*Proof.* We first arbitrarily relabel  $(b+c-r)/2$  of the  $B$  leaves in  $CG$  to be  $R$  leaves, and relabel the remaining  $(b+r-c)/2$   $B$  leaves to be  $C$  leaves. The effect is that  $CG$  now contains an equal number of  $R$  and  $C$  leaves and no  $B$  leaves. We now claim that it is possible to connect  $CG$  into a single tree,  $T^*$ , using a set of node disjoint  $(R, C)$  edges. In fact, this can be done myopically: as long as  $CG$  is not connected there must exist two components in  $CG$  such that one contains an  $R$  leaf and one contains a  $C$  leaf. To see this, suppose that  $CG$  is not connected, and let  $CC$  be a component containing an  $R$  leaf. Since each component is a tree, each component has a leaf, and if a component other than  $CC$  has a  $C$  leaf, the claim is proved. If there are no  $C$  leaves outside of  $CC$ , then all leaves outside of  $CC$  are  $R$  leaves, and one of these can be connected to a  $C$  leaf in  $CC$ . There must be such  $C$  leaves, since the number of  $R$  and  $C$  leaves are equal before any phase one edge additions and this equality is maintained with each edge addition.

After  $T^*$  is formed, the number of  $R$  and  $C$  leaves are still equal, hence the number of  $(R, R)$  edges added by Algorithm ET (in solving the unlabeled augmentation problem on  $T^*$ ) must equal the number of  $(C, C)$  edges added. Edge exchanges strictly between these (phase two) edges can then be done to form a legal solution to the labeled augmentation problem for  $CG$ . This solution contains all phase one edges, and is optimal since it adds exactly  $p/2$  edges. Hence there exists an optimal solution to the labeled augmentation problem for  $CG$ , containing all the phase one edges.  $\square$

There are other ways of connecting the trees in phase one, and it is often useful to have several choices available. This is particularly true for the case when  $D(i, j) > 0$  for the sensitive cells, but nonsensitive cells can be zero (see [G] for a more complete discussion of this).

*Labeled augmentation when  $r+b < c$ .* We briefly discuss the labeled augmentation problem in the case when  $r+b < c$ . We assume that  $r+b \geq 1$  since the complementary suppression problem is simple to solve directly when  $CG$  only has  $C$  leaves. When  $r+b < c$ , at least  $c$  edges must be added. If  $CG$  is a single tree, we can achieve this bound by taking the solution given by ET (which contains  $p/2$  edges) and make edge exchanges until the only edges in  $E^*$  are  $(R, C)$ ,  $(C, B)$  and  $(C, C)$  edges. This can always be done since  $r+b < c$ . At this point we can arbitrarily pick an  $R$  or  $B$  node,  $v$ , in  $CG$ , delete all  $(C, C)$  edges from  $E^*$  and attach each exposed  $C$  leaf to  $v$ . In the case that  $CG$  is a forest, a similar argument to those above shows a way to connect the forest with phase one edges which have the property that they can be together in an optimal solution. As before, the problem then reduces to the case of a single tree. Unlike the previous case, however, the phase one edges need not all be node disjoint, since even in the case of a single tree, as many as  $c-(r+b)$  edges may touch nodes that are touched by other edges of the augmentation.

Figure 7 shows a complete example of complementary suppression when  $D$  is strictly positive. Since cycles in  $H$  are traversable when  $D$  is strictly positive, we only indicate which cells have been suppressed, and can ignore all numerical values.

*Labeled augmentation and necessary conditions for protection.* Cox in [COX80] discusses the utility of using simple necessary conditions for protection in heuristic methods for complementary suppression. In particular, he discusses the necessary condition that every row or column containing a sensitive cell must contain at least two suppressed cells. This is the condition that  $H$  contains no leaves. A stronger necessary condition that subsumes this is that  $H$  contains no bridges, i.e., that every edge in  $H$  is in a simple cycle (ignoring the directions of the edges). When  $D$  is strictly positive, every cycle in  $H$  is traversable, and so the necessary condition is also sufficient. In the general case this is not true, but the above labeled augmentation methodology

FIG. 7(e). Table  $D$  with complementary suppressions added (shown as circles).

can still be used to add the fewest number of complementary suppressions to satisfy the necessary condition that every edge in  $H$  be in a simple cycle (ignoring directions). Hence this stronger necessary condition can be efficiently and optimally imposed, and therefore may be useful in practice.

*Special case:  $X$  strictly positive.* Above we solved the complementary suppression problem when  $D$  is assumed to be strictly positive. A less restrictive and more useful assumption is that the original sensitive cells are strictly positive (no zero valued data is sensitive), but other cells in  $D$  may have zero value. We do not know how to solve this problem efficiently, but under the assumption that the zero valued cells are not extremely dense, the above methodology may often be used to efficiently produce optimal solutions, or near optimal solutions. Full details on this problem are contained in [G1].

**4. Interval estimation: tightest general upper and lower bounds.**

DEFINITION. If cell  $(i, j)$  is suppressed in  $D$  then the tightest upper bound on its value is the largest value that  $x(i, j)$  can take on in any legal solution of  $D$ . Similarly the tightest lower bound on its value is the smallest value that  $x(i, j)$  can take on in a legal solution of  $D$ .

In this section, we first show how to compute each tightest bound with a single network flow computation. This improves previous methods (cited in the introduction) which were based on *minimum cost* network flow or linear programming. Each network flow computation takes  $O(n^3)$  time, hence, in an  $n$  by  $n$  table if  $\Theta(n^2)$  bounds need to be computed, the best time guarantee based on this method would be  $O(n^5)$ . We next show that this time bound can be reduced to  $O(n^4)$ , and that  $O(n \log n)$  maximum flow computations suffice to find all the tightest upper bound values in any table. A biproduct is that in any table (even those with  $\Theta(n^2)$  missing values), there are never more than  $2n - 1$  distinct upper bound values. These results are obtained by reducing the problem of computing tightest upper bounds to a problem discussed by Schnorr [SC]. The problem of computing all the lower bounds is more directly seen to take only  $O(n^4)$  time.

**4.1. Computing a single bound.**

DEFINITION. Given the complete table  $D$ , construct the graph  $G(H)$  from  $H$  and  $D$  as follows: replace every edge in  $H$  with two edges between the same nodes, with one edge in each direction; for each edge  $\langle i, j \rangle$  from  $R$  to  $C$ , set the capacity of  $\langle i, j \rangle$  to  $M$ , a finite number larger than the largest  $R^*(i)$ ; for each edge  $\langle j, i \rangle$  from  $C$  to  $R$ , set the capacity of  $\langle j, i \rangle$  to  $D(i, j)$ .

Graph  $G(H)$  can be thought of as the augmentation graph [FF] of the flow in network  $G$  given by the original values in  $D$ .

DEFINITION. Let  $FG(i, j)$  be the value of the maximum flow from node  $i$  to node  $j$  in  $G(H)$ . Note that  $FG(i, j)$  is not just the flow on the single edge  $\langle i, j \rangle$ .

THEOREM 5. If  $(i^*, j^*)$  is a suppressed cell in  $D$ , with  $i^* \in R$  and  $j^* \in C$ , then  $FG(j^*, i^*)$  is the tightest upper bound on the value of cell  $(i^*, j^*)$  in  $D$ , and  $\max [0, D(i^*, j^*) - FG(i^*, j^*) + M]$  is the tightest lower bound on the value of cell  $(i^*, j^*)$  in  $D$ .

*Proof.* Let  $F$  be the maximum flow from  $j^*$  to  $i^*$  in  $G(H)$ , and recall that  $F(i, j)$  is the flow from node  $i$  to node  $j$  along the single edge  $\langle i, j \rangle$ .

We first show that  $F$  defines a legal solution  $x$  of  $D$  where  $x(i^*, j^*)$  has value  $FG(j^*, i^*)$ . Define  $x(i^*, j^*) = FG(j^*, i^*)$ , and for every other suppressed cell  $(i, j) \neq (i^*, j^*)$ ,  $i \in R$ ,  $j \in C$ , define  $x(i, j) = D(i, j) + F(i, j) - F(j, i)$ . Since  $F(j, i) \leq D(i, j)$ ,  $x(i, j) \geq 0$ . Now consider any node  $i$  in  $R$  other than  $i^*$ . Then with the above assignment,

the sum in row  $i$  is

$$\sum_{j \in X(i)} x(i, j) = \sum_{j \in X(i)} D(i, j) + \sum_{j \in X(i)} F(i, j) - \sum_{j \in X(i)} F(j, i).$$

But the flow into  $i$  must equal the flow out of  $i$ , so

$$\sum_{j \in X(i)} x(i, j) = \sum_{j \in X(i)} D(i, j) = R^*(i).$$

For  $i^*$ ,

$$\sum_{j \in X(i^*)} x(i^*, j) = FG(j^*, i^*) + \sum_{j \in X(i^*)-j^*} D(i^*, j) + \sum_{j \in X(i^*)-j^*} [F(i^*, j) - F(j, i^*)].$$

But  $\sum_{j \in X(i^*)-j^*} [F(i^*, j) - F(j, i^*)]$  is the negative of the net flow into  $i^*$  from all nodes other than  $j^*$ , hence it is  $-(FG(j^*, i^*) - D(i^*, j^*))$ . So

$$\begin{aligned} \sum_{j \in X(i^*)} x(i^*, j) &= FG(j^*, i^*) + \sum_{j \in X(i^*)} D(i^*, j) - FG(j^*, i^*) \\ &= \sum_{j \in X(i^*)} D(i^*, j) = R^*(i^*). \end{aligned}$$

The argument for any column is similar, so  $x$  is indeed a legal solution to  $D$ .

We now show that there is no legal solution where cell  $(i, j)$  has a value larger than  $FG(j^*, i^*)$ . Suppose there is a solution  $x$  such that  $x(i^*, j^*) > FG(j^*, i^*)$ . Consider the differences  $x(i, j) - D(i, j)$ , for each suppressed cell  $(i, j) \neq (i^*, j^*)$ ,  $i \in R, j \in C$ ; assign  $F'(i, j)$  to be  $x(i, j) - D(i, j)$  when the difference is positive, and  $F'(j, i)$  to be  $|x(i, j) - D(i, j)|$  when the difference is negative; and assign  $F'(j^*, i^*)$  to be  $D(i^*, j^*)$ . We first show that  $F'$  is a flow in  $G(H)$  from  $j^*$  to  $i^*$ . Clearly, all values in  $F'$  are positive, and no capacity constraints are exceeded. Now for any  $i \neq i^*, i \in R$ ,

$$\begin{aligned} \sum_{j \in X(i)} [F'(i, j) - F'(j, i)] &= \sum_{j \in X(i)} [x(i, j) - D(i, j)] \\ &= \sum_{j \in X(i)} x(i, j) - \sum_{j \in X(i)} D(i, j) = 0, \end{aligned}$$

since  $x$  and  $D$  are both legal solutions, and hence both terms add to  $R^*(i)$ . So  $F'$  is a flow in  $G(H)$ . To calculate its value, consider the net flow into  $i^*$ . That flow value is

$$\begin{aligned} D(i^*, j^*) + \sum_{j \in X(i^*)-j^*} [D(i^*, j) - x(i^*, j)] &= R^*(i^*) - \sum_{j \in X(i^*)-j^*} x(i^*, j) \\ &= x(i^*, j^*) > FG(j^*, i^*). \end{aligned}$$

This contradicts the assumption that  $F$  is the maximum flow from  $j^*$  to  $i^*$  in  $G(H)$ . Hence  $FG(j^*, i^*)$  is the tightest upper bound on the value of cell  $(i, j)$ .

The formal proof for the lower bound is very similar to that for the upper bound, and is omitted. The intuition behind the lower bound formula is that the flow from  $i^*$  to  $j^*$  is  $M$  plus the largest amount by which  $D(i^*, j^*)$  can be decreased while keeping the row and column sums correct. So to find the largest possible decrement, subtract  $M$  from  $FG(i^*, j^*)$ ; then to find the tightest lower bound, subtract the decrement from the initial value of the cell. The result will be the tightest lower bound, unless the decrement is so large that the result is negative. A negative result is not meaningful for our problem, and so in this case the tightest lower bound is zero.  $\square$

**4.2. Speeding up the computation of tightest bounds.** If each bound is computed independently as above, and there are  $\Theta(n^2)$  suppressed cells in an  $n$  by  $n$  table, the best implied time bound for finding all the bounds would be  $O(n^5)$ . However, there

is a great deal of interdependence between the bounds, and it is not necessary to compute each one independently. It is possible to exploit this interdependence to obtain an  $O(n^4)$  time method to compute all bounds in an  $n \times n$  table, no matter how many cells are suppressed. Another reflection of the interdependence of the bounds is that there can never be more than  $n + m - 1$  distinct upper bound values in any  $n \times m$  table, no matter how many cells are suppressed; similarly there are never more than  $n + m$  distinct lower bound values.

DEFINITION. For two nodes  $i$  and  $j$  in  $G(H)$  define  $\beta(i, j)$  as the minimum of the flow values  $FG(i, j)$  and  $FG(j, i)$ .

LEMMA 1. Let  $(i, j)$  be a suppressed cell in  $D$ . Then in  $G(H)$ ,  $FG(i, j) > FG(j, i)$ , where  $i \in R$ , and  $j \in C$ .

Proof. This is trivially true because there is a direct edge from  $i$  to  $j$  with large capacity  $M$ , hence  $FG(i, j) \cong M$ , while by Theorem 5,  $FG(j, i)$  is the tightest upper bound on the value of cell  $(i, j)$  which is certainly bounded by  $R^*(i) < M$ .  $\square$

Lemma 1 and Theorem 5 together imply the following.

LEMMA 2. For a suppressed cell  $(i, j)$  in  $D$ ,  $\beta(i, j)$ , computed on  $G(H)$ , is the tightest upper bound on the value of cell  $(i, j)$ .

The computation of tightest bounds involves many network flow computations on the unchanging graph  $G(H)$ , where the choice of source and sink varies in each computation. Hence, we would like an efficient method (significantly faster than computing each flow separately) to compute  $FG(i, j)$  for all pairs  $(i, j)$  in  $X$ . Such methods are known for undirected graphs [GH], [G2]; in those methods, all  $\Omega(k^2)$  flow values can be computed with only  $k - 1$  flows in a  $k$  node undirected graph. For directed graphs, no such equivalent method is known. However, if  $\beta(i, j)$  is defined to be the minimum of the flow values from  $i$  to  $j$ , and from  $j$  to  $i$ , then it is known how to compute the  $\Omega(k^2)$  values of  $\beta(i, j)$  for all pairs of nodes in a directed graph with  $k$  nodes, using at most  $O(k \log k)$  maximum flows. Further, the total time needed for all the flows together can be bounded by  $O(k^4)$  [SC]. We refer the reader to [SC], but note that these results follow from the structure and interdependence of the beta values. Graph  $G(H)$  has  $n + m$  nodes if the table is  $n \times m$ , hence given Lemma 2, we have the following.

THEOREM 6. All tightest upper bounds on the values of suppressed cells can be computed in  $O((n + m)^4)$  time in an  $n \times m$  table, and hence in  $O(n^4)$  in an  $n \times n$  table.

To compute the tightest lower bounds in  $O(n^4)$  time, note first that there can only be  $2n - 1$  nonzero lower bounds. This follows from viewing the network flow problem on  $G$  (the problem of finding a single legal solution to  $D$ ) as a linear programming problem, and noting that for such a linear programming problem, all but  $2n - 1$  variables are set to zero in any basic feasible solution [MUR]. Such a basic feasible solution can be constructed from any feasible solution in time  $O(n^4)$ , and hence all but  $2n - 1$  lower bounds of zero are identified in that time. The lower bounds for the remaining  $2n - 1$  cells can each be computed independently, in total time  $O(n^4)$ .

In [G1], we present a completely different network flow method for computing each individual bound. In that method, the graph is changed for each cell, so the method is not easily combined with Schnorr's beta method.

The number of distinct upper bound values. We have shown that for any suppressed cell  $(i, j)$  the tightest upper bound on the value of cell  $(i, j)$  is equal to  $\beta(i, j) = \min [FG(i, j), FG(j, i)]$  in  $G(H)$ . It is known [SC] that there can never be more than  $k - 1$  distinct values for  $\beta(i, j)$  in any directed graph with  $k$  nodes. Since  $G(H)$  has  $n + m$  nodes, and the  $\beta$  values define the tightest upper bounds in  $D$ , there can never be more than  $n + m - 1$  distinct tightest upper bounds in  $D$ . This is easily verified on

the table where all cells are suppressed, but holds in general. The proof in [SC] is extracted from the details of the method to compute the betas; for a simpler proof, see [G1]. In summary, we have the following.

**THEOREM 7.** *In any  $n \times m$  table  $D$ , there are at most  $n + m - 1$  distinct tightest upper bounds on the values of the suppressed cells in  $D$ .*

**5. Tightest upper and lower bounds in a totally suppressed table.** There are applications of the estimation problem where all entries in the table are suppressed. Here we show that trivial methods suffice in this case to compute the tightest upper and lower bounds on the cell values.

**THEOREM 8.** *In a totally suppressed table the tightest upper bound on the value of cell  $(i, j)$  is  $\min [R(i), C(j)]$ .*

Before proving Theorem 8, we establish the following lemma.

**LEMMA 3.** *Let  $R(1), \dots, R(n)$  and  $C(1), \dots, C(m)$  be any nonnegative integers such that  $\sum_{i=1}^n R(i) = \sum_{j=1}^m C(j)$ . Then there exists a legal solution to the table  $D$  where all cells are suppressed and  $R(i)$  is the  $i$ th row total and  $C(j)$  is the  $j$ th column total in  $D$ .*

*Proof.* In the network flow interpretation of table  $D$  above, graph  $H$  is a complete bipartite graph, and so in  $G$  any  $s-t$  cut must contain either all edges incident with  $s$ , or all edges incident with  $t$ . Hence the minimum cut and maximum flow have value  $\sum_{i=1}^n R(i)$ , and there is a legal solution to  $D$ .  $\square$

*Proof of Theorem 8.* Clearly  $\min [R(i), C(j)]$  is an upper bound on the value of cell  $(i, j)$ . Assume  $\min [R(i), C(j)] = R(i)$ . To show that the bound can be met we must exhibit a solution to  $D$  in which  $(i, j)$  is given value  $R(i)$ . We simply give cell  $(i, j)$  the value  $R(i)$ , and give all other cells in row  $i$  the value 0; we then remove row  $i$  from  $D$  and set  $C(j)$  to  $C(j) - R(i)$ . The row totals still equal the column totals in the reduced table, and so by Lemma 3, the reduced table has a solution, and hence  $\min [R(i), C(j)]$  is an attainable value for  $(i, j)$ .  $\square$

Now we examine the lower bound.

**THEOREM 9.** *In the totally suppressed table the tightest lower bound on the value of cell  $(i, j)$  is  $\max [0, R(i) + C(j) - T]$ , where  $T = \sum_{i=1}^n R(i)$ .*

*Proof.* We first show that the above is a lower bound. The cell values in row  $i$  must add up to  $R(i)$ , but without cell  $(i, j)$ , the total that all other cells in row  $i$  can contribute is  $T - C(j)$ . Hence cell  $(i, j)$  must have value at least  $R(i) + C(j) - T$ . The same lower bound is obtained by doing the analysis along column  $j$ . To show that this bound is tight, give cell  $(i, j)$  the value  $\max [0, R(i) + C(j) - T]$ , and assign values to the other cells in row  $i$  so that the total assigned in row  $i$  is exactly  $R(i)$  (this is always possible). After deleting row  $i$  and reducing each  $C(k)$  by the amount assigned to cell  $(i, k)$ , the row and column totals are still equal, and so, by Lemma 3, the reduced table has a solution, and the theorem is proved.  $\square$

**COROLLARY 1.** *In a totally suppressed table of size  $n \times m$ , let  $C(k)$  be the largest row or column total. Then only cells in column  $k$  can have a nonzero lower bound. Further, cells in column  $k$  can have a nonzero lower bound only if  $C(k) > T/2$ .*

*Proof.*  $\max [0, R(i) + C(j) - T] = 0$  unless  $R(i) + C(j) > T$ , which can happen only if either  $R(i) > T/2$  or  $C(j) > T/2$ , in which case  $C(k) > T/2$  also. Now for any  $j \neq k$ ,  $C(j) \leq T - C(k)$ , and so  $R(i) + C(j) - T \leq R(i) + [T - C(k)] - T = R(i) - C(k) \leq 0$ . So only cells in column  $k$  can possibly have a nonzero lower bound.  $\square$

A symmetric statement holds when the largest row or column sum is a row sum. Hence we need to compute lower bounds only for the cells in the row or column with maximum sum; all other cells have lower bounds of zero. Therefore  $O(\max [n, m])$

arithmetic operations and comparisons suffice in this case, although the output is of size  $O(nm)$ .

**COROLLARY 2.** Any  $n \times m$  totally suppressed table is protected, for  $n, m > 1$ .

*Proof.* Cell  $(i, j)$  is protected if  $\min [R(i), C(j)] > \max [0, R(i) + C(j) - T]$ . We assumed that every row and column sum was nonzero, so  $(i, j)$  is protected if  $\min [R(i), C(j)] > R(i) + C(j) - T$ . Assume that  $R(i) \leq C(j)$ . If  $R(i) = R(i) + C(j) - T$  then  $C(j) = T$ , but when  $n > 1$  this is a contradiction to the assumption that all column sums are nonzero.  $\square$

**6. Extensions and open questions.** As mentioned in the introduction, the Census Bureau and Adversary problems can also be efficiently solved when there are known independent upper and lower bounds on the value of each suppressed cell. In that case, graph  $H$  is constructed as before, but for cell  $(i, j)$ , the  $(i, j)$  edge in  $H$  is directed from  $i$  to  $j$  if  $D(i, j)$  is at its lower bound, from  $j$  to  $i$  if  $D(i, j)$  is at its upper bound, and undirected otherwise. Cell  $(i, j)$  is then protected if and only if edge  $(i, j)$  is in a traversable cycle in  $H$ , and the linear time algorithm to find the traversable edges presented in this paper works for this case as well.

Several of the ideas in this paper have been extended in nontrivial ways, and appear in [K], [KG]. In particular, one may ask whether a given linear function of a set of suppressed cells is invariant over all the legal solutions of  $D$ . In this paper we essentially considered the simplest linear function, that of a single cell value. In [KG] it is shown that given any linear function of a set of suppressed cells in  $D$ , one can determine in linear time in  $|X|$  if that function is an invariant.

We mention a few of the many interesting open questions that remain.

(1) Generalize the approach in this paper to tables of three or more dimensions. Even the totally suppressed case is open for three dimensions. For example, the three-dimensional analogues of Theorems 8 and 9 do not even hold (see Fig. 8).

u 1	1	0
L 0	1, 0 u L	0, 0 u L
u 5	5	1
L 1	4, 1 u L	1, 0 u L
	u 5	1
	L 1	0

**FIG. 8.** Three-dimensional table of size  $2 \times 2 \times 2$ . The two numbers in each cell below the triangle are the upper and lower table entries respectively, i.e., cell  $(1, 1, 1)$  has entry 1, cell  $(2, 1, 1)$  has value 4, cell  $(2, 1, 2)$  has value 1, etc. The numbers in the triangles are the sums of the cells looking downward. The numbers on the left side are upper and lower sums of the cells looking horizontally along a line, and the numbers on the bottom are upper and lower sums of the cells looking vertically along a line. The minimum of the sums constraining cell  $(2, 1, 1)$  is 5, and so the "analogue" of Theorem 8 suggests that in the totally suppressed table with these sums  $(2, 1, 1)$  could have value 5. But this is not possible since then cell  $(2, 2, 1)$  would be forced to be zero and then cell  $(1, 2, 1)$  would be forced to be 1, which contradicts the fact that cell  $(1, 2, 1)$  is forced to be zero by the zero in the triangle.

(2) In this paper a cell was defined to be protected if the tightest upper and lower bounds differ by at least one. A more useful condition is that they should differ by some  $\delta > 1$ . Can we efficiently (in linear time) determine whether  $D$  is protected for a given  $\delta > 1$  specified ahead of time? What about for  $\delta$  given as input? What about the complementary suppression problem in these cases?

(3) It may be realistic to assume bounds on the sums of a set of cell values, or correlations between the values of certain cells. How can these be handled in the protection, suppression, and estimation problems?

(4) Can the general tightest upper bounds be computed faster than  $O(n^4)$  time? There is an easy reduction from the maximum flow problem to the problem of computing a single bound, hence  $O(n^3)$  seems the best realistic target for the time needed to compute all the bounds. We conjecture that this bound is attainable.

**Acknowledgments.** I would like to thank everyone in the Yale theory group and Dick Karp for listening to parts of this work as it evolved. Special thanks to Gregory Sullivan for reading early drafts of this paper.

## MINIMUM SPANNING TREES IN $k$ -DIMENSIONAL SPACE\*

PRAVIN M. VAIDYA†

**Abstract.** We study the problem of finding a minimum spanning tree in the complete graph on a set  $V$  of  $n$  points in  $k$ -dimensional space. The points are the vertices of this graph and the weight of an edge between two points is the distance between the points under some  $L_q$  metric. We give an  $O(\varepsilon^{-k} n \log n)$  algorithm for finding an approximate minimum spanning tree in such a graph; the weight of the approximate minimum spanning tree is guaranteed to be at most  $(1 + \varepsilon)$  times the weight of a minimum spanning tree. We also present an algorithm to find a minimum spanning tree in the complete graph on  $V$ . Under the assumption that  $V$  consists of  $n$  random points, independently and uniformly distributed in the unit  $k$ -cube  $[0, 1]^k$ , the expected running time of this minimum spanning tree algorithm is shown to be  $O(n\alpha(cn, n))$  where  $c$  is a constant dependent on  $k$  and  $\alpha$  is the inverse Ackermann function.

**1. Introduction.** Given an undirected graph with a weight assigned to each edge, a spanning tree is a connected acyclic subgraph, and a minimum spanning tree (MST) is a spanning tree whose edges have a minimum total weight among all spanning trees. The classical algorithms for finding an MST were given by Dijkstra [4], Kruskal [9], Prim [10], and Sollin [1]. It is well known that for a graph on  $n$  vertices, an MST may be found in  $O(n^2)$  time. For a graph with  $m$  edges and  $n$  vertices, it was shown by Yao [15] that an MST may be found in  $O(m \log \log n)$  time. Further results on MST's may be found in [6], [8].

We study the problem of finding an MST in the complete graph on a given set  $V$  of  $n$  points in  $k$ -dimensional space. The points are the vertices of this graph and the weight of an edge between any two points is the distance between the points under some distance metric  $L_q$ . Each point  $x$  is given as a vector  $(x_1, x_2, \dots, x_k)$ . The  $L_q$ ,  $q = 1, 2, \dots, \infty$ , distance between any two points  $x$  and  $y$  is given by  $(\sum_{i=1}^k |x_i - y_i|^q)^{1/q}$ . (Note that the  $L_\infty$  distance is given by  $\max_i |x_i - y_i|$ .) We assume that the dimension  $k$  and the distance metric  $L_q$  are fixed (so distance is to be always interpreted as  $L_q$  distance).

The problem of finding an MST on a set of points in  $k$ -dimensional space differs from the problem of finding an MST in a general weighted undirected graph in two respects. First, the input consists only of  $kn$  numbers, the edges and the edge weights being implicitly defined. Second, in many applications of MST on points in space, like clustering, pattern recognition [5], [17], and other geometric and statistical applications, a spanning tree whose weight is close to the weight of an MST would serve just as well. So it is useful and interesting to investigate if the geometric nature of the problem can be exploited to obtain fast algorithms for finding a spanning tree on points in space whose weight is minimum or close to minimum.

Shamos and Hoey were the first to utilize the geometric nature of this problem, and in [12] they give an  $O(n \log n)$  algorithm for  $n$  points in the plane ( $k = 2$ ) with Euclidian metric. In [16] Yao gives algorithms which construct an MST in time

$O(n^{2-2^{-(k+1)}}(\log n)^{1-2^{-(k+1)}})$  for any fixed  $k \geq 3$ , and distance metrics  $L_q$ ,  $q = 1, 2, \infty$ . In [7],  $O(n(\log n)^{k-\theta})$ ,  $\theta \leq 2$ , algorithms are given for fixed  $k \geq 2$  and  $L_1, L_\infty$  distance metrics. An algorithm for finding a spanning tree, with weight at most  $(1 + \varepsilon)$  times minimum, for  $k = 3$  and  $L_2$  distance metric is given in [2] but the running time is dependent on the ratio of the maximum to the minimum distance between any two points. In [14], an  $O(n(\log n)^{k+1}\varepsilon^{-(k-1)})$  algorithm is given for finding a spanning tree with weight at most  $(1 + \varepsilon)$  times minimum, for  $\varepsilon > 0$ , and fixed  $k$  and fixed metric  $L_q$ .

We give two algorithms for fixed dimension  $k$  and fixed metric  $L_q$ . The first algorithm, given in § 3, runs in  $O(\varepsilon^{-k}n \log n)$  time and finds an approximate minimum spanning tree whose weight is at most  $(1 + \varepsilon)$  times the weight of an MST. The second algorithm, presented in § 4.1, always finds an MST. For  $n$  random points, independently and uniformly distributed in the unit  $k$ -cube  $[0, 1]^k$ , the expected running time of the second algorithm is shown to be  $O(n\alpha(cn, n))$ , where  $c$  is a constant dependent on  $k$  and  $\alpha$  is the inverse Ackermann function defined in [13]. As  $\alpha$  grows extremely slowly with  $n$ , the expected running time of the second algorithm is almost linear. We note that the constants in the running times of both the algorithms depend on the dimension  $k$ . The probabilistic analysis of the second algorithm is given in § 4.2.

As far as the model of computation is concerned, we assume that all access, arithmetic and comparison operations require constant time. We also assume that some form of indirect addressing is available so that the process of distributing  $n$  numbers into  $m$  buckets can be carried out in  $O(m + n)$  time.

Without loss of generality we assume that all the  $n$  points in the given set  $V$  are located in the unit  $k$ -cube  $[0, 1]^k$ . We let  $d(p, p')$  denote the distance between two points  $p$  and  $p'$ , and we let  $W_{\text{MST}}$  denote the weight (length) of an MST in the complete graph on  $V$ . A box is defined to be the product  $J_1 \times J_2 \times \dots \times J_k$  of  $k$  intervals, or alternatively the set of those points  $x = (x_1, x_2, \dots, x_k)$  such that  $x_i$  is in interval  $J_i$ ,  $i = 1, 2, \dots, k$ . A box is cubical if and only if all the  $k$  intervals defining it have the same length, and the size of a cubical box is the length of each of the  $k$  intervals defining it. For a set of points  $S$ , we let  $d_{\text{max}}(S)$  denote the greatest distance between two points in  $S$ . For sets of points  $S_1$  and  $S_2$ , we let  $d_{\text{min}}(S_1, S_2)$  and  $d_{\text{max}}(S_1, S_2)$ , respectively, denote the minimum and maximum distance between a point in  $S_1$  and a point in  $S_2$ .

**2. A brief overview.** In the approximate minimum spanning tree algorithm we first extract a sparse graph  $G = (V, E)$  from the given set of points  $V$ , and then find an MST in  $G$  using a standard procedure [6], [7], [11]. There are  $O(\varepsilon^{-k}n)$  edges in  $G$  and there is a spanning tree in  $G$  of weight at most  $(1 + \varepsilon)W_{\text{MST}}$ . We obtain the graph  $G$  as follows. Using a collection of grids the region containing the given points is divided into cubical boxes, each grid partitioning the region into boxes of identical size. In each box  $b$ , we select a representative point from among the points in  $V$  that are located in box  $b$ . An edge between the representative in box  $b$  and the representative in box  $b'$  is included in  $G$  if and only if  $b$  and  $b'$  are of identical dimensions and the minimum distance between  $b$  and  $b'$  is below a certain threshold. In addition to edges between representatives,  $G$  contains an adequate number of short edges (of length  $< \varepsilon W_{\text{MST}}/3n^2$ ) suitably chosen to ensure that  $G$  is connected. Now suppose  $V$  is partitioned into  $V_1$  and  $V_2$ , and  $(p_1, p_2)$ ,  $p_1 \in V_1$ ,  $p_2 \in V_2$ , is the unique edge in an MST from  $V_1$  to  $V_2$ . Then either there are points  $p'_1 \in V_1$ ,  $p'_2 \in V_2$ , such that  $(p'_1, p'_2)$  is in  $G$ ,  $p'_1$  and  $p'_2$  are representative points in boxes, and  $d(p'_1, p'_2) \leq (1 + \varepsilon)d(p_1, p_2)$ , or among the short edges in  $G$  there is a path from  $p_1$  to  $p_2$  of length at most  $\varepsilon W_{\text{MST}}/n^2$ . This guarantees the existence of a good spanning tree in  $G$ .

The procedure to extract  $G$  may be implemented in  $O(\varepsilon^{-k}n \log n)$  time, and as  $G$  contains  $O(\varepsilon^{-k}n)$  edges, an MST in  $G$  may be found in  $O(\varepsilon^{-k}n \log n)$  time using a standard procedure [6], [8], [11], [15]. So the overall running time of the approximate minimum spanning tree algorithm is  $O(\varepsilon^{-k}n \log n)$ .

In the exact minimum spanning tree algorithm we first extract a graph  $G' = (V, E')$  from the given set of points  $V$  such that  $G'$  always contains a spanning tree of weight  $W_{\text{MST}}$ . The graph  $G'$  is sparse with high probability, and can be extracted in  $O(|E'|)$  time. We then try to sort the edges in  $G'$  by weight, in  $O(|E'|)$  (linear) time, by running a fixed number of passes of radix (bucket) sort [11], with radix  $2^{\lceil \log_2 n \rceil}$ . If this approach fails to sort the edges in  $G'$ , we sort them in  $O(|E'| \log |E'|)$  time using a standard algorithm [11]. Once a sorted list of edges in  $G'$  is available, utilizing Kruskal's algorithm an MST in  $G'$  may be obtained in  $O(n\alpha(|E'|, n))$  time where  $\alpha$  is the inverse Ackermann function defined in [13]. Suppose the given set  $V$  consists of  $n$  random points, independently and uniformly distributed in the unit  $k$ -cube  $[0, 1]^k$ . Then the probability that  $G'$  has more than  $cn$  edges, where  $c$  is a constant dependent on the dimension  $k$ , is  $o(1/n^2)$ . Also, the probability that a fixed number of passes of radix sort, with radix  $2^{\lceil \log_2 n \rceil}$ , fail to sort the edges is  $o(1/n^2)$ . Then it follows that the expected running time of the minimum spanning tree algorithm is  $O(n\alpha(cn, n))$ .

$G'$  is obtained in a manner similar to  $G$  above. Using a collection of grids the unit  $k$ -cube  $[0, 1]^k$  is divided into cubical boxes, each grid partitioning the unit  $k$ -cube into boxes of identical size. Let  $b_1, b_2$ , be boxes of identical dimensions such that the minimum distance between  $b_1$  and  $b_2$  is above a certain threshold and below another threshold. We test an easy to compute condition such that (i) if the condition is false, then none of the edges between a point in  $b_1 \cap V$  and a point in  $b_2 \cap V$  can be included in an MST in the complete graph on  $V$ , whereas (ii) if the condition is true, then there is an empty region which does not contain a point in  $V$  and whose volume is greater than or equal to the volume of  $b_1$  or  $b_2$ . We include every edge between a point in  $b_1 \cap V$  and a point in  $b_2 \cap V$  in  $G'$  if and only if this condition holds. In addition, we also include most of the short edges (length  $< c'n^{-1/k}$ ,  $c'$  a constant) in  $G'$ . We thereby ensure that  $G'$  always contains an MST in the complete graph on  $V$ . If the number of edges in  $G'$  exceeds  $cn$ , then either there is a large region in the unit  $k$ -cube which does not contain a point in  $V$  or there is some region in the unit  $k$ -cube that contains a concentration of points in  $V$ , and under the assumption that the points in  $V$  are independently and uniformly distributed in the unit  $k$ -cube both these events occur with very low probability.

**3. Approximate minimum spanning tree algorithm.** The algorithm to find an approximate MST in the complete graph on the given set  $V$  of  $n$  points consists of two stages: in the first stage we extract a sparse graph  $G = (V, E)$  from the given set  $V$  of points, and in the second stage we use a standard procedure [6], [7], [11] to find a minimum spanning tree in the graph  $G$ . The graph  $G = (V, E)$  has the following properties.

(1)  $G$  contains a spanning tree whose weight (length) is at most  $(1 + \varepsilon + 1/n)$  times  $W_{\text{MST}}$ .

(2)  $|E| = O(\varepsilon^{-k}n)$ .

We shall require a few definitions before we can describe the algorithm to extract  $G$ . Let  $g_0$  be a smallest cube enclosing all the  $n$  points in  $V$ , and let  $L_0$  be the length of a side of  $g_0$ . Let  $g_i$  be a grid that partitions  $g_0$  into  $2^{ki}$  identical cubical boxes, and let  $\delta = \lceil (\log_2(24(\lceil \varepsilon^{-1} \rceil)^2 k^2 n^2)) \rceil$ . Let  $B_i$  denote the set of those boxes (cubes) in  $g_i$  which contain a point in  $V$ , and let  $B = \bigcup_{i=0}^{\delta} B_i$ . Let  $L_i = c_a \lceil \varepsilon^{-1} \rceil 2^{-i} L_0$ , where  $c_a = 6k^{1/q}$

for  $L_q$  metric,  $q = 1, 2, 3, \dots, \infty$ . We let  $r(b)$  denote the representative point in box  $b$ . We now give an algorithm to extract the graph  $G = (V, E)$  from the set of points  $V$ .

**ALGORITHM SPARSE-GRAPH.**

1. For each box  $b \in B$ , pick a representative point  $r(b)$  from among the points in  $b \cap V$ , and let  $R_i = \{r(b) : b \in B_i\}$ , for  $i = 1, \dots, \delta$ . We pick representatives so that  $R_1 \subseteq R_2 \subseteq \dots \subseteq R_i \subseteq \dots \subseteq R_\delta$ .
2. Let  $X = \bigcup_{i=1}^\delta X_i$  where

$$X_i = \{(r(b_1), r(b_2)) : b_1 \in B_i, b_2 \in B_i, d_{\min}(b_1, b_2) \leq L_i\}.$$

3. Let  $Y = \{(p, r(b)) : p \in b, b \in B_\delta\}$ .
  4. Let  $E = X \cup Y$ .
- end Sparse-Graph

The edges in  $X_i$  connect representatives in boxes  $b_1, b_2$ , in  $B_i$  such that  $d_{\min}(b_1, b_2)$  lies between two thresholds  $L_i$  and  $L_i/3$ . The edges in  $Y$  are small in length compared to  $W_{\text{MST}}$  and they ensure that  $G = (V, E)$  is connected.

We need some additional definitions before we can show that  $G$  has the desired properties. Let  $Z$  denote the set of all the edges in the complete graph on  $V$ , and let

$$Z_i = \{(p_1, p_2) : p_1 \in b_1, p_2 \in b_2, b_1 \in B_i, b_2 \in B_i, d_{\min}(b_1, b_2) \geq L_i/3\}.$$

The following two lemmas follow directly from the definitions.

**LEMMA 1.** For  $1 \leq i \leq \delta$ , if  $b_1 \in B_i, b_2 \in B_i$ , and  $d_{\min}(b_1, b_2) \geq L_i/3$  then  $d_{\max}(b_1) = d_{\max}(b_2) \leq (\varepsilon/2)d_{\min}(b_1, b_2)$  and  $d_{\max}(b_1, b_2) \leq (1 + \varepsilon)d_{\min}(b_1, b_2)$ .

**LEMMA 2.**  $Z_0 \subseteq Z_1 \subseteq \dots \subseteq Z_i \subseteq \dots \subseteq Z_\delta \subseteq Z$ .

**LEMMA 3.** For  $1 \leq i \leq \delta$ , if  $(p_1, p_2) \in (Z_i - Z_{i-1})$  then  $p_1, p_2$ , are located in boxes  $b_1, b_2$ , which satisfy  $b_1 \in B_i, b_2 \in B_i$ , and  $L_i/3 \leq d_{\min}(b_1, b_2) \leq L_i$ .

*Proof.* Suppose  $p_1, p_2$  are located in boxes  $b_1, b_2$ , in  $B_i$ , respectively. Since  $(p_1, p_2) \in Z_i, d_{\min}(b_1, b_2) \geq L_i/3$ . Let  $b'_1 \in B_{i-1}, b'_2 \in B_{i-1}$ , and let  $b_1 \subseteq b'_1, b_2 \subseteq b'_2$ . Since  $(p_1, p_2) \in (Z_i - Z_{i-1})$ , we have  $d_{\min}(b'_1, b'_2) \leq L_{i-1}/3$ . Then

$$\begin{aligned} d_{\min}(b_1, b_2) &\leq d_{\min}(b'_1, b'_2) + d_{\max}(b'_1)/2 + d_{\max}(b'_2)/2 \\ &\leq L_{i-1}/3 + k^{1/q} 2^{-(i-1)} L_0 \\ &\leq L_i. \end{aligned} \quad \square$$

We now show that  $G = (V, E)$  contains a spanning tree whose weight is at most  $(1 + \varepsilon + 1/n)W_{\text{MST}}$ . Let  $T$  be an MST in the complete graph on  $V$ . We shall give a function  $f: T \rightarrow 2^E$  such that the graph  $(V, \bigcup_{e \in T} f(e))$  is connected and the sum of the weights of the edges in  $\bigcup_{e \in T} f(e)$  is at most  $(1 + \varepsilon + 1/n)W_{\text{MST}}$ . The function  $f(e)$  is defined as follows.

- (1) If  $e \in T$  and  $e \in E$ , then we let  $f(e) = \{e\}$ .
- (2) Suppose  $e \in ((T - E) \cap (Z - Z_\delta))$ . Let  $e = (p_1, p_2)$ , and let  $b_1, b_2$  be the boxes in  $B_\delta$  which contain  $p_1, p_2$ , respectively. Then  $f(e) = \{(p_1, r(b_1)), (r(b_1), r(b_2)), (r(b_2), p_2)\}$  and  $f(e) \subseteq (Y \cup X_\delta)$ . The length of an edge in  $Y$  is at most  $\varepsilon W_{\text{MST}}/3n^2$  and  $d(r(b_1), r(b_2)) \leq \varepsilon W_{\text{MST}}/3n^2$ , so the sum of the lengths of the edges in  $f(e)$  is at most  $\varepsilon W_{\text{MST}}/n^2$ .
- (3) Let  $e \in ((T - E) \cap (Z_i - Z_{i-1}))$ ,  $i \leq \delta$ , and let  $b_1, b_2$  be the boxes in  $B_i$  which contain the endpoints  $p_1, p_2$ , of  $e$ . Then by Lemma 3,  $(r(b_1), r(b_2)) \in X_i$ , and hence  $(r(b_1), r(b_2)) \in E$ . We let  $f(e) = \{(r(b_1), r(b_2))\}$ . By Lemma 1,  $d(r(b_1), r(b_2)) \leq (1 + \varepsilon) d(p_1, p_2)$ .

It remains to be shown that the graph  $(V, \bigcup_{e \in T} f(e))$  is connected. Consider a partition of  $V$  into  $V_1$  and  $V_2$ . Let  $e = (p_1, p_2)$ , where  $p_1 \in V_1$  and  $p_2 \in V_2$ , be the unique edge in  $T$  from  $V_1$  to  $V_2$ .

(1) Suppose  $e \in (Z - Z_\delta)$ . Then  $f(e)$  defines a path from  $p_1$  to  $p_2$ .  
 (2) Suppose  $e \in (Z_i - Z_{i-1})$ ,  $i \leq \delta$ , and boxes  $b_1, b_2$  in  $B_i$  contain  $p_1, p_2$ , respectively. Then we must have that  $(b_1 \cap V) \subseteq V_1$  and  $(b_2 \cap V) \subseteq V_2$ . This is seen as follows. Assume that there is a point  $p'$  in  $b_1 \cap V_2$ . As  $d_{\min}(b_1, b_2) > d_{\max}(b_1)$ , replacing  $(p_1, p_2)$  by  $(p_1, p')$  in  $T$  gives a spanning tree on  $V$  of smaller length which cannot happen. So  $(b_1 \cap V) \subseteq V_1$ . It follows similarly that  $(b_2 \cap V) \subseteq V_2$ . Then the edge  $(r(b_1), r(b_2))$  connects  $V_1$  and  $V_2$ .

We now show that  $E$  contains a linear number of edges. We note that  $R_1 \subseteq R_2 \subseteq \dots \subseteq R_i \subseteq \dots \subseteq R_\delta$ . If there is an edge in  $X_i$  between two points in  $R_{i-1}$  then the same edge is also present in  $X_{i-1}$ , and hence every edge in  $X_i - X_{i-1}$  is incident on a representative point in the set of representatives  $R_i - R_{i-1}$ . There are at most  $O((2c_a \varepsilon^{-1})^k)$  edges in  $X_i$  incident on any point in  $V$ , and so we get

$$\begin{aligned} |X| &= \sum_{i=1}^{\delta} |X_i - \bigcup_{j=0}^{i-1} X_j| + |X_0| = O((2c_a \varepsilon^{-1})^k \sum_{i=1}^{\delta} (|R_i| - |R_{i-1}|)) \\ &= O((2c_a \varepsilon^{-1})^k |R_\delta|) = O((2c_a \varepsilon^{-1})^k n). \end{aligned}$$

Then since  $|Y| \leq n$ , and  $E = X \cup Y$  we get that  $|E| = O((2c_a \varepsilon^{-1})^k n) = O(\varepsilon^{-k} n)$  for fixed  $k$ .

To obtain a fast implementation of *Algorithm Sparse-Graph* we construct a data structure which is best described as a *tree-of-boxes*.

(1) The root of the tree is the box  $g_0$ , and the children of each box  $b$  in  $B_i$  are those boxes in  $B_{i+1}$  which are sub-boxes of  $b$ .

(2) The leaf boxes are the boxes in  $B_\delta$ , and each leaf box contains a list of points in  $V$  that are in the box.

(3) The boxes at each level  $i$ , i.e., the boxes in  $B_i$  are linked together in a doubly linked list.

(4) From each box  $b$  in  $B_i$  there are pointers to (i) its father in  $B_{i-1}$ , (ii) its sons in  $B_{i+1}$ , (iii) each box  $b'$  in  $B_i$  satisfying  $d_{\min}(b, b') \leq L_i$ , and (iv) the leftmost leaf box in the subtree rooted at box  $b$ .

The *tree-of-boxes* has  $O(\log n)$  levels and at most  $n$  boxes per level. For each box  $b \in B_i$ , there are at most  $O((2c_a \varepsilon^{-1})^k)$  boxes  $b'$  in  $B_i$  such that  $d_{\min}(b, b') \leq L_i$ . So the *tree-of-boxes* requires  $O((2c_a \varepsilon^{-1})^k n \log n)$  storage, and can be constructed in  $O((2c_a \varepsilon^{-1})^k n \log n)$  time by starting from the root and proceeding towards the leaves level by level.

Once the *tree-of-boxes* is available, the representatives in boxes may be chosen in time proportional to  $|B| = O(n \log n)$ . For boxes  $b_1$  and  $b_2$ , we can find points  $p_1 \in b_1, p_2 \in b_2$ , such that  $d(p_1, p_2) = d_{\min}(b_1, b_2)$  in  $O(k)$  time. Utilizing the *tree-of-boxes*, each of the edge sets  $X_i$  can be extracted in  $O(k(2c_a \varepsilon^{-1})^k n)$  time, and so  $G$  may be extracted in  $O(k(2c_a \varepsilon^{-1})^k n \log n)$  time.

Once we have the sparse graph  $G = (V, E)$  one of the standard algorithms in [6], [8], [11], [15] may be used to find an MST in  $G$ . We thus have an algorithm for finding an approximate minimum spanning tree on a set  $V$  of  $n$  points in  $k$ -dimensional space. The running time is  $O(\varepsilon^{-k} n \log n)$  for fixed  $k$ , and the weight of the approximate minimum spanning tree obtained is at most  $(1 + \varepsilon)$  times the weight of a minimum spanning tree.

#### 4. MST algorithm with almost linear expected running time.

**4.1. Description.** Like the approximate minimum spanning tree algorithm in the previous section, the algorithm to find a minimum spanning tree in the complete graph on  $V$  also consists of two stages. In the first stage we extract a graph  $G' = (V, E')$

which is guaranteed to contain a spanning tree of weight  $W_{\text{MST}}$ , and in the second stage we find a minimum spanning tree in  $G'$ . Unlike the graph  $G$  in the previous section,  $G'$  is not necessarily sparse; however,  $G'$  is sparse with high probability under the assumption that the given points are uniformly and independently distributed in  $[0, 1]^k$ .

Let  $g_0$  be the unit  $k$ -cube  $[0, 1]^k$  and let  $g_i$  be a grid that divides  $g_0$  into  $2^{ki}$  identical cubical boxes. Let  $B_i$  be the set of all the boxes in  $g_i$  (rather than just the set of occupied boxes) and let  $B = \bigcup_{i=0}^{\delta} B_i$ . Define  $\delta$  to be  $\lceil \log_2 n/k \rceil$ . Let  $L_i = c_e 2^{-i}$  where  $c_e = 12.1k^{1/q}$  for  $L_q$  metric,  $q = 1, 2, 3, \dots, \infty$ . Let  $Z$  be the set of all the edges in the complete graph on  $V$  and let the edge sets  $Z_i$  be defined as in § 3. We note that Lemma 2 and Lemma 3 in § 3 are still valid under these definitions.

For a box  $b$ , let  $\mu(b)$  denote the singleton set containing the center of box  $b$ . For a pair of boxes  $b_1, b_2$ , we define  $\pi(b_1, b_2, i)$  to be the union of those boxes  $b_j$  which are such that

- (i)  $b_j \in B_i$ ,
- (ii)  $d_{\max}(b_j, \mu(b_1)) < d_{\min}(b_1, b_2) - d_{\max}(b_1, \mu(b_1))$ , and
- (iii)  $d_{\max}(b_j, \mu(b_2)) < d_{\min}(b_1, b_2) - d_{\max}(b_2, \mu(b_2))$ .

We now give an algorithm to extract  $G'$ .

ALGORITHM PROBABLY-SPARSE-GRAPH.

1. Let  $C = \bigcup_{i=1}^{\delta} C_i$  where

$$C_i = \{(p_1, p_2): p_1 \in b_1, p_2 \in b_2, b_1 \in B_i, b_2 \in B_i, L_i/3 \leq d_{\min}(b_1, b_2) \leq L_i, \pi(b_1, b_2, i) \cap V = \emptyset\}.$$

2. Let  $D = \{(p_1, p_2): p_1 \in b_1, p_2 \in b_2, b_1 \in B_{\delta}, b_2 \in B_{\delta}, d_{\min}(b_1, b_2) \leq L_{\delta}\}$ .
3. Let  $E' = C \cup D$ .

end Probably-Sparse-Graph

We have to show that  $G' = (V, E')$  contains a spanning tree which is an MST in the complete graph on  $V$ . Let  $T$  be an MST in the complete graph on  $V$  and let  $e = (p_1, p_2)$  be an edge in  $T$ .

- (1) Suppose  $e \in (Z - Z_{\delta})$ . We have that  $(Z - Z_{\delta}) \subseteq D$  and so  $e \in D$ .

(2) Suppose  $e \in (Z_i - Z_{i-1})$ ,  $i \leq \delta$ , and  $p_1, p_2$  are located in boxes  $b_1, b_2$  in  $B_i$ . We shall show that  $\pi(b_1, b_2, i)$  is nonempty, so the condition  $\pi(b_1, b_2, i) \cap V = \emptyset$  is not vacuously true. By Lemma 3 in § 3,  $L_i/3 \leq d_{\min}(b_1, b_2) \leq L_i$ . Let  $\hat{p}$  be the center of the line segment joining the centers of boxes  $b_1$  and  $b_2$ . It is easily shown that there is a cubical box  $\hat{b}$  of size  $2^{-(i-1)}$  centered at  $\hat{p}$ , such that  $d_{\max}(\hat{b}, \mu(b_1)) < d_{\min}(b_1, b_2) - d_{\max}(b_1, \mu(b_1))$ , and  $d_{\max}(\hat{b}, \mu(b_2)) < d_{\min}(b_1, b_2) - d_{\max}(b_2, \mu(b_2))$ . As  $\hat{b}$  must contain a box in  $B_i$  we conclude that  $\pi(b_1, b_2, i)$  is nonempty. Since  $(p_1, p_2) \in T$ , for each point  $p$  in  $V$  either  $d(p, p_1) \geq d(p_1, p_2)$  or  $d(p, p_2) \geq d(p_1, p_2)$ , and it then follows that  $\pi(b_1, b_2, i) \cap V$  must be empty. So  $e \in C_i$ . Hence  $T \subseteq C \cup D \subseteq E'$ .

*Algorithm Probably-Sparse-Graph* can be implemented in  $O(|E'| + k(2c_e)^k n)$  time by using a *tree-of-boxes*, similar to the one in § 3 for the boxes in  $B$ . We first build a skeleton for the *tree-of-boxes*. The skeleton differs from the *tree-of-boxes* described in § 3 in that there are no points in  $V$  stored at any of the leaf boxes. The skeleton has  $O(n)$  boxes and can be constructed in  $O((2c_e)^k n)$  time. Once the skeleton is available, we utilize a radix (bucket) sort [11], with radix  $2^{k\delta}$  ( $= O(n)$ ), to distribute the  $n$  points into the  $2^{k\delta}$  leaf boxes in  $O(n)$  time. We note that at this stage the *tree-of-boxes* contains all the boxes in  $B$  irrespective of whether they do or do not contain a point in  $V$ . Then in  $O(n)$  time we delete from the *tree-of-boxes* all those boxes which do not contain a

point in  $V$ , and add to each occupied box  $b$  a pointer to the leftmost leafbox in the subtree rooted at box  $b$ .

Utilizing the *tree-of-boxes*, we can check whether  $\pi(b_1, b_2, i) \cap V$  is empty in  $O(k(2c_e)^k)$  time if  $b_1 \in B_i, b_2 \in B_i$ , and  $d_{\min}(b_i, b_2) \leq L_i$ . The edge set  $C_i$  may be extracted in  $O(|C_i| + k(2c_e)^k n)$  time, for  $i = 1, \dots, \delta$ , and  $D$  may be obtained in  $O(|D| + k(2c_e)^k n)$  time. So *Algorithm Probably-Sparse-Graph* may be implemented in  $O(|E'| + k(2c_e)^k n)$  time.

We shall now describe a procedure for finding an MST in the graph  $G' = (V, E')$ . We first try to sort the edges in  $G'$  by employing a fixed number of passes of radix (bucket) sort [11], with radix (base)  $2^{\lceil \log_2 n \rceil}$ . If this approach fails to sort the edges in  $G'$  we sort them in  $O(|E'| \log |E'|)$  time using a standard algorithm [11]. After sorting the edges, we utilize Kruskal's algorithm [9], [11] to find an MST in  $G'$ . The edges are examined in increasing order of weight and an edge is chosen if and only if it does not form a cycle with the previously chosen edges. The chosen edges form an MST in  $G'$ . Once a sorted list of edges is available, Kruskal's algorithm may be implemented in  $O(|E'| \alpha(|E'|, n))$  time, where  $\alpha$  is the inverse Ackermann function defined in [13].

The algorithm to find an MST in the complete graph on  $V$  consists of first extracting  $G'$  using *Algorithm Probably-Sparse-Graph*, and then finding an MST in  $G'$  using the above described procedure. Let us assume that  $V$  consists of  $n$  random points, independently and uniformly distributed in the unit  $k$ -cube  $[0, 1]^k$ . Let  $P_L$  be the probability that for some  $i, 0 \leq i \leq kn^7 - 1$ , the lengths of at least two edges lie in the interval  $[in^{-7}, (i+1)n^{-7}]$ . In § 4.2 we show that  $P_L$  is  $o(1/n^2)$ . So the probability that eight passes of radix sort, with radix  $2^{\lceil \log_2 n \rceil}$ , fail to sort the edges in  $G'$  is  $o(1/n^2)$ ; thus the probability that the edges in  $G'$  cannot be sorted in  $O(|E'|)$  time, using a fixed number of passes of radix sort, is  $o(1/n^2)$ . Let  $P_{G'}$  be the probability that  $G'$  contains more than  $cn$  edges, where  $c$  is a constant dependent on the dimension  $k$ . In § 4.2 we also show that  $P_{G'}$  is  $o(1/n^2)$ . So with probability  $1 - o(1/n^2)$ , the running time of the algorithm to find an MST in the complete graph on  $V$  is  $O(cn\alpha(cn, n) + k(2c_e)^k n)$ . The worst case running time of the same algorithm is  $O(n^2 \log n)$ . Therefore, when  $k$  is fixed, the expected running time of the algorithm for finding an MST in the complete graph on  $V$  is  $O(n\alpha(cn, n))$ .

**4.2. Probabilistic analysis.** We assume that the set  $V$  consists of  $n$  random points which are independently and uniformly distributed in the unit  $k$ -cube  $[0, 1]^k$ . Let  $P_L$  be the probability that for some  $i, 0 \leq i \leq kn^7 - 1$ , the lengths of at least two edges lie in the interval  $[in^{-7}, (i+1)n^{-7}]$ . Let  $P_{G'}$  be the probability that  $G'$  contains more than  $cn$  edges, where  $c$  is a constant dependent on the dimension  $k$ . We have to show that both  $P_{G'}$  and  $P_L$  are  $o(1/n^2)$ .

We shall first bound  $P_L$ . Fix an ordering on the points in the unit  $k$ -cube. Assume that there are at least two edges  $e_1$  and  $e_2$  whose lengths lie in the interval  $[in^{-7}, (i+1)n^{-7}]$ , for some  $i$ . Suppose  $e_1, e_2$  have an endpoint in common and  $e_1 = (x, y), e_2 = (y, z)$ . Then the points  $x$  and  $z$  are restricted to lie in a shell, of thickness  $n^{-7}$  and radius at most  $k$ , around point  $y$ , and there are at most  $n^3$  possibilities for triples  $(x, y, z)$ . Suppose  $e_1, e_2$  do not have an endpoint in common and  $e_1 = (x, y), e_2 = (z, w)$ . Without loss of generality let  $x \leq y$  and  $z \leq w$ . Then  $x$  is restricted to lie in a shell, of thickness  $n^{-7}$  and radius at most  $k$ , around  $y$ ;  $z$  must lie in a similar shell around  $w$ ; and there are at most  $n^4$  choices for tuples  $(x, y, z, w)$ . We thus have

$$P_L \leq kn^7 \left( \left( \frac{c_1}{n^7} \right)^2 n^3 + \left( \frac{c_2}{n^7} \right)^2 n^4 \right) = o\left( \frac{1}{n^2} \right)$$

where  $c_1$  and  $c_2$  are constants dependent on dimension  $k$ .

We shall now estimate  $P_{G'}$ . Let us assume that  $n$  is a power of  $2^k$ . Let  $m_i = 2^{ki}$ ,

$$\beta_i = \{b: b \in B_i, (p_1, p_2) \in C_i, \text{ either } p_1 \in b \text{ or } p_2 \in b\},$$

and

$$\Pi_i = \{\pi(b_1, b_2, i): b_1 \in B_i, b_2 \in B_i, p_1 \in b_1, p_2 \in b_2, (p_1, p_2) \in C_i\}.$$

We note that the volume of each region in  $\Pi_i$  is at least  $m_i^{-1}$ . There exists a constant  $c_5 \geq 1$ , dependent on  $k$ , such that for each  $i, i = 1, \dots, \delta$ , each region in  $\Pi_i$  intersects at most  $c_5$  other regions in  $\Pi_i$ . Let  $c_3 = (36k + 3)^k$ . There are at most  $c_3 m_i$  possibilities for regions in  $\Pi_i$ . We let  $c_6$  be the smallest positive integer greater than 16 such that  $2^{c_6}/c_5 > 2 + \log_e(c_3 c_5) + 6c_6$  and  $c_6 \geq 1 + 2^{c_6} \log_e(1 + 2^{-c_6})$ .

We define  $P_i$  as follows.

- (1) For  $n/m_i > 6c_3 \log_2 n$ , let  $P_i$  be the probability that  $C_i$  is not empty.
- (2) For  $2^{c_6} < n/m_i \leq 6c_3 \log_2 n$ , let  $P_i$  be the probability that  $C_i$  contains more than  $c_3 m_i$  edges.
- (3) For  $1 \leq n/m_i \leq 2^{c_6}$ , let  $P_i$  be the probability that the number of edges in  $C_i$  exceeds  $c_3 c_7 m_i$  where  $c_7 = 2e^4 2^{2c_6}$ .

Let  $P_D$  be the probability that the number of edges in  $D$  exceeds  $c_3 c_7 n$ .

Let the constant  $c$  in the definition of  $P_{G'}$  be  $4c_3 c_7$ . If the number of edges in  $G'$  exceeds  $4c_3 c_7 n$  then either  $D$  contains more than  $c_3 c_7 n$  edges, or for some  $i, 1 \leq i \leq \delta$ ,  $C_i$  contains more than  $c_3 c_7 m_i$  edges. Hence,

$$P_{G'} \leq \sum_{i=1}^{\delta} P_i + P_D.$$

We shall show that each of  $P_i$  and  $P_D$  is  $o(1/n^4)$  and it then follows that  $P_{G'} = o(1/n^2)$  as  $\delta \leq \log_2 n$ . In order to bound  $P_i$  we consider three cases depending on the value of  $n/m_i$ .

*Case 1.*  $n/m_i > 6c_3 \log_2 n$ . In this case we show that there is a large empty region in the unit  $k$ -cube  $[0, 1]^k$ . If  $C_i$  is nonempty there is at least one region in  $\Pi_i$  and this region does not contain a point in  $V$ . There are at most  $c_3 m_i$  possibilities for regions in  $\Pi_i$  and each of these regions has volume at least  $(m_i)^{-1}$ . Hence,

$$P_i \leq c_3 m_i \left(1 - \frac{1}{m_i}\right)^n = o\left(\frac{1}{n^4}\right).$$

We shall now give a lemma that will be useful for Case 2 and Case 3. Let  $P_{ij}$  be the probability that the number of boxes in  $B_i$ , which contain at least  $e^{2j}$  and at most  $e^{2j+1}$  points in  $V$ , exceeds  $m_i/2^{3j}$ .

LEMMA 4. Let  $2^{j_0} \geq (n/m_i) \geq 1$ , and  $(n/m_i) \leq 6c_3 \log_2 n$ . Then  $\sum_{j=j_0}^{\log_2 n} P_{ij} = o(1/n^4)$ .

*Proof.* Suppose  $2^j \geq 6c_3 \log_2 n$ , and  $2^j \geq (n/m_i)$ . As  $P_{ij}$  is bounded by the probability that there is at least one box in  $B_i$  with at least  $e^{2j}$  points, we have

$$\begin{aligned} P_{ij} &\leq m_i \binom{n}{e^{2j}} (m_i)^{-e^{2j}} \\ &\leq m_i \frac{n^{e^{2j}}}{(e^{2j})!} (m_i)^{-e^{2j}} \\ &\leq O\left(m_i \left(\frac{n}{m_i 2^j}\right)^{e^{2j}} e^{-e^{2j}}\right) \quad (\text{using Stirling's approx.}) \\ &= o\left(\frac{1}{n^5}\right). \end{aligned}$$

Suppose  $1 \leq (n/m_i) \leq 2^j < 6c_3 \log_2 n$ . We can get a bound on  $P_{ij}$  by first choosing  $m_i/2^{3j}$  boxes in  $B_i$ , then choosing  $e^2 m_i/2^{2j}$  points to be located in the chosen boxes and letting the remaining points lie anywhere in the unit  $k$ -cube. So

$$\begin{aligned} P_{ij} &\leq \binom{m_i}{m_i/2^{3j}} \binom{n}{e^2 m_i/2^{2j}} 2^{-3je^2 m_i 2^{-2j}} \\ &\leq \frac{(m_i)^{m_i 2^{-3j}} n^{e^2 m_i 2^{-2j}}}{(m_i 2^{-3j})! (e^2 m_i 2^{-2j})!} 2^{-3je^2 m_i 2^{-2j}} \\ &\leq O\left( (e2^{3j})^{m_i 2^{-3j}} e^{-e^2 m_i 2^{-2j}} \left(\frac{n}{m_i 2^j}\right)^{e^2 m_i 2^{-2j}} \right) \quad (\text{Stirling's approx.}) \\ &= o\left(\frac{1}{n^5}\right). \end{aligned}$$

The proof of the lemma then follows.  $\square$

*Case 2.*  $2^{c_6} < n/m_i \leq 6c_3 \log_2 n$ . This case is broken down into two subcases depending on the number of boxes in  $\beta_i$ . We have

$$\begin{aligned} P_i &\leq \Pr(|\beta_i| > 8m_i^7 n^{-6}) + \Pr(|\beta_i| \leq 8m_i^7 n^{-6} \text{ and } |C_i| > c_3 m_i) \\ &= o(1/n^4) + o(1/n^4) = o(1/n^4). \end{aligned}$$

If  $|\beta_i| > 8m_i^7 n^{-6}$  then there is a large empty region, whereas if  $|\beta_i| \leq 8m_i^7 n^{-6}$  and  $|C_i| > c_3 m_i$  then there is a concentration of points in some region.

*Case 2.1.* Suppose  $|\beta_i| > 8m_i^7 n^{-6}$ . There are at least  $|\beta_i|/2$  regions in  $\Pi_i$  and as a region in  $\Pi_i$  intersects at most  $c_5$  other regions in  $\Pi_i$ , we can find at least  $c_5^{-1} m_i^7 n^{-6}$  disjoint regions in  $\Pi_i$  each of which does not contain any point in  $V$ . As there are at most  $c_3 m_i$  choices for regions in  $\Pi_i$ , and each region in  $\Pi_i$  has volume at least  $m_i^{-1}$ , we have

$$\begin{aligned} \Pr(|\beta_i| > 8m_i^7 n^{-6}) &\leq \binom{c_3 m_i}{c_5^{-1} m_i^7 n^{-6}} (1 - c_5^{-1} m_i^6 n^{-6})^n \\ &\leq \frac{(c_3 m_i)^{c_5^{-1} m_i^7 n^{-6}}}{(c_5^{-1} m_i^7 n^{-6})!} (1 - c_5^{-1} m_i^6 n^{-6})^n. \end{aligned}$$

Using Stirling's approximation for factorials, taking logarithms and noting that  $\log_e(1-x) \leq -x$ , for  $0 \leq x < 1$ , we get

$$\begin{aligned} \log_e (\Pr(|\beta_i| > 8m_i^7 n^{-6})) &\leq nc_5^{-1} \left(\frac{m_i}{n}\right)^6 \left(-1 + \frac{m_i}{n} \left(1 + \log_e(c_3 c_5) + 6 \log_e\left(\frac{n}{m_i}\right)\right)\right) \\ &\leq -\frac{n}{c_5 2^{c_6} (6c_3 \log_2 n)^6}. \end{aligned}$$

Thus

$$\Pr(|\beta_i| > 8m_i^7 n^{-6}) = o(1/n^4).$$

*Case 2.2.* Suppose  $|\beta_i| \leq 8m_i^7 n^{-6}$  and  $|C_i| > c_3 m_i$ . Let  $j_0 = 2 \log_2(n/m_i) - 1$ . A point in any box  $b$  in  $B_i$  is joined to points in at most  $c_3$  other boxes in  $B_i$  by edges in  $C_i$ , and so we have that

$$c_3 \sum_{b \in \beta_i} (|b \cap V|)^2 \geq |C_i| > c_3 m_i$$

and hence

$$\sum_{b \in \beta_i, |b \cap V| \geq 2^{j_0}} (|b \cap V|)^2 > (1 - 2^{-c_6+1}) m_i.$$

Then for some  $j, j = j_0 (= 2 \log_2(n/m_i) - 1), \dots, \log_2 n$ , the number of boxes in  $\beta_i$  (and hence  $B_i$ ), which contain at least  $e^{2^j}$  and at most  $e^{2^{j+1}}$  points in  $V$ , exceeds  $m_i/2^{3j}$ . Then from Lemma 4,

$$Pr(|\beta_i| \leq 8m_i^7 n^{-6} \text{ and } |C_i| > c_3 m_i) \leq \sum_{j=j_0}^{\log_2 n} P_{ij} = o\left(\frac{1}{n^4}\right).$$

Case 3.  $1 \leq n/m_i \leq 2^{c_6}$ . Suppose  $|C_i| > c_3 c_7 m_i$ . A point in box  $b$  in  $B_i$  is joined to points in at most  $c_3$  other boxes in  $B_i$  by edges in  $C_i$ , and so we get

$$c_3 \sum_{b \in B_i} (|b \cap V|)^2 \geq |C_i| > c_3 c_7 m_i = 2e^4 2^{2c_6} c_3 m_i;$$

hence,

$$\sum_{b \in B_i, |b \cap V| \geq 2^{c_6}} (|b \cap V|)^2 > (2e^4 - 1) 2^{2c_6} m_i.$$

Then for some  $j, j = c_6, \dots, \log_2 n$ , the number of boxes in  $B_i$ , which contain at least  $e^{2^j}$  points and at most  $e^{2^{j+1}}$  points in  $V$  exceeds  $m_i/2^{3j}$ . Then from Lemma 4 we can conclude that

$$P_i \leq \sum_{j=c_6}^{\log_2 n} P_{ij} = o\left(\frac{1}{n^4}\right).$$

By reasoning in the same manner as in Case 3 above we can show that  $P_D = o(1/n^4)$ .

**5. Conclusions.** We have given an  $O(\varepsilon^{-k} n \log n)$  algorithm for finding an approximate minimum spanning tree on a set  $V$  of  $n$  points in  $k$ -dimensional space, the weight of the approximate minimum spanning tree is guaranteed to be at most  $(1 + \varepsilon)$  times the weight of a minimum spanning tree. We have also presented an algorithm for finding a minimum spanning tree on a set  $V$  of  $n$  points in  $k$ -dimensional space. Under the assumption that the set  $V$  consists of  $n$  random points, independently and uniformly distributed in the unit  $k$ -cube  $[0, 1]^k$ , the expected running time of this minimum spanning tree algorithm is shown to be  $O(n\alpha(cn, n))$  where  $c$  is a constant dependent on  $k$  and  $\alpha$  is the inverse Ackermann function.

**Acknowledgments.** The author would like to thank Professor C. L. Liu, S. Kapoor, and P. Ramanan for helpful discussions.

## SOME GEOMETRY FOR GENERAL RIVER ROUTING\*

ALAN SIEGEL† AND DANNY DOLEV‡

**Abstract.** Efficient solutions are given to compute the optimal placement for a pair of VLSI modules interconnected by river routing. Specifically, let the (perpendicular) distance between the two modules be the **separation**, and call the (transverse) displacement the **offset**. This paper principally considers the separation problem: Given an offset and a wiring rule, find the minimum separation permitting a legal wiring. The design rules might use wires which are exclusively rectilinear, polygonal with a finite number of slopes, or possibly restricted to some other class of shapes such as circular arcs plus linear pieces.

Techniques are developed which unify a variety of different placement problems, and give efficient solutions under extremely general conditions. The advantage of these generalizations is not only their theoretical framework; the results extend naturally to more precise models of real river routing, and the theory is applicable to placement problems for collections of modules.

**Key words.** VLSI, river routing, placement

**AMS(MOS) subject classifications.** F.2.2, B.7.2

**1. Introduction.** VLSI circuits are often designed in pieces analogous to macros or subroutines of computer programs. Each piece, called a **module**, has **terminals**, which are connection points for wires distributing signals and power among the modules. **River routing** is wiring that has no crossovers; it can essentially be implemented on a single layer. Although such a routing cannot be used to make arbitrary connections, it is commonly used wherever practical, since designs with higher percentages of river routing are often easier to lay out, more compact, and faster than circuits with more complex interconnections. Two rows of terminals, for example, may be connected by river routing when the corresponding terminals for each row are in the same order (but are not necessarily in perfect alignment). Input pads, arrays of identical cells, PLAs, and bristle block constructions (as defined in [J]) are likely to have interconnections free from crossovers.

We analyze the problem of efficiently computing optimal placements for a pair of interconnected modules. The specific definitions of optimality will be given in the next section. The requirement of efficiency precludes taking the quadratic time necessary to determine all possible  $O(n^2)$  coordinates of the interconnection wires; the goal is to have fast primitives to compute the space required for the wiring.

These utilities would be useful in automated hierarchical design systems. They can also be used to find optimal solutions to more complicated problems such as placement for two rows of modules interconnected by river routing [Si1]. Furthermore, the iteration of fast primitives, such as the ones presented here, ought to provide satisfactory solutions to more general placement problems, which are computationally too complex to solve optimally. Finally, the algorithms and VLSI properties developed in this paper have application to other problems of placement and routing as well as to the theory of computational geometry.

**2. The wiring problem.** The wiring problem is illustrated in Fig. 2.1. Two rows of  $n$  corresponding terminals,  $\{P_i\}$  and  $\{Q_i\}$ , are to be interconnected by wires. The rows are parallel, and each row represents a rigid module; the inter-terminal spacings between the  $P_i$  are fixed, as are the  $Q_i$  spacings. A relative placement of the terminals is thus completely determined by two values: the vertical distance between the rows, which is the **separation**, and the horizontal distance between the first pair of terminals  $P_1$  and  $Q_1$ , which is the **offset**. The connecting wires will be subject to various constraints (design rules) described later. These constraints determine the permissible shapes for wires and the spacing between adjacent wires. Consequently they determine which offsets and separations are permissible for the modules. As shown, the rows are taken to be horizontal, with the  $\{Q\}$  above the  $\{P\}$ .

We examine the following.

(1) *The Separation Problem.* Given an offset and a wiring rule, find the minimum separation permitting a legal wiring.

The principal conclusion is:

For general curvilinear wiring rules, the separation can be found in  $O(n \log n)$  time.

Related problems include:

(2) *The Optimal Offset Problem.* Given a wiring rule, find an offset minimizing the separation.

(3) *The Offset Range Problem.* Given a wiring rule and a separation, find all offsets permitting a legal wiring.

In [Si2], the separation problem is solved in  $O(n)$  time for polygonal wiring. In [Si3], the optimal offset problem is solved in time<sup>1</sup>  $O(\Psi(n) \log n)$  where  $\Psi(n)$  is the time to find the separation. The results in this paper, therefore, are directly applicable to the optimal offset problem. In [Si1], the offset range problem is solved in  $O(n \log n)$  time for general curvilinear wiring rules, and in time  $O(n)$  for polygonal wiring; the results are then extended to solve placement problems for ensembles of modules interconnected by river routing channels.

Tompa examined river routing for two parallel rows of terminals in [T1]. His work gives a quadratic solution for locating (if possible) the interconnection wires when the terminals are given fixed positions. This solution is optimal since the wiring description may have  $O(n^2)$  coordinates. Although the solution is optimal, it does not give efficient methods to answer the important questions of finding good module placements solving the separation or optimal offset problems. Tompa [T2] reports the

FIG. 2.1

<sup>1</sup> Recently, a very elegant  $O(n)$  time solution was discovered for the optimal offset problem with rectilinear wiring [M].

existence of an  $O(n \log n)$  algorithm by Kirkpatrick and Seidel to solve the separation problem for linear plus circular wiring and states the optimal offset problem as an open question. The offset range problem is related to the work by Leiserson and Pinter [LP] which gives an  $O(n)$  time solution for rectilinear wiring on an integer grid, and solves placement problems for two rows of interconnected modules. [Si1] includes generalizations and refinements of results originating in [LP].

In this paper, we develop some of the techniques which unify these problems and provide efficient solutions under extremely general conditions. The advantage of these generalizations is not only their theoretical framework; the results extend naturally to more precise models of real river routing, and the techniques are applicable to other types of wiring problems and to problems in computational geometry as well. See [Si1], [Si2], and [Si3] for more of the routing theory.

**3. The models.** In VLSI design, wires on a given layer satisfy specific constraints. Wires are frequently required to be composed exclusively of rectilinear segments; sometimes 45-degree pieces are also permitted. Other fabrication processes allow a variety of segment slopes. These polygonal wiring rules and, for theoretical interest, more general wiring shapes will be included in our methods. The minimum distance between wires is set to 1, and the wire width is taken as 0 for mathematical convenience.

The limitations in the resolution of a fabrication process also affect wire shape. A circular figure, for example, can be approximated arbitrarily well by sufficiently small rectilinear segments, but a VLSI wire must be composed of pieces with a fixed minimum size. Our model can include this restriction by requiring all wire segments to have endpoints lying on a lattice (which is hereafter called a grid). We examine integer grids, which are lattices with unit spacing, and fractional grids, which have fractional spacing.<sup>2</sup> Continuous grids will also be considered.

Given  $n$  pairs of terminals,  $(P_1, Q_1), \dots, (P_n, Q_n)$ , define  $P_i$  to be both the name of a terminal on the bottom row and the horizontal position of the terminal, and take  $Q_j$  to be a similar terminal on the upper row.

Since wires must be separated by unit distance, every routing problem has forbidden regions restricting the wiring flow. Specifically, for every terminal  $P_j$  and index  $s$ , there is an  $s$ th region (specified later) around  $P_j$ , which cannot be entered by a wire connecting  $P_{j+t}$  with  $Q_{j+t}$  for  $|t| \geq s$ . See Fig. 3.1.

With a scheme permitting unrestricted wire shapes, these regions will be concentric disks centered at the terminals [T1]. We require the boundaries to conform to the shapes

FIG. 3.1. Wires restricted by rectangular barriers around  $P_1$ .

<sup>2</sup> More precisely, our models include a variety of wiring schemes defined on lattices. The specific models are in fact gridless.

FIG. 3.2. Separation barriers.

permitted by the wiring scheme and grid restrictions.<sup>3</sup> In the rectilinear case with an integer grid they are concentric rectangles. On a quarter-integer grid the separation barriers are no longer rectangular. See Fig. 3.2. We remark that the boundaries of the barriers in Fig. 3.2(a), for example, are concave, that is, the curves have a negative second derivative. The region lying below such a boundary, however, is geometrically convex, that is, any pair of points lying inside the region defines a line segment which is contained within the region. To avoid confusion, we shall always refer to this latter property as geometrical convexity.

In §§ 5 and 6, the separation problem is analyzed principally for families of similar concave barriers. In § 7, the requirements of concavity and similarity will be relaxed somewhat and the wiring models extended to include virtually all known wiring schemes. Sections 8 and 9 apply the results to more realistic wiring models.

**4. The separation function.** It has already been observed that the separation must be sufficient to allow each terminal  $Q_j$  to lie outside the  $|j-i|$ th barrier emanating from  $P_i$  for all  $i$ . The separation, of course must also be at least as high as the highest point on any wire. These two facts may be used to modify the separation barriers. Define the  $j$ th **right separation barrier** to be the curve obtained by extending the  $j$ th barrier to the left of its origin continuously as a horizontal line with height (which in most cases equals)  $j$ . **Left separation barriers** are defined analogously. These new barriers are monotone, and if the original regions are geometrically convex and similar, then

<sup>3</sup> It is not difficult to show that the boundaries do conform to the wiring shapes for, say, unrestricted curvilinear, integer-grid-rectilinear, quarter-integer-grid-rectilinear, and half-integer-grid-rectilinear-plus-45-degree wiring schemes. However, this criterion is not satisfied by design rules having an arbitrary collection of permissible wire slopes and requiring segments to have endpoints on a given grid. Furthermore, the solution to the separation problem for these arbitrary wiring rules may require wires which are not even monotone in  $x$ . These and related difficulties are eliminated in § 4 by defining wiring rules in terms of separation barriers. Another advantage of this barrier formulation is that quarter-integer rectilinear wiring, for example, can be defined for problems where the terminals are not located on a quarter-integer grid. Moreover, rectilinear-plus-45-degree wiring can be defined not only as in the half-integer-grid scheme, but also with barriers packed, say, more densely than any model having rational coordinates.

the new ones are also. Figure 4.1 shows a family of modified right separation barriers. All barriers are now assumed to be so modified. Now the **separation function**  $W(i, j)$  can be defined as the height at  $Q_j$ , for  $j > i$   $\{j < i\}$ , of the  $|j - i|$ th right  $\{left\}$  barrier emanating from  $P_i$ . See Fig. 4.2.

Let the family of right barrier curves emanating from the origin be represented by the functions  $H_\rho(x)$ , where  $\rho$  is the index. ( $H_\rho$  is taken to be lower semicontinuous, that is,  $H_\rho(x) = \min \{y \mid (x, y) \text{ is on the curve}\}$ .) Note that the convex separation regions as shown in Fig. 4.2 have concave functions defining their boundaries. The family of right barriers emanating from  $P_i$  are defined by  $H_\rho(x - P_i)$ , and the separation function (for both left and right barriers) is:

$$(4.1) \quad W(i, j) = \begin{cases} H_{j-i}(Q_j - P_i) & \text{if } j > i, \\ 0 & \text{if } j = i, \\ H_{i-j}(P_i - Q_j) & \text{if } j < i. \end{cases}$$

It follows that the separation is not less than  $\max_{i,j} W(i, j)$ . We now show the following lemma.

LEMMA 1. *The solution to the separation problem is  $\max_{i,j} W(i, j)$ .*

*Proof.* It remains to prove that  $P$  and  $Q$  can be legally connected with separation width  $\max_{i,j} W(i, j)$ . Suppose  $Q_j \leq P_j$  and  $Q_{j-1} \leq P_{j-1}$ . Connect  $P_j$  with  $Q_j$  by running wire  $j$  along the bounding envelope formed from the  $(j - i)$ th right barrier emanating from  $P_i$ ,  $i = 1, 2, \dots, j - 1$ . An envelope is illustrated in Fig. 4.3(a). The spacing requirement between wires is satisfied because any point on wire  $j - 1$  (with the exception of those on the vertical segment ending at  $Q_{j-1}$  or the horizontal segment starting at  $P_{j-1}$ ) is by definition on the  $(j - i - 1)$ th barrier emanating from  $P_i$  for some  $i < j$  while wire  $j$  is beyond the  $(j - i)$ th barrier. It is easy to see that the vertical segment terminating at  $Q_{j-1}$  and the horizontal segment terminating at  $P_{j-1}$  are at least unit

FIG. 4.1. Similar concave barriers.

FIG. 4.2. A separation from circular barriers.

(a) *Interacting barriers*(b) *Nonmonotonic separation*FIG. 4.3. *The complications of wiring.*

distance from wire  $j$ . The argument is the same if both inequalities are reversed. The two remaining possibilities cause wires  $j$  and  $j-1$  to run in opposite directions; the wires are then closest at  $Q_{j-1}$  and  $Q_j$  or  $P_{j-1}$  and  $P_j$ .  $\square$

Note that a barrier envelope may have barrier pieces with endpoints which are not on a discrete grid for, say, curvilinear barriers. The use of such an envelope as a wire path, however, is reasonable when positive wire thicknesses are included in the model, or when practical wiring shapes are considered. Consequently we shall assume that a wire can indeed follow the boundary of intersecting barriers and rise vertically when necessary to connect to a terminal  $Q_j$ . Thus a wiring scheme is determined by its separation barriers. An alternative assumption is that the wiring scheme permits legal connections when the placement satisfies the separation constraints. Tompa, for example, shows how to compute interconnections with wires as short as possible using unrestricted curvilinear (i.e., circular) barriers [T]. In this case the wires might follow a path which differs from the envelope, but the legal placements for the two wiring schemes are the same.

Define a **left block** to be a maximal sequence of pairs of terminals  $(P_i, Q_i), \dots, (P_j, Q_j)$  such that  $Q_k \leq P_k$ , for  $i \leq k \leq j$ . This condition says that all the connection points in the upper row of a *left block* are located to the left of the corresponding positions on the lower row. The previous lemma shows that a left block,

if legally wireable, can be wired so that each wire in the block decreases monotonically in height from its  $Q$ -terminal  $Q_i$  to its  $P$ -terminal  $P_i$ . Clearly analogous conclusions hold for a **right block**. It follows that a wireable left or right block can be wired within its rectangular boundary. Consequently, for a fixed offset, the separation is determined by the worst block. Therefore we may assume that the separation problem is to be solved for a single left block (which uses right separation barriers). The separation is in fact determined by the worst **strict block**, where a strict left block is a maximal sequence of pairs  $(P_i, Q_i), \dots, (P_j, Q_j)$  such that  $Q_k < P_k$  for  $i \leq k \leq j$ .

Lemma 1 shows that separation problem can be solved in  $O(n^2)$  time. For rectilinear wiring on an integer grid the complexity can be shown to be  $O(n)$  [DKSSU]. Figure 4.3 illustrates the difficulties in determining the separation for more complex wiring schemes; one example shows many wiring barriers interacting with one wire ( $P_6$  to  $Q_6$  in this case); the other shows the nonmonotonic behavior of the separation function.

**5. The partitioning property.** The barrier families discussed in this paper all satisfy some fundamental geometric properties. These properties will enable the use of a divide-and-conquer approach to reduce the time needed to find the separation. The idea behind the Partitioning Theorem is essentially the following. Consider two line segments that connect  $Q_{i_1}$  with  $P_{i_1}$  and  $Q_{i_2}$  with  $P_{i_2}$ . Suppose  $i_1$  and  $i_2$  maximize, respectively,  $W(*, j_1)$  and  $W(*, j_2)$ . The Partitioning Property then says that the segments cannot cross. It is then a simple matter to exploit this property to find the maximum separation in  $O(n \log n)$  time (Theorem 9): Set  $j = \lceil n/2 \rceil$ , and find the index  $i^*$ , which is the largest  $i \leq \lceil n/2 \rceil$  maximizing  $W(i, \lceil n/2 \rceil)$ . The separation problem will then split into two subproblems, to find  $\max_{i \in [1, i^*], j \in [1, \lceil n/2 \rceil]} W(i, j)$ , and to find  $\max_{i \in [i^*, n], j \in [\lceil n/2 \rceil + 1, n]} W(i, j)$ . The splitting is applied recursively. In this section, we identify the basic barrier properties which guarantee that the Partitioning Property is satisfied.

Define  $l(\rho, x)$ , for  $x \leq \rho$ , to be the horizontal line segment that is bounded by the curves  $H_\rho$  and  $H_{\rho-1}$  and that intersects  $H_\rho$  at  $(x, H_\rho(x))$ . Let  $l(\rho, \rho)$  have endpoints  $(\rho - 1, 0)$  and  $(\rho, 0)$ ,  $\rho > 1$ . Take  $l$  to be a half-infinite line if it does not intersect  $H_{\rho-1}$  or if  $l$  intersects the barrier along an infinite ray. (Properties P0c, P0d below will ensure that  $l$  must otherwise intersect  $H_{\rho-1}$  in exactly one point.) See Fig. 5.1. Denote the length of  $l \equiv l(\rho, w)$  by  $|l|$ , and let  $Lx(\rho, w)$  be the  $x$ -coordinate of  $l$ 's left endpoint. We first consider barrier families satisfying the following properties.

- P0a:  $H_\rho(x) = 0$  for  $x \geq \rho$ . This says if terminal  $Q_j$  is at least  $j - i$  units to the right of  $P_i$ , then the wiring from  $Q_j$  to  $P_j$  is unaffected by the presence of  $P_i$ .
- P0b:  $H_\rho(x) > H_{\rho-1}(x)$  for  $x < \rho$ . The barriers emanating from a common point do not intersect since different wires must not touch.
- P0c:  $H_\rho(x) \geq H_\rho(y)$  for  $x \leq y \leq \rho$ . The barrier functions are nonincreasing.
- P0d:  $H_\rho(x + \varepsilon) - 2H_\rho(x) + H_\rho(x - \varepsilon) \leq 0$  for  $\varepsilon > 0, x + \varepsilon \leq \rho$ . The  $H_\rho(x)$  are concave for  $x \leq \rho$ .
- P1: If  $x \leq y \leq \rho$ , then  $|l(\rho, x)| \geq |l(\rho, y)|$ . The length of the horizontal line segment between  $H_\rho$  and  $H_{\rho-1}$  does not decrease as a function of the segment's height. In other words, the left derivative of  $H_\rho$  at  $x$  is no greater than the left derivative of  $H_{\rho-1}$  at  $Lx(\rho, x)$ .
- P2: If  $x \leq \rho$ , then  $|l(\rho - 1, x - 1)| \geq |l(\rho, x)|$ . As a weak consequence, the curves  $H_\rho$  cut any horizontal line into a sequence of segments having lengths which do not increase as the sequence is traversed from left to right.

It should be noted that generalizations of these properties will be the basis of Theorems 15, 17, and 18. We avoid unnecessary complication by using properties P0, P1, and

FIG. 5.1

P2 in this section, and escape repetition by giving proofs, which, mutatis mutandis, also hold for the more general barriers.

LEMMA 2. *Let  $d > 0$  and suppose the  $H_\rho$ 's satisfy P0, P1, and P2. Then  $H_{\rho+1}(\nu) > H_\rho(u)$  implies  $H_{\rho+1}(\nu - d) > H_\rho(u - d)$ .*

*Proof.* Suppose  $H_{\rho+1}(\nu) > H_\rho(u)$ . Then  $\nu < \rho + 1$ , and we may assume that  $u \leq \rho$ . Let  $l$  be the horizontal segment with left endpoint  $(u, H_\rho(u))$  and bounded on the right by  $H_{\rho+1}$ . See Fig. 5.2. Let the  $x$ -coordinate of  $l$ 's right endpoint be  $z$ . It is not necessarily true that  $l = l(\rho + 1, z)$  since  $z$  could equal  $\rho + 1$  and the barrier  $H_{\rho+1}$  might be a vertical segment at  $\rho + 1$ . Let  $x = (z + \nu)/2$ . Then  $\nu < x < z$ ,  $Lx(\rho + 1, x) < u$  and  $|l(\rho + 1, x)| \geq |l|$ . By P0c,  $H_{\rho+1}(\nu - d) \geq H_{\rho+1}(x - d)$ . Moreover,  $Lx(\rho + 1, x - d) = x - d - |l(\rho + 1, x - d)| < z - d - |l| = u - d$ . So  $H_{\rho+1}(\nu - d) \geq H_{\rho+1}(x - d) \geq H_\rho(Lx(\rho + 1, x - d)) \geq H_\rho(u - d)$ . It is not possible that  $H_{\rho+1}(\nu - d) = H_{\rho+1}(x - d) = H_\rho(u - d)$  since P0c and P0d would then contradict P0b by saying that  $H_{\rho+1}$  must be flat to the left of  $x - d$ , which implies that  $H_{\rho+1}(s)$  and  $H_\rho(s)$  intersect at  $s = \min\{u - d, x - d\}$ .  $\square$

LEMMA 3. *Let  $r > 0$ ,  $d > 0$ , and suppose the  $H_\rho$ 's satisfy P0, P1, and P2. Then  $H_{\rho+r}(\nu) > H_\rho(u)$  implies  $H_{\rho+r}(\nu - d) > H_\rho(u - d)$ .*

FIG. 5.2

*Proof.* It suffices to assume that  $\nu < \rho + r$ , and  $u \leq \rho$ . The proof is by induction on  $r$ . Lemma 2 proves the case  $r = 1$ . Suppose Lemma 3 is true for  $r = k - 1$ , and let  $r = k$ . Let  $x_0 = Lx(\rho + k, \nu)$  and let  $x_1 = \max_x \{x: H_{\rho+k-1}(x) > H_\rho(u)\}$ . Let  $x = (x_1 + x_0)/2$ . Then  $H_{\rho+k}(\nu) > H_{\rho+k-1}(x) > H_\rho(u)$ . Thus by the induction hypothesis,  $H_{\rho+k-1}(x - d) > H_\rho(u - d)$ . Moreover,  $H_{\rho+k}(\nu - d) > H_{\rho+k-1}(x - d)$ . Combining these two inequalities shows that  $H_{\rho+k}(\nu - d) > H_\rho(u - d)$ .  $\square$

LEMMA 4. *Let  $\rho > 1$  and suppose the  $H_\rho$ 's satisfy P0, P1, and P2. Then  $H_{\rho+1}(\nu) > H_\rho(u)$  implies  $H_\rho(\nu - 1) > H_{\rho-1}(u - 1)$ .*

*Proof.* Again take  $\nu < \rho + 1$ , and  $u \leq \rho$ . Let  $l$  be the horizontal segment with left endpoint  $(u, H_\rho(u))$  and bounded by  $H_{\rho+1}$  on the right. Let  $s = Lx(\rho + 1, \nu)$ . See Fig. 5.3. Clearly  $s \in [-\infty, u)$ . P2 says  $|l(\rho, \nu - 1)| \geq |l(\rho + 1, \nu)|$ , so  $Lx(\rho, \nu - 1) = \nu - 1 - |l(\rho, \nu - 1)| \leq \nu - |l(\rho + 1, \nu)| - 1 = s - 1 < u - 1$ , and  $H_\rho(\nu - 1) \geq H_{\rho-1}(Lx(\rho, \nu - 1)) \geq H_{\rho-1}(u - 1)$ . So

$$(5.1) \quad H_\rho(\nu - 1) \geq H_{\rho-1}(u - 1).$$

The inequality is made strict with the same trick as Lemma 2. Let  $z$  be the  $x$ -coordinate of  $l$ 's right endpoint. Let  $x = (z + \nu)/2$ . Then  $x > \nu$ , but  $H_{\rho+1}(x) > H_\rho(u)$ . Substituting  $x$  for  $\nu$  in (5.1) and noting that  $x > \nu$  gives  $H_\rho(\nu - 1) \geq H_\rho(x - 1) \geq H_{\rho-1}(u - 1)$ . If equality holds everywhere,  $H_\rho(\nu - 1) = H_\rho(x - 1) = H_{\rho-1}(u - 1)$ . This says that  $H_\rho$  is flat to the left of  $x - 1$  and must intersect  $H_{\rho-1}$  at  $\min(x - 1, u - 1)$ , which contradicts P0b. Hence  $H_\rho(\nu - 1) > H_{\rho-1}(u - 1)$ .  $\square$

FIG. 5.3

LEMMA 5. *Let  $r > 0$ , and suppose the  $H_\rho$ 's satisfy P0, P1, and P2. Then  $H_{\rho+r}(\nu) > H_\rho(u)$  implies  $H_{\rho+r-1}(\nu - 1) > H_{\rho-1}(u - 1)$ .*

*Proof.* The proof uses an induction argument similar to that for Lemma 3. Once more  $\nu < \rho + r$ , and we may assume  $u \leq \rho$ . Lemma 4 proves the case  $r = 1$ . Suppose Lemma 5 is true for  $r = k - 1$ , and let  $r = k$ .  $H_{\rho+k-1}$  must have values greater than  $H_\rho(u)$  since it cannot intersect the curve  $H_\rho(x)$  for  $x < \rho$ . Since  $|l(\rho + k, \nu)| \geq 1$ ,  $H_{\rho+k-1}$  must have values less than  $H_{\rho+k}(\nu)$ . Choose  $x$  so that  $H_\rho(u) < H_{\rho+k-1}(x) < H_{\rho+k}(\nu)$ . Then by the induction hypothesis,  $H_{\rho+k-2}(x - 1) > H_{\rho-1}(u - 1)$ . Moreover  $H_{\rho+k-1}(\nu - 1) > H_{\rho+k-2}(x - 1)$ . Combining these two inequalities shows that  $H_{\rho+k-1}(\nu - 1) > H_{\rho-1}(u - 1)$ .  $\square$

We define the **Partitioning Property** as follows:

Let  $W(i, j)$  be the separation function defined by a wiring scheme.

Suppose  $P_i, P_{i+q}, Q_j$ , and  $Q_{j+r}$  are in a left block, where  $q \geq 0, r \geq 0$ , and  $j + r > i + q$ .

$$(5.2) \quad \text{If } W(i, j + r) > W(i, j), \text{ then } W(i + q, j + r) > W(i + q, j).$$

Lemmas 2, 3, 4, and 5 are summarized in the following.

**THEOREM 6 (The Partitioning Theorem).** *Let  $W(i, j)$  be the separation function defined by a barrier family satisfying properties P0, P1, and P2. Then  $W(i, j)$  has the Partitioning Property.*

*Proof. Case 1:  $j > i + q$ . We must show that*

$$(5.3) \quad \text{if } W(i, j+r) > W(i, j), \text{ then } W(i+1, j+r) > W(i+1, j),$$

since induction on  $q$  then gives Theorem 6 for all nonnegative integral values of  $q$  where  $j > i + q$ . See Fig. 5.4. According to equation (4.1), (5.3) says, suppose  $H_{j+r-i}(Q_{j+r} - P_i) > H_{j-i}(Q_j - P_i)$ ; then  $H_{j+r-i-1}(Q_{j+r} - P_{i+1}) > H_{j-i-1}(Q_j - P_{i+1})$ . Let  $\rho = j - i$ ,  $\nu = Q_{j+r} - P_i$ ,  $u = Q_j - P_i$ , and  $d + 1 = P_{i+1} - P_i$ . The unit separation requirement between terminals ensures that  $d \geq 0$ . We must show that if  $H_{\rho+r}(\nu) > H_{\rho}(u)$ , then  $H_{\rho+r-1}(\nu - 1 - d) > H_{\rho-1}(u - 1 - d)$ . Since  $H_{\rho+r}(\nu) > H_{\rho}(u)$ , Lemma 5 says that  $H_{\rho+r-1}(\nu - 1) > H_{\rho-1}(u - 1)$ . Then by Lemma 3,  $H_{\rho+r-1}(\nu - 1 - d) > H_{\rho-1}(u - 1 - d)$ .

FIG. 5.4

*Case 2:  $j \leq i + q$ . Then  $W(i + q, j) = 0$ , since  $P_{i+q}$  and  $Q_j$  belong to a left block. Thus it suffices to show if  $W(i, j+r) > 0$  then  $W(i + q, j+r) > 0$ . Now  $W(i, j+r) > 0$  says that  $Q_{j+r} - P_i < j+r - i$ . Therefore  $Q_{j+r} - P_{i+q} < j+r - i - q$ , whence  $Q(i + q, j+r) > 0$ .  $\square$*

Evidently the separation needed between  $P_i$  and  $Q_j$  is the same if determined by barriers emanating from  $P_i$  or (upside down) barriers emanating from  $Q_j$ . Hence rotating the plane 180 degrees gives an equivalent inequality by interchanging  $P$  with  $Q$ ,  $i$  with  $j+r$  and  $q$  with  $-r$ . This observation, contraposition, and renaming the variables gives the following corollary.

**COROLLARY 7.** *Suppose  $P_i, P_{i+q}, Q_j$ , and  $Q_{j+r}$  are in a left block, where  $q \geq 0, r \geq 0$ . If  $w$  is defined by separation barriers satisfying P0, P1, and P2, then:*

(1) For  $j+r > i+q$ ,

$$W(i+q, j) \geq W(i+q, j+r) \Rightarrow W(i, j) \geq W(i, j+r).$$

(2) For  $j > i$ ,

$$W(i, j+r) > W(i+q, j+r) \Rightarrow W(i, j) > W(i+q, j).$$

(3) For  $j > i$ ,

$$W(i+q, j) \geq W(i, j) \Rightarrow W(i+q, j+r) \geq W(i, j+r).$$

*Proof.* (1) Follows from contraposition. (2) Follows from rotation. (3) Follows from rotation and contraposition.  $\square$

Consequently, we have the following.

**COROLLARY 8.** *Let  $W$  be a separation function having the Partitioning Property, and suppose that all terminals are in one left block. Let  $I = [x_1, x_2]$  and  $J = [y_1, y_2]$  be arbitrary subintervals of  $[1, n]$ . Given  $j_0 \in J$ , let  $i_0 \in I$  be the maximum value in  $I \cap [1, \max(x_1, j_0)]$  satisfying  $W(i_0, j_0) = \max_{i \in I} W(i, j_0)$ . Then the separation function attains its maximum on  $I \times J$  at some  $(i_{\max}, j_{\max})$  where either  $(i_{\max}, j_{\max}) \cong (i_0, j_0)$  or  $(i_{\max}, j_{\max}) \cong (i_0, j_0)$ . The inequalities are understood to hold coordinatewise.*

*Proof.* **Case 1:**  $W(i_0, j_0) > 0$ . Suppose  $i_{\max} < i_0$  and  $j_{\max} > j_0$ . Then by Corollary 7(2)

$$W(i_{\max}, j_{\max}) > W(i_0, j_{\max}) \Rightarrow W(i_{\max}, j_0) > W(i_0, j_0).$$

Hence the requirement that  $W(i_0, j_0)$  be maximal for  $j_0$  fixed is contradicted.

Similarly, if  $i_{\max} > i_0$  and  $j_{\max} < j_0$ , then

$$W(i_{\max}, j_{\max}) \cong W(i_0, j_{\max}) \Rightarrow W(i_{\max}, j_0) \cong W(i_0, j_0)$$

by Corollary 7(3). The requirement that  $i_0$  be maximum is thus contradicted. We have assumed that  $i_{\max} < j_{\max}$  since otherwise  $W(i_{\max}, j_{\max})$  would be zero for this left block.

**Case 2:**  $W(i_0, j_0) = 0$ . Evidently  $i_0$  equals the middle value of  $x_1, j_0$ , and  $x_2$ . If  $x_1 < x_2 < j_0$ , for example, then the definition of  $i_0$  requires that it equal  $x_2$ .

If  $i_0 = x_1$ , then for  $h$  and  $k$  such that  $k < j_0 \cong x_1 < h$ , it follows that  $W(h, k) = 0$  since  $k < h$ .

Otherwise  $W(i_0 - 1, j_0) = 0$ , so  $Q_{j_0} - P_{i_0-1} \cong j_0 - i_0 + 1 > 0$  whence the unit spacing requirement for terminals ensures that  $Q_k - P_h \cong k - h$  for  $k \cong j_0$ , and  $h \cong i_0$ . For these values of  $k$  and  $h$ ,  $W(h, k) = 0$ . Similarly,  $W(h, k) = 0$  if  $k < j_0$  and  $h \in [i_0 + 1, x_2]$  since the interval of  $h$ 's (is empty or) contains no value smaller than  $j_0$ .  $\square$

It should be noted that Theorem 6 has an alternate formulation:

*Let  $W(i, j)$  be the separation function defined by a barrier family satisfying properties P0, P1, and P2. Suppose  $P_i, P_{i+q}, Q_j$ , and  $Q_{j+r}$  are in a left block, where  $q \cong 0, r \cong 0$ , and  $j + r > i + q$ . Suppose further, that  $W(i, j + r) > 0$ .*

$$\text{If } W(i, j + r) \cong W(i, j), \text{ then } W(i + q, j + r) \cong W(i + q, j).$$

The purpose of the strict inequality in Theorem 6 is to establish the positivity of  $W(i, j + r)$ . This reformulation can be proved from analogous versions of Lemmas 2-5. The alternative version of Theorem 6 allows the requirement that  $i_0$  be maximum in Corollary 8 to be replaced by the condition that it be maximum if  $\max_{i \in I} W(i, j_0) = 0$ . This reformulation, when combined with its analogue to Corollary 7, is also sufficient to give divide-and-conquer schemes for computing the separation.

**6. General wiring.** This section contains an  $O(n \log n)$  time algorithm to solve the separation problem for wiring schemes having the Partitioning Property. In particular, wiring rules defining similar concave separation barriers will be shown to satisfy this property.

**THEOREM 9.** *Suppose  $W(i, j)$  is a separation function which satisfies the Partitioning Property, and for any  $i$  and  $j$ ,  $W(i, j)$  can be computed in unit time. Then the separation can be found in  $O(n \log n)$  time.*

*Proof.* Observe that  $P$  and  $Q$  can be partitioned into their left and right blocks in linear time, and the separation problem can be solved independently for each block. Hence it suffices to assume that  $P$  and  $Q$  constitute one left block.

Let  $j = \lceil n/2 \rceil$ , and find  $i_{\lceil n/2 \rceil}$ , which is the largest  $i \leq \lceil n/2 \rceil$  which maximizes  $W(i, \lceil n/2 \rceil)$ . Corollary 8 ensures that the maximum separation is among those separations restricted to the intervals  $i \in [1, i_{\lceil n/2 \rceil}]$  and  $j \in [1, \lceil n/2 \rceil]$ , or  $i \in [i_{\lceil n/2 \rceil}, n]$ , and  $j \in [\lceil n/2 \rceil + 1, n]$ . Repeating this divide-and-conquer step of setting  $j$  to be each  $Q$ -subinterval midpoint and allowing  $i$  to vary over the corresponding  $P$ -subinterval requires  $\lceil \log(n+1) \rceil$  levels and uses a total of  $O(n \log n)$  comparisons. The separation is then  $\max_j W(i_j, j)$ .  $\square$

Theorems 6 and 9 show that the separation problem can be solved in  $O(n \log n)$  time for barrier families satisfying P0, P1, and P2. We now show that families of similar separation barriers have these properties. A family of geometrically similar separation barriers is defined by its first barrier. For a concentric family emanating from the origin, the similarity requirement says that

$$(6.1) \quad H_\rho(x) = \rho H_1\left(\frac{x}{\rho}\right).$$

Unrestricted curvilinear wiring, rectilinear wiring on an integer grid, and rectilinear plus 45-degree wiring on a half-integer grid, for example, have barrier families which are similar, concentric, and concave. It should be noted that we shall assume the function  $H_1$ , (and hence  $H_\rho$ ) can be computed in  $O(1)$  time. This is certainly the case if, for example,  $H_1$  represents a barrier that is circular, or that is defined piecewise by a fixed collection of functions, each of which can be evaluated in  $O(1)$  time. It then follows that  $W(i, j)$  can be computed in constant time.

**THEOREM 10.** *Let  $W$  be defined by a family of similar separation barriers  $H_\rho(x) = \rho h(x/\rho)$ , where  $h(x) = 0$  for  $x \geq 1$ , and  $h(x)$  is concave and nonincreasing for  $x \leq 1$ . Then the separation problem can be solved in  $O(n \log n)$  time.*

*Proof.* It suffices to show that  $H_\rho$  satisfy P0, P1, and P2.

P0: These properties are trivially satisfied.

P1: Figure 6.1 shows  $H_\rho$ ,  $H_{\rho-1}$ , and  $l(\rho, y)$ . By similarity,  $H_\rho$  and  $H_{\rho-1}$  have parallel tangents at their intersections with the ray from the origin through  $(y, H_\rho(y))$ .<sup>4</sup> By concavity of  $H_{\rho-1}$ , the left endpoint of  $l(\rho, y)$  must have a left tangent with slope

FIG. 6.1

<sup>4</sup> A more precise statement includes the fact that the separation curves might not have tangents at a denumerable number of points. Concave curves are not everywhere differentiable, but are everywhere left differentiable and right differentiable. Define the left tangent of  $H_\rho$  at  $x$  to be the line through  $(x, H_\rho(x))$  with a slope as large (close to 0) as possible which has no point  $(z, H_\rho(z))$  for  $z \leq \rho$  on its right. This slope equals the left derivative of  $H_\rho$  at  $x$ . More precisely, then, the ray from the origin to  $(y, H_\rho(y))$  has parallel left tangents at its intersection points with  $H_{\rho-1}$  and  $H_\rho$ .

FIG. 6.2

no less (i.e., no steeper) than the slope of the left tangent at  $y$ . Consequently  $|l(\rho, y)|$  cannot decrease as  $y$  decreases. Formally, let  $l$  have endpoints  $(x(w), w)$  and  $(y(w), w)$ . Then

$$\frac{d}{dw}|l| = \frac{d}{dw}(y(w) - x(w)) = \frac{1}{H'_\rho(y)} - \frac{1}{H'_{\rho-1}(x)} \geq 0.$$

P2: Let, as in Fig. 6.2, the ray from the origin intersect  $H_{\rho-2}$ ,  $H_{\rho-1}$ , and  $H_\rho$  at  $A$ ,  $B$  and  $C$ , respectively, and intersect the positive  $x$  axis at an angle  $\omega$ . Let  $D$  and  $E$  be on  $H_{\rho-2}$  and  $H_{\rho-1}$  so that  $\angle ECB = \angle DBA = \theta$ . Let  $|\overline{DB}| = r_2$ ,  $|\overline{EC}| = r_1$ .

CLAIM. The ray  $R$  which runs from the origin through  $D$  lies above  $E$ .

Proof. If triangle  $OBD$  is magnified by  $\rho/(\rho - 1)$ , with  $O$  as the fixed point, and with no rotation, then  $B$  is mapped to  $C$ , and the ray along  $\overline{BD}$  is mapped onto the ray along  $\overline{CE}$ . Ray  $R$  is mapped onto itself. Note that  $D$  is not sent to  $E$ , but instead becomes some point inside barrier  $H_{\rho-1}$  because the magnification factor is less than  $(\rho - 1)/(\rho - 2)$ .  $R$  must therefore intersect  $H_{\rho-1}$  somewhere above the line through  $C$  and  $E$ .

The same reasoning as that used for property P1 shows that  $H_{\rho-2}$  is no steeper at  $D$  than  $H_{\rho-1}$  is at  $E$ . It is tempting to conclude that  $(d/d\theta)r_2 \geq (d/d\theta)r_1$ , but this inequality need not hold. As shown in Fig. 6.2, let  $\alpha_2$  be the angle between the left tangent to  $H_{\rho-2}$  at  $D$  and  $DB$ . Let  $\alpha_1$  be the analogous angle at  $E$ . As observed above,  $\alpha_2 \geq \alpha_1$ . In fact,  $\pi > \alpha_2 \geq \alpha_1 > 0$ . Elementary trigonometry gives  $(d/d\theta)r_1 = -r_1 \cot \alpha_1$ ,  $(d/d\theta)r_2 = -r_2 \cot \alpha_2$ . When  $\alpha_2 < \pi/2$ , it is possible that  $(d/d\theta)r_2 < (d/d\theta)r_1$ . In any case,  $(dr_2/r_2 d\theta) = -\cot \alpha_2 \geq -\cot \alpha_1 = (dr_1/r_1 d\theta)$ . Integrating the differential inequality as  $\theta$  goes from 0 to  $\omega$  gives  $\log(|l(\rho - 1, \nu)|/|\overline{AB}|) \geq \log(|l(\rho, x)|/|\overline{BC}|)$ , where  $\nu$  is the  $x$ -coordinate of  $B$ , and  $x$  is the  $x$ -coordinate of  $C$ . Exponentiating shows that

$$(6.2) \quad \frac{|l(\rho - 1, \nu)|}{|\overline{AB}|} \geq \frac{|l(\rho, x)|}{|\overline{BC}|}.$$

Since the similarity properties of  $H_\rho$  guarantee that the lengths of  $\overline{AB}$  and  $\overline{BC}$  are equal,  $|l(\rho - 1, \nu)| \geq |l(\rho, x)|$ . The similarity properties also ensure that  $x - \nu = x/\rho \leq 1$ . Hence  $x - 1 \leq \nu$ , so  $|l(\rho - 1, x - 1)| \geq |l(\rho - 1, \nu)|$ , whence  $|l(\rho - 1, x - 1)| \geq |l(\rho, x)|$ .  $\square$

The explicit form of the inequality in (6.2) makes the proof directly applicable to Theorem 18.

Theorem A in the Appendix gives a direct proof that the separation function defined by similar concave barrier curves enjoys the Partitioning Property. The proof is slightly stronger since it shows quantitatively “by just how much” the Partitioning Property is satisfied, that is, it gives a formula for  $W(i + q, j + r) - W(i + q, j)$ .

COROLLARY 11. *The separation for a wiring scheme with circular barriers can be found in  $O(n \log n)$  time.  $\square$*

COROLLARY 12. *The separation for a wiring scheme with similar convex polygonal barriers can be found in  $O(n \log n)$  time.  $\square$*

**7. Weakening the similarity and curvature restrictions.** Evidently any algorithm which finds the separation for a particular wiring scheme will, with one proviso, find the separation for the same wiring scheme where the notion of distance is now redefined. The proviso is that the new measure of separation distance be a nondecreasing function  $\Phi$  of the original distance measure. Then

$$(7.1) \quad \max \Phi(W(i, j)) = \Phi(\max W(i, j)).$$

Under the map  $\Phi(x) = \frac{1}{4} \lfloor 4x \rfloor$ , rectilinear wiring on a quarter-integer grid turns out to be equivalent to wiring defined by a particular family of similar separation barriers which are composed of rectilinear plus 45-degree segments. The first barrier has a 45-degree segment connecting rectilinear pieces terminating at  $(1, \frac{3}{4})$  and  $(\frac{3}{4}, 1)$ . In concrete terms, given a separation problem for rectilinear wiring on a quarter-integer grid, one way to find the solution is by using rectilinear plus 45-degree wiring (as defined by the oversized barrier family described above) to connect  $P$  and  $Q$ . Then apply the map  $(x', y') = (x, \frac{1}{4} \lfloor 4y \rfloor)$  to each point of the wiring pictorial. The new pictorial (with added requisite vertical segments) is an optimal solution to the original problem. In particular, the separation is  $\frac{1}{4} \lfloor 4w \rfloor$ , where  $w$  is the separation found for the particular rectilinear plus 45-degree wiring. See Fig. 7.1. It should be noted that this barrier family is oversized so that the resulting rectilinear barriers are separated by distances of at least 1.

We have proven the following.

COROLLARY 13. *The separation problem for rectilinear wiring on a quarter-integer grid can be solved in  $O(n \log n)$  time.  $\square$*

For completeness, it should be noted that rectilinear plus 45-degree wiring, in this model, is the same for quarter-integer and for half-integer grids; the separation barriers turn out to be identical for the two cases because of the need for neighboring barriers

FIG. 7.1

to be separated by at least unit distance. Similarly, one-third and one-half integer grid rectilinear wiring schemes turn out to be the same as integer grid wiring.

It is clear that the separation problem can be solved in  $O(n \log n)$  time for any separation problem that can be decomposed into a fixed number of subfamilies which satisfy the Partitioning Property. The decomposition should be of the form  $W(i, j) = \max_k W_k(i, j)$  where  $W_k(i, j)$  is the separation induced by the  $k$ th subfamily. In addition, if there is a strictly monotone map  $\Phi$  which transforms one barrier subfamily into another, then the two subfamilies induce separation problems having the same time complexity.

The Partitioning Property holds for some barrier families which fail to satisfy P0, P1, and P2. When all terminals are located on a quarter-integer grid, for example, the separation function defined by rectilinear wiring on a quarter-integer grid satisfies the Partitioning Property. Evidently there ought to be criteria for barrier subfamilies which induce separation problems solvable in  $O(n \log n)$  time, and the criteria seemingly ought to be invariant over monotone maps. However, the Partitioning Property need not hold for a quarter-integer grid rectilinear wiring scheme if the terminals are not located on gridpoints. More generally, if  $W$  has the Partitioning Property, and  $\Phi$  is nondecreasing, but not necessarily strictly increasing, then  $\Phi(W)$  only satisfies a Weak Partitioning Property: if  $\Phi(W(i, j+r)) > \Phi(W(i, j))$  then  $\Phi(W(i+q, j+r)) \cong \Phi(W(i+q, j))$ . It is not evident how this weaker property can be used to give an  $O(n \log n)$  time algorithm to find the maximum of  $\Phi(W)$ . Of course  $\max \Phi(W)$  can be found efficiently by applying Theorem 9 to  $W$ .

The inadequacy of the Weak Partitioning Property is made more precise in the following.

**THEOREM 14.** *Let  $W$  be the separation function defined by separation barriers composed of quarter-integer rectilinear segments. Then the worst-case behavior of any optimal algorithm to find  $\max_{i,j} W(i, j)$  based solely on the values of  $W$  is  $\Theta(n^2)$  comparisons.*

*Proof.* It suffices to construct a family of separation barriers that has the Weak Partitioning Property, and that satisfies the conclusion of this theorem. We use the barrier family defined by quarter integer rectilinear segments, but allow terminal locations to be on a finer grid. The barrier function for a left block is  $H_\rho(x) = \lfloor 4\rho h(x/\rho) \rfloor / 4$ , where  $h(x) = 1$  if  $x < 3/4$ ,  $h(x) = 7/4 - x$  if  $3/4 \leq x < 1$ , and  $h(x) = 0$  if  $x \geq 1$ .

Let  $P_i = (7/4)i$  and  $Q_i = (7/4)i - (3/4)n + 1/8$  for  $i = 1, 2, \dots, n$ . Then the solution to the separation problem is  $W(1, n) = (3/4)n - 1/4$ . In fact, for all  $i$  and  $j$  where  $1 \leq i, j \leq n$ , and  $j - i \geq (3/4)n$ ,  $W(i, j) = (1/4) \lfloor 4((7/4)(j - i) - Q_j + P_i) \rfloor = (1/4) \lfloor 4((3/4)n - 1/8) \rfloor = (3/4)n - 1/4$ . Pick any  $i_0$  and any  $j_0$  where  $j_0 - i_0 \geq (3/4)n$ . Change the problem by letting  $P_{i_0} = (7/4)i_0 + 3/32$  and  $Q_{j_0} = (7/4)j_0 - (3/4)n + 1/32$ . Call the separation function induced by this new problem  $\tilde{W}(i, j)$ . Then  $W(i, j) = \tilde{W}(i, j)$  if  $i \neq i_0$  or  $j \neq j_0$ . Finally,  $\tilde{W}(i_0, j_0) = (3/4)n$ . Therefore no algorithm can determine if a given separation function is  $W$  rather than a  $\tilde{W}$  without testing  $\Omega(n^2)$  pairs of  $i$  and  $j$ . Clearly  $n^2$  is a trivial upper bound on the number of comparisons necessary to find the separation.  $\square$

It should be noted that the separation problem for quarter-integer rectilinear separation barriers can be solved in linear time; see [Si2] for the details.

Evidently properties P0, P1, and P2 ought to be extended to characterize a class of wiring schemes which is invariant under strictly increasing maps. The proof technique for Theorem 6 shows the following.

THEOREM 15. Let  $H_\rho$  satisfy:

Q0a:  $H_\rho(x) = 0$  for  $x \geq \rho$ .

Q0b:  $H_\rho(x) > H_{\rho-1}(x)$  for  $x < \rho$ .

Q0c:  $H_\rho(x) \geq H_\rho(y)$  for  $x \leq y \leq \rho$ .

Q0d: If  $x < y < \rho$  and  $H_\rho(x) = H_\rho(y)$ , then  $H_\rho(v) = H_\rho(y)$  for  $v \leq y$ . In other words, if  $H_\rho$  is flat at  $y$ , then it must be constant to the left of  $y$ .

Q1: If  $x \leq y \leq \rho$ , then  $|l(\rho, x)| \geq |l(\rho, y)|$ .

Q2: If  $x \leq \rho$ , then  $|l(\rho - 1, x - 1)| \geq |l(\rho, x)|$ .

Then the separation function  $W$  defined by barriers  $H_\rho$  satisfies the Partitioning Property.  $\square$

**8. A better wiring model.** All constructions considered so far implicitly permit wires to terminate at  $P$  or  $Q$  in a horizontal direction. If, for example, the wiring in the integer rectilinear case is required to leave rows  $P$  and  $Q$  vertically for at least one unit in length, then the physical separation  $w$  is

$$w = \begin{cases} 1 & \text{if } P_i = Q_i \text{ for all } i, \\ 2 + \max W(i, j) & \text{otherwise.} \end{cases}$$

Figure 8.1 illustrates rectilinear wiring with this restriction. The purpose is to avoid

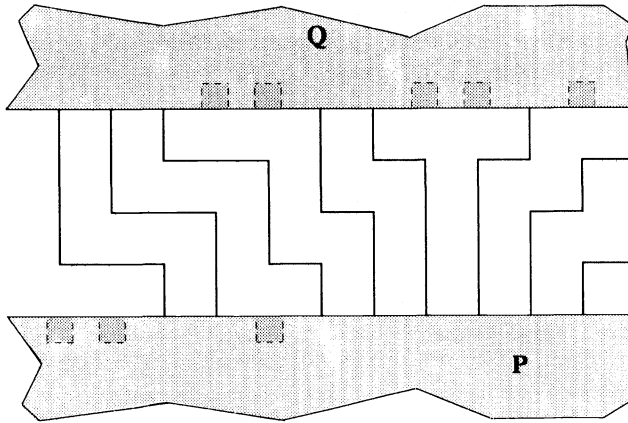

FIG. 8.1. A physical separation—rectilinear wiring avoiding internal wires.

FIG. 8.2. Barrier modifications.

unknown wires inside modules  $P$  and  $Q$  (the black boxes denote possible internal wires).

More generally, we may imagine, as shown in Fig. 8.2, wiring internal to modules  $P$  and  $Q$  located (for left blocks) one unit to the left of  $P_i$  and to the right of  $Q_j$ . Now the separation induced by terminals  $P_i$  and  $Q_j$  is influenced by a first barrier around  $P_i - 1$  and a final point at  $Q_j + 1$ . The separation function for a left block is then<sup>5</sup>

$$(8.1) \quad W(i, j) = \begin{cases} \max \{1, \hat{H}_{j+2-i}(Q_j + 2 - P_i)\} & \text{if } j \geq i, \\ 0 & \text{if } j < i. \end{cases}$$

The reason the curves  $\hat{H}_\rho$  are different from the  $H_\rho$ 's is that the imaginary wire terminating at  $Q_j + 1$  need not obey the wiring limitations. Its only requirement is it must be at least one unit away from the preceding wire. Consequently its curve is described by the locus of points one unit beyond the wireable barrier curve  $H_{j+1-i}(x)$  emanating from  $P_i - 1$ . For polygonal wiring, the locus is a new polygonal barrier (corresponding in some sense to  $H_{j+2-i}$ ) with corners replaced by tangential circular arcs of radius 1. For families of similar concave wiring barriers, the unit distance locus curves are still concave but no longer similar. The Partitioning Property, however, is nevertheless applicable.

**THEOREM 16.** *Let  $H_\rho$  be the locus of points unit distance beyond barrier  $K_{\rho-1}$ ,  $\rho = 2, 3, \dots$ , where the  $K_\rho$ 's are a family of similar barriers satisfying P0. Then the separation function defined by the  $H_\rho$  satisfies the Partitioning Property.*

*Proof.* It suffices to show that  $H_\rho$  satisfies P0, P1, and P2. The proof, of course, is similar to the proof of Theorem 10.

P0: These properties are trivially satisfied.

P1: Figure 8.3 shows  $K_{\rho-2}$ ,  $H_{\rho-1}$ ,  $K_{\rho-1}$ , and  $H_\rho$ . Let  $A, B, C, D, E,$  and  $F$  be as shown. Let  $\overline{AC}$ ,  $\overline{BD}$  be of unit length and perpendicular to  $H_{\rho-1}$  and (to some local support line of)  $K_{\rho-2}$ .  $\overline{EF}$  is parallel to  $\overline{AC}$ , of unit length, and perpendicular to  $H_\rho$  and (to some local support line of)  $K_{\rho-1}$ .  $A$  and  $E$  are on a ray from the origin, and  $\overline{AE}$  intersects the  $x$ -axis at a nonzero angle.  $D$  and  $F$  are on a horizontal segment;  $l = \overline{DF}$ . Since  $\overline{EF}$  has nonnegative slope,  $F$  is at least as high as  $E$ .  $E$  is above  $A$ , and

FIG. 8.3

<sup>5</sup> We have assumed that the presence of unknown wires on other layers within modules  $P$  and  $Q$  prevents the modules from being separated by less than unit distance. It is not difficult to include other minimum separation requirements in this model, or to include additional separation requirements due to interactions between different layers.

FIG. 8.4

since  $\overline{AC}$  is parallel to  $\overline{EF}$ ,  $D$  is above  $C$ . By P0d,  $\overline{AC}$  cannot cross  $\overline{BD}$ , so  $B$  must be above  $A$ . Hence  $\overline{BD}$  must have a slope at least as large as  $\overline{AC}$  by P0d. Thus  $H_{\rho-1}$  is no steeper at  $D$  than  $H_{\rho}$  at  $F$ . Consequently  $|I|$  cannot decrease as  $F$  moves up  $H_{\rho}$ .

P2: Let  $A, B, C, D, E, F, G, I, J,$  and  $L$  be as shown in Fig. 8.4.  $K_{\rho-3}, H_{\rho-2}, K_{\rho-2}, H_{\rho-1},$  and  $K_{\rho-1}, H_{\rho}$  are as shown.  $A, E,$  and  $J$  are on a ray from the origin, which intersects the positive  $x$ -axis at an angle  $\omega$ . The symmetry of  $K_{\rho}$  and the orthogonality of unit segments  $\overline{AC}, \overline{EG},$  and  $\overline{JL}$  ensure that  $C, G,$  and  $L$  are a translation of  $A, E,$  and  $J$  by  $\overline{AC}$ .  $\overline{BD}$  and  $\overline{FI}$  are unit perpendiculars such that  $B$  is on  $K_{\rho-3}, D$  is on  $H_{\rho-2}, F$  is on  $K_{\rho-2},$  and  $I$  is on  $H_{\rho-1}$ . Let  $\angle DGC = \angle ILG = \theta$ . Then the ray from the origin through  $B$  lies above  $F$ . Consequently  $H_{\rho-1}$  is at least as steep at  $I$  as  $H_{\rho-2}$  is at  $D$ . Now  $|\overline{CG}| = |\overline{GL}|$ . Integrating, over  $\theta \in [0, \omega]$ , the same kind of differential inequality as in the proof of Theorem 10 gives  $\log(|\overline{GD}|/|\overline{GC}|) \geq \log(|\overline{LI}|/|\overline{LG}|)$ , whence P2 must hold.  $\square$

**9. Modeling wire thickness.** More accurate wiring models should also include wire thickness. Evidently the solutions to the separation problem are applicable if, say, the barrier curves represent the outer edges of densely packed wires with positive thickness. If, as illustrated in Fig. 9.1, these curves  $H_{\rho}$  are similar, and concave, the wire thickness is  $2\mu$ , and the minimum separation space between wires is 1, the separation function still has the Partitioning Property. The separation algorithm for these cases need not be changed. These results also apply to barrier families which model a wire as the set of points within a fixed distance  $\mu$  of a skeleton curve. In particular, if the skeleton curves are similar and convex, Theorem 16 is applicable.

FIG. 9.1. A model including wire thickness.

Separation barriers might also be defined by similar subfamilies when wire thickness depends on the power load. This case is best handled by using real barrier and terminal indices. Let the terminal indices be  $\rho_1, \rho_2, \dots, \rho_n$ , where the  $\rho_i$ 's are real. Let the thickness of wire  $\rho_i$  be  $\rho_i - \rho_{i-1} - 1$ , where  $\rho_0$  is set to 0. Then if the thicknesses are zero, the indices  $\rho_i$  are just 1, 2,  $\dots$ ,  $n$ . The physical location of a "thick" terminal  $P_{\rho_i}$  is the right endpoint of the connection interval for the terminal. This location value is assigned to  $P_{\rho_i}$ . The unit spacing requirement for terminals is formalized by

$$(9.1) \quad P_{\rho_i} - P_{\rho_{i-1}} \geq \rho_i - \rho_{i-1}, \quad Q_{\rho_i} - Q_{\rho_{i-1}} \geq \rho_i - \rho_{i-1}.$$

Let  $l(i, x)$  be the horizontal line segment bounded on the left by  $H_{\rho_{i-1}}$  and with right endpoint  $(x, H_{\rho_i}(x))$ . We define the following properties for the separation barriers of a left block:

- R0a:  $H_{\rho}(x) = 0$  for  $x \geq \rho$ .
  - R0b:  $H_{\rho}(x) > H_{\delta}(x)$  for  $\delta < \rho, x < \rho$ .
  - R0c:  $H_{\rho}(x) \geq H_{\rho}(y)$  for  $x \leq y \leq \rho$ .
  - R0d:  $H_{\rho}(x + \varepsilon) - 2H_{\rho}(x) + H_{\rho}(x - \varepsilon) \leq 0$  for  $\varepsilon > 0, x + \varepsilon \leq \rho$ .
  - R1: If  $x \leq y \leq \rho$ , then  $|l(\rho, x)| \geq |l(\rho, y)|$ .
  - R2: If  $x \leq \rho_i$ , then  $|l(\rho_{i-1}, x - \rho_i + \rho_{i-1})| / (\rho_{i-1} - \rho_{i-2}) \geq |l(\rho_i, x)| / (\rho_i - \rho_{i-1})$ .
- This is just the direct generalization of P2.

Suppose, for example, that  $P_{\rho_i}$ 's barriers emanate from location  $P_{\rho_i}$ , and the indexing for these barriers is given by  $H_{\rho_{i+1}-\rho_i}, H_{\rho_{i+2}-\rho_i}, H_{\rho_{i+3}-\rho_i}, \dots$ . Then the proofs of Lemmas 2, 3, 4, 5 and Theorem 6 show the following.

**THEOREM 17.** *Let  $\{P, Q\}$  be a separation problem satisfying (9.1), and  $H_{\rho}$  the separation barriers satisfying R0, R1, and R2. Then the separation function  $W$  defined by the separation barriers has the Partitioning Property.  $\square$*

If the routing wires must avoid unknown wires inside modules  $P$  and  $Q$ , then  $P_{\rho_i}$ 's barrier family will have an origin at  $P_{\rho_i} - \rho_i + \rho_{i-1}$ . The barriers will be the locus of points unit distance beyond the similar family  $K_{\rho_i - \rho_{i-1}}, K_{\rho_{i+1} - \rho_{i-1}}, K_{\rho_{i+2} - \rho_{i-1}}, \dots$ , which emanates from  $P_{\rho_i}$ 's family origin. The separation function for a left block will be given by

$$(9.2) \quad W(i, j) = \begin{cases} \max \{1, H_{\rho_{j+1}-\rho_{i-1}}(Q_{\rho_j} + 1 - P_{\rho_i} + \rho_i - \rho_{i-1})\} & \text{if } j \geq i, \\ 0 & \text{if } j < i. \end{cases}$$

It is worth noting that if the wire thickness is zero, i.e., if  $\rho_j = j$ , then (9.2) reduces to (8.1).

**THEOREM 18.** *Let  $H_{\rho}$  be the locus of points unit distance beyond the similar barrier family  $K_{\rho-1} = (\rho - 1)k(x / (\rho - 1))$  for  $\rho \geq 2$ , where  $k(x)$  is nonincreasing and concave for  $x \leq 1$ , and  $k(x) = 0$  for  $x \geq 1$ . Then for terminals satisfying (9.1) the separation function  $W$  defined in (9.2) by the  $H_{\rho}$  has the Partitioning Property.  $\square$*

Theorem 15 can also be extended to the case of wires with thicknesses.

Notice that the wiring models have in a sense come around full circle; in the most realistic models of the separation problem as characterized by Theorem 18, the "terminal origins" are idealized points, the wiring barriers have zero width and shapes which cannot be fabricated, and the barrier indices may not even be integer valued.

**10. Appendix.** The idea behind the Partitioning Theorem is essentially the following. Consider two line segments which connect  $Q_{j_1}$  with  $P_{i_1}$  and  $Q_{j_2}$  with  $P_{i_2}$ . Suppose  $i_1$  and  $i_2$ , respectively, maximize  $W(*, j_1)$  and  $W(*, j_2)$ . The Partitioning Property then says that the segments cannot cross. Figure 10.1 illustrates this result in the context of Theorem A.

FIG. 10.1. A left-block separation. Variables in the proof are as shown. Variables between the horizontal lines are barrier number ( $\rho$ ) while  $x, y, z, r,$  and  $s$  are measures of distance. Note that only  $z$  can be negative. We note that  $k$  must be positive because of the supposition that the term  $W(i+r, j)$ , in (10.1), is positive.

The following is a direct proof that the Partitioning Property holds for a separation function defined by similar concave barriers. Although not as general as the techniques of § 5, the proof may give better insight into the behavior of separation barriers and their intrinsic properties.

**THEOREM A.** *Let  $W(i, j)$  be the separation function defined by similar concave separation barriers  $H_\rho$ , where  $H_1 = h(x)$ . Suppose  $P_i, P_{i+r}, Q_j,$  and  $Q_{j+s}$  are in a left block, where  $r \geq 0, s \geq 0,$  and  $j+s > i+r$ .*

$$(10.1) \quad \text{If } W(i, j+s) > W(i, j), \text{ then } W(i+r, j+s) > W(i+r, j).$$

*Proof.* Let

$$x = P_{i+r} - P_i - r, \quad y = Q_{j+s} - Q_j - s, \quad z = Q_j - P_{i+r}, \quad k = j - i - r.$$

The wire separation restrictions imply that  $x \geq 0$  and  $y \geq 0$ .

Now suppose that all four terms in (10.1) are positive. It suffices to show that

$$\{W(i, j) - W(i, j+s)\} - \{W(i+r, j) - W(i+r, j+s)\} \geq 0.$$

Substituting the definition for  $W$  gives

$$\begin{aligned} \text{L.H.S.} = & \left\{ (j-i)h\left(\frac{Q_j - P_i}{j-i}\right) - (j+s-i)h\left(\frac{Q_{j+s} - P_i}{j+s-i}\right) \right\} \\ & - \left\{ (j-i-r)h\left(\frac{Q_j - P_{i+r}}{j-i-r}\right) - (j+s-i-r)h\left(\frac{Q_{j+s} - P_{i+r}}{j+s-i-r}\right) \right\}. \end{aligned}$$

This expression is just a weighted difference of  $h$  at four points.

If  $x$  and  $y$  are zero,

$$(10.2) \quad \begin{aligned} \text{R.H.S.} = & \left\{ (k+r)h\left(\frac{z+r}{k+r}\right) - (k+r+s)h\left(\frac{z+r+s}{k+r+s}\right) \right\} \\ & - \left\{ kh\left(\frac{z}{k}\right) - (k+s)h\left(\frac{z+s}{k+s}\right) \right\}. \end{aligned}$$

Suppose  $h$  is twice differentiable. Then the concavity of  $h$  says that  $h''(x) \leq 0$  for  $x < 1$ . The Fundamental Theorem of Calculus says

$$\int_0^s f'(v) \, dv = f(s) - f(0).$$

Using it to express each inner difference in (10.2) as the integral of a derivative gives:

$$\begin{aligned} \text{R.H.S.} &= - \int_0^s \left\{ h\left(\frac{z+r+v}{k+r+v}\right) + \frac{k-z}{k+r+v} h'\left(\frac{z+r+v}{k+r+v}\right) \right\} dv \\ &\quad + \int_0^s \left\{ h\left(\frac{z+v}{k+v}\right) + \frac{k-z}{k+v} h'\left(\frac{z+v}{k+v}\right) \right\} dv \\ (10.3) \quad &= - \int_0^s \left\{ \left[ h\left(\frac{z+r+v}{k+r+v}\right) - h\left(\frac{z+v}{k+v}\right) \right] \right. \\ &\quad \left. + (k-z) \left[ \frac{1}{k+r+v} h'\left(\frac{z+r+v}{k+r+v}\right) - \frac{1}{k+v} h'\left(\frac{z+v}{k+v}\right) \right] \right\} dv. \end{aligned}$$

Applying the Fundamental Theorem of Calculus to (10.3) gives

$$\begin{aligned} \text{R.H.S.} &= - \int_0^r \int_0^s \left\{ \frac{k-z}{(k+u+v)^2} h'\left(\frac{z+u+v}{k+u+v}\right) \right. \\ &\quad \left. + (k-z) \left[ \frac{-1}{(k+u+v)^2} h'\left(\frac{z+u+v}{k+u+v}\right) \right. \right. \\ (10.4) \quad &\quad \left. \left. + \frac{k-z}{(k+u+v)^3} h''\left(\frac{z+u+v}{k+u+v}\right) \right] \right\} du \, dv \\ &= - \int_0^r \int_0^s \left\{ \frac{(k-z)^2}{(k+u+v)^3} h''\left(\frac{z+u+v}{k+u+v}\right) \right\} du \, dv. \end{aligned}$$

The concavity of  $h$  and the nonnegativity of  $r, s$ , and  $k$  ensure that (10.4) is nonnegative.

However,  $x, y$  can be positive. The complete proof uses auxiliary points which correspond to  $\tilde{P}_i = P_i + x$  and  $\tilde{Q}_{j+s} = Q_{j+s} - y$ . There follows:

$$\begin{aligned} &W(i, j) - W(i, j+s) - W(i+r, j) + W(i+r, j+s) \\ &= \left\{ (k+r)h\left(\frac{z+r}{k+r}\right) + \left[ -(k+r)h\left(\frac{z+r}{k+r}\right) + (k+r)h\left(\frac{z+r+x}{k+r}\right) \right] \right. \\ &\quad \left. - (k+r+s)h\left(\frac{z+r+s}{k+r+s}\right) \right. \\ &\quad \left. + \left[ (k+r+s)h\left(\frac{z+r+s}{k+r+s}\right) - (k+r+s)h\left(\frac{z+r+s+x+y}{k+r+s}\right) \right] \right. \\ &\quad \left. - kh\left(\frac{z}{k}\right) + (k+s)h\left(\frac{z+s}{k+s}\right) - \left[ (k+s)h\left(\frac{z+s}{k+s}\right) - (k+s)h\left(\frac{z+s+y}{k+s}\right) \right] \right\} \end{aligned}$$

The inner terms (in square brackets) are differences, and the remaining terms are exactly as in (10.2). The Fundamental Theorem of Calculus and (10.4) give

$$\begin{aligned}
 \text{R.H.S.} &= \int_0^x \left\{ h' \left( \frac{z+r+\nu}{k+r} \right) \right\} d\nu \\
 &\quad + \int_0^{y+x} \left\{ -h' \left( \frac{z+r+s+\nu}{k+r+s} \right) \right\} d\nu + \int_0^y \left\{ h' \left( \frac{z+s+u}{k+s} \right) \right\} du \\
 &\quad - \int_0^r \int_0^s \left\{ \frac{(k-z)^2}{(k+u+\nu)^3} h'' \left( \frac{z+u+\nu}{k+u+\nu} \right) \right\} du d\nu. \\
 (10.5) \quad &= \int_0^x \left\{ h' \left( \frac{z+r+\nu}{k+r} \right) - h' \left( \frac{s+z+r+\nu}{s+k+r} \right) \right\} d\nu \\
 &\quad + \int_0^y \left\{ h' \left( \frac{z+s+u}{k+s} \right) - h' \left( \frac{x+r+z+s+u}{r+k+s} \right) \right\} du \\
 &\quad + \int_0^r \int_0^s \left\{ \frac{-(k-z)^2}{(k+u+\nu)^3} h'' \left( \frac{z+u+\nu}{k+u+\nu} \right) \right\} du d\nu.
 \end{aligned}$$

We have already seen that the last term in (10.5) is nonnegative. The Mean Value Theorem says that  $f(b) - f(a) = f'(\xi)(b - a)$  for some  $\xi$  where  $\min(a, b) \leq \xi \leq \max(a, b)$ . It follows that the first two integrals in (10.5) can each be replaced by expressions of the form  $\int h''(\xi) \Delta \arg d\nu$ . It remains to show that  $\Delta \arg$  is not positive, that is,

$$\left( \frac{z+r+\nu}{k+r} \right) - \left( \frac{s+z+r+\nu}{s+k+r} \right) \leq 0 \quad \text{and} \quad \left( \frac{z+s+u}{k+s} \right) - \left( \frac{x+r+z+s+u}{r+k+s} \right) \leq 0.$$

The assumption that  $W(i, j)$  and  $W(i+r, j+s)$  in (10.1) are positive says that  $(k+r)h((z+r+x)/(k+r))$  and  $(k+s)h((z+s+y)/(k+s))$  are positive. Since  $h(t) = 0$  for  $t \geq 1$ , it follows that  $(z+r+x)/(k+r) < 1$ , and  $(z+s+y)/(k+s) < 1$ . The denominators are positive. Hence  $(z+r+\nu)/(k+r) < 1$  for  $0 \leq \nu \leq x$ , and  $(z+s+u)/(k+s) < 1$  for  $0 \leq u \leq y$ . Since the fractions are less than one, adding a nonnegative quantity such as  $r$  or  $s$  to both the numerator and denominator of  $((z+r+\nu)/(k+r))$  or  $((z+s+u)/(k+s))$  cannot decrease their values. An additional  $x$  in the numerator has the same result. These operations give  $((s+z+r+\nu)/(s+k+r)) \geq ((z+r+\nu)/(k+r))$  and  $((x+r+z+s+u)/(r+k+s)) \geq ((z+s+u)/(k+s))$ . Consequently each term in (10.5) is nonnegative.

There remains the possibility that some of the terms in (10.1) could be equal to zero. These cases are trivial.

It should be noted that the derivation and the nonnegativity of (10.5) hold even if  $h$  is not twice differentiable. As explained in, say, [CH], even discontinuous functions possess generalized derivatives which are usually called distributional derivatives. The Dirac delta function  $\delta(x) = (d/dx)H(x)$ , where  $H(x) \equiv (0 \text{ if } x < 0 \text{ else } 1)$ , for example, is a distributional derivative (which happens to be nonnegative). The concavity requirement for separation barriers ensures that on  $(-\infty, 1]$ ,  $h'' \leq 0$  in the distributional sense, and this is sufficient for our purposes. Alternatively, it suffices to observe that Theorem A is essentially a statement about four points on a concave curve, and any such four points can be interpolated by a smooth concave function  $h$ .  $\square$

## RELATIONS BETWEEN CONCURRENT-WRITE MODELS OF PARALLEL COMPUTATION\*

FAITH E. FICH†, PRABHAKAR RAGDE‡, AND AVI WIGDERSON‡

**Abstract.** Shared memory models of parallel computation (e.g., parallel RAMs) that allow simultaneous read/write access are very natural and already widely used for parallel algorithm design. The various models differ from each other in the mechanism by which they resolve write conflicts. To understand the effect of these communication primitives on the power of parallelism, we extensively study the relationship between four such models that appear in the literature, and prove nontrivial separations and simulation results among them.

**Key words.** parallel computation, lower bounds, parallel random access machines

**AMS(MOS) subject classification.** 68Q10

**1. Introduction.** Parallel computation has been the object of intensive study in recent years. Many models of synchronous parallel computation have been proposed. One important model is the CRCW PRAM (concurrent-read concurrent-write parallel random access machine, sometimes denoted WRAM). Not only have numerous algorithms been designed for the CRCW PRAM (examples include [Ga], [KMR], [SV], and [TV]), but it has also been shown to be closely related to unbounded fan-in circuits and alternating Turing machines ([CSV], [LY2]).

Specifically, a CRCW PRAM consists of a set of processors (i.e., random access machines)  $P_1, P_2, \dots, P_n$  together with a shared memory. One step consists of three phases. In the read phase, every processor may read one shared memory cell. In the compute phase, every processor may perform computation. In the write phase, every processor may write into one shared memory cell. Any number of processors can simultaneously read from the same memory cell, and any number may attempt to simultaneously write into the same memory cell.

An arbitrary amount of computation will be allowed in each compute phase. Although this is unrealistic, it enables us to concentrate on communication between processors. For all the problems we consider, communication rather than computation is the limiting factor. In fact, the algorithms presented in this paper actually perform very little computation at each step. Furthermore, the powerfulness of the model makes the lower bounds we present very strong.

A fundamental question concerning CRCW PRAMs is how to resolve write conflicts. One method is to assign priorities to processors and, if more than one processor attempts to write to the same memory cell, then the one with the highest priority will succeed. Without loss of generality (by reordering processors), we can assume that priorities are assigned in order of processor index, with highest priority given to the processor of lowest index [Go]. We call this the PRIORITY model.

Other mechanisms for conflict resolution appear in the literature. In the ARBITRARY model, if more than one processor attempts to write to the same memory cell, an arbitrary one will succeed [V]. Algorithms for the ARBITRARY model must

‡The Hebrew University, Jerusalem, Israel.

work regardless of who wins the competition to write at each step. The COMMON model allows simultaneous writes to the same memory cell only if all processors doing so are writing a common value [Ku].

When more than one processor attempts to write to the same memory cell in the COLLISION model, a special collision symbol will appear in that cell. No information is given about which processors were involved in the collision nor what values they were trying to write. This write-conflict resolution scheme is a synchronous version of that used by Ethernet and other multiple access channels [Gr].

Write conflicts can also be avoided by not allowing them; in the concurrent-read exclusive-write (CREW) PRAM, at most one processor can attempt to write to a given memory cell at each time step [FW]. An even more restrictive model is the exclusive-read exclusive-write (EREW) PRAM, in which both reads and writes are restricted in this manner.

Any algorithm that runs on the ARBITRARY model will run unchanged on the PRIORITY model; if an algorithm works regardless of who wins a competition to write, then it will certainly work if the processor of lowest index always wins. Thus the PRIORITY model is at least as powerful as the ARBITRARY model. Similarly, the ARBITRARY model is at least as powerful as the COMMON model, the COMMON and COLLISION models are at least as powerful as the CREW PRAM, and the CREW PRAM is at least as powerful as the EREW PRAM.

One step of the COLLISION model can be simulated by two steps on the ARBITRARY model, using the same number of processors and shared memory cells. First, each processor in the ARBITRARY model writes where the corresponding processor in the COLLISION model wrote. However, it writes its index in addition to the value originally written. Then each processor reads from the cell to which it has just written. If the index written there is not its own, a collision must have occurred during the previous write step. In this case, the processor writes the collision symbol to the memory cell.

Our aim is to understand the relative power of these models. Algorithms running on these models have appeared in the literature, and their expositions often include attempts to implement them on the most restrictive model possible. Such attempts are of little value without knowing which of the inclusions described above are strict.

Cook, Dwork, and Reischuk have shown that the CREW PRAM is strictly less powerful than the CRCW PRAM. In particular, their work [CDR] shows that the  $n$ -way OR function, which can be computed in one step on the COMMON model, requires  $\Omega(\log n)$  steps using a CREW PRAM. By considering the problem of searching in a sorted list of distinct elements, Snir [S] has shown that the EREW PRAM is strictly less powerful than the CREW PRAM.

In this paper, we obtain separation results for the four CRCW models as a function of the number of shared memory cells  $m$  (called the *communication width* [VW]) when the number of processors is held fixed at  $n$ . This is an important restriction, since one step on the PRIORITY model is easily simulated by two steps on the COMMON or COLLISION model if the number of processors is squared and sufficient common memory is allowed [Ku]. When width is restricted, however, the four models are not equivalent. Restricting width has a meaning in a practical as well as theoretical sense; a bus or a satellite relay may be considered to be a CRCW PRAM with width 1.

Table 1 summarizes our results on simulations and separations. A particular model is denoted by its name followed by the number of shared memory cells in parentheses (e.g., COMMON(1)). The time bound given is the number of steps on the weaker machine required to simulate one step on the more powerful machine. All logarithms are to the base 2. The results in §2 and §3 are, for the most part, easy

adversary arguments; those in the remaining sections are harder and more revealing. Among the results we consider particularly significant is an information-theoretic lower bound for computation on COMMON(1) which is applicable in a more general setting (Theorem 6). The characterization of the global state of information proven in that theorem also allows us to prove a surprising constant time simulation of COMMON(1) by COLLISION(1) (Theorem 10).

TABLE 1

New lower bound techniques are developed to obtain the results below. We consider this work as another step (following [S], [CDR], and [VW]) in forming a foundation of lower bound techniques for parallel computation. Also, as our lower bounds concern the communication between processors, we believe these techniques may be applied to distributed (asynchronous) computation as well (e.g., in the Ethernet model). Recently, results have been obtained using more powerful techniques for models with infinite shared memory ([FMW], [MW]) and an infinite number of processors [B]. Li and Yesha ([LY1],[LY2]) have extended many of these results to models with the input in read-only memory (ROM) and have proved other results on this related model.

**2. Simulating PRIORITY(1) by weaker models.** Let us consider how to simulate one step of an algorithm for PRIORITY( $m$ ) on a machine with a weaker write

conflict resolution method, but with at least as much shared memory. Each processor in the  $\text{PRIORITY}(m)$  machine will be simulated by one processor in the simulating machine. Likewise, the contents of each shared memory cell in the  $\text{PRIORITY}(m)$  will appear in a specific shared memory cell. Simulation of the read phase is trivial. However, in the write phase on the simulating machine, processors must know if they are the processor of lowest index writing into the cell that they wish to write into. This requires some extra computation and leads to the definition of the following problem.

**m-colour MINIMIZATION.**

Before: Each processor  $P_i$ , for  $i = 1, \dots, n$ , has a colour  $x_i \in \{0, \dots, m\}$  known only to itself.

After: Each processor  $P_i$  knows the value  $a_i$ , where

$$a_i = \begin{cases} 1 & \text{if for all } j < i, x_i \neq x_j \text{ and } x_i > 0, \\ 0 & \text{otherwise.} \end{cases}$$

Thus  $a_i = 1$  if and only if  $P_i$  is the processor of lowest index with colour  $x_i$  and  $x_i \neq 0$ .

In the simulation,  $x_i$  represents the memory cell into which the simulated processor  $P_i$  wishes to write;  $x_i = 0$  if  $P_i$  does not wish to write. Once the problem is solved,  $P_i$  will write if and only if  $a_i = 1$ , thus resolving the write conflict in the fashion that  $\text{PRIORITY}$  machine would.

Clearly, the  $m$ -colour  $\text{MINIMIZATION}$  problem takes only one step to solve on  $\text{PRIORITY}(m)$ .

**THEOREM 1.** *On  $\text{COMMON}(m)$ , the 1-colour  $\text{MINIMIZATION}$  problem can be solved in  $O(\frac{\log n}{\log(m+1)})$  steps.*

*Proof.* Without loss of generality, we may assume  $m \leq \sqrt{n}$ . If  $m > \sqrt{n}$  we only use the first  $\sqrt{n}$  cells of memory. This is because with  $m = \sqrt{n}$  we already achieve  $O(1)$  running time.

Throughout the algorithm, memory cells will contain only 1's and 0's. Note that for the 1-colour  $\text{MINIMIZATION}$  problem,  $x_i \in \{0, 1\}$ . We call the processor of lowest index whose colour is 1 the *winner*.

The algorithm repeatedly performs the following sequence of steps. First, all shared memory cells are set to 0 by having processor  $P_i$ , for  $i = 1, \dots, m$ , write 0 into cell  $M_i$ . The processors are divided into  $m + 1$  nearly equal groups, where each group contains a set of consecutively numbered processors. The first  $n \bmod (m + 1)$  groups contain  $\lceil \frac{n}{m+1} \rceil$  processors and the rest contain  $\lfloor \frac{n}{m+1} \rfloor$ . A processor  $P_i$  in the  $j$ th group, where  $1 \leq j \leq m$ , will write 1 into  $M_j$  if and only if  $x_i = 1$ . At this point, if all memory cells are unchanged (i.e., contain the value 0), the winner is in the  $(m + 1)$ st group; otherwise it is in the group corresponding to the memory cell of lowest index containing a 1.

We note that a processor does not have to know which group contains the eventual winner, only whether its group wins. The following subroutines are used to decide which of the above two cases holds, in constant time.

**LEFTMOST ONE IN MEMORY.**

Before: Cells  $M_i$ , for  $i = 1, \dots, m$ , each contain 1 or 0.

After:  $M_i$  contains 1 if and only if all  $M_j$  for  $j < i$  were initially 0, and  $M_i$  was initially 1.

Procedure: Processor  $P_i$  forms the ordered pair  $(j, k)$  from its name by setting  $j \leftarrow (i \bmod m) + 1$  and  $k \leftarrow i - m(j - 1)$ . If  $j < k \leq m$  and  $M_j$  contains 1,  $P_i$  writes 0 into  $M_k$ .

**EMPTY MEMORY (m-way OR).**

Before: Cells  $M_i$ , for  $i = 1, \dots, m$ , each contain 1 or 0.

After:  $M_1$  contains 0 if and only if all  $M_i$  were initially 0.

Procedure: Processor  $P_i$  will read  $M_i$  and, if it contains 1,  $P_i$  writes 1 into  $M_1$ .

After the LEFTMOST ONE IN MEMORY algorithm is applied, the processors in group  $i$  look at  $M_i$  to see if they are in the winning group or not (depending on whether  $M_i$  contains 1 or 0, respectively). Note that this algorithm uses  $m^2$  processors; the assumption  $m \leq \sqrt{n}$  ensures that sufficient processors are available. Application of EMPTY MEMORY will then allow the  $(m + 1)$ st group to decide if it is the winning group or not, by looking at  $M_1$ .

All processors except the ones in the winning group set  $a_i = 0$  and stop; the ones in the winning group repeat the above procedure with  $n$  replaced by the size of the group. This continues until the size of the winning group is equal to 1; at this point, the winner is determined.

Intuitively, the algorithm cuts the size of the winning group by a factor of  $m + 1$  each time. More precisely, if  $g_t$  is the size of the set of processors that may still be the winner after the  $t$ th step, then

$$g_0 = n \quad \text{and} \\ g_t \leq \left\lceil \frac{g_{t-1}}{m+1} \right\rceil.$$

If  $T \geq \log n / \log(m + 1)$ , then  $g_T \leq \lceil \frac{n}{(m+1)^T} \rceil \leq 1$ . Thus the algorithm takes at most  $\lceil \frac{\log n}{\log(m+1)} \rceil$  iterations. Since each iteration takes a constant number of steps, we have the desired upper bound.  $\square$

**COROLLARY 1.1.** *On ARBITRARY( $m$ ) and COLLISION( $m$ ), the 1-colour MINIMIZATION problem can be solved in  $O\left(\frac{\log n}{\log(m+1)}\right)$  steps.*

*Proof.* The algorithm described in the proof of Theorem 1 will run on ARBITRARY( $m$ ). It will also run on COLLISION( $m$ ) provided that, before performing LEFTMOST ONE IN MEMORY, each processor  $P_i$  for  $i = 1, \dots, m$ , reads memory cell  $M_i$  and, if  $M_i$  contains the collision symbol, writes 1 into  $M_i$ .  $\square$

It follows that ARBITRARY( $m$ ), COLLISION( $m$ ), and COMMON( $m$ ) can simulate one step of PRIORITY(1) in  $O\left(\frac{\log n}{\log(m+1)}\right)$  steps. One cell of the simulating machine (say  $M_1$ ) is designated as being equivalent to the single cell of PRIORITY(1). Processor  $P_i$  then sets  $x_i = 1$  if it wishes to write at that step, and sets  $x_i = 0$  otherwise. The algorithm for 1-colour MINIMIZATION is then followed, with the following change: the value 0 is replaced by the value presently in  $M_1$ , and the value 1 is replaced by some other value. At the end, the winner writes into  $M_1$  the value that the corresponding processor would have written in the PRIORITY(1) algorithm.

