

## ON BOUNDED DATABASE SCHEMES AND BOUNDED HORN-CLAUSE PROGRAMS\*

YEHOShUA SAGIV†

**Abstract.** A lossless database scheme with full implicational dependencies is considered. The following condition is necessary in order that restricted projections of the representative instance could be expressed in relational algebra (i.e., in first-order logic): The dependencies of the database scheme are equivalent to a single join dependency and some equality-generating dependencies. An important special case is when the database scheme has only full tuple-generating dependencies. In this case, restricted projections of the representative instance can be expressed in relational algebra if and only if the following condition is true: The dependencies of the database scheme are equivalent to a single join dependency. Testing this condition is decidable. This result also applies to the class of Horn-clause programs consisting only of typed rules with one predicate symbol  $R$  (and without function symbols). A program consisting of rules of this form is equivalent to a nonrecursive program if and only if it is equivalent to a project-join mapping. Finally, it is also shown that a tableau mapping is idempotent if and only if it is a project-join mapping.

**Key words.** database, dependency, Horn-clause rule, losslessness, query, relational algebra, representative instance, tableau

**1. Introduction.** The decomposition of a relation produces several new relations in some normal form and, consequently, certain update and storage anomalies are removed (cf. [Ma], [U1]). The original relation, however, remains a correct representation of the various relationships among its attributes, and frequently it is easier to formulate a query with respect to the original relation rather than the new relations. More specifically, many queries that can be formulated over the original relation as a projection and a selection, also require joins and possibly unions when formulated over the new relations, because all the correct access paths among the new relations have to be included in the answer. Surprisingly, in some simple cases it is (not just more difficult but actually) impossible to express projections of the original relation in relational algebra (i.e., first-order logic) if we insist that the new relations be the only operands [MUV]. When making statements like the previous one, we have, of course, to describe the connection between the new relations that are actually stored in the database and the original relation that does not exist in the database. We adopt the *representative instance* model [Ho], [Me], [Sa1], [Sa3], [Ya] that has been widely accepted as the correct way of producing the original relation from the new ones. The representative instance contains all the data that is obtained by losslessly joining (cf. [U1]) some of the new relations; and it has null values in order to account for partial information, i.e., tuples that cannot be extended, using lossless joins, to complete tuples over all the attributes, because of missing information.

If we choose to allow users to formulate queries over the representative instance, we are faced with the problem of optimizing these queries. Queries usually involve only a few attributes of the original relation and, therefore, it is desirable to have algebraic (i.e., relational algebra) expressions, with the new relations as their operands,

that compute restricted projections<sup>1</sup> of the representative instance. Hopefully, these expressions could be optimized by known techniques, and evaluated in considerably less time than required to compute the whole representative instance.

Maier et al. [MUV] showed (using the Compactness Theorem) that if there is a first-order formula that expresses the restricted projection onto some  $X$ , then there is also a union of tableaux that expresses it. Since the result of [MUV] uses the Compactness Theorem, it is valid in the unrestricted case, i.e., when databases are either finite or infinite. In this paper we consider lossless database schemes with *full implicational dependencies* [BV2], [Fa], [YP]. We give a necessary condition for the existence of a union of tableaux expressing the restricted projection onto the set of all the attributes. The condition states that the dependencies of the database scheme must be equivalent to a single join dependency and some equality-generating dependencies, and testing whether it is satisfied is decidable. Moreover, if the dependencies of the database scheme are only full tuple-generating dependencies (and no equality-generating dependencies), then equivalence to a single join dependency is both necessary and sufficient for the existence of unions of tableaux that compute restricted projections of the representative onto any set of attributes. Our results hold for finite databases. For unrestricted databases, “a union of tableaux” can be replaced with “an algebraic expression” (i.e., “a first-order formula”) in the above results, by combining them with those of [MUV].

Our results also apply to the following fragment of Horn-clause programs. The only rules allowed are typed rules with only one predicate symbol  $R$  and neither function symbols nor equality (“typed” means that no variable appears in more than one column of  $R$ , but of course a variable may appear in several occurrences of  $R$  as long as it is always in the same column). A program consisting of a set of rules of this form is equivalent to a nonrecursive program if and only if it is equivalent to a project-join mapping. Testing this condition is decidable. Cosmadakis and Kanellakis [CK] have recently investigated this class of Horn-clause programs.

## 2. Preliminaries.

**2.1. Schemes, states and instances.** Relations are tables of information in which the rows are *records* or *tuples* of data, and the columns are labeled by *attributes*. A *relation scheme* is a set of attributes, and it describes the fixed structure of a table. A *relation  $r$  over a relation scheme  $R$*  is a finite set of tuples, where each tuple is conveniently regarded as a mapping from the attributes of  $R$  to their domains. The value of a tuple  $\mu$  for an attribute  $A$  is denoted  $\mu(A)$ . We assume that each attribute has an infinite domain of *constants* (e.g., integers).

A *database scheme* consists of relation schemes and *dependencies*, and is denoted by  $([R_1, \dots, R_n], D)$ , where each  $R_i$  is a relation scheme, and  $D$  is a set of dependencies that will be defined later. The set of all the attributes, i.e.,  $\cup_{i=1}^n R_i$ , is denoted by  $U$ . A *state* of the database scheme  $([R_1, \dots, R_n], D)$  is a collection of relations  $r_1, \dots, r_n$  over  $R_1, \dots, R_n$ , respectively.

The *projection* of a relation  $r$  onto a set of attributes  $X$ , written  $\pi_X(r)$ , is obtained by removing columns not in  $X$  and eliminating duplicate tuples. A (universal) *instance  $I$*  is a relation over  $U$ . An instance  $I$  *generates* the state  $\pi_{R_1}(I), \dots, \pi_{R_n}(I)$ , which is denoted by  $state(I)$ .

---

<sup>1</sup> A restricted projection is a projection followed by elimination of all tuples that have nulls in some columns. Essentially, restricted projections correspond to the most basic queries that can be posed over the representative instance.

**2.2. Tableaux and tableau mappings.** Tableaux are formulas that express queries over a given database scheme  $([R_1, \dots, R_n], D)$ . A *tableau*  $[ASU1], [ASU2]$  is a table, similar to a relation, with columns that correspond to the attributes of  $U$  and rows that are filled with *variables*. We denote a tableau either by a single letter (e.g.,  $T$ ) or by explicitly specifying its rows, i.e.,  $(w_1, \dots, w_n)/s$ , where  $w_1, \dots, w_n$  are the rows of the tableau and  $s$  is a special row called the *summary*. The summary  $s$  may have blanks in some columns; the rows  $w_i$  have variables in all the columns. Each variable appearing in the summary must also appear in some  $w_i$ , and no variable appears in more than one column. The variables appearing in the summary are called *distinguished variables*, and other variables are called *nondistinguished variables*. Each row has a *tag*, which is one of the relation schemes  $R_i$ . A row with a tag  $R_i$  has a unique nondistinguished variable (i.e., a variable that appears nowhere else) in each column whose attribute is not in  $R_i$ . The phrase “the rows of the tableau  $(w_1, \dots, w_n)/s$ ” refers only to the  $w_i$ , i.e., the summary is excluded.

*Example 2.1.* In examples we usually represent a tableau as a table in which the summary appears at the top and is underlined. Distinguished variables are represented by  $a$ 's with subscripts, and nondistinguished variables are represented by  $b$ 's with subscripts (and sometimes also by other letters). In this example we explicitly show the attribute of each column, but we will not do so in future examples. Suppose that the set<sup>2</sup> of all the attributes is  $ABCD$ . The following is a tableau whose rows are tagged with the relation schemes  $AB, ABC, ABD$ .

	A	B	C	D
	$a_1$	$a_2$	$a_3$	$a_4$
$AB$	$a_1$	$a_2$	$b_1$	$b_2$
$ABC$	$b_5$	$a_2$	$a_3$	$b_3$
$ABD$	$b_5$	$a_2$	$b_4$	$a_4$

We say that  $h$  is a *symbol mapping* of a tableau  $T$  if  $h$  maps each variable of  $T$  to a constant. The result of applying  $h$  to  $u$ , where  $u$  is either a row or the summary of  $T$ , is a tuple defined naturally as follows. The tuple  $h(u)$  maps attribute  $A$  to  $h(u(A))$ , where  $u(A)$  is the variable appearing in column  $A$  of  $u$ . If  $u$  has a tag  $R_i$ , only the projection of  $h(u)$  onto  $R_i$  is of interest, and by a slight abuse of notation, we will denote that projection by  $h(u)$ . The symbol mapping  $h$  is a *valuation* of  $T$  into a database  $r_1, \dots, r_n$  if  $h$  maps every row of  $T$  with tag  $R_i$  to a tuple of  $r_i$ .

A tableau  $T$  defines a mapping from states (of the given database scheme) to relations. Tableau  $T$  maps a state  $r_1, \dots, r_n$  to the following relation, denoted  $T(r_1, \dots, r_n)$ ,

$$\{h(s) \mid s \text{ is the summary of } T \text{ and } h \text{ is a valuation of } T \text{ into } r_1, \dots, r_n\}.$$

Note that  $T(r_1, \dots, r_n)$  is a relation over the set of attributes in which the summary of  $T$  has nonblank symbols.

We also consider tableaux that map instances to relations. A tableau defines a mapping of instances if all its rows have the tag  $U$ , and traditionally, we refer to a

<sup>2</sup> We use the common notation in which the letters  $A, B, C, \dots$  represent single attributes, the letters  $\dots, X, Y, Z$  represent sets of attributes, and a set or union of sets is written as a string of attributes.

tableau of this kind as an *untagged* tableau (and in examples we write it without tags). Unless explicitly said otherwise, tagged and untagged tableaux considered in this paper are *full* in the sense that their summaries have variables in all the columns, i.e., the value of a tableau is always an instance. It is easy to see that a full untagged tableau mapping  $T$  is *monotonic*, i.e., for all instances  $I$ ,  $I \subseteq T(I)$ .

A *union of tableaux* [SY] is an expression of the form  $\bigcup_{i=1}^m T_i$ , where  $T_1, \dots, T_m$  are tableaux. If the  $T_i$  are tagged, the value of  $\bigcup_{i=1}^m T_i$ , given a state  $r_1, \dots, r_n$ , is  $\bigcup_{i=1}^m T_i(r_1, \dots, r_n)$ . If the  $T_i$  are untagged, the value for an instance  $I$  is  $\bigcup_{i=1}^m T_i(I)$ . The mappings defined by tableaux and union of tableaux can always be expressed in relational algebra [Co].

**2.3. Dependencies.** Untagged tableaux also define *full implicational dependencies*<sup>3</sup> [BV2], [Fa], [YP]. These dependencies are either *tuple-generating dependencies* (tgds) or *equality-generating dependencies* (egds). A tgd  $d$  is written as an untagged tableau  $(w_1, \dots, w_n)/s$ , and it is *satisfied* by an instance  $I$  if for all valuations  $h$  of  $(w_1, \dots, w_n)/s$  into  $I$ , the tuple  $h(s)$  is in  $I$ . An egd is also written as an untagged tableau, but its summary is of the form  $a = b$ , where  $a$  and  $b$  are variables (both  $a$  and  $b$  must appear in the same column of the tableau). An egd  $(w_1, \dots, w_n)/a = b$  is *satisfied* by an instance  $I$  if for all valuations  $h$  of  $(w_1, \dots, w_n)/a = b$  into  $I$ , the equality  $h(a) = h(b)$  holds. As a technicality, we consider one of  $a$  and  $b$ , say  $a$ , as the only distinguished variable of the egd.

A tgd in which no nondistinguished variable occurs more than once is called a *join dependency*. A database scheme  $([R_1, \dots, R_n], D)$  has an associated join dependency, denoted by  $\bowtie R_i$ , such that for each  $R_i$ , the join dependency  $\bowtie R_i$  has a row with distinguished variables in the columns of  $R_i$  and distinct nondistinguished variables in the rest of the columns. When a tableau for a join dependency is viewed as an untagged tableau mapping, it is usually called a *project-join* mapping (because this tableau mapping is the same as joining some projections of an instance).

**2.4. Tableaux as mappings, dependencies and instances.** Given an untagged tableau  $T$ , we call it either a mapping or a tgd, depending on how we view it. We use the term “tableau” as a generic name for either mappings or tgds (but not egds). In some proofs in this paper we alternate between viewing a given tableau  $T$  as a mapping and as a tgd. Similarly, a tagged tableau may also be considered as an untagged mapping or a tgd simply by ignoring the tags.

A tableau (or more precisely, the rows of a tableau) may be converted into an instance by mapping each variable to a distinct constant. Since the one-to-one mapping that converts a tableau to an instance is only a formality, we shall refer to the tableau itself as an instance instead of using a mapping. When viewing a tableau as an instance, we always consider only the rows without the summary.

**2.5. The chase.** We permit the use of *nulls* in instances. A null represents an unknown value and is denoted by  $\delta_i$ . Two nulls are equal only if they have the same subscript, and a null is never equal to a constant. If we assume that an instance  $I$  should satisfy a set of dependencies  $D$ , then we may infer that some nulls can be replaced with constants or with other nulls, and tuples currently not in  $I$  must belong to it. The process of making these inferences is called the *chase* [ABU], [MMS], and it is defined in terms of rules that are associated with the dependencies of  $D$ .

<sup>3</sup> We do not consider embedded dependencies in this paper.

The rule for a  $\text{tgd } (w_1, \dots, w_n)/s$  states that if there is a valuation  $h$  of the  $w_i$  into  $I$ , such that  $h(s)$  is not a tuple of  $I$ , then  $h(s)$  is added to  $I$ . The rule for an  $\text{egd } (w_1, \dots, w_n)/a=b$  states that if there is a valuation  $h$  of the  $w_i$  into  $I$ , such that  $h(a) \neq h(b)$  and at least one of  $h(a)$  and  $h(b)$  is a null, then  $h(a)$  and  $h(b)$  are equated as follows. We arbitrarily choose a null among  $h(a)$  and  $h(b)$ , say  $h(b)$ , and replace all occurrences of  $h(b)$  in  $I$  with  $h(a)$ . The *chase* of  $I$  with respect to  $D$ , written  $\text{CHASE}_D(I)$ , is obtained by repeatedly applying the rules for the dependencies in  $D$  to the instance  $I$  until no rule can be applied anymore. The chase process terminates (since all dependencies are full), and  $\text{CHASE}_D(I)$  is uniquely defined up to renaming of nulls, provided that it satisfies (the dependencies of)  $D$  [MMS]. Clearly,  $\text{CHASE}_D(I)$  satisfies all the  $\text{tgds}$  of  $D$ , but not necessarily all the  $\text{egds}$  of  $D$ .

Let  $([R_1, \dots, R_n], D)$  be a database scheme. Given a state  $r_1, \dots, r_n$ , we create a special instance, called the *representative instance* [Ho], [Me], [Sa1], [Sa3], [Ya], in the following way. First, we augment each  $r_i$  with columns for the attributes in  $R - R_i$ , and fill each entry of these columns with a unique null (i.e., it appears nowhere else). The union of all the augmented relations is an instance denoted by  $A(r_1, \dots, r_n)$ . The representative instance of  $r_1, \dots, r_n$ , denoted  $RI(r_1, \dots, r_n)$ , is  $\text{CHASE}_D(A(r_1, \dots, r_n))$ .

A *consistent state* of the database scheme  $([R_1, \dots, R_n], D)$  is a state  $r_1, \dots, r_n$  such that  $RI(r_1, \dots, r_n)$  satisfies  $D$ . A *consistent instance* of  $D$  is an instance  $I$  without nulls, such that  $\text{CHASE}_D(I)$  satisfies  $D$ . The set of all consistent instances of  $D$  is denoted  $\text{CON}(D)$ . Clearly, an instance that satisfies  $D$  is also a consistent instance, but the converse is not necessarily true. Another important observation is the fact that if  $I$  is a consistent instance, then  $\text{state}(I)$  is a consistent state.

The chase can also be applied to the rows of a tableau  $T$ . When equating variables, distinguished variables are treated as constants and nondistinguished variables as nulls. Since each column of  $T$  has at most one distinguished variable, the set of rows of  $\text{CHASE}_D(T)$  always satisfies  $D$ . Note that  $\text{CHASE}_D(T)$  is a tableau with the same summary as  $T$  and with the rows that were generated from those of  $T$  by the chase ( $\text{CHASE}_D(T)$  includes the original rows of  $T$  but possibly with some nondistinguished variables replaced by other variables).

**2.6. Implications of dependencies and lossless database schemes.** A set of dependencies  $D$  implies a dependency  $d$ , written  $D \models d$ , if whenever an instance  $I$  satisfies  $D$ , then  $I$  also satisfies  $d$ . We can use the chase to test implications of dependencies [BV2], [MMS]. The set  $D$  implies  $d$  if and only if (the set of rows of)  $\text{CHASE}_D(d)$  satisfies  $d$ , or equivalently,

- (1)  $\text{CHASE}_D(d)$  contains a row which is equal to  $s$ , when  $d$  is a  $\text{tgd}$  with a summary  $s$ , and
- (2)  $a$  and  $b$  are equated during the chase of  $d$ , when  $d$  is an  $\text{egd}$  with a summary  $a = b$ .

A set of dependencies  $D_1$  implies another set  $D_2$ , written  $D_1 \models D_2$ , if  $D_1$  implies every dependency of  $D_2$ .  $D_1$  and  $D_2$  are *equivalent*, written  $D_1 \models \Leftrightarrow D_2$ , if  $D_1 \models D_2$  and  $D_2 \models D_1$ .

The following is an important observation. Two sets of dependencies  $D_1$  and  $D_2$  are equivalent if and only if for all instances  $I$ ,  $\text{CHASE}_{D_1}(I) = \text{CHASE}_{D_2}(I)$ . We will further discuss this observation in § 2.8.

A database scheme  $([R_1, \dots, R_n], D)$  is *lossless* if  $D \models \bowtie R_i$ . A database scheme has to be lossless in order to reconstruct tuples over  $U$  whose projections are stored in the database. Recall that the representative instance of a database state represents

all the data that either exist in the database state or can be inferred by correctly connecting tuples from various relations. If the database scheme is not lossless, then the representative instance can never have tuples with constants in all the columns of  $U$ , i.e., tuples without nulls [MUV]. In this paper we consider only lossless database schemes.

**2.7. Containment of tableau expressions.** We define tableau containment only for untagged tableau mappings. It is similarly defined for tagged tableaux [ASU1], but we do not use it in this paper. A tableau  $T_1$  *contains* a tableau  $T_2$  *over* a set of instances  $C$ , written  $T_2 \subseteq_C T_1$ , if for all instances  $I \in C$ ,  $T_2(I) \subseteq T_1(I)$ . Tableaux  $T_1$  and  $T_2$  are *equivalent over*  $C$ , written  $T_1 \equiv_C T_2$ , if for all instances  $I \in C$ ,  $T_2(I) = T_1(I)$ . If  $C$  is omitted, then  $C$  is assumed to be the set of all instances. Containment and equivalence are similarly defined for unions of tableaux.

A *homomorphism*  $h$  of  $T_1$  into  $T_2$  is a mapping of the variables of  $T_1$  into the variables of  $T_2$  that preserves summary and rows, that is

- (1) if  $w$  is a row of  $T_1$ , then  $h(w)$  is a row of  $T_2$ , and
- (2) for each column  $A$ , the distinguished variable of  $T_1$  in  $A$  is mapped to the distinguished variable of  $T_2$  in  $A$ .

If the rows of  $T_2$  are viewed as an instance, then a homomorphism is a valuation of  $T_1$  into the rows of  $T_2$  with the additional restriction that distinguished variables are mapped to distinguished variables. The existence of a homomorphism from  $T_1$  into  $T_2$  is a sufficient condition for  $T_2 \subseteq_C T_1$ , and it is also a necessary condition if the rows of  $T_2$  form an instance of  $C$  [ASU1]. The mapping of the rows of  $T_1$  into the rows of  $T_2$  induced by a homomorphism  $h$  is called a *containment mapping*. Essentially, a containment mapping  $\psi: T_1 \rightarrow T_2$  satisfies the following two conditions:

- (1) If rows  $w_1$  and  $w_2$  are equal in some column  $A$ , then so are  $\psi(w_1)$  and  $\psi(w_2)$ , and
- (2) If row  $w_1$  has a distinguished variable in some column  $A$ , then so does  $\psi(w_1)$ .

If there is a containment mapping from a tableau  $T$  into itself whose image does not include all the rows of  $T$ , then rows not in the image of the mapping can be eliminated and the result is a tableau equivalent to  $T$  (over all instances) [ASU2], [CM]. A tableau  $T$  is *minimal* if no row can be eliminated by some containment mapping. Efficient algorithms for minimizing tableaux are given in [ASU2], [Sa2].

A union of tableaux  $\bigcup_{i=1}^n T_i$  is contained in another union of tableaux  $\bigcup_{i=1}^m V_i$  if and only if each tableau  $T_i$  is contained in some  $V_j$  [SY].

**2.8. Bounded tgds and Horn-clause rules.** The chase can be viewed as an iterative process. For some sets of dependencies this iterative process is *bounded*, i.e., a fixed number of iterations is sufficient regardless of the input. To simplify the formal definitions, we assume that  $D$  has only tgds; the definition of boundedness when there are both tgds and egds can be found in [MUV]. So, suppose that  $D$  is a set of tgds and  $I$  is an instance, and consider the computation of  $CHASE_D(I)$ . The first iteration of the chase consists of repeatedly applying the dependencies of  $D$  to the original tuples of  $I$ , but not to the newly added tuples. Generally, in each iteration the dependencies are applied repeatedly to the rows generated in all previous iterations. Note that the following is true for any set of untagged tableaux  $\{T_1, \dots, T_m\}$  and any instance  $I$  (recall that  $\bigcup_{i=1}^m T_i(I)$  is the result of applying the mapping  $\bigcup_{i=1}^m T_i$  to  $I$ ): The instance  $\bigcup_{i=1}^m T_i(I)$  is equal to the result of the first iteration of chasing  $I$  with the tgds  $T_1, \dots, T_m$ .

The chase process with respect to a set of dependencies  $D$  is *bounded* if there is a fixed integer  $k$ , such that for all instances  $I$ , the computation of  $CHASE_D(I)$  requires

$k$  or fewer iterations. We will say that  $D$  is a *bounded* set of dependencies if the chase with respect to  $D$  is bounded.

The problem of determining boundedness is an important one, since the chase can be executed more efficiently when it is bounded. In fact, the chase can be expressed in relational algebra when it is bounded, but not in general [MUV]. We will elaborate on this point in § 4.

The boundedness problem also occurs in *deductive databases* (cf. [GM]). Deductive databases use *Horn-clause rules* in order to express queries, and tgds are essentially Horn-clause rules. A tgd  $(w_1, \dots, w_n)/s$  is just the following Horn-clause formula.

$$\forall \bar{x}(R(w_1) \wedge \dots \wedge R(w_n) \rightarrow R(s)).$$

Here  $R$  is relation scheme<sup>4</sup> consisting of all the attributes, i.e.,  $R = U$ , and  $\bar{x}$  is a list of all the variables in the tgd. In the notation of deductive databases (or logic programming), the above formula is written as the following rule.

$$R(s) :- R(w_1), \dots, R(w_n).$$

In general, Horn-clause rules may have many different predicates and need not be typed (they may also have function symbols). We will consider, however, only rules that correspond to tgds.

*Example 2.2.* Consider the following untagged tableau:

$a_1$	$a_2$	$a_3$	$a_4$
$a_1$	$a_2$	$b_1$	$b_2$
$e$	$a_2$	$a_3$	$b_3$
$e$	$a_2$	$b_4$	$a_4$

The tgd expressed by this tableau can also be written as the following Horn-clause rule.

$$R(a_1, a_2, a_3, a_4) :- R(a_1, a_2, b_1, b_2), R(e, a_2, a_3, b_3), R(e, a_2, b_4, a_4).$$

A set  $P$  of Horn-clause rules is viewed as a recursive program whose value for an instance  $I$  is just  $CHASE_P(I)$ , where the rules of  $P$  are considered as tgds when the chase is applied. Thus, viewing tableaux as tgds is essentially the same as viewing them as Horn-clause rules, whereas viewing tableaux as tgds is different from viewing them as mappings.

In this paper we will characterize when a set of tgds (and hence the corresponding set of Horn-clause rules), is bounded. This result is important not only for relational databases, but also in the context of developing efficient methods for evaluating Horn-clause rules. When a set of Horn-clause rules is bounded, it can be replaced with a relational expression and, thus, the task of optimizing the evaluation of the rules becomes considerably easier. Characterizations of boundedness for other fragments of Horn-clause rules have recently been described in [Io], [Na].

<sup>4</sup> Technically a relation scheme is a set of attributes, but we use it also as a relation name, or in logic terminology, as a predicate name.

In summary, a set  $S$  of untagged tableaux can be viewed either as

- (1) a set of Horn-clause rules,
- (2) a set of tgds, or
- (3) a mapping defined by the union of its tableaux.

Let  $S_1$  and  $S_2$  be two sets of untagged tableaux. The following are two important observations regarding the equivalence of  $S_1$  and  $S_2$ . First, the two sets are equivalent as sets of Horn-clause rules (i.e., they produce the same result for all instances) if and only if they are equivalent as sets of tgds. Second, if the two sets are equivalent as unions of tableaux, then they are also equivalent as sets of tgds (or Horn-clause rules), but the converse is not necessarily true. Equivalences among Horn-clause rules in more general cases are discussed in [Sa5].

**2.9. Composition of untagged tableaux.** Let  $T$  and  $V$  be untagged tableaux corresponding to either mappings or tgds. We will shortly describe how to construct a tableau  $V \circ T$ , called the *composition* of  $T$  and  $V$ , that has the following properties. If  $T$  and  $V$  are considered as mappings, then for all instances  $I$ ,  $V \circ T(I) = V(T(I))$ . If  $T$  and  $V$  are considered as dependencies, then  $V \circ T$  is equivalent to  $\{T, V\}$ , i.e.,  $V \circ T \models T, V$ .

First, we define the result of *substituting* a row  $w$  for the summary  $s$  of a tableau  $T$ , written  $T/w$ , as the tableau obtained in the following way. For each column  $A$ , we replace all occurrences of the distinguished variable  $s(A)$  with  $w(A)$ . Note that  $w$  becomes the summary of  $T/w$ . Next, we will describe how to construct  $V \circ T$ . Let  $w_1, \dots, w_n$  be the rows of  $V$ . We create  $n$  copies of  $T$ , denoted  $T_1, \dots, T_n$ , and in each copy we use variables that do not appear in any other copy. The tableau  $V \circ T$  has the summary of  $V$  and all the rows of the tableaux  $T_1/w_1, \dots, T_n/w_n$ . It is easy to prove that  $V \circ T$  has the above properties [BV1], [FMUY].

We will now consider the composition of a tableau  $T$  with itself, denoted  $T^2$ . At first, note that this composition can be viewed as taking a Horn-clause rule and replacing each predicate in the right-hand side with its definition. Next, we will show explicitly how  $T^2$  is constructed and develop a notation for its rows that will be used in later proofs. Let  $T_1, \dots, T_n$  be the copies of  $T$  as described above, and suppose that in all of them the rows  $w_1, \dots, w_n$  of  $T$  appear in the same order. We denote the rows of  $T_i/w_i$  as  $w_1^i, \dots, w_n^i$ . Tableau  $T^2$  consists of all the rows  $w_j^i (1 \leq i, j \leq n)$  and it has the same summary as  $T$ . Note that row  $w_j^i$  has in column  $A$  either

- (1) the same variable as row  $w_i$  (of  $T$ ) if row  $w_j$  has a distinguished variable in column  $A$ , or
- (2) a nondistinguished variable that appears only in  $w_1^i, \dots, w_n^i$  if row  $w_j$  has a nondistinguished variable in column  $A$ .

Thus, the variables of  $T^2$  are those of  $T$  and  $T_i$ .

*Example 2.3.* Let  $T$  be the following tableau, which was also considered in Example 2.2.

$a_1$	$a_2$	$a_3$	$a_4$
$a_1$	$a_2$	$b_1$	$b_2$
$e$	$a_2$	$a_3$	$b_3$
$e$	$a_2$	$b_4$	$a_4$

The rows of  $T$  are denoted, from top to bottom,  $w_1$ ,  $w_2$  and  $w_3$ . Note that  $e$  is the only repeated (i.e., appearing in more than one row) nondistinguished variable of  $T$ .

In order to construct  $T^2$ , we first create three copies of  $T$  with disjoint sets of variables.

$$T_1 = \begin{array}{|c|c|c|c|} \hline a_1^1 & a_2^1 & a_3^1 & a_4^1 \\ \hline a_1^1 & a_2^1 & b_1^1 & b_2^1 \\ e^1 & a_2^1 & a_3^1 & b_3^1 \\ e^1 & a_2^1 & b_4^1 & a_4^1 \\ \hline \end{array}, \quad T_2 = \begin{array}{|c|c|c|c|} \hline a_1^2 & a_2^2 & a_3^2 & a_4^2 \\ \hline a_1^2 & a_2^2 & b_1^2 & b_2^2 \\ e^2 & a_2^2 & a_3^2 & b_3^2 \\ e^2 & a_2^2 & b_4^2 & a_4^2 \\ \hline \end{array},$$

$$T_3 = \begin{array}{|c|c|c|c|} \hline a_1^3 & a_2^3 & a_3^3 & a_4^3 \\ \hline a_1^3 & a_2^3 & b_1^3 & b_2^3 \\ e^3 & a_2^3 & a_3^3 & b_3^3 \\ e^3 & a_2^3 & b_4^3 & a_4^3 \\ \hline \end{array}.$$

In each  $T_i$  we substitute  $w_i$  for the summary to obtain  $T_i/w_i$ . The resulting tableaux are as follows.

$$T_1/w_1 = \begin{array}{|c|c|c|c|} \hline a_1 & a_2 & b_1 & b_2 \\ \hline a_1 & a_2 & b_1^1 & b_2^1 \\ e^1 & a_2 & b_1 & b_3^1 \\ e^1 & a_2 & b_4^1 & b_2 \\ \hline \end{array}, \quad T_2/w_2 = \begin{array}{|c|c|c|c|} \hline e & a_2 & a_3 & b_3 \\ \hline e & a_2 & b_1^2 & b_2^2 \\ e^2 & a_2 & a_3 & b_3^2 \\ e^2 & a_2 & b_4^2 & b_3 \\ \hline \end{array},$$

$$T_3/w_3 = \begin{array}{|c|c|c|c|} \hline e & a_2 & b_4 & a_4 \\ \hline e & a_2 & b_1^3 & b_2^3 \\ e^3 & a_2 & b_4 & b_3^3 \\ e^3 & a_2 & b_4^3 & a_4 \\ \hline \end{array}.$$

$T^2$  has the nine rows of  $T_1/w_1$ ,  $T_2/w_2$  and  $T_3/w_3$ ; the summary is  $(a_1, a_2, a_3, a_4)$ . However,  $T^2$  can be minimized [ASU2], [CM], and the result is

$$\begin{array}{|c|c|c|c|} \hline a_1 & a_2 & a_3 & a_4 \\ \hline a_1 & a_2 & b_1^1 & b_2^1 \\ e^2 & a_2 & a_3 & b_3^2 \\ e^3 & a_2 & b_4^3 & a_4 \\ \hline \end{array}.$$

Note that  $T^2$  does not have repeated nondistinguished variables, namely, it is a project-join mapping (i.e., a join dependency). It is easy to show that if we compose  $T^2$  with itself, the result (after it is minimized) is the same as  $T^2$  (up to renaming of variables).

As another example, let  $V$  be the tableau

$a_1$	$a_2$
$a_1$	$b_1$
$b_2$	$b_1$
$b_2$	$a_2$

The following three tableaux are obtained after substituting each row of  $V$  for the summary of some copy of  $V$ :

$a_1$	$b_1$	$b_2$	$b_1$	$b_2$	$a_2$
$a_1$	$b_1^1$	$b_2$	$b_1^2$	$b_2$	$b_1^3$
$b_2^1$	$b_1^1$	$b_2^2$	$b_1^2$	$b_2^3$	$b_1^3$
$b_2^1$	$b_1$	$b_2^2$	$b_1$	$b_2^3$	$a_2$

$V^2$  has the nine rows of the above three tableaux, and its summary is  $(a_1, a_2)$ . No row of  $V^2$  can be removed by minimization. Essentially, if we continue to compose  $V$  with itself, we get a growing chain of the form

$$((a_1, b_1), (b_2, b_1), (b_2, b_3), \dots, (b_n, b_{n-1}), (b_n, a_2))/(a_1, a_2).$$

Note that each nondistinguished variable appears exactly twice. No two tableaux in the sequence  $V, V^2, V^3, \dots$  are equivalent as mappings, but they are all equivalent as tgds. As noted earlier, the composition of a tableau with itself always produces an equivalent tgd.

Recall that a tableau mapping is monotonic and, therefore,  $T \subseteq T^2$  (as the above example shows,  $T$  and  $T^2$  are not necessarily equivalent). Next, we will define two specific containment mappings from  $T^2$  to  $T$  that will be used later. The first, denoted  $\bar{\theta}$ , is defined for  $i, j$  by  $\bar{\theta}(w_j^i) = w_i$ . The second, denoted  $\underline{\theta}$ , is defined by  $\underline{\theta}(w_j^i) = w_j$ .

**PROPOSITION 2.1.** *Both  $\bar{\theta}$  and  $\underline{\theta}$  are containment mappings.*

*Proof.* The proof follows from observations (1) and (2) that were stated prior to Example 2.3. Suppose that  $w_j^i$  has a distinguished variable in column  $A$ , then so do  $w_i$  and  $w_j$ . Therefore, both  $\bar{\theta}$  and  $\underline{\theta}$  map distinguished variables to distinguished variables. Now suppose that  $w_j^i$  and  $w_k^m$  have the same variable  $b$  in column  $A$ . We claim that  $\bar{\theta}$  and  $\underline{\theta}$  map  $w_j^i$  and  $w_k^m$  to rows that have the same variable in column  $A$ .

**CASE 1.**  $b$  appears in  $T$ . In this case, both  $w_i$  and  $w_m$  must have  $b$  in column  $A$ , and both  $w_j$  and  $w_k$  must have a distinguished variable in column  $A$ . Thus, the claim is true.

**CASE 2.**  $b$  does not appear in  $T$ . In this case, by observation (2),  $i = m$ , and  $w_j$  and  $w_k$  have the same variable in column  $A$ . Thus,  $\bar{\theta}$  maps  $w_j^i$  and  $w_k^m$  to the same row, and  $\underline{\theta}$  maps them to rows that have the same variable in column  $A$ . Hence, the claim is true.  $\square$

### 3. Idempotent tableaux.

**3.1. Idempotency over all instances.** Let  $T$  be an untagged tableau mapping.  $T$  is *idempotent* if  $T \equiv T^2$ . In this section we will characterize idempotent tableaux, i.e., we will show that a tableau is idempotent if and only if it is a project-join mapping (i.e., a join dependency). Later we will use this result to show that a set  $D$  of tgds is bounded

if and only if it is equivalent to a join dependency. Note that a join dependency is not only bounded, but is also idempotent (i.e., its bound is 1).

**THEOREM 3.1.** *Let  $T$  be a minimal tableau. There is a homomorphism from  $T$  into  $T^2$  if and only if  $T$  is a project-join mapping (i.e., a join dependency).*

*Proof.* Let  $T$  be a minimal tableau which is not a project-join mapping. We will show that there is no homomorphism from  $T$  into  $T^2$ . Suppose that the claim is false and, so, let  $\psi$  be a containment mapping from the rows of  $T$  to the rows of  $T^2$ . Since  $T$  is not a project-join mapping, it has (by definition) a repeated nondistinguished variable  $b$ , i.e.,  $b$  appears in more than one row. Since  $\psi$  is a containment mapping from  $T$  into  $T^2$ , we can compose either  $\bar{\theta}$  or  $\theta$  with  $\psi$  in order to get a containment mapping from  $T$  to itself. The composed mappings are denoted  $\bar{\theta} \circ \psi$  and  $\theta \circ \psi$ . We will consider three cases depending upon the type of the variable to which  $\psi$  maps  $b$ , and contradict the minimality of  $T$  in each case.

**CASE 1.**  $\psi$  maps  $b$  to a distinguished variable. Thus,  $\bar{\theta} \circ \psi$  also maps  $b$  to a distinguished variable. If we compose  $\bar{\theta} \circ \psi$  with itself  $n$  times (where  $n$  is the number of rows of  $T$ ), we will get a containment mapping from  $T$  to itself whose image does not include any row having  $b$  (since a distinguished variable cannot be mapped to  $b$ ), and that contradicts the minimality of  $T$ .

**CASE 2.**  $\psi$  maps  $b$  to a nondistinguished variable that does not appear in  $T$ . In this case, the containment mapping  $\bar{\theta} \circ \psi$  maps all the rows that have  $b$  to a single row of  $T$ , in contradiction to the minimality of  $T$ .

**CASE 3.**  $\psi$  maps  $b$  to a nondistinguished variable of  $T$ . Suppose that  $b$  appears in column  $A$  of some row  $w_k$  of  $T$ , and  $\psi(w_k) = w_j^i$ . Since  $w_j^i$  has a variable of  $T$  in column  $A$ , it follows that  $w_j$  has a distinguished variable in column  $A$ . Therefore,  $\theta \circ \psi$  maps  $b$  to a distinguished variable and, consequently, the minimality of  $T$  is contradicted as in Case 1.

Since the minimality of  $T$  is contradicted in all these cases, it follows that there is no containment mapping from  $T$  to  $T^2$  if  $T$  has a repeated nondistinguished variable. Conversely, if  $T$  has no repeated nondistinguished variables (i.e., it is a project-join mapping), then  $T \equiv T^2$  [BMSU], and therefore there is a homomorphism from  $T$  into  $T^2$  [ASU1], [CM].  $\square$

It follows immediately from Theorem 3.1 that a minimal tableau  $T$  is idempotent if and only if it is a project-join mapping. In fact, it is easy to extend this result to idempotency over any set of instances  $C$  provided that the rows of  $T^2$  form an instance of  $C$ . This is shown in the next corollary.

**COROLLARY 3.1.** *Let  $T$  be a minimal untagged tableau.*

(1)  $T \equiv T^2$  if and only if  $T$  is a project-join mapping (i.e., a join dependency).

(2) Let  $C$  be a set of instances, and suppose that the rows of  $T^2$  form an instance of  $C$ . Then  $T \equiv_C T^2$  if and only if  $T$  is a project-join mapping.

*Proof.* At first, note that (1) is a special case of (2) (simply choose  $C$  to be the set of all instances). Thus, it remains to prove (2). If  $T$  is a project-join mapping, then there is a homomorphism from  $T$  into  $T^2$  (by Theorem 3.1) and hence  $T \equiv_C T^2$  (for any  $C$ ). If  $T \equiv_C T^2$  and the rows of  $T^2$  form an instance of  $C$ , then we can show as in [ASU1] that there is a homomorphism from  $T$  into  $T^2$ , and hence by Theorem 3.1,  $T$  is a project-join mapping.  $\square$

**3.2. Idempotency over consistent instances.** When a database scheme has egds as well as tgds, the only instances of interest are the consistent ones. Consequently, we would like to characterize the tableaux that are idempotent over  $CON(D)$ , where  $D$  is a set of tgds and egds. It may seem at first that Corollary 3.1 characterizes idempotency

over any set of instances  $C$ . However, the characterization of Corollary 3.1 applies to a tableau  $V$  only when the rows of  $V^2$  form an instance of  $C$ . This does not present a problem when  $D$  has only tgds, since  $CON(D)$  includes all instances when there are no egds. However, when there are egds, the rows of  $V^2$  do not necessarily form a consistent instance<sup>5</sup> of  $D$ . In order to overcome this difficulty, we will introduce a tableau  $\bar{V}$  (to be defined shortly), such that

- (1)  $V \equiv_{CON(D)} \bar{V}$ , and
- (2) the rows of  $\bar{V}^2$  form a consistent instance of  $D$ .

In fact, we need an additional assumption that states that  $V$  is a lossless tableau, i.e.,  $D \models V$ . This assumption is a reasonable one, since only lossless tableaux correspond to semantically correct queries (we will further discuss this point in § 4). The above properties of  $V$  and  $\bar{V}$  imply the following. By (2), the characterization of Corollary 3.1 applies to  $\bar{V}$ . Moreover, as we shall prove shortly,  $V$  is idempotent over  $CON(D)$  if and only if it is equivalent over  $CON(D)$  to  $\bar{V}$ , which must also be idempotent. Therefore,  $V$  is idempotent over  $CON(D)$  if and only if  $V$  is equivalent over  $CON(D)$  to a project-join mapping. Before we formally prove all these facts in the next theorem, we will define  $\bar{V}$ .

Tableau  $\bar{V}$  is the *equality chase* of  $V$  with respect to  $D$ , written  $ECHASE_D(V)$ . Tableau  $ECHASE_D(V)$  is obtained from  $V$  by equating variables of  $V$  whenever they are equated in  $CHASE_D(V)$ . In other words,  $ECHASE_D(V)$  is the result of computing  $CHASE_D(V)$  and then deleting the rows that were added during the chase. At first, we will show that  $V$  and  $ECHASE_D(V)$  are equivalent over  $CON(D)$ .

**PROPOSITION 3.1.** *The set of rows of  $ECHASE_D(V)$  is a consistent instance of  $D$ , and  $ECHASE_D(V) \equiv_{CON(D)} V$ .*

*Proof.* The set of rows of  $ECHASE_D(V)$  is a consistent instance of  $D$ , since (by definition) no variables are equated when it is chased with  $D$ .

We will now prove the equivalence of  $V$  and  $ECHASE_D(V)$  over  $CON(D)$ . At first, we will show that if  $I$  is a consistent instance of  $D$ , then every tuple of  $V(I)$  is also in  $ECHASE_D(V)(I)$ . So, suppose that  $h$  is a valuation of  $V$  into  $I$ , and let  $w$  and  $u$  be rows of  $V$ . If the variables in column  $A$  of these rows become equal in  $ECHASE_D(V)$ , then  $h(w)$  and  $h(u)$  must be equal on  $A$ , because  $I$  is a consistent instance of  $D$  (see [ASU1], [MMS] for a more detailed proof of this fact). Therefore,  $h$  is also a valuation of  $ECHASE_D(V)$  into  $I$  and, so, every tuple in  $V(I)$  is also in  $ECHASE_D(V)(I)$ . Thus, we have shown that for all  $I \in CON(D)$ ,  $V(I) \subseteq ECHASE_D(V)(I)$ . Containment in the other direction follows from the fact that there is a homomorphism of  $V$  into  $ECHASE_D(V)$ , since equalities among rows of  $V$  are preserved in  $ECHASE_D(V)$ . Thus,  $ECHASE_D(V) \equiv_{CON(D)} V$ .  $\square$

The next theorem shows that a lossless tableau  $V$  is idempotent over  $CON(D)$  if and only if  $ECHASE_D(V)$  is idempotent over  $CON(D)$ . It is also shown that the characterization of Corollary 3.1 applies to  $ECHASE_D(V)$ . Therefore, by the equivalence of  $V$  and  $ECHASE_D(V)$  over  $CON(D)$ , tableau  $V$  is idempotent over  $CON(D)$  if and only if it is equivalent to a project-join mapping over  $CON(D)$ .

**THEOREM 3.2.** *Let  $D$  be a set of egds and tgds, and  $V$  be an untagged tableau such that  $D \models V$ . We denote  $ECHASE_D(V)$  by  $\bar{V}$ . The following are equivalent:*

- (1)  $V \equiv_{CON(D)} V^2$ .
- (2)  $\bar{V} \equiv_{CON(D)} \bar{V}^2$ .
- (3) *When  $\bar{V}$  is minimized, the result is a project-join mapping.*

<sup>5</sup> Note that the rows of a tableau  $T$  form a consistent instance of  $D$  if no variables are equated during  $CHASE_D(T)$ .

*Proof.* Suppose that  $\bar{V}$  is minimal. At first, we will show that  $V \equiv_{CON(D)} V^2$  if and only if  $\bar{V} \equiv_{CON(D)} \bar{V}^2$ . Let  $I \in CON(D)$ . By Proposition 3.1,

$$(A) \quad \bar{V}(I) = V(I).$$

Since  $D \models V$ , it follows (by [MMS]) that  $CHASE_D(V(I)) = CHASE_D(I)$  and, therefore,  $V(I)$  is also a consistent instance of  $D$  (since no constants are equated during the chase of  $I$ ). Thus, Proposition 3.1 implies

$$(B) \quad \bar{V}^2(I) = V^2(I).$$

By (A) and (B),  $V \equiv_{CON(D)} V^2$  if and only if  $\bar{V} \equiv_{CON(D)} \bar{V}^2$ .

Next, we will show that  $\bar{V}^2 \in CON(D)$  (i.e., the rows of  $\bar{V}^2$  form a consistent instance of  $D$ ). By Corollary 3.1, that will prove that (2) and (3) are equivalent. Let  $(w_1, \dots, w_n)$  be the rows of  $\bar{V}$ , and  $(w_j^i)$  be the rows<sup>6</sup> of  $\bar{V}^2$ . Clearly,  $\bar{V} \in CON(D)$ . Suppose that  $\bar{V}^2 \notin CON(D)$ , that is, when we compute  $CHASE_D(\bar{V}^2)$ , two variables of  $\bar{V}^2$ , say  $a$  and  $b$ , are equated. Thus,  $D \models (w_j^i)/a = b$ . We will show that (the rows of)  $CHASE_D(\bar{V})$  violates  $(w_j^i)/a = b$ , which contradicts the fact that  $D \models (w_j^i)/a = b$  (because  $CHASE_D(\bar{V})$  satisfies  $D$ ) and, hence, completes the proof.

CASE 1. Both  $a$  and  $b$  are variables of  $\bar{V}^2$  that appear also in  $\bar{V}$ . Consider  $\bar{\theta}$  as a valuation of  $\bar{V}^2$  into  $\bar{V}$ . Since  $\bar{V} = ECHASE_D(V)$ , no variables are equated during the chase of  $\bar{V}$ , and so  $\bar{\theta}$  is also a valuation of  $\bar{V}^2$  into  $CHASE_D(\bar{V})$  that maps  $a$  and  $b$  to distinct variables of  $CHASE_D(\bar{V})$  (since in this case each one of  $a$  and  $b$  is mapped to itself). Therefore,  $\bar{\theta}$  is a valuation showing that  $CHASE_D(\bar{V})$  violates  $(w_j^i)/a = b$ .

CASE 2. At most one of  $a$  and  $b$  appears also in  $\bar{V}$ . If there is an  $i$ , such that  $a$  and  $b$  appear in rows  $w_j^i$  and  $w_k^i$ , respectively, then  $\bar{\theta}$  maps  $a$  and  $b$  to distinct variables. If there is no  $i$  satisfying the above condition, then there are two subcases to be considered.

SUBCASE 1. Exactly one of  $a$  and  $b$ , say  $a$ , appears also in  $\bar{V}$ . In this case,  $\bar{\theta}$  maps  $a$  to a distinguished variable and  $b$  to a nondistinguished variable.

SUBCASE 2. Neither  $a$  nor  $b$  is in  $\bar{V}$ . By the assumption leading to the two subcases, there are  $w_j^i$  and  $w_k^m$  that contain  $a$  and  $b$ , respectively, and  $i \neq m$ . We define a valuation  $h$  by mapping all the rows  $w_q^p$  ( $p \neq i$  and  $1 \leq q \leq n$ ) using  $\bar{\theta}$ , and mapping the rows  $w_1^i, \dots, w_n^i$  to the row of  $CHASE_D(\bar{V})$  consisting of all the distinguished variables (since  $D \models V$ , this row exists). Since  $h$  maps  $a$  and  $b$  to a distinguished variable and a nondistinguished variable, respectively, the desired violation is shown. It remains to be proved that  $h$  is indeed a valuation. Suppose that rows  $w_q^p$  ( $p \neq i$ ) and  $w_k^i$  have the same variable  $v$  in some column  $A$ . Since  $v$  appears in both  $w_q^p$  and  $w_k^i$  and  $p \neq i$ , it follows that  $w_q^p$  has a distinguished variable in column  $A$ . Thus, both  $w_q^p$  ( $p \neq i$ ) and  $w_k^i$  are mapped to rows having the same variable in column  $A$ . Clearly,  $h$  preserves equalities among any pair of rows  $w_q^p$  and  $w_k^m$  whenever both  $p$  and  $m$  are either equal or not equal to  $i$ , since  $\bar{\theta}$  is a containment mapping and rows  $w_1^i, \dots, w_n^i$  are mapped to a single row. Hence, we have shown that  $h$  is indeed a valuation.  $\square$

#### 4. Computing restricted projections of representative instances.

**4.1. Bounded database schemes.** There are two modes of retrieving information from a database. Either the information is found in a single relation, or it has to be obtained by joining tuples of various relations. The first mode is conceptually easy, whereas the second requires either the user or the system to determine which joins are correct. Correctness of joins is based on the semantics of the database scheme, which

<sup>6</sup> We write  $(w_j^i)$  instead of  $(w_1^i, \dots, w_n^i)$ .

is described by the dependencies. Since dependencies are formal statements in first-order logic, they can be used to infer formally all the tuples that are obtained by correct joins. In fact, this is exactly what happens during the chase that generates the representative instance  $RI(r_1, \dots, r_n)$ . The chase starts with  $A(r_1, \dots, r_n)$ , which consists of all the tuples of  $r_1, \dots, r_n$  (after they have been augmented with nulls), and generates new tuples from existing ones (either by adding tuples or equating symbols). The generation of new tuples amounts to correctly (or losslessly) joining existing tuples according to the dependencies of the database scheme. Therefore, the representative instance  $RI(r_1, \dots, r_n)$  contains all the data that is either in the relations  $r_1, \dots, r_n$  or can be inferred by correct joins. Clearly, the conclusion that the representative instance gives the complete picture of the data is based only on the premise that the dependencies fully describe the semantics of the database scheme.

Of course, the dependencies are stated for a universal relation scheme consisting of all the attributes. This is appropriate when the relation schemes are the result of decomposing one universal relation scheme  $R$  (which consists of all the attributes). If this is not the case, then our results apply to each group of relation schemes obtained by decomposing a bigger relation scheme. Since decomposition is a common tool in designing database schemes, our results are relevant in practice. To simplify the discussion, we will continue to consider a database scheme  $([R_1, \dots, R_n], D)$  in which all the relation schemes  $R_1, \dots, R_n$  have been obtained by decomposing one universal relation scheme  $R$ .

So far, we have concluded that the representative instance contains all the data that can be inferred from the database. Consequently, queries should be evaluated according to the representative instance and, so, they may as well be formulated in terms of the universal relation scheme  $R$  rather than  $R_1, \dots, R_n$ . Before going on with the discussion of query evaluation, we will further explain why formulation in terms of  $R$  is natural and easy. It is well known that decomposition is intended to remove certain operational (i.e., update and storage) anomalies, and it does so while preserving the semantics of the database scheme (cf. [U1]). Thus,  $R_1, \dots, R_n$  and  $R$  have the same semantics and so, in principle, any query can be formulated either in terms of  $R_1, \dots, R_n$  or in terms of  $R$ . There are, however, substantial differences between the two formulations. First, formulating a query in terms of  $R_1, \dots, R_n$  is generally more cumbersome, since the query should specify how to join the  $R_i$  (unless it refers to only one of the  $R_i$ ). In comparison, many queries that refer to attributes of several  $R_i$  can be formulated in terms of  $R$  using only projection and selection. Second, sometimes it is just impossible to formulate a query in terms of  $R_1, \dots, R_n$  in relational algebra (i.e., in first-order logic), whereas the same query can be formulated in terms of  $R$  using projection alone. The reason for that is the fact that the chase process is recursive,<sup>7</sup> and recursion cannot be expressed in relational algebra. In this paper we essentially investigate when a project query on  $R$  can also be expressed in terms of  $R_1, \dots, R_n$  in relational algebra.

We will now explain how to evaluate a query according to the representative instance. If a query refers to a set of attributes  $X$ , then it should be evaluated, in principle, according to the projection of  $RI(r_1, \dots, r_n)$  onto  $X$ . However, since  $\pi_X(RI(r_1, \dots, r_n))$  may still have nulls that were introduced during the computation

---

<sup>7</sup> A common misconception is the belief that a fixed number of joins describes all the lossless joins among relation schemes  $R_1, \dots, R_n$ . This is not true even if there are only functional dependencies [MUV]. In general, the chase is the only method for joining tuples losslessly in all possible ways, and that requires a number of iterations that depend on the actual relations  $r_1, \dots, r_n$ .

of the representative instance, it is probably not the most suitable choice. A more natural choice is the *restricted projection* of  $RI(r_1, \dots, r_n)$  onto  $X$ , denoted  $\pi \downarrow_X (RI(r_1, \dots, r_n))$ , which is defined to be the projection of  $RI(r_1, \dots, r_n)$  onto  $X$  followed by the elimination of all the tuples with nulls in some columns.

Since a query that refers to  $X$  is evaluated according to  $\pi \downarrow_X (RI(r_1, \dots, r_n))$ , a desirable property of a database scheme is the ability to compute efficiently restricted projections of the representative instance. Of course, we can always perform the chase on  $A(r_1, \dots, r_n)$ , which is the initial instance created by augmenting the database relations with nulls, but that involves all the data in the database and, consequently, is time consuming. An alternative approach is to look for an expression  $E_X$  in relational algebra, such that for all consistent states  $r_1, \dots, r_n$ ,

$$E_X(r_1, \dots, r_n) = \pi \downarrow_X (RI(r_1, \dots, r_n)).$$

Note that the operands of  $E_X$  are only the relations  $r_1, \dots, r_n$ , and not the representative instance itself; the operators of  $E_X$  are the ordinary operators of relational algebra. If  $E_X$  satisfies the above condition, then we say that  $E_X$  *computes*  $\pi \downarrow_X (RI(r_1, \dots, r_n))$ . Hopefully, if  $E_X$  exists and can be constructed, then it might be optimized by known techniques and evaluated in considerably less time than required to perform the chase on  $A(r_1, \dots, r_n)$ .

Maier et al. [MUV] have shown that for unrestricted databases if there is a relational algebra expression that computes  $\pi \downarrow_X (RI(r_1, \dots, r_n))$ , then there is also a (finite) union of (tagged) tableaux  $\cup_{i=1}^m T_i$  that computes  $\pi \downarrow_X (RI(r_1, \dots, r_n))$ . Not surprisingly, the tableaux in this union (when considered as tgds) are all lossless, i.e.,  $D \models T_1, \dots, T_m$ . Maier et al. [MUV] have also shown that for finite databases the following two conditions are equivalent:

- (1) For all  $X$ , there is a union of tableaux that computes  $\pi \downarrow_X (RI(r_1, \dots, r_n))$ .
- (2) The database scheme  $([R_1, \dots, R_n], D)$  is bounded.

Boundedness of the database scheme is similar, but not identical, to boundedness of  $D$ , which was defined in § 2.8 (boundedness of the database scheme depends on both  $D$  and  $R_1, \dots, R_n$ , and is formally defined in [MUV]). However, when  $D$  has only full tgds, our results imply that the two are the same, i.e., (1) is equivalent to the following:

- (2') The set of dependencies  $D$  is bounded.

In the next section, we will show that a set of tgds  $D$  is bounded if and only if it is equivalent to a join dependency. We will also show that this condition is decidable. In § 6, we will consider database schemes with both tgds and egds, and give a necessary condition for the existence of a union of tableaux that computes  $\pi \downarrow_U (RI(r_1, \dots, r_n))$ . This condition states that the set of dependencies is equivalent to a single join dependency and some egds; and the condition is decidable. Thus, a database scheme cannot be bounded unless the effect of its tgds is equivalent to that of a single join dependency (i.e., the tgds are equivalent to a join dependency over all consistent instances). In obtaining these results, we assume that the database scheme is lossless, i.e.,  $D \models R_i$ . This assumption is reasonable, since a database scheme has to be lossless in order to reconstruct tuples over all the attributes whose projections are stored in the database (in other words, unless the database scheme is lossless,  $\pi \downarrow_U (RI(r_1, \dots, r_n))$  is always empty [MUV]).

**4.2. Idempotency of tableaux computing restricted projections.** In this section, we consider a lossless database scheme  $([R_1, \dots, R_n], D)$  with a set  $D$  of full tgds and egds. We will show that if  $\pi \downarrow_U (RI(r_1, \dots, r_n))$  is computed by a union of tagged tableaux  $\cup_{i=1}^m T_i$ , then  $\cup_{i=1}^m T_i$  is idempotent over  $CON(D)$ , which is the set of all

consistent instances of  $D$ . In fact,  $\bigcup_{i=1}^m T_i$  is equivalent to a single idempotent tableau over  $CON(D)$ .

In the following proofs, we will use  $T$  to denote the composition of the  $T_i$ , i.e., we start by composing  $T_1$  and  $T_2$ , then composing the result with  $T_3$ , and so on, until we get  $T$ . Note that when we compose the  $T_i$ , we ignore the tags and  $T$  is an untagged tableau. The following lemma of [MUV] states that any union of tableaux that computes a restricted projection consists of lossless tableaux.

LEMMA 4.1. [MUV]. *Let  $([R_1, \dots, R_n], D)$  be a database scheme with tgds and egds. Suppose that  $\bigcup_{i=1}^m T_i$  computes  $\pi \downarrow_X (RI(r_1, \dots, r_n))$ . When the  $T_i$  are considered as dependencies,<sup>8</sup>  $D \models T_1, \dots, T_m$ .*

The next lemma describes fundamental properties of any union of tableaux  $\bigcup_{i=1}^m T_i$  and the composition  $T$  of its tableaux.

LEMMA 4.2. [BV1], [FMUY]. *Let  $\bigcup_{i=1}^m T_i$  be any union of tableaux, and  $T$  be the result of composing  $T_1, \dots, T_m$ .*

$$(1) \quad T \models T_1, \dots, T_m, \text{ and}$$

$$(2) \quad \bigcup_{i=1}^m T_i \subseteq T.$$

Note that in (1), all tableaux are considered as dependencies, and in (2), as untagged tableau mappings.

We will now prove the main lemma of this section.

LEMMA 4.3. *Let  $([R_1, \dots, R_n], D)$  be a database scheme with full tgds and egds. If  $\bigcup_{i=1}^m T_i$  computes  $\pi \downarrow_U (RI(r_1, \dots, r_n))$ , then  $T \equiv_{CON(D)} T^2$ , where  $T$  is the composition of the  $T_i$ .*

*Proof.* Let  $\rho = (r_1, \dots, r_n)$  be any consistent state of  $D$ . By our assumption

$$(1) \quad \pi \downarrow_U (RI(\rho)) = \bigcup_{i=1}^m T_i(\rho).$$

By the definition of the application of tableaux to instances and states

$$(2) \quad \bigcup_{i=1}^m T_i(\rho) \subseteq \pi \downarrow_U \left( \bigcup_{i=1}^m T_i(A(\rho)) \right)$$

where the  $T_i$  are considered with tags on the left-hand side, and without tags on the right-hand side. Since  $\bigcup_{i=1}^m T_i \subseteq T$  and  $T$  (as a dependency) is implied by  $D$  (by Lemmas 4.1 and 4.2), we get

$$(3) \quad \pi \downarrow_U \left( \bigcup_{i=1}^m T_i(A(\rho)) \right) \subseteq \pi \downarrow_U (T(A(\rho))) \subseteq \pi \downarrow_U (RI(\rho)).$$

It follows from equations (1)-(3)

$$(4) \quad \pi \downarrow_U (RI(\rho)) = \pi \downarrow_U (T(A(\rho))).$$

For each row  $w$  of  $T$  there is an  $R_i$ , such that  $w$  has distinguished or repeated nondistinguished variables only in the columns of  $R_i$  (since  $T$  is the composition of tagged tableaux). Consequently, for all universal instances  $I \in CON(D)$ ,

$$(5) \quad T(I) = \pi \downarrow_U (T(A(\pi_{R_1}(I), \dots, \pi_{R_n}(I)))).$$

It follows from (4) and (5) that for all instances  $I \in CON(D)$ ,

$$(6) \quad T(I) = \pi \downarrow_U (RI(\pi_{R_1}(I), \dots, \pi_{R_n}(I))).$$

<sup>8</sup> Note that when  $X \neq U$ , the  $T_i$  are not full tableaux. Although we do not consider embedded dependencies in this paper, the meaning of the lemma should be clear. We are going to use the lemma only when  $X = U$ .

By Lemmas 4.1 and 4.2,  $D \models T$  and, so, for all instances of  $I \in \text{CON}(D)$ , we have  $T(I) = T(T(I))$  (otherwise, (6) cannot hold).  $\square$

**COROLLARY 4.1.** *Let  $\bigcup_{i=1}^m T_i$  and  $T$  be as in Lemma 4.3.*

(1)  $\bigcup_{i=1}^m T_i \equiv_{\text{CON}(D)} T$ .

(2) *If  $\text{CON}(D)$  is the set of all instances, then there exists a  $T_i$  such that  $T_i \equiv T$ .*

*Proof.* Similarly to (6), we can also show that  $\bigcup_{i=1}^m T_i(I) = \pi \downarrow_U (RI(\text{state}(I)))$  for all instances  $I \in \text{CON}(D)$  and, thus, (1) is true. Condition (2) follows from (1) by the results of [SY].  $\square$

**5. Database schemes with full tuple-generating dependencies.** In this section, we consider a lossless database scheme  $([R_1, \dots, R_n], D)$  where  $D$  consists of only full tgds. We will show that there is a union of tableaux  $\bigcup_{i=1}^m T_i$  that computes  $\pi \downarrow_U (RI(r_1, \dots, r_n))$  if and only if  $D$  is equivalent to a join dependency. There are two interesting corollaries of this result. First, if there is a union of tableaux that computes  $\pi \downarrow_U (RI(r_1, \dots, r_n))$ , then for all  $X \subseteq U$ , there is a union of tableaux that computes  $\pi \downarrow_X (RI(r_1, \dots, r_n))$ . Second,  $D$  is bounded if and only if it is equivalent to a join dependency.

Note that since  $D$  has only tgds,  $\text{CON}(D)$  is the set of all instances (without nulls). In the following proofs, we will replace  $D$  with a single equivalent tgd  $d$  by composing the tableaux of the tgds of  $D$  (by Lemma 4.2, this composition results in a tgd equivalent to  $D$ ). The first theorem in this section shows that when  $D$  has only tgds, and there is a union of tableaux  $\bigcup_{i=1}^m T_i$  that computes  $\pi \downarrow_U (RI(r_1, \dots, r_n))$ , then  $T_1, \dots, T_m$  are not only implied by  $D$  (as shown in Lemma 4.1), but actually are equivalent to  $D$ .

**THEOREM 5.1.** *Suppose that  $([R_1, \dots, R_n], D)$  is a lossless database scheme, where  $D$  consists of only full tgds. If  $\bigcup_{i=1}^m T_i$  is a union of tableaux that computes  $\pi \downarrow_U (RI(r_1, \dots, r_n))$ , then  $T_1, \dots, T_m \models D$ .*

*Proof.* Since the database scheme is lossless,  $\pi \downarrow_U (RI(\text{state}(I))) = \text{CHASE}_{\{d\}}(I)$  for all instances  $I$  (without nulls). In particular, we can view the rows of  $d$  as an instance, and since  $\text{CHASE}_{\{d\}}(d)$  contains a row with only distinguished variables, so does  $\bigcup_{i=1}^m T_i(\text{state}(d))$  ( $\text{state}(d)$  is the state generated by the set of rows of  $d$ ). Thus,  $T_1, \dots, T_m \models d$ . The other direction follows from Lemma 4.1.  $\square$

We will now prove the main theorem of this section.

**THEOREM 5.2.** *Let  $([R_1, \dots, R_n], D)$  be a lossless database scheme, where  $D$  is a set of full tgds. The following are equivalent:*

- (1) *For all  $X \subseteq U$ , there is a union of tableaux that computes  $\pi \downarrow_X (RI(r_1, \dots, r_n))$ .*
- (2) *There is a union of tableaux that computes  $\pi \downarrow_U (RI(r_1, \dots, r_n))$ .*
- (3)  *$D$  is equivalent to a single join dependency.*

*Moreover, the above conditions are decidable; and when they hold there is an algorithm that constructs the join dependency to which  $D$  is equivalent, and an algorithm that constructs for all  $X \subseteq U$ , a union of tableaux that computes  $\pi \downarrow_X (RI(r_1, \dots, r_n))$ .*

*Proof.* Clearly, (1) implies (2).

Now suppose that (2) is true, and we will show that (3) is true as well. So, let  $\bigcup_{i=1}^m T_i$  be a union of tableaux that computes  $\pi \downarrow_U (RI(r_1, \dots, r_n))$ , and let  $T$  be obtained by taking the composition of the  $T_i$  and then minimizing it. By Lemma 4.3 and Corollary 3.1,  $T$  is a join dependency, and by Theorem 5.1 and Lemma 4.2,  $T$  is equivalent to  $D$ . Thus, (2) implies (3).

The proof that (3) implies (1) follows from [Sa4]. In particular, when  $D$  consists of a single join dependency, then for every  $X \subseteq U$ , we can construct in exponential time (in the size of the database scheme alone) a union of tableaux that computes

$\pi \downarrow_X (RI(r_1, \dots, r_n))$  [Sa4]. If  $D$  consists of the join dependency  $\bowtie R_i$ , then we can construct in polynomial time an expression that computes  $\pi \downarrow_X (RI(r_1, \dots, r_n))$  [Sa1], [Sa4]. The only operators in this expression are project, join, and union and, so, it can be converted into a union of tableaux in exponential time [SY], but there is really no need to do that in order to evaluate it efficiently.

We have shown that the three conditions are equivalent, and expressions can be constructed when  $D$  consists of a single join dependency. Now we will show how to test whether  $D$  is equivalent to a join dependency, and how to find this join dependency when it exists. Recall that  $d$  is obtained from  $D$  by composing the tgds of  $D$  in some arbitrary order. Let  $J(d)$  be the join dependency obtained from  $d$  by replacing all occurrences of repeated nondistinguished variables with new distinct nondistinguished variables. We claim that if  $j$  is a join dependency such that  $d \models j$ , then  $d \models J(d)$ . First, we show that  $j \models J(d)$ . Since  $j$  is a join dependency, a single application of the chase rule for  $j$  shows that  $j \models d$  (because  $j$  is idempotent). Therefore, there is a valuation  $h$  of  $j$  into  $d$  that maps each distinguished variable of  $j$  to a distinguished variable of  $d$ , since  $CHASE_{\{j\}}(d)$  contains the row consisting of all the distinguished variables (because  $j \models d$ ). Clearly,  $h$  is also a valuation of  $j$  into  $J(d)$  that maps distinguished variables to distinguished variables and, hence, shows that  $j \models J(d)$ .

By mapping each row of  $J(d)$  to its corresponding row in  $d$ , we get a valuation that maps distinguished variables to distinguished variables and, thus,  $J(d) \models d$ . By our assumption,  $d \models j$ . Thus, we have shown that  $j \models J(d) \models d \models j$  and, so,  $d$  and  $J(d)$  are equivalent, as claimed. Consequently, in order to test whether  $D$  is equivalent to a join dependency, we construct  $d$  and then  $J(d)$ , and test whether  $d \models J(d)$  (note that  $J(d) \models d$  is always true).  $\square$

The following example shows that even if a tgd is equivalent to a join dependency, it is not necessarily a join dependency.

*Example 5.1.* Let  $d$  be the following tgd (which is the same as tableau  $T$  of Example 2.3). Note that the tableau of  $d$  is minimal.

$a_1$	$a_2$	$a_3$	$a_4$
$a_1$	$a_2$	$b_1$	$b_2$
$e$	$a_2$	$a_3$	$b_3$
$e$	$a_2$	$b_4$	$a_4$

The tgd  $d$  is equivalent to  $J(d)$ , which is the following join dependency:

$a_1$	$a_2$	$a_3$	$a_4$
$a_1$	$a_2$	$b_1$	$b_2$
$e^2$	$a_2$	$a_3$	$b_3$
$e^3$	$a_2$	$b_4$	$a_4$

Recall that in Example 2.3, tableau  $J(d)$  was obtained after minimizing the composition of  $d$  with itself. Thus,  $d$  and  $J(d)$  are indeed equivalent.

We can also show that  $d \models J(d)$  by considering the computation of  $CHASE_{\{d\}}(J(d))$ . The computation starts with the rows of  $J(d)$ . At first, we can map the first row of  $d$  to the first row of  $J(d)$ , and the last two rows of  $d$  to the second row of  $J(d)$ , and that application generates the row

$$(A) \quad (a_1, a_2, a_3, b_3).$$

Next, we can map the first row of  $d$  to the first row of  $J(d)$ , and the last two rows of  $d$  to the third row of  $J(d)$ , and obtain the row

$$(B) \quad (a_1, a_2, b_4, a_4).$$

Now the first row of  $d$  can be mapped to the first row of  $J(d)$ , the second row to (A), and the third to (B), and the result is

$$(a_1, a_2, a_3, a_4)$$

which shows that  $d \equiv J(d)$ . Obviously,  $J(d) \equiv d$  and, thus, the two are equivalent.

As discussed in § 2.8, the following corollary is important in deductive databases, where tgds are viewed as Horn-clause rules:

**COROLLARY 5.1.** *Suppose that  $D$  is a set of full tgds. The following are equivalent and decidable.*

- (1)  $D$  is bounded, i.e., there is a  $k$ , such that for all instances  $I$ , the computation of  $CHASE_D(I)$  takes  $k$  or fewer iterations.
- (2) There is a union of tableaux  $E$  such that for all instances  $I$ ,  $E(I) = CHASE_D(I)$ .
- (3)  $D$  is equivalent to a single join dependency.

*Proof.* In order to prove the theorem, we consider the special database scheme  $([U], D)$ , i.e., this database scheme has a single relation scheme consisting of all the attributes. A database state for this database scheme is any instance  $I$ . The representative instance of  $I$  is just  $CHASE_D(I)$ , and that is also the restricted projection of the representative instance onto  $U$ .

Boundedness of  $D$  coincides with boundedness of the database scheme  $([U], D)$ , as defined in [MUV]. Thus, by the results of [MUV], condition (1) of Theorem 5.2 is equivalent to (1) of this corollary. Therefore, by Theorem 5.2, (1), (2) and (3) are equivalent and decidable.  $\square$

**6. Database schemes with full tgds and egds.** In this section we consider a lossless database scheme  $([R_1, \dots, R_n], D)$ , where  $D$  consists of full tgds and egds. We will show that if there is a union of tagged tableaux  $\bigcup_{i=1}^m T_i$  that computes  $\pi \downarrow_U (RI(r_1, \dots, r_n))$ , then  $D$  is equivalent to a join dependency and some egds (i.e.,  $D$  is equivalent to a join dependency over all consistent instances). We will also show that this necessary condition is decidable.

Let  $E$  be the set of all the egds in  $D$ . All the tgds in  $D$  can be replaced with a single equivalent tgd  $d$ , as done in the previous section. Thus,  $D$  is equivalent to  $\{d\} \cup E$ . The next theorem shows that  $\{d\} \cup E$  can be replaced with an equivalent set in which the only tgd is  $ECHASE_D(d)$ .

**THEOREM 6.1.** *Let  $B$  be a set of dependencies consisting of a tgd  $t$  and a set of egds  $F$ . There is a set of egds  $G$  (that can be constructed effectively) such that*

$$ECHASE_B(t), F, G \equiv t, F.$$

*Proof.* Let  $(w_1, \dots, w_n)$  be the rows of  $t$ .  $G$  consists of all egds  $(w_1, \dots, w_n)/a = b$ , where  $a$  and  $b$  are equated in  $CHASE_B(t)$ .  $\square$

Since the rows of  $ECHASE_D(d)$  form a consistent instance of  $D$ , we can show that  $D$  is equivalent to some egds and the tgds  $T_1, \dots, T_m$ .

**THEOREM 6.2.** *Suppose that  $([R_1, \dots, R_n], D)$  is a lossless database scheme, and there is a union of tagged tableaux  $\bigcup_{i=1}^m T_i$  that computes  $\pi \downarrow_U (RI(r_1, \dots, r_n))$ . Let  $E$  be the set of all egds in  $D$ , and  $d$  be the composition of all the tgds in  $D$ . The following are equivalent:*

- (1) There is a set of egds  $G_1$ , such that  $ECHASE_D(d), E, G_1 \equiv d, E$ .
- (2)  $T_1, \dots, T_m \equiv ECHASE_D(d)$ .
- (3)  $T_1, \dots, T_m, E, G_1 \equiv D$ .

*Proof.* Part (1) follows from Theorem 6.1. Part (2) follows from the fact that the rows of  $ECHASE_D(d)$  form a consistent instance, using the same argument as in the proof of Theorem 5.1. Part (3) follows from parts (1) and (2), and Lemma 4.1.  $\square$

We will now prove the main theorem of this section.

**THEOREM 6.3.** *Consider a lossless database scheme  $([R_1, \dots, R_n], D)$  with egds and full tgds. Suppose that  $\bigcup_{i=1}^m T_i$  is a union of tableaux that computes  $\pi \downarrow_U (RI(r_1, \dots, r_n))$ . Then  $D$  is equivalent to a set consisting of a single join dependency and some equality-generating dependencies. Moreover, this condition is decidable.*

*Proof.* Let  $T$  be the pairwise composition of the  $T_i$ , and recall that  $CON(D)$  is the set of all consistent instances of  $D$ . By Lemma 4.3,  $T \equiv_{CON(D)} T^2$  and, so, by Theorem 3.2,  $ECHASE_D(T)$  (after it is minimized) is a join dependency. By part (1) of Lemma 4.2 and part (3) of Theorem 6.2, there is a set of egds  $G_1$ , such that  $T, E, G_1 \models D$ . Therefore, by Theorem 6.1, there is a set of egds  $G_2$ , such that  $ECHASE_D(T), E, G_1, G_2 \models D$ .

We have shown that  $D$  is equivalent to a single join dependency and some egds when  $\pi \downarrow_U (RI(r_1, \dots, r_n))$  is computed by a union of tableaux. Next, we will show how to test whether  $D$  satisfies this necessary condition, i.e., whether  $D$  is equivalent to a single join dependency and some egds. Consider  $D = d \cup E$  and  $j \cup K$ , where  $j$  is a join dependency,  $d$  is a tgd, and  $E$  and  $K$  are sets of egds. By Theorem 6.1,  $d \cup E$  is equivalent to  $ECHASE_D(d) \cup H$ , where  $H$  is a set of some egds. We claim that if  $ECHASE_D(d), H \models j, K$ , then  $ECHASE_D(d), H \models J(ECHASE_D(d)), H$ , where  $J(ECHASE_D(d))$  is obtained from  $ECHASE_D(d)$  by replacing all occurrences of repeated nondistinguished variables with new distinct nondistinguished variables.

First, we show that  $j, K \models J(ECHASE_D(d)), H$ . Since no variables are equated when  $ECHASE_D(d)$  is chased with  $D$  and we have assumed that  $j, K \models ECHASE_D(d), H$ , it follows that  $j \models ECHASE_D(d)$ . Since  $j$  is a join dependency, a single application of the rule for  $j$  shows that  $j \models ECHASE_D(d)$  (because of the idempotency of  $j$ ). Therefore, there is a valuation  $h$  of  $j$  into  $ECHASE_D(d)$  that maps each distinguished variable of  $j$  to a distinguished variable of  $ECHASE_D(d)$ . Clearly,  $h$  is also a valuation of  $j$  into  $J(ECHASE_D(d))$  that maps distinguished variables to distinguished variables and, hence, shows that  $j \models J(ECHASE_D(d))$ . By our assumption,  $j, K \models H$  and, therefore,  $j, K \models J(ECHASE_D(d)), H$ .

By mapping each row of  $J(ECHASE_D(d))$  to its corresponding row in  $ECHASE_D(d)$ , we get a valuation that maps distinguished variables to distinguished variables and, therefore

$$J(ECHASE_D(d)) \models ECHASE_D(d)$$

and consequently

$$J(ECHASE_D(d)), H \models ECHASE_D(d), H.$$

By our assumption,

$$ECHASE_D(d), H \models j, K.$$

Thus, we have shown that

$$j, K \models J(ECHASE_D(d)), H \models ECHASE_D(d), H \models j, K$$

and, so,  $ECHASE_D(d) \cup H$  and  $J(ECHASE_D(d)) \cup H$  are equivalent, as claimed. Thus, in order to check whether  $D$  is equivalent to a join dependency and some egds, we construct  $J(ECHASE_D(d))$  and test whether it is implied by  $D$ .  $\square$

**7. Conclusion.** We have considered lossless database schemes with full implicational dependencies. If there is a union of tableaux for the restricted projection of the representative instance onto the set of all the attributes, then the dependencies of the database scheme are equivalent, over the set of all consistent instances, to a single join dependency. If there are no equality-generating dependencies, then the condition is also sufficient, and a restricted projection onto any set of attributes can be expressed by a union of tableaux.

The only known case in which there are equality-generating dependencies and expressions for restricted projections is in that of *independent* database schemes [GY], [Sa3] with functional dependencies and a single join dependency. In this case, a union of tableaux for any restricted projection (and even for tableau queries) can be constructed in the worst case in exponential time (only in the size of the database scheme), and in some cases (e.g., when there are only functional dependencies) in polynomial time [Sa4]. This result is a generalization of [AC], [IIK] who have considered independent database schemes with only functional dependencies.

Our results also characterize when a set of tgds (which can also be viewed as Horn-clause rules) is bounded. A set of tgds is bounded if and only if it is equivalent to a single join dependency. As shown in § 5, this condition is decidable.

**Acknowledgment.** The author thanks Moshe Vardi for helpful comments.

## ANALYSIS OF A HYBRID ALGORITHM FOR PACKING UNEQUAL BINS\*

D. K. FRIESEN† AND F. S. KUHL†

**Abstract.** We consider a bin-packing problem where the sizes of the bins are allowed to vary and where the goal is to maximize the number of pieces packed. This problem is NP-hard. We examine a new efficient approximation algorithm which is a hybrid of two algorithms reported earlier, First-Fit Decreasing (FFD) and Best-Two Fit (B2F). The hybrid is iterative: it attempts to pack smaller and smaller suffixes of its list of pieces until it succeeds in packing an entire suffix. During each attempt, the hybrid operates by partitioning the current list of pieces and packing one part by B2F and afterward packing the other part of its list by FFD. We prove that no instance of the problem exists where an optimal algorithm can pack more than  $\frac{4}{3}$  the number of pieces the hybrid can pack.

We also give a sequence of examples for which the ratio of the number of pieces packed optimally and by our algorithm increases asymptotically to  $\frac{4}{3}$ .

**Key words.** heuristic, approximation algorithm, bin packing, worst-case performance

**1. Introduction.** A one-dimensional bin-packing problem is, in general, a combinatorial optimization problem involving the partition of a set of objects into subsets. Specifically we are given: a set of *bins*  $\mathbf{B} = \{B_1, B_2, \dots, B_M\}$  and a list of *pieces*  $L = \{p_1, p_2, \dots, p_N\}$ . For each bin  $B_i$  and piece  $p_j$  we are also given a finite, positive size, denoted  $s(B_i)$  or  $s(p_j)$ . Two problems of interest are:

(BP) Given  $\mathbf{B}$  and  $L$  as above. Question: Does there exist an assignment of each  $p \in L$  to a bin of  $\mathbf{B}$  such that for each bin  $B'$  the set of pieces assigned to  $B'$  is  $P'$   $\sum_{p \in P'} s(p) \leq s(B')$ ?

(BPN) Given  $\mathbf{B}$  and  $L$  as above, and positive integer  $J$ . Question: Does there exist a subset  $L^*$  of  $L$  such that  $|L^*| \geq J$ , each  $p \in L^*$  is assigned to some bin of  $\mathbf{B}$ , and, if the set of pieces assigned to bin  $B'$  is  $P'$ , then  $\sum_{p \in P'} s(p) \leq s(B')$ ?

In problem BP we seek to pack the entire list  $L$  of pieces into the given bins. In BPN, we seek to pack a subset of  $L$  of specified size. As an optimization problem, BPN asks: What is the largest subset of  $L$  that can be packed into  $\mathbf{B}$ ? If all the bins of  $\mathbf{B}$  have the same size, BP may be stated as an optimization problem: What is the smallest number of bins needed to pack all of  $L$ ?

Bin-packing problems arise in a variety of storage-allocation and scheduling problems. Given a set of varying-length strings to be stored in fixed-length blocks, if the goal is to minimize the number of blocks needed to store all the strings, we have BP [7]. If the goal is to store a subset of the strings of greatest cardinality in a fixed number of blocks, we have BPN. The nonpreemptive scheduling of a system of independent tasks can also be viewed as a bin-packing problem, where the tasks are viewed as pieces and the bins as processors. If the processors are identical and the goal is to minimize the number needed to achieve a given makespan, we have BP. If the goal is to schedule the largest subset of tasks on a given number of processors, we have BPN. The goal of minimizing the makespan has been considered as a variant of BP [5].

Bin packing is known to be NP-hard [6], so it is unlikely that any efficient algorithm exists for the solution of the general problem. Various approximation algorithms have been reported. Some of the first efforts at establishing guarantees of performance for approximation algorithms involved bin packing [6], and the present work follows a similar course.

For a given instance of BPN and approximation algorithm  $A$ , we let  $n_O$  be the number of pieces an optimal algorithm packs, and  $n_A$  be the number of pieces  $A$  packs. Define  $R_A = n_O/n_A$ . Evidently  $R_A \geq 1$  for all instances. As a measure of performance of  $A$ , we choose the “worst-case performance,” i.e., the supremum of  $R_A$  over all instances of  $BPN$ .

The algorithm analyzed here is a hybrid of First-Fit Decreasing (FFD) and Best-Two Fit (B2F). The latter was defined and its worst-case performance on BP was analyzed in [3]. We call our new algorithm a hybrid because a given input is partitioned and different parts are given to the FFD and B2F algorithms. This is in contrast to a compound algorithm, where both B2F and FFD are run on a given input and the better packing selected [4]. For the hybrid algorithm  $H$  to be presented here, we prove an asymptotically tight bound of  $\frac{4}{3}$  on its worst-case performance. This bound is lower than the lowest published bound for an approximation algorithm applied to BPN with bins of varying size.

In [2], BPN is considered with bins of equal size. The authors give bounds for two algorithms. The Smallest-Piece-First (SPF) approximation algorithm has  $n_{OPT}/n_{SPF} \leq 2 - 1/m$ , where  $m$  is the number of bins, and  $n_{OPT}$  and  $n_{SPF}$  are the numbers of pieces packed optimally and by SPF, respectively. And this bound is tight, in the sense that [2] exhibits examples which achieve this bound. They also give a tight bound for First-Fit Increasing (FFI) of  $\frac{4}{3}$ .

The Iterated FFD (FFD\*) is analyzed in [1]. The authors outline a proof that  $n_{OPT} \leq \frac{7}{6}n_{FFD^*} + 3$ . (The original proof in [9] takes over 100 pages.) They give examples for even numbers of bins that achieve  $n_{OPT} = \frac{8}{7}n_{FFD^*}$ . If the limit exists of the ratio  $n_{OPT}/n_{FFD^*}$  as the number of pieces packed increases, it therefore lies in  $[\frac{8}{7}, \frac{7}{6}]$ .

Langston [8] repeats the analysis of [1] and [2] with varying bin sizes. SPF has a tight bound of 2, regardless of the order the bins are sorted in. FFI also has a tight bound of 2. The iterated FFD, FFD\*, from [8], does best with the bins sorted in increasing size. It is shown that, if  $n_F$  is the number of pieces packed by FFD\* with bins sorted by increasing size,  $n_{OPT} \leq \frac{3}{2}n_F + 1$ , and gives an example where  $n_{OPT} = \frac{11}{8}n_F$ . Thus the limit of  $n_{OPT}/n_F$  lies in  $[\frac{11}{8}, \frac{3}{2}]$ .

## 2. Main result.

**2.1. The hybrid algorithm.** Our algorithm is defined by procedures HSTAR, H, B2F and FFD, given below. The input to HSTAR is a set of bins  $\{B_1, \dots, B_M\}$ , each bin  $B_i$  having its positive size  $s(B_i)$ . We assume the bins are sorted so that  $s(B_1) \leq s(B_2) \leq \dots \leq s(B_M)$ . We also give HSTAR a set of pieces  $\{p_1, \dots, p_N\}$  and, for each piece  $p_i$ , its positive size  $s(p_i)$ . We assume the pieces are sorted so that  $s(p_1) \geq s(p_2) \geq \dots \geq s(p_N)$ . Procedures H, B2F and FFD each return a Boolean value which indicates whether or not they succeeded in packing all the pieces passed to them. The only purpose of H is to partition its input into two lists. The larger pieces, defined as those  $p_i$  such that  $s(p_i) > s(p_f)/2$  ( $f$  is defined in the algorithm), are packed by B2F; the remainder (whose relative size may vary greatly) are packed by FFD. HSTAR is an iterative algorithm which will take successively smaller suffixes of  $\{p_1, \dots, p_N\}$  until it succeeds in packing an entire suffix.

```

proc HSTAR;
  f:= 1;
  while (H( $p_f, \dots, p_N$ ) = false) f:= f + 1;
end HSTAR;

proc H( $p_f, \dots, p_N$ );
  mark all bins as empty;
  let k be the largest i such that  $s(p_i) > s(p_f)/2$ ;
  if ( $k > f$ )
    then b2fok := B2F( $p_f, \dots, p_k$ );
    else b2fok := true;
  end if;
  if ( $k < N$ )
    then ffdok := FFD( $p_{k+1}, \dots, p_N$ );
    else ffdok := true;
  end if;
  return (b2fok and ffdok);
end H;

proc B2F( $p_f, \dots, p_k$ );
  mark  $p_f, \dots, p_k$  as available (unpacked);
  for j:= 1 to M do
    /* pack bin  $B_j$  */
    for i:= f to k do
      if ( $p_i$  is available and fits in unused space) then
        /* pack  $p_i$  */
        mark  $p_i$  unavailable;
        decrease space in  $B_j$  by  $s(p_i)$ ;
      end if;
    end for;
    /* can we replace top piece with two? */
    if (some piece has been packed in  $B_j$ , and the
        two smallest available pieces will fit in  $B_j$ 
        after removing the top piece) then
      let  $p_t$  be the top piece currently packed in  $B_j$ ;
      let  $p_a$  be the smallest available piece;
      let empty be the space in  $B_j$  left after removing  $p_t$ ;
      let  $p_b$  be the largest available piece such that
         $empty \geq s(p_a) + s(p_b)$ ;
      let  $p_c$  be the largest available piece such that
         $empty \geq s(p_c) + s(p_b)$ ;
      /* then  $p_b$  and  $p_c$  replace  $p_t$  */
      mark  $p_t$  available and  $p_b$  and  $p_c$  unavailable;
      adjust total size of pieces packed in  $B_j$ ;
    end if;
  end for;
  if (no  $p_i$  in  $p_f, \dots, p_k$  is available)
    then return (true);
    else return (false);
  end if;
end B2F;

```

```

proc FFD( $p_{k+1}, \dots, p_N$ );
  for  $i := k + 1$  to  $N$  do
    /* pack piece  $p_i$  */
     $j := 1$ ;
    while ( $j \leq M$  and  $p_i$  will not fit in  $B_j$ )  $j := j + 1$ ;
    if ( $j < M$  or  $p_i$  fits in  $B_M$ )
      then assign  $p_i$  to  $B_j$ ;
      else return (false);
    end if;
  end for;
  return (true);
end FFD;

```

The chief reason for considering this hybrid algorithm, instead of simply an iterative version of B2F, is that the analysis of the hybrid appears to be much easier than analysis of B2F operating on pieces of unrestricted size. The worst-case example for our hybrid, presented below, involves only the operation of B2F, so the worst-case bound for B2F\* on varying bins cannot be better than  $\frac{4}{3}$ .

Expected performance is another matter. We performed computational experiments on HSTAR, B2F\* and FFD\* to estimate their expected behavior. For each instance, bin sizes were made to increase linearly and piece sizes were generated pseudorandomly from a uniform distribution and then sorted. For each instance we computed  $R_A = n_O/n_A$ , estimating  $n_O$  by assuming that the optimal algorithm could pack perfectly.  $R_A$  for each algorithm and all instances averaged within a few percent of 1, supporting the notion that worst-case behavior is rare. In general, B2F\* and HSTAR performed significantly better than FFD\*. For some instances, B2F\* outperformed HSTAR; for others, the reverse was true.

Several remarks on the design of H are worthwhile. Firstly, because every piece  $p_i$  that B2F considers has  $s(p_i) > s(p_f)/2$ , the total size of any two pieces B2F considers is strictly larger than that of any one piece. This affects the structure of B2F packings in ways discussed below. Secondly, we note that the method of replacement in B2F is used in the analysis. Finally, we note that the consecutive search employed by HSTAR on its list avoids the possibility of anomalies. But our main theorem as given would still apply if HSTAR used a nonconsecutive, e.g., binary, search.

Let us consider the time complexity of HSTAR. FFD runs in time  $O(MN)$ , and B2F in  $O(5MN) = O(MN)$ . H adds nothing to the order of the time complexity, so HSTAR as given is  $O(MN^2)$ . One must add time for the sorting of bins and pieces that we assume when HSTAR is invoked.

We denote the number of pieces HSTAR succeeds in packing from  $L$  into  $\mathbf{B}$  by  $n_{H^*}(L, \mathbf{B})$ . We denote the optimal algorithm by OPT and the number of pieces it packs of  $L$  into  $\mathbf{B}$  by  $n_O(L, \mathbf{B})$ . From the definition of the algorithm, HSTAR does not succeed until it packs all the pieces from some  $p_i$  to  $p_N$ . In view of the ordering of  $L$ , it is evident that when HSTAR succeeds it packs a suffix  $\{p_i, p_{i+1}, \dots, p_N\}$  of  $L$ , for some  $i$ . The measure of worst-case performance we use is

$$R_{H^*} = \sup_{\text{all}(L, \mathbf{B})} n_O(L, \mathbf{B}) / n_{H^*}(L, \mathbf{B}).$$

We shall show that  $R_{H^*} \leq \frac{4}{3}$ .

Before that, we present a family of instances of  $L$  and  $\mathbf{B}$  such that  $n_O(L, \mathbf{B}) / n_{H^*}(L, \mathbf{B}) \rightarrow \frac{4}{3}$ . For a positive integer  $k$ , an instance of the family is as follows.  $\mathbf{B}$  contains 1 bin of size  $2 - 2e$ , 2 bins of size  $2 - e$ , 4 bins of size  $2 - e/2, \dots$ , and  $2^{k-1}$

bins of size  $2 - e/2^{k-2}$ , for a total of  $2^k - 1$  bins.  $L$  contains  $2^k - 1$  pieces of size 1, 2 pieces of size  $1 - e$ , 4 pieces of size  $1 - e/2, \dots$ , and  $2^{k-1}$  pieces of size  $1 - e/2^{k-2}$ , for a total of  $2(2^k - 1) - 1$  pieces. The packing by OPT and HSTAR of such an instance is given in Fig. 1.

Define  $n_H(L, \mathbf{B})$  to be the number of pieces H (not HSTAR) will pack out of  $L$  into  $\mathbf{B}$ , if the entire list  $L$  is presented to H. Suppose an  $L$  and  $\mathbf{B}$  such that OPT can pack all of  $L$  into  $\mathbf{B}$ . If H always succeeds in packing suffixes of  $L$  that have  $\leq \frac{3}{4}$  the pieces of  $L$ , then HSTAR will always halt having packed a suffix containing  $\geq \frac{3}{4}$  the pieces of  $L$ , and  $R_{H^*} \leq \frac{4}{3}$ . Our main result may be stated as follows.

**THEOREM 2.1.1.** *Given any  $L$  and  $\mathbf{B}$  for which  $n_O(L, \mathbf{B}) = N$  (i.e., OPT packs all pieces of  $L$ ), H will succeed in packing into  $\mathbf{B}$  every suffix of  $L \{p_i, p_{i+1}, \dots, p_N\}$  for which  $n_O(L, \mathbf{B}) \leq \frac{4}{3}n_H(L, \mathbf{B})$ , i.e., for which  $N - i + 1 \leq 3N/4$ .*

The proof of this theorem will occupy §§ 2.2 and 2.3, and is organized as follows. In § 2.2 we assume the existence of an  $L$  and  $\mathbf{B}$  that constitute a counterexample which is minimal in a sense to be defined below, and which fails in the FFD portion of H. We derive a contradiction showing that in a minimal counterexample only the B2F portion of H is actually used. In § 2.3, we examine the behavior of B2F on pieces meeting the restriction we arrive at in § 2.2, and we show that under that restriction the packing of B2F never violates the  $\frac{4}{3}$  bound of Theorem 2.1.1. We conclude that no minimal counterexample, and hence no counterexample whatever, exists to Theorem 2.1.1.

B2F:

OPT:

FIG. 1

**2.2. The minimal counterexample.** A counterexample to Theorem 2.1.1 is some  $L = \{p_1, p_2, \dots, p_N\}$ , suffix  $L_f = \{p_f, p_{f+1}, \dots, p_N\}$  and  $\mathbf{B} = \{B_1, B_2, \dots, B_M\}$  such that  $n_O(L, \mathbf{B}) = N$ ,  $N - f + 1 \leq 3N/4$ , and H will fail to pack into  $\mathbf{B}$  one or more pieces out of  $L_f$ . If such a counterexample exists, we construct from it a counterexample that is minimal in the number of pieces retained from  $L$ . Before doing so, we must discuss properties common to all H packings.

We extend the definition of the size of a piece or bin to sets. If  $P$  is a set of pieces, then  $s(P) = \sum_{p \in P} s(p)$ , and similarly for sets of bins.

Let us classify the pieces packed by B2F. Suppose that when B2F packs bin  $B_i$  it has available the ordered list of pieces  $L' = \{q_1, q_2, q_3, \dots\}$ , a subset of  $L_f$ . If B2F is

able to pack the first  $k$  pieces of  $L'$ , say  $q_1, q_2, \dots, q_k$ , in  $B_i$ , then we say pieces  $q_1, q_2, \dots, q_k$  have *type X* or, are *X-pieces*, more specifically,  *$X_k$ -pieces*. Any piece  $q_{k+j}$ ,  $j \geq 2$ , packed after omitting an available piece, has *type Y* (or *type  $Y_k$* ). If B2F replaces the top piece in  $B_i$  with two smaller pieces, the replacements have *type F* (or *type  $F_k$* ). We can also similarly classify small pieces as types *X* or *Y* with respect to the way FFD packs them. (Type *F* and *Y* pieces are sometimes called *fallback* pieces.)

We say that a bin (rather than a piece)  $B_i$  has *type  $X_k$*  (or, is an  $X_k$  bin) if B2F packs  $k$  *X* pieces in  $B_i$  and no other pieces, and B2F does not replace the top *X* piece with two *F* pieces. Bin  $B_i$  has *type  $F_k$*  if B2F packs  $k$  *X* pieces and then replaces the top piece with two *F* pieces. Bin  $B_i$  has *type  $Y_k$*  if B2F packs  $k$  *X* pieces and a *Y* piece.

LEMMA 2.2.1. *Given a list of pieces  $L$  and set of bins  $\mathbf{B}$  and the H packing of  $L$  into  $\mathbf{B}$ . Let  $B'_i$  be the set of pieces H packs into bin  $B_i$ . Suppose we form  $L'$  and set  $\mathbf{B}'$  of bins by either of the following methods.*

- (A) *Form  $L'$  by deleting from  $L$  all pieces in  $B'_i$ . Form  $\mathbf{B}'$  by deleting  $B_i$  from  $\mathbf{B}$ .*
- (B) *Let  $p \in L$  be a piece not packed into any bin of  $\mathbf{B}$ . Form  $L'$  by deleting  $p$  from  $L$ . Let  $\mathbf{B}' = \mathbf{B}$ .*

*Then in either case, any bin in the new packing (of  $L'$  into  $\mathbf{B}'$ ) will be packed with the same set of pieces it was packed with in the old (of  $L$  into  $\mathbf{B}$ ).*

*Proof.* We begin with the first construction.

Consider first bin  $B_j$ ,  $j < i$ . If all (large) pieces originally packed by B2F in  $B_j$  had type *X*, then no  $p \in B'_i$  was examined in packing  $B_j$  and the new B2F packing of  $B_j$  will be the same. If B2F packed  $B_j$  with one or more *Y*-pieces and some  $p \in B'_i$  was examined during the packing of  $B_j$ ,  $p$  evidently would not fit in  $B_j$  and its absence from  $L'$  affects nothing. These remarks apply also to small pieces packed in  $B_j$ .

Now suppose that in the original packing of  $B_j$  some  $p \in B'_i$  had been the top piece and was replaced by B2F with two *F* pieces. We consider the moment in the packing of  $L'$  (the new packing) when B2F would pack  $p$  in  $B_j$  if it were available. Let the two *F* pieces in the original packing be  $f_1$  and  $f_2$ , and assume  $s(f_1) \geq s(f_2)$ . If in  $L'$  there is a piece  $p'$ ,  $s(p) \geq s(p') > s(f_1)$  and no other piece of  $L'$  will fit in the space with  $p'$ , then  $p'$  will be packed by B2F as type *X* (or *Y*) and will then be replaced by  $f_1$  and  $f_2$ . Now suppose that  $p'$  is packed in the space and that  $L'$  contains piece  $y$ ,  $s(p') \geq s(y) > s(f_1)$ , which fits with  $p'$ . Then  $p'$  would have fit with the smallest piece in  $L$  and would have been used in the original replacement instead of  $f_1$ . Thus no such  $y$  exists, and  $f_1$  and  $f_2$  will always replace the top piece. Therefore the set of pieces packed from  $L'$  into  $B_j$  will be the same as the set packed from  $L$ .

We note that with the foregoing, the set of pieces available from  $L'$  to pack  $B_{i+1}$  for both B2F and FFD will be the same as was available from  $L$ . Thus the packing from  $L'$  of any  $B_j$ ,  $j > i$ , will not differ from the original.

Now let us consider the second construction. Suppose  $p \in L$  is not packed by H at all. If we form  $L'$  by deleting  $p$  from  $L$  then H will pack into each  $B_j$  of  $\mathbf{B}$  the same set of pieces it packed from  $L$ . To see this, we consider the packing of  $L$  into  $B_j$ . If  $p$  was never packed into  $B_j$ , its absence affects nothing. If  $p$  was packed into  $B_j$  as the top piece and then replaced, the absence of  $p$  does not affect the replacement, as we showed above.  $\square$

Given a counterexample, we now form a minimal counterexample. We form list  $L'$  by deleting from  $L$  all but the largest of the pieces H failed to pack out of  $L_f$ . We form  $\mathbf{B}'$  by deleting from  $\mathbf{B}$  any bin  $B_i$  in which neither OPT nor H packs any piece of  $L$ . Now OPT can pack  $L'$  into  $\mathbf{B}'$  and, by Lemma 2.2.1, H cannot pack  $L' \cap L_f$  into  $\mathbf{B}'$ , since one unpacked piece remains. The one piece in  $L'$  which H fails to pack when it starts at  $p_f$  we shall call  $p_l$ . If  $s(p_l) \leq s(p_f)/2$ , the construction of the FFD part of

H ensures that  $p_l$  is the last piece H examines. If  $p_l$  is the last piece that H examines, define  $L_1 = L' \cap \{p_1, p_2, \dots, p_l\}$  and  $L_2 = L' \cap \{p_f, p_{f+1}, \dots, p_l\}$ , and we have  $n_O(L_1, \mathbf{B}') \cong \frac{4}{3}[n_H(L_2, \mathbf{B}') + 1]$ . (Note that we had  $n_O(L, \mathbf{B}) \cong \frac{4}{3}[n_H(L_f, \mathbf{B}) + 1]$  and that in forming  $L_1$  and  $L_2$  we have deleted an equal number of pieces from each.) If  $p_l$  is not the last piece H examines (which could happen if  $s(p_l) > s(p_f)/2$  and B2F fails to pack  $p_l$ ), we then define  $L_1 = L' \cap \{p_1, \dots, p_N\}$  and  $L_2 = L' \cap \{p_f, \dots, p_N\}$ . Now  $\mathbf{B}'$ ,  $L_1$  and  $L_2$  provide us with our minimal counterexample.

We wish to compare the H packing of  $L_2$  to any optimal packing of  $L_1$ . The goal of this section is to show that if  $p_l$  is the last piece H examines, then  $s(p_l) > s(p_f)/2$  and thus that FFD will never operate on a minimal counterexample. For the rest of this section  $n_O$  shall mean  $n_O(L_1, \mathbf{B}')$  and  $n_H$  shall mean  $n_H(L_2, \mathbf{B}')$ , unless otherwise qualified.

We normalize the sizes of pieces and bins so that  $s(p_f) = 1$ , and we assume that  $s(p_1) = s(p_2) = \dots = s(p_{f-1}) = 1$ . (If there is an optimal packing of  $L_1$  including  $p_1, p_2, \dots, p_{f-1}$  and they are larger than 1, the same packing is valid if the sizes of  $p_1, \dots, p_{f-1}$  are reduced to 1.) The pieces  $p_1, p_2, \dots, p_f$  are the largest in  $L_1$ . H packs at least one piece ( $p_f$ ) of size 1, and the pieces, aside from  $p_l$ , packed by OPT but not by H, ( $p_1, \dots, p_{f-1}$ ), have size 1. The bins are ordered in increasing size, and there is at least one bin as large as 1, since H can pack additional pieces of size 1. The B2F part of H will attempt to pack all the pieces of  $L_2$  with size  $> \frac{1}{2}$ , while the FFD part will attempt to pack all the pieces with size  $\leq \frac{1}{2}$ . We say  $p_i$  is *large* when  $s(p_i) > \frac{1}{2}$ ; if  $p_i$  is *small* we mean  $s(p_i) \leq \frac{1}{2}$ .

We now give as lemmas several elementary properties of a minimal counterexample. Note that Lemmas 2.2.2-2.2.5 do not depend on  $p_l$  being the last piece in  $L_2$ .

LEMMA 2.2.2. *The H packing of a minimal counterexample has no empty bins.*

*Proof.* If H packs no pieces in  $B_i$ , then  $s(B_i) < 1$ , since every piece  $p$  available to pack  $B_i$  has  $s(p) \leq 1$  and none would fit. Suppose OPT packs  $B_i$  with pieces  $q_1, q_2, \dots$ . Each  $q_i$  must be packed in some  $B_k$ ,  $k < i$ , or else the  $q_i$  would have been available to be packed in  $B_i$ . No  $q_i$  can be packed by B2F as an  $F$ -piece because there can be no  $F$  bins of size  $< 1$ . Since each  $q_i$  is either a small piece or is packed by B2F as type  $X$  or  $Y$ , we can delete  $q_i$  from  $L_1$  and  $L_2$  and form a smaller counterexample, contradicting minimality.  $\square$

LEMMA 2.2.3. *The optimal packing of a minimal counterexample has no empty bins.*

*Proof.* If  $B_i$  is empty in the optimal packing, form  $\mathbf{B}^*$  by deleting  $B_i$  from  $\mathbf{B}'$  and form  $L'_1$  and  $L'_2$  by deleting the pieces H packs into  $B_i$  from  $L_1$  and  $L_2$ , respectively. By Lemma 2.2.1,  $L'_1$ ,  $L'_2$  and  $\mathbf{B}^*$  are a smaller counterexample, thus contradicting minimality.  $\square$

LEMMA 2.2.4. *If in the optimal packing of a minimal counterexample,  $B_i$  contains only one piece  $p_j$ , then  $p_j$  is packed by H (if H packs  $p_j$  at all) in  $B_k$ ,  $k > i$ , and, for every piece  $p$  packed by H in  $B_i$ ,  $s(p) < s(p_j)$ .*

*Proof.* Suppose  $p_j$  is packed in  $B_k$ ,  $k \leq i$ . We then contradict minimality by forming a new counterexample as follows. Delete the pieces H packs in  $B_k$  from  $L_1$  and  $L_2$ . In the optimal packing, move whatever remains of the former contents of  $B_k$  to the now empty  $B_i$  (note that  $s(B_k) \leq s(B_i)$ ). Delete  $B_k$  from  $\mathbf{B}'$ .

Now we show that the H packing of  $B_i$  contains no pieces as large as  $p_j$ . If  $p_j$  is packed by H in  $B_k$ ,  $k > i$ , and H packs a piece  $p_m$  in  $B_i$  with  $s(p_m) \geq s(p_j)$ , we contradict minimality as follows. Delete any pieces H packs in  $B_i$  (notably  $p_m$ ) from  $L_1$  and  $L_2$ . In the optimal packing, move  $p_j$  (if it remains) to the position formerly occupied by  $p_m$ . Delete  $B_i$  from  $\mathbf{B}'$ . Thus if OPT packs  $p_j$  by itself, H cannot pack  $p_j$  in  $B_i$ , nor can H pack any  $p_m$  in  $B_i$  with  $s(p_m) \geq s(p_j)$ .  $\square$

To establish  $s(p_i) > \frac{1}{2}$ , we need another fact which we give as a lemma.

LEMMA 2.2.5. *If OPT packs but one piece  $p_j$  of a minimal counterexample in bin  $B_i$ , then  $p_j$  is a large piece, and B2F packs  $B_i$  as an  $F_1$  bin.*

*Proof.* Suppose  $p_j$  is a small piece. If H packed  $p_j$ , then, by Lemma 2.2.4, H packed  $p_j$  in  $B_k$ ,  $k > i$ , and H packed no large pieces in  $B_i$ . But  $p_j$  was available to FFD to pack  $B_i$  and  $p_j$  would have fit. If FFD packed  $p_j$  later, it packed some  $p_m$  in  $B_i$  with  $s(p_m) \cong s(p_j)$ , in violation of Lemma 2.2.4. If H did not pack  $p_j$ , then it packed some  $p_m$  with  $s(p_m) \cong s(p_j)$  in  $B_i$ , violating Lemma 2.2.4. Therefore  $p_j$  is not a small piece.

Now suppose  $p_j$  is a large piece. By Lemma 2.2.4, H must pack  $p_j$  (or  $p_f$  if  $j < f$ ); recall that then  $s(p_f) = s(p_j) = 1$  in  $B_k$ ,  $k > i$ . Now B2F had room in  $B_i$  to pack  $p_j$  ( $p_f$ ) and  $p_j$  ( $p_f$ ) was available to it. If B2F did not pack  $B_i$  as an  $F_1$  bin, it packed some piece  $p_m$  of type  $X$  or  $Y$ ,  $s(p_m) \cong s(p_j)$ , in  $B_i$  in violation of Lemma 2.2.4. Thus B2F packed  $B_i$  as an  $F_1$ .  $\square$

Recall that  $M$  is the number of bins in a minimal counterexample. Let  $F$  be the set of bins packed by OPT with only one piece. (By Lemma 2.2.5, B2F packs every bin of  $F$  as type  $F_1$ .) Let  $f = |F|$ . Recall that  $L_1$  and  $L_2$  are the sets of pieces packed by OPT and H, respectively. Let  $L_{OF}$  and  $L_{HF}$  be the sets of pieces packed by OPT and H, respectively, in bins of  $F$ . Let  $L_{OR}$  and  $L_{HR}$  be the sets of pieces packed by OPT and H in bins not in  $F$ .

LEMMA 2.2.6. *If  $p_i$  is the last piece in  $L_2$ ,  $s(p_i) > \frac{1}{2}$ .*

*Proof.* Because we consider a counterexample,  $n_O > \frac{4}{3}$  or  $n_O - n_H > n_O/4$ . But  $n_O \cong 2M - f$  because, by Lemma 2.2.5, OPT packs every bin outside  $F$  with at least 2 pieces, and every bin in  $F$  with 1 piece. Therefore  $n_O - n_H > \frac{1}{4}(2M - f)$ . But OPT packs at most 1 piece that H does not which has size  $< 1$ ; all other additional pieces have size 1 by assumption. Thus

$$(1) \quad s(L_1) - s(L_2) > \frac{1}{4}(2M - f).$$

Now  $s(L_1) = s(L_{OF}) + s(L_{OR})$  and  $s(L_2) = s(L_{HF}) + s(L_{HR})$  and

$$(2) \quad s(L_{OF}) - s(L_{HF}) + s(L_{OR}) - s(L_{HR}) \cong \frac{1}{4}(2M - f).$$

But  $s(L_{OF}) - s(L_{HF}) < 0$ . To see this, let  $B_i$  be any bin of  $F$ . Recall that B2F packs  $B_i$  as a type  $F_1$  (with two large pieces), so that the total size of pieces packed in  $B_i$  by H is  $> 1$ . By definition of  $F$ , OPT packs but one piece in  $B_i$ , with size  $\leq 1$ . Summing over all bins  $B_i$ ,  $s(L_{OF}) - s(L_{HF}) < 0$ . Substituting in (2) yields

$$(3) \quad s(L_{OR}) - s(L_{HR}) > \frac{1}{4}(2M - f).$$

There are  $M - f$  bins outside  $F$ , so among those bins the average empty space in the H packing must be

$$> \frac{1}{4} \left[ \frac{2M - f}{M - f} \right] > \frac{1}{4} \left[ \frac{2M - 2f}{M - f} \right] = \frac{1}{2}.$$

There must be some bin  $B_i$  outside  $F$  whose H packing has empty space  $> \frac{1}{2}$ . Since  $p_i$  would not fit in  $B_i$ ,  $s(p_i) > \frac{1}{2}$ .  $\square$

**2.3. B2F operating on large pieces.** We consider in this section the behavior only of the B2F part of H on a minimal counterexample.

We assume we are given a minimal counterexample consisting of bins  $\mathbf{B} = \{B_1, \dots, B_M\}$ , sorted so that  $s(B_1) \cong s(B_2) \cong \dots \cong s(B_M)$ , and pieces  $L = \{p_1, \dots, p_N\}$  sorted so that  $s(p_1) \cong s(p_2) \cong \dots \cong s(p_N)$ . Further, OPT packs all of  $L$  into  $\mathbf{B}$ , so that  $n_O(L, \mathbf{B}) = N$ , and there is a suffix of  $L$ ,  $L_1 = \{p_f, p_{f+1}, \dots, p_N\}$  such that B2F packs

all but one piece of  $L_1$  into  $\mathbf{B}$ . Therefore  $n_H(L_1, \mathbf{B}) = N - f$ , and because we consider a counterexample,  $3N/4 \geq N - f + 1$ . In the previous section we assumed that the one piece  $H$  failed to pack was the last piece of its list; here we make no such assumption, as it is possible for B2F to fail to pack a piece from the middle.

As before, we normalize the size of pieces and bins so that  $s(p_f) = 1$ . By assumption,  $s(p_N) > \frac{1}{2}$ . We also assume that  $s(B_1) > 1$ : each bin  $B_i$  with  $s(B_i) \leq 1$  must be packed by OPT with 2 pieces. Since all pieces have size  $> \frac{1}{2}$ , there can be no  $B_i$  with  $s(B_i) \leq 1$ .

Throughout this section we shall for notational convenience let  $n_O = n_O(L, \mathbf{B})$  and  $n_H = n_H(L_1, \mathbf{B})$  (it being understood that B2F is the only part of  $H$  actually executed).

We retain the previous definitions of bin and piece types. Note that B2F cannot, with the size pieces we consider here, omit a piece and then pack two more pieces further down the list: the two pieces would be larger than the omitted piece. Similarly it is not possible that B2F would pack the first  $k$  pieces of  $L_1$ , pack a noncontiguous ( $Y$ ) piece  $p_j$  and then replace  $p_j$  with two smaller pieces. Because we assume that  $s(B_1) > 1$ ,  $B_1$  is packed as type  $X_i, F_i$ , or  $Y_i$ ,  $i \geq 1$ . Because  $B_1$  is the smallest bin and  $p_f$  will necessarily fit in  $B_1$ , B2F is always able to pack at least the first piece available to it when it begins to pack each bin.

After the first appearance of a bin of type  $X_k, F_k$  or  $Y_k$ , there can be no bins of type  $X_{k-1}, F_{k-1}$ , or  $Y_{k-1}$ . To see this, suppose bin  $B_i$  has type  $X_k, F_k$  or  $Y_k$ . There was room to pack the first  $k$  pieces available to B2F at the time. When B2F packs  $B_j$ ,  $j > i$ ,  $s(B_j) \geq s(B_i)$ , and the first  $k$  pieces available to pack  $B_j$  are no larger than those that were available to pack  $B_i$ . So  $B_j$  will have type  $X_r, F_r$  or  $Y_r$  with  $r \geq k$ .

Let  $B_i$  be a bin of a B2F packing and let  $P$  be the set of pieces B2F packs in  $B_i$ . If  $s(P) < \frac{3}{4}s(B_i)$ , we say  $B_i$  is *bad*.

In the following definitions,  $P$  and  $Q$  are regions and  $i$  is a positive number. Define:

$x_{PQ}^i$  to be the number of type  $X$  pieces packed by B2F in region  $P$  but packed by OPT in  $Q$  in a bin with  $i$  pieces;

$f_{PQ}^i$  the number of type  $Y$  or  $F$  pieces packed by B2F in  $P$  but by OPT in  $Q$  in a bin with  $i$  pieces;

$f_{PQ}$  the same as  $f_{PQ}^i$  but without regard to how many pieces are in the optimal packing:  $f_{PQ} = \sum_i f_{PQ}^i$ ;

$q_{PQ}^i$  the number of pieces of any type packed by B2F in  $P$  but by OPT in  $Q$  in a bin with  $i$  pieces;

$M_P$  the number of bins of region  $P$ ;

$n_{OP}$  the number of pieces packed by OPT in region  $P$ ;

$n_{HP}$  the number of pieces packed by B2F in region  $P$ .

The symbol  $x_{(r < D)D}^i$  denotes the number of  $X$ -pieces packed by B2F in any region before  $D$  (in this case  $X, F$  or  $Y$ ), but packed by OPT in  $D$ . Similar symbols are defined analogously. When we consider the number of pieces packed in a particular bin  $B$ ,  $n_{HB}$  will be the number of pieces  $H$  packs in  $B$ ;  $n_{OB}$  the number of pieces OPT packs in  $B$ ; and for a region  $P$ ,  $x_{PB}^i, f_{PB}^i, x_{PB}$ , and  $f_{BP}$  are defined analogously.

LEMMA 2.3.1. *Let  $X$  be the region through the last  $X_1$  bin. Then*

$$n_{OX} - n_{HX} \leq \frac{1}{3}n_H - \frac{2}{3}f_{(X, r > X)}.$$

*Proof.* Let  $B_X$  be the last bin of region  $X$ . Since no second piece would fit in  $B_X$ ,  $s(B_X) < 2$ . Thus, because each piece has size  $> \frac{1}{2}$ , OPT can pack no more than three pieces in  $B_X$ . Further, if OPT packs three pieces in any bin  $B_i$  of region  $X$ , all must be  $F$  pieces packed by  $H$  in a bin before  $B_X$ . To see this, suppose OPT packed 3 pieces  $a, b$  and  $c$  in bin  $B_i$ . Let  $p_X$  be the piece B2F packed in  $B_X$ . Then  $s(p_X) + s(c) < s(a) + s(b) + s(c) \leq s(B_i) \leq s(B_X)$ , so  $c$  would have fit with  $p_X$  in  $B_X$ . But  $p_X$  was

packed alone, so  $c$  must not have been available when B2F packed  $B_X$ . If  $c$  were type  $X_1$  it would be larger than  $p_X$  and any other remaining pieces, so another piece would have fit with  $p_X$ . Thus  $c$  was packed as type  $F$  before  $B_X$ . This argument applies to  $a$  and  $b$  as well. Thus

$$(1.1) \quad n_O - 2M_X \leq \frac{1}{3}f_{XX}^3$$

and

$$(1.2) \quad 2M_X - n_H \leq x_X$$

because any piece packed by H in a bin by itself must be a single  $X_1$  piece. Adding (1.1) and (1.2) yields

$$(1.3) \quad n_O - n_H \leq \frac{1}{3}f_{XX}^3 + x_X.$$

Suppose OPT packs two pieces in a bin of region  $X$ . If both were available when H packed  $B_X$ , or if one were available and the other were at least as large as the last  $X_1$  piece packed, then  $B_X$  would have been type  $Y_1$  or  $F_1$ . Hence at least one of those pieces must be a type  $F$  piece packed by H before  $B_X$ . Thus

$$(1.4) \quad n_O - M_X \leq \frac{2}{3}f_{XX}^3 + f_{XX}^2.$$

Also, because any bin packed by H with a fallback piece is a type  $Y_1$  or  $F_1$  bin and thus has two pieces,

$$(1.5) \quad n_H - M_X \geq \frac{1}{2}f_X.$$

Subtracting (1.5) from (1.4) yields

$$(1.6) \quad n_O - n_H \leq \frac{2}{3}f_{XX}^3 + f_{XX}^2 - \frac{1}{2}f_X.$$

Multiplying (1.3) by  $\frac{1}{3}$  and (1.6) by  $\frac{2}{3}$  and adding yields

$$\begin{aligned} n_O - n_H &\leq \left(\frac{1}{9} + \frac{4}{9}\right)f_{XX}^3 + \frac{2}{3}f_{XX}^2 + \frac{1}{3}x_X - \frac{1}{3}f_X \\ &\leq \frac{2}{3}f_{XX}^3 + \frac{1}{3}x_X - \frac{1}{3}f_X. \end{aligned}$$

Now  $f_X = f_{XX} + f_{(X,r>X)}$ , so

$$n_O - n_H \leq \frac{1}{3}f_{XX} + \frac{1}{3}x_X - \frac{1}{3}f_{(X,r>X)}.$$

Moreover,  $n_H = f_X + x_X$  so

$$n_O - n_H \leq \frac{1}{3}n_H - \frac{2}{3}f_{(X,r>X)},$$

as the lemma requires.  $\square$

LEMMA 2.3.2. *Let region  $F$  be the region beyond  $X$  through the last  $F_1$  bin.*

$$n_{OF} - n_{HF} \leq \frac{1}{3}n_{HF} - \frac{2}{3}f_{(F,r \neq F)} + \frac{2}{3}f_{XF}.$$

*Proof.* Let  $B_F$  be the last bin in region  $F$ . Since no piece available when H packed  $B_F$  would fit with the last piece H packed in  $B_F$  and then replaced (or  $B_F$  would have been type  $Y_1$ ), the same arguments used in the proof of Lemma 2.3.1 imply that if OPT packs three pieces in a bin of  $F$ , none were available when H packed  $B_F$ . Those pieces must be  $f_X$  or  $f_F$  pieces. Hence

$$(2.1) \quad n_{OF} - n_{HF} = n_{OF} - 2M_F \leq \frac{1}{3}[f_{FF}^3 + f_{XF}^3].$$

Also, if OPT packs two pieces in a bin of  $F$ , at least one is a fallback piece from  $F$  or  $X$ . Hence

$$(2.2) \quad n_{OF} - M_F \leq \frac{2}{3}(f_{FF}^3 + f_{XF}^3) + f_{FF}^2 + f_{XF}^2.$$

And

$$(2.3) \quad n_{HF} - M_F \geq \frac{1}{2}f_F.$$

Combining (2.2) and (2.3) yields

$$(2.4) \quad n_{OF} - n_{HF} \leq \frac{2}{3}f_{FF}^3 + \frac{2}{3}f_{XF}^3 + f_{FF}^2 + f_{XF}^2 - \frac{1}{2}f_F.$$

Multiplying (2.1) by  $\frac{1}{3}$ , (2.4) by  $\frac{2}{3}$ , and adding gives

$$\begin{aligned} n_{OF} - n_{HF} &\leq \frac{5}{9}f_{FF}^3 + \frac{5}{9}f_{XF}^3 + \frac{2}{3}f_{FF}^2 + \frac{2}{3}f_{XF}^2 - \frac{1}{3}f_F \\ &\leq \frac{2}{3}f_{FF}^3 + \frac{2}{3}f_{XF}^3 - \frac{1}{3}[f_{FF} + f_{(F,r \neq F)}] \\ &\leq \frac{1}{3}f_{FF} + \frac{2}{3}f_{XF} - \frac{1}{3}f_{(F,r \neq F)} \\ &\leq \frac{1}{3}n_{HF} + \frac{2}{3}f_{XF} - \frac{2}{3}f_{(F,r \neq F)} \end{aligned}$$

as desired.  $\square$

LEMMA 2.3.3. *If there are no bad  $X_2$  bins, then  $n_O \leq \frac{4}{3}n_H$ .*

*Proof.* Let  $A$  be the union of regions  $X$  and  $F$ . Lemmas 2.3.1 and 2.3.2 imply that

$$(3.1) \quad n_{OA} - n_{HA} \leq \frac{1}{3}n_{HA} - \frac{2}{3}f_{(A,r > A)}.$$

Let  $R$  be the union of the remaining regions; let  $q$  be the piece not packed by H; let  $R^*$  be the set of pieces packed by OPT in  $R$ ; and let  $R'$  be the set of pieces packed by H in  $R$ . Let  $S$  be the set of pieces of  $R^*$  packed by H as type  $Y$  or  $F$  pieces in  $A$  (thus  $|S| = f_{AR}$ ). If  $p \in R^* \setminus (S \cup R' \cup \{q\})$ ,  $p$  is packed by OPT in  $R$  but by B2F in neither  $R$  nor  $A$ , since  $p \neq q$ ,  $p$  is an  $X_1$  or  $s(p) = 1$ , and  $s(p) \geq s(p')$  for all  $p' \in R'$ . Since each bin of  $R$  is at least  $\frac{3}{4}$  full,

$$(3.2) \quad s(R^*) \leq \frac{4}{3}s(R').$$

Let  $Q = R^* \cap \{q\}$  (thus  $Q = \emptyset$  if  $q$  was not packed by OPT in  $R$ ). Then

$$s(R^*) = s(R^* \cap R') + s(Q) + s(S) + s(R^* \setminus (R' \cup S \cup Q))$$

and  $s(R') = s(R' \cap R^*) + s(R' \setminus R^*)$ .

Substituting into (3.2) and combining terms yields

$$(3.3) \quad s(Q) + s(S) + s(R^* \setminus (R' \cup S \cup Q)) \leq \frac{1}{3}s(R' \cap R^*) + \frac{4}{3}s(R' \setminus R^*).$$

If we let  $m = \max_{p \in R'} s(p)$ , then  $m \leq 1$ ; and for  $p \in S \cup Q$ ,  $s(p) > m/2$ . Further, for  $p \in R^* \setminus (R' \cup S \cup Q)$ ,  $s(p) \geq m$ . Substituting these into (3.3) yields

$$(3.4) \quad \begin{aligned} &s(Q) + \left(\frac{m}{2}\right)|S| + m(|R^*| - |S| - |R^* \cap R'|) - s(Q) \\ &< \left(\frac{m}{3}\right)(|R' \cap R^*|) + \left(\frac{4}{3}m\right)(|R' \setminus R^*|). \end{aligned}$$

Combining like terms and dividing by  $m$  yields

$$\frac{s(Q)}{m} - |Q| - \frac{1}{2}|S| + |R^*| < \frac{4}{3}|R'|$$

or

$$|R^*| < \frac{1}{2}|S| + \frac{4}{3}|R'| + |Q| - \frac{s(Q)}{m}.$$

If  $Q = \emptyset$ ,

$$n_{OR} < \frac{1}{2}f_{AR} + \frac{4}{3}n_{HR} < \frac{1}{2}f_{AR} + \frac{4}{3}n_{HR} + \frac{1}{2}.$$

If  $Q \neq \emptyset$ ,  $s(q) > m/2$  and  $m \leq 1$ , so

$$(3.5) \quad n_{OR} < \frac{1}{2}f_{AR} + \frac{4}{3}n_{HR} + \frac{1}{2}.$$

Combining (3.5) and (3.1),

$$(3.6) \quad n_O < \frac{4}{3}n_H - \frac{1}{6}f_{AR} + \frac{1}{2}.$$

Since  $n_O$  is an integer, if  $f_{AR} \geq 1$ , we would have  $n_O \leq \frac{4}{3}n_H$ . Thus  $f_{AR} = 0$ , and all pieces packed by OPT in  $R$  are also packed by H in  $R$ , if H packs them at all. Pieces packed by H in  $R$ , but not packed by OPT in  $R$  must be replaced by larger pieces by OPT, so region  $R$  is a counterexample; by minimality there is no region  $A$ . From the argument used to show (3.6) we see that if we consider  $R$ ,  $R^*$ , and  $R'$  as a counterexample,

$$s(q) + s(R') + |R^*| - |R'| - 1 \leq \sum_{B \in \mathbf{B}} s(B) = \frac{4}{3}s(R') - \frac{4}{3} \left[ s(R') - \frac{3}{4} \sum_{B \in \mathbf{B}} s(B) \right].$$

Therefore

$$(3.7) \quad \begin{aligned} |R^*| &\leq \frac{1}{3}s(R') - \frac{4}{3} \left[ s(R') - \frac{3}{4} \sum_{B \in \mathbf{B}} s(B) \right] + |R'| + 1 - s(q) \\ &= \frac{4}{3}|R'| - \frac{1}{3} \sum_{p \in R'} [1 - s(p)] - \frac{4}{3} \left[ s(R') - \frac{3}{4} \sum_{B \in \mathbf{B}} s(B) \right] + 1 - s(q). \end{aligned}$$

If all terms on the right of (3.7) except  $\frac{4}{3}|R'|$  sum to less than  $\frac{1}{3}$ , then since  $|R^*|$  is an integer,  $|R^*| \leq \frac{4}{3}|R'|$  as desired. Therefore we shall show that for any bin  $B$ ,

$$-\frac{1}{3} \sum_{p \in B} [1 - s(p)] - \frac{4}{3} \left[ \sum_{p \in B} s(p) - \frac{3}{4}s(B) \right] + 1 - s(q) < \frac{1}{3}.$$

If this were not so,

$$\frac{1}{3} \sum_{p \in B} [1 - s(p)] + \frac{4}{3} \left[ \sum_{p \in B} s(p) - \frac{3}{4}s(B) \right] - 1 + s(q) \leq -\frac{1}{3}$$

and

$$\frac{1}{3}|B| + \sum_{p \in B} s(p) + s(q) - s(B) \leq \frac{2}{3}.$$

But  $|B| \geq 2$  (since region  $R$  is beyond  $F$ ) and  $\sum_{p \in B} s(p) + s(q) > s(B)$  and we have a contradiction.  $\square$

There must therefore be a bad  $X_2$  bin if we have a counterexample.

LEMMA 2.3.4. *If  $B$  is the last  $X_2$  bin and  $q_1$  and  $q_2$  are any two pieces available but not used when H packed  $B$ , then*

$$s(q_1) + s(q_2) > \frac{5}{6} \sum_{p \in B} s(p).$$

*Proof.* Let  $x_1$  and  $x_2$  be two  $X$  pieces packed in  $B$ . Since  $q_1$  and  $q_2$  did not replace  $x_2$ ,

$$s(x_1) + s(q_1) + s(q_2) > s(B) > \frac{4}{3}[s(x_1) + s(x_2)]$$

and

$$\begin{aligned} s(q_1) + s(q_2) &> \frac{4}{3}[s(x_1) + s(x_2)] - s(x_1) \\ &> \frac{4}{3}[s(x_1) + s(x_2)] - \frac{1}{2}[s(x_1) + s(x_2)] \end{aligned}$$

and the lemma follows.  $\square$

Recall that region  $A$  contains all the  $F_1$  and  $X_1$  bins. We define region  $S$  to include all  $Y_1$  bins where the fallback piece is smaller than the last piece  $q_s$  packed beyond the last  $X_2$  bin. All other  $Y_1$  bins not in  $A$  constitute region  $Y$ , except those bins where the fallback piece is as large as the last  $X_2$  piece. These bins, and all bins through the last  $X_2$  bin, constitute region  $D$ . All remaining bins constitute region  $Q$ . Note that all bins of  $S$  precede all bins of  $Y$ . Either region may be empty. Note further that pieces smaller than  $q_s$  are fallback pieces if they are packed in  $Q$ .

LEMMA 2.3.5.

$$n_{OS} - n_{HS} \leq \frac{1}{3}n_{HS} + \frac{2}{3}f_{AS} + \frac{2}{3}f_{DS} + \frac{5}{9}f_{QS} + \frac{2}{9}x_{QS} - \frac{2}{3}f_{(S,r \neq S)}.$$

*Proof.* Any bin  $B$  of  $S$  has  $n_{HB} = 2$ . If a bin of  $S$  contains more than 2 pieces in the OPT packing, it must contain 3, and each piece must be already packed by H ( $f_A$  or  $f_S$ ) or no larger than the piece used by H ( $f_D$  or  $f_Q$ ). Hence

$$\begin{aligned} n_{OS} - n_{HS} &\leq \frac{1}{3}f_{AS} + \frac{1}{3}f_{SS} + \frac{1}{3}f_{DS} + \frac{1}{3}f_{QS} \\ &\leq \frac{2}{3}f_{AS} + \frac{2}{3}f_{DS} + \frac{5}{9}f_{QS} + \frac{1}{3}n_{HS} - n_{HS} - \frac{1}{3}x_S - \frac{1}{3}f_{(S,r \neq S)} \end{aligned}$$

and, since  $x_S \geq f_{(S,r \neq S)}$ , the lemma follows.  $\square$

LEMMA 2.3.6.

$$n_{OY} - n_{HY} \leq \frac{2}{3}f_{AY} + \frac{2}{3}f_{DY} + \frac{2}{3}f_{SY} + \frac{5}{9}f_{QY} + \frac{2}{9}x_{QY} + \frac{1}{3}n_{HY} - \frac{1}{3}f_{(Y,r \neq Y)}.$$

*Proof.* As in Lemma 2.3.5, we need consider only bins packed by OPT with 3 pieces, and again those pieces were already packed by H ( $f_A, f_S, f_Y$ ) or are no larger than the fallback piece. But we must include  $X_Q$  pieces. Thus

$$\begin{aligned} n_{OY} - n_{HY} &\leq \frac{1}{3}f_{AY} + \frac{1}{3}f_{SY} + \frac{1}{3}f_{YY} + \frac{1}{3}f_{DY} + \frac{1}{3}f_{QY} + \frac{1}{3}x_{QY} \\ &\leq \frac{1}{3}f_{YY} + \frac{1}{3}f_{(r \neq Y, Y)} + \frac{1}{3}x_{QY} + \frac{1}{3}n_{HY} - \frac{2}{3}f_Y. \end{aligned}$$

Now  $f_Y = M_Y \geq \frac{1}{3}x_{QY}$ , so  $\frac{1}{3}f_Y \geq \frac{1}{9}x_{QY}$  and

$$n_{OY} - n_{HY} \leq \frac{1}{3}f_{YY} + \frac{1}{3}f_{(r \neq Y, Y)} + \frac{2}{9}x_{QY} + \frac{1}{3}n_{HY} - \frac{1}{3}f_{(Y,r \neq Y)}$$

and the lemma follows.  $\square$

LEMMA 2.3.7.

$$n_{OD} - n_{HD} \leq \frac{1}{3}n_{HD} + \frac{2}{3}f_{AD} + \frac{2}{3}f_{SD} + \frac{2}{9}x_{QD} + \frac{2}{9}f_{QD} + \frac{2}{9}f_{YD} - \frac{2}{3}f_{(D,r \neq D)}.$$

*Proof.* If  $B$  is a bin of  $D$  in which OPT packed 3 pieces, either one of the pieces was not available when H packed  $B$  and is smaller than any piece that was available ( $f_A, f_S, f_D$ ), or OPT packed at least 3 pieces smaller than any  $X_2$  piece ( $f_Q, x_Q, f_Y$ ). (Otherwise the two smaller pieces would be able to replace the smallest  $X_2$  piece in the last  $X_2$  bin.) Thus, abusing the notation by making it refer to numbers of pieces in bin  $B$ ,

$$(7.1) \quad n_{OB} - 2 \leq f_{AB} + f_{SB} + f_{DB} + \frac{1}{3}f_{QB} + \frac{1}{3}f_{YB} + \frac{1}{3}x_{QB}.$$

If OPT packs  $B$  with more than 3 pieces, we claim that

$$(7.2) \quad n_{OB} - 2 \leq \frac{3}{4}f_{AB} + \frac{3}{4}f_{DB} + \frac{3}{4}f_{SB} + \frac{1}{4}f_{QB} + \frac{1}{4}x_{QB} + \frac{1}{4}f_{YB}.$$

To see this, let  $f = f_{AB} + f_{DB} + f_{SB}$  and  $x = f_{QB} + x_{QB} + f_{YB}$ , and let  $m$  be the average size of the  $X$  pieces in the last  $X_2$  bin. Then, since  $s(B) < 3m$ ,

$$\frac{1}{2}mf + \frac{5}{6}mx + m(n_{OB} - x - f) < 2m + s(q),$$

where  $q$  is the piece not packed by H. Then

$$(7.3) \quad n_{OB} - 2 < \frac{1}{2}f + \frac{1}{6}x + \frac{1}{m}s(q).$$

If the claim is false,  $\frac{3}{4}f + \frac{1}{4}x < \frac{1}{2}f + \frac{1}{6}x + (1/m)s(q)$ , and, since  $q$  is smaller than any  $X_2$ ,  $\frac{1}{4}f + \frac{1}{12}x < (1/m)s(q) \leq 1$ . Thus  $f \leq 3$ .

If  $f = 3$ , then  $x \leq 2$  and  $n_{OB} - 2 < \frac{1}{2} \cdot 3 + \frac{1}{6} \cdot 2 + (1/m)s(q) < 3$ . But then  $n_{OB} - 2 \leq \frac{3}{4}f + \frac{1}{4}x$ .

If  $f = 2$ , then  $x \leq 5$  and from (7.3),  $n_{OB} - 2 \leq \frac{1}{2} \cdot 1 + \frac{1}{6} \cdot 5 + (1/m)s(q) < 3$  and  $n_{OB} - 2 \leq \frac{3}{4}f + \frac{1}{4}x$  unless  $x \leq 1$ . If  $x \leq 1$ ,  $n_{OB} - 2 \leq \frac{1}{2} \cdot 2 + \frac{1}{6} \cdot 1 + (1/m)s(q) < 2$ .

If  $f = 1$ , then  $\frac{1}{2} \cdot 1 + \frac{5}{6}x < 3$ , so  $x \leq 2$  and  $n_{OB} - 2 \leq \frac{1}{2} \cdot 1 + \frac{1}{6} \cdot 2 + (1/m)s(q) < 2$ .

If  $f = 0$ , then  $x \leq 3$  and  $n_{OB} - 2 \leq \frac{1}{6} \cdot 3 + (1/m)s(q) < 2$ . Thus the claim is true.

Combining (7.1) and (7.2), using  $f^1$  to refer to bins where  $n_{OB} - 2 = 1$ , and  $f^2, x^2$  to refer to bins where  $n_{OB} - 2 \geq 2$ ,

$$(7.4) \quad n_{OD} - 2M_D = \sum_{B \in D} n_{OB} - 2 \leq \frac{3}{4}f_{AD}^2 + \frac{3}{4}f_{DD}^2 + \frac{3}{4}f_{SD}^2 + \frac{1}{4}f_{QD}^2 + \frac{1}{4}x_{QD}^2 + \frac{1}{4}f_{YD}^2 + f_{AD}^1 + f_{DD}^1 + f_{SD}^1 + \frac{1}{3}f_{QD}^1 + \frac{1}{3}x_{QD}^1 + \frac{1}{3}f_{YD}^1.$$

Also  $n_{HD} - 2M_D \geq \frac{1}{2}f_D$ , so

$$(7.5) \quad n_{OD} - n_{HD} \leq \frac{3}{4}f^2 + \frac{1}{4}x_{QD}^2 + f^1 + \frac{1}{3}x_{QD}^1 - \frac{1}{2}f_D.$$

We now obtain another inequality by computing  $n_{OD} - 3M_D$ . For any bin  $B$  packed by OPT with more than 3 pieces,  $n_{OB} - 3 \leq \frac{2}{3}[n_{OB} - 2]$  (since  $n_{OB} \leq 5$ ), so  $n_{OD} - 3M_D \leq \frac{1}{2}f_D^2 + \frac{1}{6}x_D^2$ . Also  $3M_D - n_{HD} \leq \frac{1}{2}[x_D - \frac{1}{2}f_D]$ . Combining these yields

$$(7.6) \quad n_{OD} - n_{HD} \leq \frac{1}{2}f_{DD}^2 + \frac{1}{2}f_{AD}^2 + \frac{1}{2}f_{SD}^2 + \frac{1}{6}x_{DD}^2 + \frac{1}{2}x_D - \frac{1}{4}f_D.$$

Multiplying (7.5) by  $\frac{2}{3}$  and (7.6) by  $\frac{1}{3}$  and adding yields:

$$\begin{aligned} n_{OD} - n_{HD} &\leq \frac{2}{3}f_{DD} + \frac{2}{3}f_{AD} + \frac{2}{3}f_{SD} + \frac{2}{9}x_{DD} + \frac{2}{9}x_{QD} + \frac{1}{6}x_D - \frac{5}{12}f_D \\ &\leq \frac{2}{3}[f_{AD} + f_{SD}] + \frac{2}{9}[x_{QD} + f_{QD} + f_{YD}] + \frac{1}{3}n_{HD} - \frac{2}{3}f_{(D,r \neq D)} \end{aligned}$$

as desired in the lemma.  $\square$

LEMMA 2.3.8 (Summary Lemma). *Let  $I$  be the region consisting of all bins through the last  $X_2$  bin, and let  $Q$  be all remaining bins.*

$$n_{OI} - n_{HI} \leq \frac{1}{3}n_{HI} + \frac{2}{9}x_{QI} - \frac{2}{3}f_{IQ} + \frac{5}{9}f_{QI} - \frac{1}{3}f_{YQ},$$

where  $f_{IQ}$  does not contain the  $f_{YQ}$  contribution.

*Proof.* The lemma follows from adding the inequalities for the subregions A, S, Y, and D. The  $\frac{5}{9}f_{QI}$  term contains only contributions from the Y region. The term  $f_{YQ}$  is nonzero only if a piece larger than  $q_s$  is packed by H in a  $Y_1$  bin but is packed by OPT in  $Q$ . By Lemma 2.3.6, such pieces can be subtracted with a coefficient no larger than  $\frac{1}{3}$ .  $\square$

We examine the remaining bins in the following lemmas. Because of a slight problem with small fallback pieces in the  $F_2$  region, we give separate proofs for the  $F_2$  and  $X_3$  regions. All other  $F_n$  and  $X_n$  bins are treated together.

LEMMA 2.3.9. *In region  $R = F_2 \cup Y_2$ ,*

$$n_{OR} - n_{HR} \leq \frac{1}{3}n_{HR} + \frac{2}{3}f_{IR} + \frac{5}{9}f_{QR} + \frac{2}{9}x_{QR} + \frac{2}{9}f_{YR} - \frac{2}{3}f_{RQ_s} - \frac{2}{9}x_{RQ} - \frac{5}{9}f_{RQI}$$

where region  $Q$  contains all bins after region  $R$ ;  $f_{RQ_s}$  and  $f_{RQ_l}$  refer, respectively, to fallback  $F_2$  pieces which are smaller than  $q_s$  and at least as large as  $q_s$ .

*Proof.* We prove the lemma by examining bins individually and summing over all bins in the region. If we can show, for each bin  $B$  in region  $R$ , that

$$(9.1) \quad n_{OB} - n_{HB} \leq \frac{2}{3}f_{IB} + \frac{5}{9}f_{QB} + \frac{2}{9}x_{QB} + \frac{2}{9}f_{YB} + \frac{5}{9}f_{RB} + \frac{2}{9}x_{RB} - \frac{1}{3}f_{Bs} - \frac{2}{9}f_{BI} + \frac{1}{9}x_B$$

then the lemma will follow from summing this formula over all bins in  $R$ .

Suppose that  $B$  is a bin of  $R$  for which (9.1) fails. Throughout  $R$  we know that  $n_{HB}$  is 3, that  $x_B$  is 1 or 2, and that  $f_{Bs} + f_{BI}$  is 1 or 2. Since any piece that OPT packs in  $B$  is at least half the size of any piece of type  $X$  that H packs in  $B$ , and all other pieces (besides  $f_I$ ) are at least  $\frac{5}{6}$  the size, we have easily that

$$\frac{1}{2}f_{IB} + \frac{5}{6}(f_{QB} + f_{RB} + f_{YB} + x_{QB} + x_{RB}) + n_{OB} - (f_{IB} + f_{QB} + f_{RB} + f_{YB} + x_{QB} + x_{RB}) < 3.$$

This gives us the following, letting  $f$  stand for  $f_{IB}$ , and  $q$  for all the other types of pieces listed above:

$$(9.2) \quad n_{OB} - 3 < \frac{1}{2}f + \frac{1}{6}q.$$

If (9.1) fails, it is easy to see that  $n_{OB}$  must be at least 3 and that no bin in  $R$  can contain more than 5 pieces. We have 3 cases to consider.

*Case 1.*  $n_{OB} = 5$ . In this case, we have from (9.2) that  $f_{IB} \geq 4$ , and (9.1) follows, since  $2 \leq \frac{2}{3} \cdot 4 - \frac{1}{3} \cdot 2 + \frac{1}{9} \cdot 1$ .

*Case 2.*  $n_{OB} = 4$ . In this case, (9.2) implies  $f \geq 2$ . If  $f \geq 3$ , (9.1) follows as in Case 1. If  $f = 2$ , then (9.2) implies  $q \geq 1$ . Then  $1 \leq \frac{2}{3} \cdot 2 + \frac{2}{9} \cdot 1 - \frac{1}{3} \cdot 2 + \frac{1}{9} = 1$ , and (9.1) follows.

*Case 3.*  $n_{OB} = 3$ . In this case, we know from (9.2) that  $f$  or  $q$  must be at least 1. If  $f_{IB} \geq 1$  or  $f_{QB} \geq 1$ , then (9.1) follows. If  $B$  is type  $Y_2$  and  $f_{IB} = f_{QB} = 0$ , then (9.1) still follows if  $f_{IB} = f_{QB} = 0$ . If  $B$  is type  $F_2$ , then  $B$  cannot contain 2 pieces as large as the  $X$  piece H packs in  $B$  and also a piece as large as any available when H packed  $B$ . Thus  $f_{YB} + x_{QB} = 2$ . In that case, at least one of the fallback pieces packed by H must be at least as large as  $q_s$  because of the way H replaces pieces, and  $f_{BI} \geq 1$ . Substituting into (9.1) yields the lemma.  $\square$

LEMMA 2.3.10. *If region  $R$  is the region  $X_3$ ,*

$$n_{OR} - n_{HR} \leq \frac{1}{3}n_{HR} + \frac{2}{3}f_{IR} + \frac{5}{9}f_{IR} + \frac{5}{9}f_{QR} + \frac{2}{9}x_{QR} - \frac{2}{9}x_{RQ} - \frac{5}{9}f_{RQ},$$

where  $f_{IR}$  is the number of pieces at least as large as  $q_s$  packed by H and OPT in  $R$ .

*Proof.* As for the previous lemma, this proof is carried out by showing that, for each bin  $B$  in region  $R$ ,

$$(10.1) \quad n_{OB} - n_{HB} \leq \frac{2}{3}f_{IB} + \frac{2}{3}f_{sB} + \frac{5}{9}f_{IB} + \frac{2}{9}x_{QB} + \frac{1}{9}x_B - \frac{2}{9}f_B.$$

This inequality certainly holds if  $n_{OB} \leq 3$ , since  $n_{HB} + \frac{1}{9}x_B - \frac{2}{9}f_B > 3$ . Suppose  $4 \leq n_{OB} \leq 7$ . We know that

$$(10.2) \quad n_{OB} - 4 < \frac{1}{2}f + \frac{1}{6}q$$

where  $f = f_{IB}$  and  $q = f_{sB} + f_{IB} + x_{QB} + f_{QB}$ .

*Case 1.*  $n_{OB} = 7$ . In this case, (10.2) implies  $f_{IB} \geq 6$ , and (10.1) follows easily.

*Case 2.*  $n_{OB} = 6$ . In this case,  $f_{IB} \geq 4$ , and (10.1) follows.

*Case 3.*  $n_{OB} = 5$ . Now  $f_{IB} \geq 1$ . If  $f_{IB} \geq 3$ , (10.1) follows easily. Suppose  $f_{IB} = 2$ . Then  $q \geq 1$ , so if  $B$  is a fallback bin,  $5 - 4 \leq \frac{4}{3} + \frac{2}{9} + \frac{2}{9} - \frac{4}{9}$  and (10.1) holds again. If  $B$  is not a fallback bin, then a similar computation shows that (10.1) holds if  $q \geq 3$ , or if  $f_{IB}$  or  $f_{sB}$  is nonzero. If there are two  $X_Q$  pieces packed by OPT in  $B$ , they would replace the last  $X$  piece H packed, and if there is only one  $X_Q$  piece, it would fit with

the 3 pieces H packed in  $B$ . (If the pieces are larger than  $q_s$  but already packed, then other pieces could be used.)

Suppose  $f_{IB} = 1$ . If  $B$  is a fallback bin, then  $n_{OB} - n_{HB} = 1 \leq \frac{2}{3} \cdot 1 + \frac{2}{9} \cdot 4 + \frac{1}{9} \cdot 2 - \frac{2}{9} \cdot 2$ . If  $B$  is not a fallback bin, then (10.1) holds if  $f_{IB} + f_{sB} + f_{QB} \geq 1$ , since  $2 \leq \frac{2}{3} + \frac{5}{9} + 3 \cdot \frac{2}{9} + 3 \cdot \frac{1}{9}$  and  $q = 4$ . If  $x_{QB} = 4$ , however, any  $x_{QB}$  piece would fit in  $B$  as a fallback piece, contradicting the fact that  $B$  has type  $X_3$ . This follows since any  $f_{IB}$  piece and any three  $x_{QB}$  pieces are at least as large as the three pieces H packed in  $B$ .

*Case 4.*  $n_{OB} = 4$ . In this case, all we know from (10.2) is that  $f + q \geq 1$ . If  $B$  is a fallback bin then (10.1) holds. So suppose that  $B$  is an  $X_3$  bin. If  $f_{IB}$  or  $f_{sB}$  are at least 1, then again (10.1) holds. If  $f_{IB}$ ,  $x_{QB}$  or  $f_{QB}$  are 1, then  $q_s$  would have fit, making  $B$  type  $Y_3$ . Similarly, if  $f_{IB} + x_{QB} = 2$ ,  $B$  would be type  $F_3$ . But if  $f_{IB} - x_{QB} \geq 3$ , then  $1 \leq \frac{2}{9} \cdot 3 + \frac{1}{9} \cdot 3$  and (10.1) holds.  $\square$

LEMMA 2.3.11. *If  $R = F_n$  or  $Y_n$ ,  $n \geq 3$ , or  $X_n$ ,  $n \geq 4$ , then*

$$n_{OR} - n_{HR} \leq \frac{1}{3}n_{HR} + \frac{2}{3}f_{IR} + \frac{5}{9}f_{QR} + \frac{2}{9}x_{Q'R} - \frac{2}{9}x_{RQ} - \frac{5}{9}f_{RQ},$$

where region  $Q$  contains all bins after  $I$ , and  $Q'$  contains all bins after  $R$ .

*Proof.* We begin by proving a general inequality that applies in each of the cases. Let  $B$  be any bin of  $R$ . Then any pieces from region  $I$  must have size at least half that of the  $X$  pieces that H packs in  $B$ . Any other pieces that are smaller than the  $X$  pieces must be at least  $\frac{5}{6}$  their size. Consequently,

$$\frac{1}{2}f_{IB} + \frac{5}{6}(f_{QB} + x_{Q'B}) + n_{OB} - f_{IB} - f_{QB} - x_{Q'B} < n + 1$$

and we can simplify this to

$$n_{OB} - n < \frac{1}{2}f_{IB} + \frac{1}{6}(f_{QB} + x_{Q'B}) + 1.$$

Since  $n_{OB} - n$  is an integer,

$$(11.1) \quad n_{OB} - n \leq \frac{1}{2}f_{IB} + \frac{1}{6}(f_{QB} + x_{Q'B}) + \frac{5}{6}.$$

Now we assume that  $B$  is a bin of  $R$  in which OPT packs at least  $n + 2$  pieces. We claim that if  $R$  is a region  $F_n$  or  $X_n$ , then

$$n_{OB} - n \leq \frac{3}{4}f_{IB} + \frac{1}{2}f_{QB} + \frac{1}{4}x_{Q'B}$$

while, if  $R$  is  $Y_n$ , then

$$n_{OB} - n \leq \frac{3}{4}f_{IB} + \frac{1}{2}f_{QB} + \frac{1}{4}x_{Q'B} + \frac{1}{4}.$$

Note that the only difference between the claim for  $Y_n$  and the others is the  $\frac{1}{4}$  on the end. We shall proceed with the proof for the case when  $R$  is  $X_n$  or  $F_n$  and point out where the  $\frac{1}{4}$  is needed in three places to fill in the details for the  $Y_n$  case.

If the claim fails for  $R = X_n$  or  $F_n$  then from (11.1) we have by simplifying

$$\frac{1}{4}f_{IB} + \frac{1}{3}f_{QB} + \frac{1}{12}x_{Q'B} < \frac{5}{6},$$

and consequently  $f_{IB} \leq 3$  and  $f_{IB} + f_{QB} + x_{Q'B} \leq 9$ .

If  $f_{IB} = 3$ , then  $f_{QB}$  and  $x_{Q'B}$  must be 0. But then  $n_{OB} - n$  must be at most  $\frac{1}{2} \cdot 3 + \frac{5}{6}$  if the claim fails. Since it must be an integer, it can only be 2; and then  $2 \leq \frac{3}{4} \cdot 3$ , contradicting the supposition that the claim failed.

If  $f_{IB} = 2$ , then  $f_{QB} = 0$ , and  $x_{Q'B} \leq 3$ . Again we have  $n_{OB} - n \leq 2$  from (11.1) and the claim holds unless  $x_{Q'B} \leq 1$ . In this case, however, the  $x_{Q'B}$  piece would fit with the  $n$  pieces packed by H in the last bin of region  $R$ , contradicting the fact that  $R$  is  $X_n$  or  $F_n$ . If  $R$  is region  $Y_n$ , then the additional  $\frac{1}{4}$  added to the claim is sufficient if  $x_{Q'B} = 1$ . Note that  $x_{Q'B}$  cannot be 0 by (11.1).

If  $f_{IB} = 1$ , then  $f_{QB} + x_{Q'B} \leq 6$ , if the claim is false. From (11.1) we again obtain  $n_{OB} - n = 2$  and the claim holds unless  $f_{QB} \leq 2$  and  $f_{QB} + x_{Q'B} \leq 4$ . But also from (11.1),

$$2 \leq \frac{1}{2} + \frac{1}{6}(f_{QB} + x_{Q'B}) + \frac{5}{6}$$

implies that  $f_{QB} + x_{Q'B} = 4$  and, if  $f_{QB} \geq 1$ , the claim holds. Thus if the claim is false,  $f_{QB} = 0$  and  $x_{Q'B} = 4$ . As above we now find that any of the  $x_{Q'B}$  pieces would fit in the last bin of  $R$ , contradicting the fact that the bin is of  $F$  or  $X$  type. And again the  $\frac{1}{4}$  in the claim when  $R = Y_n$  is sufficient for this case as well.

Finally, if  $f_{IB} = 0$ , then we can again show that  $n_{OB} - n = 2$ , and that  $f_{QB} = 0$  and  $x_{Q'B} \leq 7$ . If  $x_{Q'B} < 7$  the claim holds, so it must be exactly 7. Again we find that any of the smaller pieces would fit in the last bin of  $R$ . And again in the  $Y_n$  case, the additional  $\frac{1}{4}$  is sufficient to cause the claim to hold.

Suppose now that  $n_{OB} = n + 1$ , and that  $R$  is of type  $X_n$  or  $F_n$ . If OPT packs  $B$  with no pieces smaller than those available to pack the last bin  $B_R$  of  $R$ , then there must be at least two pieces smaller than the pieces of type  $X$  in  $B_R$ , if  $R$  is an  $F_n$ , and 3 such pieces if  $R$  is an  $X_n$ . Thus if  $R = F_n$ , (using  $f^1$  and  $x^1$  to denote pieces packed by OPT in a bin with  $n + 1$  pieces)

$$(11.2) \quad n_{OB} - n \leq f_{IB}^1 + f_{QB}^1 + \frac{1}{2}x_{Q'B}^1,$$

and if  $R$  is  $X_n$ ,

$$(11.3) \quad n_{OB} - n \leq f_{IB}^1 + f_{QB}^1 + \frac{1}{3}x_{Q'B}^1.$$

For  $R = F_n$  we have from (11.2) and the claim (using  $f^2$  and  $x^2$  to denote pieces packed by OPT in a bin of  $n + 2$  pieces):

$$n_{OB} - n \leq \frac{3}{4}f_{IB}^2 + f_{IB}^1 + f_{QB}^1 + \frac{1}{2}f_{QB}^2 + \frac{1}{4}x_{Q'B}^2 + \frac{1}{2}x_{Q'B}^1,$$

and summing over all bins of  $R$ , using  $n_{HR} \geq n|R| + \frac{1}{2}f_R$ ,

$$(11.4) \quad n_{OR} - n_{HR} \leq \frac{3}{4}f_{IR}^2 + f_{IR}^1 + f_{QR}^1 + \frac{1}{2}f_{QR}^2 + \frac{1}{4}x_{Q'R}^2 + \frac{1}{2}x_{Q'R}^1 - \frac{1}{2}f_R.$$

Thus, for  $R = F_n$ ,

$$(11.5) \quad n_{OR} - n_{HR} \leq \frac{3}{4}f_{IR}^2 + f_{IR}^1 + \frac{1}{2}f_{QR}^2 + f_{QR}^1 + \frac{1}{4}x_{QR}^2 + \frac{1}{2}x_{QR}^1 - \frac{1}{2}f_R$$

For  $R = Y_n$  we can obtain the same result since  $n_{HR} = n|R| + f_R$ . Also, from (11.1),

$$n_{OB} - (n + 1) \leq \frac{1}{2}f_{IB}^2 + \frac{1}{6}f_{QB}^2 + \frac{1}{6}x_{Q'B}^2$$

and, summing over all bins of  $R$ ,

$$(11.6) \quad n_{OR} - n_{HR} \leq \frac{1}{2}f_{IR}^2 + \frac{1}{6}f_{QR}^2 + \frac{1}{6}x_{QR}^2.$$

Multiplying (11.5) by  $\frac{5}{9}$  and (11.6) by  $\frac{4}{9}$ ,

$$\begin{aligned} n_{OR} - n_{HR} &\leq \frac{2}{3}f_{IR} + \frac{5}{9}f_{QR} + \frac{2}{9}x_{QR} - \frac{1}{2}f_R \\ &\leq \frac{1}{3}n_{HR} + \frac{2}{3}f_{IR} + \frac{5}{9}f_{QR} + \frac{2}{9}x_{QR} - \frac{1}{3}x_{QR} - \frac{5}{9}f_R \end{aligned}$$

and the lemma holds when  $R = F_n$  or  $Y_n$ .

Similarly when  $R$  is an  $X_n$  region, we get from (11.3) and the claim, and from summing over all bins of  $R$ ,

$$(11.7) \quad n_{OR} - n_{HR} \leq \frac{3}{4}f_{IR}^2 + f_{IR}^1 + f_{QR}^1 + \frac{1}{2}f_{QR}^2 + \frac{1}{4}x_{Q'R}^2 + \frac{1}{3}x_{Q'R}^1 - \frac{1}{2}f_R.$$

For any bin  $B$  of  $R$ ,  $n_{HB} \cong (1/n)x_B - (n-1)f_B/2n$ . Thus

$$n_{OB} - n_{HB} \cong \frac{1}{2}f_{IR}^2 + \frac{1}{6}(f_{QB}^2 + x_{QB}^2) + \frac{1}{n}x_B - \frac{n-1}{2n}f_B$$

and

$$(11.8) \quad n_{OR} - n_{HR} \cong \frac{1}{2}f_{IR}^2 + \frac{1}{6}(f_{QR}^2 + x_{QR}^2) + \frac{1}{n}x_R - \frac{n-1}{2n}f_R.$$

Multiplying (11.7) by  $\frac{5}{9}$  and (11.8) by  $\frac{4}{9}$  yields

$$n_{OR} - n_{HR} \cong \frac{2}{3}f_{IR} + \frac{5}{9}f_{QR} + \frac{2}{9}x_{QR} + \frac{4}{9}x_R.$$

Since  $n \geq 4$ , the lemma follows in this case as well.  $\square$

Adding Lemmas 2.3.8 through 2.3.11 yields the final result.

## AN OPTIMAL ALGORITHM FOR FINDING A MAXIMUM INDEPENDENT SET OF A CIRCULAR-ARC GRAPH\*

SUMIO MASUDA† AND KAZUO NAKAJIMA‡

**Abstract.** A new algorithm is presented for finding a maximum independent set of a circular-arc graph. When the graph is given in the form of a family of  $n$  arcs, our algorithm requires only  $O(n \cdot \log n)$  time and  $O(n)$  space. Furthermore, if the endpoints of the arcs are already sorted, it runs in  $O(n)$  time. This algorithm is time- and space-optimal to within a constant factor.

**Key words.** optimal algorithm, circular-arc graph, maximum independent set

**AMS(MOS) subject classifications.** 68C25, 68E10

**1. Introduction.** Let  $G = (V, E)$  be a graph. Two distinct vertices  $u$  and  $v$  in  $V$  are said to be *independent* from each other if  $(u, v) \notin E$ ; otherwise they are said to be *adjacent* to each other. A subset  $X$  of  $V$  is called an *independent set* of  $G$  if any two vertices in  $X$  are independent. A *maximum independent set* of  $G$  is an independent set whose cardinality is the largest among all independent sets of  $G$ .

Consider a finite family  $S$  of nonempty sets. A graph  $G = (V, E)$  is called an *intersection graph* for  $S$  if there is a one-to-one correspondence between  $S$  and  $V$  such that two sets in  $S$  have a nonempty intersection if and only if the corresponding vertices in  $V$  are adjacent to each other. If  $S$  is a family of intervals on the real line, then  $G$  is called an *interval graph*. When  $S$  is a family of arcs on a circle,  $G$  is called a *circular-arc graph* for  $S$ .

Interval graphs have been used in many practical applications [6], [12], [14], [15], and, as such, a wide variety of algorithms have been developed [2], [5], [7], [9]–[11]. Furthermore, as a generalization of interval graphs, circular-arc graphs have received considerable attention in recent years. Tucker [13] gave an  $O(n^3)$  time algorithm for recognizing circular-arc graphs, where  $n$  is the number of the vertices in a given graph. Garey, Johnson, Miller and Papadimitriou [3] showed that the vertex coloring problem is NP-complete for circular-arc graphs. Gavril [4] developed polynomial time algorithms for finding a maximum clique, a maximum independent set, and a minimum covering by disjoint cliques of a circular-arc graph. When the graph is given in the form of a family of  $n$  arcs, the algorithms produce solutions in  $O(n^{3.5})$ ,  $O(n^4)$ , and  $O(n^5)$  time, respectively. Later, Gupta, Lee and Leung [7] gave  $O(n^2)$  time implementations of the last two algorithms of Gavril's. Leung [10] developed an efficient algorithm for generating all maximal independent sets of a circular-arc graph. Recently, Hsu [8] presented an algorithm for finding a maximum weight clique for the case when each vertex is assigned a real number as its weight. Its time complexity is  $O(n \cdot m)$ , where  $m$  is the number of edges of the graph.

‡ Electrical Engineering Department, Institute for Advanced Computer Studies and Systems Research Center, University of Maryland, College Park, Maryland 20742.

In this paper, we present a new algorithm for finding a maximum independent set of a circular-arc graph. We show an  $O(n \cdot \log n)$  time and  $O(n)$  space implementation of the algorithm when the graph is given in the form of a family of  $n$  arcs on a circle. If the endpoints of the arcs are already sorted, the algorithm is shown to run in  $O(n)$  time.

It should be noted that Gupta et al. [7] have proven that it requires  $\Omega(n \cdot \log n)$  time in the worst case to find a maximum independent set of an interval graph with  $n$  vertices. Since every interval graph is a circular-arc graph, our algorithm is both time- and space-optimal to within a constant factor.

**2. Definitions and notation.** Let  $S = \{a_1, a_2, \dots, a_n\}$  be a family of arcs on a circle  $C$ . Each endpoint of the arcs is assigned a positive integer, called a *coordinate*. The endpoints are located on the circumference of  $C$  in ascending order of the values of the coordinates in the clockwise direction. Without loss of generality, we can assume that (i) all endpoints of the arcs in  $S$  are distinct, and (ii) no single arc in  $S$  covers the entire circle  $C$  by itself.

For simplicity, we call the endpoint with coordinate  $j$  as point  $j$ . Suppose that an arc begins at point  $j$  and ends at point  $k$  in the clockwise direction. Then, we denote such an arc by  $(j, k)$ , and call points  $j$  and  $k$  as the *head* and the *tail*, respectively, of the arc  $(j, k)$ . For  $i = 1, 2, \dots, n$ , let  $h_i$  and  $t_i$  denote the coordinates of the head and tail, respectively, of arc  $a_i$ , that is,  $a_i = (h_i, t_i)$ . We show an example of a family of arcs in Fig. 1, where  $a_1 = (1, 7)$ ,  $a_2 = (3, 5)$ ,  $a_3 = (6, 9)$ ,  $a_4 = (8, 12)$ ,  $a_5 = (10, 13)$ ,  $a_6 = (11, 15)$ ,  $a_7 = (14, 4)$  and  $a_8 = (16, 2)$ .

FIG. 1. A family of arcs on a circle  $C$ .

For an arc  $a_i \in S$  and an endpoint  $j$  of another arc in  $S$ , we say that  $a_i$  *contains* point  $j$  if one of the following three conditions holds (see Fig. 2):

- (i)  $1 \leq h_i < j < t_i \leq 2n$ .
- (ii)  $1 \leq t_i < h_i < j \leq 2n$ .
- (iii)  $1 \leq j < t_i < h_i \leq 2n$ .

For two distinct arcs  $a_i$  and  $a_j$  in  $S$ , we say that they *intersect* with each other if one of them contains at least one of the endpoints of the other arc; otherwise  $a_i$  and  $a_j$  are said to be *independent* from each other. If  $a_i$  contains both endpoints of  $a_j$ , we

FIG. 2. Cases in which arc  $a_i$  contains point  $j$ . (a)  $1 \leq h_i < j < t_i \leq 2n$ . (b)  $1 \leq t_i < h_i < j \leq 2n$ . (c)  $1 \leq j < t_i < h_i \leq 2n$ .

say that  $a_i$  contains  $a_j$ . The circular-arc graph for  $S$ , denoted by  $G_S$ , is defined as follows:

$$G_S \triangleq (V_S, E_S), \text{ where}$$

$$V_S \triangleq \{v_1, v_2, \dots, v_n\} \text{ and}$$

$$E_S \triangleq \{(v_i, v_j) \mid a_i \text{ and } a_j \text{ intersect with each other}\}.$$

For example, Fig. 3 depicts the circular-arc graph for the family of arcs given in Fig. 1.

A subfamily  $S'$  of  $S$  is called an *independent arc family* (abbreviated to an IAF) if any two arcs in  $S'$  are independent from each other. A *maximum independent arc family* (abbreviated to an MIAF) of  $S$  is an IAF whose cardinality is the largest among all IAF's of  $S$ . For example, the family of arcs shown in Fig. 1 has two MIAF's,  $\{a_2, a_3, a_5, a_8\}$  and  $\{a_2, a_3, a_6, a_8\}$ . Clearly, the MIAF's of  $S$  and the maximum independent sets of  $G_S$  are in one-to-one correspondence. In the following section, we will present an algorithm for finding an MIAF of a family of arcs.

FIG. 3. The circular-arc graph for the family of arcs in Fig. 1.

**3. Outline of the algorithm.** Let  $S = \{a_1, a_2, \dots, a_n\}$  be a family of  $n$  arcs on a circle  $C$ .  $S$  is said to be *canonical* if (i)  $h_i$ 's and  $t_i$ 's for  $i = 1, 2, \dots, n$  are all distinct integers between 1 and  $2n$ , and (ii) point 1 is the head of arc  $a_1$ . For instance, the family of arcs shown in Fig. 1 is canonical, but the one given in Fig. 4 is not. It should be noted, however, that these two families of arcs correspond to the same circular-arc graph, which is shown in Fig. 3. When  $S$  is not canonical, by using a regular sorting

FIG. 4. A noncanonical family of arcs.

algorithm [1], one can construct, in  $O(n \cdot \log n)$  time, a family of arcs  $S'$  such that  $G_S = G_{S'}$ . Throughout this paper, we assume that the family  $S$  is canonical.

For a subfamily  $S'$  of  $S$ , let  $\alpha(S')$  denote the cardinality of a maximum independent set of  $G_{S'}$ , or equivalently that of an MIAF of  $S'$ . We start with the following theorem.

**THEOREM 1.** *Suppose that an arc  $a_i \in S$  contains another arc  $a_j \in S$ . Then, any MIAF of  $S - \{a_i\}$  is an MIAF of  $S$ .*

*Proof.* It is clear that  $\alpha(S) \geq \alpha(S - \{a_i\})$ . Let  $X$  be an MIAF of  $S$ . If  $a_i \notin X$ , then  $X$  is an IAF of  $S - \{a_i\}$ . On the other hand, if  $a_i \in X$ , then  $(X - \{a_i\}) \cup \{a_j\}$  is an IAF of  $S - \{a_i\}$ . These imply that  $\alpha(S) \leq \alpha(S - \{a_i\})$ . Thus,  $\alpha(S) = \alpha(S - \{a_i\})$ , and hence any MIAF of  $S - \{a_i\}$  is an MIAF of  $S$ .  $\square$

An arc  $a_i = (h_i, t_i) \in S$  is called a *forward arc* if  $h_i < t_i$ ; otherwise  $a_i$  is called a *backward arc*. For example, there are two backward arcs,  $a_7$  and  $a_8$ , in the family of arcs of Fig. 1. In our algorithm, we first remove all forward arcs which contain other forward arcs. Let  $S_F$  denote the resultant family of the forward arcs, and let  $S_B$  denote the family of all backward arcs in  $S$ . Then, we have the following lemma and theorem.

**LEMMA 1.**  $S_F \neq \emptyset$ .

*Proof.* Since  $S$  is canonical, it has at least one forward arc, that is,  $a_1$ . If  $a_1$  is the only forward arc in  $S$ ,  $S_F = \{a_1\} \neq \emptyset$ . On the other hand, if  $S$  has more than one forward arc, there exists at least one forward arc which does not contain any other forward arc. Thus,  $S_F \neq \emptyset$  in either case.  $\square$

**THEOREM 2.**  $1 \leq \alpha(S_F) \leq \alpha(S) \leq \alpha(S_F) + 1$ .

*Proof.* Since  $S_F \neq \emptyset$  from Lemma 1 and  $S_F \subseteq S$ ,  $1 \leq \alpha(S_F) \leq \alpha(S)$ . From Theorem 1,  $\alpha(S) = \alpha(S_F \cup S_B)$ , and hence  $\alpha(S) \leq \alpha(S_F) + \alpha(S_B)$ . Furthermore, it is clear that  $\alpha(S_B) = 1$  if  $S_B \neq \emptyset$ , and that  $\alpha(S_B) = 0$  if  $S_B = \emptyset$ . Therefore, the theorem holds.  $\square$

Our algorithm tests whether there exist an MIAF,  $X$  of  $S_F$  and an arc  $a_j \in S_B$  such that  $X \cup \{a_j\}$  is an IAF. From Theorem 2, if such an MIAF,  $X$  and an arc  $a_j$  exist, then  $X \cup \{a_j\}$  is an MIAF of  $S$ ; otherwise any MIAF of  $S_F$  is an MIAF of  $S$ . In general, the number of MIAF's of  $S_F$  may be an exponential function of  $|S_F|$ . However, our algorithm efficiently performs this test by exploiting a property of an MIAF of  $S$  which will be described later in Theorem 3.

Let  $X = \{a_{i_1}, a_{i_2}, \dots, a_{i_k}\}$  with  $h_{i_1} < t_{i_1} < h_{i_2} < t_{i_2} < \dots < h_{i_k} < t_{i_k}$  be an IAF of  $S_F$ . Then we call  $h_{i_1}$  (resp.,  $t_{i_k}$ ) the *starting coordinate* (resp., the *ending coordinate*) of  $X$

and denote it by  $sc(X)$  (resp.,  $ec(X)$ ). Let  $X_1$  and  $X_2$  be two IAF's of  $S_F$ . We say that  $X_1$  dominates  $X_2$  if one of the following conditions holds:

- (i)  $sc(X_2) < sc(X_1)$  and  $ec(X_1) \leq ec(X_2)$ .
- (ii)  $sc(X_2) \leq sc(X_1)$  and  $ec(X_1) < ec(X_2)$ .

An MIAF,  $X$  of  $S_F$  is called a *dominant maximum independent arc family* (abbreviated to a DMIAF) of  $S_F$  if no other MIAF of  $S_F$  dominates  $X$ .

LEMMA 2. *Let  $X$  be an MIAF of  $S_F \cup S_B$ . If there exists an MIAF,  $X_1$  of  $S_F$  which dominates  $X \cap S_F$ , then  $X_1 \cup (X \cap S_B)$  is an MIAF of  $S$ .*

*Proof.* Suppose that  $X \cap S_B = \emptyset$ . Then  $\alpha(S_F) = \alpha(S_F \cup S_B) = \alpha(S)$ . Since  $|X_1| = \alpha(S_F)$ ,  $X_1 \cup (X \cap S_B) = X_1$  is an MIAF of  $S$ . On the other hand, suppose that  $X \cap S_B \neq \emptyset$ . Since  $\alpha(S_B) \leq 1$ ,  $|X \cap S_B| = 1$ . Let  $a_i$  be the unique element in  $X \cap S_B$ . Then, it is clear that  $t_i < sc(X - \{a_i\})$  and  $ec(X - \{a_i\}) < h_i$ . Since  $X_1$  dominates  $X \cap S_F = X - \{a_i\}$ ,  $sc(X \cap S_F) \leq sc(X_1)$  and  $ec(X_1) \leq ec(X \cap S_F)$ . Therefore, we have  $t_i < sc(X_1)$  and  $ec(X_1) < h_i$  (see Fig. 5). This implies that  $X_1 \cup \{a_i\}$  is an IAF of  $S$ . Since  $|X_1 \cup \{a_i\}| = \alpha(S_F) + 1$ ,  $X_1 \cup (X \cap S_B) = X_1 \cup \{a_i\}$  is an MIAF of  $S$  from Theorem 2.  $\square$

FIG. 5. An illustration for the proof of Lemma 2.

LEMMA 3. *Let  $X$  be an MIAF of  $S_F \cup S_B$ . Then, there exists a DMIAF,  $X_1$  of  $S_F$  such that  $X_1 \cup (X \cap S_B)$  is an MIAF of  $S$ .*

*Proof.* If  $X \cap S_F$  is a DMIAF of  $S_F$ , then the theorem trivially holds. Otherwise, there exists a DMIAF of  $S_F$ , say  $X_2$ , which dominates  $X \cap S_F$ . From Lemma 2,  $X_2 \cup (X \cap S_B)$  is an MIAF of  $S$ .  $\square$

Lemma 3 implies that it suffices to consider DMIAF's of  $S_F$  in order to test whether there exist an MIAF,  $X$  of  $S_F$  and an arc  $a_j \in S_B$  such that  $X \cup \{a_j\}$  is an IAF of  $S$ . In the following, we will show that the space which must be searched to find a desired MIAF of  $S_F$  can be reduced further.

The next lemma is obvious from the definition of a DMIAF.

LEMMA 4. *Let  $X_1$  and  $X_2$  be two DMIAF's of  $S_F$ . Then,  $sc(X_1) = sc(X_2)$  if and only if  $ec(X_1) = ec(X_2)$ . Furthermore,  $sc(X_1) < sc(X_2)$  if and only if  $ec(X_1) < ec(X_2)$ .  $\square$*

Let  $D$  be the set of all DMIAF's of  $S_F$ . A subset of  $D$ ,  $R = \{X_1, X_2, \dots, X_k\}$  is called an *essential DMIAF set* for  $S_F$  if it satisfies the following two conditions:

- (i)  $sc(X_i) \neq sc(X_j)$  for any  $1 \leq i \neq j \leq k$ .
- (ii) For any DMIAF,  $X$  of  $S_F$ , there exists an integer  $j$  such that  $1 \leq j \leq k$  and  $sc(X_j) = sc(X)$ .

Let us consider the family  $S$  of arcs shown in Fig. 6. In this particular case,  $S_F$  consists of eight arcs  $a_1, a_2, \dots, a_8$ , and has ten MIAF's:  $\{a_1, a_4, a_7\}$ ,  $\{a_1, a_4, a_8\}$ ,  $\{a_1, a_5, a_8\}$ ,

FIG. 6. A canonical family of arcs  $S$ .  $\{\{a_2, a_4, a_7\}, \{a_3, a_5, a_8\}\}$  and  $\{\{a_2, a_4, a_7\}, \{a_3, a_6, a_8\}\}$  are essential DMIAF sets for  $S_F$ .

$\{a_1, a_6, a_8\}$ ,  $\{a_2, a_4, a_7\}$ ,  $\{a_2, a_4, a_8\}$ ,  $\{a_2, a_5, a_8\}$ ,  $\{a_2, a_6, a_8\}$ ,  $\{a_3, a_5, a_8\}$  and  $\{a_3, a_6, a_8\}$ . Among them,  $\{a_2, a_4, a_7\}$ ,  $\{a_3, a_5, a_8\}$  and  $\{a_3, a_6, a_8\}$  are DMIAF's. Since the last two have the same starting coordinate, each of the sets  $\{\{a_2, a_4, a_7\}, \{a_3, a_5, a_8\}\}$  and  $\{\{a_2, a_4, a_7\}, \{a_3, a_6, a_8\}\}$  is an essential DMIAF set for  $S_F$ .

From Lemma 3 and the first half of Lemma 4, we have the following theorem.

**THEOREM 3.** *Let  $X$  be an MIAF of  $S_F \cup S_B$ , and let  $R_F$  be an essential DMIAF set for  $S_F$ . Then, there exists a DMIAF,  $X_1 \in R_F$  such that  $X_1 \cup (X \cap S_B)$  is an MIAF of  $S$ .  $\square$*

We now show the framework of our algorithm. Its correctness follows directly from Theorems 2 and 3.

#### ALGORITHM FIND-MIAF.

**Input:** A canonical family of arcs  $S = \{a_1, a_2, \dots, a_n\}$ .

**Output:** An MIAF of  $S$ .

**Method:**

1. Determine  $S_F$  and  $S_B$ .
2. Find an essential DMIAF set for  $S_F$ ,  $R_F = \{X_1, X_2, \dots, X_k\}$ .
3. If there exist a DMIAF  $X_i \in R_F$  and an arc  $a_j \in S_B$  such that  $t_j < sc(X_i)$  and  $ec(X_i) < h_j$ , then generate  $X_i \cup \{a_j\}$ ; otherwise generate an arbitrary MIAF of  $S_F$ .  $\square$

In the next section, we give a linear time implementation of this algorithm.

#### 4. Efficient implementation of the algorithm.

**4.1. Determination of  $S_F$  and  $S_B$ .** Suppose that a canonical family of arcs  $S = \{a_1, a_2, \dots, a_n\}$  is given as an input to Algorithm FIND-MIAF. Let  $S'_F$  denote the family of all forward arcs in  $S$ . Recall that  $S_F$  is the family of all forward arcs in  $S$  which do not contain any other forward arc in  $S$ . Note that  $S = S'_F \cup S_B$  and  $S'_F \cap S_B = \emptyset$ . We can partition  $S$  into  $S'_F$  and  $S_B$  in  $O(n)$  time. In order to extract  $S_F$  from  $S'_F$ , we

first create an empty queue  $Q$  and initialize  $S_F$  to be empty. Then we visit the endpoints of the arcs in  $S'_F$  one by one in ascending order of their coordinates. If we find the head of some arc  $a_i$ , we insert integer  $i$  into  $Q$ . If we find the tail of some arc  $a_i$ , we check whether integer  $i$  exists in  $Q$  or not. If it does not, we do nothing; otherwise we delete from  $Q$  the integer  $i$  and all integers which are placed before  $i$ , and then we add arc  $a_i$  to  $S_F$ .

Suppose that an integer  $j$  is deleted when the tail of  $a_i (i \neq j)$  is visited. Since the tail of  $a_j$  has not been visited,  $t_i < t_j$ . Furthermore,  $h_j < h_i$  since the integers are inserted into  $Q$  in ascending order of the coordinates of the heads of the corresponding arcs. These imply that  $a_j$  contains  $a_i$ . Thus,  $a_j \notin S_F$ . On the other hand, arc  $a_i$  does not contain any other forward arc; otherwise the tail of some arc  $a_k$  such that  $h_k > h_i$  would have been visited earlier than that of  $a_i$  and integer  $i$  would have already been deleted. Therefore,  $a_i \in S_F$ .

Since  $S$  is canonical, the coordinates of the endpoints of the arcs in  $S'_F$  are distinct integers between 1 and  $2n$ . Therefore, this procedure determines  $S_F$  in  $O(n)$  time and with  $O(n)$  space. Thus, the next theorem follows.

**THEOREM 4.** *Determination of  $S_F$  and  $S_B$  can be done in  $O(n)$  time and with  $O(n)$  space.  $\square$*

**4.2. Finding an essential DMIAF set for  $S_F$ .** Suppose that  $S_F$  has been obtained. Without loss of generality, we assume that  $S_F = \{a_1, a_2, \dots, a_{|S_F|}\}$  with  $h_1 < h_2 < \dots < h_{|S_F|}$ . (The renumbering of the subscripts of the arcs can be performed in  $O(n)$  time by a bucket sort [1], if necessary.) The following lemma provides an important property of an essential DMIAF set for  $S_F$ .

**LEMMA 5.** *Let  $R_F = \{X_1, X_2, \dots, X_k\}$  be an essential DMIAF set for  $S_F$ . Then,  $X_i \cap X_j = \emptyset$  for  $1 \leq i \neq j \leq k$ .*

*Proof.* Let  $i$  and  $j$  be integers such that  $1 \leq i \neq j \leq k$ . By definition,  $X_i$  and  $X_j$  are DMIAF's of  $S_F$ . Without any loss of generality, we can assume that  $sc(X_i) < sc(X_j)$  and  $ec(X_i) < ec(X_j)$ .

Assume that  $X_i \cap X_j \neq \emptyset$ , and let  $a_k$  be an element in  $X_i \cap X_j$ . Let  $X_i^-$  and  $X_i^+$  denote  $\{a_q \in X_i | t_q < h_k\}$  and  $\{a_q \in X_i | h_q > t_k\}$ , respectively. Similarly, let  $X_j^-$  and  $X_j^+$  denote  $\{a_q \in X_j | t_q < h_k\}$  and  $\{a_q \in X_j | h_q > t_k\}$ , respectively. Then, clearly  $X_j^- \cup \{a_k\} \cup X_i^+$  is an IAF of  $S_F$ . This implies that  $|X_j^-| \geq |X_i^+|$  since  $X_j = X_j^- \cup \{a_k\} \cup X_j^+$  is an MIAF of  $S_F$ . Similarly, since  $X_i^- \cup \{a_k\} \cup X_j^+$  is an IAF of  $S_F$  and  $X_i$  is an MIAF of  $S_F$ , we have  $|X_j^+| \geq |X_i^-|$ . Therefore,  $|X_j^+| = |X_i^-|$ . This implies that  $X_j^- \cup \{a_k\} \cup X_i^+$  is an MIAF of  $S_F$  since it is an IAF of  $S_F$  and  $|X_j^- \cup \{a_k\} \cup X_i^+| = |X_j|$ . It is clear that  $sc(X_i) < sc(X_j) = sc(X_j^- \cup \{a_k\} \cup X_i^+)$  and  $ec(X_i) = ec(X_j^- \cup \{a_k\} \cup X_i^+) < ec(X_j)$ . Therefore,  $X_j^- \cup \{a_k\} \cup X_i^+$  dominates both  $X_i$  and  $X_j$ . This contradicts the facts that  $X_i$  and  $X_j$  are DMIAF's of  $S_F$ . Consequently,  $X_i \cap X_j = \emptyset$ .  $\square$

**COROLLARY 1.** *Let  $R_F = \{X_1, X_2, \dots, X_k\}$  be an essential DMIAF set for  $S_F$ . Then  $|X_1| + |X_2| + \dots + |X_k| \leq |S_F|$ .*

*Proof.* It is clear from Lemma 5.  $\square$

Let  $Z$  be defined as  $\{a_i \in S_F | h_1 \leq h_i < t_1\}$ . Then, the following lemma is obtained.

**LEMMA 6.** *For any MIAF,  $X$  of  $S_F$ ,  $|X \cap Z| = 1$ .*

*Proof.* Any two arcs in  $Z$  intersect with each other, and hence  $|X \cap Z| \leq 1$ . Furthermore,  $|X \cap Z| \neq 0$ ; otherwise,  $X \cup \{a_1\}$  would be an IAF of  $S_F$ . Therefore,  $|X \cap Z| = 1$ .  $\square$

For an IAF of  $S_F$ ,  $X = \{a_{i_1}, a_{i_2}, \dots, a_{i_j}\}$  with  $h_{i_1} < h_{i_2} < \dots < h_{i_j}$ ,  $a_{i_1}$  is called the *starting arc* of  $X$ . For each arc  $a_i \in S_F$ , an IAF containing  $a_i$  as its starting arc is called a *largest IAF* for  $a_i$  if it contains the maximum number of arcs. Then we define  $YS_i$

as the set of all largest IAF's for  $a_i$ . For example, consider the family of arcs of Fig. 6 again. Then,  $YS_1 = \{\{a_1, a_4, a_7\}, \{a_1, a_4, a_8\}, \{a_1, a_5, a_8\}, \{a_1, a_6, a_8\}\}$  and  $YS_3 = \{\{a_3, a_5, a_8\}, \{a_3, a_6, a_8\}\}$ .

For  $i = 1, 2, \dots, |S_F|$ , let  $Y_i$  be an IAF in  $YS_i$  whose ending coordinate is the minimum among all IAF's in  $YS_i$ . Suppose that  $Z = \{a_1, a_2, \dots, a_m\}$ . By assumption,  $h_1 < h_2 < \dots < h_m$ . We show below several theorems and lemmas which play important roles in finding an essential DMIAF set for  $S_F$ .

**LEMMA 7.** *Let  $X$  be a DMIAF of  $S_F$  and let  $a_i$  be its starting arc. Then,  $1 \leq i \leq m$  and  $Y_i$  is a DMIAF of  $S_F$ .*

*Proof.* From Lemma 6,  $a_i \in Z$ , that is,  $1 \leq i \leq m$ . It is clear that  $X$  is a largest IAF for  $a_i$ . Therefore,  $|Y_i| = |X|$ , and hence  $Y_i$  is an MIAF of  $S_F$ . Furthermore, since  $Y_i$  has the minimum ending coordinate among all IAF's in  $YS_i$  and  $X$  is not dominated by  $Y_i$ ,  $ec(Y_i) = ec(X)$ . These imply that  $Y_i$  is a DMIAF of  $S_F$ .  $\square$

**THEOREM 5.** *Let  $R$  be the set of all DMIAF's in  $\{Y_1, Y_2, \dots, Y_m\}$ . Then,  $R$  is an essential DMIAF set for  $S_F$ .*

*Proof.* Let  $X$  be any DMIAF of  $S_F$ . Then, from Lemma 7, a DMIAF of  $S_F$ ,  $Y_i$  exists in  $R$  such that  $1 \leq i \leq m$  and  $sc(X) = sc(Y_i)$ . Therefore, there exists a subset of  $R$  which is an essential DMIAF set for  $S_F$ . Since  $h_1 < h_2 < \dots < h_m$ ,  $sc(Y_1) < sc(Y_2) < \dots < sc(Y_m)$ . This implies that no two DMIAF's in  $R$  have the same starting coordinate. Thus,  $R$  itself is an essential DMIAF set for  $S_F$ .  $\square$

**LEMMA 8.** *Suppose that  $Y_i$  is not an MIAF of  $S_F$  for some integer  $i$  such that  $1 \leq i < m$ . Then,  $Y_j$  is not an MIAF of  $S_F$  for  $j = i+1, i+2, \dots, m$ .*

*Proof.* Assume that  $Y_k$  is an MIAF of  $S_F$  for some  $k$  such that  $i+1 \leq k \leq m$ . Then  $|Y_k| > |Y_i| \geq 1$ , and hence  $|Y_k| \geq 2$ . Since  $h_i < h_k$  and  $a_i$  does not contain  $a_k$ ,  $t_i < t_k$ . Furthermore, it is clear that  $t_k < sc(Y_k - \{a_k\})$ . Therefore,  $\{a_i\} \cup (Y_k - \{a_k\})$  is an MIAF of  $S_F$ . Since its starting arc is  $a_i$ , every IAF in  $YS_i$  is an MIAF of  $S_F$ . This contradicts the hypothesis that  $Y_i$  is not an MIAF of  $S_F$ . Therefore, there does not exist such an integer  $k$  that  $i+1 \leq k \leq m$  and that  $Y_k$  is an MIAF of  $S_F$ .  $\square$

**COROLLARY 2.**  $Y_1$  is an MIAF of  $S_F$ .

*Proof.* It is clear from Lemmas 7 and 8.  $\square$

**LEMMA 9.** *Suppose that  $Y_i$  is an MIAF of  $S_F$  for some integer  $i$  such that  $1 \leq i \leq m$ . Then, if  $Y_i$  is not a DMIAF of  $S_F$ , there exists an integer  $j$  such that  $i < j \leq m$  and that  $Y_j$  is a DMIAF of  $S_F$  which dominates  $Y_i$ .*

*Proof.* If  $Y_i$  is not a DMIAF of  $S_F$ , then there exists a DMIAF of  $S_F$ , say  $X$ , which dominates  $Y_i$ . By definition,  $Y_i$  has the smallest ending coordinate among all largest IAF's for  $a_i$ , and hence  $a_i \notin X$ . This implies that  $h_i = sc(Y_i) < sc(X)$  and  $ec(X) \leq ec(Y_i)$ . Let  $a_j$  be the starting arc of  $X$ . Then, from Lemma 7,  $j \leq m$  and  $Y_j$  is a DMIAF of  $S_F$ . Since  $sc(X) = h_j$ ,  $h_i < h_j$ , and hence  $i < j \leq m$ . Furthermore, since  $sc(Y_j) = sc(X)$ ,  $ec(Y_j) = ec(X)$  from Lemma 4. Therefore,  $Y_j$  dominates  $Y_i$ .  $\square$

**COROLLARY 3.** *If  $Y_m$  is an MIAF of  $S_F$ , then it is a DMIAF of  $S_F$ .*

*Proof.* It is clear from Lemma 9.  $\square$

**COROLLARY 4.** *Suppose that  $Y_i$  is an MIAF of  $S_F$  for some integer  $i$  such that  $1 \leq i < m$ . Then, if  $Y_{i+1}$  is not an MIAF of  $S_F$ ,  $Y_i$  is a DMIAF of  $S_F$ .*

*Proof.* It is clear from Lemmas 8 and 9.  $\square$

**LEMMA 10.** *Suppose that both  $Y_i$  and  $Y_{i+1}$  are MIAF's of  $S_F$  for some integer  $i$  such that  $1 \leq i < m$ . Then,  $Y_i$  is a DMIAF of  $S_F$  if and only if  $ec(Y_i) < ec(Y_{i+1})$ .*

*Proof.* Clearly  $h_i = sc(Y_i) < sc(Y_{i+1}) = h_{i+1}$ . So, if  $ec(Y_i) \geq ec(Y_{i+1})$ , then  $Y_{i+1}$  dominates  $Y_i$ . Thus, if  $Y_i$  is a DMIAF of  $S_F$ , then  $ec(Y_i) < ec(Y_{i+1})$ .

Suppose that  $Y_i$  is not a DMIAF of  $S_F$ . From Lemma 9, there exists an integer  $j$  such that  $i+1 \leq j \leq m$  and that  $Y_j$  is a DMIAF of  $S_F$  which dominates  $Y_i$ . Since  $a_i$

does not contain  $a_j$  and  $Y_j$  dominates  $Y_i$ ,  $|Y_i| \geq 2$ , and hence  $|Y_j| \geq 2$ . Furthermore, if  $j \neq i+1$ ,  $t_{i+1} < t_j$ , and hence  $t_{i+1} < sc(Y_j - \{a_j\})$ . This inequality also holds when  $j = i+1$ . Therefore,  $ec(Y_{i+1}) \leq ec(Y_j - \{a_j\})$ ; otherwise  $\{a_{i+1}\} \cup (Y_j - \{a_j\})$  would be selected as  $Y_{i+1}$ . Since  $ec(Y_j - \{a_j\}) = ec(Y_j) \leq ec(Y_i)$ , we have  $ec(Y_{i+1}) \leq ec(Y_i)$ . Thus, if  $ec(Y_i) < ec(Y_{i+1})$ , then  $Y_i$  is a DMIAF of  $S_F$ .  $\square$

**THEOREM 6.** *Suppose that  $Y_i$  is an MIAF of  $S_F$  for some integer  $i$  such that  $1 \leq i \leq m$ . Then,  $Y_i$  is a DMIAF of  $S_F$  if and only if one of the following three conditions holds:*

- (i)  $i < m$  and  $Y_{i+1}$  is not an MIAF of  $S_F$ .
- (ii)  $i < m$  and  $ec(Y_i) < ec(Y_{i+1})$ .
- (iii)  $i = m$ .

*Proof.* It is clear from Lemma 10 and Corollaries 3 and 4.  $\square$

We now present a procedure to find an essential DMIAF set for  $S_F$ . Its correctness can be easily proven by using Theorems 5 and 6, Lemma 8 and Corollary 2.

**PROCEDURE FIND-EDS.**

1.  $Z \leftarrow \{a_i \in S_F \mid h_1 \leq h_i < t_1\}$ . Suppose that  $Z = \{a_1, a_2, \dots, a_m\}$ .
2. For  $i = 1, 2, \dots, m$ , find  $ec(Y_i)$  and  $|Y_i|$ , where  $Y_i$  is defined as before.
3.  $R \leftarrow \emptyset$ .  $i \leftarrow 1$ .
4. While  $|Y_i| = |Y_1|$  and  $i < m$ , execute the following instructions 1 and 2.
  - (1) If  $|Y_{i+1}| < |Y_1|$  or  $ec(Y_i) < ec(Y_{i+1})$ , then determine  $Y_i$  and  $R \leftarrow R \cup \{Y_i\}$ .
  - (2)  $i \leftarrow i+1$ .
5. If  $i = m$  and  $|Y_m| = |Y_1|$ , then determine  $Y_m$  and  $R \leftarrow R \cup \{Y_m\}$ .
6. Generate  $R$ .  $\square$

As an example, consider the family of arcs of Fig. 6. Since  $t_1 = 6$ ,  $Z$  is determined as  $\{a_1, a_2, a_3\}$  at Step 1. Then, Step 2 finds  $ec(Y_1) = 17$ ,  $|Y_1| = 3$ ;  $ec(Y_2) = 17$ ,  $|Y_2| = 3$ ; and  $ec(Y_3) = 19$ ,  $|Y_3| = 3$ . At Step 4,  $Y_1$  is not added to  $R$  since  $|Y_2| = |Y_1| = 3$  and  $ec(Y_1) = ec(Y_2)$ . On the other hand,  $Y_2$  is added to  $R$  since  $ec(Y_2) < ec(Y_3)$ . Similarly,  $Y_3$  is added to  $R$  at Step 5. While  $Y_2$  is uniquely determined as  $\{a_2, a_4, a_7\}$ ,  $Y_3$  may be chosen from two candidates,  $\{a_3, a_5, a_8\}$  and  $\{a_3, a_6, a_8\}$ . Therefore, the resultant essential DMIAF set is either  $\{\{a_2, a_4, a_7\}, \{a_3, a_5, a_8\}\}$  or  $\{\{a_2, a_4, a_7\}, \{a_3, a_6, a_8\}\}$ .

In what follows, we describe an efficient implementation of Procedure FIND-EDS.

For each arc  $a_i \in S_F$ , let  $\text{NEXT}(a_i)$  be defined as an arc  $a_k$  such that  $h_k = \text{Min}\{h_j \mid a_j \in S_F \text{ and } h_j > t_i\}$  if  $\{a_j \in S_F \mid h_j > t_i\} \neq \emptyset$ , and otherwise defined as "null." For example, for the family of arcs of Fig. 6,  $\text{NEXT}(a_1) = a_4$ ,  $\text{NEXT}(a_2) = a_4$ ,  $\text{NEXT}(a_3) = a_5$ ,  $\text{NEXT}(a_4) = a_7$ ,  $\text{NEXT}(a_5) = a_8$ ,  $\text{NEXT}(a_6) = a_8$ ,  $\text{NEXT}(a_7) =$  "null," and  $\text{NEXT}(a_8) =$  "null."

For each arc  $a_i \in S_F$ , let  $N_i$  be defined as  $\{a_{i_1} = a_i, a_{i_2}, \dots, a_{i_k}\}$  such that  $\text{NEXT}(a_{i_j}) = a_{i_{j+1}}$  for  $j = 1, 2, \dots, k-1$  and  $\text{NEXT}(a_{i_k}) =$  "null." Then we have the following lemma.

**LEMMA 11.** *For each arc  $a_i \in Z$ ,  $N_i$  is an IAF of  $S_F$ . Furthermore,  $|Y_i| = |N_i|$  and  $ec(Y_i) = ec(N_i)$ .*

*Proof.* It is clear from the definitions that  $N_i$  is an IAF of  $S_F$ . Suppose that  $N_i = \{a_{i_1} = a_i, a_{i_2}, \dots, a_{i_k}\}$  with  $h_{i_1} < h_{i_2} < \dots < h_{i_k}$  and  $Y_i = \{a_{i_1} = a_i, a_{i_2}, \dots, a_{i_j}\}$  with  $h_{i_1} < h_{i_2} < \dots < h_{i_j}$ . By definition,  $Y_i$  is a largest IAF for  $a_i$ , and hence  $j \geq k$ . Since no arc in  $S_F$  contains any other arc in  $S_F$ , we can show that  $h_{i_p} \leq h_{i'_p}$  and  $t_{i_p} \leq t_{i'_p}$  for  $p = 1, 2, \dots, k$  by an easy induction proof on the value of  $p$ . Thus,  $t_{i_k} \leq t_{i'_k}$ , and hence  $ec(N_i) \leq ec(Y_i)$ . Since  $\text{NEXT}(a_{i_k}) =$  "null,"  $\text{NEXT}(a_{i'_k}) =$  "null." This implies that  $k = j$ , that is,  $|N_i| = |Y_i|$ . This further implies from the definition of  $Y_i$  that  $ec(N_i) \leq ec(Y_i)$ . Therefore,  $ec(N_i) = ec(Y_i)$ .  $\square$

For each arc  $a_i \in S_F$ ,  $\text{NEXT}(a_i)$  can be determined as follows. We first create an empty set  $P$ , and then start visiting the endpoints of the arcs of  $S_F$  in ascending order of their coordinates. Suppose we find the head of some arc  $a_j$ . If  $P$  is empty, we do nothing. On the other hand, if  $P$  is not empty, we set  $\text{NEXT}(a_k)$  to  $a_j$  for each element  $a_k$  in  $P$  and then delete all such elements from  $P$ . If we find the tail of some arc  $a_j$  which is not the last endpoint, we add  $a_j$  to  $P$ . If the tail is the last endpoint, we set  $\text{NEXT}(a_k)$  to “null” for each element  $a_k$  in  $P \cup \{a_j\}$ . Since the coordinates of the endpoints of the arcs in  $S_F$  are distinct integers between 1 and  $2n$ , this procedure requires  $O(n)$  time and space.

We now define a digraph  $H_F$  as follows:

$$H_F = (W_F, A_F), \quad \text{where}$$

$$W_F = \{w_i | a_i \in S_F\} \quad \text{and}$$

$$A_F = \{(w_i \rightarrow w_j) | \text{NEXT}(a_i) = a_j\}.$$

As an example, Fig. 7 illustrates the graph  $H_F$  which corresponds to the family of arcs of Fig. 6.

FIG. 7. The graph  $H_F$  for the family of arcs of Fig. 6.

Since the outdegree of each vertex in  $H_F$  is at most one,  $|A_F| < |S_F|$ . Thus, we have the following lemma.

LEMMA 12. *The construction of  $H_F$  with the aforementioned computation of  $\text{NEXT}(\cdot)$  requires  $O(n)$  time and space.  $\square$*

The next lemma is obvious from the definition of  $H_F$ .

LEMMA 13.  *$H_F$  has the following properties.*

- (i) *For each vertex  $w_i$  with outdegree 0,  $|N_i| = 1$  and  $ec(N_i) = t_i$ .*
- (ii) *For each edge  $(w_i \rightarrow w_j)$  in  $A_F$ ,  $|N_i| = |N_j| + 1$  and  $ec(N_i) = ec(N_j)$ .*
- (iii) *For each arc  $a_i \in Z$ , the maximal directed path in  $H_F$  starting from  $w_i$  corresponds to  $N_i$ .  $\square$*

According to Lemma 13 (i) and (ii), one can easily determine  $|N_i|$  and  $ec(N_i)$  for all arcs  $a_i \in S_F$  in  $O(|S_F|)$  time. From Lemma 11, for each arc  $a_i \in Z$ ,  $|Y_i| = |N_i|$  and  $ec(Y_i) = ec(N_i)$ . Therefore, the following lemma is obtained from Lemma 12.

LEMMA 14. *Step 2 of Procedure FIND-EDS requires  $O(n)$  time and space.  $\square$*

Steps 4 and 5 of Procedure FIND-EDS can be performed based on Lemma 11 and Lemma 13 (iii). Each time we find an integer  $i$  for which the conditions of Step 4 (i) or Step 5 are satisfied, we can determine  $Y_i$  by finding a maximal directed path in  $H_F$  starting from  $w_i$ . Therefore, Steps 4 and 5 can be executed in  $O(|Z| + \sum_{Y_i \in R} |Y_i|)$  time, where  $R$  is the essential DMIAF set which is obtained at the termination of the

procedure. Since  $\sum_{Y_i \in R} |Y_i| \leq |S_F|$  from Corollary 1, the following theorem is obtained from Lemma 14.

**THEOREM 7.** *An essential DMIAF set for  $S_F$  can be formed in  $O(n)$  time and with  $O(n)$  space.  $\square$*

**4.3. Determination of an MIAF of  $S$ .** Suppose that an essential DMIAF set for  $S_F$ ,  $R_F = \{X_1, X_2, \dots, X_k\}$  has been obtained. For each arc  $a_j \in S_B$ , let  $\text{NEXT}(a_j)$  be defined as  $X_i$  such that  $sc(X_i) = \text{Min}\{sc(X_p) | X_p \in R_F \text{ and } sc(X_p) > t_j\}$  if  $\{X_p \in R_F | sc(X_p) > t_j\} \neq \emptyset$ , and otherwise defined as “null.” Then, the following theorem holds.

**THEOREM 8.** *Suppose that there exist an arc  $a_j \in S_B$  and a DMIAF,  $X_i \in R_F$  such that  $t_j < sc(X_i)$  and  $ec(X_i) < h_j$ . Then,  $t_j < sc(\text{NEXT}(a_j))$  and  $ec(\text{NEXT}(a_j)) < h_j$ .*

*Proof.* Assume that  $X_i \neq \text{NEXT}(a_j)$ . From the definition of  $\text{NEXT}(a_j)$ ,  $t_j < sc(\text{NEXT}(a_j)) < sc(X_i)$ . Therefore,  $ec(\text{NEXT}(a_j)) < ec(X_i)$  from Lemma 4, and hence  $ec(\text{NEXT}(a_j)) < h_j$ .  $\square$

By a procedure similar to the one for computing  $\text{NEXT}(\cdot)$  for the arcs in  $S_F$ , one can determine  $\text{NEXT}(a_j)$  for all arcs  $a_j \in S_B$  in  $O(n)$  time. In this case, after the creation of an empty set  $P$ , we visit the tails of the arcs in  $S_B$  and the heads of the starting arcs of the DMIAF’s in  $R_F$  in ascending order of their coordinates until the last head is visited. The other part of the procedure is almost the same as that of the previous one.

After finding  $\text{NEXT}(\cdot)$  for all arcs in  $S_B$ , according to Theorem 8, we can easily find, in  $O(|S_B|)$  time, an arc  $a_j \in S_B$  and a DMIAF,  $X_i \in R_F$  such that  $t_j < sc(X_i)$  and  $ec(X_i) < h_j$ , if they exist. If such an arc and a DMIAF do not exist, any DMIAF in  $R_F$  is an MIAF of  $S$ . Thus, we have the following theorem.

**THEOREM 9.** *Suppose that an essential DMIAF set for  $S_F$  has been obtained. Then, an MIAF of  $S$  can be obtained in  $O(n)$  time and with  $O(n)$  space.  $\square$*

**4.4. Time and space complexities of the algorithm.** We now show the following two theorems.

**THEOREM 10.** *The time and space complexities of Algorithm FIND-MIAF each are  $O(n)$ .*

*Proof.* It is clear from Theorems 4, 7 and 9.  $\square$

**THEOREM 11.** *Given a family  $S$  of  $n$  arcs on a circle, a maximum independent set of its corresponding circular-arc graph  $G_S$  can be found in  $O(n \cdot \log n)$  time and with  $O(n)$  space. These complexities are optimal to within a constant factor.*

*Proof.* As mentioned before, one can construct a canonical family of arcs  $S'$  such that  $G_S = G_{S'}$  in  $O(n \cdot \log n)$  time and with  $O(n)$  space. The application of Algorithm FIND-MIAF to the resultant family of arcs  $S'$  requires  $O(n)$  time and space due to Theorem 10. Therefore, we can find a maximum independent set of  $G_S$  in  $O(n \cdot \log n)$  time and with  $O(n)$  space.

Every interval graph is a circular-arc graph. Furthermore, it is known that it requires  $\Omega(n \cdot \log n)$  time in the worst case to find a maximum independent set of an interval graph when the graph is given in the form of a family of  $n$  intervals [7]. Therefore, our algorithm is time- and space-optimal to within a constant factor.  $\square$

**5. Conclusion.** In this paper, we have presented an optimal algorithm for finding a maximum independent set of a circular-arc graph. When the graph is given in the form of a family of  $n$  arcs on a circle, our algorithm runs in  $O(n \cdot \log n)$  time and with  $O(n)$  space. Moreover, it requires only  $O(n)$  time if the endpoints of the arcs are already sorted, in other words, if the order of their appearances on the circle is known.

It does not seem that our algorithm can be extended to the problem of finding a maximum weight independent set when each vertex is assigned a weight. It is interesting to develop an optimal algorithm for such a problem.

## ON THE COMPLEXITY OF COVERING VERTICES BY FACES IN A PLANAR GRAPH\*

DANIEL BIENSTOCK† AND CLYDE L. MONMA†

**Abstract.** The pair  $(G, D)$  consisting of a planar graph  $G = (V, E)$  with  $n$  vertices together with a subset of  $d$  special vertices  $D \subseteq V$  is called  $k$ -planar if there is an embedding of  $G$  in the plane so that at most  $k$  faces of  $G$  are required to cover all of the vertices in  $D$ . Checking 1-planarity can be done in linear-time since it reduces to a problem of checking planarity of a related graph. We present an algorithm which given a graph  $G$  and a value  $k$  either determines that  $G$  is not  $k$ -planar or generates an appropriate embedding and associated minimum cover in  $O(c^k n)$  time, where  $c$  is a constant. Hence, the algorithm runs in linear time for any fixed  $k$ . The fact that the time required by the algorithm grows exponentially in  $k$  is to be expected since we also show that for arbitrary  $k$ , the associated decision problem is strongly NP-complete, even when the planar graph has essentially a unique planar embedding,  $d = \theta(n)$ , and all facial cycles have bounded length. These results provide a polynomial-time recognition algorithm for special cases of Steiner tree problems in graphs which are solvable in polynomial time.

**Key words.** complexity, planar graphs, Steiner trees

**AMS(MOS) subject classifications.** 05, 68

**1. Introduction.** Recently, there has been a great deal of interest in solving the Steiner tree problem in graphs. This problem is NP-complete even for planar grid graphs [GJ1]. (See [GJ2] for an excellent introduction to the area of computational complexity.) So recent work has centered on efficiently-solvable special cases and heuristic methods; see [Wi] for a survey of work on this problem.

Throughout this paper we deal with undirected graphs of the form  $G = (V, E)$ , where  $V$  is a set of  $n$  vertices and  $E$  is a set of edges connecting pairs of vertices. A graph is called *planar* if it can be embedded in the plane. A graph  $G = (V, E)$  together with  $d$  special vertices  $D \subseteq V$  is called  *$k$ -planar* if there is a planar embedding of  $G$  so that at most  $k$  faces of  $G$  are required to cover all of the vertices in  $D$ . Clearly, a planar graph is the same as an  $n$ -planar graph. The *planarity number* of  $G$  is the minimum  $k$  such that  $G$  is  $k$ -planar.

A recent paper by [EMV] presents an algorithm which solves the Steiner problem in an arbitrary graph; their algorithm runs in polynomial time for  $k$ -planar graphs, for any fixed  $k$ , with  $D$  being the vertices required to be in the Steiner tree. It is easy to see that checking 1-planarity of  $G = (V, E)$  with special vertices  $D \subseteq V$  is equivalent to testing the planarity of the associated graph  $G^* = (V^*, E^*)$ , where  $V^* = V \cup \{\sigma\}$  and  $E^* = E \cup \{(\sigma, v) : v \in D\}$ , and so can be done in linear time [HT2]. They leave as an open question the complexity of testing  $k$ -planarity for fixed  $k \geq 2$ .

In § 2, we present an algorithm which checks to see if a given  $(G, D)$  pair is  $k$ -planar given a *fixed* embedding of  $G$  and if so, determines the planarity number of  $G$  in  $O(c^k n)$  time, when  $c$  is a constant. This is used in § 3 to generate an appropriate embedding of  $G$  and a cover of  $D$  by  $k$  or fewer faces, if possible, in  $O(c^k n)$  time. Hence, the algorithm runs in linear time for any fixed  $k$ . The fact that the time required grows exponentially in  $k$  is to be expected as we show in § 4 that for arbitrary  $k$ , the associated decision problem is strongly NP-complete, even when the planar graph has essentially a unique planar embedding,  $d = \theta(n)$ , and all facial cycles have bounded length.

† Bell Communications Research, Morristown, New Jersey 07960.

In § 5, we present an optimization algorithm which finds the minimum number of faces required to cover all special vertices of a planar graph with a fixed embedding in  $2^{O(\sqrt{d})}$  time. This exact algorithm is used to obtain a polynomial-time approximation algorithm which is asymptotically optimal (i.e., the relative error converges to zero), for the class of graphs we showed to be NP-complete in § 4.

**2. Testing  $k$ -planarity for a fixed embedding.** Consider a fixed embedding of the graph  $G = (V, E)$ . In this section we describe an algorithm that tests whether  $k$  faces are sufficient to cover all special vertices of  $D$  in this particular embedding and, if so, whether it determines the planarity number. This algorithm requires  $O(c^k n)$  time for some constant  $c$ , and is used as a subroutine in our  $k$ -planarity testing algorithm for a variable embedding in the next section. We note that if  $G$  is three-vertex connected, then  $G$  has essentially a unique embedding and so the results of this section apply.

Throughout this section, we assume that the embedding of  $G$  is fixed. We transform the problem of covering  $D$  with faces into one of covering certain special faces as follows. We transform each vertex of  $D$  into a polygon, that is, if  $v \in D$  has edges  $e_1, e_2, \dots, e_m$  incident on it, we replace  $v$  by a polygon with vertices  $v_1, \dots, v_m$  and edges  $(v_1, v_2), \dots, (v_m, v_1)$ ; such that for  $1 \leq i \leq m$ ,  $e_i$  becomes incident to  $v_i$  (if the degree of  $v$  is 2, the polygon is a face of length two). We will refer to the new graph by  $\hat{G}$ , and the set of faces enclosed by the new polygons will be called  $\hat{D}$ .

Let  $G' = (V', E')$  denote the dual graph of  $\hat{G}$ . The vertices of  $G'$  will be called points. The set of points of  $G'$  corresponding to  $\hat{D}$  will be called  $D'$ . Now our problem becomes that of testing whether  $G'$  contains a set  $X$  of points such that

- (i)  $X \cap D' = \emptyset$ ,
- (ii)  $X$  dominates  $D'$ ,
- (iii)  $|X| \leq k$ .

If such a set  $X$  exists, the corresponding set of faces  $\hat{G}$  will be called a face cover.

Let  $S$  denote the subgraph of  $G'$  induced by all points in  $D'$  and all points adjacent to some point in  $D'$ . Now if  $S$  has more than  $k$  connected components, then certainly no set  $X$  satisfying (i)–(iii) exists. Hence assume otherwise. We have the following result.

**LEMMA 1.** *If a set  $X$  satisfying (i)–(iii) exists, the diameter of every connected component of  $S$  is at most  $O(k)$ .*

*Proof.* Aiming for a contradiction, let  $C$  be a connected component of  $S$  with diameter larger than  $8k + 6$ , and let  $p = f_1, f_2, \dots, f_j$  be such a diameter. There are two cases.

(i)  $|p \cap D'| \geq 3(k + 1)$ . By construction, no point of  $D'$  is adjacent to another point of  $D'$ . Let  $p \cap D' = \{s_0, s_1, \dots, s_t\}$  with labeling to reflect the ordering of these points in  $p$ , and set  $Z = \{s_0, s_3, s_6, \dots, s_{3i}, s_{3(i+1)}, \dots\}$ . Then at least  $|Z|$  points are needed to dominate  $Z$ . But this is a contradiction since  $|Z| \geq 3(k + 1)/3 = k + 1$ .

(ii)  $|p \cap D'| < 3(k + 1)$ . By construction, every point of  $S - D'$  is adjacent to at least one point of  $D'$ . Let  $p - D' = \{g_0, \dots, g_r\}$  with labeling to reflect the ordering of these points in  $p$ , and set  $Y = \{g_0, g_5, g_{10}, \dots, g_{5i}, g_{5(i+1)}, \dots\}$ . For each  $i$ , set  $d_i$  to be an arbitrary point of  $D'$  adjacent to  $g_{5i}$ . Clearly, if  $i \neq j$ , then  $d_i \neq d_j$ . Further, a different point of  $S - D'$  is required to dominate each point  $d_i$ . But the number of such points is at least  $\frac{1}{5}(8k + 7 - 3k - 2) = k + 1$ , again a contradiction.  $\square$

Our algorithms will exploit this bounded dual diameter structure. The computations take place in the primal graph. Now, if a graph has dual diameter  $t$ , then every face is within distance  $t$  of an arbitrary face. Algorithm XTND given below will, when input an embedded planar graph  $H$  with  $n$  vertices, distinguished subset of faces  $E$ ,

and a constant  $L$ , test in linear time whether every face of  $H$  is within distance  $L$  of the outer face. If so, XTND will compute a minimum face cover of  $E$  in time bounded by  $2^{O(L)}n$ . In order to motivate XTND, we will describe it in three steps. First we consider a special type of planar graph called a Halin graph. Next, we analyze the structure of bounded diameter planar graphs. Finally, we describe XTND in the general case.

**2.1. Halin graphs.** An embedded planar graph  $H$  is called a *Halin graph* if its dual has a dominating set of cardinality one. Assume that the corresponding face of  $H$  is the outer face. Without loss of generality, the outer facial cycle  $C$  of  $H$  is simple. For if  $v$  is a multiple vertex of  $C$ , let  $e_1 = (u_1, v)$  and  $e_2 = (v, u_2)$  be two consecutive edges of  $C$ . Then we subdivide  $e_1$  and  $e_2$  by adding vertices  $w_1$  and  $w_2$ , and add the edge  $(w_1, w_2)$  embedded in the outer face. Clearly the new graph is still Halin. This type of operation is called a *patching*. Patchings can also be used to ensure that all vertices in  $C$  have degree two or three. Similarly, if an interior vertex of  $H$  has degree one, we can shrink the corresponding edge. The final graph  $H'$  we obtain will be the union of a cycle  $C$  and forest  $T$  embedded inside  $C$  with all leaves in  $C$ . Moreover, from a face cover problem in  $H$  we obtain an equivalent problem in  $H'$ . Now we need some definitions adapted from [CNP].

(1) A *level 1 fan* of  $H'$  is a maximal set of paths  $p_1, p_2, \dots, p_n$  with a common endpoint  $u \notin C$ , which are otherwise disjoint, with opposite endpoint in  $C$ , and all interior vertices of degree 2 in  $H'$ . The vertex  $u$  will be called the *center* of the fan.

(2) To define *level  $t$  fans*, for  $t > 1$ , we proceed as follows. As above, let  $p_1, \dots, p_m$  be a maximal set of paths with common endpoint  $u \notin C$ , otherwise disjoint, and with degree two interior vertices. Suppose that for  $1 \leq i \leq m$ , the endpoint of  $p_i$  different from  $u$  is the center of a level  $j_i$  fan, with  $j_i \leq t - 1$ , and that for some  $i$ ,  $j_i = t - 1$ . Then the collection of paths and fans is called a *level  $t$  fan*, and  $u$  its center. The fan whose center is the endpoint of  $p_i$  is called the *descendant fan* of  $p_i$ .

(3) If  $H'$  is the union of a level 1 fan and  $C$ , we say  $H'$  is a *wheel*.

**THEOREM 2** (Adapted from [CNP]). *The Halin graph  $H'$  has at least one level 1 fan, and this fan can be constructed in linear time.*  $\square$

This theorem was used in [CNP] to construct a polynomial-time dynamic programming algorithm for the traveling salesman problem in Halin graphs. We will make a similar use here towards the face cover problem.

The intuition behind the approach is the following: we can describe the properties of a fan using a bounded size list. This works because a level 1 fan has only two faces that share edges with other fans. When constructing the list for a level  $t$  fan, we only need to look separately at the lists for the descendant fans. Thus if  $F$  is a level  $t$  fan with  $m$  descendant fans, the list for  $F$  can be constructed in  $O(m)$  time. Altogether this translates into a linear time algorithm for solving the minimum face cover in  $H'$ . Details are provided next.

If the forest  $T$  located inside  $C$  is not a tree, we reduce this to the single tree case as follows. Let  $e_1, e_2$  be consecutive edges incident on vertices of  $C$ , that belong to different trees. Then subdivide  $e_i$  by introducing a new vertex  $w_i$ , for  $i = 1, 2$  and add the edge  $(w_1, w_2)$ . This new edge, together with the position of  $e_i$  between  $w_i$  and  $C$ ,  $i = 1, 2$ , and a segment of  $C$ , bounds a “new” face of  $H'$ . We make this face forbidden (that is, we cannot use it towards a cover).

Clearly this procedure does not change the problem and repeatedly applying it will merge the forest into a single tree. Now if the outer face of  $H'$  is in  $E$ , then any internal face of  $H'$  will cover it. On the other hand, if the outer face of  $H'$  is not in

$E$ , then it will cover every other face of  $H'$ , and this is obviously optimal. Hence we may assume, without loss of generality, that the outer face is forbidden.

Suppose  $f$  is a fan of  $H'$  with center  $u$  and paths  $p_1, \dots, p_m$  in clockwise order. For  $1 \leq i \leq m$  let  $\hat{p}_i$  be the *continuation* of  $p_i$ ; that is, a path of the form  $p_i, p'_i$  ending in  $C$ , such that  $p'_i$  is obtained by following the most counterclockwise path out of  $p_i$ , and for  $i > 1$ ,  $p'_i$  is obtained by following the most clockwise path out of  $p_i$ . The endpoints of  $\hat{p}_1$  and  $\hat{p}_m$  in  $C$  are called the *extremes* of  $f$ . For  $2 \leq i \leq m$ , denote by  $f_i$  the region bounded by  $\hat{p}_1, \hat{p}_i$  and the corresponding section of  $C$ ; and set  $E_i$  to be the subset of faces of  $E$  contained in  $f_i$ . For  $i = 1$ ,  $f_1$  consists of  $p_1$  and its descendant fan  $f$ , while  $E_1$  is the subset of  $E$  contained in  $f$ . Finally, define  $l(f, i, a_1, a_i)$  to be the minimum number of internal faces needed to cover  $E_i$ , with the constraints that:

(1) If  $a_1 = 0$ , at least one face of  $E_i$  that has an edge on  $\hat{p}_1$  has not been covered.  
 (2) If  $a_1 = 1$ , (1) does not apply and at least one face with an edge of  $\hat{p}_1$  is used in the cover.

(3) If  $a_1 = 2$ , neither (1) nor (2) apply.

(4) Similar considerations apply for  $a_i = 0, 1$  or  $2$ .

Algorithm XTND takes as input a graph  $H'$  and keeps track of an auxiliary graph  $A$ . At the start,  $A = H'$ . In general, the vertices of  $A$  in its outer facial cycle will correspond to fans of  $H'$ ; these vertices will be labeled by the corresponding fans. The output of Algorithm XTND is  $M$ , the minimum number of faces of  $H'$  needed to cover  $E$ . It is well known that repeatedly shrinking fans in a Halin graph eventually leads to a wheel.

ALGORITHM XTND (HALIN CASE).

- (1) Find a level 1 fan  $g$  in  $A$ . Let  $f$  be the corresponding fan in  $H'$ , with center  $u$ , defining paths  $p_1, \dots, p_m$  and continuations  $\hat{p}_1, \dots, \hat{p}_m$ . For  $1 \leq i \leq m$ , let  $h_i$  be the descendant fan of  $p_i$ , with  $s_i$  defining paths (if  $h_i$  is a vertex, set  $s_i = 0$ ).
  - (a) Set  $l(f, 1, x, y) = l(h_1, s_1, x, y)$  for all  $x, y$ .
  - (b) For  $i > 1$ , suppose first that the face between  $p_{i-1}$  and  $p_i$  is not in  $E$ , and it is not forbidden. Then, for example,

$$l(f, i, 2, 2) = \min_{x,y} \{ \min \{ l(f, i-1, 2, x) + 1 \\ + l(h_i, s_i, y, 2) \}, \min_{x>0, y>0} \{ l(f, i-1, 2, x) + l(h_i, s_i, y, 2) \} \}.$$

Similar formulas are used to compute all other parameters  $l(f, i, \cdot, \cdot)$ , and also when the face between  $p_{i-1}$  and  $p_i$  is forbidden, or if it is in  $E$ .

- (2) If  $g$  is a wheel in  $A$ , then let  $x$  be the face of  $H'$  between  $\hat{p}_m$  and  $\hat{p}_1$ .

$$(a) \text{ If } x \notin D, \text{ then } M = \min \left\{ \min_{x,y} \{ l(f, m, x, y) + 1 \}, \min_{x>0, y>0} \{ l(f, m, x, y) \} \right\}.$$

$$(b) \text{ If } x \in E, \text{ then } M = \min \left\{ \min_y \{ l(f, m, 1, y) \}, \min_x \{ l(f, m, x, 1) \} \right\}.$$

(c) Stop and output the value of  $M$ .

- (3) Otherwise, shrink  $g$  into a single vertex in the outer face of  $A$ , and go to (1).

Algorithm XTND clearly works correctly, and since the workload in finding and shrinking fans in  $A$  is linear in the size of each fan, the total complexity is linear.

Notice that there is a last center  $r$  of a fan found in graph  $A$ . In fact, it is not difficult to see that this vertex may be prescribed before running XTND, by choosing fans with center  $u \neq r$  whenever possible.

There are two observations concerning the Halin case that will be very useful later. First, let  $f$  be a fan of  $H'$  with center  $u$ , and consider a set of contiguous faces of  $f$ ; that is, a set  $S$  of faces of  $f$  incident to  $u$  that appear consecutively as we travel around  $f$ . Then if we want to force all faces in  $S$  to take the same *value* (that is, all chosen or rejected), Algorithm XTND given above can still be used, almost verbatim, to compute a minimum face cover of  $E$ . Similar considerations apply if all faces of  $S$  are in  $E$  and covering any of them is interpreted as covering *all* of them. In both cases we will refer to the set  $S$  as a *split face*.

Second, suppose  $e_1$  and  $e_2$  are edges incident to  $C$  that appear consecutively as we travel around it. Then either at some point of the algorithm  $e_1$  and  $e_2$  will be part of consecutive paths in a fan, or they will be part of the first and last paths in the very last fan (a wheel) considered by the algorithm. In any case, let  $u$  be the center of the fan, and let  $x$  be the face of  $H'$  bounded by  $C$  and the paths containing  $e_1$  and  $e_2$ . Then we can split  $x$  by adding arbitrary edges incident to  $u$ . By making the set of additional faces a split face, we obtain an equivalent problem. This new problem is easily solved by using the same sequence of fans as before. The vertex  $u$  will be called the ancestor of  $e_1$  and  $e_2$ . This concludes the analysis of the Halin case.

**2.2. Structure of bounded dual diameter graphs.** We next investigate the structure of planar graphs of dual diameter bounded by a certain constant, as it pertains to our problem. Intuitively, our approach is as follows (this description is slightly incorrect as we describe later). Given a plane graph of dual diameter at most  $L$ , by consecutively “peeling” away layers of faces at a given distance from the outer face we will reach a “central” graph after at most  $L$  layers. This central graph must be Halin; we use a version of the algorithm in § 2.1 where we now consider fans that are extended with gridlike graphs with at most  $L$  rows, to solve the minimum face cover.

This description is incorrect in that there may be more than one “central” graph; as we peel layers the graph may decompose arbitrarily. We deal with this difficulty by using a special partial order on the components that we encounter recursively, and proceed essentially as outlined in the previous paragraph. [Ba] introduces a class of planar graphs called  $k$ -outerplanar. If a graph is  $k$ -outerplanar its dual diameter is at least  $k$ ; both concepts are somewhat related (in turn, the radius  $r$  of the graph [RS] satisfies  $k - 1 \leq r \leq k$  and these two parameters are closely related).<sup>1</sup> [Ba] describes an algorithm for decomposing  $k$ -outerplanar graphs. Our procedure UNWRAP for peeling a bounded dual diameter graph is reminiscent of the one in [Ba], with some important differences which are necessary to make our face cover algorithm work.

Let  $H$  be an  $n$ -vertex plane graph of dual diameter  $L$ , with outer facial cycle  $C$ . Procedure UNWRAP proceeds as follows. First, any vertex of degree two and its two incident edges can be replaced by a single edge. Also, the patch operation allows us to assume that  $C$  contains no cutvertices. Further, if  $e$  is an edge incident to a vertex of  $C$ , we can assume that both endpoints have degree three (using patchings or expanding the endpoints into polygons, which will later be used as forbidden faces). Next, we delete  $C$ , together with all edges incident to it. Then  $H$  will be split into several connected components, each of which is a union of trees and maximal two-connected graphs, joined in a treelike manner. If two of the two-connected graphs share one vertex (a cutvertex) we can use the patch operation to obtain a larger graph. Assume we carry this out as many times as necessary. The final two-connected graphs

<sup>1</sup> In polynomial time, one can minimize over all embeddings the radius, the maximum dual distance to the outer face, and the outerplanarity. However, minimizing the dual diameter is NP-hard [BM].

will be called the *height-1 islands* (see Fig. 1). Clearly, if  $X$  is such an island, the distance from an internal face of  $X$  to the outer face of  $X$  is at most  $L-1$ . Finally, it is not difficult to see that a vertex in the outer face of  $X$  may be assumed to be adjacent to at most one vertex not in  $X$ . Now we can recursively use UNWRAP with each height-1 island to obtain height-2 islands. The procedure will terminate with at most  $L-1$  recursive calls. The top islands found (all of height at most  $L-1$ ) will be Halin graphs. The set of islands constitutes a partial order, which is constructed by UNWRAP in time  $O(n)$ . Having peeled away all of the layers we put them back together while preserving the modifications that were introduced (i.e., all of the subdivisions and new edges). It is in this graph  $H^*$ , rather than  $H$ , that we apply XTND, after a few more modifications described in the next section.

**2.3. General case of XTND.** We need one more piece of notation. The edges joining the outer face of a height- $i$  island  $I$  to the outer face of the height- $(i-1)$  island enclosing  $I$  are called the *links* of  $I$ . Notice that if  $u$  is an endpoint of a link, then  $u$  has degree at most four, by the construction used. The edges of  $H^*$  that are not links are called layer edges. Let  $R$  be the maximum dual distance to the outerface.

We first consider the simplest possible case, which we call the *concentric case*. This arises when in every call to UNWRAP we discover precisely one island (and no trees). That is, there is exactly one height- $i$  island for each  $1 \leq i \leq R-1$  (see Fig. 2(a)). Let  $K$  denote the height- $(R-1)$  island.

We modify  $H^*$  as follows, if necessary. Let  $C^*$  be the outer facial cycle of  $H^*$ . Then by subdividing layer edges and introducing some new link edges and edges inside  $K$ , we can assume that every link edge is contained in a (unique) path from  $C^*$  to the interior of  $K$ , of length  $R$ , and similarly, every vertex in the outer facial cycle of  $K$  is contained in such a path. Notice that the new edges will split faces, but all members of a split face are “consecutive”. For convenience, we still refer to the graph by  $H^*$ .  $H^*$  has  $O(Rn)$  vertices. See Fig. 2(b), 2(c).

The final problem we obtain will have split faces, but an extremely simple structure. This structure allows us to essentially use the same Algorithm XTND given before, with the fan structure of  $K$  driving the computation. The main difference lies in that, for every fan  $f$  of  $K$ , we simultaneously consider the entire “grid” of faces stretching

FIG. 1

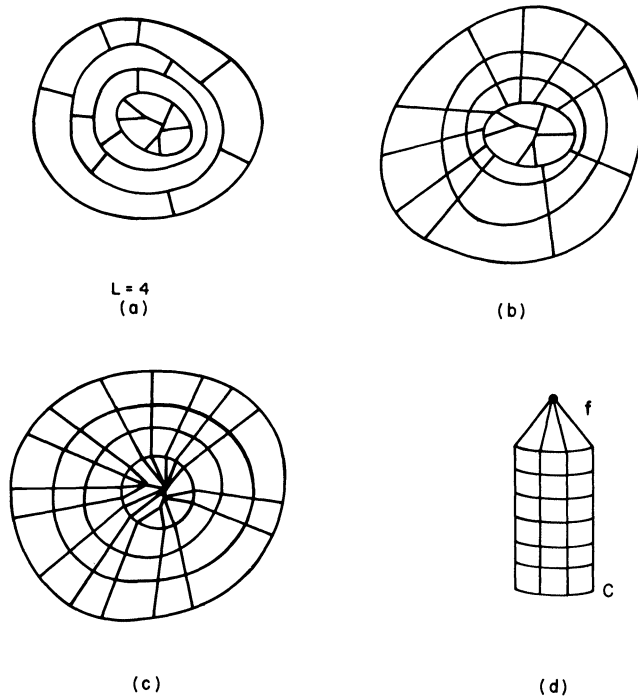

FIG. 2

from  $f$  to  $C$  (see Fig. 2(d)). Such a grid  $g$  will have arbitrarily many faces; however, the “left” and “right” paths of it are incident to at most  $O(L)$  faces. The dynamic programming recursion will consider all possibilities for each such face (whether chosen or rejected for the cover, and in or not in the set  $E$ ) in addition to the usual recursion for the fan  $f$ . Clearly there will be at most  $2^{O(L)}$  possible states. Further, if a face  $f_1$ , adjacent to the left path in  $g$ , and a face  $f_2$ , incident to the right path in  $g$ , actually correspond to the same split face, then we need only consider states of the dynamic program where  $f_1$  and  $f_2$  take the same value. It is easy to see that the overall procedure takes time at most  $2^{O(L)}n$ . This ends the description of the concentric case.

The general case is only slightly more complex, but we need to develop a bit more machinery. We essentially construct a partial order on the various islands, and solve a sequence of problems moving upwards in the partial order. The last (i.e., topmost) problem to be solved will be of the concentric type described above.

As before, let  $H$  denote the overall graph, with outer facial cycle  $C$ . Choose an arbitrary height- $(L-1)$  island  $K$ , with outer facial cycle  $C'$ . Let  $e_1, e_2$  be two consecutive links joining  $C'$  to the height- $(L-2)$  island enclosing  $K$ , then as in the concentric case, by splitting faces we can assume that for  $i=1, 2$ ,  $e_i$  is contained in a length  $R-1$  simple path from  $C'$  to  $C$  (notice that the length restriction says that  $p_i$  does not unnecessarily cut through islands). Then the wedge of  $e_1, e_2$  is the subgraph of  $H$  bounded by  $p_1, p_2$  and the corresponding segments of  $C', C$ . The wedges of  $K$  are constructed for all consecutive links (see Fig. 3(a), 3(b)).

Proceeding recursively, let  $W$  be a wedge of some island; and  $J$  be a highest island enclosed by  $W$ , say  $J$  of height  $i$ . The boundary of  $W$  will be made up of two paths  $p_1, p_2$ , a segment of  $C$  and a segment  $x$  of at most two layer edges. Notice that at most one link edge  $e$  joins  $J$  to  $x$ . By face splitting we can guarantee that  $e$  exists.

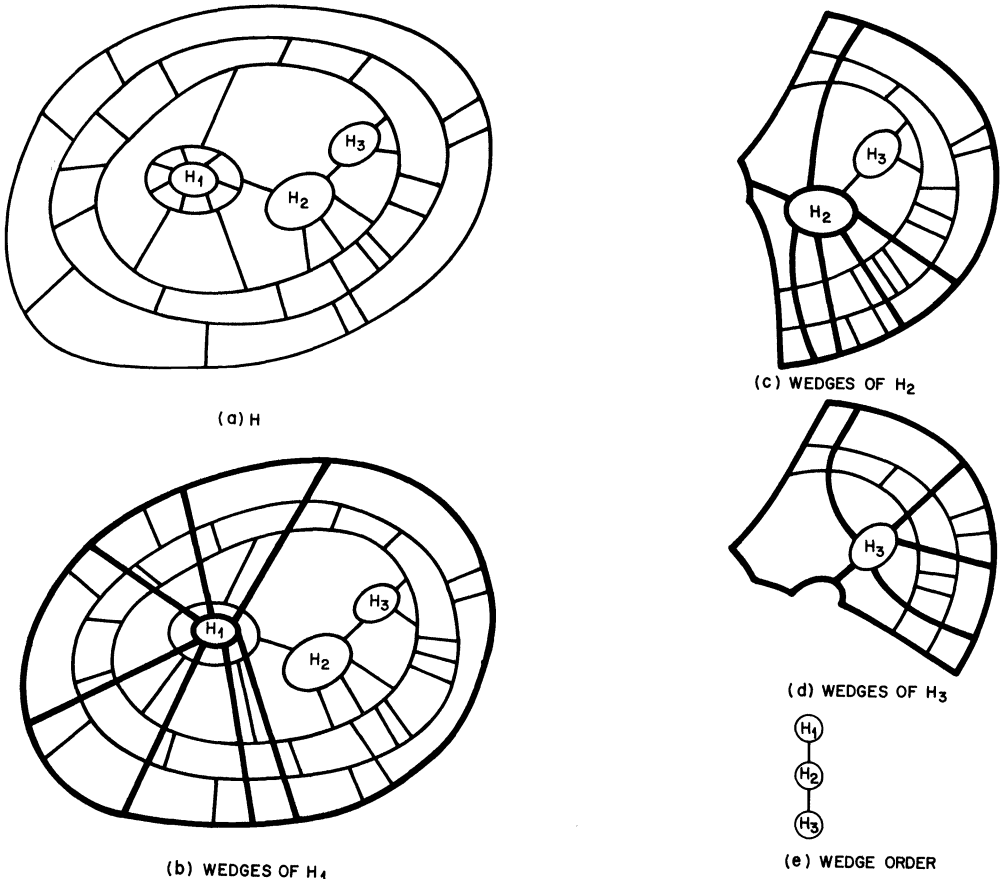

FIG. 3

Now we construct the wedges of  $J$  by including the link edges incident to vertices of the outer face of  $J$  in paths of length  $i$  to  $C$ , contained in  $W$ . The only exception is the edge  $e$  which will define two special wedges called the boundary wedges. This procedure is repeated recursively until we have computed wedges for all islands; trees are handled in a similar way (see Figs. 3(c) and 3(d)). Notice that this procedure constructs a partial order on a subset of islands and trees, with  $K$  at the top. We call this order the *wedge order* of  $H$  (see Fig. 3(e)).

One fact is worth pointing out: through additional face splitting if necessary, for every wedge  $W$  of a height- $i$  island, the number of faces in the two boundary wedges enclosed by  $W$  (if any) is altogether  $2i$ .

Let  $H^*$  denote the graph resulting from  $H$  after applying all the face splittings. Then  $H^*$  contains  $O(Ln)$  vertices, since each set of face splitting is caused by some edge or island of  $H$ .

Our Algorithm XTND will operate on  $H^*$  by moving up the wedge order. As shown previously,  $E$  denotes the set of faces to be covered. Let  $I$  be an island at the bottom of the order.  $I$  is contained inside some wedge  $W$  that belongs to the father of  $I$  in the wedge order. Let  $I'$  denote the union of  $I$  and all its wedges except for the two boundary ones.  $I'$  has the structure of a Halin graph with a grid glued to part of its outer face. Then we compute the minimum number of internal faces of  $I'$  needed to cover all faces of  $E \cap I'$ ; subject to each possible set of *constraints* corresponding

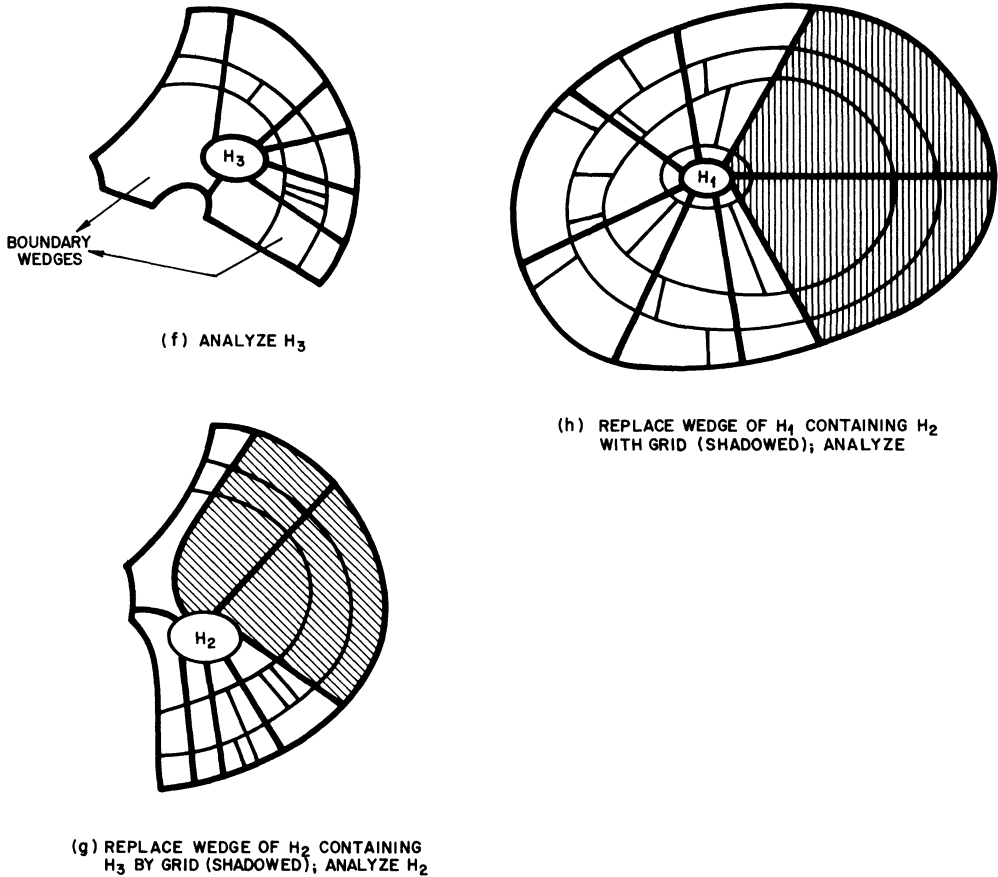

FIG. 3. (Continued.)

to the patterns of the faces in the boundary wedges of  $I$  (i.e., whether chosen, left uncovered or rejected; taking split faces into account, there are  $2^{O(L)}$  such patterns). Each of the computations is carried out much as in the case for Halin graphs.

Having carried out these computations, we replace  $W$  with a grid of width two, remove  $I$  from the wedge order and proceed. For the general step, we again pick an island from the bottom of the order and proceed as above. The only difference is that we may encounter wedges of the island containing width two grids that correspond to previously analyzed islands. But we have computed all relevant information for such grids, and it is easy to work this into the dynamic programming recursion. Details are left to the reader.

To analyze the complexity of the algorithm, notice that the total amount of work done on each wedge  $W$  is at most  $2^{O(L)}|W|$ . Hence, the complexity of the overall algorithm is at most  $2^{O(L)}n$ .

**3. Testing  $k$ -planarity for a variable embedding.** In this section, we return to the original problem of testing whether an  $n$ -vertex planar graph  $G = (V, E)$  containing a distinguished subset of vertices  $D$ , admits an embedding in which  $D$  can be covered with  $k$  or fewer faces.

If  $G$  is three-connected, then we use Algorithm XTND of § 2, after expanding  $D$  into polygons. We show later how to reduce the one-connected case to that of two-connectivity. In what follows, we will therefore assume  $G$  is two-connected.

The basic approach consists of decomposing  $G$  into (roughly) its triconnected components [HT1]. These components are then inductively assembled into  $G$ , using dynamic programming. Next we will give some definitions.

(1) A *block* of  $G$  is a connected subgraph  $H$  of  $G$  with two distinguished vertices  $u_1$  and  $u_2$  with the property that either  $G = H$ , or all paths from  $H - \{u_1, u_2\}$  to  $G - H$  must pass through  $u_1$  and  $u_2$ . The vertices  $u_1$  and  $u_2$  will be called the *extremes* of  $H$ . Notice that since  $G$  is two-connected, then in any embedding of  $G$ ,  $u_1$  and  $u_2$  will be in a common face.

(2) Let  $H$  be a block of  $G$  with extremes  $u_1$  and  $u_2$ . Let  $xyzw$  be a binary vector of length four. Define  $F(H, xyzw)$  to be the minimum number of internal faces of  $H$  needed to cover all vertices of  $D$  in  $H$ , taken over all embeddings of  $H$  with  $u_1$  and  $u_2$  in the outer face, with the following constraints:

- (i) If  $x = y = 1$  then there exist vertices  $v_1$  and  $v_2$  in  $D \cap H$  with  $v_1 \neq v_2$  and  $v_i \neq u_j$  for all  $i, j$ , that are *not* covered by the chosen internal faces of  $H$ , and such that  $v_1$  is in one path from  $u_1$  to  $u_2$  in the outer face of  $H$ , and  $v_2$  in the other (in an optimal embedding that attains  $F(H, 11zw)$ ).
- (ii) If  $x + y = 1$ , exactly one of the paths from  $u_1$  to  $u_2$  in the outer face of  $H$  contains an uncovered vertex  $v \in D \cap H$ , with  $v \neq u_1, u_2$ .
- (iii) If  $x = y = 0$ , then all vertices of  $D \cap H$ , with the possible exception of  $u_1$  or  $u_2$ , are covered.
- (iv) If  $z = 0$  (resp., 1), then  $u_1 \in D$  is (resp., is not) covered.
- (v) If  $w = 0$  (resp., 1), then  $u_2 \in D$  is (resp., is not) covered.

(If,  $u_1 \notin D$ , then we always set  $z = 0$ ; similarly for  $u_2 \notin D$ . An embedding that attains  $F(H, xyzw)$  will be denoted by  $E(H, xyzw)$ .)

Notice that if in an optimal embedding of  $G$ , we use  $E(H, xyzw)$  to embed  $H$ , where  $x + y \geq 1$  and  $z + w \geq 1$ , then any face of  $G - H$  used to cover the uncovered vertices of  $H$  different from  $u_1$  and  $u_2$  will also cover  $u_1$  and  $u_2$ . Hence, for  $x + y \geq 1$ , we reset  $F(H, xy00) = \min_{z,w} F(H, xyzw)$ . Therefore, the only 4-vectors we need to keep track of are (0000), (1000), (1100), (0010), (0001) and (0011).

Every planar graph admits a recursive decomposition into blocks. This decomposition can be represented by a rooted tree, where each vertex corresponding to some block of  $G$ , with the root representing  $G$ , and the leaves (essentially) correspond to the triconnected components of  $G$ . For each block appearing in the tree, one of three canonical ways of decomposing it occurs: a "Series" Case, a "Parallel" Case and a "Messy" Case. Our Algorithm DYN for testing  $k$ -planarity proceeds upwards from the leaves in the decomposition tree by computing the  $F$  parameters. Once a block  $B$  has been analyzed, it is replaced in its parent by a small (bounded size) gadget (and we keep track of the  $F$  parameters of  $B$  to compute those of its parent).

In order to simplify the description, we will present together Algorithm DYN and the recursive decomposition structure. Further, the algorithm will be described recursively (i.e., proceeding from the root down). The complexity is analyzed later.

Now suppose  $\{u_1^*, u_2^*\}$  is an arbitrary cutset of  $G$ . Then in any embedding of  $G$ ,  $u_1^*$  and  $u_2^*$  will be in at least one common face, without loss of generality, the outer face of  $G$ . Then testing  $k$ -planarity of  $G$  is achieved by regarding  $G$  as a block with extremes  $u_1^*$  and  $u_2^*$ , and computing

$$\min \{F(G, 0000), 1 + \min \{F(G, xyzw): x + y + z + w \geq 1\}\}.$$

ALGORITHM DYN.

Input: a block  $H$  with extremes  $u_1, u_2$

Output: all quantities  $F(H, xyzw)$

There are three cases.

(1) *Series Case.*  $H$  has a cutvertex  $v$ . Then  $v \neq u_i, i = 1, 2$ , and we write  $H = H_1 \cup H_2$ , where  $u_i \in H_i, i = 1, 2$ , and  $H_1 \cap H_2 = v$  (see Fig. 4(a)). It is easy to compute the  $F$  parameters for  $H$  in constant time from those of  $H_1, H_2$ . Refer to Appendix A(1) for details.

(2) *Parallel Case.* Fix  $z$  and  $w$ .  $H$  is two-connected and  $\{u_1, u_2\}$  is a cutset of  $H$ . Write  $H = \cup_{j=1}^m H_j$ , where  $H_j \cap H_k = \{u_1, u_2\}$  for each  $j \neq k$ , and each  $H_j$  is a block with extremes  $\{u_1, u_2\}$  (see Fig. 4(b)).

Intuitively, we proceed as follows. Suppose we select two blocks to act as “leftmost” and “rightmost.” In Appendix A(2) we show that it is possible to select either a “best” embedding for each of the remaining “internal” blocks, or else a simple tie situation may arise. In either case we are allowed to essentially ignore the detailed structure of the internal blocks, and there is an efficient (linear time) procedure to pair them up and obtain an optimal embedding (permutation and rotations of the internal blocks). Further, we are always able to select a “best” leftmost and rightmost block. The overall procedure runs in time linear in  $m$ . Details are provided in Appendix A(2).

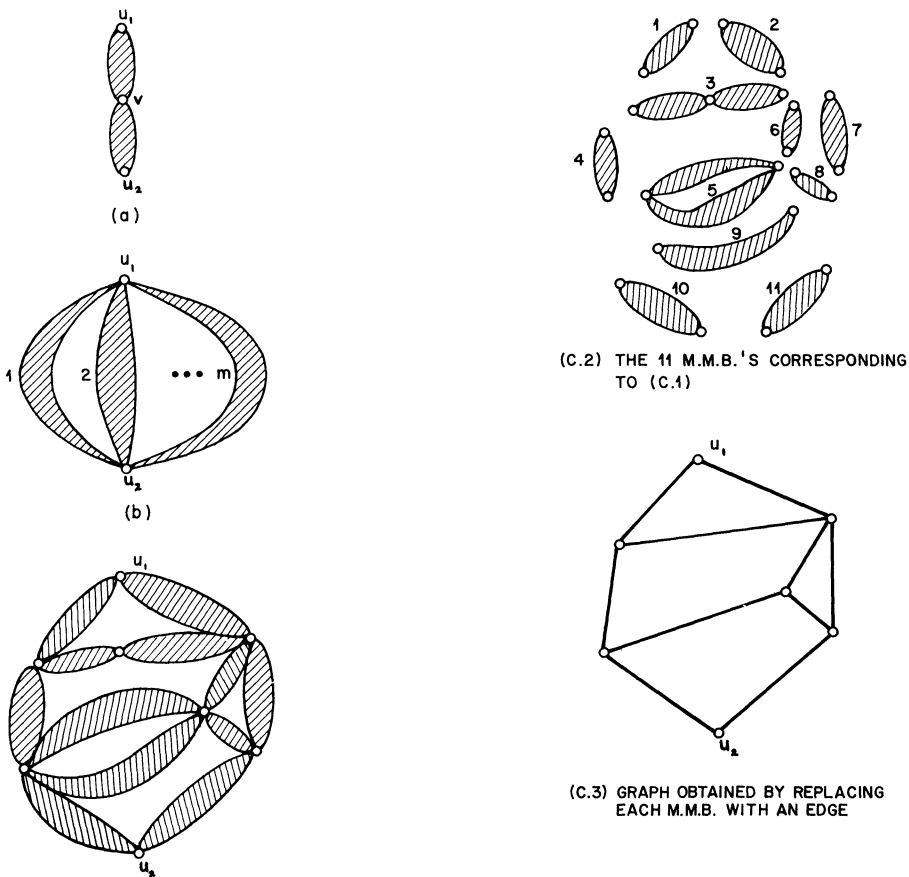

FIG. 4

(3) *Messy Case.* Cases (1) and (2) do not apply (see Fig. 4(c.1)). Then either (i) there is a cutset  $\{v, w\} (\neq \{u_1, u_2\})$  of  $H$ , or (ii)  $H$  is three connected. In the latter case, we can apply the results of § 2 (by using forbidden faces, if necessary). So assume (i) occurs.

Now for every cutset  $\{v, w\}$  of  $H$  we can define the main block of  $\{v, w\}$  as the union of all connected components of  $H - \{v, w\}$  not containing  $u_1$  or  $u_2$ , together with  $\{v, w\}$ , if any such components exist. Now if for all cutsets  $\{v, w\}$  the main block is empty, it is easy to see that  $H$  has a unique embedding with  $\{u_1, u_2\}$  restricted to lie in the outer face, and therefore we are essentially in alternative (ii). Otherwise, the main blocks can be ordered by inclusion; call those at the top the maximal main blocks (see Fig. 4(c.2)), or m.m.b.'s for short. If we replace every m.m.b. by an edge, the resulting graph  $H'$  has a unique embedding with  $\{u_1, u_2\}$  restricted to lie in the outer face (Fig. 4(c.3)).

Our strategy is to analyze each m.m.b.  $W$  recursively first. Next we replace  $W$  by an appropriate small gadget, attached to the rest of  $H$  by the extremes of  $W$ . We want the gadget to "retain" all the relevant properties of  $W$ , while having essentially a unique embedding (it will turn out that either we can find a "best" embedding for  $W$ , or there are a few ties; the gadgets we use will take care of either case). In this manner, we will reduce the problem on  $H$  to one where the embedding has been prescribed, and we can use the results of § 2. In summary, the approach is as follows:

- (a) Analyze every m.m.b.
- (b) For every m.m.b.  $W$ , compute its best embedding(s) and replace  $W$  with a small gadget. We will keep track of a *weight* corresponding to  $W$  that describes the cost of "internal" faces of  $W$ .
- (c) Compute each parameter  $F$  for the resulting graph  $\hat{H}$ , and to each, add the sum of the weights of the m.m.b.'s to obtain the  $F$  parameters of  $H$ .

Details are provided in Appendix A(3). The overall complexity of this case will be, at most,  $2^{O(k)}|\hat{H}|$ .

This concludes the description of Algorithm DYN. An efficient implementation of DYN would first compute the block decomposition. This is accomplished by using the algorithm in [HT1] to decompose a graph into its "split components". This algorithm is easily modified to output the decomposition tree in linear time, with each block labeled series, parallel or messy (in the messy case the decomposition is into m.m.b.'s). If  $v$  is a vertex of the tree that represents a block  $W$ , at  $v$  we store the graph  $W'$  resulting from  $W$  by replacing each of its children with an edge. The overall space required is linear. Finally, we "force" the original extremes  $u_1^*$ ,  $u_2^*$  chosen for  $G$  to lie in the outer face by adding at the start the edge  $(u_1^*, u_2^*)$  if necessary.

Having computed the decomposition, we proceed upwards with DYN. If  $W'$  is the graph stored at some vertex of the tree, the work involved in analyzing  $W'$  (when we reach it) is  $O(|W'|)$  in the series and parallel cases, and at most  $2^{O(k)}|W'|$  in the messy case. Thus we conclude as follows.

**LEMMA 3.** *The complexity of testing whether  $G$  is  $k$ -planar with DYN is at most  $O(c^k n)$ , where  $c$  is independent of  $n$ .  $\square$*

Next we pass to the one-connected case.

