's coincidence degree theory is a powerful tool to study the existence of periodic solutions. However, different estimation techniques for the priori bounds of unknown solutions to the equation $Lx = \lambda Nx$ may lead to different results. There are many papers obtaining the priori bounds by employing the inequality

$$|x(t)| \leq |x(t_0)| + \int_0^{\omega} |\dot{x}(t)|dt.$$

For more details, one can refer to [11, 27, 28, 29, 30, 31, 32, 33, 34, 35]. To the best of our knowledge no author has been concerned with employing the matrix's spectral theory to obtain the priori bounds for biological systems so far. For this reason, our aim is to propose a new methodology to revisit system (3). By combing matrix's spectral theory with Mawhin's coincidence degree theory, we manage to obtain a set of new and interesting conditions which are much different from the known results in the literature.

The structure of this paper is as follows. In section 2, some new and interesting sufficient conditions for the existence of periodic solution of system (3) are obtained. Section 3 is devoted to examining the stability of this periodic solution. In section 4, some discussions and remarks on the difference between our results and the previous ones are presented. Finally, some examples and their simulations are given to show the feasibility of our results.

2. Existence of periodic solutions. In this section, we shall obtain some new sufficient conditions for the existence of periodic solution of system (3).

For convenience, we introduce some notation, definitions, and lemmas. If $f(t)$ is a continuous ω-periodic function defined on R, denote

$$\underline{f} = \min_{t\in[0,\omega]} |f(t)|, \qquad \overline{f} = \max_{t\in[0,\omega]} |f(t)|, \qquad m(f) = \frac{1}{\omega}\int_0^{\omega} f(t)dt.$$

For matrix $D = (d_{ij})_{n\times n}$, D^T denotes the transpose of D, and E_n denotes the identity matrix of size n. $\mathrm{diag}(\cdot)$ represents a diagonal matrix with specified diagonal entries. A matrix or vector $A \geq 0$ means that all entries of A are greater than or equal to zero. $A > 0$ can be defined similarly. For matrices or vectors A and B, $A \geq B$ (resp., $A > B$) means that $A - B \geq 0$ (resp., $A - B > 0$). We denote the spectral radius of the matrix A by $\rho(A)$.

Definition 2.1 (see [34, 35]). *Let X, Z be normed real Banach spaces, let $L : \mathrm{Dom}L \subset X \to Z$ be a linear mapping, and let $N : X \to Z$ be a continuous mapping. The mapping L is called a Fredholm mapping of index zero if* $\mathrm{dim}KerL = \mathrm{codim}\ \mathrm{Im}L < +\infty$ *and* $\mathrm{Im}L$ *is closed in Z. If L is a Fredholm mapping of index zero and there exist continuous projectors $P : X \to X$ and $Q : Z \to Z$ such that* $\mathrm{Im}P = \mathrm{Ker}L$, $\mathrm{Ker}Q = \mathrm{Im}L = \mathrm{Im}(I - Q)$, *it follows that* $L|\mathrm{dom}L \cap \mathrm{Ker}P : (I - P)X \to \mathrm{Im}L$ *is invertible. We denote the inverse of that map by K_P. If Ω is an open bounded subset of X, the mapping N will be called L-compact on $\overline{\Omega}$ if $QN(\overline{\Omega})$ is bounded and $K_P(I - Q)N : \overline{\Omega} \to X$ is compact. Since* $\mathrm{Im}Q$ *is isomorphic to* $\mathrm{Ker}L$, *there exists an isomorphism* $J : \mathrm{Im}Q \to \mathrm{Ker}L$.

Definition 2.2 (see [35]). *Let $\Omega \subset R^n$ be open and bounded, $f \in C^1(\Omega, R^n) \cap C(\overline{\Omega}, R^n)$, and $y \in R^n/f(\partial\Omega \cup N_f)$, i.e., y is a regular value of f. Here, $N_f = \{x \in \Omega : J_f(x) = 0\}$, the critical set of f, and J_f is the Jacobian of f at x. Then the degree $deg\{f, \Omega, y\}$ is defined by*

$$\deg\{f, \Omega, y\} = \sum_{x\in f^{-1}(y)} \mathrm{sgn} J_f(x)$$

with the agreement that $\sum \phi = 0$. For more details about degree theory, the reader is referred to [35].

Lemma 2.1 (continuation theorem [34]). *Let $\Omega \subset X$ be an open and bounded set. Let L be a Fredholm mapping of index zero, and let N be L-compact on $\overline{\Omega}$ (i.e., $QN(\overline{\Omega})$ is bounded and $K_P(I - Q)N : \overline{\Omega} \to X$ is compact). Assume the following:*

(i) *For each $\lambda \in (0, 1)$, $x \in \partial\Omega \cap \mathrm{Dom}L$, $Lx \neq \lambda Nx$.*

(ii) *For each $x \in \partial\Omega \cap \mathrm{Ker}L$, $QNx \neq 0$ and* $\deg\{JQN,\ \Omega \cap \mathrm{Ker}L, 0\} \neq 0$.

Then $Lx = Nx$ has at least one solution in $\overline{\Omega} \cap \mathrm{Dom}L$.

Definition 2.3 (see [25, 42]). *A real $n \times n$ matrix $A = (a_{ij})$ is said to be an M-matrix if $a_{ij} \leq 0$, $i, j = 1, 2, \ldots, n$, $i \neq j$, and $A^{-1} \geq 0$.*

Lemma 2.2 (see [25, 26]). *Let $A \geq 0$ be an $n \times n$ matrix and let $\rho(A) < 1$. Then $(E_n - A)^{-1} \geq 0$, where E_n denotes the identity matrix of size n.*

Lemma 2.3 (see [20, 29]). *Assume that*

$$m(b_i) > \sum_{j=1,j\neq i}^{n} m(a_{ij}) \frac{m(b_j)}{m(a_{jj})}, \qquad i = 1, 2, \ldots, n.$$

Then the system of algebraic equations

$$\sum_{j=1}^{n} m(a_{ij})u_j = m(b_i), \qquad i = 1, 2, \dots, n,$$

has a unique solution $(u_1^*, u_2^*, \dots, u_n^*)^T \in R_+^n$ *with* $u_i^* > 0$.

In what follows, we shall introduce some function spaces and their norms, which are valid throughout this paper. Denote

$$X = \{x(t) = (x_1(t), x_2(t), \dots, x_n(t))^T \in C^1(R, R^n) | x(t+\omega) = x(t) \text{ for all } t \in R\},$$

$$Z = \{x(t) = (x_1(t), x_2(t), \dots, x_n(t))^T \in C(R, R^n) | x(t+\omega) = x(t) \text{ for all } t \in R\}.$$

The norms are given by

$$|x_i(t)|_0 = \max_{t\in[0,\omega]} |x_i(t)|, \qquad |x_i(t)|_1 = |x_i(t)|_0 + |\dot{x}_i(t)|_0, \quad i = 1, 2, \dots, n,$$

$$\|x(t)\|_0 = \max_{1\le i\le n} \{|x_i(t)|_0\}, \qquad \|x(t)\|_1 = \|x(t)\|_0 + \|\dot{x}(t)\|_0 = \max_{1\le i\le n} \{|x_i(t)|_1\}.$$

Obviously, X and Z, respectively endowed with the norms $\|\cdot\|_1$ and $\|\cdot\|_0$, are Banach spaces.

THEOREM 2.1. *Assume that the following conditions hold:*

(H₁) $m(b_i) > \sum_{j=1, j\neq i}^{n} m(a_{ij}) \dfrac{m(b_j)}{m(a_{jj})}$, $i = 1, 2, \dots, n$;

(H₂) $\rho(\mathcal{K}) < 1$, *where* $\mathcal{K} = (\Gamma_{ij})_{n\times n}$ *and* $\Gamma_{ij} = \begin{cases} 0, & i = j, \\ \overline{a}_{ij}\underline{a}_{jj}^{-1}, & i \neq j. \end{cases}$

Then system (3) *has at least one positive* ω*-periodic solution.*

Proof. Note that every solution $y(t) = (y_1(t), y_2(t), \dots, y_n(t))^T$ of system (3) with the initial value condition (4) is positive. Make the change of variables

$$x_i(t) = \ln y_i(t), \quad i = 1, 2, \dots, n. \tag{5}$$

Then system (3) can be rewritten as

$$\dot{x}_i(t) = b_i(t) - \sum_{j=1}^{n} a_{ij}(t) e^{x_j(t)}, \quad i = 1, 2, \dots, n. \tag{6}$$

Obviously, system (3) has at least one ω-periodic solution which is equivalent so that system (6) has at least one ω-periodic solution. To prove Theorem 2.1, our main tasks are to construct the operators (i.e., L, N, P, and Q) appearing in Lemma 2.1 and to find an appropriate open set Ω satisfying conditions (i), (ii) in Lemma 2.1. To this end, we proceed with three steps.

Step 1. In this step, we intend to construct the operators appearing in Lemma 2.1 and verify that they satisfy the conditions of Lemma 2.1. For any $x(t) \in X$, in view of the periodicity, it is easy to check that

$$\Delta_i(x, t) = b_i(t) - \sum_{j=1}^{n} a_{ij}(t) e^{x_j(t)} \in Z.$$

Now we define the operators $L : \mathrm{DomL} \subset \mathrm{X} \to \mathrm{Z}$ and $N : X \to Z$ as follows:

$$X \ni x(t) \to (Lx)(t) = \frac{\mathrm{d}x(t)}{\mathrm{d}t} \in Z,$$

$$X \ni x(t) \to (Nx)(t) = \big((Nx)_1(t), (Nx)_2(t), \ldots, (Nx)_n(t)\big)^T \in Z,$$

where

$$(Nx)_i(t) = \Delta_i(x,t), \quad i = 1, 2, \ldots, n.$$

Define, respectively, the projectors $P : X \to X$ and $Q : Z \to Z$ by

$$Px(t) = \frac{1}{\omega}\int_0^\omega x(t)dt, \qquad Qz(t) = \frac{1}{\omega}\int_0^\omega z(t)dt, \quad x \in X,\ z \in Z.$$

It is obvious that the domain of L in X is actually the whole space, and

$$\mathrm{Ker}L = \{x(t) \in X | Lx(t) = 0,\ \text{i.e., } \dot{x}(t) = 0\} = R^n,$$

$$\mathrm{Im}L = \left\{z(t) \in Z | \int_0^\omega z(t)dt = 0\right\} \text{ is closed in } Z.$$

Moreover, P, Q are continuous operators such that

$$\mathrm{Im}P = R^n = \mathrm{Ker}L, \qquad \mathrm{Im}L = \mathrm{Ker}Q = \mathrm{Im}(I - Q),$$

and

$$\mathrm{dimKer}L = \mathrm{codimIm}L = n < +\infty.$$

It follows that L is a Fredholm mapping of index zero. Furthermore, the generalized inverse (to L) $K_P : \mathrm{Im}L \to \mathrm{Dom}L \cap \mathrm{Ker}P$ exists, which is given by

$$K_P(y) = \int_0^t y(s)ds - \frac{1}{\omega}\int_0^\omega \int_0^t y(s)dsdt.$$

Then $QN : X \to Z$ and $K_P(I - Q)N : X \to X$ are defined by

$$QNx = \left(\frac{1}{\omega}\int_0^\omega \Delta_1(x,t)\mathrm{d}t, \frac{1}{\omega}\int_0^\omega \Delta_2(x,t)\mathrm{d}t, \ldots, \frac{1}{\omega}\int_0^\omega \Delta_n(x,t)\mathrm{d}t\right)^T,$$

$$K_P(I - Q)Nx = (\Psi_1(x,t), \Psi_2(x,t), \ldots, \Psi_n(x,t))^T, \tag{7}$$

where

$$\Psi_k(x,t) = \int_0^t \Delta_k(x,u)du - \frac{1}{\omega}\int_0^\omega \int_0^t \Delta_k(x,u)dudt - \Big(\frac{t}{\omega} - \frac{1}{2}\Big)\int_0^\omega \Delta_k(x,u)du,$$
$$k = 1, 2, \ldots, n.$$

Clearly, QN and $K_P(I - Q)N$ are continuous. Now we turn to the fact that for any open bounded set $\Omega \subset X$, denoted by

$$\Omega = \{x(t) \in X \big| |x_i(t)|_1 = |x_i(t)|_0 + |\dot{x}_i(t)|_0 < h_i\},$$

the mapping N is L-compact on $\overline{\Omega}$. Here, the constants h_i are independent of the choice of $x(t)$. In view of Definition 2.1, to show the above fact, it suffices to show that $QN(\overline{\Omega})$ is bounded and $K_P(I-Q)N : \overline{\Omega} \to X$ is compact. We first arrive at

$$|(QNx)_i|_0 = \left|\frac{1}{\omega}\int_0^\omega \Delta_i(x,t)dt\right|_0 \leq |\Delta_i(x,t)|_0 := M_i \text{ for all } x \in \overline{\Omega},$$

which implies that $QN(\overline{\Omega})$ is bounded in the space $(Z, \|\cdot\|_0)$. Second, we shall show that $\big(K_P(I-Q)Nx\big)(\overline{\Omega})$ is relatively compact in the space $(X, \|\cdot\|_1)$. In fact, it follows from (7) that

$$(K_P(I-Q)Nx)' = (\Psi_1'(x,t), \Psi_2'(x,t), \ldots, \Psi_n'(x,t))^T, \tag{8}$$

where $' = d/dt$ and

$$\Psi_k'(x,t) = \Delta_k(x,t) - \frac{1}{\omega}\int_0^\omega \Delta_k(x,u)du, \quad k = 1, 2, \ldots, n.$$

This, combined with (7), gives

$$\begin{aligned} |\big(K_P(I-Q)Nx\big)_i(t)|_1 &= |\big(K_P(I-Q)Nx\big)_i(t)|_0 + |\big(K_P(I-Q)Nx\big)_i'(t)|_0 \\ &\leq M_i\omega + \tfrac{1}{2}M_i\omega + \tfrac{1}{2}M_i\omega + M_i + M_i = 2(\omega+1)M_i, \end{aligned}$$

which implies that $K_P(I-Q)N(\overline{\Omega})$ is bound in the space $(X, \|\cdot\|_1)$.

On the other hand, we prove that $\big(K_P(I-Q)Nx\big)(\overline{\Omega})$ is equicontinuous. In view of the uniform continuity of b_i and a_{ij}, for any $\varepsilon > 0$, there exists $\delta_1 > 0$ such that for any $t, s \in R$, provided that $|t-s| < \delta_1$, we have

$$|b_i(t) - b_i(s)| < \varepsilon, \quad |a_{ij}(t) - a_{ij}(s)| < \varepsilon. \tag{9}$$

Since any $x(t) = (x_1(t), x_2(t), \ldots, x_n(t))^T \in \overline{\Omega}$ is equicontinuous, for the same ε, there exists $0 < \delta_2 \leq \delta_1$ such that for any $t, s \in R$, provided that $|t-s| < \delta_2$, we have

$$|x_i(t) - x_i(s)|_0 < \varepsilon. \tag{10}$$

It follows from (9) and (10) that

$$\begin{aligned} & |\Delta_i(x(t),t) - \Delta_i(x(s),s)|_0 \\ \leq\ & |b_i(t) - b_i(s)|_0 + \sum_{j=1}^n |a_{ij}(t)e^{x_j(t)} - a_{ij}(s)e^{x_j(s)}|_0 \\ \leq\ & |b_i(t) - b_i(s)| + \sum_{j=1}^n |a_{ij}(t)|_0 |e^{x_j(t)} - e^{x_j(s)}|_0 + \sum_{j=1}^n |a_{ij}(t) - a_{ij}(s)|_0 |e^{x_j(s)}|_0 \\ <\ & \varepsilon + \sum_{j=1}^n \overline{a}_{ij} e^{h_j} |x_i(t) - x_i(s)|_0 + \sum_{j=1}^n e^{h_j}\varepsilon \\ <\ & \varepsilon + \sum_{j=1}^n \overline{a}_{ij} e^{h_j}\varepsilon + \sum_{j=1}^n e^{h_j}\varepsilon \\ =\ & \left[1 + \sum_{j=1}^n (1 + \overline{a}_{ij})e^{h_j}\right]\varepsilon. \end{aligned}$$

Thus, it follows from (8) that

$$\begin{aligned} & |\big(K_P(I-Q)Nx\big)_i'(t) - \big(K_P(I-Q)Nx\big)_i'(s)|_0 \\ =\ & |\Delta_i(x(t),t) - \Delta_i(x(s),s)|_0 \\ <\ & \left[1 + \sum_{j=1}^n (1 + \overline{a}_{ij})e^{h_j}\right]\varepsilon. \end{aligned} \tag{11}$$

On the other hand, the mean value theorem together with (8) gives

$$\begin{aligned}&|\big(K_P(I-Q)Nx\big)_i(t)-\big(K_P(I-Q)Nx\big)_i(s)|_0\\ =\;&\|\big(K_P(I-Q)Nx\big)_i'(\xi)\|_0|t-s|\leq 2M_i|t-s|,\end{aligned}\tag{12}$$

where ξ lies between t and s. Taking $\delta=\min\{\frac{\varepsilon}{2M_i},\delta_2\}$, it follows from (11) and (12) that $|t-s|<\delta$ implies

$$\begin{aligned}&|\big(K_P(I-Q)Nx\big)_i(t)-\big(K_P(I-Q)Nx\big)_i(s)|_1\\ =\;&|\big(K_P(I-Q)Nx\big)_i(t)-\big(K_P(I-Q)Nx\big)_i(s)|_0\\ &+|\big(K_P(I-Q)Nx\big)_i'(t)-\big(K_P(I-Q)Nx\big)_i'(s)|_0\\ <\;&\left[1+\sum_{j=1}^{n}(1+\overline{a}_{ij})e^{h_j}\right]\varepsilon+2M_i\delta\\ <\;&\left[1+\sum_{j=1}^{n}(1+\overline{a}_{ij})e^{h_j}\right]\varepsilon+\varepsilon:=\widetilde{M}\varepsilon,\end{aligned}$$

which implies that $\big(K_P(I-Q)Nx\big)(\overline{\Omega})$ is equicontinuous.

Therefore, by the generalized Arzela–Ascoli theorem, we have that $\big(K_P(I-Q)Nx\big)(\overline{\Omega})$ is relatively compact in the space $(X,\|\cdot\|_1)$. The proof of this step is complete.

Step 2. In this step, we are in a position to search for an appropriate open bounded subset Ω satisfying condition (i) of Lemma 2.1. Specifically, our aim is to search for an appropriate h_i defined by Ω in Step 1 such that Ω satisfies condition (i) of Lemma 2.1. To this end, assume that $x(t)\in X$ is a solution of the equation $Lx=\lambda Nx$ for each $\lambda\in(0,1)$; that is,

$$\dot{x}_i(t)=\lambda\left[b_i(t)-\sum_{j=1}^{n}a_{ij}(t)e^{x_j(t)}\right],\quad i=1,2,\dots,n.\tag{13}$$

Since $x(t)\in X$, each $x_i(t)$, $i=1,2,\dots,n$, as components of $x(t)$, is continuously differentiable and ω-periodic. In view of continuity and periodicity, there exists $t_i\in[0,\omega]$ such that $x_i(t_i)=\max_{t\in[0,\omega]}|x_i(t)|$, $i=1,2,\dots,n$. Accordingly, $\dot{x}_i(t_i)=0$, and we arrive at

$$b_i(t_i)-\sum_{j=1}^{n}a_{ij}(t_i)e^{x_j(t_i)}=0,\quad i=1,2,\dots,n.$$

That is,

$$a_{ii}(t_i)e^{x_i(t_i)}=b_i(t_i)-\sum_{j=1,j\neq i}^{n}a_{ij}(t_i)e^{x_j(t_i)},\quad i=1,2,\dots,n.$$

Noticing that $x_j(t_j)=\max_{t\in[0,\omega]}|x_j(t)|$ implies $x_j(t_i)\leq x_j(t_j)$, it follows that

$$\begin{aligned}\underline{a}_{ii}e^{x_i(t_i)}\leq\left|a_{ii}(t_i)e^{x_i(t_i)}\right|\;&=\;\left|b_i(t_i)-\sum_{j=1,j\neq i}^{n}a_{ij}(t_i)e^{x_j(t_i)}\right|\\ &\leq\;\overline{b}_i+\sum_{j=1,j\neq i}^{n}\overline{a}_{ij}e^{x_j(t_i)}\leq\overline{b}_i+\sum_{j=1,j\neq i}^{n}\overline{a}_{ij}e^{x_j(t_j)}.\end{aligned}\tag{14}$$

Letting $\underline{a}_{ii}e^{x_i(t_i)} = z_i(t_i)$, it follows from (14) that

$$z_i(t_i) \le \overline{b}_i + \sum_{j=1, j\neq i}^{n} \overline{a}_{ij}\underline{a}_{jj}^{-1} z_j(t_j)$$

or

$$z_i(t_i) - \sum_{j=1, j\neq i}^{n} \overline{a}_{ij}\underline{a}_{jj}^{-1} z_j(t_j) \le \overline{b}_i,$$

which implies

$$\left(\begin{array}{llll} \;\;1 & -\underline{a}_{22}^{-1}\overline{a}_{12} & \dots & -\underline{a}_{nn}^{-1}\overline{a}_{1n} \\ -\underline{a}_{11}^{-1}\overline{a}_{21} & \;\;1 & \dots & -\underline{a}_{nn}^{-1}\overline{a}_{2n} \\ \dots & \dots & \dots & \dots \\ -\underline{a}_{11}^{-1}\overline{a}_{n1} & -\underline{a}_{22}^{-1}\overline{a}_{n2} & \dots & \;\;1 \end{array}\right) \left(\begin{array}{c} z_1(t_1) \\ z_2(t_2) \\ \dots \\ z_n(t_n) \end{array}\right) \le \left(\begin{array}{c} \overline{b}_1 \\ \overline{b}_2 \\ \dots \\ \overline{b}_n \end{array}\right). \tag{15}$$

Set $D = (D_1, D_2, \dots, D_n)^T = (\overline{b}_1, \overline{b}_2, \dots, \overline{b}_n)^T$. It follows from (15) that

$$(E - \mathcal{K})\big(z_1(t_1), z_2(t_2), \dots, z_n(t_n)\big)^T \le D. \tag{16}$$

In view of $\rho(\mathcal{K}) < 1$ and Lemma 2.2, $(E_n - \mathcal{K})^{-1} \ge 0$. Let

$$H = (\widetilde{h}_1, \widetilde{h}_2, \dots, \widetilde{h}_n)^T := (E - \mathcal{K})^{-1} D \ge 0. \tag{17}$$

Then it follows from (16) and (17) that

$$\big(z_1(t_1), z_2(t_2), \dots, z_n(t_n)\big)^T \le H, \text{ or } z_i(t_i) \le \widetilde{h}_i, \quad i = 1, 2, \dots, n, \tag{18}$$

which implies

$$|x_i(t)|_0 = \max_{t\in[0,\omega]} |x_i(t)| = x_i(t_i) \le \ln \frac{\widetilde{h}_i}{\underline{a}_{ii}}, \quad i = 1, 2, \dots, n.$$

On the other hand, it follows from (17) that

$$(E - \mathcal{K})H = D, \text{ or } H = \mathcal{K}H + D, \text{ that is,} \tag{19}$$
$$\widetilde{h}_i = \sum_{j=1}^{n} \Gamma_{ij}\widetilde{h}_j + D_i, \; i = 1, 2, \dots, n.$$

Estimating (13), by using (18) and (19), we have

$$\begin{array}{rcl} |\dot{x}_i(t)|_0 & = & \lambda\Big|b_i(t) - \sum\limits_{j=1}^{n} a_{ij}(t)e^{x_j(t)}\Big|_0 \\ & \le & \overline{b}_i + \sum\limits_{j=1}^{n} \overline{a}_{ij}|e^{x_j(t)}|_0 = \overline{b}_i + \sum\limits_{j=1}^{n} \overline{a}_{ij}e^{x_j(t_j)} \\ & \le & \overline{b}_i + \sum\limits_{j=1}^{n} \overline{a}_{ij}\underline{a}_{jj}^{-1} z_j(t_j) \\ & = & \overline{b}_i + \sum\limits_{j=1, j\neq i}^{n} \overline{a}_{ij}\underline{a}_{jj}^{-1} z_j(t_j) + z_i(t_i) \\ & \le & D_i + \sum\limits_{j=1}^{n} \Gamma_{ij}\widetilde{h}_j + \widetilde{h}_i \\ & \le & \widetilde{h}_i + \widetilde{h}_i = 2\widetilde{h}_i. \end{array} \tag{20}$$

We can choose a large enough real number ($d > 1$) such that

$$\ln \frac{d\widetilde{h}_i}{\underline{a}_{ii}} > \ln \frac{\widetilde{h}_i}{\underline{a}_{ii}} + 2\widetilde{h}_i.$$

Set $h_i = \ln \frac{d\widetilde{h}_i}{\underline{a}_{ii}}$. Then for any solution of $Lx = \lambda Nx$, we have $|x_i(t)|_1 = |x_i(t)|_0 + |\dot{x}_i(t)|_0 \leq \ln \frac{\widetilde{h}_i}{\underline{a}_{ii}} + 2\widetilde{h}_i < h_i$ for all $i = 1, 2, \ldots, n$. Obviously, h_i are independent of λ and the choice of $x(t)$. Consequently, taking $h_i = \ln \frac{d\widetilde{h}_i}{\underline{a}_{ii}}$, the open subset Ω satisfies that $Lx \neq \lambda Nx$ for each $\lambda \in (0, 1)$, $x \in \partial\Omega \cap \mathrm{Dom}L$, i.e., the open subset Ω satisfies the assumption (i) of Lemma 2.1.

Step 3. In what follows, we verify that for the given open bounded set Ω obtained in Step 2, the assumption (ii) of Lemma 2.1 also holds. That is, for each $x \in \partial\Omega \cap \mathrm{Ker}L$, $QNx \neq 0$, and $\deg\{JQN,\ \Omega \cap \mathrm{Ker}L, 0\} \neq 0$.

Take $x \in \partial\Omega \cap \mathrm{Ker}L$. Then, in view of $\mathrm{Ker}L = R^n$, x is a constant vector in R^n, denoted by $x = (x_1, x_2, \ldots, x_n)^T$ and with the property

$$|x_i| = |x_i|_0 = |x_i|_1 = h_i = \ln \frac{d\widetilde{h}_i}{\underline{a}_{ii}} > \ln \frac{\widetilde{h}_i}{\underline{a}_{ii}} + 2\widetilde{h}_i \text{ for all } i = 1, 2, \ldots, n. \tag{21}$$

Operate x by QN, and we obtain that for $i = 1, 2, \ldots, n$,

$$(QNx)_i = m(b_i) - \sum_{j=1}^{n} m(a_{ij}) e^{x_j}, \quad i = 1, 2, \ldots, n.$$

We claim that $|(QNx)_i| > 0$ for $i = 1, 2, \ldots, n$. If this is not valid, suppose that there exists a certain $k \in \{1, 2, \ldots, n\}$ such that $|(QNx)_k| = 0$, i.e.,

$$m(b_k) - \sum_{j=1}^{n} m(a_{kj}) e^{x_j} = 0 \text{ or } m(a_{kk}) e^{x_k} = m(b_k) - \sum_{j=1, j\neq k}^{n} m(a_{kj}) e^{x_j}.$$

Letting $m(a_{kk}) e^{x_k} = y_k$, we have

$$y_k = m(b_k) - \sum_{j=1, j\neq k}^{n} \frac{m(a_{kj})}{m(a_{jj})} y_j. \tag{22}$$

In view of (21), we get
(23)

$$|y_i| = |y_i|_0 = |y_i|_1 = m(a_{ii}) e^{h_i} = m(a_{ii}) e^{\ln \frac{d\widetilde{h}_i}{\underline{a}_{ii}}} = m(a_{ii}) \frac{d\widetilde{h}_i}{\underline{a}_{ii}} \text{ for all } i = 1, 2, \ldots, n.$$

Note that $\underline{f} \leq m(f) \leq \overline{f}$. It follows from (22), (23), and (19) that

$$\begin{aligned}
d\widetilde{h}_k \leq m(a_{kk})\frac{d\widetilde{h}_k}{\underline{a}_{kk}} = |y_k| &= \left| m(b_k) - \sum_{j=1,j\neq k}^{n} \frac{m(a_{kj})}{m(a_{jj})} y_j \right| \\
&\leq \sum_{j=1,j\neq k}^{n} \frac{m(a_{kj})}{m(a_{jj})} |y_j| + \overline{b}_k \\
&\leq \sum_{j=1,j\neq k}^{n} \frac{m(a_{kj})}{m(a_{jj})} m(a_{jj}) \frac{d\widetilde{h}_j}{\underline{a}_{jj}} + \overline{b}_k \\
&\leq \sum_{j=1,j\neq k}^{n} \overline{a}_{kj} \underline{a}_{jj}^{-1} d\widetilde{h}_j + D_k \\
&< d \sum_{j=1,j\neq k}^{n} \overline{a}_{kj} \underline{a}_{jj}^{-1} \widetilde{h}_j + dD_k \\
&< d \Bigg[\sum_{j=1,j\neq k}^{n} \Gamma_{kj} \widetilde{h}_j + D_k \Bigg] \\
&= d\widetilde{h}_k,
\end{aligned}$$

which is a contradiction. Therefore, for any $x \in \partial\Omega \cap \mathrm{Ker}L$, $|(QNx)_i| > 0$ for all $i = 1, 2, \ldots, n$. That is, $(QNx) \neq 0$ for $x \in \partial\Omega \cap \mathrm{Ker}L$.

Next, we show that the topological degree is nonzero. In fact, it follows from (H$_1$) and Lemma 2.3 that the algebraic equation

$$\sum_{j=1}^{n} m(a_{ij}) u_j = m(b_i), \quad i = 1, 2, \ldots, n,$$

has a unique solution $u^* = (u_1^*, u_2^*, \ldots, u_n^*)^T \in R_+^n$ with $u_i^* > 0$. Obviously, the algebraic equation

$$\sum_{j=1}^{n} m(a_{ij}) e^{v_j} = m(b_i), \quad i = 1, 2, \ldots, n, \tag{24}$$

has a unique solution $v^* = (v_1^*, v_2^*, \ldots, v_n^*)^T \in R^n$. Now we further claim that the unique solution $v^* \in \Omega \cap \mathrm{Ker}L$. Indeed, if this is not the case, suppose that

$$|v_i^*| = |v_i^*|_0 = |v_i^*|_1 = h_i = \ln \frac{d\widetilde{h}_i}{\underline{a}_{ii}} > \ln \frac{\widetilde{h}_i}{\underline{a}_{ii}} + 2\widetilde{h}_i \text{ for all } i = 1, 2, \ldots, n. \tag{25}$$

Letting $m(a_{ii})e^{v_i} = u_i$, we have

$$u_i = m(b_i) - \sum_{j=1,j\neq i}^{n} \frac{m(a_{ij})}{m(a_{jj})} u_j. \tag{26}$$

By using (25), (26), and (19), a similar argument in the above leads to

$$\begin{aligned}
d\widetilde{h}_i \leq m(a_{ii})\frac{d\widetilde{h}_i}{\underline{a}_{ii}} = |u_i| &= \left| m(b_i) - \sum_{j=1,j\neq i}^{n} \frac{m(a_{ij})}{m(a_{jj})} u_j \right| \\
&< d \left[\sum_{j=1,j\neq k}^{n} \Gamma_{ij} \widetilde{h}_j + D_i \right] = d\widetilde{h}_i,
\end{aligned}$$

which is a contradiction. Therefore, for any $v^* \in \Omega \cap \mathrm{Ker}L$, in view of Definition 2.2, it is easy to see that

$$\deg\{\,\mathrm{JQN}, \Omega \cap \mathrm{Ker}L, 0\} = \mathrm{sign}\left[(-1)^n \det[m(a_{ij})] \exp\left\{\sum_{i=1}^{n} v_j^*\right\}\right] \neq 0,$$

where $\deg(\cdot)$ is the Brouwer degree and J is the identity mapping since $\mathrm{Im}Q = \mathrm{Ker}L$.

We have shown that the open subset $\Omega \subset X$ satisfies all the assumptions of Lemma 2.1. Hence, by Lemma 2.1, system (6) has at least one positive ω-periodic solution in $\mathrm{Dom}L \cap \overline{\Omega}$. By (5), system (3) has at least one positive ω-periodic solution. This completes the proof of Theorem 2.1. □

3. Globally asymptotic stability. Under the assumption of Theorem 2.1, we know that system (3) has at least one positive ω-periodic solution, denoted by $y^*(t) = \left(y_1^*(t), \ldots, y_n^*(t)\right)^T$. The aim of this section is to derive a set of sufficient conditions which guarantee the existence and global asymptotic stability of the positive ω-periodic solution $y^*(t)$.

Before the formal analysis, we recall some facts which will be used in the proof.

DEFINITION 3.1. *Let* $y^*(t) = \left(y_1^*(t), \ldots, y_n^*(t)\right)^T$ *be the* ω*-periodic solution of* (3) *and let* $y(t) = \left(y_1(t), \ldots, y_n(t)\right)^T$ *be any positive solution of* (3). *We say* $y^*(t)$ *is globally asymptotically stable if the following conditions hold:*

(i) $y^*(t)$ *is Lyapunov stable;*

(ii) $y^*(t)$ *is globally attractive in the sense that* $\lim_{t\to+\infty}[y_i(t) - y_i^*(t)] = 0$ *for all* $i = 1, 2, \ldots, n$.

LEMMA 3.1 (see [22, 24, 30]). *Let f be a nonnegative function defined on* $[0, +\infty]$ *such that f is integrable on* $[0, +\infty]$ *and is uniformly continuous on* $[0, +\infty]$. *Then* $\lim_{t\to+\infty} f(t) = 0$.

LEMMA 3.2 (see [25, 26, 42, 43]). *Let* $\mathcal{K} = (\Gamma_{ij})_{n\times n}$ *be a matrix with nonpositive off-diagonal elements.* $\mathcal{K}$ *is an* M*-matrix if and only if there exists a positive diagonal matrix* $\xi = \mathrm{diag}(\xi_1, \xi_2, \ldots, \xi_n)$ *such that*

$$\xi_i \underline{a}_{ii} > \sum_{j\neq i} \xi_j \overline{a}_{ij}, \quad i = 1, 2, \ldots, n.$$

THEOREM 3.1. *Assume that all the assumptions in Theorem* 2.1 *hold. Then system* (3) *has a unique positive* ω*-periodic solution* $y^*(t)$ *which is globally asymptotically stable.*

Proof. Let $y(t) = \left(y_1(t), \ldots, y_n(t)\right)^T$ be any positive solution of system (3). Set

$$Y_i(t) = \ln y_i(t), \quad Y_i^*(t) = \ln y_i^*(t). \tag{27}$$

Then, it follows from (27) and (3) that

$$D^+\left[|Y_i(t) - Y_i^*(t)|\right] \leq -a_{ii}(t)|y_i(t) - y_i^*(t)| + \sum_{j=1, j\neq i}^{n} a_{ij}(t)|y_j(t) - y_j^*(t)|. \tag{28}$$

It is easy to see that $\rho(\mathcal{K}^T) = \rho(\mathcal{K}) < 1$. Thus, in view of Lemma 2.2 and Definition 2.3, $(E - \mathcal{K}^T)$ is an M-matrix, where E denotes an identity matrix of size n. Therefore, by Lemma 3.2, there exists a diagonal matrix $\xi = \mathrm{diag}(\xi_1, \ldots, \xi_n)$ with positive diagonal elements such that the product $(E - \mathcal{K}^T)\xi$ is strictly diagonally dominant with positive diagonal entries, namely,

$$\xi_i \Gamma_{ii} > \sum_{j=1, j\neq i}^{n} \xi_j \Gamma_{ji} \text{ or } \xi_i \underline{a}_{ii} - \sum_{j=1, j\neq i}^{n} \xi_j \overline{a}_{ji} > 0, \quad i = 1, \dots, n. \tag{29}$$

Now, we define a Lyapunov function $V(t)$ as follows:

$$V(t) = \sum_{i=1}^{n} \xi_i |Y_i(t) - Y_i^*(t)|, \quad t \geq t_0. \tag{30}$$

Let $Z_i(t) = |y_i(t) - y_i^*(t)|$. Calculating the upper right derivative of $V(t)$, it follows from (30) and (28) that

$$\begin{aligned} D^+V(t) &\leq \sum_{i=1}^{n} \xi_i \left\{ -a_{ii}(t)|y_i(t) - y_i^*(t)| + \sum_{j\neq i, j=1}^{n} a_{ij}(t)|y_j(t) - y_j^*(t)| \right\} \\ &= -\sum_{i=1}^{n} \xi_i a_{ii}(t) Z_i(t) + \sum_{i=1}^{n} \sum_{j\neq i, j=1}^{n} \xi_j a_{ji}(t) Z_i(t) \\ &= -\sum_{i=1}^{n} \left\{ \xi_i a_{ii}(t) - \sum_{j\neq i j=1}^{n} \xi_j a_{ji}(t) \right\} Z_i(t) \\ &\leq -c \sum_{i=1}^{n} Z_i(t) \leq 0, \quad t \geq t_0, \end{aligned} \tag{31}$$

where $c = \max_{1\leqslant i\leqslant n} \sup_{t\in[0,\omega]} \{\xi_i a_{ii}(t) - \sum_{j=1, j\neq i}^{n} \xi_j a_{ji}(t)\} > 0$. It follows from (31) that $D^+V(t) \leq 0$. Obviously, the zero solution of (3) is Lyapunov stable. On the other hand, integrating (31) over $[t_0, t]$ leads to

$$V(t) - V(t_0) \leqslant -c \int_{t_0}^{t} \sum_{i=1}^{n} Z_i(s) ds, \qquad t \geqslant 0,$$

or

$$V(t) + c \int_{t_0}^{t} \sum_{i=1}^{n} |y_i(s) - y_i^*(s)| ds \leqslant V(t_0) < +\infty, \quad t \geqslant t_0.$$

Noting that $V(t) \geqslant 0$, it follows that

$$\int_{t_0}^{t} \sum_{i=1}^{n} |y_i(s) - y_i^*(s)| ds \leqslant \frac{V(t_0)}{c} < +\infty, \quad t \geqslant t_0. \tag{32}$$

Therefore, by Lemma 3.1, it is not difficult to conclude that

$$\lim_{t\to+\infty} |y_i(t) - y_i^*(t)| = 0.$$

From Definition 3.1, Theorem 3.1 follows. □

4. Corollaries, remarks, and conclusions. In order to illustrate some features of our main results, we will present some corollaries and remarks in this section.

From the proofs of Theorems 2.1 and 3.1, a direct corollary follows immediately.

Corollary 4.1. *In addition to* (H_1)*, suppose further that* $E-\mathcal{K}$ *or* $E-\mathcal{K}^T$ *is an* M*-matrix. Then system* (3) *has a unique positive* ω*-periodic solution which is globally asymptotically stable.*

Now recall that for a given matrix $\mathcal{K}$, its spectral radius $\rho(\mathcal{K})$ is equal to the minimum of all matrix norms of $\mathcal{K}$, i.e., for any matrix norm $\|\cdot\|$, $\rho(\mathcal{K}) \le \|\mathcal{K}\|$. Therefore, we have the following corollary.

Corollary 4.2. *In addition to* (H_1)*, suppose further that there exist positive constants* ξ_i, $i=1,2,\ldots,n$ *such that one of the following conditions holds:*

(1) $\max\limits_{1\le j\le n}[\underline{a}_{jj}^{-1}\xi_j^{-1}\sum_{i=1,i\neq j}^{n}\xi_i\overline{a}_{ij}]<1$*, or, equivalently,* $\underline{a}_{jj}>\sum_{i=1,i\neq j}^{n}\overline{a}_{ij}$ *for all* $j=1,2,\ldots,n$.

(2) $\sum_{i=1}^{n}\sum_{j=1}^{n}(\xi_i^{-1}\xi_j\Gamma_{ij})^2<1$*, where*

$$\Gamma_{ij}=\begin{cases}0, & i = j,\\ \underline{a}_{jj}^{-1}\overline{a}_{ij}, & i \neq j.\end{cases}$$

(3) $\max\limits_{1\le i\le n}[\underline{a}_{ii}^{-1}\xi_i^{-1}\sum_{j=1,j\neq i}^{n}\xi_j\overline{a}_{ji}]<1$*, or, equivalently,* $\underline{a}_{ii}>\sum_{j=1,j\neq i}^{n}\overline{a}_{ji}$ *for all* $i=1,2,\ldots,n$.

Then system (3) *has a unique positive* ω*-periodic solution which is globally asymptotically stable.*

Proof. For any matrix norm $\|\cdot\|$ and any nonsingular matrix S, $\|\mathcal{K}\|_S=\|S^{-1}\mathcal{K}S\|$ also defines a matrix norm. Let $D=\operatorname{diag}(\xi_1,\xi_2,\ldots,\xi_n)$. Then the conditions (1) and (2) correspond to the column norms and Frobenius norm of matrix $D\mathcal{K}D^{-1}$, respectively. Condition (3) corresponds to the row norms of $D\mathcal{K}^TD^{-1}$, and note that $\rho(D\mathcal{K}^TD^{-1})=\rho(D\mathcal{K}D^{-1})$. Corollary 4.2 follows immediately. □

Remark 4.1. Taking $\xi_i=1, i=1,2,\ldots,n$, condition (1) reduces to the main results in Gopalsamy [9, 10]. Therefore, the previous results in [9, 10] are special cases of our results. In the next section, an example will be given to show that our results can be applied to that example while those of [9, 10] cannot be applied.

Now apply our results to the classical two-species Lotka–Volterra competition system which has been studied extensively in [3, 11, 20, 21, 22, 23]:

$$\begin{cases}\dot{y}_1(t) &= y_1(t)[b_1(t)-a_{11}(t)y_1(t)-a_{12}(t)y_2(t)],\\ \dot{y}_2(t) &= y_2(t)[b_2(t)-a_{21}(t)y_1(t)-a_{22}(t)y_2(t)].\end{cases}\tag{33}$$

Corollary 4.3. *Assume that the following conditions hold:*

(a) $m(a_{11})m(b_1)>m(a_{12})m(b_2)$, $m(a_{22})m(b_2)>m(a_{21})m(b_1)$*;*

(b) $\rho(\widetilde{K})<1$*, where*

$$\widetilde{K}=\begin{pmatrix}0 & \underline{a}_{22}^{-1}\overline{a}_{12}\\ \underline{a}_{11}^{-1}\overline{a}_{21} & 0\end{pmatrix}.$$

Then system (33) *has a unique positive* ω*-periodic solution which is globally asymptotically stable.*

Remark 4.2. By way of comparing our results, we first recall some previously known results in the literature [3, 11, 20, 21, 22, 23].

Theorem A. *Assume that the following condition holds:*

(I) $m(a_{11})m(b_1) > m(a_{12})m(b_2)\exp\{[m(b_2)+m(|b_2|)]\omega\}$ *and* $m(a_{22})m(b_2) > m(a_{21})m(b_1)\exp\{[m(b_1)+m(|b_1|)]\omega\}$.