**COROLLARY 1.2.** *COMMON( $m$ ), COLLISION( $m$ ), and ARBITRARY( $m$ ) can simulate one step of PRIORITY( $m$ ) in  $O(\log n)$  steps.*

*Proof.* The write conflict resolution problems for each of the  $m$  memory cells of the PRIORITY machine can be treated as separate 1-colour MINIMIZATION problems that are solved simultaneously.

In the write conflict resolution problem for memory cell  $M_j$ , let  $x_i = 1$  if the simulated processor  $P_i$  wishes to write into memory cell  $M_j$ ; otherwise, let  $x_i = 0$ . This subproblem is solved via the algorithm described in Theorem 1 or Corollary 1.1, using the single cell  $M_j$ .

In the algorithm, a processor only writes if its colour is 1. Each processor will have colour 1 for at most one of the subproblems, namely the subproblem corresponding to where the processor it is simulating wished to write. In fact, this is the only subproblem that the processor can win. Thus the processor can ignore the rest of the subproblems. Although many subproblems are being solved simultaneously, each processor is required to participate in the solution of at most one.  $\square$

**COROLLARY 1.3.** *If  $m = O(n/c)$ , then COMMON( $cm$ ), COLLISION( $cm$ ), and ARBITRARY( $cm$ ) can simulate one step of PRIORITY( $m$ ) in  $O(\frac{\log n}{\log(c+1)})$  steps.*

*Proof.* As in the proof of Corollary 1.2, the write conflict resolution problems for each of the  $m$  memory cells of the PRIORITY machine can be treated as separate 1-colour MINIMIZATION problems. Each of these  $m$  problems will be solved simultaneously, with  $c$  memory cells devoted to each problem.

Essentially, the algorithm described in Theorem 1 or Corollary 1.1 is used. However, the allocation of processors is done somewhat differently for the computation of LEFTMOST ONE IN MEMORY and EMPTY MEMORY. The  $n$  processors are divided into groups of  $c$  consecutively numbered processors. Since  $m = O(n/c)$ , each group is responsible for the solution of a constant number of subproblems.

Unfortunately, the LEFTMOST ONE IN MEMORY algorithm requires  $c^2$  processors. Instead, each processor reads one of the  $c$  cells of memory and then they use the 1-colour MINIMIZATION algorithm again to decide which processor read the lowest index cell containing the value 1. This takes a constant number of steps, since the number of memory cells and the number of processors are the same.  $\square$

Unlike the proof of Corollary 1.2, it is not sufficient to have only those processors that wish to write into memory cell  $M_j$  participate in the solution of the 1-colour MINIMIZATION problem associated with  $M_j$ . There may be far fewer than  $c$  processors wanting to write into some cells. Even if there were a sufficient number of processors wanting to write into each shared memory cell, a processor would not necessarily know the identities of the other processors working with it. Therefore, it would not know what to do during the execution of the LEFTMOST ONE IN MEMORY algorithm.

When  $m = O(n^{1-\epsilon})$  for some constant  $\epsilon > 0$ , choosing  $c = n^\epsilon$  in Corollary 1.3 provides us with constant time simulations of PRIORITY( $m$ ), without increasing the number of processors.

The following lower bound shows that the algorithm in Theorem 1 is optimal, to within a constant factor. The proof uses a fairly simple adversary argument, which we present in detail, as it serves as a paradigm for subsequent proofs.

**THEOREM 2.** *The 1-colour MINIMIZATION problem requires at least  $\frac{\log(n+1)-1}{\log(m+1)}$  steps to solve on ARBITRARY( $m$ ).*

Consider an algorithm solving this problem. An *input* to the algorithm is a specification of the values of all the colours  $x_i$ . (Recall that  $x_i \in \{0, 1\}$ .) We will use an adversary argument, constructing an input on which the algorithm requires this many steps.

The write action of a particular processor  $P_i$  at step  $t$  depends only on  $x_i$  and the sequence of contents  $(H_0, H_1, \dots, H_{t-1})$  of the  $m$  shared memory cells. Here  $H_i$  is a specification of the contents of memory cells  $M_1, M_2, \dots, M_m$  immediately before step  $i + 1$ . We call this sequence the *history* through time  $t$ . Given a fixed history, we say  $P_i$  writes into  $M_j$  on value  $v$  if it attempts to write to memory cell  $M_j$  when  $x_i = v$ .

At each step we will “fix” the values of certain input variables and maintain a set of *allowable* inputs. The set of *allowable* inputs will consist of those inputs in which each fixed variable has the value to which it was fixed. This will be done in a manner such that all *allowable* inputs will produce the same history up to that step.

The term *position* is used to denote the index of an input variable. A position  $i$  is said to be fixed to a certain value if the corresponding variable  $x_i$  is fixed to that value. If the variable  $x_i$  is not fixed, the position  $i$  is said to be *free*. We will maintain a set  $S$  of fixed positions and a set  $F$  of free positions such that  $S \cup F = \{1, \dots, n\}$ . Associated with each position in  $S$  will be the value to which that position is fixed. Furthermore, we will ensure that, for each free position in  $F$ , there will be no lower numbered positions fixed to 1.

Suppose there are at least two free positions  $i$  and  $j$  after some step  $T$ , and  $i < j$ . Consider the following two inputs:  $I_{ij}$ , in which  $x_i$  and  $x_j$  are the only variables in free positions that equal 1, and  $I_j$ , in which  $x_j$  is the only variable in a free position that equals 1. Both these inputs put  $P_j$  in the same state at the end of step  $T$ , since in both  $P_j$  sees the same input value and the same history. But, for  $I_j$ ,  $a_j = 1$ , and for  $I_{ij}$ ,  $a_j = 0$ . Thus  $P_j$  cannot know the value  $a_j$  after the  $T$ th step. We can conclude that, when the algorithm terminates, there is at most one free position.

Initially,  $S = \phi$ ,  $H_0$  is the initial contents of memory, and the conditions stated above are satisfied. Now suppose that, after the  $t$ th step, we have fixed a set of positions  $S$  so that all allowable inputs produce the same history  $(H_0, H_1, \dots, H_t)$  through step  $t$ . Furthermore, for any free position in  $F$ , there is no lower numbered position fixed to 1. Let  $f_t$  denote the number of free positions remaining after step  $t$ .

We determine  $H_{t+1}$  by fixing certain free positions, as follows.

- 1) If position  $i$  is fixed before step  $t + 1$  and processor  $P_i$  writes to some memory cell  $M_j$  at step  $t + 1$ , then the contents of  $M_j$  in  $H_{t+1}$  can be fixed by declaring  $P_i$  to win the competition to write into  $M_j$ . Notice that we do not need to fix any additional free positions in this case.
- 2) For all cells  $M_j$  into which some processor writes on 0 at step  $t + 1$  given history  $(H_0, \dots, H_t)$ , choose one processor  $P_{i_j}$  doing so, fix position  $i_j$  to 0, and declare  $P_{i_j}$  to win the competition to write into  $M_j$  at step  $t + 1$  for all inputs consistent with  $S$ . This fixes the contents of  $M_j$  in  $H_{t+1}$  to a unique value.
- 3) Suppose there are  $r$  memory cells not taken care of above. Processors only write on value 1 into these remaining cells. Let  $f$  be the number of remaining free positions. Divide these free positions into  $r + 1$  nearly equal groups; the first group will contain the lowest  $\lfloor \frac{f}{r+1} \rfloor$  positions, the second the next  $\lfloor \frac{f}{r+1} \rfloor$  positions, and so on. The last  $f \bmod (r + 1)$  groups will contain  $\lceil \frac{f}{r+1} \rceil$  free positions. For each such cell  $M_j$ , let  $P_{i_j}$  denote the processor of *highest* index writing on 1 into  $M_j$  and associate this cell with the group containing  $P_{i_j}$ . Since there are  $r$  cells and  $r + 1$  groups, at least one group will have no cells associated with it. Let  $G$  be such a group and suppose that it comprises free positions  $k$  through  $l$ . The idea is that, for each memory cell, by either forcing no processor to write to it or forcing the highest index processor wishing to write to it to do so, we can provide *no information* about group  $G$ .
  - i) Fix all free positions with index less than  $k$  to 0. Consider any cell  $M_j$  associated with a group consisting of free positions less than  $k$ . All processors that write into  $M_j$  at step  $t + 1$  only do so on 1. However, they will have all had their colours  $x_i$  set to 0. Hence, no processor will write into these cells at step  $t + 1$  for any allowable input and the contents of these cells in  $H_{t+1}$  will remain as they were in  $H_t$ .

- ii) Fix all free positions with index greater than  $l$  to 1. For any cell  $M_j$  associated with a group consisting of free positions greater than  $l$ , we declare  $P_{i_j}$  to win the competition to write into  $M_j$  at step  $t+1$  for every allowable input. This fixes the contents of  $M_j$  in  $H_{t+1}$  to a unique value.
- 4) The remaining cells have no processor writing into them on any allowable input at step  $t+1$ . The contents of these cells in  $H_{t+1}$  will be the same as they were in  $H_t$ .

Intuitively, the number of free positions is cut down by at most a factor of  $m+1$  at each step. More precisely, if  $f_t$  is the number of free positions at time  $t$ , then  $f \geq f_t - (m-r)$  and

$$f_{t+1} \geq \min_{0 \leq r \leq m} \left\lfloor \frac{f_t - m + r}{r + 1} \right\rfloor = \left\lfloor \frac{f_t}{m + 1} \right\rfloor.$$

Let  $T$  be the total number of steps taken by the algorithm. Since  $f_0 = n$  and  $f_T \leq 1$ , it follows that  $T \geq \frac{(\log(n+1)-1)}{\log(m+1)}$ .  $\square$

It has been shown [Ra] that  $\Omega\left(\frac{\log n}{\log(m+1)}\right)$  steps are required to solve 1-colour MINIMIZATION on ARBITRARY( $m$ ) even if processors are allowed to make random choices to determine their behaviour at each step.

**3. Simulating ARBITRARY(1) by weaker models.** The preceding section demonstrated a separation between PRIORITY(1) and ARBITRARY( $m$ ). We can show a similar separation between ARBITRARY(1) and COMMON( $m$ ) and between ARBITRARY(1) and COLLISION( $m$ ) by considering the following problem.

**$m$ -colour REPRESENTATIVE.**

Before: Each processor  $P_i$ , for  $i = 1, \dots, n$  has a colour  $x_i \in \{0, \dots, m\}$  known only to itself.

After: Each processor  $P_i$  knows the value  $a_i \in \{0, 1\}$ , where  $a_i = 1$  for exactly one processor among those with each particular nonzero colour  $c$ .

Notice that the  $m$ -colour REPRESENTATIVE problem requires only one step on ARBITRARY( $m$ ).

**THEOREM 3.** *On COMMON( $m$ ) or COLLISION( $m$ ), the 1-colour REPRESENTATIVE problem can be solved in  $O\left(\frac{\log n}{\log(m+1)}\right)$  steps.*

Theorem 3, in fact, follows easily from Corollary 1.1, as any solution to the 1-colour MINIMIZATION problem is also a solution to the 1-colour REPRESENTATIVE problem. The following theorem provides the separation between ARBITRARY(1) and COMMON( $m$ ).

**THEOREM 4.** *On COMMON( $m$ ), the 1-colour REPRESENTATIVE problem requires at least  $\frac{\log n}{\log(m+1)}$  steps to solve.*

*Proof.* The proof is similar to that of Theorem 2; here we merely sketch the differences. As before, we maintain a set  $S$  of fixed positions, a set  $F$  of free positions, and  $H_t$ , a specification of the contents of the  $m$  memory cells after step  $t$ . In this proof, we only fix positions to the value 0, but we do not allow the all-zero input. All other consistent inputs are allowed. The number of free positions is initially  $n$ .

Suppose there are at least two free positions  $i$  and  $j$  after some step  $T$ . Consider the following three inputs:  $I_i$ , in which  $x_i$  is the only variable that has value 1,  $I_j$ , in which  $x_j$  is the only variable that has value 1, and  $I_{ij}$ , in which  $x_i$  and  $x_j$  are the

only variables that have value 1. Both  $I_i$  and  $I_{ij}$  put  $P_i$  in the same state at the end of step  $T$ , since in both  $P_i$  sees the same input value and the same history. Similarly,  $I_j$  and  $I_{ij}$  both put  $P_j$  in the same state at the end of step  $T$ . For  $I_i$ ,  $a_i = 1$  and for  $I_j$ ,  $a_j = 1$ . If step  $T$  is the last step of the algorithm, then, for  $I_{ij}$ ,  $a_i = a_j = 1$ . This contradicts the fact that the algorithm solves the 1-colour REPRESENTATIVE problem. We can conclude that, when the algorithm terminates, there is at most one free position.

Given the set of fixed positions  $S$  and the history  $(H_0, H_1, \dots, H_t)$ , through time  $t$  we need to show how to fix some free positions in a way that defines  $H_{t+1}$ . Those memory cells into which no processors write on either 0 or 1 retain their values. Memory cells that are written into by some processor on 0 (including any processors in a fixed position) are handled as in the proof of Theorem 2.

The difficulty occurs for those cells into which processors write only on 1. Let the set of indices of such cells be denoted  $C$ . For  $j \in C$ , let  $W_j$  be the set of processors in the remaining free positions that, at step  $t + 1$ , write on 1 into  $M_j$  and let  $W_0$  be those that do not write on 1 at this step. Note that none of these processors write into  $M_j$  on 0 for any  $j \in C$ .

Now, the number of remaining free positions is at least  $|F| - (m - |C|)$ . Thus, for some  $j \in C \cup \{0\}$ , it follows that

$$|W_j| \geq \frac{|F| - m + |C|}{|C| + 1} \geq \frac{|F|}{m + 1}.$$

For one such  $j$ , we fix the colours of all processors not in  $W_j$  to 0. This defines the contents of all memory cells  $M_k$  with  $k \in C - \{j\}$ . Specifically, their contents in  $H_{t+1}$  remain as they were in  $H_t$ .

Finally, when  $j \in C$ , consider the processors in  $W_j$ . There is an allowable input in which all these processors have colour 1 and, thus, they must all write the same value on 1. Since we prohibited the all 0 input, all allowable inputs result in at least one processor in  $W_j$  receiving an input value that causes it to write at this step. Thus  $H_{t+1}$  is determined, at the cost of cutting down the number of free positions by at most a factor of  $m + 1$ . As before, we can define a recurrence bounding the number of free positions at step  $t$  and conclude that Theorem 4 is true.  $\square$

A lower bound of  $\Omega\left(\frac{\log n}{\log(m+1)}\right)$  steps holds for the 1-colour REPRESENTATIVE problem on COMMON( $m$ ) even if processors are allowed to make random choices [Ra]. The following theorem provides an analogous separation between ARBITRARY(1) and COLLISION( $m$ ).

**THEOREM 5.** *On COLLISION( $m$ ), the 1-colour REPRESENTATIVE problem requires at least  $\frac{\log(n+1) - \log 3}{\log(m+1)}$  steps to solve.*

*Proof.* The proof of this theorem is very similar to that of Theorems 2 and 4. We must define the set of consistent inputs to be those with at least two 1's in free positions, in order to enable us to fix collisions in a history. It is not difficult to reason that, as long as there are at least three positions left free by the adversary at the end of the algorithm, there is an input on which the algorithm answers incorrectly. (The conclusion follows easily from the fact that any processor  $P_i$  cannot distinguish consistent inputs that agree on the private bit of  $P_i$ .)

In the course of fixing the history in a cell after a particular step, there are three cases to consider: where no processors write into that cell, where exactly one processor writes, and where two or more processors write. The precise details of how to fix positions are thus slightly more complicated than those of Theorem 4, but no new techniques are involved. A recurrence for the number of free positions left after  $t$  steps can be defined, and the result obtained.  $\square$

**4. A lower bound for COMMON(1) and its applications.** We say that a PRAM with one cell  $M$  of shared memory computes a surjective function  $f : \{0, 1\}^n \rightarrow R$  for some range set  $R$  if, at the beginning of the computation,  $P_i$  has the  $i$ th argument (denoted by  $x_i$ ) in its local memory and, at the end of the computation, the value of  $f(x_1, x_2 \dots x_n)$  appears in  $M$ .

Our definition can be thought of as *public computation*, since the answer must appear in shared memory. The REPRESENTATIVE and MINIMIZATION problems defined earlier can be thought of as *private computation*, since each processor is required to compute a private answer bit  $a_i$ . A good lower bound for public computation can lead to a good lower bound for private computation if  $(a_1, a_2, \dots, a_n)$  can be made public in a small number of steps. For example, in 1-colour MINIMIZATION, the unique processor with  $a_i = 1$  can take one more step and write  $i$  into  $M$ .

The following theorem gives a lower bound on the number of steps required to publicly compute any function on COMMON(1). The lower bound depends only on the number of function values that are possible.

**THEOREM 6.** *On COMMON(1), any algorithm that publicly computes a surjective function  $f : \{0, 1\}^n \rightarrow R$  requires at least  $\lceil \log_3 |R| \rceil$  steps for some input.*

It is important to notice that Theorem 6 does not apply to private computation. For example, no communication is required to privately compute the answer bits  $(a_1, \dots, a_n)$  given the input bits  $(x_1, \dots, x_n)$ , where  $a_i = x_i$  for  $i = 1, \dots, n$ . However, by Theorem 6, a linear number of steps must be performed to publically compute the identity function  $id : \{0, 1\}^n \rightarrow \{0, 1\}^n$  on COMMON(1).

Furthermore, Theorem 6 does not apply when the domain is *cleft*, that is, a proper subset of  $\{0, 1\}^n$  [Re]. Consider the case where inputs are restricted so that in all valid input, exactly one input variable has value 1 and the function to be computed is the index of that variable. This function has a range of size  $n$ , but only requires a single step to publicly compute on COMMON(1).

Although the theorem, as stated, applies to the case of a single shared memory cell, it is powerful enough to use in a more general setting.

**LEMMA 6.1.**  *$T$  steps of COMMON( $m$ ) can be simulated by  $mT$  steps of COMMON(1).*

*Proof.* Each processor in COMMON(1) keeps a picture in its local memory of what shared memory on COMMON( $m$ ) would contain at the corresponding step. The simulation of each step of COMMON( $m$ ) proceeds in phases: in the  $i$ th phase, the single cell in the simulating machine takes the role of  $M_i$  in the simulated machine. All processors that would write the value  $v$  into  $M_i$  on COMMON( $m$ ) at this step write the ordered pair  $(v, i)$  into  $M_1$  on COMMON(1). Then all processors read  $M_1$  and update the contents of  $M_i$  in their picture of the shared memory of COMMON( $m$ ). Each phase takes one step and so one step of COMMON( $m$ ) is simulated by  $m$  steps of COMMON(1).  $\square$

**COROLLARY 6.2.** *On COMMON( $m$ ), any algorithm that publicly computes a surjective function  $f : \{0, 1\}^n \rightarrow R$  requires at least  $\lceil \frac{(\log_3 |R|)}{m} \rceil$  steps for some input.*

When COMMON( $m$ ) publicly computes a function, we require the value of the function to appear in shared memory at the end of the computation, but it may be distributed among the  $m$  shared memory cells. Note that this definition of computation is particularly weak when  $m$  is large; consider the identity function, whose value is just an  $n$ -tuple consisting of the input bits. When  $m = n$ , this can be publicly computed in one step under our definition; but Beame [B] has shown that if the tuple must appear in a single cell,  $\Omega(\log n)$  steps are required on PRIORITY( $n^{O(1)}$ ).

By specifying a particular function to be computed, we can separate the ARBITRARY and COMMON models, with the separation varying as a function of the size

of shared memory.

**COROLLARY 6.3.** *Simulating one step of COLLISION( $km$ ) on COMMON(1) requires  $\Omega(km \log(n/km))$  steps; on COMMON( $m$ ), it requires  $\Omega(k \log(n/km))$  steps.*

*Proof.* Partition the input positions into  $m$  groups of size  $\lfloor n/km \rfloor$  or  $\lfloor n/km \rfloor + 1$ , and consider the function  $f$  defined on domain  $\{0, 1\}^n$  whose value is an  $km$ -tuple  $(a_1, a_2, \dots, a_{km})$  such that  $a_i = j$  if  $x_j$  is the only variable in group  $i$  with value 1 and  $a_i = 0$  if either no variable or more than one variable in group  $i$  has value 1.

This function can be publicly computed in two steps on COLLISION( $km$ ), assuming each shared memory cell is initialized to 0. In the first step, each processor  $P_i$  in group  $j$  writes  $i$  into  $M_j$  on value 1. Each processor  $P_i$ , for  $i = 1, \dots, m$ , then reads cell  $M_i$  and, if it sees the collision symbol, writes 0 into  $M_i$  at the second step.

The function  $f$  has at least  $(\lfloor \frac{n}{km} \rfloor)^{km}$  possible values. Applying Theorem 6 and Corollary 6.2 give lower bounds of  $\Omega(km \log(n/km))$  and  $\Omega(k \log(n/km))$  for COMMON(1) and COMMON( $m$ ), respectively.  $\square$

By letting  $k = 1$ , Corollary 6.3 proves a separation between COLLISION( $m$ ) and COMMON( $m$ ) when  $m = o(n)$ . In particular, when  $m = O(n^{1-\epsilon})$  for some constant  $\epsilon > 0$ ,  $\Omega(\log n)$  steps are required.

We introduce some terminology to be used in the proof of Theorem 6. The *tree of possible computations* has nodes that intuitively correspond to the different states that the PRAM can be in during the course of the computation. Formally, with each node  $v$  at depth  $t$ , we associate a history  $(H_0, H_1, \dots, H_t)$  and a set  $I_v$  consisting of all inputs that generate this history through step  $t$ . An input is said to *reach* node  $v$  if it is a member of  $I_v$ . The children of  $v$  correspond to all possible extensions to the history at  $v$ ; each child is labelled with a different extension  $(H_0, H_1, \dots, H_t, H_{t+1})$ . The last entry in the history associated with a leaf of the tree will be the function value for all inputs that reach that leaf.

The statement of the theorem has an “information theory” flavour, and if we could show that the degree of fanout in the computation tree is bounded by a constant, the result would follow easily. Unfortunately, arbitrarily high fanout is possible, as the example with cleft domain showed. The intuition behind this theorem is that a node of high fanout corresponds to a step at which many different values can be written, depending on the input. Since for a particular input, two processors may not attempt to write different values, this implies that some knowledge of “mutual exclusion” can be inferred from the history. In the example with cleft domain, the knowledge that only one processor had an input variable with value 1 allowed  $n$  different values to be written at step 1, depending on the input. We will show that this “mutual exclusion” takes time to set up and is not reusable.

With each node  $v$  in the computation tree, we can associate a formula  $f_v$  in conjunctive normal form, whose variables are the private input bits  $x_i$ . This formula will have the property that the set of inputs  $I_v$  associated with this node is exactly the set of inputs that satisfy the formula  $f_v$ . The construction of these formulas will proceed by induction on the depth of a node. Formulas will have two types of clauses: *trivial* clauses will contain exactly one literal, and *nontrivial* clauses will contain more than one literal.

For the root  $r$  of the computation tree, we define  $f_r$  to be the empty formula. Now suppose we have a node  $w$  with associated history  $(H_0, H_1, \dots, H_{t-1})$  and associated formula  $f_w$ . Suppose, furthermore, that  $w$  has a child  $v$  and that the history at  $v$  is the history at  $w$  extended by the value  $H_t$ . This means that for some inputs in  $I_w$ , the content of  $M$  after the  $t$ th step is the value  $H_t$ . The action of any processor at step  $t$  for an input in  $I_w$  is completely determined by the history through step  $t - 1$  (the history associated with  $w$ , which is the same for all inputs in  $I_w$ ) and by the

processor's private input bit  $x_i$ . Thus, it is possible to determine which private bit values would cause processors to write  $H_t$ .

For inputs that reach  $v$ , at least one processor must have a value that causes it to write  $H_t$ . Thus inputs with history  $(H_0, H_1, \dots, H_{t-1}, H_t)$  must satisfy  $f_w$  and also a clause consisting of the OR of the literals corresponding to these possible bit values. For example, if  $P_1$  writes  $H_t$  when  $x_1 = 1$ , and  $P_2$  does so when  $x_2 = 0$ , then the added clause would be  $(x_1 \vee \bar{x}_2)$ . This is the only (possibly) nontrivial clause that we add. In two cases we do not add such a clause: when one processor  $P_i$  writes regardless of what its private bit is, and when no processor writes, i.e.,  $H_t = H_{t-1}$ . Since there is only one memory cell, each processor reads its content during every read phase. Therefore, we can assume, without loss of generality, that processors write into the memory cell  $M$  only to change its value.

All possible bit values that would have resulted in something other than  $H_t$  being written will result in additional trivial clauses. For example, if  $P_3$  would have written  $H'_t$  (different from  $H_t$ ) if  $x_3 = 1$ , we add the trivial clause  $(\bar{x}_3)$ , since the fact that  $H_t$  and not  $H'_t$  was written implies that  $x_3 = 0$ . We can also substitute these known values into other clauses. In our example, a clause containing the literal  $x_3$  would have that literal removed; a clause containing the literal  $\bar{x}_3$  would be entirely removed. This simplification is crucial to our proof, as it removes nontrivial clauses.

LEMMA 6.4. *If a node  $w$  with  $q$  children has a formula  $f_w$  with  $c$  nontrivial clauses, the formula at each child of  $w$  has at most  $c + 3 - q$  nontrivial clauses.*

*Proof.* If  $q \leq 2$  this follows from the construction, as at most one nontrivial clause is added. Thus we may assume  $q > 2$ . There are  $q$  possible extensions of the computation history at this node. One of them could correspond to the case where no one writes ( $H_t = H_{t-1}$ ), but there are at least  $q - 1$  different values that could be written at the next step.

No processor may write more than one of these values, for otherwise that processor would always write, and  $w$  would have exactly two children. For each value written, we arbitrarily select one processor that writes it; assume without loss of generality that for  $i = 1, 2, \dots, q - 1$ , value  $V_i$  is written by  $P_i$  at this step if literal  $l_i$  is true. (Note that  $l_i$  is either  $x_i$  or  $\bar{x}_i$ .)

The formula  $f_w$  implies that at most one of the literals  $l_1, l_2, \dots, l_{q-1}$  is true. Otherwise, there would exist an input in  $I_w$  for which two different processors would attempt to simultaneously write different values, a violation of the COMMON model.

Now consider the formula  $f_v$  at the child  $v$  of  $w$  that corresponds to  $V_{q-1}$  being written. This is created by first adjoining one nontrivial clause to  $f$ , and also some trivial clauses as a result of the knowledge that  $l_1, l_2, \dots, l_{q-2}$  are all false. This knowledge also results in some substitutions. Let  $\beta = (\beta_1, \beta_2, \dots, \beta_n)$  be an input in  $I_v$  which makes  $l_{q-1}$  true. Since  $I_v$  is a subset of  $I_w$ , the input  $\beta$  satisfies  $f_w$  and makes each of the literals  $l_1, l_2, \dots, l_{q-2}$  false.

For  $j = 1, \dots, q - 2$ , let  $\beta^j$  be the input obtained from  $\beta$  by complementing  $\beta_j$  (i.e.,  $\beta^j$  makes both  $l_j$  and  $l_{q-1}$  true). The input  $\beta^j$  cannot satisfy  $f_w$ , because it makes two literals in  $\{l_1, l_2, \dots, l_{q-1}\}$  true. Let  $C_j$  be some clause in  $f_w$  that  $\beta^j$  does not satisfy. Since there exists an input in  $I_w$  which makes  $l_j$  true, and another that makes  $l_j$  false,  $C_j$  must be nontrivial. The only difference between  $\beta$  and  $\beta^j$  is in the value of the  $j$ th bit. Thus  $C_j$  must contain the literal  $\bar{l}_j$ . Furthermore,  $\bar{l}_j$  is the only literal in  $C_j$  that  $\beta$  makes true.

Note that  $C_j$  contains the literal  $\bar{l}_j$  and  $\beta^i$  makes  $l_j$  false. Thus  $\beta^i$  satisfies  $C_j$ , but not  $C_i$ . Hence, for  $1 \leq i < j \leq q - 2$ , the clauses  $C_i$  and  $C_j$  are distinct.

Consider the creation of  $f_v$ . The substitutions that follow from the knowledge that  $l_1, l_2, \dots, l_{q-2}$  are false will remove the nontrivial clauses  $C_i$ , for  $i = 1, \dots, q - 2$ .

Thus  $f_v$  can have at most  $c - (q - 2) + 1$  nontrivial clauses, as required. A similar argument works for the other children of  $v$ ; in fact, the child that corresponds to the case when no process writes will have at most  $c + 2 - q$  nontrivial clauses.  $\square$

The importance of Lemma 6.4 is that, although we cannot bound the degree of a node in the computation tree, high degree requires accumulating and then destroying nontrivial clauses, and only one nontrivial clause is accumulated per level. We use this idea to prove the following lemma.

LEMMA 6.5. *The maximum number of leaves in a computation tree of height  $h$  is  $3^h$ .*

*Proof.* Let  $L(s, h)$  be the maximum number of leaves in a subtree of height  $h$  whose root formula has  $s$  nontrivial clauses. By Lemma 6.4, we have

$$L(s, 1) \leq s + 3 \text{ and} \\ L(s, h) \leq \max_{2 \leq q \leq s+3} \{q \cdot L(s + 3 - q, h - 1)\}.$$

This can be shown by induction on  $h$  to satisfy the inequality  $L(s, h) \leq (3 + s/h)^h$ . The base case is obvious; suppose the statement is true for  $h < k$ . Then

$$L(s, k) \leq \max_{2 \leq q \leq s+3} \{q \cdot L(s + 3 - q, k - 1)\} \\ \leq \max_{2 \leq q \leq s+3} \left\{ q \left( 3 + \frac{s + 3 - q}{k - 1} \right)^{k-1} \right\}.$$

The quantity inside the curly brackets, considered as a function over real  $q$ , can be shown by elementary calculus to reach its maximum at  $q = 3 + s/k$ . This yields  $L(s, k) \leq (3 + s/k)^k$ , as required.  $\square$

Theorem 6 then follows from the fact that each leaf of the computation tree can be labelled with at most one function value. All function values must appear, so the tree has at least  $|R|$  leaves. By Lemma 6.5, the computation tree must have height at least  $\lceil \log_3 |R| \rceil$ .

We can extend this result and obtain a theorem similar to Theorem 6 for probabilistic algorithms. In the probabilistic COMMON model, each processor is allowed to make random choices to determine its behaviour at each step. We insist that no sequence of choices results in two processors attempting to write different values into the same cell at the same time. Theorem 7 gives a bound on the expected number of steps to compute a function in terms of the size of its range.

THEOREM 7. *In the probabilistic COMMON(1) model, any algorithm that publicly computes a surjective function  $f : \{0, 1\}^n \rightarrow R$  has an expected running time of at least  $\lceil \log_3 |R| \rceil$  steps on some input.*

As in Corollary 6.3, we obtain a logarithmic separation between the probabilistic COMMON( $m$ ) model and the deterministic ARBITRARY( $m$ ) model, for  $m = O(n^{1-\epsilon})$  where  $\epsilon$  is a positive constant. In this case, randomization does not help the COMMON model to simulate the more powerful model.

Theorem 7 is proved using the following two lemmas.

LEMMA 7.1. *The sum of the root-leaf distances to any set  $S$  of leaves in a tree of possible computations is at least  $|S| \cdot \lceil \log_3 |S| \rceil$ .*

*Proof.* Let us define a *tree skeleton* to be a tree whose nodes can be labelled with nonnegative integers, such that the root is labelled with zero, and any node labelled with  $s$  that has  $q$  children has each child labelled no higher than  $s + 3 - q$ . Lemma 6.5 is actually a statement about tree skeletons; any computation tree leads in a natural way to a tree skeleton, where the label of a node is just the number of nontrivial

clauses in its formula. Let  $S$  be our set of chosen leaves and let  $Q$  be the sum of the root-leaf distances. We can prune away everything but the root-leaf paths to leaves in  $S$ . This still leaves a tree skeleton, since deleting a node does not invalidate the labels of its siblings. The pruning also leaves  $Q$  unchanged.

We can then transform the tree skeleton in a way that will never increase the sum of the root-leaf distances to leaves in  $S$ . Suppose we can find two leaves  $v_1$  and  $v_2$ , where  $v_i$  is at depth  $t_i$  and  $t_2 - t_1 \geq 2$ . We add two children  $v'_1, v'_2$  to  $v_1$ , label them with the same number as  $v_1$ , and delete  $v_2$ . We remove  $v_1, v_2$  from  $S$  and add  $v'_1, v'_2$ .

Continuing in this fashion, we can obtain a tree skeleton and a set  $S'$  of leaves, where  $|S| = |S'|$ , and the depths of all leaves in  $S'$  differ by no more than 1. Lemma 6.5 implies that the depth of each leaf is at least  $\lfloor \log_3 |S| \rfloor$ . Since the sum of root-leaf distances to leaves in  $S'$  is less than or equal to  $Q$ , the result follows.  $\square$

LEMMA 7.2. *Let  $T_1$  be the expected running time for a given probabilistic algorithm solving problem  $P$ , maximized over all possible inputs. Let  $T_2$  be the average running time for a given input distribution, minimized over all possible deterministic algorithms to solve  $P$ . Then  $T_1 \geq T_2$ .*

Lemma 7.2 was stated by Yao [Y] in a stronger form; the weak form here can be proved in a few lines. We can consider a probabilistic algorithm as a probabilistic distribution of deterministic algorithms. Let  $A$  be our set of deterministic algorithms, and  $I$  our set of inputs. Let  $r[A_i, I_j]$  be the running time of algorithm  $A_i$  on input  $I_j$ . Suppose our given probabilistic algorithm chooses to run deterministic algorithm  $A_i$  with probability  $p_i$ , and that our given input distribution gives probability  $q_j$  to  $I_j$ . Then

$$\begin{aligned} T_1 &= \max_{I_j \in I} \left\{ \sum_{A_i \in A} p_i r[A_i, I_j] \right\} \\ &\geq \sum_{I_j \in I} q_j \sum_{A_i \in A} p_i r[A_i, I_j] \\ &= \sum_{A_i \in A} p_i \sum_{I_j \in I} q_j r[A_i, I_j] \\ &\geq \min_{A_j \in A} \left\{ \sum_{I_j \in I} q_j r[A_i, I_j] \right\} \\ &= T_2. \end{aligned} \quad \square$$

We wish to bound  $T_1$  from below. By Lemma 7.2, it suffices to bound  $T_2$  from below. To do this, we must specify an input distribution that results in a large average running time for any algorithm to compute  $f$ . This input distribution must depend on  $f$ , but not on a particular program. For each possible value of  $f$ , choose one input that results in that value. This selects a set of  $|R|$  inputs; our chosen distribution will give probability  $1/|R|$  to each of these.

To bound  $T_2$  from below for this distribution, consider the tree of possible computations associated with some deterministic algorithm. Our set of inputs reaches some set of  $|R|$  leaves. Then the expected running time on the given input distribution is the average depth of these leaves which by, Lemma 7.1, is at least  $\lfloor \log_3 |R| \rfloor$ . This proves Theorem 7.

By a more careful analysis, the base of the logarithm in the lower bounds of Theorems 6 and 7 can be reduced to  $1 + \sqrt{2}$ . It is possible to define a somewhat artificial family of functions  $\{f_i\}$  such that  $f_i$  has range  $R_i$  and can be publicly computed in  $\log_\beta |R_i| + O(1)$  steps on COMMON(1), where  $\beta = \frac{1 + \sqrt{13}}{2}$  [Ra].

**5. The relationship between COMMON and COLLISION.** It is not immediately obvious whether COMMON is at least as powerful as COLLISION, whether COLLISION is at least as powerful as COMMON, or whether the power of these two models are incomparable.

To begin with, consider the following problem.

**EXACTLY ONE.**

Before: Each processor  $P_i$ , for  $i = 1, \dots, n$ , has a bit  $x_i$  known only to itself.

After:  $M_1$  contains the value 1 if and only if exactly one bit  $x_i$  is initially one.

If  $M_1$  is initialized to 0, the EXACTLY ONE problem can be solved on COLLISION(1) by having each processor  $P_i$  write the value 1 into  $M_1$  when  $x_i = 1$ . However, in a model without the ability to detect collisions, it can take significantly longer.

**THEOREM 8.** *The EXACTLY ONE problem requires at least  $\frac{\log n}{\log(m+1)}$  steps to solve on COMMON( $m$ ).□*

The proof of this result is essentially identical to the proof of Theorem 4. It then follows that  $\Theta\left(\frac{\log n}{\log(m+1)}\right)$  steps on COMMON( $m$ ) are needed, in the worst case, to simulate one step of COLLISION(1). The lower bound comes from Theorem 8, and the upper bound follows from the simulation of ARBITRARY by COMMON given in Theorem 1 and the fact that ARBITRARY can simulate COLLISION in constant time (as observed in §1).

Conversely, consider the following problem which can be solved in a constant number of steps on COMMON(1).

**k-GROUP IDENTIFICATION.**

Before: The processors are divided into  $k$  groups of size  $s$  or  $s + 1$ , where  $s = \lfloor n/k \rfloor$ .

Each processor knows the indices of all other processors in its group. Each processor  $P_i$ , for  $i = 1, \dots, n$ , has a private bit  $x_i \in \{0, 1\}$  known only to itself. Furthermore, for  $1 \leq i, j \leq n$ , if  $x_i = x_j = 1$ , then  $P_i$  and  $P_j$  are in the same group.

After:  $M_1$  contains the value  $a \neq 0$  if and only if  $x_i = 1$  for some processor  $P_i$  in group  $a$ .  $M_1$  contains the value 0 if and only if all input variables are 0.

**THEOREM 9.** *On COLLISION( $m$ ), the  $\lfloor \sqrt{n} \rfloor$ -GROUP IDENTIFICATION problem requires  $\Omega\left(\frac{\log n}{\log(m+1)}\right)$  steps to solve.*

*Proof.* The proof is similar to that of Theorems 2,4, and 5. In addition to maintaining a set  $S$  of fixed positions, a set  $F$  of free positions, and the history  $(H_0, H_1, \dots, H_t)$  through time  $t$ , we maintain a set  $A \subseteq \{1, \dots, \lfloor \sqrt{n} \rfloor\}$  of groups whose positions have not yet been completely fixed. Positions are fixed only to 0. Allowable inputs are consistent with the fixed positions and also with the restriction mentioned in the statement of the problem.

At each step of the construction, we not only fix individual positions within groups to 0, but fix whole groups to 0 as well. It is possible to do this in such a way that if  $|A| = s$  before step  $t$ , then it has size  $\frac{s}{m+1}$  after step  $t$ . Furthermore, if  $b$  is a lower bound, for each  $a \in A$ , on the number of free positions in group  $a$ , then  $\frac{b-1}{m+1}$  is a lower bound afterwards. This is essentially done by associating with each group the cell into which the most processors in that group write on 1, and then finding the cell that is associated with the most groups. All groups not associated with that cell are fixed to

0 and removed from A; all processors in groups associated with that cell that write on 1 into different cells have their positions fixed to 0. As long as two free positions remain in two different groups, the algorithm cannot answer. Again, the details are omitted.  $\square$

The above result is somewhat unsatisfying. In an essential way, the proof depends on the fact that the  $k$ -GROUP IDENTIFICATION problem has a cleft domain. Recall, this means that the input is a proper subset of  $\{0, 1\}^n$ . Such an unrealistic assumption might never arise in the computation of a function defined on the domain  $\{0, 1\}^n$ . Indeed, the following theorem shows that COLLISION(1) is at least as powerful as COMMON(1) for computing functions on the domain  $\{0, 1\}^n$ . This simulation result uses the same structure that was used in the lower bound result of Theorem 6.

**THEOREM 10.** *The public computation of any function  $f : \{0, 1\}^n \rightarrow R$  requires at most twice as many steps on COLLISION(1) as it does on COMMON(1).*

*Proof.* We show how to convert any algorithm that publicly computes a function  $f : \{0, 1\}^n \rightarrow R$  on COMMON(1) into an algorithm, using at most twice as many steps, that works on COLLISION(1). This new algorithm simulates the original algorithm in a step by step fashion, using two steps to simulate each step of the COMMON(1) algorithm.

For any input, the COLLISION(1) algorithm will produce a history  $(H_0, H_1, \dots, H_{2t})$  through step  $2t$ , with the property that  $(H_0, H_2, \dots, H_{2t})$  is the history through step  $t$  produced by the COMMON(1) algorithm on that input. Thus, the set of inputs  $I_v$  that reach any even depth node  $v$  in the tree of possible computations for the COLLISION(1) algorithm is a subset of  $I_{v'}$  for some node  $v'$  occurring at the half the depth in the tree of possible computations for the COMMON(1) algorithm. The node  $v'$  will be called the COMMON(1) node corresponding to  $v$ .

The COLLISION(1) algorithm is obtained from the COMMON(1) algorithm as follows. At any even depth node in the COLLISION(1) algorithm, each processor  $P_i$  writes its index  $i$ , provided processor  $P_i$  writes on the input  $x_i$  at the corresponding COMMON(1) node. Without loss of generality, we will assume that all the values written in every possible execution of the COMMON(1) algorithm are distinct from the processor indices  $1, \dots, n$ . If no write takes place, then, at the next step, the processors do nothing. If the value  $i$  appears in the shared memory cell, indicating that processor  $P_i$  was the only processor attempting to write, then processor  $P_i$  writes the value it would have written in the COMMON(1) algorithm. Finally, if a collision occurred, then processor  $P_1$  writes the value that would have been written into the shared memory cell in the COMMON(1) algorithm. It remains to show that there is enough information for processor  $P_1$  to determine this value.

As in the proof of Theorem 6, the set of inputs  $I_{v'}$  that reach a node  $v'$  in the COMMON(1) tree can be described by a Boolean formula  $f_{v'}$  in conjunctive normal form. For each even depth node  $v$  in the COLLISION(1) tree, the Boolean formula  $f_{v'}$  associated with the corresponding COMMON(1) node  $v'$ , is satisfied by each input in  $I_v$ . This is because  $I_v \subseteq I_{v'}$ . There is additional information about the input that the COLLISION(1) algorithm also accumulates during the course of the simulation.

**CLAIM.** *For each (nontrivial) clause in  $f_{v'}$ , either every input in  $I_v$  satisfies at least two literals in that clause (although not necessarily the same literals for different inputs) or there is a particular literal in that clause which is true for all inputs in  $I_v$ .*

*Proof.* The proof of this claim proceeds by induction on the depth of the node  $v$ . If  $v$  is the root of the COLLISION(1) tree, then the root of the COMMON(1) tree is its corresponding node. Its associated formula, the empty formula, has no clauses. In this case, the claim is satisfied.

Now suppose  $v$  has depth  $2t$ , where  $t \geq 1$ , and assume that the claim is true for

the grandparent  $w$  of  $v$ . Let  $w'$  and  $v'$  be the COMMON(1) nodes corresponding to  $w$  and  $v$ , respectively.

Consider the history  $(H_0, H_1, H_2, \dots, H_{2t-1}, H_{2t})$  through step  $2t$  produced by the COLLISION(1) algorithm on inputs in  $I_v$ . By construction, no write occurs at step  $2t - 1$  in the COLLISION(1) algorithm (i.e.,  $H_{2t-1} = H_{2t-2}$ ) if and only if no write would have occurred at step  $t$  in the COMMON(1) algorithm. In this case, each nontrivial clause in  $f_{v'}$  is also a nontrivial clause in  $f_{w'}$ . Since  $I_v \subseteq I_w$ , there is nothing to prove.

Otherwise, node  $v'$  is the child of  $w'$  arising when the value  $H_{2t}$  is written at the  $t$ th step in the COMMON(1) algorithm. Compared to  $f_{w'}$ , the formula  $f_{v'}$  contains at most one additional nontrivial clause, consisting of the literals corresponding to those private bit values that cause processors to write the value  $H_{2t}$ .

If  $H_{2t-1}$  is the index of processor  $P_i$ , then, for every input in  $I_v$ ,  $P_i$  is the only processor that writes at step  $2t - 1$  in the COLLISION(1) algorithm. Thus, the literal (either  $x_i$  or  $\bar{x}_i$ ) causing  $P_i$  to write the value  $H_{2t}$  at step  $t$  in the COMMON(1) algorithm is true for all inputs in  $I_v$ . Notice that the additional nontrivial clause in  $f_{v'}$ , if there is one, contains this literal, thereby satisfying the conditions of the claim.

Finally, if  $H_{2t-1}$  is the collision symbol, then, for every input in  $I_v$ , at least two processors write at step  $2t - 1$  in the COLLISION(1) algorithm and, therefore, would have written at step  $t$  in the COMMON(1) algorithm. Hence at least two literals in the additional clause are true. This concludes the proof of the claim.  $\square$

We are now ready to complete the proof of Theorem 10. Let  $v$  be a node of depth  $2t$  in the COLLISION(1) tree and let  $u$  be the child corresponding to a collision occurring at step  $2t + 1$ . We will show that the values written by any processor at the  $(t + 1)$ st step of the COMMON(1) algorithm, for any input in  $I_v$ , are all the same. Hence,  $P_1$  can determine this value from its knowledge of  $I_v$  and the programs of the other processors.

Let  $a$  be an input in  $I_u$  and assume that there is another input in  $I_v$  for which, at the  $(t + 1)$ st step in the COMMON(1) algorithm, a different value is written. Suppose that  $P_j$  is a processor writing this other value and that it does so because literal  $l_j = 1$ .

Consider the input  $b$  obtained from  $a$  by making  $l_j = 1$ . Then  $b \notin I_{v'}$ ; otherwise the COMMON model would be violated. Since a collision occurs, two or more true literals occurring in  $a$  cause a particular value to be written. Thus at least one processor would write that value at step  $t + 1$  on input  $b$ . Since  $l_j = 1$  in  $b$ ,  $P_j$  would simultaneously write another value.

Because  $a \in I_{v'}$  and  $b \notin I_{v'}$ ,  $f_{v'}(a) = 1$  and  $f_{v'}(b) = 0$ . Now  $f_{v'}$  is a formula in conjunctive normal form. Therefore  $f_{v'}$  contains a clause  $g$  such that  $g(a) = 1$  and  $g(b) = 0$ . Since  $b$  is obtained from  $a$  by changing  $l_j$  from 0 to 1,  $\bar{l}_j$  is the only literal in  $g$  satisfied by  $a$ . By the claim,  $\bar{l}_j = 1$  is true for all inputs in  $I_v$ . This is a contradiction.  $\square$

**6. Simulating PRIORITY( $km$ ) by ARBITRARY( $m$ ).** Section 2 considered the simulation of PRIORITY machines by ARBITRARY machines with more memory. Here we study the ‘‘complementary’’ problem of simulating PRIORITY machines by ARBITRARY machines with less memory. As a corollary, we obtain a separation between PRIORITY and ARBITRARY machines with the same amount of memory.

Our goal is to solve the  $km$ -colour MINIMIZATION problem in the ARBITRARY( $m$ ) model. This can clearly be done in time  $O(k \log n)$ , by dividing the colours into  $k$  groups of  $m$  colours and solving one group at a time by the algorithm of Theorem 1. A proof similar to that of Corollary 6.3 shows that the  $km$ -colour MIN-

MINIMIZATION problem requires  $\Omega(km \log(n/km))$  steps on COMMON(1), and thus  $\Omega(k \log(n/km))$  steps on COMMON( $m$ ). In fact, it is possible to do considerably better on ARBITRARY( $m$ ), as the following theorem and corollary demonstrate. Hence ARBITRARY is another example of a computational model in which “mixing” the computation of several functions on disjoint sets of inputs enhances efficiency. Boolean and arithmetic circuits also exhibit this property ([P], [U], [AHU]).

**THEOREM 11.** *On ARBITRARY(1), the  $m$ -colour MINIMIZATION problem can be solved in  $O\left(\frac{m \log n}{\log m}\right)$  steps.*

When  $m = O(n^\epsilon)$  for some constant  $\epsilon > 0$ , this upper bound  $O(m)$  matches the trivial lower bound. In comparison with algorithms that solve the problem one colour at a time, this solution uses an average of  $O(1)$  steps per colour. This disproves a conjecture of Vishkin [V].

The idea is to try to solve the  $m$  different problems concurrently, although we have only one common memory cell. We say that a processor  $P_i$  has colour  $c$  if  $x_i = c$ . For each colour  $c$ , processors maintain an ordered set  $S_c \subset \{1, \dots, n\}$  and a “current winner”  $w_c \in \{1, \dots, n, \infty\} - S_c$ . If  $w_c < \infty$ , then  $w_c$  is the smallest index of any processor globally known to have colour  $c$ . When there is no processor that is globally known to have colour  $c$ , as is the case initially,  $w_c = \infty$ . The set  $S_c$  consists of the indices of those processors that may replace the current winner. In particular,  $i \in S_c$  implies that  $i < w_c$ . Initially,  $S_c = \{1, 2, \dots, n\}$ .

The algorithm proceeds in phases. In a single phase, each set  $S_c$  is shrunk by approximately a factor of  $m$ . When  $S_c = \emptyset$  for all  $c$ , the algorithm can halt.

At the beginning of a phase, each set  $S_c$  is divided into  $m$  pieces  $S_c^1, S_c^2, \dots, S_c^m$  of size at most  $\left\lceil \frac{|S_c|}{m} \right\rceil$ , where the processors in  $S_c^a$  have lower indices than those in  $S_c^b$  for  $a < b$ . The goal in a phase is to publicly determine, for each colour  $c$ , the first group among  $S_c^1, S_c^2, \dots, S_c^m$  containing the index of some processor having colour  $c$ . Then  $S_c$  is updated appropriately.

Conceptually, these sets are arranged in an  $m \times m$  array; the entry in row  $c$  and column  $i$  is  $S_c^i$ . At each step of the phase, we either eliminate a row or the leftmost column of the array. The set  $C$  will consist of those colours whose rows have not yet been eliminated in this phase.

If processor  $P_j$  has colour  $c$  and  $j$  belongs to the group in the leftmost column of the row corresponding to colour  $c$ , then it attempts to write its index and colour into memory cell  $M_1$ . Throughout the phase, the invariant is maintained that for any colour  $c \in C$ , no processor with that colour lies in  $S_c^k$  for any eliminated column  $k$ . Hence, when  $(j, c)$  appears in  $M_1$ , any processor having colour  $c$  and with index lower than  $j$  must be in the group currently in the leftmost column of row  $c$ . In this case, row  $c$  is eliminated from the array. If no write occurs at a given step, then none of the groups in the leftmost column contain the winner for their row and the column can be eliminated. More formally, the phase proceeds as follows.

$C \leftarrow \{1, 2 \dots m\}$

$i \leftarrow 1$

While  $C \neq \emptyset$  and  $i \leq m$  do

    If  $j \in S_{x_j}^i$  and  $x_j \in C$ , processor  $P_j$  will attempt to write  $(j, x_j)$  into  $M_1$ .

    If  $(j, c)$  appears in  $M_1$

        Remove  $c$  from  $C$ , set  $w_c \leftarrow P_j$ , and shrink  $S_c$  to  $\{k \in S_c^i : k < j\}$

    Otherwise set  $i \leftarrow i + 1$ .

At each step, either  $|C|$  is decreased by one or  $i$  is increased by one. A phase thus takes at most  $2m - 1$  steps, and any set  $S_c$  which was of size  $s$  before the phase is of

size at most  $\lceil \frac{s}{m} \rceil - 1 < \frac{s}{m}$  at the end of the phase. Thus  $O\left(\frac{\log n}{\log m}\right)$  phases suffice.  $\square$

**COROLLARY 11.1.** *One step of PRIORITY( $km$ ) can be simulated by  $O\left(\frac{k \log n}{\log k}\right)$  steps of ARBITRARY( $m$ ), for  $k > 1$ .*

*Proof.* Simulating one step of PRIORITY( $km$ ) is equivalent to solving the  $km$ -colour MINIMIZATION problem; divide the colours into  $m$  groups of  $k$  colours each, and use the algorithm above to solve each group in parallel.  $\square$

The following lower bound proves this procedure optimal for  $km = O(n^{1-\epsilon})$ , and proves a separation between PRIORITY( $m$ ) and ARBITRARY( $m$ ).

**THEOREM 12.** *The  $km$ -colour MINIMIZATION requires  $\Omega\left(\frac{k \log(n/km)}{\log(k+1)}\right)$  steps to solve on ARBITRARY( $m$ ).*

**COROLLARY 12.1.** *ARBITRARY( $m$ ) requires at least  $\Omega(\log(n/m))$  steps to simulate one step of PRIORITY( $m$ ).*

To simplify the proof of Theorem 12, we divide the processors into  $km$  groups of size at least  $\lfloor n/km \rfloor$ , and declare that the processors in group  $i$  will have colour either  $i$  or 0. Note that we can define this restricted problem over domain  $\{0, 1\}^n$ .

We maintain a history  $H_0, H_1 \dots$ , a set  $S$  of fixed positions, and a set  $F$  of free positions. Initially, the processor of highest index in each group has its colour fixed to 1, and all other positions are free. We maintain the invariant that for any free position, there are no positions of lower index that are within the group and fixed to 1.

Our measure of the algorithm's progress against the adversary strategy will be by means of a potential function. If there are  $s_i$  free positions in group  $i$ , then this function has value  $\sum_{i=1}^{km} \log_{k+1}(s_i + 1)$ . Initially, then, the function has value at least  $km \log_{k+1}(n/km)$ . We shall show that the adversary can fix positions in such a fashion so that the history is determined through step  $t$  and the value of this function decreases by at most  $ctm$ , for some absolute constant  $c$ .

As long as there is at least one free position (that is, the value of the potential function is nonzero), the algorithm has not solved all colours, thus establishing the lower bound.

Given history  $H_0, H_1 \dots H_t$ , and the fact that group  $i$  contains  $s_i$  free positions, we show how to fix  $H_{t+1}$  and cause a drop in the potential function of at most  $cm$ . Initially, the contents of each cell in  $H_{t+1}$  are unfixed. Suppose the free positions in group  $i$  at any point are  $j_1, j_2, \dots, j_s$ . We define  $lower_i$  to be the lowest  $\frac{1}{k+1}$ st of the free positions in group  $i$ , that is, positions  $j_1$  through  $j_{\lceil s/(k+1) \rceil}$ .  $upper_i$  is defined to be all free positions in group  $i$  not in  $lower_i$ .

- 1) If a processor in any fixed position writes at step  $t+1$  into an unfixed cell, declare one such processor to win the competition to write into that cell for all allowable inputs. The value of the potential function does not change. Repeat this step until all cells are fixed or no such processor exists.
- 2) If any processor in any free position writes on 0 into an unfixed cell, choose one such processor, fix its colour to 0, and declare it to win the competition to write at time  $t+1$ . If it is in group  $i$ , then the potential function drops by

$$\log_{k+1}(s_i + 1) - \log_{k+1} s_i = \log_{k+1} \left(1 + \frac{1}{s_i}\right) \leq \log_{k+1}(2) \leq 1.$$

Repeat this step until all cells are fixed or no such processor exists.

- 3) Once the first two cases are taken care of, then processors write into unfixed cells only if they receive their colour. If there is a processor  $P_j$  in a free position in group  $i$  such that  $P_j$  writes into an unfixed cell on colour  $i$ , and  $j \in upper_i$ , then

fix  $upper_i$  to colour  $i$  and declare  $P_j$  to win the competition to write into that cell for all consistent inputs. The potential function drops by at most

$$\log_{k+1}(s_j + 1) - \log_{k+1}\left(\frac{s_j + 1}{k + 1}\right) = 1.$$

Repeat this step until all cells are fixed or no such processor exists.

- 4) Fix  $lower_i$  to 0 for all groups. This ensures that no processor writes into any unfixed cells at this step, for any consistent input. The drop in the potential function is at most

$$\begin{aligned} \sum_{j=1}^{km} \log_{k+1}(s_j + 1) - \sum_{j=1}^{km} \log_{k+1}\left(s_j - \frac{(s_j + 1)}{k + 1} + 1\right) &= m \log_{k+1}\left(\frac{k + 1}{k}\right) \\ &\leq c' m \text{ for some constant } c'. \end{aligned}$$

Steps 2 and 3 of the adversary argument can be repeated at most  $m$  times, since each step fixes one cell. Hence these steps cause a potential drop of at most  $m$ . The total potential drop is thus at most  $(c' + 1)m$ .  $\square$

The proof of Theorem 12 is a generalization of the argument used for the case  $m = 1$  in [Ra], and of the similar argument used in [LY2] to prove a weaker lower bound for the case  $k = 1$ , when inputs are stored in read-only memory.

**7. Conclusions.** In this paper, we have thoroughly investigated the problem of simulating one step of a machine with one shared memory cell by another with  $m$  shared memory cells. If the domains of the functions being computed can be arbitrary, then either the programs for the first machine can be run directly on the second or  $\Theta\left(\frac{\log n}{\log(m+1)}\right)$  steps are required. When the domain of the function is  $\{0, 1\}^n$ , the results are, for the most part, the same. The only exception is that, in this case, COMMON(1) can be simulated by COLLISION(1), and hence by COLLISION( $m$ ), in constant time.

The converse problem of simulating one step of a machine with  $m$  shared memory cells by another with one shared memory cell is not as well understood. The complexity of simulating PRIORITY( $m$ ) by ARBITRARY(1) is  $\Theta\left(\frac{m \log n}{\log m}\right)$ . For COMMON(1) simulating PRIORITY( $m$ ), ARBITRARY( $m$ ), or COLLISION( $m$ ) the lower bound can be improved to  $\Omega(m \log(n/m))$ . However, our upper bound is  $O(m \log n)$ .

The upper bound for COLLISION(1) simulating PRIORITY( $m$ ), ARBITRARY( $m$ ), or COMMON( $m$ ) is the same, except when COMMON( $m$ ) is computing a function with domain  $\{0, 1\}^n$ . In this case, an  $O(m)$  upper bound follows from Lemma 6.1 and Theorem 10. This is clearly optimal. The  $\Omega\left(\frac{m \log n}{\log m}\right)$  lower bound for simulating PRIORITY( $m$ ) on COLLISION(1) is a direct consequence of the lower bound on ARBITRARY(1).

The case of simulating a model with  $m$  cells by another with  $m$  cells is also not as well understood. We have shown that the complexity of simulating COLLISION( $m$ ) by COMMON( $m$ ) or simulating PRIORITY( $m$ ) by ARBITRARY( $m$ ) is  $\Omega(\log n - \log m)$ . For small values of  $m$ , i.e.  $m = O(n^{1-\epsilon})$  for some constant  $\epsilon > 0$ , these results are tight to within a constant factor. Nothing is known about the complexity of simulating COMMON( $m$ ) by COLLISION( $m$ ) (for  $m > 1$ ) except the upper bounds of  $O(\log n)$  (implied by Corollary 1.1) and  $O(m)$  (implied by Theorem 10). Is it possible to do this simulation in  $O(1)$  time?

No other separation between models with the same (finite) amount of shared memory is known for higher values of  $m$ . More work and probably other techniques are needed to extend these results for all ranges of  $m$ . To improve these results, we must understand in a more fundamental way how processors can use larger amounts of memory to communicate. Li and Yesha [LY1],[LY2] have made a first step in this direction by considering concurrent-read concurrent-write PRAM's with a small shared memory plus  $n$  cells of read-only memory containing the input.

Another relevant result concerns the problem of element distinctness on machines with an infinite amount of shared memory. In this problem,  $n$  integers are stored in the first  $n$  cells of shared memory, and the machine must decide whether or not there exist two which are equal. In [FMW] it is shown that element distinctness requires  $\Omega(\log \log \log n)$  steps on COMMON( $\infty$ ) but  $O(1)$  steps on COLLISION( $\infty$ ). The lower bound has been improved to  $\Omega(\sqrt{\log n})$  steps [RSSW]. Both these results imply the existence of a function  $f(n)$  such that the corresponding separation holds between COMMON( $f(n)$ ) and COLLISION( $f(n)$ ). For the  $\Omega(\log \log \log n)$  result,  $f(n) = 2^{n^{O(1)}}$ , but for the  $\Omega(\sqrt{\log n})$  result,  $f(n)$  grows much more rapidly with  $n$ .

We conclude by mentioning a surprising recent result [FRW2], which shows that one step of PRIORITY( $m$ ) can be simulated by  $O\left(\frac{\log n}{\log \log n}\right)$  steps of COMMON( $nm$ ). This shows that allowing more memory can lead to improved simulations even if the number of processors is held fixed, and also that the separation between PRIORITY( $\infty$ ) and COMMON( $\infty$ ) is **not**  $\Theta(\log n)$ .

## EXISTENCE, UNIQUENESS, AND CONSTRUCTION OF REWRITE SYSTEMS\*

NACHUM DERSHOWITZ†, LEO MARCUS‡, AND ANDRZEJ TARLECKI§

**Abstract.** The construction of term-rewriting systems, specifically by the Knuth–Bendix completion procedure, is considered. We look for conditions that might ensure the existence of a finite canonical rewriting system for a given equational theory and that might guarantee that the completion procedure will find it. We define several notions of equivalence between rewriting systems in the ordinary and modulo case, and examine uniqueness of systems and the need for backtracking in implementing completion.

**Key words.** term-rewriting systems, termination, Knuth–Bendix completion procedure, equational theories, rewriting modulo a congruence

**AMS(MOS) subject classifications.** 68Q50, 68T15, 08B05, 03C05, 03B35

**1. Introduction.** Much is known about the theory of term-rewriting systems (see [15] and [10] for surveys). However, there have been many unanswered questions about the existence of rewrite systems and the applicability of the Knuth–Bendix completion procedure (KB) [14], [19] and its extensions [16], [21], [26], [3] for finding them. In certain cases KB generates a “canonical” term-rewriting system that decides validity in a given equational theory. In general, the procedure takes a finite set of equations and an ordering on terms, and either halts with success, aborts (fails), or loops infinitely. KB completion is being used in many program-specification and theorem-proving applications (see, for example, [8], [9], [12], [13], [15], [23], [18], and [6]).

Two basic questions arise: when does a given decidable equational theory have a decision procedure in the form of a canonical rewrite system, and when does the Knuth–Bendix procedure generate such a rewrite system for a given equational theory? As a partial answer, the following facts are discussed in this paper:<sup>1</sup>

1. There are decidable equational theories which require an expanded language in order to obtain a canonical rewrite system to decide them, and others which do not have canonical rewrite systems in any language (Examples 1 and 2).
2. For a given reduction ordering KB cannot terminate successfully with two different systems ([6], [24], Theorem 5).
3. Conditions are given which imply the uniqueness of a term-rewriting system modulo a congruence (§ 4). If any one of these conditions is relaxed, uniqueness is lost (Corollary 12, Examples 6–11).
4. For a given theory and ordering on terms, KB cannot both succeed and loop, depending on the choice of equation to orient into a rule ([8], Theorem 17).
5. Given a theory with an equivalent rewrite system,  $R$ , and the ordering induced by  $R$ , KB will not abort on the first step, but can abort on a later step (Theorem 2, Example 3).
6. KB can abort with different results (Example 12).

<sup>1</sup> The numbers refer to theorems and examples in the sections that follow.

7. KB can succeed or abort, depending on choice of representation for the theory (Example 4).
8. KB can succeed or abort, depending on the choice of equation to orient, thus backtracking is necessary (Example 14).
9. Any total monotonic well-ordering on terms allows KB to succeed (without backtracking) on a ground (variable-free) theory ([20], Theorem 18).
10. Success of KB cannot be guaranteed by adding function symbols to the language (Example 13).

These results have important implications for the implementation of the Knuth-Bendix procedure in general, and in the modulo case, for associative commutative theories.

This paper expands on [11], which was originally motivated by a seminar on term-rewriting systems given by the first author at The Aerospace Corporation in the summer of 1981.

**2. Definitions and notation.** If  $L$  is an alphabet (denumerable set of function symbols and constants, signature),  $T(L, X)$  denotes the (countably infinite) set of (first-order) terms constructed from symbols in  $L$  and variables from a (fixed denumerable) set  $X$ . It is well known that  $T(L, X)$  with the operations defined in the natural way constitutes a free  $L$ -algebra over  $X$ , which we denote by  $T(L, X)$  as well. Terms are usually denoted by small letters of the English alphabet:  $l, r, s, t$ , etc. A *term-rewriting system* (or simply *rewrite system*)  $R$  is a set of ordered pairs of terms called *rules*, and is written  $l \rightarrow r$ . (We do not insist a priori that all variables in  $r$  are also in  $l$ .)

If  $\sigma: X \rightarrow T(L, X)$  is a substitution of terms for variables, then  $l\sigma$  denotes the term  $l$  with each occurrence of a variable  $x$  that appears in  $l$  replaced by the term  $x\sigma$  to which  $x$  is mapped under  $\sigma$ . We use the notation  $s = c[u]$  to indicate that a term  $s$  contains a subterm  $u$  within context  $c$ ; then we refer to the term  $s$  with that occurrence of  $u$  replaced by  $v$  as  $c[v]$ . If a term  $s$  contains an instance  $l\sigma$  of the left-hand side of a rule  $l \rightarrow r \in R$ , then  $s = c[l\sigma]$  rewrites to  $t = c[r\sigma]$  and we write  $s \xrightarrow{1}{R} t$ . Clearly,  $\xrightarrow{1}{R}$  is closed with respect to substitution and subterm replacement, i.e.,  $s \xrightarrow{1}{R} t$  implies  $c[s\sigma] \xrightarrow{1}{R} c[t\sigma]$ , for any context  $c$  and substitution  $\sigma$ . A *derivation* in  $R$  is a sequence  $t_0 \xrightarrow{1}{R} t_1 \xrightarrow{1}{R} t_2 \xrightarrow{1}{R} \dots$ . The notation  $s \xrightarrow{*}{R} t$  indicates that there is a (perhaps empty) derivation in  $R$  from  $s$  to  $t$ , and  $s \xrightarrow{+}{R} t$  indicates that there is a nonempty derivation in  $R$  from  $s$  to  $t$ . The notation  $s \xleftrightarrow{*}{R} t$  indicates that there is a sequence of applications of  $\xrightarrow{1}{R}$  and  $\xleftarrow{1}{R}$  between  $s$  and  $t$ . (In other words,  $\xrightarrow{*}{R}$ ,  $\xleftarrow{*}{R}$  and  $\xleftrightarrow{*}{R}$  are the reflexive-transitive, transitive, and symmetric-reflexive-transitive closures, respectively, of  $\xrightarrow{1}{R}$ .)

A rewrite system  $R$  is (*finitely*) *terminating* if there is no infinite  $R$ -derivation. Note that a system containing a rule  $l \rightarrow r$  with a variable in  $r$  but not in  $l$  is nonterminating. A term  $s$  is in ( $R$ -) *normal form* if there is no  $t$  (other than perhaps  $s$ ) such that  $s \xrightarrow{1}{R} t$ . (The standard definition of normal form is slightly stronger in that it does not allow a normal form to reduce to itself.) We write  $s \xrightarrow{1}{R} t$  if  $s \xrightarrow{*}{R} t$  and  $t$  is in normal form;  $R(s)$  denotes the set of normal forms of  $s$ . Two terms  $r$  and  $s$  are *confluent* in  $R$  if there is a  $t$  such that  $r \xrightarrow{*}{R} t$  and  $s \xrightarrow{*}{R} t$ , written  $r \downarrow_R s$ . If  $R$  is finite and terminating, then the relation  $\downarrow_R$  is recursive. A rewrite system  $R$  is *confluent* if for every  $r$  and  $s$ ,  $r \xleftrightarrow{*}{R} s$  implies that  $r$  and  $s$  are confluent in  $R$ .

Let  $E$  be an equational theory, presented as a set of equations between terms in  $T(L, X)$  of the form  $s \equiv t$ . Thus,  $s \equiv t \in E$  means that the given equation actually appears in the set  $E$ , while  $E \vdash s \equiv t$  means that  $s \equiv t$  is valid in  $E$ , i.e., it follows from  $E$  by equational logic (substitution of equals for equals). Two theories are *equivalent*

if they give the same set of valid equations. A theory is *finitely based* if it is presentable as a finite set of equations. The alphabet  $L(E)$  (or  $L(R)$ ) is the set of function symbols actually appearing in  $E$  (or  $R$ ). A system  $R$  *recognizes* the equational theory  $E$  if  $E \vdash s \equiv t$  if and only if  $s \downarrow_R t$ ;  $R$  *recognizes  $E$  in an expanded language*  $L(R) \supseteq L(E)$  if for all  $s, t \in T(L(E), X)$ ,  $E \vdash s \equiv t$  if and only if  $s \downarrow_R t$ .

A system  $R$  is *canonical* if it is terminating and confluent. It is *canonical for a theory  $E$*  if it is terminating and recognizes  $E$ . Note that if  $R$  recognizes  $E$ , then it must be confluent. If  $R$  recognizes  $E$  and is finite and terminating, then  $R$  decides  $E$ .

Let  $\sim$  be an arbitrary congruence on  $T(L, X)$ , closed with respect to substitution. A set of rules  $R$  is a rewrite system *modulo* a congruence relation  $\sim$  if the left and right sides of the rules in  $R$  are  $\sim$ -congruence classes. Operationally, we let the left and right sides be terms, but allow a term  $u$  to reduce to  $v$  (mod  $\sim$ ) if  $u \sim u'[l\sigma]$  and  $u'[r\sigma] \sim v$  for some  $l \rightarrow r \in R$ .<sup>2</sup> (If  $l \sim l', r \sim r'$ , then  $l \rightarrow r$  and  $l' \rightarrow r'$  are considered to be the same rule.) Thus, for the modulo case,  $\frac{1}{R}$  is a binary relation on the quotient algebra  $T(L, X)/\sim$ , closed with respect to substitution and subterm replacement. If  $\sim$  is the identity relation, then  $R$  modulo  $\sim$  reduces to the case of an ordinary rewrite system. All the previous definitions, viz. termination, normal form, and confluence, generalize to modulo systems  $R$ .

A prime use for rewrite systems modulo a congruence is in rewrite systems for associative-commutative theories (see [26]). Notice that in the modulo case, if  $s \sim t$  and  $t \xrightarrow{*}_R u$ , then  $s \xrightarrow{*}_R u$ ; in particular, if  $s \sim t$  then  $s \xrightarrow{*}_R t$ .

**3. Equational theories and rewrite systems.** There are inherent limitations to rewriting. Not all classes of algebras can be described equationally (e.g., fields). Not all equational theories are finitely based (e.g., the equational theory of the algebra over  $T(\{\cdot, 0, 1, 2\}, X)$  with binary function  $\cdot$  satisfying  $0 \cdot x \equiv x \cdot 0 \equiv 0$ ,  $1 \cdot 1 \equiv 0$ ,  $1 \cdot 2 \equiv 1$ ,  $2 \cdot 1 \equiv 2 \equiv 2 \cdot 2$ : see [28]). Not all finitely based equational theories are decidable (e.g., some Thue systems; see [7]). Not every decidable equational theory is amenable to canonical (modulo identity) rewriting (e.g., the commutativity axiom). See [5], [17] and [25] for related theorems and examples pertaining to string rewriting. Work on related questions appears in [2].

*Example 1.* Let  $E = \{fg^i hx \equiv fg^j hx: 0 \leq i, j < \omega\}$  be a theory over  $T(\{f, g, h, a\}, \{x\})$ . Then there is no finite rewrite system recognizing  $E$  (since all rules must be of the form  $fg^m hx \rightarrow fg^n hx$ , all but finitely many  $fg^k hx$  would be irreducible), but there is a finite rewrite system that recognizes  $E$  in an expanded language:  $R = \{fgx \rightarrow fg'x, g'gx \rightarrow gg'x, g'hx \rightarrow hx\}$  in the language  $\{f, g, h, g', a\}$  ( $fg^i hx \xrightarrow{*}_R fhx$ ).

*Example 2.* Not all decidable equational theories have finite recognizing rewrite systems in extended languages. For example, let  $E$  be the theory of one commutative binary function symbol  $f$ . Assume  $R$  is system in an extended language that recognizes  $E$ . Let  $fx y$  and  $fy x$  reduce to some normal form  $N$ . Then a derivation of  $N$  from  $fy x$  can be obtained from the derivation of  $N$  from  $fx y$  by reversing the roles of  $x$  and  $y$ . Thus,  $N$  cannot contain the variables  $x$  or  $y$ . (Either  $x$  appears “before”  $y$  in  $N$  or it does not.) Therefore  $N$  is also derivable from  $fuv$ , for any variables (or terms)  $u, v$ . But this represents a new equality not valid in  $E$ , namely  $fx y = fuv$ , a contradiction.

This raises the open question: For which decidable equational theories are there extended canonical rewrite systems?

Of course, by encoding or ordering variables we may transform a decidable equational theory to a Turing machine, and that Turing machine to a rewrite system.

<sup>2</sup> A weaker system is obtained by just allowing a rule  $l \rightarrow r$  to be applicable to any term  $l' \sim l\sigma$ , yielding a term  $r' \sim r\sigma$ ; the congruence cannot be applied in the rest of  $u$ . See [26] and [16].

But that rewrite system does not serve as a canonical system for the original theory. Next we give some examples of the relation between an equational theory and a finite canonical rewrite system that recognizes it. First, a lemma in which  $E$  and  $R$  need not be related.

**LEMMA 1.** *Let  $R$  be any rewrite system and  $E$  any equational theory. If  $E \vdash u \equiv v$  for some term  $v$  in  $R$ -normal form and any other term  $u$ ,  $u \neq v$ , then there is an axiom  $s \equiv t \in E$  such that  $s$  or  $t$  is in  $R$ -normal form.*

*Proof.* Let  $u = w_0 \equiv w_1 \equiv \dots \equiv w_n = v$  ( $n \geq 1$ ) be an equational proof of  $u \equiv v$  in  $E$ . That is, for each  $i$  ( $1 \leq i \leq n$ ),  $w_{i-1} = c[s_i\sigma]$  and  $w_i = c[t_i\sigma]$ , for some context  $c$ , substitution  $\sigma$ , and axiom  $s_i \equiv t_i$  (or  $t_i \equiv s_i$ ) in  $E$ . Since  $v = w_n$  is in  $R$ -normal form,  $t_n$  must also be. Hence  $s_n \equiv t_n$  (or  $t_n \equiv s_n$ ) is an axiom of  $E$ , one side of which ( $t_n$ ) is in  $R$ -normal form.  $\square$

**THEOREM 2.** *If  $R$  is a canonical rewrite system for an equational theory  $E$ , and  $E$  is nontrivial, then there is  $s \equiv t \in E$  such that  $s \xrightarrow{+}_R t$  (or  $t \xrightarrow{+}_R s$ ).*

*Proof.*  $R \neq \emptyset$  since  $E$  is not trivial. Therefore, there is  $s' \rightarrow t' \in R$  such that  $t'$  is in  $R$ -normal form; otherwise  $R$  would not be terminating. Now,  $E \Vdash s' \equiv t'$ , and so by Lemma 1, there is  $t$  in  $R$ -normal form and  $s$  such that  $s \equiv t \in E$ . But then it follows that  $s \xrightarrow{+}_R t$ .  $\square$

The above theorem however does not generalize to more than one equation. Instead, we have that even if  $R$  is a finite canonical rewrite system for  $E' \cup R'$  (interpreting the rules in  $R'$  as equations), every term appearing in  $E'$  is in  $R'$ -normal form,  $E'$  is nontrivial, and  $R' \subseteq R$ , there still may be no  $s \equiv t \in E'$  such that  $s \xrightarrow{+}_R t$  or  $t \xrightarrow{+}_R s$ .

*Example 3.* Let  $R' = \{1x \rightarrow x, x1 \rightarrow x, xx^{-1} \rightarrow 1, x^{-1}x \rightarrow 1, x^{-1-1} \rightarrow x, x(x^{-1}y) \rightarrow y, x^{-1}(xy) \rightarrow y, (xy)^{-1} \rightarrow y^{-1}x^{-1}, (xy)z \rightarrow x(yz)\}$ , and  $R = R' \cup \{1^{-1} \rightarrow 1\}$ . Then  $R$  is a finite canonical rewrite system for groups (see [15]) and is equivalent to  $R' \cup \{1^{-1}x \equiv x1^{-1}\}$ . (It is sufficient to show that  $R' \cup \{1^{-1}x \equiv x1^{-1}\} \vdash 1^{-1} = 1$ .) The terms  $1^{-1}x$  and  $x1^{-1}$  are in  $R'$ -normal form, but  $1^{-1}x \not\xrightarrow{+}_R x1^{-1}$  and  $x1^{-1} \not\xrightarrow{+}_R 1^{-1}x$ . (Of course, both terms rewrite in  $R$  to  $x$ .)

Even if  $E = \{s_1 \equiv t_1, \dots, s_n \equiv t_n\}$  has a finite canonical rewrite system, and the equations in  $E$  are independent, there need not be a finite canonical  $S$  for  $E$  such that for every  $i$ ,  $s_i \rightarrow t_i \in S$  or  $t_i \rightarrow s_i \in S$ .

*Example 4.* Let  $E$  be the axiomatization  $\{x(yz) \equiv (xy)z, xx^{-1} \equiv 1, 1x \equiv x, x1 \equiv 1x\}$  of group theory. It can be shown that  $E$  is independent, but there can be no finite canonical rewrite system in which  $x1 \rightarrow 1x$  or vice versa.

Even if  $E$  has a finite canonical rewrite system,  $E \vdash s_i \equiv t_i$  for  $i = 1, \dots, n$ , and  $\{s_1 \rightarrow t_1, \dots, s_n \rightarrow t_n\}$  is terminating, there need not be a canonical  $R$  for  $E$  with  $s_i \rightarrow t_i \in R$  for all  $i$ .

*Example 5.* Let  $E = \{a \equiv b\}$ , in which case  $E \vdash fa \equiv fb, gb \equiv ga$ . The system  $R = \{fa \rightarrow fb, gb \rightarrow ga\}$  is terminating, but cannot be extended to include either  $a \rightarrow b$  or  $b \rightarrow a$  without engendering nontermination.

**LEMMA 3.** *Let  $S$  be a finite canonical rewrite system which recognizes an equational theory  $E$  and let  $R$  be any system with  $\xrightarrow{+}_R \subseteq \xrightarrow{+}_S$  that does not recognize  $E$ . Then there are terms  $s$  and  $t$  in  $R$ -normal form such that  $E \vdash s \equiv t$  and  $s \not\xrightarrow{+}_S t$ .*

*Proof.* If  $R$  is terminating (since  $S$  is) and does not recognize  $E$ , then there must exist two distinct  $R$ -normal forms,  $u$  and  $v$ , such that  $E \vdash u \equiv v$ . Let  $t$  be the common  $S$ -normal form of  $u$  and  $v$ . Then  $t$  is also in  $R$ -normal form. Since  $u \neq v$ , we have  $u \not\xrightarrow{+}_S t$  or  $v \not\xrightarrow{+}_S t$  (or both).  $\square$

**4. Uniqueness.** In this section we examine various criteria for similarity of rewrite systems with the goal of characterizing varieties of uniqueness.

First, let us give some informal examples which answer some of the obvious questions. Must two rewrite systems that decide the same theory be identical? No; consider  $R = \{fx \rightarrow a\}$ ,  $S = \{fy \rightarrow a\}$ . Must they be the same up to variable renaming? No; consider  $R = \{a \rightarrow b\}$ ,  $S = \{b \rightarrow a\}$ . What if  $R \cup S$  has no cycles? No:  $R = \{a \rightarrow b, b \rightarrow c\}$ ,  $S = \{a \rightarrow c, b \rightarrow c\}$ . What if the right-hand sides are irreducible? No:  $R = \{fx \rightarrow gx, fa \rightarrow c, ga \rightarrow c\}$ ,  $S = \{fx \rightarrow gx, ga \rightarrow c\}$ . Assume in addition that the left-hand sides reduce to only one term. Then we do get that  $R$  and  $S$  have the same “semantics,” i.e.,  $\frac{1}{R} = \frac{1}{S}$  (compare Theorem 10). But we still have the example of  $R = \{fa \rightarrow fb, a \rightarrow b\}$ ,  $S = \{a \rightarrow b\}$ . If no rule contains an instance of another, then  $R = S$  up to renaming of variables (see Theorem 5).

Let us illustrate additional problems we have to cope with in the case of modulo systems.

*Example 6.* The following two different modulo systems decide the same theory over  $T(\{f, g, a, b\}, \{x\})$  and satisfy the conditions mentioned above for ordinary (modulo identity) rewrite systems:  $R = \{a \rightarrow b\}$ ,  $S = \{ga \rightarrow gb\}$ , and  $\sim$  is presented by  $\{fgx \sim x\}$ .

*Example 7.* What if no left-hand side is congruent to its own subterm? Still the systems can be different: Take  $fg hx \sim fx$ ,  $R = \{fx \rightarrow a\}$ ,  $S = \{fgx \rightarrow a\}$ .

As we will see, if no nontrivial instance of a left-hand side is a proper subterm of a congruent term, then the systems are the same up to renaming and congruence (see Corollary 12 and Lemma 13).

Now more formally, given rewrite systems  $R$  and  $S$ , some notions of similarity are:

- (1) If  $R$  and  $S$  satisfy for all  $l \rightarrow r \in R$  there is a renaming of variables  $\theta$  such that  $l\theta \rightarrow r\theta \in S$ , we say that  $R$  is *syntactically contained in  $S$* . If  $S$  is also syntactically contained in  $R$ , then they are *isomorphic*, or *syntactically equivalent*.
- (2) If  $R$  and  $S$  satisfy for all  $l \rightarrow r \in R$ ,  $l \xrightarrow{\frac{1}{S}} r$ , we say that  $R$  is *semantically contained in  $S$* . If  $S$  is also semantically contained in  $R$ , we say they are *semantically equivalent*.
- (3) If  $R$  and  $S$  satisfy for all  $l \rightarrow r \in R$ ,  $l \xrightarrow{\frac{*}{S}} r$  (or equivalently: for all  $l$  and  $r$ , if  $l \xrightarrow{\frac{*}{R}} r$ , then  $l \xrightarrow{\frac{*}{S}} r$ ), we say that  $R$  is *derivationally contained in  $S$* . If also  $S$  is derivationally contained in  $R$ , we say they are *derivationally equivalent*.
- (4) If  $R$  and  $S$  satisfy for all terms  $s$  and  $t$ , if  $s \downarrow_R t$ , then  $s \downarrow_S t$ , we say that  $R$  is *operationally contained in  $S$* . If  $S$  is also operationally contained in  $R$ , then they are *operationally equivalent*.
- (5) If  $R$  and  $S$  satisfy for all terms  $s$  and  $t$ , if  $s \xrightarrow{\frac{\diamond}{R}} t$ , then  $s \xrightarrow{\frac{\diamond}{S}} t$ , we say that  $R$  is *deductively contained in  $S$* . If  $S$  is also deductively contained in  $R$ , then they are *deductively equivalent*.

These criteria can be compactly defined as:

- (1)  $R \subseteq S$  (up to renaming) syntactic containment,
- (2)  $\frac{1}{R} \subseteq \frac{1}{S}$  semantic containment,
- (3)  $\frac{*}{R} \subseteq \frac{*}{S}$  derivational containment,
- (4)  $\downarrow_R \subseteq \downarrow_S$  operational containment,
- (5)  $\frac{\diamond}{R} \subseteq \frac{\diamond}{S}$  deductive containment,
- (6)  $R = S$  isomorphism,
- (7)  $\frac{1}{R} = \frac{1}{S}$  semantic equivalence,

- (8)  $\xrightarrow{*}_R = \xrightarrow{*}_S$  derivational equivalence,
- (9)  $\downarrow_R = \downarrow_S$  operational equivalence,
- (10)  $\xleftrightarrow{*}_R = \xleftrightarrow{*}_S$  deductive equivalence.

These criteria all apply to rewriting modulo a congruence  $\sim$  as well (in which case if  $l\theta \sim l'$  and  $r\theta \sim r'$  for some variable renaming  $\theta$ , then  $l \rightarrow r$  and  $l' \rightarrow r'$  are considered the same).

LEMMA 4. *The above criteria satisfy: (1)  $\Rightarrow$  (2)  $\Rightarrow$  (3)  $\Rightarrow$  (4)  $\Rightarrow$  (5), and hence (6)  $\Rightarrow$  (7)  $\Rightarrow$  (8)  $\Rightarrow$  (9)  $\Rightarrow$  (10).*

*Proof.* All clear, except perhaps (4)  $\Rightarrow$  (5), for which we note that  $\xleftrightarrow{*}_R$  and  $\xleftrightarrow{*}_S$  are the transitive closures of  $\downarrow_R$  and  $\downarrow_S$ , respectively.  $\square$

The reverse implications (5)  $\Rightarrow$  (4)  $\cdots$  do not hold. The obvious question is: Under what (interesting) additional conditions do they hold?

For ordinary rewrite systems (mod identify) we say that  $R$  is *reduced* if all right-hand sides are in  $R$ -normal form and all left-hand sides are in normal form with respect to all other rules in  $R$ . Any ordinary canonical system can be reduced to a deductively equivalent one ([24]; see also [2]).

The following is known.

THEOREM 5 (due to M. Ballantyne; mentioned without proof in [6]; a proof is given in [24]). *If two reduced systems  $R$  and  $S$  both recognize the same equational theory  $E$ , and if for some strict partial order  $>$ ,  $\frac{1}{R}, \frac{1}{S} \subseteq >$ , then  $R$  and  $S$  are isomorphic.*

We include the proof here for motivation, even though this is a special case of Corollary 12.

*Proof.* Let  $R$  and  $S$  be two canonical rewrite systems that recognize  $E$ , and for which  $\frac{+}{R}, \frac{+}{S} \subseteq >$ . Assume  $l \rightarrow r \in R$ . Since  $E \vdash l \equiv r$  and  $S$  recognizes  $E$ , there is a term  $u$  such that  $l \xrightarrow{*}_S u$  and  $r \xrightarrow{*}_S u$ . Since  $E \vdash r \equiv u$ ,  $R$  recognizes  $E$ , and  $R$  is reduced,  $u \xrightarrow{!}_R r$ . Thus we have that  $r \cong u$  and  $u \cong r$  ( $\cong$  is the reflective closure of  $>$ ), and so  $r = u$ . It follows that  $l \xrightarrow{+}_S r$ .

Similarly,  $l \rightarrow r \in S$  implies  $l \xrightarrow{+}_R r$ , and thus  $s \xrightarrow{1}{S} t$  implies  $s \xrightarrow{+}_R t$ .

Assume now that  $l \rightarrow r \in R$  but  $l \rightarrow r \notin S$  (even up to a renaming of variables). If  $l \xrightarrow{1}{S} t \xrightarrow{+}_S r$  for some  $t$ , then  $l \xrightarrow{+}_R t \xrightarrow{+}_R r$ . But this contradicts the premise that no rule in  $R$  other than  $l \rightarrow r$  can reduce  $l$ . So it must be that  $l \xrightarrow{1}{S} r$  by a single application of a rule  $l' \rightarrow r' \in S$  such that  $l \neq l'$  (even up to a renaming of variables). But then, too,  $l' \xrightarrow{+}_R r'$  would contradict  $R$  being reduced.  $\square$

We can extend and split the definition of reduced for  $R \text{ mod } \sim$  by using the following definitions:

- (i)  $R$  is *rhs-reduced* if the right-hand side of each rule is in  $R$ -normal form mod  $\sim$ ;
- (ii)  $R$  is *lhs-reduced* if  $l \xrightarrow{1}{R} u \xrightarrow{*}_R r$  implies  $r \sim u$  for any left-hand side  $l$  of a rule  $l \rightarrow r \in R$ ;
- (iii)  $R$  is *reduced* if it is both rhs-reduced and lhs-reduced.

But the uniqueness theorem does not extend immediately.

Example 8. The following reduced, canonical systems  $R$  and  $S \text{ mod } \sim$  for the same theory over  $T(\{f, g, c, d\}, \emptyset)$  are not isomorphic: Let  $\sim$  be presented by  $fgc \sim c$ ,  $fgd \sim d$ , and take  $R = \{c \rightarrow d\}$ ,  $S = \{gc \rightarrow gd\}$ .

THEOREM 6. *Let  $R$  be a rewrite system mod  $\sim$  deductively contained in a confluent system  $S \text{ mod } \sim$ . Then  $R$  is operationally contained in  $S$ .*

*Proof.* Let  $s \downarrow_R t$ . Then  $s \xleftrightarrow{*}_S t$  by deductive containment and  $s \downarrow_S t$  by confluence of  $S$ .  $\square$

**COROLLARY 7.** For confluent systems  $R$  and  $S \text{ mod } \sim$ ,  $R$  and  $S$  are operationally equivalent if and only if  $l \downarrow_S r$  for all  $l \rightarrow r \in R$  and  $l \downarrow_R r$  for all  $l \rightarrow r \in S$ .

*Proof.* If  $l \rightarrow r \in R$  implies  $l \downarrow_S r$ , then  $s \xrightarrow{1}{R} t$  implies  $s \downarrow_S t$  and  $R$  is deductively contained in  $S$ .  $\square$

We say that two rewrite systems  $\text{mod } \sim$ ,  $R$  and  $S$ , are *noninverting* if for all terms  $s$  and  $t$ ,  $s \xrightarrow{*}{R} t \xrightarrow{*}{S} s$  implies  $s \sim t$ .

**LEMMA 8.** Let  $R$  and  $S$  be two operationally equivalent systems  $\text{mod } \sim$ . If  $R$  and  $S$  are noninverting, then  $\xrightarrow{1}{R} = \xrightarrow{1}{S}$ .

*Proof.* We show only one direction; the other follows from symmetry. Let  $s \xrightarrow{1}{R} t$ . By operational equivalence there is a  $u$  such that  $s \xrightarrow{*}{S} u$  and  $t \xrightarrow{*}{S} u$ . Again, by operational equivalence,  $t \xrightarrow{*}{R} v$ ,  $u \xrightarrow{*}{R} v$  for some  $v$ . Since  $t$  is an  $R$ -normal form, we have  $u \xrightarrow{*}{R} t$ . By the noninverting property, it must then be that  $u \sim t$ , and therefore  $s \xrightarrow{*}{S} t$ . Suppose  $t \xrightarrow{+}{S} w$  for some  $w$ . As before, we must have  $w \sim t$ . But then  $t$  is an  $S$ -normal form, since it only reduces to congruent terms.  $\square$

*Example 9.* The following pair,  $R$  and  $S$ , of operationally equivalent rewrite systems modulo the identity are not derivationally equivalent:  $R = \{a \rightarrow b, c \rightarrow b\}$ ,  $S = R \cup \{a \rightarrow c\}$ .

**THEOREM 9.** Let  $R$  and  $S$  be two rewrite systems  $\text{mod } \sim$  for which  $R$  is operationally contained in  $S$ ,  $R$  is rhs-reduced, and every  $R$ -normal form is an  $S$ -normal form. Then  $R$  is derivationally contained in  $S$ .

Note that if  $\xrightarrow{1}{R} \subseteq \xrightarrow{1}{S}$ , then trivially any  $R$ -normal form is an  $S$ -normal form.

*Proof.* Let  $l \rightarrow r \in R$ . Then  $l \downarrow_S r$ . But since  $R$  is rhs-reduced and all  $R$ -normal forms are  $S$ -normal forms, it follows that  $l \xrightarrow{*}{S} r$ .  $\square$

*Example 10.* The following pair,  $R$  and  $S$ , of derivationally equivalent systems  $\text{mod } \sim$  over  $T(\{f, g, a, b\}, \emptyset)$  are not semantically equivalent: Let  $\sim$  be presented by  $\{fga \sim a\}$ ,  $R = \{a \rightarrow b, fgb \rightarrow b\}$ ,  $S = \{ga \rightarrow gb, fgb \rightarrow b\}$ .

**THEOREM 10.** Let  $R$  and  $S$  be two reduced rewrite systems  $\text{mod } \sim$  which are derivationally equivalent. Then  $R$  and  $S$  are semantically equivalent.

*Proof.* We shall prove that  $l \rightarrow r \in R$  implies  $l \xrightarrow{1}{S} r$ . Let  $l \rightarrow r \in R$ . Since  $l \not\sim r$  and  $R$  is derivationally contained in  $S$ ,  $l \xrightarrow{+}{S} r$ . Now assume that  $l \xrightarrow{1}{S} u \xrightarrow{*}{S} r$ ,  $l \not\sim u$ . Since  $S$  is derivationally contained in  $R$ , there is some  $v$  such that  $l \xrightarrow{1}{R} v \xrightarrow{*}{R} u \xrightarrow{*}{R} r$ .  $R$  is lhs-reduced so  $v \sim r$ , and so  $r \xrightarrow{*}{R} u$ . Now using the fact that  $R$  is rhs-induced,  $r \sim u$  and thus  $l \xrightarrow{1}{S} r$ .  $\square$

Were we to weaken the definition of reduced to allow trivial rules  $l \rightarrow r$ , where  $l \sim r$ , then we would only get  $\xrightarrow{0,1}{R} = \xrightarrow{0,1}{S}$ , which is slightly weaker than semantic equivalence.

*Example 11.* The following pair,  $R$  and  $S$ , of systems  $\text{mod } \sim$  over  $T(\{f, g, c\}, \{x\})$  are semantically equivalent, but not isomorphic: Let  $\sim$  be presented by  $fx \sim fghx$ , and take  $R = \{fx \rightarrow c\}$ ,  $S = \{fgx \rightarrow c\}$ .

A rewrite system  $R$  is *minimal* if no left-hand side  $l$  of a rule in  $R$  contains a proper instance of a left-hand side  $l'$  of a (not necessarily different) rule in  $R$ , that is,  $l \not\sim c[l'\sigma]$  for any nonempty context  $c$  or substitution  $\sigma$  that is more than a renaming of variables in  $l'$ .

**THEOREM 11.** Suppose  $R$  and  $S$  are semantically equivalent rewrite systems  $\text{mod } \sim$ . If  $R$  and  $S$  are both minimal, then  $R$  and  $S$  are isomorphic.

*Proof.* Let  $l \rightarrow r \in R$ . Then  $l \sim u[l'\sigma] \xrightarrow{1}{S} u[r'\sigma] \sim r$  for some  $l' \rightarrow r' \in S$ . Similarly,  $l' \sim v[\bar{l}\mu] \xrightarrow{1}{R} v[\bar{r}\mu] \sim r'$  for some  $\bar{l} \rightarrow \bar{r} \in R$ . That is,  $l \sim u[v[\bar{l}\mu]\sigma]$  and  $r \sim u[v[\bar{r}\mu]\sigma]$ . By minimality,  $u$  and  $v$  are empty and  $\sigma$  and  $\mu$  are no more than renamings (on the

appropriate sets of variables,  $\mu$  on variables of  $\bar{l}$ ,  $\sigma$  on variables of  $\bar{l}\mu$ ). Hence,  $l \sim u[l'\sigma] = l'$  and  $r \sim u[r'\sigma] = r'$  as desired up to renaming.  $\square$

**COROLLARY 12.** *Let  $R$  and  $S$  be deductively equivalent confluent rewrite systems  $\text{mod } \sim$ . If  $R$  and  $S$  are noninverting and  $R$  and  $S$  are each reduced and minimal, then  $R$  and  $S$  are isomorphic.*

This extends a result of Lankford and Ballantyne [22] in which they assume that the  $\sim$ -congruence classes are finite. None of the conditions can be omitted.

**LEMMA 13.** *A rewrite system  $R \text{ mod } \sim$  is minimal if no left-hand side  $l$  is reducible by another rule, and if  $l \not\sim c[l\sigma]$  for any nonempty context  $c$  or substitution  $\sigma$  that is more than renaming.*

*Proof.* Straightforward from the definition of minimality.  $\square$

**LEMMA 14.** *A terminating rewrite system  $R \text{ mod } \sim$  is reduced if it is minimal and no rule applies to either the left- or right-hand side of another rule.*

*Proof.* Let  $l \rightarrow r \in R$ . We are given that no other rule applies to  $l$  and by minimality,  $\sim$  does not create any nontrivial way for  $l$  to apply to itself. Furthermore, the right-hand side  $r$  must be a normal form, since no other rule applies, and were  $l$  to apply, the system would not be terminating. Hence  $R$  is reduced,  $\square$

**COROLLARY 15.** *A rewrite system  $R \text{ mod } \sim$  is minimal if no left-hand side  $l$  is reducible by another rule and  $\sim$  generates only finite congruence classes.*

*Proof.* Were  $l \sim c[l\sigma]$  for nonempty context  $c$ , then there would be an infinite congruence class  $l \sim c[l\sigma] \sim c[c[l\sigma]\sigma] \sim \dots$ . Suppose, then, that  $l \sim l\sigma$ . If either  $l$  or  $l\sigma$  contains a variable  $x$  not in the other, then by substituting terms for  $x$  we would obtain an infinite set of congruent terms. So were  $\sigma$  not a renaming it would have to map some variable to a nonvariable, in which case  $l \sim l\sigma \sim l\sigma\sigma \sim \dots$  would be an infinite congruence class.  $\square$

It is however undecidable if  $\sim$ -congruence classes are finite, even if  $\sim$  is presented by a finite, canonical rewrite system. If, however,  $\sim$  is presented by a finite set of ground equations, then finiteness is decidable (see [27]).

**5. Completion.** In this section we consider the relationship between the Knuth-Bendix completion procedure [19] and the existence of a finite canonical rewrite system for an equational theory. The procedure has been extended to the modulo  $\sim$  case by [16], [21], [26], [3], and [4], although we shall not consider that more complicated procedure here.

Let  $l \rightarrow r$  and  $l' \rightarrow r'$  be two (not necessarily distinct) rules in  $R$  whose variables have been renamed, if necessary, so that they are distinct. Assume  $l'$  overlaps  $l$ , that is,  $l = c[v]$  for some context  $c$  and nonvariable subterm  $v$  such that  $v\sigma = l'\sigma$  for some (most general) substitution  $\sigma$  for the variables of  $l$  and  $l'$ . Then the overlapped term  $l\sigma (= c\sigma[l'\sigma])$  can be rewritten as either  $r\sigma$  or  $c\sigma[r'\sigma]$ . These two possibilities are called a *critical pair*.

The *Knuth-Bendix completion procedure* ( $\text{KB}(E, >)$  or just  $\text{KB}$ ) takes as input a finite set  $E$  of equations and (a program to compute) a well-founded ordering  $>$  that is closed with respect to substitution and subterm replacement, i.e., a well-founded partial order on  $T(L(E), X)$  such that  $c[s\sigma] > c[t\sigma]$  where  $s > t$ , for any context  $c$ , substitution  $\sigma$ , and terms  $s$  and  $t$ .

The procedure consists of the following steps:

Repeat as long as equations are left in  $E$ . If none remain, terminate successfully.

- (1) Remove an equation  $s \equiv t$  (or  $t \equiv s$ ) from  $E$  such that  $s > t$ . If none exists, terminate with failure (abort).
- (2) Add the rule  $s \rightarrow t$  to  $R$ .
- (3) Use  $R$  to reduce the right-hand sides of existing rules.

- (4) Add to  $E$  all critical pairs formed using the new rule.
- (5) Remove from  $R$  all other rules whose left-hand side contains an instance of  $s$ .
- (6) Use  $R$  to reduce both sides of equations in  $E$ . Remove any equation whose reduced sides are identical.

We use the notation  $R \cup E \xrightarrow{\text{KB}} R' \cup E'$  to indicate the effect of one iteration of the above procedure. For an abstract version see [4]. The procedure can be optimized in various ways that do not concern us here.

**THEOREM 16** [19], [14]. *If KB terminates successfully for input equations  $E$ , then it returns as output a finite canonical system  $R$  for  $E$ .*

The completion procedure may fail in one of two fashions: it may be unable to add any rule because  $s$  and  $t$  are incomparable under the given ordering  $>$  for all equations  $s \equiv t$  in  $E$ ; or it may go on generating an infinite number of new rules without ever finding a finite canonical system. In the former case, we will say that the procedure *aborts*, in the latter that it *loops*. Clearly,  $\text{KB}(E, >)$  only generates rules  $l \rightarrow r$  that are true in the theory  $E$ , i.e.,  $E \vdash l \equiv r$ , and for which  $l > r$ .

**THEOREM 17** ([8], based on [14]). *Let  $R$  be a reduced finite canonical rewrite system for a finite equational theory  $E$ , and let KB be implemented by a “fair” scheduler, i.e., no critical pair that persists is ignored indefinitely. Then  $\text{KB}(E, \frac{+}{R})$  will generate  $R$  if it does not abort.*

*Proof.* Assume KB does not abort. Then in the limit (i.e., considering only those rules which persist from some point on) a reduced canonical system  $S$  will be generated for  $E$  (see [14] and [3]). By Theorem 5,  $R = S$ . KB terminates once  $R$  is generated, since critical pairs must now reduce to triviality.  $\square$

Even if  $R$  is a reduced finite canonical rewrite system for  $E$ ,  $\text{KB}(E, \frac{+}{R})$  need not generate  $R$  since it might abort. By Theorem 2,  $\text{KB}(E, \frac{+}{R})$  will not abort on the first step.

*Example 12.* Despite the existence of  $R = \{m \rightarrow c, n \rightarrow c, fc \rightarrow c\}$ ,  $\text{KB}(\{fn \equiv c, fm \equiv m, m \equiv n\}, \frac{+}{R})$ , aborts on all paths (see also [1].)

*Example 13.* As pointed out in [19], varying the procedure by expanding the language (adding rules  $s \rightarrow h(\bar{x})$  and  $t \rightarrow h(\bar{x})$ , where  $h$  is a new function symbol and  $\bar{x}$  are the variables in an unorientable equation  $s \equiv t$ ) may sometimes circumvent the abort case of completion. However, the following example shows that such expansions may also cause KB to become nonterminating:  $\{fm \equiv m, fn \equiv c, m \equiv n\} \xrightarrow{\text{KB}} \{fh \equiv h, fh \equiv c, m \rightarrow h, n \rightarrow h\} \xrightarrow{\text{KB}} \{fh \rightarrow h, h \equiv c, m \rightarrow h, n \rightarrow h\} \xrightarrow{\text{KB}} \{fk \equiv k, c \rightarrow k, h \rightarrow k, m \rightarrow k, n \rightarrow k\} \xrightarrow{\text{KB}} \dots \xrightarrow{\text{KB}} \{fl \equiv l, k \rightarrow l, \dots\} \xrightarrow{\text{KB}} \dots$  (using the subterm ordering for  $>$ ).

We now show that backtracking is sometimes necessary, that is, there are  $E$  and  $>$  for which  $\text{KB}(E, >)$  can either abort or succeed depending on the sequence in which the equations are chosen for orienting.

*Example 14.* Given the theory

$$E = \{k \equiv m, k \equiv n, fm \equiv m, fk \equiv c\}$$

and the ordering

$$k > m, n,$$

$$m, n, fm, fn, fc > c,$$

$$fm > m,$$

$$fn > n,$$

$$\#(m, n, fc), \#(k, fm, fn, fc), \text{ etc. } (\# \text{ designates pairwise incomparability})$$

Knuth–Bendix can either succeed and find:

$$E \xrightarrow{\text{KB}} \{k \rightarrow m, m \equiv n, fm \equiv m, fm \equiv c\} \xrightarrow{\text{KB}} \{k \rightarrow m, m \equiv n, fm \rightarrow m, m \equiv c\} \\ \xrightarrow{\text{KB}} \{k \rightarrow c, n \rightarrow c, fc \rightarrow c, m \rightarrow c\}$$

or else it can fail (abort) along the path:

$$E \xrightarrow{\text{KB}} \{n \equiv m, k \rightarrow n, fm \equiv m, fn \equiv c\} \xrightarrow{\text{KB}} \cdots \xrightarrow{\text{KB}} \{n \equiv m, k \rightarrow n, fm \rightarrow m, fn \rightarrow c\}.$$

Hence, KB should backtrack to try alternative choices, even for ground systems. Note that if in the previous example  $n$  and  $k$  were incomparable or the given order were extended to include either  $m > n$  or  $n > m$ , then KB would succeed along every path.

In general, we have Theorem 18.

**THEOREM 18.** *If the set of terms  $T(L, X)$  is totally ordered by  $>$ , then  $\text{KB}(E, >)$  does not need to backtrack.*

*Proof.* Obviously, KB cannot abort, and we have already seen (Theorem 17) that KB cannot both succeed and loop.  $\square$

As pointed out in [20], there is always such a total ordering for ground systems. As pointed out in [15], there need not be such an ordering for nonground systems.

**6. Conclusion.** We have discussed the question of when a given decidable equational theory possesses a canonical rewrite system in the original or expanded language. We have pointed to some inherent limitations in the ability of the Knuth–Bendix completion procedure to discover appropriate rewrite systems, even if the procedure is extended to backtrack upon failure or to introduce new function symbols. These limitations can be partially circumvented by allowing more deduction in the procedure (see [20], [3], [4]). In practice completion is frequently quite effective. We have shown that barring failure (and under reasonable conditions) the procedure will find the same rewrite system regardless of the choices made.

One of the remaining open questions is: Suppose there exists some finite canonical system for an equational theory  $E$ . Must there exist an ordering  $>$  for which the completion algorithm, given  $E$  and  $>$ , has a successful outcome. Another area worth investigating is the extent to which systems that rewrite modulo a congruence (whose classes are all finite) are sure to exist for decidable  $E$ .

## A NEW LOWER BOUND FOR THE SET-PARTITIONING PROBLEM\*

JOHN WELLIAVEETIL JOHN†

**Abstract.** Let  $S$  be a set of  $n$  elements that allows all possible total ordering and on which a total order exists that is initially not known. The problem of determining the  $t$  largest elements of  $S$  using binary comparisons between elements of  $S$  is the set-partitioning problem. In this paper we establish a new lower bound on the number of comparisons required for the set-partitioning problem. For sufficiently large  $n$ , our lower bound improves on all previous lower bounds for this problem for almost all values of  $t$ . Our technique is based on estimating the number of leaves of a decision tree, say  $T$ , for the problem. Let  $P$  denote the set of total orderings allowed on  $S$ . Let  $P'_1, P'_2, \dots, P'_m$  be a partition of  $P$  such that the set of leaves of  $T$  corresponding to  $P'_i$  is disjoint from those corresponding to  $P'_j$  whenever  $i \neq j$ . We determine subsets  $P_1, P_2, \dots, P_r$  of  $P$  and an integer  $k$ , such that for each  $i, 1 \leq i \leq m, P'_i \cap P_j \neq \emptyset$  holds for at most  $k$  distinct  $P_j$ 's. For each subset  $P_j, 1 \leq j \leq r$ , we establish a lower bound, say  $t_j$ , on the number of leaves of a decision tree for the set-partitioning problem when  $S$  is restricted to a total order from  $P_j$ . Then  $T$  has at least  $\sum_{j=1}^r t_j/k$  leaves.

**1. Introduction.** Let  $S$  be the set of elements  $\{a_1, a_2, \dots, a_n\}$  that allows all possible total ordering and on which a total order exists that is initially not known. The problem of determining the set of  $t$  largest elements of  $S$  is the *set-partitioning problem*. We measure the complexity of this problem in terms of the number of binary comparisons required to determine the set of  $t$  largest elements of  $S$ . The minimax complexity of the set-partitioning problem, denoted by  $U_t(n)$ , is the number of comparisons which is minimum over all permissible algorithms and maximum over all inputs of  $n$  elements for each algorithm. Since the complexity of finding the set of  $t$  largest elements of  $S$  is the same as that of finding the set of  $t$  smallest elements of  $S$ , we restrict ourselves to  $t \leq \lfloor n/2 \rfloor$ .

A problem that is closely related to the set-partitioning problem is the *selection problem*, where we are required to determine the  $t$ th largest element of  $S$ . The minimax complexity of the selection problem is denoted by  $V_t(n)$ . Since after determining the  $t$ th largest element of  $S$ , we know the  $t$  largest elements of  $S$  [12, Problem 2, § 5.3.3], we conclude that  $V_t(n) \geq U_t(n)$ . Both these problems have been extensively studied [1]–[12], [14]–[18] and the advances made in establishing upper and lower bounds for  $V_t(n)$  are given in [8], while those for  $U_t(n)$  are given in [11]. A new lower bound for the selection problem is given in [8]. Here it is shown that

$$V_t(n) \geq n + \lg \binom{n}{t-1} + O\left(\left[\lg \binom{n}{t-1}\right]^{1/2}\right)$$

where  $\lg$  denotes logarithm to the base 2.

The best general lower bound for the set-partitioning problem is due to Kirkpatrick. From [11] we can establish that for all  $t \geq 2$

$$(1) \quad U_t(n) \cong \begin{cases} \left\lfloor \frac{3n+t}{2} \right\rfloor - 3, & 2t \leq n < 3t, \\ n+t-3 + \sum_{j=0}^{t-2} \left\lceil \lg \frac{n-t+1}{t+j} \right\rceil, & n \geq 3t. \end{cases}$$

For small values of  $t$ , the Hadian-Sobel algorithm [6] for determining  $V_t(n)$  may be modified to determine  $U_t(n)$ . This modification yields the upper bound

$$U_t(n) \leq n - t + (t - 1) \lceil \lg(n - t + 1) \rceil.$$

Several modifications of the Hadian-Sobel algorithm for  $V_t(n)$  have been proposed [8], [10], [16] and these in turn may be adapted to give improved upper bounds for  $U_t(n)$  for a wide range of values of  $n$  and  $t$ . For large  $t$ , the algorithm of Schönhage et al. [17] gives the bound

$$U_t(n) \leq V_t(n) \leq 3n + o(n).$$

In this paper we establish a new lower bound for the set-partitioning problem. In § 3 we establish that

$$U_t(n) \geq J_t(n) = n + h$$

where  $h = \lg \binom{n}{t} - 2x - \lg(t(n-t)+1)$  and  $x$  is the least positive integer greater than  $[\lg \binom{n}{t} - \lg(t(n-t)+1)]^{1/2}$ . We further show that  $J_t(n)$  is an improvement over (1) for all  $t > c \lg n$  and  $n > n_0$  for some  $c > 0$  and  $n_0$  a positive integer. We establish that the improvement over this range is greater than  $c't$  for some  $c' > 0$ . In particular, when  $t = \lfloor n/2 \rfloor$ ,  $J_t(n)$  gives an improvement of  $n/4 - O(\sqrt{n})$  comparisons over (1).

**2. Definitions.** Comparison-based algorithms may be represented by a binary tree. We call such a tree a *decision tree* for the algorithm. Let  $T$  be a decision tree for the set-partitioning problem. Each internal node of  $T$  is labelled by a pair of elements from  $S$ . Let  $u$  be an internal node of  $T$  carrying the label  $e : f$ , where  $e$  and  $f$  belong to  $S$ . Then  $u$  denotes the comparison between  $e$  and  $f$  and one of the branches leading from  $u$  represents the relation  $e > f$  and the other the relation  $e < f$ . The *depth* of a node  $v$  is the number of internal nodes that precede  $v$  on the path from the root to  $v$  and hence by our definition the root has depth 0. The *height* of  $T$  is the maximum of the depth of any leaf of  $T$ . The tree  $T$  is *optimum* if it has the least height among all decision trees representing valid algorithms for the problem. The height of an optimal tree is denoted by  $U_t(n)$ .

Let  $u$  be a node of  $T$ . Define  $P_u$  to be the set of relations corresponding to the branches on the path from the root to  $u$ . Thus a decision tree  $T$  for a problem is a binary tree such that if  $v$  is a leaf of  $T$ , then from  $P_v$  and the hypothesis on the allowed orders on  $S$  we can deduce a solution to the problem. Let  $H_u$  be the directed graph, whose vertices correspond to the elements of  $S$ , with the edge  $(e, f)$  in  $H_u$  if and only if the relation  $e > f$  belongs to  $P_u$ . The directed graph  $H_u$  is *weakly connected* if the corresponding undirected graph, obtained by ignoring the direction of the edges in  $H_u$ , is connected.

Let  $Q$  be a set of leaves of  $T$ . Then  $T'(Q)$  is the subtree of  $T$  such that a node in  $T$  belongs to  $T'(Q)$  if and only if it lies on a path from the root to a leaf in  $Q$ . Consider a node that has only one child. The outcome of the comparison corresponding to this node may be deduced from the comparisons already made by the algorithm

and the restriction that the order on  $S$  be consistent with the partial order associated with a leaf in  $Q$ . If  $u$  is a node with one child, say  $v$ , then we delete  $u$  from  $T'(Q)$  and replace it with  $v$ . Repeating this process as many times as possible results in the decision tree  $T(Q)$  that distinguishes between two partial orders on  $S$  corresponding to two distinct leaves in  $Q$ . We call  $T(Q)$  the *subtree of  $T$  defined by  $Q$* .

Let  $W$  be a set of relations consistent with the total ordering on  $S$  and let  $C$  be a subset of  $S$ . Then  $W|C$  is the subset of  $W$  restricted to the elements of  $C$ . An element  $e$  of  $C$  is maximal (minimal) in  $C$ , with respect to  $W|C$ , if and only if there is no element  $f$  in  $C$  such that  $f > e$  ( $f < e$ ) is in  $W|C$ . Since a total order is assumed on  $S$ , every subset of it may be totally ordered. Let  $C[k]$  denote the  $k$ th largest element of  $C$  with respect to the total order on  $S$ .

**3. A lower bound for the general set-partitioning problem.** In this section we present our construction that yields a new lower bound for the set-partitioning problem. We establish a lower bound on the number of leaves of  $T$ , from which a lower bound on the height of  $T$  is obtained. In order to simplify our calculation, we denote the height of  $T$  by  $n+h$ . Our task then is to establish a lower bound on  $h$ . We shall consider values of  $t$  greater than 1, which implies from (1) that  $h$  is greater than 0 for sufficiently large  $n$ . Let  $C$  be a  $t$ -subset of  $S$ . To illustrate our construction, assume without loss of generality that  $C$  is the set  $\{a_1, a_2, \dots, a_t\}$ . For  $1 \leq j \leq t$ , let  $A_j = C - \{a_j\}$  and let  $B_j = S - A_j$ . From the definition of  $T$  it follows that if  $v$  is a leaf of  $T$  then from  $P_v$  we can deduce the set of  $t$  largest elements of  $S$ . Let  $L(C)$  denote the set of leaves of  $T$  that correspond to  $C$  being the set of  $t$  largest elements of  $S$ . Now consider the set of leaves of  $T$  denoted by  $Q_j$ , where  $Q_j = \{v \mid v \in L(A_j \cup \{a\}) \wedge a \in B_j\}$ . The following lemma is useful in establishing a lower bound on  $|Q_j|$ .

LEMMA 3.1. *If  $A_j$  belongs to the set of  $t$  largest elements of  $S$ , then  $T(Q_j)$  is a decision tree that determines the largest element of  $B_j$ .*

*Proof.* It is sufficient to show that if  $v'$  is a leaf of  $T(Q_j)$  then we can deduce from  $P_{v'}$  the largest element of  $B_j$  assuming  $A_j$  belongs to the set of  $t$  largest elements of  $S$ . Note that for every leaf  $v'$  of  $T(Q_j)$  there is a corresponding leaf  $v$  in  $L(A_j \cup \{a'\})$  for some  $a'$  belonging to  $B_j$ . If  $u$  is an internal node of  $T$  on the path from the root to  $v$  then by our construction of  $T(Q_j)$ ,  $u$  is in  $T(Q_j)$  only if the outcome of the comparison corresponding to  $u$  cannot be deduced from  $P_u$  and the hypothesis that  $A_j$  belongs to the set of  $t$  largest elements of  $S$ . From  $P_v$  we can deduce that  $a'$  belongs to the set of  $t$  largest elements of  $S$ . Hence from  $P_{v'}$  we can deduce that  $a'$  is the largest element of  $B_j$  assuming that  $A_j$  belongs to the set of  $t$  largest elements of  $S$ .  $\square$

We next consider the set of permissible orders on  $S$  for which the elements of  $C$ , with the possible exception of one, belong to the set of  $t$  largest elements of  $S$ . More precisely we consider the orders on  $S$  for which  $C[t-1] > (S-C)$  [2]. Let  $Q = \bigcup_{1 \leq i \leq t} Q(i)$ .

LEMMA 3.2. *Under the hypothesis  $C[t-1] > (S-C)$ [2],  $T(Q)$  is a decision tree that determines the set of  $t$  largest elements of  $S$  as  $C - \{\min(C)\} \cup \{\max(\{\min(C)\} \cup S - C)\}$ .*

*Proof.* Let  $v''$  be a leaf in  $T(Q)$  and let  $v$  be the corresponding leaf in  $Q_j$  for some  $j$ ,  $1 \leq j \leq t$ . Let  $v'$  be the leaf in  $T(Q_j)$  corresponding to  $v$ . Our construction of  $T(Q)$  implies that  $P_{v''}$  is contained in  $P_{v'}$ . Note that  $v$  corresponds to  $A_j$  belonging to the set of  $t$  largest elements of  $S$ . This implies that  $P_v$  and hence  $P_{v''}$  do not contain the relation  $a < b$  for any  $a$  in  $A_j$  and  $b$  in  $S - C$ .

We first consider the case when  $v$  corresponds to  $a_j$  belonging to the set of  $t$  largest elements of  $S$ . This implies that  $\min(C) = \max(\min(C) \cup S - C)$  and from  $P_v$

we can deduce  $C$  as the set of  $t$  largest elements of  $S$ . Let  $u$  be an internal node of  $T$  lying on the path from the root to  $v$ . Since  $P_u$  does not contain the relation  $a < b$  for any  $a$  in  $C$  and  $b$  in  $S - C$ , the definition of  $Q$  implies that both the left subtree and the right subtree of  $u$  have leaves belonging to  $Q$ . Hence  $u$  belongs to  $T(Q)$ . This implies that  $P_{v'} = P_v$  and hence from  $P_{v'}$  we can deduce  $C$  as the set of  $t$  largest elements of  $S$ .

Now consider the case where  $v$  corresponds to  $a_j$  not belonging to the set of  $t$  largest elements of  $S$ . Thus  $P_v$  contains the relation  $a_j < b$  for some  $b$  in  $S - C$ . Let  $u$  be the internal node of minimum depth on the path from the root to  $v$  that corresponds to the comparison between  $a_j$  and  $b$  for some  $b$  in  $S - C$  such that  $a_j < b$  is in  $P_v$ . By our choice of  $u$ ,  $P_u$  does not contain the relation  $a < b$  for any  $a$  in  $C$  and  $b$  in  $S - C$ . Thus  $u$  belongs to  $T(Q)$  and hence  $a_j < b$  is in  $P_{v'}$ . Now  $a_j < b$  and  $C[t - 1] > (S - C)[2]$  implies that  $A_j$  belongs to the set of  $t$  largest elements of  $S$  and  $a_j = \min(C)$ . Hence the  $t$  largest elements of  $S$  are  $A_j \cup \{\max(B_j)\}$ . By Lemma 3.1 we can deduce  $\max(B_j)$  from  $P_{v'}$  and the hypothesis  $A_j$  belongs to the set of  $t$  largest elements of  $S$ . Since  $P_{v'}$  is a subset of  $P_{v''}$ , we can deduce  $\max(B_j)$  from  $P_{v''}$  and the hypothesis  $C[t - 1] > (S - C)[2]$ . Hence from  $P_{v''}$  we can deduce the  $t$  largest elements of  $S$  as  $A_j \cup \{\max(B_j)\} = C - \{\min(C)\} \cup \{\max(\min(C) \cup S - C)\}$  assuming  $C[t - 1] > (S - C)[2]$ .  $\square$

Next we turn to the task of establishing a lower bound on  $|Q|$ . This is realized by establishing a lower bound on the number of leaves of  $T(Q)$  a decision tree of height at most  $n + h$  that determines  $C - \{\min(C)\} \cup \{\max(\{\min(C)\} \cup S - C)\}$  as the set of  $t$  largest elements of  $S$  under the hypothesis  $C[t - 1] > (S - C)[2]$ .

Let  $u$  be a node of  $T(Q)$  such that  $H_u$  does not contain an edge directed from an element of  $S - C$  to an element of  $C$ . The next four lemmas establish certain properties of  $u$  that are used in proving Theorem 3.7. This theorem establishes a lower bound on the number of leaves of  $T(Q)$  and hence a lower bound on  $|Q|$ . We define a *straddle* as an edge in  $H_u$  from an element in  $C$  to an element in  $S - C$ . Let  $m_u$  be the set of minimal elements of  $C$  with respect to  $P_u|C$  and let  $M_u$  be the set of maximal elements of  $S - C$  with respect to  $P_u|S - C$ . With each node  $u$  associate a function  $E_u$  with domain as  $m_u$  and whose range is the power set of  $M_u$ . For each  $e$  in  $m_u$  define  $E_u(e) = \{f | f \in M_u \wedge (e, f) \in H_u\}$  and let  $e_u$  be an element in  $m_u$  such that  $|E_u(e_u)| \leq |E_u(e)|$  for all  $e$  belonging to  $m_u$ . Now let  $x$  be the least positive integer satisfying the inequality  $x^2 - 2x \geq h$ . Our assumption of  $h > 0$  implies that  $x$  is greater than 1. The following lemma establishes an upper bound on  $|E_u(e_u)|$ .

LEMMA 3.3. *If  $|m_u| = x$ , then  $|E_u(e_u)| \leq x$ .*

*Proof.* Since  $P_u$  does not contain the relation  $a < b$  for any  $a$  in  $C$  and  $b$  in  $S - C$ , the subtree rooted at  $u$  contains leaves from  $L(C)$ . Since  $e_u$  is a minimal element of  $P_u|C$  there exists a leaf, say  $v$ , among these leaves of  $L(C)$  for which  $e_u$  is a minimal element of  $C$  with respect to  $P_v|C$ . From  $P_v$  we can deduce that  $e_u = \max(\{e_u\} \cup S - C)$ . Hence the subgraph of  $H_v$  induced by  $\{e_u\} \cup S - C$  is weakly connected and must have at least  $n - t$  edges. The subgraph of  $H_u$  induced by  $C$  has at most  $x$  components and hence has at least  $t - x$  edges in it. If  $|E_u(e_u)| > x$ , then  $m_u - \{e_u\}$  must have more than  $x(x - 1)$  straddles between them. This implies that  $H_v$  has more than  $(n - t) + (t - x) + x(x - 1) = n + x^2 - 2x \geq n + h$  edges. Since each edge in  $H_v$  results from a comparison corresponding to a node in  $T(Q)$  we conclude that  $T(Q)$  has height greater than  $n + h$ , contradicting our assumption on the height of  $T(Q)$ . Hence  $|E_u(e_u)| \leq x$ .  $\square$

We next turn to the problem of estimating the number of leaves in the subtree rooted at node  $u$  of the decision tree. The following lemma helps in establishing a lower bound for this problem.

LEMMA 3.4. *The subtree rooted at  $u$  may be pruned such that each leaf of the pruned tree has depth at least*

$$|M_u \cup \{e_u\} - E_u(e_u)| - 1.$$

*Proof.* Let  $e_u$  correspond to  $a_k$ , where  $k \in \{1 \cdots t\}$ . The node  $u$  belongs to  $T(Q_k)$  which, by Lemma 3.1, determines the largest element of  $B_k = \{e_u\} \cup S - C$  assuming  $A_k = C - \{e_u\}$  belongs to the set of  $t$  largest elements of  $S$ . The maximal elements of  $\{e_u\} \cup S - C$  in  $P_u$  is the set  $M_u \cup \{e_u\} - E_u(e_u)$  and hence the subgraph of  $H_u$  induced by  $M_u \cup \{e_u\} - E_u(e_u)$  contains only singletons. Let  $T_u$  denote the subtree of  $T(Q_k)$  rooted at  $u$ . Let  $Q'$  be the set of leaves of  $T_u$  such that  $v$  belongs to  $Q'$  if and only if  $P_v$  does not contain the relation  $a < b$  for any  $a$  in  $A_k$  and  $b$  in  $B_k$ . Hence if  $v$  belongs to  $Q'$  then from  $P_v$  we can deduce the largest element of the set  $M_u \cup \{e_u\} - E_u(e_u)$  without assuming  $C - \{e_u\}$  belongs to the set of  $t$  largest elements of  $S$ . Hence the subgraph of  $H_v$  induced by  $M_u \cup \{e_u\} - E_u(e_u)$  is weakly connected and has at least  $|M_u \cup \{e_u\} - E_u(e_u)| - 1$  edges. Since each of these edges correspond to a comparison we conclude that each leaf of  $T_u(Q')$ , the subtree of  $T_u$  defined by the set of leaves  $Q'$ , has depth at least  $|M_u \cup \{e_u\} - E_u(e_u)| - 1$ . The lemma follows from the fact that  $T_u(Q')$  is a subtree of  $T_u$ .  $\square$

From the symmetry of the problem,  $T(Q)$  is a decision tree that identifies the set  $(S - C) - \{\max(S - C)\} \cup \{\min(\{\max(S - C)\} \cup C)\}$  as the  $n - t$  smallest elements of  $S$ . This allows us to state the following two lemmas that may be proved along the lines of Lemmas 3.3 and 3.4 and hence their proofs are omitted here. As before, with each node  $u$  of  $T(Q)$  we associate a function  $\hat{E}_u$  with domain as  $M_u$  and whose range is the power set of  $m_u$ . For each  $f$  in  $M_u$  define  $\hat{E}_u(f) = \{e \mid e \in m_u \wedge (e, f) \in H_u\}$  and let  $f_u$  be an element in  $M_u$  such that  $|\hat{E}_u(f_u)| \leq |\hat{E}_u(f)|$  for all  $f$  belonging to  $M_u$ .

LEMMA 3.5. *If  $|M_u| = x$ , then  $|\hat{E}_u(f_u)| \leq x$ .*

LEMMA 3.6. *The subtree rooted at  $u$  may be pruned to obtain a decision tree each leaf of which has depth at least*

$$|m_u \cup \{f_u\} - \hat{E}_u(f_u)| - 1.$$

We are now ready to establish a lower bound on the number of leaves in  $T(Q)$ .

THEOREM 3.7. *The decision tree  $T(Q)$  has at least  $2^{n-2x}$  leaves.*

*Proof.* If  $x \geq t$  then  $|E_{\text{root}}(e) = 0|$  for all  $e$  belonging to  $C$  and  $|M_{\text{root}}| = |S - C| = n - t$ . By Lemma 3.4,  $T(Q)$  may be pruned to obtain a decision tree each leaf of which has depth at least  $|S - C|$ . In this case  $T(Q)$  has at least  $2^{n-t}$  leaves which are greater than  $2^{n-2x}$ .

Now assume  $x < t$ . We will prune  $T(Q)$  so that every leaf of the resulting tree has depth at least  $n - 2x$ . We start with the root and use a depth-first strategy to examine the nodes of  $T(Q)$ . Let  $u$  be a node of  $T(Q)$  examined during the pruning strategy. Our pruning is based on the value of  $|m_u|$  and  $|M_u|$ . For nodes with both  $|m_u| > x$  and  $|M_u| > x$ , the strategy given by case (a) is followed while case (b) deals with a node  $u$  for which  $|m_u| = x$  and case (c) for a node with  $|M_u| = x$ . Now  $|M_{\text{root}}| = n - t$ ,  $|m_{\text{root}}| = t$  and  $t \leq \lfloor n/2 \rfloor$  implies that  $|M_{\text{root}}| \geq |m_{\text{root}}| = t > x$ . Hence case (a) of the pruning strategy is applicable to the root.

(a) If  $|m_u| > x$  and  $|M_u| > x$  then the pruning strategy retains a child  $u'$  of  $u$  if and only if  $P_{u'}$  does not contain the relation  $a < b$  for any  $a$  in  $C$  and  $b$  in  $S - C$ . Furthermore, the number of minimal elements in  $m_{u'}$  (number of maximal elements in  $M_{u'}$ ) is at most one less than in  $m_u$  ( $M_u$ ). More specifically, we distinguish the following two cases:

(a.1) Let  $u$  denote the comparison between  $e$  and  $f$  belonging to  $S$ . If  $e$  belongs to  $C$  and  $f$  belongs to  $S - C$  then delete the subtree of the branch correspond-

ing to the outcome  $e < f$  and retain  $u$  and the branch corresponding to the outcome  $e > f$ . Since  $u$  has only one child we do not regard  $u$  as an internal node of the pruned tree. Note that if  $u'$  is the child of  $u$  then  $m_u = m_{u'}$  and  $M_u = M_{u'}$ . We next apply the pruning procedure to  $u'$ .

(a.2) In all other cases retain the node  $u$ . The pruning procedure is applied to each of the children of  $u$ .

(b) If  $|m_u| = x$  then by Lemma 3.4,  $m_u$  has an element  $e_u$  with  $|E_u(e_u)| \leq x$ . Let  $y = |M_u|$ . At least  $t - x$  internal nodes corresponding to comparisons between elements in  $C$  and  $n - t - y$  nodes corresponding to comparisons between elements in  $S - C$  must have preceded  $u$  in the pruned tree and these nodes resulted from case (a.2) given above. Hence each of these nodes has two children. Lemma 3.4 allows us to prune the subtree rooted at  $u$  such that each leaf of the resulting tree, say  $T'_u$ , has depth at least  $|M_u \cup \{e_u\} - E_u(e_u)| - 1$  with respect to  $u$  as the root. Since the depth of  $u$  in  $T(Q)$  is at least  $t - x + n - t - y = n - x - y$ , the depth of each leaf of  $T'_u$  in  $T(Q)$  is at least  $n - x - y + |M_u \cup \{e_u\} - E_u(e_u)| - 1 \geq n - x - y + y - x = n - 2x$ .

(c) The case  $|M_u| = x$  is similar to case (b) given above. From Lemmas 3.5 and 3.6 we conclude that the subtree rooted at  $u$  may be pruned such that each leaf in the pruned subtree has depth at least  $n - 2x$ .

Note that case (a) will never encounter a leaf node. This follows from the observation that if  $u$  is a child of  $u''$  then the pruning procedure will retain  $u$  if and only if  $P_u$  does not contain the relation  $a < b$  for any  $a$  in  $C$  and  $b$  in  $S - C$ . Hence if  $u$  is a leaf then at least  $t - |m_u| + n - t - |M_u| + |m_u||M_u|$  comparisons must have preceded  $u$  since each element in  $m_u$  must have been compared with each element in  $M_u$ . If  $|m_u| > x$  and  $|M_u| > x$ , then since  $x > 1$ , the leaf  $u$  has depth at least  $n + |m_u||M_u| - |m_u| - |M_u| > n + x^2 - 2x \geq n + h$ , contradicting our assumption on the height of  $T$ . Hence the pruning strategy will eventually encounter an internal node for which either  $|m_u| = x$  or  $|M_u| = x$ .

Thus the pruning strategy produces a tree for which every leaf has depth at least  $n - 2x$ . Hence  $T(Q)$  has at least  $2^{n-2x}$  leaves.  $\square$

Having computed a lower bound on the number of leaves in  $Q$ , we get an estimate on the number of leaves of  $T$  from the number of distinct  $Q$ 's and the number of times a specific leaf occurs in the different  $Q$ 's. We can choose the  $t$ -subset  $C$  in  $\binom{n}{t}$  ways. With each  $C$  is associated a  $T(Q)$  with at least  $2^{n-2x}$  leaves. The total number of leaves accounted for in this way is at least  $\binom{n}{t} 2^{n-2x}$ . However we must compensate for a leaf being counted more than once. Observe that if  $C$  and  $C'$  are distinct  $t$ -subsets of  $S$  corresponding to the decision trees  $T(Q)$  and  $T(Q')$ , respectively, of Lemma 3.2, then  $Q$  and  $Q'$  will have a leaf in common if and only if  $C$  and  $C'$  have exactly  $t - 1$  elements in common. For a given  $C$  there are  $t(n - t)$  distinct  $t$ -subsets of  $S$ , each different from  $C$ , that satisfy this property. Hence a leaf is counted at most  $t(n - t) + 1$  times in the summation over all  $t$ -subsets of  $S$ . This implies that  $T$  has at least

$$\frac{\binom{n}{t} 2^{n-2x}}{t(n-t)+1}$$

leaves. Since the height of  $T$  is  $n + h$ , we conclude that

$$2^{n+h} \geq \frac{\binom{n}{t} 2^{n-2x}}{t(n-t)+1}.$$

To summarize, if  $J_t(n)$  denotes our lower bound, then we have shown that

$$\begin{aligned} U_t(n) &\geq J_t(n) = n + h \\ &= n + \lg \binom{n}{t} - 2x - \lg(t(n-t) + 1) \end{aligned}$$

where  $x$  is the least positive integer satisfying  $x^2 - 2x \geq h$ . This implies that  $x$  is the least positive integer greater than or equal to  $[\lg \binom{n}{t} - \lg(t(n-t) + 1)]^{1/2}$ . Thus

$$J_t(n) = n + h = n + \lg \binom{n}{t} + O\left([\lg \binom{n}{t}]^{1/2}\right)$$

for  $t = \Omega(\lg n)$ .

**4. Comparison with Kirkpatrick's bounds.** We next establish that  $J_t(n)$  improves on Kirkpatrick's lower bounds as given by (1) for  $t > c \lg n$  and  $n > n_0$  where  $n_0$  is an integer and  $c$  a positive constant. We further show that for  $t$  in this range the improvement is  $c't$  comparisons for some  $c' > 0$ . Using Stirling's approximation for  $n!$ , a routine calculation establishes that

$$\lg \binom{n}{t} = t(\lg n - \lg t) - (n-t)(\lg(n-t) - \lg n) + O(\log t).$$

Setting  $z = t/n$  we find that over the interval  $2t - 1 \leq n < 3t$ , the difference between  $J_t(n)$  and Kirkpatrick's bound as given by (1) is  $n(-z \lg z - (1-z) \lg(1-z) - (1+z)/2) + O(\sqrt{n})$ . The function  $-z \lg z - (1-z) \lg(1-z) - (1+z)/2$  is convex over the region  $\frac{1}{3} \leq z \leq \frac{1}{2}$  and its minimum value over this interval is 0.25. This implies that our lower bound improves on Kirkpatrick's bound by at least  $0.50t + O(\sqrt{t})$  for  $t$  and  $n$  satisfying  $2t - 1 \leq n < 3t$ . For  $n \geq 3t$  we consider the sum

$$(2) \quad \sum_{j=0}^{t-2} \left[ \lg \frac{n-t+1}{t+j} \right]$$

in (1). Let  $2^k$  be the largest power of 2 that divides  $n/t$ . Then  $n/t = 2^k(1+a)$ , where  $0 \leq a < 1$  and the summand in (2) is less than or equal to  $k+1$ . We note that the summand in (2) can take the value  $k+1$  only when  $j < ta$ . This in turn implies that (2) is less than  $ta(k+1) + k(t-2-ta+1) = t(k+a) - k < t(k+a)$ . Hence the difference between  $J_t(n)$  and Kirkpatrick's lower bound for  $n \geq 3t$  is greater than

$$(3) \quad (t \lg n - t \lg t - tk - ta) + ((n-t)(\lg n - \lg(n-t)) - t) + O\left([\lg \binom{n}{t}]^{1/2}\right).$$

Since  $n = 2^k t(1+a)$  the term  $(t \lg n - t \lg t - tk - ta)$  in (3) reduces to  $t(\lg(1+a) - a)$  which is nonnegative for  $0 \leq a < 1$ . Since  $\ln(1-t/n) = -t/n - t^2/(2n^2) - O(t^3/n^3)$  for  $t/n \leq \frac{1}{3}$ , the term  $((n-t)(\lg n - \lg(n-t)) - t)$  is greater than  $((n-t)/\ln 2) \times [t/n + t^2/(2n^2)] - t$  which is greater than  $c''t$  for  $t/n \leq \frac{1}{3}$ , where  $c''$  is a positive constant. Since  $\lg \binom{n}{t} = O(t \lg n)$  we conclude that (3) is greater than  $c't$  for  $t > c \lg n$  and  $n > n_0$  for some  $c' > 0$ ,  $c > 0$  and  $n_0$  a positive integer.

## ON THE EXPECTED SUBLINEARITY OF THE BOYER-MOORE ALGORITHM\*

R. SCHABACK†

*The author gratefully dedicates this paper to the memory  
of his academic teacher, Professor H. Werner.*

**Abstract.** This paper analyzes the expected performance of a simplified version  $BM'$  of the Boyer-Moore string-matching algorithm. A probabilistic automaton  $A$ , which models the expected behavior of  $BM'$ , is set up under the assumption that both text and pattern are generated by a source which emits independent and uncorrelated symbols with an arbitrary distribution of probabilities. Formal developments lead then to the conclusion that  $A$  takes expected sublinear time in a variety of situations. The sublinear behavior can be quantitatively predicted by simple formulae involving the pattern length  $m$  and the alphabet's probabilistic properties. Finally, empirical evidence is provided which is in satisfactory accordance with the theory.

**Key words.** string searching, pattern matching, average case analysis of algorithms

**AMS(MOS) subject classifications.** 68Q25, 68P10, 68T10

**1. The problem.** Let  $\mathcal{A}$  be a finite alphabet,  $|\mathcal{A}| = n$ , and suppose strings

$$T = t_1 \cdots t_N, \quad t_i \in \mathcal{A}, \quad 1 \leq i \leq N \quad (\text{the "text"}),$$

$$S = s_1 \cdots s_m, \quad s_i \in \mathcal{A}, \quad 1 \leq i \leq m \leq N \quad (\text{the "pattern"})$$

are given. To avoid formal difficulties in later discussions, we assume  $S$  to be expanded to the left by "jokers," i.e., characters that match any other character from  $\mathcal{A}$ .

To determine the leftmost occurrence of  $S$  as a substring of  $T$  means then:

Find the smallest  $j$ ,  $m \leq j \leq N$ , such that  $s_{m-i} = t_{j-i}$  for  $0 \leq i \leq m-1$ , or output that no such  $j$  exists.

To solve this problem, Boyer and Moore [2] defined an algorithm of the following form:

```
j := m; k := 0;
REPEAT
{At this stage, k characters match:  $t_{j-i} = s_{m-i}$ ,  $0 \leq i \leq k-1$ }
  IF  $t_{j-k} = s_{m-k}$ 
  THEN  $k := k+1$ 
  ELSE BEGIN
     $j := j + \text{MOVE}(m, k, t_{j-k})$ ;
     $k := 0$ 
  END
UNTIL ( $k = m$ ) OR ( $j > N$ );
IF  $k = m$  THEN output (Pattern is found at position j)
ELSE output (No occurrence of pattern in text);
```

Variations of this algorithm depend on the function

$\text{MOVE}(m, k: \text{INTEGER}; t: \text{CHARACTER}): \text{INTEGER}$

which determines how many positions  $S$  may be moved forward along  $T$  to the next position where  $S$  can occur as a substring of  $T$ . In case  $k = 0$ , i.e., if the text character  $t = t_j$  does not match the last pattern character  $s_m$ , the pattern can be moved along the text as long as  $t$  does not occur within the pattern:

$$(1) \quad \text{MOVE}(m, 0, t) := \min \{ p \mid 1 \leq p \leq m, s_{m-p} = t \}.$$

For  $k > 0$  there are  $k$  matching characters  $s_{m-k+1} \cdots s_m = t_{j-k+1} \cdots t_j$  and we know that  $s_{m-k} \neq t_{j-k}$ . The simplest way to shift the pattern is to ignore most of this information and to match  $t_{j-k+1} = s_{m-k+1}$  with the next possible occurrence in the pattern:

$$(2) \quad \text{MOVE}(m, k, \cdot) := \text{MOVE}(0, m - k + 1, s_{m-k+1}) \quad (1 \leq k < m).$$

We use the notation  $BM'$  for the Boyer-Moore algorithm using (1) and (2) and consider the  $j$ -increment given by the MOVE function as the *progress* of the algorithm.

The original Boyer-Moore algorithm,  $BM$ , tries to match the whole subpattern  $s_{m-k+1} \cdots s_m$  with its rightmost recurrence in the pattern; an additional condition makes sure that the unsuccessful subpattern  $s_{m-k} \cdots s_m$  does not occur again:

$$\text{MOVE}^*(m, k, \cdot) := \min \left\{ p \mid \begin{array}{l} 1 \leq p \leq m, s_{m-i} = s_{m-p-i}, 0 \leq i \leq k-1 \\ s_{m-k} \neq s_{m-p-k} \text{ if } p+k < m \end{array} \right\} \quad (1 \leq k < m).$$

These definitions of MOVE formally require the pattern  $s$  to be expanded to the left by  $\max(1, m-1)$  jokers.

Since more progress may be possible when matching the rightmost occurrence of  $t = t_{j-k}$  in the subpattern  $s_1 \cdots s_{m-k}$ ,  $BM$  finally takes the maximum of  $\text{MOVE}^*(m, k, \cdot)$  and  $\text{MOVE}(m-k, 0, t)$  to define  $\text{MOVE}(m, k, t)$ . The effective construction of lookup tables for the implementation of MOVE is treated in the cited literature (e.g., [6]).

The worst-case performance of  $BM$  increases linearly with  $N$ , measured by the number of pairwise character comparisons. Knuth, Morris, and Pratt [6] first proved the bound  $7N$  in case the pattern does not occur in the text. This bound has been improved to  $4N$  by Guibas and Odlyzko [5], while the lower bound  $N - m + 1$  for **any** algorithm was established by Rivest [7]. The case of  $r$  occurrences of the pattern in the text led to the bound  $7N + 8rm - 14r$  in [6] (see also [4]), and Galil [4] introduced a variation of  $BM$  to get the bound  $14N$  for **any**  $r$ . Finally, Apostolico and Giancarlo [1] proved the bound  $2N$  for their variation of  $BM$ .

In this paper we neglect the problem of multiple occurrences of the pattern in the text and do not incorporate the corresponding variations of [4] and [1]. These are extensions for handling multiple occurrences and could be added on, if necessary. Since the occurrence of a large random pattern in a large random text is a highly improbable event, a study of the expected behavior of  $BM$  for large patterns can neglect multiple occurrences altogether.

The expected behavior of  $BM$  was studied only for the very special case of equally probable characters. The sublinearity (i.e., the expected number of character comparisons is less than  $N$ ) was proved in the original paper [2] by Boyer and Moore, while Knuth, Morris, and Pratt [6] gave a variation with expected  $\mathcal{O}(N/(m \log m))$  character comparisons. This behavior is optimal due to results of Yao [8].

This paper tries to eliminate the assumption of equally probable characters and to bridge the gap between theory and applications. For patterns and texts from natural languages the observed average behavior of  $BM$  and  $BM'$  is clearly sublinear, and we give useful formulae that predict this behavior.

In addition, the  $\mathcal{O}(N/(m \log m))$  result of [6] is carried over to the general case of arbitrary character probabilities, while a blocked variation of the simplified algorithm  $BM'$  will need  $\mathcal{O}(N/(m \log^2 m))$  comparisons.

**2. Probabilistic assumptions.** In the sequel, we consider an alphabet  $\mathcal{A}$  with characters  $c$  having probabilities

$$(3) \quad 0 < p(c) < 1, \quad \sum_{c \in \mathcal{A}} p(c) = 1.$$

We use  $q$  to denote the probability  $\sum_{c \in \mathcal{A}} p^2(c)$  that two randomly chosen characters match.

We switch now from  $BM'$  to a **completely randomized** model algorithm by assuming that

(1) any reference to some character of the text or the pattern will produce a (possibly new) random character;

(2) the MOVE  $(m, k, t)$  function is replaced by its expected value  $M(m, k)$  for all characters  $t$  and patterns  $S \in \mathcal{A}^m$ .

The first assumption means that each reference to some  $t_{j-k}$  or  $s_{m-k}$  acts like a procedure call that generates a random character independent of  $S, T, k$ , and  $j$ .

This seems to be quite restrictive and unrealistic at first glance, but we shall see later that the progress of the algorithm is so large that multiple references to text characters are rare events under a variety of circumstances. Therefore, the randomized algorithm can be expected to perform on its random data sources in the same way as the deterministic version of  $BM'$  performs on an input that is randomly chosen before execution. Furthermore, later results will show that for alphabets with the probabilistic properties of natural languages, the algorithm  $BM'$  spends most of the time comparing the last pattern character  $s_m$  with text characters  $t_i$  for values of  $i$  that are far away from each other. Then the randomized algorithm will model the behavior of the deterministic algorithm quite well even for natural languages, since natural language characters sampled over large intervals can be considered as random characters with fixed probabilities.

Our randomized algorithm replaces the comparison of  $t_{j-k}$  with  $s_{m-k}$  with a random decision between two alternatives with probabilities  $q$  and  $1 - q$ , respectively. Moreover, the terminating conditions of  $BM'$  (including detection of the pattern and exhaustion of the text) are completely ignored in order to simplify the following discussion. Thus, we get the following algorithm A:

```

j := m; k := 0;
REPEAT
  With probability q : k := k + 1
  ELSE (with probability 1 - q)
    BEGIN
      j := j + M(m, k)
      k := 0
    END
UNTIL FALSE;

```

The variable  $k$  in the algorithm A denotes a "state" corresponding to the situation of  $k$  matches in  $BM$  and  $BM'$ . In this sense A is a probabilistic automaton with an unbounded number of states. Transitions from state  $k$  to state  $k + 1$  occur with the probability  $q$  of a match, yielding no progress in  $j$ . With the probability  $1 - q$  of a mismatch, transitions from state  $k$  to state zero with progress  $M(m, k)$  occur. Reaching state  $m$  corresponds to an occurrence of the pattern in the text; higher states of A are purely formal. Each REPEAT-cycle will be called a *step*, and since  $BM$  has one character comparison for each step, we have one unit of "cost" per step in A. Expected sublinearity means then that the expected progress per step is larger than one.

**3. Theoretical considerations.** The expected behavior of  $A$  is described by the following.

LEMMA 3.1. *The probability  $\mu_{rk}$  that  $A$  is in state  $k$  after  $r$  steps is*

$$\mu_{rk} = q^k(1-q) \quad \text{for all } r > k \geq 0.$$

*The expected progress counted in states up to  $m-1$  is*

$$(4) \quad E_m = (1-q)^2 \sum_{k=0}^{m-1} q^k M(m, k)$$

*after at least  $m$  steps.*

*Proof.* Algorithm  $A$  starts in state 0 with probability one. Then the probability  $\mu_{rk}$  of  $A$  being in state  $k$  after  $r$  steps is

$$\begin{aligned} \mu_{rk} &= q^k(1-q), & 0 \leq k < r, \\ \mu_{rr} &= q^r, \\ \mu_{rk} &= 0, & k > r, \end{aligned}$$

as is easily seen by induction. After  $k$  steps, transitions from state  $k$  to state 0 occur with probabilities  $(1-q)^2 q^k$ , and these lead to the progress  $M(m, k)$ . Summing up gives (4).  $\square$

The lemma implies the following:

- The transient start phase of algorithm  $A$  to reach a step-independent probability for states  $0 \cdots m-1$  is short ( $m$  steps).
- The finiteness of the number  $m+1$  of actual states of  $BM$  and  $BM'$  as opposite to the infinite number of states of  $A$ , does not matter much because choosing small values of  $q$  ensures that higher states of  $A$  are very improbable.

We now evaluate  $M(m, k)$ .

LEMMA 3.2. *If  $S$  is a random string of length  $m$  (with a joker  $s_0$  added) and  $c$  is a random character, the random function*

$$f_m(c, S) = \min \{k \mid 1 \leq k \leq m, s_{m-k} = c\}$$

*has the expected value*

$$(5) \quad F_m = |\mathcal{A}| - \sum_{c \in \mathcal{A}} (1-p(c))^m.$$

*Furthermore,*

$$(6) \quad \begin{aligned} M(m, 0) &= F_m, \\ M(m, k) &= F_{m-k+1} \quad (1 \leq k < m), \\ M(m, k) &= 0 \quad \text{otherwise.} \end{aligned}$$

*Proof.* Clearly,  $f_m$  has the expected value

$$F_m = \sum_{i=1}^{m-1} i \cdot \sum_{c \in \mathcal{A}} (1-p(c))^{i-1} \cdot p^2(c) + m \cdot \sum_{c \in \mathcal{A}} (1-p(c))^{m-1} p(c),$$

because the progress  $i$ ,  $1 \leq i < m$ , implies  $(i-1)$  mismatches and one match, while  $i = m$  implies  $m-1$  mismatches (note that we ignore  $s_m$ ). A little calculation gives (5), and (1), (2) imply (6).  $\square$

We can now write (4) as

$$(7) \quad E_m = (1 - q)^2 \left( F_m + \sum_{k=1}^{m-1} q^k F_{m-k+1} \right)$$

where the values  $F_k$  are available from (5).

For small values of  $m$  we can use (7) and (5) directly to estimate the efficiency of the algorithm  $A$ . Using the probability distributions of characters of natural languages, we can tabulate (7) and (5) via (3). For example, Table 1 exhibits the corresponding values for the distribution of the 26 characters of the English language (data from [3]). Since later examples will show that  $A$  closely resembles  $BM$  and  $BM'$  even for natural languages, the user can easily estimate the expectable progress of  $BM$  and  $BM'$  by looking at such a table. Average patterns  $S$  of length 20 will, for instance, be moved forward about 11 characters per single-character comparison, when searched for in average English texts.

TABLE 1  
 $F_m$  and  $E_m$  for the English alphabet,  $q = 0.0658$ ,  $n = |A| = 26$ .

$m$	$F_m$	$E_m$	$m$	$F_m$	$E_m$
1	1.0000	0.8728	21	12.1401	11.3402

19	11.4916	10.7342	39	16.0279	14.9730
20	11.8236	11.0445	40	16.1756	15.1111

We now prove some lower bounds of  $F_m$ . First we concentrate on the case of small patterns.

LEMMA 3.3. For  $m \leq 1/q$ ,

$$(8) \quad F_m \geq m - m^2 q / 2 \geq m / 2.$$

*Proof.* For any real number  $x \geq 0$  we have

$$1 - (1 - x)^k \geq 1 - e^{-kx} \geq kx - \frac{k^2}{2} x^2$$

and (8) follows from (5).  $\square$

The progress of  $A$  for small patterns from large alphabets with small values of  $q$  (this occurs for natural languages) can be predicted by a useful rule of thumb.

THEOREM 3.1. *The algorithm A has expected progress*

$$E_m \geq (1 - q)(1 - q^2)(m - m^2q/2) \geq (1 - q)(1 - q^2)m/2,$$

$$E_m \approx m/2 \quad \text{for small } q$$

per character comparison, provided that  $2 \leq m \leq 1/q$ .

*Proof.* Combine the two major terms of (7) with (8).  $\square$

In Table 1,  $1/q \approx 15.2$ , so Theorem 3.1 is applicable for pattern lengths up to 15, when the probability distribution of characters in English texts is assumed. Within this range, expected progress is at least about  $m/2$ . This observation for a series of practical cases was the starting point for our investigation.

We now treat the case of large  $m$  but still keep the alphabet fixed. Our main result in this direction is the following.

THEOREM 3.2. *A distribution of  $n$  character probabilities  $p_i$  leads to sublinearity of A for sufficiently large pattern lengths  $m$ , if  $q = \sum_{i=1}^n p_i^2$  satisfies*

$$n(1 - q) > 1.$$

This is the case, if

$$(9) \quad q < \hat{q}_n := 1 - \frac{1}{n}.$$

The proof will be a consequence of the lemma following below, if  $m$  is large enough. If we sort the characters of  $\mathcal{A}$  in the form

$$1 > p_1 \geq p_2 \geq \dots \geq p_n > 0, \quad n = |\mathcal{A}|,$$

then there is some  $\gamma$  satisfying

$$(10) \quad q < \gamma < 1, \quad 1 - p_n \leq \gamma,$$

and we get the following.

LEMMA 3.4.

$$(11) \quad E_m \geq n(1 - q) \left( 1 - q^m - \frac{\gamma^{m+1}}{\gamma - q} \right).$$

*Proof.* Equation (5) implies

$$(12) \quad F_m \geq n(1 - (1 - p_n)^m) \geq n(1 - \gamma^m).$$

Using this in (7) gives

$$(13) \quad \begin{aligned} E_m &\geq (1 - q)^2 \sum_{k=0}^{m-1} q^k F_{m-k} \\ &\geq (1 - q)^2 n \sum_{k=0}^{m-1} q^k (1 - \gamma^{m-k}) \\ &= (1 - q)^2 \left( n \frac{1 - q^m}{1 - q} - n \gamma^m \frac{1 - q^m / \gamma^m}{1 - q / \gamma} \right) \\ &\geq n(1 - q) \left( 1 - q^m - \frac{\gamma^{m+1}}{\gamma - q} \right). \end{aligned}$$

Expected sublinearity of  $A$  means that the expected progress  $E_m$  per character comparison is greater than one. Equation (11) shows that for large patterns the product  $n(1 - q)$  occurs as the maximal expected progress; this proves Theorem 3.2.  $\square$

*Remarks.* (1) The model and the algorithm are in state 0 with probability circa  $1 - q$ . Higher states  $k$  have probability  $q^k(1 - q)$  and are very improbable indeed for small values of  $q$ .