A one-connected graph  $G$  is the union of *bricks*; that is, edges or 2-connected subgraphs that intersect at cutvertices only.  $G$  will have a "treelike" structure; namely, if a path leaves a brick  $B$  through a cutvertex  $v$ , the only way the path can return to  $B$  is by crossing  $v$  again. Now suppose  $G = (V, E)$  has connectivity one; let  $v$  be an arbitrary cutvertex, and write  $G = \bigcup_{i=0}^m G_i$ , where  $G_j \cap G_k = v$ , for all  $j \neq k$ , and each  $G_i - v$  is nonempty and connected. Let  $D_i = D \cap G_i$ .

If  $v \in D$ , then  $v$  will be covered by some face  $f$ . Now we can always embed every  $G_i$  simultaneously so that  $f$  is a face of it without requiring more than the minimum number of faces to cover all of  $D$ . Thus, if

$$\hat{k} = \text{planarity number of } G$$

and

$$\hat{k}_i = \text{planarity number of } G_i, \text{ for } i = 0, \dots, m \text{ (where we cover } D_i),$$

then

$$\hat{k} = \sum_{i=0}^m \hat{k}_i - (m-1),$$

and the problem decomposes with  $v$  in each  $D_i$ .

Now suppose  $v \notin D$ . By not including  $v$  in  $D$ , we can compute  $\hat{k}_i$  and use  $\sum_{i=0}^m \hat{k}_i$  as the number of faces to cover  $D$ . If we use  $\bar{D}_i = \{v\} \cup D_i$  instead of  $D_i$  for a given graph  $G_i$ , we might increase the planarity number of  $G_i$  by 1. However, if we add  $v$  to  $D$  and compute the planarity number of  $G$  as before, we might actually decrease the number of faces required to cover  $D$  because the graphs  $G_i$  will be able to share the additional face. Hence, if we try both possibilities (i.e., whether or not to add  $v$  to  $D$ ), and decompose into a problem for each  $G_i$ , we will certainly solve the original problem. However, this may create too much work if a brick of  $G$  contains too many cutvertices. Instead we will use an approach inspired by the next lemma.

LEMMA 4.

$$\hat{k}_{i,1} = \text{planarity number of } G_i \text{ to cover } D_i.$$

$$\hat{k}_{i,2} = \text{planarity number of } G_i \text{ to cover } \bar{D}_i.$$

Then

- (a) If, for at least one  $i \geq 1$ ,  $\hat{k}_{i,2} = \hat{k}_{i,1}$ , then it is optimal to add  $v$  to  $D$ .
- (b) If, for all  $i \geq 1$ ,  $\hat{k}_{i,2} = \hat{k}_{i,1} + 1$ , then it is optimal not to add  $v$  to  $D$ .

*Proof.* The proof is clear.  $\square$

Notice that  $G_0$  is not considered in the lemma.

Next we proceed as follows. Let  $G$  be a graph whose  $k$ -planarity we want to test; exactly one brick  $B$  of  $G$  has been painted red. Let  $v \in B$  be a cutvertex of  $G$ . If  $v \in D$ , then proceed as outlined above. If  $v \notin D$ , then (as previously) we form the graphs  $G_i$ , so that  $B$  is contained in  $G_0$ , and we paint red the brick of  $G_i$  for  $i \geq 1$ , that contains  $v$ . Next, we solve, in each  $G_i$  for  $i \geq 1$ , the two problems to cover  $D_i$ , and to cover  $\bar{D}_i$ ; we then use Lemma 4 to decide whether or not to add  $v$  to  $D$ . Notice that each graph  $G_i$  contains exactly one red brick. Clearly, repeating this procedure will eventually reduce the problem in  $G$  to at most two separate problems in each brick. Thus the complexity is again linear.

**4. NP-completeness for arbitrary  $k$ .** In this section we show that the problem of determining whether a  $(G, D)$  pair is  $k$ -planar or not is strongly NP-complete when  $k$  is variable. Hence, it is unlikely that a polynomial-time algorithm exists for recognizing a  $k$ -planar graph for arbitrary  $k$ .

In order to do this, we define the following decision problem which we call FACE COVER: "Given a planar graph  $G = (V, E)$  together with a subset of vertices  $D \subseteq V$  and an integer  $K$ , can  $G$  be embedded in the plane so that at most  $K$  faces are required to cover all of the vertices in  $D$ ?" We will show that FACE COVER is strongly NP-complete even when  $G$  is three-connected and so has essentially a unique planar

embedding, when  $d = \theta(n)$ , and when all of the faces of  $G$  have bounded length. A graph  $G$  is 3-connected if the removal of any two vertices of  $G$  leaves the rest of  $G$  connected. It is well known [Wh] that a 3-connected planar graph has an embedding which is essentially unique; i.e., all embeddings have the same facial structure and differ only in which face is the outer face.

The reduction will be from VERTEX COVER: “Given a graph  $G = (V, E)$  and integer  $L$ , is there a subset of vertices  $W \subseteq V$  with  $|W| \leq L$ , such that for every edge  $(u, v) \in E$  at least one of  $u$  or  $v$  belongs to  $W$ ?” VERTEX COVER is strongly NP-complete for cubic planar graphs [GJS].

**THEOREM 5.** FACE COVER is strongly NP-complete even when  $G$  is 3-connected,  $d = \theta(n)$ , and all faces of  $G$  have bounded length.

*Proof.* Consider an instance of VERTEX COVER given by a cubic planar graph  $G = (V, E)$  and integer  $K$ , where  $G$  has no loops or parallel edges and every edge is contained in exactly two faces. This problem is known to be strongly NP-complete [GJS].

We obtain an instance of FACE COVER by setting  $K = L$  and  $\bar{G} = (\bar{V}, \bar{E})$  being the planar dual of  $G$ , i.e., place a vertex  $v \in \bar{V}$  in every face  $f_v$  of  $G$ , and an edge  $(u, v) \in \bar{E}$  if faces  $f_u$  and  $f_v$  of  $G$  share an edge. Subdivide each edge  $(u, v) \in \bar{E}$  by adding a vertex  $x(u, v)$  and denote the new graph by  $\hat{G} = (\hat{V}, \hat{E})$ . Let  $D$  be the set of vertices  $x(u, v)$  for  $(u, v) \in \bar{E}$ . Given the particular embeddings of  $G$  and  $\hat{G}$ , there is clearly a one-to-one correspondence between vertices in  $D$  and edges of  $G$ , and similarly, between faces of  $\hat{G}$  and vertices of  $G$ . Thus, there is a one-to-one correspondence between a face cover of  $(\hat{G}, D)$  and a vertex cover of  $G$  of the same cardinality.

In general,  $\hat{G}$  might have other planar embeddings where a face cover in this new embedding of  $\hat{G}$  does not correspond to any vertex cover in  $G$ . To remedy this, we form the graph  $G^* = (V^*, E^*)$  from  $\hat{G}$  by adding, inside each face of  $\hat{G}$ , edges to form a cycle containing all vertices of  $D$  in that face, and embed the cycle inside the face. It is easy to see that the face cover problem on  $G^*$  is equivalent to the face cover problem in  $\hat{G}$ . We will show that  $G^*$  is 3-connected and so this embedding is essentially unique [Wh] which will complete the proof. To see that  $G^*$  is three-connected, notice that in  $\bar{G}$ , all facial cycles consist of precisely three edges. However, these cycles may not be simple (i.e., triangles) if  $G$  has bridges. Nevertheless, in  $G^*$  all facial cycles have length three and are simple, in other words  $G^*$  is triangulated and, thus, three-connected, since  $G^*$  is a simple graph.

Finally, note that  $|D|$  equals the number of edges of  $\bar{G}$ , which is  $\theta(n)$ .  $\square$

(Note: An alternative proof of NP-completeness for the case  $D = V$  appears in [FHS].)

**5. An exact and an approximate algorithm for fixed embeddings.** Consider the variation of FACE COVER in which we are forced to use a given embedding. That is, FIXED EMBEDDING FACE COVER (FEFC): “Given an embedded planar graph  $G = (V, E)$ , an integer  $k$ , and a subset  $D \subseteq V$ , can  $D$  be covered with at most  $k$  faces?” Clearly FEFC is NP-complete.

In this section we will present:

- (a) A set of transformations for FEFC that allow us to assume that  $d = \theta(n)$ , while not increasing the maximum facial length.
- (b) An exact algorithm for FEFC that runs in time  $2^{O(\sqrt{n})}$ .
- (c) A polynomial-time approximation algorithm for FEFC that is asymptotically optimal if  $G$  has bounded length facial cycles, as is the case in our NP-

completeness proof. (Our basic approach is similar to that of [LT] in that we use the planar separator theorem.)

The following set of transformations can be visualized as simplifying the problem. Their main objective is to allow us to assume that  $d = \theta(n)$  without increasing the facial cycle length and preserving the value of the optimal solution. These transformations are crucial for the proof of Theorem 6 presented later.

- (1) Every vertex of  $V - D$  of degree one is shrunk into its neighbor.
- (2) Every facial cycle of length two (resp. one) is shrunk into a single edge (resp. vertex).
- (3) In every face  $g$  with at most one vertex in  $D$ , all vertices in  $V - D$  are shrunk into a single vertex.
- (4) Every vertex  $v$  in  $V - D$  of degree two, adjacent to vertices  $u$  and  $w$ , is deleted, and edges  $(u, v)$  and  $(v, w)$  are replaced by the edge  $(u, w)$ .
- (5) Any two vertices of  $V - D$  that are adjacent are shrunk into a single vertex.
- (6) For every loop  $e = (v, v)$  such that (say) the subgraph contained in the interior of  $e$  has an outer facial cycle consisting of  $v$  and vertices of  $V - D$  only,  $e$  is deleted.
- (7) If a vertex  $v \in D$  is contained in a unique face of  $f$ , then  $f$  must appear in any cover; hence, we delete  $v$ , and remove from  $D$  all members in  $f$ .

This concludes the list of transformations. Clearly, Transformations (1)–(7) can be applied until no longer possible, in polynomial time, to obtain an equivalent problem.

Theorem 6 given below places a lower bound on the size of  $D$  in a loop-free graph where none of Transformations (1)–(7) can be applied. However, if we apply (1)–(7) to a graph  $G$ , the resulting graph  $G'$  may contain loops. In order to count vertices of  $D$  in  $G'$ , we modify it as follows:

- (a) Every loop  $(v, v)$  with  $v \in D$  or  $v$  adjacent to at least three vertices of  $D$  is deleted.
- (b) Otherwise, let  $e = (v, v)$  be a loop, and let  $x$  be the only neighbor of  $v$  in the interior of  $e$ , with  $x \in D$ . Now, (7) or (2) cannot be applied; hence, the interior of  $e$  contains vertices other than  $x$ . But there must be at least one such vertex  $w \in D$  such that  $(w, v)$  can be added while preserving planarity; this is true because of (a), and the fact that neither (3) nor (6) can be applied. In that case,  $(w, v)$  is added. Now  $v$  has three neighbors in  $D$ .

It is easy to verify that after applying (a) and (b) to  $G'$ , the resulting graph  $G''$  is such that none of the transformations (1)–(7) can be applied, and that  $G''$  is loop-free.

**THEOREM 6.** *Let  $G = (V, E)$  be a loop-free planar graph with a fixed embedding, where  $|V| = n$  and  $|D| = d$ , and suppose that none of the Transformations (1)–(7) can be applied. Then  $d \geq (n + 4)/3$ .*

*Proof.* Notice that every vertex of  $V - D$  has degree at least three and is only adjacent to vertices of  $D$ . Suppose that  $G$  contains a pair of parallel edges  $e = (u, v) = e'$ , with say,  $v \in V - D$ . Then the interior region bounded by  $e$  and  $e'$  must contain a vertex  $w \in D$  with  $w \neq u$  such that either  $v$  and  $w$  are adjacent, or the edge  $(v, w)$  can be added to the embedding (in which case we do so). Similar considerations apply to the exterior of  $e'$ .

Now, delete all edges with both endpoints in  $D$ , let  $C$  be an arbitrary connected component with  $\hat{n}$  vertices and  $\hat{d}$  elements of  $D$ . Clearly,  $C$  has no facial cycles of length one or two. The latter follows because if  $e = (u, v) = e'$  are a pair of parallel edges with  $u \in D$ ,  $v \in V - D$ , then there exist vertices  $w_1, w_2 \in D$  adjacent to  $v$ , and located in the interior and exterior of  $e'$ ; this is guaranteed by the previous paragraph.

Consequently, the number of  $\hat{e}$  of edges of  $C$  satisfies  $\hat{e} \geq 3\hat{n} - 6$ . On the other hand, if  $\hat{f}$  denotes the number of faces of  $C$ ,  $\hat{f} = \sum_{k \geq 3} \hat{f}_k$ , where  $\hat{f}_k$  is the number of

faces of length  $k$ . Since  $C$  is bipartite,  $\hat{f}_3 = 0$ . Thus,  $\hat{e} = \frac{1}{2} \sum_k k \hat{f}_k \geq 2 \sum_{k \geq 4} \hat{f}_k = 2\hat{f}$ . Moreover,  $\hat{e} \geq 3(\hat{n} - \hat{d})$ , since for each vertex of  $C$  not in  $D$ , we count at least three edges. Hence,

$$\hat{e} = 3\hat{n} - x \quad \text{where } 6 \leq x \leq 3\hat{d}.$$

By Euler's formula,

$$\hat{f} = 2\hat{n} - x + 2 \leq \frac{3\hat{n} - x}{2},$$

or

$$\hat{n} + 4 \leq x \leq 3\hat{d},$$

i.e.,

$$\hat{d} \geq \frac{\hat{n}}{3} + \frac{4}{3},$$

which concludes the proof.  $\square$

We note that the bound in Theorem 6 is best possible.

We now present an exact algorithm for finding the minimum number of faces required to cover all special vertices of a planar graph given a fixed embedding in  $2^{O(\sqrt{n})}$  time. As in Theorem 7, we may take  $d = \theta(n)$  by the application of appropriate transformations in the embedded graph. Let  $G = (V, E)$ ,  $D \subseteq V$ ,  $d = |D|$ , and  $n = |V|$  be the input. The algorithm proceeds as follows:

- (1) Let  $S$  be an  $O(\sqrt{n})$ -separator of  $G$ . Write  $G = G_1 \cup G_2$ , where  $G_1 \cap G_2 = G(S)$ , the subgraph of  $G$  induced by  $S$ . Let  $D_i$  be the subset of  $S$  contained in  $G_i$ . Write  $G_i = (V_i, E_i)$ , and embed  $G_i$  as it appears in  $G$ .
- (2) A face  $f$  of  $G$  that contains vertices of  $G_1 - S$  and of  $G_2 - S$  will be called a boundary face. Ideally, we would like to proceed independently with  $G_1$  and  $G_2$ . However, these two graphs interact on the boundary faces. Thus, we modify  $G_1$  (and similarly,  $G_2$ ) so that the boundary face structure is "preserved" in a "legal" way. This is attained in two steps.
  - (i) For every boundary face  $f$ , we replace each path of  $f$  that intersects  $V_1$  at its endpoints with an edge. The resulting graph contains a face  $f_1$  that corresponds to  $f$ ; we call  $f_1$  an inherited face. Select an arbitrary added edge  $(u, v)$  of  $f_1$  and subdivide it by introducing a grey vertex  $w(f)$ . Carry out this transformation for all boundary faces of  $G_1$ ; call the resulting graph  $G'_1$ .

Now we are essentially ready to proceed independently with graph  $G'_1$ .

**The** idea is to use the grey vertices to force boundary faces to be used in a **cover**: if  $f$  is such a face and we change the color of  $w(f)$  from grey to black, **this** should force us to use  $f$ . However, there is a problem.  $G_2$  may have several connected components and the removal of each component could introduce in  $G'_1$  a (possibly large) new face that does not correspond to any face of  $G$ . We call such a face a gap face. Each gap face is made up of edges added in (i). We handle this problem as follows.

- (ii) In each gap face subdivide every edge by introducing a new white vertex. Connect all such vertices consecutively as we travel around the face with red edges. Call the resulting graph  $\hat{G}_1$ . Similarly, define  $\hat{G}_2$ .

- (3) Write  $\hat{S} = S \cap D$ . Next, for every partition  $\hat{S} = \hat{S}_1 \cup \hat{S}_2$  with  $\hat{S}_1 \cap \hat{S}_2 = \emptyset$ , and every subset  $X$  of grey vertices, we color  $X$  black, the remaining grey vertices white, and solve the following two face cover problems.
- (a) In  $\hat{G}_1$ , cover  $(D_1 - S) \cup \hat{S}_1 \cup X$ , with minimum value  $k_1(\hat{S}_1, X)$ .
- (b) In  $\hat{G}_2$ , cover  $(D_2 - S) \cup \hat{S}_2 \cup X$ , with minimum value  $k_2(\hat{S}_2, X)$ ; set  $f(\hat{S}_1, \hat{S}_2, X) = k_1(\hat{S}_1, X) + k_2(\hat{S}_2, X) - |Y|$ , where  $Y$  is the set of inherited faces used in both covers. Then the minimum cover of  $D$  has value  $\min_{\hat{S}_1, \hat{S}_2, X} f(\hat{S}_1, \hat{S}_2, X)$ .

The proof of correctness of the algorithm proceeds as follows.

- (1) Consider any face cover of  $D$  in  $G$ . Then an arbitrary subset of the boundary faces will be used, and if any vertex of  $S \cap D$  is not covered by a boundary face, then it is either covered by a face of  $G_1$  that contains no vertices of  $G_2 - S$  (an internal face of  $G_1$ ), or it is covered by a face of  $G_2$  that has no vertices of  $G_1 - S$  (an internal face of  $G_2$ ).
- (2) Consider any of the problems on graph  $\hat{G}_1$ , with  $\hat{S}_1$  and  $X$  as above. Then, without loss of generality, *none* of the faces containing red edges is ever used in an optimal solution, since the black vertices that any such face may cover are also covered by an inherited or an internal face. Thus, all vertices of  $X$  are covered by inherited faces; and all vertices of  $\hat{S}_1$  are either covered by inherited faces, or by faces of  $\hat{G}_1$  that are copies of internal faces of  $G_1$  (similarly for  $\hat{G}_2$ ). Consequently, for each  $\hat{S}_1, \hat{S}_2$  and  $X$ , we can take the two optimal solutions on  $\hat{G}_1$  and  $\hat{G}_2$ , respectively, and obtain a face cover of  $D$  in  $G$  of cardinality precisely  $f(\hat{S}_1, \hat{S}_2, X)$ .
- (3) Finally, consider an arbitrary face cover  $F$  of  $D$  in  $G$ . Let  $F_i$  be the set of internal faces of  $G_i$  used in  $F$  for  $i = 1, 2$ . Let  $Z$  be the set of boundary faces used in  $F$ . Notice that  $|F| = |F_1 \cup Z| + |F_2 \cup Z| - |Z|$ . Also, set  $\hat{S}_1$  is the set of vertices of  $S \cap D$  covered by internal faces of  $G_1$ , and  $\hat{S}_2 = (S \cap D) - \hat{S}_1$ . Let  $X(Z)$  be the set of grey vertices of  $\hat{G}_1$  contained in those inherited faces corresponding to  $Z$ . Then  $k_i(\hat{S}_i, X(Z)) \leq |F_i \cup Z|$  for  $i = 1, 2$ , and thus,  $k_1(\hat{S}_1, X(Z)) + k_2(\hat{S}_2, X(Z)) \leq |F| + |Z|$  which implies that  $f(\hat{S}_1, \hat{S}_2, X(Z)) \leq |F|$ .

This concludes the proof of the correctness of the algorithm.

To derive the complexity of the algorithm, the number of edges and vertices added to each graph  $G_i$  to obtain  $\hat{G}_i$  is  $O(|S|)$ . Consequently,  $G_i$  has at most  $\frac{2}{3}n + O(\sqrt{n})$  vertices. Furthermore, the total number of triples  $(\hat{S}_1, \hat{S}_2, X)$  is at most  $2^{O(|S|)}$ . As a result, if  $T(n)$  is the worst-case complexity of the algorithm, we have  $T(n) \leq 2^{O(\sqrt{n})} T(\frac{2}{3}n + O(\sqrt{n}))$ ; from which  $T(n) \leq 2^{O(\sqrt{n})}$  is straightforward.

The approximation algorithm is somewhat similar to the exact algorithm, with the exception that we will use planar separators that produce "equal" size subgraphs. Let  $G = (V, E)$  be the input with  $D \subseteq V$ . Let  $S$  be a "50/50" separator of  $G$ . Write  $G = G_1 \cup G_2$ , where each  $G_i = (V_i, E_i)$  is defined as in the exact algorithm. Next, add edges to each  $G_i$  to obtain the inherited faces, and call the resulting graph  $\bar{G}_i$ . Notice that the faces of  $\bar{G}_i$  correspond to the internal faces of  $G_1$ , boundary faces, and also (possibly) to a third type of face that corresponds to connected components of  $G_2$ . (The vertices on these faces are all contained in  $S$ .) Proceed similarly with  $G_2$ . Set  $D_i = (D \cap V_i) - S$ . Now, suppose we solve the following problems with  $i = 1, 2$ :

- (\*) In  $\bar{G}_i$ , cover  $D_i$ ; let the optimum cover have size  $\bar{k}_i$ .

Now, by taking the union of the optimum covers we can obtain a cover of  $D$  in  $G$  by adding at most  $|S|$  faces. Hence, if we denote by  $k$  the size of an optimum cover

of  $D$  in  $G$ , we have  $k \leq \bar{k}_1 + \bar{k}_2 + |S|$ . On the other hand, given a cover  $F$  for  $G$  we can obtain a cover for  $\bar{G}_1$  and one for  $\bar{G}_2$  by restricting  $F$  appropriately. Hence,  $|F| \geq \bar{k}_1 + \bar{k}_2 - O(|S|)$ , or  $|k - \bar{k}_1 + \bar{k}_2| = O(|S|) = O(\sqrt{n})$ .

Our algorithm will not solve the problems on  $\bar{G}_i$  exactly. Rather, we keep subdividing each graph and modifying the resulting subgraphs until we obtain (on each branch of the recursion) graphs of size  $O(\log^2 n)$ . We solve these problems using the exact algorithm, and by piecing together their solutions, we will obtain a face cover of  $D$  in  $G$ . It is not difficult to verify that the problems produced at the  $i$ th recursive step have at most  $O(n2^{-i})$  vertices. Hence, the total number of recursive levels is at most  $T = \log n - 2 \log \log n + O(1)$ . Consequently, the total error is, up to a constant, at most

$$\sum_{i=0}^T 2^i \sqrt{\frac{n}{2^i}} = O(\sqrt{n}2^{T/2}) = O\left(\frac{n}{\log n}\right).$$

Hence, if  $G$  has bounded length facial cycles, and since  $d = \theta(n)$ , the relative error of our approximation algorithm is  $O(1/\log n)$ .

To estimate the complexity of this procedure, notice that the number of problems to be solved exactly is  $O(2^T) = O(n/\log n)$ , and each such problem takes time at most  $2^{O(\sqrt{\log^2 n})} = n^{O(1)}$ . The total number of vertices in the recursion tree is also  $O(2^T)$ , and we conclude that the algorithm runs in polynomial time.

**6. Concluding remarks.** We have shown that checking  $k$ -planarity of graph  $G$  with  $n$  vertices  $D \subseteq V$  can be done in linear time for any fixed  $k$ . This provides an efficient recognition algorithm for this class of graphs for which the Steiner tree problem can be solved in polynomial time [EMV]. We have also shown that if  $k$  is not fixed, the associated decision problem is NP-Complete even if  $G$  has essentially a unique embedding,  $d = \theta(n)$ , and all facial cycles have bounded length. We obtain a polynomial-time algorithm for this latter case which is asymptotically optimal.

We note that the work of Robertson and Seymour on Wagner's conjecture could be used to check  $k$ -planarity for any fixed  $k$  in  $O(n^4)$  time [Se]. However, their algorithm would *not* provide an embedding and covering as our algorithm does. It might be possible to specialize their result to our problem. We leave this as an open problem.

#### Appendix A—The three cases of DYN.

(1) *Series Case.* The formulas for this case are: Fix  $z$  and  $w$ . Then

$$F(H, 00zw) = \min \left\{ F(H_1, 00z0) + \min_t \{F(H_2, 00tw)\}, \min_t \{F(H_1, 00zt)\} \right. \\ \left. + F(H_2, 000w) \right\}.$$

Similarly,

$$F(H, 10zw) = \min \left\{ \min_{w'} \{F(H_1, x'y'zw') : x' + y' = 1\} \right. \\ \left. + \min_{z''} \{F(H_2, x''y''z''w) : x'' + y'' \leq 1\}, \right.$$

$$\begin{aligned} & \min_{w'} \{F(H_1, x'y'zw'): x' + y' \leq 1\} \\ & + \min_{z''} \{F(H_2, x''y''z''w): x'' + y'' = 1\}, \\ & \min \{F(H_1, x'y'z1): x' + y' \leq 1\} \\ & + \min \{F(H_2, x''y''1w): x'' + y'' \leq 1\} \}. \end{aligned}$$

All other parameters are computed analogously.

(2) *Parallel Case.* Fix  $z$  and  $w$ . Suppose we choose two candidates  $H_l$  and  $H_r$  as the “left” and “right” blocks in  $E(H, xyzw)$ , where, for example, we would use embeddings  $E(H_l, xb_lzw)$  and  $E(H_r, b_r yzw)$  for some  $b_l, b_r \in \{0, 1\}$ . Subject to this specific choice (i.e.,  $l, r, b_l$  and  $b_r$ ), we show how to compute the best embedding of  $H$ . Now suppose  $k \neq l, r$ . Which embedding should be used for  $H_k$ ? Now, if  $z + w \geq 1$ , we must always use  $E(H_k, x'y'00)$  for some  $x', y'$  (and also,  $b_l = b_r = 0$ ). Assume  $z = w = 0$ .

- (a) If  $F(H_k, 0100) \leq F(H_k, 0000) - 1$ , then  $E(H_k, 0100)$  is preferred over  $E(H_k, 0000)$ ; if the reverse inequality holds, then the opposite choice is preferred.
- (b)  $E(H_k, 0100)$  and  $E(H_k, 1100)$  are compared in a similar way.
- (c) If  $F(H_k, 1100) \leq F(H_k, 0000) - 2$  then  $E(H_k, 1100)$  is preferred; if  $F(H_k, 0000) \leq F(H_k, 1100)$  then  $E(H_k, 0000)$  is preferred. The only possible tie occurs precisely when  $F(H_k, 0000) = F(H_k, 1100) + 1$ . We will represent the better embedding, in this case, by  $E(H_k, **00)$ .

Running through all cases (a)–(c) yields the best embedding for  $H_k$ , with a possible tie between (0000) and (1100). We still have to decide how to permute the  $H_k$ 's, and how to rotate each individual  $H_k$ . This is done as follows. Assume first that no ties occurred, and for each  $H_k$  with  $k \neq l, r$ , we create a binary vector of two entries corresponding to the best embedding, together with an additional vector  $(b_l, b_r)$ , where  $b_l$  and  $b_r$  specify the status of the inside face of  $H_l$  and  $H_r$ , respectively. Now we have to order these vectors cyclically and rotate them so that the total number of consecutive vectors  $(\alpha, \beta)$  followed by  $(\gamma, \lambda)$  with  $\beta + \gamma \geq 1$  is minimum. For example, if the vectors are  $(0, 0)(0, 1)(0, 1)(0, 0)(0, 1)(0, 1)(1, 1)(1, 1)$ , the best ordering is  $(0, 1)(1, 0)(0, 0)(0, 0)(0, 1)(1, 1)(1, 1)(1, 0)$  of value 4. In general, is it easy to see that an optimal arrangement is obtained by putting all (1,1)'s in a string; if there is at least one (0, 1) put it at one end of the string; if there is another, put it at the other end; next pair up all remaining (0, 1)'s (at most one will not be paired up), and pair up all (0, 0)'s. Let  $n_{ij}$  equal the number of  $(i, j)$ 's; the value will be

$$\begin{aligned} n_{11} + 1 + \left\lceil \frac{n_{01}}{2} \right\rceil - 1 &= n_{11} + \left\lceil \frac{n_{01}}{2} \right\rceil \quad \text{if } n_{01} > 0, \\ n_{11} + 1 &\quad \text{if } n_{01} = 0, n_{00} > 0, \\ n_{11} &\quad \text{if } n_{01} = n_{00} = 0. \end{aligned}$$

Now, if a tie occurred in at least one  $H_k$ , i.e.,  $n_{**} > 0$ , using a (1, 1) embedding increases the  $n_{11}$  count by one but saves one internal face. Therefore, we either make all  $(*, *)$ 's into (1, 1)'s, or we make all of them into (0, 0)'s. That is, if  $n_{**} > 0$  and

$n_{01} > 0$  or  $n_{00} > 0$ , then make all  $(*, *)$ 's into  $(0, 0)$ 's, and if  $n_{01} = n_{00} = 0$ , then make them all into  $(1, 1)$ 's.

In this way, we compute the value  $m(b_l, b_r)$  of an optimal arrangement to account for faces between the  $H_i$ 's. Let  $f_k(b_l, b_r)$  be the number of internal faces used by each  $H_k$  in the optimal embedding. Thus,

$$F(H, xy00) = \min_{l,r} \left\{ \min_{b_l, b_r} \left\{ F(H_l, xb_l00) + F(H_r, b_r y00) + \sum_{k \neq l,r} f_k(b_l, b_r) + m(b_l, b_r) \right\} \right\}.$$

The above procedure can be implemented easily in a quadratic amount of work. We next sketch how to improve on it so that the  $F(\cdot)$  parameters are obtained in linear time. Assume that we want to compute  $F(H, xy00)$  (the general case is simpler), and fix  $b_l$  and  $b_r$  (there are four cases), without yet fixing  $H_l$  or  $H_r$ . We first consider the case where there are *no* ties in any of the blocks. Then the quantity  $m(b_l, b_r)$  is well defined. We can also select a "best" block to act as a left end, namely, select  $k$  such that

$$F(H_k, xb_l00) - f_k(b_l, b_r)$$

is minimized, where we use the notation given above. Similarly, we can choose a "best" right block. It is not difficult to show that these blocks should indeed occupy the ends.

We now pass to the case of ties. If either

- (i)  $b_l + b_r \leq 1$ , or
- (ii)  $n_{01} + n_{00}$  is 0 or at least 3,

Then the ties will always be resolved, and we proceed as in the previous paragraph. Otherwise, we also try all possible ways of using, as end blocks, the (at most two) blocks whose best embedding is of type 01 or 00. This only adds a constant number of additional cases. Hence, this case can indeed be computed in linear time.

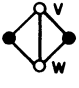

(3) *Messy Case.* Assume we have computed the m.m.b.'s. Let  $W$  be an m.m.b., with extremes  $v, w$ ; we want to describe the behavior of  $W$  with a small gadget.

Suppose  $W$  is an interior m.m.b.; that is, the extremes of  $W$  are contained in the interior of  $H'$ . We can compare the possible embeddings of  $W$  as follows:

- (a) For fixed  $z$  and  $w$ , we compare each pair  $(xyzw)$  and  $(x'y'zw)$  precisely as in case (2) of DYN. For example, if  $F(W, 1000) \leq F(W, 1100)$ , then  $E(W, 1000)$  is preferred over  $E(W, 1100)$  (and if the inequalities are reversed, otherwise). Recall that we have a tie between  $E(W, 0000)$  and  $E(W, 1100)$  if  $F(W, 0000) = 1 + F(W, 1100)$ .
- (b) If  $F(W, 1000) \geq F(W, 00zw)$  with  $z + w \geq 1$ , then  $E(W, 00zw)$  is preferred over  $E(W, 1000)$ . The reason for this is that if in an optimal embedding of  $H$  we use  $E(W, 1000)$ , we can instead use  $E(W, 00zw)$  and keep everything else fixed to obtain a feasible embedding that must also be optimal.
- (c) If  $F(W, 0000) \leq F(W, 0011)$  then  $E(W, 0000)$  is preferred; if  $F(W, 0011) + 1 \leq F(W, 0000)$  then  $E(W, 0011)$  is preferred.
- (d) If  $F(W, 1100) + 2 \leq F(W, 0011)$  then  $E(W, 1100)$  is preferred; if  $F(W, 0011) \leq F(W, 1100)$  then  $E(W, 0011)$  is preferred, with a tie if  $F(W, 1100) + 1 = F(W, 0011)$ .
- (e) In a similar way, we compare  $E(W, 1100)$  with  $E(W, 00zw)$  where  $z + w = 1$ , with a tie if  $F(W, 1100) + 1 = F(W, 00zw)$ . We may even have a three way tie between  $E(W, 1100)$ ,  $E(W, 0010)$  and  $E(W, 0001)$ .

Now suppose we are able to select a best embedding  $E(W, x^*y^*z^*w^*)$ ; that is, there are no ties for best. Then we replace  $W$  with the appropriate graph in Table 1

TABLE 1  
Replacement graphs with no ties.

(0000)	
(1000)	
(1100)	
(0011)	
(0010)	
(0001)	

(where black vertices represent vertices of  $D$ ). Let  $\hat{H}$  be the new graph. It is easy to prove that  $F(\hat{H}, xyzw) + F(W, x^*y^*z^*w^*) = F(H, xyzw)$ . Thus, we solve the problem on  $\hat{H}$  first and then add the weight  $F(W, x^*y^*z^*w^*)$ .

By induction, we can replace any set of interior m.m.b.'s (with no ties for best embedding) whenever they have no common extremes. If, on the other hand, say  $W_1, \dots, W_k$  have a common extreme  $v \in D$ , then: (i) if the best embedding for each  $W_k$  prescribes that  $v$  not be covered, then leave  $v$  uncovered in each replacement graph, and (ii) if, in at least one  $W_j$ , the best embedding covers  $v$ , then use the same replacement for each  $W_i$ , except that  $v$  is removed from  $D$ .

A few complications arise if a particular interior m.m.b.  $W$  has ties for best embeddings. The list of all possible ties is given here:

$$(T1) \quad F(W, 0000) = F(W, 1100) + 1,$$

$$(T2) \quad F(W, 0011) = F(W, 1100) + 1,$$

$$(T3) \quad F(W, 1100) + 1 = F(W, 0010),$$

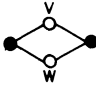

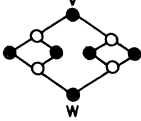

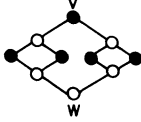

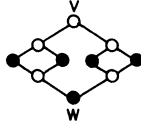

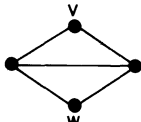

$$(T4) \quad F(W, 1100) + 1 = F(W, 0001),$$

$$(T5) \quad F(W, 1100) + 1 = F(W, 0010) = F(W, 0001),$$

$$(T6) \quad F(W, 0010) = F(W, 0001).$$

Table 2 contains the replacement graph to be used for each tie, together with the appropriate weight to be added after solving. It is not difficult to verify that these are all correct; here we will do so for the most complicated case (T2). Let  $\hat{H}$  be obtained from  $H$  by replacing  $W$  with the corresponding graph in case (T2). Now in any optimal embedding  $E(H, xyzw)$ , at least one internal face of the replacement graph will be

TABLE 2  
Replacement graphs with ties.

CASE	GRAPH	WEIGHT
T1		$F(W, 1100)$
T2		$F(W, 1100) - 1$
T3		$F(W, 1100) - 1$
T4		$F(W, 1100) - 1$
T5		$F(W, 1100)$
T6		$F(W, 0010)$

NOTICE THAT ALL WEIGHTS ARE NONNEGATIVE

used. It is easy to see that, without loss of generality, it is either the face containing  $v$  and  $w$  (but none of the other faces), or the two other faces (but not the one containing  $v$  and  $w$ ). Given our choice for the weight,  $F(W, 1100) - 1$ , this gives the correct result.

Thus, we can replace interior m.m.b.'s with small graphs, with the small caveat concerning extremes that are common to several m.m.b.'s as given before. Noninterior m.m.b.'s are dealt with similarly:

(i) Suppose we want to compute  $F(H, 0000)$ ; then we replace every m.m.b. using the above rules.

(ii) Suppose we are trying to compute  $F(H, 00zw)$  where  $z + w \geq 1$ ; say,  $F(H, 0010)$  (i.e.,  $u_1$  is not covered). Then we proceed exactly as in (i), except that now if an m.m.b.  $W$  contains  $u_1$  as an extreme, we use the best embedding for  $W$  of the form  $E(W, xy1w)$ , and all faces of the resulting graph  $\hat{H}$  that are incident on  $u_1$  are rejected. (There is a small wrinkle if there is an m.m.b.  $W_1$  with extremes  $u_1$  and  $v, v \in D$ , and such that  $v$  is an extreme of only one other m.m.b.,  $W_2$ . In this case we may have to force  $v$  to be covered by  $W_1$  or  $W_2$ . Since there are at most two vertices such as  $v$ , this yields only four or fewer problems.)

In cases (i) and (ii), we use Algorithm XTND in the resulting graph  $\hat{H}$  after the replacement. If XTND finds a cover of cardinality  $k$  or less, then we add the sum of the weights of the replacement graphs to the cardinality of a minimum cover of  $\hat{H}$ . If, on the other hand, XTND finds that  $\hat{H}$  has no covers of cardinality  $k$  or less, then

the corresponding embedding  $E(H, 0000)$  or  $E(H, 0010)$  should not be considered. (Similarly with  $F(H, 0001)$  and  $F(H, 0011)$ .)

(iii) The final case occurs for  $F(H, xyzw)$  where  $x + z \geq 1$ ; say, we want to compute  $F(H, 10zw)$ . We proceed in two stages. Let  $p_1$  and  $p_2$  be the two paths from  $u_1$  to  $u_2$  in the outer face of  $H'$ . Then we obtain  $\hat{H}$  as for computing  $F(H, 00zw)$ , and we remove from  $D$  all vertices in the segment of the outer face of  $\hat{H}$  corresponding to  $p_1$ . We then apply XTND to this graph, add the weights of the replacement graphs to the returned cardinality, and denote the obtained quantity by  $m(p_1)$ . Similarly compute  $m(p_2)$ . Then  $m(H, z, w) = \min(m(p_1), m(p_2))$  is the minimum number of faces needed to cover  $D \cap H$  (with the exception of  $u_1$  and  $u_2$  as indicated by  $z$  and  $w$ ) where we do not require that we cover one of the segments of the outer face.

Now if  $m(H, z, w) < F(H, 00zw)$ , then we are done; set  $m(H, z, w) = F(H, 10zw)$ . If  $m(H, z, w) = F(H, 00zw)$ , then we proceed to the second stage. Let  $W$  be an arbitrary m.m.b. whose corresponding edge in  $H'$  is contained in  $p$  or  $p'$ . Let  $\hat{H}(W)$  be the graph obtained from  $H$  by replacing  $W$  with the best embedding of the form  $E(W, 1y00)$ , and all other m.m.b.'s replaced with graphs as for cases (i) and (ii).

Notice that the replacement graph for  $W$  will contain a vertex of  $D$  in the outer face of  $\hat{H}(W)$  (see Table 1); call this vertex  $w'$ , and set  $f(W)$  to be the min cardinality of face cover of  $D \cap \hat{H}(W)$ , with all faces incident to  $w'$  rejected plus weight of replacement graphs. Then  $\min_w f(W)$  finds the best embedding of  $H$  that does not cover at least one vertex (which is not an extreme of an m.m.b.) in the outer face. In a similar way, we compute all quantities  $g(v)$ , where  $v \in D$  is extreme of an m.m.b. in the outer face of  $H'$  that we want not to cover. Then  $\min\{\min_w f(W), \min_v g(v)\}$  is the quantity  $F(H, 1000)$  we seek.

There is one shortcut that we can take to improve the algorithm above. Suppose there are at least  $k$  possible graphs  $W$  for which  $F(W, 1y00) \leq k$  that can be used to compute  $\min_w f(W)$ . Now, the fact that we have reached Stage 2 implies that  $F(H, 10zw) \geq F(H, 00zw)$ . However, any internal face of  $H$  can cover at most one of the vertices of  $D$  counted above; otherwise,  $H'$  would contain a cutset of two vertices in one of the segments  $p_1$  and  $p_2$ , which is impossible. Therefore,  $F(H, 00zw) > k$ , and we can avoid Stage 2 altogether. Similar considerations apply towards computing  $\min_v g(v)$ . Consequently, we can assume that each of the minimums in Stage 2 at most has  $O(k)$  arguments.

## FAST SIMULATION OF TURING MACHINES BY RANDOM ACCESS MACHINES\*

JYRKI KATAJAINEN<sup>†</sup>, JAN VAN LEEUWEN<sup>‡</sup> AND MARTTI PENTTONEN<sup>†</sup>

**Abstract.** We prove that a  $T(n)$  time-bounded,  $S(n)$  space-bounded and  $U(n)$  output-length-bounded Turing machine can be simulated in  $O(T(n) + (n + U(n)) \log \log S(n))$  time by a random access machine (with no multiplication or division instructions) under the logarithmic cost criterion.

**Key words.** Turing machine, random access machine, simulation, computational complexity

**1. Introduction.** In the theory of computation one uses both the Turing Machine (TM) and the Random Access Machine (RAM) as standard models of effective computing (see e.g., [1]). Whereas the models are vastly different in detail, it is well known that the machines are “equivalent” in computational strength. More precisely, one can show that the machines are polynomially related in the sense of computational complexity theory (see [1, § 1.7] or [2]): a TM can simulate a RAM in  $O(T(n)^2)$  time and a RAM can simulate a TM in  $O(T(n) \log T(n))$  time, where  $T(n)$  is the time complexity of the simulated machine and RAMs are assumed to use the so-called logarithmic cost criterion. In the result, RAMs are assumed without explicit “single” multiplication or division instructions in their instruction set. Slot and van Emde Boas [15] have shown that TMs and RAMs can simulate one another within only a constant factor of extra space.

When we speak of the simulation of one machine by another, we require that on the same input the latter machine produce the same output as the former one. In general, the simulating machine passes through an analogous computation, but it may also contain some auxiliary computations intermixed. These auxiliary steps are, of course, included in the complexity of the simulating machine.

Several studies have attempted to refine or lower the simulation costs between the two models, especially for the case of simulating RAMs by TMs (see e.g., Wiedermann [16] for some recent results). In this paper we consider the efficient simulation of TMs by RAMs. Let  $T(n)$  denote the time complexity,  $S(n)$  the space complexity and  $U(n)$  an upperbound on the length of the longest output on inputs of length  $n$ . The following results are known.

**THEOREM A** (Folklore, see e.g., [1, § 1.7]). *A TM can be simulated in  $O(T(n) \log S(n))$  time by a RAM (with no multiplication or division instructions) under the logarithmic cost criterion.*

**THEOREM B** (Paul [11, § 3.3]). *A TM can be simulated in  $O(T(n) + n \log n + U(n) \log T(n))$  time by a RAM (with no multiplication or division instructions) under the logarithmic cost criterion.*

Theorem B shows that TMs can be simulated by RAMs with no essential time-loss provided  $T(n) \geq n \cdot \log n$  and  $U(n) \leq T(n)/\log T(n)$ . Note, however, that [11, § 3.3] assumes stronger RAMs with shift instructions, that is (multiplication and) division by 2. Related results are also found in literature: Dymond and Tompa [4] proved that

<sup>‡</sup> Department of Computer Science, University of Utrecht, P.O. Box 80012, 3508 TA Utrecht, The Netherlands.

a TM can be simulated in time  $\sqrt{T(n)}$  by a parallel RAM. Hopcroft, Paul and Valiant [7] simulate a TM in time  $T(n)/\log T(n)$  by a unit-cost RAM. Robson [13] speeds up a TM computation by a probabilistic RAM.

In this paper we improve Theorem A to Theorem C as follows.

**THEOREM C.** *A TM can be simulated in  $O(T(n) \log \log S(n))$  time by a RAM (with no multiplication or division instructions) under the logarithmic cost criterion.*

We also can improve Theorem B to Theorem D as follows.

**THEOREM D.** *A TM can be simulated in  $O(T(n) + (n + U(n)) \log \log S(n))$  time by a RAM (with no multiplication, division or shift instructions) under the logarithmic cost criterion.*

This is, indeed, an improvement of Theorem B because in the case  $\log n < \log \log S(n)$ ,  $T(n)$  is the dominating term. This theorem improves also Theorem C, because  $T(n) \geq n$  and  $T(n) \geq U(n)$ . None of the results assume that  $T(n)$ ,  $S(n)$  or  $U(n)$  are constructible.

As an example of the use of Theorem C we mention the following corollary.

**COROLLARY E.** *Any linear time TM can be simulated in  $O(n \log \log n)$  logarithmic time by a RAM (with no multiplication or division instructions).*

It follows that e.g. the reversal of a string of  $n$  inputs can be output by a RAM in  $O(n \log \log n)$  units of logarithmic time. We can apply the above corollary also to the string-matching problem, where the task is to find all occurrences of a given pattern of length  $m$  from the text of length  $n$ ,  $m \leq n$ . The string-matching can be done in  $O(n)$  time on a TM as shown by Fischer and Paterson [5] (see also [6]), and therefore in  $O(n \log \log n)$  units of logarithmic time on a RAM.

In language acceptance the size of the output is constant. Hence, by Theorem D we also have

**COROLLARY F.** *Any language accepted by a  $T(n)$  time-bounded,  $S(n)$  space-bounded TM can be accepted in  $O(T(n) + n \log \log S(n))$  time on a RAM.*

The paper is organized as follows. In § 2 we recapitulate some basic definitions. In § 3 we prove Theorem C and Theorem D. Finally, in § 4 we discuss how these improvements were achieved and how the results could probably be improved further.

**2. Machine models.** We define TMs and RAMs such that they appear as instances of the same abstract model, following the guidelines of [14]. The machines have very similar input, output and control structures, but differ in the structure and the use of the memory. The definition of TMs and RAMs is included to fix the particular instruction sets.

**2.1. Turing machines.** We describe the “parts” of a Turing machine without much formal notation. We assume that the input, output and work-tape alphabet is  $\{0, 1\}$  and refer to the individual symbols as bits. A (multitape) TM consists of the following parts (compare [1, § 1.6]):

(i) *a one-way read-only input tape*, containing a bit string followed by an endmarker #.

(ii) *a one-way write-only output tape*, where a bit string will be written.

(iii) *k two-way read-write work-tapes* (“memory”), containing bits in successive memory cells. The tapes are two-way infinite. On each tape there is a separate read-write head that can be activated for reading, writing or moving one tape-cell to the left or to the right.

(iv) *a TM program*, which is a finite sequence of labelled or unlabelled instructions from a fixed instruction set (see below). No two instructions should carry the same label.

The instruction set of a TM contains eight instruction types:

(1) **input**  $\lambda_0, \lambda_1, \lambda_{\#}$ : causes a “next” input symbol  $\alpha$  to be read, and the input head moves one cell to the right (except on  $\#$ ). Depending on whether  $\alpha$  is 0, 1 or  $\#$ , control is transferred to the instruction with label  $\lambda_0, \lambda_1, \lambda_{\#}$ .

(2) **output**  $\beta$ : causes a bit  $\beta$  to be output, and the output head moves one cell to the right.

(3) **jump**  $\lambda$ : transfers control to the instruction with label  $\lambda$ .

(4) **halt**: halts the program.

(5) **head**  $i$ : activates the read-write head on the  $i$ th work-tape ( $1 \leq i \leq k$ ). Only one read-write head will be active at a time.

(6) **write**  $\beta$ : causes a bit  $\beta$  to be written in the tape-cell designated by the active read-write head.

(7) **branch**  $\lambda_0, \lambda_1$ : causes the bit  $\beta$  to be read from the tape-cell designated by the active head. Depending on whether  $\beta$  is 0 or 1 control is transferred to the instruction with label  $\lambda_0$  or  $\lambda_1$ .

(8) **move**  $\delta$  (with  $\delta \in \{L, R\}$ ): moves the active read-write head one cell to the left or to the right depending on whether  $\delta$  is  $L$  or  $R$ .

We assume that initially all work-tapes contain 0 in every cell, and that head 1 is active. The computation starts from the first instruction and thereafter the instructions of a program are executed in their successive order unless a jump instruction orders otherwise.

The *time complexity*  $T(n)$  of a TM is the largest number of instructions executed in halting computations on inputs of length  $n$ . The *space complexity*  $S(n)$  is the largest number of cells occupied on any work-tape in halting computations on inputs of length  $n$ . The *output complexity*  $U(n)$  is the length of the longest output produced in halting computations on inputs of length  $n$ .

Because a TM with a two-way infinite tape can be simulated by a TM with a one-way infinite tape in real time (see e.g., [8, § 7.5]), we shall assume that the work-tapes of a TM are one-way infinite, say infinite to the right. Initially all read-write heads are positioned on the leftmost cell of their work-tape. By the standard construction used in the above simulation [8, § 7.5], we can further assume that a read-write head is never moved off the left end of the work-tape. (Thus the computation is stopped by a halt instruction, not by the fall of a read-write head.) Although in the construction the tape alphabet is enlarged, it is straightforward to return into the binary alphabet (see also [8, § 7.8]).

**2.2. Random access machines.** In describing the random access machine, we only emphasize the parts that are different from those of a TM. Parts (i) and (ii) are very similar for a RAM but instead of (iii) one has the following set-up (compare [1, § 1.2]):

(iii') a special register called the *accumulator* (AC) and a countable sequence of ordinary *registers* (“memory”) indexed by the nonnegative integers (used as addresses). Each register can hold an arbitrary nonnegative integer in binary notation. Only data stored in the AC can be operated upon.

A RAM *program* is defined as in (iv), but the instruction set of a RAM differs from the instruction set of a TM. In instructions, the contents of register  $j$  are denoted by  $\langle j \rangle$ . The instruction set of a RAM contains twelve instruction types:

(1')–(4'): similar to the instructions (1)–(4) of a TM.

(5') **jzero**  $\lambda$ : transfers control to the instruction with label  $\lambda$  if  $\langle \text{AC} \rangle = 0$ , and continues to next instruction otherwise.

(6') **load**  $= j$ : loads the integer  $j$  into AC.

(7') **load**  $j$ : loads  $\langle j \rangle$  into AC.

- (8') **load** \* $j$ : loads  $\langle\langle j \rangle\rangle$  into AC (“indirect addressing”).
- (9') **store**  $j$ : stores  $\langle AC \rangle$  into register  $j$ .
- (10') **store** \* $j$ : stores  $\langle AC \rangle$  into register  $\langle j \rangle$ .
- (11') **add**  $j$ : adds  $\langle j \rangle$  to the current value in AC.
- (12') **sub**  $j$ : subtracts  $\langle j \rangle$  from the current value in AC. In order to keep the contents of the AC nonnegative, we assume that subtraction is proper, i.e., the result is 0 whenever  $\langle AC \rangle \leq \langle j \rangle$ .

We assume that all registers, including the AC, initially contain 0. Memory need not be used contiguously.

We do not simply count the number of instructions executed in a RAM program but use the so-called *logarithmic cost criterion*: the “time” charged for an instruction is equal to the sum of the sizes (in bits) of the integers (addresses and data) involved in its execution. Note that the size of a positive integer  $m$  is  $\lceil \log(m+1) \rceil \sim \log m$ , and the size of zero is 1. The *time complexity*  $T(n)$  of a RAM is the largest amount of time, measured according to the logarithmic cost criterion, used in halting computations on inputs of length  $n$ . See Slot and van Emde Boas [15] for notions of space complexity for RAMs.

It will be convenient to use various extensions to the basic RAM instruction set, provided that the execution time is adequately measured by the logarithmic cost criterion. By using subtractions and a trick introduced in [13, pp. 495–496], one can easily show that this is the case for comparison instructions. It should be noted, however, that the properness of the subtraction operation is not needed anywhere in the subsequent proofs because we always know which of the two operands is greater. Also in some algorithms it is convenient to have a RAM with  $k$  separate *memories* (or *arrays* as called by Cook and Reckhow [2]),  $k > 1$ , each consisting of a countable sequence of registers indexed  $0, 1, 2, \dots$ . We call this a “multimemory” RAM.

LEMMA 2.2.1. *Every  $T(n)$  time-bounded multimemory RAM can be simulated in  $O(T(n))$  time by an ordinary RAM.*

*Proof.* The technique was essentially given in [2]. The idea is simply to interleave the RAM memories into one, using addresses  $i + kj - 1$  for register  $j$  of the  $i$ th memory ( $1 \leq i \leq k, j \geq 0$ ). Those addresses can be computed in  $O(k \log j)$  time, which multiplies the time bound by a constant factor.  $\square$

It is important to state explicitly the basic instruction set of the RAM. However, for the sake of the readability, we extend it with some Pascal-like control structures that have obvious translations to the basic RAM instructions.

**3. The simulation of a TM by a RAM.** Consider a  $T(n)$  time-bounded,  $S(n)$  space-bounded TM. The simple idea underlying Theorem A is to represent the cells of the work-tapes in consecutive registers of a RAM, with additional registers containing current read-write head positions. Every step of the TM is easily simulated in  $O(\log S(n))$  time on a RAM, assuming the logarithmic cost criterion. In the simulation underlying Theorem B, a saving in the cost per step is achieved by precomputing in a table the action of the TM on all blocks of a suitable size. A subcomputation corresponding to the size of the block reduces to a table look-up.

We will also use blocking to balance the costs of the address and the contents of a memory location. At first we keep the idea of step-wise simulation. We use blocking merely to localize the active region of the work-tape during a time-interval. For step-wise simulation, the active block is swapped to a low-indexed region of the memory in order to save in the access time under logarithmic cost criterion. (It is interesting to compare this technique to the swapping of pages to and from disk in paged virtual

memory operating systems, see e.g., Deitel [3]. Another analogy is a hardware cache. The cache idea was also used by Loui in [9].)

A serious problem is determining the optimal block size together with efficient algorithms for unpacking and packing blocks. A further problem is that  $T(n)$  and  $S(n)$  need not be constructible. For simplicity, we denote these values by  $T$  and  $S$ . In § 3.1 we assume that  $n$  and  $S(n)$  are known at the beginning of the computation, and determine the optimal block size in this case. In § 3.2 we remove this assumption and notice that the same time bound holds even though the block size is determined dynamically during the computation. Ultimately, in § 3.3 we improve the table look-up method of [11]. Interestingly, the packing and unpacking techniques developed in §§ 3.1 and 3.2 will now be useful in reading input blocks and writing output blocks.

**3.1. The static step-wise simulation using blocked memory.** We assume now that  $n$  and  $S(n)$  are known in advance. We will begin the basic simulation algorithm together with the necessary blocking and deblocking algorithms. By the time analysis of this algorithm we determine the optimal block size. For simplicity, we speak of one TM tape only; if there are many work-tapes, they are treated analogously, independently.

The basic idea of the simulation is to divide the tape into  $S/b$  blocks of  $b$  cells. Hence,  $b$  successive cells of the TM are represented by a number (in the range  $0, \dots, 2^b - 1$ ) in a register of the RAM. By Lemma 2.2.1 we can assume that the RAM keeps the “blocked” representation of the work-tape in a separate memory. The position of the tape head of the TM is indicated by an address to the active block (a number in the range  $1, \dots, S/b$ ) together with an address within a block ( $0, \dots, b - 1$ ), both stored in fixed RAM registers. One simulation cycle, corresponding to  $b$  steps of the TM, consists of accessing the active block with two neighbours, unpacking them to low-indexed registers, directly simulating the next  $b$  steps of the TM, and packing the updated bits back to the same registers. The neighbouring blocks are taken along in order to guarantee that in all cases  $b$  simulation steps can be taken staying in the unpacked zone. This unpacked  $3b$  bit zone, kept in a separate memory, is called the *window*.

The simulation of the single TM instructions is quite obvious; it is done as in the proof of Theorem A. It is easy to construct a procedure simulating an instruction of the TM, updating the contents of the window, the head address and the current instruction label. Now we can represent the simulation in the form of a RAM program as follows:

```

procedure simulate
  {Suppose that the block size  $b$  is given.}
  activeblock := 1
  {the first block is active, with empty left neighbour}
  head := the first address of the middle block of the window
  loop {until a halt instruction in the simulation}
    loadwindow(activeblock,  $b$ )
    for  $b$  times do simulate an instruction
    storewindow(activeblock,  $b$ )
    if head moved to neighbour then
      update head and activeblock addresses

```

The procedure `loadwindow` fetches the contents of the active block and its neighbours into low-indexed registers, and unpacks the  $b$ -bit integers. The procedure `storewindow` packs the window blocks, and stores them by overwriting their older copies.

We shall now attack the problem of packing and unpacking the blocks efficiently. As our RAM model does not include division or shift instructions, we have to invent another method for finding the bit representation of a number and vice versa. We will see that unpacking and packing can be done efficiently with precomputed tables.

As a first attempt one could decode numbers to bit-strings by building a table that gives the decoding directly. For example the table could contain the  $b$  bits of a number  $n (<2^b)$  in the registers  $nb, nb + 1, \dots, nb + b - 1$ . A disadvantage of this method is that, while bits are obtained directly, the access of them may cost  $O(\log n)$ . For this reason loading a window takes  $O(b^2)$  time. By a similar analysis as what follows, one can see that this would give  $O(T\sqrt{\log S})$  simulation algorithm. However, we can do unpacking and packing in  $O(b \log b)$  time.

The efficient decoding of a number to its bit representation and vice versa is based on a divide-and-conquer strategy with precomputed shift tables. We will first build the necessary tables and then give the unpacking and packing algorithms.

We assume that each table is stored in its own memory. We will need tables *lshift*, *rshift*, *origin* and *power*. By *lshift(i)*, *rshift(i)*,  $\dots$ , we denote the contents of the register  $i$  reserved for *lshift*, *rshift*,  $\dots$ .

The tables *lshift* and *rshift* in Fig. 1 contain as subtables shift tables for 1-bit numbers, 2-bit numbers, 4-bit numbers etc. The divide-and-conquer strategy implies that  $b$ -bit numbers are shifted  $b/2$  bits to the right or  $b$  bits to the left. The entries of the tables are numbers rather than bit strings. Thus, for example, the number  $75 = 01001011_2$  has the right shift  $4 = 0100_2$  and  $4 = 0100_2$  has the left shift  $64 = 01000000_2$ . The origin table expresses where subtables begin: The shift tables for  $2^i$ -bit numbers begin at *origin(i)*.

<i>origin</i> :	register	0	1	2	3	4	$\dots$	$i$						
	contents	0	2	6	22	278	$\dots$	$2^{2^0} + 2^{2^1} + \dots + 2^{2^{i-1}}$						
<i>rshift</i> :	register	0	1	2	3	4	5	6	7	8	$\dots$	21	$\dots$	<i>origin(i) + j</i>
	block size	1 bit	2 bits				4 bits				$\dots$	$2^i$ bits		
	block value	0	1	0	1	2	3	0	1	2	$\dots$	15	$\dots$	$j$
	contents	0	0	0	0	1	1	0	0	0	$\dots$	3	$\dots$	$j \text{ div } 2^{2^{i-1}}$
<i>lshift</i> :	register	0	1	2	3	4	5	6	7	8	$\dots$	21	$\dots$	<i>origin(i) + j</i>
	block size	1 bit	2 bits				4 bits				$\dots$	$2^i$ bits		
	block value	0	1	0	1	2	3	0	1	2	$\dots$	15	$\dots$	$j$
	contents	0	2	0	4	8	12	0	16	32	$\dots$	240	$\dots$	$j \cdot 2^{2^i}$

FIG. 1. The origin, rshift and lshift tables.

We have to first analyze how much the building of the tables costs.

LEMMA 3.1.1. *The tables origin, rshift and lshift up to block size  $b (=2^k)$  can be built in logarithmic time  $O(b2^b)$ .*

*Proof.* Assuming that the values *origin(i-2)* and *origin(i-1)* are already computed, the following program will compute the  $i$ th origin value,  $i \geq 2$ .

```

procedure buildorigin( $i$ )
 $t := \text{origin}(i-1) - \text{origin}(i-2)$   { $t := 2^{2^{i-2}}$ }
 $\text{origin}(i) := \text{origin}(i-1)$ 
for  $t$  times do  $\text{origin}(i) := \text{origin}(i) + t$ 
    
```

Clearly, its time complexity is  $O(2^{2^{i-2}} \cdot 2^{i-1})$ .

When constructing the  $i$ th  $rshift$  and  $lshift$  subtables we can use the origin values for  $i-1$ ,  $i$  and  $i+1$ .

```

procedure build $rshift$ ( $i$ )
 $j := origin(i)$ ;  $x := 0$ ;  $t := origin(i) - origin(i-1)$   { $t := 2^{2^{i-1}}$ }
for  $t$  times do
  for  $t$  times do  $rshift(j) := x$ ;  $j := j + 1$ 
   $x := x + 1$ 

procedure build $lshift$ ( $i$ )
 $j := origin(i)$ ;  $x := 0$ ;  $t := origin(i+1) - origin(i)$   { $t := 2^{2^i}$ }
for  $t$  times do  $lshift(j) := x$ ;  $j := j + 1$ ;  $x := x + t$ 

```

The execution of both procedures requires  $O(2^{2^i} \cdot 2^i)$  time. Thus the tables up to  $k$  can be constructed in time  $O(\sum_{i=1}^k 2^{2^i} \cdot 2^i) = O(2^k \cdot 2^{2^k}) = O(b2^b)$ .  $\square$

We also need powers of 2 for unpacking numbers to bit strings, and for packing bit strings to numbers. It is useful to precompute them, too, in the table *power*.

LEMMA 3.1.2. *The table  $power(i) = 2^i$  up to  $k$ th power can be built in  $O(k^2)$  logarithmic time.*

*Proof.* A new power can be computed by doubling the previous one by addition. This method gives the time bound  $O(k^2)$ .  $\square$

Now we are ready to present the unpacking and packing algorithms.

LEMMA 3.1.3. *Assuming that the tables  $lshift$ ,  $rshift$ ,  $origin$  and  $power$  up to the block size  $b$  are available, it is possible to compute the  $b$ -bit representation of an integer  $n < 2^b$ , and the numeric value of a  $b$ -bit string, both in  $O(b \cdot \log b)$  time.*

*Proof.* The procedure  $unpack(n, j, a)$  unpacks a number  $n < 2^{2^j}$  to its  $2^j$ -bit representation beginning at the  $a$ th register of the window. The procedure is as follows:

```

procedure  $unpack(n, j, a)$ 
if  $j = 0$  then  $window(a) := n$ 
else  $n_1 := rshift(origin(j) + n)$ ;  $n_2 := n - lshift(origin(j-1) + n_1)$ 
   $unpack(n_1, j-1, a)$ ;  $unpack(n_2, j-1, a + power(j-1))$ 

```

For clarity, we have written the algorithm in recursive form. The recursion can be eliminated by using one memory as a stack where the second recursive call is stored while the first is executed. While unpacking a number  $n < 2^j$  there are never more than  $\log j$  calls in the stack. In order to balance access cost it is economical to initiate the stack at the address  $\log b$  and let it grow downwards. If we denote by  $t(x)$  the logarithmic time of unpacking an  $x$ -bit number, by analyzing the program we get

$$t(1) = k_1 \log b,$$

$$t(x) = 2t(x/2) + k_2x + k_3 \log b$$

which gives  $t(b) = O(b \cdot \log b)$ .

The procedure  $pack(a, j, n)$  computes the numeric value of the bit string  $window(a)$ ,  $window(a+1)$ ,  $\dots$ ,  $window(a+2^j-1)$ . Also it is written recursively:

```

procedure  $pack(a, j, n)$ 
if  $j = 0$  then  $n := window(a)$ 
else  $pack(a, j-1, n_1)$ ;  $pack(a + power(j-1), j-1, n_2)$ 
   $n := lshift(origin(j-1) + n_1) + n_2$ 

```

The recursion is controlled as in unpacking. Also the time analysis is analogous.  $\square$

We can now obtain a preliminary version of Theorem C:

THEOREM 3.1.4. *Assuming that  $n$  and  $S(n)$  are known, a  $T(n)$  time-bounded,  $S(n)$  space-bounded TM can be simulated in  $O(T(n) \log \log S(n))$  logarithmic time by a RAM.*

*Proof.* The total time of the static simulation is bounded by

$$T_{\text{RAM}} = b2^b + T/b(\log S + b \cdot \log b + b \cdot \log b + b \cdot \log b + \log S)$$

where  $b2^b$  is needed for the construction of the tables,  $T/b$  is the number of cycles in the simulation loop,  $\log S$  is the cost of loading and storing the blocks,  $b \cdot \log b$  is the cost of unpacking and packing the blocks of the window, and another  $b \cdot \log b$  is needed for the elementary simulation steps. By choosing  $b = c \cdot \log S$ ,  $c < 1$ , we get  $T_{\text{RAM}} = O(T \cdot \log \log S)$ .  $\square$

**3.2. The dynamization.** Until now we have assumed that the space requirement  $S$  of the TM on an input is known in advance, which is not the case. Now we shall remove this assumption by using the well-known technique (see, e.g., [10]) which consists of using one space bound while sufficient and increasing it when necessary. As long as the space bound

$$S_0, S_1, \dots, S_i = 2^{2^{i+1}}, \dots$$

is sufficient, the block size  $b_0, b_1, \dots, b_i = 2^i, \dots$ , is used respectively. Every time a space bound is exceeded, the simulating memory must be reorganized by combining the blocks pairwise. As the size of the blocks grows also the tables must be grown accordingly. It is worth noting that, unlike in [11], input head need not be reset and the computation be restarted from the beginning when the block's size is increased.

The dynamic simulating algorithm gets the following form.

**procedure** simulate

activeblock := 1

head := the first address of the middle block of the window

$b := 1$ ;  $S := 4$

Initialize tables  $l$ shift,  $r$ shift, origin and power;

**loop** {until a **halt** instruction in the simulation}

**while**  $\lceil \log(S+1) \rceil \leq 4b$  **do**

    loadwindow(activeblock,  $b$ )

**for**  $b$  times **do**

      Simulate an instruction

**if** head on a previously unvisited cell **then**  $S := S + 1$

    storewindow(activeblock,  $b$ )

**if** head moved to neighbour **then**

      update head and activeblock addresses

$b := b + b$

  Combine successive blocks pairwise

  Update head and activeblock corresponding to the reorganization

  Update  $l$ shift,  $r$ shift, origin and power to the new block size

The analysis of the dynamic simulation is basically the same as in the previous section, but now there is the extra work of reorganizing the memory. In spite of using wrong block sizes at the beginning, the program still behaves asymptotically fast. Before going to the time analysis of the program, we prove a small counting lemma, also used in [2], [12].

**LEMMA 3.2.1.** *A binary counter of any event occurring  $t$  times during the computation can be maintained in  $O(t)$  time. As a by-product we get easily the length of the binary representation of the count, which is  $\lceil \log(t+1) \rceil$ .*

*Proof.* A memory is reserved for the binary representation of the count. For each bit of the count (without leading zeros), two bits are used. The  $i$ th least significant bit 0 or 1 is represented by  $00_2$  or  $01_2$  in the register  $i$ . If the actual value of the count is  $t$ ,  $2^{j-1} \leq t \leq 2^j$ , then  $11_2$  in the register  $j$  marks the end of the representation.

Each counting step is simulated by a sweep over the representation in the memory, beginning at the register 0.  $01$ 's are replaced by  $00$ 's, until  $00$  is met which becomes  $01$ . However, if  $11$  is met instead of  $00$ , it is replaced by  $01$  and  $11$  is stored in the next register. At any moment, the address of  $11$  corresponds to the logarithm of the count, and the registers below it correspond to the bit representation of the count.

The linear time bound is seen as follows. During a count up to  $t = 2^j$ , the length of the sweep is  $t/2$  times 1,  $t/4$  times 2,  $t/8$  times 3 and so forth. Hence the total logarithmic time is proportional to

$$2^{j-1} \cdot 1 \cdot \log 1 + \dots + 2^{j-i} \cdot i \cdot \log i + \dots + 1 \cdot j \cdot \log j = O(t)$$

as can be seen by the quotient test applied to the infinite series  $2^{-1} \cdot 1 \cdot \log 1 + \dots + 2^{-i} \cdot i \cdot \log i + \dots$ .  $\square$

The complexity analysis of the dynamic simulation is basically the same as in the previous subsection, but we have to take into account the following differences. A counter must be maintained in order to determine when block size must be increased. Whenever the block size is increased, the simulating memory must be reorganized by combining blocks pairwise. This is extra work, following from the fact that nonoptimal block size was used. Fortunately, the amount of extra work caused by reblockings and nonoptimal block size proves to be insignificant.

By Lemma 3.2.1, no more than  $O(S)$  time is used in the computation of  $S$ . The time needed for the comparison  $\lceil \log(S+1) \rceil \leq 4b$  is  $O(\log b)$  which is covered by the  $O(b \cdot \log b)$  used in the simulation. Whenever the test fails,  $b$  is doubled and tables are updated. Note that by Lemmas 3.1.1 and 3.1.2 the total time needed in the construction of the tables is  $O(b2^b) = O(S)$ , because  $2b \leq \log S < 4b$ . Each doubling of  $b$  is followed by reblocking. This is most easily done by the  $l$ shift table in  $O((S_i/b_i) \cdot b_i)$  time. The superexponential growth of the series  $\{S_i\}$  implies that all reblockings can be done in time  $O(S)$ .

For the final analysis of the simulation, assume that  $T_i$  steps of the TM are simulated using block size  $b_i$ . Hence the total time of the simulation is bounded by

$$\begin{aligned} \sum_{i=0}^{\log \log S} (T_i/b_i)(\log(S_i) + b_i \log b_i) &= \sum_{i=0}^{\log \log S} T_i \log b_i \\ &\leq \log b \sum_{i=0}^{\log \log S} T_i = T \cdot \log b = T \cdot \log \log S. \end{aligned}$$

Hence, the time bound  $O(T \cdot \log \log S)$  holds also for the dynamic simulation. We have proved

**THEOREM 3.2.1.** *A  $T(n)$  time-bounded and  $S(n)$  space-bounded TM can be simulated in  $O(T(n) \log \log S(n))$  time on a RAM without multiplication and division instructions.*

**3.3. Simulation with precomputed transition tables.** A further improvement in the simulation is achieved by combining the fast packing and unpacking algorithms of § 3.1 with the use of precomputed transition tables as in [7], [11].

As in § 3.1, we shall first assume that the optimal block size is known at the beginning of the simulation. The computation is speeded up by precomputing in a table all subcomputations of length  $b$ . For this purpose, the work-tape is divided into

blocks of size  $b$ , as in previous constructions. Now, input and output must also be handled blockwise, because a subcomputation of length  $b$  may read  $b$  bits and write  $b$  bits.

In the new construction, the simulation itself is simply table look-up and takes, as we will see, only  $O(T(n))$  logarithmic time. Paul [11] organizes the table as a heap (like in heapsort) and uses shift operations in the calculation of the pointers. We store the table as a multidimensional array and calculate the addresses by precomputed shift tables, avoiding the use of shift operations. For input and output blocking, the packing and unpacking techniques of § 3.1 are used. We shall see that, if  $U(n)$  is the maximum output length for inputs of length  $n$ ,  $O((n + U(n)) \log \log S(n))$  is sufficient for input and output, when it is done to and from low addresses, not higher than  $O(\log S(n))$ . Hence, the total time of the simulation is  $O(T(n) + (n + U(n)) \log \log S(n))$ .

In order to guarantee that large enough input blocks are always available, and there is not too frequent need for filling the blocks, we will use an input buffer of length  $2b$ . It is filled every time when more than half of the bits have been consumed. The same idea is useful for outputting.

We shall precompute the transition table

$$\text{transit}(i, x, l, p, v_{-1}, v_0, v_1, j, y) = (i', l', p', v'_{-1}, v'_0, v'_1, d, j', y')$$

where all entries are integers:  $i, j, p, p' < b$ ;  $i', j' < 2b$ ;  $x, y, y' < 2^{2b}$ ;  $l, l'$  are program line numbers;  $v_k, v'_k < 2^b$ ; and  $d = -1, 0, 1$ . The intuitive meaning of the table is the following: If  $i$  bits of the contents  $x$  of the input buffer have been consumed before, the TM is at its instruction  $l$ , the work-tape head is at the position  $p$  of the block  $v_0$  whose neighbours are  $v_{-1}$  and  $v_1$ , and there are already  $j$  bits of  $y$  in the output buffer, then after  $b$  elementary steps of the TM,  $i' (< 2b)$  bits of  $x$  have been consumed, TM is at line  $l'$ , the work-tape blocks have changed to  $v'_k$  and the head is at the position  $p'$  of  $v'_d$ , and there are  $j'$  bits of  $y'$  in the output buffer. With this notation, we can write the *static* simulating algorithm as follows:

**procedure** simulate

$i := 2b - 1$ ;  $j := 0$  {input and output buffers are empty}

$l := 1$ ; activeblock := 1;  $p := 0$ ;

**loop** {until the simulation of a **halt** causes an exit}

**if**  $i \geq b$  **then** fill input buffer to a new  $x$  with  $i = 0$ ;

**for**  $k = -1, 0, 1$  **do**  $v_k := \text{work-tape}(\text{activeblock} + k)$

$(i, l, p, v_{-1}, v_0, v_1, d, j, y) := \text{transit}(i, x, l, p, v_{-1}, v_0, v_1, j, y)$

**for**  $k = -1, 0, 1$  **do**  $\text{work-tape}(\text{activeblock} + k) := v_k$

  activeblock := activeblock +  $d$

**if**  $j \geq b$  **then** output the  $j$  bits of  $y$  and make  $j := 0$ ;

Some points of the program need closer examination.

First, as  $b$  successive steps of the TM are composed, the main loop is iterated  $T/b$  times.

If  $i \geq b$ , the input buffer is filled as follows. First the  $2b$  bits of  $x$  are unpacked by Lemma 3.1.3 in time  $O(b \cdot \log b)$ . Then the unused  $2b - i$  bits are moved to positions  $0, 1, \dots$ , followed by  $i$  new bits read from the input tape. This is easily done in  $O(b \cdot \log b)$  time. Output is treated analogously.

Loading and storing work-tape blocks obviously takes  $O(\log S)$  time. The transition table can easily be linearized to  $2^{kb}$  registers, where  $k$  is a constant. By the shift tables similar to those in § 3.1, additions and subtractions, the address of a table entry can be computed, and the value can be decoded in  $O(b)$  time.

We observe that input and output take  $O(\log b)$  time for each bit, and hence  $O((n + U(n)) \log b)$  time in total. The cost of the simulation is of order  $(T/b)(\log S + b)$ . Hence, by choosing  $b = O(\log S)$ , we see that  $O((n + U(n)) \log \log S(n) + T(n))$  time is sufficient for simulation.

Finally, we shall show that the table can be built in  $O(S)$  time. It can be done in the obvious way: For each table entry, simulate  $b$  steps of the TM and store the result in a register. The generation of the entries is controlled by nine nested loops, one for each argument of the table. To compute the value of each table entry, it is first unpacked to low-indexed registers in time  $O(b \cdot \log b)$ , then  $b$  steps of the TM are simulated in time  $O(b \cdot \log b)$ , and finally the result is packed in time  $O(b \cdot \log b)$  and stored in time  $O(b)$ . Hence, the construction of the table takes  $O(2^{kb} \cdot b \cdot \log b)$  time, which is  $O(S)$ , if  $b = c \cdot \log S$  with a constant  $c < 1/k$  is chosen.

Thus, we have proved Theorem D in the static case. As in § 3.2, the efficiency of the static construction can be achieved even though the optimal block size is not known in advance. We let the block size grow in the series  $b_0, b_1, \dots, b_i = 2^i, \dots$ , when the space requirement reaches the bounds

$$S_0, S_1, \dots, S_i = 2^{2^{i+a}}, \dots,$$

respectively. In  $S_i$ , the constant  $a$  is chosen such that  $k < 2^a$ . The *dynamic* simulating program is as follows.

**procedure** simulate

$i := 2b - 1; j := 0$

$l := 1; \text{activeblock} := 1; p := 0;$

$b := 1; S := 2^{2^a}$  { $a$  is a small constant}

Initialize  $l\text{shift}$ ,  $r\text{shift}$ , origin, power and transit tables;

**loop** {until a **halt** in the simulation}

**while**  $\lceil \log(S + 1) \rceil \leq 2^{a+1} b$  **do**

**if**  $i \geq b$  **then** fill input buffer;

**for**  $k = -1, 0, 1$  **do**  $v_k := \text{work-tape}(\text{activeblock} + k)$

$(i, l, p, v_{-1}, v_0, v_1, d, j, y) := \text{transit}(i, x, l, p, v_{-1}, v_0, v_1, j, y)$

    Increase  $S$  when necessary;

**for**  $k = -1, 0, 1$  **do**  $\text{work-tape}(\text{activeblock} + k) := v_k$

$\text{activeblock} := \text{activeblock} + d$

**if**  $j \geq b$  **then** flush the output buffer;

$b := b + b;$

  Combine successive memory blocks pairwise;

  Update  $p$  and activeblock corresponding to the reorganization;

  Update  $l\text{shift}$ ,  $r\text{shift}$ , origin and power;

  Construct transit for the block size  $b$ ;

There is very little new in the analysis of the program. During the whole simulation,  $O(S)$  time is used in the construction of the tables  $l\text{shift}$ ,  $r\text{shift}$ , origin and power. Every time when a new transit table is constructed,  $O(S_i)$  time is spent, hence  $\sum S_i = O(S)$  in total.

As the block size never exceeds  $O(\log S)$ , input and output packing, as well as unpacking, can be done in  $O(\log \log S)$  time per bit,  $O((n + U(n)) \log \log S(n))$  time in total. As the simulation for each block size is linear, the total simulation is linear, too.

Hence, we have proved

**THEOREM 3.3.1.** *Any  $T(n)$  time-bounded,  $S(n)$  space-bounded and  $U(n)$  output length-bounded TM can be simulated in  $O(T(n) + (n + U(n)) \log \log S(n))$  logarithmic time by a RAM.*

**4. Discussion.** We have improved the simulations of TMs by RAMs that can be found in [1] and [11]. We first improved the strategy of [1] by introducing blocking, a well-known technique used for speed-ups. Essential in our constructions was how to pack and unpack blocks efficiently. We did it with a precomputed table. The same tabulation technique was also used to improve the method of [11]. First, it allowed a natural look-up method, and second, with it input and output could be done more efficiently.

It is interesting to observe that in the simulation of Theorem D, faster input and output would improve the time bound. With a better input/output pattern the simulation could perhaps be sped up further. Whether such an improvement is possible remains as an open problem.

**Acknowledgments.** We are grateful to the referee for remarks and references that have improved the representation.

## DESIGNING A UNIFORM RANDOM NUMBER GENERATOR WHOSE SUBSEQUENCES ARE $k$ -DISTRIBUTED\*

MASANORI FUSHIMI†

**Abstract.** A method for designing a uniform random number generator based on  $M$ -sequence is described. It generates a  $k$ -distributed sequence  $\{x_t; t=0, 1, 2, \dots\}$  such that its decimated sequences  $\{x_{nt}; t=0, 1, 2, \dots\}$  are also  $k$ -distributed for several values of  $n$ . The sequence is obtained by permuting the bits in Tausworthe sequence; a suitable permutation is found by solving a special 0-1 integer linear programme, a set covering problem. The constraint matrix of the programme is obtained by applying a modified Gaussian elimination to another 0-1 matrix. Two simple heuristic algorithms for the programme are given and demonstrated to find good approximate solutions to an illustrative example.

**Key words.** Tausworthe sequence, decimated sequence,  $k$ -distribution, set covering problem, heuristic algorithm

**AMS (MOS) subject classification.** 65C10, 12C10, 15A03, 90C50

**1. Introduction.** When one uses a sequence  $\{x_t; t=0, 1, 2, \dots\}$  of uniform random numbers, it often happens that numbers are used in batches. For example, in a simulation dealing with three random variables  $X$ ,  $Y$  and  $Z$ , three numbers in the sequence  $\{x_t\}$  may be used at each step in the simulation. In such applications it is important that not only the original sequence  $\{x_t\}$  but also the subsequences consisting of every third term of  $\{x_t\}$  are random. In general, if the simulation requires  $n$  random numbers at a time, the  $n$  subsequences  $\{x_{nt+i}; t=0, 1, 2, \dots\}$ ,  $0 \leq i \leq n-1$ , must be random. Since a random number generator may be used for various applications, it is desirable that the above property hold for various values of  $n$ .

Knuth [9, p. 71] says "experience with linear congruential sequences has shown that these derived sequences rarely if ever behave less randomly than the original sequence, unless  $n$  has a large factor in common with the period length," although there is no theoretical proof that this is always the case. Then how about other uniform number generators? What we shall be concerned with in this paper is the design of uniform random number generators with the above property based on the maximal-length linearly recurring sequence modulo 2 ( $M$ -sequence for short). In § 2, we will review some uniform random number generators based on  $M$ -sequences. Section 3 will show that our problem can be formulated as a special form of 0-1 integer linear programme, in fact, a set covering problem, for which approximate solutions can be obtained quite easily by simple algorithms. We will show in § 4 two such algorithms as well as the fact that the constraint matrix of the programme can be obtained by using a modified Gaussian elimination method. The final section will illustrate our procedure by an example which leads to a uniform random number generator useful for practical applications.

**2. Uniform random number generators based on  $M$ -sequence.** An  $M$ -sequence is a sequence of 0's and 1's generated by a linear recurrence relation

$$(2.1) \quad a_t = c_1 a_{t-1} + c_2 a_{t-2} + \dots + c_p a_{t-p} \pmod{2}$$

whose characteristic polynomial

$$f(D) = 1 + c_1 D + c_2 D^2 + \dots + c_p D^p, \quad c_p = 1,$$

† Department of Mathematical Engineering and Instrumentation Physics, Faculty of Engineering, University of Tokyo, Bunkyo-ku, Tokyo 113, Japan.

is primitive over the Galois field  $GF(2)$ , given any initial values  $(a_1, a_2, \dots, a_p) \neq (0, 0, \dots, 0)$ .  $\{a_i\}$  is a periodic sequence with period  $2^p - 1$ .

Tausworthe [11] proposed to construct a sequence  $\{x_i\}$  of  $l$ -bit binary numbers using the  $M$ -sequence  $\{a_i\}$  as follows:

$$(2.2) \quad x_i = 0.a_{\sigma i+1}a_{\sigma i+2} \cdots a_{\sigma i+l},$$

where  $\sigma$  is a constant which satisfies the following conditions.

$$(2.3) \quad \sigma \geq l \quad \text{and} \quad \gcd(\sigma, 2^p - 1) = 1.$$

Properties of the sequence  $\{x_i\}$  so constructed were investigated by Tausworthe himself and some others [2], [12], [13].

Lewis and Payne [10] proposed to construct an apparently different sequence  $\{y_i\}$ , called the GFSR sequence, using the  $M$ -sequence generated by the primitive trinomial  $f(D) = D^p + D^q + 1$  as follows.

$$(2.4) \quad y_i = 0.a_i a_{i+\tau} a_{i+2\tau} \cdots a_{i+(l-1)\tau},$$

where  $\tau$  is a "judiciously selected" constant. The crucial point of their idea is that the sequence  $\{y_i\}$  can be generated very fast by using the recurrence relation  $y_i = y_{i-p} \oplus y_{i-q}$ , where  $\oplus$  means the bitwise addition modulo 2.

Kashiwagi [8] and Fushimi [4] have shown the following equivalence relation between the class of Tausworthe sequences without the first one of the conditions (2.3) and that of GFSR sequences dropping the condition that  $f(D)$  is a trinomial. The key point in the following is the notion of "proper decimation" [7] of the  $M$ -sequence, in which "decimation" means selecting every  $n$ th term of the  $M$ -sequence, and "proper" means that  $n$  is relatively prime to the period  $2^p - 1$ . If  $\{a_i\}$  is an  $M$ -sequence whose characteristic polynomial  $f$  is of degree  $p$ , then a properly decimated sequence  $\{a_{ni}; i = 0, 1, 2, \dots\}$  is also an  $M$ -sequence whose characteristic polynomial, say  $f_n$ , is of degree  $p$ . Let  $n^{-1}$  denote the inverse of  $n$  with respect to the multiplication modulo  $2^p - 1$ , i.e.,  $n \cdot n^{-1} = 1 \pmod{2^p - 1}$ . In the following theorem, we use the notation  $\{x_i(f; \sigma)\}$  and  $\{y_i(f; \tau)\}$  to specify the primitive polynomials and the parameters used to construct  $\{x_i\}$  and  $\{y_i\}$ . Finally we write  $\{x_i\} \simeq \{y_i\}$  when the two sequences  $\{x_i\}$  and  $\{y_i\}$  are equivalent in the sense they are the same sequence except possibly the location of the starting point.

**THEOREM 1.** *If  $f$  is a primitive polynomial of order  $p$ , and  $\sigma$  and  $\tau$  are relatively prime to  $2^p - 1$ , then the following equivalence relations hold.*

$$\{x_i(f; \sigma)\} \simeq \{y_i(f_\sigma; \sigma^{-1})\},$$

$$\{y_i(f; \tau)\} \simeq \{x_i(f_\tau; \tau^{-1})\}.$$

It follows from the theorem that  $\{x_i(f; \sigma)\}$  can also be generated very fast if  $f_\sigma$  is a trinomial or a polynomial with few terms; if, for example,  $f_\sigma = D^p + D^r + 1$ , then  $\{x_i(f; \sigma)\}$  can be generated by the recurrence relation  $x_i = x_{i-p} \oplus x_{i-r}$ .

Fushimi and Tezuka [5] investigated the  $k$ -distribution, i.e., multidimensional equidistribution, property<sup>1</sup> of a generalization of the GFSR sequence

$$(2.5) \quad y'_i = 0.a_{i+\tau_1} a_{i+\tau_2} a_{i+\tau_3} \cdots a_{i+\tau_l},$$

and established a necessary and sufficient condition for the sequence  $\{y'_i\}$  to be  $k$ -distributed, which is reproduced below in a slightly different form.

<sup>1</sup>The reader who is unfamiliar with the notion of  $k$ -distribution and its relation to randomness is referred to Knuth [9, § 3.5].

**THEOREM 2.**  $\{y'_i\}$  is  $k$ -distributed if and only if the  $kl$  terms of the basic  $M$ -sequence contained in  $y'_i, 0 \leq i \leq k-1$ , are linearly independent.

It follows from the theorem that the maximum possible order of equidistribution for  $\{y'_i\}$  is

$$(2.6) \quad m = [p/l],$$

where  $[\cdot]$  is the greatest integer function, since the maximum number of linearly independent terms of the  $M$ -sequence is  $p$ .

It is clear from Theorem 1 and the arguments in [5] that Theorem 2 also holds for Tausworthe sequence as well as any properly decimated sequence  $\{x_{nt}; t = 0, 1, 2, \dots\}$ , in which case the words "linearly independent" mean the following. Each of the  $kl$  bits of  $x_{nt}, 0 \leq t \leq k-1$ , can be expressed as a linear combination of the initial  $p$  terms of the basic  $M$ -sequence, i.e., in the form  $e_1 a_1 + e_2 a_2 + \dots + e_p a_p \pmod{2}$ , by (repeated, if necessary,) application(s) of the recurrence relation (2.1), and thus the unique weight vector  $(e_1, e_2, \dots, e_p)$  is associated with each bit of  $x_{nt}, 0 \leq t \leq k-1$ . The phrase "linearly independent" implies that these weight vectors are linearly independent over  $GF(2)$ .

At this point we introduce the following notation.

$$A_{n,j} = \{a_{\sigma_{nt+j}} | 0 \leq t \leq m-1\}, \quad 1 \leq j \leq l,$$

$$A_n = \bigcup_{j=1}^l A_{n,j}.$$

Thus  $A_{n,j}$  is the set of the terms of the basic  $M$ -sequence which constitute the  $j$ th bits of the first  $m$  terms of the decimated sequence  $\{x_{nt}\}$ . In addition we use the symbol  $E_n$  to denote the  $lm \times p$  matrix whose  $m(j-1) + t + 1$ st row is the weight vector associated with  $a_{\sigma_{nt+j}}$ .

Fushimi [3] considered a generalization  $\{x'_t\}$  of Tausworthe sequence  $\{x_t\}$ , which is obtained by a rearrangement of the bits of  $\{x_t\}$  as follows:

$$(2.7) \quad x'_t = 0.a_{\sigma_{t+j(1)}} a_{\sigma_{t+j(2)}} \dots a_{\sigma_{t+j(l)}},$$

where  $\{j(1), j(2), \dots, j(l)\}$  is a permutation of  $\{1, 2, \dots, l\}$  independent of  $t$ . It is clear that Theorem 2 is also applicable to the sequence  $\{x'_t\}$  and any properly decimated sequence of it. We remark that the sequence  $\{x'_t\}$  can be generated exactly as fast as the sequence  $\{x_t\}$  once the initial values  $\{x'_t; 0 \leq t \leq p-1\}$  are given (see the remark following Theorem 1).

In what follows we also use  $\{x_t\}$  and  $\{x'_t\}$ , and consider which permutation is appropriate for our purpose. It must be noted that the maximum orders of equidistribution of  $\{x_{nt}\}$  and  $\{x'_{nt}\}$  are equivalent for any permutation of bits since the number of linearly independent vectors in a given set of vectors is invariant under any permutation of the vectors in the set. Then one may naturally raise a question: in what sense can we improve the sequence  $\{x_{nt}\}$  by considering the rearrangement of bits? The answer is as follows. If we form the sequences of  $l'$ -bit ( $l' < l$ ) numbers by reading the first  $l'$  bits of the terms in the sequences  $\{x_{nt}\}$  and  $\{x'_{nt}\}$ , respectively, then the orders of equidistribution for these  $l'$ -bit sequences may be different. To be more specific, suppose the sequence  $\{x_{nt}\}$  is  $m$ -distributed if the terms in the sequence are read to  $l'_1$ -bit accuracy,<sup>2</sup> but not  $m$ -distributed if read to more than  $l'_1$ -bit accuracy. Then the sequence

<sup>2</sup> In such a case, we will say the sequence is  $m(l'_1)$ -distributed.

$\{x'_{ni}\}$  is considered to be better than  $\{x_{ni}\}$  if the former is  $m\langle l'_2 \rangle$ -distributed for some  $l'_2 > l'_1$ . Thus it is worthwhile to ask for a permutation for which  $\{x'_{ni}\}$  is  $m\langle l' \rangle$ -distributed with  $l'$  as large as possible.

**3. A 0-1 integer programme.** Now let  $N$  be a set of integers relatively prime to  $2^p - 1$ , and we require all the decimated sequences  $\{x'_{ni}\}$ ,  $n \in N$ , be  $m\langle l' \rangle$ -distributed. There are an immense number of integers which are relatively prime to  $2^p - 1$  when  $p$  is large, and there is no obvious way to solve the problem if  $N$  consists of all of them. On the other hand, we usually use the decimated sequences  $\{x'_{ni}\}$  with relatively small  $n$ 's. Thus it is natural, from practical points of view, to take  $N$  as a set of small integers relatively prime to  $2^p - 1$ .

Our problem can be stated as follows.

*Design problem.* Given  $f$ ,  $\sigma$  and  $l$ , to find a permutation  $\{j(1), j(2), \dots, j(l)\}$  of  $\{1, 2, \dots, l\}$  for which the  $l'$  in the following statement is maximum: all the decimated sequences  $\{x'_{ni}\}$ ,  $n \in N$ , are  $m\langle l' \rangle$ -distributed, where  $m$  is defined by (2.6).

In order to solve this problem, we must first find minimal linear dependence relations,<sup>3</sup> for each  $n \in N$ , among the  $ml$  terms in  $A_n$ , or equivalently among the row vectors of  $E_n$ , and this can be accomplished, as will be explained in detail in the next section, by applying Gaussian elimination method to  $E_n$ . To each minimal linear dependence relation thus found, we associate an  $l$ -dimensional row vector  $\mathbf{g} = (g_1, g_2, \dots, g_l)$  as follows. If the terms in, say,  $A_{n,j_1}, A_{n,j_2}, \dots, A_{n,j_\nu}$  are linearly dependent, then  $g_{j_1} = g_{j_2} = \dots = g_{j_\nu} = 1$  and all the other components of  $\mathbf{g}$  are set equal to 0. Then we form a matrix  $G$  whose rows consist of  $\mathbf{g}$ 's corresponding to all the minimal dependence relations found for all  $n \in N$ .

Using  $G$  as the coefficient matrix of the constraints, we formulate the following 0-1 integer linear programming problem.

$$(3.1) \quad \text{ILP: minimize} \quad z_0 = \sum_{j=1}^l z(j)$$

$$(3.2) \quad \text{subject to} \quad G\mathbf{z} \geq \mathbf{1}, \quad \text{and}$$

$$(3.3) \quad z(j) = 0 \text{ or } 1, \quad 1 \leq j \leq l.$$

Here,  $\mathbf{z}$  is an  $l$ -dimensional column vector whose  $j$ th component is  $z(j)$ , and  $\mathbf{1}$  is the column vector whose components are all equal to 1.

**THEOREM 3.** *The 0-1 integer linear programming problem ILP is equivalent to the design problem.*

*Proof.* Let  $G^*$  be a matrix obtained by applying permutation  $\{j(1), j(2), \dots, j(l)\}$  to the columns of  $G$ , i.e., the  $k$ th column of  $G^*$  is the  $j(k)$ -th column of  $G$ , and  $G_0^*$  and  $G_1^*$  be the submatrices of  $G^*$  consisting of the first  $l'$  and the last  $(l - l')$  columns of  $G^*$ , respectively.

We have shown in the previous section that a necessary and sufficient condition for the sequence  $\{x'_{ni}\}$  defined by (2.7) to be  $m\langle l' \rangle$ -distributed is that there is no linear dependence relation among the  $ml'$  terms of the  $M$ -sequence contained in the leading  $l'$  bits of  $x'_{ni}$ ,  $0 \leq i \leq m - 1$ . This is equivalent to the condition that there is at least one 1 in every row of  $G_1^*$  since every row of  $G$  or  $G^*$  represents a *minimal* linear dependence relation. The inequality (3.2) is nothing but this condition. Since our objective is to maximize  $l'$ , our objective function is (3.1). Q.E.D.

<sup>3</sup> A linear dependence relation among a set of vectors is said to be minimal if no proper subset of the vectors is linearly dependent.

#### 4. Methods for solving the design problem.

**4.1. Algorithms for finding approximate solutions to ILP.** The 0-1 integer linear programming problem ILP we formulated in the previous section is a well-known problem in combinatorics, i.e., a set covering problem. It is one of NP-hard problems, i.e., there are no algorithms known at present to find an optimal solution to it with time complexity of a polynomial order of  $l$ , although several algorithms have been proposed using standard techniques for solving integer linear programmes, e.g., a branch-and-bound method and a cutting plane method. Approximate solutions to it, however, may be obtained in a very short time by simple heuristic algorithms. We will list two of them below.

Let  $J_0$  be the set of indices  $j$  such that  $z(j) = 0$ . Algorithm P starts with  $J_0 = \emptyset$ , when all the inequalities in (3.2) are satisfied but the value of the objective function  $z_0$  is maximum, and decreases  $z_0$  by iteratively including a  $j$  in  $J_0$  in the increasing order of the column sum of  $G$  as long as the constraint (3.2) is satisfied. On the contrary, Algorithm D starts with  $J_0 = \{1, 2, \dots, l\}$ , when all the inequalities in (3.2) are violated, and decreases the number of violated inequalities by iteratively excluding a  $j$  from  $J_0$  until all the inequalities are satisfied. At each iteration, such a  $j$  that decreases the number of violated inequalities most is excluded from  $J_0$ . Details of both algorithms are as follows.

##### ALGORITHM P.

1. Compute the column sum  $s(j)$  of  $G$  for  $j = 1, 2, \dots, l$ .
2. Sort  $s(j)$ 's in increasing order. Assume we have got  $s(j_1) \leq s(j_2) \leq \dots \leq s(j_l)$ .
3. Set  $z(j) = 1$  for  $j = 1, 2, \dots, l$ .  $J_0 \leftarrow \emptyset$ .
4. *for*  $i := 1$  *to*  $l$  *do*  
     *begin*  
          $z(j_i) := 0$ ;  
         *if*  $GZ \geq 1$  *is violated then*  $z(j_i) := 1$  *else*  $J_0 \leftarrow J_0 \cup \{j_i\}$   
     *end*

##### ALGORITHM D.

1.  $J_0 \leftarrow \{1, 2, \dots, l\}$ .  $G_0 \leftarrow G$ .  $k \leftarrow 0$ .
2.  $k \leftarrow k + 1$ .
3. Compute the column sum  $s_k(j)$  of  $G_{k-1}$  for each  $j \in J_0$ .
4. Let  $j^*$  be a maximizer of  $s_k(j)$  among  $j \in J_0$ .
5.  $J_0 \leftarrow J_0 - \{j^*\}$ .
6. Let  $G_k$  be the matrix consisting of all the row vectors of  $G_{k-1}$  whose  $j^*$ th component equals 0.
7. If  $G_k$  is not empty then go to step 2.

**4.2. How to find the constraints.** We shall be concerned in this subsection with a method of obtaining the constraint matrix  $G$  in (3.2). As was explained in the previous section, it is easily constructed once we know all the minimal linear dependence relations among the row vectors in  $E_n$  for each  $n \in N$ , but this problem itself is nonpolynomial in the number of the rows of  $E_n$ . We will present below an algorithm for solving this problem. The algorithm consists of two stages: first, we find *some* dependence relations by using a modification of Gaussian elimination method; second, we generate *enough* dependence relations to solve the problem by combining the relations obtained in the first stage. It is to be noted that we do not necessarily generate *all* the dependence relations exploiting the special structure of the problem.

Gaussian elimination is basically a method for solving systems of linear equations by performing a sequence of basic row operations, i.e., a multiplication of a row by

a constant and an addition of a row to another row, and usually the “history” of row operations is not recorded. In our case, however, where the objective is to find the linear dependence relations among the rows, the history of row operations is the crucial information. Here the word “history” means the record of the information which row was added to which row at each step. (Note that we need not perform a multiplication because the arithmetics are done on  $GF(2)$ .) In order to record the history, we introduce the variables  $h(i', i)$  and set  $h(i', i) = 1$  if the  $i'$ th row is added to the  $i$ th row at some step of elimination, and set  $h(i', i) = 0$  otherwise.

Now fix an  $n \in N$ , and let the  $i$ th row of  $E_n$  be denoted by  $\mathbf{e}_i^{(0)}$ ,  $1 \leq i \leq lm$ . Linear dependence relations among the row vectors of  $E_n$ , if any, are found by the following procedure, in which  $\mathbf{e}_i$  denotes an  $l$ -dimensional row vector whose  $j$ th component is  $e_{ij}$ .

```

procedure GAUSS;
  begin
    for  $i := 1$  to  $lm$  do  $\mathbf{e}_i := \mathbf{e}_i^{(0)}$ ;
    for  $i := 1$  to  $lm$  do
      begin
        if  $\mathbf{e}_i = \mathbf{0}$  then DEPENDENCE( $i$ )
        else if  $i < lm$  then
          begin
             $j_0 :=$  the minimum  $j$  for which  $e_{ij} = 1$ ;
            for  $k := i + 1$  to  $lm$  do
              if  $e_{kj_0} = 1$  then
                begin
                   $\mathbf{e}_k := \mathbf{e}_k + \mathbf{e}_i \pmod{2}$ ;
                   $h(i, k) := 1$ 
                end
              else  $h(i, k) := 0$ 
            end
          end
        end
      end
    end
  end

```

The procedure DEPENDENCE( $i$ ) is called when  $\mathbf{e}_i = \mathbf{0}$ , which is the case if and only if the vector  $\mathbf{e}_i^{(0)}$  is equivalent to some linear combination of the vectors  $\mathbf{e}_1^{(0)}, \mathbf{e}_2^{(0)}, \dots, \mathbf{e}_{i-1}^{(0)}$ . A method for finding a linear dependence relation among these vectors shall be illustrated by a simple example. Suppose  $i = 6$  and the relevant part of the history  $h(i', i)$  is as shown in Table 1, which means the following.<sup>4</sup>

$$(4.1a) \quad \mathbf{e}_6 = \mathbf{e}_1 + \mathbf{e}_3 + \mathbf{e}_4 + \mathbf{e}_5 + \mathbf{e}_6^{(0)},$$

TABLE 1  
An example of the history  $h(i', i)$ .

		1	2	3	4	5	6	
$i'$	1							
	2		1	1	1	0	1	
	3			0	0	1	0	
	4				0	0	1	
	5					1	1	
	6						1	

<sup>4</sup> In (4.1) and the following three equations, equality sign is to be understood on  $GF(2)$ .

$$(4.1b) \quad \mathbf{e}_5 = \mathbf{e}_2 + \mathbf{e}_4 + \mathbf{e}_5^{(0)},$$

$$(4.1c) \quad \mathbf{e}_4 = \mathbf{e}_1 + \mathbf{e}_4^{(0)},$$

$$(4.1d) \quad \mathbf{e}_3 = \mathbf{e}_1 + \mathbf{e}_3^{(0)},$$

$$(4.1e) \quad \mathbf{e}_2 = \mathbf{e}_1 + \mathbf{e}_2^{(0)}.$$

Substituting (4.1b) in (4.1a), we get

$$\mathbf{e}_6 = \mathbf{e}_1 + \mathbf{e}_2 + \mathbf{e}_3 + \mathbf{e}_5^{(0)} + \mathbf{e}_6^{(0)},$$

which, upon substitution of (4.1d), leads to

$$\mathbf{e}_6 = \mathbf{e}_2 + \mathbf{e}_3^{(0)} + \mathbf{e}_5^{(0)} + \mathbf{e}_6^{(0)}.$$

If we substitute (4.1e) in the above expression and use the fact that  $\mathbf{e}_1 = \mathbf{e}_1^{(0)}$ , we finally obtain the following linear dependence relation.

$$\mathbf{0} = \mathbf{e}_6 = \mathbf{e}_1^{(0)} + \mathbf{e}_2^{(0)} + \mathbf{e}_3^{(0)} + \mathbf{e}_5^{(0)} + \mathbf{e}_6^{(0)}.$$

Thus, in general, a linear dependence relation can be obtained by the following successive substitution.

```

procedure DEPENDENCE(i);
  begin
     $d_1 := d_2 := \dots := d_{i-1} := 0; d_i := 1;$ 
    for  $j := i$  downto 2 do
      if  $d_j \neq 0$  then
        for  $i' := j - 1$  downto 1 do  $d_{i'} := d_{i'} + h(i', j) \pmod{2}$ 
      end
    end
  
```

If  $d_{i_1} = d_{i_2} = \dots = d_{i_\nu} = d_i = 1$  and the other  $d$ 's are 0 after the above procedure is executed, we know that there is a linear dependence relation

$$(4.2) \quad \mathbf{e}_{i_1}^{(0)} + \mathbf{e}_{i_2}^{(0)} + \dots + \mathbf{e}_{i_\nu}^{(0)} + \mathbf{e}_i^{(0)} = \mathbf{0}.$$

It is clear, by the property of Gaussian elimination, that the set of vectors  $\{\mathbf{e}_{i_1}^{(0)}, \mathbf{e}_{i_2}^{(0)}, \dots, \mathbf{e}_{i_\nu}^{(0)}\}$  is independent, and that (4.2) is a minimal linear dependence relation.

There remains a question whether the minimal linear dependence relations found by the above procedure are all that exist among the row vectors of  $E_n$ . The answer is no in general, and the reason is as follows. Suppose there are two minimal linear dependence relations, (4.2) and (4.3) below.

$$(4.3) \quad \mathbf{e}_{k_1}^{(0)} + \mathbf{e}_{k_2}^{(0)} + \dots + \mathbf{e}_{k_\lambda}^{(0)} + \mathbf{e}_k^{(0)} = \mathbf{0}.$$

If  $\{i_1, i_2, \dots, i_\nu, i\} \cap \{k_1, k_2, \dots, k_\lambda, k\} \neq \emptyset$ , there is a possibility that the linear dependence relation obtained by adding (4.2) and (4.3) modulo 2 happens to be minimal, and the similar argument applies when there are more than two linear dependence relations. Hence we must, in principle, check all the combinations of the linear dependence relations found by procedure GAUSS in order to find all the linear dependence relations among the rows of  $E_n$ , which would be extremely time consuming. It must be remembered, however, that what we need finally is not the linear dependence relations among the rows of  $E_n$ , i.e., among the elements in  $A_n$ , but the dependence relations among the columns  $A_{n,1}, A_{n,2}, \dots, A_{n,l}$ . Hereafter we will use the words “ $b$ -dependence” and “ $c$ -dependence” as abbreviations for “linear dependence among the elements (bits) in  $A_n$ ” and “linear dependence among the columns” respectively.

It often happens, as will be illustrated in the next section, that several  $b$ -dependence relations give rise to the same  $c$ -dependence relation, and this observation leads to a rather efficient procedure for finding all the  $c$ -dependence relations, which will be best illustrated by an example in the next section.

**5. An illustrative example.** As an example, we take a primitive trinomial  $f(D) = D^{521} + D^{32} + 1$ , which was also used by many authors, see, e.g., [1]-[3], [5]. The period of the  $M$ -sequence generated by this trinomial,  $2^{521} - 1$ , is a Mersenne prime, hence all the decimated sequences are also  $M$ -sequences. We have chosen as the set  $N$  the first sixteen natural numbers:

$$N = \{1, 2, 3, \dots, 16\}.$$

The bit length  $l$  and the parameter  $\sigma$  of the Tausworthe sequence (2.2) are chosen to be 32. The maximum possible order of equidistribution,  $m$ , for the sequences  $\{x_{ni}\}$  is equal to  $\lfloor 521/32 \rfloor = 16$ .

For each  $n \in N$ , we constructed the matrix  $E_n$ , to which procedure GAUSS was applied. It was found that there exists no linear dependence relation among the rows of  $E_n$  for  $n = 1, 2, 4, 8, 9$  and  $16$ . Table 2 shows the maximum  $l'$ , for each  $n \in N$ , such that Tausworthe sequence (2.2) is  $m(l')$ -distributed.

TABLE 2  
Maximum  $l'$  such that the decimated sequence of the Tausworthe sequence in the illustrative example is  $16(l')$ -distributed.

$n$	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16
$l'$	32	32	23	32	9	27	27	32	32	18	28	28	27	31	27	32

Now we will show the  $b$ -dependence relations found by GAUSS and interrelations among them. For  $n = 3$ , 45  $b$ -dependence relations were found among the  $lm = 512$  rows of  $E_3$ , or equivalently among the bits in  $\{x_{3t}; 0 \leq t \leq 15\}$ . The first<sup>5</sup> one of them is shown in Fig. 1, which indicates that the shaded bits are linearly dependent. It is clear that any set of four bits whose configuration is equivalent to the one in Fig. 1 is also linearly dependent. Let  $\mathcal{R}(\Delta t, \Delta j)$  denote the  $b$ -dependence relation among the four bits obtained by translating the shaded bits in Fig. 1 by  $\Delta t$  downward and by  $\Delta j$  rightward. For example,  $\mathcal{R}(4, 8)$  means the  $b$ -dependence relation among the four bits at  $(t, j) = (9, 9), (14, 18), (15, 18)$  and  $(4, 32)$ . We shall say that the two  $b$ -dependence relations are essentially the same (different) if their configurations are equivalent (different). There are 45 ( $= 5 \times 9$ )  $b$ -dependence relations which are essentially the same as the one in Fig. 1, including itself, i.e.,  $\mathcal{R}(\Delta t, \Delta j), 0 \leq \Delta t \leq 4$  and  $0 \leq \Delta j \leq 8$ , and they are all that were found by GAUSS when  $n = 3$ .

It is evident that, for any fixed  $\Delta j$ , five  $b$ -dependence relations,  $\mathcal{R}(\Delta t, \Delta j), 0 \leq \Delta t \leq 4$ , or any other  $b$ -dependence relations obtained by adding these modulo 2, give rise to the same  $c$ -dependence relation. It is also clear that any two relations  $\mathcal{R}(\Delta t_1, \Delta j_1)$  and  $\mathcal{R}(\Delta t_2, \Delta j_2)$  have no bit in common if  $\Delta j_1 \neq \Delta j_2$ , hence a minimal  $b$ -dependence relation cannot be obtained by combining these.

<sup>5</sup> The word "first" means "the  $i$  was minimum when procedure DEPENDENCE( $i$ ) was called in procedure GAUSS."

the sequence number of  $c$ -dependence relations for each  $n$ , and “ $r$ ” means the number of rows of the constraint matrix  $G$  to be generated by each  $c$ -dependence relation. Thus 99 rows of  $G$  are generated in all.

We have applied the Algorithms P and D to our set covering problem with the constraint matrix  $G$  obtained above. They have found solutions with  $z_0 = 14$  ( $l' = 18$ ) and  $z_0 = 13$  ( $l' = 19$ ), respectively.

It is well known, see e.g. [6], and easy to see that if the two rows  $\mathbf{g}_i$  and  $\mathbf{g}_{i'}$  of  $G$  satisfy the dominance relation  $\mathbf{g}_i \geq \mathbf{g}_{i'}$ , then  $\mathbf{g}_i$  may be deleted from the constraint. In our example, 48 rows can be deleted by this dominance relation. Asterisks in Table 3 show the  $c$ -dependence relations corresponding to the remaining 51 rows. We have applied again the Algorithms P and D to the set covering problem with the reduced constraint matrix, obtaining solutions with  $z_0 = 13$  ( $l' = 19$ ) and  $z_0 = 14$  ( $l' = 18$ ), respectively.

One of the solutions thus found with  $z_0 = 13$  ( $l' = 19$ ) is such that  $J_0 = \{j | z(j) = 0\} = \{1, 2, 3, 4, 5, 6, 7, 8, 9, 19, 20, 21, 22, 23, 24, 29, 30, 31, 32\} = \{j(1), j(2), \dots, j(19)\}$  and  $J_1 = \{j | z(j) = 1\} = \{10, 11, 12, 13, 14, 15, 16, 17, 18, 25, 26, 27, 28\} = \{j(20), j(21), \dots, j(32)\}$ . Therefore, if we construct the sequence  $\{x'_i\}$  by

$$x'_i = 0.a_{32i+j(1)}a_{32i+j(2)} \cdots a_{32i+j(32)}$$

using the permutation  $\{j(1), j(2), \dots, j(32)\}$  defined above, all the decimated sequences  $\{x'_n\}$ ,  $1 \leq n \leq 16$ , are 16-distributed when they are read to 19-bit accuracy.

Finally we briefly describe a method of implementing the generator thus obtained, using similar techniques as Tootill et al. [12], [13]. Let  $\{X_t\} = \{2^{32}x_t\}$  and  $\{X'_t\} = \{2^{32}x'_t\}$  be sequences of 32-bit integer random numbers. Since  $\sigma (= 32)$  is a power of 2, we have  $f_\sigma(D) = D^{521} + D^{32} + 1$  so that  $\{X'_t\}$  can be generated by the recurrence

$$X'_t = X'_{t-521} \oplus X'_{t-32}.$$

To initialize  $\{X'_t\}$ , we first set the initial values of the sequence  $\{X_t\}$ , i.e.,  $\{X_t; 0 \leq t \leq 520\}$ , and then perform the permutation of the bits of these initial values. Since  $521 (= 32 \times 16 + 9)$  initial values of the basic  $M$ -sequence  $\{a_t\}$  can be given arbitrarily, we can set  $X_t$  ( $0 \leq t \leq 15$ ) and the leading 9 bits of  $X_{16}$  arbitrarily. Practically, however, it would be convenient for one to give all the bits of  $X_t$  ( $0 \leq t \leq 16$ ) arbitrarily by using, for example, a congruential generator, and then to modify  $X_{16}$  by the following formula based on the “principle of complementary shifting” [13, p. 478]:

$$X_{16} = M^{32}((L^{23}X_{t-17} + R^9X_0) \oplus X_{15}).$$

Here  $L^{23}$  denotes the logical left shift 23 bits, and  $M^{32}$  means taking the least significant 32 bits by a masking operation. Then the remaining 504 initial values,  $\{X_t; 17 \leq t \leq 520\}$ , are generated by use of the recurrence

$$X_t = M^{32}((L^{23}X_{t-17} + R^9X_{t-16}) \oplus X_{t-1}).$$

Now that the initial values of the sequence  $\{X_t\}$  are set, we have only to permute the bits of  $X_t$  to obtain  $X'_t$  for each  $t$ ,  $0 \leq t \leq 520$ . This can be conveniently done in FORTRAN by using double length integer variables. A sample program for a computer with the word length 32 bits is given below, in which LSHFR(K, J) is a generic function for the logical right shift  $J$  bits operation.

## SORTING AND RECOGNITION PROBLEMS FOR ORDERED SETS\*

U. FAIGLE† AND GY. TURÁN‡

**Abstract.** How many questions are needed to decide whether an unknown ordered set is isomorphic to a fixed ordered set  $P_0$ ? This recognition problem is considered, together with some related computational problems concerning ordered sets.

**Key words.** sorting, recognition, identification, order, complexity, algorithm

**AMS(MOS) subject classifications.** 68E05, 68C25

**Introduction.** The standard sorting problem is to identify an unknown order knowing that it is a linear order. This formulation suggests the following generalization to ordered sets, called the  $P_0$ -*sorting problem*: determine an unknown order, knowing that it is isomorphic to a fixed “pattern” order  $P_0$  (thus  $P_0$  is a chain in the classical case).

A related question is the  $P_0$ -*recognition problem*: decide whether the unknown order is isomorphic to  $P_0$ . The *identification problem* asks for determining the unknown order without any a priori information.

In this paper we discuss the complexity of these problems. The model of computation is the usual decision tree model with the only modification that now every node has three sons since two elements can turn out to be incomparable as well. For the sorting and recognition problems we use the worst-case measure of complexity. This measure is of no use for the identification problem as clearly every identification algorithm has to ask every pair in order to identify an antichain. Instead, we introduce a refined measure of complexity which assigns a function  $C_A(P)$  to every algorithm  $A$  giving the worst-case behavior of  $A$  on orders isomorphic to  $P$  for every order  $P$ .

In § 2 we observe some connections between the complexities of the above problems. We need the notion of an *essential set* (consisting of covering and critical pairs), essentially defined in Rabinovitch and Rival [8] and Kelly [4], to describe these connections.

An example is given of an adversary argument to bound the sorting complexity in § 3. In § 4 the recognition complexity of Boolean algebras is determined to be  $\Theta(n \log_2 n)$ . It is shown that the minimal recognition complexity of orders with height 1 on  $n$  elements is asymptotically  $n \log_2 n$ . (Also, an  $\Omega(n \log_2 n)$  lower bound holds for ordered sets with width less than  $n^{1-\varepsilon}$  for any  $\varepsilon > 0$ , in particular for orders with bounded width.)

Section 5 contains identification algorithms. The first uses Dilworth decomposition, the second is based on a recent result of Linial and Saks [6] on the existence of central elements; both generalize sorting by insertion. These algorithms are optimal for orders of bounded width but they can perform badly in general. The third algorithm is optimal for orders of height 1, the “other extreme.” The merging of these algorithms is still not optimal as is shown by their behavior on Boolean algebras.

Some remarks and open problems are given in § 6. In particular, it is pointed out that the problems discussed are special cases of more general problems which are ordered set versions of graph property recognition problems in the sense discussed in Bollobás [1].

**1. Definitions.** Ordered sets  $P$  on  $n$  elements are assumed to have a fixed ground set  $\{a_1, \dots, a_n\}$ ; the order relation is  $<$ ; incomparability is denoted by  $\parallel$ . An element  $x$  is *isolated* if  $x \parallel y$  for every  $y$ . The pair  $(a_i, a_j)$  is a *covering pair* if  $a_i < a_j$  and there is no  $a_k$  with  $a_i < a_k < a_j$  (these pairs form the Hasse diagram of  $P$ ). The *width*  $w(P)$  (resp. the *height*  $h(P)$ ) of  $P$  is the size of a maximum antichain in  $P$  (resp. the length of a maximum chain in  $P$ ).

An *ideal*  $I$  (resp. a *filter*  $F$ ) is a subset of elements subject to  $x \in I, y < x$ , which implies  $y \in I$  (resp.  $x \in F, y > x$  implies  $y \in F$ ).  $I_P(x) = \{y: y < x\}$  is the ideal generated by  $x$ ,  $F_P(x) = \{y: y > x\}$  denotes the filter generated by  $x$ .  $N_P$  is the total number of ideals in  $P$  and  $N_P(x)$  is the number of ideals containing  $x$ .

The theorem of Dilworth [2] relates the width of  $P$  to a chain cover of the ground set: a chain cover of  $P$  with  $k$  chains exists if and only if  $k \geq w(P)$ .

Let  $P_0$  be an ordered set on  $n$  elements.

The  $P_0$ -*sorting problem* is to determine an unknown order  $P$  knowing only that  $P$  is isomorphic to  $P_0$ .

An *algorithm*  $A$  to solve the  $P_0$ -sorting problem is a *ternary decision tree* with nonleaves labeled " $a_i: a_j$ " for some  $1 \leq i < j \leq n$  and outgoing edges labeled " $a_i < a_j$ ," " $a_i \parallel a_j$ ," " $a_i > a_j$ ." A leaf is either labeled by an order  $P \simeq P_0$  or by a sign  $xx$ . If it is labeled by  $P$ , then  $P$  is the only order isomorphic to  $P_0$  consistent with the answers obtained along the path leading to that leaf. If it is labeled by  $xx$ , then there is no order isomorphic to  $P_0$  satisfying the answer on the corresponding path. For  $P \simeq P_0$ ,  $A(P)$  is the number of questions used to find  $P$  (the length of the unique path leading to the leaf labeled  $P$ ).

The *complexity* of  $A$  is

$$C_A^s := \max \{A(P): P \simeq P_0\}$$

and

$$C^s(P_0) := \min \{C_A^s: A \text{ is a } P_0\text{-sorting algorithm}\}$$

is the *sorting complexity* of  $P_0$ .

The  $P_0$ -*recognition problem* is to decide if an unknown order  $P$  is isomorphic to  $P_0$ .

An *algorithm*  $A$  to solve the recognition problem is again a ternary tree with nonleaves and edges labeled as above. Leaves are labeled with "yes" or "no." If a leaf is labeled "yes," then all orders satisfying the answers given along the path leading to the leaf must be isomorphic to  $P_0$ . If it is labeled "no," then there can be no order isomorphic to  $P_0$  consistent with these answers.

The *complexity*  $C_A^r$  of  $A$  is the depth of the tree and

$$C^r(P_0) := \min \{C_A^r: A \text{ is a } P_0\text{-recognition algorithm}\}$$

is the *recognition complexity* of  $P_0$ .

The *identification problem* is to determine an unknown order without any a priori information.

An *algorithm*  $A$  to solve the identification problem is a sequence  $A = (A_1, A_2, \dots)$ , where  $A_n$  is an algorithm to solve the identification problem on  $n$  elements. Thus  $A_n$  is a ternary tree as above, with leaves labeled by orders on  $\{a_1, \dots, a_n\}$  subject to a

leaf labeled  $P$  if  $P$  is the only ordered set consistent with the answers on the corresponding path.

$A(P)$  is the number of questions used by  $A_n$  to identify  $P$  and

$$C_A(P) := \max \{A(P') : P' \simeq P\}$$

is the *complexity* of  $A$  to identify orders isomorphic to  $P$ . Note that here the complexity of  $A$  is a function.

An identification algorithm is defined to be *optimal* if for every identification algorithm  $B$

$$C_A(P) = O(C_B(P)).$$

(Notation:  $f(P) = O(g(P))$  means  $|f(P)/g(P)| \leq \alpha$  for some constant  $\alpha > 0$ ,  $f(P) = \Omega(g(P))$  if  $g(P) = O(f(P))$  and  $f(P) = \Theta(g(P))$  if  $f(P) = O(g(P))$  and  $f(P) = \Omega(g(P))$ ,  $f(n) = o(g(n))$  if  $f(n)/g(n) \rightarrow 0$  as  $n \rightarrow \infty$ .)

If  $P$  is an ordered set on  $\{a_1, \dots, a_n\}$ , then  $E = E_1 \cup E_2 \subseteq \{a_1, \dots, a_n\} \times \{a_1, \dots, a_n\}$  is an *essential set* for  $P$  if

- (a)  $(a_i, a_j) \in E_1$  implies  $a_i < a_j$  and  $(a_i, a_j) \in E_2$  implies  $a_i \parallel a_j$ ,
- (b)  $P$  is the only order satisfying (a).

(Thus  $E$  is a set of comparabilities and incomparabilities which uniquely determines  $P$ .) The size of a minimum essential set is denoted by  $e(P)$ .

**2. Some observations.** In this section we collect some useful facts about the problems defined above.

LEMMA 1. For every order  $P_0$ ,

$$\max(C^s(P_0), e(P_0)) \leq C^r(P_0) \leq C^s(P_0) + e(P_0).$$

*Proof.* Consider a  $P_0$ -recognition algorithm and apply it to an order  $P \simeq P_0$ . Then arriving at the leaf,  $P$  must be identified. Indeed, if the relation between  $a_i$  and  $a_j$  were not determined then it is easy to see that  $a_i \parallel a_j$  and, say,  $a_i > a_j$  would both be consistent. It is impossible, however, that both relations yield orders isomorphic to  $P_0$  (i.e., the number of incomparable pairs is not the same). Thus every recognition algorithm can be used for sorting and hence  $C^s(P_0) \leq C^r(P_0)$ . Furthermore,  $e(P_0) \leq C^r(P_0)$  because in the above case enough questions must be asked to determine  $P$  uniquely.

A recognition algorithm for  $P_0$  can be obtained as follows: assume that the unknown order is isomorphic to  $P_0$  and apply a sorting algorithm. Then check the elements of a minimal size essential set to justify the assumption. Thus  $C^r(P_0) \leq C^s(P_0) + e(P_0)$ .  $\square$

LEMMA 2. If  $A$  is an identification algorithm then for every order  $P_0$ ,

$$C_A(P_0) \geq C^r(P_0).$$

*Proof.* Every identification algorithm can be used as a  $P_0$ -recognition algorithm: run  $A$  for  $C_A(P_0)$  steps. Then every  $P \simeq P_0$  is already identified. If the order is not identified yet it cannot be isomorphic to  $P_0$ .  $\square$

LEMMA 3. An identification algorithm  $A$  is optimal iff

$$C_A(P_0) = O(C^r(P_0)).$$

*Proof.* ( $\leftarrow$ ) Follows from Lemma 2 above.

( $\rightarrow$ ) If  $C_A(P_0)/C^r(P_0)$  is not bounded, choose, for every  $k$ , an order  $P_k$  on  $n_k$  elements with  $C_A(P_k) > k \cdot C^r(P_k)$  such that  $n_1 < n_2 < \dots$ . Let  $B$  be an identification algorithm obtained from  $A$  by merging  $A_{n_k}$  with an optimal recognition algorithm for

$P_k$  (merging means asking questions of the two algorithms alternatingly). It follows from the proof of Lemma 1 that B in fact is an identification algorithm and  $C_B(P_k) \leq 2C^r(P_k)$ . Thus  $C_A(P_k) > (k/2)C_B(P_k)$  and A is not optimal. (Also note that B is a “better” algorithm as  $C_B(P) \leq 2C_A(P)$  holds for every  $P$ .)  $\square$

The next lemma is a reformulation of observations made by Rabinovitch and Rival [8] and Kelly [4].

A pair  $(a_i, a_j)$  is *critical* if  $a_i \parallel a_j$ ,  $x > a_i$  implies  $x > a_j$ , and  $y < a_j$  implies  $y < a_i$ .

LEMMA 4. *For every  $P_0$ , the covering and critical pairs form the unique minimal essential set.*

*Proof.* These pairs are necessary as their status is not implied by the other relations. Covering pairs imply all comparabilities. Incomparability of critical pairs implies all incomparabilities. (See [8], [4].)  $\square$

In the sequel this unique minimal essential set will be denoted by  $E(P_0)$ .

**3. Sorting.** There are simple examples with small sorting complexity. For example, if  $P_0$  has a unique maximal element and all other elements are incomparable, then  $C^s(P_0) = \lceil (n-1)/2 \rceil$ .

If  $\#(P_0)$  denotes the number of orders isomorphic to  $P_0$  on the ground set  $\{a_1, \dots, a_n\}$  then clearly

$$C^s(P_0) \geq \log_3 \#(P_0).$$

Partitioning the elements into antichains according to their height (i.e., the length of the longest chain ending with them) and considering the sizes  $s_1, \dots, s_n$  of these antichains we get

$$\#(P_0) \geq \frac{n!}{s_1! \cdots s_n!}$$

and with  $s_i \leq w(P_0)$  this implies

$$C^s(P_0) \geq n \log_3 n - n \log_3 w(P_0) - 5n.$$

Later we shall see (Corollary 18 in § 5) that

$$C^s(P_0) \leq w(P_0) \cdot 2n \log_2 n + 3nw(P_0).$$

Thus, when  $w$  is fixed, the sorting complexity is determined within a constant factor.

Another obvious example where the information-theoretic bound is not sharp, besides the example above, is given by the  $n$ -element order containing only one comparable pair. Here  $\#(P_0) = n(n-1)$  and  $C^s(P_0) = \binom{n}{2}$ .

A special case which may be of some interest is the order consisting of independent comparable pairs (a “matching”), where the information-theoretic bound is  $\Omega(n \log_2 n)$ .

The following theorem determines the sorting complexity of a matching. The upper bound was observed by M. Aigner.

THEOREM 5. *Let  $n$  be even and  $P_0$  be the parallel composition of  $n/2$  2-element chains. Then for the sorting complexity of  $P_0$*

$$C^s(P_0) = \frac{n^2}{4}.$$

*Proof.* For the lower bound we use the “greedy” adversary strategy: assume that at every stage of the algorithm the answer to a question “ $a_i : a_j$ ” is always “ $a_i \parallel a_j$ ” unless adding this incomparability to the information provided already leaves no order

isomorphic to  $P_0$  consistent with these data. In the latter case the answer is “ $a_i > a_j$ .” (It is easy to see that the direction of the inequality in the answer is arbitrary; it is only fixed for being definite.)

Assume that the algorithm stops by determining the order  $P \simeq P_0$  with comparable pairs  $a_1 > a_2, a_3 > a_4, \dots, a_{n-1} > a_n$ . Then it is clear that each of these pairs must have been asked by the algorithm as otherwise reversing one inequality would also be consistent with every other answer. Letting  $E(>)$  denote the set of these comparable pairs, we assume that they have been asked by the algorithm in the above order. Further, let  $E(\parallel)$  be the set of pairs  $(a_i, a_j)$  asked by the algorithm with answer “ $a_i \parallel a_j$ ” obtained and  $\bar{E}$  be the set of unasked pairs.

Just before  $(a_1, a_2)$  was asked, the set of pairs not asked yet contained  $E(>) \cup \bar{E}$  and as the adversary uses the greedy strategy, it must have been the case that every perfect matching (corresponding to the comparable pairs) in this set of pairs contains  $(a_1, a_2)$ . Hence every perfect matching in  $E(>) \cup \bar{E}$  contains  $(a_1, a_2)$ .

The same argument shows that every perfect matching in  $E(>) \cup \bar{E}$  contains  $(a_3, a_4), \dots, (a_{n-1}, a_n)$  as well, thus  $E(>) \cup \bar{E}$  contains exactly one perfect matching.

Now we use the following result of Heteyi [3] (see also [7, Problem 7.24]):

LEMMA 6 [3]. *If a graph on  $n$  vertices has exactly one perfect matching then it has at most  $n^2/4$  edges.*

This implies  $|E(\parallel)| \geq n(n-2)/4$ . As all pairs in  $E(\parallel)$  and  $E(>)$  have been asked by the algorithm, the lower bound follows.

A sorting algorithm can be given as follows: starting with an arbitrary element  $a_1$ , the only element  $a_2$  comparable to it can be found with  $n-1$  questions. Elements  $a_1$  and  $a_2$  can then be discarded. To find the next comparable pair,  $n-3$  questions are needed, etc. Altogether  $(n-1) + (n-3) + \dots + 1 = n^2/4$  questions are required.

**4. Recognition.** In this section we first determine the recognition complexity of Boolean algebras (this example will be used in the next section). Then we show that the minimal recognition complexity of orders with height 1 on  $n$  elements is asymptotically  $n \log_2 n$ . Finally we construct orders of height 4 with linear size essential set (implying that the proof for height 1 does not extend to arbitrary bounded height).

In the next section it is shown (Corollary 18) that

$$C^r(P_0) \leq w(P_0) \cdot 2n \log_2 n + 3nw(P_0)$$

and, if  $h(P_0) = 1$ , then

$$C^r(P_0) \leq 2e(P_0).$$

This means that the recognition complexity is determined for orders of bounded width or of height 1 up to a constant factor. (Note that we do not have an analogous statement for the sorting complexity of orders of height 1.)

THEOREM 7. *Let  $n = 2^m$  and  $B_n$  be the Boolean algebra on  $m$  atoms. Then for the recognition complexity of  $B_n$*

$$C^r(B_n) = \Theta(n \log_2 n).$$

LEMMA 8.  $e(B_n) = (n/2 + 1) \log_2 n$  (if  $m > 2$ ).

*Proof.* We use Lemma 4. Every element has degree  $m$  in the Hasse diagram. Critical pairs form a matching of atoms and co-atoms.  $\square$

LEMMA 9. *If  $P$  is an arbitrary ordered set on  $n$  elements, then a maximal (nonextendible) chain can be found in  $n \cdot \lceil \log_2 (h(P) + 2) \rceil$  steps.*

*Proof.* Assume we found a chain  $x_1 < \dots < x_k$ . Take an unused element  $y$  and start inserting  $y$  into the chain by binary search. If the search is successful,  $y$  is inserted in at most  $\lceil \log_2(k+1) \rceil$  steps. If  $y \parallel x_i$  for some  $1 \leq i \leq k$  then the chain cannot be extended by  $y$  and hence  $y$  can be excluded from later comparisons.  $\square$

LEMMA 10.  $C^s(B_n) \leq n(\log_2 n + 2 \lceil \log(\log n + 2) \rceil + 2)$ .

*Proof.* We describe a  $B_n$ -sorting algorithm.

Find a maximal chain  $x_0 < \dots < x_m$  in  $n \lceil \log(\log n + 2) \rceil$  steps. Then  $x_1$  is an atom. Compare every element to  $x_1$ ; those incomparable to  $x_1$  form a Boolean algebra with  $m-1$  atoms. Repeat the same process altogether  $m$  times. Finally the atoms  $y_1, \dots, y_m$  are identified and we used at most  $2n(1 + \lceil \log(\log n + 2) \rceil)$  steps.

Now compare every element with  $y_1, \dots, y_m$ . This determines the Boolean algebra since

$$u \geq v \text{ iff } v \geq y_i \text{ implies } u \geq y_i \text{ for every atom } y_i.$$

The last phase needs at most  $n \log_2 n$  steps.  $\square$

*Proof of Theorem 7.* The upper bound follows directly from Lemmas 1, 8 and 10. By fixing atoms  $b_1, \dots, b_m$  all the other elements are already determined. Thus

$$\begin{aligned} C^r(B_n) &\geq C^s(B_n) \geq \log_3 \#(B_n) \geq \log_3 \left( \binom{n}{m} (n-m)! \right) = n \log_3 n + o(n \log n) \\ &= \Omega(n \log_2 n). \end{aligned} \quad \square$$

We now turn to orders of height 1.

LEMMA 11. *For every  $\varepsilon > 0$  there exists an  $n_0$  such that if  $P_0$  is an ordered set on  $n$  elements with  $n \geq n_0$  and  $h(P_0) = 1$  then*

$$C^r(P_0) \geq (1 - \varepsilon)n \log_2 n.$$

For the proof of Lemma 11, we use the following lemma.

LEMMA 12. *For every  $\varepsilon > 0$  there exists an  $n_0$  such that if  $P_0$  is an ordered set on  $n$  elements with  $n \geq n_0$  and  $h(P_0) = 1$  then*

$$e(P_0) \geq (1 - \varepsilon)n \log_2 n.$$

*Proof.* Let  $P_0 = A \cup B$  where the elements in  $A$  are maximal and the elements in  $B$  are minimal (isolated elements are distributed arbitrarily). Assume  $|A| = l$ ,  $|B| = k$ ,  $k \leq \lfloor n/2 \rfloor$ . Then every pair  $(x, y)$  with  $x \in B$ ,  $y \in A$  belongs to  $E(P_0)$  (every such pair is either critical or covering). Consider now  $x, y \in A$ . Then  $x \parallel y$  and  $(x, y)$  or  $(y, x)$  is a critical pair iff  $I_{P_0}(x)$  and  $I_{P_0}(y)$  are comparable. If  $I_{P_0}(x) = I_{P_0}(y)$  then  $(x, y)$  is critical.

Let  $H_1, \dots, H_t$  ( $t = 2^k$ ) be the subsets of  $B$  and  $s_i$  ( $1 \leq i \leq t$ ) be the number of elements  $x$  in  $A$  with  $I_{P_0}(x) = H_i$ . Then there are

$$r = \sum_{i=1}^t \binom{s_i}{2}$$

pairs  $(x, y)$  with  $I_{P_0}(x) = I_{P_0}(y)$  ( $x, y \in A$ ,  $x \neq y$ ). As  $\sum_{i=1}^t s_i = l$ , the convexity of the function  $f(x) = x^2$  implies that the above sum is minimized if all the  $s_i$  are

$$\lfloor l/2^k \rfloor \text{ or } \lceil l/2^k \rceil.$$

Thus

$$r \geq \binom{\lfloor l/2^k \rfloor}{2} \cdot 2^k.$$

Hence

$$\begin{aligned} e(P_0) &\geq k \cdot l + \binom{\lfloor l/2^k \rfloor}{2} \cdot 2^k \\ &\geq k \cdot l + \binom{\lfloor n/2^{k+1} \rfloor}{2} \cdot 2^k \\ &\geq k \cdot l + \frac{(n-2^{k+1})(n-2^{k+2})}{8 \cdot 2^k}. \end{aligned}$$

If

$$(*) \quad n \geq 4 \cdot 2^{k+1}$$

then

$$e(P_0) \geq k \cdot l + \frac{1}{32} \cdot \frac{n^2}{2^k}.$$

We distinguish two cases. If

$$k \geq \log_2 n - \log_2 \log_2 n - 5$$

then

$$e(P_0) \geq (\log_2 n - \log_2 \log_2 n - 5)(n - \log_2 n) \geq (1 - \varepsilon)n \log_2 n$$

when  $n$  is sufficiently large. If

$$k < \log_2 n - \log_2 \log_2 n - 5$$

then  $(*)$  holds and

$$2^k < \frac{n}{32 \log_2 n}.$$

Thus

$$e(P_0) \geq \frac{1}{32} \cdot \frac{n^2}{2^k} > n \log_2 n. \quad \square$$

*Proof of Lemma 11.* Using Lemma 1, the lemma follows immediately from Lemma 12 above.  $\square$

LEMMA 13. *For every  $\varepsilon > 0$ , there exists an  $n_0$ , such that if  $n \geq n_0$  then there exists an order  $P_0$  on  $n$  elements with  $h(P_0) = 1$  and recognition complexity*

$$C_r(P_0) \leq (1 + \varepsilon)n \log_2 n.$$

The proof is given in the next section after Corollary 22.

THEOREM 14. *Let  $f(n) := \min \{C'(P_0) : |P_0| = n, h(P_0) = 1\}$ . Then*

$$\frac{f(n)}{n \log_2 n} \rightarrow 1 \quad \text{as } n \rightarrow \infty.$$

*Proof.* Follows directly from Lemmas 11 and 13.  $\square$

Lemma 12 might suggest that  $e(P_0) = \Omega(n \log_2 n)$  for orders with  $h(P) \leq k$  for every fixed  $k$ . The next theorem shows that this is not true.

THEOREM 15. *There exist orders of height 4 with  $e(P) = (4 + o(1))|P|$ .*

*Proof.* Take two disjoint sets  $A, B$  with  $|A| = |B| = 2m$  and define

$$\mathcal{H}_1 := \{\{x\} : x \in A \cup B\};$$

$$\mathcal{H}_2 := \{H : |H| = m \text{ and } H \subseteq A \text{ or } H \subseteq B\};$$

$$\mathcal{H}_3 := \{H : H = H_1 \cup H_2 \text{ with } |H_1| = |H_2| = m, H_1 \subseteq A, H_2 \subseteq B\};$$

$$\mathcal{H}_4 := \{H : |H| = 3m, (A \cup B) - H \in \mathcal{H}_2\};$$

$$\mathcal{H}_5 := \{A \cup B - \{x\} : x \in A \cup B\};$$

$$\mathcal{H} := \bigcup_{i=1}^5 \mathcal{H}_i;$$

$$P_{\mathcal{H}} := \mathcal{H} \text{ ordered by inclusion.}$$

Then clearly  $P_{\mathcal{H}}$  is of height 4 and has

$$8m + 4 \binom{2m}{m} + \binom{2m}{m}^2 = \binom{2m}{m}^2 (1 + o(1))$$

elements. Furthermore, the Hasse-diagram of  $P_{\mathcal{H}}$  contains

$$8m \binom{2m-1}{m-1} + 4 \binom{2m}{m}^2 = 4 \binom{2m}{m}^2 (1 + o(1))$$

edges. The first term counts edges incident to maximal and minimal elements. The second term counts edges incident to  $\mathcal{H}_3$ : each  $H \in \mathcal{H}_3$  contains exactly two sets in  $\mathcal{H}_2$  and is contained in exactly two sets from  $\mathcal{H}_4$ .

The critical pairs in  $P_{\mathcal{H}}$  are the pairs  $(A \cup B - \{x\}, \{x\})$  as in the case of the full Boolean algebra.

Thus

$$e(P) = 4 \binom{2m}{m}^2 (1 + o(1)),$$

proving the theorem.  $\square$

(Note that if we delete some elements of  $\mathcal{H}_3$  so that each set in  $\mathcal{H}_2$  and  $\mathcal{H}_4$  has still neighbors in  $\mathcal{H}_3$ , the necessary properties of  $P_{\mathcal{H}}$  are preserved. Thus for every  $n$  there exist height 4 orders with linear size essential set.)

To close this section we note that from the bound given at the beginning of § 3 it follows that

$$C^r(P_0) = \Omega(n \log_2 n)$$

if  $w(P_0) \leq n^{1-\varepsilon}$  for any  $\varepsilon > 0$ , suggesting problem 2 in the last section.

**5. Identification.** We describe some identification algorithms and give bounds for their performance.

The first two algorithms generalize sorting by insertion. Inserting an element  $x$  into an ordered set  $P'$  means to determine which elements are smaller, larger or incomparable to  $x$ .

Both algorithms A and B proceed in  $n$  stages on orders on  $\{a_1, \dots, a_n\}$ . After stage  $i$  the suborder  $P_i$  on  $\{a_1, \dots, a_i\}$  of  $P$  is determined. Stage  $i+1$  consists of inserting  $a_{i+1}$  into  $P_i$ . We only give the insertion methods.

*Insertion in algorithm A.* Choose a minimum chain cover  $C_1, \dots, C_{l_i}$  of  $P_i$  and insert  $a_{i+1}$  into each chain. Insertion into a chain is done by a straightforward modification of binary search.

To describe algorithm B we note that the elements of  $\{a_1, \dots, a_i\}$  that are smaller than  $a_{i+1}$  in  $P$  form an ideal  $I_i$  in  $P_i$  (resp. the elements which are larger form a filter  $F_i$  of  $P_i$ ).

*Insertion in algorithm B.* Determine  $I_i$  and  $F_i$  by algorithm C below.

Obviously, the two tasks are equivalent so we only formulate the algorithm to determine  $I_i$ .

An element  $z$  of  $P'$  is called a *central element* if for every  $z'$  in  $P'$

$$\left| \frac{N_{P'}(z)}{N_{P'}} - \frac{1}{2} \right| \leq \left| \frac{N_{P'}(z')}{N_{P'}} - \frac{1}{2} \right|.$$

Algorithm C below determines the ideal  $P'(x) = \{y: y \in P', y < x\}$  for an already identified order  $P'$  and a new element  $x$  recursively.

ALGORITHM C.

Given  $P'$  and  $x$  choose a central element  $z$  of  $P'$  and compare it with  $x$ .

If  $x > z$  then put  $P'(x) := I_{P'}(z) \cup \{z\} \cup P''(x)$ , where  $P'' = P' - (I_{P'}(z) \cup \{z\})$ .

If  $x \not> z$  then put  $P'(x) := P''(x)$ , where  $P'' = P' - (F_{P'}(z) \cup \{z\})$ .

We need the following result of Linial and Saks [6].

LEMMA 16 [6]. *If  $z$  is a central element then*

$$\delta_0 \leq \frac{N_{P'}(z)}{N_{P'}} \leq 1 - \delta_0,$$

where

$$\delta_0 = \frac{1}{4}(3 - \log_2 5) \approx 0.17.$$

THEOREM 17. *A and B are correct identification algorithms. For every ordered set  $P$  it holds that*

$$C_A(P) \leq 2nw(P)^{\frac{1}{2}} + \log_2(n + w(P)) - \log_2 w(P)$$

and

$$C_B(P) \leq 7.46n \log_2 N_P.$$

*Proof.* The correctness of A is obvious. The correctness of B follows from observing that if  $x > z$  then  $x > z'$  for every  $z' < z$  in  $P'$  and if  $x \not> z$  then  $x \not> z'$  for every  $z' > z$  in  $P'$ .

The bound for A holds since insertion into a chain of length  $m$  is easily seen to require at most  $2 \log_2(m+1) + 1$  steps and at each stage  $l_i \leq w(P)$  by Dilworth's theorem. (The computation uses the concavity of  $\log_2(x)$ .)

The bound for B is obtained as in [6] noting that the choice of a central element always reduces the number of ideals by a factor of  $(1 - \delta_0)$  at least, using Lemma 16 above.  $\square$

COROLLARY 18. For every order  $P_0$

$$C^s(P_0) \leq C^r(P_0) \leq w(P_0)2n \log_2 n + 3nw(P_0).$$

*Proof.* Immediate from Lemmas 1 and 2.  $\square$

Comparing A and B we note that A is simpler to compute. The bound of B is not worse than that of A but we do not know of any examples where it performs much better.

Now we describe another identification algorithm, efficient for orders of height

1. We use the following variables:

- $P'$  denotes the actual order obtained up to a certain stage of the algorithm (including the comparabilities and incomparabilities deduced);
- MAX (resp. MIN) is the set of elements that are maximal (resp. minimal) in  $P'$ ; (where now  $x$  is maximal (resp. minimal) if  $x \prec z$  for every  $z$  and  $x > y$  for some  $y$  (resp.  $x \succ z$  and  $x < y$  for some  $y$ ));
- ISO is the set of elements that are known to be isolated in  $P$  (thus  $x \in \text{ISO}$  iff it is already known to be incomparable to every element);
- $U$  is the set of "unprocessed" elements ( $U = P - (\text{MAX} \cup \text{MIN} \cup \text{ISO})$ ).

A pair  $(x, y)$  is called *undetermined* in  $P'$  if neither  $x \parallel y$ ,  $x > y$  nor  $x < y$  is in  $P'$ ; otherwise it is determined.

ALGORITHM D.

1.  $P' := \emptyset$ , MAX :=  $\emptyset$ , MIN :=  $\emptyset$ , ISO :=  $\emptyset$ ,  $U := \{a_1, \dots, a_n\}$ .
2. If  $U = \emptyset$  compare every undetermined pair  $x, y \in \text{MAX}$  subject to  $I_P(x) \subseteq I_P(y)$  and every undetermined pair  $x, y \in \text{MIN}$  subject to  $F_P(x) \subseteq F_P(y)$ , go to 6.
3. Choose a  $z \in U$  and compare it to every  $x$  subject to  $(z, x)$  is undetermined in  $P'$ . Update  $P'$ , MAX, MIN, ISO,  $U$ . If  $h(P') > 1$ , go to 5.
4. If  $|\text{MAX}| \leq |\text{MIN}|$  compare every  $x \in \text{MAX}$  with every  $y$  s.t.  $(x, y)$  is undetermined in  $P'$ . Update  $P'$ , MAX, MIN, ISO,  $U$ . If  $h(P') > 1$  go to 5. If  $|\text{MIN}| \leq |\text{MAX}|$  compare every  $x \in \text{MIN}$  with every  $y$  s.t.  $(x, y)$  is undetermined in  $P'$ . Update  $P'$ , MAX, MIN, ISO,  $U$ . If  $h(P') > 1$  go to 5, else go to 2.
5. Compare every undetermined pair.
6. Stop.

Informally, the algorithm proceeds as follows. Sets MAX, MIN and ISO contain elements already known to be maximal, minimal or isolated. If there is an element  $z$  not contained in any of them, it is compared to every element. To update necessary information, elements in the smaller of the two new sets MIN and MAX (or elements in both sets, if they are of equal size) are compared to every other element. If  $\text{MAX} \cup \text{MIN} \cup \text{ISO}$  contains every element, all remaining undetermined pairs are compared. If at any point the order turns out to have height  $> 1$ , all pairs are compared.

PROPOSITION 19. Algorithm D is a correct identification algorithm.

*Proof.* If  $h(P') > 1$  during an execution of steps 3 or 4 then every undetermined pair is compared in step 5. So the order is obviously identified. Otherwise the algorithm reaches the execution of step 2: after an execution of step 3  $z$  belongs to MAX, MIN or ISO. So  $|U|$  decreases.

If step 2 is reached then the elements in ISO are already compared with every other element. Furthermore, every pair  $(x, y)$  with  $x \in \text{MAX}$ ,  $y \in \text{MIN}$  is determined as can be seen from the previous execution of step 4. Thus the only undetermined pairs  $(x, y)$  must satisfy either  $x, y \in \text{MAX}$  or  $x, y \in \text{MIN}$  (we have  $P = \text{MAX} \cup \text{MIN} \cup$

ISO at that point). If  $x, y \in \text{MAX}$  (resp.  $x, y \in \text{MIN}$ ) and  $I_P(x)$  and  $I_P(y)$  are incomparable sets then  $(x, y)$  is determined as it must be true that  $x \parallel y$ . Therefore all undetermined pairs are compared in step 2 and the order is identified indeed.  $\square$

**THEOREM 20.** *If  $h(P) = 1$  then  $C_D(P) \leq 2e(P)$ .*

*Proof.* Let  $P$  be an order of height 1. Since every pair is compared at most once, it is sufficient to show that the number of nonessential pairs ever compared by the algorithm is at most  $e(P)$ .

The definition of critical pairs implies that every pair compared in step 2 is essential. (In fact, only pairs from the larger of the two sets MAX, MIN are compared at that step.) If in step 3 the element  $z$  turns out to be isolated, then every pair containing  $z$  is critical and in this case MAX and MIN are not modified.

Therefore, the algorithm can compare nonessential pairs  $(x, y)$  only during those executions of steps 3 and 4 where the element  $z$  turns out to be maximal or minimal. (Furthermore, for every such pair either both  $x, y$  are maximal or both are minimal.) An execution of steps 3 and 4, where  $z$  turns out to be maximal or minimal, is called a *phase*.

Let  $\text{MAX}_i, \text{MIN}_i, \text{ISO}_i$  and  $U_i$  denote the values of the sets MAX, MIN, ISO and  $U$  after phase  $i$ . Let  $z_i$  be the element selected in phase  $i$  and  $V_i$  be the set of elements comparable to  $z_i$ .  $\square$

**LEMMA 21.** *For every  $i$ :*

- (a) *if  $|\text{MAX}_i| \leq |\text{MIN}_i|$ , then after phase  $i$  every pair containing an element from  $\text{MAX}_i$  is determined;*
- (b) *if  $|\text{MIN}_i| \leq |\text{MAX}_i|$ , then after phase  $i$  every pair containing an element from  $\text{MIN}_i$  is determined.*

*Furthermore, there are sets  $\text{MAX}_i^*, \text{MIN}_i^*$  with the following properties:*

- (c)  $\text{MAX}_i^* \cup \text{MIN}_i^*$  covers all pairs  $(u, v)$  compared by the algorithm in phases  $1, \dots, i$  subject to  $\{u, v\} \cap \text{ISO}_i = \emptyset$ ;
- (d)  $|\text{MAX}_i^* \cup \text{MIN}_i^*| \leq 2 \min(|\text{MAX}_i|, |\text{MIN}_i|)$ ;
- (e)  $\text{MAX}_i^* \subseteq \text{MAX}_i, \text{MIN}_i^* \subseteq \text{MIN}_i$ ;
- (f) *if  $|\text{MAX}_i| \leq |\text{MIN}_i|$  then  $\text{MAX}_i^* = \text{MAX}_i$ ;*
- (g) *if  $|\text{MIN}_i| \leq |\text{MAX}_i|$  then  $\text{MIN}_i^* = \text{MIN}_i$ .*

*Proof.* By induction on  $i$ . For  $i = 0$  all sets are empty. We distinguish several cases.

*Case 1.*  $|\text{MAX}_i| < |\text{MIN}_i|$ .

*Case 1.1.*  $z_{i+1}$  is a maximal element.

Then in step 3 of phase  $i+1$ ,  $z_{i+1}$  is added to MAX and  $V_{i+1}$  is added to MIN. (It may be the case that  $V_{i+1} \subseteq \text{MIN}_i$ .)

*Case 1.1.1.*  $|\text{MAX}_i \cup \{z_{i+1}\}| < |\text{MIN}_i \cup V_{i+1}|$ .

Then using (a) by induction, no further comparisons are performed in step 4 of phase  $i+1$ . Putting  $\text{MAX}_{i+1}^* := \text{MAX}_i^* \cup \{z_{i+1}\}$ ,  $\text{MIN}_{i+1}^* := \text{MIN}_i^*$ , all conditions remain satisfied.

*Case 1.1.2.*  $|\text{MAX}_i \cup \{z_{i+1}\}| = |\text{MIN}_i \cup V_{i+1}|$ .

(This may occur only if  $V_{i+1} \subseteq \text{MIN}_i$ .) In this case, no further comparisons are performed in the first "if" of step 4 of phase  $i+1$ , but there may be comparisons involving elements from  $\text{MIN}_i$  in the second "if" of step 4 of phase  $i+1$ . However,  $\text{MIN}_{i+1} = \text{MIN}_i$ ,  $\text{MAX}_{i+1} \subseteq \text{MAX}_i \cup \{z_{i+1}\}$  and thus  $|\text{MIN}_{i+1}| \leq |\text{MAX}_{i+1}|$ , so  $\text{MAX}_{i+1}^* := \text{MAX}_i^* \cup \{z_{i+1}\}$ ,  $\text{MIN}_{i+1}^* := \text{MIN}_i$  satisfies the requirements.

*Case 1.2.*  $z_{i+1}$  is a minimal element.

By (a),  $V_{i+1} \cap \text{MAX}_i = \emptyset$ , otherwise  $z_{i+1}$  would be contained in  $\text{MIN}_i$ . So in step 3 of phase  $i+1$ , new maximal element(s) will be added to MAX.

*Case 1.2.1.*  $|\text{MAX}_i \cup V_{i+1}| < |\text{MIN}_i \cup \{z_{i+1}\}|$ .

Then in step 4 of phase  $i + 1$ , all undetermined pairs containing an element from  $V_{i+1}$  are compared and no other pairs. We can choose  $\text{MAX}_{i+1}^* := \text{MAX}_i^* \cup V_{i+1}$ ,  $\text{MIN}_{i+1}^* := \text{MIN}_i^* \cup \{z_{i+1}\}$ .

Case 1.2.2.  $|\text{MAX}_i \cup V_{i+1}| = |\text{MIN}_i \cup \{z_{i+1}\}|$ .

In the first "if" of step 4 of phase  $i + 1$ , all undetermined pairs involving an element from  $V_{i+1}$  are compared. Possibly all undetermined pairs involving an element from  $\text{MIN}_i$  are compared in the second "if" of step 4. We can choose  $\text{MAX}_{i+1}^* := \text{MAX}_i^* \cup V_{i+1}$ ,  $\text{MIN}_{i+1}^* := \text{MIN}_i \cup \{z_{i+1}\}$ .

Case 1.2.3.  $|\text{MAX}_i \cup V_{i+1}| > |\text{MIN}_i \cup \{z_{i+1}\}|$ .

Then in step 4 of phase  $i + 1$ , undetermined pairs containing an element from  $\text{MIN}_i$  are compared and we can choose  $\text{MAX}_{i+1}^* := \text{MAX}_i^*$ ,  $\text{MIN}_{i+1}^* := \text{MIN}_i \cup \{z_{i+1}\}$ .

Case 2.  $|\text{MAX}_i| = |\text{MIN}_i|$ .

Case 2.1.  $z_{i+1}$  is a maximal element.

By (b) of the induction hypothesis,  $V_{i+1} \cap \text{MIN} = \emptyset$  and we get two cases.

Case 2.1.1.  $|V_{i+1}| = 1$ .

Let  $V_{i+1} = \{z'_{i+1}\}$ , then all undetermined pairs involving  $z'_{i+1}$  are compared in the second "if" of step 4 of phase  $i + 1$ . We can choose  $\text{MAX}_{i+1}^* := \text{MAX}_i^* \cup \{z'_{i+1}\}$ ,  $\text{MIN}_{i+1}^* := \text{MIN}_i^* \cup \{z'_{i+1}\}$ .

Case 2.1.2.  $|V_{i+1}| > 1$ .

In this case no further comparisons are performed in step 4 of phase  $i + 1$  and we can put  $\text{MAX}_{i+1}^* := \text{MAX}_i^* \cup \{z_{i+1}\}$ ,  $\text{MIN}_{i+1}^* := \text{MIN}_i^*$ .

The remaining cases require analogous arguments, so we give the definitions of the sets  $\text{MAX}_{i+1}^*$ ,  $\text{MIN}_{i+1}^*$  only.

Case 2.2.  $z_{i+1}$  is a minimal element.

Case 2.2.1.  $|V_{i+1}| = 1$ .

$$\text{MAX}_{i+1}^* := \text{MAX}_i^* \cup \{z'_{i+1}\}, \quad \text{MIN}_{i+1}^* := \text{MIN}_i^* \cup \{z_{i+1}\}.$$

Case 2.2.2.  $|V_{i+1}| > 1$ .

$$\text{MAX}_{i+1}^* := \text{MAX}_i^*, \quad \text{MIN}_{i+1}^* := \text{MIN}_i^* \cup \{z_{i+1}\}.$$

Case 3.  $|\text{MAX}_i| > |\text{MIN}_i|$ .

(Note that step 4 is not symmetric in MAX and MIN.)

Case 3.1.  $z_{i+1}$  is a maximal element.

Case 3.1.1.  $|\text{MAX}_i \cup \{z_{i+1}\}| > |\text{MIN}_i \cup V_{i+1}|$ .

$$\text{MAX}_{i+1}^* := \text{MAX}_i^* \cup \{z_{i+1}\}, \quad \text{MIN}_{i+1}^* := \text{MIN}_i^* \cup V_{i+1}.$$

Case 3.1.2.  $|\text{MAX}_i \cup \{z_{i+1}\}| = |\text{MIN}_i \cup V_{i+1}|$ .

$$\text{MAX}_{i+1}^* := \text{MAX}_i \cup \{z_{i+1}\}, \quad \text{MIN}_{i+1}^* := \text{MIN}_i^* \cup V_{i+1}.$$

Case 3.1.3.  $|\text{MAX}_i \cup \{z_{i+1}\}| < |\text{MIN}_i \cup V_{i+1}|$ .

$$\text{MAX}_{i+1}^* := \text{MAX}_i \cup \{z_{i+1}\}, \quad \text{MIN}_{i+1}^* := \text{MIN}_i^*.$$

Case 3.2.  $z_{i+1}$  is a minimal element.

Case 3.2.1.  $|\text{MAX}_i \cup V_{i+1}| > |\text{MIN}_i \cup \{z_{i+1}\}|$ .

$$\text{MAX}_{i+1}^* := \text{MAX}_i^*, \quad \text{MIN}_{i+1}^* := \text{MIN}_i^* \cup \{z_{i+1}\}.$$

Case 3.2.2.  $|\text{MAX}_i \cup V_{i+1}| = |\text{MIN}_i \cup \{z_{i+1}\}|$ .

$$\text{MAX}_{i+1}^* := \text{MAX}_i, \quad \text{MIN}_{i+1}^* := \text{MIN}_i^* \cup \{z_{i+1}\}.$$

Returning to the proof of Theorem 20, let  $i$  be the last phase,  $\text{MAX}^* := \text{MAX}_i^*$  and  $\text{MIN}^* := \text{MIN}_i^*$ . The rest of the argument is symmetric in  $\text{MAX}$  and  $\text{MIN}$ , so assume  $|\text{MAX}| \leq |\text{MIN}|$ . Then Lemma 21 implies  $\text{MAX}^* = \text{MAX}$  and as  $|\text{MAX}^*| + |\text{MIN}^*| \leq 2|\text{MAX}|$ , also  $|\text{MIN}^*| \leq |\text{MAX}^*|$  holds. All nonessential pairs compared by the algorithm are either pairs of maximal elements or pairs of minimal elements covered by  $\text{MIN}^*$ . So their number is at most

$$\begin{aligned} & \binom{\text{MAX}}{2} + \left( \binom{\text{MIN}}{2} - \binom{\text{MIN} - \text{MIN}^*}{2} \right) \\ & \leq \binom{\text{MAX}}{2} + \binom{\text{MIN}}{2} - \binom{\text{MIN} - \text{MAX}}{2} = \text{MAX} \cdot (\text{MIN} - 1) \\ & < \text{MAX} \cdot \text{MIN} \leq e(P). \quad \square \end{aligned}$$

(We remark that the example of a matching shows that the factor 2 in the bound is sharp for the algorithm.)

**COROLLARY 22.** *If  $h(P) = 1$  then  $C_D(P) \leq 2 \cdot C^r(P)$  and  $C^r(P) \leq 2 \cdot e(P)$ .*

*Proof.* Immediate from Lemmas 1 and 2.  $\square$

Now we prove Lemma 13 of previous section.

*Proof of Lemma 13.* We construct the order  $P_0$  as follows:  $P_0$  has  $\lceil (1 + \varepsilon) \log_2 n \rceil$  maximal elements and  $n - \lceil (1 + \varepsilon) \log_2 n \rceil$  minimal elements. Each minimal element has  $\lceil (1 + \varepsilon)/2 \cdot \log_2 n \rceil$  upper covers so that the set of upper covers is different for each minimal element. This condition is easy to satisfy as there are

$$\binom{\lceil (1 + \varepsilon) \log_2 n \rceil}{\lceil \frac{1 + \varepsilon}{2} \log_2 n \rceil} \geq c_\varepsilon \cdot \frac{n^{1 + \varepsilon}}{\sqrt{\log_2 n}}$$

choices. Furthermore, it can also be required that the set of lower covers be different for each maximal element and each be of size between, e.g.,  $n/4$  and  $3n/4$ . Then

$$e(P_0) = \lceil (1 + \varepsilon) \log_2 n \rceil (n - \lceil (1 + \varepsilon) \log_2 n \rceil).$$

Thus a  $2(1 + \varepsilon)n \log_2 n$  recognition algorithm for  $P_0$  is given by running  $D$  for  $C_D(P_0)$  steps. (If the order is not identified up to this point, it cannot be isomorphic to  $P_0$ .)

A slight modification gives the smaller upper bound. A pair  $x > y$  can be found in  $n - 1$  steps;  $y$  can be compared to everything in at most  $(n - 2)$  steps. Then  $y$  must have  $\lceil (1 + \varepsilon)/2 \log_2 n \rceil$  upper covers (otherwise  $P \neq P_0$ ). Comparing the upper covers of  $y$  to everything we get every minimal element except at most one. Comparing the remaining at most  $\lceil (1 + \varepsilon)/2 \log_2 n \rceil + 1$  elements to everything,  $P$  is identified whenever  $P \approx P_0$ .  $\square$

Finally we point out that algorithms B and D are not sufficient to produce an optimal algorithm. Let algorithm  $E$  be obtained by merging B and D (in the sense of the proof of Lemma 3).

Then for the Boolean algebras  $B_n$  we have

$$C^r(B_n) = O(n \log_2 n)$$

from Theorem 7 and

$$C_E(B_n) = \Omega\left(\frac{n^2}{\log_2 n}\right).$$

Indeed, if the antichain of size

$$\binom{m}{m/2} = \Omega\left(\frac{m}{\sqrt{\log_2 n}}\right)$$

is examined first then every pair is compared in order to perform the insertion in B, and D is of no help in this case.

**6. Some open problems.** (1) It would be interesting to find good bounds for the sorting complexity in general.

(2) The special cases discussed in § 4 suggest that perhaps the recognition complexity is  $\Omega(n \log n)$  for every order  $P_0$ .

(3) Is it true that there is no optimal identification algorithm in the strong sense of optimality defined here (cf. Lemma 3)? Are there other measures of complexity for identification algorithms?

(4) The definition of sorting and recognition problems introduced here is actually a special case of a more general one. One can consider sorting and recognition problems for arbitrary classes of orders (in this paper we considered classes that consist of isomorphic copies of a fixed order  $P_0$ ). It seems reasonable to assume that these classes are closed under isomorphism, i.e., they are *ordered set properties*. In this framework the identification problem is just the sorting problem with respect to the class of all orders. The recognition problems arising this way are natural ordered set versions of analogous problems concerning graphs (see Bollobás [1, Chap. 8] for an excellent survey). The ordered set properties are substantially different as there are many “easy” properties with complexity  $o(n^2)$  like having a unique maximal element, being a linear order, having bounded width or setup number. Nevertheless it is not difficult to give  $\Omega(n^2)$  lower bounds, e.g., for connectivity, bounded height, being a lattice, an interval order, etc. What properties can be proved to be “elusive,” i.e., to have complexity  $\Omega(n^2)$ ?

**Acknowledgment.** We are grateful to M. Aigner for his remarks (in particular for pointing out the upper bound in Theorem 5) and to a referee for suggesting a simplification of the proof of Theorem 20.

*Note added in proof.* There are some further results concerning problems 2 and 3. It was shown that interval orders have recognition complexity  $\Omega(n \log n)$  and there is an optimal identification algorithm for semiorders (U. Faigle and Gy. Turán, *The complexity of interval orders and semiorders*, Discrete Math., to appear). It was also shown that almost all orders have recognition complexity  $\Omega(n \log n)$  (H. J. Prömel, *Counting unlabeled structures*, J. Combin. Theory Ser. A, 44 (1987), pp. 83–93). Recently M. Saks solved problem 2. In general, he showed that every  $n$  element order has recognition complexity at least  $\frac{2}{3}n \log_2 n + o(n \log n)$  (M. Saks, *Recognition problems for transitive relations*, to be published).

## EXPECTED PERFORMANCE OF $m$ -SOLUTION BACKTRACKING\*

DAVID M. NICOL†

**Abstract.** This paper derives upper bounds on the expected number of search tree nodes visited during an  $m$ -solution backtracking search, a search which terminates after some preselected number  $m$  problem solutions are found. The search behavior is assumed to have a general probabilistic structure. Our results are stated in terms of node expansion and contraction. A visited search tree node is said to be *expanding* if the mean number of its children visited by the search exceeds 1, and is *contracting* otherwise. We show that if every node expands, or if every node contracts, then the number of search tree nodes visited by a search has an upper bound which is linear in the depth of the tree, in the mean number of children a node has, and in the number of solutions sought. Bounds linear in the depth of the tree are derived for the case where the upper portion of the tree contracts while the lower portion expands. We derive linear bounds for some special cases of an expanding upper portion and contracting lower portion; however, in the general case we have exponentially complex bounds. While previous analyses of 1-solution backtracking have concluded that the expected performance is always linear in the tree depth, our model allows super-linear expected performance. By generalizing previous work in the expected behavior of backtracking, we are better able to identify classes of trees which can be searched in linear expected time.

**Key words.** random search, random trees, backtracking, depth-first search

**AMS(MOS) subject classifications.** 68C25, 68E05

**1. Introduction.** Backtracking (or depth-first search) is a powerful tool for quickly finding solutions to certain types of problems whose potential solution space is huge. Such a search may terminate upon finding one solution, or may attempt to discover all solutions. We will study  $m$ -solution searches, which terminate once a preselected number  $m$  solutions are discovered (or when it is determined that fewer than  $m$  solutions exist). Backtracking is used to solve problems which seek an  $n$ -vector  $\langle X_1, \dots, X_n \rangle$  where each  $X_i$  is an element of a finite set  $S_i$ , such that some condition  $C(\langle X_1, \dots, X_n \rangle)$  is satisfied. For example, backtracking is often used to solve the  $n$ -Queen's problem. In this case, each vector coordinate position represents a chess board column,  $X_i = j$  means that a queen is placed in column  $i$  and row  $j$ , and the condition  $C$  is that no queen attacks any other. A backtracking search exploits necessary subconditions for a solution. The necessary subconditions  $\{C_j\}$  are chosen so that if  $C_j(\langle X_1, \dots, X_j \rangle)$  is satisfied, then  $C_i(\langle X_1, \dots, X_i \rangle)$  is satisfied for  $i$  such that  $1 \leq i < j$ . Given a candidate partial solution  $\langle X_1, \dots, X_k \rangle$ , the search checks condition  $C_k(\langle X_1, \dots, X_k \rangle)$ . If that condition is satisfied, the partial solution is extended to  $\langle X_1, \dots, X_{k+1} \rangle$  for some  $X_{k+1} \in S_{k+1}$ , and the extended candidate partial solution is tested against  $C_{k+1}$ . If on the other hand  $C_k(\langle X_1, \dots, X_k \rangle)$  is not satisfied, then an alternate value  $\hat{X}_k \in S_k$  which has not yet been appended to  $\langle X_1, \dots, X_{k-1} \rangle$  (if one exists) is chosen, and the partial solution  $\langle X_1, \dots, X_{k-1}, \hat{X}_k \rangle$  is checked against  $C_k$ . If all elements of  $S_k$  have already been appended to  $\langle X_1, \dots, X_{k-1} \rangle$  and have failed to satisfy  $C_k$ , the algorithm "backtracks" and attempts new extensions to

$\langle X_1, \dots, X_{k-2} \rangle$ . Most basic algorithm texts discuss the details of backtracking, for example, see [5].

The search space of a backtracking search can be represented by a tree. A tree node is uniquely identified by the path between it and the tree root; a path of length  $j$  identifies a unique partial solution with  $j$  coordinate assignments; a node's set of children represent all possible extensions to the partial solution represented by the node. Leaf nodes represent potential full solutions. Viewed in this way, backtracking is a depth-first search of the tree with pruning. Pruning occurs if a tested partial solution fails to satisfy the appropriate condition: the entire subtree rooted in the failing node is pruned from the search space, and the search "backtracks." Backtracking's success lies in this (problem-dependent) ability to dynamically prune large portions of the search tree. However, backtracking's worst case performance is exponential in the size of the problem; nevertheless, many problems do not exhibit this worst case performance. A more meaningful measure is the *expected* performance. The usual method for determining the expected or average performance of an algorithm is to assume that problem parameters are random, or that the outcome of a decision is random (for examples, see [6]). One way of introducing randomness into backtracking is to suppose that the success or failure of a visited node is random. This approach is adopted by [12], and is the one we will explore. While a probabilistic model may not describe any particular backtracking search very accurately, it is useful for determining performance as a function of general search space characteristics. As pointed out in [7], such a model can also reveal the sensitivity of performance to the search space parameters.

A number of researchers have considered the expected performance of backtracking, or related problems. Extensive analysis of branch and bound methods on random search trees is found in [11]. That work employs the theory of branching processes [4], which provides a very uniform probability structure for the search tree. In [7], the problem of finding a least cost path in a random binary tree is considered; this analysis also employs the theory of branching processes. Backtracking searches which seek all solutions to random CNF satisfiability problems are considered in [2]. The randomness introduced to the search model there is intimately related to the problem type (CNF satisfiability), allowing a tight analysis of that problem. Close approximations for the mean and variance of the number of nodes visited in a depth-first search which terminates with one solution are derived in [12]. Our search model closely resembles theirs, but our approach is quite different. The analysis in [12] assumes that the search tree is binary, and that the randomness in node evaluation outcomes is uniform across the entire tree; every visited node has probability  $p$  of being a successful partial solution. The search tree has an extremely uniform structure under these assumptions, allowing [12] to identify recurrence relations and closely approximate their solution. Renewal theory is employed in [14] to derive approximate expected bounds on memory requirements for general branch-and-bound methods.

All of the research mentioned above introduces randomness in a very uniform way. This is accepted practice and is usually required for analytic tractability. For the purposes of general behavioral description, uniform randomness is adequate, unless the model deviates strongly from known behavior. For backtracking, this is exactly the case. Intuition suggests that in general, the larger the size of the partial solution, the harder it will be to extend that solution. Yet under the assumption of uniform randomness, the likelihood of pruning a node and its subtree is the same anywhere in the search tree. Furthermore, the assumption of uniform randomness has led to surprising results. Both [12] and [11] derive bounds on the expected number of search nodes visited during a 1-solution search; these bounds are linear in the tree depth

regardless of the probability parameter  $p$ . Under their modeling assumptions, we must conclude that the average number of nodes visited by a 1-solution search is always linear in the depth of the search tree.

Uniform randomness does not accurately model our expectations about pruning behavior; furthermore, its assumption produces results whose strength is counter-intuitive. These observations have led us to consider a more general probabilistic model of backtracking's behavior. In doing so, we reaffirm much of the strength of the results derived in [12] and [11]. However, unlike the models in [12] and [11], our model allows super-linear complexity under the normally anticipated behavior of a backtracking search. By generalizing the probabilities which model searching behavior, we are thus better able to classify searches which will have linear expected performance. We will allow a general probability structure on a tree with depth  $D$ , whose nodes have random numbers of children. Defining natural notions of node expansion and contraction, we will show that if all nodes expand, or if all nodes contract, then there exist linear upper bounds on the number of nodes visited in a backtracking search for  $m$  solutions. These bounds are derived in terms of the probability structure, the number of solutions sought and the depth of the search tree. We then derive linear upper bounds for any search tree whose upper portion has all contracting nodes, and whose lower portion has all expanding nodes. We also derive linear upper bounds for trees having an expanding upper portion and contracting lower portion, where the degree of contraction is bounded in a depth independent way. If the degree of contraction cannot be bounded, we show that super-linear complexity can be expected.

**2. Model definition.** A backtracking search is a depth-first search, with the provision that it does not traverse any subtree rooted in a failed node. We model the decision to prune by supposing that every explored node has an *extension probability* of representing a successful partial solution. The extension probability for a leaf node is the probability that the leaf node represents a full solution. We also assume that a given visited node's success is independent of any other node's at the same depth. It is important to observe that this probability is conditioned on the event of the node being visited by the search. Given that a node is successful, we suppose that it has a random number of children, and that the mean number of children is  $n$  (this assumption is similar to one in [11]). We allow each node's distribution of children to be unique, but assume that each distribution is "new better than used in expectation," or NBUE [10]. A nonnegative random variable  $Y$  is NBUE if  $E[Y - a | Y > a] \leq E[Y]$  for all  $a \geq 0$ . Common examples of continuous NBUE distributions are hypo-exponentials, normals and certain classes of gamma and Weibull distributions. An appropriately constructed discrete approximation to a continuous NBUE random variable will be NBUE, and the degenerate constant random variable is NBUE. Treating  $Y$  as a life-time of some object,  $Y$  is *not* NBUE if a used object's expected remaining life-time after living  $a > 0$  time units is larger than its unconditional expectation  $E[X]$ ; mixtures of exponential random variables fall into this class [10]. We say that a node with extension probability  $p$  *expands* if  $p > 1/n$ , because given that the node is visited, the expected number of its children which are visited is

$$pn + (1 - p) \cdot 0 > 1.$$

We say that a search tree is expanding if each of its nodes expands. Likewise, if  $p \leq 1/n$ , we say that the node contracts; we say that the search tree contracts if every one of its nodes contracts.

Figures 1, 2 and 3 illustrate some of these ideas. Figure 1 depicts a small search tree, where each node is labeled with its extension probability. Figure 2 shows a

FIG. 1. Search tree with extension probabilities.

FIG. 2. Realization of full search, two solutions.

FIG. 3. Realization of 1-solution search.

possible realization of the nodes searched, where the entire left subtree is traversed, but the right child of the root fails, so that none of its children are visited. Assuming that  $n = 2$ , we see that the root's left child is expanding ( $0.6 > \frac{1}{2}$ ) while the root's right child is contracting ( $0.4 < \frac{1}{2}$ ). It is important to note that the definition of expanding and contracting nodes are in terms of the *mean* value  $n$ , not the number of children actually realized by a parent. Figure 3 depicts the nodes searched during a 1-solution search which discovers that the second leaf node visited is a successful full solution.

We will alternately consider two types of backtracking searches. A *full* search is one which terminates only after all solutions have been found. We let  $N$  denote the

random number of nodes visited during a full search, we also let  $N_j$  denote the random number of nodes visited at depth  $j$ . For many problems, we are satisfied with finding only one solution, and may substantially reduce the number of nodes visited by stopping with the first solution. We call a search which terminates with the first solution (or exhausts the search tree) a 1-solution search. Let  $T$  denote the random number of nodes visited during a 1-solution search, and let  $T_j$  denote the random number of nodes visited at depth  $j$  during a 1-solution search. Our approach also supports generalization of 1-solution searching, an  $m$ -solution search. An  $m$ -solution search might be used in a situation where it is too costly to search for all solutions, but a sizable sampling of solutions is desired. The random variables  $T(m)$  and  $T_j(m)$  are the immediate  $m$ -solution analogues to  $T$  and  $T_j$ . We will use  $E[N]$  and  $E[T(m)]$  as measures of backtracking's average complexity. As noted in [11] and [12], the average *time* complexity of searching may be larger, being dependent on the complexity of the evaluation of the necessary subconditions.

Our results are stated in terms of bounds on the maximal and minimal extension probabilities among all search tree nodes. We let  $p_j^{\max}$  denote the maximum extension probability among all nodes at depth  $j$ ; we similarly define the depth-dependent minimum  $p_j^{\min}$ . For every depth  $J$  (recall that the tree has depth  $D$ ) we define

$$p_{+J}^{\max} = \max_{1 \leq j \leq J} \{p_j^{\max}\}, \quad p_{+J}^{\min} = \min_{1 \leq j \leq J} \{p_j^{\min}\},$$

$$p_{J+}^{\max} = \max_{J < j \leq D} \{p_j^{\max}\}, \quad p_{J+}^{\min} = \min_{J < j \leq D} \{p_j^{\min}\},$$

and finally,  $p^{\min} = p_{+D}^{\min}$  and  $p^{\max} = p_{+D}^{\max}$ . Table 1 summarizes our model definitions.

Under our model assumptions, it is possible to find extension probabilities which lead to exponentially complex 1-solution searches. Suppose that the extension probabilities for all nodes at depths  $1, 2, \dots, D-1$  are equal to 1, and that the solution probabilities at depth  $D$  are all equal to 0. The 1-solution search will never find a solution, but will visit every node in the search tree. This degenerate case clearly has complexity which grows exponentially in the depth of the tree. While this example is not likely to represent any interesting problem particularly well, it does illustrate that the complexity of a 1-solution search can be high. By identifying classes of trees which yield good expected complexity, we are better able to identify classes of trees which do not.

TABLE 1  
*Model parameters.*

Notation	Definition
$D$	Depth of search tree
$N$	Number of nodes visited in full search
$m$	Number of solutions sought
$T(m)$	Number of nodes visited in $m$ -solution search
$n$	Mean number of children of successful node
$p_{+J}^{\max}$	Maximum extension probability at depths up to $J$
$p_{+J}^{\min}$	Minimum extension probability at depths up to $J$
$p_{J+}^{\max}$	Maximum extension probability at depths greater than $J$
$p_{J+}^{\min}$	Minimum extension probability at depths greater than $J$
$p^{\max}$	Maximum extension probability among all nodes
$p^{\min}$	Minimum extension probability among all nodes

**3. Summary of results.** Our analysis will consider four classes of search trees. We first treat the class of contracting trees ( $p^{\max} \leq 1/n$ ), and show by Lemma 1 that  $E[N] \leq nD$ . We then examine the class of expanding trees ( $p^{\min} > 1/n$ ), and give in Lemma 2 an upper bound on  $E[T(m)]$ . This bound is linear in  $D$ , in  $m$ , and in  $n$ . Together, Lemmas 1 and 2 address the model assumptions considered in [12]. While our bounds are not as tight as the results in [12], they are considerably more general. Lemmas 3, 4 and 5 treat trees with mixtures of expanding and contracting nodes. In Lemma 3 we give a bound which is marginally linear in  $D$ ,  $m$  and  $n$  for the situation where an upper portion (near the root) of the tree has contracting nodes, and the lower portion has expanding nodes. This indication of good performance is not surprising; contracting nodes near the root tend to prune large portions of the tree. These results serve as analytic vindication of the search rearrangement strategies studied in [1], [3] and [13] (a formal analysis of average behavior under this strategy for the CNF satisfiability problem is reported in [9]). Search rearrangement strives to reorder the sequence of variable assignments so as to increase the likelihood of pruning at shallow levels of the search tree. Finally, Lemmas 4 and 5 treat intuitively appealing situations where it is relatively easier to extend small partial solutions than it is to extend larger partial solutions. We can model this phenomenon with search trees having an expanding upper portion and contracting lower portion. When the extent and degree of contraction is bounded independently of the tree depth, the bound on  $E[T(m)]$  is marginally linear in  $D$ , polynomial in  $n$  and exponential in the extent of contraction. Thus we see that our general model allows linear performance in a situation we expect to encounter in practice, but which is not well described by previous average performance analysis. Furthermore, the constraints required to achieve this linearity are a guide towards identifying trees which do not have linear expected performance. We discuss that issue further in § 7.

Our results are stated below. Derivations are given in following sections.

LEMMA 1 (Contracting Trees). *If  $p^{\max} \leq 1/n$ , then  $E[N] < nD$ .  $\square$*

LEMMA 2 (Expanding Trees). *If there is an  $\varepsilon > 1$  such that  $p^{\min} \geq \varepsilon/n$ , then*

$$E[T(m)] < \frac{n(D+m-1)}{\varepsilon-1}. \quad \square$$

LEMMA 3 (Contracting/Expanding Trees). *If there is an  $I \geq 1$  and  $\varepsilon > 1$  such that  $p_{+I}^{\max} \leq 1/n$  and  $p_{I+}^{\min} \geq \varepsilon/n$ , then*

$$E[T(m)] < In + \frac{n(D-I+m-1)}{\varepsilon-1}. \quad \square$$

LEMMA 4 (Expanding/Contracting Trees). *If there is a  $\delta > 1$  and  $J \geq 1$  such that  $p_{+(D-J)}^{\max} \leq \delta/n$  and  $p_{(D-J)+}^{\max} \leq 1/n$ , then*

$$E[N] \leq n \left( \frac{\delta^{D-J}-1}{\delta-1} \right) + nJ\delta^{D-J-1}. \quad \square$$

LEMMA 5 (Expanding/Contracting Trees). *If there are  $\varepsilon > 1$ , and  $J, C \geq 1$  such that  $p_{+(D-J)}^{\min} \geq \varepsilon/n$  and  $1/Cn \leq p_{(D-J)+}^{\min} \leq 1/n$ , then*

$$E[T(m)] < \frac{m(Cn)^{J+1} + n(D-J-1)}{\varepsilon-1} + m(Cn)^{J+1}nJ. \quad \square$$

**4. Contracting trees (Lemma 1).** We first derive an upper bound on  $E[N]$ , the expected number of nodes visited during a full search. Recalling that  $N_j$  is the random

number of nodes visited at depth  $j$  during a full search, note that

$$E[N] = \sum_{j=1}^D E[N_j].$$

In order to calculate  $E[N_j]$ , observe that if  $N_{j-1} = s$  for a given full search, then

$$(1) \quad E[N_j | N_{j-1} = s] \leq sp^{\max} n.$$

This follows because every visited node has an extension probability less than  $p^{\max}$ , and a successful node has  $n$  children on the average. Taking the expectation with respect to  $N_{j-1}$ ,

$$E[N_j] \leq E[N_{j-1}]p^{\max} n.$$

In a full search, every node at depth 1 is visited, so  $E[N_1] = n$ . From inequality (1),

$$E[N_2] \leq n^2 p^{\max},$$

and in general,

$$(2) \quad E[N_j] \leq n^j (p^{\max})^{j-1}.$$

The expected number of nodes visited during a full search is thus bounded from above by

$$E[N] \leq \sum_{j=1}^D n^j (p^{\max})^{j-1}.$$

Recalling the identity [8]

$$\sum_{j=0}^k r^j = \frac{1-r^{k+1}}{1-r} \quad \text{for } r \neq 1,$$

we see that

$$(3) \quad E[N] \leq \begin{cases} nD & \text{if } np^{\max} = 1, \\ n \frac{1-(np^{\max})^D}{1-np^{\max}} & \text{otherwise.} \end{cases}$$

It is also clear from (2) that our bound is an increasing function of  $p^{\max}$ .

A contracting search tree is characterized by  $p^{\max} \leq 1/n$ . Thus Lemma 1 follows from (3) above.

LEMMA 1. *If  $p^{\max} \leq 1/n$ , then*

$$E[N] \leq nD. \quad \square$$

When the extension probabilities are all small enough, the total number of nodes visited in a full search (and hence any search) is bounded from above by  $nD$ . This bound is marginally linear in  $n$  and in  $D$ . The key reason for this linearity is the high probability of large subtrees being pruned as a result of extension failures at shallow depths.

**5. Expanding trees (Lemma 2).** We next consider an expanding search tree. Inequality (3) provides an exponentially large upper bound on  $E[N]$  when  $np^{\max} > 1$ ;

furthermore, this bound is tight if all extension probabilities are identical. However, the number of nodes visited in an  $m$ -solution search may be substantially smaller than that of a full search. Under the assumption at  $p^{\min} \geq \varepsilon/n$  for some  $\varepsilon > 1$ , we will next show that the number of nodes visited by an  $m$ -solution search is bounded above by a function which is marginally linear in  $D$ , in  $n$  and in  $m$ .

The tactic we adopt in deriving this bound is to embed the search tree into an infinitely wide tree, and then analyze an  $m$ -solution search on the infinite tree from the bottom up. An  $m$ -solution search on an infinite tree with expanding nodes will always find  $m$  solutions; by analyzing a search there we avoid having to condition on whether or not exactly  $m$ -solutions are discovered in the original search tree. The bottom up analysis is supported by two basic observations. One is that we can bound  $E[T_D(m)]$  without worrying about the behavior of the search at depths other than  $D$ . The second observation is that in an  $m$ -solution search of the infinite tree, the knowledge of how many nodes have been visited at depth  $j+1$  allows us to bound the number of nodes which have been visited at depth  $j$ . The bound on  $E[T_D(m)]$  allows us to quantify the bound on  $E[T_{D-1}(m)]$ ; repeating this back-substitution we can quantify  $E[T_j(m)]$  for each  $j$ , and sum these bounds to bound  $E[T(m)]$ .

We embed an expanding search tree into an infinite tree as follows. If the search tree root has  $K$  children, we may view the tree as a collection of  $K$  major subtrees  $B_1, B_2, \dots, B_K$ , each being rooted in a child of the search tree root. Now consider a tree with depth  $D$  consisting of a root and a countably infinite number of major subtrees, each with depth  $D-1$ . We assume that for  $j=1, 2, \dots, K$ , the  $j$ th major subtree in the infinite search tree is probabilistically identical to the  $j$ th major subtree in the finite search: their corresponding nodes have identical extension probabilities. Subtrees  $K+1, K+2, \dots$ , in the infinite tree are taken to be arbitrary expanding subtrees. The infinite tree so constructed does not correspond to an expansion of a given problem; rather, we use its probabilistic properties as a convenient tool. We can couple the behavior of a search on the original tree with a search on the infinite tree by requiring the evaluation outcomes in the original tree to be identical to the infinite tree's outcomes in its first  $K$  subtrees. Thus the tree expansions in the original tree and in the first  $K$  major subtrees of the infinite tree are taken to be identical. If exactly  $m$  solutions are discovered in the original tree then exactly  $m$  "solutions" are discovered in the first  $K$  subtrees of the infinite tree; if fewer than  $m$  solutions are discovered in the original tree, its search will terminate while the search on the infinite tree continues on major subtrees  $K+1, K+2, \dots$ , until  $m$  "solutions" are found. From this definition it is clear that for every search, at every depth  $j$ , the number of nodes visited in the infinite tree at depth  $j$  is an upper bound on the number of nodes visited by the search in the finite tree. We will therefore bound  $E[T(m)]$  by bounding the expected number of nodes visited in an  $m$ -solution search of the infinite tree. At the risk of abusing our notation, we will now let  $T_j(m)$  denote the number of nodes visited at depth  $j$  in an  $m$ -solution search of the infinite tree;  $T(m)$  is similarly redefined. Any upper bounds we derive on the infinite tree apply equally well to the finite problem tree. Our notational modification is understood to apply only to this section. For the remainder of this section, we will refer only to searches of the infinite tree; consideration of this tree is also limited to this section.

We initially consider the behavior of an  $m$ -solution search at the tree's deepest level  $D$ . Any time a leaf node is visited it is found to be a solution with probability no less than  $p^{\min}$ , it is otherwise found to fail. Because of the independence in leaf node evaluation outcomes, we can view the search behavior at depth  $D$  as a sequence of independent (but not necessarily identical) Bernoulli trials [10], each with success

probability greater than or equal to  $p^{\min}$ . If the success probabilities at each node visit were identically  $p^{\min}$ , the number of visits to depth  $D$  required to find a solution would be a geometric random variable with mean  $1/p^{\min}$ . Because each visit to depth  $D$  has probability of success at least as large as  $p^{\min}$ ,  $1/p^{\min}$  is an upper bound on the mean number of visits required to find one solution;  $m/p^{\min}$  bounds the mean number of visits required to find  $m$  solutions. Recalling that  $p^{\min} \geq \varepsilon/n$  by definition of an expanding tree, we have

$$(4) \quad E[T_D(m)] \leq \frac{m}{p^{\min}} \leq \frac{mn}{\varepsilon}.$$

We next derive upper bounds on  $E[T_j(m)]$  for each  $j$ , bounding  $E[T_j(m)]$  in terms of  $E[T_{j+1}(m)]$ . Following that, we will use (4) to quantify these upper bounds, and sum the bounds over all depths to bound  $E[T(m)]$ . Our discussion is facilitated by another definition. Let  $S_j(m)$  be the number of *successful* nodes visited in an  $m$ -solution search. We will first bound  $E[T_j(m)]$  in terms of  $E[S_j(m)]$ . Note that the last node visited by an  $m$ -solution search is always a successful leaf node, implying that the last node visited at depth  $j$  by a search is successful (being an ancestor of the last solution). Given that  $S_j(m) = k$ , it follows that  $E[T_j(m)] \leq k/p^{\min}$ , since the mean number of nodes at depth  $j$  visited between successful visits at that depth is no greater than  $1/p^{\min}$ . It follows immediately that

$$(5) \quad E[T_j(m)] \leq \frac{E[S_j(m)]}{p^{\min}}.$$

We now bound  $E[S_j(m)]$  from above in terms of  $E[T_{j+1}(m)]$ . Call a node *activated* if its parent has been explored and is successful. Note that nodes are activated in groups, the group size being the number of children spawned by the parent. Furthermore, group sizes are independent random variables, each with mean  $n$ . If we focus our attention during a search on the activity at depth  $j+1$ , we will see a succession of groups activated, with group sizes being random variables  $\{Y_k\}$ . From this viewpoint, the search behavior at depth  $j+1$  is very much like a renewal process [10], except that inter-renewal times need not have identical distributions. We call this stochastic process a *quasi-renewal* process. “Time” in this process is the number of nodes visited by the search at depth  $j+1$ , minus 1 (so that time begins at 0); a quasi-renewal occurs at “time”  $t$  if node  $t$  (the  $t+1$ st node visited) is the first node in its group to be visited (excluding node 0). Now define  $S_j(m, t)$  to be the number of successful nodes visited at depth  $j$  by “time”  $t$ . As the search progresses, at any given “time”  $t$  the number of quasi-renewals which have occurred is exactly the number of parents of depth  $j+1$  nodes already visited, minus 1:  $S_j(m, t) - 1$ . The renewal function  $R(t)$  studied by renewal theory is the expected number of renewals which occur by time  $t$ . Thus for the problem at hand,  $R(t) = E[S_j(m, t)] - 1$ . In [10, p. 275] it is shown that the renewal function for a quasi-renewal process with NBUE inter-quasi-renewal times each having mean  $n$  is bounded from above by the renewal function  $R(t) = t/n$  of a Poisson process with mean inter-renewal time  $n$ . Since the  $\{Y_k\}$ ’s are NBUE by assumption, it follows that

$$E[S_j(m, t)] \leq \frac{t}{n} + 1.$$

“Time” stops at value  $T_{j+1}(m)$ , when the search terminates. The inequality above then

implies that

$$E[S_j(m)] \leq \frac{E[T_{j+1}(m)]}{n} + 1.$$

By substituting this bound into inequality (5) and noting that  $p^{\min} \geq \varepsilon/n$ , we find that

$$(6) \quad E[T_j(m)] \leq \frac{E[T_{j+1}(m)]}{\varepsilon} + \frac{n}{\varepsilon},$$

which establishes our goal of a bound on  $E[T_j(m)]$  in terms of  $E[T_{j+1}(m)]$ .

Inequality (6) gives us a sequence of bounds as we vary  $j$  from  $D-1$  to 1. We quantify these inequalities by employing the bound on  $E[T_D(m)]$  given by (4), and then repeatedly apply inequality (6) to obtain bounds on  $E[T_j(m)]$  for  $j = D-1, D-2, \dots, 1$ . We know that

$$E[T_D(m)] \leq \frac{nm}{\varepsilon}.$$

Substituting this bound for  $E[T_D(m)]$  into inequality (6) we obtain

$$E[T_{D-1}(m)] \leq \frac{nm}{\varepsilon^2} + \frac{n}{\varepsilon}.$$

Repeating this process, we find that for  $0 \leq k \leq D-1$

$$(7) \quad \begin{aligned} E[T_{D-k}(m)] &\leq \frac{nm}{\varepsilon^{k+1}} + n \sum_{j=1}^k \left( \frac{1}{\varepsilon^j} \right) \\ &= \frac{nm}{\varepsilon^{k+1}} + \frac{n(1-1/\varepsilon^k)}{\varepsilon-1}. \end{aligned}$$

We can then bound  $E[T(m)]$  by summing the upper bounds of the different depths given by (7):

$$\begin{aligned} E[T(m)] &\leq \sum_{k=0}^{D-1} \left( \frac{nm}{\varepsilon^{k+1}} + \frac{n(1-1/\varepsilon^k)}{\varepsilon-1} \right) \\ &= \frac{1}{\varepsilon-1} \left[ nm \left( 1 - \frac{1}{\varepsilon^D} \right) + n(D-1) - n \left( \frac{\varepsilon}{\varepsilon-1} \right) \left( 1 - \frac{1}{\varepsilon^D} \right) \right]. \end{aligned}$$

A less strict, but less involved bound follows immediately from the fact that  $\varepsilon > 1$ .

LEMMA 2. *If there is an  $\varepsilon > 1$  such that  $p^{\min} \geq \varepsilon/n$ , then*

$$(8) \quad E[T(m)] < \frac{n(D+m-1)}{\varepsilon-1}. \quad \square$$

This bound is marginally linear in  $n$ ,  $D$  and  $m$ . Furthermore, its change with respect to  $m$  is interesting. Doubling  $m$  increases the bound by less than a factor of two. This supports our intuitive understanding that after one solution is found, the additional cost of finding a second solution is (in expectation) less. The bound given in (8) is very sensitive to  $\varepsilon$  when  $\varepsilon$  is close to 1. Yet for  $\varepsilon \geq 1.1$ ,  $E[T(m)]$  is no greater than  $10n(D+m-1)$ , which seems quite reasonable.

**6. Contracting/expanding trees (Lemma 3).** Lemmas 1 and 2 give us means of bounding the expected performance of an  $m$ -solution search on contracting and on expanding trees. We next employ these bounds to derive bounds for trees which

contract at shallow depths, and expand at deep depths. As expected, we obtain these bounds by considering the expanding and contracting regions separately, and combine the results for an overall bound. We derive a bound on  $E[T(m)]$  which is linear in  $n$ , in  $D$  and in  $m$ .

We suppose there is a depth  $I$  such that  $p_{+I}^{\max} \leq 1/n$ ; and  $p_{I+}^{\min} \geq \varepsilon/n$  for some  $\varepsilon > 1$ . Consider the search tree truncated at depth  $I$ ; Lemma 1 states that the expected number of nodes visited by a full search of the truncated tree is no greater than  $nI$ , and (2) shows that the expected number of depth  $I$  nodes visited by a full search is bounded by  $n$ . It follows that the expected number of successful depth  $I$  nodes found in a full search, and hence an  $m$ -solution search, is no greater than 1. We can bound the expected number of nodes visited by an  $m$ -solution search at depths  $I+1, \dots, D$  by considering the subtrees rooted in successful nodes at depth  $I$ . Each such subtree has depth  $D-I$ , and extension probabilities (excluding the subtree root) which all exceed  $1/n$ . Now consider a *total subtree search* of depths  $I+1, \dots, D$ , which conducts an  $m$ -solution search of every subtree rooted in a successful node at depth  $I$ . Clearly the expected number of nodes visited by such a search is greater than the expected number of visited nodes in a usual  $m$ -solution search: the usual  $m$ -solution search will stop with the first  $m$  solutions, while the total subtree search will continue on to explore all subtrees with successful roots at depth  $I$ . The expected number of successful nodes at depth  $I$  is no greater than 1, so that the expected number of nodes at depths greater than  $I$  visited by a total subtree search is bounded from above by

$$\frac{n(D-I+m-1)}{\varepsilon-1}.$$

This bound follows from the application of Lemma 2 to one subtree rooted in depth  $I$ . We have already bounded the number of nodes visited at depths  $1, \dots, I$  by  $nI$ . The expected number of nodes visited in an  $m$ -solution search is therefore bounded as described in Lemma 3.

LEMMA 3. *If there is an  $I \geq 1$  and  $\varepsilon > 1$  such that  $p_{+I}^{\max} \leq 1/n$  and  $p_{I+}^{\min} \geq \varepsilon/n$ , then*

$$(9) \quad E[T(m)] \leq nI + \frac{n(D-I+m-1)}{\varepsilon-1}. \quad \square$$

This bound has the same marginal properties in  $n$ ,  $D$  and  $m$  as does the bound given by Lemma 2.

**7. Expanding/contracting trees (Lemmas 4 and 5).** We earlier gave an example of a tree which expanded in all but the last depth, and then contracted completely at the leaf nodes. This tree has the worst possible performance because it searches all nodes, but finds no solutions. This tree falls in the class of trees we next consider, trees which expand in upper levels and contract in lower levels. However, we are able to show that if the degree and extent of contraction is bounded, then we achieve marginal linear performance in the depth of the tree. Our bound is more sensitive to  $n$ : it increases as a polynomial in  $n$  and in the degree of contraction. This bound is exponential in the extent of the contracting region.

We suppose there is a depth  $D-J$  such that  $p_{+(D-J)}^{\min} \geq \varepsilon/n$  for some  $\varepsilon > 1$  and  $1/n \geq p_{(D-J)+}^{\max} \geq 1/Cn$  for some  $C \geq 1$ . The parameter  $J$  describes the extent of the contracting region ( $J$  depth levels), and  $C$  describes the degree of the contraction. We derive two bounds for this case. Our bound on  $E[N]$  is useful when the extension probabilities are small or when the expanding portion of the tree is limited; the other bound is useful if the contracting region is small.

To bound  $E[N]$ , we make the additional assumption that  $p^{\max} \leq \delta/n$ . By (3), the expected number of nodes visited at depths  $1, \dots, D-J$  by a full search is bounded from above by

$$n \left( \frac{\delta^{D-J} - 1}{\delta - 1} \right).$$

As a consequence of (2), the expected number of successful nodes at depth  $D-J$  is bounded from above by  $\delta^{D-J-1}$ . By Lemma 1, the expected number of nodes visited in a subtree rooted in a successful depth  $D-J$  node is bounded from above by  $nJ$ . Lemma 4 combines these observations.

LEMMA 4. *If there is a  $\delta > 1$  and  $J \geq 1$  such that  $p_{+(D-J)}^{\max} \leq \delta/n$  and  $p_{(D-J)+}^{\max} \leq 1/n$ , then*

$$(10) \quad E[N] \leq n \left( \frac{\delta^{D-J} - 1}{\delta - 1} \right) + nJ\delta^{D-J-1}. \quad \square$$

The key parameters in this inequality are  $\delta$  and  $J$ . When  $\delta$  is small, say  $\delta < 2$ , the exponential growth of (10) in  $D-J$  is slow. If  $D-J$  is small, then the troublesome expanding portion of the tree is limited, and (10) may yield a reasonably small bound. If neither of these cases is satisfied, we should consider another bound on  $E[T(m)]$ , which we derive next.

The assumption that  $p_{(D-J)+}^{\min} \geq 1/Cn$  bounds the degree to which the search tree contracts. We can use this restriction to bound  $E[T(m)]$ . The first step is to look at a subtree rooted in a visited depth  $D-J$  node and find a lower bound on the probability  $p_S$  of finding a solution in that subtree. One potential path to discovering a solution in this subtree occurs if the first  $J+1$  successive visits in a depth-first search of the subtree (we include the root here) each discover successful nodes. The last successful node is the full solution. The probability of this occurrence is at least

$$p_L = \frac{1}{(Cn)^{J+1}} \leq p_S.$$

This bound holds for every subtree (and hence every probability of finding a solution in a subtree). We will say that a depth  $D-J$  node is *ultimately successful*, or *u-successful*, if it is an ancestor of a successful complete solution.  $p_L$  is a lower bound on the probability of a visited depth  $D-J$  node being *u-successful*. The behavior of a 1-solution search at depths  $1, 2, \dots, D-J$  is probabilistically identical to the behavior of a 1-solution search on a modified tree having depth  $D-J$  and the same extension probabilities as the original search tree, except that depth  $D-J$  nodes' extension probabilities are replaced by their *u-success* probabilities. Since a subtree rooted in depth  $D-J$  may contain multiple solutions, an  $m$ -solution search of the original tree will visit fewer nodes at depths  $1, \dots, D-J$  than will an  $m$ -solution search of the modified tree. The arguments presented in § 5 establish that the mean number of nodes visited at depth  $D-J$  by an  $m$ -solution search of the modified tree is bounded from above by  $m/p_L = m(Cn)^{J+1}$ . Then the same type of analysis which leads to equation (8) shows that

$$(11) \quad \sum_{j=1}^{D-J} E[T_j(m)] < \frac{m(Cn)^{J+1} + n(D-J-1)}{\varepsilon - 1}.$$

Reconsidering the original depth  $D$  tree, we use Lemma 1 to see that the expected number of nodes visited by a total search of a subtree rooted in depth  $D-J$  is bounded

from above by  $nJ$ .  $m(Cn)^{J+1}nJ$  is thus an upper bound on the expected number of nodes visited at depths  $D-J+1, \dots, D$  in an  $m$ -solution search of the original tree. Summing this bound with the one given by (11), we have the following lemma.

LEMMA 5. *If there are  $\varepsilon > 1$ , and  $J, C \geq 1$  such that  $p_{+(D-J)}^{\max} \geq \varepsilon/n$  and  $1/Cn \leq p_{(D-J)+}^{\min} \leq 1/n$ , then*

$$E[T(m)] < \frac{m(Cn)^{J+1} + n(D-J-1)}{\varepsilon - 1} + m(Cn)^{J+1}nJ. \quad \square$$

This bound is reasonably small only if  $J$  is small. We can expect marginal linear performance in the depth of the tree, provided there are depth independent bounds on the number of tree levels which contract and the degree to which nodes in that region contract. Lemma 5 also hints at the relative sensitivity of performance to changes in the different model parameters. The bound grows as a polynomial in  $n$  and in  $C$ ; it grows exponentially in  $J$ .

Reconsider the example of the tree which visited all nodes and found no solutions. If we slightly change the example so that a leaf node has some fixed probability  $p > 0$  of being a solution, then Lemma 5 gives us marginal linear performance in the depth of the tree (supporting empirical data presented in [12].) This is more of an indictment of asymptotic results than it is an indication of good performance. If  $J$  is fixed and quite large, Lemma 5 can still give us linear performance in  $D$ . That does not mean that we can expect to find a solution quickly.

The example highlighting exponential complexity hinged on having extension probabilities equal to zero. There exist trees with all nonzero extension probabilities which have exponential performance asymptotically. It is not difficult to see (or prove) that as the depth of a contracting tree increases, the probability of discovering a solution in that tree approaches zero. Now consider a tree which expands in the upper half of its levels and contracts in the lower half. In the limit of increasing tree depth, a full search of the tree's upper half occurs because the search is always pruned in the lower half before reaching a solution. Since the upper half is expanding, the number of nodes visited there increases exponentially in the tree depth. Clearly the dividing line between expanding and contracting tree regions need not be at  $D/2$  to cause this type of asymptotic behavior; we can expect asymptotic exponential complexity in the general case of such a tree. This example re-illustrates the need for extending past work in average performance analysis of backtracking, particularly as empirical data suggests that common problems exhibit expanding/contracting search trees [13]. Using uniform probability structures, previous performance models conclude that all 1-solution searches have expected linear complexity. The example above shows that under a general model, there are 1-solution searches with super-linear complexity. Our general model is more selective in its identification of trees leading to low complexity and specifically excludes the example outlined above from the class of searches with linear complexity.

**8. Summary.** Previous analysis of the average case performance of 1-solution backtracking searches have assumed uniform probability structures and have subsequently shown that 1-solution backtracking always has complexity linear in the depth of the search tree. However, using a more general probability model, it is possible to construct 1-solution backtracking searches which have expected super-linear complexity. This paper investigates the implications of assuming a general probability structure for the average case analysis. Using the notions of "expanding" and "contracting" nodes, we have derived expected linear complexity bounds on  $m$ -solution searches

of trees with all nodes contracting and trees with all nodes expanding. We present linear bounds on trees which have an upper portion contracting with the lower portion expanding. We also derive linear bounds on special cases of trees with an expanding upper portion and a contracting lower portion and show that this latter class generally yields super-linear complexity. By extending previous work in the average complexity of backtracking, we have both provided further assurance of good expected performance under appropriate conditions and indirectly shown where classes of searches with high complexity lie.

**Acknowledgments.** Use of the terms “expanding” and “contracting” is due to a discussion with Harold Stone. I also thank Shahid Bokhari and Bob Voigt for suggestions regarding the presentation of this paper.

## APPROXIMATE PARALLEL SCHEDULING. PART I: THE BASIC TECHNIQUE WITH APPLICATIONS TO OPTIMAL PARALLEL LIST RANKING IN LOGARITHMIC TIME\*

RICHARD COLE† AND UZI VISHKIN‡

**Abstract.** We define a novel scheduling problem; it is solved in parallel by repeated, rapid, approximate reschedulings. This leads to the first optimal logarithmic time PRAM algorithm for list ranking. Companion papers show how to apply these results to obtain improved PRAM upper bounds for a variety of problems on graphs, including the following: connectivity, biconnectivity, Euler tour and  $st$ -numbering, and a number of problems on trees.

**Key words.** PRAM algorithm, list ranking, approximate scheduling, expander graphs, optimal speed-up

**AMS(MOS) subject classifications.** 68C05, 68C25

**1. Introduction.** The model of parallel computation used in this paper is a member of the parallel random access machine (PRAM) family. A PRAM employs  $p$  synchronous processors all having access to a common memory. In this paper we use an exclusive-read exclusive-write (EREW) PRAM. The EREW PRAM does not allow simultaneous access by more than one processor to the same memory location for read or write purposes. See [Vi-83] for a survey of results concerning PRAMs.

Let  $\text{Seq}(n)$  be the fastest known worst-case running time of a sequential algorithm, where  $n$  is the length of the input for the problem at hand. Obviously, the best upper bound on the parallel time achievable using  $p$  processors, without improving the sequential result, is of the form  $O(\text{Seq}(n)/p)$ . A parallel algorithm that achieves this running time is said to have *optimal speed-up* or more simply to be *optimal*. A primary goal in parallel computation is to design optimal algorithms that also run as fast as possible. Some authors use optimal to mean that as well as achieving an  $O(\text{Seq}(n))$  processor time product, the parallel running time is as small as possible (typically  $O(\log n)$ ).

Most of the problems we consider can be solved by parallel algorithms that obey the following framework. Given an input of size  $n$  the parallel algorithm employs a *reducing* procedure to produce a smaller instance of the same problem (of size  $\leq n/2$ , say). The smaller problem is solved recursively until this brings us below some threshold for the size of the problem. An alternative procedure is then used to complete the parallel algorithm. We refer the reader to [CV-86d] where this algorithmic technique, which is called accelerating cascades, is discussed. Typically, we need to reschedule

the processors in order to apply the reducing procedure efficiently to the smaller sized problem. Suppose the input for a problem of size  $n$  is given in an array of size  $n$ . A natural approach is to compress the smaller problem instance into a smaller array, of size  $\leq n/2$ . This is often done using a prefix sum algorithm (it takes  $O(\log n)$  time on  $n/\log n$  processors to compute the prefix sums for  $n$  inputs stored in an array). Thus if we need to reschedule the processors repeatedly it is unclear how to achieve logarithmic time. Sometimes the rescheduling need not be performed very often: In [CV-86a], [C-86] the authors show that for some problems (list ranking and selection)  $\log^* n$  reschedulings suffice. Alternatively, one can use a fast random algorithm to perform the rescheduling, or at least an approximate rescheduling. (By approximate rescheduling we mean that we may not be able to partition the work evenly among the processors, but only approximately evenly.) Thus the need for rescheduling does not preclude  $O(\log n)$  time optimal random algorithms. One of the main contributions of this paper is to provide an algorithm for performing approximate rescheduling deterministically in  $O(1)$  time. This is used to solve a novel scheduling problem, called the *duration-unknown task scheduling* problem. The solution to the scheduling problem leads to a logarithmic time optimal deterministic parallel algorithm for list ranking. A related rescheduling procedure is one of the tools that leads to a logarithmic time connectivity algorithm which is optimal unless the graph is extremely sparse.

The *duration-unknown task scheduling* problem is defined as follows.  $n$  tasks are given, each of length between 1 and  $e \log n$ ,  $e$  a constant; the total length of the tasks is bounded by  $cn$ ,  $c$  a constant. (A task can be thought of as a program.) However, we do not know, in advance, the lengths of the individual tasks; in fact, they may vary, depending on the order of execution of the tasks. The problem is to schedule the  $n$  tasks on an EREW PRAM of  $n/\log n$  processors so that the tasks are completed in  $O(\log n)$  time; it is solved in § 3.

We now discuss how to design algorithms that take advantage of this task scheduling algorithm. Given a problem, our job is to design a “protocol” for solving the problem by using a set of short tasks (each of length between 1 and  $e \log n$ ). This provides an important new opportunity for the designer of a protocol which is based on using the scheduling algorithm: the designer of the protocol need not know anything about the order of execution of the tasks. Such an opportunity for designing parallel tasks, without knowing in advance their lengths, with the guarantee that they will be scheduled efficiently, sounds very promising. However, this opportunity cannot be separated from a considerable difficulty in designing such a protocol: we have no control over the order of execution of the tasks, so we must ensure that the protocol works correctly regardless of the order of execution. We note that this style of protocol design may be useful for distributed systems that are not tightly synchronized; here too, we have to be sure that the protocol works correctly regardless of the order of execution. Section 4 demonstrates how to design such a protocol for the following problem.

#### LIST RANKING.

*Input.* A linked list of length  $n$ . It is given in an array of length  $n$ , not necessarily in the order of the linked list. Each of the  $n$  elements (except the last element in the linked list) has the array index of its successor in the linked list.

*The problem.* For each element, compute the number of elements following it in the linked list.

*Result.* On the EREW PRAM,  $O(\log n)$  time using  $n/\log n$  processors.

*Previous results.* On the EREW PRAM,

(i)  $O(n/p \cdot \log n/\log n/p)$  time using  $p < n$  processors [KRS-85] (this was the first optimal algorithm to achieve sublinear time).

- (ii)  $O(\log n \log^* n)$  time using  $n/(\log n \log^* n)$  processors [CV-86a].
- (iii) for fixed  $k$ ,  $O(k \log n)$  time using  $n \log^{(k)} n / \log n$  processors [CV-86a].

Our new result is asymptotically better than (ii). However, as it involves considerably larger constants, for all practical purposes the older result seems stronger.

The following randomized algorithms are also known.

(i)  $O(\log n \log^* n)$  time using  $n/(\log n \log^* n)$  processors [Vi-84]. The journal version of this paper uses the new parallel prefix sums algorithm of [CV-86e] to achieve  $O(\log n)$  time using  $O(n/\log n)$  processors.

(ii)  $O(\log n)$  time using  $O(n/\log n)$  processors is implicitly achieved by [MR-85].

*Comment.* The list ranking problem is often encountered as a subproblem in other parallel algorithms. The Euler tour technique on trees [TV-85], [Vi-85] reduces a variety of tree functions into list ranking. [TV-85] used list ranking to reduce graph biconnectivity to graph connectivity. List ranking plays a central role in the “accelerated centroid decomposition (ACD)” parallel method for evaluating tree expressions [CV-86b]. Recently, in [SV-86] Schieber and Vishkin have shown how to apply the new list ranking algorithm for responding to queries regarding lowest common ancestors of pairs of vertices on a tree.

Part 2 of this research (the paper [CV-86c]) shows how to apply the approximate scheduling method together with the new list ranking algorithm in order to derive improved PRAM upper bounds for a variety of problems on graphs, including the following: connectivity, biconnectivity, Euler tour and  $st$ -numbering.

As can be seen, the results presented here improve on previous work in [CV-86a]. The main contributions of [CV-86a] were the deterministic coin tossing technique and a methodology for scheduling that used as few reschedulings as possible. While the details of their reschedulings were quite intricate, the rescheduling procedure itself was standard. We make two main contributions here. First, we provide a new approach to the rescheduling problem. Second, we show how to solve the list ranking problem in the novel framework imposed by our solution to the rescheduling problem. In addition, the companion papers show anew the central role played by the list ranking problem.

We note that a preliminary version of this paper appeared in [CV-86e].

In § 3 we present the duration-unknown task scheduling algorithm. In § 4 we give the new list ranking algorithm. In § 5 we provide a summary of the results obtained and pose an open problem.

**2. Preliminaries.** We give below a useful and simple scheme, due to Brent [B-74], for designing parallel algorithms. Later, we discuss implications of this scheme for the formulation of complexity results regarding the performance of parallel algorithms.

**THEOREM (Brent).** *Any synchronous parallel algorithm of time  $t$  that consists of a total of  $x$  elementary operations can be implemented by  $p$  processors in time  $\lceil x/p \rceil + t$ .*

*Remark.* Brent’s theorem is stated for parallel models of computation where not all computational overheads are taken into account. Specifically, the proof of Brent’s theorem ignores the problem of assigning processors to their jobs. Often, in the present paper, it is straightforward to overcome this implementation problem without increasing the running time or the number of processors in order of magnitude. Therefore, we allow ourselves to switch freely from a result of the form “ $O(x)$  operations and  $O(t)$  time” to “ $x/t$  processors and  $O(t)$  time” (and vice versa, which is always correct). However, we avoided doing this where there are difficulties with the implementation problem.

**3. Approximate scheduling.** We solve the following dynamic scheduling problem: the *duration-unknown task scheduling* problem (which is encountered in the list ranking problem). Our solution requires repeated rapid rescheduling of the processors. The mechanism that provides each rescheduling is a *redistribution* procedure (it solves the *object redistribution* problem). We start by defining the two problems. Then we give the redistribution procedure. Following this, we show how to solve the task scheduling problem using repeated applications of the redistribution procedure. Finally, we prove the correctness of the redistribution procedure.

We define the *duration-unknown task scheduling* problem (for short, the task scheduling problem), as follows. We are given  $n$  tasks. A task is a program that is to be run by one processor. The *length* of a task is its sequential running time (we will measure this as a specific number of  $O(1)$  time steps, which we call *real steps*). The lengths of individual tasks may be dependent on the scheduling; in fact, the length of an individual task may not be known until its execution terminates; however, we are guaranteed that no task has length greater than  $e \log n$ , and that the total length of all the tasks is bounded by  $cn$ , regardless of the scheduling, for some constants  $c$  and  $e$ . The problem is to execute these tasks on  $n/\log n$  processors in  $O(\log n)$  time. We are allowed to schedule and reschedule the tasks as we wish, so long as the scheduling occupies only  $O(\log n)$  time.

We define the *object redistribution* problem, as follows. We are given  $r$  objects, partitioned among  $p$  collections of objects. We are also given one processor per collection. Loosely speaking, the problem is to redistribute the objects among the collections so that they are more evenly distributed. For a more precise description we need some definitions.  $size_i$ , the *size* of collection  $i$ ,  $1 \leq i \leq p$ , is the number of objects in collection  $i$ ; note that  $r = \sum_{i=1}^p size_i$ . The *weight* of collection  $i$  is  $size_i^2$ , the square of its size; let  $W = \sum_{i=1}^p size_i^2$  be the total weight of all the collections. Let  $WMIN_r$  denote the minimum possible weight over all possible distributions of  $r$  objects among  $p$  collections; we note that  $p \lfloor r/p \rfloor^2 \leq WMIN_r \leq p \lceil r/p \rceil^2 \leq 4WMIN_r$ . When the value of  $r$  is clear from the context, we simply write  $WMIN$ . Let  $f$  and  $g$  be constants ( $f \geq g = 298$ , with  $f$  specified more precisely later in this section). If  $W$  is bounded by either  $f p$  or  $g WMIN$  then the collections are said to be *balanced* (i.e. either there are few objects present, or objects are roughly evenly distributed). We distinguish the following *classes* of collections: class 0 comprises those collections of size 0 or 1; class  $i$ ,  $i > 0$ , comprises those collections whose size is in the range  $[2^i, 2^{i+1})$ .

The *object redistribution problem* is the following: Redistribute the objects (using the redistribution procedure) so that the following properties hold:

- (1) The total weight is not increased.
- (2) The maximum number of objects in any one collection does not increase.
- (3) If the collections are unbalanced, the total weight of the collections is reduced by a multiplicative constant factor.
- (4) The redistribution takes  $O(1)$  time.

We describe the redistribution procedure and then show how to implement it in  $O(1)$  time. Later we show how to use this procedure to solve the task scheduling problem.

The redistribution procedure will perform a cascade of redistributions of objects from heavier collections to lighter collections. As we will see, this provides the desired weight reduction. We note that we have little control over the distribution of objects at the start of the redistribution procedure, and hence we have little control over the distribution of collections among the classes. Nonetheless, for any class containing many collections, we want to be able to perform redistributions of objects from most

of these collections to other collections of considerably smaller size. This motivates us to consider expander graphs.

**DEFINITION.** A graph  $G = (V, E)$  is a  $(d, \epsilon, \gamma)$ -expander graph,  $\epsilon < 1$ , if for any subset  $U \subseteq V$ , with  $|U| \leq \epsilon|V|$ , the set  $N(U)$  of neighbors of vertices in  $U$  has size  $|N(U)| \geq \gamma|U|$ , and  $G$  has vertex degree  $d$ .

It is convenient to assume that  $d$  is a power of 2 (if not, we can add additional edges to  $G$ ; this will not affect the expander property). Given any  $\epsilon < 1$ , it is known that there exist expander graphs with  $\gamma = (1 - \epsilon)/\epsilon$ , for sufficiently large  $d$  (where  $d$  is a function of  $\epsilon$  only). Further, such an expander graph can be built in  $O(\log |V|)$  time using  $|V|/\log |V|$  processors, for each fixed  $\epsilon$ , as we show in Appendix B. (See [LPS-86], [JM-85], [GG-81] for results on expander graphs.)

*Remark.* Peleg and Upfal recently applied expander graphs to a similar but not fully comparable problem [PU-86].

*The redistribution procedure.* For each collection we create a node; these nodes are connected by a  $(d, \epsilon, (1 - \epsilon)/\epsilon)$ -expander graph. We perform the following object redistribution. Suppose there is an edge connecting collections  $C_1$  and  $C_2$ . Let  $C_1$  and  $C_2$  be in classes  $i_1$  and  $i_2$ , respectively. If  $i_1 > i_2 + 1$ , then a number of objects are removed from  $C_1$  and added to  $C_2$ . More precisely, let  $\beta = 2^{i_1}$  (then  $C_1$  contains at least  $\beta$  objects and fewer than  $2\beta$  objects); if  $\beta \geq 8d$  then the number of objects transferred is  $\beta/8d$ ; otherwise, no objects are moved. If such an object transfer from  $C_1$  to  $C_2$  occurs, we call  $C_1$  a *giving* collection and  $C_2$  a *receiving* collection. A collection can be both giving and receiving.

We note that an attempted redistribution from a giving collection of size less than  $8d$  has no effect. Thus we would like the collections to be balanced if  $W \leq (8d)^2 n / \log n$ . This is achieved by requiring  $f \geq (8d)^2$ .

Next, we describe the data structure we use to implement the redistribution in  $O(1)$  time.

*Implementation of the redistribution procedure.* The objects are stored at the leaves of complete binary trees. Formally, suppose a collection has  $\alpha$  objects. If  $\alpha = 1$  then this single object forms a (complete binary) tree. Otherwise, suppose  $2^i \leq \alpha < 2^{i+1}$ ,  $i \geq 1$ . Then,  $2^i$  of these objects form a complete binary tree and the remaining  $\alpha - 2^i$  objects recursively form complete binary trees. So, in each collection, the objects are stored in a set of complete binary trees, no two of the same size. We maintain the following pointers: for each internal node in such a tree, pointers to its leftmost and rightmost leaves; in addition, we keep the leaves in each tree in a linked list, in left to right order (these pointers are needed for the solution to the scheduling problem). Finally, for each collection, we keep its trees in a doubly linked list, in increasing order by size.

The object transfer can be performed in  $O(1)$  time since it only involves manipulating the top  $O(\log d)$  levels of the largest tree in  $C_1$  (followed by a constant amount of tree reconstruction in  $C_1$  and  $C_2$ ). More precisely, for each collection with at least  $8d$  objects, we divide the largest tree in the collection (of size  $\beta \geq 8d$ ) into  $8d$  equal sized subtrees. Up to  $d$  of these trees are transferred in the object redistribution. The remaining trees of size  $\geq \beta/8d$  in the collection are then repeatedly paired together (only equal sized trees are paired), until there is at most one tree of each size. Since this involves at most  $8d + \log 8d$  trees it takes  $O(1)$  time using one processor per collection. The pairing process is then repeated with the trees that are transferred to the collection. There are at most  $d + \log 4d$  trees involved in the latter pairing; so it also takes  $O(1)$  time using one processor per collection. We note that care must be taken to maintain the pointers for the tree nodes as the trees are manipulated; however, this is straightforward.

The theorem below claims the correctness of the redistribution procedure.

*The redistribution procedure (RP) Correctness Theorem.* The redistribution procedure solves the object redistribution problem (i.e., it satisfies the four properties of the problem).

So far we have only shown that the redistribution procedure needs  $O(1)$  time (property (4)). The second half of this section is devoted to the proof of the other three properties of the RP Correctness Theorem. However, in the description of the algorithm for task scheduling and its proof, which follow, we will already assume the RP Correctness Theorem.

*The algorithm for the duration-unknown task scheduling problem.* We solve the task scheduling problem as follows. When applying the redistribution procedure, we view the tasks as the objects; also, we set  $p = n/\log n$  and define  $r$  to be the number of tasks at hand. Initially, we distribute  $\log n$  tasks to each collection. Each collection will never contain more than  $\log n$  tasks. We perform  $O(\log^{(2)} n)$  of the following stages.

(i) For each processor, perform  $\log n/\log^{(2)} n$  real steps on the tasks in its collection in  $O(\log n/\log^{(2)} n)$  time.

(ii) Apply the redistribution procedure. This requires  $O(1)$  time.

The following lemma justifies going to the final stage at this point; the lemma will be proved later.

LEMMA 3.1. *After  $h \log^{(2)} n$  stages there are at most  $fn/\log n$  incomplete tasks, for some constant  $h$ .*

*The final stage.* Distribute the remaining (at most  $fn/\log n$ ) tasks evenly among the processors (this is done using a standard prefix sum computation, as in [FL-80], in a further  $O(\log n)$  time using  $n/\log n$  processors). Each processor will then complete its allotted tasks by performing at most  $fe \log n$  more real steps.

Thus the task scheduling problem can be solved in  $O(\log n)$  time on  $n/\log n$  processors.

*Remark.* There are several implementation details of the scheduling algorithm that should be mentioned. First, the links in the trees containing the tasks allow us to access each successive task in  $O(1)$  time, starting at the leftmost task (leaf) in the smallest tree. Thus we can perform  $\log n/\log^{(2)} n$  real steps, in part (i), in  $O(\log n/\log^{(2)} n)$  time. Second, it is convenient, in the list ranking application, to ensure that having started one task, the processor completes it before beginning another. All we have to do is ensure that we do not redistribute the tasks that processors are currently executing. This is easily done by redistributing from the right end of trees in the distribution procedure. We will then never redistribute the current task, which is at the leftmost end of some tree. Third, we need to explain how to reformat the trees, at the end of part (i) of a typical stage, so that they are of the form assumed by the redistribution procedure. Let the task being processed at the end of part (i) be at leaf  $\nu$  of tree  $T$ . To ensure all the trees are complete and distinct we need to partition  $T$  into complete subtrees (recall that  $T$  is the smallest tree associated with the collection; thus we are guaranteed that if we create distinct sized complete binary trees from  $T$  then no two trees in the collection will have the same size and we get a proper set of complete binary trees). To partition  $T$ , we follow a path from  $\nu$  to the root of  $T$ . Each maximal right subtree that we encounter is made into a new tree. This traversal takes  $O(\log^{(2)} n)$  time.

*Complexity.* Assuming the RP Correctness Theorem and Lemma 3.1 we can conclude that the task scheduling problem can be solved in  $O(\log n)$  time on  $n/\log n$  processors.

Next, we prove Lemma 3.1.

*Proof of Lemma 3.1.* Consider a single stage and consider the end of part (i) of that stage. There are three possibilities.

Case 1. The collections are not balanced.

Case 2. The collections are balanced; so either

Case 2a. the total weight is bounded by  $gWMIN$  but not by  $fn/\log n$ , or

Case 2b. the total weight is bounded by  $fn/\log n$ .

In Case 1, part (ii) reduces the total weight by a constant factor by property (3) of the RP Correctness Theorem. Since the initial weight is  $n \log n$ , this can happen only  $O(\log^{(2)} n)$  times, say at most  $h_1 \log^{(2)} n$  times, for some constant  $h_1$  (for at that point the weight will have been reduced to  $fn/\log n$ ; i.e., the collections are balanced).

We claim that in Case 2a at least  $1/(16g) \cdot n/\log n$  of the collections are not empty. This is seen as follows. We first note that  $r$ , the number of objects present, is at least  $p(=n/\log n)$  for otherwise we would have  $WMIN \leq p$ . This would imply  $gWMIN \leq fp$  (remember  $f \geq g$ ), and therefore contradicts the assumption of Case 2a. Next, suppose  $x$  of the collections are nonempty. Then  $W$ , the total weight of all the collections, is at least  $x \cdot \lfloor r/x \rfloor^2$ ; also  $W \leq gWMIN$  and  $WMIN \leq p \cdot \lceil r/p \rceil^2$ . That is,  $x \lfloor r/x \rfloor^2 \leq gp \lceil r/p \rceil^2$ , and since  $r \geq p \geq x$ , we have  $r^2/4x \leq 4gr^2/p$ , or  $x \geq p/(16g)$ .

For each nonempty collection, in part (i) of the stage,  $\log n/\log^{(2)} n$  real steps were performed on the tasks at hand. Thus, in Case 2(a), at least  $n/(16g \log^{(2)} n)$  real steps were performed on the tasks in part (i) of this stage. We conclude that there are at most  $16gc \log^{(2)} n$  instances of Case 2(a).

In Case 2(b), there are at most  $fn/\log n$  tasks remaining.

Let  $h = h_1 + 16gc$ . We have shown that following  $h \log^{(2)} n$  iterations there can be at most  $fn/\log n$  tasks remaining incomplete.  $\square$

It remains to prove that properties (1)–(3) of the RP Correctness Theorem hold. Property (2) is clear. In the rest of this section we prove properties (1) and (3). We start by providing an outline of their proofs. We then prove individual lemmas.

For purposes of the analysis, it is convenient to serialize the redistributions that occur during the redistribution procedure (in fact, the redistributions are performed simultaneously); we refer to a redistribution between two collections as a *redistribution step*. We consider each redistribution step to be an ordered pair comprising the weight of the receiving collection followed by the weight of the giving collection. The redistribution steps are ordered lexicographically, and are performed in this order. Thus the redistribution steps into the lightest receiving collection are performed first; among these redistribution steps, the one from the lightest giving collection is performed first.

Consider a single redistribution step involving giving collection  $C_g$ , of size  $s_g$  at the start of the redistribution procedure, and receiving collection  $C_r$ , of size  $s_r$  at the start of the redistribution procedure.

LEMMA 3.2. *The weight reduction produced by the redistribution step is at least  $s_g^2/32d$ .*

COROLLARY 3.1. *Any sequence of redistribution steps reduces the total weight (property (1) of the RP Correctness Theorem).*

COROLLARY 3.2. *Let  $W_g$  be the total weight of the giving collections, counting multiplicities, at the start of the redistribution procedure. Then the weight reduction for these collections, due to the redistribution procedure, is at least  $W_g/32d$ .*

The remainder of the proof is concerned with proving property (3) of the RP Correctness Theorem. So henceforth we assume that the collections are unbalanced. We show that in this case  $W_g$  is a constant fraction of  $W$ .

We need additional notation and definitions. Let  $S_i$  be the set of collections in class  $i$ . Let  $L_i = \bigcup_{k \geq i} S_k$ . Let  $|S_i|$  (resp.  $|L_i|$ ) denote the number of collections in  $S_i$  (resp.  $L_i$ ), and let  $wt(S_i)$  (resp.  $wt(L_i)$ ) denote the sum of the weights of the collections

in  $S_i$  (resp.  $L_i$ ). On the average there are  $s/p$  objects in each one of the  $p$  collections. Define the variable *average* to be  $\lfloor \log_2 s/p \rfloor$ . We refer to class *average* as the average class. Let  $\alpha$  denote the smallest  $i > \text{average} + 2$  such that  $|S_i| > |S_{i-1}|/32$ , if any. We define a set  $S_i$ ,  $i \geq \alpha$ , to be *giving* if there are at least  $|S_i|$  giving collections in  $S_i$ , counting multiplicities. We implement the expander graph so that whenever  $|S_i| \geq 1/32|S_{i-1}|$  and  $|S_i| \geq |L_{i+1}|$  then  $S_i$  is giving.

We now give a proof outline.

LEMMA 3.3.  $\alpha$  exists.

LEMMA 3.4. The weight of  $L_\alpha$  is at least  $W/2$ .

LEMMA 3.5. The weight of the giving collections in  $L_\alpha$ , counting multiplicities, is at least  $1/40 \text{ wt}(L_\alpha) > 1/2^6 \text{ wt}(L_\alpha)$ .

COROLLARY 3.3. The weight of the giving collections in  $L_\alpha$ , counting multiplicities, is at least  $1/2^7 W$ .

We conclude, from Corollaries 3.2 and 3.3 the following.

THEOREM 3.1. If the collections are not balanced then, in  $O(1)$  time, the redistribution algorithm reduces the total weight by a multiplicative factor of at least  $1 - (1/32d)$  ( $1/2^7 \geq 1 - (1/2^{12}d)$ ).

Theorem 3.1 demonstrates property (3) of the RP Correctness Theorem, and thus completes its proof.

We now elaborate on the proof of Lemma 3.5, which is a consequence of several sublemmas. We need additional definitions. For Lemma 3.5, we only consider sets  $S_i$  with  $i \geq \alpha$ . We need to classify these sets according to whether they must contain many giving collections. Thus, we define a set  $S_i$  to be *large* if  $|S_i| \geq |S_{i-1}|/32$ . Likewise, it is *small* if  $|S_i| < |S_{i-1}|/32$ . We will show that the weight of the large sets is at least half the weight of  $L_\alpha$ . The neighbors, for giving collections, are provided by the edges of an expander graph. Thus if  $|L_{i+1}|$  is large compared to  $|S_i|$ , we may not be able to guarantee that there are many giving collections in  $S_i$ . So we define  $S_i$  to be *useful* if  $|S_i| \geq |L_{i+1}|$ . We will show that the weight of the useful large sets is at least one-fifth of the weight of the large sets. Finally, by choosing the right constant  $\varepsilon$  for the expander graph ( $\varepsilon = \frac{1}{36}$ ), we will ensure that each useful large set is a giving set.

LEMMA 3.5.1. The weight of the large sets is at least  $\frac{1}{2} \text{ wt}(L_\alpha)$ .

LEMMA 3.5.2. The weight of the useful large sets is at least  $\frac{1}{5}$  of the weight of the large sets.

LEMMA 3.5.3. A useful large set  $S_i$  has at least  $|S_i|$  neighbors in  $\cup_{j=0}^{i-2} S_j$ , i.e., it is a giving set.

*Proof of Lemma 3.5.* In Lemma 3.5.1 we showed that the weight of the large sets was at least  $\frac{1}{2} \text{ wt}(L_\alpha)$ . In Lemma 3.5.2 we showed that the weight of the useful large sets was at least one-fifth the weight of the large sets. In Lemma 3.5.3 we showed that each useful large set  $S_i$  has at least  $|S_i|$  giving collections, counting multiplicities. Finally, since the size of the collections in each useful large set  $S_i$  lie in the range  $[2^i, 2^{i+1})$ , we conclude that the giving collections in  $S_i$ , counting multiplicities, have weight at least  $\frac{1}{4} \text{ wt}(S_i)$ . Thus the weight of the giving collections in  $L_\alpha$  is at least  $\frac{1}{2} \cdot \frac{1}{5} \cdot \frac{1}{4} \text{ wt}(L_\alpha) = \frac{1}{40} \text{ wt}(L_\alpha)$ .  $\square$

It remains to prove Lemmas 3.2, 3.3, 3.4, 3.5.1, 3.5.2 and 3.5.3.

*Proof of Lemma 3.2. Claim.* Following the redistribution step,  $C_g$  has size at least  $\frac{7}{8} s_g$ , and  $C_r$  has size at most  $s_r + \frac{1}{8} s_g$ . (This follows from the lexicographic ordering of the redistribution steps, and the fact that each giving collection redistributes at most  $\frac{1}{8}$  of its objects.)

Let  $\frac{7}{8} s_g + a + b$  be the size of  $C_g$  immediately before the redistribution step, let  $s_r + c$  be the size of  $C_r$  immediately before the redistribution step, and let  $a$  be the number of items transferred. We know that: (1)  $s_r < s_g/2$  (since if  $s_g$  belongs to some

class  $i$  then  $s_r$  can belong only to a class  $j$ , where  $j \leq i - 2$ . (2)  $c + a \leq \frac{1}{8} s_g$ . (This follows from the above claim regarding the size of  $C_r$ .) (3)  $a + b \geq 0$  (this is trivial). And, (4)  $16da > s_g$  (since  $a$ , the number of elements transferred is  $> s_g/16d$ ). The weight reduction  $W_R$  is given by:

$$W_R = (\frac{7}{8} s_g + a + b)^2 + (s_r + c)^2 - (\frac{7}{8} s_g + b)^2 - (s_r + c + a)^2 = 2a(\frac{7}{8} s_g + b - s_r - c).$$

Observe that (2) and (3) above imply that  $b - c = -((c + a) - (b + a)) \geq -s_g/8$ . Using this and (1) above we get,

$$W_R \geq 2a(\frac{7}{8} s_g - s_g/2 - \frac{1}{8} s_g) = \frac{as_g}{2}.$$

By (4) above we get,

$$W_R \geq \frac{s_g^2}{32d} \quad \square$$

*Proof of Lemma 3.3.* We assume, in contradiction, that  $\alpha$  does not exist and show that the collections must have been balanced, which is contrary to assumption. To show this we observe the following:

(a) The total weight of the collections in classes  $0, \dots, average - 1$  is less than  $WMIN$ .

(b)  $wt(S_{average}) \leq 4WMIN$ ;  $wt(S_{average+1}) \leq 16WMIN$ ;  $wt(S_{average+2}) \leq 64WMIN$ .

(c)  $wt(S_i) \leq wt(S_{i-1})/2$  for  $i > average + 2$  (since otherwise  $\alpha$  would exist).

The total weight is therefore,

$$\sum_{i < average} wt(S_i) + wt(S_{average}) + wt(S_{average+1}) + wt(S_{average+2}) + \sum_{i > average+2} wt(S_i).$$

Observations (a), (b) and (c) above imply that this is

$$\leq WMIN + 4WMIN + 16WMIN + 64WMIN + 64WMIN = 149WMIN.$$

Since  $g \geq 298$  we conclude that the collections are balanced.  $\square$

*Proof of Lemma 3.4.* The proof of Lemma 3.3 shows that  $wt(L_\alpha) \geq W - 149WMIN$ . By assumption, since the collections are unbalanced,  $W \geq gWMIN \geq 298WMIN$ ; we conclude that  $wt(L_\alpha) \geq W/2$ .  $\square$

*Proof of Lemma 3.5.1.* Let  $S_i, S_{i+k}$  be large sets and suppose that for each  $j, 1 \leq j < k, S_{i+j}$  is not large. Then, as in the proof of Lemma 3.3, we can show that  $wt(S_i) \geq \sum_{j=1}^{k-1} wt(S_{i+j})$ . Let  $S_h$  be the large set of greatest index; we can also show that  $wt(S_h) \geq \sum_{j \geq 1} wt(S_{h+j})$ . Since  $S_\alpha$  is large the lemma follows.  $\square$

*Proof of Lemma 3.5.2.* Observe that the large set whose index is maximal must be useful. Consider a sequence of sets  $S_{i_{k+1+1}}, S_{i_{k+1+2}}, \dots, S_{i_0}$ , which satisfies the following: (1)  $S_{i_0}$  is the only set in the sequence which is both useful and large. (2) Either  $S_{i_{k+1}}$  is both useful and large; or  $i_{k+1}$  is  $\alpha - 1$ . (3)  $S_{i_k}, S_{i_{k-1}}, \dots, S_{i_1}, S_{i_0}$  is the subsequence of large sets in this sequence. We show that  $\sum_{j=1}^k wt(S_{i_j}) \leq 4wt(S_{i_0})$ . Since any large set must lie in such a sequence the lemma follows.

Let  $T_j$  be the union of the small sets between  $S_j$  and  $S_{j-1}$ . Let the sequence  $R_{i_h}, R_{i_{h-1}}, \dots, R_{i_0}$ , comprise the merge of the sequence  $S_{i_k}, \dots, S_{i_0}$ , and the nonempty sets in the sequence  $T_{i_k}, \dots, T_{i_1}$ . We actually prove that  $\sum_{j=1}^h wt(R_{i_j}) \leq 4wt(R_{i_0}) = 4wt(S_{i_0})$ . This result is an immediate consequence of the following claim: *Claim 1.* For  $1 \leq j \leq h, wt(R_{i_j}) \leq 2^{2-j} wt(R_{i_0})$ . This in turn, is an immediate consequence of the following two claims: *Claim 2.* For  $1 \leq j \leq h, |R_{i_j}| \leq 2^j |R_{i_0}|$ . *Claim 3.* For  $1 \leq j \leq h$ , the weight of any collection in  $R_{i_j}$  is at most  $2^{2-2j}$  of the weight of any collection in  $R_{i_0}$ . Claim 3 is immediate.

*Proof of Claim 2.* For each set  $R_j, j \geq 1$ , we prove the following *assertion*: the number of collections in  $\bigcup_{x=0}^{j-1} R_x \cup L_0$  is greater than the number of collections in  $R_j$ . Claim 2 follows by induction on  $j$ , from the assertion, when we note that  $|L_{i_0}| \leq |R_{i_0}|$ . The proof of the assertion breaks into two cases.

*Case 1.*  $R_j$  is a set  $S_{i_y}$ . Because  $S_{i_y}$  is not useful  $|S_{i_y}| < |L_{i_y+1}|$ , and the assertion follows.

*Case 2.*  $R_j$  is a set  $T_{i_x}$ . We note that  $|T_{i_x}| < \frac{1}{31}|S_{i_x}|$ . Also, since  $S_{i_x}$  is not useful,  $|S_{i_x}| < |T_{i_x}| + |L_{i_x-1}|$ . Thus  $|T_{i_x}| < \frac{1}{31}(|T_{i_x}| + |L_{i_x-1}|)$ . We deduce that  $|T_{i_x}| < |L_{i_x-1}|$ . Again, the assertion follows.  $\square$

*Proof of Lemma 3.5.3.* We note that  $|S_{i-1}| + |S_i| + |L_{i+1}| \leq 34|S_i|$  for  $S_i$  large and useful. There are two possibilities:

*Possibility 1.*  $|S_i| \leq p/36$ . Then  $S_i$  has at least  $35|S_i|$  neighbors, of which at least  $|S_i|$  lie outside  $S_{i-1} \cup S_i \cup L_{i+1}$ .

*Possibility 2.*  $|S_i| > p/36$ . Then  $S_i$  has at least  $35p/36$  neighbors. Observe that  $|\bigcup_{j=0}^{i-2} S_j| \geq p/2$  (since  $i > \text{average} + 2$ ). Therefore, at least  $17p/36$  of these neighbors are in  $\bigcup_{j=0}^{i-2} S_j$ . Also,  $i > \text{average} + 2$ , implies that  $|S_i| \leq p/4$ . Thus  $S_i$  has at least  $17/9|S_i| > |S_i|$  neighbors in  $\bigcup_{j=0}^{i-2} S_j$ . This completes the proof of Lemma 3.5.3.  $\square$

Note that we have required that  $f \geq g, f \geq (8d)^2$ . Thus, in the definition of balanced above, we set  $f = \max \{g, (8d)^2\}$ .

**4. List ranking.** We give an optimal  $O(\log n)$  time algorithm to solve the following generalization of list ranking.

*Input.* A linked list of  $n$  nodes, stored in an array with index range  $[0: n-1]$ . In addition, for each node, we are given the distance to its successor in the list (typically this distance is unity, though in general it need not be). For each node, we store the pointer and the distance to its successor in the arrays  $D(0: n-1)$  and  $R(0: n-1)$ , respectively. For the last node  $v$  in the list we have  $R(v) = 0$  and  $D(v) = \text{nil}$ .

*Problem.* Compute into array  $R$ , for each node  $u$ , the distance from  $u$  to the end of the list.

It is useful to assume that each node knows its predecessor in the list. We store the predecessors in array  $P$ .  $P$  can be computed in  $O(1)$  time using  $O(n)$  operations, in the obvious way.

The algorithm starts with a series of  $O(\log n)$  steps. Each step takes  $O(1)$  time. In each step we reduce the problem to a smaller subproblem by removing a set of nonadjacent nodes from the list. We remove node  $u$ , the successor of node  $v$  (that is  $u = D(v)$ ), by the following group of assignments.

$$\begin{aligned} R(v) &:= R(v) + R(u); \\ D(v) &:= D(D(v)) \\ \text{if } D(v) \neq \text{nil} &\text{ then } P(D(v)) := v \end{aligned}$$

At each step of the algorithm each processor is associated with a node. If these assignments are performed by a processor associated with node  $v$  this is called a *traversal* by node  $v$ ; if they are performed by a processor associated with node  $u$  this is called a *removal* by node  $u$ . Since, in any given step the removed nodes are nonadjacent, it is easy to perform the removals by an EREW algorithm.

Our algorithm has three stages.

*Stage 1.* In  $O(\log n)$  steps the input list will be reduced to a list of at most  $n/\log n + 1$  nodes. This will take  $O(\log n)$  time and  $O(n)$  operations.

*Stage 2.* We compute the list ranking on the remaining list (the *reduced* list) using Wyllie's list ranking algorithm [W-79]; it will perform  $O(n)$  operations in time  $O(\log n)$ .

*Stage 3.* We show how to “reconstruct” the list ranking of nodes that were removed in Stage 1; it is reconstructed from the list ranking of the reduced list, computed in Stage 2. We first observe that given the list ranking for the list present at the end of a step of Stage 1, the ranking for the nodes present at the start of the step can be computed in  $O(1)$  time. Specifically, let the vector  $R_{actual}$  contain the final list ranking (to be computed). Let  $u$  be a node, other than the last node, which was removed from the list at a step of Stage 1. Suppose that  $R_{actual}(D(u))$  is known. (Note that neither  $D(u)$  nor  $R(u)$  was changed by our algorithm after this removal). Then  $R_{actual}(u)$  can be computed by  $R_{actual}(u) := R(u) + R_{actual}(D(u))$ . Second we apply the idea of backtracking. Specifically, each processor “revisits” the operations it performed at Stage 1 from the most recent to the earliest; at the time of revisiting the operation of removing node  $u$  it simply computes  $R_{actual}(u)$ . We refer the reader to [CV-86a] for a more detailed discussion of the “backtracking” procedure required. The time complexity of Stage 3 is dominated by the time complexity of the forward steps of Stage 1.

So the total complexity of the algorithm is  $O(n)$  operations and  $O(\log n)$  time.

The rest of this section is concerned only with the traversals and removals of Stage 1. The goal is to obtain a reduced list of at most  $n/\log n + 1$  nodes (the reduced list will include the first node of the input list). We call the nodes in the reduced list *full* nodes. The traversals and removals are performed by a set of  $n - 1$  tasks, associated with each node in the list (except the first node). Each task performs at most  $5 \log n - 1$  steps of traversals and removals. Our main effort in this section is to show how to formulate these tasks so that we can use the duration-unknown task scheduling algorithm from § 3 to schedule them. We need the following definition.

**DEFINITION.** An  $r$ -ruling set of a linked list is a subset  $U$  of the nodes of the list such that

- (i) No two nodes of  $U$  are adjacent in the list.
- (ii) If  $v$  is a node in the list, the next node from  $U$  in the list is at most  $r$  edges (links) distant from  $v$ .

We recall that there is a  $4 \log n$ -ruling set algorithm that performs  $O(n)$  operations in  $O(1)$  time [CV-86a]. To make the paper self-contained we have described a slightly modified version of this algorithm in Appendix A. The algorithm has the following property: The first node in the list is always placed into the ruling set unless its successor is the last node in the list (i.e. the list contains exactly two nodes). We remark, that by definition, the ruling set contains the last node in the list. Also, the algorithm actually provides a *stronger result that we use below*: Suppose we assign a processor to each node in the list. Then, solely by looking at  $v$ , its predecessor and two successors, the processor can determine in  $O(1)$  time whether  $v$  is in the  $\log n$ -ruling set.

*The task of  $v$ , for any node  $v$  in the list.* At the beginning, the task of node  $v$  will be *waiting*. At some step of Stage 1 a processor will be assigned to node  $v$  and the task will become *active*. The task will remain active until it is completed. Upon completing this task the processor will be able to determine whether  $v$  is in the reduced list (i.e. whether  $v$  is a *full node*) or not. If  $v$  is not in the reduced list then node  $v$  either: performs a removal, or “marks itself for removal,” or is already removed.

On becoming active the task determines if node  $v$  has been removed from the present linked list. If so, in one step, the processor completes the task of node  $v$  without removing any node and  $v$  is not a full node. So, suppose that  $v$  is in the present list. The processor of  $v$  will complete its task with the decision that  $v$  is a full node if and when the following two conditions hold:

- (i) Node  $v$  has performed at least  $\log n$  traversals.

(ii) The successor of node  $v$  in the present list is not marked for removal. Each step comprises three **synchronized** substeps.

*Substep 1.*

**If** node  $v$  has performed at least  $\log n$  traversals and the successor of node  $v$  in the present list is not marked for removal  
**then** the task is completed (without even proceeding to Substep 2);  $v$  is a full node.

*Substep 2.*

**If** the successor of  $v$  has completed and is a full node  
**then if** the predecessor of  $v$  is not active  
**then**  $v$  performs a removal; the task is completed;  $v$  is not a full node.  
**else** mark  $v$  for removal; the task is completed;  $v$  is not a full node.

*Substep 3.*  $v$  belongs to a “chain” of presently active nodes; the chain is of length at least one and is followed by a node that is not full (either a node whose task is waiting or a node marked for removal).

Use the stronger version of the  $\log n$ -ruling set algorithm to find whether  $v$  is in a  $\log n$ -ruling set with respect to this chain. (Note: the last node in the chain is always placed in the ruling set. Specifically, in the trivial case, where the chain consists of a single node, this node is in the ruling set.)

**If**  $v$  is not in the ruling set and is not the first node in the chain  
**then** mark  $v$  for removal; the task is completed;  $v$  is not a full node.  
**else if**  $v$  is not in the ruling set and is the first node in the chain  
**then**  $v$  performs a removal; the task is completed;  $v$  is not a full node.  
**else** (\*  $v$  is in the ruling set \*)  $v$  performs a traversal.

Let us analyze the algorithm.

The reduced list comprises nodes that have traversed at least  $\log n$  nodes each, plus the first node in the input list. This implies:

LEMMA 4.1. *The length of the reduced list is at most  $n/\log n + 1$ .*

LEMMA 4.2. *The task of each node includes at most  $5 \log n - 1$  traversals.*

*Proof.* We need the following observation. Consider the time at which node  $u$  is marked for removal (but not removed). There must be a chain of length  $x \leq 4 \log n + 1$  nodes which ends at (and includes)  $u$  and satisfies the following: (1) The last  $x - 1$  nodes of this chain are marked for removal simultaneously. (2) The first node of the chain is active and has performed less than  $\log n$  traversals.

Now consider node  $v$  that has performed at least  $\log n$  traversals. After the time at which node  $v$  performed its  $\log n$ th traversal, its successors could have formed a chain of at most  $4 \log n - 1$  nodes marked for removal. This chain cannot grow while node  $v$  traverses the chain. Finally, Substep 1 implies that node  $v$  completes its task after traversing the  $\leq 4 \log n - 1$  nodes in this chain. Lemma 4.2 follows.  $\square$

Each removed node was subject to exactly one traversal or removal operation in one of the  $n - 1$  tasks. This implies the following corollary.

COROLLARY 4.1. *There are  $n - 1$  tasks. Each task is of length  $O(\log n)$  and the total length of the tasks is  $O(n)$ . Further, a task, once active, remains active until it is completed.*

Corollary 4.1 describes exactly the problem solved by the duration-unknown task scheduling algorithm of § 3. Thus these tasks require  $O(\log n)$  time and  $O(n)$  operations.

We have shown the following.

**THEOREM 4.1.** *There is an EREW PRAM algorithm for list ranking that runs in  $O(\log n)$  time using  $n/\log n$  processors, which is optimal.*

**5. Summary.** This paper has identified two scheduling problems, namely the *object redistribution* problem and the *duration-unknown task scheduling* problem. The object redistribution problem is solved optimally in  $O(1)$  time on  $n/\log n$  processors (by the *redistribution procedure*), and the task scheduling problem is solved in  $O(\log n)$  time on  $O(n/\log n)$  processors; it used the redistribution procedure as a subroutine, repeatedly. A key feature of the redistribution procedure is that it makes use of expander graphs, resulting in large constants in the running time.

The other major problem solved in this paper is the list ranking problem. An optimal deterministic algorithm is given:  $O(\log n)$  time and  $O(n/\log n)$  processors.

We pose the following open problem. Can a solution to the task scheduling problem, that does not involve the use of expander graphs, be found?

**Appendix A. The  $4 \log n$ -ruling set algorithm.** The algorithm we describe is a simplified presentation of the algorithm given in [CV-86a]; this presentation is due to Goldberg, Plotkin and Shannon [GPS-87].

*Assumptions about the input representation.* The vertices are given in an array of length  $n$ . The entries of the array are numbered from 0 to  $n-1$ . Each entry number is called the *label* of its vertex. The labels are represented as binary strings of length  $\lceil \log n \rceil$ . We refer to each binary symbol (bit) of this representation by a number between 0 and  $\lceil \log n \rceil - 1$ . The rightmost (least significant) bit is called bit number 0 and the leftmost bit is called bit number  $\lceil \log n \rceil - 1$ . Each vertex has a pointer to the next vertex in the list (representing its outgoing edge). For simplicity we assume that  $\log n$  is an integer.<sup>1</sup>

We show how to find a  $4 \log n$ -ruling set.

First, we show how to relabel the vertices. The new label of a vertex is called the *color* of the vertex. Let  $a = a_{k-1}, \dots, a_0$  and  $b = b_{k-1}, \dots, b_0$  be the labels of vertex  $u$  and its successor, respectively. Let  $j$  be the index of the least significant binary digit in which  $a$  and  $b$  differ. The *color of vertex  $u$*  is  $\langle j, a_j \rangle$ . We consider the color to be a binary number between 0 and  $2k-1$ . It is easy to see that the colors satisfy the following two properties:

- (1) There are at most  $2 \log n$  different colors.
- (2) Each pair of adjacent vertices are colored differently.

A remark in [CV-86a] explains how a vertex can compute its label in constant time using standard operations.

Second, we show how to select a  $4 \log n$ -ruling set. We define a vertex to be a local maximum if its color is larger than the colors of its two neighbors. Then a  $(4 \log n - 2)$ -ruling set can be chosen as follows: select all vertices that are local maxima. Since a monotone chain can have length at most  $2 \log n$ , it follows that we have selected a  $(4 \log n - 2)$ -ruling set. A slight modification of this algorithm creates a  $4 \log n$ -ruling set that contains the last vertex of the list, and if it is not adjacent to the last vertex, the first vertex also, again in  $O(1)$  time.