Then system (33) *has at least one positive* ω*-periodic solution.*

THEOREM B. *In addition to* (I)*, further assume that*

(II) $\underline{a}_{11} > \overline{a}_{21}$ *and* $\underline{a}_{22} > \overline{a}_{12}$.

Then system (33) *has a unique positive* ω*-periodic solution which is globally asymptotically stable.*

We remark that conditions (a) and (b) in Corollary 4.3 are completely different from (I) and (II) in Theorems A and B. More specifically, it seems that we need condition (b) to guarantee the existence of a periodic solution, but actually, to guarantee the existence and global asymptotic stability of a unique periodic solution, conditions (a) and (b) in Corollary 4.3 are much weaker than (I) in Theorem A and (II) in Theorem B. It is in this sense that Corollary 4.3 generalizes and improves Theorems A and B. Therefore, our results are much different from the known results and thus essentially new.

Remark 4.3. The results in Gopalsamy [8, 20] require $\underline{a}_{11} > \overline{a}_{21}$ and $\underline{a}_{22} > \overline{a}_{12}$. That is, it is required that $\underline{a}_{11}^{-1}\overline{a}_{21} < 1$ and $\underline{a}_{22}^{-1}\overline{a}_{12} < 1$. We note that those conditions imply $\rho(\widetilde{K}) < 1$, where

$$\widetilde{K} = \begin{pmatrix} 0 & \underline{a}_{22}^{-1}\overline{a}_{12} \\ \underline{a}_{11}^{-1}\overline{a}_{21} & 0 \end{pmatrix}.$$

However, $\underline{a}_{11}^{-1}\overline{a}_{21} < 1$ and $\underline{a}_{22}^{-1}\overline{a}_{12} < 1$ cannot be inferred by $\rho(\widetilde{K}) < 1$. That is to say, there is a case: $\rho(\widetilde{K}) < 1$, but $\underline{a}_{11}^{-1}\overline{a}_{21}$ and $\underline{a}_{22}^{-1}\overline{a}_{12}$ may be bigger than 1. An example in the next section shows this fact. Therefore, our results also significantly improve the results in [8, 20].

Conclusions. (1) In this paper, we revisit the famous n-species Lotka–Volterra competitive system in a periodic environment. A set of new sufficient conditions are obtained to guarantee the existence and global asymptotic stability of a periodic solution in the multiple-species competition system. Our results are essentially new and much different from some previously known results. Moreover, applying our results to some special systems, we obtain some new criteria which generalize and improve the previously known results such as [3, 8, 9, 11, 20, 21, 22, 23].

(2) The main purpose of this paper is to propose a new methodology to study the Lotka–Volterra competitive system. The approaches used in this paper are based on Mawhin's coincidence degree, Lyapunov function, and matrix theory and its spectral theory. Mawhin's coincidence degree theory is extensively used to study the existence of periodic solutions. Note that different estimation techniques for the priori bounds of unknown solutions to the equation $Lx = \lambda Nx$ may lead to different results. There are many papers obtaining the priori bounds by employing the inequality $|x(t)| \leq |x(t_0)| + \int_0^\omega |\dot{x}(t)|dt$ (see, e.g., [11, 27, 28, 29, 30, 31, 32, 33, 34, 35]). To the best of our knowledge, no study has employed the matrix's spectral theory to obtain the priori bounds for biological systems so far. It is the first time that this new estimation technique for the priori bounds is employed to study global asymptotic stability and existence of periodic solution for the population dynamics. The method is much different from those in the previous references [1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 27, 28, 29, 30, 31, 32, 33, 34, 35]. Due to this new method, our results are essentially new and very interesting.

5. Examples. In this section, some examples and their simulations are presented to illustrate the feasibility and effectiveness of our results.

Example 1. Consider the two-species competitive system

$$\left\{\begin{array}{lcl}\dot{x}_1(t) &=& x_1(t)[4-(3+\sin t)x_1(t)-\frac{1}{4}(1+\cos t)x_2(t)],\\ \dot{x}_2(t) &=& x_2(t)[8-(2+\sin t)x_1(t)-(3-\cos t)x_2(t)].\end{array}\right. \tag{34}$$

Corresponding to system (33), we have $\underline{a}_{11}=\underline{a}_{22}=2, \overline{b}_1=4, \overline{b}_2=8, \overline{a}_{12}=\frac{1}{2}, \overline{a}_{21}=3$. We see that $\underline{a}_{11}=2<\overline{a}_{21}=3$. This cannot meet the requirement $\underline{a}_{11}>\overline{a}_{21}$ and $\underline{a}_{22}>\overline{a}_{12}$ of the theorem in Gopalsamy [8]. Thus, the results obtained in [8] cannot be applied to this case.

However, it is not difficult to show that our results can be easily applied to system (34). In fact, on one hand, it is easy to check that system (34) satisfies condition (a) in Corollary 4.2. On the other hand, simple computation leads to

$$\widetilde{K}=\begin{pmatrix}0 & \frac{1}{2}\times\frac{1}{2}\\ \frac{1}{2}\times 3 & 0\end{pmatrix}=\begin{pmatrix}0 & \frac{1}{4}\\ \frac{3}{2} & 0\end{pmatrix}$$

and $\rho(\widetilde{K})=\frac{\sqrt{6}}{4}<1$. Thus, by Corollary 4.2, system (34) has a unique positive equilibrium $(\frac{8}{5},\frac{8}{5})$, which is globally asymptotically stable. Figure 1 shows the asymptotic behavior of system (34).

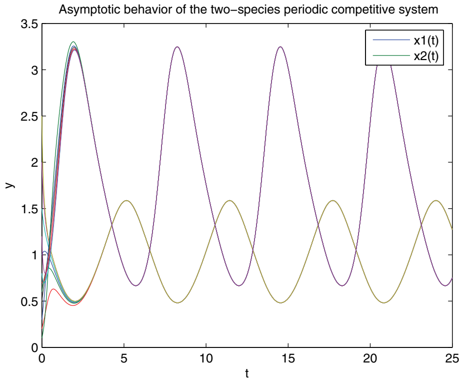

FIG. 1. *Asymptotic behavior of system* (34) *with initial values* $(x_1(0),x_2(0))=(0.2,0.1)$, $(0.6,0.3),(1,0.5),(1.5,0.7),(2,0.8),(2.5,1.2)$, *respectively,* $t\in[0,35]$.

Example 2. Consider the three-species competitive system

$$\left\{\begin{array}{lcl}\dot{x}_1(t) &=& x_1(t)[4-(3+\sin t)x_1(t)-\frac{1}{4}(1+\cos t)x_2(t)-\frac{1}{5}(1+\sin t)x_3(t)],\\ \dot{x}_2(t) &=& x_2(t)[4-\frac{1}{4}(1-\sin t)x_1(t)-(3+\sin t)x_2(t)],\\ \dot{x}_3(t) &=& x_3(t)[10-(2-\sin t)x_1(t)-\frac{1}{4}(1+\sin t)x_2(t)-(3+\cos t)x_3(t)].\end{array}\right. \tag{35}$$

Corresponding to system (3), we have $\underline{a}_{11}=\underline{a}_{22}=\underline{a}_{33}=2, \overline{b}_1=\overline{b}_2=4, \overline{b}_3=10, \overline{a}_{12}=\frac{1}{2}, \overline{a}_{13}=\frac{2}{5}, \overline{a}_{21}=\frac{1}{2}, \overline{a}_{23}=0, \overline{a}_{31}=3, \overline{a}_{32}=\frac{1}{2}$. We see that $\underline{a}_{11}=2<a_{21}+a_{31}=\frac{7}{2}$. This cannot meet the requirement $\underline{a}_{jj}>\sum_{i=1,i\neq j}^{3}\overline{a}_{ij}$ for $i=1,2,3$ of the theorem in [9, 10]. Thus, the results obtained in [4, 9, 10] cannot be applied to this case.

However, it is not difficult to show that our results can be easily applied to system

(35). In fact, simple computation leads to

$$\mathcal{K} = \begin{pmatrix} 0 & \underline{a}_{22}^{-1}\overline{a}_{12} & \underline{a}_{33}^{-1}\overline{a}_{13} \\ \underline{a}_{11}^{-1}\overline{a}_{21} & 0 & 0 \\ \underline{a}_{11}^{-1}\overline{a}_{31} & \underline{a}_{22}^{-1}\overline{a}_{32} & 0 \end{pmatrix} = \begin{pmatrix} 0 & \frac{1}{2}\times\frac{1}{2} & \frac{1}{2}\times\frac{2}{5} \\ \frac{1}{2}\times\frac{1}{2} & 0 & 0 \\ \frac{1}{2}\times 3 & \frac{1}{2}\times\frac{1}{2} & 0 \end{pmatrix} = \begin{pmatrix} 0 & \frac{1}{4} & \frac{1}{5} \\ \frac{1}{4} & 0 & 0 \\ \frac{3}{2} & \frac{1}{4} & 0 \end{pmatrix}.$$

Hence, by using mathematica, we get

$$\rho(\mathcal{K}) = \max\ eigenvalues[\mathcal{K}] = 0.633982 < 1.$$

Thus, by Theorem 3.1, system (35) has a unique positive equilibrium which is globally asymptotically stable. Figure 2 shows the asymptotic behavior of system (35).

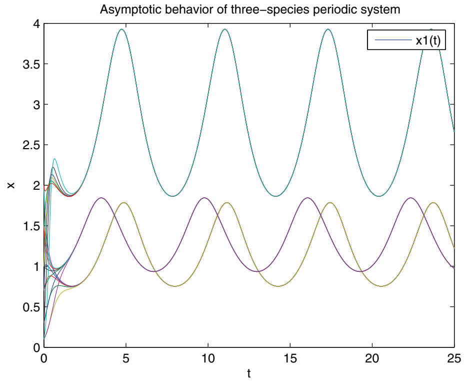

Fig. 2. *Asymptotic behavior of system* (35) *with initial values* $(x_1(0), x_2(0), y_1(0)) = (0.1, 0.1, 0.1), (0.3, 0.3, 0.3), (0.7, 0.7, 0.7), (1, 1, 1), (1.5, 1.5, 1.5), (2, 2, 2)$*, respectively,* $t \in [0, 35]$.

Remark 5.1. In this example, one can observe that though the spectral $\rho(\mathcal{K}) < 1$, the matrix norms (including the row norm, the column norm, and the Frobenius norm) of matrix $\mathcal{K}$ are all bigger than 1. For instance, the column norm

$$\|\mathcal{K}\|_1 = \max_{1\le j\le 3}\left\{\underline{a}_{jj}^{-1}\sum_{i=1, i\ne j}^{3}\overline{a}_{ij}\right\} = 0 + \frac{3}{2} + \frac{1}{4} > 1.$$

This fact implies that our results are more general than those in [8, 9, 10].

Acknowledgments. The authors are very grateful to the editor and referees for their careful reading of the manuscript and a number of excellent suggestions which improved the presentation of this paper.

BOUNDS FOR THE EFFECTIVE STRESS OF CLASSICAL AND STRAIN GRADIENT PLASTIC COMPOSITES*

VIET HA HOANG†

Abstract. Given an average strain, rigorous bounds are established for the stress in a deformation of a plastic composite material, which follows a power law. The deformation theory of strain gradient plasticity, which introduces an internal material length scale, is used. It falls into the classical deformation theory of elasto-plasticity when this length scale equals zero. The method employs the idea by Milton and Serkov [*J. Mech. Phys. Solids*, 48 (2000), pp. 1259–1324] and other techniques for bounding effective energy. We derive two stress bounds which closely relate to the Reuss lower bound and the Hashin–Shtrikman upper bound for the energy. We then study numerically the dependence on the internal length scale of the magnitude of the stress and the region in the stress space determined by these two bounds in which the macro stress must lie. The results confirm the prediction made by Fleck and Willis [*J. Mech. Phys. Solids*, 52 (2004), pp. 1855–1888] for the macroscopic uniaxial response by differentiating their energy bounds.

Key words. stress bounds, plastic composites, strain gradient, compensated compactness, null-Lagrangian

1. Introduction.

For nonlinear composite materials, a correct bound for the constitutive relation (e.g., a bound for the average stress in terms of the average strain) may not be induced from an energy bound: Differentiating an energy bound with respect to the average strain may not give a bound for the average stress. A separate technique for bounding the constitutive relations needs to be developed. Milton and Serkov [8] propose an approach for bounding the current in nonlinear conducting composites. They present it as an extension of earlier works on bounding the yield surface of plastic composites (Kohn and Little [5] and Nesi et al. [10]) which are applications of the compensated compactness due to Tartar [20, 21] and Murat and Tartar [9] and also the translation method of Lurie and Cherkaev [6, 7] and Murat and Tartar [9]. The key idea is to use a functional of the current $j(x)$ and the electric field $e(x)$ which equals 0 in the admissible range of (j, e) and equals infinity elsewhere, and to employ a translated function $Q(j, e)$ such that $Q(j(x), e(x))$ is quasiconvex. For simplicity, they use $Q = j.e$ which is a null Lagrangian, but predict that better bounds may be obtained by using other functions. The method is further developed for nonlinear elastic composites by Talbot and Willis [19], using a homogeneous comparison linear material, and by Peigney [11].

In this paper, we study bounds for the effective stress of a power law plastic composite under a uniform boundary strain. We use the strain gradient plasticity theory of Fleck and Willis [3] which introduces an internal material length scale. This is a modification of the phenomenological constitutive law by Fleck and Hutchinson [2]. It reduces to classical deformation theory of elasto-plasticity when the internal

length scale is 0; thus this work holds for classical plasticity. We cannot apply directly the techniques of [8] and [19] as the stress is not a function of the strain. It depends nonlinearly on the plastic strain and its derivatives. The approach we develop is an adaptation of that of Milton and Serkov [8], and the ideas for bounding the effective energy of nonlinear composites.

In the next section, we introduce the strain gradient plasticity theory. A bound that resembles the Reuss bound for the energy is deduced in section 3, which gives a lower bound for the stress magnitude. This lower bound, indeed, can be deduced by differentiating the Reuss lower bound for the effective energy in Fleck and Willis [3]. A stress bound which closely relates to the Hashin–Shtrikman upper bound is found in section 4. For the stress magnitude, deep in the plastic range, it gives a bound which can be obtained by differentiating the Hashin–Shtrikman upper energy bound in [3]. This is expected as deep in the plastic range, the upper energy bound in [3] follows a power law, and given that the exact effective energy also follows a power law, the energy bound in effect gives a bound for the reference strength. However, for smaller total strain, the energy upper bound does not follow a power law; differentiating the energy bound does not give a rigorous bound for the magnitude of the stress. Our results provide rigorous stress bounds for the whole range of the total strain. We present some numerical results in section 5. They show that the Hashin–Shtrikman type bound for the magnitude of the stress increases with the material length scale. This is in agreement with the prediction Fleck and Willis [3] made by differentiating the upper energy bound. Deep in the plastic regime, the upper bound for the magnitude of the stress follows a power law, which is also in agreement with [3]. For a specific boundary strain, our bounds give a particular region in the stress space in which the stress tensor lies. We give and analyze some examples for a couple of particular boundary strains, which show that the region for a larger material length scale contains the region for smaller ones. This agrees with the previously mentioned fact that bounds for the stress magnitude increase with the material length scale. The paper ends with a short concluding section 6 in which the main results are summarized.

Before Fleck and Willis [3], bounds and estimates for the overall properties of plastic composites had been studied in several works. A number of them, e.g., Ponte Castañeda [12], Ponte Castañeda and De Botton [13], and Suquet [17], study conventional plastic materials where bounds and estimates for the effective energy density, and thus for the yield strength, are deduced. Extending these works, composites, whose components are under the effect of strain gradient which introduces internal length scales, are considered in Smyshlyaev and Fleck [14, 15, 16]. The present paper complements these works by contributing rigorous bounds for the effective stress.

2. Strain gradient energy.

We consider a plastic composite material whose energy functional follows the strain gradient deformation theory of Fleck and Willis [3], which modifies the original theory of Fleck and Hutchinson [2]. We assume that the material is incompressible and is elastically homogeneous. The energy density function is defined as

$$U(\varepsilon_{ij}, \varepsilon^P_{ij}, \varepsilon^P_{ij,k}) = \mu(\varepsilon_{ij} - \varepsilon^P_{ij})(\varepsilon_{ij} - \varepsilon^P_{ij}) + V(\varepsilon^P_{ij}, \varepsilon^P_{ij,k}),$$

where the potential $V = V(E_P)$; E_P is the effective plastic strain measure defined by

$$E_P = \sqrt{\frac{2}{3}}(\varepsilon^P_{ij}\varepsilon^P_{ij} + l^2\varepsilon^P_{ij,k}\varepsilon^P_{ij,k})^{1/2}.$$

The underlying idea is that $\varepsilon^P_{ij}\varepsilon^P_{ij}$ provides a measure of the density of the statistically stored dislocations while $\varepsilon^P_{ij,k}\varepsilon^P_{ij,k}$ provides a measure of the geometrically necessary dislocations. The original theory of Fleck and Hutchinson [2] contains three material scales l_1, l_2, and l_3. Here following [3], we consider a simplified version which contains a single scale l. The material is a composite so that the potential V depends on the position x and is rapidly oscillating. We restrict our attention to the case of power law components; i.e., the potential V has the form

$$V(x,\varepsilon^P_{ij},\varepsilon^P_{ij,k})=\frac{\Sigma(x)e_0}{N+1}\Big(\frac{E_P}{e_0}\Big)^{N+1}, \tag{2.1}$$

where $\Sigma(x)$ is the reference strength, and $0<N<1$. The strain ε_{ij} is defined as usual as

$$\varepsilon_{ij}=\frac{1}{2}\Big(\frac{\partial u_i}{\partial x_j}+\frac{\partial u_j}{\partial x_i}\Big).$$

In this setting, the displacement u_i and the plastic strain ε^P_{ij} are treated as dependent variables on equal footing. Assuming that an affine displacement $u_i=\bar\varepsilon_{ij}x_j$ ($\bar\varepsilon$ is a constant tensor) is prescribed on the boundary of a domain $\Omega\in\mathbb{R}^3$ which has unit volume, the deformation minimizes the energy functional

$$\Psi(u_i,\varepsilon^P_{ij})=\int_\Omega U(\varepsilon_{ij},\varepsilon^P_{ij},\varepsilon^P_{ij,k})dx. \tag{2.2}$$

We introduce the conjugate variables

$$\begin{aligned}\sigma_{ij}&=\frac{\partial U}{\partial\varepsilon_{ij}}=2\mu(\varepsilon_{ij}-\varepsilon^P_{ij}),\\ s_{ij}&=\frac{\partial U}{\partial\varepsilon^P_{ij}}=-2\mu(\varepsilon_{ij}-\varepsilon^P_{ij})+\frac{\partial V}{\partial\varepsilon^P_{ij}},\\ \tau_{ijk}&=\frac{\partial U}{\partial\varepsilon^P_{ij,k}}=\frac{\partial V}{\partial\varepsilon^P_{ij,k}}.\end{aligned} \tag{2.3}$$

Setting to zero the first variation of (2.2), we get the equilibrium equations

$$\begin{aligned}\sigma_{ij,j}&=p_{,i},\\ \sigma_{ij}+\tau_{ijk,k}&=\frac{\partial V}{\partial\varepsilon^P_{ij}},\\ \tau_{ijk}n_k&=0,\end{aligned} \tag{2.4}$$

where p is a pressure field whose presence is due to the incompressibility. From this we have

$$\tau_{ijk,k}=s_{ij}, \tag{2.5}$$

and

$$\sigma_{ij}=\frac{\partial V}{\partial\varepsilon^P_{ij}}-\Big(\frac{\partial V}{\partial\varepsilon^P_{ij,k}}\Big)_{,k}. \tag{2.6}$$

As the constitutive materials are incompressible, $\varepsilon_{ii}=\varepsilon^P_{ii}=0$. The phases are assumed to be perfectly bonded together so that there is no energy built up on the surface between different components as considered in, e.g., Gudmundson [4] and Aifantis and Willis [1]. Throughout, $\langle.\rangle$ denotes the mean value of a function in Ω; we denote $\bar\sigma=\langle\sigma\rangle$, $\bar\varepsilon=\langle\varepsilon\rangle$, and $\bar\varepsilon^P=\langle\varepsilon^P\rangle$. As usual, repeated indices indicate summation.

3. Reuss-type bound for the stress. In this section, we adopt the approach by Milton and Serkov [8] to find a Reuss-type bound for the stress, using the null Lagrangian $\sigma : \varepsilon$. However, unlike the situations in [8], [19], and [11], here we need to take into account both the strain fields ε and ε^P, and the stress σ is a complicated nonlinear function of ε^P and its derivatives. For a constant tensor λ, it is not possible to deal with $\sup_\varepsilon\{\lambda : \varepsilon - \sigma : \varepsilon/2\}$ as in [8]. We, instead, work with

$$F(\lambda) = \sup\left\{\int_\Omega \left(\lambda : \varepsilon^P - \frac{1}{2}\sigma : \varepsilon^P\right) dx\right\},$$

where the supremum is taken with respect to all the tensor fields $\varepsilon^P(x)$ and $\sigma(x)$ that satisfy conditions (2.6), (2.3c), and (2.4c). From these conditions

$$\begin{aligned}\int_\Omega \sigma_{ij}\varepsilon^P_{ij} dx &= \int_\Omega \frac{\partial V}{\partial \varepsilon^P_{ij}}\varepsilon^P_{ij} dx + \int_\Omega \frac{\partial V}{\partial \varepsilon^P_{ij,k}}\varepsilon^P_{ij,k} dx\\ &= \int_\Omega \Sigma(x) e_0^{-N}\left(\frac{2}{3}\right)^{\frac{N+1}{2}} (\varepsilon^P : \varepsilon^P + l^2\nabla\varepsilon^P : \nabla\varepsilon^P)^{\frac{N+1}{2}} dx.\end{aligned} \tag{3.1}$$

Therefore

$$F(\lambda) \le \sup_{\varepsilon^P}\left\{\int_\Omega \left(\lambda : \varepsilon^P - \frac{\Sigma(x)e_0^{-N}}{2}\left(\frac{2}{3}\right)^{\frac{N+1}{2}} (\varepsilon^P : \varepsilon^P + l^2\nabla\varepsilon^P : \nabla\varepsilon^P)^{\frac{N+1}{2}}\right) dx\right\}, \tag{3.2}$$

where the supremum is taken over all the tensor fields $\varepsilon^P_{ij}(x)$. Since

$$\begin{aligned}\lambda : \varepsilon^P - \frac{\Sigma(x)e_0^{-N}}{2}\left(\frac{2}{3}\right)^{\frac{N+1}{2}} &(\varepsilon^P : \varepsilon^P + l^2\nabla\varepsilon^P : \nabla\varepsilon^P)^{\frac{N+1}{2}}\\ &\le \sup_{\varepsilon^P}\left\{\lambda : \varepsilon^P - \frac{\Sigma(x)e_0^{-N}}{2}\left(\frac{2}{3}\varepsilon^P : \varepsilon^P\right)^{\frac{N+1}{2}}\right\}\\ = Ne_0 2^{1/N}(\Sigma(x))^{-1/N}&\left(\frac{2}{3}\right)^{-\frac{N+1}{2N}}(N+1)^{-\frac{N+1}{N}}(\lambda : \lambda)^{\frac{N+1}{2N}},\end{aligned}$$

we have

$$F(\lambda) \le Ne_0 2^{1/N}\langle\Sigma^{-1/N}\rangle\left(\frac{2}{3}\right)^{-\frac{N+1}{2N}}(N+1)^{-\frac{N+1}{N}}(\lambda : \lambda)^{\frac{N+1}{2N}}.$$

From

$$\int_\Omega (\lambda : \varepsilon^P - \frac{1}{2}\sigma : \varepsilon^P) dx - F(\lambda) \le 0,$$

we deduce

$$\begin{aligned}\int_\Omega (\lambda : \varepsilon - \frac{1}{2}\sigma : \varepsilon)dx - F(\lambda) &\le \int_\Omega (\lambda(\varepsilon - \varepsilon^P) - \frac{1}{2}\sigma : (\varepsilon - \varepsilon^P))dx\\ &= \int_\Omega \Big(\frac{1}{2\mu}\lambda : \sigma - \frac{1}{4\mu}\sigma : \sigma\Big) dx.\end{aligned}$$

Hence

$$\lambda : \bar\varepsilon - \frac{1}{2}\bar\sigma : \bar\varepsilon - F(\lambda) \le \frac{1}{2\mu}\lambda : \bar\sigma - \frac{1}{4\mu}\bar\sigma : \bar\sigma$$

(from the Cauchy–Schwarz inequality, $\int_\Omega \sigma : \sigma dx \geq \bar{\sigma} : \bar{\sigma}$). Thus

$$\lambda : \Big(\bar{\varepsilon} - \frac{\bar{\sigma}}{2\mu}\Big) - Ne_0 2^{1/N} \langle \Sigma^{-1/N} \rangle \Big(\frac{2}{3}\Big)^{-\frac{N+1}{2N}} (N+1)^{-\frac{N+1}{N}} (\lambda : \lambda)^{\frac{N+1}{2N}} \leq \frac{1}{2}\bar{\sigma} : \Big(\bar{\varepsilon} - \frac{\bar{\sigma}}{2\mu}\Big).$$

Optimizing over the field λ, the optimal value of the left-hand side is obtained when

$$\lambda : (\bar{\varepsilon} - \frac{\bar{\sigma}}{2\mu}) = e_0 2^{1/N} \langle \Sigma^{-1/N} \rangle \Big(\frac{2}{3}\Big)^{-\frac{N+1}{2N}} (N+1)^{\frac{-1}{N}} (\lambda : \lambda)^{\frac{N+1}{2N}}.$$

We then obtain the bound

$$\Big(\Big(\bar{\varepsilon} - \frac{\bar{\sigma}}{2\mu}\Big) : \Big(\bar{\varepsilon} - \frac{\bar{\sigma}}{2\mu}\Big)\Big)^{\frac{1+N}{2}} \Big(\frac{2}{3}\Big)^{\frac{N+1}{2}} e_0^{-N} \langle \Sigma^{-1/N} \rangle^{-N} \leq \bar{\sigma} : \Big(\bar{\varepsilon} - \frac{\bar{\sigma}}{2\mu}\Big). \tag{3.3}$$

From

$$\bar{\varepsilon} - \frac{\bar{\sigma}}{2\mu} = \bar{\varepsilon}^P,$$

the bound can be written as

$$(\bar{\varepsilon}^P : \bar{\varepsilon}^P)^{\frac{1+N}{2}} \Big(\frac{2}{3}\Big)^{\frac{N+1}{2}} e_0^{-N} \langle \Sigma^{-1/N} \rangle^{-N} \leq \bar{\sigma} : \bar{\varepsilon}^P.$$

Using the Cauchy–Schwarz inequality for the right-hand side

$$\bar{\sigma} : \bar{\varepsilon}^P \leq (\bar{\sigma} : \bar{\sigma})^{1/2} (\bar{\varepsilon}^P : \bar{\varepsilon}^P)^{1/2}, \tag{3.4}$$

we deduce the following bound for $\|\bar{\sigma}\|$

$$\|\bar{\varepsilon}^P\|^N \Big(\frac{2}{3}\Big)^{\frac{N+1}{2}} e_0^{-N} \langle \Sigma^{-1/N} \rangle^{-N} \leq \|\bar{\sigma}\|.$$

This can be obtained by differentiating the Reuss bound for the effective energy (3.25) of Fleck and Willis [3] with respect to $\bar{\varepsilon}^P_{ij}$; i.e., the left-hand side of the above equals

$$\Big(\frac{\partial V_R}{\partial \bar{\varepsilon}^P_{ij}} . \frac{\partial V_R}{\partial \bar{\varepsilon}^P_{ij}}\Big)^{1/2},$$

where $V_R(\bar{\varepsilon}^P_{ij})$ is the Fleck and Willis's Reuss bound and $\bar{\varepsilon}^P$ stands for ε^{P0} in Fleck and Willis's notations.

4. Hashin–Shtrikman-type bound for the stress. We now deduce a Hashin–Shtrikman-type bound for the constitutive relation. The idea follows closely those for bounding the effective energy of a nonlinear composite and those of Milton–Serkov [8] and Talbot and Willis [19]. We use the null Lagrangian $\sigma : \varepsilon$. As in the previous section, it is necessary to manipulate the quantity $\int_\Omega \sigma : \varepsilon^P dx$. We will write this in terms of σ, s, and τ rather than ε^P and $\nabla\varepsilon^P$; the reason will be given later. From (2.3a,b) and (3.1),

$$\int_\Omega \sigma : \varepsilon^P dx = e_0 \Big(\frac{2}{3}\Big)^{-\frac{N+1}{2N}} \int_\Omega \Sigma(x)^{-1/N} \Big((\sigma + s) : (\sigma + s) + \frac{1}{l^2}\tau : \tau\Big)^{\frac{N+1}{2N}} dx. \tag{4.1}$$

The expression under the integral on the right-hand side is nonlinear; thus following the well-known procedure for bounding nonlinear composites (see, for example, [3] among many other references), we choose a "linear comparison" quantity

$$b(x)\Big((\sigma+s):(\sigma+s)+\frac{1}{l^2}\tau:\tau\Big).$$

Indeed, in the unrealistic case of linear components, i.e., $N=1$,

$$\int_\Omega \sigma:\varepsilon^P dx=\int_\Omega b(x)\Big((\sigma+s):(\sigma+s)+\frac{1}{l^2}\tau:\tau\Big)dx,$$

where $b(x)=(3/2)e_0\Sigma(x)^{-1}$. We then choose a homogeneous comparison material; i.e., we compare this quantity to $b_0((\sigma+s):(\sigma+s)+\tau:\tau/l^2)$ where $b_0\le b(x)$. This again follows the usual procedure for bounding the effective energy, and for bounding the constitutive relation of Talbot and Willis [19].

For each tensor β, we define

$$\begin{aligned}F(\beta)&=\sup_\rho\{\beta:\rho+(b_0-b(x))(\rho:\rho)\}\\&=\frac{\beta:\beta}{4(b(x)-b_0)}.\end{aligned}$$

For $\rho=\sigma+s$,

$$\beta:(\sigma+s)+(b_0-b(x))((\sigma+s):(\sigma+s))-\frac{\beta:\beta}{4(b(x)-b_0)}\le 0,$$

so

$$\beta:(\sigma+s)+(b_0-b(x))\Big((\sigma+s):(\sigma+s)+\frac{1}{l^2}\tau:\tau\Big)-\frac{\beta:\beta}{4(b(x)-b_0)}\le 0.$$

From this

$$\begin{gathered}\beta:(\sigma+s)+(b_0-b(x))\Big((\sigma+s):(\sigma+s)+\frac{1}{l^2}\tau:\tau\Big)\\ \frac{-\beta:\beta}{4(b(x)-b_0)}+\frac{1}{4\mu}\sigma:\sigma-\frac{1}{2}\sigma:(\varepsilon-\varepsilon^P)\le 0.\end{gathered}$$

Taking the integral over Ω,

$$\begin{aligned}&-\frac{1}{2}\bar\sigma:\bar\varepsilon+\int_\Omega\Bigg(\frac{1}{4\mu}\sigma:\sigma+\beta:(\sigma+s)+b_0\Big((\sigma+s):(\sigma+s)+\frac{1}{l^2}\tau:\tau\Big)\\&\qquad-\frac{\beta:\beta}{4(b(x)-b_0)}\Bigg)dx+\int_\Omega\Bigg(\frac{1}{2}\sigma:\varepsilon^P-b(x)\Big((\sigma+s):(\sigma+s)+\frac{1}{l^2}\tau:\tau\Big)\Bigg)dx\le 0.\end{aligned}\tag{4.2}$$

Let K be the set of triplets of tensors (σ,s,τ) that satisfy $\sigma_{ij,j}=p_{,i}$ for a scalar function $p(x)$, $\tau_{ijk}n_k=0$ on $\partial\Omega$ and $\tau_{ijk,k}=s_{ij}$. We proceed by taking the infimum of the left-hand side of (4.2) with respect to $(\sigma,s,\tau)\in K$. From (4.1),

$$\begin{aligned}&\int_\Omega\frac{1}{2}\sigma:\varepsilon^P-b(x)\Big((\sigma+s):(\sigma+s)+\frac{1}{l^2}\tau:\tau\Big)dx\\&\ge\int_\Omega\inf_Z\left\{\left(\frac{1}{2}e_0\left(\frac{2}{3}\right)^{-\frac{N+1}{2N}}(\Sigma(x))^{-1/N}Z^{(N+1)/(2N)}-b(x)Z\right)\right\}dx,\end{aligned}\tag{4.3}$$

where Z is a scalar quantity. Computing the infimum, we get

$$\begin{aligned}&\inf_{\{\sigma,s,\tau\}\in K}\int_\Omega \frac{1}{2}\sigma : \varepsilon^P - b(x)\Big((\sigma+s):(\sigma+s)+\frac{1}{l^2}\tau:\tau\Big)dx\\ &\geq -\frac{1-N}{2N}\Big(\frac{1+N}{2N}\Big)^{\frac{N+1}{N-1}} 2^{\frac{2N}{1-N}} e_0^{\frac{2N}{N-1}} \Big(\frac{2}{3}\Big)^{\frac{1+N}{1-N}} \int_\Omega \Sigma(x)^{\frac{2}{1-N}} b(x)^{\frac{1+N}{1-N}} dx.\end{aligned}$$

Inequality (4.3) bears some resemblance to the procedure for bounding the effective energy of a nonlinear composite initiated by Ponte-Castañeda [12]. Note that it is not possible to obtain a finite infimum if we use (3.1) instead of (4.1) and a linear comparison material.

Now we find

$$\inf_{\{\sigma,s,\tau\}\in K}\int_\Omega \Big(\frac{1}{4\mu}\sigma:\sigma+\beta:(\sigma+s)+b_0\Big((\sigma+s):(\sigma+s)+\frac{1}{l^2}\tau:\tau\Big)\Big)dx.$$

Taking a variation with respect to σ, we find that for all stress tensors σ' with zero mean that satisfy (2.4a) and $\sigma'_{ii}=0$, we have

$$\int\Big(\beta+\frac{1}{2\mu}\sigma+2b_0(\sigma+s)\Big):\sigma' dx = 0. \tag{4.4}$$

Substituting $s_{ij}=\tau_{ijk,k}$ and taking a variation of τ, for all fields τ' such that $\tau'_{ijk}n_k = 0$ on $\partial\Omega$, we have

$$\int_\Omega\Big(-\beta_{ij,k}-2b_0(\tau_{ijl,lk}+\sigma_{ij,k})+\frac{2b_0}{l^2}\tau_{ijk}\Big)\tau'_{ijk}dx = 0. \tag{4.5}$$

Equation (4.4) implies that

$$\begin{aligned}\beta_{ij}+\frac{1}{2\mu}\sigma_{ij}+2b_0(\sigma_{ij}+s_{ij}) &= \frac{1}{2}(v_{i,j}+v_{j,i}),\\ v_{i,i} &= 0\end{aligned} \tag{4.6}$$

for a vector field $v(x)\in\mathbb{R}^3$ with an affine boundary displacement, i.e., $v_i=\bar{e}_{ij}x_j$ on the boundary $\partial\Omega$; so from (2.4a)

$$v_{i,jj}-(4b_0+1/\mu)p_{,i} = 2\beta_{ij,j}+4b_0 s_{ij,j}, \tag{4.7}$$

the constant tensor $\bar{e}$ satisfies

$$\bar{e}_{ij} = \langle\beta_{ij}\rangle+\frac{\bar{\sigma}_{ij}}{2\mu}+2b_0\bar{\sigma}_{ij}. \tag{4.8}$$

Choosing $\tau'_{ijk}(x)=\theta_{ij,k}(x)$ where θ satisfies the condition $\theta_{ij,k}n_k=0$ on $\partial\Omega$, we get

$$\begin{aligned}&\int_\Omega\Big(\beta_{ij,k}+2b_0(\tau_{ijl,lk}+\sigma_{ij,k})-\frac{2b_0}{l^2}\tau_{ijk}\Big)_{,k}\theta_{ij}\\ &+\int_{\partial\Omega}(\beta_{ij,k}+2b_0(\tau_{ijl,lk}+\sigma_{ij,k})-\frac{2b_0}{l^2}\tau_{ijk}\Big)n_k\theta_{ij}dS = 0.\end{aligned}$$

As $\theta(x)$ can be chosen arbitrarily, we deduce that

$$\Big(\beta_{ij,k}+2b_0(\tau_{ijl,lk}+\sigma_{ij,k})-\frac{2b_0}{l^2}\tau_{ijk}\Big)_{,k} = 0,$$

and

$$\Big(\beta_{ij,k} + 2b_0(\tau_{ijl,lk} + \sigma_{ij,k}) - \frac{2b_0}{l^2}\tau_{ijk}\Big)n_k = 0$$

on $\partial\Omega$. From these

$$\beta_{ij,kk} + 2b_0(s_{ij,kk} + \sigma_{ij,kk}) - \frac{2b_0}{l^2}s_{ij} = 0, \tag{4.9}$$

with the boundary condition

$$\Big(\beta_{ij,k} + 2b_0(\sigma_{ij,k} + s_{ij,k})\Big)n_k = 0.$$

Using $\sigma' = \sigma - \bar{\sigma}$ and $\tau' = \tau$ in (4.4) and (4.5), we deduce that

$$\begin{aligned}\inf_{\{\sigma,s,\tau\}\in K}\int_\Omega\bigg(\frac{1}{4\mu}\sigma : \sigma + \beta : (\sigma + s) + b_0\Big((\sigma + s) : (\sigma + s) + \frac{1}{l^2}\tau : \tau\Big)\bigg)dx \\ = \frac{1}{2}\int \beta : (\sigma + s)dx + \frac{1}{2}\langle\beta\rangle : \bar{\sigma} + \frac{1}{4\mu}\bar{\sigma} : \bar{\sigma} + b_0\bar{\sigma} : \bar{\sigma}.\end{aligned}$$

We then deduce the following bound for the stress:

$$\begin{aligned}\int_\Omega\bigg(\frac{1}{2}\beta : (\sigma + s) - \frac{\beta : \beta}{4(b(x) - b_0)}\bigg)dx + \frac{1}{2}\langle\beta\rangle : \bar{\sigma} + \frac{1}{4\mu}\bar{\sigma} : \bar{\sigma} + b_0\bar{\sigma} : \bar{\sigma} - \frac{1}{2}\bar{\sigma} : \bar{\varepsilon} \\ - \frac{1 - N}{2N}\Big(\frac{1 + N}{2N}\Big)^{\frac{N+1}{N-1}} 2^{\frac{2N}{1-N}} e_0^{\frac{2N}{N-1}}\Big(\frac{2}{3}\Big)^{\frac{1+N}{1-N}}\int_\Omega \Sigma(x)^{\frac{2}{1-N}} b(x)^{\frac{1+N}{1-N}}dx \le 0.\end{aligned} \tag{4.10}$$

Solving (4.7) and (4.9), we find that σ and s depend on β linearly. In particular, there are fourth-order tensors $M_{ijkl}(x)$ and $N_{ijkl}(x)$ such that

$$\sigma(x) - \bar{\sigma} = \int M_{ijkl}(x - x')(\beta(x') - \langle\beta\rangle)dx', \quad s(x) = \int N_{ijkl}(x - x')(\beta(x') - \langle\beta\rangle)dx',$$

the integral being taken over the infinite domain due to the small correlation of the phases. We deduce this in Appendix A. Optimizing (4.10) by taking the supremum of

$$\int\bigg(\frac{1}{2}\beta : (\sigma + s) - \frac{\beta : \beta}{4(b(x) - b_0)}\bigg)dx + \frac{1}{2}\langle\beta\rangle : \bar{\sigma}, \tag{4.11}$$

with respect to β, at the value of β that the supremum is attained, the bound becomes

$$\begin{aligned}&\frac{1}{2}\langle\beta\rangle : \bar{\sigma} + \frac{1}{4\mu}\bar{\sigma} : \bar{\sigma} + b_0\bar{\sigma} : \bar{\sigma} - \frac{1}{2}\bar{\sigma} : \bar{\varepsilon} \\ &-\frac{1 - N}{2N}\Big(\frac{1 + N}{2N}\Big)^{\frac{N+1}{N-1}} 2^{\frac{2N}{1-N}} e_0^{\frac{2N}{N-1}}\Big(\frac{2}{3}\Big)^{\frac{1+N}{1-N}}\int_\Omega \Sigma(x)^{\frac{2}{1-N}} b(x)^{\frac{1+N}{1-N}}dx \le 0.\end{aligned} \tag{4.12}$$

We now restrict our consideration to an M phase composite. Let $\chi_r(x)$ be the indicator of phase r. The probability that a point x is in phase r is p_r so that the volume fraction of phase r is p_r. The probability that two points x and x' are in phases r and s, respectively, is $\langle\chi_r(x)\chi_s(x')\rangle = p_{rs}(x, x')$. The composite is assumed to be statistically homogeneous isotropic so that $p_{rs}(x,x') = p_{rs}(x-x') = p_{rs}(|x-x'|)$. The function $b(x)$ is constant in each phase, i.e.,

$$b(x) = \sum_{r=1}^{M} b_r \chi_r(x).$$

We also restrict the field $\beta(x)$ to the form

$$\beta(x) = \sum_{r=1}^{M} \beta^r \chi_r(x).$$

The expression (4.11) that we need to maximize has the form

$$\frac{1}{2}\int (M+N)_{ijkl}(x)\left(\sum_{r,s=1}^{M} \beta^r_{ij}\beta^s_{kl}p_{rs}(x) - \beta^r_{ij}\beta^s_{kl}p_r p_s\right)dx + \sum_{s=1}^{M} p_s\beta^s_{ij}\bar{\sigma}_{ij} - \sum_{s=1}^{M}\frac{\beta^s_{ij}\beta^s_{ij}}{4(b_s-b_0)}p_s.$$

Taking a variation with respect to β, we deduce that the best value of β satisfies the equation

$$\sum_{r,s=1}^{M} {\beta'}^s_{ij}\beta^r_{kl}\int (M+N)_{ijkl}(x)(p_{rs}(x) - p_r p_s)dx + \left(\sum_{s=1}^{M} p_s {\beta'}^s_{ij}\right)\bar{\sigma}_{ij} - \sum_{s=1}^{M}\frac{\beta^s_{ij}{\beta'}^s_{ij}}{2(b_s-b_0)}p_s = 0$$

for all ${\beta'}^s$ for $s = 1,\ldots,M$ so that

$$\sum_{r=1}^{M}\beta^r_{kl}\int (M+N)_{ijkl}(x)(p_{rs}(x) - p_r p_s)dx + p_s\bar{\sigma}_{ij} - \frac{\beta^s_{ij}p_s}{2(b_s-b_0)} = 0.$$

Restricting to a two-phase isotropic material, there is a function $h(x) = h(|x|)$ such that

$$p_{11}(x) - p_1p_1 = p_{22}(x) - p_2p_2 = -(p_{12}(x) - p_1p_2) = -(p_{21}(x) - p_1p_2) = p_1p_2h(r),$$

where $r = |x|$. Defining the fourth-order tensor

$$A_{ijkl} = \int (M+N)_{ijkl}(x)h(x)dx,$$

the equations for β then become

$$A_{ijkl}(\beta^s_{kl} - \langle\beta_{kl}\rangle) + \bar{\sigma}_{ij} - \frac{\beta^s_{ij}}{2(b_s-b_0)} = 0.$$