(2) In state 0 the algorithms  $BM$  and  $BM'$  coincide. If  $A$  models  $BM'$  in state 0, then it models  $BM$  in that state, too.

(3) In state 0 the last character  $s_m$  of  $S$  is responsible for the progress. In case of sublinearity this character is tested against different characters from  $T$  in the major part of the character comparisons. Then the probabilistic assumptions are not very restrictive; the model  $A$  will closely resemble  $BM'$  (and  $BM$ ) in state 0 (and in general, because other states are improbable). Furthermore, the behavior of the model  $A$  and the algorithm  $BM'$  then is independent of the probability of pairs of characters; the single-character probabilities are sufficient to describe the situation, even for natural language strings.

(4) A value of  $q \approx 1$  spoils the performance of  $A$  and the quality of  $A$  as a model of  $BM'$ , while a large alphabet size  $n = |\mathcal{A}|$  and a large pattern size  $m$  act favorably.

(5) Inequality (11) shows that the size of the alphabet times the probability of a mismatch is the limiting factor for the efficiency of  $A$  for large patterns. This indicates that further speedup requires large alphabets or blocking strategies that let  $\mathcal{A}$  increase with  $m$ .

(6) The case  $q \approx 1$  would imply that a single character must have a probability close to one. Since always  $q \geq 1/n$  in an  $n$ -character alphabet, the case of a binary alphabet cannot lead to an efficiency larger than one and attains efficiency one only if both characters have equal probabilities. In this case, blocking will improve the performance of the algorithm (see below).

(7) Uniformly distributed character probabilities lead to  $q = 1/n$  and the conditions  $m \leq n$  and  $n > 2$  in Theorems 3.1 and 3.2, respectively.

(8) For states  $k \geq 1$  the efficiency of  $BM$  will exceed that of  $BM'$  (and  $A$ ) locally, because it makes at least the progress of  $BM'$  after any single specific comparison. However,  $BM$  is not superior for every text and pattern, because it may run into unfavorable regions of the text which the simplified version may happen to avoid.

To get a further speedup of the pattern-matching process, large alphabets with small values of  $q$  are needed. Therefore, we consider a  $b$ -fold blocking of the alphabet  $\mathcal{A}$ ,  $|\mathcal{A}| = n$ ,  $1 \leq b < m$  and study first the blocked  $BM$  version proposed by Knuth, Morris, and Pratt ([6, p. 341]). Their result (and proof technique) can be generalized as follows.

**THEOREM 3.3.** *There is an algorithm for pattern matching that inspects  $\mathcal{O}(N(\log_{1/q} m/m))$  characters in a random text with arbitrarily distributed characters.*

*Proof.* We follow [6] to combine steps of  $BM$  with an arbitrary linear worst-case algorithm. Each iteration shifts the pattern at least  $m - b$  positions to the right and consists of the following elementary steps:

(1) The last  $b$  characters of the pattern are compared with a block  $B$  of  $b$  text characters.

(2) In case of match, proceed to (4).

In case of mismatch, a function similar to (1) can be used to decide whether  $B$  occurs in the pattern at all.

If this is not the case, the pattern can be moved  $m - b$  positions along the text and the next iteration can be started.

Otherwise proceed to (3).

(3) In this case two blocks of pattern and text match somewhere; we ignore the possible shift given by step (2) and proceed to (4).

- (4) Use a linear worst-case algorithm to move the pattern at least  $m - b$  positions to the right (including the determination of possible occurrences of the pattern in the text) and perform another iteration. This step ignores the fact that there is some match of certain blocks of the pattern and the text.

Note that (1) and (2) are the *BM* part of the algorithm; they are equivalent to a state zero step of *A* on the blocked alphabet. Steps (3) and (4) use no more than  $2m$  characters of the text and therefore require an amount  $c \cdot m$  of work.

For small  $b$  and large  $m$  there will be no overlap of text blocks sampled in step (1) of the iteration. We can therefore assume that these parts of text and pattern are stochastically independent.

**LEMMA 3.5.** *The probability to match a random block  $B$  of  $b$  characters with an arbitrary block of  $b$  characters in a random pattern of  $m \geq b$  characters does not exceed  $(m - b + 1)q^b$ .*

*Proof.* There are  $m - b + 1$  possible positions for  $B$  to occur as a block within the pattern. The probability of occurring at a fixed position is  $q^b$ . The product of these numbers is a crude upper bound for the situation in the assertion.  $\square$

The expected progress of the algorithm in each iteration cycle is at least  $m - b$ , and the expected number of character comparisons is at most

$$(m - b + 1) \cdot q^b \cdot cm + 1 \cdot b$$

where we simply took the upper bound 1 for the probability of a mismatch of a random block. Now we use

$$b := \lfloor 2 \log_{1/q} m \rfloor$$

to get  $q^b \approx m^{-2}$ , and the expected efficiency will be

$$\frac{m - b}{\text{const.} + b} = \mathcal{O}(m / \log_{1/q} m). \quad \square$$

We do not lose too much if we simply apply the following blocked version of *A*.

**THEOREM 3.4.** *If  $A$  works on  $b$ -fold blocks in  $b$  parallel versions with  $b \approx \log_{1/q} m$ , the expected number of single-character comparisons is  $\mathcal{O}(N / m \log_{1/q}^2 m)$ .*

*Proof.* We apply former results for the alphabet  $\mathcal{A}^b$  and first use (8) to get

$$F_r \geq r - \frac{r^2}{2} q^b$$

for  $r$  blocks of  $b$  characters. We ignore the higher-order terms in  $E_r$  and find the lower bound

$$E_r \geq (1 - q^b)^2 F_r \geq r(1 - q^b)^2 \left(1 - \frac{r}{2} q^b\right).$$

Now consider a string of length  $m < q^{-m}$  over  $A$  and a blocking factor  $b$  with

$$m < \frac{1}{q^b}, \quad \text{i.e., } b \geq \lceil \log_{1/q} m \rceil, \quad 1 \leq b \leq m.$$

For simplicity, we can then define  $r \geq 1$  by

$$rb \leq m < (r + 1)b$$

and consider  $r$  blocked steps in our efficiency measure, since the efficiency is monotonic with respect to pattern length. Then

$$E_r \geq \frac{1}{2} \left( \frac{m}{b} - 1 \right) \left( 1 - \frac{1}{m} \right)^2,$$

using

$$rq^b < \frac{r}{m} \leq \frac{1}{b} \leq 1,$$

is a lower bound of our efficiency measure progress/cost in both block-by-block or character-by-character units. Since we need  $b$  versions of the algorithm, one for each block alignment, the total efficiency  $E_{m,b}$  will be at least

$$(14) \quad E_{m,b} \geq \frac{m}{2} \frac{1}{b} \left( \frac{1}{b} - \frac{1}{m} \right) \left( 1 - \frac{1}{m} \right)^2.$$

For  $b^* = \lceil \log_{1/q} m \rceil$  we have  $b^* \leq 1 + \log_{1/q} m$  and get

$$\begin{aligned} E_{m,b^*} &\geq \frac{m}{2} \frac{1}{1 + \log_{1/q} m} \left( \frac{1}{1 + \log_{1/q} m} - \frac{1}{m} \right) \left( 1 - \frac{1}{m} \right)^2 \\ &= \mathcal{O} \left( \frac{m}{\log_{1/q}^2 m} \right) \quad \text{for } m \rightarrow \infty, \end{aligned}$$

without any restrictions on  $n$ ,  $m$ , and  $q$  except  $m < q^{-m}$ , which is always satisfied for large  $m$ .  $\square$

The blocking strategy depends on  $m$  and  $q$ ; for instance, equal probabilities for 0 and 1 in the binary alphabet give  $q = \frac{1}{2}$  and  $b^* = \lceil \log_2 m \rceil$ . We can use (14) for the usual blocking factors  $b = 4, 8, 16, 32$ , provided that  $m < q^{-b}$  holds.

**4. Empirical observations.** To check the validity of our model algorithm  $A$  we tested  $A$ ,  $BM$ , and  $BM'$  on a variety of inputs. For a fixed alphabet  $\mathcal{A}$  with a specified character distribution we generated large samples of random strings  $S$  and  $T$  for values of  $m$  between 2 and 40. For each  $m$  we plotted the expected efficiency (4) of  $A$  versus the means of the observed efficiencies of  $BM$  and  $BM'$  (see Figs. 1–3). For a binary alphabet (see Fig. 1)  $BM$  exceeds  $BM'$  and  $A$  in efficiency. This is due to the fact that the efficiency of  $BM$  may well exceed the value of  $(1 - q) \cdot |\mathcal{A}| = 0.49374 \cdot 2 = 0.98748$ , which essentially bounds the efficiency of its competitors. But our theoretical results indicate that blocking should be used to avoid  $m \gg |\mathcal{A}|$ , and therefore this example is of minor significance.

For larger alphabets ( $|\mathcal{A}| = 8$  in Fig. 2,  $|\mathcal{A}| = 26$  in Fig. 3) the efficiency as modeled by  $A$  does resemble the actual efficiency of both versions of the Boyer–Moore algorithm quite well (the vertical lines denote confidence intervals at the 1 percent error level), but there is a small systematic overestimation of the efficiency of the simplified version that may be credited to multiple evaluations.

For the comparison on natural language strings we used a text of 4785 ASCII characters from a LATEX source of part of a chapter of a course in computer science, written in German. We chose a random sample of patterns occurring in the text (Fig. 4) and in a different chapter of the same course (Fig. 5). Then we plotted the expected efficiency of  $A$  against the observed efficiencies of  $BM$  and  $BM'$  as before. The results indicate once again that  $A$  closely describes the behavior of  $BM$  and  $BM'$ . Of course the examples with occurring patterns (Fig. 4) show an overestimation of the efficiency of  $A$ , because unexpectedly high states occur.

## LOCALITY, COMMUNICATION, AND INTERCONNECT LENGTH IN MULTICOMPUTERS\*

PAUL M. B. VITÁNYI†

**Abstract.** We derive a lower bound on the average interconnect (edge) length in  $d$ -dimensional embeddings of arbitrary graphs, expressed in terms of diameter and symmetry. It is optimal for all graph topologies we have examined, including complete graph, star, binary  $n$ -cube, cube-connected cycles, complete binary tree, and mesh with wraparound (e.g., torus, ring). The lower bound is technology independent, and shows that many interconnection topologies of today's multicomputers do not scale well in the physical world ( $d = 3$ ). The new proof technique is simple, geometrical, and works for wires with zero volume, e.g., for optical (fibre) or photonic (fibreless, laser) communication networks. Apparently, while getting rid of the "von Neumann" bottleneck in the shift from sequential to nonsequential computation, a new communication bottleneck arises because of the interplay between locality of computation, communication, and the number of dimensions of physical space. As a consequence, realistic models for nonsequential computation should charge extra for communication, in terms of time and space.

**Key words.** multicomputers, complexity of computation, locality, communication, wire length, general communication network, edge-symmetric graph, binary  $n$ -cube, cube-connected cycles, tree, Euclidean embedding, scalability, optical computing

**1. The tyranny of physical space.** In many areas of the theory of parallel computation we meet graph-structured computational models. These models encourage the design of parallel algorithms where the cost of communication is largely ignored. Yet it is well known that the cost of computation—in both time and space—vanishes with respect to the cost of communication in parallel or distributed computing. As multiprocessor systems with really large numbers of processors start to be constructed, this effect becomes more and more apparent. Thinking Machines Corporation of Cambridge, Massachusetts, has just marketed the "Connection Machine," a massive multiprocessor parallel computer. The prototype contains microscopically fine-grained processor/memory cells, 65,536 of them, each with 4,096 bits of memory and a simple arithmetical unit. The communication network connecting the processors is packet-switched and based on the binary 16-cube. (A binary  $n$ -cube network consists of  $2^n$  nodes, each node identified by an  $n$ -bit name, and an edge between nodes which differ in a single bit.) This is implemented by packing a cluster of 16 processors and one router circuit on a single chip. The 4,096 routers (in *casu* chips) are connected by 24,576 bidirectional wires in the pattern of the binary 12-cube. The last chapter of [3], "New Computer Architectures and their Relationship to Physics or, Why Computer Science is No Good," expresses the dissatisfaction of the designers with traditional computer science, "which abstracts the wire away into a costless and volumeless idealized connection. [The] old models do not impose a locality of connection, even though the real world does. . . . In classical computation the wire is not even considered. In current engineering it may be the most important thing." Here we shall argue that,

while getting rid of the so-called “von Neumann” bottleneck,<sup>1</sup> in the shift from serial to nonserial computing, we run into a new *communication* bottleneck due to the three-dimensionality of physical space.

Models of parallel computation that allow processors to randomly access a large shared memory, such as PRAMs, or rapidly access a large number of processors, such as NC computations, can provide new insights in the inherent parallelizability of algorithms to solve certain problems.<sup>2</sup> For instance, in the form of distributing copies of the entire problem instance, or pieces of the problem instance, among an exponential number of processors in a linear number of steps (i.e., the number of steps in the longest causal chain is linear). Or, as in NC, among a polynomial number of processors in a polylogarithmic number of steps. This sometimes leads to the obscure thought that VLSI technology opens the way to implement tree machines which solve NP-complete problems in linear time. Now, the way a problem instance can be divided and partial answers put together may give genuine insight into its parallelizability. However, it *cannot* give a reduction from an asymptotic exponential time best algorithm in the sequential case to an asymptotic polynomial time algorithm in *any* parallel case. At least, if by “time” we mean time. This is a folklore fact dictated by the Laws of Nature. Namely, if the parallel algorithm uses  $2^n$  processing elements, regardless of whether the computational model assumes bounded fan-in and fan-out or not, it cannot run in time polynomial in  $n$ , because *physical space* has us in its tyranny. Namely, if we use  $2^n$  processing elements of, say, unit size each, then the tightest they can be packed is in a three-dimensional sphere of volume  $N = 2^n$ . Assuming that the units have no “funny” shapes, e.g., are spherical themselves, no unit in the enveloping sphere can be closer to all other units than a distance of radius  $R$  (Fig. 1),

$$(1.1) \quad R = \left( \frac{3N}{4\pi} \right)^{1/3}.$$

FIG. 1

<sup>1</sup> When the operations of a computation are executed serially in a single Central Processing Unit (CPU), each one entails a “fetch data from memory to CPU; execute operation in CPU; store data in memory” cycle. The cost of this cycle, and therefore of the total computation, is dominated by the cost of the memory accesses which are essentially operation-independent. This is called the “von Neumann” bottleneck, after the brilliant Hungarian mathematician John von Neumann.

<sup>2</sup> For example, in [10] it is demonstrated that any program that requires  $T$  steps on a CRCW PRAM with  $n$  processors and  $m$  shared variables ( $m$  polynomial in  $n$ ) can be simulated by a bounded degree network of  $n$  processors such as the Ultracomputer [7] that runs in deterministic “time”  $O(T(\log n)^2 \log \log n)$  steps.

Unless there is a major advance in physics, it is impossible to transport signals over  $2^{\alpha n}$  ( $\alpha > 0$ ) distance in polynomial  $p(n)$  time. In fact, the assumption of the bounded speed of light says that the lower time bound on *any* computation using  $2^n$  processing elements is  $\Omega(2^{n/3})$  outright. Or, for the case of NC computations which use  $n^\alpha$  processors,  $\alpha > 0$ , the lower bound on the computation time is  $\Omega(n^{\alpha/3})$ .<sup>3</sup> Science fiction buffs may want to keep open the option of embedding circuits in hyper dimensions. Counter to intuition, this does not help—at least, not all the way (see the Appendix). The situation is worse than it appears. At present, many popular multicomputer architectures are based on highly symmetric communication networks with small diameter. Like all networks with small diameter, such networks will suffer from the communication bottleneck above, i.e., they necessarily contain *some* long interconnects (embedded edges). However, the desirable fast permutation properties of symmetric networks do not come free, since they require that the average of *all* interconnects is long. (Note that “embedded edge,” “wire,” and “interconnect” are used synonymously.) This brings us to the main topic of this paper, the analysis of the *amount of wire required*. To prevent arguments that the results have little practical importance because they hold only asymptotically, or because processors are huge and wires thin, we calculate precisely without hidden constants<sup>4</sup> and assume that wires have length but no volume and can pass through everything. The key Theorem 2 in the next section gives a lower bound on the *average* edge length for *arbitrary* graphs that is arguably optimal.

Let us illustrate the novel approach with a popular architecture, say the *binary n-cube*. Recall that this is the network with  $N = 2^n$  nodes, each of which is identified by an  $n$ -bit name. There is a two-way communication link between two nodes if their identifiers differ by a single bit. The network is represented by an undirected graph  $C = (V, E)$ , with  $V$  the set of nodes and  $E \subseteq V \times V$  the set of edges, each edge corresponding with a communication link. There are  $n2^{n-1}$  edges in  $C$ . Let  $C$  be embedded in three-dimensional Euclidean space, each node as a sphere with unit volume. The distance between two nodes is the Euclidean distance between their centers. Let  $x$  be any node of  $C$ . There are at most  $2^n/8$  nodes within Euclidean distance  $R/2$  of  $x$ , with  $R$  as in (1.1). Then, there are  $\geq 7 \cdot 2^n/8$  nodes at Euclidean distance  $\geq R/2$  from  $x$  (Fig. 2). Construct a spanning tree  $T_x$  in  $C$  of depth  $n$  with node  $x$  as the root. Since the binary  $n$ -cube has diameter  $n$ , such a shallow tree exists. There are  $N$  nodes in  $T_x$ , and  $N - 1$  paths from root  $x$  to another node in  $T_x$ . Let  $P$  be such a path, and let  $|P|$  be the *number of edges* in  $P$ . Then  $|P| \leq n$ . Let  $length(P)$  denote the Euclidean length of the embedding of  $P$ . Since  $7/8$ th of all nodes are at Euclidean distance at least  $R/2$  of root  $x$ , the average of  $length(P)$  satisfies

$$(N - 1)^{-1} \sum_{P \in T_x} length(P) \geq \frac{7R}{16}.$$

The average Euclidean length of an embedded edge *in a path*  $P$  is bounded below as follows:

$$(1.2) \quad (N - 1)^{-1} \sum_{P \in T_x} \left( |P|^{-1} \sum_{e \in P} length(e) \right) \geq \frac{7R}{16n}.$$

<sup>3</sup> It is sometimes argued that this effect is significant for large values of  $n$  only, and therefore can safely be ignored. However, in the theory of computation many results are of asymptotic nature, i.e., they hold only for large values of  $n$ , so the effect is especially relevant there.

<sup>4</sup>  $\Omega$  is used sometimes to simplify notation. The constant of proportionality can be reconstructed easily in all cases, and is never very small.

FIG. 2. At most 1/8th of all nodes in the large sphere are also contained in the small sphere centered on  $x$ .

This does *not* give a lower bound on the average Euclidean length of an edge, the average taken *over all edges* in  $T_x$ . To see this, note that if the edges incident with  $x$  have Euclidean length  $7R/16$ , then the average edge length *in each path* from the root  $x$  to a node in  $T_x$  is  $\geq 7R/16n$ , even if all edges not incident with  $x$  have length 0. However, the average edge length *in the tree* is dominated by the many short edges near the leaves, rather than the few long edges near the root. In contrast, in the case of the binary  $n$ -cube, because of its symmetry, if we squeeze a subset of nodes together to decrease local edge length, then other nodes are pushed farther apart increasing edge length again. We can make this intuition precise.

LEMMA 1. *The average Euclidean length of the edges in the three-space embedding of  $C$  is at least  $7R/(16n)$ .*

*Proof.* Denote a node  $a$  in  $C$  by an  $n$ -bit string  $a_1a_2 \cdots a_n$ , and an edge  $(a, b)$  between nodes  $a$  and  $b$  differing in the  $k$ th bit by

$$(a_1 \cdots a_{k-1}a_k a_{k+1} \cdots a_n, a_1 \cdots a_{k-1}(a_k \oplus 1)a_{k+1} \cdots a_n)$$

where  $\oplus$  denotes modulo 2 addition. Since  $C$  is an undirected graph, an edge  $e = (a, b)$  has two representations, namely  $(a, b)$  and  $(b, a)$ . Consider the set  $A$  of automorphisms  $\alpha_{v,j}$  of  $C$  consisting of

(1) modulo 2 addition of a binary  $n$ -vector  $v$  to the node representation, followed by

(2) a cyclic rotation over distance  $j$ .

Formally, let  $v = v_1v_2 \cdots v_n$ , with  $v_i = 0, 1$  ( $1 \leq i \leq n$ ), and let  $j$  be an integer  $1 \leq j \leq n$ . Then  $\alpha_{v,j}: V \rightarrow V$  is defined by

$$\alpha_{v,j}(a) = b_{j+1} \cdots b_n b_1 \cdots b_j$$

with  $b_i = a_i \oplus v_i$  for all  $i$ ,  $1 \leq i \leq n$ .

Consider the spanning trees  $\alpha(T_x)$  isomorphic to  $T_x$ ,  $\alpha \in A$ . The argument used to obtain (1.2) implies that for *each*  $\alpha$  in  $A$  separately, in each path  $\alpha(P)$  from root  $\alpha(x)$  to a node in  $\alpha(T_x)$ , the average of  $\text{length}(\alpha(e))$  over all edges  $\alpha(e)$  in  $\alpha(P)$  is at least  $7R/16n$ . Averaging (1.2) additionally over all  $\alpha$  in  $A$ , the same lower bound applies:

$$(1.3) \quad (N \log N)^{-1} \sum_{\alpha \in A} \left[ (N-1)^{-1} \sum_{P \in T_x} \left( |P|^{-1} \sum_{e \in P} \text{length}(\alpha(e)) \right) \right] \geq \frac{7R}{16n}.$$

Now fix a particular edge  $e$  in  $T_x$ . We sum  $length(\alpha(e))$  over all  $\alpha$  in  $A$ , and show that this sum equals twice the total edge length. Together with (1.3), this will yield the desired result. For each edge  $f$  in  $C$  there are  $\alpha_1, \alpha_2 \in A, \alpha_1 \neq \alpha_2$ , such that  $\alpha_1(e) = \alpha_2(e) = f$ , and for all  $\alpha \in A - \{\alpha_1, \alpha_2\}, \alpha(e) \neq f$ . (For  $e = (a, b)$  and  $f = (c, d)$  we have  $\alpha_1(a) = c, \alpha_1(b) = d$ , and  $\alpha_2(a) = d, \alpha_2(b) = c$ .) Therefore, for each  $e \in E$ ,

$$\sum_{\alpha \in A} length(\alpha(e)) = 2 \sum_{f \in E} length(f).$$

Then, for any path  $P$  in  $C$ ,

$$(1.4) \quad \sum_{e \in P} \sum_{\alpha \in A} length(\alpha(e)) = 2|P| \sum_{f \in E} length(f).$$

Rearranging the summation order of (1.3), and substituting (1.4), yields the lemma.  $\square$

**2. Interconnect length in Euclidean space.** Deriving the total required wire length for embeddings of networks in Euclidean space, I will not make any assumptions about the volume of a wire of unit length, or the way they are embedded in space. Compare this with previous VLSI-related arguments (see e.g., [9]) which are the only other ones on this issue known to me. It is consistent with our results that wires have zero volume, and that infinitely many wires pass through a unit area. Concretely, the problem is posed as follows. Let  $G = (V, E)$  be a finite undirected graph, without loops or multiple edges, embedded in Euclidean  $d$ -space. (For the physical space in which we put our computers,  $d = 3$ .) Let each embedded node have unit volume. For convenience of the argument, each node is embedded as a sphere, and is represented by the single point in the center. The distance between a pair of nodes is the Euclidean distance between the points representing them. The length of the embedding of an edge between two nodes is the distance between the nodes. How large does the average edge length need to be?

Theorem 2 expresses a lower bound on this quantity for any graph, in terms of certain symmetries and diameter. The new argument is based on graph automorphism, graph topology, and Euclidean metric. For each graph topology I have examined, the resulting lower bound turned out to be sharp. This includes the binary  $n$ -cube, cube-connected cycles (CCC), complete graph, star, complete binary tree, and meshes with wraparound such as ring and torus. It could be that the lower bound is optimal in general. All mentioned graphs, except the cube-connected cycles and tree, exhibit a type of symmetry called edge-symmetry. Because of the significance of this class of graphs, in Corollary 4 we set off a lower bound on the average interconnect length for edge-symmetric graphs in general.

**2.1. Lower bound based on symmetry and diameter.** What symmetry of a graph yields large edge length? Not that of the complete binary tree. There the diameter is small, yet the average Euclidean length of an embedded edge is  $O(1)$ . This is borne out by the familiar  $H$ -tree layout [9], where the average edge length is less than 3 or 4. The symmetry property we are after is "edge-symmetry." We recall the definitions from [2]. Let  $G = (V, E)$  be a simple undirected graph, and let  $\Gamma$  be the automorphism group of  $G$ . Two edges  $e_1 = (u_1, v_1)$  and  $e_2 = (u_2, v_2)$  of  $G$  are similar if there is an automorphism  $\gamma$  of  $G$  such that  $\gamma(\{u_1, v_1\}) = \{u_2, v_2\}$ . We consider only connected graphs. The relation "similar" is an equivalence relation, and partitions  $E$  into non-empty equivalence classes, called orbits,  $E_1, \dots, E_m$ . We say that  $\Gamma$  acts transitively on each  $E_i, i = 1, \dots, m$ . A graph is edge-symmetric if every pair of edges are similar ( $m = 1$ ). The following property of orbits is obvious.

*Property.* For each pair of edges  $e_1, e_2 \in E_i$ , the set  $\{\gamma \in \Gamma: \gamma(e_1) = e_2\}$  has  $|\Gamma|/|E_i|$  elements,  $i = 1, \dots, m$ . (Hint: Let  $0 \in E_i$  and  $\Gamma_0 = \{\gamma \in \Gamma: \gamma(0) = 0\}$ . For  $e, f \in E_i$ , define  $\gamma_{ef} \in \Gamma$  by  $\gamma_{ef}(e) = f$ . Fix  $e$  and  $f$  arbitrarily. Then  $\gamma \in \gamma_{e0}\Gamma_0\gamma_{0f}$  if and only if  $\gamma_{e0}^{-1}\gamma\gamma_{0f}^{-1} \in \Gamma_0$ .)

We need the following notions. Let  $D < \infty$  be the *diameter* of  $G$ . If  $x$  and  $y$  are nodes, then  $d(x, y)$  denotes the number of edges in a *shortest path* between them. For  $i = 1, \dots, m$ , define  $d_i(x, y)$  as follows. If  $(x, y)$  is an edge in  $E_i$  then  $d_i(x, y) = 1$ , and if  $(x, y)$  is an edge not in  $E_i$  then  $d_i(x, y) = 0$ . Let  $\Pi$  be the set of shortest paths between  $x$  and  $y$ . If  $x$  and  $y$  are not incident with the same edge, then  $d_i(x, y) = |\Pi|^{-1} \sum_{P \in \Pi} \sum_{e \in P} d_i(e)$ . Clearly,

$$(2.1) \quad d_1(x, y) + \dots + d_m(x, y) = d(x, y) \leq D.$$

Denote  $|V|$  by  $N$ . The *i*th orbit frequency is

$$\delta_i = N^{-2} \sum_{x, y \in V} \frac{d_i(x, y)}{d(x, y)},$$

$i = 1, \dots, m$ . Finally, define the *orbit skew coefficient* of  $G$  as  $M = \min \{|E_i|/|E|: 1 \leq i \leq m\}$ . Consider a  $d$ -space embedding of  $G$ , with embedded nodes, distance between nodes, and edge length as above. Let  $R$  be the *radius* of a  $d$ -space sphere with volume  $N$ , e.g., (1.1) for  $d = 3$ . We are now ready to state the main result. Just in case the reader does not notice, (i) is the most general form.

**THEOREM 2.** *Let graph  $G$  be embedded in  $d$ -space with the parameters above, and let  $C = (2^d - 1)/2^{d+1.5}$*

- (i) *Let  $l_i = |E_i|^{-1} \sum_{e \in E_i} l(e)$  be the average length of the edges in orbit  $E_i$ ,  $i = 1, \dots, m$ . Then,  $\sum_{1 \leq i \leq m} l_i \geq \sum_{1 \leq i \leq m} \delta_i l_i \geq CRD^{-1}$ .*
- (ii) *Let  $l = |E|^{-1} \sum_{e \in E} l(e)$  be the average length of an edge in  $E$ . Then,  $l \geq CRMD^{-1}$ .*

*Proof.* Without loss of generality, we give the proof for the physically relevant case  $d = 3$ . If  $x$  and  $y$  are nodes, let  $l(x, y)$  be the Euclidean *distance* between  $x$  and  $y$  in three-space. For  $i = 1, \dots, m$ , define  $l_i(x, y)$  as follows. If  $(x, y)$  is an edge in  $E_i$ , then  $l_i(x, y) = l(x, y)$ , and if  $(x, y)$  is an edge not in  $E_i$ , then  $l_i(x, y) = 0$ . If  $x$  and  $y$  are not incident with the same edge, then  $l_i(x, y) = |\Pi|^{-1} \sum_{P \in \Pi} \sum_{e \in P} l_i(e)$ , with  $\Pi$  as above. By the triangle inequality,

$$(2.2) \quad l(x, y) \leq l_1(x, y) + \dots + l_m(x, y).$$

Consider Fig. 2 again. Let  $x$  be any node of  $G$ . There are at most  $N/8$  nodes within distance  $R/2$  of  $x$ , with  $R$  given by (1.1). Therefore, there are  $\geq 7N/8$  nodes at distance  $\geq R/2$  from  $x$ , for  $N$  large enough. Thus, the sum of all  $l(x, y)$ , taken over all node pairs  $x, y$ , satisfies

$$(2.3) \quad \sum_{x, y \in V} l(x, y) \geq \frac{7RN^2}{16}.$$

Using (2.1) and (2.2), we obtain from (2.3),

$$(2.4) \quad \sum_{x, y \in V} \sum_{i=1}^m \frac{l_i(x, y)}{d(x, y)} \geq \sum_{x, y \in V} \frac{l(x, y)}{d(x, y)} \geq \frac{7RN^2}{16D}.$$

<sup>5</sup> This constant  $C$  can be improved. For  $d = 3$ ,  $C = 7/16$  is the value of  $c(1 - c^3)$  for  $c = 2^{-1}$ . This function reaches its optimum value  $(3/4)2^{-2/3}$  for  $c = 2^{-2/3}$ . By refining the argument we can improve the constant to  $\frac{3}{4}$ . Namely, to obtain (2.3), sum  $(c, c + dc]R\delta(x, y)$  with  $\delta(x, y) = 1$  if  $cR < l(x, y)$  and  $\delta(x, y) = 0$  otherwise, with  $c$  ranging from 0 to 1, for each pair of nodes  $x, y$ . This replaces  $C = 7/16$  in (2.3) by  $C = \int_0^1 (1 - c^3)dc = \frac{3}{4}$ . Similarly, in two dimensions we can improve  $C$  from  $3/8$  to  $2/3$ .

Now fix a particular edge  $e$  in some  $E_i$ . We average  $l(\gamma(e))$  over all  $\gamma$  in  $\Gamma$ . By the property above, there are precisely  $|\Gamma|/|E_i|$  distinct automorphisms in  $\Gamma$  that map edge  $e$  onto edge  $f$ , for each pair  $e, f \in E_i$ . Therefore, the sum of  $l(\gamma(e))$  over all  $\gamma$  in  $\Gamma$  equals precisely  $|\Gamma|/|E_i|$  times the sum of the lengths of all edges in  $E_i$ . Formally,

$$|\Gamma|^{-1} \sum_{\gamma \in \Gamma} l(\gamma(e)) = |E_i|^{-1} \sum_{f \in E_i} l(f) \quad \text{for each } e \in E_i, \quad i = 1, \dots, m,$$

and therefore, for all  $x, y \in V$ ,

$$(2.5) \quad |\Gamma|^{-1} \sum_{\gamma \in \Gamma} l_i(\gamma(x), \gamma(y)) = |E_i|^{-1} d_i(x, y) \sum_{f \in E_i} l(f) \quad \text{for } i = 1, \dots, m.$$

We now finish the argument. Averaging (2.4) additionally over all  $\gamma$  in  $\Gamma$ , leaves the lower bound invariant:

$$(2.6) \quad |\Gamma|^{-1} \sum_{\gamma \in \Gamma} \sum_{x, y \in V} \sum_{i=1}^m \frac{l_i(\gamma(x), \gamma(y))}{d(\gamma(x), \gamma(y))} \geq \frac{7RN^2}{16D}.$$

By rearranging the summation order in (2.6), and substitution of (2.5), we obtain

$$\sum_{i=1}^m \sum_{x, y \in V} \frac{d_i(x, y)}{d(x, y)} |E_i|^{-1} \sum_{e \in E_i} l(e) \geq \frac{7RN^2}{16D}.$$

That is,  $\sum_{1 \leq i \leq m} \delta_i l_i \geq 7R/(16D)$ . Since  $\delta_i \leq 1, i = 1, \dots, m$ , this proves (i). For the average edge length  $l$ , this yields  $l = \sum_{1 \leq i \leq m} (|E_i|/|E|) l_i \geq M \sum_{1 \leq i \leq m} l_i$ , which proves (ii).  $\square$

*Example 1. Binary  $n$ -cube.* Let  $\Gamma$  be an automorphism group of the binary  $n$ -cube, e.g.,  $A$  in the proof of Lemma 1. Let  $N = 2^n$ . The orbit of each edge under  $\Gamma$  is  $E$ . Substituting  $R, D, m = 1$ , and  $d = 3$  in Theorem 2(i) proves Lemma 1. Denote by  $L$  the total edge length  $\sum_{f \in E} l(f)$  in the three-space embedding of  $C$ . Then

$$(2.7) \quad L \geq \frac{7RN}{32}.$$

Recapitulating, the sum total of the lengths of the edges is  $\Omega(N^{4/3})$ , and the average length of an edge is  $\Omega(N^{1/3} \log^{-1} N)$ . (In two dimensions we obtain in a similar way  $\Omega(N^{3/2})$  and  $\Omega(N^{1/2} \log^{-1} N)$ , respectively.)

*Example 2. Cube-connected cycles.* The binary  $n$ -cube has the drawback of unbounded node degree. Therefore, in the fixed-degree version of it, each node is replaced by a cycle of  $n$  trivalent nodes [9]; whence the name *cube-connected cycles* or CCC. If  $N = n2^n$ , then the CCC version, say  $CCC = (V, E)$ , of the binary  $n$ -cube has  $N$  nodes,  $3N/2$  edges, and diameter  $D < 2.5n$ .

**COROLLARY 3.** *The average Euclidean length of edges in a three-space embedding of CCC is at least  $7R/(120n)$ .*

*Proof.* Denote a node  $a$  by an  $n$ -bit string with one marked bit,  $a = a_1 \dots a_{i-1} \bar{a}_i a_{i+1} \dots a_n$ . There is an edge  $(a, b)$  between nodes  $a = a_1 \dots a_{i-1} \bar{a}_i a_{i+1} \dots a_n$  and  $b = a_1 \dots a_{j-1} \bar{b}_j a_{j+1} \dots a_n$ , if either  $i \equiv j \pm 1 \pmod{n}$ ,  $a_i = b_i$  and  $a_j = b_j$  (edges in cycles), or  $i = j$  and  $a_i \neq b_i$  (edges between cycles). Consider the set  $A$  of automorphisms  $\alpha_{v,j}$ , with  $v = v_1 \dots v_n$  a binary  $n$ -vector and  $j$  an integer  $1 \leq j \leq n$ , such that

$$\alpha_{v,j}(a_1 \dots a_{i-1} \bar{a}_i a_{i+1} \dots a_n) = b_{j+1} \dots b_n b_1 \dots b_j,$$

with  $b_i = \overline{a_i \oplus v_i}$  and  $b_k = a_k \oplus v_k$  for  $k \neq i, 1 \leq k \leq n$ . Clearly,  $A$  is a subgroup of the automorphism group of CCC. The similarity relation induced by  $A$  partitions  $E$  in two orbits: the set of *cycle* edges and the set of *noncycle* edges. Since there are  $N/2$

noncycle edges,  $N$  cycle edges, and  $3N/2$  edges altogether, the orbit skew coefficient  $M$  is  $\frac{1}{3}$ . Substitution of  $R, D, M$ , and  $d = 3$  in Theorem 2(ii) yields the corollary.  $\square$

That is, the *total* edge length is  $\Omega(N^{4/3} \log^{-1} N)$  and the *average* edge length is  $\Omega(N^{1/3} \log^{-1} N)$ . (In two dimensions  $\Omega(N^{3/2} \log^{-1} N)$  and  $\Omega(N^{1/2} \log^{-1} N)$ , respectively.) Similar lower bounds are expected to hold for other fast permutation networks like the *butterfly*, *shuffle-exchange*, and *de Bruijn* graphs.

*Example 3.* Edge-symmetric graphs. Recall that a graph  $G = (V, E)$  is *edge-symmetric* if each edge is mapped to every other edge by an automorphism in  $\Gamma$ . We set off this case especially, since it covers an important class of graphs. (It includes the binary  $n$ -cube but excludes CCC.) Let  $|V| = N$  and  $D < \infty$  be the diameter of  $G$ . Substituting  $R, m = 1$ , and  $d = 3$  in Theorem 2(i) we obtain the following.

**COROLLARY 4.** *The average Euclidean length of edges in a three-space embedding of an edge-symmetric graph is at least  $7R/(16D)$ .*

For the complete graph  $K_N$ , this results in an average wire length of  $\geq 7R/16$ . That is, the average wire length is  $\Omega(N^{1/3})$ , and the total wire length is  $\Omega(N^{7/3})$ .

For the complete bigraph  $K_{1, N-1}$  (the star graph on  $N$  nodes) we obtain an average wire length of  $\geq 7R/32$ . That is, the average wire length is  $\Omega(N^{1/3})$ , and the total wire length is  $\Omega(N^{4/3})$ .

For an  $N$ -node  $\delta$ -dimensional mesh with wraparound (e.g., a ring for  $\delta = 1$ , and a torus for  $\delta = 2$ ; for a formal definition see Appendix), this results in an average wire length of  $\geq 7R/(8\delta N^{1/\delta})$ . That is, the average wire length is  $\Omega(\delta^{-1} N^{(\delta-3)/3\delta})$ , and the total wire length is  $\Omega(N^{(4\delta-3)/3\delta})$ .

To give some indication of the scope of Corollary 4, we note that every edge-symmetric graph with no isolated nodes is node-symmetric or bipartite, by a theorem attributed to Elayne Dauber [2], and that every Cayley graph is symmetric [1]. (A graph is symmetric if it is both node-symmetric and edge-symmetric. A graph is node-symmetric if for each pair of nodes there is an automorphism that maps one to the other.)

*Example 4.* Complete binary tree. The complete binary tree  $T_n$  on  $N - 1$  nodes ( $N = 2^n$ ) has  $n - 1$  orbits  $E_1, \dots, E_{n-1}$ . Here  $E_i$  is the set of edges at level  $i$  of the tree, with  $E_1$  is the set of edges incident with the leaves, and  $E_{n-1}$  is the set of edges incident with the root. Let  $l_i$  and  $l$  be as in Theorem 2 with  $m = n - 1$ . Then  $|E_i| = 2^{n-i}$ ,  $i = 1, \dots, n - 1$ , the orbit skew coefficient  $M = 2/(2^n - 2)$ , and we conclude from Theorem 2(ii) that  $l$  is  $\Omega(N^{-2/3} \log^{-1} N)$  for  $d = 3$ . This is consistent with the known fact  $l$  is  $O(1)$ . However, we obtain significantly stronger bounds using the more general part (i) of Theorem 2. In fact, we can show that one-space embeddings of complete binary trees with  $o(\log N)$  average edge length are impossible.<sup>6</sup>

**COROLLARY 5.** *The average Euclidean length of edges in a  $d$ -space embedding of a complete binary tree is  $\Omega(1)$  for  $d = 2, 3$ , and  $\Omega(\log N)$  for  $d = 1$ .*

*Proof.* Consider  $d$ -space embeddings of  $T_n$ ,  $d \in \{1, 2, 3\}$  and  $n > 1$ . By Theorem 2,

$$(2.8) \quad \sum_{i=1}^{n-1} \delta_i l_i \geq CRD^{-1}.$$

**CLAIM.**  $\delta_i \leq (n - 1)^{-1}$ , for  $i = 1, \dots, n - 1$ .

*Proof of claim.* The proof is by induction on  $n$ . Denote by  $\delta_i^{(n)}$  the  $i$ th orbit frequency of  $T_n$ , the complete binary tree with  $2^n - 1$  nodes. Note that  $T_{n+1}$  consists of two copies of  $T_n$ , with the roots attached to a root node that is in neither

<sup>6</sup> Using  $\sum_{i=1}^{n-1} l_i \geq CRD^{-1}$  instead of (2.8), also yields  $l$  is  $\Omega(1)$  for  $d = 2, 3$ , but only  $l$  is  $\Omega(\log \log N)$  for  $d = 1$ .

of them. Set  $\delta_i^{(j)} = 0$  for  $i \geq j$ . For  $n = 2$  the claim holds trivially. Assume the claim holds for  $n \geq 2$ . Then we prove it holds for  $n + 1$ , as follows. We obtain  $(2^{n+1} - 1)^2 \delta_i^{(n+1)}$  by dividing  $\sum_{x,y \in V} d_i(x,y)/d(x,y)$  in two parts: with both nodes  $x, y$  in the same  $T_n$  subtree and with nodes  $x, y$  in different subtrees. The first subsum equals  $2(2^n - 1)^2 \delta_i^{(n)}$ . To obtain the second subsum, we sum  $d_i(x,y)/d(x,y)$  with  $x$  and  $y$  ranging over the consecutive levels of different  $T_n$ -subtrees (so the shortest path between  $x$  and  $y$  contains the root of  $T_{n+1}$ ). This yields the following recurrences, for each  $i = 1, \dots, n$  (with  $\delta_n^{(n)} = 0$ ):

$$(2^{n+1} - 1)^2 \delta_i^{(n+1)} = 2(2^n - 1)^2 \delta_i^{(n)} + \sum_{j=0}^n 2^j \sum_{k=n-i+1}^n \frac{2^{k-1}}{k+j}.$$

Evaluating the double sum for  $i = n$ , and substituting  $\delta_i^{(n)} \leq (n - 1)^{-1}$ , we find after due computation,  $\delta_i^{(n+1)} \leq n^{-1}$ .  $\square$

Substitution of  $|E_i|, |E|, m$  in the expression for  $l$  in Theorem 2 gives

$$(2.9) \quad l = (2^n - 2)^{-1} \sum_{i=1}^{n-1} 2^{n-i} l_i.$$

Substitute in (2.8) the values of  $C, R$  (depending on  $d$ ) and  $D = 2(n - 1)$ . Next, substitute  $(n - 1)^{-1}$  for  $\delta_i$  and multiply both sides with  $n - 1$ . Use the resulting expression to substitute in (2.9), after rearranging the summation, as follows:

$$l = (2^n - 2)^{-1} \left( \sum_{j=1}^{n-1} 2^{j-1} \sum_{i=1}^{n-j} l_i + \sum_{i=1}^{n-1} l_i \right) \in \Omega \left( 2^{-(1-1/d)n} \sum_{j=1}^{n-1} 2^{(1-1/d)j} \right).$$

Therefore, for  $d = 2, 3$ , we obtain  $l$  is  $\Omega(1)$ . However, for  $d = 1, l$  is  $\Omega(\log N)$ .  $\square$

**2.2. Optimality conjecture.** There is evidence that the lower bound of Theorem 2 is optimal. Namely, it is within a constant multiplicative factor of an upper bound for several example graphs of various diameters. Consider only three-dimensional Euclidean embeddings, and recall the assumption that wires have length but no volume, and can pass through nodes. For the *complete graph*  $K_N$  with diameter 1, the lower bound on the average wire length is  $7R/16$ , while  $2R$  is a trivial upper bound. For the *star graph* on  $N$  nodes the bounds are  $7R/32$  and  $2R$ , respectively. The upper bound on the total wire length to embed the *binary  $n$ -cube* requires more work. Let  $N = 2^n$ .

The construction is straightforward. For convenience we assume now that each node is embedded as a three-space cube of volume 1. Recursively, embed the binary  $n$ -cube in a cube of three-dimensional Euclidean space with *sides* of length  $S_n$ . Use eight copies of binary  $(n - 3)$ -cubes embedded in Euclidean  $S_{n-3} \times S_{n-3} \times S_{n-3}$  cubes, with  $S_{n-3} = S_n/2$ . Place the eight small cubes into the large cube by fitting each small cube into an octant of the large cube. First connect the copies pairwise along the first coordinate to form four binary  $(n - 2)$  cubes. Connect these four pairwise along the second coordinate to form two binary  $(n - 1)$  cubes, which in turn are connected along the third coordinate into one binary  $n$ -cube. This requires no more than  $4 \cdot 2^{n-3}$  wires of length at most  $\sqrt{3/2} \cdot S_n$ , another  $2 \cdot 2^{n-2}$  wires of length at most  $3S_n/2$  and  $2^{n-1}$  wires of length at most  $\sqrt{3} \cdot S_n$ . Assume  $S_1 = 1$  and  $n - 1$  is a multiple of 3. Since  $S_n = 2S_{n-3}$ , we have  $S_n = 2^{(n-1)/3}$ . The *total* wire length  $L(n)$  required to embed the binary  $n$ -cube is

$$L(n) \leq 2^{n-1}(\sqrt{3/2} + 3/2 + \sqrt{3})S_n + 8L(n - 3) \\ \leq \sum_{i=1}^{(n-1)/3} 2^{4i} \cdot 2^{n-1-3i}(\sqrt{3/2} + 3/2 + \sqrt{3}).$$

Substitute  $i = -j + (n - 1)/3$  and round off the bracketed sum to 5 to obtain

$$L(n) < 5 \cdot 2^{4(n-1)/3} \sum_{j=0}^{(n-4)/3} 2^{-j}.$$

Summing the infinite series  $\sum_{j=0}^{\infty} 2^{-j}$  yields an upper bound  $L(n) < 4N^{4/3}$ . Together with Lemma 1, the optimum of the average interconnect length for the binary  $n$ -cube is in between  $7R/16n$  and  $8N^{1/3}/n$ .

For the *cube-connected cycles* with  $N = n2^n$  nodes, we derive an upper bound by the same argument. Squeeze the  $n$  nodes of each cycle in a three-space cube of volume  $n$  in the obvious way. This takes, say, about  $L_1 < n2^n$  total interconnect length for the cycle edges. Recall that each such cycle corresponds to a particular node of the binary  $n$ -cube above. Apply the same construction as for the binary  $n$ -cube with  $S_1 = n^{1/3}$ . Then obtain  $L_2 < 4 \cdot 2^{4n/3} n^{1/3}$  total interconnect length for the edges between cycles. Together with Corollary 3, we obtain that the optimum of the average interconnect length for the cube-connected cycles is in between  $7R/120n$  and  $8N^{1/3}/(3n) + 2/3$ . For  $\delta$ -dimensional meshes with wraparound, with  $\delta = 1, 2, 3$  and diameter  $2^{-1}\delta N^{1/\delta}$ , a lower bound of  $\Omega(1)$  follows from Corollary 4, and the upper bound is  $O(1)$  by the obvious embedding. Note that  $\delta = 1$  is the ring and  $\delta = 2$  is the torus. For the *complete binary tree*, for  $d = 2, 3$ , the  $H$ -tree construction gives an average edge length  $O(1)$  [9], matching the  $\Omega(1)$  lower bound. In the one-dimensional case, the obvious embedding gives  $O(\log N)$  average edge length, matching the lower bound  $\Omega(\log N)$  of Corollary 5.

**2.3. Robustness.** Theorem 2 is robust in the sense that if  $G' = (V', E')$  is a subgraph of  $G = (V, E)$ , and the theorem holds for either one of them, then a related lower bound holds for the other. Essentially, this results from the relation between the orbit frequencies of  $G, G'$ . Let us look at some examples, with  $d = 3$ .

Let a graph  $G$  have the binary  $n$ -cube  $C$  as a subgraph and  $N = 2^n$ . Let  $G$  have  $N' \cong 8N$  nodes and at most  $N' \log N'$  edges. The lower bound on the total wire length  $L(G)$  of a three-space embedding of  $G$  follows trivially from  $L(G) \geq L(C)$ , with  $L(C) \geq 7RN/32$  the total wire length of the binary  $n$ -cube. Therefore, expressing the lower bounds in  $N'$  and radius  $R'$  of a sphere with volume  $N'$  yields  $L(G) \geq 7R'N'/512$ , and the average edge length of  $G$  is at least  $7R'/(512 \log N')$ .

Let the binary  $n$ -cube  $C$  have a subgraph  $G$  with  $n2^{n-1} - 2^{n-5}$  edges. The lower bound on the total wire length  $L(G)$  of a three-space embedding of  $G$  follows from the observation that each deleted edge of  $C$  has length at most twice the diameter  $R$  of (1.1). That is,  $L(G) \geq L(C) - 2^{n-4}R$  with  $L(C)$  as above. Note that  $G$  has  $N' \cong 2^n - (2^{n-6}/n)$  nodes. Therefore, expressing the lower bounds in  $N'$  and radius  $R'$  of a sphere with volume  $N'$  yields  $L(G) \geq 5RN/32 \geq 5R'N'/32$ , and the average edge length of  $G$  is at least  $5R/16n \sim 5R'/(16 \log N')$ .

**3. Interconnect length and volume.** An effect that becomes increasingly important at the present time is that most space in the device executing the computation is taken up by the wires. Under very conservative estimates that the unit length of a wire has a volume which is a constant fraction of that of a component it connects, we can see above that in three-dimensional layouts for binary  $n$ -cubes, the volume of the  $N = 2^n$  components performing the actual computation operations is an asymptotic fastly vanishing fraction of the volume of the wires needed for communication:

$$\frac{\text{volume computing components}}{\text{volume communication wires}} \in o(N^{-1/3})$$

If we charge a constant fraction of the unit volume for a unit wire length and add the volume of the wires to the volume of the nodes, then the volume necessary to embed the binary  $n$ -cube is  $\Omega(N^{4/3})$ . However, this lower bound ignores the fact that the added volume of the wires pushes the nodes further apart, thus necessitating longer wires again. How far does this go? A rigorous analysis is complicated and is not important here. The following intuitive argument indicates well enough what we can expect. Denote the volume taken by the nodes as  $V_n$  and the volume taken by the wires as  $V_w$ . The total volume taken by the embedding of the cube is  $V_t = V_n + V_w$ . The total wire length required to lay out a binary  $n$ -cube as a function of the volume taken by the embedding is, substituting  $V_t = 4\pi R^3/3$  in (2.7),

$$L(V_t) \cong \frac{7N}{32} \left( \frac{3V_t}{4\pi} \right)^{1/3}.$$

Since  $\lim_{n \rightarrow \infty} V_n/V_w \rightarrow 0$ , assuming unit wire length of unit volume, we set  $L(V_t) \sim V_t$ . This results in a better estimate of  $\Omega(N^{3/2})$  for the volume needed to embed the binary  $n$ -cube. When we want to investigate an upper bound to embed the binary  $n$ -cube under the current assumption, we have a problem with the unbounded degree of unit volume nodes. There is no room for the wires to come together at a node. For comparison, therefore, consider the fixed-degree version of the binary  $n$ -cube, the CCC (see above), with  $N = n2^n$  trivalent nodes and  $3N/2$  edges. The same argument yields  $\Omega(N^{3/2} \log^{-3/2} N)$  for the volume required to embed CCC with unit volume per unit length wire. It is known, that every small degree  $N$ -vertex graph, e.g., CCC, can be laid out in a three-dimensional grid with volume  $O(N^{3/2})$  using a unit volume per unit wire length assumption [5]. This neatly matches the lower bound.

Because of current limitations to layered VLSI technology, previous investigations have focused on embeddings of graphs in two-space (with unit length wires of unit volume). We observe that the above analysis for two dimensions leads to  $\Omega(N^2)$  and  $\Omega(N^2 \log^{-2} N)$  volumes for the binary  $n$ -cube and the cube-connected cycles, respectively. These lower bounds have been obtained before, using *bisection-width* arguments and are known to be optimal [9]. It can be even worse, namely, in [6], [12] it is shown that we cannot always assume that a unit length of wire has  $O(1)$  volume (for instance, if we want to drive the signals to very high speed on chip).

**4. Conclusion.** In contrast to other investigations, my goal here was to derive *hard* lower bounds on the total wire length *independent* of the ratio between the volume of a unit length wire and the volume of a processing element. Clearly this is desirable, since this ratio changes with different technologies and granularity of computing components. The arguments we have developed are purely geometrical, apply to any graph, and give optimal lower bounds in all cases we have examined.

Such technology-independent, but huge, lower bounds are a theoretical prelude to many *wiring problems* currently starting to plague computer designers and chip designers alike. Formerly, a wire had magical properties of transmitting data "instantly" from one place to another (or better, to many other places). A wire did not take room, did not dissipate heat, and did not cost anything—at least, not enough to worry about. This was the situation when the number of wires was low, somewhere in the hundreds. Current designs use many millions of wires (on chip), or possibly billions of wires (on wafers). In a computation of parallel nature, most of the time seems to be spent on communication—transporting signals over wires. Thus, thinking that the von Neumann bottleneck has been conquered by nonsequential computation, we are unaware that a non von Neumann communication bottleneck looms large. The following innominate

quote covers this matter admirably:

Without me they fly they think;  
But when they fly I am the wings.

It is clear that these communication mishaps will influence the architecture and the algorithms to be designed for the massive multiprocessors of the future, just like existing algorithms influenced (or were inspired by) the novel architectures of today. What is needed, therefore, are *realistic* formal models for nonsequential computation. In particular, we need to formulate the appropriate cost measures for multicomputer computations. Such costs must account for the communication overhead in (physical) time due to the computer aggregates used in the computation and the overhead in space due to the topology of those aggregates. That is beyond the scope of this paper.

Mesh-connected architectures may be the ultimate solution for interconnecting the extremely large (in numbers) computer complexes of the future. Mesh architectures have desirable properties of *scalability*, *modular extensibility*, and *uniformity*, when embedded in physical space. These notions are generally used in a very loose fashion, and with a great deal of intuition, so I do not try to define them here. Circuits with lower bound  $f(N)$ ,  $f(N) \rightarrow \infty$  for  $N \rightarrow \infty$ , on the average interconnect length do not scale well. ( $N$  is the number of nodes.) Namely, composing a larger such circuit from smaller ones, the average wire length needs to increase. Thus, embeddings of such circuits are not uniformly modular extensible. This positive dependency of the interconnect length on the number of nodes to be connected we call nonscalability.

*Nonscalability.* No edge-symmetric graph on  $N$  nodes with a diameter  $o(N^{1/3})$  is scalable (i.e., uniformly modular extensible) when embedded in physical space.

Tomorrow, optical communication will be used in multicomputers, either wireless by means of lasers/infrared light or by using virtually unlimited bandwidth optical fiber or integrated waveguides [8]. In the current jargon: we can obtain three-dimensional mesh interconnect structures by stacking wafer circuit boards and providing optical interconnections vertically between wafers over the entire wafer in addition to planar connections. This may use hybrid mounting of optical components, combined with integrated optical waveguides and lenses on a large area silicon wafer-scale integrated (WSI) electronic circuit combining electronic and photonic functions [4]. However, it is unlikely that any clever scheme or technology will free us from practical communication problems forever. Even though Nature is not malicious, she is subtle.

**Appendix A.** What happens with embeddings in higher-dimensional spaces? Lest the reader conclude that I indulge in the same avoidance of reality that I decry in others, I have delegated this digression to the Appendix. These mathematical curiosities have no more bearing on realistic formal models for multicomputers than space warps have on the theory of propulsion of space vehicles.

**A.1. Communication and interconnect length in higher dimensions.** Assume that a node (processor) has unit volume, say spherical, in any number  $d$  of dimensions we care to consider. This is in order to obtain comparable reasoning to the physical relevant case of three dimensions. Our intuition about higher-dimensional Euclidean geometry turns out to be quite unreliable. The Euclidean volume  $V_d$  of a  $d$ -dimensional sphere of radius  $R_d$  is

$$V_d = \frac{(R_d)^d \pi^{d/2}}{\Gamma(1 + d/2)},$$

with  $\Gamma$  the gamma function providing a natural generalization of the factorial function. With radius 1 this gives, for dimensions  $d = 1, 2, \dots$ , the volumes 2, 3.14, 4.18, 4.93, 5.26, 4.72, 4.06,  $\dots$ . The volume of the unit radius sphere comes to a maximum for  $d = 5$  and falls off rather rapidly toward zero as  $d$  approaches infinity. On the other hand,  $d$  can be chosen to minimize the radius of a  $d$ -dimensional sphere of volume  $N$ . However, even with the optimal  $d$  (a function of  $N$ ) the radius is  $\Omega(\log^{1/2} N)$ . Namely, setting  $V_d = N$  and  $d = 2k$ , we have

$$N = \left(\frac{\pi^k}{k!}\right) (R_{2k})^{2k} = \frac{(\pi(R_{2k})^2)^k}{k!}.$$

By Stirling's approximation,

$$R_{2k} \sim \sqrt{\frac{k}{e\pi}} (N\sqrt{2\pi k})^{1/k}.$$

Observe that the lower bound in Theorem 2(i) is therefore  $\Omega(N^{1/d} \cdot d^{1/2} D^{-1})$ . Differentiating, we find that  $R_{2k}$  reaches its *minimum*  $R_{2k}^{\min}$  for

$$k \sim \log N,$$

where  $\log$  denotes the natural logarithm. Therefore, with  $N^{1/\log N} = e$ , and  $(2\pi k)^{1/k} \downarrow 1$  for  $k \rightarrow \infty$ , we obtain

$$R_{2k}^{\min} \sim \sqrt{\frac{\log N}{\pi}}.$$

We may think that it is the unfortunate accident of having a physical space of only three dimensions that makes it hard to embed edge-symmetric graphs with small diameter. However, this is not the case. By this analysis and Theorem 2, to embed edge-symmetric graphs of diameter  $o(\log^{1/2} N)$  requires the average length of an embedded edge to rise unbounded with  $N$ , independent of the number of dimensions. As another curiosity, the average edge length of the complete binary tree in  $d > 1$  dimensions is not  $O(1)$ , but turns out to be  $\Omega(d^{1/2})$ . That is, in higher dimensions the  $H$ -tree construction increasingly loses efficiency.

**A.2. Meshes in higher dimensions.** Let  $N = n^\delta$ ,  $n$  a positive integer. Define a  $\delta$ -dimensional *mesh with wraparound* as a set of nodes  $(i_1, \dots, i_\delta)$ ,  $i_j = 0, \dots, N^{1/\delta} - 1$  ( $1 \leq j \leq \delta$ ). Node  $(i_1, \dots, i_\delta)$  is connected by an edge with node  $(j_1, \dots, j_\delta)$ , if they are equal in all coordinates except one where they differ by 1 mod  $N^{1/\delta}$ .

Again assume that a node (processor) has unit volume in any number  $d$  of dimensions we care to consider. For  $d$ -dimensional embeddings of  $N$ -node,  $\delta$ -dimensional meshes with wraparound we have an average interconnect length  $\geq (2^d - 1)R_d / (2^d \delta N^{1/\delta})$ . This lower bound is a small positive constant for  $d \geq \delta$  and  $d$  is small (this is necessary because of the curious behavior of the ratio between volume and radius in higher dimensions). Since the lower bound can be matched by an upper bound, such meshes are feasible architectures for large  $N$ . However, since the average Euclidean interconnect length exceeds

$$\delta^{-1} N^{(\delta-d)/d\delta} \sqrt{\frac{d}{2\pi e}},$$

it rises unbounded with  $N$  for  $\delta > d$ . (It also rises unbounded with  $d$  for fixed  $N$  and  $\delta$ .)

## ISOMORPHISM TESTING OF UNARY ALGEBRAS\*

LUDEK KUČERA† AND VĚRA TRNKOVÁ‡

**Abstract.** Two problems are said to be polynomially equivalent if each is polynomially reducible to the other. A problem is said to be isomorphism-complete if it is polynomially equivalent to the graph isomorphism problem. We prove that the isomorphism problem in any variety of unary algebras is either isomorphism-complete, or solvable in polynomial time. We formulate a condition  $C$  under which the isomorphism problem in a variety  $V$  of unary algebras can be solved in polynomial time. We present an algorithm that can be applied to any pair of unary algebras with the same number of operations and decides whether the algebras are isomorphic or not in  $O(n^3)$  time, provided one of them belongs to a variety satisfying  $C$ . The validity of the last condition is tested by the algorithm in linear time.

**Key words.** isomorphism testing, isomorphism-complete, unary algebras

**AMS(MOS) subject classifications.** 68C25, 08A60

**1. Introduction.** The problem of the complexity of isomorphism testing of different mathematical structures has recently received much attention [17] because it is one of the most important problems in the class NP which is not known to be either NP-complete, or to belong to the class  $NP \cap \text{coNP}$  or even to the class P of polynomial-time computable problems. Originally the problem was to decide the question about the existence of an isomorphism of two graphs. It is known [7] that the isomorphism testing of any finite algebraic or relational structure can be reduced to the graph isomorphism in the sense of either Cook [5] or Karp [10]. Based on this, it was shown that the general graph isomorphism problem is equivalent (in the sense of mutual polynomial-time reducibility) to the isomorphism problem for many other structures, e.g., bipartite graphs, semigroups, automata etc. (see [4]). The problem with the computational complexity equivalent to the complexity of the graph isomorphism problem is usually called *isomorphism-complete*.

As in the theory of NP-completeness, we want to know under what constraints different problems remain isomorphism complete. This approach has already been used in the case of graphs, and the isomorphism completeness of a number of special classes of graphs has been proved. On the other hand, there exist highly nontrivial polynomial-time algorithms solving the isomorphism problem in several interesting classes of graphs (e.g., planar graphs [9], graphs of bounded genus [16], graphs of bounded degree [14] or graphs of bounded eigenvalue multiplicity [3]).

A disadvantage of graphs is that there is no natural and general procedure designed to generate special classes of them in a unified and organic way. From this point of view, there is a more suitable situation in universal algebra. Starting from the class of all universal algebras of a given type (which is known to be isomorphism-complete whenever the type consists of at least two unary operations or at least one  $n$ -ary operation,  $n \geq 2$  [7]), we can specialize the class by imposing equalities, i.e., creating varieties, to obtain a wide scale of various naturally defined classes of algebraic structures. Unlike the case of graphs, we know algebraic varieties in which the isomorphism problem could be simpler than any that is isomorphism-complete, and yet not computable in a polynomially bounded time. For example, the best-known algorithm to solve the group isomorphism problem runs in  $n^{O(\log n)}$  time [15], while all known

algorithms for the general graph isomorphism problem need time  $\Omega(\exp(\sqrt{cn \log n}))$  [2]. However, all such varieties involve at least binary operations. In the present paper we will show that no matter how rich and wide the scale of varieties of universal algebras is, there are just two degrees of complexity of isomorphism testing in unary algebras, namely isomorphism-completeness and polynomial-time computability (which, of course, can coincide if, e.g.,  $P = NP$ ).

We present the following results:

(i) In any variety of unary algebras, the isomorphism problem is either isomorphism complete or can be solved in polynomially bounded time;

(ii) A condition  $C$  on varieties of unary algebras is formulated such that if a variety  $V$  satisfies  $C$  then the isomorphism problem in  $V$  is polynomial-time solvable, else the problem is isomorphism-complete;

(iii) An algorithm is given that tests in linear time for two arbitrary unary algebras with the same number of operations whether at least one of them belongs to a variety satisfying  $C$ . If so, then it decides in  $O(n^3)$  time the existence or nonexistence of an isomorphism of the given algebras.

**2. Varieties of unary algebras.** A *unary algebra* with  $k$  operations is a tuple  $(X, f_1, \dots, f_k)$ , where  $X$  is a set and each  $f_i$  is a mapping of  $X$  into itself. The operations of a unary algebra  $A = (X, f_1, \dots, f_k)$ , being mappings of  $X$  into itself, can be composed and any word  $w = f_{i_1} \dots f_{i_m}$  is a unary operation again (the empty word is the identity map).

We denote by  $\text{ALG}(k)$  the class of all unary algebras with  $k$  operations. A *variety* in  $\text{ALG}(k)$  is a subclass  $V$  of  $\text{ALG}(k)$  which can be determined by a system of equations. Let us discuss this in more detail.

Denote by  $f^*$  the set of all words over the set  $\{f_1, \dots, f_k\}$  of operation names. Then  $V \subset \text{ALG}(k)$  is a variety if and only if there are sets  $P, \bar{P}$ , and collections  $\{(w_p, w'_p) \mid p \in P\}$ ,  $\{(w_p, w'_p) \mid p \in \bar{P}\}$  of pairs of elements of  $f^*$  such that  $V$  is precisely the class of all algebras  $(X, f_1, \dots, f_k)$  which fulfill the equations (1) and (2) below:

$$(1) \quad w_p(x) = w'_p(x) \quad \text{for all } x \in X, \quad p \in P,$$

$$(2) \quad w_p(x) = w'_p(y) \quad \text{for all } x, y \in X, \quad p \in \bar{P}$$

(where we denote by the same letter the operation name and the actual operation on an algebra).

If  $V$  can be presented by equations of the type (1) only (i.e.,  $\bar{P}$  is empty), it is called a *regular variety*.

Let us present another description of varieties in  $\text{ALG}(k)$ . Let  $M$  be a monoid (i.e., binary associative operation  $\circ$  on  $M$  is given with a unit  $1 \in M$ , i.e.,  $1 \circ m = m \circ 1 = m$  for all  $m \in M$ ). Let  $G_1, \dots, G_k$  be a  $k$ -tuple of generators of  $M$ . Then  $(M, \{G_1, \dots, G_k\})$  determines the following two varieties  $V_1(M, \{G_1, \dots, G_k\})$  and  $V_0(M, \{G_1, \dots, G_k\})$  in  $\text{ALG}(k)$ .

Define a monoid homomorphism  $H: f^* \rightarrow M$  by  $H(f_i) = G_i$  for  $i = 1, \dots, k$ .

$V_1(M, \{G_1, \dots, G_k\})$  is a regular variety defined by the following system of equations:

$$(3) \quad w(x) = w'(x) \quad \text{whenever } H(w) = H(w').$$

$V_0(M, \{G_1, \dots, G_k\})$  is a variety given by all the equations of the system (3) together with all equations of the following form:

$$(4) \quad w(x) = w(y) \quad \text{whenever } H(w) \text{ is a left zero of } M \\ \text{(i.e., } H(w) \circ m = H(w) \text{ for all } m \in M).$$

Now, let a variety  $V$  in  $\text{ALG}(k)$  be given. Denote by  $M(V)$  the monoid  $f^*/\equiv$ , where  $\equiv$  is the following congruence:

$$(5) \quad w \equiv w' \quad \text{if and only if } w(x) = w'(x) \text{ for each algebra } (X, f_1, \dots, f_k) \text{ in } V \text{ and each } x \in X.$$

Denote by  $H : f^* \rightarrow f^*/\equiv = M(V)$  the corresponding monoid-homomorphism. Put  $G_i = H(f_i)$ ,  $i = 1, \dots, k$  and  $M = M(V)$ . Then, clearly,

$$V \subset V_1(M, \{G_1, \dots, G_k\}).$$

We show that

$$\begin{aligned} &\text{either } V = V_1(M, \{G_1, \dots, G_k\}), \\ &\text{or } V = V_0(M, \{G_1, \dots, G_k\}). \end{aligned}$$

First suppose that  $V$  is a regular variety given by equations  $w_p(x) = w'_p(x)$  for  $p \in P$ . Then the above equivalence (5) on  $f^*$  is the smallest congruence on  $f^*$  for which

$$w_p \equiv w'_p \quad \text{for all } p \in P.$$

This implies that  $V = V_1(M, \{G_1, \dots, G_k\})$  (with  $M = f^*/\equiv$  and  $G_i = H(f_i)$ , of course). Next, if  $V$  is not regular, it is given by equations (1) plus some equations (2)  $w_p(x) = w'_p(y)$   $p \in \bar{P}$ . However, the monoid  $M(V) = f^*/\equiv$  is defined by (5) as in the previous case. We show that  $V = V_0(M, \{G_1, \dots, G_k\})$  with  $M$  and  $G_1, \dots, G_k$  as above.

Replace any equation

$$w_p(x) = w'_p(y)$$

in the defining system by the following two equations:

$$w_p(x) = w'_p(x) \quad \text{and} \quad w_p(x) = w_p(y).$$

The first can be added to the system (1) and this does not influence the definition of  $\equiv$  in (5), so we can suppose that the system (2) is formed by equations of the form  $w_p(x) = w_p(y)$ . For any such  $w_p$

$$w_p(x) = w_p(v(x)) \quad \text{for all } x \in X \text{ and all } v \in f^*,$$

so that  $w_p \equiv w_p \circ v$  for each  $v \in f^*$ . Consequently,  $H(w_p)$  is a left zero of the monoid  $M(V) = f^*/\equiv$ . Hence

$$V_0(M, \{G_1, \dots, G_k\}) \subset V.$$

Conversely, let  $A = (X, f_1, \dots, f_k)$  be an algebra in  $V$  and let  $H(w)$  be a left zero of  $M(V) = f^*/\equiv$ . Then  $w \equiv w \circ v$  for all  $v \in f^*$ ; hence  $w(x) = w(v(x))$  for all  $x \in X$ . Since at least one equation of the form

$$w_p(x) = w_p(y)$$

is valid in  $A$  (for all  $x, y \in X$ ), we have

$$w(x) = w(w_p(x)) = w(w_p(y)) = w(y)$$

so that  $w(x) = w(y)$  is valid in the algebra  $A$ , and hence,  $A \in V_0(M, \{G_1, \dots, G_k\})$ . Thus  $V = V_0(M, \{G_1, \dots, G_k\})$ . We conclude that any variety  $V$  in  $\text{ALG}(k)$  determines uniquely a monoid  $M = M(V)$  and a set  $\{G_1, \dots, G_k\}$  of generators of  $M$ . Moreover,

$$\begin{aligned} &\text{either } V = V_1(M, \{G_1, \dots, G_k\}) \quad (\text{if } V \text{ is regular}), \\ &\text{or } V = V_0(M, \{G_1, \dots, G_k\}). \end{aligned}$$

Let us mention explicitly that if  $M$  has no left zeros, then  $V_1(M, \{G_1, \dots, G_k\}) = V_0(M, \{G_1, \dots, G_k\})$ . If  $M$  has at least one left zero, the two varieties are distinct. In the latter case,  $V_0(M, \{G_1, \dots, G_k\})$  is precisely the class of all connected algebras in  $V_1(M, \{G_1, \dots, G_k\})$ . Let us recall that an algebra  $(X, f_1, \dots, f_k)$  is called *connected* if, for every  $x, y \in X$ , there are elements  $x = x_0, x_1, \dots, x_s = y$  in  $X$  and words  $w_j, v_j$  in  $f^*$ ,  $j = 1, \dots, s$ , such that

$$(6) \quad w_j(x_{j-1}) = v_j(x_j) \quad \text{for all } j = 1, \dots, s.$$

Indeed, if  $A = (X, f_1, \dots, f_k)$  is in  $V_0(M, \{G_1, \dots, G_k\})$  and  $H(w) \in M$  is a left zero of  $M$ , then

$$w(x) = w(y) \quad \text{in } A \text{ for all } x, y \in X,$$

and hence  $A$  is connected. Conversely, let  $A$  be a connected algebra in  $V_1(M, \{G_1, \dots, G_k\})$ . If  $H(w) \in M$  is a left zero, then  $w(x) = w(v(x))$  for all  $x \in X$  and all  $v \in f^*$ . Since  $A$  is connected, we can find  $x = x_0, \dots, x_s = y$  and  $w_j, v_j$ , which fulfill (6) for all  $x, y \in X$ . Then

$$\begin{aligned} w(x) &= w(w_1(x_0)) = w(v_1(x_1)) = \dots = w(w_s(x_{s-1})) \\ &= w(v_s(x_s)) = w(y), \end{aligned}$$

which implies  $A \in V_0(M, \{G_1, \dots, G_k\})$ .

**3. Isomorphism-complete varieties in  $\text{ALG}(k)$ .** Given a monoid  $M$ , its left ideal is a subset  $A \subset M$  such that

$$m \in M \quad \text{and} \quad a \in A \quad \text{implies} \quad m \circ a \in A.$$

Following [18], we call a monoid *linear* if and only if the set of its left ideals is linearly ordered by inclusion, i.e., if  $A$  and  $A'$  are left ideals of  $M$ , then

$$\text{either } A \subset A' \quad \text{or} \quad A' \subset A.$$

Otherwise,  $M$  is called *nonlinear*. Clearly,  $M$  is nonlinear if and only if there exist  $m_0, m_1 \in M$  such that both  $m_0 \notin M \circ m_1$  and  $m_1 \notin M \circ m_0$ . In fact, if such  $m_0, m_1$  exist, then  $A = M \circ m_0$  and  $A' = M \circ m_1$  are incompatible left ideals. Conversely, if  $A, A'$  are incompatible left ideals, then any  $m_0 \in A - A'$  and  $m_1 \in A' - A$  have the above property.

*Examples.* (a) Let  $V$  be the variety in  $\text{ALG}(2)$  given by the following equations:

$$f_1(x) = f_1 f_1(x), \quad f_2 f_1(x) = f_1 f_2(y), \quad f_2(x) = f_2 f_2(x).$$

Then  $M = M(V) = \{1, G_1, G_2, G_1 \circ G_2\}$  is the monoid with two generators  $G_1, G_2$  and the defining relations

$$G_1 = G_1 \circ G_1, \quad G_2 \circ G_1 = G_1 \circ G_2, \quad G_2 = G_2 \circ G_2.$$

The element  $G_1 \circ G_2$  is the unique left zero of  $M$ . This monoid is not linear because

$$G_1 \notin M \circ G_2 \quad \text{and} \quad G_2 \notin M \circ G_1.$$

(b) Let  $V$  be the variety in  $\text{ALG}(2)$  given by the following equations:

$$f_1(x) = f_1 f_1(x) = f_2 f_1(x), \quad f_2(x) = f_2 f_2(x) = f_1 f_2(x).$$

Then  $M = M(V) = \{1, G_1, G_2\}$  is the monoid with two generators  $G_1, G_2$  and the defining relations

$$G_1 = G_1 \circ G_1 = G_2 \circ G_1, \quad G_2 = G_2 \circ G_2 = G_1 \circ G_2.$$

This monoid has no left zero. It is also nonlinear because  $G_1 \notin M \circ G_2$  and  $G_2 \notin M \circ G_1$ .

(c) On the other hand, if  $V$  is the variety in  $\text{ALG}(2)$  given by the following equations:

$$f_1(x) = f_1 f_1(x) = f_2 f_1(y), \quad f_2(x) = f_2 f_2(x) = f_1 f_2(y),$$

then the following equations can be derived:

$$f_1(x) = f_2 f_1(x) = f_2 f_1(y) = f_1(y),$$

$$f_2(x) = f_1 f_2(x) = f_1 f_2(y) = f_2(y).$$

Hence, (with the choice  $y = f_2(x)$ )

$$f_1(x) = f_1 f_2(x) = f_2(x),$$

and  $M(V) = \{1, G_1\}$  (with  $G_1 \circ G_1 = G_1, G_2 = G_1$ ) is linear.

(d) The monoid  $M = M(V)$  of the variety  $V$  in  $\text{ALG}(2)$  given by the following equation:

$$f_1 f_2(x) = f_1(x),$$

though infinite, is also linear. Indeed,  $M = \{G_2^k \circ G_1^n \mid n, k = 0, 1, 2, \dots\}$ ; if  $m_0 = G_2^{k_0} \circ G_1^{n_0}, m_1 = G_2^{k_1} \circ G_1^{n_1}$ , then  $G_2^{k_0} \circ G_1^{n_0-n_1} \circ m_1 = m_0$  for  $n_0 > n_1$  and  $G_2^{k_0-k_1} \circ m_1 = m_0$  for  $k_0 > k_1, n_0 = n_1$ .

The following theorem is proved implicitly in [18].

**SICHLER'S THEOREM.** *Let  $V$  be an arbitrary variety in  $\text{ALG}(k)$ . If its monoid  $M(V)$  is nonlinear and finite, then  $V$  is isomorphism-complete.*

Let us present an outline of the proof. Let  $G = (X, E)$  be an undirected finite graph, i.e., the vertex set  $X$  is finite and  $E$  is a set of two-element subsets of  $X$ . Call a graph  $(X, E)$ -complete if  $E$  is the set of all two-element subsets of  $X$ . The degree  $\text{deg}(v)$  of a vertex  $v$  of  $(X, E)$  is the number of edges (i.e., elements of  $E$ ) containing  $v$ . Let  $\text{GRA}$  denote the class of all finite undirected incomplete connected graphs with all vertices of degree greater than two. It is easy to see that the isomorphism problem in  $\text{GRA}$  is isomorphism-complete. The proof of the isomorphism completeness of any variety  $V \subset \text{ALG}(k)$  with a finite nonlinear monoid  $M(V)$  proceeds as follows: we construct, for each  $G \in \text{GRA}$ , an algebra  $\phi(G) \in V$  such that

- (1) the size of  $\phi(G)$  is bounded by a polynomial in the size of  $G$ ,
- (2) graphs  $G, G' \in \text{GRA}$  are isomorphic if and only if  $\phi(G)$  and  $\phi(G')$  are isomorphic.

We sketch the construction presented in [18]. First, a graph  $G = (X, E) \in \text{GRA}$  is represented as  $(R_G, p_0, p_1)$ , where  $R_G \subset X \times E$  consists of all pairs  $(v, e)$  with  $v \in e$ ; for  $r = (v, e) \in R_G$ ,

$$p_0(r) = v \quad \text{and} \quad p_1(r) = e.$$

It is easy to verify that if  $G, G' \in \text{GRA}$  are represented as  $(R_G, p_0, p_1)$  and  $(R_{G'}, p'_0, p'_1)$ , then each isomorphism  $\varphi: G \rightarrow G'$  determines a bijection  $f: R_G \rightarrow R_{G'}$  such that, for  $i = 0, 1$ ,

$$(7) \quad p_i(r) = p_i(s) \Rightarrow p'_i(f(r)) = p'_i(f(s))$$

and vice versa: each bijection  $f: R_G \rightarrow R_{G'}$ , which fulfills (7) determines an isomorphism  $\varphi: G \rightarrow G'$ . (Given  $\varphi, f$  is defined by  $f((v, \{v, v'\})) = (\varphi(v), \{\varphi(v), \varphi(v')\})$ .)

Now, let  $V$  be a variety in  $\text{ALG}(k)$  with nonlinear  $M(V) = M$ . There are  $m_0, m_1 \in M$  such that  $m_0 \notin M \circ m_1$  and  $m_1 \notin M \circ m_0$ . The idea of the construction of the algebra  $\phi(G) \in V$  is to use the operations  $m_0, m_1$  in the role of the above maps  $p_0$  and  $p_1$  on  $R_G$ . Hence, given a graph  $G = (X, E) \in \text{GRA}$ , let  $F(R_G)$  be the algebra generated

freely in  $V$  by the set  $R_G$  and let  $\theta_G$  denote the least congruence on  $F(R_G)$  containing all the pairs:

- (i)  $(m_0(r), m_0(s))$  for  $r, s \in R_G$  with  $p_0(r) = p_0(s)$ ;
- (ii)  $(m_1(r), m_1(s))$  for  $r, s \in R_G$  with  $p_1(r) = p_1(s)$ ; and, for technical reasons, also pairs
- (iii)  $(r, b(r))$  for  $r \in R_G, b \in B$ , where  $B \subset M$  is the set of all invertible elements  $b$  with  $m_i \circ b, m_i \circ b^{-1} \in M \circ m_i, i = 0, 1$ .

Then we put

$$\phi(G) = F(R_G) / \theta_G.$$

Let us mention explicitly that if  $M$  is finite, the size of  $F(R_G)$  (hence of  $\phi(G)$ ) is bounded by a polynomial depending on the size of  $G$ . Indeed, for a regular variety  $V$ , the elements of  $F(R_G)$  are in one-to-one correspondence with the elements of  $M \times R$  (under the bijection  $(m, r) \rightarrow m(r)$ ) and if  $V = V_0(M, \{G_1, \dots, G_k\})$ , we identify every  $m(r)$  with every  $m(s), r, s \in R_G$ , whenever  $m$  is a left zero of  $M$ .

The algebras  $\phi(G) \in V$  have the following property: for every  $G, G' \in \text{GRA}, G$  and  $G'$  are isomorphic if and only if  $\phi(G)$  and  $\phi(G')$  are isomorphic.

The proof of the implication

$$G \cong G' \Rightarrow \phi(G) \cong \phi(G')$$

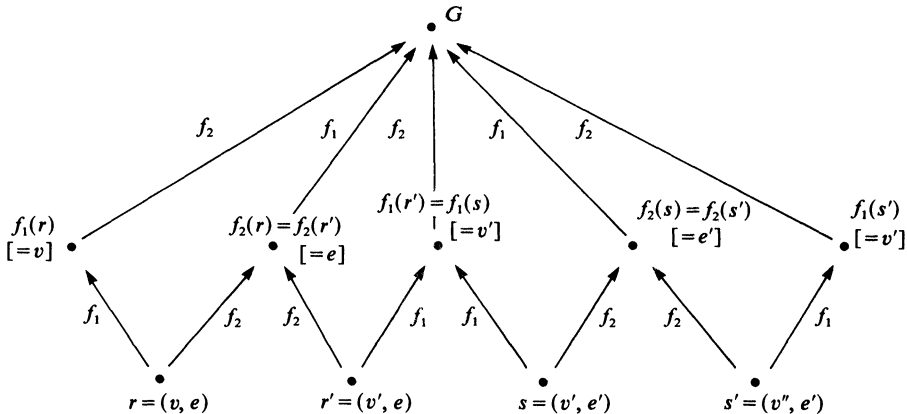

is quite easy. If  $G$  and  $G'$  are isomorphic, then there is a bijection  $f: R_G \rightarrow R_{G'}$ , which fulfills (7). This implies that its free extension  $F(f): F(R_G) \rightarrow F(R_{G'})$  preserves the congruences  $\theta_G, \theta_{G'}$  and the same is true for  $F(f^{-1}): F(R_{G'}) \rightarrow F(R_G)$ , so that  $F(f)$  determines an isomorphism of  $\phi(G)$  onto  $\phi(G')$ .

The proof of the converse, i.e.,

$$\phi(G) \cong \phi(G') \Rightarrow G \cong G'$$

is more delicate and we illustrate the idea in the above examples (a), (b) of varieties in  $\text{ALG}(2)$ .

(a) Since  $M = \{1, G_1, G_2, G_1 \circ G_2\}$ , no element distinct from 1 is invertible so that the condition (iii) in the definition of  $\theta_G$  is trivial. Since  $G_1 \circ G_2$  is a left zero of  $M$ ,  $F(R_G) = \{r, f_1(r), f_2(r) \mid r \in R_G\} \cup \{\sigma_G\}$ , where  $\sigma_G = f_1 f_2(r) = f_2 f_1(r)$  for all  $r \in R_G$ . Hence, for each pair of edges with a common vertex in  $G$ , say  $e = \{v, v'\}, e' = \{v', v''\}$ , we have elements  $r = \{v, e\}, r' = \{v', e\}, s = \{v', e'\}, s' = \{v'', e'\}$  in  $R_G$ ; hence elements  $r, r', s, s', f_i(r), f_i(r'), f_i(s), f_i(s') (i = 1, 2)$  and  $\sigma_G$  in  $F(R_G)$ . Let us take  $f_1$  as  $m_0$  and  $f_2$  as  $m_1$ . Then the congruence  $\theta_G$  gives the following identifications:

If  $h: \phi(G) \rightarrow \phi(G')$  is an isomorphism, then necessarily  $h(\sigma_G) = \sigma_{G'}$  because  $\sigma_G$  is the unique point of  $\phi(G)$  with  $f_1(\sigma_G) = f_2(\sigma_G) = \sigma_G$  and similarly  $\sigma_{G'}$  in  $\phi(G')$ . Then  $h$

has to map any point  $x \in \phi(G)$  with  $f_2(x) = \sigma_G \neq x$  onto a point  $x' \in \phi(G')$  with  $f_2(x') = \sigma_{G'} \neq x'$ . This defines a bijection of the vertex set of  $G$  onto the vertex set of  $G'$ . It can be easily seen from the above diagram that this bijection is an isomorphism of  $G$  onto  $G'$ .

(b) Since  $M = \{1, G_1, G_2\}$ , the condition (iii) in the definition of  $\theta_G$  is trivial again;  $F(R_G)$  consists of  $\{r, f_1(r), f_2(r) \mid r \in R_G\}$ . Hence, for every pair of edges  $e = \{v, v'\}$ ,  $e' = \{v', v''\}$  with a common vertex we have  $r = \{v, e\}$ ,  $r' = \{v', e\}$ ,  $s = \{v', e'\}$ ,  $s' = \{v'', e'\}$  in  $R_G$  as before; and  $r, r', s, s', f_i(v), f_i(r'), f_i(s), f_i(s'), i = 1, 2$  in  $F(R_G)$ . The congruence  $\theta_G$  identifies them as follows:

If  $h : \phi(G) \rightarrow \phi(G')$  is an isomorphism, it maps any  $x \in \phi(G)$  with  $f_1(x) = f_2(x) = x$  to a point  $x' \in \phi(G')$  with the analogous property; hence  $h$  preserves the “levels.” Since  $h$  has also to preserve the following property:

$$\text{There is } y \neq x \text{ with } f_1(y) = x,$$

it defines a bijection of the vertex set of  $G$  onto the vertex set of  $G'$ . This bijection is an isomorphism of  $G$  onto  $G'$  because the following property:

$$\text{There is } y \neq x \text{ with } f_2(y) = x$$

has also to be preserved by  $h$ .

If the monoid  $M$  is more complicated, the construction is less lucid, but the above two “levels” appear in  $\phi(G)$  always and their points cannot be glued together by  $\theta_G$ —this is caused by the nonlinearity of  $M$ . The assumptions about graphs in GRA make it possible “to recognize these two levels in  $\phi(G)$ ” in the general case. The general proof is rather technical and difficult, and the reader is kindly referred to [18]. An outline of the proof of Sichler’s Theorem has been presented to emphasize some properties of the construction (above all the finiteness), which were not explicitly stated in the original paper.

**4. Algorithms for isomorphism testing of unary algebras.** Before we describe our algorithm, we introduce some notation, and prove some lemmas.

Given an algebra  $A = (X, f_1, \dots, f_k)$ , we denote by  $n$  the number of elements of  $X$  and by  $M$  the smallest set of mappings of  $X$  into itself containing the identity mapping of  $X$ , and mappings  $f_1, \dots, f_k$ , which is closed under the composition. Given  $x \in X$ , define  $\text{tr}(x) = \{f(x) \mid f \in M\}$  and  $\text{TR}(x) = \text{tr}(x) \cup \{y \mid f(y) = x \text{ for some } f \in M\}$ .

Let us write  $x \rightarrow y$  if  $f(x) = y$  for some  $f \in M$ , and  $x \sim y$  if both  $x \rightarrow y$  and  $y \rightarrow x$ . Notice that  $\rightarrow$  is a reflexive and transitive relation, and  $\sim$  is an equivalence.

Denote by  $\bar{X} = X/\sim$  the set of all equivalence classes of  $\sim$ . Then  $x, y \in a \in \bar{X}$  implies  $\text{tr}(x) = \text{tr}(y)$  and  $\text{TR}(x) = \text{TR}(y)$ . Sometimes, we write  $\text{tr}(a)$  instead of  $\text{tr}(x)$ , and similarly for  $\text{TR}(a)$ . Given  $a, b \in \bar{X}$ , let us write  $a \Rightarrow b$  if  $x \rightarrow y$  for some  $x \in a, y \in b$ ,  $a \Rightarrow b$  if  $a \Rightarrow b, a \neq b$ , and  $a \Rightarrow c \Rightarrow b$  for no  $c$  different from  $a, b$ .

LEMMA.  $\Rightarrow$  is the smallest transitive and reflexive relation on  $\bar{X}$  containing  $\Rightarrow$ .

We say that an algebra  $A$  is *linear* if for every  $a \in \bar{X}$  there exists at most one  $b \in \bar{X}$  such that  $a \Rightarrow b$ . The linearity of unary algebras is related to the previously defined concept of linearity of monoids as follows.

LEMMA. *Let  $V$  be a variety in  $\text{ALG}(k)$ . If the monoid  $M(V)$  is linear, then any algebra  $A \in V$  is linear.*

*Proof.* Let  $A = (X, f_1, \dots, f_k)$  be an element of  $V$  and  $a, b_1, b_2$  be elements of  $\bar{X}$  such that  $a \Rightarrow b_i, i = 1, 2$ . There are  $x \in a, y_1 \in b_1, y_2 \in b_2$  such that  $x \rightarrow y_1, x \rightarrow y_2$  and therefore  $y_1 = w_1(x), y_2 = w_2(x)$  for some  $w_1, w_2 \in f^*$ . Let  $m_1, m_2$ , respectively be elements of  $M(V)$ , determined by  $w_1, w_2$ , respectively, and denote  $I_i = M(V) \circ m_i$  for  $i = 1, 2$ .  $I_1$  and  $I_2$  are left ideals of  $M(V)$  and therefore if  $M(V)$  is linear, then either  $I_1 \subset I_2$  or  $I_2 \subset I_1$ . Suppose, without loss of generality, that  $I_1 \subset I_2$ . Since  $m_1 \in I_1$ ,  $m_1$  is equal to  $m \circ m_2$  for some  $m \in V$  and therefore

$$y_1 = w_1(x) = w(w_2(x)) = w(y_2) \quad \text{for some } w \in f^*.$$

In this case we have  $y_2 \rightarrow y_1, a \Rightarrow b_2 \Rightarrow b_1$  and hence  $b_2 = b_1$ , because  $a \Rightarrow b_1$  and  $a \neq b_2$ .  $\square$

Our algorithm is based on the solution of the following two problems:

PROBLEM 1. Given an algebra  $A$ , decide whether  $A$  is linear.

PROBLEM 2. Given two linear algebras  $A, B$ , decide whether  $A$  and  $B$  are isomorphic.

If two algebras  $A, B$  are given, our algorithm first uses the procedure solving Problem 1 and applies it to both  $A$  and  $B$ . There are three possibilities:

(1) Neither  $A$  nor  $B$  is linear. In this case the algorithm reports that it is not able to solve the problem, and it stops.

(2) Just one of the algebras  $A, B$  is linear. In this case  $A$  and  $B$  are not isomorphic.

(3) Both  $A$  and  $B$  are linear, and the second procedure is applied to solve the isomorphic problem.

In the next section, we shall show that the algorithm has the properties announced in the Introduction. Now, let us turn to Problem 1. Given  $x, y \in X, a, b \in \bar{X}$ , we shall write  $x \succ y$  if  $y = f_i(x)$  for some  $i = 1, \dots, k$ , and  $a \succ b$  if  $a \neq b$  and  $x \succ y$  for some  $x \in a, y \in b$ .

LEMMA.  $\Rightarrow$  is the smallest reflexive and transitive relation containing  $\succ$ .

LEMMA. If  $a \Rightarrow b$ , then  $a \succ b$ .

*Proof.* Consider  $a, b \in \bar{X}$ . If  $a \Rightarrow b$ , then  $a \neq b$  and  $a \Rightarrow b$ . Since  $\Rightarrow$  is the reflexive and transitive closure of  $\succ$ , there is a sequence  $a = a_0 \succ a_1 \succ \dots \succ a_m = b$  such that  $m \geq 1$  and  $a_i \neq a_j$  for  $i \neq j$ .

If  $m > 1$  then  $a \Rightarrow a_1 \Rightarrow b, a \neq a_1 \neq b$ , which contradicts the definition of  $\Rightarrow$ .  $\square$

LEMMA.  $\succ$  is an acyclic relation.

*Proof.* If  $a_0 \succ \dots \succ a_m \succ a_0$ , then there are  $x_i, y_i \in a_i$  such that  $x_{i-1} \rightarrow y_i$  for  $i = 1, \dots, m$  and  $x_m \rightarrow y_0$ . Since  $x_i \sim y_i$  for all  $i, x_0 \rightarrow y_1 \rightarrow x_1 \rightarrow \dots \rightarrow y_m \rightarrow x_m \rightarrow y_0 \rightarrow x_0$  and therefore  $x_0 \sim x_1 \sim \dots \sim x_m$ , which is a contradiction because it implies  $a_0 = \dots = a_m$ .  $\square$

LEMMA. *Let  $A$  be a linear algebra and suppose that the set  $\bar{X}$  is topologically ordered with respect to  $\succ$ , i.e., elements of  $\bar{X}$  are denoted by  $a_1, \dots, a_m$  in such a way that  $a_i \succ a_j$  implies  $i < j$ . Then  $a \Rightarrow b$  if and only if*

$$b = a_I \quad \text{where } I = \min \{i \mid a \succ a_i\}.$$

*Proof.* Denote  $Y = \{i \mid a \succ a_i\}$ . The set  $Y$  is nonempty if and only if there exists  $c \in \bar{X}$  such that  $a \Rightarrow c$ , because  $a \Rightarrow c$  implies  $a \succ c$ , and the relations  $\Rightarrow$  and  $\succ$  have the same reflexive and transitive closure (equal to  $\Rightarrow$ ). Since  $A$  is linear, if there is  $b$

such that  $a \Rightarrow b$ , then  $b$  is unique. Hence, it is sufficient to prove that if  $Y$  is nonempty and  $I = \min(Y)$ , then  $a \Rightarrow a_I$ .

Since  $a \succcurlyeq a_I$ , we have  $a \Rightarrow a_I$  and  $a \neq a_I$ . If there is  $c$  such that  $a \Rightarrow c \Rightarrow a_I$  and  $a \neq c \neq a_I$ , then there are  $j_1, \dots, j_p$  such that  $a = a_{j_0} \succcurlyeq a_{j_1} \succcurlyeq \dots \succcurlyeq a_{j_p} = c$ , which implies  $j_1 \leq j_p < I$  and we obtain a contradiction with the definition of  $I$ .  $\square$

We are now ready to formulate the following algorithm.

ALGORITHM FOR PROBLEM 1.

1. Determine the relation  $\succcurlyeq$ .
2. Determine the equivalence classes of  $\sim$  by finding strong components of the relation  $\succcurlyeq$ .
3. Determine the relation  $\succcurlyeq$ .
4. Find a topological ordering of  $X$  with respect to the relation  $\succcurlyeq$  (the ordering exists because the relation is acyclic).
5. For any  $a \in \bar{X}$ , find the minimum of the set  $\{b \mid a \succcurlyeq b\}$  with respect to the topological ordering constructed in 4, and denote it by  $m_a$  ( $m_a$  is undefined if  $a \succcurlyeq b$  for no  $b \in \bar{X}$ ). Denote by  $\Rightarrow'$  the relation consisting of all arrows  $a \Rightarrow' m_a$ . (Note that if  $A$  is linear, then  $\Rightarrow'$  is equal to  $\Rightarrow$ .)
6. The relation  $\Rightarrow'$  is a forest whose connected components are trees directed to their roots. Using the depth-first search (see, e.g., [19]), determine whether the following is true:

for every edge  $a \Rightarrow b$ , the element  $b$  belongs to the path from  $a$  to the root of the component of the relation  $\Rightarrow'$  containing  $a$ .

7. Use the fact that the condition given in 6 is valid if and only if the investigated algebra is linear.

LEMMA. *The running time of the algorithm for Problem 1 is  $O(nk)$ .*

*Proof.* The number of edges of the relation  $\succcurlyeq$  is at most  $nk$ . The relation  $\succcurlyeq$  cannot have more edges than the relation  $\succcurlyeq$ . The possibility to perform the computation in the time  $O(nk)$  is obvious for parts 1, 3, 5 of the algorithm and follows from [19] or [11], respectively, for parts 2, 4, respectively. The relation  $\Rightarrow'$  has at most  $n$  edges and therefore time  $O(n)$  is sufficient to search it. At any moment of the search we know which vertices belong to the path from the current vertex to the root of the component, and therefore the testing of the condition given in 6 needs  $O(nk)$  time.  $\square$

As a by-product of the computation, we have constructed the relation  $\Rightarrow$ , provided  $A$  is linear. The relation  $\Rightarrow$  will be used in further computation.

Our solution of Problem 2 is based on a canonical encoding of the sets  $\text{tr}(x)$ . By a *canonical encoding* we mean a mapping  $C$  from the class of all pairs  $(A, x)$ , where  $A \in \text{ALG}(k)$  and  $x$  is an element of  $A$ , into the class of all finite sequences of natural numbers such that  $C(A, x) = C(B, y)$  if and only if there exists a bijection  $F: \text{tr}_A(x) \rightarrow \text{tr}_B(y)$  with the following property:

$$F(x) = y, \quad F(f_i(z)) = g_i(F(z)) \quad \text{for each } z \in \text{tr}_A(x) \text{ and } i = 1, \dots, k,$$

where  $f_1, \dots, g_1, \dots$ , respectively, denote the operation of  $A, B$ , respectively.

We shall deal with the following canonical encoding: Let  $\triangleleft$  be a linear ordering of  $f^*$  defined as follows:  $w_1 \triangleleft w_2$  if either the length of  $w_1$  is less than the length of  $w_2$ , or the length of  $w_1$  and  $w_2$  are equal and  $w_1$  is lexicographically smaller than  $w_2$  (we suppose that  $f_1 \triangleleft f_2 \triangleleft \dots \triangleleft f_k$ ).

In other words,  $1 \triangleleft f_1 \triangleleft \dots \triangleleft f_k \triangleleft f_1 f_2 \triangleleft \dots \triangleleft f_1 f_k \triangleleft f_2 f_1 \triangleleft \dots \triangleleft f_2 f_2 \triangleleft \dots \triangleleft f_k f_k \triangleleft f_1 f_1 f_1 \triangleleft \dots$ .

$C(A, x)$  is determined as follows.

*Canonical encoding of the sets  $\text{tr}(x)$ .*

- (1) Given  $y \in \text{tr}(x)$ , denote by  $w(y)$  the smallest element  $w$  of  $f^*$  with respect to  $\triangleleft$  such that  $y = w(x)$ .
- (2) Order elements of  $\text{tr}(x)$  as  $y_1, \dots, y_m$  in such a way that  $w(y_1) \triangleleft w(y_2) \triangleleft \dots \triangleleft w(y_m)$ .
- (3) The encoding  $C(A, x)$  is the unique sequence

$$c_{11}, \dots, c_{1,k}, \dots, c_{n,1}, \dots, c_{m,k}$$

such that  $f_j(y_i) = y_{c_{i,j}}$  for  $i = 1, \dots, m, j = 1, \dots, k$ .

It is easy to see that  $C$  is really a canonical encoding because the sequence  $C(A, x)$  is, in fact, a description of the restrictions of the operations  $f_1, \dots, f_k$  of the algebra  $A$  to the set  $\text{tr}(x)$ , rewritten with respect to the isomorphism-invariant ordering  $y_1, \dots, y_m$  of  $\text{tr}(x)$ . Moreover, this encoding can be easily computed because the ordering of  $\text{tr}(x)$  can be found by the next algorithm (where  $Q$  is a first-in-first-out queue and  $M$  is a subset of  $\text{tr}(x)$ ).

*begin*

$Q :=$  the queue containing  $x$ ;  $M := \{x\}$ ;  $i := 1$ ;  $y_1 := x$ ;

*while*  $Q$  is nonempty *do*

*begin* remove the first element of  $Q$  from  $Q$  and denote it by  $z$ ;

*for*  $j := 1$  *to*  $k$  *do* *if*  $f_j(z) \notin M$  *then*

*begin*  $i := i + 1$ ;  $y_i := f_j(z)$ ;  $M := M \cup \{f_j(z)\}$ ;

*insert*  $f_j(z)$  at the end of the queue  $Q$  *end*

*end*

*end*;

□

We conclude the following lemma.

LEMMA. *There exists a canonical encoding  $C$  such that  $C(A, x)$  is a sequence of at most  $nk$  natural numbers not greater than  $n$  and  $C(A, x)$  can be computed in time  $O(nk)$ , where  $n$  ( $k$ , respectively) is the number of elements (operations, respectively) of the algebra  $A$ .*

ALGORITHM FOR PROBLEM 2. We can suppose without loss of generality that the given algebras are connected. The first part of the algorithm consists of an application of the above encoding procedure to all elements of both algebras, sorting the elements lexicographically according the values  $C(A, x)$  or  $C(B, x)$ , and partitioning them in such a way that two elements are in the same class if and only if their encodings are equal. The encoding of all elements can be clearly computed in  $O(n^2k)$  time. The same time bound applies to the sorting and the partitioning if  $nk$ -pass radix sort is used (see [12]).

As a result of the first part of the algorithm, we relabel all elements of both algebras in such a way that  $x$  and  $y$  obtain the same label if and only if their encodings are equal, i.e., there is an isomorphism of  $\text{tr}(x)$  onto  $\text{tr}(y)$  which maps  $x$  onto  $y$ . We denote the label of  $x$  by  $\lambda(x)$ .

We can suppose that during the test of linearity of algebras we choose  $x_{a,b} \in a$  and  $F_{a,b} \in \{f_1, \dots, f_k\}$  for any couple of elements  $a, b$  of  $\bar{X}$  such that  $a \Rightarrow b$  in such a way that  $F_{a,b}(x_{a,b}) \in b$ .

The second part of the algorithm is based on the recursive function  $\psi(x, a, b)$ , where  $x \in a \in \bar{X}$ ,  $b \in \bar{Y}$ , which returns the set of all  $y \in b$  such that there exists an isomorphism  $\phi: \text{Tr}(x) \rightarrow \text{TR}(y)$  for which  $\phi(x) = y$ . It is evident that the answer to Problem 2 can be obtained by calling  $\psi(x, a_0, b_0)$ , where  $a_0, b_0$ , respectively, are roots of the relation of the tested algebras, and  $x$  is an arbitrary element of  $a_0$ . (Since

we have supposed that  $A, B$  are connected linear algebras, the roots  $a_0, b_0$  are uniquely determined.)

The function  $\psi$  is given by the next algorithm:

0. function  $\psi(x, a, b)$ ;
1. begin
2. find all  $a_1, \dots, a_r \in \bar{X}$  such that  $a_i \Rightarrow a$  and denote  $x_{a_i, a}$  by  $x_i$ ;
3. find all  $b_1, \dots, b_s \in \bar{Y}$  such that  $b_i \Rightarrow b$ ;
4. if  $r \neq s$  then return the empty set else go to 5;
5.  $Z :=$  the set of all  $y \in b$  such that  $\lambda(x) = \lambda(y)$ ;
6. if  $r = 0$  or  $Z = \emptyset$  then return the set  $Z$ ;
7. for  $i := 1$  to  $r$  do for  $j := 1$  to  $r$  do  $Z_{i,j} := \psi(x_i, a_i, b_j)$ ;
8. for  $i := 1$  to  $r$  do
9.     begin find natural numbers  $j_0, \dots, j_p$  such that  $F_{a_i, a} = f_{j_0}$  and  $f_{j_p} \circ \dots \circ f_{j_1}(x_i) = x$ ;
10.     for all  $z \in b_1 \cup \dots \cup b_r$  do  $G_i(z) := g_{j_p} \circ \dots \circ g_{j_0}(z)$
11.     end;
12. for all  $y \in Z$  do
13.     begin
14.     for  $i := 1$  to  $r$  do for  $j := 1$  to  $r$  do  
             $W_{i,j} :=$  the set of all  $z \in Z_{i,j}$  such that  $G_i(z) = y$ ;
15.     if there exists no permutation  $\pi$  of  $\{1, \dots, r\}$  such that  
             $W_{m, \pi(m)} \neq \emptyset$  for every  $m = 1, \dots, r$   
            then delete  $y$  from  $Z$
16.     end
17. end;

First, we have to prove the correctness of  $\psi$ . We do it by induction on the length  $H$  of the longest sequence of the form  $c_0 \Rightarrow c_1 \Rightarrow \dots \Rightarrow c_H = a, c_0, \dots, c_H \in \bar{X}$ .

Let us suppose that  $y \in \psi(x, a, b)$ ; hence  $\lambda(x) = \lambda(y)$ . As we have already shown, there exists an isomorphism  $\phi_0: \text{tr}(x) \rightarrow \text{tr}(y)$  such that  $\phi_0(x) = y$ . If  $H = 0$ , then  $r = 0$ ,  $\text{tr}(x) = \text{TR}(x)$  and  $\text{tr}(y) = \text{TR}(y)$ , and the correctness of the algorithm is proved. Let us suppose that  $H > 0$ , i.e.,  $r > 0$ , and  $\psi$  is correct for  $H - 1$ . We know that there exists a permutation  $\pi$  of  $\{1, \dots, r\}$  and elements  $y_i \in \psi(x_i, a_i, b_{\pi(i)})$  such that  $G_i(y_i) = y$ . By the induction hypothesis, there exists isomorphisms  $\phi_i: \text{TR}(x_i) \rightarrow \text{TR}(y_i)$  such that  $\phi_i(x_i) = y_i$ . If  $j_0, \dots, j_p$  are numbers obtained in line 9 for a given value  $i$ , then we know that  $\phi_i(x) = \phi_i(f_{j_p} \circ \dots \circ f_{j_0}(x_i)) = g_{j_p} \circ \dots \circ g_{j_0}(\phi_i(x_i)) = G_i(y_i) = y = \phi_0(x)$  and therefore,  $\phi_i$  and  $\phi_0$  coincide on  $\text{tr}(x)$ .

Put

$$\phi(z) = \begin{cases} \phi_i(z) & \text{if } z \in \text{TR}(x_i), \\ \phi_0(z) & \text{if } z \in \text{tr}(x). \end{cases}$$

This formula gives an isomorphism of  $\text{TR}(x)$  onto  $\text{TR}(y)$  such that  $\phi(x) = y$ , provided  $\phi$  is defined correctly. Thus, it is sufficient to prove that

$$\begin{aligned} \text{tr}(x) \subset \text{TR}(x_i), \text{TR}(x) = \text{TR}(x_1) \cup \dots \cup \text{TR}(x_r) \quad \text{and} \\ \text{TR}(x_i) \cap \text{TR}(x_j) = \text{tr}(x) \quad \text{for } i \neq j. \end{aligned}$$

The proof follows immediately from the fact that, given  $c \in \bar{X}$ ,  $\text{tr}(c)$  is a union of  $c$  with all successors of  $c$  with respect to the relation  $\Rightarrow$ ,  $\text{TR}(c)$  is a union of  $c$  with all

successors and predecessors of  $c$  with respect to  $\Rightarrow$ , and  $a_1, \dots, a_r$  form the set of all immediate predecessors of  $a$  with respect to  $\Rightarrow$ .

Conversely, let us suppose that there exists an isomorphism  $\phi : \text{TR}(a) \rightarrow \text{TR}(b)$  such that  $\phi(x) \in b$ . We want to prove that  $\phi(x)$  is an element of  $\psi(x, a, b)$ . In line 5,  $\phi(x)$  is inserted into  $Z$ , and therefore, if  $H = 0$ , then  $\phi(x) \in Z = \psi(x, a, b)$ . Suppose that  $H > 0$ . It is evident that, in this case,  $r = s > 0$  in lines 2, 3 and according to the induction hypothesis, we know that there exists a permutation  $\pi$  of  $\{1, \dots, r\}$  such that  $W_{m, \pi(m)} \neq \emptyset$  for every  $m = 1, \dots, r$  when lines 12–17 are performed for  $y = \phi(x)$ , namely, the permutation determined by  $\phi(x_m) \in b_{\pi(m)}$ . It follows that  $\phi(x)$  is not deleted from  $Z$  and is an element of the resulting  $\psi(x, a, b)$ .

Given  $x \in a \in X$ , let us denote the number of elements of the set  $\{f^{-1}(x) \mid f \in M\} = (\text{TR}(x) - \text{tr}(x)) \cup a$  by  $n_x$ . Our last task is to prove that there exists a constant  $c_0$  such that  $\psi(x, a, b)$  can be computed in at most  $c_0 n_x^3$  steps, provided  $\Rightarrow$  and  $\lambda$  are given. Again, we proceed by the induction of the number  $H$ .

It is easy to show that  $O(n_x)$  steps are sufficient to perform the lines 1–6. Thus, our proposition is true for  $H = 0$ . Let us denote the number of elements of  $a$  by  $n_0$  and use  $n_i$  instead of  $n_{x_i}$ . If our time bound is true for  $H - 1$ , then the line 7 requires at most

$$\begin{aligned} c_0 \sum_{i=1}^r \sum_{j=1}^r n_i^3 &\leq c_0 \sum_{i=1}^r n_i \sum_{j=1}^r n_j^2 \leq c_0 (n_1 + \dots + n_r) \cdot (n_1 + \dots + n_r)^2 \\ &\leq c_0 n_x^3 \end{aligned}$$

steps if we ignore terms of smaller order.

To perform line 9, it is sufficient to find a path from  $F_{a_i, a}(x_i)$  to  $x$  in the set  $a$  with respect to the relation  $\rightarrow$  defined in the first part of the section. Thus,  $O(n_0)$  steps are sufficient (see e.g., [1]) and  $p = O(n_0)$ . It follows that the total time spent on line is  $O(n_0 r) = O(n_0 (n_1 + \dots + n_r))$ .

An efficient search for a permutation  $\pi$  in line 15 can be based on the next lemma.

LEMMA. *If  $W_{u,w}, W_{v,w}, W_{v,z}$  are nonempty for some  $u, v, w, z$ , then the set  $W_{u,z}$  is also nonempty.*

*Proof.* If  $W_{u,w}$  is nonempty, then there exists an isomorphism  $\phi_{u,v} : \text{TR}(u) \rightarrow \text{TR}(w)$  such that  $G_u(\phi_{u,v}(x_u)) = y$ , which implies  $y = G_u \phi_{u,v}(x_u) = \phi_{u,w} f_{j_p} \dots f_{j_0}(x_u) = \phi_{u,w}(x)$ . Similarly, we can suppose that there are isomorphisms  $\phi_{v,w} : \text{TR}(v) \rightarrow \text{TR}(w)$  and  $\phi_{v,z} : \text{TR}(v) \rightarrow \text{TR}(z)$  such that  $\phi_{v,w}(x) = \phi_{v,z}(x) = y$ .

Now, the mapping  $\phi_{v,z} \phi_{v,w}^{-1} \phi_{u,w} : \text{TR}(u) \rightarrow \text{TR}(z)$  is also an isomorphism which maps  $x$  into  $y$ . Since  $\phi_{u,z}(x_u) \in Z_{u,z} = \psi(x_u, a_u, b_z)$  and  $G_i(\phi_{u,z}(x_u)) = y$ , it is easy to see that  $W_{u,z} \neq \emptyset$ .  $\square$

It follows from the above lemma that a permutation  $\pi$ , if it exists, can be found by putting

$$\pi(m) = \text{an arbitrary element } j \text{ of the set } \{1, \dots, r\} - \{\pi(1), \dots, \pi(m-1)\} \text{ such that } W_{m,j} \neq \emptyset,$$

for  $m = 1, \dots, r$ . It follows that  $O(r^2)$  steps are sufficient to decide the existence of  $\pi$ .

It is easy to see that lines 1–6 and 8–17 require at most  $c n_0 (n_1 + \dots + n_r)^2$  steps for some constant  $c$ . If  $c_0$  has been chosen so that  $c_0 \geq c$ , then  $\psi$  can be computed in at most

$$c n_0 (n_1 + \dots + n_r)^2 + c_0 (n_1 + \dots + n_r)^3 \leq c_0 (n_0 + \dots + n_r)^3 = c_0 n_x^3$$

steps.

Combining the computation of  $\lambda$  and  $\psi$ , we obtain the following theorem.

**THEOREM.** *The existence of an isomorphism of two linear unary algebras with  $n$  elements and  $k$  operations can be tested in time  $O(n^2k + n^3)$ .*

If we work in a fixed variety of algebras then  $k$  is fixed, and we obtain the  $O(n^3)$  time bound.

**5. Main results.** The next two theorems are the main results of the present paper.

**THEOREM 1.** *There exists an algorithm  $\mathcal{A}$  such that, given two unary algebras  $A$  and  $B$  with  $n$  elements and  $k$  operations, either  $\mathcal{A}$  fails after  $O(nk)$  steps, this occurs only if each variety  $V$  containing either  $A$  or  $B$  is isomorphism-complete, or  $\mathcal{A}$  decides the existence of an isomorphism of  $A$  and  $B$  after  $O(n^2(n+k))$  steps.*

**THEOREM 2.** *Let  $V$  be a variety of unary algebras. If  $M(V)$  has a finite nonlinear factor-monoid then the isomorphism problem in  $V$  is isomorphism-complete, else we can solve the isomorphism problem in  $V$  in a polynomially bounded time (hence the condition  $C$ , mentioned in the abstract, is that every finite factor-monoid of  $M(V)$  is linear).*

*Proof of Theorems.* Let  $A = (X, f_1, \dots, f_k)$  be a unary algebra and let  $M_A$  be the monoid of maps  $X \rightarrow X$  generated by the operations  $f_1, \dots, f_k$ . If  $A$  is not linear (in the sense of § 4), then  $M_A$  is also not linear (in the sense of § 3). Now, we show that the algorithm described in § 4 satisfies Theorem 1. Indeed, given two unary algebras  $A$  and  $B$  with  $n$  elements and  $k$  operations, it decides after  $O(nk)$  steps whether they are linear or not. If both  $A$  and  $B$  are nonlinear, then both varieties  $V_A$  and  $V_B$  in  $\text{ALG}(k)$ , generated by  $A$  and by  $B$  have nonlinear finite monoids  $M(V_A)$  and  $M(V_B)$ , because  $M(V_A)$  is isomorphic to  $M_A$ , and analogously for  $B$  (see [6]); hence  $V_A$  and  $V_B$  are isomorphism-complete in view of the Sichler Theorem. Any variety with  $A \in V$  contains  $V_A$ , and hence, it is also isomorphism-complete, and analogously for  $B$ . Thus, if  $V$  is a variety such that either  $A \in V$  or  $B \in V$ , then  $V$  is isomorphism-complete.

If  $M(V)$  has a finite nonlinear factor-monoid  $M'$ , then  $V(M') \subset V$  and  $V(M')$  is isomorphism complete, by the Sichler Theorem. It follows that  $V$  is also isomorphism complete. If  $M(V)$  has no finite nonlinear factor-monoid, then any finite algebra  $A \in V$  must be linear, because the monoid  $M_A$ , being a finite factor-monoid of  $M(V)$ , is linear. Thus, the algorithm described in § 4 solves the isomorphism problem in  $V$  in the polynomially bounded time.  $\square$

**Acknowledgment.** We are indebted to J. Sichler for fruitful correspondence and for turning our attention to the nonlinear monoids and to paper [18].

## EFFICIENT PARALLEL EVALUATION OF STRAIGHT-LINE CODE AND ARITHMETIC CIRCUITS\*

GARY L. MILLER<sup>†</sup>, VIJAYA RAMACHANDRAN<sup>‡</sup>, AND ERICH KALTOFENS<sup>§</sup>

**Abstract.** A new parallel algorithm is given to evaluate a straight-line program. The algorithm evaluates a program over a commutative semi-ring  $R$  of degree  $d$  and size  $n$  in time  $O((\log n)(\log nd))$  using  $M(n)$  processors, where  $M(n)$  is the number of processors required for multiplying  $n \times n$  matrices over the semi-ring  $R$  in  $O(\log n)$  time.

**Key words.** parallel computation, straight-line code, arithmetic circuits

**AMS(MOS) subject classifications.** 68Q40, 68Q35, 68Q25

**1. Introduction.** In this paper, we consider the problem of dynamic evaluation of a straight-line program in parallel. This is a generalization of the result of Valiant, Skyum, Berkowitz, and Rackoff [VSBR]. They consider the problem of taking a straight-line program and transforming it into a program of "shallow" depth. Their transformation is performed by a sequential polynomial time algorithm. We show how to construct this "shallow" program with at most the same size and the same time bounds on-line, no preprocessing, as their off-line algorithm.

We consider two basically equivalent models of evaluation over a semi-ring: straight-line programs and arithmetic circuits. In the introduction we will restrict our discussion to the former model while most of the rest of the paper will deal with the latter model. A *straight-line program* over a commutative semi-ring  $R = (R, +, \times, 0, 1)$  is a sequence of assignment statements of the form  $a \leftarrow b + c$  or  $a \leftarrow b \times c$ , where  $b$  and  $c$  are either elements of  $R$  or previously assigned variables. We will assume that the semi-ring operations can be performed in unit time. Let  $M(n)$  denote the number of processors required to multiply two  $n \times n$  matrices in  $\log n$  time over the semi-ring  $R$  [AHU], [CWb].

A special case of a straight-line program is a Boolean circuit. Ladner has shown that the Boolean circuit evaluation problem is  $P$ -complete [Lad]. It is therefore believed that this evaluation problem is not in  $NC$  [Coo]. In this paper, we show that circuits of degree  $d$  and size  $n$  (we define the degree of a circuit in Definition 2.3) can be evaluated in time  $O(\log n(\log nd))$  using  $M(n)$  processors. The crucial difference between this result and the result in Valiant, Skyum, Berkowitz, and Rackoff [VSBR] is that our algorithm need not know the degree of the circuit in advance. As a nontrivial application of our procedure we can also compute the degree of a circuit in the above time and processor bounds. This follows because the operations of maximum and sum form a commutative semi-ring over the nonnegative integers. We know of no other

parallel algorithm for computing the degree that satisfies the above time and processor bounds.

**2. Preliminaries.** We view a straight-line program as a special case of a more general object, an arithmetic circuit. Our results are more easily applied to arithmetic circuits:

DEFINITION 2.1. An *arithmetic circuit* is an edge-weighted directed acyclic graph (DAG) (where the weights on the edges are from the semi-ring  $R$ ) satisfying the following conditions:

- Each node is labeled as one of three types: a leaf, a multiplication node, or an addition node.
- Leaves are assigned a value in  $R$ , denoted  $\text{value}(v)$  for a leaf  $v$ .
- The indegree of a leaf node is zero, a multiplication node is two, and an addition node is nonzero.
- All edges are directed away from leaves.
- There are no edges from multiplication nodes to multiplication nodes.

Note that any circuit can be modified to satisfy the last condition by simply adding a dummy addition node of indegree and outdegree 1 in the middle of each edge that connects two multiplication nodes. We say an edge is a *plus-plus* edge if it connects two addition nodes. The *size* of an arithmetic circuit  $U$  is the number of nodes in  $U$ . The *subcircuit evaluating  $v$* , denoted by  $U_v$ , is the subcircuit induced by all nodes that are contained on some path to  $v$ . A node  $w$  is a *child* of  $v$  if there exists an edge from  $w$  to  $v$ . A node of outdegree 0 is called an *output node*.

DEFINITION 2.2. We define the *value* of each node  $v$  in an arithmetic circuit  $U_v$  by induction on the size of  $U_v$ . The value for a leaf is given by the definition of an arithmetic circuit. If the node  $v$  is an additional node with children  $v_1, \dots, v_k$  then the value of  $v$  is defined by:

$$\text{value}(v) = \sum_{i=1}^k \text{value}(v_i) \cdot U(v_i, v),$$

where  $U(v_i, v)$  is the weight on the edge from  $v_i$  to  $v$ . If, on the hand,  $v$  is a multiplication node with children  $v_1$  and  $v_2$ , then

$$\text{value}(v) = \text{value}(v_1) \cdot \text{value}(v_2) \cdot U(v_1, v) \cdot U(v_2, v).$$

We will restrict our attention to circuits where any edge entering a multiplication node has weight 1. All the algorithms in this paper preserve this restriction. Thus, the value of the multiplication node  $v$  is  $\text{value}(v_1) \cdot \text{value}(v_2)$ . The *value* of a circuit is a vector of all its node values.

Given a straight-line program, we obtain its arithmetic circuit by constructing a node for each statement and for each input variable, and an edge from node  $i$  to node  $j$  if  $j$  is a statement that uses the variable evaluated at statement  $i$ . All edge weights are set to 1, and nodes corresponding to input variables are given values assigned to the corresponding variables.

DEFINITION 2.3. The (*algebraic*) *degree* of a node in an arithmetic circuit is defined inductively: a leaf has degree 1, an addition node has degree equal to the maximum degree of its children, and a multiplication node has degree equal to the sum of the degree of its children. The *degree* of an arithmetic circuit is the maximum over the degree of its nodes.

**3. The algorithm.** In this section, we describe our algorithm for arithmetic circuit evaluation. The value of the circuit will be obtained by repeated application of a procedure called *Phase*. This procedure takes as input an arithmetic circuit and returns

a new circuit with the same nodes such that every node will have the same value as before. Repeated application of *Phase* will eventually return with the value of the circuit.

In a natural way an arithmetic circuit can be viewed as an upper-triangular matrix  $U$  with zero diagonal, where the entry  $U_{ij}$  is the weight on the edge from node  $v_i$  to node  $v_j$  if the edge exists; it is zero otherwise. We need three submatrices derived from  $U$ :

$$U(+, +)_{ij} = \begin{cases} U_{ij} & \text{if } v_i \text{ and } v_j \text{ are addition nodes} \\ 0 & \text{otherwise,} \end{cases}$$

$$U(X, +)_{ij} = \begin{cases} U_{ij} & \text{if } v_j \text{ an addition node} \\ 0 & \text{otherwise,} \end{cases}$$

$$U(X, X)_{ij} = \begin{cases} U_{ij} & \text{if } v_i \text{ or } v_j \text{ is not an addition node} \\ 0 & \text{otherwise.} \end{cases}$$

The matrix  $U(+, +)$  corresponds to the subcircuit containing only plus-plus edges, while  $U(X, +)$  corresponds to the subcircuit containing any edge terminating at an addition mode. While the matrix  $U(X, X)$  corresponds to the subcircuit containing those only edges such that at least one end node is not an addition node. Thus,  $U(+, +) + U(X, X) = U$ . We can now define the procedure Matrix Multiply (MM). The procedure uses one matrix multiplication and one matrix addition over the semi-ring  $R$ . Thus, it can be performed in  $O(\log n)$  time using  $O(n^{2.49})$  processors for many semi-rings. In Fig. 1, we give an example of procedure MM.

**Procedure MM( $U$ )**

$$U \leftarrow U(X, +) \cdot U(+, +) + U(X, X)$$

We need two more procedures called Plus Evaluate ( $Eval_+$ , see Fig. 2), and Multiplication Evaluate or Shunt ( $Eval_\times$ , see Fig. 3). The first of these procedures simply evaluates an addition node if all its children have been evaluated. The first part of the second procedure evaluates a multiplication node if both its children have been evaluated. The new idea is the second part of the procedure which we call *Shunt*. Here we do partial evaluation of a multiplication node when only one of its arguments

$$\begin{pmatrix} 0 & a & a\gamma + b & a\alpha + b\beta + c \\ 0 & 0 & 0 & \beta\gamma \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} = \begin{pmatrix} 0 & a & b & c \\ 0 & 0 & \gamma & \alpha \\ 0 & 0 & 0 & \beta \\ 0 & 0 & 0 & 0 \end{pmatrix} \cdot \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & \gamma & \alpha \\ 0 & 0 & 0 & \beta \\ 0 & 0 & 0 & 0 \end{pmatrix} + \begin{pmatrix} 0 & a & b & c \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}$$

FIG. 1. An arithmetic circuit before and after an application of procedure MM.

has been evaluated. Figure 4 shows the effect of applying  $Eval_x$  to a circuit. Leaves are denoted by square boxes and nonleaves by circles. The value of each leaf is written in its box and the weight of an edge is written alongside it. The left circuit is before  $Eval_x$  and the right is after  $Eval_x$ . Zero weight edges have been removed.

The procedures  $Eval_+$ ,  $Eval_x$ , and MM can all be performed on a PRAM in  $O(\log n)$  time. The processor count for MM is the number of processors required for matrix multiplication for the particular semi-ring of the circuit. Procedures  $Eval_+$  and  $Eval_x$  need only  $O(n^2)$  processors. To see that  $Eval_x$  can be performed with  $O(n^2)$  processors, note that the number of terms  $F_{lji}$  in line (\*) is at most the number of edges. Thus, we simply sort these terms on their key  $(l, i)$  using say a randomized parallel bucket sort [Rei] or a deterministic comparison-based sorting algorithm [Col], [AKS] and then sum the terms using parallel list-ranking [MR], [Vis], [CV], [AM].

It is interesting to point out a strong analogy between the procedures Rake and Compress used to evaluate expression trees, see [MR], and our new procedures. One can view  $Eval_+$  and  $Eval_x$  as removing the leaves of an arithmetic circuit, i.e., Rake; while Matrix Multiplication, MM, “compresses” addition chains, a natural generalization of Compress [MR]. In fact, the  $Eval_x$  is a combination of a Rake and a Compress step since it removes leaves in the first part and does a partial compress in the second part.

Another analogy can be made between Top-Down algorithms and Bottom-Up ones. Brent gave a Top-Down parallel algorithm for expression evaluation [Bre], while Miller and Reif gave a Bottom-Up parallel algorithm for the problem [MR]. On the other hand, Valiant, Skyum, Berkowitz, and Rackoff gave a Top-Down parallel algorithm for arithmetic circuit evaluation [VSBR]; in this paper, we give a Bottom-Up parallel algorithm for this problem.

**Procedure  $Eval_+(U)$**

```

for all addition nodes  $v_j$  whose children are leaves do
  value  $(v_j) \leftarrow \sum_{i=1}^n \text{value}(v_i) \cdot U_{ij}$ 
  set  $v_j$  to a leaf
   $U_{ij} \leftarrow 0$  for  $i \in \{1, \dots, n\}$ 
od

```

FIG. 2. The procedure plus evaluation.

**Procedure  $Eval_x(U)$**

```

for all multiplication nodes  $v_j$  with children  $v_k$  and  $v_l$ , both of which are leaves,
do
  value  $(v_j) \leftarrow \text{value}(v_k) \cdot \text{value}(v_l)$ 
  Set  $v_j$  to a leaf
   $U_{kj} \leftarrow 0$  and  $U_{lj} \leftarrow 0$ 
od
for all  $U_{ji}$  where  $v_j$  is a multiplication node with children  $v_k$  and  $v_l$ 
  and  $v_k$  is a leaf and  $v_l$  is not do
   $F_{lji} \leftarrow \text{value}(v_k) \cdot U_{ji}$ 
od
for all pairs  $(l, i)$  do
   $W_{li} \leftarrow \sum_j F_{lji}$ 
   $U_{li} \leftarrow U_{li} + W_{li}$ 
   $U_{ji} \leftarrow 0$ 
od

```

(\*)

FIG. 3. The procedure multiplication evaluation or shunt.

FIG. 4. An arithmetic circuit before and after an application of procedure  $Eval_x$ .

We combine these three procedures,  $MM$ ,  $Eval_+$ , and  $Eval_x$ , into a single procedure *Phase* that we will repeatedly apply until the value of the arithmetic circuit is returned:

```

Procedure Phase ( $U$ )
  do
     $U \leftarrow MM(U)$ 
     $U \leftarrow Eval_+(U)$ 
     $U \leftarrow Eval_x(U)$ 
  od
    
```

To show that *Phase* is correct (sound) it will suffice to prove the following lemma.

LEMMA 3.1. *The procedures  $MM$ ,  $Eval_+$ , and  $Eval_x$  applied to an arithmetic circuit return new circuits with the same value.*

The proof of the lemma follows, by a straightforward proof by induction on the size of  $U$ , using the associative, commutative, and distributive properties of  $R$ .

In Fig. 5, we show the effect of applying the different procedures to a circuit. We represent leaves by square boxes and addition or multiplication nodes by circles. All isolated nodes have been deleted and edge weights have been ignored. We start with the circuit (a) and apply procedure  $MM$  obtaining circuit (b), to which circuit (b) we apply procedure  $Eval_+$  obtaining circuit (c), to which we then apply  $Eval_x$  obtaining circuit (d).

**4. The height of an arithmetic circuit.** In this section, we define the height of a node. This notion is the main tool we shall use to analyse the procedure *Phase*. In Theorem 4.2, we will prove an upper bound on the height in terms of the size and the degree of a circuit. We will show in the next section that every application of *Phase* reduces the height of the circuit by a factor of approximately one half. The above two facts prove the main theorem of this paper.

DEFINITION 4.1. The *height* of a node is defined inductively:

- (1) A leaf has *height* 1.
- (2) A multiplication node has height equal to the sum of the heights of its children.
- (3) If  $v$  is an addition node then the height of  $v$  equals  $\max(a + 1/2, m)$ , where  $a$  equals the maximum height of any child of  $v$  which is an addition node, and  $m$  equals the maximum of the heights of the children which are either a leaf or a multiplication node.

The *height* of a circuit  $U$  is the maximum height of any node in  $U$ .

FIG. 5. An arithmetic circuit after successive application of the procedures: MM, Eval<sub>+</sub>, and Eval<sub>×</sub>.

We say a child  $w$  of an addition node  $v$  is *dominant* if either  $w$  is a multiplication node and  $h(v) = h(w)$  or it is an addition node and  $h(v) = h(w) + \frac{1}{2}$ , i.e., the height of  $w$  determines the height of  $v$ . We can now prove the upper bound on the height of a circuit.

**THEOREM 4.2.** *If  $U$  is an arithmetic circuit of degree  $d$  and  $e$  is the number of plus-plus edges, then the height of  $U \leq \frac{1}{2}e \cdot d + d$ .*

*Proof.* The proof is by induction on the number of nodes  $n$  in the subcircuit  $U_v$ . We start with subcircuits of size one, leaves. The height of a leaf is one which is clearly less than or equal to  $e + 1$ . Suppose the theorem is true for subcircuits of size  $\leq n$ . We show the theorem holds for circuits of size  $n + 1$ . Let  $U_v$  be a subcircuit with  $n + 1$  nodes. Let  $v_1, \dots, v_k$  be the children of  $v$  having degrees  $d_1, \dots, d_k$  and heights  $h_1, \dots, h_k$ , respectively. The subcircuits evaluating  $v_1, \dots, v_k$  are of size  $\leq n$ . Therefore, by induction  $h_i \leq \frac{1}{2}e'd_i + d_i$ , for  $1 \leq i \leq k$ , where  $e'$  is the number of plus-plus edges in

$U_v$ . There are two cases:  $v$  is either an addition node or a multiplication node. We treat the two cases separately.

First, suppose that  $v$  is a multiplication node. The degree  $d$  of  $v$  equals  $d_1 + \dots + d_k$  and the height, by induction, is  $\leq \sum_{i=1}^k \frac{1}{2}e'd_i + d_i$ , which is equal to  $\frac{1}{2}e'd + d$ . Thus, the theorem holds in this case, since  $e' \leq e$ . Second, suppose that  $v$  is an addition node. Again, there are two cases: either a dominant child is an addition node or it is a multiplication node. The most interesting case is the first case. Suppose that  $v_1$  is a dominant addition node, i.e.,  $h_1 \geq h_i, 1 \leq i \leq k$ . Here the degree  $d$  of  $v$  will be greater than or equal to  $d_1$ , while the height  $h = h_1 + \frac{1}{2} \leq \frac{1}{2}e'd_1 + d_1 + \frac{1}{2} \leq \frac{1}{2}e'd + d + \frac{1}{2}$ . Since we have at least one new plus-plus edge we know that  $e' \leq e - 1$ . Thus,  $h \leq \frac{1}{2}(e - 1)d + d + \frac{1}{2} = \frac{1}{2}ed - \frac{1}{2}d + d + \frac{1}{2}$ . Using the fact that  $d \geq 1$  we get the desired estimate,  $h \leq \frac{1}{2}ed + e$ .  $\square$

**5. Analysis of the algorithm.** In this section we use the height of a circuit to analyse the number of applications of *Phase* needed to evaluate a circuit of height  $h$ . We start by stating and proving the main technical lemma from which the main theorem will follow. Recall that all procedures defined so far take circuits to circuits. They modify the edge structure but map nodes to nodes in a one-to-one way. Thus, we may view the procedures as maps of circuits to circuits which are themselves surjective on nodes. Throughout this section let  $U$  be a circuit and  $U'$  its image under the transformation *Phase*. Similarly, if  $v$  is a node of  $U$  then its image under *Phase* will be denoted by  $v'$ .

LEMMA 5.1. *If  $U$  and  $U'$  are arithmetic circuits as above and  $v'$  is a node of  $U'$  which is not a leaf and not an output node, then the height of  $v$  is at least twice the height of  $v'$ .*

*Proof.* Let  $v'$  be a node of  $U'$  which is neither a leaf nor an output node. The proof will be by induction on the size of the subcircuit  $U'_v$ . We begin with the case when all the children of  $v'$  are leaves. There are two subcases: either  $v'$  is an addition node or it is a multiplication node. First, suppose that  $v'$  is an addition node. We must show that the height of  $v$  is at least 2, where  $v$  is the preimage of  $v'$ . Suppose by way of a contradiction that the height of  $v$  is  $< 2$ . Now,  $v$  cannot be of height 1 because a height 1 node must either be a leaf or all its children are leaves. Thus, one application of  $Eval_+$  will transform  $v$  into a leaf, a contradiction. If, on the other hand, the height is  $3/2$  then all the dominant children of  $v$  are addition nodes whose children are leaves. Thus, after MM and  $Eval_+$  the node  $v$  will be a leaf, and hence  $v'$  will be a leaf. This proves the case when  $v'$  is an addition node of height 1.

We next consider the more interesting case when  $v'$  is a multiplication node with both its children leaves. It will suffice to show that both children of  $v$  have height at least 2. Suppose that one child  $w$  has height less than 2. In this case, after MM and  $Eval_+$  the node  $w$  will be a leaf. Thus, after  $Eval_\times$  the vertex  $v$  will be either a leaf or an output node, depending on whether the other child of  $v$  is a leaf or not after  $Eval_+$ , a contradiction. This proves the initial cases of the induction.

The inductive case for multiplication nodes is rather straightforward. The only difficulty arises when one of the two children of  $v'$  is a leaf. We handle this by noting that in the last paragraph we actually proved something slightly stronger. Namely, if  $v'$  is a multiplication node which is not an output node and  $w'$  is a child of  $v'$  which is a leaf then the height of  $w$  is at least 2. Thus, induction for the multiplication nodes follows. We have only to prove the induction for addition nodes.

Suppose that  $v'$  is an addition node. Let  $w'$  be a dominant child of  $v'$ . If  $w'$  is a multiplication node the theorem follows easily. Thus, we may assume that  $w'$  is an addition node. It will suffice to prove the following claim.

CLAIM. The height of  $w$  is  $\leq$  the height of  $v$  minus 1, i.e.,  $h(w) \leq h(v) - 1$ .

*Proof of claim.* Note that both  $v$  and  $w$  are addition nodes. If there is a path in  $U$  from  $w$  to  $v$  containing two or more edges, then the claim follows by the definition of height. Thus, the only path from  $w$  to  $v$  is a singleton edge. But this is a contradiction, since procedure  $MM$  will then remove this edge and the procedures  $Eval_+$  and  $Eval_\times$  cannot replace it since there are now no paths from  $w$  to  $v$ . This proves the claim and the theorem.  $\square$

By Lemma 5.1, after  $\lceil \log_2 h \rceil$  applications of  $Phase$  to a circuit of height  $h$  the resulting circuit will contain only leaves and output nodes. Thus, in one more application of  $Phase$  (only  $Eval_+$  and  $Eval_\times$  are needed) all nodes will be leaves; the circuit has been evaluated. With a slightly more careful analysis the number of applications can be bounded by  $\lceil \log_2 h \rceil + 1$ . We state this fact as a theorem.

**THEOREM 5.2.** *If  $U$  is an arithmetic circuit with height  $h$ , then after  $\lceil \log_2 h \rceil + 1$  applications of  $Phase$ , all nodes of  $U$  are evaluated.*

The upper bounds given in Theorem 5.2 are optimal for our procedure  $Phase$ . In Fig. 6 we exhibit a circuit  $C_k$ , for  $k \geq 2$ , of height  $2^k - \frac{1}{2}$  which requires  $2^k$  applications of  $Phase$ . It is not hard to see that  $C_2$  requires 2 applications of  $Phase$ ; and the subcircuit evaluating  $v$  contained in  $Phase(C_{k+1})$  equals  $C_k$ , for  $k \geq 2$ .

We can now prove the main theorem of the paper.

**THEOREM 5.3.** *If  $U$  is an arithmetic circuit of degree  $d$  and size  $n$  then the value can be computed in parallel in time  $O((\log n)(\log nd))$  using at most  $M(n)$  processors.*

FIG. 6. The arithmetic circuit  $C_k$ ; a worst-case example for  $Phase$ .

*Proof.* By Theorem 5.2, procedure  $Phase$  need only be applied  $\lceil \log h \rceil + 1$  times, where  $h$  is the height of  $U$ . By Theorem 4.2,  $h = O(e \cdot d)$ . Thus,  $Phase$  is applied  $O(\log nd)$  times. Now, each application of  $Phase$  requires only  $\log n$  parallel time. The processor-expensive step is the matrix multiplication in  $MM$ , which can be performed using  $O(M(n))$  processors.  $\square$

We give a few simple corollaries to Theorem 5.3. We say a function  $g(n)$  is pseudopolynomial in  $n$  if  $g(n) = O(n^{\log^k n})$  for some constant  $k$ . That is  $\log(g(n)) = O((\log n)^{k+1})$ .

**COROLLARY 5.4.** *To determine if a straight-line program has pseudopolynomial degree is in  $NC$  for each constant  $k$ .*

COROLLARY 5.5. *The value of a straight-line program of pseudopolynomial degree can be computed in NC for each constant  $k$  where the input values are integers and operations are addition and multiplication.*

To see the last corollary we observe that the output of a straight-line program of pseudopolynomial degree has polynomial size in binary in terms of the size of the program.

**6. Open questions.** We know of no similar results for noncommutative rings. We note that for arithmetic circuits over the ring of  $n \times n$  matrices one can expand the matrix operations into the underlying commutative ring operations and apply the methods of this paper.

Extension of this work to rings with division would also be interesting.

Several new related results have occurred since the original writing of this paper. Matrix multiplication can now be performed using  $O(n^{2.376})$  processors, [CWa]. The ideas in this paper have been extended to more complex domains, [MT]. Finally, an analysis of the main theorem has been found that does not use the height metric, [May].

## THE COMPLEXITY OF NEAR-OPTIMAL PROGRAMMABLE LOGIC ARRAY FOLDING\*

S. S. RAVI† AND ERROL L. LLOYD‡

**Abstract.** The problem of optimally folding a Programmable Logic Array (PLA) is known to be NP-complete. Motivated by the practical importance of this problem, we address the question of obtaining good, though not necessarily optimal, foldings. Two sets of results are presented. First, we show that three natural variants of the folding problem are equivalent with respect to approximation, in the sense that either they are all efficiently approximable or none of them is efficiently approximable. Next, we show for one of the variants (optimal bipartite folding) that if there is a polynomial time approximation algorithm (heuristic) which, for every PLA, produces a folding that is within a fixed factor of an optimal folding, then for any constant  $\epsilon > 0$ , there is a heuristic which, for every PLA, produces a folding that is within a factor of  $(1 + \epsilon)$  of the optimal folding. This result strongly suggests that the optimal folding problem is not efficiently approximable for arbitrary PLAs. In a companion paper, we have presented efficient heuristics for certain restricted classes of PLAs.

**Key words.** NP-complete, approximation, heuristics, PLA, folding, VLSI

**AMS(MOS) subject classification.** 68Q25

**1. Introduction.** Programmable Logic Arrays (PLAs) are used extensively in VLSI systems to implement combinational logic functions [MC80]. The regularity in the structure of PLAs facilitates the automatic generation and compaction of their layouts. A PLA consists of two matrices of circuit elements, called the AND and OR planes. The inputs to the PLA are combined in the AND plane to produce the necessary product terms. These product terms are then combined in the OR plane to produce the required outputs. For details regarding the implementation of a PLA, we refer the reader to [MC80]. For our purposes, a schematic diagram (Fig. 1) is adequate. In Fig. 1, the inputs and the outputs are along the columns and the product terms are along the rows. The **area** of a PLA is proportional to the product of the number of rows and columns. The logic function implemented by a PLA is determined by the **personalized** row-column intersections (these have been indicated by dark circles in Fig. 1). The other row-column intersections have no electrical significance.

In practice, it is often the case that only 10 percent of the intersections are personalized [EL84], [HNS82]. For such sparse PLAs, if the structure shown in Fig. 1 is implemented directly, a considerable amount of chip area will be wasted. To reduce the area, a technique called **folding** is commonly used [W79], [HNS82], [EL84]. This technique combines two electrical lines (rows or columns) and makes them share the same physical line. The two electrical lines are, however, disconnected by placing a *cut*. We obtain column folding or row folding depending upon whether we combine columns or rows. Due to the symmetry in the structure of a PLA, algorithms used to perform column folding can be directly used to perform row folding.<sup>1</sup> In view of this observation, we present our results in terms of column folding.

<sup>1</sup> It is possible to perform both row and column folding on the same PLA [HNS82].

FIG. 1. Schematic diagram of a PLA.

FIG. 2. A column-folded PLA.

A column-folded version of the PLA of Fig. 1 is shown in Fig. 2. Notice that when a pair of columns is folded, one of the columns is introduced from the top and the other from the bottom. By folding pairs of columns, the number of columns (and hence also the area) of a PLA is reduced. Thus, the larger the number of columns folded, the smaller the area of the PLA. However, two constraints restrict the number of column pairs that can be folded. First, a pair of columns can be folded only if they are not both personalized along the same row. Second, since folding permutes the rows (see Fig. 2), we can physically implement the folding of a given set of column pairs only if there is some permutation of the rows that allows all of the pairs in the set to be folded. For a detailed discussion of these constraints, the reader is referred to [HNS82] and [R84]. We say that a set of folding pairs is **implementable** if and only if it satisfies both of the above constraints. The **optimal folding problem** is to find a largest implementable set of folding pairs. This problem has been shown to be NP-complete in [LV82]. Only exponential time algorithms are currently known for NP-complete problems and it is widely believed that polynomial time algorithms do not exist for such problems [GJ79]. However, exponential time algorithms may not be suitable for the optimal folding problem since PLAs with a few hundred lines arise in practice [HNS82], [EL84]. This motivates the study of heuristics for the optimal folding problem. In this paper, we present results which suggest strongly that the optimal folding problem is not efficiently approximable for arbitrary PLAs. In a companion paper [RL84b], we have presented efficient heuristics for certain restricted classes of PLAs.

The remainder of this paper has been organized as follows. Section 2 provides a brief description of the graph theoretic model (due to Hachtel et al. [HNS82]) for the optimal folding problem. Section 3 discusses a restricted form of folding, namely **bipartite folding** (proposed by Egan and Liu [EL84]). In that section, it is shown that the optimal bipartite folding problem is just as hard to approximate as the unrestricted folding problem. It is also shown that if there is a polynomial time approximation algorithm for the optimal bipartite folding problem that approaches the optimal value to within *any* constant factor  $K$  for an arbitrary PLA, then for every  $\epsilon > 0$ , there is a heuristic which approaches the optimal value to within  $(1 + \epsilon)$ . Section 4 discusses a constrained form of bipartite folding. In that section, it is shown that the constrained bipartite folding problem is just as hard to approximate as the unrestricted folding and the bipartite folding problems. Section 5 offers conclusions and suggestions for further research.

**2. Graph theoretic model for folding.** The formulation of the PLA folding problem in graph theoretic terms is due to Hachtel, Newton, and Sangiovanni-Vincentelli [HNS82]. In this formulation, each PLA is represented by an undirected graph<sup>2</sup>  $G(V, E)$ , called its **intersection graph**. Each node in this graph corresponds to a column of the PLA. There is an edge between nodes  $i$  and  $j$  if columns  $i$  and  $j$  of the PLA are both personalized along the same row (i.e., columns  $i$  and  $j$  *cannot* be folded with each other). A pair of distinct columns  $p, q$  which can be folded with each other forms an **unordered folding pair**. An **ordered folding pair**  $(p, q)$  specifies that the columns  $p$  and  $q$  are to be folded in such a way that  $p$  is above  $q$ . A set  $S$  of ordered folding pairs which has the property that each line of the PLA appears in at most one element of each pair in  $S$ , forms an **ordered folding set**. Throughout this paper, we use the term “folding set” to mean an ordered folding set. Each ordered pair in  $S$  is represented

<sup>2</sup> We do not allow “self-loops” in undirected graphs.

in the intersection graph by a directed edge. If columns  $p$  and  $q$  have been folded with column  $p$  above column  $q$ , we add the directed edge from  $p$  to  $q$ . Thus, we obtain a mixed graph  $M(V, E, A)$ , where  $A$  is the set of directed edges. Since each column is folded at most once, notice that the edges in  $A$  form a *matching* (i.e., no two edges in  $A$  are incident on the same node).

The advantage of the mixed graph representation is that it is possible to provide a graph theoretic characterization of the implementability of a folding set [HNS82]. In order to state that result, we need to introduce the notion of an **alternating cycle** in a mixed graph. Informally, an alternating cycle is a cycle in which directed and undirected edges are traversed alternately. Formally, an alternating cycle  $C$  in the mixed graph  $M(V, E, A)$  is a sequence of edges  $\langle (v_1, v_2), \{v_2, v_3\}, (v_3, v_4), \dots, \{v_{2k-2}, v_{2k-1}\}, (v_{2k-1}, v_{2k}), \{v_{2k}, v_1\} \rangle$  such that each directed edge in  $C$  is in  $A$  and each undirected edge in  $C$  is in  $E$ . With this definition, we can state the theorem characterizing the implementability of a folding set.

**THEOREM 1.** *Given an intersection graph  $G(V, E)$  and an ordered folding set  $S$ , the set  $S$  is implementable if and only if the mixed graph  $M(V, E, A)$  obtained from  $G$  and  $S$  does not contain an alternating cycle.*

For a proof of this theorem, we refer the reader to [HNS82]. We observe that the above result makes it possible for us to study the PLA folding problem as a problem on mixed graphs.

As pointed out in § 1, the optimal folding problem has been shown to be NP-complete in [LV82]. In that paper, the authors have also shown that the problem remains NP-complete even when only one of the planes of the PLA is to be folded. In view of that result, we assume throughout this paper that there is only one plane to be folded. Thus, we use the words “PLA” and “one plane of a PLA” interchangeably. In this paper, our goal is to study the complexity of obtaining “near-optimal” folding sets. We now provide a formal definition of a near-optimal folding set. We assume that an instance of a folding problem is specified by an undirected graph  $G(V, E)$ , with  $|V| = n$ . The term **heuristic** is used to refer to any *polynomial time* algorithm that produces implementable folding sets. Let  $\text{OPT}(G)$  and  $H(G)$  denote, respectively, the number of folding pairs in an optimal folding set and in a folding set produced by a heuristic  $H$ . The **folding ratio** of the heuristic  $H$  is the maximum value of the ratio  $\text{OPT}(G)/H(G)$ , where the maximization is carried out over all intersection graphs with at most  $n$  nodes. Thus, the folding ratio of a heuristic is a worst-case measure of its performance. The smaller the folding ratio, the better the performance of the heuristic. In general, the folding ratio of a heuristic is a function of  $n$ . However, if the ratio grows with  $n$ , we can make the performance of the heuristic arbitrarily poor by choosing a sufficiently large  $n$ . Therefore, we will investigate whether there is a heuristic whose folding ratio is a **constant  $K$**  independent of  $n$ . Such a heuristic will be referred to as a **good heuristic**.

We should point out that there are numerous NP-complete problems for which constant worst-case ratios are obtainable in polynomial time. Examples of such problems include vertex cover, bin packing, and the traveling salesman problem with triangle inequality [GJ79]. On the other hand, for some problems such as the traveling salesman problem without triangle inequality [GJ79] and the augmented set basis problem [GM82], it has been shown that constant worst-case ratios cannot be obtained in polynomial time if the complexity classes **P** and **NP** are different.

Approximation algorithms for PLA folding have also been considered in [LV82]. They proved the following theorem which shows a relationship between the bandwidth minimization problem [GJ79] and the optimal folding problem.

**THEOREM 2.** *Let  $G$  be an intersection graph with  $n$  nodes. Then  $G$  has an ordered and implementable folding set of  $k$  pairs if and only if the bandwidth of  $G$  is strictly less than  $n - k$ .*

The authors of [LV82] point out that the above result makes it possible for us to obtain a heuristic for the optimal folding problem from a heuristic for the bandwidth problem. In fact, such a folding heuristic was implemented by Elaine Eschen (Master's Thesis, University of California, Berkeley) and was found to compare favorably with industrial codes.<sup>3</sup> From a worst-case standpoint, however, it is not clear from Theorem 2 whether a good heuristic for the bandwidth problem can be used directly to obtain good folding sets. Elaborating on this question, we assume for a moment that there is a heuristic  $B$  for the bandwidth problem, which is guaranteed to approach the optimal bandwidth to within a factor of (say) 2. Consider an undirected graph  $G$  with  $n$  nodes, whose bandwidth is  $n/2$  (assume also that  $n$  is even). By Theorem 2, the size of an optimal folding set for the corresponding PLA is as large as  $n/2 - 1$ . When we run the heuristic  $B$  on  $G$ , it is possible that  $B$  might report the bandwidth of  $G$  as  $n - 1$ . Thus according to Theorem 2, we may not be able to select any folding pair. Hence, the existence of a good heuristic for the bandwidth problem does not necessarily imply the existence of a good heuristic for the folding problem. Analogously, the results presented in this paper do not have any obvious impact on the approximability of the bandwidth problem.

In the sequel, we address the near-optimal folding problem and two of its variants. In this context, a problem is **efficiently approximable** if there is a good heuristic for it. Two problems are **equivalent with respect to approximation** if the existence of a good heuristic for one implies the existence of a good heuristic for the other and vice versa. This notion allows us to build a class of problems which has the property that either all of the problems in the class are efficiently approximable or none of them is efficiently approximable.

Throughout this paper we use undirected graphs to represent PLAs. Our choice is justified by the following observation.

**OBSERVATION 1.** Every undirected graph  $G(V, E)$  is the intersection graph of some PLA.

*Proof.* Let  $|V| = n$  and  $|E| = m$ . Assume without the loss of generality that  $V = \{1, 2, 3, \dots, n\}$  and that the nodes  $1, 2, 3, \dots, t$  of  $G$  are **isolated nodes**. (If  $G$  does not have isolated nodes, then  $t = 0$ .) We will construct a PLA  $P$  with  $m + t$  rows (numbered 1 through  $m + t$ ) and  $n$  columns (numbered 1 through  $n$ ) such that  $G$  is the intersection graph of  $P$ . The first  $t$  rows of the PLA are personalized to correspond to the isolated nodes. This is done by personalizing only the intersection of row  $i$  with column  $i$ , for  $i = 1, 2, \dots, t$ . Each of the remaining  $m$  rows of the PLA will represent one edge of  $G$ . We arbitrarily label the edges of  $G$  with the numbers 1 through  $m$ . If the edge numbered  $k$  is incident on nodes  $i$  and  $j$ , we personalize the intersections of columns  $i$  and  $j$  with row  $k$ . It is easy to verify that  $G$  is the intersection graph of the resulting PLA.  $\square$

In view of Theorem 1 and Observation 1, it is possible to study the complexity of the near-optimal folding problem in the graph theoretic domain. The subsequent sections of this paper describe how certain restricted forms of folding can be characterized in terms of properties of undirected graphs and how the near-optimal versions of all of these problems are related.

<sup>3</sup> We thank one of the referees for providing this information.

**3. Bipartite folding.** Thus far, we have discussed a general (**unrestricted**) form of folding. In this section, we examine a restricted form of folding, called **bipartite folding**. We prove that the bipartite folding problem can also be formulated as a graph problem. Moreover, the graph problem does not involve directed edges and so the condition for a bipartite folding set to be implementable is much simpler than the corresponding condition for an unrestricted folding set. Using this restricted form of folding, we prove results which strongly suggest that good heuristics do not exist for the optimal unrestricted and bipartite folding problems unless  $P = NP$ .

**3.1. Characteristics of bipartite folding.** Bipartite folding was introduced by Egan and Liu [EL84]. The unrestricted form of folding places the cuts (separating the two electrical lines) at various heights. In a bipartite folding, all of the cuts are required to be **at the same height**. Thus, the folding shown in Fig. 2 is *not* a bipartite folding. A bipartite-folded version of the PLA of Fig. 1 appears in Fig. 3. A bipartite folding set  $S$  is **implementable** if and only if there is some arrangement of the product terms that satisfies the constraints induced by each folding pair in  $S$  and allows all of the cuts to be placed at the same height. Bipartite folding derives its name from the fact that it partitions the set of product terms into only *two* sets, those above the cut level and those below.

FIG. 3. A bipartite-folded PLA.

Bipartite folding is attractive in practice due to the ease with which a row folding can be carried out after a bipartite column folding. This row folding is easier because after a bipartite column folding, we can treat the two halves of the PLA as two separate PLAs and carry out row folding. Again, we can use the same algorithm to perform both row and column folding. Further, the following result from [EL84] points out that we can effectively bound the loss due to this restricted form of folding.