**Appendix B. Building the expander graph.** For our construction we need  $\varepsilon = \frac{1}{36}$ . In other words, for  $|U| \leq |V|/36$ , we need that  $|N(U)| \geq 35|U|$ . We use an expander graph based on the construction described following Theorem 2 of [JM-85]. There, a different definition of expander graphs, which is due to Margulis [M-75] is given. The

<sup>1</sup> The base of all logarithms in the Appendix is 2.

definition follows: A bipartite graph  $K = (V_1, V_2, E)$  is an  $(n, k, \delta)$  expander graph if  $|V_1| = |V_2| = n$ , the degree is  $k$ , and for each subset  $U$  of  $V_1$ ,  $|N(U)| \geq (1 + \delta(1 - |U|/|V_1|))|U|$ . (Comment: actually in [JM-85] Jimbo and Maruoka do not restrict the degree; they merely require  $|E| \leq kn$ ; however, their constructions all obey this less liberal definition.) To obtain an expander obeying the definition of § 3, simply identify the sets  $V_1$  and  $V_2$ ; for a given pair of values  $\varepsilon$  and  $\delta$  it is easy to deduce the corresponding  $\gamma$ .

Jimbo and Maruoka [JM-85] give an expander graph  $K$  with  $k = 5$  and  $\delta > \frac{1}{10}$ . From this graph, using standard methods, we can obtain the expander graph  $G$  needed for our construction, as follows. We "iterate" the construction  $r$  times, for some constant  $r$  (which depends only on  $\varepsilon$ ), creating graph  $H$ . Namely, the vertices of  $H$  comprise the disjoint vertex sets  $V_1, V_2, \dots, V_{r+1}$ ; we place a copy of the edges of  $K$  between  $V_i$  and  $V_{i+1}$ , for  $1 \leq i \leq r$ .  $G$  has vertex sets  $V_1$  and  $V_{r+1}$ . If in  $H$ , vertices  $v \in V_1$  and  $w \in V_{r+1}$  are connected by a path of length  $r$ , then in  $G$ ,  $v$  and  $w$  are joined by an edge.  $K$  has vertex degree 5; thus  $G$  has vertex degree at most  $5^r$ . Finding the constant  $r$  is easy: For  $|U| \leq \frac{35}{36}|V_1|$  the graph  $K$  satisfies that  $|N(U)| \geq (1 + \frac{1}{10} \frac{1}{36})|U| \geq (1 + \frac{1}{360})|U|$ . It is easy to see that in  $G$ ,  $|N(U)| \geq \min\{\frac{35}{36}|V_1|, (1 + \frac{1}{360})^r|U|\}$ . Determining  $r$  is now straightforward. (A more careful argument provides a much tighter bound.) There are two more issues to be considered in order to adapt the construction of [JM-85] to our needs:

(1) In [JM-85] Jimbo and Maruoka provide expander graphs for which  $|V_1| = |V_2| = m^2$ , where  $m$  is an integer. We actually wanted an expander graph on  $n$  vertices, not on  $m^2$  vertices. So let  $(m-1)^2 < n \leq m^2$ . Instead of using an expander graph on  $n$  vertices, we use the expander graph on  $m^2$  vertices. This implies the algorithm assumes  $m^2$  processors are available; but such an algorithm is readily simulated on  $n$  processors, slowing it down by a factor of at most 2.

(2) We comment on the complexity of constructing the edges of  $K$  (and implicitly of  $G$ ). Each vertex has degree five. Each edge can be readily determined in  $O(1)$  time by a single processor.

**Acknowledgments.** The authors thank the referees for their comments; in particular, the comments that led to a clearer presentation of § 3.

## AN $O(n \log \log n)$ -TIME ALGORITHM FOR TRIANGULATING A SIMPLE POLYGON\*

ROBERT E. TARJAN†‡ AND CHRISTOPHER J. VAN WYK†

**Abstract.** Given a simple  $n$ -vertex polygon, the *triangulation problem* is to partition the interior of the polygon into  $n-2$  triangles by adding  $n-3$  nonintersecting diagonals. We propose an  $O(n \log \log n)$ -time algorithm for this problem, improving on the previously best bound of  $O(n \log n)$  and showing that triangulation is not as hard as sorting. Improved algorithms for several other computational geometry problems, including testing whether a polygon is simple, follow from our result.

**Key words.** amortized time, balanced divide and conquer, heterogeneous finger search tree, homogeneous finger search tree, horizontal visibility information, Jordan sorting with error-correction, simplicity testing

**AMS(MOS) subject classifications.** 51M15, 68P05, 68Q25

**1. Introduction.** Let  $P$  be an  $n$ -vertex simple polygon, defined by a list  $v_0, v_1, \dots, v_{n-1}$  of its vertices in clockwise order around the boundary. (The interior of the polygon is to the right as one walks clockwise around the boundary.) We denote the boundary of  $P$  by  $\partial P$ . We assume throughout this paper (without loss of generality) that the vertices of  $P$  have distinct  $y$ -coordinates. For convenience we define  $v_n = v_0$ . The *edges* of  $P$  are the open line segments whose endpoints are  $v_i, v_{i+1}$  for  $0 \leq i < n$ . The *diagonals* of  $P$  are the open line segments whose endpoints are vertices and that lie entirely in the interior of  $P$ . The *triangulation problem* is to find  $n-3$  nonintersecting diagonals of  $P$ , which partition the interior of  $P$  into  $n-2$  triangles.

If  $P$  is convex, any pair of vertices defines a diagonal, and it is easy to triangulate  $P$  in  $O(n)$  time. If  $P$  is not convex, not all pairs of vertices define diagonals, and even finding one diagonal, let alone triangulating  $P$ , is not a trivial problem. In 1978, Garey, Johnson, Preparata and Tarjan [10] presented an  $O(n \log n)$ -time triangulation algorithm. Since then, work on the problem has proceeded in two directions. Some authors have developed linear-time algorithms for triangulating special classes of polygons, such as monotone polygons [10] and star-shaped polygons [31]. Others have devised triangulation algorithms whose running time is  $O(n \log k)$  for a parameter  $k$  that somehow quantifies the complexity of the polygon, such as the number of reflex angles [13] or the "sinuosity" [5]. Since these measures all admit classes of polygons with  $k = \Omega(n)$ , the worst case running time of these algorithms is only known to be  $O(n \log n)$ . Determining whether triangulation can be done in  $o(n \log n)$  time, i.e. asymptotically faster than sorting, has been one of the foremost open problems in computational geometry.

In this paper we propose an  $O(n \log \log n)$ -time triangulation algorithm, thereby showing that triangulation is indeed easier than sorting. The paper is a revised and corrected version of a conference paper [27] which erroneously claimed an  $O(n)$ -time algorithm. The goal of obtaining a linear-time algorithm remains elusive, but our

approach suggests some directions in which to look and clarifies the difficulties that must be overcome.

The starting point for our algorithm is a reduction of the triangulation problem to the problem of computing visibility information along a single direction, which we take to be horizontal. A *vertex-edge visible pair* is a vertex and an edge that can be connected by an open horizontal line segment that lies entirely inside  $P$ . Similarly, an *edge-edge visible pair* is a pair of edges that can be connected by an open horizontal line segment that lies entirely inside  $P$ . Fournier and Montuno [9] showed that triangulating  $P$  is linear-time equivalent to computing all vertex-edge visible pairs. The reduction of triangulation to computing visible pairs was independently obtained by Chazelle and Incerpi [5]. What we shall actually produce is an  $O(n \log \log n)$ -time algorithm for computing visible pairs, which by this reduction leads to an  $O(n \log \log n)$ -time triangulation algorithm.

Our visibility algorithm computes not only vertex-edge visible pairs but also possibly some edge-edge visible pairs. It is reassuring that the total number of visible pairs of either kind is linear.

LEMMA 1. *There are at most  $2n$  vertex-edge visible pairs and at most  $2n$  edge-edge visible pairs.*

*Proof.* Each vertex can be in at most two vertex-edge visible pairs, for a total over all vertices of at most  $2n$ . Partition  $P$  into trapezoids and triangles by drawing a horizontal line segment between each visible pair (of either kind) through the interior of  $P$ . (See Figure 1.) Each edge-edge visible pair corresponds to the bottom boundary of exactly one such trapezoid or triangle, the top boundary of which is either one or two line segments corresponding to vertex-edge visible pairs (in the case of a trapezoid) or a vertex that is in no visible pairs (in the case of a triangle). A vertex

FIG. 1. A simple polygon  $P$ , showing visibility information: dashed horizontal lines correspond to vertex-edge visible pairs; dotted horizontal lines correspond to edge-edge visible pairs.

gives rise to at most two top boundary segments of trapezoids or to at most one top boundary of a triangle. Thus there are at most  $2n$  trapezoids and triangles whose bottom boundaries correspond to edge-edge visible pairs, and hence at most  $2n$  such pairs.

□

The second cornerstone of our method is the intimate connection between visibility computation and the Jordan sorting problem. For a simple polygon  $P$  and a horizontal line  $L$ , the *Jordan sorting problem* is to sort the intersection points of  $\partial P$  and  $L$  by  $x$ -coordinate, given as input only a list of the intersections in the order in which they occur clockwise around  $\partial P$ . (The list of vertices of  $P$  is *not* part of the input.) Hoffman, Mehlhorn, Rosenstiehl and Tarjan [14] have presented a linear-time Jordan sorting algorithm, which actually works for any simple curve, open or closed. This algorithm, which we call “the Jordan sorting algorithm,” requires that  $\partial P$  actually cross  $L$  wherever it touches it, but the algorithm is easily modified to handle tangent points, provided that each intersection point is labeled in the input as being either crossing or tangent.

Computing visible pairs is at least as hard as Jordan sorting, in the sense made precise in the following lemma:

**LEMMA 2.** *Using an algorithm to compute vertex-edge visible pairs, one can solve the Jordan sorting problem for an  $n$ -vertex polygon  $P$  in  $O(n)$  additional time, given as input the polygon and the line  $L$  (and not the intersections).*

*Proof.* Compute all vertex-edge visible pairs for  $P$ . Next, turn  $P$  “inside out” by breaking  $P$  at its lowest vertex and drawing a box around it as shown in Figure 2, forming a polygon  $Q$  with  $n+5$  vertices. Compute the vertex-edge visible pairs for  $Q$ . These pairs specify vertex-edge visibilities on the outside of  $P$ , and indicate which vertices of  $P$  can see arbitrarily far left or right on the outside. Partition the inside and outside of  $P$  into trapezoids, triangles, and unbounded trapezoidal regions by drawing horizontal line segments corresponding to each visible pair. Given a line  $L$ , the intersection points of  $\partial P$  and  $L$  can be read off in increasing  $x$ -order by moving left to right through the regions that intersect  $L$ . The total time for this algorithm, not including the two visibility computations, is  $O(n)$ . □

Since any visibility computation does Jordan sorting implicitly, it is natural to try using Jordan sorting explicitly to compute visible pairs. This leads to the following divide-and-conquer visibility algorithm (see Figure 3):

*Step 1.* Given  $P$ , choose a vertex  $v$  of  $P$  that does not have maximum or minimum  $y$ -coordinate. If no such  $v$  exists, stop: there are no visible pairs to compute. Otherwise, let  $L$  be the horizontal line through  $v$ .

*Step 2.* Determine the intersection points of  $\partial P$  and  $L$  in the order in which they occur along the boundary of  $P$ .

*Step 3.* Jordan sort the intersection points and report the visible pairs that correspond to consecutive intersection points along  $L$ .

*Step 4.* Slice  $P$  along  $L$ , dividing  $P$  into a collection of subpolygons.

*Step 5.* Apply the algorithm recursively to each subpolygon computed in Step 4.

The Jordan sorting algorithm has the fortuitous side effect of computing enough extra information so that Step 4 is easy. The hard part of the computation is Step 2. There are two major bottlenecks in the algorithm, either of which will make a naive implementation run in quadratic time. First, it is possible for the algorithm to report redundant visibility pairs; indeed, the example in Figure 4 shows that it can report  $\Omega(n^2)$  nondistinct pairs.

We eliminate this bottleneck by modifying Step 2 to compute only some of the intersections of  $\partial P$  with  $L$ . This can cause the Jordan sorting algorithm used in Step

FIG. 2. Polygon  $P$  of Figure 1 turned "inside out," and showing exterior vertex-edge visible pairs.

3 to detect an error, since the sequence to be sorted need no longer consist of all intersections of a simple polygon with a line. Fortunately the sorting algorithm is incremental, and when it detects an error, we can restart it in a correct state by computing a few additional intersections and making local changes in its data structure. We call this augmented sorting method *Jordan sorting with error-correction*.

By computing only some of the intersections of  $\partial P$  and  $L$  and using Jordan sorting with error-correction, we obtain a visibility algorithm that reports only  $O(n)$  visible pairs and runs in  $O(n)$  time not counting the time needed to find intersections. This approach requires the use of a two-level data structure to represent polygon boundaries, but imposes no further constraints on the details of the data structure.

The second, far more serious bottleneck is the problem of actually finding the intersections. The line  $L$  divides  $\partial P$  into pieces. If each of these pieces ended up in a different subpolygon boundary, then we could obtain (with a little work) an overall  $O(n)$  time bound for the visibility algorithm by using finger search trees in the boundary data structure and appealing to the linearity of the following recurrence [20, p. 185]:

$$(1) \quad T(n) = \begin{cases} O(1) & \text{if } n = 1; \\ \max_{1 \leq k < n} \{T(k) + T(n-k) + O(1 + \log \min\{k, n-k\})\} & \text{if } n > 1. \end{cases}$$

Unfortunately the pieces of the original boundary do not stay apart but are regrouped to form the subpolygon boundaries. To beat the  $O(n \log n)$  time bound of previous triangulation algorithms, we need another idea, that of *balanced divide and conquer*. We refine the visibility algorithm to choose  $L$  judiciously, so that each of the subpolygon boundaries contains a relatively small number of pieces of the original

FIG. 3. Illustrating Steps 1 and 4 of the visibility algorithm.

boundary. Balanced divide and conquer combined with the use of finger search trees in the boundary data structure produces a visibility algorithm that runs in  $O(n \log \log n)$  time.

The remainder of this paper consists of five sections and an appendix. In Section 2 we review the Jordan sorting algorithm and modify it to do error-correction. In Section 3 we present a generic visibility algorithm, based on Jordan sorting with error-correction, that reports  $O(n)$  visible pairs. In Section 4 we refine the algorithm so that it uses balanced divide and conquer. In Section 5 we propose a data structure for representing the polygon boundary that consists of two levels of finger search trees. We show that with this data structure the visibility algorithm of Section 4 runs in  $O(n \log \log n)$  time. We close in Section 6 with some remarks, applications, and open problems. The appendix contains a discussion of finger search trees, which are needed not only in the visibility algorithm itself but also in the Jordan sorting algorithm.

**2. Jordan sorting with error-correction.** Let  $P$  be a simple polygon and let  $v$  be a vertex of  $P$ . Let  $L$  be the horizontal line through  $v$ , and let  $x_0 = v, x_1, \dots, x_{m-1}$  be the intersection points of  $\partial P$  and  $L$  in clockwise order around  $\partial P$ . (Since throughout this paper we are assuming that the vertices of  $P$  have distinct  $y$ -coordinates,  $\partial P$  and

FIG. 4. This class of polygons can cause the naive algorithm to produce a quadratic amount of output. A first slice through  $v_0$  cuts off  $k+1$  triangles. Successive slices at  $v_{2i}$ ,  $i=1, 2, \dots, k$ , report  $k-i+1$  visible pairs, but only two are new each time.

$L$  intersect in a finite set of points.) Points  $x_1, x_2, \dots, x_{m-1}$  are crossing points of  $\partial P$  and  $L$ ; point  $x_0$  is either a crossing point or a tangent point. We impose a total order on the points  $x_i$  given by the order of their  $x$ -coordinates. We wish to sort  $x_0, x_1, \dots, x_{m-1}$  according to this total order.

The sequence  $x_0, x_1, \dots, x_{m-1}$  gives rise to two forests, in the following way. For convenience let  $x_m = x_0$ . Without loss of generality assume that the part of  $\partial P$  from  $x_0$  to  $x_1$  lies above  $L$ . For  $0 < i \leq m$ , let  $\ell_i = \min\{x_{i-1}, x_i\}$  and  $r_i = \max\{x_{i-1}, x_i\}$ . We say a pair  $\{x_{i-1}, x_i\}$  *encloses* a point  $x$  if  $\ell_i \leq x < r_i$ . We say two pairs  $\{x_{i-1}, x_i\}$  and  $\{x_{j-1}, x_j\}$  *cross* if  $\{x_{i-1}, x_i\}$  encloses exactly one of  $x_{j-1}$  and  $x_j$ ;  $\{x_{i-1}, x_i\}$  *encloses*  $\{x_{j-1}, x_j\}$  if it encloses both of  $x_{j-1}$  and  $x_j$ . The simplicity of  $P$  implies that if  $i \equiv j \pmod{2}$ , then the two pairs  $\{x_{i-1}, x_i\}$  and  $\{x_{j-1}, x_j\}$  do not cross. We call this the *noncrossing property*. The Hasse diagram of the “encloses” relation on the set of pairs  $\{\{x_{2i}, x_{2i+1}\} \mid 0 \leq i < m/2\}$  is a forest, called the *upper forest*. The Hasse diagram of “encloses” on the set of pairs  $\{\{x_{2i-1}, x_{2i}\} \mid 0 < i \leq m/2\}$  is also a forest, called the *lower forest*. We order each set of siblings in either forest by placing  $\{x_{i-1}, x_i\}$  before  $\{x_{j-1}, x_j\}$  if  $r_i \leq \ell_j$ . This makes each forest into an ordered forest. We make the two forests into trees by adding the dummy pair  $\{-\infty, \infty\}$  to each. Thus we obtain two trees, called the *upper tree* and the *lower tree*. (See Figure 5.) We call the set consisting of a parent in either tree and its children a *family*.

FIG. 5. Hasse diagram of the "encloses" relation with respect to line L. (Point  $x_i$  is labelled  $i$ .)

We shall restate the Jordan sorting algorithm [14] in a form suitable for extension to the visibility computation. The algorithm proceeds incrementally, processing the points  $x_1, x_2, \dots, x_m$  one at a time and building the upper tree, the lower tree, and a list of the points in sorted order. Initialization consists of making  $\{-\infty, \infty\}$  the only pair in both trees and defining the sorted list to be  $(-\infty, x_0, \infty)$ . The general step consists of processing point  $x_i$  by performing the following steps. Suppose  $i$  is odd, i.e.  $\{x_{i-1}, x_i\}$  is to be added to the upper tree. Assume  $x_{i-1} < x_i$ . (The case  $x_{i-1} > x_i$  is symmetric.)

- Step 1. Find the point  $x$  that follows  $x_{i-1}$  in the sorted list.
- Step 2. Find the pair  $\{x_{j-1}, x_j\}$  in the upper tree such that  $x \in \{x_{j-1}, x_j\}$ .
- Step 3. Apply the appropriate one of the following four cases (see Figure 6):
  - Case A ( $\ell_j < x_{i-1} < r_j < x_i$ ). Halt:  $\{x_{i-1}, x_i\}$  and  $\{x_{j-1}, x_j\}$  cross.
  - Case B ( $\ell_j < x_{i-1} < x_i \leq r_j$ ). Make  $\{x_{i-1}, x_i\}$  the new last child of  $\{x_{j-1}, x_j\}$ . If  $i < m$ , insert  $x_i$  after  $x_{i-1}$  in the sorted list.

FIG. 6. The four cases for Jordan sorting.

Case C ( $x_i \leq \ell_j$ ). Insert  $\{x_{i-1}, x_i\}$  into the list of siblings of  $\{x_{j-1}, x_j\}$  just before  $\{x_{j-1}, x_j\}$ . If  $i < m$ , insert  $x_i$  after  $x_{i-1}$  in the sorted list.

Case D ( $x_{i-1} < \ell_j < x_i$ ). In the list of siblings of  $\{x_{j-1}, x_j\}$ , find the last one, say  $\{x_{k-1}, x_k\}$ , such that  $\ell_k < x_i$ . If  $r_k > x_i$ , halt:  $\{x_{i-1}, x_i\}$  and  $\{x_{k-1}, x_k\}$  cross. Otherwise, if  $\{x_{k-1}, x_k\}$  is the last child of its parent pair  $\{x_{p-1}, x_p\}$  and  $r_p < x_i$ , halt:  $\{x_{i-1}, x_i\}$  and  $\{x_{p-1}, x_p\}$  cross. If neither of these crossings is found, remove from the list of siblings of  $\{x_{j-1}, x_j\}$  the sublist from  $\{x_{j-1}, x_j\}$  to  $\{x_{k-1}, x_k\}$  (inclusive) and replace it by  $\{x_{i-1}, x_i\}$ . Make the removed sublist the list of children of  $\{x_{i-1}, x_i\}$ . If  $i < m$ , insert  $x_i$  after  $r_k$  in the sorted list.

Observe that if  $\{x_{i-1}, x_i\}$  and  $\{x_{j-1}, x_j\}$  are two pairs with  $i > j$  and  $i \equiv j \pmod 2$ , all four points  $x_{i-1}, x_i, x_{j-1}, x_j$  are distinct unless  $i = m$  and  $m$  is odd, in which case possibly  $x_i \in \{x_{j-1}, x_j\}$ . This means that Cases A-D exhaust the possible ordering relationships among the four points.

If  $i$  is even, i.e.  $\{x_{i-1}, x_i\}$  is to be added to the lower tree, the processing is analogous to the above, with a few changes needed to accommodate the fact that  $x_0$  is in no pair in the lower tree until  $x_m = x_0$  is processed (if then). The changes are as follows:

- (i) Just before Step 2, if  $x = x_0$ , replace  $x$  by the point that follows  $x_0$  in the sorted list.
- (ii) In Step 2, find the pair  $\{x_{j-1}, x_j\}$  that contains  $x$  in the lower tree (instead of in the upper tree).
- (iii) In Step 3, Cases B and C, if  $x_{i-1} < x_0 < x_i$ , insert  $x_i$  in the sorted list after  $x_0$  (instead of after  $x_{i-1}$ ).
- (iv) In Step 3, Case D, if  $r_k < x_0 < x_i$ , insert  $x_i$  in the sorted list after  $x_0$  (instead of after  $r_k$ ).

The sorting algorithm as stated tests for crossing pairs. If the input is guaranteed to be correct (i.e. to have the noncrossing property), we can simplify the algorithm by eliminating Case A and the two tests for crossing pairs in Case D.

Making the algorithm run in linear time requires the use of appropriate data structures. Each list of siblings in the upper and lower trees is represented by a homogeneous finger search tree (see the appendix) in which each leaf is a pair in the list. In addition, there are bidirectional pointers between each pair and its first and last children (in whichever tree contains the pair). Thus each family forms a doubly-linked circular list, with the additional property that any pair in the list can be accessed from any other pair  $d$  away in either direction in  $O(1 + \log d)$  time. Furthermore the amortized time<sup>1</sup> to insert a pair next to a given one in a family list is  $O(1)$ , and the amortized time to remove a sublist of  $d$  pairs from a list of  $s$  pairs, given the end pairs of the sublist, is  $O(1 + \log(\min\{d, s-d\} + 1))$ .

The running time of the Jordan sorting algorithm is dominated by the time spent doing "remove a sublist/insert a pair" operations on family lists. Let  $T(p,s)$  be the maximum amortized time needed to do a total of  $p$  such operations on an initial list of size  $s$  and on the removed sublists. Then  $T(p,s)$  obeys the following recurrence:

$$(2) \quad T(p,s) = \begin{cases} 0 & \text{if } p=0; \\ \max_{\substack{0 \leq i < p \\ 0 \leq d \leq s}} \{T(i,d+1) + T(p-i-1, s-d+1) \\ \quad + O(1 + \log(\min\{d, s-d\} + 1))\} & \text{if } p > 0. \end{cases}$$

A proof by induction shows that  $T(p,s) = O(p+s)$ . The list manipulation time of the Jordan sorting algorithm is at most  $T(\lceil m/2 \rceil, 1) + T(\lfloor m/2 \rfloor, 1)$ , from which it follows that the algorithm runs in  $O(m)$  time. For further details of the algorithm and the analysis see the original paper [14]. (In our restatement of the algorithm, we have modified the data structure slightly, the main change being to eliminate circular level links in the finger search trees. These changes do not affect the  $O(m)$  time bound.)

We now want to augment the Jordan sorting algorithm so that when it detects two crossing pairs, it can in certain cases restart itself in a corrected state that represents the partial sorting of a sequence modified to eliminate the crossing. In the application of Jordan sorting to the visibility computation, the sorting algorithm receives as input only a possibly noncontiguous subsequence of the sequence of intersections. In this subsequence, certain pairs are designated as *special*. (All other pairs are *normal*.)

To accommodate the operation of the triangulation algorithm, we impose on each special pair  $\{x_{i-1}, x_i\}$  the additional requirement that it enclose no given intersections other than  $x_{i-1}$  and  $x_i$ . We call this the *nonenclosure property*. On the other hand, special pairs are potentially modifiable: if  $\{x_{i-1}, x_i\}$  is a special pair, there may be additional intersections between  $x_{i-1}$  and  $x_i$  along  $\partial P$ . The Jordan sorting algorithm is allowed to request such additional intersections if it detects a crossing or a violation of the nonenclosure property.

The mechanism for providing additional intersections is a procedure named *refine*, whose input parameters consist of a special pair  $\{x_{i-1}, x_i\}$  and a point  $x$  enclosed by

---

<sup>1</sup>Amortized time is the time per operation averaged over a worst-case sequence of operations that begins with an empty data structure. For a discussion of this concept see the first author's survey paper [26].

$\{x_{i-1}, x_i\}$ . The procedure returns a *bracketing pair*  $x', x''$  such that  $x'$  and  $x''$  are intersections of  $\partial P$  and  $L$ , the four intersections occur in the order  $x_{i-1}, x', x'', x_i$  along  $\partial P$ , and the five points occur in the order  $x_{i-1}, x', x, x'', x_i$  (or its reverse) along  $L$ . If there is no such pair, *refine* returns nothing. If a pair is returned, the new sequence to be sorted is the old sequence with  $x'$  followed by  $x''$  inserted between  $x_{i-1}$  and  $x_i$ . Of the three pairs that replace  $\{x_{i-1}, x_i\}$ , the pairs  $\{x_{i-1}, x'\}$  and  $\{x'', x_i\}$  are special and the pair  $\{x', x''\}$  is normal. (This means that  $\{x', x''\}$  is the *closest* pair of intersections to  $x$ .)

We shall modify the Jordan sorting algorithm so that it can handle special pairs, using *refine* when possible to eliminate violations of the noncrossing and nonenclosure properties. The modification consists of the following three additions to the algorithm (see Figure 7):

(i) In Step 1, if  $\{x_{i-1}, x_i\}$  is special and  $x < x_i$ , call *refine* ( $\{x_{i-1}, x_i\}, x$ ). If *refine* returns no pair, halt:  $\{x_{i-1}, x_i\}$  violates the nonenclosure property. If *refine* returns a pair  $(x', x'')$ , insert  $x'$  and  $x''$  in the sequence to be sorted between  $x_{i-1}$  and  $x_i$  and restart the processing with  $x'$ .

(ii) In Step 3, Case B, if  $\{x_{j-1}, x_j\}$  is special, halt: the nonenclosure property has been violated. Even if it can be restored by refining  $\{x_{j-1}, x_j\}$ , this will produce a violation of the noncrossing property. (This also happens in Step 3, Case A: even if

FIG. 7. Modifications to make Jordan sorting error-correcting.

$\{x_{j-1}, x_j\}$  is special and the crossing of  $\{x_{i-1}, x_i\}$  and  $\{x_{j-1}, x_j\}$  can be eliminated by refining  $\{x_{j-1}, x_j\}$ , this will produce a new crossing pair.)

(iii) In Step 3, Case D, if  $\{x_{k-1}, x_k\}$  is special and  $r_k > x_i$ , do not halt, but instead call *refine* ( $\{x_{k-1}, x_k\}, x_i$ ). If *refine* returns no pair, halt:  $\{x_{k-1}, x_k\}$  violates the nonenclosure property. If *refine* returns a pair  $(x', x'')$ , replace  $\{x_{k-1}, x_k\}$  in the upper forest by  $\{x_{k-1}, x'\}$  followed by  $\{x'', x_k\}$ . Insert  $\{x', x''\}$  in the appropriate place in the lower forest (as a sibling or child of the pair containing  $x_k$ , whichever is appropriate). Proceed as in the remainder of Step 3, Case D, using  $\{x_{k-1}, x'\}$  in place of  $\{x_{k-1}, x_k\}$  and also in place of  $\{x_{j-1}, x_j\}$  if  $\{x_{j-1}, x_j\} = \{x_{k-1}, x'\}$ . That is, if  $\{x_{j-1}, x_j\} = \{x_{k-1}, x_k\}$ , replace  $\{x_{j-1}, x'\}$  in its list of siblings by  $\{x_{i-1}, x_i\}$  and make  $\{x_{j-1}, x'\}$  a child of  $\{x_{i-1}, x_i\}$ . If  $\{x_{j-1}, x_j\} \neq \{x_{k-1}, x_k\}$ , replace the sublist from  $\{x_{j-1}, x_j\}$  to  $\{x_{k-1}, x'\}$  (inclusive) by  $\{x_{i-1}, x_i\}$ , and make the sublist the list of children of  $\{x_{i-1}, x_i\}$ . In either case insert  $x_i$  after  $x'$  in the sorted list (or after  $x_0$  if  $x' < x_0 < x_i$ ).

The correctness of the error-correcting Jordan sorting algorithm follows from the observation that, while the algorithm is running, a special pair  $\{x_{j-1}, x_j\}$  can enclose at most one intersection point  $x_i \notin \{x_{j-1}, x_j\}$ . To see this, suppose without loss of generality that  $\{x_{j-1}, x_j\}$  is a pair in the upper tree. An intersection  $x_i \notin \{x_{j-1}, x_j\}$  can be inserted between  $x_{j-1}$  and  $x_j$  in the sorted list because of the addition of a pair  $\{x_{i-1}, x_i\}$  to the lower tree, but the violation of the enclosure property will be detected when the point  $x_{i+1}$  is processed, as illustrated in Figure 7(ii).

The additions necessary to make the algorithm error-correcting cost only  $O(1)$  time per point processed and per refinement, not including the time spent inside calls of *refine*. (There are at most two insertions in sibling lists per refinement.) Thus the error-correcting algorithm runs in  $O(m)$  time, where  $m$  is the number of intersection points in the final refined sequence. In the next section, we shall see how error-correcting Jordan sorting can be used to compute visible pairs.

**3. An efficient visibility algorithm.** Our algorithm for computing visible pairs follows the outline laid out in Section 1. It is a divide-and-conquer method that cuts up the original polygon into subpolygons, cuts these into smaller subpolygons, and so on, until none of the subpolygons can be further divided. In order to present the details of the method, we must first discuss the structure of the subpolygons, which we call *visibility regions*. The interior of a visibility region is a simply connected subset of the original polygon interior contained between two horizontal lines, denoted by  $y = y_{\min}$  and  $y = y_{\max}$  (with  $y_{\min} < y_{\max}$ ). We require that the region boundary actually intersect both of these lines. (See Figure 8.)

The boundary of a visibility region consists of connected pieces of the boundary of the original polygon, called *boundary segments*, alternating with segments of the lines  $y = y_{\min}$  and  $y = y_{\max}$ . Each such horizontal segment that is not a single point corresponds to a visible pair. At most one vertex of the original polygon lies on each of the lines  $y = y_{\min}$  and  $y = y_{\max}$ . Although a visibility region is itself a simple polygon, when we speak of its vertices we mean *only* those that are vertices of the original polygon  $P$ . A boundary segment begins with a vertex or part of an edge, called a *partial edge*, and ends with a vertex or partial edge. We call the edge of the original polygon that contains such a partial edge an *end edge* of the segment.

We divide the boundary segments into three types:

*top*: no end edge or vertex intersects the line  $y = y_{\min}$ ;

*bottom*: no end edge or vertex intersects the line  $y = y_{\max}$ ;

*side*: one end edge or vertex intersects the line  $y = y_{\max}$  and one intersects the line  $y = y_{\min}$ .

FIG. 8. Schematic illustration of a visibility region. Each curve represents a segment of the polygon boundary.

The degenerate case of a top or bottom boundary segment is a single vertex and no partial edges; the degenerate case of a side boundary segment is a single partial edge and no vertices. Clockwise around the boundary of a region, the boundary segments consist of four contiguous parts: a set of top segments, which together with the adjacent pieces of the line  $y = y_{\max}$  forms the *top* of the boundary; a side segment, which forms the *right side* of the boundary; a set of bottom segments, which together with the adjacent pieces of the line  $y = y_{\min}$  forms the *bottom* of the boundary; and another *side segment*, which forms the *left side* of the boundary. Both side segments must be present; either the top or the bottom or both can be empty.

We shall represent a visibility region by specifying  $y_{\min}$  and  $y_{\max}$  and the four parts of the boundary (left, right, top, and bottom). We represent the top and the bottom by lists of the boundary segments they contain, in clockwise order around the boundary. We represent the left and right sides by their single boundary segments. Finally, we represent each boundary segment by a list of the vertices in it, in clockwise order around the boundary, together with its end edges (if any). We leave unspecified the implementation of the lists that represent the boundary segments and the top and bottom boundaries of the region; this is the topic of Section 5.

Having discussed the structure of visibility regions, we now need to introduce some terminology concerning the intersections of the boundary of a region with a horizontal line. (See Figure 9.) Let  $V$  be a visibility region and let  $L$  be a horizontal line that intersects its interior. We partition the boundary segments of  $V$  into three types, depending on their relationship to  $L$ :

*shallow*: a segment that does not intersect  $L$ ;

FIG. 9. Illustrating three kinds of boundary segment. The top group includes a deep section of three segments. Both top and bottom groups include shallow sections of two segments.

*deep*: a top segment whose vertices are all strictly below  $L$  or a bottom segment whose vertices are all strictly above  $L$ ;

*mixed*: any other segment.

A side segment is definitely mixed; a top or bottom segment can be of any type. We define a *shallow section* to be a (contiguous) sublist of shallow boundary segments in the list of boundary segments clockwise around  $\partial V$ ; we define a *deep section* similarly. A deep or shallow section consists entirely of top segments or entirely of bottom segments. Each of the partial edges of a deep section intersects  $L$  and these are the only intersections of the section with  $L$ . We classify the intersections of  $\partial V$  with  $L$  into two types:

*nonessential*: an intersection within a maximal deep section that is not the first or the last within the section;

*essential*: any other intersection.

The last issues we must discuss before presenting the visibility algorithm are the notion of a *special pair* and the effect of the *refine* procedure, both of which affect the running of the error-correcting Jordan sorting algorithm. A pair of intersections of  $\partial V$  and  $L$  is *special* if the intersections are the first and last in some deep section (along  $\partial V$ ) and *normal* otherwise. (Observe that the intersections of a deep section with  $L$  occur in the same order along  $L$  as they do along  $\partial V$ , or in reverse order.) A call *refine* ( $\{x_{i-1}, x_i\}, x$ ) has the following effect. Points  $x_{i-1}$  and  $x_i$  are the first and last intersections in some deep section, say  $S$ . If  $S$  can be split into two deep sections  $S_1$  and  $S_2$  with first and last intersections  $x_{i-1}, x'$  and  $x'', x_i$ , respectively, such that  $\{x', x''\}$  encloses  $x$ , then *refine* returns  $(x', x'')$ . If  $S$  cannot be so split, *refine* returns no pair. Observe that if a pair  $(x', x'')$  is returned,  $\{x_{i-1}, x'\}$  and  $\{x'', x_i\}$  are special pairs and  $(x', x'')$  is a normal pair, as required by the Jordan sorting algorithm.

There is one more crucial observation about special pairs. Consider a special pair  $\{x_{i-1}, x_i\}$  that comprises the first and last intersections of a single deep boundary segment. If the segment is a top segment  $T$ , then  $T$  together with the appropriate seg-

ment of the line  $y = y_{\max}$  forms a simple closed curve whose interior contains the line segment joining  $x_{i-1}$  and  $x_i$  and whose exterior contains the boundary of  $V$  other than  $T$ . By the Jordan curve theorem,  $\{x_{i-1}, x_i\}$  can enclose no intersections other than  $x_{i-1}$  and  $x_i$ . Thus every special pair either can be refined or has the nonenclosure property, as required by the Jordan sorting algorithm.

We are at last ready to discuss the visibility algorithm itself. The input to the algorithm is a single visibility region  $V$ . To apply the algorithm to the original polygon, we convert the polygon into a visibility region by dividing its boundary into two side boundary segments whose end vertices are the vertices of minimum and maximum  $y$ -coordinate. The  $y$ -coordinates of these two vertices become  $y_{\min}$  and  $y_{\max}$  for the region. The algorithm is the same as that in Section 1 except that it computes only the essential intersections of  $\partial V$  and  $L$  in Step 2 and uses Jordan sorting with error-correction in Step 3. That is, it consists of the following five steps:

*Step 1.* Given  $V$  with bounding lines  $y = y_{\min}$  and  $y = y_{\max}$ , choose a vertex of  $V$  having  $y$ -coordinate  $y_{\text{cut}}$  such that  $y_{\min} < y_{\text{cut}} < y_{\max}$ . If there is no such  $v$ , stop: there are no visible pairs to compute. Otherwise, let  $L$  be the line  $y = y_{\text{cut}}$ .

*Step 2.* Find the essential intersections of  $\partial V$  and  $L$  in the order in which they occur along  $\partial V$ .

*Step 3.* Use Jordan sorting with error-correction to sort by  $x$ -coordinate the essential intersections and any others introduced by refinement. Report the visible pairs corresponding to consecutive sorted intersections along  $L$ .

*Step 4.* Slice  $V$  along  $L$ , dividing  $V$  into a collection of subregions.

*Step 5.* Apply the algorithm recursively to each subregion formed in Step 4.

The observations made above concerning special pairs and refinement imply that the Jordan sorting step works correctly; any nonessential intersection occurs along  $\partial V$  between the members of a special pair and is available by refinement if needed.

The last detail we must fill in before undertaking an analysis of the algorithm is the effect of Step 4. The boundaries of the subregions are formed as follows. (See Figure 10.) Split  $\partial V$  at each of the intersections sorted in Step 3. Each of the pieces so formed corresponds to a pair in the upper or lower tree constructed by the Jordan sorting algorithm. Each family in each of the trees whose parent has odd depth (counting the dummy roots as being of depth zero) corresponds to a subregion. The boundary of the subregion consists of the pieces of  $\partial V$  that correspond to the pairs of the family, in the order in which the members of the family occur in the family list in the lower tree or the reverse of this order in the upper tree, interspersed with appropriate segments of the line  $y = y_{\text{cut}}$ , *with one crucial exception*: if  $D$  is a piece of  $\partial V$  that corresponds to a deep boundary section, before using  $D$  as part of a subregion boundary, each of its segments of the line  $y = y_{\min}$  or  $y = y_{\max}$  must be replaced by a corresponding segment of the line  $y = y_{\text{cut}}$ . Observe that this has *no* effect on the representation of the deep boundary section, which means that no change in the data structure representing the section is necessary. Furthermore the visibility regions cut off by this replacement and henceforth ignored are trapezoids, on which the visibility algorithm would terminate in Step 1 were it invoked on them. The visibility algorithm obtains its efficiency by avoiding any computation associated with these trivial trapezoids.

We define  $y_{\min}$  and  $y_{\max}$  for the subregions as follows. Consider a subregion above  $L$ , which corresponds to a family in the upper tree. The value of  $y_{\min}$  for this subregion is  $y_{\text{cut}}$ . The value of  $y_{\max}$  for the subregion is  $y_{\max}$  for the region if the parent of the family is at depth one in the upper tree, or otherwise the maximum  $y$ -coordinate of a vertex in the piece of  $\partial V$  corresponding to the parent of the family. In

FIG. 10. *Assembling subregions. The family tree nodes associated with several regions are shown. Trapezoids labeled "0" are ignored completely.*

the latter case, the piece of  $\partial V$  corresponding to the parent consists of a single piece of a boundary segment of  $V$ . We split this piece at the vertex with maximum  $y$ -coordinate to form two pieces, which become the side boundary segments of the subregion; the top of the subregion is empty. The definitions are symmetric for subregions below  $L$ .

Let us restate the difference between the algorithm above and the one outlined in Section 1. In the former, a maximal deep section is treated as if it had only two intersections with  $L$  (the essential ones), until it is discovered that some intersection not in the section is enclosed by these two. This approximation to the truth works because the intersections in the section occur in the same order along the section as they do along  $L$  (or in reverse order). If no "foreign" intersections intervened, the algorithm of Section 1 would merely chop the section between each pair of contiguous boundary segments in Step 2 and put them back together in exactly the same order in Step 4. The new algorithm avoids this unnecessary work.

We now want to quantify the work saved by the new algorithm. Our main result is that the total number of visible pairs reported during the processing of an  $n$ -vertex polygon is  $O(n)$ . This implies that the time spent doing Jordan sorting, not including calls of *refine*, is  $O(n)$ .

LEMMA 3. *The processing of an  $n$ -vertex polygon requires at most  $n-2$  invocations of Steps 2-4.*

*Proof.* Each vertex except the ones of maximum and minimum  $y$ -coordinate can be selected as  $v$  in Step 1 at most once.  $\square$

LEMMA 4. Consider a single invocation of Step 3. Let  $k$  be the number of visible pairs reported during this invocation that were not reported during previous invocations. The total number of intersections sorted during this invocation, including those introduced by refinement, is  $O(k+1)$ .

*Proof.* First we count the essential intersections. We call an essential intersection  $x$  good if  $x$  is a vertex (i.e.  $x=v$ ) or if the two vertices preceding and following  $x$  along  $\partial V$ , say  $v'$  and  $v''$ , are in the same part of  $\partial V$  (top, bottom, left, or right) and not strictly on the same side of  $L$ . Otherwise  $x$  is bad. We claim that if  $x$  is a good intersection other than  $v$ , then the edge that contains  $x$  belongs to a newly reported visible pair. This is true if the part of  $\partial V$  from  $v'$  to  $v''$  consists of the line segment joining  $v'$  and  $v''$ , since the visible pair containing the edge from  $v'$  to  $v''$  that will be reported is the first one reported containing that edge. It is also true if the part of  $\partial V$  from  $v'$  to  $v''$  consists of a partial edge from  $v'$  to the line  $y = y_{\max}$  (or  $y = y_{\min}$ ), a segment of the line  $y = y_{\max}$  (or  $y = y_{\min}$ , respectively), and a partial edge from the line  $y = y_{\max}$  (or  $y = y_{\min}$ , respectively) to  $v''$ . To see this, suppose without loss of generality that  $v'$  is strictly below  $L$  and  $\partial V$  contains a partial edge from  $v'$  to the line  $y = y_{\max}$ . (See Figure 11.) Intersection  $x$  is on this partial edge. Along the line  $L$ , the edge from  $v'$  sees something other than the edge into  $v''$ , and thus will be contained in a newly reported visible pair, since if two edges see each other horizontally, the part of each edge that sees the other is connected. Thus in either case the claim is true. The claim implies that the number of good intersections is  $O(k+1)$ .

Consider the bad intersections. Any mixed boundary segment contains at most two bad intersections (the first and last in the segment) and, if it is a top or bottom segment, at least one good intersection. Any maximal deep section contains at most two bad intersections (the first and last in the section). Such a section either (i) is followed by a shallow segment, (ii) is followed by a mixed top or bottom boundary segment, or (iii) contains the last segment on its side. In case (i) the last intersection is good. The number of bad intersections in case (ii) is  $O(k+1)$ , since the mixed segment contains at least one good intersection. At most four bad intersections (the last two within each of the top and bottom boundaries) can fall into case (iii). There are also at most two bad intersections within each of the left and right sides. Thus the number of bad intersections is  $O(k+1)$ .

It remains for us to count the nonessential intersections introduced by refinement. Suppose that a call *refine*  $(\{x_{i-1}, x_i\}, x)$  returns a pair  $x', x''$ . Both of the edges that contain  $x'$  and  $x''$  will be contained in newly reported visible pairs, since along  $L$  they

FIG. 11. The edge that contains  $x$  belongs to a newly reported visible pair.

see something other than each other. Thus the number of intersections introduced by refinement is  $O(k)$ .  $\square$

The following theorem summarizes our analysis of the algorithm so far.

**THEOREM 1.** *In processing an  $n$ -vertex polygon, the visibility algorithm reports  $O(n)$  visible pairs and spends  $O(n)$  time in Jordan sorting, not including its calls to refine. This includes all processing of subregions.*

*Proof.* Immediate from Lemmas 1, 3 and 4.  $\square$

**4. Use of balanced divide and conquer.** The visibility algorithm of Section 3 can in the worst case generate regions containing a total of  $\Omega(n^2)$  boundary segments (counting a boundary segment each time it occurs in a region). As we shall see in Section 5, obtaining an  $O(n \log \log n)$ -time implementation of the algorithm requires reducing the total number of boundary segments to  $O(n \log n)$ . We do this by refining the algorithm so that it uses a balanced divide-and-conquer strategy. The refinement consists of choosing the vertex  $v$  carefully in Step 1. Roughly speaking, we want to slice a region with many boundary segments so that at most a proper fraction of the segments end up in any one of the subregions. A choice that works and that can be made quickly is the following:

*Choose splitting vertex.* Let region  $V$  have  $t$  top boundary segments and  $b$  bottom boundary segments. Suppose  $t \geq b$ . (Otherwise, proceed symmetrically.) If  $t \leq 2$ , choose any vertex  $v$  whose  $y$ -coordinate is not in  $\{y_{\min}, y_{\max}\}$ . Otherwise, divide the list of top boundary segments into three sublists, with the first and last containing  $\lfloor t/3 \rfloor$  segments and the middle one the remainder. Among the segments in the middle sublist, choose as  $v$  the vertex whose  $y$ -coordinate is minimum.

We call the visibility algorithm refined to use this selection strategy the *balanced division algorithm*; we call the algorithm with an arbitrary selection strategy the *generic algorithm*. In the analysis to follow, we regard two boundary segments as distinct only if their vertex sets or their end edges (if there are any end edges) are different.

**LEMMA 5.** *In processing an  $n$ -vertex polygon, the generic visibility algorithm creates  $O(n)$  distinct boundary segments altogether.*

*Proof.* The only way the algorithm can create new boundary segments is by splitting an old boundary segment in two, at an intersection point that is input to the Jordan sorting algorithm or at the vertex of maximum or minimum  $y$ -coordinate in a subregion. By Theorem 1 there are  $O(n)$  such splitting points. Hence there are  $O(n)$  distinct boundary segments.  $\square$

**LEMMA 6.** *Let  $V$  be a region that has  $s$  boundary segments. If  $V$  is sliced using balanced division, then no subregion contains more than  $7s/8$  of the original boundary segments of  $V$ .*

*Proof.* Let  $V$  contain  $t$  top boundary segments and  $b$  bottom boundary segments. We have  $s = b + t + 2$ . Suppose without loss of generality that  $t \geq b$ . If  $t \leq 2$  the lemma is immediate, since some boundary segment is cut into new boundary segments distinct from the original; thus the original appears in no subregion. Suppose  $t \geq 3$ . Consider where the top boundary segments of  $V$  end up after slicing. A segment that is mixed with respect to the slicing line  $L$  is cut into new boundary segments distinct from the original; thus the original appears in no subregion. There are at most  $2 \lfloor t/3 \rfloor$  deep top boundary segments, which implies that each subregion below  $L$  contains at most  $b + 2t/3 + 2 \leq 7s/8$  of the boundary segments of  $V$ . A deep top segment cannot end up in a subregion above  $L$ ; only a part of it, constituting a distinct boundary segment, can. Thus among the top segments, only the shallow ones can end up in regions above  $L$ . A set of shallow segments can end up in the same subregion only if it forms a shallow section. By the choice of  $L$ , any such shallow section can contain at

most  $t - \lfloor t/3 \rfloor - 1 \leq 2t/3$  top boundary segments of  $V$ . Thus any subregion above  $L$  contains at most  $b + 2t/3 + 2 \leq 7s/8$  of the boundary segments of  $V$ .  $\square$

**THEOREM 2.** *When the balanced division algorithm processes an  $n$ -vertex polygon, the sum over all regions of the number of boundary segments per region is  $O(n \log n)$ .*

*Proof.* One way to prove this theorem is to write down a recurrence based on Lemma 6 and solve it. Instead, we shall use an amortization argument based on a credit analysis (see [26]). When the balanced division algorithm creates a distinct new boundary segment, we assign  $15 \log_{16/15} n$  credits to the segment. Each subsequent time that the segment appears in a subregion, we remove a credit. We shall show that the number of credits always remains nonnegative, which implies by Lemma 5 that the sum over all regions of the number of boundary segments is  $O(n \log n)$ .

To show that the number of credits remains nonnegative, we actually prove the following stronger *credit invariant*: a region that has  $s$  boundary segments has at least  $s \log_{16/15} s$  credits. The invariant is certainly true initially. Suppose it is true before some invocation of Steps 1-4. Let  $V$  be the region to be subdivided, and let  $s$  be its number of boundary segments. Before the subdivision,  $V$  has at least  $s \log_{16/15} s$  credits, of which we allocate  $\log_{16/15} s$  to each boundary segment. One of these pays for the appearance of the segment in  $V$ , leaving  $(\log_{16/15} s) - 1 = \log_{16/15} (15s/16)$  as its contribution to the credits of the subregion in which it appears. Consider a subregion  $V'$  formed by splitting  $V$ . Suppose its boundary contains  $p$  of the boundary segments of  $V$  and  $q$  newly created boundary segments; let  $s' = p + q$ . To verify that  $V'$  has  $s' \log_{16/15} s'$  credits, there are two cases to consider. If  $q > s'/15$ , then the total number of credits is at least the number of credits assigned to new segments:

$$15q \log_{16/15} n \geq s' \log_{16/15} n \geq s' \log_{16/15} s'.$$

If  $q \leq s'/15$ , then since  $p \leq 7s/8$  by Lemma 6, we have  $s' \leq 15s/16$ . The total number of credits is

$$\begin{aligned} p \log_{16/15} (15s/16) + 15q \log_{16/15} n &\geq p \log_{16/15} (15s/16) + 15q \log_{16/15} (15s/16) \\ &\geq s' \log_{16/15} (15s/16) \geq s' \log_{16/15} s'. \end{aligned}$$

By induction on the number of steps, the credit invariant is always true, from which the theorem follows.  $\square$

**5. Representation of the boundary using finger search trees.** We have now almost completed our presentation of the visibility algorithm. The task that remains is to choose a data structure for the lists that represent the boundary segments and boundary groups, and to analyze the effects of this choice. To represent both kinds of lists we use heterogeneous finger search trees (see the appendix). As we shall see, this gives an overall  $O(n \log \log n)$  running time for the balanced division visibility algorithm.

We represent each boundary segment by a heterogeneous finger search tree in which each leaf contains a vertex in the segment. Left-to-right order in the tree corresponds to the order of the vertices along the segment. In addition, if the segment has one or two end edges, we store these edges with the tree. Within the tree, we maintain two heap orders, both with respect to the  $y$ -coordinates of the vertices. One is by increasing  $y$ -coordinate, the other is by decreasing  $y$ -coordinate. That is, each node in the tree contains the maximum and minimum  $y$ -coordinates of all leaves reachable from it in the tree. (See Figure 12.) This allows us, for any given value of  $y$ , to find the leftmost (or rightmost) vertex with  $y$ -coordinate less than (or greater

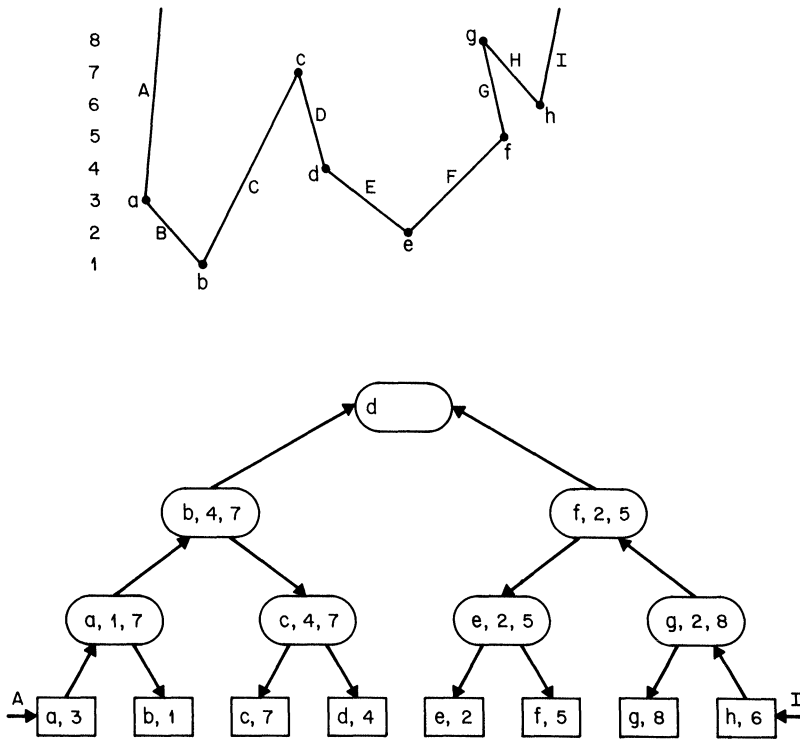

FIG. 12. A boundary segment and its representation as a heterogeneous finger search tree. (The drawing conventions are explained in Figure 22.)

than) the given value, in  $O(1 + \log(\min\{d, s-d\} + 1))$  time, where  $s$  is the total number of vertices stored in the tree and the one found is the  $d$ th. We can also find the vertex of maximum (or minimum)  $y$ -coordinate in the same time. The amortized time to split the tree at the  $d$ th out of  $s$  vertices is also  $O(1 + \log(\min\{d, s-d\} + 1))$ .

We represent each list of top boundary segments or bottom boundary segments constituting the top or bottom boundary of a region by a heterogeneous finger search tree in which each leaf represents a boundary segment. Left-to-right order in the tree corresponds to the order of the boundary segments clockwise around the boundary. Each leaf contains a pointer to the tree representing the corresponding boundary segment, as well as the end vertices or edges of the segment, and the maximum and minimum  $y$ -coordinates of the vertices within the segment. We think of each node in the tree as representing the section (sublist of boundary segments) corresponding to the set of leaves reachable from the node. We store in each node the first and last end vertices or edges of the corresponding section, the number of segments in the section, and the maximum and minimum  $y$ -coordinates of vertices in the section. (See Figure 13.) All these values can be updated bottom-up in the interior of the tree and top-down along the left and right paths.

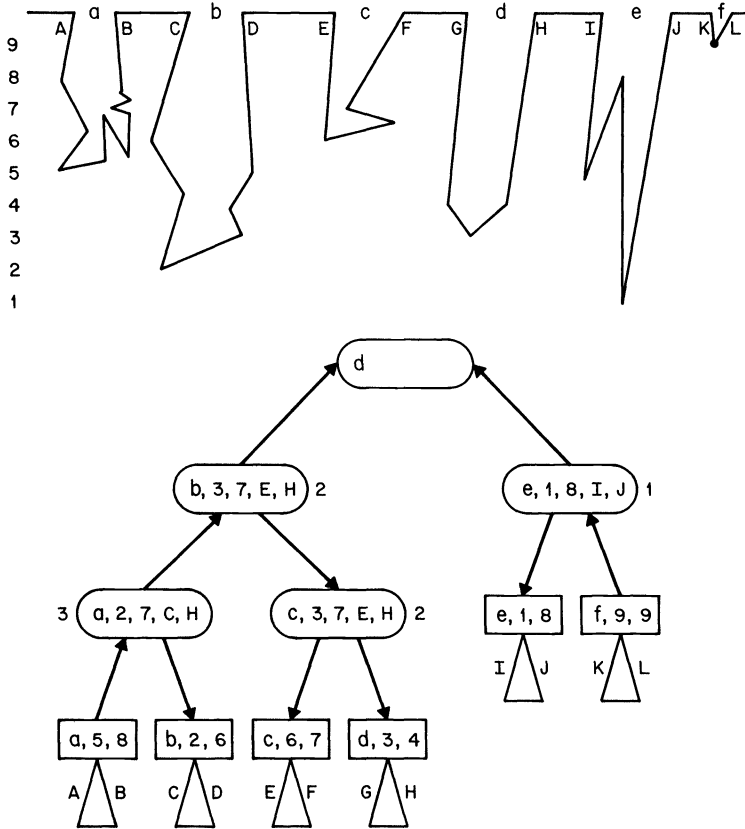

FIG. 13. A group of boundary segments and its representation as a heterogeneous finger search tree. (The drawing conventions are explained in Figure 22; capital letters represent end edges.)

All of the following operations can be performed in  $O(1 + \log(\min\{d, s-d\} + 1))$  time, where the segment found is the  $d$ th out of  $s$ :

- (i) Find the leftmost (or rightmost) segment in the tree that contains a vertex with  $y$ -coordinate less than (or greater than) a given value;
- (ii) Find the  $d$ th segment;
- (iii) Suppose all the segment vertices lie strictly above (or strictly below) a given horizontal line  $L$ , and that all end edges of the segments cross  $L$ . Given a value  $x$ , find the leftmost (or rightmost) segment in the tree having an edge whose intersection with  $L$  has  $x$  coordinate less than (or greater than)  $x$ . (All four possibilities, leftmost less than, leftmost greater than, etc., are allowed.)

In addition, inserting a new segment next to the  $d$ th out of  $s$  or splitting at the  $d$ th segment out of  $s$  takes  $O(1 + \log(\min\{d, s-d\} + 1))$  amortized time. Concatenating two trees takes  $O(1)$  amortized time.

Let us examine the manipulations of the boundary data structures required to carry out the steps of the balanced division visibility algorithm. We describe these step by step, including a timing estimate for some of the computations.

*Step 1.* Given  $V$ , determine the number of top and bottom boundary segments in its boundary, say  $t$  and  $b$ , respectively ( $O(1)$  time). Assume  $t \geq b$ . (The other case is symmetric.) If  $t \leq 2$ , choose a segment of the boundary that contains some vertex with  $y$ -coordinate strictly between  $y_{\min}$  and  $y_{\max}$ , and select as  $v$  the first such vertex in the segment ( $O(1)$  time). If  $t \geq 3$ , find the minimum  $y$ -coordinate of the vertices in the middle third of the top boundary segments (time to be analyzed below). This defines the slicing line  $L$ .

*Step 2.* Split the tree representing the top boundary between each pair of segments that differ in type among the types shallow, deep, and mixed (time to be analyzed below). This splits the top boundary list into mixed segments and maximal deep and shallow sections. Repeat this for the tree representing the bottom boundary (time to be analyzed below). For each mixed segment, split its tree between each pair of consecutive vertices, one on each side of  $L$  (time to be analyzed below). Split the tree that contains the vertex lying on  $L$  at that vertex, putting the vertex in both of the resulting trees (time to be analyzed below). Each of the splits performed corresponds to an essential intersection of the boundary with  $L$ . Form a list of these intersections, in the order in which they occur along the boundary, by examining the list of trees representing the deep sections and the new boundary segments that have been formed by splitting mixed segments ( $O(1)$  time per essential intersection).

*Step 3.* To execute a call *refine* ( $\{x_{i-1}, x_i\}, x$ ), examine the tree representing the deep section whose first and last intersections with  $L$  are  $x_{i-1}$  and  $x_i$ . Assume  $x_{i-1} < x_i$ . (The other case is symmetric.) Find in this tree the rightmost segment whose first intersection with  $L$  is less than  $x$  (time to be analyzed below). If the last intersection of this segment with  $L$  is greater than  $x$ , return no pair ( $O(1)$  time). Otherwise, split the section between this segment and the next one, and return as  $x'$  and  $x''$  the last intersection of this segment and the first intersection of the next one (time to be analyzed below).

*Step 4.* For each pair in the upper tree whose depth is odd and greater than one, split the tree representing the corresponding boundary segment at its vertex of maximum  $y$ -coordinate (time to be analyzed below). Put the splitting vertex in both of the resulting trees. Proceed symmetrically for the boundary segments corresponding to pairs in the lower tree. For each family in both trees, concatenate the boundary segments and deep sections corresponding to the pairs in the family to form the boundary of the subregion corresponding to the family ( $O(1)$  time per pair). Because the input polygon is simple, the order in which polygon vertices appear on the boundary of the subregion is consistent with their order in the original polygon. (See Figure 14.) This means that the concatenation will never need to reverse the order of boundary segments.

Now let us analyze the running time of this implementation of the balanced division algorithm. Observe that for each segment found within a top or bottom boundary, and for each vertex found within a segment, a split occurs at that segment or vertex. Since the timing estimates for finding and splitting are the same, the time spent splitting dominates the time spent finding such segments and vertices, including the time to find the  $y$ -coordinates of the splitting vertices in Step 1. Thus, by the timing estimates above and Theorem 1, the total running time of the algorithm is  $O(n)$  plus at most a constant times the time for tree insertions, splits, and concatenations.

It remains to estimate the time for tree update operations. Every insertion is at one end of a finger search tree and thus takes  $O(1)$  amortized time. The updates on

FIG. 14. A subregion that would cause trouble for Step 4. The arrows indicate the direction of the two boundary segments in the original polygon. Such subregions cannot occur for simple polygons.

the trees representing segments are only splits and insertions, of which there are  $O(n)$ . The total running time of these updates obeys a recurrence that is essentially the same as (1) (Section 1) and is thus  $O(n)$ .

The updates on the trees representing top and bottom boundaries include concatenations, and recurrence (1) does not apply. To analyze these operations, we first observe that the amortized time per concatenation or insertion is  $O(1)$ . Since the total number of such operations is  $O(n)$ , their total time is  $O(n)$ .

To analyze the  $O(n)$  splits, consider a particular visibility region  $V_i$  that has a total of  $s_i$  boundary segments. The total time to split the two trees representing the top and bottom boundaries is  $O(k_i + \sum_{j=0}^{k_i+1} \log s_{i,j})$ , where  $k_i$  is the total number of splits and  $s_{i,0}, s_{i,1}, \dots, s_{i,k_i+1}$  are the numbers of segments in each of the trees that are created by the splits. (Starting from two trees,  $k_i$  splits produce  $k_i + 2$  trees; if there is only one tree initially, we take  $s_{i,k_i+1} = 1$ .) We have  $s_{i,j} \geq 1$  for all  $j$ , and  $\sum_{j=0}^{k_i+1} s_{i,j} \leq s_i + 1$ . Since the logarithm is a concave function, the estimate of splitting time is maximized when all the pieces are of equal size, giving a bound of  $O(k_i + (k_i + 2) \log((s_i + 1)/(k_i + 2)))$ .

We evaluate the total time to perform all  $O(n)$  splits,  $O(\sum_i (k_i + (k_i + 2) \log((s_i + 1)/(k_i + 2))))$ , in two parts. Call  $V_i$  a *good region* if  $k_i \leq s_i / (\log n)^2$ , and *bad* otherwise. By Theorem 2,  $\sum_i s_i = O(n \log n)$ , so the total number of splits that occur while processing good regions,  $\sum_{k_i \leq s_i / (\log n)^2} k_i$ , is  $O(n \log n)$ ; using  $O(\log n)$  as a generous time bound for these splits, the total time to split good regions is  $O(n)$ . It remains to bound the time to split bad regions:

$$\begin{aligned} & O \left( \sum_{k_i \geq s_i / (\log n)^2} (k_i + (k_i + 2) \log((s_i + 1)/(k_i + 2))) \right) \\ &= O \left( \sum_{k_i \geq s_i / (\log n)^2} (k_i + (k_i + 2) \log \log n) \right) = O(n \log \log n), \end{aligned}$$

since  $\sum_i k_i = O(n)$ .

We conclude that the total running time of the visibility algorithm with balanced division is  $O(n \log \log n)$ .

**6. Remarks, applications and open problems.** We have presented an  $O(n \log \log n)$ -time algorithm for computing horizontally visible edge-vertex pairs

inside a simple polygon. By the linear-time reduction of triangulation to the visibility problem [5],[9] we obtain an  $O(n \log \log n)$ -time triangulation algorithm. The main ingredients of our algorithm are Jordan sorting, balanced divide and conquer, and finger search trees. It is intriguing to note that both the Jordan sorting algorithm and the visibility algorithm use finger search trees, but of two different kinds. The Jordan sorting algorithm requires fast access in the vicinity of any position in the tree but does not need to search on a secondary heap order. Homogeneous finger search trees satisfy these requirements. The visibility algorithm itself does need to search on secondary heap orders, but requires fast access only in the vicinity of the first and last positions. Heterogeneous finger search trees satisfy these requirements. Our algorithm exploits to the fullest the properties of these structures.

Finger search trees are sufficiently complicated that one would probably not want to use them in an actual implementation. The dynamic optimality conjecture of Sleator and Tarjan [23] suggests that the  $O(n \log \log n)$  time bound is still valid if splay trees (a form of self-adjusting search tree) are used in place of finger search trees. The use of splay trees might lead to a practical implementation of our algorithm, although this must be verified by experiment. Other minor changes in the algorithm might be useful in practice. We leave this as a topic for future research.

Our visibility algorithm can be modified to accommodate vertices having the same  $y$ -coordinate. To handle the resulting tangent intersection points in the Jordan sorting step (Section 2), we represent such a point  $x_i$  by a dummy pair  $(x_i, x_i)$  which we add to the lower tree if the tangency is on the top side of the splitting line  $L$ , or to the upper tree otherwise. The remaining changes to the algorithm are straightforward. (See e.g. [30].)

An efficient triangulation algorithm has a number of applications in computational geometry. These applications typically involve one (or possibly a few) triangulations and some linear-time pre- and postprocessing. Our triangulation algorithm gives  $O(n \log \log n)$ -time algorithms for these applications. Any improvement in the time to triangulate would give corresponding improvements in the applications. Such applications include:

- (i) several polygon decomposition problems [9] (where minimality, as in [17], is not required);
- (ii) regularizing (or triangulating) a planar subdivision that is given as a connected planar graph [8];
- (iii) computing the internal distance between two points in a polygon, and finding the point visibility polygon for a point inside the polygon [3];
- (iv) solving the single source shortest path problem inside a polygon, and computing internal visibility information from an edge inside a polygon [11];
- (v) testing two polygons for intersection, and decomposing simple splinegons [24] into a union of differences of unions of convex sets [7];
- (vi) determining translation separability of two simple polygons [1];
- (vii) finding a shortest watchman route in a simple rectilinear polygon ([6, Thm. 3]).

An important application of our visibility algorithm is to test whether an  $n$ -vertex polygon  $P$  is simple, and to exhibit a self-intersection of  $\partial P$  if it is not simple. We shall show how to modify our algorithm to perform these tasks in  $O(n \log \log n)$  time.

Even though the error-correcting Jordan sorting algorithm detects some instances of nonsimplicity as uncorrectable crossings or violations of the nonenclosure property, the successful completion of the visibility algorithm is not proof against nonsimplicity of the input polygon. Among the problems with which a guaranteed simplicity test

FIG. 15. Nonsimple polygons that cause no trouble in the algorithm for computing visibility information. In (c), a slice through  $v_5$  separates the polygon into three simple pieces.

must cope are polygons that are self-tangent at a vertex (Figure 15a), polygons for which an interior cannot be defined by any consistent labeling of the edges (Figure 15b), and nonsimple polygons that can be sliced into simple pieces (Figure 15c).

Our algorithm for testing simplicity is as follows. First we check that no two consecutive edges of  $P$  intersect in more than their common endpoint. Next, we run the visibility algorithm on the polygon  $P$  and on its “inside-out” partner  $Q$ , defined as in the proof of Lemma 2. We abort the algorithm and declare that  $P$  is nonsimple if one of the following cases occurs:

- (i) the Jordan sorting step finds an intersection point common to two parts of  $P$  other than an endpoint of two consecutive edges (see Figure 15a);
- (ii) the Jordan sorting step detects an uncorrectable crossing or violation of the nonenclosure property;

FIG. 16. The ordering of the four corners of this visibility region implies that it is not simple.

(iii) a subregion is constructed in Step 4 whose side boundary segments, say  $S_1$  and  $S_2$ , are known to cross, because the intersections of  $S_1$  and  $S_2$  with the top bounding line are in the opposite order from the order of their intersections with the bottom bounding line (see Figure 16).

If the visibility algorithm runs to completion on both  $P$  and  $Q$ , we declare that  $P$  is simple.

In our discussion of Step 4 in Section 4, we noted that if the polygon is simple, then the order of vertices along the boundary segments is consistent with the order of the boundary of the subregion being reassembled. It is conceivable if the polygon is not simple that Step 4 could be presented with a subregion whose boundary segments appear in an anomalous order, as in Figure 14. Fortunately, this situation cannot in fact occur: the existence of such a nested pair implies by the Jordan curve theorem that the current region being processed has a nonsimple boundary, and indeed that the segments of the boundary defined by the slicing line do not have the noncrossing property. Therefore, the nonsimplicity will be detected in Step 3.

**THEOREM 3.** *The simplicity-testing algorithm is correct.*

*Proof.* Certainly if the simplicity-testing algorithm declares that  $P$  is not simple then  $\partial P$  has a self-intersection. Suppose the algorithm reports that  $P$  is simple. The visibility computations in the algorithm produce two sets of regions. Let  $\mathbf{P}$  and  $\mathbf{Q}$  be the sets of regions produced when the visibility algorithm runs on  $P$  and  $Q$ , respectively; each region in  $\mathbf{P}$  and  $\mathbf{Q}$  is either a trapezoid or a triangle. Some of the regions in  $\mathbf{Q}$  are bounded by one or more edges of  $Q-P$ , i.e., by edges that were added to invert polygon  $P$ . Let  $\mathbf{Q}'$  be the set of regions formed by taking each region in  $\mathbf{Q}$  and extending it to infinity in the direction of any edge in  $Q-P$ . Regions in  $\mathbf{Q}'$  can be trapezoids, triangles, halfplanes, or infinite regions bounded by two horizontal lines and part of a side of  $P$ .

It is tempting to say that the regions in  $\mathbf{P}$  partition the "interior" of  $P$ , but we cannot say this, because we do not yet know that  $P$  has an interior. However, because of the way in which the regions in  $\mathbf{P}$  were produced, we know that they can be glued

together along shared horizontal visibility edges to form a region that is topologically equivalent to a disk. This is necessary but not sufficient for  $P$  to be simple (consider the polygon in Figure 15c). The visibility algorithm could be modified easily to produce this “gluing,” or, more properly, its dual graph, in which regions are vertices, and regions that share a horizontal visibility edge are joined by an edge in the dual graph.

Since the visibility algorithm succeeded, we also know that the regions in  $Q$  can be glued together along horizontal visibility edges to form a region that is topologically equivalent to the disk. This gluing can be extended naturally to  $Q'$ , which is topologically equivalent to the punctured plane. In what follows, we use the regions in  $P$  and  $Q'$  to construct a mapping from the plane onto itself.

Let  $C$  be a circle in the plane, and choose  $n$  distinct points on  $C$  corresponding to the vertices of  $P$ ; this induces a natural correspondence between points of  $\partial P$  and points of  $C$ . For each vertex-edge or edge-edge visible pair in  $P$  reported by the visibility algorithm, connect corresponding points on  $C$  by a path through the interior of  $C$ ; make all these paths disjoint except for corresponding endpoints. (The dual graph of the regions in  $P$  provides a natural way to do this constructively. Processing a vertex of degree one in the dual requires that we draw a path between two points on  $C$ ; that path divides the disk into two parts, one of which can be discarded and never enters into further computation of the mapping. Thus we can perform the complete construction by processing and deleting vertices of degree one from the dual until the dual is empty.) These paths divide the interior of  $C$  into regions corresponding to the regions of  $P$ . Similarly, for each piece of visibility information in  $Q'$ , construct a corresponding path joining two points of  $C$  and passing through the exterior of  $C$ . If the piece of information represents a vertex or edge that sees arbitrarily far to the left or right, the corresponding path leads from  $C$  to infinity. Make all the paths on the exterior of  $C$  noncrossing. This partitions the exterior of  $C$  into regions corresponding to the regions of  $Q'$ . (See Figure 17.)

We can construct a continuous mapping  $h$  of the plane onto itself that takes each region of the interior of  $C$  onto the corresponding region of  $P$  and each region of the exterior of  $C$  onto the corresponding region of  $Q'$ . The mapping is onto because every point in the plane is in some region of  $P$  or  $Q'$ : For any point  $x$ , move horizontally right from  $x$  until hitting  $\partial P$ . If the right side of  $\partial P$  is hit (with respect to clockwise order around  $\partial P$ ),  $x$  is in some region of  $P$ . Otherwise  $x$  is in some region of  $Q'$ . If  $\partial P$  is not hit,  $x$  is in some region of  $Q'$ .

Because  $P$  and  $Q'$  are finite and the preimages of distinct regions have disjoint interiors, the mapping  $h$  is a covering map from the plane onto itself: any point  $x$  in the plane has an open neighborhood  $N$  such that  $h^{-1}(N)$  is the disjoint union of a finite number of open sets [21]. Moreover, since the domain of  $h$  is connected, every point in its range is the image under  $h$  of the same number of points of its domain [21, ex. 8-3.5, p. 336]. Since any point in the open half plane that lies above the horizontal line through the highest vertex of  $P$  is the image under  $h$  of only one point,  $h$  is 1-1. Thus  $h$  is a homeomorphism of the plane onto itself. This proves that  $\partial P$  is homeomorphic to  $C$ , so  $P$  is simple.  $\square$

If the simplicity-testing algorithm reports that  $P$  is not simple, we can produce a witness to its nonsimplicity in  $O(n)$  additional time. If the nonsimplicity is detected in Case (i), the self-intersection is available immediately. Otherwise (if Case (ii) or (iii) occurs) we can find one or two bounding lines and two boundary segments  $S_1$  and  $S_2$  with ends on the bounding lines such that the two boundary segments are guaranteed to cross. There are seven possible configurations of the two boundary seg-

FIG. 17. Illustrating the mapping  $h$  constructed in the proof of Theorem 3. For  $0 \leq i \leq 5$ ,  $h(u_i) = v_i$ . Dashed paths in the upper figure correspond to vertex-edge visibility segments in the lower figure. Arrowheads indicate paths to infinity.

ments, illustrated in Figures 18 and 15b. We apply the following three steps repeatedly until an explicit crossing is found:

*Step 1.* Choose a vertex on  $S_1 \cup S_2$  not having maximum or minimum  $y$ -coordinate. Let  $L$  be the horizontal line through this vertex.

*Step 2.* Find all intersections of  $S_1$  and  $S_2$  with  $L$ , in the order in which they occur along  $S_1$  followed by  $S_2$ .

*Step 3.* Jordan sort the intersections. The Jordan sorting step must either find an explicit self-intersection or a violation of the noncrossing property. If such a violation is found, let  $S'_1$  and  $S'_2$  be the crossing subsegments. Replace  $S_1$  and  $S_2$  by  $S'_1$  and  $S'_2$ . If  $S'_1$  and  $S'_2$  are both single partial edges, report their intersection.

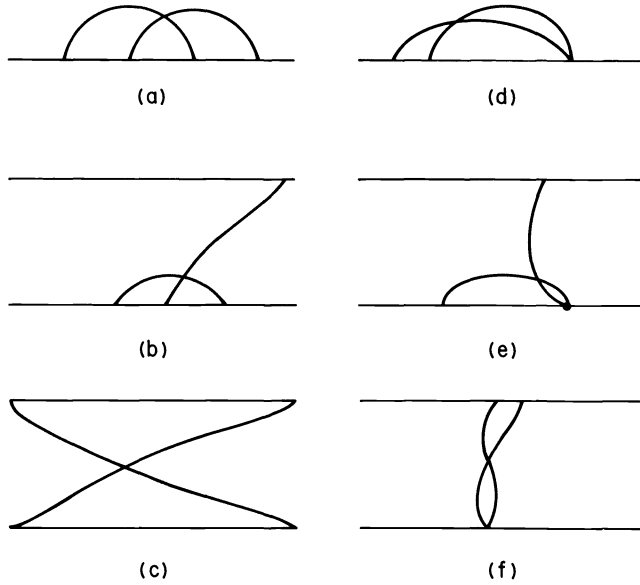

FIG. 18. Possible configurations of crossing boundary segments: (a) four points on one bounding line; (b) three points on one bounding line and one on the other; (c) two points on each bounding line; (d), (e), and (f) are degenerate cases of (a), (b), and (c), respectively. Figure 15b depicts a degenerate case of (f). Degenerate cases can be detected by examining the interior angle at the point or points of degeneracy.

An analysis like that in Sections 3–5 shows that this postprocessing takes  $O(n)$  time if the segments are represented by finger search trees. (Concatenation of finger search trees and balanced division are not needed.)

The algorithms for testing simplicity and producing a witness to nonsimplicity are easily extended to work on connected polygonal paths that are not closed. The first step of the extension is to draw a line through the two endpoints of the path, thus chopping the path into boundary segments that lie entirely on one side of the line, and to Jordan sort the points of intersection between the path and the line. If the Jordan sorting detects a violation of the noncrossing property, the algorithm for finding a crossing can be applied directly to the two boundary segments involved. Otherwise we use processing akin to that in Step 4, augmented to cope with boundary reversals as in Figure 14, to construct polygons that lie entirely on one side of the line; the path is simple if and only if each of those polygons is simple.

The algorithms for computing horizontal visibility information, for testing simplicity, and for producing a witness to nonsimplicity, can be extended to work on curves that obey certain mild restrictions. (See e.g. [22],[24].) To prepare the curve for processing add vertices to each edge to form a curve each of whose edges is monotone in the  $y$ -direction. The algorithms can now be run directly (given suitable procedures for

computing the intersection of a curved edge and a line), because the edges of the object have the property that if a collection of edges crosses two horizontal lines then the edges cross both lines in the same order. The other extension occurs in simplicity testing: we must check that the left and right sides of each trivial visibility region do not cross. If all of the output regions have this property, then the curve is simple; otherwise we have an immediate witness to its nonsimplicity. Both the preparation of the curves and the postprocessing of the output regions can be performed in  $O(n)$  time.

Several open problems remain. First and foremost, of course, is determining whether there is a linear-time triangulation algorithm, or even a  $o(n \log \log n)$ -time algorithm. Resolving this question seems to require a new idea. One possible approach is to invent a data structure for representing a polygonal curve that will allow fast computation of its intersections with an arbitrary horizontal line segment, or even with an arbitrary horizontal half line. Perhaps such a data structure can be built using information computed by the visibility algorithm called recursively on small pieces of the boundary, say of size  $O(\log n)$ . The result might be a visibility algorithm running in  $O(n \log^* n)$  time. Another open problem is to determine how fast all the self-intersections of a polygonal curve can be computed: can bounds better than those for an arbitrary collection of line segments [4] be obtained?

**Appendix. Finger search trees.** A *finger search tree* is a type of balanced search tree in which access in the vicinity of certain preferred positions, indicated by *fingers*, is especially efficient. Finger search trees were introduced by Guibas, McCreight, Plass and Roberts [12] and further developed by many other researchers [2],[15],[18],[28],[29]. We shall discuss two kinds of finger search trees with slightly different properties, *heterogeneous trees* and *homogeneous trees*. We base our development on a particular kind of balanced tree, the *red-black tree* [20],[25], although other kinds of balanced trees, such as *a,b-trees* [16],[19], form a suitable basis as well. We are mainly interested in amortized, not worst-case, complexity bounds.

For our purposes a *binary search tree* is a full binary tree in which each external node contains a distinct item selected from a totally ordered universe, with the left-to-right order of external nodes consistent with the total order on the items. Each internal node contains a *key*, which is an item greater than or equal to all items in its left subtree and less than all items in its right subtree. We can use the keys to search for the largest item in the tree less than or equal to a given one, by starting from the root and going to the left child if the item in the current node is greater than or equal to the given one, going to the right child otherwise, and repeating until an external node is reached. The desired item is either the one in the external node reached or the one in the preceding external node, which can be found by backing up the search path to a right child, starting from its left sibling, and going through right children to an external node. The time to search for an item is proportional to the tree depth.

A *red-black tree* is a binary search tree in which each node has one of two colors, *red* or *black*. The node colors obey the following constraints (see Figure 19):

- (i) all external nodes are black;
- (ii) all paths from the root to an external node contain the same number of black nodes;
- (iii) any red node, if it has a parent, has a black parent.

The depth of a red-black tree containing  $n$  items is  $O(\log n)$ . To insert a new item into a red-black tree, we search for the greatest item less than it in the tree. When the search reaches an external node, we replace this node by an internal node having two children, the old external node and a new external node containing the new

FIG. 19. A red-black tree; solid nodes are black; hollow nodes are red. (Only the colors of the nodes are shown.)

item. The new internal node contains as its key the smaller of the two items in its children. The new internal node is colored red. This may violate the red constraint (iii). To restore the red constraint, we proceed bottom-up along the search path, applying the recoloring transformation in Figure 20a until it no longer applies, followed by one application of Figure 20b, c, or d if necessary.

A deletion is similar. To delete an item, we find the external node containing it. We replace the parent of this node by the sibling of the node to be deleted. This may violate the black constraint (ii), producing a node that is *short*: all paths down from it to external nodes contain one fewer black node than paths down from its sibling. To restore the black constraint, we proceed bottom-up, applying the recoloring transformation of Figure 21a until it no longer applies, followed by one application of Figure 21b if necessary, and then possibly one application of Figure 21a, c, d, or e.

The worst-case insertion or deletion time in an  $n$ -item red-black tree is  $O(\log n)$ , but the amortized insertion/deletion time is only  $O(1)$ , not counting the time to search for the node at which the insertion or deletion takes place. (This is a restatement of a result of Huddleston and Mehlhorn [16] and Maier and Salveter [19] concerning  $a, b$ -trees.) To prove this, we define the *potential* of a red-black tree to be the number of black nodes with two black children plus twice the number of black nodes with two red children. We define the *actual time* of an insertion or deletion to be one plus the number of local transformations applied and the *amortized time* to be the actual time plus the net increase in potential caused by the operation. With these definitions, if we start with an empty tree, the total actual time for a sequence of insertions and deletions is at most the sum of the amortized times, since the initial potential is zero and the potential is always nonnegative. Furthermore the amortized time of an insertion or deletion is  $O(1)$ , since any of the transformations in Figures 20 and 21 increases the potential by  $O(1)$  and the nonterminal transformations 20a and 21a both decrease the potential by at least one.

FIG. 20. *The rebalancing transformations in red-black tree insertion. Symmetric cases are omitted. All unknown children of red nodes are black. In cases (c) and (d) the bottommost black node shown can be external.*

In an ordinary binary search tree, each node points to its two children. We convert such a tree into a *heterogeneous finger search tree* by making each node along the left path<sup>2</sup> point to its parent instead of its left child, and each node along the right path point to its parent instead of its right child. Access to the tree is by two fingers pointing to the leftmost and rightmost external nodes. (See Figure 22.)

In an  $n$ -item heterogeneous search tree, we can search for an item  $d$  positions away from either end in  $O(1 + \log(\min\{d, n-d\} + 1))$  time, by searching up along the left and right paths concurrently until we find a subtree or two subtrees guaranteed to contain the desired item, and then searching down in this subtree or subtrees. Furthermore we can insert or delete an item  $d$  positions from either end in  $O(1 + \log(\min\{d, n-d\} + 1))$  amortized time. We can also search for an item based on its position or based on a secondary heap order. To accommodate search by position, we store in each internal node the number of external nodes reachable from it (by paths of pointers). To accommodate search based on a secondary heap order, we assume each item has an associated secondary value. We store in each internal node the minimum and maximum values of items reachable by paths of pointers. (See Figure 22.) By searching up along the left and right paths concurrently and then down into an appropriate subtree or subtrees, we can perform the following kinds of searches in  $O(1 + \log(\min\{d, n-d\} + 1))$  time:

- (i) Find the  $d$ th item in the tree;

<sup>2</sup>The *left path* in a binary tree is the path from the root through left children to an external node. The right path is defined symmetrically.

FIG. 21. *The rebalancing transformations in red-black tree deletion. The two ambiguous (half-solid) nodes in (d) have the same color, as do the two in (e). Minus signs denote short nodes. In (a), the top node after the transformation is short unless it is the root.*

(ii) Find the leftmost (or rightmost) item whose secondary value is at least (or at most) a given value, if the item found is the  $d$ th.

The auxiliary position and secondary value information must be updated when insertions and deletions are performed. This updating can be done bottom-up along the search path, i.e. bottom-up within the tree and top-down along the left or right path. The amortized time to insert or delete the  $d$ th item, including the search time, is  $O(1 + \log(\min\{d, n-d\} + 1))$ .

We now wish to extend our repertoire of update operations to include concatenation and splitting of trees. We shall discuss only the effect of these operations on the tree structure; it is easy to verify that the pointers, keys, and auxiliary position and secondary value information can be updated in the claimed time bounds. We define the *rank* of a node in a red-black tree to be the number of black internal nodes on any path from the node down to an external node; the rank of an external node is zero. We can compute the rank of a node in time proportional to the rank by walking down through the tree.

Concatenation is the simpler operation to describe. Suppose we wish to combine two trees  $T_1$  and  $T_2$  into a single tree; we assume that all items in  $T_1$  are less than all items in  $T_2$ . Let  $x_1$  with rank  $r_1$  and  $x_2$  with rank  $r_2$  be the roots of  $T_1$  and  $T_2$ , respectively. Assume  $r_1 \leq r_2$ . (The other case is symmetric.) To concatenate  $T_1$

FIG. 22. A heterogeneous red-black finger search tree. The colors of nodes are not shown. The items are the letters *a* through *f*. The numbers in external nodes are secondary values. The numbers in internal nodes are the minimum and maximum secondary values reachable from the nodes. The numbers outside the nodes are the number of external nodes reachable from them.

and  $T_2$ , we walk up the left path of  $T_2$  until we reach a node, say  $y$ , with rank equal to  $r_1$ . We replace  $y$  in  $T_2$  by a new red node whose left child is  $x_1$  and whose right child is  $y$ , correcting any violation of the red constraint as in the case of an insertion. The amortized time for the concatenation is  $O(1 + \min\{r_1, r_2\})$ . If we change the definition of potential so that the potential of a tree is the rank of its root plus the number of black nodes with no black children, then the amortized time of a concatenation is  $O(1)$ ; the amortized time for inserting or deleting the  $d$ th item out of  $n$  remains  $O(1 + \log(\min\{d, n-d\} + 1))$ .

Suppose we wish to split a tree  $T$  containing  $n$  items at the  $d$ th item, dividing it into a tree  $T_1$  containing the first  $d$  items and a tree  $T_2$  containing the last  $n-d$  items. First we locate the  $d$ th item. Then we walk up along the search path to the left or right path, deleting every node along the search path except the external node containing the  $d$ th item. Assume we reach a node  $x$  on the left path. We concatenate the trees to the left of the search path (including the one consisting of the single node containing the  $d$ th item) in right-to-left order to form  $T_1$ . We concatenate the trees to the right of the search path whose roots are descendants of  $x$  to form a tree  $T'_2$ . If node  $x$  has no parent, then tree  $T'_2$  is the desired  $T_2$ . Otherwise, there remains another tree  $T''_2$  containing the parent of  $x$ , say  $y$ . Tree  $T''_2$  is missing a node, since node  $x$  was deleted. We replace node  $y$  by its right child, and repair the possible resulting shortness as in a deletion. Then we concatenate  $T_2$  and  $T'_2$  to form  $T_2$ . A careful analysis (see e.g. [20, pp. 214-216]) shows that the amortized time for splitting is  $O(1 + \log(\min\{d, n-d\} + 1))$  for either the new or the old definition of potential.

FIG. 23. *The pointers in a homogeneous red-black finger search tree.*

Heterogeneous finger search trees are used in the visibility algorithm to represent parts of region boundaries. The term “heterogeneous” refers to the fact that the pointer structure favors certain specific access positions, namely the two ends. In contrast, *homogeneous* finger search trees support fast access in the vicinity of *any* item. We make a red-black tree into a homogeneous finger search tree by adding additional pointers to it; namely, we make each node point to its two children and to its parent. Each black node also points to its *left* and *right neighbors*, the black nodes of the same rank that precede and follow the given node in symmetric order. (See Figure 23.) These extra pointers are called *level links*.

The level links support searching for a given item starting from an arbitrary item in the tree in  $O(1 + \log(\min\{d, n-d\} + 1))$  time, where  $d$  is the number of items between the two given items. The search proceeds up from the starting item following parent pointers and level links until a subtree or two in which the desired item must be located are found; then the search proceeds downward in the standard way. Simultaneously with the search from the given starting item, searches are performed starting from the first and last items in the list; all three searches terminate when the desired item is first located (or discovered not to be in the tree).

Homogeneous finger search trees support fast searches only with respect to the total order on the items, not searches by position or searches based on secondary heap order. On the other hand, the extra time needed to update level links is only  $O(1)$  per local transformation (of the kinds in Figures 19 and 20), and thus the amortized time bounds of insertion, deletion, concatenation, and splitting are the same in homogeneous trees as they are in heterogeneous trees. Furthermore, homogeneous trees support a more drastic splitting operation, called *three-way splitting*: given two items  $x$  and  $y$  in a tree  $T$ , remove from  $T$  the sublist of items from  $x$  to  $y$  (inclusive) to form two trees, one representing the removed sublist and the other representing the remaining

items. The amortized time for a three-way splitting operation is  $O(1 + \log(\min\{d, n-d\} + 1))$ , where  $d$  is the number of items in the removed sublist. See [14] for details on how a three-way split can be performed within this time bound.

**Acknowledgments.** We thank Brenda Baker for her many helpful comments on an earlier draft of this paper, and Bernard Chazelle for his thorough reading of this version of the paper.

## PREFACE

In June 1985, a workshop on the mathematical theory of security was held at the Massachusetts Institute of Technology's Endicott House. The workshop, which was run by Silvio Micali and Shafi Goldwasser, had three goals: to provide the necessary mathematical framework for rigorously discussing security issues, to select archetypal problems and provide concrete solutions, and to generate momentum and critical mass.

The participants in the workshop were invited to submit papers to this special issue. Most of the papers in this issue were presented at the workshop. The submitted papers went through the normal refereeing process; not all of them were accepted. Finally, after two years, the issue is ready for publication.

The papers cover the following topics: randomization, pseudorandom number generators, specific cryptographic protocols with certain provable security properties, some cryptanalytic attacks against specific protocols, and the theory of zero knowledge. In addition, there are papers on various notions of security, as well as relevant topics in complexity theory and hardware. Below, I discuss very briefly the main results of the papers in this issue.

Some cryptographic protocols require generating a random integer in a certain range with known factorization. The obvious method of selecting a random integer and then factoring it is usually unfeasible, as factoring is assumed to be hard. In "How to generate factored random numbers," Bach presents an efficient method. For a range of the form  $N/2 < x < N$ , the algorithm requires  $O(\log N)$  primality tests of integers not larger than  $N$ . It can thus be performed in random polynomial time.

In "RSA and Rabin functions: Certain parts are as hard as the whole," Alexi, Chor, Goldreich, and Schnorr prove the following property of the RSA and Rabin encryption functions. If  $E_N: Z_N \rightarrow Z_N$  is either one of the two functions, then the following computational tasks are equivalent under random polynomial-time transformations, given  $E_N(x)$ : (i) computing  $x$ ; and (ii) guessing the least significant bit of  $x$  with success probability  $\frac{1}{2} + 1/\text{poly}(n)$ , where  $n$  is the length of  $N$ . Assuming integer factoring is hard, they derive improved pseudorandom number generation and probabilistic encryption schemes as a result.

In "Privacy amplification by public discussion," Bennett, Brassard, and Robert consider the following setting: Two persons have an imperfect private channel and a perfect public channel. The authors design protocols that allow the two persons to assess the damage to the message sent and, in case it is not too severe, to extract from it an undamaged part about which the eavesdropper has no information.

Recently, there were several papers that defined a model for weak random sources and then showed how perfect or almost-perfect random bits can be generated using such sources. In "Unbiased bits from sources of weak randomness and probabilistic communication complexity," Chor and Goldreich define such a model, which generalizes previous models. They show how to extract random bits from such sources. They also derive results from probabilistic communication complexity and draw conclusions about the robustness of the complexity class *BPP*.

In "Reconstructing truncated integer variables satisfying linear congruences," Frieze, Hastad, Kannan, Lagarias, and Shamir propose a polynomial-time algorithm that finds small integer solutions to systems of linear congruences. They derive from it polynomial-time algorithms that reconstruct the values of variables  $x_1, \dots, x_k$ , when

there are some linear congruences relating them, together with certain bits from the binary representations of these values (e.g., the high-order bits, the low-order bits, or even an arbitrary window of consecutive bits). These algorithms yield two applications: predicting linear congruential generators with truncated outputs, and breaking the simplest version of Blum's protocol for exchanging secrets.

In "The knowledge complexity of interactive proof systems," Goldwasser, Micali, and Rackoff define the notion of zero-knowledge proofs as those proofs that convey no additional information aside from the correctness of the assertion being proved. The usual NP-proof that upholds the validity of the assertion (e.g., exhibiting a Hamiltonian tour) is not zero-knowledge since it conveys much more than the fact that the given string is in the language (e.g., it gives a tour which is much more than merely the fact that the graph is Hamiltonian). They give two examples of zero-knowledge proofs: one for the language of quadratic residues and another for its complement.

In "A digital signature scheme secure against adaptive chosen-message attacks," Goldwasser, Micali, and Rivest present a new signature scheme that is based on the assumed computational difficulty of integer factoring. The scheme has the strongest security property, as it is secure against adaptive chosen-message attack: an adversary who generates messages that may depend on previous signatures and who receives signatures for such messages cannot forge the signature of an additional message. (The task of forging a signature is equivalent to factoring.)

In "Minimum-knowledge interactive proofs for decision problems,"<sup>1</sup> Galil, Haber, and Yung introduce a protocol for two parties, the prover and the verifier, with the following properties: Following the protocol, the prover gives to the verifier a proof of the value, 0 or 1, of a particular Boolean predicate that is hard for the verifier to compute. This extends the "interactive proof systems" of Goldwasser, Micali, and Rackoff, which are only used to confirm that a certain predicate has value 1. The protocol is provably minimum-knowledge in the sense that it communicates no additional knowledge to the recipient aside from the value of the predicate. The protocol is result-indistinguishable: an eavesdropper, overhearing an execution of the protocol, does not learn the value of the predicate that is proved, or anything else.

In "Complexity measures for public-key cryptosystems," Grollmann and Selman use complexity theory to formulate two equivalent versions of cracking a public-key cryptosystem. They prove several complexity-theoretic results related to these formulations.

In "Solving simultaneous modular equations of low degree," Hastad shows how to solve polynomial modular equations. His algorithm is polynomial when the degree of the polynomial is small relative to the number of equations. Consequently, the use of the RSA with a small exponent as a public-key cryptosystem is not secure in a large network. A previously proposed protocol is broken using the new algorithm.

In "Unique extrapolation of polynomial recurrences," Lagarias and Reeds show how to correctly extrapolate the values of an unknown polynomial recurrence modulo  $M$  in  $k$  variables of degree at most  $d$ , where  $d$  and  $k$  are known and  $M$  is not known. A polynomial-time algorithm predicts the next value given the first  $n$  values, and is wrong for at most a constant number (that depends on  $d$ ,  $k$ , and  $M$ ) of values of  $n$ .

The first pseudorandom number generators gave methods that generate bits one at a time, such that any advantage in guessing the next bit generated was computationally equivalent to a hard problem. In "The discrete logarithm hides  $O(\log n)$  bits,"

---

<sup>1</sup> This paper was handled by a different editor.

Long and Wigderson show that obtaining any information about the  $O(\log |p|)$  most significant bits of  $x$ , given  $g^x \bmod p$ , is equivalent to computing the discrete logarithm mod  $p$ . So the method yields a pseudorandom bit generator, using seeds of length  $n$ , that generates  $\log n$  pseudorandom bits at once.

It is known how to construct a pseudorandom function generator from a pseudorandom bit generator. In “How to construct pseudorandom permutations from pseudorandom functions,” Luby and Rackoff show how to construct a pseudorandom invertible permutation generator from a pseudorandom function generator. An implication of this result is that any pseudorandom bit generator can be used to construct a private-key cryptosystem that is secure against chosen plaintext attack.

In “The notion of security for probabilistic cryptosystems,” Micali, Rackoff, and Sloan consider three formal definitions of security that have been proposed in the literature and prove that they are equivalent. They consider their result evidence that each one of the definitions captures the right notion of security.

In “A pipeline architecture for factoring large integers with the quadratic sieve algorithm,” Pomerance, Smith, and Tuler consider integer factoring from the practical, economic point of view. Specifically, their “complexity measure” of a given algorithm is the size of the largest numbers it can factor in one year while using equipment costing less than \$10 million. They describe an architecture and implementation of the quadratic sieve algorithm that would yield 144 decimal digits as the measure. Currently, the two best algorithms yield 101 and 126. The authors remark that the annual cost of factoring a 200-digit number with their strategy would be about  $\$10^{11}$ —or only 5 percent of the current U.S. national debt.

In “Efficient parallel pseudorandom number generation,” Reif and Tygar present a simple parallel pseudorandom bit generator, assuming that the multiplicative inverse problem is almost always not in the class *RNC*. Under this assumption, problems in *RNC* can be solved by using only  $n^\epsilon$  random bits to serve as a seed for the generator. They deduce some complexity-theoretic results.

At the time of the writing of this introduction the final versions of the two papers on zero knowledge (by Goldwasser, Micali, and Rackoff and by Galil, Haber, and Yung) were not ready. They may appear in a later issue of this journal.

## HOW TO GENERATE FACTORED RANDOM NUMBERS\*

ERIC BACH†

**Abstract.** This paper presents an efficient method for generating a random integer with known factorization. When given a positive integer  $N$ , the algorithm produces the prime factorization of an integer  $x$  drawn uniformly from  $N/2 < x \leq N$ . The expected running time is that required for  $O(\log N)$  prime tests on integers less than or equal to  $N$ .

If there is a fast deterministic algorithm for primality testing, this is a polynomial-time process. The algorithm can also be implemented with randomized primality testing; in this case, the distribution of correctly factored outputs is uniform, and the possibility of an incorrectly factored output can in practice be disregarded.

**Key words.** factorization, primality, random variate generation

**AMS(MOS) subject classifications.** 1104, 11A51, 11Y05, 65C10

**1. Introduction.** Let  $N$  be a positive number, and suppose that we want a random integer  $x$  uniformly distributed on the interval  $N/2 < x \leq N$ . Further suppose that we do not want to output  $x$  in the usual decimal form, but rather as an explicit product of primes.

This is clearly possible if we are willing to factor  $x$ . However, the best known algorithms for factorization [8], [16] require roughly  $O(\log x)^{\sqrt{\log x}/\log \log x}$  steps on input  $x$ , so this approach is out of the question if  $N$  is large. In contrast, the method of this paper uses primality testing rather than factorization. Since there are efficient algorithms for determining primality [1], [10], [13], [17], the method is useful even when  $N$  is so large that factorization is infeasible.

The algorithm works by assembling random primes, but it is not clear a priori with what distribution these should be selected, nor how to efficiently implement a desired distribution on the primes. Much of the paper will deal with these questions, in a rather detailed fashion. However, if one is willing to overlook these technicalities, the resulting method can be easily sketched.

It selects a factor  $q$  of  $x$  whose length is roughly uniformly distributed between 0 and the length of  $N$ , then recursively selects the factors of a number  $y$  between  $N/2q$  and  $N/q$  and sets  $x = y \cdot q$ . It has now chosen  $x$  with a known bias; to correct this, it flips an unfair coin to decide whether to output  $x$  or repeat the whole process.

The results of this paper show not only that the distribution of  $x$  is uniform, but that this is a fast algorithm. A rough measure of its running time is the number of primality tests required; this quantity has expected value and standard deviation that are both  $O(\log N)$ —the same as required to generate a random prime of the same size.

This estimate is the basis for a finer analysis of the running time, which uses some assumptions about primality testing. If there is a deterministic polynomial-time prime test, as proved under the Extended Riemann Hypothesis by Miller [10], then the

expected number of single-precision operations needed to generate  $x$  in factored form can be bounded by a polynomial in  $\log N$ .

If the method uses a probabilistic polynomial-time prime test such as those of Rabin [13] and Solovay and Strassen [17], a similar result holds. In this case, the distribution of correctly factored numbers is still uniform, and the possibility of producing an incompletely factored output can in practice be disregarded — all within an expected polynomial time bound.

The method has been implemented; on a medium-sized computer, it will generate a 120-digit number in about 2 minutes.

The rest of this paper is organized as follows. Section 2 gives a heuristic derivation of the algorithm, and § 3 gives a general discussion of random variate generation. Section 4 presents the algorithm in explicit form; its running time is analyzed in §§ 5–8. Finally, § 9 gives experimental results.

**2. Heuristics.** Later sections present a detailed algorithm; this one provides motivation and sketches a design based on heuristic arguments.

First, what is meant by a “random factor” of a number? If we write down all numbers between  $N/2$  to  $N$  in factored form, we will have an array that is roughly rectangular, because the juxtaposition of a number’s factors is about as long as the number itself. If the factorizations are arranged one per line, and given in binary notation, the picture will look something like this:

```

      ⋮
10 10 10 10011 1001110111 100001100111001
11 11 11 1011011101 10100010111000111
10 101 11010011 10111110111110101011
10111111 100000111101110001010101
10 10 11 1111111010011 100000111110011
100101 1101101 1100011111010101101
10 111 111 111 10010100011 11111101011
11 101 1011 1101 10111011110111001111
10 10 10 10 11101 11111 11100000000111101
11010100011 11101101001011011011
      ⋮

```

Choosing a random factorization is equivalent to picking a row at random from this list; if the list were perfectly rectangular, we could do this by choosing a bit at random and taking the row in which it appears.

Now suppose that we wanted to get the effect of this process by choosing a prime factor  $p$  first and selecting one of the remaining  $N/p$  possibilities uniformly. To do this, we would pick  $p$  with probability proportional to its “surface area,” that is, proportional to the total number of bits occurring in all copies of  $p$ .

This suggests selecting the first factor  $p$  with probability about  $\log p/p \log N$ , since  $p$  occurs in about  $1/p$  of the numbers, and a random bit of such a number will be in  $p$  about  $\log p/\log N$  of the time (ignoring repeated factors).<sup>1</sup>

It is instructive to see what effect this would have on the *length* of  $p$ . A weak form of the prime number theorem [6, Thm. 7] implies that for  $0 < x < N$ ,

$$\sum_{p \leq x} \frac{\log p}{p \log N} \cong \frac{\log x}{\log N}.$$

<sup>1</sup> Unless otherwise indicated, all logarithms in this paper are to the base  $e = 2.718281 \dots$

Therefore, if we chose  $p$  with the proposed probability, the length of  $p$  (relative to the length of  $N$ ) would be close to that produced by a uniform distribution, since for  $0 \leq \alpha \leq 1$ ,  $\log p / \log N < \alpha$  with roughly the same frequency in both cases.

One can justify this uniform length heuristic in another fashion. The factorization of numbers into primes is analogous to the decomposition of permutations into disjoint cycles; for instance, one can easily prove the “prime permutation theorem”: a random permutation on  $n$  letters is prime (a cycle) with probability  $1/n$ . This analogy extends to the distribution of factor lengths: Knuth and Trabb Pardo have shown that the relative length of the  $k$ th largest factor of a random number has the same asymptotic distribution as the relative length of the  $k$ th largest cycle in a random permutation [7, § 10]. Under this analogy, our prime selection technique corresponds to a process that selects a random letter in a random permutation and outputs the cycle to which it belongs. Results on random permutations [5, p. 258] imply that the length of this cycle is uniformly distributed.

Thus, to choose  $x$  uniformly with  $N/2 < x \leq N$ , we might proceed as follows. Select a length  $\lambda$  uniformly from  $(0, \log N)$  and pick the largest prime  $p$  with  $\log p \leq \lambda$ . Then recursively select  $y$  (the remaining bits of  $x$ ) to satisfy  $N/2p < y \leq N/p$ , and output  $x$ , as  $p$  times the prime factorization of  $y$ .

If the distribution of  $y$  were uniform, the probability of selecting  $x$  would be about

$$\sum_{p|x} \frac{\log p}{p \log N} \cdot \frac{1}{N/p - N/2p}.$$

This is  $2/N$ , the correct probability for a uniform distribution, times a bias factor of

$$\frac{1}{\log N} \sum_{p|x} \log p.$$

This bias should be close to 1, and it is, provided that  $x$  does not have too many repeated prime factors.

Thus, one would suspect that this method is almost right; however, a closer look at the algorithm reveals the complications listed below.

- 1) Merely picking the biggest prime less than some given value will not do; for one thing, the first member of a twin prime pair will be chosen less frequently than the second. A correct method must be insensitive to these local irregularities.
- 2) The bias factor is quite small for certain  $x$ , say powers of 2. This problem can be eliminated by also including prime power factors in the first step, but we must further decide how often these are chosen.
- 3) At the end of the algorithm,  $x$  will have been chosen with a certain bias, but the recursion will not work unless all  $x$ 's are equally likely. The odds must be changed somehow to make the eventual output uniform.
- 4) Finally, we imagine selecting  $y$ , the rest of  $x$ , from  $(N/2p, N/p]$  with probability  $2p/N$ . However, it is by no means certain, and in general not true, that there are  $N/2p$  integers in this range.

Dealing with these problems requires some machinery that will be developed in the next section.

**3. Doctoring the odds.** This section discusses a general technique for using one distribution to simulate another, called the “acceptance-rejection” method [11], [15]. It requires only a little information about the distributions, a source of uniform  $(0,1)$  random real numbers, and some extra time.

This method is usually applied in situations where everything is known about the distributions. In our case, we will only know the relative probabilities involved, hence we need the following definition.

Let  $(x_1, \dots, x_n)$  be a finite set. We will say that  $X$  has a finite distribution with odds  $(p_1, \dots, p_n)$  if  $X = x_i$  with probability  $p_i / \sum_{j=1}^n p_j$ . The odds of a distribution are only defined up to a multiplicative constant; this conforms to ordinary usage, in which odds of 2:1 and 10:5 are regarded as identical.

To see how to turn one distribution into another, consider an example. Suppose we have a coin that is biased in favor of heads with odds of 2:1, and we wish to make it fair. This can be done by the following trick. Flip the coin. If it comes up tails, say "tails"; if it comes up heads, say "heads" with probability 1/2, and with probability 1/2 repeat the process.

The stopping time can be analyzed by the following "renewal" argument. The process must flip the biased coin once no matter what happens, and after this first step, it has one chance in three of being born again. Thus the expected stopping time  $E(T)$  must satisfy  $E(T) = 1 + E(T)/3$ , so  $E(T) = 3/2$ . More generally,  $T = t$  with probability  $(2/3) \cdot (1/3)^{t-1}$ ; this is a geometric distribution with expected value 3/2. At each reincarnation, the process has no memory of its past, so the stopping time and the ultimate result are independent.

This example is not very useful, as it requires a fair coin to produce the effect of one; however, it points out some important features of the method. First, decisions are only made locally; after getting, say, heads, a decision can be made without knowing the other possible outcomes or even their total number. Second, only the odds matter; knowing only the relative probability of each outcome is sufficient for undoing the bias.

Here is the general version; we are given odds  $(p_1, \dots, p_n)$  but want odds  $(q_1, \dots, q_n)$ . Assume that  $q_i \leq p_i$  for all  $i$ ; we can use the following recipe:

PROCESS A: Acceptance-rejection method.

- (\*) Select  $X$  from the original distribution.
- Choose a real number  $\lambda$  from the  $U(0,1)$  distribution.
- If  $X = x_i$  and  $\lambda < q_i/p_i$ , output  $Y = x_i$ .
- If not, go back to (\*).

**THEOREM 1.** *Let  $X$  have a finite distribution with odds  $(p_1, \dots, p_n)$ . If  $q_i \leq p_i$  for  $1 \leq i \leq n$ , then the output of Process A has a finite distribution with odds  $(q_1, \dots, q_n)$ . The stopping time  $T$  and the output value  $Y$  are independent random variables. If  $P = \sum_{i=1}^n p_i$ ,  $Q = \sum_{i=1}^n q_i$ , then the stopping time is distributed geometrically with expected value  $P/Q$ .*

*Proof.* A direct calculation shows that the joint distribution of  $T$  and  $Y$  is

$$\Pr[T = t, Y = x_i] = \frac{q_i}{Q} \cdot \frac{Q}{P} \left(1 - \frac{P}{Q}\right)^{t-1}. \quad \square$$

This technique is at the heart of the method, in two ways:

At the top level, the algorithm generates  $x$ ,  $N/2 < x \leq N$ , with probability proportional to  $\log x$ . It accepts  $x$  with probability  $\log(N/2)/\log x$ , producing a uniform distribution.

To select a factor with approximately uniform length, the algorithm chooses prime powers  $q$  with odds  $\Delta_N(q)$  (defined below). To do this, it first chooses integers  $q$  in the following way: 2 and 3 each appear with odds 1/2, 4, 5, 6, and 7 each appear with odds 1/4, and so on. It turns out that  $\Delta_N(q) < 1/q$ , so acceptance-rejection is used twice: first to produce the distribution  $\Delta_N(q)$ , and then to throw away  $q$ 's that are not prime powers.

**4. The complete algorithm.** This section presents an explicit program for generating factored random integers, using the language of real numbers. It assumes the uniform (0,1) distribution as a source of randomness; § 7 will show how this can be simulated by a fair coin.

For real numbers  $a$  and  $b$ , let  $\#(a,b]$  denote the number of integers  $x$  satisfying  $a < x \leq b$ . For prime powers  $q = p^\alpha$ , and integers  $N$ , let

$$(1) \quad \Delta_N(q) = \frac{\log p}{\log N} \cdot \frac{\#(N/2q, N/q)}{N}.$$

Note that if  $[x]$  denotes the greatest integer  $\leq x$ , then  $\#(a/2, a] = [(a+1)/2]$ ; this implies the frequently used estimate

$$(2) \quad (a-1)/2 \leq \#(a/2, a] \leq (a+1)/2$$

and also shows that for  $q \leq N$ ,

$$\Delta_N(q) \leq \frac{N/q+1}{2N}.$$

The innermost part of the program selects random prime powers; using the above notation, it is defined below.

PROCESS F: Factor generator.

- (\*) Select a random integer  $j$  with  $1 \leq j \leq \log_2 N$ .  
 Let  $q = 2^j + r$ , where  $r, 0 \leq r < 2^j$ , is chosen at random.  
 Choose a random real number  $\lambda$  from the  $U(0, 1)$  distribution.  
 If  $q$  is a prime power,  $q \leq N$ , and  $\lambda < \Delta_N(q)2^{\lceil \log_2 q \rceil}$ , output  $q$ .  
 If not, go back to (\*).

The salient features of this process are given by the following result.

**THEOREM 2.** *Process F almost surely halts; the number of times (\*) is reached has a geometric distribution whose expected value is  $O(\log N)$ . It outputs a prime power  $q = p^\alpha$ ,  $2 \leq q \leq N$ , with odds  $\Delta_N(q)$ . The stopping time and the output value are independent.*

*Proof.* The first two steps select  $q$  with odds  $2^{-\lceil \log_2 q \rceil}$ , and since  $2^{\lceil \log_2 q \rceil} \Delta_N(q) \leq (N+q)/2N \leq 1$  for  $q \leq N$ , Theorem 1 implies that  $q$  is output with the stated probability. For the stopping time estimate, since

$$P = \sum_{q=2}^N 2^{-\lceil \log_2 q \rceil} \leq \log_2 N,$$

it will suffice to show that

$$Q = \sum_{q \leq N} \Delta_N(q)$$

is bounded below by an absolute constant. This follows from two consequences of the prime number theorem given by Rosser and Schoenfeld [14, p. 65]:

$$(3) \quad \sum_{p \leq N} \log p = N + O(N/\log N)$$

and

$$(4) \quad \sum_{p \leq N} \log p/p = \log N + O(1).$$

Using (3) and (4),

$$(5) \quad \sum_{q \leq N} \Delta_N(q) \geq \sum_{p \leq N} \Delta_N(p) \geq \sum_{p \leq N} \frac{\log p}{2p \log N} - \sum_{p \leq N} \frac{\log p}{2N \log N} = \frac{1}{2} + O\left(\frac{1}{\log N}\right).$$

The independence statement is a consequence of Theorem 1.  $\square$

Just as in the heuristic sketch, the factor generator is a subroutine in the main program, presented below. This process uses a “stopping value”  $N_0$ , which can be any convenient number.

**PROCESS R: Random factorization generator.**

If  $N \leq N_0$ , pick a random  $x$ ,  $N/2 < x \leq N$ , output the factors of  $x$ , and stop.

(†) Select a prime power  $q = p^\alpha$ ,  $2 \leq q \leq N$ , using Process F.

Let  $N' = \lfloor N/q \rfloor$ .

Call Process R recursively to choose a factored random  $y$  with  $N'/2 < y \leq N'$ .

Let  $x = y \cdot q$ .

(§) Choose a real number  $\lambda$  from the  $U(0,1)$  distribution.

If  $\lambda < \log(N/2)/\log x$ , output the factors of  $x$  and stop.

If not, return to (†).

The main result of this paper is the following theorem.

**THEOREM 3.** *Process R generates uniformly distributed random integers  $x$ ,  $N/2 < x \leq N$ , in factored form.*

*Proof.* If  $N \leq N_0$ , there is nothing to prove. Otherwise, note that for integers  $y$ ,  $\lfloor x \rfloor / 2 < y \leq \lfloor x \rfloor$  if and only if  $x/2 < y \leq x$ , and so the recursive step chooses an integer  $y$  uniformly with  $N/2q < y \leq N/q$ . Therefore, by Theorem 2,  $x$  is chosen at step (§) with probability proportional to

$$\sum_{q=p^\alpha | x} \frac{\Delta_N(q)}{\#(N/2q, N/q)} = \sum_{q=p^\alpha | x} \frac{\log p}{\log N} \cdot \frac{\#(N/2q, N/q)}{N} \cdot \frac{1}{\#(N/2q, N/q)} = \frac{\log x}{N \log N}.$$

By Theorem 1, the last part of the algorithm ensures that  $x$  is output with probability  $1/\#(N/2, N)$ .  $\square$

**5. The distribution of factor lengths.** It was stated earlier that Process F produces a factor  $q$  whose length is roughly uniformly distributed. This can be refined into the following precise statement: as  $N \rightarrow \infty$ ,  $\log q/\log N$  converges in distribution to a uniform (0,1) random variable.<sup>2</sup> This implies the following: if we define

$$F_N(x) = \Pr[q \leq x \text{ in Process F}],$$

then  $F_N(x)$  is close to  $\log x/\log N$ . Similarly, the expected values  $E[\log(N/q)]$  and  $E[\log^2(N/q)]$  are close to  $\frac{1}{2} \log N$  and  $\frac{1}{3} (\log N)^2$ , respectively. The next three lemmas give upper bounds corresponding to these approximations, which are used in the next section.

**LEMMA 1.** *If  $N > 30$ , and  $2 \leq x \leq N$ , then*

$$F_N(x) \leq \frac{\log x + 2}{\log N - 2}.$$

*Proof.* For  $N > 30$ ,

$$\sum_{p^\alpha \leq N} \log p \leq 1.04N$$

<sup>2</sup> I will not prove this as it is not needed later.

and

$$\log N - \gamma - \beta - \frac{1}{2 \log N} \leq \sum_{p \leq N} \frac{\log p}{p} \leq \log N,$$

where

$$\gamma = 0.577215 \dots$$

is Euler's constant and

$$\beta = \sum_{\alpha \geq 2} \log p / p^\alpha = 0.755366 \dots$$

(these are (3.21), (3.24) and (3.35) from Rosser and Schoenfeld [14]). Using these inequalities, plus (1) and (2),

$$2 \log N \sum_{q \leq N} \Delta_N(q) \geq \log N - \gamma - \beta - \frac{1}{2 \log N} + \sum_{\substack{p^\alpha \leq N \\ \alpha \geq 2}} \frac{\log p}{p^\alpha} - 1.04 > \log N - 2.$$

Similarly

$$2 \log N \sum_{q \leq x} \Delta_N(q) \leq \sum_{p \leq x} \frac{\log p}{p} + \beta + \sum_{q \leq x} \frac{\log p}{N} \leq \log x + 2.$$

Now apply these to the formula  $F_N(x) = \sum_{q \leq x} \Delta_N(q) / \sum_{q \leq N} \Delta_N(q)$ .  $\square$

LEMMA 2. For  $N > 30$ ,

$$E[\log(N/q)] \leq \frac{\log N}{2} \cdot \frac{\log N + 4}{\log N - 2}.$$

*Proof.* The expectation can be expressed as a Stieltjes integral:

$$\int_{2^-}^N \log(N/x) dF_N(x).$$

Using integration by parts and Lemma 1,

$$\int_{2^-}^N \log(N/x) dF_N(x) = \int_2^N \frac{F_N(x)}{x} dx \leq \int_1^N \frac{\log x + 2}{\log N - 2} \cdot \frac{dx}{x},$$

now computing the integral gives the result.  $\square$

LEMMA 3. For  $N > 30$ ,

$$E \log^2(N/q) \leq \frac{(\log N)^2}{3} \cdot \frac{\log N + 6}{\log N - 2}.$$

*Proof.* As in the last proof, the expectation is

$$\int_{2^-}^N \log^2(N/x) dF_N(x) \leq \frac{2}{\log N - 2} \int_1^N (\log N - \log x)(2 + \log x) \frac{dx}{x}. \quad \square$$

**6. The expected number of prime-power tests.** This section proves that the number of prime-power tests done by Process R on input  $N$  has expected value and standard deviation that are both  $O(\log N)$ .

For every  $N$ , define random variables as follows.  $T_N$  is the number of prime-power tests done by Process R on input  $N$ , and  $U_N$ ,  $V_N$ , and  $W_N$  count the prime-power tests done during the first call to Process F, the recursive call, and after the first return to  $(\dagger)$ , respectively.

**THEOREM 4.** *If  $N_0 > 10^6$ ,  $E(T_N) = O(\log N)$ .*

*Proof.* Let  $N > N_0$ , for otherwise the theorem is true immediately. By Theorem 2, we can choose  $C > 0$  so that  $U_N \leq C \log N$ ; we now prove by induction on  $N$  that  $T_N \leq 6C \log N$ .

Since  $T_N = U_N + V_N + W_N$ ,  $E(T_N) = E(U_N) + E(V_N) + E(W_N)$ . By the definition of  $C$  and the formula  $E(X) = E_Y(E(X|Y))$  applied to  $V_N$ , this gives

$$E(T_N) \leq C \log N + E_q(E(T_{\lfloor N/q \rfloor})) + \frac{\log 2}{\log N} E(T_N),$$

since the probability of renewal is at most  $1 - \log(N/2)/\log N$ . By induction and Lemma 2,

$$\begin{aligned} E(T_N) &\leq C \log N + 6CE(\log N/q) + \frac{\log 2}{\log N} E(T_N) \\ &\leq C \log N + 6C \frac{\log N}{2} \cdot \frac{\log N + 4}{\log N - 2} + \frac{\log 2}{\log N} E(T_N). \end{aligned}$$

This implies

$$E(T_N) \leq \frac{1}{1 - \log 2/\log N} \left( 1 + 3 \frac{\log N + 4}{\log N - 2} \right) C \log N,$$

and for  $N > 10^6$  the coefficient of  $C \log N$  is less than 6.  $\square$

The corresponding estimate for the variance is given below.

**THEOREM 5.** *If  $N_0 > 10^6$ ,  $\sigma^2(T_N) = O(\log N)^2$ .*

*Proof.* Let  $\bar{R}$  denote the process obtained by replacing the top level stopping condition  $\lambda < \log(N/2)/\log x$  by  $\lambda < 1 - \log 2/\log N$ ; the recursive call uses the unaltered Process R. We can consider both processes to be defined on the same sample space; then (extending the notation in an obvious fashion)

$$\bar{T}_N = U_N + V_N + \bar{W}_N.$$

Since  $U_N$ ,  $V_N$ , and  $\bar{W}_N$  are independent,

$$\sigma^2(\bar{T}_N) = \sigma^2(U_N) + \sigma^2(V_N) + \sigma^2(\bar{W}_N).$$

Using the formulas  $\sigma^2(X) = E(X^2) - E(X)^2$  and  $E(X) = E_Y(E(X|Y))$ ,

$$E(\bar{T}_N^2) \leq \sigma^2(U_N) + E(\bar{T}_N)^2 + E_q(E(T_{\lfloor N/q \rfloor}^2)) + \frac{\log 2}{\log N} E(\bar{T}_N^2).$$

The proof of Theorem 4 actually shows that  $E(\bar{T}_N) = O(\log N)$ ; we can therefore choose  $D > 0$  so that  $\sigma^2(U_N) + E(\bar{T}_N)^2 \leq D(\log N)^2$ . Furthermore, for any  $N$ ,  $T_N \leq \bar{T}_N$ , so

$$E(\bar{T}_N^2) \leq D(\log N)^2 + E_q(E(\bar{T}_{\lfloor N/q \rfloor}^2)) + \frac{\log 2}{\log N} E(\bar{T}_N^2).$$

An argument similar to the proof of Theorem 4, using Lemma 3, will show that  $E(\bar{T}_N^2) \leq 4D(\log N)^2$ . Since

$$\sigma^2(T_N) \leq E(T_N^2) \leq E(\bar{T}_N^2),$$

the result follows.  $\square$

**7. A single-precision time bound.** The next two sections analyze the average number of single-precision operations needed to generate a random factorization. Any serious discussion of this must answer two questions. First, the algorithm uses real numbers, which are not finite objects; how can these be simulated? Second, one might wish to use randomized prime testing; what happens when the prime tester can make mistakes?

This section addresses the real-number issue, assuming perfect prime testing; probabilistic prime testing will be treated in the next section. In what follows, a “step” means one of the basic arithmetic operations (including comparison) on single-bit numbers, or a coin flip. All questions of addressing and space requirements will be ignored.

The following result will be used repeatedly.

LEMMA 4. *Let  $T_1, T_2, \dots$  be a sequence of random variables, and let  $n$  be a positive integer-valued random variable, such that  $T_i = 0$  for every  $i > n$ . If  $E(T_i | n \geq i) \leq A$  and  $E(n) \leq B$ , then  $E(\sum_{i=1}^n T_i) \leq AB$ .*

*Proof.*

$$E\left(\sum_{i=1}^n T_i\right) = \sum_{i=1}^{\infty} E(T_i) = \sum_{i=1}^{\infty} E(T_i | n \geq i) \Pr[n \geq i] \leq A \cdot \sum_{i=1}^{\infty} \Pr[n \geq i] \leq AB. \quad \square$$

At several points in our algorithm we need to flip a coin with success probability  $\theta$ , where  $\theta$  is a fixed real number between 0 and 1. This means we compare  $\theta$  with a randomly generated real value  $\lambda$ , thus:

$$\begin{aligned} \theta &= .0101010101 \dots, \\ \lambda &= .0110010111 \dots \end{aligned}$$

A finitary procedure with the same effect simply does the comparison bit-by-bit from the left, only generating bits as they are needed. This is clearly fast; since the bits of  $\lambda$  are specified by independent coin flips, we expect to use only two of them before reaching a decision. However, it may not be convenient to generate the true bits of  $\theta$  one at a time; to avoid this difficulty, we base our procedure on approximations that might be produced by some scheme like interval arithmetic.

We need the following definition. Let  $\theta$ ,  $0 \leq \theta \leq 1$ , be a real number. A *k-bit approximation to  $\theta$*  is an integer multiple  $\theta_k$  of  $2^{-k}$  with  $|\theta_k - \theta| \leq 2^{-k}$  and  $0 < \theta_k < 1$ .

The lemma below eliminates real numbers from our algorithm; it states, in effect, that if  $\theta$  is approximable by *any* polynomial-time procedure, then a biased coin flip with success probability  $\theta$  takes constant time on the average.

LEMMA 5. *Let  $0 \leq \theta \leq 1$ , and assume that a k-bit approximation to  $\theta$  can be computed in  $f(k)$  steps, where  $f$  is a polynomial of degree  $m$  with nonnegative coefficients. Then the expected time to decide if a uniform  $(0,1)$  random variable is less than  $\theta$  is at most  $C_m f(1)$ , where  $C_m$  depends only on  $m$ .*

*Proof.* Let  $\lambda$  be the uniform  $(0,1)$  value; we can assume it is irrational, since the set of rational numbers has measure 0. Consider the following procedure: for  $k = 1, 2, 3, \dots$ , compute a  $k$ -bit approximation  $\theta_k$  to  $\theta$  and compare this to  $\lambda_k$ , the number formed from the first  $k$  bits of  $\lambda$ ; if  $\theta_k + 2^{-k} \leq \lambda_k$  or  $\lambda_k < \theta_k - 2^{-k}$ , terminate the process. The probability that no decision is reached after  $k$  steps is at most  $2^{1-k}$ , so the expected

total time is at most a constant times

$$\sum_{k=1}^{\infty} f(k)2^{1-k} = 2 \sum_{k=1}^{\infty} \sum_{j=0}^m a_j k^j 2^{-k} = 2 \sum_{j=0}^m a_j \sum_{k=1}^{\infty} k^j 2^{-k},$$

where  $a_0, \dots, a_m$  are the coefficients of  $f$ . Polyá and Szegö [12, p. 9] give the formula (valid for  $|z| < 1$ )

$$\sum_{k=1}^{\infty} k^j z^k = \frac{g_j(z)}{(1-z)^{j+1}},$$

where  $g_j$  is a polynomial with nonnegative coefficients, satisfying  $g_j(1) = j!$ . The result follows by taking  $z = 1/2$  and  $C_m = 2^{m+2} m!$ .  $\square$

LEMMA 6. *Let  $p, q, N$  be integers with  $2 \leq p \leq q \leq N$ . Then a  $k$ -bit approximation to*

$$\theta = \frac{\log p}{\log N} \cdot \frac{\#(N/2q, N/q) 2^{\lceil \log_2 q \rceil}}{N}$$

can be computed in  $O(k^3 + \log \log N)$  steps.

*Proof.* Let  $p = 2^{\alpha} \cdot \varepsilon$  and  $N = 2^{\beta} \cdot \eta$ , where  $\alpha$  and  $\beta$  are integers and  $1 \leq \varepsilon, \eta < 2$ . Then

$$(6) \quad \theta = \frac{\alpha \log 2 + \log \varepsilon}{\beta \log 2 + \log \eta} \cdot \frac{[(N+q)/2q] 2^{\lceil \log_2 q \rceil}}{N}.$$

We approximate  $\theta$  by using floating-point numbers to perform the computation implicit in the above expression;  $k + O(1)$  bits of precision suffice to get an absolute error less than  $2^{-k}$ , by the following argument. First, since  $0 \leq \theta \leq 1$ , it suffices to make the relative error in the result less than  $2^{-k}$ . Brent [3, Thm. 6.1] shows that on the interval  $1 \leq x \leq 2$ , one can compute  $\log x$  with relative error  $2^{-n}$  in  $O(n^3)$  steps. If we take  $n = k + O(1)$ , we will have enough guard bits to nullify the effect of any remaining error, since there are only a finite number of further operations. All the numbers involved have exponents that are less than  $\log_2 N$ , so the bound follows.  $\square$

LEMMA 7. *Let  $x$  and  $N$  be positive integers with  $N/2 < x \leq N$ . Then a  $k$ -bit approximation to  $\log(N/2)/\log x$  can be computed in  $O(k^3 + \log \log N)$  steps.*

*Proof.* Approximate the logarithms as indicated in the proof of Lemma 6.  $\square$

LEMMA 8. *Let  $q > 1$  be an integer. Then solving  $p^\alpha = q$  for an integer  $p$  and the largest possible integer  $\alpha$  can be done in  $O(\log q)^3 (\log \log q)^2$  steps.*

*Proof.* Let  $d = \lceil \log_2 q \rceil$ ; then necessarily  $\alpha \leq d$ . For each such value of  $\alpha$ , we solve  $X^\alpha = q$  by bisection, using 0 and  $2^{\lceil d/\alpha \rceil + 1}$  as starting values. This will find a solution or prove that none exists after  $O(d/\alpha)$  evaluations of  $f(X) = X^\alpha$ . The total time is therefore at most a constant times

$$(\log q)^3 \sum_{2 \leq \alpha \leq d} 2 \leq \alpha \leq d \frac{\log \alpha}{\alpha} = O(\log q)^3 (\log \log q)^2. \quad \square$$

The next two results assume the Extended Riemann Hypothesis (ERH), a famous conjecture of analytic number theory. The details of this hypothesis (for which see Davenport's book [4, p. 124]) are not important here; what matters is the following consequence, first proved by Miller [10].

LEMMA 9 (ERH). *To test if an integer  $p$  is prime requires  $O(\log p)^5$  operations.*

*Proof.* We write  $\nu_2(x)$  for the largest  $e$  such that  $2^e | x$ , and  $\mathbb{Z}_p^*$  for the multiplicative subgroup of integers modulo  $p$ . Then Miller's primality criterion states that  $p$  is prime

if and only if every  $a \in \mathbb{Z}p^*$  satisfies

$$(7) \quad a^{p-1} \equiv 1 \text{ and for all } k < \nu_2(p-1), a^{(p-1)/2^k} \equiv 1 \text{ implies } a^{(p-1)/2^{k+1}} \equiv \pm 1$$

(all congruences are interpreted modulo  $p$ ). If  $p$  is composite, there is a proper subgroup  $G$  of  $\mathbb{Z}p^*$  such that (7) is violated for all  $a \notin G$  [9, proof of Thm. 6]. The ERH implies that there is some number outside  $G$  that is less than  $2(\log p)^2$  [2, Thm. C]. Therefore  $p$  is prime if and only if condition (7) holds for all positive  $a \leq 2(\log p)^2$ ; the result follows.  $\square$

We now make the following changes to our algorithm: prime-power testing is done as indicated in the proofs of lemmas 8 and 9, and the real number calculations are done as indicated in Lemmas 5, 6, and 7. With these modifications we have our single-precision result.

**THEOREM 6 (ERH).** *The expected number of single-precision operations (arithmetic, comparison, coin flips) needed by Process R on input  $N$  is  $O(\log N)^6$ .*

*Proof.* Theorem 4 and inspection of the algorithm imply that none of its steps can be executed more than  $O(\log N)$  times on the average. By Lemma 4, it suffices to show that no single step of the algorithm has expected time greater than the  $O(\log N)^5$  steps sufficient to test a number less than  $N$  for primality. By Lemmas 5, 6, and 7, this is true for the real number comparisons. Everything else is easily estimated.  $\square$

The real point to this extravagant bound is that it is a polynomial in  $\log N$ . By using the prime test of Adleman, Pomerance, and Rumely [1], one can also prove an unconditional almost-polynomial time bound of  $O(\log N)^{O(\log \log \log N)}$ . However, much better estimates can be obtained by using probabilistic prime testing, as described in the next section.

**8. The use of probabilistic primality tests.** This section proves theorems analogous to the preceding results, assuming that a randomized prime test is used. First, a definition: call a factorization  $x = p_1^{e_1} \dots p_k^{e_k}$  *complete* if all the  $p_i$ 's are prime; if it uses a probabilistic prime test, Process R may output an incompletely factored number. The results in this case can be simply summarized: the distribution of completely factored numbers is still uniform, and incompletely factored numbers can be made exponentially unlikely at very little cost.

The following result is analogous to Lemma 9.

**LEMMA 10.** *To test if  $p$  is prime with bounded by  $4^{-n}$  (error only being possible when  $p$  is composite) requires  $n \cdot O(\log p)^3$  operations.*

*Proof.* Rabin [13, Thm. 1] shows that condition (7) is violated for a random  $a$  with probability at most  $1/4$ , so choose  $n$  independent random values of  $a$ .  $\square$

The prime tests referred to above have a very nice property; the decision is never wrong unless the input is composite. This is the key observation in the next proof.

**THEOREM 7.** *If the prime test used in Process F produces correct answers when the input is prime, then the distribution of completely factored outputs is uniform.*

*Proof.* Use induction on  $N$ ; if  $N < N_0$ , this is clear. Otherwise, the prime powers produced by Process F have the same relative distribution as before, since the prime tester never makes a mistake on prime input. Since every subfactorization of a complete factorization is complete, the calculation that proves Theorem 3 is still valid.  $\square$

The order-of-magnitude bound for the average number of prime power tests still holds, if the prime test used is sufficiently accurate. Since the average number of tests increases with  $N$ , a constant number of the tests (7) per prime will not suffice. Instead, we choose a bound  $\varepsilon(N)$  in advance, and make every prime test used by the algorithm have a chance of error at most  $\varepsilon(N)$ .

**THEOREM 8.** *Assume that the prime test used in Process F is correct on prime input, and has error probability at most  $\varepsilon(N)$  on composite input. If  $\varepsilon(N) < N^{-2}$ , then the number of prime-power tests done by Process R on input  $N$  has mean and standard deviation that are  $O(\log N)$ , and the probability that an incompletely factored number is produced is  $O(\varepsilon(N) \log N) = O(\log N / N^2)$ .*

*Proof.* For the time bound, it is only necessary to show that Lemma 1 still holds, say for  $N > 10^6$ . The proof of Lemma 1 amounted to a lower bound on the relative probability that  $q \leq N$  and an upper bound on the relative probability that  $q \leq x$ . The lower bound still holds, and the new upper bound is at most

$$\sum_{q \leq x} \Delta_q + \sum_{y \leq x} \varepsilon \frac{\log y \cdot \#(N/2y, N/y]}{\log N \cdot N}.$$

The second term is at most

$$\frac{1}{2 \log N} \cdot \frac{1}{N^2} \sum_{y \leq x} \left( \frac{\log y}{y} + \frac{\log y}{N} \right) \leq \frac{1}{2 \log N} \cdot \left( \frac{\log N}{N} \right)^2,$$

and this will not cause the bound to be exceeded. For the estimate relating to incorrect output, apply Lemma 4 to the random variables  $X_i$  that are 1 if the  $i$ th prime test is incorrect, and 0 otherwise, and use the inequality  $\Pr[X \geq 1] \leq E(X)$ .  $\square$

By Lemma 10, error probability less than  $N^{-2}$  can be obtained with about  $\log_2 N$  tests, each using  $O(\log N)^3$  steps. This will give a polynomial time bound analogous to Theorem 6.

**9. Experiments.** This section has two purposes: to show how the algorithm actually behaves in practice, and to discuss what modifications are necessary to implement it efficiently.

Call an arrival at (\*) in Process F a *probe*; Theorem 4 implies that Process R requires  $O(\log N)$  probes on the average. The constant implied by the “ $O$ ” symbol can be estimated by the following heuristic argument. Typically the algorithm will produce factors whose lengths are  $1/2, 1/4, 1/8, \dots$  the length of  $N$ . Presumably, then, the average number of probes is close to

$$2 \log_2 N (1 + 1/2 + 1/4 + \dots) = 4 \log_2 N,$$

since by (5), we expect Process F to use about  $2 \log_2 N$  probes on input  $N$ .

This value of  $4 \log_2 N$  is also the best bound provable as the stopping value  $N_0 \rightarrow \infty$ , and the first set of experiments were designed to see if this estimate is at all realistic when  $N_0$  is small.

To do this, I coded the algorithm verbatim in C (the “real” numbers have about 15 decimal digits of precision) with  $N_0 = 4$ . Table 1 gives statistics on the number of probes required to generate 100 random numbers for various values of  $N$ , together with the presumed mean value  $4 \log_2 N$ .

It will be seen from this table that the standard deviation tends to be a bit smaller than the mean; however, I do not even have a heuristic argument to justify this observation.

To test its feasibility for large  $N$ , I also coded the algorithm with multiprecision arithmetic on a DEC VAX 11-780, a machine that takes about 5 microseconds to multiply two 32-bit integers. When dealing with multi-word numbers, efficiency is of primary importance; this concern led to the following version of Process F.

- 1) After building the random value  $q$ , the program first checks that  $q \leq N$ , and then computes  $\Delta_N(q) 2^{\lceil \log_2 q \rceil}$  in single precision with the formula (6), as if  $q$

TABLE 1  
*Statistics on the number of probes.*

$N$	$4\log_2 N$	Average	Maximum	Standard deviation
$10^2$	26.56	20.77	60	13.95
$10^3$	39.86	35.59	218	34.31
$10^4$	53.15	56.30	367	47.49
$10^5$	66.44	71.30	329	62.24
$10^6$	79.73	72.49	472	59.58
$10^7$	93.01	74.61	346	63.43
$10^8$	106.30	111.78	491	85.30
$10^9$	119.59	120.82	453	96.78

were prime. Only if this exceeds the random value  $\lambda$  does it subject  $q$  to a prime-power test.

- 2) The first part of this test sees if for any small prime  $p$ ,

$$p|q \text{ and } p^2 \nmid q;$$

if this is true,  $q$  cannot be a prime power. This sieve procedure eliminates most  $q$  from further consideration, for the probability that a random number  $q$  survives this test for all  $p \leq B$  is about

$$\prod_{p \leq B} \left( \frac{p-1}{p} + \frac{1}{p^2} \right).$$

If we let

$$\alpha = \prod_p \left( 1 + \frac{1}{p(p-1)} \right) = 1.943596 \dots$$

then the survival probability is, by Mertens's theorem [6, p. 22], close to

$$\alpha \cdot \frac{e^{-\gamma}}{\log B}.$$

The program used  $B = 1000$ , which screens out approximately 84% of the  $q$ 's.

- 3) If  $q$  passes through the sieve, it is subjected to a "pseudo" test designed to cheaply eliminate numbers that are not prime powers. This checks that  $2^{q-1} \not\equiv 1$  and  $\gcd(2^{q-1} - 1, q) = 1$ ; if so,  $q$  can be thrown away. The average cost of this is one modular exponentiation and one gcd computation.
  - 4) Any number  $q$  that has survived so far is tested for primality, using (7) with  $a = 2, 3, 5, \dots, 29$  (the first ten primes). There is a slight advantage to small values of  $a$ , since about one-third of the multiplications done by the modular exponentiation algorithm will involve a single-word quantity.
  - 5) Only if  $q$  is not declared "prime" by the above procedure does the program try to see if it is a perfect power.
- (Various orderings of steps 1-5 were tried, and the one above seems to be the best.)

For the multiprecise implementation, a more realistic measure of the work done is the number of times  $q$  reaches the sieve. Statistics on these values are given in Table 2, from runs that generated 50 numbers each; the last column gives the average CPU time required per random factorization.

TABLE 2  
*Statistics on the number of sieve tests, and the running time in seconds.*

$N$	Average	Maximum	Standard deviation	Average time
$10^{15}$	29.66	67	17.70	1.51
$10^{30}$	65.42	225	46.36	4.66
$10^{60}$	158.92	387	95.04	20.52
$10^{120}$	250.34	805	174.54	100.08

It is worth noting that for these values of  $N$  the average running time is only slightly worse than  $O(\log N)^2$ .

Table 3 presents the mean values of four quantities related to the output values  $x$ : the number of prime factors of  $x$ , and the number of decimal digits in the largest three factors of  $x$  (from the same experiments). It will be seen that the average number of prime factors grows very slowly with  $N$ ; the observations are close to the mean values of  $\log \log N + 1.03465 \dots$  predicted by prime number theory [7, p. 346]. Finally, the average lengths of the largest three factors are roughly proportional to the length of  $N$ ; again, this is predicted by theory [7, p. 343], with constants of proportionality close to 0.62, 0.21, and 0.088, respectively.

TABLE 3  
*Statistics on the prime factors.*

$N$	Average number	Digits in largest	2nd largest	3rd largest
$10^{15}$	4.48	10.06	3.76	1.50
$10^{30}$	5.32	19.84	6.80	2.80
$10^{60}$	6.18	37.36	13.48	5.94
$10^{120}$	6.70	78.54	26.56	8.46

## RSA AND RABIN FUNCTIONS: CERTAIN PARTS ARE AS HARD AS THE WHOLE\*

WERNER ALEXI<sup>†</sup>, BENNY CHOR<sup>‡</sup>, ODED GOLDRZEICH<sup>§</sup> AND CLAUD P. SCHNORR<sup>†</sup>

**Abstract.** The RSA and Rabin encryption functions  $E_N(\cdot)$  are respectively defined by raising  $x \in Z_N$  to the power  $e$  (where  $e$  is relatively prime to  $\varphi(N)$ ) and squaring modulo  $N$  (i.e.,  $E_N(x) = x^e \pmod{N}$ ,  $E_N(x) = x^2 \pmod{N}$ , respectively). We prove that for both functions, the following problems are computationally equivalent (each is probabilistic polynomial-time reducible to the other):

- (1) Given  $E_N(x)$ , find  $x$ .
- (2) Given  $E_N(x)$ , guess the least-significant bit of  $x$  with success probability  $\frac{1}{2} + 1/\text{poly}(n)$  (where  $n$  is the length of the modulus  $N$ ).

This equivalence implies that an adversary, given the RSA/Rabin ciphertext, cannot have a non-negligible advantage (over a random coin flip) in guessing the least-significant bit of the plaintext, unless he can invert RSA/factor  $N$ . The proof techniques also yield the simultaneous security of the  $\log n$  least-significant bits. Our results improve the efficiency of pseudorandom number generation and probabilistic encryption schemes based on the intractability of factoring.

**Key words.** cryptography, concrete complexity, RSA encryption, factoring integers, partial information, predicate reductions

**1. Introduction.** One-way functions are the basis for modern cryptography [11] and have many applications to pseudorandomness and complexity theories [6], [29]. One-way functions are easy to evaluate, but hard to invert. Even though no proof of their existence is known (such proof would imply  $P \neq NP$ ), it is widely believed that one-way functions do exist. In particular, if factoring large numbers (a classical open problem) is hard, then the simple function of squaring modulo a composite number is one-way [22].

*Randomness and computational difficulty play dual roles.* If a function  $f$  is one-way then, given  $f(x)$ , the argument  $x$  must be "random." It cannot be the case that every bit of the argument  $x$  is easily computable from  $f(x)$ . Therefore, some of these bits are unpredictable, at least in a weak sense. A natural question is whether these bits are strongly unpredictable. That is, are there specific bits of the argument  $x$  which cannot be guessed with the slightest advantage (over a random coin flip), given  $f(x)$ .

This question was first addressed by Blum and Micali [6]. They demonstrated such a strongly unpredictable bit for the discrete exponentiation function (which is believed to be one-way). This was done by reducing the problem of inverting the discrete exponentiation function to the problem of guessing a particular bit with any non-negligible advantage.

In this paper, we deal with two functions related to the factorization problem: Rabin's function (squaring modulo a composite number) [22] and the RSA (raising to a fixed exponent modulo a composite number) [23]. Both functions are believed to

be one-way. We show that both functions have strongly unpredictable bits. In particular, inverting each of them is probabilistic polynomial-time reducible to guessing the least-significant bit of their argument with any non-negligible advantage.

Our results have various applications. They allow the construction of more efficient pseudorandom bit generators [6] than those previously known, based on the intractability assumption of factoring. They allow the construction of efficient probabilistic encryption schemes [15], which hide all partial information. Finally, our results imply that the RSA public-key perfectly hides all partial information about the  $\log n$  least-significant bits of the plaintext (where  $n$  is the size of the RSA modulus).

*Organization of the paper.* In § 2 we formally define the question of security for RSA least-significant bit and cover previously known results. In § 3 we review the proof of the Ben-Or, Chor and Shamir result. This investigation is the basis for our work, which is described in § 4. Section 5 extends our proof to other RSA bits, and § 6, to bits in Rabin's scheme. In § 7 we discuss applications of our results for the construction of pseudorandom bit generators and probabilistic encryption schemes. Section 8 contains concluding remarks and two open problems.

**2. Problem definition and previous results.** We begin this section by presenting notations for two number theoretic terms which will be used throughout the paper.

**DEFINITION 1.** Let  $N$  be a natural number.  $Z_N$  will denote the ring of integers modulo  $N$ , where addition and multiplication are done modulo  $N$ .

It would be convenient to view the elements of  $Z_N$  as points on a circle (see Fig. 1).

*Convention.* Throughout the paper,  $n = \lceil \log_2 N \rceil$  will denote the length of the modulus  $N$ . All algorithms discussed in this paper have inputs of length  $O(n)$ .

FIG. 1. Cyclic representation of  $Z_N$ .

**DEFINITION 2.** Let  $N$  be a natural number, and  $x$  an integer.  $[x]_N$  will denote the remainder of  $x$  modulo  $N$  (notice that for all  $x$ ,  $0 \leq [x]_N < N$ ).

The *RSA encryption function* is operating in the message space  $Z_N$ , where  $N = pq$  is the product of two large primes (which are kept secret). The encryption of  $x$  is  $E_N(x) = [x^e]_N$ , where  $e$  is relatively prime to  $\varphi(N) = (p-1)(q-1)$ .

We now formally define the notion of bit security for the RSA.

**DEFINITION 3.** For  $0 \leq x < N$ ,  $L_N(x)$  denotes the least-significant bit in the binary representation of  $x$ .

**DEFINITION 4.** Let  $\varepsilon(\cdot)$  be a function from integers into the interval  $[0, \frac{1}{2}]$ . Let  $\mathcal{O}_N$  be a probabilistic oracle which, given  $E_N(x)$ , outputs a guess,  $\mathcal{O}_N(E_N(x))$ , for  $L_N(x)$  (this guess might depend on the internal coin tosses of  $\mathcal{O}_N$ ). We say that  $\mathcal{O}_N$  is an  $\varepsilon(n)$ -oracle for the least-significant bit (in short,  $\varepsilon(n)$ -oracle) if the probability that  $\mathcal{O}_N$  is correct, given  $E_N(x)$  as its input, is at least  $\frac{1}{2} + \varepsilon(n)$ . The probability space is that of all  $x \in Z_N$  and all 0-1 sequences of internal coin tosses, with uniform distribution.

**DEFINITION 5.** We say that RSA least-significant bit is  $\varepsilon(n)$ -secure if there is a probabilistic polynomial time algorithm which on input  $N$ ,  $e$  (relatively prime to  $\varphi(N)$ ) and  $x \in Z_N$ , and access to an arbitrary  $\varepsilon(n)$ -oracle  $\mathcal{O}_N$ , outputs  $y$  such that  $x = E_N(y) = y^e \pmod{N}$ . (That is, the algorithm inverts  $E_N$  using any  $\varepsilon(n)$ -oracle  $\mathcal{O}_N$ .)

**DEFINITION 6.** We say that RSA least-significant bit is unpredictable if it is  $n^{-c}$ -secure for every constant  $c > 0$ .

**2.1. Previous work.** Goldwasser, Micali and Tong [17] were the first to investigate the security question of least-significant bit in RSA. They showed that the least-significant bit is as hard to determine as inverting the RSA. Furthermore, they showed that it is  $(\frac{1}{2} - 1/n)$ -secure.

In a key paper, Ben-Or, Chor and Shamir [2] showed a  $(\frac{1}{4} + 1/\text{poly}(n))$ -security result. They showed that inverting the RSA is polynomially reducible to determining the parity of messages taken from a certain small subset of the message space. To determine the parity of these messages, they performed many independent “measurements,” each consisting of querying the oracle on a pair of related points. This sampling method amplified the  $\frac{1}{4} + 1/\text{poly}(n)$  overall advantage of the oracle to “almost certainty” in determining parity for the above-mentioned subset. On the negative side, the sampling of pairs of points doubles the error of the oracle and prevents the use of less reliable oracles.

Vazirani and Vazirani [27] showed that the “error doubling” phenomena could be overcome by introducing a new oracle-sampling technique. They proved that incorporating their technique in the Ben-Or, Chor and Shamir algorithm, yields a 0.232-security result. Goldreich [13] used a better combinatorial analysis to show that the Vazirani and Vazirani algorithm yields a 0.225 result. He also pointed out some limitations of the Vazirani and Vazirani proof techniques.

All these results leave a large gap towards the desired result of proving that the least-significant bit is unpredictable (i.e.,  $1/\text{poly}(n)$  secure).

**3. A description of Ben-Or, Chor and Shamir reduction.** In this section, we present the reduction used by Ben-Or, Chor and Shamir [2]. It consists of two major parts: An algorithm which inverts the RSA using a *parity subroutine*, and a method of implementing the parity subroutine by querying an oracle for the least-significant bit.

**3.0. Definition of parity.** Let  $x$  be an integer. We define

$$\text{abs}_N(x) \stackrel{\text{def}}{=} \begin{cases} [x]_N & \text{if } [x]_N < N/2, \\ N - [x]_N & \text{otherwise.} \end{cases}$$

Pictorially,  $\text{abs}(x)$  can be viewed as the distance from  $[x]_N$  to 0 on the  $Z_N$  circle (see Fig. 2). Notice that  $\text{abs}_N(x) = \text{abs}_N(-x)$ .

The *parity* of  $x$ ,  $\text{par}_N(x)$ , is defined as the least-significant bit of  $\text{abs}_N(x)$ . For example,  $\text{par}_N(N-3) = 1$ .

**3.1. Inverting RSA using a parity subroutine.** Given an encrypted message,  $E_N(x)$ , the plaintext  $x$  is reconstructed as follows. First, two integers  $a, b \in Z_N$  are picked at

FIG. 2. The  $\text{abs}_N$  function.

random. A Brent-Kung gcd procedure [7] is applied to  $[ax]_N$  and  $[bx]_N$ . This gcd procedure uses a parity subroutine PAR which we assume, at this point, to give correct answers. Even though neither  $[ax]_N$  nor  $[bx]_N$  are explicitly known, we can manipulate them via their encryption. In particular, we can compute the encryption of any linear combination  $A[ax]_N + B[bx]_N$  when both  $A, B$  are known (since  $N$  and  $e$  are given, and  $E_N$  is a multiplicative function). When the gcd procedure terminates, we get a representation of  $\text{gcd}([ax]_N, [bx]_N) = [lx]_N$  in the form  $l$  and  $E_N(lx)$ . If  $[ax]_N$  and  $[bx]_N$  are relatively prime, then  $[lx]_N = 1$ . This fact can be detected since  $E_N(1) = 1$ . Therefore,  $x \equiv l^{-1} \pmod{N}$  can be easily computed.

1. **procedure** RSA INVERSION:
2. INPUT  $\leftarrow E_N(x)$  (and  $N, e$ )
3. **Step 1—Randomization**
4. Pick  $a, b \in Z_N$  at random.
5. **Step 2—Brent-Kung GCD** of  $[ax]_N, [bx]_N$   
 $\{z_1 = [ax]_N, z_2 = [bx]_N\}$
6.  $\alpha \leftarrow n,$
7.  $\beta \leftarrow n$
8. count  $\leftarrow 0$
9. **repeat**
10. **while** PAR  $(b, E_N(x)) = 0$  **do**  
*Comment: PAR  $(b, E_N(x))$  returns a guess for  $\text{par}_N(bx)$*   
 $b \leftarrow [b/2]_N$   
 $\{\text{gcd}([ax]_N, [bx]_N) = \text{gcd}(z_1, z_2)\}$
11.  $\beta \leftarrow \beta - 1$
12. count  $\leftarrow$  count + 1
13. **if** count  $> 6n + 3$  **then go to line 3**
14. **od**
15. **if**  $\beta \leq \alpha$  **then swap**  $(a, b), \text{swap}(\alpha, \beta)$
16. **if** PAR  $((a + b)/2, E_N(x)) = 0$   
*Comment: PAR  $((a + b)/2, E_N(x))$  returns a guess for  $\text{par}_N((ax + bx)/2)$*   
**then**  $b \leftarrow [(a + b)/2]_N$

```

17.           else  $b \leftarrow [(a - b)/2]_N$ 
                {gcd ( $[ax]_N, [bx]_N$ ) = gcd ( $z_1, z_2$ )}
18.           count  $\leftarrow$  count + 1
19.           if count  $> 6n + 3$  then go to line 3
20.       until  $b = 0$ 
;   Step 3—Inverting
21.   if  $E_N(ax) \neq \pm 1$  then go to line 3. ( $E(ax) = E(a) \cdot E(x)$ .)
22.    $x \leftarrow [\pm a^{-1}]_N$ 
23.   return  $x$ .

```

We now consider a single run of Step 2. The assertions in the braces guarantee that if the parity subroutine does not err, then the gcd of the current  $[ax]_N, [bx]_N$  is invariant. It is not hard to verify that the Brent-Kung gcd makes at most  $6n + 3$  calls to the parity subroutine.<sup>1</sup> Therefore, if the original pair  $[ax]_N, [bx]_N$  is relatively prime and the parity subroutine answered correctly on all queries, the algorithm will retrieve  $x$ . By a famous theorem of Dirichlet [19, p. 324], the probability that two random integers in the range  $[-K, K]$  are relatively prime converges to  $6/\pi^2$  as  $K$  tends to  $\infty$ .

We assume so far that the parity subroutine always returns the correct answer. As a matter of fact, the test in line 21 of the code makes sure that the algorithm never errs, even if the answers of the parity subroutine are incorrect. The variable *count* guarantees that even if the parity subroutine occasionally errs, we will not make more than  $6n + 3$  parity calls in a single gcd iteration. The probability that  $x$  will be retrieved in any single gcd attempt is

$$\frac{6}{\pi^2} \cdot \Pr(\text{all answers of PAR in this gcd attempt are correct}).$$

Thus, to invert  $E_N$  in probabilistic polynomial-time it suffices to have a “reliable” parity subroutine. In fact, it suffices to have a parity subroutine which is almost always correct on every argument  $y$  with “small”  $\text{abs}_N(y)$ . This is the case since, if  $\text{abs}_N(z_1)$  and  $\text{abs}_N(z_2)$  are “small,” then (unless the parity errs) all intermediate arguments to the parity subroutine are also “small.” More formally, we use the following definition.

**DEFINITION 7.** Let  $\varepsilon(\cdot), \delta(\cdot)$  be functions from integers into the interval  $(0, \frac{1}{2})$ . Let PAR be a parity subroutine, that on input  $d$  and  $E_N(x)$  outputs a guess for  $\text{par}_N(dx)$ . We say that PAR is  $(\varepsilon(n), \delta(n))$ -reliable if for every  $d, x \in Z_N$  with  $\text{abs}_N(dx) < \varepsilon(n)N/2$ ,

$$\text{Prob}(\text{PAR}(d, E_N(x)) \neq \text{par}_N(dx)) < \delta(n).$$

From the above discussion we derive the following lemma.

**LEMMA 1** (Ben-Or, Chor and Shamir [2]). *The RSA function  $E_N$  is invertible in  $O(\varepsilon^{-2}(n) \cdot n)$  expected number of calls to a  $(\varepsilon(n), 1/(12n + 6))$ -reliable parity subroutine.*

*Proof.* Let PAR be a  $(\varepsilon(n), 1/(12n + 6))$ -reliable parity subroutine. It suffices to give a lower bound on the probability that all PAR calls in a single gcd attempt yield correct answers. We define the following events, as functions of the random variables  $a$  and  $b$  (assuming values in  $Z_N^*$ ): Event  $S_x(a, b)$  holds if both  $\text{abs}_{S_x}(ax)$  and  $\text{abs}_{S_x}(bx)$  are smaller than  $\varepsilon(n)N/2$ . Event  $C_{i,x}(a, b)$  holds if the  $i$ th answer of PAR, on a run

<sup>1</sup> This follows from the fact that  $\alpha + \beta$  decreases by 1 in every execution of line 10, and that throughout the execution of the gcd  $|a| \leq 2^\alpha$  and  $|b| \leq 2^\beta$ . For further details see [7], [8].

of  $\gcd([ax]_N, [bx]_N)$ , is correct. Then

$$\begin{aligned}
 & \text{Prob}((\forall i)A_{i,x}(a, b)) \\
 & \geq \text{Prob}(S_x(a, b)) \cdot \text{Prob}((\forall i)A_{i,x}(a, b) | S_x(a, b)) \\
 & = \varepsilon^2(n) \cdot \left( 1 - \sum_{i=1}^{6n+3} \text{Prob}(\neg A_{i,x}(a, b) | S_x(a, b) (\forall j < i) A_{j,x}(a, b)) \right) \\
 & \geq \varepsilon^2(n) \cdot \left( 1 - (6n+3) \cdot \frac{1}{12n+6} \right) \\
 & = \varepsilon^2(n)/2. \quad \square
 \end{aligned}$$

*Remark.* In Step (2) of the RSA inversion procedure, we used a Brent-Kung gcd, which is faster than the binary gcd originally used in [2].

**3.2. Implementing the parity subroutine.** Given  $d$  and  $E_N(x)$  where  $\text{abs}_N(dx) < \varepsilon(n)N/2$ , the parity subroutine PAR determines (with overwhelming probability)  $\text{par}_N(dx)$ , by querying  $\mathcal{O}_N$ , an oracle for RSA least-significant bit, as follows. It picks a random  $r$  and asks the oracle for the least-significant bit of both  $[rx]_N$  and  $[rx+dx]_N$ , by feeding the oracle in turn with  $E_N(rx) = E_N(r)E_N(x)$  and  $E_N((r+d)x) = E_N(r+d)E_N(x)$ . The oracle's answers are processed according to the following observation. Since  $\text{abs}_N(dx)$  is small, with very high probability ( $\geq 1 - \varepsilon(n)/2$ ) no wraparound<sup>2</sup> occurs when  $[dx]_N$  is added to  $[rx]_N$ . If no wraparound occurs, the parity of  $[dx]_N$  is equal to 0 if the least-significant bits of  $[rx]_N$  and  $[rx+dx]_N$  are identical; and equal to 1 otherwise. This sampling is repeated many times; every repetition (instance) is called a *dx-measurement*.

1. **procedure PAR:**

*Comment:* PAR has access to a least-significant bit oracle  $\mathcal{O}_N$

2. INPUT  $\leftarrow d, E_N(x)$
3.      $\text{count}_0 \leftarrow 0$
4.      $\text{count}_1 \leftarrow 0$
5.     **for**  $i \leftarrow 1$  to  $m$  **do**
6.         pick  $r_i \in Z_N$  at random
7.         **if**  $\mathcal{O}_N(E_N(r_i x)) = \mathcal{O}_N(E_N(r_i x + dx))$
8.             **then**  $\text{count}_0 \leftarrow \text{count}_0 + 1$
9.             **else**  $\text{count}_1 \leftarrow \text{count}_1 + 1$
10.     **od**
11.     **if**  $\text{count}_0 > \text{count}_1$
12.         **then return** 0
13.     **else return** 1

**3.3. Discussion.** Analyzing the error probability of PAR on input  $d, E_N(x)$  reduces to analyzing the error probability of a single *dx-measurement*. Suppose that the success probability of a single *dx-measurement* can be made at least  $\frac{1}{2} + 1/\text{poly}(n)$ . Then by performing sufficiently many independent *dx-measurements*, the majority gives the correct answer for  $\text{par}_N(dx)$  with overwhelming probability.

There are two sources of error in the parity subroutine. One source is wraparound 0 in a *dx-measurement*, the other is oracle errors. Wraparounds are unlikely (i.e., they

<sup>2</sup> If  $[dx]_N = \text{abs}_N(dx)$  then *wraparound* 0 means  $[rx]_N + \text{abs}_N(dx) > N$ . If  $[dx]_N = N - \text{abs}_N(dx)$  then *wraparound* 0 means  $[rx]_N - \text{abs}_N(dx) < 0$ .

occur with probability  $\leq \varepsilon(n)/2$ , since  $\text{abs}_N(dx) \leq \varepsilon(n)N/2$ . Thus, the main source of errors in a  $dx$ -measurement is the errors of the oracle.

If no wraparound occurs, then the  $dx$ -measurement may be wrong only if the oracle errs on either end points ( $[rx]_N, [rx+dx]_N$ ). Thus the error probability of a  $dx$ -measurement is no more than *twice* the error probability of the oracle. However, there are oracles for which the error probability of a  $dx$ -measurement is *twice* the oracle error. Overcoming the *error-doubling* phenomena requires a new parity subroutine, which constitutes the core of our improvement.

**4. The main result.** In this section we prove that RSA least-significant bit is unpredictable. Working in the Ben-Or, Chor and Shamir framework, we modify the parity subroutine. For this modification we introduce two new ideas. The first idea is to avoid the error-doubling phenomena which occurred in the  $dx$ -measurement as follows. Instead of querying the oracle for the least-significant bit of both end points, we query the oracle only for the least-significant bit of one end point. The least-significant bit of the other end point is known beforehand. The second idea is a method for generating many end points with known least-significant bits. These end points are generated in a way that guarantees them “random” enough to be used as a good sample of the oracle.

**4.1. Generating  $m = \text{poly}(n)$  “random” points with known least-significant bits.** We present a method for generating  $m = \text{poly}(n)$  random points, represented as multiples of  $x$ , with the following properties:

- (1) Each point is uniformly distributed in  $Z_N$ ;
- (2) The points are pairwise independent;
- (3) The least-significant bit of each point is known, with probability  $\geq 1 - \varepsilon(n)/4$ .

We generate  $m$  points  $[r_i x]_N$  by picking two random independent elements  $k, l \in Z_N$  with uniform distribution, and computing  $[r_i x]_N = [(k + il)x]_N$  for  $1 \leq i \leq m$  (see Fig. 3). Define the random variables  $y, z \in Z_N$  by  $y = [kx]_N, z = [lx]_N$ . Each of the  $[r_i x]_N$  is uniformly distributed in  $Z_N$ . We now show that (for  $1 \leq i \neq j \leq m$ )  $[r_i x]_N$  and  $[r_j x]_N$  are two independent random variables. For every  $c_1, c_2 \in Z_N$ , the equations  $y + iz \equiv c_1 \pmod{N}$  and  $y + jz \equiv c_2 \pmod{N}$  have a unique solution in terms of  $y, z \in Z_N$ . (This is the case since all of  $N$ 's divisors are larger than  $m$ , and thus  $i - j$  has a multiplicative inverse modulo  $N$ .) Thus, for every  $c_1, c_2 \in Z_N$ ,

$$\Pr([r_i x]_N = c_1 \text{ and } [r_j x]_N = c_2) = \frac{1}{N^2} = \Pr([r_i x]_N = c_1) \cdot \Pr([r_j x]_N = c_2).$$

FIG. 3. The points  $y, z$  and  $[r_2 x]_N = y + 2z$ .

The least-significant bits of the  $[r_i x]_N$ 's are computed as follows: We try all possibilities for the least-significant bit of  $y$ , and for its location in one of the intervals  $[j(\varepsilon(n)N/4), (j+1)(\varepsilon(n)N/4)]$ ,  $0 \leq j < 4\varepsilon^{-1}(n)$ . We try all possibilities for the least-significant bit of  $z$ , and for its location in one of the intervals

$$\left[ j \frac{\varepsilon(n)N}{4m}, (j+1) \frac{\varepsilon(n)N}{4m} \right], 0 \leq j < 4m\varepsilon^{-1}(n).$$

There are  $(2 \cdot 4\varepsilon^{-1}(n)) \cdot (2 \cdot 4m\varepsilon^{-1}(n)) = 2^6 m \varepsilon^{-2}(n)$  possibilities altogether, and exactly one of them is correct. We will refer to that possibility as the *right alternative for  $y$  and  $z$* .

Let us now assume that we are dealing with the right alternative for  $y$  and  $z$ . Since the location of  $y$  and  $z$  are known up to  $\varepsilon(n)N/4$  and  $\varepsilon(n)N/4m$ , respectively, the integer  $w_i =_{\text{def}} y + iz$  is known up to  $\varepsilon(n)N/2$  (remember  $1 \leq i \leq m$ ). As  $[w_i]_N$  is uniformly distributed in  $Z_N$ , the probability that the integer  $w_i$  falls in an interval of length  $\varepsilon(n)N/2$  containing an integral multiple of  $N$  is exactly  $\varepsilon(n)/2$ . If  $w_i$  is not in such interval, then the integral quotient of  $w_i/N$  is determined by  $i$  and the approximate locations of  $y$  and  $z$ . This in turn, together with the least-significant bits of  $y$  and  $z$ , determines the least-significant bit of  $[w_i]_N = [r_i x]_N$ . In case the interval  $w_i$  belongs to contains an integral multiple of  $N$ , we make the (arbitrary) assumption that  $w_i$  is at the bigger part of the interval (out of the two parts determined by the integral multiple of  $N$ ).

**4.2. Using the generated  $[r_i x]_N$  in the parity subroutine.** The parity subroutine described in § 3.2 makes use of mutually independent random  $r_i$ 's, and queries the oracle for the least-significant bits of both  $[r_i x]$  and  $[r_i x + dx]_N$ . We modify it by using  $r_i$ 's generated as in § 4.1, and querying the oracle only for the least-significant bit of  $[r_i x + dx]_N$ . In the sequel we will refer to the modified parity subroutine as to PAR\*.

The generation of  $[r_i x]_N$ 's is performed once per each gcd invocation, as part of Step 1 (the randomization step) in the inversion procedure of § 3.1. The choice of  $k$  and  $l$  ( $y = [kx]_N, z = [lx]_N$ ) is independent of the choice of  $a, b$ . We run  $2^8 m \varepsilon^{-2}(n)$  copies of the gcd procedure in parallel, each with one of the possibilities for the approximate locations and least-significant bits of  $y$  and  $z$ . Each copy of the gcd procedure supplies its corresponding possibility for  $y$  and  $z$  as an auxiliary input to all calls of PAR\* that it makes. Note that the run with the right alternative for  $y$  and  $z$  has the least-significant bit of  $[r_i x]_N$  correct, for all  $1 \leq i \leq m$ , with very high probability.

**4.3. Probability analysis of the modified parity subroutine.** In this subsection we analyze the success probability of the modified parity subroutine PAR\*. We show that given an  $\varepsilon(n)$ -oracle for RSA least-significant bit,  $\mathcal{O}_N$ , and setting  $m = O(n \cdot \varepsilon^{-2}(n))$ , makes the parity subroutine PAR\* be  $(\varepsilon(n), 1/(12n+6))$ -reliable. The running time of the subroutine is polynomial in  $n$  and  $\varepsilon^{-1}(n)$ , and so is the expected running time of the entire RSA inversion procedure.

In analyzing the success probability of PAR\* on input  $d, E_N(x)$ , we assume that  $[dx]_N$  is small ( $\text{abs}_N(dx) < \varepsilon(n)N/2$ ) and it is given, as auxiliary input, the right alternative for  $y$  and  $z$ . From this point on, probabilities are taken over all choices of  $y, z$  with uniform probability distribution ( $x$  and  $d$  are considered as fixed).

Recall that on input  $d, E_N(x)$  the parity subroutine conducts  $m$   $dx$ -measurements. Each measurement "supports" either  $\text{par}_N(dx) = 0$  or  $\text{par}_N(dx) = 1$ . The subroutine returns the majority decision. For every  $1 \leq i \leq m$ , the  $i$ th individual  $dx$ -measurement consists of comparing the precomputed least-significant bit of  $[r_i x]_N$  to the answer of

the oracle for the least-significant bit of  $[r_i x + dx]_N$ . Such measurement has three potential sources of error:

- (1) The oracle errs on the least-significant bit of  $[r_i x + dx]_N$ ;
- (2) A wraparound 0 occurs when  $[dx]_N$  is added to  $[r_i x]_N$ ;
- (3) The precomputed least-significant bit of  $[r_i x]_N$  is wrong.

Note that  $[r_i x + dx]_N$  is uniformly distributed in  $Z_N$ . Therefore, a type 1 error has probability  $\frac{1}{2} - \varepsilon(n)$ . Since  $\text{abs}_N(dx) < \varepsilon(n)N/2$ , a type 2 error has probability at most  $\varepsilon(n)/2$ . A type 3 error may occur only if  $\text{abs}_N(r_i x) < \varepsilon(n)N/2$ . A more careful look at the way the least-significant bit of  $[r_i x]_N$  is determined in these “fuzzy” cases show that a type 3 error has probability at most  $\varepsilon(n)/4$ . (This follows from the assignment of correct least-significant bit values to points in the larger part of the interval.)

Thus, the overall error probability in a single  $dx$ -measurement is bounded above by  $\frac{1}{2} - \varepsilon(n)/4$ . Define the random variable

$$\zeta_i = \begin{cases} 1 & \text{if the } i\text{th } dx\text{-measurement is wrong,} \\ 0 & \text{if the } i\text{th } dx\text{-measurement is correct.} \end{cases}$$

Clearly,  $\text{Exp}(\zeta_i) = \text{Pr}(\zeta_i = 1) < \frac{1}{2} - \varepsilon(n)/4$  and  $\text{Var}(\zeta_i) < \frac{1}{4}$ . Since  $\text{Exp}(\zeta_i) < \frac{1}{2} - \varepsilon(n)/4$ , we get

$$\text{Pr}\left(\frac{1}{m} \sum_{i=1}^m \zeta_i \geq \frac{1}{2}\right) \leq \text{Pr}\left(\left|\frac{1}{m} \sum_{i=1}^m \zeta_i - \text{Exp}(\zeta_i)\right| \geq \frac{\varepsilon(n)}{4}\right).$$

Applying Chebyshev’s inequality (see [12, p. 219]) we get

$$\text{Pr}\left(\left|\frac{1}{m} \sum_{i=1}^m \zeta_i - \text{Exp}(\zeta_i)\right| \geq \frac{\varepsilon(n)}{4}\right) \leq \frac{\text{Var}\left(\frac{1}{m} \sum_{i=1}^m \zeta_i\right)}{(\varepsilon(n)/4)^2}.$$

Since (for  $1 \leq i \neq j \leq m$ )  $[r_i x]_N$  and  $[r_j x]_N$  are two independent random variables,  $\zeta_i$  and  $\zeta_j$  are also independent random variables with identical distribution. (Whenever the same function is applied to two independent random variables, the two results are independent random variables.) Let  $\bar{\zeta}_i = \zeta_i - \text{Exp}(\zeta_i)$ . By pairwise independence  $\text{Exp}(\bar{\zeta}_i \cdot \bar{\zeta}_j) = \text{Exp}(\bar{\zeta}_i) \cdot \text{Exp}(\bar{\zeta}_j)$ . Hence,

$$\begin{aligned} \text{Var}\left(\frac{1}{m} \sum_{i=1}^m \zeta_i\right) &= \frac{1}{m^2} \sum_{i=1}^m \sum_{j=1}^m \text{Exp}(\bar{\zeta}_i \cdot \bar{\zeta}_j) \\ &= \frac{1}{m^2} \left( \sum_{i=1}^m \text{Exp}(\bar{\zeta}_i^2) + \sum_{1 \leq i \neq j \leq m} \text{Exp}(\bar{\zeta}_i) \text{Exp}(\bar{\zeta}_j) \right) \\ &= \frac{1}{m^2} \cdot m \cdot \text{Exp}(\bar{\zeta}_1^2) \\ &< \frac{1}{4m}. \end{aligned}$$

Thus,  $\text{Pr}(1/m \sum_{i=1}^m \zeta_i \geq \frac{1}{2}) < 4/m\varepsilon^2(n)$ . The probability that  $1/m \sum_{i=1}^m \zeta_i \geq \frac{1}{2}$  is exactly the error probability of the parity subroutine  $\text{PAR}^*$  on a single input  $d, E_N(x)$ . To summarize, we have proved

**LEMMA 2.** *Let  $d, x \in Z_N$  and suppose that  $\text{abs}_N(dx) < \varepsilon(n)N/2$ . Let  $m \stackrel{\text{def}}{=} 64n \cdot \varepsilon^{-2}(n)$  be the number of measurements done by  $\text{PAR}^*$ . On input  $d, E_N(x)$ , the right alternative for  $y$  and  $z$ , and access to an  $\varepsilon(n)$ -oracle for RSA least-significant bit,  $\mathcal{O}_N$ , the probability that the parity subroutine  $\text{PAR}^*$  outputs  $\text{par}_N(dx)$  is at least  $1 - 1/(12n + 6)$ . The probability space is that of all choices of  $y, z \in Z_N$  and all internal coin tosses of  $\mathcal{O}_N$ . In other words, with the right alternative for  $y$  and  $z$  as an auxiliary input, the parity subroutine  $\text{PAR}^*$  is  $(\varepsilon(n), 1/(12n + 6))$ -reliable.*

**4.4. Main theorem.** Combining Lemmas 1 and 2, we get the following theorem.

**THEOREM 1.** *RSA least-significant bit is unpredictable.*

*Proof.* In Lemma 2, we have analyzed the success probability of PAR\*, assuming that it is given the right alternative for  $y$  and  $z$  as an auxiliary input. When executing the RSA inversion procedure, only one of the copies of PAR\* satisfies this condition, but this is good enough.

We conclude the proof by calculating the overall expected running time of the RSA inversion algorithm, given an  $\epsilon(n)$ -oracle for the least-significant bit. We count elementary  $Z_N$  operations (addition, multiplication, division), RSA encryptions, and oracle calls at unit cost. The expected number of times that Step 1 of the RSA inversion procedure is repeated equals  $O(\epsilon^{-2}(n))$ . For each execution of Step 1,  $O(m\epsilon^{-2}(n))$  copies of the gcd procedure are invoked. Each copy makes  $O(n)$  calls to PAR\*. The parity subroutine, in turn, makes  $O(m)$  operations. Multiplying these terms and substituting  $m = 64n\epsilon^{-2}(n)$ , the overall expected run time is

$$O(\epsilon^{-4}(n) \cdot m^2 n) = O(\epsilon^{-8}(n) \cdot n^3). \quad \square$$

**5. Extensions.** By reductions due to Ben-Or, Chor and Shamir [2], we get

**COROLLARY** (to Theorem 1).

(a) *Let  $I \subset [0, N - 1]$  be an interval of length  $N/2$ . The  $I$ -bit of  $x$  is the characteristic function of  $I$  (i.e., 1 if  $x \in I$  and 0 otherwise). This bit is unpredictable.*

(b) *The  $k$ th least-significant bit is  $(1/4 + (1/2^{n-k}) + (1/2^k) + 1/\text{poly}(n))$ -secure. At least half of these bits are  $(1/6 + (1/2^{n-k}) + (1/2^k) + 1/\text{poly}(n))$ -secure.*

**5.1. Simultaneous security.**

**DEFINITION.** We say that the  $j$  least-significant bits are *simultaneously secure* if inverting  $E_N$  is polynomial-time reducible to distinguishing, given  $E_N(x)$ , between the string of  $j$  least-significant bits of  $x$  and a randomly selected  $j$ -bit string.

We have defined the notion of simultaneous security in terms of an indistinguishability test. It is also possible to define simultaneous security in terms of an unpredictability test: Given  $E_N(x)$  and the  $j - 1$  least-significant bits of  $x$ , the  $j$ th least-significant bit of  $x$  is still  $1/\text{poly}(n)$  secure. Yao [29] has shown that the indistinguishability test is equivalent to the unpredictability test. (Although Yao's proof was given in a different setting, it still applies here.)

Our proof technique easily extends to show that  $\log n$  least-significant bits pass the unpredictability test.

**THEOREM 2.** *Let  $j \stackrel{\text{def}}{=} O(\log n)$ .*

(a) *The  $j$ th least-significant bit in the binary expansion of the plaintext is  $1/\text{poly}(n)$  secure.*

(b) *The  $j$  least-significant bits of the plaintext are simultaneously secure.*

*Proof.* (a) First note that when generating  $y$  and  $z$ , it is feasible to guess not only their 1st least-significant bit, but all  $j$  least-significant bits of  $y$  and  $z$ . The overhead for trying all possibilities is  $2^{2j}$ , which is polynomial in  $n$ . Together with the locations of  $y$  and  $z$ , these bits will determine (with high probability) all  $j$  least-significant bits of each  $[r_i x]_N$ . Also, with probability about  $2^{-2j}$ , the gcd of  $[ax]_N$  and  $[bx]_N$  is  $2^{j-1}$  (instead of 1), which we will assume is the case. This way all  $[dx]_N$ 's in the gcd calculation will have zeros in all  $j - 1$  least-significant bits. Finally, we replace all references to the least-significant bit in the inverting algorithm, by references to the  $j$ th least-significant bit. This can be done since we now have access to an oracle for the  $j$ th least-significant bit. The reader may find it convenient to view this process as taking the gcd of  $[ax/2^{j-1}]_N$  and  $[bx/2^{j-1}]_N$ . (This method of transforming certain inverting algorithms which use an oracle for the first least-significant bit into inverting

algorithms which use an oracle for the  $j$ th least-significant bit originates from Vazirani and Vazirani [27].)

(b) Going through the proof of part (a), notice that when querying the oracle about the  $j$ th least-significant bit of  $[r_i x + dx]_N$  we can give it the  $j-1$  previous bits of  $[r_i x + dx]_N$ . This is the case since, if no wraparound occurs, these  $j-1$  bits are the same as the  $j-1$  least-significant bits of  $[r_i x]_N$ , which we know.  $\square$

*Remark.* Vazirani and Vazirani [28] had previously shown that certain inverting algorithms which use an  $\varepsilon(n)$ -oracle for RSA least-significant bit, can be transformed into inverting algorithms which use an  $\varepsilon(n)$ -oracle for predicting  $x_j$  (given  $x_{j-1}, \dots, x_1$ ). It turns out that the inverting algorithm of § 4 falls into the above category [28]; this yields an alternative (but much harder) way of proving Theorem 2(b).

**5.2. Multi-prime moduli with partial factorization.** The results about bit security for the RSA function were described with respect to composite numbers  $N$  which are the product of two large primes. However, the same proofs hold for the case of multi-prime composite  $N = p_1 p_2 \cdots p_k$ , where the exponent  $e$  is relatively prime to  $\varphi(N)$ . In fact, exactly the same proofs hold also in the case that partial factorization of the modulus is given. Namely, given  $N$ ,  $e$  and some of the  $p_i$ 's, the following tasks are computationally equivalent:

- (1) Given  $E_N(x)$ , find  $x$ ;
- (2) Given  $E_N(x)$ , guess the least-significant bit of  $x$  with success probability  $\frac{1}{2} + 1/\text{poly}(n)$ .

In this context, one may wonder whether RSA remains hard to invert given partial factorization of its modulus. Using the Chinese Remainder Theorem it is not hard to show that inverting  $E_M$  ( $M = p_1 p_2$ ) is equivalent to inverting  $E_N$  ( $N = p_1 p_2 p_3 \cdots p_k$  and both exponents in  $E_M$  and  $E_N$  are the same) when all primes but  $p_1, p_2$  are known. For details see [8].

**6. Bits equivalent to factoring in Rabin's encryption function.** The Rabin encryption function is operating on the message space  $Z_N$ , where  $N = pq$  is the product of two large primes (which are kept secret). The encryption of  $x$  is  $E_N(x) = [x^2]_N$ . The ciphertext space is  $Q_N \stackrel{\text{def}}{=} \{y \mid \exists x: y \equiv x^2 \pmod{N}\}$ . Rabin [22] has shown that extracting square roots ("inverting  $E_N$ ") is polynomially equivalent to factoring.

**6.1. Previous results.** The function  $E_N$  defined above is 4 to 1 rather than being 1 to 1 (as is the case in the RSA). Blum [3] has pointed out the cryptographic importance of the fact that for  $p \equiv q \equiv 3 \pmod{4}$ ,  $E_N$  induces a permutation over  $Q_N$ . Composite numbers of this form will be called *Blum integers*.

Goldwasser, Micali and Tong [17] have presented a predicate the evaluation of which is as hard as factoring. Specifically, they showed that if  $p \equiv 3 \pmod{4}$  and  $p \equiv q \pmod{8}$  then factoring  $N$  is polynomially reducible to guessing their predicate with success probability  $1 - (1/n)$ .

Ben-Or, Chor and Shamir [2] considered the same predicate. Using a modification of their RSA techniques, they showed  $\frac{1}{4} + 1/\text{poly}(n)$  security also for this predicate. Their modification requires that  $N$  be a Blum integer and furthermore that there exist a small odd number  $h$  ( $h = \text{poly}(n)$ ) with  $(h/N) = -1$ . The correctness proof makes use of nonelementary number theory.

**6.2. Our result.** Using the techniques of § 4, we show that the least-significant bit in a variant of Rabin's encryption function is also unpredictable. Our proof uses only elementary number theory, and holds for all Blum integers.

Throughout this section we make use of the *Jacobi symbol*. Let us review the definition and some properties of the Jacobi symbol. Let  $p$  be an odd prime number, and  $h$  an integer relatively prime to  $p$ . The *Legendre symbol*  $(h/p)$  is defined to be 1 if  $h$  is a quadratic residue modulo  $p$ , and  $-1$  otherwise. For  $N = pq$ , a product of two odd primes, and  $h$  relatively prime to  $N$ , the *Jacobi symbol*  $(h/N)$  is defined to be  $(h/p) \cdot (h/q)$ . Even though the definition of the Jacobi symbol uses the factorization of  $N$ , it can be easily computed even if  $N$ 's factorization is not given. Other facts which are used in this section are:  $(h \cdot h'/N) = (h/N) \cdot (h'/N)$ , and for a Blum integer  $N$ ,  $(-1/N) = 1$ . For further details, see [21, Chap. 3].

Let  $N$  be a Blum integer. Define

$$S_N \stackrel{\text{def}}{=} \left\{ x \mid 0 \leq x < \frac{N}{2} \right\},$$

$$M_N \stackrel{\text{def}}{=} \left\{ x \mid 0 \leq x < \frac{N}{2} \wedge \left( \frac{x}{N} \right) = 1 \right\}.$$

Redefine  $E_N$  for  $x \in M_N$  as

$$E_N(x) = \begin{cases} [x^2]_N & \text{if } [x^2]_N < \frac{N}{2}, \\ [N - x^2]_N & \text{otherwise.} \end{cases}$$

This makes  $E_N$  a 1-1 mapping from  $M_N$  onto itself. The intractability result of Rabin still holds. That is, factoring  $N$  is polynomially reducible to inverting  $E_N$ . Let  $L_N(x)$  denote the least-significant bit of  $x$ .

The security of the least-significant bit of this function is now defined in a manner analogous to the RSA case. We would like to use the same techniques to demonstrate that the least-significant bit of the modified Rabin function is unpredictable. The difficulty is that the queries to the oracle may not be of the right form. Namely, we would like to feed the oracle with  $E_N(r_i x + dx)$  and get the least-significant bit of  $[r_i x + dx]_N$ , but it might happen that  $[r_i x + dx]_N \notin M_N$  and then the oracle's answer does not correspond to  $[r_i x + dx]_N$  (but rather to the square root of  $[(r_i x + dx)^2]_N$  which resides in  $M_N$ ). This ( $[r_i x + dx]_N \notin M_N$ ) may happen if either  $[r_i x + dx]_N \notin S_N$  or  $((r_i x + dx)/N) = -1$ . Both cases are easy to detect with very high probability. When any of them occur, we discard this  $dx$ -measurement. We will show that we only discard about  $\frac{3}{4}$  of the  $dx$ -measurements, and the remaining points constitute a large enough sample to retain the high reliability of the parity subroutine. A more elaborate exposition follows.

For technical reasons, we slightly change the definition of "small" here. In this section,  $h$  is small means  $\text{abs}_N(h) < \varepsilon(n)N/8$  (instead of  $\text{abs}_N(h) < \varepsilon(n)N/2$  as in § 4). This will restrict all  $[dx]_N$ 's in the gcd calculation to have  $\text{abs}_N(dx) < \varepsilon(n)N/8$ . Doing this, the probability that a wraparound of either 0 or  $N/2$  occurs when  $[dx]_N$  is added to  $[r_i x]_N$  is no greater than  $\varepsilon(n)/4$ . Similarly, the partition of  $Z_N$  (for both  $y$  and  $z$ ) is refined by a factor of 4.

Given the original encryption  $E_N(x)$ , pick  $y = kx$  and  $z = lx$ , two random multiples of  $x$ . By exhausting all possibilities, the approximate magnitude in  $Z_N$  of  $y$  and  $z$ , and their least-significant bits are known. Let  $[r_i x]_N = [y + iz]_N$  as before. If  $[r_i x]_N$  is not in an  $\varepsilon(n)N/8$  interval around either 0 or  $N/2$ , then we can determine whether  $[r_i x]_N \in S_N$ , and compute the least-significant bit of  $[r_i x]_N$  as before. In the "fuzzy" cases, where  $[r_i x]_N$  is in an  $\varepsilon(n)N/8$  interval around either 0 or  $N/2$ , we determine its least-significant bit assuming that  $[r_i x]_N \in S_N$ .

It remains to determine the parity of  $[dx]_N$  by comparing the known least-significant bit of  $[r_i x]_N$  with the least-significant bit of  $[r_i x + dx]_N$ . We consider the following three cases:

- (1) If  $[r_i x]_N \notin S_N$  (according to  $y, z$  locations), then we ignore this  $dx$ -measurement;
- (2) If  $((r_i + d)/N) = -1$ , then we ignore this  $dx$ -measurement;
- (3) If  $[r_i x]_N \in S_N$  (according to  $y, z$  locations) and  $((r_i + d)/N) = 1$ , then we feed the oracle  $\mathcal{O}_N$  with  $E_N(r_i x + dx)$ , and take its answer as our guess for the least-significant bit of  $[r_i x + dx]_N$ .

In the analysis of this procedure, we assume that we are dealing with the right alternative for  $y$  and  $z$ . With high probability ( $\geq 1 - (\varepsilon(n)/8$ ) we correctly determine whether  $[r_i x]_N \in S_N$ .

We first estimate the probability that we ignore the  $dx$ -measurement. Since the cardinality of  $M_N$  is  $|Z_N^*|/4$ , and our only error is in testing membership in  $S_N$ , we end up in Case (3) with probability  $\geq \frac{1}{4} - \varepsilon(n)/8$ .

We now estimate the error probability given that we are in Case (3). It is easier to estimate the error given that  $[r_i x]_N \in S_N$  and  $((r_i + d)/N) = 1$  (i.e., given that we should have been in Case (3)). These two conditional probabilities are very close, as we will see below. Let  $\mathcal{A}$  denote the event that we produce an incorrect value for the  $i$ th  $dx$ -measurement,  $\mathcal{B}$  denotes the event that we are in Case (3), and  $\mathcal{C}$  denotes the event  $[r_i x]_N \in S_N$  and  $((r_i + d)/N) = 1$ .

$$\begin{aligned} \Pr(\mathcal{A} | \mathcal{B}) &= \Pr(\mathcal{A} \cap \mathcal{C} | \mathcal{B}) + \Pr(\mathcal{A} \cap \bar{\mathcal{C}} | \mathcal{B}) \\ &\leq \Pr(\mathcal{A} | \mathcal{C}) \cdot \frac{\Pr(\mathcal{C})}{\Pr(\mathcal{B})} + \Pr(\bar{\mathcal{C}} | \mathcal{B}). \end{aligned}$$

The reader can easily verify that

$$\begin{aligned} \Pr(\bar{\mathcal{C}} | \mathcal{B}) &< \frac{\varepsilon(n)}{4}, \\ \Pr(\mathcal{C}) &\leq \frac{1}{4} + \frac{\varepsilon(n)}{8}, \\ \Pr(\mathcal{B}) &\geq \frac{1}{4} - \frac{\varepsilon(n)}{8}. \end{aligned}$$

The error we would have made when  $[r_i x]_N \in S_N$  and  $((r_i + d)/N) = 1$  stems from two sources.<sup>3</sup> The oracle's error and the possibility that  $[r_i x + dx]_N \notin S_N$  (although  $[r_i x]_N \in S_N$ ). The first conditional probability is bounded above by  $\frac{1}{2} - \varepsilon(n)$  and the second by  $\varepsilon(n)/8$ . Thus,  $\Pr(\mathcal{A} | \mathcal{C}) < \frac{1}{2} - \varepsilon(n) + \varepsilon(n)/8$ . Using the calculations above, we get

$$\begin{aligned} \Pr(\mathcal{A} | \mathcal{B}) &\leq \left( \frac{1}{2} - \frac{7\varepsilon(n)}{8} \right) \cdot \frac{\frac{1}{4} + \varepsilon(n)/8}{\frac{1}{4} - \varepsilon(n)/8} + \frac{\varepsilon(n)}{4} \\ &< \frac{1}{2} - \frac{\varepsilon(n)}{8}. \end{aligned}$$

Define the random variable

$$\zeta_i = \begin{cases} \frac{1}{2} & \text{if the } i\text{th } dx\text{-measurement is ignored,} \\ 1 & \text{if the } i\text{th } dx\text{-measurement is wrong,} \\ 0 & \text{if the } i\text{th } dx\text{-measurement is correct.} \end{cases}$$

<sup>3</sup> In case  $[r_i x]_N \in S_n$  we have determined correctly the least-significant bit of  $[r_i x]_N \in S_N$ . This follows by the manner in which we determine the least-significant bit of  $[r_i x]_N$ .

The reader can easily verify that  $\text{Exp}(\zeta_i) = \Pr(\zeta_i = 1) < \frac{1}{2} - \varepsilon(n)/64$  and  $\text{Var}(\zeta_i) < \frac{1}{4}$ . The rest of the analysis is similar to the analysis presented in § 4 (as also here the probability that  $(1/m) \sum_{i=1}^m \zeta_i \cong \frac{1}{2}$  is exactly the error probability of the parity subroutine). This implies

**THEOREM 3.** *The least-significant bit for the modified Rabin encryption function is unpredictable. (That is, inverting  $E_N(\cdot)$  is probabilistic polynomial-time reducible to the following: Given  $E_N(x)$  (for  $x \in M_N$ ), guess the least-significant bit of  $x$  with success probability  $\frac{1}{2} + 1/\text{poly}(n)$ .)*

**COROLLARY (to Theorem 3).** *Factoring a Blum integer,  $N$ , is polynomially reducible to guessing  $L_N(x)$  with success probability  $\frac{1}{2} + 1/\text{poly}(n)$  when given  $E_N(x)$ , for  $x \in M_N$ .*

The proofs from the previous section about simultaneous security of the  $\log n$  least significant bits hold here just as well. The extension of the result to multi-prime moduli is possible, but much harder. For details see [10].

**7. Applications.** In this section we present applications of our result to the construction of pseudorandom bit generators and probabilistic encryption schemes.

**7.1. Construction of pseudorandom bit generators.** A pseudorandom bit generator is a device that “expands randomness.” Given a truly random bit string  $s$  (the seed), the generator expands the seed into a longer pseudorandom sequence. The question of “how random” this pseudorandom sequence is depends on the definition of randomness we use. A strong requirement is that the expanded sequence will pass all polynomial time statistical tests. Namely, given a pseudorandom and a truly random sequence of equal length, no probabilistic polynomial time algorithm can tell which is which with success probability greater than  $\frac{1}{2}$  (this definition was proposed by Yao [29], who also showed it is equivalent to another natural definition—unpredictability [6]).

Blum and Micali [6] presented a general scheme for constructing such *strong pseudorandom* generators. Let  $g: M \rightarrow M$  be a 1-1 one-way function, and  $B(x)$  be an unpredictable predicate for  $g$ . Starting with a random  $s \in M$ , the sequence obtained by iterating  $g$  and outputting the bit  $b_i = B(g^i(s))$  for each iteration is strongly pseudorandom. Using their unpredictability result for the “*half<sub>p</sub>* bit” in discrete exponentiation modulo a prime  $p$ , Blum and Micali gave a concrete implementation of the scheme, based on the intractability assumption of computing discrete logarithm. More generally, if  $B_1(x), \dots, B_k(x)$  are simultaneously secure bits for  $g$ , then the sequence obtained by iterating  $g$ , and outputting the string  $\langle b_{i,1} \dots b_{i,k} \rangle = \langle B_1(g^i(s)) \dots B_k(g^i(s)) \rangle$  for each iteration, is strongly pseudorandom. Long and Wigderson [20] have shown that the discrete exponentiation function has  $\log \log p$  simultaneous secure bits.<sup>4</sup> Their result implies a pseudorandom bit generator which produces  $\log \log p$  bits per each iteration of the discrete exponentiation.

Using our results, we get an efficient implementation of strong pseudorandom generators, based on the intractability assumption of factoring. The modified Rabin function  $E_N$  is iteratively applied to the random seed  $s \in M_N$ . In the  $i$ th iteration, the generator outputs the  $\log n$  least-significant bits of  $E_N^i(s) = \pm s^{2^i} \bmod N$ . Thus it outputs  $\log n$  pseudorandom bits at the cost of one squaring and one subtraction modulo  $N$ , and is substantially faster than the discrete exponentiation generator. Previous strong pseudorandom generators based on factoring ([17], [2], [27]) required the use of the exclusive-or construction of Yao [29] and were less efficient.

Another efficient pseudorandom generator was previously constructed by Blum, Blum and Shub [4]. Their generator output one pseudorandom bit per one modular

<sup>4</sup> Kaliski [18] has recently simplified and generalized the argument.

multiplication. Blum, Blum and Shub proved that their generator is a strong pseudorandom generator if the problem of deciding quadratic residuity modulo a composite number is intractable. Vazirani and Vazirani [28] have pointed out that, using our techniques, the Blum, Blum and Shub generator is strong also with respect to the problem of factoring Blum integers.

**7.2. Construction of probabilistic public-key encryption schemes.** A probabilistic encryption scheme is said to leak no partial information if the following holds: *Whatever is efficiently computable about the plaintext given the ciphertext, is also efficiently computable without the ciphertext* [15]. Goldwasser and Micali presented a general scheme for constructing public-key probabilistic encryption schemes which leak no partial information, using a “secure trap-door predicate” [15]. A *secure trap-door predicate* is a predicate that is easy to evaluate given some “trap-door” information, but infeasible to guess with the slightest advantage without the “trap-door” information. Goldwasser and Micali also gave a concrete implementation of their scheme, under the intractability assumption of deciding quadratic residuity modulo a composite number. A drawback of their implementation is that it expands each plaintext bit into a ciphertext block (of length equal to that of the composite modulus).

Using our results, we get an implementation of a probabilistic public-key encryption scheme that leaks no partial information, based on the intractability assumption of factorization. This implementation is more efficient than the one in [14], which is also based on factoring. However, our implementation still suffers from a large bandwidth expansion.

Recently, Blum and Goldwasser [5] used our result to introduce a new implementation of probabilistic encryption, equivalent to factoring, in which the plaintext is only expanded by a *constant factor*. Blum and Goldwasser’s scheme is approximately as efficient as the RSA while provably leaking no partial information, provided that factoring is intractable.

**8. Concluding remarks and open problems.** Standard sampling techniques draw mutually independent elements from a large space. We employed a strategy of getting elements with limited mutual independence (only pairwise independence). This strategy allows more control on properties of the chosen elements.

Trading off statistical independence for control turned out to be fruitful in our context. We believe that such trade-off may be useful in other contexts as well.

We conclude by presenting two open problems:

- (1) In § 5 (6), we have shown simultaneous security results of  $O(\log n)$  bits in RSA (Rabin) encryption function. Extending the result beyond  $O(\log n)$  bits is of major theoretical and practical importance. In particular, if more bits are shown to be simultaneously secure, then the efficiency of the resulting pseudorandom generator will be greatly improved.
- (2) Another interesting question is that of investigating the bit security of the internal RSA bits—are they also  $1/\text{poly}(n)$  secure?

**Acknowledgments.** We would like to thank Michael Ben-Or, Shafi Goldwasser, Silvio Micali, Ron Rivest and Adi Shamir for very helpful discussions and useful ideas.

## PRIVACY AMPLIFICATION BY PUBLIC DISCUSSION\*

CHARLES H. BENNETT†, GILLES BRASSARD‡ AND JEAN-MARC ROBERT§

**Abstract.** In this paper, we investigate how the use of a channel with perfect authenticity but no privacy can be used to repair the defects of a channel with imperfect privacy but no authenticity. More precisely, let us assume that Alice and Bob wish to agree on a secret random bit string, and have at their disposal an imperfect private channel and a perfect public channel. The private channel is imperfect in various ways: transmission errors can occur, and partial information can leak to an eavesdropper, Eve, who also has the power to suppress, inject, and modify transmissions arbitrarily. On the other hand, the public channel transmits information accurately, and these transmissions cannot be modified or suppressed by Eve, but their entire contents becomes known to her. We consider the situation in which a random bit string  $x$  has already been transmitted from Alice to Bob over the private channel, and we describe interactive public channel protocols that allow them, with high probability: (1) to assess the extent to which the private channel transmission has been corrupted by tampering and channel noise; and (2) if this corruption is not too severe, to repair Bob's partial ignorance of the transmitted string and Eve's partial knowledge of it by distilling from the transmitted and received versions of the string another string, in general shorter than  $x$ , upon which Alice and Bob have perfect information, while Eve has nearly no information (or in some cases exactly none), except for its length. These protocols remain secure against unlimited computing power.

**1. Introduction.** Alice and Bob wish to agree on a secret random bit string. In order to achieve this goal, they have at their disposal an imperfect private channel and an authenticated public channel. The private channel is imperfect in various ways: transmission errors can occur, and partial information can leak to Eve, the eavesdropper, who also can modify the transmissions arbitrarily, as explained below. The only limitation we impose on Eve is the knowledge by Alice and Bob of an upper bound on the amount of partial information that can leak to her when she eavesdrops on a private channel transmission.

We allow Eve to tamper arbitrarily with the private channel transmissions. For instance, she can suppress the transmission of selected bits, perhaps to replace them with bits of her choice, to inject new bits, to toggle transmitted bits or to jumble them around. We allow her to introduce as much malicious noise as she wishes. In this paper, we granted Eve unlimited tampering power even though probably no real channel performs quite this badly, so that our results will hold true in any circumstance.

The quantum channel of [BB1], [BB2] is a prime example of an imperfect private channel, and this paper effectively allows the removal of its previous defects. Indeed,

the quantum channel allows an eavesdropper to attempt reading a few bits of the transmission with a reasonable probability of not perturbing it, and hence of escaping detection. It also allows several types of blind tampering, such as toggling a selected bit (even if unable to read it) by passing the corresponding faint light pulse through an appropriate sugar solution. More classically, Diffie and Hellman's public-key distribution scheme [DH] can be thought of as an imperfect private "channel." Indeed, it efficiently leaks partial information on the (not-so-random) string exchanged, even if the discrete logarithm is hard to compute, because it is easy for an eavesdropper to determine whether the resulting secret is a quadratic residue or not.

On the other hand, the public channel transmits information accurately (possibly because it is supplemented by a classic error-correcting code [vL], [MS]), and these transmissions cannot be modified or suppressed by Eve, but their entire contents becomes known to her. Newspapers are an example of a secure public channel on which eavesdropping is easy but tampering nearly impossible. Such inherently authentic public channels are commonly suggested for disclosing public keys in a public-key cryptography/digital signature system such as [RSA]. If message authenticity is not thus enforced by the physical properties of the channel, it can be provided by an unconditionally secure authentication scheme such as that of [WC]. In this latter case, a small number of shared secret random bits must be known initially between Alice and Bob, and some of these are used up in the process of authentication; thus the net effect of our protocol in this case can be viewed as key expansion rather than key distribution. Computationally secure authentication [Br], [GGM] can also be used if protection against unlimited computing power is not sought. We shall assume throughout that Alice and Bob did not share initially any secret information, except perhaps for what is needed to implement this public channel authentication feature.

In this paper, we assume that some random bit string has already been transmitted from Alice to Bob over the private channel. We investigate authenticated public channel protocols that, with high probability, detect tampering and transmission errors. Subsequent protocols transform both strings in such a way as to eliminate most, and in some cases all, of Eve's information on the resulting string, except for its length. These public channel protocols remain secure against unlimited computing power, so that the entire exchange is as secure as the initial private channel transmission. It should be noted that excessive tampering on the private channel can result in suppressing communications between Alice and Bob, but it cannot fool them into thinking that they share a secret random string when in fact their strings are different or otherwise compromised.

Let us make our setting mathematically precise. Alice and Bob initially share no secret information. Alice chooses a random string  $x$  of length  $N$  and transmits it over the private channel. Independently, Eve chooses an eavesdropping function  $e: \{0, 1\}^N \rightarrow \{0, 1\}^K$ , where  $K < N$ , and a tampering function  $t: \{0, 1\}^N \times \{0, 1\}^\omega \rightarrow \{0, 1\}^N$ . Alice and Bob know  $K$  but otherwise nothing about  $e$  or  $t$ . When Alice transmits  $x$ , Eve learns the value  $e(x)$  and forwards the potentially corrupted value  $y = t(x, R)$  to Bob, where  $R$  is a random string representing channel noise. Notice that Eve does not herself learn the value of  $t(x, R)$  nor can she influence the random string  $R$  (although she may choose a function  $t$  that does not take  $R$  into consideration). Her information about  $x$  from the private channel transmission consists *only* of knowing  $e$  and  $e(x)$ ; her information about  $y$  consists only of knowing  $e$ ,  $e(x)$ , and knowing the function  $t$  that was applied to  $x$  in order to obtain  $y$ . In this very hostile context, we show that Alice and Bob can *publicly* agree on a protocol that will allow them to ascertain whether  $x = y$  (with an exponentially small error probability) and, if this is so, to end up with

a shorter shared string  $z$  on which Eve has nearly no information or, in some cases, no information at all. If  $x \neq y$ , they can detect this with high probability and, if the differences are not too great, continue with the protocol.

To summarize, we investigate how the use of a channel with perfect authenticity but no privacy can be used to repair the defects of a channel with imperfect privacy but no authenticity. In § 2, we explain why classic error-correcting codes are inappropriate in this context. In § 3, we investigate how transmission errors and tampering can be detected with high probability, and sometimes corrected, at the cost of leaking some information to Eve. In § 4, we investigate how Alice and Bob can subsequently reduce arbitrarily Eve's information at the cost of reducing slightly the length of their shared random string, assuming they have an a priori upper bound on the amount of information that Eve collected on the private channel. In § 5, we investigate the possibility of depriving Eve entirely of any information on the final shared random string at the cost of reducing its length more substantially.

Before we get started, let us give the following definition and some notation: if  $i < j$ , a function  $f: \{0, 1\}^j \rightarrow \{0, 1\}^i$  is *equitable* if  $\#\{x | f(x) = a\} = 2^{j-i}$  for every binary string  $a$  of length  $i$ . If  $x$  and  $y$  are bit strings of equal length,  $x \oplus y$  denotes their bit-by-bit exclusive-or. Finally, if  $x$  is a length  $N$  bit string and if  $0 \leq K \leq N$ ,  $x \bmod 2^K$  denotes the length  $K$  bit string consisting of the rightmost  $K$  bits of  $x$ , and  $x \operatorname{div} 2^K$  denotes the length  $N - K$  bit string obtained from  $x$  by deleting its rightmost  $K$  bits. We shall herein assume that the reader is familiar with the notions of information theory [G], [Mc], [S], universal hashing [CW], [WC], error-correcting codes [vL], [MS], and the theory of finite fields [Be].

**2. The inadequacy of classical error-correcting codes.** Let us recall that the imperfect private channel considered here is susceptible not only to random transmission errors, but also to any amount of controlled and malicious tampering. This tampering capability does not directly give Eve any additional information on  $x$ . It could, however, give her indirect information, because it may force Alice and Bob to subsequently discuss the situation over the public channel, as explained in § 3. The classic theory of error-correcting codes [vL], [MS] is not quite adequate for our purposes because it is based on the assumptions that few errors are more likely to occur than many, and that errors are not maliciously set by an opponent.

For instance, let  $x$  and  $y$  be Alice and Bob's strings, respectively, and let  $N$  be their length. Eve's tampering ability enables her to actually select  $x \oplus y$ , barring actual transmission errors. This is clearly intolerable if error detection is attempted through a linear error-correcting code [MS]. Indeed, let  $x$  be the private channel transmitted code word corresponding to Alice's chosen random string. Let  $z$  be any code word chosen by Eve. If she perturbs the private channel transmission so that Bob receives  $y = x \oplus z$ , it will not be possible for him to detect tampering. Notice that Eve can achieve this without gaining any knowledge of the contents of the original transmission  $x$ .

Nonlinear error-correcting codes are not susceptible to the above threat, but they fall to an even simpler one because Eve is also capable of replacing Alice's bits by bits of her choice. If Alice sends some code word over the private channel, it suffices for Eve to suppress the original communications entirely, and inject any other code word of her choice instead. This simple-minded attack can be hindered by the post facto application of an error-correcting code, as discussed in § 3.2.

Classic error detection is therefore impossible in our context if Eve knows in advance of the private channel transmission which code is to be used. On the other

hand, we assumed that Alice and Bob did not initially share any secret, except perhaps to implement the authenticated public channel. A solution is that Alice randomly chooses an error-correcting code, produces the code word  $x$  corresponding to her chosen random string, and sends  $x$  to Bob through the private channel. She then waits for Bob to use the authenticated public channel in order to acknowledge receipt of the private transmission. Only at this point does Alice use the public channel to send Bob a description of the error-correcting code. This allows Bob to recover the original string and to check for errors and tampering. This randomization approach allows Alice to reveal sensitive information to Bob, hence to Eve, only after it is already too late for her to efficiently alter the private channel transmission in an undetectable way.

Although such use of randomness is our main tool in this paper, it remains true that classic linear error-correcting codes are not appropriate because, even randomly chosen, they still assume few errors to be more likely than many. For instance, let us assume that Alice uses a Hamming code of dimension  $[N, K]$  and that the random part of the protocol is the order in which she sends the code-word bits. It is no longer possible for Eve to toggle selected bits and to be certain to escape detection because she does not know which bits to toggle. However, there are exactly  $\binom{N}{2}/3$  code words of Hamming weight 3 [MS], whereas there are  $\binom{N}{3}$  length  $N$  bit strings of weight 3. Therefore, Eve can toggle 3 random bits and escape detection with probability

$$\left( \binom{N}{2} / 3 \right) / \binom{N}{3} = (N-2)^{-1}.$$

Using such a protocol, Alice and Bob could only achieve a very high probability of not being fooled, say  $1 - 2^{-50}$ , at the cost of exchanging unreasonably long strings.

It is instructive to compare our setting with the problem solved by the wiretap channel of Wyner [W] which achieves similar results in a more classically information-theoretic setting. In Wyner's setting, Alice encodes information by a channel code of her choice. The output of her encoder is fed into two classic (discrete, memoryless) communication channels: the *main channel*, leading to the intended receiver Bob, and the *wiretap channel*, of lesser capacity than the main channel, leading to the eavesdropper. All participants know the channel code and the statistical properties of the two channels. Under these conditions, Wyner showed that by appropriate choice of the channel code, Alice can exploit the difference in capacity between the two channels communicate reliably with Bob while maintaining almost perfect secrecy from the eavesdropper.

In our setting, the users have an additional resource: the authenticated public channel. This allows them to cope with a more powerful eavesdropper. Our eavesdropper is more powerful in two ways, either of which would be fatal in Wyner's setting: she can tamper with Alice's communications as well as listen to them, and she eavesdrops by evaluating an arbitrary  $N$ -bit to  $K$ -bit function of her choice, unknown to Alice and Bob.

In § 3.1, we describe error-detection schemes such that the probability of undetected tampering and transmission errors is independent of the number and position of altered bits. Moreover, this probability can be exponentially small in the length of the strings transmitted. Although never fully appropriate for the detection of tampering, classic error-correcting codes remain interesting in order to correct actual transmission errors over the private channel, as we investigate in § 3.2.

**3. Detection and correction of transmission errors and tampering.** Let  $x$  be some random bit string selected by Alice. Assume she transmits it directly through the imperfect private channel, and let  $y$  be the string thus received by Bob. Let  $N$  be the

length of both strings. The public channel protocols described in § 3.1 allow Alice and Bob to detect whenever  $x \neq y$  with an arbitrarily small error probability, independently of how  $y$  differs for  $x$ . Should  $y$  be found to differ from  $x$ , the protocol of § 3.2 can be used to reconcile them with high probability. The reconciliation protocol can also be used *preventively*, before using an error-detection protocol from § 3.1, if  $y$  is expected to be different from  $x$  merely due to normal transmission errors. The fact that these protocols leak information to Eve about  $x$  is considered in § 4.

**3.1. Error detection.** A very simple but impractical way of testing whether  $x = y$  is for Alice to choose a random function  $f: \{0, 1\}^N \rightarrow \{0, 1\}^K$ , where  $K$  is a security parameter. After the private channel transmission is completed, she sends  $f(x)$  to Bob over the public channel, together with a complete description of the function  $f$ . Should Bob find out that  $f(y) = f(x)$ , this would be considered as strong evidence that  $y = x$ , the error probability being  $2^{-K}$ , independently of the length of the strings and how they might differ. On the other hand, should  $f(y)$  be different from  $f(x)$ , Bob could report to Alice with certainty that he did not receive the correct string. Notice that the amount of information on  $x$  leaking to Eve from this protocol depends only on the security parameter  $K$ , and not on the length  $N$  of the strings (except of course for the fact that  $K < N$ ). This would not be the case if a classic error-detecting code has been used. Unfortunately, this scheme cannot be used in practice because there are  $2^{K2^N}$  different such functions, and therefore as many as  $K2^N$  bits are typically needed to merely transmit a description of the randomly chosen function.

In some cases, it may be preferable for Alice to choose randomly the function  $f$  among the set of *equitable* functions only. This can be done in theory (although not in practice when  $N$  is large) by randomly selecting a permutation  $\pi: \{0, 1\}^N \rightarrow \{0, 1\}^N$  and defining  $f(x) = \pi(x) \bmod 2^K$  for each string  $x$  of length  $N$ . Notice that this allows a (very slight) reduction of the probability of undetected transmission errors or tampering from  $2^{-K}$  to  $(2^{N-K} - 1)/(2^N - 1)$ .

Universal hashing [CW] provides an efficient way to achieve the same goal. After the private channel transmission is completed, Alice randomly chooses a function  $f: \{0, 1\}^N \rightarrow \{0, 1\}^K$  among some universal<sub>2</sub> class of functions. She then sends both  $f(x)$  and a description of  $f$  to Bob. Thanks to universal hashing, the description of  $f$  can be transmitted efficiently this time. After computing  $f(y)$ , Bob checks whether it agrees with  $f(x)$ . If it does, a basic property of universal hashing allows them to assume that  $x = y$ , their probability of error being bounded again by  $2^{-K}$ .

We refer the reader to [CW], [WC] for definition and discussion of universal hashing. Several universal<sub>2</sub> and strongly universal<sub>2</sub> classes are described there. Let us only stress here that they are entirely reasonable in practice. For instance, it suffices to send about  $2N$  bits over the public channel to describe a function  $f: \{0, 1\}^N \rightarrow \{0, 1\}^K$  randomly selected among  $H_1$  [CW] or  $P$  (§ 4), once the private channel transmission is completed. Compare this with the unreasonable  $K2^N$  bits needed to describe a random function! Moreover, the computation of  $f(x)$  is very efficient. Therefore, universal<sub>2</sub> hashing provides all the advantages of truly random functions, but none of the inconveniences.

As we mentioned in § 2, it is crucial that the actual verification function be transmitted to Bob only after Alice has received confirmation through the public channel that the private channel transmission is completed. This deprives Eve of any strategy that would reduce her chances of being detected. For instance, if she knew in advance that the function  $f(x)$  simply returns the last  $K$  bits of  $x$ , she could arbitrarily tamper with the other  $N - K$  bits without fear of detection.

It is interesting to compare our use of universal hashing with the classic use of this technique for message authentication [WC]. The use of hashing for authentication depends on randomly choosing a hash function and keeping it secret at least until after the message to be authenticated has been received. In our protocol for error detection, the hash function cannot be kept secret, but it must be chosen randomly *after* the message has been transmitted.

An alternative to universal hashing comes to mind: polyrandom collections [GGM]. However, universal hashing is more appropriate in this context because it offers security against unlimited computing power. It does not rely on unproved assumptions, and it can be computed more efficiently.

**3.2. Reconciliation of the strings.** Whether  $f: \{0, 1\}^N \rightarrow \{0, 1\}^K$  is chosen as a purely random function or within some universal<sub>2</sub> class of functions, what should Alice and Bob do if they find that  $f(x)$  differs from  $f(y)$ ? Whether anything can be done to recover from this situation depends on how much  $x$  differs from  $y$ . If the Hamming distance between  $x$  and  $y$  is relatively small, due to limited channel noise and/or limited tampering, we show here how Alice and Bob can find and correct the errors in  $y$ . Using subsequent protocols from § 4, Alice and Bob can then distill from  $x$  and  $y$  a shorter string on which Eve has nearly (and in some cases exactly) no information. On the other hand, if the distance between  $x$  and  $y$  is large, Alice and Bob will be able to discover this fact, but they will have no recourse but to discard  $x$  and  $y$  and begin the protocol all over again by transmitting a new random string through the private channel. As mentioned in the introduction, Eve can effectively prevent Alice and Bob from agreeing on a secret bit string by interfering strongly with every private channel transmission, but she cannot (except with low probability) fool them into thinking they have succeeded when in fact they have not.

Reconciliation is particularly easy if it is suspected that only one or two errors have occurred. Then Bob can try computing  $f(z)$  on all strings differing from  $y$  by only one or two bits, in the hope of finding a match for  $f(x)$  and thus a likely candidate for  $x$ . We call this approach *bit twiddling*.

In the presence of more than a very few errors, bit twiddling becomes too time-consuming, but it is still practical to find and remove the errors by a post facto application of error-correcting codes, as described below. If many errors are expected even when no tampering occurs, the error detection protocol of § 3.1 should be deferred until after most or all of the errors have thus been found and corrected.

Many traditional error-correcting codes, such as Hamming codes, can be written in a *systematic* format, in which each code word consists of the original source word followed by a string of check bits. Given a source word  $x$ , the encoder thus generates the concatenation  $xC(x)$ , where  $C(x)$  is some check string depending on  $x$ , and sends this longer string into the channel. At the receiving end, the redundancy in the code is used (if one is lucky) to recover the original  $x$  despite the potential corruption of both  $x$  and  $C(x)$  by channel noise. Systematic codes have no special advantage over unsystematic ones (in which source and check information are mixed) for most ordinary error-correcting applications, but they are useful in the present setting because they allow the calculation of the check information  $C(x)$  to be performed post facto, after the uncoded source data  $x$  has been sent through the private channel. They also allow sending  $x$  and  $C(x)$  on different channels.

In § 2, it was pointed out that error-correcting codes used in the traditional non-post facto manner cannot defend against malicious tampering, because Eve, knowing the code, can escape detection by deliberately mutating one channel code word into

another. For example, in the case of a systematic code, if  $xC(x)$  was sent by Alice on the channel, Eve could substitute  $zC(z)$ , even without learning anything about  $x$ , and Bob would be none the wiser. This threat can be avoided by applying the code in a post facto manner, and by taking two further precautions:

(i) The check string  $C(x)$  generated by the code is not transmitted through the private channel, where Eve could alter it, but through the public channel, where she can only listen to it.

(ii) Before application of the error-correcting code, the strings  $x$  and  $y$  to be reconciled are subjected to a preliminary *uniformization transformation*, consisting of random permutation and complementation. The purpose of this transformation is to make the difference between  $x$  and  $y$  behave as if  $y$  were the result of sending  $x$  through a memoryless binary symmetric channel. To achieve this preliminary goal, Alice randomly chooses a permutation  $\sigma: \{1, 2, \dots, N\} \rightarrow \{1, 2, \dots, N\}$  and a length  $N$  bit string  $w$ . She then transmits both  $w$  and a description of  $\sigma$  to Bob over the public channel. Finally, Alice and Bob transform their strings  $x$  and  $y$ , respectively, by first shuffling the bits according to  $\sigma$ , then taking the exclusive-or of the permuted string with  $w$ . It is clear that this leaves the number of errors unchanged, but redistributes them to random places not under the control of Eve, who is thus prevented from exploiting knowledge of the error-correcting code  $C$  to introduce a pattern of errors against which the code would perform less well than average. It is also clear that the uniformization transformation releases no new information to Eve about  $x$  and  $y$ .

To summarize, in order to use a systematic error-correcting code  $C$  for reconciliation, Alice and Bob first uniformize their strings  $x$  and  $y$ , thus producing  $x_0$  and  $y_0$ . Alice then applies  $C$  to  $x_0$  and transmits the result  $C(x_0)$  to Bob over the public channel, thereby giving away at most  $|C(x_0)|$  bits of information to Eve about  $x_0$ . Bob uses  $C(x_0)$  to correct the errors in  $y_0$ , thereby recovering  $x_0$  if the code  $C$  is sufficient to correct the errors that have occurred between  $x_0$  and  $y_0$ . If  $C(x_0)$  is significantly shorter than  $x_0$ , there is still some information about  $x_0$  that Eve does not know, and the methods of § 4 can be used to nearly obliterate the information known to her, by allowing Alice and Bob to derive from  $x_0$  a shorter string, of length approximately  $|x_0| - |C(x_0)|$ , about which Eve has less than one bit of information.

It remains to be decided what kind of systematic error-correcting code to use. If  $\varepsilon$ , the density of errors, is not too great to begin with, a simple block code (such as a Hamming code if we expect at most two errors per block) would suffice to reduce the number of errors to the point where they can be found and corrected by bit twiddling. If  $\varepsilon$  is greater (say 0.01 or more), a systematic convolutional code [G] would be better, since these tree codes, unlike block codes, can achieve exponential error reduction without exponential decoding effort, while still transmitting data at a rate at least half the theoretical channel capacity. As emphasized above, whatever error-correcting code is used should be used in a post facto manner, being applied to the uniformized version of Alice's data, and the resulting check information  $C(x_0)$  being sent to Bob over the noiseless, tamper-proof public channel.

In the traditional non-post facto situation, where both  $x$  and  $C(x)$  are sent through a binary symmetric channel with error probability  $\varepsilon$ , the capacity  $|x|/(|x| + |C(x)|)$  achievable by convolutional codes with polynomial expected decoding effort is denoted  $R_{\text{comp}}$ , and has the value  $1 - \log^1(1 + 2\sqrt{\varepsilon(1-\varepsilon)})$ , which ranges between 0.5 and 1.0 times the theoretical capacity  $1 - \mathbf{H}(\varepsilon)$ , where  $\mathbf{H}(\varepsilon) = \varepsilon \log 1/\varepsilon + (1-\varepsilon) \log 1/(1-\varepsilon)$  is the *entropy function* [G]. In the present situation, the original data is transmitted

<sup>1</sup> Unless otherwise stated, all logarithms in this paper are to the base 2.

with error probability  $\epsilon$ , but the check information is transmitted noiselessly; and capacity should thus be defined differently, as the maximum of  $(|x_0| - |C(x_0)|) / |x_0|$ , taken over all possible codes  $C$ , since this is the fraction of the original information in  $x_0$  that remains secret after reconciliation. Nevertheless, in the post facto situation, Shannon showed that the theoretical capacity is still given by  $1 - H(\epsilon)$ . By arguments parallel to the derivation of  $R_{\text{comp}}$  [G], it can be shown that the effective capacity achievable by convolutional coding is still given by

$$R_{\text{comp}} = 1 - \log(1 + 2\sqrt{\epsilon(1 - \epsilon)}).$$

In practice, the parameter  $\epsilon$  would not need to be known beforehand, since it can be determined interactively, by having Alice first compute a generous amount of check information, but then release only as much of this as Bob finds he needs for efficient decoding. A table comparing  $R_{\text{comp}}$  with Shannon's theoretical capacity  $c$  for some values of  $\epsilon$  follows.

$\epsilon$	$R_{\text{comp}}$	$c$
0.001	0.9116	0.9886

**4. Reduction of the eavesdropper's information.** Assuming that Alice and Bob agree on their strings as a result of one of the protocols discussed above, Eve has two different sources of information on that string: partial eavesdropping on the private channel, as the original random bit string was being transmitted, and complete eavesdropping on the public channel, as the agreement protocol was being carried out.

We now investigate how to reduce Eve's information arbitrarily close to zero at the cost of slightly shrinking the random bit string shared between Alice and Bob. In § 4.1, we assume that no eavesdropping on the private channel has occurred, but that transmission errors were possible. We also assume that the number of errors, if any, is small enough to be handled by bit twiddling (this assumption is removed in § 4.3). In § 4.2, we assume, on the contrary, that the eavesdropper has acquired partial information on the private channel transmission, but that tampering and transmission errors have not occurred. We finally consider in § 4.3 the more realistic case where both eavesdropping and arbitrary tampering on the private channel are possible, so the eavesdropper may gain information both directly from eavesdropping on the private transmission and indirectly by listening to the public channel reconciliation and error-detection protocols of § 3. All these protocols are secure against an eavesdropper with unlimited computing power.

**4.1. Eliminating the public channel eavesdropper's information.** Let us assume for the moment that Eve is unable to eavesdrop on the private channel but that transmission errors may have occurred. Assuming the number of errors is small enough to be handled by bit twiddling, we now show that Alice and Bob can agree on a secret random string on which Eve has *no* information, except for its length. In a companion paper [BBR], we investigate how to handle efficiently an error rate that would make bit twiddling ineffective. The interactive public discussion protocol discussed there allows Alice and

Bob to agree with high probability on a (shorter) secret random string on which Eve still has no information. Alternatively, § 4.3 of the present paper uses the post facto systematic convolutional codes of § 3.2 in order to handle normal transmission errors, but at the cost of leaking to Eve an arbitrarily small fraction of one bit of information about the final random bit string.

Let  $x$  be the random string sent from Alice to Bob over the imperfect private channel. Let  $y$  be the string received by Bob. An error detection protocol of § 3.1 is first applied to make sure, with high probability, that the random strings of Alice and Bob are identical. If not, bit twiddling is attempted by Bob to transform  $y$  into  $x$ . If bit twiddling fails, either repeat the whole process (Alice sends a fresh new random string to Bob, etc.), use the interactive protocol of [BBR], or refer to § 4.3. At this point, assume that Alice and Bob agree with high probability on some length  $N$  string  $x$ , but that Eve has gained information on this string by listening to the public channel error-detection protocol. We wish to eradicate this information of hers.

Let  $f: \{0, 1\}^N \rightarrow \{0, 1\}^K$  be the function used in the error-detection protocol. Eve knows the  $K$  bit value of  $f(x)$ , together with the function  $f$  itself. Although this may not give her any physical bits of  $x$ , she has  $K$  bits of information on  $x$  in the sense of Shannon's information theory [S], assuming that  $f$  is equitable. If  $f$  is not equitable, Eve's expected information is less than  $K$  bits, although she could know more occasionally. Her information can be characterized by the set  $C = \{z \in \{0, 1\}^N \mid f(z) = f(x)\}$  of possible candidates for  $x$ . From Eve's point of view, each element of  $C$  is equally likely to be the string  $x$  currently shared between Alice and Bob. Notice that Alice and Bob also have complete knowledge on the set  $C$ .

In order to eliminate Eve's information, Alice and Bob publicly agree on a function  $g: \{0, 1\}^N \rightarrow \{0, 1\}^R$ , for some integer  $R \leq N - K$ , such that knowledge of the set  $C$  yields no information on  $g(x)$ , the final string on which Alice and Bob agree. In other words, the purpose of this function  $g$  is to shrink the string  $x$  by at least  $K$  bits, in order to compensate for the  $K$  bits of information that Eve knows on  $x$ . It is clear that at least  $K$  bits of  $x$  must be sacrificed to privacy, but are  $K$  bits enough in general? The proper choices of  $R$  and of this information-reduction function  $g$  depend on which error-detection function  $f$  was chosen from § 3.1.

**4.1.1. Eliminating the information given by a truly random error-detection function.** Assume the error-detection function  $f$  was chosen randomly from among all functions from  $\{0, 1\}^N$  to  $\{0, 1\}^K$ . This error-detection protocol is of no practical interest, because it would require  $K2^N$  bits to merely transmit function  $f$ . It is nonetheless instructive to figure out how the information given on  $x$  by  $f(x)$  can be eliminated in this context. Indeed, this provides a nice intuitive insight into the realm of information reduction. Moreover, it is interesting to compare what can be achieved in the truly random case with the practical world (§ 4.1.2). By analogy, recall Shannon's result that any channel can come arbitrarily close to achieving its theoretical transmission capacity through the use of random codes that cannot be implemented in practice [S], and that no practical codes known thus far can perform nearly as well. As we will see, such is not the case here. For this reason, we only state the main results pertaining to truly random functions and we refer the reader to [R] for the somewhat tedious proofs.

Recall that Eve's information about  $x$  is characterized by the set  $C$  of possible candidates, and that this set is also known for Alice and Bob. Let  $\#C$  denote the number of elements in  $C$ . Let  $y$  be the index of  $x$  in  $C$  when  $C$  is ordered in lexicographic order. Then  $y$  is available to both Alice and Bob, whereas it is just as likely to take any value between 1 and  $\#C$  as far as Eve is concerned. If  $\#C$  is large enough, such

a  $y$  can thus be used as the resulting shared secret. The ideal situation occurs when the function  $f$  is equitable. In this case, we always have  $\#C = 2^{N-K}$  and thus  $y$  is a uniformly distributed random bit string of length  $N - K$  on which Eve has no information whatsoever save its length. This idea is captured in the following theorem:

**THEOREM 1.** *Let  $N$  be the length of the originally transmitted bit string and let  $K < N$  be the safety parameter used for error detection. Let  $\pi : \{0, 1\}^N \rightarrow \{0, 1\}^N$  be a randomly chosen permutation. Let  $f : \{0, 1\}^N \rightarrow \{0, 1\}^K$  and  $g : \{0, 1\}^N \rightarrow \{0, 1\}^{N-K}$  be equitable functions defined by  $f(x) = \pi(x) \bmod 2^K$  and  $g(x) = \pi(x) \operatorname{div} 2^K$ . Then, knowledge of  $\pi$  (hence of  $f$  and  $g$ ) and  $f(x)$  yields no information on  $g(x)$ , except that it is of length  $N - K$ .*

From an information theoretic point of view, one might wonder if it is necessary that this information-reduction function  $g$  be custom made for the particular error-detection function  $f$  being used. At least two ideas come to mind: What happens if  $g$  itself is chosen randomly, independently of  $f$ ? and Could  $g$  be known to Eve even before the private channel transmission takes place? Although these ideas do not allow wiping out Eve’s information with certainty, they come close.

Let us first consider the case when the information-reduction function  $g$  is randomly chosen among all functions  $\{0, 1\}^N \rightarrow \{0, 1\}^R$ , where  $R \leq N - K$  is the desired length of the final string. The intuitive hope is that a random  $g$  is very likely to map the elements of  $C$  nearly uniformly onto  $\{0, 1\}^R$ , thus releasing very little information on the value of  $g(x)$  from knowledge of  $C$  and  $g$  alone.

In order to state the theorems precisely, we need to introduce some information-theoretic formalism that will be used throughout § 4. Let  $N$  and  $K$  be as in Theorem 1. Let  $S$  be any nonnegative integer smaller than  $N - K$ . Let  $R = N - K - S$ . Let  $\mathbf{X}$ ,  $\mathbf{F}$  and  $\mathbf{G}$  be three independent uniformly distributed random variables ranging over  $\{0, 1\}^N$ ,  $\{f|f : \{0, 1\}^N \rightarrow \{0, 1\}^K\}$  and  $\{g|g : \{0, 1\}^N \rightarrow \{0, 1\}^R\}$ , respectively. Define new dependent random variables  $\mathbf{Y}$  and  $\mathbf{Z}$  ranging over  $\{0, 1\}^K$  and  $\{0, 1\}^R$ , respectively, by setting  $y = f(x)$  and  $z = g(x)$ .

The *expected amount of (Shannon) information* given on  $g(x)$  by  $y = f(x)$ ,  $f$  and  $g$  is defined by following formula:

$$\mathbf{I}(\mathbf{Z}; \mathbf{YFG}) = \sum_z \sum_y \sum_f \sum_g \operatorname{prob} [z, y, f, g] \log \frac{\operatorname{prob} [z|yfg]}{\operatorname{prob} [z]}.$$

Notice that “expected” means “averaged over all possible choices for  $f$ ,  $g$  and  $x$ .”

**THEOREM 2.** *Let  $N$ ,  $K$ ,  $S$ ,  $R$ ,  $\mathbf{F}$ ,  $\mathbf{G}$ ,  $\mathbf{Y}$  and  $\mathbf{Z}$  be as above, then*

$$\mathbf{I}(\mathbf{Z}; \mathbf{YFG}) \leq \log (1 + 2^{-S}) < 2^{-S} / \ln 2.$$

*Furthermore, this bound is fairly tight because*

$$\mathbf{I}(\mathbf{Z}; \mathbf{YFG}) \cong \left( \frac{1}{2} - \frac{1}{2^r} \right) \frac{2^{-S}}{\ln 2} - \frac{2}{2^N - 1}$$

*whenever  $3 \leq S \leq N - K - 2$ .*

Intuitively, this says that if  $f$  and  $g$  are randomly chosen functions from  $\{0, 1\}^N$  to  $\{0, 1\}^K$  and to  $\{0, 1\}^R$ , respectively, and if  $x$  is randomly chosen among all bit strings of length  $N$ , then the expected amount of Shannon information given on  $g(x)$  by  $f(x)$ ,  $f$  and  $g$  is less than  $2^{-S} / \ln 2$  bits.

As for the second idea, it turns out that a comparable level of information reduction can be achieved through the use of any ad hoc equitable function. In particular, it is enough to simply chop off any  $K + S$  physical bits of  $x$  in order to reduce the expected eavesdropper’s information below  $2^{-S} / \ln 2$  bits. This remains true even if the reduction function is chosen a priori and known to the eavesdropper before the private channel transmission.

**THEOREM 3.** *Let  $N$ ,  $R$  and  $S$  be as above. Let  $g: \{0, 1\}^N \rightarrow \{0, 1\}^R$  be any fixed equitable function, then the expected amount of information given on  $g(x)$  by  $f(x)$ ,  $f$  and  $g$  is less than  $2^{-S}/\ln 2$  bits.*

**4.1.2. Eliminating the information given by universal hashing error detection.** Let us now assume that a practical error-detection protocol was used from those proposed in § 3.1: the function  $f: \{0, 1\}^N \rightarrow \{0, 1\}^K$  was randomly chosen among some universal<sub>2</sub> class of hash functions. Rather than developing a general theory of information elimination in this context, let us design an ad hoc technique for a specific universal<sub>2</sub> class mentioned in [WC], which we call  $P$ . We assume here that the reader is familiar with Galois field theory [Be].

Consider  $a, b \in \text{GF}(2^N)$  such that  $a \neq 0$ . The degree one polynomial  $q_{a,b}(x) = ax + b$ , arithmetic being done in  $\text{GF}(2^N)$ , defines a permutation of  $\text{GF}(2^N)$ . If we let  $\sigma: \text{GF}(2^N) \rightarrow \{0, 1\}^N$  stand for the natural one-to-one correspondence, this induces a permutation  $\pi_{a,b}(x): \{0, 1\}^N \rightarrow \{0, 1\}^N$  defined by  $\pi_{a,b}(x) = \sigma(q_{a,b}(\sigma^{-1}(x)))$ . Therefore, for any fixed  $K \leq N$ , the function  $h_{a,b}(x): \{0, 1\}^N \rightarrow \{0, 1\}^N$  defined by  $h_{a,b}(x) = \pi_{a,b}(x) \bmod 2^K$  is equitable. Define the class  $P = \{h_{a,b} \mid a, b \in \text{GF}(2^N), a \neq 0\}$ . It is elementary to prove that  $P$  forms a universal<sub>2</sub> class of hash functions, so that it can be used for the error-detection protocol of § 3.1. (In fact, the class becomes *strongly* universal<sub>2</sub> if we allow  $a = 0$ , but this is to be avoided here because  $h_{0,b}$  is not equitable.)

**THEOREM 4.** *Let  $a$  and  $b$  be any elements of  $\text{GF}(2^N)$  such that  $a \neq 0$ . Let  $x$  be a random string of length  $N$ . Then knowledge of  $a$ ,  $b$  and  $h_{a,b}(x)$  gives no information on the string defined as  $g_{a,b}(x) = \pi_{a,b}(x) \bmod 2^K$ , except that it is of length  $N - K$ .*

*Proof.* This is an immediate consequence of the fact that  $\pi_{a,b}$  is a permutation of  $\{0, 1\}^N$ : knowledge of the last  $K$  bits of  $\pi_{a,b}(x)$  gives no information on its first  $N - K$  bits.  $\square$

In conclusion, use of the universal<sub>2</sub> class  $P$  allows Alice and Bob to verify whether their strings are identical, with an error probability of at most  $2^{-K}$ . If they turn out to be the same (or if they differ little enough that bit twiddling is applicable), they can be transformed into new strings that are only  $K$  bits shorter, on which Eve has no information at all. This is clearly optimal.

It is worth mentioning that the conceptually simpler universal<sub>2</sub> class  $H_1$  of [CW] can be used instead of  $P$  for error detection. This still allows subsequently a good, efficient information-reduction scheme, but wiping out with certainty Eve's information does not seem to be feasible. This is due to the fact that the functions in  $H_1$  are not equitable. Using this class, it is nonetheless always possible to reduce the eavesdropper's expected information below 2 bits, and even below any threshold  $\delta > 0$  by choosing  $N$  large enough. For more details, please consult [R].

The following section investigates the situation in which eavesdropping has occurred, but tampering and transmission errors are not a concern for Alice and Bob.

**4.2. Reducing the private channel eavesdropper's information.** Let us now assume that partial eavesdropping may have occurred on the private channel. Recall that eavesdropping consists of Eve selecting a function  $e: \{0, 1\}^N \rightarrow \{0, 1\}^K$  of her choice, whose value  $e(x)$  she learns when  $x$  is transmitted over the private channel. Alice and Bob know  $K$  but otherwise have no information on which function  $e$  was chosen by Eve. If Eve chooses an equitable function,  $e(x)$  gives her  $K$  bits of information on  $x$ . Otherwise, her expected amount of information is smaller, but she could occasionally get more. In this section, we assume that transmission errors and tampering are not a worry for Alice and Bob, so that an error-detection protocol of § 3.1 is not carried out. This assumption is removed in § 4.3.

To summarize, let  $x$  be the length  $N$  bit string common to Alice and Bob, and let  $e(x)$  be the  $K$  bits of information known by Eve about  $x$ . Alice and Bob wish to publicly agree on some function  $g: \{0, 1\}^N \rightarrow \{0, 1\}^R$ , for some  $R \leq N - K$ , such that knowledge of  $e$ ,  $e(x)$  and  $g$  leaves Eve with an arbitrary small fraction of one bit of information about  $g(x)$ .

A similar question was addressed by Ozarow and Wyner [OW]. However, their solution is nonconstructive (based on random coding), it assumes that the eavesdropper can only read physical bits from the private channel, and it does not reduce her information below one bit. On the other hand, their setting is not restricted to the exchange of a random string, as they wish Alice to be able to safely transmit a message of her choice to Bob. Moreover, they do not need to use an authenticated public channel after the private transmission. Their results should also be compared with our information-elimination protocol from § 5.

Back to the analogy with Wyner's *original* wiretap channel [W], the requirement that the eavesdropping function be compressive is analogous to Wyner's requirement that the wiretap channel have less capacity than the main channel. One might hope to generalize our setting to cover eavesdropping through an arbitrary channel of capacity  $K/N$ , selected by Eve but unknown to Alice and Bob. However, this generalization would weaken our results rather than strengthen them. For example, Eve could satisfy the  $K/N$  capacity bound by asking for all  $N$  bits of Alice's message  $K/N$  of the time, while asking for none of it the rest of the time.

Notice that the effect of eavesdropping over the private channel is very similar to that of eavesdropping over the public channel described in § 4.1 in that the information gained by Eve can be characterized by a set  $E = \{z \in \{0, 1\}^N \mid e(z) = e(x)\}$  of possible candidates for  $x$ . However, there is a fundamental difference: contrary to the previously discussed set  $C$ , it is not the case that Alice and Bob have complete knowledge of  $E$ . For this reason, it is not possible for them, in general, to eliminate Eve's information with certainty.

**THEOREM 5.** *If Eve is free to choose her function  $e: \{0, 1\}^N \rightarrow \{0, 1\}^K$  without any constraints, there is always a chance that she will gain complete information on  $g(x)$ , no matter how Alice and Bob choose the function  $g: \{0, 1\}^N \rightarrow \{0, 1\}^R$ .*

*Proof.* The idea is to make  $e$  very nonequitable, so as to have a small chance of learning  $x$  exactly from  $e(x)$ . For example, Eve could choose:

$$e(x) = \begin{cases} x \bmod 2^K & \text{if } x \operatorname{div} 2^K = 0^{N-K}, \\ 0^K & \text{otherwise.} \end{cases}$$

With probability  $(2^K - 1)/2^N$ ,  $e(x)$  yields complete information on  $x$ ; hence on  $g(x)$ .  $\square$

The eavesdropping function described above is for gamblers only: with probability greater than  $1 - 2^{K-N}$ ,  $e(x)$  gives almost no information on  $x$ . In fact, the expected information on  $x$  given by  $e(x)$  is less than  $(N + 1/\ln 2)2^{K-N}$  bits. For instance, if Eve is allowed to observe the result of a 50-bit function applied to a 56-bit DES key [NBS], her expected information would be less than one bit if she had used the above very nonequitable eavesdropping function. Clearly, it would be more prudent for Eve to select some equitable function, so as to maximize her expected amount of information on  $x$ . Even then, an analogue to Theorem 5 can be given:

**THEOREM 6.** *No matter how Alice and Bob choose their function  $g: \{0, 1\}^N \rightarrow \{0, 1\}^R$ , for any  $R > 0$ , there is always an equitable function  $e: \{0, 1\}^N \rightarrow \{0, 1\}^K$ , for any  $K > 0$ , such that knowledge of  $e$ ,  $g$  and  $e(x)$  yields some information on  $g(x)$ .*

*Proof.* Should Alice and Bob choose a nonequitable function  $g$ , Eve would have some information on  $g(x)$  from the mere knowledge that  $x$  is truly random, without

even looking at  $e(x)$ . On the other hand, assuming that  $g$  is equitable,  $e(x)$  could give as much as  $\min(K, R)$  bits of information on  $g(x)$ . This is accomplished if one of the two functions is an equitable refinement of the other. Of course, Eve cannot select  $e$  so that this will happen, because she does not yet know  $g$  when she has to choose  $e$ . However, Alice and Bob cannot prevent this coincidence from happening, or even detect it, because they never get to know the function  $e$ .  $\square$

The above two theorems show that the best Alice and Bob can hope for is to reduce Eve's information arbitrarily close to zero. There can be no analogue to Theorems 1 and 4. Nonetheless, if we restrict even further Eve's choice of  $e$ , so that she can only read a selection of *physical* bits of  $x$ , it becomes possible again for Alice and Bob to eliminate her information entirely, as discussed in § 5.

As usual, we consider two approaches for the reduction of Eve's information: one based on truly random functions and one based on universal hashing techniques. Section 4.2.1 is only of theoretical interest, and the proofs can be found in [R]. Here again, it is nice to find out that the practical schemes of § 4.2.2 are just as efficient for information reduction as the unrealistic random scheme.

**4.2.1. A random information-reduction approach.** Recall that knowledge of  $e: \{0, 1\}^N \rightarrow \{0, 1\}^K$  allows Eve to restrict the set of her possible candidates for  $x$  to  $E = \{z \in \{0, 1\}^N \mid e(z) = e(x)\}$ , where  $\#E = 2^{N-K}$  if  $e$  is equitable.

LEMMA 7. *Let  $E$  be a nonempty set of equally likely candidates for  $x$ , and let  $R$  be an integer. Let  $g: \{0, 1\}^N \rightarrow \{0, 1\}^R$  be a randomly chosen function. Then, knowledge of  $E$  and  $g$  yields less than an expected  $\log(1 + 2^R / \#E)$  bits of information on  $g(x)$ . Here, the result holds for any specific  $E$  and the average is only over all choices for  $g$ .*

THEOREM 8. *Let  $e: \{0, 1\}^N \rightarrow \{0, 1\}^K$  be any function, let  $S < N - K$  be a safety parameter, and let  $R = N - K - S$ . If  $g: \{0, 1\}^N \rightarrow \{0, 1\}^R$  is chosen randomly, the expected amount of information on  $g(x)$  given by knowledge of  $e$ ,  $g$  and  $e(x)$  is less than  $\log(1 + 2^{-S})$  bits, hence less than  $2^{-S} / \ln 2$  bits.*

**4.2.2. A universal hashing information-reduction approach.** Contrary to the error detection protocols of § 3, it is no longer sufficient to consider  $\text{universal}_2$  classes: here, we need *strongly universal* $_2$  classes [WC].

LEMMA 9. *Let  $E$  and  $R$  be as in Lemma 7. Let  $H$  be a publicly known strongly  $\text{universal}_2$  class of hash functions from  $\{0, 1\}^N$  to  $\{0, 1\}^R$ . Let  $g$  be a function chosen randomly within  $H$ . Then, knowledge of  $E$  and  $g$  yields less than an expected  $\log(1 + 2^R / \#E)$  bits of information on  $g(x)$ . Again, the average is only over all choices of  $g$ , not over  $E$  or  $H$ .*

*Proof.* Let us first recall some notation from universal hashing: if  $x \in \{0, 1\}^N$ ,  $z \in \{0, 1\}^R$  and  $g \in H$ , then

$$\Delta_z^{x,g} = \begin{cases} 1 & \text{if } g(x) = z, \\ 0 & \text{otherwise.} \end{cases}$$

If  $E \subseteq \{0, 1\}^N$ , then

$$\Delta_z^{E,g} = \sum_{x \in E} \Delta_z^{x,g} = \#\{x \in E \mid g(x) = z\}.$$

Similarly, if  $F \subseteq H$ , then

$$\Delta_z^{x,F} = \sum_{g \in F} \Delta_z^{x,g} = \#\{g \in F \mid g(x) = z\}.$$

By definition of strong  $\text{universal}_2$ ,

$$\#\{g \in H \mid g(x) = z \text{ and } g(x') = z'\} = \#H / 2^{2R}$$

for any  $x, x' \in \{0, 1\}^N$  and  $z, z' \in \{0, 1\}^R$ , provided  $x \neq x'$ .

An immediate consequence of this definition is that

$$\begin{aligned}\Delta_z^{x,H} &= \#\{g \in H \mid g(x) = z\} \\ &= \sum_{z' \in \{0,1\}^R} \#\{g \in H \mid g(x) = z \text{ and } g(x') = z'\} \\ &= 2^R \#H / 2^{2R} = \#H / 2^R,\end{aligned}$$

where  $x'$  is chosen as any string different from  $x$  in  $\{0, 1\}^N$ . Therefore,

$$\sum_{g \in H} \Delta_z^{E,g} = \sum_{x \in E} \Delta_z^{x,H} = \#E \#H / 2^R.$$

Similarly,

$$\begin{aligned}\sum_{g \in H} (\Delta_z^{E,g})^2 &= \sum_{g \in H} \left( \sum_{x \in E} \Delta_z^{x,g} \right)^2 \\ &= \sum_{g \in H} \sum_{x \in E} \sum_{x' \in E} \Delta_z^{x,g} \Delta_z^{x',g} \\ &= \sum_{x \in E} \sum_{x' \in E} \#\{g \in H \mid g(x) = z \text{ and } g(x') = z\} \\ &= \#E [\#H / 2^R + (\#E - 1) \#H / 2^{2R}]\end{aligned}$$

(from splitting the cases  $x' = x$  and  $x' \neq x$ )

$$= \frac{\#E \#H}{2^R} \left[ 1 + \frac{\#E - 1}{2^R} \right].$$

Let us now come back to Eve's set  $E \subseteq \{0, 1\}^N$  of equally likely candidates for  $x$ . In this proof, we consider two independent random variables  $\mathbf{X}$  and  $\mathbf{G}$  ranging over  $\{0, 1\}^N$  and the set of functions from  $\{0, 1\}^N$  to  $\{0, 1\}^R$ , respectively, with the probability distributions

$$\text{prob} [\mathbf{X} = x] = \begin{cases} 1/\#E & \text{if } x \in E, \\ 0 & \text{otherwise,} \end{cases}$$

and

$$\text{prob} [\mathbf{G} = g] = \begin{cases} 1/\#H & \text{if } g \in H, \\ 0 & \text{otherwise.} \end{cases}$$

Consider also the dependent random variable  $\mathbf{Z}$  ranging over  $\{0, 1\}^R$  corresponding to the equation  $z = g(x)$ . We wish to find an upper bound on  $\mathbf{I}(\mathbf{Z}; \mathbf{G})$ , the expected information on  $g(x)$  given from the knowledge of  $g$  and of the fact that  $x \in E$ . For this, we need to compute a few conditional, joint and marginal probabilities: given  $z \in \{0, 1\}^R$  and  $g \in H$ ,

$$\begin{aligned}\text{prob} [\mathbf{Z} = z \mid \mathbf{G} = g] &= \Delta_z^{E,g} / \#E, \\ \text{prob} [\mathbf{Z} = z, \mathbf{G} = g] &= \text{prob} [\mathbf{G} = g] \text{prob} [\mathbf{Z} = z \mid \mathbf{G} = g] \\ &= \Delta_z^{E,g} / \#E \#H,\end{aligned}$$

and

$$\begin{aligned} \text{prob} [\mathbf{Z} = z] &= \sum_{g \in H} \text{prob} [\mathbf{Z} = z, \mathbf{G} = g] \\ &= \frac{1}{\# E \# H} \sum_{g \in H} \Delta_z^{E,g} = 2^{-R}. \end{aligned}$$

By information-theoretic definitions, we therefore obtain:

$$\begin{aligned} \mathbf{I}(\mathbf{Z}; \mathbf{G}) &= \sum_{z \in \{0,1\}^R} \sum_{g \in H} \text{prob} [\mathbf{Z} = z, \mathbf{G} = g] \log \frac{\text{prob} [\mathbf{Z} = z | \mathbf{G} = g]}{\text{prob} [\mathbf{Z} = z]} \\ &= \sum_z \sum_g \frac{\Delta_z^{E,g}}{\# E \# H} \log \frac{\Delta_z^{E,g} 2^R}{\# E} \\ &= 2^{-R} \sum_z \sum_g \Delta_z^{E,g} \frac{2^R}{\# E \# H} \log \frac{\Delta_z^{E,g} 2^R}{\# E} \\ &\leq 2^{-R} \sum_z \log \sum_g (\Delta_z^{E,g} 2^R / \# E)^2 / \# H \end{aligned}$$

(by Jensen's lemma [Mc], because  $\sum_g \Delta_z^{E,g} 2^R / \# E \# H = 1$ )

$$\begin{aligned} &= 2^{-R} \sum_z \log \left( \frac{2^{2R}}{(\# E)^2 \# H} \sum_g (\Delta_z^{E,g})^2 \right) \\ &= 2^{-R} \sum_z \log \left( \frac{2^R}{\# E} + \frac{\# E - 1}{\# E} \right) \\ &< \log (1 + 2^R / \# E). \quad \square \end{aligned}$$

**THEOREM 10.** *Let  $e$ ,  $S$  and  $R$  be as in Theorem 8, and let  $H$  and  $g$  be as in Lemma 9. The expected amount of information on  $g(x)$  given by knowledge of  $e$ ,  $g$  and  $e(x)$  is less than  $\log (1 + 2^{-S})$  bits, hence less than  $2^{-S} / \ln 2$  bits. Notice that this is true for every  $e$ , despite the fact that Eve already knows the class  $H$ , but of course not the specific function  $g$ , when she gets to choose her function  $e$ .*

*Proof.* This is an immediate consequence of Lemma 9 if  $e$  is equitable. Indeed, the eavesdropper's set  $E$  is then always reduced to exactly  $2^{N-K}$  equally likely candidates for  $x$ . The expected information on  $g(x)$  given by knowledge of  $E$  and  $g$  is thus less than  $\log (1 + 2^R / 2^{N-K}) = \log (1 + 2^{-S}) < 2^{-S} / \ln 2$  bits.

If  $e$  is not equitable, the theorem still follows from Lemma 9, but through the use of Jensen's lemma [Mc]. For any  $x \in \{0, 1\}^N$ , let  $E_x = \{y \in \{0, 1\}^N | e(y) = e(x)\}$ . Since each  $x \in \{0, 1\}^N$  is equally likely a priori, Lemma 9 tells us that the expected information on  $g(x)$  given by knowledge of  $g$ ,  $e$  and  $e(x)$  is less than

$$\sum_{x \in \{0,1\}^N} 2^{-N} \log (1 + 2^R / \# E_x) \leq \log \sum_x (2^{-N} + 2^{R-N} / \# E_x)$$

(by Jensen's lemma, because  $\sum_x 2^{-N} = 1$ )

$$\leq \log (1 + 2^{-S})$$

(because  $\sum_x 1 / \# E_x \leq 2^K$ , by an easy exercise left to the reader).  $\square$

Let us finally point out that *almost* strongly universal<sub>2</sub> classes [WC] can also be used in this information-reduction context. A similar analysis shows that if  $g$  is chosen

randomly from an almost strongly universal<sub>2</sub> class, knowledge of  $e$ ,  $g$  and  $e(x)$  yields at most  $1 + \log(1 + 2^{-(S+1)})$  bits of information to Eve about  $g(x)$ . This could be interesting when  $R$  is much smaller than  $N$ : in that case the description of a randomly chosen function within an almost strongly universal<sub>2</sub> class requires significantly fewer bits to be transmitted over the public channel [WC].  $\square$

**4.3. Putting the concepts together.** If Eve obtained some information on the string  $x$  as it was being transmitted over the private channel, and additional information by listening to the public channel messages exchanged during the error-correction and error-detection protocols of §§ 3.2 and 3.1, it may still be possible for Alice and Bob to efficiently agree on a random string on which Eve has nearly no information. The key idea is that if Eve obtained an expectation of  $K$  bits from the private channel transmission, and an expectation of  $L$  more bits from eavesdropping on the subsequent public discussion, then she can expect at most  $K + L$  bits from both sources combined. This is formalized in the following easily proven lemma.