To determine the left-hand side of (4.12), we need to compute $\langle\beta\rangle$. In Hill's notation, $A = (0, 2\mu_A)$. The equations for β are written as

$$(0,2\mu_A)(\beta^s - \langle\beta\rangle) + \bar{\sigma} - \frac{\beta^s}{2(b_s-b_0)} = 0,$$

which gives

$$\beta^s = \frac{2(b_s-b_0)}{4\mu_A(b_s-b_0)-1}\Big((0,2\mu_A)\langle\beta\rangle - \bar{\sigma}\Big).$$

From this we get

$$\langle \beta \rangle = \frac{\sum_{s=1}^{2} p_s 2(b_s - b_0)/(4\mu_A(b_s - b_0) - 1)}{4\mu_A \sum_{s=1}^{2} p_s(b_s - b_0)/(4\mu_A(b_s - b_0) - 1) - 1} \bar{\sigma}.$$

Letting $b_0 = b_1$ and $b_2 = \gamma b_0$ where $\gamma > 1$,

$$\langle \beta \rangle = \frac{2p_2 b_0(\gamma - 1)}{1 - 4p_1\mu_A b_0(\gamma - 1)} \bar{\sigma}.$$

We now maximize the left-hand side of (4.12) with respect to b_0 and γ to get

$$\begin{aligned} &\sup_{b_0} \sup_{\gamma \geq 1} \Bigg\{ \frac{p_2 b_0(\gamma - 1)}{1 - 4p_1\mu_A b_0(\gamma - 1)} \bar{\sigma} : \bar{\sigma} + \frac{1}{4\mu} \bar{\sigma} : \bar{\sigma} + b_0 \bar{\sigma} : \bar{\sigma} - \frac{1}{2} \bar{\sigma} : \bar{\varepsilon} \\ &- \frac{1 - N}{2N} \Big(\frac{1 + N}{2N}\Big)^{\frac{N+1}{N-1}} \Big(\frac{2}{e_0}\Big)^{\frac{2N}{1-N}} \Big(\frac{2}{3}\Big)^{\frac{1+N}{1-N}} b_0^{\frac{1+N}{1-N}} \Big(\Sigma_1^{\frac{2}{1-N}} p_1 + \gamma^{\frac{1+N}{1-N}} \Sigma_2^{\frac{2}{1-N}} p_2\Big) \Bigg\} \leq 0. \end{aligned} \tag{4.13}$$

A bound for the modulus of the stress can then be found from

$$\begin{aligned} &\sup_{b_0} \sup_{\gamma \geq 1} \Bigg\{ \frac{p_2 b_0(\gamma - 1)}{1 - 4p_1\mu_A b_0(\gamma - 1)} \|\sigma\|^2 + \frac{1}{4\mu} \|\sigma\|^2 + b_0 \|\sigma\|^2 - \frac{1}{2} \|\sigma\| \|\bar{\varepsilon}\| \\ &- \frac{1 - N}{2N} \Big(\frac{1 + N}{2N}\Big)^{\frac{N+1}{N-1}} \Big(\frac{2}{e_0}\Big)^{\frac{2N}{1-N}} \Big(\frac{2}{3}\Big)^{\frac{1+N}{1-N}} b_0^{\frac{1+N}{1-N}} \Big(\Sigma_1^{\frac{2}{1-N}} p_1 + \gamma^{\frac{1+N}{1-N}} \Sigma_2^{\frac{2}{1-N}} p_2\Big) \Bigg\} \leq 0. \end{aligned} \tag{4.14}$$

In Appendix B, we show that when the function $h(r) = e^{-r/a}$,

$$\mu_A = \frac{3}{20b_0} \frac{1}{(l/a + (1 + 4\mu b_0)^{1/2})^2} + \frac{1}{10b_0} \frac{1}{(l/a + 1)^2} - \frac{1}{4b_0}.$$

The quantity a represents the correlation length scale for the microstructure. When $|x - x'| >> a$, $p_{rs}(x, x') \approx p_r(x)p_s(x')$. Since we use a linear comparison material whose strength reference is of the order $1/b_0$, deep in the plastic range, we expect that the inverse of the optimal b_0 is of the order of the secant modulus which is much less than μ, i.e., $\mu b_0 >> 1$. Therefore, only the last two terms in the expression of μ_A have significant contribution; μ_A is approximated as

$$\mu_A = \frac{1}{10b_0} \frac{1}{(l/a + 1)^2} - \frac{1}{4b_0}.$$

We then take the maximum of the sum of the terms involving b_0 in (4.13)

$$\begin{aligned} &\frac{5\gamma(l/a + 1)^2 - 2p_1(\gamma - 1)}{(p_2 + \gamma p_1)5(l/a + 1)^2 - 2p_1(\gamma - 1)} b_0 \bar{\sigma} : \bar{\sigma} \\ &- \frac{1 - N}{2N} \Big(\frac{1 + N}{2N}\Big)^{\frac{N+1}{N-1}} \Big(\frac{2}{e_0}\Big)^{\frac{2N}{1-N}} \Big(\frac{2}{3}\Big)^{\frac{1+N}{1-N}} b_0^{\frac{1+N}{1-N}} \Big(\Sigma_1^{\frac{2}{1-N}} p_1 + \gamma^{\frac{1+N}{1-N}} \Sigma_2^{\frac{2}{1-N}} p_2\Big) \end{aligned}$$

with respect to b_0. The approximated bound is

$$\Sigma^+ e_0 \Big(\frac{2}{3}\Big)^{-\frac{1+N}{2N}} (\bar{\sigma} : \bar{\sigma})^{\frac{1+N}{2N}} - \bar{\sigma} : (\bar{\varepsilon} - \frac{\bar{\sigma}}{2\mu}) \leq 0, \tag{4.15}$$

where

$$\Sigma^+ = \max_{\gamma\ge 1}\left\{\left(\frac{5\gamma(l/a+1)^2-2p_1(\gamma-1)}{(p_2+\gamma p_1)5(l/a+1)^2-2p_1(\gamma-1)}\right)^{\frac{1+N}{2N}}\left(p_1\Sigma_1^{\frac{2}{1-N}}+p_2\gamma^{\frac{1+N}{1-N}}\Sigma_2^{\frac{2}{1-N}}\right)^{\frac{N-1}{2N}}\right\}.$$

Using the Cauchy–Schwarz inequality, a bound for $\|\bar\sigma\|$ can be found from

$$\Sigma^+ e_0\Big(\frac{2}{3}\Big)^{-\frac{1+N}{2N}}\|\bar\sigma\|^{\frac{1+N}{N}}-\|\bar\sigma\|\|\bar\epsilon\|+\frac{1}{2\mu}\|\bar\sigma\|^2\le 0. \tag{4.16}$$

Regarding

$$\bar\varepsilon-\frac{\bar\sigma}{2\mu}=\bar\varepsilon^P,$$

and using the Cauchy–Schwarz inequality, we get the bound for the modulus of the stress

$$\|\sigma\|\le(\Sigma^+)^{-N}e_0^{-N}\Big(\frac{2}{3}\Big)^{\frac{1+N}{2}}\|\bar\varepsilon^P\|^N. \tag{4.17}$$

This bound can be obtained by differentiating the energy upper bound U^+ in (5.12) of [3] with respect to $\bar\varepsilon^P$ ($\bar\varepsilon^P$ here stands for ε^{P0} in [3]) when we disregard the elastic part; i.e., it equals

$$\frac{\partial U^+}{\partial\bar\varepsilon^P_{ij}}\frac{\partial U^+}{\partial\bar\varepsilon^P_{ij}}.$$

5. Numerical results.

We study the effect of the length scale l on the stress bounds found in the previous sections. By differentiating the Hashin–Shtrikman upper bound for the energy, in the case of macroscopic uniaxial response, Fleck and Willis [3] show that when the material length scale l increases, the stress increases. This is confirmed from our bound (4.14) for the magnitude $\|\bar\sigma\|$ of the stress. In Figure 5.1, we plot on the log-log axes the magnitude of the stress $\|\bar\sigma\|$ versus the magnitude of the strain $\|\bar\varepsilon\|$ for the example where $N = 0.3$, $p_1 = 0.3$, $p_2 = 0.7$, $\Sigma_1 = 0.03$, $\Sigma_2 = 0.01$, $e_0 = 1$, $\mu = 1$ for the values 0.01, 0.1, and 1 of l/a. It is clear that the stress bound increases with increasing l/a. An additional feature that manifests from this plot is that when the total strain magnitude $\|\bar\varepsilon\|$ exceeds 0.015, the plots asymptote straight lines; i.e., the stress-strain relation follows a power law. This is consistent with (4.17), where we made the approximation (4.15) of the stress bound. (Note that deep in the plastic range, the magnitude of $\bar\varepsilon^P$ approximates $\|\bar\varepsilon\|$.)

Similar features are shown in Figure 5.2 for the same parameters except that $N = 0.1$. In the range plotted, since N is now smaller, we see that for small $\|\bar\varepsilon\|$, the bounds for different values of l/a are almost the same. The elastic strain dominates in this range so the material scale l has no effect.

Figure 5.3 shows that the approximated formula (4.16) gives about the same bound for the magnitude of the stress when the magnitude of the strain exceeds about 0.015. The dashed line is the stress versus strain curve found from the (4.16) where the solid line is the exact bound (4.14). When the total stress is smaller than 0.01, (4.16) may not adequately represent (4.14). The parameters we use are $N = 0.3, p_1 = 0.3, p_2 = 0.7, \Sigma_1 = 0.03, \Sigma_2 = 0.01, l/a = 0.1, e_0 = 1, \mu = 1$.

Keeping the same parameters except that $N = 0.1$, Figure 5.4 shows the exact Hashin–Shtrikman bound (4.14) and the approximated bound (4.16) for the magnitude of the stress in the log-log axis. We see that the two bounds are almost the same for small strain. This is because of the dominance of the elastic strain.

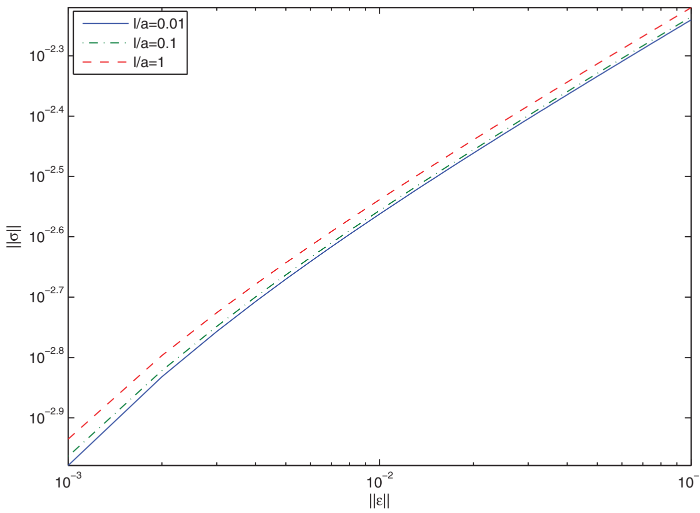

FIG. 5.1. *The stress bound increases with l/a.*

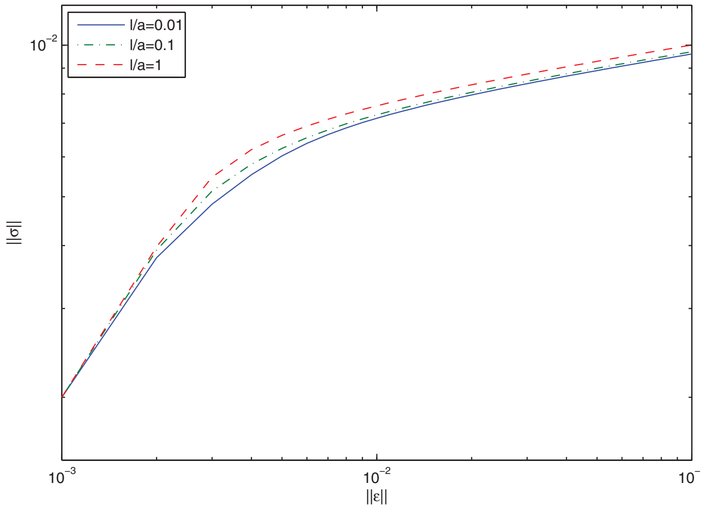

FIG. 5.2. *The stress versus the strain for the exact Hashin–Shtrikman bounds ($N = 0.1$).*

Given the boundary strain $\bar{\varepsilon}$, (3.3) and (4.13) give a region in the stress space where the effective stress tensor should lie for all the microstructures. In Figure 5.5, we plot the area restricted by the bounds (3.3) and (4.13) for the two-dimensional stress space $\bar{\sigma} = (\sigma_1, \sigma_2)$. The two-dimensional strain $\bar{\varepsilon} = (\varepsilon_1, \varepsilon_2)$ is $\varepsilon_1 = 0.001$ and $\varepsilon_2 = 0.0005$. This corresponds to the small stress magnitude area in Figure 5.3. Other parameters are $N = 0.3$, $l/a = 0.1$, $p_1 = 0.3$, $p_2 = 0.7$, $\Sigma_1 = 0.03$, $\Sigma_2 = 0.01$, $e_0 = 1$, $\mu = 1$.

Figure 5.6 shows the area of the stress for $\varepsilon_1 = 0.08$ and $\varepsilon_2 = 0.04$. The stress magnitude is in the larger end in Figure 5.3. Other parameters are kept the same. The area bounded by (3.3) seems to blow up as the magnitude of $\bar{\sigma}$ is now much

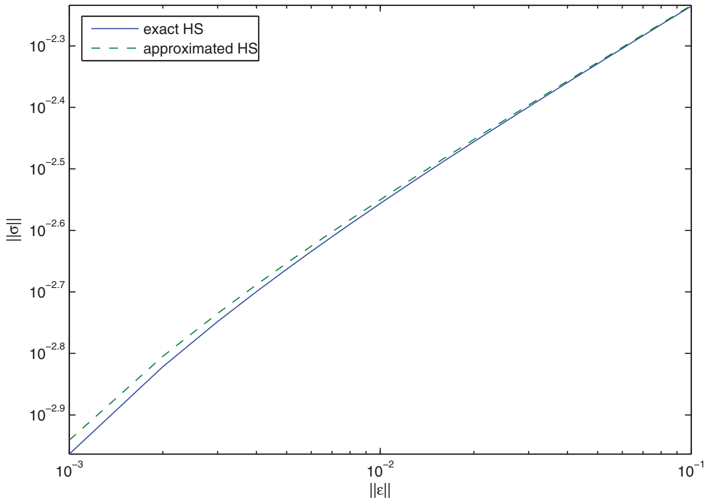

FIG. 5.3. *Stress versus strain for the exact and approximated Hashin–Shtrikman-type bounds.*

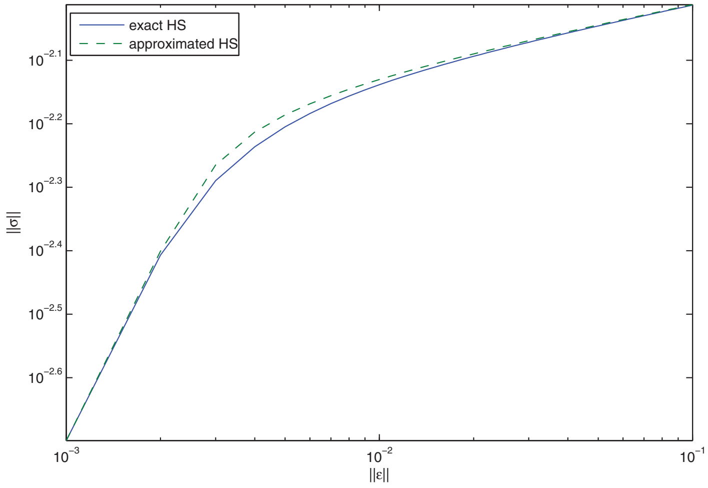

FIG. 5.4. *Stress versus strain for the exact and approximated Hashin–Shtrikman bounds ($N = 0.1$).*

smaller than the magnitude of $\bar{\varepsilon}$. The bound (3.3) now behaves like the linear bound

$$(\bar{\varepsilon} : \bar{\varepsilon})^{\frac{1+N}{2}} \left(\frac{2}{3}\right)^{\frac{N+1}{2}} e_0^{-N} \langle \Sigma^{-1/N} \rangle^{-N} \leq \bar{\sigma} : \bar{\varepsilon};$$

this is shown in Figure 5.7.

The bound (3.3) is insensitive to l/a. As shown in Figure 5.1, the bound for $\|\sigma\|$ increases as l/a increases. We predict that given a boundary strain $\bar{\varepsilon}$, the area in the stress space that bounds $\bar{\sigma}$ gets larger with increasing l/a. This is shown in Figure 5.8 for $\bar{\varepsilon} = (\varepsilon_1, \varepsilon_2)$ where $\varepsilon_1 = 0.001$ and $\varepsilon_2 = 0.0005$. Other parameters are as for Figure 5.6. The area for $l/a = 0.1$ is strictly contained inside the area for $l/a = 1$.

For the same parameters, Figure 5.9 presents the bound for the stress $\bar{\sigma} = (\sigma_1, \sigma_2)$ given that $\bar{\varepsilon} = (0.001, 0.0005)$. The dashed line shows the bound given by the ap-

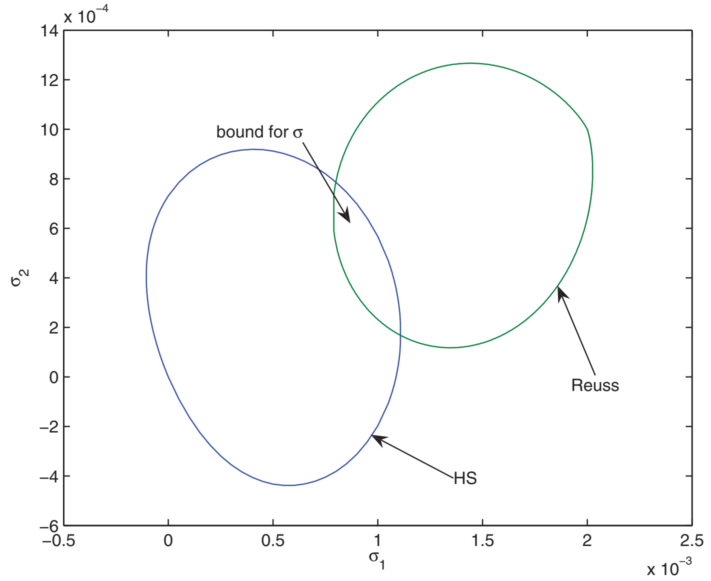

FIG. 5.5. *Bound for the stress when* $\bar{\varepsilon} = (0.001, 0.0005)$.

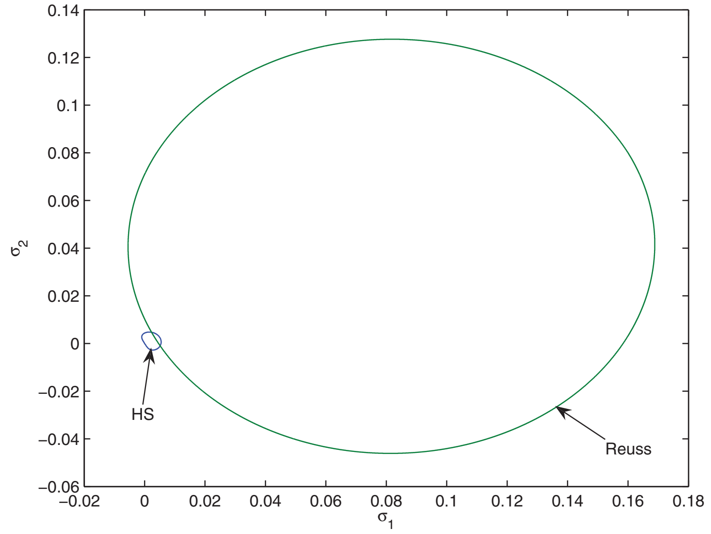

FIG. 5.6. *The stress bounds* (3.3) *and* (4.13) *in the two-dimensional space for* $\bar{\varepsilon} = (0.08, 0.04)$.

proximated stress bound (4.15). It is clear that in the small stress magnitude range, (4.15) does not give a good approximation to the exact bound. However, for large stress magnitude, (4.15) gives an excellent approximation. This is shown in Figure 5.10 for $\bar{\varepsilon} = (0.08, 0.04)$.

6. Conclusions. We established bounds for the average stress in terms of the average strain for an elasto-plastic composite whose components follow the strain gradient theory of Fleck and Willis [3]. We confirmed rigorously the prediction by [3] on the dependence of the average stress on the internal length scale, made by

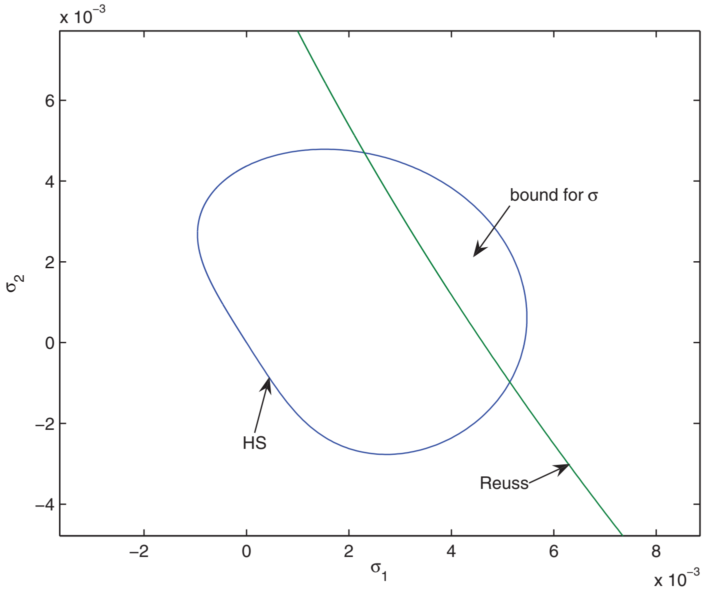

Fig. 5.7. *Bound for the stress when* $\bar{\varepsilon} = (0.08, 0.04)$.

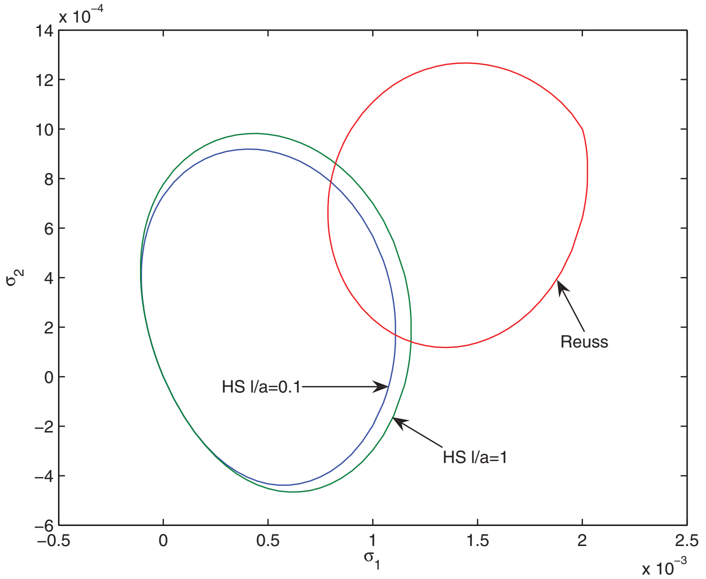

Fig. 5.8. *Bound for the the stress increases when* l/a *increases.*

formally differentiating their energy bounds. Our results provide stress bounds for all the range of the plastic strain. Deep in the plastic regime, they coincide with the formal approximations by Fleck and Willis [3]. Given an average strain, the bounds obtained here provide a specific region in the stress space in which the average stress must lie, which is not available from the energy bounds. Our method is a combination of the known bounding approaches for composite materials. It is a modification of the elegant techniques for bounding the constitutive relations by Milton and Serkov

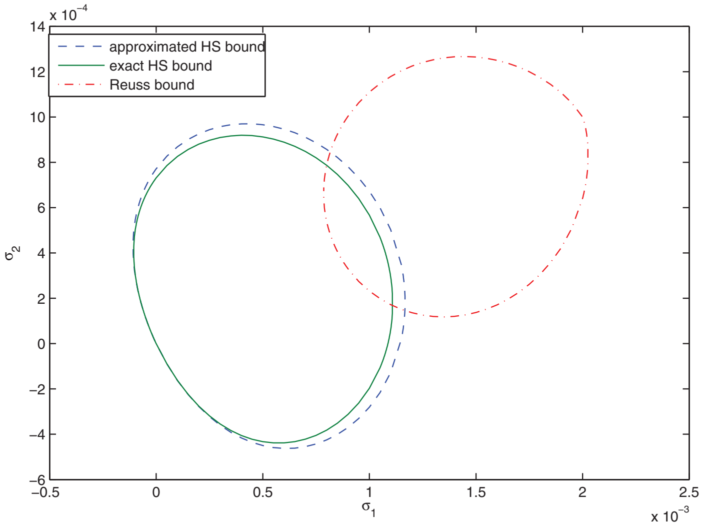

FIG. 5.9. *Exact and approximated bounds for* $\bar{\varepsilon} = (0.001, 0.0005)$.

[8] and Talbot and Willis [19]. It also follows the ideas developed for the "nonlinear Hashin–Shtrikman" bounds by Talbot and Willis [18], and Ponte-Castañeda [12].

Appendix A. In this appendix, we solve the equations (4.7) and (4.9). Let $G_{ip}(x, x')$ be the Green function satisfying

$$\frac{\partial^2 G_{ip}(x,x')}{\partial x_j \partial x_j} + \delta_{ip}\delta(x - x') = P_{,i},$$

subjecting to the incompressible condition $\partial G_{ip}(x,x')/\partial x_i = 0$ with the homogeneous boundary condition. The solution v for (4.7) can be written as

$$v_i(x') = \bar{e}_{ij}x_j + \int_\Omega \frac{\partial G_{ki}(x,x')}{\partial x_l}(2\beta_{kl}(x) + 4b_0 s_{kl}(x))dx.$$

Since

$$\int_\Omega \frac{\partial G_{ki}(x,x')}{\partial x_l}dx = 0,$$

we can write v as

$$v_i(x') = \bar{e}_{ij}x_j + \int_\Omega \frac{\partial G_{ki}(x,x')}{\partial x_l}(2\beta_{kl}(x) + 4b_0 s_{kl}(x) - 2\langle\beta_{kl}\rangle)dx.$$

Let

$$e_{ij}(x') = \frac{1}{2}(v_{i,j}(x') + v_{j,i}(x')).$$

Differentiating both sides and taking the symmetrization, we get

$$e_{ij}(x') = \bar{e}_{ij} + \int_\Omega \Gamma_{ijkl}(x,x')(2\beta_{kl}(x) + 4b_0 s_{kl}(x) - 2\langle\beta_{kl}\rangle)dx \tag{A.1}$$

where the fourth-order tensor Γ is defined as

$$\Gamma_{ijkl}(x,x') = \frac{\partial^2 G_{ki}(x,x')}{\partial x_l \partial x'_j} \quad \text{symm } (i,j)(k,l).$$

Assuming that the correlation length is small, following [3], we can substitute Γ by its infinite body form, which depends only on $x - x'$; i.e., $\Gamma(x,x') = \Gamma(x-x')$. Then from (4.6) and (4.8), we have

$$\begin{aligned} &\beta_{ij} + \frac{1}{2\mu}\sigma_{ij} + 2b_0(\sigma_{ij} + s_{ij}) = \langle\beta_{ij}\rangle + \frac{\bar{\sigma}_{ij}}{2\mu} + 2b_0\bar{\sigma}_{ij} \\ &\quad + \int \Gamma_{ijkl}(x-x')(2\beta_{kl}(x) + 4b_0 s_{kl}(x) - 2\langle\beta_{kl}\rangle)dx. \end{aligned} \tag{A.2}$$

Note that the integral now can be approximated by an integral over the infinite domain.

To solve (4.9), we consider the function $g(x,x')$ that satisfies the equation

$$\nabla_x^2 g(x,x') - \frac{1}{l^2}g(x,x') + \delta(x-x') = 0,$$

with the Neumann boundary condition. The solution of (4.9) can be writen as

$$s_{ij}(x') + \sigma_{ij}(x') + \frac{\beta_{ij}(x')}{2b_0} = \frac{1}{l^2}\int_\Omega g(x,x')\Big(\sigma_{ij}(x) + \frac{\beta_{ij}(x)}{2b_0}\Big)dx.$$

Since $(1/l^2)\int_\Omega g(x,x')dx = 1$, we can write this as

$$s_{ij}(x') + \sigma_{ij}(x') + \frac{\beta_{ij}(x')}{2b_0} = \frac{1}{l^2}\int_\Omega g(x,x')\Big(\sigma_{ij}(x) + \frac{\beta_{ij}(x)}{2b_0} - \bar{\sigma}_{ij} - \frac{\langle\beta_{ij}\rangle}{2b_0}\Big) + \bar{\sigma}_{ij} + \frac{\langle\beta_{ij}\rangle}{2b_0}.$$

In the asymptotic limit, we can substitute $g(x, x')$ by its infinite body form $g(x - x')$. The equation then becomes

$$\begin{aligned} & s_{ij}(x') + \sigma_{ij}(x') + \frac{\beta_{ij}(x')}{2b_0} \\ & = \frac{1}{l^2} \int_\Omega g(x - x') \left(\sigma_{ij}(x) + \frac{\beta_{ij}(x)}{2b_0} - \bar{\sigma}_{ij} - \frac{\langle \beta_{ij} \rangle}{2b_0} \right) + \bar{\sigma}_{ij} + \frac{\langle \beta_{ij} \rangle}{2b_0}. \end{aligned} \tag{A.3}$$

We now need to solve (A.2) and (A.3) for σ and s. Taking the Fourier transform

$$\hat{f}(\xi) = \int e^{i\xi.x} f(x) dx,$$

we then have

$$\begin{aligned} \hat{\beta}_{ij} + \frac{\hat{\sigma}_{ij}}{2\mu} + 2b_0(\hat{\sigma}_{ij} + \hat{s}_{ij}) = \widehat{\langle \beta \rangle}_{ij} + \frac{\hat{\bar{\sigma}}_{ij}}{2\mu} + 2b_0 \hat{\bar{\sigma}}_{ij} \\ + \hat{\Gamma}_{ijkl}(2\hat{\beta}_{kl} + 4b_0 \hat{s}_{kl} - 2\widehat{\langle \beta \rangle}_{kl}), \end{aligned}$$

and

$$\hat{\sigma}_{ij} + \hat{s}_{ij} + \frac{\hat{\beta}_{ij}}{2b_0} = \frac{1}{l^2} \hat{g} \left(\hat{\sigma}_{ij} + \frac{\hat{\beta}_{ij}}{2b_0} - \hat{\bar{\sigma}}_{ij} - \frac{\widehat{\langle \beta \rangle}_{ij}}{2b_0} \right) + \hat{\bar{\sigma}}_{ij} + \frac{\widehat{\langle \beta \rangle}_{ij}}{2b_0}.$$

Rearranging these equations we have

$$\hat{\sigma} - \hat{\bar{\sigma}} = \frac{2\mu(2\hat{\Gamma} - I)}{1 + 4b_0\mu}(\hat{\beta} - \widehat{\langle \beta \rangle}) + \frac{4\mu b_0(2\hat{\Gamma} - I)}{1 + 4b_0\mu} \hat{s},$$

and

$$\hat{\sigma} - \hat{\bar{\sigma}} = \frac{-1}{2b_0}(\hat{\beta} - \widehat{\langle \beta \rangle}) - \frac{l^2}{l^2 - \hat{g}} \hat{s},$$

where

$$I_{ijkl} = \frac{1}{2} \left(\delta_{ik}\delta_{jl} + \delta_{il}\delta_{jk} - \frac{2}{3}\delta_{ij}\delta_{kl} \right)$$

is the incompressible identity tensor. From this

$$\left(\frac{2\mu(2\hat{\Gamma} - I)}{1 + 4b_0\mu} + \frac{I}{2b_0} \right)(\hat{\beta} - \widehat{\langle \beta \rangle}) + \left(\frac{4\mu b_0(2\hat{\Gamma} - I)}{1 + 4\mu b_0} + \frac{l^2 I}{l^2 - \hat{g}} \right) \hat{s} = 0. \tag{A.4}$$

On using $\hat{\Gamma}(2\hat{\Gamma} - I) = 0$,

$$\hat{\Gamma}\hat{s} = -\frac{l^2 - \hat{g}}{2b_0 l^2} \hat{\Gamma}(\hat{\beta} - \widehat{\langle \beta \rangle}).$$

Substituting this into (A.4), we get

$$\frac{8\mu b_0 \hat{g} \hat{\Gamma} + l^2 I}{2b_0 l^2 (1 + 4\mu b_0)}(\hat{\beta} - \widehat{\langle \beta \rangle}) + \frac{l^2 + 4\mu b_0 \hat{g}}{(l^2 - \hat{g})(1 + 4\mu b_0)} \hat{s} = 0.$$

From this we find

$$\hat{s} = \frac{-(8\mu b_0 \hat{g}\hat{\Gamma} + l^2 I)(l^2 - \hat{g})}{2b_0 l^2 (l^2 + 4\mu b_0 \hat{g})}(\hat{\beta} - \widehat{\langle\beta\rangle}), \tag{A.5}$$

and

$$\hat{\sigma} - \hat{\bar{\sigma}} = \frac{2\mu \hat{g}(2\hat{\Gamma} - I)}{l^2 + 4\mu b_0 \hat{g}}(\hat{\beta} - \widehat{\langle\beta\rangle}), \tag{A.6}$$

which we denote as

$$\hat{s} = \hat{N}(\hat{\beta} - \widehat{\langle\beta\rangle}),$$

and

$$\hat{\sigma} = \hat{M}(\hat{\beta} - \widehat{\langle\beta\rangle}).$$

The values of $\hat{\Gamma}$ and $\hat{g}$ are

$$\hat{g}(\xi) = \frac{l^2}{1 + l^2|\xi|^2}, \quad \hat{\Gamma}_{ijkl}(\xi) = \frac{\delta_{ik}\xi_j\xi_l}{|\xi|^2} - \frac{\xi_i\xi_j\xi_k\xi_l}{|\xi|^4}.$$

Appendix B. We now compute the value of μ_A. We have

$$10\mu_A = A_{ijij} = \int (M+N)_{ijij}(x)h(x)dx.$$

From (A.5) and (A.6),

$$(\hat{M} + \hat{N})_{ijij} = \frac{2\mu \hat{g}^2 (2\hat{\Gamma}_{ijij} - I_{ijij})}{l^2(l^2 + 4\mu b_0 \hat{g})} + \frac{\hat{g} I_{ijij}}{2b_0 l^2} - \frac{I_{ijij}}{2b_0}.$$

Since $\hat{\Gamma}_{ijij} = 1$ and $I_{ijij} = 5$,

$$(\hat{M} + \hat{N})_{ijij} = \frac{3}{2b_0}\frac{1}{l^2|\xi|^2 + 1 + 4\mu b_0} + \frac{1}{b_0(l^2|\xi|^2 + 1)} - \frac{5}{2b_0}.$$

We then apply the same procedure as in [3].

EFFECTIVE EQUATIONS FOR LOCALIZATION AND SHEAR BAND FORMATION*

THEODOROS KATSAOUNIS[†] AND ATHANASIOS E. TZAVARAS[‡]

Abstract. We develop a quantitative criterion determining the onset of localization and shear band formation at high strain-rate deformations of metals. We introduce an asymptotic procedure motivated by the theory of relaxation and the Chapman–Enskog expansion and derive an effective equation for the evolution of the strain rate, consisting of a second order nonlinear diffusion regularized by fourth order effects and with parameters determined by the degree of thermal softening, strain hardening, and strain-rate sensitivity. The nonlinear diffusion equation changes type across a threshold in the parameter space from forward parabolic to backward parabolic, what highlights the stable and unstable parameter regimes. The fourth order effects play a regularizing role in the unstable region of the parameter range.

Key words. shear band, localization, thermoviscoplasticity, Chapman–Enskog expansion

1. Introduction.

One striking instance of material instability is observed in the course of deformations of metals at high strain rates. It appears as an instability in shear and leads to regions of intensely concentrated shear strain, called shear bands. Since shear bands are often precursors to rupture, their study has attracted attention in the mechanics literature (e.g., [1, 7, 8, 13, 14, 17, 22, 24, 25]).

In experimental investigations of high strain-rate deformations of steels, observations of shear bands are typically associated with strain softening response—past a critical strain—of the measured stress-strain curve [8]. It was recognized by Zener and Hollomon [27] that the effect of the deformation speed is twofold: First, an increase in the deformation speed changes the deformation conditions from isothermal to nearly adiabatic. Second, strain rate has an effect per se and needs to be included in the constitutive modeling.

Under isothermal conditions, metals, in general, strain harden and exhibit a stable response. As the deformation speed increases, the heat produced by the plastic work causes an increase in the temperature. For certain metals, the tendency for thermal softening may outweigh the tendency for strain hardening and deliver net softening. A destabilizing feedback mechanism is then induced, which operates as follows (see [8]): Nonuniformities in the strain rate result in nonuniform heating. Since the material is softer at the hotter spots and harder at the colder spots, if heat diffusion is too weak to equalize the temperatures, the initial nonuniformities in the strain rate are, in turn, amplified. This mechanism tends to localize the total deformation into narrow regions. On the other hand, there is opposition to this process by "viscous effects"

induced by strain-rate sensitivity. The outcome of the competition depends mainly on the relative weights of thermal softening, strain hardening, and strain-rate sensitivity, as well as the loading circumstances.

This qualitative scenario is widely accepted as the mechanism of shear band formation. However, despite several attempts, a quantitative explanation of the phenomenon of shear bands is presently lacking. Moreover, the above picture is somewhat imprecise in terms of what determines (or rules out) the onset of localization. It is this aspect of the problem that we attempt to address in the present work. We use the model

$$\begin{aligned} v_t &= \frac{1}{r}\,\sigma_x, \\ \theta_t &= \kappa\theta_{xx} + \sigma\gamma_t, \\ \gamma_t &= v_x, \end{aligned} \tag{1.1}$$

where r, κ are nondimensional constants and the stress is given by an empirical power law in the normalized form

$$\sigma = \theta^{-\alpha}\gamma^m\gamma_t^n, \tag{1.2}$$

appropriate for the flow rule of a viscoplastic material exhibiting thermal softening, strain hardening, and strain-rate sensitivity. The model and its relevance to the problem of shear band formation is explained in section 2.

There is extensive literature on the problem, including experimental [7, 14], mechanics and linearized analysis (e.g. [8, 1, 13, 17, 24, 25] and references therein), numerical [26, 11], as well as nonlinear analysis [9, 18, 19, 20, 4, 3] and asymptotic analysis studies [10, 12, 25]. With regard to the analysis of the shear band formation process, analytical results account for either the case where the forcing is effected by a boundary force [20, 22] causing a shear band at the boundary or in situations where the initial data involve a localization in shear (or in the temperature) and the subsequent evolution leads to an intensification process to a fully developed band [3, 23]. It is indicated by numerical evidence in [24] and the analysis in [20, 3] that a collapse of the stress-diffusion mechanisms is associated with the development of the bands. There is a class of special solutions to (1.1) describing uniform shearing

$$\begin{aligned} v_s &= x, \\ \gamma_s &= t + \gamma_0, \\ \theta_s &= \left[\theta_0^{1+\alpha} + \frac{1+\alpha}{m+1}\Big[(t+\gamma_0)^{m+1} - \gamma_0^{m+1}\Big]\right]^{\frac{1}{1+\alpha}}, \\ \sigma_s &= \theta_s^{-\alpha}(t)(t+\gamma_0)^m, \end{aligned} \tag{1.3}$$

and much of the analysis on (1.1) has centered on the issue of their stability. The form of (1.3) suggests the change of variables (3.3) that transforms the stability problem into the study of the asymptotic behavior for the reaction–diffusion-type system (3.4); see section 3. In the special case of a fluid with temperature-dependent viscosity ($m = 0$) the kinematic equation decouples from the remaining equations, and the problem reduces to the study of the simplified model (4.1)–(4.2). This simpler system is indeed the one that has been analyzed in most detail both analytically [3, 9, 18] but also in numerical investigations [26, 11]. Its rescaled variant (4.4) admits invariant rectangles in the parameter range $q = -\alpha + n > 0$ but misses this property in the range $q = -\alpha + n < 0$. It is this dichotomy that provides a quantitative threshold to stability, as shown in section 4: In the parameter range $q > 0$ the invariant rectangles yield asymptotic stability of the uniform shearing solution; cf. Theorem 4.1. By contrast, in the complementary region $q < 0$ moderate perturbations of the uniform solutions can lead to instability and formation of shear bands; cf. Theorem 4.2.

The analysis on invariant domains of section 4 suggests a connection of the present problem with the theory of relaxation systems (e.g., [5]) that turns out to be instrumental for understanding the onset of localization. This connection is studied in detail in section 5 and motivates the derivation of an effective equation for the onset of localization in section 6. We outline the result in the following: Let T be a parameter describing a time-scale, and consider a change of variables of the form

$$\theta(x,t) = (t+1)^{\frac{m+1}{\alpha+1}}\Theta^T\left(x, \frac{s(t)}{T}\right), \quad v_x(x,t) = V_x^T\left(x, \frac{s(t)}{T}\right), \tag{1.4}$$

where $s(t)$ is an appropriate rescaling of time (in fact, see (6.1) for the full transformation). The new functions $(U^T, \Theta^T, \Gamma^T, \Sigma^T)$, with $U^T = V_x^T$ satisfy the system (6.3). It is clear that if $(U^T, \Theta^T, \Gamma^T, \Sigma^T)$ stabilizes as $T \to \infty$, then its limiting profile will describe the asymptotic form of (v_x, θ, γ) as $t \to \infty$. This reduces the problem of studying the asymptotic behavior into the problem of identifying the large T behavior of (6.3), which lies within the realm of relaxation theory. Using a technique analogous to the Chapman–Enskog expansion (e.g., [5]), we show in section 6 that $U^T = V_x^T$ satisfies for $T >> 1$ and $r = O(T)$ the effective equation

$$\partial_s U = \partial_{xx}\left(c\,U^p + \frac{\lambda c^2}{T}(\beta s + 1)U^{p-1}\partial_{xx}U^p\right), \tag{1.5}$$

within order $O(\frac{1}{T^2})$ and with parameters $p = \frac{q}{1+\alpha} = \frac{-\alpha+m+n}{1+\alpha}$, $\beta = \frac{m+1}{1+\alpha}$, $c = \beta^{\frac{\alpha}{1+\alpha}}$, and the coefficient of the fourth order term

$$\lambda = \frac{\alpha(1+m+n) - m(m+1)}{(m+1)(1+\alpha)}.$$

We note that (1.5) changes type from forward parabolic when $q = -\alpha + m + n > 0$ to backward parabolic when $q = -\alpha + m + n < 0$, what captures the parameter regime associated with the onset of localization. We also note that in the region of instability $q < 0$, the coefficient $\lambda > 0$, and the fourth order term has a regularizing effect. Numerical comparisons between the effective equation (1.5) and the system (6.3) are performed in section 6 and indicate good agreement between the effective and the actual problem.