**THEOREM 3.** *Let  $OPT$  and  $OPTB$  denote, respectively, the sizes of an optimal unrestricted folding set and an optimal bipartite folding set for a PLA. Then  $OPTB \cong \lceil OPT/2 \rceil$ .*

Egan and Liu found experimentally that an optimal bipartite folding set is usually much larger than the lower bound given by the above theorem. They also showed that the optimal bipartite folding problem is NP-complete. Thus, the restriction to bipartite folding does not convert the NP-complete optimal folding problem into an easy (polynomial time solvable) problem. More importantly, it presents an interesting approximation problem, namely the problem of obtaining near-optimal bipartite folding sets. Theorem 3 indicates that the approximation problems for unrestricted folding and bipartite folding may actually be related to each other. We will examine the nature of this relationship in the subsequent sections. To begin, we show how the bipartite folding problem may be expressed as a graph problem.

**3.2. Graph theoretic characterization.** In § 2, we saw that the optimal folding problem may be phrased as a problem on mixed graphs. In this section, we show that the optimal bipartite folding problem can also be phrased as a graph theoretic problem. This formulation is useful in studying the problem of obtaining near-optimal bipartite folding sets.

**OBSERVATION 2.** Let  $G(V, E)$  be the intersection graph of a PLA and let  $S = \{(p_i, q_i) : 1 \leq i \leq r\}$  be an ordered and implementable folding set for  $G$ . Then,  $S$  is an implementable bipartite folding set if and only if for all  $i$  and  $j$ ,  $1 \leq i, j \leq r$ , the edge  $\{p_i, q_j\}$  is *not* in  $E$ .

*Sketch of proof.*

**IF.** Suppose that for all  $i, j$ ,  $1 \leq i, j \leq r$ , the edge  $\{p_i, q_j\}$  is not in  $E$ . It follows that the set  $T_P$  of rows personalized along any of the columns  $p_1, p_2, \dots, p_r$  and the set  $T_Q$  of rows personalized along any of the columns  $q_1, q_2, \dots, q_r$  must be *disjoint*. Therefore, we can obtain a bipartite folding by placing all of the rows in  $T_P$  (in any order) followed by all of the rows in  $T_Q$ . The cuts are made between the last row in  $T_P$  and the first row in  $T_Q$ . The lines  $p_1, p_2, \dots, p_r$  are run from the top and the lines  $q_1, q_2, \dots, q_r$  are run from the bottom.

**ONLY IF.** Suppose  $S$  is an implementable bipartite folding set, yet the edge  $\{p_i, q_j\}$  is in  $E$  for some  $i$  and  $j$ . Clearly  $i \neq j$ , because  $(p_i, q_i)$  is a folding pair. Since the edge  $\{p_i, q_j\}$  is in  $E$ , there is some row  $t_k$  which is personalized along both  $p_i$  and  $q_j$ . However, since  $p_i$  is run from the top and  $q_j$  is run from the bottom, it is easy to see that the position of  $t_k$  with respect to the cut level cannot be specified unambiguously. This contradicts the implementability of  $S$ .  $\square$

The above observation leads to the following definition of implementable bipartite folding sets.

**DEFINITION.** Let  $G(V, E)$  be the intersection graph of a PLA. Suppose  $P$  and  $Q$  are subsets of  $V$ . The **bipartite folding formed by  $P$  and  $Q$**  (denoted by  $[P, Q]$ ) is **implementable** if and only if the following conditions hold:

- (i) The sets  $P$  and  $Q$  are *disjoint*.
- (ii) For every node  $p \in P$  and  $q \in Q$ , the edge  $\{p, q\}$  is not in  $E$ .

The **size** of a bipartite folding  $[P, Q]$  is defined as

$$\text{SIZE}([P, Q]) = \text{Min} \{|P|, |Q|\},$$

where  $|P|$  and  $|Q|$  denote the cardinalities of sets  $P$  and  $Q$ , respectively. For convenience, we allow the cardinalities of the sets  $P$  and  $Q$  to be different. However, the size of an implementable bipartite folding set is the smaller of  $|P|$  and  $|Q|$ . Notice that every implementable bipartite folding set is (trivially) also an implementable unrestricted folding set.

The optimal bipartite folding problem requires that we find an implementable bipartite folding set of largest size. As indicated in § 3.1, this problem is NP-complete.

Thus, it is interesting to consider heuristics for this problem. The performance measure is again the folding ratio, except that we define the folding ratio with respect to the size of an optimal bipartite folding set. In particular, we are interested in examining whether there is a good heuristic for the bipartite folding problem.

In [EL84], Egan and Liu have discussed an exponential time (backtracking) algorithm that produces optimal bipartite folding sets. However, they report that for a PLA with about 100 lines, the folding program took about 23 minutes of CPU time. Such a program may not be desirable in an interactive chip design environment. For these applications, a fast heuristic which produces near-optimal bipartite folding sets would be more suitable. No results on heuristics for bipartite folding are currently available so it is not clear whether we need to resort to exponential time algorithms. Finally, in addition to its practical importance, the approximation problem for bipartite folding has an impact on the approximation problem for unrestricted folding as discussed in the next section.

**3.3. Near-optimal bipartite folding.** In this section, we prove that the optimal unrestricted folding problem and the optimal bipartite folding problem are equivalent with respect to approximation. This is accomplished by showing how a good heuristic for one problem may be converted into a good heuristic for the other problem. Before we can do this, however, we need to discuss an efficient method to convert an unrestricted folding set into a bipartite folding set without losing too many folding pairs.

**3.3.1. Obtaining bipartite folding sets from unrestricted folding sets.** Given an implementable unrestricted folding set  $S$  of size  $r$ , we can find an implementable bipartite folding set of size at least  $\lceil r/2 \rceil$  in the following manner:

(1) Find an implementation of the given folding set  $S$ . This step requires us to find an arrangement of the rows that satisfies all of the constraints induced by the folding pairs. This can be done in polynomial time as discussed in [HNS82].

(2) Arrange the folding pairs in  $S$  such that the heights of the cuts are in nonincreasing order. Note that this does not require any rearrangement of the rows.

(3) Form a bipartite folding set  $[P, Q]$  with the first  $\lceil r/2 \rceil$  upper lines as the set  $P$  and the last  $\lceil r/2 \rceil$  lower lines as the set  $Q$ .

The correctness of this procedure is obvious and from the above comments it is seen that the procedure can be implemented in polynomial time. Fig. 4 illustrates this conversion procedure. Fig. 4(a) shows a set of folding pairs arranged according to the heights of their cuts and Fig. 4(b) shows the resulting bipartite folding set.

A graph theoretic method to carry out the above conversion appears in [RL84a].

**3.3.2. Relationship between near-optimal unrestricted folding and near-optimal bipartite folding.** We are now ready to relate the near-optimal unrestricted folding and the near-optimal bipartite folding problems. In this section, we prove that these two problems are equivalent with respect to approximation. The next section examines the complexity of near-optimal bipartite folding.

**THEOREM 4.** *The optimal unrestricted folding problem and the optimal bipartite folding problem are equivalent with respect to approximation.*

*Proof.* The proof is in two parts. In Part 1, we assume that there is a good heuristic for the optimal bipartite folding problem and prove that there is a good heuristic for the unrestricted folding problem. In Part 2, we assume that the unrestricted folding problem has a good heuristic and show how we can obtain a good heuristic for the bipartite folding problem.

Part 1. Suppose that there is a good heuristic  $H_B$  for the optimal bipartite folding problem. We claim that  $H_B$  is also a good heuristic for the optimal unrestricted folding

FIG. 4. Obtaining a bipartite folding set from an unrestricted folding set.

problem. To see this, let  $R$  denote the folding ratio of  $H_B$ . (Note that  $R$  is defined with respect to an optimal bipartite folding set.) Let  $G$  be an arbitrary intersection graph. We use  $OPT(G)$  and  $OPTB(G)$  to denote the sizes of an optimal unrestricted folding set and an optimal bipartite folding set for  $G$ , respectively. Suppose that  $H_B$  produces a bipartite folding set  $[P, Q]$  of size  $r$  for  $G$ . Since the folding ratio of  $H_B$  is  $R$ , we must have

$$(1) \quad \frac{OPTB(G)}{r} \leq R.$$

We can produce an “unrestricted” folding set of size  $r$  from  $[P, Q]$  by arbitrarily pairing up a node in  $P$  with a node in  $Q$ . Therefore, the folding ratio  $R'$  of  $H_B$  with respect to an optimal unrestricted folding set would be given by

$$R' = \frac{OPT(G)}{r}.$$

However, by Theorem 3,  $OPTB(G) \geq \lceil OPT(G)/2 \rceil$  or  $OPT(G) \leq 2 OPTB(G)$ . Hence,

$$(2) \quad R' \leq 2 \frac{OPTB(G)}{r}.$$

From inequalities (1) and (2) we see that  $R' \leq 2R$ . Hence, the folding ratio for  $H_B$ , when used for the unrestricted folding problem, is bounded by another constant, namely  $2R$ .

Part 2. Suppose  $H_U$  is a good heuristic for the unrestricted folding problem, with a folding ratio of  $R$ . Consider the following heuristic  $H_B$  for the bipartite folding problem:

(1) Run  $H_U$  on the given intersection graph  $G$ . Let  $S = \{(p_i, q_i) : 1 \leq i \leq r\}$  be the implementable folding set of size  $r$  produced by  $H_U$ .

(2) Produce a bipartite folding set  $[P, Q]$  of size at least  $\lceil r/2 \rceil$  from  $S$ , using the conversion procedure discussed in § 3.3.1.

Since conversion procedure runs in polynomial time,  $H_B$  is a polynomial time heuristic. By proceeding in a manner analogous to Part 1, it is easy to show that  $H_B$  has a folding ratio of at most  $2R$ . Thus,  $H_B$  is a good heuristic for the bipartite folding problem. This completes the proof of Part 2 and also that of Theorem 4.  $\square$

**3.3.3. On the complexity of near-optimal bipartite folding.** Theorem 4 shows that obtaining a good heuristic for the unrestricted folding problem is at least as hard as obtaining a good heuristic for the bipartite folding problem. We now prove an important result which provides substantial evidence for us to conclude that the bipartite folding problem (and hence also the unrestricted folding problem) is hard to approximate. The essence of this result is the following: if there is a heuristic  $H$  for the optimal bipartite folding problem with a folding ratio of  $K$  (a constant), however large  $K$  may be, we can find a heuristic  $H'$  whose folding ratio is arbitrarily close to 1. In this section, we present a proof of this result and then examine its significance. We begin with a lemma which forms the basis for the above result.

LEMMA 1. *Suppose  $H_B$  is a polynomial time heuristic for the optimal bipartite folding problem, with a constant folding ratio  $K > 1$ . Then there is a polynomial time heuristic  $H'_B$  for the optimal bipartite folding problem, for which the folding ratio is at most  $\sqrt{K}$ .*

*Proof.* Let  $G(V, E)$  be an arbitrary intersection graph. Given the heuristic  $H_B$ , the steps of heuristic  $H'_B$  are as follows:

(1) Transform the graph  $G(V, E)$  into another graph  $G'(V', E')$ . This transformation is such that if an optimal bipartite folding set for  $G$  is of size  $b$ , the size of an optimal bipartite folding set for  $G'$  is at least  $b^2$ .

(2) Execute  $H_B$  on  $G'$ . Let  $[P', Q']$  be the bipartite folding set produced, with  $\text{SIZE}([P', Q']) = r$ . Since  $H_B$  has a folding ratio of  $K$ , notice that  $r \geq b^2/K$ .

(3) Transform the bipartite folding set  $[P', Q']$  of size  $r$  for  $G'$  into a bipartite folding set  $[P, Q]$  for  $G$  with  $\text{SIZE}([P, Q]) \geq \lceil \sqrt{r} \rceil$ . The heuristic  $H'_B$  outputs  $[P, Q]$ . Suppose we assume, for a moment, that the transformations in steps (1) and (3) above can be carried out in polynomial time. Then  $H'_B$  would be a polynomial time heuristic. Further, the size of the folding set  $[P, Q]$  produced by  $H'_B$  satisfies the inequality

$$\text{SIZE}([P, Q]) \geq \left\lceil \left( \frac{b^2}{K} \right)^{1/2} \right\rceil \geq \frac{b}{\sqrt{K}}.$$

Thus, the folding ratio for  $H'_B$  is at most  $b/(b/\sqrt{K}) = \sqrt{K}$ . Therefore, we have only to prove that the transformations in steps (1) and (3) can be carried out in polynomial time to complete the proof of this lemma. Let us denote these transformations by T1 and T2, respectively. We now present the details of T1 and T2.

TRANSFORMATION T1. Let  $V = \{1, 2, 3, \dots, n\}$ . The graph  $G'(V', E')$  is obtained as follows:

$$V' = \{\langle i, j \rangle : 1 \leq i \leq n, 1 \leq j \leq n\},$$

$$E' = \{ \{ \langle i, j \rangle, \langle k, l \rangle \} : \{ i, j \} \cap \{ k, l \} \neq \emptyset \text{ or } \{ i, k \} \in E \text{ or } \{ i, l \} \in E \text{ or } \{ j, k \} \in E \text{ or } \{ j, l \} \in E \}.$$

Since  $G'$  has only  $n^2$  nodes, and hence only  $O(n^4)$  edges, it is clear that the above transformation can be carried out in polynomial time. We now prove that the graph  $G'$  has the required property.

CLAIM 1. Let  $[P, Q]$  be an implementable bipartite folding set of size  $b$  for  $G$ .<sup>4</sup> Suppose  $P = \{ p_1, p_2, \dots, p_b \}$  and  $Q = \{ q_1, q_2, \dots, q_b \}$ . Define sets  $P'$  and  $Q'$  by

$$P' = \{ \langle p_i, p_j \rangle : 1 \leq i \leq b, 1 \leq j \leq b \}, \quad Q' = \{ \langle q_i, q_j \rangle : 1 \leq i \leq b, 1 \leq j \leq b \}.$$

Then,  $[P', Q']$  is an implementable bipartite folding set of size  $b^2$  for  $G'$ .

*Proof.* Since  $P'$  and  $Q'$  contain  $b^2$  nodes each, we need only prove that  $[P', Q']$  is an implementable bipartite folding set for  $G'$ . We begin by noting that since  $P$  and  $Q$  are disjoint,  $P'$  and  $Q'$  are also disjoint. Thus if  $[P', Q']$  is not implementable, by Observation 2, we must have  $\langle p_u, p_v \rangle$  in  $P'$  and  $\langle q_x, q_y \rangle$  in  $Q'$  (for some  $u, v, x, y$ ) such that the edge  $e = \{ \langle p_u, p_v \rangle, \langle q_x, q_y \rangle \}$  is in  $E'$ . However, by our construction of  $G'$ , it follows that at least one of the edges  $\{ p_u, q_x \}$ ,  $\{ p_u, q_y \}$ ,  $\{ p_v, q_x \}$ , and  $\{ p_v, q_y \}$  must be in  $E$  and that contradicts the implementability of  $[P, Q]$ . Therefore,  $[P', Q']$  must be implementable. This completes the proof of Claim 1.

TRANSFORMATION T2. Transformation T2 produces a bipartite folding set of an appropriate size for  $G$ , starting from a bipartite folding set for  $G'$ . We present the details of transformation T2 in the proof of the following claim.

CLAIM 2. Let  $[P', Q']$  be an implementable bipartite folding set of size  $r$  for  $G'$ . Then, we can find, in polynomial time, an implementable bipartite folding set of size at least  $\lceil \sqrt{r} \rceil$  for  $G$ .

*Proof.* Suppose that  $P' = \{ \langle p_i, q_i \rangle : 1 \leq i \leq r \}$  and  $Q' = \{ \langle x_i, y_i \rangle : 1 \leq i \leq r \}$ . Define

$$P = \{ p_i : \langle p_i, q_i \rangle \in P' \text{ or } \langle q_i, p_i \rangle \in P' \text{ for some } i, 1 \leq i \leq r \},$$

$$Q = \{ x_i : \langle x_i, y_i \rangle \in Q' \text{ or } \langle y_i, x_i \rangle \in Q' \text{ for some } i, 1 \leq i \leq R \}.$$

It is easy to see that  $|P| \geq \lceil \sqrt{r} \rceil$  and  $|Q| \geq \lceil \sqrt{r} \rceil$ . Further, it is straightforward to verify that  $[P, Q]$  is an implementable bipartite folding set for  $G$ . This completes the proof of Claim 2 as well as that of Lemma 1.  $\square$

THEOREM 5. Suppose  $H$  is a polynomial time heuristic for the optimal bipartite folding problem, with a folding ratio of  $K$  (a constant). Then for every  $\varepsilon > 0$ , there is a polynomial time heuristic  $H_\varepsilon$  with a folding ratio of at most  $1 + \varepsilon$ .

*Proof.* The idea is to apply Lemma 1 an appropriate number of times. In particular, given an  $\varepsilon > 0$ , choose the smallest integer  $t$  which satisfies the inequality

$$(3) \quad 2^t \geq \frac{\log_2 K}{\log_2 (1 + \varepsilon)}.$$

Since  $K$  and  $\varepsilon$  are constants,  $t$  is also a constant. For convenience, we let  $x = 2^t$ . From inequality (3) it is easy to see that

$$(4) \quad K^{1/x} \leq (1 + \varepsilon).$$

---

<sup>4</sup> If either  $P$  or  $Q$  contains more than  $b$  nodes, we arbitrarily discard the extra nodes. Hence from now on, we will assume that unless otherwise specified, both of the sets in a bipartite folding contain the same number of nodes.

Let  $G(V, E)$  be an arbitrary intersection graph with an optimal bipartite folding set of size  $b$ . We transform  $G$  into a graph  $G'$  by successively applying transformation T1,  $t$  times. Since  $t$  is a constant and T1 is a polynomial time transformation, the construction of  $G'$  can be done in polynomial time. Let  $\text{OPTB}(G')$  denote the size of an optimal bipartite folding set for  $G'$ . Since every application of T1 at least squares the size of an optimal folding set (Claim 1 in Lemma 1), it follows that

$$(5) \quad \text{OPTB}(G') \geq b^{2^t} = b^x.$$

We use  $G'$  as the input to  $H$ . Since  $H$  has a folding ratio of  $K$ ,  $H$  must obtain a bipartite folding set of size at least  $b^x/K$ .

From this folding set, however, we can obtain a folding set for  $G$  by applying transformation T2, also  $t$  times. Clearly, this can also be done in polynomial time. From Claim 2 of Lemma 1, it is easy to see that the resulting bipartite folding set has a size  $s$  given by

$$(6) \quad s \geq \frac{b}{(K^{1/x})}.$$

We let  $H_\epsilon$  output this folding set. Hence the folding ratio of  $H_\epsilon$  is at most  $b/s \leq K^{1/x} \leq (1 + \epsilon)$  from inequality (4).

Therefore, assuming that  $H$  is given, we have found a heuristic  $H_\epsilon$  which has a folding ratio of at most  $(1 + \epsilon)$ . This completes the proof of Theorem 5.  $\square$

We believe that Theorem 5 is an important contribution of this paper. It suggests strongly that any search for a good heuristic for bipartite folding is unlikely to succeed. Theorem 5 in conjunction with Theorem 4 indicates that a similar search for the unrestricted folding problem is also likely to be futile. We now expand on these observations.

Since the optimal bipartite folding problem is not a number problem, the NP-completeness result of [EL84] implies that the problem is NP-complete in the *strong sense* [GJ79]. Further, since the size of an optimal bipartite folding set is at most  $n/2$ , it follows from a result of Garey and Johnson [GJ79, pp. 140-141] that there is no *fully* polynomial time approximation scheme (i.e., an approximation algorithm whose running time is a polynomial function of both  $n$  and  $1/\epsilon$ ) for this problem. This does not, however, rule out the possibility of a polynomial time approximation scheme (i.e., an approximation algorithm whose running time is a polynomial in  $n$ , but the exponent is a function of  $1/\epsilon$ ). Theorem 5 indicates that if there is a heuristic with a constant folding ratio  $K$ , irrespective of how large  $K$  is, we have a polynomial time approximation scheme for the bipartite folding problem. No such approximation scheme is currently known for any problem which is not a number problem. Worse yet, Theorem 5 also shows that if we can prove that approaching the optimal value to within a factor of  $1 + \epsilon$  is hard, however small  $\epsilon$  may be, achieving *any* constant factor is hard. A result similar to Theorem 5 is known for the maximum clique problem. In view of that result, it is widely believed that the clique problem does not have a good heuristic [GJ79]. The same appears to be true for the bipartite folding problem.

**3.4. Constrained bipartite folding.** What makes the bipartite folding problem difficult? It is tempting to conclude that the difficulty lies in deciding the position of a column with respect to the cut level (i.e., whether a column is to be placed above or below the cut level). We now consider a variation of the bipartite folding problem in which the position of each column is known a priori. We are simply required to

find the largest implementable bipartite folding set. We call this the **constrained bipartite folding problem**. Our motivation in studying this problem was to investigate whether this constrained version of the bipartite folding problem is easier than the unconstrained version. The results presented in this section provide a negative answer to this question.

The graph model for the constrained bipartite folding problem is the following: We are given a *bipartite intersection graph*  $G(V1, V2, E)$ , where  $V1$  corresponds to the set of columns to be placed on one side of (say, above) the cut and  $V2$  corresponds to the set of columns to be placed on the other side of the cut. Given such a graph, the optimum constrained bipartite folding problem requires us to find node sets  $P$  and  $Q$  such that

- (a)  $P \subseteq V1$  and  $Q \subseteq V2$ ,
- (b) for every  $p \in P$  and  $q \in Q$ , the edge  $\{p, q\}$  is not in  $E$ , and
- (c)  $\text{Min}\{|P|, |Q|\}$  is maximized.

The above problem is known as the **maximum balanced independent set problem**, and (as can be expected) is NP-complete [GJ79]. In view of this result, it is interesting to investigate whether there are good heuristics for this problem. However, our next theorem shows that the constrained bipartite folding problem is no easier to approximate than the (unconstrained) bipartite folding problem.

**THEOREM 6.** *The constrained bipartite folding problem and the (unconstrained) bipartite folding problem are equivalent with respect to approximation.*

*Proof.* The proof is again in two parts.

Part 1. Suppose there is a good heuristic  $H_C$  for the constrained bipartite folding problem.

Let  $R$  be the folding ratio for  $H_C$ . We now show that we can devise a heuristic  $H_B$  (which also has a folding ratio of  $R$ ) for the unconstrained bipartite folding problem. Let  $G(V, E)$  be an arbitrary intersection graph. The heuristic  $H_B$  consists of two steps:

(i) Transform the graph  $G(V, E)$  into a bipartite graph  $G'(V1, V2, E')$  as follows. Assume that  $V = \{1, 2, 3, \dots, n\}$ . Let  $V1 = \{v_{11}, v_{12}, \dots, v_{1n}\}$  and  $V2 = \{v_{21}, v_{22}, \dots, v_{2n}\}$ . For each  $i, 1 \leq i \leq n$ , we add the edge  $\{v_{1i}, v_{2i}\}$  to  $E'$ . Further, for every edge  $\{i, j\}$  in  $E$ , we add the edges  $\{v_{1i}, v_{2j}\}$  and  $\{v_{1j}, v_{2i}\}$  to  $E'$ .

(ii) Execute  $H_C$  on  $G'$ . From the folding set produced by  $H_C$ , construct a folding set for  $G$ , as described in the following claim.

**CLAIM 1.** Suppose  $[P', Q']$  is any implementable bipartite folding set for  $G'$ , with  $P' = \{v_{1i_1}, v_{1i_2}, \dots, v_{1i_m}\}$  and  $Q' = \{v_{2j_1}, v_{2j_2}, \dots, v_{2j_m}\}$ . Define  $P = \{i_1, i_2, \dots, i_m\}$  and  $Q = \{j_1, j_2, \dots, j_m\}$ . Then  $[P, Q]$  is an implementable bipartite folding set for  $G$ .

*Proof of Claim 1.* First, we note that the sets  $P$  and  $Q$  are disjoint. This is because if  $i_x = j_y$ , for some  $x$  and  $y$ , the construction would have added the edge  $\{v_{1i_x}, v_{2j_y}\}$  to  $E'$ . This would contradict the implementability of  $[P', Q']$ .

Also, if for some  $i_x$  in  $P$  and some  $j_y$  in  $Q$  the edge  $\{i_x, j_y\}$  is in  $E$ , then in the course of constructing  $G'$ , we would have added the edge  $\{v_{1i_x}, v_{2j_y}\}$  to  $E'$ , and this again contradicts the implementability of  $[P', Q']$ . This completes the proof of Claim 1.

Observe that the size of the folding set produced by  $H_B$  is the same as that produced by  $H_C$ . In order to prove that the folding ratio of  $H_B$  is the same as that of  $H_C$ , we need the following result.

**CLAIM 2.** The graph  $G'$  has an implementable bipartite folding set of size  $m$  if and only if  $G$  has an implementable bipartite folding set of size  $m$ .

*Proof of Claim 2.* The "only if" part is precisely Claim 1. So, we prove only the "if" part. Suppose  $[P, Q]$  is an implementable bipartite folding set of size  $m$  for  $G$ .

Let  $P = \{i_1, i_2, \dots, i_m\}$  and  $Q = \{j_1, j_2, \dots, j_m\}$ . Define,

$$P' = \{v_{1i_1}, v_{1i_2}, \dots, v_{1i_m}\}, Q' = \{v_{2j_1}, v_{2j_2}, \dots, v_{2j_m}\}.$$

Notice that  $P' \subseteq V1$  and  $Q' \subseteq V2$ . It is easy to verify that  $[P', Q']$  is an implementable bipartite folding set for  $G'$ . This completes the proof of Claim 2.

From Claim 2 it follows immediately that the sizes of the *optimal* bipartite folding sets for  $G$  and  $G'$  are equal. Claim 1 shows that the size of the bipartite folding set for  $G$  produced by  $H_B$  is exactly equal to the size of the bipartite folding set for  $G'$  produced by  $H_C$ . Hence the folding ratio for  $H_B$  is equal to that of  $H_C$ . Thus,  $H_B$  is also a good heuristic.

Part 2. Suppose there is a good heuristic  $H_B$  for the unconstrained bipartite folding problem. We now describe how to obtain a heuristic  $H_C$  for the constrained bipartite folding problem. Further,  $H_C$  will have the same folding ratio as  $H_B$ .

Given  $G(V1, V2, E)$ , we construct  $G'(V', E')$  as follows. Let  $V' = V1 \cup V2$ . The nodes in  $V1$  are connected together to form a clique, as are the nodes in  $V2$ . The edge set  $E'$  consists of all the edges in  $E$  and the clique edges just added. It is straightforward to verify (using Observation 2) that any nonempty implementable bipartite folding set  $[P, Q]$  for  $G'$  is such that  $P \subseteq V1$  and  $Q \subseteq V2$ . Since the set of edges between  $V1$  and  $V2$  is the same in  $G$  and  $G'$ , it follows that *any* implementable bipartite folding set for  $G'$  is also an implementable bipartite folding set for  $G$  and vice versa. In particular, *optimal* bipartite folding sets for  $G$  and  $G'$  are identical.

The heuristic  $H_C$  constructs  $G'$  and runs  $H_B$  on  $G'$ . Then  $H_C$  outputs the bipartite folding set produced by  $H_B$ . It is immediate that the folding ratios for  $H_C$  and  $H_B$  are equal. Hence  $H_C$  is a good heuristic for the constrained bipartite folding problem. This completes the proof of Theorem 6.  $\square$

The following corollary is a direct consequence of Theorems 4 and 6.

**COROLLARY 1.** *The unrestricted folding problem, the unconstrained bipartite folding problem and the constrained bipartite folding problem are all equivalent with respect to approximation.*

It also follows from the proof of Theorem 6 that a result identical to Theorem 5 holds for the constrained bipartite folding problem. That is, if there is a heuristic for the constrained bipartite folding problem with a constant folding ratio, then there is a heuristic with a folding ratio arbitrarily close to 1.

**4. Conclusions.** In this paper, we addressed the problem of obtaining near-optimal folding sets. With respect to this problem, we showed that three versions of the optimal folding problems are equivalent. We also presented results which strongly suggest that there are no good heuristics for the optimal folding problem.

The main problem left open by our work is to actually prove that the approximation problem is NP-hard. Theorem 5 suggests an approach towards solving this problem: For some  $\epsilon > 0$  (probably very small), show that the problem of obtaining a folding ratio of  $(1 + \epsilon)$  is NP-hard. A proof of this result might suggest a way to attack the similar question for the clique problem. It will also be interesting to examine whether the clique problem and the bipartite folding problem are equivalent with respect to approximation. (The currently known reduction from the clique problem to the constrained bipartite folding problem [J83] does not preserve approximations.) As far as we have been able to ascertain, the bipartite folding problem is only the second "bonafide" member (the first being the clique or the independent set problem) of the class of nonnumber problems for which a result similar to Theorem 5 has been proven. It will be interesting to investigate whether there are other problems in this class.

**Acknowledgment.** We thank the referees for providing several valuable suggestions. The construction used in the proof of Lemma 1, which is substantially simpler than our original construction, was provided by one of the referees. This referee also provided the conversion algorithm of § 3.3.1.

## PARALLEL ALGORITHMS FOR TERM MATCHING\*

CYNTHIA DWORK<sup>†</sup>, PARIS C. KANELLAKIS<sup>‡</sup>, AND LARRY STOCKMEYER<sup>†</sup>

**Abstract.** We present a randomized parallel algorithm for term matching. Let  $n$  be the number of nodes of the directed acyclic graphs (dags) representing the terms to be matched. Then our algorithm uses  $O(\log^2 n)$  parallel time and  $M(n)$  processors, where  $M(n)$  is the complexity of  $n \times n$  matrix multiplication. The randomized algorithm is of the Las Vegas type, that is, the answer is always correct, although with small probability the algorithm might fail to produce an answer. The number of processors is a significant improvement over previously known bounds. Under various syntactic restrictions on the form of the input dags, only  $O(n^2)$  processors are required in order to achieve deterministic  $O(\log^2 n)$  parallel time. Furthermore, we reduce directed graph reachability to term matching using constant parallel time and  $O(n^2)$  processors. This is evidence that no deterministic algorithm can significantly beat the processor bound of our randomized algorithm. We also improve the P-completeness result of Dwork, Kanellakis, and Mitchell on the unification problem, showing that unification is P-complete even if both input terms are linear, i.e., no variable appears more than once in each term.

**Key words.** unification, term matching, parallel algorithms, logic programming

**AMS(MOS) subject classification.** 68Q

**1. Introduction.** Unification of terms is an important step in resolution theorem proving [14], with applications to a variety of symbolic computation problems. In particular, unification is used in PROLOG interpreters [2], [7], type inference algorithms [10] and term-rewriting systems [6]. Informally, two symbolic terms  $s$  and  $t$  are unifiable if there exists a substitution of additional terms for variables in  $s$  and  $t$  such that under the substitution the two terms are syntactically identical. For example, the terms  $f(x, x)$  and  $f(g(y), g(g(z)))$  are unified by substituting  $g(z)$  for  $y$  and  $g(g(z))$  for  $x$ .

Unification was defined in 1964 by Robinson in his seminal paper "A Machine Oriented Logic Based on the Resolution Principle" [14]. Robinson's unification algorithm required time exponential in the size of the terms. The following years saw a sequence of improved unification algorithms, culminating in 1976 with the linear time algorithm of Paterson and Wegman [12]. A general interest in parallel computing, together with specific interest in parallelizing PROLOG, led Dwork, Kanellakis, and Mitchell to search for a fast (time polynomial in  $\log n$ ) processor efficient (polynomially many processors) parallel unification algorithm [4]. Their results were negative: they proved that unification is complete for polynomial time, even if the input terms are represented as trees. A similar result was independently derived by Yasuura [18]. (The result in [18] is slightly weaker because it proves completeness for a more restricted class of inputs.) Thus, the existence of a fast, efficient parallel algorithm is *popularly unlikely*, in that it would contradict the popularly believed complexity theoretic conjecture that P, the class of problems solvable sequentially in polynomial time, is not

contained in NC, the class of problems solvable in polylogarithmic time using polynomially many processors. However, Dwork et al. [4] found that term matching, a special case of unification in which one of the terms contains no variables, is in NC. Term  $s$  matches term  $t$  if there exists a substitution  $\sigma$  mapping variables in  $s$  to terms, such that  $\sigma(s)$ , the term obtained by replacing each occurrence of each variable  $x$  in  $s$  by  $\sigma(x)$ , is syntactically equal to  $t$ . Dwork et al. [4] obtained a matching algorithm requiring  $O(\log^2 n)$  time and about  $O(n^5)$  processors. Motivated by [4] some researchers interested in parallelizing PROLOG examined extant PROLOG programs to see whether in practice unification can be replaced by term matching. Preliminary results show that “often” the full power of general unification is not needed, and that term matching indeed suffices [9].

Let  $\text{NC}^k(f(n))$  be the class of problems solvable in time  $O(\log^k n)$  using  $f(n)$  processors on inputs of size  $n$ . Similarly, let  $\text{RNC}^k(f(n))$  be the class of problems solvable by a randomized algorithm in time  $O(\log^k n)$  using  $f(n)$  processors on inputs of size  $n$ . In defining these classes, our model of computation is the Concurrent-Read Exclusive-Write Parallel RAM (PRAM) [5], with word size  $O(\log n)$  on inputs of size  $n$ .

The algorithm of [4] shows that term matching is in  $\text{NC}^2(M(n^2))$ , where  $M(m)$  is the number of arithmetic operations required for  $m \times m$  matrix multiplication. Coppersmith and Winograd [3] show that  $M(m) = O(m^{2.5})$ , so the algorithm of [4] uses about  $n^5$  processors. The current paper provides substantially improved upper bounds on processors for the term-matching problem at no asymptotic cost in running time. However, the new algorithm is randomized, in that the individual processors make random choices (flip coins). It is a Las Vegas algorithm: an answer is always correct, but there is some small probability (taken over the set of coin tosses) that an execution of the algorithm will fail to produce an answer. In that case the algorithm can be run again. Our approach will be to show how to test two terms for syntactic equivalence in  $\text{RNC}^2(M(n))$ , where  $n$  is the total number of nodes in the dag representations of the two terms. This is the only randomized portion of the algorithm. We then show that term matching reduces to equivalence testing, and the reduction can be performed in  $\text{NC}^2(n^2)$ . Since  $M(n) \cong n^2$  the principal result for term matching then follows as an easy corollary.

The remainder of the paper is organized as follows. Section 2 contains results on testing two terms for syntactic equivalence. In addition, this section contains some “evidence” that  $M(n)$  is a lower bound on the number of processors needed for NC solutions to both term matching and equivalence, by showing that the directed acyclic graph reachability problem reduces to testing for equivalence by an  $\text{NC}^0(n^2)$  reduction. Section 3.1 describes the reduction from term matching to equivalence testing. For certain special cases we can improve on the time and/or processor bounds obtained in the general case when both terms are represented by arbitrary dags. These results are described in § 3.2. Finally, § 4 strengthens the known P-completeness results for unification, showing that unification is P-complete even if both terms are linear (each variable appears at most once in each term) and are represented by trees, but where there can be sharing of variables. (In contrast, if there is no sharing of variables and one of the terms is linear, then the problem can be solved in NC as we show in § 3.3.) The proof of P-completeness of unification of linear terms is quite different from and more intricate than that of [4], and in a sense provides a strongest possible P-completeness result for a restricted form of unification.

**2. Testing for equivalence of terms.** A *term* is defined recursively as follows. A variable symbol is a term; if  $f$  is a  $k$ -ary function symbol,  $k \geq 0$  (0-ary function symbols correspond to constants), and  $t_1, \dots, t_k$  are terms, then  $f(t_1, \dots, t_k)$  is a term.

A *dag* is a directed acyclic graph. If  $G$  is a dag and  $u$  is a node of  $G$ , then the subdag *rooted at  $u$*  is the subdag consisting of all nodes and edges reachable from  $u$ . A term  $t$  can be represented by a labeled dag in a very natural way. If  $t$  is a constant or a variable, then the representation is just a single node labeled  $t$ . When  $t = f(t_1, \dots, t_k)$ ,  $k \geq 1$ ,  $t$  can be represented by a dag consisting of a node labeled  $f$  with  $k$  outedges, labeled, respectively, 1 through  $k$ , such that the head of the edge labeled  $i$  is the root of a subdag representing  $t_i$ , for each  $i = 1, \dots, k$ . Figure 1 shows some examples of labeled dags and their corresponding terms. Note that if the term contains a repeated subexpression then its corresponding dag is not unique; for example, a term  $g(t, t)$  may be represented by using a single dag for both occurrences of  $t$  or by using a separate dag for each occurrence. A node  $u$  of a dag is a *root* if there are no edges directed into  $u$ , and  $u$  is a *leaf* if there are no edges directed out of  $u$  (each leaf must be labeled by either a constant or a variable). A term is *linear* if no variable appears more than once in the term. If the term  $t$  is linear and if  $G$  is any dag representation of  $t$ , then for each variable  $x$  occurring in  $t$  there is exactly one path in  $G$  from the root to a node labeled  $x$ . Let  $u$  and  $v$  be nodes of outdegree  $k$ , and let  $u_i$  (respectively,  $v_i$ ) denote the head of the edge from  $u$  (respectively,  $v$ ) with label  $i$ ,  $i = 1, \dots, k$ . Then we say  $u_i$  ( $v_i$ ) is the  *$i$ th child of  $u$*  (respectively, of  $v$ ), and we say  $u_i$  and  $v_i$  are *corresponding children* of  $u$  and  $v$ .

FIG. 1. Some examples of term dags.

Two rooted dags  $G$  and  $H$  are said to be *equivalent*, written  $G \equiv H$ , if they represent the same term. An instance of the equivalence problem is a triple  $(D, r_1, r_2)$ , where  $D$  is a labeled dag with two roots  $r_1$  and  $r_2$ . The two terms to be tested for equivalence are the terms represented by the subdags rooted at the two roots. ( $D$  could consist of two connected components, one with root  $r_1$  and the other with root  $r_2$ . In general, we allow the dags rooted at  $r_1$  and  $r_2$  to share nodes since our equivalence algorithm handles this smoothly.) The time and processor complexities of our algorithms are expressed as functions of  $n$ , the size of an instance, defined to be the maximum of the number of nodes of  $D$  and the maximum outdegree of any node of  $D$ . Since in most applications the number of nodes will dominate the maximum outdegree, there is no harm in viewing  $n$  as the number of nodes. For cases where the maximum outdegree dominates, it is easy to express the complexities of our algorithms as functions of two separate parameters, the number of nodes and the maximum outdegree.

All logarithms in this paper are to the base 2.

**2.1. A Las Vegas algorithm for testing equivalence of terms.** Let  $M(n)$  be an upper bound of the form  $cn^\omega$ , for constants  $c > 0$  and  $\omega > 2$ , on the number of arithmetic

operations in a straight-line algorithm which computes  $n \times n$  matrix multiplication where the algorithm contains no divisions and where all scalars (i.e., numerical constants) are integers. The Coppersmith–Winograd algorithm [3] is of this form, so  $M(n) = O(n^{2.5})$ .

Consider an instance  $(D', r_1, r_2)$  of the equivalence problem and let  $n$  be its size. Let  $G'$  and  $H'$  be the dags rooted at  $r_1$  and  $r_2$ , respectively. Since two terms are equal if and only if they are equal when we substitute constants for variables, we may assume that  $D'$  contains no variables. This will simplify matters in this section since we will want to use “variable” to refer to polynomial variables rather than term variables. Briefly, our approach is to represent  $G'$  and  $H'$  by multivariate polynomials  $P_{G'}$  and  $P_{H'}$  in such a way that  $G'$  and  $H'$  are equivalent if and only if the corresponding polynomials are equivalent. We then use a randomized algorithm of Schwartz [15] to check the equivalence of the polynomials. Since Schwartz’s result deals with sequential algorithms, we have some additional work to prove that the algorithm can be modified to run in  $\text{RNC}^2(M(n))$ .

In defining the polynomials, it is useful to first perform some modifications to the dag as follows. Given a labeled dag  $D'$ , we first add a new node  $z$  to  $D'$ , and add edges from every node in  $D'$  to the new node  $z$ , making  $z$  the unique leaf of the resulting dag, call it  $D$ . Each new edge  $(v, z)$  is  $D$  labeled with the outdegree of  $v$  in  $D$ . This process of adding a new leaf, connecting it to all nodes in the original dag, and labeling the new edges, is called *preparing* the dag, and  $D$  is said to be *prepared*. We view  $D$  as a term dag with the single constant symbol  $z$ ; the arity of each function symbol labeling a node of  $D$  (except the new node) is one more than the arity of the function symbol labeling the corresponding node of  $D'$ . If  $G$  and  $H$  are the prepared dags rooted at  $r_1$  and  $r_2$ , respectively, in  $D$  then it is obvious that  $G$  and  $H$  are equivalent if and only if  $G'$  and  $H'$  are equivalent. Therefore, we shall work with prepared dags in the remainder of this section.

Given a labeled prepared dag  $G$ , we define the corresponding polynomial  $P_G$  as follows. Our intention is to assign variables to edges; in § 2.1, “variable” means a variable of some polynomial  $P_G$ . Each path from the root to the leaf will then yield a monomial defined as the product of the variables assigned to the edges along the path. The final polynomial will then be the sum over all paths  $p$  from root to leaf of the monomial corresponding to  $p$ . We will show that two dags are equivalent if and only if their corresponding polynomials are equivalent. Reducing equivalence testing for term dags, which is in NC, to testing equivalence of polynomials, which is not even known to be in P, is not obviously progress. However, we will then apply the algorithm of Schwartz, modified to run in RNC, testing equivalence of the polynomials at a randomly selected point. A negative answer to this test is a proof of inequivalence. As we will see, a positive answer can sometimes be turned into a proof of equivalence. Sometimes a positive result will be inconclusive, in which case the algorithm can be run again.

We now describe the selection of the variables. Consider an arbitrary path from the root to the leaf. In selecting the variables corresponding to the edges of the path, care must be taken that the ordering information is not lost. In other words, given the monomial corresponding to the path we must be able to reconstruct the path. To this end, for each node  $v$  we compute the number of paths from  $v$  to  $z$  in  $G$ . Note that since  $G$  is prepared, if  $v$  is a proper ancestor of  $u$  then the number of paths from  $v$  to  $z$  exceeds the number from  $u$  to  $z$ ; this fact will play an important role in the proof of Lemma 1.

**VARIABLE NAMING RULE.** Let  $v$  be a node of  $G$  labeled with the  $k$ -ary function

symbol  $f$ , and let  $m$  be the number of paths from  $v$  to the leaf  $z$ . Then for each  $j \in \{1, \dots, k\}$ ,  $f_j^m$  is the variable assigned to the edge from  $v$  labeled  $j$ .

For each path  $p$  directed from the root of  $G$  to  $z$ , let the monomial  $\mu(p)$  be the product of all the variables corresponding to the edges of  $p$ . Then  $P_G = \sum_p \mu(p)$ .

LEMMA 1. *Two prepared term dags  $G$  and  $H$  are equivalent if and only if  $P_G$  and  $P_H$  are equivalent polynomials.*

*Proof.* We begin with the if direction. Let the *degree* of a polynomial denote the maximum number of variables in any monomial of the polynomial. Then  $P_G \equiv P_H$  implies that the two polynomials are of the same degree. The proof proceeds by induction on  $k$ , the degree of the polynomials.

$k = 1$ . In this case the two polynomials each consist of a single monomial (this is because of the way we defined a prepared dag). Thus, for some unary function symbols  $g$  and  $h$  we have  $P_G = g_1^1$  and  $P_H = h_1^1$ . Clearly, these polynomials can be equivalent if and only if  $g_1^1 = h_1^1$ , so the symbols  $g$  and  $h$  must be identical.

$k > 1$ . We assume the result inductively for polynomials of degree less than  $k$  and prove it for  $k$ . Let  $g$  (respectively,  $h$ ) be the label of the root of  $G$  (respectively,  $H$ ) and let  $i$  (respectively,  $j$ ) be the number of paths from the root of  $G$  (respectively,  $H$ ) to the leaf  $z$ . Write  $P_G = \sum_{x=1}^a g_x^i t_x$  and  $P_H = \sum_{x=1}^b h_x^j s_x$ , where the superscripts in the  $t_x$  and  $s_x$  are less than  $i$  and  $j$ , respectively. Then  $i = j$ , as otherwise the maximum superscripts of the two sets of variables differ. Thus, none of the  $t_x$  contain any variable name of the form  $h_y^i$  and similarly, no  $s_x$  contains any  $g_y^i$ . Because the only function symbol superscripted with  $i$  in  $P_H$  is  $h$ , it follows that  $g = h$ , whence  $a = b$ . Rewriting  $P_H$  with  $g$  replacing  $h$  yields  $P_H = \sum_{x=1}^a g_x^i s_x$ . For any  $x \in \{1, \dots, a\}$ , setting  $g_y^i$  to 0 for all  $y \neq x$  yields  $g_x^i t_x = g_x^i s_x$ , whence  $t_x = s_x$ . Since the degree of  $t_x$  is strictly less than  $k$ , we see by the inductive hypothesis that the term represented by  $t_x$  is equivalent to the term represented by  $s_x$ . Let  $r_1$  and  $r_2$  be the roots of  $G$  and  $H$ , respectively. Since  $g = h$  both roots are labeled with the same function symbol. Further,  $t_x = s_x$  for all  $x$ , so the corresponding arguments of  $g$  are the same in the two dags. Thus, the two dags are equivalent.

We now prove that if the two prepared dags are equivalent then the corresponding polynomials are equivalent. Because the height of a dag corresponds to the maximum depth of nesting of parentheses in the term it represents, if  $G \equiv H$  then the two dags are of the same height. The proof proceeds by induction on  $k$ , the height of the dags. We strengthen the induction hypothesis, showing that if two dags are equivalent then the number of paths from the root to the leaf is the same in the two dags.

$k = 1$ . All prepared dags of height 1 contain a unique edge, from root to leaf, so the corresponding terms are just 1-ary function symbols. Thus,  $G \equiv H$  implies the two dags are identical, whence they give rise to the same polynomial.

$k > 1$ . We assume the result inductively for dags of height less than  $k$  and prove it for  $k$ . Let  $r_1$  and  $r_2$  be the roots of  $G$  and  $H$ , respectively. If  $G \equiv H$  then the two roots are labeled with the same function symbol, say  $g$ , whence both roots have the same outdegree, say  $a$ . Further, because the dags are equivalent, for each  $i \in \{1, \dots, a\}$ , the subdag rooted at the  $i$ th child of  $r_1$  is equivalent to the subdag rooted at the  $i$ th child of  $r_2$ . Since these subdags are of height strictly less than  $k$  we see by the inductive hypothesis the polynomials corresponding to the subdags rooted at the  $i$ th children of the roots are equivalent, and the number of paths from the  $i$ th child of  $r_1$  to the leaf is equal to the number of paths from the  $i$ th child of  $r_2$  to the leaf, for all  $i$ . Thus, the total number of root-leaf paths is the same in the two dags. Let  $m$  denote this number. Let  $P_i$  denote the polynomial corresponding to the subdag rooted at the  $i$ th child of either root. Then  $P_G = g_1^m P_1 + \dots + g_a^m P_a$ , and this is precisely  $P_H$ .  $\square$

*Remarks.* (1) If the variables were not superscripted with the path numbers Lemma 1 would not hold. This is because the variables  $f_1$  and  $f_2$  commute, i.e.,  $f_1 f_2 = f_2 f_1$ , but the directed paths labeled  $f_1 f_2$  and  $f_2 f_1$  are not the same in a dag.

(2) Two very natural approaches to handling the commutativity problem do *not* work. Affixing  $c \times c$  matrices to the edges, for some constant  $c$ , cannot work. This follows from a theorem of Amitsur and Levitzki [1] which states that there are polynomials  $Q_1(x_1, \dots, x_{2c})$  and  $Q_2(x_1, \dots, x_{2c})$  with zero-one coefficients, involving noncommuting variables  $x_1, \dots, x_{2c}$ , such that  $Q_1$  and  $Q_2$  are not equivalent in general, but  $Q_1$  and  $Q_2$  are equivalent over the ring of  $c \times c$  matrices. A second approach, computing for each node  $v$  the maximum distance from  $v$  to  $z$  (instead of the number of paths) requires a special kind of matrix multiplication, in which the inner operation is  $+$  and the outer operation is  $\max$ . It is not known how to compute the “product” of two  $n \times n$  matrices in  $M(n)$  steps using this definition of multiplication.

In order to use Lemma 1 to test for equivalence of term dags, we must address several issues.

The number of paths from a node to the leaf may be as large as  $n^{n-1}$ , even though the outdegree of each node is bounded by  $n$ . Since the word size of our parallel random access machine (PRAM) is at most logarithmic in  $n$  we cannot actually compute these numbers. Similarly, we cannot evaluate the polynomials  $P_G$  and  $P_H$ , as for many possible choices of values for the variables the values of the polynomials will be too large to handle. We use modular arithmetic to handle these problems, performing all arithmetic modulo random primes, which in turn raises the question of how to obtain a random prime.

Testing equivalence of multivariate polynomials is not even known to be solvable in polynomial time, let alone in NC, even when we can actually evaluate the polynomials, much less when we cannot. For this we resort to a modification of Schwartz’s randomized algorithm.

The Schwartz algorithm is Monte Carlo, in that an answer of “inequivalent” is always correct, but an answer of “equivalent” is correct only with high probability. Thus, the final issue is that of deriving a proof of equivalence when Schwartz’s algorithm tells us two polynomials are equivalent. If the polynomials are arbitrary this problem is open. Our polynomials are not arbitrary; they are constructed from term dags. This can sometimes be exploited to obtain a proof of equivalence.

LEMMA 2. *For each constant  $k$ , there is an  $\text{RNC}^2(\log^3 n)$  algorithm that, on input  $n$ , with probability at least  $1 - n^{-k}$  produces a random prime  $q \in I = \{2, \dots, n^k\}$ .*

*Proof.* Our approach is to choose  $r$  random numbers,  $q_1, \dots, q_r \in I$  where  $r = d \log^2 n$  for an appropriate constant  $d$ . Each  $q_i$  is tested for primality  $(k+2) \log n$  times in parallel using Rabin’s randomized test [13]. Of those  $q_i$  having passed all tests one is selected at random. Rabin’s algorithm runs in time  $O(\log^2 n)$  on inputs from  $I$ . When given a prime, the algorithm always answers “prime”; when given a composite, it answers “composite” with probability at least  $\frac{1}{2}$ .

There are two ways in which the algorithm could fail to produce a prime. It may be that none of the  $q_i$  are prime. The Prime Number Theorem implies that for some constant  $c$ , independent of  $n$ , the probability that all  $r$  are composite is at most  $(1 - c/\log n)^r$ , which is at most  $n^{-k}/2$  if  $r = d \log^2 n$ , for some constant  $d$  independent of  $n$ . If at least one  $q_i$  is actually prime, it is still possible that a composite will be chosen. However, since Rabin’s algorithm errs with probability at most  $\frac{1}{2}$ , the probability that a composite passes all  $(k+2) \log n$  tests is at most  $n^{-k-2}$ . Thus, the probability that even one composite passes all tests is at most  $nn^{-k-2}$ , which is less than  $n^{-k}/2$  for sufficiently large  $n$ .  $\square$

The first source of error in our randomized protocol for testing equivalence of term dags is in the selection of  $q$ , because our algorithm may fail to produce a prime. However, even if a prime  $q$  is produced, performing arithmetic modulo  $q$  introduces a second source of error, as distinct numbers  $r$  and  $s$  may be congruent mod  $q$ . Thus, when computing the superscripts for the variables mod  $q$ , two variables assigned to edges from nodes with differing numbers of paths to the leaf may receive the same superscript. We must therefore choose  $q$  from a range sufficiently large as to make this event unlikely.

DEFINITION. Integer  $m$  is *bad* for the pair of integers  $(r, s)$  if  $r \neq s$  but  $r$  and  $s$  are congruent mod  $m$ .

LEMMA 3. For every pair of distinct numbers  $r, s \leq n^n$  there are at most  $n \log n$  bad primes.

*Proof.* Let  $\{p_1, \dots, p_x\}$  be the set of primes bad for  $(r, s)$ . Then the product  $\pi = p_1 p_2 \dots p_x$  is also bad for  $(r, s)$ . Since  $r, s \leq n^n$  it must be that  $\pi \leq n^n$  (otherwise the two numbers could not be congruent mod  $\pi$ ). On the other hand, since each  $p_i \geq 2$  we have  $2^x \leq \pi$ . Thus,  $2^x \leq \pi \leq n^n$ , whence  $x \leq n \log n$ , as was to be shown.  $\square$

Let us say a prime  $q$  is *bad* for a prepared dag if there exist two nodes  $u$  and  $v$  in the dag such that  $r$  and  $s$  are the number of paths to the leaf from  $u$  and  $v$ , respectively,  $r \neq s$ , and  $q$  is bad for  $r, s$ .

COROLLARY 4. Let  $D$  be a prepared dag with  $n$  nodes in which each node has outdegree at most  $n$ . Then a random prime  $q$  drawn from  $[2, n^k]$  is bad for  $D$  with probability at most  $O(n^{3-k} \log^2 n)$  for any fixed  $k \geq 3$ .

*Proof.* There are at most  $n^2$  pairs of nodes, and for each pair there are at most  $n \log n$  bad primes, so there are at most  $n^3 \log n$  primes bad for  $D$ . By the Prime Number Theorem there are  $\Omega(n^k / (k \log n))$  primes in  $[2, n^k]$ . Thus, if a prime is selected uniformly at random from this range, then the probability that the chosen prime is bad for  $D$  is at most

$$O\left(n^2 \log n \frac{k \log n}{n^k}\right) = O(n^{3-k} \log^2 n). \quad \square$$

Let  $Q$  be a polynomial in  $t$  variables with integer coefficients. An *assignment* for  $Q$  is a  $(t+1)$ -tuple of integers  $A = (i_1, \dots, i_t, p)$ . We define

$$Q(A) = Q(i_1, \dots, i_t) \pmod{p}.$$

An assignment  $A$  is a *modular zero* of  $Q$  if  $Q(A) = 0$ . We let  $\max_v(Q, m)$  denote the maximum value attained by  $Q$  over the rectangle in which the absolute value of each variable is bounded by  $m$ .

In order to bound the probability of error in testing the polynomials for equality, we appeal to the following theorem due to Schwartz [15].

THEOREM (Schwartz). Let  $2m + 1 \geq c \cdot \deg(Q)$ , let  $I$  be the set of integers of absolute value  $\leq m$ , let  $J$  be a set of primes, and suppose that the product of the  $c^{-1}|J| + 1$  smallest primes in  $J$  exceeds  $\max_v(Q, m)$ . Then if  $Q$  is not identically equal to zero, the number of elements of  $I^t \times J$  which are modular zeros of  $Q$  is at most  $2c^{-1}|I|^t|J|$ .

The  $Q$  we will be considering is  $P_G - P_H$ , which is of degree at most  $n$  (the number of nodes in the union of the two dags), and contains  $t \leq n^2$  variables. Suppose we wish to bound the probability of choosing a modular zero by  $n^{-k}$ . We apply Schwartz's Theorem as follows. Let  $b \geq k + 1$  and  $m = n^b$ . Let  $J$  be the set of primes in  $[2, n^{2b}]$ , and  $I = [-n^b, n^b]$ , where  $J$  is the set from which we select our random prime  $p$  and  $I$  is the interval from which each of our  $t$  variables is chosen. Each term in  $Q$  is the

product of at most  $n$  variables, and  $Q$  contains at most  $n^n$  terms, so

$$\max_v (Q, n^b) \leq n^{bn}.$$

To satisfy the conditions of the theorem we take  $c = (2n^b + 1)/n$ . Estimating the number of primes in  $J$  to be  $dn^{2b}/2b \log n$ , for some constant  $d$ , the condition that the product of the  $c^{-1}|J| + 1$  smallest primes exceeds  $\max_v (Q, m)$  is clearly satisfied if

$$\frac{dn^{2b+1}}{(2n^b + 1)2b \log n} \geq n(b+1) \log n$$

(because each prime is no smaller than 2). This reduces to

$$dn^{2b} \geq 2b(b+1)(2n^b + 1)(\log n)^2,$$

which is clearly true for all sufficiently large  $b$ , assuming  $n \geq 2$ . We therefore have the following corollary.

**COROLLARY 5.** *Let  $Q$  be a polynomial of degree  $n \geq 2$  such that  $Q \neq 0$ . For any fixed  $k$  there is a constant  $b$ , depending only on  $k$ , such that by choosing a random assignment  $A$  for  $Q$  by choosing a random prime in the interval  $[2, n^{2b}]$  and randomly selecting values for the variables in  $Q$  from  $I = [-n^b, n^b]$ ,  $\Pr[Q(A) = 0] \leq n^{-k}$ .  $\square$*

When our polynomial  $Q$  is formed from two term dags it is obvious how we obtain a proof of inequality ( $Q(A) \neq 0$ ), while if  $Q(A) = 0$  we may have hit a modular zero at  $A$ . However, in some cases we can actually obtain a proof of equivalence. In part this is due to the fact that when we evaluate the polynomials corresponding to the two roots of our dags, we simultaneously evaluate all  $n$  polynomials corresponding to the subdags rooted at each of the  $n$  nodes, just as when testing directed graph reachability by computing the transitive closure of the adjacency matrix we obtain reachability information for all pairs of points.

Let  $D$  be a prepared dag with two roots, and let  $G$  and  $H$  be the subdags rooted at these roots. Choose variables for the edges according to the Variable Naming Rule. For each node  $v$ , let  $P_v$  be the polynomial induced by the subdag rooted at  $v$ . By convention,  $P_z$  is the identically zero polynomial where  $z$  is the unique leaf added when the dag was prepared. Running our parallelized version of Schwartz's algorithm with a particular assignment  $A$  to the variables induces an equivalence relation on the nodes of  $D$ , where distinct nodes  $x$  and  $y$  are in the same class if and only if the algorithm tells us  $P_x(A) = P_y(A)$ . Let us denote this relation by  $x \equiv_A y$ . For each pair of  $\equiv_A$  nodes we check two things. First, we verify that both nodes are labeled with the same function symbol. Second, we check that the corresponding children of each pair of  $\equiv_A$  nodes are also  $\equiv_A$ . We claim that if both these tests are passed for all pairs of  $\equiv_A$  nodes then the subdags rooted at  $x$  and  $y$  are equivalent.

**LEMMA 6.** *Let  $D$  and  $A$  be as above. Let  $x$  and  $y$  be nodes of  $D$  satisfying  $x \equiv_A y$ . If for all  $u, v$  such that  $u \equiv_A v$  and  $u$  and  $v$  both belong to the union of the subdags induced by  $x$  and  $y$ , it is the case that the labels of  $u$  and  $v$  agree and each pair of corresponding children of  $u$  and  $v$  are  $\equiv_A$ , then the subdags rooted at  $x$  and  $y$  are equivalent.*

*Proof.* The proof is by induction on  $k$ , the length of the longest path from  $x$  to the leaf  $z$ .

$k = 0$ . In this case  $x = z$ , which has the label  $z$ . If the conditions of the lemma are satisfied then  $y$  has label  $z$ , so  $y = z$  as well.

$k > 0$ . Assume the result inductively for  $k - 1$ , and assume the conditions of the lemma hold. Then the labels of  $x$  and  $y$  agree. Further, corresponding children of  $x$  and  $y$  are  $\equiv_A$ . Thus, by induction, the subdags rooted at their corresponding children are equivalent. It follows immediately that the subdags rooted at  $x$  and  $y$  are equivalent.  $\square$

Lemma 6 says it is sometimes possible to prove equivalence of polynomials generated from term dags. In particular, this can be done when for every pair of  $\equiv_A$  nodes, the subdags rooted at the two nodes are actually equivalent. It is possible that two nodes labeled with different function symbols are “equivalent” under  $\equiv_A$ . In this case we can prove nothing about the ancestors of these nodes and we must run the algorithm again.

**THEOREM 7.** *The problem of testing equivalence of two term dags can be solved by a Las Vegas algorithm in  $\text{RNC}^2(M(n))$ . For any fixed  $k$  the probability that no answer is produced can be bounded above by  $n^{-k}$ .*

*Proof.* The algorithm is as follows. The algorithm involves an integer parameter  $k'$  which is chosen depending on  $k$ . Let  $(D', r_1, r_2)$  be an instance of the equivalence problem, consisting of a dag  $D'$  and two roots.

1. Prepare  $D'$  by adding a new leaf  $z$ , adding an edge from each node to  $z$ , and labeling the added edges. Let  $D$  denote the resulting dag.
2. Choose a random prime  $q \in [2, n^{k'}]$ .
3. For each node  $v$  compute the number (mod  $q$ ) of paths from  $v$  to  $z$ .
4. For each edge  $e$  compute the name of the associated variable according to the Variable Naming Rule.
5. Sort the variable names and remove duplicates from the sorted list.
6. Choose an assignment  $A$  by choosing random values from the range  $[-n^{k'}, n^{k'}]$  for the variables in the list produced at the previous step and by choosing a random prime  $p \in [2, n^{2k'}]$ .
7. For each node  $v$  in  $D$  evaluate  $P_v$ , the polynomial corresponding to the subdag rooted at  $v$ , at the point  $A$  chosen in step 6. If  $r_1 \not\equiv_A r_2$  then output “inequivalent” and halt.
8. If  $r_1 \equiv_A r_2$  then try to prove equivalence by the method of Lemma 6. If successful, output “equivalent,” else output “?”.

We now describe steps 3, 7, and 8 in more detail.

For simplicity, let  $n$  denote the number of nodes in the prepared dag  $D$  (the original dag plus the new leaf). To perform step 3, we define an  $n \times n$  matrix  $E$  whose  $ij$  entry is the number of edges from  $i$  to  $j$  (mod  $q$ ). In other words,  $E_{ij}$  is the number (mod  $q$ ) of paths of length 1 from  $i$  to  $j$  (diagonal entries are 0). In general,  $(E^k)_{ij}$  is the number (mod  $q$ ) of paths of length  $k$  from  $i$  to  $j$ . Since we are interested in all paths of all lengths from each node to  $z$ , we compute the sum of all powers of  $E$  from  $E^0$  to  $E^{m-1}$  where  $n \leq m < 2n$  and  $m$  is a power of 2. To do this we use the well-known identity

$$I + E + E^2 + E^3 + \dots + E^{m-1} = (I + E)(I + E^2)(I + E^4) \dots (I + E^{m/2}).$$

Multiplication of  $m \times m$  matrices can be computed in  $\text{NC}^1(M(n))$  (see, e.g., Pan and Reif [11, Appendix A]). Therefore, the powers of  $E$  needed to compute the rhs can be computed in  $\text{NC}^2(M(n))$  by repeated squaring. All arithmetic is done mod  $q$ . Since the rhs contains at most  $\log n$  terms the product can also be computed in  $\text{NC}^2(M(n))$  once the powers of  $E$  are computed. Let  $E^* = \sum_{i=0}^{m-1} E^i$  (mod  $q$ ). Then for each node  $v$ ,  $E_{vz}^*$  is the number (mod  $q$ ) of paths from  $v$  to  $z$ .

The evaluations of the polynomials  $P_v$  proceed in a similar fashion. Thus, to perform step 7 we define a matrix  $B$  whose  $ij$  entry is the sum of the values chosen for the variables assigned to the edges from  $i$  to  $j$ . Viewed differently,  $B_{ij}$  is the value of the polynomial corresponding to the subdag containing paths of length 1 from  $i$  to  $j$ . In general,  $(B^k)_{ij}$  is the value of the polynomial which is the sum of the monomials

corresponding to all paths of length  $k$  from  $i$  to  $j$ . As in the case of the computation of path numbers, we are interested in  $B^* = I + B + B^2 + B^3 + \dots + B^{m-1}$ . This is computed as described above, all arithmetic being performed mod  $p$ . Then  $B_{uz}^* = P_v(A)$ . For any two nodes  $x$  and  $y$  we have

$$x \equiv_A y \Leftrightarrow B_{xz}^* = B_{yz}^*.$$

To perform step 8, the verification of equivalence, we proceed as follows. For all nodes  $x$  and  $y$  such that  $x \equiv_A y$  we check that the labels of  $x$  and  $y$  are equal (if they are not then we can prove nothing, and the algorithm outputs “?”). Given that they are equal, we wish to check that corresponding children of  $\equiv_A$  nodes are themselves  $\equiv_A$ . Let  $e = (u, v)$  be an edge with label  $i$ . Corresponding to  $e$  there is a triple  $(B_{uz}^*, i, B_{vz}^*) = (P_u(A), i, P_v(A))$ . The set of triples corresponding to all the edges of the prepared dag are sorted lexicographically. We then examine the sorted list for a pair of adjacent triples whose first and second components match but whose third components differ. If no such pair exists the algorithm outputs “equivalent,” else it outputs “?”.

This completes the description of the algorithm. It remains to prove correctness when the random choices are good and to analyze the probability of making a bad random choice. Let  $G$  and  $H$  be the subdags rooted at  $r_1$  and  $r_2$ , respectively.

By Lemma 1,  $G \equiv H$  implies  $P_G \equiv P_H$ , and in the absence of a bad random choice in step 2,  $G \not\equiv H$  implies  $P_G \not\equiv P_H$ . If  $P_G \not\equiv P_H$ , then in the absence of a bad choice for the assignment  $A$  at step 6,  $r_1 \not\equiv_A r_2$ , so we have a proof that  $G \not\equiv H$ . If  $P_G \equiv P_H$ , then, in the absence of a bad choice for  $A$ , for all pairs of nodes  $u, v$  such that  $u \equiv_A v$  it is the case that the subdags rooted at  $u$  and  $v$  represent the same terms, in which case we have a proof of equivalence by Lemma 6.

This proves correctness in the absence of bad choices. We now bound the probability of making a bad choice.

As shown in Lemma 2 and Corollary 4, we can bound the probability of a bad choice in step 2 by  $n^{-k}$  for any fixed  $k$ . We now examine the probability of obtaining a “?” output given that no bad choice was made in step 2.

A “?” will be produced if for some pair of nodes  $u$  and  $v$ , the subdags rooted at the nodes are inequivalent but  $u \equiv_A v$ . By Lemma 2 and Corollaries 4 and 5 the probability of this occurring for a particular pair of nodes can be bounded above by  $n^{-k}$  for any fixed  $k$ . As there are only  $n^2$  pairs of nodes, the probability of this event occurring for any pair of nodes can be similarly bounded.

This completes the proof of Theorem 7.  $\square$

**2.2. Directed reachability reduces to equivalence testing.** The *dag reachability* problem is: Given a dag  $D$  and two distinguished nodes  $s$  and  $t$  of  $D$ , does there exist a path from  $s$  to  $t$ ? The size of the instance is the number of nodes in  $D$ . While directed reachability is known to be complete for  $\text{NSPACE}(\log n)$  with respect to logspace reductions, and therefore to be in NC, little is known about the number of processors needed to solve this problem in polylog time. In fact, all known NC or RNC algorithms compute the transitive closure of the adjacency matrix for  $D$  by repeated squaring and therefore use  $M(n)$  processors (to within logarithmic factors). Thus, while reducing directed reachability to term equivalence does not yield a lower bound on the number of processors needed to test for equivalence in NC, it does provide some “evidence” that  $M(n)$ , the processor bound obtained in Theorem 7, cannot be significantly improved.

**THEOREM 8.** *The directed acyclic graph reachability problem is  $\text{NC}^0(n^2)$  reducible to the equivalence testing problem.*

*Proof.* Given a dag  $D_1$  with distinguished nodes  $s_1$  and  $t_1$  we will construct a pair of term dags  $E_1$  and  $E_2$  which will be equivalent if and only if there is no path from  $s_1$  to  $t_1$  in  $D_1$ . The construction is illustrated in Fig. 2.

Without loss of generality we assume  $D_1$  has a unique root (if this is not the case then create a new root with edges to each of the original roots). We begin by turning  $D_1$  into a term dag. For each  $k$ ,  $0 \leq k \leq n$ , and for each node  $v$  of  $D_1$  with outdegree  $k$ , label  $v$  with the function symbol  $f^k$ . Label the outedges from 1 to  $k$  in arbitrary order.

FIG. 2. The dags constructed in the proof of Theorem 8.

Create a copy  $D_2$  of  $D_1$ , identical to  $D_1$  but with  $t_2$ , the  $D_2$  copy of  $t_1$ , labeled with a new function symbol  $g$ . Let  $s_2$  be the  $D_2$  copy of  $s_1$ . There is a path from  $s_1$  to  $t_1$  if and only if  $s_1$  and  $s_2$  are the roots of inequivalent subdags. However, we are not done, since the  $s$  nodes are internal, and we have been assuming that an equivalence algorithm takes as input two roots and determines whether the dags rooted at these roots represent equivalent terms.

We next create a new dag  $E_1$  composed of  $D_1$  and  $D_2$  by creating a new root  $r_1$  and making the roots of  $D_1$  and  $D_2$  first and second children, respectively, of  $r_1$ . Let  $s_1$  be the third child of  $r_1$ . The edges from  $r_1$  to its children are labeled accordingly, and  $r_1$  is labeled with function symbol  $f^3$ .

Finally, we create a copy  $E_2$  of  $E_1$ , identical to  $E_1$  but with the 3-edge of  $r_2$ , the root of  $E_2$ , pointing to the  $E_2$  copy of  $s_2$  (instead of to the copy of  $s_1$ ). The subdags rooted at the first and second children of the two roots are identical by construction. Thus, the two dags are equivalent if and only if the subdags rooted at the third children are equivalent. As observed above, this holds if and only if there is no path from  $s_1$  to  $t_1$  in  $D_1$ .

If  $D_1$  contains  $n$  nodes then the four copies can be constructed in  $O(1)$  time using  $n^2$  processors (one per edge). The two new roots and six additional edges are added in constant time as well.  $\square$

**3. Reducing term matching to equivalence testing.** In § 2.1, we showed that two term dags can be tested for equivalence in  $\text{RNC}^2(M(n))$ . We now show that these bounds apply to the term-matching problem as well. Recall that term  $s$  matches term  $t$  if and only if there exists a  $\sigma$  mapping variables to terms such that  $\sigma(s) = t$ . Note

that matching is not a symmetric relation. An instance of the term-matching problem is a pair of disjoint labeled term dags representing the terms  $s$  and  $t$  to be matched. The size of the instance is the number of nodes in the union of the two dags. Although our matching algorithm requires the two dags to be disjoint, nondisjoint instances can be transformed to disjoint instances by performing a reachability computation from the two roots; as in the proof of Theorem 7, this can be done in  $\text{NC}^2(M(n))$ . In particular, disjointness is not needed in Corollary 10. Both term matching and equivalence testing are special cases of the unification problem. In the term-matching problem one of the terms (the second one) is considered *constant*:  $\sigma$  is not applied to the second term. In the equivalence problem, both terms are considered constant.

In § 3.1, we describe our results for general dags. Special cases are discussed in § 3.2.

**3.1. Term matching on general dags.** In this section we will prove the following theorem.

**THEOREM 9.** *Term matching reduces to testing for equivalence in  $\text{NC}^2(n^2)$ .*

From Theorems 7 and 9 we obtain our main result.

**COROLLARY 10.** *Term matching can be solved by a Las Vegas algorithm in  $\text{RNC}^2(M(n))$ .*

As mentioned in the Introduction we also have some specialized algorithms for term matching which depend on the form of the constant term. However, the general outline of the algorithm is the same in all cases. For ease of exposition we break the algorithm into four main steps. Since the first term, henceforth  $s$ , will always be represented by an arbitrary dag  $G$ , we may assume without loss of generality that each variable of  $s$  is the label of exactly one node of  $G$  (multiple copies of  $x$  can be merged into one copy).

Steps 1–4 below outline all our matching algorithms. Let  $G$  and  $H$  denote the dags representing  $s$  and  $t$ , respectively.

**Match ( $G, H$ ).**

1. A processor is assigned to each node of  $G$ . A spanning tree  $T$  of  $G$  is formed by having the processor assigned to each node  $v$  of  $G$  (except the root) arbitrarily choose one of the edges directed into  $v$ .

For each node  $v$  in  $G$ , there is a unique sequence of spanning tree edges from the root of  $G$  to  $v$ . We use  $\rho(v)$  to denote the sequence of edge labels along this path. An *embedding* is a mapping  $d$  from nodes of  $G$  to nodes of  $H$  such that  $d$  maps the root of  $T$  to the root of  $H$  and if  $v$  and  $u$  satisfy  $\rho(v) = \rho(u) \cdot i$  then there is an edge labeled  $i$  from  $d(u)$  to  $d(v)$ . In other words,  $d(u)$  is that node in  $H$  reached by following the edge sequence  $\rho(u)$  from the root of  $H$ . If  $T$  cannot be embedded in  $H$  then there is a sequence of edge labels present in  $G$  but absent from  $H$ ; hence  $G$  does not match  $H$ .

2. Embed  $T$  in  $H$ , if possible, and let  $d$  be the resulting embedding. Check that for all nodes  $u$  of  $T$ ,  $u$  and  $d(u)$  are labeled by the same function symbol. If there is no embedding or if the check fails, then output “no match.”
3. For each node  $v$  of  $G$  labeled by a variable, say  $x$ , let  $\sigma(x)$  be the term rooted at  $d(v)$  in  $H$ . Apply the substitution  $\sigma$  to  $G$  by replacing all edges of the form  $(u, v)$  by  $(u, d(v))$ . Let  $C = \sigma(G)$  denote the dag obtained from  $G$  by performing the substitution.
4. Test dags  $C$  and  $H$  for equivalence.  $G$  matches  $H$  if and only if  $C \equiv H$ .

Note that the mapping  $\sigma$  can be described by specifying, for each variable  $x$  labeling a node  $v$  of  $G$ , the pair  $(x, d(v))$ .

To prove correctness of the algorithm we need the following lemma.

LEMMA 11. *Let  $G$ ,  $H$ , and  $C$  be as in Algorithm Match. Then  $G$  matches  $H$  if and only if  $C \equiv H$ .*

*Proof.* Clearly, if  $C \equiv H$  then  $G$  matches  $H$ , as then  $C \equiv \sigma(G) \equiv H$ , where  $\sigma$  is the substitution described in step 3.

To prove the opposite direction we note that if  $G$  matches  $H$ , then the substitution  $\sigma$  found by the algorithm is the only one possible. Suppose otherwise that there was some other  $\sigma'$  such that  $\sigma'(G) \equiv H$ . Let  $x$  be any variable of  $G$  and let  $v$  be the node labeled by  $x$ . Since the roots of  $\sigma'(G)$  and  $H$  are equivalent, the two nodes reached by following the path  $\rho(v)$  from both roots must be equivalent. These nodes are  $v$  in  $G$  and  $d(v)$  in  $H$ , where  $d$  is the embedding found by the algorithm. Therefore,  $\sigma'(x) = \sigma(x)$ .  $\square$

To prove Theorem 9 we need only prove we can perform the embedding (step 2) in  $NC^2(n^2)$ . To do this, we will need a few lemmas.

LEMMA 12. *Given a directed path  $p$  with  $n$  nodes whose nodes are labeled with function symbols and whose edges are labeled with integers, and given a term dag  $H$  with  $k$  nodes ( $k \geq n$ ), there is an algorithm which checks whether  $p$  can be embedded in  $H$  (and produces an embedding if there is one) in  $NC^1(kn)$ .*

*Proof.* We form the product graph  $Z = p \times H$  whose nodes are all pairs of nodes  $(u, v)$  where  $u \in p$  and  $v \in H$ . There is an edge labeled  $i$  from  $(u, v)$  to  $(u', v')$  in  $Z$  if and only if there are edges  $(u, u')$  in  $p$  and  $(v, v')$  in  $H$  both labeled  $i$ . Let  $p_1$  and  $p_n$  be the initial and final nodes of  $p$ , respectively, and let  $r$  be the root of  $H$ . Then  $p$  can be embedded in  $H$  if and only if there is a path in  $Z$  from  $(p_1, r)$  to  $(p_n, w)$  for some node  $w$  of  $H$ .

Note that since  $p$  is a path, each node in the product graph  $Z$  has outdegree at most 1. We can therefore apply the standard technique of "pointer chasing." We assign a processor to each node of  $Z$ . These processors initialize two arrays; a bit array  $E$  which indicates whether a node is known to be reachable from  $(p_1, r)$  (should one exist), and a successor array  $S$ .

1. Initialization:

If  $a = (p_1, r)$  then  $E(a) := 1$ , else  $E(a) := 0$ .

If there is an edge of  $Z$  from  $a$  to  $b$ , then  $S(a) := b$ .

For all nodes  $w$  in  $H$ ,  $S((p_n, w)) := (p_n, w)$ .

2. Repeat  $\lceil \log n \rceil$  times:

If  $E(a) = 1$  then  $E(S(a)) := 1$ ;

$S(a) := S(S(a))$ .

3. Test for embedding:

If  $S((p_1, r)) = 0$  then output "No embedding" and halt.

4. Find embedding given that one exists:

If  $E((u, v)) = 1$  then  $v$  is the embedding of  $u$ .

The number of nodes  $a$  for which  $E(a) = 1$  doubles at each step until all nodes reachable from  $(p_1, r)$  are found. Thus, after execution of the algorithm  $E(a) = 1$  if and only if  $a$  is reachable from  $(p_1, r)$ . Moreover, after execution of the algorithm  $S((p_1, r)) \neq 0$  if and only if a node of the form  $(p_n, w)$  is reachable from  $(p_1, r)$ .  $\square$

LEMMA 13 (Tarjan and Vishkin [16]). *Let  $T$  be a tree of size  $m$ . There are  $NC^1(m)$  algorithms which produce (a) the depth-first numbering of  $T$  and, (b) for each node  $u$  of  $T$ , the number of nodes in the subtree rooted at  $u$ .*

The following lemma shows that the embedding of a tree in a dag can be accomplished in  $NC^2(n^2)$ , completing the proof of Theorem 9.

LEMMA 14. *The problem of embedding a tree  $T$  having  $m$  nodes in a dag  $H$  having  $k$  nodes is in  $\text{NC}^2(km)$ .*

*Proof.* The embedding is done by a recursive divide-and-conquer approach.

1. For each node  $v \in T$  compute the size of the subtree rooted at  $v$ . This can be done in  $\text{NC}^1(m)$  by Lemma 13(b). Let the *weight* of a directed edge  $(u, v)$  be the size of the subtree rooted at  $v$ . Consider any path originating at the root of  $T$  defined by selecting the heaviest edge out of each node to be in the path (ties are broken arbitrarily). Let us call such a path a *heavy path*.
2. Embed the heavy path. This can be done in  $\text{NC}^1(km)$ , by Lemma 12.
3. For each node  $v$  in the heavy path embedded in step 2, embed all the children of  $v$ . This can be accomplished in  $\text{NC}^0(km)$ .
4. For each node  $u$  embedded in step 3, embed the subtree rooted at  $u$  in the subdag rooted at  $d(u)$  where  $d$  is the embedding constructed in step 3. These embeddings are performed recursively in parallel.

Although the number of nodes not embedded by the end of step 3 may be quite large, each remaining *subtree* contains at most  $m/2$  nodes. Letting  $\text{Time}(m)$  be the parallel time to embed a tree of size  $m$ , this yields the recurrence relation

$$\text{Time}(m) = c \log m + \text{Time}(m/2),$$

which has solution  $O(\log^2 m)$ . Since the subtrees embedded in step 4 are pairwise disjoint, it is easy to see that  $km$  processors suffice to do all these embeddings in parallel.  $\square$

**3.2. Special cases of term matching.** In this section, we describe algorithms for checking equivalence of constant dags  $C$  and  $H$  (as obtained in step 3 of Algorithm Match) when  $H$  is of a special form. When used in step 4 of Algorithm Match these yield improved results for term matching. We assume as in § 3.1 that the two input dags are disjoint.

Let  $u$  and  $v$  be nodes of a term dag. We say  $u \equiv v$  if the term represented by the subdag rooted at  $u$  equals the term represented by the subdag rooted at  $v$ . A dag is *compact* if  $u \equiv v \Rightarrow u = v$ , for all nodes  $u$  and  $v$ .

The proof of the following lemma is straightforward.

LEMMA 15. *Let  $G$  be an arbitrary dag with spanning tree  $T$ . Let  $H$  be a second dag and let  $d$  be an embedding of  $T$  in  $H$ . Then  $G$  matches  $H$  if and only if the following two conditions are satisfied.*

(a) *For each node  $v$  of  $G$  not labeled with a variable name, the label of  $v$  equals the label of  $d(v)$ .*

(b) *For each edge  $e = (u, v)$  in  $G$  but not in the spanning tree  $T$ ,  $d(u)_i \equiv d(v)$ , where  $i$  is the label of  $e$  and  $d(u)_i$  denotes the  $i$ th child of  $d(u)$  in  $H$ .  $\square$*

Lemma 15 implies term matching is particularly easy when  $H$  is a compact dag, for in that case checking conditions of the form  $d(u)_i \equiv d(v)$  reduces to checking  $d(u)_i = d(v)$ .

COROLLARY 16. *The problem of determining whether an arbitrary dag matches a compact dag is in  $\text{NC}^2(n^2)$ .  $\square$*

A slightly harder case is when  $H$  is a tree. However, since the tree representation of a term is unique, testing equivalence of trees (as required by Condition (b) of Lemma 15) reduces to checking that the trees are identical, and while this is more difficult than checking equality of nodes we can solve it efficiently using some of the results of Tarjan and Vishkin stated in Lemma 13. In effect, we will change  $H$  into a compact dag by determining, for all nodes  $u$  and  $v$  of  $H$ , whether  $u \equiv v$ .

The following uses the depth-first numbering produced by Lemma 13(a). This numbering respects the edge labels, in the sense that for each node  $v$  the numbers in the subtree rooted at the  $i$ th child of  $v$  are smaller than those assigned to nodes in the subtree rooted at the  $(i + 1)$ st child.

LEMMA 17. *Checking equivalence of trees of size  $n$  is in  $NC^1(n)$ .*

*Proof.* We will show that the depth-first numbers and node labels of the nodes in a tree completely specify the tree. The lemma then follows by Lemma 13(a).

Given a tree  $T$  of size  $n$  we show by induction on  $k$  that the subtree consisting of the first  $k$  nodes in the depth-first numbering of  $T$  can be recreated from the depth-first numbers and labels of these nodes. In the following, let “node  $i$ ” denote the node in  $T$  with depth-first number  $i$ .

The basis  $k = 1$  is trivial, since the root is always labeled 1.

$k > 1$ . We assume the result for subtrees of size  $k - 1$  and prove it for  $k$ . Given the subtree  $S$  consisting of the first  $k - 1$  nodes of  $T$ , we find the largest  $i \leq k$  such that  $m$ , the number of children of node  $i$  in  $S$ , is less than the arity of the label of node  $i$ . Then node  $k$  is the  $(m + 1)$ st child of node  $i$ . Clearly,  $k$  cannot be the child of any node with depth-first number greater than  $i$ , since all of these have all their children in  $S$ . On the other hand, node  $k$  cannot be the child of any node with depth-first number less than  $i$ . To see this, assume for the sake of contradiction that node  $k$  is the child of a node  $u$ , where  $u < i$ . Let  $w$  be the least common ancestor of  $u$  and  $i$ . Let  $j$  be the label of the edge from  $w$  on the path to  $i$ . By the inductive hypothesis,  $w$  was correctly given its first  $j$  children in the construction of  $S$ . In particular, the  $j$ th child of  $w$  is added only if the subtrees rooted at the first  $j - 1$  children are complete. Thus, if  $u$  does not have all its children in  $S$  it must be that  $u = w$ . In this case, the first available slot for another child of  $u$  is the  $(j + 1)$ st. But all descendants of the  $j$ th child of  $u$  must have numbers smaller than that of the  $(j + 1)$ st, so if  $i$  does not have all its children in  $S$ ,  $k$  cannot be a child of  $u$ .  $\square$

Our approach to matching a general dag with a tree is to find all equivalent nodes, thereby effectively turning the tree into a compact dag. We first eliminate many pairs of nodes from consideration since they are obviously not equivalent, and then apply Lemma 17 in parallel to the remaining pairs.

The size of a node  $v$ , denoted  $size(v)$ , is the number of nodes in the subtree rooted at  $v$ . Clearly, nodes  $u$  and  $v$  can be equivalent only if  $size(u) = size(v)$ , but the converse is false. However, this observation allows us to bound the total cost of checking the subtree equivalences to yield the following.

LEMMA 18. *The problem of determining all equivalent nodes of a tree is in  $NC^1(n^2)$ , where  $n$  is the size of the tree.*

*Proof.* The general idea is to apply Lemma 17 in parallel to all pairs of nodes  $u, v$  for which  $size(u) = size(v)$ . However, we must be careful, as a brute force analysis leads to a processor bound of  $O(n^3)$ . For each  $i, 1 \leq i \leq n$ , let  $n_i$  denote the number of nodes of size  $i$ . By Lemma 17, the number of processors sufficient to check equivalence of all pairs  $u, v$  of nodes of size  $i$  is  $in_i^2$ . Thus, the total number of processors needed to find all equivalent nodes is  $\sum_i in_i^2$ .

Now,  $\sum_i n_i \leq n$ , and for each  $i, in_i \leq n$ . Multiplying each side of the last inequality by  $n_i$  yields  $in_i^2 \leq nn_i$ . Putting all this together we obtain

$$\sum_i in_i^2 \leq \sum_i nn_i \leq n \sum_i n_i \leq n^2. \quad \square$$

Applying the algorithm of Lemma 18 and then using the approach of Lemma 15 proves that testing whether an arbitrary dag matches a tree is in  $NC^2(n^2)$ . In fact we can do better in terms of time.

**THEOREM 19.** *Term matching for a general dag  $G$  and a constant tree  $H$  can be done in  $\text{NC}^1(n^2)$ .*

*Proof.* We only have to argue for  $O(\log n)$  instead of  $O(\log^2 n)$  parallel time.

In the case that  $H$  is a tree, the only part of the algorithm which uses time  $\log^2 n$  is the embedding of the spanning tree  $T$  in the tree  $H$ . Since  $T$  and  $H$  are both trees, the embedding can be done in time  $O(\log n)$  as follows.

Construct the product graph  $Z$  whose nodes are all pairs  $(u, v)$  such that  $u$  is a node of  $T$  and  $v$  is a node of  $H$ . There is an edge labeled  $i$  directed from  $(u, v)$  to  $(u', v')$  if there is an edge labeled  $i$  from  $u$  to  $u'$  in  $T$  and an edge labeled  $i$  from  $v$  to  $v'$  in  $H$ . Since  $T$  and  $H$  are both rooted trees, it is easy to see that  $Z$  is a forest of rooted trees. Letting  $r_1$  and  $r_2$  be the roots of  $T$  and  $H$ , respectively, we want to find all nodes of  $Z$  which are reachable from  $(r_1, r_2)$  since the embedding maps  $u$  to  $v$  if and only if  $(u, v)$  is reachable from  $(r_1, r_2)$ . Since  $Z$  contains at most  $m = n^2$  nodes this can be done in  $\text{NC}^1(n^2)$  as follows.

We first transform  $Z$  from a forest of trees to a single tree by creating a new root and creating an edge from the new root to each of the roots in  $Z$ . For simplicity, let  $Z$  denote the resulting tree. We then compute a depth-first numbering of  $Z$  and  $\text{size}(a)$  for each node  $a$  in  $Z$ . By Lemma 13 these tasks can be accomplished in  $\text{NC}^1(m)$ . Let  $a$  be a node of  $Z$  and let  $k$  be the depth-first number of  $a$ . Then the descendants of  $a$  are those nodes with depth-first numbers  $k, \dots, k + \text{size}(a) - 1$ .  $\square$

Verma, Krishnaprasad, and Ramakrishnan [17] have recently shown that term matching of two trees is in  $\text{NC}^2(n)$  (whereas  $\text{NC}^1(n^2)$  is a corollary of Theorem 19).

**3.3. Another special case of unification in NC.** In this section, we examine unification of two terms in the special case that the terms share no variables and at least one of the terms is linear. In performing unification on term dags we need a way of representing the result. In general, two terms are unifiable if and only if a certain type of equivalence relation can be constructed on the nodes of the labeled dag representing these terms. Given this relation, we can define the *reduced* graph, obtained by coalescing all equivalent nodes into a single node. We can extract a unifier  $\sigma$  from the reduced graph by taking  $\sigma(x)$  to be the term in the reduced graph that is represented by the node formed from the equivalence class of  $x$ .

A relation  $R$  on the nodes of a term dag is a *correspondence* relation if for all pairs of nodes  $u, v$  in the dag

$$uRv \Rightarrow u_iRv_i,$$

where  $u_i$  and  $v_i$  are corresponding children, respectively, of  $u$  and  $v$ . A correspondence relation that is also an equivalence relation will be called a *c-e relation*.

A relation  $R$  on the nodes of a term dag is *homogeneous* if for all pairs of nodes  $u, v$  which are labeled by function symbols we have

$$uRv \Rightarrow \text{label}(u) = \text{label}(v).$$

An equivalence relation  $R$  on the nodes of a dag is *acyclic* if the  $R$ -equivalence classes are partially ordered by the arcs of the dag. Paterson and Wegman [12] have shown that if  $u$  and  $v$  are nodes of a labeled dag  $G$  then the terms represented by the subdags with roots  $u$  and  $v$ , respectively, are unifiable if and only if there exists an acyclic homogeneous c-e relation  $R$  on the nodes of the dags satisfying  $uRv$ . Since we are considering the special case where one of the terms is linear and the two terms do not have any variables in common, it is easy to see that cyclic c-e relations cannot arise, so we do not mention the acyclicity condition further.

A substitution  $\sigma$  is *more general* than a substitution  $\tau$  if there exists a substitution  $\rho$  with  $\tau = \rho \circ \sigma$ . If  $R$  is the minimal c-e relation with  $uRv$  then the unifying substitution obtained from the reduced graph defined by  $R$  as described above is the most general unifier. The size of the most general unifier is the number of nodes in the reduced graph obtained by coalescing nodes equivalent under  $R$ , where  $R$  is minimal.

LEMMA 20. *Unification of two linear terms represented by trees with no shared variables can be solved in  $NC^1(n^2)$ . Moreover, the most general unifier is linear and has size at most the sum of the sizes of the original trees.*

*Proof.* Let  $T_1$  and  $T_2$  be trees representing linear terms with no shared variables, and  $n$  be the size of the instance. As in the proof of Theorem 19, we construct the product graph  $Z$  whose nodes are all pairs of the form  $(u, v)$ , where  $u$  is a node of  $T_1$  and  $v$  is a node of  $T_2$ . There is an edge labeled  $i$  directed from  $(u, v)$  to  $(u', v')$  in  $Z$  if there are edges labeled  $i$  from  $u$  to  $u'$  in  $T_1$  and from  $v$  to  $v'$  in  $T_2$ . As in the proof of Theorem 19, letting  $r_1$  and  $r_2$  denote the roots of the two trees, respectively, we find all nodes in the product graph reachable from  $(r_1, r_2)$ . We do not repeat the details here. Let  $R$  be the relation on nodes of  $T_1 \cup T_2$  defined by:  $uRv$  if and only if  $(u, v)$  is reachable in  $Z$  from  $(r_1, r_2)$ . For all pairs of internal nodes  $u, v$  we see that  $uRv \Rightarrow u_i R v_i$ , where  $u_i$  and  $v_i$  are corresponding children of  $u$  and  $v$ , respectively. It is also clear that because each node in the union of the original trees is related to at most one other node,  $R$  is an equivalence relation (trivially). We note that  $R$  is the minimal c-e relation in which the two roots are related. Once we have constructed  $Z$  and determined  $R$ , we can easily check  $R$  for homogeneity. If so, then as shown in [12], the two trees are unifiable. We construct the reduced graph and, from it, the most general unifier, as described in the beginning of this section.

Because  $Z$  contains at most  $n^2$  nodes, this can all be done in  $NC^1(n^2)$ . Further, because the reduced graph contains no more nodes than the union of  $T_1$  and  $T_2$ , the most general unifier has size at most the sum of the sizes of the two trees. Finally, the most general unifier is linear since it is obtained by a substitution which maps each variable to a linear term such that different variables are mapped to linear terms involving disjoint sets of variables.  $\square$

Using Lemma 20 we can now prove the main result of this section.

THEOREM 21. *Let  $T$  be a tree representing a linear term and  $H$  be an arbitrary rooted dag sharing no variables with  $T$ . Then the unification problem for  $T$  and  $H$  can be solved in  $NC^2(n^2)$ .*

*Sketch of Proof.* Without loss of generality we assume that for each variable  $x$  there is at most one node of  $H$  labeled with  $x$ . Let  $r_1$  and  $r_2$  be the roots of  $T$  and  $H$ , respectively. Again we are searching for the minimal c-e relation  $R$  on the nodes of  $T \cup H$  such that  $r_1 R r_2$ . We first modify the recursive embedding technique of Lemma 14 to handle the embedding of a tree in a dag when the dag is not necessarily constant, as in the present case. Thus, there could be some nodes of  $T$  that cannot be embedded in  $H$  because some path in  $H$  ends with a node labeled by a variable while the corresponding path in  $T$  continues. As in the case of Lemma 14, the modified algorithm is in  $NC^2(n^2)$ . We define  $R$  to be the reflexive transitive closure of  $R'$ , where  $uR'v$  if  $u$  is mapped to  $v$  by the embedding. Check  $R$  for homogeneity.

If  $uRv$  where  $u$  is a node of  $T$  and  $v$  is a node of  $H$ , and  $u$  is labeled by a variable  $x$ , then we define  $\sigma(x)$  to be the term represented by the subdag rooted at  $v$ . Because there is a unique path to a node labeled  $x$  in  $T$  there is nothing to check. More interesting is the case when there exist several nodes  $u_1, \dots, u_k$  in  $T$  and a node  $v$  in  $H$  labeled with a variable  $y$  such that  $u_i R v$ ,  $i = 1, \dots, k$ . This can happen if there are  $k$  paths to  $v$  in  $H$ . In this case we must unify all  $k$  trees rooted at the  $u_i$ . However,

because  $T$  is linear these subtrees share no variables, so we can apply Lemma 20. In order to perform all the unifications quickly in parallel, we split the subtrees into at most  $k/2$  pairs, and unify all pairs in parallel. By Lemma 20 the size of the most general unifier for each pair is no larger than the sum of the sizes of the original trees. We can therefore apply the lemma recursively on the  $\leq \lceil k/2 \rceil$  remaining trees. Because  $k \leq n$  and each application of Lemma 20 can be performed in  $\text{NC}^1(n^2)$  the entire procedure is in  $\text{NC}^2(n^2)$ .  $\square$

*Remark.* By modifications to the proofs of Lemma 20 and Theorem 21, it is easy to see that unification of a linear term with an arbitrary term can be done in NC even if both terms are represented by general dags. An outline of the algorithm follows. Let  $G$  and  $H$  be the given dags with roots  $r_1$  and  $r_2$ , respectively, where  $G$  represents a linear term and  $H$  represents an arbitrary term. Form the product graph  $Z$  as in the proof of Lemma 20, and solve a reachability problem (in  $\text{NC}^2(M(n^2))$ ) to find all nodes of  $Z$  reachable from  $(r_1, r_2)$ . Let  $R$  be the reflexive transitive closure of the relation  $R'$  defined by  $uR'v$  if and only if  $(u, v)$  is reachable from  $(r_1, r_2)$ . Proceeding as in the proof of Theorem 21, the only difference is the case where there are several nodes  $u_1, \dots, u_k$  in  $G$  and a node  $v$  in  $H$  labeled with a variable such that  $u_i R v$  for all  $i$ . Now the  $u_i$  are roots of subdags which represent linear terms; as before, these subdags share no variables. By again solving a reachability problem on a product graph, the unification problem for two linear terms which do not share variables and which are represented by general dags can be solved in NC. As before, the most general unifier is linear and its size is at most the size of the union of the two dags (nodes which appear in both dags are counted only once in the union).

**4. Unification of linear terms is complete for P.** Recall that a term is linear if no variable appears more than once in the term.

**THEOREM 22.** *Unification is P-complete even if both terms are linear, are represented by trees, and have all function symbols with arity  $\leq 2$ .*

*Proof.* The proof is by a reduction from the circuit value problem (CVP) which was proved P-complete by Ladner [8]. Because of the nature of our reduction, it is useful to require that instances of CVP be in a particular form described next. An instance of CVP is a dag whose nodes are of four types. An *input node* has no edges directed in and one edge directed out; this edge is called an *input edge*. An *output node* has one edge directed in and no edges directed out; each dag has exactly one output node and the edge directed into this node is called the *output edge*. A *NAND node* has two edges directed in and one edge directed out. A *fan-out node* has one edge directed in and any nonzero number of edges directed out. In addition, each input edge is labeled with a Boolean value, either 0 (false) or 1 (true). Given the assignments of Boolean values to the input edges, Boolean values are associated with all the other edges in the obvious way: the value of the edge directed out of a NAND-node is the Boolean NAND of the values of the two edges directed in; the value of all edges directed out of a fan-out node is the same as the value of the edge directed in. The problem CVP is to recognize the set of instances such that the output edge has value 1. (Although Ladner's proof of the P-completeness of CVP uses Boolean functions other than NAND, any such function can be built from a small number of NANDs and Boolean constants, so CVP as defined above is P-complete.)

Given an instance  $G$  of CVP, we transform it to a pair of linear tree terms,  $T_1$  and  $T_2$ , with roots  $r_1$  and  $r_2$ , respectively. For simplicity, we let the two trees have function symbols with arities greater than 2. The trees can then be further transformed by replacing each subterm  $f^{(k)}(t_1, t_2, \dots, t_k)$  involving a  $k$ -ary function symbol by

the term  $f(t_1, f(t_2, \dots, f(t_{k-1}, t_k)) \dots)$  involving the 2-ary function symbol  $f$ . In addition to the two roots,  $T_1$  has nodes  $A_e$  and  $B_e$  and  $T_2$  has nodes  $C_e$  and  $D_e$  for each edge  $e$  of  $G$ . Unifications among these four nodes encode the Boolean value of  $e$  as follows (in this proof we indicate a unification between two nodes by writing  $\sim$  between them): if  $e$  has value 0, then  $A_e \sim D_e$  and  $B_e \sim C_e$ ; if  $e$  has value 1, then  $A_e \sim C_e$  and  $B_e \sim D_e$ . The appropriate unifications of nodes corresponding to input edges are forced by making these nodes be corresponding children of the roots. For example, if  $e$  is the  $i$ th input edge and if  $e$  is assigned value 1, then there is an edge labeled  $2i-1$  from  $r_1$  to  $A_e$ , an edge labeled  $2i-1$  from  $r_2$  to  $C_e$ , an edge labeled  $2i$  from  $r_1$  to  $B_e$ , and an edge labeled  $2i$  from  $r_2$  to  $D_e$ .

For each fan-out node and NAND node of  $G$ , edges and nodes are added to the trees to force the unifications encoding Boolean values to be propagated correctly. For each fan-out node of  $G$ , if the node has edge  $e$  directed in and edges  $e_1, \dots, e_k$  directed out, then for each  $i$  with  $1 \leq i \leq k$ , there is an edge labeled  $i$  from  $A_e$  to  $A_{e_i}$ , from  $B_e$  to  $B_{e_i}$ , from  $C_e$  to  $C_{e_i}$ , and from  $D_e$  to  $D_{e_i}$ . For each NAND node, with edges  $e'$  and  $e''$  directed in and edge  $e$  directed out, the trees contain the nodes and edges shown in Fig. 3 (to simplify notation,  $A'$  is written for  $A_e$  etc.).

FIG. 3. The transformation of a NAND node used in the proof of Theorem 22. Nodes of  $T_1$  (resp.,  $T_2$ ) are drawn as open circles (resp., solid circles). Edges of  $T_1$  (resp.,  $T_2$ ) are drawn as solid lines (resp., dashed lines). Common leaves which are labeled by variables are drawn as solid squares.

We must also define the labeling of tree nodes. Each nonleaf node is labeled by the function symbol  $f^{(k)}$  where  $k$  is the outdegree of the node. The leaves which are drawn as squares in Fig. 3 are each labeled by a different variable symbol. If  $p$  is the output edge of  $G$ , then  $A_p$  and  $C_p$  are labeled with the constant symbol  $g$ , and  $B_p$  and  $D_p$  are labeled with a different constant symbol  $h$ . This completes the description of the transformation.

We must argue that the output edge of  $G$  has value 1 if and only if  $T_1$  and  $T_2$  are unifiable. To do this it is sufficient to show that the transformations of fan-out nodes and NAND nodes correctly propagate Boolean values according to the encoding

of values by unifications described above. For fan-out nodes this is obvious. To verify this for the NAND construction in Fig. 3, it is helpful to break the construction into two parts. The first part, which consists of the part of the figure above the nodes marked  $a, b, c, u, v, w$  (including these six nodes), computes the numerical sum of the two input values, viewing these values as integers rather than Boolean values. The three possible sums, 0, 1, and 2, are encoded by unifications among  $a, b, c, u, v, w$ . It is easy to check that the four possible values for  $e'$  and  $e''$  force unifications among  $a, b, c, u, v, w$  as follows:

$$\begin{aligned} e' = 0 \text{ and } e'' = 0 & \text{ implies } a \sim u, b \sim v, c \sim w, \\ e' = 0 \text{ and } e'' = 1 & \text{ implies } a \sim v, b \sim w, c \sim u, \\ e' = 1 \text{ and } e'' = 0 & \text{ implies } a \sim v, b \sim w, c \sim u, \\ e' = 1 \text{ and } e'' = 1 & \text{ implies } a \sim w, b \sim u, c \sim v. \end{aligned}$$

We can now forget about the top half of Fig. 3 and just check that these three possible unifications among  $a, b, c, u, v, w$  force the proper unifications among  $A, B, C, D$ . The verification of the following is again straightforward:

$$\begin{aligned} a \sim u, b \sim v, c \sim w & \text{ implies } A \sim C \text{ and } B \sim D (e = 1), \\ a \sim v, b \sim w, c \sim u & \text{ implies } A \sim C \text{ and } B \sim D (e = 1), \\ a \sim w, b \sim u, c \sim v & \text{ implies } A \sim D \text{ and } B \sim C (e = 0). \end{aligned}$$

If the output edge  $p$  of  $G$  has value 0, then an attempt to unify the roots  $r_1$  and  $r_2$  will force the unification of two nodes  $A_p$  and  $D_p$  labeled with different constant symbols. On the other hand, if the output edge has value 1, then the two roots can be unified.  $\square$

In the case that the two terms do not share any variables, we have noted in § 3.3 that unification can be solved in NC if one of the terms is linear. The following easy corollary of Theorem 22 shows that this is in some sense the best possible, since if both terms are barely nonlinear the problem becomes P-complete.

**THEOREM 23.** *Unification is P-complete even if both terms are represented by trees, no variable appears in both terms, each variable appears at most twice in some term and all function symbols have arity  $\leq 2$ .*

*Proof.* As in the previous proof, we allow function symbols with large arities. The proof is by a reduction from the unification problem for linear trees. Let  $T_1$  and  $T_2$  be a given pair of trees representing linear terms, and let  $x_1, x_2, \dots, x_m$  be the variables which appear in both trees. For each  $i$  with  $1 \leq i \leq m$ , replace the single occurrence of  $x_i$  in  $T_1$  by a new variable  $x_{i1}$  and replace the single occurrence of  $x_i$  in  $T_2$  by  $x_{i2}$ . For each  $i$ , we can force  $x_{i1}$  and  $x_{i2}$  to be equal by increasing the arity of the roots from 2 to  $2+m$ , adding a new edge labeled  $i+2$  from the root of  $T_1$  to a new node labeled  $x_{i1}$ , and adding a new edge labeled  $i+2$  from the root of  $T_2$  to a new node labeled  $x_{i2}$ . Clearly, the transformed trees are unifiable if and only if  $T_1$  and  $T_2$  are unifiable.  $\square$

## THE PROBABILISTIC ANALYSIS OF A HEURISTIC FOR THE ASSIGNMENT PROBLEM\*

DAVID AVIS† AND C. W. LAI‡

**Abstract.** We present a heuristic to solve the  $m \times m$  assignment problem in  $O(m^2)$  time. The assignment problem is formulated as a weighted complete bipartite graph  $G = (S, T, E)$ ,  $|S| = |T| = m$ . For convenience we assume that  $m$  is even. The main procedure in the heuristic is to construct a graph  $G_d = (S, T, E_d)$  which is a subgraph of  $G$ ,  $|E_d| = 4dn$ ,  $n = m/2$ , such that we can find a perfect matching in  $G_d$  with probability at least  $1 - \frac{1}{3}(d/n)^{d^2-4d-1}$ . An  $O(|S||E|)$  exact algorithm is used to find a minimum weight matching  $M$  in  $G_d$ . Any unmatched vertices in  $G$  relative to  $M$  are then matched by a greedy algorithm. The expected value of the total cost of the matching found by the heuristic is shown to be less than six if the costs are independent and identically distributed uniformly in the unit interval. Further, with the above probability, the heuristic produces a solution which is at most six times the optimal solution.

**Key words.** assignment problem, heuristics, probabilistic analysis of algorithms, weighted matchings

**AMS(MOS) subject classifications.** 68Q25, 68R05

**1. Introduction.** Let  $G = (S, T, E)$  be the complete bipartite graph with vertex sets  $S$  and  $T$ , each of cardinality  $m$ , and  $E$  the set of edges between  $S$  and  $T$ . Associated with each edge  $(i, j)$  there is a weight  $c_{i,j}$ . A matching  $M$  in  $G$  is a set of edges such that no two edges in  $M$  are incident to the same vertex of  $G$ . The matching is perfect if each vertex in  $G$  is adjacent to some edge in  $M$ . A minimum weight perfect matching for  $G$  is a perfect matching for which the sum of the edge weights is minimum. The assignment problem is to find such a minimum weight matching.

There are exact algorithms to solve the assignment problem in  $O(m^3)$  time [10]. Karp [7] has found an algorithm that finds an optimal solution in expected time  $O(m^2 \log m)$ . Several heuristics exist for the assignment problem [8], [6], [1], [2]. A survey of heuristics for the weighted matching problem and some applications is contained in [3]. In order to evaluate the solutions produced by these heuristics, it is natural to ask what is the expected size of the optimal solution, given a probability distribution for the edge weights. If the edge weights are independently distributed on the unit interval, Walkup [12] has proved that this expected value is bounded above by the constant 3, for all  $m$ , a very remarkable result. The idea behind Walkup's proof is the construction of a sparse subgraph of  $G$  in which the edges all have low weight. He defines a subgraph  $G_d$ , for some small integer  $d$ , by choosing  $d$  edges randomly from each vertex in  $S$  and  $T$ . In [13] it is shown that with probability approaching one as  $m$  tends to infinity, this graph has a perfect matching. The natural candidate for such a subgraph would be to choose for each vertex, the  $d$  smallest weight edges that are incident with it. Unfortunately this will not work, since the edges chosen in such a way will not be independent. Consider, for example, the minimum weight edge in  $G$ . It will be chosen twice, once by a vertex in  $S$  and once by a vertex in  $T$ . Walkup avoids this problem by using a probabilistic trick: each edge is replaced by two directed edges with opposite directions. The weights on the directed edges are chosen from

distributions such that the minimum of the two edge weights still has uniform distribution on the unit interval. This is sufficient for proving the result stated, but does not provide a constructive method that can be used to produce a heuristic.

In this paper, we avoid the dependency problem by constructing a different kind of random graph. We prove analogues of Walkup's results for this new graph. It is shown to almost surely have a perfect matching, and it is shown how to construct this graph directly from the given edge weights. We prove that the perfect matching thus found has expected weight at most 6. The heuristic runs in  $O(m^2)$  time and produces a solution which, with probability approaching one, is at most 6 times the optimum value. This is the only known heuristic with a constant ratio bound, with probability approaching one. In § 2 the heuristic is presented along with a complexity analysis. In § 3 we show that the random graph constructed by the heuristic has a perfect matching with probability approaching one. This is followed in § 4 by a proof that the expected weight of the matching produced is less than 6. The results given in this paper were first published in the second author's Master's thesis [9]. This thesis also contains extensive numerical results.

**2. The heuristic.** For convenience we assume that  $m$  is even and set  $n = m/2$ . The heuristic is supplied with an integer parameter  $d$  which must be at least 5. This parameter controls the quality of the solution and the cost of the computation. In practice, setting  $d = 5$  appears to be most satisfactory. The algorithm consists of three steps: the construction of a sparse directed random graph  $G_d$  with  $4dn$  edges; the solution of the maximum cardinality minimum weight matching problem in the undirected graph obtained by ignoring the directions on edges of  $G_d$ ; and the matching of any unmatched vertices in  $G_d$  using a greedy heuristic.

*Step 1.* (Construction of a directed graph  $G_d = (S_1 \cup S_2, T_1 \cup T_2, E_d)$  with  $4dn$  edges; see Fig. 1.)

Partition  $S$  and  $T$  into subsets  $S_1, S_2$  and  $T_1, T_2$ , each of cardinality  $n$ .

$N(v) = \{w \in T_i \mid c_{v,w} \text{ is one of the } d \text{ smallest edge weights from } T_i \text{ incident } v\}$ .

For  $w \in T_i$ ,  $i = 1, 2$

$N(w) = \{v \in S_{3-i} \mid c_{v,w} \text{ is one of the } d \text{ smallest edge weights from } S_{3-i} \text{ incident } w\}$ .

Set  $E_d = \{(v, w) \mid v \in S_i \cup T_i, w \in N(v), i = 1, 2\}$ .

Step 2. (Find a minimum weight matching in  $G_d$ .)

Apply an  $O(|S||E_d|)$  minimum weight matching algorithm to  $G_d$ , ignoring the directions on the edges. Let  $M_d$  be the resulting matching.

Step 3. (Match the unmatched vertices in  $G_d$  by a greedy algorithm.)

$$S^* = \{\text{unmatched vertices in } S \text{ relative } M_d\},$$

$$T^* = \{\text{unmatched vertices in } T \text{ relative } M_d\}.$$

**while**  $|S^*| \geq 1$  **do**

Choose a vertex  $s \in S^*$  and find a vertex  $t \in T^*$  such that

$$c_{s,t} = \min \{c_{s,v} \mid v \in T^*\}, \quad S^* = S^* - s, \quad T^* = T^* - t, \quad M_d = M_d \cup (s, t).$$

**end.**

Step 1 involves at most  $O(2d|S|)$  operations, Step 2 needs  $O(|S||E_d|) = O(|S|^2)$  operations and Step 3 requires at most  $O(|S|^2)$  operations. The memory space required by  $G$  and  $G_d$  is  $O(|S|^2)$  and  $O(2d|S|)$ , respectively. There are exact algorithms for Step 2 that require  $O(|S|^2)$  space. Therefore the overall time and space requirements for the algorithm are  $O(m^2)$ .

**3. Probability of a perfect matching in  $G_d$ .** In this section, we show that with probability approaching one, the graph  $G_d = (S, T, E_d)$  constructed by the heuristic contains a perfect matching. It is convenient to consider the following random graph model for a random  $2n \times 2n$  directed bipartite graph with vertex sets  $(S_1, S_2; T_1, T_2)$ ,  $|S_i| = |T_i| = n$ ,  $i = 1, 2$ . For  $i = 1, 2$  and each vertex  $v \in S_i$ , select  $d$  neighbours at random in  $T_i$ . For  $i = 1, 2$  and each vertex  $w \in T_i$ , select  $d$  neighbours at random in  $S_{3-i}$ . A graph constructed in such a way will arise with equal probability by an application of Step 1 of the heuristic. This follows from the fact that selecting the  $d$  smallest from a set of  $n$  independent and identically distributed random variables gives a uniform random subset of  $d$  of the random variables. In this section, we deal with the equivalent formulation mentioned above which does not involve edge weights. Finally, in § 4 we reintroduce the edge weights to prove our main result. We will apply the Konig-Hall Theorem (see, for example, Bondy and Murty [4]), to show that  $G_d$  almost surely has a perfect matching. We require the following definitions.

Let  $k$  be a positive integer, satisfying  $d + 1 \leq k \leq 2n - d$ , let  $A$  be a subset of  $T$  with cardinality  $k - 1$  and let  $B$  be a subset of  $S$  with cardinality  $k$ . Set

$$A_i = T_i \cap A, \quad a_i = |A_i|, \quad i = 1, 2,$$

$$B_i = S_i \cap B, \quad b_i = |B_i|, \quad i = 1, 2.$$

For any subset  $U$  of vertices, let

$$\Gamma(U) = \{w : (v, w) \in E_d \text{ for some } v \in U\}.$$

We say that  $(A, B)$  is a *blocking  $k$ -pair* in  $G_d$  if the following hold (see Fig. 2):

$$\Gamma(B_i) \subseteq A_i, \quad \Gamma(T_i - A_i) \subseteq S_{3-i} - B_{3-i}, \quad i = 1, 2.$$

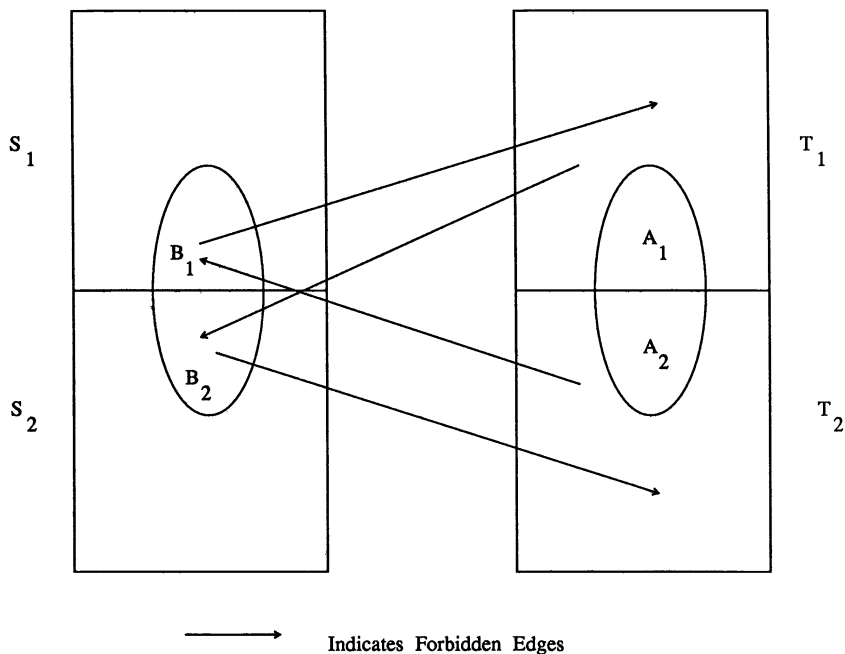

FIG. 2. Illustrating a blocking  $k$ -pair in  $G_d$ .

It can be seen from the construction that certain values of  $a_i$  place restrictions on the corresponding values of  $b_i$ . In particular:

- (i) If  $a_i < d$  then  $b_i = 0$ ;
- (ii) If  $a_i = 0$  then  $d + 1 \leq k \leq n - d$ ;
- (iii) If  $a_1, a_2 \geq d$  then  $b_1, b_2 \leq n - d$ ; and
- (iv)  $a_1 + a_2 = k - 1, b_1 + b_2 = k$ .

We say that the 4-tuple is *valid* if it is consistent with (i)-(iv) above.

By the Konig-Hall Theorem,  $G_d$  has a perfect matching if and only if it has no blocking  $k$ -pair. Let  $P_{a_1, b_1}^{(d)}(k)$  be the probability that  $(A, B)$  is a blocking  $k$ -pair in  $G_d$ . This notation is justified by observing that the probability of the algorithm creating a blocking  $k$ -pair  $(A, B)$  is determined only by the cardinalities  $a_1, a_2, b_1, b_2$ . Since  $a_2$  and  $b_2$  are determined once  $a_1$  and  $b_1$  are fixed, we omit them as subscripts of  $P$ . Then if  $a_1, b_1$  satisfy the above conditions for a blocking  $k$ -pair,

$$(1) \quad P_{a_1, b_1}^{(d)}(k) = \frac{\binom{a_1}{d}}{\binom{n}{d}}^{b_1} \frac{\binom{a_2}{a}}{\binom{n}{d}}^{b_2} \frac{\binom{n-b_2}{d}}{\binom{n}{d}}^{n-a_1} \frac{\binom{n-b_1}{d}}{\binom{n}{d}}^{n-a_2} .$$

We denote by  $\beta^{(d)}(k)$  the expected number of blocking  $k$ -pairs. Then we have

$$(2) \quad \beta^{(d)}(k) = \sum_{b_1+b_2=k} \sum_{a_1+a_2=k-1} \binom{n}{a_1} \binom{n}{a_2} \binom{n}{b_1} \binom{n}{b_2} P_{a_1, b_1}^{(d)}(k).$$

Our main result is the following. Let  $\beta^{(d)}$  denote the expected number of blocking pairs in  $G_d$ .

**THEOREM 1.** For  $n \geq 2d \geq 10$

$$\beta^{(d)} < \frac{1}{3} \left( \frac{d}{n} \right)^{d^2-4d-1} .$$

The theorem proves the claim that  $G_d$  almost certainly has a perfect matching, since by the Markov inequality,

$$P\{G_d \text{ has no perfect matching}\} \leq \beta^{(d)}.$$

In order to prove this result we need a series of combinatorial lemmas.

LEMMA 1 (see [11]). For positive integers  $k, m$  with  $k < m$ ,

(a) 
$$\binom{m}{k} \leq \frac{1}{\sqrt{2\pi k}} \left(\frac{em}{k}\right)^k,$$

(b) 
$$\binom{m}{k} \leq \frac{m^m}{k^k(m-k)^{(m-k)}}. \quad \square$$

LEMMA 2.

$$\binom{p}{j} / \binom{q}{j} \leq \left(\frac{p}{q}\right)^j, \quad 0 \leq j \leq p \leq q. \quad \square$$

LEMMA 3. For  $2 \leq d+1 \leq k < n$ , every valid 4-tuple  $(a_1, a_2, b_1, b_2)$  satisfies:

(a) 
$$\left(\frac{a_1}{n}\right)^{b_1} \left(\frac{a_2}{n}\right)^{b_2} \leq \left(\frac{k-1}{n}\right)^k;$$

(b) 
$$\left(\frac{n-b_2}{n}\right)^{n-a_1} \left(\frac{n-b_1}{n}\right)^{n-a_2} \leq \left(\frac{n-k}{n}\right)^{n-k}.$$

(c) 
$$\left(\frac{a_1}{n}\right)^{b_1} \left(\frac{a_2}{n}\right)^{b_2} \left(\frac{n-b_2}{n}\right)^{n-a_1} \left(\frac{n-b_1}{n}\right)^{n-a_2} \leq \left(\frac{d}{n}\right)^d.$$

(d) If, in addition,  $k \leq n-d$  then

$$\left(\frac{k-1}{n}\right)^k \left(\frac{n-k}{n}\right)^{n-k} \leq \left(\frac{d}{n}\right)^d.$$

*Proof.* The various parts of the lemma are proved in more or less the same way. We just outline their proof, leaving the details to the interested reader.

(a) This is an immediate consequence of the arithmetic-geometric mean inequality (see [11, p. 76]).

(b) Set  $a = a_2, b = b_1, a_1 = k - a - 1$ , and  $b_2 = k - b$ . We first assume that  $a_1, a_2 \geq d$ . Then, using elementary calculus,

$$\begin{aligned} n^{-1}(n-b_1)^{n-a_2}(n-b_2)^{n-a_1} &\leq (n-b)^{n-a}(n-k+b)^{n-k+a} \\ &\leq (n-a)^{n-a}(n-k+a)^{n-k+a} \\ &\leq (n-d)^{n-d}(n-k+d)^{n-k+d} \\ &\leq n^n(n-k)^{n-k}. \end{aligned}$$

Now, suppose that  $a_1 < d$ . Since  $a_1, a_2, b_1, b_2$  is valid,  $b_1 = 0$ ; hence  $b_2 = k$ . Then the left-hand side of  $b$  reduces to

$$\left(\frac{n-k}{n}\right)^{n-a_1} \leq \left(\frac{n-k}{n}\right)^{n-d+1} \leq \left(\frac{n-k}{n}\right)^{n-k}$$

as required. The case  $a_2 < d$  is symmetric.

(c) Let  $h$  denote the left-hand side. Then from the third inequality in the proof of (b), part (a), and elementary calculus, we obtain

$$h \leq \left(\frac{k}{n}\right)^k \left(\frac{n-k+d}{n}\right)^{n-k+d} \leq \left(\frac{d}{n}\right)^d.$$

(d) The proof follows from elementary calculus.  $\square$

The following rather technical lemma will be required in the proof of Lemma 6, but can be skipped without loss of continuity.

LEMMA 4. *If  $1 \leq n/4 \leq k/2 \leq a < k-1$  and  $a < b \leq k \leq n$ , then*

$$h = a^{b-a-1}(k-1-a)^{a-b+1}(n-b)^{(a+b)-k}(n-k+b)^{k-(a+b)} \leq 1.$$

*Proof.* Using standard inequalities for logarithms [11] we obtain

$$\frac{1}{2} \log \left(\frac{a}{k-1-a}\right) \leq \frac{2a-k+1}{k-1} + \frac{1}{3} \left(\frac{2a-k+1}{k-1}\right)^3 / \left(1 - \left(\frac{2a-k+1}{k-1}\right)^2\right),$$

and

$$\frac{1}{2} \log \left(\frac{n-k+b}{n-b}\right) \leq \frac{2b-k}{2n-k}.$$

An elementary calculation shows that

$$(b-a-1) \frac{2a-k+1}{k-1} - (a+b-k) \frac{2b-k}{2n-k} \leq -\frac{(2a-k+1)(2a-k+2)}{3k}.$$

Therefore,

$$\begin{aligned} \frac{1}{2} \log h &\leq \frac{1}{2} \left[ (b-a-1) \log \left(\frac{a}{k-1-a}\right) - (a+b-k) \log \left(\frac{n-k+b}{n-b}\right) \right] \\ &\leq (b-a-1) \left[ \frac{2a-k+1}{k-1} + \frac{1}{3} \left(\frac{2a-k+1}{k-1}\right)^3 / \left(1 - \left(\frac{2a-k+1}{k-1}\right)^2\right) \right] \\ &\quad - (a+b-k) \frac{2b-k}{2n-k} \\ &\leq -\frac{(2a-k+1)(2a-k+2)}{3k} + \frac{(b-a-1)}{3} \frac{(2a-k+1)^2(2a-k+2)}{2ak(2k-2a-2)} \\ &\leq \frac{(2a-k+1)(2a-k+2)}{3k} \left( -1 + \frac{(b-a-1)(2a-k+1)}{4a(k-a-1)} \right) \\ &\leq 0, \end{aligned}$$

since  $2a-k+1 \geq 1$ ,  $k-a-1 \geq b-a-1$  and  $2a > 2a-k+1$ . Therefore  $h \leq 1$ , proving the lemma.  $\square$

We are now ready to proceed with the evaluation of (1). By Lemma 2,

$$P_{a_1, b_1}^{(d)}(k) \leq \left[ \frac{a_1^{b_1} a_2^{b_2} (n-b_2)^{n-a_1} (n-b_1)^{n-a_2}}{n^{2n+1}} \right]^d, \quad a_1, a_2 > 0.$$

Applying Lemma 3(c) repeatedly, we obtain the following set of inequalities parameterized by  $i$ :

$$(3) \quad P_{a_1, b_1}^{(d)}(k) \leq \left(\frac{d}{n}\right)^{d(d-i)} \left[ \frac{a_1^{b_1} a_2^{b_2} (n-b_2)^{n-a_1} (n-b_1)^{n-a_2}}{n^{2n+1}} \right]^i, \\ a_1, a_2 > 0, \quad i = 0, 1, \dots, d.$$

The following bound holds for all  $a_1, a_2$ . If  $a_1 = 0$  or  $a_2 = 0$  it follows from Lemmas 2 and 3(d). Otherwise it follows from Lemma 3(a), (b), (c):

$$(4) \quad P_{a_1, b_1}^{(d)}(k) \leq \left(\frac{d}{n}\right)^{d(d-i)} \left(\frac{k}{n}\right)^{ik} \left(\frac{n-k}{n}\right)^{i(n-k)}, \quad i = 0, 1, \dots, d.$$

We are now able to derive upper bounds for the expected number of blocking  $k$ -pairs. We divide the proof into two parts, depending on whether  $k$  is less than or greater than  $n/2$ .

LEMMA 5. *If  $5 \leq d \leq k \leq n/2$  then*

$$\beta^{(d)}(k) \leq \frac{1}{2\pi k} \left(\frac{d}{n}\right)^{d(d-4)}.$$

*Proof.* From (1) and (4) with  $i = 4$  we obtain

$$\beta^{(d)}(k) \left(\frac{n}{d}\right)^{d(d-4)} \leq \left(\frac{k}{n}\right)^{4k} \left(\frac{n-k}{n}\right)^{4(n-k)} \sum_{b_1+b_2=k} \sum_{a_1+a_2=k-1} \binom{n}{a_1} \binom{n}{a_2} \binom{n}{b_1} \binom{n}{b_2}.$$

Now an elementary calculation shows that

$$\sum_{a_1+a_2=k-1} \binom{n}{a_1} \binom{n}{a_2} \leq \binom{2n}{k-1}$$

and

$$\sum_{b_1+b_2=k} \binom{n}{b_1} \binom{n}{b_2} \leq \binom{2n}{k}.$$

Therefore,

$$(5) \quad \begin{aligned} \beta^{(d)}(k) \left(\frac{n}{d}\right)^{d(d-4)} &\leq \left(\frac{k}{n}\right)^{4k} \left(\frac{n-k}{n}\right)^{4(n-k)} \binom{2n}{k}^2 \frac{k}{2n-k+1} \\ &\leq \left(\frac{k}{n}\right)^{4k} \left(\frac{n-k}{n}\right)^{4(n-k)} \left[ \frac{1}{\sqrt{2\pi k}} \left(\frac{2en}{k}\right)^k \right]^2 \\ &\leq \left(\frac{k}{n}\right)^{2k} \left(1 - \frac{k}{n}\right)^{4(n-n/2)} \frac{(2e)^{2k}}{2\pi k} \\ &\leq 2^{-2k} e^{-2k} \frac{(2e)^{2k}}{2\pi k} \\ &= \frac{1}{2\pi k}. \end{aligned}$$

Inequality (5) follows from Lemma (1a). This completes the proof of Lemma 5.  $\square$

LEMMA 6. *If  $5 \leq d \leq n/2 \leq k \leq n$  then*

$$\beta^{(d)}(k) \leq \left(\frac{k}{e}\right)^2 \left(\frac{d}{n}\right)^{d(d-2)}.$$

*Proof.* At first we assume that  $a_1 > 0, a_2 > 0$ , and  $0 < b_1 \leq b_2 < n$ . Let

$$f = \frac{a_1^{b_1} a_2^{b_2} (n-b_2)^{(n-a_1)} (n-b_1)^{(n-a_2)}}{b_1^{b_1} b_2^{b_2} (n-a_1)^{(n-a_1)} (n-a_2)^{(n-a_2)}}$$

and

$$(6) \quad g = \frac{a_1^{b_1} a_2^{b_2} (n-b_2)^{(n-a_1)} (n-b_1)^{(n-a_2)}}{a_1^{a_1} a_2^{a_2} (n-b_2)^{(n-b_2)} (n-b_1)^{(n-b_1)}} \frac{1}{n^2}.$$

Applying Lemma 1(b) and (3) with  $i = 2$ , we see that

$$\binom{n}{a_1} \binom{n}{a_2} \binom{n}{b_1} \binom{n}{b_2} P_{a_1, b_1}^{(d)}(k) \leq \left(\frac{d}{n}\right)^{d(d-2)} fg.$$

We will show that  $f \leq e^{-2}$  and  $g \leq 1$ .

The bound for  $f$  is obtained by applying the inequality  $(1 + y/x)^x \leq e^y$  to the expression. Therefore,

$$f = \left(1 - \frac{b_1 - a_1}{b_1}\right)^{b_1} \left(1 - \frac{b_2 - a_2}{b_2}\right)^{b_2} \left(1 - \frac{b_2 - a_1}{n - a_1}\right)^{n - a_1} \left(1 - \frac{b_1 - a_2}{n - a_2}\right)^{n - a_2} \leq e^{-2},$$

as  $b_1 + b_2 = k$  and  $a_1 + a_2 = k - 1$ .

The bound for  $g$  is lengthier. We begin by eliminating two variables from (6). Set  $a_2 = a$ ,  $a_1 = k - 1 - a$ ,  $b_2 = b$ ,  $b_1 = k - b$ . Then we have

$$(7) \quad g = \left(\frac{k - 1 - a}{a}\right)^{a - b + 1} \left(\frac{n - b}{n - k + b}\right)^{a + b - k} \frac{a(n - b)}{n^2}.$$

By our initial assumptions  $d \leq a \leq k - d - 1$ ,  $k/2 \leq b \leq k < n$ . We consider two main cases.

*Case 1.*  $a \geq (k - 1)/2$ . Since  $a$  and  $b$  are integers,  $a + b \geq k$ . Clearly

$$\frac{k - 1 - a}{a} \leq 1 \quad \text{and} \quad \frac{n - b}{n - k + b} \leq 1.$$

If  $a \geq b$  then the first exponent of (7) is also greater than one and we are done. If  $a = (k - 1)/2$  we are also done because the first term is equal to one. The remaining case,  $a \geq k/2$ ,  $b > k/2$ , is settled by Lemma 4. Hence  $g \leq 1$ .

*Case 2.*  $a < (k - 1)/2$ . In this case

$$\frac{k - 1 - a}{a} > 1, \quad \frac{n - b}{n - k + b} \leq 1, \quad \text{and} \quad a - b + 1 \leq 0.$$

If in addition,  $a + b - k \geq 0$  or  $b = k/2$  we are done immediately. Otherwise we have

$$a - b + 1 \leq a + b - k \quad \text{and} \quad b - a \leq k - 2a - 1.$$

Therefore, from (7) we obtain

$$g \leq \left(\frac{k - 1 - a}{a} \frac{n - b}{n - k + b}\right)^{a + b - k}.$$

A simple calculation shows that

$$(k - 1 - a)(n - b) - a(n - k + b) = (k - 2a - 1)n + b - (b - a)k \geq 0.$$

Hence,  $g \leq 1$ .

We now show that the initial assumptions can be lifted. We first observe that  $f$  and  $g$  are symmetric in the subscripts 1 and 2. Hence the above results hold if  $b_1 > b_2$ . Next, consider the degenerate case when  $a_1 = 0$  and hence  $a_2 = k - 1$ ,  $b_1 = 0$ ,  $b_2 = k$ . The case  $a_2 = 0$  is identical. A simple argument based on Lemma 1(b) and equation (4) with  $i = 2$  shows that

$$\binom{n}{k - 1} \binom{n}{k} P_{0,0}^{(d)}(k) \leq \frac{1}{2} \left(\frac{d}{n}\right)^{d(d-2)}.$$

The lemma now follows from the definition of  $\beta^{(d)}(k)$  in equation (2) and the observation that the double sum involves at most  $k^2 - k$  terms.  $\square$

We may now prove the main result of this section.

*Proof of Theorem 1.* Suppose  $(A, B)$  is a blocking  $k$ -pair with  $|B| = k > n$ . Then  $(S - B, T - A)$  is a blocking  $(2n - k + 1)$ -pair in the graph  $G_d^* = (T, S, E_d)$ , and  $2n - k + 1 \leq n$ . Therefore, the expected number of blocking pairs is bounded by

$$\begin{aligned} \beta^{(d)} &\leq 2 \left\{ \sum_{k=d+1}^{n/2} \beta^{(d)}(k) + \sum_{k=n/2}^n \beta^{(d)}(k) \right\} \\ &\leq 2 \left\{ \sum_{k=d+1}^{n/2} \left(\frac{d}{n}\right)^{d(d-4)} \frac{1}{2\pi k} + \sum_{k=n/2}^n \frac{k^2}{e^2} \left(\frac{d}{n}\right)^{d(d-2)} \right\} \\ &\leq 2 \left\{ \left(\frac{d}{n}\right)^{d(d-4)} \frac{n}{4\pi d} + \left(\frac{d}{n}\right)^{d(d-2)} \frac{n^3}{2e^2} \right\} \\ &\leq 2 \left(\frac{d}{n}\right)^{d^2-4d-1} \left\{ \frac{1}{4\pi} + \left(\frac{d}{n}\right)^{2d+1} \frac{1}{e^2} \frac{n^3}{2} \right\} \\ &\leq 2 \left(\frac{d}{n}\right)^{d^2-4d-1} \left( \frac{1}{4\pi} + \frac{1}{2e^2} \right). \end{aligned}$$

This completes the proof of the theorem.  $\square$

**4. Expected value of the heuristic solution.** In this section, we derive an upper bound on the expected value of the heuristic solution to the assignment problem described in § 2. Suppose initially that  $G_d$  contains a perfect matching  $M_d$ . We estimate the expected weight of a randomly chosen edge from  $G_d$ . We first recall that the expected value of the  $r$ th-order statistic from  $n$  uniform independent random variables in  $[0, 1]$  is  $r/(n + 1)$  [5]. Therefore, the  $d$  directed edges selected from each vertex by the heuristic have expected weights  $1/(n + 1), 2/(n + 1), \dots, d/(n + 1)$ . An arbitrarily selected edge therefore has expected weight  $(d + 1)/2(n + 1)$ . If  $G_d$  has a perfect matching, then such a matching chosen at random without regard to edge weights will have expected weight  $n(d + 1)/(n + 1)$ . The minimum weight perfect matching in such a graph therefore has expected weight bounded above by this amount. Let  $Z_d$  be the cost of the matching found by the heuristic. Then we have

$$E(Z_d \mid G_d \text{ has a perfect matching}) \leq \frac{n(d + 1)}{n + 1}.$$

However,  $G_d$  may not have a perfect matching. In this case, we take the trivial upper bound of  $2n$  for  $Z_d$ . Hence,

$$\begin{aligned} E(Z_d) &\leq E(Z_d \mid G_d \text{ has a perfect matching}) \\ &\quad + E(Z_d \mid G_d \text{ has no perfect matching})P(G_d \text{ has no perfect matching}) \\ &\leq \frac{n(d + 1)}{n + 1} + \frac{2n}{3} \left(\frac{d}{n}\right)^{d^2-4d-1}, \end{aligned}$$

by Theorem 1. Setting  $d = 5$  we obtain

$$\begin{aligned} E(Z_d) &\leq \frac{6n}{n + 1} + \frac{2n}{3} \left(\frac{5}{n}\right)^4 \\ &\leq 6 \quad \text{if } n \geq 11. \end{aligned}$$

Since  $G_d$  is a subgraph of  $G_{d+1}$ , any matching in  $G_d$  exists also in  $G_{d+1}$ . Therefore,

$$E(Z_{d+1}) \leq E(Z_d).$$

Thus, we have proved the following theorem.

**THEOREM 2.** *If  $n \geq 11$ , and  $d \geq 5$  then  $E(Z_d) \leq 6$ .*

We remark that the bound holds for  $d = 5$  if the heuristic is modified to simply find any maximum cardinality matching in Step 2, rather than one of minimum weight. Such a heuristic is considerably simpler to implement.

**Acknowledgment.** We thank an anonymous referee for a careful reading resulting in, we hope, many clarifications.

## THE STRUCTURE OF THE STABLE ROOMMATE PROBLEM: EFFICIENT REPRESENTATION AND ENUMERATION OF ALL STABLE ASSIGNMENTS\*

DAN GUSFIELD†

**Abstract.** The stable *roommates* problem is a well-known problem of matching  $2n$  people into disjoint pairs to achieve a certain type of stability. The problem strictly generalizes the better-known stable *marriage* problem. It has been previously shown [Irving and Leather, *SIAM J. Comput.*, 15 (1986), pp. 655–667], that the set of stable marriages, for a given instance, can be compactly represented and this representation has been exploited to yield a number of very efficient algorithms concerned with stable marriage [Irving, Leather, and Gusfield, *J. Assoc. Comput. Mach.*, 34 (1987), pp. 532–543], [Gusfield, *SIAM J. Comput.*, 16 (1987), pp. 111–128], [Gusfield et al., *J. Combin. Theory, Ser. A.*, (1987), pp. 304–309]. In this paper, we generalize the structure of the stable marriages to obtain two efficiently computed, small, implicit representations of the set of all stable roommate assignments, for any given instance. One representation is a partial order  $\Pi$  on  $O(n^2)$  elements such that the stable assignments are in one-one correspondence with certain easily recognized subsets of  $\Pi$ . Partial order  $\Pi$  is a strict generalization of the stable marriage representation of [Irving and Leather, *SIAM J. Comput.*, 15 (1986), pp. 655–667]. The second representation is an efficiently constructed, undirected graph  $G$  with  $O(n^2)$  nodes, such that there exists a one-one correspondence between the *maximal* (not maximum) independent sets of  $G$  and the stable roommate assignments. In either representation,  $G$  or  $\Pi$ , given a set representing a stable assignment, the assignment itself can be constructed in  $O(n^2)$  time. We also give an algorithm to generate each stable assignment for any given instance in  $O(n^2)$  time per assignment. The efficiency of this method depends heavily on special properties of the stable assignment problem developed in this paper. Finally, we give a succinct characterization of the set of all “stable pairs,” those pairs of people who are roommates in at least one stable assignment, and we give an  $O(n^3 \log n)$  time algorithm to find them all.

**1. Introduction.** The stable *roommates* problem is a well-known problem of matching  $2n$  people into disjoint pairs to achieve a certain type of stability. The input to the problem is a set of  $2n$  preference lists, one for each person  $i$ , where person  $i$ 's list is a rank ordering (most preferred first) of the  $2n - 1$  people other than  $i$ . A roommate assignment  $A$  is a pairing of the  $2n$  people into  $n$  disjoint pairs. Assignment  $A$  is said to be *unstable* if there are two people who are not paired together in  $A$ , but who each prefer the other to their respective mates in  $A$ ; such a pair is said to *block* assignment  $A$ . An assignment which is not unstable is called *stable*. An instance of the stable roommates problem is called *solvable* if there is at least one stable assignment. It is known [GS], [L], [K], [PTW] that there are unsolvable instances of the stable roommate problem; the problem of finding an efficient algorithm to determine if an instance is solvable was proposed by Knuth [K] and only recently solved by Irving [I].

The stable roommates problem is closely related to, and is a strict generalization of, another well-known problem, the stable *marriage* problem. In the stable marriage problem, the  $2n$  people consist of  $n$  men and  $n$  women, and each pair is constrained to consist of a man and a woman. Each man ranks only the women and each woman

ranks only the men, and an assignment in this problem is called a *marriage* (from here on, the word “assignment” will be used only for roommate assignment). A marriage  $M$  is unstable if there is a man and a woman who are not married to each other in  $M$ , but who mutually prefer each other to their respective mates in  $M$ . It is easy to reduce an instance of the stable marriage problem to an instance of the stable roommates problem. However, in contrast to the stable roommates problem, it is well known [GS] that every instance of the stable marriage problem is solvable, i.e., has at least one stable marriage, and for any instance, one stable marriage is easy to find.

For a given instance of the stable marriage problem, there may be many distinct stable marriages, and as a function of  $n$ , the numbers of stable marriages can grow exponentially [K]. Despite this exponential growth, for any given problem instance, there exists an extremely small, efficiently computed, implicit representation of the set of all stable marriages for the instance, where any particular stable marriage can be extracted from the representation very quickly. The structure of the stable marriages which gives rise to this implicit representation was first made explicit by Irving and Leather [IL], and, as pointed out in [GILS], can also be seen via a more algebraic approach based on the theory of distributive lattices. This efficiently constructed representation of the set of all stable marriages was exploited in [IL], [ILG], [G], [GILS] to solve a number of problems related to stable marriage. For example, for any given instance of the stable marriage problem, the implicit representation of all the stable marriages can be constructed in  $O(n^2)$  time, and thereafter, each stable marriage can be generated from the representation in  $O(n)$  time per marriage [G], which is time optimal.

In this paper, we generalize the structure of the stable marriages to obtain two efficiently computed, small, implicit representations of the set of all stable roommate assignments, for any given instance. One representation is a partial order  $\Pi$  on  $O(n^2)$  elements such that the stable assignments are in one-one correspondence with certain easily recognized subsets of  $\Pi$ . Partial order  $\Pi$  is a strict generalization of the stable marriage representation given in [IL] and [GILS]. The second representation is an efficiently constructed, undirected graph  $G$  with  $O(n^2)$  nodes, such that there exists a one-one correspondence between the *maximal* (not maximum) independent sets of  $G$  and the stable roommate assignments. In either representation,  $G$  or  $\Pi$ , given a set representing a stable assignment, the assignment itself can be constructed in  $O(n^2)$  time. We then give an algorithm to generate each stable assignment for any given instance in  $O(n^2)$  time per assignment. This compares favorably to the  $O(n^3)$  time, per marriage, method given by Knuth [K] to generate all stable *marriages*. The faster method given in this paper does not follow immediately from the representations above, since the fastest known time to generate maximal independent sets in a general graph on  $O(n^2)$  nodes runs in  $O(n^4)$  time per independent set, and methods based on general partial orders appear even less efficient. Finally, we give a succinct characterization of the set of all “stable pairs,” those pairs of people who are roommates in at least one stable assignment, and we give an  $O(n^3 \log n)$  time Algorithm to find all the stable pairs.

The results and algorithms in this paper are obtained by close examination of Irving’s algorithm [I] which finds *one* stable assignment if there is one, or reports that no stable assignment exists. Hence we will begin by describing Algorithm 1.

## 2. Algorithm I and its execution tree $D$ .

**2.1. Algorithm I.** Algorithm I successively deletes entries from preference lists until either each person has only one entry on its list, or until someone has no entries.

In the first case, the entries specify a stable roommate assignment, and in the second case, there are no stable assignments; the algorithm runs in time  $O(n^2)$ . The algorithm is divided into two phases. In Phase 1, entries are removed from lists, but no stable assignments are affected, i.e., if  $j$  is removed from  $i$ 's list, then  $(i, j)$  is a pair in no stable assignment. In Phase 2, the removed entries may affect stable assignments, but the invariant is maintained at each iteration, that *if* there is a stable assignment in the lists before the current iteration of removals, *then* there is a stable assignment in the lists resulting from the iteration of removals. Hence if any list becomes empty in either phase, there can be no stable assignment. Before describing the algorithm, we need the following definitions.

DEFINITION. The current set of lists at any point in the algorithm is called a *table*.

DEFINITION. Let  $e_i$  denote a person. At any point in the algorithm,  $h_i$  will denote the current head of person  $e_i$ 's list, and  $s_i$  will denote the current second entry on  $e_i$ 's list.

DEFINITION. At any point in Algorithm I, a person  $e_i$  is said to be *semi-engaged* to  $h_i$  if and only if  $e_i$  is the bottom entry on  $h_i$ 's list. A person who is not semi-engaged is called *free*. A person may alternate between being free and semi-engaged.

Note that semi-engagement is not a symmetric relation. However, if everyone is semi-engaged, then it follows easily that the set of list heads is a permutation of the  $2n$  people. We now describe Algorithm I.

PHASE 1 of Algorithm I iterates the following:

1. If there is an empty list, then terminate Algorithm I; there is no stable assignment.
2. Else, if everyone is semi-engaged, then go to Phase 2.
3. Else, pick an arbitrary free person  $e_i$ , and execute the following operations for each person  $k$  who is ranked below  $e_i$  on  $h_i$ 's list in  $T$ : remove  $k$  from  $h_i$ 's list, and remove  $h_i$  from  $k$ 's list.

Note that throughout Phase 1, person  $i$  is on  $j$ 's list if and only if  $j$  is on  $i$ 's list. Hence in a step where  $e_i$  becomes semi-engaged to  $h_i$ , if there is a person  $p$  who is semi-engaged to  $h_i$  just before that step, then  $p$  is (automatically) not semi-engaged to  $h_i$  after that step. This follows since at the start of the step,  $p$  must be below  $e_i$  on  $h_i$ 's list, so during that step,  $p$  is removed from  $h_i$ 's list, and  $h_i$  is removed from  $p$ 's list. After the step,  $p$  might be free, or it might have become (automatically) semi-engaged to the new head of its list.

The set of lists at the end of Phase 1 is called the *Phase 1 table*. It is proved in [I] that if  $j$  is missing from  $i$ 's list in the Phase 1 table, then there are no stable assignments which pair  $i$  to  $j$ . Hence if some list in the Phase 1 table is empty, there are no stable assignments. Otherwise, when Phase 1 terminates with everyone semi-engaged,  $j$  is the head of  $i$ 's list if and only if  $i$  is the bottom of  $j$ 's list, and so the set of head entries of the Phase 1 table are a permutation of the  $2n$  people.

Figure 1(a) gives an instance of the stable roommate problem, and 1(b) shows the three stable assignments for the table. Figure 2(a) shows the Phase 1 table for the example.

PHASE 2. Throughout Phase 2 all the people remain semi-engaged, although who they are semi-engaged to may change. Hence at any point in Phase 2,  $j$  is the head of  $i$ 's list if and only if  $i$  is the bottom of  $j$ 's list. It will also be true that  $i$  is on  $j$ 's list if and only if  $j$  is on  $i$ 's list. Phase 2 starts with the Phase 1 table and removes entries from lists in a way similar to Phase 1, but the selection of lists is more constrained. We first need some definitions.

3	5	2			

FIG. 2(b). Rotation  $R_1 = (E_1, H_1, S_1)$ , Rotation  $R_2 = (E_2, H_2, S_2)$  both exposed in the Phase 1 table. In the Phase 1 table 6, 7, 8 is a tail of  $R_1$ , and  $R_2$  has no tail.

DEFINITION. In a table  $T$ , an *exposed rotation*  $R$  is an ordered subset of people  $E = \{e_1, e_2, \dots, e_r\}$ , such that  $s_i = h_{i+1}$ , for all  $i$  from 1 to  $r$ , where  $i + 1$  is taken modulo  $r$ . Note that since the order of  $E$  is cyclic, the actual selection of which element in  $E$  is named  $e_1$  is arbitrary, but that selection determines the rest of the ordering.

Figure 2(b) shows two rotations that are exposed in the Phase 1 table of the running example.

We will often write " $R = (E, H, S)$ ," where  $H$  is the set of head entries of  $E$  ordered to correspond to the order of  $E$ , and  $S$  is the set of second entries of  $E$ , with corresponding order. Note that, as sets,  $S = H$ , and that, as ordered sets,  $S$  is a (backwards) cyclic rotation of  $H$ ; when that point is central, we will write  $S = H'$ . We will sometimes say that " $e$  is in  $R$ " to mean that  $e$  is the  $E$  set of  $R$ ; we will also say that " $(e, h)$  is a pair in  $R$ " to mean that  $e = e_i$  and  $h = h_i$  for some  $e_i$  in  $E$ .

DEFINITION. If  $R = (E, H, S)$  is an exposed rotation in table  $T$ , then the *elimination* of  $R$  from  $T$  is the following operation: for every  $s_i$  in  $S$ , remove every entry below  $e_i$  in  $s_i$ 's list in  $T$ , i.e., move the bottom of  $s_i$ 's list up to  $e_i$  (from  $e_{i+1}$ ). Then remove  $s_i$  from  $k$ 's list, for each person  $k$  who was just removed from  $s_i$ 's list.

Notice that if all people are semi-engaged in a table  $T$  before a rotation elimination, then all people are semi-engaged after that elimination; hence, one effect of the elimination is to move the head of  $e_i$ 's list down one place, for each  $e_i$  in  $R$ , i.e.,  $e_i$  becomes semi-engaged to the  $s_i$  of table  $T$ . Figure 2(c) shows the table resulting from eliminating  $R_1$  from the Phase 1 table.

8	4	5	6	7				

FIG. 2(c). Table after eliminating  $R_1$  from the Phase 1 table. Note that  $R_2$  is still exposed, and now has a tail of 3. Rotation  $R_3 = (E_3, H_3, S_3)$ , where  $E_3 = \{2, 6, 7, 8\}$ , is now also exposed.

PHASE 2 of the algorithm is simply:

1. While some person has more than one entry on his list, and no list is empty, find and eliminate a rotation.
2. If every person has exactly one entry on his list, then pairing each person with their head entry specifies a stable assignment.
3. If there is an empty list, then there are no stable assignments.

Figure 2(d) completes the execution of Phase 2, eliminating rotations  $R_3$  and  $R_4$ .

**2.2. Correctness of Algorithm I.** The correctness of Algorithm I is proved in [I], and will not be fully repeated here. However, we need the statements of the central lemmas that prove correctness, and we need to extend some of them; we will give proofs of the extended lemmas.

**DEFINITION.** If  $T$  is a table, then roommate assignment  $A$  is said to be *contained in*, or *in*,  $T$ , if and only if every pair in  $A$  is in  $T$ , i.e.,  $i$  is on  $j$ 's list, and  $j$  is on  $i$ 's list for each pair  $(i, j)$  in  $A$ .

The following lemmas imply the correctness of Algorithm I.

**LEMMA 2.1 [I].** *If  $T$  is a table (in Phase 2) where no list is empty, and at least one person has more than one entry, then there is a rotation exposed in  $T$ .*

Lemma 2.1 will be proved and extended in the next section.

**LEMMA 2.2 [I].** *Let  $R = (E, H, S)$  be an exposed rotation in  $T$ , and let  $A$  be any stable assignment contained in  $T$ . If  $e_i \in E$  and  $(e_i, h_i)$  is a pair in  $A$ , then  $(e_i, h_i)$  must also be a pair in  $R$ , for every  $e_i$  in  $E$ .*

Lemma 2.2 will be proved and extended in the next section.

**LEMMA 2.3 [I].** *If rotation  $R = (E, H, S)$  is exposed in  $T$ , and there exists a stable assignment in  $T$  where  $e_1 \in E$  pairs with  $h_1$ , then there also exists a stable assignment in  $T$  where  $e_1$  does not pair with  $h_1$ , and by Lemma 2.2, no  $e_i$  pairs with  $h_i$ , for any  $e_i$  in  $E$ .*

**LEMMA 2.4 [I].** *If the algorithm ends with a single entry on each list, then pairing each person to that entry gives a stable assignment.*

**2.3. Extensions of the central lemmas.** We will prove Lemmas 2.1 and 2.2 in order to extend them.

*Proof of Lemma 2.1.* Let  $e_i$  be a person who has at least two entries,  $h_i$  and  $s_i$ , on its list in  $T$ . Since the head entries are a permutation of the people, and  $s_i \neq h_i$ , there must be a person  $e_j$  such that  $s_i = h_j$ . We claim that  $e_j$  must have two or more entries on its list. If not, then  $h_j$  is its only entry, and so  $e_j$  is the only entry on  $h_j$ 's list. To see this, note that  $h_j$  is both the head and bottom entry on  $e_j$ 's list, so  $e_j$  must also be both the head and bottom of  $h_j$ 's list. But,  $h_j = s_i$  which is on  $e_i$ 's list, so  $e_i$  (which cannot be  $e_j$ ) must also be on  $h_j$ 's list, and so both  $h_j$  and  $e_j$  must have at least two entries on their lists. Repeating this argument, we must eventually cycle, in which case a rotation has been found.  $\square$

**DEFINITION.** The proof above gives an (implicit) algorithm for finding a rotation  $R$ , starting from any person  $e$  who has at least two entries on its list in  $T$ . Let  $e_1$  denote the person who is visited twice by the algorithm (i.e., where the cycle is detected). Every person who is visited before the first visit to  $e_1$  is said to be on a *tail* of  $R$ , and the other people are in the *body* of  $R$ .

Note that in a given table, an exposed rotation may have many tails, and in a different table, the same exposed rotation may have different tails. This is illustrated in the example of Fig. 2. We will need the following extension of Lemma 2.1.

**COROLLARY 2.1.** *If  $e$  is a person with two or more entries on its list in table  $T$ , then  $e$  is either in a tail or in the body of a rotation exposed in  $T$ .*

The following lemma extends Lemma 2.2.

**LEMMA 2.5.** *Let  $R$  be a rotation exposed in table  $T$ , and  $(e_i, h_i)$  a pair in  $R$ . If  $A$  is a stable assignment contained in  $T$  where  $e_i$  pairs with  $h_i$ , and if  $(e, h)$  is any pair in either the body of  $R$  or a tail of  $R$ , then  $(e, h)$  must be a pair in assignment  $A$ .*

*Proof.* Let  $e_j$  be a person either in  $R$  or in a tail of  $R$ . If  $e_k$  is any other person such that  $s_k = h_j$ , then in  $A$ ,  $e_k$  must pair with  $h_k$  if  $e_j$  pairs with  $h_j$ ; if not, then  $e_k$  must be paired with a person below  $s_k$  on its list, since  $h_k$  is already paired with  $e_j$ , and  $A$  is in  $T$ . But  $s_k$  is the head of  $e_j$ 's list in  $T$ , so  $e_j$  must be the bottom of  $s_k$ 's list, and

since  $s_k$  is on  $e_k$ 's list,  $e_k$  is on  $s_k$ 's list, and is preferred to  $e_j$  by  $s_k$ . Hence  $e_k$  and  $s_k$  would block  $A$ . It follows that if  $e_j$  is in the body of  $R$ , and if  $e_j$  pairs with  $h_j$  in  $A$ , then every  $e_i$  in  $R$  must pair with  $h_j$  in  $A$ . Now consider any tail of  $R$  (relative to  $T$ ). If  $(e, h, s)$  is the last triple of the tail, then  $s = h_i$  for some  $e_i$  in  $R$ , so  $(e, h)$  must be a pair in  $A$ , and the implication follows backwards along the tail. Hence in  $A$ , each person in the tail must also pair with the head person on their list in  $T$ .  $\square$

**2.4. The execution tree  $D$ .** Algorithm I is guaranteed to produce a stable assignment if there is one. However, in this paper we are concerned with the structure of the set of all the stable assignments for a particular instance; most of what we will deduce will be by examining the possible executions of Algorithm I. Hence we need the following theorem.