LEMMA 11. *Let  $e: \{0, 1\}^N \rightarrow \{0, 1\}^K$  and  $f: \{0, 1\}^N \rightarrow \{0, 1\}^L$  be any two functions. Let  $x$  be a random string of length  $N$ . The expected information on  $x$  given by knowledge of  $e$ ,  $e(x)$ ,  $f$  and  $f(x)$  is at most  $K + L$  bits.*

Therefore, an obvious adaptation of the protocol implied by Theorem 10 allows for the efficient reduction of Eve's information to less than  $2^{-S}/\ln 2$  bits for any  $S < N - K - L$ , at the cost of ending up with a random string of length  $N - K - L - S$ . Notice that ad hoc information-elimination schemes, such as those in Theorems 1 and 4, offer no advantages in this context (unless an information-elimination scheme from § 5 is used initially). Therefore, the choice of a universal<sub>2</sub> class in the error-detection part of the protocol does not have to be motivated by the existence of a subsequent information-elimination scheme.

**5. Elimination of the eavesdropper's information.** The protocols of § 4.2 should be sufficient for most applications, despite the fact that Eve retains an arbitrarily small fraction of one bit of information on the resulting shared random string. Although we were able to eliminate her information entirely in Theorems 1 and 4, the techniques used could only be applied because Alice and Bob had complete knowledge of Eve's information. As shown in Theorems 5 and 6, this cannot be extended whenever Eve is allowed to access a limited amount of information *of her choice* from the private channel transmission.

In this section, we investigate a protocol by which Alice and Bob can nonetheless wipe out Eve's information, assuming that she obtained a maximum of  $K$  *physical* bits of her choice from the private channel transmission, as opposed to the more general  $K$  bits of information in Shannon's sense discussed in § 4. Although the value of  $K$  is known to Alice and Bob, they do not know, of course, which particular bits of their string are compromised. This protocol is expensive in the sense that the resulting string is generally substantially shorter than those resulting from the protocols of § 4; however, this is the unavoidable price to pay in order to make sure that Eve is left with no information at all.

An error-detection protocol could be applied, if desired, after Eve's information has been eliminated, still leaving her with no information if the universal<sub>2</sub> class  $P$  of Theorem 4 is used. Bit twiddling on the initial strings is also possible afterwards in order to reconcile the final strings, if there were only one or two transmission errors. Unfortunately, the more sophisticated protocol of § 3.2 would transform Eve's knowledge from physical bits to information in Shannon's sense, so that the elimination

protocols described below could no longer be applied. We do not know how to efficiently eliminate Eve's information and reconcile Alice and Bob's strings if several transmission errors occurred.

**5.1. The notion of  $(N, J, K)$ -functions.** In order to eliminate Eve's information, we introduce the following definition: for any integers  $N, J$  and  $K$  such that  $N \geq J + K$ ,  $J > 0$  and  $K > 0$ , a function  $f: \{0, 1\}^N \rightarrow \{0, 1\}^J$  is  $(N, J, K)$  if, no matter how one fixes any  $K$  of its input bits, each of the  $2^J$  output bits can be produced in exactly  $2^{N-J-K}$  different ways by varying the remaining  $N - K$  input bits. Intuitively, an  $(N, J, K)$ -function compresses an  $N$  bit string into a  $J$  bit string in such a way that knowledge of any  $K$  of the input bits gives no information on the output. This is equivalent to the notion of  $t$ -resilient functions independently introduced by [CGHFRS].

Given such a function, Alice and Bob can apply it to their respective strings, thus producing a new (shorter) string on which Eve has no information. Notice that this still holds even if she already knows which function will be used by Alice and Bob in advance of her deciding which  $K$  bits to read from the private channel. Therefore, the subsequent public transmission between Alice and Bob is not necessary in this case. By analogy with [OW], these  $(N, J, K)$ -functions are not restricted to the exchange of random strings. If Alice wished to communicate some *specific*  $J$  bit string  $y$  to Bob, she could send over the private channel some randomly chosen  $N$  bit string  $x$  such that  $f(x) = y$ . This would allow Bob to obtain  $y$  unambiguously, assuming no transmission errors occurred, whereas Eve would gain no information on  $y$  from eavesdropping over any  $K$  bits of  $x$ . One (nonconstructive) protocol in [OW] achieves something similar with  $N = J + K$ , which is better than what we get here, but it yields slightly more than one bit of information to Eve about  $y$ .

*Example.* The function  $f(u, v, w, x, y, z) = (u \oplus v \oplus w \oplus x, w \oplus x \oplus y \oplus z)$  is  $(6, 2, 3)$ : knowledge of any 3 of the input bits yields no information at all on the output.

The case  $J = N - K$  is the best possible because there is obviously no hope of producing a completely secret string of length  $N - K + 1$  if Eve knows  $K$  of the  $N$  original bits. A function  $f$  that is  $(N, N - K, K)$  is said to be  $(N, K)$ . The following theorem shows how to build  $(N, K)$ -functions whenever they exist.

**THEOREM 12.** (1) For any  $N > 1$ , there are  $(N, 1)$  and  $(N, N - 1)$ -functions.

(2) For any  $N > 3$ , there are no  $(N, K)$ -functions whenever  $1 < K < N - 1$ .

*Proof.* (1) Produce the  $i$ th output bit as the exclusive-or of the  $i$ th and the  $(i + 1)$ st input bits to get an  $(N, 1)$ -function; and produce the only output bit as the exclusive-or of all  $N$  input bits to get an  $(N, N - 1)$ -function.

(2) Assume for a contradiction that some  $f: \{0, 1\}^N \rightarrow \{0, 1\}^{N-K}$  is  $(N, K)$  for  $N > 3$  and  $1 < K < N - 1$ . By definition  $f(x_1) \neq f(x_2)$  for any two distinct strings  $x_1$  and  $x_2$  that have at least  $K$  bits in common. Let  $X = \{x \in \{0, 1\}^N \mid x \neq 0^N \text{ and } x \bmod 2^K = 0^K\}$ , the set of nonzero  $N$  bit strings ending with  $K$  zeros. Notice that  $f$  must be one-to-one on  $X$  because any two strings in  $X$  have their last  $K$  bits in common. Now, consider the strings  $u = 1^{N-K+1}0^{K-1}$  and  $v = 1^{N-K}0^{K-1}1$ . Both  $u$  and  $v$  have at least  $K$  bits in common with each string of  $X$ . Therefore,  $f(u) \notin f[X]$  and  $f(v) \notin f[X]$ . Since  $f[X]$  spans all of  $\{0, 1\}^{N-K}$  but one string, we must have  $f(u) = f(v)$ . This is a contradiction because  $u$  and  $v$  have  $(K - 2) + (N - K) = N - 2 \geq K$  bits in common.  $\square$

Moreover, there exist only two distinct  $(N, N - 1)$ -functions for each  $N > 1$ : the one given in the proof of Theorem 12 and its complement:

**THEOREM 13.** The only  $(N, N - 1)$  functions are  $f(x_1, x_2, \dots, x_N) = x_1 \oplus x_2 \oplus \dots \oplus x_N$  and its complement.

*Proof.* This easy proof by induction on  $N$  is left to the reader.  $\square$

**5.2. How to build  $(N, J, K)$ -functions.** We wish to answer the following question: given  $N$  and  $K$ , what is the maximum value for  $J$  such that an  $(N, J, K)$ -function exists? Alternatively, given  $N$  and  $J$ , find the maximum value for  $K$ . In other words, what is the longest secret random string on which Alice and Bob can agree if they start from a random string of length  $N$ , of which  $K$  bits are compromised? Theorem 12 showed that  $J$  must be strictly smaller than  $N - K$  unless  $K = 1$  or  $K = N - 1$ .

We were unable to answer the above question in its full generality. For this reason, we restrict our attention to the special class of  $(N, J, K)$ -functions for which every output bit is produced as the exclusive-or of some of the input bits. Such functions are referred to as xor- $(N, J, K)$ -functions. We conjecture that these functions are as efficient as possible, in the sense that if no xor- $(N, J, K)$ -functions exist for given values of  $N, J$  and  $K$ , then no general  $(N, J, K)$ -functions exist either. This *Xor-Conjecture* is proved in [CGHFRS] for the case  $J = 2$ .

The following characterization, known as the *Xor-Lemma*, allows us to establish an equivalence between xor- $(N, J, K)$ -functions and binary linear codes [vL].

LEMMA 14 (independently discovered by [CGHFRS]). *Let  $M$  be a  $J \times N$  Boolean matrix. Let  $f: \{0, 1\}^N \rightarrow \{0, 1\}^J$  be the function represented by  $M$  in the natural way (i.e.,  $f(x) = xM'$ , all operations being performed modulo 2). The function  $f$  is  $(N, J, K)$  if and only if the exclusive-or of any set of rows of  $M$  contains at least  $K + 1$  ones.*

*Proof.* One direction is obvious: if the exclusive-or of some subset of the rows contains  $K$  ones or less, it is sufficient to know the value of these  $K$  input bits to infer the exclusive-or of the corresponding output bits.

Conversely, assume that the exclusive-or of any set of rows of  $M$  contains at least  $K + 1$  ones. We have to show that, no matter how many  $K$  input bits are fixed, each of the  $2^J$  output strings can be obtained in exactly  $2^{N-J-K}$  different ways by varying the other  $N - K$  input bits. Without loss of generality, let us assume that the first  $K$  input bits are fixed, say to some  $u \in \{0, 1\}^K$ . Let  $M_1$  and  $M_2$  stand for the first  $K$  and the last  $N - K$  columns of  $M$ , respectively.

The key observation is that  $M_2$  has full rank, because if the exclusive-or of some rows of  $M_2$  were zero, the exclusive-or of the same rows of  $M$  would contain at most  $K$  ones. A classic result of linear algebra applies to conclude that there exists a nonsingular  $(N - K) \times (N - K)$  matrix  $F$  such that  $M_2 = RF$ , where  $R$  is the  $J \times (N - K)$  matrix such that  $R_{ij} = 1$  for  $1 \leq i \leq J$  and  $R_{ij} = 0$  otherwise [ND].

Now, consider any  $y \in \{0, 1\}^J$ . Let  $z$  be any string in  $\{0, 1\}^{N-K-J}$ . Let  $v = (y \oplus uM_1', z)(F')^{-1}$ . Let  $x = (u, v)$ . We have  $f(x) = xM' = uM_1' \oplus vM_2' = uM_1' \oplus [(y \oplus uM_1', z)(F')^{-1}F'R'] = y$ . Furthermore, it is clear that different values for  $z$  give in this way different values for  $v$ , hence for  $x$ . Therefore for any  $y \in \{0, 1\}^J$ , there are at least  $2^{N-K-J}$  different  $x \in \{0, 1\}^N$  such that the first  $K$  bits of  $x$  are  $u$  and  $f(x) = y$ . By a pigeonhole argument,  $2^{N-K-J}$  is the exact number of such  $x$ 's. This is the required condition for  $f$  to be  $(N, J, K)$ .  $\square$

THEOREM 15 (independently discovered by [CGHFRS]). *For given values of  $N, J$  and  $K$ , there exists an xor- $(N, J, K)$ -function if and only if there exists an  $[N, J]$  binary linear code with minimum distance at least  $K + 1$  between any two code words.*

*Proof.* This is an immediate consequence of Lemma 14, if one makes the correspondence between the matrix  $M$  used to represent the  $(N, J, K)$ -function and the generator matrix  $G$  of the binary linear code.  $\square$

Consequently, our problem is equivalent to a classic problem of algebraic coding theory. Unfortunately, no efficient algorithms, much less closed-formed formulae, are known to determine the largest possible minimum code-word distance among all  $[N, J]$  binary linear codes. There are, however, several well-known lower and upper bounds

on this value  $[vL]$ ,  $[HS]$ ,  $[MS]$ , and these bounds apply just as well to our problem.

For instance, Hamming codes  $[MS]$  tell us that  $\text{xor}-(2^L-1, 2^L-L-1, 2)$ -functions exist for every  $L \geq 2$ . Conversely, Hamming's upper bound  $[MS]$  shows that no  $\text{xor}-(2^L-1, 2^L-L, 2)$ -functions can exist because

$$2^{(2^L-1)-(2^L-L-1)} = \sum_{i=0}^1 \binom{2^L-1}{i}.$$

Notice that elimination of Eve's information in this case ( $K=2$ ) costs  $L-2-S$  additional bits than if we had been satisfied to reduce her information below  $2^{-S}/\ln 2$  bits, as in § 4.2.

Similarly, Griesmer's upper bound and the simplex code  $[MS]$  allow for the building of  $\text{xor}-(2^L-1, L, 2^{L-1}-1)$ -functions for any  $L \geq 2$ , whereas neither  $\text{xor}-(2^L-1, L, 2^{L-1})$ -functions nor  $\text{xor}-(2^L-1, L+1, 2^{L-1}-1)$ -functions can exist. Moreover, Varsharmov-Gilbert's lower bound together with McEliece's upper bound  $[vL]$ ,  $[MS]$  allow for the construction of  $\text{xor}-(N, J, K)$ -functions such that  $J$  is at least half the optimal ( $\text{xor}$ ) value, as long as  $K/N < 0.3$  and  $N$  is large enough. Also, the *zigzag* of  $[BCR]$  yields an  $\text{xor}-(3^L, 2^L, 2^L-1)$ -function, for every positive integer  $L$ .

Finally, the general question of  $(N, J, K)$ -functions is solved completely when  $K > \frac{2}{3}N-1$ , thanks to the proof of the Xor-Conjecture for  $J=2$   $[CGHFRS]$ . In this case, it is easy to see that no  $\text{xor}-(N, 2, K)$ -functions can exist, and therefore no general  $(N, 2, K)$ -functions can exist either. Since the exclusive-or of all the input bits is  $(N, 1, K)$ , we conclude that 1 is the maximum possible value for  $J$  when  $\frac{2}{3}N-1 < K < N$ . On the other hand, there is always an  $(N, 2, \lfloor \frac{2}{3}N-1 \rfloor)$ -function. We encourage the reader to consult  $[CGHFRS]$  for additional results on  $(N, J, K)$ - (*alias*  $t$ -resilient) functions.

**6. Conclusions.** If no eavesdropping occurred over the private channel, it is possible for Alice and Bob to publicly verify that no transmission errors or tampering occurred either, with a  $2^{-K}$  error probability, and end up with an entirely secret final string that is only  $K$  bits shorter than the original private transmission. This is optimal.

If partial eavesdropping occurred over the private channel, leaking up to  $K$  bits of information to Eve, in Shannon's sense, it is still possible for Alice and Bob to publicly verify that no transmission errors or tampering occurred, with a  $2^{-L}$  error probability, and end up with a final string that is  $K+L+S$  bits shorter than the original private transmission, on which Eve has less than  $2^{-S}/\ln 2$  bits of information on the average. Moreover, discrepancies between the transmitted and received versions of the private channel transmission, whether they are due to channel noise or tampering, can be handled at the cost of a further reduction in the length of the final shared secret string. If the discrepancies are too numerous, no final shared secret string can be constructed, but Alice and Bob will detect this condition with very high probability, and will not be misled into constructing a string that is neither shared nor secret.

Finally, if partial eavesdropping over the private channel is restricted to  $K$  physical bits secretly chosen by Eve, it becomes possible again for Alice and Bob to verify with high probability that no errors or tampering occurred, and to end up with a new string on which Eve has no information whatsoever. However, the new string will be substantially shorter than if Alice and Bob had tolerated knowledge by Eve of an arbitrarily small fraction of one bit of information. This remains possible even if a small number of transmission errors occurred, but we do not know how to eliminate Eve's information and reconcile the strings efficiently in the presence of severe transmission errors.

## UNBIASED BITS FROM SOURCES OF WEAK RANDOMNESS AND PROBABILISTIC COMMUNICATION COMPLEXITY\*

BENNY CHOR<sup>†</sup> AND ODED GOLDREICH<sup>‡</sup>

**Abstract.** A new model for weak random physical sources is presented. The new model strictly generalizes previous models (e.g., the Santha and Vazirani model [27]). The sources considered output strings according to probability distributions in which *no single string is too probable*.

The new model provides a fruitful viewpoint on problems studied previously such as:

- *Extracting almost-perfect bits from sources of weak randomness.* The question of possibility as well as the question of efficiency of such extraction schemes are addressed.
- *Probabilistic communication complexity.* It is shown that most functions have linear communication complexity in a very strong probabilistic sense.
- *Robustness of BPP* with respect to sources of weak randomness (generalizing a result of Vazirani and Vazirani [32], [33]).

**Key words.** randomness, physical sources, discrete probability distributions, communication complexity, randomized complexity classes

**1. Introduction.** The notion of randomness is central to the theory of computation. Thus, the question of whether and how randomness can be implemented in a computer is of major importance. Our intention is not to address the metaphysical aspect of the above question. Rather we assume that there are physical phenomena which appear to be “somewhat random,” and study the consequences of such an assumption.

In reality, there is a variety of physical sources, the output of which appears to be unpredictable in some sense (e.g., noise diodes, Geiger counters, etc.). However, these sources do not seem to be perfect (i.e., they do not output a uniform distribution). This phenomenon is amplified when trying to convert the analogue signal to a digital one, and in particular when sampling the physical source very frequently.

The main contribution of this paper is in presenting a general model for sources of weak randomness. This model not only generalizes previous models, but is also very convenient to manipulate and analyze. The new model provides a new viewpoint on several problems studied previously, and enables us to obtain interesting new results:

- *Extracting almost-perfect bits from sources of weak randomness.* It is shown that almost all functions can be used for extracting many “almost-unbiased” bits from two independent sources of “weak” randomness. An explicit function which performs almost as well is also presented. These results yield an extraction scheme which is efficient both in terms of output entropy and computational complexity.
- *Probabilistic communication complexity.* It is shown that most Boolean functions have linear communication complexity in a very strong probabilistic sense. This resolves an open problem of Yao [35].
- *Robustness of BPP* with respect to sources of weak randomness. It is shown that any probabilistic polynomial-time algorithm can be modified so that it works with bits supplied by a *single* source of weak randomness.

**1.1. Previous models.** Previous works on extracting unbiased bits from nonperfect sources have implicitly or explicitly proposed models of “weak randomness.” Von Neumann’s classic algorithm [18] deals with sequences of bits generated by independent tosses of a single coin with fixed bias. This model is totally memoryless. Blum [6] models physical sources as finite state Markov chains (with unknown transition probabilities). In this model, it is possible to describe a dependency of the next bit (output by the source) on the previous  $c$  bits (for any fixed  $c$ ).

Santha and Vazirani [27] have further relaxed the restrictions on the physical source. Their model, hereafter referred to as the *SV-model*, is the starting point for our investigations. In the SV-model each bit in the output sequence is “slightly random” in the sense that it is 0 with probability at least  $\delta$  and 1 with probability at least  $\delta$ , where  $\delta \leq \frac{1}{2}$  is a constant. This allows us to model a probabilistic dependency of the next bit (output by the source) on all previous bits. However, no bit of the output may be totally determined by the previous bits. It follows that in the SV-model, every bit sequence is output with some positive probability. This restriction could be violated by some “random” physical sources, which are constrained in a way that prevents certain bit sequences.

**1.2. The new model.** We introduce and study a general model for physical sources, hereafter referred to as the *model of Probability-Bounded sources (PRB-sources)*. Loosely speaking, the probability that a PRB-source will output a particular *string* is bounded above by some parameter. This allows the source to be very imperfect, still it may not concentrate its probability mass on too few strings.

The PRB-model is formalized using two constants  $l$  (length parameter) and  $b$  (probability bound). A physical source  $S$  is a device which outputs an infinite sequence of bits. We say that  $S$  is an  $(l, b)$ -source if for every prefix  $\alpha$  of the output sequence, and every  $l$ -bit string  $\beta$ , the conditional probability that the next  $l$  bits output by  $S$  equal  $\beta$  is at most  $2^{-b}$  (i.e.,  $\Pr(\beta | \alpha) \leq 2^{-b}$ ).

The PRB-model is a strict generalization of the SV-model. To see the inclusion, note that any SV-source with parameter  $\delta$  is a  $(1, \log_2(1 - \delta)^{-1})$ -source. To see that the inclusion is proper, consider the  $(2, 1)$ -source which outputs 11 with probability  $\frac{1}{2}$  and 10 with probability  $\frac{1}{2}$ . Clearly, this source is not an SV-source. Thus, *all positive results* (with respect to the PRB-model) *presented in this paper apply also to the SV-model*.

**1.3. Extracting unbiased bits from sources of weak randomness.** Algorithms for extracting unbiased bits from nonperfect sources depend on the underlying source model. Von Neumann’s algorithm [18] for generating a sequence of unbiased bits by using a coin with fixed bias, is a well-known classic:

- (1) Toss the biased coin twice. Denote the outcome by  $\sigma\tau \in \{HH, HT, TH, TT\}$ .
- (2) If  $\sigma = \tau$  then goto step (1). (Nothing is output.)
- (3) If  $\sigma\tau = HT$  output 0; If  $\sigma\tau = TH$  output 1; Goto step (1).

Elias [11] improved upon von Neumann’s algorithm, showing how to nearly achieve the entropy of the source. He also considered special types of visible finite Markov chains. Elias’s algorithm produces perfect bits from such sources.

Blum [6] has considered extracting (perfect) unbiased bits from general finite Markov chains with *unknown* structure and transition probabilities. He gave algorithms which work in linear expected time. Using Elias’s techniques [11], the extracted bits reach the entropy of the source in the limit.

It seems that as far as extracting *perfect* unbiased bits is concerned, Blum’s schemes are optimal. However, as pointed out by Santha and Vazirani [27], for practical purposes we may lower the standards and settle for “almost” unbiased bits. Having this goal

in mind, they further relaxed the restrictions on the physical source and introduced the SV-model (see § 1.1). Santha and Vazirani showed that a single SV-source cannot be used to extract almost unbiased bits, while sufficiently many independent SV-sources can be used for this purpose. Vazirani [29] showed that by applying inner-product mod 2 to strings of length  $C_\delta \cdot \log_2 \varepsilon^{-1}$  output by two independent SV-sources, a bit with bias  $\leq \frac{1}{2} + \varepsilon$  is produced.

Summarizing the results in [27] and [29], we conclude that the SV-model presents a sufficient condition for the extraction of almost unbiased bits from two independent physical sources. We substantially relax this condition.

In this paper we show that almost all functions can be used to extract many independent unbiased bits from the output of any two independent  $(l, b)$ -sources. To be more specific, let  $m = \frac{1}{3}(b - 3 - \log l) > 0$ , and consider extraction functions from  $l+l$  bits to  $m$  bits. The  $m$  extracted bits are *almost unbiased and independent* in the sense that each  $m$ -bit string appears with probability at least  $(1 - 1/2^m) \cdot 2^{-m}$  and at most  $(1 + 1/2^m) \cdot 2^{-m}$ . This is achieved by a  $1 - 2^{-2^b}$  fraction of all functions from  $2l$ -bit strings to  $m$ -bit strings. Notice that the number of bits we extract from the two sources is within a constant factor ( $\approx 1/6$ ) of the information theoretic bound, a feature not achieved in previous works [27], [29].

We also prove that, for all  $b_1 + b_2 \geq l + 2 + 2 \log_2 \varepsilon^{-1}$ , all functions corresponding to  $2^l$ -by- $2^l$  Hadamard matrices can be used to extract a single bit with bias  $\leq \frac{1}{2} + \varepsilon$  from any two independent PRB-sources which are  $(l, b_1)$ - and  $(l, b_2)$ -distributed, respectively.

A new result contained in this paper, resolves a problem left open in the preliminary version of this work [9]: *an extraction scheme which is efficient both in terms of information rate and computation complexity*. The core of the new method is the discrete logarithm function, and its analysis is based on the method of trigonometric sums. Recently, this open problem was resolved independently by Vazirani [31]. His solution is simpler than ours.

**1.4. Probabilistic communication complexity.** Vazirani pointed out that “good” bit-extraction functions have high communication complexity [29]. We establish further connections between the two notions. We show that functions which can be used for extracting an almost unbiased bit from two probability-bounded sources have *linear* communication complexity in a very strong sense. It follows that almost all functions, and in particular all functions corresponding to Hadamard matrices, have linear communication complexity. This resolves Yao’s open problem [35] regarding the probabilistic communication complexity of random functions and of the set intersection function. (Related lower bounds on the communication complexity of random functions were presented independently by Alon, Frankl and Rödl [5] and by Orlitsky and El-Gamal [20]. Our linear  $(\Omega(n))$  lower bound on the inner product modulo 2 function, improves over Vazirani’s  $\Omega(n/\log n)$  bound presented in [29].)

Another contribution in the field of communication complexity is the presentation of definitions and results for the case that the inputs are taken from probability-bounded distributions (i.e., distributions in which no string is too likely). This contribution is in the spirit of Vazirani’s suggestion to analyze the communication complexity with respect to inputs chosen by an SV-model [29]. However, we feel that probability-bounded distributions are more natural in the context of communication complexity. We consider *randomized* protocols where the objective is to guess the value of the function with *average* success probability exceeding  $\frac{1}{2} + \varepsilon$ . Both the average length of a run and the average success probability are taken with respect to the “best” (for the protocol) probability-bounded distribution. We show that, even with respect to such

protocols and distributions, the *average* communication complexity of almost all functions is linear in the probability bound  $b$  (where no input appears with probability greater than  $2^{-b}$ ).

**1.5. On the robustness of BPP.** The class  $R$  [1] and its symmetric version BPP [13] consist of problems which can be solved with high probability in polynomial time. The probability is taken over the tosses of an unbiased coin. Umesh Vazirani raised the question whether BPP problems can be efficiently solved if a (single) SV-source is producing the coin tosses. Recently, Vazirani and Vazirani have answered this question affirmatively [32], [33]. In this paper, we generalize their result by showing that BPP problems can be efficiently solved if a (single) PRB-source is producing the coin tosses. The underlying principles of our proof originate from Vazirani and Vazirani [32], [33] and [30].

The main idea of the proof is that while a single PRB-source is useless for producing a *single* unbiased bit, it can nevertheless be used for producing polynomially many bits, most of which are unbiased. Our key observation is that *any* function which extracts almost unbiased bits from any two independent PRB-sources, can be used for this purpose. Thus, our contribution in explicitly reducing the problem of “the robustness of BPP” to the problem of “extracting almost unbiased bits from two independent sources.”

**1.6. Organization.** In § 2, we present our basic definitions and results concerning the extraction of unbiased bits from sources of weak randomness. These results are the basis for the rest of the paper. Section 2.1 consists of definitions. In § 2.2, we present impossibility results. In § 2.3, we introduce the notion of flat distributions and demonstrate its importance. In § 2.4, we show that almost all functions extract unbiased bits from any two independent PRB-sources, and in § 2.5 we show that functions corresponding to Hadamard matrices also perform well.

Each of the next three sections is based on § 2 only, and can be read independently of the others. In § 3, we further study the problem of extracting unbiased bits from probability-bounded sources. In § 3.1, we analyze extraction schemes with respect to two efficiency measures: rate and computation complexity. In § 3.2, we present and analyze the “discrete logarithm” extraction scheme. In § 3.3, we consider extraction from slightly dependent sources. In § 3.4, we consider various extensions of our model and results.

In § 4, we present results concerning probabilistic communication complexity. In § 4.1, we present old and new definitions of probabilistic communication complexity. In § 4.2, we prove linear lower bounds on the communication complexity of functions, and in § 4.3 we present almost-matching upper bounds. In § 4.4, we suggest and investigate a robust notion of communication complexity.

In § 5, we deal with the robustness of BPP with respect to probability-bounded sources.

**2. Extracting unbiased bits—Part I.** In this section we present our basic definitions and results concerning the extraction of unbiased bits from sources of weak randomness. These results will be the basis for our more advanced study of the efficiency of extraction schemes, as well as our results concerning communication complexity and the robustness of BPP. In § 2.1, we define probability bounded sources (distributions) and robust extraction schemes. In § 2.2, we present impossibility results which will be used later to demonstrate the optimality of our positive results. In § 2.3, we introduce the notion of flat distributions and demonstrate its importance. In § 2.4, we use a counting

argument to prove the existence of good extraction schemes. In § 2.5, we show that functions corresponding to Hadamard matrices constitute good extraction schemes.

**2.1. Definitions.** The first two definitions are used to characterize the PRB-sources.

**DEFINITION 1.** Let  $l$  be a positive integer, and  $b > 0$  a real number. Let  $X$  be a random variable assuming values in  $\{0, 1\}^l$ . We say that  $X$  is  $(l, b)$ -distributed if for every  $\alpha \in \{0, 1\}^l$ , the probability that  $X = \alpha$  is  $\leq 2^{-b}$ .

**DEFINITION 2.** Let  $X_1, X_2, \dots, X_t$  be a sequence of random variables, each assuming values in  $\{0, 1\}^l$ . The random variable  $X_t$  is  $(l, b)$ -distributed given  $X_1, \dots, X_{t-1}$  if for every  $\alpha \in \{0, 1\}^{(t-1) \cdot l}$  and  $\beta \in \{0, 1\}^l$ ,  $\Pr(X_t = \beta \mid X_1 \cdots X_{t-1} = \alpha) \leq 2^{-b}$ .

An  $(l, b)$ -source is an infinite sequence of random variables  $X_1, X_2, X_3 \cdots$  each assuming values in  $\{0, 1\}^l$  such that for every  $t$ , the random variable  $X_t$  is  $(l, b)$ -distributed given the values of the variables  $X_1$  through  $X_{t-1}$ .<sup>1</sup> Unless otherwise stated, all distributions are conditioned on the entire past.

The next definitions will be used in evaluating the quality of the extracted bits.

**DEFINITION 3.** Let  $Z$  be a random variable assuming values in  $\{0, 1\}^m$ .  $Z$  is said to be  $\epsilon$ -robust if for every  $\alpha \in \{0, 1\}^m$ ,

$$(1 - \epsilon) \cdot 2^{-m} \leq \Pr(Z = \alpha) \leq (1 + \epsilon) \cdot 2^{-m}.$$

**DEFINITION 4.** Let  $X_1, X_2, \dots, X_s$  be  $s$  independent random variables, each assuming values in  $\{0, 1\}^l$ . A function  $f: \{0, 1\}^{s \cdot l} \rightarrow \{0, 1\}^m$  is said to be  $\epsilon$ -robust on  $X_1, X_2, \dots, X_s$  if the random variable  $Z \stackrel{\text{def}}{=} f(X_1, X_2, \dots, X_s)$  is  $\epsilon$ -robust.

A function  $f: \{0, 1\}^{s \cdot l} \rightarrow \{0, 1\}^m$  is said to be  $\epsilon$ -robust with respect to properties  $P_1, P_2, \dots, P_s$  if  $f$  is  $\epsilon$ -robust on every  $s$  independent random variable  $X_1, X_2, \dots, X_s$ , satisfying  $P_1, P_2, \dots, P_s$ , respectively.

**2.2. Impossibility results.** It is no surprise that one probability-bounded source cannot be used to generate unbiased bits, since probability-bounded sources include SV-sources for which an impossibility result was shown [27]. Yet, a stronger impossibility result holds for our model.

**THEOREM 1.** Let  $k \geq 1$  be an integer, and  $f: \{0, 1\}^{k \cdot l} \rightarrow \{0, 1\}$  be a Boolean function. Then there exists a  $\sigma \in \{0, 1\}$  and a sequence of  $k$  random variables  $X_1, X_2, \dots, X_k$ , each  $(l, l-1)$ -distributed given the previous ones, such that  $f(X_1 X_2 \cdots X_k)$  is identically  $\sigma$ .

*Proof.* The proof is by induction on  $k$ . For the base case  $k = 1$ , assume without loss of generality, that  $f$  attains the value 1 on at least half the inputs. Setting  $X_1$ 's probability distribution to be uniform on these inputs and 0 otherwise,  $f(X_1)$  is identically 1. By the induction hypothesis, for every  $\alpha \in \{0, 1\}^l$ , there is a  $\sigma \in \{0, 1\}$  such that the function  $f_\alpha(X_2, \dots, X_k) = f(\alpha, X_2, \dots, X_k)$  can be made identically  $\sigma$ . Without loss of generality, for at least half the  $\alpha$ 's,  $f_\alpha$  can be made identically 1. When we set  $X_1$ 's probability distribution to be uniform on these  $\alpha$ 's and 0 elsewhere, the theorem follows.  $\square$

While a single source cannot be used at all, there is a lower bound on the robustness of functions applied to the output of two probability-bounded sources. We start with a combinatorial lemma.

**LEMMA 2.** Let  $M$  be an  $L \times N$  Boolean matrix. Then there exists a  $\sigma \in \{0, 1\}$  and an  $L/16 \times N/2$  submatrix of  $M$  containing at least  $\frac{1}{2} \cdot (L/16)(N/2 + \sqrt{N/2})$   $\sigma$ -entries.

*Proof.* Without loss of generality, at least half the rows contain at least half 1's. We restrict ourselves to these  $L/2$  rows. Fix any such row, pick  $N/2$  columns at random, and let  $P$  denote the probability that at least  $T = \frac{1}{2}(N/2 + \sqrt{N/2})$  of the

<sup>1</sup> This definition is somewhat less restrictive than the one sketched in the Introduction.

corresponding entries are 1's. Clearly,  $P$  is minimized when each of these rows contains exactly  $N/2$  ones. In that case  $P$  is the tail of a hypergeometric distribution, and by Uhlmann (see [16, Chap. 6, § 5, p. 151]) is bounded below by the corresponding tail of the binomial distribution. That is,

$$P \geq 2^{-N/2} \sum_{i=T}^{N/2} \binom{N/2}{i}.$$

This last expression can be approximated by the normal distribution, and in particular is bounded below by  $1 - \Phi(1) \geq 1 - 0.8413 > \frac{1}{8}$ . By standard probabilistic arguments, this implies that there is a choice of  $N/2$  columns and  $\frac{1}{8} \cdot L/2 = L/16$  rows which have the desired proportion of 1's.  $\square$

**THEOREM 3.** *Let  $b \leq l - 1$ , and  $f: \{0, 1\}^{2^l} \mapsto \{0, 1\}$  be an arbitrary Boolean function. Then there exist a  $\sigma \in \{0, 1\}$  and two independent random variables  $X$  and  $Y$ , such that  $X$  is  $(l, l - 4)$ -distributed  $Y$  is  $(l, b)$ -distributed, and  $\Pr(f(X, Y) = \sigma) > \frac{1}{2}(1 + 2^{-b/2})$ .*

*Proof.* View  $f$  as a  $2^l$ -by- $2^l$  Boolean matrix, with the  $(i, j)$ th entry specifying  $f(i, j)$ . Let  $L = 2^l$  and  $N = 2^{b+1}$ . Applying Lemma 2 to an arbitrary  $L$ -by- $N$  submatrix  $S$ , there exist a  $\sigma$  and a  $2^{l-4}$ -by- $2^b$  submatrix  $S'$  of  $S$  with a fraction  $\frac{1}{2}(1 + 2^{-b/2})$  of  $\sigma$ -entries. Making  $X$  flat on the rows of  $S'$ , and  $Y$  flat on its columns, we get the desired result.  $\square$

The above argument was based on estimating the probability that the number of ones in randomly selected columns is at least one standard deviation away from the mean. One can consider the probability that this number is several standard deviations away from the mean. This yields a bigger bias but fewer rows, and thus a more concentrated  $X$ . Thus, for every constant  $\nu$  and sufficiently large  $b$ , there exists  $\sigma \in \{0, 1\}$  such that  $\Pr(f(X, Y) = \sigma) > \frac{1}{2}(1 + 2^{-(b-\nu)/2})$ .

When  $b$  is very small, the situation is even worse.

**THEOREM 4.** *Let  $b \leq \log_2(1 - \log_2 l) - 1$ , and  $f: \{0, 1\}^{2^l} \mapsto \{0, 1\}$  be an arbitrary Boolean function. Then there exist a  $\sigma \in \{0, 1\}$  and two independent random  $(l, b)$ -distributed variables  $X$  and  $Y$ , such that  $\Pr(f(X, Y) = \sigma) = 1$ .*

The statement here is actually a (slightly weaker) version of a known Ramsey type theorem that every  $n \times n$  Boolean matrix contains a monochromatic  $t \times t$  submatrix, where  $t \approx \log_2 n - \log_2 \log_2 n$ .

*Proof.* Consider (arbitrarily) the first  $r \stackrel{\text{def}}{=} 2^{b+1}$  columns in the  $2^l \times 2^l$  matrix of  $f$ . This defines a  $2^l \times r$  submatrix. There is an  $r$ -bit string which occurs in at least  $2^l/2^r$  rows of the submatrix. Pick these rows. Let  $\sigma \in \{0, 1\}$  be a bit which occurs  $t \geq r/2$  times in each of these rows. Picking the  $t$  columns containing  $\sigma$ , we get a  $2^{l-r} \times t$  submatrix with identical entries  $\sigma$ . As  $2^{l-r} > 2^b$  and  $t \geq 2^b$ , this submatrix corresponds to a pair of  $(l, b)$ -distributed variables.  $\square$

**2.3. Flat distributions.** In this section we introduce the notion of flat distributions. The importance of this notion stems from two facts. First, as we will shortly show, the worst behaviour of extraction functions occurs on flat distributions. Second, as demonstrated through the paper, flat distributions are very easy to deal with.

**DEFINITION 5.** Let  $X$  be a random variable assuming values in  $\{0, 1\}^l$ , and  $S \subset \{0, 1\}^l$ . We say that  $X$  is *equiprobable on  $S$*  if for every  $\alpha, \beta \in S$ ,

$$\Pr(X = \alpha) = \Pr(X = \beta).$$

We say that  $X$  is *flat on  $S$*  if  $X$  is equiprobable on  $S$  and for  $\alpha \notin S$ ,  $\Pr(X = \alpha) = 0$ . We say that  $X$  is  *$(l, b)$ -flat* if  $X$  is  $(l, b)$ -distributed and there exists some  $S$  such that  $X$  is flat on  $S$ .

For simplicity, we assume throughout this section that  $2^b, 2^{b_1}$  and  $2^{b_2}$  are integers. Flat distributions are interesting because the “worst-case behaviour” of a function occurs on them. Namely,

LEMMA 5. For every function  $f: \{0, 1\}^{2l} \mapsto \{0, 1\}^m$  and every  $\alpha \in \{0, 1\}^m$

$$\sup_{\substack{X, Y \text{ are independent} \\ X \text{ is } (l, b_1)\text{-distributed} \\ Y \text{ is } (l, b_2)\text{-distributed}}} \{\Pr(f(X, Y) = \alpha)\} = \max_{\substack{X, Y \text{ are independent} \\ X \text{ is } (l, b_1)\text{-flat} \\ Y \text{ is } (l, b_2)\text{-flat}}} \{\Pr(f(X, Y) = \alpha)\}$$

and

$$\inf_{\substack{X, Y \text{ are independent} \\ X \text{ is } (l, b_1)\text{-distributed} \\ Y \text{ is } (l, b_2)\text{-distributed}}} \{\Pr(f(X, Y) = \alpha)\} = \min_{\substack{X, Y \text{ are independent} \\ X \text{ is } (l, b_1)\text{-flat} \\ Y \text{ is } (l, b_2)\text{-flat}}} \{\Pr(f(X, Y) = \alpha)\}.$$

*Proof.* Denote  $p_i = \Pr(X = i)$  and  $q_j = \Pr(Y = j)$ . Let  $f_\alpha(i, j) = 1$  if  $f(i, j) = \alpha$  and 0 otherwise. Then

$$\begin{aligned} P_\alpha(X, Y) &\stackrel{\text{def}}{=} \Pr(f(X, Y) = \alpha) \\ &= \sum_{i,j} \Pr(X = i, Y = j) \cdot f_\alpha(i, j) \\ &= \sum_{i,j} p_i q_j f_\alpha(i, j). \end{aligned}$$

The last equality follows from the independence of  $X$  and  $Y$ .  $P_\alpha(X, Y)$  is a function of the variables  $p_i, q_j$ , and it attains a global maximum in the range  $0 \leq p_i \leq 2^{-b_1}, 0 \leq q_j \leq 2^{-b_2}, \sum_i p_i = \sum_j q_j = 1$ . We look for a characterization of this global maximum. Fixing the probability distribution of  $X$  (i.e., fixing the  $p_i$ 's),  $P_\alpha(X, Y)$  is a linear program in the  $q_j$ 's, subject to the constraints  $0 \leq q_j \leq 2^{-b_2}$  and  $\sum_j q_j = 1$ . (For basic linear programming terminology consult [22, Chap. 2].) One can verify that every basic feasible solution has exactly  $2^{b_2}$  nonzero variables  $q_j$ , each equals  $2^{-b_2}$ . Thus, we have shown that for every fixed  $X$ , flat distributions are among the distributions which maximize/minimize the value  $P_\alpha(X, Y)$ , over all possible choices of  $(l, b)$ -distributions for  $Y$ . The same obviously holds for fixed  $Y$ . Now let  $X_0, Y_0$  be the pair of  $(l, b_1)$ -distribution and  $(l, b_2)$ -distribution where  $P_\alpha(X, Y)$  attains its maximum. Then both  $X_0$  and  $Y_0$  must be flat. Note that the characterization holds for *any* function  $f$ .  $\square$

We demonstrate the utility of Lemma 5 by using it to argue that the following Boolean function  $f: \{0, 1\}^2 \times \{0, 1\}^2 \mapsto \{0, 1\}$  (tabulated below) is  $\frac{1}{2}$ -robust with respect to all pairs of independent  $(2, 1)$ -distributed variables.

$X \setminus Y$	00	01	10	11
00	0	0	1	1
01	1	0	0	1
10	0	1	0	1
11	1	0	1	0

Using Lemma 5, it suffices to consider the behaviour of the function on all pairs of independent  $(2, 1)$ -flat variables. There are  $6^2 = 36$  possibilities altogether, each corresponding to a  $2 \times 2$  submatrix of this table. It is readily verified that no such

submatrix contain all 1's (or all 0's). Thus, for every pair of independent  $(2, 1)$ -distributed variables,  $X$  and  $Y$ , we have  $\frac{1}{4} \leq \Pr(f(X, Y) = 1) \leq \frac{3}{4}$ .

**2.4. A counting argument.** In this section we show that two independent probability-bounded sources can be used to get almost-unbiased bits. In fact we show that almost all functions can be used for this purpose. To this end, we use the characterization of the distributions on which the “worst-case behaviour” of any function occurs (i.e., Lemma 5), and apply a counting argument to estimate the fraction of functions which are good with respect to all flat distributions.

It is helpful to note that there is a natural correspondence between flat distributions and the set of strings on which they are concentrated. This suggests the following notation: Let  $Z$  be an arbitrary fixed  $(l, b)$ -flat variable. We write  $z \in S_Z$  if  $\Pr(Z = z) = 2^{-b}$ .

In the next lemma we consider two fixed and independent flat variables, and bound below the fraction of functions which are  $\epsilon$ -robust for these two *specific* variables.

LEMMA 6. *Let  $X$  and  $Y$  be two independent distributions, such that  $X$  is  $(l, b_1)$ -flat and  $Y$  is  $(l, b_2)$ -flat, and  $0 < \epsilon < \frac{1}{2}$ . The fraction of functions  $f: \{0, 1\}^{2l} \mapsto \{0, 1\}^m$ , which are  $\epsilon$ -robust on  $X$  and  $Y$ , is at least  $1 - 2^{m - \epsilon 2^{2b_1 + b_2 - m - 2}}$ .*

*Proof.* We say that a function  $f: \{0, 1\}^{2l} \mapsto \{0, 1\}^m$  is  $\epsilon$ -bad on the string  $\alpha$  ( $\alpha \in \{0, 1\}^m$ ) if

$$\frac{|\{(x, y) \in S_X \times S_Y : f(x, y) = \alpha\}|}{2^{b_1 + b_2}} \notin [(1 - \epsilon) \cdot 2^{-m}, (1 + \epsilon) \cdot 2^{-m}].$$

Let  $P_{\alpha, \epsilon}$  denote the fraction of functions which are  $\epsilon$ -bad on the string  $\alpha$ . To study  $P_{\alpha, \epsilon}$  we consider the probability space of the functions in  $f: \{0, 1\}^{2l} \mapsto \{0, 1\}^m$  taken with uniform distribution. For each  $i \in S_X$  and  $j \in S_Y$ , let the random variables  $\zeta_{ij}$  be defined as follows:

$$\zeta_{ij} = \begin{cases} 1 & \text{if } f(i, j) = \alpha, \\ 0 & \text{otherwise.} \end{cases}$$

Then

$$P_{\alpha, \epsilon} = \Pr \left( \frac{1}{2^{b_1 + b_2}} \left| \sum_{i \in S_X, j \in S_Y} \left( \zeta_{ij} - \frac{1}{2^m} \right) \right| \geq \frac{\epsilon}{2^m} \right).$$

Recall the Chernoff Bound [26, Chap. VII, § 4, Thm. 2]: Let  $\zeta_1, \zeta_2, \dots, \zeta_t$  be independent random variables with  $\Pr(\zeta_i = 1) = p$  and  $\Pr(\zeta_i = 0) = 1 - p$ , where  $p \leq \frac{1}{2}$ . Then for all  $0 < \delta \leq p(1 - p)$  we have

$$\Pr \left( \frac{1}{t} \cdot \left| \sum_{i=1}^t (\zeta_i - p) \right| \geq \delta \right) \leq 2 \cdot \exp \left[ - \frac{t\delta^2}{2p(1-p) \left( 1 + \frac{\delta}{2p(1-p)} \right)^2} \right].$$

Letting  $p = 2^{-m}$ ,  $t = 2^{b_1 + b_2}$  and  $\delta = 2^{-m} \cdot \epsilon$ , we get

$$P_{\alpha, \epsilon} < \exp \left[ - \frac{1}{4} \epsilon^2 2^{b_1 + b_2 - m} \right].$$

Switching to base 2 and summing over all possible  $\alpha$ 's, the probability that a function  $f: \{0, 1\}^{2l} \mapsto \{0, 1\}^m$  is  $\epsilon$ -bad on some  $\alpha \in \{0, 1\}^m$  is at most

$$\sum_{\alpha \in \{0, 1\}^m} P_{\alpha, \epsilon} < 2^{m - \epsilon^2 2^{b_1 + b_2 - m - 2}}$$

The lemma follows.  $\square$

We are now ready to prove that almost all functions work.

**THEOREM 7.** *Let  $1 \leq m \leq b$  be an integer, and  $0 < \varepsilon \leq \frac{1}{2}$ . Let  $F$  be the set of functions  $f: \{0, 1\}^{2l} \mapsto \{0, 1\}^m$ .*

(1) *Let  $G_{b,\varepsilon} \subset F$  the set of functions which are  $\varepsilon$ -robust for any two independent  $(l, b)$ -distributed random variables. If  $m + 2 \log_2 \varepsilon^{-1} \leq b - 2 - \log_2(2l + 1)$  then*

$$\frac{|G_{b,\varepsilon}|}{|F|} > 1 - 2^{-2^b}.$$

(2) *Let  $H_{b,\varepsilon} \subset F$  the set of functions which are  $\varepsilon$ -robust for any two independent random variables which are  $(l, b_1)$ -distributed and  $(l, b_2)$ -distributed, respectively, where  $b_1 + b_2 \geq 2b$ . If  $m + 2 \log_2 \varepsilon^{-1} \leq 2b - l - 5$  then*

$$\frac{|H_{b,\varepsilon}|}{|F|} > 1 - 2^{-2^l}.$$

*Proof.* For part (1), by Lemma 5,  $f \in G_{b,\varepsilon}$  if and only if it is  $\varepsilon$ -robust for every two independent  $(l, b)$ -flat random variables. By Lemma 6, the fraction of functions in  $F$  which fail on a particular pair of independent  $(l, b)$ -flat variables is double-exponentially vanishing ( $< 2^{m - \varepsilon^2 2^{2b - m - 2}}$ ). Evidently, the fraction of functions which could fail on some pair of independent  $(l, b)$ -flat variables, is at most the number of pairs of  $(l, b)$ -flat variables times the above fraction. Let  $N_b$  denote the number of  $(l, b)$ -flat variables. Clearly

$$N_b = \binom{2^l}{2^b} < \frac{2^{l \cdot 2^b}}{2^b}.$$

Thus,

$$\frac{|G_{b,\varepsilon}|}{|F|} \geq 1 - N_b^2 \cdot 2^{m - \varepsilon^2 2^{2b - m - 2}} > 1 - 2^{2^b \cdot (2l - \varepsilon^2 2^{2b - m - 2})}.$$

Since  $m + 2 \log_2 \varepsilon^{-1} \leq b - 2 - \log_2(2l + 1)$ , we get  $2l - \varepsilon^2 2^{b - m - 2} \leq -1$ , and (1) follows.

Part (2): For every fixed  $b_1$  and  $b_2$ , the fraction of functions in  $F$  which fail on a particular pair of independent variables which are  $(l, b_1)$ -flat and  $(l, b_2)$ -flat resp., is  $< 2^{m - \varepsilon^2 2^{b_1 + b_2 - m - 2}}$ . We multiply this fraction by  $(2^{2^l})^2 = 2^{2^{l+1}}$ , which is an obvious upper bound on the number of possible pairs of flat variables. We get

$$\frac{|H_{b,\varepsilon}|}{|F|} \geq 1 - 2^{2^{l+1}} \cdot 2^{m - \varepsilon^2 2^{2b - m - 2}} > 1 - 2^{2^{l+1} + m - \varepsilon^2 2^{2b - m - 2}}.$$

Since  $m + 2 \log_2 \varepsilon^{-1} \leq 2b - l - 5$ , we get  $2^{l+1} + m - \varepsilon^2 2^{2b - m - 2} \leq -2^l$ , and (2) follows.  $\square$

There is a trade-off between  $m$ , the number of extracted bits, and  $\varepsilon$ , the robustness of these bits. Some cases of special interest are listed below:

(1) Setting  $m = b - 4 - \log_2(2l + 1)$  and  $\varepsilon = \frac{1}{2}$ , we convert two independent  $(l, b)$ -sources to a single  $(m, m - 1)$ -source. Intuitively, this conversion is very efficient in terms of rate: even if the entropy of the input sources is  $b$  units per each block, we extract a block of  $\approx b$  bits with entropy  $\approx b$ .

(2) Setting  $m = (b - 2 - \log_2(2l + 1))/3$  and  $\varepsilon = 2^{-m}$ , we see that most functions can be used to extract many high-quality bits per each block of the two independent  $(l, b)$ -sources.

(3) Setting  $m = 1$  and  $\varepsilon = 2^{-(b - 3 - \log_2(2l + 1))/2}$ , we see that all but a  $2^{-2^b}$  fraction of the Boolean functions are  $\varepsilon$ -robust with respect to two independent  $(l, b)$ -sources. This bias is almost optimal: Theorem 3 states that no Boolean function can be

$2^{-(b-O(1))/2}$ -robust with respect to such sources. Theorem 4 asserts that “nothing can be extracted” if  $b < \log_2(l - \log_2 l) - 1$ .

(4) Setting  $m = 1$  and  $\epsilon = 2^{-(2b-6-l)/2}$ , we see that all but a  $2^{-2^l}$  fraction of the Boolean functions are  $\epsilon$ -robust for any pair of  $(l, b_1), (l, b_2)$  sources satisfying  $b_1 + b_2 = 2b$ .

**2.5. Hadamard matrices.** In § 2.3 we showed that the bias of a Boolean function  $f: \{0, 1\}^{2^l} \mapsto \{0, 1\}$  with respect to two independent  $(l, b)$ -sources, can be estimated by considering flat distributions only. Viewing  $f$  as a  $2^l \times 2^l$  matrix of  $\pm 1$ , this corresponds to taking all  $2^b \times 2^b$  submatrices of  $f$  (not necessarily consecutive), and estimating the maximum submatrix elements’ sum. While in the previous section we showed that most functions have a small submatrix sum, this section deals with a specific class of functions, whose matrices are Hadamard matrices.

A *Hadamard matrix* is a  $\pm 1$  matrix in which every two distinct rows (columns) are orthogonal (see [14, Chap. 14] and [17, Chap 2, § 3]). Hadamard matrices are a subject of rich literature. In particular it is well known that submatrices of any Hadamard matrix are “balanced.” In order to make the paper self-contained, we present a proof of this fact, following Erdős and Spencer [12, p. 88].

LEMMA 8 (J. H. Lindsey). *Let  $H = (h_{i,j})$  be a  $t \times t$  Hadamard matrix. Then the sum of elements in every  $r \times s$  submatrix of  $H$  is at most  $\sqrt{s} \cdot r \cdot t$ .*

Lindsey’s lemma, as it appears in [12, p. 88], is only a special case of Lemma 8 (although the proof generalizes easily). The lemma as it appears here, with a slightly different proof, appears in [4].

*Proof.* Since orthogonality is preserved under any row and column permutation, it suffices to consider  $|\sum_{i=1}^r \sum_{j=1}^s h_{i,j}|$ , the sum of elements in the leftmost/uppermost  $r \times s$  submatrix. Let  $\vec{h}_i$  denote the  $i$ th row of  $H$ , and

$$\vec{I} \stackrel{\text{def}}{=} (\overbrace{1, 1, \dots, 1}^{s \text{ ones}}, \overbrace{0, 0, \dots, 0}^{t-s \text{ zeros}}).$$

Then by the Cauchy-Schwartz inequality

$$\begin{aligned} \left| \sum_{i=1}^r \sum_{j=1}^s h_{i,j} \right| &= \left| \sum_{i=1}^r \vec{h}_i \cdot \vec{I} \right| \\ &\leq \left\| \sum_{i=1}^r \vec{h}_i \right\|_2 \cdot \|\vec{I}\|_2 \\ &= \left\| \sum_{i=1}^r \vec{h}_i \right\|_2 \cdot \sqrt{s}. \end{aligned}$$

Since the  $\vec{h}_i$  are orthogonal,

$$\left\| \sum_{i=1}^r \vec{h}_i \right\|_2 = \sqrt{\sum_{i=1}^r \|\vec{h}_i\|_2^2} = \sqrt{r \cdot t}$$

and the bound on  $|\sum_{i=1}^r \sum_{j=1}^s h_{i,j}|$  follows.  $\square$

THEOREM 9. *Let  $M$  be an  $2^l \times 2^l$  Hadamard matrix corresponding to the Boolean function  $f$  (i.e.,  $f(i, j) = \frac{1}{2}(1 + M_{i,j})$ ). Suppose  $b_1 + b_2 \geq l + 2 + 2 \log_2 \epsilon^{-1}$ , where  $\epsilon < 1$ . Then the function  $f$  is  $\epsilon$ -robust with respect to any pair of independent random variables  $X, Y$  which are  $(l, b_1)$ -distributed and  $(l, b_2)$ -distributed, respectively.*

*Proof.* By Lemma 5, it suffices to show that every  $2^{b_1} \times 2^{b_2}$  submatrix has a relatively small elements’ sum. Substituting in Lemma 8,  $r = 2^{b_1}$ ,  $s = 2^{b_2}$  and  $t = 2^l$ , the submatrix sum is at most  $(\epsilon/2) \cdot 2^{b_1+b_2}$ .  $\square$

Subsequently Noga Alon proved a more general statement (without using Lemma 5) [3].

*Remarks.* (1) The case where  $b_2 = l - 1$  will be useful in § 5. We get that any Hadamard matrix is  $2^{-(b-3)/2}$ -robust with respect to any pair of independent random variables which are  $(l, l - 1)$ -distributed and  $(l, b)$ -distributed, respectively.

(2) Inner-product modulo 2 corresponds to a special form of Hadamard matrices, known as Sylvester matrices. This provides an alternative proof for Vazirani’s Theorem [29], for the case  $\delta > 1 - \sqrt{1/2} \approx 0.293$  (but not for smaller  $\delta$ ’s).

For inner-product modulo 2, Theorem 9 cannot be significantly improved (with respect to probability bounded sources).

**PROPOSITION 10.** *Let  $b_1 + b_2 \leq l - 4 + 2 \log_2 \varepsilon^{-1}$ , where  $\varepsilon < 1$ . Then the inner-product modulo 2 function is not  $\varepsilon$ -robust on some pair of independent,  $(l, b_1)$ -distributed and  $(l, b_2)$ -distributed variables.*

*Proof.* First, consider the case where  $b_1 + b_2 \leq l$ . Picking  $X$  to be flat on strings of the form  $0^{l-b_1}\{0, 1\}^{b_1}$  and  $Y$  to be flat on  $\{0, 1\}^{b_2}0^{l-b_2}$  the inner product of  $X$  and  $Y$  is identically 0. For the case  $b_1 + b_2 > l$ , repeating exactly the same construction does not yield the desired bias. However, we can modify it using Theorem 3. Let  $\Delta \stackrel{\text{def}}{=} b_1 + b_2 - l$ . Consider the following family of  $(l, b_1)$ -distributed variables  $\mathcal{X}$ . Each variable  $X \in \mathcal{X}$  is the concatenation of three independent variables  $X_1, X_2, X_3$ , where  $X_1$  is uniformly distributed over  $\{0, 1\}^{b_1 - \Delta - 4}$ ,  $X_2$  is  $(\Delta + 8, \Delta + 4)$ -distributed, and  $X_3$  has  $l - b_1 - 4$  bits which are identically 0. Similarly,  $Y = Y_1 Y_2 Y_3 \in \mathcal{Y}$  satisfies  $Y_1$  is identically  $0^{l-b_2-4}$ ,  $Y_2$  is  $(\Delta + 8, \Delta + 4)$ -distributed, and  $Y_3$  is uniformly distributed over  $\{0, 1\}^{b_2 - \Delta - 4}$ . For every pair  $X \in \mathcal{X}$  and  $Y \in \mathcal{Y}$ , the inner product of  $X$  and  $Y$  equals the inner product of  $X_2$  and  $Y_2$ . Since both  $X_2$  and  $Y_2$  could be any  $(\delta + 8, \delta + 4)$ -distributed variables, by Theorem 3 their inner product may have bias  $> \frac{1}{2}(1 + 2^{-(\delta+4)/2}) = \frac{1}{2}(1 + 2^{(l-b_1-b_2-4)/2})$ . Thus, for  $\varepsilon \leq 2^{(l-b_1-b_2-4)/2}$ , the function is not  $\varepsilon$ -robust.  $\square$

The last proposition demonstrates an inherent limitation of the inner-product function with respect to  $(l, b)$ -distributions when  $b \leq l/2$ . This limitation need not be shared by all Hadamard matrices. In fact, a simple construction, known as *the Paley Graph*, is conjectured in the combinatorial folklore to have a stronger imbalance (small submatrix sum) property.

Let  $p$  be a prime, and  $\binom{i}{p}$  be the Legendre symbol of the residue  $i \pmod p$ . The matrix  $M$  with  $M_{i,j} = \binom{i-j}{p}$  is “almost” Hadamard [17, p. 47], as for any  $0 \leq a < b \leq p - 1$ ,

$$\sum_{i=0}^{p-1} \binom{i-a}{p} \cdot \binom{i-b}{p} = -1.$$

Thus, with minor modifications, Theorem 9 applies also to the matrix  $M$ .

**CONJECTURE.** For any constant  $0 < \mu < 1$ , there exists a constant  $1.5\mu < c_\mu < 2\mu$  such that every  $p^\mu \times p^\mu$  submatrix of  $M$  has elements’ sum at most  $p^{c_\mu}$ , for large enough  $p$ .

*Remark.* By Theorem 3, the constant  $c_\mu$  must satisfy  $c_\mu > 1.5\mu$ .

**COROLLARY 11.** *Let  $f(i, j) = \frac{1}{2} \cdot (1 + \binom{i-j}{p})$ . Under the Paley Graph conjecture, the function  $f$  is  $p^{c_\mu - 2\mu}$ -robust with respect to any pair of independent  $(\log_2 p, \mu \cdot \log_2 p)$ -distributed random variables.*

**3. Extracting unbiased bits—Part II.** In this section we further investigate the problem of extracting unbiased bits from probability-bounded sources. In § 3.1, we introduce two efficiency measures: rate and computation complexity and consider extraction schemes, arising from our results, with respect to these measures. In § 3.2, we present and analyze the discrete logarithm extraction scheme (this result did not

appear in the preliminary version of this paper [9]). In § 3.3, we consider extraction from slightly dependent sources. In § 3.4, we further extend the probability-bounded model: we consider sources with lower bound on entropy, and sources with varying block length and probability bound.

**3.1. Efficiency considerations.** Before going any further, let us discuss the significance of the results presented in § 2. A first consequence is that it is possible to generate a sequence of almost-unbiased and independent bits from the output of two independent probability-bounded sources. Once the question of possibility is resolved, we are interested in the efficiency of the extraction schemes. We consider two measures—*rate* and *computational complexity*—both with respect to the desired robustness.

**3.1.1. Efficiency measures.** In § 2, we have considered functions which operate on corresponding  $l$ -bit blocks of two  $(l, b)$ -sources. In order to improve the robustness, we now consider deterministic algorithms (families of functions) which may use several blocks from each  $(l, b)$ -source at a time. Given a “robustness parameter”  $n$ , the algorithm will output bits with bias in the range  $\frac{1}{2} \pm \varepsilon(n)$ . The number of blocks used by the algorithm will typically increase with  $n$ . Of special interest is the case where  $\varepsilon^{-1}(n)$  grows faster than any polynomial. In this case the extracted bits are as good as perfect bits for all “poly( $n$ )-time purposes.”

In the following definition of an extraction scheme,  $\varepsilon(n)$  denotes the robustness of the scheme,  $s(n)$  denotes the number of bits taken from each source,  $e(n)$  denotes the number of extracted bits, and  $c$  denotes the number of  $(l, b)$ -sources used.

**DEFINITION 6.** Let  $\varepsilon$  be a function from integers to the interval  $(0, 1)$ , and  $s, e$  be functions from integers to integers. Let  $c, l$  be integers and  $b$  ( $0 \leq b \leq l$ ) be real. An  $(\varepsilon(\cdot), s(\cdot), e(\cdot), l, b, c)$ -*extraction scheme* is a family of functions  $\{f_n\}$  such that for every  $n$  the following holds:

- (1) For every  $\alpha_1, \alpha_2, \dots, \alpha_c \in \{0, 1\}^{s(n)}$   $f_n(\alpha_1, \alpha_2, \dots, \alpha_c) \in \{0, 1\}^{e(n)}$ .
- (2) The function  $f_n: \{0, 1\}^{c \cdot s(n)} \rightarrow \{0, 1\}^{e(n)}$  is  $\varepsilon(n)$ -robust with respect to any  $c$  independent variables  $X_1, X_2, \dots, X_c$ , where each of the  $X_i$ 's is the first  $s(n)$  bits output by some  $(l, b)$ -source.

The efficiency of an algorithmic scheme should be evaluated with respect to the resources it uses. In the setting of randomness extraction schemes the resources to be considered are the amount of “randomness” in the input sources and the deterministic computation required to effect the extraction. We measure the efficiency with respect to the randomness resource by the ratio of the entropy entering the extraction scheme and the entropy leaving it.

**DEFINITION 7.** The *rate* of an  $(\varepsilon(\cdot), s(\cdot), e(\cdot), l, b, c)$ -extraction scheme is defined as

$$r(n) \stackrel{\text{def}}{=} \frac{e(n) \cdot H_O}{c \cdot s(n) \cdot H_I},$$

where  $H_O$  is the entropy of each output bit ( $H_O \approx 1 - \varepsilon^2(n)$ ), and  $H_I = b/l$  is a lower bound on the average entropy of each input bit. If there exists a constant  $r > 0$  such that for every  $n$ ,  $r(n) > r$ , then we say that the extraction scheme has *constant rate*.

For every  $n$ , the rate  $r(n)$  is the ratio of the input and output entropies to  $f_n$ . The entropy of the input is taken by the worst possible one since the extraction scheme cannot “adapt” to better sources without an explicit guarantee.

**DEFINITION 8.** The *computational complexity* of an extraction scheme,  $\{f_n\}$ , is defined as the complexity of a family of circuits  $\{C_n\}$  such that for every  $n$ , the circuit  $C_n$  implements  $f_n$ .

**3.1.2. Efficient extraction schemes.** We now present several extraction schemes, which follow immediately from the results presented in § 2, and analyze their performance with respect to the above efficiency measures. The following is a simple but important observation used in developing these schemes: for every integer  $q > 1$ , an  $(l, b)$ -source is also a  $(q \cdot l, q \cdot b)$ -source.

*A rate efficient scheme which is not computationally efficient.* One consequence of Theorem 7 is that for every  $l$  and  $b$  and every desired bias  $\varepsilon(\cdot)$ , there is a nonuniform circuit family  $\{C_n\}$  which extracts bits at constant rate from any two independent  $(l, b)$ -sources. This is obtained by letting  $s(n) = (3l/b) \log_2 \varepsilon^{-1}(n)$ ,  $e(n) = \log_2 \varepsilon^{-1}(n)$ , and using Theorem 7 with respect to two  $(s(n), (b/l) \cdot s(n))$ -sources. Since the entropy per input block is at least  $b$ , the rate is  $\approx 1/6$ . The size of  $C_n$  is  $\varepsilon^{-6l/b}(n) \cdot \log_2 \varepsilon^{-1}(n)$ .

*Computationally efficient schemes which do not have constant rate.* By Theorem 9, for every  $l$  and  $b > l/2$  and every desired bias  $\varepsilon(\cdot)$ , taking the binary inner product of  $l \cdot (b - l/2)^{-1} \log_2 \varepsilon^{-1}(n)$  bits from two independent  $(l, b)$ -sources, a single  $\varepsilon(n)$ -robust bit is extracted. While this yields an efficient algorithm, its rate is  $1/\theta(\log \varepsilon^{-1}(n))$ .

Under the number theoretic conjecture of § 2.5, efficient algorithms exist for *any*  $l$  and  $b$ . For every desired bias  $\varepsilon(\cdot)$ , let  $p > \varepsilon^{-C(l/b)}(n)$  be a prime (where  $C(\rho) > 0$  is a constant depending on  $\rho$ ). Taking  $\log_2 p$  bits from each of the two independent  $(l, b)$ -sources, and computing the Legendre symbol of their integer difference modulo  $p$ , we get an  $\varepsilon(n)$ -robust bit. The extracted bit can be computed by an algorithm running in time polynomial in  $\log_2 \varepsilon^{-1}(n)$  (and  $l/b$ ).

A direct consequence of Theorem 7 is that for every  $l$  and  $b > 5 + \log_2 l$  there exists a table of size  $2^{2l}$  which transforms two independent  $(l, b)$ -sources into one  $(m, m - 2^{-m})$ -source, where  $m = (b - 3 - \log_2 l)/3$ . In other words, we can transform two independent but very weak sources into one source which is quite good (although it is far from being “almost perfect”). For every bias  $\varepsilon(n)$ , using the inner-product function on the output of the virtual  $(m, m - 2^{-m})$ -source and a third independent  $(l, b)$ -source, we get the desired bias. We conclude that for every  $0 < b \leq l$  and  $\varepsilon(\cdot)$ , there is a fast algorithm (running in time  $O(\log_2 \varepsilon^{-1}(n))$ ) that on input  $n$  and access to three independent  $(l, b)$ -sources, generates  $\varepsilon(n)$ -robust bits.

The problem of finding an extraction scheme which combines both rate and computational efficiency was left open in our preliminary report [9]. This was true even for the SV-model. In the following section we present a solution to that problem.

**3.2. An extraction scheme efficient in both measures.** In this section we present an extraction scheme based on  $k$ th power residues modulo a prime. The scheme is efficient both in terms of information rate and computation complexity. This scheme is a generalization of the Paley graph construction, and was developed through conversations with László Babai. We begin this section by presenting the scheme. We then use results of Ajtai, Babai, Hajnal, Komlós, Pudlák, Rödl, Szemerédi and Turán [2] to show that the scheme has high robustness. To guarantee high information rate, our scheme uses large values of  $k$ , and is related to computing (partial) discrete logarithms in  $Z_p$ . We investigate the conditions under which the scheme is efficiently computable, and show that primes satisfying these conditions can be precomputed in expected polynomial time, given access to two probability-bounded sources.

**DEFINITION 9.** Let  $p$  be a prime,  $g$  a primitive element of  $Z_p$ , and  $k > 1$  an integer dividing  $p - 1$ . We define  $f_k: Z_p \times Z_p \mapsto \{0, 1, \dots, k - 1\}$  by  $f_k(x, y) = (\log_g(x - y)) \bmod k$ , where  $\log_g^t$  is the discrete logarithm of  $t$  to base  $g$  in  $Z_p$ .

*Comments.* (1) For  $\alpha \in \{0, 1, \dots, k - 1\}$ , let  $R_\alpha = \{g^{\alpha+ik}: 0 \leq i \leq (p - 1)/k\}$ . Then  $f_k(x, y) = \alpha$ , if and only if  $x - y = z$  for some  $z \in R_\alpha$ .

(2) By restricting the function to a subset of  $Z_p$ , the function  $f_k$  can be viewed as a function from  $\{0, 1\}^l \times \{0, 1\}^l$  to  $\{0, 1, \dots, k-1\}$ , for  $l = \lfloor \log_2 p \rfloor$ .

(3) The range of  $f_k$  is  $\{0, 1, \dots, k-1\}$ . Taking  $m = \lfloor \log_2 k \rfloor$ , the range of  $f_k$  can be viewed as  $\{0, 1\}^m \cup \{\perp\}$  (in case of  $\perp$ , the function is undefined). This causes at most a factor 2 loss in entropy.

To evaluate the robustness of  $f_k$ , we would like to have upper and lower bounds on  $\Pr(f(X, Y) = \alpha)$  for all pairs of independent  $(l, b_1)$ -distributed,  $(l, b_2)$ -distributed sources  $X, Y$ . By Lemma 5, it suffices to consider flat distributions. Therefore, we are interested in bounds on the number of solutions  $x - y = z$  for  $x \in A, y \in B, z \in R_\alpha$ , where  $A, B \subset Z_p$  are arbitrary subsets of size  $2^{b_1}, 2^{b_2}$ , respectively. Let  $\nu(A, B, \alpha)$  denote this number. Clearly,  $\nu(A, B, \alpha) = \nu(g^{-\alpha}A, g^{-\alpha}B, 0)$ , and thus it suffices to consider  $R_0$ , the set of  $k$ th residues modulo  $p$ .

Let  $\omega \in C$  ( $C$  denotes the complex field) be a primitive  $p$ th root of unity. Let  $\varphi_k(j) = \sum_{x \in R_0} \omega^{jx}$ , and  $\Phi_k = \max_{1 \leq j \leq p-1} |\varphi_k(j)|$ . A result of [2] relates  $\nu(A, B, \alpha)$  to the size of  $A, B$  via  $\Phi_k$ .

LEMMA 12 [2]. *Let  $A, B \subset Z_p$  be two arbitrary subsets, and  $\alpha$  an integer,  $0 \leq \alpha \leq (p-1)/k$ . Then*

$$\left| \nu(A, B, \alpha) - \frac{|A| \cdot |B|}{k} \right| \leq \Phi_k \sqrt{|A| \cdot |B|}.$$

The following bound on  $\Phi_k$  was given by László Babai (private communication).

LEMMA 13.  $\Phi_k < \sqrt{p}$ .

*Proof.* The proof uses methods of trigonometric sums over finite fields (see [28]).

We start by presenting some definitions and notation. An additive character of  $Z_p$  is a mapping  $\psi: Z_p \mapsto C$  satisfying  $\psi(a+b) = \psi(a) \cdot \psi(b)$ ; the unit character satisfies  $\psi_0(\cdot) = 0$ . A multiplicative character of  $Z_p$  is a mapping  $\chi: Z_p^* \mapsto C^*$  satisfying  $\chi(a \cdot b) = \chi(a) \cdot \chi(b)$ ; the unit character satisfies  $\chi_0(\cdot) = 1$  ( $\chi(0) \stackrel{\text{def}}{=} 0$  unless  $\chi = \chi_0$ ). A Gaussian sum  $S(\chi, \psi)$  is defined as  $\sum_{x \in Z_p} \chi(x)\psi(x)$ . It is well known [28, p. 47, Thm. 3A] that for  $\chi \neq \chi_0, \psi \neq \psi_0, |S(\chi, \psi)| = \sqrt{p}$ , while  $S(\chi_0, \psi) = 0$ .

Let  $\xi \in C$  be a primitive  $k$ th root of unity. For  $0 \leq t \leq k-1$ , define  $\chi_t: Z_p^* \mapsto C^*$  by  $\chi_t(x) = \xi^{t \log_g x}$ , then  $\chi_t$  is a multiplicative character,  $\chi_0$  is indeed the unit character and

- (1)  $x \in R_0 \Rightarrow \log_g x = ki \Rightarrow \chi_t(x) = 1,$
- (2)  $0 \neq x \notin R_0 \Rightarrow \log_g x = ki + \alpha \quad \text{for some } 1 \leq \alpha \leq k-1$   
 $\Rightarrow \sum_{t=0}^{k-1} \chi_t(x) = \sum_{t=0}^{k-1} (\xi^\alpha)^t = 0,$
- (3)  $x = 0 \Rightarrow \sum_{t=0}^{k-1} \chi_t(x) = 1.$

For  $1 \leq j \leq p-1$ , define  $\psi_j: Z_p \mapsto C$  by  $\psi_j(x) = \omega^{jx}$ , then  $\psi_j$  is an additive character  $\neq \psi_0$ . Using (1), (2) and (3), we get (for all  $j$ )

$$\begin{aligned} \sum_{t=0}^{k-1} S(\chi_t, \psi_j) &= \sum_{t=0}^{k-1} \sum_{x \in Z_p} \chi_t(x)\psi_j(x) \\ &= \sum_{x \in R_0} \omega^{jx} \sum_{t=0}^{k-1} \chi_t(x) + \sum_{0 \neq x \notin R_0} \omega^{jx} \sum_{t=0}^{k-1} \chi_t(x) + \sum_{t=0}^{k-1} \chi_t(0) \\ &= k \sum_{x \in R_0} \omega^{jx} + 1. \end{aligned}$$

Using the above-mentioned equalities for Gaussian sums, the last equality implies that for every  $1 \leq j \leq p-1$

$$\begin{aligned} |\varphi_k(j)| &= \left| \sum_{x \in \mathbb{R}_0} \omega^{jx} \right| = \frac{1}{k} \left| -1 + \sum_{t=0}^{k-1} S(\chi_t, \psi_j) \right| \\ &\leq \frac{1}{k} \left( 1 + \sum_{t=0}^{k-1} |S(\chi_t, \psi_j)| \right) \\ &= \frac{1}{k} (1 + 0 + (k-1)\sqrt{p}) \\ &< \sqrt{p}. \end{aligned} \quad \square$$

Reformulating these bounds in terms of sources and robustness, we get Theorem 14.

**THEOREM 14.** *Let  $p(n)$ ,  $k(n)$ ,  $l(n) = \lfloor \log_2 p(n) \rfloor$ ,  $f_{k(n)}$  be as above, and  $\varepsilon(n) > 0$ . Suppose  $b_1(n) + b_2(n) \geq l(n) + 1 + 2 \log_2 \varepsilon^{-1}(n) + 2 \log_2 k(n)$ . Then  $f_{k(n)}: Z_{p(n)} \times Z_{p(n)} \mapsto \{0, 1, \dots, k(n)-1\}$  is  $\varepsilon(n)$ -robust for any pair of independent,  $(l(n), b_1(n))$ -distributed,  $(l(n), b_2(n))$ -distributed sources.*

*Proof.* It suffices to consider flat sources  $X, Y$ . Let  $A \subset Z_{p(n)}$  be the set where  $\Pr(X = a) = 1/2^{b_1(n)}$  (similarly for  $B, Y, b_2(n)$ ). Then  $|A| = 2^{b_1(n)}$ ,  $|B| = 2^{b_2(n)}$ , and for every  $\alpha \in \{0, 1, \dots, k(n)-1\}$  we have

$$\Pr(f(X, Y) = \alpha) = \frac{\nu(A, B, \alpha)}{2^{b_1(n)} \cdot 2^{b_2(n)}}.$$

Combining Lemmas 12 and 13, we have

$$\frac{1}{k(n)} \left( 1 - k(n) \sqrt{\frac{p(n)}{2^{b_1(n)+b_2(n)}}} \right) < \Pr(f(X, Y) = \alpha) < \frac{1}{k(n)} \left( 1 + k(n) \sqrt{\frac{p(n)}{2^{b_1(n)+b_2(n)}}} \right).$$

Substituting  $p(n) < 2^{l(n)}$ ,  $b_1(n) + b_2(n) \geq l(n) + 1 + 2 \log_2 \varepsilon^{-1}(n) + 2 \log_2 k(n)$ , the claim follows.  $\square$

We now establish some relations between the various quantities above. We denote by  $n$  the security parameter, and parameterize by it the block length, the probability bounds, the prime  $p$ , the divisor of  $p-1$ ,  $k$  and the bias guarantee  $\varepsilon$  (that is, they will be denoted by  $l(n), b_1(n), b_2(n), p(n), k(n)$  and  $\varepsilon(n)$ , respectively). Typically,  $\varepsilon(n) = 1/n^{h(n)}$  where  $h(n) \geq 0$  is either a constant (the case of a polynomial bias) or a function tending to  $\infty$  with  $n \rightarrow \infty$  (the case of a subpolynomial bias).

The information rate of the scheme is  $\approx \log k(n)/2 \log p(n)$ . Therefore, in order to guarantee a constant rate,  $k(n)$  must be  $> p(n)^d$  for some constant  $d, 0 < d < 1$ . We will typically use  $\frac{3}{16} \leq d \leq \frac{1}{4}$ . Assuming  $b_1(n) + b_2(n) \geq 1.75l(n) + 1$  (an assumption we will later justify), and substituting  $\log_2 \varepsilon^{-1}(n) = h(n) \log_2 n$ ,  $\log_2 k(n) = d \cdot l(n)$  in the equality of the last theorem, we see that  $l(n) \geq h(n)/(3/8 - d) \log_2 n$  is a necessary condition for the scheme to produce  $\varepsilon(n) = n^{-h(n)}$ -robust bits. The case of equality in the last equation implies that  $\varepsilon^{-1}(n) \leq k(n) \leq \varepsilon^{-2}(n)$  for  $\frac{3}{16} \leq d \leq \frac{1}{4}$ , an expression which relates the size of  $k(n)$  to the robustness of bits produced by  $f_{k(n)}$ .

The computation complexity of the scheme equals the (deterministic) complexity of finding discrete logarithms modulo  $k(n)$  in the field  $Z_{p(n)}$ . We first assume that  $p(n), k(n)$  and  $g$ , a primitive element of  $Z_{p(n)}$ , are given, and analyze the run time of the scheme. We then turn to the complexity of the preprocessing stage, in which  $p(n), k(n)$  and  $g$  are produced.

Given  $p(n), k(n)$  and  $g$ , a primitive element of  $Z_{p(n)}$ , then by essentially trying all possible candidates, we can compute  $\log_g(\cdot) \bmod k(n)$  in time  $O(k(n) \log^3(p(n)))$

(see [19]). Thus, if the bias  $\epsilon(n)$  is required to be just polynomial in  $n$  ( $\epsilon(n) = n^{-O(1)}$ ), then by employing our scheme with brute-force discrete logarithm subroutine, the computational complexity is polynomial in  $n$ .

In order to generate subpolynomially biased bits  $\epsilon(n) = n^{-h(n)}$ , with  $h(n) \rightarrow \infty$ , we need more efficient ways of computing discrete logarithms (modulo  $k(n)$ ) in  $Z_{p(n)}$ . There are known algorithms with complexity  $2^{O(\sqrt{\log p(n)} \log \log p(n))}$ , and this run-time would suit our needs, but unfortunately these algorithms are randomized, so we cannot use them to (deterministically) evaluate  $f_{k(n)}$ . Instead, we look for  $p(n)$ 's with smooth  $k(n)$ , and use an algorithm of Pohlig and Hellman [24] which is sufficiently fast in such circumstances.

A positive integer  $z$  is called  $y$ -smooth if all its prime factors are  $\leq y$ . Suppose  $p(n)$  is a prime in the range  $n^{\sqrt{\log \log n}} \leq p(n) \leq n^{2\sqrt{\log \log n}}$ , so that  $k(n) \mid (p(n) - 1)$  is  $n$ -smooth. Given a primitive element  $g$  of  $Z_{p(n)}$ , the Pohlig and Hellman algorithm [24] finds  $\log_g(\cdot) \pmod{k(n)}$  in  $O(n \log^3 n)$  deterministic time.

Given  $l(n)$ , every pair of  $(l, b_1)$ -distributed,  $(l, b_2)$ -distributed sources can be viewed as  $(l(n), l(n) \cdot b_1/l)$ ,  $(l(n), l(n) \cdot b_2/l)$  sources, respectively. Using "nice" primes as above, we have the following theorem.

**THEOREM 15.** *Suppose  $p(n)$  is a prime in the range  $n^{\sqrt{\log \log n}} \leq p(n) \leq n^{2\sqrt{\log \log n}}$ , so that  $k(n) \mid p(n) - 1$ ,  $p(n)^{3/16} \leq k(n) \leq p(n)^{1/4}$ , and  $k(n)$  is  $n$ -smooth. Let  $g \in Z_{p(n)}$  be a given primitive element. Furthermore, let  $l, b_1, b_2$  satisfy  $b_1 + b_2 \geq 1.75l$ . Then for any pair of independent  $(l, b_1)$ -distributed and  $(l, b_2)$ -distributed sources, the function  $f_{k(n)}: Z_{p(n)} \times Z_{p(n)} \mapsto \{0, 1, \dots, k(n) - 1\}$  produces  $1/n^{\sqrt{\log \log n}/8}$ -robust bits, with information rate at least  $\frac{3}{32}$  and computational complexity  $O(n \log^3 n)$ .*

We now turn to the preprocessing stage, starting with the question of finding appropriate primes. Let  $\Psi(x, y)$  denote the number of positive integers not exceeding  $x$  which are  $y$ -smooth. Canfield, Erdős and Pomerance [8] proved the following theorem concerning  $\Psi(x, y)$ :

**THEOREM 16** [8]. *For  $y \geq \log^2 y$ ,  $\Psi(x, y) = xu^{-u+o(u)}$ , where  $u = \log x / \log y$ .*

In particular, for large enough  $x$ ,  $\Psi(x, y) \geq xu^{-2u}$ . Choosing  $h(n) = 2\sqrt{\log \log n}$ ,  $y = n$  and  $x = n^{h(n)}$ , we have that  $u = \log x / \log y = h(n)$ . Substituting these quantities in the last theorem, we conclude that for large enough  $n$ , the probability that a randomly chosen  $z \leq n^{h(n)}$  will be  $n$ -smooth is bounded below by  $h(n)^{-2h(n)} = 1/(2\sqrt{\log \log n})^{4\sqrt{\log \log n}} > \log^{-1/3} n$ . Obviously, the same lower bound holds for the probability that a random  $z$  has an  $n$ -smooth divisor  $d$  such that  $z^{3/16} < d < z^{1/4}$ . However, for our purposes it is not enough for  $z$  to have such divisor, but  $z + 1$  must be a prime as well. Carl Pomerance (private communication) has provided us with an estimate of the probability of this event.

**THEOREM 17.** *For a randomly chosen  $n^{\sqrt{\log \log n}} \leq z \leq n^{2\sqrt{\log \log n}}$ ,*

$$\Pr(z \text{ has an } n\text{-smooth divisor in the range } [z^{3/16}, z^{1/4}] \text{ and } z + 1 \text{ is prime}) \geq \frac{1}{\log^2 n}.$$

By choosing random integers in the above range, an appropriate prime  $p(n)$  with a large  $n$ -smooth divisor  $k(n)$  and a generator for  $Z_p$  can be found in expected polynomial time, given access to an unbiased independent coin. This is done as follows. First, we choose  $p(n)$  at random, factor  $p(n) - 1$  and look for a sufficiently large  $n$ -smooth divisor  $k(n)$ . For factoring  $p(n) - 1$ , we use Dixon's algorithm [10], that runs in expected time  $2^{O(\sqrt{\log p(n)} \log \log n)}$  (which is polynomial in  $n$ ). Next, we verify that  $p(n)$  is a prime, using Pratt's algorithm [25] (again using Dixon's algorithm as a factoring subroutine, and trying to find primitive elements by choosing elements at random). In case  $p(n)$  is indeed a prime, Pratt's algorithm yields a primitive element

of  $Z_{p(n)}$ . We now substitute the unbiased independent coin used in the preprocessing, by bits extracted from two probability-bounded sources, using any of the computationally efficient (but not necessarily rate-efficient) schemes of § 3.1.

Finally, in order to satisfy  $b_1 + b_2 > 1.75l$ , we start with *four* independent  $(l_0, b_0)$ -distributed sources (where the ratio between the constants  $b_0$  and  $l_0$  can be arbitrarily small). Using Theorem 7 and the observation that (for every integer  $q > 1$ ) an  $(l, b)$ -source is also a  $(q \cdot l, q \cdot b)$ -source, we convert every pair of these sources into a single  $(l, 0.9l)$ -distributed source (where  $l = 2l_0(l_0/b_0) \log_2(l_0/b_0)$ ). This conversion is rate efficient, and its complexity does not depend on  $\varepsilon(n)$ .

**3.3. Slightly dependent sources.** In § 2, we showed how to extract unbiased bits from the output of two independent probability-bounded sources. A natural question is whether the independence requirement can be relaxed, and if so, to what extent. We suggest the following definition and investigate its ramifications.

**DEFINITION 10.** Let  $\delta \geq 0$ . We say that two variables  $X$  and  $Y$  are  $\delta$ -dependent if, for every  $\alpha, \beta \in \{0, 1\}^l$  with  $\Pr(X = \alpha) \cdot \Pr(Y = \beta) \neq 0$  the following holds:

$$(1 + \delta)^{-1} \leq \frac{\Pr(X = \alpha \text{ and } Y = \beta)}{\Pr(X = \alpha) \cdot \Pr(Y = \beta)} \leq (1 + \delta).$$

Thus, 0-dependence identifies with independence. Also, notice that this is a more refined measure of dependency than correlation. A different definition of slightly dependent SV-sources was presented in [29], and does not seem to extend to PRB-sources. The following lemma can be easily verified.

**LEMMA 18.** *Suppose that  $f$  is  $\varepsilon$ -robust for any two independent variables satisfying properties  $P_1$  and  $P_2$ , respectively. Then  $f$  is  $(\delta + (1 + \delta)\varepsilon)$ -robust for any two  $\delta$ -dependent variables satisfying properties  $P_1$  and  $P_2$ , respectively.*

Applications to extracting unbiased bits from slightly dependent functions follow immediately by combining Lemma 18 with Theorems 7, 9 and 15. Lemma 18 may seem weak at first glance. It only guarantees that, for small  $\delta$ , the added bias introduced by the  $\delta$ -dependency does not exceed  $\delta$ . However, this result is almost optimal! We will show that  $\delta$ -dependency may add an  $\Omega(\delta)$  term to the bias.

**THEOREM 19.** *Let  $0 < \delta \leq 4$  and  $f: \{0, 1\}^{2l} \mapsto \{0, 1\}$  be an arbitrary Boolean function. Then at least one of the following two conclusions holds:*

(1) *There exist a  $\sigma \in \{0, 1\}$  and a pair of  $\delta$ -dependent  $(l, l - 2)$ -distributed variables  $X$  and  $Y$  such that  $\Pr(f(X, Y) = \sigma) \geq \frac{1}{2} \cdot (1 + \delta/64)$ .*

(2) *There exist a  $\sigma \in \{0, 1\}$  and a pair of independent  $(l, l - 7 - \log_2 \delta^{-1})$ -distributed variables  $X$  and  $Y$  such that  $\Pr(f(X, Y) = \sigma) \leq \frac{1}{3}$ .*

*Proof.* Without loss of generality, we assume that  $|\{(i, j) \in \{0, 1\}^{2l} : f(i, j) = 1\}| \geq \frac{1}{2} \cdot 2^{2l}$ . The function  $f$  is represented as a bipartite graph  $G(V, E)$ , where  $V = A \cup B$  ( $A = \{a_i : i \in \{0, 1\}^l\}$  and  $B = \{b_j : j \in \{0, 1\}^l\}$ ) is the bipartition and the edge set  $E \subset A \times B$  satisfies

$$(a_i, b_j) \in E \text{ iff } f(i, j) = 1.$$

Throughout the rest of the proof, we assume that conclusion (2) of the theorem does not hold: namely, we assume that the function  $f$  is  $\frac{1}{3}$ -robust with respect to any two independent  $(l, l - 7 - \log_2 \delta^{-1})$ -distributed variables. The idea of the proof is to show the existence of a large regular subgraph with relatively high degree. Once this subgraph is found, the variables are defined to be flat on the vertex sets of the subgraph, and the dependency allowance is used to make the edges of the subgraph “heavy.” Thus, the probability mass is concentrated more on entries on which the function has value

1, and the function is biased towards 1 as required in conclusion (1) of the theorem. The following lemma guarantees the existence of such a subgraph.

LEMMA 20. *Let  $0 < \delta \leq 4$  and  $G((A, B), E)$  be a bipartite graph with  $n$  vertices on each side and at least  $\frac{1}{2}n^2$  edges. Suppose that the number of edges in every subgraph of  $G$ , with  $q \stackrel{\text{def}}{=} \delta/128 \cdot n$  vertices on each side, is in the range  $[q^2/3, 2q^2/3]$ . Then there exist  $m \geq n/4$  and  $k = m/32$  such that  $G$  contains a  $k$ -regular subgraph with  $m$  vertices on each side.*

The proof of Lemma 20 is given in the Appendix. A similar statement was attributed by the referee to Pyber and Rödel (as yet unpublished). They showed that every graph with  $n$  vertices and  $\Omega(n^2)$  edges contains an  $\Omega(n)$ -regular subgraph.

Let  $G_0((A_0, B_0), R)$  be the regular subgraph guaranteed by Lemma 20. We now use this regular subgraph to present a pair of  $\delta$ -dependent probability-bounded sources,  $X$  and  $Y$ , which make the function bias.  $X$  will be flat on  $A_0$  and  $Y$  will be flat on  $B_0$ ; that is,

$$\Pr(X = i) \stackrel{\text{def}}{=} \begin{cases} |A_0|^{-1} & \text{if } a_i \in A_0, \\ 0 & \text{otherwise,} \end{cases}$$

$$\Pr(Y = j) \stackrel{\text{def}}{=} \begin{cases} |B_0|^{-1} & \text{if } b_j \in B_0, \\ 0 & \text{otherwise.} \end{cases}$$

Now consider two cases. If the number of edges in the subgraph induced by  $A_0$  and  $B_0$  is smaller than  $\frac{1}{2}(1 - \delta/64) \cdot q^2$  then we let  $X$  and  $Y$  be independent and get the desired bias (towards 0). If the number of edges in the induced subgraph is  $\geq \frac{1}{2}(1 - \delta/64) \cdot q^2$  then we use the dependency allowance as follows:

$$\Pr(X = i, Y = j) \stackrel{\text{def}}{=} \begin{cases} (1 + \delta) \cdot \Pr(X = i) \cdot \Pr(Y = j) & \text{if } (a_i, b_j) \in R, \\ (1 - \delta/31) \cdot \Pr(X = i) \cdot \Pr(Y = j) & \text{otherwise.} \end{cases}$$

The reader may verify the validity of the above definition, by noting that  $1/32 \cdot (1 + \delta) + \frac{31}{32} \cdot (1 - \delta/31) = 1$ . It follows that

$$\Pr(f(X, Y) = 1) \geq \frac{1}{32} \cdot (1 + \delta) + \left(\frac{15}{32} - \frac{\delta}{128}\right) \cdot \left(1 - \frac{\delta}{31}\right)$$

$$> \frac{1}{2} + \frac{\delta}{128}.$$

The theorem follows.  $\square$

**3.4. Variations: entropy, varying length.** We conclude our investigation into the problem of extracting unbiased bits from weak sources of randomness by two remarks. The first remark concerns the probability bound  $b$ , while the second remark concerns both  $b$  and  $l$ .

We have defined probability-bounded variables as having an upper bound ( $2^{-b}$ ) on the probability for each individual  $l$ -bit string. A more “natural” but less convenient definition considers variables with a lower bound on the (information-theoretic) entropy. Every  $(l, b)$ -variable has entropy  $\geq b$ , but the converse does not hold. Nevertheless, every source which has nonzero entropy is in fact a probability-bounded source (a quantitative statement is omitted).

So far, we have considered sources where for some fixed integer  $l$ , given the history, the next  $l$  bits have a particular distribution. A natural question, raised by Jeff Lagarias, is what happens when the number of next bits is a variable. More precisely, let  $l(\cdot)$  and  $b(\cdot)$  be functions, and consider a source  $S$  with the following output distribution: for every integer  $n > 0$ , for every  $\alpha \in \{0, 1\}^n$  and every  $\beta \in \{0, 1\}^{l(n)}$ , the conditional probability that the next  $l(n)$  bits output by  $S$  equal  $\beta$  given that the first  $n$  bit output by  $S$  equals  $\alpha$  does not exceed  $2^{-b(n)}$ . We call this a varying probability-

bounded source (VPRB-source). Extending Theorems 7 and 4, we get an almost sharp threshold for the value of  $b(\cdot)$  which allows the extraction of almost-unbiased bits from two VPRB-sources. Such an extraction is possible whenever  $b(n) > 4 + \log_2 l(n)$ , and is impossible whenever  $b(n) < \log_2(l(n) - \log_2 l(n)) - 1$ .

**4. Communication complexity.** In this section, we present results concerning probabilistic communication complexity. In § 4.1, we recall the common definitions of communication complexity, present new definitions and compare them. In § 4.2, we prove lower bounds on the communication complexity of the functions considered in § 2. In § 4.3, we demonstrate the tightness of our results by presenting upper bounds on the communication complexity of all functions. In § 4.4, we suggest a robust notion of communication complexity and extend our lower bounds to it.

Consider two interactive parties  $A$  and  $B$ , such that  $A$  knows an input  $x \in \{0, 1\}^n$  and  $B$  knows an input  $y \in \{0, 1\}^n$ . The inputs are randomly and independently chosen, each with uniform probability distribution. Let  $f: \{0, 1\}^n \times \{0, 1\}^n \mapsto \{0, 1\}$  be a function and assume that  $A$  and  $B$  wish to compute  $f(x, y)$ . To this end they use a possibly *randomized* protocol  $P$ . As commonly assumed, the messages sent at each round are prefix-free. The protocol is terminated by party  $A$  and the last bit  $B$  sent to  $A$  is their *joint guess of the value of  $f(x, y)$* . A natural question is how many bits should be exchanged among the party so that their joint guess is significantly better than the a priori guess. The answer depends on the exact definitions of the notions “number of bits” and “success probability.”

**4.1. Definitions.** Let  $x, y \in \{0, 1\}^n$ . We consider the probability space defined by the coin tosses of the parties  $A$  and  $B$ . Let  $l_P(x, y)$  be the random variable denoting the number of bits  $A$  and  $B$  exchange on the pair  $(x, y)$ , using the protocol  $P$ . Let  $L_P(x, y)$  denote the expected value of  $l_P(x, y)$  and  $l_P^*(x, y)$  denote the supremum of  $l_P(x, y)$ . Let  $s_{P,f}(x, y)$  be the random variable denoting the success of  $P$  with respect to  $f$  on the pair  $(x, y)$ ; and let  $S_{P,f}(x, y)$  denote the expected value of  $s_{P,f}(x, y)$ . That is,  $S_{P,f}(x, y)$  is the probability that the last bit exchanged by  $A$  and  $B$  on inputs  $x$  and  $y$  equals  $f(x, y)$ .

The *average operator* (denoted *Ave*), and the *minimum* and *maximum operators* (denoted *Min* and *Max*, respectively) are defined in the obvious manner. These operators are used in defining the various measures. For example,  $Ave(L_P) = 2^{-2n} \sum_{x,y \in \{0,1\}^n} L_P(x, y)$  is the average number of bits exchanged in the protocol  $P$ ;  $Max(L_P)$  is the expected number of bits on the worst pair of inputs; and  $Max(l_P^*) = \max_{x,y \in \{0,1\}^n} \{l_P^*(x, y)\}$  is the maximum number of bits taken over all possible executions and pairs. Two measures for success are  $Min(S_{P,f})$  (worst pair) and  $Ave(S_{P,f})$  (averaged over all pairs).

*Previous definitions.* Various definitions of randomized communication complexity have appeared. We present some of them<sup>2</sup> (other definitions can be found in [21], [15] and [29]):

- Yao’s definition of randomized communication complexity [35] (hereby denoted  $C_\epsilon(f)$ ) is thus the infimum of  $Max(l_P)$ , when taken over all *randomized* protocols  $P$  satisfying  $Min(S_{P,f}) \geq \frac{1}{2} + \epsilon$ .
- Yao’s definition of distributed communication complexity [36] (hereby denoted  $D_\epsilon(f)$ ) is the infimum of  $Ave(L_P)$ , when taken over all *deterministic* protocols  $P$  satisfying  $Ave(S_{P,f}) \geq \frac{1}{2} + \epsilon$ .

---

<sup>2</sup> The role of  $\epsilon$  in our notation differs from its role in [35], [36], [20]. Here  $\epsilon$  denotes the advantage of the protocol over  $\frac{1}{2}$ , while originally it was used to denote the error probability.

- Orlitsky and El-Gamal [20] measure the *average communication complexity* (hereby denoted  $\bar{C}_\varepsilon(f)$ ) as the infimum of  $Ave(L_P)$ , when taken over all randomized protocols  $P$  satisfying  $Min(S_{P,f}) \geq \frac{1}{2} + \varepsilon$ .

- Paturi and Simon [23] define the *unbounded communication complexity* (hereby denoted  $U(f)$ ) to be the infimum of  $Max(I_P^*)$ , when taken over all randomized protocols  $P$  satisfying  $Min(S_{P,f}) > \frac{1}{2}$ .

*Our definitions.* We say that the protocol  $P$  has *average  $\varepsilon$ -advantage in guessing  $f$*  if  $Ave(S_{P,f}) \geq \frac{1}{2} + \varepsilon$ . In the following definitions we consider protocols with *average  $\varepsilon$ -advantage*.

- We define the *average randomized communication complexity of function  $f$*  (denoted  $A_\varepsilon^R(f)$ ) as the infimum of  $Ave(L_P)$ , when taken over all *randomized* protocols  $P$  which have average  $\varepsilon$ -advantage in guessing  $f$ .

- The *worst-case randomized communication complexity of function  $f$*  (denoted  $W_\varepsilon^R(f)$ ) is defined as the infimum of  $Max(I_P^*)$ , when taken over all *randomized* protocols  $P$  which have average  $\varepsilon$ -advantage in guessing  $f$ .

- The *deterministic communication complexities* ( $A_\varepsilon^D(f)$  and  $W_\varepsilon^D(f)$ ) of the function  $f$  are defined similarly, for deterministic protocols.

*Comparison of definitions.* For all functions  $f \in F_n$ , the following inequalities are immediate from the definitions;

$$A_\varepsilon^R(f) \leq \bar{C}_\varepsilon(f) \leq C_\varepsilon(f),$$

$$A_\varepsilon^R(f) \leq A_\varepsilon^D(f) = D_\varepsilon(f) \leq W_\varepsilon^D(f).$$

Yao showed that  $C_{\frac{1}{2}-\eta}(f) \geq \frac{1}{2} D_{\frac{1}{2}-2\eta}(f)$  [34], [36].

There are, however, functions for which  $A_\varepsilon^R(f) \ll C_\varepsilon(f), D_\varepsilon(f)$ . One such function is the ordering function  $g$  defined by  $g(x, y) = 1$  if and only if  $x \leq y$ . Yao showed that for any fixed  $\varepsilon > 0$ ,  $C_\varepsilon(g) = \Omega(\log n)$  [35]. The protocol in which  $A$  sends the most significant bit of  $x$  has a  $\frac{1}{4}$ -advantage in guessing  $g$ , and thus  $A_{1/4}^R(g) = 1$  (in fact,  $W_{1/4}^D(g) = 1$ ). (Paturi and Simon [23] showed that  $U(g) = 2$ .) The three measures  $W_\varepsilon^R(f), U(f)$  and  $C_\varepsilon(f)$  are not always comparable.

**4.2. Lower bounds.** We begin this section by stating our lower bounds, and comparing them to recent results of other researchers.

**THEOREM 21.** *Let  $0 < \varepsilon \leq \frac{1}{2}$ .*

(1) *For at least a  $1 - 2^{-2^n}$  fraction of the Boolean functions  $f \in F_n$ ,*

$$W_\varepsilon^R(f) > n - 7 - 3 \log_2 \varepsilon^{-1},$$

$$A_\varepsilon^R(f) > 2\varepsilon \cdot (n - 7 - 3 \log_2 \varepsilon^{-1}n) - 1.$$

(2) *For every  $f \in F_n$  representable by a Hadamard matrix, the following holds:*

$$W_\varepsilon^R(f) > n - 3 - 3 \log_2 \varepsilon^{-1},$$

$$A_\varepsilon^R(f) > 2\varepsilon \cdot (n - 3 - 3 \log_2 \varepsilon^{-1}n) - 1.$$

*In particular, this holds for the inner-product function.*

*Comparison to other works.* Our result implies that for almost all  $f \in F_n$ ,  $\bar{C}_\varepsilon(f) \geq 2\varepsilon(n - 7 - 3 \log_2 \varepsilon^{-1}n) - 1$ . This is related to a recent independent result of Orlitsky and El-Gamal [20], who showed that almost all  $f \in F_n$  have  $\bar{C}_\varepsilon(f) \geq 2\varepsilon(n - 1 - \log_2 n)$ . (Actually, they showed that for all  $2^{-n} < r \leq \frac{1}{2}$ , almost all functions  $f$  with  $r \cdot 2^{2^n}$  ones in their table, have  $\bar{C}_\varepsilon(f) \geq 2\varepsilon(n - \log_2 r^{-1}n)$ .)

Our bound on  $W_\epsilon^R(f)$  (for almost all  $f \in F_n$ ) is related to a recent independent result of Alon, Frankl and Rödl [5] who showed that almost all  $f \in F_n$  have  $U(f) \geq n - 5$ . Their result implies that  $C_\epsilon(f) > 2\epsilon(n - 5)$ .

All three works resolve Yao's open problem [35]: *What is  $C_\epsilon(f)$  for a random  $f \in F_n$ ?*

**4.2.1. Proof of Theorem 21.**

PROPOSITION 22. *Let  $0 < \delta \leq 1$ . Then  $A_\epsilon^R(f) \geq (2 - \delta)\epsilon \cdot W_{\delta\epsilon/2}^R(f)$ . (In particular,  $A_\epsilon^R(f) \geq \epsilon \cdot W_{\epsilon/2}^R(f)$ .)*

*Proof.* Consider runs of protocol  $P$  which have an  $\epsilon$ -advantage in guessing  $f$  and average length  $a$ . Truncate runs of  $P$  that exceed  $\epsilon^{-1}a/(2 - \delta)$  bits. In the event of a long run, flip a coin to determine the final guess. Such runs occur with probability  $\leq (2 - \delta)\epsilon$ , and by guessing at random we lose at most  $(2 - \delta)\epsilon/2$  of the average success probability. This yields a protocol with  $(\delta/2) \cdot \epsilon$ -advantage, the runs of which are no more than  $\epsilon^{-1}a/(2 - \delta)$  bits long.  $\square$

PROPOSITION 23.  $W_\epsilon^R(f) = W_\epsilon^D(f)$ .

*Proof.* For a randomized protocol, the average advantage is a sum over both the inputs and the coin tosses. There must be at least one sequence of coin tosses which does at least as well as the average. Using this string, we get a deterministic protocol with the same length and at least the same average advantage.  $\square$

Notice that both the above argument holds since we are interested in average advantage; the advantage on individual pairs may decrease. Using Propositions 22 and 23, we may concentrate on studying  $W_\epsilon^D(f)$ .

THEOREM 24. *Let  $k, n$  be integers, and  $0 < \epsilon \leq 1$ . Suppose that for every  $b_1 + b_2 \geq 2n - k - 1 + \log_2 \epsilon$ , the Boolean function  $f: \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$  is  $\epsilon$ -robust with respect to any pair of independent random variables  $X, Y$  satisfying:  $X$  is  $(n, b_1)$ -distributed and  $Y$  is  $(n, b_2)$ -distributed. Then*

$$W_\epsilon^D(f) > k.$$

*Proof.* Suppose, towards a contradiction, that  $P$  is a deterministic protocol with average  $\epsilon$ -advantage in guessing  $f$ , such that  $\text{Max}(I_P^*) \leq k$ . Consider all possible executions of  $P$  and assume, without loss of generality, that  $A$  and  $B$  exchange exactly  $k$  bits on each pair of inputs.

For every  $\gamma \in \{0, 1\}^k$ , denote by  $C(\gamma)$  the set of  $(x, y)$  pairs on which the communication of  $A$  and  $B$  consists of  $\gamma$ . Note that by prefix freeness, the parsing of  $\gamma$  is unique. Let  $A(\gamma) = \{x: \exists y \text{ s.t. } (x, y) \in C(\gamma)\}$ , and  $B(\gamma) = \{y: \exists x \text{ s.t. } (x, y) \in C(\gamma)\}$ . By a cut-and-paste argument of Yao [35],  $C(\gamma) = A(\gamma) \times B(\gamma)$ .

Denote by  $\text{last}(\gamma)$  the last bit exchanged in the communication  $\gamma$ , and let  $G(\gamma) = \{(x, y) \in C(\gamma): \text{last}(\gamma) = f(x, y)\}$ . since  $P$  has  $\epsilon$ -advantage on  $f$ , we have that  $\sum_{\gamma \in \{0, 1\}^k} |G(\gamma)| \geq (\frac{1}{2} + \epsilon) \cdot 2^{2n}$ . Let us say that  $C(\gamma)$  is small if  $|C(\gamma)| < \epsilon \cdot 2^{2n-k-1}$ . Since there are at most  $2^k$  rectangles  $C(\gamma)$ , the number of points in all small rectangles is at most  $\epsilon \cdot 2^{2n-1}$ . Thus

$$\sum_{\gamma \text{ s.t. } |C(\gamma)| \geq \epsilon \cdot 2^{2n-k-1}} |G(\gamma)| \geq \left(\frac{1}{2} + \frac{\epsilon}{2}\right) \cdot 2^{2n}.$$

This implies that there exists a  $\gamma \in \{0, 1\}^k$  such that both  $|C(\gamma)| \geq \epsilon \cdot 2^{2n-k-1}$  and  $|G(\gamma)| \geq (\frac{1}{2} + \epsilon/2) \cdot |C(\gamma)|$  (i.e.,  $C(\gamma)$  is sufficiently large, and the protocol has nonnegligible advantage on the pairs in it). Fix such a  $\gamma$ .

Set  $X$  and  $Y$  to be two independent random variables, flat on  $A(\gamma)$  and  $B(\gamma)$ , respectively. Then  $\text{Pr}(f(X, Y) = \text{last}(\gamma)) \geq \frac{1}{2} \cdot (1 + \epsilon)$ . Let  $b_1 = \log_2 |A(\gamma)|$  and  $b_2 =$

$\log_2 |B(\gamma)|$ . Then  $X$  is  $(n, b_1)$ -distributed,  $Y$  is  $(n, b_2)$ -distributed, and  $b_1 + b_2 \geq \log_2(\varepsilon \cdot 2^{2n-k-1}) = 2n - k - 1 + \log_2 \varepsilon$ . This contradicts the  $\varepsilon$ -robustness of  $f$ .  $\square$

Theorem 21 (above) is a consequence of combining Theorem 24 (and Propositions 22 and 23) with Theorems 7 and 9 (of §§ 2.4 and 2.5, respectively). The arithmetic details are as follows.

Part (1): Let  $0 \leq \varepsilon \leq \frac{1}{2}$ . By Theorem 7 (see special case 4), all but at most  $2^{-2^n}$  of the functions  $f: \{0, 1\}^{2^n} \mapsto \{0, 1\}$  are  $\varepsilon$ -robust for any pair of  $(n, b_1), (n, b_2)$  sources satisfying  $b_1 + b_2 \geq n + 6 + 2 \log_2 \varepsilon^{-1}$ . Setting  $k = n - 7 - 3 \log_2 \varepsilon^{-1}$ , these functions  $f$  satisfy the condition of Theorem 24 (being  $\varepsilon$ -robust for sources with  $b_1 + b_2 \geq 2n - k - 1 - \log_2 \varepsilon^{-1}$ ). Thus, these functions  $f$  have  $W_\varepsilon^D(f) > n - 7 - 3 \log_2 \varepsilon^{-1}$ . To get the bound on  $A_\varepsilon^R(f)$ , we use Propositions 23 and 22:

$$\begin{aligned} A_\varepsilon^R(f) &\geq \max_{0 < \delta \leq 1} (2 - \delta)\varepsilon \cdot W_{\delta\varepsilon/2}^R(f) \\ &\geq (2 - 2/n)\varepsilon \cdot W_{\varepsilon/n}^D(f) \\ &> 2\varepsilon \cdot (n - 7 - 3 \log_2 \varepsilon^{-1}) - 1. \end{aligned}$$

Part (2): Similarly, by using Theorem 9, and setting  $k = n - 3 - 3 \log_2 \varepsilon^{-1}$ . This completes the proof of Theorem 21.  $\square$

**4.3. Upper bounds.** The lower bound on  $A_\varepsilon^R(f)$  for almost all  $f$ 's is nearly optimal, since Orlitsky and El-Gamal showed that most  $f \in F_n$  have  $C_\varepsilon(f) \leq 2\varepsilon(n + 6 \log_2 \varepsilon^{-1}n)$  [20] (recall that  $A_\varepsilon^R(f) \leq C_\varepsilon(f)$ ). The lower bound on  $W_\varepsilon^R(f)$  is also nearly optimal, since we have the following upper bounds.

**THEOREM 25.** (1) For every  $f \in F_n$  and every  $2^{-n/2+1} < \varepsilon < \frac{1}{32}$ ,  $W_\varepsilon^D(f) \leq n + 11 - 2 \log_2 \varepsilon^{-1}$ .

(2) For all  $f \in F_n$ ,  $W_{2^{-n/2+5.5}}^D(f) \leq 2$ .

*Proof.* For part (1), we use the following protocol. Party  $B$  sends the  $n + 9 - 2 \log_2 \varepsilon^{-1}$  most significant bits of  $y$  to party  $A$ . This defines a  $2^n \times 2 \cdot (32\varepsilon)^{-2}$  strip in  $f$ 's table. By Lemma 2 each such strip contains a  $2^{n-4} \times (32\varepsilon)^{-2}$  submatrix  $S$  with  $\frac{1}{2} + 32\varepsilon$  fraction of identical entries  $\sigma$  in it. In addition, party  $B$  sends a bit specifying whether  $y$  corresponds to a column in  $S$ . Party  $A$  replies by  $\sigma$  if  $(x, y)$  is in  $S$ , and by the outcome of a coin flip otherwise. In this way, we get an average  $\varepsilon$ -advantage.

For part (2), let  $S$  be a  $2^{n-4} \times 2^{n-1}$  submatrix containing a  $\frac{1}{2} + 2^{-\frac{1}{2}(n-1)}$  fraction of identical entries  $\sigma$  in it (Lemma 2 guarantees the existence of  $S$ ). Party  $B$  sends a bit specifying whether  $y$  corresponds to a column in  $S$ . Party  $A$  replies by  $\sigma$  if  $(x, y)$  is in  $S$ , and by the outcome of a coin flip otherwise. In this way, we get an average  $\frac{1}{32} \cdot 2^{(n-1)/2}$ -advantage.  $\square$

**4.4. Extension to  $(n, m)$ -distributions.** In the definitions and results presented above, we have assumed that the inputs to the protocol are uniformly distributed in  $\{0, 1\}^n$ . A natural question is what happens if we allow the inputs to be  $(n, m)$ -distributed. In particular, we consider protocols which have advantage with respect to some  $(n, m)$ -distributions, and study the infimum average number of bits they exchanged under these ‘‘advantageous’’ distributions. We show that most functions in  $F_n$  have  $\Theta(m)$  complexity, even in this weak measure.

**DEFINITION 11.** Let  $D_1$  and  $D_2$  be two  $(n, m)$ -distributions, and let  $P_i(z)$  be the probability that  $D_i$  assigns to  $z$ . For any protocol  $P$ , a function  $f \in F_n$ , and a metric  $M_{P,f}$  over runs of  $P$ , we define the *average operator on  $D_1 \times D_2$*

$$Ave_{D_1, D_2}(M_{P,f}) = \sum_{x, y \in \{0, 1\}^n} P_1(x) \cdot P_2(y) \cdot M_{P,f}(x, y).$$

Similarly, we define the *maximum operator on  $D_1 \times D_2$*

$$\text{Max}_{D_1, D_2}(M_{P,f}) = \max_{x \in \text{supp}(D_1), y \in \text{supp}(D_2)} \{M_{P,f}(x, y)\},$$

where  $\text{supp}(D_i) = \{z \in \{0, 1\}^n \mid P_i(z) > 0\}$ .

We say that the protocol  $P$  has  $D_1 \times D_2$ -average  $\varepsilon$ -advantage in guessing  $f$  if  $\text{Ave}_{D_1, D_2}(S_{P,f}) \geq \frac{1}{2} + \varepsilon$ .

- We define the *average randomized communication  $(n, m)$ -complexity of function  $f$*  (denoted  $(n, m)$ - $A_\varepsilon^R(f)$ ) as the infimum of  $\text{Ave}_{D_1, D_2}(L_P)$ , when taken over all  $(n, m)$ -distributions  $D_1, D_2$  and all *randomized* protocols  $P$  which have  $D_1 \times D_2$ -average  $\varepsilon$ -advantage in guessing  $f$ .

- The *worst-case randomized communication  $(n, m)$ -complexity of function  $f$*  (denoted  $(n, m)$ - $W_\varepsilon^R(f)$ ) is defined as the infimum of  $\text{Max}_{D_1, D_2}(L_P^*)$ , when taken over all  $(n, m)$ -distributions  $D_1, D_2$  and all *randomized* protocols  $P$  which have  $D_1 \times D_2$ -average  $\varepsilon$ -advantage in guessing  $f$ .

- The *deterministic communication  $(n, m)$ -complexities* of the function  $f$  are defined similarly, for deterministic protocols.

The key to dealing with  $(n, m)$ -complexities, is the fact that they are minimized on flat distributions (the proof is analogous to Lemma 5). Using the proof techniques of Theorem 21, the problem reduces to the existence of large submatrices with significant advantage inside the submatrix specified by the pair of flat distributions. We get the following.

**THEOREM 26.** *Let  $0 < \varepsilon \leq \frac{1}{2}$ .*

(1) *For at least a  $1 - 2^{-2^m}$  fraction of the Boolean functions  $f \in F_n$ ,*

$$(n, m)\text{-}W_\varepsilon^R(f) > m - 7 - 3 \log_2 \varepsilon^{-1},$$

$$(n, m)\text{-}A_\varepsilon^R(f) > 2\varepsilon \cdot (m - 7 - 3 \log_2 \varepsilon^{-1}m) - 1.$$

(2) *For every  $f \in F_n$  representable by a Hadamard matrix, the following holds:*

$$(n, m)\text{-}W_\varepsilon^R(f) > 2m - n - 3 - 3 \log_2 \varepsilon^{-1},$$

$$(n, m)\text{-}A_\varepsilon^R(f) > 2\varepsilon \cdot (2m - n - 3 - 3 \log_2 \varepsilon^{-1}m) - 1.$$

*In particular, this holds for the inner-product function.*

**5. On the robustness of BPP.** The class  $R$  [1] and its symmetric version BPP [13] consist of problems which can be solved with high probability in polynomial time, with the use of an unbiased coin. Recently, Vazirani and Vazirani [32] showed that all BPP problems can be efficiently solved even if a single SV-source is producing the coin tosses. In this section, we generalize their result by showing that BPP problems can be efficiently solved if a (single) PRB-source is producing the coin tosses.

The main idea of the proof is that *any* function which is robust with respect to *two independent* PRB-sources, can be used to produce *polynomially many* bits such that almost all of them are unbiased. Repeating this process  $m$  times, we get poly( $m$ ) strings of length  $m$  each. Most of these strings are almost uniformly distributed, and thus the fraction of these strings which hit the witness set  $W \subset \{0, 1\}^m$  is close to the density of  $W$ . If  $W$ 's density is large enough (say,  $\geq 0.8$ ) then with probability bounded away from 0.5 (e.g.,  $\geq 0.55$ ), the majority of the generated strings hit  $W$ . This argument needs careful formalization, which is carried out below. The final observation is that there are explicit and efficiently computable functions which are appropriate for the above procedure (e.g., the inner-product or the Paley graph functions).

The key technical lemma used in the proof is the following.

LEMMA 27. Let  $0 < \varepsilon < 1$  be a real and  $f: \{0, 1\}^l \times \{0, 1\}^l \mapsto \{0, 1\}$  be a Boolean function. Define  $f_i: \{0, 1\}^l \mapsto \{0, 1\}$  by  $f_i(j) = f(i, j)$  for every  $i, j \in \{0, 1\}^l$ . Suppose that the  $f$  is  $\varepsilon$ -robust with respect to any two independent random variables which are  $(l, l-1)$ -distributed and  $(l, b)$ -distributed, respectively. Then for every  $(l, b)$ -distributed  $Y$ , all but  $\sqrt{\varepsilon}$  fraction of the  $f_i$ 's are  $4\sqrt{\varepsilon}$ -robust on  $Y$ .

The reader may find it convenient to picture the two-argument Boolean function  $f: \{0, 1\}^l \times \{0, 1\}^l \mapsto \{0, 1\}$  as a table where the  $(i, j)$ -entry corresponds to  $f(i, j)$ . The lemma can be stated (informally) as follows: *if a function can be used for extracting almost unbiased bits from the output of any two independent PRB-sources, then most of its "rows" can be used for extracting an almost unbiased bit from a single PRB-source.* The identity of these "good" rows depends on the specific PRB-source, but for each source most of the rows will work. The proof is by contradiction, showing that if the conclusion of the lemma is violated, then it is possible to find a pair of probability bounded sources which falsify the robustness of  $f$ . While the proof of this lemma is rather simple, it seems much harder to prove a similar statement based merely on robustness with respect to SV-sources.

*Proof.* Let  $Y$  be an arbitrary  $(l, b)$ -distributed random variable. This defines a probability space on the entries of the rows. We will show that the number of rows which are biased too much towards 1 is small (rows with high 0 bias are treated identically). Let  $B$  denote the set of these rows, that is,

$$B = \{i: \Pr(f_i(Y) = 1) > \frac{1}{2}(1 + 4\sqrt{\varepsilon})\},$$

and let  $k$  denote the size of  $B$ .

We first show that  $k \leq 2^{l-1}$ . Assume, on the contrary, that  $k > 2^{l-1}$ . We will reach a contradiction by defining an  $(l, l-1)$ -distributed source  $X_1$  to be flat on  $B$ . Then

$$\begin{aligned} \Pr(f(X_1, Y) = 1) &= k^{-1} \sum_{i \in B} \Pr(f_i(Y) = 1) \\ &> \frac{1}{2} \cdot (1 + 4\sqrt{\varepsilon}) \\ &> \frac{1}{2} \cdot (1 + \varepsilon). \end{aligned}$$

Now that we know  $k \leq 2^{l-1}$ , we define an  $(l, l-1)$ -distributed source  $X_2$  to be flat on  $\{0, 1\}^l - B$ . Applying the  $\varepsilon$ -robustness of  $f$  to the pair  $(X_0, Y)$ , where  $X_0$  is the uniform source, we have

$$\begin{aligned} \frac{1}{2^l} \sum_{i \in \{0, 1\}^l} \Pr(f_i(Y) = 1) &= \Pr(f(X_0, Y) = 1) \\ &< \frac{1}{2}(1 + \varepsilon). \end{aligned}$$

In order to bound  $k$  from above, we first derive an upper bound on  $\Pr(f(X_2, Y) = 1)$ :

$$\begin{aligned} \Pr(f(X_2, Y) = 1) &= \frac{1}{2^l - k} \cdot \sum_{i \in \{0, 1\}^l - B} \Pr(f_i(Y) = 1) \\ &= \frac{\sum_{i \in \{0, 1\}^l} \Pr(f_i(Y) = 1) - \sum_{i \in B} \Pr(f_i(Y) = 1)}{2^l - k} \\ &< \frac{2^l \cdot (\frac{1}{2}(1 + \varepsilon)) - k \cdot (\frac{1}{2}(1 + 4\sqrt{\varepsilon}))}{2^l - k} \\ &= \frac{1}{2} \left( 1 + \frac{2^l \varepsilon - k \cdot 4\sqrt{\varepsilon}}{2^l - k} \right). \end{aligned}$$

Applying the  $\varepsilon$ -robustness of  $f$  to the pair  $(X_2, Y)$  we get

$$\Pr(f(X_2, Y) = 1) > \frac{1}{2}(1 - \varepsilon).$$

Combining the upper and lower bounds on  $\Pr(f(X_2, Y) = 1)$ , we have

$$\frac{1}{2} \left( 1 + \frac{2^l \varepsilon - 4k\sqrt{\varepsilon}}{2^l - k} \right) \cong \frac{1}{2}(1 - \varepsilon).$$

By a simple manipulation,  $k \leq \frac{1}{2}\sqrt{\varepsilon} \cdot 2^l$  follows.  $\square$

With Lemma 27 at our disposal, we can use a single source to generate many strings, most of which are almost unbiased. These strings are generated one bit at a time (i.e., in step  $t$ , the  $t$ th bit of all strings is generated). In the BPP application, the generated strings are tested for membership in a witness set  $W$ . A careful probabilistic analysis shows that if  $W$  is dense enough, then there is a fairly large probability that the majority of these strings will hit  $W$ .

**PROPOSITION 28.** (1) Let  $m$  be an integer, and  $W \subset \{0, 1\}^m$  be an arbitrary set. Denote by  $p$  the density of  $W$  (i.e.,  $p \stackrel{\text{def}}{=} |W|/2^m$ ), and let  $q \stackrel{\text{def}}{=} 1 - p$ .

(2) Let  $l$  be an integer, and  $0 < b < l$ . Let  $0 < \varepsilon < \frac{1}{2}$  and  $f: \{0, 1\}^l \mapsto \{0, 1\}$  be a Boolean function. Suppose that  $f$  is  $\varepsilon$ -robust with respect to any two independent random variables which are  $(l, l-1)$ -distributed and  $(l, b)$ -distributed, respectively.

(3) Let  $Y_1, Y_2, \dots, Y_m$  be a sequence of arbitrary random variables assuming values in  $\{0, 1\}^l$  such that for every  $1 \leq t \leq m$  the variable  $Y_t$  is  $(l, b)$ -distributed given  $Y_1, Y_2, \dots, Y_{t-1}$ . Let  $Y$  denote the concatenation of the  $Y_t$ 's.

(4) For every  $i \in \{0, 1\}^l$ , let  $f_i: \{0, 1\} \mapsto \{0, 1\}$  be defined as in Lemma 27 (i.e.,  $f_i(j) = f(i, j)$  for every  $i, j \in \{0, 1\}^l$ ). Let  $h_i(Y)$  be a random variable assuming values in  $\{0, 1\}^m$ , such that  $h_i(Y)$  is the concatenation of the random variables  $f_i(Y_1), f_i(Y_2), \dots, f_i(Y_m)$ .

Then the probability that a majority of the  $h_i(Y)$ 's miss  $W$ , does not exceed  $2q + 8m\sqrt{\varepsilon}$ . That is,

$$\Pr(|\{h_i(Y) : i \in \{0, 1\}^l\} \cap W| \leq 2^{l-1}) \leq 2q + 8m\sqrt{\varepsilon}.$$

**5.1. Proof of Proposition 28.** *Convention.* Throughout the proof, the probability space is the Cartesian product of  $Y$  (of item (3) above) with an  $(m, m)$ -distributed random variable  $Z$ . The random variable  $Y = Y_1 Y_2 \dots Y_m$  assumes values in  $\{0, 1\}^{m \cdot l}$ , and  $Z = Z_1 Z_2 \dots Z_m$  is uniformly distributed in  $\{0, 1\}^m$  independently of  $Y$ . A value which  $Y$  may assume will be denoted by  $\alpha = \alpha_1 \alpha_2 \dots \alpha_m$ , where  $\alpha_t \in \{0, 1\}^l$ . A value which  $Z$  may assume will be denoted by  $\beta = \beta_1 \beta_2 \dots \beta_m$ , where  $\beta_t \in \{0, 1\}$ . We will also use the notation  $Y'_t = Y_1 Y_2 \dots Y_t$  and  $\alpha'_t = \alpha_1 \alpha_2 \dots \alpha_t$  to denote the prefix consisting of first  $t$  elements of  $Y$  and  $\alpha$ , respectively.

**DEFINITIONS.** (1) For every  $i \in \{0, 1\}^l$ ,  $0 \leq t \leq m$ , we define a Boolean function  $\xi_{i,t}: \{0, 1\}^{lm} \times \{0, 1\}^m \mapsto \{0, 1\}$  as follows:

$$\xi_{i,t}(\alpha, \beta) = \begin{cases} 0 & \text{if } f_i(\alpha_1) f_i(\alpha_2) \dots f_i(\alpha_t) \beta_{t+1} \beta_{t+2} \dots \beta_m \in W, \\ 1 & \text{otherwise.} \end{cases}$$

(2) For every  $i \in \{0, 1\}^l$ ,  $0 \leq t \leq m$  we define a Boolean function  $\eta_{i,t}: \{0, 1\}^{lm} \mapsto \{0, 1\}$  as follows:

$$\eta_{i,t}(\alpha) = \begin{cases} 0 & \text{if } \frac{1}{2} - 2\sqrt{\varepsilon} \leq \Pr(f_i(Y_{t+1}) = 1 \mid Y'_t = \alpha'_t) \leq \frac{1}{2} + 2\sqrt{\varepsilon}, \\ 1 & \text{otherwise.} \end{cases}$$

*Explanation.* Letting  $\alpha$  assume values in  $\{0, 1\}^{lm}$  according to the random variable  $Y$ , and  $\beta$  assume values in  $\{0, 1\}^m$  according to the uniform distribution  $Z$ , the two functions above induce two random variables  $\xi_{i,t}(Y, Z)$  and  $\eta_{i,t}(Y)$ . These random

variables correspond to hybrids of the  $(l, b)$ -source and truly unbiased, independent coin tosses. The random variable  $\xi_{i,t}(Y, Z)$  equals 0 (“a success”) when a hybrid element, generated by applying the function  $f_i$  to the first  $t$  blocks output by the source  $Y$  and letting the rest be truly random, hits the set  $W$ . The random variable  $\eta_{i,t}(Y)$  equals 0 (“a good bit”) if, given the first  $t$  blocks of the source, the bit generated by applying  $f_i$  to the  $(t + 1)$ st block is almost unbiased.

**Elementary observations.**

FACT 1. For every  $i \in \{0, 1\}^l$ , we have

$$\Pr(\xi_{i,0}(Y, Z) = 0) = p.$$

*Proof.* Immediate by the definition of  $\xi_{i,0}(Y, Z)$  and  $|W| = p2^m$ .  $\square$

FACT 2.

$$\sum_{i \in \{0,1\}^l} \sum_{t=0}^{m-1} \exp(\eta_{i,t}(Y)) \leq 2^l m \sqrt{\epsilon}.$$

*Proof.* By Lemma 27, for every  $0 \leq t < m$  and every  $\alpha \in \{0, 1\}^{m-l}$ , we have

$$\sum_{i \in \{0,1\}^l} \eta_{i,t}(\alpha) \leq 2^l \sqrt{\epsilon}.$$

Thus, for every  $0 \leq t \leq m - 1$ ,

$$\sum_{i \in \{0,1\}^l} \eta_{i,t}(Y) \leq 2^l \sqrt{\epsilon}.$$

The sum of  $m$  such expressions (for the  $m$  values of  $t$ ) is thus bounded above by  $2^l m \sqrt{\epsilon}$ , and so is the expected value. Changing the order of summation, we get the claimed bound.  $\square$

The next fact formulates the intuition that, when the  $(t + 1)$ st bit produced in the  $i$ th row is almost unbiased, then the  $(t + 1)$ th hybrid of this row has almost the same success probability as the  $t$ th hybrid to hit  $W$ .

FACT 3. For every  $i \in \{0, 1\}^l$  and  $0 \leq t < m$ , we have

$$\Pr(\xi_{i,t+1}(Y, Z) = 0 \mid \eta_{i,t}(Y) = 0) \geq \Pr(\xi_{i,t}(Y, Z) = 0 \mid \eta_{i,t}(Y) = 0) - 2\sqrt{\epsilon}.$$

*Proof.* Consider an arbitrary  $\alpha \in \{0, 1\}^{m-l}$  such that  $\eta_{i,t}(\alpha) = 0$ . Let  $r = \Pr(f_i(Y_{t+1}) = 1 \mid Y'_t = \alpha'_t) - \frac{1}{2}$ . Then  $|r| \leq 2\sqrt{\epsilon}$ . Let  $s = \Pr(\xi_{i,t}(Y, Z) = 0 \mid Y'_t = \alpha'_t)$ ,  $s_0 = \Pr(\xi_{i,t}(Y, Z) = 0 \mid Y'_t = \alpha'_t, Z_{t+1} = 0)$  and  $s_1 = \Pr(\xi_{i,t}(Y, Z) = 0 \mid Y'_t = \alpha'_t, Z_{t+1} = 1)$ . By definition  $s = \frac{1}{2}s_0 + \frac{1}{2}s_1$ . Then

$$\begin{aligned} \Pr(\xi_{i,t+1}(Y, Z) = 0 \mid Y'_t = \alpha'_t) &= (\frac{1}{2} - r) \cdot s_0 + (\frac{1}{2} + r) \cdot s_1 \\ &= s - r(s_0 - s_1) \\ &\geq s - 2\sqrt{\epsilon}. \end{aligned}$$

Averaging over all such  $\alpha'_t$ 's, Fact 3 follows.  $\square$

**Probability calculation.** The next fact is crucial to our proof. It expresses the (unconditional) success probability of the  $(t + 1)$ st hybrid of the  $i$ th row, in terms of the  $t$ th hybrids of this row. The difference between the  $(t + 1)$ st and  $t$ th hybrids is bounded by the sum of a small error probability ( $\leq 2\sqrt{\epsilon}$ ), introduced by runs in which the  $(t + 1)$ st bit is almost unbiased, and the probability that the  $(t + 1)$ st bit is biased.

FACT 4. For every  $i \in \{0, 1\}^l$  and  $0 \leq t < m$ , we have

$$\Pr(\xi_{i,t+1}(Y, Z) = 0) \geq \Pr(\xi_{i,t}(Y, Z) = 0) - 2\sqrt{\epsilon} - 2 \cdot \Pr(\eta_{i,t}(Y) = 1).$$

*Proof.* By following manipulation, using Fact 3 (when passing from the first line to the second line), and the inequality  $\Pr(A|B) \geq \Pr(A) - \Pr(\bar{B})$  (passing from the third line to the fourth line), we have

$$\begin{aligned} \Pr(\xi_{i,t+1}(Y, Z) = 0) &\geq \Pr(\xi_{i,t+1}(Y, Z) = 0 | \eta_{i,t}(Y) = 0) \cdot \Pr(\eta_{i,t}(Y) = 0) \\ &\geq (\Pr(\xi_{i,t}(Y, Z) = 0 | \eta_{i,t}(Y) = 0) - 2\sqrt{\varepsilon}) \cdot (1 - \Pr(\eta_{i,t}(Y) = 1)) \\ &\geq \Pr(\xi_{i,t}(Y, Z) = 0 | \eta_{i,t}(Y) = 0) - 2\sqrt{\varepsilon} - \Pr(\eta_{i,t}(Y) = 1) \\ &\geq \Pr(\xi_{i,t}(Y, Z) = 0) - 2\sqrt{\varepsilon} - 2 \cdot \Pr(\eta_{i,t}(Y) = 1). \quad \square \end{aligned}$$

This yields an upper bound on the probability that the  $i$ th row does not hit  $W$ , when being generated from the blocks of the  $(l, b)$ -source using the function  $f_i$ .

FACT 5. For every  $i \in \{0, 1\}^l$

$$\text{Exp}(\xi_{i,m}(Y, Z)) \leq q + 2\sqrt{\varepsilon}m + 2 \sum_{t=0}^{m-1} \text{Exp}(\eta_{i,t}(Y)).$$

*Proof.* Follows by combining Fact 1 with repeated use of Fact 4, and using the fact that for any 0-1 random variable  $V$ ,  $\text{Exp}(V) = \Pr(V = 1)$ .  $\square$

**Conclusion.** We now bound the probability that the majority of rows produce elements which *do not hit* the set  $W$ .

FACT 6.

$$\Pr\left(\sum_{i \in \{0,1\}^l} \xi_{i,m}(Y, Z) \geq 2^{l-1}\right) \leq 2q + 8\sqrt{\varepsilon}m.$$

*Proof.* Applying the Markov inequality (the sum of the  $\xi_{i,t}(Y, Z)$ ), using Fact 5 (when passing from the first line to the second line) and Fact 2 (when passing from the second line to the third line), we have

$$\begin{aligned} \Pr\left(\sum_{i \in \{0,1\}^l} \xi_{i,m}(Y, Z) \geq 2^{l-1}\right) &\leq \frac{\text{Exp}(\sum_{i \in \{0,1\}^l} \xi_{i,m}(Y, Z))}{2^{l-1}} \\ &\leq 2^{-l+1} \cdot \left(2^l \cdot (q + 2\sqrt{\varepsilon}m) + 2 \cdot \sum_{i \in \{0,1\}^l} \sum_{t=0}^{m-1} \text{Exp}(\eta_{i,t}(Y))\right) \\ &\leq 2q + 4\sqrt{\varepsilon}m + 4 \cdot \sqrt{\varepsilon}m \\ &= 2q + 8\sqrt{\varepsilon}m. \quad \square \end{aligned}$$

Since  $\xi_{i,m}(Y, Z) = 1$  is just a fancy way of writing  $h_i(Y) \notin W$ , we get

$$\Pr(|\{h_i(Y) : i \in \{0, 1\}^l\} \cap W| \leq 2^{l-1}) \leq 2q + 8\sqrt{\varepsilon}m,$$

and Proposition 28 follows.  $\square$

**5.2. The transformation of BPP algorithms.** It will be convenient to consider randomized algorithms as deterministic algorithms with an auxiliary random input. The performance of such an algorithm (on input  $x$ ) will be evaluated with respect to the distribution of the auxiliary random input (denoted  $y$ ). The issue of the robustness of the class BPP is then stated as follows: *can a BPP algorithm be converted to a polynomial-time algorithm which has an advantage bounded away from  $\frac{1}{2}$  even when its random input is generated by a single probability-bounded source?*

DEFINITION. The class  $(l, b)$ -BPP consists of all decision problems  $D: \{0, 1\}^* \mapsto \{0, 1\}$  for which there exists polynomials  $P, Q$  and an algorithm  $A: \{0, 1\}^* \times \{0, 1\}^* \mapsto \{0, 1\}$  such that for every  $(l, b)$ -source  $Y$  the following holds:

(1) On each input of length  $n$ , algorithm  $A$  runs at most  $P(n)$  steps, and then stops, outputting a single bit.

(2) Let  $x \in \{0, 1\}^m$  be an input and let  $y \in \{0, 1\}^{P(n)}$  be the auxiliary random input generated by the  $(l, b)$ -source  $Y$ . Then

$$\Pr(A(x, y) = D(x)) \geq \frac{1}{2} + Q^{-1}(n).$$

Clearly,  $(l, l)$ -BPP is just a fancy way of writing BPP. Theorem 29 states that so is  $(l, b)$ -BPP.

**THEOREM 29.** *For every integer  $l$  and real  $0 < b \leq l$ ,*

$$(l, b)\text{-BPP} = \text{BPP}.$$

*Proof.* Let  $D$  be a decision problem in BPP, and  $A_0$  be a randomized polynomial-time algorithm for  $D$ . Let  $P(n)$  be the number of random bits used by the algorithm  $A_0$  on inputs of length  $n$ . Without loss of generality, we may assume that for every input  $x \in \{0, 1\}^m$ , the witness set  $W(x)$  for  $x$  (i.e., the  $y$ 's satisfying  $A_0(x, y) = D(x)$ ) contains  $p \geq 0.8$  of the strings in  $\{0, 1\}^{P(n)}$ .

Given  $l$  and  $b$ , let  $\varepsilon(n) \stackrel{\text{def}}{=} (160 \cdot P(n))^{-2}$ ,  $B(n) \stackrel{\text{def}}{=} 3 + 2 \log_2 \varepsilon^{-1}(n)$ , and  $L(n) \stackrel{\text{def}}{=} \lceil lB(n)/b \rceil$ . By Theorem 9, every function corresponding to a Hadamard matrix is  $\varepsilon(n)$ -robust with respect to any pair of independent random variables  $X, Y$  which are  $(L(n), L(n) - 1)$ -distributed and  $(L(n), B(n))$ -distributed, respectively. Furthermore, some of these families of functions, such as the inner-product modulo 2 or the quadratic residuosity modulo  $a$  prime (the Paley Graph function), can be computed by poly( $n$ )-time algorithms. Let  $f$  be one of these functions. Let  $F$  be an algorithm that on inputs  $n$  and  $i, j \in \{0, 1\}^{L(n)}$ , outputs  $f(i, j)$ .

By Proposition 28, we can use a single  $(L(n), B(n))$ -source to efficiently generate  $2^{L(n)}$  strings such that for every  $x \in \{0, 1\}^n$ , the majority of these strings hit the witness set  $W(x)$ , with probability greater than  $1 - 2q - 8P(n)\sqrt{\varepsilon(n)} \geq 0.55$  ( $q \leq 0.2$ ). We remind the reader that the  $(l, b)$ -source can be used as an  $(L(n), B(n))$ -source. Consider the following Algorithm A for deciding membership in  $D$  (with a two-sided error bounded above by 0.45).

1. **Algorithm A**
2. INPUT  $\leftarrow x$
- ; Let  $n = |x|$ , and  $m = P(n)$ .
3. AUXILIARY INPUT:  $y \in \{0, 1\}^{L(n)m}$  generated by an arbitrary  $(l, b)$ -source.
- ; Let  $y = y_1 y_2 \cdots y_m$ , where each  $y_i \in \{0, 1\}^{L(n)}$ .
4. For every  $i \in \{0, 1\}^{L(n)}$  and  $1 \leq j \leq m$ , compute  $f(i, y_j)$ , by invoking  $F(n, i, y_j)$ .
- ; For every  $i \in \{0, 1\}^{L(n)}$ , let  $w_i$  denote the concatenation  $f(i, y_1) \cdot f(i, y_2) \cdots f(i, y_m)$ .
5. For every  $i \in \{0, 1\}^{L(n)}$ , compute  $v_i \stackrel{\text{def}}{=} A_0(x, w_i)$ .
6. If  $\sum_{i \in \{0, 1\}^{L(n)}} v_i \leq 2^{L(n)-1}$  then  $d \leftarrow 0$  else  $d \leftarrow 1$ .
7. OUTPUT:  $d$ .

By the above discussion,  $\Pr(A(x, y) = D(x)) \geq 0.55$ . The running time of  $A(x, y)$  is polynomial in  $2^{L(n)} = n^{O(1)}$ , and in the running time of  $A_0(x, \cdot)$  and  $F(|x|, \cdot, \cdot)$ . The theorem follows.  $\square$

*Remarks.* (1) Algorithm A above is identical to the algorithm used in [32], [30], except that the auxiliary input is generated by a PRB-source instead of an SV-source. The difference is in the analysis of the success probability of this algorithm. Vazirani and Vazirani rely on properties of a particular function (inner-product modulo 2) to show that the different runs of  $A_0$  use auxiliary inputs related in a “good way.” We

reduce the existence of “good runs” of  $A_0$  to the robustness of the function with respect to two independent sources.

(2) Clearly, the same algorithm also works for the class  $R$ . It produces one-sided error, since for  $x \notin D$  the original algorithm  $A_0$  never errs.

(3) Proposition 28 can be viewed as proving a method for using a single PRB source to distinguish “high-density” sets from “low-density” sets. That is, given  $K \subset \{0, 1\}^k$  so that either  $|K| \geq p2^k$  or  $|K| \leq q2^k$ , determine which of the two cases occurs, with success probability about  $1 - 2q$ .

This viewpoint is helpful in solving the following additive approximation problem: for any  $\epsilon, \delta > 0$ , and any set  $S \subset \{0, 1\}^m$ , find an *additive*  $(\delta, \epsilon)$  approximation of the density of  $S$ , denoted  $\rho$ , using a single probability-bounded source (when we have an oracle for deciding membership in  $S$ ). By an *additive*  $(\delta, \epsilon)$ -approximation we mean that with probability  $\geq 1 - \epsilon$ ,  $|\rho - a| \leq \delta$  where  $a$  is the approximated values and  $\rho \stackrel{\text{def}}{=} |S|/2^m$  is the true density. To get this approximation, we first transform the problem of additive approximation into  $2/\delta$  problems of the form “ $P_j$ : is  $\rho \in [j \cdot \delta/2, j \cdot \delta/2 + \delta]$ ?” where  $0 \leq j \leq (2 - 2\delta)/\delta$  (notice that every pair of consecutive intervals overlaps by  $\delta/2$ ). By sampling  $k = O(\delta^{-2} \log(\epsilon\delta)^{-1})$  points in  $\{0, 1\}^m$ , and counting the number of times  $S$  is hit, every  $P_j$  has a corresponding witness set  $S_j \subset \{0, 1\}^{mk}$ . It is easy to see that for at most two consecutive  $j$ 's in the above range,  $S_j$  has more than  $(1 - \epsilon\delta)2^{kn}$  points, while all other  $j$ 's (except possibly another consecutive  $j$ ) has fewer than  $\epsilon\delta 2^{kn}$  points. Now we use the ideas above to try and hit all  $S_j$ 's by strings generated from a single probability-bounded source. With probability  $> 1 - \epsilon$ , we get positive answers only for  $j$ 's in a  $\delta$  neighbourhood of  $\rho$ . In case we get positive answers for several  $P_j$ 's, we choose the median  $j$ , and estimate  $\rho$  as being in the middle of the  $j$ th interval.

#### Appendix: Proof of Lemma 20.

LEMMA 20. Let  $0 < \delta \leq 4$  and  $G((A, B), E)$  be a bipartite graph with  $n$  vertices on each side and at least  $\frac{1}{2}n^2$  edges. Suppose that the number of edges in every subgraph of  $G$ , with  $q \stackrel{\text{def}}{=} \delta/128 \cdot n$  vertices on each side, is in the range  $[q^2/3, 2q^2/3]$ . Then there exist  $m \geq n/4$  and  $k = m/32$  such that  $G$  contains a  $k$ -regular subgraph with  $m$  vertices on each side.

*Proof.* Our proof is constructive. The construction proceeds in two phases. First, we use brute force to find a subgraph  $G'$  of  $G$ , which has  $m \geq n/4$  vertices on each side, average degree  $\geq (\frac{1}{2} - \delta/128) \cdot m$ , and minimum degree  $\geq m/8$ . Next we apply Hall's Theorem to find a spanning  $k$ -regular subgraph of the latter.

The subgraph  $G'$  is found by applying the following procedure.

1. **procedure 1: FIND LARGE SUBGRAPH  $G'$**   
; A vertex  $a \in A$  in a bipartite graph  $G((A, B), E)$  is called *bad* if its degree is  $< \frac{1}{4} \cdot |B|$ .
2. INPUT  $\leftarrow G(V, E)$   
; **Step 1—Omitting bad vertices from both sides**
3.  $G' \leftarrow G$
4. *While* both sides of  $G'(V, E')$  contain bad vertices *do begin*  
; Let  $L$  (resp.  $R$ ) be the set of bad vertices in the left (resp. right) side of  $G'$ .
5.  $\beta \leftarrow \min\{|L|, |R|\}$ ;
6. Omit  $\beta$  vertices of  $L$  and  $\beta$  vertices of  $R$  from  $G'$ .  
; The resulting graph is referred to as  $G'$ .
7. *end*;

- ; **Step 2—Omitting bad vertices from the remaining side**
- ; Let  $L$  (resp.  $R$ ) be the set of bad vertices in the left (resp. right) side of  $G'$ .  
 [By the above, either  $L$  or  $R$  is empty.  $W \log$  let  $R = \emptyset$ .]
- 8. Omit all remaining bad vertices (i.e.,  $L$ ) from the graph.
- 9. Omit, from the right side of the remaining graph,  $|L|$  vertices of minimum degree.
- 10. **return**  $G'$ .

Throughout the execution of Step (1) of the above procedure, we only omit vertices with degree not exceeding half the current average degree. Thus, at the end of Step (2) average degree in the remaining graph is no less than half the number of vertices in one side of the graph.

Let  $2t$  denote the number of vertices omitted in Step (1). Then the number of edges deleted in Step (1) is at most

$$t \cdot \frac{n}{4} + t \cdot (n - t).$$

(We charge deleted edges with a bad leftpoint to vertices omitted from the left side of the graph, while charging all other deleted edges to the vertices omitted from the right.) Using the above upper bound on  $|E - E'|$ , we get

$$\frac{n^2}{2} \leq |E| = |E - E'| + |E'| \leq t \cdot \frac{n}{4} + t \cdot (n - t) + (n - t)^2$$

which yields  $t \leq \frac{2}{3} \cdot n$ .

Now we claim that in Step (2),  $L$  could not be too big. If  $|L| \geq 3\delta/128 \cdot r$ , where  $r$  is the number of vertices in the right side of  $G'$  after Step (1), we reach contradiction by considering the subgraph induced on  $G'$  by all the vertices of the right side and the vertices in  $L$ . (This subgraph has at most  $\frac{1}{4}$  of all possible edges, contradicting the Lemma's hypothesis.) It is easy to see that after Step (2) the number of vertices on each side of the graph, denoted  $m$ , is  $\geq (1 - 3\delta/128)n/3 > n/4$ . Also, the minimum degree in the remaining graph is  $\geq r/4 - 3\delta \cdot r/128 \geq m/8$ , and the average degree is  $\geq (\frac{1}{2} - \delta/(32 \cdot 4)) \cdot m$ .

The second phase of our construction consists of finding a spanning  $k$ -regular graph of  $G_0 = G'$ . This is done by applying the following procedure.

1. **procedure 2:** FIND SPANNING  $k$ -REGULAR SUBGRAPH
2. INPUT  $\leftarrow G_0((A_0, B_0), E_0)$
3.  $R \leftarrow \emptyset$
4. For  $i = 1$  to  $k$  do begin
5. Find a perfect matching  $M_i$  in  $G_{i-1}$ .
6.  $R \leftarrow R \cup M_i$ .
7. Omit  $M_i$  from  $G_{i-1}$ , resulting in  $G_i$ .
8. end;
9. **return**  $R$ .

We now show that Procedure 2 does not fail. Assume on the contrary that in some iteration  $i + 1 \leq k$  a perfect matching is not found. Namely,  $G_i$  does not contain a perfect matching. By Hall's Theorem [7, § 5.2, p. 72], the left side of  $G_i$  (i.e.,  $A_0$ ) contains a set of vertices  $A'$  such that the neighbourhood of  $A'$  (denoted  $B'$ ) has cardinality smaller than  $|A'|$ . Since the residual degree of  $G_i$  is  $\geq m/8 - i$ , we get

$$|A'| > |B'| \geq \frac{m}{8} - k.$$

Consider the neighbourhood of a node in  $B_0 - B'$  (such a node does exist since  $|B'| < |A'| \leq |B_0|$ ). This neighbourhood has cardinality  $\geq m/8 - k$  and does not intersect with  $A'$ . We conclude that

$$|B_0 - B'| > |A_0 - A'| \geq \frac{m}{8} - k.$$

It should be noted that there are no edges in  $G_i$  between  $A'$  and  $B_0 - B'$ . Thus,  $G_0$  (or  $G$  for this matter) contain at most  $i \cdot \min\{|A'|, |B_0 - B'|\}$  edges between  $A'$  and  $B_0 - B'$ . This is at most one-third of  $|A'| \cdot |B_0 - B'|$  (since  $i < k = m/32$  and  $\min\{|A'|, |B_0 - B'|\} \geq m/8 - k = 3m/32$ ), which contradicts the lemma's hypothesis.  $\square$

**Acknowledgments.** We wish to thank Baruch Awerbuch for collaborating with us at the early stages of this research. We are very grateful to Noga Alon, László Babai and Carl Pomerance for sharing with us some of their mathematical knowledge. Noga Alon has referred us to the properties of Hadamard matrices, which turned out to be very suitable for our purposes. László Babai has referred us to the  $k$ th residues construction used in § 3 and Carl Pomerance has provided us with the estimates on the density of primes suitable for this construction. Their help enabled us to get the extraction scheme which is efficient in both rate and computation measures.

We are grateful to Jeff Lagarias for suggesting that we consider “extraction at the limit,” Nati Linial for pointing out Theorem 4, Mike Luby for pointing out that the entropy bound does suffice, Andrew Odlyzko for referring us to Paley Graph Conjecture, and Avi Wigderson for his interpretation of the result in [32].

We also wish to thank Reuven Bar-Yehuda, Shimon Even, Michael Fischer, Mihali Gerek, Shafi Goldwasser, Abraham Lempel, Leonid Levin, Silvio Micali, Ron Rivest, David Shmoys and Umesh Vazirani for very helpful discussions. Finally, we would like to thank the referees for their helpful comments.

## RECONSTRUCTING TRUNCATED INTEGER VARIABLES SATISFYING LINEAR CONGRUENCES\*

ALAN M. FRIEZE†, JOHAN HASTAD‡, RAVI KANNAN§, JEFFREY C. LAGARIAS¶  
AND ADI SHAMIR||

**Abstract.** We propose a general polynomial time algorithm to find small integer solutions to systems of linear congruences. We use this algorithm to obtain two polynomial time algorithms for reconstructing the values of variables  $x_1, \dots, x_k$  when we are given some linear congruences relating them together with some bits obtained by truncating the binary expansions of the variables. The first algorithm reconstructs the variables when either the high order bits or the low order bits of the  $x_i$  are known. It is essentially optimal in its use of information in the sense that it will solve most problems almost as soon as the variables become uniquely determined by their constraints. The second algorithm reconstructs the variables when an arbitrary window of consecutive bits of the variables is known. This algorithm will solve most problems when twice as much information as that necessary to uniquely determine the variables is available. Two cryptanalytic applications of the algorithms are given: predicting linear congruential generators whose outputs are truncated and breaking the simplest version of Blum's protocol for exchanging secrets.

**Key words.** pseudorandom numbers, linear congruential generators, lattice basis reduction algorithm, cryptography

**AMS(MOS) subject classifications.** 11T71, 11K45

**1. Introduction.** The basic techniques of cryptanalysis are methods for solving various sorts of reconstruction problems. Given diverse kinds of information about a cryptosystem together with some enciphered messages, the cryptanalyst wishes to combine this information to recover the original plaintext messages, which is the *message reconstruction problem*. The cryptanalyst often accomplishes this by solving the possibly harder problem of finding the key used by the encipherer, which is the *key reconstruction problem*. From this perspective a general method of cryptanalysis is one that solves a wide class of reconstruction problems. General reconstruction methods serve as building blocks in the cryptanalysis of complex cryptosystems and also serve to set limitations of the possible design of secure cryptosystems.

This paper studies a reconstruction problem arising from the combination of two basic operations used in the design of pseudorandom number generators and cryptosystems. These two operations consist of modular arithmetic operations used as a computationally efficient way to “mix” the values of certain variables and the (non-linear) operation of truncating the binary representation of the results. A simple scheme of this type (which was used extensively on early computers) generates a pseudorandom sequence of integers by alternately squaring the previous  $n$ -bit value and discarding the top and bottom  $n/2$  bits of the  $2n$ -bit result. A related scheme is that of using the high-order bits of a linear congruential sequence, which is generally called a *truncated linear congruential pseudorandom number generator*. This was proposed by Knuth [10].

The problem we consider is that of reconstructing a set  $(x_1, x_2, \dots, x_k)$  of integer variables given two sorts of information about them. First we are given a set of  $l$  modular equations

$$(1.1) \quad \sum_{j=1}^k a_{ij}x_j \equiv c_i \pmod{M} \quad \text{for } 1 \leq i \leq l,$$

that the variables satisfy. We assume that the  $a_{ij}$ ,  $c_i$  and  $M$  are known, and that the unknowns  $x_i$  satisfy the bounds

$$(1.2) \quad 0 \leq x_j < M \quad \text{for } 1 \leq j \leq k.$$

Second, we are given side information about some of the bits of the  $x_j$ , which consists of knowledge of blocks of consecutive binary digits of the variables  $x_j$ . More precisely, this partial information consists of knowledge of

$$(1.3) \quad y_j \equiv \left[ \frac{x_j}{2^{l_j}} \right] \pmod{2^{l_j}} \quad \text{for } 1 \leq j \leq k.$$

Here  $[z]$  denotes the greatest integer of a real number  $z$ . In this case we know a fraction  $\delta$  of the bits of each  $x_i$ , where  $\delta$  is given by

$$\delta = \frac{l_1}{[\log_2 M]}$$

whenever  $l_1 + l_2 \leq [\log_2 M]$ . The interesting case for cryptanalysis occurs when the number of equations  $l$  is less than the number of unknowns  $k$ . In this case the congruences  $\pmod{M}$  taken by themselves constrain the variables  $x_j \pmod{M}$  but do not determine them uniquely.

The first question to deal with is: how much side information is needed to make unique reconstruction possible? We may obtain an information-theoretic lower bound for the amount of side information required as follows. Suppose  $2^{n-1} \leq M < 2^n$  so that the  $x_j$  are  $n$  bit integers, and that we know a block of  $\delta n$  bits of each  $x_j$ . Now  $l$  modular equations  $\pmod{M}$  with side conditions  $0 \leq x_i < M$  can normally be used to eliminate  $l$  of the variables. The remaining  $k-l$  variables contain  $(k-l)n$  unknown bits of information which must be uniquely determined by the  $k\delta n$  bits given by the variables  $y_j$ . Consequently we infer that a necessary condition for unique reconstruction is that  $k\delta n \geq (k-l)n$ , which is

$$(1.4) \quad \delta \geq 1 - \frac{l}{k}.$$

In fact it turns out that the fraction  $\delta = 1 - (l/k) + \epsilon$  of the highest-order bits of each  $x_j$  suffice to guarantee unique reconstruction for the overwhelming majority of systems (1.1)–(1.3), in a sense made precise in § 2. However, there does exist a small minority of such systems which require a larger  $\delta$  than given by (1.4) to guarantee unique reconstructibility.

The main result of this paper is a general technique for solving this type of problem. It uses lattice basis reduction ideas and is guaranteed to run in polynomial time, but is not always guaranteed to produce a reconstruction. In the problems we are considering there are two major cases. The first case applies when the truncated variables  $y_j$  either consist of the highest-order bits of the  $x_j$ , or consist of the lowest-order bits of

the  $x_j$  and  $M$  is odd. We show in Theorem 2.1 that our general algorithm succeeds for “most” instances when

$$\delta > 1 - \frac{l}{k} + \varepsilon,$$

where

$$\varepsilon = \frac{c_k}{\log M}.$$

We will quantify what “most” means in § 2. The constants  $c_k$  are of size  $O(k)$ . Our second case applies to systems with arbitrarily truncated variables  $y_j$ . To be effective it requires that twice as much side information be given as that needed to guarantee uniqueness, that is,

$$\delta > 2 \left( 1 - \frac{l}{k} \right) + \varepsilon,$$

and it then works for “most” systems (Theorem 2.3). There is a small fraction of problems on which the algorithms fail, and there is a smaller fraction of exceptional problems for which unique reconstruction is not possible.

We demonstrate the usefulness of these reconstruction procedures with two applications:

(1) We show that truncated linear congruential pseudorandom number generators are cryptographically insecure in most cases.

(2) We show that the simplest version of Blum’s protocol [1] for exchanging secrets is insecure. We remark that Blum suggests other implementations of this protocol which do not seem vulnerable to the attack described here.

The two applications are described in §§ 3 and 4, respectively, where we give an analysis of our algorithm applied to these cases. The main technical difficulty is to analyze the behavior of the lattices arising in the special problems.

Some of the results of this paper appeared in preliminary form in Frieze, Kannan and Lagarias [5] and Hastad and Shamir [6].

**2. Reconstructing truncated variables satisfying linear congruences.** Let  $M$  be a given modulus and  $x_1, \dots, x_k$  unknown values in the range  $0 \leq x_j < M$  satisfying  $l$  independent linear congruences (mod  $M$ ):

$$(2.1) \quad \sum_{j=1}^k a_{ij} x_j \equiv c_i \pmod{M} \quad \text{for } 1 \leq i \leq l,$$

where  $l \leq k$ . The coefficients  $a_{ij}$  and  $c_i$  and the modulus  $M$  are assumed to be known. We are given (or somehow obtain) certain bits  $y_j$  of each  $x_j$  where

$$(2.2) \quad y_j \equiv \left\lfloor \frac{x_j}{2^{l_2}} \right\rfloor \pmod{2^{l_1}},$$

and our goal is to combine this partial knowledge with the given linear relationship to compute the remaining bits of all the  $x_j$ ’s. Our main tools to do this will come from the geometry of numbers, see [3], [4]. Let us recall some facts. A (full rank) *lattice*  $L$  is defined to be the set of points

$$L = \left\{ \mathbf{y}: \mathbf{y} = \sum_{i=1}^k n_i \mathbf{b}_i, n_i \in \mathbb{Z} \right\}$$

where the  $\mathbf{b}_i$  are linearly independent vectors in  $\mathbb{R}^k$ . The set  $\{\mathbf{b}_i; 1 \leq i \leq k\}$  is called a *basis* of  $L$  and  $k$  is the *dimension* of the lattice. The *determinant*  $d(L)$  of a lattice  $L$  is defined to be the absolute value of the determinant of a matrix whose rows are the  $\mathbf{b}_i$ . Geometrically the determinant can be interpreted as the volume of the parallelepiped spanned by the basis vectors. Using this interpretation it is possible to prove that the determinant is equal to the inverse of the density of the lattice (where the density is the average number of lattice points per unit volume). This characterization shows that the determinant is independent of the choice of basis.

We define the  $i$ th *successive minimum*  $\lambda_i = \lambda_i(L)$  of a lattice  $L$  to be the smallest radius  $r$  such that the sphere or radius  $r$  around 0 in  $\mathbb{R}^k$  contains  $i$  linearly independent points of  $L$  in it or on its boundary. We will be interested in lattices whose successive minima are roughly the same size.

We will be interested in bounding  $\lambda_k$  from above. To do so, we use the *dual lattice*  $L^*$  which is defined to be

$$L^* = \{\mathbf{y} \mid \langle \mathbf{y}, \mathbf{x} \rangle \in \mathbb{Z} \text{ for all } \mathbf{x} \in L\}.$$

It is well known that  $d(L^*) = d(L)^{-1}$ . A classical result asserts that  $\lambda_1 \lambda_k^* \leq k!$  [3, p. 371], and a recent result of Lagarias, Lenstra and Schnorr [12, Thm. 4.4] shows that  $\lambda_1^* \lambda_k \leq k^2/6$  for  $k \geq 7$ , where  $\lambda_1^*$  denotes the length of the shortest vector of  $L^*$ , and  $\lambda_1^* \lambda_k \leq k^2$  for all  $k$ . Thus a lower bound for  $\lambda_1^*$  gives the desired upper bound for  $\lambda_k$ .

The idea to use the dual lattice was suggested to us by C. P. Schnorr [17]. Our original method gave constants having a worse dependence on  $k$ .

Let us return to our problem. Let  $L(\mathbf{a}, M)$  be the lattice in  $\mathbb{R}^k$  spanned by the  $l$  vectors  $\mathbf{a}_i = (a_{i,1}, \dots, a_{i,k})$  (the coefficients of the known modular relations) in (2.1) and by the  $k$  vectors  $M\mathbf{e}_i$  where  $\mathbf{e}_i$  are the unit vectors along the coordinate axes. We will use this lattice in our algorithm, and the performance of the algorithm depends on properties of this lattice. Observe that the dual lattice  $L^* = L^*(\mathbf{a}, M)$  is

$$\left\{ \frac{1}{M} \mathbf{y} \mid \langle \mathbf{y}, \mathbf{a}_i \rangle \equiv 0 \pmod{M} \text{ for } 1 \leq i \leq l \right\},$$

where  $\langle \mathbf{y}, \mathbf{a}_i \rangle$  is the Euclidean inner product.

Let us start by giving the theorem which will be our main tool.

**THEOREM 2.1.** *The system of modular equations*

$$\sum_{j=1}^k a_{ij} x_j \equiv c_i \pmod{M}, \quad i = 1, 2, \dots, l$$

has at most one solution  $\mathbf{x} \in \mathbb{Z}^k$  satisfying the bound

$$(2.3) \quad \|\mathbf{x}\| \leq M \lambda_k^{-1} 2^{-(k/2)-1},$$

where  $\lambda_k$  is the largest successive minimum of the lattice  $L(\mathbf{a}, M)$ . If the  $a_{ij}$ ,  $c_i$  and  $M$  are known then there is a polynomial time algorithm that either finds  $\mathbf{x}$  or proves that no such  $\mathbf{x}$  exists.

*Proof.* We use a three-stage algorithm. First, we apply a lattice basis reduction algorithm to the lattice  $L = L(\mathbf{a}, M)$  of known modular relations to get modular relations with small coefficients. Second, we use size constraints on the  $x_j$  to transform these equations to equations over the integers. Third, we use these equations over the integers to recover the exact values of the  $x_j$ .

We apply the lattice basis reduction algorithm of Lenstra, Lenstra and Lovász [13] to the lattice  $L$  of modular relations to obtain a good basis. They prove the following result.

THEOREM 2.2. *There exists an algorithm, the  $L^3$ -algorithm, that when given as input a basis  $\{\mathbf{b}_i: 1 \leq i \leq k\}$  of an integer lattice  $L \subseteq \mathbb{R}^k$  finds a basis  $\{\mathbf{b}_i^*: 1 \leq i \leq k\}$  such that*

$$(2.4) \quad \|\mathbf{b}_i^*\| \leq 2^{k/2} \lambda_i(L) \quad \text{for } 1 \leq i \leq k.$$

*This algorithm always halts in  $O(n^6(\log B)^3)$  bit operations, where  $B^2 = \sum_{i=1}^k \|\mathbf{b}_i\|^2 = \sum_{i=1}^k \sum_{j=1}^k b_{ij}^2$ .*

We do not have a basis for the lattice  $L(\mathbf{a}, M)$  but we can obtain one as follows. Using a Hermite normal form reduction algorithm (see [8]) we obtain in polynomial time an integer matrix  $V$  in  $GL(k+l, \mathbb{Z})$  such that

$$\begin{bmatrix} \mathbf{w}'_1 \\ \mathbf{w}'_k \\ 0 \\ \vdots \\ 0 \end{bmatrix} = V \begin{bmatrix} \mathbf{a}_1 \\ \vdots \\ \mathbf{a}_l \\ M\mathbf{e}_1 \\ \vdots \\ M\mathbf{e}_k \end{bmatrix},$$

where the matrix on the left is in Hermite normal form and  $\{\mathbf{w}'_i: 1 \leq i \leq k\}$  is a basis of  $L(\mathbf{a}, M)$ . Now the  $L^3$ -algorithm applied to this basis produces an  $L^3$ -reduced basis  $\{\mathbf{w}_i: 1 \leq i \leq k\}$  and a unimodular matrix  $U$  in  $GL(k, \mathbb{Z})$  such that

$$\begin{bmatrix} \mathbf{w}_1 \\ \vdots \\ \mathbf{w}_k \end{bmatrix} = U \begin{bmatrix} \mathbf{w}'_1 \\ \vdots \\ \mathbf{w}'_k \end{bmatrix}$$

and

$$\|\mathbf{w}_i\| \leq 2^{k/2} \lambda_k, \quad 1 \leq i \leq k.$$

Combining these steps we obtain an integer matrix  $Y$  such that

$$(2.5) \quad \begin{bmatrix} \mathbf{w}_1 \\ \vdots \\ \mathbf{w}_k \end{bmatrix} = Y \begin{bmatrix} \mathbf{a}_1 \\ \vdots \\ \mathbf{a}_l \\ M\mathbf{e}_1 \\ \vdots \\ M\mathbf{e}_k \end{bmatrix}$$

(Alternatively the  $L^3$ -algorithm can be adapted to work on a set of generators of a lattice and produce (2.5) directly.) Now by multiplying (2.5) on the right by  $\mathbf{x}$  and reducing (mod  $M$ ) using (2.1) we obtain modular relations with small coefficients:

$$(2.6) \quad \sum_{j=1}^k w_{ij} x_j \equiv c'_i \pmod{M}, \quad 1 \leq i \leq k.$$

Note that, although we started with  $l$  modular equations in (2.1), we have now obtained a full set of  $k$  modular relations which are independent over the integers.

To perform the second stage of the algorithm we observe that

$$\left| \sum_{j=1}^k w_{ij} x_j \right| \leq \|\mathbf{w}_i\| \|\mathbf{x}\| < 2^{k/2} \lambda_k M \lambda_k^{-1} 2^{-(k/2)-1} < \frac{M}{2}.$$

Thus if we choose  $c'_i$  to satisfy  $|c'_i| < M/2$  we know that

$$\sum_{j=1}^k w_{ij} x_j = c'_i, \quad 1 \leq i \leq k,$$

holds over the integers.

Finally we solve this system of  $k$  linearly independent equations in  $k$  unknowns.  $\square$

Let us see how to use Theorem 2.1 if the variables are not small but some of the bits are known. Define for convenience

$$(2.7) \quad s_0 = \log \lambda_k + \frac{k}{2} + \frac{1}{2} \log k + 1,$$

where  $\lambda_k = \lambda_k(L(\mathbf{a}, M))$ .

COROLLARY 2.3. *The system of modular equations*

$$\sum_{j=1}^k a_{ij}x_j \equiv c_i \pmod{M}, \quad i = 1, 2, \dots, l$$

has at most one solution  $\mathbf{x}$  in which either of the following conditions holds:

- (i) The  $s_0$  most significant bits of each  $x_j$  are specified.
- (ii) The  $s_0$  least significant bits of each  $x_j$  are specified, and  $M$  is odd.

If the  $a_{ij}$ ,  $c_i$  and  $M$  are known there is a polynomial time algorithm that either finds  $\mathbf{x}$  or proves that no such  $\mathbf{x}$  exists.

*Proof.* To prove case (i) we just observe that  $x_i = x_i^{(1)} + x_i^{(2)}$  where  $x_i^{(1)}$  are the known most significant bits and  $|x_i^{(2)}| \leq M\lambda_k^{-1}2^{-(k/2)-1}\sqrt{k}^{-1}$ . Substituting the known  $x_i^{(1)}$  we come into position to use Theorem 2.1.

For the case (ii) write  $x_i = 2^{s_0}x_i^{(1)} + x_i^{(2)}$  where  $x_i^{(2)}$  are known and  $x_i^{(1)}$  satisfies the same size bounds. Since  $M$  is odd  $(2^{s_0})^{-1} \pmod{M}$  is defined, and after multiplying the equations by  $(2^{s_0})^{-1} \pmod{M}$  we can use Theorem 2.1.  $\square$

Note that the algorithm of Theorem 2.1 can be applied without knowing the value of  $\lambda_k$  or whether or not the bound (2.3) holds. To explain this, we associate with any basis  $\{\mathbf{b}_i: 1 \leq i \leq k\}$  of a lattice  $L$  in  $\mathbb{R}^k$  the quantity

$$(2.8) \quad \Delta_k(\mathbf{b}_1, \dots, \mathbf{b}_k) = \max_{1 \leq i \leq k} (\|\mathbf{b}_i\|).$$

Then by the proof of Theorem 2.1 the algorithm succeeds whenever

$$(2.9) \quad s_0 \geq \log \Delta_k(\mathbf{b}_1^*, \dots, \mathbf{b}_k^*) + \frac{1}{2} \log k + 1,$$

where  $\{\mathbf{b}_i^*: 1 \leq i \leq k\}$  is the  $L^3$ -reduced basis of the lattice  $L(\mathbf{a}, M)$  obtained in the algorithm. The bound (2.9) can be checked during the algorithm.

When can the algorithms of Corollary 2.2 be expected to succeed? This depends on the value of  $\lambda_k$ , and to get an idea how large it usually is we estimate it in the case where the modulus  $M$  is a fixed prime and the coefficients  $a_{ij}$  of the modular relations (2.1) are drawn independently from the uniform distribution on  $[0, M - 1]$ .

THEOREM 2.4. *Let  $p$  be prime. For the  $p^{kl}$  possible systems  $\mathbf{A}$  of modular equations*

$$\sum_{j=1}^k a_{ij}x_j \equiv 0 \pmod{p} \quad \text{for } 1 \leq i \leq l$$

arising by choosing

$$0 \leq a_{ij} < p \quad \text{for } 1 \leq i \leq l \text{ and } 1 \leq j \leq k$$

at least  $(1 - \varepsilon - O(p^{-1/k}))p^{kl}$  of these give rise to lattices  $L(\mathbf{A}, p)$  which have

$$(2.10) \quad \lambda_k < 5k^{3/2} \varepsilon^{-1/k} p^{1-1/k}.$$

*Proof.* We will use the previously mentioned result by Lagarias, Lenstra and Schnorr [12] that  $\lambda_1^* \lambda_k \leq k^2$  for all  $k \geq 1$ .

We estimate the probability that  $L^*$  contains a short vector. We know that  $pL^*$  is the integer lattice  $\{y \mid \langle y, \mathbf{a}_i \rangle \equiv 0 \pmod{p}; 1 \leq i \leq l\}$ . Take a sphere  $S$  centered around 0 of radius  $R$  where  $R < p$ . For any nonzero point  $\mathbf{z}$  in  $S$  the probability that  $\mathbf{z} \in pL^*$  is  $p^{-l}$ . Thus the probability that any point inside  $S$  is in  $pL^*$  is bounded by  $S_k(R) \cdot p^{-l}$ , where  $S_k(t)$  counts the number of lattice points in a  $k$ -dimensional sphere of radius  $t$  centered at the origin. Since  $S_k(t) = V_k t^k + O(kV_k t^{k-1})$  with  $V_k = \pi^{k/2} / \Gamma(k/2 + 1)$  as  $t \rightarrow \infty$  we conclude that if we choose  $R = (\pi^{k/2} / \Gamma(k/2 + 1))^{-1/k} \varepsilon^{1/k} p^{l/k}$  then  $p^{-l} S_k(R) = \varepsilon + O(p^{-l/k})$  as  $p \rightarrow \infty$ . Hence we conclude that with probability  $1 - \varepsilon - O(p^{-l/k})$  the inequality

$$\lambda_1^* \leq \frac{1}{p} \left( \frac{\pi^{k/2}}{\Gamma(k/2 + 1)} \right)^{-1/k} \varepsilon^{1/k} p^{l/k} \leq \frac{1}{5} \sqrt{k} \varepsilon^{1/k} p^{l/k-1}$$

holds, and thus

$$\lambda_k \leq 5k^{3/2} \varepsilon^{-1/k} p^{1-1/k}.$$

This completes the proof.  $\square$

A slightly weaker result than Theorem 2.4 can be proved to hold for all moduli  $M$ . We omit the details.

We may now infer that the algorithm of Corollary 2.3 succeeds in most cases for a random system (2.1) whenever the number  $s$  of known bits exceeds the information bound  $(1 - (l/k)) \log M$  by a small amount. Indeed for  $M$  a prime  $p$ , for most lattices  $L(\mathbf{a}, p)$  the bound (2.7) implies that this happens if  $s$  satisfies

$$(2.11) \quad s \geq \left(1 - \frac{l}{k}\right) \log p + \frac{k}{2} + 2 \log k + \frac{1}{k} |\log \varepsilon| + 3,$$

which exceeds the information bound by a constant depending only on the dimension  $k$  and desired failure rate  $\varepsilon$ .

In cryptanalytic applications, the set of problems (2.1) that arises may be distributed in an entirely different way than the uniform distribution studied in Theorem 2.4. For this reason, in §§ 3 and 4 we separately analyze the distributions of  $\lambda_k$  arising in our two applications. However in the absence of other information, the bound (2.11) is a useful heuristic to use.

We now describe and analyze our second algorithm, which applies to the set of modular equations

$$(2.12) \quad \sum_{j=1}^k a_{ij} x_j \equiv c_i \pmod{M}, \quad 1 \leq i \leq l$$

where we are given an arbitrarily located window of bits for each  $x_i$ . We suppose that the window of  $s$  truncated bits is from bit  $w$  to bit  $w + s - 1$ , i.e.,

$$x_i = x_i^{(1)} + 2^w x_i^{(2)} + 2^{w+s} x_i^{(3)}$$

where  $x_i^{(1)} < 2^w$ ,  $x_i^{(2)} < 2^s$  and  $x_i^{(3)} < M2^{-w-s}$ , and  $x_i^{(2)}$  is assumed to be known. Thus the unknown is  $x_i^{(1)} + 2^{w+s} x_i^{(3)}$ .

To use Theorem 2.1 we want to transform (2.12) to an equation with small unknowns. To do this we find  $a$  which satisfies

$$(2.13) \quad |a| \leq M2^{-w-s/2} \quad \text{and} \quad |a2^{w+s} \pmod{M}| \leq 2^{w+s/2}.$$

Such an  $a$  always exists and we can find it in polynomial time using the result of Lenstra [14] that there is a polynomial time algorithm for solving integer programs in

a fixed number of variables. This is because (2.13) can be written as the integer program in three variables  $(a, y_1, y_2)$  given by

$$\begin{aligned} -M2^{-w-(s/2)} &\leq a - My_1 \leq M2^{-w-(s/2)}, \\ -2^{w+(s/2)} &\leq a2^{w+s} - My_2 \leq 2^{w+(s/2)}, \\ 0 &< a < M. \end{aligned}$$

Multiplying the equation (2.12) by  $a$  and using the unknowns

$$z_i = ax_i^{(1)} + a2^{w+s}x_i^{(3)}$$

we obtain the modular equation

$$\sum_{j=1}^k a_{ij}z_j \equiv c'_i \pmod{M}, \quad 1 \leq i \leq l,$$

where the quantities

$$c'_i = a \left( c_i - 2^w \sum_{j=1}^k a_{ij}x_i^{(2)} \right)$$

are known. Now we know by (2.13) that

$$|z_i| \leq |a||x_i^{(1)}| + |a2^{w+s} \pmod{M}||x_i^{(3)}| \leq M2^{-s/2+1}.$$

Thus provided that

$$s > 2 \log \lambda_k + k + \log k + 4$$

holds that we can apply Theorem 2.1 and find  $z_i$ . If  $(a, M) = 1$  then all that remains is to compute  $a^{-1}z_i \pmod{M}$ . If  $M$  is prime then  $(a, M) = 1$  is guaranteed to hold and we have proved the following result.

**COROLLARY 2.5.** *Suppose  $M$  is prime and we are given a known system of modular equations*

$$\sum_{j=1}^k a_{ij}x_j \equiv c_i \pmod{M}, \quad 1 \leq i \leq l,$$

and a window of  $s$  truncated bits of each  $x_i$  consisting of bits  $w$  to  $w + s - 1$  where

$$s > 2 \log \lambda_k + k + \log k + 4.$$

Then there is a polynomial time algorithm that either finds a solution  $\mathbf{x}$  to the modular equations matching the truncated window data, or else proves that no such  $\mathbf{x}$  exists.

However in the case of a general modulus  $M$  we cannot assume that  $(a, M) = 1$ . There might not even exist an  $a$  such that  $(a, M) = 1$  which has the desired properties. To get around this problem we will use a different approach. We will prove a result for general  $M$  which depends on Diophantine approximation properties of the number  $M/2^{w+s}$ . Define for a real number  $\theta$  the quantity

$$(2.14) \quad \alpha(\theta, x) = \min_{\substack{m, n \in \mathbb{Z} \\ 1 \leq n \leq x}} |n\theta - m|.$$

We have the following result.

**THEOREM 2.6.** *Suppose that we are given a known system of modular equations*

$$\sum_{j=1}^k a_{ij}x_j \equiv c_i \pmod{M}, \quad i = 1, 2, \dots, l$$

and that we are given a window of  $s$  bits of each of the variables  $x_i$  whose largest bit is the  $(w + s)$ th bit. If

$$(2.15) \quad s \geq \log \lambda_k + \frac{k}{2} + \left| \log \alpha \left( \frac{M}{2^{w+s}}, \sqrt{k} 2^{(k/2)+1} \lambda_k \right) \right| + \frac{1}{2} \log k + 1$$

then the  $x_i$  are uniquely determined and can be found in polynomial time.

*Proof.* As in the proof of Theorem 2.1 we get a system of equations

$$\sum_{j=1}^k w_{ij} x_j \equiv c'_i \pmod{M}, \quad 1 \leq i \leq k,$$

where  $\|w_i\| \leq 2^{k/2} \lambda_k$ . Over the integers we can write this as

$$(2.16) \quad \sum_{j=1}^k w_{ij} x_j = c'_i + d_i M, \quad 1 \leq i \leq k,$$

where we know by the bound for the  $w_i$  that  $|d_i| \leq \sqrt{k} 2^{k/2} \lambda_k$ . Using  $x_j = x_j^{(1)} + x_j^{(2)} 2^w + x_j^{(3)} 2^{w+s}$  where  $x_j^{(2)}$  are known we get

$$(2.17) \quad \sum_{j=1}^k w_{ij} x_j^{(1)} \equiv c''_i + d_i M \pmod{2^{w+s}},$$

where the integers  $c''_i$  are known. Since  $|x_j^{(1)}| \leq 2^w$  the bounds on  $w_i$  imply that

$$(2.18) \quad \left| \sum_{j=1}^k w_{ij} x_j^{(1)} \right| \leq 2^{(k/2)+w} \lambda_k \sqrt{k}.$$

Using (2.17) we obtain

$$c''_i + d_i M \equiv z_i \pmod{2^{w+s}},$$

where  $|z_i| \leq \sqrt{k} 2^{(k/2)+w} \lambda_k$ . Now we know that each  $d_i$  satisfies the integer program in two variables  $(\tilde{d}_i, t_i)$  given by

$$(2.19a) \quad -\sqrt{k} 2^{(k/2)+w} \lambda_k \leq c'_i + \tilde{d}_i M + 2^{w+s} t_i \leq \sqrt{k} 2^{(k/2)+w} \lambda_k,$$

$$(2.19b) \quad -\sqrt{k} 2^{k/2} \lambda_k \leq \tilde{d}_i \leq \sqrt{k} 2^{k/2} \lambda_k.$$

We can find a solution  $(\tilde{d}_i, t_i)$  to this integer program in polynomial time by Lenstra [14] (see also [7]). We claim that all solutions of (2.19) have  $\tilde{d}_i = d_i$ . Suppose not, and let  $d_i^{(1)}, d_i^{(2)}$  be distinct solutions. Then their difference  $\bar{d}_i = d_i^{(1)} - d_i^{(2)}$  satisfies

$$(2.20a) \quad |\bar{d}_i M + 2^{w+s} (t_i^{(1)} - t_i^{(2)})| \leq \sqrt{k} 2^{(k/2)+w+1} \lambda_k,$$

$$(2.20b) \quad |\bar{d}_i| \leq \sqrt{k} 2^{(k/2)+1} \lambda_k.$$

Then

$$\left| \frac{\bar{d}_i M}{2^{w+s}} - r \right| \leq \sqrt{k} 2^{(k/2)-s+1} \lambda_k$$

for some integer  $r = t_i^{(1)} - t_i^{(2)}$ . Using the bound on  $\bar{d}$  and the definition of  $\alpha(M/2^{w+s}, \sqrt{k} 2^{(k/2)+1} \lambda_k)$  if  $\bar{d} \neq 0$  this yields

$$\alpha \left( \frac{M}{2^{s+w}}, \sqrt{k} 2^{(k/2)+1} \lambda_k \right) \leq \sqrt{k} 2^{(k/2)-s+1} \lambda_k.$$

This inequality contradicts the bound for  $s$  in (2.15). Consequently  $\tilde{d}_i = d_i$ . Hence we have found  $d_i$  by solving (2.19). Now we determine the  $x_j$  by solving the invertible linear system (2.16).  $\square$

To estimate the useful range of Theorem 2.6 we need information about the quantities  $\alpha(M/2^{s+w}, \sqrt{k} 2^{(k/2)+1} \lambda_k)$ . Dirichlet's theorem for Diophantine approximation (see [3, p. 165], [9]) asserts that for all real  $\theta$  one has

$$\alpha(\theta, x) \leq \frac{1}{x}$$

for integer  $x$ , and it is known that for most pairs  $(\theta, x)$  one has  $\alpha(\theta, x)$  of size about  $1/x$ . Hence one expects that for most triples  $(M, w, s)$  one has  $\alpha(M/2^{s+w}, \sqrt{k} 2^{(k/2)+1} \lambda_k) \sim k^{-1/2} 2^{-k/2} \lambda_k^{-1}$  and hence that the bound (2.15) is about twice that necessary to uniquely determine the variables  $x_i$ . The loss of efficiency of this algorithm in the information-theoretic sense arises in stage 2 of the algorithm. We are given a window of  $s$  truncated bits. The effect of the low-order bits  $y_j''$  is inflated by the coefficients  $w_{ij}$  of the reduced basis and in the integer program (2.19) they destroy the information in the bottom  $\log \lambda_k$  bits of the "window." Since we need about  $\log \lambda_k$  information bits to recover the input, the window must contain this many undestroyed bits of information, so it must have at least  $2 \log \lambda_k$  bits, i.e., its efficiency is halved.

**3. Cryptanalysis of truncated linear congruential pseudorandom number generators.** A linear congruential pseudorandom number generator is based on the recurrence

$$(3.1) \quad x_{i+1} \equiv ax_i + c \pmod{M}.$$

Several kinds of reconstruction problems relating to linear congruential generators have been studied previously. In the case where the parameters  $(a, c, M)$  are *unknown* and  $\{x_i: 1 \leq i \leq k\}$  are known, J. Boyar [2] shows that one can start predicting subsequent values of the sequence with high accuracy given a short initial segment. Her method is to find parameters  $(\hat{a}, \hat{c}, \hat{M})$  consistent with the available data (in polynomial time) and to extrapolate the sequence using these parameters. If a later disagreement occurs, the values  $(\hat{a}, \hat{c}, \hat{M})$  are changed to remain consistent with the new data. She shows that at most  $O(\log M)$  disagreements can ever occur, using this procedure. Knuth [11] considered problems arising when only truncated high-order bits  $y_i$  of the generator are known. He supposed that  $M = 2^n$  is known and that the parameters  $(a, c)$  are unknown, and he gave an attack which, when given  $\{y_i: 1 \leq i \leq k\}$  where  $y_i \equiv [x_i/2^l] \pmod{M}$ , will usually reconstruct the parameters  $(a, c)$  and seed  $x_0$  in  $O(n^2 2^{2l}/k^2)$  steps. This running time bound is exponential time, as may be seen for example in the case when half of the bits are truncated and when the number  $k$  of values  $y_i$  observed is small. Reeds [15], [16] was the first to study linear congruential generators from a cryptographic viewpoint. In [16] he studied a cryptosystem which in its simplest version enciphers the plaintext  $P_i$  as

$$E_i \equiv y_i + P_i \pmod{256},$$

where  $y_i = [257x_i/M]$  and  $x_i \equiv ax_{i-1} \pmod{M}$ . He showed how to break it in a reasonable time when both the modulus  $M = 2^{31} - 1$  and multiplier  $a = 7^5$  are *known*, using a partially known plaintext attack. His attack appears to take exponential time for general parameters  $(M, a, c)$ .

We consider here the situation in which the modulus  $M$  and multiplier  $a$  are *known*, the constant term  $c$  is *unknown* and a segment  $y_i$  of truncated high-order bits

$$(3.2) \quad y_i = \left[ \frac{x_i}{2^l} \right] \quad \text{for } 1 \leq i \leq k$$

of the linear congruential generator are given as data. We give a polynomial time reconstruction procedure and prove that it succeeds on nearly all problems in which sufficient data is available to permit unique reconstruction (Theorem 3.1), provided the modulus  $M$  is squarefree. We also prove a similar result which applies to *all* moduli  $M$ , provided that any fraction greater than one third of the bits of the original  $x_i$  is given as input (Theorem 3.5). In our analysis for simplicity we treat only the case that high-order truncated bits  $y_i$  are given as data, but our technique applies to the cases where the low-order truncated bits are given, or where an interior window of truncated bits is given. In the interior window case we would achieve only 50 percent efficiency in the use of the available information.

We will show that unique reconstruction of the sequence  $x_k$  is usually possible in the case that the parameter  $c = 0$ . The case  $c \neq 0$  is different. In the case  $c \neq 0$  we set  $x'_i = x_{i+1} - x_i$  and  $y'_i = y_{i+1} - y_i$  and observe that  $x'_i$  satisfies the recurrence

$$x'_{i+1} \equiv ax'_i \pmod{M}$$

with  $c = 0$  and  $y'_i$  is essentially a truncated version of  $x'_i$ . Now the methods of this section will show that  $x'_i$  can usually be uniquely reconstructed. However,  $x'_i$  does not determine the sequence  $x_i$  since  $x_i$  and  $x_i + d$  for any  $d$  will give the same  $x'_i$  and both are generated by linear congruential generators. In fact for small  $d$  the two sequences  $\{x_i\}$  and  $\{x_i + d\}$  will usually have the same  $s$  most significant bits, and so it is impossible to uniquely reconstruct the original  $\{x_i\}$  in this case. What we *can* do in the general case that  $c \neq 0$  is to *predict* future values of the truncated sequence  $\{y_i\}$  with great accuracy, using the  $s$  most significant bits of  $x_1$  together with the uniquely reconstructed sequence  $\{x'_i\}$ .

Now we consider the case where the parameter  $c = 0$ . The  $k$  unknowns  $\{x_i: 1 \leq i \leq k\}$  satisfy

$$x_{i+1} \equiv ax_i \pmod{M}$$

and consequently are related by the following system of  $k - 1$  independent homogeneous congruences:

$$(3.3) \quad a^{i-1}x_1 - x_i \equiv 0 \pmod{M} \quad \text{for } 2 \leq i \leq k.$$

Since we are given the high-order bits  $y_i$  of the  $x_i$  as input, we have exactly a problem of the kind analyzed in Corollary 2.2. In this case  $L(\mathbf{a}, M) = L_a$  is the lattice consisting of all vectors  $(\nu_1, \dots, \nu_k) \in \mathbb{Z}^k$  satisfying (3.3), which has as a basis the vectors

$$\begin{aligned} \mathbf{b}_1 &= (M, 0, 0, \dots, 0), \\ \mathbf{b}_2 &= (a, -1, 0, \dots, 0), \\ \mathbf{b}_3 &= (a^2, 0, -1, \dots, 0), \\ &\vdots \\ \mathbf{b}_k &= (a^{k-1}, 0, 0, \dots, -1). \end{aligned}$$

The determinant  $D = D(L_a)$  is given by

$$(3.4) \quad D(L_a) = M.$$

The analysis of the size of  $\lambda_k(L_a)$  is the only problem in applying Corollary 2.2. In the case where  $M$  is squarefree we are able to prove that  $\lambda_k$  is small for most  $L_a$ .

**THEOREM 3.1.** *For squarefree  $M > c(\varepsilon, k)$  there is an exceptional set  $E(M, \varepsilon, k)$  of multipliers of cardinality  $|E(M, \varepsilon, k)| \leq M^{1-\varepsilon}$  such that for any multiplier not in  $E(M, \varepsilon, k)$  the following is true. The  $x_i$  are uniquely determined by knowledge of the  $(1/k + \varepsilon) \log M + c(k)$  leading bits of all  $\{x_i: 1 \leq i \leq k\}$ , where*

$$c_k = \frac{k}{2} + (k-1) \log 3 + \frac{7}{2} \log k + 2.$$

Furthermore, there is an algorithm which runs in time polynomial in  $\log M + k$  which finds the  $x_i$ .

*Remarks.* (1) The number of bits needed for unique reconstruction is essentially optimal on information theory grounds, except for the presence of the  $\varepsilon$ .

(2) Some sort of exceptional set  $E(m, \varepsilon, k)$  is necessary because  $a = 1$  is always a “bad” multiplier. In the case  $a = 1$ , all the observed truncated bits  $y_i$  will be equal to the high-order bits of the seed  $x_0$ , and one never gets any information about the low-order bits of the seed. (Of course we can *extrapolate* future values of the generator very well in this case.) There are usually other multipliers  $a$  in the exceptional set  $E(M, \varepsilon, k)$  defined below, though they are in general not easy to characterize.

(3) The proof actually shows that we could take  $\varepsilon$  to be a constant times  $1/\log \log M$  as  $M \rightarrow \infty$ .

*Proof.* Our object is to apply Theorem 2.1, and our only problem is to bound the number of lattices  $L_a$  which have a large  $\lambda_k$ . We define the exceptional set

$$E(M, \varepsilon, k) = \{L_a: \lambda_k(L_a) > 2k^3 3^{k-1} M^{(1/k)+\varepsilon}\}$$

and our object will be to show that for squarefree  $M \geq c(\varepsilon, k)$  there are at most  $M^{1-\varepsilon}$  lattices  $L_a$  in the exceptional set  $E(M, \varepsilon, k)$ .

We will study the dual lattice  $L_a^*$ , which is generated by  $1/M(1, a, a^2, \dots, a^{k-1})$  and the unit vectors  $e_i, i = 1, \dots, k$ . For notational simplicity let us study  $ML_a^*$ . A short vector in  $ML_a^*$  corresponds to an integer  $t$  such that  $\{ta^i: 0 \leq i \leq k-1\}$  are all small (mod  $M$ ). For a fixed  $R$  we are interested in estimating the size of the set

$$S_R = \{a | \exists t, 1 \leq t < M, |ta^i \pmod M| < R \text{ for } 0 \leq i \leq k-1\}.$$

Define for  $d$  dividing  $M$  the sets

$$S_{R,d} = \{a: \exists t, 1 \leq t < M, (M, t) = d, |ta^i \pmod M| < R \text{ for } 0 \leq i \leq k-1\}.$$

It is clearly true that  $S_R = \bigcup_{d|M} S_{R,d}$ . Let us first estimate the size of  $S_{R,1}$ .

**LEMMA 3.2.** *If  $a \in S_{R,1}$  then  $a$  satisfies an equation*

$$(3.5) \quad \sum_{i=1}^k \nu_i a^{i-1} \equiv 0 \pmod M$$

with

$$(3.6) \quad |\nu_i| \leq (2kR)^{1/(k-1)}.$$

*Proof.* By assumption we have  $t$  such that  $(t, M) = 1$  and  $|ta^i| < R$  for  $0 \leq i \leq k-1$ . Consider all linear combinations  $\sum_{i=0}^{k-1} s_i ta^i$  with  $0 \leq s_i < (2kR)^{1/(k-1)}$  for  $0 \leq i \leq k-1$ . There are  $(2kR)^{k/(k-1)}$  such combinations and the value of any such combination is bounded in absolute value by  $kR(2kR)^{1/(k-1)}$ . Thus by the pigeonhole principle there are two different sets of  $s_i$ 's which give the same value. Subtracting the two expressions and dividing by  $t$  we get the desired solution to (3.5).  $\square$

To estimate the size of  $S_{R,1}$  we must estimate how many numbers  $a$  satisfy an equation (3.5) with small coefficients. Let  $M = \prod_{i=1}^f p_i$ . We count the number of  $a$ 's satisfying this equation having

$$(3.7) \quad d = \text{g.c.d.} (M, \nu_1 \cdots \nu_k).$$

If  $d$  is the product of  $g$  of the prime factors of  $M$  then an upper bound for the number of solutions is  $d(k-1)^{f-g}$ . The reason for this is that we have at most  $k-1$  solutions to the congruence

$$\sum_{i=1}^k \nu_i a^{i-1} \equiv 0 \pmod{p_i}$$

for each of the  $f-g$  primes  $p_i$  of  $M$  not dividing  $d$ . We next bound the number of vectors  $\mathbf{v} = (\nu_1, \dots, \nu_k)$  satisfying the condition (3.7), using the following lemma.

LEMMA 3.3. *If  $d$  divides  $M$  then the number of nonzero integer vectors satisfying*

$$\text{g.c.d.} (M, \nu_1, \dots, \nu_k) = d$$

and  $|\nu_i| \leq T$  for  $1 \leq i \leq k$  is less than  $(3T/d)^k$ .

*Proof.* Dividing all  $\nu_i$  and  $M$  by  $d$  shows it is enough to prove the lemma for  $d = 1$ . In this case the estimate follows from a trivial bound on the number of lattice points in the region considered.  $\square$

Combining the above results we get

$$\begin{aligned} |S_{R,1}| &\leq \sum_{d|M} k^{f-g} d \left( \frac{(2kR)^{1/(k-1)} \cdot 3}{d} \right)^k \\ &< k^f (2kR)^{k/(k-1)} \cdot 3^k \sum_{d|M} d^{1-k}. \end{aligned}$$

To simplify this further we use a well-known number-theoretic estimate valid for squarefree numbers  $M$  that shows that there is a constant  $c_0$  such that for  $M \geq 20$  one has

$$f \leq c_0 \frac{\log M}{\log \log M}.$$

Hence

$$k^f \leq M^{(c_0 \log k)/(\log \log M)}$$

and

$$\sum_{d|M} d^{1-k} \leq \sum_{d|M} 1 \leq 2^f \leq M^{(c_0 \log 2)/(\log \log M)},$$

giving

$$(3.8) \quad |S_{R,1}| < 3^k (2kR)^{k/(k-1)} M^{c_0 \log 2k / \log \log m}.$$

Next let us consider  $S_{R,d}$  for  $d > 1$ . Whether  $a \in S_{R,d}$  only depends on  $a \pmod{M/d}$ . To be more precise  $a \in S_{R,d}$  if and only if there exists an integer  $t$  with  $1 \leq t < M/d$ , and  $(t, M/d) = 1$  with

$$|ta^i \pmod{M/d}| \leq R/d, \quad 0 \leq i \leq k-1.$$

Reasoning as in Lemma 3.2 we find that  $a$  solves an equation with small coefficients (mod  $M/d$ ). Using that each solution (mod  $M/d$ ) lifts to at most  $d$  solutions (mod  $M$ ) we get

$$\begin{aligned} |S_{R,d}| &< d 3^k \left(\frac{2kR}{d}\right)^{k/(k-1)} M^{(c_0 \log 2k)/(\log \log M)} \\ &= 3^k d^{-1/(k-1)} (2kR)^{k/(k-1)} M^{(c_0 \log 2k)/(\log \log M)}. \end{aligned}$$

Thus we obtain

$$\begin{aligned} |S_R| &= \left| \bigcup_d S_{R,d} \right| \leq \sum_d |S_{R,d}| < 3^k (2kR)^{k/(k-1)} M^{(c_0 \log 2k)/(\log \log M)} \sum_{d|M} d^{-1/(k-1)} \\ (3.9) \quad &\leq 3^k (2kR)^{k/(k-1)} M^{(c_0 \log 2k)/(\log \log M)} 2^f \\ &\leq 3^k (2kR)^{k/(k-1)} M^{(c_0 \log 4k)/(\log \log M)}. \end{aligned}$$

Now choose  $R = M^{(k-1)/k} 3^{-(k-1)} (2k)^{-1}$ . Then (3.9) yields for  $M \geq c(\varepsilon, k)$  that

$$|S_R| < M^{1-\varepsilon},$$

and that for all  $a$  not in  $S_R$  we have

$$\lambda_1(L_a^*) \geq \frac{1}{2k} 3^{-(k-1)} M^{-1/k-\varepsilon}.$$

Then the inequality  $\lambda_1^* \lambda_k \leq k^2$  proved in [12] yields

$$(3.10) \quad \lambda_k(L_a) \leq 2k^3 3^{k-1} M^{1/k+\varepsilon}.$$

Hence  $E(M, \varepsilon, k) \subseteq S_R$  so  $|E(M, \varepsilon, k)| \leq M^{1-\varepsilon}$ .

To complete the proof of Theorem 3.1, we choose

$$s \geq \left(\frac{1}{k} + \varepsilon\right) \log M + c(k)$$

with  $c(k) = k/2 + (k-1) \log 3 + \frac{7}{2} \log k + 2$ , and apply Corollary 2.2, after observing that if  $a \notin E(M, \varepsilon, k)$  then (3.10) implies that

$$s \geq s_0 = \log \lambda_k + \frac{k}{2} + \frac{1}{2} \log k + 1. \quad \square$$

This proof of Theorem 3.1 does not carry over very well to non-squarefree moduli  $M$ , the worst case being  $M = p^e$  a prime power. The problem in that case is that polynomials (mod  $p^e$ ) may have many roots, e.g.,

$$\sum_{i=1}^k v_i a^{i-1} \equiv 0 \pmod{p^e}$$

may have up to  $kp^{e-1}$  roots, and we get a much weaker estimate for  $|S_R|$  in this case. We can still use this weaker bound to extend the proof of Theorem 3.1 to apply to moduli  $M$  which are almost squarefree. Define a number  $M$  to be  $\delta$ -squarefree if

$$M = \prod_{i=1}^f p_i^{e_i} \quad \text{and} \quad \prod_{i=1}^f p_i^{e_i-1} \leq M^\delta.$$

Then we have the following result.

**THEOREM 3.4.** *Suppose that the modulus  $M$  is  $\delta$ -squarefree and let the number of iterates  $k$  and a constant  $\varepsilon > 0$  be given. Then there exists a constant  $c_2(\varepsilon, \delta)$  such that*

for all such  $M > c_2(\epsilon, \delta)$  and all residues not in an exceptional set  $E(\epsilon, M)$  of cardinality at most  $M^{1-\epsilon}$  given knowledge of  $s$  leading bits of  $\{x_i: 1 \leq i \leq k\}$  where

$$s > \left(\frac{1}{k} + \epsilon + \delta\right) \log M + c(k)$$

suffices to determine the  $\{x_i: 1 \leq i \leq k\}$  uniquely. Furthermore, there is an algorithm that runs in time polynomial in  $\log M + k$  which always reconstructs all the  $x_i$  in this case.

The proof is essentially the same as that of Theorem 3.1, using the weaker bound for  $|S_R|$ , and we omit the details.

For the special case  $k=3$  we are able by a more careful argument to prove an essentially optimal bound valid for all moduli  $M$ .

**THEOREM 3.5.** *Given  $\epsilon > 0$ , for any  $M$  the knowledge of  $(\frac{1}{3} + \epsilon) \log M + c(k)$  leading bits of  $x_1, x_2$  and  $x_3$  allows the recovery of  $x_1, x_2$  and  $x_3$  in polynomial time for all multipliers a set of cardinality  $c(\epsilon)M^{1-\epsilon/2}$ .*

*Proof.* As we have seen the hard part of the proof will be to count the number of solutions to second-degree congruences when the modulus is highly composite. To fix notation let  $V(x) = \nu_0 + \nu_1 x + \nu_2 x^2$  and  $\mathbf{v} = (\nu_0, \nu_1, \nu_2)$  with  $\|\mathbf{v}\| = (\nu_0^2 + \nu_1^2 + \nu_2^2)^{1/2}$ . We want to estimate the size of the following set:

$$F(\mu) = \{a: 1 \leq a < M \text{ and } \exists \|\mathbf{v}\| \leq M^\mu \text{ with } V(a) \equiv 0 \pmod{M}\}.$$

Assume first that  $\text{g.c.d.}(\nu_0, \nu_1, \nu_2, M) = 1$ . Suppose  $M = \prod_{i=1}^f p_i^{e_i}$  where the  $p_i$  are distinct primes. We study the number of solutions to a quadratic equation modulo prime powers  $p^e$ . Let  $D(V) = \nu_1^2 - 4\nu_0\nu_2$  denote the discriminant of the quadratic polynomial  $V(x)$ . Note that the polynomial has a double root  $\pmod{p}$  if and only if  $D(V) \equiv 0 \pmod{p}$ . We have the following lemma.

**LEMMA 3.6.** *If  $p$  does not divide  $\text{g.c.d.}(\nu_0, \nu_1, \nu_2)$  then the number of solutions of*

$$\nu_2 x^2 + \nu_1 x + \nu_0 \equiv 0 \pmod{p^e}$$

*is at most  $2 \min(p^{\lfloor e/2 \rfloor}, p^{\lfloor r/2 \rfloor})$  where  $r$  is the largest integer such that*

$$D(V) \equiv 0 \pmod{p^r}.$$

*Proof.* We can assume that the highest-degree coefficient of  $V$  is not divisible by  $p$  since otherwise the congruence has at most one solution.

Suppose now that there is at least one solution, so that  $V$  factors as  $t(x+a)(x+b) \pmod{p^e}$  with  $(t, p) = 1$ . The discriminant  $D(V) \pmod{p^e}$  is  $t^2(a-b)^2$  and if  $s$  is the largest integer such that  $a \equiv b \pmod{p^s}$  then  $r \geq \min(2s, e)$ . We have two cases, depending on the size of  $2s$ .

If  $2s < e$  then the solutions of the congruence are precisely those  $x \equiv a \pmod{p^{e-s}}$  and those  $x \equiv b \pmod{p^{e-s}}$ . There are  $2p^s$  solutions in this case.

If  $2s \geq e$  then the solutions of the congruence are exactly those  $x \equiv a \equiv b \pmod{p^{\lfloor e/2 \rfloor}}$  and there are  $p^{\lfloor e/2 \rfloor}$  such  $x \pmod{p^e}$ .

In both these cases the bound of the lemma holds.  $\square$

We next estimate the frequency with which the condition in Lemma 3.6 is satisfied.

**LEMMA 3.7.** *Given  $\epsilon > 0$  and  $d < M^{2\mu}$  the number of  $\|\mathbf{v}\| \leq M^\mu$  that satisfy*

$$D(V) \equiv 0 \pmod{d}$$

*is  $O((1/d)M^{3\mu+\epsilon})$ .*

*Proof.* The congruence  $\nu_1^2 - 4\nu_0\nu_2 \equiv 0 \pmod{d}$  splits into the  $O((1/d)M^{2\mu})$  equations

$$\nu_1^2 - 4\nu_0\nu_2 = kd \quad \text{for } |k| \leq \frac{1}{d} M^{2\mu},$$

over the integers. For each fixed  $\nu_1$  the equation is of the form  $4\nu_0\nu_2 = c$ . If  $c \neq 0$  this equation has as many solutions as divisors of  $c$ , and it is not hard to see that this number is  $O(M^\varepsilon)$  since  $c \leq M^{2\mu}$ . The remaining case  $c = 0$  gives  $4M^\mu$  possibilities for  $\nu_0$  and  $\nu_2$  but in this case  $\nu_1$  is determined by  $k$  and hence the total number of solutions is  $O((1/d)M^{3\mu+\varepsilon})$ .  $\square$

Now we are able to estimate  $F(\mu)$  in the general case.

LEMMA 3.8. *For any  $\varepsilon > 0$  it is true that*

$$|F(\mu)| \leq c(\varepsilon) \max(M^{3\mu+\varepsilon}, M^{1/2+(3\mu/2)+\varepsilon}).$$

*Proof.* First observe that by Lemma 3.6 if  $(D(V), M) = d$  then the number of solutions to  $V(x) = 0$  is bounded by  $d2^f$ , where  $f$  is the number of prime factors of  $M$ . The contribution  $S_1(\mu)$  to  $|F(\mu)|$  from  $V(x)$  with  $\text{g.c.d.}(\nu_0, \nu_1, \nu_2, M) = 1$  and  $D(V) \neq 0$  can be estimated using Lemma 3.7 by

$$\begin{aligned} S_1(\mu) &\leq \sum_{\substack{d|M \\ d \leq M^{2\mu}}} c_1 d 2^f \left( \frac{1}{d} M^{3\mu+\varepsilon/2} \right) \\ (3.11) \qquad &\leq c_1 d(M) 2^f M^{3\mu+\varepsilon/2} \leq c_3 M^{3\mu+\varepsilon}, \end{aligned}$$

where  $d(M) = O(M^{f_0/(\log \log M)})$  denotes the number of divisors of  $M$ .

Now we let  $S_d(\mu)$  count the set of  $a$  in  $|F(\mu)|$  arising from polynomials  $V(x)$  with  $\text{g.c.d.}(M, \nu_0, \nu_1, \nu_2) = d$  and  $D(V) \neq 0$ . Dividing such an equation for  $V(x)$  by  $d$  we get a polynomial  $(1/d)V(x)$  with integer coefficients of size  $(1/d)M^\mu$  and modulus  $M/d$ , and  $\text{g.c.d.}(M/d, \nu_0/d, \nu_1/d, \nu_2/d) = 1$ . Looking at the corresponding  $F$ -set  $(\text{mod } (M/d))$  we see by the argument giving (3.11) that the  $F$ -set has cardinality  $O((1/d^3)M^{3\mu+\varepsilon})$  and furthermore that each solution to it  $(\text{mod } M/d)$  will lift to exactly  $d$  distinct solutions  $(\text{mod } M)$ . This leaves us with the bound

$$S_d(\mu) = O\left(\frac{1}{d^2} M^{3\mu+\varepsilon}\right).$$

We need also to estimate the number of  $a$  that satisfy the congruence  $V(x) \equiv 0 \pmod{M}$  with  $D(V) = 0$  and  $\|\mathbf{v}\| < M^\mu$ . If  $\text{g.c.d.}(\nu_0, \nu_1, \nu_2, M) = d$  then the congruence is

$$(3.12) \qquad \frac{\nu_2}{d} x^2 + \frac{\nu_1}{d} x + \frac{\nu_0}{d} \equiv 0 \pmod{\frac{M}{d}}.$$

By the analysis of the second case in Lemma 3.6 this congruence has at most  $2^{\omega(M/d)}(M/d)^{1/2}$  solutions  $(\text{mod } M/d)$ , where  $\omega(M/d)$  counts the number of distinct prime divisors of  $M/d$ . These lift to a total of at most  $2^{\omega(M)}\sqrt{Md}$  solutions  $x \pmod{M}$ . Since  $d \leq M^\mu$ , we have at most  $2^{\omega(M)}d(M)M^{1/2+\mu/2}$  solutions to (3.12). This is  $O(M^{1/2+\mu/2+\varepsilon/2})$  for any fixed  $\varepsilon$ , as  $M \rightarrow \infty$ . Finally the number of polynomials  $V$  that satisfy  $D(V) = 0$  and  $\|\mathbf{v}\| < M^\mu$  is  $O(M^{\mu+\varepsilon/2})$  for any fixed  $\varepsilon$ , by similar reasoning to that of Lemma 3.7.

The total count of solutions  $F(\mu)$  therefore satisfies

$$\begin{aligned} |F(\mu)| &\leq \sum_{d|M} S_d(\mu) + M^{1/2+\mu/2+\varepsilon/2} \#\{V: D(V) = 0\} \\ &\leq c_3 M^{3\mu+\varepsilon} \left( \sum_{d|M} \frac{1}{d^2} \right) + c_2 M^{1/2+3\mu/2+\varepsilon} \\ &\leq c_4 (M^{3\mu+\varepsilon} + M^{1/2+3\mu/2+\varepsilon}). \end{aligned}$$

This proves Lemma 3.8.  $\square$

Now Lemma 3.8 implies Theorem 3.5 by a proof similar to that of Theorem 3.1.  $\square$

**4. Cryptanalysis of Blum’s protocol for exchanging secrets.** Blum’s paper [1] was one of the first to deal with the issue of simultaneity in sequential processes. He proposed several versions of a protocol to enable two parties to exchange the factorizations of their two published moduli  $m_A$  and  $m_B$ , which are the products of two large primes in a fair and verifiable way. The simplest of these is as follows. Let  $n = \log m_A = \log m_B$  be the size parameter. The protocol is symmetric, and the two parties alternately perform the following steps:

- (1) Choose  $k$  random numbers  $y_1, \dots, y_k$  and send their squares modulo the opponent’s modulus to the other party.
- (2) Extract the four square roots modulo your own number of each number  $y_i^2$  received from the other party. This is possible since you know the factorization. Now write the  $4k$  square roots in a  $4k \times n$  binary matrix where the least significant bits are in the last column.
- (3) Send the  $i$ th column of the matrix to the other party (for  $i = 1, \dots, n$ ).

The idea behind this procedure is that by having one of the square roots of  $y_i^2$  at hand it is possible to check that what you receive is correct information. If  $B$  wants to cheat he can guess which square root  $A$  has and send that square root and its negation correctly while the rest are unrelated bits. The probability that such cheating would not be detected by  $A$  is  $2^{-k}$ . The security of the protocol depends on the inability of the parties to factor efficiently before all (or almost all) the columns have been exchanged. Blum stated this as an assumption in the proof of correctness in this protocol. We show that this assumption is incorrect.

**THEOREM 4.1.** *There is an algorithm which when given as input  $k$  random numbers  $y_i$  and the  $n/k + c_{k,\epsilon}$  most significant bits of all square roots of the  $y_i^2 \pmod{M}$  factors  $M$  with probability  $1 - \epsilon$ . The probability is taken over the probability distribution on the  $y_i$  and the running time of the algorithm is polynomial in  $n$  but not in  $k$ .*

*Proof.* For each  $i$  the four square roots of  $y_i^2$  can be denoted by  $y_i, -y_i, x_i \equiv ry_i$  and  $-x_i \equiv -ry_i \pmod{M}$  where  $r$  is a square root of 1  $\pmod{M}$  different from  $\pm 1$ . Since  $y_i$  is known, we can easily pair  $y_i$  and  $-y_i$  with their  $N/k + c_{k,\epsilon}$  most significant bits in the data received. However, we do not know how to pair the remaining two sets of most significant bits with  $x_i$  and  $-x_i$ , so we must guess. However, for fixed  $k$  the total number of guesses is the constant  $2^k$ . When the correct guess is made we have paired each  $x_i$  with its  $N/k + c_{k,\epsilon}$  most significant bits. Observe that if we can recover any of the  $x_i$  we can factor  $M$  since g.c.d.  $(x_i - y_i, M)$  will be nontrivial.

Since the unknown values of the  $x_i$  are fixed multiples of the known values of the  $y_i$ , they are related by  $k - 1$  modular linear equations:

$$y_i x_1 - y_1 x_i \equiv 0 \pmod{M} \quad \text{for } i = 2, \dots, k.$$

The lattice  $L_y$  spanned by the  $k - 1$  coefficient vectors

$$(y_i, 0, \dots, 0, -y_1, 0, \dots, 0)$$

together with the vectors  $M\mathbf{e}_1, \dots, M\mathbf{e}_k$  is the set of vectors

$$\left( \sum_{i=2}^k y_i v_i, -y_1 v_2, \dots, -y_1 v_k \right) + (a_1 M, \dots, a_k M)$$

for all possible choices of  $v_2, \dots, v_k$  and  $a_1, \dots, a_k$  in  $\mathbb{Z}$ . When  $y_1$  is invertible  $\pmod{M}$ , as is usually the case, we obtain the following characterization of this lattice:

$$L_y = \left\{ \mathbf{v} \in \mathbb{Z}^k \mid \sum_{i=1}^k y_i v_i \equiv 0 \pmod{M} \right\},$$

and  $L_y$  has determinant  $M$ . To apply our general technique, we only have to bound  $\lambda_k(L_y)$  from above for almost all choices of  $y$ .

As usual we do this by bounding from below the length of the shortest vector in the dual lattice  $L_y^*$ . In this case  $L_y^*$  is the lattice spanned by  $(1/M)(y_1, \dots, y_k)$  and the unit vectors  $e_i$ . We use the following lemma.

LEMMA 4.2. *Let  $\varepsilon > 0$  and  $k$  be given. Then there is a positive constant  $d_{k,\varepsilon}$  such that for a random drawing of integers  $(y_1, \dots, y_k)$  in  $(\mathbb{Z}/M\mathbb{Z})^k$  where  $M = p_1 p_2$  and  $\min(p_1, p_2) \geq \frac{1}{2} d_{k,\varepsilon} M^{1/k}$ , then with probability at least  $1 - \varepsilon$  the inequalities*

$$(4.1) \quad |ty_i \pmod{M}| \leq d_{k,\varepsilon} M^{(k-1)/k}$$

cannot be solved with  $0 < t < M$ , and so

$$\lambda_1(L_y^*) \geq d_{k,\varepsilon} M^{-1/k}.$$

*Proof.* For each fixed  $t$  and a fixed index  $i$  the probability that

$$|ty_i \pmod{M}| \leq d_{k,\varepsilon} M^{(k-1)/k}$$

is at most

$$\frac{(t, M)}{M} + 2d_{k,\varepsilon} M^{-1/k} \leq 3d_{k,\varepsilon} M^{-1/k},$$

since

$$\frac{(t, M)}{M} \leq \frac{M}{p_1} + \frac{M}{p_2} \leq d_{k,\varepsilon} M^{(k-1)/k}.$$

Since the draws for different  $i$  are independent, the probability that (4.1) holds for fixed  $t$  is  $\leq (3d_{k,\varepsilon})^k M^{-1}$ . Summing over  $0 < t < M$  the total probability that (4.1) holds is at most  $\leq (3d_{k,\varepsilon})^k$ , and we may choose  $d_{k,\varepsilon} = \frac{1}{3} \varepsilon^{1/k}$ .  $\square$

Now we complete the proof of Theorem 4.1. By Corollary 2.2 we can recover  $(x_1, \dots, x_k)$  if we know  $s_0 = \log \lambda_k + (k/2) + \frac{1}{2} \log k + 1$  significant bits of each  $x_i$ . Using Lemma 4.2 and the bound  $\lambda_1^* \lambda_k \leq k$  we obtain

$$\lambda_k(L_y) \leq k^2 d_{k,\varepsilon}^{-1} M^{1/k}.$$

Since  $n = \log M$  this yields

$$s_0 \leq \frac{n}{k} + \frac{k}{2} + \frac{3}{2} \log k - \log d_{k,\varepsilon} + 1.$$

We are given  $s_1 = n/k + c_{k,\varepsilon}$  significant bits, so on choosing

$$c_{k,\varepsilon} = \frac{k}{2} + \frac{3}{2} \log k - \log d_{k,\varepsilon} + 1$$

we can find the  $x_i$ . As pointed out earlier, this enables us to factor  $M$  by calculating g.c.d.  $(x_i - y_i, M)$  so the theorem follows.  $\square$

Theorem 4.1 shows that Blum's original protocol can be broken by somebody who only deviates from the protocol by stopping early and using this algorithm—there is no need to control the choice of random bits or to lie to the other party.

The alternative protocol in which the columns of the matrices are exchanged in reverse order (from least significant bits to most significant bits) is just as insecure, again using the algorithm of Corollary 2.2, noting that  $M$  is odd.

*Discussion.* Blum proved that his protocol is secure assuming the truth of certain (unproved) assumptions. Due to the care with which Blum listed his assumptions, it is easy to trace the source of the cryptographic weakness we exploit to the following one [1, p. 187]:

“Alice cannot use the  $100 \times k$  most significant bits,  $y_1^k, \dots, y_{100}^k$ , to split  $M_B$  any better than she can use just the  $k$  most significant bits  $y_i^k$ .”

Our attack shows that this assumption was too strong. Blum considered the possibility that his original protocol might be insecure, and in his paper he described a modified protocol in which the participants use several moduli each. A second possible modification is to ask the parties to exchange fewer columns from their matrices and to use our algorithm to factor the moduli at an earlier stage. Neither of these variants seems to be vulnerable to the cryptanalytic attack proposed in this paper.

The existence of this cryptanalytic attack demonstrates once more the extremely delicate nature of proofs of security in cryptology. It also shows the importance when proposing cryptographic protocols to clearly distinguish sources of insecurity. Blum’s paper certainly does this.

**Acknowledgments.** We thank M. Blum, J. Boyer, O. Goldreich and S. Micali for bringing this problem to our attention. We thank Shafi Goldwasser and Rick Statman for useful discussion and comments.

## A DIGITAL SIGNATURE SCHEME SECURE AGAINST ADAPTIVE CHOSEN-MESSAGE ATTACKS\*

SHAFI GOLDWASSER<sup>†</sup>, SILVIO MICALI<sup>†</sup> AND RONALD L. RIVEST<sup>†</sup>

**Abstract.** We present a digital signature scheme based on the computational difficulty of integer factorization.

The scheme possesses the novel property of being robust against an adaptive chosen-message attack: an adversary who receives signatures for messages of his choice (where each message may be chosen in a way that depends on the signatures of previously chosen messages) cannot later forge the signature of even a single additional message. This may be somewhat surprising, since in the folklore the properties of having forgery being equivalent to factoring and being invulnerable to an adaptive chosen-message attack were considered to be contradictory.

More generally, we show how to construct a signature scheme with such properties based on the existence of a “claw-free” pair of permutations—a potentially weaker assumption than the intractibility of integer factorization.

The new scheme is potentially practical: signing and verifying signatures are reasonably fast, and signatures are compact.

**Key words.** cryptography, digital signatures, factoring, chosen-message attacks, authentication, trap-door permutations, randomization

**AMS(MOS) subject classification.** 94A05

**1. Introduction.** The idea of a “digital signature” first appeared in Diffie and Hellman’s seminal paper, *New Directions in Cryptography* [DH76]. They propose that each user  $A$  publish a “public key” (used for validating signatures), while keeping secret a “secret key” (used for producing signatures). In their scheme user  $A$ ’s signature for a message  $M$  is a value which depends on  $M$  and on  $A$ ’s secret key, such that anyone can verify the validity of  $A$ ’s signature using  $A$ ’s public key. However, while knowing  $A$ ’s public key is sufficient to allow one to validate  $A$ ’s signatures, it does not allow one to easily forge  $A$ ’s signatures. They also proposed a way of implementing signatures based on “trap-door functions” (see § 2.1.1).

The notion of a digital signature is useful and is a legal replacement for handwritten signatures [LM78], [Ma79]. However, a number of technical problems arise if digital signatures are implemented using trap-door functions as suggested by Diffie and Hellman [DH76]; these problems have been addressed and solved in part elsewhere. For example, [GMY83] showed how to handle arbitrary or sparse message sets and how to ensure that if an enemy sees previous signatures (for messages that he has not chosen) it does not help him to forge new signatures (this is a “nonadaptive chosen-message attack”; see § 2.2).

The signature scheme presented here, using fundamentally different ideas than those presented by Diffie and Hellman, advances the state of the art of signature schemes with provable security properties even further; it has the following important characteristics:

- What we prove to be difficult is *forgery*, and not merely obtaining the secret key used by the signing algorithm (or obtaining an efficient equivalent algorithm).

- Forgery is proven to be difficult for a “most general” enemy who can mount an *adaptive chosen-message attack*. (An enemy who can use the real signer as “an oracle” cannot in time polynomial in the size of the public key forge a signature for any message whose signature was not obtained from the real signer.) In contrast to all previous published work on this problem, we prove the scheme invulnerable against such an adaptive attack where each message whose signature is requested may depend on all signatures previously obtained from the real signer. We believe that an adaptive chosen-message attack is the most powerful attack possible for an enemy who is restricted to using the signature scheme in a natural manner.

- The properties we prove about the new signature scheme do not depend in any way on the set of messages to be signed or on any assumptions about a probability distribution on the message set.

- Our scheme can be generalized so that it can be based on “hard” problems other than factoring whenever one can create claw-free trap-door pair generators.

Our scheme can be based on any family of pairs of claw-free permutations, yielding a signature scheme that is *invulnerable* to a chosen-message attack even if the claw-free permutations are *vulnerable* to a chosen-message attack when used to make a trap-door signature scheme (see § 2.1.1).

Fundamental ideas in the construction are the use of randomization, signing by using two authentication steps (the first step authenticates a random value which is used in the second step to authenticate the message), and the use of a treelike branching authentication structure to produce short signatures.

We note that our signature scheme is not of the simple Diffie–Hellman “trap-door” type. For example, a given message can have many signatures.

Our signature scheme is seemingly “paradoxical,” in that we prove that forgery is equivalent to factoring even if the enemy uses an *adaptive* chosen-message attack. We can restate the paradox as follows:

- Any general technique for forging signatures can be used as a “black box” in a construction that enables the enemy to factor one of the signer’s public moduli (he has two in our scheme), but

- The technique of “forging” signatures by getting the real signer to play the role of the “black box” (i.e., getting the real signer to produce some desired genuine signatures) does not help the enemy to factor either of the signer’s moduli.

Resolving this paradox was previously believed to be impossible and contradictory ([Wi80] misled by Rivest).

The rest of this paper is organized as follows. In § 2 we present definitions of what it means to “break” a signature scheme and what it means to “attack” a signature scheme. In § 3 we review previously proposed signature schemes. In § 4 we review more closely the nature of the “paradox,” and discuss how it can be resolved. Section 5 defines some useful conventions and notation, and § 6 describes the complexity-theoretic foundations of our scheme. In § 7 we give some of the fundamental notions for our signature scheme, and in § 8 we give the details. In § 9 we prove that it has the desired properties. In the last section we discuss some ways to improve the running time and memory requirements of this scheme.

**2. Fundamental notions.** To properly characterize the results of this paper, it is helpful to answer the following questions:

- What is a digital signature scheme?
- What kinds of attacks can the enemy mount against a digital signature scheme?
- What is meant by “breaking” the signature scheme?

Little attention has been devoted so far to precisely answering these questions. For instance, signature schemes have been generically called “secure” without specifying against what kind of attack. This way, it would not be surprising that “secure” signature schemes were later broken by an unforeseen attack. We hope that the classification we propose in this section may prove useful in resolving unpleasant ambiguities.

**2.1. What is a digital signature scheme?** A *digital signature scheme* contains the following components:

- A *security parameter*  $k$ , which is chosen by the user when he creates his public and secret keys. The parameter  $k$  determines a number of quantities (length of signatures, length of signable messages, running time of the signing algorithm, overall security, etc).
- A *message space*  $\mathcal{M}$ , which is the set of messages to which the signature algorithm may be applied. Without loss of generality, we assume in this paper that all messages are represented as binary strings, that is,  $\mathcal{M} \subseteq \{0, 1\}^+$ . To ensure that the entire signing process is polynomial in the security parameter, we assume that the length of the messages to be signed is bounded by  $k^c$ , for some constant  $c > 0$ .
- A *signature bound*  $B$ , which is an integer bounding the total number of signatures that can be produced with an instance of the signature scheme. This value is typically bounded above by a low-degree polynomial in  $k$ , but may be infinite.
- A *key generation algorithm*  $G$ , which any user  $A$  can use on input  $1^k$  (i.e.,  $k$  in unary) to generate in polynomial time a pair  $(P_A^k, S_A^k)$  of matching *public* and *secret* keys. The secret key is sometimes called the *trap-door information*.
- A *signature algorithm*  $\sigma$ , which produces a signature  $\sigma(M, S_A)$  for a message  $M$  using the secret key  $S_A$ . Here  $\sigma$  may receive other inputs as well. For example, in the scheme we propose first,  $\sigma$  has an additional input which is the number of previously signed messages.
- A *verification algorithm*  $V$ , which tests whether  $S$  is a valid signature for message  $M$  using the public key  $P_A$ . (That is,  $V(S, M, P_A)$  will be **true** if and only if it is valid.) Any of the above algorithms may be “randomized” algorithms that make use of auxiliary random bit stream inputs. We note that  $G$  *must* be a randomized algorithm, since part of its output is the secret key, which must be unpredictable to an adversary. The signing algorithm  $\sigma$  may be randomized—we note in particular that our signing algorithm is randomized and is capable of producing many different signatures for the same message. In general, the verification algorithm need not be randomized, and ours is not.

We note that there are other kinds of “signature” problems that are not dealt with here; the most notable being the “contract-signing problem” where two parties wish to exchange their signatures to an agreed-upon contract *simultaneously* (for example, see [BI83], [EGL82], [BGMR85]).

**2.1.1. A classical example: trap-door signatures.** To create a signature scheme, Diffie and Hellman proposed that  $A$  use a “trap-door function”  $f$ : informally, a function for which it is easy to evaluate  $f(x)$  for any argument  $x$  but for which, given only  $f(x)$ , it is computationally infeasible to find *any*  $y$  with  $f(y) = f(x)$  without the secret “trap-door” information. According to their suggestion,  $A$  publishes  $f$  and any one can validate a signature by checking that  $f(\text{signature}) = \text{message}$ . Only  $A$  possesses the “trap-door” information allowing him to invert  $f$ :  $f^{-1}(\text{message}) = \text{signature}$ . (Trap-door functions will be formally defined in § 6.) We call any signature scheme that fits into this model (i.e., uses trap-door functions and signs by applying  $f^{-1}$  to the message) a *trap-door signature scheme*.

We note that not all signature schemes are trap-door schemes, although most of the ones proposed in the literature are of this type.

**2.2. Kinds of attacks.** We distinguish two basic kinds of attacks:

- *Key-only attacks* in which the enemy knows only the real signer's public key, and
- *Message attacks* where the enemy is able to examine some signatures corresponding to either known or chosen-messages before his attempt to break the scheme.

We identify the following four kinds of message attacks, which are characterized by how the messages whose signatures the enemy sees are chosen. Here  $A$  denotes the user whose signature method is being attacked.

- *Known-message attack.* The enemy is given access to signatures for a set of messages  $m_1, \dots, m_t$ . The messages are known to the enemy but are not chosen by him.
- *Generic chosen-message attack.* Here the enemy is allowed to obtain from  $A$  valid signatures for a chosen list of messages  $m_1, \dots, m_t$  before he attempts to break  $A$ 's signature scheme. These messages are *chosen* by the enemy, but they are *fixed* and *independent* of  $A$ 's public key (for example the  $m_i$ 's may be chosen at random). This attack is *nonadaptive*: the entire message list is constructed before any signatures are seen. This attack is "generic" since it does not depend on the  $A$ 's public key; the same attack is used against everyone.
- *Directed chosen-message attack.* This is similar to the generic chosen-message attack, except that the list of messages to be signed may be created after seeing  $A$ 's public key but before any signatures are seen. (The attack is still nonadaptive.) This attack is "directed" against a particular user  $A$ .
- *Adaptive chosen-message attack.* This is more general yet: here the enemy is also allowed to use  $A$  as an "oracle"; not only may he request from  $A$  signatures of messages which depend on  $A$ 's public key but he may also request signatures of messages which depend additionally on previously obtained signatures.

The above attacks are listed in order of increasing severity, with the adaptive chosen-message attack being the most severe natural attack an enemy can mount. That the adaptive chosen-message attack is a natural one can be seen by considering the case of a notary public who must sign more-or-less arbitrary documents on demand. In general, the user of a signature scheme would like to feel that he may sign arbitrary documents prepared by others without fear of compromising his security.

**2.3. What does it mean to "break" a signature scheme?** One might say that the enemy has "broken" user  $A$ 's signature scheme if his attack allows him to do any of the following with a nonnegligible probability:

- *A total break.* Compute  $A$ 's secret trap-door information.
- *Universal forgery.* Find an efficient signing algorithm functionally equivalent to  $A$ 's signing algorithm (based on possibly different but equivalent trap-door information).
- *Selective forgery.* Forge a signature for a particular message chosen a priori by the enemy.
- *Existential forgery.* Forge a signature for at least one message. The enemy has no control over the message whose signature he obtains, so it may be random or nonsensical. Consequently this forgery may only be a minor nuisance to  $A$ .

Note that to forge a signature means to produce a *new* signature; it is not forgery to obtain from  $A$  a valid signature for a message and then claim that he has now "forged" that signature, any more than passing around an authentic handwritten signature is an instance of forgery. For example, in a chosen-message attack it does

not constitute selective forgery to obtain from the real signer a signature for the target message  $M$ .

Clearly, the kinds of “breaks” are listed above in order of decreasing severity; the least the enemy might hope for is to succeed with an existential forgery.

We say that a scheme is respectively *totally breakable*, *universally forgeable*, *selectively forgeable* or *existentially forgeable* if it is breakable in one of the above senses. Note that it is more desirable to prove that a scheme is not even existentially forgeable than to prove that it is not totally breakable. The above list is not exhaustive; there may be other ways of “breaking” a signature scheme which fit in between those listed, or are somehow different in character.

We utilize here the most realistic notion of forgery, in which we say that a forgery algorithm succeeds if it succeeds probabilistically with a nonnegligible probability. To make this notion precise, we say that the forgery algorithm succeeds if its chance of success is at least as large as one over a polynomial in the security parameter  $k$ .

To say that the scheme is “broken,” we not only insist that the forgery algorithm succeed with a nonnegligible probability, but also that it must run in probabilistic polynomial time.

We note here that the characteristics of the signature scheme may depend on its message space in subtle ways. For example, a scheme may be existentially forgeable for a message space  $\mathcal{M}$  but not existentially forgeable if restricted to a message space which is a sufficiently small subset of  $\mathcal{M}$ .

The next section exemplifies these notions by reviewing previously proposed signature schemes.

**3. Previous signature schemes and their security.** In this section we list a number of previously proposed signature schemes and briefly review some facts about their security.

(1) *Trap-door signature schemes* [DH76]. Any trap-door signature scheme is existentially forgeable with a key-only attack since a valid (message, signature) pair can be created by beginning with a random “signature” and applying the public verification algorithm to obtain the corresponding “message.” A common heuristic for handling this problem in practice is to require that the message space be sparse (i.e., requiring that very few strings actually represent messages—for example this can be enforced by having each message contain a reasonably long checksum). In this case this specific attack is not likely to result in a successful existential forgery.

(2) *Rivest–Shamir–Adleman* [RSA78]. The RSA scheme is selectively forgeable using a directed chosen-message attack, since RSA is *multiplicative*: the signature of a product is the product of the signatures. (This can be handled in practice as above using a sparse message space.)

(3) *Merkle–Hellman* [MH78]. Shamir showed the basic Merkle–Hellman “knapsack” scheme to be universally forgeable using just a key-only attack [Sh82]. (This scheme was perhaps more an encryption scheme than a signature scheme, but had been proposed for use as a signature scheme as well.)

(4) *Rabin* [Ra79]. Rabin’s signature scheme is totally breakable if the enemy uses a directed chosen-message attack (see § 4). However, for nonsparse message spaces selective forgery is as hard as factoring if the enemy is restricted to a known-message attack.

(5) *Williams* [Wi80]. This scheme is similar to Rabin’s. The proof that selective forgery is as hard as factoring is slightly stronger, since here only a single instance of selective forgery guarantees factoring (Rabin needed a probabilistic argument).

Williams uses effectively (as we do) the properties of numbers which are the product of a prime  $p \equiv 3 \pmod{8}$  and a prime  $q \equiv 7 \pmod{8}$ . Again, this scheme is totally breakable with a directed chosen-message attack.

(6) *Lieberherr* [Li81]. This scheme is similar to Rabin's and Williams', and is totally breakable with a directed chosen-message attack.

(7) *Shamir* [Sh78]. This knapsack-type signature scheme has recently been shown by Tulpan [Tu84] to be universally forgeable with a key-only attack for any practical values of the security parameter.

(8) *Goldwasser-Micali-Yao* [GMY83]. This paper presents for the first time signature schemes which are not of the trap-door type, and which have the interesting property that their security characteristics hold for *any* message space. The first signature scheme presented in [GMY83] was proven not to be even existentially forgeable against a *generic* chosen-message attack unless factoring is easy. However, it is not known to what extent *directed* chosen-message attacks or adaptive chosen-message attacks might aid an enemy in "breaking" the scheme.

The second scheme presented there (based on the RSA function) was also proven not to be even existentially forgeable against a generic chosen-message attack. This scheme may also resist existential forgery against an adaptive chosen-message attack, although this has not been proved. (A proof would require showing certain properties about the density of prime numbers and making a stronger intractability assumption about inverting RSA.) We might note that, by comparison, the scheme presented here is much faster, produces much more compact signatures, and is based on much simpler assumptions (only the difficulty of factoring or more generally the existence of claw-free permutation pair generators).

Several of the ideas and techniques presented in [GMY83], such as bit-by-bit authentication, are used in the present paper.

(9) *Ong-Schnorr-Shamir* [OSS84a]. Totally breaking this scheme using an adaptive chosen-message attack has been shown to be as hard as factoring. However, Pollard [Po84] has recently been able to show that the "OSS" signature scheme is universally forgeable in practice using just a key-only attack; he developed an algorithm to forge a signature for any given message without obtaining the secret trap-door information. A more recent "cubic" version has recently been shown to be universally forgeable in practice using just a key-only attack (also by Pollard). An even more recent version [OSS84b] based on polynomial equations was similarly broken by Estes, Adleman, Kompella, McCurley and Miller [EAKMM85] for quadratic number fields.

(10) *El-Gamal* [EG84]. This scheme, based on the difficulty of computing discrete logarithms, is existentially forgeable with a generic message attack and selectively forgeable using a directed chosen-message attack.

(11) *Okamoto-Shiraishi* [OS85]. This scheme, based on the difficulty of solving quadratic inequalities modulo a composite modulus, was shown to be universally forgeable by Brickell and DeLaurentis [BD85].

**4. The paradox of proving signature schemes secure.** The paradoxical nature of signature schemes which are provably secure against chosen-message attacks made its first appearance in Rabin's paper, *Digitalized Signatures as Intractable as Factorization* [Ra79]. The signature scheme proposed there works as follows. User  $A$  publishes a number  $n$  which is the product of two large primes. To sign a message  $M$ ,  $A$  computes as  $M$ 's signature one of  $M$ 's square roots modulo  $n$ . (When  $M$  is not a square modulo  $n$ ,  $A$  modifies a few bits of  $M$  to find a "nearby" square.) Here signing is essentially just extracting square roots modulo  $n$ . Using the fact that extracting square roots

modulo  $n$  enables one to factor  $n$ , it follows that selective forgery in Rabin's scheme is equivalent to factoring if the enemy is restricted to at most a known-message attack.

However, it is true (and was noticed by Rabin) that an enemy might totally break the scheme using a directed chosen-message attack. By asking  $A$  to sign a value  $x^2 \bmod n$  where  $x$  was picked at random, the enemy would obtain with probability  $\frac{1}{2}$  another square root  $y$  of  $x^2$  such that  $\gcd(x+y, n)$  was a prime factor of  $n$ .

Rabin suggested that one could overcome this problem by, for example, having the signer concatenate a fairly long randomly chosen pad  $U$  to the message before signing it. In this way the enemy cannot force  $A$  to extract a square root of any particular number.

However, the reader may now observe that the proof of the equivalence of selective forgery to factoring no longer works for the modified scheme. That is, being able to selectively forge no longer enables the enemy to directly extract square roots and thus to factor. Of course, breaking this equivalence was really the whole point of making the modification.

**4.1. The paradox.** We now “prove” that it is impossible to have a signature scheme for which it is both true that forgery is provably equivalent to factoring, and yet the scheme is invulnerable to adaptive chosen-message attacks. The argument is essentially the same as the one given in [Wi80]. By *forgery* we mean in this section any of universal, selective, or existential forgery; we assume that we are given a proof that forgery of the specified type is equivalent to factoring.

Let us begin by considering this given proof. The main part of the proof presumably goes as follows: given a subroutine for forging signatures, a constructive method is specified for factoring. (The other part of the equivalence, which shows that factoring enables forgery, is usually easy, since factoring usually enables the enemy to totally break the scheme.)

But it is trivial then to show that an adaptive chosen-message attack enables an enemy to totally break the scheme. The enemy merely executes the constructive method for factoring given in the proof, using the real signer instead of the forgery subroutine! That is, whenever he needs to execute the forgery subroutine to obtain the signature of a message, he merely performs an “adaptive chosen-message attack” step—getting the real user to sign the desired message. In the end the unwary user has enabled the enemy to factor his modulus! (If the proof reduces factoring to universal or selective forgery, the enemy has to get the real user to sign a particular message. If the proof reduces factoring to existential forgery, the enemy need only get him to sign anything at all.)

**4.2. Breaking the paradox.** How can one hope to get around the apparent contradictory natures of equivalence to factoring and invulnerability to an adaptive chosen-message attack?

The key idea in resolving the paradox is to have the constructive proof that forgery is as hard as factoring be a *uniform* proof which makes *essential* use of the fact that the forger can forge for *arbitrary* public keys with a nonnegligible probability of success. However, in “real life” a signer will only produce signatures for a *particular* public key. Thus the constructive proof cannot be applied in “real life” (by asking the real signer to unwittingly play the role of the forger) to factor.

In our scheme this concept is implemented using the notion of “random rooting.” Each user publishes not only his two composite moduli  $n_1$  and  $n_2$ , but also a “random root”  $r$ . This value  $r$  is used when validating the user's signatures. The paradox is resolved in our case as follows:

- It is provably equivalent to factoring for an enemy to have a *uniform* algorithm for forging; uniform in the sense that if for all pairs of composite numbers  $n_1$  and  $n_2$  if the enemy can randomly forge signatures for a significant fraction of the possible random roots  $r$ , then he can factor either  $n_1$  or  $n_2$ .

- The above proof *requires* that the enemy be able to pick  $r$  himself—the forgery subroutine is fed triples  $(n_1, n_2, r)$ , where the  $r$  part is chosen by the enemy according to the procedure specified in the constructive proof. However, in “real life” the user has picked a *fixed*  $r$  at random to put in his public key, so an adaptive chosen-message attack will not enable the enemy to “forge” signatures corresponding to any other values of  $r$ . Thus the constructive method given in the proof cannot be applied! More details can be found in § 9.

## 5. General notation and conventions.

**5.1. Notation and conventions for strings.** Let  $\alpha = \alpha_0\alpha_1 \cdots \alpha_x$  be a binary string, then  $\bar{\alpha}$  will denote the integer  $\sum_{k=0}^x \alpha_k 2^{x-k}$ . (Note that a given integer may have several denotations, but only one of a given length.) The strings in  $\{0, 1\}^*$  are ordered as follows: if  $\alpha$  and  $\beta$  are binary strings, we write  $\alpha < \beta$  if there exists a string  $\gamma$  such that  $\alpha$  is a prefix of  $\gamma$ ,  $\gamma$  has exactly the same length as  $\beta$ , and  $\bar{\gamma} < \bar{\beta}$ .

If  $i$  is a  $k$ -bit string, we let  $\text{DFS}(i) = \{\beta \mid \beta \preceq i\}$ . (Imagine a full binary tree of depth  $k$  whose root is labelled  $\varepsilon$ , and the left (right) son of a node labelled  $\alpha$  is  $\alpha 0$  ( $\alpha 1$ ) and let  $\text{DFS}$  be the Depth First Search algorithm that starts at the root and explores the left son of any node before the right son of that node. Then  $\text{DFS}(i)$  represents the set of nodes visited by  $\text{DFS}$  up to and including the time when it reaches node  $i$ .) Note that  $\text{DFS}(i)$  contains the empty string.

**5.2. Notation and conventions for probabilistic algorithms.** We introduce some generally useful notation and conventions for discussing probabilistic algorithms. (We make the natural assumption that all parties, including the enemy, may make use of probabilistic methods.)

We emphasize the number of inputs received by an algorithm as follows. If algorithm  $A$  receives only one input we write “ $A(\cdot)$ ,” if it receives two inputs we write “ $A(\cdot, \cdot)$ ,” and so on.

We write “PS” for “probability space;” in this paper we only consider countable probability spaces. In fact, we only deal with probability spaces arising from probabilistic algorithms.

If  $A(\cdot)$  is a probabilistic algorithm then, for any input  $i$ , the notation  $A(i)$  refers to the PS which assigns to the string  $\sigma$  the probability that  $A$ , on input  $i$ , outputs  $\sigma$ . We point out the special case that  $A$  takes no inputs; in this case the notation  $A$  refers to the algorithm itself, whereas the notation  $A(\cdot)$  refers to the PS defined by running  $A$  with no input. If  $S$  is a PS, we denote by  $\mathbf{P}_S(e)$  the probability that  $S$  associates with element  $e$ . Also, we denote by  $[S]$  the set of elements which  $S$  gives positive probability. In the case that  $[S]$  is a singleton set  $\{e\}$  we will use  $S$  to denote the value  $e$ ; this is in agreement with traditional notation. (For instance, if  $A(\cdot)$  is an algorithm that, on input  $i$ , outputs  $i^3$ , then we may write  $A(2) = 8$  instead of  $[A(2)] = \{8\}$ .)

If  $f(\cdot)$  and  $g(\cdot, \cdots)$  are probabilistic algorithms then  $f(g(\cdot, \cdots))$  is the probabilistic algorithm obtained by composing  $f$  and  $g$  (i.e., running  $f$  on  $g$ 's output). For any inputs  $x, y, \cdots$  the associated probability space is denoted  $f(g(x, y, \cdots))$ .

If  $S$  is a PS, then  $x \leftarrow S$  denotes the algorithm which assigns to  $x$  an element randomly selected according to  $S$ ; that is,  $x$  is assigned the value  $e$  with probability  $\mathbf{P}_S(e)$ .

The notation  $\mathbf{P}(p(x, y, \dots) | x \leftarrow S; y \leftarrow T; \dots)$  will then denote the probability that the predicate  $p(x, y, \dots)$  will be true, after the (ordered) execution of the algorithms  $x \leftarrow S, y \leftarrow T$ , etc.

We let  $\mathcal{RA}$  denote the set of probabilistic polynomial-time algorithms. We assume that a natural representation of these algorithms as binary strings is used. By  $1^k$  we denote the binary representation of integer  $k$ , i.e.,

$$\underbrace{11 \cdots 1}_k.$$

**6. The complexity theoretic basis of the new scheme.** A particular instance of our scheme can be constructed if integer factorization is computationally difficult. However, we will present our scheme in a general manner without assuming any particular problem to be intractable. This clarifies the exposition, and helps to establish the true generality of the proposed scheme. We do this by introducing the notion of a “claw-free permutation pair,” and by showing the existence of such objects under the assumption that integer factorization is difficult.

This section builds up the relevant concepts and definitions in stages. In § 6.1 we give a careful definition of the notions of a trap-door permutation and a trap-door permutation generator. These notions are not directly used in this paper, but serve as a simple example of the use of our notation. (Furthermore, no previous definition in the literature was quite so comprehensive.) The reader may, if he wishes, skip § 6.1 without great loss.

In § 6.2 we define claw-free permutation pairs and claw-free permutation pair generators.

In § 6.3 we show how to construct claw-free permutation pair generators under the assumption that factoring is difficult.

Finally, in § 6.4 we show how to construct an infinite family of pairwise claw-free permutations, given a generating pair  $f_0, f_1$ , of claw-free permutations.

Altogether, then, this section provides the underlying definitions and assumptions required for constructing our signature scheme. The actual construction of our signature scheme will be given in §§ 7 and 8.

**6.1. Trap-door permutations.** Informally, a family of trap-door permutations is a family of permutations  $f$  possessing the following properties:

- It is easy, given an integer  $k$ , to randomly select permutations  $f$  in the family which have  $k$  as their security parameter, together with some extra “trap-door” information allowing easy inversion of the permutations chosen.
- It is hard to invert  $f$  without knowing  $f$ ’s trapdoor.

We can interpret the two properties above by saying that any user  $A$  can easily randomly select a pair of permutations,  $(f, f^{-1})$ , inverses of each other. This will enable  $A$  to easily evaluate and invert  $f$ ; if now  $A$  publicizes  $f$  and keeps secret  $f^{-1}$ , then inverting  $f$  will be hard for all other users.

In the informal discussion above, we used the terms “easy” and “hard.” The term “easy” can be interpreted as “in polynomial time”; “hard,” however, is of more difficult interpretation. By saying that  $f$  is hard to invert we cannot possibly mean that  $f^{-1}$  cannot be easily evaluated at any of its arguments.<sup>1</sup> We mean, instead, that  $f^{-1}$  is hard to evaluate at a *random* argument. Thus, if one wants (as we do) to use trap-door functions to generate problems computationally hard for an “adversary,” he must be

<sup>1</sup> For example, any  $f$  can be easily inverted at the image of a fixed argument, say 0. In fact, we may consider inverting algorithms that, on inputs  $x$  and  $f$ , first check whether  $x = f(0)$ .

able to randomly select a point in the domain of  $f$  and  $f^{-1}$ . This operation is easy for all currently known candidates of a trap-door permutation, and we explicitly assume it to be easy in our formal treatment.

DEFINITION. Let  $G$  be an algorithm in  $\mathcal{RA}$  that on input  $1^k$ , outputs an ordered triple  $(d, f, f^{-1})$  of algorithms. (Here  $D = [d(\cdot)]$  will denote the domain of the trap-door permutation  $f$  and its inverse  $f^{-1}$ .) We say that  $G$  is a *trap-door permutation generator* if there is a polynomial  $p$  such that

(1) Algorithm  $d$  always halts within  $p(k)$  steps and defines a uniform probability distribution over the finite set  $D = [d(\cdot)]$ . (That is, running  $d$  with no inputs uniformly selects an element from  $D$ .)

(2) Algorithms  $f$  and  $f^{-1}$  halt within  $p(k)$  steps on any input  $x \in D$ . (For inputs  $x$  not in  $D$ , the algorithms  $f$  and  $f^{-1}$  either loop forever or halt and print an error message that the input is not in the appropriate domain.) Furthermore, the functions  $x \mapsto f(x)$  and  $x \mapsto f^{-1}(x)$  are permutations of  $D$  which are inverses of each other.

(3) For all (inverting) algorithms  $I(\cdot, \cdot, \cdot, \cdot) \in \mathcal{RA}$ , for all  $c$  and sufficiently large  $k$ :

$$P(y = f^{-1}(z) | (d, f, f^{-1}) \leftarrow G(1^k); z \leftarrow d(\cdot); y \leftarrow I(1^k, d, f, z)) < k^{-c}.$$

We make the following informal remarks corresponding to parts of the above definition.

(1) This condition makes it explicit that it is possible to sample the domain of  $f$  in a uniform manner.

(3) This part of the definition states that if we run the experiment of generating  $(d, f, f^{-1})$  using the generator  $G$  and security parameter  $k$ , and then randomly generating an element  $z$  in the range of  $f$ , and then running the “inverting” algorithm  $I$  (for polynomially in  $k$  many steps) on inputs  $d, f$ , and  $z$ , the chance that  $I$  will successfully invert  $f$  at the point  $z$  is vanishingly small as a function of  $k$ .

DEFINITION. If  $G$  is a trap-door permutation generator, we say that  $[G(1^k)]$  is a *family of trap-door permutations*. We say that  $f$  and  $f^{-1}$  are *trap-door permutations* if  $(d, f, f^{-1}) \in [G(1^k)]$  for some  $k$  and trap-door permutation generator  $G$ .

**6.2. “Claw-free” permutation pairs.** The signature scheme we propose is based on the existence of “claw-free” permutation pairs; informally, these are permutations  $f_0$  and  $f_1$  over a common domain for which it is computationally infeasible to find a triple  $x, y$ , and  $z$  such that  $f_0(x) = f_1(y) = z$  (a “claw” or “ $f$ -claw”—see Fig. 1).

DEFINITION. Let  $G$  be an algorithm in  $\mathcal{RA}$  that, on input  $1^k$ , outputs an ordered quintuple  $(d, f_0, f_0^{-1}, f_1, f_1^{-1})$  of algorithms. We say that  $G$  is a *claw-free permutation pair generator* if there is a polynomial  $p$  such that:

(1) Algorithm  $d$  always halts within  $p(k)$  steps and defines a uniform probability distribution over the finite set  $D = [d(\cdot)]$ .

FIG. 1. A claw.

(2) Algorithms  $f_0, f_0^{-1}, f_1$  and  $f_1^{-1}$  halt within  $p(k)$  steps on any input  $x \in D$ . (For inputs  $x$  not in  $D$ , these algorithms either loop forever or halt with an error message that the input is not in the necessary domain.) Furthermore, the functions  $x \mapsto f_0(x)$  and  $x \mapsto f_0^{-1}(x)$  are permutations of  $D$  which are inverses of each other, as are  $x \mapsto f_1(x)$  and  $x \mapsto f_1^{-1}(x)$ .

(3) For all (claw-making) algorithms  $I(\cdot, \cdot, \cdot, \cdot) \in \mathcal{RA}$ , for all  $c$  and sufficiently large  $k$ :

$$\mathbf{P}(f_0(x) = f_1(y) = z \mid (d, f_0, f_0^{-1}, f_1, f_1^{-1}) \leftarrow G(1^k); (x, y, z) \leftarrow I(1^k, d, f_0, f_1)) < k^{-c}.$$

*Note.* It would be possible to use a variant of the above definition, in which the function  $f$  may actually return answers for inputs outside of  $D$  as long as it is understood that the difficulty of creating a “claw” applies to all  $x, y$  for which the function  $f$  returns an answer. Thus, it should be hard to find *any* triplet  $(x, y, z)$  such that  $f_0(x) = f_1(y) = z$  even when  $x, y$  are not in  $D$ . We do not pursue this variation further in this paper.

**DEFINITION.** We say that  $f = (d, f_0, f_1)$  is a *claw-free permutation pair* (or *claw-free pair* for short) if  $(d, f_0, f_0^{-1}, f_1, f_1^{-1}) \in [G(1^k)]$  for some  $k$  and claw-free permutation pair generator  $G$ . In this case,  $f^{-1}$  will denote the pair of permutations  $(f_0^{-1}, f_1^{-1})$ .