2. The nature of shear band formation.

2.1. Description of the model.

As shear bands appear and propagate as one-dimensional structures (up to interaction times), most investigations have focused on one-dimensional, simple shearing deformations. In a Cartesian coordinate system an infinite plate, located between the planes $x = 0$ and $x = d$, is subjected to simple shear. The thermomechanical process is described (upon neglecting the normal stresses) by the list of variables: Velocity in the shearing direction $v(x,t)$, shear strain $\gamma(x,t)$, temperature $\theta(x,t)$, heat flux $Q(x,t)$, and shear stress $\sigma(x,t)$. They are connected through the balance of linear momentum

$$\rho v_t = \sigma_x, \tag{2.1}$$

the kinematic compatibility relation

$$\gamma_t = v_x, \tag{2.2}$$

and the balance of energy equation

$$c\rho\theta_t = Q_x + \beta\sigma\gamma_t, \tag{2.3}$$

where ρ is the reference density, c is the specific heat, and β is the portion of plastic work converted to heat. The upper plate is subjected to a prescribed constant velocity V, while the lower plate is held at rest: $v(0,t) = 0$, $v(d,t) = V$. It is further assumed that the plates are thermally insulated: $\theta_x(0,t) = 0$, $\theta_x(d,t) = 0$. Thermal insulation is appropriate for the analysis of shear band formation, since heat transfer at positions distant from the bands via radiation is negligible at sufficiently short loading times.

For the heat flux we will use either the adiabatic assumption $Q = 0$ or a Fourier law $Q = k\theta_x$, with the thermal diffusivity parameter k. Imposing adiabatic conditions projects the belief that, at high strain rates, heat diffusion operates at a slower timescale than the one required for the development of a shear band. It appears a plausible assumption for the shear band initiation process but not necessarily for the evolution of a developed band, due to the high temperature differences involved.

For the shear stress we set

$$\sigma = f(\theta, \gamma, \gamma_t), \tag{2.4}$$

where f is a smooth function, with $f(\theta,\gamma,0) = 0$ and $f_p(\theta,\gamma,p) > 0$ for $p \neq 0$. In terms of classification, the resulting model belongs to the framework of one-dimensional thermoviscoelasticity and is compatible with the requirements imposed by the Clausius–Duhem inequality.

It is instructive to interpret (2.4) in the context of a constitutive theory for thermal elastic-viscoplastic materials. In this context, it is assumed that the shear strain γ is decomposed, additively, into elastic and plastic components: $\gamma = \gamma^e + \gamma^p$. The elastic component γ^e satisfies linear elasticity with shear modulus G_e, that is, $\gamma^e = \frac{1}{G_e}\sigma$. The evolution of the plastic component is dictated by a plastic flow rule:

$$\gamma_t^p = g(\theta, \gamma^p, \sigma) \quad \text{or} \quad \sigma = f(\theta, \gamma^p, \gamma_t^p), \tag{2.5}$$

where g is an increasing function in the variable σ and $f(\theta,\gamma,\cdot)$ is the inverse function of $g(\theta,\gamma,\cdot)$. In summary,

$$\begin{aligned} \frac{1}{G_e}\sigma + \gamma^p &= \gamma, \\ \frac{1}{G_e}\sigma_t + g(\theta, \gamma^p, \sigma) &= v_x. \end{aligned} \tag{2.6}$$

Note that (2.4) can be obtained from the constitutive theory (2.6) in the limit as the elastic shear modulus $G_e \to \infty$. Accordingly, γ should then be interpreted as the plastic strain and (2.4) as an inverted plastic flow rule.

Viewing (2.4) as a plastic flow rule suggests the following terminology: The material exhibits thermal softening at state variables (θ,γ,p), where $f_\theta(\theta,\gamma,p) < 0$, strain hardening at state variables where $f_\gamma(\theta,\gamma,p) > 0$, and strain softening when $f_\gamma(\theta,\gamma,p) < 0$. The amounts of the slopes of f in the directions θ, γ, and p measure the degree of thermal softening, strain hardening (or softening), and strain-rate sensitivity, respectively. The difficulty of performing high strain-rate experiments causes uncertainty as to the specific form of the constitutive relation (2.4). Examples that have been extensively used are the power law or the Arrhenius law outlined later.

2.2. Nondimensionalization. To turn the system into a dimensionless form we introduce the following nondimensional variables:

$$\hat{x} = \frac{x}{d}, \qquad \hat{t} = t\dot{\gamma}_0, \qquad \hat{v} = \frac{v}{V}, \qquad \hat{\theta} = \frac{\theta}{\tau_0/\rho c}, \qquad \hat{\sigma} = \frac{\sigma}{\tau_0}, \tag{2.7}$$

where we introduce a nominal stress τ_0 to be appropriately selected later, a nominal temperature $\theta_0 = \frac{\tau_0}{\rho c}$, and a nominal strain rate $\dot{\gamma}_0 = \frac{V}{d}$.

With these choices we obtain the nondimensional system

$$\begin{aligned} \hat{v}_{\hat{t}} &= \frac{1}{r}\ \hat{\sigma}_{\hat{x}}, \\ \hat{\theta}_{\hat{t}} &= \kappa \hat{\theta}_{\hat{x}\hat{x}} + \beta \hat{\sigma}\ \hat{v}_{\hat{x}}, \\ \hat{\gamma}_{\hat{t}} &= \hat{v}_{\hat{x}}, \end{aligned} \tag{2.8}$$

where the nondimensional numbers are

$$r = \frac{\rho V^2}{\tau_0}, \qquad \kappa = \frac{k}{\rho c V d}, \tag{2.9}$$

while β is nondimensional by its very nature. The number r is a ratio of inertial to viscoplastic stresses and depends on the choice of the normalizing stress τ_0. The constitutive law (2.4) turns to the nondimensional form

$$\hat{\sigma} = \hat{f}(\hat{\theta}, \hat{\gamma}, \hat{\gamma}_{\hat{t}}) = \frac{1}{\tau_0} f\left(\frac{\tau_0}{\rho c}\hat{\theta}, \hat{\gamma}, \dot{\gamma}_0 \hat{\gamma}_{\hat{t}}\right).$$

The freedom in the choice of τ_0 is useful in normalizing the form of $\hat{f}$.

2.3. Power laws. In the experimental literature on shear bands at high strain-rates there is extensive use of constitutive laws in the form of power laws (e.g., [15], [14])

$$\sigma = G\ \left(\frac{\theta}{\theta_r}\right)^{-\alpha}\ \left(\frac{\gamma}{\gamma_r}\right)^{m}\ \left(\frac{\gamma_t}{\dot{\gamma}_r}\right)^{n} = G_0\ \theta^{-\alpha}\gamma^m\gamma_t^n. \tag{2.10}$$

Here, α, m, n denote the thermal softening, strain hardening, and strain-rate sensitivity parameters, respectively, G is a material constant, and $\theta_r,\ \gamma_r, \dot{\gamma}_r$ are some reference values for temperature, strain, and strain rate, respectively. Specifically, $\gamma_r \simeq 0.01$ is the strain at yield in a quasi-static simple shear test at a nominal strain rate $\dot{\gamma} = 10^{-4}/s$ for most steels. There is no unique choice for the other reference values, but the simplest choices are $\dot{\gamma}_r = 10^3/s,\ \theta_r = 300K$. This corresponds to the nominal strain rate and ambient temperature of the usual torsional experiment. In (2.10) θ and θ_r are measured in Kelvin. This power law model has been used extensively to model steels that exhibit shear bands [15], [14] and is entirely empirical, but it allows considerable flexibility in fitting experimental data over an extended range. According to experimental data for most steels we have $\alpha = O(10^{-1}),\ m = O(10^{-2})$, and $n = O(10^{-2})$.

The freedom in the choice of the nominal stress τ_0 is useful to simplify the form of $\hat{f}$. For (2.10), if we select τ_0 such that

$$\frac{1}{\tau_0} G\ \left(\frac{\frac{\tau_0}{\rho c}}{\theta_r}\right)^{-\alpha}\ \left(\frac{1}{\gamma_r}\right)^{m}\ \left(\frac{\dot{\gamma}_0}{\dot{\gamma}_r}\right)^{n} = 1,$$

it yields the nondimensional form $\hat{\sigma} = \hat{\theta}^{-\alpha}\hat{\gamma}^m\hat{\gamma}_t^n$.

2.4. The mathematical model. We collect the nondimensional form of the equations, dropping the hats, in the form

$$\begin{aligned} v_t &= \frac{1}{r}\,\sigma_x, \\ \theta_t &= \kappa\theta_{xx} + \sigma\gamma_t, \\ \gamma_t &= v_x, \\ \sigma &= f(\theta,\gamma,\gamma_t), \end{aligned} \tag{2.11}$$

where r, κ are given by (2.9) and we have taken the (not so important) constant $\beta = 1$. For the stress, we use the empirical power law, which, for the appropriate choice of τ_0, takes the normalized form

$$\sigma = \theta^{-\alpha}\gamma^m\gamma_t^n. \tag{2.12}$$

The parameters $\alpha > 0$, m and $n > 0$ serve as measures of the degree of thermal softening, strain hardening (or softening), and strain-rate sensitivity. Another commonly used constitutive relation is the Arrhenius law

$$\sigma = e^{-\alpha\theta}\gamma_t^n. \tag{2.13}$$

In the form (2.13) the Arrhenius law does not exhibit any strain hardening, and the parameters α and n measure the degree of thermal softening and strain-rate sensitivity, respectively. The boundary conditions are prescribed velocities at the ends of the plates, in the nondimensional form

$$v(0,t) = 0, \quad v(1,t) = 1, \quad t \geq 0, \tag{2.14}$$

and thermal insulation at the two ends

$$\theta_x(0,t) = 0, \quad \theta_x(1,t) = 0, \quad t \geq 0. \tag{2.15}$$

We impose initial conditions

$$v(x,0) = v_0(x),\ \theta(x,0) = \theta_0(x) > 0,\ \gamma(x,0) = \gamma_0(x) > 0, \quad x \in [0,1]. \tag{2.16}$$

For the initial data, we take $v_{0x} > 0$, in which case a maximum principle shows that $\gamma_t = v_x > 0$ at all times, and thus all powers are well defined.

2.5. Isothermal versus adiabatic deformations. To illustrate the effect of thermal softening on *spatially uniform* deformations, the isothermal and adiabatic cases are contrasted. Consider a deformation where the plate is subjected to steady shearing, with boundary velocities $v = 0$ at $x = 0$ and $v = 1$ at $x = 1$.

(i) In an *isothermal* deformation the temperature is kept constant, say θ_0, by appropriately removing the produced heat due to the plastic work. The "measured" stress-strain response in this idealized situation coincides with the $\sigma - \gamma$ graph of the function $\sigma = f(\theta_0, \gamma, 1)$. The slope of the graph is measured by $f_\gamma(\theta_0, \gamma, 1)$, and, for a strain-hardening material, the graph $\sigma - \gamma$ is monotonically increasing.

(ii) The situation in an *adiabatic* deformation is understood by studying a special class of solutions describing *uniform shearing.* These are

$$\begin{aligned} v_s(x,t) &= x, \\ \gamma_s(x,t) &= \gamma_s(t) = t + \gamma_0, \\ \theta_s(x,t) &= \theta_s(t), \end{aligned}$$

where

$$\begin{aligned} \frac{d\theta_s}{dt} &= f(\theta_s, t+\gamma_0, 1), \\ \theta_s(0) &= \theta_0, \end{aligned}$$

and γ_0, θ_0 are positive constants, standing for the initial values of the strain and temperature. The resulting stress is given by the graph of the function

$$\sigma_s(t) = f(\theta_s(t), t+\gamma_0, \dot{\gamma}_0),$$

which may be interpreted as stress versus time but also as stress versus (average) strain. This effective stress-strain curve coincides with the $\sigma_s - t$ graph, and the material exhibits effective hardening in the increasing parts of the graph and effective softening in the decreasing parts. The slope is determined by the sign of the quantity $f_\theta\, f + f_\gamma$, when this sign is negative, the combined effect of strain hardening and thermal softening delivers net softening. For instance, for a strain-hardening ($m > 0$) power law (2.12), the uniform shearing solution reads

$$\begin{aligned} \gamma_s(t) &= t+\gamma_0, \\ \theta_s(t) &= \left[\theta_0^{1+\alpha} + \frac{1+\alpha}{m+1}\left[(t+\gamma_0)^{m+1} - \gamma_0^{m+1}\right]\right]^{\frac{1}{1+\alpha}}, \\ \sigma_s(t) &= \theta_s^{-\alpha}(t)(t+\gamma_0)^m, \end{aligned} \tag{2.17}$$

and a simple computation yields

$$\frac{d\sigma_s}{dt} = \theta_s(t)^{-2\alpha-1}\gamma_s(t)^{2m}\left[\frac{-\alpha+m}{m+1} + \frac{m}{(t+\gamma_0)^{m+1}}\left[\theta_0^{1+\alpha} - \frac{1+\alpha}{m+1}\gamma_0^{m+1}\right]\right].$$

For parameter values ranging in the region $m > \alpha$, the graph $\sigma_s(t)$-t is increasing, and the material exhibits net hardening. By contrast, for parameter values ranging in the region $m < \alpha$, $\sigma_s(t)$ may initially increase but eventually decreases with t. In this range, the combined effect of thermal softening and strain-hardening results to net softening, and it is precisely this effect that is considered as a necessary (though not sufficient) cause of the shear band formation process.

2.6. Strain softening versus strain-rate sensitivity. It is generally maintained that strain softening has a destabilizing influence, tending to amplify small nonuniformities. To illustrate the nature of the instability, consider the model

$$\begin{aligned} v_t &= \tau(\gamma)_x, \\ \gamma_t &= v_x, \end{aligned} \tag{2.18}$$

with $\tau'(u) < 0$. This model describes isothermal motions of a strain-softening, inelastic material. The system (2.18) is elliptic in the t-direction, and the initial value problem is ill-posed. The uniform shearing solution

$$\hat{v} = x, \quad \hat{\gamma} = t+\gamma_0,$$

γ_0 constant, is still a special class of solutions to this problem.

By contrast, strain-rate dependence tends to diffuse nonuniformities in the strain-rate and/or the stress, and it may hinder or even altogether suppress instability. That is confirmed, for example, by considering the system

$$\begin{aligned} v_t &= (\tau(\gamma)v_x^n)_x, \\ \gamma_t &= v_x, \end{aligned} \tag{2.19}$$

with $\tau(u) > 0$ and $\tau'(u) < 0$. This system is a parabolic regularization of the elliptic problem (2.18), and it is precisely the competition between an ill-posed equation and a regularizing effect that is hidden behind the shear band formation problem. If one considers the linearization of the uniform shear solution

$$v = x + \hat{V}, \quad \gamma = t + \gamma_0 + \hat{\Gamma}, \tag{2.20}$$

we see that the linearized problem from $(\hat{V}, \hat{\Gamma})$ reads

$$\begin{aligned} \hat{V}_t &= n\tau(t+\gamma_0)\hat{V}_{xx} + \tau'(t+\gamma_0)\hat{\Gamma}_x, \\ \hat{\Gamma}_t &= \hat{V}_x. \end{aligned} \tag{2.21}$$

The form of the linearized problem is a parabolic regularization of an elliptic initial value problem and indicates that strain-rate sensitivity provides a stabilizing effect to the destabilizing mechanism of strain softening.

To quantify the role of the various effects—thermal softening, strain-hardening, strain-rate sensitivity, and heat diffusion—at the level of the linearized problem, Molinari and Clifton [17] suggest the notion that the uniform shearing solution is stable if the perturbation of the uniform shearing solution grows slower than the basic solution (2.17) and is unstable if the perturbation grows faster than the solution (2.17). It has been conjectured in [17], based on linearized analysis of such "relative perturbations" and some additional plausibility arguments, that, for power laws, the uniform shearing solution is stable in the parameter range $q = m + n - \alpha > 0$ and unstable in the complementary region $q = m + n - \alpha < 0$. The relative perturbation analysis is not straightforward to rigorously justify, as it requires stability analysis for nonautonomous systems. Nevertheless, the linearized analysis was carried out for (2.21) using maximum principles (see [22]), and, in this case, the conjecture was verified.

Nonlinear analysis has been more efficient for providing stability results and validating the above criterion in various special cases [9, 18, 19, 21]. A complete understanding for the full model exists only in the case of stress boundary conditions which are energetically fairly demanding: it is shown in [20] that unstable response and formation of shear bands occurs in certain parameter regimes and that the process of shear band formation is concurrent with a collapse of the stress diffusion mechanisms of the material. The case of velocity boundary conditions is energetically more benign and closer to the experimental setup. For this case, the only available instability results concern a temperature-dependent Newtonian fluid [3] (or a strain softening rate-sensitive solid [22]) and indicate that a large perturbation of the temperature (or the strain) can lead to localization and formation of bands at large times. However, a precise quantification of the onset of localization is at present unavailable and will be pursued in later sections of this work.

2.7. Effect of thermal diffusion. Although the early deformation can with no considerable error be regarded as adiabatic, when localization sets in and temperature gradients across a band become very large, thermal diffusion effects can no longer be regarded as negligible. The morphology of a fully formed band in the late stages of deformation is thus influenced by heat conduction balancing the heat production from plastic work. In [26], an extensive numerical treatment of fully developed shear bands, Walter noticed that, due to heat conduction, the strain rate essentially becomes independent of time in late stages of deformation, even though the temperature and stress continue to evolve. We refer to [16, 10, 12] for studies of the effect of heat conduction in a variety of models.

3. Adiabatic shear. We consider now the adiabatic form ($\kappa = 0$) of the nondimensional system (2.11) with a power law stress

$$\begin{aligned} v_t &= \frac{1}{r}\ \sigma_x, \\ \theta_t &= \sigma \gamma_t, \\ \gamma_t &= v_x, \\ \sigma &= \theta^{-\alpha} \gamma^m \gamma_t^n. \end{aligned} \tag{3.1}$$

In this section we outline various formulations of the problem that are useful in what follows.

Stress formulation. There is a reformulation of the problem (3.1), in the form of a reaction-diffusion system, that has been quite instructive in the development of shear band theory (see [20]). Suppose that σ, θ, γ are considered the independent variables. A simple but lengthy computation shows that they satisfy the reaction-diffusion system

$$\begin{aligned} \sigma_t &= \frac{n}{r}\ \theta^{-\frac{\alpha}{n}}\ \gamma^{\frac{m}{n}}\ \sigma^{\frac{n-1}{n}} \sigma_{xx} + \left(-\alpha \frac{\sigma}{\theta} + \frac{m}{\gamma} \right) \theta^{\frac{\alpha}{n}}\ \gamma^{-\frac{m}{n}}\ \sigma^{\frac{n+1}{n}}, \\ \gamma_t &= \theta^{\frac{\alpha}{n}}\ \gamma^{-\frac{m}{n}}\ \sigma^{\frac{1}{n}}, \\ \theta_t &= \theta^{\frac{\alpha}{n}}\ \gamma^{-\frac{m}{n}}\ \sigma^{\frac{n+1}{n}}. \end{aligned} \tag{3.2}$$

Conversely, given a solution (σ, θ, γ) of (3.2), if we define v_x by

$$v_x = \theta^{\frac{\alpha}{n}}\ \gamma^{-\frac{m}{n}}\ \sigma^{\frac{1}{n}},$$

then (v, θ, γ) satisfies (3.1).

Time rescaling. Motivated by the form of the uniform shearing solutions (2.17), one may introduce a rescaling of the dependent variables and time in the following form:

$$\begin{aligned} &\theta(x,t) = (t+1)^{\frac{m+1}{\alpha+1}} \Theta(x, \tau(t)), \quad \gamma(x,t) = (t+1)\Gamma(x, \tau(t)), \\ &\sigma(x,t) = (t+1)^{\frac{m-\alpha}{\alpha+1}} \Sigma(x, \tau(t)), \quad v(x,t) = V(x, \tau(t)), \quad \tau = \ln(1+t). \end{aligned} \tag{3.3}$$

In the new variables $(V, \Theta, \Gamma, \Sigma)$ the system (3.1) becomes

$$\begin{aligned} V_\tau &= \frac{1}{r} e^{\frac{m+1}{1+\alpha}\tau}\ \Sigma_x, \\ \Gamma_\tau &= V_x - \Gamma, \\ \Theta_\tau &= \Sigma V_x - \frac{m+1}{1+\alpha} \Theta, \\ \Sigma &= \Theta^{-\alpha} \Gamma^m V_x^n. \end{aligned} \tag{3.4}$$

Accordingly, the system (3.2) takes the form

$$
\begin{aligned}
\Sigma_\tau &= \frac{n}{r}\, e^{\frac{m+1}{1+\alpha}\tau}\Theta^{-\frac{\alpha}{n}}\ \Gamma^{\frac{m}{n}}\ \Sigma^{\frac{n-1}{n}}\Sigma_{xx} \\
&\qquad\qquad + \left(-\alpha\frac{\Sigma}{\Theta} + \frac{m}{\Gamma}\right)\Theta^{\frac{\alpha}{n}}\ \Gamma^{-\frac{m}{n}}\ \Sigma^{\frac{n+1}{n}} + \Sigma\frac{\alpha - m}{1+\alpha}, \\
\Gamma_\tau &= \Theta^{\frac{\alpha}{n}}\ \Gamma^{-\frac{m}{n}}\ \Sigma^{\frac{1}{n}} - \Gamma, \\
\Theta_\tau &= \Theta^{\frac{\alpha}{n}}\ \Gamma^{-\frac{m}{n}}\ \Sigma^{\frac{n+1}{n}} - \frac{m+1}{1+\alpha}\Theta.
\end{aligned}
\tag{3.5}
$$

Various properties of (3.5) will be noted in forthcoming sections. To understand its usefulness, note that the rescaled variants of the uniform shearing solutions (2.17), given by

$$
\theta_s(t) = (t+1)^{\frac{m+1}{\alpha+1}}\Theta_s(\tau(t)), \quad \gamma_s(t) = (t+1)\Gamma_s(\tau(t)), \quad \sigma_s(t) = (t+1)^{\frac{m-\alpha}{\alpha+1}}\Sigma_s(\tau(t)),
$$

have the long-time behavior

$$
\begin{aligned}
&\Theta_s(\tau) \to \left(\frac{1+\alpha}{1+m}\right)^{\frac{1}{1+\alpha}}, &&\Gamma_s(\tau) \to 1, \\
&\Sigma_s(\tau) \to \left(\frac{1+\alpha}{1+m}\right)^{-\frac{\alpha}{1+\alpha}}, &&\Sigma_s^{\frac{1}{n}}\Theta_s^{\frac{\alpha}{n}}\Gamma_s^{-\frac{m}{n}} \to 1,
\end{aligned}
\tag{3.6}
$$

as $\tau \to \infty$ independently of the values of the initial constants θ_0, γ_0.

4. Non-Newtonian fluids with temperature-dependent viscosity. Various simplified models have been used in the mathematical and mechanics literature of shear band formation. One example is models that neglect thermal softening like (2.19). Another class neglects the effect of strain hardening ($m = 0$) in which case the kinematic compatibility equation decouples, and the system consists of two equations. In the adiabatic case ($\kappa = 0$), the resulting model reads

$$
\begin{aligned}
v_t &= \frac{1}{r}\sigma_x, \\
\theta_t &= \sigma\, v_x,
\end{aligned}
\tag{4.1}
$$

with the power law

$$
\sigma = \theta^{-\alpha} v_x^n, \tag{4.2}
$$

and may be viewed as describing a non-Newtonian fluid with temperature-dependent viscosity. The problem is set in $[0, 1]$ with velocity boundary conditions (2.14), and the objective is to examine the stability of uniform shearing flows (2.17). In this context, the question becomes whether the destabilizing effect of the decreasing and spatially nonhomogeneous viscosity is sufficiently powerful to overcome the stabilizing influence of momentum diffusion and induce localization of shear. We introduce the change of variables

$$
\begin{aligned}
&\theta(x,t) = (t+1)^{\frac{1}{\alpha+1}}\Theta(x,\tau(t)), \quad \sigma(x,t) = (t+1)^{-\frac{\alpha}{\alpha+1}}\Sigma(x,\tau(t)), \\
&v(x,t) = V(x,\tau(t)), \quad \tau = \ln(1+t),
\end{aligned}
\tag{4.3}
$$

(analogous to (3.3)) and obtain the rescaled system

$$\begin{aligned}\Sigma_\tau &= \frac{n}{r}\, e^{\frac{1}{1+\alpha}\tau}\Theta^{-\frac{\alpha}{n}}\ \Sigma^{\frac{n-1}{n}}\Sigma_{xx} + \left(-\alpha\Theta^{\frac{\alpha}{n}-1}\Sigma^{\frac{n+1}{n}} + \frac{\alpha}{1+\alpha}\right)\Sigma,\\ \Theta_\tau &= \left(\Theta^{\frac{\alpha}{n}-1}\ \Sigma^{\frac{n+1}{n}} - \frac{1}{1+\alpha}\right)\Theta.\end{aligned} \tag{4.4}$$

(V, Θ, Σ) also satisfy the equations

$$\Sigma = \Theta^{-\alpha} V_x^n, \tag{4.5}$$

$$V_\tau = \frac{1}{r} e^{\frac{1}{1+\alpha}\tau}\Sigma_x. \tag{4.6}$$

The rescaled variants of the uniform shearing solution (2.17) enjoy the asymptotic behavior

$$\begin{aligned}&\Theta_s(\tau) \to (1+\alpha)^{\frac{1}{1+\alpha}},\\ &\Sigma_s(\tau) \to (1+\alpha)^{-\frac{\alpha}{1+\alpha}},\\ &\Sigma_s^{\frac{1}{n}}\Theta_s^{\frac{\alpha}{n}} \to 1 \qquad\qquad \text{as } \tau \to \infty.\end{aligned}$$

In this section we discuss the stability properties of the uniform shearing solutions in the model (4.4).

4.1. Equilibria and orbits. Consider the reaction part of the system (4.4), i.e., the associated system of ordinary differential equations

$$\begin{aligned}\Sigma_\tau &= -\alpha\Sigma\left(\Theta^{\frac{\alpha}{n}-1}\Sigma^{\frac{n+1}{n}} - \frac{1}{1+\alpha}\right),\\ \Theta_\tau &= \Theta\left(\Theta^{\frac{\alpha}{n}-1}\ \Sigma^{\frac{n+1}{n}} - \frac{1}{1+\alpha}\right).\end{aligned} \tag{4.7}$$

We observe that

$$\frac{\Sigma_\tau}{\Sigma} + \alpha\frac{\Theta_\tau}{\Theta} = 0 \Longleftrightarrow \partial_\tau\left(\frac{\Sigma}{\Theta^{-\alpha}}\right) = 0,$$

which implies that $\Sigma\ \Theta^\alpha$ is constant along the orbits of (4.7). The equilibria of (4.7) are located on the curve

$$\Sigma = \left(\frac{1}{1+\alpha}\right)^{\frac{n}{n+1}}\Theta^{\frac{n-\alpha}{n+1}}. \tag{4.8}$$

The curve of equilibria changes monotonicity depending on the sign of

$$q = -\alpha + n; \tag{4.9}$$

it is increasing for $q > 0$ and decreasing for $q < 0$. In Figure 4.1 the orbits of the system (4.7) along with the curve (4.8) are presented in the case $q > 0$ as well as for the case $q < 0$. The point

$$(\Theta_m, \Sigma_m) = ((1+\alpha)^{\frac{1}{1+\alpha}}, (1+\alpha)^{-\frac{\alpha}{1+\alpha}}), \tag{4.10}$$

see Figure 4.1, corresponds to the asymptotic state of uniform shear in the rescaled variables. When the uniform shearing solution (3.6) is asymptotically stable, then trajectories of the system (4.4) should approach the point (Θ_m, Σ_m) as $\tau \to \infty$.

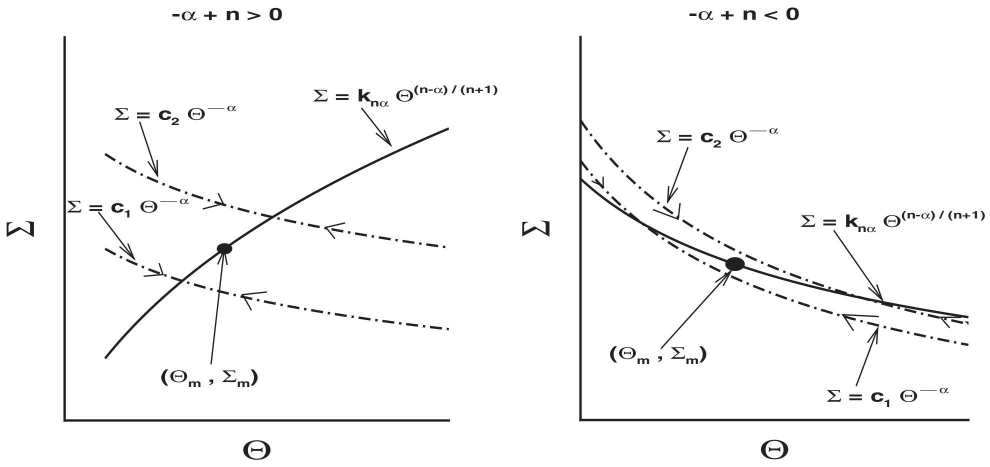

FIG. 4.1. *Orbits of ODE system* (4.7), $k_{n\alpha} = \left(\frac{1}{\alpha+1}\right)^{\frac{n}{n+1}}$.

4.2. Invariant regions, the stable regime. In the case $q = -\alpha + n > 0$, any rectangle

$$[\Theta_-, \Theta_+] \times [\Sigma_-, \Sigma_+], \quad \text{with } (\Theta_-, \Sigma_-),\ (\Theta_+, \Sigma_+) \text{ equilibria},$$

is invariant under the flow of (4.7). The theory of invariant regions for parabolic systems [6] then implies that such rectangles are also invariant under the flow of the reaction-diffusion system (4.4). For initial data taking values in one of the invariant rectangles

$$\begin{aligned} \Theta_- &< \Theta_0(x) < \Theta_+, \\ \Sigma_- &< \Sigma_0(x) < \Sigma_+, \end{aligned}$$

the solutions of (4.4) satisfy

$$\begin{aligned} \Theta_- &< \Theta(x,\tau) < \Theta_+, \\ \Sigma_- &< \Sigma(x,\tau) < \Sigma_+, \\ \Sigma_-^{\frac{1}{n}} \Theta_-^{\frac{\alpha}{n}} &< V_x(x,\tau) = \Sigma^{\frac{1}{n}}(x,\tau) \Theta^{\frac{\alpha}{n}}(x,\tau) < \Sigma_+^{\frac{1}{n}} \Theta_+^{\frac{\alpha}{n}}. \end{aligned} \tag{4.11}$$

The reader should note that the invariant regions property is lost in the complementary region $q < 0$, and no rectangle of the form $[\Theta_-, \Theta_+] \times [\Sigma_-, \Sigma_+]$ is invariant for the reaction system (4.7). The bounds (4.11) yield time-dependent estimates for solutions of (4.1), (4.2):

$$\begin{aligned} \Theta_-(t+1)^{\frac{1}{1+\alpha}} &< \theta(x,t) < \Theta_+ t + 1)^{\frac{1}{1+\alpha}}, \\ \Sigma_-(t+1)^{\frac{-\alpha}{1+\alpha}} &< \sigma(x,t) < \Sigma_+(t+1)^{\frac{-\alpha}{1+\alpha}}, \\ \Sigma_-^{\frac{1}{n}} \Theta_-^{\frac{\alpha}{n}} &< v_x(x,t) < \Sigma_+^{\frac{1}{n}} \Theta_+^{\frac{\alpha}{n}}. \end{aligned} \tag{4.12}$$

These are used to show that the uniform shear solution is asymptotically stable.

THEOREM 4.1. *Let* $q = -\alpha + n > 0$, *and consider a solution* (v, θ) *of* (4.1), (4.2), *with initial data* $\theta_0(x) > 0$ *and* $\sigma_0(x) > 0$. *Then* (v, θ) *is defined for all times and has* *the asymptotic behavior*

$$v_x(x,t) = 1 + O\left((t+1)^{-\frac{n-\alpha}{n(1+\alpha)}}\right), \tag{4.13}$$

$$\theta(x,t) = \Theta_m (t+1)^{\frac{1}{1+\alpha}}\left(1 + O\big((t+1)^{-\frac{n-\alpha}{n(1+\alpha)}}\big)\right), \tag{4.14}$$

$$\sigma(x,t) = \Sigma_m (t+1)^{\frac{-\alpha}{1+\alpha}}\left(1 + O\big((t+1)^{-\frac{n-\alpha}{n(1+\alpha)}}\big)\right), \tag{4.15}$$

as $t \to \infty$, where (Θ_m, Σ_m) are given in (4.10).

Theorem 4.1 was proved in [9, 18] using detailed energy estimates to derive the time-dependent bounds (4.12). These estimations are considerably simplified using the invariant regions presented above. The remainder of the asymptotic stability proof is presented in the appendix.

4.3. The unstable regime. The stability of the uniform shearing solution in the complementary region $q = -\alpha + n < 0$ is at present unknown. In fact, it is even unknown whether solutions exist globally in time or, in contrast, blow up in finite time. Numerical investigations indicate development of shear bands in this regime. In addition, there are two theoretical results that are also backing this direction. First, consider initial data $\theta_0(x)$, $v_0(x)$ such that

$$v_0(x) = x, \tag{4.16}$$

$$\theta_0(x) = \begin{cases} \bar{\theta} & x \notin I_\delta, \\ U(x) & x \in I_\delta, \end{cases} \tag{4.17}$$

where $\bar{\theta}$ is a constant, $I_\delta = (y-\delta, y+\delta)$ is a (small) interval centered around a given point $y \in (0,1)$, and $U(x)$ is the initial temperature profile in I_δ and is selected so that θ_0 is smooth.

Theorem 4.2. *Let $q < 0$ and (v, θ) be a solution of* (4.1), (4.2) *with initial data* (4.16), (4.17). *If $U(y)$ is selected sufficiently large, then either the solution blows up in finite time,*

$$\limsup_{t \to T^*} \sup_{x \in [0,1]} \theta(x,t) \to \infty \quad \textit{for some } T^* < \infty,$$

or else $T^* = \infty$ and (v, θ) has the asymptotic behavior

$$v(x,t) = \begin{cases} 0 + O\left((t+1)^{-\frac{1}{n+1}}\right) & x < y - \delta, \\ 1 + O\left((t+1)^{-\frac{1}{n+1}}\right) & y + \delta < x, \end{cases} \tag{4.18}$$

and $\theta(x,t)$ approaches a limiting temperature profile for $x \notin I_\delta$ as $t \to \infty$.

Theorem 4.2 was proved in [3] for the case of a Newtonian fluid ($n = 1$). We extend this result for non-Newtonian temperature-dependent flows. The proof is provided in the appendix, and it yields a quantitative criterion for a size of an initial temperature perturbation $U(x)$ that suffices to induce instability. The reader can check that even a moderate perturbation will suffice, but an arbitrarily small perturbation of the uniform temperature is excluded. The question remains, what is the basic mechanism that induces this instability? This question is answered at the level of the full system (3.1) in the following two sections, of course, including the special case (4.1), (4.2).

5. The long-time response of adiabatic shear as a relaxation limit. Our next goal is to derive an effective equation describing the long-time behavior of the system (3.1) by using convenient scaling limits. This is done in three steps: First, we consider the system (3.5) or the equivalent form (3.4) and point out certain analogies with the structure of relaxation systems (like equilibrium manifolds, moment equations). Then we consider a modified version of the system (3.4) and show how to introduce a scaled limit that describes the long-time response and how to compute the effective response by a process analogous to the Chapman–Enskog expansion. The analysis applies to the modified system (see (5.9)) which shares the same general structure as (3.5) but also has an important difference. Then in section 6, we consider the original system (3.5) and modify the change of variables (3.3), keeping in mind that we calculate perturbed profiles of time-dependent solutions. An analogous procedure then leads to the effective equation describing the long-time response of (3.1).

5.1. Some analogies to the theory of relaxation systems. We first point out certain analogies between (3.4) and the theory of relaxation processes. Consider a solution (Σ, Θ, Γ) of (3.5), and note that it satisfies the identity

$$\frac{\Sigma_\tau}{\Sigma} - m\frac{\Gamma_\tau}{\Gamma} + \alpha\frac{\Theta_\tau}{\Theta} = \frac{n}{r}\, e^{\frac{m+1}{1+\alpha}\tau}\Theta^{-\frac{\alpha}{n}}\ \Gamma^{\frac{m}{n}}\ \Sigma^{-\frac{1}{n}}\Sigma_{xx}, \tag{5.1}$$

that is, $U = (\Sigma\ \Theta^{\alpha}\ \Gamma^{-m})^{\frac{1}{n}}$ satisfies a conservation law

$$\partial_\tau U = \frac{1}{r}\, e^{\frac{m+1}{1+\alpha}\tau}\ \Sigma_{xx}. \tag{5.2}$$

Equation (5.2) is precisely the first equation in (3.4), and it may be interpreted as a conservation law for the quantity $U = V_x$ that arises as a moment equation for the reaction-diffusion system (3.5). The reaction system associated to (3.5) is

$$\begin{aligned}
\Sigma_\tau &= -\alpha\Sigma\left(\frac{\Sigma}{\Theta}\ \Theta^{\frac{\alpha}{n}}\ \Gamma^{-\frac{m}{n}}\ \Sigma^{\frac{1}{n}} - \frac{m+1}{1+\alpha}\right) + m\Sigma\left(\frac{1}{\Gamma}\ \Theta^{\frac{\alpha}{n}}\ \Gamma^{-\frac{m}{n}}\ \Sigma^{\frac{1}{n}} - 1\right),\\
\Gamma_\tau &= \Gamma\left(\frac{1}{\Gamma}\ \Theta^{\frac{\alpha}{n}}\ \Gamma^{-\frac{m}{n}}\ \Sigma^{\frac{1}{n}} - 1\right),\\
\Theta_\tau &= \Theta\left(\frac{\Sigma}{\Theta}\ \Theta^{\frac{\alpha}{n}}\ \Gamma^{-\frac{m}{n}}\ \Sigma^{\frac{1}{n}} - \frac{m+1}{1+\alpha}\right).
\end{aligned} \tag{5.3}$$

For the initial data, we assume that $\Gamma_0(x) > 0$, $\Theta_0(x) > 0$, $\Sigma_0(x) > 0$, and they depend parametrically on x.

Equilibria. The equilibria of (5.3) are the solutions of the algebraic system

$$\begin{aligned}
&\frac{1}{\Gamma}\ \Theta^{\frac{\alpha}{n}}\ \Gamma^{-\frac{m}{n}}\ \Sigma^{\frac{1}{n}} - 1 = 0,\\
&\frac{\Sigma}{\Theta}\ \Theta^{\frac{\alpha}{n}}\ \Gamma^{-\frac{m}{n}}\ \Sigma^{\frac{1}{n}} - \frac{m+1}{1+\alpha} = 0
\end{aligned}$$

or equivalently,

$$\frac{\Sigma\Gamma}{\Theta} = \frac{m+1}{1+\alpha}, \quad \Sigma = \Theta^{-\alpha}\ \Gamma^{m+n}. \tag{5.4}$$

The equilibria form a one-parameter family, determined in terms of a parameter $U \in \mathbb{R}^+$, by the equations

$$\begin{aligned}
&\Gamma = U, \\
&\Theta = \left(\frac{1+\alpha}{m+1} \right)^{\frac{1}{1+\alpha}} U^{\frac{m+n+1}{1+\alpha}}, \\
&\Sigma = \left(\frac{1+\alpha}{m+1} \right)^{-\frac{\alpha}{1+\alpha}} U^{\frac{-\alpha+m+n}{1+\alpha}}.
\end{aligned} \tag{5.5}$$

Orbits. Although the system (5.3) is complex in appearance, its orbits are easily computed due to the property that solutions of (5.3) satisfy the conservation law

$$\frac{\Sigma_\tau}{\Sigma} - m\frac{\Gamma_\tau}{\Gamma} + \alpha\frac{\Theta_\tau}{\Theta} = 0 \iff \partial_\tau \left(\Sigma \ \Theta^\alpha \ \Gamma^{-m} \right) = 0.$$

The quantity $\Sigma \ \Theta^\alpha \ \Gamma^{-m}$ thus remains constant along an orbit,

$$\Sigma \ \Theta^\alpha \ \Gamma^{-m} = U^n = \text{constant in time}, \tag{5.6}$$

with the value of $U = V_x$ determined by the values of the initial data. As a result of (5.6), Γ satisfies the differential equation

$$\frac{\Gamma_\tau}{\Gamma} = \frac{U}{\Gamma} - 1.$$

Since U is constant in time and the initial data $\Gamma_0(x) > 0$ are positive, $\Gamma(x, \tau)$ remains bounded above and below by positive bounds depending on $U(x)$ and $\Gamma_0(x)$ and that

$$\Gamma \to U \qquad \text{as } \tau \to \infty.$$

Furthermore, concerning the dynamics of the system of differential equations (5.3), we have

$$\begin{aligned}
\partial_\tau \left(\frac{\Sigma \ \Gamma}{\Theta} \right) &= \frac{\Sigma \ \Gamma}{\Theta} \left(\frac{\Sigma_\tau}{\Sigma} + \frac{\Gamma_\tau}{\Gamma} - \frac{\Theta_\tau}{\Theta} \right) = \frac{\Sigma \ \Gamma}{\Theta} \Theta^{\frac{\alpha}{n}} \ \Gamma^{-\frac{m}{n}} \ \Sigma^{\frac{1}{n}} \left(\frac{m+1}{\Gamma} - (\alpha+1)\frac{\Sigma}{\Theta} \right) \\
&= -(\alpha+1) \left(\frac{\Sigma \ \Gamma}{\Theta} \right) \frac{U}{\Gamma} \left(\frac{\Sigma\Gamma}{\Theta} - \frac{m+1}{1+\alpha} \right).
\end{aligned}$$

This implies $\left| \frac{\Sigma \ \Gamma}{\Theta} - \frac{m+1}{1+\alpha} \right|$ is a decreasing function of τ and

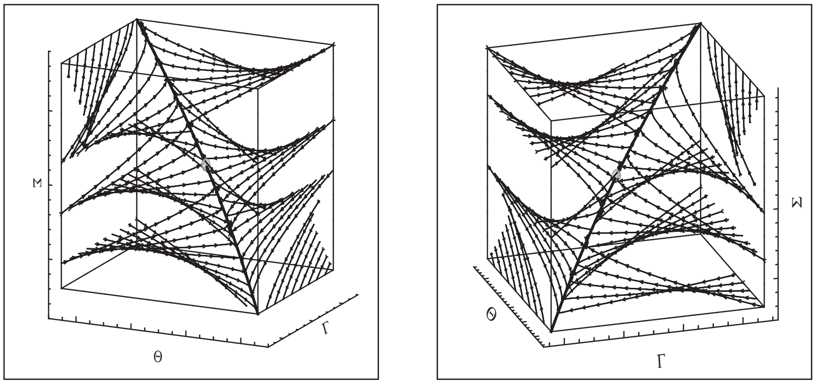
$$\frac{\Sigma \ \Gamma}{\Theta} - \frac{m+1}{1+\alpha} \to 0 \ \text{ as } \tau \to \infty. \tag{5.7}$$

Finally, the identity

$$\begin{aligned}
\frac{\partial_\tau \left(\Sigma^{\frac{1}{n}} \ \Theta^{\frac{\alpha}{n}} \ \Gamma^{-\frac{m+n}{n}} \right)}{\left(\Sigma^{\frac{1}{n}} \ \Theta^{\frac{\alpha}{n}} \ \Gamma^{-\frac{m+n}{n}} \right)} &= \frac{1}{n} \ \frac{\Sigma_\tau}{\Sigma} + \frac{\alpha}{n} \ \frac{\Theta_\tau}{\Theta} - \frac{m+n}{n} \ \frac{\Gamma_\tau}{\Gamma} \\
&= -\left(\Sigma^{\frac{1}{n}} \ \Theta^{\frac{\alpha}{n}} \ \Gamma^{-\frac{m+n}{n}} - 1 \right)
\end{aligned}$$

implies that $\Phi(\tau) = \Sigma^{\frac{1}{n}} \ \Theta^{\frac{\alpha}{n}} \ \Gamma^{-\frac{m+n}{n}}$ satisfies the ordinary differential equation

$$\partial_\tau \Phi = -\Phi \left(\Phi - 1 \right),$$



(a) (b)

FIG. 5.1. *Two views of the flow of the ODE system* (5.3) *in the stable case:* $-\alpha+m+n>0$.

and thus $\Phi(\tau)\to 1$ as $\tau\to\infty$, that is,

$$\Sigma\ \Theta^{\alpha}\ \Gamma^{-(m+n)}\to 1 \quad \text{as } \tau\to\infty. \tag{5.8}$$

We conclude that the orbits of the differential system (5.3) approach the line of equilibria (5.5). Each orbit lies entirely on the surface (5.6), and the specific value of the parameter U is selected by the initial data. Unlike the system with two equations, strong numerical evidence (Figure 5.1) indicates that the system of three equations does not have invariant regions. In particular, Figure 5.1 shows the flow of the vector field generated by (5.3). Notice in the upper-left corner and/or in the lower-right corner of Figure 5.1(a), there are orbits always exiting the box. One can notice the same type of behavior in the bottom and/or the top part of Figure 5.1(b); there are orbits that are no longer confined in a box around the equilibrium manifold.