**THEOREM 2.1.** *If  $A$  is any stable roommate assignment, then there is an execution of Algorithm I which produces  $A$ .*

*Proof.* Let  $T$  be any table obtained from a (partial) execution of Algorithm I, where stable assignment  $A$  is in  $T$ . If in  $T$ , the head of each person's list is their partner in  $A$ , then, as in the proof of Lemma 2.1, each list has only a single entry, and so  $T$  is the final table of an execution of Algorithm I, and  $A$  is the resulting stable assignment. So, assume that there is a person  $p$  whose partner in  $A$  is not the head element of  $p$ 's list in  $T$ . Hence  $p$ 's list has at least two entries, and, by Corollary 2.1,  $p$  is either in the body or in a tail of a rotation  $R = (E, H, S)$  exposed in  $T$ . We claim that no person  $e_i$  in the body of  $R$  pairs with  $h_i$  in  $A$ . This follows directly from Lemma 2.5, since if  $(e_i, h_i)$  is a pair in  $A$ , then  $p$ 's partner in  $A$  must also be its head entry in  $T$ , contradicting the selection of  $p$ .

We will show that when  $R$  is eliminated from  $T$ , assignment  $A$  is still contained in the resulting table. The elimination of  $R$  from  $T$  can be viewed as a two-step process. First, the head of each element  $e_i$  in  $R$  is moved down one position to  $h_i$ . By the argument in the paragraph above, assignment  $A$  is in the table after these moves. Hence in  $A$ , each  $e_i$  in  $E$  must be paired with  $s_i$  or below in its list, and for the stability of  $A$ , it follows that each  $s_i$  in  $S$  must be paired with  $e_i$  or above, in its list. Hence  $A$  will be in the remaining table if, for each  $s_i$  in  $S$ , we remove all the elements below  $e_i$  in  $s_i$ 's list, and remove  $s_i$  from the lists of each of these elements. But these are exactly the elements that are removed when  $R$  is eliminated from  $T$ . Hence rotation  $R$  can be eliminated from  $T$ , creating a smaller table  $T'$  which still contains the stable assignment  $A$ . The theorem follows by repeating this argument until no rotations remain.  $\square$

**COROLLARY 2.2.** *Let  $R = (E, H, S)$  be an exposed rotation in table  $T$ , and let  $T'$  be the table after eliminating  $R$  from  $T$ . If  $e_i$  is any person in  $E$ , then  $T'$  contains all stable assignments that  $T$  contains, except for those assignments where  $e_i$  mates with  $h_i$ .*

**DEFINITION.** We use  $D$  to refer to the resulting execution tree, when, for a given Phase 1 table, Phase 2 of Algorithm I is executed in all possible ways. Each node  $x$  in  $D$  represents the table  $T(x)$ , which is the current state of the algorithm at node  $x$ . Each edge out of  $x$  is labeled with a rotation which is exposed in  $T(x)$ , and which is the next rotation eliminated from  $T(x)$  on that execution path out of  $x$ . We use  $D(x)$  to denote the subtree of  $D$  rooted at  $x$ .

Note that  $D$  is defined only for the Phase 2 executions. In the remainder of the paper, when we talk about Algorithm I, we will be referring to Phase 2, unless we specifically state otherwise.

*Naive enumeration of all stable assignments.* Given Theorem 2.1, we could generate all stable assignments by forcing all possible executions of Algorithm I. This would be simple to do, but would be terribly inefficient, as it would most often generate the

same stable assignment several times. However, we will show in this paper that an efficiently implemented modification of this naive approach generates each stable assignment exactly once, at a cost of  $O(n^2)$  time per assignment. Although the modification is simple, its proof of correctness and time is not, and most of this paper centers on developing the needed tools for the proof. We will return to the enumeration problem after examining the structure of  $D$ , and the rotations in the next several sections.

**3. Basic lemmas.** In this section, we develop the basic (technical) tools and definitions that will be used in the rest of the paper. Before going on, it is useful to examine the execution tree  $D$  in a running example (see Fig. 3). Three initial observations stand out: first, if  $P$  and  $P'$  are distinct paths in  $D$  that lead to the same stable assignment, then the edges of  $P$  and  $P'$  are marked with the same *set* of rotations, although in different order; second, every path in  $D$  has the same length; and third, many of the rotations seem to come in dual pairs as defined below.

FIG. 3. Tree  $D$  for the example. The tables at the nodes are not shown. All paths have length 4.  $(R_4, R_5)$  and  $(R_2, R_6)$  are each a dual pair of rotations.  $R_1$  and  $R_3$  have no duals.

**DEFINITION.** If  $R = (E, H, S)$  is a rotation in  $D$  then we define  $R^d$  to be the triple  $(S, E, E')$ , where  $S$  and  $E$  have the same order in  $R^d$  as they have in  $R$ . Note that with this definition  $(R^d)^d = R$ . Note also that  $R^d$  has the *form* of a rotation; if  $R^d$  is actually a rotation in  $D$  (i.e., is a rotation exposed in some table  $T$  in  $D$ ), then we call  $R$  and  $R^d$  a *dual pair of rotations*. Any rotation without a dual is called a *singleton rotation*.

In the example, rotations  $R_1$  and  $R_3$  are singletons, and  $(R_4, R_5)$  and  $(R_2, R_6)$  are each a dual pair of rotations. With this terminology, we can make a more precise

observation, which replaces the second and third observations above: Each path from the root to a leaf in  $D$  contains every singleton rotation, and exactly one of each pair of dual rotations. We will prove that these observations are facts which hold for any execution tree  $D$  of Algorithm I, and these facts will then be exploited to reveal the structure of the set of stable roommate assignments. However, we first need several technical definitions and lemmas.

LEMMA 3.1. *If  $R = (E, H, S)$  and  $R^d = (S, E, E')$  are dual rotations that are both exposed in a table  $T$ , then in  $T$  each list of  $E \cup S$  has exactly two elements.*

*Proof.* This follows simply from definition of duals, and the fact that person  $i$  is the head of  $j$ 's list in any table if and only if person  $j$  is the bottom of  $i$ 's list in that table.  $\square$

DEFINITION. For a table  $T$ , the *active part* of  $T$  is the subtable of  $T$  consisting of those lists which contain more than one person.

LEMMA 3.2. *If  $R = (E, H, S)$  and  $R^d = (S, E, E')$  are both exposed in  $T$ , then the active part of the table resulting from eliminating  $R$  from  $T$  is the same as the active part of the table resulting from eliminating  $R^d$  from  $T$ . Further, that active part is just the active part of  $T$  minus the lists of  $E \cup S$ .*

*Proof.* This follows directly from the definition's dual rotations and rotation elimination, and Lemma 3.1 above.  $\square$

DEFINITION. Let  $T$  be a table and  $R = (E, H, S)$  be a rotation. If there is a subset of elements of  $T$  which form a table  $T'$ , such that  $R$  is exposed in  $T'$ , then we say that  $R$  is *embedded* in  $T$ . Note that the definition does not require that some execution of Algorithm I actually expose  $R$ , when started with  $T$ .

LEMMA 3.3. *If  $R$  and  $R^d$  are dual rotations, then  $R$  is embedded in table  $T$  if and only if  $R^d$  is.*

*Proof.* This follows directly from the definition of duals, and the fact that  $i$  is on  $j$ 's list if and only if  $j$  is on  $i$ 's list.  $\square$

DEFINITION. Let  $R$  be a rotation exposed in table  $T$ , and let  $T(R)$  be the table resulting from eliminating  $R$  from  $T$ . If rotation  $R' = (E', H', S')$  is embedded in  $T$  but not in  $T(R)$ , then we say that  $R$  *removes*  $R'$  from  $T$ . Note that for  $R$  to remove  $R'$  from  $T$  all that is required is that  $h'_i$  or  $s'_i$  not appear on  $e'_i$ 's list in  $T(R)$ , for at least one  $e'_i$  in  $R'$ .

DEFINITION. A path  $P$  in  $D$  is said to *contain* the rotations that label the edges of  $P$ .

LEMMA 3.4. *If  $P$  is a path from the root of  $D$  to a node  $x$  in  $D$ , and  $P'$  is a path from the root to a node  $x'$ , and  $P$  and  $P'$  contain the same rotations in different order, then table  $T(x)$  and table  $T(x')$  are identical. Hence a table is determined from the phase 1 table by the set of rotations leading to it, not by their order.*

*Proof.* It is clear from the way that elements are removed in Phase 1 and Phase 2, that at any point in Phase 2, the current table  $T$  is determined by the Phase 1 table and the bottom elements of each list in  $T$ . In Phase 2, the bottom element of person  $i$ 's list is changed only if person  $i$  is in the  $S$  set of an eliminated rotation. Hence if  $i$  is not the second element in any rotation on the path, then  $i$ 's bottom element in  $T$  is its bottom in the Phase 1 table; otherwise, the bottom of  $i$ 's list in  $T$  is given by the person  $p$  who  $i$  most prefers, such that  $i$  is the second element in  $p$ 's list in some rotation on the path to  $T$ .  $\square$

DEFINITION. The set of rotations that appear on a path from the root to a leaf in  $D$  is called a *path set*. We will use this term when the order of the rotations is not important.

Lemma 3.4 shows a mapping from the path sets onto the stable assignments, but Lemma 3.4 does not show that two different path sets cannot generate the same stable assignment. We will later show that the mapping is in fact one-one, i.e., that any two paths in  $D$  which lead to the same table must contain the same set of rotations. This fact, which is more difficult to prove than Lemma 3.4, will be central in the efficient enumeration of the stable assignments.

We are now ready to state and prove the first nontrivial technical lemma.

LEMMA 3.5. *If  $R = (E, H, S)$  and  $R' = (E', H', S')$  are two distinct rotations exposed in a table  $T$ , then  $R$  removes  $R'$  from  $T$  if and only if  $R' = R^d$ . Hence the only way to remove an exposed rotation is to explicitly eliminate it or its dual rotation, if it has one.*

*Proof.* One direction is trivial. If  $R$  and  $R^d$  are dual rotations, then since one is embedded in  $T$  if and only if the other is, the elimination of  $R$  must remove  $R^d$ . To prove the other direction, suppose that  $R$  and  $R'$  are exposed in  $T$ , and that  $R \neq R'$  eliminates  $R'$  from  $T$ . We will show that  $R'$  must be  $R^d$ . When  $R$  is eliminated, person  $q$  is removed from the list of a person  $p$  if and only if  $p = s$ ; or  $q = s$ ; for some  $s_i \in S$ . Clearly, these removals of individual people from  $T$  affect the lists of people in  $E'$  only if  $s_i$  is in  $H'$  (hence in  $S'$ ), or if  $s_i$  is in  $E'$ . To see that the first case is not possible, recall that in table  $T$  the elements in the  $H$  column are a permutation of the  $2n$  people, and that in each rotation  $R$ , the set of  $S$  elements and  $H$  elements in  $R$  are the same. So even though the  $S$  column of table  $T$  is not necessarily a permutation (i.e., a person can appear more than once in the  $S$  column), no person can appear in the  $S$  set of more than one rotation exposed in  $T$ . Hence  $S \cap S' = S \cap H' = \emptyset$ , and so the first case is not possible. Hence the elimination of  $R$  removes  $R'$  from  $T$  only if some  $s_i$  is in  $S \cap E'$ . For ease of discussion, assume without loss of generality that  $s_1 \in S \cap E'$ , and that  $s_1 = e'_j$ .

If  $e_1 \neq h'_j$ , then the change of the bottom of  $s_1$  to  $e_1$  (the consequence of eliminating  $R$ ) will not affect  $R'$ , so we assume also that  $e_1 = h'_j$ . Let  $T(R)$  be the table resulting from eliminating  $R$  in  $T$ . Since the bottom of  $s_1$ 's list moves up to  $e_1$ , which is the head of  $s_1$ 's list in  $T$  (since  $s_1 = e'_j$  and  $e_1 = h'_j$ ),  $s_1$ 's list in  $T(R)$  contains only the single element  $e_1$ . We claim that if  $e'_i \in E'$ , then  $e'_i$ 's list in  $T(R)$  must also contain only a single element. If not, then in  $T(R)$ ,  $e'_i$  is on a tail that leads to no rotation. To see this, note first that  $H'$  cannot be affected by the elimination of  $R$ , and if  $e'_i$  has two elements in its list in  $T(R)$ , then its first two elements in  $T(R)$  are the same as in  $T$ . Hence, following the proof of Lemma 2.1, the unique path from  $e'_i$  in  $T(R)$  is the same as in  $T$ , but that path cannot form a cycle, since it will encounter a member of  $R'$  ( $s_1$  or earlier) which has only one element on its list. Hence if  $e'_i$  has more than one element on its list in  $T(R)$  then it will be on a tail leading to no rotation. But this contradicts Corollary 2.1, so in  $T(R)$  each  $e'_i$  in  $E'$  contains only a single element in its list. Now  $R'$  is exposed in  $T$ , so each  $e'_i$  in  $E'$  has two or more elements on its list in  $T$ , so the effect of eliminating  $R$  in  $T$  is to move the bottom of each  $e'_i$  in  $R'$ . But this is possible only if for each  $e'_i \in E'$ ,  $e'_i = s_k$  and  $h'_i = e_k$ , for some  $e_k$  in  $R$ .

So we now know that if  $R$  removes  $R'$  from  $T$ , then as sets,  $E' = H$ , and  $H' = E = S'$ . This is necessary if  $R' = R^d$ , but in order to actually prove that equality, we need to show that the order inside the sets is correct. We already know that the correspondence between  $E'$  and  $H'$  is correct, i.e., that  $e'_i = s_k$  and  $h'_i = e_k$ , for the same  $k$ . So, assuming without loss of generality that  $s_1 = e'_1$ , we must show that  $s'_i = e_{i+1}$  for each  $i$ , where  $i + 1$  is taken (mod  $r$ ), and  $r$  is the size of  $R$ . To do this, we first note that in  $T$  the list of every element in  $R$  contains exactly two elements; this follows from what we just showed, since in  $T$ , each  $e_i$  in  $R$  is the head of  $s_i$ 's list, so  $s_i$  is the bottom of  $e_i$ 's list,

so each element in  $R$  has exactly two people on its list in  $T$ . But then each  $e_i$  can be only on the list of  $h_i$  or  $s_i$  in  $T$ . Further,  $e_i$  appears once in  $H'$  and once in  $S'$ . Now  $e_i$  is the head of  $s_i$ 's list in  $T$ , so  $e_i$  must be the second element in  $h_i$ 's list in  $T$ . So  $e'_i = s_i = h_{i+1}$ , and the second element on  $h_{i+1}$ 's list is  $e_{i+1}$ , so  $s'_i = e_{i+1}$ , as claimed. Hence if  $R$  removes  $R'$  from  $T$ , then  $R' = R^d$ .  $\square$

Later in the paper we will strengthen this theorem to show that if  $R$  is exposed in  $T$ , and  $R'$  is *embedded* in  $T$ , but perhaps not exposed, then  $R$  removes  $R'$  from  $T$  if and only if  $R' = R^d$ .

**4. The structure of  $D$ .** In this section we examine the structure of  $D$ , as this structure will reveal the structure of the set of stable assignments.

**4.1. Covering rotations.** DEFINITION. Let  $x$  be a node in  $D$  and  $D(x)$  the subtree of  $D$  rooted at  $x$ . The *active part* of  $D(x)$  is the tree  $D(x)$  where at each node  $y$  in  $D(x)$ ,  $T(y)$  is replaced by the active part of  $T(y)$ . Note that the edge labels of  $D(x)$  do not change.

DEFINITION. If  $R$  and  $R^d$  are dual rotations, and path  $P$  in  $D$  contains *either* of them, then we say that  $P$  *covers*  $R$  and  $R^d$ . If  $R$  is a singleton, and  $P$  contains it, then  $P$  covers  $R$ .

LEMMA 4.1. *Let  $x$  be a node in  $D$  with associated table  $T(x)$ . Every path from  $x$  to a leaf in  $D(x)$  covers the same set of rotations.*

*Proof.* Let  $d(x)$  denote the maximum number of edges on any path from  $x$  to a leaf in  $D$ . The theorem will be proved by induction on  $d(x)$ . For  $d(x) = 1$ , if there is only one edge out of  $x$  (i.e., only one rotation exposed in  $T(x)$ ), then the basis is trivially true. If there are two rotations  $R$  and  $R'$  exposed in  $T(x)$ , then, by Lemma 3.5, they must be duals of each other, since eliminating either one of them results in a table with no rotations (i.e., each removes the other). Similarly, there cannot be more than two rotations in  $T(x)$ , since the elimination of any of them removes them all. So the basis is proved.

Assuming that the theorem holds for  $d(x) \leq k$ , let  $x$  be a node in  $D$  where  $d(x) = k + 1$ , and let  $z$  be a child of  $x$  such that  $d(z) = k$ ; by the induction hypothesis, all paths from  $x$  through  $z$  to a leaf must cover the same rotations; let  $P$  be any such path, and let  $R$  be the rotation labeling the edge  $(x, z)$ . If  $R$  is the only rotation exposed in  $T(x)$  then there is nothing to prove, so let  $y$  be another child of  $x$ , and let  $R'$  be the rotation on the edge  $(x, y)$ . We will show that every path from  $x$  through  $y$  to a leaf of  $D(y)$  covers the same set of rotations as  $P$ .

If  $R' = R^d$ , then by Lemma 3.2 (since both  $R$  and  $R^d$  are exposed in  $T(x)$ ), the *active parts* of  $T(z)$  and  $T(y)$  are identical, and hence the active parts of  $D(z)$  and  $D(y)$  are identical. Further,  $d(z) = k$ , and  $d(y) \leq k$ , so each path from  $z$  covers the same rotations, and each path from  $y$  covers the same rotations, so, since the subtrees from  $z$  and  $y$  are identical, any path from  $z$  must cover the same rotations as any path from  $y$ . Then every path from  $x$  through  $y$  covers the same rotations as  $P$ .

If  $R' \neq R^d$ , then, by Lemma 3.5,  $R$  is still exposed in table  $T(y)$ , and  $R'$  is still exposed in table  $T(z)$ . Let  $z'$  be the node associated with the table obtained by eliminating  $R'$  from  $T(y)$ , and let  $y'$  be the node associated with the table obtained by eliminating  $R$  from  $T(y)$ ; and let  $P(z')$  and  $P(y')$  be paths from  $x$  to leafs in  $D$  that pass through  $z'$  and  $y'$ , respectively. Now the set of rotations on the path from the root of  $D$  to  $z'$  is exactly the same as the set of rotations on the path to  $y'$ , hence by Lemma 3.4,  $T(z')$  is identical to  $T(y')$ , and so  $D(z') = D(y')$ . It follows, as in the case above, that  $P(z')$  and  $P(y')$  cover the same set of rotations. But,  $P(z')$  covers the same set as  $P$ , and since  $d(y) \leq k$ , any path out of  $y$  covers the same set of rotations

as  $P(y')$ , hence covers the same set as  $P$ . Node  $y$  was an arbitrary child of  $x$  such that  $y \neq z$ , so the theorem is proved.  $\square$

By definition, every rotation is exposed somewhere in  $D$ ; hence the major consequence of this theorem is the following theorem.

**Path Theorem.**

**THEOREM 4.1.** *Every path from the root of  $D$  to a leaf covers all the rotations. Further, since no path can contain both a rotation and its dual, each path contains every singleton and exactly one of each dual pair of rotations.*

**COROLLARY 4.1.** *Every path in  $D$  from the root to a leaf has the same length.*

Hence the observations in the example hold in general.

We can now strengthen Lemma 3.5.

**COROLLARY 4.2.** *If  $R$  is exposed in table  $T$ , and  $R' \neq R$  is embedded in  $T$ , then  $R$  removes  $R'$  if and only if  $R' = R^d$ .*

*Proof.* Clearly,  $R$  removes  $R^d$  whether  $R^d$  is exposed or not. To prove the converse, let  $x$  be a node in  $D$  with associated table  $T(x)$ , and let  $y$  be the child of  $x$  obtained by eliminating  $R$  from  $T(x)$ . Since  $R'$  is embedded in  $T(x)$ , neither  $R'$  nor  $(R')^d$  are on the path from the root to  $x$ . If  $R$  removes  $R'$ , it removes  $(R')^d$  also, so neither of these rotations is on any path from  $x$  to a leaf. Hence to avoid contradicting Theorem 4.1, it follows that  $R' = R^d$ .  $\square$

**5. The structure of the rotations and stable assignments.** In this section we derive two compact representations of the set of all stable assignments. We first need a few more technical observations.

**5.1. Unique elimination.**

**DEFINITION.** Let  $e_i, h_i, s_i$  be a triple in rotation  $R$ ; hence when  $R$  is eliminated from any table it is exposed in, the bottom of  $s_i$ 's list moves from  $e_{i+1}$  to  $e_i$ , where  $i+1$  is taken mod  $r$ . Let  $A(R, i)$  denote the set of people on  $s_i$ 's original list between  $e_i$  and  $e_{i+1}$ , including  $e_i$  but excluding  $e_{i+1}$ . Similarly, let  $B(R, i)$  be the people between  $e_i$  and  $e_{i+1}$ , including  $e_{i+1}$  but excluding  $e_i$ .

**LEMMA 5.1.** *For any  $e_i$  in  $R$ ,  $R$  is the only rotation whose elimination moves the bottom of  $s_i$ 's list to a person in  $A(R, i)$ , and is the only rotation whose elimination moves the bottom of  $s_i$ 's list from a person in  $B(R, i)$ .*

*Proof.* Let  $R'$  be a different rotation whose elimination moves the bottom of  $s_i$ 's list to a person  $p$  in  $A(R, i)$  from a person  $q$ . Clearly, since  $e_i$  is above  $q$ , and  $p$  is above  $e_{i+1}$ , no path in  $D$  can contain both  $R$  and  $R'$ . Further,  $R^d$  (if it is a rotation) cannot precede  $R'$  on any path, since  $R^d$  moves the head of  $s_i$ 's list to  $e_{i+1}$ , which is below  $p$ . Similarly,  $R'$  cannot precede  $R^d$  on any path, since it moves  $s_i$ 's bottom to  $p$ , which is above  $e_{i+1}$ . But every path contains either  $R$  or  $R^d$ , so no path contains  $R'$ , contradicting the definition of a rotation. The proof for moves from  $B(R, i)$  is similar.  $\square$

**COROLLARY 5.1.** *A person  $p$  is the  $H$  element of person  $q$ 's list in at most one rotation, and is the  $S$  element of  $q$ 's list in at most one rotation. Hence there is at most one rotation whose elimination moves the head of  $q$ 's list to  $p$ , and there is at most one rotation whose elimination moves the bottom of  $p$ 's list to  $q$ .*

**COROLLARY 5.2.** *If  $p \neq e_i$ , and  $p \in A(R, i)$ , then  $s_i$  can never be paired with  $p$  in any stable roommate assignment.*

*Proof.* Consider any path  $P$  where  $p$  is paired with  $s_i$  in the resulting assignment. Since  $s_i$  prefers  $p$  to  $e_{i+1}$ ,  $p$  is not the bottom of  $s_i$ 's list in the Phase 1 table. Hence, somewhere on  $P$ ,  $p$  must become the bottom of  $s_i$ 's list. By the nature of rotation eliminations, for any person  $z$ , the only way that the bottom of  $z$ 's list can change is

by the elimination of a rotation  $R = (E, H, S)$ , where  $z$  is in  $S$ . Hence for  $p$  to become the bottom of  $s_i$ 's list, some rotation must have explicitly moved the bottom of the list to  $p$ . But this contradicts Lemma 5.1 above.  $\square$

*Necessary elimination.* Let  $R$  be a rotation with the triple  $e_i, h_i, s_i$  in  $R$ . If  $p \neq h_i$ , and  $p$  is above  $s_i$  in  $e_i$ 's list in the Phase 1 table, then  $R$  will never be exposed until  $p$  is removed from  $e_i$ 's list.

LEMMA 5.2. *Let  $p$  be a person who must be removed from  $e_i$ 's list before  $R$  is exposed. There exists a unique rotation  $R'$ , such that  $R'$  appears before  $R$  on every path that contains  $R$ , and such that of all the rotations which appear before  $R$  on any path in  $D$ ,  $R'$  is the only one whose elimination removes  $p$  from  $e_i$ 's list.*

*Proof.* From examination of Algorithm I, there are only two ways in which  $p$  is removed from  $e_i$ 's list: either  $p$  is removed when the bottom of  $e_i$ 's list moves up above  $p$ , or when the bottom of  $p$ 's list moves up above  $e_i$ . If  $p$  is removed by the first case event, then  $R$  is not embedded in the table after  $e_i$ 's bottom moves above  $p$ , since  $p$  is above  $s_i$ . Hence  $p$  is removed by the first case event only on paths that do not contain  $R$ . By Lemma 5.1, the second case can happen only when a particular unique rotation,  $R'$ , is eliminated. Since  $p$  must be removed from  $e_i$ 's list before  $R$  can be exposed,  $R'$  must precede  $R$  on any path that contains  $R$ .  $\square$

DEFINITION. If  $p$  must be removed from  $e_i$ 's list before  $R$  is exposed, and if  $R'$  is the (unique) rotation discussed in Lemma 5.2, then we say that  $R'$  explicitly precedes  $R$ .

**5.2. The partial order  $\Pi^*$  and the structure of the stable assignments.**

DEFINITION. Let  $\Pi^*$  be the reflexive transitive closure of the above relation of explicit precedence. It is clear that  $\Pi^*$  is a partial order on the rotations. Figure 4 shows the Hasse diagram of  $\Pi^*$  for the running example.

FIG. 4

DEFINITION. In partial order  $\Pi^*$ , a subset  $C$  of rotations is called *closed* if and only if it is closed under the predecessor relation, i.e., if  $R$  is in  $C$ , and  $R'$  precedes  $R$  in  $\Pi^*$ , then  $R'$  is in  $C$ .

LEMMA 5.3. *There is a one-one correspondence between the path sets in  $D$  and the set of those closed subsets of  $\Pi^*$  which contain all the singleton rotations, and contain exactly one of each dual pair of rotations.*

*Proof.* One direction is trivial. Let  $C$  be a path set in  $D$ , and let  $P$  be any of the paths in  $D$  containing path set  $C$ . We claim that  $C$  forms a closed subset in  $\Pi^*$  of the required type. We know that each path in  $D$  contains all the singleton rotations and exactly one of each dual pair of rotations; hence we only need to show that  $C$  is closed

in  $\Pi^*$ . But, by Lemma 5.2 above, any rotation that precedes  $R \in C$  must be contained on  $P$ ; hence  $C$  is closed. Conversely, let  $C$  be a closed set of the required type; we will show that there is a path  $P$  in  $D$  which contains  $C$  exactly. First, the maximal elements  $C_0 \subseteq C$  (those with no predecessors in  $\Pi^*$ ) must be exposed rotations in the Phase 1 table, and since only one of any dual pair is in  $C$ , there is a subpath from the root of  $D$  consisting of the rotations  $C_0$ . After the  $C_0$  rotations are eliminated, the elements  $C_1 \subset C$  whose only predecessors are in  $C_0$  must now be exposed, and (since only one of each dual pair is in  $C$ ) each remains exposed until eliminated, and hence there is a path from the root consisting of  $C_0$  followed by  $C_1$ . Continuing in this way, there is a path from the root to a leaf in  $D$  consisting of the rotations in  $C$ .  $\square$

The proof of the following is essentially the same as the second part of the above proof of Lemma 5.3.

**COROLLARY 5.3.** *If  $C$  is a closed set in  $\Pi^*$ , and is contained in some path  $P$  in  $D$ , then there exists a path  $P'$  in  $D$  containing the same rotations as  $P$ , such that in  $P'$ , all rotations in  $C$  appear before any rotations not in  $C$ . Further, the internal order of the rotations in  $C$  is the same on both paths, as is the internal order of the rotations not in  $C$ , i.e., in  $P'$  the rotations in  $C$  simply move above the non- $C$  rotations, but keep their same internal order.*

Since each path set maps to a unique stable assignment, Lemma 5.3 implies that each closed subset in  $\Pi^*$  of the required type maps to a unique stable assignment. We now show that distinct closed subset map to distinct stable assignments.

**LEMMA 5.4.** *Let  $C$  and  $C'$  be two distinct closed subsets of  $\Pi^*$  which both contain all the singletons and exactly one of each dual pair of rotations. Then, as path sets,  $C$  and  $C'$  yield distinct stable assignments.*

*Proof.* Suppose to the contrary that both the path sets  $C$  and  $C'$  produce the same stable assignment  $A$ . We claim that the minimal rotations in  $C$  must be in  $C'$ . Let  $R = (E, H, S)$  be a minimal rotation in  $C$ , and let  $e_i$  be in  $E$ . Then in  $A$ ,  $e_i$  must be mated to  $s_i$ . To see this, note that the elimination of  $R$  moves  $e_i$ 's head to  $s_i$ , and every rotation that moves  $e_i$ 's head below  $s_i$  (and moves  $s_i$ 's bottom above  $e_i$ ) must be preceded by  $R$ . But  $R$  is a minimal rotation in  $C$ , so the head of  $e_i$ 's list must end up at  $s_i$ , and  $e_i$  is mated to  $s_i$  in  $A$ . Now  $s_i$  is not the head of  $e$ 's list in the Phase 1 table, and the head of any list  $e$  can change only by the elimination of a rotation  $R^* = (E^*, H^*, S^*)$  where  $e$  is in  $E^*$ , so  $C'$  must contain a rotation that moves the head of  $e_i$ 's list to  $s_i$ . But by Corollary 5.1, there is only one rotation,  $R$ , that moves the head of  $e_i$  to  $s_i$ . Hence  $R$ , and all minimal rotations in  $C$ , must also be in  $C'$ . But since  $C$  and  $C'$  are closed, all the predecessors of the minimal rotations in  $C$  must also be in  $C$ , and hence in  $C'$ . But any closed subset is precisely the set of its minimal elements, plus the predecessors of those minimal elements. Hence  $C \subseteq C'$ , but since they both have the same cardinality,  $C = C'$ .  $\square$

The following two theorems connect the preceding lemmas and summarize what we now know about the structure of the stable assignments.

**THEOREM 5.1.** *There is a one-one correspondence between stable assignments and those closed sets in  $\Pi^*$  which contain every singleton rotation and exactly one of each dual pair.*

Hence  $\Pi^*$  is a small ( $O(n^2)$  size) representation of the set of all stable assignments. We will later discuss how to efficiently construct  $\Pi^*$ , and how to construct a stable assignment from a closed subset of the correct type.

**THEOREM 5.2.** *There is a one-one correspondence between path sets in  $D$  and stable assignments.*

Theorem 5.2 is Lemma 3.4 and its converse, and is one of the keys to efficient enumeration of the stable assignments. Before discussing enumeration, we derive an alternative representation for the stable assignments.

**5.3. Independent set representation of stable assignments.** In this section, we present a second compact representation of the set of all stable assignments. We first need some additional observations.

**5.3.1. Refining  $\Pi^*$ .**

LEMMA 5.5. *Let  $(R, R^d)$  and  $(R_1, R_1^d)$  be two dual pairs of rotations, and  $R'$  a singleton rotation. Then:*

(1) *Neither  $R$  nor  $R^d$  can precede  $R'$  in  $\Pi^*$ , i.e., only a singleton rotation can precede a singleton.*

(2)  *$R$  precedes  $R_1$  in  $\Pi^*$  if and only if  $R_1^d$  precedes  $R^d$  in  $\Pi^*$ .*

*Proof.* Since each singleton rotation is on every path in  $D$ , any rotation which precedes a singleton rotation in  $\Pi^*$  must be on every path in  $D$ . So if  $R$  precedes  $R'$ ,  $R$  is on every path, and  $R^d$  is on no paths in  $D$ , contradicting the assumption that  $R^d$  is a rotation; so the first fact is proved. For the second fact, observe first that since  $R$  precedes  $R_1$ , no path can contain both  $R_1$  and  $R^d$ , so any path containing  $R^d$  contains  $R_1^d$ . We must show that in any such path,  $R_1^d$  appears before  $R^d$ . Let  $P$  be a path containing  $R^d$ , and consider the point  $x$  where  $R^d$  is eliminated. Since no path can contain both  $R_1$  and  $R^d$ ,  $R_1$  cannot be exposed anywhere in  $D(x)$ , the subtree of  $D$  below  $x$ . But Corollary 6.2, which will be proven later, states that if any nonsingleton rotation is embedded in  $T(x)$ , then both it and its dual are exposed somewhere in  $D(x)$ . Hence it must be that  $R_1^d$  is not embedded in  $T(x)$ , so  $R_1^d$  must appear on  $P$  before  $R^d$ , and fact 2 is proved.  $\square$

**5.3.2. Graph  $G$ .** We define an undirected graph  $G$  as follows. There exists one node in  $G$  for each nonsingleton rotation, and two rotations  $R_1$  and  $R_2$  are connected by an edge in  $G$  if and only if there exists a rotation  $R$  (possibly  $R_1$  or  $R_2$ , since a node precedes itself by definition) such that in  $\Pi^*$ ,  $R$  precedes  $R_1$  and  $R^d$  precedes  $R_2$ . It follows that  $R$  and  $R^d$  are connected for each dual pair  $(R, R^d)$  and if two rotations are adjacent in  $G$ , then they cannot appear together on any path in  $D$ .

LEMMA 5.6. *Every maximal independent set in  $G$  contains exactly one node from each dual pair of rotations.*

*Proof.* First, no independent set can contain both nodes of a dual pair. For the other side, let  $S$  be an independent set in  $G$  which does not contain either  $R$  or  $R^d$ . If neither  $R$  nor  $R^d$  can be added to  $S$ , then there must be a node  $R_1$  in  $S$  such that  $(R, R_1)$  is an edge in  $G$ , and there must be a node  $R_2$  in  $S$  such that  $(R^d, R_2)$  is an edge in  $G$ . But then there exists a rotation  $R_3$  such that  $R_3$  precedes  $R$ , and  $R_3^d$  precedes  $R_1$ , so  $R_1^d$  precedes  $R_3$  (by Lemma 5.5(2)), and it follows that  $R_1^d$  precedes  $R$ . Also, there exists a rotation  $R_4$  such that  $R_4$  precedes  $R^d$  and  $R_4^d$  precedes  $R_2$ , so  $R$  precedes  $R_4^d$  precedes  $R_2$ . So  $R_1^d$  precedes  $R$  precedes  $R_2$ . But then  $R_1$  and  $R_2$  would be connected in  $G$ . Hence it cannot happen that neither  $R$  nor  $R^d$  could be added to  $S$  to create a larger independent set, and continuing in this way, the lemma is proved.  $\square$

DEFINITION. Let  $\Pi$  be the partial order  $\Pi^*$  with the singletons removed.

The following is directly implied by Theorem 5.1 and Lemma 5.5 (1).

LEMMA 5.7. *Let  $\Sigma$  be the set of all singleton rotations in  $\Pi^*$ . A set of rotations  $C$  is closed in  $\Pi^*$  if and only if  $C - \Sigma$  is closed in  $\Pi$ . Hence there is a one-one correspondence between the stable assignments and the closed subsets of  $\Pi$  that contain exactly one of each dual pair.*

We can now show a one-one correspondence between the maximal independent sets in  $G$  and the stable assignments.

LEMMA 5.8. *Any closed subset  $C$  in  $\Pi$  that contains exactly one of each dual pair, is a maximal independent set in  $G$ .*

*Proof.* No path in  $D$  can contain two rotations which are connected in  $G$ . But since  $C$  is closed in  $\Pi$ ,  $C \cup \Sigma$  corresponds to a path set from  $D$ , hence to at least one path in  $D$ . Hence no rotations in  $C$  can be connected in  $G$ , and  $C$  is an independent set in  $G$ . It is maximal, because it has one rotation from each dual pair, and no independent set in  $G$  has more.  $\square$

LEMMA 5.9. *Any maximal independent set in  $G$  is a closed set in  $\Pi$ .*

*Proof.* Let  $S$  be a maximal independent set in  $G$ , and let  $R$  be any rotation in  $S$ . Suppose  $R'$  precedes  $R$  in  $\Pi$ . Then, since  $R'^d$  precedes itself,  $R$  and  $R'^d$  are connected in  $G$ , so  $R'^d$  is not in  $S$ . But  $S$  must contain one of each dual pair, so  $S$  contains  $R'$ . It follows that  $S$  is closed in  $\Pi$ .  $\square$

In summary, we have Theorem 5.3.

THEOREM 5.3. *There is a one-one correspondence between the maximal independent sets in  $G$  and the set of stable assignments.*

Hence,  $G$  is another small implicit representation of the set of all stable assignments. We can simplify the definition of  $G$  with the following lemma.

LEMMA 5.10. *Rotations  $R$  and  $R'$  are connected in  $G$  if and only if  $R^d$  precedes  $R'$  in  $\Pi$ .*

*Proof.* First, if  $R^d$  precedes  $R'$ ,  $R$  and  $R'$  are connected in  $G$ , since  $R$  precedes itself. Conversely, if  $R$  and  $R'$  are connected in  $G$ , then there is a rotation  $R^*$  such that  $R^*$  precedes  $R$  and  $R^{*d}$  precedes  $R'$ . But by Lemma 5.5,  $R^*$  precedes  $R$  implies that  $R^d$  precedes  $R^{*d}$  so  $R^d$  precedes  $R'$ .  $\square$

The above lemma allows a more efficient method to construct  $G$ : we can determine whether to connect two nodes by looking directly at a single entry in the precedence relation, rather than looking for a third rotation to satisfy the initial requirement for connecting two nodes in  $G$ . It turns out that  $G$  can be constructed in time  $O(n^4)$ ; details are omitted, but are very similar to the construction of a related partial order  $\Pi$  given in [G].

**5.4. Equivalent sets and representations.** We now know that the path sets of  $D$ , the closed subsets of  $\Pi^*$  that contain each singleton and exactly one of each dual pair, and the maximal independent sets of  $G$  augmented with the singletons, are all exactly the same sets of rotations, and these sets are in one-one correspondence with the stable assignments. We will see later that each such set can be used to generate the associated stable assignment in  $O(n^2)$  time.

**6. Efficient enumeration of all stable assignments.** We now discuss an efficient method to generate all stable assignments. The method is a modification of a very general, naive method that is often suggested as a way to enumerate constrained sets; the naive method is rarely efficient, but is efficient in the stable assignment problem. The efficiency here is a consequence of very special properties of the stable assignment problem, and the way the enumeration is implemented.

By Theorem 2.1, the stable assignments can be generated by forcing all execution behaviors of Algorithm I. This would not be guaranteed to be efficient, since the same assignment would likely be generated many times. However, by Theorem 5.2, we need not generate each path in  $D$ , but only each path set. One approach is to use graph  $G$  to generate each maximal independent set (path set) in  $G$ , and, as we will show below, then use the path set to generate the associated stable assignment. The fastest known methods to generate all maximal independent sets in a general graph appear in [LLR], but applying those methods to  $G$  yields a time bound of  $O(n^4)$  per independent set. Alternatively, we could try to generate all the closed subsets of  $\Pi^*$  which contain all

singletons and exactly one of each dual pair. However, general techniques for such constrained enumeration in general partial orders seem very inefficient. Here, we will use a different approach, heavily exploiting results about the structure of  $D$  and the rotations, to obtain a method which, after  $\Pi^*$  is constructed, will generate each path set, and each stable assignment, in  $O(n^2)$  time per assignment. This compares favorably with the  $O(n^3)$  methods given in [K] and [MW] to construct each stable *marriage*.<sup>1</sup> In the first section we will present the method and prove it correct, and in the second section we will discuss the time it requires. We first need the following definitions.

DEFINITION. Let SR be a set of rotations. For each person  $p$ , let  $SR(p)$  be the highest person on  $p$ 's list such that  $SR(p) = e_i$  and  $p = s_i$  in some rotation  $R = (E, H, S)$  in SR.

DEFINITION. Let  $T$  be a table and SR be a set of rotations. The *elimination of SR from  $T$*  is the following: For each person  $p$ , delete all people in  $p$ 's list below  $SR(p)$ , if there are any, and delete  $p$  from the lists of all of those deleted people, if  $p$  exists in those lists.

Note that the definition does not require that all the rotations in SR be embedded in  $T$ , or that SR is contained in any path set.

DEFINITION. For a rotation  $R$ , define  $\Pi^*(R)$  as the set of rotations consisting of  $R$  and all the predecessors of  $R$  in  $\Pi^*$ .

**6.1. The dual enumeration method.** The idea of the method is to simulate Algorithm I forcing it to generate each path set, and associated stable assignment, exactly once. We will represent the simulation by a binary tree  $B$ . As in tree  $D$ , each node  $x$  in  $B$  will represent a table; when node  $x$  is a nonleaf, one edge out of  $x$  will be labeled by a single rotation which is exposed in  $T(x)$ , but the other edge, if it exists, will be labeled by a set of rotations, not necessarily embedded in  $T(x)$ . We will call the first edge the *left* edge and the second edge the *right* edge. If the left edge  $(x, y)$  in  $B$  is labeled by  $R$ , then the table  $T(y)$  at node  $y$  is obtained from  $T(x)$  by eliminating  $R$  from  $T(x)$ . When  $R$  is a singleton, then there will be no right edge out of  $x$ , but when  $R$  is a nonsingleton, then the right edge  $(x, z)$  will exist and will be labelled with

FIG. 5. Tree  $B$  given by the dual enumeration method. The labels at the leaves refer to assignments given in Fig. 3.

<sup>1</sup> It is reported in [K] that the time is  $O(n^2)$ , per marriage, but this is incorrect. Constructions appear in the appendix of [G1] showing that the algorithm can take  $\Omega(n^3k/[\log k^2])$  time for  $k$  stable marriages.

$\Pi^*(R^d)$ , and the resulting table  $T(z)$  will be the table obtained by the elimination of the set  $\Pi^*(R^d)$  from  $T(x)$ . Each leaf of  $B$  will contain a table with no exposed rotations. The simulation begins with a node representing the phase one table, and each node  $x$  in  $B$  is expanded by arbitrarily choosing an exposed rotation  $R$  in  $T(x)$ , eliminating  $R$  from  $T(x)$  on the left edge out of  $x$ , and, if  $R$  is a nonsingleton, eliminating  $\Pi^*(R^d)$  from  $T(x)$  on the right edge out of  $x$ . A table with no exposed rotations is not expandable; we will show that such a table must specify a stable assignment. The simulation ends when no unexpanded nodes in  $B$  are expandable. We call this method the *dual enumeration* method. Figure 5 illustrates this method on the running example.

### 6.1.1. Correctness of the dual enumeration method.

LEMMA 6.1. *The dual enumeration method never generates a path set (stable assignment) more than once.*

*Proof.* Let  $x$  be a nonleaf node in  $B$ , and let  $R$  be the rotation on the left edge out of  $x$ . Consider the leaves in the subtree rooted at  $x$ , and the path sets associated with those leaves. Those path sets are divided into those sets containing  $R$  and those containing  $R^d$  (none, if  $R$  is a singleton). Since no path set contains both a rotation and its dual, there is no intersection between these two sets of path sets. Applying this fact inductively upward from the leaves to the root in  $B$ , it follows that no path set is generated more than once. Theorem 5.2 then implies that no stable assignment is generated more than once.  $\square$

LEMMA 6.2. *Every stable assignment (path set) is generated at least once by the above method.*

*Proof.* Let  $x$  be a nonleaf node in  $B$  which is also a node in  $D$  (the root of  $B$  is such a node, although we will later see that all nodes of  $B$  are in  $D$ ). Let  $A$  be a stable assignment contained in  $T(x)$ . Let  $R$  be the exposed rotation eliminated from  $T(x)$  on the left edge out of  $x$  in  $B$ , and let  $T(y)$  be the resulting table. Suppose first that the path set for  $A$  contains  $R$ . Then by Corollary 2.2, and the fact that  $T(x)$  is in  $D$  as well as in  $B$ , it follows that node  $y$  is in both  $D$  and  $B$ , and assignment  $A$  is contained in table  $T(y)$ .

Now suppose that the path set for  $A$  contains  $R^d$ , and let  $w$  be any node in  $D(x)$ , the subtree of  $x$  in  $D$ , such that  $T(w)$  contains  $A$  and such that the edge into  $w$  is labeled with  $R^d$ . Clearly, every path from  $x$  which leads to a leaf labeled with  $A$  contains such a node  $w$ . Also, every rotation in  $\Pi^*(R^d)$  must be on the path in  $D$  from the root to  $w$ . Now, as in the proof of Corollary 5.3, a rotation  $R^d$  is exposed if all of its predecessors in  $\Pi^*$  have been eliminated and  $R$  has not been removed, so there must also be a path in  $D$  from  $x$  to a node  $z$ , containing exactly those rotations in  $\Pi^*(R^d)$  that are on the path from  $x$  to  $w$  (i.e., this second path is obtained by deleting all the rotations on the first path from  $x$  that are not in  $\Pi^*(R^d)$ ). Further, the elements of  $T(w)$  are all contained in  $T(z)$ , since the rotations leading to  $w$  are a superset of those leading to  $z$ . Hence  $A$  must be contained in  $T(z)$  as well as in  $T(w)$ . But  $T(z)$  is exactly the table obtained in  $B$  by the elimination of  $\Pi^*(R^d)$  from  $T(x)$ . Hence, if the path set for  $A$  contains  $R^d$ , then the right child of node  $x$  in  $B$  is the above node  $z$  in  $D$ , and  $T(z)$  in  $B$  contains assignment  $A$ .

Now the phase one table is in both  $D$  and  $B$ , and so by iterating the above arguments downward from the root, we see that there is a path in  $B$  consisting of nodes in both  $D$  and  $B$ , such that assignment  $A$  is contained in each of the tables on the nodes in the path. Since the nodes on this path are in  $D$ , and the table sizes decrease with each edge on the path, the path ends with a table containing assignment  $A$  exactly. Hence assignment  $A$  appears at some leaf of tree  $B$ .  $\square$

The above lemmas show that every stable assignment is generated exactly once, but this does not prove the correctness of the dual method, since we have not proved that the method never generates tables that are not in  $D$ . If it did, then it could generate assignments that are not stable, or it could generate tables that have “rotations” that are not in  $D$ . Lemma 6.2 does not show that every table in  $B$  is also in  $D$ , although it is immediate that if  $x$  is in  $B$  and  $D$ , then  $y$ , the left child of  $x$  in  $B$ , is also in  $D$ . What remains to show is that the right child of  $x$  in  $B$  is necessarily in  $D$ . The point is that even though there is an assignment in  $T(x)$  whose path set contains the nonsingleton rotation  $R$ , which is exposed in  $T(x)$ , we do not know for sure that there is an assignment in  $T(x)$  whose path set contains  $R^d$ . If there is no such assignment, then the dual enumeration method will either generate a table which does not specify an assignment but which has no exposed rotations (in which case it will have done excess work), or it will generate an assignment which is not stable. Neither of these things can happen if each table in  $B$  is also in  $D$ . To prove that each table of  $B$  is in  $D$ , we show that for any node  $x$  in  $D$ , if  $R$  is exposed in  $T(x)$ , then  $R^d$  is exposed in some table in  $D(x)$ , the subtree of  $D$  rooted at  $x$ . This implies that  $T(x)$  contains a stable assignment whose path set contains  $R^d$  in  $D(x)$ , if  $R$  is exposed in  $T(x)$ . Of course, since  $R$  is exposed in  $T(x)$ ,  $R^d$  appears below  $x$  on any of these paths.

**THEOREM 6.1.** *Let  $R$  and  $R^d$  be dual rotations, and  $x$  a point in  $D$ . If  $R$  is exposed in  $T(x)$ , then  $R^d$  is exposed in  $D(x)$ . Hence if  $R$  is exposed in  $T(x)$ , then there is a stable assignment in  $T(x)$  whose path set contains  $R^d$  as well as one which contains  $R$ .*

To prove this theorem we first need the following.

**LEMMA 6.3.** *If  $P$  is a path from the root of  $D$  to a node  $x$  in  $D$ , and  $P'$  is a path from the root to a node  $x'$ , and  $P$  and  $P'$  cover the same set of rotations, then the active parts of table  $T(x)$  and table  $T(x')$  are identical, and hence the active parts of  $D(x)$  and  $D(x')$  are also identical.*

*Proof.* Note first that since no path can contain both rotations in a dual pair, the length of  $P$  and  $P'$  are the same. Let  $dP$  and  $dP'$  be the parts of  $P$  and  $P'$ , respectively, after the point  $v$  in  $D$  where  $P$  and  $P'$  diverge. The proof of the lemma is by induction of the length of  $dP$  (which is, of course, also the length of  $dP'$ ). For length of one,  $dP$  must contain  $R$  while  $dP'$  contains  $R^d$ , for some dual pair of rotations. Then in  $T(x)$ , both  $R$  and  $R^d$  are exposed and the basis follows from Lemma 3.2. Now assuming the theorem holds for  $dP$  of length  $k$ , consider  $dP$  of length  $k+1$ , and let  $R$  and  $R'$  be the first rotations on  $dP$  and  $dP'$  respectively, and let  $\nu_R$  and  $\nu_{R'}$  be the first nodes below  $v$  on these paths (see Fig. 6(a)). If  $R' = R^d$ , then the active tables are the same after eliminating either rotation, and hence there must be a path from  $\nu_R$  that is identical to the part of  $dP'$  starting at  $\nu_{R'}$ . Hence the table  $T$  at the end of that path is  $T(x')$ . But, by the induction hypothesis, the active part of  $T(x)$  is the same as the active part of  $T$ ; hence the theorem follows in this case.

Now suppose that  $R' \neq R^d$ . There are two cases to consider: either  $R$  is on  $dP'$ , or  $R^d$  is on  $dP'$ .

Let  $w$  be the point on  $dP'$  where  $R$  (in the first case) or  $R^d$  (in the second case) is eliminated. Since both  $R$  and  $R'$  are exposed at  $v$ ,  $R$  must be exposed at every table on  $dP'$  down to  $w$ .

In the first case, consider the edge on  $dP'$  into  $w$ , and let  $R^*$  be the rotation eliminated there (see Fig. 6(b)). If instead of eliminating  $R^*$ ,  $R$  is eliminated at that point,  $R^*$  will not be removed (since  $R^* \neq R^d$ ). Hence the path which is identical to  $dP'$  except that the order of  $R^*$  and  $R$  is reversed, is in fact a path from  $v$ ; call that path  $dP^*$ . Now  $dP'$  and  $dP^*$  contain exactly the same rotations, so, by Lemma 3.4, the table at the end of  $dP^*$  is  $T(x')$ . Repeating this argument up the length of  $dP'$ ,

FIG. 6(a). Proof of Lemma 6.3, when  $R' = R^d$ . Wavy lines are known paths in  $D$ , solid edges are known single edges in  $D$ , labeled dashed lines are inferred edges, and unlabeled dashed lines are inferred paths in  $D$ .

FIG. 6(b).  $R' \neq R^d$  and  $R^d$  is on  $dP'$ .

FIG. 6(c).  $R' \neq R^d$  and  $R^d$  is on  $dP'$ .

moving  $R$  up at each step and leaving the rest of the path the same, it follows that there is a path from  $v$  through  $\nu_R$  which contains the same rotations as  $dP'$ , and hence ends with table  $T = T(x')$ . But, by the inductive hypothesis, as above, the active parts of  $T(x)$  are identical to the active parts of  $T$ , and hence of  $T(x')$ .

In the second case, when  $R^d$  is on path  $dP'$ , there must be a path,  $P(R)$ , from  $v$  through  $\nu_R$ , which is identical to  $dP'$ , except that  $R$  replaces  $R^d$  (see Fig. 6(c)). This follows from Lemma 3.2, and the fact that  $R$  is exposed at  $w$ . But now  $dP'$  and  $P(R)$  diverge below  $v$ ; hence by the induction hypothesis, the active part of the table,  $T$ , at the end of  $P(R)$  is identical to the active part of  $T(x')$ . Now we can repeat the step argument of the first case, moving  $R$  up  $P(R)$  to  $v$ , and conclude that there is a path from  $v$  through  $\nu_R$  which contains exactly the same rotations as  $P(R)$ . Then, by the inductive hypothesis, the active part of  $T(x)$  is the same as the active part of  $T$ , which is the same as the active part of  $T(x')$ .  $\square$

*Proof of Theorem 6.1.* Let  $z$  be the closest ancestor of  $x$  such that  $R^d$  is exposed in  $D(z)$ , and let  $y$  (possibly  $x$ ) be the child of  $z$  on the path from  $z$  to  $x$ . Let  $R_1$  be the rotation on the  $(z, y)$  edge. Let  $P$  be a path from  $z$  to a leaf, where  $P$  contains  $R^d$ , and let  $R_2$  be the first rotation on  $P$  (see Fig. 7(a)). If  $R_1 = R_2^d$ , then the active tables after eliminating either rotation are the same, so the subtrees below those two points must be the same; hence  $D(y)$  must contain  $R^d$ . So, assume that  $R_1 \neq R_2^d$ . Neither  $R_1$  nor  $R_1^d$  is on the path from the root to  $z$ , so either  $R_1$  or  $R_1^d$  must be on  $P$ , say at a point  $w$ . Note that in either case,  $R_1$  is exposed at  $w$ . Hence if  $R^d$  is before  $w$  on  $P$ , then we can assume  $P$  contains  $R_1$ . If  $P$  contains  $R_1^d$  and  $R^d$  is after  $w$  (see Fig. 7(b)), then consider the effect of eliminating  $R_1$  at  $w$ ; the resulting active table is the same as after eliminating  $R_1^d$ , so there is a path from  $w$  which contains  $R^d$ . So we can always assume that  $P$  contains  $R_1$  and  $R^d$ . But now, we can move  $R_1$  up a step at a time, as in the preceding proof, concluding that there is a path from  $z$  through  $y$  that contains  $R^d$ . This contradicts the selection of  $z$ , and proves the theorem.  $\square$

Theorem 6.1 completes the proof of correctness of the dual enumeration method. In summary, we have Theorem 6.2.

**THEOREM 6.2.** *The dual enumeration method generates each stable assignment exactly once, and the table at each leaf in  $B$  specifies a stable assignment.*

There are several useful corollaries of Theorem 6.1.

**COROLLARY 6.1.** *For any table  $T(x)$  in  $D$ , if  $R$  is the only rotation exposed in  $T(x)$ , then  $R$  is a singleton.*

**COROLLARY 6.2.** *If  $R$  and  $R^d$  are duals embedded in  $T(x)$ , then both are exposed somewhere in  $D(x)$ .*

7a.

FIG. 7(a)

FIG. 7(b).  $R^d$  is on  $P$  after  $w$ .

Recall that the proof of Lemma 5.5 (2) depended on Corollary 6.2, so Lemma 5.5 is now fully proved.

**COROLLARY 6.3.** *If  $R$  and  $R^d$  are duals, then there is a point  $x$  in  $D$  where both  $R$  and  $R^d$  are exposed in the table  $T(x)$ .*

**COROLLARY 6.4.** *If  $R$  is a nonsingleton rotation, and  $e_i \in R$ , then there is a stable roommate assignment where each  $e_i$  is paired with  $h_i$ , and also one where each  $e_i$  is paired with  $s_i$ .*

*Proof.* By Lemma 3.1, at the point  $x$  where both  $R = (E, H, S)$  and  $R^d$  are exposed, each list in  $E \cup S$  contains exactly two elements, and eliminating  $R^d$  makes  $h_i$  the only element on  $e_i$ 's list, and eliminating  $R$  makes  $s_i$  the only element on  $e_i$ 's list. With either elimination, the algorithm is guaranteed to find a stable assignment in the resulting table.  $\square$

**6.2. Complexity analysis.** In this section we show that the dual enumeration method works in time  $O(n^3 \log n + kn^2)$  to enumerate  $k$  stable assignments. The  $O(n^2 \log n)$  term is the time needed to find all the rotations in  $D$  and to construct  $\Pi^*$ . Thereafter, each stable assignment is generated in  $O(n^2)$  time, per assignment. To prove the above bound, we first examine the computational steps needed before and in the dual method: how to find all the rotations and recognize the singletons, how to eliminate a set of rotations, how to generate “enough” of  $\Pi^*$ , and how to find  $\Pi^*(R)$  for a rotation  $R$ . We then show how to charge the work during the dual algorithm, and prove the above time bound.

**6.2.1. Finding all the rotations in  $O(n^3 \log n)$  time.** Even though the number of stable assignments, hence the size of  $D$ , grows exponentially in  $n$ , the Path Theorem, and the fact that Algorithm I runs in  $O(n^2)$  time, imply that there can be at most  $O(n^2)$  rotations in  $D$ . In fact, Corollary 5.1 shows that there can be at most  $n(n-1)$  rotations. We show here that all the rotations in  $D$  can be found in  $O(n^3 \log n)$  time. To do this, we run Algorithm I once, following a path  $P$  in  $D$ , finding the rotations on  $P$ . By the Path Theorem,  $P$  covers all the rotations on  $D$ , but we still have to determine which are singletons and which have duals. If  $R$  is a rotation on  $P$ , then

we can test if  $R^d$  is a rotation by simply returning to the point on  $P$  where  $R$  is eliminated and successively choosing and eliminating any rotation other than  $R$ . By Corollary 4.2, we will either expose and eliminate  $R^d$ , or we will have a table where only  $R$  is exposed; in the latter case,  $R$  must be a singleton, by Corollary 6.1. There are at most  $n(n-1)$  rotations on  $P$ , and each run of Algorithm I costs  $O(n^2)$  time, so although the size of  $D$  can be exponential in  $n$ , all rotations in  $D$  can be found in  $O(n^4)$  time. Of course, in practice this procedure can be sped up by noting at each step which other rotations are exposed.

We can speed up the above method to run in time  $O(n^3 \log n)$ . The idea is that we can find  $2n$  chains in  $\Pi^*$  that contain all the rotations on path  $P$ ; there is one chain for each person  $p$ , and it simply consists of the ordered list of the rotations on  $P$  that move the head of  $p$ 's list. The rotations in the chain are ordered by the relative order that they appear on  $P$ . It is easy to see that if rotation  $R$  moves  $p$ 's head before rotation  $R'$  does, on  $P$ , then  $R$  precedes  $R'$  in the partial order  $\Pi^*$ . Now Lemma 5.5 (1) says that in  $\Pi^*$  only singleton rotations can precede a singleton, so this implies that there is a point on each chain where all the rotations above the point are singletons, and all below it are nonsingletons; we search for that point using binary search. Each query in the search costs  $O(n^2)$  time, as above, and since there are only  $n(n-1)$  rotations per chain, the breakpoint for each chain is found in  $O(n^2 \log n)$  time. There are only  $2n$  chains, so at most  $O(n^3 \log n)$  total time is required. Since the form of the dual rotations (not on  $P$ ) are known, and the total size of their description is  $O(n^2)$ , once the singletons have been identified, the rotations not on  $P$  can be generated in  $O(n^2)$  total time.

**6.2.2. Time needed for the elimination of a set of rotations.** Any arbitrary set of rotations  $SR$  can be eliminated from any table  $T$  in  $O(n^2)$  time. The key is that the total size of the description of  $SR$  is  $O(n^2)$ , so a simple scan through the rotations in  $SR$  finds  $SR(p)$  for each person  $p$ , and this takes  $O(n^2)$  time in total. Further, any table is of size  $O(n^2)$ , and when  $SR$  is eliminated, each element to be removed can be found and removed in constant time, so the elimination of the elements only requires  $O(n^2)$  time. This also shows that given a path set, the associated stable assignment can be generated in  $O(n^2)$  time, by simply eliminating the path set from the phase one table.

**6.2.3. Time needed to “construct”  $\Pi^*$  and to find  $\Pi^*(R)$ .** The partial order  $\Pi^*$  has  $O(n^2)$  elements, and if we represent  $\Pi^*$  as a directed graph,  $DG$ , where each node is an element in  $\Pi^*$  and each edge corresponds to a pair in the relation, then there might be as many as  $\Omega(n^4)$  edges in the graph. However, in the dual enumeration method, we only need to know  $\Pi^*$  in order to find the predecessors of a rotation. Hence it will suffice to know any subgraph of  $DG$  whose transitive closure is  $\Pi^*$ . By definition, the Hasse diagram of  $\Pi^*$  is the smallest such subgraph. It turns out that the Hasse diagram has at most  $O(n^2)$  edges, and there is a supergraph,  $DG^*$ , of the Hasse diagram, which also contains only  $O(n^2)$  edges, and  $DG^*$  can be found from the set of rotations in  $O(n^2)$  time. Then since  $DG^*$  has only  $O(n^2)$  nodes and edges, given any rotation  $R$ , we can find  $\Pi^*(R)$  in  $O(n^2)$  time by backwards search from  $R$  in the obvious way.

Summarizing, we have Lemma 6.4.

**LEMMA 6.4.** *There exists a directed acyclic subgraph,  $DG^*$ , of  $DG$  containing all the nodes of  $DG$ , such that  $R$  leads to  $R'$  by a path in  $DG^*$  if and only if  $R$  is connected by a directed edge to  $R'$  in  $DG$ . Further,  $DG^*$  has  $O(n^2)$  edges, and it can be constructed from the set of rotations in  $O(n^2)$  time.*

*Proof.* Let  $e_i, h_i, s_i$  be a triple in rotation  $R$ . Recall that when  $R$  is eliminated from any table it is exposed in, the bottom of  $s_i$ 's list moves from  $e_{i+1}$  to  $e_i$ , where  $i+1$  is taken mod  $|R|$ . Recall also that  $A(R, i)$  is the set of people on  $s_i$ 's original list between  $e_i$  and  $e_{i+1}$ , including  $e_i$  but excluding  $e_{i+1}$ . In order to "construct"  $\Pi^*$ , we first examine each rotation  $R = (E, H, S)$ , and for each person  $s_i$  in  $S$ , we find  $A(R, i)$  and then for each person  $p$  in  $A(R, i)$ , we mark  $s_i$  in  $p$ 's list with rotation  $R$ . All of these markings can be done in  $O(n^2)$  time, since each  $A(R, i)$  is a contiguous list of elements in  $s_i$ 's original list, and by Lemma 5.1, no two  $A(R, i)$  sets intersect.

The rest of the construction method, and the proof of its correctness and time, essentially appear in [G] § 4.2 where enumeration for the stable *marriage* problem is discussed. In the stable marriage problem, the set of stable marriages are also represented by a supergraph of the Hasse diagram of a particular partial order. That supergraph has  $O(n^2)$  nodes and edges and is constructed from a marked table similar to the one above. What is important is that the only properties of the marked table that are needed in the construction of the supergraph of [G], and to prove the size and time bounds, also hold for the above marked table used here. The reader is referred to [G] for the complete details.  $\square$

**6.2.4. Time needed for the dual enumeration method.**

**THEOREM 6.3.** *Given  $DG^*$  as above, each stable assignment can be generated in  $O(n^2)$  time, per assignment. In fact, the assignments can be generated on-line in this time.*

*Proof.* Consider a node  $x$  in  $B$ , and define  $x$  as a left node if it is the root of  $B$ , or if the edge into it from its parent is a left edge. From each leaf which is also a left node there is a unique maximal path upward from the leaf consisting only of left nodes (see Fig. 8). For example, the path from the leftmost leaf in  $B$  runs to the root of  $B$ . These paths are edge disjoint, and cover every left edge in  $B$ . Now consider the top node  $x$  of one of these paths. Starting from this top node  $x$ , the work of the dual enumeration method along the path down to the associated leaf, consists of an execution of Algorithm I starting from  $T(x)$ , which is a subtable of the Phase 1 table. Hence the total time for the work along this path is  $O(n^2)$ . But these paths are disjoint, each ends at a distinct leaf of  $B$ , hence at a distinct stable assignment, and these paths cover all the left edges in  $B$ . Hence the total work of the dual enumeration method along the left edges of  $B$  is  $O(n^2)$ , per assignment.

FIG. 8. Schematic tree  $B$ . The maximal paths of left edges are drawn with wavy lines.

The work on any right edge out of any node  $x$  in  $B$  consists of finding  $\Pi^*(R^d)$  for a given  $R^d$ , and eliminating  $\Pi^*(R^d)$  from  $T(x)$ . As shown above, each of these

operations can be done in  $O(n^2)$  time. If  $(x, y)$  is a right edge, and  $y$  is a leaf, then we can charge the  $O(n^2)$  time for edge  $(x, y)$  to the assignment at node  $y$ . If  $(x, y)$  is a right edge and  $y$  is not a leaf, then  $y$  is the top node of one of the maximal left paths discussed above. We charge the work on  $(x, y)$  to the assignment at the end of that path. Clearly, no assignment gets charged for more than one right edge, so the work for all the right edges in  $B$  is also  $O(n^2)$ , per assignment.

In order to make the time bound on-line, simply expand  $B$  in a depth-first manner, going left whenever possible. In such a traversal, no more than  $O(n^2)$  time can pass between the generation of new stable assignments.  $\square$

In the above analysis, the time for the left edges can be accounted for more closely, to get an  $O(n)$  time bound per assignment for the left edges. However, the work for the right edges remains  $O(n^2)$  per assignment, and it is an open question whether this can be substantially reduced.

### 7. Characterizing the stable pairs.

**DEFINITION.** If persons  $i$  and  $j$  are paired together in some stable assignment, then they are called a *stable pair*. If they are paired together in all assignments, then they are called a *fixed pair*.

Knuth [K] mentions the utility of knowing the stable pairs in the stable marriage problem, and in [G] it is shown how to find all the stable pairs for the marriage problem in  $O(n^2)$  time. Here we examine the equivalent question for the stable roommate problem.

**DEFINITION.** Let  $\Sigma$  be the set of singleton rotations, and let  $P$  be a subpath from the root in  $D$  containing all and only the singleton rotations. Let  $x^*$  be the end of path  $P$ .

By Lemmas 5.3 and 5.5, it is clear that such a  $P$  exists, and that all stable assignments are in  $D(x^*)$ . In other words, if all the singleton rotations are eliminated as a set from the phase one table,  $T(x^*)$  results, and it contains all stable assignments.

**LEMMA 7.1.** *Person  $i$  is in a fixed pair if and only if  $i$ 's list in  $T(x^*)$  has only a single entry.*

*Proof.* First, since  $D(x^*)$  contains all the stable assignments, if  $i$ 's list in  $T(x^*)$  contains only one entry,  $j$ , then  $(i, j)$  is a pair in every stable assignment. If  $i$ 's list in  $T(x^*)$  is not a single entry, then  $i$  must be in the  $E$  set of a rotation  $R$ , and in the  $H = S$  sets of rotation  $R^d$ . Hence by Corollary 6.4,  $i$  is in at least two stable pairs, and so is not in a fixed pair.  $\square$

We claim that if  $i$  is not in a fixed pair, then  $i$  can mate with person  $p$  only if  $p$  is in the  $S$  set for  $i$  in some nonsingleton rotation  $R$ , or if  $i$  is in the  $S$  set for  $p$  in  $R^d$ . This follows easily from the workings of Algorithm I, and the fact that  $T(x^*)$  is generated by the singletons. Combining this observation with Corollary 6.4 gives Theorem 7.1.

**THEOREM 7.1.** *If  $(e_i, j)$  is not a fixed pair, then it is a stable pair if and only if  $j = h_i$  or  $j = s_i$  in some nonsingleton rotation  $R = (E, H, S)$ .*

Hence the nonfixed stable pairs can be found immediately from the nonsingleton rotations, and the fixed pairs can be found in  $O(n^2)$  time from the singletons, by eliminating the singletons from the Phase 1 table. Hence the set of all stable pairs can be found in  $O(n^3 \log n)$ , and any speed up, down to  $O(n^2)$  time, in finding the rotations will speed up finding the stable pairs. It is not difficult, using Theorem 7.1, to find all the fixed pairs in  $O(n^3)$  time, but it is open whether this leads to a faster way of finding all the stable pairs, or of finding the singletons.

### 8. Specializing the roommate structure to marriage.

DEFINITION. Let  $MP$  be an instance of the stable marriage problem on  $n$  men  $M$ , and  $n$  women  $W$ . Let  $RMP$  be an instance of the stable roommate problem on  $M \cup W$ , obtained from  $MP$  by adding to the end of each man (woman)  $p$ 's list all the men (women) other than  $p$ .

It is easy to prove that each stable assignment in  $RMP$  is a stable marriage in  $MP$  and conversely. Hence the structure of the stable roommate problem applies to the marriage problem, and it is of interest to see how the general structure specializes in the case of stable marriage. In particular, it is interesting to compare the results here to those of [IL], where a structure of the set of stable marriages was first obtained. The results in this paper specialize to those in [IL] for the marriage problem. However, the structure of stable marriages is somewhat simpler than the structure of stable roommate assignments, and this allows faster algorithms to construct it, and a simpler view of how to construct stable marriages from the partial order(s). Hence the structure resulting from specializing the roommate structure to stable marriage at first appears different than that in [IL]. In the next paragraphs we sketch additional observations that connect the structures and the expositions.

The following facts are stated without proof:

(1) In  $\Pi^*$  resulting from  $RMP$ , there are no singleton rotations.  
 (2) If  $R = (E, H, S)$  is a rotation in  $\Pi^*$  resulting from  $RMP$ , then all people in  $E$  have the same sex, and all people in  $H$  have the opposite sex. Hence the  $E$  set in  $R$  is male if and only if the  $E$  set in  $R^d$  is female, and the rotations partition naturally into two equal-sized sets of rotations, one in which each rotation has a male  $E$  set and one in which each rotation has a female  $E$  set. We call the first type the male rotations and the second type the female rotations.

(3) In every pair in relation  $\Pi^*$  resulting from  $RMP$ , the two rotations have the same sex. Hence, the partial order  $\Pi^*$  in  $RMP$  is composed of two disjoint partial orders:  $M\Pi^*$  containing the male rotations, and  $F\Pi^*$  containing the female rotations.

(4) Let  $C$  be a closed set in  $M\Pi^*$ , and let  $C'$  be the rotations in  $M\Pi^* - C$ , and let  $C'^d$  be the duals, in  $F\Pi^*$ , of the rotations in  $C'$ . If  $C$  is closed in  $M\Pi^*$ , then  $C'^d$  is closed in  $F\Pi^*$ , and hence their union is closed in  $\Pi^*$ , and since the union contains exactly one of each dual pair, it represents a stable assignment in  $RMP$  (stable marriage in  $MP$ ). The converse is obviously also true. Hence, there is a one-one correspondence between the closed sets in  $M\Pi^*$  (without further constraints) and the stable marriages of  $MP$ .

This paper introduced the concepts of dual rotation and singleton rotation. Facts 1 and 4 explain why these concepts were not needed in the structure of stable marriage. Although the exposition is quite different here, the representation of the set of stable marriages given in [IL] can be expressed as  $M\Pi^*$ . Facts 3 and 4 help "explain" why the representation of stable marriages is simpler than the representation of stable assignments: each closed subset in  $M\Pi^*$  represents a stable marriage, and conversely, while in the general case of stable assignment, only particular, highly constrained closed subsets in  $\Pi^*$  represent stable assignments. This also partly "explains" why each stable marriage can be constructed in  $O(n)$  time in [G], while in this paper,  $O(n^2)$  time for each stable assignment is the best bound obtained. Hence what makes the roommate problem more involved is the existence of singleton rotations, and the fact that the nonsingletons do not partition in a nice way, as they do in the marriage problem. As a final comment, note that given fact 1, all rotations in  $M\Pi^*$  can be obtained from a single pass through Algorithm I in  $O(n^2)$  time. This bound was first

obtained for the stable marriage problem by a very different method and argument in [G].

**9. Open problems.** First, given the  $O(n)$ -time method in [G] to enumerate each stable marriage, compared to the  $O(n^2)$  method for the more general problem of stable assignment, a natural problem is to bring down the time for enumerating assignments, or to more fully explain why the stable assignment problem is more complex than the marriage problem. Second, the  $O(n^3 \log n)$  bound for finding all the rotations, and hence the stable pairs, seems too large. We conjecture that  $O(n^2)$  is the correct bound, and that the singletons should be recognizable after a single execution of Algorithm I. It seems likely that there are additional structural observations about rotations that will lead to this time bound. For example, it is an easy corollary of Theorem 6.1 that if  $R = (E, H, S)$  is a rotation such that  $E \cap H \neq \emptyset$ , then  $R$  is a singleton rotation. In the example presented in this paper, that fact identifies the singletons, but it is not true in general that for every singleton rotation  $E \cap H \neq \emptyset$ . Finally, there is the more general question of what algebraic structure is generated by the set of stable assignments, under some reasonable relation. It is known that the stable marriages generate a distributive lattice under the relation of "domination" [K], and as pointed out in [GILS], this is the essential key to the efficient representation of the set of stable marriages. Further, there is a good sized class of interesting combinatorial problems each of whose solution sets generate a distributive lattice over some natural relation. It then follows (see [IR] or [N]) that for each of these problems, the solution sets can be represented by a compact partial order where the solutions are in one-one correspondence with the closed subsets of the partial order, although the time needed to find the partial order and to extract the solutions differs in each case. This partial order representation has many algorithmic uses; applications in stable marriage appear in [IL], [ILG] and [GILS], but there are many other applications in other combinatorial problems (see [IR] for a good bibliography). The stable assignments are not known to be representable as closed subsets in a partial order, but their representation in  $\Pi$  (closed subsets which contain exactly one of each dual pair) is certainly related, and it raises the question of whether an algebraic study of this structure would be fruitful. In particular: what sort of algebraic structure do these closed subsets of  $\Pi$  generate, and is there a natural relation that ties them together? Is there an interesting general class of problems with this structure? Can such problems be reduced to problems of the first (seemingly simpler) type? Does this more general algebraic approach lead to more efficient or generalizable algorithms?

**History and acknowledgments.** The structure  $\Pi^*$ , the material in §§ 1-5.2, and in §§ 7 and 8, were first derived and presented in [G2]. That report then used  $\Pi^*$  to efficiently reduce the roommate problem to the marriage problem. However, the "proof" of that reduction was in error, and the main corollary of the reduction, the claimed "partition theorem," is not true. I thank Sally Floyd for first catching this error and Robert Irving for finding the same error. The present paper, with its focus on enumeration, first appeared as [G3]. Independently, Robert Irving [I1] developed a different approach leading to a structure similar to  $\Pi^*$ , and an enumeration method similar to the method presented in this paper. His report also gives a solution to the minimum regret stable roommate problem.

I want to thank the students in the fall 1985 Yale computer science 260 class, who generated many useful execution trees at the beginning of this research; the trees of A. Zoler and E. Winters were particularly helpful, the latter demonstrating a counter-

example to an early conjecture. I thank David Warren who acted as a sounding-board, and who contributed the version of Phase 1 of Algorithm I that appears in this paper. Particular thanks go to Dana Angluin, who listened to many parts of this work as it developed. Finally, I thank Carrie Shepard, my stable roommate and partner in stable marriage.

## PARALLEL MERGE SORT\*

RICHARD COLE†

**Abstract.** We give a parallel implementation of merge sort on a CREW PRAM that uses  $n$  processors and  $O(\log n)$  time; the constant in the running time is small. We also give a more complex version of the algorithm for the EREW PRAM; it also uses  $n$  processors and  $O(\log n)$  time. The constant in the running time is still moderate, though not as small.

**Key words.** sort, merge, parallel algorithm, sample

**AMS(MOS) subject classifications.** 68E05, 68C05, 68C25

**1. Introduction.** There are a variety of models in which parallel algorithms can be designed. For sorting, two models are usually considered: circuits and the PRAM; the circuit model is the more restrictive. An early result in this area was the sorting circuit due to Batcher [B-68]; it uses time  $\frac{1}{2} \log^2 n$ . More recently, Ajtai et al. [AKS-83] gave a sorting circuit that ran in  $O(\log n)$  time; however, the constant in the running time was very large (we will refer to this as the AKS network). The huge size of the constant is due, in part, to the use of expander graphs in the circuit. The recent result of Lubotzky et al. [LPS-86] concerning expander graphs may well reduce this constant considerably; however, it appears that the constant is still large [CO-86], [Pa-87].

The PRAM provides an alternative, and less restrictive, computation model. There are three variants of this model that are frequently used: the CRCW PRAM, the CREW PRAM, and the EREW PRAM; the first model allows concurrent access to a memory location both for reading and writing, the second model allows concurrent access only for reading, while the third model does not allow concurrent access to a memory location. A sorting circuit can be implemented in any of these models (without loss of efficiency).

Preparata [Pr-78] gave a sorting algorithm for the CREW PRAM that ran in  $O(\log n)$  time on  $(n \log n)$  processors; the constant in the running time was small. (In fact, there were some implementation details left incomplete in this algorithm; this was rectified by Borodin and Hopcroft in [BH-85].) Preparata's algorithm was based on a merging procedure given by Valiant [V-75]; this procedure merges two sorted arrays, each of length at most  $n$ , in time  $O(\log \log n)$  using a linear number of processors. When used in the obvious way, Valiant's procedure leads to an implementation of merge sort on  $n$  processors using  $O(\log n \log \log n)$  time. More recently, Kruskal [K-83] improved this sorting algorithm to obtain a sorting algorithm that ran in time  $O(\log n \log \log n / \log \log \log n)$  on  $n$  processors. (The basic algorithm was Preparata's; however, a different choice of parameters was made.) In part, Kruskal's algorithm depended on using the most efficient versions of Valiant's merging algorithm; these are also described in Kruskal's paper.

More recently, Bilardi and Nicolau [BN-86] gave an implementation of bitonic sort on the EREW PRAM that used  $n/\log n$  processors and  $O(\log^2 n)$  time. The constant in the running time was small.

† Courant Institute of Mathematical Sciences, New York University, New York, New York 10012.

In the next section, we describe a simple CREW PRAM sorting algorithm that uses  $n$  processors and runs in time  $O(\log n)$ ; the algorithm performs just  $5/2n \log n$  comparisons. In § 3, we modify the algorithm to run on the EREW PRAM. The algorithm still runs in time  $O(\log n)$  on  $n$  processors; however, the constant in the running time is somewhat less small than for the CREW algorithm. We note that apart from the AKS sorting network, the known deterministic EREW sorting algorithms that use about  $n$  processors all run in time  $O(\log^2 n)$  (these algorithms are implementations of the various sorting networks such as Batcher's sort). Our algorithms will not make use of expander graphs or any related constructs; this avoids the huge constants in the running time associated with the AKS construction.

The contribution of this work is twofold: first, it provides a second  $O(\log n)$  time,  $n$  processor parallel sorting algorithm (the first such algorithm is implied by the AKS sorting circuit); second, it considerably reduces the constant in the running time (by comparison with the AKS result). Of course, AKS is a sorting circuit; this work does not provide a sorting circuit.

In § 4, we show how to modify the CREW algorithm to obtain CRCW sorting algorithms that run in sublogarithmic time. We will also mention some open problems concerning sorting on the PRAM model in sublogarithmic time. In § 5, we consider a parametric search technique due to Megiddo [M-83]; we show that the partial improvement of this technique in [C-87b] is enhanced by using the EREW sorting algorithm.

**2. The CREW algorithm.** By way of motivation, let us consider the natural tree-based merge sort. Consider an algorithm for sorting  $n$  numbers. For simplicity, suppose that  $n$  is a power of 2, and all the items are distinct. The algorithm will use an  $n$ -leaf complete binary tree. Initially, the inputs are distributed one per leaf. The task, at each internal node  $u$  of the tree, is to compute the sorted order for the items initially at the leaves of the subtree rooted at  $u$ . The computation proceeds up the tree, level by level, from the leaves to the root, as follows. At each node we compute the merge of the sorted sets computed at its children. Use of the  $O(\log \log n)$  time,  $n$  processor merging algorithm of Valiant, will yield an  $O(\log n \log \log n)$  time,  $n$  processor sorting algorithm. In fact, we know there is an  $\Omega(\log \log n)$  time lower bound for merging two sorted arrays of  $n$  items using  $n$  processors [BH-85]; thus we do not expect this approach to lead to an  $O(\log n)$  time,  $n$  processor sorting algorithm.

We will not use the fast  $O(\log \log n)$  time merging procedure; instead, we base our algorithm on an  $O(\log n)$  time merging procedure, similar to the one described in the next few sentences. The problem is to merge two sorted arrays of  $n$  items. We proceed in  $\log n$  stages. In the  $i$ th stage, for each array, we take a sorted sample of  $2^{i-1}$  items, comprising every  $n/2^{i-1}$ th item in the array. We compute the merge of these two samples. Given the results of the merge from the  $i-1$ st stage, the merge in the  $i$ th stage can be computed in constant time (this, or rather a related result, will be justified later).

At present, this merging procedure merely leads to an  $O(\log^2 n)$  time sorting algorithm. To obtain an  $O(\log n)$  time sorting algorithm we need the following key observation:

The merges at the different levels of the tree can be pipelined.

This is plausible because merged samples from one level of the tree provide fairly good samples at the next level of the tree. Making this statement precise is the key to the CREW algorithm.

We now describe our sorting algorithm. The inputs are placed at the leaves of the tree. Let  $u$  be an internal node of the tree. The task, at node  $u$ , is to compute  $L(u)$ , the sorted array that contains the items initially at the leaves of the subtree rooted at  $u$ . At intermediate steps in the computation, at node  $u$ , we will have computed  $UP(u)$ , a sorted subset of the items in  $L(u)$ ;  $UP(u)$  will be stored in an array also. The items in  $UP(u)$  will be a rough sample of the items in  $L(u)$ . As the algorithm proceeds, the size of  $UP(u)$  increases, and  $UP(u)$  becomes a more accurate approximation of  $L(u)$ . (Note that at each stage we use a different array for  $UP(u)$ .)

We explain the processing performed in one stage at an arbitrary internal node  $u$  of the tree. The array  $UP(u)$  is the array at hand at the start of the stage;  $NEWUP(u)$  is the array at hand at the start of the next stage, and  $OLDUP(u)$  is the array at hand at the start of the previous stage, if any. Also, in each stage, we will create an array  $SUP(u)$  (short for  $SAMPLEUP(u)$ ) at node  $u$ ;  $NEWSUP(u)$ ,  $OLDSUP(u)$  are the corresponding arrays in respectively, the next, and previous, stage.  $SUP(u)$  is a sorted array comprising every fourth item in  $UP(u)$ , measured from the right end; i.e., if  $|UP(u)| = m$ , then  $SUP(u)$  contains the items of rank  $m - 3 - 4i$  in  $UP(u)$ , for  $0 \leq i < \lfloor m/4 \rfloor$ . At each stage, for each node  $u$ , the computation comprises the following two phases.

- (1) Form the array  $SUP(u)$ .
- (2) Let  $v$  and  $w$  be  $u$ 's children. Compute  $NEWUP(u) = SUP(v) \cup SUP(w)$ , where  $\cup$  denotes merging.

There are some boundary cases where we need to change Phase 1. (For example, initially, the  $UP$  arrays each contain one or zero items. Thus, the  $SUP$  arrays would all be empty and the algorithm would do nothing.) In view of this, we establish the following goal: at each stage, so long as  $0 \neq |UP(u)| \neq |L(u)|$ , the size of  $NEWUP(u)$  is to be twice the size of  $UP(u)$ . At this point, some definitions will be helpful. A node is *external* if  $|UP(u)| = |L(u)|$ , and it is *inside* otherwise. Phases 1 and 2, above, are performed at each inside node. At external nodes, Phase 2 is not performed and Phase 1 is modified as follows. For the first stage in which  $u$  is external, Phase 1 is unchanged. For the second stage,  $SUP(u)$  is defined to be every second item in  $UP(u)$ , in sorted order. And for the third stage,  $SUP(u)$  is defined to be every item in  $UP(u)$ , in sorted order. It should be clear that we have achieved our goal, namely, the following lemma.

LEMMA 1. *While  $0 < |UP(u)| < |L(u)|$ ,  $|NEWUP(u)| = 2|UP(u)|$ .*

It is also clear that 3 stages after node  $u$  becomes external, node  $t$ , the parent of  $u$ , also becomes external. We conclude the following.

LEMMA 2. *The algorithm has  $3 \log n$  stages.*

It remains for us to show how to perform the merges needed for Phase 2. We will show that they can be performed in constant time using  $O(n)$  processors. This yields the  $O(\log n)$  running time for the sorting algorithm.

A few definitions will be helpful. Let  $e, f, g$  be three items, with  $e < g$ .  $f$  is *between*  $e$  and  $g$  if  $e \leq f$  and  $f < g$ ; we also say that  $e$  and  $g$  *straddle*  $f$ . Let  $L$  and  $J$  be sorted arrays. Let  $f$  be an item in  $J$ , and let  $e$  and  $g$  be the two adjacent items in  $L$  that straddle  $f$  (if necessary, we let  $e = -\infty$  or  $g = \infty$ ); then the *rank* of  $f$  in  $L$  is defined to be the rank of  $e$  in  $L$  (if  $e = -\infty$ ,  $f$  is defined to have rank 0). We define the range  $[e, g)$  to be the interval *induced* by item  $e$  (including the cases  $e = -\infty$  and  $g = \infty$ ).  $L$  is a *c-cover* of  $J$  if each interval induced by an item in  $L$  contains at most  $c$  items from  $J$ . We also say that the items from  $J$  in the range  $[e, g)$  are *contained* in  $e$ 's interval. We define  $L$  to be ranked in  $J$  (denoted  $L \rightarrow J$ ) if for each item in  $L$  we know its rank in  $J$ , and we define  $L$  and  $J$  to be *cross-ranked* (denoted  $L \times J$ ) if both  $L \rightarrow J$  and  $J \rightarrow L$ .

We will need the following observation to show that the merge can be performed in  $O(1)$  time:

$OLDSUP(v)$  is a 3-cover for  $SUP(v)$  for each node  $v$ ; as  $UP(u) = OLDSUP(v) \cup OLDSUP(w)$ , we deduce  $UP(u)$  is a 3-cover for  $SUP(v)$ ; similarly,  $UP(u)$  is a 3-cover for  $SUP(w)$ .

This will be shown in Corollary 1, below. But first, we describe the merge (Phase 2).

We need some additional information in order to perform the merge quickly. Specifically, we assume  $UP(u) \rightarrow SUP(v)$ ,  $UP(u) \rightarrow SUP(w)$  are available. Using these rankings, in Step 1 we compute  $NEWUP(u)$ , and in Step 2 we compute  $NEWUP(u) \rightarrow NEWSUP(v)$  and  $NEWUP(u) \rightarrow NEWSUP(w)$ .

*Step 1—computing  $NEWUP(u)$ .* Let  $e$  be an item in  $SUP(v)$ ; the rank of  $e$  in  $NEWUP(u) = SUP(v) \cup SUP(w)$  is equal to the sum of its ranks in  $SUP(v)$  and  $SUP(w)$ . So to compute the merge we cross-rank  $SUP(v)$  and  $SUP(w)$  (the method is given in the following two paragraphs). At this point, for each item  $e$  in  $SUP(v)$ , besides knowing its rank in  $NEWUP(u)$ , we know the two items  $d$  and  $f$  in  $SUP(w)$  that straddle  $e$ , and we know the ranks of  $d$  and  $f$  in  $NEWUP(u)$  (these will be needed in Step 2). For each item in  $NEWUP(u)$  we record whether it came from  $SUP(v)$  or  $SUP(w)$  and we record the ranks (in  $NEWUP(u)$ ) of the two straddling items from the other set.

Let  $e$  be an item in  $SUP(v)$ ; we show how to compute its rank in  $SUP(w)$ . We proceed in two substeps.

*Substep 1.* For each item in  $SUP(v)$  we compute its rank in  $UP(u)$ . This task is performed by processors associated with the items in  $UP(u)$ , as follows. Let  $y$  be an item in  $UP(u)$ . Consider the interval  $I(y)$  in  $UP(u)$  induced by  $y$ , and consider the items in  $SUP(v)$  contained in  $I(y)$  (there are at most three such items by the 3-cover property). Each of these items is given its rank in  $UP(u)$  by the processor associated with  $y$ . Substep 1 takes constant time if we associate one processor with each item in the  $UP$  array at each inside node.

*Substep 2.* (See Fig. 1.) For each item  $e$  in  $SUP(v)$  we compute the rank of  $e$  in  $SUP(w)$ . We determine the two items  $d$  and  $f$  in  $UP(u)$  that straddle  $e$ , using the rank computed in Substep 1. Suppose that  $d$  and  $f$  have ranks  $r$  and  $t$ , respectively, in  $SUP(w)$ . Then all items of rank  $r$  or less are smaller than item  $e$  (recall we assumed that all the inputs were distinct), while all items of rank greater than  $t$  are larger than item  $e$ ; thus the only items about which there is any doubt as to their size relative to  $e$  are the items with rank  $s$ ,  $r < s \leq t$ . But there are at most three such items by the 3-cover property. By means of at most two comparisons, the relative order of  $e$  and these (at most) three items can be determined. So Substep 2 requires constant time if we associate one processor with each item in each  $SUP$  array.

FIG. 1

*Step 2—maintaining ranks.* For each item  $e$  in  $\text{NEWUP}(u)$ , we want to determine its rank in  $\text{NEWSUP}(v)$  (and in  $\text{NEWSUP}(w)$ , using an analogous method). We start by making a few observations. Given the ranks for an item from  $\text{UP}(u)$  in both  $\text{SUP}(v)$  and  $\text{SUP}(w)$  we can immediately deduce the rank of this item in  $\text{NEWUP}(u) = \text{SUP}(v) \cup \text{SUP}(w)$  (the new rank is just the sum of the two old ranks). Similarly, we obtain the ranks for items from  $\text{UP}(v)$  in  $\text{NEWUP}(v)$ . This yields the ranks of items from  $\text{SUP}(v)$  in  $\text{NEWSUP}(v)$  (for each item in  $\text{SUP}(v)$  came from  $\text{UP}(v)$ , and  $\text{NEWSUP}(v)$  comprises every fourth item in  $\text{NEWUP}(v)$ ). Thus, for every item  $e$  in  $\text{NEWUP}(u)$  that came from  $\text{SUP}(v)$  we have its rank in  $\text{NEWSUP}(v)$ ; it remains to compute this rank for those items  $e$  in  $\text{NEWUP}(u)$  that came from  $\text{SUP}(w)$ .

Recall that for each item  $e$  from  $\text{SUP}(w)$  we computed the straddling items  $d$  and  $f$  from  $\text{SUP}(v)$  (in Step 1). (See Fig. 2.) We know the ranks  $r$  and  $t$  of  $d$  and  $f$ , respectively, in  $\text{NEWSUP}(v)$  (as asserted in the previous paragraph). Every item of rank  $r$  or less in  $\text{NEWSUP}(v)$  is smaller than  $e$ , while every item of rank greater than  $t$  is larger than  $e$ ; thus, the only items about which there is any doubt concerning their size relative to  $e$  are the items with rank  $s$ ,  $r < s \leq t$ . But there are at most three such items by the 3-cover property. As before, the relative order of  $e$  and these (at most) three items can be determined by means of at most two comparisons. Thus, Step 2 takes constant time if we associate a processor with each item in the  $\text{NEWUP}$  array at each inside node.

FIG. 2

It remains to prove the 3-cover property (Corollary 1 to Lemma 3) and to determine the complexity of the algorithm (Lemmas 4 and 5).

**LEMMA 3.** *Let  $k \geq 1$ . In each stage, any  $k$  adjacent intervals in  $\text{SUP}(u)$  contain at most  $2k + 1$  items from  $\text{NEWSUP}(u)$ .*

*Proof.* We prove the result by induction on the (implicit) stage number. The claim is true initially, for when  $\text{SUP}(u)$  first becomes nonempty, it contains one item and  $\text{NEWSUP}(u)$  contains two items, and when  $\text{SUP}(u)$  is empty,  $\text{NEWSUP}(u)$  contains at most one item.

*Inductive step.* We seek to prove that  $k$  adjacent intervals in  $\text{SUP}(u)$  contain at most  $2k + 1$  items from  $\text{NEWSUP}(u)$ , assuming that the result is true for the previous stage, i.e., that for all nodes  $u'$ , for all  $k' \geq 1$ ,  $k'$  intervals in  $\text{OLDSUP}(u')$  contain at most  $2k' + 1$  items from  $\text{SUP}(u')$ .

We first suppose that  $u$  is not external at the start of the current stage. (See Fig. 3.) Consider a sequence of  $k$  adjacent intervals in  $\text{SUP}(u)$ ; they cover the same range as some sequence of  $4k$  adjacent intervals in  $\text{UP}(u)$ . Recall that  $\text{UP}(u) = \text{OLDSUP}(v) \cup \text{OLDSUP}(w)$ . The  $4k$  intervals in  $\text{UP}(u)$  overlap some  $h \geq 1$  adjacent intervals in  $\text{OLDSUP}(v)$  and some  $j \geq 1$  adjacent intervals in  $\text{OLDSUP}(w)$ , with  $h + j = 4k + 1$ . The  $h$  intervals in  $\text{OLDSUP}(v)$  contain at most  $2h + 1$  items from  $\text{SUP}(v)$ , by the inductive hypothesis, and likewise, the  $j$  intervals in  $\text{OLDSUP}(w)$  contain at

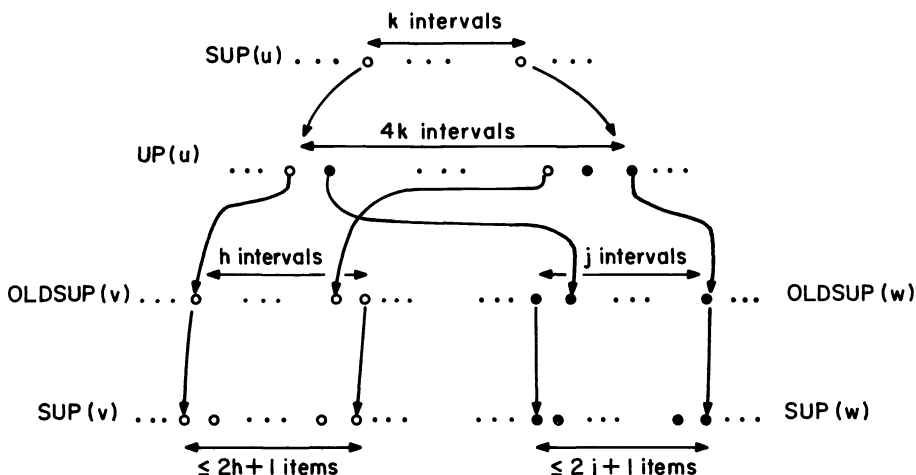

FIG. 3

most  $2j + 1$  items from  $SUP(w)$ . Recall that  $NEWSUP(u) = SUP(v) \cup SUP(w)$ . Thus the  $4k$  intervals in  $UP(u)$  contain at most  $2h + 2j + 2 = 8k + 4$  items from  $NEWSUP(u)$ . But  $NEWSUP(u)$  comprises every fourth item in  $NEWSUP(u)$ ; thus the  $k$  adjacent intervals in  $SUP(u)$  contain at most  $2k + 1$  items from  $NEWSUP(u)$ .

It remains to prove the lemma for the first and second stages in which  $u$  is external (for the third stage in which  $u$  is external there is no  $NEWSUP(u)$  array, and hence no  $NEWSUP(u)$  array). Here we can make the following stronger claim concerning the relationship between  $SUP(u)$  and  $NEWSUP(u)$ :  $k$  adjacent intervals in  $SUP(u)$  contain exactly  $2k$  items from  $NEWSUP(u)$  and every item in  $SUP(u)$  occurs in  $NEWSUP(u)$ . This is readily seen. Consider the first stage in which  $u$  is external.  $SUP(u)$  comprises every fourth item in  $UP(u) = L(u)$  and  $NEWSUP(u)$  comprises every second item in  $UP(u)$ . Clearly the claim is true for this stage; the argument is similar for the second stage.  $\square$

Taking  $k = 1$  we obtain the following.

**COROLLARY 1.**  $SUP(u)$  is a 3-cover of  $NEWSUP(u)$ .

*Remark.* An attempt to prove Lemma 3, in the same way, with a sampling strategy of every second (rather than every fourth) item will not succeed. This explains why we chose the present sampling strategy. It is not the only strategy that will work (another possibility is to sample every eighth item, or even to use a mixed strategy, such as using samples comprising every second and every fourth item, respectively, at alternate levels of the tree); however, the present strategy appears to yield the best constants.

We turn to the analysis of the algorithm. We start by computing the total number of items in the UP arrays. If  $|UP(u)| \neq 0$  and  $v$  is not external, then  $2|UP(u)| = |NEWSUP(u)| = |SUP(v)| + |SUP(w)| = \frac{1}{4}(|UP(v)| + |UP(w)|) = \frac{1}{2}|UP(v)|$ ; that is:

*Observation.*  $|UP(u)| = \frac{1}{4}|UP(v)|$ . So the total size of the UP arrays at  $u$ 's level is  $\frac{1}{8}$  of the size of the UP arrays at  $v$ 's level, if  $v$  is not external.

The observation need not be true at external nodes  $v$ . It is true for the first stage in which  $v$  is external; but for the second stage,  $|UP(u)| = \frac{1}{2}|UP(v)|$ , and so the total size of the UP arrays at  $u$ 's level is  $\frac{1}{4}$  of the total size of the arrays at  $v$ 's level; likewise, for the third stage,  $|UP(u)| = |UP(v)|$ , and so the total size of the UP arrays at  $u$ 's level is  $\frac{1}{2}$  of the total size of the UP arrays at  $v$ 's level.

Thus, on the first stage in which  $v$  is external, the total size of the UP arrays is bounded above by  $n + n/8 + n/64 + \dots = n + n/7$ ; on the second stage, by  $n + n/4 + n/32 + \dots = n + 2n/7$ ; on the third stage, by  $n + n/2 + n/16 + \dots = n + 4n/7$ . Similarly, on the first stage, the total size of the SUP arrays (and hence of the NEWUP arrays at inside nodes) is bounded above by  $n/4 + n/32 + n/256 + \dots = 2n/7$ ; on the second stage, by  $n/2 + n/16 + n/128 + \dots = 4n/7$ ; on the third stage, by  $n + n/8 + n/64 + \dots = 8n/7$ .

We conclude that the algorithm needs  $O(n)$  processors (so as to have a processor standing by each item in the UP, SUP, and NEWUP arrays) and takes constant time. Let us count precisely how many comparisons the algorithm performs.

LEMMA 4. *The algorithm performs  $15/4n \log n$  comparisons.*

*Proof.* Comparisons are performed in Substep 2 of Step 1 and in Step 2. In Step 1, at most 2 comparisons are performed for each item in each SUP array. Over a sequence of three successive stages this is  $2 \cdot (2n/7 + 4n/7 + 8n/7) = 4n$  comparisons. In Step 2, at most 2 comparisons are performed for each item in the NEWUP array at each inside node. Over a sequence of three successive stages this is also  $4n$  comparisons. However, we have overcounted here; on the third stage, in which node  $u$  becomes external, we do not perform any comparisons for items in NEWUP( $u$ ); this reduces the cost of Step 2 to  $2n$  comparisons.

So we have a total of at most  $6n$  comparisons for any three successive stages. However, we are still overcounting; we have not used the fact that during the second and third stages in which node  $v$  is external, SUP( $v$ ) is a 2-cover of NEWSUP( $v$ ) and every item in SUP( $v$ ) occurs in NEWSUP( $v$ ) (see the proof of Lemma 3). This implies that in Step 1, for each item in array SUP( $v$ ), in the second or third stage in which  $v$  is external, at most one comparison need be made (and not two). This reduces the number of comparisons in Step 1, over a sequence of three stages, by  $n/2 + n = 3/2n$ . Likewise, in Step 2, for each item in array NEWUP( $u$ ), in the first or second stages in which the children of  $u$  are external nodes, at most one comparison is performed. This reduces the number of comparisons in Step 2, over a sequence of three stages, by  $n/4 + n/2 = 3/4n$ . Thus the total number of comparisons, over the course of three successive stages, is  $5/2n$  for Step 1, and  $5/4n$  for Step 2, a total of  $15/4n$  comparisons.  $\square$

In order to reduce the number of comparisons to  $5/2n \log n$ , we need to modify the algorithm slightly. More specifically, we modify Step 1, as follows, so that it performs a total of  $5/4n \log n$  comparisons, rather than  $5/2n \log n$  comparisons. When computing the rank of each item from SUP( $v$ ) (respectively, SUP( $w$ )) in SUP( $w$ ) (respectively, SUP( $v$ )), we will allow only the items in SUP( $v$ ) to perform comparisons (or rather, processors associated with these items). We compute the ranks for items from SUP( $v$ ) as before. To obtain the ranks for items from SUP( $w$ ) we need to change both substeps. We change Substep 1 as follows. For each item  $h$  in SUP( $w$ ), we compute its rank  $r$  in UP( $u$ ) as before (the old Substep 1). Let  $k$  be the item of rank  $r$  in UP( $u$ ), and let  $s$  be the rank of  $k$  in SUP( $v$ ). We also store the rank  $s$  with item  $h$ .  $s$  is a good estimate of the rank of  $h$  in SUP( $v$ ); it is at most three smaller than the actual rank. We change Substep 2 as follows. (See Fig. 4.) Item  $e$  in SUP( $v$ ), of rank  $t$ , communicates its rank to the following, at most three, receiving items in SUP( $w$ ): those items with rank  $t$  in SUP( $v$ ) which at present store a smaller estimate for this rank. (These items are determined as follows. Let  $d$  and  $f$  be the items from UP( $u$ ) that straddle  $e$ . Let  $g$  be the successor of  $e$  in SUP( $v$ ). The receiving items are exactly those items straddled both by  $e$  and  $g$ , and by  $d$  and  $f$ ; the second constraint implies that there are at most three receiving items for  $e$ , by the 3-cover property.) For those items  $h$  in SUP( $w$ ) that

FIG. 4

do not receive a new rank from an item in  $SUP(v)$ , the rank  $s$  computed in the modified Substep 1 is the correct rank.

This new procedure reduces the number of comparisons in Step 1 by a factor of 2, and leaves unaltered the number of comparisons in Step 2. We conclude the following.

LEMMA 5. *The algorithm performs  $5/2n \log n$  comparisons.*

We have shown the following.

THEOREM 1. *There is a CREW PRAM sorting algorithm that runs in  $O(\log n)$  time on  $n$  processors, performing at most  $5/2n \log n$  comparisons.*

Remark. The algorithm needs only  $O(n)$  space. For although each stage requires  $O(n)$  space, the space can be reused from stage to stage.

**3. The EREW algorithm.** The algorithm from § 2 is not EREW at present. While it is possible to modify Step 1 of a phase so that it runs in constant time on an EREW PRAM, the same does not appear to be true for Step 2. Since we use a somewhat different merging procedure here, we will not explain how Step 1 can be modified. However, we do explain the difficulty faced in making Step 2 run in constant time on an EREW PRAM. The explanation follows. Consider  $NEWUP(u)$  and consider  $e$  and  $g$ , two items adjacent in  $SUP(v)$ ; suppose that in  $NEWUP(u)$ , between  $e$  and  $g$ , there are many items  $f$  from  $SUP(w)$ . Let  $f'$  be an item in  $NEWSUP(v)$ , between  $e$  and  $g$ . (See Fig. 5.) The difficulty is that for each item  $f$  we have to decide the relative order of  $f$  and  $f'$ ; furthermore, the decision must be made in constant time, without read conflicts, for every such item  $f$ . This cannot be done. To obtain an optimal logarithmic time EREW sorting algorithm we need to modify our approach. Essentially, the modification causes this difficult computation to become easy by precomputing most of the result.

We now describe the EREW algorithm precisely. We use the same tree as for the CREW algorithm. At each node  $v$  of the tree we maintain two arrays:  $UP(v)$  (defined as before), and  $DOWN(v)$  (to be defined). We define the array  $SUP(v)$  as before; we introduce a second sample array,  $SDOWN(v)$ : it comprises every fourth item in

FIG. 5

$\text{DOWN}(v)$ . Let  $u$ ,  $w$ ,  $x$ , and  $y$  be, respectively, the parent, sibling, left child, and right child of  $v$ . A stage of the algorithm comprises the following three steps, performed at each node  $v$ .

- (1) Form the arrays  $\text{SUP}(v)$  and  $\text{SDOWN}(v)$ .
- (2) Compute  $\text{NEWUP}(v) = \text{SUP}(x) \cup \text{SUP}(y)$ .
- (3) Compute  $\text{NEWDOWN}(v) = \text{SUP}(w) \cup \text{SDOWN}(u)$ .

We will need to maintain some other arrays in order to perform the merges in constant time; namely, the arrays  $\text{UP}(v) \cup \text{SDOWN}(v)$  and  $\text{SUP}(v) \cup \text{SDOWN}(v)$ . It is useful to note that  $\text{SDOWN}(v)$  is a 3-cover of  $\text{NEWDOWN}(v)$ ; the proof of this result is identical to the proof of the 3-cover property for the  $\text{SUP}$  arrays (given in Lemma 3 and Corollary 1).

We describe the new merging procedure. Assume that  $J$  and  $K$  are two sorted arrays of distinct items,  $J$  and  $K$  having no items in common. We show how to compute  $J \times K$  in constant time using a linear number of processors (this yields  $L = J \cup K$ ), supposing that we are given the following arrays and rankings (see Fig. 6):

- (i) Arrays  $SJ$  and  $SK$  that are 3-covers for  $J$  and  $K$ , respectively.
- (ii)  $SJ \times SK$  and  $SL = SJ \cup SK$ .
- (iii)  $SK \rightarrow J$  and  $SJ \rightarrow K$ .
- (iv)  $SJ \rightarrow J$  and  $SK \rightarrow K$ .

We will also compute  $SL \rightarrow L$ .

We note that the interval  $I$  between two adjacent items,  $e$  and  $f$ , from  $SL = SJ \cup SK$  contains at most three items from each of  $J$  and  $K$ . In order to cross-rank  $J$  and  $K$ , it suffices, for each such interval, to determine the relative order of the (at most) six items it contains. To carry out this procedure we associate one processor with each interval in the array  $SL$ . The number of intervals is one larger than the number of items in this array. The cross-ranking proceeds in two substeps: for each interval  $I$  in  $SL$ , in Substep 1 we identify the two sets of (at most) 3 items contained in  $I$ , and in Substep 2 we compute the cross-rankings for the items contained in  $I$ .

FIG. 6

**Substep 1.** The (at most) three items from  $J$  are those straddled by  $e$  and  $f$ . If  $e$  is in  $SJ$  (respectively,  $SK$ ) we determine the leftmost of these (at most) three items using  $SJ \rightarrow J$  (respectively,  $SK \rightarrow J$ ); the rightmost item is obtained similarly. The (at most) three items from  $K$  are computed analogously.

**Substep 2.** This substep is straightforward; for each interval in  $SL$ , it requires at most five comparisons, and a constant number of other operations.

**Computing  $SL \rightarrow L$ .** For each item  $e$  in  $SL$ , we simply add its ranks in  $J$  and  $K$ , which yields its rank in  $L$  (these ranks are obtained from  $SJ \rightarrow J$  and  $SJ \rightarrow K$  if  $e$  is from  $SJ$ , and from  $SK \rightarrow J$  and  $SK \rightarrow K$  if  $e$  is from  $SK$ ).

*Remark.* If  $SJ$  (respectively,  $SK$ ) is a 4-cover of  $J$  (respectively,  $K$ ) but  $SJ$  (respectively,  $SK$ ) is contained in  $J$  (respectively,  $K$ ) then (essentially) the same algorithm can be used, since the interior of any interval in  $SL$  will still contain at most three items from  $J$  and at most three items from  $K$ .

We return to the EREW sorting algorithm. We suppose that the following rankings are available at the start of a phase at each node  $v$  (see Fig. 7):

- (a)  $OLDSUP(x) \times OLDSUP(y)$ .
- (b)  $OLDSUP(v) \rightarrow SUP(v)$ .
- (c)  $OLDSUP(w) \times OLDSDOWN(u)$ .
- (d)  $OLDSDOWN(v) \rightarrow SDOWN(v)$ .
- (e)  $SUP(v) \times SDOWN(v)$ .
- (f)  $UP(v) \times SDOWN(v)$ .
- (g)  $SUP(v) \times DOWN(v)$ .

In addition, we note that since  $DOWN(v) = OLDSUP(w) \cup OLDSDOWN(u)$ , and as we have  $SUP(v) \times DOWN(v)$  from (g), we can immediately obtain:

- (h)  $OLDSUP(w) \rightarrow SUP(v)$ .
- (i)  $OLDSDOWN(u) \rightarrow SUP(v)$ .

Likewise, from  $UP(v) = OLDSUP(x) \cup OLDSUP(y)$  and from (f),  $UP(v) \times SDOWN(v)$ , we obtain:

- (j)  $OLDSUP(x) \rightarrow SDOWN(v)$ ,  $OLDSUP(y) \rightarrow SDOWN(v)$ .

The computation of (a)-(g) for the next stage at node  $v$  proceeds in five steps. In Step 1 we compute (a) and (b), in Step 2, (c) and (d), in Step 3, (e), in Step 4, (f), and in Step 5, (g).

*Remark.* We note that all the items in  $DOWN(u)$  come from outside the subtree rooted at  $u$  (this is easily verified by induction). This implies that  $SUP(w)$  and  $SDOWN(u)$  have no items in common, and likewise for  $UP(v)$  and  $DOWN(v)$ . Thus, all the cross-rankings  $J \times K$  that we compute below obey the assumption that  $J$  and  $K$  contain no items in common.

*Step 1.* Compute  $SUP(x) \times SUP(y)$  (yielding  $NEWUP(v)$ ). The computation also yields  $UP(v) \rightarrow NEWUP(v)$ , and hence  $SUP(v) \rightarrow NEWSUP(v)$ . (See Fig. 8.) We already have:

- (i)  $OLDSUP(x) \times OLDSUP(y)$  (from (a) at node  $v$ ).
- (ii)  $OLDSUP(x) \rightarrow SUP(y)$  (from (h) at node  $y$ ).
- (iii)  $OLDSUP(y) \rightarrow SUP(x)$  (from (h) at node  $x$ ).

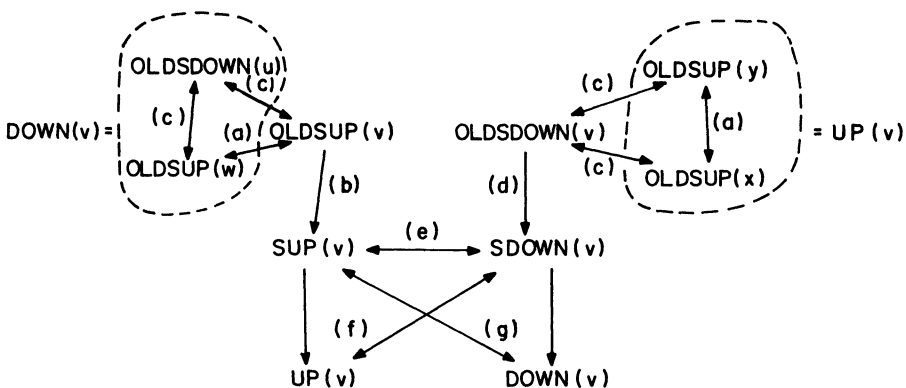

FIG. 7

FIG. 8. Step 1.

(iv)  $OLDSUP(x) \rightarrow SUP(x)$  (from (b) at node  $x$ ).

(v)  $OLDSUP(y) \rightarrow SUP(y)$  (from (b) at node  $y$ ).

Step 2. Compute  $SUP(w) \times SDOWN(u)$  (yielding  $NEWDOWN(v)$ ). This computation also yields  $DOWN(v) \rightarrow NEWDOWN(v)$ , and hence  $SDOWN(v) \rightarrow NEWSDOWN(v)$ . (See Fig. 9.) We already have:

(i)  $OLDSUP(w) \times OLDSDOWN(u)$  (from (c) at node  $v$ ).

(ii)  $OLDSUP(w) \rightarrow SDOWN(u)$  (from (j) at node  $u$ ).

(iii)  $OLDSDOWN(u) \rightarrow SUP(w)$  (from (i) at node  $w$ ).

(iv)  $OLDSUP(w) \rightarrow SUP(w)$  (from (b) at node  $w$ ).

(v)  $OLDSDOWN(u) \rightarrow SDOWN(u)$  (from (d) at node  $u$ ).

Step 3. Compute  $NEWSUP(v) \times NEWSDOWN(v)$ . (See Fig. 10.) We already have:

(i)  $SUP(v) \times SDOWN(v)$  (from (e) at node  $v$ ).

(ii)  $SUP(v) \times NEWSDOWN(v)$ , and hence  $SUP(v) \rightarrow NEWSDOWN(v)$  (this is obtained from:  $SUP(v) \times SUP(w)$ , from Step 1 at node  $u$ , and  $SUP(v) \times SDOWN(u)$ , from Step 2 at node  $w$ , yielding  $SUP(v) \times [SUP(w) \cup SDOWN(u)] = SUP(v) \times NEWSDOWN(v)$ ).

FIG. 9. Step 2.

FIG. 10. Step 3.

- (iii)  $NEWSUP(v) \times SDOWN(v)$ , and hence  $SDOWN(v) \rightarrow NEWSUP(v)$  (this is obtained from  $SUP(x) \times SDOWN(v)$ , from Step 2 at node  $y$ , and  $SUP(y) \times SDOWN(v)$ , from Step 2 at node  $x$ , yielding  $[SUP(x) \cup SUP(y)] \times SDOWN(v) = NEWSUP(v) \times SDOWN(v)$ ).
  - (iv)  $SUP(v) \rightarrow NEWSUP(v)$  (from Step 1 at node  $v$ ).
  - (v)  $SDOWN(v) \rightarrow NEWSDOWN(v)$  (from Step 2 at node  $v$ ).
- Step 4. Compute  $NEWSUP(v) \times NEWSDOWN(v)$ . (See Fig. 11.) We already have:
- (i)  $NEWSUP(v) \times SDOWN(v)$  (from Step 3(iii) at node  $v$ ).
  - (ii)  $SDOWN(v) \rightarrow NEWSUP(v)$  (from Step 3(iii) at node  $v$ ).
  - (iii)  $NEWSUP(v) \rightarrow NEWSDOWN(v)$  (from Step 3 at node  $v$ ).
  - (iv)  $NEWSUP(v) \rightarrow NEWSUP(v)$ .
  - (v)  $SDOWN(v) \rightarrow NEWSDOWN(v)$  (from Step 2 at node  $v$ ).

(Here  $NEWSUP(v)$  is a 4-cover of  $NEWSUP(v)$ , contained in  $NEWSUP(v)$ ; as explained in the remark following the merging procedure, this leaves the complexity of the merging procedure unchanged.)

- Step 5. Compute  $NEWSUP(v) \times NEWSDOWN(v)$ . (See Fig. 12.) We already have:
- (i)  $SUP(v) \times NEWSDOWN(v)$  (from Step 3(ii) at node  $v$ ).
  - (ii)  $SUP(v) \rightarrow NEWSDOWN(v)$  (from Step 3(ii) at node  $v$ ).
  - (iii)  $NEWSDOWN(v) \rightarrow NEWSUP(v)$  (from Step 3 at node  $v$ ).
  - (iv)  $SUP(v) \rightarrow NEWSUP(v)$  (from Step 1 at node  $v$ ).
  - (v)  $NEWSDOWN(v) \rightarrow NEWSDOWN(v)$ .

We conclude that each stage can be performed in constant time, given one processor for each item in each array named in (i) of each step, plus one additional processor per array.

It remains to show that only  $O(n)$  processors are needed by the algorithm. This is a consequence of the following linear bound on the total size of the DOWN arrays.

LEMMA 6.  $|DOWN(v)| \leq 16/31 |SUP(v)|$ .

*Proof.* This is readily verified by induction on the stage number.  $\square$

FIG. 11. Step 4.

FIG. 12. Step 5.

**COROLLARY 2.** *The total size of the DOWN arrays, at any one stage, is  $O(n)$ .*

This algorithm, like the CREW algorithm, has  $3 \log n$  stages. We conclude the following.

**THEOREM 2.** *There is an EREW PRAM algorithm for sorting  $n$  items; it uses  $n$  processors and  $O(n)$  space, and runs in  $O(\log n)$  time.*

We do not give the elaborations to the merging procedure required to obtain a small total number of comparisons (as regards constants). We simply remark that it is not difficult to reduce the total number of comparisons to less than  $5n \log n$  comparisons; however, as there is no corresponding reduction in the number of other operations, this complexity bound gives a misleading impression of efficiency (which is why we do not strive to attain it).

**4. A sublogarithmic time CRCW algorithm.** References [AAV-86] and [AV-87] give tight upper and lower bounds for sorting in the parallel comparison model; using  $p \geq n$  processors to sort  $n$  items the bound is  $\Theta(\log n / \log 2p/n)$ . In addition, there is a lower bound of  $\Omega(\log n / \log \log n)$  for sorting  $n$  items with a polynomial number of processors in the CRCW PRAM model [BH-87]. We give a CRCW algorithm that uses time  $O(\log n / \log \log 2p/n)$  for  $2n \leq p \leq n^2$ . It is not clear which, if any, of the upper and lower bounds are tight for the CRCW PRAM model.

We describe the algorithm; it is very similar to the CREW algorithm. Let  $r = p/n$ . It is convenient to assume that  $n$  is a power of  $r$  (the details of the general case are left to the reader). There are three major changes to the CREW algorithm. First, rather than use a binary tree to guide the merges, we use an  $r$ -way tree. This tree has height  $h = \log n / \log r$ . Second, we define the array  $SUP(v)$  to comprise every  $r^2$  item in  $UP(v)$ , rather than every fourth item; again, at the external nodes we need a special definition, namely:  $SUP(v)$  comprises every  $r^2$  item in the first stage  $v$  is external, every  $r$ th item in the second stage, and every item in the third stage. Third, the array  $NEWUP(v)$  is defined to be the  $r$ -way merge of the  $SUP$  arrays at its  $r$  children. As before, the algorithm will have  $3h = 3 \log n / \log r$  stages. But here, rather than use constant time, each stage will take  $O(\log r / \log \log 2r)$  time.

To obtain the  $r$ -way merge we perform  $\frac{1}{2}r(r-1)$  pairwise merges of the  $r$   $SUP$  arrays. To obtain the rank of an item in the array  $NEWUP(v)$  we sum its ranks in each of the  $r$   $SUP$  arrays. We use  $r$  processors to compute this sum; they take  $O(\log r / \log \log r)$  time on a CRCW PRAM using the summation algorithm from [CV-87].

Before explaining how to perform a single pairwise merge it is useful to prove a cover property.

**LEMMA 7.**  *$k$  intervals in  $SUP(v)$  contain at most  $rk + 1$  items in  $NEWSUP(v)$ .*

*Proof.* The proof is very similar to that of Lemma 2; the details are left to the reader.  $\square$

**COROLLARY 3.**  *$SUP(v)$  is an  $(r+1)$ -cover of  $NEWSUP(v)$ .*

We perform the merges essentially as in the CREW algorithm. Here, at the start of a stage, we need to assume that for each node  $u$ , for each item in  $UP(u)$  we have its rank in the  $SUP$  arrays at all  $r$  of  $u$ 's children. Let  $v, w$  be children of  $u$ . We proceed in two steps, as in the CREW algorithm.

In Step 1, we start by dividing each pairwise merge into a collection of merging subproblems, each of size at most  $2(r+1)$ ; each subproblem is then solved using Valiant's merging algorithm [V-75]. To divide a merge into subproblems, we exploit the fact that  $UP(u)$  is an  $(r+1)$ -cover of  $SUP(v)$ , as follows. For each child  $v$  of  $u$ , we label each item in  $SUP(v)$  with its rank in  $UP(u)$  (this is carried out in constant

time by providing each item in  $UP(u)$  with  $r(r+1)$  processors). A subproblem is defined by those items labeled with the same rank; it comprises two subarrays each containing at most  $r+1$  items. For the problem of merging  $SUP(v)$  and  $SUP(w)$ , for any item  $e$  in  $SUP(v)$  (respectively,  $SUP(w)$ ) the boundaries of its subproblem can be found as follows: let  $f$  and  $g$  be the items in  $UP(u)$  straddling  $e$  (obtained using the rank of  $e$  in  $UP(u)$ ); the ranks of  $f$  and  $g$  in  $SUP(v)$ ,  $SUP(w)$  yield the boundaries of the subproblem. To ensure that the merges performed using Valiant's algorithm each take  $O(\log \log 2r)$  time, we need to provide a linear number of processors for each merge. Since each item in  $SUP(v)$  participates in exactly  $r-1$  merges, it suffices to allocate  $r-1$  processors to each item in each  $SUP$  array. This gives us  $NEWUP(u)$ .

In Step 2, ranking the items from  $NEWUP(u) - SUP(v)$  in  $NEWSUP(v)$  for each child  $v$  of  $u$ , we proceed as follows. Consider an interval  $I$  induced by an item  $e$  from  $SUP(v)$ . For each such interval  $I$ , we divide each collection of items from  $NEWUP(u) - SUP(v)$ , contained in  $I$ , into sets of  $r$  contiguous items, with possibly one smaller set per interval. Using Valiant's algorithm, we merge each such set with the at most  $r+1$  items in  $NEWSUP(v)$  contained in  $I$ . If we allocate  $r$  processors to each merging problem, they will take  $O(\log \log 2r)$  time. To allocate the processors, we assign  $2(r-1)$  processors to each item in  $NEWUP(u)$ . Each item participates in  $r-1$  merging problems. In a merging problem, if the item is part of a set of size  $r$ , the item uses one of its assigned processors. If the item is part of a set of size  $< r$ , the item takes one processor from the item  $e$  defining the interval  $I$ . Each item  $e$  contributes at most  $r-1$  processors to a merging problem in the latter manner, thus it suffices to provide  $2(r-1)$  processors to each item in  $NEWUP(u)$ .

We conclude the following.

**THEOREM 3.** *There is a CRCW sorting algorithm for the CRCW PRAM that uses  $2n \leq p \leq n^2$  processors and runs in time  $O(\log n / \log \log 2p/n)$ .*

**5. A parametric search technique.** The reader is warned that this section is not self-contained. We recall Megiddo's parametric search technique [M-83] and its improvement in many instances in [C-87b]. The improvement was an asymptotic improvement, but was not practical for it was based on the AKS sorting network. As we will explain, the role played by the AKS network can be replaced by the EREW sorting algorithm from § 3.

In a nutshell, the procedure of [C-87b] can be described as follows. A comparison-based sorting algorithm is executed; however each "comparison" is an expensive operation costing  $C(n)$  time, where  $n$  is the size of the problem at hand. In addition, the comparisons have the property that they can be "batched": given a set of  $c$  comparisons, one of them can be evaluated, and the result of this evaluation resolves further  $c/2$  comparisons, in an additional  $O(c)$  time. Examples of search problems (called *parametric search problems*), mostly geometric search problems, for which this approach is fruitful, include [M-83], [C-87a], [C-87b], [CSS-88]. Megiddo showed that parallel sorting algorithms, executed sequentially, provide good sorting algorithms for this type of problem; the reason is that a parallel sorting algorithm naturally batches comparisons.

In [C-87b] it was shown how to achieve a running time of  $O(n \log n + \log n C(n))$  for the parametric search problems, when using a depth  $O(\log n)$  sorting network as the sorting algorithm. (Briefly, the solution required  $O(\log n)$  "comparisons" to be evaluated; the overhead for running the sorting algorithm and selecting the comparisons to be evaluated was  $O(n \log n)$  time.) It was also observed that to achieve this result it sufficed to have a comparison-based algorithm which could be represented as an

$O(\log n)$  depth,  $O(n)$  width, directed acyclic graph, having bounded indegree, where each node of the graph represented a comparator and the edges carried the outputs of the comparators.

In fact, a slightly more general claim holds. We start by defining a *computation graph* corresponding to an EREW PRAM algorithm on a given input. We define a parallel EREW PRAM computation to proceed in a sequence of steps of the following form. In each step, every processor performs at most  $b$  (a constant) reads, followed by at most  $b$  writes; a constant number of arithmetic operations and comparisons are intermixed (in any order) with the reads and writes. We represent the computation of the algorithm on a given input as a computation graph; the graph has depth  $2T$  (where  $T$  is the running time of the algorithm) and width  $M + P$  (where  $M$  is the space used by the algorithm and  $P$  is the number of processors used by the algorithm). In the computation graph each node represents either a memory cell at a given step, or a processor at a given step. There is a directed edge  $(\langle m, t \rangle, \langle p, t \rangle)$  if processor  $p$  reads memory cell  $m$  at step  $t$ ; likewise there is a directed edge  $(\langle p, t \rangle, \langle m, t + 1 \rangle)$  if processor  $p$  writes to memory cell  $m$  at step  $t$ . If no write is made to memory cell  $m$  at step  $t$ , there is a directed edge  $(\langle m, t \rangle, \langle m, t + 1 \rangle)$ .

Suppose we restrict our attention to algorithms such that at the start of the algorithm, for each memory cell (at step  $t + 1$ ) we know whether the in-edge (in the computation graph) comes from a processor (at step  $t$ ) or a memory cell (at step  $t$ ). For a sorting algorithm of this type, that runs in time  $O(\log n)$  on  $n$  processors using  $O(n)$  space, we can still achieve a running time of  $O(n \log n + \log n C(n))$  for the parametric search problems. (To understand this, it is necessary to read [C-87b, §§ 1–3]. The reason the result holds is that we can determine when a memory cell is active, to use the terminology of [C-87b], and thus play the game of § 2 of [C-87b] on the computation graph. In general, if we do not have the condition on the in-edges for memory cells, it is not clear how to determine if a memory cell is active. As explained in § 3 of [C-87b], given a solution to the game of § 2, we can readily obtain a solution to the parametric search problem).

*Remark.* The computation graph need not be the same for all inputs of size  $n$ . In addition, the graph does not have to be explicitly known at the start of the sorting algorithm.

Next, we show that the EREW sorting algorithm satisfies the conditions of the previous paragraph. Each of the five steps for one stage of the EREW algorithm comprises the computation of the cross-ranks of two arrays. The computation of the cross-ranks proceeds in two substeps; in the first substep, each processor performs a constant number of reads; in the second substep, each processor performs a constant number of writes.

We conclude that the result of [C-87b] can be achieved with a much smaller constant, thereby making the paradigm less impractical.

**Acknowledgments.** Thanks to Richard Anderson and Allen Van Gelder for commenting on an earlier version of this result. In particular, Allen Van Gelder suggested the term *cross-rank*. Many thanks to Jeannette Schmidt for questions and comments on several earlier versions of the result. Thanks also to Alan Siegel and Michelangelo Grigni for suggestions that simplified the presentation. Finally, I am grateful to Zvi Kedem, Ofer Zajicek, and Wayne Berke, all of whom read the penultimate version of the paper and provided a variety of useful comments. I am also very grateful to the referee for pointing out a serious error in the original version of § 3.

## A NATURAL NP-COMPLETE PROBLEM WITH A NONTRIVIAL LOWER BOUND\*

ETIENNE GRANDJEAN†

**Abstract.** Let  $SAT_{<}(\mathbb{N})$  denote the following problem. *Instance.* A conjunction  $\varphi$  of (in)equalities  $t_1 = t_2$  or  $t_1 < t_2$ , where  $t_1, t_2$  are terms of the form  $f_1 f_2 \cdots f_s(e)$ , where  $e \in \mathbb{N}$ ,  $s \geq 0$  and each  $f_i$  is a monadic function symbol. *Question.* Is  $\varphi$  satisfiable on  $\mathbb{N}$ ?

Let  $SAT_{<}^{2,2}(\mathbb{N})$  denote the following subproblem of  $SAT_{<}(\mathbb{N})$  defined by the following restriction: we assume that  $0 \leq s \leq 2$  and each  $f_i \in \{g_1, g_2\}$ . These two problems are NP-complete. We show that they are solved by a Turing machine using a polynomial number of deterministic steps and only  $n$  nondeterministic steps. This is nearly optimal since we prove that any problem in  $NTIME(n)$  is reducible in deterministic time  $O(n)$  to  $SAT_{<}(\mathbb{N})$  (respectively,  $SAT_{<}^{2,2}(\mathbb{N})$ ). It follows from the result  $\cup_c DTIME(cn) \subsetneq NTIME(n)$  of Paul et al. [*Proc. 24th Annual IEEE Symposium on Foundations of Computer Sciences*, 1983, pp. 429-438] that these problems are not in  $\cup_c DTIME(cn)$ . Further, we show that  $SAT_{<}^{2,2}(\mathbb{N})$  and  $SAT_{<}(\mathbb{N})$  belong to  $\Sigma_2(n)$ , the class of problems solved in time  $O(n)$  by alternating Turing machines using one alternation. They are the first natural problems proved to be in  $\Sigma_2(n) - \cup_c DTIME(cn)$ .

**Key words.** NP-complete problem, determinism, nondeterminism, Turing machine, alternating Turing machine, linear time reduction, random access machine, spectrum of first-order sentence

AMS(MOS) subject classification. 68Q

**1. Introduction.** In his Turing Award Lecture [Co2] S. Cook notes, "... the record for proving lower bounds on problems of small complexity is appalling. In fact there is no nonlinear time lower bound known on a general purpose computation model for any natural problem in NP, in particular, for any of the 300 problems listed in [GaJo]. Of course, one can prove by diagonal arguments the existence of problems in NP requiring time  $n^k$  for any fixed  $k$ ."

Recently, Adachi et al. [AIK] have proved lower bounds on game problems (in directed graphs) which are polynomial time complete. For instance, they show that "the cat and  $K$ -mouse game" introduced by [ChSt] is not in  $DTIME(n^{k-\epsilon})$  for any  $\epsilon > 0$  and integers  $K, k$  with  $K \geq 4k + 1 > 5$ . They essentially prove that each problem in  $DTIME(n^k)$  is reducible to the game problem in time  $O(n \log n)$ ; the result follows by the well-known hierarchy of  $DTIME$  classes (see [HoU1]). These seem to be the first natural problems in NP (in fact, in  $P = \cup_k DTIME(n^k)$ ) on which a nonlinear time lower bound is proved. However, no precise (polynomial time) upper bound is stated and we think that the stated lower bound is not optimal.

As Cook notes, it is surprising that none of the many classical NP-complete problems has a known time lower bound. One reason seems to be that the reductions of problems in NP to the generic NP-complete problems, i.e., the satisfiability of Boolean formulas (SAT) and its restriction, 3-satisfiability (3-SAT), are not efficient enough. The best-known reduction (stated by [Sr]) is as follows: there is a fixed  $k$  such that each problem in  $NTIME(n)$  is reducible to 3-SAT in deterministic time  $O(n(\log_2 n)^k)$ . Because of our lack of knowledge about relationships between  $NTIME$  classes and  $DTIME$  classes, we cannot deduce (from this reduction) any nontrivial time lower bound on problem SAT (respectively, 3-SAT). However, [PPST] obtained a very nice result about this:  $\cup_c DTIME(cn) \subsetneq NTIME(n)$ .

This is the first result which states that nondeterminism increases the power of usual (i.e., one-dimensional multitape) Turing machines. It follows that a hypothetical

\* Received by the editors October 16, 1985; accepted for publication (in revised form) July 31, 1987.

† Université de Caen, Département d'Informatique, 14032 Caen, Cedex, France.

linear time reduction of  $\text{NTIME}(n)$  to SAT (i.e., a slight improvement of the known reduction) would imply that  $\text{SAT} \notin \cup_c \text{DTIME}(cn)$ . Unhappily, such a reduction seems to be improbable (or inaccessible) for it would also imply that each problem in  $\text{NTIME}(n)$  could be solved (as problem SAT) by a Turing machine using only  $n(\log_2 n)^k$  deterministic steps and  $n/\log_2 n$  nondeterministic steps (a Boolean formula of length  $n$  contains  $O(n/\log_2 n)$  distinct variables).

In fact, some versions of the *tiling problem* (cf. [Le]) are NP-complete and can be proved to be  $\text{NTIME}(n)$ -hard (with respect to deterministic linear time reductions) by a straightforward argument. Tiling is essentially a direct encoding of a nondeterministic Turing machine (with one tape and several heads): each tile of a tiling describes one cell at one instant; so a computation of length  $n$  of a Turing machine is encoded by an  $n \times n$  tiling. It must be clear that the following problem, denoted TILE, has the desired properties:

*Instance.* A finite set of tiles  $T$  and two sequences  $T_1, T_2, \dots, T_n$  and  $T'_1, T'_2, \dots, T'_n$  of  $n$  tiles of  $T$ .

*Question.* Is there an  $n \times n$  tiling (with tiles of  $T$ ) whose first row and last row are  $T_1, T_2, \dots, T_n$  and  $T'_1, T'_2, \dots, T'_n$ , respectively? (Note.  $T_1, \dots, T_n$  and  $T'_1, \dots, T'_n$  describe the tape at the first and  $n$ th instant, respectively).

However, we think that such a (linear) lower bound result for TILE (or for any similar tiling problem) is not at all optimal and then is not very interesting: it seems that any decision algorithm of problem TILE needs  $n^2$  nondeterministic steps (in order to guess an  $n \times n$  tiling).

In the present paper, we study a new problem, denoted  $\text{SAT}_{<}(\mathbb{N})$  defined as follows.

*Instance.* A set SYMB of monadic function symbols. A conjunction  $\varphi$  of (in)equalities  $t_1 = t_2$  or  $t_1 < t_2$ , where  $t_1, t_2$  are terms of the form  $f_1 f_2 \dots f_s(e)$ , where  $s \geq 0$ , each  $f_i \in \text{SYMB}$  and  $e \in \mathbb{N}$ .

*Question.* Is there a structure  $\langle \mathbb{N}, g \rangle_{g \in \text{SYMB}}$  on domain  $\mathbb{N}$  which satisfies conjunction  $\varphi$ ?

Let  $\text{SAT}_{<}^{2,2}(\mathbb{N})$  (respectively,  $\text{SAT}_{\geq}^{2,2}(\mathbb{N})$ ) denote the following subproblem of  $\text{SAT}_{<}(\mathbb{N})$ : we assume that each  $f_i \in \{g_1, g_2\}$  (respectively,  $f_i \in \{g_1, g_2\}$ ) and  $0 \leq s \leq 2$ .

Let  $\varphi$  be an instance of  $\text{SAT}_{<}(\mathbb{N})$  of length  $n$  and  $a_0, a_1 \dots a_{m-1}$  be the list of integers which occur in  $\varphi$ . Clearly  $\varphi \in \text{SAT}_{<}(\mathbb{N})$  if and only if there is a model of  $\varphi$  (on domain  $\mathbb{N}$ ), where all terms and subterms which occur in  $\varphi$  have values in the union of intervals  $\cup_{i < m} [a_i - n, a_i + n]$ . This remark proves that problem  $\text{SAT}_{<}(\mathbb{N})$  is in NP.

Our main results (Theorems 6.3 and 6.4) are as follows: each problem in  $\text{NTIME}(n)$  is reducible to problem  $\text{SAT}_{<}(\mathbb{N})$  (respectively,  $\text{SAT}_{\geq}^{2,2}(\mathbb{N})$ ) in time  $O(n)$  on a deterministic Turing machine, in fact, a one-tape transducer (in particular problems  $\text{SAT}_{<}(\mathbb{N})$  and  $\text{SAT}_{\geq}^{2,2}(\mathbb{N})$  are NP-complete).

Hence  $\text{SAT}_{<}(\mathbb{N})$  and  $\text{SAT}_{\geq}^{2,2}(\mathbb{N})$  are not in  $\cup_c \text{DTIME}(cn)$ . Our main result seems to be optimal since these problems are solved by a Turing machine using a polynomial number of deterministic steps and only  $n$  nondeterministic steps (we also prove that  $\text{SAT}_{<}(\mathbb{N}) \in \text{NTIME}(n(\log_2 n)^2)$  and  $\text{SAT}_{\geq}^{2,2}(\mathbb{N}) \in \text{NTIME}(n \log_2 n)$ ). The linear nature of these problems is stated by the following result:  $\text{SAT}_{\geq}^{2,2}(\mathbb{N})$  and  $\text{SAT}_{<}(\mathbb{N})$  belong to class  $\Sigma_2(n)$ , i.e., are solved in time  $O(n)$  by an alternating Turing machine so that existential steps precede universal steps.

We feel that problem  $\text{SAT}_{<}(\mathbb{N})$  has an easy, natural formulation: it concerns one of the simplest classes of quantifier-free formulas interpreted over integers. The use of function symbols is essential for the NP-completeness of this problem: we can

(trivially) decide in deterministic polynomial time the satisfiability problem of a conjunction  $\varphi$  of signed atomic formulas (where individual variables are replaced by integers) if  $\varphi$  includes no function symbols but only relation symbols. Problems  $\text{SAT}_{<}(\mathbb{N})$  and  $\text{SAT}_{\leq}^{2,2}(\mathbb{N})$  are the first *natural* problems which separate classes  $\bigcup_c \text{DTIME}(cn)$  and  $\Sigma_2(n)$ ; the existence of such problems trivially follows from inclusion  $\bigcup_c \text{DTIME}(cn) \not\subseteq \text{NTIME}(n)$ .

Let us mention that the linear time reduction (by one-tape transducer) we use has been defined by Dewdney [De] who proves that some natural NP-complete problems (for instance, 3-SAT and 3-COLOURABILITY) are equivalent via this reduction.

The proof of our main result is long and rather technical; it uses intermediate results about the two following notions:

(i) The NRAM (Nondeterministic Random Access Machine), where the only arithmetical operation is the addition of unit (see [Se], [Mo1], [Mo2]).

(ii) The (generalized) spectrum of a first-order sentence.

(i) Let  $\text{NRAM}(T(n))$  denote the class of languages accepted by an NRAM in time  $T(n)$ . We use a technical version of a result of [Mo2]:

$$\text{NTIME}(T(n)) \subset \bigcup_c \text{NRAM}(cT(n)/\log_2 T(n)).$$

(Monien assumes  $T(n) \geq n \log_2 n$ ; we take  $T(n) = n$ ). The idea is essentially to use the ability of an NRAM to do operations on integers in one step and to guess an integer in one step: more precisely, by first precomputing the table of all possible  $\varepsilon \log_2 T$  moves of a (nondeterministic) Turing machine (NTM) (for a sufficiently small  $\varepsilon$ , the precomputation requires time  $O(T/\log_2 T)$ ), the NRAM simulates  $\varepsilon \log_2 T$  moves of the NTM in  $O(1)$  steps by consulting the table only once.

(ii) We use a result of [Gr2] stating that a set of positive integers (respectively, a set of finite structures) accepted by an NRAM in time  $O(m)$ , where  $m$  is the input integer (respectively, the cardinality of the domain of the input structure), is the spectrum (respectively, generalized spectrum) of a first-order sentence  $\varphi$  with only one variable and relation and function symbol of arity  $\leq 1$ .

Lastly, by unrolling the first-order sentence  $\varphi$  on domain  $m$  (it gives a formula of length  $O(m \log_2 m)$  because  $\varphi$  has only one variable) we obtain a linear time reduction to problem  $\text{SAT}_{<}(\mathbb{N})$ , i.e., our main result; we get rid of disjunctions of the first-order sentence by adding function symbols; by some encoding techniques, we state a linear time reduction to  $\text{SAT}_{\leq}^{2,2}(\mathbb{N})$ .

The structure of the paper is as follows. In § 2, we give some notation and definitions, in particular we present NRAMs. In § 3, we prove several upper bounds on problems  $\text{SAT}_{<}(\mathbb{N})$  and  $\text{SAT}_{\leq}^{2,2}(\mathbb{N})$ . The rest of the paper consists of a proof of the main result: § 4 presents the simulation of NTMs by NRAMs; in § 5, computations of NRAMs are described by one-variable first-order sentences; last, in § 6, we prove the linear time reduction of  $\text{NTIME}(n)$  to  $\text{SAT}_{<}(\mathbb{N})$  and  $\text{SAT}_{\leq}^{2,2}(\mathbb{N})$ . The proof that  $\text{SAT}_{<}(\mathbb{N}) \in \Sigma_2(n)$  is given in the Appendix.

**2. Preliminaries.** We use the usual notation and definitions in computational complexity (see [HoU1]). Our models of computation are *multitape Turing machines* (for short, TM), where every tape is one-dimensional; more precisely, a TM has one read-only tape for input, several read-write tapes (the *worktapes*) and in case it computes a function, one write-only tape for output. A deterministic (respectively, nondeterministic) TM is abbreviated as a DTM (respectively, an NTM). A *one-tape transducer* is a DTM which computes a function with only one worktape. Let  $\text{DTIME}(T(n))$  (respectively,  $\text{NTIME}(T(n))$ ) denote the class of languages accepted in time  $T(n)$  by a DTM (respectively, NTM).

We also use the *nondeterministic random access machines* (for short, NRAM) defined in [Se], [Mo1], [Mo2], [Gr2]. An NRAM consists of a finite program which operates on a sequence of registers  $R_0, R_1, R_2, \dots$ . Each register can store any natural number. The program is a finite sequence of instructions, labeled inst 0, inst 1,  $\dots$ , inst  $l$ , of the following types:

- |                            |   |
|----------------------------|---|
| (1) Read ( $R_i$ )         | (7) $R_i := \langle R_j \rangle$                                |
| (2) $R_i := 0$             | (8) $\langle R_i \rangle := R_j$                                |
| (3) $R_i := R_i + 1$       | (9) Go to inst $i_0$ or $i_1$                                   |
| (4) $R_i := R_i \dot{-} 1$ | (10) If $R_i = R_j$ then go to inst $i_0$ else go to inst $i_1$ |
| (5) Guess ( $R_i$ )        | (11) Accept   |
| (6) $R_i := R_j$           | (12) Reject   |

$\langle R_i \rangle$  denotes the register pointed to by register  $R_i$  (i.e., the address of  $\langle R_i \rangle$  is the content of  $R_i$ ). The effect of instructions (2)–(4), (6)–(8), and (10)–(12) is evident (the value of  $x \dot{-} y$  is  $x - y$  if  $x \geq y$ ; if  $x < y$ , it is 0). The control of the program is transferred from one instruction to the next one, except after instructions (9), (10). Instructions (5) and (9) are nondeterministic; the meaning of Guess ( $R_i$ ) is: guess any integer to be stored in  $R_i$ .

At the beginning of the computation of an NRAM, the control of the program points to inst 0, the content of each register is 0 and a sequence of integers  $U_0, U_1, \dots, U_{m-1}, 0$  with  $U_j > 0, j < m$ , serve as inputs. The instruction Read ( $R_i$ ) causes the NRAM to transfer the first integer  $U_j$  which has not been read in up to this time into register  $R_i$ . We assume that the execution of any instruction only requires one time unit.

A *simple* NRAM (see [Gr2]) is similar to the NRAM defined above with the following changes: it has two accumulators, i.e., special register denoted  $a$  and  $b$ , and its instructions are the following:

- |                              |   |
|------------------------------|---|
| (1) Read ( $a$ )             | (7) $b := a$  |
| (2) $a := 0$                 | (8) $\langle a \rangle := b$                                |
| (3) $a := a + 1$             | (9) Go to inst $i_0$ or $i_1$                               |
| (4) $a := a \dot{-} 1$       | (10) If $a = b$ then go to inst $i_0$ else go to inst $i_1$ |
| (5) Guess ( $a$ )            | (11) Accept   |
| (6) $a := \langle a \rangle$ | (12) Reject   |

$\langle a \rangle$  denotes the register pointed to by accumulator  $a$ . In fact, only accumulator  $a$  is used for accessing the sequence of registers (like the control head of a Turing machine).

LEMMA 2.1. *Each NRAM is simulated by a simple NRAM in linear time.*

*Proof.* The proof is easy (see [Se]).  $\square$

Let us define some generalized NRAMs. A *multitape* NRAM operates on finitely many sequences of registers  $R_0, R_1, \dots, R'_0, R'_1, \dots, R''_0, R''_1, \dots$ . A *multidimensional* NRAM has one or several multidimensional sequences of registers  $R(j_1, j_2, \dots, j_s)$ ; an address  $j_1, \dots, j_s$  is an  $s$ -tuple of natural numbers.

LEMMA 2.2. *Each multitape (respectively, multidimensional) NRAM is simulated by an ordinary NRAM in linear time.*

*Proof.* See [Mo1], [Mo2], [Gr2].  $\square$

We will use *alternating Turing machines* (see [CKS])  $M$  with a bounded number of alternations:  $M$  is a  $\Pi_1$  (respectively,  $\Sigma_2$ ) Turing machine if it has only universal

states (respectively, if in any computation of  $M$  there is only one alternation and existential steps precede universal steps).

Let  $\Pi_1(n)$  (respectively,  $\Sigma_2(n)$ ) denote the class of languages accepted by  $\Pi_1$  (respectively,  $\Sigma_2$ ) Turing machines in time  $O(n)$ .

In the proof of our main result, it is convenient to use a one-to-one representation of positive integers: the *dyadic* notation on the alphabet  $\{1, 2\}$ ; an integer  $e > 0$  such that

$$e = \sum_{i=0}^l \alpha_i 2^i,$$

where  $\alpha_i \in \{1, 2\}$ , is represented (in dyadic notation) by the word  $\alpha_l \alpha_{l-1} \cdots \alpha_1 \alpha_0$ . Similarly, we define the  $d$ -adic notation on the alphabet  $\{1, 2, \dots, d\}$  for  $d \geq 2$ .

The complexity of problem  $\text{SAT}_{<}(\mathbb{N})$  which involves a representation of integers is not modified if we prefer the usual binary notation (for example) rather than the dyadic because of the following easy lemma.

**LEMMA 2.3.** *There is a DTM which transforms a positive integer in dyadic (respectively, binary) notation into binary (respectively, dyadic) notation with  $O(n)$  moves (where  $n$  is the length of the representation).*

Let  $\text{length}(e)$  denote the length of the dyadic representation of an integer  $e > 0$  (convention:  $\text{length}(0) = 1$ ).

*Notation.* For a real number  $r > 0$ , let  $\log r$  denote the logarithm of  $r$  in base 2 and let  $\lceil r \rceil$  and  $\lfloor r \rfloor$  denote the least integer  $n_0 \geq r$  and the greatest integer  $n_1 \leq r$ , respectively.

We will use the usual notation and definitions in first-order logic and model theory (see, for example, [ChKe, Chap. 1]).

**3. Upper bounds of complexity.** For the purpose of giving an efficient algorithm to solve the problem  $\text{SAT}_{<}(\mathbb{N})$  (respectively,  $\text{SAT}_{<}^{2,2}(\mathbb{N})$ ) let us transform each instance  $\varphi$  of this problem into a more manageable formula  $\varphi'$ . Let  $e_0 = 0 < e_1 < \dots < e_{m-1}$  be the increasing list of distinct integers which occur in  $\varphi$  (we add 0 to the list). Let  $\varphi'$  denote the conjunction of (in)equalities obtained from conjunction  $\varphi$  by replacing each integer  $e_i$  by  $e'_i$ , where integers  $e'_i$  ( $i = 0, \dots, m-1$ ) are defined as follows:  $e'_0 = e_0 = 0$  and  $e'_{i+1} - e'_i = \min(n, e_{i+1} - e_i)$ , where  $n = \text{length}(\varphi)$ . Hence  $e'_i \leq (m-1)n \leq n^2 - n$  for  $i \leq m-1$ . In the sequel, formula  $\varphi'$  will also be denoted  $\text{SIMPLE}(\varphi)$ .

**LEMMA 3.1.** *Let us adopt the above notation (in particular  $\varphi' = \text{SIMPLE}(\varphi)$ ).*

(i)  $\varphi$  is satisfiable if and only if  $\varphi'$  is satisfied by a structure where all terms and subterms of  $\varphi'$  have values  $< n^2$  (respectively, if and only if  $\varphi'$  is satisfiable).

(ii)  $\text{length}(\varphi') \leq n$  and  $\text{length}(e'_i) = O(\log n)$  for  $i < m$ .

(iii) The sorted sequence  $e_0, e_1, \dots, e_{m-1}$  is obtained from input  $\varphi$  in time  $O(n \log n)$  on a DTM.

(iv) The sequence  $(e_0, e'_0)(e_1, e'_1) \cdots (e_{m-1}, e'_{m-1})$  is computable on a DTM in time  $O(n_0)$ , where  $n_0$  is the length of the input sequence  $e_0, e_1, \dots, e_{m-1}$ .

(v) Formula  $\varphi'$  is computable from input  $\varphi$  in time  $O(n \log n)$  on a DTM.

*Proof.* (i) Assume  $\varphi$  is satisfied by a structure  $\mathcal{A}$ . We associate to it the following "compressed" structure  $\mathcal{A}'$ : replace each  $e_i$  by  $e'_i$ ; transform the distinct values  $v_1 < v_2 < \dots < v_k$  ( $k \leq n$ ) of the other terms and subterms of  $\varphi$  into the respective values  $v'_1 < v'_2 < \dots < v'_k$  defined by the following induction on integer  $j$  ( $1 \leq j \leq k$ ):

if  $v_j = e_i$  (for some  $i$ ) then  $v'_j := e'_i$

else (let  $i$  be the integer such that  $i < m-1$  and

- $e_i < v_j < e_{i+1}$  or such that  $i = m - 1$  and  $e_i < v_j$   
 if  $e_i < v_{j-1} < v_j$  then  $v'_j := v'_{j-1} + 1$   
 else (i.e., in case  $j = 1$  or in case  $v_{j-1} \leq e_i < v_j$ )  $v'_j := e'_i + 1$ .

Clearly  $\mathcal{A}'$  satisfies  $\varphi'$  and (i) follows because the (in)equalities between the concerned values are all preserved.

- (ii) Clear from the fact that  $e'_i \leq e_i$  and  $e'_i < n^2$  for  $i < m$ .
- (iii) Use one of the standard sorting methods [AHU].
- (iv) Easy because addition of integers is computable in linear time.
- (v)  $\varphi'$  is computed as follows:

- (1) Compute the sequence  $(e_0, e'_0) \cdots (e_{m-1}, e'_{m-1})$  which corresponds to  $\varphi$ .
- (2) Sort the list of (in)equalities of  $\varphi$  according to the integers which occur in their first members (it requires time  $O(n \log n)$ ). In each (in)equality replace the integers  $e_i$  which occur in the first member by  $e'_i$  by using the sequence  $(e_0, e'_0) \cdots (e_{m-1}, e'_{m-1})$  (this requires time  $O(n)$ ).
- (3) It is similar to procedure (2) but we consider second members of (in)equalities instead of first members.  $\square$

The following proposition expresses that problems  $\text{SAT}_{<}(\mathbb{N})$  and  $\text{SAT}_{\geq}^{2,2}(\mathbb{N})$  can be solved in “quasi-linear” time (cf. [Sr]).

**PROPOSITION 3.2.**  $\text{SAT}_{<}(\mathbb{N}) \in \text{NTIME}(n(\log n)^2)$  and  $\text{SAT}_{\geq}^{2,2}(\mathbb{N}) \in \text{NTIME}(n \log n)$ . More precisely, problem  $\text{SAT}_{<}(\mathbb{N})$  (respectively,  $\text{SAT}_{\geq}^{2,2}(\mathbb{N})$ ) is solved by a Turing machine using  $n \log n$  (respectively,  $n$ ) nondeterministic steps and  $n(\log n)^2$  (respectively,  $n \log n$ ) deterministic steps.

*Proof.* The decision algorithm is the following. Let  $\varphi$  be an instance of  $\text{SAT}_{<}(\mathbb{N})$  (respectively,  $\text{SAT}_{\geq}^{2,2}(\mathbb{N})$ ), of length  $n$ .

- (1) Compute the transformed formula  $\varphi'$  (cf. Lemma 3.1(v)).
- (2) Delete each double occurrence of a same (in)equality in  $\varphi'$  by sorting the list of (in)equalities (notice that there remains only  $O(n/\log n)$  (in)equalities in  $\varphi'$ ).
- (3) For each (in)equality  $\theta = \theta'$  or  $\theta < \theta'$  of  $\varphi'$  guess the values of terms  $\theta$  and  $\theta'$  and of their subterms in the interval of integers  $[0, n^2[$  (for instance, if  $\theta = f_1 f_2 \cdots f_s(e)$ , guess values  $f_s(e), f_{s-1} f_s(e), \cdots, f_1 f_2 \cdots f_s(e)$ , successively so that the (in)equality between  $\theta$  and  $\theta'$  holds).
- (4) Verify that these guesses do not contradict each other (sort them).

Clearly,  $\varphi$  is satisfiable if and only if this nondeterministic algorithm leads to acceptance. Procedures (1) and (2) require time  $O(n \log n)$ . For analyzing the time required by procedure (3), note the following:

- Each guess of a value of a (sub) term has time cost  $O(\log n)$ ;
- The formula  $\varphi'$  contains no more than  $n$  occurrences of distinct or not distinct (sub)terms. Therefore procedure (3) guesses no more than  $n$  values in the general case;
- For each instance  $\varphi$  of  $\text{SAT}_{\geq}^{2,2}(\mathbb{N})$ , there are  $O(n/\log n)$  occurrences of distinct or not distinct (sub)terms in  $\varphi'$  (after the execution of procedure (2)) and then procedure (3) guesses  $O(n/\log n)$  values (for  $\text{SAT}_{\geq}^{2,2}(\mathbb{N})$ ).