**6.2.1. Claw-free permutation pairs versus trap-door permutations.** In this subsection we clarify the relation between the notions of claw-free permutation pairs and trap-door permutations, by showing that the existence of the former ones implies the existence of the latter ones. (Since trap-door permutations are not used in our signature scheme, this subsection can be skipped by the reader without loss of clarity.)

**CLAIM.** Let  $G \in \mathcal{RA}$  be a claw-free permutation generator. Then there exists a  $\bar{G} \in \mathcal{RA}$  which is a trap-door permutation generator.

*Proof.* The algorithm  $\bar{G}$  is defined as follows on input  $1^k$ : Run  $G$  on input  $1^k$ . Say,  $G$  outputs the ordered tuple  $(d, f_0, f_0^{-1}, f_1, f_1^{-1})$ . Then,  $\bar{G}$  outputs  $(d, f_0, f_0^{-1})$ .

We now show that  $\bar{G}$  is a trap-door permutation generator. Assume for contradiction that it is not the case. Namely, there exists a constant  $c > 0$  and an inverting algorithm  $\bar{I}(\cdot, \cdot, \cdot, \cdot) \in \mathcal{RA}$  such that for infinitely many  $k$ :

$$\mathbf{P}(f_0(y) = z \mid (d, f_0, f_0^{-1}) \leftarrow \bar{G}(1^k); z \leftarrow d(\cdot); y \leftarrow \bar{I}(1^k, d, f_0, z)) \geq k^{-c}.$$

Note now, that since  $f_1$  is a permutation, algorithms  $f_1(d(\cdot))$  and  $d(\cdot)$  both define the uniform probability distribution over  $[d(\cdot)]$ . Thus, for infinitely many  $k$ ,

$$\begin{aligned} \mathbf{P}(f_1(x) = f_0(y) \\ = z \mid (d, f_0, f_0^{-1}, f_1, f_1^{-1}) \leftarrow G(1^k); x \leftarrow d(\cdot); z \leftarrow f_1(x); y \leftarrow \bar{I}(1^k, d, f_0, z)) \geq k^{-c}. \end{aligned}$$

Let  $I(\cdot, \cdot, \cdot, \cdot)$  be the following inverting algorithm: On input  $1^k, d, f_0$  and  $f_1$ , compute  $x \leftarrow d(\cdot), z \leftarrow f_1(x), y \leftarrow \bar{I}(1^k, d, f_0, z)$  and output  $(x, y, z)$ .

Then,  $I$  is in  $\mathcal{RA}$  and for infinitely many  $k$ ,

$$\mathbf{P}(f_0(x) = f_1(y) = z \mid (d, f_0, f_0^{-1}, f_1, f_1^{-1}) \leftarrow G(1^k); (x, y, z) \leftarrow I(1^k, d, f_0, f_1)) \geq k^{-c}.$$

This contradicts  $G$  being a claw-free permutation generator and thus  $\bar{G}$  must be a trap-door permutation generator.  $\square$

We note, however, that the converse to the above claim may be false. For example, the pair of (“RSA”) permutations over  $Z_n^* = \{1 \leq x \leq n: \gcd(x, n) = 1\}$ , defined by

$$f_0(x) \equiv x^3 \pmod{n} \quad \text{and} \quad f_1(x) \equiv x^5 \pmod{n}$$

(where  $\gcd(\phi(n), 15) = 1$ ) is not claw-free: since the two functions commute it is easy

to create a claw by choosing  $w$  at random and then defining  $x \equiv f_1(w)$ ,  $y \equiv f_0(w)$ , and  $z \equiv f_0(x) \equiv f_1(y) \equiv w^{15} \pmod{n}$ .

However, it is likely that  $f_0$  and  $f_1$  are trap-door permutations.

In practice, one may want to relax the definition of a claw-free permutation pair generator slightly, to allow the generator to have a very small chance of outputting functions  $f_0$  and  $f_1$  which are not permutations. We do not pursue this line of development in this paper.

**6.3. Claw-free permutations exist if factoring is hard.** The assumption of the existence of claw-free pairs is made in this paper in a general manner, independent of any particular number-theoretic assumptions. Thus, instances of our scheme may be secure even if factoring integers turns out to be easy. However, for concretely implementing our scheme the following is suggested.

We first make an assumption about the intractability of factoring, and then exhibit a claw-free permutation pair generator based on the difficulty of factoring.

*Notation.* Let

$$H_k = \{n = p \cdot q \mid |p| = |q| = k, p \equiv 3 \pmod{8}, q \equiv 7 \pmod{8}\}$$

(the set of composite numbers which are the product of two  $k$ -bit primes which are both congruent to 3 modulo 4 but not congruent to each other modulo 8), and let  $H = \bigcup_k H_k$ .

*Remark.* One way to choose “hard” instances for all known factoring algorithms seems to be to choose  $k$  to be large enough and then to choose  $n$  randomly from  $H_k$ .

These numbers were used in [Wi80] and their wide applicability to cryptography was demonstrated by Blum in [Bl82]; hence, they are commonly referred to as “Blum integers.”

Let  $Q_n$  denote the set of quadratic residues  $\pmod{n}$ . We note that for  $n \in H$ :

- 1 has Jacobi symbol +1 but is not in  $Q_n$ ;
- 2 has Jacobi symbol -1 (and is not in  $Q_n$ ).

We also note that every  $x \in Q_n$  has exactly one square root  $y \in Q_n$ , but has four square roots  $y, -y, w, -w$  altogether (see [Bl82] for proof). Roots  $w$  and  $-w$  have Jacobi symbol -1, while  $y$  and  $-y$  have Jacobi symbol +1.

The following assumption about the intractability of factoring is made throughout this section.

**Intractability Assumption for Factoring (IAF).** Let  $A$  be a probabilistic polynomial-time (factoring) algorithm. Then for all constants  $c > 0$  and sufficiently large  $k$

$$P(x \text{ is a nontrivial divisor of } n \mid n \leftarrow H_k(\cdot); x \leftarrow A(n)) < \frac{1}{k^c}.$$

(Here we have used the notation  $n \leftarrow H_k(\cdot)$  to denote the operation of selecting an element of  $H_k$  uniformly at random.)

Define  $f_{0,n}$  and  $f_{1,n}$  as follows:

$$f_{0,n}(x) = \begin{cases} x^2 \pmod{n} & \text{if } x^2 \pmod{n} < n/2, \\ -x^2 \pmod{n} & \text{if } x^2 \pmod{n} \geq n/2, \end{cases}$$

$$f_{1,n}(x) = \begin{cases} 4x^2 \pmod{n} & \text{if } 4x^2 \pmod{n} < n/2, \\ -4x^2 \pmod{n} & \text{if } 4x^2 \pmod{n} \geq n/2. \end{cases}$$

The common domain of these functions is

$$D_n = \left\{ x \in Z_n \mid \left( \frac{x}{n} \right) = 1 \text{ and } 0 < x < n/2 \right\};$$

it is easy to see that the range of these functions is included in  $D_n$  for  $n \in H$ . Note also that it is easy to test whether or not a given element  $x$  is a member of  $D_n$ , since Jacobi symbols can be evaluated in polynomial time.

We now show that  $f_{0,n}$  and  $f_{1,n}$  are actually permutations of  $D_n$  for  $n \in H$ . Suppose  $f_{0,n}$  is not a permutation of  $D_n$ ; then there exist distinct elements  $x, y$  in  $D_n$  such that  $f_{0,n}(x) = f_{0,n}(y)$ . This can only happen if  $x^2 \equiv y^2 \pmod{n}$ , which would imply that  $x \equiv \pm y \pmod{n}$ . But this is impossible if  $x$  and  $y$  are both in  $D_n$ , thus proving that  $f_{0,n}$  is a permutation. The proof for  $f_{1,n}$  is similar.

Not only are  $f_{0,n}$  and  $f_{1,n}$  permutations of  $D_n$  when  $n \in H$ , but their inverses are easily computed, given knowledge of  $p$  and  $q$ . Given  $p$  and  $q$ , it is easy to distinguish quadratic residues (mod  $n$ ) from nonresidues with Jacobi symbol equal to 1; this ability enables one to negate the input to the inverse function if necessary in order to obtain a quadratic residue (mod  $n$ ). Of course, dividing by 4 is easy—this step is needed only for inverting  $f_{1,n}$ . Next, taking square roots (mod  $n$ ) is easy, since we can take square roots modulo  $p$  and  $q$  separately (making sure to pick the square root which is itself a quadratic residue) and combine the results using the Chinese Remainder Theorem. Finally, the result can be negated (mod  $n$ ) as necessary in order to obtain a result in  $D_n$ . Since all of these steps are computable in polynomial time, each of the inverse functions  $f_{0,n}^{-1}$  and  $f_{1,n}^{-1}$  is computable in polynomial time, given  $p$  and  $q$  as additional inputs.

**THEOREM 1.** *Under the IAF, the following algorithm  $G$  is a claw-free permutation pair generator. On input  $1^k$ ,  $G$ .*

- (1) *Generates two random primes  $p$  and  $q$  of length  $k$ , where  $p \equiv 3 \pmod{8}$  and  $q \equiv 7 \pmod{8}$ ,*
- (2) *Outputs the quintuple*

$$(d, f_{0,n}, f_{0,n}^{-1}, f_{1,n}, f_{1,n}^{-1})$$

where

- (a) *Algorithm  $d$  generates elements uniformly at random in  $Q_n$ ,*
- (b) *Algorithms  $f_{0,n}$  and  $f_{1,n}$  are as described in the above equations,*
- (c) *Algorithms  $f_{0,n}^{-1}$  and  $f_{1,n}^{-1}$  are algorithms for the inverse functions (these algorithms make use of  $p$  and  $q$ ).*

*Proof.* We first note that uniformly selecting  $k$ -bit guaranteed primes can be accomplished in expected polynomial (in  $k$ ) time (by the recent work of Goldwasser and Kilian [GK86]) and that asymptotically one-quarter of these will be congruent to 3 (mod 8) (similarly for those congruent to 7 (mod 8)). (In practice, one would use a faster probabilistic primality test such as the one proposed by Solovay and Strassen [SS77] or Rabin [Ra80].)

Let  $n \in H$  and  $(d, f_{0,n}, f_{0,n}^{-1}, f_{1,n}, f_{1,n}^{-1}) \in [G(1^k)]$ . First,  $f_{0,n}$  and  $f_{1,n}$  are permutations of  $D_n = [d(\cdot)]$ . Then, we need only show that if there exists a fast algorithm that finds  $x$  and  $y$  in  $D_n$  such that  $f_{0,n}(x) \equiv f_{1,n}(y) \pmod{n}$  (i.e., a claw-creating algorithm) then factoring is easy. Suppose such an  $x$  and  $y$  have been found. Then  $x^2 \equiv 4y^2 \pmod{n}$ . (Note that  $x^2 \equiv -4y^2 \pmod{n}$  is impossible: since  $4y^2$  is a quadratic residue (mod  $n$ ),  $-4y^2$  cannot be a quadratic residue (mod  $n$ ), for  $n \in H$ .) This implies that  $(x + 2y) \times (x - 2y) \equiv 0 \pmod{n}$ . Moreover, we also know that  $x \not\equiv \pm 2y \pmod{n}$ , since  $(x/n) = 1$  and  $(2y/n) = -1$ . Thus  $\gcd(x \pm 2y, n)$  will produce a nontrivial factor of  $n$ .  $\square$

**6.4. An infinite set of pairwise claw-free permutations.** For our scheme we need not only claw-free pairs of permutations, but an infinite family of permutations which are pairwise claw-free and generated by a single claw-free pair  $f = (d, f_0, f_1)$ .

We define the function  $f_i(\cdot)$  for any string  $i \in \{0, 1\}^+$  by the equation:

$$f_i(x) = f_{i_0}(f_{i_1}(\dots(f_{i_{d-1}}(f_{i_d}(x)) \dots)))$$

if  $i = i_0i_1 \dots i_{d-1}i_d$ . (Also, read  $f_i^{-1}$  as  $(f_i)^{-1}$  so that  $f_i^{-1}(f_i(x)) = x$ .)

Each  $f_i$  is a trap-door permutation: it is easy to compute  $f_i(x)$  given  $f_0, f_1, i$ , and  $x$ , and to compute  $f_i^{-1}(x)$  if  $f_0^{-1}$  and  $f_1^{-1}$  are available. However, given only  $f_0$  and  $f_1$  it should be hard to invert  $f_i$  on a random input  $z$ , or else  $f_0$  and  $f_1$  are not trap-door permutations. (By inverting  $f_i$  on a random input we also effectively invert  $f_{i_0}$  on a random input, where  $i_0$  is the first bit of  $i$ .)

This way of generating an infinite family of trap-door permutations was also used in [GMY83].

Looking ahead, we shall see that a user  $A$  of our scheme can use the  $f_i$ 's to perform basic authentication steps as follows. Let us presume that  $A$  has published  $f_0$  and  $f_1$  as part of his public key, and has kept their inverses  $f_0^{-1}$  and  $f_1^{-1}$  secret. If user  $A$  is known to have authenticated a string  $y$ , then by publishing strings  $i$  and  $x$  such that

$$f_i(x) = y,$$

he authenticates the new strings  $i$  and  $x$ .

For this to work, when the signer  $A$  reveals  $f_i^{-1}(y)$ , he should not enable anyone else to compute  $f_j^{-1}(y)$  for any other  $j$ .

The signer achieves this in our scheme by coding  $i$  using a prefix-free mapping  $\langle \cdot \rangle$ . This prevents an enemy from computing  $f_{\langle j \rangle}^{-1}(x)$  from  $f_{\langle i \rangle}^{-1}(x)$  in an obvious way since  $\langle j \rangle$  is never a prefix of  $\langle i \rangle$ . The following Lemma 1 shows that this approach is not only necessary but sufficient.

*Note.* Actually, the mapping  $\langle \cdot \rangle$  that we use is a one-to-one mapping from *tuples* of strings of bits to strings of bits. The mapping  $\langle \cdot \rangle$  is prefix-free in the sense that  $\langle a_1, \dots, a_n \rangle$  is never a prefix of  $\langle b_1, \dots, b_m \rangle$  unless  $n = m$  and  $a_1 = b_1, \dots, a_n = b_n$ . Any prefix-free mapping is usable if it and its (partial) inverses are polynomial-time computable and the lengths of  $a_1, \dots, a_n$  and  $\langle a_1, \dots, a_n \rangle$  are polynomially related. For concreteness, we suggest the following encoding scheme for the tuple of strings  $a_1, \dots, a_n$ . Each string  $a_i$  is encoded by changing each 0 to 00 and each 1 to 11, and the encoding is followed by 01. The encodings of  $a_1, \dots, a_n$  are concatenated and followed by 10.

Lemma 1 essentially says that if  $(d, f_0, f_1)$  is a claw-free pair, then it will be hard to find two different tuples of strings  $i$  and  $j$ , and elements  $x$  and  $y$  such that  $f_{\langle i \rangle}(x) = f_{\langle j \rangle}(y)$ .

**LEMMA 1.** *Let  $f = (d, f_0, f_1)$  be a claw-free pair,  $x$  and  $y$  be elements of  $d$  and  $i, j$  two different tuples of binary strings such that there exists a string  $z$  such that  $z = f_{\langle i \rangle}(x) = f_{\langle j \rangle}(y)$ . Then there exists an  $f$ -claw  $(x_1, x_2, x_3)$  where  $x_3 = f_c^{-1}(z)$  for some prefix  $c$  of  $\langle i \rangle$ .*

*Proof.* Let  $c \in \{0, 1\}^*$  be the longest common prefix of  $\langle i \rangle$  and  $\langle j \rangle$ . Such a  $c$  must exist since  $\langle \cdot \rangle$  is a prefix-free encoding scheme. Thus, setting  $x_3 \leftarrow f_c^{-1}(z)$ ,  $x_1 \leftarrow f_{c0}^{-1}(z)$ , and  $x_2 \leftarrow f_{c1}^{-1}(z)$ , we obtain an  $f$ -claw  $(x_1, x_2, x_3)$ . (If  $c$  is the empty string then  $f_c^{-1}$  denotes the identity function, so  $x_3 = z$ .) Note that the  $f$ -claw is easily computed from  $f, x$ , and  $y$ .  $\square$

**7. Building blocks for signing.** In this section we define the basic building blocks needed for describing our signature scheme. In § 8, we will define what a signature is and how to sign, using the objects and data structures introduced here.

*Assumption.* We assume from here on that all claw-free functions used are defined over domains which do *not* include the empty string  $\epsilon$ .

This assumption is necessary since we use  $\epsilon$  as a “marker” in our construction; note that it is easy, via simple recodings, to enforce this construction if necessary.

We begin by defining the essential notion of an  $f$ -item.

DEFINITION. Let  $f = (d_f, f_0, f_1)$  be a claw-free pair. A tuple of strings  $(t, r; c_1, \dots, c_m)$  is an  $f$ -item if

$$f_{(c_1, \dots, c_m)}(t) = r.$$

DEFINITION. In an  $f$ -item  $(t, r; c_1, \dots, c_m)$ ,

- $t$  is called the *tag* of the item,
- $r$  is called the *root* of the item, and
- the  $c_i$ 's are the *children* of the item. We note that the children are ordered, so that we can speak of the first child or the second child of the item.

Note that given a claw free pair  $f$  and a tuple it is easy to check if the tuple is an  $f$ -item by applying the appropriate  $f_{(i)}$  to the tag, and checking if the correct root is obtained.

Figure 2 gives our graphic representation of an  $f$ -item  $(t, r; c_1, c_2)$  with two children.

DEFINITION. We say that a sequence of  $f$ -items  $L_1, L_2, \dots, L_b$  is an  $f$ -chain starting at  $y$  if, for  $i = 1, \dots, b - 1$ , the root of  $L_{i+1}$  is one of the children of  $L_i$  and  $y$  is the root of  $L_1$ . We say the chain ends at  $x$  if  $x$  is one of the children of the item  $L_b$ .

FIG. 2. An  $f$ -item with two children.

For efficiency considerations, our signature scheme will organize a collection of a special-type of  $f$ -chains in the treelike structure defined below.

DEFINITION. Let  $i$  be a binary string of length  $b$  and  $f$  a claw-free pair. An  $f$ - $i$ -tree is a bijection  $T$  between DFS( $i$ ) and a set of  $f$ -items such that:

- (1) if string  $j$  has length  $b$ , then  $T(j)$  is an  $f$ -item with exactly two children, exactly one of which is  $\epsilon$ , the empty string. These  $f$ -items are called *bridge items*.
- (2) if string  $j$  has length less than  $b$ , then  $T(j)$  is an  $f$ -item with exactly two children,  $c_0$  and  $c_1$ , both of which are nonempty strings. Moreover,  $c_0$ , the  $0$ th child, is the root of  $T(j0)$  and  $c_1$ , the  $1$ st child, the root of  $T(j1)$ .

The  $f$ -item  $T(j)$  is said to be of *depth*  $b$  if string  $j$  has length  $d$ . (The bridge items are thus the items of depth  $b$ .) The *root* of  $T$  is the root of the  $f$ -item  $T(\epsilon)$ . The *internal nodes* of  $T$  are the root and the children of the  $f$ -items of depth less than  $b$ . The *leaves* of  $T$  are the nonempty children of the bridge items. Thus the internal nodes and the leaves of an  $f$ - $i$ -tree are actual values and not  $f$ -items. Leaves possess binary names of length  $b$ ; leaf  $j$  is the nonempty child of bridge item  $T(j)$ . The *path to leaf*  $j = j_0 \dots j_b$  is the  $f$ -chain  $T(\epsilon), T(j_0), \dots, T(j_0 \dots j_b)$ .

FIG. 3. An  $f$ -100-tree.

Figure 3 gives our graphic representation of an  $f$ -100-tree, as it would be used in our signature scheme. In this figure we denote by  $r_i^f$  the root of  $f$ -item  $T(i)$ , and by  $r_i^g$  the leaf (nonempty) child of bridge item  $T(i)$ . (Also present in Fig. 3 are a number of “ $g$ -items,” which are not part of the  $f$ -100 tree but are attached to it in a manner to be described.)

There are two reasons for letting the bridge items of an  $f$ -tree have the empty string as one of their children. First, it makes them de facto  $f$ -items with only one child, a subtle point in our proof of security that is pointed out in Remark 1. Second, it makes them distinguishable from items with two children, a simple point used, for instance, in Lemma 2.

**8. Description of our signature scheme.**

**8.1. Message spaces.** The security properties of the new signatures scheme hold for any nonempty message space  $M \subset \{0, 1\}^+$ .

**8.2. How to generate keys.** We assume the existence of a claw-free permutation pair generator  $G$  and, without loss of generality, that the bound  $B$  on the number of signatures that can be produced is a power of 2:  $B = 2^b$ .

The key-generation algorithm  $K$  runs as follows on inputs  $1^k$  and  $2^b$ :

- (1)  $K$  runs  $G$  twice on input  $1^k$  to secretly and randomly select two quintuples

$$(d_f, f_0, f_0^{-1}, f_1, f_1^{-1}) \text{ and } (d_g, g_0, g_0^{-1}, g_1, g_1^{-1}) \in [G(1^k)].$$

- (2)  $K$  then randomly selects  $r_\epsilon^f$  in  $D_f = [d_f(\cdot)]$ .

(3)  $K$  outputs the public key  $PK = (f, r_\epsilon^f, g, 2^b)$  where  $f$  is the claw-free pair  $(d_f, f_0, f_1)$  and  $g$  is the claw-free pair  $(d_g, g_0, g_1)$ .

- (4)  $K$  outputs the secret key  $SK = (f^{-1}, g^{-1})$ .

The  $PK$  and  $SK$  so produced are said to be (matching) keys of size  $k$ .

**8.3. What is a signature?** A *signature* of a message  $m$  with respect to a public key  $(f, r_\varepsilon^f, g, 2^b)$  consists of the following:

- (1) An  $f$ -chain of length  $b+1$  starting at a string  $r_\varepsilon^f$  and ending at  $r^g$ , and
- (2) A  $g$ -item with  $r^g$  as its root and  $m$  as its only child.

**8.4. How to sign.** In the remainder of this section we shall presuppose that user  $A$ 's public key is  $PK = (f, r_\varepsilon^f, g, 2^b)$  where  $f = (d_f, f_0, f_1)$  and  $g = (d_g, g_0, g_1)$ . User  $A$ 's secret key is  $SK = (f^{-1}, g^{-1})$ . We denote by  $D_f$  the domain  $[d_f(\cdot)]$ , and denote by  $D_g$  the domain  $[d_g(\cdot)]$  similarly.

Conceptually, user  $A$  creates an  $f-1^b$ -tree  $T$ , which has  $2^b$  leaves. The root of  $T$  will be  $r_\varepsilon^f$ . The other internal nodes of  $T$  are randomly selected elements of  $D_f$ . The leaves of  $T$  are randomly selected elements of  $D_g$ .

To sign  $m_i$ , the  $i$ th message in the chronological order, user  $A$  computes a  $g$ -item  $G_i$  whose root  $r_i^g \in D_g$  is the  $i$ th leaf of  $T$ , and whose only child is the message  $m_i$ . He then outputs, as the signature of  $m_i$ ,  $G_i$  and the  $f$ -chain in  $T$  starting at root  $r_\varepsilon^f$  and ending at leaf  $r_i^g$ .

In practice, it will be undesirable for user  $A$  to precompute and store all of  $T$ . He will instead "grow"  $T$  as needed and try to optimize his use of storage and time. This is taken into account by our signing procedure. In what follows, we describe a variation of our signing method that requires the signer to remember just his secret key and his most recently produced signature, in order to produce his next signature. The reader may find it helpful to refer to Fig. 3 while reading this description.

**The signing procedure (also called  $\mathcal{SP}$ ).** We presume that the procedure is initialized with the values of the public key  $PK$  and the corresponding secret key  $SK$  in its local private storage, that has already signed messages  $m_0, m_1, \dots, m_{i-1}$  and kept track of the number of previous messages signed (i.e., the variable  $i = i_0 \dots i_{b-1}$ , which is a  $b$ -long bit string, which may contain leading 0's), and the most recent signature produced.

To compute a signature for message  $m_i$ , the  $i$ th message, user  $A$  performs the following steps.

- (1) (*Output  $f$ -chain.*)
  - (1.1) (*Output  $f$ -items in common with previous signature.*) If  $i = 0^b$  this substep is skipped, and control passes to step (1.2). Otherwise, for each string  $j$  which is a common prefix of  $i$  and  $i-1$ , he outputs the  $f$ -item  $(t_j^f, r_j^f; r_{j_0}^f, r_{j_1}^f)$  which was part of the signature for message  $m_{i-1}$ , in order of increasing length of  $j$ .
  - (1.2) (*Output new  $f$ -items in  $f$ -tree.*) For each string  $j$  (if any) which is a proper prefix of  $i$ , but not a prefix of  $i-1$ , user  $A$  creates and outputs an  $f$ -item  $T(j)$ , in order of increasing length of  $j$ . The  $f$ -item  $T(j) = (t_j^f, r_j^f; r_{j_0}^f, r_{j_1}^f)$  is created as follows: If  $j = \varepsilon$  its root  $r_j^f$  is the  $r_\varepsilon^f$  from the public key; otherwise it is the  $k$ th child of the most recently output  $f$ -item, where  $k$  is the last bit of the string  $j$ . The children  $r_{j_0}^f$  and  $r_{j_1}^f$  of the  $f$ -item with root  $r_j^f$  are chosen at random from  $D_f$ . The tag  $t_j^f = f_{(r_{j_0}^f, r_{j_1}^f)}^{-1}(r_j^f)$  is computed using  $f_0^{-1}$  and  $f_1^{-1}$  from the secret key. Note that the last item output (by either step (1.1) or (1.2)) has  $r_i^f$  as one of its children.
- (1.3) (*Output bridge  $f$ -item.*) User  $A$  next outputs a single  $f$ -item with root  $r_i^f$  and whose children are  $\varepsilon$  and  $r_i^g$ , a randomly chosen element from  $D_g$ . The tag  $t_i^f$  for this item is again computed using the secret trap-door information for inverting  $f_0$  and  $f_1$ .
- (2) (*Output  $g$ -item.*) Finally, user  $A$  outputs the  $g$ -item  $G_i = (t_i^g, r_i^g; m_i)$ . The tag  $t_i^g$  for this item is computed using the  $g^{-1}$  from the secret key.

The items output by the above procedure constitute a signature for  $m_i$ . Notice that there are many possible signatures (among which  $A$  chooses one at random) for each occurrence of each message, but only one signature is actually output.

The reader may verify that the above procedure for producing a signature will have a total running time which is bounded by a polynomial in  $k$  and  $b$ .

Notice that if  $A$  has signed  $i$  messages, the function  $T$  mapping each string  $j \in \text{DFS}(i)$  to  $f$ -item  $T(j)$  is an  $f$ - $i$ -tree as defined in § 7.

**8.5. How to verify a signature.** Given  $A$ 's public key  $(f, r_e^f, g, 2^b)$ , anyone can easily verify that the first  $b+1$  elements in the signature of  $m_i$  are  $f$ -items forming an  $f$ -chain starting at  $r_e^f$  and ending at  $r_i^g$ , and that the  $g$ -item in the signature has  $r_i^g$  as its root and  $m_i$  as its only child. If these checks are all satisfied, the given sequence of items is accepted as an authentic signature by  $A$  of the message  $m_i$ .

It is easy to confirm that these operations take time proportional to  $b$  times some polynomial in  $k$ , the size of the public key.

**8.6. Efficiency of the proposed signature scheme.** Assume that if  $f = (d_f, f_0, f_1)$  is a claw-free pair of size  $k$ , then an element of  $D_f$  is specified by a  $k$ -bit string. Then the time to compute a signature for a message  $m$  of length  $l$  is  $O(bk)$   $f$ -inversions (i.e., inversions of  $f_0$  or  $f_1$ ) and  $O(l)$   $g$ -inversions.

Another relevant measure of efficiency is "amortized" time. That is, the time used for producing all possible  $2^b$  signatures divided by  $2^b$ . In our scheme, the amortized " $f$ -inversion" cost is  $O(k)$ . The amortized " $g$ -inversion" cost is  $O(l)$  if the average length of a message is  $l$ .

The length of the signature for  $m$  is  $O(bk+l)$ , where  $l$  is the length of  $m$ , as  $m$  is included in  $m$ 's signature as the child of the  $g$ -item. Clearly, if  $m$  is known to the signature recipient, the  $g$ -item need not include  $m$ : it suffices to give its root and its tag. This way the length of the signature can be only  $O(bk)$  long, which is independent of the length of  $m$  and possibly much shorter.

The memory required by the signing algorithm is  $O(bk)$ , since it consists of storing (the  $f$ -items in) the most recently produced signature.

**9. Proof of security.** Let us start by establishing a convenient terminology.

**DEFINITION.** We call *signature corpus* the first  $i$  (for some  $i > 0$ ) signatures output by our signing procedure  $\mathcal{SP}$ . We shall generally use the symbol  $\mathcal{S}$  to denote a signature corpus.

We define the following quantities relative to a signature corpus  $\mathcal{S}$ , consisting of  $i$  signatures relative to a public key  $PK = (f, r_e^f, g, 2^b)$ .

- (1) The set of *items* of  $\mathcal{S}$ , denoted by  $\mathcal{I}(\mathcal{S})$ , is the set of the items in the signatures of  $\mathcal{S}$ .
- (2) The set of  *$f$ -items* of  $\mathcal{S}$ , denoted by  $f(\mathcal{S})$ , is the set of  $f$ -items in  $\mathcal{I}(\mathcal{S})$ .
- (3) The set of  *$g$ -items* of  $\mathcal{S}$ , denoted by  $g(\mathcal{S})$ , is the set of  $g$ -items in  $\mathcal{I}(\mathcal{S})$ .
- (4) The set of *messages* of  $\mathcal{S}$ , denoted  $M(\mathcal{S})$ , is the set of messages signed by  $\mathcal{S}$ , i.e., the set of children of the  $g$ -items of  $\mathcal{S}$ .
- (5) The  *$f$ -tree* of  $\mathcal{S}$ , denoted by  $\mathcal{T}^f(\mathcal{S})$ , is the  $f$ - $i$ -tree having root  $r_e^f$  and, as path to leaf  $j$  ( $j = 0, \dots, i$ ), the  $f$ -chain of the  $j$ th signature of  $\mathcal{S}$ .
- (6) The set of *internal nodes* of  $\mathcal{S}$ , denoted by  $\mathcal{IN}(\mathcal{S})$ , is the set of the internal nodes of  $\mathcal{T}^f(\mathcal{S})$ .
- (7) The set of *nonroots* of  $\mathcal{S}$ , denoted by  $\mathcal{NR}(\mathcal{S})$ , is the set of those internal nodes of  $\mathcal{T}^f(\mathcal{S})$  that are not the root of any  $f$ -item of  $\mathcal{S}$ . We may think of these nodes as "hooks" from which additional  $f$ -items will be grown as new signatures are created.
- (8) The set of *leaves* of  $\mathcal{S}$ , denoted  $\mathcal{L}(\mathcal{S})$ , is the set of leaves of  $\mathcal{T}^f(\mathcal{S})$ .

Notice that all the above sets are unambiguously defined. For instance, an item in  $f(\mathcal{S})$  has exactly two children while an item in  $g(\mathcal{S})$  only one, the bridge elements of  $\mathcal{I}(\mathcal{S})$  have exactly one empty child and thus are distinguishable from other items in  $f(\mathcal{S})$ , and so on.

Some of these definitions can be observed in Fig. 3. For example, the leaves of the  $f$ -100-tree in Fig. 3 are  $r_{000}^f, r_{001}^f, r_{010}^f, r_{011}^f, r_{100}^f$  and its nonroots are  $r_{101}^f$  and  $r_{111}^f$ .

Let us now see how the signature of a message never signed before relates to a given signature corpus.

LEMMA 2. *Let  $\mathcal{S}$  be a signature corpus relative to a public key  $PK = (f, r_\epsilon^f, g, 2^b)$  and let  $\sigma$  be a signature (relative to the same public key) of a message  $m$  not belonging to  $M(\mathcal{S})$ . Denote by  $\mathcal{I}(\sigma)$  the set of items in  $\sigma$ . Then  $\mathcal{I}(\sigma) - \mathcal{I}(\mathcal{S})$  (the set of new items) contains either*

- (1) a  $g$ -item with root  $r \in \mathcal{L}(\mathcal{S})$ , or
- (2) an  $f$ -item with root  $r \in \mathcal{IN}(\mathcal{S})$ .

*Proof.* First notice that  $\mathcal{I}(\sigma) - \mathcal{I}(\mathcal{S})$  is not empty as it contains  $G$ , the  $g$ -item of  $\sigma$ . In fact,  $G$  cannot belong to  $f(\mathcal{S})$ , as it is a  $g$ -item, and cannot belong to  $g(\mathcal{S})$ , as  $m$  is its only child and all items in  $g(\mathcal{S})$  have elements of  $M(\mathcal{S})$  as their children. Assume  $\mathcal{I}(\sigma) - \mathcal{I}(\mathcal{S})$  also contains an  $f$ -item. Then this  $f$ -item belongs to  $F$ , the  $f$ -chain of  $\sigma$  whose first item has  $r_\epsilon^f$  as root, one of the internal nodes of  $\mathcal{S}$ . Thus, for some item in  $F$ , (2) holds. Assume now that  $\mathcal{I}(\sigma) - \mathcal{I}(\mathcal{S}) = G$ . Then the root of  $G$  is the nonempty child of  $B$ , the bridge  $f$ -item of  $\sigma$ . By hypothesis,  $B$  is in  $\mathcal{I}(\mathcal{S})$ ; thus, the root of  $G$  belongs to  $\mathcal{L}(\mathcal{S})$  and (1) holds.  $\square$

Recall Lemma 1 from § 6.4:

LEMMA 1. *Let  $f = (d, f_0, f_1)$  be a claw-free pair,  $x$  and  $y$  be elements of  $d$  and  $i, j$  be two different tuples of binary strings such that there exists a string  $z$  such that  $z = f_{\langle i \rangle}(x) = f_{\langle j \rangle}(y)$ . Then there exists an  $f$ -claw  $(x_1, x_2, x_3)$  where  $x_3 = f_c^{-1}(z)$  for some prefix  $c$  of  $\langle i \rangle$ .*

We can now prove Lemma 3:

LEMMA 3. *There exists a polynomial-time algorithm  $A$  that, on input, a corpus  $\mathcal{S}$  relative to a public key  $PK = (f, r_\epsilon^f, g, 2^b)$  and the signature  $\sigma$  of message not belonging to  $M(\mathcal{S})$ , finds either*

- (1) a  $g$ -claw, or
- (2a) an  $f$ -claw, or
- (2b) an  $f$ -item whose root belongs to  $\mathcal{NR}(\mathcal{S})$ .

*Proof.* (The cases are numbered according to the corresponding cases in Lemma 2.) If case (1) of Lemma 2 holds for  $\mathcal{S}$  and  $\sigma$ , then we have two  $g$ -items with the same root  $r$  in  $\mathcal{L}(\mathcal{S})$ . Namely, an  $i, j, x$  and  $y$  such that  $g_{\langle i \rangle}(x) = g_{\langle j \rangle}(y) = r$  and we get a  $g$ -claw by Lemma 1. Otherwise, if case (2) of Lemma 2 holds, let  $F$  be the  $f$ -item that satisfies condition (2) of Lemma 2. If  $F$  has the same root as some  $F' \in f(\mathcal{S})$ , then again by Lemma 1, we get an  $f$ -claw; otherwise, we get an  $f$ -item whose root belongs to  $\mathcal{NR}(\mathcal{S})$ .  $\square$

*Remark 1.* Notice that if  $\sigma$  is generated by the legal signer (i.e., the  $\mathcal{SP}$  procedure) then, with very high probability, case (2b) will hold in Lemma 3.

In the proof of the main theorem we will assume that there exists a successful adaptive chosen-message attack, and derive a contradiction by showing that this attack would enable an enemy to easily create either an  $f$ -claw or a  $g$ -claw with sufficiently high probability. Recall that in an adaptive chosen-message attack the enemy can repeatedly use the real signer as an “oracle” before attempting to forge a new signature. The next lemma, Lemma 4, essentially states that the signing process can be simulated perfectly by an efficient algorithm that knows the public key and only half of the secret

key: the inverses of the first claw-free pair. (That is, in some sense, this algorithm is a forger.)

To state Lemma 4, additional notation regarding “interactive” probabilistic algorithms, needs to be introduced. The notion of an adaptive, chosen-message attack involves the interaction of two algorithms:  $\mathcal{S}$  (the signer) and  $\mathcal{R}$  (the signature requestor). These algorithms “take turns”:  $\mathcal{R}$  requests a signature of a given message,  $\mathcal{S}$  signs it,  $\mathcal{R}$  requests a second signature,  $\mathcal{S}$  signs it, and so on. We might view the two routines as “co-routines” that pass control back and forth while preserving their own state. We formalize this interaction by means of the *combining algorithm*  $\mathcal{C}$  that defines a composite algorithm from two auxiliary ones. The combining algorithm  $\mathcal{C}$  will invoke repeatedly  $\mathcal{S}$  and  $\mathcal{R}$  in alternation, corresponding to their taking turns. The algorithms  $\mathcal{S}$  and  $\mathcal{R}$  have private-state variables (denoted  $V_{\mathcal{S}}$  and  $V_{\mathcal{R}}$ ) that are preserved from invocation to invocation. Algorithm  $\mathcal{S}$  (which produces signatures) takes as input a public key  $PK$ , an auxiliary input  $X$  (which for the moment is unspecified but will later denote either the corresponding secret key  $SK$  or part of it), a new message to sign, and its private-state variable. It produces as output a signature for the new message and an updated version of its private-state variable. Similarly,  $\mathcal{R}$  is a probabilistic algorithm which takes as input a public key, a sequence of previous signatures relative to that public key, and its private-state variable, and produces as output a message to be signed and an updated version of its private-state variable.

The following algorithm makes specific the process of combining  $\mathcal{S}$  and  $\mathcal{R}$ :

ALGORITHM  $\mathcal{C}(\mathcal{S}, \mathcal{R}; PK, X, i)$

Set  $\mathcal{S}_0 \leftarrow \emptyset$ .

Set  $V_{\mathcal{R}}$  and  $V_{\mathcal{S}}$  to  $\emptyset$ .

for  $j = 0$  to  $i$  do:

$(m_j, V_{\mathcal{R}}) \leftarrow \mathcal{R}(PK, \{\mathcal{S}_1, \dots, \mathcal{S}_{j-1}\}, V_{\mathcal{R}})$  (*Request signature for message  $m_j$ .*)

$(\mathcal{S}_j, V_{\mathcal{S}}) \leftarrow \mathcal{S}(PK, m_j, V_{\mathcal{S}}, X)$ . (*Produce signature for message  $m_j$ .*)

Output  $\mathcal{S}_j$ .

Here  $\mathcal{S}_j$  denotes the signature of the  $j$ th message.

We extend our notation of probabilistic algorithm in a natural way by letting  $\mathcal{C}(\mathcal{S}, \mathcal{R}; PK, X, i)$  represent the probability space that assigns the sequence  $\sigma$  the probability that  $\mathcal{C}$  outputs  $\sigma$  after invoking alternatively (for  $i$  times)  $\mathcal{S}$  (with initial input  $PK$  and  $X$ ) and  $\mathcal{R}$  (with initial inputs  $PK$ ).

We can now state Lemma 4, stating that the signing process can be simulated effectively if the  $f_i$ 's inverses are known but the  $g_i$  inverses are not.

LEMMA 4. *There exists an algorithm  $\mathcal{A}$  in  $\mathcal{RA}$  such that for all requestors  $\mathcal{R} \in \mathcal{RA}$ , for all public keys  $PK = (f, r_e^f, g, 2^b)$  and for all nonnegative integers  $i < 2^b$ ,*

$$\mathcal{C}(\mathcal{A}, \mathcal{R}; PK, \{f^{-1}\}, i) = \mathcal{C}(\mathcal{SP}, \mathcal{R}; PK, SK, i)$$

(where  $\mathcal{SP}$  is the legal signing process of § 8, and  $SK$  is the corresponding secret key to  $PK$ ).

*Proof.* Consider the following algorithm  $\mathcal{A}$ . We inductively assume that

$$\mathcal{C}(\mathcal{A}, \mathcal{R}; PK, \{f^{-1}\}, i - 1) = \mathcal{C}(\mathcal{SP}, \mathcal{R}; PK, SK, i - 1).$$

Thus the  $f$ -chains in the first  $i - 1$  signatures output by  $\mathcal{C}$  uniquely define an  $f - (i - 1)$ -tree  $T$ . Algorithm  $\mathcal{A}$  stores  $i - 1$  and the  $f$ -chain of the last produced signature and executes the following instructions to sign  $m_i$ , the  $i$ th message, where  $i = i_0 \cdots i_b$ .

- (1) (*Authenticate  $m_i$  with a  $g$ -item.*) Pick an element  $t_i^g$  at random in  $D_g$  and compute  $r_i^g = g_{(m_i)}(t_i^g)$  so as to generate the  $g$ -item  $(t_i^g, r_i^g; m_i)$ .

- (2) (*Build the  $f$ -chain from  $r_\varepsilon^f$  to  $r_i^f$  to the extent that it is not already done.*) Compute  $i_0 i_1 \cdots i_j$ , the longest proper prefix of  $i$  that is also a prefix of  $i-1$ . For  $x = 1$  to  $b-j$ , generate  $T(i_0 \cdots i_{j+x})$ , an  $f$ -item whose root is the  $i_{j+x}$ th child of  $T(i_0 \cdots i_{j+x-1})$ , and whose two children are independently and randomly selected elements of  $D_f$ . (Algorithm  $\mathcal{A}$  easily computes the tag of this new  $f$ -item by using  $f^{-1}$ .)
- (3) (*Create the bridge item authenticating  $r_i^g$ .*) Using  $f_0^{-1}$  and  $f_1^{-1}$ , create an  $f$ -item with children  $\varepsilon$  and  $r_i^g$  and having as root the  $i_b$ th child of  $T(i_0 \cdots i_{b-1})$ .
- (4) (*Output signature of  $m_i$* ) Output  $T(\varepsilon)$ ,  $T(i_0)$ ,  $\cdots$ ,  $T(i_0 \cdots i_{b-1})$ , the new bridge item  $T(i_0, \cdots, i_b)$  and the new  $g$ -item.  $\square$

In Lemma 6 we show a similar result: the signing process can be simulated if  $g^{-1}$  is known, but  $f^{-1}$  is not. The proof of Lemma 6 makes essential use of the fact that there is a known upper bound on the number of signatures to be produced. (The bound provides a limit on the amount of a preprocessing step that is the subject of Lemma 5.)

There is, however, a very important difference between the signing simulation procedure described in Lemma 4 (which uses  $f^{-1}$  but not  $g^{-1}$ ) and that of Lemma 6 (which uses  $g^{-1}$  but not  $f^{-1}$ ). The proof of Lemma 4 works with any fixed root  $r_\varepsilon^f$ , which can be fixed arbitrarily before the simulation procedure is invoked.

By contrast, the signing simulation procedure of Lemmas 5 and 6 actually *produces* the necessary root  $r_\varepsilon^f$  to be part of the public key in its preprocessing step. The root produced is uniformly distributed over  $D_f$ . Thus, from the point of view of an observer that monitors the behaviour of the signer when he publishes his public key, the preprocessing step is indistinguishable from a genuine key generation step. Moreover, by monitoring the signing process, the observer cannot tell whether the signer really knows  $f^{-1}$  or if he has first applied the preprocessing procedure of Lemma 5 to produce his public file and only then applied the simulation procedure of Lemma 6.

DEFINITION. For all strings  $m_1, \cdots, m_i$ , let *sequence*( $m_1, \cdots, m_i$ ) denote the trivial interactive algorithm that, no matter what inputs it gets, when invoked for the  $j$ th time ( $j = 1, \cdots, i$ ) outputs the string  $m_j$ .

Let us define two probability spaces over the  $f$ - $i$ -trees which are crucial to our analysis.

DEFINITION. Let  $PK = (f, r_\varepsilon^f, g, 2^b)$  and  $SK = (f^{-1}, g^{-1})$  be a pair of matching public and secret key, where  $f = (d_f, f_0, f_1)$ . Recall that  $\mathcal{C}$  is the combining algorithm. Define two probability spaces,  $\mathcal{T}_{i,PK}$  and  $\mathcal{T}_{i,f,g,2^b}$ , as follows:

$\mathcal{T}_{i,PK}$  is generated by randomly selecting  $\mathcal{S}$  in  $\mathcal{C}(\mathcal{SP}, \text{sequence}(m_1, \cdots, m_i); PK, SK, i)$  and then computing  $\mathcal{T}^f(\mathcal{S})$ . (Note that  $\mathcal{T}_{i,PK}$  does not depend on the values of the messages  $m_1, \cdots, m_i$  but it does depend on  $i$ , the number of messages.)

$\mathcal{T}_{i,f,g,2^b}$  is generated by randomly selecting  $\mathcal{S}$  in  $\mathcal{C}(\mathcal{SP}, \text{sequence}(m_1, \cdots, m_i); (f, d_f(\cdot), g, 2^b), SK, i)$  and then computing  $\mathcal{T}^f(\mathcal{S})$ .

Informally,  $\mathcal{T}_{i,PK}$  is the probability space obtained from  $\mathcal{T}_{i,f,g,2^b}$  by randomly picking  $r_\varepsilon^f \in D_f$  and fixing it in  $PK$ .

Notice that both probability spaces are easily generated if the secret key  $SK = (f^{-1}, g^{-1})$  is among the available inputs. However, both probability spaces remain easy to generate on a more restricted set of inputs. It has been implicitly proved in Lemma 2 that  $\mathcal{T}_{i,PK}$  can be generated in probabilistic polynomial-time on inputs  $i, PK$  and  $f^{-1}$  alone. The following lemma shows that  $\mathcal{T}_{i,f,g,2^b}$  is easily generated on inputs  $i, f, g, 2^b$  alone.

LEMMA 5. *There exists  $\mathcal{T} \in \mathcal{RA}$  such that for all claw-free pairs  $f = (d_f, f_0, f_1)$  and  $g = (d_g, g_0, g_1)$  and for all integers  $i < 2^b$ ,*

$$\mathcal{T}(i, f, g, 2^b) = \mathcal{T}_{i,f,g,2^b}$$

*Proof.* Consider the following algorithm  $\mathcal{T}$  that constructs an  $f$ - $i$ -tree  $T$  in “reverse order”; that is, it constructs  $f$ -item  $T(x)$  before  $f$ -item  $T(y)$  if  $y < x$ . (This is necessary since  $\mathcal{T}$  does not have access to  $f^{-1}$ .) The construction goes as follows.

If string  $j \in \text{DFS}(i)$  has length  $b$ ,  $\mathcal{T}$  selects the nonempty child of  $T(j)$  at random in  $D_g$ . Otherwise (if  $j$  has length shorter than  $b$ ),  $\mathcal{T}$  selects, as 0th child of  $T(j)$ , the root of  $T(j0)$  and, as 1st child, the root of  $T(j1)$ . In case  $j1$  does not belong to  $\text{DFS}(i)$ ,  $\mathcal{T}$  selects the second child of  $T(j)$  at random in  $D_f$ .

Having selected the two children  $c_0$  and  $c_1$  of  $T(j)$ ,  $\mathcal{T}$  selects its tag  $t$  at random in  $D_f$ . Then it computes the prefix-free encoding  $\langle (c_0, c_1) \rangle$  and selects as the root of  $T(j)$  the element  $f_{(c)}(t)$ , which  $\mathcal{T}$  easily computes using  $f_0$  and  $f_1$ .

Notice that each  $T(j)$  so computed is a proper  $f$ -item and that the resulting  $T$  is a proper  $f$ - $i$ -tree belonging to  $[\mathcal{T}_{i,f,g,2^b}]$ . Let us now analyze the probability distribution according to which  $T$  has been selected.

First notice that the leaves of  $T$  (that is the nonempty children of the items of depth  $b$ ) have the same distribution of the leaves of an  $f$ - $i$ -tree randomly selected in  $\mathcal{T}_{i,f,g,2^b}$ . In fact, in both cases, all leaves are uniformly and independently selected elements of  $D_g$ . Then notice that the roots of the items of  $T$  of depth  $k$  (that is, the children of the items of  $T$  of depth  $k - 1$ ) are selected uniformly and independently in  $D_f$ . In fact, the root of each item is obtained by applying  $f_{(x)}$ , a permutation of  $D_f$  randomly selected from some probability space, to an element  $t$  (the tag) independently and uniformly selected in  $D_f$ . From this it easily follows that  $\mathcal{T}$  selects  $T$  at random in  $\mathcal{T}_{i,f,g,2^b}$ . It is easily seen that  $\mathcal{T} \in \mathcal{RA}$  and thus satisfies all the required properties of our lemma.  $\square$

LEMMA 6. *There exists an algorithm  $\mathcal{A} \in \mathcal{RA}$  such that for all signature requestors  $\mathcal{SR} \in \mathcal{RA}$ , for all claw-free pairs  $f = (d_f, f_0, f_1)$  and  $g = (d_g, g_0, g_1)$ , and for all nonnegative integers  $i < 2^b$ ,*

$$\mathcal{C}(\mathcal{A}, \mathcal{SR}; (f, d_f(\cdot), g, 2^b), \{g^{-1}\}, i) = \mathcal{C}(\mathcal{SP}, \mathcal{SR}; (f, d_f(\cdot), g, 2^b), \{f^{-1}, g^{-1}\}, i).$$

*Proof.* Consider the following algorithm  $\mathcal{A}$ . In a preprocessing step,  $\mathcal{A}$  runs algorithm  $\mathcal{T}$  of Lemma 5 to randomly select an  $f$ - $i$ -tree  $T$  from  $\mathcal{T}_{i,f,g,2^b}$ . Let  $r_e^f$  be the root of  $T$ . This root is used to construct the public file  $PK = (f, r_e^f, g, 2^b)$ , with respect to which all subsequent signatures will be produced as follows.  $\mathcal{A}$  starts the signature requestor  $\mathcal{SR}$  on input  $PK$ . Then it simulates the signing procedure with initial inputs  $PK$  and the corresponding secret key  $SK = (f^{-1}, g^{-1})$  without using  $f^{-1}$  in the following way. When  $\mathcal{SR}$  outputs  $m_j$ , the  $j$ th message to be signed,  $\mathcal{A}$  retrieves the  $f$ -chain  $T_j$ , the path from the root of  $T$  to leaf  $j$ . Then  $\mathcal{A}$  computes the necessary  $g$ -item by using  $g^{-1}$ .  $\square$

Before stating and proving our Main Theorem, let us single out a simple lemma stating that one cannot invert a claw-free pair on a randomly selected input of its domain.

LEMMA 7. *Let  $G$  be a claw-free permutation pair generator. Then, for any inverting algorithm  $I \in \mathcal{RA}$ , any  $c > 0$  and sufficiently large  $k$ ,*

$$\mathbf{P}(h_0(z) = x \text{ or } h_1(z) = x | (d, h_0, h_0^{-1}, h_1, h_1^{-1}) \leftarrow G(1^k);$$

$$x \leftarrow d_h(\cdot); z \leftarrow I(1^k, d, h_0, h_1)) < k^{-c}.$$

*Proof.* Otherwise the following algorithm would find a claw with too high a probability: randomly select  $y$  in  $d_h$ , randomly select  $i$  between 1 and 2, compute  $x = h_i(y)$  and run  $I$  to get  $z$  such that  $h_i(z) = x$  for  $j \neq i$ .  $\square$

We are now ready to formally state and prove our Main Theorem. We start by strengthening the definition of existentially forgeable to include probabilistic success on the part of the forger.

**DEFINITION.** We say that a signature scheme is  $\varepsilon$ -*existentially forgeable* if it is existentially forgeable with probability  $\varepsilon$  where the probability space includes the random choices of the adaptive chosen-message attack, the random choices made by the legal signer in the creation of the public key, and the random choice made by the legal signer in producing signatures.

It is very important to note that the random choices made in creating the public key are included in the probability space; our proof depends critically on this definition. The Main Theorem of this paper is the following.

**MAIN THEOREM.** *Assuming that claw-free permutation pair generators exist, the signature scheme described in § 8 is not even  $1/Q(k)$ -existentially forgeable under an adaptive chosen-message attack, for all polynomials  $Q$  and for all sufficiently large  $k$ .*

*Proof of the Main Theorem.* The proof proceeds by contradiction. We assume, for the sake of contradiction, that for some polynomial  $Q$  and for infinitely many  $k$  our signature scheme is  $1/Q(k)$ -existentially forgeable under an adaptive chosen-message attack by an algorithm  $\mathcal{F}$  in  $\mathcal{RA}$ .

By definition, the forging algorithm  $\mathcal{F}$  consists of two algorithms in  $\mathcal{RA}$ : a signature requestor  $\mathcal{FR}$ , which is active in a first phase when it adaptively asks and receives signatures of messages of its choice, and a signature finder  $\mathcal{FF}$ , which is active in a second phase when it attempts to forge a signature of a message not asked about by  $\mathcal{FR}$ .

Let  $PK = (f, r_{\varepsilon}^f, g, 2^b)$  and  $SK$  be a public/secret-key pair of size  $k$ , randomly selected by our key generator using a claw-free permutation pair generator  $G$ . In the first phase a signature corpus  $\mathcal{S} \leftarrow \mathcal{C}(\mathcal{SP}, \mathcal{FR}; PK, SK, i)$  is generated, where  $i < 2^b$ . Then  $\mathcal{FF}$  is run on input  $\mathcal{S}$  and  $PK$ . Let  $\varepsilon_k$  denote the probability that  $\mathcal{FF}$  outputs  $\sigma$ , a legal signature, with respect to  $PK$ , for a message  $m \notin M(\mathcal{S})$ . (This probability is taken over all the coin tosses of  $G$ ,  $\mathcal{FR}$ ,  $\mathcal{FF}$  and  $\mathcal{SP}$ .)

What we have assumed is that, for infinitely many  $k$ ,

$$\varepsilon_k \cong \frac{1}{Q(k)}.$$

By Lemma 3, given  $\mathcal{S}$  and  $\sigma$ , it is now easy to compute either

- (1) a  $g$ -claw (i.e., a claw for the second claw-free pair in  $PK$ ), or
- (2) an  $f$ -claw (i.e., a claw for the first claw-free pair in  $PK$ ), or
- (3) an  $f$ -item whose root belongs to  $\mathcal{NR}(\mathcal{S})$ .

Denote the probability that case (1), (2) or (3) hold, respectively, by  $\delta_1$ ,  $\delta_2$  and  $\delta_3$ . Then, for infinitely many  $k$ , we have

$$\delta_1(k) + \delta_2(k) + \delta_3(k) \cong \varepsilon_k > \frac{1}{Q(k)}.$$

Thus either

- (1') there is an infinite set  $K_1$  so that for  $k \in K_1$   $\delta_1(k) > 1/3Q(k)$ , or
- (2') there is an infinite set  $K_2$  so that for  $k \in K_2$   $\delta_2(k) > 1/3Q(k)$ , or
- (3') there is an infinite set  $K_3$  so that for  $k \in K_3$   $\delta_3(k) > 1/3Q(k)$ .

We will show that either case leads to a contradiction.

Assume case (1') holds. Then consider the following algorithm in  $\mathcal{RA}$  that, on input  $1^k$  and a claw-free pair  $h = (d_h, h_0, h_1)$  of size  $k$ , randomly selected by  $G$ , finds an  $h$ -claw with sufficiently high probability.

ALGORITHM 1. Run  $G$  on input  $1^k$  to randomly select a quintuple  $(d_f, f_0, f_0^{-1}, f_1, f_1^{-1})$ . Select  $r_\epsilon^f \in D_f$  at random and construct the public key  $PK = (d_f, f_0, f_1, r_\epsilon^f, d_h, h_0, h_1, 2^b)$ . (Notice that  $PK$  is a random public key of size  $k$  of our signature scheme.) Randomly select the signature corpus  $\mathcal{S} \leftarrow \mathcal{C}(\mathcal{SP}, \mathcal{FR}; PK, SK, i)$ . Though  $PK$ 's matching secret key  $SK$  is not totally known, this random selection can be efficiently done as, by Lemma 4, there exists an  $\mathcal{A} \in \mathcal{RA}$  such that  $\mathcal{C}(\mathcal{SP}, \mathcal{FR}; PK, SK, i) = \mathcal{C}(\mathcal{A}, \mathcal{FR}; PK, f^{-1}, i)$ . Now run  $\mathcal{FF}$  on input  $\mathcal{S}$  and  $PK$  to sign a new message. From this last signature and  $\mathcal{S}$ , try to compute an  $h$ -claw.

Notice that, for  $k \in K_1$ , Algorithm 1 will successfully compute an  $h$ -claw with probability  $\delta_1(k) > 1/3Q(k)$ . This contradicts the claw-freeness of  $G$ .

Assume now that either (2') or (3') holds. Consider the following algorithm in  $\mathcal{RA}$ , whose input is  $1^k$  and a claw-free pair  $h = (d_h, h_0, h_1)$  of size  $k$  randomly selected by  $G$ .

ALGORITHM 2. Run  $G$  on input  $1^k$  to randomly select a quintuple  $(d_g, g_0, g_0^{-1}, g_1, g_1^{-1})$ . Randomly select the signature corpus

$$\mathcal{S} \leftarrow \mathcal{C}(\mathcal{SP}, \mathcal{SR}; (h, d_h(\cdot), g, 2^b), \{h^{-1}, g^{-1}\}, i),$$

which can be done as by Lemma 6 there exists an algorithm  $\mathcal{A} \in \mathcal{RA}$  such that

$$\mathcal{C}(\mathcal{SP}, \mathcal{SR}; (h, dh(\cdot), g, 2^b), \{h^{-1}, g^{-1}\}, i) = \mathcal{C}(\mathcal{A}, \mathcal{SR}; (h, d_h(\cdot), g, 2^b), g^{-1}, i).$$

Then run  $\mathcal{FF}$  on input  $\mathcal{S}$  and  $PK$ .

Assume that case (2') holds. Then, for  $k \in K_2$ , from the output of Algorithm 2 an  $h$ -claw can be computed with sufficiently high probability to violate the claw-freeness of  $G$ .

Finally, assume that case (3') holds and  $k \in K_3$ . Then, given a random  $x \leftarrow d_h(\cdot)$ , the following algorithm  $\mathcal{S}$  will invert  $h$  on  $x$  with nonnegligible probability (contradicting Lemma 7).  $\mathcal{S}$  runs Algorithm 2 except that, when constructing  $\mathcal{T}^h(\mathcal{S})$  as in Lemma 5, it makes  $x$  the value of a randomly selected nonroot of  $\mathcal{S}$ . Notice that this operation does not change the probability distribution of  $\mathcal{S}$ . (Recall that the preprocessing procedure of Lemma 5 just picks at random all the internal nodes of  $\mathcal{S}$ .) Thus  $\mathcal{S}$  is a random signature corpus with respect to a randomly selected public key of size  $k$ . Thus, from the output of Algorithm 2,  $\mathcal{S}$  computes an  $h$ -item with root  $r \in \mathcal{NR}(\mathcal{S})$  with probability  $\delta_3(k) > 1/3Q(k)$ . When this happens, with probability  $1/|\mathcal{NR}(\mathcal{S})|$ , we have  $r = x$ . Now, given the  $h$ -item computed,  $\mathcal{S}$  can easily compute either  $h_0^{-1}(x)$  or  $h_1^{-1}(x)$ , and Lemma 7 is contradicted. This completes the proof of the Main Theorem.  $\square$

**10. Variations and improvements.** In this section we describe ways to improve the efficiency of the proposed signature scheme without affecting its security.

**10.1. Using  $g_i$ 's to sign rather than  $g_i^{-1}$ 's.** This variation is of interest if it is substantially easier to compute  $g_0$  or  $g_1$  than to compute their inverses. In this case steps (3) and (4) in the signing procedure can be replaced by:

- (3) (*Output g-item.*) User  $A$  selects a random  $t_i^g \in D_g$ , and (using  $g_0$  and  $g_1$ ) computes the root  $r_i^g$  of the  $g$ -item  $(t_i^g, r_i^g; m_i)$ , and outputs this item.
- (4) (*Output bridge f-item.*) Using his knowledge of  $f_0^{-1}$  and  $f_1^{-1}$ , user  $A$  outputs an  $f$ -item with root  $r_i^f$  and an only child  $r_i^g$ .

Now each usage of  $g_0^{-1}$  or  $g_1^{-1}$  has been replaced by a usage of  $g_0$  or  $g_1$ .

Although one might be tempted to use this variation using one-way permutations instead of trap-door permutations for the  $g_i$ 's, this temptation should be resisted, since our proof of security does not hold if this change is made.

**10.2. Fast iterated square roots.** As we saw in § 6.3, if factoring is computationally hard, a particular family of trap-door permutations is claw-free. By using these permutations in a straightforward manner, we obtain a particular instance of our signature scheme. Let us discuss the efficiency of this instance. The computation of  $f_0^{-1}(x)$  consists of computing the square root which has Jacobi symbol 1 and is less than  $n/2$ , modulo a Blum-integer  $n$ . We can compute  $f_1^{-1}(x)$  as  $f_0^{-1}(x/4)$ . Computing  $g_0^{-1}(x)$  and  $g_1^{-1}(x)$  is the same, except for using the appropriate  $n$ . If  $n$  is  $k$ -bits long, this can be done in  $O(k^3)$  steps. Thus the signature of a  $k$ -bit message can be computed in time  $O(b \cdot k^4)$ , or in  $O(k^4)$  amortized time.

This particular instance of our scheme can be improved in a manner suggested in discussions with Oded Goldreich (see [Go86])—we appreciate his permission to quote these results here). The improvement relates to the computation of  $f_{\langle y \rangle}^{-1}(x)$  (or  $g_{\langle y \rangle}^{-1}(x)$ ).

We note first of all that taking square roots modulo  $n$  is equivalent to taking  $u$ th powers modulo  $n$ , where  $u \cdot 2 \equiv 1 \pmod{\phi(n)}$ , and where  $\phi(n)$  is Euler's phi function. More generally, to find a  $2^m$ th root  $w$  of  $x$  modulo  $n$  one can raise  $x$  to the  $v$ th power modulo  $n$ , where  $v \equiv u^m \pmod{\phi(n)}$ . Computing  $w$  by first computing  $v$  and then raising  $x$  to the  $v$ th power is substantially faster than repeatedly taking square roots.

To apply this observation, we note that the functions  $f$  defined in § 6.3 satisfy

$$f_{\langle y \rangle}^{-1}(x) = \pm \left( \frac{x}{r^{\text{rev}(\langle y \rangle)}} \right)^{2^{-m}},$$

where “rev” is the operation which reverses strings and interprets the result as an integer, where  $m$  is the length of  $\langle y \rangle$ , where all operations are performed modulo  $n$ , and where the final sign is chosen to make the result less than  $n/2$ . The only computationally difficult portion here is computing a  $2^m$ th root. Using the observation of the previous paragraph, the computation of such an  $f$ -inverse can be performed in time proportional to the cube of the length of  $n$ , in the case that messages have the same length  $k$  as  $n$ . Using these ideas, the signature of a  $k$ -bit message can be computed in time  $O(b \cdot k^3)$ , or in  $O(k^3)$  amortized time.

**10.3. “Memoryless” version of the proposed signature scheme.** The concept of a *random function* was introduced by Goldreich, Goldwasser and Micali in [GGM84].

Let  $I_k$  denote the set of  $k$ -bit integers. Let  $W_k$  denote the set of all functions from  $I_k$  to  $I_k$ , and let  $F_k \subseteq W_k$  be a set of functions from  $I_k$  to  $I_k$ . We say that  $F = \cup_k F_k$  is a *polyrandom* collection if:

(1) Each function in  $F_k$  has a unique  $k$ -bit index associated with it. Furthermore, picking such an index at random (thereby picking an  $f \in F_k$  at random) is easy.

(2) There exists a deterministic polynomial time algorithm that given as input an index of a function  $f \in F_k$  and an argument  $x$  computes  $f(x)$ .

(3) No probabilistic polynomial in  $k$ -time algorithm can “distinguish” between  $W_k$  and  $F_k$ . Formally, let  $T$  be a probabilistic polynomial-time algorithm, that on input  $k$  and access to an oracle  $O_f$  for a function  $f: I_k \rightarrow I_k$  outputs 0 or 1. Then, for all  $T$ ,

for all polynomials  $Q$ , for all sufficiently large  $k$ , the difference between the probability that  $T$  outputs 1 on access to an oracle  $O_f$  when  $f$  was randomly picked in  $F_k$  and the probability that  $T$  outputs 1 on access to an oracle  $O_f$  when  $f$  was randomly picked in  $W_k$  is less than  $1/Q(k)$ .

In [GGM84] it was shown how to construct a polyrandom collection assuming the existence of one-way functions. The existence of claw-free permutation pairs is a stronger assumption, and thus implies the existence of a polyrandom collection. See § 5.4 for an implementation of a claw-free family of functions based on factoring and [GGM84] for details on how to construct a polyrandom collection.

Leonid Levin suggested the following use of a polyrandom collection in order to reduce the amount of storage that a signer must keep from  $O(bk)$  to  $O(b)$  bits. His suggestion also eliminates the need to generate new random numbers (e.g.,  $r_i^g$ ) during the signing process.

Let  $k$  denote the security parameter. In the secret key generation phase, in addition to computing the secret trap-door pairs  $(f_0^{-1}, f_1^{-1}), (g_0^{-1}, g_1^{-1})$  user  $A$  also picks a random function  $h$  in a polyrandom collection  $F_k$ , and keeps  $h$  secret. (We assume that  $k > b$ .) During the signing process,  $A$  keeps a counter  $i$  to denote the number of times the signing algorithm has been invoked. To sign message  $m_i$ ,  $A$  signs as before, except that (using  $m$  to denote the length of  $j$ ):

- Instead of picking values  $r_j^f$  at random from  $D_f$ , he *computes* them as  $r_j^f = h(0^{k-m_j})$ .
- Instead of picking values  $r_j^g$  at random from  $D_g$ , he *computes* them as  $r_j^g = h(1^{k-m_j})$ .

We claim that the “memoryless” version of the signature scheme described above enjoys the same security properties as our original scheme. The proof (which we shall not give in detail) is based on the observation that if the memoryless scheme was vulnerable to an adaptive chosen-message attack, then it would be possible to efficiently distinguish pseudorandom functions from truly random functions.

A further improvement (due to Oded Goldreich [Go86]) removes even the necessity of remembering the number of previous signatures by picking the index  $i$  for a message  $M$  as a random  $b$ -bit string. To make this work, the maximum number of signatures that can be produced by an instance of this scheme is limited to  $2^{\sqrt{b}}$ , so that it is extremely unlikely that two messages would have the same index chosen for them. The security proof can be modified to accommodate these changes. (Note that in the preprocessing step that builds an  $f$ -tree, we would now only build a portion of it consisting of  $2^{\sqrt{b}}$  randomly chosen paths of length  $b$ .)

### 11. Open problems.

- It is an open question whether the RSA scheme is universally forgeable under an adaptive chosen-message attack.
- Can an encryption scheme be developed for which decryption is provably equivalent to factoring yet for which an adaptive chosen ciphertext attack is of no help to the enemy?

**Acknowledgments.** We are most grateful to Leonid Levin for his suggestion of how to use random functions in our scheme, in order to (almost) completely eliminate the need for storage in our signature scheme. We are also very grateful to Oded Goldreich for many valuable suggestions concerning the presentation of these results, and for suggesting the speedup described in § 10.3. We are also thankful to Avi Wigderson for helpful suggestions on the presentation of this research. Special thanks go to an anonymous referee for his very careful reading of our paper and suggested improvements.

## COMPLEXITY MEASURES FOR PUBLIC-KEY CRYPTOSYSTEMS\*

JOACHIM GROLLMANN† AND ALAN L. SELMAN‡

**Abstract.** A general theory of public-key cryptography is developed that is based on the mathematical framework of complexity theory. Two related approaches are taken to the development of this theory, and these approaches correspond to different but equivalent formulations of the problem of cracking a public-key cryptosystem (PKCS). The first approach is to model the cracking problem as a partial decision problem called a “promise problem.” Every NP-hard promise problem is shown to be uniformly NP-hard, and a number of results and a conjecture about promise problems are shown to be equivalent to separability assertions for sets in NP that are the natural analogues of well-known results in classical recursion theory. The conjecture, if it is true, implies nonexistence of PKCS having NP-hard cracking problems. The second approach represents the cracking problem of a PKCS as a partial computational problem directly. Using this approach, it is shown that one-way functions exist if and only if  $P \neq UP$  and that one-way functions with greater cryptographic significance exist if and only if NP contains disjoint P-inseparable sets. The paper concludes with a discussion of almost-everywhere security measures for PKCS.

**Key words.** public-key cryptography, promise problems, one-way function, UP, security, inseparable, NP-hard, uniformly NP-hard

**1. Introduction.** Since any public-key cryptosystem (PKCS) can be cracked non-deterministically in polynomial time, and since, minimally, a PKCS should not be crackable deterministically in polynomial time, a proof that a given system is secure would imply  $P \neq NP$ . Several concrete systems have been created in recent years, but none have been proved secure in this weak sense, even if  $P \neq NP$  is assumed as a hypothesis. The reasons for this vary, but some general remarks can be made. The Merkle–Hellman schemes [MH78] are based on an NP-complete problem (Knapsack), but the problem of cracking these schemes is not necessarily polynomially equivalent to the original problem [Sha82]. Similarly, the cracking problem for the Rivest–Shamir–Adleman scheme [RSA78] is not known to be equivalent to integer factorization. Even if it were, as is true of the Rabin and Williams variants [Rab79], [Wil80], it is very unlikely that intractability of integer factorization is equivalent to the  $P \neq NP$  problem itself. (It is known [Bra79] that integer factorization cannot be NP-hard unless  $NP = co-NP$ .) Security of a concrete PKCS depends on intractability of the concrete problem on which it is based, and, in particular, no concrete PKCS has been designed whose security is equivalent to any NP-hard problem.

Very informally, the “cracking problem” for a PKCS is the problem of computing the message  $M$  that is encoded by a cryptogram  $C$  without knowledge of the current decryption key. In order to make such a definition precise, it is necessary to determine appropriate complexity measures according to which the cracking problem is to be hard. Typically, computational problems (e.g., given a graph, output a hamiltonian if one exists) are transformed into polynomial time equivalent decision problems (e.g.,

given a graph, does it have a hamiltonian), and the complexity of the original computational problem is measured by classifying the associated decision problem. When this transformation works, as it does for computational problems that are NP-complete, it is because computing a partial function and accepting membership in its domain are polynomially equivalent. However, this program does not work in general and does not work for PKCS. In general, computational problems are not polynomially equivalent to their corresponding domain recognition problems [Val76], [Mil76], [Bra79] (and cf. § 4 below). Also, we will argue in the course of this paper that it is more important to know the complexity of the class of extensions of a partial function than it is to know the complexity of the given function. General studies of public-key cryptography based on these observations were initiated by Brassard [Bra79], [Bra81], [Bra83a], [Bra83b] and by Even and Yacobi [EY80a], [EY80b]. In [EY80a], Even and Yacobi propose a definition for public-key cryptography, formulate the cracking problem of a PKCS as a partial decision problem called a “promise problem,” and raise the question of whether there exist NP-hard PKCS. In this approach certain hardness criteria for cryptosystems (Is a PKCS crackable in polynomial time? Is there an NP-hard PKCS?) can be translated into properties about the associated promise problems. In [ESY84], Even, Selman, and Yacobi present a plausible conjecture about promise problems that implies that no PKCS has an NP-hard cracking problem. A major component of the work in this paper consists of further analysis of this conjecture. The main technical result is that every NP-hard promise problem is uniformly NP-hard. This result may be a step toward proving the conjecture raised in [ESY84] and consequently toward proving that PKCS that are NP-hard to crack do not exist.

The broader motivation of the research project described herein is to develop complexity theory that has cryptographic significance. Our approach is to base the investigation of questions such as “What is a secure PKCS?” and “Do secure PKCS exist?” directly on structural properties of complexity classes such as NP and on separation assertions about complexity classes, rather than on presumed intractability of individual concrete problems.

Two complexity theoretic hypotheses emerge as most relevant for capturing the complexity issues that surround public-key cryptography. These hypotheses are that  $P \neq UP$  and that NP contains P-inseparable sets. (Two disjoint sets A and B are *P-inseparable* if every set that includes one of them and is disjoint from the other does not belong to P. UP is the set of problems in NP that are accepted by unambiguous polynomial time-bounded Turing machines (UTMs) [Val76].) To see the relevance of these hypotheses, consider, for example, the “one-way function.” Informally, a one-way function is one that is easy to compute but hard to invert. To make this notion precise, let us define a (partial) function  $f$  to be a *one-way* function if  $f$  is one-one,  $f$  is honest (to be defined in § 2.2),  $f$  can be computed in polynomial time, and  $f^{-1}$  is *not* computable in polynomial time. We will prove that one-way functions exist if and only if  $P \neq UP$  and that one-way functions with range in P exist if and only if  $P \neq UP \cap \text{co-UP}$ . According to this definition, since a one-way function is polynomial time computable, its domain belongs to P (this point will be clarified in § 2.2), and so a polynomial time Turing machine that computes a one-way function must behave in a specified manner on all input instances not in its domain (for example, output a special marker). When we analyze public-key cryptosystems we will see that one should not care what happens on inputs that are not in the domain of a proposed one-way function. This defect will be remedied with a definition of a *weak* one-way function. With this notion in hand, we will prove that there exist public-key cryptosystems that cannot be cracked in polynomial time only if there exist P-inseparable sets in NP, and we will prove that

the latter property is equivalent to the existence of weak one-way functions. Furthermore, since every one-way function is a weak one-way function,  $P \neq UP$  implies all of these properties.

We cannot say that the complexity class  $UP$  forms the exact boundary of interest with regard to public-key cryptography, but we will show that there exist PKCS that cannot be cracked in polynomial time and that also satisfy reasonable restrictions only if  $P \neq UP$ , and, as described above, every problem in  $UP - P$  yields some PKCS that does not have a polynomial time solvable cracking problem. To say the least, we would know a lot more about what kinds of cryptographic systems are possible if we knew more about the class  $UP$ .

A PKCS may be uncrackable in polynomial time and yet there may be exist a polynomial time algorithm that cracks most messages. (Such a system will be exhibited in § 4.) For this reason it is understood that infinitely often (i.o.) complexity measures are insufficient for cryptography. Nevertheless, much effort is spent in this paper studying i.o. measures, and for this we give the following justification. Cryptosystems that are secure cannot exist unless there exist systems that cannot be cracked in polynomial time. In this paper we are not interested in the development of secure systems; our concern is with the development of complexity theoretic underpinnings. What we see in this paper is that questioning the existence of such intractable systems already entails difficult structural properties of  $NP$ .

We will consider measures that are more appropriate. We will see that the usual immunity and bi-immunity notions for specifying complexity almost everywhere (a.e.) do not work, and in particular, we will see that there is no elegant way to formulate a.e. security for PKCS in terms of promise problems. Primarily for this reason, we include here a development of complexity classes of functions. Once we relate function classes with the familiar classes of decision problems, then we will give definitions of security measures for PKCS directly in terms of function classes. We will demonstrate that the strongest possible sense in which a PKCS can be secure with respect to message cracking is that every deterministic, randomized, or probabilistic algorithm computable in polynomial time cracks at most a sparse subset of the message space. It will be seen finally that natural PKCS can exist that are secure in this strongest possible sense only if they are based on problems in  $NP$  that possess specific complexity theoretic properties (no nonsparse subset can be recognized by any probabilistic polynomial time Turing machine).

The paper is organized as follows. The next section is of a preliminary nature. At the risk of tediousness, it is rather long; the only way to carefully lay foundations is to be careful about the foundations. Here we collect various specialized complexity theoretic notions, present a framework for specifying computational complexity of functions, and review definitions and results from [ESY84], [EY80b] about promise problems and their relation to public-key cryptography. This synopsis is needed for completeness. Also, a number of interesting corollaries will follow from the work in those papers. Complexity issues concerning promise problems are taken up in § 3. There we focus attention on the i.o. measures “not crackable in polynomial time” and “ $NP$ -hard,” and there the proof that every  $NP$ -hard promise problem is uniformly  $NP$ -hard can be found. Sections 4 and 5 study the cracking problem directly as a computational problem, making use of the framework that was developed in § 2. Section 4 contains definitions of one-way functions and weak one-way functions, their relationships to hypotheses about  $UP$  and about  $P$ -inseparable sets, and discusses connections between one-way functions and public-key cryptography. Section 5 discusses a.e. complexity measures.

The reader will quickly observe that not every question that will be raised has been answered. In § 6, the last section of this paper, a number of relativization results are stated that suggest that answers are not readily forthcoming, for they cannot be obtained by proof techniques that relativize to oracles.

**2. Preliminaries.** Unless otherwise specified, sets are subsets of  $\Sigma^*$ ,  $\Sigma = \{0, 1\}$ , and predicates vary over  $\Sigma^*$ . The empty word is denoted by  $\lambda$ ,  $\Sigma^* - A$  is denoted by  $\bar{A}$ , and  $\leq$  denotes lexicographic ordering defined on  $\Sigma^*$ . Let  $(x, y)$  be the ordered pair with components  $x$  and  $y$  and let  $\langle \cdot, \cdot \rangle$  be a polynomial time computable pairing function with polynomial time computable inverses. The reader is assumed to be familiar with standard concepts and notations of polynomial time-bounded complexity theory [HU79], [GJ79], but a number of specialized notions are described below. The subsections on promise problems and public-key cryptosystems comprise a synopsis of the work by Even, Selman, and Yacobi [ESY84], [EY80a].

**2.1. Complexity theoretic notions.** The notations  $\leq_T^P$  and  $\leq_m^P$  denote polynomial time-bounded Turing and many-one reducibility, respectively. We follow the conventions that a set  $L$  is NP-complete if  $L \in \text{NP}$  and  $\text{SAT} \leq_m^P L$ , and that a set is NP-hard if  $\text{SAT} \leq_T^P L$ , where SAT denotes the well-known satisfiability problem.

A set  $A$  is *a.e. complex* if for every Turing machine  $M$  that accepts  $A$  and every polynomial  $p$ ,  $M$  runs for more than  $p(|x|)$  steps for all but finitely many strings  $x$  [Ber76], [Rab60]. For an arbitrary class of languages  $\mathcal{C}$ , an infinite set  $A$  is  $\mathcal{C}$ -immune (or immune to  $\mathcal{C}$ ) if no infinite subset of  $A$  is in  $\mathcal{C}$ . Immunity, and the special case of P-immunity, are defined and discussed in [Ber76], [FS74], [KM81].  $A$  is *bi-immune* to  $\mathcal{C}$  if  $A$  and  $\bar{A}$  are both immune to  $\mathcal{C}$ ; see [BS85], [KM81]. It is observed in [BS85] that a set is a.e. complex if and only if it is bi-immune to P.

Two disjoint sets  $A$  and  $B$  are called P-inseparable if no set  $L$  with the property  $A \subseteq L \subseteq \bar{B}$  is in P. Otherwise,  $A$  and  $B$  are called P-separable.

A nondeterministic Turing machine (NTM) that has at most one accepting computation for any input is called by Valiant [Val76] an *unambiguous* Turing machine (UTM). Let UP denote the set of languages accepted by UTMs in polynomial time. Obviously,  $P \subseteq \text{UP} \subseteq \text{NP}$ , and it is not known whether either inclusion is proper.

Following Papadimitriou and Yannakakis [PY84] define  $D^P = \{L_1 \cap L_2 \mid L_1 \in \text{NP} \text{ and } L_2 \in \text{co-NP}\}$ .  $D^P$  contains interesting combinatorial problems not known to belong to NP. Trivially,  $\text{NP} \subseteq D^P$ ,  $\text{co-NP} \subseteq D^P$ , and  $D^P \subseteq \Delta_2^P$  (where  $\Delta_2^P$  is defined to be  $P^{\text{NP}}$ ), and it is expected that each of these inclusions is proper. Indeed,  $\text{NP} = D^P$  if and only if  $\text{NP} = \text{co-NP}$ .

Let BPP be the class of sets that can be decided by a probabilistic Turing machine with bounded error probability in polynomial time. The definition is due to Gill [Gil77] and the reader is referred to [Gil77] for a detailed exposition. For a problem in BPP any small probability of error can be achieved by running the given machine many times on the same input and taking the majority result. For this reason, problems in BPP are tractable in practice. Gacs (see reference in [Sip83]) and Lautemann [Lau83] showed that  $\text{BPP} \subseteq \Sigma_2^P (= \text{NP}^{\text{NP}})$ . The relationship between BPP and NP is not known, but Ko [Ko82] has shown that the supposition  $\text{BPP} = \text{NP}$  has consequences that are unlikely to be true. Our work will not directly involve this class, but we must keep in mind that cryptosystems should not be susceptible to cryptanalyst attack by any tractable process.

In § 4 the reader will need to be familiar with the class R of problems that have efficient randomized algorithms. The definition of this class is due to Adleman and

Manders [AM77]. The definition implies that  $P \subseteq R \subseteq NP$  and it is well known that  $R \subseteq BPP$  [Gil77].

**2.2. Complexity classes of functions.** We take a look now at some complexity classes of functions. The development is repeated in part from [SXB83], [BLS84], [BLS85] and is also in the spirit of [Val76].

Consider nondeterministic transducers with accepting states. A transducer  $T$  computes a value  $y$  on an input string  $x$  if there is an accepting computation of  $T$  on  $x$  for which  $y$  is the final contents of  $T$ 's output tape. In general, such transducers compute partial multivalued functions, but we will be concerned only with single-valued functions.

**DEFINITION 1.** (i) NPSV is the set of all partial single-valued functions computed by nondeterministic polynomial time-bounded transducers.

(ii) UPSV is the set of all functions  $f$  in NPSV such that for some nondeterministic polynomial time-bounded transducer that computes  $f$ , for every  $x \in \text{dom}(f)$  there is exactly one accepting computation.

(iii) PSV is the set of all partial single-valued functions computed by deterministic polynomial time-bounded transducers.

If  $T$  is a transducer that computes a partial function  $f$ , then the domain of  $f$  is the set of words accepted by  $T$ . If, in addition,  $T$  is polynomial time-bounded, then there is a polynomial  $p$  such that every word  $x$  accepted by  $T$  is accepted within  $p(|x|)$  steps. Given a polynomial  $p = n^c$  there is a Turing machine  $M_p$  that on every input of length  $n$  will execute for exactly  $n^c$  steps. It is possible to design a Turing machine  $M'$  that simulates  $T$  and uses the polynomial "clock"  $M_p$  to guarantee that  $T$  is not simulated on an input  $x$  for more than  $|x|^c$  steps. Clearly  $L(M') = L(T)$ . In the case that  $T$  is deterministic, so is  $M'$ , and since  $M'$  halts within  $n^c$  steps on every input word of length  $n$ ,  $M'$  can be designed to enter a reject state for every word that is not accepted. Hence, the domain of a partial function in PSV is a set in P. Similarly, the domain of a partial function in NPSV (UPSV) is a set in NP (UP, respectively). In part, these considerations are in analogy with recursive function theory. If a Turing machine  $T$  computes a partial recursive function  $f$ , then the domain of  $f$  is the set of words accepted by  $T$ . The analogy breaks down, however, for the domain of a partial recursive function is not necessarily a recursive set. After all, since the running time of  $T$  is not necessarily recursively bounded, no Turing machine clock can be used to detect nonacceptance.

A partial function  $f$  is *honest* if there is a polynomial  $q$  such that for every  $y \in \text{range}(f)$  there exists  $x \in \text{dom}(f)$  such that  $f(x) = y$  and  $|x| \leq q(|y|)$ . If  $f$  is an honest function in PSV and  $B \in NP$ , then  $f(B) \in NP$ .

For any partial function  $f$ ,  $\text{graph}(f) = \{(x, y) \mid x \in \text{dom}(f) \text{ and } y = f(x)\}$ . Given an arbitrary class  $\mathcal{F}$  of partial functions, let  $\mathcal{F}_g = \{f \in \mathcal{F} \mid \text{graph}(f) \in \mathcal{F}\}$ . It is easy to see that  $\text{NPSV}_g = \text{UPSV}_g$ .

The *projection* of a function  $f$  is the set  $R_f = \{(x, y) \mid x \in \text{dom}(f) \text{ and } y \leq f(x)\}$ . This construction is defined in [Mil76]. Miller shows for total functions  $f$  that are polynomial length-bounded (i.e., there is a polynomial  $q$  such that for all  $x$ ,  $|f(x)| \leq q(|x|)$ ), that  $R_f \in P$  if and only if  $f \in \text{PSV}$ . The equivalence holds for partial functions as well without any change of proof. (The proof from right to left is trivial and from left to right employs a binary search algorithm.)

**PROPOSITION 1.** (i) [SXB83]  $P = NP$  if and only if  $\text{PSV} = \text{NPSV}$ .

(ii) *The following are equivalent:*

(a)  $P = UP$ .

(b)  $PSV = UPSV$ .

(c)  $PSV = UPSV_g$ .

*Proof.* We prove (ii). Obviously (b) implies (c). To show that (c) implies (a), let  $S \in UP$  and let  $M$  be a UTM that accepts  $S$  in polynomial time. For each word  $x$  in  $S$ , let  $comp_M(x)$  denote the unique accepting computation of  $M$  on input  $x$ . Then, the function  $comp_M$  belongs to  $UPS\mathcal{V}_g$  and  $dom(comp_M) = S$ . Since  $comp_M \in PSV$  follows, we conclude that  $S \in P$ .

To show that (a) implies (b), let  $f \in UPSV$ . The projection  $R_f$  is in  $UP$  as witnessed by an unambiguous machine that behaves as follows:

On input  $(x, y)$ , unambiguously compute  $f(x)$ . If successful, then determine from the output tape whether  $y \cong f(x)$ .

By assumption,  $R_f \in P$ , and so  $f \in PSV$  follows immediately from the above remarks.  $\square$

The equivalence of (a) with (c) was first proved in [Val76]. Stronger relations than given by Proposition 1 will be developed in § 4.

If primality testing belongs to  $UP$  as some apparently believe (assuming the extended Riemann hypothesis it belongs to  $P$  [Mil76]), then integer factorization belongs to  $UPS\mathcal{V}$ . A very reasonable candidate for a function in  $UPS\mathcal{V} - PSV$ , which will be discussed in detail in a later section, is the discrete logarithm problem.

A partial function  $g$  is an *extension* of a partial function  $f$  if  $dom(f) \subseteq dom(g)$  and  $f$  and  $g$  coincide on  $dom(f)$ . If  $f$  has an extension in  $PSV$ , then  $f$  also has a total extension in  $PSV$  because the domain of a function in  $PSV$  belongs to  $P$ . A function  $f \in UPS\mathcal{V}$  with  $dom(f) \notin P$  and hence  $f \notin PSV$  may have an extension in  $PSV$ ; for example, if  $S \in UP - P$ , then the partial function  $f$  defined by

$$f(x) = \begin{cases} 1 & \text{if } x \in S, \\ \uparrow & \text{else} \end{cases}$$

(we use “ $\uparrow$ ” as an abbreviation for “undefined”) belongs to  $UPS\mathcal{V} - PSV$  and obviously has a total extension in  $PSV$ . The behavior of functions in  $UPS\mathcal{V}_g$  is quite different than this, because if  $f \in UPS\mathcal{V}_g$  and  $dom(f) \notin P$ , then no extension of  $f$  is in  $PSV$ .

**2.3. Promise problems.** A promise problem is a formulation of a partial decision problem that has the structure

<b>input</b>	$x$ ;
<b>promise</b>	$Q(x)$ ;
<b>property</b>	$R(x)$ ;

where  $Q$  and  $R$  are predicates. Formally, a *promise problem* is a pair of predicates  $(Q, R)$ . A deterministic Turing machine  $M$  *solves*  $(Q, R)$  if

$$\forall x [Q(x) \rightarrow [M(x) \text{ converges} \wedge [M(x) = \text{“yes”} \leftrightarrow R(x)]]].$$

A promise problem  $(Q, R)$  is *solvable* if there is a Turing machine  $M$  that solves it. If  $(Q, R)$  is solved by  $M$ , then the language  $L(M)$  accepted by  $M$  is called a *solution* of  $(Q, R)$ . Note that the behavior of  $M$  is of interest only for those input values  $x$  for which the promise  $Q(x)$  is true.  $M$  need not give the correct answer or even halt, for instances that do not satisfy the promise.

Our interest is with promise problems  $(Q, R)$  such that  $Q$  and  $R$  are recursive predicates and the only solutions of interest are recursive sets. We assume these conditions to hold for all promise problems considered. It is easy to see that every

recursive solution of  $(Q, R)$  is of the form  $(Q \cap R) \cup X$  where  $X$  is some recursive subset of  $\bar{Q}$ . We frequently take the liberty of writing predicates as sets and vice versa.

NPP is the class of all promise problems  $(Q, R)$  that have a solution in NP. Co-NPP is the class of all promise problems  $(Q, R)$  such that  $(Q, \bar{R})$  is in NPP; equivalently, co-NPP is the class of all promise problems  $(Q, R)$  that have a solution in co-NP. This follows from the fact that a recursive set  $L$  is a solution in NP of  $(Q, \bar{R})$  if and only if  $\bar{L}$  is a solution in co-NP of  $(Q, R)$ . Every set  $S$  in NP (co-NP) may be thought of as the promise problem  $(\Sigma^*, S)$  with the universal promise  $\Sigma^*$ , and  $(\Sigma^*, S) \in$  NPP (co-NPP, respectively). From these remarks it follows that  $\text{NPP} = \text{co-NPP}$  if and only if  $\text{NP} = \text{co-NP}$ .

DEFINITION 2. (i) A promise problem  $(Q, R)$  is *Turing reducible in polynomial time* to a promise problem  $(S, T)$ , in symbols,  $(Q, R) \leq_T^{\text{PP}} (S, T)$ , if, for every solution  $A$  of  $(S, T)$ , there is a deterministic polynomial time-bounded oracle Turing machine  $M$  such that  $M$  with oracle  $A$  solves  $(Q, R)$ .

(ii) A promise problem  $(Q, R)$  is *uniformly Turing reducible in polynomial time* to a promise problem  $(S, T)$ , in symbols,  $(Q, R) \leq_{\text{UT}}^{\text{PP}} (S, T)$ , if there is a deterministic polynomial time-bounded oracle Turing machine  $M$  such that, for every solution  $A$  of  $(S, T)$ , The language recognized by  $M$  with oracle  $A$  is a solution of  $(Q, R)$ .

(iii) A promise problem  $(Q, R)$  is *NP-hard* if every solution is NP-hard, i.e., for every solution  $A$  of  $(Q, R)$  there is a deterministic polynomial time-bounded oracle Turing machine  $M$  such that  $\text{SAT} = L(M, A)$ .

(iv) A promise problem  $(Q, R)$  is *uniformly NP-hard* if there exists a deterministic polynomial time-bounded oracle Turing machine  $M$  such that for every solution  $A$  of  $(Q, R)$ ,  $\text{SAT} = L(M, A)$ .

If an NP-hard promise problem could be solved in polynomial time by some deterministic Turing machine  $M$ , then by definition  $L(M)$  is an NP-hard set, and therefore  $\text{P} = \text{NP}$  follows. So, assuming  $\text{P} \neq \text{NP}$ , no NP-hard promise problem can be solved in polynomial time. Obviously, “uniformly NP-hard” implies “NP-hard” and “uniformly Turing reducible” implies “Turing reducible,” and one would guess the converse to be false, as in fact is conjectured in [ESY84]. We will nevertheless show in § 3 that these notions are equivalent. A set  $S \subseteq \Sigma^*$  is NP-hard if and only if the promise problem  $(\Sigma^*, S)$  is NP-hard. A promise problem  $(S, T)$  is NP-hard if and only if every promise problem  $(Q, R) \in \text{NPP}$  is Turing-reducible to  $(S, T)$  in polynomial time.

The next proposition shows that finding an algorithm to compute a function in NPSV is equivalent in a natural way to finding an algorithm to solve a promise problem. Given  $f \in \text{NPSV}$  define  $Q_f = \text{dom}(f) \times \Sigma^*$  and let  $R_f$  be the projection of  $f$ . Let us call  $(Q_f, R_f)$  the promise problem *associated with*  $f$ .

PROPOSITION 2. (i) If  $f \in \text{NPSV}$  and  $A$  is a solution of  $(Q_f, R_f)$ , then there is a total function  $h$  that extends  $f$  such that  $h \leq_T^{\text{P}} A$ .

(ii) If  $f \in \text{NPSV}$  and  $h$  is a total extension of  $f$ , then there is a solution  $A$  of  $(Q_f, R_f)$  such that  $A \leq_T^{\text{P}} h$ .

*Proof.* (i) On an input string  $x$ , apply a binary search algorithm to find the largest  $y$  (whose length is within the right polynomial length of  $x$ ) such that  $(x, y) \in A$ . Let  $h(x) = y$ . If no such  $y$  exists, then define  $h(x)$  to be  $\lambda$ . Since  $A$  is a solution,  $y = h(x) = f(x)$  for  $x \in \text{dom}(f)$ .

(ii) Given  $h$ , define  $A = R_h$ , the only solution of  $(Q_h, R_h)$ . It is easy to see that  $A$  is a solution of  $(Q_f, R_f)$  and  $A \leq_T^{\text{P}} h$ .  $\square$

The next observations are most important for what will follow. Given  $f \in \text{NPSV}$ , one can conclude  $Q_f \in \text{NP}$  and  $(Q_f, R_f) \in \text{NPP} \cap \text{co-NPP}$ . Namely,  $\text{dom}(f) \in \text{NP}$ ,  $R_f$  is a solution in NP of  $(Q_f, R_f)$ , and  $\{(x, y) \mid x \in \text{dom}(f) \text{ and } y > f(x)\}$  is a solution in

NP of  $(Q_f, \bar{R}_f)$ . The cracking problem of a PKCS will be a function in NPSV, and so we will concentrate our efforts on the study of promise problems that satisfy these two properties.

It is well known that  $NP \cap \text{co-NP}$  contains an NP-hard set if and only if NP is closed under complements [Bra79], [Sel78]. Hence, the former property is unlikely to be true. To the extent that one expects complexity classes of promise problems to behave as do the corresponding classes of decision problems, it is reasonable to conjecture that no promise problem  $(Q, R)$  such that  $Q \in NP$  and  $(Q, R) \in NPP \cap \text{co-NPP}$  is also NP-hard. Indeed, this conjecture is made in [ESY84]. Now let us state it formally.

*Conjecture 1.* There exists no promise problem  $(Q, R)$  such that

- (i)  $Q \in NP$ ,
- (ii)  $(Q, R) \in NPP \cap \text{co-NPP}$ , and
- (iii)  $(Q, R)$  is NP-hard.

As a consequence of this conjecture, if  $f \in NPSV$ , then  $(Q_f, R_f)$  is not NP-hard; that is, there must be some total extension  $h$  of  $f$  that cannot be used as an oracle for deciding satisfiability in polynomial time. Also, the conjecture trivially implies  $NP \neq \text{co-NP}$  and it is proved in [ESY84] that the conjecture implies  $UP \neq NP$ .

We need to recall the following two main results of [ESY84], which we will state here as propositions. The first of these results states that a variant of the conjecture is true, assuming  $NP \neq \text{co-NP}$ .

**PROPOSITION 3.** [ESY84] *NP  $\neq$  co-NP if and only if there exists no promise problem  $(Q, R)$  such that*

- (i)  $Q \in \text{co-NP}$ ,
- (ii)  $(Q, R) \in NPP \cap \text{co-NPP}$ , and
- (iii)  $(Q, R)$  is uniformly NP-hard.

In contrast, the next result states that there do exist promise problems  $(Q, R)$  such that  $Q \in D^P$  and conditions (ii) and (iii) of the conjecture hold. Let  $\oplus$  denote the logical operator “exclusive or.” We take the liberty of writing SAT as a predicate so that  $SAT(x)$  asserts that  $x$  is the string encoding of a satisfiable formula of propositional logic. The predicates EX and SAT-1 over  $\Sigma^* \times \Sigma^*$  are defined by  $EX(x, y) \leftrightarrow SAT(x) \oplus SAT(y)$  and  $SAT-1(x, y) \leftrightarrow SAT(x)$ .

**PROPOSITION 4.** *EX is a complete set for  $D^P$  and the promise problem  $(EX, SAT-1)$  belongs to  $NPP \cap \text{co-NPP}$  and is uniformly NP-hard.*

**2.4. Public-key cryptosystems.** A PKCS consists of three deterministic and publicly known algorithms,  $E$ ,  $D$ , and  $G$ , that operate in polynomial time. Figure 1 gives the basic layout.  $E$  is the *encryption algorithm*,  $D$  is the *decryption algorithm*, and  $G$  is the

Transmitter

Receiver

FIG. 1. Layout of a public-key cryptosystem.

key generator.  $M$ ,  $C$ ,  $K_1$ ,  $K_2$ , and  $X$  will be binary words, called the *message*, *cryptogram*, *encryption key*, *decryption key*, and *trapdoor*, respectively.

Prior to transmission of messages  $M$  of length  $n$ , the receiver randomly generates some  $X$ , where  $|X|$  is bounded by a polynomial in  $n$ , and then uses  $X$  to compute the pair  $G(X) = (K_1, K_2)$ . Pairs that can be generated in this way are called *legal* pairs. Components,  $K_1$ , and  $K_2$ , of legal pairs are called *legal* encryption keys, decryption keys, respectively.  $K_1$  and  $n$ , which is assumed to be computable in polynomial time from  $K_1$ , are made publicly known, but  $X$  and  $K_2$  remain private. Legal pairs may be used for encoding and decoding purpose for a relatively long time. We also call triples  $(n, K_1, M)$  *legal*, if  $|M| = n$ , and  $K_1$  can be used for encryption of messages of length  $n$ .

When a transmitter wants to send a message  $M$  of length  $n$  to a receiver who published key  $K_1$ , he computes  $C = E(K_1, M)$  and sends  $C$  on an open channel. The receiver, knowing  $K_2$ , reconstructs  $M$  by  $M = D(K_2, C)$ . It is assumed that, if  $(K_1, K_2)$  is a legal pair for messages of length  $n$  and if  $|M| = n$ , then  $M = D(K_2, E(K_1, M))$ . This inverse condition guarantees that the function  $\lambda M E(K_1, M)$  is one-one for each legal key  $K_1$ .

**2.5. Cracking problems.** Informally, the cracking problem is the problem of computing  $M$  such that  $E(K_1, M) = C$  if such  $M$  exists, and a solution to the cracking problem is an algorithm that on input  $(n, K_1, C)$ , where  $K_1$  is a legal encryption key for messages of length  $n$ , correctly computes  $M$  such that  $E(K_1, M) = C$ . That is, a *solution* of the cracking problem is an algorithm that computes an extension (not necessarily total) of the following partial function, called “Crack.”

$\text{Dom}(\text{Crack}) = \{(n, K_1, C) \mid K_1 \text{ is legal for messages of length } n \text{ and there is a message } M, |M| = n, \text{ such that } E(K_1, M) = C\}$ . For  $(n, K_1, C) \in \text{dom}(\text{Crack})$ ,  $\text{Crack}(n, K_1, C) = M \leftrightarrow |M| = n \text{ and } E(K_1, M) = C$ .

We assume Crack is polynomial length-bounded (i.e.,  $|M|$  is bounded by some polynomial in  $|K_1| + |C|$ ), so as to avoid the uninteresting case that Crack has no solution that is computable in polynomial time simply because  $|M|$  for which  $E(K_1, M) = C$  is too long.

Clearly  $\text{Crack} \in \text{NPSV}$ . Let us define the promise problem version of the cracking problem to be the promise problem  $\text{CP} = (Q_{\text{Crack}}, R_{\text{Crack}})$  that is associated with Crack. Explicitly stated, CP is the following promise problem.

**input**  $n, K_1, C$ , and  $M'$

**promise**  $K_1$  is a legal encryption key for  
messages of length  $n$  and there exists a message  $M$ ,  
 $|M| = n$ , such that  $E(K_1, M) = C$ .

**property**  $M' \equiv M$ , where  $M$  is the message which satisfies  $E(K_1, M) = C$ .

We conclude immediately that  $Q_{\text{Crack}} \in \text{NP}$  and  $\text{CP} \in \text{NPP} \cap \text{co-NPP}$ . Recall also that solving CP is polynomial-time equivalent to computing an extension of Crack.

Attempts to formulate the cracking problem as an ordinary decision problem would lead to faulty considerations. To see this, tentatively define the conjunction  $Q_{\text{Crack}} \cap R_{\text{Crack}}$  to be the cracking decision problem. One might have a PKCS, say  $S$ , such that the cracking decision problem  $Q_{\text{Crack}} \cap R_{\text{Crack}}$  is difficult to solve. But if there is an efficient algorithm that solves Crack, i.e., that efficiently finds  $M$  when the promise predicate  $Q_{\text{Crack}}$  is true and that gives “garbage” output when  $Q_{\text{Crack}}$  is false, then  $S$  is not a usable system. On the other hand, if Crack has no efficient algorithm, then the promise problem  $(Q_{\text{Crack}}, R_{\text{Crack}})$  has no efficient solution, and so the cracking

decision problem  $Q_{\text{Crack}} \cap R_{\text{Crack}}$  is difficult to solve also, because any algorithm that solves  $Q_{\text{Crack}} \cap R_{\text{Crack}}$  also solves  $(Q_{\text{Crack}}, R_{\text{Crack}})$ .

**3. Complexity of promise problems.** In this section we present new results about promise problems—all with an eye toward setting the conjecture raised in § 2.3. Recall that the cracking promise problem CP of a PKCS has promise  $Q_{\text{Crack}} \in \text{NP}$  and  $\text{CP} \in \text{NPP} \cap \text{co-NPP}$ . The conjecture that no such promise problem can be NP-hard implies that no PKCS can be NP-hard to crack. Analysis of the conjecture will lead toward development of a theory of disjoint pairs of sets in NP, and this development in turn will give further justification for its reasonableness. Also, this development will yield complexity theoretic conditions for the existence of PKCS that have intractable cracking problems (i.e., such that CP has no solution in P).

**3.1. On NP-hard promise problems.** A corollary of our first significant result states that every NP-hard promise problem is uniformly NP-hard.

LEMMA 1.  $(Q, R)$  and  $(Q, R \cap Q)$  have the same solutions. Thus,  $(Q, R)$  is (uniformly) NP-hard if and only if  $(Q, R \cap Q)$  is (uniformly) NP-hard. And,  $(Q, R)$  is (uniformly) Turing reducible to  $(S, T')$  if and only if  $(Q, R')$  is (uniformly) Turing reducible to  $(S, T)$ , where  $R' \in \{R, R \cap Q\}$  and  $T' \in \{T, T \cap S\}$ .

Assume without loss of generality, therefore, that  $R \subseteq Q$ . Then  $S$  is a solution of  $(Q, R)$  if and only if  $S = R \cup X$ , where  $X$  is a recursive subset of  $\bar{Q}$ . Also, for “reducibility” read “polynomial time-bounded reducibility” throughout this section.

LEMMA 2. “Uniform Turing reducibility is closed under finite variations.”  $(Q, R)$  is uniformly Turing reducible to  $(S, T)$  if and only if for any finite sets  $Q', R', S', T'$  with  $R' \subseteq Q' \subseteq \bar{Q}$  and  $T' \subseteq S' \subseteq \bar{S}$ ,  $(Q \cup Q', R \cup R')$  is uniformly Turing reducible to  $(S \cup S', T \cup T')$ .

*Proof.* First observe that it suffices to show that for any promise problem  $(X, Y)$ ,  $(X, Y)$  is uniformly Turing equivalent to  $(X \cup X', Y \cup Y')$ , for any finite sets  $X'$  and  $Y'$  with  $Y' \subseteq X' \subseteq \bar{X}$ . To see that  $(X, Y)$  is uniformly Turing reducible to  $(X \cup X', Y \cup Y')$  is in fact trivial, since every solution of  $(X \cup X', Y \cup Y')$  is also a solution of  $(X, Y)$ . Hence, we only have to show that  $(X \cup X', Y \cup Y')$  is uniformly Turing reducible to  $(X, Y)$ . To this end we must construct a polynomial time-bounded deterministic oracle Turing machine  $M$  such that for every solution  $S$  of  $(X, Y)$ , the set  $L(M, S)$  (i.e., the language recognized by  $M$  with oracle  $S$ ) is a solution of  $(X \cup X', Y \cup Y')$ . The following is an algorithm describing such a machine.

```

begin
input  $x$ ;
if  $x \in S \cup Y'$  and  $x \notin X' - Y'$ 
then accept else reject
end.
```

Since  $X'$  and  $Y'$  are finite sets this algorithm can be executed in polynomial time with respect to the oracle  $S$ . For any solution  $S$  of  $(X, Y)$ ,  $L(M, S) = (S \cup Y') - (X' - Y')$  is a solution of  $(X \cup X', Y \cup Y')$ .  $\square$

THEOREM 1. If  $(Q, R)$  is Turing reducible to  $(S, T)$ , then  $(Q, R)$  is uniformly Turing reducible to  $(S, T)$ .

*Proof.* Assume that  $(Q, R)$  is not uniformly Turing reducible to  $(S, T)$ . That is, assume that for every polynomial time-bounded deterministic oracle Turing machine  $M$  there is some solution  $A$  of  $(S, T)$  such that  $L(M, A)$  does not solve  $(Q, R)$ . Let us expand this assumption one more time: For every polynomial time-bounded deter-

ministic oracle Turing machine  $M$  there exists a solution  $A$  of  $(S, T)$  and there exists a string  $y \in \Sigma^*$  such that

$$y \in R \cap \overline{L(M, A)} \quad \text{or} \quad y \in (Q - R) \cap L(M, A).$$

We want to show with this assumption that  $(Q, R)$  is not Turing reducible to  $(S, T)$ . To do so we will construct one recursive solution  $A$  of  $(S, T)$  such that for every polynomial time-bounded deterministic oracle Turing machine  $M$ ,  $L(M, A)$  is not a solution of  $(Q, R)$ . Let  $\{M_i\}_{i \geq 1}$  be an effective enumeration of polynomial time-bounded deterministic oracle Turing machines with associated polynomial time bounds  $\{p_i\}_{i \geq 1}$ .

We want to show with this assumption that  $(Q, R)$  is not Turing reducible to  $(S, T)$ . To do so we will construct one recursive solution  $A$  of  $(S, T)$  such that for every polynomial time-bounded deterministic oracle Turing machine  $M$ ,  $L(M, A)$  is not a solution of  $(Q, R)$ . Let  $\{M_i\}_{i \geq 1}$  be an effective enumeration of polynomial time-bounded deterministic oracle Turing machines with associated polynomial time bounds  $\{p_i\}_{i \geq 1}$ .

The solution  $A$  of  $(S, T)$  will be constructed inductively to be of the form  $T \cup \bigcup\{Y_i \mid i \geq 1\}$ , where  $\bigcup\{Y_i \mid i \geq 1\}$  is a recursive subset of  $\bar{S}$ . At stage  $i$  of the construction,  $i \geq 1$ , finite subset  $Y_i$  of  $\bar{S}$  will be chosen so that  $L(M_i, T \cup Y_i)$  is not a solution of  $(Q, R)$ .

*Stage 0.* Define  $Y_0 = \emptyset$  and  $n_0 = 0$ .

*Stage  $i$  ( $i \geq 1$ ).* By induction hypothesis,  $Y_{i-1}$  is defined,  $Y_{i-1}$  is a finite set,  $n_{i-1} \geq 0$  is defined, and  $Y_{i-1} \subseteq \bar{S} \cap \Sigma^{\leq n_{i-1}}$ .

Now comes a sequence of claims.

*Claim 1.* There is a recursive set  $X_i \subseteq \overline{(S \cup \Sigma^{\leq n_{i-1}})}$  and a string  $y_i \in \Sigma^*$  such that

$$(1) \quad y_i \in R \cup \overline{L(M_i, T \cup Y_{i-1} \cup X_i)} \quad \text{or} \quad y_i \in (Q - R) \cap L(M_i, T \cup Y_{i-1} \cup X_i).$$

If the claim is correct, then  $y_i$  is a witness to the fact that  $L(M_i, T \cup Y_{i-1} \cup X_i)$  is not a solution of  $(Q, R)$ . Suppose the claim is false. Then, for every recursive subset  $X_i$  of  $\overline{(S \cup \Sigma^{\leq n_{i-1}})}$ ,  $R \cap \overline{L(M_i, T \cup Y_{i-1} \cup X_i)} = \emptyset$  and  $(Q - R) \cap L(M_i, T \cup Y_{i-1} \cup X_i) = \emptyset$ . Thus,  $R \subseteq L(M_i, T \cup Y_{i-1} \cup X_i) \subseteq \overline{(Q - R)}$  and so  $L(M_i, T \cup Y_{i-1} \cup X_i)$  is a recursive solution of  $(Q, R)$ . The set of all languages  $T \cup Y_{i-1} \cup X_i$ , where  $X_i$  is a recursive subset of  $\overline{(S \cup \Sigma^{\leq n_{i-1}})}$  is exactly the set of all solutions of the promise problem  $(S \cup \Sigma^{\leq n_{i-1}}, T \cup Y_{i-1})$ . Thus,  $(Q, R)$  is uniformly Turing reducible to this promise problem. But this promise problem is a finite variation of  $(S, T)$ , and so, by Lemma 2,  $(Q, R)$  must be uniformly Turing reducible to  $(S, T)$ . This is a contradiction to our assumption. Hence, the claim is true.

*Claim 2.* There is a finite set  $X_i \subseteq \overline{(S \cup \Sigma^{\leq n_{i-1}})}$  and a string  $y_i \in \Sigma^*$  that satisfy condition (1).

For the set  $X_i$  and a string  $y_i$  whose existence is guaranteed by Claim 1, machine  $M_i$  on input  $y_i$  may query strings of length at most  $p_i(|y_i|)$ . So, for  $X'_i = X_i \cap \Sigma^{\leq p_i(|y_i|)}$  and  $y_i$ , assertion (1) is still true.

*Claim 3.* A finite set  $X_i \subseteq \overline{(S \cup \Sigma^{\leq n_{i-1}})}$  and string  $y_i$  that satisfy assertion (1) can be found effectively.

This is trivial. Effectively enumerate all pairs of finite sets and strings until a pair with the desired properties is found.

At Stage  $i$ , apply Claim 3; define  $Y_i = Y_{i-1} \cup X_i$  and define  $n_i = \max\{2^{n_{i-1}}, p_i(|y_i|)\} + 1$ .

End of Stage  $i$ .

Define  $A = T \cup \bigcup \{Y_i \mid i \geq 1\}$ . Since  $\bigcup \{Y_i \mid i \geq 1\} \subseteq \bar{S}$ ,  $A$  is a solution of  $(S, T)$ .  $A$  is a recursive set because a string  $w$  belongs to  $A$  if and only if  $w \in R$  or  $w \in Y_i$ , where  $i$  is the least index of an  $n_i$  such that  $n_i \geq |w|$ . For every  $i$ ,  $L(M_i, A)$  does not solve  $(Q, R)$  because a string  $y_i$  exists such that  $y_i \in R \cap \overline{L(M_i, T \cup Y_i)}$  or  $y_i \in (Q - R) \cap L(M_i, T \cup Y_i)$ , and therefore  $y_i \in R \cap \overline{L(M_i, A)}$  or  $y_i \in (Q - R) \cap L(M_i, A)$ .

This holds because  $(T \cup Y_i) \cap \Sigma^{\leq p_i(|y_i|)} = A \cap \Sigma^{\leq p_i(|y_i|)}$ . Furthermore, strings added to the solution in future stages cannot disturb this relation because only strings are added that are too long to be queried on input  $y_i$ . Thus,  $A$  is a recursive solution of  $(S, T)$  such that  $L(M, A)$  is not a solution of  $(Q, R)$  for any deterministic polynomial time-bounded oracle Turing machine  $M$ .

Therefore,  $(Q, R)$  is not Turing reducible to  $(S, T)$ .  $\square$

**COROLLARY 1.** *A promise problem is NP-hard if and only if it is uniformly NP-hard.*<sup>1</sup>

*Proof.*  $(Q, R)$  is NP-hard if and only if  $(\Sigma^*, \text{SAT}) \leq_T^{\text{PP}} (Q, R)$ , and  $(Q, R)$  is uniformly NP-hard if and only if  $(\Sigma^*, \text{SAT}) \leq_{\text{UT}}^{\text{PP}} (Q, R)$ .  $\square$

Corollary 1 suggests a fascinating approach to proving the conjecture. Corollary 1 states that if  $(Q, R)$  is NP-hard, then there is *one* reduction  $M$  from SAT to every solution of  $(Q, R)$ . Thus, the result of  $M$ 's computation on an input string  $x$  does not depend on the answer of the oracle to queries outside of  $Q$ . If an oracle responds correctly to queries in  $Q$  and arbitrarily to queries outside of  $Q$ , then  $M$  accepts an input string  $x$  if and only if  $x \in \text{SAT}$ . Queries to strings in  $\bar{Q}$  are "meaningless."

Given a promise problem  $(Q, R)$  such that  $R \subseteq Q$  and a language  $L$ , say there is a *smart* reduction from  $L$  to  $(Q, R)$  if there is a polynomial time-bounded oracle Turing machine  $M$  that witnesses  $(\Sigma^*, L) \leq_{\text{UT}}^{\text{PP}} (Q, R)$  such that  $M$  never queries any word in  $\bar{Q}$ . (Smart reductions never ask meaningless questions.) The next theorem states that knowledge about the existence of smart reductions might help to solve the conjecture. First observe that if  $\text{NP} = \text{co-NP}$ , then the promise problem  $(Q, R)$ , where  $Q = \Sigma^*$  and  $R = \text{SAT}$  satisfies each of the following properties.

- (i)  $Q \in \text{NP}$ ,
- (ii)  $(Q, R) \in \text{NPP} \cap \text{co-NPP}$ , and
- (iii) there is a smart reduction from SAT to  $(Q, R)$ .

**THEOREM 2.** *If there is a promise problem  $(Q, R)$  in  $\text{NPP} \cap \text{co-NPP}$  and there is a smart reduction from SAT to  $(Q, R)$ , then  $\text{NP} = \text{co-NP}$ .*

If there exists  $(Q, R)$  such that  $Q \in \text{NP}$ ,  $(Q, R) \in \text{NPP} \cap \text{co-NPP}$ , and  $(Q, R)$  is NP-hard, then, by Corollary 1,  $(Q, R)$  is uniformly NP-hard. If these three conditions can be shown to imply existence of a smart reduction from SAT to  $(Q, R)$ , then, by Theorem 2,  $\text{NP} = \text{co-NP}$ , and so  $\text{NP} \neq \text{co-NP}$  would imply that the conjecture is true. However, the situation is probably more subtle than this, for in [ESY84] it is shown that  $\text{UP} = \text{NP}$  implies existence of a promise problem that satisfies the conditions listed in the conjecture, and intuition does not suggest that  $\text{NP} \neq \text{co-NP}$  implies  $\text{UP} \neq \text{NP}$ .

*Proof.* Let  $(Q, R)$  be a promise problem in  $\text{NPP} \cap \text{co-NPP}$  for which there is a smart reduction from SAT to  $(Q, R)$ . We will show that  $\overline{\text{SAT}} \in \text{NP}$  and conclude therefore that  $\text{NP} = \text{co-NP}$ . Let  $M$  be a deterministic oracle Turing machine that uniformly reduces SAT to solutions of  $(Q, R)$  and that never queries any word in  $\bar{Q}$ . Then,  $M$  with its accepting and rejecting states reversed (call this machine  $M'$ ) reduces  $\overline{\text{SAT}}$  to solutions of  $(Q, R)$  and never queries any word in  $\bar{Q}$ . By Lemma 1, assume without loss of generality that  $R \subseteq Q$ . Let  $M_i$ ,  $i = 1, 2$ , be NP-acceptors that solve

<sup>1</sup> A noneffective version of this result has been obtained independently by Regan [Reg86].

$(Q, R)$  and  $(Q, \bar{R})$ , respectively. We now describe an NP-acceptor  $N$  for  $\overline{\text{SAT}}$ . On input  $x$ ,  $N$  begins a simulation of  $M'$  on  $x$  but replaces each query  $w$  to the oracle by simulations of  $w$  on the NP-acceptors  $M_i$ ,  $i=1, 2$ , according to the following nondeterministic algorithm.

- if  $M_1$  accepts  $w$ 
  - continue simulation of  $M'$  in the YES state
- $M_2$  accepts  $w$ 
  - continue simulation of  $M'$  in the NO state

If the algorithm is executed on a word  $w$  and the guard that is chosen does not evaluate to *true*, then the simulation by  $N$  of  $M'$  on input  $x$  is to terminate without accepting. Since  $M_1$  has an accepting computation on a query string  $w$ , if  $w \in R$ ,  $M_2$  has an accepting computation on  $w$ , if  $w \in Q - R$ , and every word queried belongs to either  $R$  or  $Q - R$ , it follows, for every input word  $x$  to  $N$ , that the simulation by  $N$  of  $M'$  on  $x$  can be completed.

It is obvious that the language accepted by  $N$  belongs to NP. To see that this language is  $\overline{\text{SAT}}$ , simply observe for each input word  $x$  to  $N$  that  $N$  simulates  $M'$ , relative to some solution of  $(Q, R)$ . The latter fact follows readily because for every solution  $L$  of  $(Q, R)$ ,  $R \subseteq L$  and  $Q - R \subseteq \bar{L}$ . Thus,  $\overline{\text{SAT}} \in \text{NP}$  and so  $\text{NP} = \text{co-NP}$ . □

The next corollary follows from Proposition 4 in § 2.3.

**COROLLARY 2.** *If there is a smart reduction from SAT to (EX, SAT-1), then  $\text{NP} = \text{co-NP}$ .*

Thus, smart reductions cannot be expected to exist for all NP-hard promise problems in  $\text{NPP} \cap \text{co-NPP}$ .

**3.2. P-separability.** Recall that a disjoint pair of sets  $A$  and  $B$  are P-separable if there exists a set  $L$  in P such that  $A \subseteq L$  and  $B \subseteq \bar{L}$ ; they are P-inseparable otherwise. The following theorem gives a characterization of the conjecture that is strictly in terms of the fine structure of NP.

**THEOREM 3.** *There exists a promise problem  $(Q, R)$  satisfying the conditions of the conjecture if and only if there exist disjoint  $\cong_P^P$ -complete sets  $A$  and  $B$  in NP such that for every recursive set  $L$ , if  $A \subseteq L$  and  $B \subseteq \bar{L}$ , then  $L$  is NP-hard.*

*Proof.* Given a promise problem  $(Q, R)$  that satisfies the conditions of the conjecture, the sets  $A = Q \cap R$  and  $B = Q - R$  are  $\cong_P^P$ -complete sets in NP. The sets that separate  $A$  and  $B$  are precisely the solutions of  $(Q, R)$  so every set that separates  $A$  and  $B$  is NP-hard. Conversely, given such  $A$  and  $B$ ,  $(A \cup B, A)$  satisfies the conditions of the conjecture. □

We will be showing that P-inseparable sets in NP probably do exist. But, the property given in Theorem 3 is a much stronger constraint than P-inseparability. It is tempting to compare P-inseparability and “separability by NP-hard sets only” with the analogous notions from classical recursive function theory (recursive sets and recursively enumerable sets for P and NP, respectively). It is a fundamental result that there exist disjoint recursively enumerable sets that are recursively inseparable. On the other hand, Shoenfield [Sho60] has shown that every disjoint pair of recursively enumerable sets can be separated by some set whose degree is strictly less than  $\mathbf{0}'$ . Thus, the analogue of our conjecture for the recursively enumerable sets is a theorem.

The following corollaries are reformulations of one of the principal results (Proposition 4) proved in [ESY84]. Let  $\text{SAT-UNSAT} = \{(x, y) | x \text{ encodes a satisfiable formula of propositional logic while } y \text{ encodes an unsatisfiable formula}\}$  and let  $\text{UNSAT-SAT} = \{(x, y) | x \text{ is unsatisfiable and } y \text{ is satisfiable}\}$ . It is shown in [PY84] that  $\text{SAT-UNSAT}$

is complete for  $D^P$ , and trivially UNSAT-SAT is complete for  $D^P$  also. Now,  $SAT-UNSAT = EX \cap SAT-1$  and  $UNSAT-SAT = EX - SAT-1$ . Thus, from Theorem 3 applied to Proposition 4 we immediately obtain the following.

**COROLLARY 3.**  $D^P$  contains disjoint complete sets SAT-UNSAT and UNSAT-SAT such that every set that separates them is NP-hard.

Here is a property about  $D^P$  that very likely does not hold for NP and so Corollary 3 provides structural evidence that  $D^P$  is not equal to NP. Corollary 3 yields the following result also.

**COROLLARY 4.**  $P = NP$  if and only if SAT-UNSAT and UNSAT-SAT are P-separable.

The following corollary to Theorem 3 presents a provocative connection to the structure of the class of all NP-hard sets in NP.

**COROLLARY 5.** Statement (a) implies statement (b).

(a) For all sets  $A$  and  $B$ , if  $A$  and  $B$  are disjoint  $\cong_T^P$ -complete sets in NP, then  $A \cup B$  is  $\cong_T^P$ -complete in NP.

(b) If there exists a promise problem  $(Q, R)$  that satisfies the conditions of the conjecture, then  $Q$  is a  $\cong_T^P$ -complete set in NP.

The proof follows from the observation that  $Q \cap R$  and  $Q - R$  are both  $\cong_T^P$ -complete sets. It is an interesting open question whether statement (a) is true, but statement (b) would be a surprising consequence. The cracking problem for a PKCS is formulated as a promise problem specifically (i) so that its complexity is determined by the effort required to crack cryptograms correctly, and (ii) because we do not want the complexity to depend on the effort required to determine whether an arbitrary string is a legitimate cryptogram or a sham. Nevertheless, if statement (b) is true, then a given PKCS does have an NP-hard cracking problem only if its promise predicate is NP-hard.

Now we turn our attention to the existence of PKCS with intractable cracking problems, for surely a PKCS cannot be deemed secure if it can be cracked in polynomial time. For such a PKCS,  $CP = (Q_{Crack}, R_{Crack})$  and in addition to the conditions (i)  $Q_{Crack} \in NP$ , and (ii)  $CP \in NPP \cap co-NPP$ , the following property holds also: (iii)' No solution of CP is in P.

**THEOREM 4.** There is a promise problem  $(Q, R)$  satisfying conditions (i), (ii), and (iii)' if and only if  $NP - P$  contains disjoint P-inseparable sets.

Thus, PKCS with intractable cracking problems exist only if there exist P-inseparable sets. The proof is a straightforward variation of the proof of Theorem 3.

Do there exist P-inseparable sets in NP? There probably do. First of all because it is essentially trivial that if  $A \in (NP \cap co-NP) - P$ , then  $A$  and  $\bar{A}$  are P-inseparable and, secondly, because of the following theorem.

**THEOREM 5.** If  $P \neq UP$ , then NP contains P-inseparable sets.

*Proof.* Assume  $P \neq UP$  and by Proposition 1, let  $f \in NPSV_g - PSV$ . By Theorem 4, it suffices to show that  $(Q_f, R_f)$  has no solution in P. By Proposition 2, this is equivalent to showing that  $f$  has no extension in P. Since  $graph(f) \in P$  but  $f \notin PSV$ , it follows that the last assertion is true.  $\square$

**THEOREM 6.** If NP contains P-inseparable sets, then there exist NP-complete P-inseparable sets.

This is a very intriguing result. Theorems 5 and 6 together tell us that information about a subset of NP that probably does not contain the NP-complete sets, yet nevertheless influences the structure of the NP-complete sets.

*Proof.* Let  $\{M_i\}_{i \geq 1}$  be an enumeration of polynomial time-bounded nondeterministic Turing machines with associated polynomial time bounds  $\{p_i\}_{i \geq 1}$ . It is well known

that the set  $K = \{\langle i, x, 0^n \rangle \mid \text{some computation of } M_i \text{ accepts } x \text{ in at most } n \text{ steps}\}$  is NP-complete [BGS75]. For every set  $A$  in NP there exists  $i \geq 1$  such that  $A = L(M_i)$ , and there exists an honest many-one reduction  $f$  from  $A$  to  $K$  defined by  $f(x) = \langle i, x, 0^{p_i(|x|)} \rangle$ . Let  $A$  and  $B$  be P-inseparable sets in NP and let  $f$  be an honest reduction from  $A$  to  $K$ . Our first goal is to show that the sets  $f(B)$  and  $K$  are P-inseparable sets in NP. Since  $B \in \text{NP}$  and  $f$  is honest,  $f(B) \in \text{NP}$ . Since  $f$  is a reduction from  $A$  to  $K$  and  $A \cap B = \emptyset$ ,  $f(A) \subseteq K$  and  $f(B) \subseteq \bar{K}$ , and so  $f(B)$  and  $K$  are disjoint sets. In order to prove that  $f(B)$  and  $K$  are P-inseparable, assume that  $K \subseteq L \subseteq \bar{f(B)}$  and  $L \in \text{P}$ . Then,  $A \subseteq f^{-1}(L) \subseteq \bar{B}$ . Also,  $f^{-1}(L) \in \text{P}$  because  $f^{-1}(L) \leq_m^{\text{P}} L$ . Thus, P-inseparability of  $A$  and  $B$  are contradicted. Hence,  $f(B)$  and  $K$  are P-inseparable.

Now we have obtained two disjoint P-inseparable sets in NP and one of them is NP-complete. To prove the theorem, apply the construction once again, this time with an honest reduction  $g$  from  $f(B)$  to  $K$ . Namely,  $g(f(B)) \subseteq K$  and  $g(K) \subseteq \bar{K}$ . Then,  $K$  and  $g(K)$  are disjoint NP-complete sets and the argument already given shows that they are P-inseparable.  $\square$

**3.3. Almost-everywhere complexity.** If a PKCS cannot be cracked in polynomial time, then for every polynomial time-bounded algorithm there exist infinitely many messages whose codes the algorithm cannot crack. This leaves open the possibility that there exist some algorithm and infinitely many messages whose codes this algorithm can crack in polynomial time. Indeed, this leaves open the possibility that there exists some algorithm that can crack codes for *most* messages in polynomial time. NP-hardness is not a good measure for the security of a cryptographic system, for it is at the same time both too strong and too weak. It is too strong because there is no need to require that every set in NP is reducible to every solution of CP. It is too weak because it too is an i.o. measure and therefore allows the possibility of cracking nearly all codes in polynomial time. (An NP-hard classical cryptosystem that exhibits this feature has been constructed by Even and Yacobi and is described in the survey article by Lempel [Lem79].) Rather, a PKCS should be difficult to crack on as many instances of its message space as possible. Therefore, it seems worthwhile to formulate a.e. complexity measures for promise problems.

Define a promise problem to be *immune* to a complexity class  $\mathcal{C}$  if every solution is immune to  $\mathcal{C}$  and to be *bi-immune* to  $\mathcal{C}$  if every solution is bi-immune to  $\mathcal{C}$ . Here we will just consider immunity and bi-immunity to P, but our remarks hold for other classes as well.

An adversary who has available a P-immune solution  $S$  to CP may still be able to efficiently compute Crack for many input instances by applying a reduction technique (as indicated in the proof of Proposition 2) that uses easy instances of  $\bar{S}$ . Thus, immunity to P is not a sufficiently strong measure for public-key cryptography.

Analogous to Theorems 3 and 4, it is easy to show that there exists a bi-immune to P promise problem  $(Q, R)$  such that  $Q \in \text{NP}$  and  $(Q, R) \in \text{NPP} \cap \text{co-NPP}$  if and only if there exist disjoint sets  $A$  and  $B$  in NP such that every set which separates them is bi-immune to P. Furthermore, the latter condition is equivalent to the existence of disjoint sets in NP which are both bi-immune to P. Thus, we state the following proposition.

**PROPOSITION 5.** *There exists a bi-immune to P promise problem  $(Q, R)$  such that  $Q \in \text{NP}$  and  $(Q, R) \in \text{NPP} \cap \text{co-NPP}$  if and only if NP contains a disjoint pair of sets that are both bi-immune to P.*

Unfortunately, our interest in bi-immune promise problems is diminished by the following proposition.

PROPOSITION 6. For  $f \in \text{NPSV}$ ,  $(Q_f, R_f)$  is not bi-immune to  $P$ . Every solution of  $(Q_f, R_f)$  contains a nonsparse subset in  $P$ .

The proof is easy. Given  $x \in \text{dom}(f)$ , every solution of  $(Q_f, \bar{R}_f)$  includes  $\{(x, y) \mid y > f(x)\}$ . But this set is only useful for computing one value of  $f$ . The moral is this: The existence of solutions of CP with large easy subsets or with large easy subsets of the complement does not give information about the density of the domain of easy instances of Crack. Promise problems do not permit elegant ways to characterize almost-everywhere security measures which impart information about the security of the underlying functions. Primarily for this reason, the complexity of Crack is analyzed in the next two sections directly as a computational problem.

**4. One-way functions.** Recall that a function  $f$  is honest if there is a polynomial  $q$  such that for every  $y \in \text{range}(f)$  there exists  $x \in \text{dom}(f)$  such that  $f(x) = y$  and  $|x| \leq q(|y|)$ . We define a partial function  $f$  to be *one-way* if  $f$  is one-one,  $f$  is honest,  $f \in \text{PSV}$ , and  $f^{-1} \notin \text{PSV}$ . This is a common formulation that has been useful in several complexity theoretic investigations [BL86], [Ko85], [KLD86], [Wat85], [You83].

If  $f$  is a one-way function, then  $f^{-1} \in \text{UPSV}_g - \text{PSV}$ . In fact, no extension of  $f^{-1}$  is in  $\text{PSV}$ . Also,  $f^{-1} \in \text{UPSV}_g - \text{PSV}$  implies  $\text{UP} \neq P$ , by Proposition 1. The converse holds as well.

THEOREM 7. The following are equivalent.<sup>2</sup>

- (a)  $P \neq \text{UP}$ .
- (b) There exists a one-way function.
- (c) There exists a total one-way function.

*Proof.* Clearly (c) implies (b), and we just observed that (b) implies (a). Let  $L \in \text{UP} - P$  be witnessed by a UTM  $M$ . The total function  $f$  defined by

$$f(x) = \begin{cases} y0 & \text{if } x = \text{comp}_M(y), \\ x1 & \text{otherwise} \end{cases}$$

is a total one-way function.  $\square$

In some sense, for the function  $f$  just constructed,  $f^{-1}$  is hard to compute because one cannot even determine whether a string  $x$  belongs to  $\text{dom}(f^{-1})$ . Thus, it is interesting to know whether there exist one-way functions with range belonging to  $P$ .

THEOREM 8. The following are equivalent.

- (a)  $P \neq \text{UP} \cap \text{co-UP}$ .
- (b) There is a one-way function  $f$  such that  $\text{range}(f) \in P$ .
- (c) There is a one-way function  $f$  such that  $\text{range}(f) = \Sigma^*$ .
- (d) There is a total one-way function  $f$  such that  $\text{range}(f) \in P$ .

*Proof.* The equivalences can be proved from the following three implications.

(b) implies (a): Let  $f$  be a one-way function such that  $\text{range}(f) \in P$ , and let  $(Q, R)$  be the promise problem associated with  $f^{-1}$ . Then,  $Q \in P$ , because  $Q = \text{dom}(f^{-1}) \times \Sigma^* = \text{range}(f) \times \Sigma^*$ . Since no extension of  $f^{-1}$  belongs to  $\text{PSV}$ ,  $(Q, R)$  has no solution in  $P$ , by Proposition 2. Therefore, in particular,  $Q \cap R \notin P$ . On the other hand, it is easy to see that  $Q \cap R \in \text{UP}$ . Similarly,  $Q - R \in \text{UP} - P$ . Assertion (a) follows directly.

(a) implies (c): Let  $L \in (\text{UP} \cap \text{co-UP}) - P$ . Let  $M$  and  $N$  be UTMs that witness  $L \in \text{UP}$  and  $\bar{L} \in \text{UP}$ , respectively. The function  $f$  defined as follows satisfies condition (c):

<sup>2</sup> This result has been obtained independently by Ko [Ko85].

$$f(x) = \begin{cases} y & \text{if } x = \text{comp}_M(y) \text{ or } x = \text{comp}_N(y), \\ \uparrow & \text{otherwise.} \end{cases}$$

(a) implies (d): Let  $L$ ,  $N$ , and  $M$  be as in the previous implication. This time define  $f$  as follows:

$$f(x) = \begin{cases} y0 & \text{if } x = \text{comp}_M(y) \text{ or } x = \text{comp}_N(y), \\ x1 & \text{otherwise.} \end{cases} \quad \square$$

THEOREM 9. *The following are equivalent.*

(a)  $\text{UP} = \text{NP}$ .

(b) *There exists a one-one, honest function  $f \in \text{PSV}$  such that  $\text{dom}(f^{-1})$  is NP-complete.*

(c) *There exists a function  $f \in \text{UPSV}_g$  such that  $\text{dom}(f)$  is NP-complete.*

*Proof.* To see that (a) implies (b), let  $L$  be an NP-complete set. Since  $L \in \text{UP}$  is assumed, it follows that  $L = \text{dom}(f^{-1})$ , where  $f$  is defined by

$$f(x) = \begin{cases} y & \text{if } x = \text{comp}_M(y), \\ \uparrow & \text{otherwise.} \end{cases}$$

We observed previously that (b) implies (c).

Let  $f \in \text{UPSV}_g$  such that  $\text{dom}(f)$  is NP-complete. To see that  $\text{UP} = \text{NP}$ , observe first that  $\text{dom}(f) \in \text{UP}$  and secondly that

$$(A \leq_m^P B \text{ and } B \in \text{UP}) \rightarrow A \in \text{UP}.$$

Thus (c) implies (a).  $\square$

Next we will observe that one of the main results of [ESY84] follows quickly when Theorem 9 is applied to what we learned in § 2 about the promise problem  $(R_f, Q_f)$  that is associated with a function  $f$ .

COROLLARY 6 [ESY84]. *The conjecture implies  $\text{UP} \neq \text{NP}$ .*

*Proof.* Suppose  $\text{UP} = \text{NP}$  and let  $f \in \text{UPSV}_g$  such that  $\text{dom}(f)$  is NP-complete. We know already that  $Q_f \in \text{NP}$  and  $(Q_f, R_f) \in \text{NPP} \cap \text{co-NPP}$ .

To show that  $(Q_f, R_f)$  is NP-hard, by Proposition 2 it suffices to show that  $\text{dom}(f) \leq_T^P h$ , for every extension  $h$  of  $f$ . The reduction is given by the following algorithm:

**input**  $x$ ;  
**if**  $(x, h(x)) \in \text{graph}(f)$  **then** accept **else** reject.  $\square$

COROLLARY 7. *If  $\text{P} \neq \text{NP}$ , then  $\text{NP} = \text{UP}$  if and only if there is a one-way function  $f$  such that  $\text{dom}(f^{-1})$  is NP-complete.*

Now we concern ourselves with the following important question. Do one-way functions play a role in public-key cryptography? The answer is not at all obvious. The function  $\lambda ME(K_1, M)$  is not a one-way function because the inverse  $\lambda CD(K_2, C)$  is easy to compute, assuming  $(K_1, K_2)$  is a legal pair. The encoding function  $E$  is not a one-way function because it is not one-one. Consider the function  $E'$  defined as

follows:

$$E'(n, K_1, M) = \begin{cases} (n, K_1, E(K_1, M)) & \text{if } K_1 \text{ is a legal encryption key for messages} \\ & \text{of length } n, \text{ and } |M| = n, \\ \uparrow & \text{otherwise.} \end{cases}$$

$E'$  is one-one, is honest (by an assumption made in § 2.4) and has an extension in PSV.  $E'$  is a candidate therefore for being a one-way function, but  $E'$  is not necessarily in PSV, because  $\text{dom}(E')$  is not necessarily in P.

The inverse of  $E'$  is the function Crack' defined as follows:

$$\text{Crack}'(n, K_1, c) = \begin{cases} (n, K_1, \text{Crack}(n, K_1, C)) & \text{if } (n, K_1, C) \in \text{dom}(\text{Crack}), \\ \uparrow & \text{otherwise.} \end{cases}$$

$\text{Dom}(\text{Crack}') = \text{dom}(\text{Crack})$ , and it should be obvious that Crack' is computable in polynomial time if and only if Crack is computable in polynomial time. Therefore, if for a given PKCS,  $\text{Crack} \notin \text{PSV}$ , then  $E'$  will be a one-way function if and only if  $\text{dom}(E') \in \text{P}$ . In fact, the latter condition holds if and only if  $\text{Crack} \in \text{UPSV}_g$ . We conclude: If  $\text{Crack} \in \text{UPSV}_g - \text{PSV}$ , then  $E'$  is a one-way function and, furthermore, for this to occur it is necessary that  $\text{P} \neq \text{UP}$ . Indeed, even if  $\text{Crack} \in \text{UPSV} - \text{PSV}$ , it must be the case that  $\text{P} \neq \text{UP}$ .

The following propositions give some equivalent conditions for Crack to belong to one of the classes UPSV or  $\text{UPSV}_g$ .

**PROPOSITION 7.** *The following are equivalent.*

- (a)  $\text{Crack} \in \text{UPSV}$ .
- (b)  $\text{dom}(\text{Crack}) \in \text{UP}$ .
- (c)  $\text{dom}(E') \in \text{UP}$ .
- (d) *The set of legal encryption keys is in UP.*

**PROPOSITION 8.** *The following are equivalent.*

- (a)  $\text{Crack} \in \text{UPSV}_g$ .
- (b)  $\text{dom}(E') \in \text{P}$ .
- (c)  $E' \in \text{PSV}$ .
- (d) *The set of legal encryption keys is in P.*

Reasonable assumptions can be made about a PKCS which guarantee that Crack  $\in$  UPSV. One constraint to insure this is that the first component of the key generator be one-one.

**4.1. Weak one-way functions.** If the conditions listed in Proposition 8 do not hold, then we cannot conclude that  $E'$  is a one-way function. A PKCS may be intractable without the conditions listed in Proposition 7 being true. Therefore, existence of a PKCS that cannot be cracked in polynomial time does not necessarily imply  $\text{P} \neq \text{UP}$ , and so does not necessarily imply existence of one-way functions. Public-key cryptography without one-way functions is possible.

But let us focus attention on the function  $E'$  and its inverse Crack' once more. We have seen already that  $E'$  is one-one, is honest, and has an extension in PSV. Clearly,  $E' \in \text{NPSV}$ . Since a PKCS can be cracked in polynomial time if and only if some extension of Crack belongs to PSV, and since Crack has an extension in PSV if and only if Crack' has an extension in PSV, a necessary and sufficient condition that a PKCS is intractable is that Crack' cannot be extended to any function in PSV.

With these properties of  $E'$  and Crack' in mind we make the following definition. A function  $f \in \text{NPSV}$  is *weak one-way* if  $f$  is one-one,  $f$  is honest, an extension of  $f$  is in PSV, and no extension of  $f^{-1}$  is in PSV. Every one-way function is a weak one-way

function. It follows from the discussion that existence of intractable public-key cryptosystems implies the existence of weak one-way functions. In light of the fact that existence of intractable public-key cryptosystems implies the existence of P-inseparable sets in NP, the next theorem is particularly interesting.

**THEOREM 10.** *The following are equivalent.*

- (a) NP contains disjoint P-inseparable sets.
- (b) There exist functions in NPSV that have no extension in PSV.
- (c) There exist weak one-way functions.

*Proof.* To prove that (a) implies (b), let  $A$  and  $B$  be disjoint P-inseparable sets in NP. Define  $f$  as follows:

$$f(x) = \begin{cases} 1, & x \in A, \\ 0, & x \in B. \end{cases}$$

Clearly  $f \in \text{NPSV}$ . If  $f_1$  is any extension of  $f$ , then  $\{x \mid f_1(x) = 1\}$  separates  $A$  and  $B$ . Therefore, this set does not belong to P and so  $f_1$  does not belong to PSV.

Now we prove that (b) implies (c). Let  $f \in \text{NPSV}$  so that no extension of  $f$  belongs to PSV. Define  $g$  to be the natural mapping from  $\text{dom}(f)$  to  $\text{graph}(f)$ . That is,

$$g(x) = \begin{cases} \langle x, f(x) \rangle, & x \in \text{dom}(f), \\ \uparrow & \text{otherwise.} \end{cases}$$

Finally, define  $h = g^{-1}$ . Then,

$$h(\langle x, y \rangle) = \begin{cases} x, & x \in \text{dom}(f) \text{ and } y = f(x), \\ \uparrow & \text{otherwise.} \end{cases}$$

We claim that  $h$  is a weak one-way function. Clearly  $h$  is one-one, is honest, and has an extension in PSV. If  $h^{-1} = g$  has an extension in PSV, then it follows that  $f$  has an extension in PSV. Thus, no extension of  $h^{-1}$  belongs to PSV, and so  $h$  is a weak one-way function.

To prove that (c) implies (a), let  $f$  be a weak one-way function and observe that  $f^{-1} \in \text{NPSV}$  and  $f^{-1}$  has no extension in PSV. Therefore, the promise problem  $(Q_{f^{-1}}, R_{f^{-1}})$ , by Proposition 2, has no solution in P. So, by Theorem 4, NP contains disjoint P-inseparable sets.  $\square$

**4.2. Summary.** It is useful to summarize the results of this and the previous section in the following manner. Consider the following assertions of existence.

- (A) There exist PKCS satisfying reasonable conditions (e.g., the set of legal encryption keys is in UP) that cannot be cracked in polynomial time.
- (B) There exist one-way functions. Equivalently,  $\text{P} \neq \text{UP}$ .
- (C) There exist PKCS that cannot be cracked in polynomial time.
- (D) There exist weak one-way functions. Equivalently, NP contains disjoint P-inseparable sets.

We proved that (A) implies (B) and that (C) implies (D). Now we will show that (B) implies (C), thereby completing a sequence of implications. The next result also helps to explain why none of the converse implications seem to hold.

**THEOREM 11.** *If there exists a function  $f \in \text{NPSV}$  such that*

- (i)  $f$  is one-one,
- (ii)  $f$  is honest,
- (iii) there is a one-one extension of  $f$  in PSV,
- (iv) no extension of  $f^{-1}$  is in PSV,

*then there exists a PKCS that cannot be cracked in polynomial time.*

Observe that every one-way function satisfies the hypothesis of Theorem 11 and every function that satisfies these conditions is a weak one-way function. A function  $f$  may have an extension in PSV but not have any extension in PSV that is one-one, and so we can prove neither that every weak one-way function satisfies the hypothesis of Theorem 11 nor that existence of weak one-way functions imply existence of PKCS that cannot be cracked in polynomial time.

*Proof.* Let  $f$  satisfy the conditions listed and let  $f_1$  be an extension of  $f$  such that  $f_1$  is one-one and  $f_1 \in \text{PSV}$ . Since  $f \in \text{NPSV}$ ,  $\text{dom}(f) \in \text{NP}$  and so some total function  $g \in \text{PSV}$  exists such that  $\text{range}(g) = \text{dom}(f)$  [Sel78].

Define a key generator  $G$  as follows:  $G(x) = (f(g(x)), g(x))$ . Since  $f_1(g(x)) = f(g(x))$  for all  $x$ ,  $G$  is computable in polynomial time. If  $K_1 = f(g(x))$  is an enciphering key, then  $K_2 = g(x)$  is the deciphering key. (Observe that if  $(K_1, K_2)$  is a legal pair, then  $f(K_2) = K_1$  and hence “key-cracking” is equivalent to inverting  $f$ .)

As blocklength for an enciphering key  $K_1 = f(g(x))$ ,  $|K_2| = |g(x)|$  is published. Encoding and decoding functions are defined as follows, where  $|M| = |f_1^{-1}(K_1)|$ .

$$E(K_1, M) = \begin{cases} \#^{|K_1|} & \text{if } f_1(M) = K_1, \\ M & \text{otherwise,} \end{cases}$$

and

$$D(K_2, C) = \begin{cases} K_2 & \text{if } C = \#^{|K_1|}, \\ C & \text{otherwise.} \end{cases}$$

The functions  $E$  and  $D$  obviously are computable in polynomial time. Since  $f$  is an honest function, it is easy to see that the function Crack for this system is polynomial length-bounded.

To prove that the system inverse condition holds, let  $(K_1, K_2)$  be a legal pair of keys and let  $|M| = |f_1^{-1}(K_1)|$ . Consider the case that  $f_1(M) = K_1$ . Then,  $D(K_2, E(K_1, M)) = D(K_2, \#^{|K_1|}) = K_2$ . Since  $(K_1, K_2)$  is a legal pair,  $f(K_2) = K_1$ , and since  $f_1$  is one-one,  $K_2 = M$ , and so  $D(K_2, E(K_1, M)) = M$ . The other case is trivial. Thus, the system inverse condition holds and therefore  $G$ ,  $E$ , and  $D$  form a viable definition of a PKCS.

Now assume that there is an algorithm to solve Crack in polynomial time, i.e., some extension of Crack is in PSV. This algorithm can be used to compute an extension of  $f^{-1}$  in polynomial time as follows: if  $y \in \text{range}(f)$ , then  $(y, f^{-1}(y)) = (f(x), x)$ , for some  $x \in \text{range}(g)$ . Thus  $(y, f^{-1}(y))$  is a legal pair. Thus, Crack  $(|y|, y, \#^{|y|})$  is defined and has value  $f^{-1}(y)$ .  $\square$

Condition (iii) is somewhat stronger than needed, for it suffices to assume that an extension  $f'$  of  $f$  exists such that

$$\forall x \forall y [x \in \text{dom}(f) \wedge y \in \text{dom}(f') - \text{dom}(f) \rightarrow f'(x) \neq f'(y)]$$

and such that  $f' \in \text{PSV}$ .

Consider how this system might be used. Suppose  $K_1$  is the public-key and  $n = |f^{-1}(K_1)|$ . A sender who wants to send the message  $M$  with  $|M| = n$ , first checks whether  $f_1(M) = K_1$ . If so, then  $\#^{|K_1|}$  is the cyphertext transmitted and the receiver immediately knows that the cleartext is just  $f_1^{-1}(K_1) = K_2$ . If  $f_1(M) \neq K_1$ , and this is the case nearly always, then  $M$  itself is transmitted. Thus, this system is not a *usable* PKCS, rather, it illustrates by example what was said in § 3.3. Namely, intractability is a necessary component of security, but public-key cryptography requires a.e. security measures.

**4.3. Discrete logarithms.** We provide candidates for weak one-way functions, one-way functions, and problems in  $UP-P$ .

The following partial function  $f$  is examined in [Bra79].

$$\text{Dom}(f) = \{\langle p, g, c \rangle \mid p \text{ is a prime number,} \\ g \text{ is a primitive root mod } p, \text{ and } 1 \leq c \leq p-1\}$$

such that for  $\langle p, g, c \rangle \in \text{dom}(f)$ ,

$$f(\langle p, g, c \rangle) = \langle p, g, g^c(\text{mod } p) \rangle.$$

This partial function is one-one, is honest, and has an extension in PSV (perform the displayed computation for every  $p$ ,  $g$ , and  $c$ ).  $f$  is probably not in PSV because  $\text{dom}(f)$  is not in  $P$  unless both primality and primitive roots can be recognized in polynomial time.

The *discrete logarithm* problem is the problem of computing an extension of the following partial function  $h$ , where  $\text{dom}(h) = \text{dom}(f)$  and for  $\langle p, g, x \rangle \in \text{dom}(h)$ ,

$$h(\langle p, g, x \rangle) = \text{the unique integer } c, \quad 1 \leq c \leq p-1, \quad \text{such that } g^c = x(\text{mod } p).$$

Equivalently, the discrete logarithm problem is the following promise problem.

**input** integers  $p$ ,  $g$ , and  $b$

**promise**  $p$  is a prime number,  $g$  is a primitive root mod  $p$ , and  $1 \leq b \leq p-1$ .

**output** unique  $c$ ,  $1 \leq c \leq p-1$ , such that  $g^c = b(\text{mod } p)$ .

The partial function  $f^{-1}$  has no extension in PSV unless there is a polynomial time algorithm to solve the discrete logarithm problem. Therefore,  $f$  is a candidate for being a weak one-way function.

Feigenbaum [Fei85] has shown that  $f$  can be extended to a total function that is both one-one and computable in polynomial time only if there is a randomized polynomial time algorithm for testing whether an integer  $g$ ,  $1 \leq g \leq p-1$ , is a primitive root for a prime  $p$ . Therefore,  $f$  probably does not satisfy the conditions of Theorem 11.

Here is Feigenbaum's argument. Consider the following *primitive root* problem.

**input** integers  $p$  and  $g$

**promise**  $p$  is a prime number.

**property**  $g$  is a primitive root mod  $p$ .

Suppose that  $\bar{f}$  is an extension of  $f$  that is total, one-one, and computable in polynomial time. If  $g$  is *not* a primitive root, then the mapping  $c \mapsto g^c(\text{mod } p)$  is (at least two)-to-one, when we restrict both domain and range to the interval  $[1, p-1]$ . If, for every  $c$  in  $\{1, \dots, p-1\}$ ,  $\bar{f}(\langle p, g, c \rangle) = \langle p, g, y \rangle$  where  $y = g^c(\text{mod } p)$  and  $1 \leq y \leq p-1$ , then  $\bar{f}$  cannot be one-one. Thus, for a *fixed* prime, a *fixed* nonprimitive root  $g$ , and a *random*  $c \in [1, p-1]$ , the probability is at least  $1/2$  that if  $\bar{f}(\langle p, g, c \rangle) = \langle a, b, y \rangle$ , then one of these three conditions holds:

$$(1) \quad a \neq p \text{ or } b \neq g;$$

$$(2) \quad y > p-1;$$

$$(3) \quad y \neq g^c(\text{mod } p).$$

Thus, the discrete logarithm problem can be solved as follows: For  $k$  independent iterations, choose a random  $c \in [1, p-1]$  and compute  $\bar{f}(\langle p, g, c \rangle)$ . If  $g$  passes all  $k$  tests, then, with probability of error at most  $1/2^k$ ,  $g$  is a primitive root mod  $p$ . If one of the results satisfies one of conditions 1, 2, or 3, then  $g$  is not a primitive root mod  $p$ .

The primitive root problem is not believed to have a solution in  $R$ ; hence this is evidence against the existence of  $\bar{f}$ .

Now we will show that a modification of  $f$  is a candidate for being a one-way function. Observe that  $\text{dom}(f) \in NP$  by a result of Pratt [Pra75]. Hence, there exists

a polynomial  $q$  and a polynomial time recognizable relation  $R$  so that  $p$  is a prime number and  $g$  is a primitive root mod  $p \Leftrightarrow \exists y_{|y| \leq q(|p|)} R(p, g, y)$ .

Johnson [Joh85] suggests that the following partial function is a candidate for being a one-way function.

$$f_1(\langle p, g, y, c \rangle) = \begin{cases} \langle p, g, y, g^c \pmod{p} \rangle & \text{if } 1 \leq c \leq p-1, |y| \leq q(|p|), \text{ and } R(p, g, y), \\ \uparrow & \text{else.} \end{cases}$$

The partial function  $f_1$  is in PSV, and, of course,  $f_1$  is one-one and honest. It is believed that discrete logarithms remain difficult to compute even given a “short proof” that  $g$  is a primitive root mod  $p$  for a prime number  $p$ . Thus,  $f_1^{-1}$  is not believed to be computable in polynomial time.

Consider the promise problem  $(Q_{f_1^{-1}}, R_{f_1^{-1}})$  (except that the output is not padded). Then,  $R_{f_1^{-1}} = \{(p, g, y, b, x) \mid 1 \leq b \leq p-1, 1 \leq x \leq p-1, |y| \leq q(|p|), R(p, g, y), \text{ and, the unique } c \text{ such that } 1 \leq c \leq p-1 \text{ and } g^c = b \pmod{p} \text{ is less than } x\}$ . Hence,  $R_{f_1^{-1}} \in \text{UP}$ . Therefore, if  $f_1$  is a one-way function, then, since  $(Q_{f_1^{-1}}, R_{f_1^{-1}})$  has no solution in P, the set  $R_{f_1^{-1}} \in \text{UP-P}$ .

**5. Almost-everywhere complexity measures.** Given two partial functions  $f$  and  $g$ ,  $g$  is an *approximation* of  $f$  for all  $x \in \text{dom}(g) \cap \text{dom}(f)$ ,  $g(x) = f(x)$ . One might wish to design a PKCS such that every easily computable function  $g$  approximates Crack only for finitely many inputs, i.e.,  $\text{dom}(g) \cap \text{dom}(\text{Crack})$  is finite. This is an unobtainable goal. Namely, for any polynomial  $q$ , Crack can be computed in polynomial time for  $q(n)$  many input triples of the form  $(n, K_1, C)$  by the following trivial algorithm. Sequentially search all strings of length  $n$  until either a string  $M$  is found such that  $E(K_1, M) = C$  or  $q(n)$  many strings are searched. For every  $n$ , the algorithm solves the cracking problem in polynomial time for a polynomial number of input triples of the form  $(n, K_1, C)$ . Therefore, it is not possible to have  $\text{dom}(f) \cap \text{dom}(\text{Crack})$  finite for arbitrary approximations.

On the other hand, observe that the domain of the procedure just described is a sparse set. We want to consider security measures that reflect the limit of what can be achieved, and so we are led to the following definitions.

A partial function  $f$  is *partially immune* to a complexity class of functions  $\mathcal{F}$  if  $\text{dom}(f)$  is not sparse and for every approximation  $g$  of  $f$ ,  $g \in \mathcal{F}$  implies  $\text{dom}(g) \cap \text{dom}(f)$  is a sparse set. A set  $A$  is *partially immune* to a complexity class of sets  $\mathcal{C}$  if  $A$  is not sparse and every subset of  $A$  in  $\mathcal{C}$  is a sparse set.

If a partial function  $f$  is partially immune to PSV, then no extension of  $f$  is in PSV. It is not good enough to consider only approximations  $g$  which fulfill  $\text{dom}(g) \subseteq \text{dom}(\text{Crack})$ . If  $\text{dom}(\text{Crack})$  is immune to P, then for every approximation  $g \in \text{PSV}$  of Crack such that  $\text{dom}(g) \subseteq \text{dom}(\text{Crack})$ ,  $\text{dom}(g)$  is finite. Nevertheless, Crack might be extendable to a total function in PSV, and therefore not secure at all.

A partial function  $f$  may be partially immune to PSV without  $\text{dom}(f)$  being partially immune to P and vice versa. According to the following theorem the implication in one direction holds for PKCS such that  $\text{Crack} \in \text{UPSV}_g$  (cf. Proposition 8).

**THEOREM 12.** *If  $f \in \text{UPSV}_g$  and  $\text{dom}(f)$  is partially immune to P, then  $f$  is partially immune to PSV.*

*Proof.* Let  $g \in \text{PSV}$  be an approximation to  $f$ . The following algorithm shows that  $\text{dom}(f) \cap \text{dom}(g) \in \text{P}$ : on input  $x$ , **if**  $(x, g(x)) \in \text{graph}(f)$  **then** accept **else** reject. It follows that this set is sparse.  $\square$

Recall that a set  $A$  is bi-immune to P if and only if it is a.e. complex. The following proposition states that partial immunity to PSV enjoys the analogous property.

**PROPOSITION 9.** *The following are equivalent.*

- (a)  $f$  is partially immune to PSV.

(b) If  $M$  computes an extension of  $f$ , then  $M$  requires more than polynomial time on  $\text{dom}(f)$  except on a sparse set.

Now, suppose  $f$  is partially immune to PSV, and let  $g$  be any approximation of  $f$ . For most input words  $x$  in the domain of  $f$ ,  $g(x)$  is undefined, but when  $g(x)$  is defined, the output value is correct, i.e.,  $g(x) = f(x)$ . It may seem that  $f$  cannot have any good heuristics, but this is not in general true. Approximations as we have defined them satisfy a severe condition—they never give the wrong answer. In many applications, cryptography included, it may be more appropriate to consider polynomial time-bounded Turing machines that compute the correct answer for some inputs and that compute wrong answers for other inputs, and to concern oneself with the relative frequency of these two events. These considerations as applied to languages have led to a study of polynomial time random languages [Wil83], [Huy85]. Briefly, a language  $L$  is *polynomial time random* if every polynomial time algorithm is no more successful at recognizing  $L$  than is guessing. Huynh [Huy85] shows that bi-immunity and polynomial time randomness are orthogonal properties.

Now we consider public-key cryptosystems for which good heuristics to compute Crack do not exist. We formulate this for arbitrary  $f$  as follows:

(2) For every partial function  $g \in \text{PSV}$   $\{x \mid g(x) = f(x)\}$  is a sparse set.

Condition (2) is not in general equivalent to partial-immunity to PSV. But, surprisingly, as a consequence of the next theorem, these two conditions are equivalent for the cracking problem of public-key cryptosystems. Therefore, we define a PKCS to be *secure with respect to PSV* if Crack satisfies condition (2).

**THEOREM 13.** *If  $f$  is a partial function such that the promise problem  $(\text{dom}(f) \times \Sigma^*$ ,  $\text{graph}(f))$  has a solution in  $\text{P}$ , then each of the following is equivalent.*

- (a) *For every total function  $g$ ,  $g \in \text{PSV}$ ,  $\{x \mid g(x) = f(x)\}$  is a sparse set.*
- (b) *For every partial function  $g$ ,  $g \in \text{PSV}$ ,  $\{x \mid g(x) = f(x)\}$  is a sparse set.*
- (c)  *$f$  is partially immune to PSV.*

*Proof.* To show that (a) implies (b), assume (a) and let  $g \in \text{PSV}$ . Define  $g'(x) = g(x)$ , if  $x \in \text{dom}(g)$ , and  $g'(x) = x$ , if  $x \notin \text{dom}(g)$ .  $g'$  is defined for all  $x$  and, since  $\text{dom}(g) \in \text{P}$ ,  $g' \in \text{PSV}$ . Thus, by assumption,  $\{x \mid g'(x) = f(x)\}$  is sparse. Since  $\{x \mid g(x) = f(x)\} \subseteq \{x \mid g'(x) = f(x)\}$ ,  $\{x \mid g(x) = f(x)\}$  is sparse as well.

Now assume (b) and let us show that  $f$  is partially immune. Let  $g \in \text{PSV}$  such that  $\forall x(x \in \text{dom}(f) \cap \text{dom}(g) \rightarrow f(x) = g(x))$ . Then,  $\text{dom}(f) \cap \text{dom}(g) = \{x \mid g(x) = f(x)\}$  and so, by assumption,  $\text{dom}(f) \cap \text{dom}(g)$  is sparse.

Finally, we use the hypothesis that  $(\text{dom}(f) \times \Sigma^*$ ,  $\text{graph}(f))$  has a solution in  $\text{P}$  to show that with this assumption (c) implies (a). Let  $S \in \text{P}$  be a solution, assume (c), and let  $g \in \text{PSV}$  be a total function. Define  $g'(x) = g(x)$ , if  $(x, g(x)) \in S$ , and to be undefined otherwise. Clearly,  $g' \in \text{PSV}$  and we show now that for every word  $x$ ,  $x \in \text{dom}(f) \cap \text{dom}(g')$  implies  $f(x) = g'(x)$ . Given  $x \in \text{dom}(f) \cap \text{dom}(g')$ ,  $(x, g(x)) \in \text{dom}(f) \times \Sigma^*$  and so the promise is satisfied. Therefore,  $(x, g(x)) \in S \Leftrightarrow f(x) = g(x)$ . Since  $x \in \text{dom}(g')$ ,  $g'(x) = g(x)$ , and  $(x, g(x)) \in S$ , and therefore  $g'(x) = g(x) = f(x)$ .

It follows that  $\text{dom}(f) \cap \text{dom}(g')$  is sparse, for we are assuming that  $f$  is partially immune. Next we will observe that  $\{x \mid f(x) = g(x)\} \subseteq \text{dom}(f) \cap \text{dom}(g')$ , from which the claim in assertion (a) follows. If  $f(x) = g(x)$ , then  $x \in \text{dom}(f)$  and so  $(x, g(x)) \in S \Leftrightarrow f(x) = g(x)$ . Then, by definition  $x \in \text{dom}(g')$  and so  $x \in \text{dom}(f) \cap \text{dom}(g')$ , and the proof is complete.  $\square$

Observe from the proof of the theorem that condition (2) implies  $f$  is partially immune to PSV for all  $f$ . To complete the argument that condition (2) is equivalent to partial immunity for the cracking problem of public-key cryptosystems, recall that

the encoding algorithm  $E$  is computable in polynomial time and observe that the set  $S = \{(n, K_1, C, M) \mid |M| = n \text{ and } E(K_1, M) = C\}$  is a solution in  $P$  of  $(\text{Crack} \times \Sigma^*, \text{graph}(\text{Crack}))$ . Therefore, the following corollary is proved.

**COROLLARY 8.** *A PKCS is secure with respect to PSV if and only if Crack is partially immune to PSV.*

Next we will examine security with respect to functions that are computed probabilistically in polynomial time with bounded error. With that exception, we stress that the security measure we have been discussing represents a theoretical limit of what can be achieved and may even be stronger than what a usable system need attain. For example, Goldwasser and Micali [GM84] permit (when the message space has normal distribution) a super-polynomial number of messages of size  $n$  to be cracked.

**5.1. Cryptanalysis by probabilistic algorithms.** The informal view does not change. If a cryptanalyst has available a transducer  $T$  that on many inputs to Crack probabilistically computes Crack with bounded error probability, then the PKCS under attack is rendered useless, even if  $T$  behaves arbitrarily on other inputs, and even if it is not possible to decide when  $T$  is correctly computing Crack. Formally, we make the following definitions.

Let  $T$  be a nondeterministic transducer as described in § 2.2 and let  $p$  be a polynomial. A partial function  $f_{T,p}$  is defined as follows:

$$\text{dom}(f_{T,p}) = \{x \mid \text{every computation of } T \text{ on input } x \text{ halts within } p(|x|) \text{ steps} \\ \text{and there exists a string } y \text{ such that } \Pr(T(x) = y) \geq 3/4\}.$$

For each string  $x \in \text{dom}(f_{T,p})$ ,

$$f_{T,p}(x) = \text{unique } y \text{ such that } \Pr(T(x) = y) \geq 3/4.$$

(The choice of  $3/4$  is somewhat arbitrary and  $1/2 + \epsilon$ , for fixed  $\epsilon > 0$ , would suffice [BG81].)

**DEFINITION 3.**  $\text{BPPSV} = \{f_{T,p} \mid T \text{ is a transducer and } p \text{ is a polynomial}\}$ .

A definition for total functions was given in [RZ83] and this definition agrees with that one for total functions. Also, note that if a language  $L$  belongs to BPP, then the characteristic function of  $L$  belongs to BPPSV.

**THEOREM 14.** *If the promise problem  $(\text{dom}(f) \times \Sigma^*, \text{graph}(f))$  has a solution in  $P$ , then  $f$  is partially immune to BPPSV if and only if for every partial function  $g \in \text{BPPSV}$ ,  $\{x \mid g(x) = f(x)\}$  is a sparse set.*

The reader can construct a proof of this theorem easily from the proof of Theorem 13. In Theorem 13, the proof that (a) implies (b) depends on the fact that  $f \in \text{PSV}$  implies  $\text{dom}(f) \in P$ . This property does not seem to hold for  $f \in \text{BPPSV}$ , and so we do not include the corresponding assertion in this theorem.

Define a PKCS to be *secure with respect to BPPSV* if for every partial function  $g \in \text{BPPSV}$ ,  $\{(n, K_1, C) \mid g(n, K_1, C) = \text{Crack}(n, K_1, C)\}$  is a sparse set.

**COROLLARY 9.** *A PKCS is secure with respect to BPPSV if and only if Crack is partially immune to BPPSV.*

**5.2. Discussion.** Now that almost everywhere security measures have been studied, it might be appropriate to revisit the notion of one-way function. Suppose one-way functions are redefined based on the intuition that they should be difficult to invert on *most* inputs. Namely, let us say that a function is one-way if it is one-one, honest, computable in polynomial time, and its inverse is partially immune to BPPSV. Though we will not carry out the development here, it is possible to revisit § 4 and to obtain analogous conclusions.

The salient feature of public-key cryptosystems, as studied in this paper, is that

messages are encrypted deterministically. A number of researchers have been actively investigating systems that encrypt messages probabilistically [Gol84], [GM84], [BG85]. An advantage of this technique is that it makes it possible to send single bits securely over insecure channels. Improving a result of Shamir [Sha81], Blum and Micali [BM84] introduced the notion of *strong pseudorandom generator*. Here we do not need to say what strong pseudorandom generators are; we mention only that they have known applications to cryptography, that they have been used to design public-key cryptosystems [BM84], [BG85], but that their exact relationship to public-key cryptosystems remains unclear. By the latter assertion we mean that there is no theorem known of the form “strong pseudorandom generators imply secure public-key cryptosystems.” The papers [Yao82], [Lev85] each show that the existence of certain types of one-way functions imply the existence of pseudorandom generators. Thus, even though existence of one-way functions as they are defined in [Lev85] are in fact equivalent to existence of strong pseudorandom generators, the exact relationship between one-way functions and public-key cryptosystems remains unclear. It is interesting to observe that Yao’s notion of one-way function is similar to the one given in the previous paragraph in that both notions assert that one-way functions are hard to invert on most inputs. The fractions of inputs for which the inverses are difficult to compute are different.

**6. Oracles.** The first significant relativization results having to do with cryptography are due to Brassard [Bra83b], [Bra81]. In [Bra83b] it is shown that there is a recursive oracle relative to which there is a public-key cryptosystem that is secure with respect to PSV, and in [Bra81] this result is extended to security with respect to BPPSV.

We showed in this paper that there exist PKCS such that  $\text{Crack} \in \text{UPS}V - \text{PS}V$  only if  $P \neq \text{UP}$ , that there exist PKCS that cannot be cracked in polynomial time only if  $\text{NP} - P$  contains a disjoint pair of  $P$ -inseparable sets, and that there exist PKCS that are secure with respect to PSV only if there exist functions that are partially immune to PSV. Here we state relativization results that establish possibilities of existence and relationships between the pertinent complexity theoretic necessary conditions.

**6.1. The class UP.** Rackoff [Rac82] obtained oracles  $A$  and  $B$  such that  $P^A \neq \text{UP}^A = \text{NP}^A$  and  $P^B = \text{UP}^B \neq \text{NP}^B$ . Geske and Grollmann [GG86] obtained a number of strong relativized separation results for UP, among which we mention only the following: There exists a recursive oracle  $C$  and a nonsparse language  $L$  such that  $P^C \neq \text{UP}^C \neq \text{NP}^C$  and  $L \in \text{NP}^C$  is partially immune to  $\text{UP}^C$ . (In fact,  $L \in \text{R}^C$ , cf. [Gil77] and [AM77].)

The existence of functions in UPSV that are partially immune to BPPSV is a necessary condition for there to exist secure PKCS with  $\text{Crack} \in \text{UPS}V$ . Such functions exist if UP contains a set which is partially immune to R for it is well known that  $\text{R} \subseteq \text{BPP}$  [Gil77].

**6.2. Inseparability.** Since Theorem 5 holds for all oracles, the oracle  $C$  for which  $P^C \neq \text{UP}^C$  is also an oracle for which  $P$ -inseparable sets in NP exist. We do not believe that  $P$ -inseparable sets can be obtained from the hypothesis “ $P \neq \text{NP}$ .” Note that this conviction is paramount to saying that in order for there to exist PKCS that are secure in even the weakest sense,  $P \neq \text{NP}$  is not a sufficiently strong complexity theoretic hypothesis. However, we have not been successful at obtaining an oracle relative to which  $P \neq \text{NP}$  and  $P$ -inseparable sets do not exist. Such an oracle  $X$  also must satisfy  $P^X = \text{UP}^X = \text{NP}^X \cap \text{co-NP}^X$  and, trivially,  $\text{EXP}^X \not\subseteq \text{NP}^X$ , where  $\text{EXP} = \bigcup \{ \text{DTIME}(2^{cn}) \mid c > 0 \}$  (because  $A \in \text{EXP} - P$  implies  $\bar{A} \in \text{EXP} - P$ , and  $A$  and  $\bar{A}$  are  $P$ -inseparable).

The NP-complete set  $K$  (cf. Theorem 6) belongs to EXP. Hence  $\bar{K}$  is in EXP and

$K$  and  $\bar{K}$  can be separated only by  $K$  which is NP-hard. Thus, EXP contains disjoint sets which can be separated only by NP-hard sets. An oracle is constructed in [GH83] relative to which  $\text{EXP} \subseteq \text{NP}$ . Therefore, relative to this oracle NP contains disjoint sets that can be separated by NP-hard sets only. *We have not been able to construct an oracle  $Y$  relative to which the conjecture is true.* Such an oracle must satisfy  $\text{UP}^X \neq \text{NP}^X \neq \text{co-NP}^X$  and  $\text{EXP}^X \not\subseteq \text{NP}^X$ .

## SOLVING SIMULTANEOUS MODULAR EQUATIONS OF LOW DEGREE\*

JOHAN HASTAD†

**Abstract.** We consider the problem of solving systems of equations  $P_i(x) \equiv 0 \pmod{n_i}$   $i = 1 \cdots k$  where  $P_i$  are polynomials of degree  $d$  and the  $n_i$  are distinct relatively prime numbers and  $x < \min(n_i)$ . We prove that if  $k > d(d+1)/2$  we can recover  $x$  in polynomial time provided  $\min(n_i) > 2^{d^2}$ . As a consequence the RSA cryptosystem used with a small exponent is not a good choice to use as a public-key cryptosystem in a large network. We also show that a protocol by Broder and Dolev [Proceedings on the 25th Annual IEEE Symposium on the Foundations of Computer Science, 1984] is insecure if RSA with a small exponent is used.

**Key words.** cryptography, lattice algorithm, RSA, coin flipping, modular equations

**AMS(MOS) subject classifications.** 68Q20, 11H99, 11Y99

**1. Introduction.** Let us start with some cryptographic motivation. The RSA function [10] is defined as  $f(x) \equiv x^e \pmod{n}$ . Here  $n$  is usually taken of the form  $n = pq$  where  $p$  and  $q$  are two large primes and  $e$  is an integer relatively prime to  $(p-1)(q-1)$ . Using these parameters the function is 1-1 when restricted to  $1 \leq x \leq n$ ,  $(x, n) = 1$ . Furthermore the function is widely believed to be a *trapdoor function*, i.e., given  $n$  and  $e$  it is easy to compute  $f(x)$  and given  $f(x)$  it is also easy to recover  $x$  provided one has some secret information but otherwise it is difficult to compute  $x$ . In this case the secret information is the factorization of  $n$ .

The RSA function can be used to construct a deterministic Public Key Cryptosystem (PKC) in the following way: Each user  $B$  in a communication network chooses two large primes  $p$  and  $q$  and multiplies them together and publishes the result  $n_B$  together with a number  $e_B$  which is relatively prime to  $(p-1)(q-1)$ . He keeps the factorization of  $n_B$  as his private secret information. If any user  $A$  in the system wants to send a secret message  $m$  to another user  $B$  she retrieves  $B$ 's published information, computes  $y \equiv m^{e_B} \pmod{n_B}$  and sends  $y$  to  $B$ .  $B$  now obtains the original message using his secret information, while somebody who does not know the secret information presumably faces an intractable computational task.

Public Key Cryptosystems are different and more complex objects than are trapdoor functions. The reason is that a PKC involves a protocol consisting of several steps. For example the use of RSA in a PKC may present obstacles that did not occur when we considered it as a trapdoor function. Several people (including Blum, Lieberherr and Williams) have observed the following possible attack. Assume that 3 is chosen as the exponent and that  $A$  wants to send the same message  $m$  to users  $U_1$ ,  $U_2$  and  $U_3$ . She will compute and send  $y_i \equiv m^3 \pmod{n_i}$ ,  $i = 1, 2, 3$ . If someone gains access to  $y_1$ ,  $y_2$  and  $y_3$  then by using the fact that  $n_1$ ,  $n_2$  and  $n_3$  will be relatively prime he can combine the messages by Chinese remaindering to get  $m^3 \pmod{n_1 n_2 n_3}$  and since  $m^3 < n_1 n_2 n_3$  he can recover  $m$ . In general if the exponent is  $e$  the number of messages needed is  $e$ .

A natural question is therefore: Is there a better way to send the same message to many people using this PKC?

\* Received by the editors September 16, 1985; accepted for publication (in revised form) July 7, 1986.

† Massachusetts Institute of Technology, Laboratory for Computer Science, Cambridge, Massachusetts 02139. This work was supported by an IBM fellowship, and was partially supported by National Science Foundation grant DCR-8509905.

A common heuristic tells us to use a “time stamp.” Instead of sending the same message  $m$  to everybody one attaches the time and thus sends the encryption of  $2^{|t_i|}m + t_i$  where  $2^{|t_i|}m$  is the shifted message and  $t_i$  is the time when the message is sent to user  $U_i$ . This time will be different for the different receivers. The previous attack then fails.

If we assume that the times  $t_i$  are known to the cryptanalyst we are led to consider the following computational problem (for  $e = 3$ ).

Given  $(a_i m + b_i)^3 \pmod{n_i}$  where all the  $a_i$  and  $b_i$  are known is it possible to recover  $m$  in polynomial time?

We will prove in § 3 that the answer is YES if the number of similar messages is at least 7. In fact we will prove this as a special case of our main result, which is: Given a set of  $k$  polynomial equations

$$P_i(x) \equiv 0 \pmod{n_i}, \quad i = 1, \dots, k$$

each of degree  $\leq d$ , it is possible to recover all solutions in time polynomial in both  $k$  and  $\log n_i$  if  $k > d(d + 1)/2$  provided  $\min(n_i) > 2^{d^2}$ .

Observe that the described attack does not work if the values of the  $t_i$  are not known to the cryptanalyst. Thus if a random padding were used or if the time stamp were unknown then the present attack would not work. However, this weakness seems severe enough so that if one uses RSA as a PKC then, as a matter of prudence, one should use a large exponent or, even better, a probabilistic encryption scheme [3], [7] based on RSA. By [1], [3] this can be done with as much efficiency as in the deterministic case.

The outline of the paper is as follows. In § 2 we state some results from geometry of numbers which will be needed in later sections. In § 3 we state and prove our main result and in § 4 we derive some cryptographic applications.

**2. Background from geometry of numbers.** The main tool in our algorithm will be the use of lattices. In this section we will gather the relevant background information. A *lattice*  $L$  is defined to be the set of points

$$L = \left\{ y \mid y = \sum_{i=1}^n a_i \vec{b}_i, a_i \in \mathbf{Z} \right\}$$

where  $\vec{b}_i$  are linearly independent vectors in  $\mathbf{R}^n$ . The set  $\vec{b}_i$  is called a *basis* for the lattice and  $n$  is the dimension. The *determinant* of a lattice is defined as the absolute value of the determinant of the matrix with rows  $\vec{b}_i$ . It is not hard to see that the determinant is independent of the choice of basis. The length of the shortest nonzero vector in the lattice is denoted by  $\lambda_1$ . Let us recall the following well-known fact:

**THEOREM (Minkowski).**  $\lambda_1 \leq \gamma_n^{1/2} (\det(L))^{1/n}$  where  $\gamma_n$  is Hermite’s constant.

Hermite’s constant is not known exactly for  $n > 8$  but Minkowski’s convex body theorem [5, ix.7] implies that  $\gamma_n \leq n$ . Lenstra et al. showed in [8] that it was possible to find a vector in  $L$  of length at most  $2^{(n-1)/2} \lambda_1$  in polynomial time. From their proof we can, however, derive a slightly better bound in the present case.

**THEOREM (LLL).** *Given a lattice  $L$  as a basis for integer vectors of length at most  $B$  we can find a vector  $\vec{b}$  in time  $O(n^6 (\log B)^3)$  which satisfies  $\|\vec{b}\| \leq 2^{(n+1)/4} (\det(L))^{1/n}$ .*

This gives an effective variant of Minkowski’s theorem. Here  $\|\vec{b}\|$  is the euclidean length of the vector  $\vec{b}$ . The bound on the running time assumes that multiplication of  $r$  bit numbers is done by classical arithmetic taking  $O(r^2)$  steps. Using faster multiplication routines the bounds can be improved by a factor close to  $n \log B$ . Armed with this information we return to the original problem.

**3. Main theorem.** Let us start by fixing some notation. Let  $N = \prod_{i=1}^k n_i$  and  $n = \min n_i$ . Now we can state the problem formally:

*Problem.* Given a set of  $k$  equations  $\sum_{j=0}^d a_{ij}x^j \equiv 0 \pmod{n_i}, i = 1, \dots, k$ . Suppose that the system has a solution  $x < n$  and the numbers  $n_i$  are pairwise relatively prime. Can we find such a solution efficiently?

Before we state our main result let us give the basic ideas. Define  $u_j < N$  to be the Chinese remaindering coefficients, i.e.,  $u_j \equiv \delta_{ij} \pmod{n_i}$  ( $\delta_{ij} = 1$  if  $i = j$  and 0 otherwise). We can combine the equations to a single equation using the Chinese Remainder Theorem.

$$0 \equiv \sum_{j=0}^d x^j \sum_{i=1}^k u_i a_{ij} \equiv \sum_{j=0}^d x^j c_j \pmod{N}.$$

One of the important parts of the entire paper is the following simple lemma.

LEMMA 1. *If  $|c_j| < N/(d+1)n^j$  and we have at least one nonzero  $c_j$  then we can find all  $x$  satisfying  $x < n$  and  $\sum_{j=0}^d c_j x^j \equiv 0 \pmod{N}$  in time  $O((d \log N)^3)$ .*

*Proof.* If  $|c_j| < N/(d+1)n^j$  then

$$\left| \sum_{j=0}^d c_j x^j \right| \leq \sum_{j=0}^d |c_j| n^j < N.$$

Thus the condition  $\sum_{j=0}^d c_j x^j \equiv 0 \pmod{N}$  implies  $\sum_{j=0}^d c_j x^j = 0$ . In other words  $x$  solves the equation over the integers and to prove the lemma we just need the fact that we can solve polynomial equations over the integers quickly. Since this is a special case in which we are looking for an integer solution, we can proceed as follows. Find all linear factors modulo a small prime. Now apply Hensel lifting to obtain these factors modulo a large power of the prime and finally check if any of the roots is a root over the integers. The estimate for the running time in the lemma is correct but not the best possible.  $\square$

The condition of Lemma 1 is quite unlikely to be fulfilled when we start with a general set of equations. In spite of this, Lemma 1 will be one of our main tools for proving our main result, which is as follows.

THEOREM. *Given a set of equations  $\sum_{j=0}^d a_{ij}x^j \equiv 0 \pmod{n_i}, i = 1, 2, \dots, k$  where the moduli  $n_i$  are pairwise relatively prime and  $\gcd(\langle a_{ij} \rangle_{j=0}^d, n_i) = 1$  for all  $i$ . Then we can find all  $x < n$  satisfying the equations in time  $O(d^6(\log N)^3)$  if*

$$N > n^{d(d+1)/2} 2^{(d+2)(d+1)/4} (d+1)^{(d+1)}.$$

As before,  $N = \prod_{i=1}^k n_i, n = \min n_i, d$  is the degree of the equations and  $k$  is the number of equations. By  $\gcd(\langle a_{ij} \rangle_{j=0}^d, n_i)$  we mean the greatest common divisor of all  $d+2$  numbers.

*Proof.* The idea is to use Lemma 1, though it is unlikely that it will apply to our equations directly. However, we have an extra degree of freedom. We can multiply the equation by an arbitrary constant  $S$  and we still get a valid equation. Using this trick we will be able to make the coefficients small. Thus, we want to make  $Sc_i \pmod{N}$  less than  $N/n^i(d+1)$  in absolute value. Set up the following lattice  $L$  of dimension  $d+2$ :

$$\begin{aligned} \vec{b}_1 &= (c_0, nc_1, n^2c_2, \dots, n^dc_d, 1/(d+1)), \\ \vec{b}_2 &= (N, 0, 0, \dots, 0, 0), \\ \vec{b}_3 &= (0, nN, 0, \dots, 0, 0), \\ \vec{b}_4 &= (0, 0, n^2N, \dots, 0, 0), \\ &\vdots \\ \vec{b}_{d+2} &= (0, 0, 0, \dots, n^dN, 0). \end{aligned}$$

Let us see why this lattice is relevant to our purposes. Look at a generic vector  $S\vec{b}_1 + \sum_{i=2}^{d+2} s_i \vec{b}_i$ . Call the  $i$ th coordinate  $d_i$ . From the definition, it follows that  $d_i$  is

divisible by  $n^{i-1}$  and  $d_i/n^{i-1} \equiv S c_{i-1} \pmod{N}$ . Thus if we find a vector  $\vec{b} \in L$  satisfying  $\|\vec{b}\| < N/(d+1)$  we know that  $|d_i| < N/(d+1)$  and we get the desired bound for  $S c_i \pmod{N}$ . The last coordinate is there to prevent  $S = N$ , which would make  $d_i = 0$  for  $i = 1, \dots, d+1$ .

We have only one term in the expansion of the determinant and we get

$$\text{Det}(L) = \frac{n^{d(d+1)/2} N^{d+1}}{(d+1)}.$$

Using the theorem of LLL in § 2 we know that we can find a vector  $\vec{b}$  in  $L$  that satisfies

$$\|\vec{b}\| \leq 2^{(d+1)/4} \left( \frac{n^{d(d+1)/2} N^{d+1}}{d+1} \right)^{1/(d+2)}.$$

As observed above we need  $\|\vec{b}\| < N/(d+1)$  in order to get the desired bound for the coefficients and thus we need,

$$2^{(d+1)/4} \left( \frac{n^{d(d+1)/2} N^{d+1}}{d+1} \right)^{1/(d+2)} < \frac{N}{d+1}.$$

Raising both sides to the  $d+2$  power and rearranging we see that this is equivalent to the condition in the theorem.

To finish the proof we need to prove that we have at least one nonzero coefficient. Since  $\|\vec{b}\| < N/(d+1)$ , we see by looking at the last coordinate that the coefficient  $S$  multiplying  $\vec{b}_1$  satisfies  $|S| < N$ . Furthermore we know that  $S \neq 0$  since all nonzero vectors with  $S = 0$  are of length at least  $N$ . This means that there is an  $n_i$  such that  $S \not\equiv 0 \pmod{n_i}$ . Look at the equation modulo this  $n_i$ . Using that  $\gcd(\langle a_{ij} \rangle_{j=0}^d, n_i) = 1$  we see that the equation is nontrivial. The bottleneck in the computation is the lattice computation and this gives the running time of the algorithm.  $\square$

*Remark.* One interesting open question is whether we can solve the problem with fewer equations. It does not seem possible to use this line of attack with substantially fewer equations. To see this one might argue as follows:

The probability that  $|c_j| < N/(d+1)n^j$  for  $j = 0, 1, \dots, d$  for a fixed  $S$  is approximately  $n^{-d(d+1)/2}$  and this would indicate that we should have  $n^{d(d+1)/2}$  different  $S$  to choose between; we would, therefore, need at least  $d(d+1)/2$  equations.

**4. Cryptographic applications.** We get some immediate applications of the main theorem.

*APPLICATION 1.* *Sending linearly related messages using RSA with low exponent  $e$  is insecure. Sending more than  $e(e+1)/2$  messages enables an adversary to recover the messages provided that the moduli  $n_i$  satisfy  $n_i > 2^{(e+2)(e+1)/4}(e+1)^{(e+1)}$ .*

*Proof.* Suppose we are given the encryption of  $k$  linearly dependent messages. We expand the  $e$ th power and we get  $k$  equations of degree  $e$  with the different moduli used  $n_i$ . We now apply the main theorem. We need to verify that the conditions of the main theorem are satisfied. If one of the gcd conditions is not satisfied we can obtain the message by factoring one of the  $n_i$ . Finally,

$$N = \prod_{i=1}^k n_i \geq n_1 \prod_{i=2}^{d(d+1)/2+1} n_i > 2^{(e+1)(e+2)/4}(e+1)^{(e+1)} n^{d(d+1)/2}$$

and hence we can apply our main theorem.  $\square$

If one is prepared to do computation which is exponential in the number of equations, one can also attack the cryptosystem given exactly  $e(e+1)/2$  messages. The way to proceed is to use an almost identical lattice. The only difference is to replace

the last coordinate of the first vector with  $2^{(e+2)/4}$ . Now the algorithm of LLL finds a vector in the lattice of length at most  $N2^{(e+2)/4}$ . This implies in particular that  $c_i < N2^{(e+2)/4}n^{-i}$ . Now it is no longer possible to conclude that  $x$  solves the equation over the integers. We do know, however, that the right-hand side is a multiple of  $N$  not exceeding  $e2^{(e+2)/4}N$  and so we try all  $e2^{(e+2)/4}$  possibilities.

Another way of encrypting messages was proposed by Rabin [9]. He uses  $f(x) \equiv x^2 \pmod{n}$  where also here  $n$  is chosen to be a specific composite number for each user. Using the same methods we get:

**APPLICATION 2.** *Sending linearly related messages using the Rabin encryption function is insecure. If three such messages are sent it is possible to retrieve the message in polynomial time.*

Broder and Dolev proposed a protocol for flipping a coin in a distributed system [4]. Two of their essential ingredients were Shamir's method of sharing a secret [11] and the use of a deterministic PKC. The secret they use is the constant coefficient of a polynomial of degree  $t$  over a finite field. The secret is distributed by evaluating the polynomial at a given set of points. It is easy to see that  $t+1$  pieces, each consisting of the value of the polynomial at a point, are enough to get the secret back while  $t$  pieces are not sufficient to determine the polynomial. Broder and Dolev claim that  $t$  pieces are insufficient to find the secret, even in the presence of the encryption of other pieces. This is not correct if the cryptosystem used is RSA with small exponent. This is because when knowing  $t$  pieces the secret enters linearly in the remaining pieces and hence we can use Application 1.

**APPLICATION 3.** *The protocol by Broder and Dolev is insecure if RSA with small exponent is used.*

Of course if other cryptosystems are used then this attack does not work. A different type of attack on the Broder-Dolev protocol has been proposed by Benny Chor [6]. This attack just relies on the protocol and not on the cryptosystem. A provably secure protocol has been designed by Awerbuch et al. [2]. For further discussion of coin-flipping protocols see [2] and [4].

Finally we remark that there does not seem to be any way to extend the above attack to RSA with large exponent. The reason is that the integers involved are too big even to write down. There is still a large amount of structure present and it would be interesting to investigate whether this structure could be exploited to yield a successful cryptanalytic attack on RSA with large exponent.

**Acknowledgments.** I would like to thank Silvio Micali, Shafi Goldwasser and Benny Chor for suggesting the problem, listening to early solutions and suggesting improvements and simplifications. They also pointed out the incorrectness in the proof of Broder and Dolev. I am also very grateful to Ron Rivest for greatly simplifying the proof and finally I would like to thank Jeff Lagarias for many helpful comments.

## UNIQUE EXTRAPOLATION OF POLYNOMIAL RECURRENCES\*

JEFFREY C. LAGARIAS† AND JAMES A. REEDS†

**Abstract.** Let a sequence of  $k$ -dimensional vectors  $\mathbf{x}_0, \mathbf{x}_1, \dots$  (over a ring  $A$ ) be determined by a polynomial recurrence of form  $\mathbf{x}_n = T(\mathbf{x}_{n-1})$ , where  $T: A^k \rightarrow A^k$  itself is known to be a polynomial map in  $k$  variables of degree at most  $d$  but is otherwise unknown. We show that there is a finite  $N$  such that the entire sequence  $\{\mathbf{x}_n : n \geq 0\}$  can be deduced from the first  $N+1$  terms  $\mathbf{x}_0, \mathbf{x}_1, \dots, \mathbf{x}_N$  alone. The number  $N = \phi(d, k, A)$  depends on  $d$  and  $k$  and the ring  $A$  but not on  $T$ .

Let  $\phi^*(d, k)$  denote the maximum of  $\phi(d, k, A)$  over all commutative rings with unit. Then we show that  $\phi^*(d, k) < \infty$ . In particular,  $\phi^*(d, 1) = d + 1$  and  $\phi^*(1, k) = k + 1$ . In the general case  $\phi^*(d, k) \cong \binom{k+d}{k}$  and equality does not always hold because  $\phi^*(2, 2) \cong 7$ . In addition, we show that for each  $k$  that  $\max \{\phi(d, k, \mathbb{F}) : \mathbb{F} \text{ a field}\}$  is bounded by a polynomial in  $d$ .

These results are applied to the problem of correctly extrapolating the values  $\{x_i : i \geq 0\}$  of an unknown polynomial recurrence (mod  $M$ ) in  $k$  variables of degree at most  $d$ , where  $d$  and  $k$  are known and  $M$  is not known. A polynomial-time algorithm is given which computes a value  $\hat{x}_{n+1}$  given the values  $\{x_i : 0 \leq i \leq n\}$  of such a recurrence as input, and it is shown that  $\hat{x}_{n+1} \neq x_{n+1}$  for at most

$$1 + \phi^*(d, k) + \log(M^{dN} N^{\frac{1}{2}N})$$

values of  $n$ , where  $N = 1 + k \binom{k+d}{k}$ .

**Key words.** recurrences, pseudorandom numbers, cryptanalysis

**AMS(MOS) subject classifications.** 11K45, 11B37, 11T71

**1. Introduction.** One of the general methods of pseudorandom number generation is to iterate a function  $T$  starting with a "seed"  $x_0$  to obtain the  $T$ -orbit of  $x_0$ , namely the sequence  $x_0, x_1, x_2, \dots$  with  $x_n = T(x_{n-1})$  for  $n \geq 1$ . For example, the linear congruential generator [K] with *modulus*  $m$ , *multiplier*  $a$  and *increment*  $b$  arises from iteration of the linear function  $T(x) = ax + b$  in the finite ring  $\mathbb{Z}/m\mathbb{Z}$ .

In this paper we study the possibility of correctly predicting (or extrapolating) an entire orbit  $\{x_n : n \geq 0\}$  given only a finite segment of initial values  $x_0, x_1, \dots, x_N$  and given only minimal qualitative information about the function  $T$ .

Sometimes it is possible to deduce the whole orbit from a finite segment even if it is not possible to deduce the transformation  $T$ . For example, if  $N = 2$  and  $x_0 = x_1$  we know the whole orbit but know nothing about  $T$  except its value at a single point:  $T(x_0) = x_0$ .

The following result, conjectured by J. Boyar [B2], is a special case of those proved in this paper: Suppose the sequence  $\{x_n : n \geq 0\}$  is determined by a polynomial recurrence modulo  $m$ :

$$x_n \equiv P(x_{n-1}) \pmod{m}$$

where the degree of the polynomial  $P$  is  $d$  or less. Then the whole sequence  $\{x_n : n \geq 0\}$  is determined by the initial segment  $x_0, x_1, \dots, x_{d+1}$ . In other words, if  $\{y_n : n \geq 0\}$  is another such sequence, determined by a polynomial recurrence

$$y_n \equiv Q(y_{n-1}) \pmod{m}$$

\* Received by the editors March 12, 1986; accepted for publication (in revised form) June 11, 1987.

† AT&T Bell Laboratories, Murray Hill, New Jersey 07974.

where the degree of  $Q$  is also less than or equal to  $d$ , and if for  $0 \leq n \leq d + 1$

$$x_n \equiv y_n \pmod{m},$$

then  $x_n \equiv y_n \pmod{m}$  for all  $n \geq 0$ .

This work arises from cryptography. A number of simple cryptosystems are based on masking a plaintext using a sequence of pseudorandom bits. A subproblem in the cryptanalysis of such systems is the correct prediction of the sequence of pseudorandom bits from a short initial segment of bits. Linear congruential generators are one of the simplest and most well studied pseudorandom number generators, and the problem of extrapolating the output of such generators was studied by J. Boyar [B1], [B2], [B3]. She showed that linear congruential generators are cryptographically insecure in the sense that even without knowledge of  $a, b, m$  there are polynomial-time algorithms which successfully extrapolate  $x_{n+1}$  given  $\{x_i : 0 \leq i \leq n\}$  for  $n = 1, 2, 3, \dots$  and which make at most  $2 + \log m$  incorrect extrapolations in the process. In the case that the modulus  $m$  is known but  $a, b$  are unknown, knowledge of the first three iterates suffices to permit correct extrapolation for all  $n$ . One might hope that polynomial recurrences give more cryptographic security than linear recurrences. This paper shows, in a qualitative sense, that this is not the case.

Motivated by the case of polynomial congruential generators we study the unique extrapolation properties of the orbits of multivariate polynomial recurrences over general commutative rings with unit. Throughout this paper “ring” will mean “commutative ring with unit.” Let  $A$  be a ring and let  $A^k$  be the  $k$ -tuples of elements of  $A$ . We consider polynomial maps  $T: A^k \rightarrow A^k$  defined by

$$T(X_1, \dots, X_k) = (T_1(X_1, \dots, X_k), \dots, T_k(X_1, \dots, X_k))$$

where each  $T_i(X_1, \dots, X_k) \in A[X_1, \dots, X_k]$  is a polynomial with coefficients in  $A$ . We define the degree of  $T$  by

$$\text{deg}(T) = \max \{ \text{total degree } T_i(X_1, \dots, X_k) : 1 \leq i \leq k \}.$$

A polynomial map  $T$  and an initial vector or seed  $\mathbf{x}_0 \in A^k$  determine a sequence of elements  $\mathbf{x}_n = T(\mathbf{x}_{n-1})$  of  $A^k$ , the  $T$ -orbit of  $\mathbf{x}_0$ . We let  $T^{(n)}$  denote the  $n$ -fold composition of  $T$  so that  $\mathbf{x}_n = T^{(n)}(\mathbf{x}_0)$ . We study conditions which guarantee that two orbits coincide. We say that a collection  $\Sigma$  of sequences of elements of  $A^k$  is  $m$ -prefix distinguishable if whenever  $\{\mathbf{x}_n : n \geq 0\}$  and  $\{\mathbf{y}_n : n \geq 0\}$  are two sequences in  $\Sigma$  for which  $\mathbf{x}_n = \mathbf{y}_n$  for  $0 \leq n \leq m$ , it follows that  $\mathbf{x}_n = \mathbf{y}_n$  for all  $n \geq 0$ . An arbitrary collection of sequences need not be  $m$ -prefix distinguishable for any finite  $m$ .

Let  $S(d, k, A)$  denote the set of all orbits of all polynomial maps  $T: A^k \rightarrow A^k$  of degree at most  $d$ . Let  $\phi(d, k, A)$  be the smallest  $m$  such that  $S(d, k, A)$  is  $m$ -prefix distinguishable and let  $\phi^*(d, k)$  be the supremum of  $\phi(d, k, A)$  over all rings  $A$ . If  $A$  is a subring of  $B$ , then  $\phi(d, k, A) \leq \phi(d, k, B)$ . Our first result is as follows.

**THEOREM 1.1.**  $\phi^*(d, k) < \infty$ .

Note that it is not a priori obvious that  $\phi(d, k, A) < \infty$  for any given ring  $A$ , let alone that the  $S(d, k, A)$  for different rings  $A$  should be  $m$ -prefix distinguishable for the same value of  $m$  at once. Our proof of this result is nonconstructive and uses Hilbert’s basis theorem.

We next obtain explicit bounds for  $\phi^*(d, k)$  in special cases. The simplest case is when the equations are linear, i.e., when  $d = 1$ .

**THEOREM 1.2.** For all dimensions  $k \geq 1$ ,

$$\phi^*(1, k) = k + 1.$$

In fact,  $\phi(1, k, \mathbf{Q}) = k + 1$ .

The main result of this paper concerns the one-dimensional case.

**THEOREM 1.3.** *For all degrees  $d \geq 1$ ,*

$$\phi^*(d, 1) = d + 1.$$

*In fact,  $\phi(d, 1, \mathbf{Q}) = d + 1$ .*

Boyar’s conjecture follows from this result, since

$$\phi(d, 1, \mathbf{Z}/m\mathbf{Z}) \leq \phi^*(d, 1) = d + 1.$$

The situation where the dimension  $k$  and the degree  $d$  are both at least two seems more complicated. We obtain a lower bound for  $\phi(d, k, \mathbf{F})$  when  $\mathbf{F}$  is an algebraically closed field using elementary methods from algebraic geometry.

**THEOREM 1.4.** *For any algebraically closed field  $\mathbf{F}$ ,  $\phi(d, k, \mathbf{F}) \geq \binom{d+k}{d}$ . Hence*

$$\phi^*(d, k) \geq \binom{d+k}{d}.$$

This result holds because a “generic” polynomial map  $T$  of degree  $d$  is uniquely determined by its values at  $\binom{k+d}{d}$  points (Theorem 4.1). Theorems 1.2 and 1.3 show this inequality is sharp when  $k = 1$  or  $d = 1$ . However, for  $k \geq 2$  and  $d \geq 2$  the quantity  $\phi(d, k, \mathbf{F})$  is apparently determined by “nongeneric” recurrences, and an example due to James Butler shows that  $\phi(2, 2, \mathbf{Q}) \geq 7$  (Proposition 4.2). (The “generic” bound is  $\binom{2+2}{2} = 6$ .)

We have not obtained any effective upper bounds for  $\phi^*(d, k)$  when  $d \geq 2$  and  $k \geq 2$ . In § 5 we obtain effective upper bounds for  $\phi(d, k, \mathbf{F})$  when  $\mathbf{F}$  is a field, using methods from algebraic geometry related to Bezout’s inequality (Theorem 5.7). In particular, we prove that

$$(1.1) \quad \phi(d, 2, \mathbf{F}) \leq d^4 + d,$$

and our results imply the asymptotic bound

$$\phi(d, k, \mathbf{F}) \leq d^{(2^{k-1}-1)k+2^{k-1}} \left( 1 + \mathcal{O}\left(\frac{1}{d}\right) \right),$$

as the degree  $d \rightarrow \infty$  with  $k$  fixed. By comparison the “generic” lower bound of Theorem 1.4 implies that

$$\phi(d, k, \mathbf{F}) \geq \frac{1}{k!} d^k + \mathcal{O}(d^{k-1})$$

as  $d \rightarrow \infty$  with  $k$  fixed. For the case  $k = d = 2$  we can show that  $\phi(2, 2, \mathbf{F}) \leq 15$  by more detailed arguments. These upper bounds are probably far from the best possible.

To summarize, if either  $d = 1$  or  $k = 1$  there are two kinds of recurrences: generic recurrences and exceptionally good recurrences. The generic recurrences can be uniquely extrapolated from an initial sequence  $x_0, x_1, \dots, x_n$ , with  $n = \binom{k+d}{d}$ , and the exceptionally good recurrences can be uniquely extrapolated from a shorter initial segment. If, however, both  $d > 1$  and  $k > 1$  then a new class occurs, the exceptionally bad recurrences for which initial segments of length more than  $1 + \binom{k+d}{d}$  are needed for unique extrapolation. Both kinds of exceptional recurrences are sparse: the generic recurrences form a dense open subset (in the Zariski topology) of the set of all recurrences of given degree and dimension. But now the worst case for  $d \geq 2$  and  $k \geq 2$  is not the generic case.

These results on unique extrapolation of recurrences can be applied to the problem of extrapolating the value  $\mathbf{x}_{n+1}$  of an unknown polynomial recurrence (mod  $M$ ) in  $k$  variables which is known to be of degree at most  $d$ , given  $\{\mathbf{x}_i; 0 \leq i \leq n\}$  as data, where the modulus  $M$  is itself unknown. The data  $\{\mathbf{x}_i; 0 \leq i \leq n\}$  are assumed to be given with integer entries that are least-positive residues (mod  $M$ ). In § 6 we show that there is a polynomial-time algorithm that produces an extrapolation  $\hat{\mathbf{x}}_{n+1}$  given  $\{\mathbf{x}_i; 0 \leq i \leq n\}$  as input, and that  $\hat{\mathbf{x}}_{n+1} \neq \mathbf{x}_{n+1}$  for at most

$$\phi^*(d, k) + 1 + \left[ 1 + k \binom{k+d}{d} \right] \left\{ d \log_2 M + \frac{1}{2} \log_2 \left( 1 + k \binom{k+d}{d} \right) \right\}$$

values of  $n$ . The proofs of this section essentially follow the approach of Boyar [B1], [B2], [B3].

There remain a number of open problems. The most important is that of finding an exact formula (or failing that, an effective upper bound) for  $\phi^*(d, k)$  when  $d \geq 2$  and  $k \geq 2$ . In another direction, Theorems 1.1 and 1.2 are proved by exhibiting certain “universal” polynomial identities. The identity used to prove  $\phi^*(1, k) = k + 1$  is just the Cayley–Hamilton identity stating that a matrix  $M$  satisfies its characteristic equation  $\chi_M(M) = 0$ . Do the identities used to show  $\phi^*(d, 1) = d + 1$  in Theorem 1.2 also have an interesting algebraic interpretation? (C. Mallows [Mal] has obtained a nice answer to this question.) A third problem area concerns the nature of exceptionally bad recurrences. Can the set of exceptionally bad recurrences be characterized in a simple way? Do exceptionally bad recurrences have interesting algebraic, combinatorial or cryptographic properties?

Other results concerning the cryptographic and pseudorandom properties of linear recurrences may be found in [K], [Mar], [FHKLS], [FKL], [HS].

**2. Unique extrapolation property for polynomial recurrences.** We derive Theorem 1.1 as a corollary of the following general result.

**THEOREM 2.1.** *For any dimension  $k$  and any degree bound  $d$  there is a finite integer  $f(d, k)$  with the following property: For any ring  $A$  (commutative, with unit), and any polynomial maps*

$$T: A^k \rightarrow A^k,$$

$$S: A^k \rightarrow A$$

*both having degree at most  $d$ , and any initial value  $\mathbf{x}_0 \in A^k$ , if*

$$\mathbf{x}_i = T^{(i)}(\mathbf{x}_0)$$

*and*

$$S(\mathbf{x}_i) = 0 \quad \text{for } 0 \leq i \leq f(d, k),$$

*then*

$$S(\mathbf{x}_i) = 0 \quad \text{for } 0 \leq i < \infty.$$

Theorem 1.1 is an easy consequence of Theorem 2.1.

*Proof of Theorem 1.1.* We show that  $f(d, k) + 1$  is an upper bound for  $\phi(d, k, A)$  for all  $A$ . Then

$$(2.1) \quad \phi^*(d, k) \leq f(d, k) + 1.$$

To see this, suppose  $P: A^k \rightarrow A^k$  and  $Q: A^k \rightarrow A^k$  are two polynomial maps of degree  $\leq d$ , and let

$$\mathbf{x}_i = P(\mathbf{x}_{i-1}) = P^{(i)}(\mathbf{x}_0)$$

and

$$\mathbf{y}_i = Q(\mathbf{y}_{i-1}) = Q^{(i)}(\mathbf{y}_0)$$

and suppose that

$$\mathbf{x}_i = \mathbf{y}_i \quad \text{for } 0 \leq i \leq f(d, k) + 1.$$

It suffices to prove that  $\mathbf{x}_i = \mathbf{y}_i$  for all  $i \geq 0$ . Let  $S_j(X_1, \dots, X_k) = P_j(X_1, \dots, X_k) - Q_j(X_1, \dots, X_k)$  be the difference of the  $j$ th components of  $P = (P_1, \dots, P_k)$  and  $Q = (Q_1, \dots, Q_k)$ . Then  $S_j$  is a polynomial of degree  $\leq d$ , and since  $S_j(\mathbf{x}_i) = 0$  for  $0 \leq i \leq f(d, k)$ , by Theorem 2.1 applied with  $T$  equal to  $P$  we know that  $S_j(\mathbf{x}_i) = 0$  for all  $i \geq 0$ . Repeating for all  $j$  we see that  $P(\mathbf{x}_i) = Q(\mathbf{x}_i)$  for all  $i$ .  $\square$

We can in fact derive a stronger result than Theorem 1.1 from Theorem 2.1.

**COROLLARY 2.2.** *Let  $\mathbf{P}(d, k, A)$  denote the set of all sequences  $\{z_n\}$  in  $A$  arising from polynomial maps*

$$\begin{aligned} T: A^k &\rightarrow A^k, \\ U: A^k &\rightarrow A \end{aligned}$$

via

$$\begin{aligned} \mathbf{x}_n &= T(\mathbf{x}_{n-1}), \\ z_n &= U(\mathbf{x}_n) \end{aligned}$$

where both  $T$  and  $U$  have degrees at most  $d$ . Then  $\mathbf{P}(d, k, A)$  is  $f(d, 2k)$ -prefix distinguishable.

*Proof of Corollary 2.2.* Suppose  $T_1, T_2: A^k \rightarrow A^k$  and  $U_1, U_2: A^k \rightarrow A$  are such that

$$\begin{aligned} \mathbf{x}_n &= T_1(\mathbf{x}_{n-1}), & \hat{\mathbf{x}}_n &= T_2(\hat{\mathbf{x}}_{n-1}), \\ z_n &= U_1(\mathbf{x}_n), & \hat{z}_n &= U_2(\hat{\mathbf{x}}_n) \end{aligned}$$

and that

$$(2.2) \quad z_i = \hat{z}_i \quad \text{for } 0 \leq i \leq f(d, 2k).$$

We want to show that  $z_i = \hat{z}_i$  for all  $i \geq 0$ .

Define mappings

$$\begin{aligned} T^*: A^{2k} &\rightarrow A^{2k}, \\ S: A^{2k} &\rightarrow A \end{aligned}$$

by  $T^* = T_1 \times T_2$  so that

$$T^*(X_1, \dots, X_{2k}) = (T_1(X_1, \dots, X_k), T_2(X_{k+1}, \dots, X_{2k}))$$

and

$$S(X_1, \dots, X_{2k}) = U_1(X_1, \dots, X_k) - U_2(X_{k+1}, \dots, X_{2k}).$$

The hypothesis (2.2) asserts that for

$$\mathbf{x}_n^* = T^*(\mathbf{x}_{n-1}^*) = (\mathbf{x}_n, \hat{\mathbf{x}}_n)$$

one has

$$S(\mathbf{x}_i^*) = 0 \quad \text{for } 0 \leq i \leq f(d, 2k).$$

Hence, by Theorem 2.1,

$$S(\mathbf{x}_i^*) = U_1(\mathbf{x}_i) - U_2(\hat{\mathbf{x}}_i) = 0 \quad \text{for all } i \geq 0;$$

then  $z_i = \hat{z}_i$  for all  $i \geq 0$  as desired.  $\square$

We note in passing that Corollary 2.2 can be applied to “sliding window” functions of nonlinear feedback shift registers. Suppose the sequence  $\{y_n : n \geq 0\}$  of elements of  $A$  is determined by a recurrence of form  $y_n = \psi(y_{n-1}, y_{n-2}, \dots, y_{n-k})$  where  $\psi$  is a polynomial of degree  $\leq d$ , and that the sequence  $z_n$  is determined by  $z_n = U(y_n, y_{n-1}, \dots, y_{n-k+1})$ , where  $U$  is another polynomial of degree  $\leq d$ . Then  $\{z_n\}$  is a sequence in  $\mathbf{P}(d, k, A)$  and Corollary 2.2 applies, as can be seen using the standard “state vector” trick of letting  $\mathbf{x}_n = (y_n, y_{n-1}, \dots, y_{n-k+1})$ .

Now we prove Theorem 2.1 using the Hilbert basis theorem.

*Proof of Theorem 2.1.* We prove the result first for a *specific* pair of “universal maps”

$$\begin{aligned} \hat{T} : \mathbf{A}^k &\rightarrow \mathbf{A}^k, \\ \hat{S} : \mathbf{A}^k &\rightarrow \mathbf{A} \end{aligned}$$

in a “universal ring”  $\mathbf{A} = \mathbf{A}_{dk}$ . The ring  $\mathbf{A}_{dk}$  is a polynomial ring  $\mathbf{Z}[\mathbf{X}, \mathbf{T}, \mathbf{S}]$  in  $(k+1) \times \binom{k+d}{d} + k$  intermediates over  $\mathbf{Z}$ . Here  $\binom{k+d}{d}$  indeterminates are

$$\mathbf{S} = \{S_{\mathbf{i}} : \mathbf{i} = (i_1, \dots, i_k) \text{ with } i_1 + \dots + i_k \leq d \text{ and all } i_j \geq 0\}$$

and  $k \binom{k+d}{d}$  indeterminates are

$$\mathbf{T} = \{T_{j\mathbf{i}} : 1 \leq j \leq k \text{ and } \mathbf{i} = (i_1, \dots, i_k) \text{ with } i_1 + \dots + i_k \leq d \text{ and all } i_j \geq 0\}$$

and  $k$  more indeterminates are

$$\mathbf{X} = \{X_i : 1 \leq i \leq k\}.$$

We think of the indeterminates  $\mathbf{X}$  as being *symbolic* or *generic* versions of the coordinates of the initial vector  $\mathbf{x}_0$  of the recurrence, and the  $\mathbf{T}$  and  $\mathbf{S}$  indeterminates as generic versions of the coefficients of the polynomial maps  $T$  and  $S$ . The universal polynomial map

$$\hat{T} = (\hat{T}_1, \dots, \hat{T}_k) : \mathbf{A}^k \rightarrow \mathbf{A}^k$$

of degree  $d$  is defined by

$$\hat{T}_j(Z_1, \dots, Z_k) = \sum_{\substack{\mathbf{i} = (i_1, \dots, i_k) \\ i_1 + \dots + i_k \leq d}} T_{j\mathbf{i}} Z_1^{i_1} \cdots Z_k^{i_k}$$

for  $1 \leq j \leq k$ , and the universal polynomial map

$$\hat{S} : \mathbf{A}^k \rightarrow \mathbf{A}$$

by

$$\hat{S}(Z_1, \dots, Z_k) = \sum_{\substack{\mathbf{i} = (i_1, \dots, i_k) \\ i_1 + \dots + i_k \leq d}} S_{\mathbf{i}} Z_1^{i_1} \cdots Z_k^{i_k}.$$

Now we define a series  $\{P_i\}$  of elements of  $\mathbf{A}$  by

$$\begin{aligned} P_0 &= \hat{S}((X_1, \dots, X_k)), \\ P_1 &= \hat{S}(\hat{T}(X_1, \dots, X_k)), \\ P_2 &= \hat{S}(\hat{T}(\hat{T}(X_1, \dots, X_k))), \\ &\dots \end{aligned} \tag{2.3}$$

Here we use the fact that the functional composition of polynomials is itself a polynomial in the coefficients of the original polynomials. We use these to define an ascending chain  $I_0 \subseteq I_1 \subseteq \dots$  of ideals in  $\mathbf{A}$  by

$$\begin{aligned} I_0 &= (P_0), \\ I_1 &= (P_0, P_1), \\ I_2 &= (P_0, P_1, P_2), \\ &\dots \end{aligned}$$

By Hilbert’s basis theorem [L, pp.144-145] the polynomial ring  $\mathbf{A} = \mathbf{Z}[\mathbf{X}, \mathbf{T}, \mathbf{S}]$  is Noetherian, so this ascending chain of ideals must eventually stabilize: For some finite  $n = f(d, k)$ , we have that

$$I_n = I_{n+1} = I_{n+2} = \dots$$

The relation  $I_n = I_{n+1}$  is equivalent to

$$P_{n+1} \in (P_0, P_1, \dots, P_n),$$

which is

$$(2.4) \quad \hat{S}(\hat{T}^{(n+1)}(\mathbf{X})) = \sum_{j=0}^n A_j(\mathbf{X}, \mathbf{T}, \mathbf{S}) \hat{S}(\hat{T}^{(j)}(\mathbf{X}))$$

for some polynomials  $A_j(\mathbf{X}, \mathbf{T}, \mathbf{S}) \in \mathbf{A}$ . This is a formal identity in the polynomial ring  $\mathbf{A}$ . Note that (2.3) gives

$$P_{j+1}(\mathbf{X}, \mathbf{T}, \mathbf{S}) = P_j(\hat{T}(\mathbf{X}), \mathbf{T}, \mathbf{S})$$

so that (2.4) implies that

$$\hat{S}(\hat{T}^{n+m+1}(\mathbf{X})) = \sum_{j=0}^n A_j(\hat{T}^{(m)}(\mathbf{X}), \mathbf{T}, \mathbf{S}) \hat{S}(\hat{T}^{(m+j)}(\mathbf{X})).$$

Also, since the  $P_i(\mathbf{X}, \mathbf{T}, \mathbf{S}) = \hat{S}(\hat{T}^{(i)}(\mathbf{X}))$  are homogeneous of degree one in the variables  $\{S_i\}$  by (2.3), it follows that (2.4) still holds if we drop all terms in  $A_j(\mathbf{X}, \mathbf{T}, \mathbf{S})$  depending on the variables  $\{S_i\}$ , so that we have the existence of a *universal identity* of the form

$$(2.5) \quad \hat{S}(\hat{T}^{(n+1)}(\mathbf{X})) = \sum_{j=0}^n A_j(\mathbf{X}, \mathbf{T}) \hat{S}(\hat{T}^{(j)}(\mathbf{X}))$$

valid in the ring  $\mathbf{A}_{dk} = \mathbf{Z}[\mathbf{X}, \mathbf{T}, \mathbf{S}]$ , where

$$A_j(\mathbf{X}, \mathbf{T}) \in \mathbf{Z}[\mathbf{X}, \mathbf{T}].$$

Now suppose we are given a ring  $A$  and polynomial maps  $T: A^k \rightarrow A^k$  and  $S: A^k \rightarrow A$  of degree  $\leq d$ . We apply (2.5) as follows. Define a homomorphism  $\rho: \mathbf{A}_{dk} \rightarrow A$  by mapping

- $\rho(1) = 1_A$  the identity element of  $A$ ,
- $\rho(T_{ji}) = t_{ji}$  the corresponding coefficient of  $T_j$  where  $T = (T_1, \dots, T_k)$ ,
- $\rho(S_i) = s_i$  the corresponding coefficient of  $S$ ,
- $\rho(X_i) = x_{0i} = i$ th coordinate of initial value  $\mathbf{x}_0$ .

Under this homomorphism

$$\rho(\hat{S}(\hat{T}^{(j)}(\mathbf{X}))) = S(T^{(j)}(\mathbf{x}_0)) = S(\mathbf{x}_j).$$

Set  $\mathbf{t} = \{t_{ji} : 0 \leq j \leq d \text{ and } \mathbf{i} = (i_1, \dots, i_k) \text{ with } i_1 + \dots + i_k \leq d \text{ and all } i_k \geq 0\}$ . Applying  $\rho$  to (2.5) gives the identity in  $A$  that

$$S(\mathbf{x}_{n+1}) = \sum_{j=0}^n A_j(\mathbf{x}_0, \mathbf{t})S(\mathbf{x}_j).$$

Now since  $S(\mathbf{x}_j) = 0$  for  $0 \leq j \leq n = f(d, k)$  by hypothesis, this equation implies

$$S(\mathbf{x}_{n+1}) = 0.$$

By induction on  $j$  it follows that

$$S(\mathbf{x}_{n+j}) = 0, \quad j = 1, 2, 3, \dots$$

using the hypothesis that  $\{S(\mathbf{x}_{n+j-i-1}) = 0 : 0 \leq i \leq f(d, k)\}$ .  $\square$

**3. Exact bounds for  $\phi^*(d, k)$  in the cases  $d = 1$  and  $k = 1$ .** We can obtain upper bounds for  $\phi^*(d, k)$  via upper bounds for  $f(d, k)$ , from

$$(3.1) \quad \phi^*(d, k) \leq f(d, k) + 1$$

obtained in the course of proving Theorem 1.1. To get upper bounds for  $f(d, k)$  we observe that any identity of the form

$$(3.2) \quad \hat{S}(\hat{T}^{(n+1)}(\mathbf{X})) = \sum_{j=0}^n A_j(\mathbf{X}, \mathbf{T})\hat{S}(\hat{T}^{(j)}(\mathbf{X}))$$

in the polynomial ring  $\mathbf{A}_{dk} = \mathbf{Z}[\mathbf{X}, \mathbf{T}, \mathbf{S}]$  implies that  $f(d, k) \leq n$ . Hence finding an explicit identity of form (3.2) yields an upper bound for  $f(d, k)$ .

We can obtain lower bounds for  $\phi^*(d, k)$  by explicit construction. If we find a ring  $A$  and two orbits in  $S(d, k, A)$  that agree for  $n$  consecutive values and then disagree, then we may conclude that  $\phi^*(d, k) \geq \phi(d, k, A) \geq n$ .

These methods can determine  $\phi^*(d, k)$  exactly only for those values of  $d$  and  $k$  for which the equality

$$(3.3) \quad \phi^*(d, k) = f(d, k) + 1$$

holds. The proof of Theorem 1.1 leaves open the possibility that  $\phi^*(d, k) < f(d, k) + 1$  can occur for some values of  $k$  and  $d$ . This is so because the universal identities found in Theorem 2.1 actually give the smallest value  $f(d, k)$  such that every test polynomial  $S$  of degree of at most  $d$  has the property that if  $S(\mathbf{x}_i) = 0$  for  $0 \leq i \leq f(d, k)$  for the iterates of a recurrence of degree  $\leq d$ , then  $S(\mathbf{x}_i) = 0$  for all  $i \geq 0$ , while the bound for  $\phi^*(d, k)$  used in the proof of Theorem 1.1 only requires that this property hold for those particular test polynomials  $S$  of the form  $S = T_1 - T_2$  where  $T_1$  and  $T_2$  produce the given set of iterates observed. For a particular set of iterates the set of such  $S$  will in general be of much lower dimension than the set of all  $S$ .

We prove that (3.3) does hold in the cases  $d = 1$  and  $k = 1$ , and we obtain exact formulae for  $\phi^*(d, k)$  in these cases. We begin with the case  $d = 1$ , and prove the following result, which implies Theorem 1.2.

**THEOREM 3.1.** For all dimensions  $k \geq 1$ ,

$$\phi^*(1, k) = f(1, k) + 1 = k + 1.$$

*Proof. Upper bound.* We first show that  $f(1, k) \leq k$  by explicit construction of a suitable identity (3.2), which turns out to be the Cayley–Hamilton theorem.

In the case  $d = 1$ , we have that

$$\hat{T}(\mathbf{x}) = (\hat{T}_1(\mathbf{x}), \dots, \hat{T}_k(\mathbf{x}))$$

where

$$\hat{T}_i(x_1, \dots, x_k) = t_{i0} + \sum_{j=1}^k t_{ij}x_j$$

for  $1 \leq i \leq k$ . We let  $\mathbf{x} = (1, x_1, \dots, x_k)^T$  and observe that

$$(3.4) \quad (1, \hat{T}(\mathbf{x}))^T = L\mathbf{x}$$

where  $L$  is the  $(k+1) \times (k+1)$  matrix with rows

$$\begin{aligned} \mathbf{L}_0 &= (1, 0, \dots, 0), \\ \mathbf{L}_i &= (t_{i0}, t_{i1}, \dots, t_{ik}), \quad 1 \leq i \leq k. \end{aligned}$$

For an arbitrary  $k+1$  by  $k+1$  matrix  $M$  over any commutative ring with unit  $A$ , the characteristic polynomial  $\chi_M(z)$  of  $M$  is

$$(3.5) \quad \chi_M(z) = \det(zI - M) = \sum_{j=0}^{k+1} c_j(M)z^j$$

where the  $c_j(M)$  are polynomial functions of the entries of  $M$ , with integer coefficients, and  $c_{k+1}(M) = 1$ . The Cayley-Hamilton theorem [L, p. 400] asserts that the matrix  $\chi_M(M)$  is the zero matrix, i.e.,

$$(3.6) \quad M^{k+1} = -\sum_{j=0}^k c_j(M)M^j.$$

In particular, we obtain

$$(3.7) \quad L^{k+1}\mathbf{x} = -\sum_{j=0}^k c_j(L)L^j\mathbf{x}.$$

Finally, let

$$(3.8) \quad \hat{S}(x_1, \dots, x_k) = s_0 + \sum_{i=1}^k s_i x_i = \mathbf{s}\mathbf{x}$$

where  $\mathbf{s} = (s_0, s_1, \dots, s_k)$  is a row vector of indeterminates. Then (3.7) gives the identity

$$(3.9) \quad \mathbf{s}L^{k+1}\mathbf{x} = -\sum_{j=0}^k c_j(L)\mathbf{s}L^j\mathbf{x}.$$

This is exactly an identity of the form (3.2) that we are looking for in the ring

$$\mathbf{A}_{1,k} = \mathbf{Z}[x_1, \dots, x_k; s_0, \dots, s_k; t_0, \dots, t_k]$$

since

$$\hat{\mathbf{S}}(\hat{T}^{(i)}(x_1, \dots, x_k)) = \mathbf{S}L^i\mathbf{x}$$

using (3.4) and (3.8), where

$$A_j(\mathbf{x}, \mathbf{T}) = A_j(\mathbf{T}) = -c_j(L).$$

The identity (3.9) implies that

$$f(1, k) \leq k,$$

as required.

*Lower bound.* For the bound  $\phi^*(1, k) \geq k + 1$  we take  $A = \mathbf{Q}$  and the transformations

$$T(x_1, \dots, x_k) = (x_k + 1, x_1, x_2, \dots, x_{k-1})$$

and

$$U(x_1, \dots, x_k) = (2x_k + 1, x_1, x_2, \dots, x_{k-1}).$$

Then for  $\mathbf{x}_0 = (0, 0, \dots, 0)$  and  $0 \leq i \leq k$ , we have that

$$T^{(i)}(\mathbf{x}_0) = U^{(i)}(\mathbf{x}_0) = (1, 1, \dots, 1, 0, \dots, 0)$$

with the 1's in the first  $i$  places. But  $T^{(k+1)}(\mathbf{x}_0) = (2, 1, 1, \dots, 1)$  and  $U^{(k+1)}(\mathbf{x}_0) = (3, 1, 1, \dots, 1)$ , so that  $\phi^*(1, k) \geq k + 1$ .  $\square$

We derive Theorem 1.3 from the following result.

**THEOREM 3.2.** *For all degrees  $d \geq 1$ ,*

$$\phi^*(d, 1) = f(d, 1) + 1 = d + 1.$$

*Proof. Upper bound.* To obtain the upper bound  $f(d, 1) \leq d$  we will show that in the polynomial ring  $\mathbf{A}_{d1} = \mathbf{Z}[X, T_0, T_1, \dots, T_d, S_0, S_1, \dots, S_d]$  there exists an identity of the form

$$(3.10) \quad \hat{S}(\hat{T}^{(d+1)}(X)) = \sum_{i=0}^d A_i(X, T) \hat{S}(\hat{T}^{(i)}(X))$$

with  $A_i(X, T) \in \mathbf{Z}[X, T_0, \dots, T_d]$ . Recall that the universal maps  $\hat{T}$  and  $\hat{S}$  are given by

$$\hat{T}(X) = \sum_{j=0}^d T_j X^j, \quad \hat{S}(X) = \sum_{j=0}^d S_j X^j;$$

hence,

$$\hat{S}(\hat{T}^{(i)}(X)) = \sum_{j=0}^d S_j [\hat{T}^{(i)}(X)]^j.$$

By the Lagrange interpolation formula

$$\hat{S}(\hat{T}^{(d+1)}(X)) = \sum_{i=0}^d A_i(X, T) \hat{S}(\hat{T}^{(i)}(X))^j$$

where

$$A_i(X, T) = \prod_{\substack{j=0 \\ j \neq i}}^d \left( \frac{\hat{T}^{(d+1)}(X) - \hat{T}^{(j)}(X)}{\hat{T}^{(i)}(X) - \hat{T}^{(j)}(X)} \right).$$

To establish the upper bound it suffices to show that the rational functions  $A_i(X, T)$  are actually polynomials in the ring  $\mathbf{Z}[X, T]$ . To prove this we work with certain non-Archimedean norms on  $\mathbf{Z}[X, T]$  and on its quotient field  $\mathbf{F} = \mathbf{Q}(X, T)$ . Since  $\mathbf{Z}$  is a unique factorization domain, so is  $\mathbf{Z}[X, T]$ . Let  $\mathbf{P}$  be a set of representatives of the irreducible elements of  $\mathbf{Z}[X, T]$  modulo the units of  $\mathbf{Z}[X, T]$ . Then any element  $f \in \mathbf{F}$  can be written uniquely as  $f = u \prod_{p \in \mathbf{P}} p^{\nu_p(f)}$  where  $u$  is a unit in  $\mathbf{Z}[X, T]$ . Define the  $p$ -norm of  $f$  by  $|f|_p = e^{-\nu_p(f)}$ . Then

$$\mathbf{Z}[X, T] = \{f \in \mathbf{F} : |f|_p \leq 1 \text{ for all } p \in \mathbf{P}\}.$$

(See [ZS, Ex. 2, p. 38]). Our method for showing that  $A_j(X, T) \in \mathbf{Z}[X, T]$  is to show that  $|A_j(X, T)|_p \leq 1$  for all  $p \in \mathbf{P}$ .

This follows from a general result about non-Archimedean norms, which contains the main idea of the proof, presented as Proposition 3.3 below. First we show that the sequence of iterates  $\hat{T}^{(0)}(X), \hat{T}^{(1)}(X), \dots$  is a contracting sequence for the norms  $|\cdot|_p$ , where a sequence  $x_0, x_1, \dots$  is said to be a *contracting sequence* if  $|x_{i+1} - x_{j+1}| \leq |x_i - x_j|$  for all  $i$  and  $j$ . We then apply the following proposition.

PROPOSITION 3.3. *Let  $\mathbf{F}$  be a field with non-Archimedean norm  $|\cdot|$ , and let  $x_0, x_1, \dots$  be a contracting sequence. Assume that the  $x_i$  are distinct.*

(1) *Let*

$$\theta_i(x_0, \dots, x_{d+1}) = \prod_{\substack{j=0 \\ j \neq i}}^d \left( \frac{x_{d+1} - x_j}{x_i - x_j} \right)$$

for  $0 \leq i \leq d$ . Then  $|\theta_i(x_0, \dots, x_{d+1})| \leq 1$ .

(2) *If  $S \in \mathbf{F}[X]$  has degree  $\leq d$ , then*

$$|S(x_{d+1})| \leq \max_{0 \leq i \leq d} |S(x_i)|.$$

(The proof of Proposition 3.3 is deferred until after Theorem 3.2 is proved.) Since  $A_j(X, \mathbf{T}) = \theta_j(\hat{T}^{(0)}(X), \dots, \hat{T}^{(d+1)}(X))$  we see that  $|A_j(X, \mathbf{T})|_p \leq 1$  as desired, and hence  $A_j(X, \mathbf{T}) \in \mathbf{Z}[X, \mathbf{T}]$ .

So to complete the proof of the upper bound it suffices to check that  $\{\hat{T}^{(i)}(X)\}$  is a contracting sequence for each  $|\cdot|_p$ . To see this we start from the polynomial identity

$$\begin{aligned} \hat{T}^{(1)}(V) &= \sum_{j=0}^d T_j V^j = \sum_{j=0}^d T_j (U + (V - U))^j \\ &= \hat{T}^{(1)}(U) + g(\mathbf{T}, U, V)(V - U) \end{aligned}$$

where  $U$  and  $V$  are indeterminates and  $g$  is a polynomial with integer coefficients. Substituting  $U = \hat{T}^{(i)}(X)$  and  $V = \hat{T}^{(j)}(X)$ , we have that

$$\hat{T}^{(i+1)}(X) - \hat{T}^{(j+1)}(X) = g(\mathbf{T}, \hat{T}^{(i)}(X), \hat{T}^{(j)}(X))(\hat{T}^{(i)}(X) - \hat{T}^{(j)}(X))$$

so that

$$|\hat{T}^{(i+1)}(X) - \hat{T}^{(j+1)}(X)|_p = |g(\mathbf{T}, \hat{T}^{(i)}(X), \hat{T}^{(j)}(X))|_p |\hat{T}^{(i)}(X) - \hat{T}^{(j)}(X)|_p.$$

Since  $\hat{T}^{(i)}(X)$  and  $\hat{T}^{(j)}(X)$  are in  $\mathbf{Z}[X, \mathbf{T}]$ , and since  $g$  has integer coefficients, the norm of the  $g$  factor is bounded by 1 and the contracting sequence property is verified.

Then by Proposition 3.3 we know that  $|A_j(X, \mathbf{T})|_p \leq 1$ . Repeating this argument for all irreducibles  $p$ , we know that  $A_j(X, \mathbf{T})$  is in  $\{f \in \mathbf{F}: |f|_p \leq 1 \text{ for all } p\}$  which we have already seen is  $\mathbf{Z}[X, \mathbf{T}]$ . This establishes the upper bound.

*Lower bound.* We let  $A = \mathbf{Q}$ . Take  $T(X) = X + 1$  and starting value  $x_0 = 0$ . Let

$$U(X) = 1 + X + \prod_{j=0}^{d-1} \left( \frac{X - j}{d - j} \right),$$

so that  $U(l) = l + 1$  for  $0 \leq l \leq d - 1$  and  $U(d) = d + 2$ . Then  $T^{(j)}(0) = U^{(j)}(0) = j$  for  $0 \leq j \leq d$ , but  $T^{(d+1)}(0) \neq U^{(d+1)}(0)$ . Hence  $\phi^*(d, 1) \geq d + 1$ .  $\square$

It remains to prove Proposition 3.3.

*Proof of Proposition 3.3.* Statement (2) follows from (1) by the Lagrange Interpolation Theorem and from the ultrametric inequality.

To prove (1), we first note that

$$(3.11) \quad |x_{i+k} - x_{j+k}| \leq |x_i - x_j|$$

holds for all  $i, j, k \geq 0$ . Now we write

$$|\theta_i(x_0, \dots, x_{d+1})| = A_{di}(x_0, \dots, x_{d+1})B_{di}(x_0, \dots, x_{d+1})$$

where

$$A_{di}(x_0, \dots, x_{d+1}) = \prod_{j=i+1}^k \left| \frac{x_{d+1} - x_j}{x_i - x_j} \right|,$$

$$B_{di}(x_0, \dots, x_{d+1}) = \prod_{j=0}^{i-1} \left| \frac{x_{d+1} - x_j}{x_i - x_j} \right|,$$

where in both cases empty products are taken to be one. In fact each of  $A_{di}(x_0, \dots, x_{d+1})$  and  $B_{di}(x_0, \dots, x_{d+1})$  are individually less than 1. We show  $A_{di}(x_0, \dots, x_{d+1}) \leq 1$  directly, and  $B_{di}(x_0, \dots, x_{d+1}) \leq 1$  by induction on  $d$ .

First we show that  $A_{di}(x_0, \dots, x_{d+1}) \leq 1$ . We have, on multiplying out and on permuting the factors in the denominator,

$$\begin{aligned} A_{di}(x_0, \dots, x_{d+1}) &= \prod_{j=i+1}^d \left| \frac{x_{d+1} - x_j}{x_i - x_j} \right| \\ &= \left| \frac{x_{d+1} - x_{i+1}}{x_d - x_i} \right| \left| \frac{x_{d+1} - x_{i+2}}{x_{d-1} - x_i} \right| \dots \left| \frac{x_{d+1} - x_d}{x_{i+1} - x_i} \right| \\ &\leq 1, \end{aligned}$$

where each of the  $d - i$  factors has norm less than or equal to one by (3.11).

Now we go to work on  $B_{di}(x_0, \dots, x_{d+1})$ . Suppose, as the induction hypothesis, that for all  $0 \leq i \leq d - 1$  and for all contracting sequences of distinct elements  $y_0, y_1, \dots$  we have  $B_{d-1,i}(y_0, \dots, y_d) \leq 1$ . By the ultrametric inequality either  $|x_{d+1} - x_0|$  is less than or equal to  $|x_i - x_0|$  or is less than or equal to  $|x_{d+1} - x_i|$  or both. In the first case

$$\begin{aligned} B_{di}(x_0, \dots, x_{d+1}) &\leq \prod_{j=1}^{i-1} \left| \frac{x_{d+1} - x_j}{x_i - x_j} \right| \\ &= B_{d-1,i-1}(x_1, \dots, x_{d+1}) \leq 1 \end{aligned}$$

by the induction hypothesis.

In the second case

$$\begin{aligned} B_{di}(x_0, \dots, x_{d+1}) &= \left| \frac{x_{d+1} - x_0}{x_i - x_0} \right| \left| \frac{x_{d+1} - x_1}{x_i - x_1} \right| \dots \left| \frac{x_{d+1} - x_{i-1}}{x_i - x_{i-1}} \right| \\ &\leq \left| \frac{x_{d+1} - x_i}{x_i - x_0} \right| \left| \frac{x_{d+1} - x_1}{x_i - x_1} \right| \dots \left| \frac{x_{d+1} - x_{i-1}}{x_i - x_{i-1}} \right|. \end{aligned}$$

By cyclicly permuting the factors of the numerator, we obtain

$$\begin{aligned} B_{di}(x_0, \dots, x_{d+1}) &\leq \left| \frac{x_{d+1} - x_1}{x_i - x_0} \right| \left| \frac{x_{d+1} - x_2}{x_i - x_1} \right| \dots \left| \frac{x_{d+1} - x_i}{x_i - x_{i-1}} \right| \\ &\leq \left| \frac{x_d - x_0}{x_i - x_0} \right| \left| \frac{x_d - x_1}{x_i - x_1} \right| \dots \left| \frac{x_d - x_{i-1}}{x_i - x_{i-1}} \right| \\ &= B_{d-1,i}(x_0, \dots, x_d) \leq 1, \end{aligned}$$

using the contraction property and the induction hypothesis.

It is easy to check that the induction can be started at say,  $d = 0$  or at  $d = 1$ .  $\square$

**4. Lower bounds for  $\phi^*(d, k)$ .** Let  $\mathbf{M}(d, k, l, A)$  denote the set of all polynomial maps  $T: A^k \rightarrow A^l$  of degree at most  $d$ . In the case that  $\mathbf{F}$  is an algebraically closed field, we will obtain the lower bound  $\phi(d, k, \mathbf{F}) \cong \binom{d+k}{k}$  by showing that most recurrences  $T$  in  $\mathbf{M}(d, k, k, \mathbf{F})$  are determined uniquely by their iterates  $\{T^{(i)}(x_0): 0 \leq i \leq \binom{d+k}{k}\}$  and by no fewer than this number of iterates. We do this by relating the extrapolation problem to the problem of interpolation of polynomials. A polynomial  $P(\mathbf{X})$  of degree  $\leq d$  in  $k$  variables has  $\binom{d+k}{k}$  coefficients, so that at least  $\binom{d+k}{k}$  distinct interpolation points are needed to determine it uniquely. For dimension  $k = 1$ , unique interpolation is possible for any set of  $d + 1$  distinct points by Lagrange’s interpolation formula, but for higher dimensions this is no longer true. We set  $N = \binom{d+k}{k}$  and call a set

$$S = \{\mathbf{x}_i \in \mathbf{F}^k: 1 \leq i \leq N\}$$

a *unique interpolation set* for  $\mathbf{M}(d, k, l, \mathbf{F})$  if for every sequence  $\mathbf{z}_i \in \mathbf{F}^l, 1 \leq i \leq N$  there is a unique polynomial map  $P(\mathbf{X})$  in  $\mathbf{M}(d, k, l, \mathbf{F})$  for which

$$(4.1) \quad P(\mathbf{x}_i) = \mathbf{z}_i \quad \text{for } 1 \leq i \leq N.$$

Note that  $S$  is a unique interpolation set for  $\mathbf{M}(d, k, l, \mathbf{F})$  if and only if it is a unique interpolation set for  $\mathbf{M}(d, k, 1, \mathbf{F})$ .

**THEOREM 4.1.** *Let  $\mathbf{F}$  be an algebraically closed field, and let  $N = \binom{d+k}{k}$ .*

(1) *The set  $Z_{dk} = \{S: S \text{ is a unique interpolation set for } \mathbf{M}(d, k, k, \mathbf{F})\}$  is an open dense subset of  $\mathbf{F}^{kN}$  in the Zariski topology.*

(2) *The sets of values  $S = \{\mathbf{x}_i \in \mathbf{F}^k: 0 \leq i \leq N\}$  in  $\mathbf{F}^{kN+k}$  such that there is a unique recurrence  $T \in \mathbf{M}(d, k, k, \mathbf{F})$  with*

$$(4.2) \quad T(\mathbf{x}_i) = \mathbf{x}_{i+1} \quad \text{for } 0 \leq i \leq N - 1$$

*contains the Zariski open subset  $Z_{dk} \times \mathbf{F}^k$  of  $\mathbf{F}^{kN+k}$ .*

(3)  $\phi(d, k, \mathbf{F}) \cong N$ .

*Proof.* (1) A point fails to be in  $Z_{dk}$  only if the linear equations (4.1) that the coefficients of  $P$  obey have deficient rank, i.e., a certain determinant vanishes. The coefficients of the system (4.1) are polynomial functions of the  $\mathbf{x}_i$ , and hence  $Z_{dk}$  is the complement of a closed set.

(2) We claim that if  $S = \{\mathbf{x}_i: 0 \leq i \leq N - 1\}$  is a unique interpolation set, then for each  $\mathbf{x}_N \in \mathbf{F}^k$  a unique recurrence  $T$  in  $\mathbf{M}(d, k, k, \mathbf{F})$  exists satisfying (4.2). Write  $T = (T_1, \dots, T_k)$  and observe that (4.2) is equivalent to

$$(4.3) \quad T_j(x_{1i}, \dots, x_{ki}) = x_{j,i+1}, \quad 0 \leq i \leq N - 1,$$

for  $1 \leq j \leq k$ . If  $S$  is a unique interpolation set, then by definition there exists a unique  $T_j$  satisfying (4.3), for each  $j$ . Hence  $T$  exists and is unique, so that  $Z_{dk} \times \mathbf{F}^k$  is contained in the desired set of values.

(3) Choose a unique interpolation set  $S = (\mathbf{x}_0, \mathbf{x}_1, \dots, \mathbf{x}_{N-1})$  with  $N = \binom{d+k}{k}$ . Then by (2) we may choose two different vectors  $\mathbf{x}_N \neq \mathbf{x}_N^*$  in  $\mathbf{F}^k$  and find unique recurrences  $T, T^*$  in  $\mathbf{M}(d, k, k, \mathbf{F})$  with

$$T(\mathbf{x}_i) = T^*(\mathbf{x}_i) = \mathbf{x}_{i+1} \quad \text{for } 0 \leq i \leq N - 1,$$

while

$$T(\mathbf{x}_{N-1}) = \mathbf{x}_N \neq \mathbf{x}_N^* = T^*(\mathbf{x}_{N-1}).$$

Hence  $\phi(d, k, \mathbf{F}) \cong N = \binom{d+k}{k}$ .  $\square$

The problem of unique extrapolation of polynomial recurrences is in fact more complicated than the “generic” behavior of polynomial recurrences given by Theorem

4.1 suggests. The worst cases appear to be attained by orbits of recurrences that do not form unique interpolation sets. We are indebted to Dr. James Butler for the following example with  $d = 2$  and  $k = 2$ , where the generic bound is  $\binom{2+2}{2} = 6$ .

PROPOSITION 4.2.  $\phi(2, 2, \mathbf{Q}) \geq 7$ .

*Proof.* We consider the collection of transformations

$$T_{\lambda\mu}(x, y) = (-xy + y^2 + x - 2y + \lambda(x^2 - 1), -1/2xy + 1/2y^2 + x + \mu(x^2 - 1)),$$

parametrized by the constants  $\lambda, \mu$  in  $\mathbf{Q}$ . All of these transformations agree on the set

$$V = \{(x, y) : x = \pm 1\} = \{(x, y) : x^2 - 1 = 0\}.$$

It is easy to check that

$$T_{\lambda\mu}(\mathbf{x}_i) = \mathbf{x}_{i+1} \quad \text{for } 0 \leq i \leq 5,$$

with  $\mathbf{x}_0 = (1, 0)$ ,  $\mathbf{x}_1 = (1, 1)$ ,  $\mathbf{x}_2 = (-1, 1)$ ,  $\mathbf{x}_3 = (-1, 0)$ ,  $\mathbf{x}_4 = (-1, -1)$ ,  $\mathbf{x}_5 = (1, -1)$ ,  $\mathbf{x}_6 = (5, 2)$ , because the points  $\mathbf{x}_i$  for  $0 \leq i \leq 5$  all lie on the set  $V$ . However,

$$T_{\lambda\mu}(\mathbf{x}_6) = (-5 + 24\lambda, 2 + 24\mu)$$

depends on  $\lambda$  and  $\mu$ . Hence the  $T_{\lambda\mu}$  agree for seven consecutive values and then disagree.  $\square$

In this case the set  $\{\mathbf{x}_0, \mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3, \mathbf{x}_4, \mathbf{x}_5\}$  is not a unique interpolation set in  $\mathbf{M}(2, 2, 1, \mathbf{Q})$ .

**5. Upper bounds for  $\phi(d, k, \mathbf{F})$  for general  $d$  and  $k$ .** We apply methods from algebraic geometry to obtain upper bounds for  $\phi(d, k, \mathbf{F})$  when  $\mathbf{F}$  is a field. We assume without loss of generality that  $\mathbf{F}$  is algebraically closed. Let  $\mathbf{F}^k$  be affine  $k$ -space over  $\mathbf{F}$ , equipped with the Zariski topology. (A collection of basic open sets for the Zariski topology consists of those sets of points where a polynomial  $p(x_1, \dots, x_k) \neq 0$ .) We freely use the concepts of dimension and irredundant decomposition into irreducible closed sets, as expounded by [Fu], [H] and [Sh]. The (Zariski) closure of a set  $S \subseteq \mathbf{F}^k$  is denoted by  $\bar{S}$ . The cardinality of  $S$  is denoted by  $|S|$ .

The *degree*  $\deg(W)$  of a closed set is the sum of the degrees of its irreducible components, which in turn are defined as follows. If  $V$  is irreducible, its degree is the maximum cardinality of a finite intersection with a linear closed set:

$$\deg(V) = \max \{|V \cap L| : L \text{ linear and } |V \cap L| < \infty\}.$$

It can be shown that every closed set has finite degree, and for “most” linear closed sets  $L$  of dimension  $k - \dim(V)$ ,  $|V \cap L| = \deg V$ . The degree of a linear closed set is one. The degree of a singleton point is one. The degree of a hypersurface defined by a single polynomial equation of degree  $d$  is at most  $d$ . See [H, Chap. I, § 7] or [S] for details.

Our main tool is a generalization of Bezout’s theorem.

THEOREM 5.1 (Bezout’s Inequality). *Let  $V, W \subseteq \mathbf{F}^k$  be closed sets. Then*

$$\deg(V \cap W) \leq \deg(V) \deg(W).$$

This result is due to Fulton (see [FL]).

Let  $T : \mathbf{F}^k \rightarrow \mathbf{F}^k$  be a polynomial map. We need a series of elementary results relating the degrees of  $T, V$  and  $T(V)$  for closed sets  $V$ .

LEMMA 5.2. *Let the graph of  $T$  be*

$$\Gamma_T = \{(\mathbf{x}, T(\mathbf{x})) \in \mathbf{F}^{2k} : \mathbf{x} \in \mathbf{F}^k\} \subseteq \mathbf{F}^{2k}.$$

*Then  $\deg(\Gamma_T) \leq (\deg T)^k$ .*

*Proof.*  $\Gamma_T = \bigcap_{i=1}^k W_i$  where  $W_i$  is the hypersurface in  $\mathbf{F}^{2k}$  defined by the equation  $T_i(X_1, \dots, X_k) = X_{k+i}$ . So  $W_i$  has degree at most  $\deg(T)$ , and by Bezout's inequality,  $\deg(\bigcap_{i=1}^k W_i) \leq (\deg(T))^k$ .  $\square$

LEMMA 5.3. *Let  $S_1, S_2 \subseteq \mathbf{F}^k$  be closed. Then*

$$\deg(S_1 \times S_2) \leq \deg(S_1) \deg(S_2).$$

*Proof.* We may suppose that  $S_2 = \mathbf{F}^k$  for  $S_1 \times S_2 = (S_1 \times \mathbf{F}^k) \cap (\mathbf{F}^k \times S_2)$  and so by Bezout's inequality  $\deg(S_1 \times S_2) \leq \deg(S_1 \times \mathbf{F}^k) \deg(\mathbf{F}^k \times S_2)$ . Let  $D = \deg(S_1 \times \mathbf{F}^k)$ , let  $L$  be a closed linear set such that  $|L \cap (S_1 \times \mathbf{F}^k)| = D$ , and for  $s \in S_1$  let  $n(s) = |L \cap \{s\} \times \mathbf{F}^k|$  so that  $D = \sum_{s \in S_1} n(s)$ . Since  $\mathbf{F}$  is algebraically closed it is infinite and, by linearity, if  $n(s) > 1$ , then  $n(s) = \infty$ . But  $D < \infty$ , so  $n(s) \leq 1$  for all  $s \in S_1$ . Then  $n(s) = |L' \cap \{s\}|$  where  $L' = \{x \in \mathbf{F}^k : (x, y) \in L\}$  is a linear subspace of  $\mathbf{F}^k$ , so  $D = \sum n(s) = |L' \cap S_1| \leq \deg(S_1)$ .  $\square$

LEMMA 5.4. *Let  $p: \mathbf{F}^{2k} \rightarrow \mathbf{F}^k$  be the projection onto the first  $k$  coordinates. If  $S \subseteq \mathbf{F}^{2k}$  is closed, then*

$$\deg(\overline{p(S)}) \leq \deg(S).$$

*Proof.* Using irredundant decomposition into irreducibles, it suffices to prove this for irreducible  $S$ . Let  $V = \overline{p(S)}$ . Let  $L$  be a linear closed set such that  $|L \cap V| = \deg(V)$ . Then by the definition of the projection  $p$

$$(p^{-1}(L \cap V)) \cap S = (L \times \mathbf{F}^k) \cap S.$$

Since  $L \cap V$  is finite,  $p^{-1}(L \cap V)$  consists of  $\deg(V)$  many linear closed sets, each one of which has nonempty intersection with  $S$ . Thus  $\deg((L \times \mathbf{F}^k) \cap S)$  is the sum of  $\deg(V)$  positive integers so  $\deg(V) \leq \deg((L \times \mathbf{F}^k) \cap S)$ . By Bezout's inequality  $\deg((L \times \mathbf{F}^k) \cap S) \leq \deg(L \times \mathbf{F}^k) \cdot \deg(S) = \deg(S)$ . Hence  $\deg(V) \leq \deg(S)$ .  $\square$

LEMMA 5.5.  $\deg(\overline{T(V)}) \leq \deg(\Gamma_T) \deg(V) \leq (\deg T)^k \deg(V)$ .

*Proof.* Use  $\overline{T(V)} = \overline{p(W)}$  where  $W = \Gamma_T \cap (V \times \mathbf{F}^k)$ . The result then follows from Lemmas 5.2, 5.3 and 5.4.  $\square$

LEMMA 5.6. *Let  $V$  be a closed set. If  $V \subseteq \overline{T(V)}$  then*

$$T(V) \subseteq V = \overline{T(V)}.$$

*Proof.* Let  $d = \dim(V)$ . We use induction on increasing values of  $d$ . The case  $d = 0$  is trivial. For  $d > 0$ , let  $V_d$  be the union of those irreducible components of  $V$  that have dimension  $d$ ; let  $W_d$  be the union of the remaining components of  $V$ . We have  $\dim(W_d) < d$  and  $\dim \overline{T(W_d)} < d$ . Since each component of  $V_d$  has dimension  $d$  it must be contained in  $\overline{T(V_d)}$ , and hence  $V_d \subseteq \overline{T(V_d)}$ . Indeed, the irreducible components of  $\overline{T(V_d)}$  are the irreducible components of  $V_d$ , in possibly permuted order, and so  $V_d = \overline{T(V_d)}$ . By irredundance, none of the components of  $W_d$  are contained in any of the components of  $V_d = \overline{T(V_d)}$ . Since  $W_d \subseteq \overline{T(V_d)} \cup \overline{T(W_d)}$  we see that  $W_d \subseteq \overline{T(W_d)}$ . But  $\dim(W_d) < d$  so the induction hypothesis implies  $W_d = \overline{T(W_d)}$ . Hence

$$V = V_d \cup W_d = T(V_d) \cup \overline{T(W_d)} = \overline{T(V)}. \quad \square$$

With these preliminaries out of the way we derive a bound for  $\phi(d, k, \mathbf{F})$  expressed in terms of  $g(d, k)$  defined recursively in terms of a function  $h(i, d, k)$  by

$$h(1, d, k) = d, \quad h(i, d, k) = d^k (h(i-1, d, k))^2 + d$$

for  $1 \leq i \leq k$ , and

$$g(d, k) = h(k, d, k).$$

A computation shows that

$$g(d, 2) = d^4 + d, \quad g(d, 3) = d^{13} + 2d^9 + d^5 + d,$$

and that

$$g(d, k) = d^{(2^{k-1}-1)k+2^{k-1}} \left( 1 + O\left(\frac{1}{d}\right) \right)$$

as  $d \rightarrow \infty$  with  $k$  fixed.