5.2. Effective equation for a simplified system. Our ultimate goal is to give an effective equation describing the long-time response of the system (3.1). We will present an argument that leads to such an effective equation in the following section. In preparation, we consider a simplified problem that accounts for the main structure of (3.4), by studying a variant where the time dependence of the diffusion term is frozen,

$$\begin{aligned} V_\tau &= \frac{1}{r}\Sigma_x, \\ \Gamma_\tau &= V_x-\Gamma, \\ \Theta_\tau &= \Sigma V_x-\frac{m+1}{1+\alpha}\Theta, \\ \Sigma &= \Theta^{-\alpha}\ \Gamma^m V_x^n. \end{aligned} \tag{5.9}$$

For this modified system, we calculate an effective equation in an asymptotic limit motivated by the theory of relaxation approximations. To this end, set $U=V_x$ in (5.9), and consider a rescaling of time in the form

$$\begin{aligned} &U(x,\tau)=\bar{U}^T\left(x,\frac{\tau}{T}\right), \quad \Theta(x,\tau)=\bar{\Theta}^T\left(x,\frac{\tau}{T}\right), \\ &\Gamma(x,\tau)=\bar{\Gamma}^T\left(x,\frac{\tau}{T}\right), \quad \Sigma(x,\tau)=\bar{\Sigma}^T\left(x,\frac{\tau}{T}\right), \quad s=\frac{\tau}{T}. \end{aligned} \tag{5.10}$$

Then, $(\bar{U}^T, \bar{\Theta}^T, \bar{\Gamma}^T, \bar{\Sigma}^T)$ satisfies the system of equations

$$\begin{aligned} U_s &= \frac{T}{r}\Sigma_{xx}, \\ \Gamma_s &= T(U-\Gamma), \\ \Theta_s &= T\left(\Sigma U - \frac{m+1}{1+\alpha}\Theta\right), \\ \Sigma \ &= \Theta^{-\alpha}\ \Gamma^m U^n, \end{aligned} \tag{5.11}$$

where in (5.11) we dropped the bars to simplify notations. Given a family of solutions of (5.11), we may use the relations

$$\lim_{T\to\infty} U(x,Ts) = \lim_{T\to\infty} \bar{U}^T(x,s)$$

in order to calculate the long-time behavior of solutions of (5.9). Therefore, it suffices to calculate the effective response in the limit $T \to \infty$ of solutions to (5.11). This goal can be achieved by using the procedure of the Chapman–Enskog expansion (e.g., [5]), familiar from the kinetic theory of gases. In order for the conservation law $(5.11)_1$ to provide a nontrivial effective response, we will consider the limit $T \to \infty$, $r \to \infty$ such that $\frac{T}{r} < \infty$ (and for simplicity will take $\frac{T}{r} = 1$). Consider the ansatz for solutions of (5.11):

$$\begin{aligned} \bar{U}^T &= U_0 + \frac{1}{T}U_1 + O\left(\frac{1}{T^2}\right), \quad \bar{\Gamma}^T = \Gamma_0 + \frac{1}{T}\Gamma_1 + O\left(\frac{1}{T^2}\right), \\ \bar{\Theta}^T &= \Theta_0 + \frac{1}{T}\Theta_1 + O\left(\frac{1}{T^2}\right), \quad \bar{\Sigma}^T = \Sigma_0 + \frac{1}{T}\Sigma_1 + O\left(\frac{1}{T^2}\right). \end{aligned} \tag{5.12}$$

Upon introducing the expansions into (5.11) and expanding in orders of T, keeping in mind that $r = T \to \infty$, we obtain consecutively

$$\partial_s\left(U_0 + \frac{1}{T}U_1 + \cdots\right) = \partial_{xx}\left(\Sigma_0 + \frac{1}{T}\Sigma_1 + \cdots\right), \tag{5.13}$$

$$\partial_s\left(\Gamma_0 + \frac{1}{T}\Gamma_1 + \cdots\right) = T\,(U_0 - \Gamma_0) + (U_1 - \Gamma_1) + \cdots, \tag{5.14}$$

$$\partial_s\left(\Theta_0 + \frac{1}{T}\Theta_1 + \cdots\right) = T\left(\Sigma_0 U_0 - \frac{m+1}{1+\alpha}\Theta_0\right) \tag{5.15}$$

$$+\left(\Sigma_1 U_0 + \Sigma_0 U_1 - \frac{m+1}{1+\alpha}\Theta_1\right) + \cdots, \tag{5.16}$$

and finally

$$\begin{aligned} &\Sigma_0 + \frac{1}{T}\Sigma_1 + \cdots \\ &\quad = \left(\Theta_0 + \frac{1}{T}\Theta_1 + \cdots\right)^{-\alpha}\left(\Gamma_0 + \frac{1}{T}\Gamma_1 + \cdots\right)^{m}\left(U_0 + \frac{1}{T}U_1 + \cdots\right)^{n} \\ &\quad = \Theta_0^{-\alpha}\Gamma_0^m U_0^n\left(1 + \frac{1}{T}\left(-\alpha\frac{\Theta_1}{\Theta_0} + m\frac{\Gamma_1}{\Gamma_0} + n\frac{U_1}{U_0}\right) + \cdots\right). \end{aligned} \tag{5.17}$$

Collecting terms of the same order together, we obtain for the 0th order perturbations the equations

$$\begin{aligned} U_0 &= \Gamma_0, \\ \Sigma_0 U_0 &= \frac{m+1}{1+\alpha}\Theta_0, \\ \Sigma_0 &= \Theta_0^{-\alpha}\Gamma_0^m U_0^n, \end{aligned} \tag{5.18}$$

while for the 1st order perturbations, we deduce the equations

$$\begin{aligned} U_1 - \Gamma_1 &= \partial_s \Gamma_0, \\ \Sigma_1 U_0 + \Sigma_0 U_1 - \frac{m+1}{1+\alpha}\Theta_1 &= \partial_s \Theta_0, \\ \left(-\alpha\frac{\Theta_1}{\Theta_0} + m\frac{\Gamma_1}{\Gamma_0} + n\frac{U_1}{U_0}\right)\Sigma_0 &= \Sigma_1, \\ \partial_s U_1 &= \partial_{xx}\Sigma_1. \end{aligned} \tag{5.19}$$

Solving (5.18) we obtain that all 0th order terms can be expressed in terms of the conserved quantity U_0:

$$\begin{aligned} \Gamma_0 &= U_0, \\ \Sigma_0 &= \left(\frac{m+1}{1+\alpha}\right)^{\frac{\alpha}{1+\alpha}} U_0^{\frac{-\alpha+m+n}{1+\alpha}}, \\ \Theta_0 &= \left(\frac{m+1}{1+\alpha}\right)^{-\frac{1}{1+\alpha}} U_0^{\frac{1+m+n}{1+\alpha}}, \\ \partial_s U_0 &= \partial_{xx}\Sigma_0. \end{aligned} \tag{5.20}$$

Note that U_0 is the conserved quantity and that such structure is typical in the theory of relaxation. In addition, we may obtain an evolution equation governing the behavior of the 0th order approximation in closed form as

$$\partial_s U_0 = \partial_{xx}\left(\left(\frac{m+1}{1+\alpha}\right)^{\frac{\alpha}{1+\alpha}} U_0^{\frac{-\alpha+m+n}{1+\alpha}}\right). \tag{5.21}$$

The nature of (5.21) changes, depending on the sign of

$$q = -\alpha + m + n$$

from forward parabolic when $q > 0$ to backward parabolic when $q < 0$. For the parameters ranging in the region $q < 0$, (5.21) is ill-posed, and one needs to derive the next order of the asymptotics. This is accomplished by solving (5.19) for the 1st order approximants $(\Gamma_1, \Theta_1, \Sigma_1)$ and using the expressions (5.20). We then obtain

$$\begin{aligned} \Gamma_1 &= U_1 - \partial_s U_0, \\ \frac{\Sigma_1}{\Sigma_0} &= \frac{-\alpha+m+n}{1+\alpha}\frac{U_1}{U_0} - \frac{m}{1+\alpha}\frac{\partial_s U_0}{U_0} + \frac{\alpha}{1+\alpha}\frac{\partial_s\Theta_0}{\Sigma_0 U_0}, \\ \frac{\Theta_1}{\Theta_0} &= \frac{1+m+n}{1+\alpha}\frac{U_1}{U_0} - \frac{m}{1+\alpha}\frac{\partial_s U_0}{U_0} - \frac{1}{1+\alpha}\frac{\partial_s\Theta_0}{\Sigma_0 U_0}. \end{aligned} \tag{5.22}$$

The corrected form—up to order $O(\frac{1}{T^2})$—of the effective equation is now easily calculated, using (5.20) and (5.22), leads to the equation

$$
\begin{aligned}
\partial_s \left(U_0 + \frac{1}{T} U_1 + O\left(\frac{1}{T^2}\right)\right) &= \partial_{xx}\left(\Sigma_0 + \frac{1}{T}\Sigma_1 + O\left(\frac{1}{T^2}\right)\right) \\
&= \partial_{xx}\Bigg[\left(\left(\frac{m+1}{1+\alpha}\right)^{\frac{\alpha}{1+\alpha}} U_0^{\frac{-\alpha+m+n}{1+\alpha}}\right) \\
&\quad + \frac{1}{T}\Sigma_0\left(\frac{-\alpha+m+n}{1+\alpha}\frac{U_1}{U_0} - \frac{m}{1+\alpha}\frac{\partial_s U_0}{U_0} + \frac{\alpha}{1+\alpha}\frac{\partial_s \Theta_0}{\Sigma_0 U_0}\right) + O\left(\frac{1}{T^2}\right)\Bigg] \\
&= \partial_{xx}\Bigg[\left(\frac{m+1}{1+\alpha}\right)^{\frac{\alpha}{1+\alpha}} U_0^{\frac{-\alpha+m+n}{1+\alpha}}\left(1 + \frac{-\alpha+m+n}{1+\alpha}\frac{U_1}{U_0}\frac{1}{T} + O\left(\frac{1}{T^2}\right)\right) \\
&\quad + \frac{1}{T}\Sigma_0\left(-\frac{m}{1+\alpha}\frac{\partial_s U_0}{U_0} + \frac{\alpha}{1+\alpha}\frac{\partial_s \Theta_0}{\Sigma_0 U_0}\right) + O\left(\frac{1}{T^2}\right)\Bigg].
\end{aligned}
\tag{5.23}
$$

The last objective is to obtain an equation for U that, up to 2nd order, will agree with (5.23). To this end, observe that the first term in the right side of (5.23) satisfies

$$
I_1 = \left(\frac{m+1}{1+\alpha}\right)^{\frac{\alpha}{1+\alpha}} U^{\frac{-\alpha+m+n}{1+\alpha}} + O\left(\frac{1}{T^2}\right),
$$

while the second term may be reexpressed using (5.20) and (5.21) as

$$
\begin{aligned}
I_2 = \Sigma_0\left(-\frac{m}{1+\alpha}\frac{\partial_s U_0}{U_0} + \frac{\alpha}{1+\alpha}\frac{\partial_s \Theta_0}{\Sigma_0 U_0}\right) &= \Sigma_0 \frac{\alpha(1+m+n) - m(m+1)}{(m+1)(1+\alpha)}\frac{\partial_s U_0}{U_0} \\
= \frac{\alpha(1+m+n) - m(m+1)}{(m+1)(1+\alpha)}\left(\frac{m+1}{1+\alpha}\right)^{\frac{2\alpha}{1+\alpha}} & U_0^{\frac{-\alpha+m+n}{1+\alpha}-1}\partial_{xx}(U_0^{\frac{-\alpha+m+n}{1+\alpha}}).
\end{aligned}
$$

The effective equation is thus, up to order $O(\frac{1}{T^2})$,

$$
\partial_s U = \partial_{xx}\left(c U^p + \frac{\lambda c^2}{T} U^{p-1}\partial_{xx} U^p\right),
\tag{5.24}
$$

where

$$
p = \frac{-\alpha+m+n}{1+\alpha}, \quad c = \left(\frac{m+1}{1+\alpha}\right)^{\frac{\alpha}{1+\alpha}}, \quad \lambda = \frac{\alpha(1+m+n) - m(m+1)}{(m+1)(1+\alpha)}.
$$

We thus see that the 2nd order approximation acquires an additional effect comprising of a nonlinear fourth order term. When $q = -\alpha+m+n > 0$, this term is a perturbation of a forward parabolic equation. As the forward parabolic term has a stabilizing response, the fourth order term is a small perturbation, and the sign of λ has no effect on the stability properties. By contrast, in the region $q < 0$, the first term provides backward parabolic response, and any stabilization is due only to the fourth order term. Note that

$$
\lambda = \frac{(\alpha - m - n) + n(1+\alpha) + (\alpha - m)m}{(m+1)(1+\alpha)},
$$

and thus when $q = -\alpha + m + n < 0$, it is $\lambda > 0$. The uniform shear solution corresponds to $U = 1$, and, for this reason, we write $U = 1 + u$ and compute the linearized equation for the perturbation u. This reads

$$\partial_s u = c\,p\,\partial_{xx} u + \frac{\lambda c^2}{T}\,p\,\partial_{xxxx} u. \tag{5.25}$$

The Fourier transform of (5.25) satisfies

$$\partial_s \hat{u} = \left(-c\,p\,\xi^2 + \frac{\lambda c^2}{T}\,p\,\xi^4 \right) \hat{u},$$

and thus when $q < 0$, the low frequencies will grow, but the high frequency modes still decay. Hence, for $\lambda > 0$, the linearized equation (5.25) is well posed.

6. Effective response at the onset of localization. We now consider the system (3.1) and will calculate an effective equation for its time response. We consider a modified time-rescaling of the form

$$\begin{aligned} \theta(x,t) &= (t+1)^{\frac{m+1}{\alpha+1}}\,\Theta\left(x, \frac{s(t)}{T}\right), \quad \gamma(x,t) = (t+1)\Gamma\left(x, \frac{s(t)}{T}\right), \\ \sigma(x,t) &= (t+1)^{\frac{m-\alpha}{\alpha+1}}\,\Sigma\left(x, \frac{s(t)}{T}\right), \quad v_x(x,t) = V_x\left(x, \frac{s(t)}{T}\right), \end{aligned} \tag{6.1}$$

where T is a parameter representing a change of time-unit and $s(t) : [0,\infty) \to [0,\infty)$ is to be selected as a monotone increasing, surjective map that represents a change of time-scale. This should be compared to (3.3) that has been used before. Introducing this transformation to (3.1), we obtain the equations

$$\begin{aligned} \partial_s V_x &= \frac{T}{r}\frac{1}{\dot{s}}(t+1)^{\frac{m-\alpha}{1+\alpha}}\,\Sigma_{xx}, \\ (t+1)\frac{\dot{s}}{T}\Theta_s &= \Sigma V_x - \frac{m+1}{1+\alpha}\Theta, \\ (t+1)\frac{\dot{s}}{T}\Gamma_s &= V_x - \Gamma, \\ \Sigma &= \Theta^{-\alpha}\Gamma^m V_x^n. \end{aligned}$$

We select $s(t)$ so that

$$\dot{s} = (t+1)^{\frac{m-\alpha}{1+\alpha}}, \tag{6.2}$$

that is,

$$s(t) = \frac{1}{\beta}\left[(t+1)^{\beta} - 1\right] \iff t(s) = \left(1 + \beta s\right)^{\frac{1}{\beta}} - 1,$$

where $\beta = \frac{m+1}{1+\alpha}$. We are interested in the limit $T \to \infty$, $r \to \infty$ so that $\frac{T}{r} = O(1)$, and, for simplicity, we will take $T = r$. The choice $r = O(T)$ is done for the following reasons: (i) it is expected that the inertial terms play an important role in the shear band formation process, (ii) we wish to retain both terms of the momentum equation at $O(1)$ as $T \to \infty$ (see also Remark 6.1). With these identifications, we deduce that the scaled functions Θ^T, Σ^T, $U^T = V_x^T$, and Γ^T satisfy

$$\begin{aligned} \partial_s U &= \Sigma_{xx}, \\ \frac{1}{T}(\beta s + 1)\Theta_s &= \Sigma U - \frac{m+1}{1+\alpha}\Theta, \\ \frac{1}{T}(\beta s + 1)\Gamma_s &= U - \Gamma, \\ \Sigma &= \Theta^{-\alpha}\Gamma^m U^n. \end{aligned} \tag{6.3}$$

If in the limit $T \to \infty$ the functions $(U^T, \Gamma^T, \Theta^T, \Sigma^T) \to (U_0, \Gamma_0, \Theta_0, \Sigma_0)$, then the limiting $(U_0, \Gamma_0, \Theta_0, \Sigma_0)$ lies in the "quilibrium" manifold

$$\begin{aligned} \Sigma_0 U_0 &= \beta\Theta_0, \\ U_0 &= \Gamma_0, \\ \Sigma_0 &= \Theta_0^{-\alpha}\Gamma_0^m U_0^n \end{aligned} \tag{6.4}$$

and satisfies the conservation law

$$\partial_s U_0 = \partial_{xx}\Sigma_0. \tag{6.5}$$

The latter can be expressed into closed form and leads to an effective equation for the long-time response, in the form

$$\begin{aligned} \Sigma_0 &= \beta^{\frac{\alpha}{1+\alpha}} U_0^{\frac{-\alpha+m+n}{1+\alpha}}, \\ \partial_s U_0 &= \partial_{xx}\left(\beta^{\frac{\alpha}{1+\alpha}} U_0^{\frac{-\alpha+m+n}{1+\alpha}}\right). \end{aligned} \tag{6.6}$$

Observe that U_0 describes the limiting dynamics of v_x as can be seen by taking the change of variable formula

$$v_x(x, t(\tau T)) = U^T(x, \tau) \tag{6.7}$$

to the limit as the unit-scale $T \to \infty$. Equation (6.6) changes type from forward parabolic for $q > 0$ to backward parabolic for $q < 0$, where $q = -\alpha + m + n$.

Remark 6.1. In order to preserve the moment equation at $O(1)$ in the limit $T \to \infty$, we have used the parameter r, by assuming $r = O(T)$. The same effect can be achieved by using a different scaling: One could alternatively scale the x-variable in the parabolic scaling $x \to \frac{x}{\sqrt{T}}$ and retain $r = O(1)$. This scaling would again preserve the equation $\partial_s U = \partial_{xx}\Sigma$ and lead to the same system (6.3) with a coefficient $r = O(1)$. In return, (6.7) would be replaced by

$$v_x\left(y\sqrt{T}, t(\tau T)\right) = U^T(y, \tau),$$

which indicates that the limit $T \to \infty$ would proceed along parabolic rays.

Finally, we perform the Chapman–Enskog procedure to calculate the next term of the correction. This is entirely analogous to the procedure outlined in section 5.2, and the details are omitted. To this end, the ansatz (5.12) is introduced into (6.3); collecting terms of the same order together, we obtain (6.4), (6.5) at the 0th order (leading to (6.6)) and obtain at the 1st order the equations

$$\begin{aligned} (\beta s + 1)\partial_s\Theta_0 &= \Sigma_0 U_1 + \Sigma_1 U_0 - \beta\Theta_1, \\ (\beta s + 1)\partial_s\Gamma_0 &= U_1 - \Gamma_1, \\ \Sigma_1 &= \Sigma_0\left(-\alpha\frac{\Theta_1}{\Theta_0} + m\frac{\Gamma_1}{\Gamma_0} + n\frac{U_1}{U_0}\right), \end{aligned}$$

together with

$$\partial_s U_1 = \partial_{xx}\Sigma_1. \tag{6.8}$$

Solving the former equations yields

$$\begin{aligned}
\frac{\Gamma_1}{U_0} &= \frac{U_1}{U_0} - (\beta s + 1)\frac{\partial_s U_0}{U_0},\\
\frac{\Sigma_1}{\Sigma_0} &= \frac{-\alpha + m + n}{1+\alpha}\frac{U_1}{U_0} - \frac{m}{1+\alpha}(\beta s + 1)\frac{\partial_s U_0}{U_0} + \frac{\alpha}{1+\alpha}(\beta s + 1)\frac{\partial_s \Theta_0}{\Sigma_0 U_0},\\
\frac{\Theta_1}{\Theta_0} &= \frac{1 + m + n}{1+\alpha}\frac{U_1}{U_0} - \frac{m}{1+\alpha}(\beta s + 1)\frac{\partial_s U_0}{U_0} - \frac{1}{1+\alpha}(\beta s + 1)\frac{\partial_s \Theta_0}{\Sigma_0 U_0}.
\end{aligned}$$

We next introduce the values of U_0, U_1, Σ_0, Σ_1 into the equation

$$\partial_s \left(U_0 + \frac{1}{T}U_1 + O\left(\frac{1}{T^2}\right)\right) = \partial_{xx}\left(\Sigma_0 + \frac{1}{T}\Sigma_1 + O\left(\frac{1}{T^2}\right)\right) \tag{6.9}$$

and regroup the terms following section 5.2 to deduce that U^T satisfies up to order $O\left(\frac{1}{T^2}\right)$ the equation

$$\partial_s U = \partial_{xx}\left(c\,U^p + \frac{\lambda c^2}{T}(\beta s + 1)U^{p-1}\partial_{xx}U^p\right), \tag{6.10}$$

where

$$p = \frac{-\alpha + m + n}{1+\alpha}, \quad \beta = \frac{m+1}{1+\alpha}, \quad c = \beta^{\frac{\alpha}{1+\alpha}}, \quad \lambda = \frac{\alpha(1+m+n) - m(m+1)}{(m+1)(1+\alpha)}.$$

When $q < 0$, the second order term is backward parabolic and has a destabilizing role, at the same time $\lambda > 0$ and the fourth order term offers a stabilizing influence.

System versus effective equation: Numerical comparison. Next, we compare numerically the solution of system (6.3) with (6.10). The effective equation (6.10) is a highly nonlinear fourth order equation whose behavior depends drastically on the sign of p. In the stable case $p > 0$, (6.10) is a forward parabolic equation and a fourth order correction term whose sign depends on the parameter λ. In the stable case, the fourth order term does not have a definite sign, since the parameter λ can be either positive or negative but nevertheless without any essential effect on the qualitative behavior of the effective equation. We compare numerically the solution of the system (6.3) and (6.10) for $T = 1000$ at various time instances. We use a standard finite element method for the spatial discretization, coupled with Newton's method for linearization, while the Crank–Nicolson method is used for time stepping. In this case we expect the solution $U = V_x$ to converge as $t \to \infty$ to the uniform shearing solution (2.17). In Figure 6.1 we see an excellent agreement of the two solutions, especially as t grows.

In the unstable case $p < 0$, the behavior of the effective equation (6.10) changes drastically. The leading second order term has a negative sign, thus the effective equation changes to an unstable backward parabolic type. On the other hand, the parameter λ in the unstable case is positive, thus the fourth order term provides a stabilizing effect. The balance of these two mechanisms is a delicate issue theoretically as well as numerically. In general, the numerical solution of linear or nonlinear fourth

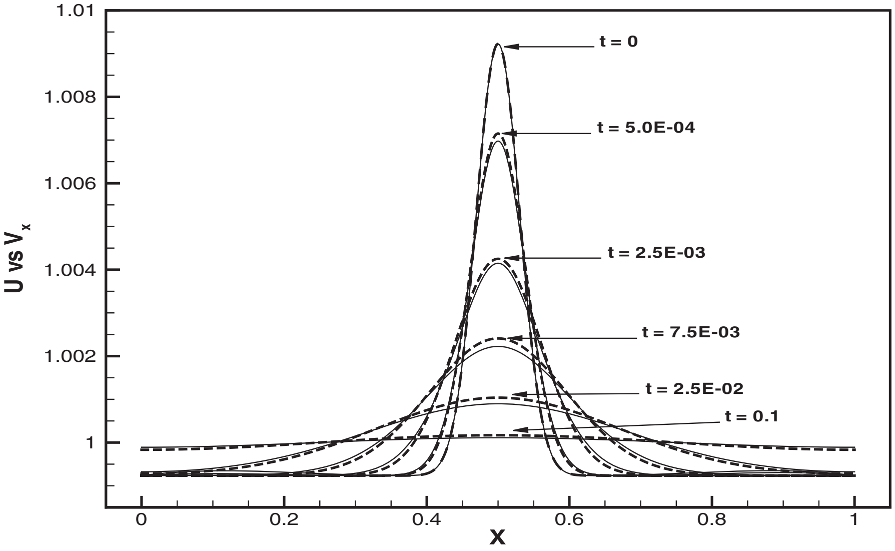


FIG. 6.1. *Comparison in the parameter range* $p > 0$ *of system* (6.3) *(solid line) versus effective equation* (6.9)*(dashed line) for* $T = 1000$.

order equations is not a trivial task. Special numerical techniques have to be applied to capture correctly the behavior of the underlying phenomena. These issues go beyond the scope of the present article and will be the subject of a future work. Detailed numerical results on the behavior of systems (2.11) and the companion system with Fourier heat conduction can be found in [2].

Appendix A. We present in this appendix the proofs of Theorems 4.1 and 4.2. Let (v, θ, σ) be a smooth solution of (4.1), (4.2), and (V, Θ, Σ) the rescaled functions defined in (4.3) and satisfying (4.4), (4.5), and (4.6).

Proof of Theorem 4.1. In the range $q = -\alpha + n > 0$, the system (4.4) is endowed with invariant regions, and (Θ, Σ) and V_x satisfy the bounds (4.11). In what follows, C stands for a generic constant that is independent of time.

Set $g(\tau) = \frac{1}{r} e^{\frac{1}{1+\alpha}\tau}$. Using (4.6), we obtain the identity $\partial_\tau \left(\frac{1}{2g^2} V_\tau^2 \right) = \frac{1}{g} \Sigma_{x\tau} V_\tau$. Integrating by parts over $[0, 1]$ and using $(4.4)_1$, (4.6), and (2.14), we obtain

$$\frac{d}{d\tau} \frac{1}{2} \int_0^1 \frac{1}{g^2} V_\tau^2 dx + \int_0^1 n \Theta^{-\frac{\alpha}{n}} \Sigma^{\frac{n-1}{n}} \frac{1}{g} V_{x\tau}^2 \, dx \\ = \int_0^1 \alpha \frac{1}{g} \Big(\Theta^{\frac{\alpha}{n}-1} \Sigma^{\frac{n+1}{n}} - \frac{1}{1+\alpha} \Big) \Sigma V_{x\tau} \, dx.$$

Next use of the bounds (4.11) and the Poincarè inequality to obtain

$$\frac{d}{d\tau} \int_0^1 \frac{1}{g^2} V_\tau^2 dx + g(\tau) \frac{1}{C} \int_0^1 \frac{1}{g^2} V_\tau^2 dx \leq \frac{C}{g(\tau)}.$$

In turn, Gronwall's inequality implies

$$\int_0^1 V_\tau^2(x, \tau) dx \leq C, \tag{A.1}$$

and, by (4.6),

$$\int_0^1 |\Sigma_x| dx \le \left(\frac{1}{g^2} \int_0^1 V_\tau^2 dx \right)^{\frac{1}{2}} \le C e^{-\frac{1}{1+\alpha}\tau}. \tag{A.2}$$

From (4.4) we obtain the identity

$$\partial_\tau \left(e^{\frac{n-\alpha}{n(1+\alpha)}\tau} \big(\Theta^{1-\frac{\alpha}{n}}\big)_x \right) = \frac{n-\alpha}{n} e^{\frac{n-\alpha}{n(1+\alpha)}\tau} \big(\Sigma^{\frac{n+1}{n}}\big)_x,$$

which using (4.11) and (A.2) leads to using (4.11) and (A.2):

$$\int_0^1 |\Theta_x| dx \le C e^{-\frac{n-\alpha}{n(1+\alpha)}\tau}. \tag{A.3}$$

Moreover, starting from (4.5) we obtain $V_{xx} = \frac{1}{n}\Sigma^{\frac{1}{n}-1}\Theta^{\frac{\alpha}{n}}\Sigma_x + \frac{\alpha}{n}\Theta^{\frac{\alpha}{n}-1}\Theta_x\Sigma^{\frac{1}{n}}$, which is used, in conjunction with (A.2) and (A.3), to deduce

$$|V_x(x,\tau) - 1| \le \int_0^1 |V_{xx}|\, dx = O\left(e^{-\frac{n-\alpha}{n(1+\alpha)}\tau} \right). \tag{A.4}$$

Finally, from $(4.4)_2$, (4.5), and (A.4), we obtain

$$\partial_\tau \left(e^\tau \frac{1}{1+\alpha} \Theta^{1+\alpha} \right) = e^\tau V_x^{n+1} = e^\tau \left(1 + O\big(e^{-\frac{n-\alpha}{n(1+\alpha)}\tau}\big) \right)^{n+1},$$

which implies

$$\Theta = (1+\alpha)^{\frac{1}{1+\alpha}} + O\left(e^{-\frac{n-\alpha}{n(1+\alpha)}\tau} \right), \tag{A.5}$$

$$\Sigma = \Theta^{-\alpha} V_x^n = (1+\alpha)^{-\frac{\alpha}{1+\alpha}} + O\left(e^{-\frac{n-\alpha}{n(1+\alpha)}\tau} \right). \tag{A.6}$$

The estimates (A.4), (A.5), and (A.6) together with (4.3) yield the asymptotic behaviors stated in Theorem 4.1. □

Proof of Theorem 4.2. Let $q = -\alpha + n < 0$, consider initial data satisfying (4.16) and (4.17), and let (v, θ, σ) be a smooth solution of (4.1), (4.2) defined on a maximal interval of existence $[0, T_\star)$. The stress σ satisfies the boundary value problem for the parabolic equation

$$\begin{aligned} \sigma_t &= \frac{n}{r}\ \theta^{-\frac{\alpha}{n}}\ \sigma^{\frac{n-1}{n}} \sigma_{xx} - \alpha\theta^{\frac{\alpha}{n}-1}\ \sigma^{2+\frac{1}{n}}, \\ \sigma_x(0,t) &= \sigma_x(1,t) = 0. \end{aligned} \tag{A.7}$$

By the maximum principle, $\sigma(x,t) > 0$. Let $S(t)$ be the solution of the initial value problem

$$\begin{cases} \dfrac{dS}{dt} = -\alpha \underline{\theta_0}^{\frac{\alpha}{n}-1} S^{2+\frac{1}{n}}, \\ S(0) = S_0 = \sup_{x\in[0,1]} \sigma_0(x), \end{cases} \tag{A.8}$$

where $\underline{\theta_0} = \inf_{x\in[0,1]} \theta_0(x)$. S is given by the formula

$$S(t) = \left(S_0^{-\frac{n+1}{n}} + \alpha \frac{n+1}{n} \underline{\theta_0}^{\frac{\alpha}{n}-1} t \right)^{-\frac{n}{n+1}}.$$

For $\frac{\alpha}{n} > 1$, S is a supersolution of (A.7), and thus

$$0 < \sigma(x,t) \le O\left((t+1)^{-\frac{n}{n+1}}\right), \quad x \in [0,1],\ 0 < t < T_*. \tag{A.9}$$

We multiply $(4.1)_1$ by $\sigma^{\frac{1}{n}-1} v_t$, integrate over $[0,1]$ by parts, and use $(4.1)_2$ to obtain

$$\begin{aligned}\frac{n}{2}\int_0^1 \theta^{-\frac{\alpha}{n}} v_x^2 dx + \int_0^t\int_0^1 \sigma^{\frac{1-n}{n}} v_t^2 dxdt + \frac{\alpha}{2}\int_0^t\int_0^1 \theta^{-\frac{\alpha}{n}-1-\alpha} v_x^{n+3} dx \\ = \frac{n}{2}\int_0^1 \theta_0(x)^{-\frac{\alpha}{n}} v_{0x}(x)^2 dx = I_0.\end{aligned}$$

Next, we employ the calculus inequality

$$f^2(x) - \left(1+\frac{1}{r}\right) f^2(y) \le (1+r)\left(f(x)-f(y)\right)^2 \le (1+r)\int_0^1 f_x^2 d\xi$$

and put $f = \sigma^{\frac{n+1}{2n}}$ in order to obtain (for $r=2$, say)

$$\sigma^{\frac{n+1}{n}}(x,t) - \frac{3}{2}\sigma^{\frac{n+1}{n}}(y,t) \le 3\Big(\frac{n+1}{2n}\Big)^2 \int_0^1 \sigma^{\frac{1-n}{n}} v_t^2 dx.$$

Let now the data be as in (4.16), (4.17). In the region $\frac{\alpha}{n} > 1$, the identity

$$\partial_t \theta^{-\left(\frac{\alpha}{n}-1\right)} = -\left(\frac{\alpha}{n}-1\right)\sigma^{\frac{n+1}{n}},$$

taken at two distinct points x and y, gives

$$\begin{aligned}\theta^{-\left(\frac{\alpha}{n}-1\right)}(x,t) - \frac{3}{2}\theta^{-(\frac{\alpha}{n}-1)}(y,t) &= \left(\theta_0^{-\left(\frac{\alpha}{n}-1\right)}(x) - \frac{3}{2}\theta_0^{-\left(\frac{\alpha}{n}-1\right)}(y)\right) \\ &\quad - \left(\frac{\alpha}{n}-1\right)\int_0^t \left(\sigma^{\frac{n+1}{n}}(x,\tau) - \frac{3}{2}\sigma^{\frac{n+1}{n}}(y,\tau)\right) d\tau \\ &\ge \theta_0^{-\left(\frac{\alpha}{n}-1\right)}(x) - \frac{3}{2}\theta_0^{-\left(\frac{\alpha}{n}-1\right)}(y) - C(\alpha,n) I_0 \\ &= m(x,y),\end{aligned} \tag{A.10}$$

where $C(\alpha,n)$ is an explicit positive constant. Suppose now that the solution θ does not blow up. Then $\theta(x,t)$ can be estimated outside the band I_δ by the bound (A.10). The latter is, of course, meaningful only when $m(x,y) > 0$. This can be achieved provided the value $\theta_0(y) = U(y)$ in (4.17) is sufficiently large and the base state $\bar{\theta}$ suitably chosen.

Once x, y are selected so that $m(x,y) > 0$, (A.10) provides a bound for the temperature

$$\theta(x,t) \le M \quad x \notin I_\delta,\ 0 < t < \infty.$$

Since θ is increasing, it converges to a limiting profile for $x \notin I_\delta$. Inside the band θ might increase indefinitely. In addition, (A.9) and (4.2) imply

$$v_x(x,t) = O\left((t+1)^{-\frac{1}{n+1}}\right), \quad x \notin I_\delta,\ 0 < t < \infty,$$

in turn giving (4.18). □

A NONAUTONOMOUS JUVENILE-ADULT MODEL: WELL-POSEDNESS AND LONG-TIME BEHAVIOR VIA A COMPARISON PRINCIPLE*

AZMY S. ACKLEH† AND KENG DENG†

Abstract. A nonautonomous nonlinear continuous juvenile-adult model where juveniles and adults depend on different resources is developed. It is assumed that juveniles are structured by age, while adults are structured by size. Existence-uniqueness results are proved using the monotone method based on a comparison principle established in this paper. Conditions on the model parameters that lead to extinction or persistence of the population are obtained via the upper-lower solution technique.

Key words. continuous juvenile-adult model, comparison principle, existence-uniqueness, extinction, uniform persistence

1. Introduction.

Amphibians have a biphasic lifestyle where juveniles (tadpoles) live in water while adults (frogs) live on land. For many amphibians tadpoles are herbivorous, while adults are carnivorous. Thus, juveniles and adults depend on different resources, and no resource competition takes place between them. In [2, 7, 9], we developed and analyzed discrete-time discrete-stage models that describe the dynamics of such populations. A particular amphibian example that motivated these theoretical studies is the green tree frog (*Hyla cinerea*) which we have been monitoring since 2004 [26]. Similar discrete-time discrete-stage models have been formulated and studied in [14, 31]. These models have been applied to two amphibian species, *Bufo boreas* and *Ambystoma macrodactylum.* Elasticity analysis was used to determine the most influential stage survival rate on amphibian declines, a problem which was extensively discussed in [16, 29].

In this paper, we extend our modeling efforts and develop a nonautonomous continuous age-size–structured model which describes the dynamics of a population composed of juveniles and adults who depend on different resources. In our setting below we assume that juveniles are structured by age (e.g., for the green tree frogs it requires 5–6 weeks for a juvenile to metamorphose into an adult [21, 22, 28]). We assume that adults are structured by size, since fertility and mortality depend on the size of the adult (see, e.g., [33] for the green tree frogs). Furthermore, we assume that the vital parameters are time-dependent functions due to the seasonality of such populations.

Well-posedness and long-time behavior of continuous nonlinear autonomous age-size–structured population models have been investigated in many articles (e.g., see [5, 6, 11, 12, 13, 18, 19, 23, 27, 32] and the references cited therein). Structured juvenile-adult models with time-independent parameters have also been developed and studied in the literature. For example, in [15] a juvenile-adult model was developed with both juvenile and adult populations being age-structured. Therein, the

†Department of Mathematics, University of Louisiana at Lafayette, Lafayette, LA 70504 (ackleh@louisiana.edu, deng@louisiana.edu).

authors tackled the question of whether juvenile versus adult intraspecific competition is stabilizing or destabilizing. It was shown that suppressed adult fertility due to juvenile competition is destabilizing in that equilibrium levels are lowered and equilibrium resilience is weakened. However, the effect of increased juvenile mortality due to adult competition is complicated in that equilibrium levels are lowered but the resilience can be weakened or strengthened. In [20] a nonlinear size-structured juvenile-adult model was developed, and the linearized dynamical behavior of stationary solutions was analyzed using semigroup theory.

As is discussed in [14], the growth, reproduction, and mortality rates of many biological populations are subject to regular (time) fluctuations, which is the case for amphibians. Thus, in this paper we study the existence-uniqueness and long-time behavior of solutions to a nonautonomous nonlinear structured juvenile-adult model. Our arguments are different from those used in the above-mentioned articles and are based on a novel definition of upper and lower solutions, the establishment of a comparison principle, and the construction of monotone approximations. This comparison principle extends those developed in [10, 24, 25] to a system of nonlocal nonlinear first order hyperbolic equations. However, its establishment is distinct from those in [10, 24, 25], but is in the spirit of the one we developed in [4] for a size-structured model.

Other traditional approaches, including the employment of the method of characteristics to convert the problem to a system of delay integral equations and then apply the fixed point theory (e.g., [11]), may perhaps work for establishing existence-uniqueness results. However, we are unaware of abstract results for nonautonomous delay systems such as those developed in [17] for the autonomous counterpart, which can be used for investigating the long-time behavior of solutions to the model presented here.

The paper is organized as follows. In section 2 we introduce the model. In section 3 we give the definition of upper and lower solutions and establish a comparison principle. In section 4 we develop monotone sequences and prove their convergence to the unique solution of the model. In section 5 we investigate the asymptotic behavior of the model. Finally, concluding remarks are given in section 6.

2. The juvenile-adult model.

Let $J(a,t)$ and $A(x,t)$ denote the densities of juveniles of age a and adults of size x, respectively, at time t. Thus, $\int_{a_1}^{a_2} J(a,t)da$ denotes the number of juveniles in the age interval (a_1,a_2) at time t. We denote by $a_{\max}$ the age at which juveniles (tadpoles) metamorphose into adults (frogs) of minimum size $x_{\min}$, and $x_{\max}$ denotes the maximum size of adults. Hence, $\int_{x_1}^{x_2} A(x,t)dx$ denotes the number of adults in the size interval (x_1,x_2) at time t. We assume that juveniles live in an environment with abundant resources and thus do not compete, while adults live in an environment with limiting resources and thus competition between them takes place. Consider the following system of partial differential equations which describe the dynamics of interacting juveniles and adults:

$$\begin{array}{lll}
J_t(a,t) + J_a(a,t) + \nu(a,t)J(a,t) = 0, & 0 < a < a_{\max}, & 0 < t < T,\\
A_t(x,t) + (g(x,t)A(x,t))_x + \mu(x,t,\varphi(t))A(x,t) = 0, & x_{min} < x < x_{\max}, & 0 < t < T,\\
J(0,t) = \displaystyle\int_{x_{\min}}^{x_{\max}} \beta(x,t,\varphi(t))A(x,t)dx, & & 0 < t < T,\\
g(x_{\min},t)A(x_{\min},t) = J(a_{\max},t), & & 0 < t < T,\\
J(a,0) = J_0(a), & 0 \le a \le a_{\max}, & \\
A(x,0) = A_0(x), & x_{\min} \le x \le x_{\max}, &
\end{array} \tag{2.1}$$

where $\varphi(t) = \int_{x_{min}}^{x_{\max}} A(x,t)dx$ is the total population of adults. The parameters ν and μ are mortality rates for juveniles and adults, respectively. The functions g and β are the growth and reproduction rates, respectively, for adults. Since amphibians breed seasonally, the birth rate β typically depends on t and is positive during the breeding season and zero otherwise (see, e.g., [7, 9]).