Therefore, procedure (3) requires nondeterministic time  $O(n \log n)$  for  $\text{SAT}_{<}(\mathbb{N})$  (respectively,  $O(n)$  for  $\text{SAT}_{\geq}^{2,2}(\mathbb{N})$ ). Procedure (4) requires deterministic time  $O(n(\log n)^2)$  for  $\text{SAT}_{<}(\mathbb{N})$  (respectively,  $O(n \log n)$  for  $\text{SAT}_{\geq}^{2,2}(\mathbb{N})$ ): this is the time needed to sort a list of expressions of total length  $O(n \log n)$  (respectively,  $O(n)$ ).  $\square$

The following proposition improves in some way the nondeterministic time upper bound of  $\text{SAT}_{<}(\mathbb{N})$ .

**PROPOSITION 3.3.** Problem  $\text{SAT}_{<}(\mathbb{N})$  is solved by a Turing machine using  $O(n)$  nondeterministic steps and a polynomial number of deterministic steps.

*Proof.* The algorithm is the following. Let  $\varphi$  be an instance of  $\text{SAT}_{<}(\mathbb{N})$ , of length  $n$ . Execute procedures (1) and (2) of the proof of Proposition 3.2 and the following procedures (3)–(6):

(3) For each (in)equality  $\theta = \theta'$  or  $\theta < \theta'$  of  $\varphi'$  guess the values of the terms  $\theta, \theta'$  in the interval  $[0, n^2[$  so that the (in)equality holds (of course, if term  $\theta$  or  $\theta'$  is only an integer, do not guess its value; also examine the (in)equalities  $e = e'$  or  $e < e'$  between terms  $e, e'$  which are only integers: if any of them is (trivially) false then the algorithm rejects because  $\varphi'$  is not satisfiable; if they are (trivially) true, delete them).

Let  $\varphi''$  be the conjunction  $\bigwedge_i \theta_i = v_i$  of the equalities which are guessed in procedure (3) ( $\theta_i$  is a term,  $v_i$  is an integer). Clearly,  $\varphi'$  is satisfiable if and only if at least one of the conjunctions  $\varphi''$  is satisfiable. The following procedures (4) and (5) gradually simplify formula  $\varphi''$  by successive substitutions justified by the following equivalence where  $\mathcal{F}, \mathcal{G}$  are sequences of composed functions and  $e, e', e''$  are integers:

$$(*) \quad (\mathcal{F}e = e' \wedge \mathcal{G}\mathcal{F}e = e'') \leftrightarrow (\mathcal{F}e = e' \wedge \mathcal{G}e' = e'').$$

(4) Sort the list of conjuncts  $\theta_i = v_i$  of  $\varphi''$  according to the lexicographical order of terms  $\theta_i$  (which are read *from right to left*) and then in case a term  $\theta_i$  is a proper subterm of another term  $\theta_j$ , i.e.,  $\theta_j = \mathcal{G}\theta_i$  (regard this equality as an identity of *words*), replace the equality  $\mathcal{G}\theta_i = v_j$  by  $\mathcal{G}v_i = v_j$  (this is justified by (\*)).

In case two terms  $\theta_i$  and  $\theta_j$  are identical: if  $v_i = v_j$  then delete the repeated equality  $\theta_j = v_j$ ; if  $v_i \neq v_j$  then we obtain a contradiction.

(5) Iterate procedure (4) as long as it can be executed (i.e., some terms  $\theta_i$  are subterms of some other  $\theta_j$ ) and no contradiction is reached.

(6) If we get a contradiction then reject. Otherwise accept.

An execution of procedure (4) decreases the number of occurrences of function symbols in  $\varphi''$ . So, it is repeated only  $O(n)$  times. Notice that this does not increase the number of occurrences of integers (each of length  $O(\log n)$ ) in  $\varphi''$ : this number remains  $O(n/\log n)$ . Therefore, the length of  $\varphi''$  is always  $O(n)$ .

Clearly this algorithm needs  $O(n)$  nondeterministic steps which are only used in procedure (3) to guess the values of  $O(n/\log n)$  terms in  $[0, n^2[$  and needs a polynomial number of deterministic steps.

It remains to prove the correctness of this nondeterministic algorithm. Clearly, if it rejects then each formula  $\varphi''$  is contradictory. An acceptance means that procedure (5) leads to a conjunction  $\varphi'' = (\bigwedge_i \theta_i = v_i)$ , where no term  $\theta_i$  is a subterm of another term  $\theta_j$ . To conclude the proof, it suffices to prove the following lemma.

**LEMMA 3.4.** *If no term  $\theta_i$  is a subterm of another term  $\theta_j$  then the conjunction  $\varphi'' = (\bigwedge_i \theta_i = v_i)$  (where each  $v_i$  denotes an integer) is satisfiable.*

*Proof.* Let  $E$  denote the set of integers which occur in  $\varphi''$ . For all terms  $\theta_i = f_1 f_2 \cdots f_r(e)$  that occur in  $\varphi''$ , define the values of subterms  $f_i(e)$ ,  $f_{r-1} f_r(e), \dots, f_2 f_3 \cdots f_r(e)$  out of  $E$  so that distinct subterms have distinct values. Last, define the values of  $\theta_i = f_1 f_2 \cdots f_r(e)$  to be  $v_i$  (so,  $\varphi''$  is satisfied by the constructed structure). There is no double definition of a same value because no  $\theta_i$  is a subterm of another term  $\theta_j$ . So, Lemma 3.4 and Proposition 3.3 are proved.  $\square$

For the purpose of proving a linear time upper bound for problem  $\text{SAT}_{\leq}^{2,2}(\mathbb{N})$  on an *alternating* TM, let us present a useful language and an algorithm to recognize it.

*Notation.* Let  $\mathcal{L}$  denote the following language on an alphabet  $\Sigma \cup \{\#, \$\}$  (where  $\Sigma \cap \{\#, \$\} = \emptyset$ ):

$$\mathcal{L} = \{u_1 \# u_2 \cdots \# u_m \$ u'_1 \# u'_2 \cdots \# u'_p : u_i, u'_j \in \Sigma^*, \text{ each } u_i \text{ is a word } u'_j, \text{ each } u'_j \text{ is a word } u_i \text{ and the sequence } u'_1, u'_2 \cdots u'_p \text{ is lexicographically ordered}\}.$$

LEMMA 3.5. *Language  $\mathcal{L}$  belongs to  $\Pi_1(n)$ .*

*Proof.*  $\mathcal{L}$  is decided by the following algorithm.

- (1) Verify that words  $u'_1, u'_2 \cdots u'_p$  are lexicographically ordered.
- (2) Universally choose an index  $i \in [1, m]$  and verify that  $u_i$  is a word  $u'_j$ .
- (3) Universally choose an index  $j \in [1, p]$  and verify that  $u'_j$  is a word  $u_i$ .

This clearly requires  $O(n)$  universal (or deterministic) steps.  $\square$

THEOREM 3.6. *Problem  $\text{SAT}_{\leq}^{2,2}(\mathbb{N})$  belongs to  $\Sigma_2(n)$ .*

*Proof.* The required algorithm is obtained by transformations of the nondeterministic algorithm, denoted  $\mathfrak{A}$ , of Proposition 3.2. Let us analyse algorithm  $\mathfrak{A}$ . It has three kinds of procedures:

- (i) A nondeterministic procedure (procedure (3)) of time cost  $O(n)$ .
- (ii) Some procedures which sort lists of integers (respectively, lists of (in)equalities) of total length  $O(n)$  (examples: sort the integers which occur in  $\varphi$ ; in Procedure (4) sort a list of equalities).
- (iii) Other deterministic procedures (example: construct the sequence  $(e_0, e'_0) \cdots (e_{m-1}, e'_{m-1})$  from the sorted sequence  $e_0, \cdots, e_{m-1}$ ): they only require time  $O(n)$ .

Let us (informally) present our  $\Sigma_2$  algorithm. Let  $\varphi$  be an input of length  $n$  and  $\mathcal{C}(\varphi)$  denote a computation of  $\mathfrak{A}$  on input  $\varphi$ .

(1') Guess (existentially) all the sorted sequences obtained in  $\mathcal{C}(\varphi)$ . Examples: guess the sorted sequence of integers  $e_0, e_1 \cdots e_{m-1}$  which occur in  $\varphi$ ; guess formula  $\varphi'$  and all the transformed forms of formula  $\varphi'$  and all the transformed forms of formula  $\varphi$  constructed before (cf. Proof of Lemma 3.1(v)).

(2') Execute the nondeterministic procedure (3).

(3') Execute the deterministic procedures of  $\mathfrak{A}$ .

(4') Verify that each (guessed) sorted list is a "good" sorted list by comparing it with the corresponding (nonsorted) sequence: execute an appropriate version of the algorithm of Lemma 3.5 (it uses  $O(n)$  universal steps).

(5') Reject if one of the above procedures (3') or (4') leads to a contradiction. Otherwise accept.

This is clearly a  $\Sigma_2$  algorithm (existential steps precede universal steps) which solves problem

$\text{SAT}_{\leq}^{2,2}(\mathbb{N})$  in time  $O(n)$  on an alternating TM.  $\square$

*Remarks.* The universal steps of our  $\Sigma_2$ -algorithm are only needed in order to sort some inputs (cf. procedure (4')). Note that the proofs of upper bounds on the complexity of  $\text{SAT}_{\leq}^{2,2}(\mathbb{N})$  do not depend upon the fact that the number of distinct function symbols is bounded (by 2) but only depend upon the fact that  $s$ , the number of composed functions of a term is bounded by a fixed number (for instance 2). In fact we have even the following theorem.

THEOREM 3.7. *Problem  $\text{SAT}_{<}(\mathbb{N})$  belongs to  $\Sigma_2(n)$ .*

*Idea of the proof.* The complete proof is long and needs much care. We present it in the Appendix. The idea is as follows. A difficulty (for proving a linear time upper bound for  $\text{SAT}_{<}(\mathbb{N})$ ) originates from the *unboundedness* of the number of composed function symbols in a term of an instance of  $\text{SAT}_{<}(\mathbb{N})$ : therefore first we reduce  $\text{SAT}_{<}(\mathbb{N})$  (in linear time) to a similar problem where an instance  $\varphi$  has no term with more than  $\log n$  composed functions ( $n = \text{length}(\varphi)$ ). Second, we solve the simplified problem by associating to each satisfiable instance  $\varphi$  a conjunction  $\varphi'' = (\bigwedge_i \theta_i = v_i)$  such that:

(i)  $\varphi''$  “derives” from  $\varphi$ , i.e., is a consequence of  $\varphi$  (“derivation” will be precisely defined);

(ii) No term  $\theta_i$  is a subterm of another term  $\theta_j$  ( $\varphi''$  is satisfiable by Lemma 3.4).

This is exactly the conjunction  $\varphi''$  of length  $O(n)$  produced by the deterministic procedures (4), (5) in the proof of Proposition 3.3. However, we no longer produce the formula  $\varphi''$  deterministically, but guess it.

**4. Simulation of NTMs by NRAMs.** In order to prove our main result we need a technical version of a result of [Mo2]. The idea of its proof (given in the Introduction) is simple but the precise proof is rather long and tedious.

Let  $S \subset \{1, 2\}^*$  be a language accepted by an NTM in time  $cn$  for a constant  $c$ . We are going to exhibit an NRAM which simulates the NTM in time  $O(n/\log n)$ . An input  $w$  of the NRAM is not read one bit at a time (it would require time  $n = \text{length}(w)$ ), but is read by blocks. More precisely, let  $k$  be a (sufficiently large) fixed integer, only depending upon set  $S$  (the exact value of  $k$  will be given below); each word  $w \in \{1, 2\}^n$  is divided into subwords  $w_0, w_1, \dots, w_{m-1}$  so that:

(i)  $w = w_0 \wedge w_1 \cdots \wedge w_{m-1}$ ;

(ii) For each  $i < m - 1$   $\text{length}(w_i) = h(n)$  where  $h(n) = \lfloor 1/k \log n \rfloor$ ;

(iii)  $0 < \text{length}(w_{m-1}) \leq h(n)$ .

Consequently,  $m = \lceil n/h(n) \rceil$  (we assume  $n \geq 2^k$  so that  $h(n) \geq 1$ ).

For convenience we identify a word  $w$  with its corresponding  $m$ -tuple  $(w_0, w_1, \dots, w_{m-1})$ . Each word  $w_i$  is also identified with the integer it represents in dyadic notation: so,  $0 < w_i < 2^{h(n)+1} \leq 2n^{1/k}$ . Each instruction  $\text{Read}(R_j)$  causes the NRAM to transfer the first integer  $w_i$  which has not been read in up to this time into register  $R_j$  (convention:  $w_m = 0$ ).

Let  $\text{NRAM}^*(T(n))$  denote the class of languages  $S \subset \{1, 2\}^*$  accepted by such an NRAM for some  $k$  in time  $T(n)$  ( $n$  is the length of the input word  $w$ ).

LEMMA 4.1. (see [Mo2]). *If a language  $S \subset \{1, 2\}^*$  belongs to  $\text{NTIME}(n)$  then  $S \in \cup_c \text{NRAM}^*(cn/\log n)$ .*

*Proof.* We can assume without loss of generality that an NTM accepts  $S$  in time  $cn$  ( $c$  is a fixed integer) and has only one input tape, numbered 0, and two worktapes, numbered 1 and 2.

The time of a computation of the NTM (on an input of length  $n$ ) is divided into intervals of  $h(n)$  instants:  $\Delta_0, \Delta_1, \dots$  ( $h(n) = \lfloor 1/k \log n \rfloor$ ). Similarly, each tape of the NTM is divided into blocks of  $h(n)$  adjacent cells. If  $\Sigma = \{1, \dots, d\}$  is the tape alphabet, each description  $\delta \in \Sigma^{h(n)}$  of a block is identified with the integer  $\delta$  represents in  $d$ -adic notation: so;  $\delta < d^{h(n)+1}$ . Tape  $i$  ( $i = 0, 1, 2$ ) of the NTM is represented by a sequence of registers  $R_0^i, R_1^i \cdots$  of the NRAM so that the content of  $R_j^i$  is the description of block  $j$ .

It is clear that if a head of the NTM scans block  $j$  at a given instant, then this head can only visit blocks  $j, j-1$ , and  $j+1$  during the next  $h(n)$  instants. In order to simulate  $h(n)$  steps of the NTM in  $O(1)$  steps (cf. Part 5 below), the NRAM precomputes a binary relation  $\mathcal{R}$ : roughly,  $\tau \mathcal{R} \tau'$  will mean that the NTM transforms a “partial description”  $\tau$  into another one  $\tau'$ , in  $h(n)$  moves. More formally, a (partial) *description*  $\tau$  of type 1 (of the NTM) is defined to be a tuple of integers which consists of:

(i) A control state  $\sigma$  (encoded by an integer);

(ii) For each tape  $i = 0, 1, 2$ :

- The head position  $\pi_i$  on the visited block;

- Descriptions  $\delta_i^0, \delta_i^+, \delta_i^-$  of the visited block and of the right and left adjacent blocks, respectively. We adopt the convention  $\delta_i^- = 0$  (respectively,  $\delta_i^+ = 0$ )

in case  $\delta_i^0$  describes the leftmost (respectively, rightmost) block of tape  $i$ . Recall that all blocks have length  $h(n)$  exactly, except blocks described by 0 and the block of the input tape which contains  $w_{m-1}$ .

A description  $\tau'$  of type 2 is similar to a description of type 1 with the following change: the visited block of tape  $i$  is not necessarily the block described by  $\delta_i^0$  but must be any of the blocks  $\delta_i^0$ ,  $\delta_i^{-1}$  or  $\delta_i^{+1}$ ; the tuple  $\tau'$  includes a number 0, -1, or 1 (i.e., center, left, or right) indicating the visited block.

Clearly, the number of possible descriptions (of type 1 or 2) is  $\beta(n) = O([h(n) \cdot d^{3h(n)}]^3)$  (for each 3 blocks on a tape  $i=0, 1, 2$  there are at most  $3h(n)$  possible head positions and  $d^{3h(n)}$  possible block descriptions ( $\delta_i^0, \delta_i^{+1}, \delta_i^{-1}$ )). We write  $\tau\mathcal{R}\tau'$  if the NTM transforms description  $\tau$  (of type 1) into description  $\tau'$  (of type 2) in  $h(n)$  moves. Let us describe the work of the NRAM.

*Part 1.* Copy the input integers  $w_0, w_1, \dots, w_{m-1}, 0$  into registers  $R_0^0, R_1^0 \dots R_m^0$ , respectively. Guess the integer  $n$  and compute  $h(n)$ . Verify that  $m = \lceil n/h(n) \rceil$  and that the input is suitable, i.e., length  $(w_i) = h(n)$  for each  $i < m-1$  (verify  $2^{h(n)} - 1 \leq w_i \leq 2(2^{h(n)} - 1)$ ) and  $0 < \text{length}(w_{m-1}) \leq h(n)$ . Part 1 requires time  $O(m) = O(n/\log n)$ .

*Part 2.* Compute the addition table of integers  $< d^{h(n)+1}$  (in time  $O(d^{2h(n)})$ ) and a table  $T_{\text{div}}$  which gives the quotient and the remainder of the division of each integer  $< d^{h(n)+1}$  by  $d$  (it requires time  $O(d^{h(n)})$ ). Construct also the table  $T_{\text{div}}$  for base 2 (instead of base  $d$ ).

*Part 3.* Construct the table  $T_1$  of the possible transitions from a description  $\tau$  of type 1 or 2 to a description  $\tau'$  of type 2 by only one move of the NTM (this will be denoted as  $\tau\mathcal{R}_1\tau'$ ). For convenience, we assume that our NRAM is multidimensional. We use the fact that an integer which encodes a word of length  $h(n)$  on the alphabet  $\Sigma = \{1, \dots, d\}$  (for instance, the description  $\delta$  of a block) is decoded, i.e., analyzed by bits, in time  $O(h(n))$  (by using table  $T_{\text{div}}$ ) and that conversely, an encoding subroutine requires a similar time. Let us exhibit it:

SUBROUTINE ENCODING {Comment: it reads a sequence of  $h(n)$  symbols of  $\Sigma$   
and returns the integer  $e$  it represents}

```
begin e := 0;
  for i := 1 to h(n) do
    begin Read (u); e := de + u end
end.
```

For each description  $\tau$  the set  $\{\tau' | \tau\mathcal{R}_1\tau'\}$  can be constructed in time  $O(h(n))$ . Therefore, the NRAM computes table  $T_1$  in time  $O(\beta(n)h(n))$  since there are  $O(\beta(n))$  descriptions (of type 1 or 2).

*Part 4.* Construct the table  $T_{\mathcal{R}}$  of relation  $\mathcal{R}$ , using table  $T_1$ . For each description  $\tau$  of type 1 do as follows:

*Stage 4(i).* ( $1 \leq i \leq h(n)$ ). Construct the set  $D_i$  of descriptions  $\tau_i$  such that  $\tau_{i-1}\mathcal{R}_1\tau_i$  for a description  $\tau_{i-1} \in D_{i-1}$  (convention:  $D_0 = \{\tau\}$ ).

It is clear that  $D_{h(n)} = \{\tau' | \tau\mathcal{R}\tau'\}$ . Stage 4(i) ( $1 \leq i \leq h(n)$ ) requires time  $O(\beta(n))$ . Therefore, the construction of the set  $\{\tau' | \tau\mathcal{R}\tau'\}$ , for a fixed  $\tau$ , requires time  $O(\beta(n)h(n))$  and table  $T_{\mathcal{R}}$  is computed in time  $O(\beta(n)^2h(n))$ .

Parts 2-4 of the precomputation require time  $O(\beta(n)^2h(n)) = O(h(n)^7d^{18h(n)})$  where  $h(n) = \lfloor 1/k \log n \rfloor$ .

For a sufficiently large integer  $k$  ( $k \geq 20 \log d$  is sufficient) we obtain  $O(h(n)^7d^{18h(n)}) = O(n/\log n)$ .

*Part 5.* This is the main part of the simulation. Each interval  $\Delta_e$  (of length  $h(n) = \lfloor 1/k \log n \rfloor$ ) of a computation of the NTM is simulated in  $O(1)$  steps as follows:

exhibit the description  $\tau$  (of type 1) of the NTM at the first instant of  $\Delta_e$ ; guess a tuple  $\tau'$  (of type 2) such that  $\tau \mathcal{R} \tau'$ ; for each tape  $i = 0, 1, 2$ , transform the contents of the three visited registers  $R_{j-1}^i, R_j^i, R_{j+1}^i$  according to the new description  $\tau'$ .  $\square$

**5. NRAMs and first-order generalized spectra.** In the present section, we give a key lemma (Lemma 5.2) for the proof of our main result. It uses a logical notion: the (*generalized*) *spectrum* of a *first-order sentence*. Our idea is roughly the following. We encode  $m$  moves of an NRAM (which simulates  $\Omega(m \log m)$  of an NTM by Lemma 4.1) into a structure of domain  $m = \{0, 1, \dots, m-1\}$ . More precisely our input is encoded by a function  $f: m \rightarrow m$  (note that such a function encodes a word  $w \in \{1, 2\}^*$  of length about  $m \log m$ ); the  $m$  moves of our NRAM are encoded by a “computation structure”  $\langle m, f, <, \dots \rangle$  expanding the input structure  $\langle m, f \rangle$  (with the natural order  $<$  of the domain  $m$  and with some functions from  $m$  to  $m$  and some constants); lastly we define the “computation structures” to be exactly the finite models of some first-order sentence with only one (universally quantified) variable; the variable intuitively represents each of the  $m$  instants of the computation of the NRAM. The precise definitions and proofs are given below.

In § 4, we have identified each word  $w \in \{1, 2\}^n$  with an  $m$ -tuple  $(w_0, \dots, w_{m-1})$  of integers where  $m = \lceil n/h(n) \rceil$  ( $h(n) = \lfloor 1/k \log n \rfloor$ ) and each  $w_i < 2n^{1/k}$ . Now let us identify each sufficiently long word  $w \in \{1, 2\}^n$  with the structure  $\langle m, f \rangle$ , where domain  $m$  is  $\{0, 1, \dots, m-1\}$  and  $f$  is the function  $m \rightarrow m - \{0\}$  such that for all  $i < m, f(i) = w_i$  (this is possible since  $w_i < 2n^{1/k} \leq m$  except for finitely many  $n$ ). So, a set of words  $S \subset \{1, 2\}^*$  is identified with a set of structures  $\langle m, f \rangle$  (except for finitely many words  $w$  of  $S$ : we can eliminate these words without changing the complexity of  $S$ ).

*Notation.* Let  $S$  be a set of structures  $\langle m, f \rangle$ , where  $m$  is a positive integer and  $f$  is a function:  $m \rightarrow m - \{0\}$ . We write  $S \in \text{NRAM}(T(m))$  to mean that  $S$  is accepted by an NRAM in time  $T(m)$ .

*Remarks.*  $m$  is the cardinality of the input structure ( $m$  is not the length of the encoding of this structure!). We still use the above convention: a Read instruction reads the first value  $f(0), f(1), \dots, f(m-1), 0$  which has not been read in up to this time.

Let us reformulate Lemma 4.1.

**LEMMA 5.1.** *If a language  $S \subset \{1, 2\}^*$  belongs to  $\text{NTIME}(n)$ , then there is an integer  $c$  such that  $S \in \text{NRAM}(cm)$  (where  $S$  is regarded as a set of structures  $\langle m, f \rangle$ ).*

*Proof.* Note that  $n/\log n = O(m)$  since  $m = \lceil n/h(n) \rceil$ .  $\square$

*Remark.* The assertion  $S \in \text{NRAM}(cm)$  of Lemma 5.1 implicitly refers to the integer  $k$  used in the partition of an input  $w \in \{1, 2\}^*$  into an  $m$ -tuple  $(w_0, \dots, w_{m-1})$ . It does not matter because  $k$  only depends upon set  $S$ .

*Notation.* For an integer  $c > 1$  and a function  $f: m \rightarrow m - \{0\}$ , let  ${}^c f$  denote the function:  $cm \rightarrow cm$  such that:  ${}^c f(e) = f(e)$  for  $e < m$  and  ${}^c f(e) = 0$  for  $m \leq e < cm$ . If  $w = (w_0, \dots, w_{m-1}) = \langle m, f \rangle$  we also denote

$$c(w) = (w_0, \dots, w_{m-1}, \underbrace{0, \dots, 0}_{(c-1)m \text{ times}}) = \langle cm, {}^c f \rangle.$$

**DEFINITION.** Let  $\varphi$  be a first-order sentence whose type is  $\mathcal{T} \cup \{<, F\}$  where

- (i)  $<$  is a binary relation symbol (for linear order);
- (ii)  $F$  is a specified monadic function symbol.

The *generalized spectrum* of  $\varphi$ , denoted  $\text{GenSp}(\varphi)$ , is the set of structures  $\langle M, F \rangle$  ( $M$  is a positive integer) which have an expansion  $\langle M, <, F, g \rangle_{g \in \mathcal{T}}$  which satisfies  $\varphi$  and where:

- (i)  $<$  is the natural linear order on  $M$ ;

(ii) Symbol  $F$  is interpreted by function  $F$ . (More generally, for convenience, we confuse each symbol and its interpretation.)

The following lemma is similar to Theorem 6 of [Gr2]. We present a proof of this lemma in order to make the paper self-contained.

LEMMA 5.2. *If  $S$  is a set of structures  $\langle m, f \rangle$  such that  $S \in \text{NRAM}(cm)$  for an integer  $c \geq 1$ , then there is a sentence  $\varphi = \forall x \psi(x)$  (with only one variable  $x$ ) of type  $\mathcal{T} \cup \{<, F\}$  such that:*

- (i)  $\psi$  is quantifier-free;
- (ii)  $\mathcal{T}$  only contains monadic function symbols and constant symbols;
- (iii) For any structure  $\langle m, f \rangle$ ,  $f: m \rightarrow m = \{0\}$ , we have  $\langle m, f \rangle \in S$  if and only if  $\langle cm, {}^c f \rangle \in \text{GenSp}(\varphi)$ .

*Proof.* Let  $S \in \text{NRAM}(cm)$ . Without loss of generality we assume that a simple NRAM,  $\mathcal{M}$ , accepts  $S$  in time  $cm$ ,  $c \geq 1$  an integer. Let  $\text{inst } 0, \text{inst } 1 \cdots \text{inst } l$  be the sequence of instructions of the program of  $\mathcal{M}$ . We want to encode an accepting computation of length  $M = cm$  in a structure of domain  $M$ . We can require that all integers encountered in it be smaller than  $M$ . The type  $\mathcal{T} \cup \{<, F\}$  of our structure includes the monadic function symbols denoted  $I, A, \langle A \rangle, \langle A' \rangle, B$ , and  $P$  with the following (intuitive) meaning (note that the argument  $t$  of the functions intuitively means: "at the instant  $t$ "), see Fig. 1.

$I(t) = i$	holds iff the current instruction is $\text{inst } i$
$A(t)$	is the content of accumulator $a$
$\langle A \rangle(t)$	is the integer currently stored in register $\langle a \rangle$
$\langle A' \rangle(t)$	is the integer written in register $\langle a \rangle$
$B(t)$	is the content of accumulator $b$
$P(t) = e$	iff the next input integer to be read in is $F(e)$

FIG. 1

The conjunction,  $\varphi_0$ , of sentences  $\forall x \exists y \text{ suc}(y) = x$  and  $(\forall x \neq L) [x < \text{suc}(x) \wedge \text{suc}(L) = 0]$  defines (on domain  $M$ ) the constants  $0, L = M - 1$  and the monadic function  $\text{suc}$  such that  $\text{suc}(e) = e + 1$  modulo  $M$ , for each  $e \in M$ : in case  $e < M - 1$ , we use the more suggestive notation  $e + 1$ . Define the constants  $1 = 0 + 1, 2 = 1 + 1 \cdots$  as abbreviations.

For the purpose of describing an accepting computation of  $\mathcal{M}$ , let us give some sentences of type  $\mathcal{T} \cup \{<, F\}$ :

$$\varphi_1: [A(0) = 0 \wedge \langle A \rangle(0) = 0 \wedge B(0) = 0 \wedge I(0) = 0 \wedge P(0) = 0],$$

$\varphi_1$  describes the initial conditions. The following sentence:

$$\varphi_2: \forall t \bigvee_{i \leq l} I(t) = i$$

means that exactly one instruction of the program is current at each instant.

Let (same  $a$ )( $t$ ), (same  $\langle a \rangle$ )( $t$ ), (same  $b$ )( $t$ ), and (same  $p$ )( $t$ ), respectively, denote equalities  $A(t+1) = A(t)$ ,  $\langle A' \rangle(t+1) = \langle A \rangle(t)$ ,  $B(t+1) = B(t)$ , and  $P(t+1) = P(t)$ . Define the formula (same  $\langle a \rangle, b$ )( $t$ ) for example, as the conjunction (same  $\langle a \rangle$ )( $t$ )  $\wedge$  (same  $b$ )( $t$ ).

Figure 2 associates to each instruction a formula which describes its action.

Let  $\varphi_3$  be the sentence  $(\forall t \neq L) \bigwedge_{i \leq l} [I(t) = i \rightarrow \Psi_i(t)]$ . We want to express the following facts (recall that the content of a register remains unchanged until this register is pointed out by accumulator  $a$ ):

Instruction inst $i$	Formula $\Psi_i(t)$
Read ( $a$ )	$A(t+1) = F(P(t)) \wedge P(t+1) = P(t) + 1 \wedge (\text{same } \langle a, b \rangle(t) \wedge I(t+1) = i + 1)$
$a := a + 1$ (similarly for $a := a - 1$ and $a := 0$ )	$A(t+1) = A(t) + 1 \wedge (\text{same } \langle a, b, p \rangle(t) \wedge I(t+1) = i + 1)$
Guess ( $a$ )	$\exists y A(t+1) = y \wedge (\text{same } \langle a, b, p \rangle(t) \wedge I(t+1) = i + 1)$
$a := \langle a \rangle$	$A(t+1) = \langle A \rangle(t) \wedge (\text{same } \langle a, b, p \rangle(t) \wedge I(t+1) = i + 1)$
$b := a$	$B(t+1) = A(t) \wedge (\text{same } a, \langle a, p \rangle(t) \wedge I(t+1) = i + 1)$
$\langle a \rangle := b$	$\langle A \rangle'(t+1) = B(t) \wedge (\text{same } a, b, p)(t) \wedge I(t+1) = i + 1)$
Go to inst $i_0$ or $i_1$	$(\text{same } a, \langle a, b, p \rangle(t) \wedge [I(t+1) = i_0 \vee I(t+1) = i_1])$
If $a = b$ then go to inst $i_0$ else go to inst $i_1$	$(\text{same } a, \langle a, b, p \rangle(t) \wedge [A(t) = B(t) \rightarrow I(t+1) = i_0] \wedge [A(t) \neq B(t) \rightarrow I(t+1) = i_1])$
Accept (or Reject)	$I(t+1) = i$

FIG. 2

(1) If  $t'$  is the last instant before  $t$  when  $A(t) = A(t')$ , i.e., for all  $t''$  with  $t' < t'' < t$  it holds  $A(t'') \neq A(t)$ , then the integer currently stored in the register pointed out (by accumulator  $a$ ) at instant  $t$  is the integer written in this register at instant  $t' + 1$ .

(2) If register  $A(t)$  has never been pointed out before instant  $t$ , then the integer currently stored in this register at instant  $t$  is its initial content which is 0.

For this purpose we will define a new function symbol  $N$  ( $N$  for "numbering"), which has one argument and two values. Define the "current registers" of a computation as the couples  $(A(t), t)$ , where  $A(t)$  is the address (a natural number) of the register pointed out (by accumulator  $a$ ) at instant  $t$ ,  $t < M$ . There are exactly  $M$  "current registers." Let  $N(x)$  denote the "current register" of rank  $x$  ( $x < M$ ) in lexicographical ordering.

Clearly, function  $N$  is defined by the following sentences:

$$\varphi_4: \forall t \exists x (A(t), t) = N(x),$$

$$\varphi_5: (\forall x \neq L) N(x) < N(x+1).$$

The following sentence,  $\varphi_6$  indicates which is the integer read in the register pointed out (by  $a$ ) at each noninitial instant  $t$ . It uses function  $N$  in an essential manner.

$$\varphi_6: (\forall t \neq 0) \exists t' \exists x$$

$$[N(x) = (A(t'), t') \wedge N(x+1) = (A(t), t)$$

$$(*)1 \quad \wedge (A(t) = A(t') \rightarrow \langle A \rangle(t) = \langle A \rangle'(t' + 1))$$

$$(*)2 \quad \wedge (A(t) \neq A(t') \rightarrow \langle A \rangle(t) = 0)].$$

Implications  $(*1)$  and  $(*2)$ , respectively, describe the above-mentioned cases (1) and (2).

Let  $\varphi_7$  be the sentence  $\bigvee I(L) = i$ , where the disjunction extends over all  $i \leq l$  such that inst  $i = \text{Accept}$ .

Clearly, an input  $\langle m, f \rangle$  is accepted by a computation of  $\mathcal{M}$  (of length  $M = cm$ ) if and only if the sentence  $\varphi = \bigwedge_{i \leq 7} \varphi_i$  has a model which expands the structure  $\langle M, F \rangle = \langle cm, {}^c f \rangle$  (a model of  $\varphi$  “mimics” an accepting computation). In other words,  $\langle m, f \rangle \in S$  if and only if  $\langle cm, {}^c f \rangle$  belongs to  $\text{GenSp}(\varphi)$ . Moreover, it is easy to put the conjunction  $\varphi$  in an equivalent form with only one universal quantifier and no existential one as required: we use (Skolem) function symbols to eliminate existentially quantified variables (see [Gr1], [Gr2] for more details).  $\square$

*Remark.* Moreover, using a “folding” technique as in [Ly], [Gr2], we can prove a stronger result than Lemma 5.2: replace condition (iii) by: (iii') the set  $S$  is  $\text{GenSp}(\varphi)$ .

**6. Linear time reduction to  $\text{SAT}'_{<}(\mathbb{N})$ .** In order to give a clear idea of the proof of Lemma 6.2 which follows, we first prove a weakened form of this lemma: we consider the problem  $\text{SAT}'_{<}(\mathbb{N})$ . This problem is similarly defined as  $\text{SAT}_{<}(\mathbb{N})$  but disjunctions (with, of course, conjunctions) are permitted in an instance of  $\text{SAT}'_{<}(\mathbb{N})$ .

LEMMA 6.1. *Let  $S$  be a set of structures  $\langle m, f \rangle, f: m \rightarrow m - \{0\}$ . If  $S \in \text{NRAM}(cm)$ , for an integer  $c$ , then  $S$  is reducible to problem  $\text{SAT}'_{<}(\mathbb{N})$  in time  $O(m \log m)$  on a DTM.*

*Proof.* By Lemma 5.2 there is a sentence  $\varphi = \forall x \psi(x)$  of type  $\mathcal{T} \cup \{<, F\}$  such that:

- (i)  $\psi$  is quantifier-free;
- (ii)  $\mathcal{T}$  only contains monadic function symbols, denoted  $G$ , and constant symbols, denoted  $C$ ;
- (iii)  $\langle m, f \rangle \in S$  if and only if  $\langle cm, {}^c f \rangle \in \text{GenSp}(\varphi)$ .

Moreover, we assume that  $\psi$  contains no negation because each subformula of the form  $\uparrow t_1 = t_2$  (respectively,  $\uparrow t_1 < t_2$ ) can be replaced by the disjunction  $t_1 < t_2 \vee t_2 < t_1$  (respectively,  $t_1 = t_2 \vee t_2 < t_1$ ).

Let  $\langle M, F \rangle$  be a structure identified with the  $M$ -tuple  $W = (W_0, \dots, W_{M-1})$ , where  $0 \leq W_e = F(e) < M$  for  $e < M$ . Associate to  $W$  the conjunction  $\varphi_w$  of the following formulas  $\psi_1, \psi_2, \psi_3$ :

$$\psi_1 = \bigwedge_{G \in \mathcal{T}} \bigwedge_{e < M} G(e) < M \wedge \bigwedge_{C \in \mathcal{T}} C < M,$$

$\psi_1$  expresses that each constant  $C$  is in the domain  $M$  and that the image of domain  $M$  for each (monadic) function  $G$  is also included in  $M$ ;

$$\psi_2 = \bigwedge_{e < M} \psi(e), \quad \psi_3 = \bigwedge_{e < M} F(e) = W_e,$$

$\psi_2$  is an “unrolled” version of formula  $\varphi = \forall x \psi(x)$  and then because of formula  $\psi_3$  the conjunction  $\varphi_w = \psi_1 \wedge \psi_2 \wedge \psi_3$  expresses that  $\langle M, F \rangle = (W_0, W_1, \dots, W_{M-1})$  belongs to the generalized spectrum of sentence  $\varphi$ . Hence  $\langle M, F \rangle = W$  belongs to  $\text{GenSp}(\varphi)$  if and only if  $\varphi_w \in \text{SAT}'_{<}(\mathbb{N})$ . (Note that each occurrence of a constant symbol  $C$  can be replaced by  $C(0)$ :  $C$  is now regarded as a monadic function symbol). From condition (iii) we obtain the equivalence:  $w = \langle m, f \rangle$  belongs to  $S$  if and only if  $\varphi_{c(w)} \in \text{SAT}'_{<}(\mathbb{N})$ .

Formula  $\varphi_{c(w)}$  is a Boolean combination of  $O(cm) = O(m)$  atomic formulas, each of length  $O(\log m)$ . Hence, length  $(\varphi_{c(w)}) = O(m \log m)$ . The construction of  $\varphi_{c(w)}$  essentially consists of:

- (1) Read the input  $w = (w_0, w_1, \dots, w_{m-1})$  and copy the  $cm$ -tuple

$$c(w) = (w_0, \dots, w_{m-1}, 0, \dots, 0).$$

- (2) Write the list  $0, 1, \dots, cm - 1$  (a fixed number of times).

Clearly, the reduction  $w = (w_0, \dots, w_{m-1}) \mapsto \varphi_{c(w)}$  (from  $S$  to  $\text{SAT}'_{<}(\mathbb{N})$ ) is computable in time  $O(m \log m)$  on a DTM.  $\square$

*Remark.* We have used the same notation for symbols of the type  $\mathcal{T}$  of  $\varphi$  and for the corresponding function symbols of  $\varphi_w$ . Note that the function symbols of  $\varphi_w$  are interpreted by functions:  $\mathbb{N} \rightarrow \mathbb{N}$  whose values out of the interval of integers  $[0, M[$  can be defined arbitrarily.

*Notation.* Let  $D_q^M$  denote the set  $\{0, q, 2q, \dots, (M-1)q\}$ .

LEMMA 6.2. *Let  $S$  be a set of structures  $\langle m, f \rangle, f: m \rightarrow m - \{0\}$ . If  $S \in \text{NRAM}(cm)$  for an integer  $c$ , then  $S$  is reducible to problem  $\text{SAT}_{<}(\mathbb{N})$  in time  $O(m \log m)$  on a DTM.*

*Proof.* By Lemma 5.2, there is a sentence  $\varphi$  of type  $\mathcal{T} \cup \{<, F\}$  of the following form:

$$\varphi = \forall x \bigvee_{i < q} \bigwedge_{j < r} \sigma_j^i(x) *^i_j \tau_j^i(x) \quad \text{such that:}$$

- (i)  $\mathcal{T}$  only contains monadic function symbols, denoted  $G$  and constant symbols, denoted  $C$ ;
- (ii)  $*^i_j$  is written for “=” or “<”;
- (iii)  $\sigma_j^i$  and  $\tau_j^i$  are terms (with only one variable  $x$ );
- (iv)  $\langle m, f \rangle \in S$  if and only if  $\langle cm, {}^c f \rangle \in \text{GenSp}(\varphi)$ .

Sentence  $\varphi$  is the disjunctive normal form of the sentence  $\varphi$  of Lemma 5.2 where negation has been eliminated.

Let  $\langle M, F \rangle$  be a structure identified with the  $M$ -tuple  $W = (W_0, \dots, W_{M-1})$ , where  $0 \leq W_e = F(e) < M$  for  $e < M$ . As in Lemma 6.1, the idea of the proof is to “unroll” the sentence  $\varphi$  in an ordered domain of  $M$  elements: we now choose the domain  $D_q^M = \{0, q, 2q, \dots, (M-1)q\}$  (intuitively, an integer  $e < M$  is “represented” by  $eq$ ). We will use the intermediate elements  $eq + i$  ( $e < M, 1 \leq i < q$ ) to suppress the disjunction  $\bigvee_{i < q}$ .

Let  $P_0, P_1, Q$  be new monadic function symbols. Define  $\varphi_w$  to be the conjunction of the following formulas  $\psi_1 \cdot \dots \cdot \psi_6$ :

$$\psi_1 = \bigwedge_{e < M} Q(eq) = 1 \wedge \bigwedge_{e < M} \bigwedge_{i=1}^{q-1} Q(eq+i) = 0,$$

$\psi_1$  means  $Q$  is the characteristic function of the subset  $D_q^M$  of  $q$ -multiples in the interval of integers  $[0, Mq[$ ;

$$\begin{aligned} \psi_2 = & \bigwedge_{G \in \mathcal{T}} \bigwedge_{e < M} [G(eq) < Mq \wedge Q(G(eq)) = 1], \\ & \wedge \bigwedge_{C \in \mathcal{T}} [C(0) < Mq \wedge Q(C(0)) = 1], \end{aligned}$$

$\psi_2$  means the set  $D_q^M$  is invariant for each function  $G$  and contains the constants  $C(0)$  ( $C$  is now regarded as a function symbol);

$$\psi_3 = \bigwedge_{e < M} \bigwedge_{i < q} \left[ \bigwedge_{s=0,1} eq - 1 < P_s(eq+i) < eq + q \wedge P_0 P_1(eq+i) = eq + i \right],$$

$\psi_3$  means  $P_0$  and  $P_1$  permute each interval  $[eq, (e+1)q[$ ,  $e < M$ , and are inverses each other.

Let  $F_j^i$  and  $G_j^i$  ( $i < q, j < r$ ) be new monadic function symbols.

$$\begin{aligned} \psi_4 = & \bigwedge_{e < M} \bigwedge_{i < q} \bigwedge_{j < r} F_j^i(P_0(eq+i)) *^i_j G_j^i(P_0(eq+i)), \\ \psi_5 = & \bigwedge_{e < M} \bigwedge_{i < q} \bigwedge_{j < r} [F_j^i(eq) = \sigma_j^i(eq) \wedge G_j^i(eq) = \tau_j^i(eq)]. \end{aligned}$$

Because of the property  $\psi_3$  of permutation  $P_0$ , it is clear that  $\psi_4 \wedge \psi_5$  implies the following formula  $\varphi'$  which paraphrases sentence  $\varphi$ :

$$\varphi' = \bigwedge_{e < M} \bigvee_{i < q} \bigwedge_{j < r} \sigma_j^i(eq) *^i_j \tau_j^i(eq)$$

$(\psi_4 \wedge \psi_5$  implies for each  $e < M$  the conjunction  $\bigwedge_{j < r} \sigma_j^i(eq) *^i_j \tau_j^i(eq)$  where  $i$  is the index such that  $P_0(eq + i) = eq$ ).

Conversely, in case  $\varphi'$  is satisfied, let us construct permutation  $P_0$  and functions  $F_j^i, G_j^i$  as follows: for each  $e < M$ , choose an index  $i$  such that  $\bigwedge_{j < r} \sigma_j^i(eq) *^i_j \tau_j^i(eq)$  is satisfied and take  $P_0(eq + i) = eq$ ; then complete the definition of function  $P_0$  so that it permutes each interval  $[eq, (e + 1)q[$ .

For all  $e < M, i < q$ , and  $j < r$ , take  $F_j^i(eq) = \sigma_j^i(eq)$  and  $G_j^i(eq) = \tau_j^i(eq)$ , and for  $1 \leq i' < q$  take

$$F_j^i(eq + i') = 0 \quad \text{and} \quad G_j^i(eq + i') = 0 \quad \text{in case } *^i_j \text{ is } "="$$

and take

$$F_j^i(eq + i') = 0 \quad \text{and} \quad G_j^i(eq + i') = 1 \quad \text{in case } *^i_j \text{ is } "<".$$

From these definitions,  $\psi_5$  is trivially satisfied and so conjuncts of  $\psi_4$  corresponding to pairs  $(e, i)$  such that  $P_0(eq + i) = eq$  are also satisfied. The other conjuncts of  $\psi_4$  are satisfied because from the definition of  $F_j^i, G_j^i$  we have  $F_j^i(eq + i') *^i_j G_j^i(eq + i')$  for all  $i' \in [1, q[$ .

Finally, let us define the formulas  $\psi_6 = \bigwedge_{e < M} F(eq) = qW_e$  (where  $qW_e$  denotes the product of the integers  $q$  and  $W_e$ ) and  $\varphi_w = \bigwedge_{u \leq 6} \psi_u$ . Let  $\mathcal{A} = \langle D_q^M, <, F, G, C \rangle_{G, C \in \mathcal{T}}$  be a structure of type  $\mathcal{T} \cup \{<, F\}$  on the domain  $D_q^M$ . It must be clear that the two following assertions are equivalent:

(1) Structure  $\mathcal{A}$  satisfies formula  $\varphi'$  (which paraphrases  $\varphi$ ) and its reduct  $\langle D_q^M, F \rangle$  is isomorphic to structure  $W = \langle M, F \rangle$  by the isomorphism  $e \mapsto eq$  (notice that this isomorphism is expressed by  $\psi_6$ ).

(2) Structure  $\mathcal{A}$  is the restriction (to  $D_q^M$ ) of a reduct of a structure

$$\mathcal{B} = \langle Mq, <, F, G, C, P_0, \dots \rangle_{G, C \in \mathcal{T}, \dots}$$

(on domain  $Mq$ ) which satisfies  $\varphi_w$ .

(Note. For convenience, our notation does not distinguish between a function symbol and its interpretation in some domain  $D_q^M, M$ , or  $Mq$ , however, we must remember that they are distinct.)

Notice that in assertion (2) the domain  $Mq$  of  $\mathcal{B}$  may be replaced by  $\mathbb{N}$ . The equivalence (1)  $\leftrightarrow$  (2) implies: a structure  $W = \langle M, F \rangle$  has an expansion (of type  $\mathcal{T} \cup \{<, F\}$ ) which satisfies  $\varphi$  if and only if  $\varphi_w$  has a model on domain  $Mq$  (respectively,  $\mathbb{N}$ ).

Thus  $\langle M, F \rangle = W$  belongs to  $\text{GenSp}(\varphi)$  if and only if  $\varphi_w \in \text{SAT}_{<}(\mathbb{N})$ . From condition (iv) we obtain the equivalence:  $w = \langle m, f \rangle$  belongs to  $S$  if and only if  $\varphi_{c(w)} \in \text{SAT}_{<}(\mathbb{N})$ . As in Lemma 6.1, we easily see that the reduction  $w = (w_0, \dots, w_{m-1}) \mapsto \varphi_{c(w)}$  (from  $S$  to  $\text{SAT}_{<}(\mathbb{N})$ ) is computable in time  $O(m \log m)$  on a DTM.  $\square$

*Remark.* In the proof of Lemma 6.2 note the following facts:

FACT 6.2.1. If formula  $\varphi_{c(w)}$  is satisfiable, then it is satisfied by a structure where all terms and subterms that occur in  $\varphi_{c(w)}$  have values  $< cqm$ .

FACT 6.2.2. There is a finite set of function symbols SYMB (only depending on set  $S$ ) such that each function symbol of  $\varphi_{c(w)}$  belongs to SYMB.

FACT 6.2.3. There is a constant  $c_0$  (only depending on set  $S$ ) such that no term of  $\varphi_{c(w)}$  contains a composition of more than  $c_0$  (distinct or not distinct) function symbols of SYMB.

It is now easy to prove the main theorem.

**THEOREM 6.3.** *If a language  $S \subset \{1, 2\}^*$  belongs to  $\text{NTIME}(n)$  then  $S$  is reducible to problem  $\text{SAT}_{<}(\mathbb{N})$  in time  $O(n)$  on a one-tape transducer.*

*Proof.* From Lemma 5.1, there is an integer  $c$  such that  $S \in \text{NRAM}(cm)$  and then from Lemma 6.2 the set  $S$  (regarded as a set of structures  $\langle m, f \rangle$ ) is reducible to problem  $\text{SAT}_{<}(\mathbb{N})$  in time  $O(m \log m)$  via the reduction  $w = (w_0, \dots, w_{m-1}) \mapsto \varphi_{c(w)}$ . It remains to prove that this reduction is computable on a one-tape transducer. The algorithm is the following:

Let  $w \in \{1, 2\}^n$  be an input word.

*Part 1.* Computation of  $h(n)$  and  $m$ : write  $n$  in binary notation (in time  $O(n)$ ); compute the integers  $\lfloor n^{1/k} \rfloor$ ,  $h(n) = \lfloor \log(n^{1/k}) \rfloor$ , and  $m = \lceil n/h(n) \rceil$  (it requires a polynomial time in the length of  $n$ ).

*Part 2.* Construction of formula  $\varphi_{c(w)} = \bigwedge_{i \leq 6} \psi_i$ : we only present the construction of the conjunct  $\psi_6$  which fully depends on input  $w$  (the other conjuncts  $\psi_1 \dots \psi_5$  only depend upon length of  $w$ ). We have  $\psi_6 = \psi'_6 \wedge \psi''_6$  where  $\psi'_6 = \bigwedge_{e < m} F(eq) = qw_e$  and  $\psi''_6 = \bigwedge_{m \leq e < cm} F(eq) = 0$ . Construct  $\psi'_6$ . That is, for each  $e < m$ :

- copy the subword  $w_e$  of length  $h(n)$  on the worktape.
- multiply  $e$  and  $w_e$  (now regarded as an integer) by  $q$ .
- write the conjunct  $F(eq) = qw_e$  on the output tape.

$\psi''_6$  is constructed in a similar (simpler) manner. Part 1 of the algorithm clearly requires time  $O(n)$ . Part 2 requires time  $O(m \log m) = O(n)$ .  $\square$

We strengthen Theorem 6.3 by the following theorem.

**THEOREM 6.4.** *If a language  $S \subset \{1, 2\}^*$  belongs to  $\text{NTIME}(n)$ , then  $S$  is reducible to problem  $\text{SAT}_{<}^2(\mathbb{N})$  (respectively,  $\text{SAT}_{<}^{2,2}(\mathbb{N})$ ) in time  $O(n)$  on a one-tape transducer.*

*Proof.* We use the reduction  $w \mapsto \varphi_{c(w)}$  (from  $S$  to  $\text{SAT}_{<}(\mathbb{N})$ ) of Lemma 6.2. Let  $\text{SYMB} = \{f_\alpha \mid \alpha \in \{1, 2\}^l\}$  denote the finite set of function symbols which occur in formulas  $\varphi_{c(w)}$  (cf Fact 6.2.2). For each  $w \in \{1, 2\}^*$  let  $\varphi'_w$  denote the formula (with function symbols  $g_1, g_2$ ) obtained from  $\varphi_{c(w)}$  by replacing each occurrence of any symbol  $f_\alpha$  ( $\alpha \in \{1, 2\}^l$ ) by the composition  $g_{\alpha_1} g_{\alpha_2} \dots g_{\alpha_l}$ , where  $\alpha = \alpha_1 \alpha_2 \dots \alpha_l$ . Let us prove the equivalence  $\varphi_{c(w)} \in \text{SAT}_{<}(\mathbb{N}) \leftrightarrow \varphi'_w \in \text{SAT}_{<}^2(\mathbb{N})$ . Clearly  $\varphi'_w \in \text{SAT}_{<}^2(\mathbb{N})$  implies  $\varphi_{c(w)} \in \text{SAT}_{<}(\mathbb{N})$ .

Conversely, assume that a structure  $\mathcal{A} = \langle \mathbb{N}, F_\alpha \rangle_{\alpha \in \{1, 2\}^l}$  satisfies formula  $\varphi_{c(w)}$ . We can assume that all terms and subterms of  $\varphi_{c(w)}$  have values  $< cqm$  in structure  $\mathcal{A}$  (Fact 6.2.1).

For each integer  $e < cqm$  and each  $f_{\alpha_1 \dots \alpha_l} \in \text{SYMB}$ , let us define the values of:

$$g_{\alpha_1}(e), g_{\alpha_1-1} g_{\alpha_1}(e), \dots, g_{\alpha_2} g_{\alpha_3} \dots g_{\alpha_l}(e) \quad \text{to be integers } \cong cqm$$

(i.e., distinct from the values of the terms and subterms of  $\varphi_{c(w)}$ ) such that distinct terms have distinct values.

Last, for each  $e < cqm$ , define  $g_{\alpha_1} g_{\alpha_2} \dots g_{\alpha_l}(e)$  to be the value of  $f_{\alpha_1 \dots \alpha_l}(e)$  in structure  $\mathcal{A}$ . (This construction is similar to that of Lemma 3.4.) It follows from these last definitions that structure  $\langle \mathbb{N}, g_1, g_2 \rangle$  (where undefined values of  $g_1, g_2$  can be fixed in any manner) satisfies  $\varphi'_w$ . Hence  $\varphi'_w \in \text{SAT}_{<}^2(\mathbb{N})$ . It is obvious that reduction  $w \mapsto \varphi'_w$  from  $S$  to  $\text{SAT}_{<}^2(\mathbb{N})$  (similar to reduction  $w \mapsto \varphi_{c(w)}$ ) is computable in time  $O(n)$  on a one-tape transducer.

*Remark.* The above argument proves also that  $\text{SAT}_{<}(\mathbb{N})$  is linear time reducible to  $\text{SAT}_{<}^2(\mathbb{N})$ .

Let us state two useful facts to prove Theorem 6.4 for  $\text{SAT}_{<}^{2,2}(\mathbb{N})$ .

**FACT 6.4.1.** There is a constant integer  $c'$  (depending only upon set  $S$ ) such that if  $\varphi'_w$  is satisfiable, then it is satisfied by a structure where all terms and subterms of  $\varphi'_w$  have values  $< c'm$ . In particular, the length of each integer  $e$  which occurs in  $\varphi'_w$  is bounded by length  $(c'm) = O(\log m)$ .

FACT 6.4.2. It follows from Fact 6.2.3 that no term of  $\varphi'_w$  contains a composition of more than  $c_0l = O(1)$  function symbols  $g_1, g_2$ .

For each  $w \in \{1, 2\}^*$ , define formula  $\varphi''_w$  to be the conjunction of the following formulas:

- (i) A formula denoted  $\tilde{\varphi}_w$  obtained from  $\varphi'_w$  by replacing each term of the form  $g_{\alpha_1}g_{\alpha_2} \cdots g_{\alpha_s}(e)$  ( $\alpha_i \in \{1, 2\}, s \geq 1$ ) by  $g_1(\alpha_1\alpha_2 \cdots \alpha_s \hat{\bar{e}})$  where  $\bar{e}$  denotes the word of  $\{1, 2\}^*$  (identified to an integer) obtained by the concatenation:  $\bar{e} = 1^t 2^t e$  (where  $1^t$  denotes symbol "1" repeated  $t$  times) with  $t$  such that  $\text{length}(\bar{e}) = 1 + \text{length}(c'm)$ . (Note. We can construct  $\bar{e}$  since  $\text{length}(e) \leq \text{length}(c'm)$  by Fact 6.4.1.)
- (ii) For each term  $\theta = g_{\alpha_1}g_{\alpha_2} \cdots g_{\alpha_s}(e)$  of  $\varphi'_w$  the formula:

$$\psi_\theta = \left[ g_1(\bar{e}) = e \wedge \bigwedge_{1 \leq i \leq s} g_i(\alpha_i \alpha_{i+1} \cdots \alpha_s \hat{\bar{e}}) = g_{\alpha_i} g_1(\alpha_{i+1} \cdots \alpha_s \hat{\bar{e}}) \right].$$

Note that  $\psi_\theta$  is equivalent to the conjunction

$$\psi'_\theta = \left[ g_1(\bar{e}) = e \wedge \bigwedge_{1 \leq i \leq s} g_i(\alpha_i \cdots \alpha_s \hat{\bar{e}}) = g_{\alpha_i} \cdots g_{\alpha_s}(e) \right].$$

Clearly  $\varphi''_w$  is an instance of problem  $\text{SAT}_{\leq}^{2,2}(\mathbb{N})$ . It follows from Fact 6.4.2 that each formula  $\psi_\theta$  contains  $O(1)$  atomic subformulas and then has length  $O(\log m)$  (cf. Fact 6.4.1), so,  $\text{length}(\varphi''_w) = O(m \log m)$ .

We easily see that the application  $w \mapsto \varphi''_w$  is computable in time  $O(m \log m) = O(n)$  on a one-tape transducer.

It remains to prove the equivalence:  $\varphi'_w \in \text{SAT}_{<}(\mathbb{N}) \leftrightarrow \varphi''_w \in \text{SAT}_{\leq}^{2,2}(\mathbb{N})$ . The conjunction of  $\tilde{\varphi}_w$  and formulas  $\psi'_\theta$  clearly imply  $\varphi'_w$ . Hence  $\varphi''_w$  implies  $\varphi'_w$ .

Conversely, assume that a structure  $\langle \mathbb{N}, g_1, g_2 \rangle$  satisfies  $\varphi'_w$ . By Fact 6.4.1 we can assume that values of terms and subterms which occur in  $\varphi'_w$  are  $< c'm$ . For each term  $\theta = g_{\alpha_1}g_{\alpha_2} \cdots g_{\alpha_s}(e)$  of  $\varphi'_w$  redefine  $g_i(\alpha_i \cdots \alpha_s \hat{\bar{e}})$  to be  $g_{\alpha_i} \cdots g_{\alpha_s}(e)$  for each  $i \in [1, s]$  and redefine  $g_1(\bar{e})$  to be  $e$ .

There is no double definition of the same value because if we have any equality  $\alpha \hat{\bar{e}} = \beta \hat{\bar{e}'}$ , where  $\alpha, \beta \in \{1, 2\}^*$ , then  $\alpha = \beta$  and  $\bar{e} = \bar{e}'$  (because of the equality  $\text{length}(\bar{e}) = \text{length}(\bar{e}') = 1 + \text{length}(c'm)$ ) and consequently  $e = e'$ . These modifications of function  $g_1$  do not affect the truth of  $\varphi'_w$  in structure  $\langle \mathbb{N}, g_1, g_2 \rangle$  since they only affect values  $g_1(u)$  for some  $u > c'm$ .

Our structure  $\langle \mathbb{N}, g_1, g_2 \rangle$  trivially satisfies formulas  $\psi'_\theta$  (and, consequently  $\psi_\theta$ ) and then satisfies  $\tilde{\varphi}_w$  (which paraphrases  $\varphi'_w$ ). Hence  $\varphi''_w \in \text{SAT}_{\leq}^{2,2}(\mathbb{N})$ . This concludes the proof of Theorem 6.4.  $\square$

COROLLARY 6.5. *Theorem 6.3 (respectively, Theorem 6.4) still holds for  $\text{SAT}_{<}(\mathbb{N})$  (respectively,  $\text{SAT}_{\leq}^2(\mathbb{N})$ ) in the absence of the equality symbol "=".*

*Sketch of proof.* Let us modify the formula  $\varphi_{c(w)}$  of the proof of Theorem 6.3: replace each equality  $\sigma = \tau$  by the conjunction  $\sigma < \text{SUC}(\tau) \wedge \tau < \text{SUC}(\sigma)$ , where SUC is a new function symbol (intuitively, SUC is the successor function); take the conjunction of the obtained formula with the following formulas  $\bigwedge_{i < cqm} (G(i) < cqm)$  for all function symbols  $G$  of  $\varphi_{c(w)}$  (cf. Fact 6.2.1), and with the formula

$$\bigwedge_{i < cqm} [i < \text{SUC}(i) \wedge \text{SUC}(i) < i + 2]$$

which clearly defines the successor function restricted to the interval of integers  $[0, cqm[$ . This proves Corollary 6.5 for  $\text{SAT}_{<}(\mathbb{N})$ . Starting from this result, we prove the last part of Corollary 6.5 exactly as we proved Theorem 6.4 for  $\text{SAT}_{\leq}^2(\mathbb{N})$ .  $\square$

From the separation result of [PPST],  $\cup_c \text{DTIME}(cn) \not\subseteq \text{NTIME}(n)$  Corollary 6.6 follows.

**COROLLARY 6.6.** (i) *Problems  $\text{SAT}_{<}(\mathbb{N})$  and  $\text{SAT}_{<}^2(\mathbb{N})$  do not belong to  $\cup_c \text{DTIME}(cn)$ , even in the absence of the equality symbol.*

(ii) *Problem  $\text{SAT}_{\leq}^{2,2}(\mathbb{N})$  does not belong to  $\cup_c \text{DTIME}(cn)$ .*

*Final remarks.* Corollary 6.6 is a modest result because on one hand it concerns an NP-complete problem (often regarded as intractable) and on the other hand the linear time lower bound it states is a deterministic lower bound. It would be interesting to exhibit a (natural) NP-complete problem  $\mathcal{E}_0$  to which each problem in  $\text{NTIME}(n \log n)$ , for example, is linear time reducible; then it would follow from the hierarchy theorem on  $\text{NTIME}$  classes [Co1], [SFM] that  $\mathcal{E}_0 \notin \text{NTIME}(n)$ .

We would like to exhibit a problem  $\mathcal{E}_1 \in \text{NTIME}(n)$  to which all problems of this class are linear time reducible (on a DTM), so that  $\mathcal{E}_1 \notin \cup_c \text{DTIME}(cn)$ . However it is hard to find a (sufficiently expressible) problem the solution of which does not involve sorting.

*Note added in proof.* We have recently proved that a problem listed in [GaJo], “Reduction of Incompletely Specified Automata” has the same complexity theoretical properties as  $\text{SAT}_{\leq}^{2,2}(\mathbb{N})$  (cf. E. Grandjean, “A Nontrivial Lower Bound for an NP-Problem on Finite Automata,” to be submitted).

**Appendix A.** A proof of Theorem 3.7. Let us introduce several definitions and lemmas.

**DEFINITION.** An *elementary conjunction* is an instance of problem  $\text{SAT}_{<}(\mathbb{N})$  of the form  $\bigwedge_i \theta_i = v_i$ , where  $\theta_i$  denotes a term which includes at least one function symbol and  $v_i$  denotes an integer. If no term  $\theta_i$  is a subterm of another term  $\theta_j$ , then we say that the elementary conjunction is *suffix-free*.

Lemma 3.4 can be restated as follows.

**LEMMA A.1.** *Each suffix-free elementary conjunction is satisfiable.*

**DEFINITION.** A *partition*  $\Delta$  of an elementary conjunction  $\Phi$  is a function which associates to each conjunct  $\mathcal{F}e = e'$  of  $\Phi$  a decomposition of  $\mathcal{F}$ , i.e., a sequence  $\mathcal{F}_1, \mathcal{F}_2, \dots, \mathcal{F}_k$  of nonempty words (on the alphabet SYMB) such that  $\mathcal{F} = \mathcal{F}_k \cdots \mathcal{F}_2 \mathcal{F}_1$ .

**DEFINITION.** Let  $\Phi, \Phi'$  be two elementary conjunctions and  $\Delta$  be a partition of  $\Phi$ . We say that  $\Phi$  *derives from  $\Phi'$  modulo  $\Delta$*  if for each conjunct  $\mathcal{F}e = e'$  of  $\Phi$ , to which  $\Delta$  associates the decomposition  $\mathcal{F} = \mathcal{F}_k \cdots \mathcal{F}_2 \mathcal{F}_1$ , there exist integers  $e_0, e_1, \dots, e_k$  such that:

- (i)  $e_0 = e$ ;
- (ii)  $\mathcal{F}_i e_{i-1} = e_i$  is a conjunct of  $\Phi'$ , for each  $i = 1, 2, \dots, k$ ;
- (iii)  $e_k = e'$ .

*Remark.* Clearly, the derivation (between elementary conjunctions) is a transitive relation.

**DEFINITION.** The *depth* of an elementary conjunction  $\Phi$ , denoted  $\text{depth}(\Phi)$ , is the maximal number of occurrences of function symbols in a term of  $\Phi$ .

Of course, an elementary conjunction which derives from a suffix-free elementary conjunction is satisfiable (by Lemma A.1). Conversely we have Lemma A.2.

**LEMMA A.2.** *If an elementary conjunction  $\Phi$  is satisfiable, then it derives from a suffix-free elementary conjunction  $\Phi'$  (modulo some partition  $\Delta$ ) such that:*

- (i)  $\text{depth}(\Phi') \leq \text{depth}(\Phi)$ ;
- (ii) *the function symbols and integers which occur in  $\Phi'$  are those of  $\Phi$ ;*
- (iii)  $\text{length}(\Phi') \leq \text{length}(\Phi) + l \cdot \text{conj}$ ;

where  $l$  is the length of the largest integer which occurs in  $\Phi$  and  $\text{conj}$  is the number of conjuncts of  $\Phi$ .

*Proof.* The construction of  $\Phi'$  is given by procedures (4), (5) of the proof of Proposition 3.3. Recall that we make successive substitutions (starting from conjunction  $\Phi = \bigwedge_r \theta_r = v_r$ ) as follows: in case a term  $\theta_i$  is a proper subterm of another  $\theta_j$ , i.e.,  $\mathcal{G}\theta_i = \theta_j$ , replace the conjunct  $\theta_j = v_j$  of  $\bigwedge_r \theta_r = v_r$  by  $\mathcal{G}v_i = v_j$  (and suppress any duplicate conjunct). We obtain a sequence of elementary conjunctions  $\Phi_0 = \Phi, \Phi_1, \dots, \Phi_m = \Phi'$  such that  $\Phi_s$  derives from  $\Phi_{s+1}$  modulo some (simple) partition  $\Delta_s$  ( $s = 0, 1, \dots, m-1$ ). Clearly there are strictly fewer occurrences of function symbols in  $\Phi_{s+1}$  than in  $\Phi_s$  (in particular  $m \leq \text{length}(\Phi)$ ) and there are no more conjuncts (respectively, occurrences of integers) in  $\Phi_{s+1}$  than in  $\Phi_s$ : this proves (iii). Assertions (i) and (ii) are obvious.  $\square$

*Notation.* Let DERIVE denote the following problem.

*Instance.* A tuple  $(\Phi, \Phi', \Delta)$ , where  $\Phi, \Phi'$  are elementary conjunctions such that:

- (i) Only two distinct function symbols  $g_1, g_2$  occur in  $\Phi, \Phi'$ ;
- (ii)  $\Phi'$  is suffix-free;
- (iii)  $\Delta$  is a partition of  $\Phi$ .

*Question.* Does  $\Phi$  derive from  $\Phi'$  modulo  $\Delta$ ?

LEMMA A.3. *There is a  $\Pi_1$  Turing machine  $\mathcal{U}$  which decides the problem DERIVE in time  $O(n + d^2(d + l))$ , where  $n, d, l$  denote the following measures of an input  $(\Phi, \Phi', \Delta)$ :  $n = \text{length}(\Phi) + \text{length}(\Phi')$ ,  $d = \max(\text{depth}(\Phi), \text{depth}(\Phi'))$  and  $l$  is the length of the largest integer occurring in  $\Phi, \Phi'$ .*

*Proof.* Let  $\mathcal{U}$  be the  $\Pi_1$  Turing machine with the following program an input of which is an instance  $(\Phi, \Phi', \Delta)$  of problem DERIVE.

- ( $\mathcal{U}_1$ ) Universally choose a conjunct  $\mathcal{F}e = e'$  of  $\Phi$ .
- ( $\mathcal{U}_2$ ) If  $\Delta$  associates to this conjunct the decomposition  $\mathcal{F} = \mathcal{F}_k \cdots \mathcal{F}_2 \mathcal{F}_1$ , universally choose a set  $E_k$  of at most  $k$  conjuncts of  $\Phi'$ .
- ( $\mathcal{U}_3$ ) The last part of the algorithm is deterministic: we want to check that one of the following conditions ( $*j$ ) is true ( $0 \leq j \leq k$ ).

For  $0 \leq j < k$ , condition ( $*j$ ) is:

There are integers  $e_0 = e, e_1, \dots, e_j, e_{j+1}$  such that  $(\mathcal{F}_i e_{i-1} = e_i) \in E_k$  for each  $i = 1, \dots, j$ , and  $(\mathcal{F}_{j+1} e_j = e_{j+1})$  is a conjunct of  $\Phi'$  which does not belong to  $E_k$ .

Condition ( $*k$ ) is as follows: There are integers  $e_0 = e, e_1, \dots, e_k$  such that  $(\mathcal{F}_i e_{i-1} = e_i) \in E_k$  for each  $i = 1, \dots, k$  and  $e_k$  is  $e'$ .

( $\mathcal{U}_3$ ) uses the following recursive PROCEDURE CHECK ( $j$ ), whose parameter belongs to  $\{1, \dots, k+1\}$ .

PROCEDURE CHECK ( $j$ ).

{We assume that  $e_0 = e, e_1, \dots, e_{j-1}$  have been found so that each conjunct  $(\mathcal{F}_i e_{i-1} = e_i)$  belongs to  $E_k$ , for  $i = 1, \dots, j-1$ }

BEGIN

IF  $j \leq k$  THEN

BEGIN

look for an equality of the form  $\mathcal{F}_j e_{j-1} = a$  in  $E_k$ ;

IF such an equality is found THEN

BEGIN  $e_j := a$ ; call CHECK ( $j+1$ ) END

ELSE

BEGIN

look for such an equality  $(\mathcal{F}_j e_{j-1} = a)$  in  $\Phi'$ ;

```

    IF such an equality is found THEN
      BEGIN  $e_j := a$ ; ACCEPT {Condition  $(*j-1)$  is true} END
    ELSE REJECT
  END
END;
IF  $j = k+1$  THEN
  IF  $e_k = e'$  THEN ACCEPT {Condition  $(*k)$  is true}
  ELSE REJECT
END;

```

$(\mathcal{U}_3)$  is precisely the following:

BEGIN  $e_0 := e$ ; call CHECK (1) END.

It is clear that (for each conjunct  $\mathcal{F}e = e'$  and each set  $E_k$ )  $(\mathcal{U}_3)$  accepts if and only if one of the conditions  $(*j)$  is true (recall that  $\Phi'$  is suffix-free and then is satisfiable).

We easily see that if  $\Phi$  derives from  $\Phi$  modulo the partition  $\Delta$ , then the  $\Pi_1$  Machine  $\mathcal{U}$  accepts the input  $(\Phi, \Phi', \Delta)$ .

Conversely, assume that  $\mathcal{U}$  accepts an instance  $(\Phi, \Phi', \Delta)$ . Let  $\mathcal{F}e = e'$  be a conjunct of  $\Phi$  and let  $\mathcal{F} = \mathcal{F}_k \cdots \mathcal{F}_2 \mathcal{F}_1$  be its associated decomposition (by  $\Delta$ ). We are going to construct by induction a sequence of integers  $e_0, e_1, \dots, e_j$  ( $0 \leq j \leq k$ ) such that the following condition  $(\mathcal{C}_j)$  holds:

$(\mathcal{C}_j)$ :  $e_0$  is  $e$  and  $(\mathcal{F}_i e_{i-1} = e_i)$  is a conjunct of  $\Phi'$  for each  $i = 1, \dots, j$ .

Assume that for some  $j < k$   $(\mathcal{C}_j)$  holds for the sequence  $e_0, e_1, \dots, e_j$ . Let  $E_k$  be a set of  $k$  conjuncts (of  $\Phi'$ ) which include the  $j$  conjuncts  $(\mathcal{F}_i e_{i-1} = e_i)$  for  $1 \leq i \leq j$ . Since  $\mathcal{U}$  accepts the input  $(\Phi, \Phi', \Delta)$  there is  $j' \leq k$  such that Condition  $(*j')$  is true for the conjunct  $\mathcal{F}e = e'$  and the set  $E_k$ . We necessarily have  $j' \geq j$  and then there is an integer  $e_{j+1}$  such that  $(\mathcal{F}_{j+1} e_j = e_{j+1})$  is a conjunct of  $\Phi'$ . This proves Condition  $(\mathcal{C}_{j+1})$ . So the induction is complete and we have constructed for the conjunct  $\mathcal{F}e = e'$  a sequence  $e_0, e_1, \dots, e_k$  such that:

$(\mathcal{C}_k)$ :  $e_0$  is  $e$  and  $(\mathcal{F}_i e_{i-1} = e_i)$  is a conjunct of  $\Phi'$  for each  $i = 1, \dots, k$ .

Now defining  $E_k$  to be the set of  $k$  conjuncts  $(\mathcal{F}_i e_{i-1} = e_i)$ , for  $i = 1, \dots, k$  we clearly see that Condition  $(*k)$  holds (for the conjunct  $(\mathcal{F}e = e')$  and the set  $E_k$ ) and then  $e_k$  is  $e'$ . It proves that  $(\mathcal{F}e = e')$  derives from  $\Phi'$  modulo  $\Delta$  and then  $(\Phi, \Phi', \Delta) \in \text{DERIVE}$ .

It remains to analyze the time used by machine  $\mathcal{U}$ . Parts  $(\mathcal{U}_1)$  and  $(\mathcal{U}_2)$  clearly need time  $O(n)$ . Let us examine the time required by  $(\mathcal{U}_3)$  for a fixed conjunct  $\mathcal{F}e = e'$  of  $\Phi$  (decomposed into  $\mathcal{F} = \mathcal{F}_k \cdots \mathcal{F}_2 \mathcal{F}_1$  by  $\Delta$ , with  $k \leq d$ ) and a fixed set  $E_k$  of  $k$  conjuncts of  $\Phi'$ . Clearly each conjunct of  $E_k$  has length  $O(d+l)$ . Therefore the search of a conjunct (respectively, of  $k$  conjuncts) of the form  $\mathcal{F}_j e_{j-1} = a$  in  $E_k$  requires  $k \cdot O(d+l)$  steps (respectively,  $k^2 \cdot O(d+l)$  steps). The end of  $(\mathcal{U}_3)$  consists in either looking for such a conjunct in  $\Phi'$  or checking that  $e_k$  is  $e'$ ; it needs  $O(n)$  steps. Thus  $(\mathcal{U}_3)$  requires a time  $O(n + d^2(d+l))$ .  $\square$

Recall that an instance  $\varphi$  of  $\text{SAT}_{<}(\mathbb{N})$  is satisfiable if and only if the corresponding conjunction,  $\text{SIMPLE}(\varphi)$  (defined at the beginning of § 3) is satisfiable. Let  $\text{SHORT}(\varphi)$  denote the conjunction of the distinct conjuncts of  $\text{SIMPLE}(\varphi)$  presented in lexicographical order.

**LEMMA A.4.** *There is a  $\Sigma_2$  Turing machine which accepts the set  $\{(\varphi, \varphi') : \varphi' = \text{SHORT}(\varphi)\}$  in linear time.*

*Proof.* It is similar to (simpler than) the proof of Theorem 3.6.  $\square$

LEMMA A.5. *There is a linear time bounded nondeterministic Turing machine  $\mathcal{N}$  which for each input  $\varphi'$  of the form  $\varphi' = \text{SHORT}(\varphi)$  with  $n = \text{length}(\varphi)$ , constructs an elementary conjunction  $\Phi$  such that:*

- (i)  $\varphi'$  is satisfiable if and only if it produces some conjunction  $\Phi$  which is satisfiable;
- (ii)  $\text{Depth}(\Phi) = \lceil \log n \rceil$  and each integer which occurs in  $\Phi$  is less than  $n^2$ ;
- (iii) Function symbols of  $\Phi$  are exactly those of  $\varphi'$  (or  $\varphi$ );
- (iv)  $\Phi$  has only  $O(n/\log n)$  conjuncts and  $\text{length}(\Phi) = O(n)$ .

*Proof.* The algorithm of  $\mathcal{N}$  is the following:

(1) For each (in)equality  $\theta = \theta'$  or  $\theta < \theta'$  of  $\varphi'$ , guess the values of the terms  $\theta, \theta'$  in the interval  $[0, n^2[$  so that the (in)equality holds: it produces an elementary conjunction  $\varphi'' = (\bigwedge_i \theta_i = v_i)$ . (By Lemma 3.1(i)  $\varphi'$  is satisfiable if and only if it produces some conjunction  $\varphi''$  which is satisfiable.)

(2) Let  $l = \lceil \log n \rceil$ . For each conjunct  $\theta_i = v_i$  of  $\varphi''$  of the form  $f_p \cdots f_2 f_1(e) = e'$ , compute the quotient  $q$  and the remainder  $r$  of the Euclidean division of  $p$  by  $l$  ( $p = ql + r$ ) and guess  $q$  "intermediate" integers values  $u_1, u_2, \dots, u_q$  in the interval  $[0, n^2[$ , i.e., replace the conjunct  $\theta_i = v_i$  of  $\varphi''$  by the "guessed" conjunction:

$$\gamma_i = \bigwedge_{1 \leq j \leq q+1} \mathcal{F}_j(u_{j-1}) = u_j,$$

where  $u_0 = e$ ,  $u_{q+1} = e'$ , each  $u_j \in [0, n^2[$ ,  $\mathcal{F}_j = f_{jl} f_{j-1} \cdots f_{(j-1)l+1}$  for  $j = 1, 2, \dots, q$  and  $\mathcal{F}_{q+1} = f_{ql+r} \cdots f_{q+1}$  (in case  $r = 0$  take  $u_q = e'$  and delete the last conjunct of  $\gamma_i$ ).

Let  $\Phi$  be the conjunction  $\bigwedge_i \gamma_i$ .

(i) is a direct consequence of Lemma 3.1(i). The assertions (ii) and (iii) are obvious. It remains to prove (iv). We have

$$\text{length}(\varphi'') = \text{length}(\varphi') + \text{conj} \cdot O(\log n)$$

where  $\text{conj}$  denotes the number of distinct conjuncts of  $\varphi'$  (or  $\varphi$ ) and then is  $O(n/\log n)$ . Therefore  $\text{length}(\varphi'') = O(n)$ . The number of conjuncts of  $\Phi$  is no more than the number of conjuncts of  $\varphi''$  (i.e.,  $O(n/\log n)$ ) plus  $O(n/l) = O(n/\log n)$  (we add a conjunct for each block of  $l$  composed functions). We have  $\text{length}(\Phi) = O(n)$  since each conjunct of  $\Phi$  has length  $O(\log n)$ .  $\square$

We can prove Theorem 3.7 as follows.

THEOREM 3.7. *Problem  $\text{SAT}_{<}(\mathbb{N})$  belongs to  $\Sigma_2(n)$ .*

*Proof.* As we have noticed in the proof of Theorem 6.4, problem  $\text{SAT}_{<}(\mathbb{N})$  is linear time reducible to problem  $\text{SAT}_{<}^2(\mathbb{N})$ . Thus it suffices to prove  $\text{SAT}_{<}^2(\mathbb{N}) \in \Sigma_2(n)$  and even to prove that the set

$$\text{SET} = \{(\varphi, \varphi') : \varphi' = \text{SHORT}(\varphi) \text{ and } \varphi' \in \text{SAT}_{<}^2(\mathbb{N})\}$$

belongs to  $\Sigma_2(n)$  (because  $\text{length}(\varphi') \leq \text{length}(\varphi)$  for  $\varphi' = \text{SHORT}(\varphi)$  and then for an input  $\varphi$  we can "guess" such a conjunction  $\varphi'$  in linear time).

The following algorithm clearly decides if  $(\varphi, \varphi') \in \text{SET}$  (cf. Lemmas A.4, A.5, A.2, A.3):

- (1) Check that  $\varphi' = \text{SHORT}(\varphi)$  (cf. Lemma A.4).
- (2) Simulate the nondeterministic Turing machine  $\mathcal{N}$  (on input  $\varphi'$ ): it produces an elementary conjunction  $\Phi$  (cf. Lemma A.5).
- (3) Guess a partition  $\Delta$  of  $\Phi$  and another elementary conjunction  $\Phi'$  (cf. Lemma A.2).
- (4) Check that  $\Phi'$  is suffix-free (in linear time on a  $\Pi_1$  Turing machine).
- (5) Check that  $(\Phi, \Phi', \Delta)$  belongs to  $\text{DERIVE}$  (using the  $\Pi_1$  Turing machine of Lemma A.3).

CLAIM. *The algorithm (1)–(5) works in linear time on an alternating Turing machine.*

*Proof of the claim.* If  $\varphi' = \text{SHORT}(\varphi)$  and belongs to  $\text{SAT}_{<}^2(\mathbb{N})$ , then (by Lemma A.5)  $\mathcal{N}$  produces (starting from input  $\varphi$ ) a satisfiable elementary conjunction  $\Phi$  of depth  $\lceil \log n \rceil$  and length  $O(n)$  (where  $n = \text{length}(\varphi)$ ). It follows from Lemma A.2 that  $\Phi$  is derivable from a suffix-free elementary conjunction  $\Phi'$  (modulo some partition  $\Delta$ ) such that:  $\text{length}(\Phi') \leq \text{length}(\Phi) + l \cdot \text{conj}$  where  $l$  is the length of the largest integer occurring in  $\Phi$  and then is  $O(\log n)$  (by Lemma A.5(ii)) and  $\text{conj}$  is the number of conjuncts of  $\Phi$  which is  $O(n/\log n)$  (by Lemma A.5(iv)): hence  $\text{length}(\Phi') = O(n)$ . It follows from Lemma A.3 that the  $\Pi_1$  Turing machine  $\mathcal{U}$  accepts the input  $(\Phi, \Phi', \Delta)$  in time  $O(n + (\log n)^2(\log n + \log n)) = O(n)$ . This proves the claim.

In order to get a  $\Sigma_2$  algorithm (i.e., existential steps precede universal steps) we do not execute the whole of Part (1) before Parts (2)–(5) but execute all the existential steps of Part (1) and of Parts (2)–(5) before we execute their universal steps. This completes the proof of Theorem 3.7.  $\square$

## SCHEDULING UET SYSTEMS ON TWO UNIFORM PROCESSORS AND LENGTH TWO PIPELINES \*

HAROLD N. GABOW †

**Abstract.** A set of jobs related by precedence constraints is to be executed in minimum time on two uniform processors, the faster one using  $f$  time units per job and the slower  $s \geq f$  time units. When  $s = f + 1$  the desired schedule can be characterized as HLA, "highest-level-first with abstentions." It can be found in linear time when there is no idle time; in general the time is exponential in the number of levels of the precedence graph. The problem of scheduling jobs related by precedence constraints on a length two pipeline processor is isomorphic to a simple version of the uniform processor problem. The optimum schedule is HLF, "highest-level-first," and can be found in linear time. Approximately optimum schedules for two uniform processors can be found in linear or nearly linear time. The schedule that is optimum for two identical processors has accuracy at most a factor  $2 - (f/s)$  above optimum, for arbitrary  $f$  and  $s$ . The HLF schedule has accuracy  $5/4$  for  $f/s = 1/2$  and  $6/5$  for  $f/s = 2/3$ .

**1. Introduction.** Much work has been done on the problem of finding a shortest multiprocessor schedule for a set of unit execution time jobs subject to precedence constraints (so-called *UET systems* [C]). The most encouraging results are for two identical processors. This problem is  $P2 \mid prec, p_j = 1 \mid C_{\max}$  in the notation of [GLLRK]. Several efficient algorithms have been given [FKN], [CG], [GJ77], including one with linear running time [G82a], [GT]. The problem can be efficiently solved even in the presence of release times and deadlines [GJ76], [GJ77]. On the other hand the problem is NP-complete when the two processors are identical but the job execution times are one or two ( $P2 \mid prec, p_j \in \{1, 2\} \mid C_{\max}$ ) [U].

This paper investigates the problem for two uniform processors ( $Q2 \mid prec, p_j = 1 \mid C_{\max}$ . A "uniform" processor runs at constant speed). Suppose a job can be executed in  $f$  time units on the fast processor and  $s$  units on the slow processor,  $f \leq s$ . Write  $\Delta = s - f$ . The case  $\Delta = 1$  is most amenable to analysis. We show that the HLF, "highest-level-first," characterization of an optimum schedule for two identical processors [G82a] generalizes to this case. Here the optimum schedule is HLA, "highest-level-first with abstentions." Such a schedule differs from HLF in that it contains "unforced idle time," i.e., idle that from a local viewpoint is unnecessary [GLLRK]. An HLA schedule can be constructed in linear time if the location of the

idle time is known. So if an optimum schedule has no idle time, it can be found in  $O(n + m)$  time, where  $n$  and  $m$  are the number of nodes and edges of the precedence graph, respectively. In general the algorithm runs in  $O(2^L(n + m))$  time, where  $L$  is the number of levels in the precedence graph.

Recent developments in computer architecture motivate the problem of scheduling a pipeline computer. The case of a length two pipeline is isomorphic to a simple version of the  $\Delta = 1$  problem. In this case an HLF schedule is optimum and can be found in  $O(n + m)$  time.

To handle general speeds  $f$  and  $s$  and also to obtain polynomial running times, we study algorithms that find a schedule that is guaranteed to be nearly optimum. One strategy is to use the optimum schedule for two identical processors. This gives a uniform processor schedule that is at most a factor  $2 - (f/s)$  above optimum. (As expected this approaches one as  $f/s$  approaches one.) Another strategy is to use an HLF schedule for the two uniform processors. This gives better accuracy for two important cases:  $f/s = 1/2$  has accuracy  $5/4$  and  $f/s = 2/3$  has accuracy  $6/5$ . (All bounds on accuracies are tight.)

Section 2 gives definitions and reviews relevant results for two identical processors. Section 3 derives the HLA characterization of an optimum schedule for the  $\Delta = 1$  case. This gives the above-mentioned algorithms for uniform processors and pipelines. It also provides a new proof that HLF schedules are optimum for two identical processors. Section 4 explores the use of the identical processor schedule to approximate the optimum uniform processor schedule. Section 5 explores the HLF approximation algorithm. Section 6 gives concluding remarks.

**2. Preliminaries.** This section gives basic terminology and reviews some results in scheduling.

A scheduling problem is defined on a *dag* (directed acyclic graph). A node of the dag represents a job that requires one unit of processing time; an edge represents a precedence constraint.  $G$  always denotes the given dag;  $n$  and  $m$  denote the number of nodes and edges, respectively. If there is an edge from node  $x$  to node  $y$ , then  $x$  is an *immediate predecessor* of  $y$  and we write  $x \rightarrow y$ ; if there is a directed path (of zero or more edges) from  $x$  to  $y$ , then  $x$  is a *predecessor* of  $y$ ,  $y$  is a *successor* of  $x$  and we write  $x \rightarrow^* y$ . A node with no predecessors is *initial*. A dag can be partitioned into *levels*  $\ell$ ,  $L \geq \ell \geq 1$ : level  $\ell$  consists of all nodes  $x$  that start paths with  $\ell$  nodes but not paths with  $\ell + 1$  nodes. We write  $level(x) = \ell$ .  $L$  always denotes the highest level of the dag. Figure 2.1 shows a dag. In all figures dags are drawn with the convention that edges are directed vertically from higher node to lower.

FIG. 2.1. Dag with four levels.

The nodes of the dag (jobs) are executed on two *uniform* processors, i.e., processors of constant speed. The speeds are two relatively prime positive integers  $f$  and  $s$ ,  $f \leq s$ . The *fast processor*  $P_f$  executes a node in  $f$  time units, while the *slow processor*  $P_s$  executes a node in  $s$  time units. (Strictly speaking parameters  $f$  and  $s$  are the inverses of speed. This will not cause confusion.) Define  $\Delta = s - f$ . If  $\Delta = 0$  the processors are *identical*.

Suppose  $P_f$  and  $P_s$  start simultaneously and execute nodes without interruption. Every  $fs$  time units  $P_f$  executes  $s$  nodes and  $P_s$  executes  $f$  nodes. These  $f + s$  nodes are executed in a repetitive pattern called the *execution period* (Figure 2.2). A time interval on  $P_f$  or  $P_s$  in the execution period during which one node is executed is a *slot*. The slots of a period are numbered from 1 to  $f + s$  in order of increasing right endpoint (finish time), with ties broken by left endpoint (start time); hence the last two slots are  $f + s - 1$  on  $P_s$  and  $f + s$  on  $P_f$ .

FIG. 2.2. Execution period for  $f/s = 2/3$ .

For identical processors the execution period is trivial. Assume otherwise,  $\Delta > 0$ . Then a slot on  $P_f$  overlaps at most two slots on  $P_s$ ; also a slot on  $P_s$  overlaps at least two slots on  $P_f$ . Exactly  $\Delta + 1$  slots on  $P_f$  are contained in a slot of  $P_s$ . (To show this note that each of  $f - 1$  borders of slots on  $P_s$  is in the interior of a different slot of  $P_f$ . This leaves  $s - f + 1 = \Delta + 1$  slots of  $P_f$  contained in a slot of  $P_s$ .)

When  $\Delta = 1$  every slot overlaps at most two others. This is the basic reason why the results of §3 hold. It implies the following properties, which are assumed in §3 (Figure 2.2): The slots are numbered from 1 to  $2f + 1$ . The odd-numbered slots are on  $P_f$ , the evens on  $P_{f+1}$ . The left endpoint of a slot is nondecreasing with slot number, as is the right endpoint.

A "schedule" specifies how to process each node and obey every precedence constraint. More precisely a *schedule* is an assignment of each node  $x$  to an ordered pair  $(p(x), t(x))$ , where  $p(x) \in \{f, s\}$ ,  $t(x) \geq 0$  is the *start time* for  $x$ ,  $t'(x) = t(x) + p(x)$  is the *finish time*, and for any distinct nodes  $x$  and  $y$  with either  $x \rightarrow y$  or  $p(x) = p(y)$ <sup>1</sup> and  $t(x) \leq t(y)$ , we have  $t'(x) \leq t(y)$ . Processor  $P_{p(x)}$  executes  $x$  from its start time to finish time. A processor is *idle* when it is not executing any node.  $\omega$ , the largest finish time of a node, is the *length (makespan)* of the schedule. An *optimum schedule* has length  $\omega^*$ , the minimum length possible. For further material on schedules see [C], [GLLRK].

For any slot  $\sigma$ ,  $1 \leq \sigma \leq f + s$ , a " $\sigma$ -schedule" starts in  $\sigma$ . More precisely let slot  $\sigma$  be on processor  $P$ . Let  $P'$  be the other processor and let  $\sigma'$  be the first slot on  $P'$  starting no earlier than  $\sigma$  (for  $\sigma < f + s$ ,  $\sigma' = \sigma + 1$ ; for  $\sigma = f + s$ ,  $\sigma' = 2$  of the next execution period). In a  $\sigma$ -schedule,  $P(P')$  starts at slot  $\sigma(\sigma')$  or later. So an ordinary schedule is a 1-schedule. The *length* of a  $\sigma$ -schedule is measured starting at the beginning of slot  $\sigma$ . An *optimum  $\sigma$ -schedule* is a  $\sigma$ -schedule whose length is as small

<sup>1</sup> If the processors are identical, values  $f$  and  $s$  designate distinct processors so  $f \neq s$  in the equation  $p(x) = p(y)$ .

as possible (among all  $\sigma$ -schedules. In general for a fixed dag, the optimum length varies with  $\sigma$ ). Section 3 proves most results for  $\sigma$ -schedules (and a fortiori for ordinary schedules). It should be clear how to interpret a phrase like “an optimum  $\sigma$ -schedule that has property  $P$ ”—when in doubt, “optimum” modifies only “ $\sigma$ -schedule,” so this schedule is an optimum  $\sigma$ -schedule, that happens to also have property  $P$ .

The following definitions generalize HLF, highest-level-first, schedules. HLF schedules are optimum for identical processors ( $\Delta = 0$ ) [G82a]. The definitions are given for  $\Delta = 1$ , where we will show they lead to optimum schedules. However they are relevant for arbitrary  $\Delta$ .

A level schedule “executes levels” in decreasing order. More precisely let  $\sigma$  be a slot,  $1 \leq \sigma \leq 2f + 1$ . Let  $H$  be the set of all nodes on the highest level  $L$ . A *level  $\sigma$ -schedule* executes the nodes of  $H$  in the first  $|H|$  slots  $\sigma, \sigma + 1, \dots, \tau$  (where  $\tau = 1 + ((|H| + \sigma - 2) \bmod (2f + 1))$ ). There are three cases for  $\tau$ :

- (i)  $\tau = 2f + 1$  is the last slot of an execution period.
- (ii)  $\tau < 2f + 1$  and no node is in slot  $\tau + 1$ .
- (iii)  $\tau < 2f + 1$  and a node  $y$  is in slot  $\tau + 1$ .

In cases (i) - (ii) the rest of the schedule is a level 1-schedule for  $G - H$ . In case (iii) the rest of the schedule is a level  $\tau'$ -schedule for  $G - H - y$ , where  $\tau' = \tau + 2$  if  $\tau < 2f$  and  $\tau' = 1$  if  $\tau = 2f$ . A *level schedule* is a level 1-schedule. Figure 2.3 shows two level schedules.

(a)

(b)

FIG. 2.3. *Level schedules for Fig. 2.1,  $f/s = 1/2$ . (a)  $\omega = 6$ . (b)  $\omega^* = 5$ .*

In a level schedule consider a level  $\ell$ ,  $L \geq \ell \geq 1$ , where case (iii) applies. Let  $x$  be the node in slot  $\tau$ . So  $level(x) = \ell$ ,  $level(y) < \ell$ , and  $x \overset{*}{\rightarrow} y$  since slots  $\tau$  and  $\tau + 1$  overlap. The ordered pair  $(x, y)$  is a *jump from  $x$  to  $y$* ; alternatively the jump goes *from level  $\ell$  to level  $\ell(y)$* , *level  $\ell$  jumps  $y$* . If case (ii) applies to level  $\ell$ ,  $\ell$  has an *idle jump*; by convention an idle jump goes to level 0 (level 0 is a fictitious level). *Level  $\ell$  has a jump* in cases (ii) and (iii) but not (i). In Figure 2.3 and all other figures nodes that are jumped are dotted. The idle times in Figure 2.3 are idle jumps.

The *execution of level  $\ell$* , for  $L \geq \ell \geq 1$ , is defined inductively. For  $\ell = L$  it consists of the above slots  $\sigma, \sigma + 1, \dots, \tau$  plus slot  $\tau + 1$  if  $L$  jumps a node. For smaller  $\ell$  it is defined in the obvious way by induction. Observe that nodes of  $\ell$  that are jumped are not included in the execution of  $\ell$  (e.g., in Figure 2.3(a),  $g$  is not in the execution of level 1).

The slots of a level schedule are linearly ordered (as in an execution period, the order is by increasing right endpoint with ties broken by left endpoint). If  $\sigma$  is a slot,  $\sigma^+$  denotes the next slot in this order. We extend this linear ordering to the nodes of the dag, e.g., if node  $x$  is in slot  $\sigma$ , the *node after  $x$*  is the node in  $\sigma^+$ .

In a level schedule let the levels with jumps be  $f_1 > \dots > f_k$ , where level  $f_i$  jumps to level  $t_i$ . The *jump sequence* of the schedule is the ordered  $k$ -tuple  $(t_1, t_2, \dots, t_k)$ . In Figure 2.3 the jump sequences are  $(1, 0, 0, 0)$  in (a) and  $(0, 1)$  in (b). Observe that the dag and the jump sequence together determine the slots where nodes are executed. In particular the length  $\omega$  can be deduced.

Jump sequences are compared using lexicographic order. That is,  $(t_1, \dots, t_k) > (s_1, \dots, s_r)$  if for some  $j$ ,  $1 \leq j \leq \min\{k, r\}$ ,  $t_i = s_i$  for  $1 \leq i < j$  and  $t_j > s_j$ . (Lexicographic order allows the possibility that  $(t_1, \dots, t_k) > (s_1, \dots, s_r)$  if  $t_i = s_i$  for  $1 \leq i \leq r$  and  $k > r$ . This cannot occur with jump sequences: If  $t_i = s_i$  for  $1 \leq i \leq r$  then  $k = r$  and  $(t_1, \dots, t_k) = (s_1, \dots, s_r)$ .)

A *highest-level-first (HLF) schedule* is a level schedule whose jump sequence is as large as possible. Such a schedule is essentially a critical-path schedule. HLF schedules are optimum for several types of identical processor scheduling: two processors [CG], [G82a], forest precedence [H61], [H82], and interval orders [PY], [G81] (the last is shown HLF in [G83]). Figure 2.3 shows HLF schedules are not optimum for uniform processors: (a) is HLF but (b) is optimum. Observe that the optimum schedule jumps to the highest level *except* when it has idle jumps. This is characteristic of an “HLA” schedule, defined as follows.

In a level schedule, a level is *abstentious* if it ends in slot  $\tau < 2f$  and has an idle jump. A level that has a jump but is not abstentious is *nonabstentious*. So a nonabstentious level either ends in slot  $\tau < 2f$  and jumps a node or ends in slot  $2f$ . (The motivation for the latter condition is that when a level ends in slot  $2f$ , the schedule includes a complete slot  $2f + 1$  regardless of whether the level jumps a node.)

Let  $A$  be a set of levels,  $A \subseteq \{1, \dots, L\}$ , and let  $\sigma$  be a slot,  $1 \leq \sigma \leq 2f + 1$ . An *HLA  $\sigma$ -schedule* for  $A$  is a level  $\sigma$ -schedule with abstentious levels  $A$ , whose jump sequence is as large as possible. An *HLA (highest-level-first with abstentions) schedule* is an HLA 1-schedule. Figure 2.3 shows HLA schedules, with abstentions 1, 2 in (a) and 4 in (b).

For identical processors an HLF schedule is an HLA schedule with no abstentions. (Any idle jump is in the slot that is the analogue of  $2f$ , the slot that never abstains.) Such a schedule can be constructed in linear time.

Similar algorithms can be used for uniform processors. In one instance we shall see the set of abstentious levels  $A$  is known in advance. (This is a nontrivial assumption. A given set of levels  $A$  may not even have an HLA schedule, since the precedence constraints may force idle jumps at levels not in  $A$ .)

**THEOREM 2.1.** *Given set of abstentious levels  $A$  and processor speeds  $f, f + 1$ , an HLA schedule, if it exists, can be found in  $O(n + m)$  time and space.*

*Proof.* The algorithm is a straightforward adaptation of the identical processor algorithm of [G82a]. The latter works in two passes: Pass I processes the levels  $t$  in descending order  $t = L, L - 1, \dots, 1$ ; it finds all levels that jump to level  $t$ . Pass II

finds the specific nodes jumped.

The same strategy works for uniform processors. The important point is that after level  $t$  is processed in Pass I it is easy to decide whether or not  $t$  jumps a node: The number of nodes on level  $t$  that are jumped is known. This determines the slot  $\tau$  that executes the last node of  $t$ . Level  $t$  jumps a node if  $t \notin A$  and  $\tau \neq 2f + 1$ . Both these conditions are easy to test.

The time and space are  $O(n + m)$ . The time bound depends on using the set merging algorithm of [GT].  $\square$

The key fact in analyzing HLF schedules is that they decompose into "blocks." The blocks are defined from a set of boundary levels  $\ell_i$ ,  $1 \leq i \leq B + 1$ , where  $\ell_1 = 1$ ,  $\ell_{B+1} = L + 1$ . The exact definition of  $\ell_i$  can be found in [G82a]. For  $1 \leq i \leq B$ , block  $X_i$  consists of all nodes scheduled after  $\ell_{i+1}$  up to and including  $\ell_i$ , except for the node (if any) jumped from  $\ell_i$ . Every node is in a block except nodes jumped from boundary levels  $\ell_i$ . The blocks partition the time units of the schedule. The following result is proved in [G82a].

**THEOREM 2.2.** *Assume  $\Delta = 0$ .*

(a) *In an HLF schedule any block  $X$  is executed in  $\lceil |X|/2 \rceil$  time units.*

(b) *For any block  $X_i$ ,  $1 < i \leq B$ ,  $X_i \xrightarrow{*} X_{i-1}$ , i.e., any node of  $X_i$  precedes any node of  $X_{i-1}$ .*  $\square$

Theorem 2.2 implies that an HLF schedule for identical processors is optimum, since its length is  $\sum_{i=1}^B \lceil |X_i|/2 \rceil$ . HLA schedules have a similar block structure, but it is not needed in this paper (although a block structure is used in §5).

**3. HLA schedules.** This section proves that when  $\Delta = 1$  there is an optimum HLA schedule. This leads to an algorithm that finds an optimum schedule in  $O(n + m)$  time when there is no idle and  $O(2^L(n + m))$  time in general. It also gives a linear-time algorithm for length two pipelines.

The proof is organized as follows. Lemmas 3.1–3.3 show that an optimum schedule that is level always exists. Lemma 3.4–3.6 establish some "highest-level-first" types of properties. Theorem 3.1 shows that an optimum schedule that is HLA always exists. All these results are for the case  $\Delta = 1$ . They simplify to show that an HLF schedule is optimum for length two pipelines (Corollary 3.2), and also  $\Delta = 0$ , i.e., two identical processors (Corollary 3.3). If  $\Delta > 1$  the results do not apply; in fact there need not even exist an optimum schedule that is level (Theorem 3.2).

The first result will allow us to consider only schedules that execute nodes in slots (Lemma 3.3).

**LEMMA 3.1.** *For any slot  $\sigma$ , there is an optimum  $\sigma$ -schedule that executes a node in the first slot  $\sigma$ .*

*Proof.* Let  $S$  be an optimum  $\sigma$ -schedule ( $S$  does not necessarily execute nodes in slots). Slot  $\sigma$  ends at the first time any schedule can complete a job (even when  $\sigma = 2f$ ). If  $S$  does not use any portion of  $\sigma$ , let  $x$  be the first node to start executing in  $S$ . Moving  $x$  to  $\sigma$  gives a valid  $\sigma$ -schedule no longer than  $S$  (recall length starts at  $\sigma$ ). Similarly if  $S$  executes a portion of some node  $x$  in  $\sigma$ , move  $x$  to  $\sigma$ .  $\square$

The next lemma is the heart of the transformation of an optimum schedule to a level schedule. First some notation. Let  $S$  be a schedule that executes nodes in slots, such as a level schedule.  $S/x$  denotes the schedule  $S$  starting at the slot after  $x$ . For example for  $S$  the schedule Figure 2.3(b),  $S/c$  is a 3-schedule for nodes  $d, e, f, g$ . (Sometimes it is convenient to use  $S/x$  to refer to the nodes after  $x$ ; no confusion will result.) An *almost-level* schedule  $S$  is a schedule such that for the first node executed

$x$ ,  $S/x$  is a level  $\sigma$ -schedule for  $G - x$  (and some  $\sigma$ ). Recall that  $L$  denotes the number of levels in the dag.

LEMMA 3.2. *If  $G$  has an optimum  $\sigma$ -schedule that is almost-level then it has an optimum  $\sigma$ -schedule with a level  $L$  node in the first slot.*

*Proof.* The proof is by induction on  $L$ . The base case  $L = 1$  is trivial. Assume the lemma holds for graphs with less than  $L$  levels and prove it for  $L$  as follows.

Consider an optimum  $\sigma$ -schedule  $S$  that is almost-level; without loss of generality assume  $x$ , the node in the first slot, has  $level(x) < L$ . Let  $y$  be the node after  $x$ ; since  $S$  is almost-level  $level(y) = L$ . Let  $S'$  be  $S$  with nodes  $x$  and  $y$  interchanged. If  $S'$  is not a valid schedule, it violates a precedence constraint  $x \xrightarrow{*} z$ , where node  $z$  is in the slot originally overlapping  $y$ . Clearly  $level(z) < level(x) \leq L - 1$ . So  $G - \{x, y\}$  is an  $L - 1$  level graph and  $S/y$  is an almost-level schedule for it. By induction it has an optimum schedule  $T$  whose first node  $w$  is on level  $L - 1$  and is in the first slot of  $S/y$ . Since  $level(x) < L$ ,  $x \not\xrightarrow{*} w$ . So a valid schedule for  $G$  results from scheduling  $y$  and  $x$  in the first two slots and then  $T$ . This is the desired schedule.  $\square$

Now we show that an optimum schedule can be transformed to a level schedule.

LEMMA 3.3. *Any slot  $\sigma$  has a level  $\sigma$ -schedule that is an optimum  $\sigma$ -schedule.*

*Proof.* The proof is by induction on  $n$ , the number of nodes in  $G$ . The base  $n = 1$  is trivial. Assume the lemma for graphs with fewer than  $n$  nodes and prove it for  $G$  as follows.

Observe that  $G$  has an optimum  $\sigma$ -schedule  $S$  that starts with a level  $L$  node in slot  $\sigma$ : There is an optimum  $\sigma$ -schedule with some node  $x$  in  $\sigma$  by Lemma 3.1. Suppose  $level(x) < L$ . By induction  $G - x$  has a level  $\sigma^+$ -schedule that is optimum. This schedule preceded by  $x$  in  $\sigma$  is an almost-level  $\sigma$ -schedule for  $G$  that is optimum. ( $x$  does not precede the node in  $\sigma^+$  since  $level(x) < L$ .) Now Lemma 3.2 shows the desired schedule  $S$  exists.

Let  $x$  be the first node of  $S$ . If  $x$  is not the only level  $L$  node then  $x$ , followed by the schedule for  $G - x$  given by induction, is the desired schedule. So suppose  $x$  is the only node of  $L$ . If in  $S$  the processor opposite  $x$  is idle during the entire duration of slot  $\sigma$ , then  $x$  is followed by a 1-schedule for  $G - x$ . By induction this schedule can be assumed level, as desired.

Otherwise the processor opposite  $x$  executes a portion of some node  $y$  during  $\sigma$ . Clearly  $y$  can be assumed to be in slot  $\sigma^+$ . By induction  $G - \{x, y\}$  has a level  $\sigma^{++}$ -schedule that is optimum. This schedule preceded by  $x$  in  $\sigma$  and  $y$  in  $\sigma^+$  is the desired schedule. ( $y$  does not precede the node in  $\sigma^{++}$  since the latter is on level  $L - 1$ .)  $\square$

The next two lemmas show initial nodes have "highest-level-first" properties.

LEMMA 3.4. *If  $x$  is an initial node then any slot  $\sigma$  has an optimum level  $\sigma$ -schedule where all nodes before  $x$  are on level( $x$ ) or higher.*

*Proof.* The proof is by contradiction. Let  $S$  be an optimum level  $\sigma$ -schedule where  $x$  is in the earliest slot possible. Suppose a node  $y$  with  $level(y) < level(x)$  is scheduled before  $x$ ; choose  $y$  as the last such node. Node  $y$  is jumped since  $x$  is scheduled at  $level(x)$  or before. We derive a contradiction by showing  $x$  can be scheduled earlier.

Let  $T$  be the result of interchanging  $x$  and  $y$  in  $S$ . The first case is when  $T$  is a valid schedule.  $T$  is a level schedule up to and including  $x$ , which is jumped. Let  $x$  be in slot  $\tau$  in  $T$ . Let  $U$  be an optimum level  $\tau^+$ -schedule for  $T/x$  (by Lemma 3.3). Let  $V$  be the schedule  $T$  with  $T/x$  replaced by  $U$ .  $V$  is a valid schedule. ( $x$  does not precede the node in  $\tau^+$ , which is on  $level(x)$  or higher.)  $V$  gives the desired contradiction.

The second case is when  $T$  is not a valid schedule.  $T$  can only violate a precedence

constraint  $y \xrightarrow{*} z$  for some node  $z$  with  $level(z) < level(y) < level(x)$ .  $S$  does not schedule  $z$  before  $x$ , by choice of  $y$ . Thus in  $S$ ,  $z$  is the node after  $x$ , and  $level(x)$  jumps from  $x$  to  $z$ .

Let  $y$  be in slot  $\kappa$  in  $T$  (so  $z$  is in  $\kappa^+$ ). Let  $U$  be an optimum level  $\kappa^+$ -schedule for  $T/y$ . Let  $V$  be  $T$  with  $T/y$  replaced by  $U$ .  $V$  is a valid schedule. ( $y$  does not precede the node in  $\kappa^+$ , which is on  $level(x) - 1$ .) If  $V$  is level it gives the desired contradiction.

If  $V$  is not level then  $\kappa = 1$  (in this case  $level(x)$  has a jump in  $S$  but not in  $T$ ). Let  $w$  be the node before  $y$  in  $V$ . Let  $W$  be  $V$  with  $V/w$  replaced by an optimum level 1-schedule.  $W$  gives the desired contradiction.  $\square$

LEMMA 3.5. *Let  $X$  and  $Y$  be dags where node  $x$  is initial in  $X$ , node  $y$  is initial in  $Y$  and  $X - x = Y - y$ . Suppose  $level(x) > level(y)$ . Then for any slot  $\sigma$  an optimum  $\sigma$ -schedule for  $Y$  is no longer than one for  $X$ .*

*Proof.* By Lemma 3.4 let  $S$  be an optimum level  $\sigma$ -schedule for  $X$  where all nodes before  $x$  are on  $level(x)$  or higher. Let  $T$  be  $S$  with  $x$  replaced by  $y$ . Suppose  $T$  is not a valid schedule for  $Y$ .  $T$  can only violate a precedence constraint  $y \xrightarrow{*} z$  for some node  $z$  with  $level(z) < level(y) < level(x)$ . This implies  $S$  jumps from  $x$  to  $z$ , so in  $T$ ,  $z$  is in the slot  $\tau$  after  $y$ . Thus  $T/y = S/x$  is a  $\tau$ -schedule for a dag with  $level(x) - 1$  levels.

Let  $U$  be an optimum level  $\tau$ -schedule for  $T/y$ . Let  $V$  be  $T$  with  $T/y$  replaced by  $U$ .  $V$  is a valid schedule for  $Y$ . ( $y$  does not precede the node in  $\tau$ , which is on  $level(x) - 1$ .) This gives the lemma.  $\square$

The next lemma investigates the situation where there is a choice of nodes to jump on the same level.

LEMMA 3.6. *Let  $X$  and  $Y$  be dags where node  $x$  is initial in  $X$ , node  $y$  is initial in  $Y$ ,  $level(x) = level(y) = \ell$  and  $X - x = Y - y$ . Let  $\sigma$  be any slot and let  $A$  be a set of abstaining levels. Let  $S$  be an HLA  $\sigma$ -schedule for  $A$  on  $X$ . Then there exists  $T$ , an HLA  $\sigma$ -schedule for  $A$  on  $Y$ , with these properties:*

- (i)  *$S$  and  $T$  have the same jump sequence before  $\ell$ ;*
- (ii) *Let  $X'$  be the subgraph of  $X$  that remains after the execution of level  $\ell$ , and similarly for  $Y'$ . Either  $X' = Y'$ , or  $\ell$  jumps a node  $y'$  in  $S$  and  $x'$  in  $T$  such that  $X' - x' = Y' - y'$ .*

*Proof.* For succinctness in this argument, “good schedule” stands for “HLA  $\sigma$ -schedule for  $A$ .” We first prove property (i). It asserts that any two good schedules for  $X$  and  $Y$  have the same jump sequence before  $\ell$ . We will show that if  $S$  is a good schedule for  $X$  its jump sequence before  $\ell$  is at most that of a good schedule for  $Y$ . Symmetry gives (i).

So let  $S$  be a good schedule for  $X$  and let  $T$  be  $S$  with  $x$  replaced by  $y$ . First observe that  $T$  is a valid schedule unless  $\ell$  jumps from  $x$  to a successor of  $y$ : Suppose  $T$  is not valid. It can only violate a precedence constraint  $y \xrightarrow{*} z$  for a node  $z$  with  $level(z) < \ell$ . Since  $S$  is HLA and  $x$  is initial,  $S$  does not jump  $z$  before  $x$  is executed. Thus in  $S$ ,  $\ell$  jumps from  $x$  to  $z$ , as desired.

The observation implies that before  $\ell$ ,  $T$  is a valid level  $\sigma$ -schedule with abstentions  $A$  ( $T$  is level since  $level(x) = level(y)$ ). So the jump sequence before  $\ell$  of a good schedule for  $Y$  is at least that of  $T$ . This is the same as that of  $S$  (again recall  $level(x) = level(y)$ ). Property (i) follows.

To show property (ii) consider two cases. First suppose that in  $S$  no level above  $\ell$  jumps below  $\ell$ . Let  $T$  be any good schedule for  $Y$ . By (i)  $T$  has the property supposed for  $S$ . Clearly (ii) holds.

The second case is when in  $S$  some level  $f > \ell$  jumps below  $\ell$ . By (i)  $f$  jumps below  $\ell$  in any good schedule for  $Y$ . Since  $S$  is HLA, it jumps  $x$  before  $f$ . Similarly any good schedule for  $Y$  jumps  $y$  before  $f$ . Now the argument for (i) shows that a good schedule has the same jump sequence in  $X$  as in  $Y$ , and that  $S$ , with  $x$  replaced by  $y$ , is a good schedule for  $Y$ . Choosing it as  $T$  gives (ii).  $\square$

Now we show the main result.

**THEOREM 3.1.** *Assume  $\Delta = 1$ . Any slot  $\sigma$  has a set of levels  $A$  such that any HLA  $\sigma$ -schedule for  $A$  is an optimum  $\sigma$ -schedule.*

*Proof.* The proof is by induction on  $L$ . If  $L = 1$  the theorem is trivial. Assume the theorem for fewer than  $L$  levels and prove it for  $L$ , as follows. Let  $S$  be an optimum level  $\sigma$ -schedule. Let  $z$  be the last node in the execution of  $L$ . By induction assume  $S/z$  is an HLA schedule. Choose  $S$  so that subject to the above conditions its jump sequence is as high as possible. Let  $A$  be the abstentious levels for  $S$ , i.e.,

$$A = \{\ell \mid \text{level } \ell \text{ ends in slot } \tau, 1 \leq \tau < 2f, \text{ but } \ell \text{ does not jump a node}\}.$$

To prove the theorem it suffices to show  $S$  is an HLA schedule for  $A$ . This is obvious if  $S$  does not jump from  $L$  (i.e., either  $L \in A$  or  $L$  ends at slot  $2f + 1$ ). So assume  $S$  does a jump from  $L$ .

We will argue inductively to find an HLA schedule  $T$  for  $A$  and levels  $\ell_j$ ,  $L = \ell_1 > \ell_2 > \dots > \ell_k = 0$ , such that:

- (i) For  $1 \leq j \leq k$ ,  $S$  and  $T$  have the same jump sequence above  $\ell_j$ .
- (ii) For  $1 \leq j < k$ ,  $\ell_j$  jumps a node  $y_j$  in  $S$  and  $x_j$  in  $T$  such that  $X_j - x_j = Y_j - y_j$ , where  $X_j$  ( $Y_j$ ) is the subgraph induced on all nodes after the execution of  $\ell_j$  in  $S$  ( $T$ ).

Property (i) for  $j = k$  gives the desired conclusion.

Start by choosing  $T$  as an arbitrary HLA schedule for  $A$ . For the base case  $j = 1$ , property (i) is vacuous. For (ii) recall  $S$  jumps a node  $y_1$  from  $L$ . So clearly  $T$  jumps a node  $x_1$  from  $L$ . Both  $X_1 - x_1$  and  $Y_1 - y_1$  are the subgraph of all nodes below level  $L$  excluding  $x_1$  and  $y_1$ .

For the inductive step assume (i)–(ii) for  $j < k$ , and prove it for  $j + 1$  as follows. Write  $\ell = \text{level}(x_j)$ . Since  $T$  is an HLA schedule for  $A$ ,  $\ell \geq \text{level}(y_j)$ . To show equality holds (as required by property (i)) suppose the contrary,  $\ell > \text{level}(y_j)$ . Let  $\tau$  be the slot after  $x_j$  (equivalently after  $y_j$ ). Let  $U$  be  $T$ , with  $T/x_j$  replaced by an optimum, HLA  $\tau$ -schedule (for  $Y_j$ ). This schedule exists by induction, although it may not abstain at the levels in  $A$ . Since  $\ell < \ell_j$ ,  $U$  is a valid level  $\sigma$ -schedule. Further Lemma 3.5 implies  $U$  is optimum for  $G$ . But  $U$  shows that  $S$  does not have the highest jump sequence possible, contradicting its definition. We conclude  $\ell = \text{level}(y_j)$  as desired.

Now Lemma 3.6 can be applied to graphs  $X_j$  and  $Y_j$  (the choice of  $S$  makes it HLA on  $X_j$ ). It shows  $S$  and  $T$  have the same jump sequence above  $\ell$ . Further  $T$  can be chosen so that (ii) of Lemma 3.6 holds. Using the notation of Lemma 3.6, either  $X' = Y'$  or  $X' - x' = Y' - y'$ .

In the first case  $X' = Y'$ ,  $S$  and  $T$  can be assumed identical after  $\ell$ . Take  $\ell_{j+1} = 0$  and  $k = j + 1$  to complete the induction.

In the second case  $X' - x' = Y' - y'$ , take  $\ell_{j+1} = \ell$ ,  $y_{j+1} = y'$  and  $x_{j+1} = x'$  (so

$X_{j+1} = X'$  and  $Y_{j+1} = Y'$ ).  $k$  will be a value  $> j + 1$ . Clearly (i) and (ii) hold for  $j + 1$ .  $\square$

The key to finding the optimum HLA schedule is finding the abstentious levels. We have not succeeded in doing this. Here are two simple applications of the theorem.

**COROLLARY 3.1.** *Assume  $\Delta = 1$ .*

(a) *If there is a schedule with no idle time, it can be found in  $O(n + m)$  time and space.*

(b) *An optimum schedule can be found in  $O(2^L(n + m))$  time and  $O(n + m)$  space.*

*Proof.* (a) Apply Theorems 3.1 and 2.1 with  $A = \emptyset$ .

(b) There are at most  $2^L$  possible sets of abstentious levels  $A$ . Find an HLA schedule for each and select the shortest.  $\square$

Note also that if the amount of idle time is  $O(1)$  the schedule can be found in polynomial time. This follows since a schedule with  $I$  units of idle abstains at most  $I$  times. This fact may be of theoretic interest: We have not eliminated the possibility that the general  $\Delta = 1$  problem is NP-complete. This fact shows that a reduction must use an unbounded amount of idle time, unlike most other scheduling problems.

We give two more applications of Theorem 3.1, for the case of no abstentions. The first is to pipeline scheduling. A *length  $k$  pipeline processor* has  $k$  stages, connected in series. A job is executed in  $k$  time units—it passes through each stage in order, spending one time unit at each stage. Thus jobs are executed in slots corresponding to the time intervals  $[t, t + k)$  for nonnegative integers  $t$ . The pattern of slots does not change even when there is idle: If a job is not started at time  $t$ , the complete slot  $[t, t + k)$  is idle.

For a length two pipeline, the pattern of slots is similar to the  $\Delta = 1$  case, since each slot (except the first and last) overlaps two others. Since the slot pattern does not change, there is no advantage in abstaining.

**COROLLARY 3.2.** *For a length two pipeline any HLF schedule is optimum. Such a schedule can be found in  $O(n + m)$  time and space.*

*Proof.* The argument of Theorem 3.1 shows any HLF schedule (i.e., an HLA schedule with  $A = \emptyset$ ) is optimum. The only change is to adopt the above notion of slot. The HLF schedule is found as in Theorem 2.1.  $\square$

The proof of Theorem 3.1 is easily adapted to show that an HLF schedule is optimum for identical processors. This derivation is independent from the one in [G82a].

**COROLLARY 3.3.** *For two identical processors any HLF schedule is optimum.*

*Proof.* For identical processors an execution period is one time unit long with slots numbered one and two. By convention a jumped node goes in slot two. The proofs of the lemmas and the theorem are simpler because slot two does not overlap the following slot.  $\square$

Returning to uniform processors, the HLA characterization holds only for speeds with  $\Delta = 1$ . When  $\Delta > 1$  some dags do not even admit an optimum level schedule.

**THEOREM 3.2.** *Assume  $\Delta > 1$ . There is a dag where no level schedule is optimum.*

*Proof.* The argument depends on the relative sizes of  $2f$  and  $s$ . Equality does not occur since it implies  $f = 1, s = 2, \Delta = 1$ .

Case  $2f > s$ . Consider Figure 3.1. It consists of components  $S$  and  $F$ , where  $S$  is a chain of  $s - 1$  nodes and  $F$  has two nodes  $a, a'$  that precede a chain of  $f - 1$  nodes.

An optimum schedule  $O$  has length  $fs$  with no idle time:  $P_f$  executes node  $a$  followed by the nodes of  $S$ .  $P_s$  executes  $a'$  followed by the remaining nodes of  $F$ .  $O$  is not a level schedule since  $a$  and  $a'$  are on level  $f < s - 1 = L$ .

To prove the theorem it suffices to show  $O$  is the only optimum schedule. First consider a dag consisting of two chains. If a schedule with no idle exists, each processor executes nodes from one chain for  $fs$  time units. At this point the processors can switch chains but not before.

Now consider a schedule with no idle for Figure 3.1. There are three cases, depending on the nodes executed at time zero. If  $a$  and  $a'$  are executed the preceding observation implies the schedule is  $O$ . If  $P_s$  executes  $b$  the observation implies  $P_f$  executes the entire  $F$  component while  $P_s$  executes  $S$ . But  $F$  has  $f + 1 < s$  nodes, giving idle time on  $P_f$ .

FIG. 3.1. Nonlevel dag for  $2f > s$ .

FIG. 3.2. Nonlevel dag for  $2f < s$ .

The last case is where  $P_f$  executes  $b$  and  $P_s$  executes  $a$  at time zero. If  $P_f$  executes  $a'$  after  $b$ ,  $2f > s$  implies  $P_s$  switches to component  $S$  while  $P_f$  executes  $F$ . This gives idle time as in the previous case. If  $P_f$  does not execute  $a'$  after  $b$ ,  $2f > s$  implies  $P_s$  executes  $F$  while  $P_f$  executes  $S$ . But since  $S$  has only  $s - 1$  nodes this gives idle time on  $P_f$ .

*Case  $2f < s$ .* In Figure 3.2, the dag has height  $\lceil s/f \rceil \geq 3$ . An optimum schedule  $O$  has length  $\omega^* = (\lceil s/f \rceil + 1)f$ : First  $P_f$  executes node  $a$  while  $P_s$  is idle. Then  $P_f$  executes all nodes but  $b$  while  $P_s$  executes  $b$ . ( $P_s$  can finish at time  $f + s \leq \omega^*$ .) Clearly  $O$  is not level.

The optimum is unique: Observe  $2s > s + 2f > \omega^*$ . Hence to achieve  $\omega^*$ ,  $P_s$  must execute precisely one node; further that node must be  $b$ . Now it is easy to see the schedule must be  $O$ .  $\square$

**4. The AI approximation algorithm.** This section investigates the strategy of using an optimum identical processor schedule for two uniform processors. The worst-case accuracy bound is  $2 - (f/s)$ . The time and space to find the schedule are  $O(n + m)$ .

An AI (*Approximately Identical*) schedule  $T$  is constructed as follows. Start with an HLF schedule  $S$  for two identical processors. Then convert it to  $T$ : A time unit of  $S$  where one node is executed corresponds to  $f$  time units of  $T$  where the same node is executed on  $P_f$ . A time unit of  $S$  where two nodes are executed corresponds to  $s$  time units of  $T$  where the same two nodes are executed.  $P_s$  executes one node while  $P_f$  executes the other with  $\Delta$  units of idle.

An AI schedule can be found in  $O(n + m)$  time. To derive the accuracy bound define these quantities from the AI schedule:

- $t$  = the number of nodes on  $P_f$  scheduled with a node on  $P_s$ ;
- $u$  = the number of nodes on  $P_f$  scheduled with idle on  $P_s$ .

Clearly  $\omega = st + fu$ . Since the optimum schedule executes at most  $(1/f + 1/s)\omega^*$  nodes, it is clear that

$$(1) \quad (1/f + 1/s)\omega^* \geq 2t + u.$$

Now we derive another bound on  $\omega^*$ .

LEMMA 4.1.  $\omega^* \geq tf + uf$ .

*Proof.* The lemma is proved by decomposing the schedule into blocks  $X_j$ ,  $j = 1, \dots, B$  (recall Theorem 2.2). Define these quantities for a block  $X$ .

- $\omega^*(X)$  = the length of an optimum schedule for the nodes of  $X$ ;
- $t(X)$  = the contribution to  $t$  made by  $X$  in the AI schedule;
- $u(X)$  = the contribution to  $u$  made by  $X$  in the AI schedule.

Observe that  $\omega^* \geq \sum_{j=1}^B \omega^*(X_j)$  by Theorem 2.2(b). Also  $t + u = \sum_{j=1}^B t(X_j) + u(X_j)$ . So it suffices to show  $\omega^*(X) \geq t(X)f + u(X)f$  for every block  $X$ .

Theorem 2.2(a) implies that in the AI schedule  $P_f$  executes exactly  $\lceil |X|/2 \rceil$  nodes of  $X$ . So  $\lceil |X|/2 \rceil = t(X) + u(X)$ . Clearly  $\omega^*(X) \geq \lceil |X|/2 \rceil f$ , since a schedule executes at least  $\lceil |X|/2 \rceil$  nodes on some processor. This gives the desired conclusion.  $\square$

THEOREM 4.1. (a) *On any dag the AI schedule achieves the bound  $\omega/\omega^* \leq 2 - (f/s)$ .*

(b) *There is a dag where the AI schedule has  $\omega/\omega^* = 2 - (f/s)$ .*

*Proof.* (a) Multiplying (1) by  $s - f$ , Lemma 4.1 by  $2 - (s/f)$ , and adding gives  $(2 - (f/s))\omega^* \geq st + fu$ . The right-hand side is  $\omega$ .

(b) Consider a dag consisting of a chain of  $s$  nodes plus  $f$  isolated nodes. The AI schedule executes a chain node with an isolated node until all isolated nodes are exhausted. Then it executes chain nodes with idle. So  $\omega = fs + \Delta f$ .

The optimum schedule executes the chain nodes on  $P_f$  and the isolated nodes on  $P_s$ , so  $\omega^* = fs$ .  $\square$

The obvious way to improve the AI schedule is to compress idle on  $P_f$ : When two consecutive nodes on  $P_f$  are on the same level, the second node can be scheduled after the first with no intervening idle. Similarly when a node is jumped on  $P_s$ , the node following it on  $P_f$  can be scheduled right after its predecessor. The *compressed AI (CAI) schedule* is the result of applying these rules as much as possible to remove idle. (If  $\lceil f/\Delta \rceil$  nodes are compressed a whole new slot is available on  $P_f$ . We will not concern ourselves with how this slot is used since our lower bounds do not depend on it.) The CAI schedule has an alternate description: It is a level schedule that never jumps from processor  $P_s$  but otherwise has the highest jump sequence possible.

Our results on CAI indicate that compression does not help—there are dags where the accuracy is the same as AI. The main result is stated below. The proof is a construction similar to §5. Details and other results can be found in [G82b].

**THEOREM 4.2.** *Assume  $f/s \geq 4/5$  ( $\Delta$  is arbitrary). For any  $\epsilon > 0$  there is a dag where the CAI schedule has  $\omega/\omega^* > 2 - (f/s) - \epsilon$ .  $\square$*

**5. The HLF approximation algorithm.** This section investigates the HLF scheduling rule as an approximation algorithm. When  $\Delta = 1$  an HLF schedule can be found in  $O(m + n \log \log n)$  time and  $O(n + m)$  space. Two important cases of HLF scheduling are analyzed: When  $s/f = 1/2$  the worst-case accuracy bound is  $5/4$ . When  $s/f = 2/3$  the bound is  $6/5$ . These are the main cases where HLF is preferable to the AI schedule, which is more accurate than HLF when  $s/f \geq 4/5$ .

The HLF scheduling algorithm differs from the HLA algorithm of Theorem 2.1 because the slots are not known in advance. Nonetheless a similar algorithm works for HLF scheduling: Pass I processes levels  $\ell$  in decreasing order. When processing  $\ell$  it finds the level  $t$  (if any) that  $\ell$  jumps to. (Note that since all idle jumps from levels above  $\ell$  are known, it is easy to decide if  $\ell$  has a jump or not. This organization differs from Theorem 2.1, which when processing  $\ell$  finds the levels that jump to it.) Pass II finds the specific jumps.

The main data structure of the algorithm is a priority queue that finds the highest level  $\ell$  can jump. Since levels are integers between 1 and  $n$  the queue can be efficiently implemented using the data structure of van Emde Boas [E76], [E77].

**THEOREM 5.1.** *Assume  $\Delta = 1$ . An HLF schedule can be found in  $O(m + n \log \log n)$  time and  $O(m + n)$  space.*

*Proof.* Further details are similar to the identical processor case of [G82a]. They are given explicitly in [G82b].  $\square$

HLF schedules decompose into blocks, as in Theorem 2.2:

**THEOREM 5.2.** *Assume  $\Delta = 1$ .*

(i) *In an HLF schedule any block  $X$  is executed in consecutive time slots  $\sigma, \sigma + 1, \dots, \tau$  with no intervening idle. Here  $1 \leq \sigma, \tau \leq 2f + 1$  and  $\sigma \neq \tau$ .*

(ii) *For any block  $X_i$ ,  $1 < i \leq B$ ,  $X_i \xrightarrow{*} X_{i-1}$ .*

*Proof.* In part (i),  $\sigma \neq \tau$  since a level schedule never jumps a node in slot one. The rest of the proof follows the identical processor case of [G82a]. The details can

be found in [G82b].  $\square$

The analysis of HLF schedules is done on blocks. Define the following quantities for any block  $X$ :

- $\omega(X)$  = the length of the HLF schedule for  $X$ ;
- $\omega^*(X)$  = the length of an optimum schedule for  $X$ ;
- $\delta(X) = \omega(X) - \omega^*(X)$ .

If  $\sigma$  is the first slot of  $X$  in the HLF schedule then it gives a  $\sigma$ -schedule for  $X$ .  $\omega(X)$  is the length of this  $\sigma$ -schedule, i.e., time zero is at the start of slot  $\sigma$ . So the length of the HLF schedule is  $\omega = \sum_{j=1}^B \omega(X_j)$ .  $\omega^*(X)$  is the length of an optimum 1-schedule for  $X$ . This allows both processors to start simultaneously, unlike  $\omega(X)$ . The length of an optimum schedule is  $\omega^* \geq \sum_{j=1}^B \omega^*(X_j)$ , by Theorem 5.2(b).

FIG. 5.1. The six block shapes for  $f/s = 1/2$ .

First we analyze the HLF schedule for  $f/s = 1/2$ . Figure 5.1 shows the six possible shapes for the slots of a block. It justifies the following result.

LEMMA 5.1. *In a nonoptimum block  $X$  the first slot is three, the last slot is two and  $\delta(X) = 1$ .*  $\square$

To analyze the accuracy of the HLF schedule let  $i$  be the number of nonoptimum blocks. The bound follows from two inequalities.

- LEMMA 5.2. (a)  $\omega^* \geq \omega - i$ .
- (b)  $(3/2)\omega^* \geq \omega + i$ .

*Proof.* (a) Lemma 5.1 shows the number of time units the schedule can decrease is at most the number of nonoptimum blocks.

(b) Observe there are at least  $\omega + i$  nodes: Figure 5.1 shows that each time unit of the schedule can be associated with a distinct node in some block. In addition there are  $i$  nodes not in any block: Every nonoptimum block starts in slot three, and the node jumped in slot two is not in any block.

This implies (b) since the optimum schedule executes at most  $(3/2)\omega^*$  nodes.  $\square$

THEOREM 5.3. Assume  $f/s = 1/2$ .

(a) On any dag the HLF schedule has  $\omega/\omega^* \leq 5/4$ .

(b) For any  $\epsilon > 0$  there is a dag where the HLF schedule has  $\omega/\omega^* > 5/4 - \epsilon$ .

FIG. 5.2. Bad dag for the HLF schedule for  $f/s = 1/2$ .

6		4	
...			

(a)

2	3	5	1
4		6	
		.....	

(b)

FIG. 5.3. Module schedules. (a) HLF schedule. (b) Better schedule.

*Proof.* (a) Add the inequalities of Lemma 5.2.

(b) For any positive integer  $r$  consider Figure 5.2. This dag consists of  $r$  repetitions of a “module” with six nodes. (Node six is on level one but is drawn higher for clarity. Note the resemblance to Figure 2.1.)

The HLF schedule is  $r$  repetitions of the module schedule shown in Figure 5.3(a). Thus  $\omega = 5r$ . However this schedule shows  $\omega^* \leq 4r + 1$ :  $P_1$  executes node one of the first module. Then come  $r$  repetitions of the module schedule of Figure 5.3(b), where each module executes node one of the next module. (The last module has idle in the last slot three.)

Thus  $\omega/\omega^* \geq 5r/(4r + 1)$ , which approaches  $5/4$  as  $r$  approaches  $\infty$ .  $\square$

We turn to the HLF schedule for  $f/s = 2/3$ . It has a different character from previous approximate schedules. Regarding the lower bound dags, recall that in the previous algorithms the optimum schedule has  $\Theta(1)$  idle time. This is true in all other examples for level-type scheduling algorithms that we know of [L], [LS]. We have not found such examples for this algorithm— the dag that achieves the tight lower bound has  $\Theta(\omega^*)$  idle time.

This property manifests itself in the proof of the upper bound. The previous schedules are analyzed by inequalities based on the fact that the number of nodes gives a lower bound on  $\omega^*$ . Inequalities of this type cannot be tight in dags with  $\Theta(\omega^*)$  idle in the optimum schedule. Hence a different approach must be used. We use an estimate of how much  $\omega$  can decrease, derived from the precedence constraints.

We first investigate how much a block can shrink. For generality consider two processors of speeds  $f$  and  $s = f + 1$ , and a block  $X$  in some HLF schedule. Define this quantity from the HLF schedule:

$$T(X) = i/f + j/s, \text{ where } i(j) \text{ is the number of time units in } \omega(X) \text{ when } P_f(P_s) \text{ is not executing a node of } X.$$

In the HLF schedule for  $X$  both processors are always busy except possibly during the first slot (if one processor is executing the node jumped before  $X$ ) and the last slot (if one processor is idle or executing the node jumped from  $X$ ).  $T(X)$  gives the number of nodes (possibly fractional) that could have been executed in these two slots.

LEMMA 5.3.  $\delta(X) \leq T(X)/(1/f + 1/s)$ .

*Proof.* If  $n$  is the number of nodes in  $X$  then  $(1/f + 1/s)\omega(X) = n + T(X)$  and  $(1/f + 1/s)\omega^*(X) \geq n$ .  $\square$

TABLE 1  
Slot contributions to  $T(X)$  for  $f/s = 2/3$ .

		slot				
		1	2	3	4	5
first		0	—	1/3	1/2	2/3
last		2/3	1/2	1/3	1	0

Table 1 gives the contribution of each slot to  $T(X)$  when it is the first or last slot in  $X$ . For instance if the first slot of  $X$  is three then during the initial time unit of this slot  $P_3$  is idle, contributing  $1/3$  to  $T(X)$ . (If  $X$  consists of only one slot, its contribution to  $T(X)$  is the sum of the first and last contributions.)

LEMMA 5.4. *Let  $X$  be a block.*

(a)  $\delta(X) \leq 2$ .

(b) *If  $\delta(X) = 2$  then slot five is first in  $X$  and four is last.*

(c) *If  $\delta(X) > 0$  then slot three, four or five is first in  $X$ .*

*Proof.* Table 1 shows that  $T(X) \leq 5/3$ , with equality only when slot five is first and four is last. Applying Lemma 5.3 gives (a) and (b). For (c) note that any block with slot one first is optimum and slot two is never first.  $\square$

To obtain a global view of how the schedule can shrink, merge blocks into "segments." These are the portions of the schedule between idle jumps: A *segment*  $W$  consists of consecutive blocks,  $W = \cup_{i=t}^s X_i$ , where  $X_{s-1}$  and  $X_t$ , but no  $X_i$ ,  $s \geq i > t$ , end with an idle jump. (For boundary conditions allow  $s = B$  in the first segment and  $t = 1$  in the last segment.)

The segments partition the blocks. Each segment starts in slot one of a period. Both processors run uninterrupted, jumping a node between consecutive blocks of the segment, until the last slot of the segment (where an idle jump may be made). To analyze the length of the schedule for a segment  $W$  define these quantities:

$\omega(W)$  = the length of the HLF schedule for  $W$ ;

$\omega^*(W)$  = the length of the optimum schedule for  $W$ .

Note that  $W$  does not contain the nodes jumped from the last level of each of its blocks. So possibly  $\omega^*(W) < \omega(W)$ .

LEMMA 5.5. *For any segment  $W$ ,  $\omega^*(W) \geq (5/6)\omega(W)$ .*

*Proof.* Let  $W = \cup_{i=t}^s X_i$ . Set  $\delta(W) = \sum_{i=t}^s \delta(X_i)$ . Write  $\omega(W) = 6p + q$ ,  $p \geq 0$ ,  $6 > q \geq 0$ , so  $p$  is the number of complete execution periods in the segment. It suffices to show  $\delta(W) \leq p$  since this implies  $\omega^*(W) = \omega(W) - \delta(W) \geq 5p + q$ .

Consider a block  $X$  in  $W$  with  $\delta(X) > 0$ .  $X$  contains slot four or five of the execution period it starts in; also if  $\delta(X) = 2$  then  $X$  ends in another execution period, where it contains slot four. This follows from Lemma 5.4(b)-(c), and the fact that if  $X$  starts in slot three it contains slot four (otherwise  $X$  has only one node, making  $\delta(X) = 0$ ).

This implies we can assign each unit of  $\delta(W)$  to slot four or five of a distinct complete execution period of  $W$ . Hence  $\delta(W) \leq p$  as desired.  $\square$

THEOREM 5.4. *Assume  $f/s = 2/3$ .*

(a) *On any dag the HLF schedule achieves  $\omega/\omega^* \leq 6/5$ .*

(b) *For any  $\epsilon > 0$  there is a dag where the HLF schedule has  $\omega/\omega^* > 6/5 - \epsilon$ .*

*Proof.* (a) Let the segments of the HLF schedule be  $W_j$ ,  $j = S, S-1, \dots, 1$ . From Theorem 5.2(b),  $W_j \xrightarrow{*} W_{j-1}$  for  $S \geq j > 1$ . Hence  $\omega^* \geq \sum_{j=1}^S \omega^*(W_j)$ . Clearly  $\omega = \sum_{j=1}^S \omega(W_j)$ . So the theorem follows from Lemma 5.5.

(b) For any positive integer  $r$  consider Figure 5.4. It consists of  $r$  repetitions of a module with eight nodes. (As in Figure 5.2 nodes 7 and 8 are on level 1 but are drawn higher.)

FIG. 5.4. Bad dag for the HLF schedule for  $f/s = 2/3$ .

<u>1</u> <u>2</u>	<u>4</u> <u>8</u> ..
..   .. <u>3</u>	<u>5</u> <u>6</u>

(a)

<u>2</u> .. <u>7</u> <u>5</u>	<u>6</u> <u>1</u>
<u>3</u> .. <u>4</u>	.. <u>8</u> ..

(b)

FIG. 5.5. Module schedules. (a) HLF schedule. (b) Better schedule.

The HLF schedule is  $r$  repetitions of the module schedule shown in Figure 5.5(a). Thus  $\omega = 12r$ . However this schedule shows  $\omega^* \leq 10r + 1$ :  $P_1$  executes node one of the first module. Then come  $r$  repetitions of the module schedule of Figure 5.5(b), where each module executes node one of the next module. (The last module has idle in the last slot three.)

Thus  $\omega/\omega^* \geq 12r/(10r + 1)$  which approaches  $6/5$  as  $r$  approaches  $\infty$ .  $\square$

The remaining results on HLF schedules are negative. The following bound is proved similar to the others; details are in [G82b].

**THEOREM 5.5.** *Assume  $f/s \geq 4/5$  ( $\Delta$  is arbitrary). There is a dag where the HLF schedule has  $\omega/\omega^* = 6/5$ .*  $\square$

Note that when  $f/s \geq 4/5$ , the AI schedule has accuracy  $2 - (f/s) \leq 6/5$ , so it beats the theorem. Since the AI scheduling algorithm has a slightly lower time bound, it is preferable.

Results for lower speed ratios are in [G82b].

**6. Conclusions.** We have shown that an HLF schedule is optimum for length two pipelines, and can be found in linear time. Also an optimum HLA schedule exists for two uniform processors when  $\Delta = 1$ . This gives a linear-time algorithm for an optimum schedule on dags that have no idle time. It would be interesting to extend this to a polynomial time algorithm for the general  $\Delta = 1$  case.

Before summarizing the results for approximate schedules consider one more scheme, oriented toward processors of disparate speed. An *Approximately One Processor (AO) Schedule* is any schedule with no idle time on  $P_f$ . Note that  $\omega/\omega^* \leq 1 + (f/s)$  for AO, since  $(1/f + 1/s)\omega^* \geq \omega/f$ .

FIG. 6.1. Accuracy bounds for approximate schedules.

Figure 6.1 plots the accuracy of the approximate schedules. The AI schedule is found in linear time and has accuracy  $2 - (f/s)$ . It is more accurate than AO when  $f/s \geq 1/2$ . It is more accurate than HLF when  $f/s \geq 4/5$  and perhaps other cases. The HLF schedule is defined for  $\Delta = 1$ . It is found in  $O(m + n \log \log n)$  time. It is the most accurate for  $f/s = 1/2$  and  $2/3$ .

## A RANDOMIZED ALGORITHM FOR CLOSEST-POINT QUERIES\*

KENNETH L. CLARKSON†

*For Quentin Deane Clarkson, in loving memory*

**Abstract.** An algorithm for closest-point queries is given. The problem is this: given a set  $S$  of  $n$  points in  $d$ -dimensional space, build a data structure so that given an arbitrary query point  $p$ , a closest point in  $S$  to  $p$  can be found quickly. The measure of distance is the Euclidean norm. This is sometimes called the *post-office problem*. The new data structure will be termed an *RPO tree*, from Randomized Post Office. The expected time required to build an RPO tree is  $O(n^{\lceil d/2 \rceil(1+\epsilon)})$ , for any fixed  $\epsilon > 0$ , and a query can be answered in  $O(\log n)$  worst-case time. An RPO tree requires  $O(n^{\lceil d/2 \rceil(1+\epsilon)})$  space in the worst case. The constant factors in these bounds depend on  $d$  and  $\epsilon$ . The bounds are average-case due to the randomization employed by the algorithm, and hold for any set of input points. This result approaches the  $\Omega(n^{\lceil d/2 \rceil})$  worst-case time required for any algorithm that constructs the Voronoi diagram of the input points, and is a considerable improvement over previous bounds for  $d > 3$ . The main step of the construction algorithm is the determination of the Voronoi diagram of a random sample of the sites, and the triangulation of that diagram.

**Key words.** closest points, Voronoi diagrams, computational geometry

**AMS(MOS) subject classifications.** 68U05, 68P10

**1. Introduction.** The post-office problem is a fundamental problem of computational geometry, having many applications in statistics, operations research, interactive graphics, coding theory, and other areas.

Several algorithms that are asymptotically fast in the worst-case sense are known for this problem in the planar ( $d = 2$ ) case. They involve the construction of the Voronoi diagram of the sites [12], [26], and the use of fast methods for searching planar subdivisions resulting from that diagram [19], [17], [11]. By these methods, a data structure requiring  $O(n)$  space can be constructed in  $O(n \log n)$  time, so that a query can be answered in  $O(\log n)$  time.

The higher-dimensional cases are much less examined and understood. Dobkin and Lipton have described a data structure requiring  $O(n^{2^{d+1}})$  time and space to construct, giving a query time of  $O(\log n)$  [10]. Chazelle has given an algorithm for the case  $d = 3$  that requires  $O(n^2)$  preprocessing for  $O(\log^2 n)$  query time [4].

Although the time and space bounds for RPO trees are rather large for large  $d$ , they are a considerable improvement over previous general bounds. The key step in the construction of the data structure is the determination of Voronoi diagrams of small subsets of the sites. (For convenience, points in  $S$  will be called *sites*.) The bounds depend on the complexity of these Voronoi diagrams. If the diagrams have  $O(n)$  vertices, the construction requires an expected time bounded by  $O(n^C)$ , where  $C$  is a constant independent of  $d$ . Indeed, when a set of sites is uniformly distributed in a hypercube [1], or spatially Poisson-distributed [13], their Voronoi diagram has linear complexity on the average. These facts suggest that RPO trees may do considerably better in practice than the worst-case bounds would show. On the other hand, in the worst case Voronoi diagrams may require  $\Omega(n^{\lceil d/2 \rceil})$  storage [18], [24], so in a sense any algorithm using Voronoi diagrams could not perform too much better than RPO trees.

**1.1. Overview.** The initial observation for the data structure is just this: if we want to find a closest site in  $S$  to a point  $p$ , then knowing a closest site to  $p$  in some  $R \subset S$  can help restrict the search in  $S$ . The terms *candidate sets* and *candidate sites* help to formalize this notion.

**DEFINITION.** For a given subset  $R \subset S$ , and any point  $x$ , let  $r_x$  denote the distance of  $x$  to a closest site in  $R$ . Then the *candidate region*  $C(x)$  for  $x$ , relative to  $R$ , is the ball of points whose distance to  $x$  is less than  $r_x$ . The corresponding closed ball will be denoted  $\overline{C}(x)$ . The *candidate set* for  $x$  is  $S \cap C(x)$ . The candidate region for a set of points  $A$  is  $C(A) = \cup_{x \in A} C(x)$ , with the candidate set  $S \cap C(A)$ .

Thus, for a query point  $p$  and region  $A$  with  $p \in A$ , the set  $S \cap \overline{C}(A)$  contains all the closest sites to  $p$ . If  $q$  is a closest site in  $R$  to  $p$ , then the candidate set  $S \cap C(A)$  contains all sites closer to  $p$  than  $q$ . The key idea is to find some  $R \subset S$ , and some collection of regions, such that for every region  $A$  in the collection, the candidate set of  $A$  relative to  $R$  contains few sites.

Such a collection of regions can be found using random sampling, as follows: take a random sample  $R$  of the sites, determine the Voronoi diagram  $\mathcal{V}(R)$  of that sample, and then compute  $\Delta(\mathcal{V}(R))$ , a triangulation of the Voronoi diagram. (Voronoi diagrams are defined in §2; triangulations are discussed in §3.) The result is a collection of simple regions with the following properties:

- The union of the regions covers  $E^d$ , that is,  $E^d = \cup_{A \in \Delta(\mathcal{V}(R))} A$ ;
- The number of regions is  $O(r^{\lceil d/2 \rceil})$ , for  $r \rightarrow \infty$ , where  $r$  is the size of  $R$ ;
- With high probability, the candidate sets  $S \cap C(A)$  are “small” for all regions  $A \in \Delta(\mathcal{V}(R))$ , specifically,  $|S \cap C(A)| = nO(\log r/r)$  as  $r \rightarrow \infty$ ;
- The regions in  $\Delta(\mathcal{V}(R))$  are simple, so that for point  $p$  and  $A \in \Delta(\mathcal{V}(R))$ , we can tell in  $O(1)$  time if  $p \in A$ , for fixed dimension  $d$ ;
- For each  $A \in \Delta(\mathcal{V}(R))$ , there is a site  $q \in R$  such that all points in  $A$  are as close to  $q$  as to any other site in  $R$ .

These properties suggest a two-step process for answering closest-point queries: given query point  $p$ , determine a region  $A \in \Delta(\mathcal{V}(R))$  that contains it, then determine the closest site to  $p$  in  $R \cup (S \cap C(A))$  by linear search. For a suitable sample size, with high probability this procedure is faster than directly searching  $S$ . By repeatedly taking random samples until a sample is found for which the corresponding candidate sets are all small, a data structure with an improved worst-case query time can be constructed. Since a random sample will satisfy this condition with high probability, on average only  $O(1)$  sampling repetitions need be done.

Rather than search the candidate sets in linear time, this construction can be applied recursively, using a sample size  $r$  that is independent of the number of sites. The resulting search structure is an RPO tree, in which the number of children of a node is independent of the number of sites, as is the size of the set of sites associated with each leaf node.

Each node  $t$  of an RPO tree corresponds to a collection of sites  $S'$  that contains the closest site to a set of potential query points. If  $t$  is an internal node, a suitable sample  $R' \subset S'$  is found, and for each  $A \in \Delta(\mathcal{V}(R'))$ , there is a child  $t'$  of  $t$  for which a record  $t'.region$  is  $A$ . The children of  $t$  form a list  $t.children$ . A closest-point query can be answered by tracing down from the root, moving from a current node  $t$  to a child  $t' \in t.children$ , whose associated  $t'.region$  contains the query point. If  $t$  is a leaf node, the sites  $t.sites$  associated with  $t$  are given a linear search to answer the query.

The procedures *Make\_RPO\_Tree* and *Answer\_Query* are shown in Fig. 1. The procedure *New\_RPO\_Tree* returns a new RPO tree, whose regions and subtrees are

subsequently defined. From Theorem 4.5, the sample size  $r$  should be at least about  $(d+1)^3$ . The constant  $K$  should be no smaller than  $r$ . The constant  $\alpha_{r,d} = O(\log r/r)$  is defined in Theorem 4.5.

FIG. 1. *Procedures Make\_RPO\_Tree and Answer\_Query.*

Before making a more detailed description of the algorithm, it may be helpful to consider informally the simplest interesting example of a set  $S \cap \overline{C}(A)$ , which occurs when  $A$  is a triangular region in the plane, a region in the triangulation of the Voronoi diagram of a sample  $R$ . In Fig. 2, the set  $R = \{q, p_1, \dots, p_5\}$ , and  $A$  has vertices  $a, b$ , and  $c$ , part of a triangulation of the Voronoi region  $\mathcal{V}_q$ . As will be shown in §4, the region  $\overline{C}(A)$  has a particularly simple description: it is simply  $\overline{C}(a) \cup \overline{C}(b) \cup \overline{C}(c)$ . Since  $a, b$ , and  $c$  are vertices of  $\mathcal{V}_q$ , the circles bounding  $\overline{C}(a)$ ,  $\overline{C}(b)$ , and  $\overline{C}(c)$  are *Delaunay circles* of the Voronoi diagram  $\mathcal{V}_R$ . To restate this fact, suppose  $p \in A$ . Then since  $q \in S$ , the closest site to  $p$  is contained in the disk defined by the circle centered at  $p$  that passes through  $q$ . This disk is contained in the union of the Delaunay disks at  $a, b$ , and  $c$ .

For the RPO construction to work, with high probability all these Delaunay disks should contain few sites. Why should this be? The reason is based on the fundamental fact that these Delaunay disks contain no sample sites. Intuitively, this provides some evidence that these disks contain few sites: if some arbitrary disk contains a large fraction of the sites, then with high probability, some sample site will be chosen from that disk, and it cannot be a Delaunay disk. This argument is made precise in §4.3.

FIG. 2. A triangle  $A \in \Delta(\mathcal{V}_q)$  and  $\bar{C}(A)$ .

**1.2. Outline of the paper.** To complete the description of the algorithms, it is necessary to specify the triangulation procedure  $\Delta$ , and to characterize formally the candidate regions  $C(A)$  for  $A \in \Delta(\mathcal{V}(R))$ . To analyze the algorithms, we must bound the number of children that a node can have, that is, the number of regions in  $\Delta(\mathcal{V}(R))$ , and also bound the size of the resulting subproblems, that is, the size of each  $C(A) \cap S$ . Before addressing these questions, some notation and basic lemmas will be given in §2. Many readers should be able to skim most of this section, or refer to it as needed. In §3, the triangulation procedure is given, and a bound on the size of its output is developed. In §4, it is shown that the candidate regions to be used have simple descriptions, generalizing the above example. It is also shown that with high probability, all the corresponding candidate sets have few sites. Also given in this section are the modifications to the algorithms for handling a variant of the post-office problem, in which all closest sites to a query point are desired. In §5, the complexity analysis of the algorithms is completed. Some concluding remarks are made in §6, with discussion of subsequent and related work.

The basic idea for the RPO data structure is simple, and the critical algorithmic step is the fundamental operation of computing the Voronoi diagram, followed by triangulation. Nonetheless, several factors complicate the discussion. The algorithms generalize for an arbitrary dimension, so that the descriptions and proofs of correctness are abstract. An operation of triangulation must be applied to the unbounded polyhedral sets of a Voronoi diagram, as must the determination of candidate regions. This is best done using the notion of “points at infinity,” considering an unbounded polyhedral set as the convex hull of a set of points, some of which are at infinity. This idea is made precise using *two-sided space*, described in the next section. The sample  $R$  may be degenerate, that is, not have full affine dimension. This possibility must be accounted for. These factors imply that the description must be more abstract and complicated than it otherwise would be.

**2. Notation, terminology, and background.** The notation in this paper will follow [14] in general, and use basic results from that text. The concepts of *oriented projective geometry* [27] will also play a large role. The following notation is gathered here for reference:

$E^d$  denotes  $d$ -dimensional Euclidean space;

$A + B$  is the pointwise sum  $\{x + y \mid x \in A, y \in B\}$ , for  $A, B \subset E^d$ ;

$x + A$  and  $A + x$  denote  $\{x\} + A$ , for  $x \in E^d$ ;

$\alpha A$  denotes the product  $\{\alpha x \mid x \in A\}$ , for a real number  $\alpha$  and  $A \subset E^d$ ;

$S_{x,y}$  denotes the sphere that has center  $x$  and that contains  $y$ .  $B_{x,y}$  and  $\overline{B}_{x,y}$  denote the corresponding open and closed balls;

A *flat*  $F \subset E^d$  is an *affinely closed* set, that is, if  $x, y \in F$ , then the straight line through  $x$  and  $y$  is contained in  $F$ .