**THEOREM 5.7.** *Let  $\mathbf{F}$  be an algebraically closed field and let  $T: \mathbf{F}^k \rightarrow \mathbf{F}^k$  be a polynomial map of degree at most  $d$ . Let  $C$  be a Zariski closed set of degree  $\text{deg}(C) \leq d$ . If*

$$T^{(j)}(\mathbf{x}) \in C \quad \text{for } 0 \leq j \leq g(d, k),$$

then

$$T^{(j)}(\mathbf{x}) \in C \quad \text{for } 0 \leq j < \infty.$$

Hence, taking  $C = \{\mathbf{x}: S(\mathbf{x}) = 0\}$ , we obtain

$$\phi(d, k, \mathbf{F}) \leq f(d, k, \mathbf{F}) + 1 \leq g(d, k) + 1.$$

*Proof.* We define a descending sequence of closed sets  $C_0 \supseteq C_1 \supseteq C_2 \supseteq \dots$  by  $C_0 = C$  and

$$(5.1) \quad C_j = C_{j-1} \cap \overline{T(C_{j-1})}.$$

Note that  $\bigcap_{i=0}^j T^{(i)}(C) \subseteq C_j$ . We have the following claim.

**CLAIM 1.** If  $T^{(i)}(\mathbf{x}) \in C$  for  $0 \leq i \leq n$ , then  $T^{(i)}(\mathbf{x}) \in C_i$  for  $0 \leq i \leq n$ .

In other words, successive iterates are more and more constrained by the condition that they be in  $C$ . The claim is obvious: If  $0 \leq i \leq n$ , then  $T^{(i)}(\mathbf{x}) = T^{(j)}(T^{(i-j)}(\mathbf{x}))$  for all  $0 \leq j \leq i$ . Since  $T^{(i-j)}(\mathbf{x}) \in C$  for such  $j$ , we have  $T^{(i)}(\mathbf{x}) \in T^{(j)}(C)$  and indeed  $T^{(i)}(\mathbf{x}) \in \bigcap_{j=0}^i T^{(j)}(C) \subseteq C_i$ .

Returning to the sequence  $C_0 \supseteq C_1 \supseteq \dots$ , we observe that because the Zariski topology is Noetherian this decreasing sequence of closed sets must eventually stabilize, i.e.,  $C_n = C_{n+1}$  for some  $n$ .

**CLAIM 2.** If  $C_n = C_{n+1}$ , then  $T(C_n) \subseteq C_n$ , and in fact  $\overline{T(C_n)} = C_n$ .

This follows directly from Lemma 5.6:  $C_{n+1} = C_n \cap \overline{T(C_n)}$ . If  $C_n = C_{n+1}$ , then  $C_n \subseteq \overline{T(C_n)}$ , and Lemma 5.6 applies.

An immediate consequence of Claim 2 is that if  $\mathbf{x} \in C_n$  with  $C_n = C_{n+1}$ , then  $T^{(j)}(\mathbf{x}) \in C_n$  for all  $j \geq 0$ . Using Claim 1 we then see that if  $T^{(j)}(\mathbf{x}) \in C$  for  $0 \leq j \leq n$ , where  $C_n = C_{n+1}$ , then  $T^{(j)}(\mathbf{x}) \in C_j \subseteq C$  for all  $j \leq 0$ . Hence the theorem follows from an upper bound on how soon the sequence  $\{C_j\}$  stabilizes.

**CLAIM 3.** The sequence  $\{C_j\}$  stabilizes after at most  $g(d, k)$  steps, i.e.,

$$C_n = C_{n+1}$$

for some  $n \leq g(d, k)$ .

The idea of the proof of Claim 3 is to bound the degrees and dimensions of the various irreducible components in the closed sets  $C_j$ . If  $C_{j+1} \neq C_j$  then, in going from  $C_j$  to  $C_{j+1}$  one or more irreducible components  $V$  “disappears” and is replaced by subvarieties of lower dimension, but of possibly higher degree. As a result  $C_{j+1}$  might have higher degree than  $C_j$  but only in higher codimension components than the ones that “disappear.” Meanwhile  $\text{deg}(V)$  of  $C_j$  has “leaked out” from dimension  $d = \dim(V)$  and is not in  $C_{j+1}$ .

Now define  $D(i, d, k)$  to be the maximum sum of the degrees of all components having dimension  $\geq i$  that ever occur in any element  $C_n$  of the descending sequence  $\{C_j\}$ . Then the sequence  $\{C_j\}$  must stabilize after at most  $D(0, d, k)$  steps, since at each step a component of degree at least one “disappears.” We develop recursive bounds for  $D(i, d, k)$ . First

$$(5.2) \quad D(k-1, d, k) \leq \deg C_0 \leq d$$

because this is an upper bound on the degree of all varieties in  $C_0$ , and because no new irreducible varieties of dimension  $k-1$  can arise during the intersection process (5.1). Next we prove inductively that

$$(5.3) \quad D(i, d, k) \leq d + d^k (D(i+1, d, k))^2.$$

Indeed each variety  $V$  of dimension  $\geq i$  is either in  $C_0$  or else arises as a component of an intersection  $\overline{T(V_1)} \cap V_2$  of two irreducible varieties  $V_1, V_2$  of dimension  $\geq i+1$  occurring during the intersection process  $\{C_j\}$ . Hence, using Theorem 5.1 and Lemma 5.5, we obtain

$$\begin{aligned} D(i, d, k) &\leq d + \sum_{\substack{V_1, V_2 \\ \dim(V_1), \dim(V_2) \geq i+1}} \deg(\overline{T(V_1)} \cap V_2), \\ &\leq d + \left( \sum_{\substack{V_1 \\ \dim(V_1) \geq i+1}} \deg(\overline{T(V_1)}) \right) \left( \sum_{\substack{V_2 \\ \dim(V_2) \geq i+1}} \deg(V_2) \right), \\ &\leq d + d^k \left[ \sum_{\substack{V_1 \\ \dim(V_1) \geq i+1}} \deg(V_1) \right]^2 \end{aligned}$$

which yields (5.3). The recursions (5.2), (5.3) immediately imply by induction on  $i$  that

$$D(k-i, d, k) \leq h(i, d, k)$$

for  $1 \leq i \leq k$ . In particular,

$$f(d, k, \mathbf{F}) \leq D(0, d, k) \leq h(k, d, k) = g(d, k).$$

Claim 3 is proved.  $\square$

We remark that the inequality (5.3) for  $D(i, d, k)$  is not sharp. In fact with more care one can show that

$$(5.4) \quad D(i, d, k) \leq d + d^k \binom{D(i+1, d, k) + 1}{2}$$

holds. (This bound is essentially the sharpest attainable using Bezout’s inequality alone.) The recursion (5.4) improves the bound of Theorem 5.5 asymptotically to

$$f(d, k, \mathbf{F}) \leq 2^{1-2^{k-1}} d^{(2^{k-1}-1)(k+2^{k-1})} \left( 1 + O\left(\frac{1}{d}\right) \right).$$

Also for  $k=2$  the bound (5.4) implies that

$$\phi(d, 2, \mathbf{F}) \leq f(d, 2, \mathbf{F}) + 1 \leq \frac{1}{2}(d^4 + d^3) + d + 1$$

so that  $\phi(2, 2, \mathbf{F}) \leq 15$ .

**6. Extrapolation of modular polynomial recurrences with unknown modulus  $M$ .** As an application we consider the problem of predicting the values  $\{\mathbf{x}_n : n = 1, 2, \dots\}$  generated by a polynomial recurrence of degree at most  $d$  in  $k$  variables defined over

a ring  $\mathbf{Z}/M\mathbf{Z}$  where  $d$  and  $k$  are known but the modulus  $M$  is *unknown*. Assume that the observed values of the  $\mathbf{x}_i$  are given with integer entries which are least positive residues modulo  $M$ . The problem of finding a good extrapolation  $\hat{\mathbf{x}}_{n+1}$  given  $\mathbf{x}_0, \dots, \mathbf{x}_n$  is a generalization of those studied by Boyar [B1], [B2], [B3]. Our algorithm, which we call Algorithm  $\mathbf{B}_{dk}$ , is based on Boyar's ideas. At stage  $n$  it takes as input the vectors  $\mathbf{x}_0, \dots, \mathbf{x}_n$  and produces output  $(T_n, m_n, \hat{\mathbf{x}}_{n+1})$  as its estimate of the unknown transformation, modulus and next value  $(T, M, \mathbf{x}_{n+1})$ . Here the  $T_n$  is a set of  $\mathbf{Z}/m_n\mathbf{Z}$ -valued coefficients for the transformation  $T$ , with the property that the equations  $\mathbf{x}_i \equiv T_n(\mathbf{x}_{i-1})$  hold in  $\mathbf{Z}/m_n\mathbf{Z}$  for  $i=1, 2, \dots, n$ , where we adopt the notational convention that  $\mathbf{Z}/m\mathbf{Z} = \mathbf{Q}$  if  $m = +\infty$ . The prediction  $\hat{\mathbf{x}}_{n+1}$  at step  $n$  is simply  $\hat{\mathbf{x}}_{n+1} \equiv T_n(\mathbf{x}_n)$  (modulo  $m_n$ ).

Let  $\Sigma_n$  denote the system of inhomogeneous linear equations with integer coefficients that the coefficients of  $T$  must satisfy if they are to explain the data  $\mathbf{x}_0, \dots, \mathbf{x}_n$ . That is to say,  $\Sigma_n$  is the system of  $nk$  equations  $\mathbf{x}_i = T(\mathbf{x}_{i-1})$  for  $1 \leq i \leq n$  in the  $k \binom{k+d}{k}$  coefficients of  $T$ . The general strategy of the algorithm is to keep track of the set of moduli  $m$  for which it is possible to solve  $\Sigma_n$  modulo  $m$ . (Of course  $\Sigma_n$  are always solvable modulo  $M$ , but not necessarily for other moduli.) For any system  $\Sigma$  of linear inhomogeneous equations with integer coefficients let  $m^*(\Sigma)$  denote the largest modulus  $m$  for which  $\Sigma$  are solvable in  $\mathbf{Z}/m\mathbf{Z}$ , the case  $m = +\infty$  not excluded. (See Lemma 6.3 below for more information about  $m^*(\Sigma)$ .)

With this notation we may state our algorithm  $\mathbf{B}_{dk}$ :

- $\mathbf{B}_{dk}(0)$  Start at step  $n = 0$ .
- $\mathbf{B}_{dk}(1)$  Attempt to solve  $\Sigma_n$  over  $\mathbf{Q}$ . If there is no solution go to  $\mathbf{B}_{dk}(2)$ . If there is no solution call it  $T_n$ , set  $m_n = +\infty$  and set  $\hat{\mathbf{x}}_{n+1} = T_n(\mathbf{x}_n)$ . Deliver  $(T_n, m_n, \hat{\mathbf{x}}_{n+1})$  and go on to the next  $n$ .
- $\mathbf{B}_{dk}(2)$  If  $\Sigma_n$  has no solution over  $\mathbf{Q}$  let  $m_n = m^*(\Sigma_n)$  as described in Lemma 6.3. Let  $T_n$  solve  $\Sigma_n$  modulo  $m_n$  and set  $\hat{\mathbf{x}}_{n+1} = T_n(\mathbf{x}_n)$  reduced modulo  $m_n$ . Deliver  $(T_n, m_n, \hat{\mathbf{x}}_{n+1})$  and go on to the next  $n$ .

The linear equation solving can be done in polynomial time using standard algorithms [CC], [KB]. Some shortcuts are possible in the above algorithm. For example, if  $m_{n-1} < \infty$ , then we know  $\Sigma_n$  has no solution over  $\mathbf{Q}$  and that statement  $\mathbf{B}_{dk}(2)$  will have to be used. In this case, then, step  $\mathbf{B}_{dk}(1)$  may safely be omitted. A less obvious observation is due to Boyar [B1]: if  $n > \phi^*(d, k)$  and  $m_{n-1} < \infty$ , then  $m_n$  and  $T_n$  may be very cheaply computed by using the following fact:  $m_n$  is the greatest common divisor of  $m_{n-1}$  and the entries of  $\mathbf{x}_n - \hat{\mathbf{x}}_n$ , and one may take  $T_n = T_{n-1}$  since  $T_{n-1}$  solves  $\Sigma_n$  modulo  $m_n$ . This is proven below as Proposition 6.5.

The correctness of algorithm  $\mathbf{B}_{dk}$  is summarized in the following theorem, which depends on the unique extrapolation results of the earlier part of the paper.

**THEOREM 6.1.** *If the sequence  $\mathbf{x}_0, \mathbf{x}_1, \dots$  obeys  $\mathbf{x}_n \equiv T(\mathbf{x}_{n-1})$  (modulo  $M$ ) for  $n = 1, 2, \dots$ , then:*

- (1) *For all  $1 \leq i \leq n$ ,  $\mathbf{x}_i \equiv T_n(\mathbf{x}_{i-1}) \pmod{m_n}$ .*
- (2) *If  $m_n < \infty$ , then  $M \mid m_n$ .*
- (3) *If  $m_n < \infty$ , then  $m_{n+1} \mid m_n$ .*
- (4) *If  $n \geq \phi^*(d, k)$  and  $\hat{\mathbf{x}}_{n+1} \neq \mathbf{x}_{n+1}$ , then  $m_{n+1} \neq m_n$ .*

The performance of the algorithm depends essentially on the magnitude of the quantities  $m^*(\Sigma_n)$  used in calculating  $m_n$  in  $\mathbf{B}_{dk}(2)$ :

**THEOREM 6.2.** *Let  $N = 1 + k \binom{k+d}{k}$ .*

- (1) *If  $m_n < \infty$ , then  $m_n \leq N^{N/2} M^{dN}$ .*
- (2)  *$\hat{\mathbf{x}}_n \neq \mathbf{x}_n$  for at most  $\phi^*(d, k) + 1 + \log_2(N^{N/2} M^{dN})$  values of  $n$ .*

The proofs of Theorems 6.1 and 6.2 are given later in this section. The following two lemmas give the details of the computation in  $\mathbf{B}_{ak}(2)$  promised above.

LEMMA 6.3. *Let the  $e$  by  $n$  matrix  $\mathbf{A}$  and the  $e$  vector  $\mathbf{b}$  have integer entries. Suppose the system  $\Sigma$  of inhomogeneous linear equations*

$$\mathbf{Ax} = \mathbf{b}$$

has no solution over  $\mathbf{Q}$ .

(1) *Then there is a unique modulus  $m^*(\Sigma)$  such that  $\Sigma$  is solvable modulo  $m$  if and only if  $m$  divides  $m^*(\Sigma)$ .*

(2) *If all the entries  $\mathbf{A}$  and  $\mathbf{b}$  are bounded by  $\lambda$  in absolute value, then*

$$m^*(\Sigma) \leq (n + 1)^{(n+1)/2} \lambda^{n+1}.$$

(3) *There is a polynomial-time algorithm which solves  $\Sigma$  over the rationals if possible, and otherwise determines  $m^*(\Sigma)$  and solves  $\Sigma$  modulo  $m^*(\Sigma)$ .*

*Proof.* Claim (1) can be seen by reducing  $\Sigma$  over  $\mathbf{Z}$  using the Smith normal form for  $\mathbf{A}$  (see [KB]) into a new system of the form

$$\lambda_1 z_1 = \mu_1,$$

$$\lambda_2 z_2 = \mu_2,$$

...

$$\lambda_r z_r = \mu_r,$$

$$0 = \mu_{r+1},$$

$$0 = \mu_{r+2},$$

...

$$0 = \mu_e.$$

(Here  $r$  is the rank of  $\mathbf{A}$ .) If  $r = e$  or if  $\mu_{r+1} = \mu_{r+2} = \dots = \mu_e = 0$ , the system has a solution over the rationals:  $z_i = \mu_i / \lambda_i$ . Otherwise only a mod  $m$  solution can exist, where  $m$  must divide each of  $\mu_{r+1}, \mu_{r+2}, \dots, \mu_e$ . Thus the set  $\mathbf{M} = \{m : \Sigma \text{ is solvable modulo } m\}$  is finite. Certainly  $\mathbf{M}$  contains 1. If  $m$  is in  $\mathbf{M}$  and  $m'$  divides  $m$ , then  $m'$  is also in  $\mathbf{M}$ . Suppose  $m_1$  and  $m_2$  are in  $\mathbf{M}$ , so  $m_2 / \gcd(m_1, m_2)$  is also in  $\mathbf{M}$ . By the Chinese Remainder Theorem the product  $m_1 m_2 / \gcd(m_1, m_2) = \text{lcm}(m_1, m_2)$  is also in  $\mathbf{M}$ . Hence  $\mathbf{M}$  contains the l.c.m. of all its elements, which is the promised  $m^*(\Sigma)$ . The value of  $m^*(\Sigma)$  can be computed from the  $\lambda_i$  and  $\mu_i$  by repeated application of the recipe of Lemma 6.4 below. This value of  $m^*(\Sigma)$  is used as  $m_n$  in  $\mathbf{B}_{ak}(2)$  above.

Claim (3), that all the indicated computations can be done in polynomial time (polynomial in the number of bits to specify  $\mathbf{A}$  and  $\mathbf{b}$  in binary), follows when the algorithms of [KB] and especially [CC] are used in the above sketch.

It remains to prove the bound of claim (2). Suppose that  $\mathbf{x}$  solves  $\Sigma$  modulo  $m$ . Consider the augmented coefficient matrix  $\mathbf{A}'$  obtained by adjoining the column  $\mathbf{b}$  to the right of  $\mathbf{A}$ , and let  $\mathbf{x}'$  be obtained by appending the entry  $-1$  to the end of  $\mathbf{x}$ . Then there is an integer vector  $\mathbf{v}$  such that

$$\mathbf{A}'\mathbf{x}' = m\mathbf{v}$$

(over the integers). Now reduce  $\mathbf{A}'$  to Smith normal form:  $\mathbf{A}' = \mathbf{K}_1 \mathbf{S} \mathbf{K}_2$  where  $\mathbf{K}_1$  is in  $SL(e, \mathbf{Z})$  and  $\mathbf{K}_2$  is in  $SL(n, \mathbf{Z})$ , and  $\mathbf{S}$  has nonzero entries  $s_1, s_2, \dots, s_r$  only on the main diagonal, all of the  $s_i$  dividing  $s_r$ , where  $r$  is the rank of  $\mathbf{A}'$ . Let  $\mathbf{y} = \mathbf{K}_2 \mathbf{x}'$  and let  $\mathbf{w} = \mathbf{K}_1^{-1} \mathbf{v}$ . Then

$$\mathbf{S}\mathbf{y} = m\mathbf{w},$$

so  $m \mid s_i y_i$  for all  $i = 1, 2, \dots, r$ , and hence  $m \mid s_r y_i$  for all  $i$ . Since the greatest common divisor of the entries of  $\mathbf{x}'$  is one and since  $\mathbf{K}_2 \in SL(n, \mathbf{Z})$ , the greatest common divisor of the entries of  $\mathbf{y}$  is also one and there exist integers  $k_i$  such that  $\sum_{i=1}^{n+1} k_i y_i = 1$ . Hence  $m$  divides  $\sum_{i=1}^{n+1} k_i s_r y_i = s_r$ . But  $s_r$  in turn is a divisor of the greatest common divisor of all  $r$  by  $r$  minors of  $\mathbf{A}'$ , each one of which, by Hadamard's inequality, is bounded by  $r^{r/2} \lambda^r \leq (n+1)^{(n+1)/2} \lambda^{n+1}$ .  $\square$

LEMMA 6.4. For given  $(m, a, b)$  the set of divisors  $\mu$  of  $m$  such that the congruence

$$ax \equiv b \pmod{\mu}$$

is solvable is precisely the set of divisors of  $f(m, a, b)$  where

$$f(m, a, b) = m / \gcd \left( \left( \frac{a}{\gcd(a, b)} \right)^j, \frac{m}{\gcd(m, a, b)} \right),$$

where  $j = \lceil \log_2 m \rceil$ .

*Proof.* (This is essentially Lemma 3 of Boyar [B1], who presents a recursive algorithm for computing  $f(m, a, b)$ .) For each prime  $p$ , if  $p^{m_p} \parallel m$ ,  $p^{a_p} \parallel a$  and  $p^{b_p} \parallel b$ , then  $p^{\mu_p} \parallel \mu$  where  $\mu_p \leq \min(m_p, b_p)$  if  $a_p > b_p$  and  $\mu_p \leq m_p$  otherwise. By a routine calculation we check that the maximal such  $\mu$  is  $f(m, a, b)$ .  $\square$

Now we proceed to the proofs of Theorems 6.1 and 6.2.

*Proof of Theorem 6.1.* Claim (1) is obvious from the construction of  $m_n$  and  $T_n$  in  $\mathbf{B}_{dk}$ . To see claim (2) note that the true  $T$  solves  $\Sigma_n$  modulo  $M$ , so Lemma 6.3 tells us that  $M \mid m_n$ . Claim (3) is also easy: the system  $\Sigma_n$  is a subset of  $\Sigma_{n+1}$  so  $m_{n+1} < \infty$  and  $T_{n+1}$  solves  $\Sigma_n$  modulo  $m_{n+1}$ . By Lemma 6.3 this means  $m_{n+1} \mid m_n$ . Finally, to prove claim (4), suppose at stage  $n$  the algorithm produces  $(T_n, m_n, \hat{\mathbf{x}}_{n+1})$  satisfying  $\Sigma_n$  modulo  $m_n$  and at stage  $n+1$  the algorithm produces  $(T_{n+1}, m_{n+1})$  satisfying  $\Sigma_{n+1}$  modulo  $m_{n+1}$ . If  $m_n = m_{n+1}$ , then by the unique extrapolation property for the ring  $\mathbf{Z}/m_n\mathbf{Z}$  we must have  $T_n(\mathbf{x}_n) = T_{n+1}(\mathbf{x}_n)$ , i.e.,  $\hat{\mathbf{x}}_{n+1} = \mathbf{x}_{n+1}$ .  $\square$

*Proof of Theorem 6.2.* Claim (1) follows directly from claim (2) of Lemma 6.3. There are  $k \binom{k+d}{k}$  coefficients in  $T$ , and hence that many variables in the equations to be solved in  $\mathbf{B}_{dk}(2)$ . The entries in the coefficient matrix are monomials of total degree  $\leq d$  in the data vector components, and hence are bounded by  $M^d$ . Claim (2) follows from this observation and from claims (3) and (4) of Theorem 6.1: the number of distinct elements in a chain of divisors

$$M \mid \dots \mid m_{n+1} \mid m_n$$

is bounded by  $1 + \log_2 m_n$ .  $\square$

Finally, we show that the "speed up" for  $\mathbf{B}_{dk}(2)$  mentioned above is correct.

PROPOSITION 6.5. Suppose  $n > \phi^*(d, k)$  and  $m_{n-1} < \infty$ . Let  $m$  denote the greatest common divisor of  $m_{n-1}$  and the entries of  $\mathbf{x}_n - \hat{\mathbf{x}}_n$ . Then  $m_n = m$  and  $T_{n-1}$  solves  $\Sigma_n$  modulo  $m_n$ .

*Proof.* By Theorem 6.1 we know  $m_n \mid m_{n-1}$  and that both  $T_{n-1}$  and  $T_n$  solve  $\Sigma_{n-1}$  modulo  $m_n$ . Use both  $T_{n-1}$  and  $T_n$  to predict  $\mathbf{x}_n$  modulo  $m_n$ . By the unique extrapolation property for the ring  $\mathbf{Z}/m_n\mathbf{Z}$  both predictions agree, so that  $T_{n-1}(\mathbf{x}_{n-1}) = T_n(\mathbf{x}_{n-1})$  modulo  $m_n$ . This means that  $\hat{\mathbf{x}}_n = \mathbf{x}_n$  modulo  $m_n$  and hence  $m_n$  is a divisor of all the coefficients of  $\hat{\mathbf{x}}_n - \mathbf{x}_n$  as well as of  $m_{n-1}$ . Since  $m$  is defined as the greatest such divisor,  $m_n \mid m$ . On the other hand,  $T_{n-1}$  solves  $\Sigma_n$  modulo  $m$  so by Lemma 6.3 we know  $m \mid m_n$ .  $\square$

*Remarks.* (1) Theorem 6.2 bounds the number of mistakes that the extrapolation algorithm may make, but it does not bound the number of values seen before the last mistake occurs. As an example, Algorithm  $\mathbf{B}_{11}$  takes  $M+1$  steps to distinguish the

simple recurrence  $y_0 = 0$  and  $y_n = y_{n-1} + 1$  over  $\mathbf{Z}$  from the recurrence  $y_0 = 0$  and  $y_n \equiv y_{n-1} + 1 \pmod{M}$ . This number of steps is exponential in  $\log M$ , which is the number of bits needed to specify the modulus  $M$ .

(2) The extrapolation method of this section does not apply to the more general problem of extrapolating a sequence  $\{z_i : i \leq 0\}$  generated by polynomial maps  $T : (\mathbf{Z}/M\mathbf{Z})^k \rightarrow \mathbf{Z}/M\mathbf{Z}$  and  $S : (\mathbf{Z}/M\mathbf{Z})^k \rightarrow \mathbf{Z}/M\mathbf{Z}$ , where

$$\mathbf{x}_n = T(\mathbf{x}_{n-1}), \quad z_n = S(\mathbf{x}_n),$$

even when *both the maps  $T$  and  $S$  and the modulus  $M$  are known*. In this case the problem of reconstructing a seed  $\mathbf{x}_0$  that produces the observed data  $\{z_i : 0 \leq i \leq n\}$  is nonlinear, and we do not know of a polynomial-time algorithm to solve it. The problem of extrapolating the  $\{z_i : 0 \leq i \leq n\}$  seems equally difficult.

**Acknowledgments.** We are indebted to J. H. Conway for suggesting that our preliminary results should hold over arbitrary commutative rings with unit, to C. P. Schnorr for references to a multidimensional Bezout's theorem, to J. P. Butler for Proposition 4.2 and to L. A. Shepp for helpful comments.

## THE DISCRETE LOGARITHM HIDES $O(\log n)$ BITS\*

DOUGLAS L. LONG† AND AVI WIGDERSON‡

**Abstract.** The main result of this paper is that obtaining any information about the  $O(\log |p|)$  “most significant” bits of  $x$ , given  $g^x \pmod{p}$ , even with a tiny advantage over guessing, is equivalent to computing discrete logarithms mod  $p$ .

**Key words.** discrete logarithm, one-way functions, secure transactions, bit security, pseudorandom bit generator, public-key cryptography

**AMS(MOS) subject classifications.** 68P25, 68Q15

**1. Introduction.** A function  $f: [1, N] \rightarrow [1, N]$  is said to be one-way if computing  $f(x)$  from  $x$  is easy, but computing  $x$  from  $f(x)$  is hard. One-way functions are extremely attractive in cryptographic applications (see [5], [6], [16], [18], [19]). However, one should use them with care. The reason is that while  $x$  is hard to compute from  $f(x)$ , it may be possible to obtain *almost all* bits of  $x$  easily. It is clear, however, that some bits of  $x$  are hard to obtain.

In a key paper, Blum and Micali [5] introduced the notion of hiding a bit in a one-way function. A Boolean predicate  $B: [1, N] \rightarrow \{0, 1\}$  is said to be hard for  $f$  if an oracle for  $B(f(x))$  allows one to invert  $f$  easily. They prove that a certain Boolean predicate is hard for the discrete logarithm function, and show how to use that to construct good pseudorandom number generators.

Some natural questions arise in light of their work. Given a one-way function  $f$ :

- 1) What are its hard bits?
- 2) How many hard bits are there?
- 3) How many bits are hard simultaneously?

To explain what we mean by the last question, consider  $B$ , a hard Boolean predicate for  $f$ , and its complement,  $\bar{B}$ . Clearly,  $\bar{B}$  is also hard for  $f$ . However, some information about the pair of bits  $(B(f(x)), \bar{B}(f(x)))$  is available, namely the information that they are different. Therefore this two-bit predicate is not hard for  $f$ . We say that a  $k$ -bit predicate  $B^k: [1, N] \rightarrow \{0, 1\}^k$  is hard for  $f$  if for every Boolean predicate  $B: \{0, 1\}^k \rightarrow \{0, 1\}$ , an oracle for  $B(B^k(f(x)))$  will allow us to invert  $f$  easily. If such a  $B^k$  exists, we say that  $f$  hides  $k$  bits.

The fact that hiding only one bit suffices for many applications seems to reduce the motivation for the questions above. We would like to argue that this is not the case. From the practical point of view, the ability to hide  $k$  bits cuts the computation/communication per secure bit by a factor of  $k$ . One can flip  $k$  coins at a time or generate  $k$  bits at a time with a pseudorandom number generator without hurting security.

But what really motivates us is the theoretic point of view. Very little is known about one-way functions. In particular, a major open problem is whether they exist. We believe that discovering and studying the “hard core” (the collection of hard bits) of functions that are believed to be one-way may shed some light on this problem.

In this paper we focus our attention on the discrete logarithm function, which is widely believed to be one-way. Our main result states that the discrete log function hides  $c \cdot \log |p|$  bits for any constant  $c$ , where  $p$  is the modulus and  $|p|$  is the number of bits in the binary representation of  $p$ . This paper subsumes the results of [11] where we proved the same result using an additional assumption (see § 5 for details). Similar results for the case of the RSA and Rabin encryption functions were subsequently obtained by Alexi, Chor, Goldreich and Schnorr [3] and by Vazirani and Vazirani [17].

Results similar to those of [11] were obtained by Long [12], using similar techniques but a different set of bits. Recently, using a different technique (similar in spirit to that used in [17]), Peralta [13] showed that the discrete log function can be used for a pseudorandom bit generator which outputs  $O(\log |p|)$  bits at time, a result which is equivalent to ours.

Section 2 states the main results of the paper. Section 3 contains some technical lemmas. In § 4 we extend the techniques of [5] to prove our main result for the case where the oracle is always correct. In § 5 we extend our results to the case where the oracle is more correct than incorrect. In § 6 we discuss an application of our work to pseudorandom bit generation. Section 7 concludes with an open problem.

**2. Hiding bits.** We start with some definitions. From this point on  $p$  will represent an  $n$ -bit prime,  $Z_p^*$  the group of units mod  $p$ ,  $g$  a generator of  $Z_p^*$ , and  $k$  an integer such that  $k \leq n$ .

**DEFINITION 2.1.** Suppose  $z \in Z_p^*$ . The **index of  $z$** ,  $\text{index}(z)$ , is the unique  $x \in Z_p^*$  such that  $z \equiv g^x \pmod{p}$ .  $x$  is also known as the **discrete logarithm of  $z$** .

Blum and Micali [5] showed how to use the discrete logarithm to hide a single bit. They hide their bit by dividing the range  $[1, p - 1]$  into two equal-size intervals called the left and the right. A “0” bit is encoded by choosing  $x$  from the left and computing  $g^x$ . A “1” bit is encoded by choosing  $x$  from the right. They prove that even a small advantage in determining from  $g^x$  if  $x$  is in the left or the right can be used to solve the discrete logarithm problem. In fact, it is only necessary to be able to do this for  $x$  that are in the beginning of the left or beginning of the right. We can state this formally as the

*t-Left-Right Problem.* Given  $g^x \in Z_p^*$ , such that  $x \in [1, (p-1)/t] \cup [(p-1)/2, (p-1)/2 + (p-1)/t]$ , determine if  $x \in [1, (p-1)/t]$  or  $x \in [(p-1)/2, (p-1)/2 + (p-1)/t]$ .

Blum and Micali’s result can be stated as the following:

**THEOREM 2.1** (Blum and Micali). *Suppose  $p$  is an  $n$ -bit prime and  $\delta < \frac{1}{2}$ . Suppose there exists an oracle which solves the  $t$ -left-right problem correctly with probability at least  $1 - \delta$ . Then there exists a Las Vegas algorithm for the discrete logarithm which makes calls to this oracle and has expected running time  $O(t \cdot n^3(1 - \delta)^{-n})$ .*

We generalize Blum and Micali’s method of hiding 1 bit to  $k$  bits by dividing the interval  $[1, p - 1]$  into  $2^k$  consecutive, roughly equal, intervals  $I_i^k = [L_i^k, U_i^k]$  for  $i$  from 0 to  $2^k - 1$ , where  $L_i^k = \lfloor ((p-1)/2^k)i \rfloor + 1$ , and  $U_i^k = \lfloor ((p-1)/2^k)(i+1) \rfloor$ . We will call this a partition at the  $k$ th level. For  $x \in [1, p - 1]$  let  $I^k(x)$  be the interval which contains  $x$ , i.e., the integer  $i$  such that  $x \in I_i^k$ . Let  $R^k = \lfloor (p-1)/2^k \rfloor$ . The lower indices of  $I_i^k$  are computed modulo  $2^k$ , i.e.,  $I_{r+s}^k$  means  $I_{r+s \pmod{2^k}}^k$ .

In order to hide the  $k$  bits representing the integer  $i$ ,  $0 \leq i < 2^k$ , choose a random  $x \in I_i^k$  and compute  $g^x \pmod{p}$ . An integer  $z \in Z_p^*$  hides the bits which represent the interval of its index.

We claim that these bits are securely hidden. In order to justify this claim we must show that any advantage in determining not only the bits, but any partial information

about the bits, can be used to solve the discrete logarithm problem. Determining partial information about the bits means evaluating some nontrivial Boolean predicate on  $k$  bits. We will call such a predicate a decision.

DEFINITION 2.2. A **decision on  $k$  bits** is a nonconstant function  $d : \{0, 1\}^k \rightarrow \{0, 1\}$ . If we consider  $d$  as a function from the integers  $0, \dots, 2^k - 1$  into  $\{0, 1\}$  then we can extend  $d$  to all integers by defining  $d(i) = d(i \pmod{2^k})$ .

We claim any advantage in evaluating any decision on  $k$  bits can be used to solve the discrete log problem. First we formalize what we mean by an advantage.

DEFINITION 2.3. Suppose  $d$  is a decision on  $k$  bits. Let  $f_d$  = the fraction of  $k$ -tuples  $(b_1, b_2, \dots, b_k)$  such that  $d(b_1, b_2, \dots, b_k) = 1$ .

Without loss of generality we assume that  $f_d \geq \frac{1}{2}$ .

DEFINITION 2.4. Suppose  $d$  is a decision on  $k$  bits. A function  $\theta_d : [1, p - 1] \rightarrow \{0, 1\}$  is an  $\alpha$ -**oracle** for  $d$  if  $\theta_d(g^x) = d(I^k(x))$  for the fraction  $\alpha$  of  $x \in [1, p - 1]$ . A 1-oracle is known as a **perfect oracle** (i.e., an oracle that never makes a mistake). An  $\alpha$ -oracle has an  $\varepsilon$ -**advantage** in evaluating  $d$  if  $\alpha = f_d + \varepsilon$ .

An oracle with an  $\varepsilon$ -advantage does  $\varepsilon$  better than an oracle that always guesses 1.

We can now state the main result of this paper. Any nontrivial advantage in evaluating any decision on  $k$  bits can be used to solve the discrete log problem. We state this formally as the following theorem and corollary.

THEOREM 2.2. For any  $k$ , let  $d$  be a decision on  $k$  bits. Let  $\theta_d$  be an  $\varepsilon$ -advantage oracle for  $d$ . Then, using  $\theta_d$ , it is possible to construct an algorithm that solves the  $s$ -left-right problem correctly with probability  $1 - \delta$ . The parameter  $s$  and the running time of the conversion algorithm are polynomial in  $\varepsilon^{-1}$ ,  $\delta^{-1}$ ,  $n$ , and  $2^k$ . (Note that  $\varepsilon^{-1}$  may be polynomial in  $n$ .)

COROLLARY 2.1. Suppose  $k = O(\log n)$ . Let  $d$  be a decision on  $k$  bits. If there exists an  $\varepsilon$ -advantage oracle for  $d$ , then there exists a Las Vegas algorithm for the discrete log that runs in time polynomial in  $n$  and  $\varepsilon^{-1}$ .

*Proof.* Follows from Theorem 2.1 and Theorem 2.2.  $\square$

**3. Properties of partitions.** In this section we present a series of technical lemmas outlining some of the properties of partitions. The reader may wish to skip the proofs on first reading.

The following lemma shows that the intervals  $I_i^k$  are of roughly the same size.

LEMMA 3.1. For  $0 \leq i \leq 2^k - 1$ ,  $|I_i^k| = R^k$  or  $R^k + 1$ .

*Proof.*

$$|I_i^k| = U_i^k - L_i^k + 1 = \left\lfloor \frac{p-1}{2^k} (i+1) \right\rfloor - \left\lfloor \frac{p-1}{2^k} \right\rfloor.$$

Let  $0 \leq r_i < 1$  and  $0 \leq s_i < 1$  be the fractional parts of the expressions in the floors. Then

$$|I_i^k| = \frac{p-1}{2^k} i + \frac{p-1}{2^k} - r_i - \left( \frac{p-1}{2^k} i - s_i \right) = \frac{p-1}{2^k} - r_i + s_i.$$

But  $|s_i - r_i| < 1$  and  $\lfloor (p-1)/2^k \rfloor \leq (p-1)/2^k < \lfloor (p-1)/2^k \rfloor + 1$  so  $|I_i^k|$  must be either  $\lfloor (p-1)/2^k \rfloor$  or  $\lfloor (p-1)/2^k \rfloor + 1$ .  $\square$

The following lemma shows that the partition at the  $k$ th level refines the partition at the  $(k-1)$ st level.

LEMMA 3.2.  $L_i^{k-1} = L_{2i}^k$ ,  $U_i^{k-1} = U_{2i+1}^k$ . Consequently  $I_i^{k-1} = I_{2i}^k \cup I_{2i+1}^k$ .

*Proof.* Follows immediately from the definition of  $I_i^k$ .  $\square$

Throughout this paper, given an element  $z \in \mathbb{Z}_p^*$ , we will apply the operations  $w \leftarrow zg^{iR^k}$ ,  $w \leftarrow \sqrt{z}$  ( $z$  is a quadratic residue and we pick the root with the smaller index), and  $w \leftarrow zg^{-1}$  ( $z$  is a nonresidue). The effect of these operations on the index of  $z$  is

to shift it by a multiple of  $R^k$ , to divide it by two (when even), and to subtract one from it (when odd), respectively. We will call these operations *index operations* because they change the index in a specific way. The following lemmas show into which intervals the new index may fall.

LEMMA 3.3. *Let  $x \in I_j^k$ . Then for every  $1 \leq i \leq 2^k - 1$*

- (1)  $x + iR^k \in I_{i+j}^k$ , or
- (2)  $x + tR^k = L_{t+j}^k$  for some  $0 \leq t < i$ .

*Proof.* By induction on  $i$ . If  $i = 1$  then from Lemma 3.1  $x + R^k \in I_j^k$  if and only if  $|I_j^k| = R^k + 1$  and  $x = L_j^k$ . If  $i > 1$  then let  $x' = x + (i - 1)R^k$ . If  $x' \notin I_{i+j-1}^k$  then case (2) holds for  $x'$  and therefore for  $x$ . Otherwise  $x' \in I_{i+j-1}^k$  so  $x + iR^k \equiv x' + R^k \pmod{p - 1}$  and the lemma follows by the same argument as for  $i = 1$ .  $\square$

LEMMA 3.4. *If  $2x \in I_j^{k-1}$ , then*

- (1)  $x \in I_j^k$  or  $x \in I_{j+2^{k-1}}^k$ , or
- (2)  $2x = L_j^{k-1}$  or  $2x = U_j^{k-1}$ .

*Proof.* Suppose  $x \leq (p - 1)/2$ . (The case  $x > (p - 1)/2$  is analogous.)

Suppose  $2x > L_{2j}^k = L_j^{k-1}$ . Then  $1 + \lfloor ((p - 1)/2^k)2j \rfloor < 2x$ . So  $((p - 1)/2^k)2j < 2x$  and  $\lfloor ((p - 1)/2^k)j \rfloor \leq ((p - 1)/2^k)j < x$ . Therefore  $L_j^k = 1 + \lfloor ((p - 1)/2^k)j \rfloor \leq x$ .

Now suppose  $2x < U_{2j+1}^k = U_j^{k-1}$ . Then  $2x < \lfloor ((p - 1)/2^k)((2j + 1) + 1) \rfloor \leq ((p - 1)/2^k)2(j + 1)$ . Thus  $x \leq \lfloor ((p - 1)/2^k)(j + 1) \rfloor = U_j^k$ .  $\square$

LEMMA 3.5. *If  $x \in I_j^k$  (and  $x$  is odd), then either*

- (1)  $(x - 1) \in I_j^k$ , or
- (2)  $x = L_j^k$ .

*Proof.* Follows immediately from the definition.  $\square$

The index operations given above are well behaved (in the sense that they change the index of  $z$  in a specified way) except when  $z = g^{L_j^k}$  or  $z = g^{U_j^k}$ . We call these points the *boundary points*. We can easily determine if  $z$  is a boundary point (and thereby compute  $\text{index}(z)$ ) by maintaining a sorted list of these values. There are  $O(2^k)$  values to maintain so sorting will cost  $O(k2^k)$  time and each query  $O(k)$  time. If  $z$  is not a boundary point then the index operations will result in the index of  $z$  falling in the intervals given in case (1) of Lemmas 3.3, 3.4 or 3.5. Henceforth, we will assume that whenever an index operation is performed on  $z$ , a test for case (2) of Lemmas 3.3, 3.4 or 3.5 is performed by checking to see if  $z$  is a boundary point.

**4. Oracles which are always correct.** This section considers the case of a perfect oracle. In the next section we will consider what happens if the oracle is not perfect.

We will prove the following

THEOREM 4.1. *Let  $k = O(\log n)$ . If there exists a decision  $d$  on  $k$  bits, and a perfect oracle for  $d$ ,  $\theta_a$ , then it is possible to solve the  $2^k$ -left-right problem. This can be done in time polynomial in  $n$ , including time for the boundary tests.*

We first note the following facts about decisions.

Decisions repeat themselves at intervals of  $2^k$ . Some decisions repeat themselves at smaller intervals.

DEFINITION 4.1. Let  $d$  be a decision on  $k$  bits. The **period of  $d$**  is the smallest  $r$  such that  $d(i) = d(i + r)$  for all  $i$ .

The period of a decision is always a power of two.

LEMMA 4.1. *Let  $d$  be a decision on  $k$  bits and let  $r$  be the period of  $d$ . Then  $r = 2^l$  where  $0 < l \leq k$ .*

*Proof.* Immediate from the definition of period.  $\square$

LEMMA 4.2. *Let  $d$  be a decision on  $k$  bits with period  $2^l$ . Then there exists an  $j < 2^{l-1}$  such that  $d(j) \neq d(j + 2^{l-1})$ . Moreover, such a  $j$  can be found in  $O(2^k)$  time by linear search.*

*Proof.* Immediate from the definition of period and the fact that a decision is nonconstant.  $\square$

Theorem 2.1 says that solving the  $t$ -left-right problem is as hard as inverting the discrete log. In the following we will show how to use the information provided by any decision on  $k$  bits to solve the  $t$ -left-right problem. For every  $j$ ,  $1 \leq j \leq k$ , consider the partition of the set of intervals  $\{I_i^j\}$  into two types, even and odd, depending on whether  $i$  is even or odd. The method is based on the following observation. The roots of quadratic residues in even (odd) intervals at level  $j$  fall in even (odd) intervals at level  $j+1$  (except at interval boundaries). For example, note that the roots of quadratic residues in  $I_0^1$  (the left half) are contained in  $I_0^2$  and  $I_2^2$ , while the roots of quadratic residues in  $I_1^1$  (the right-half) are contained in  $I_1^2$  and  $I_3^2$ .

A decision gives us information about the intervals at some level. To translate this information to information about the first level we repeatedly take square roots as shown by procedure REDUCE and the following lemmas.

For  $z \in [1, p-1]$  and  $0 \leq l \leq k$  define the procedure REDUCE  $(z, l)$ .

Procedure REDUCE  $(z, l)$

```

 $w \leftarrow z$ 
for  $i = 1$  to  $k-l$  do
    if  $w$  is a nonresidue then  $w \leftarrow wg^{-1}$ 
     $w \leftarrow \sqrt{w}$  (either root)
endfor
return  $(w)$ 
    
```

LEMMA 4.3. For any  $z \in [1, p-1]$  and  $0 \leq l \leq k$ , procedure REDUCE can be evaluated in time polynomial in  $n$ .

*Proof.* Since a quadratic nonresidue,  $g$ , is known, the extraction of square roots in the above procedure can be performed in time  $O(n^2)$  [1], [7].  $\square$

We proceed by showing how to use an oracle for a decision on  $k$  bits, with period  $2^l$ , and REDUCE to solve the  $2^k$ -left-right problem. This amounts to deciding, given  $g^x$ , if  $x \in I_0^k$  or  $x \in I_{2^{k-1}}^k$ . If the period,  $2^l$ , is less than  $2^k$  then it will always be the case that  $d(0) = d(2^{k-1})$  so an oracle for such a decision is not of direct use. However, it is possible to use REDUCE to get around this problem.

LEMMA 4.4. Let  $z \in [1, p-1]$  and let  $w = \text{REDUCE}(z, l)$ . Let  $x = \text{index}(z)$  and  $y = \text{index}(w)$ . If  $I^k(x) \equiv 0 \pmod{2^k}$  then  $I^k(y) \equiv 0 \pmod{2^l}$ . If  $I^k(x) \equiv 2^{k-1} \pmod{2^k}$  then  $I^k(y) \equiv 2^{l-1} \pmod{2^l}$ .

*Proof.* Suppose  $I^k(x) \equiv 0 \pmod{2^k}$ . (The other case is similar.)

The case  $l=k$  is clear. Assume the lemma is true for  $l+1$ . Let  $w' = \text{REDUCE}(z, l+1)$  and  $y' = \text{index}(w')$ . If  $y'$  is odd set  $w' \leftarrow w' \cdot g^{-1}$  and  $y' \leftarrow y' - 1$ . (This operation does not change  $I^k(y')$  by Lemma 3.5.) Let  $w = \sqrt{w'}$  and  $y = \text{index}(w)$ . (For example,  $w = \text{REDUCE}(z, l)$  and  $y' \equiv 2y \pmod{p-1}$ .) By the induction hypothesis  $I^k(y') \equiv 0 \pmod{2^{l+1}}$ . Let  $I^k(y') = 2j$ . Since  $2y \in I_{\beta j}^k \subset I_j^{k-1}$ , by Lemma 3.4  $y \in I_j^k$  or  $I_{j+2^{k-1}}^k$ . In other words,  $I^k(y) = I^k(y')/2$  or  $(I^k(y')/2) + 2^{k-1}$ . Therefore  $I^k(y) \equiv 0 \pmod{2^l}$ .  $\square$

Now we are ready to prove Theorem 4.1.

*Proof of Theorem 4.1.* Suppose there exists a perfect oracle  $\theta_d$  for some decision  $d$  on  $k$  bits. Let the period of  $d$  be  $2^l$ . Choose a  $j$  such that  $d(j) \neq d(j+2^{l-1})$ .

We will construct an algorithm for the  $2^k$ -left-right problem. Suppose  $z \in Z_p^*$  such that  $x = \text{index}(z) \in I_0^k \cup I_{2^{k-1}}^k$ . Let  $w = \text{REDUCE}(z, l)$  and  $y = \text{index}(w)$ . By Lemma 4.4  $x \in I_0^k$  if  $I^k(y) \equiv 0 \pmod{2^l}$ . Otherwise,  $x \in I_{2^{k-1}}^k$ . Let  $w' = w \cdot g^{jR^k}$  and  $y' = \text{index}(w')$ .

Then  $d(I^k(y')) = d(I^k(y + jR^k)) = d(I^k(y) + j)$ . If  $I^k(y) \equiv 0 \pmod{2^l}$  then  $d(I^k(y')) = d(j)$ . Otherwise  $d(I^k(y')) = d(j + 2^{l-1})$ . Since  $d(j) \neq d(j + 2^{l-1})$  the query  $\theta_a(w')$  will determine  $I^k(y) \pmod{2^l}$  and thus  $I^k(x) \pmod{2^k}$ .  $\square$

**5. Oracles which make mistakes.** We now consider the case of a nonperfect oracle. For example, there exists an oracle that gives some partial information about the  $k$  bits, but it does not always give the correct answer.

Blum and Micali handled the case of a nonperfect oracle by using a random sampling technique which they called ‘‘Concentrating the Stochastic Advantage.’’ They were able to use this technique to correctly determine the value of their predicate with high probability because they were able to sample over the entire range  $[1, p - 1]$ . In order to extend these results to  $k$  bits using an oracle with an  $\epsilon$ -advantage and the techniques developed in the previous section, it is necessary to be able to evaluate the value of the predicate correctly with high probability on a single interval  $I_i^k$ . Unfortunately, within an interval nothing is known about the proportion of  $x$  for which  $\theta_a(g^x)$  gives the correct value. In [11], we assumed that the error in every interval was bounded. Here we make no such assumptions. It might be the case that  $\theta_a$  gives the wrong answer for every  $x$  in some interval  $I_i^k$ . However, if this occurs there must be some other interval (or intervals) that have a higher percentage of correct answers. Many intervals can be sampled to obtain the necessary information.

As explained below, here we are faced with a continuous analogue of the discrete problem of § 4. In the previous section we used the Boolean values of a decision to extract information required to solve the left-right problem. We can interpret the values of a decision as a probability. For example, if  $d(I^k(x)) = 1$  then the probability that  $\theta_a(g^y) = 1$  for any  $y \in I^k(x)$  is 1 since a perfect oracle always gives the same answer for all values within an interval. When the oracle makes mistakes the probability that the oracle answers 1 on a random value in an interval is no longer either 0 or 1, but could be any value in between. In the following we develop the techniques to extract the information needed to solve the left-right problem from this sequence of probabilities.

DEFINITION 5.1. For  $0 \leq i < 2^k$ , let  $q(i) =$  the fraction of  $y \in I_i^k$  such that  $\theta_a(g^y) = 1$ .

If  $x$  is chosen randomly from  $I_i^k$ , then  $q(i)$  is the probability that  $\theta_a(g^x) = 1$ . We will postpone discussion of how to measure the  $q(i)$  and assume for the moment that given  $g^x$  we can measure  $q(I^k(x))$ .

We will also need the following definition.

DEFINITION 5.2. For  $0 \leq i < 2^k$ , let  $r(i) =$  the fraction of  $y \in I_i^k$  such that  $\theta_a(g^y) = d(i)$ .

If  $x$  is chosen randomly from  $I_i^k$ , then  $r(i)$  is the probability that  $\theta_a(g^x) = d(i)$ . Note that if  $d(i) = 1$  then  $r(i) = q(i)$  and otherwise  $r(i) = 1 - q(i)$ .

We are interested in certain families of subsequences of the  $q(i)$ . The indices of these subsequences are given below.

DEFINITION 5.3. Suppose  $0 \leq m \leq k$  and  $0 \leq j < 2^m$ . Let

$$Q_k(j, m) = (j, j + 2^m, j + 2 \cdot 2^m, \dots, j + (2^{k-m} - 1) \cdot 2^m).$$

The sequence  $Q_k(0, 0)$  is denoted by  $Q_k$ . Also note that  $i \in Q_k(j, m)$  if and only if  $j \equiv i \pmod{2^m}$ .

DEFINITION 5.4. The average value of the probabilities whose indices are given in each sequence  $Q_k(j, m)$  is given by

$$EQ_k(j, m) = \frac{1}{|Q_k(j, m)|} \sum_{i=0}^{2^{k-m}-1} q(j + i \cdot 2^m).$$

The average  $EQ_k(0, 0)$  is denoted by  $EQ_k$ .

In the discrete case a decision had to be nonconstant in order to be able to extract information from it. In the following recursive definition we formalize the continuous analogue.

**DEFINITION 5.5.** Suppose  $0 \leq \gamma \leq 1$ ,  $0 \leq j < 2^k$ , and  $0 \leq m \leq k$ . For  $m = k$  (i.e.,  $|Q_k(j, m)| = 1$ ), then  $Q_k(j, m)$  is  $\gamma$ -constant. For  $m < k$ ,  $Q_k(j, m)$  is  $\gamma$ -constant if and only if  $|EQ_k(j, m+1) - EQ_k(j+2^m, m+1)| \leq \gamma$  and  $Q_k(j, m+1)$  and  $Q_k(j+2^m, m+1)$  are each  $\gamma$ -constant.

The following lemma shows that in a  $\gamma$ -constant subsequence all values are close to the average.

**LEMMA 5.1.** *If  $Q_k(j, l)$  is  $\gamma$ -constant then for all  $i \in Q_k(j, l)$*

$$|EQ_k(j, l) - q(i)| \leq \frac{k-l}{2} \gamma.$$

*Proof.* The proof is by backwards induction on  $l$ .

If  $l = k$  then  $Q_k(j, k) = (j)$  and so  $EQ_k(j, k) = q(j)$ .

Assume the lemma holds for  $l+1$ . Suppose  $Q_k(j, l)$  is  $\gamma$ -constant. Then  $|EQ_k(j, l+1) - EQ_k(j+2^l, l+1)| \leq \gamma$  and  $Q_k(j, l+1)$  and  $Q_k(j+2^l, l+1)$  are both  $\gamma$ -constant. By the induction hypothesis, for all  $i \in Q_k(j, l+1)$

$$|EQ_k(j, l+1) - q(i)| \leq \frac{k-(l+1)}{2} \gamma$$

and for all  $i \in Q_k(j+2^l, l+1)$

$$|EQ_k(j+2^l, l+1) - q(i)| \leq \frac{k-(l+1)}{2} \gamma.$$

But

$$EQ_k(j, l) = \frac{EQ_k(j, l+1) + EQ_k(j+2^l, l+1)}{2}.$$

Therefore, for all  $i \in Q_k(j, l)$

$$|EQ_k(j, l) - q(i)| \leq \frac{\gamma}{2} + \frac{k-(l+1)}{2} \gamma = \frac{k-l}{2} \gamma. \quad \square$$

In § 4 we were able to obtain information from a nonconstant decision. In this section the analogous situation will be that the sequence  $Q_k$  must be nonconstant in the following sense.

**LEMMA 5.2.** *If  $\theta_d$  is an  $\varepsilon$ -advantage oracle for a decision  $d$  then  $Q_k$  is not  $(\varepsilon/k)$ -constant.*

*Proof.* Suppose  $Q_k$  is  $(\varepsilon/k)$ -constant. By Lemma 5.1, for  $0 \leq i < 2^k$ ,  $|q(i) - EQ_k| \leq (\varepsilon/2)$ . Thus  $q(i) \leq EQ_k + (\varepsilon/2)$  and  $1 - q(i) \leq 1 - EQ_k + (\varepsilon/2)$ . Let  $t = 2^k \cdot f_d$  = the number of  $k$ -tuples  $(b_1, b_2, \dots, b_k)$  such that  $d(b_1, b_2, \dots, b_k) = 1$ . Recall that if  $d(i) = 1$  then  $r(i) = q(i)$  and if  $d(i) = 0$  then  $r(i) = 1 - q(i)$ . Hence, there are  $2^k - t$  disjoint pairs  $(i_1, i_2)$  such that  $r(i_1) = q(i_1)$  and  $r(i_2) = 1 - q(i_2)$ . For these pairs  $r(i_1) + r(i_2) \leq EQ_k + (\varepsilon/2) + 1 - EQ_k + (\varepsilon/2) = 1 + \varepsilon$ . For each of the other  $2 \cdot t - 2^k$  numbers  $i$  which are not among these pairs,  $r(i) \leq 1$ . Since the oracle gives the correct answer for the

fraction  $(1/2^k) \sum r(i)$  we have

$$\begin{aligned} f_d + \varepsilon &= \frac{1}{2^k} \sum_{i=0}^{2^k-1} r(i) \leq \frac{1}{2^k} [(2^k - t)(1 + \varepsilon) + 2 \cdot t - 2^k] \\ &= \frac{1}{2^k} [t - t\varepsilon + 2^k\varepsilon] < \frac{1}{2^k} [t + 2^k\varepsilon] = \frac{t}{2^k} + \varepsilon = f_d + \varepsilon \end{aligned}$$

which is a contradiction. Therefore,  $Q_k$  is not  $(\varepsilon/k)$ -constant.  $\square$

Lemma 4.2 showed that a nonconstant decision must have a pair of distinguishable values, i.e., two values that differ by a power of two where the decision is different. The following corollary is the analogue of Lemma 4.2. It shows that there exists two indices that differ by a power of two and distinguish between two subsequences of the sequence  $Q_k$ .

**COROLLARY 5.1.** *If  $\theta_d$  is an  $\varepsilon$ -advantage oracle for a decision  $d$  then there exists numbers  $j$  and  $l$  such that  $0 < l \leq k, j < 2^{l-1}$  and*

$$|EQ_k(j, l) - EQ_k(j + 2^{l-1}, l)| > \frac{\varepsilon}{k}.$$

*Proof.* Follows immediately from Lemma 5.2 and Definition 5.5.  $\square$

We still must answer the questions: How do we measure  $q(i)$  given  $i$  and how do we measure  $q(I^k(x))$  given  $g^x$ ? The answer to these questions is that it is not possible to measure these values exactly. However we can make high precision estimates of the values by using the technique of ‘‘Concentrating the Stochastic Advantage’’ developed by Blum and Micali [5].

This technique is based on the weak law of large numbers. We summarize it here as the

**SAMPLING LEMMA.** *Suppose  $0 \leq \phi < \frac{1}{2}$  and  $0 \leq \delta < \frac{1}{2}$ . Let trials  $(\phi, \delta) = 9/16\delta\phi^2$  and  $M = \text{trials}(\phi, \delta)$ . Let  $Y_i$  be the outcome of an independent random trial that has outcome 1 with probability  $\alpha$  and 0 otherwise. Suppose  $M$  trials are made and the results are recorded as follows. With probability  $1 - 1/M$  let  $X_i = Y_i$  and with probability  $1/M$  let the value of  $X_i$  be set by an adversary. This latter case is known as a defective trial. Let  $S_M = \sum_{i=1}^M X_i$ . Then with probability at least  $1 - \delta$*

$$\left| \frac{S_M + 1}{M} - \alpha \right| \leq \phi.$$

*Note that if none of the trials are defective then  $S_M/M$  is an even better estimate of  $\alpha$ .*

We can use the Sampling Lemma to measure  $q(i)$ .

**LEMMA 5.3.** *Suppose  $\phi > 0$  and  $\psi > 0$ . Given  $i$ ,  $q(i)$  can be measured in time polynomial in  $\phi^{-1}$  and  $\psi^{-1}$  with error at most  $\phi$  with probability at least  $1 - \psi$ .*

*Proof.* Let  $z = g^{L_i^k}$  and  $M = \text{trials}(\phi, \psi)$ . Choose  $M$  random values  $r_1, r_2, \dots, r_M$  with uniform probability such that  $0 \leq r_i \leq R^k$ . Let  $z_i = z \cdot g^{r_i}$ . The indices of the  $z_i$  will be uniformly distributed in  $I_i^k$ . Let  $X_i = \theta_d(z_i)$ . The probability that  $X_i = 1$  is  $q(i)$ . Let  $\bar{q}(i) = (1/M) \sum_{i=1}^M X_i$ . Then by the Sampling Lemma

$$|\bar{q}(i) - q(i)| \leq \phi$$

with probability at least  $1 - \psi$ .  $\square$

Unfortunately, if we are given  $g^x$  and wish to compute  $q(I^k(x))$  the above sampling technique fails. However, under some circumstances the above technique will work.

**LEMMA 5.4.** *Suppose  $\phi > 0$  and  $\psi > 0$ . Suppose  $M = \text{trials}(\phi, \psi)$ . Given  $g^x$  such that  $L_i^k \leq x \leq L_i^k + (R^k/M)$ ,  $q(I^k(x))$  can be measured with error at most  $\phi$  with probability at least  $1 - \psi$ .*

*Proof.* For any  $r_i$  such that  $0 \leq r_i \leq ((M-1)/M)R^k$ ,  $x+r_i \in I_i^k$ . If  $((M-1)/M)R^k < r_i < R^k$  then  $x+r_i$  may not be in  $I_i^k$ . In this latter case the trial may be defective. This occurs with probability  $1/M$ . If we define  $\tilde{q}(i) = (1/M)[1 + \sum_{i=1}^M X_i]$  then by the Sampling Lemma

$$|\tilde{q}(i) - q(i)| \leq \phi$$

with probability at least  $1 - \psi$ .  $\square$

We can use the above sampling techniques to distinguish between  $EQ_k(j, l)$  and  $EQ_k(j + 2^{k-l}, l)$  with high probability.

LEMMA 5.5. *Suppose  $j$  and  $l$  are as in Corollary 5.1. Suppose  $\delta > 0$  and  $\phi > 0$  and let  $M = \text{trials}(\phi, \delta/2^{k-l})$ . Let  $m = I^k(y)$ . Suppose  $m \equiv j \pmod{2^{l-1}}$  and  $L_i^k \leq y \leq L_m^k + (R^k/M)$ . Then given  $g^y$  it is possible to distinguish  $EQ_k(j, l)$  from  $EQ_k(j + 2^{l-1}, l)$  with probability at least  $1 - \delta$ .*

*Proof.* For each interval  $m, m + 2^l, m + 2 \cdot 2^l, \dots, m + (2^{k-l} - 1)2^l$  use Lemma 5.4 to estimate the corresponding probability  $q(m + i \cdot 2^l)$  and let  $\tilde{E} = (1/2^{k-l}) \times \sum_{i=0}^{2^{k-l}-1} \tilde{q}(m + i \cdot 2^l)$ . Let  $E = (1/2^{k-l}) \sum_{i=0}^{2^{k-l}-1} q(m + i \cdot 2^l)$ . We must compare  $\tilde{E}$  with

$$\overline{EQ}_k(j, l) = \frac{1}{|Q_k(j, l)|} \sum_{i=0}^{2^{k-l}-1} \tilde{q}(j + i \cdot 2^l)$$

and  $\overline{EQ}_k(j + 2^{l-1}, l)$  which is defined similarly. These values are estimated using Lemma 5.3. The probability that

$$|\overline{EQ}_k(j, l) - EQ_k(j, l)| \leq 2^{k-l}\phi$$

is at least  $(1 - (\delta/2^{k-l}))^{2^{k-l}} > 1 - \delta$ . Similarly the probability that

$$|\tilde{E} - E| \leq 2^{k-l}\phi$$

is at least  $1 - \delta$ . If  $\phi = (1/2^{k-l})(\epsilon/8k)$  then with probability at least  $1 - \delta$  either  $|\tilde{E} - \overline{EQ}_k(j, l)| \leq \epsilon/4k$  or  $|\tilde{E} - \overline{EQ}_k(j + 2^{l-1}, l)| \leq \epsilon/4k$ . By Corollary 5.1 only one of these will hold with probability at least  $1 - \delta$ .  $\square$

We are now ready to prove Theorem 2.2.

*Proof of Theorem 2.2.* Let  $s = \text{trials}((1/2^{k-l})(\epsilon/8k), \delta/2^{k-l})$ . We will construct an oracle for the  $s$ -left-right problem. The construction is the same as in the proof of Theorem 4.1 except that Lemma 5.5 is used to distinguish  $EQ_k(j, l)$  from  $EQ_k(j + 2^{l-1}, l)$ . The number of samples required to estimate  $\tilde{q}(i)$  and  $\tilde{q}(i)$  is polynomial in  $\delta^{-1}$ ,  $\epsilon^{-1}$ , and  $2^k$ . The number of values estimated is  $O(2^k)$  and all other calculations are polynomial in  $n$  so the time bound follows.  $\square$

**6. Pseudorandom bit generation.** We keep this section informal. It can be easily formalized using the notation of [5] and [17].

It is natural at this point to extend the Blum-Micali pseudorandom bit generator to output  $k$  bits per step. If the current value in the generator is  $g^x$ , then it will output the  $k$  bits hidden by it, namely  $I^k(x) = b_1 b_2 \dots b_k$ . The security of this generator is ensured if for every  $i$ , given  $b_1 b_2 \dots b_i$ , guessing  $b_{i+1}$  with an  $\epsilon$ -advantage is as hard as computing discrete logarithms.

This definition of "hard bits" seems to differ from the one we give in § 2. We are concerned with computing any Boolean function of the  $b_i$ 's. However, a connection between the two definitions was established in [17], at least when  $k = O(\log n)$ . Their result holds for a wide class of generators, but we state it here only for the one above.

THEOREM 6.1 (Vazirani and Vazirani). *Assume  $k = O(\log n)$ . The generator above is secure if and only if for every  $I \subset \{1, 2, \dots, k\}$ , obtaining any partial information about the exclusive or of  $b_i, i \in I$ , is equivalent to computing the discrete log.*

As Theorem 2.2 states that any decision on  $k$  bits, including all these exclusive or's, are hard, it implies the security of this generator.

**7. Beyond  $O(\log n)$  bits.** The problem of showing that the discrete log (or any other function) hides asymptotically more than  $O(\log n)$  bits seems to us a fundamental question. In our proof of Theorem 2.2 the factor  $2^k$  comes into the complexity analysis in three different places, and we have no way of circumventing even one of them. A similar situation occurs in [3], [13] and [17]. We strongly believe that any improvement will involve totally new techniques.

## HOW TO CONSTRUCT PSEUDORANDOM PERMUTATIONS FROM PSEUDORANDOM FUNCTIONS\*

MICHAEL LUBY† AND CHARLES RACKOFF‡

**Abstract.** We show how to efficiently construct a pseudorandom invertible permutation generator from a pseudorandom function generator. Goldreich, Goldwasser and Micali ["How to construct random functions," Proc. 25th Annual Symposium on Foundations of Computer Science, October 24–26, 1984.] introduce the notion of a pseudorandom function generator and show how to efficiently construct a pseudorandom function generator from a pseudorandom bit generator. We use some of the ideas behind the design of the Data Encryption Standard for our construction. A practical implication of our result is that any pseudorandom bit generator can be used to construct a block private key cryptosystem which is secure against chosen plaintext attack, which is one of the strongest known attacks against a cryptosystem.

**Key words.** cryptography, pseudorandom, Data Encryption Standard, security

**AMS(MOS) subject classifications.** 68P25, 68Q15, 68Q25

**1. Introduction.** The main result of this paper is a method for efficiently constructing a pseudorandom invertible permutation generator from a pseudorandom function generator. The question of whether pseudorandom permutation generators exist was first posed by Goldreich et al. [GGM]. A practical application of our result is that a pseudorandom bit generator can be used to efficiently construct a block private key cryptosystem which is provably secure against chosen plaintext attack, which is one of the strongest possible attacks known against a cryptosystem. We expect that there will be other applications of pseudorandom invertible permutation generators in cryptographic protocols. Before describing in detail our results, we discuss the basic questions which motivated our work and the partial answers we can give to these questions.

The field of cryptography has changed dramatically over the past few years. Several years ago, cryptography was an art more than a science. Cryptosystem design was based on clever ad hoc ideas. The security of the cryptosystem rested solely on the cleverness of the designer; a cryptosystem was deemed secure until it was broken (in many cases the cryptographer only knew it was broken long after the breaker). Certain design rules were recognized as playing a crucial role in improving security. Eventually, the apparent increase in security obtained by using these design rules became part of the folklore, although there were no formal proofs that security was increased. The foundations of cryptography were not yet established, there was no established formal framework for talking about a cryptographic protocol, security, etc. Thus, there was no formal way to either confirm or dispute the folklore.

More recently, researchers have formalized the notions of cryptographic protocols and security and today cryptography is an integral part of computational complexity. Many cryptosystems whose security is based on mathematical assumptions have come out of this research. However, the security of cryptosystems typically used in practice is still based on the old folklore. This paper uses the new cryptographic rigor to formalize and to analyze some of the previously unexamined folklore.

‡ Department of Computer Science, University of Toronto, Toronto, Canada M5S 1A4. The work of this author was supported by Natural Sciences and Engineering Research Council of Canada grant A3611.

Our primary motivation when we started this work was to investigate the soundness of some of the design rules used in the development of the Data Encryption Standard (hereafter called DES). DES, which was designed to be used as a block private key cryptosystem, was developed by IBM for the U.S. National Bureau of Standards, with an undisclosed amount of highly classified kibbitzing by the super-secret National Security Agency. The reader can consult [De] for more information about DES and [Ba] for more information about the National Security Agency and its role in the development of DES.

DES has features which make it very practical to use. However, one of the properties that DES does not have (as far as we know) is that it is provably secure, even assuming some reasonable mathematical hypothesis. DES certainly has several very clever features, but there is no formal justification that these features help achieve security. We abstract and formalize what we think are some of the more interesting design features of DES to see if they can be used to achieve security or if they are inherently flawed.

The construction of a pseudorandom invertible permutation generator from a pseudorandom function generator is based on one of the main design features of DES. We view this as partial justification for the use of this design rule in DES. What our result intuitively says is that if DES used pseudorandom function generators in its construction then it would be secure when used as a block private key cryptosystem. However, this is a weak justification because the function generators used in DES are not at all pseudorandom. Our result is more of a justification of the use of the design rule than it is a statement about the security of the entire DES system.

Section 2 gives terminology used throughout the remainder of the paper. In § 3, we discuss block private key cryptosystems, describe how DES is used as a block private key cryptosystem, make the connection between secure block private key cryptosystems and pseudorandom invertible permutation generators, and present the design rule of DES which we use to construct a pseudorandom invertible permutation generator from a pseudorandom function generator. In § 4, we give formal definitions of pseudorandom bit generators, pseudorandom function generators and pseudorandom permutation generators and state our main results. In § 5, we give the construction for an invertible permutation generator from a function generator and prove that if the function generator is pseudorandom then the invertible permutation generator is pseudorandom. A preliminary version of these results appears in [LR].

**2. Terminology.** A **string** is a bit string. Let  $\{0, 1\}^n$  be the set of all  $2^n$  strings of length  $n$ . Let  $a$  and  $b$  be two equal length strings. Define  $a \oplus b$  to be the bit-by-bit **exclusive or** of  $a$  and  $b$ , where the resulting string has the same length as  $a$ . Let  $a \bullet b$  denote the **concatenation** of the two strings  $a$  and  $b$ .

Let  $F^n$  be the set of all  $2^{n^2}$  functions mapping  $\{0, 1\}^n$  into  $\{0, 1\}^n$ . Let  $f_1$  and  $f_2$  be functions in  $F^n$ . We use  $f_1 \circ f_2$  to denote the function in  $F^n$  which is the composition of  $f_1$  and  $f_2$ . Let  $P^n \subset F^n$  be the set of such functions that are permutations, i.e., they are 1-1 onto functions.

In all cases, a random choice of an object from a set of objects is such that each object is equally likely to be chosen. For example, a random choice of a string from  $\{0, 1\}^n$  will choose each such string with probability  $1/2^n$ . As another example, a random choice of a function from  $F^n$  will choose each such function with probability  $1/2^{n^2}$ .

**3. Connections between cryptosystems and invertible permutation generators.** Suppose agent  $A$  wants to send plaintext to agent  $B$ .  $A$  wants to do this securely, i.e., in

a way such that any agent  $L$ , who is able to read all the information sent from  $A$  to  $B$ , has no significant idea about the content of the plaintext. A very practical way to achieve this goal is for  $A$  and  $B$  to use a secure block private key cryptosystem. Both  $A$  and  $B$ , but not  $L$ , have the same randomly chosen private key  $k$ . When  $A$  sends plaintext  $M$  to  $B$ ,  $M$  is partitioned into equal length plaintext blocks.  $A$  encrypts each plaintext block into a ciphertext block of the same length using  $k$ .  $B$ , upon receiving a ciphertext block, decrypts it back into the plaintext block using  $k$ .

There are two very attractive features of block private key cryptosystems. First, the total number of bits sent from  $A$  to  $B$  is the minimum number possible, because the number of encrypted bits sent from  $A$  to  $B$  is exactly the same as the number of plaintext bits. Second, since the plaintext is encrypted in blocks, if the encryption of one block is lost in transmission then the other blocks can still be decrypted by  $B$ , whether or not  $B$  knows that a block was lost. Other cryptosystems tend to send many more encrypted bits than there are plaintext bits and/or are not robust to transmission losses.

There is one inherent weakness in any block private key cryptosystem, which is that any listener  $L$  can always tell if exactly the same plaintext block is repeated from the encryption. In our definition of a secure block private key cryptosystem, this is essentially the only insecurity of the system. There are encryption systems which avoid this problem, but these systems tend to be less efficient than a block private key cryptosystem, in certain respects, as explained above.

As far as we know, there is no provably secure block private key cryptosystem. One of the main implications of the results given in this paper is that, under the assumption that there is a pseudorandom bit generator, there is a provably secure block private key cryptosystem.

One of the main motivations of this work is to study the security of DES, when it is used as a block private key cryptosystem. In this context, DES works as follows. Both  $A$  and  $B$ , but not  $L$ , have the same 56-bit private key  $k$ . Suppose  $A$  wants to send plaintext  $M$  to  $B$ .  $A$  first partitions  $M$  into plaintext blocks of 64 bits each.  $A$  encrypts each plaintext block, using the DES encryption algorithm with key  $k$ , into a 64-bit ciphertext block and sends the ciphertext blocks to  $B$ .  $B$  decrypts the ciphertext blocks, using the DES decryption algorithm with key  $k$ , to recover the plaintext blocks. One important property of DES is that, given  $k$ , it is easy to encrypt and decrypt. An important implication of this is that, given  $k$ , each string of length 64 has a unique encryption and a unique decryption.

The encryption algorithm for DES can be thought of as a family of  $2^{56}$  permutations  $h^{64} = \{h_k^{64} : k \in \{0, 1\}^{56}\}$ , where each permutation is a member of  $P^{64}$  indexed by a key  $k$ . Similarly, the decryption algorithm for DES can be thought of as a family of  $2^{56}$  permutations  $\bar{h}^{64} = \{\bar{h}_k^{64} : k \in \{0, 1\}^{56}\}$ , where each permutation is a member of  $P^{64}$  indexed by a key  $k$ . Furthermore,  $h_k^{64} \circ \bar{h}_k^{64}$  and  $\bar{h}_k^{64} \circ h_k^{64}$  are both the identity permutation. DES has the property that, given  $k$  and  $\alpha$ , both  $h_k^{64}(\alpha)$  and  $\bar{h}_k^{64}(\alpha)$  can be computed very efficiently.

One of the strongest attacks known against a cryptosystem is a chosen plaintext attack. We would deem DES secure if it was secure against chosen plaintext attack (which is a stronger notion of security than that given in the first paragraph of this section). Intuitively, in a chosen plaintext attack an agent  $L$ , who does not know the key  $k$ , is nevertheless able to trick  $A$  into sending to  $B$  encryptions of plaintext blocks chosen by  $L$ .  $L$  is allowed to choose a "reasonable" number of plaintext blocks  $M_1, \dots, M_i$ .  $A$  encrypts these plaintext blocks and  $L$  sees the encryptions of these plaintext blocks  $h_k^{64}(M_1), \dots, h_k^{64}(M_i)$ . During this process,  $L$  interactively chooses

the next plaintext block for  $A$  to encrypt based on all previous plaintext blocks and their encryptions. Let  $M_{i+1}$  be a plaintext block chosen by  $A$  which is different from all plaintext blocks chosen by  $L$  during the attack. Intuitively, the cryptosystem is secure against  $L$  if  $L$  cannot predict  $M_{i+1}$  given the information gained from the attack and given the encryption  $h_k^{64}(M_{i+1})$  of  $M_{i+1}$  (but not  $M_{i+1}$ ) “significantly” better than if  $L$  had not received the information obtained from the attack and from seeing  $h_k^{64}(M_{i+1})$ . The cryptosystem is secure against chosen plaintext attack if it is secure against all such agents  $L$ .

The apparent security of DES when it is used as a block private key cryptosystem rests on the fact that DES seems to pass the black box test, which was informally suggested by Turing [Hod]. The black box test is the following:

Say that we have two black boxes, one of which computes a fixed randomly chosen function from  $F^{64}$  and the other computes  $h_k^{64}$  for a fixed randomly chosen  $k$ . Then no algorithm which examines the boxes by feeding inputs to them and looking at the outputs can obtain, in a “reasonable” time, any “significant” idea about which box is which.

If DES passes the black box test then it is secure against a chosen plaintext attack when used as a block private key cryptosystem. We do not give a formal definition of security for a block private key cryptosystem. A rigorous definition in a somewhat different setting appears in [Ra].

The black box test, and therefore security, is very informally stated, i.e., the terms “reasonable” and “significant” are not well defined. The tools of mathematics and computer science are designed to analyze asymptotic behavior; to utilize these tools we introduce an asymptotic version of DES and define security in terms of asymptotic security. We introduce a collection of private key block cryptosystems, one for each possible plaintext block length  $n$ . Let  $h = \{h^n : n \in \mathbb{N}\}$  where, for each  $n$ ,  $h^n$  is the generalization of  $h^{64}$  defined for DES, i.e.,  $h^n$  is used to encrypt plaintext blocks of length  $n$ . Similarly, let  $\bar{h} = \{\bar{h}^n : n \in \mathbb{N}\}$ , where for each  $n$ ,  $\bar{h}^n$  is the generalization of  $\bar{h}^{64}$  defined for DES, i.e.,  $\bar{h}^n$  is used to decrypt plaintext blocks of length  $n$ . Thus, both  $h^n$  and  $\bar{h}^n$  specify for each key  $k$  of a given length a permutation,  $h_k^n \in P^n$ ,  $\bar{h}_k^n \in P^n$ , respectively, where  $h_k^n \circ \bar{h}_k^n$  is the identity permutation. We require that, given  $\alpha \in \{0, 1\}^n$  and a key  $k$  of a given length, both  $h_k^n(\alpha)$  and  $\bar{h}_k^n(\alpha)$  can be computed in time polynomial in  $n$ . In the terminology of § 4, both  $h$  and  $\bar{h}$  are invertible permutation generators. A very similar notion, a function generator, was first formally defined in [GGM]. We give the definition of a function generator in § 4, but intuitively it is the same as the definition of an invertible permutation generator except that each function specified by  $n$  and  $k$  is not necessarily 1-1 onto function, i.e., not necessarily a permutation. Thus, an invertible permutation generator is a special case of a function generator.

It is enough that  $h$  be pseudorandom for  $h$  to be secure against chosen plaintext attack when used as a block private key cryptosystem. The concept of a pseudorandom function generator was introduced in [GGM]. An invertible permutation generator is pseudorandom if it is a pseudorandom function generator. Informally, a pseudorandom function generator is a function generator which passes the black box test for all sufficiently large  $n$ , where  $n$  replaces all occurrences of 64 in the description of the black box test, “reasonable” time corresponds to time polynomial in  $n$  and “significant” corresponds to probability polynomial in  $1/n$ . We give a formal definition of a pseudorandom function generator in § 4.

Goldreich et al. [GGM] show how to construct a pseudorandom function generator

from a pseudorandom bit generator. Pseudorandom function generators have many applications in cryptography, but, unless they are also invertible permutation generators, they cannot be used directly in a block private key cryptosystem as described above. A natural question to ask is can we construct a pseudorandom invertible permutation generator from a pseudorandom function generator. In § 5, we give an efficient construction of an invertible permutation generator based on a function generator and we prove that if the function generator is pseudorandom then so is the invertible permutation generator. This construction uses some of the ideas behind the design of DES. Below, we describe the design details of DES relevant to our construction together with some comments about DES.

DES begins with  $f^{32}$ , where  $f^{32}$  specifies for each key  $k$  of length 48 a function  $f_k^{32} \in F^{32}$ . Alternatively,  $f^{32}$  can be thought of as an algorithm which, given  $k$  and an input  $\alpha$ , computes  $f_k^{32}(\alpha)$ . Let  $L, R \in \{0, 1\}^{32}$ . Define  $g^{64}$  such that for each key  $k$  of length 48,  $g_k^{64}(L \cdot R) = R \cdot [L \oplus f_k^{32}(R)]$ . It is easy to see that  $g_k^{64}$  is 1-1 onto and easy to invert if  $k$  is known. Let  $h^{64}$  be  $g^{64}$  composed with itself 16 times, so that the key length function for  $h^{64}$  is  $768 = 48 \cdot 16$ . Given a 768-bit key  $k$ ,  $h_k^{64}$  is 1-1 onto and easily invertible. We refer to  $h^{64}$  as MDDES for modified DES. MDDES differs from DES in certain inconsequential ways, but also in one way that might be very important: DES only has a 56-bit key, which is used to generate (in a very simple way) the  $16 \cdot 48$ -bit key to be used in MDDES. It is not clear if this makes DES more or less secure than MDDES, but most observers feel that MDDES would be much more secure than DES. In any case, no one has yet succeeded (as far as we know) in breaking DES.

The  $f^{32}$  used in DES is not by any stretch of the imagination pseudorandom. The creators of DES apparently feel that  $f^{32}$  does enough "mixing up" so that, together with the rest of the construction, DES as a whole is secure. Our construction replaces  $f^{32}$  with a pseudorandom function generator  $f$ . Invertible permutation generator  $g$  is constructed from  $f$  as described above. The invertible permutation generator  $h$  is formed by composing  $g$  three times with itself (instead of 16 times as in MDDES). We prove in § 5 that  $h$  formed in this way is a pseudorandom invertible permutation generator if  $f$  is a pseudorandom function generator.

**4. Formal definitions and statement of results.** In this section we present some necessary formal definitions and state the main results of the paper.

**4.1. Pseudorandom bit generators.** The original definitions for pseudorandom bit generators are due to Blum and Micali [BM] and are generalized to those given here by Yao [Yao]. A **bit generator** is a collection of functions  $f = \{f^n: n \in \mathbb{N}\}$  such that  $f^n$  maps  $\{0, 1\}^n$  into  $\{0, 1\}^{t(n)}$ , where  $t(n) \geq n + 1$  (for example,  $t(n) = n^3$ ) and, given  $n$  and  $\alpha$ ,  $f^n(\alpha)$  can be computed in time polynomial in  $n$  (this implies that  $t(n)$  is polynomial in  $n$ ). Informally,  $f$  is pseudorandom if there is no (probabilistic) polynomial in  $n$  time algorithm which, for infinitely many  $n$ , can significantly distinguish a string  $\beta = f^n(\alpha)$ , where  $\alpha$  is a randomly chosen from  $\{0, 1\}^n$ , from a string randomly chosen from  $\{0, 1\}^{t(n)}$ . Formally,  $f$  is **pseudorandom** if there is no distinguishing circuit family for  $f$ . A distinguishing circuit family for  $f$  is an infinite family of Boolean circuits consisting of and/or/not unbounded fan-out gates (for readers unfamiliar with this model of computation, replace all occurrences of a family of Boolean circuits with a probabilistic polynomial time algorithm and all the results are the same)  $C = \{C_{n_1}, C_{n_2}, \dots\}$ , where  $n_1 < n_2 < \dots$ , such that for some pair of constants  $s$  and  $c$ , for each  $n$  for which there is a circuit  $C_n$ :

(1) The size of  $C_n$  is less than or equal to  $n^s$ . The size of a circuit is the total number of wires plus the number of gates in the circuit.

(2) The input to  $C_n$  is a string of length  $t(n)$  and the output is a single bit.

(3) Let  $r_n$  be the probability that the output bit of  $C_n$  is one when the input to  $C_n$  is a string randomly chosen from  $\{0, 1\}^{t(n)}$ . Let  $p_n$  be the probability that the output bit of  $C_n$  is 1 when a string  $\alpha$  is randomly chosen from  $\{0, 1\}^n$  and the input is  $f^n(\alpha)$ . Let  $d_n = |p_n - r_n|$  be the distinguishing probability for  $C_n$ . Then,  $d_n \geq 1/n^c$ .

It is important to note that if  $f$  is a pseudorandom bit generator, then  $f$  is a pseudorandom bit generator even if we allow distinguishing circuit families for  $f$  to be probabilistic. A probabilistic circuit  $C_n$ , besides the inputs described above, has an additional number of input bits whose values are randomly chosen. It is not hard to see that there is some way of fixing these additional bits to  $C_n$ , forming a deterministic circuit  $C'_n$ , such that the distinguishing probability for  $C'_n$  is at least as great as the distinguishing probability for  $C_n$ , i.e.,  $d'_n \geq d_n$ . Hence, if  $f$  has a distinguishing probabilistic circuit family then  $f$  has a distinguishing deterministic circuit family, which implies that if  $f$  has no distinguishing deterministic circuit family then  $f$  has no distinguishing probabilistic circuit family.

Whether or not pseudorandom bit generators exist is an open question. Blum and Micali [BM] introduce conditions which are sufficient for constructing pseudorandom bit generators. They show how to construct a pseudorandom bit generator based on the assumption that the Discrete Log problem is hard. Yao [Yao] generalizes these conditions and shows how to construct a pseudorandom bit generator based on the assumption that the factoring problem is hard. A series of results has improved the efficiency of the Yao construction [ACGS], [BCS], [GMT], and [VV]. Levin [Le] introduces weaker conditions which are sufficient to construct a pseudorandom bit generator.

**4.2. Pseudorandom function generators.** The concept of a pseudorandom function generator is defined in [GGM]. They give a construction for a pseudorandom function generator using a pseudorandom bit generator. We give the definition of a pseudorandom function generator in this section. Let  $l(n)$  be polynomial in  $n$ . A **function generator** with key length function  $l(n)$  is a collection  $f = \{f^n : n \in \mathbb{N}\}$ , where  $f^n$  specifies for each key  $k$  of length  $l(n)$  a function  $f_k^n \in F^n$ . It is required that, given a key  $k \in \{0, 1\}^{l(n)}$ , and a string  $\alpha \in \{0, 1\}^n$ ,  $f_k^n(\alpha)$  can be computed in time polynomial in  $n$ .

Informally,  $f$  is pseudorandom if there is no polynomial time in  $n$  algorithm which, for infinitely many  $n$ , is able to even slightly distinguish whether a function was randomly chosen from  $f^n$  or from  $F^n$  after seeing polynomial in  $n$  input/output pairs of the function, even when the algorithm is allowed to choose the next input based on all previously seen input/output pairs. Formally,  $f$  is **pseudorandom** if there is no distinguishing circuit family for  $f$ . A distinguishing circuit family for  $f$  is an infinite family of circuits  $\{C_{n_1}, C_{n_2}, \dots\}$ , where  $n_1 < n_2 < \dots$ , such that for some pair of constants  $s$  and  $c$ , for each  $n$  for which there is a circuit  $C_n$ :

(1)  $C_n$  is an acyclic circuit which contains Boolean gates of type **and**, **or** and **not** (these gates are interpreted in the usual way, i.e., the **and** gate computes the “and” of the two inputs). In addition there are constant gates of type **zero** and **one**. Each constant gate has no inputs, and the output is 0 if it is a **zero** gate and 1 if it is a **one** gate.  $C_n$  also contains **oracle gates**. Each oracle gate has an input and an output which are both strings of length  $n$ . Each oracle gate is to be evaluated using some function from  $F^n$ , which for now is left unspecified and is to be thought of as a variable of the circuit. All gates can fan-out their output bits to an unbounded number of other gates. The output of  $C_n$  is a single bit. Such a circuit is called an **oracle circuit**.

(2) The size of  $C_n$  is less than or equal to  $n^s$ . The size of  $C_n$  is the total number

of connections between gates, Boolean gates, constant gates and oracle gates.

(3) We let  $\Pr[C_n(F^n)]$  be the probability that the output bit of  $C_n$  is one when a function is randomly chosen from  $F^n$  and used to evaluate the oracle gates. We let  $\Pr[C_n(f^n)]$  be the probability that the output bit of  $C_n$  is one when a key  $k$  of length  $l(n)$  is randomly chosen and  $f_k^n$  is used to evaluate the oracle gates. The distinguishing probability for  $C_n$ ,  $|\Pr[C_n(F^n)] - \Pr[C_n(f^n)]|$ , is greater than or equal to  $1/n^c$ .

**THEOREM [GGM].** *If there is a pseudorandom bit generator then there is a pseudorandom function generator.*

In fact, Goldreich et al. [GGM] give an explicit construction for a function generator  $f$  based on a bit generator  $g$  and prove that if  $g$  is a pseudorandom bit generator then  $f$  is a pseudorandom function generator. The converse of this theorem is easily seen to be true.

**4.3. Pseudorandom invertible permutation generators and block private key cryptosystems.** A **permutation generator**  $f$  is a function generator such that each function  $f_k^n$  is 1-1 onto. Let  $\bar{f} = \{\bar{f}^n : n \in \mathbb{N}\}$ , where  $\bar{f}^n = \{\bar{f}_k^n : k \in \{0, 1\}^{l(n)}\}$ , where  $\bar{f}_k^n$  is the inverse function of  $f_k^n$ . We say  $f$  is **invertible** if  $\bar{f}$  is also a permutation generator. In this case,  $\bar{f}$  is the inverse permutation generator for  $f$  (of course,  $f$  is the inverse permutation generator for  $\bar{f}$  also). We say  $f$  is **pseudorandom** if it is pseudorandom as a function generator as defined in the previous section. (The definition of pseudorandom is provably no different if we replace  $F^n$  with  $P^n$  in part 3 of the definition of an oracle circuit.) In § 5, we give a construction for a pseudorandom invertible permutation generator based on a pseudorandom function generator.

**4.4. Super pseudorandom invertible permutation generators.** There is even a stronger notion of pseudorandom for invertible permutation generators which is very natural. Let  $f$  be an invertible permutation generator. We say that  $f$  is a **super pseudorandom** if there is no super distinguishing circuit family for  $f$ . A super distinguishing circuit family for  $f$  is an infinite family of circuits  $C = \{C_{n_1}, C_{n_2}, \dots\}$  where  $n_1 < n_2 < \dots$ , where each circuit is an oracle circuit containing two types of oracle gates, **normal** and **inverse**. For some pair of constants  $s$  and  $c$ , for each  $n$  for which there is a circuit  $C_n$ :

(1) The size of  $C_n$  is less than or equal to  $n^s$ .

(2) We let  $\Pr[C_n(P^n)]$  be the probability that the output bit of  $C_n$  is one when a permutation  $\sigma$  is randomly chosen from  $P^n$  and  $\sigma$  and  $\bar{\sigma}$  are used to evaluate normal and inverse gates in  $C_n$ , respectively, where  $\bar{\sigma}$  is the inverse permutation of  $\sigma$ . We let  $\Pr[C_n(f^n)]$  be the probability that the output bit of  $C_n$  is one when a key  $k$  of length  $l(n)$  is randomly chosen and  $f_k^n$  and  $\bar{f}_k^n$  are used to evaluate the normal and inverse oracle gates in  $C_n$ , respectively. The distinguishing probability for  $C_n$ ,  $|\Pr[C_n(P^n)] - \Pr[C_n(f^n)]|$ , is greater than or equal to  $1/n^c$ .

We state in § 5 that there is a super pseudorandom invertible permutation generator if there is a pseudorandom function generator. Although every super pseudorandom invertible generator is also a pseudorandom invertible generator, we show in § 5 that the converse is not necessarily true.

Let  $f$  be a super pseudorandom invertible permutation generator. We can use  $f$  as described above in a block private key cryptosystem. This cryptosystem is secure against chosen plaintext/ciphertext attack, which is an even stronger attack than chosen plaintext attack. In chosen plaintext/ciphertext attack,  $L$  can interactively choose plaintext blocks and see their encryptions and choose encryptions and see their corresponding plaintext blocks. Thus,  $L$  is allowed to attack the cryptosystem from

“both ends.” Let  $M$  be a plaintext block which is different than all plaintext blocks seen in the attack. Intuitively, the cryptosystem is secure against chosen plaintext/ciphertext attack if for all agents  $L$ , given the information  $L$  gained from the attack and given the encryption  $f_k^n(M)$  of  $M$  (but not  $M$ ),  $L$  cannot predict the value of  $M$  any better than if  $L$  had no information about  $M$ . Symmetrically, let  $E$  be the encryption of a plaintext block which is different than all encryptions of plaintext blocks seen in the attack: The cryptosystem is secure against chosen plaintext/ciphertext attack if for all agents  $L$ , given the information  $L$  gained from the attack and given the decryption  $\tilde{f}_k^n(E)$  of  $E$  (but not  $E$ ),  $L$  cannot predict the value of  $E$  any better than if  $L$  had no information about  $E$ .

**4.5. Definition of cryptographic composition.** In this section, we formally define the composition of function generators. Let  $g$  and  $h$  be two function generators, where  $l_1(n)$  and  $l_2(n)$  are the key length functions for  $g$  and  $h$ , respectively (we allow the possibility that  $g = h$ ). Then  $f = g \circ h$  is a function generator defined as follows.

- (1) The key length function for  $f$  is  $l(n) = l_1(n) + l_2(n)$ .
- (2)  $f_{k_2 \cdot k_1}^n = h_{k_2}^n \circ g_{k_1}^n$ , where  $k_1$  is of length  $l_1(n)$  and  $k_2$  is of length  $l_2(n)$ .

Note that if both  $g$  and  $h$  are (invertible) permutation generators then so is  $f$ .

**5. Generating permutations from functions.** In this section we show how to construct a pseudorandom invertible permutation generator from a pseudorandom function generator (see § 4 for definitions). A natural thing to try is an abstraction of MDDES. Let  $f = \{f^n\}$  be a pseudorandom function generator where the key length function is  $l(n)$ . Define a function generator  $g = \{g^n\}$  in terms of  $f$  as follows. Let  $k$  be a string of length  $l(n)$ , let  $k'$  be a string of length  $l(n + 1)$ , let  $L, R$  and  $L'$  be strings of length  $n$  and let  $R'$  be a string of length  $n + 1$ . Then

$$g_k^{2n}(L \cdot R) = R \cdot [L \oplus f_k^n(R)],$$

$$g_{k'}^{2n+1}(L' \cdot R') = R' \cdot [L' \oplus \text{first } n \text{ bits of } f_{k'}^{n+1}(R')].$$

Note that  $g$  is an invertible permutation generator. The inverse permutation generator for  $g, \bar{g}$ , is computed as follows. Let  $\alpha, \beta$  and  $\beta'$  be strings of length  $n$  and let  $\alpha'$  be a string of length  $n + 1$ . Then

$$\bar{g}_k^{2n}(\alpha \cdot \beta) = [\beta \oplus f_k^n(\alpha)] \cdot \alpha,$$

$$\bar{g}_{k'}^{2n+1}(\alpha' \cdot \beta') = [\beta' \oplus \text{first } n \text{ bits of } f_{k'}^{n+1}(\alpha')] \cdot \alpha'.$$

Thus,

$$\bar{g}_k^{2n}(g_k^{2n}(L \cdot R)) = L \cdot R,$$

$$\bar{g}_{k'}^{2n+1}(g_{k'}^{2n+1}(L' \cdot R')) = L' \cdot R'.$$

Let  $h = g \circ g \circ g$ . Since  $g$  is an invertible permutation generator,  $h$  is also an invertible permutation generator. Theorem 1 shows that  $h$  is pseudorandom if  $f$  is pseudorandom. Before proving this theorem, we show that  $h = g \circ g$  is not at all pseudorandom, and then we state and prove the main lemma used in the proof of Theorem 1. The proof of the main lemma, which is a combinatorial lemma not based on any unproven assumptions, is the interesting and difficult portion of the proof of the theorem.

We show that  $h = g \circ g$  is *not* pseudorandom as follows. Let  $k_1$  and  $k_2$  be keys of length  $l(n)$ . For all strings  $L_1, L_2$  and  $R$  of length  $n$ , the  $\oplus$  of the first  $n$  bits of  $h_{k_2 \cdot k_1}^{2n}(L_1 \cdot R)$  and  $h_{k_2 \cdot k_1}^{2n}(L_2 \cdot R)$  is equal to  $L_1 \oplus L_2$ . Thus, a distinguishing circuit  $C_{2n}$  for  $h^{2n}$  can be described as follows. Choose  $L_1$  and  $L_2$  such that  $L_1 \neq L_2$  and let  $R$  be

any string of length  $n$ , e.g., a string of  $n$  zeros.  $C_{2n}$  has two oracle gates: the input to the first oracle gate is  $L_1 \bullet R$  and the input to the second oracle gate is  $L_2 \bullet R$ . The output of  $C_{2n}$  is 1 iff the  $\oplus$  of the first  $n$  bits of the outputs from the two oracle gates is equal to  $L_1 \oplus L_2$ . Thus, the output of  $C_{2n}$  is always 1 when the oracle gates are evaluated using a function in  $h^{2n}$ . On the other hand, if the oracle gates are evaluated using a function randomly chosen from  $F^{2n}$ , the output of  $C_{2n}$  is 1 with probability  $1/2^n$ .

The following definitions are used in the main lemma and in Theorem 1. We define the operator  $H : F^n \times F^n \times F^n \rightarrow P^{2n}$  as follows. Let  $f_0, f_1$  and  $f_2$  be three functions from  $F^n$ . Let  $L$  and  $R$  be strings of length  $n$ . Define

$$\alpha = f_0(R), \quad \beta = f_1(L \oplus \alpha), \quad \gamma = f_2(R \oplus \beta),$$

$$H(f_2, f_1, f_0)(L \bullet R) = [R \oplus \beta] \bullet [L \oplus \alpha \oplus \gamma].$$

$H$  is derived from three applications of the DES design rule described in § 3. The main lemma states that any Boolean circuit with  $m$  oracle gates, where each oracle gate has an input and an output which are both strings of length  $2n$ , can distinguish with probability at most  $m^2/2^n$  between the case when the oracle gates are evaluated using a randomly chosen function from  $F^{2n}$  and the case when the oracle gates are evaluated using  $H(f_2, f_1, f_0)$  and  $f_2, f_1$  and  $f_0$  are randomly chosen from  $F^n$ . This result is surprising in the sense that it uses no unproven assumptions and that the number of distinct permutations generated by  $H$  is at most  $2^{3n}$ , which is a very small fraction of the  $2^{2n}$  functions in  $F^{2n}$ . On the other hand, it is not so surprising given that we allow the distinguishing circuit to examine only a very small portion of the domain of the function (there are only  $m$  oracle gates).

**PROPOSITION.** *Let  $D_n$  be an oracle circuit with  $m$  oracle gates and size  $s$ , where the input and output of each oracle gate is a string of length  $n$  and where  $m \leq 2^n$ .  $D_n$  can be easily modified to another circuit  $D'_n$  which never repeats an input value to an oracle gate such that: (1) For each function  $f_0 \in F^n$ , the output bit of  $D'_n$  when  $f_0$  is used to evaluate the oracle gates is exactly the same as the output bit of  $D_n$  when  $f_0$  is used to evaluate the oracle gates; (2) The number of oracle gates in  $D'_n$  is  $m$ ; (3) The size of  $D'_n$  is at most  $s^3$ .*

*Proof.* Omitted but easy.  $\square$

**MAIN LEMMA.** *Let  $C_{2n}$  be an oracle circuit with  $m$  oracle gates such that no input value is repeated to an oracle gate as in the above proposition. Then,  $|\Pr [C_{2n}(F^{2n})] - \Pr [C_{2n}(H(F^n, F^n, F^n))]| \leq m^2/2^n$ .*

*Proof.* There are really two experiments occurring in different probability spaces in the statement of the Main Lemma. For  $\Pr [C_{2n}(F^{2n})]$  the sample space is  $F^{2n}$  with the uniform probability distribution, and for  $\Pr [C_{2n}(H(F^n, F^n, F^n))]$  the sample space is  $F^n \times F^n \times F^n$  with the uniform probability distribution. To be able to analyze the behavior of  $C_{2n}$  with respect to these two probability distributions we introduce a new probability space with sample space  $\Omega = \{0, 1\}^{3nm}$  and the uniform probability distribution, i.e., for all  $\omega \in \Omega$ ,  $\Pr [\omega] = \frac{1}{2^{3nm}}$ . We define two random variables  $A, B$  on the new probability space with the following properties:

(1)  $A : \Omega \rightarrow \{0, 1\}, B : \Omega \rightarrow \{0, 1\}$ .

(2)  $E[A] = \Pr [C_{2n}(F^{2n})]$ . (The left-hand side is with respect to the new probability space, the right-hand side is with respect to the probability space for the original experiment.)

(3)  $E[B] = \Pr [C_{2n}(H(F^n, F^n, F^n))]$ . (Same remarks as for (2).)

(4)  $|E[A] - E[B]| \leq m^2/2^n$ .

Note that  $|E[A] - E[B]| = |\sum_{\omega \in \Omega} (A(\omega) - B(\omega))|/2^{3nm}$ . Our objective is to define  $A$  and  $B$  with properties (1), (2) and (3) such that for most sample points  $A$  and  $B$  take on the same value, so that property (4) is also satisfied. A sample point in  $\Omega$  is a string  $\omega = \omega_1, \dots, \omega_{3nm}$ . For  $1 \leq i \leq m$  we define the random variables  $X_i: \Omega \rightarrow \{0, 1\}^n$ ,  $Y_i: \Omega \rightarrow \{0, 1\}^n$ ,  $Z_i: \Omega \rightarrow \{0, 1\}^n$  as follows:

$$X_i(\omega) = \omega_{(i-1)n+1} \bullet \dots \bullet \omega_{(i-1)n+n},$$

$$Y_i(\omega) = \omega_{mn+(i-1)n+1} \bullet \dots \bullet \omega_{mn+(i-1)n+n},$$

$$Z_i(\omega) = \omega_{2mn+(i-1)n+1} \bullet \dots \bullet \omega_{2mn+(i-1)n+n}.$$

We define the vector  $X(\omega) = \langle X_1(\omega), \dots, X_m(\omega) \rangle$ .  $Y(\omega)$  and  $Z(\omega)$  are defined similarly.

At sample point  $\omega \in \Omega$ ,  $B(\omega)$  is defined as the output bit of  $C_{2n}$  when the oracle gates of  $C_{2n}$  are computed as described below. This description also defines  $L(\omega)$  and  $R(\omega)$ , where  $L$  and  $R$  are vectors of  $m$  random variables corresponding to the left half of the inputs to the oracle gates and the right half of the inputs to the oracle gates, respectively. In addition,  $\alpha'(\omega)$ ,  $\beta'(\omega)$  and  $\gamma'(\omega)$  are defined, where  $\alpha'$ ,  $\beta'$  and  $\gamma'$  are each vectors of  $m$  random variables defined by the following circuit. The  $i$ th oracle gate of  $C_{2n}$  is computed as follows:

**$B$ -gate $_i$ :**

The input is  $L_i(\omega) \bullet R_i(\omega)$ ,  
 $l \leftarrow \min \{j: 1 \leq j \leq i \text{ and } R_i(\omega) = R_j(\omega)\}$ ,  
 $\alpha'_i(\omega) \leftarrow L_i(\omega) \oplus X_i(\omega)$ ,  
 $l \leftarrow \min \{j: 1 \leq j \leq i \text{ and } \alpha'_i(\omega) = \alpha'_j(\omega)\}$ ,  
 $\beta'_i(\omega) \leftarrow R_i(\omega) \oplus Y_i(\omega)$ ,  
 $l \leftarrow \min \{j: 1 \leq j \leq i \text{ and } \beta'_i(\omega) = \beta'_j(\omega)\}$ ,  
 $\gamma'_i(\omega) \leftarrow \alpha'_i(\omega) \oplus Z_i(\omega)$ ,  
 The output is  $\beta'_i(\omega) \bullet \gamma'_i(\omega)$ .

The circuit defining  $B$  can be thought of as a circuit with Boolean **and**, **or** and **not** gates and constant **zero** and **one** gates. The input to the entire circuit can be thought of as  $X(\omega)$ ,  $Y(\omega)$  and  $Z(\omega)$ .

We now describe a random variable  $B'$  which is exactly the same as  $B$  except that it is the output bit of  $C_{2n}$  when the  $i$ th oracle gate is computed as follows:

**$B'$ -gate $_i$ :**

The input is  $L_i(\omega) \bullet R_i(\omega)$ ,  
 $l \leftarrow \min \{j: 1 \leq j \leq i \text{ and } R_i(\omega) = R_j(\omega)\}$ ,  
 $\alpha'_i(\omega) \leftarrow L_i(\omega) \oplus X_i(\omega)$ ,  
 $l \leftarrow \min \{j: 1 \leq j \leq i \text{ and } \alpha'_i(\omega) = \alpha'_j(\omega)\}$ ,  
 $Y'_i(\omega) \leftarrow Y_i(\omega) \oplus R_i(\omega)$ ,  
 $\beta'_i(\omega) \leftarrow R_i(\omega) \oplus Y'_i(\omega)$ ,  
 $l \leftarrow \min \{j: 1 \leq j \leq i \text{ and } \beta'_i(\omega) = \beta'_j(\omega)\}$ ,  
 $Z'_i(\omega) \leftarrow Z_i(\omega) \oplus \alpha'_i(\omega)$ ,  
 $\gamma'_i(\omega) \leftarrow \alpha'_i(\omega) \oplus Z'_i(\omega)$ ,  
 The output is  $\beta'_i(\omega) \bullet \gamma'_i(\omega)$ .

$B$  and  $B'$  are exactly the same except that  $Y'_i$  and  $Z'_i$  are computed from  $Y_i$  and  $Z_i$

and used in place of  $Y_i$  and  $Z_i$  in the oracle gate computation. The definition of  $B'$  also redefines the vectors of random variables  $L, R, \alpha', \beta', \gamma'$ .

FACT.  $E[B'] = E[B]$ . This follows because the random variables  $X_i, Y_i$  and  $Z_i$  are identically and uniformly distributed and because  $R_i$  and  $\alpha'_i$  do not depend on  $Y_i$  and  $Z_i$ , respectively. Thus,  $Y'_i$  and  $Z'_i$  are independently and randomly chosen strings from  $\{0, 1\}^n$ .

We now describe the computation of  $B'$  in an equivalent way. This alternative description is used in all further references to  $B'$ .  $B'$  is the output of  $C_{2n}$  when the  $i$ th oracle gate in  $C_{2n}$  is evaluated as follows:

**$B'$ -gate $_i$ :**

The input is  $L_i(\omega) \bullet R_i(\omega)$ ,  
 $u_i(\omega) \leftarrow \min \{j : 1 \leq j \leq i \text{ and } R_i(\omega) = R_j(\omega)\}$ ,  
 $\alpha'_i(\omega) \leftarrow L_i(\omega) \oplus X_{u_i(\omega)}(\omega)$ ,  
 $v_i(\omega) \leftarrow \min \{j : 1 \leq j \leq i \text{ and } \alpha'_i(\omega) = \alpha'_j(\omega)\}$ ,  
 $\beta'_i(\omega) \leftarrow R_i(\omega) \oplus R_{v_i(\omega)}(\omega) \oplus Y_{v_i(\omega)}(\omega)$ ,  
 $w_i(\omega) \leftarrow \min \{j : 1 \leq j \leq i \text{ and } \beta'_i(\omega) = \beta'_j(\omega)\}$ ,  
 $\gamma'_i(\omega) \leftarrow \alpha'_i(\omega) \oplus \alpha'_{w_i(\omega)}(\omega) \oplus Z_{w_i(\omega)}(\omega)$ ,  
 The output is  $\beta'_i(\omega) \bullet \gamma'_i(\omega)$ .

From the above discussion, it is clear that  $E[B'] = \Pr [C_{2n}(H(F^n, F^n, F^n))]$ . In addition to defining  $L, R, \alpha', \beta'$  and  $\gamma'$  in terms of  $X, Y$  and  $Z$ , this also defines the vectors  $u, v$  and  $w$  in terms of  $X, Y$  and  $Z$ .

Let  $A$  be the random variable which is defined to be the output of  $C_{2n}$  when the oracle gates are evaluated exactly the same way as in the definition of  $B'$  except that the output of the  $i$ th oracle gate is  $Y_i(\omega) \bullet Z_i(\omega)$ . This defines different vectors of random variables  $L, R, \alpha', \beta', \gamma', u, v$  and  $w$  in terms of  $X, Y$  and  $Z$  then those defined for  $B'$ . In the following, the vectors of random variables we are considering are explicitly mentioned as needed. Because  $A$  is determined by  $C_{2n}$  when the output values from each oracle gate are independently and identically distributed random variables and because  $C_{2n}$  never repeats an input value to an oracle gate,  $E[A] = \Pr [C_{2n}(F^{2n})]$ . Our goal now is to show that  $|E[A] - E[B']| \leq m^2/2^n$ .

DEFINITION.  $\omega \in \Omega$  is **preserving** if for  $1 \leq i \leq m$ ,  $v_i(\omega) = i$  and  $w_i(\omega) = i$ , where  $v_i$  and  $w_i$  are the random variables defined with respect to  $A$ .

CLAIM. For all  $\omega \in \Omega$ , if  $\omega$  is preserving then  $A(\omega) = B'(\omega)$ .

Justification. If for  $1 \leq i \leq m$ ,  $v_i(\omega) = i$  and  $w_i(\omega) = i$ , then for  $1 \leq i \leq m$ ,  $\beta'_i(\omega) = Y_i(\omega)$  and  $\gamma'_i(\omega) = Z_i(\omega)$ , where all these random variables are those defined with respect to  $A$ . Thus, all the outputs of the oracle gates are the same as though they were calculated as in  $B'$ , and thus all the variables defined with respect to  $A$  have exactly the same values as the corresponding variables defined with respect to  $B'$ .

For all  $\omega \in \Omega$ , if  $\omega$  is preserving then  $A(\omega) - B'(\omega) = 0$  and even if  $\omega$  is not preserving then  $|A(\omega) - B'(\omega)| \leq 1$ . Thus,  $|E[A] - E[B']| \leq \Pr [\omega \text{ is not preserving}]$ . In the following discussion, all variables are defined with respect to  $A$ .

DEFINITION. For all  $\omega \in \Omega$ ,  $Y(\omega)$  is **bad** if there is  $i, j, 1 \leq j < i \leq m$ , such that  $Y_i(\omega) = Y_j(\omega)$ . It is not hard to verify that  $\Pr [Y \text{ is bad}] \leq m^2/2^{n+1}$ .

DEFINITION. For all  $\omega \in \Omega$ ,  $X(\omega)$  is **bad** if there is  $i, j, 1 \leq j < i \leq m$ , such that  $\alpha'_i(\omega) = \alpha'_j(\omega)$ .

CLAIM.  $\Pr [X \text{ is bad}] \leq m^2/2^{n+1}$ .

Proof. For  $1 \leq i \leq m$ , let  $\tilde{y}_i$  and  $\tilde{z}_i$  be strings of length  $n$ , let  $\tilde{y} = \langle \tilde{y}_1, \dots, \tilde{y}_m \rangle$  and let  $\tilde{z} = \langle \tilde{z}_1, \dots, \tilde{z}_m \rangle$ . Let  $\Omega_{\tilde{y}, \tilde{z}} = \{\omega \in \Omega : Y(\omega) = \tilde{y} \text{ and } Z(\omega) = \tilde{z}\}$ . We show that for each

$\tilde{y}, \tilde{z}$ ,  $\Pr[X(\omega) \text{ is bad} \mid \Omega_{\tilde{y}, \tilde{z}}] \leq m^2/2^{n+1}$  which implies that  $\Pr[X \text{ is bad}] \leq m^2/2^{n+1}$ .  $Y, Z, L, R$  and  $u$  are constants  $\tilde{y}, \tilde{z}, \tilde{l}, \tilde{r}$  and  $\tilde{u}$  on  $\Omega_{\tilde{y}, \tilde{z}}$ , respectively. This is by definition for  $Y$  and  $Z$ , and it is true for  $L$  and  $R$  because the outputs from all oracle gates are constant on  $\Omega_{\tilde{y}, \tilde{z}}$ , which implies that the inputs to all oracle gates are also constant.  $u$  is constant because it depends only on  $R$ . On the other hand,  $X$  is a vector of  $m$  independently and identically distributed random variables on the probability space restricted to  $\Omega_{\tilde{y}, \tilde{z}}$ , and each such variable has uniform distribution on  $\{0, 1\}^n$ . Let  $eqn(i, j)$  be the equation  $\alpha'_j(\omega) = \alpha'_i(\omega)$ . On  $\Omega_{\tilde{y}, \tilde{z}}$ , this equation reduces to

$$\tilde{l}_j \oplus X_{\tilde{u}_j}(\omega) = \tilde{l}_i \oplus X_{\tilde{u}_i}(\omega).$$

When  $\tilde{u}_j = \tilde{u}_i$ ,  $\Pr[eqn(i, j) \text{ is satisfied} \mid \Omega_{\tilde{y}, \tilde{z}}] = 0$  because  $\tilde{u}_j = \tilde{u}_i$  implies that  $\tilde{r}_j = \tilde{r}_i$  which implies that  $\tilde{l}_j \neq \tilde{l}_i$  (because  $C_{2n}$  does not repeat an input value to an oracle gate) which implies that  $eqn(i, j)$  is not satisfied (because  $eqn(i, j)$  simplifies to  $\tilde{l}_j = \tilde{l}_i$  in this case). When  $\tilde{u}_j \neq \tilde{u}_i$ ,  $\Pr[eqn(i, j) \text{ is satisfied} \mid \Omega_{\tilde{y}, \tilde{z}}] = 1/2^n$  because  $\tilde{u}_j \neq \tilde{u}_i$  together with the fact that  $X$  is a vector of independent random variables on  $\Omega_{\tilde{y}, \tilde{z}}$  implies that for fixed  $X_{\tilde{u}_i}$ , the probability that a randomly chosen  $X_{\tilde{u}_j}$  satisfies the equation is  $1/2^n$ . Thus, summing these probabilities over all  $m(m-1)/2$  equations yields  $\Pr[X(\omega) \text{ is bad} \mid \Omega_{\tilde{y}, \tilde{z}}] \leq m^2/2^{n+1}$ .

CLAIM. For all  $\omega \in \Omega$ ,  $X(\omega)$  is not bad and  $Y(\omega)$  is not bad implies that  $\omega$  is preserving.

*Proof.*  $X(\omega)$  is not bad implies that for  $1 \leq j < i \leq m$ ,  $\alpha'_j(\omega) \neq \alpha'_i(\omega)$  which implies that for  $1 \leq i \leq m$ ,  $v_i(\omega) = i$  which implies that for  $1 \leq i \leq m$ ,  $\beta'_i(\omega) = Y_i(\omega)$ .  $Y(\omega)$  is not bad and for  $1 \leq i \leq m$ ,  $\beta'_i(\omega) = Y_i(\omega)$  implies that for  $1 \leq j < i \leq m$ ,  $\beta'_j(\omega) \neq \beta'_i(\omega)$  which implies that for  $1 \leq i \leq m$ ,  $w_i(\omega) = i$ .

CLAIM.  $\Pr[\omega \text{ is not preserving}] \leq \Pr[X \text{ is bad or } Y \text{ is bad}] \leq m^2/2^n$ . Thus,  $|E[A] - E[B']| \leq m^2/2^n$  and the Main Lemma follows.  $\square$

THEOREM 1.  $h = g \circ g \circ g$  is a pseudorandom invertible permutation generator.

*Proof.* What must be shown is that  $h$  is pseudorandom, i.e., there is no distinguishing circuit family for  $h$ . The proof is by contradiction. Assume that there is a distinguishing circuit family  $C = \{C_{2n_1}, C_{2n_2}, \dots\}$  where  $n_1 < n_2 < \dots$ , for  $h$ . We show this implies there is a distinguishing circuit family  $D = \{D_{n_i} : i \in \mathbb{N}\}$  for  $f$ , contradicting the fact that  $f$  is a pseudorandom function generator. In particular, for a fixed  $n$  we show that if  $C_{2n}$  distinguishes  $h^{2n}$  from  $F^{2n}$  with probability at least  $1/n^c$  then there is a circuit  $D_n$  (where  $D_n$  is not much bigger than  $C_{2n}$ ) which distinguishes  $f^n$  from  $F^n$  with probability at least  $1/4n^c$ . (The proof for  $C_{2n+1}$  is similar). Let us first state the definition of  $h^{2n}$  in a different way. If  $k_0, k_1$  and  $k_2$  are strings of length  $l(n)$  then

$$h_{k_2 \cdot k_1 \cdot k_0}^{2n} = H(f_{k_2}^n, f_{k_1}^n, f_{k_0}^n).$$

Let  $p_0^H, p_1^H, p_2^H, p_3^H$  be  $\Pr[C_{2n}(H(f^n, f^n, f^n))]$ ,  $\Pr[C_{2n}(H(f^n, f^n, F^n))]$ ,  $\Pr[C_{2n}(H(f^n, F^n, F^n))]$ ,  $\Pr[C_{2n}(H(F^n, F^n, F^n))]$ , respectively. Let  $p^R = \Pr[C_{2n}(F^{2n})]$ . The main lemma shows that  $|p^R - p_3^H| \leq m^2/2^n$ , where  $m$  is the number of oracle gates in  $C_{2n}$ . Since  $m$  is less than or equal to  $n^s$  for some constant  $s$ ,  $m^2/2^n \leq 1/4n^c$  for sufficiently large  $n$ . Since

$$1/n^c \leq |p^R - p_0^H| \leq |p^R - p_3^H| + |p_3^H - p_2^H| + |p_2^H - p_1^H| + |p_1^H - p_0^H|,$$

there is an  $i \in \{0, 1, 2\}$  such that  $|p_{i+1}^H - p_i^H| \geq 1/4n^c$ . The cases when  $i = 0$  and  $i = 2$  are similar to the case when  $i = 1$  and are omitted. For the case  $i = 1$ , we use  $C_{2n}$  to

construct a probabilistic circuit  $D_n$  not much larger than  $C_{2n}$  which will distinguish  $f^n$  from  $F^n$  with probability at least  $1/4n^c$ .  $D_n$  is the same as  $C_{2n}$  except that it first randomly chooses  $k_2 \in \{0, 1\}^{l(n)}$  and  $f_0 \in F^n$ , and then each oracle gate  $X$  in  $C_{2n}$  is replaced with a subcircuit which computes  $H(f_{k_2}, X', f_0)$ , where  $X'$  is an oracle gate with an input and output which are both strings of length  $n$ . The main problem with constructing  $D_n$  is how to randomly choose  $f_0$  and  $F^n$ . In fact,  $D_n$  does not specify  $f_0$  at all (since a complete description would involve  $n2^n$  bits). Instead,  $D_n$  remembers all inputs and outputs to  $f_0$ . When  $D_n$  is to compute  $f_0(\alpha)$  for some string  $\alpha$  of length  $n$ , if  $\alpha$  is the same as a previous input then the same output as before is given, otherwise  $\alpha$  is a new input and then  $f_0(\alpha)$  is a randomly chosen string from  $\{0, 1\}^n$ .

When the oracle gates in  $D_n$  are evaluated using  $f_{k_1}^n$ , where  $k_1$  is a randomly chosen key of length  $l(n)$ , then  $p_1^H = \Pr$  [The output of  $D_n$  is 1]. When the oracle gates in  $D_n$  are evaluated using  $f_1$ , where  $f_1$  is randomly chosen from  $F^n$ , then  $p_2^H = \Pr$  [The output of  $D_n$  is 1]. Since  $|p_2^H - p_1^H| \geq 1/4n^c$ ,  $D_n$  distinguishes  $F^n$  from  $f^n$  with probability greater than or equal to  $1/4n^c$ .  $\square$

**THEOREM 2.** *Let  $g$  be defined in terms of pseudorandom function generator  $f$  as described in the beginning of this section. Then  $h = g \circ g \circ g \circ g$  is a super pseudorandom invertible permutation generator.*

*Proof.* The proof of this theorem is very similar to the proof of Theorem 1 and is omitted.  $\square$

It is interesting to note that  $h = g \circ g \circ g$  is *not* super pseudorandom, although Theorem 1 shows that it is pseudorandom. This can be seen as follows. Let  $k_1, k_2$  and  $k_3$  be keys of length  $l(n)$ . A distinguishing circuit  $C_{2n}$  for  $h^{2n}$  can be described as follows. Let  $L_1, L_2$  and  $R$  be strings of length  $n$  such that  $L_1 \neq L_2$ .  $C_{2n}$  has two normal oracle gates: the input to the first normal oracle gate is  $L_1 \bullet R$  and the input to the second normal oracle gate is  $L_2 \bullet R$ . Let  $S_1 \bullet T_1$  and  $S_2 \bullet T_2$  be the outputs of these two normal oracle gates respectively.  $C_{2n}$  also has an inverse oracle gate with input  $S_2 \bullet [T_2 \oplus L_1 \oplus L_2]$ . The output of  $C_{2n}$  is 1 if and only if the last  $n$  bits of the output from this inverse oracle gate is equal to  $R \oplus S_1 \oplus S_2$ . It can be verified that the output of  $C_{2n}$  is always 1 when the normal oracle gates and inverse oracle gates are computed by first choosing a key  $k$  at random and then using  $h_k^{2n}$  for the normal oracle gates and  $\bar{h}_k^{2n}$  to compute the inverse oracle gates. On the other hand, if the oracle gates are computed using a permutation randomly chosen from  $P^{2n}$ , the output of  $C_{2n}$  is 1 with probability  $1/2^n$ .

**6. Conclusions.** Assuming the existence of a pseudorandom function generator, we have proven the existence of a super pseudorandom invertible permutation generator. This is of interest by itself, but the construction and the proof can be viewed as a partial justification of some of the methodology used in the design of DES.

Another methodology which is important both in DES and in the cryptographic literature is using cryptographic composition of permutation generators to **increase** security. In [LR] we define a **measure** of security for permutation generators, and prove that if one composes two permutation generators which are slightly secure the result is more secure than either one alone.

**Acknowledgments.** We thank Oded Goldreich for suggesting the notion of super pseudorandom and for finding a problem with an initial construction we had for a pseudorandom invertible permutation generator. We thank Johan Hastad for simplifying the proof of the Main Lemma. We thank Paul Beame for numerous suggestions which kept us on the right track.

## A PIPELINE ARCHITECTURE FOR FACTORING LARGE INTEGERS WITH THE QUADRATIC SIEVE ALGORITHM\*

CARL POMERANCE†, J. W. SMITH‡ AND RANDY TULER‡

**Abstract.** We describe the quadratic sieve factoring algorithm and a pipeline architecture on which it could be efficiently implemented. Such a device would be of moderate cost to build and would be able to factor 100-digit numbers in less than a month. This represents an order of magnitude speed-up over current implementations on supercomputers. Using a distributed network of many such devices, it is predicted much larger numbers could be practically factored.

**Key words.** pipeline architecture, factoring algorithms, quadratic sieve

**AMS(MOS) subject classifications.** 11Y05, 68M05

**1. Introduction.** The problem of efficiently factoring large composite numbers has been of interest for centuries. It shares with many other basic problems in the sciences the twin attributes of being easy to state, yet (so far) difficult to solve. In recent years, it has also become an applied science. In fact, several new public-key cryptosystems and signature schemes, including the RSA public-key cryptosystem [10], base their security on the supposed intractability of the factoring problem.

Although there is no known polynomial time algorithm for factoring, we do have subexponential algorithms. Over the last few years there has developed a remarkable six-way tie for the asymptotically fastest factoring algorithms. These methods all have the common running time

$$(1) \quad L(N) = \exp \{ (1 + o(1)) \sqrt{\ln N \ln \ln N} \}$$

to factor  $N$ . It might be tempting to conjecture that  $L(N)$  is in fact the true complexity of factoring, but no one seems to have any idea how to obtain even heuristic lower bounds for factoring. The six methods are as follows:

- (i) The elliptic curve algorithm of Lenstra [6];
- (ii) The class-group algorithm of Schnorr-Lenstra [11];
- (iii) The linear sieve algorithm of Schroepfel (see [1] and [8]);
- (iv) The quadratic sieve algorithm of Pomerance [8], [9];
- (v) The residue list sieve algorithm of Coppersmith, Odlyzko and Schroepfel [1];
- (vi) The continued fraction algorithm of Morrison-Brillhart [7].

It might be pointed out that none of these methods have actually been proved to have the running time  $L(N)$ , but rather there are heuristic arguments that give this function as the common running time. The heuristic analyses of the latter four algorithms use a new (rigorous) elimination algorithm of Wiedemann [13] for sparse matrices over finite fields. (This method may in fact be a practical tool; this is discussed further below.)

It should also be pointed out that to achieve the running time  $L(N)$ , method (vi) uses a weak form of the elliptic curve method as a subroutine.

As a last comment, the elliptic curve method has  $L(N)$  as a worst-case running time, while the other five methods have  $L(N)$  as a typical running time. The worst

case for the elliptic curve method is when  $N$  is the product of two primes of about the same length. Of course, this is precisely the case of interest for cryptography.

A proof that  $L(N)$  is the correct asymptotic complexity for factoring would of course be sensational. One corollary would be that  $P \neq NP$ . It seems to us, however, that of equal importance to practicing cryptographers is a complexity bound valid for finite values of  $N$ . Of course, such a bound necessarily enters into the amount of resources one is willing to invest in the problem.

To be specific, what is the largest number of decimal digits such that any number with this many or fewer digits can be factored in a year using equipment that would cost \$10,000,000 to replace? The dollar amount is not completely arbitrary; it is the order of magnitude of the cost of a new supercomputer. An answer to this question is not a fundamental and frozen constant, but rather a dynamic figure that reflects the state of the art at a given point in time. Nevertheless, it is an answer to precisely this kind of question that practicing cryptographers need.

Given an actual experiment where the running time is less than a year, performance for a full year can be extrapolated using the expression (1) (but ignoring the " $o(1)$ "). The factoring algorithms listed above are all "divide and conquer," that is, with  $k$  identical computers assigned to the problem, the number will be factored about  $k$  times as fast. Thus if an actual experiment involves equipment costing less than \$10,000,000, again one can extrapolate.

Here are two examples. In 1984, the Sandia National Laboratories team of Davis, Holdridge and Simmons [3] factored a 71-digit number in 9.5 hours on a Cray XMP computer. Moreover, the algorithm they used, the quadratic sieve, has running time  $L(N)$ . Since

$$\frac{1 \text{ year}}{9.5 \text{ hours}} \approx \frac{L(10^{101})}{L(10^{71})},$$

we thus predict that the Sandia group could factor any 101-digit number in a year-long run on a Cray XMP.

The other example comes from some recent work of Silverman who has implemented the quadratic sieve algorithm on a distributed network of 9 SUN 3 workstations. Although at retail a SUN 3 is fairly expensive, it may be fairer for these purposes to use a wholesale price for a stripped down version, say \$5000 each. With this system, which we value at \$45,000, Silverman was able to factor an 81-digit number in one week. Since

$$\frac{1 \text{ year}}{1 \text{ week}} \cdot \frac{10,000,000}{45,000} \approx \frac{L(10^{126})}{L(10^{81})},$$

we predict that he would be able to factor any 126-digit number in a year-long run with 2000 SUN 3's.

In this paper we shall describe a machine which should cost about \$50,000 to build and which should be able to factor 100-digit numbers in two weeks. This custom-designed processor will implement the quadratic sieve algorithm. Since

$$\frac{1 \text{ year}}{2 \text{ weeks}} \cdot \frac{10,000,000}{50,000} \approx \frac{L(10^{144})}{L(10^{100})},$$

we predict that with \$10,000,000 any 144-digit number could be factored in a year. The cost to factor a 200-digit number in a year with this strategy would be about  $10^{11}$  dollars—or only 5 percent of the current U.S. national debt!

**2. Combination of congruences factorization algorithms.** To properly describe the factoring project, it is necessary to begin with a description of the quadratic sieve (qs)

as it will be implemented. This is in fact a fairly complex algorithm with many stages. Some of these stages are common to other factoring algorithms, other stages are specific to qs.

The qs algorithm belongs to a family of factoring algorithms known as combination of congruences. With these, the basic goal in factoring  $N$  is to find two squares  $X^2, Y^2$  with  $X^2 \equiv Y^2 \pmod N$ . If these squares are found in a random or pseudorandom fashion and if  $N$  is composite, then with probability at least  $\frac{1}{2}$ , the greatest common factor  $(X - Y, N)$  will give a nontrivial factorization of  $N$ . This greatest common factor can be computed very rapidly using Euclid's algorithm.

The two congruent squares  $X^2$  and  $Y^2$  are constructed from auxiliary congruences of the form

$$(2) \quad u_i^2 \equiv v_i^2 w_i \pmod N, \quad u_i^2 \neq v_i^2 w_i.$$

If some nonempty set of indices  $I$  can be found such that  $\prod_{i \in I} w_i$  is a square, we can let

$$X \equiv \prod_{i \in I} u_i \pmod N,$$

$$Y \equiv \left( \prod_{i \in I} v_i \right) \left( \prod_{i \in I} w_i \right)^{1/2} \pmod N.$$

This special set of indices  $I$  can be found using the techniques of linear algebra. In fact, if the number  $w_i$  appearing in (2) has the prime factorization

$$w_i = (-1)^{\alpha_{0,i}} \prod_{j=1}^{\infty} p_j^{\alpha_{j,i}},$$

where  $p_j$  denotes the  $j$ th prime and there are only finitely many  $j$  for which  $\alpha_{j,i} > 0$ , then let  $\vec{\alpha}_i$  denote the vector  $(\alpha_{0,i}, \alpha_{1,i}, \dots)$ . Then the following two statements are equivalent for finite sets of indices  $I$ :

- (i)  $\prod_{i \in I} w_i$  is a square;
- (ii)  $\sum_{i \in I} \vec{\alpha}_i \equiv \vec{0} \pmod 2$ .

Thus the algorithmic problem of finding  $I$  (when given a collection of integers  $w_i$  and their prime factorizations) is reduced to the problem of finding a nontrivial linear dependency among the vectors  $\vec{\alpha}_i$  over the finite field with two elements.

For this method to work, we need the prime factorizations of the numbers  $w_i$  appearing in (2). It is the difficulty in finding enough completely factored  $w_i$  so that a linear dependency may be found among the  $\vec{\alpha}_i$  that is the major bottleneck in the combination of congruences family of algorithms.

This bottleneck is ameliorated by discarding those  $w_i$  that do not completely factor with small primes. This is a good plan for two reasons. First, those  $w_i$  with a large prime factor probably will not be involved in a dependency. Second, those  $w_i$  that can be factored completely over the small primes can be seen as having this property with a not unreasonable amount of work. The set of small primes used is fixed beforehand and is called the "factor base."

**3. The quadratic sieve algorithm.** To make the above factoring scheme into an algorithm, we need a systematic method of generating congruences of the shape (2) and a systematic method of recognizing which  $w_i$  can be factored completely over the factor base. In the qs algorithm, we use parametric solutions of (2). That is, we exhibit three polynomials  $u(x), v(x), w(x)$  such that for each integral  $x$  we obtain a solution

of (2) with  $u(x) = u_i, v(x) = v_i, w(x) = w_i$ . Moreover, those  $x$  for which  $w(x)$  completely factors over the factor base can be quickly found by a sieve procedure described below.

In the original description of the qs algorithm [8], only one triple of polynomials  $u(x), v(x), w(x)$  was used, namely

$$u(x) = [\sqrt{N}] + x, \quad v(x) = 1, \quad w(x) = ([\sqrt{N}] + x)^2 - N.$$

It was later found more advantageous to work with a family of triples of polynomials. The Sandia implementation of qs used a scheme of Davis and Holdridge [2]: If  $p$  is a large prime and  $w(x_0) \equiv 0 \pmod p, 0 \leq x_0 < p$ , then let

$$u_p(x) = u(x_0 + xp), \quad v_p(x) = 1, \quad w_p(x) = w(x_0 + xp).$$

A further refinement of this idea in [9] that has never been implemented is to choose  $x_1$  with  $w(x_1) \equiv 0 \pmod{p^2}, 0 \leq x_1 < p^2$ , and

$$u_{p^2}(x) = u(x_1 + xp^2), \quad v_{p^2}(x) = p, \quad w_{p^2}(x) = \frac{1}{p^2} w(x_1 + xp^2).$$

A different and somewhat better scheme for choosing multiple polynomials was suggested by Peter Montgomery (see [9] and [12]). This method has been implemented by Silverman and is the method that we too shall use. Suppose we know beforehand that we will only be dealing with a polynomial  $w(x)$  for values of  $x$  in  $[-M, M]$ , where  $M$  is some large, but fixed integer. Then we choose quadratic polynomials  $w(x)$  that “fit” this interval well. That is,  $w(M) \approx w(-M) \approx -w(0)$  and these approximately common values are as small as possible.

This task is done as follows. First choose an integer  $a$  with

$$(3) \quad a^2 \approx \sqrt{2N}/M$$

and such that  $b^2 \equiv N \pmod{a^2}$  is solvable. Let  $b, c$  be integers with

$$(4) \quad b^2 - N = a^2c, \quad |b| < a^2/2.$$

Then we let

$$(5) \quad u(x) = a^2x + b, \quad v(x) = a, \quad w(x) = a^2x^2 + 2bx + c.$$

How do we determine which values of  $x$  in  $[-M, M]$  give a number  $w(x)$  that completely factors over the factor base? Fix the factor base as the primes  $p \leq B$  for which

$$(6) \quad t^2 \equiv N \pmod p$$

is solvable. The parameter  $B$  is fixed at the beginning of the program. We shall only recognize those values of  $w(x)$  not divisible by any prime power greater than  $B$ . Presumably, if  $B$  is large enough compared with typical values of  $|w(x)|$  (typical values are about  $\sqrt{N} M$ ), most values that factor completely with the primes up to  $B$  will, in fact, not be divisible by any prime power greater than  $B$ .

For each prime power  $q = p^\alpha \leq B$  where  $p$  is in the factor base, solve the congruence

$$(7) \quad w(x) \equiv 0 \pmod q$$

and list the solutions  $A_q^1, A_q^2, \dots, A_q^{k(q)}$ . The number of solutions  $k(q)$  is either 1, 2 or 4. (Almost always we have  $k(q) = 2$ .)

Next we compute integral approximations to the numbers  $\log |w(x)|$  for  $x \in [-M, M]$ . Because of the relationships of  $a, b, c, M, N$  to each other given by (3) and (4), the values of  $[\log |w(x)|]$  tend to stay constant on long subintervals of  $[-M, M]$ . For example, it is about  $[\log (M\sqrt{N}/2)]$  for  $|x| < \sqrt{1/4} M$  and  $\sqrt{3/4} M < |x| < M$ . It is about  $[\log (M\sqrt{N}/2)] - 1$  for  $\sqrt{1/4} M < |x| < \sqrt{3/8} M$  and  $\sqrt{5/8} M < |x| < \sqrt{3/4} M$ , etc. Thus not only is this an easy computation for one choice of polynomial, but the results are virtually the same for each polynomial.

If  $q = p^\alpha \leq B$  where  $p$  is a prime in the factor base, let  $\Lambda(q) = \log p$ . We compute single precision values for the  $\Lambda(q)$ . This computation can be done once; it is independent of the polynomial used. For other integers  $m$  let  $\Lambda(m) = 0$ . Then every prime power factor of  $w(x)$  is at most  $B$  if and only if  $\log |w(x)| = \sum_{m|w(x)} \Lambda(m)$ .

We are now ready to sieve. A memory addressed by integers  $x$  in  $[-M, M)$  is initialized to zero. For each power  $q \leq B$  of a prime in the factor base and each  $j \leq k(q)$ , we retrieve the numbers in those memory locations addressed by integers  $x \equiv A_q^j \pmod q$ , add  $\Lambda(q)$  to the number there, and put this result back in the same place. This is what we call sieving and it is of central importance to the qs algorithm. In pseudocode it may be described as follows:

For each power  $q \leq B$  of a prime in the factor base and

$j \in \{1, \dots, k(q)\}$  do:

Let  $A = A_q^j + \lceil (-M - A_q^j)/q \rceil q$  (thus  $A$  is the first number in  $[-M, M)$  which is  $\equiv A_q^j \pmod q$ )

While  $A < M$  do:

$D \leftarrow S(A)$

$S(A) \leftarrow D + \Lambda(q)$ ;  $A \leftarrow A + q$ .

After sieving, we scan the  $2M$  memory locations for values near  $\log |w(x)|$ . Such a location  $x$  most likely corresponds to a value of  $w(x)$ , all of whose prime power factors are at most  $B$ . It is possible that there could be some false reports or some locations that should have been reported that are missed. This error, which is introduced from our approximate logarithms, should be negligible in practice.

**4. Fine points.** In §§ 2 and 3 we described the basic qs algorithm using Montgomery's polynomials. In this section we shall give some adornments to the basic algorithm which should speed things up.

**Use of a multiplier.** We may wish to replace  $N$  in (3), (4) and (6) with  $kN$  where  $k$  is some small, fixed, positive, square-free integer. This trick, which goes back to Kraitchik [5, p. 208], can sometimes speed up implementation by a factor of 2 or 3. The idea is to skew the factor base towards smaller primes. However, there is a penalty in that the values  $|w(x)|$  are larger by a factor of  $\sqrt{k}$ . We balance these opposing forces with the function

$$f(k, N) = -\frac{1}{2} \log k + \sum_{p \leq B} E_p^{(k)},$$

where the sum is over primes  $p \leq B$ ,  $E_p^{(k)} = 0$  if  $t^2 \equiv kN \pmod p$  is not solvable, and

$$E_p^{(k)} = \begin{cases} \frac{2 \log p}{p-1}, & p \text{ odd and } p \nmid k, \\ \frac{\log p}{p}, & p \text{ odd and } p \mid k, \\ \frac{1}{2} \log 2, & p = 2 \text{ and } kN \equiv 2 \text{ or } 3 \pmod 4, \\ \log 2, & p = 2 \text{ and } kN \equiv 5 \pmod 8, \\ 2 \log 2, & p = 2 \text{ and } kN \equiv 1 \pmod 8, \end{cases}$$

if  $t^2 \equiv kN \pmod p$  is solvable (see [9]).

When presented with a number  $N$  to factor, we first find the value of  $k$  which maximizes  $f(k, N)$ . In practice one can assume  $k < 100$ . Also in practice, we may replace  $B$  in the definition of  $f(k, N)$  with a smaller number, say 1000.

**Small prime variation.** If  $q \leq B$  is a power of a prime in the factor base, then the time it takes to sieve with one  $A_q^i$  is proportional to  $M/q$ . Thus we spend more time with a smaller  $q$ , less with a larger  $q$ . However, small  $q$ 's do not contribute very much. For example,

$$\sum_{q < 30} \Lambda(q) < 42,$$

which is usually small compared to  $\log |w(x)|$ . In addition, it is usually not the case that every prime less than 30 is in the factor base and it usually is the case that a number which factors over the factor base is not divisible by all the factor base primes below 30. Thus only a small error is introduced by forgetting to sieve with the prime powers below 30. By lowering the threshold which causes a value  $w(x)$  to be reported, no fully factored values need be lost. The only penalty is possibly a few more false reports. In fact, even this should not occur (see [9]). The small prime variation might save 20 percent of the running time.

**Large prime variation.** If  $x$  is such that

$$\log |w(x)| - \sum_{m|w(x)} \Lambda(m) < 2 \log B,$$

then either  $w(x)$  completely factors with the primes in the factor base, or there is some large prime  $p$ ,

$$B < p < B^2,$$

such that  $w(x)/p$  completely factors with the primes in the factor base. Thus, by again lowering the threshold for reports, we can catch these values of  $w(x)$  as well. For such a value to be eventually part of a linear dependency (see § 2), there must be at least one other report  $w_1(x_1)$  using the same large prime  $p$ . The birthday paradox suggests that duplication of large primes  $p$  should not be so uncommon. In practice we shall probably only try to use those  $w(x)$  which factor with a large prime  $p < 100 B$ . The large prime variation (also used by Silverman [12]) speeds up the algorithm by about a factor of 2 or 3. However, the larger we take  $B$ , for a fixed  $N$ , the less useful will be this variation. It should also be noted that the large prime variation has been implemented in other combinations of congruences algorithms as well.

**Generation of polynomials and sieve initialization data.** Both experience [3], [12] and theory [9] suggest that it is advantageous to change polynomials fairly often. The reason for this is as follows. On  $[-M, M)$ , the largest values of  $|w(x)|$  are about  $M\sqrt{N}/2$ . Moreover, more than half of the values are at least half this big. However, the larger is  $|w(x)|$ , the less likely it will factor completely over the factor base. Thus it would be advantageous to choose a rather small  $M$ . But  $M$  is directly proportional to the time spent sieving  $w(x)$ , so a smaller  $M$  translates to less time spent per polynomial.

Since we will want to change polynomials often, we should learn to do this efficiently. For each polynomial  $w(x) = a^2x^2 + 2bx + c$  given by (5) we shall need to find  $a, b, c$  satisfying (3) and (4) and we shall need to solve all of the congruences (7). One last criterion is that  $a$  should be divisible either by a prime greater than the large prime bound or by two primes greater than  $B$  so that we do not get duplicate solutions of (2) from different polynomials.

One possibility, suggested in [9] and implemented in [12], is to choose  $a$  as a prime  $\approx (\sqrt{2N}/M)^{1/2}$  with  $t^2 \equiv N \pmod{a^2}$  solvable. Then we may let the solution for  $t$  least in absolute value be  $b$  and choose  $c = (b^2 - N)/a^2$ . Since  $a$  is a prime, the

quadratic congruence is easily solved. This then gives a legal polynomial  $w(x)$  and it remains to solve the congruences (7) for all the powers  $q \leq B$  of a prime in the factor base. By the quadratic formula, these roots (for  $q$  coprime to  $2a$ ) are given by the expression

$$(8) \quad (-b \pm \sqrt{N})a^{-2} \pmod{q},$$

where  $\sqrt{N}$  is interpreted as a residue  $t_q \pmod{q}$  with  $t_q^2 \equiv N \pmod{q}$  and where  $a^{-2}$  is the multiplicative inverse of  $a^2 \pmod{q}$ . The numbers  $t_q$  may be stored of course, since they are used in each polynomial. However, since each polynomial uses a new value of  $a$  in this scheme, it appears that an inversion mod  $q$  (using the extended g.c.d. algorithm) is necessary for each  $q$  and for each polynomial.

Thanks to a suggestion from Peter Montgomery, sieve initialization can in fact be accomplished with much less computation. The idea is to choose  $a$  as a product of  $l$  primes  $g \approx (\sqrt{2N}/M)^{1/(2l)}$  with  $t^2 \equiv N \pmod{g^2}$  solvable. (The value of  $l$  here is quite small, we plan to use  $l=3$  or  $4$ .) Say  $a = g_1 \cdots g_l$ . Using known solutions  $\pm b_i$  of the congruences  $t^2 \equiv N \pmod{g_i^2}$  for  $i = 1, \dots, l$ , we may assemble via the Chinese Remainder Theorem  $2^l$  different values of  $b \pmod{a^2}$  which satisfy  $b^2 \equiv N \pmod{a^2}$ . Since  $b$  and  $-b$  will give essentially the same polynomial  $w(x)$ , we will get  $2^{l-1}$  different polynomials for the one value of  $a$ .

Suppose now we use  $r$  primes  $g_1, \dots, g_r$  and we form different values of  $a$  by choosing  $l$  of these primes. Thus there are  $\binom{r}{l}$  values of  $a$  and thus  $2^{l-1}\binom{r}{l}$  different polynomials. If  $a = g_{i_1} \cdots g_{i_l}$ , then

$$(9) \quad a^{-2} \pmod{q} \equiv g_{i_1}^{-2} \cdots g_{i_l}^{-2} \pmod{q}.$$

Thus if the numbers  $g_i^{-2} \pmod{q}$  are precomputed and stored for each  $i = 1, \dots, r$  and for each  $q$ , the computation of  $a^{-2} \pmod{q}$  need not require any more inversions. It appears as if  $l-1$  multiplications mod  $q$  are necessary when (9) is used to compute  $a^{-2} \pmod{q}$ . But if we form a new  $l$ -tuple of  $g$ 's by trading just one  $g$  for a new one and saving an intermediate calculation, it takes only one multiplication mod  $q$ .

Here is another idea for sieve initialization that might be practical. Let  $p_1, \dots, p_l$  be a set of factor base primes with each  $p_i \approx 500$  and with  $l$  as large as possible so that  $K = p_1 \cdots p_l$  is still small compared with  $\sqrt{N}/M$ . Let  $f(x) = ax^2 + 2bx + c$  be a polynomial with  $b^2 - ac = N$ ,  $|b| < a/2$ ,  $a \approx \sqrt{2N}/KM$ . Consider the solutions  $u$  of  $f(x) \equiv 0 \pmod{K}$ . For each solution  $u$ , let

$$g_u(x) = \frac{1}{K} f(u + xK).$$

There are  $2^l$  choices of  $u$  and for each choice we obtain a polynomial  $g_u(x)$  which may be sieved for  $x$  in  $[-M, M)$ . Suppressing the details, it turns out that with a small amount of precomputation, the sieve initialization data for each polynomial  $g_u$  may be computed with 2 additions mod  $q$  for each  $q$ . For  $N \approx 10^{100}$ , we may be able to take  $l$  as large as 14 or 15, so that  $2^{14}$  or  $2^{15}$  different polynomials may be generated in this way for the one value of  $K$ .

**5. Implementation.** Our implementation of the qs algorithm will have 5 stages: (1) preprocessing, (2) sieve initialization, (3) pipe i/o, (4) pipe, (5) postprocessing. Stages (2), (3), (4) occur simultaneously on three different devices that interact frequently. As their names suggest, stage (1) is completed before the other stages are begun and stage (5) is done only after all other stages have ended their work.

**Stage (1): Preprocessing.** This relatively minor stage involves the creation of various constants that are used in later stages of the algorithm. These include (i) choice of a multiplier, (ii) creation of the factor base, (iii) solution of the congruences  $t^2 \equiv N \pmod q$  for each power  $q \leq B$  of a prime in the factor base, (iv) construction of a list of primes  $g_1, \dots, g_r$  and solutions of the congruences  $t^2 \equiv N \pmod{g_i^2}$  as discussed in § 4, (v) computation of  $g_i^{-2} \pmod q$  for each  $i = 1, \dots, r$  and each power  $q \leq B$  of a prime in the factor base.

The necessary inputs from which all of these numbers are created are  $N$  (the number to be factored),  $B$  (the bound on the factor base),  $M$  (half the length of the interval on which a polynomial is sieved), and  $r$  (where  $4\binom{r}{3}$  is a sufficient number of polynomials to complete the factorization of  $N$ ).

Preprocessing can be completed on virtually any computer with a large memory. For example, a SUN 3 workstation would be sufficient, even for very large numbers.

**Stage (2): Sieve initialization.** In this stage a three-element subset  $i, j, k$  is selected from  $\{1, \dots, r\}$  and from this triple a polynomial  $w(x)$  is constructed together with sieve initialization data. Indeed, from the preprocessed data, the sieve initializer lets  $a = g_i g_j g_k$  and chooses  $b, c$  to satisfy (4). This then defines a polynomial  $w(x) = a^2 x^2 + 2bx + c$ . Next the sieve initializer computes  $A_q^j$  for each power  $q \leq B$  of a prime in the factor base via the formulas (8) and (9).

The actual sieving of  $w(x)$  is performed in the next two stages. The sieve initializer has a direct link to the pipe i/o which controls the sieving. As soon as the sieve initialization data has been prepared, the pipe i/o and pipe cease their work on the previous polynomial and the pipe i/o receives the data for the next polynomial.

This configuration of tasks shows how the parameters  $B$  and  $M$  are related. The time for the sieve initializer to prepare a polynomial and sieve initialization data depends only on  $B$ , while the time for the sieving units to sieve the polynomial on  $[-M, M)$  with the powers  $q \leq B$  of the primes in the factor base depends on both  $M$  and  $B$ . We choose the parameters  $B, M$  so that these two times are equal. In practice, we shall choose  $B$  first and then determine empirically the value of  $M$  that works.

Since the sieve initializer will be working as long as we are sieving, it would be desirable for it to be a dedicated piece of hardware. It is also desirable, but not crucial for the sieve initializer to be fast. A 50 percent speed-up of the sieve initializer may yield only a 15 percent speed-up in the total factorization time for a 100-digit number. While not negligible, this shows that resources might be more profitably allocated elsewhere. We are planning on dedicating a SUN 3 workstation to sieve initialization. It is likely we could build a custom processor for sieve initialization with the same performance as the SUN for less than \$5000. Although we currently do not anticipate building this custom processor, we nevertheless use the figure \$5000 for the cost of a sieve initializer in our estimate of the cost of the entire project.

**Stages (3) and (4): Pipe i/o and pipe.** It makes the best sense to give a joint overview of these two stages since the two units work in tandem to sieve a polynomial  $w(x)$  on the interval  $[-M, M)$  with the powers  $q \leq B$  of the primes in the factor base. These units form the heart of our factorization project and will be described in detail in §§ 5 and 6.

Since the number  $M$  will be relatively large in our implementation (for example, we may choose  $M \approx 10^8$ ) it would take a large memory to sieve these  $2M$  values all at once. It would be a more efficient use of resources to use a somewhat smaller memory; denote its length by  $I$ . (In one configuration of our machine we have chosen  $I = 2^{20}$ .) After the first  $I$  values are sieved, we then sieve the next  $I$  values and so on.

Thus the “polynomial interval”  $[-M, M)$  is broken into a number of subintervals of length  $I$ .

The pipe then is a unit that can sieve  $I$  consecutive values of a polynomial  $w(x)$ . The pipe i/o is a unit that (i) receives from the sieve initializer the sieving data for a polynomial, (ii) initializes the pipe, (iii) sends out the sieving data ( $A \bmod q, \Lambda(q)$ ) one arithmetic progression at a time into one end of the pipe, (iv) receives processed sieving data from the other end of the pipe and readies it for the next subinterval, (v) receives reported “successes” (locations  $x$  where  $w(x)$  has been completely factored) from the pipe and sends them out to a host computer, probably the sieve initializer.

We will custom build the pipe i/o and pipe units. It is with these units, which will be specifically designed to sieve quickly, that we hope to achieve gains over previous implementations of the qs algorithm. The pipeline architecture is particularly well suited to sieving with “adjustable stride” which the qs algorithm demands. The usual problem of pipeline architectures, that of having software that keeps the pipe filled, is met here by custom tailoring of the hardware and software in the same project.

The pipe i/o and pipe will not need any diagnostic circuitry. Errors caused by hardware fault will either be detected during reporting of successes (either too few or too many reports will signal an error) or during post processing (a false report is detected here). It also should be noted that it is not necessary to design special checkpoint/restart capability since the operation of the algorithm involves sieving a new polynomial every five to ten seconds. Unlike primality testing where one glitch can throw out an entire primality proof, the quadratic sieve is a robust algorithm where local errors will not propagate.

**Stage (5): Post-processing.** Each reported success consists of four integers  $a, b, c, x$  such that

$$(a^2x + b)^2 \equiv a^2(a^2x^2 + 2bx + c) \pmod{N}$$

and such that  $w(x) = a^2x^2 + 2bx + c$  completely factors over the factor base except possibly for one larger prime (see § 4 for a description of the large prime variation). The first step in post-processing is to compute the actual prime factorizations of the various successful numbers  $w(x)$ . This can be found by trial division. However, it is possible for the pipe i/o and pipe to immediately resieve in a special mode any subinterval in which a success is found. This special mode reports the prime powers which “hit,” that is, divide, the number  $w(x)$ . If this is done then the prime factorization of  $w(x)$  will be nearly complete and the postprocessor will have little work for this step. (Thanks are due to R. Schroepel and S. S. Wagstaff, Jr. for this idea.) Without this resieving mode, as many as  $10^{11}$  multiprecision divides would be necessary in post-processing (assuming a factor base of  $10^5$  and  $10^6$  reports). By resieving, we would have instead about the same number of low precision additions performed on specially tailored hardware.

Corresponding to each factorization of a  $w(x)$  we have a (sparse) 0, 1 vector of exponents on the primes in the factor base reduced mod 2 (see § 2). The second step in post-processing is to find several linear dependencies mod 2 among these vectors. The third step in post-processing is to use a dependency to assemble two integers  $X, Y$  with  $X^2 \equiv Y^2 \pmod{N}$ , as discussed in § 2. The fourth and final step in post-processing is to compute  $(X - Y, N)$  by Euclid’s algorithm. If this gives only a trivial divisor of  $N$ , another dependency is used to assemble another pair  $X', Y'$ , etc.

The most complex of these steps is the linear algebra required to find the dependencies. The length of the vectors depends on how large a value of  $B$  is chosen. The optimal choice of  $B$  for sieving may well be larger than  $10^6$ . This would lead to vectors

of length about 39,000 or more (even ignoring the problem of encoding a large prime involved in a factorization in the same 0, 1 format). To factor very large numbers we may even wish to use vectors of length 100,000. Note that we need about as many vectors as their length. A  $10^5$  square matrix is probably too big to store in virtual memory on any commercially available computer (with the possible exception of a Cray 2), even given that each matrix entry is and will remain a single bit.

Here are several options that are available for the storage and processing of such a huge matrix. The problem of the large primes, ignored above, can be very easily solved using a sparse encoding of the vectors and quickly eliminating large primes by Gaussian elimination. This is quick and there is little fill-in since any factored  $w(x)$  has at most one large prime in the interval  $(B, B^2)$ .

This Gaussian elimination might be continued further, but now fill-in will begin to occur. It may be possible to then switch to the 0, 1 encoding and continue with Gaussian elimination on this smaller, but no longer sparse, problem.

A promising option is to use a sparse encoding and Wiedemann's elimination algorithm [13] for sparse matrices over a finite field (after the large primes have been eliminated as described above).

An unimaginative but possible plan is to use Gaussian elimination and the 0, 1 encoding (after the large primes are eliminated), but process only two slim slices of the matrix at any given time. This would involve a certain amount of i/o between the central memory and disc storage.

The matrix portion of post-processing will be performed on a large mainframe computer, perhaps the Cyber 205 at the University of Georgia. The other stages of post-processing will be performed on the same computer or perhaps on our SUN 3. In all, post-processing should not be time-critical for factoring; its difficulties will be solved in software on conventional computers.

**6. The pipe.** As mentioned above, the pipe is a unit capable of sieving  $I$  consecutive values of a polynomial  $w(x)$  with the powers  $q \leq B$  of the primes in the factor base. We now describe details of its organization.

**Block processors.** The pipe is segmented with each segment consisting of a section of store and some arithmetic capability used in sieving. We call the section of store a *block*, and the arithmetic capability together with the store a *block processor* (BP). The size of the storage on each BP is denoted  $|BP|$ . It is necessary to choose  $|BP|$  a power of 2; our working figure is  $|BP| = 2^{16}$  which we shall assume in the following. The word length of this store is nominally eight bits, since this will provide the resolution required for the approximate logarithms in the sieving process. The number of BP's in the pipe ( $\#BP$ ) is also a power of 2; our working figure is 16. The total store in the pipe is  $\#BP \times |BP| = 2^{20} = I$ , the length of a subinterval that we sieve at a given time.

**Subinterval processing.** First, the pipe must be initialized for the subinterval. This involves setting the contents of the BP store to a constant (we use 0), and setting the threshold value  $T$  at which each BP will detect a result. The pipe i/o will direct these operations.

Next, the sieve must be run. The pipe i/o will send out the progression records. These are entered into the pipe as rapidly as possible. Then when they exit the pipe they are stored in the pipe i/o for use in successive subintervals. During sieving, the BP will add  $\Lambda(q)$  to each location at which the progression  $A \bmod q$  hits. Some locations may then reach the threshold level  $T$ .

**Reports.** If a BP detects that a location has exceeded the threshold value, it will immediately report this to the pipe i/o. At the end of sieving, the address(es) that exceeded the value is (are) reported for use in post-processing.

One refinement which increases the utility of the reports is to report not only the address, but each of the prime powers that hit at that location. This will reduce the work required in post-processing. We can accomplish this goal by running the sieve “backwards” from the new set of  $A$ 's we have calculated, observing those that hit the marked location. (There is no special need to “mark” locations, however. By setting each  $\Lambda(q) = 0$  for the re-sieving, only locations already exceeding the report tolerance from before cause a report to be made.) The pipe is wired so that information “flows” only in one direction, so sieving “backwards” must be simulated by reversing the order of the store in the pipe.

When a reportable result is found, the BP will raise a flag called “report request,” which activates a daisy chain protocol. This signal will stop all the BP's simultaneously in the middle of the next cycle. If the pipe i/o has been in sieve mode, it reads from the BP the address that caused the threshold to be surpassed and then continues to sieve normally the rest of the subinterval. The pipe i/o then enters the re-sieve mode. This begins with reversing the order of the store in the pipe. (In fact, it is only necessary to reverse the order of the store of the reported address or addresses. In practice it may be simpler to just re-initialize the key location(s) with some preset value that we know will be above the threshold.) Next each BP is set to the re-sieve mode; this entails subtracting, rather than adding in the address register. Recall that each  $\Lambda(q)$  has been set to 0. Thus there will be report requests at only those marked locations that have been preset with above threshold values. Now when there is a report request, the pipe i/o transfers the prime power from the BP, not the address. When the subinterval has been completely re-sieved the pipe i/o returns to sieve mode. When the polynomial has been completely sieved, the reports are transferred to the host.

**Pipe arithmetic.** The arithmetic capability which is on the BP is concentrated into address and data arithmetic units which do the following operations:

$$\begin{aligned} A &\leftarrow A + q, \\ D &\leftarrow S(A), \\ S(A) &\leftarrow D + \Lambda(q). \end{aligned}$$

Since there are two separate arithmetic units for address and data arithmetic, these arithmetic operations can proceed in parallel. This is an important consideration in the performance of the BP.

This arithmetic capability, while simple, allows a BP to perform several different functions:

```

Initializing:  While (A < |BP|){
                S(A) ← 0;
                A ← A + 1;
            }

Sieving:      While (A < |BP|){
                S(A) ← S(A) + Λ(q);
                If (S(A) > T) {report A}
                A ← A + q;
            }
  
```

```

Reporting:  While ( $A > 0$ ){
               $S(A) \leftarrow S(A) + 0$ ;
              If ( $S(A) > T$ ) {report  $q$ }
               $A \leftarrow A - q$ ;
            }

```

**Interconnects.** Each BP is connected to both of its neighbor BP's (predecessor and successor). The predecessor of the first BP and successor of the last BP is the pipe i/o unit. In addition, each BP has a bus connection to the pipe i/o unit. From the predecessor, each BP receives the data items  $A$ ,  $q$ ,  $\Lambda(q)$  which are the progression record for sieving and sends the signal "BUSY," which while on tells the predecessor not to send anything. To the successor, each BP sends the data items  $A$ ,  $q$ ,  $\Lambda(q)$  and receives the signal "BUSY."

From the pipe i/o bus, the BP receives initialization instructions and a report tolerance  $T$  (valid for this BP in this subinterval run). To the pipe i/o bus, the BP sends the signal "SUCCESS" if some  $S(A) > T$ . In this case, the  $A$  and  $q$  report values are sent to the pipe i/o unit over this bus. The BP control modes are broadcast to the pipe from the pipe i/o unit over this bus as well.

**Performance.** The fundamental performance parameter of the BP is the cycle time of the BP store,  $C$ . All the other performance values can be stated in terms of this value.

The time of a prime power  $q$  in a BP is at most  $\lceil |\text{BP}|/q \rceil \times 2C$ . That is, each sieve step is accomplished in two cycles. To see how this can be done we consider the worst possible case, namely when several arithmetic progressions each successively hit exactly once in a particular BP. Thus in two cycles, the BP needs to receive the sieving data, recognize that there is a hit in this BP, do the sieving, see if there is a SUCCESS, recognize that the arithmetic progression does not hit a second time, and send out the altered sieving data. Also we shall see in the next section that the sieving data is not sent all in one cycle, but the  $A$  value is sent in one cycle and the  $q$ ,  $\Lambda(q)$  values are sent in the next cycle. This worst case is outlined in Table 1 which shows what happens to two consecutive sieving records  $A_i$ ,  $q_i$ ,  $\Lambda(q_i)$  for  $i = 0, 1$ .

Thus during an even-numbered cycle in this worst-case scenario, the BP performs the five operations listed for cycle 2 above. During an odd-numbered cycle, the BP

TABLE 1

Cycle	Progression 0	Progression 1
0	In [ $A_0$ ]: BPID [=] $A \leftarrow \text{IN}[A_0]$	
1	$D \leftarrow S(A)$ $A_{in} \leftarrow A + q_{in}$ ; $A_{in}$ : BPID [ $\neq$ ] $q, \Lambda(q) \leftarrow \text{IN}[q_0, \Lambda(q_0)]$	
2	OUT [ $A'_0$ ] $\leftarrow A_{in}$ $S(A) \leftarrow D + \Lambda(q)$ ; $S(A)$ : $T$ [ $<$ ]	IN [ $A_1$ ]: BPID [=] $A \leftarrow \text{IN}[A_1]$
3	OUT [ $q_0, \Lambda(q_0)$ ] $\leftarrow q, \Lambda(q)$	$D \leftarrow S(A)$ $A_{in} \leftarrow A + q_{in}$ ; $A_{in}$ : BPID [ $\neq$ ] $q, \Lambda(q) \leftarrow \text{IN}[q_1, \Lambda(q_1)]$
4		OUT [ $A'_1$ ] $\leftarrow A_{in}$ $S(A) \leftarrow D + \Lambda(q)$ ; $S(A)$ : $T$ [ $<$ ]
5		OUT [ $q_1, \Lambda(q_1)$ ] $\leftarrow q, \Lambda(q)$

performs the five operations listed in cycle 3. Although an arithmetic progression involves the BP for 4 cycles, it can travel down the pipe spending 2 cycles in each BP.

If the first compare with BPID is [ $\neq$ ], this means the arithmetic progression does not hit in this BP and it can be sent on through to the next BP. If there is a hit (as shown in the pseudocode above) and the second compare with BPID is [ $=$ ], then this means that the arithmetic progression hits a second time in this BP in which case it is, of course, not sent out right away.

**Collision avoidance.** To avoid collisions a BP will register “BUSY” during the time a prime power occupies the BP. We classify prime powers  $q$  in three categories. A value  $q$  is “small” if  $q < |\text{BP}|$ , so that  $q$  has the potential to hit more than one location in a BP. It is “moderate” if  $|\text{BP}| \leq q \leq I$ , so that  $q$  hits at most once in any BP, but will definitely hit at least one BP in the subinterval. Finally,  $q$  is “big” if  $I < q \leq B$ . Big prime powers hit at most one BP in a subinterval. The progressions are sent through a subinterval in the following order: (i) big prime powers that actually hit some BP in the subinterval; (ii) moderate prime powers ordered by decreasing size; (iii) small prime powers ordered by decreasing size. This organization of the progressions keeps delays in the sieve caused by “BUSY” signals to a minimum. In fact there are no delays at all with big and moderate prime powers.

**7. The pipe i/o unit.** The pipe i/o unit is an interface, storage, and control mechanism for the sieving process. The pipe i/o unit interfaces to the sieve initializer to receive progression records for each polynomial, and to send reports of the sieve’s successes. It stores the progression records, since the length  $I$  of the subinterval that is sieved at one time is considerably less than the length  $2M$  of the polynomial interval. The pipe i/o sends the progression records in a proper order to the pipe, then receives the modified records from the pipe and stores them for the next subinterval. The pipe i/o contains the control and sequencing logic that controls the pipe and its modes of operation.

**Interfaces.** The pipe i/o unit has a data path to the sieve initializer (SI). When a polynomial change is to occur (determined by the SI), the operation of the pipe is halted. The storage on the pipe i/o unit is then loaded with the progression records for the next polynomial interval. When this operation is completed, the pipe i/o begins the sieving sequence for the new polynomial by sending out the progressions in order. The time required to load the pipe i/o store is a function of the amount of data to be transferred, the width of the data path between the sieve initializer and the pipe i/o, and the bandwidth of the respective memories. (We assume that the loading will be a direct memory-to-memory transfer.)

The other operational use of the data path from SI to pipe i/o is for the reporting of results. When the sieve has a result to report, it will send polynomial coefficients, a polynomial argument, and a list of powers of primes from the factor base that divide the polynomial at the argument. The sieve initializer will receive these reports and retain them for the post-processing step.

**Store.** The storage of the pipe i/o must be large enough to accommodate usually two progression records for each power  $q \leq B$  of a prime in the factor base. At the same time, it must be fast enough to feed the pipe at “full guzzle” while sieving by moderate and big prime powers. This storage unit is one of the major challenges of the qs processor.

Each progression record consists of  $A$ ,  $q$ ,  $\Lambda(q)$  for the sieving, and a link field which is used by the pipe i/o to send out only those progressions which will hit in at least one BP in the subinterval. The length of a progression record is

$$\max |A| + \max |q| + \max |\Lambda(q)| + \max |L| = 32 + 24 + 8 + 20 = 84 \text{ bits,}$$

nominally. Since the  $q$ ,  $\Lambda(q)$  are identical for usually two progressions, these fields may be shared between the two progressions, reducing the nominal size to 68 bits. There must be a progression record for every solution of (7) for each power  $q \leq B$  of a prime in the factor base. If we choose  $B = 2,750,000$ , say, there will be about 200,000 progressions requiring  $200,000 \times 68 \text{ bits} = 1.7 \text{ MB}$  store.

**Speed.** The pipe i/o store must be able to keep up with the pipe. For this reason, we wish to be able to feed out a progression record in time  $2C$ , since that is the rate at which the pipe can accept progressions with modulus a moderate or big prime power. We intend to fetch the progression record in parallel (all 84 bits) from the pipe i/o store, store it in a buffer register, then send out the  $A$  in one cycle,  $q$ ,  $\Lambda(q)$  in the next (recall that the  $L$  field is for the use of the pipe i/o only).

This makes it appear that the cycle time of the pipe i/o store can be double that of the pipe's store. However, this is not the case. Once the transaction record has made it through the pipe, it will be received by the pipe i/o and must be stored for use in the next subinterval. This means that it must be stored in the pipe i/o store. Since receive transactions are occurring while send transactions are still going on, we must be able to WRITE the pipe i/o store once and READ it once in the time  $2C$ . This means that the cycle time of the pipe i/o store must be the same as that of the pipe.

**Partitioning.** The pipe i/o requires a large, fast store. More than this, since the pipe i/o store is about twice the size of the factor base, we must partition the store horizontally if at all possible so that the factor base size is not a hard, "designed in" limit on the system.

**Operation.** Once the pipe i/o store is filled with progression records, operation of the sieve begins. The pipe i/o controls the sieving operation, which consists of a cycle in which the events:

initialize the pipe  
sieve by progressions which hit in subinterval  $i$   
report any successes in subinterval  $i$   
 $i \leftarrow i + 1$

are repeated until the sieve initializer has the next polynomial ready.

**Sending progressions.** Since a big prime power may not hit in subinterval  $i$ , we keep a linked list of those we know will hit in the subinterval. Thus we only dispatch those big prime powers that will hit in the subinterval. The pipe i/o manages the linked lists on a per-subinterval basis, so that each subinterval has a list of the prime powers that will hit in that subinterval. This list might have the big prime powers out of numerical order, but since they hit only once in  $i$  anyway, it will not result in a pipe collision. As mentioned before, progressions corresponding to moderate and small prime powers are sent out in reverse numerical order of modulus. Thus the linked list mechanism is not necessary for these progressions.

**Receiving progressions.** When a progression record  $A$ ,  $q$ ,  $\Lambda(q)$  is sent into the pipe, it is processed there to generate the next progression record by modification of the  $A$  value. The pipe will add  $q$  to the  $A$  value until the new  $A$  no longer falls in the

subinterval. Then the progression record will exit from the pipe. At the exit from the pipe is the pipe i/o receiver which will store the record for use in the progression's next subinterval.

Recall that  $|BP|$  and  $I$  are both powers of 2. This means that one field of  $A$  can be regarded as the subinterval number  $i$ . This field of  $A$  is important in the processing of the received record upon exit from the pipe; the value of  $i$  will indicate the next subinterval in which the progression will fall. For moderate and small prime powers this is always the next subinterval. For big prime powers, up to  $n - 1$  subintervals can be skipped over where  $n = \lceil B/I \rceil$ . There are  $n$  linked lists maintained in the pipe i/o, and the progression will be added to the appropriate list upon exit from the pipe.

Each progression has a home location in pipe i/o store where it resides. When the progression is sent into the pipe, its home address is entered into a FIFO store. Since the pipe preserves the time order of progressions, the home address can be retrieved from this store when the progression is received. The new  $A$  will then be stored at the home address location. Additionally, the progression is added to the proper interval list by the simple procedure of placing the list pointer in the link field of the progression, then placing the progression address in the list pointer.

Receiving this progression information must compete for pipe i/o store with the sending process. Only  $A$  and  $L$  must be stored, and this will require one cycle of store. Since the  $A$  and  $L$  are buffered and since the sending process uses only one cycle from every two, storing the progression uses the other cycle.

**8. Performance on 100 digit numbers.** In this section we give some indication how performance on 100 digit numbers can be estimated. In the sequel, we assume  $N \approx 10^{100}$ , where  $N$  is the number to be factored.

**Factor base.** We shall assume the multiplier is one (see § 4). We shall consider a factor base of 100,000 primes so that  $B$ , the bound for the largest prime in the factor base, is about 2,750,000. We estimate that sieve initialization for this choice of  $B$  will take five seconds. The pipe i/o unit will require about 1.7MB of store.

**Time to sieve a subinterval.** We shall assume that each BP has size  $2^{16}$  and that the pipe consists of  $2^4$  BP's. This gives the value  $2^{20}$  to  $I$ , the subinterval length. We assume the cycle time in the pipe i/o and pipe is 70 nanoseconds. The time to sieve a subinterval has several components (measured in milliseconds):

- (i) Initialize the pipe—4.59;
- (ii) Small prime powers—11.30;
- (iii) Moderate prime powers—10.51;
- (iv) Big prime powers—9.87;
- (v) Empty the pipe with least progression—1.47.

We shall account for reporting time later. Thus the total time to sieve a subinterval of length  $I = 2^{20}$  is 37.74 milliseconds.

With one polynomial, we sieve for 5 seconds, the sieve initialization time. Thus in this time we shall sieve about  $1.38 \times 10^8$  values, so that  $2M \approx 1.38 \times 10^8$ .

**Success rate.** The largest values of a polynomial will have size  $M\sqrt{N/2}$ . However, the smaller values will give a disproportionately high success rate. Thus we shall assume the "typical" value is

$$\frac{1}{3}M\sqrt{N/2} \approx 1.63 \times 10^{57}.$$

The probability that a random number of this size completely factors with the primes up to  $2 \times 10^6$  can be estimated from the table for " $\rho_1(\alpha)$ " given in Knuth and Trabb

Pardo [4]. We take

$$\alpha = \frac{\log(1.63 \times 10^{57})}{\log(2750000)} = 8.8848.$$

We geometrically interpolate in the table to get

$$\rho_1(\alpha) \approx 1.513 \times 10^{-9}.$$

This means that we have to sieve about  $1/\rho_1(\alpha) \approx 6.61 \times 10^8$  numbers to find one success. That is, we have one success every 23.9 seconds on average.

**Large prime variation.** Multiplying 23.9 seconds by 100,000, the nominal number of successes we shall need, we obtain a sieving time of 27.7 days. However, by also reporting polynomial values which factor completely over the factor base except for one large prime in the interval  $(B, 100B)$ , we estimate a speed-up factor of 0.415. This estimate is obtained by splitting  $(B, 100B)$  into smaller intervals, using the Knuth-Trabb Pardo table to estimate success rates for large primes in the smaller intervals, and then using a "birthday paradox" analysis to estimate the usefulness of these large prime factorizations. Thus the 27.7 day sieving time is reduced to 11.5 days.

**Enforced sieve down time.** The sieve must be down when the pipe i/o is being loaded from the sieve initializer and when it is in the reporting mode. We assume that loading time per polynomial is 0.2 seconds. This must be done for every five-second polynomial run, or for a total of 0.5 days during the factorization.

With the large prime variation, there will be about 700,000 reports during the run. We shall assume, however, there are  $10^6$  reports since some of these will be "false." We also assume that a report takes 75 milliseconds (about twice the time to sieve a subinterval) for recall that reporting involves re-sieving a subinterval in a new mode. Thus total reporting time is about 0.9 days.

**Total running time.** We shall assume that preprocessing and post-processing together take at most 0.5 days of computing time. Thus our total running time can now be estimated from the following:

- (i) Sieving time—11.5 days;
- (ii) Loading time—0.5 days;
- (iii) Reporting time—0.9 days;
- (iv) Pre- and post-processing—0.5 days;

or 13.4 days.

**Estimated cost of processor.** Pre- and post-processing are performed on conventional hardware. The most critical step is the matrix processing discussed in § 5. It is assumed that this will not be an important bottleneck. We do not include the cost of buying computer time for these stages since we are considering here only a relatively insignificant portion of the factoring project. In extrapolations to very large numbers, it might be fair to set aside 5–10 percent of monetary resources for pre- and post-processing.

Sieve initialization will be performed on a dedicated SUN 3. It would be possible to build a dedicated processor with equal performance for sieve initialization tasks for \$5,000. Even though a SUN 3 costs about ten times as much, we nevertheless use the figure \$5,000 for the cost of a sieve initializer.

We estimate the cost of parts for a pipe i/o unit with 1.7MB of store at \$10,000. Finally we estimate the cost of a pipe consisting of 16 BP's, each of size  $64k \times 8 = 64kb$ , together with a power supply, at \$10,000.

Thus we estimate a total cost of \$25,000 for parts. To figure in development costs, overhead, and a margin for error, we use a multiplier of 2, thus bringing our estimate to \$50,000.

**9. Summary.** We have described the quadratic sieve factorization algorithm and an inexpensive processor on which it can be efficiently run. If it runs as quickly and is as inexpensive as we think, then 144-digit numbers can be factored in a year with a budget of \$10,000,000.

**Acknowledgment.** The authors acknowledge the constructive criticisms and helpful suggestions of Peter Montgomery, Andrew Odlyzko, Richard Schroepel, Sam Wagstaff and the referees.

## EFFICIENT PARALLEL PSEUDORANDOM NUMBER GENERATION\*

J. H. REIF† AND J. D. TYGAR‡

**Abstract.** We present a parallel algorithm for pseudorandom number generation. Given a seed of  $n^\epsilon$  truly random bits for any  $\epsilon > 0$ , our algorithm generates  $n^c$  pseudorandom bits for any  $c > 1$ . This takes poly-log time using  $n^{\epsilon'}$  processors where  $\epsilon' = k\epsilon$  for some fixed small constant  $k > 1$ . We show that the pseudorandom bits output by our algorithm cannot be distinguished from truly random bits in parallel poly-log time using a polynomial number of processors with probability  $\frac{1}{2} + 1/n^{O(1)}$  if the Multiplicative Inverse Problem almost always cannot be solved in RNC. The proof is interesting and is quite different from previous proofs for sequential pseudorandom number generators.

Our generator is fast and its output is provably as effective for RNC algorithms as truly random bits. Our generator passes all the statistical tests in Knuth [14].

Moreover, the existence of our generator has a number of central consequences for complexity theory. Given a randomized parallel algorithm  $\mathcal{A}$  (over a wide class of machine models such as parallel RAMs and fixed connection networks) with time bound  $T(n)$  and processor bound  $P(n)$ , we show that  $\mathcal{A}$  can be simulated by a parallel algorithm with time bound  $T(n) + O((\log n)(\log \log n))$ , processor bound  $P(n)n^\epsilon$ , and only using  $n^\epsilon$  truly random bits for any  $\epsilon > 0$ .

Also, we show that if the Multiplicative Inverse Problem is almost always not in RNC, the RNC is within the class of languages accepted by uniform poly-log depth circuits with unbounded fan-in and strictly subexponential size  $\bigcap_{\epsilon > 0} 2^{n^\epsilon}$ .

**1. Introduction.** A number of parallel randomized algorithms have appeared recently. These algorithms typically use a large number of random bits which must be generated in a small amount of time. Nonetheless, the area of parallel random bit generation remains unexplored.

In reality, our computers are deterministic and unable to generate truly random values. But we can give algorithms which will give pseudorandom bits on input of a random seed  $s_0$ . These pseudorandom bits satisfy conditions which suggest that for algorithmic purposes they are as effective as truly random bits.

What conditions should a pseudorandom bit sequence satisfy?

Improving on an idea by Shamir [16], Blum and Micali [6] argue that the notion of “cryptographic strength” captures the important facets of random sequences. To demonstrate cryptographic strength they follow this schema:

- (1) Upper bound the computational resources by *Resources A*.
- (2) Assume that *Problem B* cannot be solved within the limits of *Resources A*.
- (3) Produce a *Pseudorandom Bit Generator G*.
- (4) Argue that if an opponent sees the first  $m_0$  bits generated by *Pseudorandom Bit Generator G* and can utilize *Resources A* to predict the remaining bits with an

accuracy rate of  $\frac{1}{2} + \varepsilon(m)$  (where  $m$  is the size of the seed and  $\varepsilon$  is a fixed function satisfying  $\lim_{m \rightarrow \infty} \varepsilon(m) = 0$ ), then the opponent will be able to solve *Problem B* limited to *Resources A* by consulting the bit-guessing oracle, a contradiction.

Several cryptographically-strong pseudorandom bit generators have been proposed (Blum, Blum and Shub [5], Blum and Micali [6],) and many applications have been discussed (Alexi, Chor, Goldreich and Schnorr [3], Goldreich, Goldwasser and Micali [9], Goldwasser, Micali and Tong [10], Vazirani and Vazirani [19], Yao [21].) These generators are all inherently sequential, require polynomial time, and their cryptographic strength relies on some unproven cryptographic assumption.

*Notation.* When we say a class of circuit is *uniform*, we mean that it is constructible in logarithmic space by a deterministic Turing Machine.

**NC** (**NC<sub>U</sub>**) is the class of languages accepted by (uniform, respectively) deterministic circuits constructible in log-space with poly-log depth and polynomial size.

**RNC** (**RNC<sub>U</sub>**) is the class of languages accepted by (uniform, respectively) randomized circuits constructible in log-space with two-sided error, poly-log depth, polynomial size, and acceptance probability greater than  $\frac{1}{2}$ .

We give more precise definitions of these terms in § 4.

*Our result.* We present a new cryptographically-strong pseudorandom bit generator which runs in **NC<sub>U</sub>** but which is secure against attacks taking parallel poly-log time if the Multiplicative Inverse Problem almost always is not in **RNC**. While we use the schema described above for demonstrating the cryptographic strength of our random number generator, because of the inherent parallel nature of our generator, the technical details of our proof are quite different from those of previous proofs for sequential pseudorandom number generators. In particular, we prove that if the bits output by our pseudorandom bit generator can be predicted in **RNC**, then we can solve the multiplicative inverse problem in **RNC** almost always and this requires that we construct an interesting, nontrivial, parallel algorithm for that problem. (See § 3.)

*About the assumption.* While our assumption has not been proved, it is quite interesting to observe that it is *testable* in the following sense: If an **RNC** algorithm takes more than poly-log time using our pseudorandom bits instead of truly random bits then we can observe this event by timing. Thus one of two scenarios is possible: either every application of our generator to an **RNC** algorithm yields a poly-log algorithm using only a small number of random bits, or some application of our generator is discovered to exceed its poly-log time bounds and we can immediately derive a **NC** algorithm for multiplicative inverse.

*About the measure of randomness.* Valiant, Skyum, Berkowitz and Rackoff [18] show that an **NC**-machine can evaluate any straight-line program which computes a multivariate polynomial which has degree polynomial in the length of the program. Thus if our assumption is correct, our pseudorandom bit generator is secure against any statistical test which can be so formulated as a straight-line program. This includes most standard statistical tests for random number generators (Knuth [14]).

*Applications.* Our method for parallel pseudorandom bit generation is actually very practical. It requires, for any  $\varepsilon > 0$ , only  $O(\log n(\log \log(n)))$  added depth and a factor of  $n^\varepsilon$  for a bounded fan-in circuit. Here is an example: Karp and Wigderson [12] give a deterministic algorithm for the maximal independent set problem in  $O((\log n)^4)$  time using  $O(n^3/(\log n)^3)$  processors. They also give a uniform randomized algorithm for the same problem running in  $O((\log n)^3)$  expected time with  $O(n^2)$  processors using  $O(n^2)$  random bits. Our results immediately yield a uniform algorithm with  $O((\log n)^3)$  running time and  $O(n^{2+\varepsilon'})$  processors using only  $n^\varepsilon$  random bits, where  $\varepsilon, \varepsilon' > 0$  can be set arbitrarily small.

Recently, Karp, Upfal and Wigderson [13] have shown that finding a maximum graph matching is in  $\mathbf{RNC}_U$ , and Anderson and Mayr [2] have shown that finding a maximal path is in  $\mathbf{RNC}_U$ . Our results also immediately yield efficient randomized uniform algorithms for these problems, using only  $n^\epsilon$  bits for any  $\epsilon > 0$ .

*Implications.* An interesting theoretical application of our result is that  $\mathbf{RNC}_U$  is contained within the class of languages recognized by uniform deterministic circuits of unbounded fan-in with poly-log depth and  $2^{n^\epsilon}$  size for any  $\epsilon > 0$ . (Adleman [1] proved  $\mathbf{RNC}_U$  is contained in (nonuniform)  $\mathbf{NC}$ , but the previous best construction for bounding  $\mathbf{RNC}_U$  by deterministic uniform circuits of poly-log depth required  $2^{\Omega(n)}$  size.) This extends a result of Yao [21] for sequential polynomial time computations to poly-log time parallel computations.

**2. Definitions and results.**

*Notation.* We use the following notation throughout the paper:

$N$  A positive composite integer such that each prime factor of  $N$  is greater than  $N^c$  for a fixed  $c > 0$ .

$\mathbf{Z}_N^*$  The multiplicative group of positive integers less than and relatively prime to  $N$ . (Note that the fact that  $N$  has only large factors implies that a random positive integer less than  $N$  is an element of  $\mathbf{Z}_N^*$  with high probability.)

We will sometimes use  $x \bmod N$  to indicate the residue of  $x$  modulo  $N$ .

*Definitions.* An  $\mathbf{NC}$ -machine (Cook [8]) is a deterministic parallel algorithm which runs on  $n^{O(1)}$  parallel-RAM (P-RAM) processors in time  $(\log n)^{O(1)}$  for input of size  $n$ . (Note that  $\mathbf{NC}_U$  is the class of languages accepted by  $\mathbf{NC}$ -machines.)

An  $\mathbf{RNC}$ -machine is a randomized parallel algorithm which runs on  $n^{O(1)}$  P-RAM processors in time  $(\log n)^{O(1)}$  for input of size  $n$ . (Note that  $\mathbf{RNC}_U$  is the class of languages accepted by  $\mathbf{RNC}$ -machines.)

Given  $s_0 \in \mathbf{Z}_N^*$ , the *multiplicative inverse* of  $s_0$  modulo  $N$  is the  $s_0^{-1}$  such that  $s_0 s_0^{-1} = 1 \bmod N$ .

For a fixed  $N$ , given an arbitrary  $k \in \mathbf{Z}_N^*$ , the Multiplicative Inverse Problem is to find the multiplicative inverse of  $k$  modulo  $N$ . Note that the input size to the problem is  $n = \lceil \log N \rceil$ .

The problem of finding multiplicative inverses in poly-log depth has been studied extensively. (Cook [8], Kannan, Miller and Randolph [11], Reif [15] and von zur Gathen [20].) Based on the lack of significant positive results obtained so far we conjecture the following.

*Complexity assumption.* There exists an infinite sequence of numbers  $N_1, N_2, \dots$  constructible in  $\mathbf{NC}_U$  such that for each  $n = 1, 2, \dots$  we have  $n = \lceil \log N_n \rceil$  and that no  $\mathbf{RNC}$ -machine can solve the Multiplicative Inverse Problem for arbitrary elements of  $\mathbf{Z}_{N_n}^*$  for almost all values of  $n$ .

(Actually we could replace this complexity assumption with the weaker assumption that there exists a  $k$  such that for almost all  $n$  there exists an  $n'$  such that  $n < n' < n^k$  and no  $\mathbf{RNC}$ -machine can solve the Multiplicative Inverse Problem for arbitrary elements of  $\mathbf{Z}_{N_{n'}}^*$ . All the theorems in this paper would remain true under that weaker assumption.)

*Definitions.* A set  $S$  of bit sequences  $\sigma = (b_1, \dots, b_J)$  of length  $J = n^{O(1)}$  pseudorandom bits is  $\mathbf{RNC}$ -cryptographically strong if no  $\mathbf{RNC}$ -machine can, on a random input  $b_1, \dots, b_i \in S$  ( $i < J$ ) predict any one bit  $b_i, \dots, b_J$  with expected success of  $\frac{1}{2} + 1/n^{O(1)}$ . Informally, the bit sequences are  $\mathbf{RNC}$ -cryptographically strong if no  $\mathbf{RNC}$ -machine can predict untransmitted bits with an expected success rate significantly better than  $\frac{1}{2}$ .

**THEOREM.** *If no RNC-machine can solve the Multiplicative Inverse Problem for almost all  $n$ , then there exists a deterministic NC-machine  $\mathcal{G}$  which on an input seed of  $n$  bits outputs an RNC-cryptographically strong sequence of  $J = n^{O(1)}$  pseudorandom bits.  $\mathcal{G}$  can be computed by a bounded fan-in uniform Boolean circuit of depth  $O((\log n)(\log \log n))$  and size  $n^{O(1)}$ .*

This theorem is proved in § 3.

**Definition.** An RNC-statistical test is an RNC-machine which attempts to distinguish truly random bit sequences from pseudorandom bit sequences. A statistical test succeeds if it correctly distinguishes the pseudorandom bit sequences from truly random bit sequences with probability at least  $1/n^{O(1)}$ .

By a technique due to Yao [21] we can show that no RNC statistical test can succeed on RNC-cryptographically strong bit sequences. Hence we have the following.

**COROLLARY 1.** *If no RNC-machine can solve the Multiplicative Inverse Problem for almost all  $n$ , then no RNC-statistical test can succeed on our pseudorandom bit generator  $\mathcal{G}$ .*

**COROLLARY 2.** *If the  $N_n$  are constructible in depth  $h(n)$ , then given a randomized parallel algorithm  $\mathcal{A}$  (over a wide class of machine models such as parallel RAMS and fixed connection networks) with time bound  $T(n)$  and processor bound  $P(n)$  then  $\mathcal{A}$  can be simulated by a parallel algorithm with time bound  $T(n) + h(n) + O((\log n)(\log \log n))$ , processor bound  $P(n)n^{\varepsilon'}$ , and only using  $n^\varepsilon$  truly random bits for any  $\varepsilon > 0$ , where  $\varepsilon' = O(\varepsilon)$ .*

$\text{CIRCUIT}_U(D(n), S(n))$  is the class of languages accepted by uniform deterministic circuits with unbounded fan-in, depth  $D(n)$ , and size  $S(n)$ . (See § 4 for a precise definition of these complexity classes.)

**COROLLARY 3.** *If for almost all  $n$  the Multiplicative Inverse Problem is not in RNC then*

$$\text{RNC}_U \subseteq \bigcup_{c>0} \bigcap_{\varepsilon>0} \text{CIRCUIT}_U((\log n)^c, 2^{n^\varepsilon})$$

This corollary is proved in § 4.

**COROLLARY 4.** *There exists a cryptosystem where encryption and decryption can be done by an NC-machine on  $n^{O(1)}$  bits given a secret shared key exactly  $n$  bits long (here  $n$  is a security parameter). If no RNC-machine can solve the Multiplicative Inverse Problem, then no RNC-machine can decrypt ciphertext exchanged in this cryptosystem.*

We use the pseudorandom bits as a “one-time pad”—we take the sequential exclusive-or of the plaintext and the pseudorandom bits to produce the ciphertext and take the sequential exclusive-or of the ciphertext and the pseudorandom bits to obtain the plaintext again. Encryption and decryption both take parallel poly-log time but an opponent cannot decrypt the ciphertext with RNC-machine.

### 3. The proof of the main theorem.

**Properties.** We recall the following facts which we use implicitly (Beame, Cook and Hoover [4], Reif [15], and Shonhage and Strassen [17]):

- There exists an NC-machine for multiplication of two numbers in  $\mathbf{Z}_N^*$ .
- $2 \log p$  multiplications suffice to find the  $p$ th power of a number in  $\mathbf{Z}_N^*$ .
- If  $p < (\log N)^{O(1)}$  there exists an NC-machine for finding the  $p$ th power of a number in  $\mathbf{Z}_N^*$ .

Fix  $m = \lceil \log N \rceil$  throughout this section.

Let  $\mathcal{G}$  be the NC-machine which performs the following operations:

Input: random elements  $s_0, k \in \mathbf{Z}_N^*$ .

Output:  $b_1, \dots, b_J$  where  $J = m^{O(1)}$ .

Method: In parallel each processor  $P_i$  ( $i = 1, \dots, J$ ) calculates  $s_i = ks_0^i \bmod N$  and  $b_{J-i+1} = B(s_i)$  where

$$B(x) = \begin{cases} 0 & \text{if } x \leq N/2, \\ 1 & \text{if } x > N/2. \end{cases}$$

LEMMA. *If there exists an RNC-machine which can determine the value of  $b_j$  with probability 1 (i.e., no error) on input  $b_1, \dots, b_{j-1}$ , then there exists an RNC-machine which can solve the Multiplicative Inverse Problem for  $\mathbf{Z}_{N_n}^*$ .*

*Proof of the lemma.* Suppose that MB (for “magic box”) is an oracle which can determine the value of  $b_j$  with probability 1. Then given  $s_0 \in \mathbf{Z}_N^*$  we can find  $s_0^{-1} \bmod N$ . We can find this by running in parallel the following algorithm on each processor  $P_i$  for ( $0 \leq i \leq m$ ):

Set  $k \leftarrow 2^i$ . In parallel set  $b_i \leftarrow B(ks_0^{J-i-1})$  for  $1 \leq i \leq J-1$ . Note that  $b_J = B(2^i s_0^{-1})$ . Feed the sequence  $(b_1, \dots, b_{J-1})$  to MB to get  $b_J$ . Set the  $i$ th most significant bit of  $\delta$  to be  $B(2^i s_0^{-1})$ . Define

$$\phi(\delta) = \left\lceil \frac{\delta N}{2^m} \right\rceil.$$

Then  $\phi(\delta) = s_0^{-1} \bmod N$ .  $\square$

THEOREM. *If there exists an RNC-machine which can determine the value of  $b_j$  with probability at least  $\frac{1}{2} + 1/m^{O(1)}$  on input  $b_1, \dots, b_j$ , then there exists an RNC-machine  $\mathcal{H}$  which can solve the Multiplicative Inverse Problem for  $\mathbf{Z}_{N_n}^*$ .  $\mathcal{H}$  can be computed by a bounded fan-in Boolean circuit of depth  $O((\log n)(\log \log n))$  and size  $n^{O(1)}$ .*

*Proof of the theorem.* Assume that there exists an RNC-machine MB which can predict  $b_j$  with probability  $\frac{1}{2} + 2/m^c$ . Let  $H = 2(c+1) \lceil \log m \rceil$ . Let  $\delta$  and  $\phi$  be as in the proof of the lemma.

Let  $S = \{0, 1, \dots, 2^{H-1} - 1\}$ . For each  $0 \leq y < x \leq m$ , we will create, by randomized methods, two functions  $F_{x,y} : S \rightarrow \{0, 1\}^{x-y}$  and  $G_{x,y} : S \rightarrow S$ . Informally, values in  $S$  are guesses;  $F_{x,y}$  is a rule for transforming a guess  $j_x \in S$  into the  $x$ th to  $y$ th most significant bits of  $\delta$ ; and  $G_{x,y}$  is a rule for transforming the guess  $j_x \in S$  into the guess  $j_{x-1} \in S$ .

If an RNC-machine could find  $\delta$  for arbitrary  $s_0$ , we could solve the Multiplicative Inverse Problem. It will turn out that for some  $j_m \in S$ ,  $F_{m,0}(j_m) = \delta$  with probability  $\frac{1}{2}$ . We can verify this occurrence simply by checking whether  $s_0 \phi(\delta) = 1 \bmod N$ . If we do not immediately find  $s_0^{-1} \bmod N$ , we simply form a new  $F_{m,0}$  by randomized methods and continue testing until we do find  $s_0^{-1} \bmod N$ .

Suppose we can determine  $j_x$  such that we know  $(2^x s_0^{-1} \bmod N)$  belongs to one of the two intervals

$$\left\{ \left[ \left\lceil \frac{j_x N}{2^H} \right\rceil, \left\lfloor \frac{(j_x + 1)N}{2^H} \right\rfloor \right], \left[ \left\lceil \frac{(2^{H-1} + j_x)N}{2^H} \right\rceil, \left\lfloor \frac{(2^{H-1} + j_x + 1)N}{2^H} \right\rfloor \right] \right\}.$$

We can pick  $2^H$  random values  $\beta \in \mathbf{Z}_N^*$  and let  $v$  be MB’s prediction for

$$B \left( 2^x s_0^{-1} + \left\lfloor \frac{Nj_x}{2^H} \right\rfloor + \beta \bmod N \right).$$

When  $\beta$  lies in the interval

$$\left[ 0, \left\lfloor \frac{(2^{H-1} - 1)N}{2^H} \right\rfloor \right],$$

mark a vote for  $v$ , when  $\beta$  lies in the interval

$$\left[ \left\lceil \frac{N}{2} \right\rceil, \left\lfloor \frac{(2^H - 1)N}{2^H} \right\rfloor \right],$$

mark a vote the complement of  $v$ , and mark a *null* vote when  $\beta$  lies in other intervals. By assumption, MB predicts correctly with probability at least  $\frac{1}{2} + 2/m^c$ .

We can assign a processor to calculate MB's prediction for each of the  $2^H$  randomly chosen values of  $\beta \in \mathbf{Z}_N^*$ . This computation can be done in poly-log time for each  $\beta$ . The expected fraction of *null* votes is  $2^{1-H} < 1/m^c$ . Thus we have a bias of at least  $2/m^c - 1/m^c = 1/m^c$  between 0 and 1 votes. Set  $F_{x,x-1}(j_x)$  (our guess for  $B(2^x s_0^{-1} \bmod N)$ ) to be a value which got the most votes. If our guess for  $B(2^x s_0^{-1} \bmod N)$  is right, this immediately identifies which of the two intervals  $(2^x s_0^{-1} \bmod N)$  belongs to. By the argument in the Appendix,  $2^H$  tests are sufficient to make our guess correct with probability at least  $1 - 1/2^m$ . If our guess is right, that immediately determines the value of  $j_{x-1}$ ; that is, we can determine that  $(2^{x-1} s_0^{-1} \bmod N)$  lies in one of the two intervals

$$\left\{ \left[ \left[ \frac{j_{x-1}N}{2^H} \right], \left[ \frac{(j_{x-1}+1)N}{2^H} \right] \right], \left[ \left[ \frac{(2^{H-1}+j_{x-1})N}{2^H} \right], \left[ \frac{(2^{H-1}+j_{x-1}+1)N}{2^H} \right] \right] \right\},$$

namely

$$j_{x-1} = G_{x,x-1}(j_x) = \lfloor j_x/2 \rfloor + 2^{H-2}(F_{x,x-1}(j_x)).$$

We can calculate in parallel, for each  $m \cong x \cong 1$ , the functions  $F_{x,x-1}$  and  $G_{x,x-1}$ , since the domain is finite and of polynomial size. If  $x - y > 1$ , then  $F_{x,y}$  and  $G_{x,y}$  can be recursively defined as

$$F_{x,y}(j_x) = F_{z,y}(G_{x,z}(j_x))2^{x-z} + F_{x,z}(j_x)$$

and

$$G_{x,y}(j_x) = G_{z,y}(G_{x,z}(j_x))$$

where  $z = \lceil (x+y)/2 \rceil$ . For each  $x, y$  pair ( $0 \leq y < x \leq m$ ) and each  $j_x \in S$  we repeatedly calculate the appropriate compositions of these functions for all  $j_x$  in the domain of the functions. Thus we can compute  $F_{m,0}$  in  $\lceil \log m \rceil$  stages.

Some guess  $j_m$  is correct. Suppose that for all  $1 \leq i \leq m$ , that (1)  $G_{i,i-1}(j_i)$  is the correct value of  $j_{i-1}$ . Then (2)  $F_{m,0}(j_m)$  would be the correct value of  $\delta$ . For each  $i$ , the probability that (1) is true for a particular  $j_i$  is  $(1 - 2^{-m})$ , so the probability that (2) is true is  $(1 - 2^{-m})^{m-1} > 1 - (m-1)2^{-m} > \frac{1}{2}$ .

For some  $j_m \in S$ , it will be true that  $F_{m,0}(j_m) = \delta$  with probability  $\frac{1}{2}$ . We can try all possible  $j_m$  in parallel, and find out if we have a correct value by checking whether  $\phi(F_{m,0}(j_m))s_0 = 1 \bmod N$ . (Of course, it might happen that an incorrect guess for  $j_m$  might give a correct value for  $\delta$  but this can only speed the calculation.) In the event that we do not get the correct value for  $s_0^{-1} \bmod N$ , we simply form new  $F_{x,y}$  and  $G_{x,y}$  functions and continue until we do get the correct value.  $\square$

**4. Randomized and deterministic parallel complexity.** Let  $\mathcal{C}$  be a list of circuits  $(C_1, C_2, \dots)$  of unbounded fan-in where  $C_n$  and  $n$  inputs and size  $S(n)$ . We consider  $\mathcal{C}$  to be *uniform* if there exists a  $(\log S(n))$  space deterministic Turing machine which, given any  $n$ , outputs the circuit  $C_n$ . Let  $\text{CIRCUIT}(D(n), S(n))$  be the class of all languages accepted by deterministic Boolean circuits with unbounded fan-in, depth  $D(n)$ , and size  $S(n)$ . As usual we define

$$\text{NC} = \bigcup_{k_1 > 0, k_2 > 0} \text{CIRCUIT}((\log n)^{k_1}, n^{k_2}).$$

We allow a *randomized Boolean circuit*  $\mathbf{C}$  to have  $r$  special nodes, each of which are assigned independent random bits chosen from  $\{0, 1\}$  with equal probability.  $\mathbf{C}$  *accepts* an input  $\omega \in \{0, 1\}^n$  if  $\mathbf{C}$  outputs 1 with probability  $> \frac{1}{2}$ ; otherwise  $\mathbf{C}$  *rejects* the input. For simplicity, we consider only one-sided error randomized circuits which

never output a 1 on an input they have rejected. (The construction below can easily be extended to two-sided error randomized circuits which have an acceptance probability of at least  $\frac{1}{2} + 1/n^k$  for some  $k > 1$ .) Let RCIRCUIT  $(D(n), S(n))$  be the class of languages accepted by randomized circuits with unbounded fan-in, depth  $D(n)$ , and size  $S(n)$ . We define

$$\mathbf{RNC} = \bigcup_{k_1 > 0, k_2 > 0} \text{RCIRCUIT}((\log n)^{k_1}, n^{k_2}).$$

We define CIRCUIT<sub>U</sub>, NC<sub>U</sub>, RCIRCUIT<sub>U</sub>, and RNC<sub>U</sub> analogously—restricting the circuits to be uniform.

*Proof of Corollary 3.* Let C be a (one-sided error) uniform randomized Boolean circuit with  $n$  inputs, depth  $D(n) = (\log n)^{k_1}$ , and size  $S(n) = n^{k_2}$ . Fix any  $\epsilon > 0$ .

First suppose we had a source of  $b = \lceil n^{\epsilon/2} \rceil$  truly random bits. Observe that C uses at most  $S(n) = n^{k_2}$  random bits on each execution. Since  $S(n) \leq b^{\epsilon'}$  where  $\epsilon' = \lceil \epsilon/k_2 \rceil$  is constant, we can apply our parallel pseudorandom bit generator  $\mathcal{G}$  to produce  $S(n)$  pseudorandom bits in  $(\log n)^{O(1)}$  parallel time using  $n^{O(1)}$  processors and using the  $b$  truly random bits as the seed. We can view the execution of C on the given input  $\omega$  as a statistical test. By Corollary 2, given an input  $\omega \in \{0, 1\}^n$ , we need only execute C on  $\omega$  for each of the  $2^b$  possible pseudorandom bit sequences. We accept  $\omega$  if C ever outputs 1.

Furthermore, we can avoid the use of a truly random seed by simply (1) enumerating all  $b$ -bit numbers in parallel; (2) executing the parallel pseudorandom bit generator using each of the  $b$ -bit numbers as a seed; and (3) executing C in parallel on  $\omega$  on each of the resulting pseudorandom bit sequences. If C ever outputs 1 we accept  $\omega$ . The resulting uniform circuit requires size  $2^{b^2} \leq 2^{n^\epsilon}$  and depth  $(\log n)^{O(1)} + O(D(n)) = (\log n)^{O(1)}$ .  $\square$

Note that if we require that our simulation circuit have bounded fan-in, then to simulate a circuit accepting a language in RNC<sub>U</sub>, we require  $n^{O(1)}$  (rather than  $(\log n)^{O(1)}$  depth) and  $2^{n^\epsilon}$  size. This is an improvement over previous size bounds for RNC<sub>U</sub>.

**Appendix.** Let  $X$  be the binomial variable which is the sum of  $\tau$  independent Bernoulli trials each of which has a probability  $p = \frac{1}{2} + 1/m^c$  of giving a value 1 and probability  $1 - p = \frac{1}{2} - 1/m^c$  of giving a value of 0. We need to find  $\tau$  large enough so that

$$\Pr [X < \tau/2] < 1/2^n.$$

Using Chernoff bounds (Chernoff [7]) we recall that

$$\Pr [X < (1 - \delta)\tau p] < e^{-\delta^2 \tau p/2}.$$

Substituting  $p = \frac{1}{2} - 1/m^c$  and  $(1 - \delta)p = \frac{1}{2}$  we get

$$\Pr [X < \tau/2] < e^{-(1/m^{2c})\tau(1/2 - 1/m^c)(1/2)} < e^{-\tau/8m^{2c}}.$$

If we set  $\tau = m^{2c+1}$ , our initial condition is satisfied. Since  $2^H = \tau$ , setting

$$H = 2(c + 1) \lceil \log m \rceil = O(\log m)$$

will give us conditions sufficient to prove the main theorem.

**Acknowledgments.** We would like to thank Michael Rabin for being an inspiration to us in the fields of randomized algorithms and cryptography.

We are indebted to Silvio Micali for his many helpful and insightful comments on this manuscript.

Also, thanks to Benny Chor, Shafi Goldwasser, Johan Hastad, Brian O'Toole, Charles Rackoff, Les Valiant and Vijay Vazirani for their comments.

## THE NOTION OF SECURITY FOR PROBABILISTIC CRYPTOSYSTEMS\*

SILVIO MICALI<sup>†</sup>, CHARLES RACKOFF<sup>‡</sup> AND BOB SLOAN<sup>§</sup>

**Abstract.** Three very different formal definitions of security for public-key cryptosystems have been proposed—two by Goldwasser and Micali and one by Yao. We prove all of them to be equivalent. This equivalence provides evidence that the right formalization of the notion of security has been reached.

**Key words.** cryptosystem, public-key cryptography, probabilistic encryption

**AMS(MOS) subject classifications.** 94A60, 68Q99

**1. Introduction.** The key desideratum for any cryptosystem is that encrypted messages must be secure. Before one can discuss whether a cryptosystem has this property, however, one must first rigorously define what is meant by security. Three different rigorous notions of security have been proposed. Goldwasser and Micali [6] suggested two different definitions, polynomial security and semantic security, and proved that the first notion implies the second. Yao [11] proposed a third definition, one inspired by information theory, and suggested that it implies semantic security.

Not completely knowing the relative strength of these definitions is rather unpleasant. For instance, several protocols have been proved correct adopting the notion of polynomial security. Are these protocols secure with respect to a particular definition or are they secure protocols in a more general sense? In other words, a natural question arises: Which of the definitions is the “correct” one? Even better: How should we decide the “correctness” of a definition?

The best possible answer to these questions would be to find that the proposed definitions—each attempting to be as general as possible—are all equivalent. In this case, one obviously no longer has to decide which definition is best. Moreover, the equivalence suggests that one has indeed found a strong, natural definition.

In this paper, we show that these notions are *essentially* equivalent. The three originally proposed definitions were not equivalent. However, as we point out, this inequivalence was caused only by some minor technical choices. After rectifying these marginal choices, we succeed in proving the desired equivalences, keeping the spirit of the definitions intact. We believe this to be an essential step in developing theory in the field of cryptography.

**2. Public-key scenarios.** Let us briefly review what is meant by the notion of public-key cryptography, first proposed by Diffie and Hellman [4] in 1976. As with all cryptography, the goal is that A(lice), by using an encryption algorithm  $E$ , becomes able to securely send a message  $m$  to B(ob). What is meant by “securely” is that it is impossible for any party T who has tapped A and B’s line to figure out information

about  $m$  from  $E(m)$ . The distinguishing feature of public-key cryptography is that we require this security property to hold even when T knows the encryption algorithm  $E$ .

We believe that until now, the notion of public-key cryptography has not been fully understood. In fact, it is crucial to consider exactly how the communication between A and B establishes the algorithm  $E$ . Therefore, we introduce the fundamental notion of a *pass*. We will first explain what passes are, and then explain their implications for security.

**2.1. Passes.** Within the public-key model, A and B can alternate communicating back and forth as many times as they feel are necessary to achieve security. Call each alternation a *pass*.

Any number of passes are, of course, permissible. We concentrate on what we believe are the two most interesting and important cases, one and three passes. We do not consider more than three passes, because, if trapdoor permutations exist, a well-designed probabilistic encryption scheme can achieve as much security as is possible using only three passes.

**Three-pass systems.** The three-pass case is, perhaps, the most natural to think about. It corresponds to a telephone conversation. A has a message  $m$  that she wants to securely communicate to B. A calls up B and says, "I have a message I'd like to send to you." B, so alerted, proceeds to generate an encryption/decryption algorithm pair,  $(E, D)$ , and tells A, "Please use  $E$  to encrypt your message." A then uses  $E$  to encrypt her message and tells B " $E(m)$ ."

Notice the key property of a three-pass system: The message and the encryption algorithm are selected independently of one another. We are nevertheless in a public-key model, since anyone tapping the phone line gets to hear B tell  $E$  to A.

**One-pass systems.** A one-pass system corresponds to what is commonly called a public file system. In the one-pass model, A simply looks up B's public encryption algorithm,  $E$ , in a "phone book" and uses it to encrypt her message. (One pass is a slight misnomer. At some point, in what we may view as a preprocessing stage, B must have communicated his encryption algorithm, presumably by telling it to whomever publishes the phone book of encryption algorithms, and thus indirectly to A. "One-and-a-half passes" might be more accurate. "Half" refers to the preprocessing stage that needs to be performed only once.) In this case, the choice of message *can* depend on  $E$ .

**2.2. Passes and security.** The main result of this paper is:

GM-security, semantic security, and Y-security (all formally defined in section 3) are equivalent both for one-pass and three-pass cryptosystems.

Interestingly, the equivalence still holds in the one-pass scenario, but the notions of security vary between the one-pass and three-pass scenarios. This point has not been given the proper attention, because people frequently confuse the notion of one-pass public-key cryptography with public-key cryptography in general.

The distinction, however, is crucial for avoiding errors, particularly in cryptographic protocols. Let us informally state the two definitions of security that are achievable in the two scenarios if trapdoor permutations exist.

A three-pass cryptosystem is secure if, for every message  $m$  in the message space, it is impossible to efficiently distinguish an encryption of  $m$  from random noise.

A one-pass cryptosystem is secure if, for every message  $m$  that is efficiently computable on input the encryption algorithm alone, it is impossible to efficiently distinguish an encryption of  $m$  from random noise.

In other words, in the one-pass scenario one cannot just blithely write, “For all messages  $m$ .” For instance, if one closely analyzes all known public-key cryptosystems, it is *conceivable* that if  $(E, D)$  is an encryption/decryption pair, then  $D$  can be easily computed from  $E(D)$ . For instance, the constructive reduction of security to quadratic residuosity given by Goldwasser and Micali [6] for their cryptosystem would *vanish* if the encrypted message is allowed to be  $D$  itself.<sup>1</sup>

Such problems cannot arise in the three-pass scenario because the encryption algorithm  $E$  is selected after and independently of the message  $m$ .

In this paper we concentrate on providing all the details of the proofs for the three-pass case, and sketch the results for the one-pass case in the final section. The reason for this choice is that the definitions of security are much more easily stated for three-pass systems. It is much more convenient to say, “For all messages  $m$ ,” than “For all messages  $m$  that are efficiently computable given the encryption algorithm as an input.”

**3. Notions of security for three-pass systems.** In this section we will formally specify our cryptographic scenario, and define the three notions of security. These definitions are the same in spirit as those originally chosen by Goldwasser and Micali and Yao; therefore, we will use either the names they chose or their initials. We will point out explicitly at the end of this section the minor changes we needed to make to reach the right level of generality.

**3.1. Notation and conventions for probabilistic algorithms.** We introduce some generally useful notation and conventions for discussing probabilistic algorithms. (We make the natural assumption that all parties may make use of probabilistic methods.)

We emphasize the number of inputs received by an algorithm as follows. If algorithm  $A$  receives only one input we write “ $A(\cdot)$ ”, if it receives two inputs we write “ $A(\cdot, \cdot)$ ” and so on.

“PS” will stand for “probability space”; in this paper we only consider countable probability spaces. In fact, we deal almost exclusively with probability spaces arising from probabilistic algorithms.

If  $A(\cdot)$  is a probabilistic algorithm, then for any input  $i$ , the notation  $A(i)$  refers to the PS which assigns to the string  $\sigma$  the probability that  $A$ , on input  $i$ , outputs  $\sigma$ . Notice the special case where  $A$  takes no inputs; in this case the notation  $A$  refers to the algorithm itself, whereas the notation  $A()$  refers to the PS defined by running  $A$  with no input. If  $S$  is a PS, denote by  $\Pr_S(e)$  the probability that  $S$  associates with element  $e$ . Also, we denote by  $[S]$  the set of elements which  $S$  gives positive probability. In the case that  $[S]$  is a singleton set  $\{e\}$  we will use  $S$  to denote the value  $e$ ; this is in agreement with traditional notation. (For instance, if  $A(\cdot)$  is an algorithm that, on input  $i$ , outputs  $i^3$ , then we may write  $A(2) = 8$  instead of  $[A(2)] = \{8\}$ .)

<sup>1</sup> Notice that if Bob publishes an encryption algorithm  $E$  in the public file while keeping its associated decryption algorithm  $D$  secret, then any other user, being limited to efficient computation and ignorant of  $D$ , necessarily selects her message  $m$  efficiently from the input  $E$ —maybe without even looking at  $E$ —and perhaps other inputs altogether independent of  $(E, D)$ . However, in designing cryptographic protocols, one would often like to be able to transmit things like  $E(D)$ . For instance, if that type of message were allowed, one would have a trivial solution to the problem of verifiable secret sharing [3].

If  $f(\cdot)$  and  $g(\cdot, \dots)$  are probabilistic algorithms then  $f(g(\cdot, \dots))$  is the probabilistic algorithm obtained by composing  $f$  and  $g$  (i.e., running  $f$  on  $g$ 's output). For any inputs  $x, y, \dots$  the associated probability space is denoted  $f(g(x, y, \dots))$ .

If  $S$  is any PS, then  $x \leftarrow S$  denotes the algorithm which assigns to  $x$  an element randomly selected according to  $S$ ; that is,  $x$  is assigned the value  $e$  with probability  $\Pr_S(e)$ . Note that for the sake of compactness, we may write  $x \leftarrow S$  even in cases where  $S$  has several outputs (say  $x, y$ , and  $z$ ), but  $x$  is the only output in which we are interested at the moment. If  $F$  is a finite set, then the notation  $x \leftarrow F$  denotes the algorithm which assigns to  $x$  an element randomly selected from the PS which has sample space  $F$  and the uniform probability distribution on the sample points. Thus, in particular,  $x \leftarrow \{0, 1\}$  means  $x$  is assigned the result of a coin toss.

The notation  $\Pr(x \leftarrow S; y \leftarrow T; \dots : p(x, y, \dots))$  denotes the probability that the predicate  $p(x, y, \dots)$  will be true, after the ordered execution of the algorithms  $x \leftarrow S$ ,  $y \leftarrow T$ , etc. We use analogous notation for expected value— $\text{Ex}(x \leftarrow S; y \leftarrow T; \dots : f(x, y, \dots))$ —where now  $f$  is a function which takes numerical values.

By  $1^n$  we denote the unary representation of the integer  $n$ , i.e.,

$$\underbrace{11\dots 1}_n.$$

We recall that  $n^{-\omega(1)}$  represents any function of  $n$  that vanishes faster than  $n^{-k}$  for any constant  $k$ .

**3.2. Cryptographic scenario.** Here we specify those elements that are necessary for all public-key cryptography.

A *cryptographic scenario* consists of the following components:

- A *security parameter*  $n$  which is chosen by the user when he creates his encryption and decryption algorithms. The parameter  $n$  will determine a number of quantities (length of plaintext messages, overall security, etc.).
- A sequence of *message spaces*,  $M = \{M_n\}$  from which all plaintext messages will be drawn.  $M_n$  consists of all messages allowed to be sent if the security parameter has been set equal to  $n$ . In order to make our notation simpler (but without loss of generality), we will assume that  $M_n = \{0, 1\}^n$ .

There may also be a probability distribution on each message space,  $\Pr_n : M_n \rightarrow [0, 1]$  such that  $\sum_{m \in M_n} \Pr_n(m) = 1$ . It is interesting to note that one of our definitions, GM-security, makes no mention of the probability distribution, and that definition is nevertheless equivalent to the other two which explicitly depend on the probability distribution on the messages.

We allow probability distributions over message spaces because we are interested in defeating the strongest adversaries possible. Some adversaries may possess a priori knowledge of what plaintext is encrypted by the ciphertext they have intercepted. For instance, in the case where an embassy is under attack, somebody tapping the embassy's encrypted communications will know that the messages, "Should we burn all the documents?" and "Send in the Marines!" are both much more probable than "Hello. How are things back home?"

- A *public-key cryptosystem* is an expected polynomial time algorithm that on input  $1^n$  outputs the description of two polynomial-size circuits  $E$  and  $D$  such that:
  1.  $E$  has  $n$  inputs and  $l(n)$  outputs, and  $D$  has  $l(n)$  inputs and  $n$  outputs. ( $l$  is some polynomial that gives the length of the ciphertext.)

- 2.  $E$  is probabilistic;  $D$  may be as well.
- 3. For all  $m \in \{0, 1\}^n$ ,

$$\Pr((E, D) \leftarrow \mathcal{C}(1^n); \alpha \leftarrow E(m) : D(\alpha) = m) = 1 - n^{-\omega(1)}.^2$$

Notice that  $[E(m)]$  is a set which is typically quite large. Our notation requires us to write  $\alpha \in [E(m)]$  to refer to  $\alpha$ , a particular encryption of  $m$ . Nevertheless, we will sometimes sloppily write  $E(m)$  for a particular encryption of  $m$  when the meaning is clear.

**Two examples.** To illustrate our definition, we now present two examples of a cryptosystem.

First we show how the quadratic residuosity cryptosystem of Goldwasser and Micali [6] fits our definition.  $\mathcal{C}(1^n)$  picks two random distinct primes,  $p_1$  and  $p_2$ , each of length  $n$ , and sets  $N = p_1 p_2$ , and also picks a random quadratic nonresidue with Jacobi symbol  $+1, y \pmod N$ .

The encryption algorithm,  $E$ , to encrypt  $b = b_1 \cdots b_n$  is:

- for each  $b_i \in b$ ,
  - $E$  picks  $x \in \mathbf{Z}_N^*$  at random
  - if  $b_i = 1$   $E$  sets  $e_i = yx^2 \pmod N$
  - else  $E$  sets  $e_i = x^2 \pmod N$
- $E$ 's output is the  $n$ -tuple  $(e_1, \dots, e_n) = E(b)$ .

The decryption algorithm,  $D$ , to decrypt  $e = (e_1, \dots, e_n)$  is

- for each  $e_i \in e$ ,
  - $D$  sets  $b_i$  to be 1 if  $e_i$  is a quadratic residue mod  $n$ , and 0 otherwise.
  - (Note: The whole point of this scheme is that  $D$  gets the factorization of  $N$  from  $\mathcal{C}$  and thus can determine quadratic residuosity.)
- $D$ 's output is  $b_1 \cdots b_n$ .

Our second example illustrates that  $\mathcal{C}$  need not be a *good* cryptosystem merely to meet the definition of a cryptosystem. In fact, the identity function works:  $\mathcal{C}(1^n)$  can simply output  $E = D =$  the identity function on  $\{0, 1\}^n$ .

**3.3. GM-security (three-pass).** This definition is essentially what Goldwasser and Micali [6] called polynomial security.

A *line tapper* is a family of polynomial-size probabilistic circuits  $T = \{T_n\}$ . Each  $T_n$  takes four strings as input and outputs either 0 or 1. However, to make our next equation more readable, we will treat  $T_n$ 's output as being either its second or third input (representing 0 or 1, respectively).

DEFINITION. Let  $\mathcal{C}$  be a public-key cryptosystem.  $\mathcal{C}$  is *GM-secure* if for all line tappers  $T$  and  $c > 0$ , for all sufficiently large  $n$ , for every  $m_0, m_1 \in \{0, 1\}^n$

$$(1)\Pr(m \leftarrow \{m_0, m_1\}; E \leftarrow \mathcal{C}(1^n); \alpha \leftarrow E(m) : T_n(E, m_0, m_1, \alpha) = m) < \frac{1}{2} + n^{-c}.$$

*Remark.* In reading the above definition, one should pay close attention to our notation. Upon casual consideration of equation (1), one might conclude that there are

---

<sup>2</sup> We allow probability of error in the decrypting in order to reach a reasonable level of generality. For instance, before the recent work on primality of Goldwasser and Kilian [5] and Adleman and Huang [1] if one selected primes, to implement the quadratic residuosity cryptosystem described below, by a probabilistic algorithm (such as Solovay and Strassen [10] or Rabin [8]), then an exponentially vanishing fraction of the time one might have made a mistake in determining primality, and thus produced a bogus decryption algorithm.

not any GM-secure cryptosystems! After all, the definition says that the encryption  $E$  must be secure for *any*  $m_0$  and  $m_1$ , both of which are given as inputs to the line tapper. What happens if we put  $m_0 = D$ , a description of the decryption algorithm? The answer to this question is that our notation specifies that *first* we choose  $m$  from  $\{m_0, m_1\}$  (and thus  $m_0$  and  $m_1$  already had been set), and *then* we choose our encryption algorithm. If  $\mathcal{C}$  is GM-secure, then the probability that  $\mathcal{C}(1^n)$  assigns to any given output is quite small, say  $O(2^{-n})$ . Thus there is little worry that  $\mathcal{C}$  will just happen to output a decryption algorithm  $D = m_0$ . Notice how the above definition (via our notation) models the three-pass scenario.

**3.4. Semantic security (three-pass).** Again, this definition is essentially the same as in [6]. It can be viewed as a polynomial-time bounded version of Shannon's "perfect secrecy" [9]. Informally, let  $f$  be *any* function defined on a message space sequence.  $f(m)$  constitutes information about the message  $m$ . Intuitively,  $f$  should be thought of as some particular information about the plaintext that the adversary is going to try to compute from the ciphertext—say the first seventeen bits of the plaintext. A cryptosystem is semantically secure if no adversary, on input  $E(m)$  can compute  $f(m)$  more accurately than by random guessing (taking into account the probability distribution on the message space).

DEFINITION. Let  $\mathcal{C}$  be a public-key cryptosystem, and let  $M = \{M_n\}$  be a sequence of message spaces. Let  $\mathcal{F} = \{f_E : M_n \rightarrow \Sigma^* \mid E \in [\mathcal{C}(1^n)], n \in \mathbb{N}\}$  be any set of functions on the message spaces. For any value  $v \in \Sigma^*$ , we denote by  $f_E^{-1}(v)$  the inverse image of  $v$ ; that is, the set  $\{m \in M_n \mid f_E(m) = v\}$ . Then the probability of the most probable value for  $f_E(m)$  is  $p_E = \max \left\{ \sum_{m \in f_E^{-1}(v)} \Pr_n(m) \mid v \in \Sigma^* \right\}$ .  $p_E$  is the maximum probability with which one could guess  $f_E(m)$  knowing only the probability distribution from which  $m$  has been drawn.

$\mathcal{C}$  is *semantically secure* if for all message space sequences  $M$ , for all families of functions  $\mathcal{F}$ , for every family of polynomial-size probabilistic circuits  $A = \{A_n(\cdot, \cdot)\}$ , for all  $c > 0$ , and for all sufficiently large  $n$

$$(2) \quad \Pr(m \leftarrow M_n; E \leftarrow \mathcal{C}(1^n); \alpha \leftarrow E(m) : A_n(E, \alpha) = f_E(m)) < p_E + \frac{1}{n^c}.$$

Notice that  $p_E$  implicitly depends on  $n$ , because  $E$  depends on  $n$ . Notice also that we quantify over message spaces in order to take into account all possible probability distributions on the messages.

**3.5. Y-security (three-pass).** Yao's definition [11] is inspired by information theory, but its context differs from classical information theory in that the communicating agents, A(lice) and B(ob), are limited to probabilistic polynomial-time computations. Note that the goals and knowledge of A and B in information theory have no resemblance to those of their cryptographic cousins described above in section 2.

An intuitive explanation of Yao's definition is the following: A has a series of  $n^k$  messages, selected from a probability space known to both A and B, and an encryption of each message. She wishes to transmit enough bits to B so that he can (in polynomial time with very high probability) compute all the plaintexts. A cryptosystem is Y-secure if the average number of bits A must send B is essentially the same regardless of whether or not B possesses a copy of the ciphertexts.

We now make this notion precise, first by defining "Alice and Bob," and then by eventually defining Y-security itself.

Let  $M = \{M_n\}$  be a sequence of message spaces. Each  $M_n$  is  $\{0, 1\}^n$  with a fixed probability distribution. (Note that an information theorist would consider  $M$  to be a sequence of *sources*.)

For the sake of compactness of notation, the expression  $\vec{m}$  will denote a particular series of  $n^k$  messages. That is,  $\vec{m}$  stands for  $m_1, m_2, \dots, m_{n^k}$ .

Let  $f$  be any positive function such that  $f(n) \leq n$ . Intuitively,  $f(n)$  is the number of bits per message that A must transmit to B in order for B to recover the plaintexts. Recall that all the messages in  $M_n$  have length  $n$ .

**DEFINITION.** An  $f$  compressor/decompressor pair (hereinafter  $c/d$  pair) for  $M$  is a pair of families of probabilistic polynomial-size circuits,  $\{A_n\}$  and  $\{B_n\}$ , satisfying the following three properties for some constant  $k$  and all sufficiently large  $n$ :

1. " $B_n$  understands  $A_n$ ."

$$(3) \quad \Pr(m_1 \leftarrow M_n; \dots; m_{n^k} \leftarrow M_n; \beta \leftarrow A_n(\vec{m}); \\ y \leftarrow B_n(\beta) : \vec{m} = y) = 1 - n^{-\omega(1)}.$$

2. " $A_n$  transmits at most  $f(n)$  bits per message."

$$(4) \quad \text{Ex} \left[ m_1 \leftarrow M_n; \dots; m_{n^k} \leftarrow M_n; \beta \leftarrow A_n(\vec{m}) : \frac{|\beta|}{n^k} \right] \leq f(n).$$

3. "The output of  $A_n$  can be parsed."

For all polynomials  $Q$  there exists a probabilistic polynomial-time Turing machine  $S^Q$  such that  $S^Q$  takes as input  $n$  and a concatenated string of  $Q(n)$   $\beta$ 's, each of which is a good output from  $A_n$ , and separates them. That is, its input is  $\beta_1\beta_2 \dots \beta_{Q(n)}$  and its output is  $\beta_1\#\beta_2\#\dots\#\beta_{Q(n)}$ . We require that

$$(5) \quad \Pr(S^Q \text{ correctly splits } \beta_1\beta_2 \dots \beta_{Q(n)}) = 1 - n^{-\omega(1)}.$$

*Remark.* The requirement that  $S^Q$  exist is a technical requirement. It creates a finite analogue of classical information theory's requirement that messages be transmitted one bit at a time, in an infinite sequence of bits.

We say that the *cost of communicating  $M$  is less than or equal to  $f(n)$* , in symbols  $C(M) \leq f(n)$ , if there exists an  $f(n)$   $c/d$  pair for  $M$ .

We define  $C(M) > f(n)$  to be the negation of  $C(M) \leq f(n)$ —that is, *any* circuits "communicating  $M$ " must use at least  $f(n)$  bits. The definition of  $C(M) = f(n)$  is analogous.

Let  $\mathcal{C}$  be a cryptosystem. We define  $C(M | E_{\mathcal{C}}(M)) \leq f(n)$ , and  $C(M | E_{\mathcal{C}}(M)) > f(n)$ , *the cost of communicating  $M$  given encryptions from  $\mathcal{C}$  in a manner analogous to  $C(M)$* . The only difference is that now *both  $A_n$  and  $B_n$  also get  $E$  and the  $n^k$  values of some encryption function  $E \in [\mathcal{C}(1^n)]$  as inputs*. That is, for this definition we must rewrite equation (3) above to read:

$$(6) \quad \Pr(m_1 \leftarrow M_n; \dots; m_{n^k} \leftarrow M_n; E \leftarrow \mathcal{C}(1^n); \\ \alpha_1 \leftarrow E(m_1); \dots; \alpha_{n^k} \leftarrow E(m_{n^k}); \\ \beta \leftarrow A_n(E, \vec{m}, \vec{\alpha}); y \leftarrow B_n(E, \beta, \vec{\alpha}); \vec{m} = y) = 1 - n^{-\omega(1)}.$$

An analogous change must also be made to equation (4).

Notice that for this definition, the probabilities involved must be taken over the different choices of  $E$  from  $\mathcal{C}$  as well as everything else.

**DEFINITION.** Let  $\mathcal{C}$  be a public-key cryptosystem. Fix a sequence of message spaces  $M = \{M_n\}$  (and thus the probability distribution on each  $M_n$ ). We say that  $\mathcal{C}$  is *Y-secure with respect to  $M$*  if

$$(7) \quad C(M | E_{\mathcal{C}}(M)) \leq f(n) \Rightarrow C(M) \leq f(n) + n^{-\omega(1)}.$$

We say that  $\mathcal{C}$  is *Y-secure* if for all  $M$ ,  $\mathcal{C}$  is Y-secure with respect to  $M$ .

**3.6. The original definitions versus ours.** As we pointed out in the Introduction, we made minor changes in cryptographic scenario from [6] and [11]. Here we will spell out what those changes are and why they were made.

**Changes to Goldwasser and Micali's definition.** There are two ways a cryptosystem (the server that generates encryption/decryption algorithm pairs) can achieve security:

1. The cryptosystem gets a description of a message space  $M$  (and thus its probability distribution) as one of its inputs and will output an encryption/decryption algorithm pair to securely encrypt  $M$ .
2. The cryptosystem is told nothing about the message space. The encryption algorithms it outputs are supposed to be secure for every possible message space.

We will call the former cryptosystems *adaptive* and the latter *oblivious*.

Goldwasser and Micali consider adaptive cryptosystems for both of their definitions of security [6]; Yao does not make it clear which type of cryptosystem he is assuming for his definition of security [11]. We believe it makes more sense to consider oblivious cryptosystems, for both theoretical and applied reasons.

The theoretical reason for preferring oblivious cryptosystems is that all three definitions of security are equivalent. (See section 4.) This is a desirable property that fails to hold for adaptive cryptosystems, as we will show in the next section.

The practical reason for preferring oblivious cryptosystems is that, although it is certainly conceivable that having knowledge of the message space would allow one to design a better encryption algorithm, cryptographers have in fact normally tried to design cryptosystems that are secure for all message spaces. For example, consider the cryptosystem based on arbitrary trapdoor predicates proposed by Goldwasser and Micali [6]. Although they only considered security in the adaptive cryptosystem sense, their cryptosystem is in fact secure in the stronger, oblivious sense.

**Changes to Yao's definition.** In [11], Yao assumes deterministic private-key cryptography, but the definition is immediately extended to probabilistic public-key cryptography.

Yao defines the compressor  $A$  and decompressor  $B$  to be Turing machines, not circuits. We have switched to circuits because it is not clear that there are *any* secure cryptosystems with respect to probabilistic Turing machines. It might be that one can always achieve greater polynomial-time compression given the ciphertext simply because having a *shared* pseudorandom string (in this case the ciphertext!) helps. If it does help, however, having made the compressor and decompressor nonuniform circuits, we can always hardwire in a shared random string of bits.

**3.7. Inequivalence of the original definitions.** In this section, we point out that, for adaptive cryptosystems, GM-security is a notion stronger than either semantic security or Y-security. We do this in the following two claims, each supported by

an informal argument. These claims can be easily transformed to theorems after formalizing the discussed security notions in terms of adaptive cryptosystems, a tedious effort once we have realized that the adaptive setting is not the “right” one.

**CLAIM 1.** *If any GM-secure adaptive public-key cryptosystem exists, then there exist adaptive public-key cryptosystems that are semantically secure but not GM-secure.*

Let  $\mathcal{C}(\cdot, \cdot)$  be any GM-secure (and thus semantically secure) adaptive cryptosystem. We will construct a  $\mathcal{C}'(\cdot, \cdot)$  that is still semantically secure, but is not GM-secure.

$\mathcal{C}'$  behaves identically to  $\mathcal{C}$  for all message spaces, except for the message space  $\{0, 1\}^n$  with uniform probability distribution. In this case,  $\mathcal{C}'$  runs  $\mathcal{C}$  to compute an encryption algorithm  $E$ , and then outputs the algorithm  $E'$  defined by:

$$(8) \quad E'(x) = \begin{cases} 0^n & \text{if } x = 0^n, \\ E(x) \neq 0^n & \text{otherwise.} \end{cases}$$

$\mathcal{C}'$  is clearly not GM-secure, because, for the special message space described above, there is a message,  $0^n$ , which is easily distinguished from other messages by its encryption. However,  $\mathcal{C}'$  is still semantically secure. The message  $0^n$  has such a low probability weight that it will not give an adversary any significant advantage—on average—in computing a function of the plaintext on input the ciphertext.  $\square$

Note that the above argument would not go through if  $\mathcal{C}$  were an oblivious cryptosystem. An oblivious  $\mathcal{C}$  would not receive any description of the probability distribution on the messages, so it would be unable to alter its output depending on what that probability distribution is.

**CLAIM 2.** *If any GM-secure adaptive public-key cryptosystem exists, then there exist adaptive public-key cryptosystems that are Y-secure but not GM-secure.*

We construct exactly the same  $\mathcal{C}'$  as we did for the previous claim.  $\mathcal{C}'$  is of course not GM-secure. However, the “weak message” has such low probability that it basically does not affect the average number of bits necessary to communicate messages from the message space. Thus  $\mathcal{C}'$  is Y-secure.  $\square$

**4. Main results.** In this section we provide the proof of the equivalence of GM-security, semantic security, and Y-security. We choose to do these proofs by showing that GM-security is equivalent to Y-security and that GM-security is equivalent to semantic security. We present here only three of the four necessary implications. The proof that GM-security implies semantic security may be found in [6]. We will present the three proofs in order of increasing difficulty and technical complexity.

**4.1. Semantic security implies GM-security.** This proof is quite simple. If a cryptosystem is not GM-secure, then there exist two messages,  $m_1$  and  $m_2$ , which we can easily distinguish. If we make a new message space in which these are the only messages, then given only a ciphertext, one has a better than random chance of figuring out which of the two plaintext messages this ciphertext represents.

**THEOREM 1.** *Let  $\mathcal{C}$  be a public-key cryptosystem. If  $\mathcal{C}$  is semantically secure, then  $\mathcal{C}$  is GM-secure.*

*Proof.* We prove the contrapositive. Let  $\mathcal{C}$  be a public-key cryptosystem that is not GM-secure. We will prove that  $\mathcal{C}$  is not semantically secure.

Formally,  $\mathcal{C}$  is not GM-secure means that there exist a line tapper  $T$  and a  $c > 0$  such that for infinitely many  $n$  there are  $m_1^n, m_2^n \in M_n$  for which

$$(9) \Pr(m \leftarrow \{m_1^n, m_2^n\}; E \leftarrow \mathcal{C}(1^n); \alpha \leftarrow E(m) : T_n(E, m_1^n, m_2^n, \alpha) = m) \geq \frac{1}{2} + \frac{1}{n^c}.$$

We construct a new message space  $M_n$  as follows: For those  $n$  for which equation (9) holds,  $\Pr_n(m_1^n) = 1/2$  and  $\Pr_n(m_2^n) = 1/2$ .

We have set up the message space so one can simply guess the plaintext by seeing the ciphertext. More precisely, a circuit  $A_n$  can compute the function of the plaintext  $f_E(m) = m$  from the ciphertext by having the values  $m_1^n$  and  $m_2^n$  hardwired into it, and using  $T$  as a subroutine. By equation (9), such an  $A_n$  has a polynomial advantage over random guessing. On the other hand, without seeing the ciphertext, circuits with no input can only randomly guess the plaintext.  $\square$

**4.2. Y-security implies GM-security.** In the proof of the next theorem, we use a technical lemma, one of Hoeffding's Inequalities [7], that is a variation of Chernoff's bound [2].

LEMMA 1 (HOEFFDING). *Let  $X$  be a random variable having binomial distribution, with  $r$  trials and probability of success  $p$ . For  $0 \leq \alpha \leq 1/2 \leq p \leq 1$ , we have  $\Pr(X \leq \alpha r) \leq e^{-2(p-\alpha)^2 r}$ .*

THEOREM 2. *Let  $C$  be a cryptosystem. If  $C$  is Y-secure, then  $C$  is GM-secure.*

*Proof.* Again we will prove the contrapositive. Let  $C$  be a cryptosystem that is not GM-secure for some message space  $M$ . Then there exist a family of line tappers  $T = \{T_n\}$  and an infinite subset  $N' \subseteq \mathbb{N}$  such that for some constant  $j$ , and all  $n \in N'$ , there are  $m_0^n, m_1^n \in M_n$  such that

$$\Pr(m \leftarrow \{m_1^n, m_2^n\}; E \leftarrow C(1^n); \alpha \leftarrow E(m) : T_n(E, m_1^n, m_2^n, \alpha) = m) \geq \frac{1}{2} + \frac{1}{n^j}.$$

Consider now a new message space  $M'$  that, for  $n \in N'$ , has  $\Pr_n(m_0^n) = 1/2$ ,  $\Pr_n(m_1^n) = 1/2$ , and  $\Pr_n(m) = 0$  for all other  $m \in \{0, 1\}^n$ , and for  $n \in \overline{N'}$  has  $\Pr_n(0^n) = 1/2$ ,  $\Pr_n(1^n) = 1/2$ , and  $\Pr_n(m) = 0$  for all other  $m$ .

Clearly for all  $d > 0$ ,  $C(M') > 1 - n^{-d}$ : Any circuits not sharing ciphertext would need exactly one bit per message to perfectly communicate outputs from  $M'$ , and our definition in equation (3) allows an error of at most  $n^{-\omega(1)}$ .

On the other hand, we will now show that

$$C(M' | E_C(M')) \leq \begin{cases} 1 - 1/n^k & \text{if } n \in N', \\ 1 & \text{otherwise} \end{cases}$$

where  $k = 2j + 1$ . This value is achieved by a shared ciphertext  $c/d$  pair that transmits  $n^k$  messages at a time.

$A_n$  gets  $n^k$  messages in both cleartext and ciphertext as its input. Since there are only two messages in  $M'_n$ , each message can be considered to be a bit  $b$  and each ciphertext the encryption of a bit. That is to say,  $A_n$ 's input is  $b_1, b_2, \dots, b_{n^k}, \alpha_1, \alpha_2, \dots, \alpha_{n^k}$  where  $\alpha_i \in [E(b_i)]$ .  $A_n$  now XORs each adjacent pair of messages (bits). That is, put  $c_i = b_i \oplus b_{i+1}$  for  $i = 1, 2, \dots, n^k - 1$ . Put  $\beta = c_1 c_2 \dots c_{n^k - 1}$ . This  $\beta$  is the "hint" that  $A_n$  sends to  $B_n$ . Obviously,  $|\beta|/n^k = 1 - 1/n^k$ .

Now, can  $B_n$ , given  $\beta$  and the  $\alpha_i$ 's as its input, determine the plaintext with probability  $1 - n^{-\omega(1)}$ ? Yes. The "hint",  $\beta$ , constrains  $B_n$  to only two possible choices of values for the  $b_i$ . That is, if  $B_n$  decides that  $b_1 = 0$ , then it knows the value of all the bits—say  $v_1 v_2 \dots v_{n^k}$ . On the other hand, if  $B_n$  decides that  $b_1 = 1$ , then the whole series of messages must of have been  $\bar{v}_1 \bar{v}_2 \dots \bar{v}_{n^k}$  (where  $\bar{v}$  is the complement of  $v$ ).

$B_n$  also has a line tapper,  $T_n$ , that it can use to test the  $\alpha_i$ .  $B_n$  runs  $T_n$  on each  $\alpha_i$  and obtains  $T_n$ 's opinion as to what each bit was. Call this sequence  $t_1 t_2 \dots t_{n^k}$ .

Since  $\mathcal{C}$  is not GM-secure, each  $t_i$  is correct with probability  $p = \frac{1}{2} + 1/n^j$ , for some fixed  $j$ . By Lemma 1 (with  $\alpha = 1/2$  and  $r = n^k$ ), if we make  $k \geq 2j + 1$ , then the majority of  $t_i$ 's will be correct with probability  $1 - O(e^{-2n})$ .  $B_n$  compares the  $t_i$  to both the  $v_i$  and the  $\bar{v}_i$ , and decides either  $b_1 = 0$  if the majority of  $t_i$  coincide with the  $v_i$ , or  $b_1 = 1$  if the majority of the  $t_i$  coincide with the  $\bar{v}_i$ .

Because for infinitely many  $n$ ,  $C(M' | E_{\mathcal{C}}(M')) \leq 1 - 1/n^k$ , but for all  $n$ ,  $C(M') > 1 - 1/2n^k$ ,  $M'$  is *not* Y-secure.  $\square$

### 4.3. GM-security implies Y-security.

**THEOREM 3.** *Let  $\mathcal{C}$  be a public-key cryptosystem. If  $\mathcal{C}$  is GM-secure, then  $\mathcal{C}$  is Y-secure.*

*Proof.* We will prove the contrapositive. A bird's-eye view of our proof is as follows. Assuming that  $\mathcal{C}$  is not Y-secure, there exists a good shared ciphertext c/d pair that manages to communicate using "few" bits. This pair will allow us to test (for some special pair of messages  $m_1$  and  $m_2$ ) whether a particular  $\alpha$  is the encryption of either  $m_1$  or  $m_2$  thus violating the GM-security condition. Namely, if the pair works successfully on inputs  $\alpha$  and  $m_1$ , we declare  $\alpha$  to be an encryption of  $m_1$ ; otherwise we declare  $\alpha$  to be an encryption of  $m_2$ .

Let us proceed formally. Since  $\mathcal{C}$  is not Y-secure, there is a particular message space sequence,  $M = \{M_n\}$ , such that  $\mathcal{C}$  is not Y-secure for  $M$ . That is to say, there exist a shared ciphertext c/d pair  $(A, B)$  (which we will use as shorthand for  $(\{A_n\}, \{B_n\})$ ), a positive integer  $k$ , and a polynomial  $P$  such that

- ( $\star$ )  $A_n$  communicates  $n^k$  messages from  $M_n$  to  $B_n$  using "few" bits per message—on top of the ciphertext which they get to share for free.
- ( $\star\star$ ) Furthermore, for every c/d pair  $(A', B')$ , there exists an infinite subset  $N' \subseteq \mathbb{N}$ , such that for all  $n \in N'$ , on average  $(A', B')$  uses at least  $1/P(n)$  more bits per message than does  $(A, B)$ . (Intuitively, the point is that  $(A', B')$  is not a *shared ciphertext* c/d pair;  $A'$  and  $B'$  share nothing except that  $B'$  "knows"  $\beta$ .)

We are now going to run a series of experiments to see how  $(A, B)$  behaves on inputs that it does not "expect." We begin, however, by running a control experiment.

In experiment  $n\text{-EXP}_0$ , we pick  $n^k$  messages  $m_i$  at random from  $M_n$  and an  $E$  at random from  $[\mathcal{C}(1^n)]$ , and run  $A_n$  on input

$$\begin{array}{cccccc} m_1 & m_2 & m_3 & \dots & m_{n^k} \\ E(m_1) & E(m_2) & E(m_3) & \dots & E(m_{n^k}) \end{array}$$

(The output will be a string  $\beta$  such that  $B_n$ , on input  $\beta$  and  $E(m_1), \dots, E(m_{n^k})$  will output  $m_1, \dots, m_{n^k}$  with overwhelming probability.)

Now consider the following experiment,  $n\text{-EXP}_i$ : This time we again pick  $n^k$  messages and an  $E$  at random, but we also pick one more message,  $r$ , at random from  $M_n$ , and set  $\rho = E(r)$ . Now we run  $A_n$  with  $i$  copies of  $\rho$  replacing the first  $i$  ciphertexts in its input. A "picture" of  $A_n$ 's input is

$$\begin{array}{cccccc} m_1 & \dots & m_i & m_{i+1} & \dots & m_{n^k} \\ \rho & \dots & \rho & E(m_{i+1}) & \dots & E(m_{n^k}) \end{array}$$

We then run  $B_n$  with  $A_n$ 's output and  $\rho, \rho, \dots, E(m_{n^k})$  as its inputs.

**DEFINITION.** We define the *difference between  $n\text{-EXP}_i$  and  $n\text{-EXP}_j$* ,  $d_n(i, j)$  to be the maximum of the average difference between

1. the length of the  $\beta$ 's output by  $A_n$  in the two experiments, and

2. the frequency with which  $B_n$  recovers the correct plaintexts in the two experiments.

(This definition is unusual in that we are comparing a number of bits with a probability. Nevertheless, both are numbers, so one can indeed take a maximum, and, indeed, both are handled in a similar manner in this proof.)

CLAIM 3. *There exists a polynomial  $Q$  such that for an infinite subset  $N'' \subseteq \mathbb{N}$  and for all  $n \in N''$   $d_n(0, n^k) > 1/Q(n)$ .*

*Proof of Claim 3.* By contradiction. Assume that for all sufficiently large  $n$ ,  $n\text{-EXP}_0$  is indistinguishable from  $n\text{-EXP}_{n^k}$ . Then  $A_n$  and  $B_n$  still function successfully on input

$$\begin{array}{cccccc} m_1 & m_2 & m_3 & \dots & m_{n^k} \\ \rho & \rho & \rho & \dots & \rho \end{array}$$

where  $m_i, r, \rho$ , and  $E$  are as above. We now construct  $A'_n, B'_n$  to violate  $(\star\star)$ . We simply hardwire the encryption of some random string into a pair of circuits which are identical to  $A_n$  and  $B_n$  except that they do not share any ciphertext. By assumption, these circuits are a c/d pair violating  $(\star\star)$ .  $\square$

CLAIM 4. *For all  $n \in N''$ , there is a polynomial  $Q'$  and an  $i, 0 \leq i \leq n^k - 1$ , such that  $d_n(i, i + 1) > 1/Q'(n)$ .*

*Proof of Claim 4.* Fix  $n \in N''$ .  $d_n(0, n^k) \geq 1/Q(n)$ . Therefore, there must be an  $i$  such that  $d_n(i, i + 1) \geq \frac{1}{n^k Q(n)}$ .  $\square$

Let  $n \in N''$ . We will consider the case where  $i = 0$  in Claim 4, and  $d_n(0, 1)$  is due to a difference in the length of  $A_n$ 's output, rather than  $B_n$ 's success rate. The other case, where the difference is due to a difference in  $B_n$ 's success rate, is similar, but simpler.

Let us restate Claim 4 in a more convenient form. Consider the following *joint* experiment,  $n\text{-EXP}_{01}$ . Randomly draw  $r, m_1, \dots, m_{n^k}$  from  $M_n$  and set  $E \leftarrow \mathcal{C}(1^n)$ . Run both  $n\text{-EXP}_0$  and  $n\text{-EXP}_1$  on the *same* inputs. That is, run  $n\text{-EXP}_0$  on input

$$\begin{array}{cccccc} m_1 & m_2 & m_3 & \dots & m_{n^k} \\ E(m_1) & E(m_2) & E(m_3) & \dots & E(m_{n^k}) \end{array}$$

to compute  $A_n$ 's output  $\beta_0$  and run  $n\text{-EXP}_1$  on input

$$\begin{array}{cccccc} m_1 & m_2 & m_3 & \dots & m_{n^k} \\ E(r) & E(m_2) & E(m_3) & \dots & E(m_{n^k}) \end{array}$$

to compute  $A_n$ 's output on this input,  $\beta_1$ . The output of  $n\text{-EXP}_{01}$  is  $|\beta_1| - |\beta_0|$ . Then, by the linearity of the average we get that the expected value of the output of  $n\text{-EXP}_{01}$  is at least  $1/Q'(n)$ .

From this it immediately follows that

$(\star\star\star)$  there exist  $\bar{r}, \bar{m}_1, \bar{m}_2, \dots, \bar{m}_{n^k}$  in  $M_n$  such that the expected value of the output of  $n\text{-EXP}_{01}$  is still greater than  $1/Q'(n)$  when the average of the length of  $\beta$  is computed only over the choice of  $E \leftarrow \mathcal{C}(1^n)$  and of encryptions of messages.

Now for all  $n \in N''$  we can build a tapper  $T_n$  that will succeed in distinguishing two messages  $m_1^n$  and  $m_2^n$ , described below.

Fix  $\bar{r}$  and  $\bar{m}_1$  to be messages that fit the requirements of  $(\star\star\star)$ . We set  $T_n$ 's inputs:  $m_1^n = \bar{m}_1$  and  $m_2^n = \bar{r}$ .  $T_n$  gets as inputs  $E \in [\mathcal{C}(1^n)]$ ,  $m_1^n, m_2^n$ , and  $\alpha$ , where either  $\alpha \in [E(m_1^n)]$  or  $\alpha \in [E(m_2^n)]$ .

Unfortunately, merely because the *average* length of  $\beta$  output by  $A_n$  is shorter if its input includes  $E(\bar{m}_1)$  than if its input includes  $E(\bar{r})$  does not imply that a shorter  $\beta$  occurs *more frequently* with input  $E(\bar{m}_1)$ . Indeed, it might be the case that for most  $E \in [\mathcal{C}(1^n)]$ ,  $A_n$  outputs a longer  $\beta$  given  $E(\bar{m}_1)$  than given  $E(\bar{r})$ , but for a few  $E \in [\mathcal{C}(1^n)]$ ,  $A_n$  outputs a much shorter  $\beta$  given  $E(\bar{m}_1)$ .

What we can say for certain is only that

$$(10) \quad \text{Ex}[|\beta| \mid \alpha \in [E(m_2^n)]] - \text{Ex}[|\beta| \mid \alpha \in [E(m_1^n)]] > 1/Q'(n)$$

where the expectations are computed over the choice of  $E \leftarrow \mathcal{C}(1^n)$ . Now

$$(11) \quad \text{Ex}[|\beta|] = \sum_i^{R(n)} i \Pr(A_n \text{'s output has length } i)$$

where  $R(n)$  is a bound on the running time of  $A_n$ . Therefore, there must be some  $i$  such that if  $|\beta| = i$ , then it is at least  $1/[Q'(n)R(n)]$  more likely that  $\alpha$  is an encryption of  $m_2^n$ .

$T_n$  sets  $m = m_1^n$  and runs  $A_n$  on input

$$\begin{array}{cccccc} m & \bar{m}_2 & \bar{m}_3 & \dots & \bar{m}_{n^k} \\ \alpha & E(\bar{m}_2) & E(\bar{m}_3) & \dots & E(\bar{m}_{n^k}). \end{array}$$

If  $|\beta| \neq i$ , then  $T_n$  simply flips a coin. If  $|\beta| = i$ , the  $T_n$  guesses  $m_2^n$ .  $T_n$  is correct at least polynomially more than half the time.<sup>3</sup>  $\square$

Notice that at several points in the proof we took advantage of the fact that  $T_n$  is nonuniform.  $v$  is hardwired into  $T_n$ , as are  $\bar{r}, \bar{m}_1, \dots, \bar{m}_{n^k}$ . In fact, most of these uses of nonuniformity could be replaced by polynomial-size Monte Carlo experiments. However,  $T_n$  must be nonuniform since  $A_n$  and  $B_n$  are nonuniform.

**5. One-pass scenarios.** In this section we present the proper definitions of security for one-pass cryptography. These definitions are all considerably more complicated than the analogous ones for the three-pass scenario. They are equivalent to one another but *not* to the three-pass definitions. Instead of proving all implications, we only show how to extend the proof that semantic security implies GM-security from the three-pass to the one-pass scenario. Extending the other implication presents no additional difficulties.

**5.1. GM-security (one-pass).** As discussed above in section 2.2, for a one-pass cryptosystem, we must change from requiring security “for all messages  $m$ ,” to requiring security for every message  $m$  that is efficiently computable on input of the encryption algorithm alone. In order to do this, we introduce an adversary called a message finder.

A *message finder* is a family of polynomial-size probabilistic circuits  $F = \{F_n(\cdot)\}$  each of which takes the description of an encryption algorithm as its input and has two messages of length  $n$  as its output. Intuitively, on input  $E$ ,  $F_n$  tries to find  $m_0$  and  $m_1$  such that it is easy for a fellow adversary (a line tapper) to distinguish encryptions of  $m_0$  from encryptions of  $m_1$ .

<sup>3</sup> Notice that if we were working with a difference in  $B_n$ 's success rate instead of a difference in  $|\beta|$ , then a much simpler algorithm would work:  $T_n$  guesses  $\alpha = m_1^n$  if and only if  $B_n$  decodes correctly.