Throughout the discussion, for convenience we denote $\frac{\partial \mu}{\partial \varphi}$ and $\frac{\partial \beta}{\partial \varphi}$ by μ_φ and β_φ, respectively. We assume that the parameters in (2.1) satisfy the following assumptions:

(A1) $g \in C^1([x_{\min}, x_{\max}] \times [0,T])$. Furthermore, $g(x,t) > 0$ for $(x,t) \in [x_{\min}, x_{\max}) \times [0,T]$ and $g(x_{\max}, t) = 0$ for $t \in [0,T]$.

(A2) $\nu \in L^\infty((0, a_{\max}) \times (0,T))$ is nonnegative.

(A3) $\mu(\cdot,\cdot,\varphi) \in L^\infty((x_{\min}, x_{\max}) \times (0,T))$ and for $(x,t,\varphi) \in (x_{\min}, x_{\max}) \times (0,T) \times [0,\infty)$, $\mu(x,t,\varphi)$ is nonnegative. Furthermore, μ is continuously differentiable with respect to φ with $\mu_\varphi \geq 0$.

(A4) $\beta(\cdot,\cdot,\varphi) \in L^\infty((x_{\min}, x_{\max}) \times (0,T))$ and for $(x,t,\varphi) \in (x_{\min}, x_{\max}) \times (0,T) \times [0,\infty)$, $\beta(x,t,\varphi)$ is nonnegative. Furthermore, β is continuously differentiable with respect to φ with $\beta_\varphi \leq 0$.

(A5) $J_0 \in L^\infty(0, a_{\max})$ is nonnegative.

(A6) $A_0 \in L^\infty(x_{\min}, x_{\max})$ is nonnegative.

3. Comparison principle.

We first introduce the definition of the solution of problem (2.1) via the method of characteristics. For the first equation in (2.1), the characteristic curves can be easily obtained. For the second equation in (2.1), the characteristic curves are given by

$$\begin{cases} \dfrac{d}{ds}t(s) = 1, \\ \dfrac{d}{ds}x(s) = g(x(s), t(s)). \end{cases} \tag{3.1}$$

Under assumption (A1), equation (3.1) has a unique solution for any initial point $(x(s_0), t(s_0))$. Parameterizing the characteristic curves with the variable t, a characteristic curve passing through $(\hat{x}, \hat{t})$ is given by $(X(t;\hat{x},\hat{t}), t)$, where X satisfies

$$\frac{d}{dt}X(t;\hat{x},\hat{t}) = g(X(t;\hat{x},\hat{t}), t)$$

and $X(\hat{t};\hat{x},\hat{t}) = \hat{x}$. By (A1), the function X is strictly increasing, and therefore a unique inverse function $\Gamma(x;\hat{x},\hat{t})$ exists. Let $G(x) = \Gamma(x; x_{\min}, 0)$; then $(x, G(x))$ represents the characteristic curve passing through $(x_{\min}, 0)$, and this curve divides the (x,t)-plane into two parts. Hence, we can define the solution of problem (2.1) as follows:

$$J(a,t) = J_0(a-t)\exp\left(-\int_0^t \nu(a-t+\tau,\tau)d\tau\right) \qquad \text{if } t \leq a, \tag{3.2}$$

$$J(a,t) = \int_{x_{\min}}^{x_{\max}} \beta(x, t-a, \varphi(t-a))A(x,t-a)dx \exp\left(-\int_{t-a}^t \nu(a-t+\tau,\tau)d\tau\right) \qquad \text{if } t > a, \tag{3.3}$$

$$A(x,t) = A_0(X(0;x,t)) \exp\left\{-\int_0^t [g_x(X(\tau;x,t),\tau) + \mu(X(\tau;x,t),\tau,\varphi(\tau))]d\tau\right\} \quad \text{if } t \le G(x), \tag{3.4}$$

$$A(x,t) = \frac{J(a_{\max},\Gamma(x_{\min};x,t))}{g(x_{\min},\Gamma(x_{\min};x,t))} \exp\left\{-\int_{\Gamma(x_{\min};x,t)}^t [g_x(X(\tau;x,t),\tau) + \mu(X(\tau;x,t),\tau,\varphi(\tau))]d\tau\right\} \quad \text{if } t > G(x). \tag{3.5}$$

We then introduce the definition of a pair of coupled upper and lower solutions of problem (2.1).

Definition 3.1. *A pair of functions* ($\overline{J}(a,t), \overline{A}(x,t)$) *and* ($\underline{J}(a,t), \underline{A}(x,t)$) *are called an upper solution and a lower solution, respectively, of* (2.1) *if the following statements hold:*

(i) $\overline{J}, \underline{J} \in L^\infty((0,a_{\max}) \times (0,T))$ *and* $\overline{A}, \underline{A} \in L^\infty((x_{\min},x_{\max}) \times (0,T))$.

(ii)

$$\overline{J}(a,t) \ge J_0(a-t) \exp\left(-\int_0^t \nu(a-t+\tau,\tau)d\tau\right) \qquad \text{if } t \le a. \tag{3.6}$$

$$\overline{J}(a,t) \ge \int_{x_{\min}}^{x_{\max}} \beta(x,t-a,\underline{\varphi}(t-a))\overline{A}(x,t-a)dx \exp\left(-\int_{t-a}^t \nu(a-t+\tau,\tau)d\tau\right) \quad \text{if } t > a. \tag{3.7}$$

(iii) $\overline{A}(x,0) \ge A_0(x) \ge \underline{A}(x,0)$ *a.e. in* $(x_{\min},x_{\max})$. *For each* $t \in (0,T)$ *and every nonnegative* $\xi \in C^1([x_{\min},x_{\max}] \times [0,T])$,

$$\begin{aligned} \int_{x_{\min}}^{x_{\max}} \overline{A}(x,t)\xi(x,t)dx \ge & \int_{x_{\min}}^{x_{\max}} \overline{A}(x,0)\xi(x,0)dx + \int_0^t \overline{J}(a_{\max},\tau)\xi(x_{\min},\tau)d\tau \\ & + \int_0^t \int_{x_{\min}}^{x_{\max}} [\xi_\tau(x,\tau) + g(x,\tau)\xi_x(x,\tau)]\overline{A}(x,\tau)dxd\tau \\ & - \int_0^t \int_{x_{\min}}^{x_{\max}} \mu(x,\tau,\underline{\varphi}(\tau))\overline{A}(x,\tau)\xi(x,\tau)dxd\tau. \end{aligned} \tag{3.8}$$

($\underline{J}, \underline{A}$) *satisfies* (3.6)–(3.8), *respectively, by replacing " $\ge$ " with " $\le$ " and by interchanging* $\overline{J}$ *with* $\underline{J}$, $\overline{A}$ *with* $\underline{A}$, *and* $\underline{\varphi}$ *with* $\overline{\varphi}$, *where* $\underline{\varphi}(t) = \int_{x_{\min}}^{x_{\max}} \underline{A}(x,t)dx$ *and* $\overline{\varphi}(t) = \int_{x_{\min}}^{x_{\max}} \overline{A}(x,t)dx$.

Remark 3.2. Inequality (3.8), which is used only for the establishment of the comparison principle, is motivated by an alternative definition of a weak solution of the second equation in (2.1) given by

$$\begin{aligned} \int_{x_{\min}}^{x_{\max}} A(x,t)\xi(x,t)dx = & \int_{x_{\min}}^{x_{\max}} A(x,0)\xi(x,0)dx + \int_0^t J(a_{\max},\tau)\xi(x_{\min},\tau)d\tau \\ & + \int_0^t \int_{x_{\min}}^{x_{\max}} [\xi_\tau(x,\tau) + g(x,\tau)\xi_x(x,\tau)]A(x,\tau)dxd\tau \\ & - \int_0^t \int_{x_{\min}}^{x_{\max}} \mu(x,\tau,\varphi(\tau))A(x,\tau)\xi(x,\tau)dxd\tau \end{aligned} \tag{3.9}$$

for each $t \in (0,T)$ and every $\xi \in C^1([x_{\min}, x_{\max}] \times [0,T])$. The solution (3.9) is derived by formally multiplying the second equation of (2.1) by a test function ξ and integrating by parts (cf. [1, 8]).

Remark 3.3. For the *linear* problem

$$\begin{aligned}
&A_t(x,t) + (g(x,t)A(x,t))_x + \mu(x,t)A(x,t) = 0, \quad x_{min} < x < x_{\max}, \quad 0 < t < T,\\
&g(x_{\min},t)A(x_{\min},t) = h(t), \qquad\qquad\qquad\qquad\qquad\qquad 0 < t < T,\\
&A(x,0) = A_0(x), \qquad\qquad\qquad\qquad\qquad x_{\min} \le x \le x_{\max},
\end{aligned} \tag{3.10}$$

the solution satisfies both the mild form given by (3.4)–(3.5) and the weak form given by (3.9) with $J(a_{\max},t)$ replaced by $h(t)$. Moreover, the two sequences that we construct in section 4 and apply the comparison principle to are linear and of the form (3.10).

Based on such a definition, we can establish the following comparison result.

THEOREM 3.4. *Suppose that* (A1)–(A6) *hold. Let* $(\overline{J}, \overline{A})$ *and* $(\underline{J}, \underline{A})$ *be a nonnegative upper solution and a nonnegative lower solution, respectively, of* (2.1)*. Then* $\overline{J} \ge \underline{J}$ *a.e. in* $(0, a_{\max}) \times (0, T_0)$ *and* $\overline{A} \ge \underline{A}$ *a.e. in* $(x_{\min}, x_{\max}) \times (0, T_0))$*, where* $T_0 = \min\{T, a_{\max}\}$*.*

Proof. Let $K = \underline{J} - \overline{J}$ and $B = \underline{A} - \overline{A}$. In view of (3.6), $K(a,t) \le 0$ for $t \le a$. In particular, $K(a_{\max},t) \le 0$. Furthermore, B satisfies

$$B(x,0) = \underline{A}(x,0) - \overline{A}(x,0) \le 0 \quad \text{a.e. in } (x_{\min}, x_{\max}) \tag{3.11}$$

and

$$\begin{aligned}
\int_{x_{\min}}^{x_{\max}} B(x,t)\xi(x,t)dx \le& \int_{x_{\min}}^{x_{\max}} B(x,0)\xi(x,0)dx + \int_0^t K(a_{\max},\tau)\xi(x_{\min},\tau)d\tau\\
&+\int_0^t \int_{x_{\min}}^{x_{\max}} [\xi_\tau(x,\tau) + g(x,\tau)\xi_x(x,\tau)]B(x,\tau)dxd\tau\\
&-\int_0^t \int_{x_{\min}}^{x_{\max}} \mu(x,\tau,\overline{\varphi}(\tau))B(x,\tau)\xi(x,\tau)dxd\tau\\
&+\int_0^t \int_{x_{\min}}^{x_{\max}} \xi(x,\tau)C_1(x,\tau)\int_{x_{\min}}^{x_{\max}} B(y,\tau)dydxd\tau,
\end{aligned} \tag{3.12}$$

where $C_1(x,t) = \overline{A}(x,t)\mu_\varphi(x,t,\theta_1(t))$ with $\theta_1(t)$ between $\overline{\varphi}(t)$ and $\underline{\varphi}(t)$.

Let $\xi(x,t) = e^{\lambda t}\zeta(x,t)$, where $\zeta \in C^1([x_{\min}, x_{\max}] \times [0,T_0])$ and λ (> 0) is chosen so that $\lambda - \mu(x,t,\overline{\varphi}(t)) \ge 0$ on $(x_{\min}, x_{\max}) \times (0,T_0)$. Then we find

$$\begin{aligned}
e^{\lambda t}\int_{x_{\min}}^{x_{\max}} B(x,t)\zeta(x,t)dx \le& \int_{x_{\min}}^{x_{\max}} B(x,0)\zeta(x,0)dx + \int_0^t e^{\lambda\tau} K(a_{\max},\tau)\zeta(x_{\min},\tau)d\tau\\
&+\int_0^t \int_{x_{\min}}^{x_{\max}} e^{\lambda\tau}[\zeta_\tau(x,\tau) + g(x,\tau)\zeta_x(x,\tau)]B(x,\tau)dxd\tau\\
&+\int_0^t \int_{x_{\min}}^{x_{\max}} e^{\lambda\tau}[\lambda - \mu(x,\tau,\overline{\varphi}(\tau))]B(x,\tau)\zeta(x,\tau)dxd\tau\\
&+\int_0^t \int_{x_{\min}}^{x_{\max}} e^{\lambda\tau}\zeta(x,\tau)C_1(x,\tau)\int_{x_{\min}}^{x_{\max}} B(y,\tau)dydxd\tau.
\end{aligned} \tag{3.13}$$

We now set up a backward problem as follows:

$$\begin{aligned}
&\zeta_\tau + g\zeta_x = 0, \qquad x_{\min} < x < x_{\max}, \quad 0 < \tau < t,\\
&\zeta(x_{\max}, \tau) = 0, \qquad\qquad\qquad\qquad\quad 0 < \tau < t,\\
&\zeta(x, t) = \chi(x), \qquad x_{\min} < x < x_{\max}.
\end{aligned}$$

Here $\chi \in C_0^\infty(x_{\min}, x_{\max})$ with $0 \le \chi \le 1$. The above problem can be solved by the method of characteristics, and the solution satisfies $0 \le \zeta(x,t) \le 1$ on $[x_{\min}, x_{\max}] \times [0, T_0]$. Since $B(x,0) \le 0$ and $K(a_{\max}, t) \le 0$, we find

$$\begin{aligned}
e^{\lambda t}\int_{x_{\min}}^{x_{\max}} B(x,t)\chi(x)dx \le{}& \int_0^t \int_{x_{\min}}^{x_{\max}} e^{\lambda\tau}[\lambda - \mu(x,\tau,\overline{\varphi}(\tau))]B(x,\tau)\zeta(x,\tau)dxd\tau\\
&+\int_0^t \int_{x_{\min}}^{x_{\max}} e^{\lambda\tau}\zeta(x,\tau)C_1(x,\tau)\int_{x_{\min}}^{x_{\max}} B(y,\tau)dydxd\tau.
\end{aligned} \tag{3.14}$$

Therefore, we have

$$\int_{x_{\min}}^{x_{\max}} B(x,t)\chi(x)dx \le c_1 \int_0^t \int_{x_{\min}}^{x_{\max}} B^+(x,\tau)dxd\tau, \tag{3.15}$$

where

$$c_1 = \sup_{(x,t)\in[x_{\min},x_{\max}]\times[0,T_0]} \left[\lambda - \mu(x,t,\overline{\varphi}(t)) + \int_{x_{\min}}^{x_{\max}} C_1(x,t)dx\right]$$

and $B^+(x,t) = \max\{0, B(x,t)\}$.

Since this inequality holds for every χ, we can now choose a sequence $\{\chi_n\}$ on $(x_{\min}, x_{\max})$ converging a.e. to

$$\chi(x) = \begin{cases} 1 & \text{if } B(x,t) > 0,\\ 0 & \text{otherwise.}\end{cases}$$

Consequently, we find

$$\int_{x_{\min}}^{x_{\max}} B^+(x,t)dx \le c_1 \int_0^t \int_{x_{\min}}^{x_{\max}} B^+(x,\tau)dxd\tau,$$

which by Gronwall's inequality leads to

$$\int_{x_{\min}}^{x_{\max}} B^+(x,t)dx = 0,$$

i.e., $B(x,t) \le 0$. Then it follows from (3.7) that for $t > a$

$$\begin{aligned}
K(a,t) \le{}& \int_{x_{\min}}^{x_{\max}} \beta(x, t-a, \overline{\varphi}(t-a))B(x,t-a)dx \exp\left(-\int_{t-a}^t \nu(a-t+\tau,\tau)d\tau\right)\\
&-\int_{x_{\min}}^{x_{\max}} D(x,t-a)\int_{x_{\min}}^{x_{\max}} B(y,t-a)dydx \exp\left(-\int_{t-a}^t \nu(a-t+\tau,\tau)d\tau\right)\\
\le{}& 0,
\end{aligned} \tag{3.16}$$

where $D(x,t) = \overline{A}(x,t)\beta_\varphi(x,t,\theta_2(t))$ with $\theta_2(t)$ between $\overline{\varphi}(t)$ and $\underline{\varphi}(t)$. This completes the proof. □

Based on the definition (3.2)–(3.5), we can also establish the following uniqueness result.

THEOREM 3.5. *Let* $(J(a,t), A(x,t))$ *be a nonnegative solution of problem* (2.1) *for* $0 \le t \le T_0$. *Then* (J, A) *is unique.*

Proof. Suppose that $(J_1(a,t), A_1(x,t))$ and $(J_2(a,t), A_2(x,t))$ are two nonnegative solutions of (2.1). Clearly, $J_1(a,t) = J_2(a,t)$ for $t \le a$. By (3.4) we have

$$A_1(x,t) - A_2(x,t) = A_0(X(0;x,t)) \exp\left(-\int_0^t g_x(X(\tau;x,t),\tau)d\tau - \theta_3(x,t)\right) \times \int_0^t C_2(x,\tau)\int_{x_{\min}}^{x_{\max}} [A_1(x,\tau) - A_2(x,\tau)]dxd\tau,$$

where $\theta_3(x,t)$ is between $\int_0^t \mu(X(\tau;x,t),\tau,\varphi_1(\tau))d\tau$ and $\int_0^t \mu(X(\tau;x,t),\tau,\varphi_2(\tau))d\tau$ with $\varphi_1(\tau) = \int_{x_{\min}}^{x_{\max}} A_1(x,\tau)dx$ and $\varphi_2(\tau) = \int_{x_{\min}}^{x_{\max}} A_2(x,\tau)dx$, and $C_2(x,\tau) = \mu_\varphi(X(\tau;x,t),\tau,\theta_4(\tau))$ with $\theta_4(\tau)$ between $\varphi_1(\tau)$ and $\varphi_2(\tau)$. Thus, for $t \le G(x)$

$$|A_1(x,t) - A_2(x,t)| \le c_2 \int_0^t \int_{x_{\min}}^{x_{\max}} |A_1(x,\tau) - A_2(x,\tau)|dxd\tau. \tag{3.17}$$

On the other hand, since $J_1(a_{\max}, \Gamma(x_{\min};x,t)) = J_2(a_{\max}, \Gamma(x_{\min};x,t))$, by (3.5) we have

$$\begin{aligned} &A_1(x,t) - A_2(x,t) \\ &\quad = \frac{J(a_{\max},\Gamma(x_{\min};x,t))}{g(x_{\min},\Gamma(x_{\min};x,t))} \exp\left(-\int_{\Gamma(x_{\min};x,t)}^t g_x(X(\tau;x,t),\tau)d\tau - \theta_5(x,t)\right) \\ &\qquad \times \int_{\Gamma(x_{\min};x,t)}^t C_3(x,\tau)\int_{x_{\min}}^{x_{\max}} [A_1(x,\tau) - A_2(x,\tau)]dxd\tau, \end{aligned}$$

where $\theta_5(x,t)$ is between $\int_{\Gamma(x_{\min};x,t)}^t \mu(X(\tau;x,t),\tau,\varphi_1(\tau))d\tau$ and $\int_{\Gamma(x_{\min};x,t)}^t \mu(X(\tau;x,t),\tau,\varphi_2(\tau))d\tau$, and $C_3(x,\tau) = \mu_\varphi(X(\tau;x,t),\tau,\theta_6(\tau))$ with $\theta_6(\tau)$ between $\varphi_1(\tau)$ and $\varphi_2(\tau)$. Thus, for $t > G(x)$

$$\begin{aligned} |A_1(x,t) - A_2(x,t)| &\le c_3 \int_{\Gamma(x_{\min};x,t)}^t \int_{x_{\min}}^{x_{\max}} |A_1(x,\tau) - A_2(x,\tau)|dxd\tau \\ &\le c_3 \int_0^t \int_{x_{\min}}^{x_{\max}} |A_1(x,\tau) - A_2(x,\tau)|dxd\tau. \end{aligned} \tag{3.18}$$

A combination of (3.16) and (3.17) then yields that for any $(x,t) \in [x_{\min}, x_{\max}] \times [0, T_0]$

$$|A_1(x,t) - A_2(x,t)| \le c_4 \int_0^t \int_{x_{\min}}^{x_{\max}} |A_1(x,\tau) - A_2(x,\tau)|dxd\tau. \tag{3.19}$$

Integration of (3.19) over $(x_{\min}, x_{\max})$ gives

$$\int_{x_{\min}}^{x_{\max}} |A_1(x,t) - A_2(x,t)|dx \le c_4(x_{\max} - x_{\min}) \int_0^t \int_{x_{\min}}^{x_{\max}} |A_1(x,\tau) - A_2(x,\tau)|dxd\tau,$$

which by Gronwall's inequality implies

$$\int_{x_{\min}}^{x_{\max}} |A_1(x,t) - A_2(x,t)| dx = 0.$$

Thus, by (3.19) we have $A_1(x,t) = A_2(x,t)$ for $(x,t) \in [x_{\min}, x_{\max}] \times [0, T_0]$. Consequently, taking note of (3.3), $J_1(a,t) = J_2(a,t)$ for $a < t \le T_0$. □

4. Monotone sequences and existence of the solution. We begin with the introduction of a pair of nonnegative lower and upper solutions of problem (2.1). Let $\underline{J}^0(a,t) = 0$ and $\underline{A}^0(x,t) = 0$. For $0 \le t \le T_0$ $(\equiv a_{\max})$, we set

$$\begin{aligned}
&\overline{J}^0_t(a,t) + \overline{J}^0_a(a,t) + \nu(a,t)\overline{J}^0(a,t) = 0, && 0 < a < a_{\max}, && 0 < t < T_0,\\
&\overline{A}^0_t(x,t) + (g(x,t)\overline{A}^0(x,t))_x + \mu(x,t,0)\overline{A}^0(x,t) = 0, && x_{\min} < x < x_{\max}, && 0 < t < T_0,\\
&\overline{J}^0(0,t) = \int_{x_{\min}}^{x_{\max}} \beta(x,t,0)\overline{A}^0(x,t)dx, && && 0 < t < T_0,\\
&g(x_{\min},t)\overline{A}^0(x_{\min},t) = \overline{J}^0(a_{\max},t), && && 0 < t < T_0,\\
&\overline{J}^0(a,0) = J_0(a), && 0 \le a \le a_{\max}, &&\\
&\overline{A}^0(x,0) = A_0(x), && x_{\min} \le x \le x_{\max}. &&
\end{aligned} \tag{4.1}$$

Clearly, by the method of characteristics, $\overline{J}^0$ and $\overline{A}^0$ satisfy

$$\overline{J}^0(a,t) = J_0(a-t)\exp\left(-\int_0^t \nu(a-t+\tau,\tau)d\tau\right) \qquad \text{if } t \le a, \tag{4.2}$$

$$\overline{J}^0(a,t) = \int_{x_{\min}}^{x_{\max}} \beta(x,t-a,0)\overline{A}^0(x,t-a)dx \exp\left(-\int_{t-a}^t \nu(a-t+\tau,\tau)d\tau\right) \qquad \text{if } t > a, \tag{4.3}$$

$$\overline{A}^0(x,t) = A_0(X(0;x,t))\exp\left\{-\int_0^t [g_x(X(\tau;x,t),\tau) + \mu(X(\tau;x,t),\tau,0)]d\tau\right\} \qquad \text{if } t \le G(x), \tag{4.4}$$

$$\begin{aligned}\overline{A}^0(x,t) &= \frac{\overline{J}^0(a_{\max},\Gamma(x_{\min};x,t))}{g(x_{\min},\Gamma(x_{\min};x,t))}\exp\left\{-\int_{\Gamma(x_{\min};x,t)}^t [g_x(X(\tau;x,t),\tau) + \mu(X(\tau;x,t),\tau,0)]d\tau\right\}\\ &\qquad \text{if } t > G(x).\end{aligned} \tag{4.5}$$

The above representations are uncoupled, since $\overline{A}^0(x,t)$ in (4.5) is constructed from $\overline{J}^0(a,t)$ in (4.2), and then $\overline{J}^0(a,t)$ in (4.3) is obtained from (4.4) and (4.5). Therefore,

$\overline{A}^0$ satisfies

$$\begin{aligned}\int_{x_{\min}}^{x_{\max}}\overline{A}^0(x,t)\xi(x,t)dx &= \int_{x_{\min}}^{x_{\max}}\overline{A}^0(x,0)\xi(x,0)dx + \int_0^t \overline{J}^0(a_{\max},\tau)\xi(x_{\min},\tau)d\tau \\ &\quad + \int_0^t\int_{x_{\min}}^{x_{\max}}[\xi_\tau(x,\tau)+g(x,\tau)\xi_x(x,\tau)]\overline{A}^0(x,\tau)dxd\tau \\ &\quad - \int_0^t\int_{x_{\min}}^{x_{\max}}\mu(x,\tau,0)\overline{A}^0(x,\tau)\xi(x,\tau)dxd\tau\end{aligned}$$

for each $t\in(0,T)$ and every $\xi\in C^1([x_{\min},x_{\max}]\times[0,T])$, since $\overline{J}^0(a_{\max},t)$ is explicitly obtained from (4.2) (cf. [8]).

Thus, it easily follows that $(\underline{J}^0,\underline{A}^0)$ and $(\overline{J}^0,\overline{A}^0)$ are a pair of lower and upper solutions of (2.1) for $0\le t\le T_0$.

We then define two sequences $\{\underline{J}^k,\underline{A}^k\}_{k=0}^\infty$ and $\{\overline{J}^k,\overline{A}^k\}_{k=0}^\infty$ as follows: For $k=1,2,\ldots,$

$$\begin{aligned}&\underline{J}_t^k(a,t)+\underline{J}_a^k(a,t)+\nu(a,t)\underline{J}^k(a,t)=0, && 0<a<a_{\max}, \quad 0<t<T_0,\\ &\underline{A}_t^k(x,t)+(g(x,t)\underline{A}^k(x,t))_x \\ &\qquad +\mu(x,t,\overline{\varphi}^{k-1}(t))\underline{A}^k(x,t)=0, && x_{\min}<x<x_{\max}, \quad 0<t<T_0,\\ &\underline{J}^k(0,t)=\int_{x_{\min}}^{x_{\max}}\beta(x,t,\overline{\varphi}^{k-1}(t))\underline{A}^k(x,t)dx, && 0<t<T_0,\\ &g(x_{\min},t)\underline{A}^k(x_{\min},t)=\underline{J}^k(a_{\max},t), && 0<t<T_0,\\ &\underline{J}^k(a,0)=J_0(a), && 0\le a\le a_{\max},\\ &\underline{A}^k(x,0)=A_0(x), && x_{\min}\le x\le x_{\max},\end{aligned}\tag{4.6}$$

where $\overline{\varphi}^{k-1}(t)=\int_{x_{\min}}^{x_{\max}}\overline{A}^{k-1}(x,t)dx$ and

$$\begin{aligned}&\overline{J}_t^k(a,t)+\overline{J}_a^k(a,t)+\nu(a,t)\overline{J}^k(a,t)=0, && 0<a<a_{\max}, \quad 0<t<T_0,\\ &\overline{A}_t^k(x,t)+(g(x,t)\overline{A}^k(x,t))_x \\ &\qquad +\mu(x,t,\underline{\varphi}^{k-1}(t))\overline{A}^k(x,t)=0, && x_{\min}<x<x_{\max}, \quad 0<t<T_0,\\ &\overline{J}^k(0,t)=\int_{x_{\min}}^{x_{\max}}\beta(x,t,\underline{\varphi}^{k-1}(t))\overline{A}^k(x,t)dx, && 0<t<T_0,\\ &g(x_{\min},t)\overline{A}^k(x_{\min},t)=\overline{J}^k(a_{\max},t), && 0<t<T_0,\\ &\overline{J}^k(a,0)=J_0(a), && 0\le a\le a_{\max},\\ &\overline{A}^k(x,0)=A_0(x), && x_{\min}\le x\le x_{\max},\end{aligned}\tag{4.7}$$

where $\underline{\varphi}^{k-1}(t)=\int_{x_{\min}}^{x_{\max}}\underline{A}^{k-1}(x,t)dx$. Using the method of characteristics, solutions to the above problems can be found explicitly as follows:

$$\underline{J}^k(a,t)=J_0(a-t)\exp\left(-\int_0^t\nu(a-t+\tau,\tau)d\tau\right) \qquad \text{if } t\le a,\tag{4.8}$$

$$\underline{J}^k(a,t) = \int_{x_{\min}}^{x_{\max}} \beta(x, t-a, \overline{\varphi}^{k-1}(t-a))\underline{A}^k(x,t-a)dx \exp\left(-\int_{t-a}^{t} \nu(a-t+\tau,\tau)d\tau\right) \quad \text{if } t > a, \tag{4.9}$$

$$\underline{A}^k(x,t) = A_0(X(0;x,t)) \exp\left\{-\int_0^t [g_x(X(\tau;x,t),\tau) + \mu(X(\tau;x,t),\tau,\overline{\varphi}^{k-1}(\tau))]d\tau\right\} \quad \text{if } t \le G(x), \tag{4.10}$$

$$\begin{aligned}\underline{A}^k(x,t) = {} & \frac{\underline{J}^k(a_{\max}, \Gamma(x_{\min};x,t))}{g(x_{\min}, \Gamma(x_{\min};x,t))} \\ & \times \exp\left\{-\int_{\Gamma(x_{\min};x,t)}^{t} [g_x(X(\tau;x,t),\tau) + \mu(X(\tau;x,t),\tau,\overline{\varphi}^{k-1}(\tau))]d\tau\right\} \\ & \text{if } t > G(x).\end{aligned} \tag{4.11}$$

And $\underline{A}^k$ also satisfies

$$\begin{aligned}\int_{x_{\min}}^{x_{\max}} \underline{A}^k(x,t)\xi(x,t)dx = {} & \int_{x_{\min}}^{x_{\max}} \underline{A}^k(x,0)\xi(x,0)dx + \int_0^t \underline{J}^k(a_{\max},\tau)\xi(x_{\min},\tau)d\tau \\ & + \int_0^t \int_{x_{\min}}^{x_{\max}} [\xi_\tau(x,\tau) + g(x,\tau)\xi_x(x,\tau)]\underline{A}^k(x,\tau)dxd\tau \\ & - \int_0^t \int_{x_{\min}}^{x_{\max}} \mu(x,\tau,\overline{\varphi}^{k-1}(t))\underline{A}^k(x,\tau)\xi(x,\tau)dxd\tau\end{aligned} \tag{4.12}$$

for each $t \in (0,T)$ and every $\xi \in C^1([x_{\min}, x_{\max}] \times [0,T])$.

A representation similar to (4.8)–(4.12) can be obtained for the solution $(\overline{J}^k, \overline{A}^k)$ by interchanging $\underline{J}^k$ with $\overline{J}^k$, $\underline{A}^k$ with $\overline{A}^k$, and $\overline{\varphi}^{k-1}$ with $\underline{\varphi}^{k-1}$.

Remark 4.1. By discretizing (4.8)–(4.11) and the corresponding equations for $(\overline{J}^k, \overline{A}^k)$, one can derive a numerical scheme for solving problem (2.1).

Clearly, $\underline{J}^0 \le \underline{J}^1$ and $\underline{A}^0 \le \underline{A}^1$. Meanwhile, $\overline{J}^1 = \overline{J}^0$ for $t \le a$, which implies $\overline{A}^1 = \overline{A}^0$. Thus, $\overline{J}^1 = \overline{J}^0$ for $t > a$. Moreover, since $-\mu(x,t,\underline{\varphi}^0(t)) \ge -\mu(x,t,\underline{\varphi}^1(t))$, $\overline{A}^1(x,t)$ satisfies the following: for each $t \in (0,T_0)$ and every nonnegative $\xi \in C^1([x_{\min}, x_{\max}] \times [0,T_0]$,

$$\begin{aligned}\int_{x_{\min}}^{x_{\max}} \overline{A}^1(x,t)\xi(x,t)dx \ge {} & \int_{x_{\min}}^{x_{\max}} \overline{A}^1(x,0)\xi(x,0)dx + \int_0^t \overline{J}^1(a_{\max},\tau)\xi(x_{\min},\tau)d\tau \\ & + \int_0^t \int_{x_{\min}}^{x_{\max}} [\xi_\tau(x,\tau) + g(x,\tau)\xi_x(x,\tau)]\overline{A}^1(x,\tau)dxd\tau \\ & - \int_0^t \int_{x_{\min}}^{x_{\max}} \mu(x,\tau,\underline{\varphi}^1(\tau))\overline{A}^1(x,\tau)\xi(x,\tau)dxd\tau.\end{aligned} \tag{4.13}$$

On the other hand, since $-\mu(x,t,\overline{\varphi}^0(t)) = -\mu(x,t,\overline{\varphi}^1(t))$, $\underline{A}^1(x,t)$ satisfies (4.13) with " $\ge$ " replaced by " $\le$," $\overline{J}^1$ by $\underline{J}^1$, and $\underline{\varphi}^1$ by $\overline{\varphi}^1$. Furthermore, since $\beta(x,t,\underline{\varphi}^0(t)) \ge$

$\beta(x,t,\underline{\varphi}^1(t))$, $\overline{J}^1(a,t)$ satisfies

$$\overline{J}^1(a,t) \geq \int_{x_{\min}}^{x_{\max}} \beta(x,t-a,\underline{\varphi}^1(t-a))\overline{A}^1(x,t-a)dx \exp\left(-\int_{t-a}^{t} \nu(a-t+\tau,\tau)d\tau\right) \quad \text{if } t > a, \tag{4.14}$$

and since $\beta(x,t,\overline{\varphi}^0(t)) = \beta(x,t,\overline{\varphi}^1(t))$, $\underline{J}^1(a,t)$ satisfies (4.14) with " $\geq$ " replaced by " $\leq$," $\overline{A}^1$ by $\underline{A}^1$, and $\overline{\varphi}^1$ by $\underline{\varphi}^1$. Therefore, $(\underline{J}^1, \underline{A}^1)$ and $(\overline{J}^1, \overline{A}^1)$ are a lower solution and an upper solution, respectively, and hence $\underline{J}^1 \leq \overline{J}^1$, $\underline{A}^1 \leq \overline{A}^1$.

Assume that for some $k > 1$, $(\underline{J}^k, \underline{A}^k)$ and $(\overline{J}^k, \overline{A}^k)$ are a lower solution and an upper solution, respectively, of problem (2.1). By similar reasoning, we can show that $\underline{J}^k \leq \underline{J}^{k+1} \leq \overline{J}^{k+1} \leq \overline{J}^k$, $\underline{A}^k \leq \underline{A}^{k+1} \leq \overline{A}^{k+1} \leq \overline{A}^k$, and that $(\underline{J}^{k+1}, \underline{A}^{k+1})$ and $(\overline{J}^{k+1}, \overline{A}^{k+1})$ are also a lower solution and an upper solution, respectively, of (2.1). Thus, by induction, we obtain two monotone sequences that satisfy

$$\begin{aligned} &\underline{J}^0 \leq \underline{J}^1 \leq \cdots \leq \underline{J}^k \leq \overline{J}^k \leq \cdots \leq \overline{J}^1 \leq \overline{J}^0 \qquad && \text{a.e. in } [0,a_{\max}] \times [0,T_0], \\ &\underline{A}^0 \leq \underline{A}^1 \leq \cdots \leq \underline{A}^k \leq \overline{A}^k \leq \cdots \leq \overline{A}^1 \leq \overline{A}^0 \qquad && \text{a.e. in } [x_{\min},x_{\max}] \times [0,T_0] \end{aligned}$$

for each $k = 0,1,2,\ldots$. Hence, it follows from the monotonicity of the sequences $\{\underline{J}^k, \underline{A}^k\}$ and $\{\overline{J}^k, \overline{A}^k\}$ that there exist functions $(\underline{J}, \underline{A})$ and $(\overline{J}, \overline{A})$ such that $\underline{J}^k \to \underline{J}$ and $\overline{J}^k \to \overline{J}$ pointwise in $(0,a_{\max}) \times (0,T_0)$, and $\underline{A}^k \to \underline{A}$ and $\overline{A}^k \to \overline{A}$ pointwise in $(x_{\min},x_{\max}) \times (0,T_0)$. Clearly $\underline{J} \leq \overline{J}$ and $\underline{A} \leq \overline{A}$ a.e.

Upon establishing the monotonicity of our sequences, we can prove the following convergence result.

THEOREM 4.2. *Suppose that* (A1)–(A6) *hold. Then* $\{\underline{J}^k, \underline{A}^k\}_{k=0}^\infty$ *and* $\{\overline{J}^k, \overline{A}^k\}_{k=0}^\infty$ *converge to the unique solution* (J,A) *of problem* (2.1) *in* $L^\infty((0,a_{\max}) \times (0,T_0)) \times L^\infty((x_{\min},x_{\max}) \times (0,T_0))$.

Proof. Since the monotone sequences are bounded by $(\underline{J}^0, \underline{A}^0)$ and $(\overline{J}^0, \overline{A}^0)$, from the pointwise convergence of the sequence, the solution representation for $(\underline{J}^k, \underline{A}^k)$ given in (4.8)–(4.11), and the solution representation for $(\overline{J}^k, \overline{A}^k)$, we find that $\{\underline{J}^k, \underline{A}^k\}_{k=0}^\infty$ converges to $(\underline{J}, \underline{A})$ and $\{\overline{J}^k, \overline{A}^k\}_{k=0}^\infty$ converges to $(\overline{J}, \overline{A})$ monotonically. Here, $(\underline{J}, \underline{A})$ satisfies

$$\underline{J}(a,t) = J_0(a-t)\exp\left(-\int_0^t \nu(a-t+\tau,\tau)d\tau\right) \qquad \text{if } t \leq a, \tag{4.15}$$

$$\underline{J}(a,t) = \int_{x_{\min}}^{x_{\max}} \beta(x,t-a,\overline{\varphi}(t-a))\underline{A}(x,t-a)dx \exp\left(-\int_{t-a}^{t} \nu(a-t+\tau,\tau)d\tau\right) \quad \text{if } t > a, \tag{4.16}$$

$$\underline{A}(x,t) = A_0(X(0;x,t))\exp\left\{-\int_0^t [g_x(X(\tau;x,t),\tau) + \mu(X(\tau;x,t),\tau,\overline{\varphi}(\tau))]d\tau\right\} \quad \text{if } t \leq G(x), \tag{4.17}$$

$$\underline{A}(x,t)$$
$$= \frac{\underline{J}(a_{\max}, \Gamma(x_{\min}; x,t))}{g(x_{\min}, \Gamma(x_{\min}; x,t))} \exp\left\{ -\int_{\Gamma(x_{\min};x,t)}^{t} [g_x(X(\tau; x,t),\tau) + \mu(X(\tau;x,t),\tau,\overline{\varphi}(\tau))]d\tau \right\}$$
$$\text{if } t > G(x), \tag{4.18}$$

and $(\overline{J}, \overline{A})$ satisfies (4.15)–(4.18) by interchanging $\underline{J}$ with $\overline{J}$, $\underline{A}$ with $\overline{A}$, and $\overline{\varphi}$ with $\underline{\varphi}$.

We now show that $(\underline{J}, \underline{A}) = (\overline{J}, \overline{A})$. In view of (4.15)–(4.18), it suffices to show that $\underline{A} = \overline{A}$. To this end, let $B = \overline{A} - \underline{A}$. Since $\overline{A} \geq \underline{A}$, $B(x,t) \geq 0$ and $B(x,0) = 0$. Taking note of the fact that $\underline{J}(a_{\max}, t) = \overline{J}(a_{\max}, t)$ and choosing $\xi(x,t) \equiv 1$, we have that

$$\begin{aligned}\int_{x_{\min}}^{x_{\max}} B(x,t)dx &= -\int_0^t \int_{x_{\min}}^{x_{\max}} \mu(x,\tau,\underline{\varphi}(\tau))B(x,\tau)dxd\tau \\ &\quad + \int_0^t \int_{x_{\min}}^{x_{\max}} C_4(x,\tau) \int_{x_{\min}}^{x_{\max}} B(y,\tau)dydxd\tau \\ &\leq c_5 \int_0^t \int_{x_{\min}}^{x_{\max}} B(x,\tau)dxd\tau,\end{aligned}$$

where $C_4(x,t) = \underline{A}(x,t)\mu_\varphi(x,t,\theta_7(t))$ with $\theta_7(t)$ between $\underline{\varphi}(t)$ and $\overline{\varphi}(t)$, and $c_5 = \sup_{t\in[0,T_0]} \int_{x_{\min}}^{x_{\max}} C_4(x,t)dx$. Thus, it follows from Gronwall's inequality that $B(x,t) = 0$, i.e., $\underline{A} = \overline{A}$. Defining the common limit by (J, A), we find that (J, A) satisfies (3.2)–(3.5).

By subtracting (3.2)–(3.5) from (4.8)–(4.11), respectively, and using the pointwise convergence established above, we can show that $\|\underline{J}^k - J\|_\infty$, $\|\underline{A}^k - A\|_\infty \to 0$ as $k \to \infty$. Similarly, we can show that $\|\overline{J}^k - J\|_\infty$, $\|\overline{A}^k - A\|_\infty \to 0$ as $k \to \infty$. Hence, the proof is complete. □

From the aforementioned process, we also have the following comparison result.

Corollary 4.3. *Suppose that hypotheses* (A1)–(A6) *hold. Furthermore, suppose that* $(\underline{J}, \underline{A})$ *and* $(\overline{J}, \overline{A})$ *are a nonnegative lower solution and a nonnegative upper solution, respectively, of* (2.1). *Then the solution* (J, A) *of* (2.1) *satisfies*

$$\underline{J}(a,t) \leq J(a,t) \leq \overline{J}(a,t) \qquad a.e.\ in\ (0, a_{\max}) \times (0, T_0),$$
$$\underline{A}(x,t) \leq A(x,t) \leq \overline{A}(x,t) \qquad a.e.\ in\ (x_{\min}, x_{\max}) \times (0, T_0).$$

Furthermore, since $T_0 \equiv a_{\max}$, viewing $(J(a, T_0), A(x, T_0))$ as a new initial condition, we can easily extend the above-mentioned arguments to the interval $0 \leq t \leq T$ for any $T > 0$. Thus we have the following global existence result.

Theorem 4.4. *The solution* (J, A) *of problem* (2.1) *exists for* $0 \leq t < \infty$.

Remark 4.5. Corollary 4.3 plays a crucial role in understanding the long-time behavior of the model solution. In particular, if one constructs a suitable upper and/or lower solution, one is able to conclude whether the population goes extinct or survives. An important feature of this comparison approach is that it can handle time-dependent vital rates (see next section).