$\text{aff } A$  denotes the affine closure of a point set  $A \subset E^d$ , that is, the intersection of all flats containing  $A$ ;

$\dim A$  denotes the affine dimension of  $A$ , that is, the dimension of the linear subspace  $(\text{aff } A) - p$ , for  $p \in A$ . A  $k$ -flat  $F$  has  $k = \dim F$ ;

$\text{conv } A$  denotes the convex closure of  $A$ , that is, the intersection of all convex sets containing  $A$ ;

$\text{relint } A$  is the interior of  $A$  relative to its affine closure;

$\text{relbd } A$  is the boundary of  $A$  relative to its affine closure.

**Rays and cones.** For  $x, y \in E^d$ , let  $\text{ray}_x y$  denote

$$\{x + \alpha(y - x) \mid \alpha \geq 0\}.$$

A *cone*  $C$  with apex  $a$  is a subset of  $E^d$  such that  $\text{ray}_a y \subset C$  if and only if  $y \in C$ , for  $y \in E^d$ .

**Polyhedral sets and polytopes.** A *polyhedral set* is the intersection of a finite number of closed halfspaces, and a *polytope* is a bounded polyhedral set. A polyhedral cone is a cone that is a polyhedral set. A  $d$ -polytope ( $d$ -polyhedral set)  $P$  satisfies  $d = \dim P$ .

A *supporting hyperplane*  $h$  of a polyhedral set  $P$  satisfies  $h \cap P \neq \emptyset$  and  $h^+ \cap P = \emptyset$ , where  $h^+$  is an open halfspace defined by  $h$ . A *face* of a polyhedral set  $P$  is the intersection of  $P$  with a supporting halfspace. Vertices, edges, and facets are faces of affine dimension 0, 1, and  $d - 1$ , respectively, for a  $d$ -polyhedral set. In general, a face of  $P$  with dimension  $k$  is a  $k$ -*face*, and the set of such faces is  $f_k(P)$ . The set  $f_0(P)$  of vertices (or *extreme points*) of a polyhedral set  $P$  will be denoted by  $\text{vert } P$ .

Two polyhedral sets  $A$  and  $B$  are said to be *combinatorially equivalent* if there is a bijective mapping  $\Lambda$  from the faces of  $A$  to those of  $B$  such that  $F \subset G$  if and only if  $\Lambda(F) \subset \Lambda(G)$ , for all  $F$  and  $G$  faces of  $A$ .

The set of *extreme rays* of a polyhedral set  $P$  is the set of rays  $e$  emanating from the origin such that there is some point  $q$  for which  $q + e$  is an edge (1-face) of  $P$ . The convex hull of the extreme rays of  $P$  is the *characteristic cone*  $\text{cc } P$ . From [14, 2.5.2], if  $x, y \in P$  and  $e$  is a ray from the origin, then  $x + e \subseteq P$  if and only if  $y + e \subseteq P$ . (Looking ahead, this is equivalent to the condition that  $e$  corresponds to a "point at infinity" in  $P$ , and that  $P$  is convex even when such points are included.) This fact and the convexity of  $P$  imply that  $x + \text{cc } P \subset P$  for any  $x \in P$ . It can be shown that  $\text{cc } P$  is the maximal such cone.

A set is said to be *line-free* if it contains no straight lines (no 1-flats). A line-free cone is pointed [14, p. 24], that is, it has only one apex, which is a vertex. Many basic

facts about polytopes generalize nicely to line-free polyhedral sets, using the notion of “ideal points” defined below.

**Complexes.** A *complex* is a collection of polyhedral sets such that every face of a polyhedral set in the complex is also in the complex, and the intersection of two polyhedral sets in the complex is a face of each of them. (In the complexes considered here the empty set  $\emptyset$  is a face.) A polyhedral set of dimension  $k$  in a complex is a  $k$ -*face* of that complex, and the terminology of vertices, edges, and facets carries over for complexes. The *facial lattice* of a complex is the set of faces of the complex, together with the inclusion relations between those faces.

One example of a complex is the *boundary complex*  $\mathcal{B}(P)$  of a polyhedral set  $P$ , the set of facets of  $P$  and their faces. Another example of a complex is the Voronoi diagram of a set of sites, described below.

**Two-sided space, homogeneous coordinates, and ideal points.** It will be helpful conceptually and computationally to use the notion of “points at infinity,” also known as *ideal* points, as opposed to the usual *real* points in  $E^d$ . These classes of points together make up what will be denoted  $T^d$ , or *two-sided space*. (The name will be explained below.)

To represent points in  $T^d$ , *homogeneous* coordinates will be used: a real point  $x \in E^d$  is represented by  $x_h = [x_r; x_s]$  if  $x = x_r/x_s$ , where  $x_r \in E^d$  and  $x_s \in \mathcal{R}$ ,  $x_s > 0$ . (The terminology is borrowed from projective geometry [23], although in this case, the coordinates cannot really be said to be homogeneous.) An ideal point  $x \in T^d$  is represented by the homogeneous coordinates  $[x_r; 0]$ , where  $x_r \in E^d$  and  $x_r \neq 0$ . The point  $x$  can be considered the “endpoint” of ray<sub>0</sub>  $x_r$ . If  $x$  is an ideal point and  $y$  is real, we will say that  $\text{conv}\{x, y\}$  is ray<sub>y</sub>  $(x_r + y)$ . Indeed, if  $z \in \text{conv}\{x, y\}$ , for any points  $x$  and  $y$ , then for any representations  $z_h, x_h, y_h$ , we have  $z_h = \alpha_x x_h + \alpha_y y_h$ , for some  $\alpha_x, \alpha_y \geq 0$ , and conversely. This provides a general definition of convex combination for points in  $T^d$ .

Note that homogeneous coordinate representations are not unique: if  $x_h$  is a homogeneous representation of  $x$ , then so is  $\beta x_h$ , for any  $\beta > 0$ . (This convention is different from that of projective geometry, where  $\beta$  need only be nonzero. This follows [21] and [15], and is needed to distinguish ideal points in “opposite directions.”) The two-sided nature of  $T^d$  derives from its containment of two copies of  $E^d$ , since  $[x_r; 1]$  and  $[x_r; -1]$  represent distinct points in  $T^d$  for every  $x_r \in E^d$ . There is a correspondence between points in  $T^d$  and the  $d$ -sphere

$$S^d = \{x \in E^{d+1} \mid \|x\| = 1\}.$$

A point with homogeneous coordinates  $x_h$  corresponds to  $x_h/\|x_h\|$ , where  $x_h$  is interpreted as a point in  $E^{d+1}$ . The ideal points of  $T^d$  correspond to those points of  $S^d$  on the hyperplane  $x_s = x_{d+1} = 0$ . The two halves of  $S^d$  separated by the set of ideal points correspond to the two sides of  $T^d$ .

In general, the only points in  $T^d$  considered will be those satisfying  $x_s \geq 0$ . This set of points is termed the “front range” of  $T^d$ , and will be denoted by  $F^d$ . A closed convex set  $P \subset E^d$  will be extended by including  $[b - a; 0]$  in  $P$  whenever ray<sub>a</sub>  $b \subset P$ . This implies that the set of points on  $S^d$  corresponding to  $P$  is also closed. A straight line will thus have two ideal “endpoints,” and so on for all flats. (Note that this gives a meaning to “flat” that is different from Stolfi’s [27].) This convention will extend the definition of the sum  $A + B$  for unbounded  $A$  and  $B$ . The notation for a sphere  $S_{x,y}$  can be extended to allow the center  $x$  to be an ideal point. In this case,

$S_{x,y}$  is a hyperplane normal to  $x_r$  and passing through  $y$ . The closed ball  $\overline{B}_{x,y}$  is the corresponding closed halfspace. An analytic relation describing such spheres is given below in the discussion of Voronoi diagrams.

The set  $\text{re } A$  will denote the real points of  $A$ , and  $\text{id } A$  will denote the ideal points of  $A$ . Note that  $\text{re } A = \text{re } B$  implies that  $\text{id } A = \text{id } B$ , for  $A$  and  $B$  closed and convex.

With this extension to the front range  $F^d$ , a line-free unbounded polyhedral set  $P \subset E^d$  has an implicit additional defining halfspace. That is,  $\text{id } P$  is an additional facet of  $P$ , the *ideal facet*. This facet corresponds to  $\text{cc } P$  in a natural way, and the correspondence extends to the faces of  $\text{id } P$ , so that the vertices of  $\text{id } P$  correspond to the extreme rays of  $\text{cc } P$ . Thus  $\text{vert } P$  is extended to include ideal points. The following simple lemma helps in generalizing facts about polytopes to facts about polyhedral sets.

**LEMMA 2.1.** *Let  $C$  be a polyhedral pointed cone with apex  $a$ . Let  $h$  be a supporting hyperplane of  $C$  with  $h \cap C = \{a\}$ . Let  $\nu$  be a normal vector to  $h$  contained in the same halfspace containing  $C$ . Then  $P = C \cap (h + \nu)$  is a polytope.*

*Proof.* See Appendix A.  $\square$

It is easy to show that  $C = \cup_{y \in A} \text{ray}_x y$ , and that  $x \in P$  if and only if  $x' = [x - a; 0] \in \text{id } C$ . This bijective map satisfies  $(\alpha x + \beta y)' = \alpha x' + \beta y'$ , for  $\alpha + \beta = 1$ . This implies that  $\text{id } C$  and  $P$  are combinatorially equivalent. Thus Lemma 2.1 brings  $\text{id } C$  into the “real” world of  $E^d$ .

The following lemma is a generalization of [14, 2.4.5] from polytopes to line-free polyhedral sets.

**LEMMA 2.2.** *If  $P \subset E^d$  is a line-free  $d$ -polyhedral set then  $P = \text{conv vert } P$ .*

*Proof.* See Appendix A.  $\square$

**Simplices and triangulations.** A *simplex* is a simple kind of polyhedral set: a  $d$ -simplex is a polyhedral set with  $d + 1$  vertices and affine dimension  $d$ . Note that vertices will be allowed to be ideal. For example, a triangle with two ideal vertices is a cone, and a triangle with one ideal vertex is bounded by a line segment and by two parallel rays from the endpoints of that line segment.

A *simplicial complex* is a complex composed of simplices. A *triangulation*  $\mathcal{T}$  of a complex  $\mathcal{C}$  is a simplicial complex that is a subdivision of  $\mathcal{C}$ . Every vertex of  $\mathcal{T}$  is a vertex of  $\mathcal{C}$ , every facet of  $\mathcal{T}$  is a simplex, and the union of the facets of  $\mathcal{T}$  is the union of the facets of  $\mathcal{C}$ .

In §3, a particular kind of triangulation of  $\mathcal{C}$ , denoted  $\Delta(\mathcal{C})$ , will be described. Construction of this complex is an essential procedure in the algorithm given in this paper. The complexity of  $\Delta(\mathcal{C})$  and of its construction procedure are also considered in §3.

The triangulation  $\Delta$  may involve “simplices” of even greater generality than those shown above. For example, suppose  $\dim S = 2$  but  $\dim R = 1$ , specifically,  $R$  is a set of sites on the  $x$  axis. Then each Voronoi region  $\mathcal{V}_q$  of  $R$  will be a strip bounded by two parallel lines. This can be viewed as an interval  $A$ , that is, a 1-simplex, added to the  $y$ -axis. That is,  $\mathcal{V}_q = A + l$ , where  $l$  is the  $y$ -axis line. In general, when  $d > \dim R$ , the regions of  $\Delta(\mathcal{V}(R))$  will have the form  $A + f$ , where  $A$  is a simplex and  $f$  is a flat orthogonal to  $\text{aff } A$ . This generalization is formalized by Lemma 3.4.

**Duality.** For a complex  $\mathcal{C}$ , a *dual*  $\mathcal{D}$  of  $\mathcal{C}$  is another complex for which there is an inclusion-reversing correspondence between faces of  $\mathcal{C}$  and those of  $\mathcal{D}$ . That is, there is a bijective mapping  $\Psi$  from the set of faces of  $\mathcal{C}$  to those of  $\mathcal{D}$  such that for faces  $F$  and  $G$  of  $\mathcal{C}$ , the inclusion  $F \subset G$  holds if and only if  $\Psi(F) \supset \Psi(G)$ . The facial lattice

of  $\mathcal{C}$  can be determined from the facial lattice of  $\mathcal{D}$ , and vice versa.

One particular dual relation between polyhedral sets is quite useful. For a set  $A \subset E^d$ , the polar set  $A^*$  is

$$\{y \mid y_h \cdot x_h \geq 0 \text{ for all } x \in A\}.$$

When  $P$  is a line-free  $d$ -polyhedral set in  $E^d$  with the origin in its interior, the polar set  $P^*$  of  $P$  is a polytope, even when  $P$  is unbounded. Moreover,  $P^*$  is dual to  $P$ . The ideal facet of  $P$ , if any, corresponds to the origin, which will be a vertex of  $P^*$ , for unbounded  $P$ .

**Voronoi diagrams.** The *Voronoi diagram*  $\mathcal{V}(R)$  of a set of sites (points)  $R$  in  $E^d$  is the partition of  $E^d$  into blocks, such that all points in a block have exactly the same closest sites. The Voronoi region  $\mathcal{V}_q$  associated with a site  $q \in R$  is the polyhedral set containing all points at least as close to  $q$  as they are to any other site. If  $v \in \text{revert } \mathcal{V}_q$  for some site  $q$ , then the sphere (ball) centered at  $v$  with radius  $\|v - q\|$  is termed a *Delaunay sphere* (ball) of the sites  $R$ . (A ball in the plane is also called a disk.) At least  $d + 1$  sites are on a Delaunay sphere, and none are inside it.

It is well known that  $\mathcal{V}_q$  is unbounded if and only if  $q$  is on the convex hull of  $R$ . Furthermore, each unbounded edge of  $\mathcal{V}_q$  is normal to a facet of  $\text{conv } R$  that contains  $q$ .

Brown [3] has shown that the computation of a Voronoi diagram in  $E^d$  can be reduced to the problem of computing a convex hull in  $E^{d+1}$ . The reduction is done by means of a mapping from  $E^d$  to  $E^{d+1}$ . One mapping that achieves this reduction is the function  $\Upsilon : E^d \mapsto E^{d+1}$ , which sends  $y \in E^d$  to the point  $(y_1, \dots, y_d, -y \cdot y/2) \in E^{d+1}$ . For  $x, q \in E^d$ , we have  $y \in S_{x,q}$  if and only if

$$(x_1, \dots, x_d, 1) \cdot \Upsilon(y) = (x_1, \dots, x_d, 1) \cdot \Upsilon(q).$$

This implies  $\text{aff } \Upsilon(S_{x,q})$  is a hyperplane. Furthermore, if  $\overline{B}_{x,q}$  is a Delaunay ball, then  $\Upsilon(R) \cap \Upsilon(\overline{B}_{x,q})$  is empty, so that  $\text{aff } \Upsilon(S_{x,q})$  contains a facet of  $\text{conv } \Upsilon(R)$ . It follows that  $\text{conv } \Upsilon(R)$  gives a dual complex to  $\mathcal{V}(R)$ .

Note also that the analytic condition for  $y \in S_{x,q}$  can be extended coherently to ideal  $x$  by  $x_h \cdot (\Upsilon(y) - \Upsilon(q)) = 0$ , where  $x_h$  is interpreted as a point in  $E^{d+1}$ . For ideal  $y$  and  $x$ , the appropriate condition is  $y_r \cdot x_r = 0$ .

### 3. Triangulating polytopes and Voronoi regions.

**3.1. A triangulation procedure and its correctness.** The procedure  $\Delta$  to be used for triangulating a complex  $\mathcal{C}$  is straightforward: the procedure produces a set of simplices triangulating each face of  $\mathcal{C}$ , considering these faces in increasing order of their affine dimension. Note that if  $1 \geq \dim P$ , then the face  $P$  is a simplex. If  $1 < \dim P$ , then arbitrarily pick  $v \in \text{vert } P$ , and let  $\Delta(P)$  be the collection

$$\{\text{conv}(\{v\} \cup S) \mid S \in \Delta(F), F \text{ a facet of } P, v \notin F\}.$$

For example, if  $P$  is a polygon, then for every edge  $e$  of  $P$  not containing vertex  $v$ , the triangle defined by  $e$  and  $v$  is in  $\Delta(P)$ . Note that once  $\Delta(P)$  is computed, it is “fixed,” so that the same triangulation of  $P$  is used whenever a face is triangulated for which  $P$  is a facet.

To apply  $\Delta$  to a polyhedral set, that set must have a vertex. However, not all polyhedral sets have vertices. (An example of such a polyhedral set is given in the discussion of triangulations in §2.) We will first show that  $\Delta$  can be applied to line-free polyhedral sets, and then discuss the extension of  $\Delta$  to arbitrary polyhedral sets.

LEMMA 3.1. *A line-free polyhedral set  $P$  has a vertex.*

*Proof.* If  $P$  is a real polyhedral set, the result is a special case of [14, 2.4.6]. If  $P$  is an ideal polyhedral set (say some ideal facet of an unbounded polyhedral set), then the result follows from Lemma 2.1 and [14, 2.4.6].  $\square$

This lemma implies that some choice  $v \in \text{vert } P$  can be made in  $\Delta$ . To show that  $P$  is the union of the simplices in  $\Delta(P)$ , the following lemma is useful.

LEMMA 3.2. *For a line-free polyhedral region  $P$ , if  $v \in \text{vert } P$  and  $a \in P$ , then the point  $b = \text{ray}_v a \cap \text{relbd } P$  is on a facet of  $P$  that does not contain  $v$ .*

*Proof.* See Appendix A.  $\square$

THEOREM 3.3. *Given a complex  $\mathcal{C}$  containing only line-free polyhedral sets,  $\Delta(\mathcal{C})$  is a triangulation of that complex. (Note that the simplices in  $\Delta(\mathcal{C})$  may have ideal vertices.)*

*Proof.* Induction on dimension will be applied to each polyhedral set  $P$  in  $\mathcal{C}$  to show that  $\Delta(P)$  returns a set of simplices covering  $P$ . Let  $a \in P$ . Then  $\text{ray}_v a$  intersects  $\text{relbd } P$  at  $v$  and at some point  $b$ . (If  $P$  is ideal, map the points involved to the polytope of Lemma 2.1.) By the previous lemma,  $b$  is on some facet  $F$  not containing  $v$ . Since by inductive assumption,  $b$  is in a simplex  $A$  of a triangulation of  $F$ , it follows that  $a \in \text{conv}(\{v\} \cup A)$ , and the set of regions returned by  $\Delta$  covers  $P$ .

The other properties of a triangulation follow by similar straightforward induction.  $\square$

To extend the triangulation procedure  $\Delta$  to polyhedral sets that do not have vertices, the following lemma is useful.

LEMMA 3.4. *Let  $P \subset T^d$  be a closed polyhedral set. Then there is a subspace  $L$  of maximum affine dimension for which  $x + L \subset P$  for any  $x \in P$ . Furthermore, if  $L^*$  is any flat that is orthogonally complementary to  $L$ , then  $P = (P \cap L^*) + L$ , where  $P \cap L^*$  is a line-free polyhedral set.*

*Proof.* (Recall that  $L^*$  and  $L$  orthogonal means that  $L$  and the subspace  $L^* - x$  are orthogonal, where  $x \in L^*$ . That is, every vector in  $L^* - x$  is perpendicular to every vector in  $L$ . Since  $L^*$  and  $L$  are extended to include ideal points, the sum  $L + L^*$  is the front range of  $T^d$ .)

For  $\text{re } P$ , the lemma is a restatement of [14, 2.5.4]. The extension to  $\text{id } P$  follows from this, since  $\text{re } P = \text{re}(P \cap L^*) + \text{re } L$  implies equality for the ideal parts as well.  $\square$

In the particular case where  $P$  is a Voronoi region, the flat  $L^*$  can be taken to be  $\text{aff } R$ , so that  $L$  is  $(\text{aff } R)^\perp$ , the subspace orthogonal to  $\text{aff } R$ . Observe that if  $l$  is a straight line contained in a Voronoi region  $V_q$ , then  $l = (\text{conv}\{a, c\}) \cup (\text{conv}\{a, -c\})$ , where  $a \in \text{re } l$  and  $c \in \text{id } l$ . For any other site  $q' \in R$ ,  $c \in V_q$  implies that  $q' \notin B_{c,q}$ , so that  $c_h \cdot (\Upsilon(q') - \Upsilon(q)) \geq 0$ . But  $-c \in V_q$  as well, so  $c_h \cdot (\Upsilon(q') - \Upsilon(q)) \leq 0$ . Therefore for any  $q' \in R$ , we have  $q' \in S_{c,q}$ , and so  $\text{aff } R \subseteq S_{c,q}$ . That is,  $\text{aff } R$  is perpendicular to  $c$ , and  $l \subseteq (\text{aff } R)^\perp$ .

To use this lemma to extend  $\Delta$  for Voronoi regions containing lines, simply define  $\Delta(V_q)$  to be the set of regions  $\{A + (\text{aff } R)^\perp \mid A \in \Delta(V_q \cap \text{aff } R)\}$ .

**3.2. Complexity of the complex  $\Delta(\mathcal{V}(R))$ .** In the worst case, the Voronoi diagram  $\mathcal{V}(R)$  has  $\Theta(r^{\lceil d/2 \rceil})$  faces. This follows from the correspondence discussed in §2 between  $\mathcal{V}(R)$  and  $\text{conv } \Upsilon(R) \subset E^{d+1}$ , and from the Upper Bound Theorem [20] applied to  $(d+1)$ -polytopes. As is shown below, the number of simplices in  $\Delta(\mathcal{V}(R))$  has the same  $\Theta(r^{\lceil d/2 \rceil})$  bound. First a bound will be proven for  $\Delta(P)$ , in the case where  $P$  is a *simple* polytope, defined below. Next it will be shown that for every polytope  $P$ , there is a simple polytope  $\hat{P}$  with the same number of facets, such that  $\Delta(\hat{P})$  has at least as many simplices as  $\Delta(P)$ .

LEMMA 3.5. *For a simple  $d$ -polytope  $P$  with  $n$  facets, the triangulation  $\Delta(P)$  has  $O(n^{\lfloor d/2 \rfloor})$  simplices, as  $n \rightarrow \infty$ .*

*Proof.* A simple polytope satisfies the condition that every vertex of the polytope is contained in exactly  $d$  facets of that polytope. Suppose  $P$  is a simple polytope. Then the dual  $P^*$  has the property that every facet of  $P^*$  contains exactly  $d$  vertices. (The dual and some of its properties are described in §2.) That is, the facets of  $P^*$  are all simplices, which is the definition of a *simplicial* polytope. The faces of a simplex are all simplices [14, §4.1]. That is, each  $k$ -face of  $P^*$  is a  $k$ -simplex and has  $k + 1$  facets. This means that dually, every  $(d - 1 - k)$ -face of  $P$  is a facet of  $k + 1$  faces of  $P$ . Put another way, every  $k$ -face of  $P$  is a facet of  $d - k$  faces of  $P$ .

What does this fact imply for  $\Delta(P)$ ? For a polytope  $F$ , let  $|\Delta(F)|$  denote the number of simplices in  $\Delta(F)$ . Then the definition of  $\Delta(F)$  and the above fact imply that

$$\sum_{F \in f_k(P)} |\Delta(F)| = \sum_{\substack{F \in f_k(P) \\ F' \in f_{k-1}(F)}} |\Delta(F')| \leq (d - k + 1) \sum_{F' \in f_{k-1}(P)} |\Delta(F')|.$$

The second relation holds because  $|\Delta(F')|$  appears  $d - k + 1$  times in the second sum. Putting these relations together,

$$|\Delta(P)| = \sum_{F \in f_d(P)} |\Delta(F)| \leq d! \sum_{F \in f_0(P)} |\Delta(F)| = d! |\text{vert } P|.$$

By the results of [20],  $|\text{vert } P| = O(n^{\lfloor d/2 \rfloor})$  when  $P$  is a  $d$ -polytope with  $n$  facets, so the lemma follows.  $\square$

Before proving the corresponding lemma for nonsimple polytopes, a definition is needed.

DEFINITION. Let  $P \subset E^d$  be a  $d$ -polytope and let  $h$  be a hyperplane with  $F = h \cap P$  a facet of  $P$ . Let  $\hat{h}$  be a hyperplane with nonempty intersection with  $P$ , and with all vertices of  $\text{vert } P \setminus \text{vert } F$  in the open halfspace  $\hat{h}^+$ . If  $F$  is in the open halfspace  $\hat{h}^-$ , then the polytope  $\hat{P} = P \cap \hat{h}^+$  will be said to be obtained from  $P$  by *pushing* the facet  $F$ .

This operation of pushing a facet of a polytope is the dual of the operation of *pulling* a vertex [14, §5.2]. The (polar) dual polytope of a pushed polytope  $\hat{P}$  can be obtained by pulling a vertex of  $P^*$ . In [14, §5.2] it is shown that the operation of pulling vertices, when applied successively to every vertex of a polytope, results in a simplicial polytope. Dually, the operation of pushing facets yields a simple polytope.

The following lemma is a restatement of [14, 5.2.2], together with some relevant discussion in that section.

LEMMA 3.6. *Suppose  $\hat{P} \subset E^d$  is a  $d$ -polytope obtained from the  $d$ -polytope  $P$  by pulling  $v \in \text{vert } P$ . Then the faces of  $\hat{P}$  are exactly the following:*

- *faces of  $P$  that do not contain  $v$ ;*
- *faces of the form  $\text{conv}\{v, G\}$ , where*
  - *$G$  is a face of  $P$  not containing  $v$ , and*
  - *$G$  is contained in a facet of  $P$  that contains  $v$ ;*

*Furthermore, for every face  $F$  of  $P$  containing  $v$ , there is a facet  $F'$  of  $F$  that yields a face  $\text{conv}\{v, F'\}$  of the second type.*

*Proof.* All claims except the last statement are from [14, 5.2.2]. The last statement follows by considering  $\text{conv}(\text{vert } F \setminus \{v\})$ , which does not contain  $v$ , and is either a facet of  $F$  or contains a facet of  $F$ .  $\square$

Using the inclusion-reversing correspondence between faces of a polytope and faces of its dual, the following lemma shows what pushing a facet will do:

LEMMA 3.7. *Suppose  $\hat{P} \subset E^d$  is a  $d$ -polytope obtained from the  $d$ -polytope  $P$  by pushing a facet  $F = h \cap P$  of  $P$ . Then the faces of  $\hat{P}$  correspond to the following:*

- faces of  $P$  that do not meet  $F$ ;
- faces of the form  $\hat{h} \cap G$ , where
  - $G$  is a face not contained in  $F$ , and
  - $G$  contains a vertex of  $F$ .

Furthermore, for every face  $H$  of  $F$ , there is a face  $G$  of  $P$  such that  $H$  is a facet of  $G$ , and  $G$  yields a face  $\hat{h} \cap G$  of the second type.

*Proof.* The lemma follows directly from the previous one, and duality.  $\square$

LEMMA 3.8. *For a line-free polyhedral set  $P$  of dimension  $d$  and with  $n$  facets, the triangulation  $\Delta(P)$  has  $O(n^{\lfloor d/2 \rfloor})$  simplices, as  $n \rightarrow \infty$ .*

*Proof.* If  $P$  is a line-free polyhedral set with the origin in its interior, the dual  $P^*$  is a polytope, and the operation of pushing the ideal facet of  $P$  can be defined using the dual operation of pulling the origin, which will be the vertex of  $P^*$  corresponding to  $\text{id } P$ . The analogue of Lemma 3.7 holds for the case of pushing  $\text{id } P$ , using duality.

From Lemma 3.5 and the above discussion, it suffices to show that if  $\hat{P}$  is the result of pushing facet  $F = h \cap P$  of  $P$ , then  $|\Delta(\hat{P})| \geq |\Delta(P)|$ . Lemma 3.7 implies that for every face of  $P$ , there is a face of  $\hat{P}$ ; that is, there is an injective mapping  $m : \mathcal{B}(P) \mapsto \mathcal{B}(\hat{P})$ . The lemma follows using induction on dimension.  $\square$

LEMMA 3.9. *The complex  $\Delta(\mathcal{V}(R))$  has  $O(r^{\lfloor d/2 \rfloor})$  regions, and  $O(r^{\lfloor d/2 \rfloor} \log r)$  time suffices for its construction. The constant factors are  $e^{O(d \log d)}$ .*

*Proof.* Without loss of generality, we need consider only a bound on the size of  $\Delta(\mathcal{V}(R))$  when  $d = \dim R$ .

Let  $Z_R$  denote the polytope  $\text{conv } \Upsilon(R)$ , dual to  $\mathcal{V}(R)$  from the discussion of §2. It is easy to see that  $\hat{Z}_R$  has the same facial lattice structure as  $\mathcal{V}(R)$  (is combinatorially equivalent). It follows that  $\Delta(\hat{Z}_R)$  has the same number of simplices as  $\Delta(\mathcal{V}(R))$ . Lemma 3.8 then gives the desired bound.

The time required to construct  $\Delta(\mathcal{V}(R))$  is dominated by the time necessary for determining  $\mathcal{V}(R)$ : the projection  $P_R$  can be computed in  $O(r)$  time, and  $\mathcal{V}(R)$  can be triangulated in time linear in the number of its faces.

Several algorithms are known for computing  $\mathcal{V}(R)$  in  $O(r \log r)$  time when  $2 = \dim R$  [12], [22]. As noted in §2, the computation of  $\mathcal{V}(R)$  can be reduced to the computation of the convex hull of  $\Upsilon(R)$ . This can be done in  $O(r^2 + r^{\lfloor d/2 \rfloor} \log r)$  time [25]. For  $d > 2$ , this is  $O(r^{\lfloor d/2 \rfloor} \log r)$ .  $\square$

#### 4. Candidate regions and sets for Voronoi diagram triangulations.

**4.1. Candidate regions have a simple description.** The following theorem characterizes the candidate regions of line-free simplices in  $\Delta(\mathcal{V}(R))$ . The general case is considered in Theorem 4.2 below.

THEOREM 4.1. *Let line-free  $A \in \Delta(\mathcal{V}(R))$ , with  $A \subset \mathcal{V}_q$  for a site  $q$ . Then the candidate region  $C(A)$  is*

$$C(A) = \bigcup_{a \in \text{vert } A} B_{a,q}.$$

(As noted above, the points in  $\text{vert } A$  are vertices of Voronoi regions, and the balls are either Delaunay balls or halfspaces corresponding to convex hull facets. The ideal vertices of  $A$  are ideal vertices of  $\mathcal{V}_q$ , which correspond to unbounded edges of  $\mathcal{V}_q$  that are normal to a convex hull facet containing  $q$ .)

*Proof.* It suffices to show that  $C(A) \subseteq \cup_{a \in \text{vert } A} B_{a,q}$ , as the reverse inclusion follows by definition. That is, we must show that if  $x \in A$ , then

$$C(x) = B_{x,q} \subseteq \bigcup_{a \in \text{vert } A} B_{a,q}.$$

Suppose  $y \notin B_{a,q}$  for all  $a \in \text{vert } A$ . The theorem follows if this condition implies that  $y \notin B_{x,q}$ .

From §2,  $y \notin B_{a,q}$  if and only if  $a_h \cdot (\Upsilon(y) - \Upsilon(q)) \geq 0$ . By Lemma 2.2,  $A = \text{conv vert } A$ , and so

$$x_h = \sum_{a \in \text{vert } A} \alpha_a a_h$$

for some  $\alpha_a \geq 0$ , not all zero. Therefore,

$$x_h \cdot (\Upsilon(y) - \Upsilon(q)) = \left( \sum_{a \in \text{vert } A} \alpha_a a_h \right) \cdot (\Upsilon(y) - \Upsilon(q)) = \sum_{a \in \text{vert } A} \alpha_a a_h \cdot (\Upsilon(y) - \Upsilon(q)) \geq 0.$$

This implies  $y \notin B_{x,q}$ , and the lemma follows.  $\square$

Note that the only property of the line-free polyhedral set  $A$  on which the proof depends is that  $A \subset \mathcal{V}_q$ , so that an analogous result holds for any such polyhedral set.

This characterization of  $C(A)$  must be extended to the case where  $A$  is not necessarily line-free.

**THEOREM 4.2.** *Let  $A \in \Delta(\mathcal{V}(R))$ , with  $A \subset \mathcal{V}_q$  for a site  $q$ . Then the candidate region  $C(A)$  is*

$$C(A) = C(A \cap \text{aff } R) \cup (F^d \setminus \text{aff } R).$$

*Proof.* From the discussion following Lemma 3.4,  $A$  has the form  $(A \cap \text{aff } R) + (\text{aff } R)^\perp$ . Also from that discussion,  $\text{aff } R \subseteq S_{c,q}$  for ideal  $c$  if and only if  $c \in (\text{aff } R)^\perp$ . Since  $C(A) \supseteq B_{c,q}$  for all  $c \in \text{id}(\text{aff } R)^\perp$ , we have

$$C(A) \supseteq F^d \setminus \bigcap_{c \in \text{id}(\text{aff } R)^\perp} S_{c,q},$$

that is,  $C(A) \supseteq F^d \setminus \text{aff } R$ .

The theorem now follows by showing that  $C(A) \cap \text{aff } R \subseteq C(A \cap \text{aff } R) \cap \text{aff } R$ . Let  $z \in A$ . First, suppose  $z$  is a real point. Then by the discussion following Lemma 3.4,  $z = x + y$ , for  $x \in \text{re } A \cap \text{aff } R$  and  $y \in \text{re}(\text{aff } R)^\perp$ . Since  $[x_r/x_s + y_r/y_s; 1]$  is a homogeneous representation for  $z$ , we have, for  $w \in \text{aff } R$ ,

$$z_h \cdot (\Upsilon(w) - \Upsilon(q)) = [x_r/x_s; 1] \cdot (\Upsilon(w) - \Upsilon(q)) + [y_r/y_s; 0] \cdot (\Upsilon(w) - \Upsilon(q)),$$

but  $[y_r/y_s; 0] \in \text{id}(\text{aff } R)^\perp$ , and so

$$z_h \cdot (\Upsilon(w) - \Upsilon(q)) < 0 \text{ if and only if } x_h \cdot (\Upsilon(w) - \Upsilon(q)) < 0.$$

That is,  $C(z) \cap \text{aff } R = C(x) \cap \text{aff } R$ . If  $z$  is an ideal point not in  $(\text{aff } R)^\perp$ , then  $z_h = \alpha x_h + \beta y_h$ , for some  $x \in \text{id}(A \cap \text{aff } R)$ ,  $y \in \text{id}(\text{aff } R)^\perp$ ,  $\alpha > 0$ , and  $\beta \geq 0$ . In this case, similarly,  $C(z) \cap \text{aff } R = C(x) \cap \text{aff } R$ . Finally, if  $z \in \text{id}(\text{aff } R)^\perp$ , then  $C(z) = B_{z,q}$ , and  $S_{z,q} = \text{aff } R$ , so that  $C(z) \cap \text{aff } R = \emptyset$ . Thus  $C(A)$  and  $C(A \cap \text{aff } R)$  agree on  $\text{aff } R$ , and the theorem follows.  $\square$

**4.2. Reporting all closest sites.** While an RPO tree allows a closest site to a query point to be found, sometimes it is of interest to find all the sites closest to a given point. In this case, the distinction between  $C(A)$  and  $\overline{C}(A)$  becomes important. For example, suppose the sites are all on the surface of a sphere  $S_{c,q}$ , and the query point is the center of the sphere  $c$ . Here the set  $C(c) \cap S$  will be empty, but the set  $\overline{C}(c) \cap S = S$ . To handle such situations, it will be shown below that, roughly speaking, for most points  $x \in A \in \Delta(\mathcal{V}(R))$ ,  $\overline{C}(x)$  is contained in  $C(A)$ .

**THEOREM 4.3.** *Under the conditions of Theorem 4.1, let  $x \in A$ , and  $F$  be the face of  $A$  with  $x \in \text{relint } F$ . Let  $F' = F \cap \text{aff } R$ . Then  $\overline{C}(x) \subset C(A) \cup C_{\cap}(F)$ , where*

$$C_{\cap}(F) = \bigcap_{a \in \text{vert } F'} S_{a,q} \cap \text{aff } R.$$

(The existence and uniqueness of such a face  $F$  is readily established using elementary properties of polytopes, as given in [14, §2.6]. Note that when  $x$  is in the interior of some  $\mathcal{V}_q$ , the associated region  $C_{\cap}(\mathcal{V}_q)$  is trivial: it is easy to show that  $C_{\cap}(A) = \{q\}$ . Note also that in the two-dimensional case, the region  $C_{\cap}(e)$  for some Voronoi edge  $e$  is simply the intersection of the two Delaunay circles of the endpoints of  $e$ . This intersection contains only the two sites of  $R$  that define  $e$ .)

*Proof.* It is easy to show that  $x \in \text{relint } F$  implies that  $x = z + \sum_{a \in \text{vert } F'} \alpha_a a$ , for some  $z \in (\text{aff } R)^\perp$  and some  $\alpha_a$  all strictly greater than zero. (This holds necessarily only if  $F \cap \text{aff } R$  is a simplex.) For a point  $y$ , reasoning similar to that in the proof of Theorem 4.1 implies that when  $y \notin C(A)$ , we have  $a_h \cdot (\Upsilon(y) - \Upsilon(q)) \geq 0$  for all  $a \in \text{vert } F'$ . Thus,

$$x_h \cdot (\Upsilon(y) - \Upsilon(q)) = \sum_{a \in \text{vert } F'} \alpha_a a_h \cdot (\Upsilon(y) - \Upsilon(q)) \geq 0.$$

If  $x_h \cdot (\Upsilon(y) - \Upsilon(q)) > 0$  then  $y \notin \overline{C}(x)$ , so suppose  $x_h \cdot (\Upsilon(y) - \Upsilon(q)) = 0$ . Since  $\alpha_a > 0$  and  $a_h \cdot (\Upsilon(y) - \Upsilon(q)) \geq 0$  for all  $a \in \text{vert } F'$ , we must have  $a_h \cdot (\Upsilon(y) - \Upsilon(q)) = 0$  for all  $a \in \text{vert } F'$ . The  $y$  for which this holds are precisely those in  $C_{\cap}(F)$ .  $\square$

When all sites closest to a query point are desired, the function *Make\_RPO\_Tree* is modified so that for each face  $F$  of a region  $A \in \Delta(\mathcal{V}(R))$ , the sites  $F.\text{sites} = C_{\cap}(F) \cap S$  are stored for the node  $v$  with  $v.\text{node} = A$ . When answering a query, the variable *current\_closest* represents a set of sites, the sites so far found closest to the query point  $p$ . At each step of *Answer\_Query*, the face  $F$  of  $A$  with query point  $p \in \text{relint } F$  is found, and the distance of the sites in  $F.\text{sites}$  to  $p$  is compared with the distance of those in *current\_closest*. (Note that all sites in  $F.\text{sites}$  are equidistant from  $p$ , and similarly for *current\_closest*.) If the sites in  $F.\text{sites}$  are the same distance as those in *current\_closest*, they are added to the set *current\_closest*. If they are closer, they replace that set, and if they are farther, that set is unchanged. If *current\_closest* is maintained as a list of lists of sites, this updating operation requires constant time.

**4.3. Candidate sets are likely to be small.** The theorem below implies that, with probability 1/2, the candidate sets generated by *Make\_RPO\_Tree* all contain few sites. This ensures that an RPO tree can be created that has height  $O(\log n)$ , and allows a bound on the tree's total size.

As a warm-up, here is a lemma regarding the Delaunay balls.

**LEMMA 4.4.** *For  $S \subset E^d$ , let  $R \subset S$  be a random sample (without replacement) of size  $r$ . Let  $P_\alpha$  be the probability that any open Delaunay ball  $B$  has  $|S \cap B| > \alpha n$ .*

Then  $P_\alpha \leq 1/2$ , for

$$\alpha \geq \frac{\ln(2\binom{r}{d+1})}{r-d-1}.$$

That is,  $1 - P_\alpha \geq 1/2$ , where  $1 - P_\alpha$  is the probability that for all Delaunay balls  $B$ , it holds that  $|S \cap B| \leq \alpha n$ .

*Proof.* Suppose that  $R' \subset R$  is the set of the first  $d + 1$  samples taken. If  $d = \dim R'$ , then the sphere containing  $R'$  defines an open ball  $B$ . Now suppose  $|S \cap B| > \alpha n$ . Then the probability that none of the remaining  $r - d - 1$  samples are taken from  $S \cap B$  is bounded above by  $(1 - \alpha)^{r-d-1}$ . That is, with probability at least  $1 - (1 - \alpha)^{r-d-1}$ ,  $B$  will not be a Delaunay ball of  $\mathcal{V}(R)$ . For sufficiently large  $\alpha$ , the latter probability is large.

Now let  $X$  be the set of all subsets of  $R$  of size  $d + 1$ , let  $B_{R'}$  be the open ball defined by subset  $R' \in X$ , and let  $B(X)$  be the set of open balls defined by these subsets. Let  $B_\alpha(X) \subset B(X)$  be the set of all such balls  $B$  satisfying  $|S \cap B| > \alpha n$ . If no ball  $B \in B_\alpha(X)$  satisfies  $R \cap B = \emptyset$ , then every ball in  $B(X)$  that does not contain any sample sites must not be in  $B_\alpha(X)$ . That is, every Delaunay ball of  $R$  must contain a proportion of sites smaller than  $\alpha$ .

What is an upper bound on the probability  $P_\alpha$  that at least one  $B \in B(X)$  has  $B \in B_\alpha(X)$  and  $R \cap B = \emptyset$ ? For a given ball  $B \in B(X)$ , the joint probability of these two conditions is no more than the conditional probability that  $R \cap B = \emptyset$  given  $B \in B_\alpha(X)$ . The latter probability is the same as that for the ball defined by the first  $d + 1$  sample sites. Since the probability of the union of a set of events is not more than the sum of the probabilities of the individual events, we have

$$P_\alpha = \text{Prob}\{\exists R' \in X \mid B_{R'} \in B_\alpha(X) \text{ and } R \cap B_{R'} = \emptyset\} < \binom{r}{d+1} (1 - \alpha)^{r-d-1}.$$

When  $\alpha \geq \ln(2\binom{r}{d+1})/(r - d - 1)$ , this probability is no more than  $1/2$ , using the relation  $-\ln(1 - \alpha) \geq \alpha$  for  $0 \leq \alpha < 1$ .  $\square$

This lemma is not a proof of the desired result for general  $C(A)$ , since not all regions  $C(A)$  are the union of Delaunay balls. However, the proof of the following theorem is quite similar to that of the lemma.

**THEOREM 4.5.** *For  $S \subset E^d$ , let  $R \subset S$  be a random sample of size  $r$ . Let  $P_\alpha$  be the probability that any one of the regions  $A \in \Delta(\mathcal{V}(R))$  has  $|S \cap C(A)| > \alpha n$ . Then  $P_\alpha \leq 1/2$ , for*

$$\alpha \geq \alpha_{r,d} = \frac{(d+1) \ln((d+1)^2 \binom{r}{d+1})}{r-d-1}.$$

That is,  $1 - P_\alpha \geq 1/2$ , where  $1 - P_\alpha$  is the probability that for all  $A \in \Delta(\mathcal{V}(R))$ , it holds that  $|S \cap C(A)| \leq \alpha n$ .

*Proof.* By Theorems 4.1 and 4.2, for  $A \in \Delta(\mathcal{V}(R))$  with  $A \subseteq \mathcal{V}_q$ ,

$$C(A) = \bigcup_{a \in \text{vert}(A \cap \text{aff } R)} [B_{a,q} \cup (F^d \setminus \text{aff } R)].$$

The simplex  $A \cap \text{aff } R$  has at most  $1 + \dim R$  vertices, so the number of regions making up this union is no more than  $d + 1$ . Let  $\alpha' = \alpha/(d + 1)$ . The condition  $|S \cap C(A)| > \alpha n$  thus implies that  $|S \cap C(I)| > \alpha' n$ , where  $I$  is a region  $B_{a,q} \cup (F^d \setminus \text{aff } R)$ . It suffices to prove that with probability  $1/2$ , all such regions contain no more than  $\alpha' n$  sites.

A region  $I$  may have a real or a ideal. If  $a$  is real, there is a set of  $1 + \dim R$  sites  $R' \subset R$  such that  $I$  is the union of  $F^d \setminus \text{aff } R'$  with the relatively open ball defined by the  $(\dim R)$ -sphere in  $\text{aff } R'$  that contains  $R'$ . If  $a$  is ideal, there is a set of  $\dim R$  sites  $R'$  and a site  $s \in R$  such that  $I$  is the union of  $F^d \setminus \text{aff}(R' \cup \{s\})$  with the open half-flat of  $\text{aff}(R' \cup \{s\})$  that is bounded by  $\text{aff } R'$  and that does not contain  $s$ .

Let  $X$  be the set of all nonempty subsets of  $R$  of size  $d + 1$  or less, together with the set of pairs  $(R', s)$  where  $R' \subset R$ ,  $s \in R$ , and  $1 \leq |R'| \leq d$ . Let  $I_x$  be the region corresponding to  $x \in X$  as above, and let  $I(X)$  be the set of regions corresponding to the elements of  $X$ . Let  $I_{\alpha'}(X)$  be the subset of  $I(X)$  containing regions  $I \in I(X)$  satisfying  $|S \cap I| > \alpha'n$ . We have, for any given region  $I \in I(X)$ ,

$$\text{Prob}\{R \cap I = \emptyset \text{ given } I \in I_{\alpha'}(X)\} \leq (1 - \alpha')^{r-d-1}.$$

The probability

$$\text{Prob}\{\exists x \in X \mid I_x \in I_{\alpha'}(X) \text{ and } R \cap I_x = \emptyset\}$$

is greater than  $P_\alpha$ , and is bounded above by  $(1 - \alpha')^{r-d-1}$  times the size of  $X$ . It is easy to see that  $|X| = (d + 1)\binom{r}{d+1} + d(d + 1)\binom{r}{d+1}$ , or  $|X| = (d + 1)^2\binom{r}{d+1}$ . The theorem follows, using manipulations as in the lemma above.  $\square$

**5. Time bounds for Make\_RPO\_Tree and Answer\_Query.** To bound the time needed for *Make\_RPO\_Tree*, we will first consider the work done by the procedure, aside from the recursive calls, and then bound the work for those calls.

**LEMMA 5.1.** *Let  $t(n)$  denote the expected time required by Make\_RPO\_Tree. Then  $t(n)$  satisfies*

$$t(n) \leq K_1nr^{[d/2]} \log r + K_2r^{[d/2]}t\left(K_3n\frac{\ln r}{r}\right),$$

when  $n > K$ . The constants  $K_1$  and  $K_2$  are at most exponential in  $O(d \log d)$ , and  $K_3$  is  $(d + 1)^2 + O(1/\log r)$ , as  $r \rightarrow \infty$ .

*Proof.* From Theorem 4.5, the **repeat-until** loop for determining a suitable  $\Delta(\mathcal{V}(R))$  will end after two iterations on the average, and require  $O(r^{[d/2]} \log r)$  each iteration, by Lemma 3.9.

The other operations in *Make\_RPO\_Tree* require  $O(n)$  or  $O(r)$  time, except for the recursive calls and the determination, for each  $A \in \Delta(\mathcal{V}(R))$ , of  $S \cap C(A)$ .

From the proof of Lemma 3.5 and precise bounds on the number of vertices of a  $d$ -polytope with  $r$  facets [14, §4.7], the constants  $K_1$  and  $K_2$  are dominated by  $d!$ , which is exponential in  $O(d \log d)$ .

From Theorem 4.5, the size of each subproblem is  $\alpha_{r,d}n$ . The bound for  $K_3$  follows from the value of  $\alpha_{r,d}$  and elementary approximations.  $\square$

**THEOREM 5.2.** *The expected time  $t(n)$  required by Make\_RPO\_Tree is bounded by  $t(n) = O(n^{[d/2](1+\epsilon)})$ , as  $n \rightarrow \infty$ , where*

$$\epsilon = \frac{\ln(K_3 \ln r) + (\ln K_2)/[d/2]}{\ln(r/K_3 \ln r)},$$

for fixed  $r$  and  $d$ .

*Proof.* By “unrolling” the recurrence for  $t(n)$  to depth  $m = \ln(n/K)/\ln(r/K_3 \ln r)$ , we have

$$t(n) = O(nr^{[d/2]} \log r(K_2K_3r^{[d/2]-1} \ln r)^m),$$

and the desired expression follows by algebraic manipulations.  $\square$

**THEOREM 5.3.** *The worst-case time required by procedure Answer\_Query is bounded by*

$$K + K_2 r^{\lceil d/2 \rceil} \ln(n/K) / \ln(r/K_3 \ln r).$$

*This is  $O(\log n)$  as  $n \rightarrow \infty$ , for fixed  $r$  and  $d$ .*

*Proof.* This is just the work in searching through the children of an RPO tree, times the depth of such a tree.  $\square$

**6. Conclusions.** We have seen that a simple, natural approach to the post-office problem may be used to gain great improvements in asymptotic efficiency over methods previously known for  $d > 3$ . In addition, this approach has an advantage of conceptual and programming simplicity over previous asymptotically fast methods for  $d \leq 3$ .

The approach given here may be used to yield fast algorithms for other proximity problems. For example, suppose a convex three-dimensional polytope  $P$  is given, and a data structure is to be found such that given a plane  $h$  with  $h \cap P = \emptyset$ , the vertex of  $P$  closest to  $h$  is to be determined quickly. This problem is equivalent to determining the point of vert  $P$  closest to the ideal point normal to  $h$ , and is also equivalent to linear programming in 3-D with multiple objective functions. The problem may be solved with nearly linear preprocessing and logarithmic query time using an approach analogous to that given in this paper.

After the preliminary report of these results [5], later work has shown that these ideas have applications in many other areas of discrete and computational geometry, such as arrangement searching, determining the separation of polytopes, constructing order  $k$  Voronoi diagrams [6], computing line-segment intersections, bounding ( $\leq k$ )-sets in  $E^d$  [7], computing the diameter of a point set in  $E^3$ , incremental construction of geometric structures [8], and triangulating simple polygons [9]. Independently of this work, the concept of the Vapnik-Chervonenkis (VC) dimension [28] has been applied to, for example, the problem of halfspace range queries, resulting in a randomized algorithm for the construction of a data structure for such queries [16]. This concept has also been applied to questions of learnability [2]. While apparently not equivalent, the two approaches (the VC dimension and that of this paper) are similar in spirit, and provide a useful means of applying divide-and-conquer to computational geometry.

**Appendix A.** Proofs of three technical lemmas are given below.

**LEMMA 2.1.** *Let  $C$  be a polyhedral pointed cone with apex  $a$ . Let  $h$  be a supporting hyperplane of  $C$  with  $h \cap C = \{a\}$ . Let  $\nu$  be a normal vector to  $h$  contained in the same halfspace containing  $C$ . Then  $P = C \cap (h + \nu)$  is a polytope.*

*Proof.* (Note that such a hyperplane  $h$  exists because  $a$  is a face.) Since  $C$  and  $h + \nu$  are polyhedral sets, it follows that their intersection is a polyhedral set. It remains to show that  $P$  is bounded. If not, then  $P$  contains a ray, by [14, 2.5.1]. Such a ray has the form  $\text{ray}_z y$ , where  $z, y \in P$  and  $\nu \cdot (y - z) = 0$ . Since  $C$  is a cone, the point  $(x - a) / \|x - a\| + a \in \text{ray}_a x$  is in  $C$ , for every  $x \in \text{ray}_z y$ . As  $\|x\| \rightarrow \infty$ , with  $x$  on  $\text{ray}_z y$ , the points  $(x - a) / \|x - a\| + a$  converge to  $(y - z) / \|y - z\| + a$ . Since  $C$  is closed, this point is in  $C$ . But  $(y - z) / \|y - z\| + a \in h$ , contradicting the choice of  $h$ .  $\square$

**LEMMA 2.2.** *If  $P \subset E^d$  is a line-free  $d$ -polyhedral set then  $P = \text{conv vert } P$ .*

*Proof.* The lemma is true for polytopes by [14, 2.4.5]. The unbounded case will first be considered for polyhedral cones, and then in general.

If  $C$  is a line-free polyhedral cone, then as mentioned above,  $C$  is pointed, so that Lemma 2.2 applies to  $C$ . Using the correspondence above between  $x \in P$  and  $x' \in \text{id } C$ , the fact that  $P = \text{conv vert } P$  implies that  $\text{id } C = \text{conv vert id } C$ . Since

$$C = \bigcup_{x \in \text{id } C} \text{conv}\{a, x\},$$

it follows that for any  $y \in C$ ,

$$y_h = \alpha_a a_h + \sum_{x \in \text{vert id } C} \alpha_x x_h,$$

for some  $\alpha_a, \alpha_x \geq 0$ ,  $x \in \text{vert id } C$ . That is,  $C \subset \text{conv vert } C$ . It is easy to show that  $C \supset \text{conv vert } C$ , so the lemma follows for line-free polyhedral cones.

To prove the lemma for general line-free polyhedral sets, we appeal to [14, 2.5.6], which directly implies that a line-free polyhedral set  $P$  can be expressed as  $P = \text{cc } P + \text{conv re vert } P$ . Since  $\text{cc } P$  is line-free if  $P$  is, the relation  $\text{cc } P = \text{conv vert cc } P$  holds. The lemma follows.  $\square$

**LEMMA 3.2.** *For a line-free polyhedral region  $P$ , if  $v \in \text{vert } P$  and  $a \in P$ , then the point  $b = \text{ray}_v a \cap \text{relbd } P$  is on a facet of  $P$  that does not contain  $v$ .*

*Proof.* (The relative boundary of  $P$  is generalized to include  $\text{id } P$ .) Since  $\text{relbd } P$  is the union of the facets of  $P$  [14, 2.6.3],  $b$  is on some facet of  $P$ . Suppose  $v \notin \text{id } P$ . Then the lemma follows by induction on dimension: suppose  $v$  and  $b$  are on the same facet  $F$ . Then assuming the lemma for the polytope  $F$ ,  $b$  is on some facet of  $F$  not containing  $v$ . Such a facet of  $F$  is the intersection of  $F$  with another facet  $F'$  of  $P$  [14, 2.6.4], and so  $b \in F'$  but  $v \notin F'$ . Suppose  $v \in \text{id } P$ . If  $a$  is a real point, then so is  $b$ , and the lemma follows. If  $a \in \text{id } P$ , then we map  $v$ ,  $a$ , and so  $b$  to a polytope as in Lemma 2.1, and the lemma follows by the above argument.  $\square$

## EFFICIENT SOLUTIONS TO SOME TRANSPORTATION PROBLEMS WITH APPLICATIONS TO MINIMIZING ROBOT ARM TRAVEL\*

MIKHAIL J. ATALLAH† AND S. RAO KOSARAJU‡

**Abstract.** We give efficient solutions to transportation problems motivated by the following robotics problem. A robot arm has the task of rearranging  $m$  objects between  $n$  stations in the plane. Each object is initially at one of these  $n$  stations and needs to be moved to another station. The robot arm consists of a single link that rotates about a fixed pivot. The link can extend in and out (like a telescope) so that its length is a variable. At the end of this “telescoping” link lies a gripper that is capable of grasping any one of the  $m$  given objects (the gripper cannot be holding more than one object at the same time). The robot arm must transport each of the  $m$  objects to its destination and come back to where it started. Since the problem of scheduling the motion of the gripper so as to minimize the total distance traveled is NP-hard, we focus on the problem of minimizing only the total angular motion (rotation of the link about the pivot), or only the telescoping motion. We give algorithms for two different modes of operation: (i) *No-drops*. No object can be dropped before its destination is reached. (ii) *With-drops*. Any object can be dropped at any number of intermediate points. Our algorithm for case (i) runs in  $O(m + n \log n)$  time for angular motion and in  $O(m + na(n))$  time for telescoping motion. Our algorithm for case (ii) runs in  $O(m + n)$  time for angular motion and with the same time bound for telescoping motion. The most interesting problem turns out to be that of minimizing angular motion for the with-drops mode of operation.

**Key words.** transportation problems, robotics, arm motion, Euler tour, circular track, graph augmentation

**AMS(MOS) subject classifications.** 68Q25

**1. Introduction.** A robot arm has the task of rearranging  $m$  objects between  $n$  stations in the plane. Each object is initially at one of these stations and needs to be moved to another station (its destination). The robot arm consists of a single link that rotates about a fixed pivot (see Fig. 1). The link can extend in and out (like a telescope) so that its length is a variable. At the end of this “telescoping” link lies a gripper that is capable of grasping any one of the  $m$  given objects.

The gripper can pick up an object and drop it at another station, then move to another station and continue with the transfers. Many objects can be simultaneously located at the same station, but the gripper cannot be holding more than one object at a time. When the gripper is empty and is at a station, it is free to pick up any of

FIG. 1. The robot arm can pivot and can extend like a telescope.

the objects at that station. We also require that the gripper terminate at the station where it started. Scheduling the motion of the gripper so as to minimize the total distance it travels can be shown to be NP-hard from the NP-hardness of the Euclidean Traveling Salesperson Problem [P2]. Here we focus on the problem of minimizing only the total angular motion (rotation of the link about the pivot), or only the total telescoping motion.

For the case of minimizing angular motion we henceforth assume, without loss of generality, that

- (a) the  $n$  stations are positioned on a circular track centered at the pivot, and
- (b) the motion of the gripper is always along the circumference of this circular track.

The problem is then to minimize the total length of the circular arcs traversed by the gripper. The input specification is made by listing the destinations of the objects at each station on the circular track. The stations, in clockwise cyclic order, are denoted by the integers 1 to  $n$ , and one of them is designated as being the initial position of the gripper (we call it the *start* station). The input therefore describes a directed multigraph having  $n$  vertices and  $m$  edges (we draw a directed arc for each object—the head and the tail corresponding to the destination and the source stations, respectively). Figure 2 illustrates a four-station four-object transfer problem.

FIG. 2. A transfer problem.

The problem of minimizing the total telescoping motion rather than the angular one can be viewed as a linear track problem rather than as a circular one. The circular track case is considerably more difficult than the linear track one.

We develop fast algorithms for two different modes of operation: (i) *No-drops*. Once an object is picked up by the gripper, it cannot be dropped before its destination is reached. (ii) *With-drops*. Any object can be dropped at any number of intermediate points. The algorithm for the no-drops case runs in  $O(m + n \log n)$  time for a circular track (i.e., minimizing angular motion), in  $O(m + n\alpha(n))$  time for a linear track (i.e., minimizing telescoping motion); here  $\alpha(n)$  is the extremely slowly growing functional inverse of Ackermann's function. The no-drops problem can be cast as a graph-augmentation problem [ET], [P1]—augmentation of a graph to an Eulerian graph. The with-drops problem is more interesting and does not seem to translate into a natural graphical problem. Somewhat surprisingly, we are able to design a faster

algorithm for this problem—an  $O(m+n)$  time algorithm (for either circular or linear track). One of the difficulties in the with-drops problem for a circular track is that an optimal transportation may have to transport an object through the longer of the two circular arcs between its source and destination (such an arc is henceforth called *major*, the other arc being *minor*). In § 4 we give an example for which any optimal transportation must transport an object through the major arc. However, we prove that in a with-drops problem, an optimal transportation transports at most one object through the major arc. This nontrivial result is only one of the ingredients in our linear time solution to this problem; another ingredient is a method for quickly identifying which of the  $m$  objects (if any) should be transported through the major arc.

Throughout the paper, all graphs are actually multigraphs (i.e., can have many edges with same head and tail). A graph is directed unless we explicitly state that it is undirected. All the graphs we refer to are *embedded* on the (circular or linear) track, i.e., their vertices are the stations on the track and their edges are directed arcs drawn along the track. Therefore when we henceforth refer to an edge  $e$  of a graph  $G$ , we are really talking about a particular drawing of that edge (for a circular track, the edge can be drawn two ways). We use  $|e|$  to denote the length of the portion of the track covered by  $e$ .

For a circular track we assume, without loss of generality, that the circle's circumference equals unity. The *complement* of an edge  $e$  is the edge  $e^c$  with the same source as  $e$ , same destination as  $e$ , and such that  $e$  and  $e^c$  together cover the complete circumference (see Fig. 3). Note that  $(e^c)^c = e$ , and that  $|e| + |e^c| = 1$ . An edge  $e$  is *major* if and only if  $|e| > \frac{1}{2}$ , and is *minor* otherwise (in Fig. 3,  $e$  is minor and  $e^c$  is major). Note that if  $|e| = \frac{1}{2}$  then both  $e$  and  $e^c$  are minor. *Shortening* a major edge means replacing it with its complement.

FIG. 3. An arc and its complement.

We adopt the convention that, when depicting a transportation, we draw an input source-to-destination pair as a directed (circular or linear) arc coinciding with the actual path that this transportation uses to take the object to its destination (in the with-drops case, the object transported along such an arc may be dropped many times on the way to its destination).

We assume that none of the  $n$  stations is useless, i.e., each is the source or destination of at least one object (useless stations are easily eliminated with an  $O(m+n)$  preprocessing step). This implies that  $n \leq 2m$ .

**2. No-drops problem.** In this section we prove the following result.

**THEOREM 1.** *An optimal transportation for any no-drops problem can be calculated in  $O(m + n\alpha(n))$  for a linear track, in  $O(m + n \log n)$  time for a circular track.*

The rest of this section proves the above theorem.

First, observe that in a circular no-drops problem we never need to take an object to its destination using the major arc, and therefore we always draw the input edges so that they are minor.

The no-drops problem is a graph-augmentation problem: we want to add edges to the input graph so as to make it Eulerian [E], such that the total lengths of the added edges is minimum. Any Euler tour of the resulting Eulerian graph then gives an optimal transportation. These added edges are called *augmenting edges*, and correspond to motion of the gripper when it is not holding any object. In future drawings, we distinguish such augmenting edges by drawing their arrowhead dashed, whereas that of an input edge is drawn solid.

Since the minimum Eulerian augmentation does not depend on the start vertex, the length of an optimal transportation does not depend on which vertex is the start (and hence finish) vertex. (In the with-drops case, considered in § 3, the start vertex is significant.)

Recall that a graph  $G$  is Eulerian if and only if (i) every vertex of  $G$  has its in-degree equal to its out-degree (we call this the *degree-balance* property), and (ii) the undirected version of  $G$  is connected. Condition (ii) can be replaced by “ $G$  is strongly connected,” because if (i) holds then  $G$  is strongly connected if and only if its undirected version is connected [E]. In the rest of this paper we restrict the augmenting edges to be of the form  $(i, i+1)$  or  $(i+1, i)$ , i.e., each augmenting edge covers only one of the  $n$  intervals (gaps) between adjacent stations. There is no loss of generality in doing so, since an augmenting edge that covers  $l$  intervals can always be broken into  $l$  smaller edges without increasing the total edge length, without disturbing degree balance, and without damaging undirected connectivity. Of course if there are many such augmenting edges covering an interval  $(i, i+1)$ , then we do not store each of them individually since this might take a total of  $O(mn)$  space; instead, we store a count of the number of such edges going in each direction across that interval. Thus the total storage needed for augmenting edges is  $O(n)$ .

Observe that in any optimal augmentation, if any pair of antiparallel edges  $(i, i+1)$  and  $(i+1, i)$  are augmenting edges, then between  $i$  and  $i+1$  there cannot be any other augmenting edge (otherwise removal of  $(i, i+1)$  and  $(i+1, i)$  preserves the degree-balance and undirected connectivity, contradicting the optimality of the original augmentation).

**2.1. Linear track.** We first prove the linear track part of Theorem 1, an example of which is given in Fig. 4(a), where  $n = 8$  and  $m = 5$ . We make a few trivial observations.

**OBSERVATION 1.** In any transportation, at any point  $x$  between the leftmost and the rightmost stations, the number of times the gripper moves left to right across  $x$  is the same as the number of times the gripper moves right to left across  $x$ . In addition each of these crossings is  $\geq 1$ .

Based on this observation, we add across each interval the smallest number of augmenting edges that will make the total number of edges that cross that interval from left to right equal to the number of edges that cross it from right to left. The “augmenting edges” needed for Fig. 4(a) are shown in Fig. 4(b). When the graph is augmented in this manner, every vertex will have the degree-balance property. Let this augmentation process be denoted as the *degree-balanced augmentation*.

FIG. 4. (a) A linear track problem; (b) its degree-balanced augmentation; (c) the optimal augmentation.

OBSERVATION 2. If the resulting degree-balanced augmented graph is strongly connected, then it has an Euler tour, and hence it represents an optimal transportation.

However the augmented graph need not be strongly connected (sc). For example, Fig. 4(b) has three strongly connected components (scc's):  $\{1, 4, 5, 2\}$ ,  $\{3, 6\}$ ,  $\{7, 8\}$ . If the augmented graph is not sc then its scc's are disjoint in the sense that there is no edge between any two of them (because for a graph having the degree-balance property, the scc's are the connected components of the undirected version of the graph).

Now the problem reduces to adding more augmenting edges, with minimum total length, to make the graph sc without disturbing its degree-balance property. An example of this augmentation is shown in Fig. 4(c). In general, augmentation of a  $q$ -scc degree-balanced graph can be achieved by including  $q - 1$  antiparallel pairs of augmenting edges (we needed two such pairs to go from Fig. 4(b) to 4(c): one between 5 and 6, the other between 6 and 7). To find the  $q - 1$  antiparallel pairs needed to minimally make the degree-balanced graph sc, we create a  $q$ -vertex edge-weighted undirected graph, one vertex for each scc. In that undirected graph, an edge between  $i$  and  $j$  is present if and only if a station  $x$  in the  $i$ th scc is adjacent to a station  $y$  in the  $j$ th scc (i.e.,  $|x - y| = 1$ ). The weight of this edge  $\{i, j\}$  is the distance between stations  $x$  and  $y$ . If there are many such pairs  $x, y$  for a particular  $\{i, j\}$ , then the weight of  $\{i, j\}$  is the minimum over all such pairs  $x, y$ .

OBSERVATION 3. The minimum total length augmenting pairs needed to make the degree-balanced graph sc correspond to the undirected edges of a minimum spanning tree (MST) of the above-mentioned  $q$ -vertex undirected graph of scc's. (Of course, we have to map each undirected edge  $\{i, j\}$  of the MST into one antiparallel pair of augmenting edges:  $(x, y), (y, x)$  in which  $x$  and  $y$  are the stations in scc's  $i$  and  $j$ , respectively, which contributed to the weight of the  $\{i, j\}$  edge.)

The above discussion implies an  $O(m + n\alpha(n))$  time algorithm for computing the minimum Eulerian augmentation in the linear track version of the problem, using the MST algorithm of [FT]. Any Euler tour of the resulting Eulerian graph gives an optimal

transportation. Such an Euler tour can easily be found in an additional  $O(m)$  time [AHU, Exercise 5.9].

Thus the overall time for the linear track case is  $O(m + n\alpha(n))$ . We now complete the proof of Theorem 1 by considering the circular track case.

**2.2. Circular track problem.** If we know that there exists an optimal transportation in which at least one interval is not covered by any augmenting edge, then we can solve  $n$  separate straight line problems: the  $i$ th one, assuming that there is no augmenting edge between stations  $i$  and  $i+1$  (assume that station  $n+1 =$  station 1). Then the transportation corresponding to the minimum of these  $n$  solutions gives the optimal transportation. However, it is not hard to come up with an example in which any optimal solution must have augmenting edges covering the (complete) circumference.

The circular track equivalent of Observation 1 does not hold, i.e., for the circular track it is no longer true that at every point the number of clockwise crossings of the gripper is the same as the number of counterclockwise crossings. However, if we define the *flux* across an interval to be the number of clockwise crossings minus the number of counterclockwise crossings (counting both the input edges and the augmenting ones), then we have the following.

**LEMMA 1.** *For any augmentation, the degree-balance property is satisfied if and only if the flux is the same across all intervals.*

*Proof.* It suffices to show that degree balance holds if and only if, for any  $i$ , the flux across interval  $(i-1, i)$  is the same as that across interval  $(i, i+1)$ . The difference between these two fluxes equals the difference between the in-degree of  $i$  and its out-degree.  $\square$

The flux across an interval is the sum of two components. One component is the *augmenting* flux across that interval: the number of clockwise augmenting edges across that interval minus the number of counterclockwise augmenting edges across it. The other component is the *input* flux across that interval and is the number of clockwise input edges across it minus the number of counterclockwise input edges across it. Let  $\phi(i)$  denote the input flux across the interval  $(i, i+1)$ . In Fig. 2,  $\phi(1) = \phi(2) = 1$ ,  $\phi(3) = 0$ ,  $\phi(4) = 2$ . Note that  $\phi(i)$  is the number of counterclockwise augmenting edges that must be added to interval  $(i, i+1)$  in order to make its total flux equal to zero (a negative value signifies adding clockwise edges).

The next two lemmas impose constraints on the augmenting edges and possible flux values that an optimal augmentation can have.

**LEMMA 2.** *There exists an optimal augmentation in which for some  $i$  the number of augmenting edges in between  $i$  and  $i+1$  is no more than one.*

*Proof.* Let an optimal augmentation result in at least two augmenting edges between every  $i$  and  $i+1$ . Among all such optimal augmentations, select one with the fewest clockwise augmenting edges. Select any undirected circuit of  $n$  augmenting edges covering the circumference (ignoring the directions of these augmenting edges). We distinguish two cases.

*Case 1.* On this circuit, the total length of the clockwise edges is not equal to the total length of the counterclockwise edges. If it is larger (respectively, smaller), then remove the clockwise (respectively, counterclockwise) edges and duplicate the counterclockwise (respectively, clockwise) edges one more time. This preserves undirected connectivity and also the degree-balance property. In addition, this transformation decreases the total length. This contradicts the optimality of the original augmentation.

*Case 2.* On this circuit, the total length of the clockwise edges is equal to the total length of the counterclockwise edges. Remove the clockwise edges and duplicate

the counterclockwise edges one more time. This preserves undirected connectivity, the degree-balance property, and the total length. However it results in an optimal augmentation having fewer clockwise edges than the original one, a contradiction.  $\square$

Note that Lemma 1 implies that for every optimal transportation there exists a value such that the flux across every interval is that value. In addition, Lemma 2 implies that there are only  $3n$  relevant values of flux worth considering, namely  $\cup_{i=1}^n \{\phi(i) - 1, \phi(i), \phi(i) + 1\}$ .

LEMMA 3. *There exists an optimal augmentation whose flux is between  $-m - 1$  and  $m + 1$ .*

*Proof.* Lemma 2 implies that there exists an optimal augmentation in which at least one interval has at most one augmenting edge across it. The absolute value of the flux of such an augmentation is no more more than  $1 + \max_{1 \leq i \leq n} |\phi(i)| \leq 1 + m$ .  $\square$

It is easy to come up with examples in which there is a unique optimal augmentation and it has flux  $\Theta(m)$ . The range “ $-m - 1$  to  $m + 1$ ” of Lemma 3 can be narrowed to “ $-m/2$  to  $m/2$ ” but we avoid doing so for simplicity of exposition.

Observe that fixing the value of the flux (at, say,  $\psi$ ) entirely determines the cost of the minimum augmentation achieving degree balance at that flux value, because every interval  $(i, i + 1)$  needs to add across it  $\psi - \phi(i)$  clockwise augmenting edges in order for the flux across it to become  $\psi$ . The resulting graph, however, may not be sc, and additional pairs of antiparallel edges may need to be added in order to make it sc. For a given flux value, the antiparallel pairs needed to make the degree-balanced graph sc can be determined by a minimum-cost spanning tree computation similar to the one described for the linear track case. Our main problem is therefore that of determining which flux value  $\psi_0$  is such that there is an optimal Eulerian augmentation whose flux is  $\psi_0$ .

Let the *cost* of flux  $\psi$  be the total length of the minimum Eulerian augmentation whose flux is constrained to be  $\psi$ . This cost consists of two components: (i) a degree-balance component  $db(\psi)$  equal to  $\sum_{i=1}^n |\psi - \phi(i)|l_i$ , where  $l_i$  is the length of the interval  $(i, i + 1)$ , and (ii) a connectivity component  $cc(\psi)$  which accounts for the length of the antiparallel pairs of augmenting edges needed to make sc the degree-balanced graph resulting from (i). (The  $cc(\psi)$  results from the previously mentioned MST computation.)

If we knew  $db(\psi)$  and  $cc(\psi)$  values for all  $-m - 1 \leq \psi \leq m + 1$ , then the optimal  $\psi$  would be the one which minimizes  $db(\psi) + cc(\psi)$ . The next two lemmas show how to compute all the  $db(\psi)$ 's and  $cc(\psi)$ 's efficiently (the nontrivial part is computing the  $cc(\psi)$ 's).

LEMMA 4. *The  $db(\psi)$ 's ( $-m - 1 \leq \psi \leq m + 1$ ) can all be computed in  $O(m)$  time.*

*Proof.* It suffices to show that the description of the function  $db(\cdot)$  can be computed in  $O(m)$  time. Note that  $db(\psi) = \sum_{i=1}^n |\psi - \phi(i)|l_i$  is piecewise linear and has at most  $n$  angular points (at  $\psi = \phi(i)$ ,  $1 \leq i \leq n$ ). It is easy to compute  $\phi(1), \dots, \phi(n)$  in  $O(m)$  time. If we knew the slope of  $db(\psi)$  at every value of  $\psi$ ,  $-m - 1 \leq \psi \leq m + 1$ , then we could easily obtain all the  $db(\psi)$ 's with  $O(m)$  additional work. The slope at  $\psi = -m - 1$  is equal to  $-\sum_{i=1}^n l_i = -1$ , and at  $\psi = m + 1$  it equals  $\sum_{i=1}^n l_i = 1$ ; in between it changes only at values of  $\psi$  that belong to  $\{\phi(1), \dots, \phi(n)\}$ . Therefore we sort  $\{\phi(1), \dots, \phi(n)\}$  in  $O(m)$  time, and then we scan the resulting sorted sequence, updating the slope of  $db(\cdot)$  as we go along.  $\square$

LEMMA 5. *The  $cc(\psi)$ 's ( $-m - 1 \leq \psi \leq m + 1$ ) can all be computed in  $O(m + n \log n)$ .*

*Proof.* First observe that if  $\psi \notin \cup_{i=1}^n \{\phi(i)\}$ , then  $cc(\psi) = 0$  because in that case the degree-balanced graph of flux  $\psi$  is already sc (it has an augmenting edge across

every one of the  $n$  intervals). We therefore need only concern ourselves with computing the  $cc(\psi)$ 's for all  $\psi \in \cup_{i=1}^n \{\phi(i)\}$ . By its definition,  $cc(\psi)$  is equal to twice the cost of the MST of the undirected graph  $CC(\psi)$  whose vertices are the  $n$  stations, and whose edges consist of

- (i) the undirected versions of the input edges, and
- (ii) one edge  $\{i, i + 1\}$  for each interval  $(i, i + 1)$ .

The edges in (i) have zero cost in  $CC(\psi)$ , while an edge  $\{i, i + 1\}$  in (ii) has zero cost if  $\psi \neq \phi(i)$  (because in that case the minimum degree-balanced augmentation for flux value  $\psi$  already places at least one augmenting edge across the interval  $(i, i + 1)$ ), and cost equal to the interval's length  $l_i$  if  $\psi = \phi(i)$ . Note that all  $CC(\psi)$ 's have the same set of edges, the only difference being in the weights of the  $n$  edges in (ii). Since the edges in (i) have zero cost in all  $CC(\psi)$ 's, we can "collapse" each connected component of the edges in (i) into a single vertex: let  $\nu_1, \dots, \nu_q$  be the vertices resulting from this collapsing operation; if the endpoints of an edge in (ii) collapse into a single  $\nu_i$  then the edge vanishes; otherwise it survives (of course its endpoints become the collapsed vertices rather than the original stations). This collapsing operation can easily be done in  $O(m)$  time as a preprocessing step. Assume from now on that this has already been done, so that every  $CC(\psi)$  is now a  $q$ -vertex multigraph having as edges the (at most  $n$ , at least  $q$ ) edges in (ii) that survived the collapsing operation. Each of the (possibly many) edges between  $\nu_i$  and  $\nu_j$  corresponds to an interval between one of the stations that collapsed into  $\nu_i$  and one of the stations that collapsed into  $\nu_j$ . Of course  $cc(\psi)$  is still twice the cost of the MST of the new (collapsed)  $CC(\psi)$ . Let  $CC$  be identical to the (collapsed)  $CC(\psi)$ , except that in  $CC$  the costs associated with the edges of  $CC(\psi)$  are replaced by *labels*: the edge of  $CC$  that corresponds to interval  $(i, i + 1)$  is labeled by  $\phi(i)$ . Note that  $CC(\psi)$  can be obtained from  $CC$  by assigning to each edge with label  $\phi(i)$  a cost of zero if  $\phi(i) \neq \psi$ , a cost equal to the length of  $(i, i + 1)$  if  $\phi(i) = \psi$ . Let the intervals that correspond to edges of  $CC$  be denoted by  $(i_1, i_1 + 1), \dots, (i_r, i_r + 1)$ . Find the median of  $\phi(i_1), \dots, \phi(i_r)$  (call it  $\phi_0$ ), then partition the set  $\{i_1, \dots, i_r\}$  into  $A, B, C$  as follows:  $A = \{i_j: \phi(i_j) < \phi_0\}$ ,  $B = \{i_j: \phi(i_j) = \phi_0\}$ ,  $C = \{i_j: \phi(i_j) > \phi_0\}$ . (Note that each of  $A$  and  $C$  has at most  $r/2$  elements.) The important thing to notice is that, if  $\psi \cong \phi_0$  (respectively,  $\neq \phi_0, \cong \phi_0$ ) and  $i$  belongs to  $A$  (respectively,  $B, C$ ), then in  $CC(\psi)$  the edge corresponding to interval  $(i, i + 1)$  has zero cost. This suggests the following recursive procedure for computing the  $cc(\psi)$ 's for all  $\psi \in \{\phi(i): i \in A \cup B \cup C\}$ . First, create the undirected graph  $Q_A$  (respectively,  $Q_B, Q_C$ ) whose vertices are  $\nu_1, \dots, \nu_q$  and each of whose edges correspond to an interval  $(i, i + 1)$  with  $i \notin A$  (respectively,  $B, C$ ). Let  $CC_A$  (respectively,  $CC_B, CC_C$ ) be obtained from  $CC$  by collapsing each connected component of  $Q_A$  (respectively,  $Q_B, Q_C$ ) into a single vertex. Note that  $CC_A$  (respectively,  $CC_B, CC_C$ ) has no more than  $|A|$  (respectively,  $|B|, |C|$ ) edges, and no more vertices than it has edges. Recursively compute the  $cc_A(\psi)$  values for all  $\psi \in \{\phi(i): i \in A\}$ .

*Note.*  $cc_A(\psi)$  (respectively,  $cc_B(\psi), cc_C(\psi)$ ) denotes twice the cost of the MST of  $CC_A(\psi)$  (respectively,  $CC_B(\psi), CC_C(\psi)$ ). Note that if  $\psi = \phi(i)$  for some  $i$  in  $A$  (respectively,  $B, C$ ) then  $cc(\psi)$  equals  $cc_A(\psi)$  (respectively,  $cc_B(\psi), cc_C(\psi)$ ).

Next, recursively compute the  $cc_C(\psi)$  values for all  $\psi \in \{\phi(i): i \in C\}$ . Then find  $CC_B(\phi_0)$  and compute its MST in  $O(|B|\alpha(|B|))$  time [FT] ( $cc_B(\phi_0)$  is twice the cost of this MST). If  $T(r)$  denotes the overall time for this recursive procedure, then we have

$$T(r) \leq T(|A|) + T(|C|) + c_1 r + c_2 |B| \alpha(|B|),$$

where  $|A| \leq r/2, |C| \leq r/2$ , and  $|A| + |B| + |C| = r$ . This implies that  $T(r) = O(r \log r)$ .  $\square$

This completes the proof of Theorem 1.

Now we consider the more interesting with-drops mode of operation.

**3. With-drops problem.** The main result of this section is the following.

**THEOREM 2.** *When drops are allowed, an optimal transportation for the circular track problem (and hence for the linear track one as well) can be computed in  $O(m + n)$  time.*

The proof of the above theorem is developed through the end of this section, and involves several nontrivial insights into the structure of the with-drops problem. We concern ourselves with the circular track problem only, since an  $O(m + n)$  time solution to the circular track problem automatically implies an  $O(m + n)$  time solution to the linear track problem (by first embedding the linear track problem on a very small circular arc of a circular track and then using the circular track algorithm). Since  $n \leq 2m$  it suffices to give an  $O(m)$  time algorithm.

First, observe that every object can be moved to its target station by moving it in one direction only. However this observation still allows two possibilities for transporting an object: along the minor arc between its endpoints, or along the major arc. For example, Fig. 5 proves that an optimal transportation for some problems must include transporting an object by the major arc. The (1, 2), (1, 4), and (2, 4) distances are  $\frac{1}{3}$  each, and the (3, 4) distance is very small. If we transport (1, 2) and (2, 1) by the minor arcs (Fig. 5(a)) then the complete transportation length is  $\frac{4}{3}$  (a pair of antiparallel augmenting edges between 2 and 3 is then needed). However if we transport (1, 2) by the major arc, as in Fig. 5(b), we can drop it at station 4 (we henceforth call such a drop an *intermediate stop*), then complete the (4, 3) and (3, 4) transports and finally resume the transportation of the (1, 2) arc. In this case the total path length is approximately one.

FIG. 5. (a) A with-drops problem; (b) its optimal transportation.

As in § 2, each augmenting edge corresponds to motion of the gripper when it is not holding any object, and covers only one interval (if the motion spans more than one interval, then each interval will get an augmenting edge). Also as before, if there are many augmenting edges across an interval, then we store only a count of the number of such edges going in each direction across that interval.

Lemma 1 obviously still holds. Note that the fact that the transportation may move objects to their destinations using the major arc implies that there are  $2^m$  possible

ways to draw the  $m$  input source-to-destination pairs (whereas in § 2 there was only one way to draw them). Lemma 10 will establish that we can restrict our attention to only  $m$  possibilities.

Let  $T$  be any transportation (with drops). We associate with  $T$  a graph  $G(T)$  whose vertices are the  $n$  stations, and whose edges are the  $m$  edges corresponding to the input source-to-destination pairs, plus any augmenting edges. Each input edge in the transportation might have been covered by many intermediate stops, but in the graph  $G(T)$  we simply draw the edge from its source to its destination. For example, in the transportation of Fig. 5(b), the edge  $(1, 2)$  is a single edge even though this object gets dropped at station 4 and picked up from there later on. Note that  $G(T)$  has the degree-balance property, and hence the flux corresponding to  $T$  is the same across every interval. Since  $G(T)$  is degree-balanced, its scc's are also the connected components of the undirected version of  $G(T)$ . Therefore  $G(T)$  is the union of disjoint scc's. For example, in Fig. 5(b), the graph depicted has two scc's:  $\{1, 2\}$ ,  $\{3, 4\}$ . A graph  $G$  is *transportable from vertex  $x$*  if and only if there exists a transportation  $T$  with  $x$  as its start (and hence finish) vertex, and such that  $G(T) = G$ . The graph shown in Fig. 5(b) is not transportable from vertex 3, but it is transportable from vertex 1. This example also illustrates how the length of an optimal transportation now depends on where the start vertex is.

In the following, we first establish that the graph  $G(T)$  of an optimal transportation  $T$  can be computed in  $O(m)$  time (Lemma 19). Then we show that  $T$  can be calculated from  $G(T)$  in  $O(m)$  time (Lemma 20).

For the next three lemmas, BAL is any degree-balanced graph, and the scc's of BAL are denoted by  $scc_1, \dots, scc_h$ . Observe that any  $scc_i$  can individually be transported using any vertex in  $scc_i$  as the start vertex (even without drops).

Now we define the *reachability graph* of BAL to have vertices  $scc_1, \dots, scc_h$ , and to have an edge from  $scc_i$  to  $scc_j$  if and only if there exists a vertex  $x$  of  $scc_j$  on some edge  $e$  of  $scc_i$  (i.e.,  $x$  occurs on the circular arc covered by  $e$ ). This is represented by  $scc_i \rightarrow scc_j$ , and we say that  $scc_j$  is *directly reachable* from  $scc_i$ .

The above definition of direct reachability implies that, if edges  $e_1$  and  $e_2$  of BAL overlap and neither one of them properly contains the other, then either  $e_1$  and  $e_2$  are in the same scc of BAL or the scc's containing  $e_1$  and  $e_2$  are directly reachable from each other.

We say that  $scc_j$  is *reachable* from  $scc_i$  if and only if there is a directed path from  $scc_i$  to  $scc_j$  in the reachability graph.

LEMMA 6. *In the reachability graph, if  $scc_i \rightarrow scc_j$ , then  $scc_i \cup scc_j$  can be transported using any vertex of  $scc_i$  as the start vertex.*

*Proof.* Since  $scc_i \rightarrow scc_j$ , there exists an edge  $e$  of  $scc_i$  that covers a vertex  $x$  of  $scc_j$ . Transport  $scc_i$  until point  $x$  of  $e$  is reached, drop the object, finish  $scc_j$ , and then complete  $scc_i$ .  $\square$

In fact the following generalization of Lemma 6 holds.

LEMMA 7. *If  $H$  is any directed spanning subtree of the reachability graph with  $scc_i$  as the root, then the union of all the scc's in  $H$  is transportable using any vertex of  $scc_i$  as the start vertex. In addition, the total number of intermediate stops is no more than (the number of vertices of  $H$ ) - 1.*

*Proof.* The transportation process resembles a depth-first search of  $H$ , begun at  $scc_i$ : First we mark every  $scc_j \in H$  as being "new," then we mark  $scc_i$  as being "old" and begin transporting  $scc_i$  from any start vertex in  $scc_i$ . Whenever we are transporting an edge  $e$  of the scc currently being transported, we go through every edge  $f$  that has an endpoint covered by  $e$ : if  $f$  is in a child scc of the current scc, and if the scc of  $f$

is still marked “new,” we mark the scc of  $f$  as being “old,” interrupt the transportation of the scc of  $e$ , and recursively transport the scc of  $f$  using a start (and hence finish) vertex the endpoint of  $f$  covered by  $e$ . Every  $\text{scc}_i \in H$  eventually gets transported, and every such  $\text{scc}_j$  (except the root,  $\text{scc}_i$ ) causes one intermediate stop to occur during the transportation of its parent.  $\square$

**COROLLARY 1.** *A graph is transportable from vertex  $x$  if and only if it has degree-balance and, in its reachability graph, every scc is reachable from the scc that contains  $x$ .*

*Proof.* The “only if” part of the proof is trivial; the “if” part follows from Lemma 7.  $\square$

**COROLLARY 2.** *If  $G$  is transportable from vertex  $x$ , then there is a transportation  $T$  of  $G$  (i.e.,  $G(T) = G$ ) from  $x$  such that, in  $T$ , the number of intermediate stops is no more than  $n - 1$ .*

*Proof.* The proof is an immediate consequence of Lemma 7.  $\square$

**LEMMA 8.** *Let  $S$  be a subset of the scc's of BAL such that every scc in  $S$  is reachable from  $\text{scc}_i$ . Suppose that the union of the scc's in  $S$  covers the circumference. Then for any degree-balanced graph  $G$  ( $G$  may be disconnected),  $\text{BAL} \cup G$  is transportable from any vertex in  $\text{scc}_i$ .*

*Proof.* Since the union of the scc's in  $S$  covers the circumference, every scc of BAL is reachable from at least one scc in  $S$ . This, and the fact that every scc in  $S$  is reachable from  $\text{scc}_i$ , implies that every scc of BAL is reachable from  $\text{scc}_i$ . Therefore (by Corollary 1) BAL is transportable from any vertex in  $\text{scc}_i$ . While transporting BAL, we are bound to reach a vertex in each of the scc's of  $G$ . At such vertices interrupt the main transportation of BAL and finish the scc's of  $G$ .  $\square$

**LEMMA 9.** *Let  $T$  be an optimal transportation and let  $e$  be a major edge in  $G(T)$ . Then the scc of  $G(T)$  that contains  $e$  must cover the circumference.*

*Proof.* Let  $\text{scc}(e)$  be the scc containing  $e$ , and  $\text{scc}_1$  be the scc containing the start vertex. Since  $T$  is a transportation,  $\text{scc}(e)$  is reachable in  $G(T)$  from  $\text{scc}_1$ . If  $\text{scc}(e)$  does not cover the circumference, then its individual flux (the flux due to its edges only) is zero, and hence any interval covered by  $\text{scc}(e)$  is covered by at least two edges of  $\text{scc}(e)$ . Therefore, in  $G(T) - e + e^c$ , the scc containing  $e^c$  is still reachable from  $\text{scc}_1$ , and it now covers the circumference. Therefore, by Lemma 8, all the other scc's of  $G(T) - e + e^c$  are transportable from the start vertex. Thus  $G(T) - e + e^c$  is transportable from the start vertex, which contradicts the optimality of  $T$  (since  $e$  is longer than  $e^c$ ).  $\square$

**LEMMA 10.** *In any optimal transportation, at most one object is moved to its destination along the major arc.*

*Proof.* Let  $T$  be an optimal transportation, let  $\text{scc}_1, \dots, \text{scc}_h$  be the scc's of  $G(T)$ , and let the start vertex be in  $\text{scc}_1$ . Suppose that  $G(T)$  has two major edges  $e_i$  and  $e_j$ , respectively, in  $\text{scc}_i$  and  $\text{scc}_j$ . By Lemma 9,  $\text{scc}_i$  covers the circumference, and so does  $\text{scc}_j$ .

*Case 1.*  $\text{scc}_i \neq \text{scc}_j$ . Without loss of generality, we can assume that, in the reachability graph,  $\text{scc}_i$  is reachable from  $\text{scc}_1$  without going through  $\text{scc}_j$ . Now, modify  $\text{scc}_j$  by shortening  $e_j$ . Because  $\text{scc}_i$  is still reachable from  $\text{scc}_1$  and still covers the circumference, even this modified  $\text{scc}_j$  along with all the other scc's are transportable from the start vertex (by Lemma 8). Since we made  $e_j$  shorter, the new transportation has smaller length than  $T$ , a contradiction.

*Case 2.*  $\text{scc}_i = \text{scc}_j$ . We distinguish two subcases.

*Subcase 2.1.* Every interval covered by  $e_i$  is covered by at least one other edge of  $\text{scc}_i$ . Consequently, modifying  $\text{scc}_i$  by shortening  $e_i$  leaves the circumference covered by the new  $\text{scc}_i$ , which is still reachable from  $\text{scc}_1$ . Therefore, by Lemma 8, the graph

obtained from  $G(T)$  by shortening  $e_i$  is still transportable. This contradicts the optimality of  $T$ .

*Subcase 2.2.* Some interval is covered by  $e_i$  and by no other edge of  $scc_i$ . Then the individual flux of  $scc_i$  is  $+1$  or  $-1$ , and therefore every interval in the region covered by both  $e_i$  and  $e_j$  is also covered by at least one other edge of  $scc_i$  (because the individual flux of  $scc_i$  is an odd number). In this case simultaneously shortening both  $e_i$  and  $e_j$  leaves the new  $scc_i$  still covering the circumference, leading to a contradiction.  $\square$

Lemma 10 reduces from  $2^m$  to  $m$  the number of possible drawings of the  $m$  input edges that need to be considered, but it does not yet give an  $O(m)$  time algorithm. We must still identify, in  $O(m)$  time, which edge (if any) needs to be drawn along the major arc. Even if we knew which drawing of the  $m$  input edges is best, it is not clear how to augment these into a minimum-length graph that is transportable (from the start vertex). All these nontrivial issues are addressed below.

LEMMA 11. *Let  $T$  be an optimal transportation, and let  $e$  be a major edge of  $G(T)$ . Then at least one interval covered by  $e$  is not covered by any other edge of  $G(T)$ .*

*Proof.* Suppose to the contrary that the region covered by  $e$  is also covered in  $G(T) - e$ . Then there exists in  $G(T) - e$  a sequence of edges  $f_1, \dots, f_s$  such that  $f_1 \cup \dots \cup f_s$  covers  $e$ , and every  $f_i$  contains an endpoint of  $f_{i+1}$ ,  $1 \leq i < s$ . Figure 6 illustrates this ( $s = 5$ ), ignoring edge directions as well as the distinction between input edges and augmenting ones. We assume that the sequence  $f_1, \dots, f_s$  has the smallest number of elements ( $= s$ ) among all such sequences covering  $e$ ; this implies that neither one of  $f_i$  and  $f_{i+1}$  contains the other. Note that Lemma 10 implies that  $s > 1$ . Let  $scc_1$  be the scc of  $G(T)$  that contains the start vertex, and for any edge  $x$ ,  $scc(x)$  denotes the scc that contains  $x$ . We distinguish two cases.

FIG. 6. Illustrating the two cases of the proof of Lemma 11.

*Case 1.*  $e^c$ , the complement of  $e$ , covers at least one endpoint of at least one of the  $f_i$ 's (see Fig. 6(a)). For every  $1 \leq i < s$ , the fact that  $f_i$  and  $f_{i+1}$  overlap without containment implies that we have either  $scc(f_i) = scc(f_{i+1})$ , or  $scc(f_i)$  and  $scc(f_{i+1})$  are directly reachable from each other. Therefore the  $scc(f_i)$ 's are reachable from one another and from  $scc(e)$ . Now, in  $G(T) - e + e^c$ ,  $scc(e^c)$  is still reachable from  $scc_1$ , and every  $scc(f_i)$  is still reachable from  $scc(e^c)$  (because  $e^c$  contains an endpoint of

some  $f_i$ ). Since the union of the  $scc(f_i)$ 's with  $scc(e^c)$  covers the circumference, it follows (by Lemma 8) that the graph  $G(T) - e + e^c$  is transportable (from the start vertex). This contradicts the optimality of  $T$ .

*Case 2.*  $e^c$  does not cover any endpoint of any  $f_i$  (see Fig. 6(b)). Note that this implies that some  $f_i$ , say  $f_1$ , contains  $e^c$ . Let  $l$  be the shortest distance between any endpoint of  $e$  (say,  $x$ ) and any endpoint of any  $f_i$  (say, endpoint  $y$  of  $f_\alpha$ ). Now, in  $G(T)$ , simultaneously shorten  $e$  and add two antiparallel augmenting arcs of length  $l$  each between  $x$  and  $y$ . In the resulting graph, the two additional augmenting edges that were added make  $scc(e^c) = scc(f_\alpha)$ , and therefore every  $scc(f_i)$  is reachable from  $scc_1$ . Since the union of the  $scc(f_i)$ 's covers the circle, Lemma 8 implies that the new graph is transportable. The decrease in cost with respect to the original  $G(T)$  is given by

$$|e| - |e^c| - 2 \cdot l = 1 - 2 \cdot (|e^c| + l) > 1 - 2|f_1| \geq 0$$

(note that  $|e^c| + l < |f_1| \leq \frac{1}{2}$ , and recall that the circle's circumference is unity). Thus the new transportable graph is shorter than  $G(T)$ , a contradiction.  $\square$

**COROLLARY 3.** *Let  $T$  be an optimal transportation, and let  $\psi(T)$  denote the flux of  $T$ . If  $G(T)$  contains a major edge, then  $|\psi(T)| = 1$ .*

*Proof.* The interval covered by  $e$  and by no other edge, in Lemma 11, has flux value of +1 or -1.  $\square$

We henceforth use  $D_0$  to refer to the graph which consists of all  $m$  input edges, drawn so that each of them is minor.

**LEMMA 12.** *If  $D_0$  covers the circumference, then no optimal transportation can contain a major edge.*

*Proof.* Let  $T$  be an optimal transportation and let  $e$  be a major edge of  $G(T)$ . Since  $e$  is major, its complement  $e^c$  is in  $D_0$ . Since  $D_0$  covers the circumference,  $D_0 - e^c$  covers  $e$ . Since  $G(T) - e$  contains  $D_0 - e^c$ ,  $G(T) - e$  covers the region covered by  $e$ . This contradicts Lemma 11.  $\square$

If two edges of  $D_0$  overlap without either of them containing the other, then in every degree-balanced augmentation of  $D_0$ , these two edges either belong to the same  $scc$  or to two  $scc$ 's that are directly reachable from each other. Based on this observation let us define a relation,  $\approx$ , between any two edges of  $D_0$ , as follows:

- (a) For any two input edges  $e_1$  and  $e_2$ ,  $e_1 \approx e_2$  if and only if either these two edges share a common endpoint, or they overlap but neither one of them contains the other.
- (b) Transitively close the relation  $\approx$ .

Note that  $\approx$  is an equivalence (eq.) relation, and, in addition, no two eq. classes of  $\approx$  have a vertex in common. Also note that in any degree-balanced augmentation of  $D_0$ , two input edges in the same eq. class of  $\approx$  belong to  $scc$ 's that are reachable from each other.

Define an ordering  $<$  among the eq. classes of  $\approx$  as follows: If  $C_i$  and  $C_j$  are any two distinct eq. classes of  $\approx$ , then  $C_i < C_j$  if and only if some edge of  $C_j$  covers all the vertices of  $C_i$  (and hence no edge of  $C_i$  covers any vertex of  $C_j$ ). Note that  $\approx$  is independent of the drawing of the edges, whereas  $<$  does depend on it. Based on this ordering we can draw a forest of trees  $F$  whose nodes are the eq. classes of  $\approx$  (the parent of  $C_i$  is the "smallest" class above it according to the  $<$  relation). An example of such a forest is shown in Fig. 7. Let  $\tau_1, \dots, \tau_k$  be the trees of  $F$ , listed in clockwise cyclic order and such that  $\tau_1$  contains the start vertex. Let  $root(\tau_i)$  denote the eq. class at the root of tree  $\tau_i$ . Let  $g_1, \dots, g_k$  be the lengths of the gaps that separate, on the circumference, the regions covered by the  $\tau_i$ 's;  $g_i$  is the gap between  $\tau_i$  and  $\tau_{i+1}$  (in

FIG. 7. The forest (b) corresponds to the input edges shown in (a).

Fig. 7,  $g_1$  is the arclength from the head of edge  $h$  to the tail of edge  $z$ , and  $g_2$  is the arclength from the head of edge  $j$  to the head of edge  $a$ .

LEMMA 13. *The eq. classes of  $\approx$  and the forest  $F$  of eq. classes can be computed in  $O(m)$  time.*

*Proof.* For the proof see Appendix A.  $\square$

Let  $G$  be any degree-balanced augmentation of  $D_0$ . (Note that  $G$  is not necessarily transportable and, since it is degree-balanced, its scc's are the same as the connected components of the undirected version of it.) We say that eq. classes  $C_i$  and  $C_j$  of  $\approx$  are *directly linked* in  $G$  if and only if at least one of the scc's of  $G$  contains vertices from both  $C_i$  and  $C_j$ ; they are *linked* if and only if there is a sequence of eq. classes beginning with  $C_i$  and ending with  $C_j$  such that every two eq. classes in the sequence are linked.

Let  $DB(\psi)$  be the graph corresponding to the minimum degree-balanced augmentation of  $D_0$  that results in flux  $\psi$ ; note that  $DB(\psi)$  is unique but need not be transportable. Figure 8(a) shows  $DB(0)$  for the  $D_0$  of Fig. 7. Let  $db(\psi)$  be the total length of the augmenting edges in  $DB(\psi)$  (i.e., edges in  $DB(\psi) - D_0$ ). By Lemma 4, it takes  $O(m)$  time to compute all the  $db(\psi)$  values,  $-m - 1 \leq \psi \leq m + 1$ .

Let  $C_{start}$  be the eq. class containing the start vertex (recall that  $\tau_1$  is the tree of  $F$  that contains  $C_{start}$ ). Let  $LR(\psi)$  be a minimum augmentation of  $DB(\psi)$  that makes  $C_{start}$  linked to root ( $\tau_1$ ) while keeping the flux equal to  $\psi$ . Hence  $LR(\psi)$  consists of  $DB(\psi)$  plus some augmenting pairs of antiparallel edges (in Fig. 8(b) there is one such pair, marked "in  $LR(0)$ "). Let  $lr(\psi)$  be the total length of the augmenting edges in  $LR(\psi)$  but not in  $DB(\psi)$ .

LEMMA 14. *The  $lr(\psi)$ 's, for  $-m - 1 \leq \psi \leq m + 1$ , can all be computed in  $O(m)$  time. For any given flux value  $\psi_0$ ,  $LR(\psi_0)$  can be computed in  $O(m)$  time.*

*Proof.* For the proof see Appendix B.  $\square$

In the next two lemmas, we show how to compute the optimum among all transportations in which no edge is major.

Let  $OPT_{minor}(\psi)$  be the graph corresponding to a transportation that is optimal among all transportations of flux  $\psi$  and that do not have any major edge. If  $LR(\psi)$  is transportable from the start vertex, then  $OPT_{minor}(\psi) = LR(\psi)$ . Otherwise, pairs of antiparallel edges are needed across some of the gaps (intervals not covered by  $D_0$ )

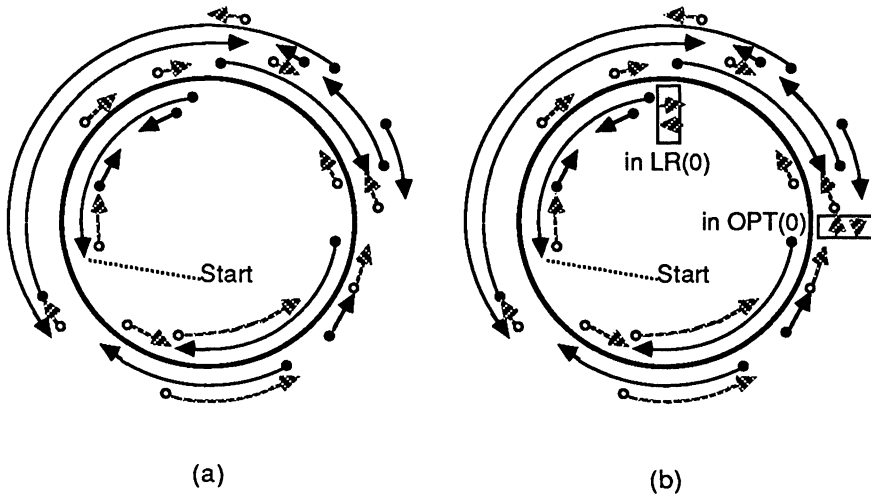

FIG. 8. Illustrating  $DB(0)$ ,  $LR(0)$ , and  $OPT(0)$  for the input edges of Fig. 7.

in order to turn  $LR(\psi)$  into  $OPT_{minor}(\psi)$ . In Fig. 8(b) there is one such antiparallel pair, and each of the two edges in it has length  $g_1$ . (Recall that  $g_1, \dots, g_k$  are the lengths of the gaps separating the  $\tau_i$ 's, listed in clockwise cyclic order, and such that  $\tau_1$  contains the start vertex.)

LEMMA 15. Let  $\hat{g}(\psi)$  be the total length of the augmenting pairs of antiparallel edges in  $OPT_{minor}(\psi) - LR(\psi)$ . If  $\psi \neq 0$  then  $\hat{g}(\psi) = 0$ ; otherwise  $\hat{g}(0) = 2 \cdot (\sum_{i=1}^k g_i - \max_i g_i)$ .

Proof.  $\hat{g}(\psi)$  is the length of the additional edges needed for linking all the root ( $\tau_i$ )'s together at flux  $\psi$ . No additional edges are needed if  $\psi \neq 0$  because then every root ( $\tau_i$ ) is already linked to root ( $\tau_{i+1}$ ) in  $LR(\psi)$ . If  $\psi = 0$  then we link the root ( $\tau_i$ )'s by adding an antiparallel pair across every gap except the longest.  $\square$

The above lemma immediately implies the following.

COROLLARY 4. The pairs of antiparallel augmenting edges in  $OPT_{minor}(\psi) - LR(\psi)$  can be computed in  $O(m)$  time.

LEMMA 16. It is possible to compute, in  $O(m)$  time, a graph  $G(T_0)$  for some transportation  $T_0$  which is optimal among all transportations none of whose edges is major.

Proof. Note that such a graph is simply an  $OPT_{minor}(\psi)$  of minimum total length. The total length of such a graph is equal to (length of edges of  $D_0$ ) +  $\min_{\psi} \{db(\psi) + lr(\psi) + \hat{g}(\psi)\}$ . Therefore Lemmas 4, 14, and 15 immediately imply that we can find a flux value  $\psi_0$  such that the length of  $OPT_{minor}(\psi)$  is minimum for  $\psi = \psi_0$ . We now show that, once we know  $\psi_0$ ,  $OPT_{minor}(\psi_0)$  itself can be computed in  $O(m)$  time. It is trivial to obtain  $DB(\psi_0)$  in  $O(m)$  time. By Lemma 14,  $LR(\psi_0)$  can be obtained from  $DB(\psi_0)$  in  $O(m)$  time. By Corollary 4,  $OPT_{minor}(\psi_0)$  can be obtained from  $LR(\psi_0)$  in  $O(m)$  time.  $\square$

We now consider transportations that have exactly one major edge.

LEMMA 17. Let  $E$  be any set of edges on the circle, exactly one of which is major (call it  $e$ ). Let  $G$  be any degree-balanced augmentation of  $E$ . If  $E$  covers the circumference, then every scc of  $G$  is reachable from the scc that contains  $e$ .

Proof. Let  $scc(e)$  denote the scc of  $G$  containing edge  $e$ . Since  $E$  covers the circumference, there exists in  $E$  a sequence of edges  $f_1, \dots, f_s$  such that  $f_1 \cup \dots \cup f_s$  covers  $e^c$ , and every  $f_i$  contains an endpoint of  $f_{i+1}$ ,  $1 \leq i < s$ . We assume that the

sequence has smallest number of elements ( $= s$ ), and hence none of  $f_i$  and  $f_{i+1}$  contains the other. See Fig. 9, and note that because  $e$  is the only major edge of  $E$ , it must contain at least one endpoint of one of the  $f_i$ 's. Therefore at least one  $\text{scc}(f_i)$  is reachable from  $\text{scc}(e)$ . For every  $1 \leq i < s$ , the fact that  $f_i$  and  $f_{i+1}$  overlap without containment implies that they belong to  $\text{scc}$ 's that are reachable from one another. Therefore every  $\text{scc}(f_i)$  is reachable from  $\text{scc}(e)$ , and hence (by Lemma 8) any  $\text{scc}$  of  $G$  is also reachable from  $\text{scc}(e)$ .  $\square$

FIG. 9. Illustrating the proof of Lemma 17.

Recall that we have already stated (in Lemma 10) that in an optimal augmentation at most one edge is major. The next lemma refines this statement.

LEMMA 18. *There exists an optimal transportation  $T$  such that, if  $e \in G(T)$  is major, then its complement  $e^c \in D_0$  is in a root eq. class of  $\approx$  and is the longest edge in that class.*

*Proof.* Let there exist an optimal transportation  $T$  in which edge  $e$  is major, and hence its complement  $e^c$  is in  $D_0$ . Note that  $|e| = 1 - |e^c|$ , and  $|e^c| < \frac{1}{2}$ . Let  $e^c$  be in eq. class  $C$  of tree  $\tau_j$  (recall that the eq. classes as well as the  $\tau_i$ 's are defined using  $D_0$ , where all edges are minor).

By Lemma 12,  $D_0$  does not cover the circumference. Lemma 11 implies that  $e$  is the only input edge that covers the  $k$  gaps not covered by  $D_0$ .

Let  $G' = G(T) - e + e^c$ , and note that  $G'$  is degree-balanced and contains  $D_0$ . No  $\text{scc}$  of  $G'$  covers the circumference, because otherwise  $G'$  is transportable (from the start vertex), contradicting the optimality of  $G(T)$ . Therefore every  $\text{scc}$  of  $G'$  has an individual flux of zero, which implies the following:

- (\*) If an interval is covered by an  $\text{scc}$  of  $G'$ , then it is covered by at least two edges of that  $\text{scc}$ .

Now we prove that  $e^c$  is longest in  $C$ . Suppose to the contrary that edge  $f \in C$  is longer than  $e^c$ . Consider the  $\text{scc}$  of  $G'$  that contains  $e^c$  (call it  $\text{scc}(e^c)$ ). In  $G'$ ,  $\text{scc}(e^c)$  and  $\text{scc}(f)$  are mutually reachable from one another because  $G'$  contains  $D_0$  and, in  $D_0$ ,  $e^c$  and  $f$  are in the same eq. class. Now, since  $T$  is a transportation, the  $\text{scc}$  of  $G(T)$  that contains  $e$  is reachable from the  $\text{scc}$  of the start vertex, and therefore in  $G'$ ,  $\text{scc}(e^c)$  is reachable from the  $\text{scc}$  of the start vertex. Therefore in  $G'$ ,  $\text{scc}(f)$  is reachable from the  $\text{scc}$  of the start vertex. Consequently, we have:

- (\*\*) In  $G' - f + f^c$ ,  $\text{scc}(f^c)$  is reachable from the  $\text{scc}$  of the start vertex.

Now, (\*) implies that in  $G'$ , every interval covered by  $f$  is also covered by at least one edge of  $\text{scc}(f)$  other than  $f$ . Therefore  $\text{scc}(f) - f + f^c$  covers the circumference,

and hence by Lemma 17 every scc of  $G' - f + f^c$  is reachable from  $\text{scc}(f^c)$ . This and (\*\*\*) together imply that in  $G' - f + f^c$ , every scc is reachable from the scc of the start vertex. Thus the graph obtained from  $G(T)$  by shortening  $e$  and simultaneously lengthening  $f$  is also transportable. This contradicts the optimality of  $T$ . Thus  $e^c$  must be longest in its eq. class.

Now we prove that there is always an optimal  $T$  in which  $C$  is root in its eq. class, i.e.,  $C = \text{root}(\tau_j)$ . Suppose that  $C \neq \text{root}(\tau_j)$ . Then the parent of  $C$  in  $\tau_j$  surely contains an edge  $f$  which is longer than  $e^c$  and covers it entirely. Let  $\hat{G} = G(T) - e + e^c - f + f^c$ . Let CYCLES be the set of augmenting edges defined as follows: across every interval covered by  $f$  but not by  $e^c$ , add two antiparallel edges. Thus the length of CYCLES is  $2 \cdot (|f| - |e^c|)$ . Simple arithmetic shows that adding CYCLES to  $\hat{G}$  results in a graph of total length no more than that of  $G(T)$ . We now show that  $\hat{G} + \text{CYCLES}$  is transportable. First note that  $\hat{G} + \text{CYCLES}$  has degree-balance. Now observe that, because of the presence of CYCLES,  $e^c$  and  $f^c$  are in the same scc of  $\hat{G} + \text{CYCLES}$  (call it  $\text{scc}_x$ ). Furthermore, since  $T$  is a transportation, the scc of  $G(T)$  that contains  $e$  is reachable from the scc of the start vertex, and therefore in  $\hat{G} + \text{CYCLES}$ ,  $\text{scc}_x$  is reachable from the scc of the start vertex. This and the fact that  $\text{scc}_x$  covers the circle implies that  $\hat{G} + \text{CYCLES}$  is transportable. Since  $\hat{G} + \text{CYCLES}$  is transportable and has length no more than that of  $G(T)$ , we have obtained from  $G(T)$  another transportable graph of optimal length, one in which the complement of the major edge is in an eq. class that is one level higher in  $\tau_j$ . We can repeatedly do this until we end up with an optimal transportation whose major edge's complement belongs to  $\text{root}(\tau_j)$ .  $\square$

LEMMA 19. *It is possible to compute, in  $O(m)$  time, a graph  $G(T)$  for some optimal transportation  $T$ .*

*Proof.* Use Lemma 16 to compute  $G(T_0)$  and let  $\text{Cost}_0$  be its total length. Use Lemma 13 to compute  $F$ : if  $F$  has one tree only then return  $G(T_0)$ . Now, suppose that  $F$  has more than one tree, i.e.,  $k > 1$ . Let  $\text{Cost}_1$  be the length of a transportation  $T_1$  having exactly one major edge in it, and which is optimal among all transportations that have exactly one major edge. The optimal transportation  $T$  will have length  $\min\{\text{Cost}_0, \text{Cost}_1\}$ . If  $\text{Cost}_1 < \text{Cost}_0$  then Lemma 11 tells us that in our search for the value  $\text{Cost}_1$ , we can restrict our attention to transportations  $T_1$  such that there exists at least one interval covered by only the major edge of  $G(T_1)$ . Within this class of transportations, any  $T_1$  will have to be such that  $G(T_1)$  has the following properties where  $e$  denotes the major edge and  $e^c$  its complement:

(i)  $G(T_1) - e + e^c$  has flux equal to zero and thus contains  $\text{DB}(0)$  (which contains  $D_0$ ).

(ii) In  $G(T_1) - e + e^c$ ,  $C_{\text{start}}$  is linked to the root eq. class of its tree ( $\tau_1$ ). Therefore  $G(T_1) - e + e^c$  contains  $\text{LR}(0)$  as well.

(iii) In  $G(T_1) - e + e^c$ , the root eq. class of the tree  $\tau_j$  that contains  $e$  is linked to  $\text{root}(\tau_1)$  (simply because  $T_1$  is a transportation). The augmenting edges that cause  $\text{root}(\tau_j)$  and  $\text{root}(\tau_1)$  to be linked are pairs of antiparallel edges across either all of gaps  $\#1, \dots, \#(j-1)$ , or all of gaps  $\#j, \dots, \#k$  (depending on whichever of  $g_1 + \dots + g_{j-1}$  or  $g_j + \dots + g_k$  is smaller).

Thus  $G(T_1) - e + e^c$  equals  $\text{LR}(0)$  plus the augmenting edges referred to in (iii). The length of  $G(T_1) - e + e^c$  is therefore equal to

$$(\text{length of } D_0) + \text{db}(0) + \text{lr}(0) + 2 \cdot \min\{g_1 + \dots + g_{j-1}, g_j + \dots + g_k\}.$$

The length of  $G(T_1)$  therefore equals (using  $|e| + |e^c| = 1$ )

$$(\dagger) (\text{length of } D_0) + \text{db}(0) + \text{lr}(0) + 2 \cdot \min\{g_1 + \dots + g_{j-1}, g_j + \dots + g_k\} + 1 - 2|e^c|.$$

The first three terms of the sum ( $\dagger$ ) are the same for any such transportation  $T_1$ . Now, the edge  $e$  of  $G(T_1)$  for which the sum of the last two terms of ( $\dagger$ ) is smallest should be the one to follow the major arc. It is trivial to identify this edge in  $O(m)$  time and compute the corresponding sum ( $\dagger$ ): If this sum is smaller than  $\text{Cost}_0$  then this  $G(T_1)$  corresponds to the optimal transportation; otherwise it is  $G(T_0)$ .  $\square$

**LEMMA 20.** *Let  $G$  be transportable from a designated start vertex. A transportation  $T$  such that  $G(T) = G$  can be found in  $O(m)$  time.*

*Proof.* The proof of Lemma 7 suggests an algorithm for obtaining such a transportation. However, we cannot afford to create the graph of the reachability relation among scc's, because such a graph can be dense. Instead, we create a graph  $\text{EQUIV}'$ , defined as  $\text{EQUIV}$  in the proof of Lemma 13 (Appendix A) except that we now use the input edges as they are drawn in  $G$  rather than as they are drawn in  $D_0$  ( $G$  may include a major edge). In addition, we compute the eq. classes of a relation  $\approx'$  and forest of eq. classes  $F'$  defined as  $\approx$  and  $F$  were before, except that we now use the input edges as they are in  $G$  rather than in  $D_0$ . For each eq. class  $C$  that is parent in  $F'$  of class  $C'$ , we arbitrarily select an edge  $e$  in  $C$  and an edge  $f$  in  $C'$  such that  $e$  properly contains  $f$  (at least one such pair  $e, f$  exists); we call edge  $e$  the *parent* of  $f$ , and we call  $f$  a *child* of  $e$ . Note that the forest  $F'$  induces at most  $n - 1$  such parent-child pairs. For each edge  $e$ , let the list of edges  $\text{ADJ}(e)$  be the union of (i) the children of  $e$  induced by  $F'$ , and (ii) the adjacency list of  $e$  in the undirected graph  $\text{EQUIV}'$ . We are now ready to describe how to obtain  $T$  such that  $G(T) = G$ . The transportation process resembles a depth-first search of the scc's, begun at  $\text{scc}_1$ : First we mark all scc's of  $G$  as being "new," then we mark  $\text{scc}_1$  as being "old" and begin transporting  $\text{scc}_1$  from the start vertex of  $G$  (recall that any scc can be individually transported using any vertex in it as start and finish). Whenever we are transporting an input edge  $e$  of the scc currently being transported, we go through the list  $\text{ADJ}(e)$ : for each  $f \in \text{ADJ}(e)$  that is in a "new" scc, we mark the scc of  $f$  as being "old," interrupt the transportation of the scc of  $e$ , and recursively transport the scc of  $f$  using as start (and hence finish) vertex an endpoint of  $f$  covered by  $e$ . It is trivial to implement this procedure in  $O(m)$  time. Correctness follows from the facts that (i)  $\text{EQUIV}'$ , even though it is sparse, captures all the "overlap without containment" relationships between pairs of input edges, and (ii) the parent-child pairs induced by  $F'$  capture enough of the "proper containment" relationships between pairs of edges. More precisely, (i) guarantees that once an edge of eq. class  $C$  is reached by the transportation, eventually every edge of that class  $C$  will be transported. On the other hand, (ii) guarantees that once an edge of an eq. class  $C$  is reached by the transportation, eventually every eq. class in the subtree of  $C$  in  $F'$  will be transported.  $\square$

The last two lemmas imply Theorem 2, which is the main result of this section.

**4. Concluding remarks.** It is easy to see that our solutions to the angular motion problem (with or without drops) also work in the presence of obstacles. A preprocessing step computes the visibility polygon from the fixed pivot point of the robot arm (of course all  $n$  stations must be visible from the pivot, since an invisible station is unreachable by the robot arm). The robot arm must remain within the visibility polygon while performing the transportation. While this does not affect the rotational distance function, the telescoping distance function has to be modified appropriately because the robot arm may have to be drawn in so as to clear an obstacle.

It would be interesting to investigate the with-drops circular track problem when the gripper can simultaneously hold  $c$  objects, where  $c$  is a constant larger than one. We conjecture that Lemma 10 generalizes to that case, i.e., no optimal transportation

can transport more than  $c$  objects along the major arc. A special case of this problem for a linear track was treated in [K].

**Appendix A.** This Appendix proves Lemma 13. Computing  $F$  in linear time when we know the eq. classes is easy and this construction is omitted. We give an  $O(m)$  time algorithm for computing the eq. classes of  $\approx$ . For the purpose of this computation all the edges in  $D_0$  can be considered undirected. An edge covers the circular region going clockwise from its *beginning* to its *end*. For an edge  $e \in D_0$ , let  $CW(e)$  (respectively,  $CCW(e)$ ) be the set of edges of  $D_0$  whose beginning (respectively, end) is in the region covered by  $e$  and whose end (respectively, beginning) is in the region not covered by  $e$ . Note that  $f \in CW(e)$  if and only if  $e \in CCW(f)$ . The *clockwise* (respectively, *counterclockwise*) *successor* of  $e$  is the edge of  $CW(e)$  (respectively,  $CCW(e)$ ) whose beginning (respectively, end) is encountered first by a clockwise (respectively, counterclockwise) sweep starting at  $e$ 's beginning (respectively, end). In Fig. 10(a),  $CW(e) = \{c, d\}$ ,  $CCW(e) = \{a, b\}$ , the clockwise successor of  $e$  is  $d$  and its counterclockwise successor is  $a$ .

FIG. 10. Illustrating EQUIV.

The clockwise and counterclockwise successors of every edge of  $D_0$  can easily be computed in  $O(m)$  time. Assume this has already been done. Now create, in  $O(m)$  time, the undirected graph EQUIV whose vertex set is  $D_0$  and such that  $\{e, f\}$  is an edge in it if and only if one of  $e$  and  $f$  is (clockwise or counterclockwise) successor of the other. Figure 10(b) shows the graph EQUIV corresponding to Fig. 10(a). Obviously, EQUIV has at most  $2m$  edges, since every  $e \in D_0$  has at most two successors (one clockwise, one counterclockwise). Hence the connected components of EQUIV can be computed in  $O(m)$  time. Thus the lemma will follow immediately when we establish that the connected components of EQUIV are the equivalence classes of  $\approx$ . To prove this, it suffices to show that if any two edges  $e$  and  $f$  overlap without containment (i.e., without either one of them properly containing the other), then there is a path between  $e$  and  $f$  in EQUIV. If edges  $e$  and  $f$  overlap without containment, then we define the *overlap number* of the pair  $\{e, f\}$  to be the number of stations covered by both  $e$  and  $f$ , not counting the endpoints of  $e$  and  $f$ . In Fig. 10(a), the overlap number of  $\{e, d\}$  is 2, that of  $\{a, w\}$  is 0, and that of  $\{e, w\}$  is undefined because  $e$  properly contains  $w$ . We prove the desired result by contradiction: suppose there exist

pairs of edges that overlap without containment and have no path between them in EQUIV. Among all such pairs, choose  $\{e, f\}$  to have maximum overlap number. Without loss of generality, assume  $f \in CW(e)$ . Let  $g$  be the clockwise successor of  $e$ , and let  $h$  be the counterclockwise successor of  $f$  (see Fig. 11). Since  $\{e, g\}$  and  $\{f, h\}$  are edges in EQUIV, and since  $e$  and  $f$  are in different connected components of EQUIV, we must have  $g \neq f$  and  $h \neq e$ . Note that, as shown in Fig. 11, the end of  $g$  must occur after that of  $f$  in the clockwise direction, because otherwise the overlap number of  $\{g, f\}$  would exceed the overlap number of  $\{e, f\}$ , a contradiction. Similarly, the beginning of  $h$  comes before that of  $e$ , since otherwise the overlap number of  $\{e, h\}$  would exceed the overlap number of  $\{e, f\}$ , a contradiction. But then, the overlap number of  $\{g, h\}$  exceeds the overlap number of  $\{e, f\}$ , a contradiction. This completes the proof of Lemma 13.

**Appendix B.** This appendix proves Lemma 14. For every eq. class  $C \in \tau_1$ , let  $L(C)$  (respectively,  $R(C)$ ) be the vertex of  $C$  such that a clockwise sweep of the region covered by  $C$  starts at  $L(C)$  (respectively, ends at  $R(C)$ ). In Fig. 7  $L(\{c\})$  is the head of edge  $c$ ,  $L(\{j, z\})$  is the tail of edge  $z$ . If  $C$  is not root  $(\tau_1)$ , let the *left* (respectively, *right*) neighbor of  $C$  be the first vertex of  $\tau_1 - C$  that is encountered by a counterclockwise (respectively, clockwise) sweep begun at  $L(C)$  (respectively,  $R(C)$ ). In Fig. 7, the left neighbor of eq. class  $\{c\}$  is the tail of edge  $b$ , its right neighbor is the tail of edge  $g$ . We use  $LN(C)$  and  $RN(C)$  to denote the left and right neighbors of  $C$ , respectively. Note that  $LN(C) = L(C) - 1$  and  $RN(C) = R(C) + 1$ . Therefore we can talk about the *intervals*  $(LN(C), L(C))$  and  $(R(C), RN(C))$ . Let the eq. class containing any vertex  $x$  be denoted by  $Class(x)$ . Note that  $Class(LN(C))$  (respectively,  $Class(RN(C))$ ) is either the left (respectively, right) sibling of  $C$  in  $\tau_1$ , or the parent of  $C$  in  $\tau_1$ . Also note that  $Class(LN(C)) = Class(RN(C))$  is possible (if both are the parent of  $C$ ). Now, imagine starting at  $C_{start}$  and repeatedly applying the function  $Class(LN(\cdot))$  until root  $(\tau_1)$  is reached. This defines a sequence  $S_{left}$  of eq. classes from  $C_{start}$  to root  $(\tau_1)$ . Starting at  $C_{start}$  and repeatedly applying the function  $Class(RN(\cdot))$  similarly defines a sequence of eq. classes  $S_{right}$ . Let us draw a directed graph  $Q$  to depict what  $S_{left}$  and  $S_{right}$  might look like; i.e., the vertices of  $Q$  are the eq. classes of  $S_{left} \cup S_{right}$  and  $Q$  has an edge from  $C_i$  to  $C_j$  if and only if  $C_j$  immediately follows  $C_i$  in  $S_{left}$  or in  $S_{right}$ . Figure 12 shows such a graph  $Q$ . Note that the two paths corresponding to  $S_{left}$  and  $S_{right}$  are not necessarily vertex-disjoint and may

FIG. 11. Illustrating clockwise and counterclockwise successors.

FIG. 12. A typical graph  $Q$ .

come together at *articulation points* more than once. Let these articulation points be  $A_1, A_2, \dots, A_t$ , listed by increasing distance from  $C_{start}$  in  $Q$ . Let  $A_0 = C_{start}$ ,  $A_{t+1} = \text{root}(\tau_1)$ .

Let the interval that *corresponds* to the pair  $\{C, \text{Class}(\text{LN}(C))\}$  be  $(\text{LN}(C), L(C))$ , and let the interval that corresponds to the pair  $\{C, \text{Class}(\text{RN}(C))\}$  be  $(R(C), \text{RN}(C))$ . Now, let  $Q(\psi)$  be the *undirected* graph obtained by removing from the undirected version of  $Q$  all the edges  $\{C, \text{Class}(\text{LN}(C))\}$  and  $\{C, \text{Class}(\text{RN}(C))\}$  whose corresponding intervals are not covered by any augmenting edge of  $\text{DB}(\psi)$ . Note that if  $Q(\psi)$  does not contain a path between  $A_0$  and  $A_{t+1}$ , then antiparallel pairs need to be added to  $\text{DB}(\psi)$  to turn it into  $\text{LR}(\psi)$ ; we next investigate which such antiparallel pairs should be added (the total length of these pairs is  $\text{lr}(\psi)$ ). Let  $E(\psi)$  be a subset of edges in the undirected version of  $Q$  such that adding these edges to  $Q(\psi)$  causes a path to exist between  $A_0$  to  $A_{t+1}$ ; choose  $E(\psi)$  to be such that the sum of the lengths of the intervals corresponding to its elements is minimum. It is not hard to see that  $\text{LR}(\psi)$  is obtained by adding to  $\text{DB}(\psi)$  an antiparallel pair across every interval corresponding to an element of  $E(\psi)$ . Thus  $\text{lr}(\psi)$  is twice the total length of the intervals corresponding to the elements of  $E(\psi)$ ; let us call this the *cost of  $E(\psi)$* . Now our problem is to keep track of the cost of  $E(\psi)$  as  $\psi$  changes from  $-m-1$  to  $m+1$ . Write  $E(\psi)$  as  $E_0(\psi) + E_1(\psi) + \dots + E_t(\psi)$  where  $E_i(\psi)$  is the subset of  $E(\psi)$  that is in the biconnected component of the undirected version of  $Q$  having  $A_i$  and  $A_{i+1}$  as articulation points. Now, as  $\psi$  changes,  $Q(\psi)$  changes as well, but it changes at no more than  $3n$  values of  $\psi$ . Each such change in  $Q(\psi)$  is due to the appearance or disappearance of an augmenting edge of  $\text{DB}(\psi)$  across an interval, and it is trivial to update, in constant time per interval affected, the cost of each  $E_i(\psi)$  affected (once we realize that the portion of  $Q$  between  $A_i$  and  $A_{i+1}$  consists of two disjoint paths, we can easily supply the other details). Thus it is possible to compute a description of the costs of all the  $E_i(\psi)$ 's in  $O(m)$  time. Getting the description of the cost of  $E(\psi)$  takes an additional  $O(m)$  time, which completes the proof of the first part of the lemma.

For a given flux value  $\psi_0$ , computing the actual set  $E(\psi_0)$  (and the intervals corresponding to its elements) is easily done in  $O(m)$  time, in view of the preceding discussion: first we compute  $Q$ , then  $Q(\psi_0)$ , then  $E(\psi_0)$ . This completes the proof of Lemma 14.

**Note added in proof.** Professor G. N. Frederickson pointed out that the  $\alpha(n)$  for the linear track case without drops is, in fact,  $\log(\log^* n)$ .

## PROBING CONVEX POLYGONS WITH X-RAYS\*

HERBERT EDELSBRUNNER<sup>†‡</sup> AND STEVEN S. SKIENA<sup>†</sup>

**Abstract.** An X-ray probe through a polygon measures the length of intersection between a line and the polygon. This paper considers the properties of various classes of X-ray probes, and shows how they interact to give finite strategies for completely describing convex  $n$ -gons. It is shown that  $(3n/2)+6$  probes are sufficient to verify a specified  $n$ -gon, while for determining convex polygons  $(3n-1)/2$  X-ray probes are necessary and  $5n+O(1)$  sufficient, with  $3n+O(1)$  sufficient given that a lower bound on the size of the smallest edge of  $P$  is known.

**1. Introduction.** Identifying and understanding objects from sensory data is a fundamental problem in robotics and computer vision. Such sensors can include imaging devices as well as simpler detectors. Clearly imaging devices provide a tremendous amount of information; however for reasons of economy and robustness, simple sensors are often used. There has been increasing interest [1]–[3] in analyzing the number of measurements which different types of sensors need to determine convex polytopes. This paper introduces another sensor model, the *X-ray probe*, and gives strategies for using it.

Probing polytopes can be viewed as a discrete case of sampling problems encountered in signal processing. The *Nyquist rate* [4] specifies the amount of sampling needed to reconstruct a continuous waveform. Since our objects of interest, convex polygons, have much more structure than continuous waveforms, it is clear that tighter bounds can be obtained. Continuous waveforms generated by probes analogous to our model are used in such medical instrumentation systems as tomography. The techniques used in reconstruction of these waveforms are unrelated to ours, (see [5]–[7] for surveys).

The most studied geometric probe is the *finger probe* [1]–[3], which is a directed line  $l$  and returns the first intersection of  $l$  with polygon  $P$ . Intuitively, it is like moving a finger towards an object and recording where it hits. An *X-ray probe*  $X(P, l)$  is defined to be the length of intersection between polygon  $P$  and the line  $l$ . We assume that we know a point  $O$  within  $P$ , which identifies the general location of  $P$  in the plane. Without such a point to provide a general idea of where  $P$  is, it is not clear how to find  $P$  in a finite number of probes. For convenience we shall assume  $O$  is within the interior of  $P$ .

A collection of X-ray probes through an object provides us with a great deal of information about it but not directly with the coordinates of a point on the surface. Obtaining such absolute information is the difficulty in working with X-ray probes. Figure 1 demonstrates some of these difficulties; the collection of probes provides very little constraint on the location, shape, or number of sides of  $P$ . Another polygon  $P'$  bears little resemblance to  $P$ , but gives identical results for the collection of probes. In fact, the complete set of probes  $X(P, l(O, \theta))$  through  $O$  over all angles  $\theta$  describes two different polygons,  $P$  and  $P$  reflected through  $O$ , denoted as  $-P$ . Thus it is a

FIG. 1. Different polygons satisfying the same collection of probes.

fundamentally different type of device from the finger probe, although it is not clear which can be considered more powerful.

This paper will give upper and lower bounds on the number of X-ray probes necessary to determine convex  $n$ -gons, as well as for the problem of verifying a conjectured convex polygon. These bounds are based on the powers of different classes of probes, each of which has capabilities and limitations to be examined.

**2. A lower bound for probing.** We can prove a nontrivial lower bound for X-ray probing by a comparison to finger probing.

LEMMA 1. *An X-ray probe  $X(P, l)$  can be simulated by two finger probes.*

*Proof.* Send finger probes down each end of the line, and compute and return the Euclidean distance between these two points.  $\square$

THEOREM 2. *At least  $(3n - 1)/2$  X-ray probes are necessary to determine a convex  $n$ -gon.*

*Proof.* Cole and Yap [1] prove a lower bound of  $3n - 1$  finger probes for determining convex polygons. The result follows from Lemma 1.  $\square$

This bound is probably loose, but the concept of a lower bound on the number of probes is complicated by difficulty in determining exactly what information can be obtained in a constant number of X-ray probes. Since their power comes from collections of probes, a tighter lower bound may be difficult to obtain.

**3. Upper bounds for probing.** To obtain absolute information about  $P$  from X-ray probes, it is necessary to think in terms of groups of probes which work together to determine something about  $P$ . This section considers four different classes of probes, what powers and limitations they possess and how they interact to lead to probing strategies.

**3.1. Origin probes.** The first class of probes are *origin probes*, a set of X-ray probes all aimed through a common point  $O$  within the object. An X-ray probe which hits a convex polygon and avoids its vertices will go through exactly two edges of the object. The largest number of such edge pairs is  $n$ .

LEMMA 3. For any convex  $n$ -gon  $P$  containing  $O$ , there are at most  $n$  distinct pairs of edges  $e_1, e_2$  of  $P$  such that there exists a line which intersects  $e_1, e_2$  and  $O$ .

*Proof.* Consider a line  $l$  through  $O$  which intersects a pair of edges. If we rotate this line clockwise, only when we sweep past a vertex do we intersect a new pair of edges. After rotating past  $n$  vertices and at most  $\pi$  radians, we will return to the original pair. No other distinct pairs can be found, so there exist at most  $n$  opposing edges. Note that there are exactly  $n$  edge pairs unless  $O$  is collinear with two vertices of the  $n$ -gon.  $\square$

We can define a mapping of  $X(P, l(O, \theta))$  to two points  $p_1$  and  $p_2$  on  $l(O, \theta)$  at a distance  $X(P, l(O, \theta))$  from  $O$ , where  $l(O, \theta)$  is the line through  $O$  that encloses an angle of  $\theta$  radians with the  $x$ -axis. By the following result, these points lie on hyperbolas defined by the edges probed through.

LEMMA 4. Let  $l_1: y = m_1x + b_1$  and  $l_2: y = m_2x + b_2$  be two distinct lines and map each angle  $\theta$  to the two points on line  $l(O, \theta)$  at distance  $d$  from  $O$ , where  $d$  is the distance between  $l_1 \cap l(O, \theta)$  and  $l_2 \cap l(O, \theta)$ . Then these points define the hyperbolas

$$y^2 - xy(m_1 + m_2) \pm y(b_1 - b_2) - x^2(m_1m_2) \pm x(m_1b_2 - m_2b_1) = 0.$$

*Proof.* Consider the situation in Fig. 2. The line  $l(O, \theta)$  contains points  $(x, y)$  such that  $y = \tan(\theta)x$ . With  $t = \tan(\theta)$ , we have

$$d = \sqrt{(1 + t^2)(b_2/(t - m_2) - b_1/(t - m_1))^2}.$$

The  $x$ -coordinates of the corresponding points can be found by subtracting the  $x$ -coordinates  $x_1$  and  $x_2$  of the intersections of  $l(O, \theta)$  with  $l_1$  and with  $l_2$ , respectively:

$$x = \pm(x_2 - x_1) = \pm(b_2/(t - m_2) - b_1/(t - m_1)).$$

This can be solved for  $t$  and used with  $y = tx$  to get  $y$  as a function of  $x$ . To obtain a simpler formula, we set  $A = m_1 + m_2$ ,  $B = m_1m_2$ ,  $C = b_1 - b_2$ , and  $D = m_1b_2 - m_2b_1$ . Then we have

$$y = \frac{Ax \mp C + \sqrt{(Ax \mp C)^2 - (4Bx^2 \pm 4Dx)}}{2}$$

and

$$y = \frac{Ax \mp C - \sqrt{(Ax \mp C)^2 - (4Bx^2 \pm 4Dx)}}{2}.$$

After simplification, this reduces to the assertion.  $\square$

FIG. 2. Hyperbolas associated with two straight lines.

We will use Lemma 4 to determine the equations of the lines that contain edge pairs. If we have some number of origin probes through a common edge pair, then we can determine the hyperbolas through the associated points. From the equations of these hyperbolas, we then deduce the equations of the lines.

It is obvious from Fig. 2 that the hyperbolas which satisfy Lemma 4 have asymptotes  $l_1$  and  $-l_2$  and  $l_2$  and  $-l_1$ . If the angle  $\theta$  is such that  $l(O, \theta)$  intersects  $l_1$  and  $l_2$  on opposite sides of  $O$ , then the two hyperbolas that avoid  $O$  are relevant. This will be the most frequent case in our discussion below. If  $l(O, \theta)$  intersects  $l_1$  and  $l_2$  on the same side of  $O$ , then the two hyperbolas through  $O$  are relevant. This occurs when  $O$  is not between the two edges of the pair considered. In both cases, the two relevant hyperbolas are central reflections of each other.

The hyperbolas that show up in Lemma 4 are defined by four constants  $A = m_1 + m_2$ ,  $B = m_1 m_2$ ,  $C = b_1 - b_2$ , and  $D = m_1 b_2 - m_2 b_1$ . It follows that, in general, four probes through a pair of edges is enough to determine the hyperbolas, and from the hyperbolas the equations of the lines that contain the two edges. Given  $A, B, C, D$ , we have

$$m_1 = \frac{A \pm \sqrt{A^2 - 4B}}{2}, \quad m_2 = \frac{A \mp \sqrt{A^2 - 4B}}{2},$$

$$b_1 = \frac{C}{2} \pm \frac{2D + AC}{2\sqrt{A^2 - 4B}}, \quad \text{and} \quad b_2 = \frac{-C}{2} \pm \frac{2D + AC}{2\sqrt{A^2 - 4B}}.$$

From these equations two limitations on our ability to reconstruct the edges are apparent. First, there is the ambiguity between  $P$  and  $-P$ . More serious is that  $b_1$  and  $b_2$  are undefined when the square root vanishes, that is, when  $m_1 = m_2$ . Thus any probing strategy using origin probes must take special action on parallel edges. Note, however, that there is no ambiguity between  $P$  and  $-P$  for parallel edges, since reflection through  $O$  is equivalent to rotation through  $\pi$  radians.

We can now recognize the structure formed by mapping origin probes to points. Each opposing pair of edges gives rise to their own pair of hyperbolas. Two adjacent hyperbolas meet on the line through  $O$  and each vertex. Thus the probes define the extremes of a "spider web"  $S(P)$  (see Fig. 3) around the object. This permits us to interpret an origin probe for  $P$  to be a finger probe on  $S(P)$ . Both  $P$  and  $-P$  generate the same spider web,  $S(P) = S(-P)$ . By Lemma 3,  $S(P)$  consists of at most  $2n$  pieces of hyperbolas.

FIG. 3. The "spider web"  $S(P)$  around a convex polygon  $P$ .

However, to make use of these properties of origin probes for a probing strategy we need some means to verify that four or possibly some higher but constant number of origin probes pass through the same pair of edges. With finger probes, it was possible to confirm an edge with three probes, two to define it and one in between to verify it. Unfortunately, a constant number of extra confirmation probes lying on the same hyperbola is not sufficient to verify an edge pair.

LEMMA 5. *There is no constant  $k$  such that  $k$  probes lying on a hyperbola defined above implies that the probes pass through the same pair of edges of  $P$ .*

*Proof.* The proof is by construction. Figure 4 indicates such a polygon. A convex chain of edges can be used to insure that as many points as desired of  $S(P)$  can be made to lie on a hyperbola of the kind defined in Lemma 4. Let one edge  $e$  lie on the line  $y = x + 1$ , and let  $h$  be the line of points  $(x, y)$  that satisfy  $y = -2$ . We construct a curve  $c$  of points  $p$  with the following property: if  $l$  is a line through  $p$  and  $O$ , then  $l$  intersects edge  $e$  in point  $q$  and line  $h$  in point  $r$  such that the distance from  $p$  to  $q$  is the same as the distance from  $O$  to  $r$ .

FIG. 4. Counterexample to the notion that  $k$  origin probes mapped onto the same hyperbola must intersect the same edge pair.

It is not hard to see that  $c$  is a piece of a hyperbola whose asymptotes are line  $h$  and the line that contains  $e$ . If we pick  $k$  vertices of  $P$  on curve  $c$ , then all origin probes through these vertices are mapped to points on line  $h$ . Thus, if a collection of probes were made through  $O$  and these vertices, they would all be taken as lying on a parallel pair of edges.

By construction,  $S(P)$  has  $k$  vertices on line  $h$  and the hyperbolic pieces connecting any two consecutive vertices lie all above line  $h$ . Thus, a hyperbola of the kind considered in Lemma 4 can be found that intersects  $S(P)$  at least  $2k$  times if it lies close enough and above  $h$ , where the vertices of  $S(P)$  on  $h$  lie.  $\square$

Verifying edge pairs is the motivation for parallel probes, discussed below.

**3.2. Parallel probes.** *Parallel probes* are a set of X-ray probes aimed with a common angle  $\theta$ . A complete collection of parallel probes for a given angle produce a histogram  $H(P, \theta)$  (see Fig. 5) of the thickness of the obstacle. This is the situation in a medical

FIG. 5. The “histogram”  $H(P, \theta)$ ,  $\theta = 0$ , of a convex polygon  $P$ .

X-ray photograph. Formally,  $H(P, \theta)$  is obtained as follows. Let  $b$ , the baseline, be normal to the probing direction  $\theta$  and call one of the half-planes defined by  $b$  its *positive side*. Let  $l(b, p)$  be the line normal to  $b$  such that  $p = b \cap l(b, p)$ ; thus,  $l(b, p)$  has angle  $\theta$ . We map the probe  $X(P, l(b, p))$  into the point on  $l(b, p)$  at distance  $X(P, l(b, p))$  from  $b$  that lies in the positive side of  $b$ .  $H(P, \theta)$  is the polygon bounded by  $b$  and the images of all probes with angle  $\theta$ . For a convex  $n$ -gon this histogram will be bounded by up to  $n$  line segments, including the one on  $b$ .  $H(P, \theta)$  is convex for all convex  $P$  over all angles  $\theta$ . Note that an X-ray probe with angle  $\theta$  can be interpreted as a finger probe on  $H(P, \theta)$ . Each vertex of  $H(P, \theta)$  determines a line on which must lie a vertex of  $P$ . Thus they provide a capability for verifying edge pairs.

LEMMA 6. *Three parallel probes are sufficient to verify an edge pair.*

*Proof.* Parallel probes measure the distance between two line segments. Thus three parallel probes are mapped to three collinear points on the boundary of  $H(P, \theta)$  if they intersect the same two segments. No three parallel probes hitting different edge pairs can be mapped to collinear points without violating convexity.  $\square$

There are two apparent weaknesses of parallel probes. First, a finite number of them cannot be guaranteed to locate certain vertices, specifically the extreme vertices that correspond to the vertices of  $H(P, \theta)$  that lie on the baseline  $b$ . Without any bounding information, repeated probes may intersect the same pair of edges. Second, once a vertex is finally located, it is impossible without more information to distinguish whether there are one or two vertices on the line. Convexity restricts the number of collinear vertices to two. This phenomenon relates to the fact that  $H(P, \theta)$  neither determines  $P$  nor the number of its vertices.

It is interesting to consider using an infinite number of parallel probes, as approximated in medical X-ray photographs where all probes perpendicular to the photographic plate are recorded at once. The first weakness vanishes although the second remains. This problem was first posed for convex sets by Hammer in 1963 [8] and has generated a substantial literature [9]–[12]. The power of such a probe which returns  $H(P, \theta)$  for a specified  $\theta$  is evident in that only a constant number of *photograph probes* are needed to determine any convex polygon.

THEOREM 7. *Three X-ray photograph probes are sufficient to determine a convex polygon  $P$ .*

*Proof.* The strategy is as follows. Each photograph probe can be defined by its baseline. For the first two probes, use baselines  $b_1$  and  $b_2$  that are not parallel to each

other. Since according to the observation above, each of these probes defines up to  $n$  lines on which all vertices of  $P$  must lie, two intersecting probes will define up to  $n^2$  points at the intersection of these lines. The vertices of  $P$  must be a subset of these points. The third baseline  $b_3$  is selected such that the line through each of these points perpendicular to  $b_3$  is unique. The  $n$  points on this histogram uniquely identify each of the vertices of  $P$ .  $\square$

Because an X-ray photograph probe captures in one probe a representation of the entire polygon, they may provide a way to extend probing results to nonconvex polygons by eliminating the need for an infinite set of probes to hunt for possible concavities.

**3.3. Determining a boundary point.** Since parallel and origin probes have complementary properties of verification and identification, by combining them we can obtain our first piece of absolute information about the polygon. The idea behind this strategy is to bound a section of the polygon where we know there must be at least one edge pair and to repeatedly send parallel probes to this section until three images on the boundary of the corresponding histogram are collinear. Once we have an edge pair, origin probes can be used to determine the lines containing the two edges.

First, a section of the polygon must be bounded. Sending one horizontal probe through  $O$  gives a thickness  $\lambda$  of  $P$  along that  $x$ -axis. At least one of two vertical probes at distance  $\lambda/2$  to the left and to the right of  $O$  must intersect  $P$  and with a vertical probe  $l_O$  through  $O$  define a section which is a vertical strip such that each vertical probe in this strip intersects  $P$ . First, we discuss certain subtleties of the determined section. If both vertical probes  $l_1$  and  $l_2$  at distance  $\lambda/2$  from  $O$  intersect  $P$ , as in Fig. 6, we cannot be sure for which side of  $O$  the  $x$ -axis is within  $P$ , and thus we cannot be certain about any new interior points. In this case, we choose our section to be either to the left or to the right of  $O$ .

To find a first edge pair, we send vertical probes in the identified section until three points on the boundary of the associated histogram  $H(P, \pi/2)$  are collinear. All points lie on at most  $n-1$  edges of  $H(P, \pi/2)$  and all but one edge contains at most two of the points. It follows that we succeed after at most  $2n-3$  additional vertical probes, since we already have two vertical probes which bounded the probed section

FIG. 6. Identifying a section to parallel probe.

of  $P$ . Once we have vertical probes through an edge pair, four origin probes through a common point, called the origin, can be used to determine the lines that contain the two edges. By picking the origin for this collection of probes to be where the center parallel probe intersects the  $x$ -axis, we need only make three new probes. One final probe can distinguish between the edges of  $P$  and those of  $-P$ .

In order to origin probe the edge pair between the section defined by two vertical probes, we must have an upper bound  $U$  on the distance the edges within this section are from the  $x$ -axis. Without this knowledge, we cannot design origin probes which we can be certain will intersect the boundary of  $P$  within the section, and thus whether the origin probes all hit the same pair of edges. For the situation where exactly one of the two initial vertical probes  $l_1, l_2$  intersects  $P$ , we know that the  $x$ -axis intersects  $P$  throughout the resulting section. In this case we can bound  $U$  because it is clear that the distance of a point from the  $x$ -axis is no larger than the height of the associated histogram at the vertical line through the point.

This argument fails in the case of Fig. 6, since we cannot be certain on which side  $P$  contains the  $x$ -axis. We will use a convexity argument to put a bound on  $U$ . Let us arbitrarily select the section to the right of  $O$ . If this section contains the  $x$ -axis, we know a bound on  $U$ . If not, we know that the other section contains the  $x$ -axis within  $P$  for a distance  $\lambda/2$ . The slope of the upper edge of  $P$  that intersects the  $y$ -axis is greatest if it is the only upper edge of the left section,  $l_1 = l(-\lambda/2, 0, \pi/2)$  intersects  $P$  entirely below the axis and  $l_0 = l(O, \pi/2)$  intersects  $P$  entirely above the axis. By convexity, no edge in the other section can increase faster than this line, which passes through the points  $(0, X(P, l_0))$  and  $(-\lambda/2, -X(P, l_1))$ . Reflecting this situation along the  $x$ -axis bounds the lower edges, and together provides the information we need to origin probe.

A further complication occurs when the edge pair is parallel, meaning  $b_1$  and  $b_2$  are undefined. If another potential edge pair exists in this section, that is, it required more than five parallel probes within the section to locate the parallel edge pair, this nonparallel edge pair can be uncovered by a total of  $2n$  parallel probes, since now two edge pairs can have three probes each.

If the first edge pair is parallel and another edge pair is not known, we must now repeat the sectioning process parallel to the original pair. Clearly, a line  $l_p$  through  $O$  parallel to the first edge pair intersects  $P$  between the edge pair. By a process of binary search, we can enlarge this strip of  $P$  known to lie between the edge pair as much as desired. If  $\delta_1$  is the distance between the two edges, a probe parallel to  $l_p$   $\delta_1/2$  below  $l_p$  widens this strip by  $\delta_1/2$ . If this probe intersects  $P$ , the strip is between  $l_p$  and the last probe. Otherwise, the strip is on the other side of  $l_p$ . Similarly, we can widen this known strip to  $3\delta_1/4$  with a probe parallel to  $l_p$   $\delta_1/4$  on either side of the known strip. We can continue to widen this strip by this method, although for our purposes two of these probes will suffice. This strip will serve to define a section for the next set of probes. Note that there is no reason to actually probe  $l_p$  and that at this point we do not know how long the edges of the first parallel pair are.

Since these probes are parallel with our previously encountered edge pair, they will intersect at least two edges different from the parallel edge pair. We will make five of these, one at each side of the boundary of our  $3\delta_1/4$  region, two more within this region  $\delta_1/2 + \epsilon$  apart for  $0 < \epsilon < \delta_1/4$ , and one between these final two probes. Note that it may be possible to reuse the binary search probes, but only if they intersected  $P$ . If the center three of these probes are not all of the same magnitude, they do not all intersect a parallel pair of edges. Thus with up to  $2n - 3$  more parallel probes we can locate a nonparallel edge pair, which can be origin probed to determine

the edge pair. Unfortunately, as in Fig. 7, the center three probes can instead intersect a parallel edge pair. This parallel edge pair must be greater than  $\delta_1/2$  in length.

If  $\delta_2$  is the distance between the second pair of parallel edges, we can define a strip  $3\delta_2/4$  wide within  $P$  through the binary search strategy using probes parallel to the second edge pair. Two parallel probes within this strip  $\delta_2/2 + \epsilon$  apart for  $0 < \epsilon < \delta_2/4$  can confirm that the first edge pair is greater than  $\delta_2/2$  in length. If this is not the case, we can find a nonparallel edge pair between the offending probe and the appropriate end of the  $3\delta_2/4$  region. Otherwise, the intersection of the two strips defines a rhombus  $Q$  which must lie within the interior of  $P$ . We note that the remainder of  $P$  must lie in strips less than  $\delta_1/2$  and less than  $\delta_2/2$  wide around  $Q$ . Extending these boundaries for each of the two edge pairs surrounds  $Q$  by a skewed grid of eight regions, which together contain all of the edges of  $P$ . None of these regions can contain parallel edges, since  $P$  is convex. Further, no three neighboring regions around  $Q$  including only one corner region contain any parallel edges.

Referring to Fig. 7, it is clear that a probe  $X$  from the upper left corner of the top-central region to the bottom right corner of the right-central region cannot intersect a parallel pair of edges. Because of the size and position of the central region, this probe must intersect  $Q$ , meaning it intersects a nonparallel edge pair. Along with a probe parallel to  $X$  that intersects the upper right-hand corner of  $Q$  this defines a section which can only contain nonparallel edge pairs, and thus can be parallel probed until three are collinear on the histogram. Using the earlier counting argument with  $n - 2$  edges, since the other two parallel edges cannot be within the section, shows finding an edge pair can require up to  $2n - 5$  additional probes.

Finally, one confirmation probe of the nonparallel edge pair will distinguish the edges on  $P$  from the pair on  $-P$ . Note that there is no ambiguity between  $P$  and  $-P$  for the parallel edge pairs.

LEMMA 8. *With restriction to origin and parallel probes,  $2n + 23$  X-ray probes are sufficient to identify the lines that contain the first pair of edges and a point on one of the two edges.*

FIG. 7. Handling parallel edge pairs.

*Proof.* The above strategy will identify the lines that contain a pair of edges and a point on one of the two edges. The final accounting of probes is as follows. Four probes were used initially to define a section to probe, at least two of which can serve as parallel probes. Three more parallel probes can identify an edge pair, with the center three probes incident on a parallel pair of edges. Three origin probes found the slopes of these lines. Two parallel probes will widen the strip to  $3\delta_1/4$ . Up to five probes between the two edges will identify that this edge pair is also parallel, and three more are necessary to origin probe it. Two more probes widen the new strip, two more enlarge  $Q$ , and two diagonal probes select a nonparallel section.  $2n - 5$  parallel probes in this section will locate a nonparallel edge pair, the first two of which were the diagonal probes. Three more origin probes find the equations of these lines. Finally, there is the confirmation probe. Thus two edges can be determined in a total of

$$4 + 3 + 3 + 2 + 5 + 3 + 2 + 2 + 2 + (2n - 5 - 2) + 3 + 1 = 2n + 23$$

probes. Any point on these two edges within the appropriate section is on the boundary of  $P$ .  $\square$

A complete probing strategy for  $P$  could perhaps be constructed along these lines by repeating the process for each pair of edges. However, since  $O(n)$  edge pairs can be parallel this would lead to a quadratic number of probes. A simpler strategy can be developed once we know a point on the boundary of  $P$ .

**3.4. Boundary probes.** The power of the finger probe is that it returns a point on the boundary of the polygon. To get a similar effect, we define the *boundary probe*, which relies on the observation that sending an X-ray line probe through a known point on the boundary of a convex polygon identifies another point on the boundary of the polygon. This means that once we have identified the coordinates of any point  $p$  on the boundary of the polygon, any X-ray probe through  $p$  determines another boundary point. If we also are given a boundary point we can formulate our first probing algorithm.

**THEOREM 9.** *With restriction to origin, boundary, and parallel probes,  $5n + 19$  probes suffice to determine a convex  $n$ -gon  $P$ .*

*Proof.* By Lemma 8,  $2n + 23$  probes suffice to find a boundary point and to semi-verify two edges, in the terminology of Cole and Yap [1]. Cole and Yap give a strategy requiring  $3n$  finger probes to determine polygons which can be adapted by using boundary probes in place of finger probes.