DEFINITION. Let  $\mathcal{C}$  be a public-key cryptosystem.  $\mathcal{C}$  is *GM-secure (one-pass)* if for all message finders  $F$ , line tappers  $T$ , and  $c > 0$ , for all sufficiently large  $n$ ,

$$(12) \quad \Pr(E \leftarrow \mathcal{C}(1^n); m_0, m_1 \leftarrow F_n(E); m \leftarrow \{m_0, m_1\}; \\ \alpha \leftarrow E(m) : T_n(E, m_0, m_1, \alpha) = m) \leq \frac{1}{2} + n^{-c}.$$

**5.2. Semantic security (one-pass).** To change the definition of semantic security to fit the one-pass scenario, we need to introduce something like the message finders of the previous section. For semantic security, however, we are concerned not with finding two “weak” messages, but rather with the probability distribution of the entire message space. Thus our second adversary will not pick out particular messages, but instead set the probability distribution of the message space. Furthermore, we now explicitly give the other adversary a description of that probability distribution.

A *message space enemy* is a family of polynomial-size probabilistic circuits  $B = \{B_n(\cdot)\}$ . Each  $B_n$  takes the description of an encryption algorithm as its input, and outputs the description of a probabilistic Turing machine  $N(\cdot)$ .  $N$  outputs elements of  $\{0, 1\}^n$  with some probability distribution.

As in the three-pass definition, we let  $V$  be any set and let  $\mathcal{F} = \{f_n^E : M_n \rightarrow V \mid E \in [\mathcal{C}(n)]\}$  be any set of functions. Again set  $p_N^E$  to be the probability of the most probable value for  $f(m)$ ; set  $p_n^E = \max\{\sum_{m \in f_n^{E^{-1}(v)}} \Pr_n(m) \mid v \in V\}$ .

DEFINITION. Let  $\mathcal{C}$  be a public-key cryptosystem.  $\mathcal{C}$  is *semantically secure* if for every message space enemy  $B$ , family of polynomial-size probabilistic circuits  $A = \{A_n(\cdot, \cdot, \cdot)\}$ , and  $c > 0$ , for all sufficiently large  $n$

$$(13) \quad \Pr(E \leftarrow \mathcal{C}(1^n); N \leftarrow B_n(E); m \leftarrow N()); \\ \alpha \leftarrow E(m) : A_n(E, N, \alpha) = f_n^E(m)) < p_n^E + \frac{1}{n^c}.$$

**5.3. Y-security (one-pass).** The changes that must be made to the definition of Y-security are completely analogous to the changes we made to the definition of semantic security.

**5.4. Equivalence.** The proofs that the three definitions of security are all equivalent are quite similar to the proofs for the three-pass case. Here we will redo only the proof of the easiest of the four implications, semantic security implies GM-security. This proof shows the additional details that must be taken into consideration when working with the one-pass scenario.

**THEOREM 4.** *GM-security (one-pass), semantic security (one-pass), and Y-security (one-pass) are all equivalent.*

*Proof that semantic security (one-pass) implies GM-security (one-pass).* We will, as usual, prove the contrapositive. Let  $\mathcal{C}$  be a public-key cryptosystem that is not GM-secure. We know that there exist a message finder family of circuits  $F = \{F_n\}$  and a line tapper family of circuits  $T = \{T_n\}$ . We will use the  $F_n$  as subroutines (circuit components to be precise) for building our message space enemy circuits and then use the  $T_n$  to do the distinguishing.

Our message space enemy,  $B_n$ , on input an encryption algorithm  $E \in [\mathcal{C}(1^n)]$ , runs  $F_n$  with input  $E$ .  $F_n$  outputs two messages,  $m_0, m_1 \in \{0, 1\}^n$ .  $B_n$  outputs the

design of a Turing machine  $N()$  such that

$$N \text{ outputs } \begin{cases} m_0 & \text{with probability } 1/2, \\ m_1 & \text{with probability } 1/2. \end{cases}$$

An adversary  $A$  who uses  $T_n$  as a subroutine can distinguish encryptions of  $m_0$  from encryptions of  $m_1$ . In other words, on the message space defined by the output of  $N()$ ,  $A$  can compute the function  $f(m) = m$  (with probability greater than at random) given only an encryption of  $m$ .  $A$  gets  $E$  and  $\alpha$  where either  $\alpha \in [E(m_0)]$  or  $\alpha \in [E(m_1)]$ . However,  $T_n$  also requires  $m_0$  and  $m_1$  as inputs.  $A$  can obtain that information for  $T_n$  simply by running  $N$  a few times.

Formally, since  $\mathcal{C}$  is not GM-secure we know that there exists a  $c > 0$  such that for infinitely many  $n$

$$(14) \quad \Pr(E \leftarrow \mathcal{C}(1^n); m_0, m_1 \leftarrow F_n(E); m \leftarrow \{m_0, m_1\}; \\ \alpha \leftarrow E(m) : T_n(E, m_0, m_1, \alpha) = m) > \frac{1}{2} + n^{-c}.$$

For those  $n$ , equation (14) in fact says that  $\Pr(A \text{ computes } f(m) = m \text{ correctly}) > \frac{1}{2} + n^{-c}$ .  $\square$

**Acknowledgments.** We wish to thank Shafi Goldwasser and Shimon Even for insight and helpful discussions about the notions of security, and general help in preparing this paper. We would like to thank Peter Elias for his help with information theory, and Ravi Boppana for his help with Chernoff bounds. We would also like to thank the referee for his extremely careful reading of our paper and the many improvements he suggested.

## A FUNCTIONAL APPROACH TO DATA STRUCTURES AND ITS USE IN MULTIDIMENSIONAL SEARCHING\*

BERNARD CHAZELLE†

**Abstract.** We establish new upper bounds on the complexity of multidimensional searching. Our results include, in particular, linear-size data structures for range and rectangle counting in two dimensions with logarithmic query time. More generally, we give improved data structures for *rectangle problems* in any dimension, in a static as well as a dynamic setting. Several of the algorithms we give are simple to implement and might be the solutions of choice in practice. Central to this paper is the nonstandard approach followed to achieve these results. At its root we find a redefinition of data structures in terms of functional specifications.

**Key words.** functional programming, data structures, concrete complexity, multidimensional search, computational geometry, pointer machine, range search, intersection search, rectangle problems

**CR Categories.** 5.25, 3.74, 5.39

**1. Introduction.** This paper has two main parts: in § 2, we discuss a method for transforming data structures using functional specifications; in the remaining sections, we use such transformations to solve a number of problems in multidimensional searching. To begin with, let us summarize the complexity results of this paper.

The generalization of the notion of rectangle in higher dimensions is called a *d-range*: it is defined as the Cartesian product of  $d$  closed intervals over the reals. Let  $V$  be a set of  $n$  points  $\mathfrak{R}^d$  and let  $v$  be a function mapping a point  $p$  to an element  $v(p)$  in a commutative semigroup  $(G, +)$ . Let  $W$  be a set of  $n$   $d$ -ranges.

- (1) **Range counting:** given a  $d$ -range  $q$ , compute the size of  $V \cap q$ .
- (2) **Range reporting:** given a  $d$ -range  $q$ , report each point of  $V \cap q$ .
- (3) **Semigroup range searching:** given a  $d$ -range  $q$ , compute  $\sum_{p \in V \cap q} v(p)$ .
- (4) **Range searching for maximum:** semigroup range searching with maximum as semigroup operation.
- (5) **Rectangle counting:** given a  $d$ -range  $q$ , compute the size of  $\{r \in W \mid q \cap r \neq \emptyset\}$ .
- (6) **Rectangle reporting:** given a  $d$ -range  $q$ , report each element of  $\{r \in W \mid q \cap r \neq \emptyset\}$ .

In each case,  $q$  represents a query to which we expect a fast response. The idea is to do some preprocessing to accommodate incoming queries in a repetitive fashion.

Note that range counting (resp., reporting) is a subcase of rectangle counting (resp. reporting). To clarify the exposition (and keep up with tradition), however, we prefer to treat these problems separately. Other well-known problems falling under the umbrella of rectangle searching include *point enclosure* and *orthogonal segment intersection*. The former involves computing the number of  $d$ -ranges enclosing a given query point, while the latter, set in two dimensions, calls for computing how many horizontal segments from a given collection intersect a query vertical segment. In both cases, the reduction to rectangle counting is immediate.

The thrust of our results is to demonstrate the existence of efficient solutions to these problems that use minimum storage. One of the key ideas is to redesign range

trees (Bentley [B2]) and segment trees (Bentley [B1], Bentley and Wood [BW]) so as to require only linear storage. Since improvements in this area typically involve trimming off logarithmic factors, one must be clear about the models of computation to be used. It is all too easy to “improve” algorithms by encoding astronomical numbers in one computer word or allowing arbitrarily complex arithmetic. To guard us from such dubious tricks, we will assume that the registers and memory cells of our machines can only hold integers in the range  $[0, n]$ . In the following, the sign  $\times$  refers to multiplication,  $\div$  to division (truncated to the floor), and *shift* to the operation  $\text{shift}(k) = 2^k$ , defined for any  $k$  ( $0 \leq k \leq \lfloor \log n \rfloor$ ).<sup>1</sup> No operation is allowed if the result or any of the operands falls outside of the range  $[0, n]$ . This will make our model very weak and thus give all the more significance to our upper bounds.

*Remark.* As observed in Gabow et al. [GBT] the “orthogonal” nature of the problems listed above makes it possible to work in rank space, that is, to deal not with the coordinates themselves but with their ranks. This is precisely what we will be doing here. The conversion costs logarithmic time per coordinate, but it has the advantage of replacing real numbers by integers in the range  $[1, n]$ . It is important to keep in mind that although our data structures will use integers over  $O(\log n)$  bits internally, no such restriction will be placed on the input and query coordinates. On the contrary these will be allowed to assume any real values.

The models of computation we will consider include variants of *pointer machines* (Tarjan [T]). Recall that the main characteristic of these machines is to forbid any kind of address calculation. New memory cells can be obtained from a free list and are delivered along with pointers to them. A pointer is just a symbolic name, that is, an address whose particular representation is transparent to the machine and on which no arithmetic operation is defined. Only pointers provided by the free list can be used. For the time being, let us assume that the only operations allowed are  $=$  and  $<$  along with the standard Booleans. We introduce our models of computation in order of increasing power. Of course, we always assume that the semigroup operations which might be defined (problems 3–4) can be performed in constant time.

- (1) An *elementary pointer machine* (EPM) is a pointer machine endowed with  $+$ .
- (2) A *semi-arithmetic pointer machine* (SAPM) is a pointer machine endowed with  $+$ ,  $-$ ,  $\times$ ,  $\div$ .
- (3) An *arithmetic pointer machine* (APM) is a pointer machine endowed with  $+$ ,  $-$ ,  $\times$ ,  $\div$ , *shift*.
- (4) A *random access machine* (RAM) is endowed with comparisons, and  $+$ ,  $-$ ,  $\times$ ,  $\div$ . See Aho et al. [AHU] for details.

Our motivation for distinguishing between these models is twofold: one reason is to show that our basic techniques still work even on the barest machines. Another is to assess the sensitivity of the complexity of query-answering to the model of computation. Next, we briefly discuss these definitions. First of all, complexity is measured in all cases under the uniform cost criterion (Aho et al. [AHU]). Note that subtraction can be simulated in  $O(\log n)$  time and  $O(n)$  space on an EPM by binary search. Similarly, *shift* can be simulated on an SAPM in  $O(\log \log n)$  time by binary search in a tree of size  $O(\log n)$  (this can also be done with constant extra space by repeated squaring). For this reason, we will drop the SAPM model from consideration altogether. Any result mentioned in this paper with regard to an APM also holds on an SAPM, up to within a multiplicative factor of  $\log \log n$  in the time complexity. All

<sup>1</sup> All logarithms are taken to the base 2. Throughout this paper, we will use the notation  $\log^c n$  to designate  $(\log n)^c$ .

the operations mentioned above are in the instruction set of any modern computer, so our models are quite realistic. We have omitted *shift* from the RAM, because this operation can be simulated in constant time by table look-up. One final comment concerns the word-size. Suppose that for some application we need to use integers in the range  $[-n^c, n^c]$ , for some constant  $c > 0$ . Any of the machines described above will work just as well. Indeed, we can accommodate any polynomial range by considering virtual words made of a constant number of actual machine words. The simulation will degrade the time performance by only a constant factor. See Knuth [K2] for details on multiple-precision arithmetic.

*The complexity results.* We have summarized our results for  $\mathfrak{R}^2$  in Tables 1 and 2. The first concerns the static case. Each pair  $(x, y)$  indicates the storage  $O(x)$  required by the data structure and the time  $O(y)$  to answer a query; we use  $\epsilon$  to denote an arbitrary positive real. In the second table one will find our results for the dynamic case. We give successively the storage requirement, the query time, and the time for an insertion or a deletion. In both cases,  $k$  indicates the number of objects to be reported plus one (we add a 1 to treat the no-output case uniformly). The time to construct each of these data structures is  $O(n \log n)$ .

TABLE 1  
The static case.

Problem	RAM	APM	EPM
range/rectangle counting	$(n, \log n)$	$(n, \log n)$	$(n, \log^2 n)$
range/rectangle reporting	$\left( n, k \left( \log \frac{2n}{k} \right)^\epsilon + \log n \right)$ $\left( n \log \log n, k \log \log \frac{4n}{k} + \log n \right)$ $(n \log^\epsilon n, k + \log n)$	$\left( n, k \log \frac{2n}{k} \right)$	$\left( n, k \left( \log \frac{2n}{k} \right)^2 \right)$
range search for max	$(n, \log^{1+\epsilon} n)$ $(n \log \log n, \log n \log \log n)$ $(n \log^\epsilon n, \log n)$	$(n, \log^2 n)$	$(n, \log^3 n)$
semigroup range search	$(n, \log^{2+\epsilon} n)$ $(n \log \log n, \log^2 n \log \log n)$ $(n \log^\epsilon n, \log^2 n)$	$(n, \log^3 n)$	$(n, \log^4 n)$

TABLE 2  
The dynamic case on an EPM.

Problem	Storage	Query time	Update time
range/rectangle counting	$O(n)$	$O(\log^2 n)$	$O(\log^2 n)$
range reporting	$O(n)$	$O(k(\log 2n/k)^2)$	$O(\log^2 n)$
range search for max	$O(n)$	$O(\log^3 n \log \log n)$	$O(\log^3 n \log \log n)$
semigroup range search	$O(n)$	$O(\log^4 n)$	$O(\log^4 n)$
rectangle reporting	$O(n)$	$O(k(\log 2n/k)^2 + \log^3 n)$	$O(\log^2 n)$

In the dynamic case, we have restricted ourselves to the EPM model. Our objective was only to show that the techniques of this paper could be dynamized even in the weakest model. It is likely that many of these bounds can be significantly lowered if we are ready to use a more powerful model such as a RAM or an APM. We leave these improvements as open problems. In the remainder of this paper we will mention upper bounds only in connection with the *weakest* models in which they hold. This is quite harmless as long as the reader keeps in mind that any result relative to an EPM holds on an APM or a RAM. Similarly, anything one can do on an APM can be done just as well on a RAM. Also for the sake of exposition, we restrict ourselves to two dimensions ( $d = 2$ ), but we recall a classical technique (Bentley [B2]) that allows us to extend all our data structures to  $\mathfrak{R}^d$  ( $d > 2$ ). To obtain the complexity of the resulting algorithms, just multiply each expression in the original complexity by a factor of  $\log^{d-2} n$  (note: the terms involving  $k$  remain unchanged, but a term  $\log^{d-1} n$  is to be included in the query times).

Update times are best thought of as amortized bounds, that is, averaged out over a sequence of transactions. A general technique can be used in most cases, however, to turn these bounds into worst-case bounds (Willard and Lueker [WL]). Similarly, a method described in Overmars [O] can often be invoked to reduce deletion times by a factor of  $\log n$ . Finally, we can use a result of Mehlhorn [Me] and Willard [W1] to show that if we can afford an extra  $\log^\epsilon n$  factor in query time then the storage can often be reduced by a factor of  $\log \log n$  with each increment in dimension. We will not consider these variants here for at least two reasons. The first is that the techniques have been already thoroughly exposed and it would be tedious but elementary to apply them to our data structures. The second is that these variants are usually too complex to be practical. We will strive in this paper to present data structures that are easy to implement. We have not succeeded in all cases, but in some we believe that we have. For example, our solutions to range counting are short, simple, and very efficient in practice. To illustrate this point we have included in the paper the code of a Pascal implementation of one of the solutions.

*Comparison with previous work.* Roughly speaking, our results constitute improvements of a logarithmic factor in storage over previous methods. In particular, we present the first linear-size data structures for range and rectangle counting in two dimensions with logarithmic query times. For these two problems our data structures are essentially memory compressed versions of the range tree of Bentley [B2], using new implementations of the idea of a downpointer introduced by Willard [W2]. As regards range and rectangle reporting on a RAM, we improve a method in Chazelle [C1] from  $(n(\log n/\log \log n), k + \log n)$  to  $(n \log^\epsilon n, k + \log n)$ . Interestingly, we have shown in Chazelle [C2] that the  $(n(\log n/\log \log n), k + \log n)$  algorithm is optimal on a pointer machine. This constitutes a rare example (outside of hashing), where a pointer machine is provably less powerful than a RAM. Concerning range search for maximum, we improve over a data structure of Gabow et al. [GBT] from  $(n \log n, \log n)$  to  $(n \log^\epsilon n, \log n)$ . As regards semigroup range searching we present an improvement of a factor  $\log^{1-\epsilon} n$  space (again for any  $\epsilon > 0$ ) over the algorithm for the same problem in Willard [W1]. In the group model (the special case of semigroup range searching where an inverse operation exists) we could not find any obvious way of taking advantage of the inverse operation to improve on the results in the table (except, of course, for the case of range counting). As a result, our  $(n \log^\epsilon n, \log^2 n)$  algorithm may compare favorably with Willard's  $(n \log n, \log n)$  [W2] in storage requirement, but it is superseded in query time efficiency. Our other results for the static case represent tradeoffs and cannot be compared with previous work. In the dynamic case,

our upper bounds improve previous results by a factor of  $\log n$  space but, except for range and rectangle counting, they also entail extra polylogarithmic costs in query and update times. Also, what makes comparisons even more difficult is that in order to prove the generality of our space-reduction techniques we have purposely chosen a very weak model of computation, i.e., the EPM.

**2. Functional data structures.** In trying to assess whether a particular data structure is optimal or not, it is natural to ask oneself: why is the data stored where it is and not elsewhere? The answer is usually “to facilitate the computation of some functions implicitly associated with the records of the data structure.” For example, one will store keys in the nodes of a binary search tree to be able to branch left or right depending on the outcome of a comparison. An important observation is that nothing demands that a node should store its own key explicitly. All that is required is that whenever the function associated with that node is called, the node had better allow for its prompt evaluation. Having the key stored at the node at all times might be handy but it certainly is more than is strictly needed. There is a classical example of this fact: in their well-known data structure for planar point location [LP1], Lee and Preparata start out with a balanced tree whose nodes are associated with various lists. Then they make the key remark that many elements in these lists can be removed because whenever they are needed by the algorithm they will always have been encountered in other lists before. This simple transformation brings down the amount of storage required from quadratic to linear. However different from the previous one the resulting data structure might be (being much smaller, for one thing), it still has the same *functional* structure as before. In other words, the functions and arguments associated with each node, as well as their interconnections, have gone unchanged through the transformation. Only the assignment of data has been altered. This is no isolated case. Actually, many data structures have been discovered through a similar process. We propose to examine this phenomenon in all generality and see if some useful methodology can be derived from it.

There are several ways of looking at data structures from a design point of view. One might choose to treat them as structured mappings of data into memory. This compiler-level view addresses implementation issues and thus tends to be rigid and overspecifying in the early stage of the design process. Instead, one can take data structures a bit closer to the notation of abstract data type, and think of them as combinatorial structures that can be used and manipulated. For example, a data structure can be modeled as a graph with data stored at the nodes (Earley [Ea]). Semantic rules can be added to specify how the structure can be modified and constraints can be placed to enforce certain “shape” criteria (e.g., balance or degree conditions). If needed, formal definitions of data structures can be provided by means of grammars or operational specifications (Gonnet and Tompa [GoT]). Note that despite the added abstraction of this setting, a data structure is still far removed from an abstract data type (Guttag [G]). In particular, unlike the latter, the former specifies an *architecture* for communicating data and operating on it.

The framework above favors the treatment of data structures as combinatorial objects. It emphasizes *how* they are made and used rather than *why* they are the way they are. This is to be expected, of course, since a data structure may be used for many different purposes, and part of its interpretation is thus best left to the user. Balanced binary trees are a case in point: they can be used as search structures, priority queues, models of parallel architecture, etc. It is thus only natural to delay their interpretation so one can appreciate their versatility. This approach is sound, for it allows us to map

rich combinatorial constructions into useful data structures. It has one negative side-effect, however. Too much concern with the definition and construction aspects of a data structure makes one forget about why it is being used in the first place. What makes the problem all the more troublesome is that algorithms often run two distinct processes: one to build data structures, and another to use them. Whether these processes be distinct in time (e.g., as in a static search tree) or interleaved (e.g., as in dynamic or self-adjusting structures), they can most often be distinguished. Surprisingly, these processes often bear little relation to each other. Building or updating a range tree (Bentley [B2]), for example, and using it to answer a query are only remotely connected tasks. This makes our earlier question all the more difficult to answer: why is a particular structuring of data preferable to another?

This question goes to the heart of our discussion. Data structures are implementations of *paradigms*. The latter, unlike the former, tend to be few and far between, so most data structures appear as variants around certain themes. It is therefore important to facilitate the task of *data structure transformation*, since this is perhaps the most common method for discovering new data structures. To do so, it is useful to think of a data structure not only in terms of its own operational semantics but also of the semantics of the algorithms that use it, the *clients*. Unfortunately, the “combinatorial” view of data structures often lacks this flexibility. Their semantics often do reflect the clients’ needs, but too indirectly to be readily modified around them. This is not to say that modeling data structures after nice, elegant combinatorial objects is not the best route to good design: we believe that it is. Occasionally, however, useful transformations will be obscured or discouraged, because they seemingly get in the way of the combinatorial identity of the objects in question.

We propose a design discipline that involves looking at the *functionality* of data structures from a client’s viewpoint. Informally, we extend the notion of a data structure by associating with each node  $v$  of a graph, not a piece of data as is usually the case, but a function  $f_v$  (or several if needed) as well as a collection of data  $S(v)$ . To evaluate  $f_v$ , it is sufficient, yet not always necessary, to have available  $S(v)$  and some values of the functions associated with nodes adjacent to  $v$ . For expressiveness, we allow  $f_v$  to be a higher-order function (i.e., a function that includes other functions among its arguments). This definition is incomplete but gives the gist of what we will call a *functional data structure* (FDS). In essence, it is a communication scheme for routing transfers of information among a collection of functions. Allowing stepwise refinement is an essential feature of an FDS. Refining an FDS is to replace nodes by other FDS’s iteratively, and in the process, get closer and closer to a data structure in the traditional sense.

An important consequence of this setting is to release the data from memory assignment. Indeed, the pairing  $(v, S(v))$  is virtual and need not correspond to any physical reality. This should not be equated with, say, the independence of linked lists with regard to memory allocation. The abstraction provided by a functional data structure is much stronger. Indeed, it will not even be required that values be physically stored in the records with which they are associated. The only requirement is that these values should be available somehow whenever needed; in particular when the functions to which they are arguments must be evaluated. Whereas a data structure emphasizes data and communication between data, an FDS emphasizes functions and communication between parameters of these functions. It can be argued, of course, that an FDS can be emulated by almost any data structure, so of what good can it be? What makes the consideration of FDS’s worthwhile is that they hint at data structures without *imposing* them. They key benefit of this setting is to allow the designer to bring upon

storage the same effect that *call by need* and *lazy evaluation* are known to have on execution time (Henderson [H]); namely to ensure that only the minimum amount of information needed to evaluate a function in some given amount of time be provided. This leads to a useful *folding* transformation, which we will describe shortly. Before going any further, let us take a simple example to illustrate our discussion. Let  $f$  be a *search* function mapping a key  $q$  to some element  $f(S, q)$  of a set  $S$ :

$$f(S, q) \equiv \text{if } t(S) \text{ then } r(S, q) \\ \text{else if } g(S, q) \text{ then } f(p(S), q) \text{ else } f(S \setminus p(S), q).$$

If  $S$  is too small, i.e.,  $t(S)$  is true, then  $r(S, q)$  provides the answer directly. Otherwise the function recurs with respect to either a subset  $p(S)$  of  $S$  or its complement  $S \setminus p(S)$ , depending on the outcome of the predicate  $g(S, q)$ . This definition suggests an infinite binary tree  $F(S)$  as an appropriate FDS for  $f$ . Each node  $v$  is associated with some set  $S(v)$  obtained by applying to  $S$  compositions of  $\lambda(s)p(s)$  and  $\lambda(s)\{s \setminus p(s)\}$  intermixed in the obvious way.<sup>2</sup> For example, the root is associated with  $S$ , its left child to  $p(S)$ , and its right child to  $S \setminus p(S)$ . The tree can be made finite by ignoring all nodes associated with empty subsets. Next, one associates an FDS for  $\lambda(q)g(S(v), q)$  with each node  $v$  of the tree. As is often the case in multidimensional searching,  $g$  may have a definition similar to  $f$ , e.g.,

$$g(V, q) \equiv \text{if } t'(V) \text{ then } r'(V, q) \\ \text{else if } h(V, q) \text{ then } g(p'(V), q) \text{ else } g(V \setminus p'(V), q).$$

This leads to an FDS,  $G(V)$ , defined for  $V \subseteq S$  with respect to  $g$  similarly to  $F(S)$ . Putting things together, we refine  $F(S)$  by associating  $G(S(v))$  with each node  $v$  of  $F(S)$ . If  $p$  and  $p'$  are very different functions then it is not clear what benefits might be gained from this formalism. But suppose that it is possible to choose  $h$  so that  $p$  and  $p'$  are the same. Then  $f$  and  $g$  have identical "communication schemes." This allows us to perform a so-called *folding* transformation: the idea is to use the same FDS's for both  $f$  and  $g$  by taking each tree  $G(S(v))$  and *folding* it over the subtree of  $F(S)$  rooted at  $v$ . In effect, this is replacing  $G(S(v))$  by an FDS for  $\lambda(q)h(S(v), q)$ . Once  $F(S)$  has been refined in this manner, one will see a data structure with several layers of functional data structures superimposed on it. As a result, the storage used might be greatly inferior to what it would have been without folding the FDS. Indeed, each node  $v$  will thus only need an FDS for  $\lambda(q)h(S(v), q)$  as opposed to an FDS for each  $\lambda(q)h(V, q)$ , where  $V$  is obtained by applying to  $S(v)$  mixed compositions of  $\lambda(s)p'(s)$  and  $\lambda(s)\{s \setminus p'(s)\}$ . To put things in perspective, we must recall that folding might entail redefining  $h$ : all benefits will be lost if the new implementation of  $g$  becomes much more complicated as a result. Although functional data structures have no complexity per se, they *hint* at the ultimate complexity of the data structure. Suppose that  $g(S, q)$  can be evaluated very fast but at great cost in storage. Then folding offers the possibility of trade-off between space and time.

*Searching in the past of mergesort.* Here is a problem which, although a bit esoteric at first, is nevertheless fundamental. Run mergesort on a set of  $n$  distinct keys  $S = \{y_1, \dots, y_n\}$  and record the list produced after each merge. The resulting data structure can be modeled as a balanced binary tree  $T$ : the leaves are assigned the keys  $y_1, \dots, y_n$  from left to right, and each node  $v$  is associated with the sorted list  $R(v)$  consisting

<sup>2</sup> We will use  $\lambda$ -expressions in the following either for sheer convenience as above or in order to distinguish between multivariate functions, such as  $\lambda(x, y)f(x, y)$ , and restrictions to univariate functions with constants, as in  $\lambda(x)f(x, y)$ .

of the keys at the leaves descending from  $v$ . For any  $q$ , define  $s(v, q) = \min \{x \in R(v) \cup \{+\infty\} \mid q \leq x\}$ . What is an efficient data structure for computing  $s(v, q)$ , assuming that  $v$  is given by its inorder rank in the tree and that we are in a pointer machine model? Consider the data structure obtained by storing at  $v$  its inorder rank as well as a pointer to the root of a complete binary tree on  $R(v)$ . This is essentially Bentley's *range tree* [B2]: it allows us to compute  $s(v, q)$  in  $O(\log n)$  time and  $O(n \log n)$  space (search for  $v$  in  $T$ , and then search for  $q$  in  $R(v)$ ). Whether the storage can be reduced to linear and the query time kept polylogarithmic has been a long-standing open problem (Lee and Preparata [LP2]).

We settle this question by interpreting the range tree in functional terms. We have  $s(v, q) \equiv f(v, \text{root}, q)$ , with

$$f(v, z, q) \equiv \text{if } v = z \text{ then } g(R(v), q) \\ \text{else if } z < v \text{ then } f(v, z.r, q) \text{ else } f(v, z.l, q);$$

$z$  is an ancestor of  $v$  or  $v$  itself, and  $z.l$  (resp.,  $z.r$ ) denotes the left (resp., right) child of  $z$ . A natural FDS for  $f$  involves taking  $T$  and associating with each node  $v$  the function  $\lambda(q)g(R(v), q)$  and the set  $R(v)$ . Since  $g$  is a *search* function it can be decomposed as follows (ignoring termination for simplicity):

$$g(V, q) \equiv \text{if } h(V, q) \text{ then } g(p(V), q) \text{ else } g(V \setminus p(V), q).$$

We can now refine the FDS for  $f$  by replacing each node  $v$  by an FDS for  $\lambda(q)g(R(v), q)$ . It is natural to think of  $p$  as a halving function taking a sorted set of numbers  $\{p_1, \dots, p_t\}$  as input and returning  $\{p_1, \dots, p_{\lfloor (t+1)/2 \rfloor}\}$  as output. This makes the implementation of  $h$  quite simple (one comparison), but unfortunately gives two widely different partitioning functions for  $f$  and  $g$ : one is based on the indices of the  $y_i$ 's, the other on their values. So, one can try to make the two partitionings identical to allow *folding*, hoping that  $h$  will not become too complex as a result. To do that, we write  $p(R(v)) \equiv R(v.l)$  (the function  $p$  becomes partial as a result, but it is all right). Instead of an FDS for  $\lambda(q)g(R(v), q)$  at  $v$ , an FDS for  $\lambda(q)h(R(v), q)$  now suffices.

Although by doing so,  $h$  increases in complexity, we must hope that  $h$  remains simpler to compute than  $g$ , otherwise the transformation would be useless. Since  $h$  is a predicate, it can be succinctly encoded as a bit vector  $B(v)$ . We have  $B(v) = [b_0, \dots, b_{|R(v)|-1}]$ , where  $b_i = 0$  (resp., 1) if the element at position  $i$  in  $R(v)$  comes from the left (resp., right) child of  $v$ . Interestingly,  $B(v)$  represents the transcript of pointer motions during the merge at node  $v$ . Note that if  $v$  is a leaf then  $B(v)$  is not defined since that node, being associated with a single key, does not witness any merge. To compute  $h(R(v), q)$  we proceed by binary search in  $B(v)$ . Unfortunately, we cannot do so with the bits of  $B(v)$  alone, so we must find a way to produce the key  $y^v(i) \in R(v)$  corresponding to a given bit position  $i$  in  $B(v)$ . This crucial operation is called *identifying* the bit  $b_i$ . Note that each bit of  $B(v)$  has a distinct *identifier* in  $R(v)$ .

We can assume that  $v$  is not a leaf. If  $b_i = 0$  (resp.,  $b_i = 1$ ) then we have  $y^v(i) = y^{v.l}(j)$  (resp.,  $y^v(i) = y^{v.r}(k)$ ), for some  $j$  (resp.,  $k$ ). In other words, the key corresponding to  $b_i$  can be *traced* either at  $v.l$  or  $v.r$ , depending on the value of  $b_i$ . We easily see that  $j$  (resp.,  $k$ ) is the number of 0's (resp., 1's) in  $[b_0, \dots, b_{i-1}]$ . Suppose that

$$R(v.l) = [2, 3, 5, 7, 11, 13, 17, 19, 23, 27, 29, 31, 37, 41]$$

and

$$R(v.r) = [1, 6, 12, 14, 15, 20, 21, 24, 25, 26, 32, 33, 44, 46].$$

We have

$$R(v) = [1, 2, 3, 5, 6, 7, 11, 12, 13, 14, 15, 17, 19, 20, 21, 23, \\ 24, 25, 26, 27, 29, 31, 32, 33, 37, 41, 44, 46]$$

and

$$B(v) = [1, 0, 0, 0, 1, 0, 0, 1, 0, 1, 1, 0, 0, 1, 1, 0, 1, 1, 1, 0, 0, 0, 1, 1, 0, 0, 1, 1]$$

so, for example, 23 is the identifier of bit #15 in  $B(v)$ . Since this bit is 0, the key 23 can be found in  $R(v.l)$ . Its position is #8, which is also the number of 0's among the first 15 bits of  $B(v)$ ,  $[1, 0, 0, 0, 1, 0, 0, 1, 0, 1, 1, 0, 0, 1, 1]$ .

Iterating on this process until we reach a leaf of  $T$  allows us to identify any bit of  $B(v)$ . For this we assume that each leaf keeps its corresponding identifier alongside. Once identification is possible, we can compute  $h(R(v), q)$  by binary search in  $B(v)$ . This will take  $O(t(n) \log^2 n)$  time, where  $t(n)$  is the time to find  $b_i$  and the sum  $c_i = \sum_{0 \leq k < i} b_k$ , given  $i$ . Computing  $g(R(v), q)$  can then be done by binary search in  $T$  (following the definition of  $g$  and the fact that its FDS has been folded). We can take a shortcut, however, by observing that the value of  $h(R(v), q)$  is given by a bit of  $B(v)$  whose identifier,  $g(R(v), q)$ , is explicitly determined in the course of evaluating  $h$ . The computation of  $g$  will then also take  $O(t(n) \log^2 n)$  operations.

Let us examine  $t(n)$ . To compute  $b_i$  and  $c_i$ , given  $i$  and  $v$ , we break up  $B(v)$  into computer words  $\beta_0, \dots, \beta_{m-1}$  (filling each word up to  $\lfloor \log n \rfloor$  bits) and we make the sequence  $\beta_0, \dots, \beta_{m-1}$  the leaves of a complete binary tree. At each internal node of the tree we indicate the number of 0's and the number of 1's among the bits of  $B(v)$  stored at the leaves descending from its left child. With this data structure, it is easy to find in  $O(\log n)$  time the word  $\beta_j$  that contains the bit  $b_i$  as well as the number of 1's or 0's among the bits of  $\beta_0, \dots, \beta_{j-1}$ . At that point, it remains to examine each bit of  $\beta_j$  to complete the task. Bit enumeration on an EPM can be done very simply by searching for the number  $\beta_j$  in a perfectly balanced binary search tree of  $2^{\lfloor \log n \rfloor}$  leaves and associating left turns with 0 and right turns with 1.

To conclude,  $O(\log^3 n)$  time suffices to compute  $s(v, q)$ . To see that only linear storage is required, we remark that besides the input the number of bits used is proportional to the number of steps taken by running mergesort on  $n$  keys. This quantity is also proportional to the number of bits needed to store the input. Therefore, without any reference to the size of a computer word, we can conclude to the linearity of the data structure (in the sense that a data structure for a Turing machine is linear). This result holds on a pointer machine whose only operations are comparisons and additions. Note that whether the keys in  $S$  are integers or real numbers is irrelevant to our analysis. Also, one should observe that the use of bits need not be explicit in the algorithm. It will actually not appear at all in the implementation which we give in the next section.

It is easy to modify the data structure to produce an  $O(n)$  space,  $O(\log^4 n)$  time solution for range counting in two dimensions. But one can do much better. We must stop at this point to notice that the transformations which we have used so far are quite crude. They treat the recursive steps of the query-answering process as a sequence of independent computations. To enable the algorithm to use at any time information gathered at previous steps we must modify the refinement of the underlying functional data structure. The idea is to exploit the fact that the operations performed in the four nested loops of an  $O(\log^4 n)$  time algorithm are unlikely to be independent. We feel that our point concerning the fruitfulness of functional data structures has been made, however, so we will not use the previous formalism any further. Rather, we will rely

on the intuition that it allowed us to develop and, in particular, we will keep the idea of folding in the back of our mind.

### 3. Range counting.

**3.1. Range counting on a random access machine.** We will describe a linear-size solution to range counting in two dimensions on a RAM with logarithmic query time. Although this result is not the strongest (the same holds on an APM as shown in the first table), it is very efficient in practice and illustrates most of the new ideas in simple terms. We have implemented the algorithm in Pascal (aiming for clarity rather than efficiency). The code is quite short, so we will give it in its entirety. For convenience, we assume that  $n \geq 2$  and that a word can store numbers not just in  $[0, n]$  as we said earlier but in the range  $[0, 4n \log^2 n]$ . Then, rather amazingly, the data structure consists *solely* of four arrays  $X, Y, B, C$ : array  $[0..n-1]$ . The arrays  $X$  and  $Y$  contain, respectively, the  $x$  and  $y$  coordinates of the points in increasing order;  $B$  and  $C$  are a bit more mysterious. Here is an example. If the input is

$$\{(34, 3), (12, 1), (28, 23), (63, 15), (2, 35), (5, 17), (52, 43), (22, 13)\},$$

then we have

$$B = [64, 97, 81, 66, 33, 82, 34, 83]$$

and

$$C = [17, 35, 69, 6, 7, 9, 10, 12].$$

How do these numbers come about? We begin with an informal description of the algorithm.

To shorten the code given in this paper we make a number of simplifying assumptions, every one of which can be easily satisfied with a bit of care: (1)  $n$  is a power of two (pad with points at infinity, if needed); (2) all coordinates are distinct (go into rank space using presorting, if needed); (3) the query does not share coordinates with the point set and falls inside the smallest 2-range containing the input points.

It is convenient to leave aside the function  $s(v, q)$  and use the related *ranking* function  $r(v, q) = |\{y \in R(v) | y < q\}|$ . To compute this function, we keep a similar data structure: each internal node  $v$  of  $T$  stores the bit vector  $B(v)$ , broken up into words  $\beta_0, \dots, \beta_{m-1}$ , as usual. We also have an array  $C(v)$ , whose cell #  $i$  contains the number of 1's in  $\beta_0, \dots, \beta_i$ . The problem is now to find the rank  $r$  of  $q$  in  $R(w)$ , assuming that we know its rank  $r'$  in  $R(v)$  (without loss of generality,  $w$  is the right child of  $v$ ). This rank is the number of 1's in  $B(v)$  at positions  $[0..r'-1]$ . To find it, we must locate the corresponding bit in  $B(v)$ : first we find the word  $\beta_j$  that contains it, which is done in  $O(1)$  time on a RAM, then we compute its relative position  $k$  in  $\beta_j$ . We also set  $r$  to the approximate count given by cell #  $(j-1)$  in  $C(v)$ . There now remains to shift  $\beta_j$  by  $k$  bits (done by division) and find the number of 1's in the remaining word by table look-up. Adding this number to  $r$  produces the desired result. So, after an initial binary search in the array  $Y = R(\text{root})$ , we find the rank of  $q$  in  $R(\text{root})$ , and percolate down to  $v$ . To carry out these computations, we need powers of two and tallies of ones for each integer in  $[0, n-1]$ . We will store all the  $B(v)$ 's and tallies in one array  $B[0..n-1]$ , and all the partial counts and powers of two in another array  $C[0..n-1]$ .

*The data structure.* The arrays  $X[0..n-1]$  and  $Y[0..n-1]$  give the  $x$  and  $y$  coordinates of the  $n$  points in increasing order. Let  $\lambda = \log n$ ,  $\mu = 2(1 + \lceil \log \lambda \rceil)$ , and  $M = 2^\mu$ . In the code below,  $n$ ,  $M$ , and  $\lambda$  (denoted lambda) will be global variables. Note that the word size  $w$  has been assumed to be at least as large as

$\lfloor \log n + 2 \log \log n + 2 \rfloor + 1 \geq \lambda + \mu$ . Let  $P, \Lambda_i, M_i$  be the sequence of bits in  $B[i]$ , from left to right.

- (1)  $P$  is a sequence of  $w - \lambda - \mu$  zeros (padding).
- (2)  $\Lambda_i$  is a sequence of  $\lambda$  bits, called the  $\lambda$ -part of  $B[i]$ . Since  $n$  is a power of two, we can nicely characterize each node of  $T$  by a pair  $(a, b)$ , where  $a$  is its height (0 for a leaf,  $\lambda$  for the root) and  $b$  is its rank at height  $a$ , counted from left to right starting at 0. Sort all the nodes in lexicographic order and concatenate into one string  $b[0..l]$ , in this order, all the bit vectors  $B(v)$  (recall that these vectors are defined only from height 1 up). The string of bits  $\Lambda_0 \cdot \Lambda_1 \cdot \dots \cdot \Lambda_{n-1}$  is set to  $b[0..l]$ . Note that the count of bits is the same in both cases ( $l = \lambda n - 1$ ) but that the boundaries of  $B(v)$ 's might not coincide at all with those of  $\lambda$ -parts. In the following, we will use the notation  $b[i]$  to indicate the  $(i+1)$ st bit of  $b[0..l]$ .
- (3)  $M_i$ , called the  $\mu$ -part of  $B[i]$ , contains the number of 1's in the binary representation of  $i$  (note that  $\mu$  bits are ample for that purpose).
- (4) The  $\lambda$ -part of  $C[i]$  is equal to  $2^i$  for  $i \in [0, \lambda - 1]$ . For each  $i \in [0, \lambda - 1]$ , let us (only in thought) turn to 0 each bit of the  $\lambda$ -part of  $C[i]$ . Then for each  $i \in [0, n - 1]$ ,  $C[i]$  is the total number of bits equal to 1 among the  $\lambda$ -parts of  $B[0..i]$ . Note that the powers of two stored in the  $\lambda$ -parts never conflict with the tallies of ones because the number of 1's among the first  $\lambda$   $\lambda$ -parts of  $B[0..\lambda - 1]$  can be encoded over  $\lfloor \log(\lambda^2) \rfloor + 1 \leq \mu$  bits.

We will illustrate these definitions with the first cells of  $B$  and  $C$ . The mergesort starts with the sequence of points  $x$ -sorted  $(2, 35), (5, 17), (12, 1), (22, 13), \dots$ , and merges  $\{35\}, \{17\}$  (which gives  $b[0] = 1$  and  $b[1] = 0$ ) and then  $\{1\}, \{13\}$  (which gives  $b[2] = 0$  and  $b[3] = 1$ ). As a result, the  $\lambda$ -part of  $B[0]$  is 100. Since  $\mu = 4$ , the  $\mu$ -part of  $B[0]$  is expressed over 4 bits. It is equal to the number of 1's in 0, that is, 0000. This gives  $B[0] = 1000000$  in binary, i.e., 64 in decimal. The  $\lambda$ -part of  $C[0]$  is equal to 1. This number, shifted by  $\mu$  bits, becomes 16, to which the number of 1's in  $B[0]$  ( $=1$ ) must now be added. This gives the final value  $C[0] = 17$ .

*The preprocessing.* We use a nonrecursive mergesort to fill the  $\lambda$ -parts of  $B$ . To do so, we declare a temporary array  $T[0..n]$ . Variables *step* and *l* form the lexicographic pair in the sort. A counter *index* maintains the current position in  $B$ . A bit is inserted to the right after multiplying the current word by two to make room for it. When a  $\lambda$ -part is full (“if lambda = fill then begin”) it is shifted by  $\mu$  bits to its final position, and the  $\mu$ -part is computed by enumerating the bits of *index*. The powers of two,  $\{2^0, 2^1, \dots, 2^{\lambda-1}\}$  stored in the  $\lambda$ -parts of  $C$  are computed in an extra pass (“for index := 0 to lambda - 1 do”). Initially,  $X$  contains the  $x$ -coordinates in increasing order and  $Y[i]$  is the  $y$ -coordinate corresponding to  $X[i]$ ;  $B$  and  $C$  are set to 0, and *maxint* stands for any integer larger than the coordinates. At the end  $Y$  contains the  $y$ -coordinates in increasing order.

**procedure** Preprocessing;

step := 2 * step
end;
fill := M;
for index := 0 to lamda - 1 do
  begin C[index] := C[index] + fill;
  fill := 2 * fill end
end;

```

*The query-answering algorithm.* Let  $[x_1, x_2] \times [y_1, y_2]$  be the query range. The function RangeCount (query) decomposes  $[x_1, x_2]$  into  $O(\log n)$  canonical pieces, each represented by a node of  $T$ . The count of points inside the query is obtained by summing up the values  $r(v, y_2) - r(v, y_1)$  for each  $v$  in the decomposition. Since we add up differences, we may redefine the function  $r(v, q)$  as follows. Let  $i$  be the number of elements in  $R(v)$  strictly less than  $q$ . By construction, the  $(i + 1)$ st bit in the vector  $B(v)$  (if defined) appears somewhere in  $b[0..l]$ , say as  $b[j]$ ; then set  $\rho(v, q) = j$ . Consistently, all the bits of the  $B(v)$ 's will be addressed from now on by their position in  $b[0..l]$ .

Next, we describe the functions needed in a bottom-up fashion. The function One (pos) returns the number of 1's in  $b[0, \text{pos} - 1]$ . First, we find the index  $i$  such that  $B[i]$  contains the bit  $b[\text{pos}]$ . To compute the number of 1's in  $B[i]$  left of the bit  $b[\text{pos}]$ , we shift and truncate  $B[i]$  accordingly to obtain the integer  $j$  (we use a little trick to avoid shifts by  $\lambda$ ). Then we use the  $\mu$ -parts of  $B$  to find  $z$ , the number of 1's in  $j$ . This number is added to  $C[i - 1]$  in order to get the final result. We need a corrective term if  $i - 1$  is less than or equal to  $\lambda - 1$  (because of the powers of two stored in the first cells of  $C$ ).

```

function One (pos: integer): integer;
  var i, j, z: integer;

```

```

begin
   $i := \text{pos} \text{ div } \text{lambda};$ 
   $j := B[i] \text{ div } (2 * M * (C[\text{lambda} * (1 + i) - \text{pos} - 1] \text{ div } M));$ 
   $z := B[j] - M * (B[j] \text{ div } M);$ 
  if  $0 < i$  then  $z := z + C[i - 1];$ 
  if  $(0 < i)$  and  $(i \leq \text{lambda})$  then  $z := z - M * (C[i - 1] \text{ div } M);$ 
   $\text{One} := z$ 
end;

```

The function `Newpos` (`dir`, `block`, `pos`, `width`) allows us to trace the position of a bit  $b[\text{pos}]$  from a node  $v$  to a child  $w$ . In other words, it computes the values  $\rho(w, q)$ , given  $\rho(v, q)$ . (The reader familiar with Willard [W2] might guess rightly that we are trying here to simulate the effect of *downpointers*). We allow the value of  $\rho(w, q)$  to be negative. Why is that so? The first cells of  $B$  store the history of the first pass of mergesort. Therefore, these do not correspond to leaves of  $T$  but to parents of leaves. From the lexicographic ordering in  $B$ , we can see that the leaves of  $T$ , if they were to be stored in  $B$ , would appear in positions  $-n, -n + 1, \dots, -1$ . We do not need to store these leaves because no identification is required for range counting. The arguments of `Newpos` (`dir`, `block`, `pos`, `width`) denote, respectively,

- (1) *dir*: which child of  $v$  is being considered (0 if left, 1 if right); we use an integer instead of a Boolean only for brevity.
- (2) *block*: the position in  $b[0..l]$  of the first bit of  $B(v)$ ,
- (3) *pos*: the position in  $b[0..l]$  of the bit of interest in  $B(v)$ ,
- (4) *width*: the number of leaves in the subtree rooted at  $v$ .

Because of the lexicographic ordering of the nodes of  $T$ , the starting position of  $B(w)$  in  $b[0..l]$  is “ $\text{block} - n$ ” (left child) or “ $\text{block} - n + \text{width}/2$ ” (right child).

```

function Newpos (dir, block, pos, width: integer): integer;
begin
  if dir = 0 then Newpos := pos - n + One(block) - One(pos)
  else Newpos := block - n + One(pos) - One(block) + (width div 2)
end;

```

The function `Path` ( $A, q$ ) searches for  $q$  in the array  $A$  of type “Tableau = array  $[0..n - 1]$  of integer”, and returns  $\min(\{i | q \cong A[i]\} \cup \{n - 1\})$ . It will be used for two purposes: first to locate  $y_1$  and  $y_2$  in  $Y$ , and then  $x_1$  and  $x_2$  in  $X$ .

```

function Path (A: Tableau; q: integer): integer;
  var l, k, r: integer;
begin
  l := 0; r := n - 1;
  while l < r do begin
    k := (l + r) div 2;
    if q <= A[k] then r := k end
    else l := k + 1 end;
  Path := l
end;

```

Let  $l_1$  and  $l_2$  be the two leaves of  $T$  returned by `Path` when applied, respectively, to  $x_1$  and  $x_2$  in  $X$ . Let  $l_0$  be the leaf preceding  $l_1$  in inorder (such a leaf is guaranteed to exist because of our assumption that the query falls entirely within the smallest box containing the input points). The nodes of the decomposition of  $[x_1, x_2]$  are precisely those adjacent to the path from  $l_0$  to  $l_2$ , but not on it, whose inorder ranks fall in

between the ranks of these two leaves. To find them, it suffices to determine the least common ancestor  $w$  of  $l_0$  and  $l_2$ , and then collect the nodes  $N_1$  (resp.,  $N_2$ ) hanging off the right (resp., left) of the path from  $l_0$  (resp.,  $l_2$ ) to  $w$ . The number of points inside the query range is

$$\sum_{v \in N_1} \rho(v, y_2) + \sum_{v \in N_2} \rho(v, y_2) - \sum_{v \in N_1} \rho(v, y_1) - \sum_{v \in N_2} \rho(v, y_1).$$

All four computations are carried out by calling the function `Cum (cut, init, path, dir)`. Let us take the case of  $\sum_{v \in N_1} \rho(v, y_2)$ , for example. Then “cut” is the number of leaves descending from  $w$ , “init” is equal to  $\rho(\text{root}, y_2)$ , “path” to  $l_0$ , and “dir” to 0 (it is 1 for  $N_2$ ). The bits of “path” indicate the sequence of turns from the root to  $l_0$ . Along with “cut,” this allows us to determine  $w$  and, hence, the nodes of  $N_1$ .

```

function Cum (cut, init, path, dir: integer): integer;
  var pos, z, bit, block, cur: integer;
begin
  pos := init; z := 0; block := (lambda - 1) * n; cut := n;
  while cur >= 2 do begin
    bit := (2 * path) div cur - 2 * (path div cur);
    if (cur < cut) and (bit = dir) then
      z := z + Newpos(1 - dir, block, pos, cur);
    pos := Newpos(bit, block, pos, cur);
    cur := cur div 2; block := block - n + bit * cur
  end;
  Cum := z
end;

```

For completeness, we also give the code of the mainline, which is quite straightforward.

```

function RangeCount (x1, x2, y1, y2: integer): integer;
  var left, right, low, high, cut, z: integer;
begin
  low := Path(Y, y1) + (lambda - 1) * n;
  high := Path(Y, y2) + (lambda - 1) * n;
  left := Path(X, x1) - 1; right := Path(X, x2); cut := n;
  while (2 * left) div cut = (2 * right) div cut do cut := cut div 2;
  z := Cum (cut, high, left, 0) + Cum (cut, high, right, 1);
  RangeCount := z - Cum (cut, low, left, 0) - Cum (cut, low, right, 1)
end;

```

The description of the algorithm is now complete. Again, observe that the coordinates can be assumed to be arbitrary reals, if needed. Note that the ratio between the storage needed and the input size is only 2. In the context of this algorithm, the  $\lambda$ -parts of  $B$  cannot be compressed. This is not true of  $C$ , however: this array can indeed be shrunken arbitrarily by skipping chunks at regular intervals. The blanks can be *made up* by further work in  $B$  at query-answering time. This simple remark shows that the ratio can be brought arbitrarily close to 1.5, while increasing the query time only by a constant factor.

One might wonder how much dependent on the RAM model the algorithm really is. We will see that, although it loses some of its simplicity in the process, the algorithm can still be ported to a pointer machine.

**3.2. Range counting on a pointer machine.** To avoid the need for address calculations, we implement the tree  $T$  with pointers. Each node  $v$  is associated with a list  $W(v)$  (assumed to be doubly-linked for convenience). Aside from pointers for the list

itself, each record of  $W(v)$  has eight fields,  $B, C, C', D, E, F, G, H$ , made of one word each. The key specification is that, concatenated together, the  $B$ -fields of  $W(v)$  form the bit vector  $B(v)$ . This statement must be clarified and refined a little. First of all, only the  $\lambda = \lfloor \log n \rfloor$  least significant bits of a  $B$ -field will contain bits of  $B(v)$ . These are called the *meaningful* bits of the  $B$ -field. We will ignore the others. With this scheme each  $B$ -field, except possibly the last one, has precisely  $\lambda$  meaningful bits. As regards the last one, we may assume that its meaningful bits are right-justified, and that an extra record is added to indicate how many bits of the  $B$ -field are indeed meaningful. Let the subscript  $k$  refer to the  $k$ th record of  $W(v)$ . Then,

- (1)  $C_k$  stores the number of 1's in  $B_0, \dots, B_k$  and  $C'_k$  the number of 0's.
- (2)  $D_k$  stores the identifier of the least significant bit of  $B_k$ . Recall that this is the value of  $R(v)$  in one-to-one correspondence with that bit.
- (3) Consider the smallest value of  $R(v)$  greater than or equal to integer  $q$  that appears as a  $D$ -field of  $W(v)$ ; we define  $n(v, q)$  as the address of the record containing this  $D$ -field if it exists, or as a null pointer if it does not. Let  $w$  (resp.,  $w'$ ) be the left (resp., right) child of  $v$ ; then  $E_k$  (resp.,  $F_k$ ) contains the address  $n(w, D_k)$  (resp.,  $n(w', D_k)$ ), or more precisely a pointer to the relevant record. These fields are left blank if  $v$  is a leaf.
- (4)  $G_k$  and  $H_k$  are not immediately needed and, for the sake of clarity, will be introduced later on.

The root of the tree receives a special treatment: we augment  $W(\text{root})$  with a balanced search tree for  $R(\text{root})$ . This will allow us to compute the rank of a  $y$ -coordinate and thus get the query-answering process started. All the fields should be well motivated from the previous discussion, except perhaps for  $E$  and  $F$ . These fields play a role somewhat similar to Willard's *downpointers* [W2]. They provide a mechanism to avoid repeated binary searches when examining sequences of lists  $W(v)$ . Unlike downpointers, however, they do not span the whole range of values in  $R(v)$ , but an evenly distributed sample. Before proceeding with a description of the query algorithm, we should make the obvious observation that, as before, the data structure is linear in size. Furthermore, it can be constructed in  $O(n)$  space and  $O(n \log n)$  time, using mergesort as a basis for the algorithm.

To answer a query, we simulate the process described in the previous section. We start with a binary search in  $R(\text{root})$  with respect to  $y_1$  and  $y_2$  and follow  $E$ - and/or  $F$ -fields appropriately. Let  $v$  be an internal node of  $T$  and  $w$  be one of its children (say, the left one, without loss of generality). We need to compute  $r(w, q)$ , given  $r(v, q)$ . We will show how to find the pair  $(n(w, q), r(w, q))$ , given  $(n(v, q), r(v, q))$ . This is called computing a *transition*. Let  $B_k$  be the  $B$ -field of the record at address  $n(v, q)$ . We assume for now the availability of a primitive operation tally  $(k, t)$  which takes the number  $B_k = 0 \dots 0.x_0 \dots x_{t-1}$  in binary and an index  $t$  ( $0 < t < \lambda$ ), and returns  $x_0 + x_1 + \dots + x_{t-1}$ . By definition, the first  $r(v, q)$  bits of  $B(v)$  are contained in the  $B$ -fields of  $W(v)$  preceding  $n(v, q)$ , and perhaps in a prefix of  $B_k$ . Using  $C_k$  and  $C'_k$  we can find the length of this prefix using  $+$ ,  $-$ . Next, we call the tally function to compute the number of 1's in the prefix, which gives us in turn the number of 0's among the first  $r(v, q)$  bits of  $B(v)$ , that is,  $r(v, q)$ . To compute  $n(w, q)$ , we just follow the pointer in  $E_k$ . Since each  $B$ -field has at most  $\lambda$  bits,  $n(w, q)$  will be either the address of the record where we land, or it will be the address of its predecessor in the list  $W(w)$ . To find out we can use  $q$  and  $D$ -fields, or if we prefer, we can use  $r(w, q)$  and  $C, C'$ -fields. We mention the latter method for the following reason: it is possible to compute a transition from  $(n(v, q), r(v, q))$  to  $(n(w, q), r(w, q))$  *without* prior knowledge of  $q$ . This will be used in the next section.

To implement  $\text{tally}(k, t)$ , we use the fields  $G_k$  and  $H_k$  as well as the primitive *shift* available on an APM. This, we should recall, takes  $i \leq \lfloor \log n \rfloor$  as input and returns  $10^i$  (1 followed by  $i$  0's). It is needed to simulate a RAM at the word level in constant time. To do so, let  $\alpha = \lfloor \log \lambda \rfloor + 1$ ,  $\beta = \lfloor \log \alpha \rfloor + 1$  and  $\gamma = \lfloor \log \beta \rfloor + 1$  (these quantities are computed by binary search in preprocessing). For any integer  $u$  ( $0 \leq u < n$ ), we define the function  $h(u, i, j) = \lfloor u/2^{\lambda-j} \rfloor - 2^{j-i} \lfloor u/2^{\lambda-i} \rfloor$  if  $0 \leq i < j \leq \lambda$ , and 0 otherwise: if  $u = u_0 \cdots u_{\lambda-1}$  in binary, then  $h(u, i, j) = u_i u_{i+1} \cdots u_{j-2} u_{j-1}$ . Next, we define a word  $\Theta = t_0 \cdots t_{\lambda-1}$  as follows: for  $i = 0, \dots, 2^\beta$ , let  $t_{i\gamma} \cdots t_{(i+1)\gamma-1}$  be the number of 1's in the binary representation of  $i$ . To set up the fields  $G_k = g_0 \cdots g_{\lambda-1}$  and  $H_k = h_0 \cdots h_{\lambda-1}$ , let  $p_0 \cdots p_{\lambda-1}$  be the  $\lambda$  meaningful bits of  $B_k$  (Fig. 1). Recall that the last  $B$ -field of  $W(v)$  might be short of  $\lambda$  meaningful bits; this special case can be treated easily, however, and will be omitted here.

- (1) For each  $i = 0, \dots, \lfloor \lambda/\alpha \rfloor - 1$ , we have  $g_{i\alpha} \cdots g_{(i+1)\alpha-1} = p_0 + \cdots + p_{(i+1)\alpha-1}$ .
- (2) For each  $i = 0, \dots, \lfloor \lambda/\alpha \rfloor - 1$  and each  $j = 0, \dots, \lfloor \alpha/\beta \rfloor - 1$ , we have  $h_{i\alpha+j\beta} \cdots h_{i\alpha+(j+1)\beta-1} = p_{i\alpha} + \cdots + p_{i\alpha+(j+1)\beta-1}$ . Since an integer  $x$  can be represented on  $\lceil \log(x+1) \rceil$  bits, one will easily check that the space provided for  $\Theta$  and the various blocks of  $G_k$  and  $H_k$  is sufficient, for  $n$  large enough.

We can now implement  $\text{tally}(k, t)$ . To do so, we evaluate in sequence

$$i = \alpha \left\lfloor \frac{t}{\alpha} \right\rfloor,$$

$$j = i - \alpha,$$

$$l = i + \beta \left\lfloor \frac{t-i}{\beta} \right\rfloor,$$

$$m = l - \beta,$$

$$p = h(B_k, l, t),$$

FIG. 1

then

$$\text{tally}(k, t) = h(G_k, j, i) + h(H_k, m, l) + h(\Theta, p\gamma, (p+1)\gamma).$$

The algorithm computes successive approximations of the answer. The vector  $p_0 \cdots p_{l-1}$  is broken up into three blocks  $p_0 \cdots p_{i-1}$ ,  $p_i \cdots p_{l-1}$ , and  $p_l \cdots p_{l-1}$ . The number of 1's in the first and second blocks are given directly by reading off one of the elementary pieces of  $G_k$  and  $H_k$ . For the last block, one turns to  $\Theta$  for the answer.

To summarize, range counting can be done in  $O(n)$  space and  $O(\log n)$  query time on an APM. What happens if we only have an EPM? In that case, we may ignore the fields  $H$  and  $G$  altogether. Given any prefix of a  $B$ -field, we can count its number of 0's or 1's by examining each of its bits. To do so, we set up a binary search tree on the keys  $\{0, \dots, 2^\lambda - 1\}$  so as to identify the turns of a search with the binary representation of the search key. At most a constant number of subtractions might be needed for each node of  $T$  visited. These can be simulated in  $O(\log n)$  time on an EPM. The query time will be  $O(\log^2 n)$ . This completes our discussion of the static case. The data structures described above for the various models form the skeleton of the remaining algorithms. We refer to them as  $M$ -structures ( $M$  for mergesort). They can all be built in  $O(n \log n)$  time.

*The dynamic case.* We begin with a number of remarks which apply to all our subsequent treatments of dynamic problems. As we said earlier on, we will always assume that in the dynamic case the underlying model of computation is an EPM. One difficulty in dynamizing the previous data structure is trying to assign a value to  $\lambda$ . Since  $n$  changes constantly in a dynamic environment, so will  $\lambda$  if we set its value to  $\lfloor \log n \rfloor$ , as in the static case. This may imply that the entire data structure will need to be reconfigured at all times. To overcome this problem we relax the assignment of  $\lambda$  and only require that its value should lie between  $\frac{1}{3} \log n$  and  $\log n$  (for  $n$  larger than some appropriate constant). This is called the *compaction invariant*. The idea is that as soon as the compaction invariant ceases to be satisfied the entire data structure is to be rebuilt from scratch for a value of  $\lambda$  equal to  $\lfloor \frac{2}{3} \log n \rfloor$ . Clearly, no such reconstruction will be needed until after  $\Omega(n)$  updates. Looking at a reconstruction as a sequence of insertions (at a polylogarithmic cost each), we will easily argue that the amortized cost of maintaining the compaction invariant is absorbed by the cost of individual updates. We now return to the specific problem of range counting in two dimensions.

A number of modifications to the  $M$ -structure are in order. To begin with, we replace fields  $C$  and  $C'$  by a dynamic search tree  $C(v)$ , e.g., a 2-3 tree (Aho et al. [AHU]), whose leaves are associated with the  $B$ -fields of  $W(v)$ . Each node (including the leaves) stores the number of meaningful 0's and the number of meaningful 1's in the  $B$ -fields of the leaves descending from it. This will essentially replace the use of  $C$ -fields while granting dynamic capabilities to the structure. Fields  $C$ ,  $C'$ ,  $D$ ,  $E$ ,  $F$ ,  $G$ ,  $H$  are no longer needed. The most important modification is the emulation of a *variable* word-size. In general,  $B$ -fields will not be filled entirely with meaningful bits. A  $B$ -field  $\beta$  will have only a suffix of meaningful bits, that is, a contiguous sequence in right-justified position. The length of this suffix varies between 0 and  $\lambda$ . It can be determined by adding the counts of 0's and 1's associated with the leaf  $\beta$  in  $C(v)$ .

**Invariant:** If  $\beta$  is not the only  $B$ -field at node  $v$ , then it must have between  $\lfloor \lambda/2 \rfloor$  and  $\lambda$  meaningful bits.

Without loss of generality, let  $w$  be the left child of  $v$ . We describe the computation of  $r(w, q)$ , given  $r(v, q)$ . Let  $\beta$  be the  $B$ -field that contains the bit of  $B(v)$  at position  $r(v, q)$ . We can find  $\beta$  by using the counts of 0's and 1's stored at each node of  $C(v)$

as partial ranks, and performing a simple binary search. This is similar to finding a key in a search tree, given its rank. Once  $\beta$  has been found, the position  $p$  of the desired bit in the  $B$ -field follows immediately. Note that this may require a subtraction, which we can afford since it takes only  $O(\log n)$  time on an EPM. As is often the case, however,  $p$  will only be used for comparisons, so it can be represented as a pair  $(r(v, q), p')$ , where  $p' = r(v, q) - p$  is the rank determined by the binary search. In this way, no subtraction is needed. While doing the search, we will collect partial counts of 0's: this is a special case of one-dimensional range search. If we visit a node  $z$  and branch to its right child, we update the partial count by adding to it the number of 0's provided with the left child of  $z$ . This is straightforward, so we omit the details. Finally, at the end of the search, we add up to this partial count the number of 0's among the first  $p$  bits of  $\beta$ . To enumerate these  $p$  bits we use binary search. Note that it is important to know the number of meaningful bits in  $\beta$ ; also the compaction invariant ensures that the tree needed for the enumeration remains of linear size. This gives us exactly  $r(w, q)$ . Clearly, a single transition takes  $O(\log n)$  steps. Answering a query can then be done in  $O(\log^2 n)$  time.

Next, we look at the problem of inserting or deleting a bit in a  $B$ -field  $\beta$ . We insert a new bit by locating its position in the  $B$ -field. To make room for the newcomer, we shift to the left the prefix of  $\beta$  ending at that position. Conversely, deleting a bit causes a right shift of a prefix of  $\beta$ . Every node of  $C(v)$  on the path from the current leaf to the root must have its partial counts updated, that is, incremented by  $-1$ ,  $0$ , or  $1$ . Although an EPM does not allow subtraction in constant time, we can get around this difficulty by maintaining a doubly-linked list of length  $n$  dynamically, each record storing its rank in the list. Instead of storing counts in  $C(v)$ , we store pointers to the record with the appropriate rank, which can always be done since no count can exceed  $n$ . This allows us to update counts in constant time while adding only a linear term to the size of the data structure.

What happens if the shift causes an overflow or an underflow? In the first case, we insert a new record in  $W(v)$  and use the  $B$ -field of that record to absorb the overflow. Since we then have  $\lambda + 1$  bits at our disposal, we clear the old  $B$ -field and allocate  $\lfloor \lambda/2 \rfloor$  of these bits to it, the remaining  $\lambda + 1 - \lfloor \lambda/2 \rfloor$  going into the new  $B$ -field. This causes the insertion of one node in  $C(v)$ . In case of underflow, we pick any adjacent  $B$ -field (one is always to be found since, by definition, no underflow can occur if  $W(v)$  has a single record) and evaluate their combined number of bits. If it exceeds  $\lambda$ , then we reassign the two  $B$ -fields with each at least  $\lfloor \lambda/2 \rfloor$  bits. Otherwise, we use a single  $B$ -field and discard the other one. If the tree  $C(v)$  falls out of balance, we apply the necessary rotations to reconfigure it into an acceptable shape. Rather than going into details, let us give a general argument, to be used again later on, showing why all counts can be updated in  $O(\log n)$  time. The main observation is that the Steiner minimal tree of all nodes whose counts need to be updated has size  $O(\log n)$ . We can then (conceptually) orient the edges of this subtree upwards and update every count by pebbling the resulting dag. Indeed, the counts at a node can be obtained from the counts of its children. See Knuth [K1] for variants.

Let us recap the sequence of operations for inserting a new point  $(x, y)$  into the structure. We start with a binary search in  $T$  with respect to  $x$ . This gives us the root-to-leaf path  $v_1, \dots, v_i$  at whose nodes an insertion must take place. At the root of  $T$  we perform a binary search in  $R(\text{root})$  to compute  $r(\text{root}, y)$ , and then descend in each of the relevant nodes by successive transitions. We are then ready to insert a new bit in each of the selected lists  $B(v_i)$ . Note that the value of this bit is determined by whether  $v_{i+1}$  is the right or left child of  $v_i$ . Deletions are handled in a similar fashion.

Of course, we must deal with the possibility of the tree  $T$  falling out of balance. For this purpose, we use a weight-balanced tree, also known as a  $\text{BB}[\alpha]$  tree. The idea, due to Lueker and Willard [L], [WL], [W2], is to rebuild the entire subtree rooted at the highest node going out of balance. This rebuilding is only expensive high up in the tree, but by chance weight-balanced trees go out of balance mostly at lower levels. With a proper choice of  $\alpha$ , it can be shown (Willard and Lueker [WL]) that a node  $v$  cannot go out of balance twice before a number of updates at least proportional to the size of the subtree rooted at  $v$  has taken place among its leaves.

A simple counting argument reveals the performance of this scheme. We create on the order of  $\log^2 n$  credits for every update, which we distribute evenly to each node  $v_i$  visited during the update. This should be enough to pay for the updates in each  $C(v_i)$  and still leave on the order of  $\log n$  credits to each node  $v_i$ . These remaining credits are stored in the *node-bank* of  $v_i$ . Suppose now that  $v_i$  falls out of balance. As we said earlier, after  $v_i$  last fell out of balance, at least  $\Omega(|H|)$  updates must have occurred at the leaves of the subtree  $H$  rooted at  $v_i$ . For this reason, the node-bank of  $v_i$  will have available at least on the order  $|H| \log n$  credits. Since constructing a data structure of size  $p$  takes  $O(p \log p)$  time, these credits can pay for the entire rebuilding of  $H$  and of all the structures in  $\{C(v) | v \in H\}$ . The node-bank at  $v_i$  is thus emptied, but ready to be refilled with future updates taking place below it. This proves that insertions and deletions can be performed in  $O(\log^2 n)$  amortized time. A more complex strategy (Willard and Lueker [WL]) can be invoked to spread the rebalancing over all the updates in an even manner and obtain an  $O(\log^2 n)$  worst-case update time.

We close this section with the problem of maintaining the compaction invariant. Our discussion will apply to range counting as well as to all the other dynamic problems considered later on. For this reason, we make the general assumption that any update among  $n$  active input elements requires  $O(\log^c n)$  amortized time ( $c$  is an arbitrary nonnegative constant). Between two consecutive reconstructions, assume that each update generates a number of credits equal to  $\log^c n$ , where  $n$  is the input size at the time of the update. We will show that these credits can cover the cost of the second reconstruction (up to within a constant factor). Let  $p$  (resp.,  $n$ ) be the size of the input during the first (resp., second) reconstruction. We have either  $\lfloor \frac{2}{3} \log p \rfloor < \frac{1}{3} \log n$  or  $\lfloor \frac{2}{3} \log p \rfloor > \log n$ . In the former case, we derive that  $n > p^2/8$ , therefore at least  $n - p = \Omega(n)$  insertions must have taken place between the two reconstructions. The credits generated thus amount to  $\Omega(n \log^c n)$ , which covers the cost of the second reconstruction. In the latter case,  $\lfloor \frac{2}{3} \log p \rfloor > \log n$ , we have  $p > n^{3/2}$ , which implies that at least  $p - n = \Omega(n^{3/2})$  deletions occurred. The credits released by these deletions trivially cover the  $O(n \log^c n)$  cost of reconstruction. Note that in both cases the credits released also cover the cost of maintaining auxiliary structures, such as the tree of size  $O(2^\lambda)$  used for bit enumeration.

**THEOREM 1.** *Range counting in two dimensions can be done in  $O(n)$  space and  $O(n \log n)$  preprocessing time. In the static case, the query time is  $O(\log n)$  on an APM. On a RAM the storage used is at most twice the number of words required to store the input. In the dynamic case, query and update times are  $O(\log^2 n)$  on an EPM.*

**4. On the process of identification.** As we will quickly find out, identifying the point associated with a given bit in  $B(v)$  is the computational bottleneck of most of the problems to be considered later on. For this reason, let us look at this process in some detail. Recall that computing a transition from  $(n(v, y), r(v, y))$  to  $(n(w, y), r(w, y))$  can be done without knowledge of  $y$ . This is convenient because it allows us to characterize any bit of  $B(v)$  by a pair  $(n_v, r_v)$ , knowing that the correspond-

ing bit in  $B(w)$ , denoted  $(n_w, r_w)$ , can be computed directly from  $(n_v, r_v)$ . This is the essential step for identification on a pointer machine.

LEMMA 1. *Let  $v$  be a node of  $T$  and let  $b$  denote an arbitrary bit of  $B(v)$ , specified by a pair of the form  $(n_v, r_v)$ . Computing a transition from  $b$  can be done in constant time on an APM. In the dynamic case, it can be done in  $O(\log n)$  time on an EPM.*

*Proof.* We review the basic steps of the algorithms, most of which we have already seen. To begin with, we determine the value of the bit  $b$  of  $B(v)$  corresponding to  $(n_v, r_v)$ . On an APM, we can find the position of the bit in the appropriate  $B$ -field in constant time, using  $C, C'$ -fields. Then we call on *shift* and  $\div$  to find  $b$ . Recall that the  $i$ th most significant bit of a  $\lambda$ -bit word  $x$  is  $h(x, i-1, i) = \lfloor x/2^{\lambda-i} \rfloor - 2 \lfloor x/2^{\lambda-i+1} \rfloor$ . Next, we set  $w$  to be the left child of  $v$  if  $b=0$ , or the right child if  $b=1$ . We are now ready to compute the transition from  $b$ , which is done exactly as described in the previous section. In the dynamic case, we use the tree  $C(v)$  to locate  $b$  in  $B(v)$  and then compute its location in  $B(w)$ . A single transition takes  $O(\log n)$  steps.  $\square$

The power or random access allows us to do much better on a RAM. The idea is to store a little more information at scattered nodes of  $T$  in order to compute repeated transitions in one fell swoop.

LEMMA 2. *Let  $v$  be a node of  $T$  and  $b$  denote an arbitrary bit of  $B(v)$  (at a known location), and let  $\varepsilon$  be any positive real. It is possible to modify an  $M$ -structure on a RAM so that identifying  $b$  can be accomplished in (1)  $O(n)$  space and  $O(\log^\varepsilon n)$  time; or (2)  $O(n \log \log n)$  space and  $O(\log \log n)$  time; or (3)  $O(n \log^\varepsilon n)$  space and constant time. In all cases, the transformation of the  $M$ -structure can be accomplished in  $O(n \log n)$  time.*

*Proof.* As usual in the static case we set  $\lambda = \lfloor \log n \rfloor$ . We define the *level* of a node of  $T$  as its number of ancestors. Let  $w$  be a descendent of  $v$ , and let  $b$  denote the bit of  $B(v)$  corresponding to  $(n_v, r_v)$ . How can we compute  $(n_w, r_w)$  from  $(n_v, r_v)$  in constant time? First note that  $w$  cannot be just any descendent of  $v$ , if  $B(w)$  is to have a bit in correspondence with  $b$ . At a given level in  $T$ , there is a unique node  $w$  that satisfies the criterion. Furthermore, recall that on a RAM the consideration of  $n_v$  and  $n_w$  is redundant, since  $r_v$  and  $r_w$  supply all the needed information in useful and efficient form. We can fully characterize the bit  $b$  by a pair of the form  $(v, r)$ . In practice, such a pair can be readily translated into an absolute address by adding  $r$  to the starting position of  $B(v)$ . Recall that this addressing at the bit level is virtual, but that it can be emulated in constant time on a RAM. By abuse of language, we will refer to  $b$  as “bit  $(v, r)$ .” The problem at hand is that of computing a batch of consecutive transitions, and more precisely, the function  $\theta(v, r, l) = (w, s)$ , where  $(w, s)$  is the bit at level  $l$  in correspondence with  $(v, r)$ . Whenever  $l$  is understood, we will say that bit  $\theta(v, r, l)$  is the *companion* of bit  $(v, r)$ .

We show how to compute  $\theta(v, r, l)$  in constant time, adding only a small amount of storage to the  $M$ -structure. We consider that  $l$  and  $v$  are both fixed and we assume that  $l$  is larger than the level of  $v$ . Let  $h$  be the difference between  $l$  and the level of  $v$ , and let the sequence  $w_0, \dots, w_{2^h-1}$  denote the descendents of  $v$  at level  $l$  (without loss of generality, we will assume that  $n$  is a power of two, so that  $v$  has exactly  $2^h$  descendents at level  $l$ ). As usual,  $B(v)$  is broken up into words  $\beta_0, \dots, \beta_{m-1}$ , each made of  $\lambda$  meaningful bits (except possibly for  $\beta_{m-1}$ , a special case that we will ignore in the remainder of this discussion). We cannot afford to attach with each bit of  $B(v)$  the address of its companion, but we might still want to do so for a sample of  $B(v)$ ; for example, to follow a known pattern, for the least significant bit of each  $\beta_i$ . There is a catch, however. Indeed, this could lead to a situation where, say, all the companions land in the same node at level  $l$ , thus providing useless information for most of the other bits of  $B(v)$ . To circumvent this difficulty, we do not link the bits to their

companions but to *neighboring bits* chosen in a round-robin fashion among the nodes at level  $l$ . We augment each  $\beta_i$  with a pointer  $\gamma_i$  and a bit vector  $\Gamma_i$ , defined as follows:

- (1) The pointers  $\gamma_i$  allow us to jump from selected places in  $B(v)$  to related places at level  $l$ . For any  $j$  such that  $0 \leq j < 2^h$ , we say that bit  $(w_j, s)$  is the  $j$ -*companion* of bit  $(v, r)$  if its identifier is the smallest value in  $R(w_j)$  that is at least as large as the identifier of  $(v, r)$ . Note that there is a unique  $j$  for which the  $j$ -companion of  $(v, r)$  is also its companion. For each  $i$  such that  $0 \leq i < m$ , we define  $\gamma_i$  as the address of the word in  $B(w_{i \bmod 2^h})$  that contains the  $(i \bmod 2^h)$ -companion of the least significant bit in  $\beta_i$ . If there is no such companion,  $\gamma_i$  need not be defined.
- (2) The bit vectors  $\Gamma_i$  allow us to correct the errors introduced by the  $\gamma_i$ 's. Let  $(v, r)$  be as usual an arbitrary bit of  $\beta_i$ . Let  $\theta(v, r, l) = (w_j, s)$ , and let  $k$  be the largest integer less than  $i$  such that  $\gamma_k$  points to a word of  $B(w_j)$ . Suppose for the time being that  $k$  is well defined. Then it cannot be too far away from  $i$  because of the round-robin scheme. We easily verify that  $k$  is always at least as large as  $i - 2^h$ . The address in  $\gamma_k$  allows us to jump from  $v$  to  $w_j$  within some reasonable accuracy. To complete the computation, we need information to (1) compute  $k$ , given  $(v, r)$ , and (2) go from  $\gamma_k$  to the actual companion of  $(v, r)$ . If  $(v, r)$  is the  $d$ th most significant bit of  $\beta_i$ , we define  $P_d$  as an  $(h+1)$ -long bit vector containing the binary representation of  $i-k$  in right-justified position. This allows us to complete the first task. For the second one, we define  $Q_d$  as a  $(\lfloor \log \lambda \rfloor + h + 3)$ -bit vector. Let  $d_0, d_1, d_2 \dots$  be the bits of  $B(w_j)$ , broken down into words,  $\delta_0, \delta_1, \delta_2$ , etc. Let  $\delta_a$  be the word pointed to by  $\gamma_k$ , let  $d_b$  be the most significant meaningful bit of  $\delta_a$ , and let  $d_c$  be the bit  $\theta(v, r, l)$ ; we define  $Q_d$  as the  $(\lfloor \log \lambda \rfloor + h + 3)$ -bit vector containing the binary representation of  $c-b$  in right-justified position (note that  $c \geq b$ ). We can verify that the number of bits provided by  $Q_d$  is sufficient for that purpose ( $\#$  bits needed  $= \lceil \log(c-b+1) \rceil < \lfloor \log \lambda \rfloor + h + 3$ ). If  $k$  is not defined then  $P_d$  and  $Q_d$  store the values of  $j$  and  $c$ , respectively, with a flag to indicate so; again  $\lfloor \log \lambda \rfloor + 2h + 4$  are more than sufficient for that purpose. Finally, we define  $\Gamma_i$  as the concatenated string  $P_1.Q_1.P_2.Q_2 \dots P_\lambda.Q_\lambda$ . Note that  $\Gamma_i$  is  $\lambda(\lfloor \log \lambda \rfloor + 2h + 4)$  bits long.

Computing  $\theta(v, r, l)$  is now straightforward. To begin with, we find the index  $i$  of the word  $\beta_i$  that contains bit  $(v, r)$ . This gives us the position  $d$  of  $(v, r)$  in  $\beta_i$ , which in turn leads to the two bit vectors  $P_d$  and  $Q_d$ . Note that both vectors can always be read in constant time. With  $P_d$  in hand, we can retrieve  $k$  as well as the address stored in  $\gamma_k$ . Using now  $Q_d$  as a relative address, we automatically gain access to  $\theta(v, r, l)$ . All these operations take constant time on a RAM. So, we have devised a technique for computing repeated transitions in constant time. But at what cost in storage? With the notation used above, the overhead amounts to one word  $\gamma_i$  and one bit vector  $\Gamma_i$  for each word  $\beta_i$  of  $B(v)$ . This gives an average of  $O((h + \log \lambda)/\lambda)$  extra words per bit of  $B(v)$ , hence a grand total of  $O(((h + \log \lambda)/\lambda)n + 2^{l-h})$  space, summing up over every node  $v$  at level  $l-h$ . Recall that there are exactly  $n$  bits in all the  $B(v)$ 's combined, at any given level. Of course,  $\Gamma_i$  will be organized as an array of words. Because each  $\Gamma_i$  is of the same length, these can be packed into one large array in order to simulate a two-dimensional matrix. To summarize, we have a scheme for computing  $h$  consecutive transitions in constant time from level  $j$ , using  $O(((h + \log \lambda)/\lambda)n + 2^j)$  added space.

What is the time needed to construct the set of  $\gamma_i$  and  $\Gamma_i$ ? With the random access features of a RAM, it is not difficult to carry out the preprocessing in  $O(n)$  time. We

briefly describe the procedure. Assuming that for each  $v$  at level  $l-h$  the array  $R(v)$  is available, we can compute the companion of each bit of  $B(v)$  in constant amortized time. To do so, we compute  $R(w_0), \dots, R(w_{2^h-1})$ , using bucket sort to place each element in its right set. This is possible because, if we work in rank space, the points of  $R(v)$  can be partitioned by vertical slabs of the same width, each corresponding to a distinct  $R(w_j)$ . Knowing the companions of the bits of  $B(v)$  serves two purposes: one is to provide the position of each companion in its list  $R(w_j)$ , and the other is to reveal the name of the node in question. With the first piece of information we compute  $Q_d$ , and with the latter we derive  $P_d$ . To do so, we compute the round-robin assignment of the bits of  $B(v)$  and form  $O(2^h)$  sorted lists of  $y$ -values, which we merge with  $R(w_0), \dots, R(w_{2^h-1})$ , in turn. This gives us all the  $\gamma_i$ 's in linear time. To compute the  $P_d$ 's, it suffices to scan  $B(v)$  and for each bit deduce  $P_d$  from the index  $j$  of the node  $w_j$  associated with its companion. Finally,  $Q_d$  can be found by simulating the computation of  $\theta(v, r, l)$  for each bit of  $B(v)$ . We can obtain  $Q_d$  as soon as it is needed in the computation, since we already know the value of  $\theta(v, r, l)$ . These explanations are more intuitive than formal, but we do not judge it necessary to dwell on this technical but simple aspect of the algorithm. For convenience, we denote the data structure which we have just described,  $\Theta(l-h, l)$ . In general,  $\Theta(a, b)$  is a structure that allows us to compute transitions from level  $a$  to level  $b$  in constant time, using  $O(((b-a + \log \lambda)/\lambda)n + 2^a)$  extra space. Incidentally, there is an obvious discrepancy with regard to this bound. If we set  $b-a=1$ , then we have just described a method for computing constant time transitions, while using an extra  $\log \log n$  bits for each bit of  $B(v)$ ! Of course, this result is useless since we already know how to compute constant time transitions with only constant overhead in space. We will therefore save the more complex method only as a way to batch many consecutive transitions together.

We are now ready to attack the main question: how to identify  $(v, r)$ ? Let  $m$  be the level of  $v$  ( $m < \lambda - 1$ ); the idea is to express  $m$  in some appropriate number system. We will build several data structures on the same model. Let  $D(x, y)$  denote a data structure for jumping from any level  $l_1$  to any level  $l_2$ , with  $\lambda - y \leq l_1 < l_2 \leq \lambda - x$ . Identification can be done by using  $D(0, \lambda)$ . We define  $D(x, y)$  in a recursive manner (for notational convenience we assume, without loss of generality, that  $x = 0$ ). Let  $\alpha(y)$  be an integer function of  $y$  such that  $0 \leq \alpha(y) \leq y/2$ . The data structure  $D(0, y)$  is made of

$$\Theta(\lambda - y, \lambda) \cup \left\{ D(0, \alpha(y) - 1), \dots, D(j\alpha(y), (j+1)\alpha(y) - 1), \dots, D\left(\left\lfloor \frac{y}{\alpha(y)} \right\rfloor \alpha(y), y\right) \right\}.$$

We stop the recursion at some threshold  $\nu$ , which is to say that  $D(a, b)$  is null for  $b - a \leq \nu$ . How do we physically store these structures? We want to emulate a situation where each  $\Theta(i, j)$  is accessible as defined earlier, that is, as though it were the only one attached to level  $i$ . Unfortunately, many  $\Theta(i, j)$ 's are bound to be assigned to the same level  $i$ . We solve this difficulty by storing the  $\Theta(i, j)$ 's as two-dimensional matrices (as before), and keeping an entry table  $E[0..\lambda + 1, 0..\lambda + 1]$  defined as follows:  $E[i, j]$  stores the address of the first entry in  $\Theta(i, j)$ , if  $\Theta(i, j)$  appears in the full expansion of  $D(0, \lambda)$ ; it stores 0 otherwise. The storage  $S(n, y)$  occupied by  $D(0, y)$  follows the recurrence

$$S(n, y) = \left\lfloor \frac{y}{\alpha(y)} \right\rfloor S(n, \alpha(y)) + S\left(n, y + 1 - \left\lfloor \frac{y}{\alpha(y)} \right\rfloor \alpha(y)\right) + O\left(\frac{y + \log \lambda}{\lambda} n\right),$$

and  $S(n, y) = 0$ , for  $y \leq \nu$  (threshold below which we stop the recursion). We have

omitted the term  $2^{\lambda-y}$  to be able to treat the recurrence uniformly. We will see later on the effect of this omission. Let  $\alpha^{(0)}(y) = y$  and, for any  $i > 0$ , let  $\alpha^{(i)}(y) = \alpha(\alpha^{(i-1)}(y))$ . Finally, let  $\alpha^*(y) = \max \{i | \alpha^{(i)}(y) \geq \nu\}$ . We derive the relation

$$(1) \quad S(n, \lambda) = O\left(\left(\alpha^*(\lambda) + 1 + r \frac{\log \lambda}{\nu}\right)n\right).$$

We can easily show that taking into account the terms of the form  $2^{\lambda-y}$  adds another term  $O((\alpha^*(\lambda) + 1)n)$ , which asymptotically is immaterial. We briefly describe the preprocessing. We define the first recursive layer  $L_1$  as the construction of  $\Theta(0, \lambda)$ . The second recursive layer  $L_2$  involves building in this order

$$\Theta\left(0, \lambda - \left\lfloor \frac{\lambda}{\alpha(\lambda)} \right\rfloor \alpha(\lambda)\right), \dots, \Theta(\lambda - (j+1)\alpha(\lambda) + 1, \lambda - j\alpha(\lambda)), \dots, \Theta(\lambda - \alpha(\lambda) + 1, \lambda),$$

and so forth, every time expanding each term with its recursive definition. If we look at the definition of  $D(0, \lambda)$  as inducing a tree of height roughly  $\alpha^*(\lambda)$ , then  $L_i$  represents the work to be accomplished to build each node of the tree at level  $i$ . Starting with  $R(\text{root})$ , we can construct each layer in time  $O(n|L_i|)$ , where  $|L_i|$  is the number of terms involved in the expression of  $L_i$ . This derives from our previous observation on the preprocessing of  $\Theta(a, b)$ . Note that when computing a  $\Theta$ -structure the set of lists  $R(v)$  needed for the computation can be obtained from the previous one in linear time. Since  $\alpha(y) \leq y/2$ , the sum  $\sum n|L_i|$  is a geometric series whose value is on the order of  $(\lambda/\nu)n$ . This gives a preprocessing time of  $O(n \log n)$ .

To identify  $(v, r)$ , we begin by checking to see if  $m$ , the level of  $v$ , is equal to 0. If this is the case, we can then use  $\Theta(0, \lambda)$  and conclude in constant time. If  $m > 0$ , we compute the starting interval of the form  $[j\alpha(\lambda), (j+1)\alpha(\lambda) - 1]$  (or  $[\lfloor \lambda/\alpha(\lambda) \rfloor \alpha(\lambda), \lambda]$ ) that contains  $\lambda - m$ . We leap from  $v$  to the companion of  $(v, r)$  at level  $\lambda - j\alpha(\lambda)$  (with  $j \leq \lfloor \lambda/\alpha(\lambda) \rfloor$ ) by calling the algorithm recursively, using  $D(j\alpha(\lambda), (j+1)\alpha(\lambda) - 1)$  (or  $D(\lfloor \lambda/\alpha(\lambda) \rfloor \alpha(\lambda), \lambda)$ ). When the recursion passes the cutoff point (i.e., is about to jump across fewer than  $\nu$  levels) we complete the computation by taking transitions one level at a time. Of course, we assume that we have the appropriate data structure for doing so. When this is done, we jump from level  $\lambda - j\alpha(\lambda)$  to level  $\lambda$  by taking intermediate steps. Let  $k$  be initially set to  $j$ .

- (1) Take a regular transition from  $\lambda - k\alpha(\lambda)$  to  $\lambda - (k\alpha(\lambda) - 1)$ ;
- (2) Jump from  $\lambda - (k\alpha(\lambda) - 1)$  to  $\lambda - (k-1)\alpha(\lambda)$ , using  $D((k-1)\alpha(\lambda), k\alpha(\lambda) - 1)$ ;
- (3) Decrement  $k$  by 1. If  $k > 0$  then go to step (1), else stop.

Let  $Q(n, m)$  be the time to identify  $(v, r)$ , that is, to jump across  $\lambda - m$  levels. We immediately find that

$$(2) \quad Q(n, m) = O\left(\nu + \sum_{\nu \leq \alpha^{(i)}(\lambda) \leq \lambda} \frac{\alpha^{(i)}(\lambda)}{\alpha^{(i+1)}(\lambda)}\right).$$

Setting  $\alpha(y) = \lfloor y/2 \rfloor$  and  $\nu = 1$ , from (1) and (2) we obtain  $S(n, \lambda) = O(n \log \log n)$  and  $Q(n, m) = O(\log \lambda) = O(\log \log n)$ . This completes the proof of the second part of Lemma 2. Let us now set  $\alpha(y) = \lfloor y/\lambda^\epsilon \rfloor$  and  $\nu = \log \lambda$ . We derive  $S(n, \lambda) = O(n)$  and  $Q(n, m) = O(\log^\epsilon n)$ , which gives us the first part of Lemma 2.

To prove the last part of Lemma 2, we must modify the overall design of the data structure:  $D(0, y)$  will now be made not only of

$$\left\{ D(0, \alpha(y) - 1), \dots, D(j\alpha(y), (j+1)\alpha(y) - 1), \dots, D\left(\left\lfloor \frac{y}{\alpha(y)} \right\rfloor \alpha(y), y\right) \right\},$$

but also of

$$\left\{ \Theta(\lambda - \alpha(y), \lambda), \dots, \Theta(\lambda - j\alpha(y), \lambda), \dots, \Theta\left(\lambda - \left\lfloor \frac{y}{\alpha(y)} \right\rfloor \alpha(y), \lambda\right), \Theta(\lambda - y, \lambda) \right\}.$$

As usual,  $D(a, b)$  is null if  $b - a \leq \nu$ . We assume that  $\alpha(y) = \lfloor y/\lambda^{\epsilon/2} \rfloor$  and  $\nu = 1$ . The storage needed follows the relation

$$S(n, y) = \left\lfloor \frac{y}{\alpha(y)} \right\rfloor S(n, \alpha(y)) + S\left(n, y + 1 - \left\lfloor \frac{y}{\alpha(y)} \right\rfloor \alpha(y)\right) + O\left(\frac{y(y + \log \lambda)}{\alpha(y)\lambda} n\right),$$

and  $S(n, y) = 0$ , for  $y \leq \nu$ . This gives  $S(n, \lambda) = O(n \log^{\epsilon/2} n \log \log n) = O(n \log^\epsilon n)$ . Once again, it is easily verified that the extra terms  $2^a$  omitted from the recurrence are absorbed asymptotically. The construction time is  $O(n \log n)$  since there are only a constant number of layers. To identify  $(v, r)$ , we proceed recursively within the starting interval. The key difference now is that at a given recursion level, only a single  $\Theta$ -structure need be used. The time thus becomes proportional to the number of recursive calls, which is constant. The proof of Lemma 2 is now complete.  $\square$

**5. Range reporting.** For this problem we use an  $M$ -structure with the various modifications described in the previous section. It is clear that to start out we might as well mimic the algorithm for range counting until all the bits in the appropriate  $B(v)$ 's have been located. These are the bits whose identifiers fall in the query range. They appear as  $O(\log n)$  sequences of consecutive bits, each sequence being associated with a distinct node of  $T$ . We call these sequences the *decomposition vectors* of the query. To complete the computation, it suffices to identify each bit of the decomposition vectors. This can be done by applying the techniques of the previous section to each bit individually.

How do we dynamize the data structure? On an EPM, there is no difficulty adapting to the problem at hand our solution to range counting. Identification proceeds by applying repeated transitions, using the methods of Lemma 1.

This technique leads to the results stated in the tables of § 1, except for one minor difference: we have just proven a slightly weaker set of results obtained by replacing each occurrence of  $n/k$  by  $n$  in the tables. Obviously, to obtain the results claimed it suffices to treat, say, the case  $k \geq n^{2/3}$  separately. Indeed, if  $k < n^{2/3}$  then  $\log n$  and  $\log(n/k)$  are within constant factors of each other. We will describe a dynamic algorithm on an EPM with a complexity of  $O(n)$  space,  $O(n \log n)$  preprocessing time,  $O(\log n)$  update time, and for  $k \geq n^{2/3}$ ,  $O(k)$  query time. Since  $k$  is not known beforehand the idea will be to dovetail between this method and the others (i.e., run the two competing algorithms in parallel). The first process to terminate will thus guarantee the upper bounds claimed in the tables. We define the alternative algorithm by combining standard data structuring techniques. Assuming for simplicity that all  $x$ -coordinates are distinct, we partition the set of  $n$  points by means of vertical slabs into groups of size between  $p(n)$  and  $4p(n)$ , where  $p(n) = \lfloor 2^{2\lceil \log n \rceil / 3} \rfloor$ . For each group of points we maintain a dynamic list containing the indices of the points sorted by  $y$ -coordinates. Given two query values  $y$  and  $y'$  we will use the list to report all the points in the group with  $y$ -coordinates between  $y$  and  $y'$ . Using, say, a 2-3 tree, it is easy to guarantee  $O(k + \log n)$  query time (where  $k$  is the number of points to be reported) and  $O(\log n)$  update time. The storage requirement is trivially linear. The utility of this data structure for the previous problem should be obvious. Given a query rectangle, our first task is to use the slabs to partition it into subrectangles, which is easily done in  $O(\log n)$  time. If the query rectangle falls entirely within a single slab,

then we naively check each point in the slab. If the partition is effective, however, then each subrectangle can be handled by using the appropriate list (checking each element in the list in the case of the leftmost and rightmost subrectangles, and using the tree structures for the other subrectangles, if any).

The query time is easily shown to be  $O(k + n^{1/3} \log n + n^{2/3})$ , which is  $O(k)$  if  $k \geq n^{2/3}$ . Insertions and deletions are performed in logarithmic time by updating the relevant lists. To handle overflows and underflows we will assume for the time being that although  $n$  varies,  $\lfloor \log n \rfloor$  and hence  $p(n)$  remain the same. Let  $m$  be the size of a group where an insertion has just taken place. If  $m > 4p(n)$  then break up the group into two subgroups of size  $\lfloor m/2 \rfloor$  and  $\lceil m/2 \rceil$ . If a deletion has taken place and  $m < p(n)$  then let  $m'$  be the size of one of its adjacent groups (guaranteed to exist if  $n$  is larger than some constant). If  $m + m' \leq 3p(n)$  then merge the two groups into one, otherwise form two groups of size  $\lfloor (m + m')/2 \rfloor$  and  $\lceil (m + m')/2 \rceil$ , respectively. In all cases the relevant lists are reconstructed from scratch. We easily check that each new group has its size  $\Omega(p(n))$  away from the two limits  $p(n)$  and  $4p(n)$ . A simple accounting argument can then be used to prove that an insertion/deletion has an  $O(\log n)$  amortized complexity. Note that once  $p(n)$  is known the only arithmetic needed is addition and subtraction by 1, which can be implemented in  $O(\log n)$  time on an EPM. (Or even in  $O(1)$ , if we maintain a linked list from 1 to  $n$  and pointers to the values of the various group sizes). If now  $\lfloor \log n \rfloor$  increases or decreases by 1, we simply rebuild the entire data structure from scratch, which is easily done in  $O(n \log n)$  time (or even  $O(n)$  using presorting). Note that to update the value of  $p(n)$  at each update can be easily done in constant amortized time (on an EPM). When it is decided that a reconstruction is needed, prior to it we replace  $p(n)$  by  $q(n) = \lfloor 2^{2 \lfloor \log(3n) \rfloor / 3} \rfloor$ , and always alternate back and forth between  $p(n)$  and  $q(n)$ . In this way, we are guaranteed to have  $\Omega(n)$  updates between two consecutive reconstructions. Obviously, everything we said earlier about  $p(n)$  applies to  $q(n)$  just as well. Since  $p(n)$  and  $q(n)$  can be computed in  $O(n)$  time, using only additions, reconstructions still preserve the logarithmic amortized complexity of an update.

**THEOREM 2.** *Data structures for range reporting in two dimensions can be constructed in  $O(n \log n)$  time in all cases. Let  $k - 1$  be the number of points to be reported, and let  $\varepsilon$  be any real  $> 0$ . On a RAM, a tradeoff is possible: in particular, we can achieve (1)  $O(k(\log(2n/k))^\varepsilon + \log n)$  query time and  $O(n)$  space; (2)  $O(k \log \log(4n/k) + \log n)$  query time and  $O(n \log \log n)$  space; (3)  $O(k + \log n)$  query time and  $O(n \log^\varepsilon n)$  space. On an APM, it is possible to achieve a query time of  $O(k \log(2n/k))$ , using  $O(n)$  space. In the dynamic case on an EPM, it is possible to achieve a query time of  $O(k(\log(2n/k))^2)$  and an update time of  $O(\log^2 n)$  time, using  $O(n)$  space.*

**6. Range searching for maximum.** As usual, we will make use of an  $M$ -structure, and we will start the algorithm by computing the decomposition vectors of the query. In general, these vectors will fail to fill whole sequences of  $B$ -fields. However, they can be broken up into three (or fewer) blocks, one of which corresponds to a sequence of  $B$ -fields, and the others to subparts. Discovering the identifier with maximum value in each block will readily lead to the final answer. Let  $v$  be an arbitrary node of  $T$ . To handle the first case, we add an  $M$ -field to each record of  $W(v)$  to indicate the maximum value attained by the identifiers of bits in the corresponding  $B$ -field. Then we set up a data structure  $M_1$  for doing one-dimensional range search for maximum with respect to the  $M$ -fields of  $W(v)$ . For the other blocks we need a data structure  $M_2$  for computing  $\maxval(\beta, k, l)$ , a function that takes as input a  $B$ -field  $\beta = x_0 \cdots x_{\lambda-1}$  and two bit positions  $0 \leq k \leq l < \lambda$ , and returns the position  $i$  of the bit  $x_i$

whose identifier has maximum value among  $\{x_k, x_{k+1}, \dots, x_l\}$ . We next show how to implement  $M_1$  and  $M_2$  in our various models of computation.

*Implementation of  $M_1$ .*

- (1) *On a RAM.* We use a technique of Gabow, Bentley, and Tarjan [GBT] to reduce one-dimensional range search for maximum to the computation of nearest common ancestors in some special tree. To begin with, we construct a *Cartesian tree* with respect to the  $M$ -fields of each  $W(v)$ . This tree, discovered by Vuillemin [V], is defined as follows: pick the maximum  $M$ -field and store it in the root of the tree. Remove this maximum from the sequence of  $M$ -fields, and define the left (resp., right) subtree recursively with respect to the left (resp., right) remaining subsequence. Two important facts about Cartesian trees state that: (a) they can be built in linear time; (b) one-dimensional range search for maximum is reducible to the computation of the nearest common ancestor (nca) of two nodes in a Cartesian tree. Harel and Tarjan [HT] have given an efficient method for computing nca's. Their method allows us to implement  $M_1$  in linear space and time, and obtain any answer in constant time.
- (2) *On an APM or an EPM.* More simply, we use a complete binary tree with each node  $v$  holding the maximum value in the range spanned by the subtree rooted at  $v$ . This heap structure is of standard use for one-dimensional range search, so we need not elaborate on it. Query time is  $O(\log n)$  in both models.

*Implementation of  $M_2$ .*

- (1) *On a RAM.* We still use Cartesian trees, but in an indirect manner. The key observation is that for our purposes Cartesian trees do not need to be labelled. Therefore they can be represented by a canonical index over a number of bits =  $O(\log \# \text{Cartesian trees of size } \lambda)$ . We can get a rough estimate on this number by representing a  $p$ -node Cartesian tree as a string of matching parentheses for internal nodes, 1 for leaves and 0 for missing leaves, as in  $((((10)((01)0))((01)1)))$ , for example. Missing leaves are the nonexistent brothers of single children (poor things!). There are  $p$  nodes and at most  $p - 1$  missing leaves, so  $6p$  bits are sufficient for the encoding. Since the number of nodes we are dealing with is quite small, we can precompute all possible Cartesian trees and preprocess them for efficient nca computation. It will then suffice to store a pointer from each record in  $W(v)$  to the appropriate Cartesian tree. Let  $\alpha p$  be the number of words required to store a  $p$ -node tree preprocessed for constant time nca computation (Harel and Tarjan [HT]). Storing all Cartesian trees of size  $\lambda$  will thus require  $4^{3\lambda} \alpha \lambda = \Theta(n^6 \log n)$  words! This is a bit too much, so we must resize the  $B$ -fields. We divide each  $B$ -field into subwords of at most  $\lfloor \lambda/7 \rfloor$  bits each, and for each piece we keep a pointer to its appropriate  $\lfloor \lambda/7 \rfloor$ -node Cartesian tree. This will multiply the query time by a constant factor, but it will also bring down the space requirement to a more acceptable  $O(n^{6/7} \log n) = O(n)$  bound. The time to compute  $\text{maxval}(\beta, k, l)$  is constant. But to identify the corresponding bit, we must resort to the techniques of Lemma 2. Since there are  $O(\log n)$  decomposition vectors, we can achieve a query time of  $O(\log^{1+\epsilon} n)$  with  $O(n)$  space; a query time of  $O(\log n \log \log n)$  with  $O(n \log \log n)$  space; or a query time of  $O(\log n)$  with  $O(n \log^\epsilon n)$  space.
- (2) *On an APM or an EPM.* We use the same technique, except for the preprocessing of Cartesian trees, now no longer needed. We compute an nca naively by examining the entire tree. This allows us to compute  $\text{maxval}(\beta, k, l)$  in

$O(\log n)$  time. The total cost of the computation will be  $O(\log^2 n)$  on an APM and  $O(\log^3 n)$  on an EPM.

In all cases (including on a RAM with constant-time nca computation), the preprocessing can be done in linear time per level of  $T$ , that is, in a total of  $O(n \log n)$  steps. This concludes our treatment of the static case.

*The dynamic case.* How can we dynamize these data structures on a pointer machine? The problem is quite similar to range counting, after all, so the proof of Theorem 1 can serve us as a guide. Certainly, the treatment of  $B$ -fields and the management of the structures  $M_1$  can follow the same lines used for range counting. Difficulties arise with  $M_2$ , however. Consider the insertion or deletion of a bit in some  $B$ -field  $\beta$ . What is wrong with the following scheme? Find which subpart of  $\beta$  houses the bit in question and follow its pointer to the appropriate Cartesian tree. Then update the tree naively by considering each of its nodes. There are two basic problems: one is to update a Cartesian tree without knowing the values of the keys. Another problem, though less serious, is that these trees are shared among many pointers, so pleasing one pointer with an update would most likely upset many others. Once again, a functional approach will take us out of this dilemma.

Instead of a Cartesian tree, we use a dynamic one-dimensional range tree (similar to  $M_1$ ); for example a 2-3 tree (Aho et al. [AHU]). Ideally, each node would store the maximum value associated with its leaves below (Fig. 2(a)). But this is as costly as having labelled trees, so we must seek a different solution. The key remark is that we need not store values in the nodes, but simply bits indicating where these values come from. These are called the *direction flags* of the tree. If the value at node  $z$  originates from a leaf of its leftmost subtree, the direction flag of  $z$  is 0; if it comes from the second subtree from the left, it is 1; else the direction flag is 2 (Fig. 2(b)).

FIG. 2

We can represent such a tree by means of balanced parentheses. Each leaf is a 1 and each internal node is a pair  $(\cdot \cdot \cdot)$  immediately followed by its direction flag. For example, the tree of Fig. 2(b) is encoded as

$$(((111)1(11)0)0((11)1(11)1(111)2)2)0.$$

We represent each character on two bits: 0, 1, 2 as they are, “(” as 2, and “)” as 3, for example. Note that although 2 is used for different purposes there is no source of ambiguity, since 2 is always preceded by “)” and “)” can never occur. Encoding and decoding any such tree can easily be done in time linear in its size. A leaf takes up 1 character and an internal node 3, so the tree associated with a  $B$ -field of  $\lambda$  meaningful bits can be encoded over  $8\lambda - 6$  bits. Since every description starts with 10 there is no need for a boundary delimiter if the bits are right-justified. We will therefore assign 8 additional words for each  $B$ -field.

How can we use these trees to compute  $\maxval(\beta, k, l)$ ? To begin with, we decode the tree  $T_\beta$  associated with  $\beta$ . For (conceptual) simplicity, we might want to request  $O(\lambda)$  temporary storage to construct a “useful” copy of  $T_\beta$ , that is, using pointers, one-word fields for direction flags, etc. We can now compute  $\maxval(\beta, k, l)$  by performing one-dimensional range search in  $T_\beta$ . The canonical decomposition of  $[k, l]$  can be computed in  $O(\log \lambda)$  operations. This reduces the investigation to  $O(\log \lambda)$  nodes of  $T_\beta$ . For each such node, we determine the leaf from which its associated value originates, and we identify the corresponding bit. This will take a total of  $O(\log \lambda \log^2 n)$  time on an EPM.

Let us now look at insertions and deletions. We proceed as in the proof of Theorem 1. Suppose that no underflow or overflow occurs within the  $B$ -field  $\beta$ . In that case, we carry out the update in  $T_\beta$  alone. Intuitively, we can look at the tree in its entirety, but we should try to minimize the number of bits that must be identified since these are the costly operations. The advantage of using a balanced tree is to limit the number of necessary identifications to  $O(\log \lambda)$  (as opposed to  $O(\lambda)$ ). For each update, we apply the standard insert or delete procedure for 2-3 trees. This can only upset the direction flags of the nodes that are effectively manipulated by the update as well as the direction flags of their ancestors. We promptly repair the damage caused to the direction flags by identifying the bits associated with the children of each of these nodes. This will take time  $O(\log \lambda \log^2 n)$  on an EPM.

How do we deal with overflow or underflow? Following the proof of Theorem 1, the reconfiguration of the  $B$ -fields necessitates splitting or concatenating one or two trees. This can be done in  $O(\log \lambda)$  steps [AHU]. Again we must ask: how many direction flags must be recomputed? A careful examination of the split and concatenate procedures on a 2-3 tree shows that after each application of these operations the number of nodes that either have been manipulated or are ancestors of nodes that have been manipulated is at most logarithmic in the size of the tree. Since these are the only ones whose direction flags might need updating, we conclude that the time spent to handle underflow and overflow is asymptotically the same as the time to insert or delete a new element.

As soon as a tree has been updated, we re-encode it as a bit vector and re-attach the result to the relevant  $B$ -field, discarding the old tree. Once  $M_2$  has been computed, updating  $M_1$  can be done in  $O(\log n)$  operations on all models, assuming that it is implemented as a dynamic one-dimensional range search tree. The procedure is similar to the updating of  $C(v)$  in the case of range counting (§ 3.2). It is also possible to unify the treatment of  $M_1$  and  $M_2$  and consider a single master tree with two modes

of representation: with pointers for  $M_1$  (the top part) and with bit vectors for  $M_2$  (the lower levels).

To summarize, it takes  $O(\log^2 n \log \log n)$  time to carry an update with respect to a given node of  $T$ . Reconfiguring a subtree of  $T$  of size  $p$  can easily be done in  $O(p \log p)$  steps: play a knock-out tournament at each level of  $T$  being reconstructed. The usual counting argument shows that the amortized cost of rebuilding  $T$  when it goes out of balance is  $O(\log^2 n)$ . Unfortunately this is largely dominated by the  $O(\log^3 n \log \log n)$  steps incurred at the time of insertion or deletion.

**THEOREM 3.** *The data structures for range searching for maximum in two dimensions can be constructed in  $O(n \log n)$  time in all cases. On a RAM, a tradeoff is possible: in particular, we can achieve (1)  $O(\log^{1+\epsilon} n)$  query time and  $O(n)$  space; (2)  $O(\log n \log \log n)$  query time and  $O(n \log \log n)$  space; (3)  $O(\log n)$  query time and  $O(n \log^\epsilon n)$  space. On an APM (resp., EPM) it is possible to achieve a query time of  $O(\log^2 n)$  (resp.,  $O(\log^3 n)$ ), using  $O(n)$  space. In the dynamic case on an EPM, it is possible to achieve query and update times of  $O(\log^3 n \log \log n)$ , using  $O(n)$  space.*

**7. Semigroup range searching.** Of course, we assume that any value in the semigroup can be stored within one or, say, a constant number of computer words. We modify the  $M$ -structures by providing each node  $v$  with a complete binary tree whose leaves are associated with the  $B$ -fields of  $W(v)$ . Each leaf stores the semigroup sum of the values associated with the bits of its corresponding  $B$ -field. Similarly each internal node stores the sum of the values stored in its descending leaves. As in the case of range searching for maximum the algorithm computes the decomposition vectors of the query in a first stage. As usual, these are broken up into three (or fewer) blocks, one of which corresponds to sequences of  $B$ -fields, and the others to subparts. The semigroup sum associated with the identifiers of the first block can be readily obtained with two binary searches in the relevant auxiliary tree (this is a standard one-dimensional range search). For the other blocks, one must identify each of their bits to complete the computation, which will take a total of  $O(t(n) \log^2 n)$ , where  $t(n)$  is the time taken to identify one bit. We can then use Lemmas 1 and 2 to derive the performance of the algorithms.

Executing updates is similar to the dynamic treatment of range search for maximum, so no further elaboration is necessary. The  $M_2$ -structures can be eliminated altogether, therefore updating the data structure will require  $O(\log^2 n)$  identifications. Note that as usual the preprocessing requires  $O(n \log n)$  time.

**THEOREM 4.** *The data structures for semigroup range searching in two dimensions can be constructed in  $O(n \log n)$  time in all cases. On a RAM, a tradeoff is possible: in particular, we can achieve (1)  $O(\log^{2+\epsilon} n)$  query time and  $O(n)$  space; (2)  $O(\log^2 n \log \log n)$  query time and  $O(n \log \log n)$  space; (3)  $O(\log^2 n)$  query time and  $O(n \log^\epsilon n)$  space. On an APM it is possible to achieve a query time of  $O(\log^3 n)$ , using  $O(n)$  space. In the dynamic case on an EPM, it is possible to achieve query and update times of  $O(\log^4 n)$ , using  $O(n)$  space.*

**8. Rectangle searching: counting and reporting.** Using an equivalence result of Edelsbrunner and Overmars [EO], rectangle counting can be reduced to range counting. The basic idea is to subtract the number of rectangles which do *not* intersect the query from the total number of rectangles. Using inclusion-exclusion relations the problem reduces to a constant number of range counting problems. We immediately derive a result similar to Theorem 1. Note that the extra subtractions needed are inconsequential in the asymptotic complexity of the algorithms on an EPM.

**THEOREM 5.** *Rectangle counting in two dimensions can be done in  $O(n)$  space and  $O(n \log n)$  preprocessing time. In the static case, the query time is  $O(\log n)$  on an APM. In the dynamic case, query and update times are  $O(\log^2 n)$  on an EPM.*

As is well known (Edelsbrunner [Ed]), rectangle reporting in two dimensions can be reduced to three subproblems:

- (1) *Range reporting.* See above.
- (2) *Orthogonal segment intersection.* Given a set of horizontal segments in the plane and a (query) vertical segment  $q$ , report all intersections between  $q$  and the horizontal segments.
- (3) *Point enclosure.* Given a set of 2-ranges in the plane and a query point  $q$ , report all the 2-ranges that contain  $q$ .

Given a set  $V$  of 2-ranges and a query rectangle  $q$ , rectangle reporting can be performed by doing (1) range reporting with respect to the lower left corners of the rectangles in  $V$  and the query  $q$ , (2) orthogonal segment intersection with respect to the bottom (resp., left) sides of the rectangles and the left (resp., bottom) side of  $q$ ; (3) point enclosure with respect to the rectangles of  $V$  and the lower left corner of  $q$ .

Multiple reports caused by singular cases can be easily avoided using extra care. To complete our treatment of the static case, we simply observe that optimal data structures already exist for both the orthogonal segment intersection and the point enclosure problem (Chazelle [C1]). The size of these data structures is  $O(n)$  and their construction takes  $O(n \log n)$  time on an EPM. Queries can be answered in time  $O(k + \log n)$ , where  $k$  is the size of the output. Using our previous solutions to range reporting, we are then equipped to solve the problem at hand. The complexity is dominated by the cost of range reporting.

To deal with the dynamic version of rectangle reporting, we use a different approach. The previous sections involved a redesign of the *range tree* in linear space. We will now undertake a similar transformation with respect to the *segment tree*, a data structure due to Bentley [B1]. The idea again is to identify the functional components of the data structure and, on that basis, re-implement it completely differently.

*The dynamic case.* (1) *Orthogonal segment intersection.* For explanatory purposes, we make various simplifying assumptions. To remove them is tedious but does not affect the validity of our results. Our main assumption is that the coordinates of the segments, including the query, are all distinct. The problem to solve can be formulated as follows: let  $V$  be a set of  $n$  horizontal segments, each of the form  $(x_i, x'_i, y_i)$ , with  $x_i < x'_i$ . Given a vertical segment  $q$  compute all intersections between  $q$  and the horizontal segments.

We begin with the static version of the problem, and as a starter we introduce a little notation. The integer  $i$  is called the *index* of segment  $(x_i, x'_i, y_i)$ . For any  $j$  ( $1 \leq j \leq 2n$ ) let  $m_j$  denote the unique  $x$ -coordinate of rank  $j$  among the  $2n$  endpoints. We are now ready to define the segment tree of  $V$ . For convenience, we use a declarative definition, as opposed to a more standard procedural definition (Bentley and Wood [BW]). Let  $T$  be a  $(4n + 1)$ -node complete binary tree. For  $i = 2, \dots, 2n$ , we put the  $i$ th leaf from the left in correspondence with both the endpoint  $m_i$  and the interval  $(m_{i-1}, m_i]$ . The leftmost leaf is in correspondence with  $m_1$ . Each internal node is associated with the union of the intervals at the leaves descending from it. We label each node  $v$  of  $T$  as follows: if  $v$  is the root,  $b(v)$  is the null string; else  $b(v)$  is the string of 0's and 1's given by the left (0) and right (1) turns of the path from the root to  $v$ .

Each node  $v$  is associated with a *node-set*  $L(v)$ . The segment  $(x_i, x'_i, y_i)$  is represented in the tree  $T$  by including the index  $i$  into the node-sets of a collection of nodes

with label-set  $C_i$ . The set of indices associated with node  $v$  constitutes  $L(v)$ . Let  $l_i$  and  $r_i$  be, respectively, the leaf corresponding to  $x_i$  and the leaf immediately to the right of the one associated with  $x'_i$ . Let  $p$  be the longest common prefix of  $b(l_i)$  and  $b(r_i)$ . We can always write  $b(l_i)$  as a string  $p0a_1 \cdots a_l$  of 1's and 0's, and  $b(r_i)$  as a string  $p1b_1 \cdots b_r$ . We define

$$C_i = \{p0a_1 \cdots a_{j-1}1 | a_j = 0\} \cup \{p1b_1 \cdots b_{k-1}0 | b_k = 1\}.$$

Each interval  $(x_i, x'_i]$  is in this way *canonically* partitioned into intervals associated with nodes of  $T$ . Where our data structures for rectangle searching, which we call *S-structures*, differ from segment trees is in the encoding of node-sets. To begin with, we construct an *M-structure* (EPM version) with respect to the  $2n$  endpoints of segments in  $V$ : to break ties between the  $y$ -coordinates of the endpoints of a segment, we may agree for consistency that the left endpoint precedes its right counterpart along the  $y$ -axis. We use  $T$  as the underlying tree of the *M-structure*.

Let us examine the relationship between  $B(v)$  and  $L(v)$ . Recall that each bit of  $B(v)$  is associated with a unique endpoint  $x_j$  or  $x'_j$ . In either case we say that the bit has *index*  $j$ . Without loss of generality, assume that  $v$  is the right child of node  $z$ . Then, by construction, for each  $i$  in  $L(v)$  the endpoint  $x_i$  is associated with a leaf descending from  $z$  and therefore has a *trace* in  $B(z)$ . This allows us to encode  $L(v)$  as a bit vector  $A(v)$  of the same length as  $B(z)$ . The  $k$ th bit of  $A(v)$  is 1 if and only if the index of the  $k$ th bit of  $B(z)$  appears in  $L(v)$ . In this manner for every index in  $L(v)$  there is a unique 1 in  $A(v)$ . All the other bits of  $A(v)$  are set to 0.

Recall that  $B(z)$  appears in compact form in  $W(z)$  as a list of  $B$ -fields. We represent  $A(v)$  exactly like  $B(z)$  ( $A(v)$  and  $B(z)$  are isomorphic). Furthermore, we add pointers between the two lists to make it possible to jump directly between any  $B$ -field in  $B(z)$  into its associated  $A$ -field in  $A(v)$ . To answer a query  $(x, y, y')$  is now straightforward. We perform a binary search to identify the leaf of  $T$  whose associated interval contains  $x$  (if any). Next, we search for  $y$  and  $y'$  in the virtual list  $R(z)$  of each ancestor  $z$  of the leaf. Proceeding down from the root to the leaf, this can be readily done with the *M-structure*. After these preliminaries, we can locate both  $y$  and  $y'$  in each virtual list  $L(v)$  by jumping directly from its virtual counterpart  $R(z)$  ( $z$  is the parent of  $v$ ). Let  $\alpha_0, \alpha_1, \cdots$  be the  $A$ -fields of  $A(v)$ . The previous search leads to two bits, one in  $\alpha_i$  and the other in  $\alpha_j$  ( $i \leq j$ ). The problem is now to identify all the bits equal to 1 in each field of  $L = \{\alpha_{i+1}, \alpha_{i+2}, \cdots, \alpha_{j-1}\}$ , as well as in a certain suffix of  $\alpha_i$  and prefix  $\alpha_j$ . The latter part of the computation can be accomplished in  $O(\log^2 n)$  time per report with  $O(\log n)$  overhead. Assuming that  $L$  is not empty, retrieving the 1's among the fields of  $L$  is more difficult. We will say that  $\alpha_i$  is *vacuous* if each of its bits is set to 0. We cannot just examine the fields  $\alpha_{i+1}, \cdots, \alpha_{j-1}$ , in search of all the 1's, since we would run the risk of visiting many vacuous fields. Instead, we link together the nonvacuous  $A$ -fields. For each relevant bit found we can return to its companion in  $B(z)$  in  $O(\log n)$  time, and then proceed to identify it, which takes another  $O(\log^2 n)$  time.

We must now dynamize this static data structure. First, we describe the data structure and its invariants, and then we give an overview of the method used to insert a new horizontal segment (the case of a deletion is similar, so it will be omitted). The data structure is built from a dynamic *M-structure* (as in range reporting) augmented with the  $A$ -fields defined above. Recall that for each internal node  $z$  of  $T$ , we have a search tree  $C(z)$ , whose leaves are associated with the  $B$ -fields of  $W(z)$ . Let  $v$  be a child of  $z$ ; we define  $\mathcal{T}(v)$  to be a tree isomorphic to  $C(z)$ . The leaves of  $\mathcal{T}(v)$  are in

one-to-one correspondence with the  $A$ -fields of  $A(v)$  and, as before, these  $A$ -fields are isomorphic to the  $B$ -fields of  $B(z)$  and connected to them via pointers. Instead of linking together nonvacuous  $A$ -fields, it suffices to keep flags at each node of  $\mathcal{T}(v)$  which is the ancestor of at least one leaf corresponding to a nonvacuous  $A$ -field. With this scheme the position of each relevant bit in the nonvacuous fields at node  $v$  can be found in  $O(\log n)$  time. As before, the identification of these bits will dominate the query time, bringing it up to  $O(k \log^2 n)$ .

How do we insert a new segment? To begin with, we take the two endpoints of the segment and insert them in the underlying  $M$ -structure. This involves the addition of two new leaves in  $T$  and the updating of  $C(v)$  for each node  $v$  on the path from these leaves to the root. Note that for each such internal node and their left ( $v.l$ ) and right ( $v.r$ ) children we must update  $\mathcal{T}(v.l)$  and  $\mathcal{T}(v.r)$  to maintain the invariant of isomorphism with  $C(v)$ . Of course, the update of the flags and the  $A$ -fields will be different depending on whether  $v.l$  or  $v.r$  are nodes of the canonical decomposition of the new segment. It is a simple exercise to show that the updating can be performed in  $O(\log n)$  time per node  $v$ . Thus updating includes checking with neighboring nodes of the new leaves if previously inserted segments may have to undergo changes in their canonical decomposition because of the new insertion. Deletions are symmetric to insertions and therefore quite similar. For details on dynamic operations on segment trees, consult Edelsbrunner [Ed] and Mehlhorn [Me].

The last part of any dynamic operation is to check whether the tree  $T$  has fallen out of balance. If that is the case, we apply the method used for the  $M$ -structure. This implies finding the highest node  $v$  of  $T$  that falls out of balance and reconstructing the entire subtree below  $v$ . The key remark is that all the segments involved in the updating must have at least one endpoint identified by a leaf descending from the parent of  $v$ . Therefore the cost of rebuilding the structure is once again  $O(|H| \log n)$ , where  $H$  is the subtree of  $T$  rooted at  $v$ . The usual counting argument shows that  $O(\log^2 n)$  is an amortized upper bound on the update time.

As in the case of range reporting, we can cut down the query time to  $O(k(\log(2n/k))^2)$  by dovetailing between the method above and a slab-based technique (§ 5). Instead of a dynamic list one will now use a dynamic *interval tree* (Edelsbrunner [Ed])—see also Mehlhorn [Me]. This data structure stores  $n$  intervals on the real axis in linear storage, so that all  $k$  intervals containing an arbitrary query value can be reported in  $O(k + \log n)$  time. Edelsbrunner has shown, moreover, that insertions and deletions can be executed in  $O(\log n)$  amortized time. Using the technique of slabs developed in § 5 we immediately obtain a dynamic algorithm for orthogonal segment intersection with a complexity of  $O(n)$  space,  $O(n \log n)$  preprocessing time,  $O(\log n)$  update time and, for  $k \geq n^{2/3}$ ,  $O(k)$  query time.

*The dynamic case.* (2) *Point enclosure.* This section will not make use of the compaction technique described earlier. The basic approach will be mostly borrowed from McCreight [Mc] and Edelsbrunner [Ed]. For this reason, we will only sketch the data structures, and refer to the aforementioned sources the reader who wishes to reconstruct all the proofs in full detail.

McCreight [Mc] has given a dynamic algorithm for point enclosure with the following performance: the storage needed is  $O(n)$  and the query time is  $O(k + \log^3 n)$ , where  $k$  is the size of the output. We must extend his algorithm a little, however, because it handles only updates over a fixed universe. We assume that the reader is familiar with the concept of a *priority search tree* (McCreight [Mc]). For this reason we only briefly sketch the main features of this data structure. Given a set of  $n$  points in the plane and a fixed line  $L$ , a priority search tree allows us to report all the points

inside a query rectangle constrained to have one of its sides collinear with  $L$ . The complexity of the data structure is  $O(n)$  space,  $O(n \log n)$  preprocessing time and  $O(k + \log n)$  query time, where  $k$  is the number of points to be reported. Furthermore any point can be inserted or deleted in  $O(\log n)$  time.

Let  $V$  be a set of  $n$  2-ranges in  $\mathfrak{R}^2$ . Consider a vertical line  $L$  that separates the collection of  $2n$  vertical sides into two equal-size sets. We associate with the root of a binary tree the set of 2-ranges that intersect  $L$ , and to create the two subtrees below the root we iterate on this process with respect to the 2-ranges falling strictly to the left and strictly to the right of  $L$ . This defines a binary tree  $T$  of height  $O(\log n)$ . The reader familiar with Edelsbrunner [Ed] will recognize in  $T$  the interval tree of the projection of  $V$  on the horizontal axis. For each node  $v$  of  $T$ , clip the 2-ranges associated with  $v$ , using the dividing line at that node. This gives us a set of left ranges  $R_l(v)$  and a set of right ranges  $R_r(v)$ . We construct two similar structures with respect to these collections. We restrict our description to  $R_l(v)$ . Apply exactly the procedure just described to  $R_l(v)$  with respect to the horizontal (and not the vertical) direction. This leads to another interval tree-like structure,  $T_l(v)$ , whose nodes store lists of 2-ranges that are adjacent to both a horizontal and a vertical line. Given any point, finding the 2-ranges that contain it is equivalent to *domination searching* (Fig. 3). This problem involves preprocessing a set of points in the plane so that, for any query point  $q$ , finding which of the given points are dominated by  $q$  in both  $x$  and  $y$  coordinates can be done efficiently. But this is right up the alley of McCreight's priority search tree [Mc]. Putting all these simple observations together leads to a data structure of linear size for solving point enclosure reporting in time  $O(k + \log^3 n)$ , where  $k$  is the size of the output. Note that the cubic term comes from the fact that McCreight's structure is called upon on the order of  $\log n$  times for each level of  $T$ .

FIG. 3

Edelsbrunner [Ed] has shown that interval trees can be updated in  $O(\log n)$  amortized time. Using the fact that a priority search tree on presorted points can be computed in linear time, we can use Edelsbrunner's method almost verbatim and derive

an algorithm for updating each  $T_l(v)$  and  $T_r(v)$  in  $O(\log n)$  amortized time. A similar argument applied to  $T$  leads to an overall  $O(\log^2 n)$  update time. We omit the details. Putting all these results together we have a linear-size data structure for dynamic reporting on an EPM with  $O(\log^2 n)$  update time and  $O(k \log^2 n)$  query time. Dovetailing with the alternative algorithms will cut down this query time to the minimum of  $O(k \log^2 n + \log^3 n)$  and  $O(k + n^{2/3})$ , which gives  $O(k \log^2(2n/k) + \log^3 n)$ . Note that a similar observation can be made in the static case. Theorem 6 summarizes our results on rectangle reporting.

**THEOREM 6.** *Data structures for rectangle reporting in two dimensions can be constructed in  $O(n \log n)$  time in all cases. Let  $k - 1$  be the number of points to be reported, and let  $\epsilon$  be any real  $> 0$ . On a RAM, a tradeoff is possible: in particular, we can achieve (1)  $O(k(\log(2n/k))^\epsilon + \log n)$  query time and  $O(n)$  space; (2)  $O(k \log \log(4n/k) + \log n)$  query time and  $O(n \log \log n)$  space; (3)  $O(k + \log n)$  query time and  $O(n \log^\epsilon n)$  space. On an APM (resp., EPM), it is possible to achieve a query time of  $O(k \log(2n/k))$  (resp.,  $O(k(\log(2n/k))^2)$ ), using  $O(n)$  space. In the dynamic case on an EPM, it is possible to achieve a query time of  $O(k(\log(2n/k))^2 + \log^3 n)$  and an update time of  $O(\log^2 n)$  time, using  $O(n)$  space.*

**9. Going into higher dimensions.** Generalizing our result to any fixed dimension is straightforward. For range problems we use a classical technique of Bentley [B2]. Let  $(x_1, \dots, x_d)$  be a system of Cartesian coordinates in  $\mathbb{R}^d$ . We build a complete binary tree with respect to the  $x_d$ -coordinates of the points. Each query range is thus decomposed into  $O(\log n)$  canonical ranges, each of which can be handled by solving a range problem in  $\mathbb{R}^{d-1}$ . The technique generalizes readily for the dynamic case (see Lueker [L], Willard [W2], Willard and Lueker [WL], for example).

As regards rectangle searching, we also follow a standard technique (Edelsbrunner and Maurer [EM]). See also Mehlhorn [Me]. The *left* coordinate of a  $d$ -range refers to its smaller coordinate in dimension  $x_d$ ; its  $x_d$ -interval denotes the interval formed by projecting the  $d$ -range on the  $x_d$ -axis. Let  $R$  be a  $d$ -range and let  $x$  be its left coordinate. We define the *left* face of  $R$  to be the  $(d - 1)$ -range obtained by projecting  $R$  on the hyperplane  $x_d = x$ . A  $d$ -range intersects another if and only if one intersects the other's left face. Since the two conditions are mutually exclusive, barring equalities among coordinates, we can use this criterion for both reporting and counting purposes. The data structure consists of a range tree and segment tree built respectively with respect to the left coordinates and  $x_d$ -intervals of the input. Each node has a pointer to a  $(d - 1)$ -dimensional structure defined recursively. Once again, this generalization is sufficiently well known to avoid further elaboration.

Note that a problem in dimension  $d$  is in this way reduced to  $O(\log^{d-2} n)$  problems in two dimensions. Analyzing the complexity in the nonreporting cases is straightforward. In the reporting problems considered earlier we obtained query times of the form  $O(kf(n, k) + \log n)$ , where  $f(n, k)$  is decreasing in  $k$  and asymptotically equivalent to  $f(n, 1)$  for  $k = O(n^{3/4})$ . To be more accurate, the query times could be expressed as the minimum of  $O(kf(n, 1) + \log n)$  and  $O(k + n^{2/3})$ . This implies that in dimension  $d$  the query times  $Q(n, k)$  are of the form

$$O\left(\log^{d-2} n + \sum_{1 \leq i \leq m} \min(k_i f(n, 1) + \log n, k_i + n^{2/3})\right),$$

where  $\sum_{1 \leq i \leq m} k_i = k$  and  $m = O(\log^{d-2} n)$ . Let  $k = A + B$ , where  $A = \sum_{k_i < n^{2/3}} k_i$  and

$B = \sum_{k_i \geq n^{2/3}} k_i$ . We have

$$Q(n, k) = O(\log^{d-1} n + Af(n, 1) + B).$$

Note that  $A < mn^{2/3}$ . If  $B \geq n^{3/4}$ , then since  $m$  and  $f(n, 1)$  are at most polylogarithmic we have  $Q(n, k) = O(B) = O(k)$ . If now  $B < n^{3/4}$  we have  $k = O(n^{3/4})$ , and therefore  $Q(n, k) = O(\log^{d-1} n + kf(n, k))$ . In all cases, we have shown that  $Q(n, k) = O(kf(n, k) + \log^{d-1} n)$ .

**THEOREM 7.** *Each of the previous data structures (Theorems 1–6) can be extended to  $\mathfrak{R}^d$  ( $d > 2$ ). The complexity of the resulting data structures can be obtained by multiplying each expression in the complexity for two dimensions by a factor of  $\log^{d-2} n$ . (Note: the terms involving  $k$  remain unchanged, but an extra term  $\log^{d-1} n$  must be included in the query time).*

**10. Discussion.** We conclude with a few remarks and open problems.

The  $M$ -structures are essentially transcripts of sorting runs. We have used mergesort as our base sort but we could have turned to other methods as well. If we visualize the preprocessing played backwards and rotate the point set by 90 degrees, what we will see in action is no longer mergesort but quicksort (with median splitting). If we use radix-sort, we will see appear the possibility of tradeoffs between space and query time in higher dimensions, depending on the size of the radix. These simple observations show that the relationship between range search and sorting is rich, indeed, and deserves further investigation. An interesting open question is to determine whether there exist linear-size data structures with polylogarithmic response-time for solving range searching in *any* fixed dimension.

Our data structure for range counting in two dimensions is quite simple. It is very fast and surprisingly economical in its use of storage. Last but not least, it can be implemented with little effort. Unfortunately, this cannot be said of all the data structures in this paper. Some of our upper bounds are obtained at the price of a fairly heavy machinery. Can the algorithms be significantly simplified while keeping the same asymptotic complexity? Can their asymptotic performance be improved?

We believe that many of our bounds for dynamic multidimensional searching can be lowered if one has access to a more powerful machine than an EPM. For example, what improvements can the added power of a RAM buy us?

All the data structures in this paper rely crucially on the use of bit vectors. These have sometimes been used in previous data structures to encode sets—often as addresses in a RAM, like in (Gabow and Tarjan [GT]). Our use of bit vectors is quite different. The nodes of the  $M$ -structures, for example, store bit vectors that encode the history of a computation. This scheme is a departure from previous solutions and raises interesting questions concerning models of computation. It is evident from this work that even seemingly *minimal* models such as pointer machines with only comparison and addition can't avoid but allow exotic encodings of the sort. Indeed, it seems that only by placing very strong semantic limitations on the models of computation one might manage to invalidate these data structures. Let us observe that with a few notable exceptions (Tarjan [T], Chazelle [C2], for example) little is known on the computational power of pointer machines. Our results suggest that these might be, indeed, more powerful than expected.

## PARALLEL TIME $O(\log n)$ ACCEPTANCE OF DETERMINISTIC CFLs ON AN EXCLUSIVE-WRITE P-RAM\*

PHILIP N. KLEIN† AND JOHN H. REIF‡

**Abstract.** We give an algorithm for accepting a deterministic context-free language on the P-RAM, an exclusive-write, concurrent-read model of parallel computation. Whereas on inputs of length  $n$ , a deterministic push-down automaton will use time linear in  $n$ , our algorithm runs in time  $O(\log n)$  on  $n^3$  processors. The algorithm is easily generalized to permit parallel simulation of any deterministic auxiliary pushdown automaton that uses space  $s(n) \cong \log n$  and time  $2^{O(s(n))}$ . The simulation runs in time  $O(s(n))$  on  $2^{O(s(n))}$  processors, and is nearly optimal, since we observe that any language accepted by a P-RAM in time  $T(n)$  is accepted by a deterministic auxiliary pushdown automaton in space  $T(n)$  and time  $2^{O(T(n)^2)}$ .

**Key words.** parallel algorithms, parallel computation, formal language theory, context-free language recognition

**AMS(MOS) subject classification.** 68Q20

**1. Introduction.** In this paper, we address the parallel complexity of parsing. The study of algorithms for parsing has a long history (see, e.g., [4]), but it is only fairly recently that parallel algorithms for parsing began to be investigated. Previous papers ([8], [10]) have contained parallel algorithms for recognition of general context-free languages. We give a faster parallel algorithm for recognition of deterministic context-free languages on an exclusive-write model of parallel computation. An algorithm for parsing such languages may be readily derived from our algorithm.

Parsing of deterministic context-free languages arises in program compilation. Deterministic context-free languages can be used to capture the syntax of many of the commonly used programming languages. The  $LR(k)$  grammars of [7], for example, generate exactly the deterministic context-free languages, so our algorithm may be applied to the parsing of programming languages generated by such grammars.

The deterministic context-free languages are exactly those accepted by deterministic pushdown automata, so our algorithm can effectively simulate any deterministic pushdown automaton. More generally, our algorithm can be used to simulate a deterministic auxiliary pushdown automaton, i.e., a deterministic pushdown automaton with a bounded worktape.

The model of parallel computation we use in this paper is the concurrent-read, exclusive-write P-RAM. The P-RAM is a parallel random access machine model defined by Fortune and Wyllie in [3]. It consists of a collection of synchronous deterministic unit-cost RAMs with shared memory locations indexed by the natural numbers. The P-RAM disallows concurrent writes. That is, no two processors can attempt to write into the same memory location on the same step. Concurrent reads, however, are permitted. During each step, any memory location may be read simultaneously by any number of processors.

---

Previously Fortune and Wyllie showed that any language accepted by a deterministic Turing machine with space bound  $s(n) \geq \log n$  is accepted in time  $O(s(n))$  by a P-RAM. Also, Ruzzo showed in [10] that any language accepted by a *nondeterministic* auxiliary pushdown machine with space  $s(n) \geq \log n$  and time  $2^{O(s(n))}$  can be accepted in time  $O(s(n)^2)$  by an apparently weaker parallel machine model, the uniform circuit family. In particular, he gave a parallel algorithm for recognition of general context-free languages that requires  $O(\log^2 n)$  time and  $n^6$  processors on a uniform circuit family. Although Ruzzo's algorithm requires only  $O(\log n)$  time on a more powerful parallel model in which concurrent writes are permitted, there seems no way to take advantage of the more limited power of the exclusive-write P-RAM to achieve  $O(\log n)$  time for recognition of an arbitrary context-free language.

Our contribution is to show that, if a context-free language is in fact deterministic, then  $O(\log n)$  time recognition is indeed possible on a P-RAM. We give a very simple algorithm to solve this problem—so simple, it might be practical to implement. Its proof, however, is rather complicated. This is perhaps understandable in view of the fact that our result implies Cook's result [2] that a deterministic context-free language can be recognized in  $O(\log^2 n)$  space and polynomial time on a Turing machine. We also show as a corollary to our main result that a P-RAM can simulate a *deterministic*  $s(n)$  space-bounded,  $2^{O(s(n))}$  time-bounded auxiliary pushdown automaton in parallel time  $O(s(n))$  with  $2^{O(s(n))}$  processors.

One further difference between Ruzzo's algorithm and ours may be of greater practical significance: the processor bounds. Ruzzo's algorithm for context-free language recognition seems to require  $n^6$  processors to achieve  $O(\log^2 n)$  parallel time on a uniform circuit family. However, if the language is *deterministic* context-free, our algorithm can recognize it in  $O(\log n)$  time on only  $n^3$  processors of a P-RAM. Moreover, our algorithm can be modified [6] to run on only  $n^2 \log n$  processors (but in  $O(\log^2 n)$  time).

The form of the paper is as follows: in § 2, we describe a well-known parallel algorithm for simulating a deterministic space-bounded Turing machine; the algorithm and its proof serve to prepare the ground for our algorithm for simulating a deterministic push-down automaton (DPDA). In § 3, we describe some assumptions we make of the simulated DPDA in order to simplify the presentation of the algorithm. In § 4, we introduce the notion of a surface configuration, and define some notation that will be useful in the algorithm's proof of correctness. In § 5, we present the parallel algorithm itself, and in § 6, we explain the algorithm and prove its correctness. In § 7, we remark on improving the processor bound of our algorithm. In § 8, we observe that the P-RAM algorithm may be generalized to simulate any deterministic auxiliary pushdown automaton. Finally, in § 9, we observe that our simulation of § 8 is almost optimal, since there is a comparable simulation of P-RAMs by deterministic auxiliary pushdown automata.

**2. Simulating a deterministic space-bounded Turing machine.** To motivate the algorithm for simulating a deterministic pushdown automaton, we first discuss the algorithm for a simpler related case, in which the simulated automaton does not possess a stack. A careful reading of the proof of correctness for this latter algorithm will aid the reader in understanding the proof of correctness for the former algorithm.

Let  $M$  be an  $S(n)$  space-bounded deterministic Turing machine, where  $S(n) = \Omega(\log n)$ . We may assume that  $M$  is  $T(n)$  time-bounded, where  $T(n) = 2^{O(S(n))}$ . We give an algorithm for simulating  $M$  that takes  $O(\log T(n))$  time on  $2^{O(S(n))}$  processors of a P-RAM. This is a well-known simulation due to Fortune and Wyllie [3].

We will call an encoding of the Turing machine's finite state, worktape contents, and tape head positions a *configuration*. Let  $\mathcal{C}_\omega$  denote the set of configurations of the Turing machine on input  $\omega$ . It is easy to see that the number of configurations  $|\mathcal{C}_\omega|$  is  $2^{O(S(n))}$ . Let  $c_0, c_{\text{accept}} \in \mathcal{C}_\omega$  be the initial and accepting configurations. Let  $\vdash \subset \mathcal{C}_\omega \times \mathcal{C}_\omega$  be the next move relation, and let  $\vdash^+$  and  $\vdash^*$  be its transitive and reflexive-transitive closures, respectively. For any nonnegative integer  $i$ , let  $\vdash^i$  be the  $i$ -fold composition of  $\vdash$  (reachability in exactly  $i$  steps). We assume that there is no next move from the unique accepting configuration  $c_{\text{accept}}$ .

We shall simulate the Turing machine  $M$  in  $O(\log T(n))$  steps, using one processor for each configuration. The algorithm consists of  $\lceil \log_2 T(n) \rceil + 1$  stages. At each stage, every processor inspects the values of a constant number of memory locations (each containing a configuration) and stores a configuration into another memory location. The memory is represented by a collection of arrays  $FAR_k$  ( $k = 0, 1, \dots, \lceil \log_2 T(n) \rceil$ ) of configurations, indexed by configurations. The  $k$ th stage of the algorithm ( $k = 0, 1, \dots, \lceil \log_2 T(n) \rceil$ ) computes, for each configuration  $c$ , the configuration  $FAR_k[c]$  such that  $c \vdash^{2^k} FAR_k[c]$ . (If there is no configuration  $2^k$  steps from  $c$ , then  $FAR_k[c]$  is the configuration that is as many steps from  $c$  as possible.) After the last stage, we can examine the configuration  $c' = FAR_{\lceil \log T(n) \rceil}[c_0]$  to determine if  $c' = c_{\text{accept}}$ . If in fact  $c'$  is the accepting configuration, we may conclude that the automaton  $M$  accepted its input. Conversely, if  $M$  eventually enters the accepting configuration  $c_{\text{accept}}$  when started in the initial configuration  $c_0$ , then it does so in at most  $T(n)$  steps. Hence  $FAR_k[c_0] = c_{\text{accept}}$ .

The algorithm for computing  $FAR_k[c]$  for each configuration  $c$  and each  $k = 0, 1, \dots, \lceil \log_2 T(n) \rceil$  is as follows:

ALGORITHM: *TM-SIM*( $M$ ).

Input: a string  $\omega \in \Sigma^n$

Output: *YES* if  $M$  accepts  $\omega$ , *NO* otherwise.

- 1 To initialize (stage 0),
- 2 for all configurations  $c$  in parallel,
- 3 set  $FAR_0[c] := \begin{cases} c' & \text{if } c \vdash c', \\ c & \text{else.} \end{cases}$
- 4 For each subsequent stage  $k+1$  ( $k = 0, 1, \dots, \lceil \log_2 T(n) \rceil$ ),
- 5 for all configurations  $c$  in parallel,
- 6 set  $FAR_{k+1}[c] := FAR_k[FAR_k[c]]$ .
- 7 Finally, output *YES* if  $FAR_k[c_0] = c_{\text{accept}}$ ,
- 8 *NO* otherwise.

Intuitively, the algorithm works by composing two computations of length  $2^k$  to get a single computation of length  $2^{k+1}$ . Figure 1 illustrates this process.

FIG. 1. Three stages of the Turing machine simulation.

The proof of correctness is a simple induction; we give it in detail in order to prepare the ground for similar proofs that are to come.

DEFINITION. Let  $c$  be a configuration, and suppose another configuration  $c'$  reachable from  $c$  is either

- at least  $2^k$  steps from  $c$ , or
- the last configuration reachable from  $c$ .

Then we say that  $c'$  is  $k$ -far from  $c$ .

THEOREM 1. For each configuration  $c$ , for each  $k = 0, 1, \dots, \lceil \log_2 T(n) \rceil$ ,  $FAR_k[c]$  is  $k$ -far from  $c$  (correctness of  $FAR_k$ ).

*Proof of Theorem 1 by induction on  $k$ .* The basis  $k = 0$  is easy to check. Suppose the theorem holds for  $k$ , and let  $c$  be any configuration. In line 6, the algorithm sets  $FAR_{k+1}[c] = FAR_k[FAR_k[c]]$ . Let  $c' = FAR_k[c]$ , so  $FAR_{k+1}[c] = FAR_k[c']$ . By the induction hypothesis,  $c'$  is  $k$ -far from  $c$  and  $FAR_k[c']$  is  $k$ -far from  $c'$ . We have immediately that  $c \vdash^* c'$  and  $c' \vdash^* FAR_k[c']$ , hence  $c \vdash^* FAR_k[c']$ .

If  $c'$  is the last configuration reachable from  $c$ , then  $FAR_k[c'] = c'$ , so  $FAR_k[c']$  is also the last configuration reachable from  $c$ . In this case, certainly  $FAR_k[c']$  is  $(k+1)$ -far from  $c$ , and we are done. Therefore, assume that  $FAR_k[c']$  is not the last configuration reachable from  $c$ . It follows that  $FAR_k[c']$  is also not the last configuration reachable from  $c'$ .

Because  $c'$  is  $k$ -far from  $c$  (but not the last configuration reachable from  $c$ ), we must conclude that  $c'$  is at least  $2^k$  steps from  $c$ . Similarly,  $FAR_k[c']$  is at least  $2^k$  steps from  $c'$ , so  $FAR_k[c']$  is at least  $2^k + 2^k = 2^{k+1}$  steps from  $c$ , and we are done.  $\square$

**3. A normal form for deterministic pushdown automata.** This section defines a normal form for deterministic pushdown automata, and proves that every deterministic context-free language is accepted by some pushdown automaton in normal form. In § 5, we will give an algorithm for simulating any pushdown automaton in normal form. Throughout this paper, we will denote the length of a string  $s$  by  $|s|$ , and the empty string by  $\epsilon$ . We denote the concatenation of strings  $s_1$  and  $s_2$  by  $s_1 \circ s_2$ . A *prefix* of a string  $s$  is an initial substring of  $s$ .

We say a deterministic pushdown automaton is in *normal form* if it satisfies the following assumptions:

*Assumptions.*

(1) All pushes and advances of the input head occur together; a step of  $M$  involves a push if and only if the head advances on that step.

(2)  $M$  accepts by a unique final state, and  $M$  has no move from a configuration with a final state.

(3) The only stack operations are to push one symbol or to erase the top element (pop).

(4) Whether  $M$ 's move from a configuration involves a push or pop does not depend on the current stack contents; it depends only on the current state and the input symbol currently being scanned.

(5) If  $M$ 's move from a configuration does not involve a pop, then the new *state* also does not depend on the stack contents.

(6)  $M$ 's initial configuration has an empty stack.

There is an apparent paradox. Let  $c$  be any configuration of  $M$  with a nonempty stack, and let  $c'$  be the corresponding configuration with an empty stack (i.e., same state, same input head position). By our assumption (4), if  $M$ 's move from  $c$  involves a pop, then  $M$ 's move from  $c'$  involves a pop—but  $c'$  has an empty stack, so a pop is impossible! We resolve this conflict by requiring that if  $M$ 's move from  $c$  involves a pop, then  $M$  has *no* move from  $c'$ , and we say that  $M$  is *stuck* at  $c'$ . Intuitively,  $M$

“tried” to pop at  $c'$ , but discovered that its stack was empty, forcing  $M$  to freeze. This situation will arise in our algorithm to simulate  $M$ .

Note that assumption 1 ensures that the stack height never grows by more than  $n$ , the size of the input.

The following lemma ensures that we can make the above assumptions of  $M$  without loss of generality.

**LEMMA 1.** *For any deterministic context-free language  $L$ , there is a deterministic pushdown automaton  $M$  satisfying assumptions (1), (2), (3), (4), (5), and (6) that accepts the language  $L\$$  ( $L\$ = \{w\$ \mid w \in L\}$ , where  $\$$  is a special symbol).*

*Proof.* For any DCFL  $L$ , there is an  $LR(0)$  grammar  $G$  generating  $L\$$ . Construct a DPDA  $M_1$  that accepts  $L\$$  as described in Theorem 10.10 of [5]; the automaton  $M_1$  is a shift-reduce parser for  $L\$$ , and can be constructed so as to push a single symbol onto the stack for each input symbol it consumes—and never push otherwise. Thus  $M_1$  satisfies assumption (1). Moreover,  $M_1$  is constructed so as to pop at most one symbol from the stack in a single move. Also,  $M_1$  can be made to accept by a unique final state, and we can easily ensure that  $M_1$  has no transitions from its final state. Thus  $M_1$  satisfies assumption (2). Next, construct a DPDA  $M_2$  that simulates  $M_1$  but keeps the top symbol of  $M_1$ 's stack in its finite control. The DPDA  $M_2$  need never look at its stack except to update the stored stack symbol in the event that it pops. Thus  $M_2$  satisfies assumptions (3), (4), and (5). Because the initial configuration of  $M_1$  had a stack of one symbol, and  $M_2$  stores one stack symbol in its finite control, the initial configuration of  $M_2$  has an empty stack. Thus  $M_2$  satisfies assumption (6).  $\square$

**4. Surface configurations.** The technique of § 2 could be directly applied to the simulation of deterministic pushdown automata. A configuration of a pushdown automaton includes the contents of its stack, however, and the stack may be  $n$  symbols high. This means that the number of configurations of a PDA could be exponential. Recall that in the algorithm of § 2, there is a processor for each configuration. In order to obtain even a subexponential processor bound for simulating a PDA, let alone a polynomial bound, we must therefore take a somewhat different approach. The question therefore arises: can we do without stack information? Surprisingly, the answer is yes. Through a more sophisticated approach to computing the  $FAR_k$  values, we can in fact make do with impoverished configurations that contain only stack height information, rather than the entire stack contents. The reason for this is the limited way in which a pushdown automaton accesses its stack. Suppose that our pushdown automaton enters the configuration  $c$  at some point during its computation, and consider the subcomputation starting from  $c$  and continuing until the stack height first goes below its height at  $c$ . We can simulate this subcomputation without knowing the stack at  $c$ , and we need only keep track of those stack symbols in excess of the stack at  $c$  to carry out this simulation. (We call  $c$  the *base* of the subcomputation.) Note, moreover, that we can apply the same technique to the subcomputation. By repeatedly applying this technique to simulate subcomputations, we can simulate the entire computation in such a way that we never need to associate with a given configuration more than one symbol of its stack. Our algorithm is in fact a dynamic-programming approach to carrying out such a simulation.

Our algorithm manipulates *surface configurations* instead of full configurations. A surface configuration is like a full configuration, but lacks information about stack contents.

Let  $M$  be a deterministic pushdown automaton in normal form with input alphabet  $\Sigma$ , state set  $Q$ , and stack alphabet  $\Gamma$ . Fix an input  $\omega_1 \cdots \omega_n \in \Sigma^n$ . For our purposes, a surface configuration  $x$  will include  $M$ 's current state  $q(x) \in Q$ , the current position

of the input head  $p(x) \in \{1, \dots, n+1\}$ , and a stack height parameter  $h(x)$ , a value between 0 and  $n$ . (By assumptions (1) and (6), the stack of  $M$  never exceeds  $n$  in height.) Let  $X_n = Q \times \{1, \dots, n+1\} \times \{0, \dots, n\}$  be the set of surface configurations associated with an input of length  $n$ . The number of such surface configurations is  $|Q|(n+1)^2$ , which is  $O(n^2)$  for a fixed pushdown automaton. A full configuration is obtained from a surface configuration by appending the stack contents. For  $s \in \Gamma^*$ , the pair  $(x, s)$  represents the configuration of  $M$  when it is in state  $q(x)$ , with input head position  $p(x)$ , and stack  $s$  (where the last symbol of  $s$  is the top of the stack).

We let  $\vdash$  denote the next-move relation:  $(x, s) \vdash (x', s')$  holds if  $M$  moves from state  $q(x)$  with input head position  $p(x)$  and stack  $s$  to state  $q(x')$  with input head position  $p(x')$  and stack  $s'$ , and the following technical condition is satisfied:

$$(1) \qquad h(x') - h(x) = |s'| - |s|.$$

Condition (1) guarantees that changes in the stack height parameter  $h(\cdot)$  reflect changes in stack height. Note that we do not require of a configuration  $(x, s)$  that  $h(x)$  be the actual height of the stack  $s$ . Indeed, in simulating the subcomputations out of which we shall construct the full computation, we find it useful to associate with a single surface configuration  $x$  a (possibly) different stack for each subcomputation in which  $x$  occurs. For example, suppose  $(x, s)$  is the base of a subcomputation in our simulation. It suffices to carry out the simulation of the subcomputation from the configuration  $(x, \varepsilon)$ . Condition 1 is a compromise that allows us this flexibility, while still enabling us to track the stack height over the course of a single subcomputation.

By a simple induction, we obtain:

LEMMA 2 (Stack Height Lemma). *For any  $x, x' \in X$  and  $s, s' \in \Gamma^*$ , if  $(x, s) \vdash^*(x', s')$  then  $|s'| - |s| = h(x') - h(x)$ .  $\square$*

Because the input head is one-way, we have

$$(2) \qquad \text{if } (x, s) \vdash^*(y, s') \text{ then } p(y) \cong p(x).$$

Because we assumed that each push is accompanied by an advance of the input head (assumption (1)), we have

$$(3) \qquad \text{if } (x, s) \vdash^*(y, s') \text{ and } |s'| > |s|, \text{ then } p(y) > p(x).$$

One might well ask: given that surface configurations lack stack contents information, what use are they? We would like to define a next-move relation, analogous to  $\vdash$ , between surface configurations, but without the addition of stack contents, such a relation would not be well defined. However, there is a way to finesse this difficulty. We will define a separate next-move relation  $\vdash_u$  for each surface configuration  $u$ . Before defining this notation, we must prove a lemma which ensures its well definedness.

LEMMA 3 (Uniqueness Lemma). *If  $(u, s) \vdash^*(x, s_1)$  and  $(u, s) \vdash^*(x, s_2)$  then  $s_1 = s_2$  (i.e.,  $s_1$  is uniquely determined by  $u, s$ , and  $x$ ).*

*Proof.* Either  $(x, s_1) \vdash^*(x, s_2)$  or  $(x, s_2) \vdash^*(x, s_1)$ . Suppose without loss of generality that  $(x, s_1) \vdash^*(x, s_2)$ . By the Stack Height Lemma,  $|s_1| = |s_2|$ . If any intermediate configuration  $(y, s_3)$  had  $|s_3| > |s_1|$  then, by (2) and (3), we would have  $p(x) \cong p(y) > p(x)$ , a contradiction. Similarly  $|s_3| < |s_1|$  leads to a contradiction. Hence  $|s_3| = |s_1|$ , i.e., every intermediate configuration has stack height equal to  $|s_1|$ . But since  $M$  never changes the stack without pushing or popping, we may conclude  $s_1 = s_2$ .  $\square$

DEFINITION. For any surface configuration  $u$ , we define the relation  $\vdash_u$  on surface configurations as follows:

$$x \vdash_u y \text{ if for some } s, s' \in \Gamma^*, (u, \varepsilon) \vdash^*(x, s) \vdash (y, s').$$

By the Uniqueness Lemma,  $u$  and  $x$  together determine  $s$ ; similarly,  $u$  and  $y$  determine  $s'$ . Thus when we write  $x \vdash_u y$ , the stack contents associated with  $x$  and  $y$  are implicit. We call  $u$  the *base* of the computation  $x \vdash_u y$ , and say that, *relative* to the base  $u$ ,  $M$  moves from  $x$  to  $y$ . The relations  $\vdash_u^*$ ,  $\vdash_u^+$ , and  $\vdash_u^i$  for  $i \geq 0$  are defined analogously.

Intuitively,  $x \vdash_u^* y$  is an assertion that there is a computation passing through  $u$ ,  $x$ , and  $y$ , in that order, in which the stack height never goes below the stack height at  $u$ .

We illustrate a possible computation  $x \vdash_u^* y$  in Fig. 2. This diagram charts the changes in stack height of the automaton  $M$  as it proceeds through the computation from  $(u, \varepsilon)$  to  $(x, s)$  to  $(y, s')$ . We use such diagrams throughout this paper. They may be viewed as plots of stack height versus number of steps taken, with the base appearing as the origin in the bottom left corner of the diagram. Figures 2 and 3 also show the stack contents associated with the labelled surface configurations.

For any surface configuration  $u$ , we define the predicate  $LAST_u(\cdot)$  on surface configurations as follows:

$LAST_u(x)$  holds iff  $u \vdash_u^* x$  but there is no surface configuration,  $y$  satisfying  $x \vdash_u y$ .

That is,  $LAST_u(x)$  holds if  $x$  is the last surface configuration reachable from  $(u, \varepsilon)$ .

Remarks.

(1)  $x \vdash_x^* y$  means simply that  $(x, \varepsilon) \vdash^*(y, s)$  for some  $s$  (determined, of course, by  $x$  and  $y$ ).

(2)  $x \vdash_u y$  implies that  $h(x) \geq h(u)$  (by the Stack Height Lemma, since  $(u, \varepsilon) \vdash^*(x, s)$  for some  $s$ ). Similarly,  $h(y) \geq h(u)$ .

FIG. 2.  $x \vdash_u^* y$ .

FIG. 3.  $x \vdash_v y$  implies  $x \vdash_u y$ .

(3) Suppose that  $(u, \varepsilon) \vdash^*(v, s)$ . Then, as illustrated in Fig. 3, we have that  $x \vdash_v y$  implies  $x \vdash_u y$  as follows (note the change in base):  $x \vdash_v y$  means that  $(v, \varepsilon) \vdash^*(x, s') \vdash (y, s'')$  for some  $s', s'' \in \Gamma^*$ . But then, by the definition of a pushdown automaton,  $(v, s) \vdash^*(x, s \circ s') \vdash (y, s \circ s'')$ . By combining the computations  $(u, \varepsilon) \vdash^*(v, s)$  and  $(v, s) \vdash^*(x, s \circ s') \vdash (y, s \circ s'')$ , we obtain  $(u, \varepsilon) \vdash^*(x, s \circ s') \vdash (y, s \circ s'')$ , which is to say  $x \vdash_u y$ .

We strengthen and generalize these remarks in the following lemma and its corollary.

**LEMMA 4 (Stack Lemma).** *Suppose  $u \vdash_u^* v$  and  $v \vdash_v^* x$ . Then for any surface configuration  $y$  and nonnegative integer  $a$ ,  $x \vdash_v^a y$  if and only if*

- $x \vdash_u^a y$ , and
- $h(w) \geq h(v)$  for each  $w$  such that  $x \vdash_u^* w \vdash_u^* y$ .

*Proof.* The *only-if* direction is a straightforward application of the definitions and the Stack Height Lemma. The argument follows the reasoning of remarks (2) and (3) above. The *if* direction is proved by induction on  $a$ . The case  $a = 0$  is trivial. Assume that  $x \vdash_u^a y \vdash_u z$ , so  $x \vdash_u^{a+1} z$ , and that  $h(w) \geq h(v)$  for each  $w$  such that  $x \vdash_u^* w \vdash_u^* y$ .

By the induction hypothesis, we have  $x \vdash_v^a y$ . We need only show that  $y \vdash_v z$  follows from  $y \vdash_u z$ . We know that for some stack  $s_y$ ,  $(v, \varepsilon) \vdash^*(y, s_y)$ , and that for some stack  $s$ ,  $(u, \varepsilon) \vdash^*(v, s)$ . Hence  $(u, \varepsilon) \vdash^*(v, s) \vdash^*(y, s \circ s_y)$  by definition of a pushdown automaton.

Now,  $y \vdash_u z$  means that  $(y, s \circ s_y) \vdash (z, s')$ . Recall that our pushdown automaton  $M$  never looks at its stack unless it is about to pop a symbol. Moreover, even if  $M$  is about to pop, it only looks at the top symbol of its stack. Thus the configurations  $(y, s \circ s_y)$  and  $(y, s_y)$  look the same to  $M$  unless  $M$  is about to pop and  $s_y = \varepsilon$ .

It follows that either  $(y, s_y) \vdash (z, s'')$  for some stack  $s''$ , or  $M$ 's move from  $(y, s \circ s_y)$  is a pop and  $s_y = \varepsilon$ . In the first case,  $y \vdash_v z$ , and we are done. In the second case,  $h(z) < h(y)$  (because the move from  $y$  to  $z$  involves a pop), and  $h(y) = h(v)$  (because  $(v, \varepsilon) \vdash^*(y, \varepsilon)$ ). We must conclude that  $h(z) < h(v)$ , which is a contradiction.  $\square$

**COROLLARY.** *Suppose  $u \vdash_u^* v \vdash_u^* x$  and  $x \vdash_v^* y$ . Then the surface configurations making up the computation  $x \vdash_u^* y$  are exactly the surface configurations making up the computation  $x \vdash_v^* y$ . Formally, any  $w$  satisfying  $x \vdash_u^* w \vdash_u^* y$  also satisfies  $x \vdash_v^* w \vdash_v^* y$ .*

*Proof.* Suppose  $w$  satisfies  $x \vdash_u^* w \vdash_u^* y$ . By the Stack Lemma, since  $x \vdash_v^* y$ , we have  $h(w') \geq h(v)$  for every  $w'$  such that  $x \vdash_v^* w' \vdash_v^* y$ . This includes all  $w'$  such that  $x \vdash_u^* w' \vdash_u^* w$ , so we have  $x \vdash_v^* w$  by the *if* direction of the Stack Lemma. We can similarly obtain  $w \vdash_v^* y$ , so  $x \vdash_v^* w \vdash_v^* y$ , and we are done.  $\square$

**5. An algorithm for simulating a deterministic PDA.** In this section, we give the algorithm for simulating a deterministic pushdown automaton  $M$  that is in normal form.

Let  $M$  be a deterministic pushdown automaton in normal form with input alphabet  $\Sigma$ , state set  $Q$ , start state  $q_0$ , accepting state  $q_{\text{accept}}$ , and stack alphabet  $\Gamma$ . Let  $x_0$  be the surface configuration with  $q(x_0) = q_0$ ,  $p(x_0) = 1$ , and  $h(x_0) = 0$ . Thus  $(x_0, \varepsilon)$  is the starting configuration. Let  $X_n = Q \times \{1, \dots, n+1\} \times \{0, \dots, n\}$  be the set of surface configurations for an input of length  $n$ .

Let  $T(n) = 2|Q|(n+1)$ . We claim that if  $M$  accepts an input of length  $n$ , it does so in at most  $T(n)$  steps. The automaton  $M$  cannot go more than  $|Q|$  steps without pushing, popping, or looping. Moreover,  $M$  cannot push more than  $n$  times, because each push is accompanied by an advance of the input head. Finally,  $M$  cannot pop more times than it pushes, so the claim follows.

Our algorithm will simulate  $T(n)$  steps of  $M$  in  $\lceil \log T(n) \rceil + 1 = O(\log n)$  stages. It makes use of the arrays  $FAR_k$ ,  $HOP_k$ , and  $LOW_k$  for  $k = 0, 1, \dots, \lceil \log_2 T(n) \rceil$ .

In direct analogy with the algorithm of § 2 for simulating an arbitrary deterministic automaton, the algorithm for simulating a pushdown automaton consists of stages  $k = 0, 1, \dots, \lceil \log_2 T(n) \rceil$ . At stage  $k$ , for each surface configuration  $x$ , the array element  $FAR_k[x]$  is a surface configuration such that  $x \vdash_x^* FAR_k[x]$ . After stage  $\lceil \log T(n) \rceil$ , in lines 21–22 the algorithm inspects  $FAR_{\lceil \log T(n) \rceil}[x_0]$  and determines whether it is an accepting configuration. If so, the algorithm concludes that the pushdown automaton  $M$  accepts its input, and outputs YES. Otherwise, it outputs NO.

ALGORITHM: *DPDA-SIM*( $M$ ).

Input: a string  $w \in \Sigma^n$

Output: YES if  $M$  accepts  $w$ , NO otherwise.

- 1 To initialize (stage 0),
- 2 for all surface configurations  $x \in X_n$  in parallel,
- 3 set  $FAR_0[x] := \begin{cases} y & \text{if } (x, \varepsilon) \vdash (y, \sigma), \\ x & \text{if } LAST_x(x), \end{cases}$
- 4 set  $HOP_0[x] := \begin{cases} FAR_0[x] & \text{if } h(FAR_0[x]) = h(x), \\ x & \text{else.} \end{cases}$

Note that  $h(x) \leq h(FAR_0[x]) \leq h(x) + 1$ .

- 5 for all  $x, y \in X_n$  such that  $h(x) \leq h(y) \leq h(FAR_0[x])$  in parallel,
- 6 if  $M$  is stuck at  $(x, \varepsilon)$  then set  $LOW_0[x, y] := x$
- 7 else let  $\sigma$  satisfy  $(x, \varepsilon) \vdash (FAR_0[x], \sigma)$ ,
- 8 and let  $s = \begin{cases} \sigma & \text{if } h(y) = h(FAR_0[x]), \\ \varepsilon & \text{if } h(y) < h(FAR_0[x]) \end{cases}$
- 9 If  $M$  is stuck at  $(y, s)$  then set  $LOW_0[x, y] := y$
- 10 else let  $z, s'$  satisfy  $(y, s) \vdash (z, s')$
- 11 and set  $LOW_0[x, y] := \begin{cases} z & \text{if } h(z) \leq h(y), \\ y & \text{else.} \end{cases}$

(See Figs. 4 and 5 for examples.)

- 11 For each subsequent stage  $k + 1$  ( $k = 0, 1, \dots, \lceil \log_2 T(n) \rceil$ ),
- 12 for all configurations  $x \in X_n$  in parallel,
- 13 let  $\hat{x}$  denote  $LOW_k[x, FAR_k[x]]$
- 14 set  $FAR_{k+1}[x] := FAR_k[\hat{x}]$ .
- 15 set  $HOP_{k+1}[x] := \begin{cases} \hat{x} & \text{if } h(\hat{x}) = h(x), \\ HOP_k[x] & \text{else} \end{cases}$
- 16 For all  $x, y \in X_n$ ,

FIG. 4.  $LOW_0[x, y] = z$  in case  $h(z) \leq h(y)$ .

FIG. 5.  $LOW_0[x, y] = y$  in case  $h(z) > h(y)$ .

17 let  $LHL_{k+1}[x, y]$  denote  $LOW_k[x, HOP_{k+1}[LOW_k[x, y]]]$   
 18 For all  $x, y \in X_n$  such that  $h(x) \leq h(y) \leq h(FAR_{k+1}[x])$  in parallel,  
 19 set  $LOW_{k+1}[x, y] := \begin{cases} LHL_{k+1}[x, y] & \text{if } h(y) \leq h(\hat{x}), \\ LHL_{k+1}[x, z] & \text{if } h(y) > h(\hat{x}) \text{ and } h(z) = h(\hat{x}), \\ z & \text{else} \end{cases}$   
 20 where  $z = LHL_{k+1}[\hat{x}, y]$ .  
 21 Finally, output YES if  $q(FAR_{\lceil \log T(n) \rceil}[x_0]) = q_{\text{accept}}$   
 22 NO otherwise.

Note that in lines 5–10 and lines 18–20, not all locations in the arrays  $LOW_k$  are assigned values. Specifically,  $LOW_k[x, y]$  is only assigned a value if  $h(x) \leq h(y) \leq h(FAR_k[x])$ . The other locations in these arrays need not be assigned values, as they have no effect on the eventual output.

**6. Proof of correctness of the algorithm.** We now proceed to explain and prove the algorithm.

There are two fundamental ideas that make the algorithm work. One idea we have already seen in action: that of composing two computations to obtain a computation of twice the length. This was the fundamental idea in the algorithm of § 2 for simulating a deterministic automaton, and it recurs several times in the algorithm for simulating a pushdown automaton. It is by no means a new idea; it has played a role in many proofs, e.g., that of Savitch's theorem. The second idea, introduced in § 4, is that of considering computations between surface configurations relative to a base surface configuration.

To show that the algorithm is correct, we prove that the arrays  $FAR_k$ ,  $HOP_k$ , and  $LOW_k$  satisfy certain *correctness conditions* for  $k = 0, 1, \dots, \lceil \log_2 T(n) \rceil$ . Then the correctness of the algorithm will follow from the fact that the array  $FAR_{\lceil \log T(n) \rceil}$  satisfies its correctness condition. The proof is by induction on  $k$ : assuming that  $FAR_k$ ,  $HOP_k$ , and  $LOW_k$  satisfy their correctness conditions, we show that  $FAR_{k+1}$ ,  $HOP_{k+1}$ , and  $LOW_{k+1}$  satisfy their correctness conditions. The algorithm and proof also make use at each stage  $k$  of a temporary array,  $LHL_{k+1}$ . The complicated dependencies in the algorithm are reflected in a complicated proof. To aid the reader in following the proof, we provide in Fig. 6 a diagram illustrating the dependencies between the correctness conditions for the various arrays.

**DEFINITION.** Let  $x$  be a surface configuration. We say that another surface configuration  $y$  reachable from  $(x, \varepsilon)$  is *k-far* from  $x$  if

- either  $y$  is at least  $2^k$  steps from  $(x, \varepsilon)$  (i.e.,  $x \vdash_x^i y$  for some  $i \geq 2^k$ ),
- or  $y$  is the last surface configuration reachable from  $(x, \varepsilon)$  (i.e.,  $LAST_x(y)$  holds).

The *correctness condition* for  $FAR_k$  is:

for all  $x \in X_n$ ,  $FAR_k[x]$  is  $k$ -far from  $x$ .

The essential idea in computing  $FAR_{k+1}$  from  $FAR_k$  is combining two  $k$ -far computations to obtain a  $(k+1)$ -far computation. There is a subtlety involved, however. Suppose that, as illustrated in Fig. 7,  $x \vdash_x^{2^k} y$  and  $LAST_y(z)$ , but  $z$  is fewer than  $2^k$  steps from  $y$ . It happens in this case that  $y$  is  $k$ -far from  $x$  and  $z$  is  $k$ -far from  $y$ , but  $z$  is not  $k$ -far from  $x$ . The reason that  $LAST_y(z)$  holds is that the computation from  $(y, \varepsilon)$  reached the configuration  $(z, \varepsilon)$ , from which the next move involved popping a symbol from the stack. The stack is empty, however—there is nothing to pop! As pointed out in § 3, the pushdown automaton  $M$  is stuck at such a configuration. We

FIG. 6. Dependencies between correctness conditions for the arrays.

FIG. 7.  $y$  is  $k$ -far from  $x$ , and  $z$  is  $k$ -far from  $y$ , but  $z$  is not  $(k+1)$ -far from  $x$ .

see that from the perspective of the base  $y$ , the surface configuration  $z$  is an impassable barrier. Viewed from the perspective of the base  $x$ , however,  $z$  is not a barrier. When the automaton  $M$  starts at  $(x, \epsilon)$  it arrives at  $z$  with a nonempty stack. It can then pop a symbol without any fuss, and continue with the computation. Thus  $z$  is a discriminating barrier. It obstructs the computation from  $(y, \epsilon)$  but permits the computation from  $(x, \epsilon)$  to continue unimpeded.

Such discriminating barriers can only arise when the pushdown automaton  $M$  has a disposition to pop a symbol but is prevented from doing so by an empty stack. This is the idea underlying the following lemma.

LEMMA 5 (Barrier Lemma). *Suppose  $x \vdash_x^* z$  and  $y \vdash_y^* z$ . If  $LAST_y(z)$  but not  $LAST_x(z)$  then  $h(z) = h(y)$ .*

*Proof.* Since  $x \vdash_x^* z$  and not  $LAST_x(z)$ , there is a surface configuration  $v$  such that  $z \vdash_x v$ . Since  $y \vdash_y^* z$  (so  $h(z) \geq h(y)$ ) but not  $z \vdash_y v$ , by the Stack Lemma we obtain  $h(v) < h(y)$ . But stack height can change by at most one in a single move, so  $h(v) \geq h(z) - 1$ . It follows that  $h(z) \leq h(v) + 1 \leq h(y)$ . We must conclude that  $h(z) = h(y)$ .  $\square$

The Barrier Lemma enables us to render barriers innocuous, by a careful choice of the surface configuration  $y$ .

DEFINITION. Let  $x, x', y \in X_n$ . We say that  $y$  is  $k$ -low from  $x'$  with respect to the base  $x$  if

1.  $x' \vdash_x^* y$ , and
2. for any  $w$  satisfying  $y \vdash_x^+ w$ , if  $x' \vdash_x^i w$  for some  $i \leq 2^k$ , then  $h(w) > h(y)$ .

We may at times leave the base unspecified if it is clear from the context which base is intended.

Figure 8 depicts a computation in which  $y$  is  $k$ -low from  $x'$  with respect to  $x$ . The intuition is that the stack height of  $y$  is as low as is possible within  $2^k$  steps of  $x'$ . Note, however, that  $y$  may in fact be  $2^k$  or more steps from  $x'$ , in which case (2) is trivially satisfied. Note, moreover, that (2) is again trivially satisfied if  $y$  is the last surface configuration reachable from  $x$ . For example, in Fig. 9, the automaton  $M$  is stuck at  $(y, \epsilon)$ , so  $y$  is  $k$ -low from  $x'$  with respect to  $x$ .

The following lemma will show how we can achieve our aim of combining two  $k$ -far computations to obtain a computation that is  $(k+1)$ -far.

LEMMA 6 (Correctness of  $FAR_{k+1}$ ). Suppose that for the surface configuration  $x$ ,

- (1)  $FAR_k[x]$  is  $k$ -far from  $x$ ;
- (2)  $\hat{x}$  is  $k$ -low from  $FAR_k[x]$  with respect to  $x$ ;
- (3)  $FAR_k[\hat{x}]$  is  $k$ -far from  $\hat{x}$ .

As in line 14 of the algorithm, let  $FAR_{k+1}[x] = FAR_k[\hat{x}]$ . Then  $FAR_{k+1}[x]$  is  $(k+1)$ -far from  $x$ . (See Fig. 10.)

FIG. 8.  $y$  is  $k$ -low from  $x'$  with respect to  $x$ .

FIG. 9.  $y$  is  $k$ -low from  $x'$  with respect to  $x$  because  $M$  is stuck at  $(y, \epsilon)$ .

FIG. 10.  $x \vdash_x^* FAR_k[x] \vdash_x^* \hat{x} \vdash_x^* FAR_k[\hat{x}] = FAR_{k+1}[x]$ .

*Proof.* It follows from (2) by definition that  $x \vdash_x^* \hat{x}$ . It follows from (3) that  $\hat{x} \vdash_x^* FAR_k[\hat{x}]$ , so  $\hat{x} \vdash_x^* FAR_k[\hat{x}] = FAR_{k+1}[x]$  by the Stack Lemma. Combining these two computations yields  $x \vdash_x^* FAR_{k+1}[x]$ .

Now if both the computations  $x \vdash_x^* FAR_k[x]$  and  $\hat{x} \vdash_x^* FAR_k[\hat{x}]$  are at least  $2^k$  steps in length, then certainly the computation  $x \vdash_x^* FAR_k[\hat{x}]$  is at least  $2^{k+1}$  steps, and hence  $FAR_k[\hat{x}]$  is  $(k+1)$ -far from  $x$ . Therefore, we can assume that one of these computations is fewer than  $2^k$  steps in length.

If the computation  $x \vdash_x^* FAR_k[x]$  is fewer than  $2^k$  steps in length, then by (1) it must be that  $LAST_x(FAR_k[x])$  holds. That is,  $FAR_k[x]$  is the last surface configuration reachable from  $(x, \epsilon)$ . But  $\hat{x}$  and  $FAR_k[\hat{x}]$  are also reachable from  $(x, \epsilon)$ , so it must be that  $\hat{x} = FAR_k[\hat{x}] = FAR_k[x]$ . Then  $LAST_x(FAR_k[\hat{x}])$ , so  $FAR_k[\hat{x}]$  is  $(k+1)$ -far from  $x$ .

Now assume that the computation  $x \vdash_x^* FAR_k[x]$  is at least  $2^k$  steps in length, and the computation  $\hat{x} \vdash_x^* FAR_k[\hat{x}]$  is fewer than  $2^k$  steps. By (3), it must be that  $LAST_{\hat{x}}(FAR_k[\hat{x}])$  holds. If in addition  $LAST_x(FAR_k[\hat{x}])$  holds, then  $FAR_k[\hat{x}]$  is  $(k+1)$ -far from  $x$ , and we are done. If  $LAST_x(FAR_k[\hat{x}])$  does not hold, then  $FAR_k[\hat{x}]$  must be a barrier. By the Barrier Lemma,  $h(FAR_k[\hat{x}]) = h(\hat{x})$ . But then, by (2),  $FAR_k[\hat{x}]$  must be more than  $2^k$  steps from  $FAR_k[x]$ , hence more than  $2^{k+1}$  steps from  $x$ , and we are done.  $\square$

Lemma 6 shows that if we can compute a  $k$ -low surface configuration  $\hat{x}$  for each surface configuration  $x$  at each stage  $k$ , we can then compute the  $FAR_{k+1}$  values and thereby carry out the DPDA simulation. The remaining problem, then, is to compute  $\hat{x}$ . We find it necessary to solve a more general problem in order to make possible the computation of a new value of  $\hat{x}$  at each stage. We first introduce yet another new term.

DEFINITION. We say that  $y$  is  $k$ -valid with respect to  $x$  if

- $FAR_k[x] \vdash_x^* y$ , and
- For each  $w$  satisfying  $FAR_k[x] \vdash_x^* w \vdash_x^* y$ , we have  $h(w) \geq h(y)$ .

That is, as Fig. 11 illustrates, there is a computation from  $FAR_k[x]$  to  $y$ , and no configuration in this computation has stack height below that at  $y$ .

FIG. 11.  $y$  is  $k$ -valid with respect to  $x$

The point of this definition is that if  $y$  is  $k$ -valid with respect to  $x$ , then the stack at  $y$  is a prefix<sup>1</sup> of the stack at each previous configuration, all the way back to  $FAR_k[x]$ . In the course of the computation from  $FAR_k[x]$  to  $y$ , the stack height never went below its height at  $y$ , and so the pushdown automaton  $M$  never had an opportunity to modify these lowest symbols of the stack. This is a consequence of our assumption that the automaton  $M$  does not change the top element of the stack.

<sup>1</sup> Recall that we represent a stack as a string with the top element of the stack being the last symbol of the string.

The choice of the term “ $k$ -valid” is motivated by the following: for any surface configuration  $x$ , the  $y$ 's that are “valid” second indices in  $LOW_k[x, \cdot]$  are those  $y$ 's that are  $k$ -valid; if  $y$  is not  $k$ -valid, then  $LOW_k[x, y]$  is meaningless.

The following lemma shows that  $k$ -validity is preserved under computations starting and ending with empty stacks.

LEMMA 7. *If  $y$  is  $k$ -valid with respect to  $x$ , and  $(y, \varepsilon) \vdash^*(y', \varepsilon)$ , then  $y'$  is also  $k$ -valid with respect to  $x$ .*

This is most easily seen by inspecting Fig. 12 and applying the definitions. A rather detailed proof follows:

*Proof.* By definition of  $k$ -validity,  $FAR_k[x] \vdash_x^* y$  and for any  $w$  such that  $FAR_k[x] \vdash_x^* w \vdash_x^* y$ ,  $w$  satisfies  $h(w) \geq h(y)$ . We have that  $(y, \varepsilon) \vdash^*(y', \varepsilon)$ , so by the Stack Lemma:

- (a)  $y \vdash_x^* y'$ , and
- (b)  $h(w) \geq h(y)$  for each  $w$  such that  $y \vdash_x^* w \vdash_x^* y'$ .

By combining the computations  $FAR_k[x] \vdash_x^* y$  and  $y \vdash_x^* y'$ , we obtain  $FAR_k[x] \vdash_x^* y'$ . Now suppose  $w$  satisfies  $FAR_k[x] \vdash_x^* w \vdash_x^* y'$ . There are two possibilities: either  $FAR_k[x] \vdash_x^* w \vdash_x^* y$  or  $y \vdash_x^* w \vdash_x^* y'$ . In the first case,  $h(w) \geq h(y)$  by the  $k$ -validity of  $y$ . In the second case,  $h(w) \geq h(y)$  by (b). In either case, since  $h(y') = h(y)$  by the Stack Height Lemma, we have  $h(w) \geq h(y')$ , so we may conclude that  $y'$  is  $k$ -valid with respect to  $x$ .  $\square$

To make it possible to compute  $\hat{x}$  for each  $x \in X_n$ , we compute a surface configuration  $LOW_k[x, y]$  for pairs  $x, y \in X_n$ . We will inductively prove the following *correctness condition for  $LOW_k$* :

- For all  $x, y \in X_n$ ,
- if  $(\dagger)$   $y$  is  $k$ -valid with respect to  $x$ ,
- then  $LOW_k[x, y]$  is
  - (A)  $k$ -valid with respect to  $x$ , and
  - (B)  $k$ -low from  $y$  with respect to  $x$ .

This means that if  $(\dagger)$  holds, then, as Fig. 13 illustrates,  $LOW_k[x, y]$  has stack height so low that (A) there is no configuration between  $FAR_k[x]$  and  $y$  having stack height

FIG. 12. *If  $y$  is  $k$ -valid with respect to  $x$  and  $(y, \varepsilon) \vdash^*(y', \varepsilon)$ , then  $y'$  is also  $k$ -valid with respect to  $x$ .*

FIG. 13.  *$LOW_k[x, y]$  is  $k$ -valid and  $k$ -low from  $y$  with respect to  $x$ .*

lower, and (B) there is no configuration after  $LOW_k[x, y]$  and within  $2^k$  steps of  $y$  having stack height even as low as that at  $LOW_k[x, y]$ .

In particular, consider  $LOW_k[x, FAR_k[x]]$ . Noting that  $FAR_k[x]$  itself is certainly  $k$ -valid with respect to  $x$ , we see that  $LOW_k[x, FAR_k[x]]$  is  $k$ -low from  $FAR_k[x]$  with respect to  $x$ . This condition is exactly what Lemma 6 requires of  $\hat{x}$ , suggesting that we let  $\hat{x}$  be  $LOW_k[x, FAR_k[x]]$ . This is, in fact, how  $\hat{x}$  is obtained, as the reader can check by inspecting line 13 of the algorithm. As a consequence, it turns out that  $\hat{x}$  is  $k$ -valid in addition to being  $k$ -low from  $FAR_k[x]$ . In what follows, as a notational convenience, we assume for all  $x \in X_n$  that  $\hat{x}$  denotes a surface configuration such that

- (I)  $x \vdash_x^* FAR_k[x] \vdash_x^* \hat{x}$ ;
- (II)  $\hat{x}$  is  $k$ -valid and  $k$ -low from  $FAR_k[x]$  with respect to  $x$ ;
- (III)  $FAR_{k+1}[x] = FAR_k[\hat{x}]$ .

Note that a consequence of (I) is that  $\hat{x} \vdash_{\hat{x}}^* FAR_k[\hat{x}]$ .

LEMMA 8. Any  $w \in X_n$  satisfying  $FAR_k[x] \vdash_x^* w \vdash_x^* FAR_{k+1}[x]$  also satisfies  $h(w) \cong h(\hat{x})$ .

*Proof.* There are two possibilities for  $w$ . Either (1)  $FAR_k[x] \vdash_x^* w \vdash_x^* \hat{x}$  or (2)  $\hat{x} \vdash_x^* w \vdash_x^* FAR_{k+1}[x]$ . In case (1),  $h(\hat{x}) \cong h(w)$  follows from (II). In case (2), using (III), (I), and the corollary to the Stack Lemma, we see that  $\hat{x} \vdash_{\hat{x}}^* w \vdash_{\hat{x}}^* FAR_{k+1}[x]$  (note the change in base). But then  $h(w) \cong h(\hat{x})$  by the Stack Height Lemma.  $\square$

The computation of the  $LOW_{k+1}[x, y]$  values makes use of an array  $HOP_k$ . For each surface configuration  $x$ ,  $HOP_k[x]$  is a surface configuration such that  $(x, \varepsilon) \vdash^*(HOP_k[x], \varepsilon)$ . The reason for the name ‘‘HOP’’ should be evident from Fig. 14.

The array  $HOP_k$  satisfies the following *correctness condition*:

For all  $x \in X_n$ ,

Either  $HOP_k[x]$  is some surface configuration  $w$  such that

$$x \vdash_x^+ w \vdash_x^* FAR_k[x] \text{ and } h(w) = h(x),$$

or, if there is no such  $w$ , then  $HOP_k[x] = x$ .

In either case, we have that  $(x, \varepsilon) \vdash^*(HOP_k[x], \varepsilon)$ . Lemma 7 shows that consequently  $HOP_k[x]$  preserves the  $k'$ -validity of  $x$ , for any  $k'$ . That is, if  $x$  is  $k'$ -valid with respect to some surface configuration  $u$ , then  $HOP_k[x]$  is also  $k'$ -valid with respect to  $u$ .

FIG. 14.  $HOP_k[x]$ .

The next lemma shows that the algorithm inductively ensures the correctness of  $HOP_k$ .

LEMMA 9 (Correctness of  $HOP_k$ ). Suppose that  $HOP_k$  satisfies its correctness condition. As in line 15 of the algorithm, let

$$HOP_{k+1}[x] := \begin{cases} \hat{x} & \text{if } h(\hat{x}) = h(x), \\ HOP_k[x] & \text{else.} \end{cases}$$

Then  $HOP_{k+1}$  satisfies its correctness condition.

Figures 15 and 16 illustrate the two cases in the definition of  $HOP_{k+1}[x]$ .

FIG. 15.  $HOP_{k+1}[x] = HOP_k[x]$  in case  $h(\hat{x}) > h(x)$ .

FIG. 16.  $HOP_{k+1}[x] = \hat{x}$  in case  $h(\hat{x}) = h(x)$ .

*Proof.* We must show that either  $HOP_{k+1}[x]$  is some surface configuration  $w$  such that  $x \vdash_x^+ w \vdash_x^* FAR_{k+1}[x]$  and  $h(w) = h(x)$ , or, if there is no such  $w$ ,  $HOP_{k+1}[x] = x$ . If  $h(\hat{x}) = h(x)$ , then by (II),  $\hat{x}$  is such a  $w$ , so setting  $HOP_{k+1}[x] = \hat{x}$  satisfies the correctness condition for  $HOP_{k+1}[x]$ . Suppose therefore, that  $h(\hat{x}) > h(x)$ . In this case  $HOP_{k+1}[x]$  is defined to be  $HOP_k[x]$ . Now, by our assumption of the correctness of  $HOP_k$ , either  $HOP_k[x]$  is some surface configuration  $w$  such that  $x \vdash_x^+ w \vdash_x^* FAR_k[x]$  and  $h(w) = h(x)$ , or, if there is no such  $w$ ,  $HOP_k[x] = x$ . In the former case,  $w$  certainly satisfies  $x \vdash_x^+ w \vdash_x^* FAR_{k+1}[x]$ , because  $FAR_k[x] \vdash_x^* FAR_{k+1}[x]$ . Consider therefore the latter case:  $HOP_k[x] = x$  because there is no  $w$  satisfying both  $x \vdash_x^+ w \vdash_x^* FAR_k[x]$  and  $h(w) = h(x)$ . Note that by Lemma 8 there is also no  $w$  satisfying both  $FAR_k[x] \vdash_x^* w \vdash_x^* FAR_{k+1}[x]$  and  $h(w) = h(x)$ , so setting  $HOP_{k+1}[x] = x$  satisfies the correctness condition for  $HOP_{k+1}[x]$ .  $\square$

We now consider how the algorithm computes the  $LOW_{k+1}$  values from the  $LOW_k$  values. The computation of the  $LOW_{k+1}$  values makes frequent use of the expression  $LOW_k[x, HOP_{k+1}[LOW_k[x, y]]]$ . For the sake of brevity, therefore, we denote this expression by  $LHL_{k+1}[x, y]$ . Here the name “LHL” is intended to signify that  $LHL_{k+1}[x, y]$  represents a composition of  $LOW_k$ ,  $HOP_{k+1}$ , and again  $LOW_k$ . The reason that this expression is so useful in deriving the  $LOW_{k+1}$  values from the  $LOW_k$  values is that it satisfies a condition “halfway” between the condition on  $LOW_k[x, y]$  and the condition on  $LOW_{k+1}[x, y]$ . Recall the correctness condition for  $LOW_k$ :

- For all  $x, y \in X_n$ ,  
 if  $y$  is  $k$ -valid with respect to  $x$ ,  
 then  $LOW_k[x, y]$  is  
 (A)  $k$ -valid with respect to  $x$ , and  
 (B)  $k$ -low from  $y$  with respect to  $x$ .

The correctness condition for  $LHL_{k+1}$  is:

- For all  $x, y \in X_n$ ,  
 if  $y$  is  $k$ -valid with respect to  $x$ ,  
 then  $LHL_{k+1}[x, y]$  is  
 (A)  $k$ -valid with respect to  $x$ , and  
 (B)  $(k + 1)$ -low from  $y$  with respect to  $x$ .

Notice that the only difference between the condition on  $LOW_k[x, y]$  and that on  $LHL_{k+1}[x, y]$  is that the latter promises  $(k + 1)$ -lowness, while the former can promise only  $k$ -lowness.

LEMMA 10 (Correctness of  $LHL_{k+1}$ ). *As in line 17 of the algorithm, let  $LHL_{k+1}[x, y] = LOW_k[x, HOP_{k+1}[LOW_k[x, y]]]$ . Then the correctness conditions for  $LOW_k$ ,  $FAR_{k+1}$ , and  $HOP_{k+1}$  imply the correctness condition for  $LHL_{k+1}$ .*

*Proof.* Let  $y' = LOW_k[x, y]$  and  $z = LOW_k[x, HOP_{k+1}[y']]$ , so  $LHL_{k+1}[x, y] = z$ . Assume that  $y$  is  $k$ -valid with respect to  $x$ . By the correctness of  $LOW_k[x, y]$ , it follows that  $y'$  is  $k$ -low from  $y$  and  $k$ -valid with respect to  $x$ . By Lemma 7 and the correctness of  $HOP_{k+1}$ , it follows from the latter that  $HOP_{k+1}[y']$  is also  $k$ -valid. Then, by the correctness of  $LOW_k$ ,  $z = LOW_k[x, HOP_{k+1}[y']]$  is also  $k$ -valid. It remains only to show that  $z$  is  $(k + 1)$ -low from  $y$ .

We distinguish two cases, corresponding to the two cases in the correctness condition for  $HOP_{k+1}[y']$ .

*Case 1.*  $HOP_{k+1}[y']$  is some surface configuration  $w$  such that  $h(w) = h(y')$  and  $y' \vdash_{y'}^+ w$ . (This case is illustrated in Fig. 17.) We know that  $y'$  is  $k$ -low from  $y$ , so  $h(HOP_{k+1}[y']) = h(y')$  implies that  $HOP_{k+1}[y']$  must be more than  $2^k$  steps from  $y$ . Now, consider  $z = LOW_k[x, HOP_{k+1}[y']]$ . Since  $z$  is  $k$ -low from  $HOP_{k+1}[y']$ , and  $HOP_{k+1}[y']$  is at least  $2^k$  steps after  $y$ , it follows that  $z$  is  $(k + 1)$ -low from  $y$ , and we are done.

*Case 2.* There is no  $w$  satisfying both  $h(w) = h(y')$  and  $y' \vdash_{y'}^+ w \vdash_{y'}^* FAR_{k+1}[y']$ . (In this case,  $HOP_{k+1}[y'] = y'$ , and so  $z = LOW_k[x, y']$ . See Fig. 18.) There are two possibilities: either  $FAR_{k+1}[y'] = y'$  (i.e.,  $LAST_{y'}(y)$  holds), or  $h(FAR_{k+1}[y']) > h(y')$ . We consider these two cases separately.

*Subcase A.*  $LAST_{y'}(y')$  holds. If in addition  $LAST_x(y')$  holds, then  $z = LOW_k[x, y'] = y'$ , and  $z$  is trivially  $k$ -low, since there is no  $w$  such that  $z \vdash_x^+ w$ . Assume therefore that  $LAST_x(y')$  does not hold, and let  $y''$  be the surface configuration such

FIG. 17.  $LHL_{k+1}[x, y] = LOW_k[x, HOP_{k+1}[y']]$ , in the case where  $y' \vdash_{y'}^+ HOP_{k+1}[y']$ .

FIG. 18.  $LHL_{k+1}[x, y] = LOW_k[x, y']$ , in the case where  $HOP_{k+1}[y'] = y'$ .

that  $y' \vdash_x y''$ . By the Stack Lemma,  $h(y'') < h(y')$ . But then by the  $k$ -lowness of  $y'$ ,  $y''$  is more than  $2^k$  steps after  $y$ . Hence  $y'$  is at least  $2^k$  steps after  $y$ . As in Case 1, since  $z$  is  $k$ -low from  $y'$  and  $y'$  is at least  $2^k$  steps after  $y$ , it follows that  $z$  is  $(k+1)$ -low from  $y$ .

*Subcase B.*  $h(FAR_{k+1}[y']) > h(y')$ . By the Barrier Lemma, it follows that  $LAST_{y'}(FAR_{k+1}[y'])$  implies  $LAST_x(FAR_{k+1}[y'])$ . (Note change in base.) But then by correctness of  $FAR_{k+1}[y']$  (Lemma 6), either  $FAR_{k+1}[y']$  is at least  $2^{k+1}$  steps from  $y'$ , or  $LAST_x(FAR_{k+1}[y'])$ . In either case it follows that every surface configuration  $w$  within  $2^{k+1}$  steps of  $y'$  satisfies  $y' \vdash_{y'}^+ w \vdash_{y'}^* FAR_{k+1}[y']$  and hence  $h(w) > h(y')$ . Since  $z = LOW_k[x, y']$  is  $k$ -low from  $y'$ , certainly  $h(z) \leq h(y')$ . It follows that  $z$  is  $(k+1)$ -low from  $y'$ , so  $z$  is certainly  $(k+1)$ -low from  $y$ , and the proof is complete.  $\square$

We finally show how to compute the  $LOW_{k+1}$  values. The correctness condition for  $LOW_{k+1}$  is:

- For all  $x, y \in X_n$ ,
- if  $y$  is  $(k+1)$ -valid with respect to  $x$
- then  $LOW_{k+1}[x, y]$  is
- (A)  $(k+1)$ -valid with respect to  $x$ , and
- (B)  $(k+1)$ -low from  $y$  with respect to  $x$ .

Note that the only difference between the condition on  $LOW_{k+1}[x, y]$  and that on  $LHL_{k+1}[x, y]$  is that  $LOW_{k+1}[x, y]$  assumes (and delivers)  $(k+1)$ -validity, whereas  $LHL_{k+1}[x, y]$  assumes (and delivers)  $k$ -validity.

We can make use of  $k$ -validity by noting special circumstances under which  $(k+1)$ -validity implies  $k$ -validity, and vice versa.

LEMMA 11. *Suppose that  $y$  is  $(k+1)$ -valid with respect to  $x$ , and  $h(y) \leq h(\hat{x})$ . Then  $y$  is  $k$ -valid with respect to  $x$ .*

*Proof.* See Fig. 19. Since  $FAR_k[x] \vdash_x^* FAR_{k+1}[x]$ , and  $FAR_{k+1}[x] \vdash_x^* y$  by the  $(k+1)$ -validity of  $y$ , it follows that  $FAR_k[x] \vdash_x^* y$ . It remains to be shown that for any  $w \in X_n$  such that  $FAR_k[x] \vdash_x^* w \vdash_x^* y$ ,  $w$  satisfies  $h(w) \geq h(y)$ .

FIG. 19.  $y$  is  $k$ -valid with respect to  $x$ .

There are two cases: either  $FAR_k[x] \vdash_x^* w \vdash_x^* FAR_{k+1}[x]$  or  $FAR_{k+1}[x] \vdash_x^* w \vdash_x^* y$ . In the former case,  $h(w) \geq h(\hat{x})$  by Lemma 8, so  $h(w) \geq h(y)$  by our assumption that  $h(y) \leq h(\hat{x})$ . In the latter case,  $h(w) \geq h(y)$  follows directly from the  $(k+1)$ -validity of  $y$ .  $\square$

LEMMA 12. *Suppose that  $y$  is  $(k+1)$ -valid with respect to  $x$  and  $h(y) \geq h(\hat{x})$ . Then  $y$  is  $k$ -valid with respect to  $\hat{x}$ .*

*Proof.* See Fig. 20. Consider the computation  $FAR_{k+1}[x] \vdash_x^* y$ . By the  $(k+1)$ -validity of  $y$ , this computation consists only of surface configurations  $w$  such that  $h(w) \geq h(y) \geq h(\hat{x})$ . Moreover, recall that  $\hat{x} \vdash_{\hat{x}}^* FAR_k[\hat{x}] = FAR_{k+1}[x]$  (note that the base is  $\hat{x}$ ). It follows by the Stack Lemma that  $FAR_k[\hat{x}] \vdash_{\hat{x}}^* y$ . It remains to show that any surface configuration  $w$  satisfying  $FAR_k[\hat{x}] \vdash_{\hat{x}}^* w \vdash_{\hat{x}}^* y$  has  $h(w) \geq h(y)$ . But any

FIG. 20.  $y$  is  $k$ -valid with respect to  $\hat{x}$ .

such  $w$  must also satisfy  $FAR_k[\hat{x}] \vdash_x^* w \vdash_x^* y$  by the corollary to the Stack Lemma, and hence  $h(w) \geq h(y)$  by the  $(k+1)$ -validity of  $y$ .  $\square$

LEMMA 13. Suppose that  $y$  is  $k$ -valid with respect to  $x$ , and  $FAR_{k+1}[x] \vdash_x^* y$ . Then  $y$  is  $(k+1)$ -valid with respect to  $x$ .

Proof. All we need to show is that for any surface configuration  $w$  such that  $FAR_{k+1}[x] \vdash_x^* w \vdash_x^* y$ , we have  $h(w) \geq h(y)$ . But this follows immediately from the  $k$ -validity of  $y$ , because any such  $w$  also satisfies  $FAR_k[x] \vdash_x^* w \vdash_x^* y$ .  $\square$

LEMMA 14. Suppose  $y$  is  $k$ -valid with respect to  $\hat{x}$ . Then  $y$  is  $(k+1)$ -valid with respect to  $x$ .

Proof. By definition of  $k$ -validity,  $FAR_k[\hat{x}] \vdash_x^* y$ , so  $FAR_k[\hat{x}] \vdash_x^* y$  by the Stack Lemma. Recalling that  $FAR_{k+1}[x] = FAR_k[\hat{x}]$ , we have  $FAR_{k+1}[x] \vdash_x^* y$ . Suppose the surface configuration  $w$  satisfies  $FAR_{k+1}[x] \vdash_x^* w \vdash_x^* y$ . We must show that  $h(w) \geq h(y)$ . But by the corollary to the Stack Lemma,  $w$  satisfies  $FAR_k[\hat{x}] \vdash_x^* w \vdash_x^* y$ , so  $h(w) \geq h(y)$  by definition of  $k$ -validity.  $\square$

LEMMA 15 (Correctness of  $LOW_{k+1}$ ). Assume that  $LHL_{k+1}$  satisfies its correctness condition. As in lines 18–19 of the algorithm, for each  $x, y \in X_n$  such that  $h(x) \leq h(y) \leq h(FAR_{k+1}[x])$ , let

$$LOW_{k+1}[x, y] = \begin{cases} LHL_{k+1}[x, y] & \text{if } h(y) \leq h(\hat{x}), \\ LHL_{k+1}[x, z] & \text{if } h(y) > h(\hat{x}) \text{ and } h(z) = h(\hat{x}), \\ z & \text{else,} \end{cases}$$

where  $z = LHL_{k+1}[\hat{x}, y]$ . Then  $LOW_{k+1}$  satisfies its correctness condition.

Proof. Assume that  $y$  is  $(k+1)$ -valid with respect to  $x$ . We consider the following two cases:

Case 1.  $h(y) \leq h(\hat{x})$ . In this case,  $LOW_{k+1}[x, y]$  is defined to be  $LHL_{k+1}[x, y]$ . See Fig. 21. By Lemma 11,  $y$  is  $k$ -valid with respect to  $x$ . Hence by the correctness of

FIG. 21.  $LOW_{k+1}[x, y] = LHL_{k+1}[x, y]$  in case  $h(y) \leq h(\hat{x})$ .

$LHL_{k+1}$ ,  $LHL_{k+1}[x, y]$  is  $k$ -valid with respect to  $x$  and  $(k+1)$ -low from  $y$  with respect to  $x$ . By Lemma 13,  $LHL_{k+1}[x, y]$  is also  $(k+1)$ -valid with respect to  $x$ , so we are done.

Case 2.  $h(y) > h(\hat{x})$ . We assumed that  $y$  is  $(k+1)$ -valid with respect to  $x$ , so by Lemma 12,  $y$  is  $k$ -valid with respect to  $\hat{x}$ . Now consider  $z = LHL_{k+1}[\hat{x}, y]$ . By the correctness of  $LHL_{k+1}$ ,  $z$  is  $k$ -valid with respect to  $\hat{x}$  and  $(k+1)$ -low from  $y$  with respect to  $\hat{x}$ . By Lemma 14,  $z$  is  $(k+1)$ -valid with respect to  $x$ . We must again distinguish two cases:

Case a.  $h(z) = h(\hat{x})$ . In this case,  $LOW_{k+1}[x, y]$  is defined to be  $LHL_{k+1}[x, z]$ . See Fig. 22. As noted above,  $z$  is  $(k+1)$ -valid with respect to  $x$ , and we assume that  $h(z) = h(\hat{x})$ , so by Lemma 11,  $z$  is  $k$ -valid with respect to  $x$ . Then by the correctness of  $LHL_{k+1}$ ,  $LHL_{k+1}[x, z]$  is  $k$ -valid with respect to  $x$ , and  $(k+1)$ -low from  $z$  with respect to  $x$ . Since  $LHL_{k+1}[x, z]$  is  $k$ -valid with respect to  $x$  and occurs after  $FAR_{k+1}[x]$ , it follows by Lemma 13 that  $LHL_{k+1}[x, z]$  is  $(k+1)$ -valid with respect to  $x$ . Since  $LHL_{k+1}[x, z]$  is  $(k+1)$ -low from  $z$ , and  $z$  occurs after  $y$ , it follows that  $LHL_{k+1}[x, z]$  is certainly  $(k+1)$ -low from  $y$ , so we are done.

Case b.  $h(z) > h(\hat{x})$ . In this case,  $LOW_{k+1}[x, y]$  is defined to be  $z$ . See Fig. 23. We already know that  $z$  is  $(k+1)$ -valid with respect to  $x$ . It remains to show that  $z$  is  $(k+1)$ -low from  $y$  with respect to  $x$ . We prove this by contradiction. We will start by assuming the existence of a counterexample  $w$ , and show that  $w$  must also be a counterexample to  $z$ 's being  $(k+1)$ -low from  $y$  with respect to  $\hat{x}$ . We know, however, that  $z$  is  $(k+1)$ -low from  $y$  with respect to  $\hat{x}$ , so there can be no such counterexample.

Let  $w$  be the first surface configuration such that  $z \vdash_x^+ w$  and  $h(w) \leq h(z)$ , and assume  $w$  is within  $2^{k+1}$  steps of  $y$ . (If there is no such surface configuration  $w$ , or if the first such  $w$  is more than  $2^{k+1}$  steps from  $y$ , then there is no counterexample to  $z$ 's being  $(k+1)$ -low from  $y$  with respect to  $x$ .) We first show that  $z \vdash_x^+ w$  (note that the base is  $\hat{x}$ ).

FIG. 22.  $LOW_{k+1}[x, y] = LHL_{k+1}[x, z]$  in case  $h(y) > h(\hat{x})$  and  $h(z) = h(\hat{x})$ .

FIG. 23.  $LOW_{k+1}[x, y] = z$  in case  $h(y) > h(\hat{x})$  and  $h(z) > h(\hat{x})$ .

Consider the surface configuration  $u$  immediately following  $z$ . That is,  $z \vdash_x u$ . Since  $h(z) > h(\hat{x})$  and the stack height can change by at most one in a single move, we have  $h(u) \geq h(\hat{x})$  and hence  $z \vdash_{\hat{x}} u$  by the Stack Lemma. Now if  $h(u) \leq h(z)$ , then  $u$  is our counterexample  $w$ , and we are done. If, on the other hand,  $h(u) > h(z)$ , we consider the surface configuration  $u'$  immediately following  $u$ , and repeat the argument. Continuing in this way, we discover that  $z \vdash_{\hat{x}} u \vdash_{\hat{x}} \cdots \vdash_{\hat{x}} w$ . Since  $h(w) \leq h(z)$  and  $w$  was assumed to be within  $2^{k+1}$  steps of  $y$ , we see that  $w$  is a counterexample to  $z$ 's being  $(k+1)$ -low from  $y$  with respect to  $\hat{x}$ . But no such counterexample can exist, for in fact  $z$  is  $(k+1)$ -low from  $y$  with respect to  $\hat{x}$  by the correctness of  $LHL_{k+1}[x, y]$ . Hence we must conclude that  $z$  is also  $(k+1)$ -low from  $y$  with respect to  $x$ .  $\square$

The following theorem asserts the correctness of our algorithm for simulating a deterministic pushdown automaton.

**THEOREM 2.** *The arrays  $FAR_k$ ,  $HOP_k$ , and  $LOW_k$  satisfy their correctness conditions for all  $k = 0, 1, \dots, \lceil \log_2 T(n) \rceil$ .*

For convenience, we reproduce the correctness conditions for  $FAR_k$ ,  $HOP_k$ , and  $LOW_k$ .

**$FAR_k$ :**

For all  $x \in X_n$ ,  $FAR_k[x]$  is  $k$ -far from  $x$ .

**$HOP_k$ :**

For all  $x \in X_n$ ,

Either  $HOP_k[x]$  is some surface configuration  $w$  such that

$x \vdash_x^+ w \vdash_x^* FAR_k[x]$  and  $h(w) = h(x)$ ,

or, if there is no such  $w$ , then  $HOP_k[x] = x$ .

**$LOW_k$ :**

For all  $x, y \in X_n$ ,

if  $y$  is  $k$ -valid with respect to  $x$ ,

then  $LOW_k[x, y]$  is

(A)  $k$ -valid with respect to  $x$ , and

(B)  $k$ -low from  $y$  with respect to  $x$ .

*Proof by induction on  $k$ .* The reader can check that the correctness conditions are satisfied for  $k = 0$  by the initialization stage, lines 1-10 of the algorithm. The induction step from  $k$  to  $k+1$  follows from Lemmas 6-15.  $\square$

We now state the main theorem of this paper.

**THEOREM 3.** *Let  $L$  be a deterministic context-free language. Then  $L$  is accepted by a P-RAM with  $O(n^4)$  processors in time  $O(\log n)$ .*

In § 3, we saw that there is a deterministic pushdown automaton  $M$  in normal form that accepts  $L$ . Use the algorithm of § 5 to simulate  $M$ . Each of the  $\lceil \log T(n) \rceil$  stages of the algorithm can be implemented in constant time on a P-RAM with one processor for each pair of surface configurations  $x, y \in X_n$ . Thus the algorithm runs in time  $O(\log T(n)) = O(\log n)$ . Since the number of surface configurations  $|X_n|$  is  $O(n^2)$ , we obtain a processor bound of  $O(n^4)$ .  $\square$

Rytter shows in [11] how the algorithm of Theorem 3 may be interpreted as a recursive procedure to recognize a deterministic context-free language in  $O(\log^2 n)$  space and polynomial time, thus giving an alternative proof that DCFL recognition is in SC, a result due to Cook [2].

**7. Improvement of the processor bounds.** The following observation leads to an easy improvement of the processor bound from  $O(n^4)$  to  $O(n^3)$ . It is sufficient for the algorithm to compute  $LOW_k[x, y]$  for the  $O(n^3)$  pairs  $x, y \in X_n$  such that  $h(x) = 0$ .

This is because, as noted in § 4, the stack height parameter reflects only relative stack height. All that matters is the difference between  $h(y)$  and  $h(x)$ . The value of  $LOW_k[x, y]$  for an arbitrary pair  $x, y \in X_n$  can be computed on demand from the value of  $LOW_k[x', y']$  for a corresponding pair  $x', y' \in X_n$  with  $h(x') = 0$  by adding  $h(x)$  to the stack height parameter of  $LOW_k[x', y']$ .<sup>2</sup> This does not increase the asymptotic running time of the algorithm. We therefore have:

**THEOREM 4.** *Let  $L$  be a deterministic context-free language. Then  $L$  is accepted by a P-RAM with  $O(n^3)$  processors in time  $O(\log n)$ .*

A more drastic reduction of the processor bound to  $O(n^2 \log n)$  can be obtained at the expense of an increase in running time to  $O(\log^2 n)$ . The essential idea is similar to the previous reduction. The algorithm computes  $LOW_k[x, y]$  only for those pairs  $x, y \in X_n$  such that  $h(x)$  is 0 and  $h(y)$  is a power of two. It is shown in [6] how the algorithm may be modified so that the value of  $LOW_k[x, y]$  for an arbitrary pair  $x, y \in X_n$  can be computed in  $O(\log n)$  time by a single processor from the values for these special pairs.

**8. Simulation of a deterministic auxiliary pushdown automaton.** We now consider the simulation by a P-RAM of a space- and time-bounded deterministic auxiliary pushdown automaton. An auxiliary pushdown automaton is a Turing machine with a work tape and a stack. Let  $dAPDA(S(n))$  denote the class of languages accepted by  $S(n)$  space-bounded,  $2^{O(S(n))}$  time-bounded deterministic auxiliary pushdown automata. Sudborough has exhibited [12] a deterministic context-free language  $L$  that is log-space complete for the class  $dAPDA(\log n)$ . That is, for any  $L' \in dAPDA(\log n)$ , there is a function  $f$  from  $L'$  to  $L$ , computable in  $O(\log n)$  space, such that  $x \in L'$  if and only if  $f(x) \in L$ , for all strings  $x$  over the alphabet of  $L'$ . This suggests a two-stage algorithm for recognizing  $L'$ : for any string  $x$  over the alphabet of  $L'$ , first compute  $f(x)$  and then determine if  $f(x) \in L$ . A log  $n$  space-bounded Turing machine can only run for  $2^{O(\log n)} = n^{O(1)}$  steps, so the length of  $f(x)$  is polynomial in the length of  $x$ . It is shown in [3] that a P-RAM can simulate any deterministic  $S(n)$  space-bounded Turing machine in parallel time  $O(S(n))$  on  $2^{O(S(n))}$  processors. Thus the first stage of our proposed two-stage algorithm can be carried out in  $O(\log n)$  time on  $n^{O(1)}$  processors. By our Theorem 3, the second stage can be carried out in time  $O(\log |f(x)|) = O(\log n)$  time on  $|f(x)|^3 = n^{O(1)}$  processors. We conclude that any language in  $dAPDA(\log n)$  can be recognized by a P-RAM in  $O(\log n)$  time on a polynomial number of processors. By a standard "padding" argument, Theorem 5 follows.

**THEOREM 5.** *For any fully space-constructible  $S(n) = \Omega(\log n)$ , a language in  $dAPDA(S(n))$  can be recognized by a P-RAM in  $O(S(n))$  time on  $2^{O(S(n))}$  processors.*

Sudborough conjectures in [12] that  $DSPACE(\log n)$  is strictly contained in  $dAPDA(\log n)$ , i.e., that adding a stack to a log  $n$  space-bounded, poly-time-bounded Turing machine gives it additional power. By our Theorem 5, Sudborough's conjecture implies that  $S(n)$  time-bounded P-RAM's are strictly more powerful than  $S(n)$  space-bounded Turing machines.

**9. Simulation of P-RAMs by deterministic auxiliary pushdown automata.** We observe in this section that our P-RAM algorithm for simulating any deterministic auxiliary pushdown automaton is nearly optimal, since there is a complementary simulation of P-RAMs by deterministic auxiliary pushdown automata.

<sup>2</sup>That is,  $q(x') = q(x)$  and  $q(y') = q(y)$ ,  $p(x') = p(x)$  and  $p(y') = p(y)$ , but  $h(x') = 0$  and  $h(y') = h(y) - h(x)$ .

**THEOREM 6.** *Let  $L$  be accepted by a P-RAM in time  $T(n)$ . Then  $L$  is accepted by a deterministic auxiliary pushdown automaton with space  $T(n)$  and time  $2^{O(T(n)^2)}$ .*

This theorem is a fairly easy consequence of some known relations between various computational models. Here we give a more direct proof:

*Proof.* Fortune and Wyllie prove in Lemma 1b of [3] that  $L$  is accepted by a deterministic Turing machine with space  $T(n)^2$  and time  $2^{O(T(n)^2)}$ . We observe that their algorithm may be implemented on a deterministic auxiliary pushdown automaton. Their algorithm is recursive and requires a pushdown stack of size at most  $T(n)$ , where each element on the stack can be represented by a bit sequence of length  $O(T(n))$ . Thus only  $T(n)$  space is required by our simulating deterministic auxiliary pushdown automaton.

**Acknowledgments.** Thanks to Charles Leiserson and David Shmoys for their helpful comments. Many thanks also to the referee for extremely conscientious and careful reading of drafts of this article.

## A NEARLY OPTIMAL PARALLEL ALGORITHM FOR CONSTRUCTING DEPTH FIRST SPANNING TREES IN PLANAR GRAPHS\*

XIN HE† AND YAACOV YESHA‡

**Abstract.** This paper presents a parallel algorithm for constructing depth first spanning trees in planar graphs. The algorithm takes  $O(\log^2 n)$  time with  $O(n)$  processors on a concurrent read concurrent write parallel random access machine (PRAM). The best previously known algorithm for the problem takes  $O(\log^3 n)$  time with  $O(n^4)$  processors on a PRAM. Our algorithm is within an  $O(\log^2 n)$  factor of optimality.

**Key words.** parallel algorithms, planar graphs, depth first spanning trees, graph algorithms

**AMS(MOS) subject classifications.** 05C05, 05C38, 68Q25, 68R10

**1. Introduction.** The *depth first spanning trees* of graphs have been used as a basis for many graph algorithms (Tarjan [11]). It has been conjectured, however, that the construction of a depth first spanning tree of a graph is inherently sequential (Reif [8] and Smith [9]). In spite of many attempts, the depth first spanning tree problem for general graphs is still not known to be in the NC class. (The NC class is the class of problems solvable in  $(\log n)^{O(1)}$  time by using  $n^{O(1)}$  processors. The NC class is widely accepted as the class of problems which can be solved fast in parallel with reasonably many processors [2].)

Recently, Smith discovered a nice parallel algorithm which finds a depth first spanning tree in a *planar* graph in  $O(\log^3 n)$  time with  $O(n^4)$  processors [9]. This work is important since it is the first which shows that the depth first spanning tree problem for planar graphs is in the NC class. However, due to the importance of the depth first spanning trees in designing graph algorithms, it is very desirable to have a more efficient parallel algorithm.

In this paper we develop such an algorithm. Our algorithm takes only  $O(\log^2 n)$  time with  $O(n)$  processors. It is within an  $O(\log^2 n)$  factor of optimal and is a substantial improvement over Smith's algorithm.

The computation model used in this paper is a *concurrent read concurrent write parallel random access machine* (CRCW PRAM). The model consists of a number of identical processors and a common memory. In each time unit, a processor can read from a memory cell, perform an arithmetic or a logical computation, and write into a memory cell. Both concurrent read from and write into the same memory cell by different processors are permitted. If a write conflict occurs, an arbitrary processor succeeds.

The model we use is slightly stronger than the *concurrent read exclusive write* (CREW) PRAM model used in [9] where the concurrent writes are disallowed. One step of our model can be simulated by the weaker CREW PRAM model in  $O(\log n)$  steps. (Vishkin [13] showed that this simulation can be performed in  $O(\log^2 n)$  steps by using parallel sorting. Later, Cole [1] showed that the sorting can be done in

$O(\log n)$  time with  $O(n)$  processors on a CREW PRAM. Hence by combining the algorithms in [13] and [1], this simulation can be performed in  $O(\log n)$  time with  $O(n)$  processors.) Therefore our algorithm can be implemented on the CREW PRAM model in  $O(\log^3 n)$  time with  $O(n)$  processors, still much better than Smith's algorithm.

In § 2, we review the basic strategy of Smith's algorithm. The implementation and analysis of our algorithm is presented in § 3.

**2. Preliminary.** Throughout this paper,  $G = (V, E)$  denotes a connected planar graph with vertex set  $V$  and edge set  $E$ .  $n = |V|$  denotes the number of vertices of  $G$ .

A *depth first spanning tree*  $T$  of  $G$  rooted at a specified vertex  $r \in V$  is constructed as follows: Starting from  $r$ , successively add edges into  $T$  until a vertex is reached all of whose exit edges (i.e., incident edges other than the one used to arrive at the vertex) are incident upon  $T$ . At this point, backtrack a minimum distance until a vertex is reached that has exit edges not incident upon  $T$  and continue. Repeat this process until all vertices of  $G$  are exhausted [11]. The problem considered in this paper is how to construct a depth first spanning tree for a given planar graph  $G$  with a specified root  $r$ .

A *plane embedding* of a planar graph  $G$  is a drawing of  $G$  in the plane such that no two edges of  $G$  intersect with each other in the drawing.

Suppose  $G$  is embedded in the plane. Let  $C$  be a (simple) cycle of  $G$ . The vertices of  $G$  are partitioned into three parts: the vertices on  $C$ , the vertices in the interior of  $C$  and the vertices in the exterior of  $C$ . If both the interior and the exterior of  $C$  contain no more than  $2n/3$  vertices,  $C$  is called a *separating cycle* of  $G$ .

Let  $T$  be any spanning tree of  $G$  rooted at a vertex  $t \in V$ .  $T$  induces a partial order on  $V$ :  $v_1 < v_2$  if and only if  $v_2$  is an ancestor of  $v_1$  in  $T$ . In general, if  $v_1$  and  $v_2$  are two arbitrary vertices they may be noncomparable in the partial order induced by  $T$ . A depth first spanning tree  $T$  can be characterized by the following well-known fact:

LEMMA 1 [9]. *A spanning tree  $T$  of  $G$  is a depth first spanning tree if and only if for any edge  $e \in E$  the end vertices of  $e$  are comparable in the partial order induced by  $T$ . □*

Let  $P_r$  be a (simple) path in  $G$  with  $r$  as one of its end vertices. Suppose  $G - P_r$  is the union of connected components  $\{G_i\}_{1 \leq i \leq k}$  for some  $k$ . Let  $e$  be an edge of  $G$ . Define  $e$  to be [9]:

(a) A *touching edge* of  $G_i$  if one end vertex of  $e$  is in  $G_i$  and another end vertex of  $e$  is in  $P_r$ —call this vertex the point where  $e$  touches  $P_r$ .

(b) An *inessential touching edge* of  $G_i$  if it is a touching edge of  $G_i$  and there exists another touching edge  $e'$  of  $G_i$  which touches  $P_r$  at a point further (in  $P_r$ ) from  $r$  than the point at which  $e$  touches  $P_r$ .

(c) An *essential touching edge* of  $G_i$  if it is a touching edge of  $G_i$  and the conditions in statement (b) are not satisfied.

Let  $e_i$  be an essential touching edge of  $G_i$  ( $1 \leq i \leq k$ ) and let  $x_i$  be the end vertex in  $e_i$  in  $G_i$ . Suppose  $T_i$  is a depth first spanning tree of  $G_i$  rooted at  $x_i$  ( $1 \leq i \leq k$ ). From Lemma 1, it is easy to show the following.

LEMMA 2 [9]. *Let  $T$  be the union of  $P_r$ ,  $\{e_i\}$  ( $1 \leq i \leq k$ ) and  $\{T_i\}$  ( $1 \leq i \leq k$ ). Then  $T$  is a depth first spanning tree of  $G$  rooted at  $r$ . □*

Figure 1 shows an example of Lemma 2. The planar graph shown in Fig. 1 is divided by the path  $P_r$  into two connected components  $G_1$  and  $G_2$ . The edges  $e_1$  and  $e_2$  are two touching edges of  $G_1$ , where  $e_2$  is the essential touching edge of  $G_1$ . The edges  $e_3$  and  $e_4$  are two touching edges of  $G_2$ , where  $e_4$  is the essential touching edge of  $G_2$ .  $T_1$  and  $T_2$  are the depth first spanning trees of  $G_1$  and  $G_2$ , respectively. The union of  $P_r$ ,  $e_2$ ,  $e_4$ ,  $T_1$ , and  $T_2$  is a depth first spanning tree of  $G$  rooted at  $r$ .

FIG. 1. An example of Lemma 2.

The basic idea of Smith's algorithm is as follows; Find a path  $P_r$  in  $G$ , with  $r$  as one end vertex such that  $G - P_r$  is a union of connected components  $\{G_i\} (1 \leq i \leq k)$  and  $|G_i| \leq 2n/3$  for each  $1 \leq i \leq k$ . Then find an essential touching edge  $e_i$  for each  $G_i (1 \leq i \leq k)$  and let  $x_i$  be the end vertex of  $e_i$  in  $G_i$ . Next recursively call the algorithm on each  $G_i (1 \leq i \leq k)$  in parallel to construct a depth first spanning tree  $T_i$  of  $G_i$  rooted at  $x_i$ . Finally construct a depth first spanning tree  $T$  for  $G$  rooted at  $r$  as in Lemma 2.

In order to find the *separating path*  $P_r$ , described above, Smith uses the following method: First find a separating cycle  $C$  in  $G$ . Then find a path  $P_1$  from the root  $r$  to an arbitrary vertex  $x$  on  $C$  such that no other vertex of  $C$  is on  $P_1$ . Let  $e$  be an edge on  $C$  incident to  $x$ . Define  $P_r = P_1 \cup C - \{e\}$ . Each connected component  $G_i$  of  $G - P_r$  is contained either in the interior or in the exterior of  $C$ . Thus each  $G_i$  contains at most  $2n/3$  vertices. Therefore  $P_r$  is the required separating path.

**3. Implementation and analysis.** We discuss the implementation and analyze the resource bounds of the parallel depth first spanning tree algorithm in this section.

Our algorithm works for any planar graph  $G = (V, E)$  given by the *edge list* form. (Namely, the edge set of  $G$  is given as a list in arbitrary order.) In order to make fast parallel computation possible, we will preprocess  $G$  to construct a more suitable representation, the *combinatorial representation*, defined as follows.

Suppose  $G = (V, E)$  is embedded in the plane.  $G$  partitions the plane into a number of connected regions. Each connected region is called a *face*. The combinatorial representation of the plane embedded graph  $G$  is defined as follows: Each edge  $e = (x, y) \in E$  is represented by two directed *darts*  $(x, y)$  and  $(y, x)$ . The combinatorial representation of  $G$  consists of two lists of these darts. The first list  $L_1$  is arranged in the order such that for each vertex  $v \in V$  the darts "leaving  $v$ " are consecutive in  $L_1$  and are in the order they appear in the embedding in the counterclockwise direction. The second list  $L_2$  is arranged in the order such that for each face  $f$  of  $G$  the darts on the boundary of  $f$  are consecutive in  $L_2$  and are in the order they appear in the embedding in the clockwise direction. Given a planar graph  $G$ , the combinatorial representation of a plane embedding of  $G$  can be found in  $O(\log^2 n)$  time with  $O(n)$  processors (Klein and Reif [3]). We will use this representation in our algorithm.

The algorithm is as follows. (It is different from Smith's algorithm in that the resources are allocated more carefully and each step is implemented more efficiently in order to achieve the  $O(\log^2 n)$  time and  $O(n)$  processor bounds.)

## DFST ALGORITHM.

Input: A connected planar graph  $G = (V, E)$  with a specified root  $r \in V$  given by edge list form;

Initialization: Find a plane embedding and a combinatorial representation for  $G$ ;

- (1) Find the *biconnected components*  $\{G_j\} (1 \leq j \leq q \text{ for some } q)$  of  $G$ . Let  $x_j (1 \leq j \leq q)$  be the vertex in  $G_j$  which is closest to the root  $r$ . Perform the following steps on each  $G_j$  simultaneously to construct a depth first spanning tree  $T_j$  rooted at  $x_j$  for each  $G_j (1 \leq j \leq q)$ . The union of  $T_j (1 \leq j \leq q)$  will be a depth first spanning tree of  $G$  rooted at  $r$  (Smith [9]). (In order to avoid double subscripts, we still use symbols  $G$  and  $r$  for  $G_j$  and  $x_j$  in the following statements.)
- (2) Find a separating cycle  $C$  in  $G$ . (Since  $G$  is a biconnected planar graph, such a separating cycle exists; see Smith [9] and Miller [6].)
- (3) Find a path  $P_1$  from the root  $r$  to any vertex  $x$  on  $C$  such that no other vertex of  $C$  is on  $P_1$ . Let  $e$  be an edge of  $C$  incident to  $x$ . Define  $P_r = P_1 \cup C - \{e\}$ .
- (4) Find the connected components  $\{G_i\} (1 \leq i \leq k \text{ for some } k)$  of  $G - P_r$ .
- (5) For each  $G_i (1 \leq i \leq k)$  find an essential touching edge  $e_i$ . Let  $x_i$  be the end vertex of  $e_i$  in  $G_i$ .
- (6) Construct the combinatorial representation of the subgraphs  $G_i (1 \leq i \leq k)$  from the combinatorial representation of  $G$ .
- (7) Recursively call the DFST algorithm on each  $G_i$  in parallel to construct a depth first spanning tree  $T_i$  for  $G_i$  rooted at  $x_i (1 \leq i \leq k)$ .
- (8) Let  $T = \cup_i (T_i \cup e_i) \cup P_r$ .  $T$  is a depth first spanning tree of  $G$  rooted at  $r$ .

End DFST.

We next discuss the implementation and analyze the resource bounds of the DFST algorithm.

The initialization step can be performed in  $O(\log^2 n)$  time with  $O(n)$  processors on a CRCW PRAM [3]. This step is performed only once. When the DFST algorithm is recursively called on a subgraph  $G_i$  of  $G$  at step (7), the combinatorial representation of  $G_i$  is obtained from the combinatorial representation of  $G$  in a more efficient way (details are discussed later).

Step (1) can be implemented by using the algorithm of Tarjan and Vishkin [12] in  $O(\log n)$  time with  $O(n)$  processors on a CRCW PRAM.

Step (2) is the most resource-consuming part of the algorithm. In Smith's algorithm, this step takes  $O(\log^2 n)$  time with  $O(n^4)$  processors. Miller [6] developed a parallel algorithm which finds a separating cycle in a biconnected planar graph with size at most  $O(n^{1/2})$ . If the input is given by the combinatorial representation form (Miller uses a slightly different variation of this representation in [6]), this algorithm takes  $O(\log n)$  time with  $O(n^3)$  processors. However, since we do not have to restrict the size of the separating cycle in the DFST algorithm, this step can be implemented much more efficiently. Actually, one subroutine in Miller's algorithm finds a separating cycle  $C$  of  $G$  in  $O(\log n)$  time with  $O(n)$  processors on a CRCW PRAM, (although the size of  $C$  might be large). Thus step (2) can be implemented by using this subroutine in  $O(\log n)$  time with  $O(n)$  processors.

Step (3) can be performed as follows: by using the algorithm of Shiloach and Vishkin [10], we first construct an arbitrary spanning tree  $\bar{T}$  of  $G$  rooted at  $r$ . This can be done in  $O(\log n)$  time with  $O(n)$  processors. Next pick up an arbitrary vertex  $x_0$  on  $C$  and identify the path  $P_0$  in  $\bar{T}$  from  $x_0$  to  $r$ . This can be done by using standard pointer jump technique in  $O(\log n)$  time with  $O(n)$  processors. Let  $x$  be the vertex on  $P_0$  which is on  $C$  and is closest to  $r$ . Let  $P_1$  be the portion of  $P_0$  from  $x$  to  $r$ . Then

$x$  and  $P_1$  is what we want to find in step (3). Thus step (3) totally takes  $O(\log n)$  time with  $O(n)$  processors.

Step (4) can be performed by using the algorithm of Shiloach and Vishkin [10] in  $O(\log n)$  time with  $O(n)$  processors on a CRCW PRAM.

In order to implement step (5), we first compute the index number of the vertices on the path  $P_r$  (i.e.,  $r$  has index number 1, the vertex on  $P_r$  adjacent to  $r$  has index number 2 and so on). The set  $E_i(1 \leq i \leq k)$  of touching edges for each connected component  $G_i$  can be identified in constant time. Next we sort each  $E_i(1 \leq i \leq k)$  according to the index number of the end vertex of each  $e \in E_i$  that is on  $P_r$ . This sorting can be done in  $O(\log n)$  time with  $O(n)$  processors [1]. The essential touching edge of  $G_i$  is the last edge in the sorted list of  $E_i$ . Thus step (5) takes  $O(\log n)$  time with  $O(n)$  processors.

Step (6) can be implemented as follows: Each subgraph  $G_i(1 \leq i \leq k)$  of  $G$  has a natural plane embedding inherited from the embedding of  $G$ . The combinatorial representation for  $G_i$  is computed from the lists  $(L_1, L_2)$  of the combinatorial representation of  $G$  as follows; In the list  $L_1$ , delete all darts that have at least one end vertex in  $P_r$ . Then perform a parallel sort on the remaining darts of  $L_1$  such that the darts belonging to the same connected component  $G_i$  are consecutive in the resulting list. Perform a similar operation for the list  $L_2$ . This gives the combinatorial representation for each  $G_i$ . Since the sorting can be done in  $O(\log n)$  time with  $O(n)$  processors (Cole [1]), step (6) can be performed within the same time and processor bounds.

Step (7) is the recursive call. Step (8) clearly takes constant time.

Since one application of the DFST algorithm on  $G$  reduces the problem to the subgraphs of size at most  $2n/3$ , the depth of recursive calls is at most  $\log_{3/2} n$ . Since each step takes at most  $O(\log n)$  time with  $O(n)$  processors, the entire algorithm takes  $O(\log^2 n)$  time with  $O(n)$  processors as claimed. In summary we have Theorem 3.

**THEOREM 3.** *Let  $G$  be a planar graph given by edge list form and let  $r$  be a specified vertex of  $G$ . A depth first spanning tree of  $G$  rooted at  $r$  can be constructed in  $O(\log^2 n)$  time with  $O(n)$  processors on a CRCW PRAM.  $\square$*

## ON SEARCH TIMES FOR EARLY-INSERTION COALESCED HASHING\*

BORIS PITTEL† AND JENN-HWA YU†

**Abstract.** The distributions of the search times for an early-insertion form of coalesced hashing (first proposed by Vitter [11], [12]) are studied. It is demonstrated, in particular, that the largest search time is very close, in probability, to the one for the late-insertion coalesced hashing [8]. In addition, a formula for the expected successful search time obtained by Chen and Vitter [1] and, independently, by Knott [7] is shown to follow directly from the presented analysis.

**Key words.** search algorithm, hashing, largest search time, probabilistic analysis

**1. Introduction. Results.** Coalesced hashing is a hashing algorithm in which collisions are resolved by forming chains of occupied locations (cells) of the table; ordering in each chain is conveniently specified by the consecutive chain references associated with every cell of the chain. To have a complete description of coalescing, one has to decide how a chain grows in cases when the next key is hashed to one of its cells. In the most well-known version [4], [6] a cell which accommodates such a key becomes the *last* cell of the corresponding chain. For the sake of references below, let us call it the late-insertion coalesced hashing method, or lich. In contrast, an early-insertion coalesced hashing method (eich) suggested by Vitter [11] and independently by Knott [7] is specified by the following agreement. Suppose that a key is hashed to an already occupied cell, say  $i$ . Then a cell which admits this key, that is its eventual location, is inserted into the chain passing through the cell  $i$  right between the cell  $i$  and its immediate successor. (Thus, only when cell  $i$  is the last in its chain, will the new cell be the last one of the enlarged chain.) As for the actual location of the key in case of collision, in the simplest case, it is found—in both lich and eich—via the sequential search of the table from, say, left to right (see, however, Knott [7]). It should be clear therefore that, for a given set of keys, the two algorithms lead to the same partition of the set of occupied cells into chains. It is the ordering in the chains where the algorithms differ from each other.

Let  $m$  be the size of the table, and let the  $n$  keys be  $x_1, x_2, \dots, x_n$ , indexed according to the order of insertion. Naturally,  $n \leq m$ . As usual, we assume that the hashing function  $h$  which maps the universe of keys into  $S = \{1, \dots, m\}$  is such that  $h(x_1), h(x_2), \dots, h(x_n)$  are independent random variables uniformly distributed over  $S$ . The central characteristics of either of the algorithms are the random search times  $T_1(i, n), T_2(i, n), 1 \leq i \leq n$ . Formally, they are defined as follows:  $T_1(i, n)$  is the number of cells of the subchain which originates at the cell  $h(x_i)$  and ends at the actual location of the key  $x_i$  after  $n$  keys have been inserted;  $T_2(i, n)$  is the number of extra cells searched sequentially when  $x_i$  is inserted to find a vacant cell for the key  $x_i$  when the cell  $h(x_i)$  is already occupied, and 0 when  $h(x_i)$  is not already occupied. The random variables  $T_1(i, n)$  and  $T_2(i, n)$  depend formally on the random keys  $x_1, x_2, \dots, x_n$ . Clearly, the sequences  $\{T_2(i, n) : 1 \leq i \leq n\}$  are the same for both algorithms. Besides,  $T_2(i, n)$  is completely determined by the values of  $\{h(x_j) : 1 \leq j \leq i\}$ , thus does not depend on those  $n - i$  keys inserted after the  $i$ th key. The same is true for  $T_1(i, n)$  in

\*Received by the editors May 27, 1986; accepted for publication (in revised form) June 11, 1987.

† Department of Mathematics, Ohio State University, Columbus, Ohio 43210.

the case of the lich algorithm, since then every chain grows only at its end. For the eich algorithm, however,  $T_1(i, n)$  does depend on those  $n - i$  keys inserted after the  $i$ th key since the keys arriving after  $x_i$  may push a cell with the key  $x_i$  in it (along the corresponding chain) farther away from the cell  $h(x_i)$ .

Exact and asymptotic moment-type formulae for  $T_j(i, n)$ ,  $j = 1, 2$ , were obtained by Knuth [6] (lich), by Chen and Vitter [1], and Knott [7] (eich) (see [2] for the mean values analysis of other versions of coalesced hashing). A central observation is that the average search times remain bounded by a constant even when the load factor  $n/m = 1$ .

The distributions of  $T_1(i, n)$ , and  $T_2(i, n)$ ,  $1 \leq i \leq n$  for lich were studied by the first author in [8]. It was shown, in particular, that when  $n, m \rightarrow \infty$ , such that  $n/m = a \in (0, 1]$  and is fixed,

$$(1.1) \quad \begin{aligned} U_1(n) &= \max \{T_1(i, n): 1 \leq i \leq n\} = \log_b n - 2 \log_b \log_b n + O_p(1), \\ U_2(n) &= \max \{T_2(i, n): 1 \leq i \leq n\} = \log_b n - \log_b \log_b n + O_p(1), \end{aligned}$$

where  $b = (1 - e^{-a})^{-1}$ , and  $O_p(1)$  stands for random terms bounded in probability as  $n, m \rightarrow \infty$ . Formally, a random variable  $A_{nm}$  is bounded in probability if  $P(|A_{nm}| \geq \omega_{nm}) \rightarrow 0$  for  $\omega_{nm} \rightarrow \infty$  however slowly as  $n, m \rightarrow \infty$ . ( $U_1(n)$  represents the largest successful search time.  $U_2(n)$  represents the largest number of the left-to-right probes needed to find a vacant cell in case of an unsuccessful search.)

Our goal in this paper is to study the sequence  $\{T_1(i, n): 1 \leq i \leq n\}$  for the eich algorithm. It turns out to be possible to derive the exact formula for the distribution of  $T_1(i, n)$ . Namely, we prove the following theorem.

THEOREM 1.

$$\begin{aligned} P(T_1(i, n) \geq l) &= (i-1)/m \sum_{j=0}^{l-2} (-1)^j \binom{l-2}{j} (1-j/m)^{n-i}, \quad 2 \leq l \leq n-i+2, \\ &= 1, \quad l = 1. \end{aligned}$$

*Comment.* The factors in the formula above have a transparent probabilistic interpretation. Namely,  $(i-1)/m$  is the probability that the key  $x_i$  is hashed to a nonempty location; the sum equals the probability that in the classical allocation model (with  $(n-i)$  balls and  $m$  cells) some specified  $(l-2)$  cells are nonempty. In a striking contrast, our derivation of the formula is quite analytic, involving contour integration and residues.

COROLLARY.

$$P(T_1(i, n) \geq l) \sim (i-1)/m [1 - \exp(-a + i/m)]^{l-2},$$

if  $n-i \rightarrow \infty$  and  $l^2 = o(n-i)$ . Here and below, the relation  $f(n) \sim g(n)$  means that  $f(n)/g(n) \rightarrow 1$  as  $n \rightarrow \infty$ .

This corollary contains a very simple approximate formula for the distribution of  $T_1(i, n)$  in cases when  $i$  the index of a key is considerably smaller than  $n$ . Furthermore, let  $\mathcal{C}_n$  be the successful search time of a key chosen at random among all  $n$  keys. The above results will enable us to prove the following theorem.

THEOREM 2. As  $n, m \rightarrow \infty$ , with  $n/m = a$ ,  $\mathcal{C}_n$  converges in distribution, and in terms of all moments, to a random variable  $\mathcal{C}$  such that

$$(1.2) \quad \begin{aligned} P(\mathcal{C} = l) &= 1 - a/2 \quad \text{if } l = 1, \\ &= a^{-1}(l-1)^{-1} \int_0^a [1 - \exp(-a+y)]^{l-1} dy \quad \text{if } l \geq 2. \end{aligned}$$

In particular,

$$(1.3) \quad \lim E(\mathcal{C}_n) = E(\mathcal{C}) = (e^a - a)/a,$$

$$(1.4) \quad \lim \text{var}(\mathcal{C}_n) = \text{var}(\mathcal{C}) = (e^{2a}/2 + e^a - a - 3/2)/a - (e^a - 1)^2/a^2.$$

The formula (1.3) was derived differently in [1], [7].

We will also study the asymptotic behavior of  $U_1(n) = \max \{T_1(i, n) : 1 \leq i \leq n\}$ , which represents the largest successful search time for each.

THEOREM 3. Let  $\omega(n) \rightarrow \infty$  however slowly. Then

$$P(|U_1(n) - \log_b n + 2 \log_b \log_b n| \leq \omega(n)) \rightarrow 1,$$

or in short

$$(1.5) \quad U_1(n) = \log_b n - 2 \log_b \log_b n + O_p(1),$$

where  $O_p(1)$  represents a random term bounded in probability.

Comments. Comparing (1.1) and (1.5) shows that the asymptotic behavior of  $U_1(n)$  is very similar for both versions of coalesced hashing. This is quite surprising since there are no close relations between these two random variables. To see it, and to better understand the difference between algorithms, let us look at a couple of examples.

Example 1.  $n = 7, m = 10, \{h(x_i) : 1 \leq i \leq 7\} = \{10, 8, 10, 7, 8, 1, 10\}$ .

(a) lich. Since a chain grows at its end, it can be easily seen that the chains of occupied cells are  $\{10, 1, 3, 4\}, \{8, 2\}$  and  $\{7\}$ . Also  $\{T_1(i, 7) : 1 \leq i \leq 7\} = \{1, 1, 2, 1, 2, 2, 4\}$  and  $U_1(7) = 4$  (Fig. 1).

(b) eich. Up until the key  $x_7$ , the algorithms do not differ. The key  $x_7$  is hashed to the cell 10, which is already occupied by the key  $x_1$ . So,  $x_7$  goes into the cell 4 which is the left-most empty cell at this moment. Now, the cell 4 is to be absorbed by the (sub)chain  $\{10, 1, 3\}$ ; unlike the lich version, it is inserted between the cells 10 and 1 which results in a larger chain  $\{10, 4, 1, 3\}$ . (Two other chains are  $\{8, 2\}$  and  $\{7\}$ .) Compared with the lich scheme,  $T_1(3, 7)$  is increased by 1, and  $T_1(7, 7)$  is reduced by 2. Hence  $\{T_1(i, 7) : 1 \leq i \leq 7\} = \{1, 1, 3, 1, 2, 2, 2\}$  and  $U_1(7) = 3$  as opposed to 4 in the lich case Fig. 2).

Example 2.  $n = 6, m = 9, \{h(x_i) : 1 \leq i \leq 6\} = \{1, 1, 1, 3, 4, 5\}$ . Here, in both schemes, there is only one chain comprised by the cells 1, 2,  $\dots$ , 6. However, in lich case,  $\{T_1(i, 6) : 1 \leq i \leq 6\} = \{1, 2, 3, 2, 2, 2\}$  and  $U_1(6) = 3$ , while, for eich,  $\{T_1(i, 6) : 1 \leq i \leq 6\} = \{1, 6, 2, 2, 2, 2\}$  and  $U_1(6) = 6$ . (See Figs. 3 and 4.)

FIG. 1. lich,  $m = 10, n = 7$ .

FIG. 2. eich,  $m = 10, n = 7$ .

FIG. 3. *lich*,  $m = 9$ ,  $n = 6$ .

FIG. 4. *eich*,  $m = 9$ ,  $n = 6$ .

The reader interested in the results regarding the expected largest search times for other hashing techniques is referred to [3], [5], [9].

**2. Distribution of  $T_1(i, n)$ .** Recall that  $T_1(i, n)$  is the length of the subchain from the cell  $h(x_i)$  to the cell which actually contains the key  $x_i$  after all  $n$  keys are inserted,  $1 \leq i \leq n$ . Denote the index of this actual location by  $\tilde{h}(x_i)$ . Clearly,

$$T_1(i, n) = 1 \quad \text{and} \quad 1 \leq T_1(i, n) \leq n - i + 2 \quad \text{for } 2 \leq i \leq n.$$

Suppose that  $2 \leq l \leq n - i + 2$ . By the definition of the *eich* algorithm,  $T_1(i, n) \geq l$  if and only if in the subchain which connects the cells  $h(x_i)$  and  $\tilde{h}(x_i)$  there are  $j \geq l - 2$  cells occupied by some  $j$  keys inserted after  $x_i$ . Let  $A = \{x_{i_1} < x_{i_2} < \dots < x_{i_{l-2}}\}$  be a set of  $l - 2$  keys inserted after  $x_i$ . Denote by  $E_A$  the event that, when the subchain from  $h(x_i)$  to  $\tilde{h}(x_i)$  is of length  $l$  for the first time, it is the keys from the set  $A$  which occupy  $l - 2$  intermediate cells. (In other words,  $E_A$  means that insertion of the key  $x_{i_{l-2}}$  results in a subchain  $\{h(x_i), \tilde{h}(y_1), \dots, \tilde{h}(y_{l-2}), \tilde{h}(x_i)\}$ , where  $\{y_1, \dots, y_{l-2}\}$  is a permutation of  $A$ .) Then obviously

$$(2.1) \quad P(T_1(i, n) \geq l) = \sum_A P(E_A),$$

where summation is taken over all  $(l - 2)$ -element subsets  $A$  of  $\{x_{i+1}, \dots, x_n\}$ . Let us compute  $P(E_A)$ . According to the definition of the *eich* algorithm, the probability of the event  $E_A$  is the product of the probability of the following  $l - 1$  independent events:  $B_1 = \{\text{the key } x_i \text{ is hashed to a nonempty cell}\}$ , with

$$P(B_1) = (i - 1)/m;$$

$B_2 = \{\text{for every key } y \text{ from } x_{i+1} \text{ to } x_{i_{l-1}}, h(y) \neq h(x_i) \text{ and } h(x_{i_l}) = h(x_i)\}$ , with

$$P(B_2) = (1 - 1/m)^{i_1 - i - 1} (1/m); \dots;$$

$B_{l-1} = \{\text{for every key } y \text{ from } x_{i_{l-3}+1} \text{ to } x_{i_{l-2}-1}, h(y) \notin \{h(x_i), \tilde{h}(x_{i_l}), \dots, \tilde{h}(x_{i_{l-3}})\} \text{ and } h(x_{i_{l-2}}) \in \{h(x_i), \tilde{h}(x_{i_l}), \dots, \tilde{h}(x_{i_{l-3}})\}\}$ , with

$$P(B_{l-1}) = (1 - (l - 2)/m)^{i_{l-2} - i_{l-3} - 1} (l - 2)/m.$$

Hence

$$(2.2) \quad \begin{aligned} P(E_A) &= (i - 1)/m (1 - 1/m)^{i_1 - i - 1} (1/m) \dots \\ &\cdot [1 - (l - 2)/m]^{i_{l-2} - i_{l-3} - 1} (l - 2)/m \\ &= [(i - 1)/m] [(l - 2)!/m^{l-2}] \prod_{j=1}^{l-2} (1 - j/m)^{s_j} \cdot 1^{s_{l-1}}, \end{aligned}$$

where

$$s_j = i_j - i_{j-1} - 1 \quad (j \geq 2), \quad s_1 = i_1 - i - 1, \quad s_{l-1} = n - i_{l-2}.$$

Then, by (2.1) and (2.2),

$$P(T_1(i, n) \geq l) = [(i-1)/m][(l-2)!/m^{l-2}] \sum_s \prod_{j=1}^{l-2} (1-j/m)^{s_j} \cdot 1^{s_{l-1}},$$

where the summation is over all tuples  $s = (s_1, \dots, s_{l-1})$  such that  $s_j \geq 0, 1 \leq j \leq l-1$  and  $\sum_j s_j = n - i - l + 2$ .

Let us simplify the last formula (as in [8]). To this end, notice first that the sequence

$$\{P[T_1(i, u + (i+l-2)) \geq l] \cdot [(i-1)m^{-1}(l-2)!m^{-(l-2)}]^{-1}; u \geq 0\}$$

is an  $(l-1)$ -fold convolution of the  $(l-2)$  sequences  $\{(1-j/m)^u; u \geq 0\}, 1 \leq j \leq l-2$ , and the sequence  $\{1^u; u \geq 0\}$ . Since the generating function of a convolution is the product of individual generating functions, we obtain

$$P(T_1(i, n) \geq l) = (i-1)m^{-1}(l-2)!m^{-(l-2)} \text{coeff}_{z^{n-i-l+2}} F(z, l),$$

where

$$F(z, l) = \prod_{j=0}^{l-2} [1 - z(1-j/m)]^{-1}, \quad |z| < 1.$$

Applying the Cauchy integral formula so as to select  $\text{coeff}_{z^{n-i-l+2}} F(z, l)$  from  $F(z, l)$ , we have

$$P(T_1(i, n) \geq l) = [(i-1)/m][(l-2)!/m^{l-2}](2\pi i)^{-1} \int_C G(z) dz,$$

where

$$G(z) = F(z, l)/z^{n-i-l+3} \quad \text{and} \quad C = \{re^{i\theta}; -\pi < \theta \leq \pi\}, \quad r < 1.$$

Outside the contour  $C$ , the function  $G(z)$  has simple poles at  $z_j = (1-j/m)^{-1}, 0 \leq j \leq l-2$ . A direct computation shows that

$$\text{res}_{z=z_j} G(z) = (-1)^{j+1} m^{l-2} (1-j/m)^{n-i} / [j!(l-2-j)!], \quad 0 \leq j \leq l-2.$$

Also, the residue at  $z = \infty$  equals 0 since

$$d \cdot \max \{|G(z)|; |z| = d\} \rightarrow 0 \quad \text{when } d \rightarrow \infty.$$

According to the residue theorem, we then have

$$\begin{aligned} P(T_1(i, n) \geq l) &= -[(i-1)/m][(l-2)!/m^{l-2}] \sum_{j=0}^{l-2} \text{res}_{z=z_j} G(z) \\ (2.3) \quad &= [(i-1)/m] \sum_{j=0}^{l-2} (-1)^j \binom{l-2}{j} (1-j/m)^{n-i}, \quad 2 \leq l \leq n-i+2. \end{aligned}$$

Therefore, Theorem 1 is proven.

The last formula is most convenient when  $l$  is not large. In fact, if  $l \geq 2$  is fixed and  $n-i \rightarrow \infty$ , we get from (2.3):

$$\begin{aligned} P(T_1(i, n) \geq l) &\sim [(i-1)/m] \sum_{j=0}^{l-2} (-1)^j \binom{l-2}{j} \exp[-j(n-i)/m] \\ (2.4) \quad &= [(i-1)/m][1 - \exp(-a + i/m)]^{l-2}, \quad n, m \rightarrow \infty. \end{aligned}$$

It is remarkable that this simple formula holds true even when  $l \rightarrow \infty$  together with  $n$  and  $m$ , slowly enough such that

$$(2.5) \quad l^2/(n-i) = o(1).$$

This result follows from the proof of Lemma 2 in [8]. For the sake of completeness, let us give a sketch of the necessary argument. Denote the sum appearing in (2.3) by  $p(n-i, l-2)$ . Because of the alternating signs in the sum, a direct asymptotic analysis appears impossible. Fortunately, we can get around this obstacle. Suppose that  $(n-i)$  distinguishable balls are allocated independently and uniformly among  $m$  cells. According to the inclusion-exclusion formula,  $p(n-i, l-2)$  happens to be the probability that the first  $(l-2)$  cells are all nonempty. Subsequently,

$$p(n-i, l-2) = \left( \sum_s (n-i)!/[s_1! \cdots s_m!] \right) m^{-(n-i)},$$

where the summation is taken over all nonnegative integer tuples  $s = (s_1, \dots, s_m)$  such that

$$\sum_{i=1}^m s_i = n-i, \quad s_i \geq 1, \quad 1 \leq i \leq l-2.$$

A little reflection shows then that

$$(2.6) \quad p(n-i, l-2) = (n-i)! \operatorname{coeff}_z z^{n-i} [(e^{z/m} - 1)^{l-2} (e^{z/m})^{m-l+2}].$$

Applying the Cauchy integral formula and the saddle-point method, we obtain (via more or less standard arguments) that under the condition (2.5):

$$p(n-i, l-2) \sim [1 - \exp(-a + i/m)]^{l-2}.$$

This, of course, leads again to (2.4).

Finally in this section, consider  $\mathcal{C}_n$  the successful search time of a key chosen uniformly at random among  $n$  keys. Clearly,

$$(2.7) \quad P(\mathcal{C}_n \geq l) = n^{-1} \sum_{i=1}^n P(T_1(i, n) \geq l).$$

Let  $l$  be fixed. Set  $n_1 = [n - \log n]$ . Then according to (2.4), we have

$$\begin{aligned} P(\mathcal{C}_n \geq l) &= n^{-1} \sum_{i=1}^{n_1} P(T_1(i, n) \geq l) + O(\log n/n) \\ &= (1 + o(1)) a^{-1} m^{-1} \sum_{i=1}^{n_1} (i/m) [1 - \exp(-a + i/m)]^{l-2} + o(1) \\ (2.8) \quad &\rightarrow a^{-1} \int_0^a u [1 - \exp(-a + u)]^{l-2} du, \quad n, m \rightarrow \infty. \end{aligned}$$

Since  $P(\mathcal{C}_n \geq 1) = 1$ , the relations show that  $\mathcal{C}_n \rightarrow \mathcal{C}$  where

$$(2.9) \quad \begin{aligned} P(\mathcal{C} \geq l) &= 1 \quad \text{for } l = 1, \\ P(\mathcal{C} \geq l) &= a^{-1} \int_0^a u [1 - \exp(-a + u)]^{l-2} du \quad \text{for } l \geq 2. \end{aligned}$$

Let us demonstrate that, in fact, for every integer  $k \geq 1$ ,

$$(2.10) \quad E(\mathcal{C}_n^k) \rightarrow E(\mathcal{C}^k), \quad n, m \rightarrow \infty.$$

It is easy to see that (2.10) takes place provided that

$$(2.11) \quad \lim_{n,m \rightarrow \infty} S_n(k) = S(k), \quad k = 1, 2, \dots,$$

where

$$S_n(k) = \sum_{l=1}^n l^k P(\mathcal{C}_n \geq l), \quad S(k) = \sum_{l=1}^{\infty} l^k P(\mathcal{C} \geq l).$$

To prove (2.11), set  $\nu = [(k+2)^3 \log_b^3 n]$ , ( $b = (1 - e^{-a})^{-1}$ ) and break the sum as follows:

$$S_n(k) = 1 + S_{n1}(k) + S_{n2}(k) + S_{n3}(k),$$

where

$$S_{n1}(k) = n^{-1} \sum_{i=2}^{n-\nu} \sum_{l=2}^{t(i)} l^k P(T_1(i, n) \geq l), \quad t(i) = [(n-i)^{1/3}],$$

$$S_{n2}(k) = n^{-1} \sum_{i=2}^{n-\nu} \sum_{l=t(i)+1}^{n-i+2} l^k P(T_1(i, n) \geq l),$$

$$S_{n3}(k) = n^{-1} \sum_{i=n-\nu+1}^n \sum_{l=2}^{n-i+2} l^k P(T_1(i, n) \geq l).$$

Consider  $S_{n1}(k)$ . By the definition of  $\nu$  and  $t(i)$ , the range of  $i$  and  $l$  in  $S_{n1}(k)$  is such that

$$l^2/(n-i) \leq t^2(i)/(n-i) \leq (n-i)^{-1/3} \leq \nu^{-1/3} \rightarrow 0, \quad m, n \rightarrow \infty.$$

Hence, by (2.4) and (2.5),

$$(2.12) \quad \begin{aligned} 1 + S_{n1}(k) &= 1 + [1 + o(1)] a^{-1} m^{-1} \sum_{i=2}^{n-\nu} (i/m) \sum_{l=2}^{t(i)} l^k [1 - \exp(-a + i/m)]^{l-2} \\ &\sim 1 + a^{-1} \int_0^a u \left\{ \sum_{l=2}^{\infty} l^k [1 - \exp(-a + u)]^{l-2} \right\} du \\ &= S(k), \end{aligned}$$

where  $S(k) = \sum_{l=1}^{\infty} l^k P(\mathcal{C} \geq l)$  (see (2.9) for  $P(\mathcal{C} \geq l)$ ). Further, the range of  $i$  in  $S_{n2}(k)$  is the same as in  $S_{n1}(k)$ . Since  $P(T_1(i, n) \geq l)$  is a decreasing function of  $l$  and  $t(i) \geq \nu^{1/3} - 1$  for  $i \leq n - \nu$ , we obtain

$$(2.13) \quad \begin{aligned} S_{n2}(k) &\leq n^{-1} \sum_{i=2}^{n-\nu} (n-i) n^k P(T_1(i, n) \geq t(i)) \\ &\leq cn^{k+1} (1 - e^{-a})^{\nu^{1/3}} = cn^{k+1} b^{-(k+2) \log_b n} \\ &= O(n^{-1}), \quad m, n \rightarrow \infty. \end{aligned}$$

Also

$$(2.14) \quad S_{n3}(k) \leq n^{-1} \sum_{i=n-\nu+1}^n (n-i+2)^{k+1} = O(\nu^{k+2}/n) = o(1), \quad m, n \rightarrow \infty.$$

The relations (2.12)–(2.14) imply (2.11). Theorem 2 is proved.

**3. The asymptotic behavior of the largest successful search time.** Recall that  $U_1(n) = \max \{T_1(i, n) : 1 \leq i \leq n\}$ . Our goal here is to prove that the largest successful search time for  $n$  stored random items is

$$U_1(n) = \log_b n - 2 \log_b \log_b n + O_p(1),$$

where  $b = (1 - e^{-a})^{-1}$ . It is plausible to conjecture that

$$E(U_1(n)) = \log_b n - 2 \log_b \log_b n + O(1),$$

but we do not propose to prove it here.

(a) *Upper estimate of  $U_1(n)$ .* Introduce an integer

$$(3.1) \quad l = \log_b n - 2 \log_b \log_b n + \omega(n),$$

where  $\omega(n) = o(\log n)$  as  $\omega(n) \rightarrow \infty$ . Let us show that

$$(3.2) \quad \lim_{n \rightarrow \infty} P(U_1(n) > l) = 0.$$

To this end, write first an obvious inequality

$$P(U_1(n) > l) \leq \sum_{i=1}^n P(T_1(i, n) > l) = \sum_{i=1}^{n-l+1} P(T_1(i, n) > l) = \sum_1 + \sum_2;$$

where  $\sum_1, \sum_2$  correspond, respectively, to sums for  $1 \leq i \leq s, s < i \leq t$ , with

$$s = [n - \log^3 n] \quad \text{and} \quad t = n - l + 1.$$

We will prove that  $\sum_1, \sum_2 \rightarrow 0$ . Begin with  $\sum_1$ , which actually dominates  $\sum_2$ . Since  $l^2/(n-i) \rightarrow 0$  uniformly for  $1 \leq i \leq s$ , by (2.4) we have

$$(3.3) \quad \sum_1 \leq c \sum_{i=1}^s (i/m) [1 - \exp(-a + i/m)]^{l-1} = c \sum_{i=1}^s F(i/m);$$

where  $F(y) = y[1 - \exp(-a + y)]^{l-1}$ , and  $c$  is a constant. It turns out (as shown in the Appendix) that, on the interval  $[0, a]$ ,  $F(y)$  achieves its maximum at

$$(3.4) \quad y_0 \sim (e^a - 1)/l,$$

and

$$(3.5) \quad F(y_0) \leq c_1/(lb^l), \quad \text{with } b = (1 - e^{-a})^{-1}, \text{ and } a = n/m.$$

Now, let  $\sum_{11} = \sum_{i=1}^r F(i/m), \sum_{12} = \sum_{i=r+1}^s F(i/m)$ , with  $r = [2y_0 m]$  so that  $y_0 m < r < s$ . Then

$$\sum_{i=1}^s F(i/m) = \sum_{11} + \sum_{12}.$$

Clearly (see (3.4)),

$$(3.6) \quad \sum_{11} \leq rF(y_0) = O(F(y_0)m/l).$$

On the other hand,

$$F((i+1)/m)/F(i/m) \leq \exp(-c_2 l/m), \quad c_2 > 0,$$

for  $r < i \leq n$  (see the Appendix). Hence,

$$(3.7) \quad \begin{aligned} \sum_{12} &\leq F(y_0) \sum_{j \geq 0} [\exp(-c_2 l/m)]^j = F(y_0) [1 - \exp(-c_2 l/m)]^{-1} \\ &= O(F(y_0)m/l). \end{aligned}$$

Combining (3.3) and (3.5)–(3.7) yields

$$(3.8) \quad \sum_1 = O(F(y_0)m/l) = O(mb^{-l}l^{-2}) = O(b^{-\omega(n)}) = o(1), \quad n \rightarrow \infty.$$

Turn now to  $\sum_2$ . Observe that, by (2.3) and (2.6),

$$\begin{aligned} P(T_1(i, n) > l) &< (n-i)! \text{coeff}_{z^{n-i}} [(e^{z/m} - 1)^{l-1} (e^{z/m})^{m-l+1}] \\ &< (n-i)! \text{coeff}_{z^{n-i}} [(e^{z/m} - 1)^{l-1} e^z] \\ &< (n-i)! [(e^{z/m} - 1)^{l-1} e^z] / z^{n-i}, \quad z > 0. \end{aligned}$$

Select  $z = n - i$ . Since  $n - i = O(\log^3 n)$  for  $i > s = \lceil n - \log^3 n \rceil$ ,

$$(e^{z/m} - 1)^{l-1} = (z/m)^{l-1} [1 + O(\log^4 n/m)] \leq 2(\log^3 n/m)^{l-1}.$$

So, by Stirling’s formula applied to  $(n - i)!$ ,

$$\begin{aligned} P(T_1(i, n) > l) &\leq 2(n-i)! (e/n - i)^{n-i} (\log^3 n/m)^{l-1} \\ &\leq c_2 \log^{3/2} n (\log^3 n/m)^{l-1}, \end{aligned}$$

and

$$(3.9) \quad \sum_2 \leq c_3 \log^{9/2} n (\log^3 n/m)^{l-1} \rightarrow 0, \quad m, n \rightarrow \infty.$$

The relations (3.8), (3.9) imply (3.2).

(b) *Lower estimate of  $U_1(n)$ .* Introduce an integer

$$l = \log_b n - 2 \log_b \log_b n - \omega(n),$$

where  $\omega(n) = o(\log n)$  as  $\omega(n) \rightarrow \infty$ . Let us show that

$$(3.10) \quad \lim P(U_1(n) > l) = 1.$$

(1) Introduce an auxiliary random variable  $X(n, l)$ , which is the total number of chains induced by insertion of all  $n$  keys, whose lengths exceed  $l$ . Since both versions of coalesced hashing yield the same—though differently ordered—chains, we can use the results obtained in [8] for the lich algorithm. First of all,

$$X(n, l) = \sum_B \delta(B),$$

where the sum is taken over all  $(l + 1)$ -element subsets  $B = \{x_{i_1} < \dots < x_{i_{l+1}}\}$  of the set of  $n$  keys  $\{x_1, \dots, x_n\}$ , and  $\delta(B) \in \{0, 1\}$  is defined as follows:  $\delta(B) = 1$  if and only if, after the key  $x_{i_{l+1}}$  is inserted, the cells occupied by the keys  $x_{i_1}, \dots, x_{i_{l+1}}$  constitute a subchain which originates at the cell occupied by the key  $x_{i_1}$  (and then, of course,  $h(x_{i_i}) = \tilde{h}(x_{i_i})$  for either of the algorithms). Hence

$$(3.11) \quad E(X(n, l)) = \sum_B E(\delta(B)) = \sum_B P(\delta(B) = 1),$$

where, similarly to (2.2),

$$\begin{aligned} P(\delta(B) = 1) &= [1 - (i_1 - 1)/m] [(1 - 1/m)^{i_2 - i_1 - 1} / m] \dots [(1 - l/m)^{i_{l+1} - i_l - 1} / m] \\ (3.12) \quad &= (l! / m^l) (1 - s_0/m) \prod_{j=1}^l (1 - j/m)^{s_j} \quad \text{with } s_j = i_{j+1} - i_j - 1 \quad (i_0 = 0). \end{aligned}$$

Also, by Lemma 2 in [8],

$$(3.13) \quad E(X(n, l)) = (1 + o(1))cm / (lb^l), \quad b = (1 - e^{-a})^{-1},$$

where  $c$  is a positive constant. The relations (3.11)–(3.13) will be needed shortly.

(2) To proceed we need a notion of a special chain. Consider a chain of length  $\geq l + 1$ , and let  $x_{i_1} < \dots < x_{i_{l+1}}$  be the first  $(l + 1)$  keys whose locations are absorbed by this chain. According to the rule, it means that  $h(x_{i_1}) = \tilde{h}(x_{i_1}) = h(x_{i_2}) \neq \tilde{h}(x_{i_2})$ ,  $h(x_j) \neq h(x_{i_1})$  for  $i_1 < j < i_2$ , or that insertion of  $x_{i_1}$  starts a new chain, while  $x_{i_2}$  is the first key whose insertion results in collision with  $x_{i_1}$  and forms a chain of length 2. We call such a chain special if insertions of all the subsequent keys  $x_{i_3}, \dots, x_{i_{l+1}}$  have resulted in pushing the cell  $\tilde{h}(x_{i_2})$  along the chain farther and farther from the cell  $h(x_{i_1})$ , so that once the key  $x_{i_{l+1}}$  has been inserted the length of the subchain connecting the cells  $h(x_{i_1}) (= h(x_{i_2}))$  and  $\tilde{h}(x_{i_2})$  becomes, for the first time, equal to  $(l + 1)$ .

Denote the total number of special chains by  $Y(n, l)$ . It should be clear from the definition above that

$$\{U_1(n) > l\} \supset \{Y(n, l) > 0\}.$$

Thus, the relation (3.10) will be proved if we can show that

$$\lim_{n \rightarrow \infty} P(Y(n, l) > 0) = 1.$$

But, by a corollary of Chebyshev's inequality,

$$P(Y(n, l) > 0) \geq E^2(Y(n, l)) / E(Y^2(n, l));$$

so, it remains to prove that

$$(3.14) \quad E(Y^2(n, l)) \leq [1 + o(1)]E^2(Y(n, l)), \quad n, m \rightarrow \infty.$$

To evaluate the first two moments of  $Y(n, l)$ , write first

$$Y(n, l) = \sum_B \varepsilon(B);$$

here the summation is taken over all  $(l + 1)$ -element subsets  $B = \{x_{i_1} < \dots < x_{i_{l+1}}\}$  of  $\{x_1, \dots, x_n\}$ ,  $\varepsilon(B) \in \{0, 1\}$  and  $\varepsilon(B) = 1$  if and only if  $x_{i_1}, \dots, x_{i_{l+1}}$  are the first  $(l + 1)$  keys whose locations are absorbed by a special chain. Similarly to (2.2) and (3.12), we have

$$\begin{aligned} P(\varepsilon(B) = 1) &= [1 - (i_1 - 1)/m][(1 - 1/m)^{i_2 - i_1 - 1} / m] \\ &\quad \cdot [(1 - 2/m)^{i_3 - i_2 - 1} / m] \cdot \dots \cdot [(1 - l/m)^{i_{l+1} - i_l - 1} (l - 1)/m] \\ &= P(\delta(B) = 1) / l = E(\delta(B)) / l. \end{aligned}$$

By (3.11) and (3.13), it follows then that

$$\begin{aligned} E(Y(n, l)) &= \sum_B E(\varepsilon(B)) = l^{-1} \sum_B E(\delta(B)) \\ &= l^{-1} E(X(n, l)) = [1 + o(1)]cm / (l^2 b^l) \\ &= [1 + o(1)]ca^{-1} b^{\omega(n)}. \end{aligned}$$

Turn now to the second-order moment. First observe that

$$\varepsilon(B_1) \cdot \varepsilon(B_2) = 0 \quad \text{if } B_1 \neq B_2 \quad \text{and} \quad B_1 \cap B_2 \neq \emptyset.$$

Subsequently,

$$(3.15) \quad E(Y^2(n, l)) = E(Y(n, l)) + \sum_{B_1, B_2} P(\varepsilon(B_1) = 1, \varepsilon(B_2) = 1),$$

where the summation is taken over all ordered pairs of disjoint subsets  $B_1, B_2$  of  $\{x_1, \dots, x_n\}$  with  $|B_1| = |B_2| = l + 1$ .

To estimate the sum in (3.15) we need the following lemma.

LEMMA. For every pair of disjoint  $(l + 1)$ -element subsets  $B_1, B_2$ ,

$$P(\varepsilon(B_1) = 1, \varepsilon(B_2) = 1) \leq c(l, m)P(\varepsilon(B_1) = 1)P(\varepsilon(B_2) = 1),$$

where

$$c(l, m) = [1 - 2(l + 1)/m]^{-2(l+1)}.$$

(This inequality is similar to Lemma 3, for the lich algorithm, proven in [8] and we omit its proof.)

By (3.15) and the lemma,

$$\begin{aligned} E(Y^2(n, l)) &\leq E(Y(n, l)) + c(l, m) \sum_{B_1, B_2} P(\varepsilon(B_1) = 1) \cdot P(\varepsilon(B_2) = 1) \\ &\leq E(Y(n, l)) + c(l, m)E^2(Y(n, l)) \\ &= E^2(Y(n, l))[O(b^{-\omega(n)}) + 1 + O(l^2/m)] \\ &= (1 + o(1))E^2(Y(n, l)), \end{aligned}$$

as  $\omega(n) \rightarrow \infty$ . Thus, the relation (3.14) is proven, and it implies the relation (3.10).

Combination of (3.2) and (3.10) enables us to conclude that, for every  $\omega(n)$ :

$$P(|U_1(n) - \log_b n + 2 \log_b \log_b n| \leq \omega(n)) \rightarrow 1 \quad \text{as } \omega(n) \rightarrow \infty$$

which proves Theorem 3.

**Appendix.** Consider a function  $F(y) = y[1 - \exp(-a + y)]^{l-1}$ ,  $y \in (0, a)$ . Denote  $\log F(y)$  by  $h(y)$ .

(i) Since

$$h'(y) = y^{-1} - (l - 1)[\exp(a - y) - 1]^{-1} \rightarrow \begin{cases} \infty & \text{if } y \rightarrow 0, \\ -\infty & \text{if } y \rightarrow a, \end{cases}$$

there must exist  $y_0 \in (0, a)$ , where  $F(y)$  achieves its maximum and

$$y_0^{-1} - (l - 1)[\exp(a - y_0) - 1]^{-1} = 0.$$

(This point is unique since  $h''(y) < 0$ ,  $y \in (0, a)$ .) Let  $l \rightarrow \infty$ ; it follows then that  $y_0 \rightarrow 0$  so

$$y_0 = [1 + o(1)](e^a - 1)/l, \quad m, n \rightarrow \infty.$$

Furthermore,

$$\begin{aligned} h(y_0) &= \log y_0 + (l - 1) \log [1 - \exp(-a + y_0)] \\ &= -\log l + \log(e^a - 1) + o(1) + (l - 1) \log(1 - e^{-a}) - 1 + o(1), \end{aligned}$$

so

$$F(y_0) = (1 + o(1))c/(lb^l), \quad (b = (1 - e^{-a})^{-1}, c = e^{a-1}).$$

(ii) Note that  $h'(y)$  is a decreasing function, since  $h''(y) < 0$ . So, for  $[2y_0m] + 1 \leq i \leq n$ ,

$$\begin{aligned} h[(i + 1)/m] - h(i/m) &\leq h'(2y_0)/m \\ &= \{(2y_0)^{-1} - (l - 1)[\exp(a - 2y_0) - 1]^{-1}\}/m \\ &= [(2y_0)^{-1} - y_0^{-1}(1 + o(1))]/m \\ &\leq -(3y_0m)^{-1} \leq -c_1l/m, \quad c_1 > 0, \end{aligned}$$

whence

$$F[(i+1)/m]/F(i/m) \leq \exp(-c_1 i/m).$$

**Acknowledgments.** We wish to express our gratitude to the referees for many insightful comments which helped us to improve the presentation of the results. One of the referees took time to read through two consecutive versions of the paper, and we are much indebted to him for his meticulous care about essence and details of the paper.

## LOWNESS PROPERTIES OF SETS IN THE EXPONENTIAL-TIME HIERARCHY\*

R. BOOK†, P. ORPONEN‡, D. RUSSO§, AND O. WATANABE¶

**Abstract.** The notion of “lowness” was introduced in computational complexity theory by Schöning [J. Comput. Systems Sci., 27 (1983), pp. 14–28] who studied sets in the class NP. This notion may be interpreted as setting an upper bound on the amount of information that can be encoded by a set. Here ideas from previous studies are incorporated in order to capture the notion of a set being exponentially low.

The main result asserts the existence of a sparse set  $E$  such that  $\text{DEXT}(E) = \text{DEXT}$ , i.e.,  $E$  is “exponentially low,” but  $E$  is not in the class  $P$ . In contrast, any set with small generalized Kolmogorov complexity that is exponentially low must be in the class  $P$ . In addition, we show that for each  $k \geq 2$ , any sparse set  $S$  that is low with respect to the class  $\Sigma_k^E$  of the exponential-time hierarchy (i.e.,  $\Sigma_k^E(S) = \Sigma_k^E$ ) must be in the class  $\Sigma_k^P$  of the polynomial-time hierarchy. Similarly, for each  $k \geq 4$ , any set with polynomial-size circuits that is low with respect to the class  $\Sigma_k^E$  must be in the class  $\Sigma_k^P$ .

**Key words.** exponential lowness, polynomial lowness, small generalized Kolmogorov complexity, sparse sets

**AMS(MOS) subject classifications.** 68Q15, 68Q30, 03D15

**1. Introduction.** How does one measure the complexity of a set of strings? The most common approach is, of course, to study the inherent computational complexity of the characteristic function of the set; for example, a set that can be recognized in exponential time but not in polynomial time is considered to be more complex than a set that can be recognized in polynomial time. A different idea is to consider a function that bounds the Kolmogorov complexity of the strings in the set. Then a set with large Kolmogorov complexity is considered to be more complex than a set with small Kolmogorov complexity. A third method is to consider how much the set, when used as an oracle, “helps” different types of computations; for example, if  $\text{NP}(A) = \Sigma_2^P$  but  $\text{NP}(B) = \Sigma_3^P$ , then  $B$  is considered to be more complex than  $A$ .

The purpose of this paper is to consider a specific case of the third method and to compare that with the first. More specifically, we consider the following question: if a set  $A$  has the property that  $\text{DEXT}(A) = \text{DEXT}$ , does this mean that  $A$  is in  $P$ ? Here,  $\text{DEXT}(A)$  denotes the class of sets reducible to  $A$  by means of Turing reducibilities that are computed deterministically in exponential time. Any set  $A$  with the property that  $\text{DEXT}(A) = \text{DEXT}$  is called *DEXT-low* (informally, “exponentially low”). Not every set in  $\text{DEXT}$  is exponentially low since  $\text{DEXT}(\text{DEXT}) \neq \text{DEXT}$ . Being exponentially low means that the set in question cannot encode a great deal of information since applying the  $\text{DEXT}(\ )$ -operator to that set does not produce sets not already in  $\text{DEXT}$ . Every set in  $P$  is already exponentially low, so the question of whether every exponentially low set is in  $P$  is equivalent to asking whether the property of being exponentially low characterizes the sets in  $P$ . We will show that the answer

to the question is “no,” that is, there exist sets  $A$  such that  $A$  is exponentially low but  $A \in \text{DEXT}-P$ : we will exhibit a sparse set  $A$  with this property. To accomplish this we consider sets whose generalized Kolmogorov complexity is bounded by certain functions, so that the second method of characterizing the information encoded by a set of strings is also considered.

The notion of “lowness” was introduced in computational complexity theory by Schöning [14] who called a set  $A$  in NP “low” if for some  $i$ ,  $\Sigma_i^P(A) = \Sigma_i^P$ . Ko and Schöning [12] showed that if  $A \in \text{NP}$  is sparse, then  $\Sigma_2^P(A) = \Sigma_2^P$ , and if  $A \in \text{NP}$  has polynomial-size circuits, then  $\Sigma_3^P(A) = \Sigma_3^P$ . Balcázar, Book, and Schöning [2] introduced a more general type of lowness in the context of sets in the union of the polynomial-time hierarchy. In general, the notion of lowness with respect to the classes  $\Sigma_i^P$ ,  $i > 0$ , may be interpreted as setting an upper bound on the amount of information that can be encoded in the set, that is, the power of a low set in the polynomial-time hierarchy is subsumed by a bounded number of alternating quantifiers or, equivalently, a bounded number of applications of the NP ( )-operator. More formally, if  $A \in \Sigma_n^P - \Sigma_{n-1}^P$  and for every  $i$ ,  $\Sigma_i^P(A) \subseteq \Sigma_{i+j}^P$  where  $j < i + n$ , then  $A$  can encode information equivalent to at most  $j$  alternating quantifiers. Here we incorporate ideas from the previous studies in order to capture the notion of a set being exponentially low.

Other types of lowness can be studied in the context of classes in the exponential hierarchy. In this direction we have several results about sets with “compact descriptions.” (The notion of a set having a “compact description” is similar to notions of “language compression by machine” which extend the classical data compression problem (see [6]).) We show that if a set with a compact description is low with respect to certain classes in the exponential-time hierarchy, then it is also low with respect to the corresponding classes in the polynomial-time hierarchy.

We establish the following results.

**THEOREM 3.3.** *A set with small generalized Kolmogorov complexity (this includes the tally sets) is DEXT-low if and only if it is in  $P$ .*

**THEOREM 4.5.** *There is a sparse set  $E \in \text{DEXT}-P$  that is DEXT-low.*

**THEOREM 5.5.** *For  $k \geq 2$ , a sparse set is  $\Sigma_k^E$ -low if and only if it is  $\Sigma_k^P$ -low.*

**THEOREM 5.6.** *For  $k \geq 4$ , a set with polynomial-size circuits is  $\Sigma_k^E$ -low if and only if it is  $\Sigma_k^P$ -low.*

Recall that there is a fundamental difference between the relativizations of polynomial-time classes and the relativizations of exponential-time classes (at least if the standard model with unrestricted access to the oracle is used). For example, while  $P(P) = P$  and  $\text{NP}(P) = \text{NP}$ , it is the case that  $\text{DEXT}(\text{DEXT}) \neq \text{DEXT}$  and  $\text{NEXT}(\text{DEXT}) \neq \text{NEXT}$ ; also, while  $\text{NP}(\text{NP}) = \Sigma_2^P$ ,  $\text{NEXT}(\text{NEXT}) \neq \Sigma_2^E$ . Because of this difference, strange anomalies arise: exponential time Turing reducibility is not a transitive relation; it is possible for the exponential-time hierarchy to collapse at some level (i.e.,  $\Sigma_i^E = \text{co-}\Sigma_i^E$ ) but be proper at a higher level (i.e.,  $\Sigma_j^E \neq \text{co-}\Sigma_j^E$  for some  $j > i$ ) [17], [9]; and it is possible to construct an oracle set such that relative to that set the exponential-time hierarchy and the alternating space classes are different [13], in contrast to the unrelativized case [4].

Basically, all of these difficulties arise from the fact that the class of single exponential functions is not closed under composition. Hence, when an oracle machine makes a query of exponential length to an exponentially complex oracle set, the amount of information it obtains is in a sense double exponential. However, this explanation is not helpful in increasing our understanding of exponential relativizations. We would like to know how this basic arithmetical fact is reflected in the structure of the sets causing the anomalous behavior, that is, in the sets in DEXT which are *not* DEXT-low.

This paper is organized in the following way. Section 2 contains notation and some facts about sets with small generalized Kolmogorov complexity. In § 3, exponentially low oracle sets are discussed. The main result is contained in § 4. A set  $E$  is defined and shown to be in  $\text{DEXT-}P$ ; in Theorem 4.4 it is shown that the set  $E$  is  $\text{DEXT-low}$ . In § 5, we consider lowness with respect to levels of the polynomial-time hierarchy and of the exponential-time hierarchy. Section 6 is devoted to remarks and open questions.

**2. Preliminaries and generalized Kolmogorov complexity.** We use  $\Sigma = \{0, 1\}$  as our alphabet. For each integer  $n \geq 0$ , let  $\text{bin}(n)$  be a standard unique binary representation of  $n$  over  $\Sigma$ . Let  $\mathbf{N}$  and  $\mathbf{bin}(\mathbf{N})$  denote the set of all nonnegative integers and  $\{\text{bin}(n) \mid n \in \mathbf{N}\}$ , respectively. Denote the length of  $x \in \Sigma^*$  by  $|x|$  and denote the cardinality of set  $S$  by  $\|S\|$ .

A set  $T$  is a *tally* set if  $T \subseteq \{0\}^*$ . For each tally set  $T$ ,  $\text{bin}(T)$  denotes  $\{\text{bin}(n) \mid O^n \in T\}$ . For each set  $B \subseteq \Sigma^*$ ,  $\text{TALLY}(B)$  denotes  $\{O^n \mid \text{bin}(n) \in B\}$ .

A set  $S$  is *sparse* if there exists a polynomial  $q$  such that for all  $n$ ,  $\|\{s \in S \mid |s| \leq n\}\| \leq q(|n|)$ .

We use standard deterministic and nondeterministic time-bounded oracle machines that act as acceptors. If  $M$  is an acceptor, then  $L(M, A)$  denotes the set of strings recognized relative to oracle set  $A$ , and  $L(M)$  is written for  $L(M, \emptyset)$ . We assume a standard enumeration of such machines, say  $M_1, M_2, \dots$ , indicating by context whether we are discussing the class of deterministic machines or the class of nondeterministic machines. A function is *time constructible* if it is the running time of some deterministic Turing machine.

We also consider standard deterministic time-bounded Turing machines that act as transducers. We assume a standard enumeration of such transducers, say  $N_1, N_2, \dots$ . For each  $i$ , let  $T_i$  be the running time of the transducer  $N_i$ , let  $f_i$  be the function computed by the transducer  $N_i$ , and let  $R_i$  denote the range of  $f_i$ . We assume that the enumeration has the property that there exists a *universal Turing transducer*  $N_u$  and a *description function*  $d$  with the following properties: for every  $i > 0$  there is a constant  $c_i$  such that for all  $x \in \Sigma^*$ ,

- (a)  $d(i)$  is not a prefix of  $d(j)$  if  $i \neq j$ ,
- (b)  $f_u(d(i)x) = f_i(x)$ , and
- (c)  $T_u(d(i)x) \leq c_i \cdot T_i(x) \cdot \log T_i(x) + c_i$ .

Hartmanis [8] introduced a “generalized Kolmogorov complexity measure.” Informally, it measures how far and how fast a string can be compressed. More formally, for each pair  $g, t$  of functions, we consider the following sets:

$$K_i[g(n), t(n)] = \{y \mid (\exists x)[|x| \leq g(n), f_i(x) = y, \text{ and } T_i(x) \leq t(n)]\}, \text{ where } n = |y|,$$

$$K[g(n), t(n)] = K_u[g(n), t(n)], \text{ where } u \text{ denotes the index of the universal Turing transducer considered above.}$$

We have the following fact.

LEMMA 2.1 [8]. *Let  $i$  be any index and let  $g(n)$  and  $t(n)$  be time-constructible functions. Then there exists  $c > 0$  and  $d > 0$  such that  $K_i[g(n), t(n)] \leq K[g(n) + d, c \cdot t(n) \cdot \log t(n) + c]$ .*

This lemma shows that the generalized Kolmogorov complexity defined by the universal Turing machine  $N_u$  is within small factors of any other complexity defined by a different Turing machine. Thus we will use the generalized Kolmogorov complexity defined by  $N_u$  to state our results.

We will say that a set  $A$  has *small generalized Kolmogorov complexity* if the elements of  $A$  have uniformly bounded generalized Kolmogorov complexity that is small in the sense that there exist constants  $c > 0$  and  $d > 0$  such that  $A \subseteq K[d \cdot \log n, n^c]$ . Properties of sets with small generalized Kolmogorov complexity are investigated in [1], [8], [19].

We assume that the reader is familiar with the classes  $P$ ,  $NP$ , and  $\Sigma_i^P$  for  $i \geq 0$ , and their relativizations to an arbitrary oracle set  $A$ ,  $P(A)$ ,  $NP(A)$ , and  $\Sigma_i^P(A)$ , respectively. We will consider the classes  $DEXT = \{L(M) \mid M \text{ is a deterministic acceptor that runs in time } 2^{cn} \text{ for some } c > 0\}$  and  $NEXT = \{L(M) \mid M \text{ is a nondeterministic acceptor that runs in time } 2^{cn} \text{ for some } c > 0\}$ , and will consider their relativizations to an arbitrary oracle set  $A$ ,  $DEXT(A)$ , and  $NEXT(A)$ .

**3. Exponentially low oracle sets.** Let  $\mathcal{C}$  be an operator that maps  $2^{\Sigma^*}$  into  $2^{2^{\Sigma^*}}$  with the property that for every set  $A \subseteq \Sigma^*$ ,  $\mathcal{C}(\emptyset) \subseteq \mathcal{C}(A)$ . For example,  $P(A) = \{B \mid B \leq_T^P A\}$ . We write  $\mathcal{C}$  for  $\mathcal{C}(\emptyset)$ . A set  $A \subseteq \Sigma^*$  is  $\mathcal{C}$ -low if  $\mathcal{C}(A) = \mathcal{C}$ .

We are particularly interested in the class of  $DEXT$ -low sets. Observe that only sets in  $DEXT$  can be  $DEXT$ -low. But there are sets in  $DEXT$  which are known *not* to be  $DEXT$ -low since  $DEXT(DEXT) = DDEXT$  (recall that  $DDEXT = \bigcup \{DTIME(2^{2^{cn}}) \mid c > 0\}$ ) which is a proper superset of  $DEXT$ . We have the following fact.

**PROPOSITION 3.1.** *Every set in  $P$  is  $DEXT$ -low.*

*Proof.* Let  $A \in P$  and let  $M_1$  be a machine recognizing  $A$  that runs in time  $n^c$ . Let  $B \in DEXT(A)$  and let  $M_2$  be an oracle machine such that  $L(M_2, A) = B$  and  $M_2$  runs in time  $2^{dn}$ . Membership in  $B$  can be decided by a machine  $M_3$  that simulates  $M_2$  but instead of querying the oracle simply simulates  $M_1$ . Clearly, such an  $M_3$  need have running time only  $O(2^{dn} \cdot (2^{dn})^c) = O(2^{d(1+c)n})$  (since on input of length  $n$ ,  $M_2$  can make at most  $2^{dn}$  oracle queries, each of length at most  $2^{dn}$ ). Thus,  $M_3$  witnesses  $B \in DEXT$ .  $\square$

We are interested in the structure of sets that are  $DEXT$ -low. Our next result (and the results in § 5) show that sets that are  $DEXT$ -low but not in  $P$  must be structurally complex.

**PROPOSITION 3.2.** *A set  $A$  is  $DEXT$ -low if and only if there are no tally sets in  $P(A) - P$ .*

*Proof.* Let  $A$  be  $DEXT$ -low so that  $DEXT(A) = DEXT$ , and suppose that  $T$  is a tally set in  $P(A)$ . Then the set  $\text{bin}(T)$  can be seen to be in  $DEXT(A)$ : an input string  $x = \text{bin}(n)$  can be expanded to be in the form  $1^n$  in time  $O(2^{c|x|})$  and whether  $1^n$  is in  $T$  can be decided relative to  $A$  in time  $O(n^d) = O(2^{d|x|})$ . But since  $DEXT(A) = DEXT$ , there is an unrelativized decision procedure for  $\text{bin}(T)$  that runs in time  $O(2^{e|x|})$  and this procedure can be used to decide membership in  $T$  in time  $O(2^{e|\text{bin}(n)|}) = O(n^e)$ . Hence,  $T$  is in  $P$ .

Conversely, let  $A$  be a set that is not  $DEXT$ -low and let  $B \in DEXT(A) - DEXT$ . We claim that the set  $\text{TALLY}(B)$  is in  $P(A) - P$ . A decision procedure for membership in  $B$  running in time  $O(2^{e|x|})$  relative to  $A$  can be used to decide membership in  $\text{TALLY}(B)$  in time  $O(2^{e|\text{bin}(n)|}) = O(n^e)$  relative to  $A$ ; hence,  $\text{TALLY}(B) \in P(A)$ . On the other hand, if  $\text{TALLY}(B)$  had an unrelativized decision procedure running in time  $O(n^d)$ , we could obtain from this a decision procedure for  $B$  running in time  $O(2^{d|x|})$  so that  $B \in DEXT$ , contrary to our hypothesis. Hence,  $\text{TALLY}(B)$  is not in  $P$ .  $\square$

The proof of Proposition 3.2 is essentially that given by Book [3]. It is a simple example of a more general technique that will be used in § 5.

Recall that every tally set has small generalized Kolmogorov complexity. This fact suggests the following result.

**THEOREM 3.3.** *Let  $A$  be a set with small generalized Kolmogorov complexity. Then  $A$  is DEXT-low if and only if  $A$  is in  $P$ .*

*Proof.* The “if” portion follows from Proposition 3.1. To prove the “only if” portion, assume that  $A$  has small generalized Kolmogorov complexity and  $A$  is not in  $P$ . There exist  $c, d > 0$  such that  $A \subseteq K[d \cdot \log n, n^c]$ . We will show that  $\text{DEXT}(A) \neq \text{DEXT}$  so that  $A$  is not DEXT-low.

Let  $N_0$  be an exponential time-bounded transducer such that the function  $f_0$  computed by  $N_0$  is defined by

$$f_0(x) = \begin{cases} f_U(x) & \text{if } N_U \text{ halts on } x \text{ within } 2^{(c/d)|x|} \text{ steps,} \\ 0 & \text{otherwise,} \end{cases}$$

where  $f_U$  and  $N_U$  are the universal function and machine, respectively (as in § 2).

Let  $L_A = \{x \mid f_0(x) \in A\}$ . Then  $L_A \in \text{DEXT}(A)$ . Notice that  $f_0$  enumerates all strings of Kolmogorov complexity less than or equal to that of the members of  $A$ . The language  $L_A$  consists of a set of witnesses for the small generalized Kolmogorov complexity of the elements of  $A$ . Assuming that  $L_A$  is in DEXT will yield the contradiction.

Let  $y$  be an element of  $A$ ; then,  $y \in K[d \cdot \log k, k^c]$  where  $k = |y|$ . Hence, there exists some  $x$  such that  $|x| \leq d \cdot \log k$  and on input  $x$ ,  $N_U$  outputs  $y$  and halts within  $k^c$  (i.e.,  $2^{(c/d)|x|}$ ) steps; hence,  $f_0(x) = y$ . This means that for all  $y, y \in A$  if and only if  $(\exists x)[|x| \leq d \cdot \log |y| \text{ and } f_0(x) = y \text{ and } x \in L_A]$ . Using this fact we can construct a polynomial time-bounded deterministic acceptor for  $A$  that for  $y$  behaves as follows:

```
begin
  input y;
  for all x such that  $|x| \leq d \cdot \log |y|$  do
    if  $x \in L_A$  and  $f_0(x) = y$  then halt and accept
end.
```

Therefore,  $A \in P$ , contradicting the hypothesis.  $\square$

**COROLLARY 3.4.** *For every tally set  $T$ ,  $T$  is DEXT-low if and only if  $T$  is in  $P$ .*

The reader should note that Corollary 3.4 demonstrates that Theorem 3.3 generalizes Proposition 3.2.

Notice that there is a tally set in DEXT that is *not* DEXT-low: if  $L$  is a set that is  $\leq_m^P$ -complete for DDEXT, the set  $T = \text{TALLY}(L)$  is not in  $P$  since  $\text{DEXT} \neq \text{DDEXT}$  so by Corollary 3.4,  $T$  is not DEXT-low. Theorem 3.3 can be deduced from Corollary 3.4 by means of the following fact.

A *polynomial semi-isomorphism* from set  $A$  to set  $B$  is a function  $f$  computable in polynomial time such that  $f$  witnesses the fact that  $A \leq_m^P B$  and the restriction of  $f$  to  $A$  is a polynomially invertible bijection from  $A$  to  $B$ . Balcázar and Book [1] showed that a set has small generalized Kolmogorov complexity if and only if it is polynomially semi-isomorphic to a tally set. Later, Allender and Rubinfeld [19] showed that “semi-isomorphic” could be replaced by “isomorphic.”

**4. There are DEXT-low sets that are not in  $P$ .** Here we establish the main result, showing the existence of a set that is DEXT-low but is not in  $P$ . We saw in § 3 that any set that is both DEXT-low and not in  $P$  cannot have small generalized Kolmogorov complexity and must contain infinitely many complex (noncompressible) strings. Recall the result of Allender and Rubinfeld [19] that a set has small generalized Kolmogorov complexity if and only if it is polynomially isomorphic to a tally set. A set that is polynomially isomorphic to a tally set must be sparse. The main result shows that there is a sparse set that is DEXT-low but not in  $P$ , so this sparse set cannot be polynomially

isomorphic to any tally set. (The reader may wish to review § 2 for notation on Kolmogorov complexity.)

Let  $\varepsilon > 0$  be arbitrarily fixed, and consider the set  $K[n/2, 2^{(1+\varepsilon)n}]$ . For brevity, we let  $K$  denote  $K[n/2, 2^{(1+\varepsilon)n}]$  and  $\bar{K}$  denote the complement of  $K$ . A simple counting argument is enough to show that for every  $n > 0$ , there exists at least one string in  $\bar{K}$  of length  $n$ : there are not enough strings in  $\Sigma^*$  of length  $n/2$  or less to map onto all of the strings of length  $n$ .

Intuitively,  $\bar{K}$  is a good candidate for a DEXT-low set in DEXT- $P$ . What follows is an intuitive explanation of our idea. Note that  $\bar{K} \in \text{DEXT}$ . Thus, if the lengths of queries made by a deterministic exponential time-bounded oracle machine  $M$  are small, e.g., linear bounded with respect to the length of the input, then it can be simulated deterministically by an exponential time-bounded machine that makes no oracle queries. On the other hand, if  $M$  makes a long query with respect to the length of the input, then this query may be computable from a short description in exponential time and may be in  $K$  (i.e., not in  $\bar{K}$ ). Thus, the answer to this query may be “no” (i.e., we do not need the oracle here). The next lemma establishes this type of property for the set  $\bar{K}$ .

LEMMA 4.1. *Let  $N_i$  be any exponential time-bounded transducer. There exists a  $d_i$  such that for all but finitely many  $x$ ,  $|f_i(x)| > d_i \cdot |x|$  implies that  $f_i(x) \in K$ .*

*Proof.* Let  $c$  be a constant such that  $N_i$  runs in time  $2^{cn}$ . Let  $d > 1$  be arbitrary. For any  $x$  such that  $|f_i(x)| > d|x|$ , we have  $f_i(x) \in K_i[n/d, 2^{c(n/d)}]$ . From Lemma 2.1 we see that  $K_i[n/d, 2^{c(n/d)}] \subseteq K[n/d + d', c'(n/d) \cdot 2^{c(n/d)}]$ , where  $d'$  and  $c'$  are constants determined by  $N_i$ .

Choose a constant  $d_i$  such that  $d' + n/d_i \leq n/2$  and  $c'(n/d_i) \cdot 2^{c(n/d_i)} < 2^n$  for all but finitely many  $n$ . Then we have  $K[n/d_i + d', c'(n/d_i) \cdot 2^{c(n/d_i)}] \subseteq K[n/2, 2^{(1+\varepsilon)n}]$  for all but finitely many  $n$ . Therefore, for all but finitely many  $n$  such that  $|f_i(x)| > d_i|x|$ , we have  $f_i(x) \in K[n/2, 2^{(1+\varepsilon)n}] = K$ .  $\square$

However, we cannot prove the DEXT-lowness of  $\bar{K}$  in this way. The machine  $M$  may use some information obtained by answers to the previous queries. So the query may not result from a short description in exponential time even if it is long. But if the oracle is very sparse, we can compress this information.

Let  $E$  be any infinite subset of  $\bar{K}$  in DEXT with the property that for each  $n > 0$ ,  $E$  contains at most one element of length between  $n$  and  $2^n$ . For example, we can define  $E$  to be the set  $\{x \mid x \text{ is the smallest element (in lexicographic order) of } \bar{K} \text{ of length } 2^{2^{\cdot^{\cdot^2}}m}, \text{ for some } m > 0\}$ ; then it is easy to show that this choice for  $E$  is in DEXT. Moreover the following lemmas show that  $E$  is not in  $P$ .

LEMMA 4.2. *Let  $t$  be any time-constructible function. Let  $A$  be any infinite set accepted by a deterministic Turing acceptor that runs in time  $t$ . Then there exists a deterministic transducer  $N_i$  such that  $A \cap K_i[\lceil \log n \rceil, 2^n \cdot t(n)]$  is infinite.*

*Proof.* Let  $M$  be any deterministic acceptor that runs in time  $t$  and recognizes  $A$ . From  $M$  construct a transducer  $N_i$  which computes the function  $f_i$  defined as

$$f_i(\text{bin}(n)) = \begin{cases} \text{the smallest (in lexicographic order) } y \in A \\ \text{such that } |y| = n \text{ if such a } y \text{ exists,} \\ 0 \text{ if no such } y \text{ exists.} \end{cases}$$

It is easy to implement  $N_i$  so that it runs in time  $2^n \cdot t(n)$ . Thus, we have  $R_i = K_i[\lceil \log n \rceil, 2^n \cdot t(n)] \subseteq A$ . Since  $A$  is infinite, it is clear that  $R_i$  is infinite.  $\square$

LEMMA 4.3. *If  $X$  is any infinite subset of  $\bar{K}$ , then  $X$  is not in  $P$ . Hence,  $E$  is not in  $P$ .*

*Proof.* Assume to the contrary that there is an infinite  $X \in P$  so that  $X \subseteq \bar{K}$ . By Lemma 4.2, for some polynomial  $p$  there exists a deterministic transducer  $N_i$  such that

$X \cap K_i[[\log n], 2^n \cdot p(n)]$  is infinite. But from Lemma 2.1 we see that  $K_i[[\log n], 2^n \cdot p(n)] \subseteq K[(\log n) + d, (cn2^n \cdot p(n) \cdot \log p(n)) + c] \subset K$  for all but finitely many  $n$ . Therefore,  $\bar{K} \cap K \neq \emptyset$ , a contradiction.  $\square$

Now we can show that  $E$  is DEXT-low.

**THEOREM 4.4.** *If  $L$  is in DEXT( $E$ ), then  $L$  is in DEXT. Hence, DEXT( $E$ ) = DEXT.*

*Proof.* Let  $M_i$  be a deterministic exponential time-bounded oracle machine that witnesses  $L \in \text{DEXT}(E)$ , that is,  $L = L(M_i, E)$ . We must prove that  $L$  is in DEXT.

**CLAIM.** There exists a constant  $d > 0$  such that for all but finitely many  $x$ , if  $y$  is a query made by  $M_i$  during its computation on  $x$ , then  $|y| > d|x|$  implies  $y$  is not in  $E$ .

*Proof of the Claim.* The proof is based on the notion that one can convert  $M_i$  to the transducer  $N_0$  that will produce each query string  $y$  from  $x$  with some additional information bits.

Let the running time of  $M_i$  be  $2^{cn}$ . Suppose that in  $M_i$ 's computation on  $x$  relative to  $E$ , the oracle is queried about string  $y$ . Let  $n = |x|$  and let  $q_1, \dots, q_m$  ( $m \leq 2^{cn}$ ) be the strings previously queried during this computation (i.e.,  $y$  is the  $(m+1)$ st query). We first show that with input  $x$  and some additional information, all of which requires at most  $(3n+3cn)$  bits to encode, this computation can be simulated up to this point without making any oracle calls.

Let  $\{\alpha_1, \dots, \alpha_k\}$  be the set of strings in  $E$  of length at most  $n$ . Notice that by the definition of  $E$ ,  $|\alpha_1| + \dots + |\alpha_k| \leq 2n$ . Hence, by using  $2n$  bits of additional information, we can simulate an oracle call to  $E$  if the length of the string is at most  $n$ .

Note that  $|q_i| \leq 2^{cn}$  for all  $i$ ,  $1 \leq i \leq m$ . Furthermore, there is at most one element in  $E$  with length greater than  $n$  but no greater than  $2^n$ . Since  $2^{cn} < 2^{2^n}$  for almost all  $n$ , there exist at most two different  $q_i$ 's that are in  $E$  and have lengths that are greater than  $n$ . Thus, if some  $q_j$  is in  $E$  but  $|q_j| > n$ , then we can indicate that fact by knowing its index  $j$  which costs at most  $cn$  bits of additional information for each  $q_j$ . This means that we can simulate the oracle calls to  $E$  even if the length of the string is greater than  $n$ , just so long as we have  $2cn$  bits of additional information.

Note that the string  $y$  is indicated by its index (i.e.,  $m+1$ ). Hence, we can conclude that it is possible to simulate  $M_i$ 's computation on  $x$  relative to  $E$  up to the query  $y$  by making no oracle calls if we have enough additional information: at most  $(2n+2cn+cn)$  bits of such information are required. We encode this information using exactly  $(2n+3cn)$  bits and add them to the input string  $x$ ; hence,  $(3n+3cn)$  bits are needed. Therefore, one can construct a deterministic exponential time-bounded transducer  $N_0$  which produces each query  $y$  from some  $z$  where  $z$  has less than  $(3+3c)n$  bits. Now it follows from Lemma 4.1 that there exists  $d_0 > 0$  such that for all but finitely many  $y$ ,  $|y| > d_0 \cdot |z|$  implies  $y \in K$  so that  $y$  is not in  $E$ . Letting  $d$  be  $d_0(3+3c)$ , we have that  $|y| > d \cdot |x| = d_0(3+3c) \cdot |x| \geq d_0|z|$  implies  $y$  is not in  $E$ , for all but finitely many  $y$ .

This concludes the proof of the claim.

To continue with the proof of the theorem, let  $M_E$  be a deterministic exponential time-bounded acceptor which recognizes  $E$ . Then there is a deterministic exponential time-bounded acceptor  $M_L$  which recognizes  $L$  without making any oracle queries that operates as follows:

```

begin
  input  $x$ ;
  simulate  $M_i$  on  $x$  where
    if  $M_i$  queries the oracle about a string  $y$  and  $|y| > d|x|$ 
      then answer "NO" to the query;

```

if  $M_i$  queries the oracle about a string  $y$  and  $|y| \leq d|x|$   
 then  
   begin  
     simulate  $M_E$  on  $y$  to determine  
     whether  $y \in E$   
     if  $y \in E$  then answer “YES” else “NO”  
   end  
 end.

It is clear that  $M_L$  recognizes  $L$  and operates in exponential time. Thus,  $L$  is in DEXT.  $\square$

From Lemma 4.2 and Theorem 4.4, we have the desired result.

**THEOREM 4.5.** *There is a sparse set  $E \in \text{DEXT} - P$  that is DEXT-low.*

The technique used in the proof of the claim in Theorem 4.4 is similar to one used by Goldberg and Sipser [6].

**5. Polynomial lowness and exponential lowness.** Here we will be concerned with lowness with respect to levels of the polynomial hierarchy or levels of the exponential hierarchy. To begin we review the definitions of the two hierarchies.

Let  $A$  be a set of strings. Define  $\Sigma_0^P(A) = \Pi_0^P(A) = \Delta_0^P(A) = \Delta_1^P(A) = P(A)$ , and for each integer  $i \geq 0$ , define  $\Delta_{i+1}^P(A) = P(\Sigma_{i+1}^P(A))$ ,  $\Sigma_{i+1}^P(A) = NP(\Sigma_i^P(A))$ , and  $\Pi_{i+1}^P(A) = \text{co-}\Sigma_{i+1}^P(A)$ . The structure  $\{(\Sigma_i^P(A), \Pi_i^P(A), \Delta_i^P(A))\}_{i \geq 0}$  is the *polynomial-time hierarchy relative to  $A$* . Define  $\text{PH}(A) = \bigcup_{i \geq 0} \Sigma_i^P(A)$ . If  $A = \emptyset$ , then we have the *polynomial-time hierarchy*, in which case we write  $\Sigma_i^P$  instead of  $\Sigma_i^P(\emptyset)$ , etc. Let  $\text{PH} = \text{PH}(\emptyset)$ .

It is useful to characterize the classes in the polynomial-time hierarchy in terms of quantifiers. To do this we use the notation  $(\exists y)_n$  and  $(\forall y)_n$  to abbreviate  $(\exists y, |y| \leq n)$  and  $(\forall y, |y| \leq n)$ , respectively.

**LEMMA 5.1** [18]. *For any  $A$  and  $k > 0$ , a set  $B$  is in  $\Sigma_k^P(A)$  if and only if there exist a set  $B_0 \in P(A)$  and a polynomial  $q$  such that for all  $x, x \in B$  if and only if  $(\exists y_1)_{q(|x|)} (\forall y_2)_{q(|x|)} \cdots (Q y_k)_{q(|x|)} [\langle x, y_1, \dots, y_k \rangle \in B_0]$ , where  $Q_k$  is  $\exists$  if  $k$  is odd and  $\forall$  if  $k$  is even.*

For properties of the polynomial-time hierarchy, see [16], [18].

Now we turn to the exponential-time hierarchy.

Let  $A$  be a set of strings. Define  $\Sigma_0^E(A) = \Pi_0^E(A) = \Delta_0^E(A) = \Delta_1^E(A) = \text{DEXT}(A)$ , and for each integer  $i \geq 0$ , define  $\Delta_{i+1}^E(A) = \text{DEXT}(\Sigma_{i+1}^E(A))$ ,  $\Sigma_{i+1}^E(A) = \text{NEXT}(\Sigma_i^E(A))$ , and  $\Pi_{i+1}^E(A) = \text{co-}\Sigma_{i+1}^E(A)$ . The structure  $\{(\Sigma_i^E(A), \Pi_i^E(A), \Delta_i^E(A))\}_{i \geq 0}$  is the *exponential-time hierarchy relative to  $A$* . If  $A = \emptyset$ , then we have the *exponential-time hierarchy*, in which case we write  $\Sigma_i^E$  instead of  $\Sigma_i^E(\emptyset)$ , etc.

Also, the classes in the exponential-time hierarchy can be characterized in terms of quantifiers.

**LEMMA 5.2** [17]. *For any  $A$  and  $k > 0$ , a set  $B$  is in  $\Sigma_k^E(A)$  if and only if there exist a set  $B_0 \in P(A)$  and a function  $e(n) = 2^{cn}$  such that for all  $x, x \in B$  if and only if*

$$(\exists y_1)_{e(|x|)} (\forall y_2)_{e(|x|)} \cdots (Q y_k)_{e(|x|)} [\langle x, y_1, \dots, y_k \rangle \in B_0].$$

Aspects of the exponential-time hierarchy have been studied by Dekhtyar [5], Heller [10], Orponen [13], Simon [15], and Wilson [17].

Now we can turn to lowness. Schöning [14] first studied the notion of lowness with respect to classes in the polynomial-time hierarchy. He showed that a set is  $P$ -low if and only if it is in  $P$ , and a set is  $NP$ -low if and only if it is in  $NP \cap \text{co-}NP$ . No similar characterizations are known for the higher levels, but the  $\Sigma_2^P$ - or  $\Sigma_3^P$ -lowness

of several types of sets was established by Ko and Schöning [12]. Our interest is in the notion of lowness with respect to the classes in the exponential-time hierarchy. We note that it is not known whether every set that is  $\Sigma_k^E$ -low is also  $\Sigma_{k+1}^E$ -low.

Our first result extends Proposition 3.1.

**THEOREM 5.3.** *For every  $k \geq 0$ , if a set is  $\Sigma_k^P$ -low, then it is  $\Sigma_k^E$ -low.*

*Proof.* The case  $k = 0$  is Proposition 3.1. Let  $k > 0$  and let  $A$  be such that  $\Sigma_k^P(A) = \Sigma_k^P$ . It suffices to show that  $\Sigma_k^E(A) \subseteq \Sigma_k^E$ , so let  $B \in \Sigma_k^E(A)$  be chosen arbitrarily. By Lemma 5.2 there exist  $B_0 \in P(A)$  and constant  $c > 0$  such that  $x \in B$  if and only if  $(\exists y_1)_{e(|x|)} (\forall y_2)_{e(|x|)} \cdots (Qy_k)_{e(|x|)} [\langle x, y_1, \dots, y_k \rangle \in B_0]$ , where  $e(n) = 2^{cn}$ . Let  $B_1 = \{\langle x, 0^{e|x|} \rangle \mid x \in B\}$ . Then there exists a set  $B_2$  in  $P(A)$  that is defined in the obvious way from  $B_0$  with the property that  $x' = \langle x, 0^{e|x|} \rangle \in B_1$  if and only if  $x \in B$  if and only if  $(\exists y_1)_{q(|x'|)} (\forall y_2)_{q(|x'|)} \cdots (Qy_k)_{q(|x'|)} [\langle x', y_1, \dots, y_k \rangle \in B_2]$ , where  $q(n) = n^c$ . Clearly,  $B_2$  is in  $P(A)$ , and so by Lemma 5.1 we have  $B_1 \in \Sigma_k^P(A) = \Sigma_k^P$ . By removing “padding,” it can be seen that  $B_1 \in \Sigma_k^P$  implies  $B \in \Sigma_k^E$ . Hence,  $\Sigma_k^E(A) = \Sigma_k^E$  as claimed.  $\square$

The results in § 4 show that for  $k = 0$ , the converse of this result does not hold. Analogously to Theorem 3.3, however, we can show that for certain types of compressible sets the notions of polynomial and exponential lowness coincide for sufficiently large values of  $k$ . To make this precise, we first prove a technical lemma.

For a set  $C$ , denote by  $P_{\log}(C)$  the class of sets recognized relative to  $C$  by deterministic polynomial time-bounded oracle machines that on input of length  $n$  make only queries of length  $O(\log n)$ . If  $A \in P_{\log}(C)$ , then we say that  $C$  is a *compact description* of  $A$ .

The reader should notice that every set  $A$  having small generalized Kolmogorov complexity has a compact description, e.g.,  $N_U^{-1}(A)$ . This is consistent with the fact that such a set is polynomially isomorphic to a tally set. It is clear that a set with a compact description need not have small generalized Kolmogorov complexity: there exist sets with polynomial size circuits that do not have small generalized Kolmogorov complexity, but all sets with polynomial size circuits have compact descriptions (see the proofs of Theorems 5.5 and 5.6).

**LEMMA 5.4.** *Let  $A$  be a set with a compact description in the class  $\Delta_k^E(A)$  for some  $k \geq 0$ . If  $A$  is  $\Sigma_k^E$ -low, then  $A$  is  $\Sigma_k^P$ -low.*

*Proof.* The case for  $k = 0$  is argued just like the proof of Proposition 3.2 and is left to the reader.

Let  $k > 0$ . Let  $A$  be  $\Sigma_k^E$ -low and let  $C \in \Delta_k^E(A)$  be such that  $A \in P_{\log}(C)$ . We must show that  $\Sigma_k^P(A) = \Sigma_k^P$  so that  $A$  is  $\Sigma_k^P$ -low. To do this we consider an arbitrary set  $B$  in  $\Sigma_k^P(A)$  and show that  $B$  is in  $\Sigma_k^P$ .

First, recall from Lemma 5.1 that there exist a set  $B_0 \in P(A)$  and a constant  $c$  such that  $x \in B$  if and only if  $(\exists y_1)_{q(|x|)} (\forall y_2)_{q(|x|)} \cdots (Qy_k)_{q(|x|)} [\langle x, y_1, \dots, y_k \rangle \in B_0]$ , where  $q(n) = n^c$ .

Second, observe that  $P(A) \subseteq P_{\log}(C)$  since  $A \in P_{\log}(C)$  implies that polynomial length queries about membership in  $A$  can be replaced by polynomial time computations with log-length queries about membership in  $C$ . Hence,  $B_0 \in P_{\log}(C)$ ; let  $M_0$  be a  $P_{\log}$ -oracle machine such that  $L(M_0, C) = B_0$  and let  $d > 0$  be such that on any input of length  $m$ ,  $M_0$  makes queries about strings of length at most  $d \cdot \log m$  (notice that there are at most  $m^{2d}$  such strings).

We will consider a machine that simulates computations of  $M_0$  but replaces oracle queries by table lookups. Let  $M_1$  be the deterministic polynomial time-bounded acceptor which accepts inputs of the form  $\langle x, T_{\text{YES}}, T_{\text{NO}}, y_1, \dots, y_k \rangle$ , where  $T_{\text{YES}}$  and  $T_{\text{NO}}$  are two disjoint finite sequences of strings, if  $M_0$  accepts input  $\langle x, y_1, \dots, y_k \rangle$  when all oracle queries are in  $T_{\text{YES}} \cup T_{\text{NO}}$  and queries in  $T_{\text{YES}}$  are answered “yes”

while queries in  $T_{\text{NO}}$  are answered “no.” Let  $B_1$  denote the set of strings accepted by  $M_1$ . Let  $B_2$  denote the  $\Sigma_k^P$  set obtained from  $B_1$  by defining  $\langle x, T_{\text{YES}}, T_{\text{NO}} \rangle \in B_2$  if and only if

$$(\exists y_1)_{q(|x|)} (\forall y_2)_{q(|x|)} \cdots (Qy_k)_{q(|x|)} [\langle x, T_{\text{YES}}, T_{\text{NO}}, y_1, \dots, y_k \rangle \in B_1].$$

Thus, for some polynomial  $p$ , we have

$$(*) \quad x \in B \text{ if and only if } (\exists T_{\text{YES}}, T_{\text{NO}})_{p(|x|)} [(y \in T_{\text{YES}} \cup T_{\text{NO}})$$

implies  $|y| \leq \log|x|^d$  and  $T_{\text{YES}}$  is included in  $C$  and

$T_{\text{NO}}$  is included in  $\bar{C}$  (the complement of  $C$ ) and  $\langle x, T_{\text{YES}}, T_{\text{NO}} \rangle \in B_2]$ .

By hypothesis  $C \in \Delta_k^E(A)$  so that  $\bar{C} \in \Delta_k^E(A)$ , and  $\Delta_k^E(A) = \text{DEX}(\Sigma_{k-1}^P(A)) \subseteq \text{NEXT}(\Sigma_{k-1}^P(A)) = \Sigma_k^E(A) = \Sigma_k^E$  since  $A$  is  $\Sigma_k^E$ -low. Thus,  $C$  and  $\bar{C}$  are in  $\Sigma_k^E$ . By Lemma 5.2 there exist a set  $C_0 \in P$  and a constant  $t$  such that  $z \in C$  if and only if  $(\exists y_1)_{f(|z|)} (\forall y_2)_{f(|z|)} \cdots (Qy_k)_{f(|z|)} [\langle z, y_1, \dots, y_k \rangle \in C_0]$ , where  $f(n) = 2^{tn}$ . A similar formula can be obtained to characterize membership in  $\bar{C}$ .

Let  $D_1$  be the set defined by  $\langle x, \langle z_1, \dots, z_m \rangle \rangle \in D_1$  if and only if  $|z_1|, \dots, |z_m| \leq \log|x|^d$  and  $\{z_1, \dots, z_m\} \subseteq C$ . Then, by Lemma 5.1 the following representation shows that  $D_1$  is in  $\Sigma_k^P$ :

$$\langle x, \langle z_1, \dots, z_m \rangle \rangle \in D_1 \quad \text{if and only if}$$

$$(\exists y_{1,1}, \dots, y_{1,m})_{h(|x|)} (\forall y_{2,1}, \dots, y_{2,m})_{h(|x|)} \cdots$$

$$(Qy_{k,1}, \dots, y_{k,m})_{h(|x|)} [\langle z_1, y_{1,1}, \dots, y_{m,1} \rangle \in C_0 \text{ and } \cdots \text{ and}$$

$$\langle z_m, y_{1,m}, \dots, y_{k,m} \rangle \in C_0] \quad \text{where } h \text{ is an appropriate polynomial.}$$

Similarly, the set  $D_2 = \{\langle x, \langle z_1, \dots, z_m \rangle \rangle \mid |z_1|, \dots, |z_m| \leq \log|x|^d \text{ and } \{z_1, \dots, z_m\} \subseteq \bar{C}\}$  is in  $\Sigma_k^P$ .

The representation (\*) for membership in  $B$  can now be rewritten as  $x \in B$  if and only if

$$(**) \quad (\exists T_{\text{YES}}, T_{\text{NO}})_{p(|x|)} [\langle x, T_{\text{YES}} \rangle \in D_1 \text{ and } \langle x, T_{\text{NO}} \rangle \in D_2 \text{ and } \langle x, T_{\text{YES}}, T_{\text{NO}} \rangle \in B_2].$$

Now  $D_1, D_2$  and  $B_2$  are all in  $\Sigma_k^P$ , and  $\Sigma_k^P$  is closed under polynomial-bounded existential quantification, so that (\*\*) shows that  $B$  is in  $\Sigma_k^P$  as desired.  $\square$

While the proof of Lemma 5.4 is quite technical, the result is very useful as is seen by the next two theorems.

**THEOREM 5.5.** *Let  $S$  be a sparse set and let  $k \geq 2$ . If  $S$  is  $\Sigma_k^E$ -low, then  $S$  is also  $\Sigma_k^P$ -low.*

*Proof.* Since  $S$  is sparse, we can apply the coding technique developed in [7], [9]. Let  $C_S = \{\langle n, c, i, j, b \rangle \mid S \text{ contains at least } c \text{ strings } x_1 < x_2 < \cdots < x_c \text{ of length } n, \text{ and the } j\text{th symbol of } x_i \text{ is } b\}$ . (For brevity, we have identified integers with their representations. To be precise, we should have written  $\langle \text{bin}(n), \text{bin}(c), \text{bin}(i), \text{bin}(j), b \rangle$  for  $\langle n, c, i, j, b \rangle$ .) The symbol  $<$  denotes the lexicographic ordering of strings of  $\Sigma^*$ .

The following  $P_{\log}$ -type algorithm recognizes  $S$  relative to  $C_S$ , which shows that  $C_S$  is a compact description for  $S$ .

```

input  $x$ ;
 $n := |x|$ ;           // Note that  $|n| \approx \log|x|$ . //
 $c := 0$ ;
while  $\langle n, c+1, 1, 1, 0 \rangle \in C_S$  or  $\langle n, c+1, 1, 1, 1 \rangle \in C_S$  do
   $c := c+1$ ;       // The maximum value of  $c$  is
                    // polynomially bounded in  $|x|$ . //
for  $i = 1$  to  $c$  do

```

```

begin
  y := λ;
  for j = 1 to n do
    if ⟨n, c, i, j, 0⟩ ∈ CS then y := y0 else y := y1
    if x = y then halt and accept
  end;
halt and reject.

```

The set  $C_S$  can be accepted nondeterministically in exponential time relative to  $S$ : on input  $\langle n, c, i, j, b \rangle$ , a nondeterministic machine can guess an appropriate sequence  $x_1, \dots, x_c$  of strings, query the oracle to determine whether each string is in  $S$ , and verify that the  $j$ th symbol of  $x_i$  is  $b$ . Hence,  $C_S \in \text{NEXT}(S) \subseteq \Delta_k^E(S)$  for every  $k \geq 2$ . Thus,  $S$  has a compact description in  $\Delta_k^E(S)$  so that  $S$  being  $\Sigma_k^E$ -low implies that  $S$  is  $\Sigma_k^P$ -low by Lemma 5.4.  $\square$

From the results in § 4, we see that the result of Theorem 5.5 does not hold for  $k = 0$ . Whether the result holds for  $k = 1$  is an open question.

Recall that a set  $A$  has polynomial-size circuits if there exists a sparse set  $S$  such that  $A \in P(S)$ . Another characterization [11], [12] is as follows:  $A$  has polynomial-size circuits if there exists a set  $A_0 \in P$  and a polynomial  $p(n)$  with the property that for every  $n$  there exists an “advice” string  $w$ ,  $|w| \leq p(n)$ , such that for all  $x$  with  $|x| \leq n$ ,  $x \in A$  if and only if  $\langle w, x \rangle \in A_0$ .

**THEOREM 5.6.** *Let  $A$  be a set that has polynomial-size circuits and let  $k \geq 4$ . If  $A$  is  $\Sigma_k^E$ -low, then  $A$  is also  $\Sigma_k^P$ -low.*

*Proof.* Let  $A_0 \in P$  be a set that witnesses the fact that  $A$  has polynomial-size circuits. A description  $C_A$  for  $A$  can be obtained as follows:  $C_A = \{ \langle n, m, i, b \rangle \mid (\exists w)_m [ (\forall x)_n (x \in A \Leftrightarrow \langle w, x \rangle \in A_0) \text{ and } (\forall w' < w) (\exists x)_n (x \in A \Leftrightarrow \langle w', x \rangle \in A_0) \text{ and the } i\text{th symbol of } w \text{ is } b] \}$ . It can be verified that  $C_A \in \Sigma_3^E(A) \subseteq \Delta_4^E(A)$ . Further, the following  $P_{\log}$ -type algorithm decides membership in  $A$  relative to  $C_A$ .

```

input x;
n := |x|;
m := 0;
while neither ⟨n, m, 1, 0⟩ nor ⟨n, m, 1, 1⟩ is in CA do
  m := m + 1;
w := λ;
for i = 1 to m do
  if ⟨n, m, i, 0⟩ ∈ CA then w := w0 else w := w1;
  if ⟨w, x⟩ ∈ A0 then halt and accept else halt and reject.

```

Since  $C_A$  is a compact description for  $A$ ,  $C_A \in \Delta_4^E(A)$ , and  $A$  is  $\Sigma_k^E$ -low for some  $k \geq 4$ , it follows from Lemma 5.4 that  $A$  is  $\Sigma_k^P$ -low.  $\square$

Balcázar, Book and Schöning [2] studied a more general type of lowness in the polynomial-time hierarchy and the notions that they introduced are of interest here.

For integers  $i, j \geq 0$ , a set  $A$  is in  $L^P(i, j)$  if  $\Sigma_i^P(A) \subseteq \Sigma_j^P$ .

It is clear that a set in some class  $L^P(i, j)$  is itself in PH. Suppose that  $A \in \Sigma_n^P$ . Then for every  $i$ ,  $\Sigma_i^P(A) \subseteq \Sigma_{i+n}^P$  so that the notion of  $A \in L^P(i, j)$  can have significance only if  $j < i + n$ . Informally, we interpret  $A \in L^P(i, j)$  with  $k = j - i$  to mean that using the set  $A$  as an oracle has the power of at most  $k$  alternating quantifiers or of at most the  $k$ -fold composition of the NP ( ) operator.

We “lift” the definition to sets in the exponential hierarchy in the obvious way.

For integers  $i, j \geq 0$ , a set  $A$  is in  $L^E(i, j)$  if  $\Sigma_i^E(A) \subseteq \Sigma_j^E$ .

Clearly, for every  $i, j$ ,  $L^E(i, j) \subseteq \Sigma_j^E$ . It is easy to see that for every choice of  $i, j$  with  $i \leq j$ ,  $L^P(i, j) \subseteq L^P(i+1, j+1)$ . However, we do not know whether  $i \leq j$  implies  $L^E(i, j) \subseteq L^E(i+1, j+1)$ .

The following result is the obvious generalization of Theorem 5.3.

PROPOSITION 5.7. *For every  $i, j$  with  $i \leq j$ ,  $L^P(i, j) \subseteq L^E(i, j)$ .*

To generalize the results in § 3 on tally sets and Theorems 5.5 and 5.6, we have the following result.

PROPOSITION 5.8. (a) *Let  $T$  be a set with small Kolmogorov complexity. For every  $i, j$  with  $i \leq j$ ,  $T \in L^E(i, j)$  if and only if  $T \in L^P(i, j)$ .*

(b) *Let  $S$  be a sparse set. For every  $i, j$  with  $2 \leq i \leq j$ ,  $S \in L^E(i, j)$ , if and only if  $S \in L^P(i, j)$ .*

(c) *Let  $A$  be a set with polynomial-size circuits. For every  $i, j$  with  $4 \leq i \leq j$ ,  $A \in L^E(i, j)$  if and only if  $A \in L^P(i, j)$ .*

Recall that a set is  $P$ -immune if it has no infinite subset in  $P$ . Lemma 4.2 shows that there is a sparse set that is both  $P$ -immune and exponentially low.

THEOREM 5.9. *If there exists an infinite set that is both  $P$ -immune and  $\Sigma_k^E$ -low, where  $k \geq 3$ , then there is an infinite  $P$ -immune set in  $\Sigma_k^P$ ; hence  $P \neq \Sigma_k^P$  so that  $P \neq \text{NP}$ .*

*Proof.* Let  $A$  be any infinite  $P$ -immune  $\Sigma_k^E$ -low set. Consider the infinite sparse set  $S = \{x \mid x \text{ is the "smallest" string of length } |x| \text{ in } A\}$ . Since  $S \subseteq A$ ,  $S$  is  $P$ -immune. It is clear that  $S$  is in  $\text{co-NP}(A)$ .

Notice that

$$\begin{aligned} \Sigma_{k-1}^E(S) &\subseteq \Sigma_{k-1}^E(\text{co-NP}(A)) \\ &= \Sigma_{k-1}^E(\text{NP}(A)) = \Sigma_k^E(A) = \Sigma_k^E \end{aligned}$$

since  $A$  is  $\Sigma_k^E$ -low. Thus,  $S \in L^E(k-1, k)$  so by Proposition 5.8(b),  $S \in L^P(k-1, k)$ . Hence,  $S \in \Sigma_k^P$ .  $\square$

Another way to generalize the notions studied here is to extend the notion of compact descriptions. Instead of requiring that  $A \in P_{\log}(C)$ , we could require that for some  $k$ ,  $A \in \Delta_{k, \log}^P(C)$ . Then we could establish the obvious generalizations of Lemma 5.4 and Theorems 5.5 and 5.6. The proof is clear but tedious and the details are left to the reader.

**6. Concluding remarks.** We have studied the existence and properties of sets relative to which exponential complexity classes do not exhibit the pathology of not being closed under relativization. As a main result, we have established the existence of a set  $E$  in  $\text{DEXT-}P$  such that  $\text{DEXT}(E) = \text{DEXT}$ . Moreover, we have shown that this set can be taken to be sparse. On the other hand, we have shown that for  $k \geq 2$ , if a sparse set  $S$  satisfies  $\Sigma_k^E(S) = \Sigma_k^E$ , then it is also true that  $\Sigma_k^P(S) = \Sigma_k^P$ . (The main result shows that this is not the case for  $k=0$ .) In the case  $k=1$ , it remains unresolved whether  $\text{NEXT}(S) = \text{NEXT}$  implies  $\text{NP}(S) = \text{NP}$  (i.e.,  $S \in \text{NP} \cap \text{co-NP}$ ) for sparse  $S$ .

For tally sets and, more generally, sets with small Kolmogorov complexity, we have shown that  $\Sigma_k^E(T) = \Sigma_k^E$  implies  $\Sigma_k^P(T) = \Sigma_k^P$  for  $k \geq 0$ . For sets with polynomial-size circuits, this implication holds when  $k \geq 4$ .

In general, our results indicate that sets that are "exponentially low" but not "polynomially low"—whenever they exist—must have complex strings. This is witnessed by the fact that under various "simplicity" assumptions about a set  $A$ , we know that for sufficiently large  $k$ ,  $\Sigma_k^E(A) = \Sigma_k^E$  if and only if  $\Sigma_k^P(A) = \Sigma_k^P$ . Also, the proof of the main result relies on choosing a set of strings having reasonably high generalized Kolmogorov complexity.

The principal open questions may be summarized as follows: for each  $k \geq 0$ , characterize the class of sets that are  $\Sigma_k^E$ -low. The case of  $k = 0$  is of particular interest due to the main result of the present paper. We have shown that for every value of  $k$ , if a set is  $\Sigma_k^P$ -low, then it is  $\Sigma_k^E$ -low, but we have only partial results regarding the converse. Since the notion of exponential lowness is less restrictive than its polynomial counterpart, it appears that it might be easier to establish the lowness characteristics of various structural properties of sets in the exponential than in the polynomial sense (cf. [12]). What must not be overlooked is that the results of Schöning [14], Ko and Schöning [12], and Balcázar, Book and Schöning [2] do not characterize sets that are  $\Sigma_k^P$ -low.

## MONOTONE BIPARTITE GRAPH PROPERTIES ARE EVASIVE\*

ANDREW CHI-CHIH YAO†

**Abstract.** A Boolean function  $P$  from  $\{0, 1\}^t$  into  $\{0, 1\}$  is said to be *evasive*, if every decision-tree algorithm for evaluating  $P$  must examine all  $t$  arguments in the worst case. It was known that any nontrivial monotone bipartite graph property on vertex set  $V \times W$  must be evasive, when  $|V| \cdot |W|$  is a power of a prime number. In this paper, we prove that every nontrivial monotone bipartite graph property is evasive.

**Key words.** bipartite graph property, complexity, decision tree, evasive, monotone property

**AMS(MOS) subject classifications.** 68Q05, 68R05, 05C25

**1. Introduction.** In [RV2], Rivest and Vuillemin proved the Aanderra-Rosenberg Conjecture [R] which states that, to evaluate any nontrivial monotone graph property on  $n$  vertices, every decision-tree algorithm must examine  $\Omega(n^2)$  entries of the adjacency matrix in the worst case. A stronger conjecture, suggested by Karp (see [R]), that all such graph properties are *evasive*, i.e., *all* entries must be examined in the worst case, was left unresolved. Recently, Khan, Saks, and Sturtevant [KSS] gave a partial solution by showing that, when  $n$  is a power of a prime, all such graph properties are evasive; their proof employed an ingenious topological approach to this complexity problem.

The method used in Rivest and Vuillemin [RV1], [RV2] (also discovered in Best et al. [BBL]) yields immediately that any nontrivial monotone bipartite graph property on vertex set  $V \times W$  must be evasive, when  $|V| \cdot |W|$  is a power of a prime number. The purpose of this paper is to show that, in fact, every nontrivial monotone bipartite graph property is evasive. We will adopt the topological view for this problem as espoused in [KSS].

**2. Main theorem.** Let  $V = \{1, 2, \dots, m\}$ ,  $W = \{1, 2, \dots, n\}$  and  $\mathcal{G}_{m,n}$  be the set of all bipartite graphs  $G = (V \times W, E)$ , where  $E \subseteq V \times W$ . For any two  $G = (V \times W, E)$ ,  $G' = (V \times W, E')$ , we write  $G \leq G'$  if  $E \subseteq E'$ ; we say that  $G$  and  $G'$  are *isomorphic* if there exist permutations  $p_1, p_2$  of  $V, W$  such that  $(i, j) \in E$  if and only if  $(p_1(i), p_2(j)) \in E'$ . A bipartite graph property on  $V \times W$  is a function  $P: \mathcal{G}_{m,n} \rightarrow \{0, 1\}$  satisfying the constraint that  $P(G) = P(G')$  if  $G$  and  $G'$  are isomorphic. A bipartite graph property  $P$  on  $V \times W$  is *monotone* if  $P(G) \leq P(G')$  for all  $G \leq G'$ ;  $P$  is *nontrivial* if it is not a constant function.

Let  $P$  be any bipartite graph property on  $V \times W$ . We are interested in evaluating  $P(G)$ , where the input graph  $G = (V \times W, E)$  is given as an  $m \times n$  adjacency matrix  $(a_{ij})$  with  $a_{ij} = 1$  for  $(i, j) \in E$  and 0 otherwise. A *decision-tree algorithm*  $T$  proceeds by asking a sequence of queries:  $a_{i_1 j_1} = ?$ ,  $a_{i_2 j_2} = ?$ ,  $\dots$ , until the value of  $P(G)$  can be determined; the choice of the  $(k+1)$ st query can depend on the results of all the preceding  $k$  values  $a_{i_1 j_1}, \dots, a_{i_k j_k}$ . The *cost* of  $T$ ,  $\text{cost}(T)$ , is the maximum number of queries asked for any input  $G \in \mathcal{G}_{m,n}$ . The *complexity* of property  $P$  is defined as  $\min \{\text{cost}(T) \mid T \in \mathcal{T}(P)\}$ , when  $\mathcal{T}(P)$  is the set of all decision-tree algorithms for property  $P$ . We say that  $P$  is *evasive* if  $C(P) = |V| \cdot |W|$ . Our main result is the following theorem; the remainder of this paper is devoted to its proof.

**THEOREM 1.** *Every nontrivial monotone bipartite graph property is evasive.*

**3. Preliminaries.** We review some needed terminology and facts from standard topology and from [KSS].

**3.1. Abstract complex.** An *abstract complex* on a finite set  $X = \{x_1, x_2, \dots, x_t\}$  is a collection  $\Delta$  of subsets of  $X$  with the property that  $A \subseteq B \in \Delta$  implies  $A \in \Delta$ . Each  $A \in \Delta$  is a *face*; the *dimension* of  $A$  is  $|A| - 1$ . We call  $x_i$  the *vertices*. The *Euler characteristic* of  $\Delta$  is  $\chi(\Delta) = \sum_{i \geq 0} (-1)^i f_i$ , where  $f_i$  is the number of  $i$ -dimensional faces of  $\Delta$ . We say that  $\Delta$  is *rationally acyclic* if the homology groups of  $\Delta$  are  $H_0(\Delta) = \mathbb{Z}$  and  $H_i(\Delta) = 0$  for all  $i > 0$ .

Let  $\Gamma$  be any permutation group of  $X$ . Assume that  $\Delta$  is *invariant under  $\Gamma$* , i.e., for all  $\sigma \in \Gamma$ ,  $(x_{i_1}, x_{i_2}, \dots, x_{i_k}) \in \Delta$  implies  $(x_{\sigma(i_1)}, x_{\sigma(i_2)}, \dots, x_{\sigma(i_k)}) \in \Delta$ . A face  $F = \{x_{i_1}, x_{i_2}, \dots, x_{i_k}\}$  is said to be *minimally invariant under  $\Gamma$*  if, for all  $\sigma \in \Gamma$ ,  $\{\sigma(i_1), \sigma(i_2), \dots, \sigma(i_k)\} = \{i_1, i_2, \dots, i_k\}$ , and if in addition, no proper nonempty subset of  $F$  has this property. Let  $\mathcal{A}(\Delta, \Gamma)$  be the set of all nonempty faces of  $\Delta$  that are minimally invariant under  $\Gamma$ .

**DEFINITION 1.** Suppose  $\Delta$  is invariant under  $\Gamma$ . If  $\mathcal{A}(\Delta, \Gamma) = \emptyset$ , let  $\Delta_\Gamma = \emptyset$ . If  $\mathcal{A}(\Delta, \Gamma) = \{A_1, A_2, \dots, A_s\} \neq \emptyset$ , let  $\Delta_\Gamma$  be the abstract complex on  $\mathcal{A}(\Delta, \Gamma)$  defined by  $\Delta_\Gamma = \{\{A_i \mid i \in D\} \mid D \subseteq \{1, 2, \dots, s\}, \cup_{i \in D} A_i \in \Delta\}$ .

**3.2. Geometric complex.** Let  $\{v_1, v_2, \dots, v_k\}$  be a set of  $k$  independent points in  $R^q$  where  $q > 0$  is an integer. Denote by  $\langle v_1, v_2, \dots, v_k \rangle$  their *convex hull*, i.e., the set

$$\left\{ \sum_{1 \leq i \leq k} \lambda_i v_i \mid \lambda_i \geq 0 \text{ for all } i, \text{ and } \sum_{1 \leq i \leq k} \lambda_i = 1 \right\}.$$

A set  $M \subseteq R^q$  is called a *geometric realization* of an abstract complex  $\Delta$  on  $X = \{x_1, x_2, \dots, x_t\}$  if there exists a set of independent points  $\{v_1, v_2, \dots, v_t\}$ , called the *base*, such that  $M = \cup_{A \in \Delta} Y_A$ , where  $Y_A = \langle v_{i_1}, v_{i_2}, \dots, v_{i_k} \rangle$  for  $A = \{x_{i_1}, x_{i_2}, \dots, x_{i_k}\}$ . Clearly, any abstract complex  $\Delta$  on  $X = \{x_1, x_2, \dots, x_t\}$  has a geometric realization in  $R^q$  if  $q \geq t - 1$ .

We will call  $M \subseteq R^q$  a *geometric complex* if  $M$  is a geometric realization of some abstract complex  $\Delta$ . It is a well-known fact in topology (see, e.g. [Mu]) that if  $M$  is a geometric realization of two abstract complexes  $\Delta$  and  $\Delta'$ , then  $\chi(\Delta) = \chi(\Delta')$ . Thus, we can define  $\chi(M)$  as  $\chi(\Delta)$  unambiguously.

**3.3. Fixed points.** Let  $\Delta$  be an abstract complex on  $X = \{x_1, x_2, \dots, x_t\}$ , invariant under a permutation group  $\Gamma$  of  $\{1, 2, \dots, t\}$ . Let  $M$  be a geometric realization of  $\Delta$  with base  $\{v_1, v_2, \dots, v_t\}$ . Then  $\Gamma$  induces a natural automorphism group on  $M$ . Precisely, for each  $\sigma \in \Gamma$ , let  $f_\sigma$  be the automorphism on  $M$  defined by

$$f_\sigma \left( \sum_{1 \leq i \leq k} \lambda_i v_i \right) = \sum_{1 \leq i \leq k} \lambda_i v_{\sigma(i)}$$

for  $\lambda_i \geq 0, \sum_{1 \leq i \leq k} \lambda_i = 1$ . Let  $M^\Gamma$  denote the set of *fixed points* of this automorphism group, i.e.,  $M^\Gamma \equiv \{v \in M, f_\sigma(v) = v \text{ for all } \sigma \in \Gamma\}$ .

**THEOREM 2 [KSS].**  $M^\Gamma$  is a geometric realization of  $\Delta_\Gamma$ .

For any two groups  $F$  and  $L$ , we say that  $L$  is a *homomorphic image* of  $F$  if there is a 1-1 homomorphism from  $F$  onto  $L$ . Let  $\mathcal{L}_l$  be the cyclic group of order  $l$ .

<sup>1</sup> In the paper all  $i_j$ 's are distinct whenever they appear in the notation  $\{x_{i_1}, x_{i_2}, \dots, x_{i_k}\}$ .

**THEOREM 3 [O].** *If  $\Delta$  is rationally acyclic and  $\Gamma$  is a homomorphic image of  $\mathcal{L}_1$ , then  $\chi(M^\Gamma) = 1$ .*

**3.4. General string properties and topology.** In the study of the complexity of evaluating graph properties, it has been found useful ([BBL], [RV2]) to consider the complexity of evaluating a more general class of functions, the *string properties*. A *string property*  $P$  is a function from  $\{0, 1\}^t$  into  $\{0, 1\}$ . As done for graph properties in § 1, we consider decision tree algorithms  $T$  for evaluating  $P(a_1, a_2, \dots, a_t)$  by asking an adaptive sequence of queries  $a_{i_1} = ?, a_{i_2} = ?, \dots$ ; we define  $\text{cost}(T)$  and  $C(P)$  in the same way. The property  $P$  is said to be *evasive* if  $C(P) = t$ . We say that  $P$  is *nontrivial* if  $P$  is not a constant;  $P$  is *monotone* if  $P(a_1, a_2, \dots, a_t) \leq P(a'_1, a'_2, \dots, a'_t)$  when  $a_i \leq a'_i$  for all  $i$ .

In [KSS], the approach to study a string property  $P$  is to associate with  $P$  the abstract complex  $\Delta$  on  $X = \{x_1, x_2, \dots, x_t\}$  defined as follows:  $\{x_{i_1}, x_{i_2}, \dots, x_{i_k}\} \in \Delta$  if  $P(a_1, a_2, \dots, a_t) = 0$  where  $a_{i_1} = a_{i_2} = \dots = a_{i_k} = 1$  and  $a_j = 0$  for  $j \neq i_l$ . The following fundamental observation was made.

**THEOREM 4 [KSS].** *If  $P$  is not evasive, then the associated  $\Delta$  is rationally acyclic.*

We need one more concept. Let  $\Gamma$  be a permutation group of  $\{1, 2, \dots, t\}$ . We say that  $P$  is *invariant under  $\Gamma$*  if  $P(a_1, a_2, \dots, a_t) = P(a_{\sigma(1)}, a_{\sigma(2)}, \dots, a_{\sigma(t)})$  for all  $\sigma \in \Gamma$ . It is clear that if  $P$  is invariant under  $\Gamma$ , so is the associated abstract complex  $\Delta$ .

**4. Proof of Theorem 1.** First we rephrase the problem in the terminology of string property (§ 3.4). Let  $\Sigma_{m,n} = S_m \oplus S_n$ , where  $S_m, S_n$  are the symmetric groups on  $V = \{1, 2, \dots, m\}, W = \{1, 2, \dots, n\}$ . Each  $\sigma \in \Sigma_{m,n}$  is a permutation of  $\{(i, j) | 1 \leq i \leq m, 1 \leq j \leq n\}$ , that is, if  $\sigma = (p_1, p_2)$ , where  $p_1 \in S_m, p_2 \in S_n$ , then  $\sigma(i, j) = (p_1(i), p_2(j))$  for all  $i, j$ . Let us regard a bipartite graph property  $P$  on  $V \times W$  as a string property in the following way: Any input graph  $G \in \mathcal{G}_{m,n}$  is identified with  $a \equiv (a_{11}, a_{12}, \dots, a_{ij}, \dots, a_{mn}) \in \{0, 1\}^{mn}$ , where  $a$  is obtained from the adjacency matrix  $(a_{ij})$  of  $G$  by concatenating the entries row by row; this naturally induces a string property  $P': \{0, 1\}^{mn} \rightarrow \{0, 1\}$ . It is easy to see that if  $P$  is nontrivial and monotone, so is  $P'$  as a string property; also  $P$  is evasive if and only if  $P'$  is. In addition,  $P'$  is invariant under  $\Sigma_{m,n}$ .

To prove Theorem 1, let  $P$  be a nontrivial monotone bipartite graph property on  $V \times W$ . Denote by  $P'$  the corresponding string property on  $\{0, 1\}^{mn}$ . Assume that  $P$  is not evasive, implying that  $P'$  is not evasive; we will derive a contradiction.

Let  $D \subseteq \{1, 2, \dots, m\}$ . Denote by  $b_D$  the vector  $(a_{11}, a_{12}, \dots, a_{ij}, \dots, a_{mn})$ , where  $a_{il} = 1$  for  $i \in D, 1 \leq l \leq n$ , and 0 otherwise.

**LEMMA 1.** *There exists an integer  $0 \leq r(P') < m$  such that  $P'(b_D) = 0$  if  $|D| \leq r(P')$  and 1 otherwise.*

*Proof.* As  $P'$  is invariant under  $\Sigma_{m,n}$ ,  $P'(b_D) = P'(b_{D'})$  if  $|D| = |D'|$ . It then follows from the monotonicity of  $P'$  that there exists an integer  $-1 \leq r(P') \leq m$  such that  $P'(b_D) = 0$  if and only if  $|D| \leq r(P')$ . Finally,  $r(P') \neq -1, m$ , since  $P'$  is nontrivial.  $\square$

Let  $\Delta$  be the abstract complex associated with  $P'$ . Then  $\Delta$  is rationally acyclic by Theorem 4. Let  $\Gamma$  be the subgroup  $1 \oplus Z_n$  of  $\Sigma_{m,n}$ , i.e.,  $\Gamma = \{\sigma_0, \sigma_1, \dots, \sigma_{n-1}\}$  with  $\sigma_l(i, j) = (i, (j+l) \bmod n)$ . Then  $\Delta$  is invariant under  $\Gamma$  since  $P'$  is invariant under  $\Gamma$ .

Now let  $M$  be a geometric realization of  $\Delta$ . As  $\Gamma$  is clearly a homomorphic image of  $\mathcal{L}_n$ , we have by Theorem 3 that  $\chi(M^\Gamma) = 1$ . Thus,  $\chi(\Delta_\Gamma) = \chi(M^\Gamma) = 1$ , since by Theorem 2  $M^\Gamma$  is a geometric realization of  $\Delta_\Gamma$ .

On the other hand, we have from the definition of  $\Delta_\Gamma$  that  $\Delta_\Gamma = \{\{A_i | i \in D\} | D \subseteq \{1, 2, \dots, m\}, P'(b_D) = 0\}$  whenever  $\Delta_\Gamma \neq \emptyset$ . Thus, either  $\Delta_\Gamma = \emptyset$  in

which case  $\chi(\Delta_\Gamma) = 0 \neq 1$ , or we have by Lemma 1 that

$$\begin{aligned}\chi(\Delta_\Gamma) &= \sum_{0 \leq j < r(P')} (-1)^j \binom{m}{j+1} \\ &= \sum_{0 \leq j < r(P')} (-1)^j \left[ \binom{m-1}{j+1} + \binom{m-1}{j} \right] \\ &= 1 + (-1)^{r(P')-1} \binom{m-1}{r(P')} \\ &\neq 1.\end{aligned}$$

This contradicts the conclusion of the last paragraph.

We have proved Theorem 1.

**5. Remarks.** The most tantalizing open question in this subject is whether all nontrivial monotone graph properties are evasive. As mentioned in [KSS], their topological approach cannot resolve this question when only the transitive nature of the underlying group for graph properties is exploited. The proof of our result on bipartite graphs, as well as the proof of evasiveness for graph properties on six vertices in [KSS], suggests that further progress might be possible if one examines in detail the structures of the geometric complexes associated with graph properties.

Another interesting direction for further work is to prove evasiveness for other classes of string properties. For example, any nontrivial monotone string properties that are transitively invariant under cyclic group  $C_m$  must be evasive (as can be seen from Theorem 2 in [KSS], or from Theorems 3 and 4 in this paper). Is the analogous result true for string properties invariant under  $C_m \oplus C_n$ ?

## DISTANCE-HEREDITARY GRAPHS, STEINER TREES, AND CONNECTED DOMINATION\*

ALESSANDRO D'ATRI<sup>†</sup> AND MARINA MOSCARINI<sup>‡</sup>

**Abstract.** Distance-hereditary graphs have been introduced by Howorka and studied in the literature with respect to their metric properties. In this paper several equivalent characterizations of these graphs are given: in terms of existence of particular kinds of vertices (isolated, leaves, twins) and in terms of properties of connections, separators, and hangings. Distance-hereditary graphs are then studied from the algorithmic viewpoint: simple recognition algorithms are given and it is shown that the problems of finding cardinality Steiner trees and connected dominating sets are polynomially solvable in a distance-hereditary graph.

**Key words.** distance-hereditary graph, crossing chords, perfect graphs, connected dominating set, Steiner tree

**1. Introduction.** A graph is *distance-hereditary* if every two vertices have the same distance in every connected induced subgraph containing both (where the *distance* between two vertices is the length of a shortest path connecting them). These graphs have been introduced and studied by Howorka [18] and further characterized by Bandelt and Mulder [2] in terms of the distance function and forbidden isometric subgraphs.

In particular, it has been proved [18] that distance-hereditary graphs are perfect and can be characterized in terms of the existence of chords in cycles in the following way: a graph is distance-hereditary if and only if each cycle on five or more vertices has at least two crossing chords (where two chords  $(u, v)$  and  $(w, z)$  *cross* if the vertices  $u, w, v, z$  are distinct and in this order on the cycle). The proofs of the results in this paper are mainly based on this characterization; for this reason in a preliminary version [10] we called these graphs *cross* graphs. Similarly, several classes of perfect graphs [16] have also been characterized in the literature by means of adjacency properties of vertices in cycles (e.g., chordal and strongly chordal graphs [14], Meyniel's graphs [21], cographs [7], parity graphs [5]). Furthermore, starting from the studies on acyclic hypergraphs in database theory [9], [12], [13], it has been shown that acyclicity properties in hypergraphs correspond to chordality properties in bipartite graphs and vice versa [1], [11].

In this paper new characterizations of distance-hereditary graphs are given; furthermore, these graphs are related to the above classes of perfect graphs, and are studied with respect to classical problems that are open or computationally hard in several classes of perfect graphs.

In § 3, the new characterizations are proved. In particular, it is shown:

(1) That the class of distance-hereditary graphs is closed under multiplication of vertices [16] and appending of leaves and isolated vertices (distance-hereditary graphs are exactly those graphs generated from a single vertex by those operations); we note that this result has been obtained independently by Bandelt and Mulder [2] in the case of connected distance-hereditary graphs;

<sup>‡</sup> Istituto di Analisi dei Sistemi ed Informatica del CNR, Viale Manzoni 30, I-00185 Rome, Italy.

(2) That these graphs correspond exactly to graphs in which all minimal connected subgraphs joining a given set of vertices have the same number of vertices (in other words, the distance-hereditary property can be extended to an arbitrary set of vertices);

(3) That distance-hereditary graphs can be characterized also in terms of properties of their minimal separators and hangings.

In § 4, distance-hereditary graphs are related to various classes of perfect graphs: cographs, parity graphs, strongly chordal graphs,  $(6, 2)$ -chordal bipartite graphs [1], comparability and permutation graphs [16].

In § 5, distance-hereditary graphs are studied from the algorithmic viewpoint. Polynomial algorithms are given:

(1) To recognize distance-hereditary graphs (based on some of the above characterizations);

(2) To solve the cardinality Steiner tree and the connected dominating set problem in this class of graphs.

We note that the Steiner and the connected domination problems play a significant role in discrete optimization and, although there is no obvious relationship between them, they are of the same complexity for a variety of classes of graphs. In particular, the cardinality Steiner tree problem is known to be polynomially solvable for the following classes of perfect graphs: strongly chordal graphs [22], permutation graphs [6], cographs [20], and  $(6, 2)$ -chordal bipartite graphs [1]; on the other hand, this problem is NP-complete [15] for chordal and split graphs [22], bipartite and comparability graphs [20]. Similar results hold for the connected dominating set problem [20].

Since the class of distance-hereditary graphs properly contains some of the largest classes of graphs in which the problems are polynomially solvable, the results given in this paper may be considered as a contribution to a better definition of the bound between tractability and intractability for these problems.

**2. Terminology and notation.** We shall consider finite, simple loopless, undirected graphs  $G = (V, E)$ , where  $V$  is the vertex set and  $E$  is the edge set, and we shall use more-or-less standard terminology from graph theory [3], [17], some of which we review here.

Let  $S$  and  $T$  be two subsets of  $V$ . We denote with  $\langle S \rangle$  the subgraph of  $G$  induced by  $S$ , with  $N_T(S)$  the *neighborhood of  $S$  in  $T$* , that is the set of vertices in  $T$  that are adjacent to any vertex in  $S$  and with  $N_T[S]$  the *closed neighborhood of  $S$  in  $T$* , that is  $N_T(S) \cup S$  (for simplicity we shall omit  $T$  if it coincides with  $V$  and we shall use  $v$  instead of  $\{v\}$  whenever no ambiguity arises). A vertex  $v$  is *isolated* if  $N(v) = \emptyset$ , is a *leaf* if  $|N(v)| = 1$ . Two vertices  $v$  and  $v'$  are *twins* if they have the same neighborhood ( $N(v) = N(v')$ ) or the same closed neighborhood ( $N[v] = N[v']$ ).

The set of vertices  $S$  is a *separator* of  $G$  if either  $|S| = |V| - 1$ , or the removal of  $S$  from  $G$  increases the number of its connected components. A separator of  $G$  is *minimal* if none of its proper subsets is a separator. A *block* of  $G$  is a maximal connected subgraph of  $G$  that contains no cutpoint.

The set of vertices  $S$  is a *domination of  $T$*  if  $T \subseteq N[S]$  and for no  $S' \subseteq V$  such that  $T \subseteq N[S']$  we have  $|S'| < |S|$ . The set  $S$  is a *connected domination of  $T$*  if  $T \subseteq N[S]$ , the induced subgraph  $\langle S \rangle$  is connected and for no  $S' \subseteq V$ , such that  $T \subseteq N[S']$  and  $\langle S' \rangle$  is connected, we have  $|S'| < |S|$ . A (*connected*) *dominating set* of  $G$  is a (connected) domination of  $V$ .

The induced subgraph  $\langle S \rangle$  of  $G$  is a *connection of  $T$*  if  $\langle S \rangle$  is connected and  $T \subseteq S$ . A connection  $\langle S \rangle$  of  $T$  is *nonredundant* if, for no  $v \in S$ , we have that  $\langle S - \{v\} \rangle$  is a connection of  $T$ ; it is a *minimum connection of  $T$*  if no connection of  $T$  has less

than  $|S|$  vertices. A *Steiner tree* of  $T$  is a spanning tree of a minimum connection of  $T$ . An *induced path* is a nonredundant connection of a pair of vertices; an induced path is a *shortest path* if it is a minimum connection. The *distance* between  $u$  and  $v$  in  $G$ , i.e., the length of a shortest path between  $u$  and  $v$  in  $G$ , will be denoted by  $d_G(u, v)$ .

If  $G$  is connected and  $v$  is one of its vertices, the *hanging* of  $G$  by  $v$  is the function  $h_v$  that associates to every  $u \in V$  the value  $d_G(u, v)$  ( $h_v(u)$  is the *level* of  $u$  in the hanging  $h_v$ ).  $L^i(h_v)$  (or simply  $L^i$ , when no ambiguity arises) denotes the set of vertices with level  $i$  in  $h_v$ . Given a hanging  $h_v$  of  $G$ , the *horizontal part* of  $G$  with respect to  $h_v$ , denoted  $H(G, v)$ , is the subgraph  $(V, E')$  of  $G$  in which  $E'$  is the set of edges in  $E$  between pairs of vertices having the same level in  $h_v$ , and the *vertical part* of  $G$  with respect to  $h_v$ , denoted  $V(G, v)$  is the complement of  $H(G, v)$  in  $G$  (see Fig. 1). The concepts of hanging, level, horizontal part and vertical part can be extended to disconnected graphs by considering one hanging vertex for every connected component.

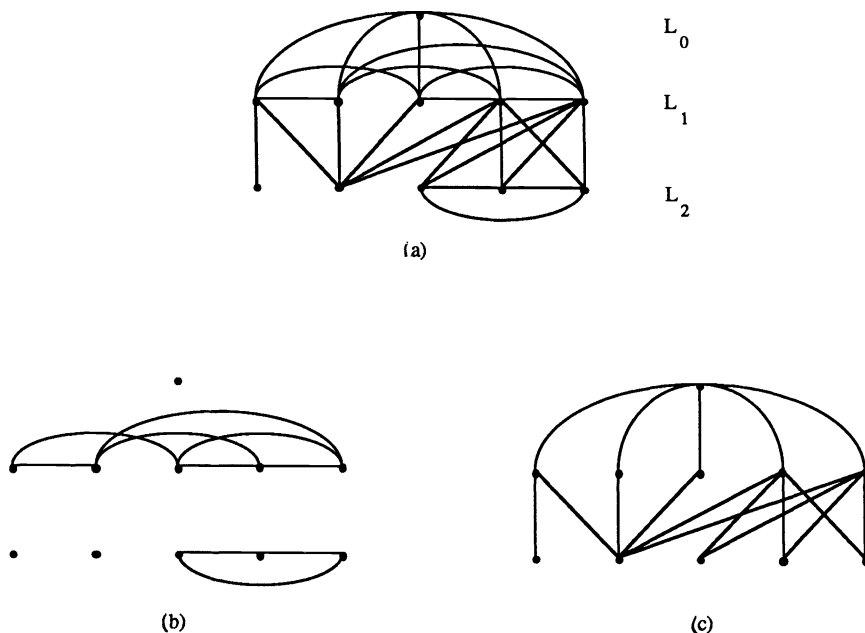

FIG. 1. A hanging of a distance hereditary graph (a) and its horizontal (b) and vertical (c) parts.

A *cograph* [5], [7] is a graph that does not contain any induced path of length three; a *chordal graph* is a graph having a chord in every cycle on four or more vertices; a *strongly chordal graph* [14] is a chordal graph in which every cycle on six or more vertices contains a strong chord (i.e., a chord joining two vertices with an odd distance in the cycle); a *ptolemaic graph* is a connected graph such that for every four vertices  $v_1, v_2, v_3$ , and  $v_4$  the following inequality is satisfied:  $d_G(v_1, v_2) * d_G(v_3, v_4) \leq d_G(v_1, v_3) * d_G(v_2, v_4) + d_G(v_1, v_4) * d_G(v_2, v_3)$ ; a *parity graph* [5] is a graph having two crossing chords in every odd cycle on five or more vertices; a *(6, 2)-chordal bipartite graph* [1] is a bipartite graph having two chords in every cycle on six or more vertices; a *comparability graph* [16] is a graph that is transitively orientable (i.e., there exists an assignment of directions to edges such that if  $(u, v)$  and  $(v, w)$  are arcs then so is  $(u, w)$ ); a *permutation graph* [16] is a comparability graph whose complement is also a comparability graph.

**3. Characterizations.** The following theorem provides several equivalent definitions of distance-hereditary graphs that characterize them in terms of existence of particular kinds of vertices (isolated, leaves, twins) and in terms of properties of connections, separators, and hangings. The results from (1) to (3) are showed by Howorka in [18]; in this section the proof of the remaining equivalences is given. Bandelt and Mulder [2] provided several interesting characterizations of connected distance-hereditary graphs, based on metric properties and forbidden configurations, and also independently proved the equivalence between (1) and (7), in the connected case, by using a different proof technique.

**THEOREM 1.** *Given a graph  $G = (V, E)$  the following statements are equivalent:*

- (1)  $G$  is a distance-hereditary graph.
- (2) Every cycle in  $G$  with five or more vertices has two crossing chords.
- (3) Every induced path in  $G$  is a shortest path.
- (4) Every nonredundant connection in  $G$  is a minimum connection.
- (5) For every  $T \subseteq V$  and every vertex  $v$  in a minimal separator  $S$  of  $\langle T \rangle$  we have  $N_{T-S}(v) = N_{T-S}(S)$ .
- (6) For every cycle  $c$  in  $G$  if  $\{u, v\}$  is a separator of the subgraph  $G'$  induced by  $c$  then  $u$  and  $v$  are twins in  $G'$ .
- (7) Every induced subgraph of  $G$  contains an isolated vertex, or a leaf or a pair of twins.
- (8) For every hanging  $h$  of  $G$  and every pair of vertices  $u, v \in L^i$ ,  $1 \leq i \leq k$ , that are connected in  $\langle V - L^{i-1} \rangle$ , we have  $L^{i-1} \cap N(u) = L^{i-1} \cap N(v)$ .

*Proof.* Throughout the proof we assume that  $|V| \geq 5$  and that  $G$  is connected. The other cases follow immediately. Since the equivalences of statements from (1) to (3) are proved in [18], we will prove the following implications:

$$(4) \Leftrightarrow (3) \Rightarrow (5) \Rightarrow (6) \Rightarrow (2) \Leftrightarrow (7) \quad \text{and} \quad (2) \Leftrightarrow (8).$$

$(3) \Rightarrow (5)$ . Statement (5) trivially holds if  $|S| = 1$  or  $|S| = |V| - 1$ . Therefore, let us suppose that  $1 < |S| < |V| - 1$ . Let  $u$  and  $v$  be two distinct vertices in  $S$  and  $C'$  and  $C''$  be two distinct connected components of  $\langle V - S \rangle$  (if  $|S| < |V| - 1$ , then  $\langle V - S \rangle$  has at least two connected components). Since  $S$  is minimal, we have that  $u$  is adjacent to at least one vertex in  $C'$  and to at least one vertex in  $C''$ ; the same must also be true for  $v$ . Let  $u'$  and  $u''$  be two vertices, in  $C'$  and  $C''$ , respectively, adjacent to  $u$ ; from these considerations it follows that there exist an induced path  $(u', v'_1, \dots, v'_n, v)$  from  $u'$  to  $v$  whose internal vertices are in  $C'$  and an induced path  $(v, v''_1, \dots, v''_m, u'')$  from  $v$  to  $u''$  whose internal vertices are in  $C''$ . Consider the path  $p = (u', v'_1, \dots, v'_n, v, v''_1, \dots, v''_m, u'')$ ; since no vertex in  $C'$  is adjacent to a vertex in  $C''$ ,  $p$  is induced and, due to (3), its length must be two. Hence, both  $u'$  and  $u''$  must be adjacent to  $v$ ; this implies that for every vertex  $v$  in a minimal separator  $S$  of  $G$  we have  $N_{V-S}(v) = N_{V-S}(S)$ . Since every induced subgraph of a distance-hereditary graph is distance-hereditary, (5) is proved.

$(5) \Rightarrow (6)$ . The proof is trivial; in fact,  $\{u, v\}$  is also a minimal separator in  $G'$ .

$(6) \Rightarrow (2)$ . Let us suppose, by contradiction, that there exists in  $G$  a cycle  $c = (v_1, v_2, \dots, v_q, v_1)$ ,  $q \geq 5$ , with no pair of crossing chords. Consider the subgraph  $G'$  of  $G$  induced by the vertices in  $c$ . If  $c$  has no chord then every pair of nonconsecutive vertices in  $c$  is a separator of  $G'$  whose vertices are not twins in  $G'$ . Otherwise, let  $(v_i, v_j)$ ,  $1 < i < j < q$ , be a chord in  $c$ . Since  $c$  has no pair of crossing chords, no vertex in  $\{v_{i+1}, \dots, v_{j-1}\}$  can be adjacent to a vertex in  $\{v_{j+1}, \dots, v_q, v_1, \dots, v_{i-1}\}$ . Therefore, the set  $S = \{v_i, v_j\}$  is a minimal separator for  $G'$ . Furthermore, since  $c$  has no pair of crossing chords,  $(v_{i-1}, v_j)$  and  $(v_i, v_{j+1})$  cannot be both in  $G'$  and a contradiction arises.

(3) $\Rightarrow$ (4). Let  $T$ , with  $|T| \geq 3$  (otherwise the implication is trivial), be the set of vertices in  $G$  to be connected and let  $G' = (V', E')$  and  $G'' = (V'', E'')$  be two distinct nonredundant connections of  $T$ ; we will show that if (3) holds, then there exists a 1-1 correspondence between  $V'$  and  $V''$ . In fact, we associate with every vertex in  $V' - V''$  a vertex in  $V'' - V'$  and we prove that such an association is a 1-1 mapping. First, we prove that:

(a) Given a vertex  $v' \in V' - V''$ , for every pair  $C_1 = \langle V_1, E_1 \rangle$  and  $C_2 = \langle V_2, E_2 \rangle$  of connected components of  $\langle V' - \{v'\} \rangle$  there exists a vertex  $v'' \in V'' - V'$  such that  $N_{V_1 \cup V_2}(v'') = N_{V_1 \cup V_2}(v')$ .

Let  $v_1$  and  $v_k$  be two vertices in  $T \cap V_1$  and  $T \cap V_2$ , respectively, such that  $p' = (v_1, \dots, v_{i-1}, v_i, v_{i+1}, \dots, v_k)$ ,  $k \geq 3$ , is an induced path in  $G'$  from  $v_1$  to  $v_k$  in which  $v_i = v'$  (such a pair of vertices always exists because of the definition of nonredundant connection). Since (3) holds, there exists in  $G''$  an induced path  $p''$  connecting  $v_1$  and  $v_k$  with the same length as  $p'$ . In order to prove (a), we will show that:

(b) There exists in  $p''$  a vertex  $v''$  that is adjacent to both  $v_{i-1}$  and  $v_{i+1}$ .

If  $k = 3$ , the existence of  $v''$  trivially follows from (3). If  $k \geq 4$ , let us suppose, by contradiction, that no vertex in  $p''$  is adjacent to both  $v_{i-1}$  and  $v_{i+1}$ . Let  $v_j, j < i$ , be a vertex in  $p'$  adjacent to at least one vertex in  $p''$  and such that no vertex in  $p'$  between  $v_j$  and  $v_i$  is adjacent to any vertex in  $p''$ ; analogously, let  $v_h, h > i$ , be a vertex in  $p'$  adjacent to at least one vertex in  $p''$  and such that no vertex in  $p'$  between  $v_i$  and  $v_h$  is adjacent to any vertex in  $p''$ ; furthermore, let  $v^*$  and  $v^+$  be two vertices in  $p''$  such that  $v^*$  is adjacent to  $v_j$ ,  $v^+$  is adjacent to  $v_h$  and no vertex in  $p''$ , between  $v^*$  and  $v^+$ , is adjacent to either  $v_j$  or  $v_h$ . Observe that if  $v_j$  and  $v_h$  coincide with  $v_{i-1}$  and  $v_{i+1}$ , respectively, then  $v^*$  and  $v^+$  have to be distinct, otherwise there would be a vertex in  $p''$  adjacent to both  $v_{i-1}$  and  $v_{i+1}$ . Therefore, due to the fact that  $p'$  and  $p''$  are induced paths, there exists an induced path in  $G$  of length greater or equal to three from  $v_{i-1}$  to  $v_{i+1}$ . This implies a contradiction and proves (b).

Now let  $w$  be a vertex in  $V_2$  distinct from  $v_{i+1}$  and adjacent to  $v'$ ; we will show that  $w$  is adjacent to  $v''$ . Let us suppose, by contradiction, that  $w$  is not adjacent to  $v''$ . Since (3) holds,  $w$  and  $v_{i+1}$  cannot be connected in  $C_2$  via an induced path of length greater than two. If  $w$  and  $v_{i+1}$  are adjacent, the path  $(v_{i-1}, v'', v_{i+1}, w)$  is an induced path longer than  $(v_{i-1}, v', w)$  (contradiction). If  $w$  and  $v_{i+1}$  are not adjacent, let  $z$  be a vertex in  $V_2$  adjacent to both  $w$  and  $v_{i+1}$ . In this case, the only admissible chord in the path  $p^* = (v_{i-1}, v'', v_{i+1}, z, w)$  is  $(v'', z)$ . Therefore, there exists an induced subpath of  $p^*$  between  $v_{i-1}$  and  $w$  longer than  $(v_{i-1}, v', w)$  (contradiction).

Since analogous considerations can be done if  $w$  is a vertex in  $V_1$  distinct from  $v_{i-1}$  and adjacent to  $v'$ , we can conclude that  $v''$  is adjacent to every vertex in  $N_{V_1 \cup V_2}(v')$ . Analogously, it is possible to prove that  $v'$  is adjacent to every vertex in  $N_{V_1 \cup V_2}(v'')$ . Furthermore,  $v''$  cannot be in  $V'$ , otherwise  $G'$  would not be nonredundant, and (a) is proved.

We now show that:

(c) There exists exactly one vertex  $v''$  belonging to  $V'' - V'$  such that  $N_{V'}(v') = N_{V' - \{v'\}}(v'')$ ; furthermore, for every  $v^* \in V'$  distinct from  $v'$  we have  $N_{V'}(v'') \neq N_{V'}(v^*)$ .

If  $|N_{V'}(v')| = 2$ , then the existence of  $v''$  trivially follows from (a). If  $|N_{V'}(v')| \geq 3$ , let  $C_1$  and  $C_2$  be as in (a); then there exists a vertex  $v''_1 \in V''$  such that  $N_{V_1 \cup V_2}(v''_1) = N_{V_1 \cup V_2}(v')$ . Therefore, if there exists a vertex  $v_3 \in N_{V'}(v')$  that is not adjacent to  $v''_1$ , such a vertex must be in a connected component  $C_3 = \langle V_3, E_3 \rangle$  of  $\langle V' - \{v'\} \rangle$  distinct from both  $C_1$  and  $C_2$ . Because of (a) there exists a vertex  $v''_2 \in V''$  (distinct from  $v''_1$ ) such that  $N_{V_2 \cup V_3}(v''_2) = N_{V_2 \cup V_3}(v')$ . We will show that every vertex in  $C_1$  adjacent to  $v'$  is adjacent to  $v''_2$ . In fact, let us suppose, by contradiction, that there exists a vertex

$v_1$  in  $C_1$  adjacent to  $v'$  and not adjacent to  $v_2''$  and let  $v_2$  be any vertex in  $C_2$  adjacent to  $v'$ . In this case, the only admissible chord in the path  $p^* = (v_1, v_1'', v_2, v_2'', v_3)$  is  $(v_1'', v_2'')$ . Therefore, there exists an induced subpath of  $p^*$  between  $v_1$  and  $v_3$  longer than  $(v_1, v', v_3)$  (contradiction).

By repeatedly applying the above argument, because of the finiteness of  $V'$ , it is possible to see that there exists a vertex  $v'' \in V''$  such that  $N_{V'}(v') \subseteq N_{V'-\{v'\}}(v'')$ . In order to prove that  $N_{V'}(v') = N_{V'-\{v'\}}(v'')$ , let  $C_1$  and  $C_2$  be as above, and let us suppose, by contradiction, that there exists a vertex  $u$  in  $C_1$  adjacent to  $v''$  and not adjacent to  $v'$ ; furthermore, let  $v_1$  and  $v_2$  be two vertices in  $C_1$  and  $C_2$ , respectively, adjacent to  $v'$ , and let  $(u, u_1, \dots, u_n, v_1, v')$ ,  $n \geq 0$ , be an induced path from  $u$  to  $v'$  whose internal vertices are in  $C_1$ ; we have that the path  $(u, u_1, \dots, u_n, v_1, v', v_2)$  is an induced path from  $u$  to  $v_2$  longer than  $(u, v'', v_2)$ ; hence, a contradiction arises.

Furthermore, due to the fact that  $G''$  is nonredundant, no vertex in  $V''$  distinct from  $v''$  can enjoy the same property. Finally, due to the fact that  $G'$  is nonredundant,  $v'' \notin V'$  and for no vertex  $v^*$  in  $G'$  distinct from  $v'$  we may have  $N_{V'}(v'') = N_{V'}(v^*)$ .

(4) $\Rightarrow$ (3). It trivially follows from the definitions of nonredundant connection and induced path.

(2) $\Rightarrow$ (7). Since an induced subgraph of a distance-hereditary graph is distance-hereditary, it is sufficient to prove that if every cycle in  $G$  of length five or more has two crossing chords then  $G$  contains an isolated vertex or a leaf or a pair of twins.

Since every cycle in a graph is contained in one block, at least one block  $G' = (V', E')$  exists in  $G$  sharing at most one vertex with the remaining blocks. If  $|V'| = 1$  then  $G$  has an isolated vertex. If  $|V'| = 2$  then the vertex belonging only to  $G'$  is a leaf in  $G$ . Therefore, it is sufficient to prove that:

(a) If  $|V'| > 2$  there exist in  $G'$  two pairs of twins.

In fact, if  $v$  is the vertex that  $G'$  shares with the remaining blocks and (a) holds then there exists at least one pair of vertices of  $G$  (both distinct from  $v$ ) that are twins in  $G'$ ; since they cannot be in a block distinct from  $G'$ , they are also twins in  $G$  and (2) $\Rightarrow$ (7) is proved. In order to prove (a) we will prove a number of facts.

(b) If every cycle in  $G$  of length five or more has two crossing chords then for every minimal separator  $S$  of  $G$  we have that  $\langle S \rangle$  is a cograph.

Since (2) $\Rightarrow$ (5), if  $v$  is a vertex in  $N_{V-S}(S)$  (because of the definition of minimal separator  $|N_{V-S}(S)| \geq 1$ ) all vertices in  $S$  have the same level in  $h_v$ . Then, by (2) $\Rightarrow$ (3), every induced path in  $\langle S \rangle$  cannot be longer than two and (b) is proved.

(c) If every cycle in  $G$  of length five or more has two crossing chords every minimal separator  $S$  of  $G$  either is a cutpoint or contains at least one pair of twins.

Because of (b),  $\langle S \rangle$  is a cograph. It has been proved in [7] that in every nontrivial cograph there are two vertices that are twins; therefore if  $S$  is not a cutpoint it contains two vertices  $u$  and  $v$  such that  $N_S(u) = N_S(v)$  or  $N_S[u] = N_S[v]$ . Since (2) $\Rightarrow$ (5) it follows that  $N_V(u) = N_V(v)$  or  $N_V[u] = N_V[v]$  and (c) is proved.

(d) In every nontrivial connected graph there exist at least two minimal separators.

Let  $G$  be a nontrivial connected graph with at least two vertices.  $G$  must contain at least one nonempty minimal separator  $S$ . Let  $v$  be a vertex in  $S$ ; we have that  $V - \{v\}$  is a separator of  $G$ , then  $G$  must have a minimal separator distinct from  $S$  and (d) is proved.

We are now able to prove (a). In fact, since  $G'$  is a block, every minimal separator  $S$  in  $G'$  contains at least two vertices. Because of (d) this implies that  $G$  has at least two minimal separators whose cardinality is greater than or equal to two. Finally, due to (c), (a) is proved.

(7) $\Rightarrow$ (2). Let us suppose, by contradiction, that there exists in  $G$  a cycle  $c = (v_1, v_2, \dots, v_q, v_1)$ ,  $q \geq 5$ , with no pair of crossing chords. Consider the subgraph  $G'$

of  $G$  induced by the vertices in  $c$ ; no vertex in  $c$  can be a leaf or an isolated vertex in  $G'$ . Furthermore, let  $v_i$  and  $v_j$  be any pair of distinct vertices in  $c$ ; since  $q \geq 5$  we may assume without loss of generality that  $1 < i < j < q$ . Since  $c$  has no pair of crossing chords,  $(v_{i-1}, v_j)$  and  $(v_i, v_{j+1})$  cannot be both in  $G'$ ; hence  $v_i$  and  $v_j$  cannot be twins in  $G'$  (contradiction).

(2) $\Rightarrow$ (8). Let  $h_v$  be a hanging of  $G$ , and  $v'$  and  $v''$  be a pair of vertices having the same level  $i$  in  $h_v$  and connected by an induced path  $p$  whose vertices have level in  $h_v$  greater or equal to  $i$ . Since the implication trivially holds for  $i = 1$ , let  $i > 1$  and let us suppose, by contradiction, that  $L^{i-1} \cap N(v') \neq L^{i-1} \cap N(v'')$ . Without loss of generality, we assume that there exists a vertex  $v^* \in L^{i-1}(h_v) \cap (N(v') - N(v''))$ . Consider two induced paths  $(v'_i, v'_{i-1}, \dots, v'_1, v'_0)$  and  $(v''_i, v''_{i-1}, \dots, v''_1, v''_0)$ , of length greater than one, such that  $v'_i = v'$ ,  $v''_i = v''$ ,  $v'_{i-1} = v^*$  and for every  $k$ ,  $0 \leq k \leq i-1$ ,  $v'_k$  and  $v''_k$  have level  $k$  in  $h_v$  (therefore  $v'_0 = v''_0 = v$ ); let  $j$  be the maximum  $k$ ,  $k < i$ , such that  $v'_k$  is adjacent to  $v''_{k-1}$  or  $v''_{k-1}$  is adjacent to  $v'_k$ . Suppose that  $v'_j$  is adjacent to  $v''_{j-1}$  and let us consider the induced paths  $p' = (v'_{i-1}, \dots, v'_j, v''_{j-1})$  and  $p'' = (v''_i, v''_{i-1}, \dots, v''_{j-1})$ . Let  $v^+$  be the nearest vertex to  $v''$  among those of  $p$  that are adjacent to  $v'_{i-1}$  and let us consider the cycle generated by  $p'$ ,  $p''$ ,  $(v'_{i-1}, v^+)$  and the subpath of  $p$  between  $v^+$  and  $v''$ . The length of such a cycle is greater than four; furthermore, the only admissible chords in this cycle are the chords  $(v'_k, v''_k)$ ,  $i-1 \leq k < j-1$  (that is chords connecting vertices with the same level), and chords connecting  $v''_{i-1}$  and a vertex in  $p$ ; therefore, the cycle contains no pair of crossing chords (contradiction). Analogous considerations can be done if  $v''_j$  is adjacent to  $v'_{j-1}$ .

(8) $\Rightarrow$ (2). Let us suppose, by contradiction, that there exists in  $G$  a cycle  $c = (v_1, v_2, \dots, v_q, v_1)$ ,  $q \geq 5$ , with no pair of crossing chords. First we prove that:

(a) There exists at least one vertex in  $c$  that is not an endpoint of any chord in  $c$ .

Let us suppose, by contradiction, that every vertex in  $c$  be an endpoint of a chord in  $c$ . Let  $(v_i, v_j)$ ,  $i < j$ , be a chord in  $c$ ; if there exists a vertex in  $c$  that is consecutive with both  $v_i$  and  $v_j$ , then every chord starting from such a vertex crosses  $(v_i, v_j)$  (contradiction).

Otherwise, if no chord crosses  $(v_i, v_j)$ , we can consider a chord  $(v_h, v_k)$ , such that  $i < h < k < j$ , and repeatedly apply the same argument until a contradiction arises and (a) is proved.

Now let  $v_n$  be a vertex in  $c$  that is not an endpoint of any chord in  $c$ . Without loss of generality, we can assume that  $2 < n < q-1$ . Consider the hanging  $h_{v_n}$  of  $G$ . Since no chord starts from  $v_n$ , we have that the only vertices in  $c$  having level one in  $h_{v_n}$  are  $v_{n-1}$  and  $v_{n+1}$ ; therefore  $v_{n-2}$  and  $v_{n+2}$  have level two in  $h_{v_n}$  and are connected by a path (the path in  $c$  that does not have  $v_{n-1}$ ,  $v_n$ , and  $v_{n+1}$  as internal vertices) whose vertices have level greater or equal to two. Since  $c$  has no pair of crossing chords, the edges  $(v_{n-2}, v_{n+1})$  and  $(v_{n-1}, v_{n+2})$  cannot be both in  $G$  and a contradiction arises.  $\square$

Characterization (8) provides a simple property to be satisfied by every hanging in order that a graph be distance-hereditary. Observe that Bandelt and Mulder, starting from an arbitrary hanging, provided a more complex characterization based on five conditions (see [2, Thm. 3]); two of them (conditions (1) and (3)) are implied by our characterization (8).

**4. Relationships between distance-hereditary graphs and other classes of perfect graphs.** We now relate distance-hereditary graphs with other kinds of graphs defined in § 2.

From the definitions of a distance-hereditary graph and a parity graph it trivially follows that a distance-hereditary graph is a parity graph. Furthermore, Howorka [19]

proved that Ptolemaic graphs are precisely chordal distance hereditary graphs. The following proposition states the relationships between the class of distance-hereditary graphs and the classes of cographs, (6, 2)-chordal bipartite graphs, comparability graphs and permutation graphs (see Fig. 2).

PROPOSITION 1. (i) *Cographs are distance-hereditary graphs; there are distance-hereditary graphs that are not cographs.*

(ii) *(6, 2)-chordal bipartite graphs are precisely bipartite distance-hereditary graphs.*

(iii) *There are distance-hereditary graphs that are not comparability graphs.*

(iv) *There are permutation graphs that are not distance-hereditary graphs.*

*Proof of (i).* It has been proved in [7] that in every nontrivial cograph there are two vertices that are twins, and that every induced subgraph of a cograph is a cograph; due to (7) in Theorem 1, this implies that a cograph is a distance-hereditary graph. The graph in Fig. 3 is a distance-hereditary graph that is not a cograph.

*Proof of (ii).* The proof immediately follows from the following result provided by Howorka [18]: a graph is distance-hereditary if and only if every cycle with five or more vertices has two chords and every cycle with five vertices has two crossing chords.

*Proof of (iii) and (iv).* See the graphs in Figs. 4 and 5.  $\square$

Finally, the following theorem gives a property of distance-hereditary graphs which is similar to a decomposition property proved in [4] and [5] for Meyniel and parity graphs; in particular it shows that a distance-hereditary graph can be easily decomposed into a cograph and a (6, 2)-chordal bipartite graph (without common edges) by hanging it with respect to one of its vertices. This property has been

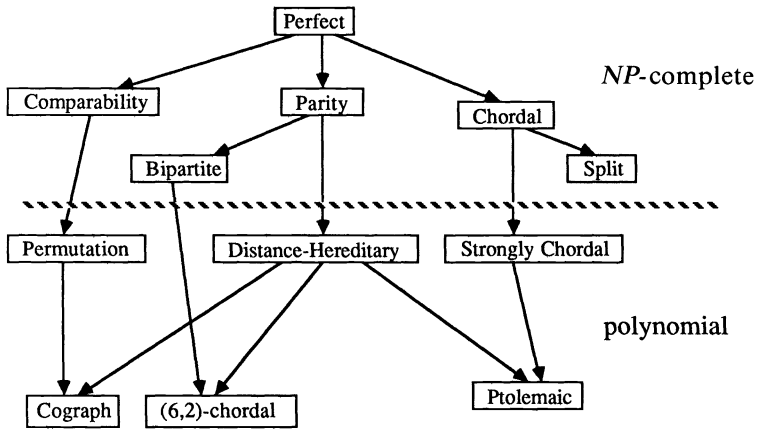

FIG. 2. Containment relations and bound between tractability and intractability of Steiner tree and connected domination problems for classes discussed in this paper.

FIG. 3. A distance-hereditary graph that is not a cograph.

FIG. 4. A distance-hereditary graph that is not a comparability graph.

FIG. 5. A permutation graph that is not a distance-hereditary graph.

independently proved by Bandelt and Mulder [2, Property (2) in Theorem 3 and Corollary 5].

**THEOREM 2.** *Let  $G$  be a distance-hereditary graph. For every hanging  $h$  of  $G$ , the horizontal and the vertical part of  $G$  with respect to  $h$  are a cograph and a  $(6, 2)$ -chordal bipartite graph, respectively.*

*Proof.* It has been shown [5] that, if  $G$  is a parity graph,  $H(G, h)$  is a cograph. Due to the containment of the class of distance-hereditary graphs in the class of parity graphs, the first part of the statement is proved.

In order to prove the second part, let us assume, without loss of generality, that  $G$  is connected and let  $h_v$  be a hanging of  $G$  and  $k$  be the maximum level of vertices of  $G$  in  $h_v$ . The statement is trivial if  $k \leq 1$ . Otherwise, let  $V_1$  and  $V_2$  be the set of vertices in  $V$  having level even and odd, respectively; it is easy to see that  $V(G, h_v)$  is bipartite with respect to  $V_1$  and  $V_2$ . Furthermore, let us suppose, by contradiction, that there exists a cycle  $c = (v_1, v_2, \dots, v_q, v_1)$  in  $V(G, h_v)$ , of length  $q \geq 6$ , with at most one chord. Let  $j$  be the maximum level in  $h_v$  of vertices in  $c$  and let  $v_i$  be a vertex in  $c$  having level  $j$ ; without loss of generality, we may assume that  $3 \leq i \leq q - 2$ . The following cases may arise.

*Case (1).* Both  $v_{i-2}$  and  $v_{i+2}$  have level  $j - 2$ . In this case  $(v_{i-1}, v_i, v_{i+1})$  is a path between  $v_{i-1}$  and  $v_{i+1}$  whose vertices have level greater than or equal to  $j$ . Since either  $(v_{i-2}, v_{i+1})$  or  $(v_{i-1}, v_{i+2})$  is not in  $E$ , due to (8) in Theorem 1, a contradiction arises.

*Case (2).* Either  $v_{i-2}$  or  $v_{i+2}$  has level  $j - 2$ . Suppose  $v_{i-2}$  has level  $j - 2$ . If  $(v_{i-2}, v_{i+1})$  is not in  $E$  then the same considerations as in Case (1) can be done. Otherwise, again by (8) in Theorem 1,  $(v_{i-2}, v_{i+3}) \in E$ ; since  $c$  has at most one chord, this implies that  $q = i + 3 = 6$ . The cycle  $c$  cannot have any of the following chords:

- $(v_2, v_5)$  and  $(v_3, v_6)$ ; in fact,  $c$  cannot have a chord distinct from  $(v_1, v_4)$  in  $V(G, h_v)$
- $(v_3, v_5)$ ; in fact, if  $(v_3, v_5) \in E$  then  $(v_2, v_5), (v_3, v_6) \in E$ .

Hence, we have that  $(v_2, v_6) \in E$ . Consider the cycle  $(v_2, v_3, v_4, v_5, v_6)$ ; this cycle has no pair of crossing chords (contradiction).

*Case (3).* Both  $v_{i-2}$  and  $v_{i+2}$  have level  $j$ . If  $q = i + 3 = 6$ , we have that the only admissible chords in  $G$  are  $(v_2, v_4)$ ,  $(v_2, v_6)$ ,  $(v_4, v_6)$  and at most one chord in  $\{(v_1, v_4), (v_2, v_5), (v_3, v_6)\}$  (otherwise  $c$  would have two chords in  $V(G, h_v)$ ). In fact, by Theorem 1, the existence of  $(v_1, v_3)$  or  $(v_1, v_5)$  or  $(v_3, v_5)$  would imply the existence of two chords in  $\{(v_1, v_4), (v_2, v_5), (v_3, v_6)\}$ . Therefore, there exists a cycle of length five in  $G$  without crossing chords (contradiction).

If  $q > 6$  we have that  $v_{i-3}$  and  $v_{i+3}$  have level  $j - 1$ . Since  $v_{i-1}$  and  $v_{i+1}$  have level  $j - 1$  in  $h_v$ , again by Theorem 1, there exists a vertex  $v'$  having level  $j - 2$  and adjacent to  $v_{i-3}$ ,  $v_{i+3}$ ,  $v_{i-1}$ , and  $v_{i+1}$ .

If neither  $(v_{i-3}, v_i)$  nor  $(v_{i-2}, v_{i+1})$  is in  $E$ , consider the cycle  $c' = (v_{i-3}, v_{i-2}, v_{i-1}, v_i, v_{i+1}, v', v_{i+3})$ . We have that  $(v_{i-2}, v_i)$  cannot be a chord of  $c'$ , in fact if  $(v_{i-2}, v_i) \in E$ , then  $(v_{i-3}, v_i)$ ,  $(v_{i-2}, v_{i+1}) \in E$ . Therefore  $(v_{i-3}, v_{i+1})$  must be in  $E$ . Consider the cycle  $(v_{i-3}, v_{i-2}, v_{i-1}, v_i, v_{i+1}, v_{i+3})$ ; this cycle has no pair of crossing chords (contradiction).

If either  $(v_{i-3}, v_i)$  or  $(v_{i-2}, v_{i+1})$  is in  $E$ , analogous considerations can be done by considering the cycle  $(v_{i-1}, v_i, v_{i+1}, v_{i+2}, v_{i+3}, v', v_{i-1})$ .  $\square$

**5. Recognition, Steiner tree, and connected domination problems.** The recognition problem (i.e., the problem of deciding in polynomial time whether or not a graph belongs to a given class) is open for the class of perfect graphs, but it has been solved for several of its subclasses, such as the ones discussed in the previous sections. In particular, Burlet and Fonlupt [4] provide an algorithm, based on a decomposition process, that recognizes in polynomial time Meyniel graphs; an easy adaptation of this algorithm (obtained by restricting the decomposition operation and the type of final inseparable components) allows us to also recognize parity graphs (see [4] and [5]).

Two recognition algorithms for distance-hereditary graphs are now presented. The first is a procedure that reduces a distance-hereditary graph into the empty graph, by recursively eliminating vertices with particular properties (similarly to what is done for cographs in [7]); the second one is based on connectivity tests in the graph hangings. Such algorithms are a straightforward consequence of characterizations (7) and (8) in Theorem 1 and it is easy to see that they work in polynomial time.

ALGORITHM 1.

```

input a graph  $G = (V, E)$ ;
output the variable succeeds (true if and only if  $G$  is a distance-hereditary graph);
procedure delete ( $G, succeeds$ );
begin
   $W := \emptyset$ ;
  for every  $v \in G$  do
    if  $v$  is an isolated vertex or a leaf or if  $v$  has a twin in  $G$  then
      begin  $G := \langle V - \{v\} \rangle$ ;  $W := W \cup \{v\}$  end;
    if  $G \neq \emptyset$  then if  $W = \emptyset$  then  $succeeds := false$  else delete ( $G, succeeds$ )
  end;
begin  $succeeds := true$ ; delete ( $G, succeeds$ ) end.

```

ALGORITHM 2

```

input and output as above;
begin
   $succeeds := true$ ;

```

```

for every connected component  $C$  of  $G$  do
  for every  $w \in C$  do
    begin
      determine  $h_w$ ;
      for every pair  $u, v \in C$  do
        if  $h_w(u) = h_w(v) = i$ 
          and  $u$  and  $v$  are connected in  $\langle V - L^{i-1}(h_w) \rangle$ 
          and  $L^{i-1}(h_w) \cap N(u) \neq L^{i-1}(h_w) \cap N(v)$  then
            begin  $succeeds := false$ ; exit end
          end
        end
      end
    end.

```

We now present two polynomial algorithms to find Steiner trees and connected dominations in distance-hereditary graphs, respectively. First, characterization (3) in Theorem 1 suggests a simple greedy technique to find Steiner trees in distance-hereditary graphs in polynomial time by using the following algorithm:

ALGORITHM 3.

```

Input a connected graph  $G = (V, E)$  and a subset  $S$  of its vertices
output a subtree of  $G$  that includes all vertices in  $S$ ;
begin
  for every  $v \in V - S$ 
    if  $\langle V - \{v\} \rangle$  is a connection of  $S$  then  $G := \langle V - \{v\} \rangle$ ;
  determine a spanning tree of  $G$ 
end.

```

THEOREM 3. *If  $G$  is a distance-hereditary graph Algorithm 3 determines a Steiner tree of  $S$  in  $O(|V| * |E|)$  time.*

*Proof.* In fact, the first step in Algorithm 3 determines a nonredundant connection of  $S$  that, by Theorem 1, is also minimum. Since such a step can be done in time  $O(|V| * |E|)$  (in fact, it requires a connectivity test for every vertex in  $V - S$ ) and a spanning tree can be found in linear time, the overall complexity is  $O(|V| * |E|)$ .  $\square$

Also characterization (8) in Theorem 1 has an interesting algorithmic impact. In fact, we now prove that a polynomial algorithm based on this characterization exists to solve the connected domination problem in distance-hereditary graphs.

In order to approach the problem, let us provide some technical lemmas.

LEMMA 1. *Let  $G = (V, E)$  be a distance-hereditary graph,  $h_w$  be a hanging of  $G$ ,  $k$  be  $\max(h_w(v) | v \in V)$ , and  $D \subseteq V$  such that  $\langle D \rangle$  is connected and  $V = N[D]$ . We have that:*

- (a) *For every  $i, 0 < i < k, D \cap L^i \neq \emptyset$ ;*
- (b) *Every vertex  $v \in L^i, 2 \leq i \leq k$ , is adjacent to a vertex  $u \in D \cap L^{i-1}$ ;*
- (c) *If  $w \notin D$ , then  $\langle D \cap (L^1 \cup L^2) \rangle$  is connected.*

*Proof.* In order to prove (a), let us suppose, by contradiction, that there exists  $i, 0 < i < k$ , such that  $D$  does not contain any vertex in  $L^i$ . Three cases arise:

— There exists a pair of vertices  $u, v \in D$  such that  $h_w(u) < i$  and  $h_w(v) > i$ ; in this case  $D$  cannot be connected;

— For every  $v \in D$ , we have  $h_w(v) < i$ ; this implies that no vertex in  $L^k$  could be in  $N[D]$ ;

— For every vertex  $v \in D, h_w(v) > i$ ; in this case  $w$  could not be in  $N[D]$ .

Since in all cases a contradiction arises, (a) is proved.

In order to prove (b), let  $v$  be a vertex of  $G$  such that  $h_w(v) = i \geq 2$  and let  $z \in D$  be adjacent to  $v$ . Let us suppose that  $h_w(z) = i$ . By (a) and by the hypothesis that  $\langle D \rangle$

is connected, there exists a vertex  $u \in D$  with  $h_w(u) = i - 1$  connected in  $\langle D \rangle$  to  $z$  via a path  $p$ . Let  $u'$  be the nearest vertex to  $z$  on  $p$  having level  $i - 1$ ; by (8) in Theorem 1,  $v$  is adjacent to  $u'$ . Since similar considerations can be done if  $h_w(z) = i + 1$ , (b) is proved.

Finally, due to (a) and (b), every vertex in  $D \cap L^2$  is adjacent to a vertex in  $D \cap L^1$ . Furthermore, if  $w \notin D$  then for every pair of nonadjacent vertices in  $D \cap L^1$ , by (3) in Theorem 1, there exists in  $\langle D \rangle$  a path of length two connecting them; the only internal vertex in such a path must be either in  $D \cap L^1$  or in  $D \cap L^2$ ; this proves (c).  $\square$

LEMMA 2. *Let  $G = (V, E)$  be a nontrivial distance-hereditary graph, and let  $h_w$  and  $k$  be as in Lemma 1. There exists a connected dominating set of  $G$  that does not contain any vertex in  $L^k$ .*

*Proof.* Let  $D$  be a subset of  $V$  such that  $\langle D \rangle$  is connected and  $V = N[D]$ , and let  $v \in D$  be a vertex such that  $h_w(v) = k$ .

If  $k = 1$ , then  $\{w\}$  is a connected dominating set of  $G$ .

If  $k = 2$ , then every vertex in  $L^1$  is adjacent to  $w$  and every vertex in  $L^2$  is adjacent to a vertex in  $D \cap L^1$  (because of (b) in Lemma 1). Therefore, if  $D$  is a connected dominating set of  $G$ , then  $D - \{v\} \cup \{w\}$  is a connected dominating set of  $G$ .

If  $k > 2$  then, by Lemma 1, there exist a vertex  $u \in D \cap L^{k-1}$  adjacent to  $v$  and a vertex  $z \in D \cap L^{k-2}$  adjacent to  $u$ ; due to (8) in Theorem 1, every vertex  $v'$  adjacent to  $v$ , with  $h_w(v') = k$ , is also adjacent to  $u$ , and every vertex  $v''$  adjacent to  $v$ , with  $h_w(v'') = k - 1$ , is also adjacent to  $z$ ; therefore  $D$  cannot be a connected dominating set of  $G$ .  $\square$

LEMMA 3. *Let  $G, h_w$  and  $k > 2$  be as in Lemma 1. Let  $G_i, 1 \leq i \leq 2$ , be the subgraph of  $V(G, h_w)$  induced by  $L^i \cup L^{i+1}$ ,  $S_1$  and  $S'_1$  be two subsets of  $L^1$  that are dominations of  $L^2$  in  $G_1$ , and  $S_2$  and  $S'_2$  be two subsets of  $L^2$  that are dominations of  $L^3$  in  $G_2$ . We have that:*

(a)  $N(S_2) \cap L^1 = N(S'_2) \cap L^1$ ;

(b) *If  $S'_1 \subseteq N[S_1]$ , then  $S_1 \subseteq N[S'_1]$ ;*

(c) *If  $\langle S_1 \cup S_2 \rangle$  is connected, then  $\langle S'_1 \cup S'_2 \rangle$  is connected;*

(d) *If  $\langle S_1 \cup S_2 \rangle$  is connected and  $|S_1| = |S'_1| > 1$ , then  $N[S_1 \cup S_2] \cap L^1 = N[S'_1 \cup S'_2] \cap L^1$ .*

*Furthermore, the properties above hold if  $k = 2$ , by assuming  $S_2 = S'_2 = \emptyset$ .*

*Proof.* In order to prove (a), let us suppose, by contradiction, that there exists a vertex  $v \in L^1$  adjacent to a vertex  $u \in S_2$  and not adjacent to any vertex in  $S'_2$ . Let  $z \in L^3$  be a vertex adjacent to  $u$ ; since  $S_2$  and  $S'_2$  are dominations of  $L^3$  in  $G_2$ , there exists a vertex  $y \in S'_2$  (hence distinct from  $u$ ) adjacent to  $z$ . Due to (8) in Theorem 1,  $y$  must be adjacent to  $v$  and a contradiction arises.

In order to prove (b), let us suppose, by contradiction, that there exists a vertex  $v \in S_1 - S'_1$  that is not adjacent to any vertex in  $S'_1$ . Since  $S_1$  is a domination of  $L^2$  in  $G_1$ , there exists a vertex  $z \in L^2$  adjacent to  $v$  and not adjacent to any vertex in  $S_1$  distinct from  $v$ . Let  $y$  be a vertex in  $S'_1 - S_1$  adjacent to  $z$ . Since  $S'_1 \subseteq N[S_1]$ , there exists a vertex  $u \in S_1$  adjacent to  $y$ .

If  $u \in S_1 \cap S'_1$ , let us consider the cycle  $c_1 = (w, v, z, y, u, w)$ . We have that  $c_1$  cannot have any of the following chords:

—  $(w, z)$ , in fact,  $h_w(z) = 2$ ;

—  $(v, u)$  and  $(v, y)$ , since  $v$  is not adjacent to any vertex in  $S'_1$ ;

—  $(z, u)$ , since  $z$  is not adjacent to any vertex in  $S_1$  distinct from  $v$ .

Therefore,  $c_1$  has no pair of crossing chords and a contradiction arises.

If  $u \in S_1 - S'_1$ ,  $u$  must be adjacent to  $v$ , otherwise  $c_1$  would have no pair of crossing chords. Let  $z' \in L^2$  be adjacent to  $u$  and not adjacent to any vertex in  $S_1$  distinct from

$u$ , and let  $y' \in S'_1 - S_1$  be adjacent to  $z'$ . Consider the cycle  $c_2 = (w, v, u, z', y', w)$ . We have that  $c_2$  cannot have any of the following chords:

- $(w, z')$ , in fact,  $h_w(z') = 2$ ;
- $(v, z')$ , since  $z'$  is not adjacent to any vertex in  $S_1$  distinct from  $u$ ;
- $(v, y')$ , since  $v$  is not adjacent to any vertex in  $S'_1$ .

Therefore,  $c_2$  has no pair of crossing chords and a contradiction arises that proves (b).

In order to prove (c), let  $|S_1| = |S'_1| \geq 2$  (in fact (c) trivially holds if  $|S_1| = |S'_1| = 1$ ) and let  $u'$  and  $u''$  be a pair of nonadjacent vertices in  $S'_1$ ; we prove that there exists a vertex  $u \in S'_1 \cup S'_2$  adjacent to both  $u'$  and  $u''$ . First we prove that:

- (i) There exists a vertex  $v \in S_1 \cup S_2$  adjacent to both  $u'$  and  $u''$ .

Three cases arise.

*Case (1)  $u', u'' \in S_1$ .* Due to the connectivity of  $\langle S_1 \cup S_2 \rangle$  and to (3) in Theorem 1, (i) trivially holds.

*Case (2)  $u'' \in S_1$ .* Since  $S'_1$  is a domination of  $L^2$  in  $G_1$ , there exists a vertex  $z' \in L^2$  such that  $N(z') \cap S'_1 = \{u'\}$ . Let  $v' \in S_1 - S'_1$  be adjacent to  $z'$ ;  $v'$  cannot be adjacent to  $u''$ , otherwise the cycle  $(w, u', z', v', u'', w)$  would have no pair of crossing chords. Hence, due to the connectivity of  $\langle S_1 \cup S_2 \rangle$  and to (3) in Theorem 1, there exists a vertex  $v \in S_1 \cup S_2$  adjacent to both  $v'$  and  $u''$ . The cycle  $c = (w, u'', v, v', z', u', w)$  must have the chord  $(v, u')$ . In fact  $c$  cannot have the following chords:

- $(w, z')$ , since  $h_w(z') = 2$ ;
- $(u, u'')$ , by hypothesis;
- $(z', u'')$ , because of the choice of  $z'$ ;
- $(v', u'')$ , see above.

*Case (3)  $u', u'' \in S'_1 - S_1$ .* Since  $S'_1$  is a domination of  $L^2$  in  $G_1$ , there exist two vertices  $z', z'' \in L^2$  such that  $N(z') \cap S'_1 = \{u'\}$  and  $N(z'') \cap S'_1 = \{u''\}$ . Let  $v'$  and  $v''$  be two vertices in  $S_1$  adjacent to  $z'$  and  $z''$ , respectively. Due to the connectivity of  $\langle S_1 \cup S_2 \rangle$  and to (3) in Theorem 1, there exists in  $\langle S_1 \cup S_2 \rangle$  an induced path from  $v'$  to  $v''$  whose length is less than or equal to two. We will show that:

- (ii)  $v'$  is distinct from  $v''$ , and
- (iii)  $v'$  and  $v''$  are not adjacent.

In fact, if  $v'$  and  $v''$  coincide then the cycle  $c_1 = (w, u', z', v', z'', u'', w)$  cannot have any of the following chords:

- $(w, z')$  and  $(w, z'')$ , in fact  $h_w(z') = h_w(z'') = 2$ ;
- $(u', u'')$ ,  $(u', z'')$  and  $(u'', z')$ , because of the choice of  $u', u'', z'$ , and  $z''$ ;
- $(z', z'')$ , in fact its existence should imply the existence of both  $(u', z'')$  and  $(u'', z')$ .

Therefore, the only admissible chords in  $c_1$  should be those starting from  $v'$  and a contradiction arises which proves (ii). If  $v'$  and  $v''$  are adjacent then, analogously, the cycle  $c_2 = (w, u', z', v', v'', z'', u'', w)$  cannot have the chords  $(w, z')$ ,  $(w, z'')$ ,  $(u', u'')$ ,  $(u', z'')$ ,  $(u'', z')$  and  $(z', z'')$ . Furthermore,  $c_2$  cannot have the chords:

- $(z', v'')$  and  $(z'', v')$ , because of (ii);
- $(u', v'')$  and  $(u'', v')$ , otherwise the cycle  $(w, u', v'', z'', u'', w)$  and the cycle  $(w, u', z', v', u'', w)$  would have no pair of crossing chords, respectively.

Therefore the only admissible chords in  $c_2$  are  $(w, v')$ ,  $(w, v'')$ ,  $(u', v')$ , and  $(u'', v'')$  (no pair crosses), and (iii) is proved.

Therefore, let  $v \in S_1 \cup S_2$  be adjacent to both  $v'$  and  $v''$ . Consider the cycle  $c_3 = (w, u', z', v', v, v'', z'', u'', w)$ ; analogously to  $c_2$ ,  $c_3$  cannot have the chords  $(w, z')$ ,  $(w, z'')$ ,  $(u', u'')$ ,  $(u', z'')$ ,  $(u'', z')$ ,  $(z', z'')$ ,  $(u', v'')$ , and  $(u'', v')$ ; furthermore it cannot have the chords  $(z', v'')$ ,  $(z'', v')$  and  $(v', v'')$ , because of (ii) and (iii), and the chords  $(z', v)$  and  $(z'', v)$ , for the same reason, if  $v \in S_1$ , and due to the absence of  $(v'', z')$  and

$(v', z'')$  and (8) in Theorem 1, if  $v \in S_2$ . Therefore the only admissible chords in  $c_3$  are  $(u', v')$ ,  $(u', v)$ ,  $(w, v')$ ,  $(w, v)$ ,  $(w, v'')$ ,  $(u'', v)$ , and  $(u'', v'')$ . If  $(u', v)$  or  $(u'', v)$  were not in  $c_3$  then one of the following cycles should have no pair of crossing chords:

- $c_3$ ;
- $(w, u', z', v', v, u'', w)$ ;
- $(w, u'', z'', v'', v, u', w)$ .

Therefore,  $v$  is adjacent to both  $u'$  and  $u''$  and (i) is proved.

Now, if  $v \in S'_1 \cup S'_2$ , such a vertex is the connecting vertex  $u$  and (c) is proved; otherwise, two cases arise.

Case (1)  $v \in S_1 - S'_1$ . Since  $S_1$  is a domination of  $L^2$  in  $G_1$ , there exists a vertex  $z \in L^2$  adjacent to  $v$  and not adjacent to any vertex in  $S_1$  distinct from  $v$ ; such a vertex cannot be adjacent to  $u'$  or to  $u''$ . In fact, suppose that  $z$  is adjacent to  $u'$  and not adjacent to  $u''$ ; then the cycle  $(w, u', z, v, u'', w)$  should have no pair of crossing chords (contradiction). Analogously, a contradiction arises if  $z$  is adjacent to  $u''$  and not adjacent to  $u'$ . Therefore, suppose that  $z$  is adjacent to both  $u'$  and  $u''$ ; in this case, due to the choice of  $z$ , we have that both  $u'$  and  $u''$  are in  $S'_1 - S_1$ . Let  $z'$ ,  $z''$ ,  $v'$ , and  $v''$  be as in Case 3 above. Since  $z'$  and  $z''$  cannot be adjacent to  $v$ , then they cannot be adjacent to  $z$  (due to (8) in Theorem 1); this implies that the cycles:

- $(u', z', v', v, z, u')$  and
- $(u'', z'', v'', v, z, u'')$ ,

cannot have any pair of crossing chords (contradiction).

Since  $S'_1$  is a domination of  $L^2$  in  $G_1$ , there exists a vertex  $u \in S'_1$  adjacent to  $z$ ; by the considerations above, such a vertex must be distinct from both  $u'$  and  $u''$ . Furthermore, the cycle  $(w, u, z, v, u', w)$  must have the chord  $(u, u')$ ; analogously,  $u$  is adjacent to  $u''$  and (c) is proved.

Case (2).  $v \in S_2 - S'_2$ . Since  $S_2$  is a domination of  $L^3$  in  $G_2$ , there exists a vertex  $z \in L^3$  adjacent to  $v$  and not adjacent to any vertex in  $S_2$  distinct from  $v$ . Since  $S'_2$  is a domination of  $L^3$  in  $G_2$ , there exists a vertex  $u \in S'_2 - S_2$  adjacent to  $z$ . Because of (8) in Theorem 1,  $u$  must be adjacent to both  $u'$  and  $u''$ , and (c) is proved.

In order to prove (d), by (a) and (b), it is sufficient to prove that  $(N(S_1 \cup S_2) \cap L^1) - S'_1 \supseteq (N(S'_1 \cup S'_2) \cap L^1) - S_1$  (due to (c), the same argument can be used to prove that  $(N(S_1 \cup S_2) \cap L^1) - S'_1 \subseteq (N(S'_1 \cup S'_2) \cap L^1) - S_1$ ). Let us suppose, by contradiction, that there exists a vertex  $x \in L^1$  adjacent to a vertex  $u \in S'_1 \cup S'_2$  and not adjacent to any vertex in  $S_1 \cup S_2$ ; due to (a),  $x$  cannot be adjacent to any vertex in  $S'_2$ , then  $u$  is in  $S'_1 - S_1$ . First we will prove that:

- (i) every vertex  $z$  in  $L^2$  adjacent to  $u$  is adjacent to  $x$ .

In fact, let  $v \in S_1$  be a vertex adjacent to  $z$  (since  $u \notin S_1$ ,  $v$  is distinct from  $u$ ); since  $x$  is not adjacent to any vertex in  $S_1$ , if  $z$  were not adjacent to  $x$  then the cycle  $(w, x, u, z, v, w)$  should have no pair of crossing chords; hence (i) is proved.

We now prove that:

- (ii)  $S_1$  and  $S'_1$  are disjoint.

Let  $x$  and  $u$  be as above; let  $z$  be a vertex in  $L^2$  such that  $N(z) \cap S'_1 = \{u\}$  and  $v$  be a vertex in  $S_1 - S'_1$  adjacent to  $z$  and let us suppose that  $u'$  is a vertex in  $S'_1$  distinct from  $u$ . If, by contradiction,  $u'$  were in  $S_1$ , due to the connectivity of  $\langle S_1 \cup S_2 \rangle$  and to (3) in Theorem 1, either  $v$  is adjacent to  $u'$  or there exists a vertex  $y \in S_1 \cup S_2$  adjacent to both  $v$  and  $u'$ . In the first case, the cycle  $(w, x, z, v, u', w)$  has no pair of crossing chords. In the second case, let us consider the cycle  $c = (w, x, z, v, y, u', w)$ ; the only admissible chords in  $c$  are  $(w, v)$ ,  $(w, y)$  and  $(z, y)$ ; hence, if  $z$  is not adjacent to  $y$ ,  $c$  has no pair of crossing chords; otherwise  $(w, x, z, y, u', w)$  has no pair of crossing chords (contradiction); hence (ii) is proved.

Since  $S'_1$  is a domination of  $L^2$  in  $G_1$  and (i) holds, there exists a vertex  $z \in L^2$  adjacent to  $u$  and  $x$  and not adjacent to  $u'$ . Furthermore, there exists a vertex  $z'$  adjacent to  $u'$  and not adjacent to  $x$ ; otherwise (by (i) and by the fact that every vertex in  $L^2$  is adjacent to a vertex in  $S'_1$ ) every vertex in  $L^2$  should be adjacent to a vertex in  $(S'_1 - \{u, u'\}) \cup \{x\}$  and, hence,  $S'_1$  should not be a domination of  $L^2$ . Let  $v, v' \in S_1$  be two vertices adjacent to  $z$  and  $z'$ , respectively (such vertices exist because of (ii)). Since  $\langle S_1 \cup S_2 \rangle$  is connected, there exists an induced path in  $\langle S_1 \cup S_2 \rangle$  connecting  $v$  and  $v'$  whose length, due to (3) in Theorem 1, is less than or equal to two. Three cases arise.

Case (1).  $v$  and  $v'$  coincide. In this case, the cycle  $c_1 = (w, x, z, v, z', u', w)$  cannot have the chords:

- $(w, z)$  and  $(w, z')$ , in fact  $h_w(z) = h_w(z') = 2$ ;
- $(u', z)$  and  $(x, z')$ , because of the choice of  $z$  and  $z'$ ;
- $(z, z')$ , because its existence should imply the existence of both  $(u', z)$  and  $(x, z')$ ;
- $(x, v)$ , since  $x$  is not adjacent to any vertex in  $S_1$ .

Hence, if  $c_1$  does not have the chord  $(x, u')$  then it has no pair of crossing chords; otherwise, the cycle  $(x, z, v, z', u', x)$  has no pair of crossing chords.

Case (2).  $v$  and  $v'$  are adjacent. In this case, the cycle  $c_2 = (w, x, z, v, v', w)$  has no pair of crossing chords, since it cannot have the chords:

- $(w, z)$  and  $(x, v)$ , as above;
- $(x, v')$ , because  $x$  is not adjacent to any vertex in  $S_1$ ;
- $(z, v')$ , because of Case (1).

Case (3). There exists a vertex  $y \in S_1 \cup S_2$  adjacent to both  $v$  and  $v'$ . If  $y \in S_1$  then the cycle  $c_3 = (w, x, z, v, y, w)$  has no pair of crossing chords, since it cannot have the chords:

- $(w, z)$  and  $(x, v)$ , as above;
- $(x, y)$ , because  $x$  is not adjacent to any vertex in  $S_1$ ;
- $(z, y)$ , because of Case (2).

If  $y \in S_2$  then the cycle  $c_4 = (w, x, z, v, y, v', w)$  has no pair of crossing chords, since it cannot have the chords:

- $(w, z)$ ,  $(w, y)$ ,  $(x, v)$ ,  $(x, v')$ , and  $(z, v')$ , as above;
- $(v, v')$ , because of Case (2);
- $(z, y)$ , since its existence would imply the existence of  $(z, v')$ ;
- $(x, y)$ , since  $x$  cannot be adjacent to any vertex in  $S_2$ .

Finally, since in all cases a contradiction arises, (d) is proved.  $\square$

The basic idea, underlying the following algorithm to solve in polynomial time the connected domination problem in distance-hereditary graphs, consists in the reduction of the global optimization problem into this local optimization problem:

Given a hanging of the distance-hereditary graph, find a minimum set of vertices with level  $i$  which is a domination of all vertices with level  $i + 1$  (see (b) in Lemma 1).

In fact, the reduction is based on the following facts:

- The local problem is solvable in polynomial time (due to Proposition (a) in the proof of Theorem 4);
- To obtain a connected dominating set, the vertices with maximum level  $k$  in the hanging can be ignored (by Lemma 2);
- Let  $S_1$  and  $S_2$  be solutions of the local optimization problem at the first and second level, respectively. By Lemma 3, if  $S_1$  contains more than one vertex then both the connectivity of the graph induced by the union of the solutions of the same problem

from the first level to the level  $k-1$  and the adjacency to such union of all vertices at the first level, are independent from the choice of  $S_1$  and  $S_2$ .

ALGORITHM 4.

**input** a connected graph  $G = (V, E)$ ;

**output** a subset  $D$  of  $V$ ;

**function**  $DOMINA(i)$ ; [determine a minimum subset  $DOMINA$  of  $L^{i-1}$   
such that  $N(DOMINA) \supseteq L^i$ ]

**begin**

$DOMINA := L^{i-1}$ ;

**for every**  $v \in DOMINA$  **do**

**if**  $N(DOMINA - \{v\}) \supseteq L^i$  **then**  $DOMINA := DOMINA - \{v\}$

**end**;

**begin**

determine any hanging  $h_w$  of  $G$ ;

$D := \emptyset$ ;  $k := \max(h_w(v) | v \in V)$ ;

**for**  $i := k$  **downto** 3 **do**  $D := D \cup DOMINA(i)$ ;

**if** there exists a vertex  $z \in L^1$  such that  $N[z] \supseteq L^1 \cup L^2$

**then**  $D := D \cup \{z\}$

**else begin**

$D := D \cup DOMINA(2)$ ;

**if**  $N[D] \not\supseteq L^1$  **or**  $\langle D \rangle$  is not connected

**then**  $D := D \cup \{w\}$

**end**

**end.**

**THEOREM 4.** *If  $G$  is a distance-hereditary graph then Algorithm 4 determines a connected dominating set of  $G$  in polynomial time.*

*Proof.* It is easy to see that Algorithm 4 works in polynomial time, that the set  $D$  of vertices obtained by it induces a connected subgraph of  $G$  and that  $V = N[D]$ . Therefore, we have to prove that if  $G$  is a distance-hereditary graph, then  $D$  is a minimum set of vertices enjoying the properties above.

In the following let  $h_w$  be a hanging of  $G$  and let  $k$  be  $\max(h_w(v) | v \in V)$ . If  $k \leq 1$ , then either  $D = \{z\}$  or  $D = \{w\}$ ; hence  $D$  is a connected dominating set of  $G$ . Therefore, let  $k \geq 2$  and let  $G_i$ ,  $1 \leq i < k$ , be the subgraph of  $V(G, h_w)$  induced by  $L^i \cup L^{i+1}$ . First we will prove that:

(a) If  $S$  is a subset of  $L^i$ ,  $1 \leq i < k$ , such that  $N(S) \supseteq L^{i+1}$  and no subset of it has the same property then  $S$  is a domination of  $L^{i+1}$  in  $G_i$ .

Let us assume, without loss of generality, that  $G_i$  is connected (otherwise the following argument can be applied to every connected component of  $G_i$ ). First we will prove that the subgraph of  $G_i$  induced by  $S \cup L^{i+1}$  is also connected. In fact, if  $u$  and  $v$  are two distinct vertices in  $S$ , by (8) in Theorem 1, there exists a vertex in  $L^{i-1}$  adjacent to both  $u$  and  $v$ ; therefore, due to (3) in Theorem 1, every induced path between  $u$  and  $v$  in  $G_i$  has length two. This implies that there exists a vertex in  $L^{i-1}$  adjacent to both  $u$  and  $v$ ; hence, the subgraph of  $G_i$  induced by  $S \cup L^{i+1}$  is a nonredundant connection of  $L^{i+1}$  in  $G_i$ . Since, by Theorem 2,  $V(G, h_w)$  is a distance-hereditary graph and an induced subgraph of a distance-hereditary graph is distance-hereditary,  $G_i$  is also a distance-hereditary graph. Due to (4) in Theorem 1, (a) is proved.

Let us suppose, by contradiction, that there exists  $D' \subseteq V$  such that  $\langle D' \rangle$  is connected,  $V = N[D']$  and  $|D'| < |D|$ . Due to Lemma 2, we may assume that no vertex in  $L^k$  is in  $D'$ . If there exists  $i$ ,  $0 < i < k$ , such that  $|D' \cap L^i| < |D \cap L^i|$  then, due to (a),

there exists a vertex in  $L^{i+1}$  that is not adjacent to any vertex in  $D' \cap L^i$  and, due to (b) in Lemma 1, a contradiction arises.

Therefore, we have that for every  $i$ ,  $0 < i < k$ ,  $|D \cap L^i| = |D' \cap L^i|$ ; then  $w \in D - D'$ . We will prove that this implies that  $|DOMINA(2)| > 1$ .

Let us suppose, by contradiction, that  $|DOMINA(2)| = 1$ . Hence  $\langle D - \{w\} \rangle$  is connected; therefore, since  $w \in D$ , by Algorithm 4 we have that  $D - \{w\}$  is not a domination of  $L^1$ . If  $k > 2$ , let  $DOMINA(2) = \{v\}$ ,  $D' \cap L^1 = \{u\}$ ,  $z$  be a vertex in  $L^1$  that is not in  $N[D - \{w\}]$  and  $y$  be a vertex in  $D' \cap L^2$ ; due to (a) in Lemma 3,  $z$  cannot be adjacent to  $y$  and, hence, the cycle  $(w, z, u, y, v, w)$  has no pair of crossing chords (contradiction). If  $k = 2$ , since  $D'$  does not contain any vertex in  $L^k$ ,  $N[u]$  must contain  $L^1 \cup L^2$ ; but in this case, by Algorithm 4,  $w$  would not be in  $D$  (contradiction).

Therefore, if  $w \in D$  then  $|DOMINA(2)| > 1$ . Furthermore, by Algorithm 4, two cases arise:

- (i)  $\langle D - \{w\} \rangle$  is not connected; or
- (ii) There exists a vertex in  $L^1$  that is not in  $N[D - \{w\}]$ .

Let us suppose that (i) holds. In this case  $\langle DOMINA(2) \rangle$  and  $\langle DOMINA(2) \cup DOMINA(3) \rangle$  are not connected. In fact, due to (b) in Lemma 1, each vertex in  $DOMINA(i+1)$ ,  $1 < i < k$ , is adjacent to at least one vertex in  $DOMINA(i)$ , then there exists a path between any vertex in  $DOMINA(i+1)$ ,  $1 < i < k$ , and a vertex in  $DOMINA(2)$ . Therefore, if it were a path in  $\langle DOMINA(2) \rangle$  or in  $\langle DOMINA(2) \cup DOMINA(3) \rangle$  between any pair of vertices in  $DOMINA(2)$ ,  $\langle D - \{w\} \rangle$  would be connected. On the other hand, since  $w \notin D'$ , due to (c) in Lemma 1,  $\langle D' \cap (L^1 \cup L^2) \rangle$  is connected; hence due to (c) in Lemma 3, a contradiction arises.

Let us now suppose that (ii) holds. Since  $L^1 \subseteq N[D' \cap (L^1 \cup L^2)]$ , due to (b) and (d) in Lemma 3, a contradiction arises.  $\square$

## A POLYNOMIAL APPROXIMATION SCHEME FOR SCHEDULING ON UNIFORM PROCESSORS: USING THE DUAL APPROXIMATION APPROACH\*

DORIT S. HOCHBAUM† AND DAVID B. SHMOYS‡

**Abstract.** We present a polynomial approximation scheme for the minimum makespan problem on uniform parallel processors. More specifically, the problem is to find a schedule for a set of independent jobs on a collection of machines of different speeds so that the last job to finish is completed as quickly as possible. We give a family of polynomial-time algorithms  $\{A_\varepsilon\}$  such that  $A_\varepsilon$  delivers a solution that is within a relative error  $\varepsilon$  of the optimum. This is a dramatic improvement over previously known algorithms; the best performance guarantee previously proved for a polynomial-time algorithm ensured a relative error no more than 40 percent. The technique employed is the dual approximation approach, where infeasible but superoptimal solutions for a related (dual) problem are converted to the desired feasible but possibly suboptimal solution.

**Key words.** scheduling, approximation algorithms

**1. Introduction.** We will consider a fundamental problem of scheduling theory. Suppose that we have a set of jobs  $J$  with independent processing times  $p_1, \dots, p_n$  that are to be executed on  $m$  nonidentical machines; these machines run at different speeds  $s_1, \dots, s_m$ . More precisely, if job  $j$  is executed on machine  $i$  it takes  $p_j/s_i$  time units to be completed. The objective is to assign the jobs to machines so as to minimize the total execution time required to run the jobs assigned to the most heavily loaded machine. In other words, it is the minimum time needed to complete the processing of all of the jobs. In the classification scheme of [GLLR] this problem is denoted  $Q//C_{\max}$ , the *minimum makespan problem on uniform parallel machines*. In this paper, we will present a family of algorithms for this problem where these algorithms are, in a sense to be indicated below, the best possible algorithms for this problem.

As is true for most scheduling problems, this problem is likely to be intractable since it is  $NP$ -complete, and therefore the existence of a polynomial-time algorithm for it would imply that  $P = NP$ . As a result, the algorithm designer must be willing to settle for a solution somewhat worse than the optimal schedule. One natural approach is to consider *approximation algorithms* for the problem which deliver a schedule with makespan that is guaranteed to be within a specified relative error of the optimum schedule length. This approach was first considered by Graham [G], who showed that if all of the machines have the same speed, then the simple "on-line" procedure of scheduling *any* job when a machine becomes idle always delivers a schedule that finishes within at most  $1 + (1 - 1/m)$  times the optimal schedule length. We shall call such a polynomial-time procedure a  $(1 - 1/m)$ -approximation algorithm. Work on this special case of identical machines culminated in the recent work of Hochbaum and Shmoys [HS], that showed that for *any* fixed  $\varepsilon > 0$  there exists an  $\varepsilon$ -approximation algorithm. This was a dramatic difference from previously known work on the more general problem with different processing speeds. Although much work had been done

on this harder problem (e.g., [CS], [GIS], [HoS]) the best algorithm published to date delivers a solution that could be up to 40 percent more than the optimum [FL].

In this paper, we present a family of polynomial-time algorithms  $\{A_\varepsilon\}$ , such that the algorithm  $A_\varepsilon$  is an  $\varepsilon$ -approximation algorithm for the more general problem. Such a family of algorithms is traditionally called a *polynomial approximation scheme*. Notice that the algorithm  $A_\varepsilon$  is polynomial in the size of the input, but not in the value of  $1/\varepsilon$ . If the family of algorithms has the property that  $A_\varepsilon$  is polynomial in  $1/\varepsilon$  and the size of the instance, then the family is known as a *fully polynomial approximation scheme*. Since this problem is strongly *NP*-complete, our results are, however, the best possible in the sense that if there were a fully polynomial approximation scheme for this problem, then  $P = NP$  [GJ].

Due to the exponential dependence on  $1/\varepsilon$  in the running time of our algorithm, it is not particularly practical for small values of  $\varepsilon$ . However, the result shows that there do exist polynomial-time algorithms that produce solutions with far superior guarantees to the previously known algorithms, and thus one might hope for practical algorithms with better guarantees than are known today. Note that the discussion above implies that there are limits to the amount of improvement that is possible; still one might hope for an  $O(n \log n)$  or  $O(n^2)$  algorithm that is guaranteed to have relative error no more than, for example, 5 percent. In addition to this existential sort of practical implication, we also believe that the framework around which our algorithm is built can lead to efficient algorithms with extremely good guarantees. As an example of this, we give an extremely efficient but exceedingly naive algorithm which is an adaptation of our framework, and is guaranteed to deliver a solution that is within 50 percent of the optimum. In addition, the analysis of this algorithm is similarly transparent.

**2. A framework for approximation algorithms for scheduling problems.** In this section we will describe the basic structure of our polynomial approximation scheme for the minimum makespan problem with uniform processors. Consider for the moment the related question of deciding whether there exists a schedule for a given instance of this problem where all of the jobs are completed by time  $T$ . If we think of the units of the processing times  $p_j$  as steps, and the units of the speeds as steps per unit of time, then machine  $i$  can process  $Ts_i$  steps before the deadline  $T$ . The decision problem can then be viewed as a *bin-packing problem with variable bin sizes*. Furthermore, notice that the notation for this problem can be simplified by rescaling both the processing requirements and the speeds by a factor of  $1/T$ : in this bin-packing variant the aim is to decide whether a set of jobs (which we will interchangeably call pieces) of sizes  $p_1, \dots, p_n$  can be packed into a set of bins of sizes  $s_1, \dots, s_m$ .

Suppose that we had an efficient procedure for solving the bin-packing problem with variable bin sizes. Then it is possible to solve the minimum makespan problem with uniform machines by a simple binary search procedure. For the midpoint  $T$  of the current range of possible optimum makespan values, we run the decision procedure; if a schedule is found then the upper bound is updated to the midpoint, otherwise the lower bound is updated. To initialize the binary search we need to obtain easy upper and lower bounds on the length of the optimum schedule. One such upper bound is  $U = \sum_j p_j / \max_i s_i$  (schedule all jobs on the fastest machine) and one such lower bound is  $L = \sum_j p_j / (m \cdot \max_i s_i)$  (even if all machines are as fast as the fastest, there must be enough total processing capacity for the machines to process the total processing requirement). Notice that these bounds have a ratio bounded by  $m$ . Thus after  $\log m + l$  iterations of a binary search procedure the difference between the upper bound and lower bound on the optimum makespan value is at most  $2^{-l}$  times the optimum value.

Unfortunately, this bin-packing problem is also *NP*-complete, so it seems unlikely that we will find an efficient procedure to solve it. Instead we will argue that solving a *relaxed* version of the bin-packing problem will be sufficient for our purposes. We first introduce some useful terminology. For each collection of jobs  $J$  with processing times  $\{p_1, \dots, p_n\}$ , and set of bin sizes  $S = \{s_1, \dots, s_m\}$ , a *truly feasible packing* is a partition of the job set into  $m$  parts,  $B_i$ ,  $i = 1, \dots, m$  where the total processing requirement of jobs in  $B_i$  is at most  $s_i$  for  $i = 1, \dots, m$ . Similarly, we define an  $\varepsilon$ -*relaxed feasible packing* to be a similar partition, but one that need only satisfy the weaker (or relaxed) condition that the total processing requirement of jobs in  $B_i$  be at most  $(1 + \varepsilon)s_i$ .

An  $\varepsilon$ -*relaxed decision procedure* is a procedure which, given a collection  $J$  of jobs with processing times  $\{p_1, \dots, p_n\}$ , and a set of bin sizes  $S = \{s_1, \dots, s_m\}$ , outputs one of two outcomes:

- (1) An  $\varepsilon$ -relaxed feasible packing; or
- (2) Some certificate that no truly feasible packing exists.

Consider now the binary search procedure described above with an  $\varepsilon$ -relaxed decision procedure in place of the algorithm assumed to solve the bin-packing problem with variable sizes. Notice that when an update of the lower bound is done, the new value must still be a valid lower bound on the optimum makespan length, since the  $\varepsilon$ -relaxed decision procedure fails to produce a packing only when no truly feasible packing exists. Similarly, if the upper bound is updated to  $t$ , then a schedule has been obtained of length at most  $(1 + \varepsilon)t$ . From these observations it is not hard to obtain the following result.

**THEOREM 1.** *An  $\varepsilon$ -approximation algorithm for the minimum makespan problem with uniform parallel machines can be obtained by executing the binary search procedure using an  $\varepsilon/2$ -relaxed decision initialized with upper and lower bounds,  $U$  and  $L$ , respectively, for  $\log m + \log(3/\varepsilon)$  iterations.*

For the complete details of the proof of this, plus a more general setting in which the same basic ideas are applicable, the reader is referred to [HS]. It is also useful to note that by continuing for more iterations (but only polynomially many) it is possible to convert an  $\varepsilon$ -relaxed decision procedure into an  $\varepsilon$ -approximation algorithm (as opposed to the result given above which uses an  $\varepsilon/2$ -relaxed decision procedure). From Theorem 1, we get the following immediate corollary.

**COROLLARY 1.** *If for all fixed  $\varepsilon > 0$  there exists a polynomial-time  $\varepsilon$ -relaxed decision procedure for the bin-packing problem with variable bin sizes, then there is a polynomial approximation scheme for the minimum makespan problem with uniform parallel machines.*

**3. An  $\varepsilon$ -relaxed decision procedure for bin packing with variable bin sizes.** In this section we will show how to construct an  $\varepsilon$ -relaxed decision procedure for the bin-packing problem with variable bin sizes for any  $\varepsilon > 0$ . For the remainder of the paper we will assume that the pieces (or jobs) have sizes  $p_1, \dots, p_n$ , and the bins have sizes  $s_1, \dots, s_m$ , where  $s_1 \geq s_2 \geq \dots \geq s_m$ .

For convenience we shall assume that  $1/\varepsilon$  is a positive integer. The description of the algorithm and the proof of its correctness will proceed in a few phases. We first construct a certain layered directed graph with two nodes designated "initial" and "success." We prove that if there is a *truly feasible packing*, then there is a directed path from "initial" to "success." Furthermore, the existence of such a path provides a means of efficiently constructing an  $\varepsilon$ -relaxed feasible packing. Hence, the procedure consisting of constructing the graph, identifying if there is a path from "initial" to "success," and then deriving the respective packing is indeed an  $\varepsilon$ -relaxed decision procedure.

An intuitive outline of the algorithm relies on the analogy to the special case of bin packing  $m$  bins of equal size ( $=1$ ). Such an algorithm is given in [HS], but its presentation, however, does not lend itself to the required generalization. Here we modify the description of the algorithm to clarify the analogous procedure in the variable-size bins case. For the equal-size case, all pieces lie in the interval  $(0, 1]$ , and the attempt is to  $\varepsilon$ -relaxed pack them in at most  $m$  bins. The first pieces to be packed are of size greater than  $\varepsilon$ ; these *large* pieces will be denoted by  $J_{\text{large}} = \{j \mid p_j > \varepsilon\}$ . The phase of the algorithm where these pieces are packed is called *large-pack*. Since these pieces are large, fewer than  $1/\varepsilon$  of them can fit in one bin. These large pieces are further partitioned according to their size in subintervals of length  $\varepsilon^2$  each. All piece sizes in such subintervals are all rounded down to the lower end of the subinterval, which is the nearest multiple of  $\varepsilon^2$  no more than the original piece size. After this rounding, the number of large piece sizes is at most  $w = (1 - \varepsilon)/\varepsilon^2$ . Thus, the packing of large pieces in a bin can be uniquely described by an array of the distribution of piece sizes that go into that bin. It is an array with one entry for each subinterval, and an integer value between 0 and  $1/\varepsilon$  in each entry. Such an array, or a *configuration*, specifies how many pieces of each subinterval go into each bin. A configuration  $(x_1, \dots, x_w)$  is called *feasible* if each  $x_i \geq 0$  and the total sum of the rounded sizes of pieces in the configuration is at most 1, the size of the bin.

The distribution of the remaining large pieces to be packed, the *state vector*, is described by a similar array, except that each entry may contain a nonnegative integer no more than  $n$ . Therefore, the total number of possible state vectors is at most  $n^w$ . A state vector  $(n_1, n_2, \dots, n_w)$  is *reachable* from a state vector  $(n'_1, n'_2, \dots, n'_w)$  if there is a feasible configuration  $(x_1, \dots, x_w)$  such that  $n_i = n'_i - x_i$  for  $i = 1, \dots, w$ . The first step of the procedure is to construct a layered directed graph where the nodes correspond to state vectors in the following way. Let  $V_0, \dots, V_m$  be the nodes in the 0th through  $m$ th layers, respectively. For  $i = 1, \dots, m-1$ ,  $V_i$  contains a vertex  $(i, \mathbf{n})$  for each possible state vector  $\mathbf{n}$ .  $V_0$  contains only one vertex, the “initial” node, and is labeled with the state vector corresponding to the initial distribution of rounded piece sizes. Similarly  $V_m$  contains only the “success” node, which is labeled with the zero state vector (corresponding to the case that all pieces are packed). From each node  $(i, \mathbf{n})$ , there is an arc directed towards the node  $(i+1, \mathbf{n}')$  if and only if the state vector  $\mathbf{n}'$  is reachable from the state vector  $\mathbf{n}$ . Given any truly feasible packing of the original instance, it is easy to see that the induced packing on the (rounded) large pieces implies that there is a path from the initial node to the success node. We next show that from any path from initial to success we can compute an  $\varepsilon$ -relaxed feasible packing of the large unrounded pieces. The path clearly specifies a packing of the rounded large pieces. If we now restore the large pieces to their original sizes (arbitrarily selecting them from the appropriate subintervals), this “inflating” process may either result in a packing that is truly feasible, or the pieces may exceed the capacity ( $=1$ ) of some bins. However, the rounding was done in such a way so that it is easy to bound the amount by which the inflated pieces will exceed the bin capacity. To round each piece it was necessary to subtract at most  $\varepsilon^2$  from its actual size, and there are no more than  $1/\varepsilon$  pieces per bin. Thus, the total difference between actual and rounded piece sizes in a bin is at most  $\varepsilon$ , and so the total actual piece size cannot exceed  $1 + \varepsilon$ . In summary, the procedure *large-pack* constructs the layered graph, finds a path from initial to success, which then yields an  $\varepsilon$ -relaxed feasible packing of the large pieces.

We now must show how to extend this  $\varepsilon$ -relaxed feasible packing to include the small pieces, in a way that will always succeed if there is a truly feasible packing of the original instance. The existence of a truly feasible packing induces a truly feasible

packing of the large pieces, with sufficient total slack in the bins in order to accommodate all the small pieces. Moreover, the *total slack* in a truly feasible packing of the large pieces,  $V^t = m - \sum_{j \in J_{\text{large}}} p_j$ , can be no more than the total slack remaining in bins packed *under capacity* in an  $\varepsilon$ -relaxed feasible packing of the large pieces, the *relaxed slack*,  $V^{\text{rel}} = \sum_{i=1}^m \max \{0, 1 - \sum_{j \in C_i} p_j\}$  where  $C_i$  is the set of pieces assigned by *large-pack* to bin  $i$ . Now let  $J_{\text{small}} = J - J_{\text{large}}$ . Since  $V^t \geq \sum_{j \in J_{\text{small}}} p_j$  and  $V^{\text{rel}} \geq V^t$ , it follows that  $V^{\text{rel}} \geq \sum_{j \in J_{\text{small}}} p_j$ . If this inequality is not satisfied then there can be no truly feasible packing; otherwise we will be able to *small-pack* the remaining (small) pieces. This is done by assigning one piece at a time to any bin with positive slack (that is, filled with less than its unit capacity), even if this slack is less than the size of the piece. This procedure guarantees that:

- (1) So long as there is positive slack, small pieces can be packed;
- (2) By packing a small piece of size  $p_j$ , the total remaining slack is reduced by at most  $p_j$ ; and
- (3) Bins that become packed over capacity in the small-pack phase are packed with at most  $1 + \varepsilon$  times their true capacity (since the capacity is exceeded only by adding a small piece (i.e.,  $< \varepsilon$ ), to a bin that was previously truly feasibly packed).

Therefore, if there is a truly feasible packing, the *large-pack* and *small-pack* procedures will find an  $\varepsilon$ -relaxed feasible packing. The complexity of the algorithm is dominated by the *large-pack* procedure, where we construct the layered graph. The graph has at most  $2 + (m + 1)n^{1/\varepsilon^2}$  nodes and each node has at most  $(1/\varepsilon)^{1/\varepsilon^2}$  arcs originating at it. The construction of each arc amounts to checking the feasibility of the corresponding packing of a bin. This is done with at most  $1/\varepsilon$  additions and one comparison. The complexity of the  $\varepsilon$ -relaxed procedure is hence  $O((m/\varepsilon)(n/\varepsilon)^{1/\varepsilon^2})$ , which is a polynomial for any fixed positive  $\varepsilon$ .

In the generalization of the equal-size bin  $\varepsilon$ -relaxed procedure to the variable-size case we come across a major obstacle. The size of the subintervals in which the pieces are partitioned depends on the size of the bins in which the pieces are to be packed. Moreover, the definition of large and small pieces depends on the size of the bin in which the pieces are to be packed. Let the largest bin size  $s_1$  be normalized to 1. The piece sizes are hence in the interval  $(0, 1]$ . We round down piece sizes as follows; for a piece in the interval  $(\varepsilon^{k+1}, \varepsilon^k]$  we round its size down to the nearest multiple of  $\varepsilon^{k+2}$ . Formally, define

$$\bar{p}_j = \lfloor p_j / \varepsilon^{k+2} \rfloor \cdot \varepsilon^{k+2}, \quad \text{where } k = \max \{q \geq 0 \mid p_j \leq \varepsilon^q\}.$$

Consider now a bin of size  $s_i$  in the interval  $(\varepsilon^{k+1}, \varepsilon^k]$ . In the previous case, the large pieces for this bin were those with sizes in the interval  $(\varepsilon s_i, s_i]$  since  $s_i = 1$  for all  $i$ . This interval can intersect both of the intervals  $(\varepsilon^{k+2}, \varepsilon^{k+1}]$  and  $(\varepsilon^{k+1}, \varepsilon^k]$  and as a result, we will slightly modify the notion of large in generalizing the algorithm to the case of variable-size bins. The pieces in the interval  $(\varepsilon^{k+1}, \varepsilon^k]$  are *large* for this bin whereas the pieces in the interval  $(\varepsilon^{k+2}, \varepsilon^{k+1}]$  are called *medium* pieces. The pieces of size less than or equal to  $\varepsilon^{k+2}$  are *small* for this bin. Notice that the definition of large, medium, and small pieces did not depend on the precise size of the bin, but only on the interval of the form  $(\varepsilon^{l+1}, \varepsilon^l]$  that contained the bin size; for convenience we will often refer to this as interval  $l$ . As before, it will always be true that a small piece for a bin is no more than  $\varepsilon$  times the bin size. The strategy will be to execute the packing of the bins  $1, 2, \dots, m$  in two phases:

- (1) Large- and medium-piece packing (*l&m-pack*);
- (2) Small-piece packing (*small-pack*).

Note that a piece can be large, medium, or small depending on the size of the bin in which it is packed. It will also be useful to classify bin sizes for a given interval of piece sizes. For pieces in interval  $k$ ,  $(\epsilon^{k+1}, \epsilon^k]$ , a bin is *large* if it is in interval  $k$ , *huge* if it is in interval  $k-1$ , and *enormous* if it is in interval  $k-2$ .

We construct a directed, layered graph where each node is labeled with a state vector describing the remaining pieces to be packed as large or medium pieces. Since each bin may generate different classes of large or medium pieces, a straightforward representation of such an array leads to roughly  $n^n$  such possible state vectors. Instead, the graph will be grouped into *stages*, where a stage will specify the *l&m-pack* of bins in one interval  $(\epsilon^{k+1}, \epsilon^k]$ . Each layer within a stage corresponds to packing a bin in the corresponding interval. Both the bins within the stage and the stages are arranged in order of decreasing bin size. At the end of the *l&m-pack* of the bins of the stage corresponding to interval  $k$ , we will provide for the packing of the remaining unpacked pieces in interval  $k$ ; these pieces will be packed as small pieces. (Note that these pieces must therefore be packed in bins that are enormous for them.)

The treatment of the bins and pieces in this conglomerate way will make it possible to reduce the amount of information encoded in the state vector. The state vector associated with each node is of the form  $(\mathbf{L}; \mathbf{M}; V_1, V_2, V)$ , where  $\mathbf{L}$  and  $\mathbf{M}$  are vectors each describing a distribution of pieces in the subintervals of  $(\epsilon^{k+1}, \epsilon^k]$  and  $(\epsilon^{k+2}, \epsilon^{k+1}]$ , respectively. The subinterval division is of length  $\epsilon^{k+2}$  and  $\epsilon^{k+3}$  respectively, so each of these vectors is of length  $w = (1 - \epsilon)/\epsilon^2$  and the value of each entry is at most  $n$ . For simplicity of notation, let  $l_1, \dots, l_w$  and  $\bar{l}_1, \dots, \bar{l}_w$  denote the values of the lower endpoints of the subintervals of  $(\epsilon^{k+1}, \epsilon^k]$  and  $(\epsilon^{k+2}, \epsilon^{k+1}]$ , respectively. (See Fig. 1.)

FIG. 1. The  $\times$  represents the size of a bin to be packed in interval 2. The identity of pieces and other bins is relative to this interval.

As was mentioned above, after the *l&m-pack* of the bins in interval  $k$ , we must allow for the packing of the pieces in interval  $k$  that will be packed as small pieces. These pieces must be packed in enormous bins (those from interval  $k-2$ ) and so we need to know that there is sufficient unused capacity in the enormous bins to at least contain the total size of these unpacked pieces. This is the function of the value  $V_1$  in the state vector; it records the slack, or unused capacity in the partial packing of the enormous bins with large and medium pieces. For stages corresponding to intervals greater than  $k$ , we will also need to know the unused capacity in the huge and large bins, and this is the function of  $V_2$  and  $V$ , respectively. However, there is a crucial point in that each node is labeled with a possible value for  $V_1$ ,  $V_2$ , and  $V$ , so we must be able to represent the possible values in some compact way. Consider the sizes of the pieces that will be packed as small pieces into this as-yet-unused capacity. For  $V_1$ , pieces in interval  $k$  are small, and thus all pieces to be packed into this unused capacity have rounded sizes that are multiples of  $\epsilon^{k+2}$ ; as a result, it will be sufficient to represent  $V_1$  as an integer multiple of  $\epsilon^{k+2}$ . Similarly,  $V_2$  and  $V$  will be represented as integer

multiples of  $\epsilon^{k+3}$  and  $\epsilon^{k+4}$ , respectively. Furthermore, we will argue below (in Lemma 1) that for the purposes of the algorithm, it will be sufficient to have one node for all multiples greater than  $n/\epsilon^2$  for any of these three parameters. As a result, the number of possible state vectors in each layer is bounded from above by  $n^{2/\epsilon^2} \cdot (n/\epsilon^2)^3$ .

Suppose that there are  $m_k > 0$  bins with size in  $(\epsilon^{k+1}, \epsilon^k]$ . The stage corresponding to this interval will actually have  $m_k + 1$  layers of nodes. In each of these layers, there is one node for every possible state vector  $(n_1, \dots, n_w; \bar{n}_1, \dots, \bar{n}_w; V_1, V_2, V)$ . A node in the  $(l+1)$ st layer of the stage labeled  $(n_1, \dots, n_w; \bar{n}_1, \dots, \bar{n}_w; V_1, V_2, V)$  is *reachable* from a node in the  $l$ th layer of the stage  $(n'_1, \dots, n'_w; \bar{n}'_1, \dots, \bar{n}'_w; V_1, V_2, V')$ , if:

- (1) There is a configuration  $(x_1, \dots, x_w; \bar{x}_1, \dots, \bar{x}_w)$  where  $x_i$  and  $\bar{x}_i$  are nonnegative integers for  $i = 1, \dots, w$  such that  $n_i = n'_i - x_i$  and  $\bar{n}_i = \bar{n}'_i - \bar{x}_i$ ;
- (2) The configuration is feasible; that is, the total sum of rounded piece sizes,  $\sum_{i=1}^w x_i l_i + \sum_{i=1}^w \bar{x}_i \bar{l}_i$  may not exceed  $s$ , the size of the  $l$ th bin in that stage; and
- (3)  $V = V' + \lceil \text{slack}_l / \epsilon^{k+4} \rceil$ , where  $\text{slack}_l = s - (\sum_{i=1}^w x_i l_i + \sum_{i=1}^w \bar{x}_i \bar{l}_i)$ .

We define here the concept of the usable slack in bin  $l$  as

$$\text{usable slack}_l = \lceil \text{slack}_l / \epsilon^{k+4} \rceil \cdot \epsilon^{k+4}.$$

Note that in the first layer of the first stage we keep only the node with the state vector corresponding to the distribution of pieces in  $(\epsilon, 1]$  and  $(\epsilon^2, \epsilon]$  with  $V_1 = V_2 = V = 0$ .

Intuitively, a node  $z$  is reachable from an initial state vector for the stage if there is an  $l$ & $m$ -pack of the first  $l$  bins in that group using feasible configurations, leaving a remaining piece distribution as in node  $z$ , and accumulating in all  $l$  bins a total of  $V \cdot \epsilon^{k+4}$  in usable slack. (See Fig. 2.)

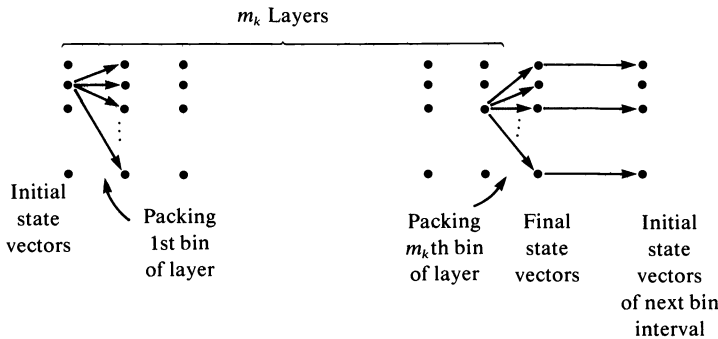

FIG. 2. One stage of the layered graph (for interval  $k$ ).

Note that the number of feasible configurations is at most  $(1/\epsilon^2)^{2/\epsilon^2}$ , since no more than  $1/\epsilon^2$  large or medium pieces can fit in a bin. This number is polynomial for any fixed positive value of  $\epsilon$  (or actually just a large constant).

The state vectors in the final layer of one stage have to be updated to the proper form of initial state vectors for the subsequent interval of higher index that contains a bin. Suppose that the next such interval is  $q$  intervals away; that is, it is the interval  $(\epsilon^{k+q+1}, \epsilon^{k+q}]$ . Let  $l_i^{(t)}$  denote the value of the lower end of the  $i$ th subinterval of  $(\epsilon^{k+t+1}, \epsilon^{k+t}]$  and let  $n_i^{(t)}$ ,  $t \geq 2$ , be the number of pieces contained in that subinterval. (For  $t = 0, 1$ ,  $n_i^{(t)}$  will be used to denote the large and medium pieces remaining after the  $l$ & $m$ -pack for interval  $k$ .) We will set  $q = \infty$  to indicate that there are no more bins.

```

function update ( $q, (n_1^{(0)}, \dots, n_w^{(0)}; n_1^{(1)}, \dots, n_w^{(1)}; V_1, V_2, V)$ )
begin
   $V_1^{(1)} := V_1 \cdot \varepsilon^{k+2} - \sum_{i=1}^w n_i^{(0)} l_i^{(0)}$ 
  if  $V_1^{(1)} < 0$  then return (“failure”)
  if  $q \geq 2$  then
    begin
       $V_1^{(2)} := V_1^{(1)} + V_2 \cdot \varepsilon^{k+3} - \sum_{i=1}^w n_i^{(1)} l_i^{(1)}$ 
      if  $V_1^{(2)} < 0$  then return (“failure”)
    end
  if  $q \geq 3$  then
    begin
       $V_1^{(q)} := V_1^{(2)} + V \cdot \varepsilon^{k+4} - \sum_{t=2}^{q-1} \sum_{i=1}^w n_i^{(t)} l_i^{(t)}$ 
      if  $V_1^{(q)} < 0$  then return (“failure”)
    end
  if  $q < \infty$  then  $V_1 := V_1^{(q)} \cdot \frac{1}{\varepsilon^{k+q+2}}$ 
  case ( $q$ ) of
    1:  $V_1 := V_1 + V_2; V_2 := V$ 
    2:  $V_1 := V_1 + V; V_2 := 0$ 
    [3,  $\dots, \infty$ ):  $V_1 := V_1; V_2 := 0$ 
     $\infty$ :  $V_1 := 0; V_2 := 0; V := 0$ 
  endcase
  return ( $(n_1^{(q)}, \dots, n_w^{(q)}; n_1^{(q+1)}, \dots, n_w^{(q+1)}; V_1, V_2, 0)$ )
end

```

The procedure *update* may result in “failure,” in which case there is no arc originating at the node examined. Otherwise, the output of the function gives the state vector of the node into which the arc will be directed. It is important to notice that in implementing the procedure we will not scan each subinterval on the line, only those with  $n_i^{(t)} > 0$ . This is readily done, since the pieces are sorted. Also note that in the updating layer there is at most one arc originating at each node.

Following the updating process of the last interval in which bins are found, we add one more arc level to the final node, “success.” A node will have an arc from it to “success” if and only if its state vector is the zero vector  $(0, 0, \dots, 0; 0, \dots, 0; V_1, V_2, V)$ . It is somewhat simpler to avoid altogether the update layer at the end of the last interval and have arcs going directly to “success” based on the outcome of “update” only if the update procedure results in the zero state vector.

LEMMA 1. *The graph constructed has at most  $O(2m \cdot n^{2/\varepsilon^2+3} \cdot 1/\varepsilon^6)$  nodes.*

*Proof.* Each of the first and last layers contains exactly one node. All other layers of nodes correspond either to the beginning or the end of a bin interval, or to packing a bin within an interval. For each interval that contains at least one bin, the number of layers is equal to one more than the number of bins in the interval. Since there are  $m$  bins the total number of layers is no more than  $2m$ .

Each layer may contain all possible state vectors. The first  $2w \leq 2/\varepsilon^2$  entries describe the distribution of large and medium pieces remaining in the interval. Every subinterval may contain  $r \in \{0, 1, \dots, n\}$  pieces, so the number of such distributions is  $O(n^{2/\varepsilon^2})$ .

Finally,  $V_1, V_2, V$  express the unused capacities that may be used to pack small pieces. Consider first  $V_1$ ; since each small piece for these bins is of size at most  $\epsilon^k$ , and there are no more than  $n$  small pieces, any volume beyond  $n\epsilon^k$  is irrelevant. The value  $V_1$  is actually given as the scalar multiple of  $\epsilon^{k+2}$ , so multiples beyond  $n \cdot \epsilon^k / \epsilon^{k+2} = n/\epsilon^2$  may be equivalently represented. Identical calculations show that for  $V_2$  and  $V$  as well, it is sufficient to consider only  $n/\epsilon^2$  possible values, where the largest value represents all remaining positive volumes. The total number of state vectors is hence  $O(2m \cdot n^{2/\epsilon^2} (n/\epsilon^2)^3)$ , as claimed.

LEMMA 2. *The number of arcs originating at each node is  $O((1/\epsilon^2)^{2/\epsilon^2})$ .*

*Proof.* Each arc corresponds to a feasible configuration  $(x_1, \dots, x_w; \bar{x}_1, \dots, \bar{x}_w)$ . The number of large pieces from a subinterval  $x_i$  that can go in a bin is in  $\{0, 1, \dots, 1/\epsilon\}$ , whereas the number of medium pieces  $\bar{x}_i$  can vary from 0 up to  $1/\epsilon^2$ . The total number of feasible configurations is therefore bounded by  $(1/\epsilon + 1)^{1/\epsilon^2} (1/\epsilon^2 + 1)^{1/\epsilon}$  which is  $O((1/\epsilon^2)^{2/\epsilon^2})$ .

COROLLARY 2. *The total number of arcs in the graph is  $O(2m(n/\epsilon^2)^{(2/\epsilon^2)+3})$ .*

Once the graph is available, the existence of a path from initial to success can be verified in time linear in the number of arcs. This computation also yields a specific path. We now prove that if there is a truly feasible packing then such a path indeed exists, and if such a path exists, then we can construct a  $(2\epsilon + \epsilon^2)$ -relaxed feasible packing. These two claims are sufficient to yield a  $(2\epsilon + \epsilon^2)$ -relaxed decision procedure.

LEMMA 3. *If there is a truly feasible packing, then there is a path in the multilayered graph from “initial” to “success.”*

*Proof.* Given a truly feasible packing, it is possible to label every piece in the  $k$ th interval  $(\epsilon^{k+1}, \epsilon^k]$  as  $L^{(k)}, M^{(k)}$ , or  $S^{(k)}$ , depending on the size of the bin in which it is packed:

- $j \in L^{(k)}$  if piece  $j$  is packed as large—in a bin in interval  $k$ ;
- $j \in M^{(k)}$  if piece  $j$  is packed as medium—in a bin in interval  $k - 1$ ;
- $j \in S^{(k)}$  if piece  $j$  is packed as small—in a bin in one of the intervals  $0, 1, \dots, k - 2$ .

In addition, let  $P^{(k)}$  denote all of the pieces in interval  $k$ .

Each node in the first layer of a stage is labeled with a state vector that specifies pieces as well as unused capacities. We will show by induction that certain induced partial packings of the truly feasible packing yield paths in the layered graph. The lemma will follow as a corollary to this stronger inductive assertion, which we will give below. Given a truly feasible packing, consider the partial packing induced by the pieces,  $M^{(k)} \cup (\cup_{i=0}^{k-1} P^{(i)})$ . This leaves a certain amount of slack  $v_1^{(k)}$  and  $v_2^{(k)}$  in the bins in the intervals 0 through  $k - 2$  (enormous bins) and in interval  $k - 1$  (huge bins), respectively.

We claim that there is a path from initial to some node in the first layer of stage  $k$  (so that interval  $k$  must contain bins) such that the state vector of that node has  $V_1 \geq v_1^{(k)}, V_2 \geq v_2^{(k)}$  and has the piece distribution of  $(L^{(k)} \cup S^{(k)}; P^{(k+1)})$ .

The claim is certainly true for  $k = 0$ , where there is a trivial path from the initial node to itself, and the initial node does have the appropriate state vector. (Note that  $M^{(0)}$  must be the empty set.)

Inductively, we can then assume that at the beginning of stage  $k$  (which contains bins) we have a path to a state vector labeled with the as-yet-unpacked pieces from interval  $k$ , all of the pieces from interval  $k + 1$ , and appropriate upper bounds on the slacks. Focus now on the packing of the bins in interval  $k$ . For each bin we have a truly feasible packing of the large and medium pieces, and this specifies a feasible

configuration. This configuration corresponds to an arc in the graph. Now we consider the change in the value of  $V$  between the tail and head of this arc. This change is the usable slack (properly represented), which is at least the true slack—for two reasons. First, we effectively round the size of the bin to the next largest multiple of  $\epsilon^{k+4}$ , and second we use the rounded (down) sizes of the pieces to compute the usable slack. Thus at each layer within the stage, the value of  $V$  in the state vector is at least as large as the actual slack in the truly feasible packing. The reader can verify with little difficulty that following the arcs specified by the feasible configurations generated by the given packing must lead to a node in the final layer of the stage that is labeled with a state vector with piece distribution corresponding to  $(S^{(k)}; L^{(k+1)} \cup S^{(k+1)})$  and where the total usable slack value  $V$  is at least the true slack.

It remains only to show that the update arcs are also present as needed. Consider the case where interval  $k + 1$  also contains bins. In this case, we need only show that the volume represented by  $V_1$  is at least  $\sum_{j \in S^{(k)}} \bar{p}_j$ , since then there is an update arc, and it leads to a node that satisfies the induction hypothesis. However, this inequality is easy to verify, since  $v_1^{(k)} \geq \sum_{j \in S^{(k)}} p_j$  and we know that  $V_1 \geq v_1^{(k)}$  (by induction) and  $p_j \geq \bar{p}_j$  (by definition). The remaining cases for the size of the next bin (corresponding to  $q = 2$ ,  $q \in [3, \infty)$  and  $q = \infty$ ) follow by similar calculations.

LEMMA 4. *If there is a path in the graph from initial to success, then there is a  $(2\epsilon + \epsilon^2)$ -relaxed feasible packing.*

*Proof.* There are two types of arcs in the graph, *l&m-pack* arcs that correspond to a feasible configuration, and the update arcs. The relaxed packing is done by tracing the path from initial to success as follows. Each bin has an arc along the path that specifies the *l&m-pack* of pieces in the bin. We pack bins in order of decreasing size (as they are encountered on the path) according to the feasible configuration specified by the arc (arbitrarily choosing pieces from each subinterval). It will be convenient to view the piece as having its rounded size, and later we will consider the effect of inflating it to its true size. In the updating phase at the end of the stage for interval  $k$ , we pack the remaining pieces from interval  $k$  as small pieces. An unpacked piece  $j$  with size in  $(\epsilon^{k+1}, \epsilon^k]$  is packed in any enormous bin  $l$  (in intervals  $1, \dots, k - 2$ ), with *positive* usable slack $_l$ . Recall that for a bin interval  $k$  its usable slack is computed as if the volume of the bin were rounded to the next highest multiple of  $\epsilon^{k+4}$ . We then update usable slack $_l := \max\{\text{usable slack}_l - \bar{p}_j, 0\}$ . This *small-pack* phase is always successfully completed since there is an update arc if and only if there is sufficient total slack to accommodate all pieces to be packed as small pieces, and the total usable slack is at least as large. Therefore, we are also able to construct a packing from the path.

Consider the (rounded) pieces packed into bin  $i$  where the size of bin  $i$  is  $s_i$ , which is in interval  $k$ . Focus on the small piece  $j$  that, when added to the bin, exhausts the usable slack; suppose that piece  $j$  is in interval  $k + 2$ . (It certainly cannot be in an interval of smaller index, since it must be small for bin  $i$ .) In this case, all pieces in the bin have rounded sizes that are multiples of  $\epsilon^{k+4}$ , and in fact, before piece  $j$  was added, the rounded piece sizes did not exceed  $s_i$ . Hence, the bin contains at most  $s_i + \epsilon^{k+2}$  in terms of rounded sizes. If piece  $j$  comes from an interval greater than  $k + 2$ , then the bin clearly contains total rounded size no more than  $s_i + \epsilon^{k+4} + \epsilon^{k+3}$ , which is less than  $s_i + \epsilon^{k+2}$  (since  $\epsilon \leq 1/2$ ). Therefore, if  $B_i$  is the set of pieces packed in bin  $i$ ,

$$\sum_{j \in B_i} \bar{p}_j \leq s_i + \epsilon^{k+2} \leq s_i + \epsilon s_i = (1 + \epsilon)s_i.$$

Furthermore, for any piece  $j$ ,  $p_j \leq (1 + \epsilon)\bar{p}_j$ , since if  $p_j \in (\epsilon^{k+1}, \epsilon^k]$ ,  $p_j \leq \bar{p}_j + \epsilon^{k+2} \leq \bar{p}_j + \epsilon\bar{p}_j$ . Combining these inequalities, we see that bin  $j$  is packed with (unrounded)

pieces of total size at most  $(1 + \varepsilon)(1 + \varepsilon)s_i$ . This is therefore a  $(2\varepsilon + \varepsilon^2)$ -relaxed feasible packing.

Thus, the procedure *all-pack* consisting of building the layered graph, finding a path from initial to success, and then (if possible) converting the path to a packing as described above, is a  $(2\varepsilon + \varepsilon^2)$ -relaxed decision procedure. By observing that  $2\varepsilon + \varepsilon^2 \leq \frac{5}{2}\varepsilon$  when  $\varepsilon \leq \frac{1}{2}$ , we see that the following theorem is a corollary of the previous discussion.

**THEOREM 2.** *For  $\varepsilon \leq \frac{1}{2}$ , the procedure *all-pack* delivers an  $\varepsilon$ -relaxed packing in  $O(m \cdot n^{(10/\varepsilon^2)+3})$  steps. Each step consists of one arc evaluation—at most  $(2/\varepsilon^2) - 1$  additions and one comparison, or for the update—at most  $n$  additions and 3 comparisons.*

**4. A  $\frac{1}{2}$ -relaxed decision procedure for bin packing with variable sizes.** In this section we consider a special case of the problem considered in the previous section: we fix  $\varepsilon = \frac{1}{2}$ . In other words, we wish to construct a procedure which, given an instance  $I = (J, S)$ , either concludes that no truly feasible packing exists, or else finds a  $\frac{1}{2}$ -relaxed feasible packing. Unlike the algorithm of the previous section, this algorithm is extremely simple and efficient. Once again, we assume that the bin sizes are  $s_1 \geq s_2 \cdots \geq s_m$ .

Consider the following recursive procedure:

```

procedure pack ( $J, S, m$ )
begin
  if  $\sum_{j \in J} p_j \leq \sum_{i \in S} s_i$  then
    begin
       $J_{\text{sml}} := \{j \mid p_j \leq s_m/2\}$ 
       $J_{\text{new}} := J - J_{\text{sml}}$ 
       $J_{\text{fit}} = \{j \in J_{\text{new}} \mid p_j \leq s_m\}$ 
      if  $J_{\text{fit}} \neq \text{empty}$  then
        begin
          choose  $\bar{j}$  such that  $p_{\bar{j}} = \max_{j \in J_{\text{fit}}} p_j$ 
          pack  $\bar{j}$  in bin  $m$  (+)
           $J_{\text{new}} := J_{\text{new}} - \{\bar{j}\}$ 
        end
         $S_{\text{new}} := S - \{m\}$ 
        if  $J_{\text{new}} \neq \text{empty}$  then call pack ( $J_{\text{new}}, S_{\text{new}}, m - 1$ )
        while there exists unpacked piece  $j \in J$ 
          find bin  $i$  packed with  $\leq s_i$  add piece  $j$  to bin  $i$  (*)
        end
      else
        output “no truly feasible packing”
      end
    end
  end

```

**LEMMA 5.** *If an instance  $I = (J, S)$  has a truly feasible packing then the instance  $I_{\text{new}} = (J_{\text{new}}, S_{\text{new}})$  created by procedure pack ( $J, S, m$ ) has a truly feasible packing.*

*Proof.* If  $(J, S)$  has a truly feasible packing, then certainly so does  $(J - J_{\text{sml}}, S)$ . Consider any such truly feasible packing. Since all of the pieces in  $J - J_{\text{sml}}$  are greater than  $s_m/2$  only one piece  $\bar{j}$  can be contained in bin  $m$ . If  $j \neq \bar{j}$  then form a new packing  $\tilde{}$  by interchanging these pieces. By the choice of  $\bar{j}$ ,  $p_j \leq p_{\bar{j}}$ , so the bin that contained  $\bar{j}$  before the interchange remains truly feasibly packed after the swap. Thus, by considering bins 1 to  $m - 1$ , we see that there is a truly feasible packing for the instance  $I_{\text{new}}$ .

**LEMMA 6.** *If the procedure pack ( $J, S, m$ ) outputs “no truly feasible packing” then there is no truly feasible packing.*

*Proof.* Suppose for a contradiction that there were a truly feasible packing. Then, by Lemma 5, for each recursive call of *pack* there is a truly feasible packing of the specified instance. However, for the failure message to be printed, the last of these instances must have  $\sum_j p_j > \sum_i s_i$ . This is clearly a contradiction, since no instance that has greater total piece size than total bin size can have a truly feasible packing.

LEMMA 7. *If the procedure  $\text{pack}(J, S, m)$  does not output “no truly feasible packing” then it successfully packs all pieces in a  $\frac{1}{2}$ -relaxed feasible packing.*

*Proof.* In considering the procedure *pack*, there is only one statement in which it could conceivably fail, and this is the statement indicated by (\*). Why should it always be possible to find a bin that is packed within its true capacity? If this were not possible, then all bins are packed beyond their true capacity, and then surely  $\sum_j p_j > \sum_i s_i$ . But this is precisely the situation we have excluded in this case of the **if** statement.

To show that the packing produced is  $\frac{1}{2}$ -relaxed feasible is also quite simple. Consider the two steps in the procedure in which pieces are packed. In the statement indicated by (+), we ensure that the piece fits within the true bin capacity. In statement (\*), we always add to some bin  $i$  a piece of size  $\leq s_m/2 \leq s_i/2$ , and since bin  $i$  previously contained  $\leq s_i$ , afterwards it contains no more than  $(3/2)s_i$ .

We now discuss an efficient implementation of the procedure  $\text{pack}(J, S, m)$ . We shall assume that the piece and bin sizes are given in sorted order. Note that the recursive procedure packs “large” pieces in bins of decreasing bin size, and then packs “small” pieces in bins of increasing size. It will be convenient to maintain two pointers to the sorted list of piece sizes: one to the largest piece no larger than the current bin size, and one to the smallest piece at least half the current bin size. By the monotonicity property just mentioned, only  $O(n)$  time is required to maintain these pointers, amortized over the running time of the procedure. Furthermore, given these pointers it is easy to see that the procedure can be implemented in linear time, since no piece need be “touched” more than a constant number of times. By combining these ideas with Lemmas 6 and 7, we get the following result.

THEOREM 3. *The procedure  $\text{pack}(J, S, m)$  is a  $\frac{1}{2}$ -relaxed decision procedure for the bin-packing problem with variable bin sizes. Furthermore, given the bin and piece sizes in sorted order, the algorithm runs in linear time.*

**5. Conclusions.** In considering the framework employed in the polynomial approximation scheme, it is important to note that this framework is not particular to this scheduling problem. As was discussed in [HS], the key notion in the success of this approach is a *dual approximation algorithm*. For the ordinary bin-packing problem, for example, an  $\varepsilon$ -dual approximation algorithm delivers a solution where the number of bins used is at most the optimum number, but is possibly infeasible. This infeasibility is bounded: each bin can contain no more than  $(1 + \varepsilon)$  times the original bin capacity.

The  $\varepsilon$ -relaxed decision procedure is essentially the same notion, except for the fact that there is no optimization involved. This can be fixed by considering the following generalized problem: given a set of pieces  $\{p_1, \dots, p_n\}$  and a profile of bin sizes  $s_1, \dots, s_m$  find the minimum number of copies of this profile needed to pack all of the pieces. It is quite simple to see how to convert the  $\varepsilon$ -relaxed decision procedure into an  $\varepsilon$ -dual approximation algorithm by using binary search.

We believe that this “dual approach” to approximation will continue to yield strong results in constructing approximation algorithms for problems for which good (traditional) approximation algorithms have been, heretofore, elusive. The work presented here certainly adds further confirming evidence.

## A GRAPH THEORETIC APPROACH TO STATISTICAL DATA SECURITY\*

DAN GUSFIELD†

**Abstract.** In this paper we study the problem of protecting sensitive data in an  $n$  by  $n$  two-dimensional table of statistics, when the nonsensitive data are made public along with the row and column sums for the table. A sensitive cell is considered unprotected if its exact value can be deduced from the nonsensitive cell values and the row and column sums. We give an efficient algorithm to identify all unprotected cells in a table. The algorithm runs in linear time if the sensitive values are known, and in  $O(n^3)$  time if they are not known. We then consider the problem of suppressing the fewest additional cell values to protect all the sensitive cells, when some cells are initially unprotected. We give a linear time algorithm for this problem in the useful special case that all cell values are strictly positive. We next consider the problem of computing the tightest upper and lower bounds on the values of sensitive cells. We show that each cell bound can be computed in  $O(n^3)$  time, but all  $\Theta(n^2)$  values can be computed in  $O(n^4)$  total time. In the case that all the cells are sensitive, we show that trivial methods compute the tightest bounds, and in fact, the  $n^2$  lower bounds can be computed in  $O(n)$  arithmetic and comparison operations. Although these problems at first appear to be problems in integer linear algebra, the solutions are based on computational graph theory, and the worst case times are significantly faster than for approaches based on linear algebraic computations.

**1. Introduction.** In this paper we study the problem of protecting sensitive data in a two-dimensional table of statistics when the nonsensitive data is made public. Work in this area was begun by Fellegi, Cox, and Sande [FEL], [COX75], [COX77], [COX78], [COX80], [SAN], and reported in Denning [DEN]. The general problem is motivated by concerns for privacy and security, and is a problem of practical importance and active interest for both the U.S. Census Bureau [USDC], and Statistics Canada [BCS]. For a more complete discussion of background and motivation see [DEN]. The problems considered in the paper all appear at first to be problems in integer linear algebra, but in this paper they are reduced to graph theoretical problems where they are more efficiently solved.

**1.1. Problem statements, definitions, and main results.** The basic setting for the paper is that one party (the Census Bureau, say) has a two-dimensional table,  $D$ , of cross-tabulated integer statistics; each entry  $D(i, j)$  is a nonnegative integer in cell  $(i, j)$  of  $D$ ;  $R(i)$  is the sum of the cell values in the  $i$ th row of  $D$ , and  $C(j)$  is the sum of the cell values in the  $j$ th column of  $D$ . We assume that  $D$  has at least two rows and at least two columns, and that each  $R(i)$  and  $C(j)$  is strictly positive. All the row and column sums are to be made public (disclosed) along with *some* of the cell values, but the remaining cell values, called *sensitive* values, are to be *suppressed* (not disclosed). Unless care is taken, however, the disclosure of the nonsensitive values might allow an adversary to deduce the *exact* value of one or more of the sensitive values. Hence, to avoid disclosing the exact value of any sensitive cell, the values of some nonsensitive cells may also need to be suppressed; these suppressions are called *complementary suppressions*. In a table  $D$ , the set of *suppressed cells* consists of the sensitive cells along with any complementary suppressed cells.

---

Given a table with suppressions, a suppressed cells is called *protected* if its exact value is not determinable from knowledge of only the row and column totals, and the values of the unsuppressed cells. To make this precise, let  $X$  be the set of all suppressed cells and for cell  $(i, j) \in X$ , let  $x(i, j)$  be a variable denoting the value of the cell. For each row  $i$  and column  $j$ , let  $R^*(i)$  and  $C^*(j)$  be, respectively, the sum of the undisclosed values in row  $i$  of  $D$ , and the sum of the undisclosed values in column  $j$  of  $D$ .

DEFINITION. Let  $R$  be the set of row indices and  $C$  be the set of column indices. For  $i \in R$ , let  $X(i)$  be the set of indices  $j \in C$  such that  $(i, j)$  is a suppressed cell. Similarly, for  $j \in C$ , let  $X(j)$  be the set of indices  $i \in R$  such that  $(i, j)$  is a suppressed cell.

DEFINITION. We define a *legal solution* of  $D$  as a nonnegative integer solution to the following system of linear equalities:

For each fixed  $i \in R$ ,  $\sum_{j \in X(i)} x(i, j) = R^*(i)$ , and

For each fixed  $j \in C$ ,  $\sum_{i \in X(j)} x(i, j) = C^*(j)$ .

DEFINITION. A cell  $(i, j)$  in  $X$  is *protected* if and only if there exists two legal solutions  $x_1$  and  $x_2$ , such that  $x_1(i, j) \neq x_2(i, j)$ .

DEFINITION. A table with suppressions is *protected* if and only if all of its suppressed cells are protected.

Notice that this definition of protection essentially implies that side information such as correlations between cell values or special bounds on cell values etc. are unknown to the adversary, or at least do not restrict the set of legal solutions. Most of the results in this paper can easily be extended to the cases when given upper and lower bounds on the values of individual cells are known to the adversary (provided that the Census Bureau knows what bounds the adversary is assuming); we will briefly discuss these extensions later. Notice also that the assumption that each  $R(i)$  and  $C(j)$  is strictly positive is reasonable, since without the assumption there is no way to protect the (all zero) entries in such a row or column.

In this paper we discuss four problems:

(a) (Census Bureau problem) Given knowledge of the complete, original table,  $D$ , and given a set of cells  $X$ , determine whether table  $D$  would be protected after the suppression of the values in set  $X$ .

We cast this problem as a graph theoretic problem and give an algorithm that identifies all unprotected cells and runs in linear time in the size of  $X$ .

(a') (Adversary problem) Given a table  $D$ , where the values in the set of cells  $X$  are suppressed, hence unknown, determine whether  $D$  is protected, and if not, determine the exact value of all the unprotected cells.

We reduce this problem to the Census Bureau problem, using a single maximum flow computation on a graph with  $|X|$  edges. Hence, after one maximum flow computation, the adversary problem can be solved, as above, in time linear in  $|X|$ .

(b) (Complementary Suppression problem) Given the full  $n \times m$  table  $D$ , and a set of sensitive cells  $X$  to be suppressed, determine the minimum number (and selection) of complementary suppressions needed so that all the sensitive cells are protected. This is a problem that the Census Bureau faces when choosing which cells to disclose in the case that additional suppressions are needed to protect the sensitive cells.

We solve this problem in time  $O((n + m)|X|)$ , for the case that all cell values are strictly positive. The solution is based on a computational problem in graph theory studied by Eswaran and Tarjan [ET]. In [G] we sketch a more complex linear time solution to this special case.

(c) (General Interval Estimation) Given a table with a set  $X$  of cell suppressions, determine the tightest upper and lower bounds on the values of each suppressed cell.

This is a generalization of problem (a') since a cell is protected if and only if the upper and lower bounds on its value are unequal.

We show how to compute each bound of a suppressed cell with a single  $O(n^3)$  time network flow computation. In an  $n \times n$  table with  $\Theta(n^2)$  sensitive cells, this yields an  $O(n^5)$  time algorithm to compute all the bounds. We then improve this running time to  $O(n^4)$ , by reducing the problem of computing all the upper bounds to a problem studied in [SC]. We also show the surprising result that in an  $n \times m$  table, there can never be more than  $n + m - 1$  distinct upper bound values, no matter how many cell values are suppressed.

(d) (Special Interval Estimation) In the case that all the cell values are suppressed, determine the tightest upper and lower bounds on the cell values. We show that trivial methods suffice here, and in fact, the lower bounds can be computed with  $O(\max [n, m])$  arithmetic operations and comparisons in an  $n \times m$  table, although the output has size  $nm$ .

In the published literature on these problems, problem (c) is solved by minimum cost flow or linear programming methods applied independently for each bound [COX77], [COX78], [COX80], [DEN]; problem (b) is solved by trial and error, iteratively using the upper and lower bounds computed by (c) [COX80]; problem (a) is solved by computing upper and lower bounds and checking for equality [COX80]; and no special, efficient method is discussed for problem (d). Hence the results here provide substantial theoretical and practical improvements for problems (a), (b), and (d), and a theoretical improvement in problem (c). It is an empirical question whether the simpler and faster (in worst case) network flow methods for problem (c) are better in practice than the linear programming methods suggested in the literature [COX78].

In actual systems concerned with statistical security, problems (a) and (c) are often in the inner loop of larger programs that repeatedly modify the table and then need to know if the cells are secure, or what the tightest bounds on their values are. For example, problem (b) is of that type. Hence any speedup in solving these two problems is particularly important.

**2. Determining if  $D$  is protected.** In this section, we discuss problem (a), giving a linear time algorithm to determine if  $D$  is protected. Although the Census Bureau problem was posed above as a problem in integer linear algebra, we will see that it is more effectively treated when viewed as a problem in computational graph theory.

**DEFINITION.** Graph  $H$  is a bipartite graph with node set  $R$  on one side representing the rows of table  $D$ , and node set  $C$  on the other side representing the columns of  $D$ . There is an edge  $(i, j)$  between node  $i$  on  $R$  and node  $j$  on  $C$  if and only if cell  $(i, j)$  is suppressed in  $D$ . An edge  $(i, j)$  in  $H$  is undirected if and only if  $D(i, j) > 0$ , and is directed from node  $i$  in  $R$  to node  $j$  in  $C$  if and only if  $D(i, j) = 0$ .

Figure 1 shows an example of a table  $D$  and Fig. 2 shows the graph  $H$  derived from  $D$ .

**DEFINITION.** We use the notation  $\langle i, j \rangle$  to indicate that edge  $(i, j)$  is directed from node  $i$  to node  $j$ . Where the distinction does not matter, we will use the term "edge" and the notation  $(i, j)$  to refer to either the undirected edge  $(i, j)$  or the directed edge  $\langle i, j \rangle$ .

**DEFINITION.** A cycle in  $H$  is called *traversable* if it is a simple cycle, and it is possible to walk around it without ever going opposite to the direction of any of the directed edges on it. Clearly any directed or undirected simple cycle is traversable. Note that an undirected edge in  $H$  can be used in one direction in one traversable cycle, and in the other direction in another traversable cycle.

FIG. 2

The following theorem reduces the Census Bureau problem to a graph theoretic problem.

**THEOREM 1.** *A suppressed cell  $(i^*, j^*)$  is protected if and only if its associated edge in  $H$  is contained in at least one traversable cycle in  $H$ .*

*Proof.* We first show sufficiency. Let  $SC$  be a traversable cycle in  $H$ . Arbitrarily pick a directed edge  $e$  in  $SC$ , and if there are none, then pick any edge  $e$  in  $SC$ . Starting with edge  $e$ , alternately label the edges around  $SC$  positive and negative. Since  $H$  is bipartite, the labeling is well defined, and since  $SC$  is traversable, all the directed edges will have positive labels. Let  $f$  be the minimum of the  $D(i, j)$  values of the negative labeled edges in  $SC$ . Adding  $f$  to  $D(i, j)$  for any positive labeled edge  $(i, j)$ , and subtracting  $f$  from  $D(i, j)$  for the negative labeled edge  $(i, j)$  gives a legal solution  $x$  to  $D$ , such that for any edge  $(i, j)$  on  $SC$ ,  $x(i, j) \neq D(i, j)$ . Hence all cells associated with edges in  $SC$  are protected.

To prove necessity, suppose cell  $(i^*, j^*)$  is protected and let  $x$  be a legal solution to  $D$  such that  $x(i^*, j^*) \neq D(i^*, j^*)$ . Define  $F(i, j) = x(i, j) - D(i, j)$ , for each suppressed cell in  $D$ . We represent  $F$  as a weighted bipartite graph,  $F^*$ , containing directed edge  $\langle i, j \rangle$ ,  $i \in R, j \in C$ , with weight  $F(i, j)$ , if  $F(i, j) > 0$ , and containing directed edge  $\langle j, i \rangle$ ,  $i \in R, j \in C$ , with weight  $F(i, j)$ , if  $F(i, j) < 0$ . Clearly, if there is no edge between nodes  $i$  and  $j$  in  $H$ , then there is none in  $F^*$ . Further, if  $\langle i, j \rangle$  is an edge in  $H$ , then edge  $\langle j, i \rangle$  cannot appear in  $F^*$ , since  $D(i, j) = 0$  and so  $F(i, j) = x(i, j) - D(i, j) \geq 0$ . Since  $x(i^*, j^*) \neq D(i^*, j^*)$ , either  $\langle i^*, j^* \rangle$  or  $\langle j^*, i^* \rangle$  is an edge in  $F^*$ . We will suppose that  $F^*$  contains edge  $\langle i^*, j^* \rangle$  and show that  $\langle i^*, j^* \rangle$  is contained in a traversable cycle in  $H$ . The case when  $F^*$  contains edge  $\langle j^*, i^* \rangle$  is symmetric.

First, note that for any fixed node  $i$  in  $F^*$ , the weights of all the edges incident with  $i$  sum to zero. Hence any node  $i$  in  $F^*$  that is incident with at least one edge is incident with at least one edge directed into  $i$  and one directed out of  $i$ ; we call this the *balance* property. It follows easily from the balance property, and from the fact

that  $\langle i, j \rangle$  is an edge in  $F^*$  only if  $\langle j, i \rangle$  is not, that there exists a traversable cycle,  $SC$ , in  $F^*$ , with at least four edges. Notice that in  $SC$  the signs on the edges alternate positive, negative around the cycle. Cycle  $SC$  must also be a traversable cycle in  $H$ , since every edge in  $SC$  is either in  $H$  with the same direction as in  $F^*$ , or is directed in  $F^*$  and undirected in  $H$ . Let  $f$  be the minimum absolute value of the weights of the edges on  $SC$ . We subtract  $f$  from each positive weight on  $SC$ , add  $f$  to each negative weight on  $SC$ , and remove any edges with resulting weight zero (there is at least one); the result is a subgraph of  $F^*$  which again has the balance property. We can therefore continue finding traversable cycles in  $F^*$ , and hence also in  $H$ , changing weights and removing edges each time, until there are no more edges left. Edge  $\langle i^*, j^* \rangle$  must be in at least one of these cycles, hence must be in a traversable cycle in  $H$ .  $\square$

Theorem 1 shows that for the question of protection, only the directions of the edges in  $H$  matter. This means that the only distinction that matters (in determining protection) is whether  $D(i, j)$  is zero or not. Notice also that the Census Bureau problem can be answered without needing to explicitly know  $R^*(i)$  or  $C^*(j)$ .

**2.1. Graph  $CG$ .** By Theorem 1, problem (a) can be solved by determining which (if any) of the edges of  $H$  are in no traversable cycles in  $H$ . We next solve this problem with a linear time algorithm that constructs the mixed graph  $CG$ ; the edges of  $CG$  are exactly those edges of  $H$  that are in no traversable cycles in  $H$ . Graph  $CG$  will also be central in the problem of minimizing the number of complementary suppressions. The construction of  $CG$  uses the graph theoretic objects of *bridges* and *strong components*. Definitions of these objects and algorithms to find them are fully developed in a number of texts, such as [AHU] and [EVE].

#### CONSTRUCTION OF GRAPH $CG$ .

(1) Find the strongly connected components of  $H$ . Let  $A$  be the set of edges running between these components. Clearly all the edges of  $A$  are directed edges in  $H$ .

(2) Consider each of the strong components as a separate undirected graph, ignoring the directions on any directed edges. Find all (if any) bridges in each of the separate graphs, and let  $B$  be the set of bridges found. It is easily proved that any edge in  $B$  is an undirected edge in  $H$ .

(3) Let  $K$  be the graph induced by the edges of  $H$  minus  $A \cup B$ , and let  $K(1), \dots, K(r)$  be the connected components of  $K$ . Graph  $CG$  is formed by condensing each  $K(i)$  in  $H$ . Hence each node in  $CG$  is in 1-1 correspondence with some  $K(i)$ , and the edges of  $CG$  are exactly  $A \cup B$ .

In Fig. 3, graph  $CG$  is constructed from  $H$  shown in Fig. 2.

**THEOREM 2.** *Edge  $\langle i, j \rangle$  is in no traversable cycle in  $H$  if and only if  $\langle i, j \rangle$  is in  $A \cup B$ . That is, cell  $\langle i, j \rangle$  is unprotected if and only if nodes  $i$  and  $j$  are in different components of  $K$ .*

*Proof.* First any edge which is in a traversable cycle in  $H$  is in some strong component of  $H$ , and so no edge in set  $A$  is in a traversable cycle. Second, any directed edge  $\langle u, v \rangle$  in a strong component is traversable, since, by definition of strong component, there must be a traversable path  $P$  from  $v$  to  $u$  in  $H$ . So edge  $\langle u, v \rangle$  followed by path  $P$  is a traversable cycle in  $H$ . Hence  $A$  exactly contains the directed edges that are on no traversable cycles. Now we consider which undirected edges of  $H$  are traversable. Since no edge in  $A$  is in a traversable cycle, we can delete set  $A$  from  $H$  without affecting which undirected edges are traversable. Any bridges in the resulting graph (considered undirected) are clearly nontraversable, so all edges in  $B$  are nontraversable. What remains to be shown is that any undirected edge  $\langle u, v \rangle$  not in  $B$  is in some traversable cycle in  $H$ . Since  $\langle u, v \rangle$  is not a bridge in the strong component it

FIG. 3. Construction of graph  $CG$  from  $H$ . Figure 3(a) shows the two strong components  $\pi(1)$  and  $\pi(2)$  of  $H$ . In  $\pi(1)$  the bridges are  $(R_3, C_2)$  and  $(R_3, C_3)$ . There are no bridges in  $\pi(2)$ . The edges of set  $A$  are  $(R_1, C_4)$  and  $(R_3, C_5)$ . Figure 3(b) shows graph  $CG$ .

is contained in, there must be a path  $P$  in  $H$ , not containing edge  $(u, v)$ , connecting (ignoring the directions of the edges on  $P$ ) node  $u$  and node  $v$ . If  $P$  is traversable in either direction, we are done. If  $P$  is not traversable, let  $\langle x, y \rangle$  be the first directed edge on  $P$  such that the walk from  $u$  to  $v$  on  $P$  goes in the wrong direction, i.e., from  $y$  to  $x$ . Since  $\langle x, y \rangle$  is not in set  $A$ , it is on some traversable cycle in  $H$ , and so there is a traversable path,  $P'$ , from  $y$  to  $x$  in  $H$ . Now the path consisting of  $P$  to  $y$ ,  $P'$  to  $x$ , and  $P$  to  $v$  is a path from  $u$  to  $v$  which traverses one less edge in the wrong direction than does  $P$ . By repeating this argument, a traversable path in  $H$  from  $u$  to  $v$  can be found, and hence  $(u, v)$  is in a traversable cycle in  $H$ .  $\square$

Hence problem (a) can be solved in time linear in the size of  $X$ , as it is well known [AHU], [EVE] that strong components and bridges can be found in time linear in the number of edges and nodes in the graph.

Figure 3 shows that cells  $(1, 4)$ ,  $(3, 2)$ ,  $(3, 3)$ , and  $(3, 5)$  of table  $D$  in Fig. 1 are unprotected.

**2.2. Solving the adversary problem (a').** Let  $x$  be any legal solution to  $D$ , and let  $D(x)$  be the complete table formed by assigning  $x(i, j)$  to each suppressed cell  $(i, j)$  in  $D$ . It follows by the definition of protection that any suppressed cell is unprotected in  $D(x)$  if and only if it is unprotected in  $D$ . Hence, although the adversary does not have the full original table  $D$ , if he knows *any* legal solution  $x$  to  $D$ , then he can input  $D(x)$  to the above algorithm and determine which cells in  $D$  are unprotected. If  $(i, j)$  is such a cell, then  $D(i, j) = x(i, j)$ , and hence the adversary knows its value.

We now show that a legal solution to  $D$  can be found in time  $O(n^3)$  using network flow.

**2.2.1. Finding a legal solution.**

**DEFINITION.** Network  $G$  is constructed from graph  $H$  as follows: first direct each edge  $(i, j)$  in  $H$  from  $i \in R$  to  $j \in C$ , and give each such edge a capacity of infinity; then add a node  $s$  to  $H$  and a directed edge from  $s$  to each node of  $R$ , and a node  $t$

to  $H$  and a directed edge from each node of  $C$  to  $t$ . The capacity of each edge  $\langle s, i \rangle$  is set to  $R^*(i)$ , and the capacity of each edge  $\langle j, t \rangle$  is set to  $C^*(j)$ . Let  $T$  be the sum of the capacities of the edges out of  $s$  ( $T$  is also the sum of the edge capacities of the edges into  $t$ ).

DEFINITION. A flow function  $F$  is an assignment of a nonnegative real number,  $F(i, j)$ , to each directed edge  $\langle i, j \rangle$  of  $G$  such that  $F(i, j)$  is less than or equal to the capacity of edge  $\langle i, j \rangle$  and so that for every node  $i \neq s, t, \sum_j F(i, j) = \sum_j F(j, i)$ . The quantity  $\sum_i F(s, i)$  is called the *value* of the flow, and it also equals  $\sum_i F(i, t)$ . A flow is called a *maximum flow* if its value is maximum over all flows in  $G$ . A flow is called *integral* if  $F(i, j)$  is an integer for every edge  $\langle i, j \rangle$ .

It is known [FF] that a maximum integral flow exists if the capacities on all the edges are integers. The following fact is immediate.

FACT 1. Let  $D$  and  $G$  be as above and let  $x$  be any legal solution of  $D$ . If  $F(i, j)$  is set to  $x(i, j)$  for each  $(i, j)$  in  $X$ , then  $F(i, j)$  is an integral maximum flow in  $G$  of value  $T$ , i.e.,  $F$  is an integral flow that saturates all edges out of  $s$ , and these edges form an  $s-t$  cut in  $G$ . Conversely, any integral maximum flow in  $G$  (of value  $T$ ) defines a solution to  $D$  in the analogous way:  $x(i, j) \leftarrow F(i, j)$  for  $(i, j) \in X$ . Hence a suppressed cell  $(i, j)$  in  $D$  is protected if and only if there exists two integral flows  $F_1$  and  $F_2$  in  $G$ , each of value  $T$ , such that  $F_1(i, j) \neq F_2(i, j)$ .

The example in Fig. 4 illustrates the above definitions and fact.

It is well established that the maximum flow can be found in time  $O(n^3)$  in a graph with  $O(n)$  nodes, and for sparse graphs, the maximum flow can be found in

FIG. 4. Graph  $G$  derived from  $D$ . A maximum flow  $F$  is indicated on the center edges.

time  $O(nE \log n)$ , where  $E$  is the number of edges in the graph [ST]. Recent papers on network flow have improved these time bounds to  $O(nE \log(n^2/E))$  [GT], and  $O(nE + n^2 \log(c_{\max}))$  [AO], where  $c_{\max}$  is the largest capacity in the network. It has also been established [GMB] that for an  $n \times m$  table where  $n < m$ , the flow can be found in  $O(n^2 m)$  time rather than  $O((n+m)^3)$ ; this distinction is important when  $n \ll m$ .

Note that problem (a) is solved in linear time while problem (a') first requires the computation of a maximum flow. These two solutions are essentially the same, but in problem (a), the Census Bureau has the advantage that it knows a particular legal solution for free, namely the one corresponding to  $D$  itself.

**3. Optimizing complementary suppressions.** In this section, we will use  $H$  and  $CG$  to represent and help determine the optimal complementary suppressions in  $D$ ; we will see that this problem can be cast as a graph augmentation problem on  $CG$ .

Each complementary suppression in  $D$  charges graph  $H$ : if cell  $(i, j)$  is suppressed and  $D(i, j) = 0$  then the directed edge  $\langle i, j \rangle$ ,  $i \in R, j \in C$ , is added to  $H$ , and if  $D(i, j) > 0$  then the undirected edge  $(i, j)$  is added to  $H$ . This direct correspondence between cell suppressions in  $D$  and edge additions in  $H$ , combined with Theorem 1, implies that the complementary suppression problem can be solved by taking any  $H$  and adding the fewest number of edges corresponding to complementary suppressions in  $D$ , so that every edge in the resulting graph is in some traversable cycle. Problems of this type are called *graph augmentation* problems.

It is easy to see (and prove) that the complementary suppression problem can be solved using  $CG$  in place of  $H$ , i.e., the smallest set of edges that must be added to  $CG$  so that every edge is traversable, is also the smallest set that must be added to  $H$  to make every edge in it traversable, and vice versa. What makes this augmentation problem difficult, is that only those edges corresponding to unsuppressed cells in  $D$  can be added to  $CG$ , and if  $(i, j)$  is an unsuppressed cell where  $D(i, j) = 0$ , then the edge corresponding to cell  $(i, j)$  is the *directed* edge  $\langle i, j \rangle$ ,  $i \in R, j \in C$ .

The above complementary suppression problem has been shown to be NP-complete [KG], but the graph  $CG$  is still useful, since one can quickly see the effect of any proposed complementary suppressions. This leads to efficient implementation of heuristics (such as those suggested in [COX80]) based on hill climbing and incremental optimization, i.e., incrementally selecting a suppression that makes the most edges traversable, updating  $CG$ , and repeating until every edge is in some traversable cycle. Further, there are useful special cases of the complementary suppression problem that can be efficiently solved. In the following section, we solve the case when  $D(i, j) > 0$  for every cell in  $D$ . This assumption is valid for a large class of problems, and is of practical interest. We can also apply the solution to the more general class of problem where  $D(i, j) > 0$  for every sensitive cell, but where other cells in  $D$  may have zero value.

**3.1. Special case:  $D$  strictly positive.** In this section, we optimally and efficiently solve the complementary suppression problem under the assumption that  $D(i, j) > 0$  for every cell in  $D$ . This condition is often satisfied in certain classes of Census Data, and the agent with the complete table can exploit the condition when it arises. We should note, however, that for the definition of protection to remain relevant, the adversary must not know when these special cases arise. That is, the adversary must work in the solution space that includes zero, while the Census Bureau can exploit more restrictive assumptions when appropriate. In this section, we present a simple  $O((n+m)|X|)$  time method based on a related problem and solution studied by Eswaran and Tarjan [ET]. In [G], we examine a more general class of graph augmenta-

tion problems (containing the special case discussed here) and sketch a solution to those problems that solves the special case in  $O(|X|)$  time. The faster solution is more involved than the one given here.

*Unlabeled graph augmentation.* In [ET], the following problem is solved: Given a forest,  $FG$ , of undirected trees, add the fewest number of undirected edges to  $FG$  so that every edge is in a simple cycle (hence of length at least three), where it is permitted to add an edge between *any* pair of nodes in  $FG$ . In our applications, we will only need the solution to this problem when  $FG$  is a single tree and contains at least three leaves (isolated nodes never arise in our applications, and the complementary suppression problem for two leaves is easy to solve directly). We sketch the solution of the unlabeled graph augmentation problem given in [ET], for the case of  $FG$  a single tree.

#### ALGORITHM ET

1. Number the leaves of  $CG$  in pre-order, i.e., traversing the tree by depth-first search, the leaves are numbered in the order that they are reached. Let  $v(i)$  be the  $i$ th leaf reached.

2. Suppose  $FG$  has  $p$  leaves and  $k = \lfloor p/2 \rfloor$ . Add an edge between leaves  $v(i)$  and  $v(k+i)$ , for  $i = 1$  through  $k$ . If  $p$  is odd ( $p = 2k + 1$ ), then add an edge between  $v(p)$  and any other leaf in  $FG$ .

For a proof that this solution is correct, see [ET]. Note that Algorithm ET clearly runs in time linear in the number of edges of  $FG$ .

*Labeled augmentation: modifying ET.* When table  $D$  is strictly positive,  $CG$  is a forest of undirected trees. If we take  $CG$  in place of  $FG$  and use Algorithm ET (adding  $\lfloor p/2 \rfloor$  edges and yielding graph  $CG^*$ ) we may not end up with a solution to the complementary suppression problem since “illegal” edges (those not corresponding to unsuppressed cells in  $D$ ) may have been added. We give here an  $O((n+m)|X|)$  time algorithm that takes  $CG^*$  and transforms it to obtain an optimal solution to the suppression problem. We first need some definitions and observations.

**DEFINITION.** In  $CG$  we give a node the label of  $R$  if it is a node on the  $R$  side of  $G$ , we give it the label  $C$  if it is on the  $C$  side of  $G$ , and we give it the label  $B$  if it is a condensed node and therefore contains nodes of  $G$  from both  $R$  and  $C$ . Let  $r$ ,  $c$  and  $b$  be the number of leaves of  $CG$  labeled  $R$ ,  $C$ , and  $B$ , respectively.

Given this notation, the complementary suppression problem for the case that  $D$  is strictly positive is a graph augmentation problem on  $CG$  with the constraint that no  $(R, R)$  edges or  $(C, C)$  edges may be added. We will refer to this graph augmentation problem as the *labeled augmentation problem*.

**FACT 2.** Assuming  $r \leq c$ , a simple lower bound on the size of the optimal solution of the labeled augmentation problem is  $c$  if  $r + b \leq c$ , and is  $\lfloor (r + c + b)/2 \rfloor$  otherwise. We will see that this bound can be exactly met.

*Assumption.* We will assume that  $CG$  has  $p = r + b + c > 2$  leaves, that  $p$  is even, that  $r \leq c$ , and until § 3.1.4, that  $r + b \geq c$ . The complementary suppression problem is trivial when  $p = 2$ . When  $p$  is odd, we reduce the analysis to the even case as follows: If  $r + b \geq c$  and  $p$  (defined as  $r + b + c$ ) is odd, it follows that  $r + b > c$ ; we remove from  $CG$  any  $B$  leaf and the unique path from it to a node of degree three or more, creating a forest with an even number of leaves where  $r + b \geq c$ . The solution to the labeled augmentation problem when  $p$  is odd is then obtained by taking the solution to the reduced case ( $p$  even) and adding an edge from the deleted  $B$  leaf to any other leaf. In § 3.1.4 we will briefly discuss the case that  $r + b < c$ .

*CG a single tree.* To explain the general idea of transforming the solution given by Algorithm ET into a solution of the labeled augmentation problem, we first assume that *CG* is a single tree; later we discuss how to handle the case of *CG* a forest.

DEFINITION. Let  $E^*$  initially be the set of edges added to *CG* by Algorithm ET, and let  $CG^*$  be the graph resulting from adding  $E^*$  to *CG*.

We note the following consequence of Algorithm ET, which is an easy extension of the correctness proof of ET given in [ET].

FACT 3. When *CG* is a single tree, every edge in *CG* is in a cycle in  $CG^*$  containing exactly one edge of  $E^*$ . That is, let  $C(e)$  be the unique cycle created by adding an edge  $e$  of  $E^*$  to *CG*, and let  $CC$  be the set of all such cycles, then every edge in *CG* is contained in at least one cycle of  $CC$ . When edge  $e'$  of *CG* is in  $C(e)$ , we say that edge  $e$  covers edge  $e'$ .

THEOREM 3.  $E^*$  can be transformed into an optimal solution to the labeled augmentation problem in time  $O((n + m)|X|)$ .

*Proof.* If  $E^*$  contains no  $(R, R)$  edge and no  $(C, C)$  edge then it is a solution to the labeled augmentation problem. However, if there is an  $(R, R)$  edge,  $e$ , in  $E^*$ , then since  $r \leq c$ , there must also be either a  $(C, C)$  edge or a  $(C, B)$  edge in  $E^*$ . Suppose there is a  $(C, C)$  edge,  $e'$ , in  $E^*$ ; the case of  $(C, B)$  is similar. Let  $S$  be the unique smallest subgraph of *CG* that connects the endpoints of  $e$  and  $e'$ . These four endpoints are leaves of  $S$ , and the topology of  $S$  is one of the three cases shown in Fig. 5. In each of the three cases there is a way to add two  $(R, C)$  edges between the endpoints of  $e$  and  $e'$  so that every edge of  $S$  is in a cycle consisting of edges of  $S$  plus exactly one of the two new edges, i.e., every edge in  $S$  is covered by one of the new edges. For example, in the first case we add an edge between the upper left  $C$  and lower right  $R$ , and an edge between the upper right  $C$  and the lower left  $R$ . Now in  $CG^*$ , all edges covered by  $e$  and  $e'$  are in  $S$ , and so by Fact 3, every edge in *CG* not in  $S$  is covered by some edge of  $E^* - \{e, e'\}$ . Hence we can delete  $e$  and  $e'$  from  $E^*$ , and add the appropriate two new  $(R, C)$  edges to  $E^*$ , so that every edge in *CG* is again covered by some edge in  $E^*$ . Note also that  $E^*$  remains disjoint from the edges of *CG*. We call such a set of edge deletions and insertions an *edge exchange*. By successive edge exchanges we can find a set of edges,  $E^*$ , containing no  $(R, R)$  edges, such that every edge in *CG* is covered by an edge in  $E^*$ . Note that in these edge exchanges, the size of  $E^*$  remains constant.

FIG. 5. Cases for edge exchanges. Each line represents a path between the endpoints.

Suppose now that  $E^*$  contains no  $(R, R)$  edges; we will remove all the  $(C, C)$  edges in  $E^*$  using edge exchanges similar to those above. If there is a  $(C, C)$  edge in  $E^*$ , but no  $(R, R)$  edge, then there must be either an  $(R, B)$  or a  $(B, B)$  edge in  $E^*$  (this follows by arithmetic from the assumptions that  $r \leq c$  and  $r + b \geq c$ ). We can again do an edge exchange to replace a  $(C, C)$  and, say, a  $(B, B)$  edge with two appropriate  $(C, B)$  edges, maintaining the size of  $E^*$ , and the property that every edge of *CG* is covered by an edge of  $E^*$ . We repeat until  $E^*$  contains no  $(R, R)$  or  $(C, C)$  edges, and

note that  $|E^*|$  has remained constant, and that  $E^*$  has throughout been disjoint from the edges of  $CG$ .

The set  $E^*$  is now a solution to the labeled augmentation problem. It is easy to see that it is optimal, since  $|E^*| = p/2 = (r + c + b)/2$ , the lower bound noted in Fact 2.

To analyze the time needed for the transformation, note that at most  $(r + c)/2$  edge exchanges are needed, and the cost of each is bounded by the number of edges in  $CG$ . Both  $(r + c)$  and the number of edges in  $CG$  are bounded by  $(n + m)$  and by  $|X|$ , hence  $O((n + m)|X|)$  time suffices. Note that this could be reduced to  $O(|X|)$  time if, in every edge exchange, both of the possible pairs of edge additions maintain the cover of the edges of  $S$ . However, as shown in the first case of Fig. 5, it is not true that both pairs of edge additions maintain the cover.  $\square$

*Labeled augmentation when  $CG$  is a forest.* In general,  $G$  may not be connected and so  $CG$  will not be a single tree. We now solve the labeled augmentation problem in the case that  $CG$  is a forest. The idea is that we first add a set of node disjoint edges (where no node is incident with more than one edge in the set) between leaves to connect the trees of  $CG$  into a single tree,  $T^*$ , and then solve the problem as before. We must be careful in the way that we add edges to form  $T^*$ . We call the first edge additions (forming  $T^*$ ) phase one, and the next edge additions (done by Algorithm ET) phase two, which is then followed by any needed edge exchanges. We let  $E^*$  now start with only those edges added in phase two. However, we must be careful about which edges are added in phase one, because when  $CG$  is a forest, Fact 3 is no longer true, i.e., it is not true that in  $CG^*$  every edge of  $CG$  is in some cycle containing *only one* edge of  $CG^* - CG$  (see Fig. 6).

FIG. 6.  $CG$  is shown in solid and the optimal augmentation is dashed. No edge in  $CG$  is covered by just a single edge of the optimal solution.

Fact 3 was crucial in the proof that all edges remain traversable after an edge exchange, and the edge exchange operation and argument become much more complicated if we ever remove edges added in phase one. To get around this problem, we want to be sure that the edges added in phase one can appear together in an optimal solution to the labeled augmentation problem. If so, then these edges become fixed after phase one, and the remaining problem is exactly the labeled augmentation problem for the single tree  $T^*$ .

**THEOREM 4.** *The trees of  $CG$  can be connected (forming  $T^*$ ) by node disjoint, phase one, edges such that there exists an optimal solution of the labeled augmentation problem for forest  $CG$ , containing all of those phase one edges.*