5. Population extinction and persistence.

In this section we study the long-time behavior of the solution of problem (2.1). In particular, we establish conditions on the parameters in (2.1) under which the population becomes extinct or survives in infinite time. Our asymptotic analysis is different from all other investigations of structured population models and relies on the comparison principle developed here and the construction of suitable pairs of lower and upper solutions. We first present the extinction result. To this end, we impose the following additional assumptions on the parameters:

(A7) There exists a positive constant δ such that

$$\nu(a,t) \geq \delta \quad \text{for } (a,t) \in [0,a_{\max}] \times [0,\infty), \quad g(x_{\min},t) \geq \delta \quad \text{for } t \in [0,\infty),$$

and

$$g_x(x,t) + \mu(x,t,0) \geq \delta \quad \text{for } (x,t) \in [x_{\min},x_{\max}] \times [0,\infty).$$

(A8) $\frac{1}{\inf_{t\in[0,\infty)} g(x_{\min},t)} \exp\big(-\int_0^{a_{\max}} \inf_{t\in[0,\infty)} \nu(q,t)dq\big) < 1$.

(A9) $\int_{x_{\min}}^{x_{\max}} \sup_{t\in[0,\infty)} \beta(x,t,0) \exp\big(-\int_{x_{\min}}^{x} \inf_{t\in[0,\infty)} \big[\frac{g_x(p,t)+\mu(p,t,0)}{g(p,t)}\big]dp\big)dx < 1$.

Remark 5.1. If the parameters are time-independent, then (A8)–(A9) reduce to

$$\frac{1}{g(x_{\min})} \exp\left(-\int_0^{a_{\max}} \nu(q)dq\right) < 1,$$

$$g(x_{\min}) \int_{x_{\min}}^{x_{\max}} \frac{\beta(x,0)}{g(x)} \exp\left(-\int_{x_{\min}}^{x} \frac{\mu(p,0)}{g(p)}dp\right) dx < 1.$$

Clearly, these conditions imply that the inherent net reproduction number of the model (2.1) is

$$R_0 = \exp\left(-\int_0^{a_{\max}} \nu(q)dq\right) \int_{x_{\min}}^{x_{\max}} \frac{\beta(x,0)}{g(x)} \exp\left(-\int_{x_{\min}}^{x} \frac{\mu(p,0)}{g(p)}dp\right) dx < 1. \tag{5.1}$$

THEOREM 5.2. *Suppose that hypotheses* (A7)–(A9) *hold. Then the solution* (J,A) *of problem* (2.1) *tends to zero uniformly in* $(a,x) \in [0,a_{\max}] \times [x_{\min},x_{\max}]$ *as* $t \to \infty$.

Proof. Let $\underline{J}(a,t) = 0$ and $\underline{A}(x,t) = 0$. We then introduce $\overline{J}(a,t) = M\mathcal{J}(a)e^{-\sigma t}$ and $\overline{A}(x,t) = M\mathcal{A}(x)e^{-\sigma t}$, where M,σ are positive constants to be determined, and $\mathcal{J},\mathcal{A}$ are continuously differentiable functions with $\mathcal{J}(0)=1, \mathcal{A}(x_{\min})=1$.

Clearly, $(\underline{J},\underline{A})$ is a lower solution. In order to ensure that $(\overline{J},\overline{A})$ is an upper solution, it suffices to require the following:

$$-\sigma\mathcal{J} + \mathcal{J}' + \nu(a,t)\mathcal{J} \geq 0 \quad \text{for } a \in (0,a_{\max}), \tag{5.2}$$

$$-\sigma\mathcal{A} + g_x(x,t)\mathcal{A} + g(x,t)\mathcal{A}' + \mu(x,t,0)\mathcal{A} \geq 0 \quad \text{for } x \in (x_{\min},x_{\max}), \tag{5.3}$$

$$1 \geq \int_{x_{\min}}^{x_{\max}} \beta(x,t,0)\mathcal{A}(x)dx \quad \text{and} \quad g(x_{\min},t) \geq \mathcal{J}(a_{\max}) \quad \text{for } t \in [0,\infty), \tag{5.4}$$

$$M\mathcal{J}(a) \geq J_0(a) \quad \text{for } a \in [0,a_{\max}] \quad \text{and} \quad M\mathcal{A}(x) \geq A_0(x) \quad \text{for } x \in [x_{\min},x_{\max}]. \tag{5.5}$$

In view of (A7), we choose $\sigma \leq \delta$ and let $\mathcal{J},\mathcal{A}$ satisfy

$$\mathcal{J}' + \left(\inf_{t\in[0,\infty)} \nu(a,t) - \sigma\right)\mathcal{J} = 0 \quad \text{for } a \in (0,a_{\max}),$$

$$\mathcal{A}' + \inf_{t\in[0,\infty)} \left(\frac{g_x(x,t) + \mu(x,t,0) - \sigma}{g(x,t)} \right) \mathcal{A} = 0 \quad \text{for } x \in (x_{\min}, x_{\max}).$$

The solutions of the above equations are given by

$$\mathcal{J}(a) = \exp\left(-\int_0^a \left(\inf_{t\in[0,\infty)} \nu(q,t) - \sigma \right) dq \right),$$

$$\mathcal{A}(x) = \exp\left(-\int_{x_{\min}}^x \inf_{t\in[0,\infty)} \left(\frac{g_x(p,t) + \mu(p,t,0) - \sigma}{g(p,t)} \right) dp \right),$$

and (5.2), (5.3) are valid. By virtue of (A8), we then choose σ so small that (5.4) holds. Finally, we choose M large enough such that

$$M\mathcal{J}(a_{\max}) \geq \sup_{[0,a_{\max}]} J_0(a) \quad \text{and} \quad M\mathcal{A}(x_{\max}) \geq \sup_{[x_{\min},x_{\max}]} A_0(x).$$

Hence, by Corollary 4.3, we have

$$0 \leq \lim_{t\to\infty} J(a,t) \leq \lim_{t\to\infty} M\mathcal{J}(a)e^{-\sigma t} \leq \lim_{t\to\infty} Me^{-\sigma t} = 0$$

and

$$0 \leq \lim_{t\to\infty} A(x,t) \leq \lim_{t\to\infty} M\mathcal{A}(x)e^{-\sigma t} \leq \lim_{t\to\infty} Me^{-\sigma t} = 0. \qquad \square$$

We now present the persistence result. For this purpose, we assume the following condition:

(A10) There exist positive values φ_0 and N such that

$$\sup_{[x_{\min},x_{\max}]\times[0,\infty)\times[\varphi_0,\infty)} [\beta(x,t,\varphi) - \mu(x,t,\varphi)] = -N < 0.$$

We show that the total population of adults is uniformly bounded.

Lemma 5.3. *There exists a positive value φ^* such that $0 \leq \varphi(t) \leq \varphi^*$ for $0 \leq t < \infty$.*

Proof. Let $\psi(t) = \int_0^{a_{\max}} J(a,t)da$. Integrating $(2.1)_1$ and $(2.1)_2$ with respect to a and x, respectively, and making use of $(2.1)_3$ and $(2.1)_4$, we obtain

$$(5.6) \qquad \begin{aligned}(\psi(t) + \varphi(t))' = &\int_{x_{\min}}^{x_{\max}} [\beta(x,t,\varphi(t)) - \mu(x,t,\varphi(t))]A(x,t)dx \\ &-\int_0^{a_{\max}} \nu(a,t)J(a,t)da.\end{aligned}$$

If there is a t_0 such that $\varphi(t_0) > \varphi_0$, then from (5.6) we have

$$\psi'(t_0) + \varphi'(t_0) \leq -N\varphi_0,$$

and it follows that either after a finite time t_1 $\varphi(t) \leq \varphi_0$ or for $t_0 \leq t < \infty$, $\varphi(t) \leq \psi(t_0) + \varphi(t_0)$. $\square$

We then impose the following additional assumptions on the parameters:

(A11) $g_x(x,t) + \mu(x,t,\varphi^*) > 0 \quad$ for $(x,t) \in [x_{\min}, x_{\max}] \times [0,\infty)$.

(A12) $\frac{1}{\sup_{t\in[0,\infty)} g(x_{\min},t)} \exp\big(-\int_0^{a_{\max}} \sup_{t\in[0,\infty)} \nu(q,t)dq\big) \geq 1$.

(A13) $\int_{x_{\min}}^{x_{\max}} \inf_{t\in[0,\infty)} \beta(x,t,\varphi^*) \exp\big(-\int_{x_{\min}}^{x} \sup_{t\in[0,\infty)} \big[\frac{g_x(p,t)+\mu(p,t,\varphi^*)}{g(p,t)}\big] dp\big) dx \geq 1$.

Remark 5.4. If the model parameters do not depend on t, then assumptions (A12)–(A13) imply that $R_0 > 1$ with R_0 given in (5.1).

THEOREM 5.5. *Suppose that hypotheses* (A10)–(A13) *hold and* $J_0(a) > 0$ *for* $a \in [0, a_{\max}]$, $A_0(x) > 0$ *for* $x \in [x_{\min}, x_{\max}]$. *Then the solution of problem* (2.1) *is uniformly persistent.*

Proof. We first introduce two new parameters $\tilde{\mu}(\cdot,\cdot,\varphi), \tilde{\beta}(\cdot,\cdot,\varphi) \in L^\infty((x_{\min}, x_{\max}) \times (0,T))$ that are nonnegative, continuously differentiable in φ, with $\tilde{\mu}_\varphi \geq 0$, $\tilde{\beta}_\varphi \leq 0$, and satisfy for every $(x,t) \in [x_{\min}, x_{\max}] \times [0,\infty)$

$$\tilde{\mu}(x,t,\varphi(t)) = \begin{cases} \mu(x,t,\varphi(t)) & \text{if } \varphi(t) \leq \varphi^* - \varepsilon, \\ \mu(x,t,\varphi^*) & \text{if } \varphi(t) \geq \varphi^* + \varepsilon \end{cases}$$

and

$$\tilde{\beta}(x,t,\varphi(t)) = \begin{cases} \beta(x,t,\varphi(t)) & \text{if } \varphi(t) \leq \varphi^* - \varepsilon, \\ \beta(x,t,\varphi^*) & \text{if } \varphi(t) \geq \varphi^* + \varepsilon, \end{cases}$$

where ε is a small positive constant. Clearly, the solution of (2.1) is the limit (as $\varepsilon \to 0$) to the solution of (2.1*), which is (2.1) with μ and β replaced with $\tilde{\mu}$ and $\tilde{\beta}$, respectively. From now on, we focus on problem (2.1*).

Set $\underline{J}(a,t) = m\mathcal{K}(a)$, $\underline{A}(x,t) = m\mathcal{B}(x)$ and $\overline{J}(a,t) = Me^{-\rho a}e^{\gamma t}$, $\overline{A}(x,t) = Me^{-\eta(x-x_{\min})}e^{\gamma t}$, where m, M, ρ, η, γ are positive constants to be determined and $\mathcal{K}, \mathcal{B}$ are continuously differentiable functions with $\mathcal{K}(0) = 1, \mathcal{B}(x_{\min}) = 1$.

If $\underline{J}, \underline{A}$ and $\overline{J}, \overline{A}$ are coupled lower and upper solutions of (2.1*), they satisfy the following:

$$\mathcal{K}' + \nu(a,t)\mathcal{K} \leq 0 \quad \text{for } a \in (0, a_{\max}), \tag{5.7}$$

$$g_x(x,t)\mathcal{B} + g(x,t)\mathcal{B}' + \tilde{\mu}(x,t,\infty)\mathcal{B} \leq 0 \quad \text{for } (x,t) \in (x_{\min}, x_{\max}) \times (0,\infty), \tag{5.8}$$

$$1 \leq \int_{x_{\min}}^{x_{\max}} \tilde{\beta}(x,t,\infty)\mathcal{B}(x)dx \quad \text{and} \quad g(x_{\min},t) \leq \mathcal{K}(a_{\max}) \quad \text{for } t \in [0,\infty), \tag{5.9}$$

$$m\mathcal{K}(a) \leq J_0(a) \ \text{ for } a \in [0, a_{\max}] \quad \text{and} \quad m\mathcal{B}(x) \leq A_0(x) \ \text{ for } x \in [x_{\min}, x_{\max}], \tag{5.10}$$

$$\gamma - \rho + \nu(a,t) \geq 0 \quad \text{for } (a,t) \in (0, a_{\max}) \times (0,\infty), \tag{5.11}$$

$$\gamma + g_x(x,t) - \eta g(x,t) + \tilde{\mu}(x,t,0) \geq 0 \quad \text{for } (x,t) \in (x_{\min}, x_{\max}) \times (0,\infty), \tag{5.12}$$

$$1 \geq \int_{x_{\min}}^{x_{\max}} \tilde{\beta}(x,t,0)e^{-\eta(x-x_{\min})}dx \quad \text{and} \quad g(x_{\min},t) \geq e^{-\rho a_{\max}} \quad \text{for } t \in [0,\infty), \tag{5.13}$$

$$Me^{-\rho a} \geq J_0(a) \ \text{ for } a \in [0, a_{\max}] \ \text{ and } \ Me^{-\eta(x-x_{\min})} \geq A_0(x) \ \text{ for } x \in [x_{\min}, x_{\max}]. \tag{5.14}$$

We first set up two equations for $\mathcal{K}$ and $\mathcal{B}$, respectively:

$$\mathcal{K}' + \sup_{t\in[0,\infty)} \nu(a,t)\mathcal{K} = 0 \quad \text{for } a \in (0, a_{\max})$$

and

$$\mathcal{B}' + \sup_{t\in[0,\infty)} \left(\frac{g_x(x,t) + \tilde{\mu}(x,t,\infty)}{g(x,t)} \right) \mathcal{B} = 0 \quad \text{for } x \in (x_{\min}, x_{\max}).$$

Solving these equations, we obtain

$$\mathcal{K}(a) = \exp\left(-\int_0^a \sup_{t\in[0,\infty)} \nu(q,t)dq \right),$$

$$\mathcal{B}(x) = \exp\left(-\int_{x_{\min}}^x \sup_{t\in[0,\infty)} \left(\frac{g_x(p,t) + \tilde{\mu}(p,t,\infty)}{g(p,t)} \right) dp \right),$$

and taking (A12), (A13) into account, we find that (5.7)–(5.9) hold. We then choose m small enough such that

$$m \le \inf_{[0,a_{\max}]} J_0(a) \quad \text{and} \quad m \le \inf_{[x_{\min},x_{\max}]} A_0(x).$$

We now turn to $\overline{J}, \overline{A}$. We first choose $\rho = \max\{0, -\ln(\inf_{t\in[0,\infty)} g(x_{\min},t))/a_{\max}\}$ and $\eta = \sup_{[x_{\min},x_{\max}]\times[0,\infty)} \tilde{\beta}(x,t,0)$ such that (5.13) is valid. We then choose γ so large that (5.11) and (5.12) hold. Finally, we choose M large enough such that

$$Me^{-\rho a_{\max}} \ge \sup_{[0,a_{\max}]} J_0(a) \quad \text{and} \quad Me^{-\eta(x_{\max}-x_{\min})} \ge \sup_{[x_{\min},x_{\max}]} A_0(x).$$

Hence, by Corollary 4.3, we have

$$m \exp\left(-\int_0^{a_{\max}} \sup_{t\in[0,\infty)} \nu(q,t)dq \right) \le J(a,t) \quad \text{for } (a,t) \in [0,a_{\max}] \times [0,\infty)$$

and

$$m \exp\left(-\int_{x_{\min}}^{x_{\max}} \sup_{t\in[0,\infty)} \left(\frac{g_x(p,t) + \tilde{\mu}(p,t,\infty)}{g(p,t)} \right) dp \right) \le A(x,t) \quad \text{for } (x,t) \in [x_{\min}, x_{\max}] \times [0,\infty).$$

Since $\lim_{\varepsilon\to 0} \tilde{\mu}(x,t,\varphi) = \mu(x,t,\varphi)$ for $\varphi \le \varphi*$, letting $\varepsilon \to 0$, the proof is now complete. □.

6. Concluding remarks. In this paper we have developed a new method for studying the long-time behavior of a nonautonomous age-size–structured model. The key idea in this method is the establishment of a comparison principle and the construction of a suitable pair of upper and lower solutions. Although comparison principles for local hyperbolic partial differential equations have been known for a long time [24], the first such principle for a nonlocal and linear size-structured model describing the evolution of a single population was developed by the authors in [3] and later extended to a nonlinear size-structured model in [4]. Here, we extend these comparison principles to a nonlinear nonautonomous juvenile-adult model, and, most importantly, we show for the first time that such a method can be used to provide conditions on the vital rates (which are related to the net reproduction number of the model (2.1) that result in population extinction or in uniform persistence of the population).

It is our hope that this method will present another approach for understanding the long-time behavior of such (complex) autonomous or nonautonomous models. Indeed, our current efforts are focused on the careful construction of upper and lower solutions that result in convergence of solutions to an equilibrium for the case of time-independent parameters (autonomous) or even for the case of asymptotically autonomous models [30].

Acknowledgment. The authors thank the referees for their constructive comments and helpful suggestions.

DETECTING INCLUSIONS IN ELECTRICAL IMPEDANCE TOMOGRAPHY WITHOUT REFERENCE MEASUREMENTS*

BASTIAN HARRACH† AND JIN KEUN SEO‡

Abstract. We develop a new variant of the factorization method that can be used to detect inclusions in electrical impedance tomography from either absolute current-to-voltage measurements at a single, nonzero frequency or from frequency-difference measurements. This eliminates the need for numerically simulated reference measurements at an inclusion-free body and thus greatly improves the method's robustness against forward modeling errors, e.g., in the assumed body's shape.

Key words. inverse problems, electrical impedance tomography, complex conductivity, frequency-difference measurements, factorization method

1. Introduction.

In electrical impedance tomography (EIT), we inject a time-harmonic current of I mA at a fixed angular frequency ω into an imaging subject using a pair of surface electrodes attached to its boundary. Then the induced time-harmonic electrical potential is dictated by the complex conductivity distribution σ^ω of the subject, the applied current, and the shape of the subject, where the real and imaginary part of the complex conductivity, $\Re(\sigma^\omega)$ and $\Im(\frac{\sigma^\omega}{\omega})$, are the real conductivity and the permittivity at the angular frequency ω, respectively. In EIT, we use measured boundary voltages generated by multiple injection currents to reconstruct an image of σ^ω inside the subject. It is well known that these boundary measurements are very insensitive and highly nonlinear to any local change of conductivity values away from the measuring points. Hence, the reconstructed image quality in terms of accuracy would be affected sensitively by unavoidable errors including the modeling errors and measurement noises.

Understanding the limited capabilities of static EIT imaging under realistic environments, numerous recent studies in EIT focus on the detection of conductivity anomalies instead of (e.g., cross-sectional) conductivity imaging; cf., e.g., [17, 21, 27, 28, 2, 9, 1, 20, 8, 15], the references therein, and the works connected with the factorization method cited further below.

Let us briefly explain the anomaly detection problem in EIT. Let the imaging object occupy a two- or three-dimensional region B with its smooth boundary ∂B, and let anomalies occupy a region Ω inside a background domain B of constant conductivity. We furthermore assume that the conductivity is isotropic. To distinguish the conductivity of the anomaly Ω and the surrounding homogeneous domain $B \setminus \Omega$, we denote the conductivity distribution at $\omega = 0$ by

$$\sigma(x) = \sigma_0 + \sigma_\Omega(x)\chi_\Omega(x),$$

where χ_Ω is the characteristic function of Ω and σ is a positive and bounded function in B. The inverse problem is to identify Ω from several pairs of Neumann-to-Dirichlet data

$$(g_j, \Lambda(g_j)) \in L^2_\diamond(\partial B) \times L^2_\diamond(\partial B), \quad j = 1, \dots, L,$$

where $L^2_\diamond(\partial B) = \{\phi \in L^2(\partial B) \ : \ \int_{\partial B} \phi \ \mathrm{d}x = 0\}$. Here, $\Lambda(g) = u|_{\partial B}$ and u is the $H^1(B)$-solution for the Neumann boundary value problem:

$$\begin{aligned} \nabla \cdot (\sigma \nabla u) &= 0 \qquad \text{in } B, \\ \sigma \frac{\partial u}{\partial \nu}|_{\partial B} &= g, \qquad \int_{\partial B} u \ \mathrm{d}x = 0, \end{aligned}$$

where ν is the unit outward normal vector to the boundary ∂B.

One of the most successful EIT-methods for locating multiple anomalies would be the factorization method introduced by Kirsch [24] for inverse scattering problems and generalized to EIT-problems by Brühl and Hanke in [5, 4]; see also the recent book of Kirsch and Grinberg [26], the work of Kirsch [25] on the complex conductivity case, and [6, 14, 18, 11, 16, 19, 30, 13, 29] for further extensions of the method in the context of EIT. The factorization method is based on a characterization using the range of the difference between the Neumann-to-Dirichlet (NtD) map in the presence of anomalies and that in the absence of anomalies: $z \in \Omega$ if and only if $\Phi_z|_{\partial B}$ is in the range of the operator $|\Lambda - \Lambda_0|^{1/2}$, where Λ_0 is the NtD map corresponding to the reference homogeneous conductivity $\sigma(x) = \sigma_0$ and $\Phi_z(x)$ is the solution of

$$\Delta_x \Phi_z(x) = d \cdot \nabla_x \delta_z(x) \quad \text{ in } B, \quad \frac{\partial}{\partial \nu}\Phi_z|_{\partial\Omega} = 0, \quad \text{ and } \quad \int_{\partial B} \Phi_z(x) \ \mathrm{d}x = 0,$$

where d is any unit vector and δ_z is the Dirac delta function at z.

For the practical application of the factorization method for static EIT systems, the requirement of the reference NtD data Λ_0 is a drawback. While, in practice, a rough approximation of the NtD map Λ can be obtained from the current-to-voltage data, the corresponding current-to-voltage data for the reference NtD map Λ_0 in the absence of anomalies is usually not available.

Hence, one uses numerically simulated data corresponding to Λ_0 by solving the forward problem $\nabla \cdot (\sigma_0 \nabla u) = 0$ in B with mimicked Neumann data representing the injection current in the EIT system. Noting that the simulated Dirichlet data is mainly depending on the geometry of ∂B and the Neumann data, instead of the conductivity σ_0 (which acts merely as a scaling factor), the requirement of the reference NtD data Λ_0 makes the factorization method very sensitive to forward modeling errors including the boundary geometry error and electrodes position uncertainty (related to the mimicked Neumann data), since its image reconstruction problem is ill-posed. Hence, it is desirable to eliminate the requirement of the reference NtD data Λ_0.

In this work, we adopt the frequency-difference EIT system [31, 32] to obtain a subsidiary NtD data Λ_ω at a fixed angular frequency ω taken from the range of 1kHz $\leq \frac{\omega}{2\pi} \leq$ 500kHz. $\Lambda_\omega(g)$ is the Dirichlet data of the complex potential u_ω which satisfies

$$\nabla \cdot (\sigma^\omega \nabla u_\omega) = 0 \quad \text{ in } B, \quad \sigma^\omega \frac{\partial}{\partial \nu} u_\omega|_{\partial B} = g, \quad \text{ and } \quad \int_{\partial B} u_\omega \ \mathrm{d}x = 0.$$

Our aim is to substitute Λ_ω for Λ_0 in the conventional factorization method and use an interrelation between Λ and Λ_ω to locate the anomalies Ω. However, due to

$\Im\{\sigma^\omega\} \neq 0$, the operator Λ_ω is not self-adjoint and $\Lambda - \Lambda_\omega$ is neither semipositive nor seminegative.

In this work, we show that, for an arbitrary fixed nonzero frequency ω, both, the imaginary part of $\sigma_0^\omega \Lambda_\omega$ and the real part of the normalized difference $\sigma_0 \Lambda - \sigma_0^\omega \Lambda_\omega$ (or actually any other normalized difference of measurements taken at two different frequencies), provide a constructive way of locating Ω, where σ_0^ω is the background complex conductivity at the angular frequency ω. To our knowledge this is the first characterization result that works without reference measurements. We numerically demonstrate that the proposed new variant of the factorization method locates successfully the region Ω with a reasonable accuracy in the presence of boundary geometry errors and measurement noise. We also describe a heuristic approach to estimate an unknown background conductivity from the measured data and numerically test it on a homogeneous, as well as on a slightly inhomogeneous, background.

In section 2 we formulate and prove our main results. In section 3 we test our method numerically, compare its sensitivity to body shape errors with the conventional factorization method, and describe a heuristic approach to estimate an unknown background conductivity. Section 4 contains some concluding remarks.

2. Characterization of an inclusion without reference data.

Let $B \subset \mathbb{R}^n$, $n \geq 2$, be a smoothly bounded domain describing the investigated body. Let $\omega > 0$ be an arbitrary fixed frequency and denote by σ^ω the body's complex conductivity at some fixed nonzero frequency $\omega > 0$. We assume that $\Re(\sigma^\omega) \in L^\infty_+(B;\mathbb{R})$ and $\Im(\sigma^\omega) \in L^\infty(B;\mathbb{R})$, where $\Re(\cdot)$ and $\Im(\cdot)$ denote the real and imaginary part, the subscript "+" indicates functions with positive (essential) infima, and throughout this work all function spaces consist of complex valued functions if not stated otherwise.

A time-harmonic current with (complex) amplitude $g \in L^2_\diamond(\partial B)$ and frequency ω that is applied to the body's surface gives rise to an electric potential $u_\omega \in H^1(B)$ that satisfies

$$\nabla \cdot (\sigma^\omega \nabla u_\omega) = 0 \quad \text{in } B \quad \text{and} \quad \sigma^\omega \partial_\nu u_\omega|_{\partial B} = g, \tag{2.1}$$

where $L^2_\diamond(\partial B)$ is the subspace of $L^2(\partial B)$-functions with vanishing integral mean, ν is the outer normal on ∂B.

It is a well-known consequence of the Lax–Milgram theorem (cf., e.g., [7, Chapter VI, §3, Theorem 7]) that there exists a solution of (2.1) and that this solution is uniquely determined up to addition of a constant function. We denote the quotient space of $H^1(B)$ modulo constant functions by $H^1_\diamond(B)$. The trace operator $v \mapsto v|_{\partial B}$ canonically extends to $H^1_\diamond(B) \to L^2(\partial B)/\mathbb{C}$, where we identify the latter space with $L^2_\diamond(\partial B)$ by appropriately fixing the ground level.

The inverse problem of frequency-dependent EIT is the problem of determining (properties of) σ^ω from measuring one or several pairs of Neumann and Dirichlet boundary values $(u_\omega|_{\partial B}, \sigma^\omega \partial_\nu u_\omega|_{\partial B})$. Mathematically, the knowledge of all such pairs is equivalent to knowing the Neumann-to-Dirichlet operator

$$\Lambda_\omega : L^2_\diamond(\partial B) \to L^2_\diamond(\partial B), \quad g \mapsto u_\omega|_{\partial B},$$

where u_ω solves (2.1). It is easily checked that Λ_ω is linear and compact.

2.1. The main results.

In this work, we assume that the conductivity of the body is constant outside one or several inclusions, i.e.,

$$\sigma^\omega(x) = \sigma_0^\omega + \sigma_\Omega^\omega(x)\chi_\Omega(x),$$

where Ω is some open (possibly disconnected) set with smooth boundary and connected complement, $\overline{\Omega} \subset B$, and $\sigma_0^\omega \in \mathbb{C}$, $\sigma_\Omega^\omega \in L^\infty(\Omega)$ are such that $\Re(\sigma^\omega) \in L_+^\infty(B;\mathbb{R})$.

We will show that the inclusion Ω can be determined from the Neumann-to-Dirichlet operator Λ_ω using the same singular dipole potentials that were introduced for the factorization method by Brühl and Hanke in [5, 4]. For an arbitrary direction $d \in \mathbb{R}^n$, $|d| = 1$, and every point $z \in B$, let Φ_z be the solution of

$$\Delta_x \Phi_z(x) = d \cdot \nabla_x \delta_z(x) \quad \text{in } B$$

with homogeneous Neumann boundary values $\partial_\nu \Phi_z(x)|_{\partial B} = 0$ and vanishing integral mean on ∂B.

THEOREM 2.1. *Assume that either*

$$\Im\left(\frac{\sigma_\Omega^\omega}{\sigma_0^\omega}\right) \in L_+^\infty(\Omega;\mathbb{R}) \quad \textit{or} \quad -\Im\left(\frac{\sigma_\Omega^\omega}{\sigma_0^\omega}\right) \in L_+^\infty(\Omega;\mathbb{R}). \tag{2.2}$$

Then

$$z \in \Omega \quad \textit{if and only if} \quad \Phi_z|_{\partial B} \in \mathcal{R}\left(\left|\Im\left(\sigma_0^\omega \Lambda_\omega\right)\right|^{1/2}\right),$$

where the imaginary part of a bounded linear operator $A \in \mathcal{L}(H)$ on a complex Hilbert space H is defined by $\Im(A) := \frac{1}{2\mathrm{i}}(A - A^*)$, and $\mathcal{R}(A)$ denotes the range of A.

We also show a complementary result for the real part of frequency-difference data. Let $0 \leq \tau \neq \omega$ be another fixed frequency (possibly being zero) for which the body's complex conductivity is σ^τ, with $\Re(\sigma^\tau) \in L_+^\infty(B;\mathbb{R})$. We assume that σ^τ is also constant outside the same inclusion Ω, i.e., $\sigma^\tau = \sigma_0^\tau + \sigma_\Omega^\tau(x)\chi_\Omega(x)$ with $\sigma_0^\tau \in \mathbb{C}$. Measurements at the frequency τ are described by the NtD operator Λ_τ which is defined analogously to Λ_ω.

THEOREM 2.2. *If either*

$$\Re\left(\tfrac{\sigma_\Omega^\tau}{\sigma_0^\tau}\right) - \Re\left(\tfrac{\sigma_\Omega^\omega}{\sigma_0^\omega}\right) - \frac{\Im\left(\frac{\sigma_\Omega^\omega}{\sigma_0^\omega}\right)^2}{\Re\left(\frac{\sigma^\omega}{\sigma_0^\omega}\right)} \in L_+^\infty(\Omega;\mathbb{R}), \tag{2.3}$$

or

$$\Re\left(\tfrac{\sigma_\Omega^\omega}{\sigma_0^\omega}\right) - \Re\left(\tfrac{\sigma_\Omega^\tau}{\sigma_0^\tau}\right) - \frac{\Im\left(\frac{\sigma_\Omega^\tau}{\sigma_0^\tau}\right)^2}{\Re\left(\frac{\sigma^\tau}{\sigma_0^\tau}\right)} \in L_+^\infty(\Omega;\mathbb{R}), \tag{2.4}$$

then

$$z \in \Omega \quad \textit{if and only if} \quad \Phi_z|_{\partial B} \in \mathcal{R}\left(\left|\Re\left(\sigma_0^\omega \Lambda_\omega - \sigma_0^\tau \Lambda_\tau\right)\right|^{1/2}\right),$$

where the real part of a bounded linear operator $A \in \mathcal{L}(H)$ on a complex Hilbert space H is defined by $\Re(A) := \frac{1}{2}(A + A^*)$.

Before we prove these two theorems in the next subsection, let us comment on their relevance. In contrast to the conventional factorization method where the measured NtD data is compared to reference data that is usually not available by experiment (with the disadvantages described in the introduction), both theorems use only experimentally available NtD measurements. Our theorems require NtD data either at just one (nonzero) frequency, which is then compared to its own adjoint (Theorem 2.1) or NtD data measured at two different frequencies (possibly one being zero), which are then compared to each other (Theorem 2.2). In particular, this means that we can replace unavailable reference measurements in the conventional factorization methods by experimentally available measurements at an arbitrary nonzero frequency, which strongly reduces the methods sensitivity to boundary geometry errors as we will demonstrate numerically in section 3. In practice, one may have access to measurements at more than two frequencies. This redundancy can surely be used to further increase the performance or robustness of our method, but we have not studied this question in detail.

The assumptions (2.2)–(2.4) are arguably not very intuitive. For the practically relevant model case that the real conductivity $\kappa = \Re(\sigma^\omega)$ and the permittivity $\epsilon = \Im(\frac{\sigma^\omega}{\omega})$ are not frequency-dependent, they can be restated as follows.

Remark 2.3. Let

$$\sigma^\tau(x) = \kappa(x) + \mathrm{i}\tau\epsilon(\mathrm{x}), \qquad \kappa(x) = \kappa_0 + \kappa_\Omega(x)\chi_\Omega(x),$$

$$\sigma^\omega(x) = \kappa(x) + \mathrm{i}\omega\epsilon(\mathrm{x}), \qquad \epsilon(x) = \epsilon_0 + \epsilon_\Omega(x)\chi_\Omega(x),$$

with $\kappa_0, \epsilon_0 \in \mathbb{R}$, $\kappa_\Omega, \epsilon_\Omega \in L^\infty(\Omega;\mathbb{R})$. Then

$$\Im\left(\frac{\sigma_\Omega^\omega}{\sigma_0^\omega}\right) = \frac{\omega}{\kappa_0^2 + \omega^2\epsilon_0^2}(\kappa_0\epsilon_\Omega - \kappa_\Omega\epsilon_0),$$

$$\Re\left(\frac{\sigma_\Omega^\tau}{\sigma_0^\tau}\right) - \Re\left(\frac{\sigma_\Omega^\omega}{\sigma_0^\omega}\right) - \frac{\Im\left(\frac{\sigma_\Omega^\omega}{\sigma_0^\omega}\right)^2}{\Re\left(\frac{\sigma^\omega}{\sigma_0^\omega}\right)} = \frac{(\kappa_0\epsilon_\Omega - \kappa_\Omega\epsilon_0)(\tau^2\kappa\epsilon_0 - \omega^2\kappa_0\epsilon)}{(\kappa_0^2 + \tau^2\epsilon_0^2)(\kappa_0\kappa + \omega^2\epsilon_0\epsilon)},$$

and the same identities hold with ω and τ interchanged. Hence, (2.2) is equivalent to

$$\kappa_0\epsilon_\Omega - \kappa_\Omega\epsilon_0 \in L_+^\infty(\Omega;\mathbb{R}) \quad \text{or} \quad \kappa_\Omega\epsilon_0 - \kappa_0\epsilon_\Omega \in L_+^\infty(\Omega;\mathbb{R}). \tag{2.5}$$

If ω is sufficiently larger than τ, then (2.5) is also equivalent to the disjunction of (2.3) and (2.4). For $\tau = 0$, every $\omega > 0$ is sufficiently large.

In particular, our method can identify inclusions where only the real conductivity or only the permittivity differs from the background, and this deviance is of the same sign in all inclusions. However, there exist combinations where a jump κ_Ω in the real conductivity and a jump ϵ_Ω in the permittivity cancel each other out, in the sense that

$$\kappa_0\epsilon_\Omega - \kappa_\Omega\epsilon_0 = 0.$$

Inclusions with this property cannot be detected by our method. In fact, they are completely invisible to weighted frequency-difference measurements, as one easily checks that in this case

$$\Im\left(\sigma_0^\omega\Lambda_\omega\right) = 0 \quad \text{and} \quad \Re\left(\sigma_0^\omega\Lambda_\omega - \sigma_0^\tau\Lambda_\tau\right) = 0.$$

There is also another drawback in our method compared to the original factorization method. The original method also works in the case of an inhomogeneous (but known) background medium, which only requires the replacement of the singular dipole potentials Φ_z by the corresponding dipole potentials in the inhomogeneous background. For our method this is not sufficient, since we also need the constant background conductivities to form the weighted differences of the NtD data. Hence, up to now, our method can only be applied to a homogeneous (constant) background medium. We believe, however, that our results cover the most relevant case in practice, where no accurate information about the background is available (except of being "almost constant"), and we describe in subsection 3.3 a heuristic approach how even an unknown background value can be estimated from the measured data. Our numerical results indicate that this approach still yields reasonable results if the unknown background is slightly inhomogeneous.

2.2. Proof of the main results. We start with some notations. The inner product on a complex Hilbert space H is denoted by $(\cdot,\cdot)$ and the pairing on H and its antidual H' is denoted by $\langle\cdot,\cdot\rangle_{H'\times H}$. Both are ordered in the way that they are linear in the first and antilinear in their second argument. For an operator $A\in\mathcal{L}(H_1,H_2)$ acting between Hilbert spaces H_1 and H_2, we rigorously distinguish between the dual operator $A'\in\mathcal{L}(H_2',H_1')$ and the adjoint operator $A^*\in\mathcal{L}(H_2,H_1)$.

Analogously to the definition of $H^1_\diamond(B)$, we denote by $H^1_\diamond(B\setminus\overline{\Omega})$, $H^1_\diamond(\Omega)$, and $H^{1/2}_\diamond(\partial\Omega)$ the quotient spaces of $H^1(B\setminus\overline{\Omega})$, $H^1(\Omega)$, and of the the trace space $H^{1/2}(\partial\Omega)$ modulo locally constant functions. (Thus, for disconnected Ω a multidimensional space is factored out.) The antidual of $H^{1/2}_\diamond(\partial\Omega)$ is denoted by $H^{-1/2}_\diamond(\partial\Omega)$, and we identify $L^2_\diamond(\partial B)$ with its antidual.

We will prove both results using a factorization of the difference of $\sigma_0^\omega\Lambda_\omega$ and the reference NtD operator Λ_0 corresponding to a constant conductivity equal to one, i.e.,

$$\Lambda_0:\ L^2_\diamond(\partial B)\to L^2_\diamond(\partial B),\quad g\mapsto u_0|_{\partial B},$$

where u solves

$$\Delta u_0=0\quad\text{ in } B\quad\text{ and }\quad \partial_\nu u_0|_{\partial B}=g.$$

It is well known and easily checked that Λ_0 is linear, compact, and self-adjoint. Let us stress again that we only require measurements at one arbitrary fixed frequency $\omega>0$ (for Theorem 2.1), or at two arbitrary, but different, fixed frequencies $\omega>0$, $\tau\geq 0$ (for Theorem 2.2). Λ_0 merely serves as an auxiliary operator that will cancel out later in our proof. Unlike other applications of the factorization method, Λ_0 does not have to correspond to real measurements.

For the factorization we also introduce the operator

$$L:\ H^{-1/2}_\diamond(\partial\Omega)\to L^2_\diamond(\partial B),\quad \psi\mapsto w|_{\partial B},$$

where $w\in H^1_\diamond(B\setminus\overline{\Omega})$ solves

$$\Delta w=0,\qquad \partial_\nu w|_{\partial B}=0,\qquad \partial_\nu w^+|_{\partial\Omega}=-\psi,$$

with ν being the normal on $\partial\Omega$ oriented into $B\setminus\overline{\Omega}$ and we denote by the superscripts "+", resp., "−" that the trace is taken from $B\setminus\overline{\Omega}$ and Ω, respectively. We also define

$$F_0:\ H^{1/2}_\diamond(\partial\Omega)\to H^{-1/2}_\diamond(\partial\Omega),\qquad F_0\phi=\partial_\nu v_0^+|_{\partial\Omega},$$

$$F_\omega:\ H^{1/2}_\diamond(\partial\Omega)\to H^{-1/2}_\diamond(\partial\Omega),\qquad F_\omega\phi=\partial_\nu v_\omega^+|_{\partial\Omega},$$

where $v_0, v_\omega \in H^1_\diamond(B \setminus \partial\Omega)$ solve

$$\begin{aligned} \Delta v_0 &= 0 \quad \text{in } B \setminus \partial\Omega, & \nabla \cdot \frac{\sigma^\omega}{\sigma_0^\omega} \nabla v_\omega &= 0 \quad \text{in } B \setminus \partial\Omega, \\ \partial_\nu v_0|_{\partial B} &= 0, & \partial_\nu v_\omega|_{\partial B} &= 0, \\ [v_0]_{\partial\Omega} &= \phi, & [v_\omega]_{\partial\Omega} &= \phi, \\ [\partial_\nu v_0]_{\partial\Omega} &= 0, & \left[\frac{\sigma^\omega}{\sigma_0^\omega} \partial_\nu v_\omega\right]_{\partial\Omega} &= 0, \end{aligned}$$

with $[\cdot]$ denoting the difference of the trace taken from $B \setminus \overline{\Omega}$ minus the trace taken from Ω. (Note that one easily checks that F_0 and F_ω are indeed well defined on these spaces.)

For the case of frequency-difference data, we also define F_τ analogously to F_ω. For the sake of readability we formulate the next two lemmas only for the frequency ω, though they just as well hold for τ.

LEMMA 2.4. *The difference of the Neumann-to-Dirichlet operators can be factorized into*

$$\Lambda_0 - \sigma_0^\omega \Lambda_\omega = L(F_0 - F_\omega)L'.$$

Proof. We proceed similarly to [10]. For given $g \in H_\diamond^{-\frac{1}{2}}(\partial B)$ let $\tilde{w} \in H^1_\diamond(B \setminus \overline{\Omega})$ solve

$$\Delta \tilde{w} = 0 \quad \text{in } B \setminus \overline{\Omega} \quad \text{and} \quad \partial_\nu \tilde{w} = \begin{cases} 0 & \text{on } \partial\Omega, \\ g & \text{on } \partial B. \end{cases}$$

Let $\psi \in H_\diamond^{-\frac{1}{2}}(\partial\Omega)$ and $w \in H^1_\diamond(B \setminus \overline{\Omega})$ be the function from the definition of $L\psi$. Then

$$\begin{aligned} \langle \psi, L'g \rangle = \overline{\langle g, L\psi \rangle} = \overline{\langle \partial_\nu \tilde{w}|_{\partial B}, w|_{\partial B} \rangle} = \int_{B \setminus \overline{\Omega}} \overline{\nabla \tilde{w}} \cdot \nabla w \, \mathrm{d}x = \left\langle -\partial_\nu w^+|_{\partial\Omega}, \tilde{w}^+|_{\partial\Omega} \right\rangle \\ = \left\langle \psi, \tilde{w}^+|_{\partial\Omega} \right\rangle, \end{aligned}$$

and thus $L'g = \tilde{w}^+|_{\partial\Omega}$.

Now let $v_0, v_\omega \in H^1_\diamond(B \setminus \partial\Omega)$ be the solutions from the definition of $F_0 \tilde{w}^+|_{\partial\Omega}$, resp., $F_\omega \tilde{w}^+|_{\partial\Omega}$. We define $u_0, u_\omega \in H^1_\diamond(B \setminus \partial\Omega)$ by setting $u_0 = -v_0$, resp., $u_\omega = -v_\omega$ on Ω and $u_0 = \tilde{w} - v_0$, resp., $u_\omega = \tilde{w} - v_\omega$ on $B \setminus \overline{\Omega}$. Then $u_0, \frac{1}{\sigma_0^\omega} u_\omega \in H^1_\diamond(B)$ and they solve the equations in the definitions of $\Lambda_0 g$ and $\Lambda_\omega g$. Thus,

$$(\Lambda_0 - \sigma_0^\omega \Lambda_\omega) g = (u_0 - u_\omega)|_{\partial B} = -(v_0 - v_\omega)|_{\partial B}.$$

Since $\Delta(v_0 - v_\omega) = 0$ in $B \setminus \overline{\Omega}$ and $\partial_\nu (v_0 - v_\omega)|_{\partial B} = 0$, we also have

$$L(\partial_\nu (v_0^+ - v_\omega^+)|_{\partial\Omega}) = -(v_0 - v_\omega)|_{\partial B},$$

and thus

$$(\Lambda_0 - \sigma_0^\omega \Lambda_\omega) g = L(\partial_\nu (v_0^+ - v_\omega^+)|_{\partial\Omega}) = L(F_0 - F_\omega) \tilde{w}^+|_{\partial\Omega} = L(F_0 - F_\omega) L' g. \qquad \square$$

Lemma 2.5. *For given $\phi \in H_\diamond^{1/2}(\partial\Omega)$ let $v_0, v_\omega \in H_\diamond^1(B \setminus \partial\Omega)$ be the solutions in the definition of F_0, F_ω and let $v_\phi \in H^1(B \setminus \partial\Omega)$ be such that $v_\phi^+|_{\partial\Omega} = \phi$ and $v_\phi|_\Omega = 0$. Set $\tilde{v}_0 := v_0 - v_\phi$ and $\tilde{v}_\omega := v_\omega - v_\phi$. Then*

$$\langle (F_0 - F_\omega)\phi, \phi\rangle = \int_B |\nabla \tilde{v}_0|^2 \, \mathrm{d}x - \int_B \frac{\overline{\sigma^\omega}}{\overline{\sigma_0^\omega}} |\nabla \tilde{v}_\omega|^2 \, \mathrm{d}x.$$

Furthermore, there exists a constant $c_\omega > 0$ such that

$$\int_\Omega |\nabla \tilde{v}_\omega|^2 \, \mathrm{d}x = \int_\Omega |\nabla v_\omega|^2 \, \mathrm{d}x \geq c_\omega \|\phi\|^2 \quad \textit{for all } \phi \in H_\diamond^{1/2}(\partial\Omega).$$

Proof. One easily checks that the functions $\tilde{v}_0, \tilde{v}_\omega \in H_\diamond^1(B)$ solve

$$\int_B \nabla \tilde{v}_0 \cdot \overline{\nabla w} \, \mathrm{d}x = -\int_{B\setminus\Omega} \nabla v_\phi \cdot \overline{\nabla w} \, \mathrm{d}x, \tag{2.6}$$

$$\int_B \frac{\sigma^\omega}{\sigma_0^\omega} \nabla \tilde{v}_\omega \cdot \overline{\nabla w} \, \mathrm{d}x = -\int_{B\setminus\Omega} \nabla v_\phi \cdot \overline{\nabla w} \, \mathrm{d}x \tag{2.7}$$

for all $w \in H_\diamond^1(B)$. Thus, we obtain

$$\begin{aligned}
\langle (F_0 - F_\omega)\phi, \phi\rangle &= \left\langle \partial_\nu v_0^+|_{\partial\Omega}, \phi \right\rangle - \left\langle \partial_\nu v_\omega^+|_{\partial\Omega}, \phi \right\rangle \\
&= \int_{B\setminus\overline{\Omega}} \nabla v_\omega \cdot \overline{\nabla v_\phi} \, \mathrm{d}x - \int_{B\setminus\overline{\Omega}} \nabla v_0 \cdot \overline{\nabla v_\phi} \, \mathrm{d}x \\
&= \int_{B\setminus\overline{\Omega}} \nabla \tilde{v}_\omega \cdot \overline{\nabla v_\phi} \, \mathrm{d}x - \int_{B\setminus\overline{\Omega}} \nabla \tilde{v}_0 \cdot \overline{\nabla v_\phi} \, \mathrm{d}x \\
&= \int_B |\nabla \tilde{v}_0|^2 \, \mathrm{d}x - \int_B \overline{\left(\frac{\sigma^\omega}{\sigma_0^\omega}\right)} |\nabla \tilde{v}_\omega|^2 \, \mathrm{d}x.
\end{aligned}$$

To prove the second assertion we first note that the Neumann boundary values

$$F_\omega \phi = \partial_\nu v_\omega^+|_{\partial\Omega} = \frac{\sigma^\omega}{\sigma_0^\omega} \partial_\nu v_\omega^-|_{\partial\Omega}$$

depend continuously on $v_\omega|_\Omega = \tilde{v}_\omega|_\Omega \in H_\diamond^1(\Omega)$, so that there exists $c'_\omega > 0$ such that

$$\int_\Omega |\nabla \tilde{v}_\omega|^2 \, \mathrm{d}x = \int_\Omega |\nabla v_\omega|^2 \, \mathrm{d}x \geq c'_\omega \|F_\omega \phi\|^2 \quad \text{for all } \phi \in H_\diamond^{1/2}(\partial\Omega).$$

Thus, it only remains to show that F_ω is bijective. Its injectivity is obvious and its surjectivity is shown as in the proof of [10, Lemma 3.3] by checking that a right inverse of F_ω is given by $-\lambda_{B\setminus\overline{\Omega}}^\omega - \lambda_\Omega^\omega$, where λ_Ω^ω and $\lambda_{B\setminus\overline{\Omega}}^\omega$ are the NtD operators on the inclusion Ω, resp., on its complement $B \setminus \overline{\Omega}$. □

Lemma 2.6. *The assumptions of Theorem* 2.1 *imply that there exist $c, C > 0$ such that*

$$c\|L'g\|^2 \leq (|\Im\,(\sigma_0^\omega \Lambda_\omega)|\, g, g) \leq C\|L'g\|^2. \tag{2.8}$$

For the case of frequency-difference data, the assumptions of Theorem 2.2 *imply that there exist* $c', C' > 0$ *such that*

$$c' \left\| L'g \right\|^2 \leq \left(\left| \Re \left(\sigma_0^\omega \Lambda_\omega - \sigma_0^\tau \Lambda_\tau \right) \right| g, g \right) \leq C' \left\| L'g \right\|^2. \tag{2.9}$$

Proof. For every $g \in L^2_\diamond(\partial B)$, $\phi := L'g$, let $\tilde{v}_\omega, v_\phi$ be the functions defined in Lemma 2.5. Noting that $\Lambda_0 = \Lambda_0'$ and $F_0 = F_0'$, we obtain from Lemmas 2.4 and 2.5 that

$$\begin{aligned} \left(\Im \left(\sigma_0^\omega \Lambda_\omega \right) g, g \right) &= \left\langle \Im \left(F_\omega \right) L'g, L'g \right\rangle \\ &= \frac{1}{2\mathrm{i}} \left(\langle (F_\omega - F_0)\phi, \phi \rangle - \overline{\langle (F_\omega - F_0)\phi, \phi \rangle} \right) \\ &= - \int_B \Im \left(\frac{\sigma^\omega}{\sigma_0^\omega} \right) \left| \nabla \tilde{v}_\omega \right|^2 \, \mathrm{d}x = - \int_\Omega \Im \left(\frac{\sigma_\Omega^\omega}{\sigma_0^\omega} \right) \left| \nabla \tilde{v}_\omega \right|^2 \, \mathrm{d}x. \end{aligned}$$

Hence, $\left| \Im \left(\sigma_0^\omega \Lambda_\omega \right) \right|$ is either $\Im \left(\sigma_0^\omega \Lambda_\omega \right)$ or $-\Im \left(\sigma_0^\omega \Lambda_\omega \right)$, the lower bound in assertion (2.8) follows from Lemma 2.5, and the upper bound follows from the the continuity of F_ω.

To prove the second assertion for the case of frequency-difference data, let $\tilde{v}_\tau$ be defined analogously to $\tilde{v}_\omega$. We now proceed similar to Ide et al. [20, Lemma 2.6]; cf. also the similar arguments in Kang, Seo, and Sheen [23] and Kirsch [25]. Using (2.7) and its analog for the frequency τ, we derive

$$\begin{aligned} 0 &\leq \int_B \Re \left(\tfrac{\sigma^\tau}{\sigma_0^\tau} \right) \left| \nabla \tilde{v}_\tau - \frac{\frac{\sigma^\omega}{\sigma_0^\omega}}{\Re \left(\frac{\sigma^\tau}{\sigma_0^\tau} \right)} \nabla \tilde{v}_\omega \right|^2 \, \mathrm{d}x \\ &= \int_B \Re \left(\tfrac{\sigma^\tau}{\sigma_0^\tau} \right) \left| \nabla \tilde{v}_\tau \right|^2 \, \mathrm{d}x - 2\Re \left(\int_B \frac{\sigma^\omega}{\sigma_0^\omega} \nabla \tilde{v}_\omega \cdot \overline{\nabla \tilde{v}_\tau} \, \mathrm{d}x \right) + \int_B \frac{\left| \frac{\sigma^\omega}{\sigma_0^\omega} \right|^2}{\Re \left(\frac{\sigma^\tau}{\sigma_0^\tau} \right)} \left| \nabla \tilde{v}_\omega \right|^2 \, \mathrm{d}x \\ &= - \int_B \Re \left(\tfrac{\sigma^\tau}{\sigma_0^\tau} \right) \left| \nabla \tilde{v}_\tau \right|^2 \, \mathrm{d}x + \int_B \frac{\left| \frac{\sigma^\omega}{\sigma_0^\omega} \right|^2}{\Re \left(\frac{\sigma^\tau}{\sigma_0^\tau} \right)} \left| \nabla \tilde{v}_\omega \right|^2 \, \mathrm{d}x. \end{aligned}$$

Thus, it follows from Lemmas 2.4 and 2.5 that

$$\begin{aligned} &\left(\Re \left(\sigma_0^\omega \Lambda_\omega - \sigma_0^\tau \Lambda_\tau \right) g, g \right) \\ &= \int_B \Re \left(\tfrac{\sigma^\omega}{\sigma_0^\omega} \right) \left| \nabla \tilde{v}_\omega \right|^2 \, \mathrm{d}x - \int_B \Re \left(\tfrac{\sigma^\tau}{\sigma_0^\tau} \right) \left| \nabla \tilde{v}_\tau \right|^2 \, \mathrm{d}x \\ &\geq \int_B \left(\Re \left(\tfrac{\sigma^\omega}{\sigma_0^\omega} \right) - \frac{\left| \frac{\sigma^\omega}{\sigma_0^\omega} \right|^2}{\Re \left(\frac{\sigma^\tau}{\sigma_0^\tau} \right)} \right) \left| \nabla \tilde{v}_\omega \right|^2 \, \mathrm{d}x \\ &= \int_\Omega \frac{\Re \left(\frac{\sigma^\omega}{\sigma_0^\omega} \right)}{\Re \left(\frac{\sigma^\tau}{\sigma_0^\tau} \right)} \left(\Re \left(\tfrac{\sigma_\Omega^\tau}{\sigma_0^\tau} \right) - \Re \left(\tfrac{\sigma_\Omega^\omega}{\sigma_0^\omega} \right) - \frac{\Im \left(\frac{\sigma_\Omega^\omega}{\sigma_0^\omega} \right)^2}{\Re \left(\frac{\sigma^\omega}{\sigma_0^\omega} \right)} \right) \left| \nabla \tilde{v}_\omega \right|^2 \, \mathrm{d}x. \end{aligned}$$

Using $\Re\left(\frac{\sigma^\omega}{\sigma_0^\omega}\right), \Re\left(\frac{\sigma^\tau}{\sigma_0^\tau}\right) \in L_+^\infty(B)$, and assumption (2.3), we obtain a $c'' > 0$ with

$$(\Re\left(\sigma_0^\omega \Lambda_\omega - \sigma_0^\tau \Lambda_\tau\right) g, g) \geq c'' \int_\Omega \left|\nabla \tilde{v}_\omega\right|^2 \, \mathrm{d}x.$$

An analog equation follows from interchanging ω and τ and using assumption (2.4). Hence, if either (2.3) or (2.4) holds, then $|\Re\left(\sigma_0^\omega \Lambda_\omega - \sigma_0^\tau \Lambda_\tau\right)|$ is either $\Re\left(\sigma_0^\omega \Lambda_\omega - \sigma_0^\tau \Lambda_\tau\right)$ or $\Re\left(\sigma_0^\tau \Lambda_\tau - \sigma_0^\omega \Lambda_\omega\right)$, and in both cases the lower bound in assertion (2.9) follows from Lemma 2.5. The upper bound in assertion (2.9) follows from the factorization in Lemma 2.4 and the continuity of F_ω and F_τ. □

We also need two known lemmas from previous applications of the factorization method. The first one relates the range of an operator to the norm of its dual or adjoint and the second one shows that the inclusion Ω can be determined from $\mathcal{R}(L)$.

LEMMA 2.7. *Let H_i, $i = 1, 2$, be two Hilbert spaces with norms $\|\cdot\|_i$, X be a third Hilbert space, and $A_i \in \mathcal{L}(X, H_i)$.*

If $\|A_1 x\|_1 \leq \|A_2 x\|_2$ for all $x \in X$, then $\mathcal{R}(A_1^*) \subseteq \mathcal{R}(A_2^*)$ and $\mathcal{R}(A_1') \subseteq \mathcal{R}(A_2')$.

Proof. This follows from the so-called "14th important property of Banach spaces" in Bourbaki [3]; cf. also [10, Lemma 3.4, Cor. 3.5] for an elementary proof for real spaces that holds as well in this complex case. □

LEMMA 2.8. *$\Phi_z|_{\partial B} \in \mathcal{R}(L)$ if and only if $z \in \Omega$.*

Proof. This has been proven by Brühl in [4, Lemma 3.5]. □

We can now prove our main theorems.

Proof of Theorems 2.1 *and* 2.2. Using Lemma 2.7, it follows from Lemma 2.6 that

$$\mathcal{R}\left(\left|\Im\left(\alpha_\omega \Lambda_\omega\right)\right|^{1/2}\right) = \mathcal{R}(L), \quad \text{resp.,} \quad \mathcal{R}\left(\left|\Re\left(\sigma_0^\omega \Lambda_\omega - \sigma_0^\tau \Lambda_\tau\right)\right|^{1/2}\right) = \mathcal{R}(L).$$

Hence, the assertions follow from Lemma 2.8. □

3. Numerical examples.

We tested our method numerically and compared it to the conventional factorization method for static (zero frequency) electrical impedance tomography using exact and inexact reference measurements. B is the two-dimensional unit-disk. The inclusions are two circles centered in $(0.4, 0.2)$ and $(-0.6, 0)$ with radii 0.3 and 0.2. For the complex conductivity at a nonzero frequency ω, we use the values of the first example from Jain et al. in [22]. The background conductivity is $\sigma_0^\omega := 0.3 + 0.1\mathrm{i}$ and inside the inclusions Ω we set this value to $\sigma^\omega|_\Omega := 0.1 + 0.1\mathrm{i}$, i.e., $\sigma_\Omega^\omega := -0.2$. To compare our method with the original factorization method we use $\tau = 0$ as the second frequency and set the imaginary part of the conductivity to zero for that case, i.e., $\sigma_0 := 0.3$ and $\sigma_\Omega := -0.2$. (Consistent with the introduction we omit the index τ for the zero frequency case.) Then

$$\frac{\sigma_\Omega^\omega}{\sigma_0^\omega} = -0.6 + 0.2\mathrm{i} \quad \text{and} \quad \frac{\sigma_\Omega}{\sigma_0} = -\frac{2}{3},$$

so that the assumptions of both Theorems 2.1 and 2.2 are fulfilled. (This also follows from Remark 2.3 as $\tau = 0$ and only the conductivity differs in the inclusions.)

On ∂B we apply

$$\left\{ \frac{1}{\sqrt{\pi}} \sin(n\phi), \, \frac{1}{\sqrt{\pi}} \cos(n\phi) \;\middle|\; n = 1, \ldots, 128 \right\}$$

as input currents, where (r, ϕ) denotes the polar coordinates with respect to the origin.

We use the notation Λ_ω for the NtD operator at the frequency ω and Λ for the corresponding operator at zero frequency (both for the setting with the inclusion Ω). For the original factorization method we also need the reference operator at zero frequency without inclusion Λ_0, i.e., the one corresponding to constant real conductivity $\sigma_0 = 0.3$ throughout B. Accordingly, we denote the corresponding potentials by u, u_ω and u_0.

We calculate these potentials separately using the commercial finite element software Comsol and expand their boundary values in the aforementioned trigonometric basis, which gives us discrete approximations $\tilde{\Lambda}_\omega, \tilde{\Lambda}, \tilde{\Lambda}_0 \in \mathbb{C}^{256\times 256}$. Consistent with our theoretical results in section 2 we describe the applied currents as continuous functions (the so-called continuum model of EIT) and do not study more realistic electrode models in our numerical examples. Also note that we do not directly calculate the difference $\tilde{\Lambda} - \tilde{\Lambda}_0$ as in [13] or $\Im(\sigma_0^\omega \tilde{\Lambda}_\omega)$, resp., $\Re(\sigma_0 \tilde{\Lambda} - \sigma_0^\omega \tilde{\Lambda}_\omega)$ in an analogous manner. Though such a direct calculation of the differences leads to a higher precision in the simulated forward data, we refrained from it in order to be able to simulate independent measurement and shape errors on each of the measurement operators.

The range criteria

$$z \in \Omega \quad \text{if and only if} \quad \Phi_z|_{\partial B} \in \mathcal{R}\left(A^{1/2}\right)$$

with $A = |\Im(\sigma_0^\omega \Lambda_\omega)|$ (see Theorem 2.1), $A = |\Re(\sigma_0 \Lambda - \sigma_0^\omega \Lambda_\omega)|$ (see Theorem 2.2) or $A = |\Lambda - \Lambda_0|$ (the conventional factorization method, see Brühl [4, Theorem 3.1]) are implemented as in [13]. For the reader's convenience we repeat the description here. Let

$$A v_k = \lambda_k v_k, \qquad k \in \mathbb{N},$$

be the spectral decomposition of the operator A, which is in all three cases compact, self-adjoint, injective, and positive. $\{v_k\} \subset L^2_\diamond(\partial B)$ is an orthonormal basis of eigenfunctions with eigenvalues $\{\lambda_k\} \subset \mathbb{R}$ (sorted in decreasing order). The Picard criterion yields that

$$\Phi_z|_{\partial B} \in \mathcal{R}(A^{1/2})$$

if and only if

$$f(z) := \frac{1}{\|\Phi_z|_{\partial B}\|^2_{L^2(\partial B)}} \sum_{k=1}^{\infty} \frac{|(\Phi_z|_{\partial B}, v_k)_{L^2(\partial B)}|^2}{\lambda_k} < \infty.$$

Using a singular value decomposition of the discrete approximation $\tilde{A} \in \mathbb{C}^{256\times 256}$ ($\tilde{A} = |\Im(\sigma_0^\omega \tilde{\Lambda}_\omega)|$, $\tilde{A} = |\Re(\sigma_0 \tilde{\Lambda} - \sigma_0^\omega \tilde{\Lambda}_\omega)|$, or $\tilde{A} = |\tilde{\Lambda} - \tilde{\Lambda}_0|$),

$$\tilde{A} \tilde{v}_k = \tilde{\lambda}_k \tilde{u}_k, \qquad \tilde{A}^* \tilde{u}_k = \tilde{\lambda}_k \tilde{v}_k, \qquad k = 1, \dots, 128,$$

with nonnegative $\{\tilde{\lambda}_k\} \subset \mathbb{R}$ (sorted in decreasing order) and orthonormal bases $\{\tilde{u}_k\}, \{\tilde{v}_k\} \subset \mathbb{C}^{256}$, we approximate the function $f(z)$ by

$$\tilde{f}(z) := \sum_{k=1}^{m} \frac{|\tilde{\Phi}_z^* \tilde{v}_k|^2}{\tilde{\lambda}_k} \Big/ \sum_{k=1}^{m} |\tilde{\Phi}_z^* \tilde{v}_k|^2,$$

where $\tilde{\Phi}_z \in \mathbb{C}^{256}$ contains the Fourier coefficients of $\Phi_z|_{\partial B}$, which for the two-dimensional unit circle can be written as (cf., e.g., Brühl [4]),

$$\Phi_z(x) = \frac{1}{\pi}\frac{(z-x)\cdot d}{|z-x|^2} \quad \text{for all } x \in \partial B.$$

m is the number of singular values that are reasonable approximations $\tilde{\lambda}_k \approx \lambda_k$. To estimate m we plot the (normalized) singular values $(\tilde{\lambda}_k)_k$ in a semilogarithmic scale; cf. the left column of Figure 3.1, where this is done for our three different choices for A. Typically, the eigenvalues show an exponential decay that stops rather abruptly due to the presence of errors in our simulated data. In our experiments we manually pick the level where this stop occurs (marked by a dashed line in our eigenvalue plots) and use only the singular values $(\tilde{\lambda}_k)_k$ above this level.

To obtain a numerical criterion telling whether a point z belongs to the unknown inclusion Ω or not, one now has to decide if the infinite sum $f(z)$ attains the value ∞ by using the approximate value $\tilde{f}(z)$, which is always finite. Thus, a threshold $C_\infty > 0$ is needed to distinguish points with *large* values $\tilde{f}(z) \geq C_\infty$ from those with *small* values $\tilde{f}(z) < C_\infty$. A reconstruction of Ω is then obtained by evaluating $\tilde{f}(z)$ on a grid of points $\{z_n\} \subset B$ and saying that all points with $\tilde{f}(z_n) < C_\infty$ belong to the inclusion. Choosing different threshold values C_∞ corresponds to choosing different level contours of $\tilde{f}(z)$ or, equivalently, of a monotone function of $\tilde{f}(z)$.

In our numerical experiments, we plot the indicator function

$$\text{Ind}(z) := \Big(\log\left(1 + \tilde{f}(z)\right)\Big)^{-1} \tag{3.1}$$

on an equidistant grid $\{z_n\} \subset B$, as well as the contour of $\tilde{f}$ that fits best to the true boundary of the inclusion $\partial\Omega$. Note that we choose this optimal contour line in order to compare optimal results for our method with optimal results for the original method. In practice, the choice of a contour line of $\tilde{f}$ has to be done on a heuristic basis or using additional information, e.g., about the size of the inclusion.

3.1. Detecting inclusions without reference measurements. Figure 3.1 shows the reconstructions that we obtain for $A = |\Im(\sigma_0^\omega \Lambda_\omega)|$ (top row), $A = |\Re(\sigma_0\Lambda - \sigma_0^\omega \Lambda_\omega)|$ (middle row), and $A = |\Lambda - \Lambda_0|$ (bottom row). The left column shows the (normalized) singular values of A and the trust level marked by a dashed line, the middle column shows the indicator function, and the right column shows the optimal contour line of it (chosen with knowledge of the true inclusions). The true boundary of the inclusions $\partial\Omega$ is plotted with a dashed line in the middle and right columns.

The reconstructions are of similar good quality. For this case of exact simulated data it does not seem to matter whether only measurements at a single nonzero frequency are being used (top row), nonzero frequency measurements are combined with zero frequency measurements (middle row), or zero frequency measurements are combined with reference measurements (bottom row).

In addition to using unperturbed simulated measurements, we also tested the method after adding 0.1% relative noise to the measurement matrix $\tilde{\Lambda}_\omega$, resp., $\tilde{\Lambda}$. More precisely, we generate an error matrix E of the same size as the measurements with uniformly distributed real and imaginary parts of the entries between -1 and 1. E is then scaled to the noise level with respect to its spectral norm and added to the respective measurement operator. (Of course, different errors are added to $\tilde{\Lambda}_\omega$ and $\tilde{\Lambda}$.) We also compare this with the results obtained with the original factorization

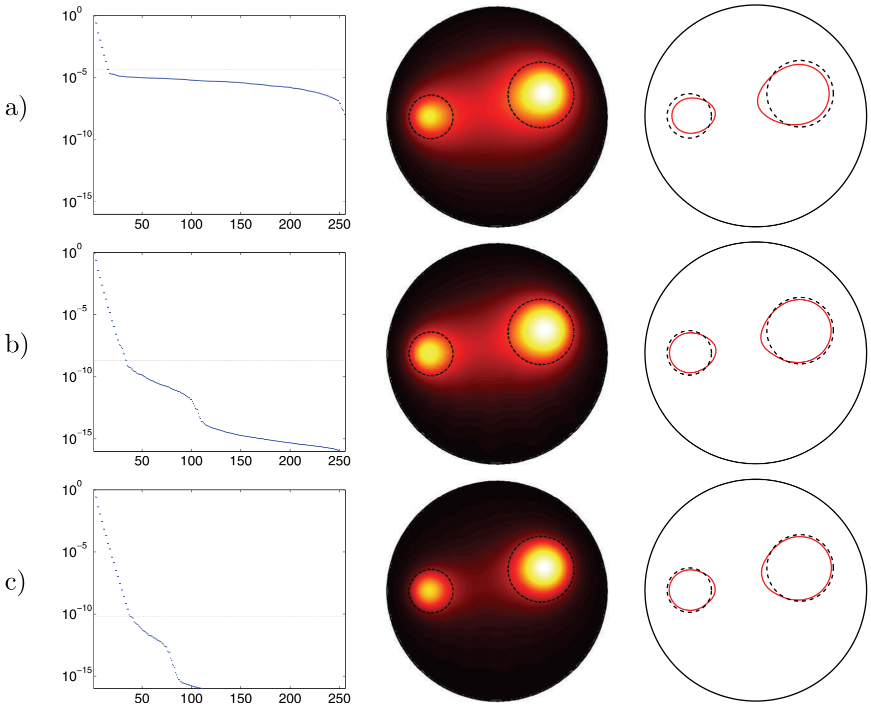

FIG. 3.1. *Numerical results for exact data: singular values (left column), indicator function (middle column), and its optimal contour (right column, chosen with knowledge of the true inclusions) for* (a) *single-frequency data,* (b) *frequency-difference data, and* (c) *static data compared with reference data.*

method, i.e., using $\tilde{\Lambda} - \tilde{\Lambda}_0$, where we take the noisy version of $\tilde{\Lambda}$ but not of $\tilde{\Lambda}_0$. The corresponding reconstructions are shown in Figure 3.2, which is organized in the same way as Figure 3.1.

The reconstructions using $A = |\Im(\sigma_0^\omega \Lambda_\omega)|$ in the top row and $A = |\Re(\sigma_0 \Lambda - \sigma_0^\omega \Lambda_\omega)|$ in the middle row seem to be more effected by the noise than those using $A = |\Lambda - \Lambda_0|$ in the bottom row. This can be explained by the fact that all three choices for A contain differences of the measurement operators Λ_ω, Λ, or Λ_0, which are much smaller than the measurement operators itself. Thus, the noise on the measurement operators is amplified in these differences. In our example we have that

$$\|\Im(\sigma_0^\omega \tilde{\Lambda}_\omega)\| \approx 0.06 \, \|\sigma_0^\omega \tilde{\Lambda}_\omega\| \, ,$$

$$\|\Re(\sigma_0 \tilde{\Lambda} - \sigma_0^\omega \tilde{\Lambda}_\omega)\| \approx 0.03 \, \|\sigma_0 \tilde{\Lambda}\| \approx 0.03 \, \|\sigma_0 \tilde{\Lambda}\| \, ,$$

$$\|\tilde{\Lambda} - \tilde{\Lambda}_0\| \approx 0.14 \, \|\tilde{\Lambda}\| \approx 0.16 \, \|\tilde{\Lambda}_0\| \, ,$$

so that the noise amplification is highest in the middle row and lowest in the bottom row, which fits well to the different quality of the reconstruction. Note that this amount of noise amplification depends on the inclusions' contrast to the background conductivity and, though we have not thoroughly investigated this question, different numerical examples did not indicate that one choice of A is generally more robust to noise than another.

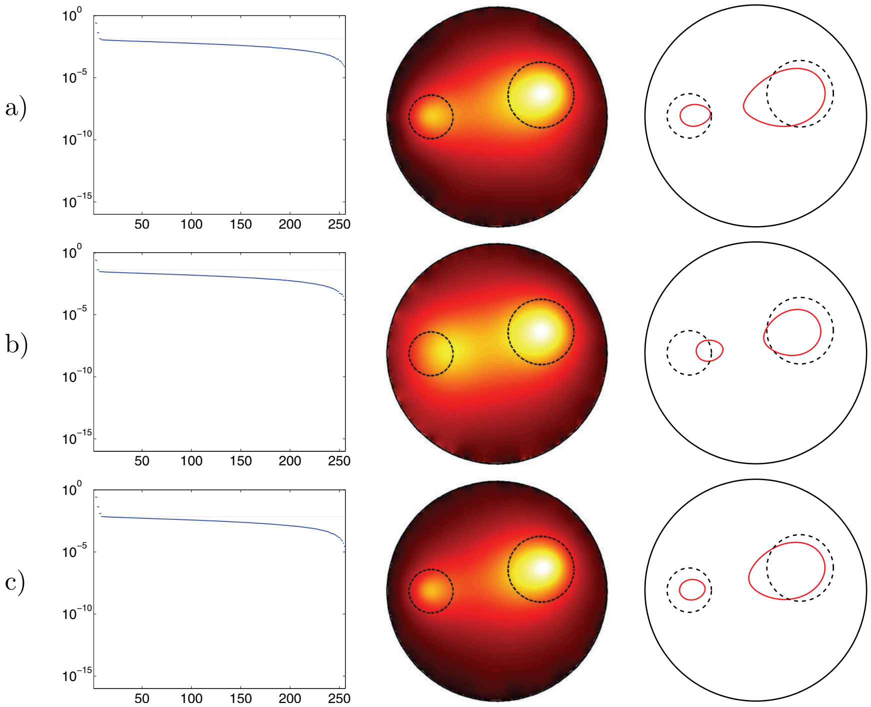

FIG. 3.2. *Numerical reconstructions for data containing* 0.1% *relative noise: singular values (left column), indicator function (middle column), and its optimal contour (right column, chosen with knowledge of the true inclusions) for* (a) *single-frequency data,* (b) *frequency-difference data, and* (c) *static data compared with reference data.*

3.2. Sensitivity to body shape errors. We also compared our method to the conventional factorization method in a setting where there are some boundary geometry errors between the computational domain of the forward model and that of the true body. To that end we replaced B by an ellipse with halfaxes $1+\delta$ and $1/(1+\delta)$ in the calculation of the forward data. Everything else remained unchanged to simulate the case where this ellipse is wrongly assumed to be the unit circle.

We used $\delta = 5\%$ and show in the first row of Figure 3.3 the reconstruction obtained from $A = |\Im(\sigma_0^\omega \Lambda_\omega)|$ and in the second row those obtained with $A = |\Re(\sigma_0 \Lambda - \sigma_0^\omega \Lambda_\omega)|$. As we explained in the introduction, for the conventional factorization method, using $A = |\Lambda - \Lambda_0|$, the effect of body shape errors strongly depends on whether the reference operator Λ_0 is experimentally obtainable or numerically simulated (resp., in easy cases, calculated analytically). In the first case, Λ_0 correctly corresponds to measurements at an ellipse (which the body really is), while in the latter case, it corresponds to a circle (which we wrongly assume the body to be). The resulting reconstructions are shown in the third and forth row of Figure 3.3.

As we expected, systematic body shape errors have a greater effect on the reconstructions when the measurement operators belong to a different geometry, as is the case for the conventional factorization method with simulated reference data, shown in the bottom row. However, also using only measurements at a single, nonzero frequency, i.e., $A = |\Im(\sigma_0^\omega \Lambda_\omega)|$ in the top row, seems to be similarly effected. If two different kinds of measurements are taken at the same body, the reconstructions improve. It does not seem to matter much whether these two are measurements at a

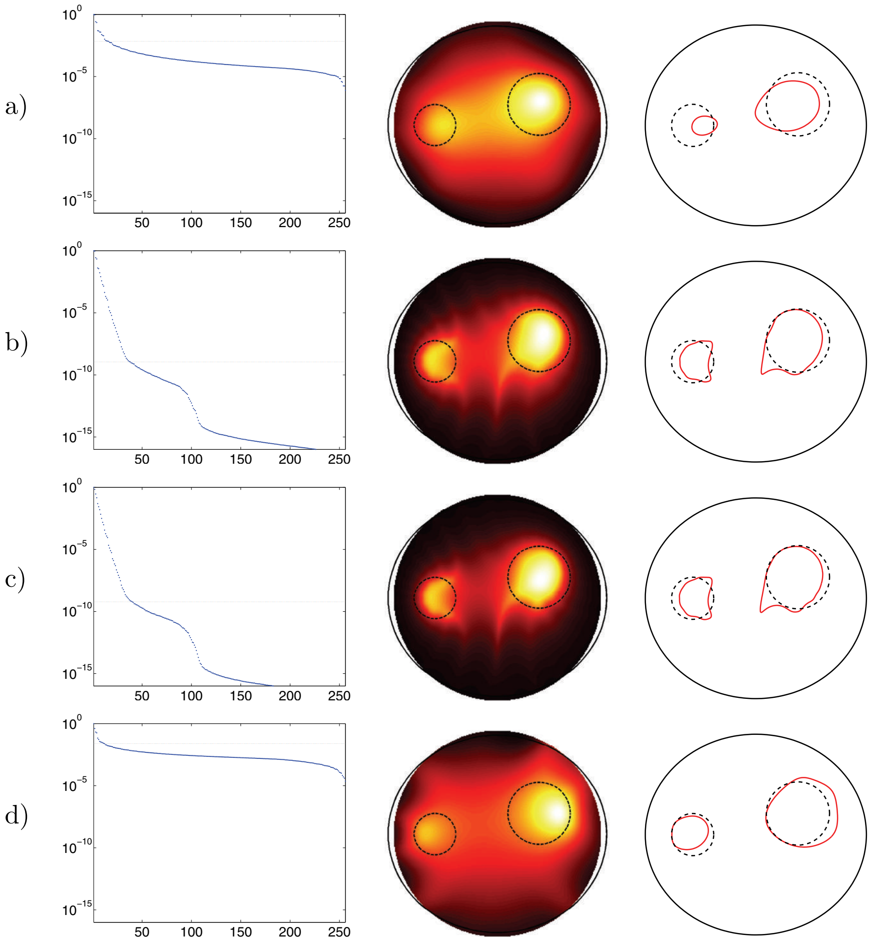

Fig. 3.3. *Numerical reconstructions for data containing $\delta = 5\%$ body shape errors: singular values (left column), indicator function (middle column), and its optimal contour (right column, chosen with knowledge of the true inclusions) for* (a) *single-frequency data,* (b) *frequency-difference data,* (c) *static data compared with reference data for the correct body shape, and* (d) *static data compared with reference data for the assumed (incorrect) body shape.*

nonzero and at zero frequency ($A = |\Re(\sigma_0\Lambda - \sigma_0^\omega\Lambda_\omega)|$ in the second row) or zero frequency measurements with and without inclusion ($A = |\Lambda - \Lambda_0|$ in the third row).

Figure 3.4, which is organized in the same way as Figure 3.3, shows the reconstructions that we obtained for an ellipse with halfaxes $1+\delta$ and $1/(1+\delta)$ for $\delta = 10\%$. Even for this rather large amount of errors in the estimated body shape the reconstructions are quite reasonable if frequency-difference measurements (second row) or the conventional factorization method is used with reference measurements belonging to the exact (elliptical) body shape (third row). If measurements at only a single, nonzero frequency are used (top row), the reconstruction gets highly blurred. The conventional method with reference measurements that are simulated for the assumed (incorrect) body shape (bottom row) performs even worse and leads to strong artifacts.

The results numerically verify that our new variant of the factorization method with frequency-difference data is much more robust against body shape errors than

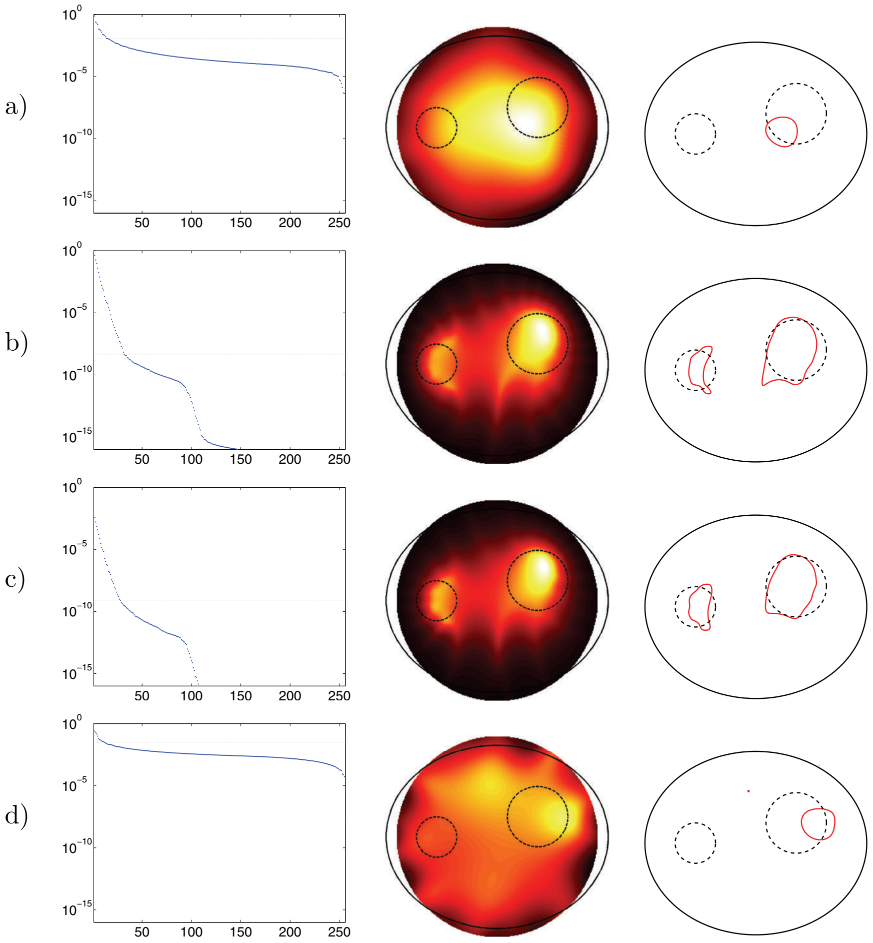

Fig. 3.4. *Numerical reconstructions for data containing $\delta = 10\%$ body shape errors: singular values (left column), indicator function (middle column), and its optimal contour (right column, chosen with knowledge of the true inclusions) for* (a) *single-frequency data,* (b) *frequency-difference data,* (c) *static data compared with reference data for the correct body shape, and* (d) *static data compared with reference data for the assumed (incorrect) body shape.*

using the conventional method with simulated (or analytically calculated) reference data. Actually, the reconstructions using frequency-difference data seem to be of equally good quality and robustness as those that one would obtain with correct reference measurements (which are usually not available in practice).

3.3. Unknown background conductivity. Though our new variant of the factorization method works without reference measurements, it still requires the knowledge of the constant conductivity value of the background. We now describe a heuristic approach with which the algorithm can also be applied to an unknown background conductivity.

Roughly speaking, we expect that fast spatial variations in the applied currents on ∂B lead to higher electric currents close to ∂B, while the electric effect of slowly spatially varying currents penetrates deeper into B (see [12] for a detailed study of how to create potentials with localized electrical energy). We also expect that the eigenfunctions of our compact measurement operators Λ^ω, resp., Λ, are functions containing increasingly high oscillations. Thus, the eigenvalues will mostly depend on the conductivity close to ∂B, i.e., the background conductivity, σ_0^ω, resp., σ_0.

The multiplication of Λ_ω with the background value σ_0^ω can be regarded as a simple change of units that sets this background conductivity value to the real value 1. Thus, we expect the eigenvalues of $\sigma_0^\omega \Lambda_\omega$ to mostly lie close to the real axis, and so the eigenvalues of Λ_ω will lie close to a straight line through the origin whose angle with the real axis is minus the phase of σ_0^ω.

To determine the range of $|\Im(\sigma_0^\omega \Lambda_\omega)|^{1/2}$, it suffices to estimate this phase of σ_0^ω. We do this by choosing the median α of the set

$$\left\{ -\frac{\Im(\tilde{\lambda}_j^\omega)}{\Re(\tilde{\lambda}_j^\omega)} \ : \ j = 1, 2, \dots \right\}$$

using all available eigenvalues $\tilde{\lambda}_j^\omega$ of $\tilde{\Lambda}_\omega$. Instead of $A = |\Im(\sigma_0^\omega \Lambda_\omega)|$ we then use $A = |\Im((1 + \alpha\mathrm{i})\Lambda_\omega)|$ in our algorithm.

To estimate the range of $|\Re(\sigma_0 \Lambda - \sigma_0^\omega \Lambda_\omega)|^{1/2}$ we proceed analogously and estimate the quotient of σ_0^ω and σ_0 by the median β of the set

$$\left\{ \frac{\tilde{\lambda}_j}{\tilde{\lambda}_j^\omega} \ : \ j = 1, 2, \dots \right\}$$

using all available eigenvalues $\tilde{\lambda}_j^\omega$ of $\tilde{\Lambda}_\omega$ and $\tilde{\lambda}_j$ of $\tilde{\Lambda}$. Then we use $A = |\Re(\Lambda - \beta\Lambda_\omega)|$ in our algorithm.

Figure 3.5 shows the reconstructions that we obtained with this approach for our numerical example. The columns are organized as in Figures 3.1–3.4. The first two rows show the reconstructions obtained with $A = |\Im((1 + \alpha\mathrm{i})\Lambda_\omega)|$ and $A = |\Re(\Lambda - \beta\Lambda_\omega)|$ and the last two rows show the according reconstructions after adding 0.1% of relative noise as in subsection 3.1. The reconstructions show almost no visual difference to those obtained with the exact background conductivity values in subsection 3.1.

Though this is not covered by the theory presented in section 2, it seems plausible that the above approach can also be applied to cases where the unknown background is slightly inhomogeneous. In our final example we test this numerically for the factorization method with frequency-difference data. We multiply the complex background conductivity used in the previous examples with the slightly oscillating function

$$1 + 0.05\cos(4\pi x)\sin(8\pi y).$$

In order to retain the conductivity jump only in the real part, we also multiply the imaginary part of the conductivity inside the inclusions with this function. Figure 3.6 shows the resulting real part (left picture) and the imaginary part (right picture) of σ^ω. As in the previous examples, we assume that the static conductivity σ has the same real part as σ^ω and that it has zero imaginary part.

We also added $\delta = 5\%$ body shape error as in subsection 3.2 and 0.05% relative noise as in subsection 3.1. Figure 3.7 shows the reconstruction that we obtain from using frequency-difference data $A = |\Re(\Lambda - \beta\Lambda_\omega)|$, where the constant $\beta \in \mathbb{C}$ is estimated from the data as explained above.

The reconstruction are comparable to those obtained with knowledge of the exact body shape, known constant background, and 0.1% relative noise in subsection 3.1. This suggests that the method can indeed be applied to the practically relevant case of an unknown inhomogeneous background that is only known to be “almost constant.”

4. Conclusions.

We have developed a new variant of the factorization method that can be used on single-frequency and on frequency-difference measurements in electrical impedance tomography and that does not require reference measurements at an inclusion-free body, which are usually not available in practice. Our new variant with single-frequency measurements delivers comparable results to using the conventional method with simulated reference data and thus eliminates one of the main computational efforts in applying the method. An even greater advantage is achieved by using frequency-difference measurements. Not only do we save the computational effort of simulating reference measurements, but our new results show the same performance in the presence of body shape errors that one would otherwise obtain from reference measurements at the correct (unknown) body shape. This greatly improves the stability of the method with respect to such unavoidable systematic errors, so that the application of the method in frequency-difference EIT systems seems very promising.