Starting from one of the semi-verified edges, we will walk along the polygon, conjecturing vertices based on the intersection of the semi-verified edge and the line defined by the next two known points. Each of the  $n$  vertices will eventually be probed, and each of the  $n - 2$  other edges will have at most two interior points probed, for a total of  $5n + 19$ .  $\square$

Being clever about reinterpreting the parallel probes may reduce the total by  $O(n)$  more probes since once the edge one of them passed through is determined, a probe on an unverified edge can be recorded. No doubt, the additive constant of Lemma 8 can be lowered by more careful arguments.

Note that Cole and Yap's optimal  $3n - 1$  strategy cannot be adapted to X-ray probes since they probe along a semi-verified edge to obtain a vertex, which will not work with X-ray probes unless the location of the other vertex is known.

**3.5. Close probes.** If the measurements we have been using were performed on real sensing devices, there will be some uncertainty with respect to accuracy. Thus for us to completely determine an  $n$ -gon we must know that no edge has length less than

this uncertainty, or else we could never find the edge. Knowing a lower bound on the length of all the edges  $\varepsilon$  gives us extra information about the polygon. We can exploit this with a collection of *close probes*, where each probe depends on intersecting a point on the boundary within some fraction of  $\varepsilon$  of another close probe.

Close probes present a problem because they suggest strategies that are somehow “unfair” as they require additional information. Certainly in any physical implementation they would be extremely nonrobust. The virtue of close probes is that they enable us to find a boundary point in a constant number of X-ray probes, as opposed to the linear probing strategy described above.

**LEMMA 10.** *Two lines that contain a pair of edges of a convex polygon  $P$  and a point on one of the two edges can be determined in 37 X-ray probes including close probes.*

*Proof.* Our strategy is similar to that used in Lemma 8, but modified to take advantage of close probes. It should be noted that there is no fraction  $\alpha$  such that parallel probes within  $\alpha\varepsilon$  of each other are guaranteed to intersect the same edge pair. The reason is that the angle between two edges can be arbitrarily close to  $\pi$ , so even a long edge can slip between two seemingly close probes. Thus the largest angle between edges will have to be bounded to take advantage of close probes.

We will replace the linear strategy of searching a bounded section of  $P$  for an edge pair by the following constant one. Within the bounded section of  $P$ , send two more parallel probes, giving four probes intersecting  $P$  labeled from left to right  $a$ ,  $b$ ,  $c$ , and  $d$ . By the argument in the proof of Lemma 8,  $a$  and  $b$  determine the steepest increasing slope possible between  $b$  and  $c$ , and probes  $c$  and  $d$  determine the steepest decreasing slope. We define  $\theta_v$  as the greater of the two angles formed by these steepest increasing and decreasing slopes with the horizontal, so  $\theta_v$  represents the angle nearest to vertical which can occur within the section without violating convexity. An edge pair will be found within seven close probes spaced  $\varepsilon \cos(\theta_v)/8$  apart between  $b$  and  $c$ . Seven are required because up to two vertices, one each from the upper and lower vertex chains of  $P$ , may slip between the close probes.

Thus we can use the strategy of Lemma 8, substituting the two parallel and seven close probes for the linear edge pair search. Using the counting argument of Lemma 8 with this change, we can determine the first edge pair in 37 probes.  $\square$

**THEOREM 11.**  *$3n + 33$  X-ray probes (including close probes) are sufficient to determine a convex polygon  $P$  given a point  $O$  within  $P$ .*

*Proof.* Lemma 10 enables us to find an edge pair in 37 probes instead of the  $2n + 23$  of Lemma 8. Substituting the new strategy for the old improves Theorem 9 by  $2n - 14$  probes, for a total of  $3n + 33$ .  $\square$

It is certainly possible that these constants can be reduced. Other strategies involving close probes are no doubt possible.

It would be nice to find an efficient X-ray probe simulation of a finger probe. It is possible by modifying the above strategy as follows. Make one of the parallel close probes along the desired probing line and then, if it hits on a parallel edge, perform additional boundary probes through the located point to finish the description of the edge pair, and calculate what the finger probe returned. However, since this constant will be over twenty it is unlikely the simulation can prove useful in any context.

**4. Bounds for verification.** A lower bound on the number of probes required to determine an object can be based on a comparison to the *verification* problem. Suppose we are given the representation of a polygon  $P$ . How many probes will be necessary to test whether  $P$  correctly describes a particular object? It is obvious that any lower bound to verification represents a lower bound to the determination problem, since it presupposes knowledge of the polygon.

For verification, clearly each vertex and edge must be confirmed. Otherwise,  $P$  could have a triangle on any unconfirmed edge or be truncated before any unconfirmed vertex. Since an X-ray probe passes through two edges or vertices, and there are at least  $2n$  points of interest, the trivial lower bound is for  $n$  probes. It can be easily shown that three probes do not suffice to verify a triangle, since no matter how the three probes are taken the object would be indistinguishable with one of four or more sides. We conjecture that the actual bound for verification is  $(3n/2)+k$  for some constant  $k$ . This is based on the observation that although  $n/2$  probes are sufficient to verify the edges given the vertices or verify the vertices given the edges, it appears at least  $n$  probes are necessary to verify either the vertices or the edges independently. This conjectured lower bound is sufficient.

**THEOREM 12.**  $(3n/2)+6$  X-ray probes are sufficient to verify a convex  $n$ -gon  $P$ .

*Proof.* Given the polygon to verify, three parallel probes are sufficient to verify the existence of a nonparallel edge pair and three origin probes are enough to define the hyperbola of it. One final probe to verify that  $P$  is not reflected through  $O$  identifies a boundary point.

From this boundary point,  $n$  boundary probes can verify the vertices. The remaining  $n-2$  edges can be verified with  $(n-2)/2$  probes, each bisecting a different pair of edges. Since  $P$  is the convex hull of its vertices, none of these probes can have length other than expected without violating convexity, unless there exists another vertex.  $\square$

**5. Open problems and extensions.** We have given strategies for probing with X-rays. In particular, we have shown that complete information about a convex  $n$ -gon can be obtained with a linear number of carefully planned X-ray probes. Still, the power of X-ray probes is not well understood. For example, no algorithm is known that decides whether or not a given collection of X-ray probes (and answers) determines the probed object.

An obvious extension of our results would be to three or more dimensions. Since the boundary probe generalizes to a finger probe in three or more dimensions, and both parallel and origin probes can identify edge pairs from slices of polytopes, a higher-dimensional probing strategy can be based on ideas in Dobkin, Edelsbrunner, and Yap [3].

A different type of probe to consider would measure the area or volume of intersection with a half-plane or half-space instead of a line. Such an "Archemedian" probe in two dimensions would have as its derivative an X-ray probe. In three dimensions, its derivative is a cross-sectional area probe. We have proved linear upper and lower bounds for determination with half-plane probes [13]. An interesting question is whether better probing strategies will result by having access to two different devices, such as finger and X-ray probing.

It is also worth considering the computational complexity of determining the location of the probes. Finally, a further study of X-ray photograph probes may generalize some of these results to simple polygons and provide some insight into standard image-reconstruction methods.

**6. Acknowledgments.** We thank Vasant Rao for motivating the problem and for his discussion of results from the field of signal processing. We also thank Raimund Seidel for suggesting the construction used in the proof of Lemma 5.

**Note added in proof.** A  $2n$  lower bound for determination can be shown by a topological argument. See [14] for details.

## DEFERRED DATA STRUCTURING\*

RICHARD M. KARP†, RAJEEV MOTWANI†, AND PRABHAKAR RAGHAVAN‡

**Abstract.** We consider the problem of answering a series of on-line queries on a static data set. The conventional approach to such problems involves a preprocessing phase which constructs a data structure with good search behavior. The data structure representing the data set then remains fixed throughout the processing of the queries. Our approach involves dynamic or query-driven structuring of the data set; our algorithm processes the data set only when doing so is required for answering a query. A data structure constructed progressively in this fashion is called a *deferred data structure*.

We develop the notion of deferred data structures by solving the problem of answering membership queries on an ordered set. We obtain a randomized algorithm which achieves asymptotically optimal performance with high probability. We then present optimal deferred data structures for the following problems in the plane: testing convex-hull membership, half-plane intersection queries and fixed-constraint multi-objective linear programming. We also apply the deferred data structuring technique to multi-dimensional dominance query problems.

**Key words.** data structure, preprocessing, query processing, lower bound, randomized algorithm, computational geometry, convex hull, linear programming, half-space intersection, dominance counting

**1. Introduction.** We consider several search problems where we are given a set of  $n$  elements, which we call the *data set*. We are required to answer a sequence of queries about the data set.

The conventional approach to search problems consists of preprocessing the data set in time  $p(n)$ , thus building up a search structure that enables queries to be answered efficiently. Subsequently, each query can be answered in time  $q(n)$ . The time needed for answering  $r$  queries is thus  $p(n) + r \cdot q(n)$ . Very often, a single query can be answered without preprocessing in time  $o(p(n))$ . The preprocessing approach is thus uneconomical unless the number of queries  $r$  is sufficiently large.

We present here an alternative to preprocessing, in which the search structure is built up “on-the-fly” as queries are answered. Throughout this paper we assume that an adversary generates a stream of queries which can cease at any point. Each query must be answered *on-line*, before the next one is received. If the adversary generates sufficiently many queries, we will show that we build up the complete search structure in time  $O(p(n))$  so that further queries can be answered in time  $q(n)$ . If on the other hand the adversary generates few queries, we will show that the total work we expend in the process of answering them (which includes building the search structure partially) is asymptotically smaller than  $p(n) + r \cdot q(n)$ . We thus perform at least as well as the preprocessing approach, and in fact better when  $r$  is small. We do so with no a priori knowledge of  $r$ . We call our approach *deferred data structuring* since we build up the search structure gradually as queries arrive, rather than all at once. In some cases we

show that our deferred data structuring algorithm is of nearly optimal efficiency, even in comparison with algorithms that know  $r$ , the number of queries, in advance.

In § 2 we exemplify our approach through the *membership query* problem. We determine the complexity of answering  $r$  queries on  $n$  elements under the comparison tree model. In § 3 we present a randomized algorithm for the membership query problem whose performance matches an information-theoretic lower bound (ignoring asymptotically smaller *additive* terms). We then proceed to exhibit deferred data structure for several geometry problems. In § 4 we show that deferred data structuring is optimal for the following two-dimensional geometric problems: (1) Given  $n$  points in the plane, to determine whether a query point lies inside their convex hull. (2) Given  $n$  half-planes, to determine whether a query point lies in their common intersection. (3) Given  $n$  linear constraints in two variables, to optimize a query objective function (also linear). Our algorithms are proved optimal by means of a tight lower bound (under the algebraic computation tree model) in § 4.4. In § 5 we consider *dominance problems* in  $d$ -space. We present theorems about the deferred construction of Bentley's ECDF *search tree* [2].

In this paper all logarithms are to the base two.

**2. General principles of deferred data structuring.** In this section we develop the basic ideas involved in deferred data structuring. Let  $X = \{x_1, x_2, \dots, x_n\}$  be a set of  $n$  elements drawn from a totally ordered set  $U$ . Consider a series of queries where each query  $q_i$  is an element of  $U$ ; for each query, we must determine whether it is present in  $X$ .

If we had to answer just one query, we could simply compare the query  $q_1$  to every member of  $X$  and answer the query in  $O(n)$  comparison operations. This would be the preferred method for answering a small number of queries. On the other hand, if we knew that the number of queries  $r$  were large, we could first sort the elements of  $X$  in  $p(n) = O(n \log n)$  operations, then building up a binary search tree  $T_X$  for the elements of  $X$ . We could then do a binary search costing  $Q(n) = O(\log n)$  comparisons for each query; this takes  $O((n+r) \cdot \log n)$  comparisons.

We proceed to determine the complexity (number of comparisons) of answering  $r$  queries on the set  $X$ ; we do not know  $r$  a priori, and each query is to be answered before we know of the next one.

**2.1. The lower bound.** We first prove an information-theoretic lower bound for this problem.

**THEOREM 1.** *The number of comparisons needed to process  $r$  queries is at least  $(n+r) \cdot \log(\min\{n, r\}) - O(\min\{n, r\})$  in the worst case.*

*Remark.* Note that neither of the strategies mentioned above (linear search, or sorting followed by binary search) achieves this bound for all  $r \leq n$ .

*Proof.* If we could collect the  $r$  queries and process them *off-line*, we would have an instance of the SET INTERSECTION problem where we have to find the elements common to the sets  $X = \{x_1, x_2, \dots, x_n\}$  and  $Q = \{q_1, \dots, q_r\}$ . We will prove a lower bound of  $\Omega((n+r) \cdot \log(\min\{n, r\}))$  comparisons for determining the intersection of two sets of cardinalities  $n$  and  $r$ . This off-line lower bound will hold a fortiori for the on-line case in which we are interested. We present the argument for the case  $r \leq n$ ; the other case is symmetrical.

Since we are interested in lower bounds on this problem, we can restrict our attention to only those cases where  $X \cap Q = \emptyset$ . In this case the algorithm has to determine the relation of each element in  $X$  to each element in  $Q$ . An adversary can ensure that for any two elements in  $Q$  there will be at least one in  $X$  whose value lies

between them. In other words, the elements of  $Q$  will partition  $X$  into at least  $r-1$  nonempty classes. Each such class will consist of all those members of  $X$  which lie between two consecutive values in the total ordering of  $Q$ . We shall give an information-theoretic lower bound by counting some ways of arranging  $X$  and  $Q$  to satisfy the above constraint.

There are  $r!$  ways of ordering the elements in  $Q$ . Given a total order on  $Q$ , there are  $(r-1)!$  ways of separating the elements in  $Q$  by some arbitrary  $r-1$  elements from  $X$ . The remaining elements of  $X$  can be placed arbitrarily. There are  $r+1$  available slots as determined by the  $r$  ordered elements of  $Q$ . This can be done in  $(r+1)^{n-r+1}$  ways. Let  $I$  be the total number of interleavings (of  $X$  and  $Q$ ) possible when  $S \cap Q = \emptyset$ . Then the number of possible arrangements specified above is a lower bound on the value of  $I$ :

$$I \geq r! \cdot (r-1)! \cdot (r+1)^{n-r+1}.$$

Since the algorithm has to identify one out of (at least) this many possible arrangements the lower bound is given by  $\log I$ :

$$\log I \geq (n+r) \cdot \log r - 2r \log e.$$

Here  $e$  represents the base of the natural logarithms.  $\square$

**2.2. Upper bounds.** We now present two approaches to obtaining an upper bound which comes within a multiplicative constant factor of the lower bound. The first approach is based on merge-sort, while the second is based on recursively finding medians.

**2.2.1. An approach based on merge-sort.** The following algorithm comes within a constant factor of the lower bound. It uses a recursive merge-sort technique to totally order the elements in  $X$ . The merge-sort proceeds in  $\log n$  stages. At the end of a stage the set  $X$  is partitioned into a number of equal-sized totally ordered subsets called *runs*. Each stage pairs off all the runs resulting from the previous stage and merges them to create longer runs. These stages are interleaved with the processing of a set of queries, until a single totally ordered run remains, whereafter no more comparisons between elements of  $X$  are required. To process a query implies a binary search through each of the existing runs. The number of queries processed between consecutive merging stages or, equivalently, the minimum length of a run before the  $i$ th query, are chosen appropriately.

This algorithm ensures that the size of each run is at least  $L(i)$  before the  $i$ th query. A suitable choice for  $L(i)$  is  $\Theta(i \log i)$ . Since the length of a run must be a power of 2 we will choose

$$L(i) = 2^{\lceil \log(i \log i) \rceil}.$$

The processing cost of going from a stage with runs of length 1 to runs of length  $L(i)$  is  $O(n \log L(i))$ . Thus the total cost of processing in answering  $r$  queries is  $O(n \log r)$ . The search cost for the  $i$ th query is upper bounded by  $n \cdot \lceil \log(L(i)+1) \rceil / L(i)$ . Summing over the first  $r$  queries, the search cost is bounded by

$$\sum_{i=1}^r \frac{n}{L(i)} \cdot \lceil \log(L(i)+1) \rceil = O(n \log r).$$

**THEOREM 2.** *For  $r \leq n$ , the total cost of answering  $r$  queries is  $O(n \log r)$ .*

When  $r > n$ , we note that the set  $X$  will be completely ordered by our strategy. All queries are then answered in time  $O(\log n)$  by binary search.

*Proof.* The processing cost and the search cost are each  $O(n \log r)$ , so that the total cost of answering the first  $r$  queries is  $O(n \log r)$ .  $\square$

**2.2.2. An approach based on recursive median finding.** We now describe an alternative approach based on median finding; a specification of the algorithm in “pseudopascal” follows. The algorithm builds the binary search tree  $T_X$  in a query-driven fashion. Each internal node  $v$  of  $T_X$  is viewed as representing a subset  $X(v)$  of  $X$ —the root represents  $X$ , its left and right children represent the smallest  $(n-1)/2$  and the biggest  $(n-1)/2$  elements of  $X$ , respectively, and so on. Let  $L\text{Son}(v)$  and  $R\text{Son}(v)$  represent the left and right children of  $v$ , respectively. We can now think of building  $T_X$  as follows. For each internal node  $v$ , *expansion* consists of partitioning  $X(v)$  into two subsets of equal size—elements smaller than the median of  $X(v)$ , which will constitute  $X(L\text{son}(v))$ , and elements larger than the median, which will make up  $X(R\text{son}(v))$ . We label  $v$  by the median of  $X(v)$ . Thus a node at level  $i$  represents at most  $n/2^i$  elements of  $X$ .<sup>1</sup> Subsequently,  $L\text{Son}(v)$  and  $R\text{Son}(v)$  may be expanded. Since the median of  $X(v)$  can be found in  $3|X(v)|$  comparisons [12], the expansion of node  $v$  takes  $3|X(v)|$  comparisons. If we begin by expanding the root of  $T_X$  (which represents the entire set  $X$ ), and then expand every node created,  $T_X$  can be built up in  $3n \log n$  comparisons.

The search for a query can be thought of as tracing a root-to-leaf path in  $T_X$ . The key observation is that for any given query  $q_i$ , we need only expand those nodes visited by the search for  $q_i$ ; this is the query-driven tree construction referred to earlier. After each expansion, at most one of the resulting offspring will be visited. The first query  $q_1$  is answered in  $O(n + n/2 + \dots) = O(n)$  operations while building up one root-to-leaf path of  $T_X$ . The time taken to answer  $q_1$  is thus within a constant factor of the time for a linear search. In the process of answering  $q_1$ , we have developed some structure that will be useful in answering subsequent queries; any future search that visits a node that is already expanded will only cost us a single comparison to proceed to the next level of the search; there is no further expansion cost at this node. Nodes that remain unexpanded will be expanded when other queries visit them. When  $n$  queries that visit all  $n$  leaves have been answered,  $T_X$  will have been completely built up. In essence, we are dispensing with an explicit preprocessing phase, i.e., we are doing “preprocessing” operations only when needed. The cost of building the data structure is distributed over several queries.

**DETAILED DESCRIPTION OF THE ALGORITHM.** With every node in the tree we associate a set of values and a label, both of which may at times be undefined.

**Main body**

- Step 1. Initialize the tree,  $T_X$ , with the  $n$  data keys at the root.
- Step 2. Get a query  $q$ .
- Step 3.  $\text{Result} \leftarrow \text{SEARCH}(\text{root}, q)$ .
- Step 4. Output the result.
- Step 5. Goto Step 2

**procedure SEARCH ( $v$ : node;  $q$ :query): boolean;**

- Step 1. If ( $v$  is not labeled) then EXPAND ( $v$ ).
- Step 2. If ( $\text{label}(v) = q$ ) then return *true*.
- Step 3. If ( $v$  is a leaf node) then return *false*.

<sup>1</sup> Actually it represents slightly fewer elements, since each node picks up one element of  $X$  as its label. This does not matter, as we are deriving an upper bound.

*Step 4.* If  $(q < \text{label}(v))$  then return SEARCH ( $\text{left\_child}(v)$ ,  $q$ ).

*Step 5.* If  $(q > \text{label}(v))$  then return SEARCH ( $\text{right\_child}(v)$ ,  $q$ ).

**procedure EXPAND ( $v$ : node);**

*Step 1.*  $S \leftarrow \text{set}(v)$ .

*Step 2.*  $m \leftarrow \text{MEDIAN\_FIND}(S)$ .

*Step 3.*  $\text{label}(v) \leftarrow m$ .

*Step 4.* if  $(|S| = 1)$  then return.

*Step 5.*  $S_l \leftarrow [x \mid x \in S \text{ and } x < m]$ .

*Step 6.*  $S_r \leftarrow [x \mid x \in S \text{ and } x > m]$ .

*Step 7.*  $\text{set}(\text{leftchild}(v)) \leftarrow S_l$ .

*Step 8.*  $\text{set}(\text{rightchild}(v)) \leftarrow S_r$ .

It should be noted that the two subsets,  $S_l$  and  $S_r$ , are computed by the procedure MEDIAN\_FIND as part of the process of finding the median. There is no extra work associated with determining these two sets once the median has been found.

In order to analyze our algorithm, let us define a function on  $n$  and  $r$  as follows:

$$\Lambda(n, r) = \begin{cases} 3n \log r + r \log n, & r \leq n, \\ (3n + r) \cdot \log n, & r > n. \end{cases}$$

Note that  $\Lambda(n, r) = \Theta((n+r) \cdot \log \min(n, r))$  since  $r \cdot \log n \leq n \cdot \log r$  for  $r \leq n$ .

**THEOREM 3.** *The number of operations needed for processing  $r$  queries is no more than  $\Lambda(n, r)$ .*

*Proof.* Consider the case  $r \leq n$ . No more than  $r$  nodes will be expanded at any level of  $T_X$ , after  $r$  queries. For nodes in the top  $\log r$  levels, the total cost is thus less than  $3n \log r$ . This is because *all* nodes may be expanded at each of the first  $\log r$  levels. The expansion of a node  $v$  entails finding the median of  $X(v)$  and this requires at least  $3|X(v)|$  comparisons in the worst case [12]. For  $i > \lceil \log r \rceil$  the node-expansion cost at level  $i$  is  $O(r \cdot n/2^i)$ . This is because the cost of expanding a node at level  $i$  is at most  $3 \cdot n/2^i$ . Summing over all but the first  $\lceil \log r \rceil$  levels, the cost of node expansion at these levels is  $O(n)$ . In addition to the expansion cost, we have to consider the cost associated with search; this is at most  $\log n$  comparisons per query. The search component of the cost is thus always less than  $r \log n$ .

When  $r$  exceeds  $n$ , the expansion cost can never exceed the cost of constructing  $T_X$  completely; this cost is  $3n \log n$ . Again, note that the factor of 3 comes from the median-finding procedure.  $\square$

**2.3. A general paradigm for deferred data structuring.** We are now ready to state the general paradigm for deferred data structuring. This paradigm will isolate some features essential for a search problem to be amenable to this approach, and will simplify our description of the geometric search problems considered in §§ 4 and 5. It also enables us to identify some problems where this approach is not likely to work.

Let  $\Pi$  be a search problem with the following properties. (1) The search is on a set  $S$  of  $n$  data points (in the above example,  $S = X$ ). (2) A query  $q$  can be answered in  $O(n)$  time. (3) In time  $O(n)$ , we can partition  $S$  into two equal-sized subsets  $S_1$  and  $S_2$  such that (i) the answer to query  $q$  on set  $S$  is equal to the answer to  $q$  on either  $S_1$  or  $S_2$ ; (ii) in the course of partitioning  $S$  we can compute a function on  $S$ ,  $f(S)$ , such that there is a constant time procedure, TEST ( $f(S)$ ,  $q$ ), which will determine whether the answer to  $q$  on  $S$  is to be found in  $S_1$  or  $S_2$ . (In the above example  $f(S) = \text{MEDIAN}(S)$  and TEST is a simple comparison operation.)

Under these conditions, we can adopt the deferred data structuring approach that builds the search tree gradually. We illustrate this paradigm by several geometric examples in §§ 4 and 5.

**3. A randomized algorithm.** In the last section we saw a deterministic algorithm to answer  $r$  queries in  $O((n+r) \cdot \log \min \{n, r\})$  time using deferred data structures. The upper bound of Theorem 3 exceeds the information-theoretic lower bound by a factor of 3 if we use the median algorithm given in [12]. Finding the median of  $n$  elements takes  $3n$  comparisons and this is what leads to the gap between the upper and lower bounds. A careful implementation would reduce the constant factor to 2.5 by passing down certain partial orders generated in the median-finding algorithm from parent to children nodes. More easily implemented algorithms given in [3] would yield even higher constant factors. There is an algorithm due to Floyd [7] which computes the median in  $3n/2$  expected time. Its use would reduce our constant to  $3/2$ . Here we present a randomized algorithm in which the number of comparisons will be optimal (with high probability).

The randomized algorithm differs from the one in § 2 in just one respect. The median of the set of values stored at a node was used earlier to get a partition for the purposes of node expansion. Here we will use a *mediocre* element for the same purpose. The mediocre element will be chosen to be quite close to the median. More precisely, the rank of a mediocre element from a set of size  $t$  will lie in the range  $t/2 \pm t^{2/3}$ . We will use randomized techniques to compute a mediocre element efficiently. First, a random subset of size  $O(t^{5/6})$  is chosen from the  $t$  elements. The median of this random subset is a good candidate for being a mediocre element. It takes  $t + O(t^{5/6})$  comparisons to pick a random sample and test its median element for “mediocrity” (see Step 5 below). This sampling is repeated until a mediocre element is found. The call to the procedure MEDIAN\_FIND, in the algorithm outlined in § 2, should be replaced by a call to the procedure MEDIOCRE\_FIND outlined below.

**procedure MEDIOCRE\_FIND (T: set of values): value;**

Step 1 Let  $t = |T|$ .

Step 2 Pick a random sample  $S$  of size  $2 \cdot \lceil t^{5/6} \rceil + 1$  from  $T$ .

Step 3  $m \leftarrow \text{MEDIAN\_FIND}(S)$ .

Step 4 Compute rank( $m$ ) by comparing with each element of  $T - S$ .

Step 5 If rank( $m$ ) is not in the range  $(t/2) \pm t^{2/3}$  then goto Step 2.

Step 6 Return  $m$ .

Note that in Step 4 we need not compare  $m$  with elements of  $S$  since we assume that the procedure MEDIAN\_FIND implicitly gives us the partition of  $S$  with respect to  $m$ . At the last few levels we will revert to deterministic median finding since the node sizes will be too small to justify randomization. A good choice is to use procedure MEDIOCRE\_FIND for the first  $\log n - 5$  levels and procedure MEDIAN\_FIND thereafter. The randomized algorithm leads to the following theorem.

**THEOREM 4.** *Let  $T(n, r)$  be the total number of comparisons made by the randomized algorithm in answering  $r$  queries on  $n$  elements. Then the following holds with probability greater than  $1 - \log r / \beta \cdot n$ ,*

$$T(n, r) \leq \begin{cases} (1 + \alpha)(n \log r + r \log n), & r \leq n, \\ (1 + \alpha)(n + r) \log n, & r > n, \end{cases}$$

where  $\beta$  depends on the value of the constant  $\alpha$ .

The remainder of this section is devoted to the proof of this theorem. The proof will be organized into five lemmas.

The use of mediocre elements (instead of the median) may result in uneven splits, causing an imbalance in the binary search tree being created. Nevertheless, the following lemma shows that the higher of the new binary search tree cannot be much worse than  $\log n$ . We also show that the number of elements associated with each node at level  $i$  is close to  $n/2^i$ . Let the size of a node in the search tree be the number of elements associated with that node.

LEMMA 1. Let  $s_i$  be the size of some node at level  $i$ . Then,

$$n_i \left( 1 - \frac{20}{n_i^{1/3}} \right) \leq s_i \leq n_i \left( 1 + \frac{20}{n_i^{1/3}} \right),$$

provided  $n_i \geq 22$ , where  $n_i = n/2^i$ .

*Proof.* We will prove one side of the inequality by means of induction on the levels. The inequality is clearly true at the root ( $i = 0$ ) since  $s_0 = n$ . Suppose the inequality holds up to level  $i - 1$ , i.e.,  $s_{i-1} \leq n_{i-1} \cdot (1 + 20/n_{i-1}^{1/3})$ . We now partition the  $s_{i-1}$  elements about the mediocre element. Let  $s_i$  denote the larger of the two partition sets. By the definition of the mediocre element we have  $s_i \leq s_{i-1}/2 + s_{i-1}^{2/3}$ . Using the fact that  $(1 + x)^a \leq 1 + a \cdot x$ ,  $0 \leq a \leq 1$  we get,

$$s_i \leq n_i \left( 1 + \frac{1}{n_i^{1/3}} \left( 11 \cdot 2^{2/3} + \frac{40}{3} \cdot \frac{2^{1/3}}{n_i^{1/3}} \right) \right).$$

For  $n_i \geq 22$ , we note that,

$$\left( 11 \cdot 2^{2/3} + \frac{40}{3} \cdot \frac{2^{1/3}}{n_i^{1/3}} \right) \leq 20.$$

This implies the desired result,

$$s_i \leq n_i \left( 1 + \frac{20}{n_i^{1/3}} \right)$$

provided  $n_i \geq 22$ .  $\square$

LEMMA 2. *The height of the binary search tree in the randomized algorithm will be  $\log n + O(1)$ .*

*Proof.* At level  $k = \log n - 5$  we will no longer be using mediocre elements to expand a node. Instead, we use the median of the set of elements stored at a node to partition those elements. At this point Lemma 1 is still applicable since  $n_k = 32 \geq 22$  and we have,

$$s_k \leq n_k \left( 1 + \frac{20}{n_k^{1/3}} \right) \leq 2^8.$$

Thus, the total number of levels is no more than  $k + 8$ . The height of the tree is bounded by  $\log n + 3$ .  $\square$

From Lemma 2 it follows that the cost of searching in the randomized binary search tree will be close to optimal. Let us now consider the cost of constructing the tree, in particular the total cost of node expansions. The following result shows that the median of the random sample is a mediocre element for the entire set with very high probability.

LEMMA 3. *Let  $p(t)$  be the probability that a single iteration of the random sampling does not come up with a mediocre element for a set of size  $t$ . Then,*

$$p(t) \leq 2 \cdot t^{1/2} \cdot \exp(-4 \cdot t^{1/6}) \leq \frac{1}{4t}.$$

*Proof.* Let  $T$  be a set of size  $t$  to which a single iteration of the random sampling process has been applied. First, a random subset  $S$  of size  $s(t) = 2 \cdot f(t) + 1$  is chosen, where  $f(t) = \lceil t^{5/6} \rceil$ . The median of  $S$  is tested for being a mediocre element of  $T$ . In other words, the rank of the median of  $S$  should be in the range  $t/2 \pm t^{2/3}$  in  $T$ . Let  $P(x_r)$  be the event that the element  $x_r$  (the element of rank  $r$  in  $T$ ) is the median of  $S$ :

$$P(x_r) = \binom{r-1}{f(t)} \cdot \binom{t-r}{f(t)} / \binom{t}{s(t)}, \quad f(t) < r \leq t - f(t).$$

Let  $d(t) = t^{2/3}$ . We will refer to  $f(t)$  and  $d(t)$  as  $f$  and  $d$ , respectively, to simplify the following description. Clearly,

$$p(t) = \sum_{r=f+1}^{t/2-d} P(x_r) + \sum_{r=t/2+d}^{t-f} P(x_r) = \frac{2s}{t-2f} \sum_{r=f+1}^{t/2-d} \binom{r-f}{r} \cdot \binom{r}{f} \cdot \binom{t-r}{f} / \binom{t}{2 \cdot f}.$$

We make use of Stirling’s formula:

$$n! = (2\pi n)^{1/2} \left(\frac{n}{e}\right)^n e^{k_n}, \quad \frac{1}{12n+1} < k_n < \frac{1}{12n}$$

to derive the following inequality upon considerable simplification:

$$p(t) < 2 \cdot f^{1/2} \cdot \exp\left(\frac{-4fd^2}{t^2}\right).$$

Given the choices for  $f(t)$  and  $d(t)$  the bound on  $p(t)$  follows immediately. The second part of the inequality given below is also easy to verify:

$$p(t) < 2 \cdot t^{1/2} \cdot \exp(-4t^{1/6}) < \frac{1}{4t}. \quad \square$$

Consider now the overall cost of expanding the nodes in the randomized algorithm. First, there is the cost of finding the medians of the small random samples. Lemma 5 will show that the cost of finding the medians of the small random samples is small even when summed over the entire tree. More important is the cost of deciding whether the median for the sample is a mediocre element for the entire set. There is no cost associated with the actual partitioning since the testing for “mediocrity” implicitly determines the precise partition (see Step 5 of the procedure `MEDIOCRE_FIND`). Consider the  $i$ th level in the tree being constructed. Let  $m = 2^i$  denote the maximum number of nodes at this level. The sizes of the sets associated with the nodes at this level must lie in the range  $(n_i/2) \pm 20 \cdot n^{2/3}$ , where  $n_i = n/m$  is the average size of these sets. Suppose each application of the random sampling yielded a mediocre element. This would imply that the total cost of testing for mediocrity is  $n$ . However, there will be some bad instances where we do not generate a mediocre element. Let the number of such instances be  $s$  at the  $i$ th level. The next lemma shows that with high probability  $s$  is bounded by  $\epsilon m$ , where  $\epsilon$  is an appropriately small constant. Let  $c_i$  denote the cost of testing for mediocrity at level  $i$ . When  $s \leq \epsilon \cdot m$  we have

$$c_i \leq n + n \cdot \epsilon \left(1 + \frac{20}{n_i^{1/3}}\right) = (1 + \alpha) \cdot n.$$

Since  $n_i > 1$  at all levels it is clear the  $\alpha \leq 21 \cdot \epsilon$ .

**LEMMA 4.** *Let  $C$  denote the sum of  $c_i$  over all but the last  $O(1/\epsilon)$  levels,  $P(C \geq (1 + \alpha) \cdot n \cdot \log r) \leq \log r / k^2 \cdot n$ .*

*Proof.* Let the random variable  $\zeta_i$  denote the number of bad instances in  $l = (1 + \epsilon) \cdot m$  iterations of the random sampling at level  $i$ . We already have bounds on

$p(t)$ , the probability of a single iteration on a node of size  $t$  being bad. The  $l$  iterations at level  $i$  do not use equal-sized sets. Therefore let  $p$  denote the largest value taken by  $p(t)$  at the nodes of that level. Let  $E(\zeta)$  and  $D(\zeta)$  denote the mean and deviation of some random variable  $\zeta$ . The Chebyshev inequality states that  $P(|\zeta - E(\zeta)| \geq \lambda \cdot D(\zeta)) \leq 1/\lambda^2$ . Since  $E(\zeta_i) = l \cdot p$  and  $D(\zeta_i) = (l \cdot p \cdot (1 - p))^{1/2}$  we have the following:

$$P(\zeta_i \geq l - m) \leq \frac{1 \cdot p \cdot (1 - p)}{m \cdot \epsilon^2} \quad \text{when } p \leq \frac{\epsilon}{2 \cdot (1 + \epsilon)}.$$

Using the bounds on  $p(t)$  and the lower bound on the size of a node at level  $i$  we get,  $P(s > \epsilon m) = P(c_i \geq (1 + \alpha) \cdot n) \leq k/\epsilon^2 \cdot n$  for all but the last  $O(\log 1/\epsilon)$  levels,  $k$  is a small constant. Choosing  $\beta = \epsilon^2/k$  and summing the probability over the first  $\log r$  levels yields the required bound.  $\square$

**LEMMA 5.** *When  $r < n$ , the total cost of finding the medians of the random samples is  $O(n^{5/6} \cdot r^{1/6})$  with probability  $1 - \log r/\beta \cdot n$ .*

*Proof.* The cost of finding the median at a node of size  $t$  is  $3t$ . Let the sizes of the two children of this node be  $k \cdot t$  and  $(1 - k) \cdot t$ , where  $k$  lies between  $\frac{1}{2}$  and 1. The cost of finding the medians for the children will be proportional to  $C(k) \cdot t^{5/6}$ , where  $C(k) = (k^{5/6} + (1 - k)^{5/6})$ . Clearly,  $C(k)$  is maximized at  $k = \frac{1}{2}$ . Define  $C = C(\frac{1}{2}) = 2^{1/6}$ . Thus, the cost of finding the medians at a single level increases by at most a factor of  $C$  in going from level  $i$  to  $i + 1$ . We know that the cost of median finding at the first level is  $3 \cdot n^{5/6}$ . Hence, the total median-finding cost for the first  $\log r$  levels is

$$3 \cdot n^{5/6} \cdot (1 + C + C^2 \dots C^{\log r - 1}).$$

This sums to  $O(n^{5/6} \cdot r^{1/6})$  since  $C \leq 2^{1/6}$ . When  $r > n$  the bound on the median-finding cost becomes  $O(n)$ . In our analysis so far we have ignored the repetitions in the median finding for a given node. This will be necessary since not every median of the random sample will be a mediocre element for the entire set. However, the analysis in Lemma 4 also applies to the median-finding cost since it just bounds the number of repetitions of the mediocre finding process at a level.  $\square$

Theorem 4 follows immediately from Lemmas 2, 4, and 5.

**4. Planar convex hull and linear programming problems.**

**4.1. Point membership in a convex hull.** In this section we consider the following problem. We are given a set  $P = \{p_1, p_2, \dots, p_n\}$  of  $n$  data points in the plane. Data point  $p_i$  is specified by its two coordinates  $p_i = (p_{ix}, p_{iy})$ . The convex hull of  $P$  will be denoted by  $CH(P)$ . We are required to answer a series of queries: "Is the query point  $q_j = (q_{jx}, q_{jy})$  included in  $CH(P)$ ?"

We first present two solutions based on the preprocessing approach. Neither of these is optimal for all values of  $r$ . Let  $BCH(P)$  denote those points of  $P$  which lie on the boundary of  $CH(P)$ . A single query can be answered in  $O(n)$  time as follows. Compute the polar angles from  $q_j$  to all the data points. The query point is included in  $CH(P)$  if and only if the range of angles  $\geq 180^\circ$ . Alternatively, we can answer  $r$  queries by first constructing  $CH(P)$  in time  $O(n \log h)$ , where  $h$  is the number of points in  $BCH(P)$  [6], [11]. Now choose a point,  $O$ , in the interior of  $CH(P)$  and divide the plane into  $h$  wedges by means of  $h$  semi-infinite lines originating at  $O$  and going through each of the  $h$  vertices of  $CH(P)$ . Each wedge contains exactly one edge from the boundary of  $CH(P)$ . In any wedge, all points on the same side of this edge as  $O$  must lie inside  $CH(P)$ . To answer a query we first determine the wedge in which it lies in  $O(\log h)$  time by doing a binary search with respect to the angles subtended at  $O$ . We can now test the query point with respect to the edge of the  $CH(P)$  which

lies in that particular wedge to decide the membership in  $\text{CH}(P)$ . This requires a total of  $O((n+r) \cdot \log h)$  operations to answer  $r$  queries.

Our approach to solving the point membership problem using deferred data structuring is based on the Kirkpatrick–Seidel top-down convex-hull algorithm [6]. The edges on the boundary of  $\text{CH}(P)$  consist of an *upper chain* and a *lower chain*. Each of these is a sequence of edges going from the leftmost to the rightmost point in  $P$ . Consider a vertical line which partitions  $P$  into two nonempty subsets. Such a line will intersect with exactly one edge of each chain; these edges will be referred to as the *upper tangent* and the *lower tangent* corresponding to the line. The tangents corresponding to a vertical line which partitions  $P$  into subsets of equal size (which we call the *median line*) are called the tangents of  $P$ . Kirkpatrick and Seidel show that a tangent can be computed in  $O(|P|)$  operations.

We now describe our deferred data structure. In the following description we only refer to the upper chain and tangents; analogous reasoning applies to the lower chain and tangents. The data structure consists of a binary search tree  $T_P$  in which each internal node  $v$  represents a subset  $P(v)$  of  $P$  (where  $P(\text{root}) = P$ ). Associated with  $v$  is an  $x$ -interval  $R_v = [x_L(v), x_R(v)]$ ;  $P(v)$  consists of exactly those data points whose  $x$ -coordinates lie in  $R_v$ . We expand a node by computing the median line of  $P(v)$ . The members of  $P(v)$  are partitioned into two subsets: points lying to the left of the median line and points lying to its right. These are associated with the two children of  $v$ . The tangent for  $P(v)$  can now be computed in  $O(|P(v)|)$  operations. It is possible that the tangents corresponding to the two vertical lines demarcating  $R_v$  may be adjacent in the chain. In fact, the two tangents may be the same. In these degenerate cases we do not need to compute the tangent of  $P(v)$ . Such degeneracies can be identified from the tangents corresponding to the vertical lines bounding  $R_v$  (these tangents will have been computed by ancestors of  $v$ ). If at a node we find that both the upper and the lower tangent are degenerate, we will not expand the node; such a node is a leaf of  $T_P$ . Since at least one new tangent is discovered each time we expand a node, the number of internal nodes of  $T_P$  (and hence the number of leaves of  $T_P$ ) will never exceed  $h$ .

The search for a query traverses a root-to-leaf path in the search tree. A node is expanded when it is first visited. At any node  $v$  the search progresses to its left or right child depending on the  $x$ -coordinate of the query point. In addition, we test whether the query point lies below the upper tangent (extended to infinity in both directions) of  $P(v)$ . If this test fails at any node along the search path we know that the query point lies outside  $\text{CH}(P)$ . Similar tests apply to the lower chain/tangent.

Figure 1 shows an example in which two queries  $q_1$  and  $q_2$  have resulted in the expansion of the root and its two children. The query  $q_1$  lay to the left of the median line of  $P$ , and above the lower tangent of  $P$  (extended to the left by dotted lines). This caused  $\text{LSON}(\text{root})$  to be expanded; at this point we find that  $q_1$  lies below the lower tangent of the left child and is thus outside  $\text{CH}(P)$ . Note that the lower tangents of  $\text{root}$  and  $\text{LSON}(\text{root})$  meet at a point of  $P$ ; this means that we will never again compute a lower tangent in the right-subtree of  $\text{LSON}(\text{root})$ . Similarly,  $q_2$  expands the right child of the root node; it is found to lie between the upper and lower tangents of  $\text{RSON}(\text{root})$ , and is thus in  $\text{CH}(P)$ .

**THEOREM 5.** *The number of operations for processing  $r$  hull-membership queries is  $O(\Lambda(n, r))$ .*

*Proof.* The depth of  $T_P$  never exceeds  $\log n$ . Moreover, a node at level  $i$  can be expanded in time  $O(n/2^i)$ . This fits our paradigm. An analysis similar to the proof of Theorem 2 establishes the result.  $\square$

FIG. 1. Membership in a hull; two queries and the resulting development of  $T_p$ .

**4.2. Intersection of half-spaces.** We consider the problem of determining whether a query point  $q_j = (q_{jx}, q_{jy})$  lies in the intersection of  $n$  half-planes. Let  $H = \{h_1, h_2, \dots, h_n\}$  denote the set of lines which bound the half-planes. We assume that each half-plane contains the origin. If not, we can apply a suitable linear transformation in  $O(n)$  time to bring the origin into the common intersection (provided the intersection of the  $h_i$  is nonempty). This can be done by finding a point in the interior of the intersection [8] and mapping the origin onto this feasible point. We can also test in linear time whether the intersection is empty [8]. Let  $H_i$  denote the half-plane (containing the origin) which is bounded by the line  $h_i$ . We assume in this section that the intersection of the  $H_i$  is bounded—in § 4.3 we will show that the case of an unbounded intersection region is easily handled.

The notion of geometric duality (or polarity) [4], [11] will prove extremely useful in the solution of the next two problems. In the plane this reduces to a transformation between points and lines. The dual of a point  $p = (a, b)$  is the line  $l_p$  whose equation is  $ax + by + 1 = 0$ , and vice versa. A more intuitive definition is illustrated in Fig. 2.

FIG. 2. Duality of points and lines.

The line  $l_p$  is perpendicular to the line joining the origin to the point  $p$ . If the distance between  $p$  and the origin is  $d$ , then the dual line  $l_p$  lies at a distance  $1/d$  from the origin in the opposite direction.

We will now apply the duality transformation to the intersection of the half-planes under consideration. The dual of the line  $h_i$  is a point, which we will denote by  $p_i$ ; we denote by  $P$  the set of these points. The dual of the intersection of the  $H_i$  is the set of all points in  $\mathbf{R}^2$  not in  $\text{CH}(P)$ . The dual of  $q_j$  is a line  $L_j$ . The query point  $q_j$  is in the intersection of the  $H_i$  if and only if  $L_j$  does not intersect  $\text{CH}(P)$ . Thus our problem reduces to determining whether each of a series of query lines intersects the convex hull of a set of points.

The search tree and the node-expansion process are exactly the same as in § 4.1. At each node  $v$ , we compute the intersection of  $L_j$  with the median line of  $P(v)$ . We know that  $L_j$  must intersect  $\text{CH}(P)$  if one of the following holds: (1) the intersection point lies between the upper and lower tangents of  $P(v)$ ; (2)  $L_j$  intersects one of the tangents of the current node. If not, we must continue the search in the left or right child of  $v$ , depending on the slopes of  $L_j$  and the tangent. These three possibilities are illustrated in Fig. 3 by lines  $L1$ ,  $L2$ , and  $L3$ , respectively. In the case of  $L3$ , we see that any intersection of  $L3$  with  $\text{CH}(P)$  must lie to the left of the median line; we therefore continue the search in  $\text{LSON}(v)$ .

The following theorem results.

**THEOREM 6.** *The number of operations for processing  $r$  half-plane intersection queries is  $O(\Lambda(n, r))$ .*

**4.3. Two-variable linear programming.** Let  $L(f)$  be a two-variable linear programming problem with  $n$  constraints and the objective function  $f$ , which is to be minimized subject to these constraints. The algorithms of Dyer [5] and Megiddo [8] can find the optimum for a single objective function in time  $O(n)$ . We consider a query version of the linear programming problem. Each query is an objective function  $f_i$ , and we are asked to solve  $L(f_i)$ .

The preprocessing approach to this problem consists of finding the intersection of the half-planes defined by the constraints. This can be done in  $O(n \log n)$  time by divide-and-conquer. The set of half-planes is partitioned into two sets of almost equal

FIG. 3. Example for testing line intersection with a hull.

sizes. The intersection of half-planes in each subproblem can be found recursively; the two intersections can then be merged in linear time [11]. A binary search for the slope of the objective function then answers each query in  $O(\log n)$  time.

As before, we resort to the geometric dual to solve the problem. We may again assume without loss of generality that the feasible region  $R_L$  is nonempty and contains the origin. Each of the  $n$  constraints defines a half-plane  $H_i$ ;  $R_L$  is the intersection of these half-planes. Using the notation of § 4.1, the dual of  $R_L$  is the exterior of  $CH(P)$ .

To begin with, we will assume that  $R_L$  is bounded. This implies that the origin in the dual plane lies in  $CH(P)$ . The objective function  $f_i$  can be looked upon as a family of parallel lines in the primal. Depending on the slope of  $f_i$ , we need only consider the set of parallel lines above or below the origin. This set of lines dualizes to a semi-infinite straight line with the origin as one endpoint. We call this the objective line  $g_i$ , and note that it intersects the boundary of  $CH(P)$  at one point which corresponds to the optimum solution.

The search tree and node expansion are as in § 4.2. While searching at a node  $v$ , we compute the intersection, if any, of  $g_i$  with the median line of  $P(v)$ . If there is no intersection or if the point of intersection does not lie between the tangents, the search proceeds to the left (right) child of  $v$  if the origin lies to the left (right) of the median line. Otherwise, we proceed in the opposite direction. The search terminates if  $g_i$  intersects a tangent of  $P(v)$ .

When  $R_L$  is unbounded, the origin in the dual plane does not lie in  $CH(P)$ . If  $g_i$  does not intersect  $CH(P)$ , the solution to the problem is unbounded. This can be detected by computing in  $O(n)$  time the polar angle from the origin to all points in  $P$ ; this is done once, at the beginning. If  $g_i$  lies outside the cone defined by this range of angles, it does not intersect  $CH(P)$ . If  $g_i$  intersects  $CH(P)$ , we use the same search procedure as in the bounded case. The two points in  $BCH(P)$  which subtend the extreme angles at the origin are joined by a tangent. Intersection with this tangent is ignored for the termination criterion above.

Figure 4 shows an unbounded feasible region, and the corresponding convex hull in the dual. Two objective functions  $f_1$  and  $f_2$  and their dual objective lines are shown. The arc in the dual indicates the locus of objective lines (e.g.,  $g_2$ ) that do not intersect  $CH(P)$ , and hence have unbounded optima.

FIG. 4. Unbounded linear-programming search example.

**THEOREM 7.** *The number of operations for processing  $r$  two-variable linear programming queries is  $O(\Lambda(n, r))$ .*

**4.4. Lower bounds under the algebraic tree model.** The information-theoretic lower bound of § 2 is not valid for the geometric problems we have been considering in this section. In § 2 we were working with the comparison-tree model of computation, whereas we are allowing arithmetic operations here. We therefore use the *algebraic tree* model of computation [1].

An algebraic computation tree is an algorithm to decide whether an input vector, a point in  $\mathbf{R}^n$ , lies in a point set  $W \subseteq \mathbf{R}^n$ . The nodes in the tree are of three types: *computation* nodes, *branching* nodes, and *leaves*. A computation node has exactly one child and it can perform one of the usual arithmetic operations or compute a square root. A branching node behaves like a node in a comparison tree, i.e., it can perform comparisons with previously computed values. It has exactly two children corresponding to the possible outcomes of the comparison. A leaf is labeled either “Accept” or “Reject,” and it has no children. Each addition operation, subtraction operation or multiplication by a constant costs zero. Every other operation or comparison has a unit cost. The complexity of an algebraic computation tree is the maximum sum of costs along a root-leaf path in the tree. If  $W \subseteq \mathbf{R}^n$ , then  $C(W)$ , the complexity of  $W$ , is the minimum complexity of a tree that accepts precisely the set  $W$ . For any point set  $S \subseteq \mathbf{R}^n$ , let  $\#(S)$  denote the number of connected components of  $W$ . It was shown in [1] that  $C(W) = \Omega(\log \#(W))$ .

We now show a lower bound of  $\Omega((n+r) \cdot \log \min \{n, r\})$  algebraic operations for processing  $r$  hull-membership queries on  $n$  data points. We will in fact show that this bound holds when the  $r$  queries are processed *off-line*. The bound is obtained through a reduction from the SET DISJOINTNESS problem, defined as follows. Given two sets  $X = \{x_1, x_2, \dots, x_n\}$  and  $Q = \{q_1, q_2, \dots, q_r\}$ , determine whether their intersection is nonempty. This problem is a simpler version of the SET INTERSECTION problem mentioned in § 2. We first prove a lower bound on SET DISJOINTNESS.

**THEOREM 8.** *Any algebraic computation tree that solves SET DISJOINTNESS must have a complexity of  $\Omega((n+r) \cdot \log \min \{n, r\})$ .*

*Proof.* Assume without loss of generality that  $r \leq n$ . Every instance of SET DISJOINTNESS can be represented as a point  $\beta = (x_1, \dots, x_n, q_1, \dots, q_r)$  in  $\mathbf{R}^{n+r}$ . Let  $W \subseteq \mathbf{R}^{n+r}$  be the set of all points representing disjoint sets. The complexity of the problem is  $\Omega(\log \#(W))$ , where  $\#(W)$  is the number of connected components of  $W$  [1]. Consider instances for which the  $q_i$  are distinct. The elements of  $Q$  can be ordered as  $\{q_{(1)} < q_{(2)} < \dots < q_{(r)}\}$ , where  $(i)$  represents the index of the  $i$ th smallest value in  $\{q_1, \dots, q_r\}$ . Let  $S_\beta(i) = \{x_k : q_{(i)} < x_k < q_{(i+1)}\}$ , for  $1 \leq i \leq r-1$ . Define  $W^* = \{\beta : |S_\beta(i)| = \lfloor n/(r-1) \rfloor, 1 \leq i \leq r-1\}$ ,  $W^* \subseteq W$ . The subsets of  $W^*$  corresponding to different choices of  $S_\beta$ 's are separated by hyperplanes of the form  $x_i = q_j$ . These hyperplanes are entirely disjoint from  $W$ . This means that if two points in  $W^*$  are separated by these hyperplanes then they must also be separated in  $W$ . Hence, the number of components of  $W$  is at least as large as the number of ways of partitioning  $\{x_1, x_2, \dots, x_n\}$  into the  $S_\beta$ 's as per the definition of  $W^*$ . A counting argument shows that this is at least as large as

$$r! \frac{n!}{(\lfloor n/r \rfloor!)^{r-1}}.$$

From this it follows that the complexity is  $\Omega((n+r) \cdot \log r)$ .  $\square$

**THEOREM 9.** *The complexity of processing  $r$  hull-membership queries is  $\Omega((n+r) \cdot \log \min \{n, r\})$ .*

*Proof.* By reduction from SET DISJOINTNESS in  $O(n+r)$  time. Without loss of generality, assume that the elements of both sets lie in the interval  $[0, 2\pi)$ . Each element  $x_i$  maps onto a point  $p_i$  on the unit circle with polar coordinates  $(1, x_i)$ . This constitutes our data set  $P$ ; note that  $\text{CH}(P) = P$ . Each element  $q_j$  of  $Q$  maps onto a point  $r_j$  with polar coordinates  $(1, q_j)$ . The point  $r_j$  lies in  $\text{CH}(P)$  if and only if  $q_j \in X$ . Thus SET DISJOINTNESS  $\alpha_{n+r}$  HULL-MEMBERSHIP.  $\square$

The lower bound extends to the problems in §§ 4.2 and 4.3.

**4.5. Effect of the number of points on the convex hull.** In this section we return to the problem of determining whether a query point lies within the convex hull of  $n$  given data points. We show that a substantial improvement is possible when  $h$ , the number of data points on the boundary of the convex hull, is much smaller than  $n$ . It is clear that the guarantees of Theorem 4 are too weak in such a case, since it is possible to find  $\text{CH}(P)$  in  $O(n \log h)$  operations by the Kirkpatrick-Seidel algorithm; subsequently, queries can be answered in time  $O(\log h)$  each. This gives a time bound of  $O((n+r) \log h)$  for answering  $r$  queries. This may seem to contradict the lower bound of Theorem 9 but recall that in the lower bound reduction all  $n$  data points were on the boundary of the convex hull. When  $r$  exceeds  $h$ , the algorithm of § 4.1 achieves a time bound of  $O(n \log h + r \log n)$ , since node expansion costs add up to only  $O(n \log h)$ . The cost of searching, however, unfortunately grows as  $r \log n$  because the depth of  $T_P$  may grow as  $\log n$  even though the number of leaves is only  $h$ .

To get around this difficulty we construct, in a dovetailed fashion, two binary search trees  $T_P$  and  $T_D$ . Let  $T$  be the fully expanded version of the search tree constructed by the algorithm of § 4.1. It has  $h$  leaves and can be constructed in  $O(n \log h)$  time. The two trees  $T_P$  and  $T_D$  will be partially expanded versions of  $T$ .  $T_P$  is the version obtained by processing queries according to the algorithm of § 4.1. The other tree  $T_D$  is obtained by partially constructing  $T$  through a deferred depth-first traversal.

The depth-first traversal of a tree with  $l$  leaves can be looked upon as consisting of  $l$  phases, each of which ends when a new leaf is reached. Similarly, the depth-first construction of  $T_D$  can be broken down into  $h$  phases. These  $h$  phases are interleaves with the processing of the first  $h$  queries on the search tree  $T_P$ . Each phase can also be looked upon as the processing of a judiciously chosen query on the tree  $T_D$ . Thus the cost of the deferred construction of  $T_D$  has the same upper bound as that for  $T_P$ .

When  $r$  exceeds  $h$ , the tree  $T_D$  will be fully constructed after the first  $h$  queries have been processed on  $T_P$ . At this point  $T_P$  itself may not be fully expanded; in fact only one leaf may have been exposed in it. Since the  $\text{CH}(P)$  is now completely determined by  $T_D$  we can do away with the two search trees for further query processing. We now resort to the *wedge* method to answer each query in time  $O(\log h)$  (see § 4.1). Since the cost of constructing  $T_D$  is  $O(n \log h)$  the following theorem results.

**THEOREM 10.** *The cost of processing  $r$  hull-membership queries is  $O(\Lambda'(n, r, h))$ , where*

$$\Lambda'(n, r, h) = \begin{cases} n \log r, & r \leq h, \\ (n+r) \cdot \log h, & r > h. \end{cases}$$

Analogous results hold for the problems in §§ 4.2 and 4.3.

**5. Domination problems.** In this section we investigate a problem related to *point domination* in  $k$ -dimensional space. This problem does not fit directly into the paradigm presented at the end of § 2. However, a higher-dimensional analogue of divide-and-conquer enables us to adapt our technique to such problems.

Let  $p_i$  denote the  $i$ th coordinate of a point  $p$  in  $k$ -space. We say that  $p$  dominates  $q$  if and only if  $p_i \geq q_i$  for all  $i, 1 \leq i \leq k$ . Bentley [2] considers the *dominance counting* problem which is also called the *ECDF Searching Problem*. In this problem we are given a set  $P = \{p_1, p_2 \dots p_n\}$  of  $n$  points in  $k$ -space. For each query point  $q$ , we are asked to report the number of points of  $P$  dominated by  $q$ .

Bentley uses a *multidimensional divide-and-conquer* strategy to solve this problem. He constructs a data structure, the *ECDF tree*, which answers each query in  $O(\log^k n)$  time following a preprocessing phase requiring  $O(n \log^{k-1} n)$  time. This result holds for fixed number of dimensions ( $k$ ) and for  $n$  a power of 2. However, a more detailed analysis due to Monier [9] shows the validity of this result for arbitrary  $n$  and  $k$ . In fact, Monier shows that the constant implicit in the  $O$  result is  $1/(k-1)!$ . In the following analysis we too will assume that the number of dimensions is fixed and that  $n$  is a power of 2. Our results can be generalized to allow for arbitrary  $k$  and  $n$  by invoking the results due to Monier.

The basic paradigm of multidimensional divide-and-conquer is as follows: given a problem involving  $n$  points in  $k$ -space, first divide into (and recursively solve) two subproblems each of  $n/2$  points in  $k$ -space, and then recursively solve one problem of at most  $n$  points in  $(k-1)$ -space. When applied to the dominance counting problem, this paradigm yields the following search or counting strategy:

(1) Find a  $(k-1)$ -dimensional hyperplane  $M$  dividing  $P$  into two subsets  $P_1$  and  $P_2$ , each of cardinality  $n/2$ . We will assume that  $M$  is of the form  $x_k = c$ . Hence, all points in  $P_1$  have their  $k$ th coordinate less than  $c$ , while those in  $P_2$  have their  $k$ th coordinate greater than  $c$ .

(2) If the query point  $q$  lies on the same side of  $M$  as  $P_1$  (i.e.,  $q_k < c$ ) then recursively search in  $P_1$  only. It is clear that the query point cannot dominate any point in  $P_2$ .

(3) Otherwise,  $q$  lies on the same side of  $M$  as  $P_2$  (i.e.,  $q_k > c$ ) and we know that  $q$  dominates every point of  $P_1$  in the  $k$ th-coordinate. Now we project  $P_1$  and  $q$  onto  $M$  and recursively search in  $(k-1)$ -space. We also search  $P_2$  in  $k$ -space.

In Fig. 5 we illustrate this strategy for two-dimensional space.

In one-dimensional space the ECDF searching problem reduces to finding the rank of a query value in the given data-set. The one-dimensional ECDF search tree is an optimal binary search tree on the  $n$  points in  $P$ . The  $k$ -dimensional ECDF tree for

FIG. 5. The two cases for dominance counting in 2-space.

the  $n$  points in  $P$  is a recursively built data structure. The root of this tree contains  $M$ , the median hyperplane for the  $k$ th dimension. The left subtree is a  $k$ -dimensional ECDF tree for the  $n/2$  points in  $P_1$ , the points in  $P$  which lie below  $M$ . Similarly, the right subtree is a  $k$ -dimensional ECDF tree for the  $n/2$  points in  $P_2$ , the points in  $P$  which lie above  $M$ . The root also contains a  $(k - 1)$ -dimensional ECDF tree representing the points in the  $P_1$  projected onto  $M$ .

To answer a query  $q$ , the search algorithm compares  $q_k$  to  $c$ , the value defining the median plane  $M$  stored at the root. If  $q_k$  is less than  $c$  then the search is restricted to the points in  $P_1$  only. The algorithm then recursively searches in the left subtree. If, on the other hand,  $q_k$  is greater than  $c$  then the algorithm recursively searches in the right subtree as well as the  $(k - 1)$ -dimensional ECDF tree stored at the root. For the one-dimensional ECDF tree the algorithm is the standard binary tree search. For fixed  $k$ , the preprocessing time to build the  $k$ -dimensional ECDF tree is  $p(n) = O(n \log^k n)$ , and the time required to answer a single query is  $q(n) = O(\log^k n)$ .

We now apply the deferred data structuring technique to the  $k$ -dimensional ECDF tree. As before, we do not perform any preprocessing to construct the search tree. The ECDF tree is constructed on-the-fly in the process of answering the queries. Initially, all the points are stored at the root of the  $k$ -dimensional ECDF tree. In general, when a query search reaches an unexpanded node  $v$  we compute the median hyperplane,  $M_v$ , and partition the data points around  $M_v$ . The two sets are then passed down to the two descendant nodes of  $v$ . We also initialize the  $(k - 1)$ -dimensional ECDF tree which is to be created at  $v$ . Even these lower-dimensional trees are created in a deferred fashion depending upon the queries being answered. The application of deferred data structuring to the ECDF tree results in the following theorem.

**THEOREM 11.** *The cost of answering  $r$  dominance search queries in  $k$ -space is  $O(F(n, r, k))$ , where*

$$F(n, r, k) = \begin{cases} n \log^k r + r \log^k n, & r \leq n, \\ n \log^k n + r \log^k n, & r > n. \end{cases}$$

*Proof.* The proof will be by induction over both  $k$  and  $n$ . It is easy to see that the time required to answer a query remains unchanged by the process of deferring the construction of the ECDF tree. This proof will concentrate on the node-expansion component of the processing cost. Clearly, we need not consider the case where  $r > n$  since the node-expansion cost cannot exceed the total preprocessing cost of the nondeferred ECDF tree. Let  $f(n, r, k)$  denote the *worst-case* node-expansion cost for answering  $r$  queries over  $n$  data points in  $k$  dimensions using a  $k$ -dimensional ECDF tree. When  $r$  exceeds  $n$  we have  $f(n, r, k) = O(n \cdot \log^k n)$  since  $n$  queries, each leading to a different leaf, are sufficient to fully expand the ECDF tree. We will now prove that  $f(n, r, k) = O(n \cdot \log^k r)$  when  $r \leq n$ .

The basis of this induction is the case where  $k = 1$ . Consider the one-dimensional ECDF tree. It is an optimal binary search tree and we can invoke Theorem 3 to show the validity of this theorem. This establishes the base case of our induction over  $k$ , in other words,  $f(n, r, 1) = O(n \cdot \log r)$  when  $r \leq n$ . The induction hypothesis is that the above result is valid for up to  $k - 1$  dimensions, i.e.,  $f(n, r, k - 1) = O(n \cdot \log^{k-1} r)$  when  $r \leq n$ . We now prove that it must be valid for  $k$  dimensions also. At the second level of our nested induction we concentrate on the  $k$ -dimensional ECDF tree and use induction over  $n$ . It is clear that the  $k$ -dimensional ECDF tree for  $n = 1$  points will satisfy the above theorem for  $r \leq n$ . We now assume that the result is valid for up to  $n - 1$  points in  $k$  dimensions. To complete the proof we show that, under the given assumptions, the result can be extended to  $n$  points in  $k$  dimensions.

Consider the root node, say  $V$ , of the  $k$ -dimensional ECDF tree for the  $n$  points in  $P$ . It contains a median hyperplane, say  $M_V$ , which partitions the  $n$  points in  $P$  into two equal subsets,  $P_1$  and  $P_2$ . Recall that  $P_1$  is the set of all those points in  $P$  which lie below  $M_V$ ;  $P_2$  is the set of those points in  $P$  which lie above  $M_V$ . The left and right subtrees of  $V$  are the  $k$ -dimensional ECDF trees for  $P_1$  and  $P_2$ , respectively. We also store at  $V$  a  $(k-1)$ -dimensional ECDF tree, say  $T_1$ , for the projections of the points in  $P_1$  onto  $M_V$ . This lower-dimension tree creates a kind of asymmetry between  $P_1$  and  $P_2$ . This asymmetry can complicate our proof considerably. Therefore, for the purposes of this proof only, we will make a simplifying assumption about the structure of the ECDF tree. We assume that  $V$  also contains a  $(k-1)$ -dimensional ECDF tree, say  $T_2$ , for the projections of the points in  $P_2$  onto  $M_V$ .

The search procedure for the ECDF tree is also modified to introduce symmetry. Given a query  $q$ , we first test it with respect to the median hyperplane  $M_V$ . If it lies above  $M_V$  the search continues in the right subtree of  $V$  and in  $T_1$ . On the other hand, if  $q$  lies below  $M_V$  we continue the search in the left subtree of  $V$  as well as  $T_2$ . The search in  $T_2$  is redundant because  $q$ , lying below  $M_V$ , cannot dominate any point in  $P_2$ . These modifications are made not just at the root but at all nodes in an ECDF tree. It is not very hard to see that these modifications can only increase the running times of our node-expansion algorithm. Moreover, these changes entail performing redundant operations which do not change the outcome of our algorithm. It is clear, therefore, that any upper bounds on the node-expansion costs for the modified ECDF tree also apply to the original deferred data structure.

We now proceed to complete the induction proof for  $r \leq n$ . Let  $r_1$  denote the number of queries which lie below the median hyperplane  $M_V$ . These queries continue the search down the left subtree of the root. Let  $r_2 = r - r_1$  denote the remaining queries which continue the search down the right subtree as they lie above the median hyperplane  $M_V$ . Consider the node-expansion costs involved in processing these queries. Finding the median hyperplane  $M_V$  requires  $O(n)$  operations. The  $r_1$  queries lying below  $M_V$  are processed in the left subtree of  $V$  (a  $k$ -dimensional ECDF tree on  $n/2$  points) and in  $T_2$  (a  $(k-1)$ -dimensional ECDF tree on  $n/2$  points). The remaining  $r_2$  queries are processed in the right subtree of  $V$  (a  $k$ -dimensional ECDF tree on  $n/2$  points) and in  $T_1$  (a  $(k-1)$ -dimensional ECDF tree on  $n/2$  points). This gives us the following bound on the total node-expansion cost entailed by processing  $r$  queries:

$$f(n, r, k) = \max_{r_1+r_2=r} \left\{ f\left(\frac{n}{2}, r_1, k\right) + f\left(\frac{n}{2}, r_2, k\right) + f\left(\frac{n}{2}, r_1, k-1\right) + f\left(\frac{n}{2}, r_2, k-1\right) + O(n) \right\}.$$

Using the induction hypotheses we know the exact form of the functions on the right-hand side of the inequality. In particular, we know that these functions are convex. This implies that the right-hand side of the inequality is maximized when  $r_1 = r_2 = r/2$ . Putting together all this we have the desired result

$$f(n, r, k) = O(n \cdot \log^k r), \quad r \leq n.$$

Again, note that this result is valid only for fixed  $k$  and  $n$  a power of 2. The constant implicit in the  $O$  will, in general, depend on  $k$ . Monier's detailed analyses [9] of Bentley's algorithm also extends our result to arbitrary  $n$  and  $k$ .  $\square$

Bentley [2] actually has a slightly better bound on the preprocessing time for constructing ECDF trees. He makes use of a *presorting* technique to improve the bound

to  $O(n \cdot \log^{k-1} n)$  for  $k$ -dimensional ECDF trees on  $n$  points. He first sorts all  $n$  points by the first coordinate in  $O(n \cdot \log n)$  time. This ordering is maintained at every step, especially when dividing the points into two sets about a median hyperplane for some other coordinate. Consider the two-dimensional ECDF tree. Initially, all  $n$  points are stored at the root in *order by the first coordinate*. After the first query, these  $n$  points are partitioned about a median hyperplane and passed down to the children nodes. The ordering by the first coordinate is maintained during this partition. Let  $P_1$  denote the points being passed down to the left subtree,  $P_2$  denotes the points passed down to the right subtree. In the original ECDF tree we would have constructed a one-dimensional ECDF tree for the points in  $P_1$  and stored it at the root. Instead, we now just store the points of  $P_1$ , in order by the first coordinate, at the root. This process is repeated at every node in the two-dimensional ECDF tree. We now use the two-dimensional ECDF tree as the basic data structure in our recursive construction of a  $k$ -dimensional ECDF tree. In effect, we have done away with the one-dimensional ECDF tree. The preprocessing cost for constructing the presorted  $k$ -dimensional ECDF tree becomes  $O(n \cdot \log^{k-1} n) + O(n \cdot \log n)$ . The new data structure is as easily deferred as the previous one and we have the following result.

**THEOREM 12.** *The cost of answering  $r$  dominance search queries in  $k$ -space is  $O(G(n, r, k))$ , where*

$$G(n, r, k) = \begin{cases} n \log n + n \log^{k-1} r + r \log^k n, & r \leq n, \\ n \log^{k-1} n + r \log^k n, & r > n. \end{cases}$$

*Proof.* The proof follows from a straightforward modification of the proof for Theorem 11. Note that cost of presorting is subsumed by the node-expansion cost when  $r > n$ .  $\square$

**6. Conclusion.** The paradigm of deferred data structuring has been applied to some search problems. In all cases, we considered on-line queries and developed the search tree as queries were processed. For the problems studied, our method improves on existing strategies involving a preprocessing phase followed by a search phase. An interesting open problem is to design deferred data structures for dynamic data sets in which insertions and deletions are allowed concurrently with query processing.

The *nearest-neighbor problem* [13] asks for the nearest of  $n$  data points to a query point. The problem is solved using *Voronoi diagrams* in  $O(\log n)$  search time; the Voronoi diagram can be constructed in  $O(n \log n)$  time. There is no known top-down divide-and-conquer algorithm for constructing the Voronoi diagram optimally. The obvious top-down method of constructing the bisector of the left and the right  $n/2$  points (see [14] for a definition of the bisector of two sets of points) fails, since sorting reduces to computing this bisector. It remains an interesting open problem whether a deferred data structure can be devised for the nearest-neighbor search problem. Note that the techniques of § 2 can be used to solve the one-dimensional nearest-neighbor problem.

## ON SETS TRUTH-TABLE REDUCIBLE TO SPARSE SETS\*

RONALD V. BOOK† AND KER-I KO‡

**Abstract.** We study sets that are truth-table reducible to sparse sets in polynomial time. The principal results are as follows: (1) For every integer  $k > 0$ , there is a set  $L$  and a sparse set  $S$  such that  $L \leq_{(k+1)\text{-tt}}^P S$ , but there is no sparse set  $S'$  such that  $L \leq_{k\text{-tt}}^P S'$ . (2) There exist a sparse set  $S$  and a set  $L$  such that  $L \leq_{\text{tt}}^P S$  but there is no integer  $k$  such that for some sparse  $S'$ ,  $L \leq_{k\text{-tt}}^P S'$ . (3) The class of sets that are bounded truth-table reducible to tally sets is equal to the class of sets that are many-one reducible to tally sets. (4) The class of sets having polynomial-size circuits is equal to the class of sets that are truth-table reducible to tally sets.

Similar results are developed for truth-table reducibilities that are computed nondeterministically in polynomial time or in polynomial space.

**Key words.** truth-table reducibilities, polynomial time, polynomial space, sparse sets, tally sets, hierarchies

**AMS(MOS) subject classifications.** 68Q15, 68Q05, 03D15, 03D30

**1. Introduction.** In recent years the class of sparse sets has received a great deal of attention by those researchers who study the structure of complexity classes and of complexity-bounded reducibilities. Perhaps the most prominent results are those that show how the complexity of sparse sets depends on the basic open questions of complexity theory such as the  $P = ?$  NP problem. Efforts by Berman [8], Fortune [14], and Mahaney [22] led to the following result: the class  $P$  is equal to the class NP if and only if there is a sparse set that is NP-complete [22]. Similarly, results by Karp and Lipton [16], Long and Selman [21], and Balcázar, Book, and Schöning [4] culminated in results such as the following: the class PSPACE is equal to the union (PH) of the classes in the polynomial-time hierarchy if and only if there exists a sparse set  $S$  such that PSPACE relativized to  $S$  is equal to PH relativized to  $S$  if and only if for all sparse sets  $S$ , PSPACE relativized to  $S$  is equal to PH relativized to  $S$  [4].

In the context of developing a structure theory for complexity classes and complexity-bounded reducibilities, we would like to develop intrinsic characterizations of reduction classes or degrees of a given set; i.e., for a set  $A$  characterize, in terms of properties other than reducibilities, the class of all sets  $B$  such that  $B \leq_m^P A$  or  $B \leq_T^P A$  or  $B \equiv_T^P A$ , etc. Similarly, we would like to develop intrinsic characterizations of reduction classes for a class of sets; i.e., for a class  $C$  of sets describe the class of all sets  $B$  such that for some  $C \in C$ ,  $B \leq_m^P C$ ,  $B \leq_T^P C$ , or  $B \equiv_T^P C$ . The results in the last paragraph suggest that this will be very difficult since, for example, the appropriate characterizations of the class of sets that are  $T \leq_m^P$ -reducible to sparse sets might require a solution of the  $P = ?$  NP problem. A few such characterizations are known: the class of sets that are  $\leq_T^P$ -reducible to sparse sets is the class of sets with polynomial-sized circuits (attributed to A. Meyer in [7]); the class of sets that are  $\leq_T^P$ -equivalent to tally sets is the class of sets with self-producible circuits (Balcázar and Book [2]);

the class of sets that are  $p$ -isomorphic to tally sets is the class of sets with small generalized Kolmogorov complexity (Allender and Rubinfeld [1]). Other characterization theorems in terms of language-theoretic properties have been developed by Book [9], Book and Selman [12], and Balcázar, Díaz, and Gabarró [5].

The known characterizations described in the last paragraph as well as the apparent difficulty in obtaining additional characterizations led the authors to investigate properties of some of the polynomial-time reducibilities to sparse sets. In the current paper we report on the results of that investigation.

Consider the various polynomial-time reducibilities to sparse sets. Here we investigate the reduction classes of truth-table, bounded truth-table,  $k$ -truth-table for each positive integer  $k$ , and many-one reducibilities to sparse sets and also to tally sets. The main results may be summarized as follows:

(1) For every  $k > 0$ , there exist a sparse set  $S$  and a set  $L$  such that  $L \leq_{(k+1)\text{-tt}}^P S$ , but there is no sparse set  $S'$  such that  $L \leq_{k\text{-tt}}^P S'$ . Thus, the class of sets that are bounded truth-table reducible to sparse sets can be decomposed into a properly infinite hierarchy based on bounding the number of queries that are allowed.

(2) There exist a sparse set  $S$  and a set  $L$  such that  $L \leq_{\text{tt}}^P S$  but there is no integer  $k$  such that for some sparse set  $S'$ ,  $L \leq_{k\text{-tt}}^P S'$ . Thus the class of sets that are bounded truth-table reducible to sparse sets is properly included in the class of sets that are truth-table reducible to sparse sets.

(3) The class of sets that are bounded truth-table reducible to tally sets is equal to the class of sets that are many-one reducible to tally sets.

(4) The class of sets having polynomial-sized circuits is equal to the class of sets that are truth-table reducible to tally sets.

It should be noted that the sparse sets  $S$  and the sets  $L$  found in results (1) and (2) can be constructed in time  $2^{O(n)}$ .

The proofs of the main theorems are stronger than the theorems themselves. First, they allow us to extend the results of (1)–(4) to the setting of truth-table reducibilities that are computable nondeterministically in polynomial time where the functions that generate the list of queries and the truth-table condition are both computable nondeterministically but are single-valued. Second, they allow us to extend the results of (1)–(4) to the setting of truth-table reducibilities that are computable deterministically and also nondeterministically in polynomial space. In this case the polynomial space bounds and the fact that the reducibilities are nonadaptive yield the notion that only a polynomial number of queries are generated so that the reducibilities can be viewed as restrictions of the PQUERY ( ) and NPQUERY ( ) operators introduced by Book [10]. Third, they yield new proofs of results of Watanabe [27], [28] showing that no sparse set can be  $\leq_r^P$ -hard for the class of sets accepted deterministically in exponential time, where  $r$  is any of the bounded truth-table reducibilities.

The paper itself is organized in the following way. Section 2 is devoted to establishing notation and reviewing definitions. In § 3 we describe the relations between the reduction classes for the polynomial time-bounded truth-table reducibilities to sparse sets. Section 4 is devoted to the proofs of the theorems yielding (1) and (2), even though the theorems themselves are stated in § 3. In § 5 we point out how the relations described in § 3 can be extended to the cases of nondeterministic polynomial time-bounded truth-table reducibilities and of polynomial space-bounded truth-table reducibilities. In § 6 we describe the results about sparse sets and the class of sets accepted deterministically in exponential time.

## 2. In this section we review some definitions and establish notation.

Throughout this paper we will consider the alphabet  $\Sigma = \{0, 1\}$ . The length of a string  $x$  will be denoted by  $|x|$ . The cardinality of a set  $X$  will be denoted by  $\|X\|$ .

For a set  $X$  and an integer  $n$ ,  $X^n = \{x \in X \mid |x| = n\}$  and  $X^{\leq n} = \{x \in X \mid |x| \leq n\}$ . For a set  $X$ ,  $\chi_X$  denotes the characteristic function of  $X$ , and  $\bar{X} = \Sigma^* - X$ .

For an oracle machine  $M$ ,  $L(M, A)$  denotes the set of strings accepted by  $M$  relative to oracle set  $A$ , and  $L(M) = L(M, \emptyset)$  denotes the set of strings accepted by  $M$  when no oracle queries are made (or allowed). We assume that the reader is familiar with the well-studied complexity classes  $P$ ,  $NP$ , and  $PSPACE$  and with their relativizations. In particular, recall that set  $A$  is Turing-reducible to set  $B$  in polynomial time, written  $A \leq_T^P B$ , if  $A \in P(B)$ .

We are particularly concerned with truth-table reducibilities that are computed in polynomial time. Recall the following definitions (see [19] for the details and formal definitions):

(i) Set  $A$  is many-one reducible to set  $B$ , written  $A \leq_m^P B$ , if there is a function  $f$  that can be computed in polynomial time with the property that for all  $x$ ,  $x \in A$ , if and only if  $f(x) \in B$ .

(ii) For every  $k > 0$ , set  $A$  is  $k$ -truth-table reducible to set  $B$ , written  $A \leq_{k-||}^P B$ , if there exist polynomial-time computable functions  $f$  and  $g$  such that for all  $x$ ,  $f(x)$  is a list of  $k$  strings,  $g(x)$  is a truth table with  $k$  variables, and  $x \in A$  if and only if the truth-table  $g(x)$  evaluates to **true** on the  $k$ -tuple  $\langle \chi_B(y_1), \dots, \chi_B(y_k) \rangle$ , where  $f(x) = \langle y_1, \dots, y_k \rangle$ .

(iii) Set  $A$  is bounded truth-table reducible to set  $B$ , written  $A \leq_{b||}^P B$ , if there is an integer  $k$  such that  $A \leq_{k-||}^P B$ .

(iv) Set  $A$  is truth-table reducible to set  $B$ , written  $A \leq_{||}^P B$ , if there exist polynomial-time computable functions  $f$  and  $g$  such that for all  $x$ ,  $f(x)$  is a list of strings,  $g(x)$  is a truth table with the number of variables being equal to the number of strings in the list  $f(x)$ , and  $x \in A$  if and only if the truth-table  $g(x)$  evaluates to **true** on  $\langle \chi_B(y_1), \dots, \chi_B(y_k) \rangle$ , where  $f(x) = \langle y_1, \dots, y_k \rangle$ .

In the above definitions we did not specify how a truth-table  $g(x)$  with  $k$  variables is represented, because the representation does not matter as long as it evaluates each truth value in polynomial time (see [19] for several equivalent formulations). What is important to notice is that the polynomial-time truth-table reducibility is equivalent to nonadaptive polynomial-time Turing reducibility. In other words, in the above definitions (ii) and (iv), we may regard the truth-table evaluator  $g$  as a  $(k+1)$ -variable function, with the first variable  $x$  in  $\Sigma^*$  and the rest  $b_1, \dots, b_k$  in  $\{0, 1\}$ . The function  $g$  is required to run in polynomial time and satisfy the condition that  $g(x, b_1, \dots, b_k) = 1$  if and only if the intended "truth-table"  $g(x)$  evaluates to **true** on values  $\langle b_1, \dots, b_k \rangle$ .

For any truth-table reducibility  $r$  computed in polynomial time and any class  $\mathcal{C}$  of sets, let  $P_r(\mathcal{C}) = \{A \mid \text{there exists } C \in \mathcal{C} \text{ such that } A \leq_r^P C\}$ . Also, for any reducibility  $r$  computed in polynomial time,  $A \equiv_r^P B$  denotes the fact that  $A \leq_r^P B$  and  $B \leq_r^P A$  so that for any class  $\mathcal{C}$  of sets, we let  $\equiv_r^P(\mathcal{C})$  denote  $\{A \mid \text{there exists } C \in \mathcal{C} \text{ such that } A \equiv_r^P C\}$ . In addition, we write  $P_T(\mathcal{C})$  for  $P(\mathcal{C})$ . In § 5 we will also consider truth-table reducibilities computed nondeterministically in polynomial time and truth-table reducibilities computed in polynomial space; similar notation will be used.

Recall that a set  $S$  is *sparse* if there is a polynomial  $q$  such that for all  $n$ ,  $\|S^{\leq n}\| \leq q(n)$ . Let SPARSE denote the class of all sparse sets. Recall that a *tally* set is any subset of  $\{0\}^*$ . Let TALLY denote the class of all tally sets.

For any  $A$  and  $B$ , the symmetric difference  $(A - B) \cup (B - A)$  is denoted  $A \Delta B$ .

**3.** In this section we study the relationships between certain classes that contain every set in  $P$  and every sparse set. These relationships are displayed in Figs. 1 and 2.

Consider the class  $P$  and the class SPARSE. Clearly, these two classes are not comparable. It is well known that both the class  $P$  and the class SPARSE are properly

included in the class  $P_m(\text{SPARSE})$ . Also, it is clear that both  $P$  and  $\text{SPARSE}$  are properly included in the Boolean closure of their union. This latter class is of independent interest.

Schöning [25] considered sets  $A$  of the form  $A = B \triangle S$ , where  $B \in P$  and  $S \in \text{SPARSE}$ . Since  $A = B \triangle S$ ,  $S = A \triangle B$  so that  $S$  being sparse implies that for some polynomial  $h$  and all  $n$ ,  $\|(A \triangle B)^{\leq n}\| \leq h(n)$ . Such a set  $A$  is called *polynomially close to  $P$* . Schöning proved that a set is polynomially close to  $P$  if and only if it is in the

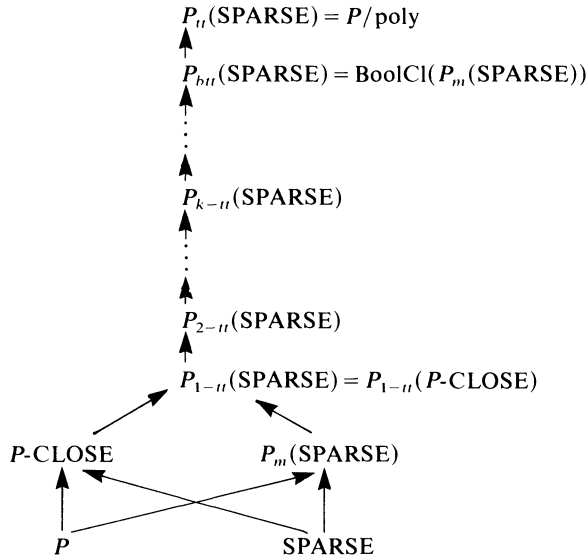

FIG. 1.  $L_1 \rightarrow L_2$  represents  $L_1 \subset L_2$ .

Boolean closure of  $P \cup \text{SPARSE}$ . Here, we refer to the class of sets that are polynomially close to  $P$  as the class  $P\text{-CLOSE}$ , so  $P\text{-CLOSE} = \{A \mid \text{for some } B \in P \text{ and } S \in \text{SPARSE}, A = B \triangle S\} = \{A \mid \text{for some } B \in P, A \triangle B \text{ is sparse}\}$ .

Since  $P \cup \text{SPARSE}$  is properly included in both  $P_m(\text{SPARSE})$  and  $P\text{-close}$ , it is appropriate to try to compare these two classes.

PROPOSITION 3.1. *The classes  $P_m(\text{SPARSE})$  and  $P\text{-CLOSE}$  are not comparable.*

*Proof.* First, we show that there is a set in  $P_m(\text{SPARSE})$  that is not in  $P\text{-CLOSE}$ . The proof is taken from that of Proposition 3.4 of Schöning [25].

Let  $T \subseteq \{0\}^*$  be a set not in  $P$  and let  $A = \{x \in \{0, 1\}^* \mid 0^{|x|} \in T\}$ . Clearly,  $T \in P\text{-CLOSE} \cap P_m(\text{SPARSE})$  and  $A \equiv_m^P T$  so that  $A \in P_m(\text{SPARSE})$ . Now  $A$  is not in  $P\text{-CLOSE}$ ; otherwise, there would be a set  $B \in P$  and a polynomial  $h$  such that for all  $n$ ,  $\|(A \triangle B)^{\leq n}\| \leq h(n)$ . Then the following algorithm would recognize  $T$  in polynomial time, contradicting the choice of  $T$ .

```

input  $0^n$ ;
determine how many of the first  $2h(n) + 1$  strings of size  $n$ 
    (in lexicographic order) are in  $B$ ;
if this number exceeds  $h(n)$  then accept else reject.
    
```

Second, we show that there is a set in  $P\text{-CLOSE}$  that is not in  $P_m(\text{SPARSE})$ . This was pointed out by Dr. José Balcázar [29]. Recall that a set  $A$  is *strongly bi-immune* for  $P$  if every  $\equiv_m^P$ -reduction from  $A$  is one-to-one almost everywhere. It is clear that

FIG. 2.  $L_1 \rightarrow L_2$  represents  $L_1 \subset L_2$ .

the class of strongly bi-immune sets is closed under complementation. Balcázar and Schöning [6] have shown that there exists a sparse set  $S$  that is strongly bi-immune; hence,  $\bar{S}$  is also strongly bi-immune. Since  $\bar{S}$  is strongly bi-immune, every  $\leq_m^P$ -reduction from  $\bar{S}$  is one-to-one almost everywhere. Hence,  $\bar{S}$  cannot be many-one reducible to a sparse set, i.e.,  $\bar{S}$  is not in  $P_m(\text{SPARSE})$ . But since  $S$  is sparse,  $\bar{S}$  is in the Boolean closure of SPARSE and, hence, in  $P\text{-CLOSE}$ .  $\square$

**COROLLARY.** *The class  $P_m(\text{SPARSE})$  is not closed under the Boolean operations.*

*Proof.* If  $P_m(\text{SPARSE})$  were closed under the Boolean operations, then  $P \cup \text{SPARSE} \subseteq P_m(\text{SPARSE})$  would imply that the Boolean closure of  $P \cup \text{SPARSE}$  would be included in  $P_m(\text{SPARSE})$ . But the Boolean closure of  $P \cup \text{SPARSE}$  is  $P\text{-CLOSE}$ , so this would contradict Proposition 3.1.  $\square$

The reducibility  $\leq_{1-tt}^P$  is weaker than the reducibility  $\leq_m^P$ . Thus, we would expect the class  $P_m(\text{SPARSE})$  to be properly included in the class  $P_{1-tt}(\text{SPARSE})$ . The next result shows that this is true and also shows that the class  $P\text{-CLOSE}$  is properly included in the class  $P_{1-tt}(\text{SPARSE})$ .

**PROPOSITION 3.2.** *Both of the classes  $P_m(\text{SPARSE})$  and  $P\text{-CLOSE}$  are properly included in  $P_{1-tt}(\text{SPARSE})$ .*

*Proof.* From the definition it follows that  $P_m(\text{SPARSE})$  is included in  $P_{1-tt}(\text{SPARSE})$ . Thus, we show first that  $P\text{-CLOSE}$  is included in  $P_{1-tt}(\text{SPARSE})$ .

Let  $A \in P\text{-CLOSE}$  so that there exist  $B \in P$  and  $S \in \text{SPARSE}$  such that  $A = B \Delta S$ . Let  $M_0$  be a polynomial-time-bounded deterministic machine that recognizes  $B$ . Consider the following algorithm.

```

input  $x$ ;
determine whether  $x$  is in  $B$  by running  $M_0$  on  $x$ ;
if  $x \in B$  then query the oracle about  $x$ 
    if the answer is "no" then accept
    else reject
else query the oracle about  $x$ 
    if the answer is "yes" then accept
    else reject
end.
    
```

It is clear that this algorithm operates in polynomial time and that, relative to the set  $S$ , it recognizes  $A = (B - S) \cup (S - B)$ . Hence, this algorithm witnesses  $A \leq_{1-tt}^P S$ .

Finally, we note that the fact that  $P\text{-CLOSE}$  and  $P_m(\text{SPARSE})$  are not comparable shows that both of the inclusions  $P\text{-CLOSE} \subseteq P_{1-tt}(\text{SPARSE})$  and  $P_m(\text{SPARSE}) \subseteq P_{1-tt}(\text{SPARSE})$  must be proper.  $\square$

In the proof of Proposition 3.2, it is shown that  $P$ -CLOSE is included in  $P_{1-ii}(\text{SPARSE})$ . This is done by arguing that if  $A = B \Delta S$ , where  $B$  is in  $P$ , then  $A \leq_{1-ii}^P S$ ; the fact that  $S \in \text{SPARSE}$  plays no role in that argument. Now  $A = B \Delta S$  if and only if  $S = B \Delta A$ , so that it is also the case that  $S \leq_{1-ii}^P A$  and, hence,  $A \equiv_{1-ii}^P S$ . We conclude that  $P$ -CLOSE is included in  $\equiv_{1-ii}^P(\text{SPARSE})$ , and the proof of Proposition 3.1 shows that this inclusion is proper. Since  $\text{SPARSE} \subset P\text{-CLOSE} \subset \equiv_{1-ii}^P(\text{SPARSE}) \subseteq P_{1-ii}(\text{SPARSE})$  and both  $\equiv_{1-ii}^P$  and  $\leq_{1-ii}^P$  are transitive, we conclude that  $\equiv_{1-ii}^P(P\text{-CLOSE}) = \equiv_{1-ii}^P(\text{SPARSE})$  and  $P_{1-ii}(P\text{-CLOSE}) = P_{1-ii}(\text{SPARSE})$ .

There is a useful result due to Köbler [17] (see also Köbler, Schöning, and Wagner [18]).

**PROPOSITION 3.3.** *For every set  $A$ , the class of sets  $B$  such that  $B \leq_{bit}^P A$  is precisely the Boolean closure of the class  $\{C \mid C \leq_m^P A\}$ .*

**COROLLARY.** *The class  $P_{bit}(\text{SPARSE})$  is equal to the Boolean closure of  $P_m(\text{SPARSE})$ .*

The reader may note that the analogue of Proposition 3.3 holds in recursive function theory, where  $\leq_{bit}$  and  $\leq_m$  are witnessed by total recursive functions.

From the Corollary we see that  $P_{bit}(\text{SPARSE})$  can also be expressed as the Boolean closure of  $P_{k-ii}(\text{SPARSE})$  for any  $k > 0$ . Thus, if  $P_{bit}(\text{SPARSE})$  can be decomposed into an infinite hierarchy based on the number of questions asked, i.e.,  $P_{k-ii}(\text{SPARSE}) \neq P_{(k+1)-ii}(\text{SPARSE})$  for all  $k$ , then there is no  $k > 0$  such that  $P_{k-ii}(\text{SPARSE})$  is closed under the Boolean operations. The fact that  $P_{bit}(\text{SPARSE})$  can be so decomposed is the main result of this paper.

**THEOREM 3.4.** *For every  $k > 0$ ,  $P_{k-ii}(\text{SPARSE}) \neq P_{(k+1)-ii}(\text{SPARSE})$ . Hence, for all  $k$ ,  $P_{k-ii}(\text{SPARSE}) \neq P_{bit}(\text{SPARSE})$  and  $P_{k-ii}(\text{SPARSE})$  is not closed under the Boolean operations.*

Theorem 3.4 will be proved in § 4.

Consider the class  $P_{ii}(\text{SPARSE})$ . From the definitions of  $\leq_{bit}^P$  and  $\leq_{ii}^P$ , it follows that  $P_{bit}(\text{SPARSE}) \subseteq P_{ii}(\text{SPARSE})$ . The fact that this inclusion is proper is the next result.

**THEOREM 3.5.** *The class  $P_{bit}(\text{SPARSE})$  is properly included in the class  $P_{ii}(\text{SPARSE})$ .*

Theorem 3.5 will be proved in § 4.

Consider the class  $P_T(\text{SPARSE})$ . Recall that  $P_T(\text{SPARSE}) = P/\text{poly}$ , where  $P/\text{poly}$  is the class of sets with polynomial-sized circuits studied by Karp and Lipton [16]. From the definitions of  $\leq_{ii}^P$  and  $\leq_T^P$ , it follows that  $P_{ii}(\text{SPARSE}) \subseteq P_T(\text{SPARSE})$ . We will see that this inclusion is not proper, that is,  $P_{ii}(\text{SPARSE}) = P_T(\text{SPARSE})$ . In this context, it is desirable to consider the class TALLY of tally sets and the classes  $P_{ii}(\text{TALLY})$  and  $P_T(\text{TALLY})$ .

The relationship between sparse sets and tally sets has been studied by many researchers. For example, Hartmanis [15] showed that every sparse set  $S$  is nondeterministically polynomial-time equivalent to some tally set, while Long [20] showed that this relationship does not hold for strong nondeterministic polynomial-time Turing reducibility. Schöning [24] proved that for every sparse set  $S$  there is a tally set  $T$  such that  $S$  is deterministically polynomial-time Turing-reducible to  $T$ . The following result relates sparse sets and tally sets by deterministic polynomial-time Turing- and truth-table reducibility. The reader should notice that it is not being claimed that for every sparse  $S$  there is a tally set  $T$  such that  $P(S) = P(T)$ ; indeed, Long [20] has shown that this is not the case.

**THEOREM 3.6.**  $P/\text{poly} = P_T(\text{SPARSE}) = P_{ii}(\text{SPARSE}) = P_{ii}(\text{TALLY}) = P_T(\text{TALLY})$ .

*Proof.* From the definitions of  $\leq_u^P$  and  $\leq_T^P$  and the fact that  $\text{TALLY} \subseteq \text{SPARSE}$ , it follows that  $P_u(\text{TALLY}) \subseteq P_u(\text{SPARSE}) \subseteq P_T(\text{SPARSE})$  and  $P_u(\text{TALLY}) \subseteq P_T(\text{TALLY}) \subseteq P_T(\text{SPARSE})$ . Recall that tally sets are self-printable in polynomial time, that is, there is a deterministic polynomial time-bounded oracle transducer that for any tally set  $T$  will compute on input  $0^n$  the list of strings in  $T$  of length at most  $n$ . Since  $\leq_u^P$  is the nonadaptive version of  $\leq_T^P$ , it follows that  $P_T(\text{TALLY}) \subseteq P_u(\text{TALLY})$ .

It is known that for every sparse set  $S$  there is a tally set  $T_S$  such that  $S \in P(T_S)$ . Since  $\leq_T^P$  is transitive, this means that  $P(S) \subseteq P(T_S)$ . Hence,  $P_T(\text{SPARSE}) \subseteq P_T(\text{TALLY})$ .  $\square$

The results in Theorem 3.6 suggest that the class of tally sets be considered with respect to truth-table reducibilities. The situation is quite different from that regarding the sparse sets.

**THEOREM 3.7.**  $P_m(\text{TALLY}) = P_{btt}(\text{TALLY})$ .

*Proof.* The proof will follow from Proposition 3.3 once it is shown that  $P_m(\text{TALLY})$  is closed under the Boolean operations. Closure under complementation follows from the fact that complementation is always taken relative to a tally set: if  $T \subseteq \{0\}^*$ , then  $\bar{T} = \{0\}^* - T$ . Closure under intersection follows from the fact that there is a polynomial-time computable pairing function  $\langle \cdot, \cdot \rangle : \{0\}^* \times \{0\}^* \rightarrow \{0\}^*$ , for if  $f$  witnesses  $A \leq_m^P T_1$  and  $g$  witnesses  $B \leq_m^P T_2$ , then  $x \in A \cap B$  if and only if  $\langle f(x); g(x) \rangle \in \{ \langle 0^m, 0^n \rangle \mid 0^m \in T_1, 0^n \in T_2 \}$ .  $\square$

**COROLLARY.** *Let  $r$  be any of the bounded truth-table reducibilities. Then there is a sparse set  $S$  such that there is no tally set  $T$  with  $S \leq_r^P T$ . Thus,  $P_r(\text{TALLY}) \neq P_r(\text{SPARSE})$ .*

*Proof.* Since  $P_m(\text{TALLY}) = P_{btt}(\text{TALLY})$ ,  $P_r(\text{TALLY}) = P_m(\text{TALLY})$ , and  $P_r(\text{TALLY})$  is closed under the Boolean operations. If  $r \neq btt$ , then  $P_r(\text{SPARSE})$  is not closed under the Boolean operations by Theorem 3.4, so  $P_r(\text{SPARSE}) \neq P_r(\text{TALLY})$ . Thus,  $P_{btt}(\text{TALLY}) = P_m(\text{TALLY}) \subset P_m(\text{SPARSE}) \subset P_{btt}(\text{SPARSE})$  and so  $P_{btt}(\text{SPARSE}) \neq P_{btt}(\text{TALLY})$ .  $\square$

Recall that a set  $A$  is in  $P$ -CLOSE if and only if there is a set  $B \in P$  and a set  $S \in \text{SPARSE}$  such that  $A = B \triangle S$ . This suggests that we consider the class of sets  $A$  such that there is a set  $B \in P$  and a set  $T \in \text{TALLY}$  such that  $A = B \triangle T$ . We refer to this class as TALLY-CLOSE. It follows from a result of Schöning [25] that TALLY-CLOSE is the Boolean closure of  $P \cup \text{TALLY}$ . From Theorem 3.7 it follows that TALLY-CLOSE is included in  $P_m(\text{TALLY})$ . That the inclusion is in fact proper follows from the proof of Proposition 3.1.

The proof of Proposition 3.1 shows that there is a set in  $P_m(\text{TALLY})$  that is not in TALLY-CLOSE. The proof of Proposition 3.2 shows that TALLY-CLOSE is included in  $P_{1-ut}(\text{TALLY})$ . Since  $P_m(\text{TALLY}) = P_{1-ut}(\text{TALLY})$ , this shows that TALLY-CLOSE is properly included in  $P_m(\text{TALLY})$ .

Notice that similar to the situation with SPARSE, we have  $\equiv_m^P(\text{TALLY-CLOSE}) = \equiv_m^P(\text{TALLY})$  and  $P_m(\text{TALLY-CLOSE}) = P_m(\text{TALLY})$ .

**4.** In this section we will prove Theorems 3.4 and 3.5. The proof of Theorem 3.4 is carried out in two steps, the first establishing that  $P_{1-ut}(\text{SPARSE}) \neq P_{2-ut}(\text{SPARSE})$  and the second that for all  $k > 1$ ,  $P_{k-ut}(\text{SPARSE}) \neq P_{(k+1)-ut}(\text{SPARSE})$ .

It will be convenient to use the following notation: for each integer  $h > 0$ ,  $\text{SPARSE}_h$  is the class of sparse sets  $S$  such that for all  $m > 0$ ,  $\|S^{\equiv m}\| \leq p_h(m)$ , where  $p_h$  is the polynomial defined for all  $m$  by  $p_h(m) = m^h + h$ . Notice that for every sparse set  $S$  there is an integer  $h > 0$  such that  $S \in \text{SPARSE}_h$ , and for all integers  $h > 0$ ,  $\text{SPARSE}_h \subseteq \text{SPARSE}_{h+1}$ .

**THEOREM 4.1.**  $P_{1-tt}(\text{SPARSE}) \neq P_{2-tt}(\text{SPARSE})$ .

*Proof.* For any set  $A$ , let  $L_1(A) = \{x \mid \text{exactly one of } 0^{|x|+1} \text{ and } x \text{ is in } A\}$  so that  $L_1(A) \leq_{2-tt}^P A$ . We will construct a sparse set  $A$  such that for all sparse sets  $S$ ,  $L_1(A) \not\leq_{1-tt}^P S$ , i.e.,  $L_1(A)$  is in  $P_{2-tt}(\text{SPARSE})$  but is not in  $P_{1-tt}(\text{SPARSE})$ . The construction will be by stages.

Assume an enumeration of  $\leq_{1-tt}^P$ -reductions:  $\{M_{i,j} \mid i, j \geq 1\}$ , where for each pair  $i, j$ ,  $M_{i,j}$  is a polynomial-time-bounded oracle machine that for each input  $x$  generates the query string  $f_i(x)$  and the  $1-tt$ -evaluator  $g_j(x)$ . (Notice that for every  $j$  and every  $x$ ,  $g_j(x)$  is a function from  $\{0, 1\}$  to  $\{0, 1\}$ .)

For each triple  $i, j, h$  let  $R_{i,j,h}$  be the predicate that is true if and only if  $L_1(A) \neq L(M_{i,j}, S)$  for all  $S \in \text{SPARSE}_h$ . Our goal is to construct  $A$  such that  $A$  is sparse and, for every triple  $i, j, h$ ,  $R_{i,j,h}$  is satisfied. This will yield  $L_1(A) \notin P_{1-tt}(\text{SPARSE})$ .

Let  $\langle i, j, h \rangle$  be a ‘‘tripling’’ function that enumerates all of the triples  $i, j, h$ .

*Stage 0.* Let  $n_0 = 1$ . Let  $A_0 = \emptyset$ .

*Stage  $\alpha = \langle i, j, h \rangle > 0$ .* Let  $q$  be a polynomial that bounds the running time of  $M_{i,j}$ . Select  $n = n_\alpha$  such that  $n \geq n_{\alpha-1} + 2$  and  $2^{n-2} > p_h(q(n))$ . For each  $1-tt$ -condition  $t$ , let  $G_t = \{x \in \Sigma^n \mid g_j(x) = t\}$ . Since each  $g_j$  can take at most four possible values, there exists some  $t$  such that  $\|G_t\| \geq 2^{n-2}$ . Choose a fixed  $t$  with this property.

Consider each possible  $1-tt$ -condition  $t$ .

*Case 1.*  $t(0) = t(1) = 1$ . In this case, for all  $x \in G_t$ ,  $x \in L(M_{i,j}, S)$  so that  $L(M_{i,j}, S) \cap G_t = G_t$  for all  $S \in \text{SPARSE}_h$ . Let  $A_\alpha := A_{\alpha-1}$ . Then  $L_1(A_\alpha) \cap G_t = \emptyset$  and so  $L_1(A_\alpha)^n \neq L(M_{i,j}, S)^n$  for all  $S \in \text{SPARSE}_h$ .

*Case 2.*  $t(0) = t(1) = 0$ . In this case, for all  $x \in G_t$ ,  $x \in L(M_{i,j}, S)$  so that  $L(M_{i,j}, S) \cap G_t = \emptyset$  for all  $S \in \text{SPARSE}_h$ . Choose an arbitrary  $x$  in  $G_t$  and let  $A_\alpha := A_{\alpha-1} \cup \{x\}$ . Then  $L_1(A_\alpha) \cap G_t = \{x\} \neq \emptyset$  and so  $L_1(A_\alpha)^n \neq L(M_{i,j}, S)^n$  for all  $S \in \text{SPARSE}_h$ .

*Case 3.*  $t(0) = 0$  and  $t(1) = 1$ .

*Subcase 3.1.* Suppose that  $f_i$  is not one-to-one on  $G_t$ , so there exist  $x, y \in G_t$ ,  $x \neq y$ , and  $f_i(x) = f_i(y)$ . Let  $A_\alpha := A_{\alpha-1} \cup \{x\}$ . Then we have that for all  $S \in \text{SPARSE}_h$ ,  $x \in L(M_{i,j}, S)^n$  if and only if  $y \in L(M_{i,j}, S)^n$ , where  $x$  and  $y$  are as in the construction. But  $x \in L_1(A_\alpha)^n$  and  $y \notin L_1(A_\alpha)^n$  so that for all  $S \in \text{SPARSE}_h$ ,  $L_1(A_\alpha)^n \neq L(M_{i,j}, S)^n$ .

*Subcase 3.2.* Suppose that  $f_i$  is one-to-one on  $G_t$ . Let  $A_\alpha := A_{\alpha-1} \cup \{0^{n+1}\}$ . Then we have that  $L_1(A_\alpha)^n \cap G_t = G_t$ . But for all  $S \in \text{SPARSE}_h$ ,  $\|L(M_{i,j}, S) \cap G_t\| \leq \|S^{\leq q(n)}\| \leq \|p_h(q(n))\| < \|G_t\|$ . Hence, for all  $S \in \text{SPARSE}_h$ ,  $L_1(A_\alpha)^n \neq L(M_{i,j}, S)^n$ .

*Case 4.*  $t(0) = 1$  and  $t(1) = 0$ . This is symmetric to Case 3.

*End of Stage  $\alpha = \langle i, j, h \rangle$ .*

We have constructed  $A_\alpha$  such that for all  $\alpha$  and all  $n = n_\alpha$ ,  $L_1(A_\alpha)^n \neq L(M_{i,j}, S)^n$  for all  $S \in \text{SPARSE}_h$ . Letting  $A := \bigcup_\alpha A_\alpha$ , the choice of  $n_\alpha$  such that  $2^{n_\alpha-2} > p_h(q(n))$  guarantees that for all  $\alpha$ , no string added to  $A$  at an earlier or a later stage can cause the relationship established at stage  $\alpha$  to change, i.e., for all  $\alpha$  and  $n = n_\alpha$ ,  $L_1(A)^n = L_1(A_\alpha)^n$ . Thus, for all  $S \in \text{SPARSE}_h$ ,  $L(M_{i,j}, S) \neq L_1(A)$ .  $\square$

The proof of Theorem 4.1 may be viewed as the simplified version of the proof of Theorem 4.2 below.

**THEOREM 4.2.** For every  $k > 1$ ,  $P_{k-tt}(\text{SPARSE}) \neq P_{(k+1)-tt}(\text{SPARSE})$ .

*Proof.* Let  $k \geq 2$ . For any set  $A$ , let  $L_k(A) = \{u_1 \cdots u_k \mid \text{for each } i, 1 \leq i \leq k, |u_i| = |u_1| = n; \text{ the number of strings in the following list that are in the set } A \text{ is odd: } 0^{k(n+1)}, u_1 0^{(k-1)(n+1)}, \dots, u_1 \cdots u_{i-1} 0^{(k-i)(n+1)}, \dots, u_1 \cdots u_k\}$ . It is clear that  $L_k(A) \leq_{(k+1)-tt}^P A$ . We will describe a specific sparse set  $A$  such that for every sparse set  $S$  it is *not* the case that  $L_k(A) \leq_{k-tt}^P S$ . This will allow us to conclude that  $P_{(k+1)-tt}(\text{SPARSE}) \neq P_{k-tt}(\text{SPARSE})$ .

Let  $k \geq 2$  be fixed. Let  $\{f_i\}$  be an enumeration of the polynomial-time computable functions that for any string  $x$  yields a list of  $k$  strings (i.e., the list of queries). Let

$\{g_j\}$  be an enumeration of all polynomial-time computable functions that for any single string  $x$  yields one of the  $2^{2^k}$   $k$ -*tt*-conditions. We can enumerate all of the  $\leq_{k-tt}^P$ -reduction machines as  $\{M_{ij}\}$  where on input  $x$ ,  $M_{i,j}$  computes the list  $f(x) = \langle x_1, \dots, x_k \rangle$  and the  $k$ -*tt*-condition  $g_j(x)$ .

We want to construct a set  $A$  such that for every integer  $n$  and every integer  $r$ ,  $0 \leq r \leq k$ , there is at most one string in  $A$  of the form  $u_1 \cdots u_{k-r} 0^{r(n+1)}$  and there is at most one string in  $A$  having length  $|u_1 \cdots u_{k-r} 0^{r(n+1)}| = kn + r$ . Thus,  $A$  will be sparse. Furthermore,  $A$  must satisfy the condition that for all  $i, j$  and every sparse set  $S$ ,  $L_k(A) \neq L(M_{i,j}, S)$ ; to accomplish this latter point it is sufficient to show that for some  $n > 0$ ,  $L_k(A)^n \neq L(M_{i,j}, S)^n$ .

The construction of  $A$  will be by stages so that for all  $i, j$ , there are infinitely many opportunities to diagonalize against  $M_{i,j}$ . At stage  $\alpha = \langle i, j, h \rangle$ , the machine  $M_{i,j}$  and the polynomial  $p_h$  are considered. At the end of stage  $\alpha = \langle i, j, h \rangle$ , the following condition will be satisfied: for every sparse set  $S \in \text{SPARSE}_h$ ,  $L(M_{i,j}, S)^{kn} \neq L_k(A)^{kn}$ .

Let  $\langle i, j, h \rangle$  be a "tripling" function that enumerates all of the triples  $i, j, h$ . Let  $\varepsilon = 1/(16k^2)$ .

*Stage 0.* Let  $n_0 = 2^{k+3}$  and  $A_1 = \emptyset$ .

*Stage  $\alpha = \langle i, j, h \rangle > 1$ .* Let  $q$  be a polynomial that bounds the running time of  $M_{i,j}$ . Choose  $n$  such that  $n > kn_{\alpha-1} + 1$  and  $2^{\varepsilon n} > p_h(q(kn))$ . Let  $n_\alpha = n$ .

For each of the  $2^{2^k}$   $k$ -*tt*-conditions  $t$ , let  $G_t = \{x \in \Sigma^{kn} \mid g_j(x) = t\}$ . Then there must exist some  $t$  such that  $\|G_t\| \geq 2^{kn} / 2^{2^k} = 2^{kn-2^k}$ . Choose any fixed  $t$  with this property.

*Case 1.*  $f_i$  is not one-to-one on  $G_t$ .

In this case, there exist  $x, y \in G_t$  with  $x \neq y$  and  $f_i(x) = f_i(y)$ . Thus, for any set  $S \in \text{SPARSE}_h$ ,  $x \in L(M_{i,j}, S)$  if and only if  $y \in L(M_{i,j}, S)$ . Let  $A_\alpha := A_{\alpha-1} \cup \{x\}$ , and notice that  $y$  is not in  $A_\alpha$ . This means that  $x \in L_k(A_\alpha)$  and  $y \notin L_k(A_\alpha)$ , and so we conclude that for every  $S \in \text{SPARSE}_h$ ,  $L_k(A_\alpha)^{kn} \neq L(M_{i,j}, S)^{kn}$ .

*Case 2.*  $f_i$  is one-to-one on  $G_t$ .

Recall that  $f_i$  always outputs a list of  $k$  strings. Let  $f_i(x) = \langle x_1, \dots, x_k \rangle$ .

*Subcase 2.1.* There exist  $r$ ,  $1 \leq r \leq k$ , and  $z$  such that  $H_r(z) =_{\text{def}} \{x \in G_t \mid x_r = z\}$  has size  $\|H_r(z)\| \geq 2^{(k-(1/4))n}$ .

This implies that there exist  $u, v \in \Sigma^n$ ,  $u \neq v$ , such that  $\|H_r(z) \cap \{u\} \Sigma^{(k-1)n}\| \geq 2^{(k-\varepsilon-(5/4))n}$  and  $\|H_r(z) \cap \{v\} \Sigma^{(k-1)n}\| \geq 2^{(k-\varepsilon-(5/4))n}$ . (Choose  $u$  such that  $H_r(z) \cap \{u\} \Sigma^{(k-1)n}$  has the maximum size. Then its size is at least  $2^{(k-(1/4))n} \cdot 2^{-n} = 2^{(k-(5/4))n}$ . Choose  $v$  such that the size of  $H_r(z) \cap \{v\} \Sigma^{(k-1)n}$  is the next largest. Then  $\|H_r(z) \cap \{v\} \Sigma^{(k-1)n}\| \geq \|H_r(z) - \{u\} \Sigma^{(k-1)n}\| \cdot 2^{-n} \geq (2^{(k-(1/4))n} - 2^{(k-1)n}) \cdot 2^{-n} \geq 2^{(k-\varepsilon-(5/4))n}$ .)

Now we claim that we can extend  $A_{\alpha-1}$  to  $A_\alpha$  to satisfy the requirement that for any  $S \in \text{SPARSE}_h$ ,  $L(M_{i,j}, S)^{kn} \neq L_k(A_\alpha)^{kn}$ . Since the proof of this claim involves a long inductive argument, we state a technical lemma and leave the proof of the lemma to the end.

**LEMMA.** *Suppose there exist a set  $G \subseteq \Sigma^{kn}$ , a function  $f(x) = \langle x_1, \dots, x_{k-1} \rangle$  on  $G$  and two strings  $u, v \in \Sigma^n$  satisfying the following conditions:*

(1)  *$f$  is one-to-one on  $G$ , and for all  $r \leq k-1$ ,  $|x_r| \leq q(kn)$ .*

(2)  *$\|G \cap U\| \geq 2^{(k-\varepsilon-(5/4))n}$  and  $\|G \cap V\| \geq 2^{(k-\varepsilon-(5/4))n}$ , where  $U = \{u\} \Sigma^{(k-1)n}$  and  $V = \{v\} \Sigma^{(k-1)n}$ .*

*Then, there exists a set  $C \subseteq \{y \mid kn \leq |y| \leq k(n+1)\}$  such that for all  $r$ ,  $0 \leq r \leq k-1$ ,  $\|C \cap \Sigma^{kn+r}\| \leq 1$ , and having the property that for every set  $S \in \text{SPARSE}_h$ , and every  $(k-1)$ -*tt*-condition  $t$ , it is not the case that for all  $x \in G$ ,  $x \in L_k(C)$  if and only if  $t(\chi_S(x_1), \dots, \chi_S(x_{k-1})) = 1$ .*

Note that by letting  $G = H_r(z)$  and  $f(x) = \langle x_1, \dots, x_{r-1}, x_{r+1}, \dots, x_k \rangle$ , the hypothesis of the lemma is satisfied. Let  $t$  be the fixed  $k$ -*tt*-condition we chose such that  $\|G_t\| \geq 2^{kn-2^k}$ , and let  $t_0$  and  $t_1$  be the two  $(k-1)$ -*tt*-conditions induced by  $t$  by

removing the  $r$ th input, i.e., for any  $k-1$  bits of inputs  $b_1, \dots, b_{r-1}, b_{r+1}, \dots, b_k$ ,  $t_0(b_1, \dots, b_{r-1}, b_{r+1}, \dots, b_k) = 1$  if and only if  $t(b_1, \dots, b_{r-1}, 0, b_{r+1}, \dots, b_k) = 1$  and  $t_1(b_1, \dots, b_{r-1}, b_{r+1}, \dots, b_k) = 1$  if and only if  $t(b_1, \dots, b_{r-1}, 1, b_{r+1}, \dots, b_k) = 1$ . Then, by the lemma, for any  $S \in \text{SPARSE}_h$ , it is not the case that for all  $x \in H_r(z)$ ,  $x \in L_k(C)$  if and only if  $t_0(\chi_S(x_1), \dots, \chi_S(x_{r-1}), \chi_S(x_{r+1}), \dots, \chi_S(x_k)) = 1$ , nor the case that for all  $x \in H_r(z)$ ,  $x \in L_k(C)$  if and only if  $t_1(\chi_S(x_1), \dots, \chi_S(x_{r-1}), \chi_S(x_{r+1}), \dots, \chi_S(x_k)) = 1$ . Since  $x_r = z$  for all  $x \in H_r(z)$ , for any  $S \in \text{SPARSE}_h$ , depending upon whether or not  $z$  is in  $S$ , we have that  $t(\chi_S(x_1), \dots, \chi_S(x_k))$  is either equal to  $t_0(\chi_S(x_1), \dots, \chi_S(x_{r-1}), \chi_S(x_{r+1}), \dots, \chi_S(x_k))$  or equal to  $t_1(\chi_S(x_1), \dots, \chi_S(x_{r-1}), \chi_S(x_{r+1}), \dots, \chi_S(x_k))$ . This implies that it is not the case that for all  $x \in H_r(z)$ ,  $x \in L_k(C)$  if and only if  $t(\chi_S(x_1), \dots, \chi_S(x_k)) = 1$ . By letting  $A_\alpha := A_{\alpha-1} \cup C$ , we have established that  $L_k(A_\alpha)^{kn} \neq L(M_{i,j}, S)^{kn}$  for every  $S \in \text{SPARSE}_h$ .

*Subcase 2.2.* The conditions for Subcase 2.1 do not hold.

There are two sub-subcases.

*Subcase 2.2.1.*  $t(0, \dots, 0) = 0$ . For every set  $S \in \text{SPARSE}_h$  and every  $x \in G_t$ ,  $x \in L(M_{i,j}, S)$  implies that there exists  $r$ ,  $1 \leq r \leq k$ , with  $x_r \in S$ . Since  $|x_r| \leq q(|x|) = q(kn)$ , there are only  $P_h(q(kn)) < 2^{\epsilon n}$  such  $x_r$ . Thus,

$$\|L(M_{i,j}, S) \cap G_t\| \leq \sum_{r=1}^k \sum_{z \in S} \|H_r(z)\| < k \cdot 2^{\epsilon n} \cdot 2^{(k-1/4)n} < 2^{(k-(1/8))n}$$

(since  $k\epsilon = 1/(16k) < 1/8$ ). However, if  $A_\alpha := A_{\alpha-1} \cup \{0^{k(n+1)}\}$ , then every element of  $\Sigma^{kn}$  enters  $L_k(A_\alpha)$ . It follows that  $G_t \subseteq \Sigma^{kn} \subseteq L_k(A_\alpha)^{kn}$  and so  $\|L_k(A_\alpha)^{kn} \cap G_t\| \geq 2^{kn-2} > 2^{(k-(1/8))n}$ . This implies that  $L_k(A_\alpha) \neq L(M_{i,j}, S)$  for all  $S \in \text{SPARSE}_h$ .

*Subcase 2.2.2.*  $t(0, \dots, 0) = 1$ . Similarly to the argument in Subcase 2.2.1, we can conclude that for every  $S \in \text{SPARSE}_h$ ,  $\|\overline{L(M_{i,j}, S)} \cap G_t\| < 2^{(k-(1/8))n}$ . Let  $A_\alpha := A_{\alpha-1}$ . Then every element of  $\Sigma^{kn}$  enters  $\overline{L_k(A_\alpha)}$ . It follows that  $G_t \subseteq \Sigma^{kn} \subseteq \overline{L_k(A_\alpha)^{kn}}$  and so  $\|\overline{L_k(A_\alpha)^{kn}} \cap G_t\| = \|G_t\| > 2^{kn-2^k} > 2^{(k-(1/8))n}$ , which implies that  $L_k(A_\alpha) \neq L(M_{i,j}, S)$  for all  $S \in \text{SPARSE}_h$ .

This concludes the proof for Subcase 2.2 and, hence, for Case 2 and Stage  $\alpha$ .

Let  $A = \bigcup_{\alpha \geq 1} A_\alpha$ .

Since the justification for the stage construction of set  $A$  was given as the construction was carried out, we can conclude that for every choice of  $i, j, h$ , and every set  $S \in \text{SPARSE}_h$ ,  $L_k(A) \neq L(M_{i,j}, S)$ .  $\square$

Now we prove the lemma. We state and prove a stronger statement.

**LEMMA** (in stronger form). *For each  $j$ ,  $1 \leq j \leq k-1$ , the following holds. Suppose there exist a set  $G \subseteq \Sigma^{kn}$ , a function  $f(x) = \langle x_1, \dots, x_j \rangle$ , a constant  $c$ , and  $k-j+1$  strings  $u_1, \dots, u_{k-j-1}, u_{k-j}, v_{k-j}$  in  $\Sigma^n$  satisfying the following conditions:*

(0)  $\frac{1}{4} \leq c \leq \frac{1}{2} - 2jk\epsilon$ ;

(1)  $f$  is one-to-one on  $G$ , and for all  $r \leq j$ ,  $|x_r| \leq q(kn)$ ;

(2) if  $U_{j+1}$  is defined to be  $\{u_1 \dots u_{k-j-1}\} \Sigma^{(j+1)n}$  and  $U_j = \{u_1 \dots u_{k-j-1} u_{k-j}\} \Sigma^{jn}$ ,  $V_j = \{u_1 \dots u_{k-j-1} v_{k-j}\} \Sigma^{jn}$ , then  $G \subseteq U_{j+1}$ ,  $\|G \cap U_j\| \geq 2^{(j-c)n}$ , and  $\|G \cap V_j\| \geq 2^{(j-c)n}$ .

Also assume that there is a set  $B$  such that

(3) for every  $i$ ,  $j+1 \leq i \leq k$ ,  $\|B \cap \Sigma^{kn+i}\| \leq 1$ , and

(4) for every  $i$ ,  $0 \leq i \leq j$ ,  $B \cap \Sigma^{kn+i} = \emptyset$ .

Then, there exists a set  $C \subseteq \{y \mid kn \leq |y| \leq kn+j\}$  such that for every  $i$ ,  $0 \leq i \leq j$ ,  $\|C \cap \Sigma^{kn+i}\| \leq 1$  and, in addition,  $C$  has the property that for every set  $S \in \text{SPARSE}_h$  and every  $j$ -tt-condition  $t$ , it is not the case that for all  $x \in G$ ,  $x \in L_k(B \cup C)$  if and only if  $t(\chi_S(x_1), \dots, \chi_S(x_j)) = 1$ .

It is easy to verify that the above statement implies the lemma used in the proof of Theorem 4.2.

*Proof of Lemma.  $j = 1$ .* Let  $C = \{u_1 \cdots u_{k-1} 0^{n+1}\}$ . This choice of  $C$  satisfies the requirements; otherwise, there exists a sparse set  $S$  and a  $j$ -tt-condition  $t$  such that for all  $x \in G$ ,  $x \in L_k(B \cup C)$  if and only if  $t(\chi_S(x_1)) = 1$ .

CLAIM 1.  $\|L_k(B \cup C) \cap G\| \geq 2^{(1-c)n}$  and  $\|\overline{L_k(B \cup C)} \cap G\| \geq 2^{(1-c)n}$ .

*Proof.* Since by hypothesis  $G \subseteq U_2$  and  $B$  contains no strings of length  $kn$  or  $kn+1$ , the set  $U_2 = \{u_1 \cdots u_{k-2}\Sigma^{2n}$  must be included in  $L_k(B)$  or in  $\overline{L_k(B)}$  depending on whether there is an odd number or an even number of strings in  $\{0^{(k+1)}, u_1 0^{(k-1)(n+1)}, \dots, u_1 \cdots u_{k-2} 0^{2n+2}\} \cap B$ . If the string  $u_1 \cdots u_{k-1} 0^{n+1}$  is added to  $C$ , then membership in  $L_k(B \cup C)$  (or in  $\overline{L_k(B \cup C)}$ ) will not change for those strings in  $U_2 - U_1$ , but membership in  $L_k(B \cup C)$  (or in  $\overline{L_k(B \cup C)}$ ) will change for strings in  $U_1$ . Thus, either  $\|L_k(B \cup C) \cap G\| = \|G - U_1\|$  and  $\|\overline{L_k(B \cup C)} \cap G\| = \|G \cap U_1\|$  with both values being no less than  $2^{(1-c)n}$ , or  $\|L_k(B \cup C) \cap G\| = \|G \cap U_1\|$  and  $\|\overline{L_k(B \cup C)} \cap G\| = \|G - U_1\|$ , with both values being no less than  $2^{(1-c)n}$ .  $\square$

CLAIM 2. If for all  $x \in G$ ,  $x \in L_k(B \cup C)$  if and only if  $t(\chi_S(x_1)) = 1$ , then  $\|L_k(B \cup C) \cap G\| < 2^{\varepsilon n}$  or  $\|\overline{L_k(B \cup C)} \cap G\| < 2^{\varepsilon n}$ .

*Proof.* There are four cases.

Case 2.1.  $t(0) = t(1) = 0$ . This implies  $L_k(B \cup C) \cap G = \emptyset$ .

Case 2.2.  $t(0) = t(1) = 1$ . This implies that  $x \in L_k(B \cup C)$  if and only if  $f(x) \in S$ . Since  $f$  is one-to-one,  $\|L_k(B \cup C) \cap G\| \leq \|S^{\leq q(kn)}\| < 2^{\varepsilon n}$ .

Case 2.3.  $t(0) = 1, t(1) = 0$ . This implies that  $x \in \overline{L_k(B \cup C)}$  if and only if  $f(x) \in S$ . Since  $f$  is one-to-one,  $\|\overline{L_k(B \cup C)} \cap G\| \leq \|S^{\leq q(kn)}\| < 2^{\varepsilon n}$ .

Case 2.4.  $t(0) = t(1) = 1$ . This implies that  $\overline{L_k(B \cap C)} \cap G = \emptyset$ .

This concludes the proof of Claim 2.  $\square$

Recall that  $2^{(1-c)n} > 2^{\varepsilon n}$ . Thus, Claims 1 and 2 yield a contradiction. Hence, the proof of the lemma for  $j = 1$  is complete.  $\square$

*Proof of Lemma. Inductive step.* Let  $j$  be such that  $1 < j \leq k-1$ . Consider two cases.

Case 1. Suppose there exist  $r, 1 \leq r \leq j$ , and  $z$  such that either  $\|H_r(z) \cap U_j\| \geq 2^{(j-c)n}$  or  $\|H_r(z) \cap V_j\| \geq 2^{(j-c)n}$ , where  $H_r(z) = \{x \in G \mid x_r = z\}$ , where  $x_r$  is the  $r$ th element in  $f(x)$  and  $c' = c + k\varepsilon$ .

Assume, without loss of generality, that  $\|H_r(z) \cap U_j\| \geq 2^{(j-c)n}$ . Then, there exist  $u, v \in \Sigma^n$ ,  $u \neq v$ , such that  $\|H_r(z) \cap U_{j-1}\| \geq 2^{(j-1-c'')n}$  and  $\|H_r(z) \cap V_{j-1}\| \geq 2^{(j-1-c'')n}$ , where  $U_{j-1} = \{u_1 \cdots u_{k-j} u\} \Sigma^{(j-1)n}$  and  $V_{j-1} = \{u_1 \cdots u_{k-j} v\} \Sigma^{(j-1)n}$  and  $c'' = c' + \varepsilon$ . Consider the induction hypothesis for  $j-1$ , set  $H_r(z) \cap U_j$ , function  $f'(x) = \langle x_1, \dots, x_{r-1}, x_{r+1}, \dots, x_j \rangle$ , constant  $c''$ , and strings  $u_1, \dots, u_{k-j}, u, v \in \Sigma^n$ . Then we can check that

(0)  $\frac{1}{4} \leq c \leq \frac{1}{2} - 2jk\varepsilon$  implies  $\frac{1}{4} \leq c'' = c + (k+1)\varepsilon \leq \frac{1}{2} - 2(j-1)k\varepsilon$ ;

(1)  $f'$  is one-to-one on  $H_r(z) \cap U_j$  (otherwise,  $f$  would not be one-to-one on  $G$ ) and for all  $i, |x_i| \leq q(kn)$ .

(2)  $H_r(z) \cap U_j \subseteq U_j$  and  $\|H_r(z) \cap U_j \cap U_{j-1}\| = \|H_r(z) \cap U_{j-1}\| \geq 2^{(j-1-c'')n}$  and  $\|H_r(z) \cap U_j \cap V_{j-1}\| = \|H_r(z) \cap V_{j-1}\| \geq 2^{(j-1-c'')n}$ .

Also,  $B$  satisfies conditions (3) and (4). By the induction hypothesis there exists a set  $C_1$  such that for all sparse sets  $S \in \text{SPARSE}_h$  and all  $(j-1)$ -tt-conditions  $t$ , it is not the case that for all  $x \in H_r(z) \cap U_j$ ,  $x \in L_k(B \cup C_1)$  if and only if  $t(\chi_S(x_1), \dots, \chi_S(x_{r-1}), \chi_S(x_{r+1}), \dots, \chi_S(x_j)) = 1$ . Let  $C = C_1$ .

CLAIM. For every sparse  $S \in \text{SPARSE}_h$  and every  $j$ -tt-condition  $t$ , it is not the case that for all  $x \in G$ ,  $x \in L_k(B \cup C)$  if and only if  $t(\chi_S(x_1), \dots, \chi_S(x_{r-1}), \chi_S(x_r), \chi_S(x_{r+1}), \dots, \chi_S(x_j)) = 1$ .

*Proof.* Suppose that this is false. So for some  $j$ - $tt$ -condition  $t$  and some sparse set  $S \in \text{SPARSE}_h$ ,  $x \in L_L(B \cup C)$  if and only if  $t(\chi_S(x_1), \dots, \chi_S(x_{r-1}), \chi_S(x_r), \chi_S(x_{r+1}), \dots, \chi_S(x_j)) = 1$ . For this  $j$ - $tt$ -condition  $t$ , there are two induced  $(j-1)$ - $tt$ -conditions  $t_0$  and  $t_1$  such that  $t_0(\chi_S(x_1), \dots, \chi_S(x_{r-1}), \chi_S(x_{r+1}), \dots, \chi_S(x_j)) = 1$  if and only if  $t(\chi_S(x_1), \dots, \chi_S(x_{r-1}), 0, \chi_S(x_{r+1}), \dots, \chi_S(x_j)) = 1$ , and  $t_1(\chi_S(x_1), \dots, \chi_S(x_{r-1}), \chi_S(x_{r+1}), \dots, \chi_S(x_j)) = 1$  if and only if  $t(\chi_S(x_1), \dots, \chi_S(x_{r-1}), 1, \chi_S(x_{r+1}), \dots, \chi_S(x_j)) = 1$ . Depending upon whether or not  $z$  is in  $S$ , we have two possibilities: either

(a) for all  $x \in H_r(z)$ ,  $x \in L_k(B \cup C)$  if and only if  $t_0(\chi_S(x_1), \dots, \chi_S(x_{r-1}), \chi_S(x_{r+1}), \dots, \chi_S(x_j)) = 1$ , or

(b) for all  $x \in H_r(z)$ ,  $x \in L_k(B \cup C)$  if and only if  $t_1(\chi_S(x_1), \dots, \chi_S(x_{r-1}), \chi_S(x_{r+1}), \dots, \chi_S(x_j)) = 1$ .

Either case contradicts the induction hypothesis.  $\square$

*Case 2.* The condition specifying Case 1 is false.

Let  $C = \{u_1 \cdots u_{k-j-1} u_{k-j} 0^{j(n+1)}\}$ . Assume, by way of contradiction, that for some sparse set  $S$ , some  $j$ - $tt$ -condition  $t$ , and all  $x \in G$ ,

(\*)  $x \in L_k(B \cup C)$  if and only if  $t(\chi_S(x_1), \dots, \chi_S(x_j)) = 1$ .

CLAIM.  $\|L_k(B \cup C) \cap G \cap U_j\| \geq 2^{(j-c)n}$  or  $\|L_k(B \cup C) \cap G \cap V_j\| \geq 2^{(j-c)n}$ .

*Proof.* Since by hypothesis  $G \subseteq U_{j+1}$  and  $B$  contains no strings of length  $\leq kn + j$ , the set  $U_{j+1} = \{u_1 \cdots u_{k-j-1}\} \Sigma^{(j+1)n}$  must be included in  $L_k(B)$  or in  $\overline{L_k(B)}$ , depending on whether there is an odd number or an even number of strings in  $\{0^{k(n+1)}, u_1 0^{(k-1)(n+1)}, \dots, u_1 \cdots u_{k-j-1} 0^{(j+1)(n+1)}\} \cap B$ . By adding  $C = \{u_1 \cdots u_{k-j-1} u_{k-j} 0^{j(n+1)}\}$  to  $B$ , the membership in  $L_k(B \cup C)$  (or in  $\overline{L_k(B \cup C)}$ ) will not change for those strings in  $U_{j+1} - U_j$ , but the membership in  $L_k(B \cup C)$  (or in  $\overline{L_k(B \cup C)}$ ) will change for those strings in  $U_j$ . Thus we have that either  $[G \cap U_j \subseteq U_j \subseteq L_k(B \cup C)$  and  $G \cap V_j \subseteq U_{j+1} - U_j \subseteq \overline{L_k(B \cup C)}$ ] or  $[G \cap U_j \subseteq U_j \subseteq \overline{L_k(B \cup C)}$  and  $G \cap V_j \subseteq U_{j+1} - U_j \subseteq L_k(B \cup C)]$ . Therefore, we have either  $\|L_k(B \cup C) \cap G \cap U_j\| = \|G \cap U_j\| \geq 2^{(j-c)n}$  or  $\|L_k(B \cup C) \cap G \cap V_j\| = \|G \cap V_j\| \geq 2^{(j-c)n}$ .  $\square$

Now consider the  $j$ - $tt$ -condition  $t$  in (\*).

*Subcase 2.1.*  $t(0, \dots, 0) = 0$ . Then, for all  $x \in G$ ,  $x \in L_k(B \cup C)$  if and only if there exists  $r$ ,  $1 \leq r \leq j$ , such that  $x_r \in S$ . But for each  $r$  and each  $z \in S$ ,  $\|H_r(z) \cap U_j\| < 2^{(j-c)n}$  and  $\|H_r(z) \cap V_j\| < 2^{(j-c)n}$ . So,

$$\|L_k(B \cup C) \cap G \cap U_j\| \leq \sum_{r=1}^j \sum_{z \in S} \|H_r(z) \cap U_j\| < j \cdot 2^{\epsilon n} \cdot 2^{(j-c)n} \leq 2^{(j-c'+k\epsilon)n} = 2^{(j-c)n},$$

and similarly,  $\|L_k(B \cup C) \cap G \cap V_j\| < 2^{(j-c)n}$ . This contradicts the above claim.

*Subcase 2.2.*  $t(0, \dots, 0) = 1$ . Then, for all  $x \in G$ ,  $x \in \overline{L_k(B \cup C)} \cap G$  if and only if there exists  $r$ ,  $1 \leq r \leq k$ , such that  $x_r \in S$ . But then

$$\|\overline{L_k(B \cup C)} \cap G \cap U_j\| \leq \sum_{r=1}^j \sum_{z \in S} \|H_r(z) \cap U_j\| < 2^{(j-c)n}$$

and  $\|\overline{L_k(B \cup C)} \cap G \cap V_j\| < 2^{(j-c)n}$ . Again, we have a contraction.

This concludes the proof of Case 2 and, hence, the proof of the inductive step.  $\square$

Now we turn to the proof of Theorem 3.5. To a very large extent the proof follows the outline of the proof of Theorem 3.4, and so only a sketch will be given here.

**THEOREM 4.3.**  $P_{bit}(\text{SPARSE}) \neq P_{it}(\text{SPARSE})$ .

*Sketch of the proof.* For any set  $A$ , let  $L_\infty(A) = \{u_1 \cdots u_n \mid |u_1| = \dots = |u_n| = n\}$ ; the number of strings in the following list that are in the set  $A$  is odd:  $0^{n(n+1)}, u_1 0^{(n-1)(n+1)}, \dots, u_1 \cdots u_i 0^{(n-i)(n+1)}, \dots, u_1 \cdots u_n$ . It is clear that  $L_\infty(A) \leq_{it}^P A$ . We will describe a specific sparse set  $A$  such that  $L_\infty(A) \not\leq_{k-it}^P S$  for every  $k$  and every sparse set  $S$ .

Similar to the proof of Theorem 4.2, we assume an enumeration of polynomial-time-bounded deterministic machines witnessing bounded truth-table reductions:  $M_{i,j,k}$  computes the  $i$ th polynomial-time function  $f_i$  that generates  $k$  queries and the  $j$ th polynomial-time function  $g_j$  that generates a  $k$ - $tt$ -condition.

The following lemma is established in the proof of Theorem 4.2.

LEMMA. *For any pair  $k, h$  of positive integers and any machine  $M$  that witnesses an instance of a  $\leq_{k- $tt$$ -reduction, there exist arbitrarily large  $n$  and a finite set  $B \subseteq \{x \mid kn \leq |x| \leq k(n+1)\}$  such that*

(1) *for any  $m, kn \leq m \leq k(n+1), \|B \cap \Sigma^m\| \leq 1$ , and*

(2)  *$L_k(B)^{kn} \neq L(M, S)^{kn}$  for all  $S \in \text{SPARSE}_h$ .*

At stage  $\alpha = \langle i, j, k, h \rangle$ , consider the machine  $M'_{i,j,k}$  which operates as follows:

on input  $x$  whose length is at least  $k^2$  and is a multiple of  $k$ , say  $|x| = kn$ , and any set  $C$ , simulate  $M_{i,j,k}$  on  $0^{(n-k)n}x$  relative to  $C$ ;

on input  $x$  whose length is less than  $k^2$  or is not a multiple of  $k$ , reject.

The machine  $M'_{i,j,k}$  witnesses an instance of a  $\leq_{k- $tt$$ -reduction so that for the polynomial  $p_h$  the lemma shows that there exist an integer  $n > n_{\alpha-1}^2 + k$  and a finite set  $B \subseteq \{x \mid kn \leq |x| \leq k(n+1)\}$  satisfying (1) and (2) of the lemma. Then,  $L_k(B)^{kn} \neq L(M'_{i,j,k}, S)^{kn}$  for all  $S \in \text{SPARSE}_h$ .

Letting  $n_\alpha = n$ , define  $A_\alpha$  by adding strings in  $\{x \mid n^2 \leq |x| \leq n(n+1)\}$  to  $A_{\alpha-1}$  as follows:  $0^{(n-k)n}u_1 \cdots u_i 0^{(k-i)(n+1)} \in A_\alpha$  if and only if  $u_1 \cdots u_i 0^{(k-i)(n+1)} \in B$ , where  $1 \leq i \leq k$  and  $|u_1| = \cdots = |u_i| = n$ . Thus, for any  $x \in \Sigma^{n^2}$ ,  $x \in L_\infty(A)$  if and only if there exists  $y \in L_k(B)^{kn}$  such that  $x = 0^{(n-k)n}y$ . This implies that  $L_\infty(A) \cap \{0^{(n-k)n}\Sigma^{kn} = \{0^{(n-k)n}\}L_k(B)^{kn} \neq \{0^{(n-k)n}\}L(M'_{i,j,k}, S)^{kn} = L(M_{i,j,k}, S) \cap \{0^{(n-k)n}\Sigma^{kn}$  so that  $L_\infty(A) \neq L(M_{i,j,k}, S)$  for all  $S \in \text{SPARSE}_h$ .  $\square$

In the proofs of Theorems 4.1, 4.2, and 4.3, it is easy to verify that the set  $A$  is computable in time  $2^{O(n)}$  and, hence, that each of the sets  $L_k(A)$ ,  $k \geq 1$ , and  $L_\infty(A)$  is in  $\text{DXT} (= \cup_{c>0} \text{DTIME}(2^{cn}))$ .

5. Consider the proofs given in § 4. If we look carefully, it becomes clear that bounding the time needed to compute the reducibilities served as a method of bounding the number and the lengths of the query strings and nothing else. Thus it is reasonable to consider other reducibilities specified in such a way that the number and the lengths of the query strings are bounded by a polynomial in the length of the input. This section is devoted to such considerations.

Consider reducibilities computed nondeterministically in polynomial time. Ladner, Lynch, and Selman [19] defined  $\leq_{tt}^{\text{NP}}$  in such a way that  $\leq_{tt}^{\text{NP}} = \leq_T^{\text{NP}}$ . Later, Book, Long, and Selman [11] considered a variation of the notion of  $\leq_{tt}^{\text{NP}}$  by requiring that both the function that generates the list of queries and the function that generates the  $tt$ -condition be functions that are computed nondeterministically but are single-valued. It is this notion of  $\leq_{tt}^{\text{NP}}$  that is considered here.

It is clear that for any set  $A$  and any of the reducibilities  $r$  considered here,  $P_r(A) \subseteq \text{NP}_r(A)$ . What we have here are the observations that simple modifications of the proofs of Theorems 4.1, 4.2, and 4.3 yield the following results.

THEOREM 5.1. (a) *For every  $k > 0$ ,  $\text{NP}_{k- $tt$ }(\text{SPARSE}) \neq \text{NP}_{(k+1)- $tt$ }(\text{SPARSE})$ .*

(b)  $\text{NP}_{bt}(\text{SPARSE}) \neq \text{NP}_{tt}(\text{SPARSE})$ .

(c) *There is no  $k$  such that  $P_{(k+1)- $tt$ }(\text{SPARSE}) \subseteq \text{NP}_{k- $tt$ }(\text{SPARSE})$ .*

(d)  $P_{tt}(\text{SPARSE}) \not\subseteq \text{NP}_{bt}(\text{SPARSE})$ , that is,  $P/\text{poly} \not\subseteq \text{NP}_{bt}(\text{SPARSE})$ .

Proof. In the proofs of Theorems 4.1 and 4.2, we enumerate, instead of  $\leq_{k- $tt$$ -reduction machines  $\{M_{i,j}\}$ ,  $\leq_{k- $tt$$ -reduction machines  $\{N_{i,j}\}$ , and construct a sparse set  $A$  in the same way. Then, for all  $i, j$ , and all sparse sets  $S$ ,  $L_k(A) \neq L(N_{i,j}, S)$ , and hence  $L_k(A) \notin \text{NP}_{k- $tt$ }(\text{SPARSE})$ . Recall that for all sparse sets  $A$ ,  $L_k(A) \in$

$P_{(k+1)-it}(\text{SPARSE})$ . This proves parts (a) and (c). A similar modification yields a proof for part (b). A similar modification of the proof of Theorem 4.3 yields a proof of part (d).  $\square$

Unlike the set  $A$  constructed in the proofs of Theorems 4.1 and 4.2, the set  $A$  constructed above is not known to be computable deterministically in exponential time. Note that in stage  $\alpha = \langle i, j, h \rangle$  of the construction, we need to simulate function  $f_i$  on all strings of length  $kn$  (where  $n = n_\alpha$ ) in order to determine their membership in  $A$  or in  $\bar{A}$ . Since the function  $f_i$  is only known to be computable nondeterministically in polynomial time, no deterministic exponential time bound is known for the computation of all of the  $f_i$ .

We can interpret parts (c) and (d) of Theorem 5.1 as asserting that the (potential) additional computational power of nondeterministic operation is not sufficient to overcome the power of a deterministic machine to make additional queries, even though these queries are made in a nonadaptive (truth-table) manner to sets that are sparse.

Analogous to Theorem 3.6, we have the following fact.

**THEOREM 5.2.**  $\text{NP/poly} = \text{NP}_T(\text{SPARSE}) = \text{NP}_it(\text{SPARSE}) = \text{NP}_it(\text{TALLY}) = \text{NP}_T(\text{TALLY})$ .

*Proof.* The proof that  $\text{NP}_it(\text{TALLY}) = \text{NP}_T(\text{TALLY})$  is just like the proof that  $P_it(\text{TALLY}) = P(\text{TALLY})$ . The proof that  $\text{NP}_T(\text{SPARSE}) = \text{NP}_T(\text{TALLY})$  is just like the proof that  $P_T(\text{SPARSE}) = P_T(\text{TALLY})$ . The result follows since  $\text{NP}_it(\text{TALLY}) \subseteq \text{NP}_it(\text{SPARSE})$ .  $\square$

Now consider reducibilities computed in polynomial space. Assume that all queries are of length bounded by a polynomial in the length of the input. The various truth-table reducibilities are nonadaptive and the list of queries must be computed and stored on a work tape before any evaluation is carried out; thus, even with polynomial space-bounded machines, only a polynomial number of queries can be made. Book [10], Book and Wrathall [13], and Balcázar, Book, and Schöning [3] have investigated the Turing reducibilities computed by deterministic and nondeterministic polynomial space-bounded oracle machines that in any computation make only a polynomial number of queries. For any set  $A$ , the class specified by deterministic machines of this type is denoted  $\text{PQUERY}_T(A)$  and the class specified by nondeterministic machines of this type is denoted  $\text{NPQUERY}_T(A)$ . It is known [3] that for any set  $A$ ,  $\text{PQUERY}_T(A) = P_T(Q \oplus A)$  and  $\text{NPQUERY}_T(A) = \text{NP}_T(Q \oplus A)$ , where  $Q$  is any set that is  $\leq_m^P$ - or  $\leq_T^P$ -complete for PSPACE. As reducibilities, let  $A \leq_T^{\text{PQ}} B$  denote  $A \in \text{PQUERY}_T(B)$  and let  $A \leq_T^{\text{NPQ}} B$  denote  $A \in \text{NPQUERY}_T(B)$ ; notice that  $\text{PQUERY}_T(\emptyset) = \text{NPQUERY}_T(\emptyset) = \text{PSPACE}$ . On the other hand, it is shown in [10] that there is a sparse set  $S$  such that  $\text{PQUERY}_T(S) \neq \text{NPQUERY}_T(S)$ .

By considering functions computable deterministically in polynomial space, we can define the various truth-table reducibilities computable deterministically in polynomial space and view them as restrictions of  $\leq_T^{\text{PQ}}$ . Again observing that the role of the polynomial time bounds in the proofs in § 4 is only to restrict the number and length of queries, we see the following facts.

**THEOREM 5.3.**

- (a) For every  $k > 0$ ,  $\text{PQUERY}_{k-it}(\text{SPARSE}) \neq \text{PQUERY}_{(k+1)-it}(\text{SPARSE})$ .
- (b)  $\text{PQUERY}_{bit}(\text{SPARSE}) \neq \text{PQUERY}_it(\text{SPARSE})$ .
- (c) There is no  $k$  such that  $P_{(k+1)-it}(\text{SPARSE}) \subseteq \text{PQUERY}_{k-it}(\text{SPARSE})$ .
- (d)  $P_it(\text{SPARSE}) \not\subseteq \text{PQUERY}_{bit}(\text{SPARSE})$ , that is,  $P/\text{poly} \not\subseteq \text{PQUERY}_{bit}(\text{SPARSE})$ .

By considering functions that are computable nondeterministically in polynomial space but are single-valued, we can define the various truth-table reducibilities compu-

table nondeterministically in polynomial space and view them as restrictions of  $\leq_T^{\text{NPQ}}$ . Combining the arguments needed for the proofs of Theorems 5.1 and 5.3, we see the following facts.

THEOREM 5.4.

- (a) For every  $k > 0$ ,  $\text{NPQUERY}_{k\text{-tt}}(\text{SPARSE}) \neq \text{NPQUERY}_{(k+1)\text{-tt}}(\text{SPARSE})$ .
- (b)  $\text{NPQUERY}_{\text{btt}}(\text{SPARSE}) \neq \text{NPQUERY}_{\text{tt}}(\text{SPARSE})$ .
- (c) There is no  $k$  such that  $P_{(k+1)\text{-tt}}(\text{SPARSE}) \subseteq \text{NPQUERY}_{k\text{-tt}}(\text{SPARSE})$ .
- (d)  $P_{\text{tt}}(\text{SPARSE}) \not\subseteq \text{NPQUERY}_{\text{btt}}(\text{SPARSE})$ , that is,  $P/\text{poly} \not\subseteq \text{NPQUERY}_{\text{btt}}(\text{SPARSE})$ .

Parts (c) and (d) of Theorems 5.3 and parts (c) and (d) of Theorem 5.4 can be interpreted as asserting that the (potential) additional computational power of space, as opposed to time, is not sufficient to overcome the ability to make additional queries, even though these queries are made in a truth-table (nonadaptive) manner to a sparse set.

Even though there is a sparse set  $S$  such that  $\text{PQUERY}_T(S) \neq \text{NPQUERY}_T(S)$ , an argument of Long [20] can be used to show that for every sparse set  $S_1$  there is a sparse set  $S_2$  such that  $\text{NPQUERY}_T(S_1) \subseteq \text{PQUERY}_T(S_2)$  and, hence,  $\text{PQUERY}_T(\text{SPARSE}) = \text{NPQUERY}_T(\text{SPARSE})$ . We will show something somewhat stronger.

THEOREM 5.5. Each of the following classes is equal to  $\text{PSPACE}/\text{poly}$ :

- (a)  $\text{PQUERY}_T(\text{SPARSE})$ ;
- (b)  $\text{PQUERY}_{\text{tt}}(\text{SPARSE})$ ;
- (c)  $\text{PQUERY}_{\text{tt}}(\text{TALLY})$ ;
- (d)  $\text{PQUERY}_T(\text{TALLY})$ ;
- (e)  $\text{NPQUERY}_T(\text{TALLY})$ ;
- (f)  $\text{NPQUERY}_{\text{tt}}(\text{TALLY})$ ;
- (g)  $\text{NPQUERY}_{\text{tt}}(\text{SPARSE})$ ;
- (h)  $\text{NPQUERY}_T(\text{SPARSE})$ .

*Proof.* First, we show that all of the classes listed in (a)–(h) are equal. Notice that each class is included in  $\text{NPQUERY}_T(\text{SPARSE})$ , and  $\text{PQUERY}_{\text{tt}}(\text{TALLY})$  is included in each of these classes. Thus, it is sufficient to show that  $\text{NPQUERY}_T(\text{SPARSE}) \subseteq \text{NPQUERY}_T(\text{TALLY}) \subseteq \text{NPQUERY}_{\text{tt}}(\text{TALLY}) \subseteq \text{PQUERY}_{\text{tt}}(\text{TALLY})$ . The first inclusion follows from the proof of Hartmanis [15] that  $\text{NP}_T(\text{SPARSE}) = \text{NP}_T(\text{TALLY})$ . The second inclusion follows from the argument that  $P_T(\text{TALLY}) = P_{\text{tt}}(\text{TALLY})$  in the proof of Theorem 3.6. The third inclusion follows from Savitch's Theorem [23].

Second, recall that  $\text{PSPACE}/\text{poly} = \text{PSPACE}_T(\text{SPARSE})$  so that each of the classes in (a)–(h) is included in  $\text{PSPACE}/\text{poly}$ . Long [20], among others, has shown that for any sparse set  $S_1$  there exist a sparse set  $S_2$  (=prefix set of  $S_1$ ) and a deterministic polynomial-time oracle machine  $M_0$  that, relative to  $S_2$ , will enumerate  $S_1$ . Let  $q$  be a polynomial that bounds the running time of  $M_0$ . Let  $L \in \text{PSPACE}(S_1)$  and let  $M_1$  be a deterministic polynomial space-bounded oracle machine that witnesses this. (Notice that Savitch's theorem allows us to take  $M_1$  as deterministic since there is no bound on the number of oracle queries.) Let  $M_2$  be a machine that on input  $x$  first simulates  $M_0$  to compute in time  $q(|x|)$ , a list containing precisely the strings in  $S_1^{\leq q(|x|)}$  and then simulates  $M_1$ 's computation on  $x$ , using the list to determine whether a query string is in  $S_1$  instead of actually querying the oracle. Clearly,  $L(M_2, S_2)$  is in  $\text{PQUERY}(S_2) \subseteq \text{PQUERY}_T(\text{SPARSE})$  and  $L = L(M_2, S_2)$ . Since  $L$  was taken arbitrarily in  $\text{PSPACE}_T(\text{SPARSE})$ , this yields the fact that  $\text{PSPACE}/\text{poly} \subseteq \text{PQUERY}_T(\text{SPARSE})$ .  $\square$

Consider reducibilities computed deterministically by machines that use work space  $\log n$ . Recall that  $\leq_T^{\log}$  is transitive. For any fixed  $k$ , the queries may be computed one at a time and the answers stored so that the list of  $k$  answers can be stored in  $\log n$  space. Thus, the reducibilities  $\leq_{k-nt}^{\log}$ ,  $k > 0$ , can be defined. For every set  $A$  and every  $k > 0$ , let  $\text{DLOG}_{k-nt}(A)$  denote the collection of sets  $B$  such that  $B \leq_{k-nt}^{\log} A$ . Also, for every  $k > 0$ , let  $\text{DLOG}_{k-nt}(\text{SPARSE})$  denote the union of all classes  $\text{DLOG}_{k-nt}(S)$  as  $S$  takes values in  $\text{SPARSE}$ . Then we have the following fact.

**THEOREM 5.6.** *For every  $k > 0$ ,  $\text{DLOG}_{k-nt}(\text{SPARSE}) \neq \text{DLOG}_{(k+1)-nt}(\text{SPARSE})$ .*

6. Consider the proofs given in § 4. The proof of Theorem 4.2 is such that for every  $k > 0$  the set that witnesses the fact that  $P_{k-nt}(\text{SPARSE}) \neq P_{(k+1)-nt}(\text{SPARSE})$  is a set that can be accepted by a deterministic Turing machine that runs in exponential time, that is, in the class  $\text{DEXT} = \bigcup_{c>0} \text{DTIME}(2^{cn})$ . Hence, there is no sparse set that can be  $\leq_{k-nt}^P$ -hard for  $\text{DEXT}$ . This yields a new proof of a result of Watanabe [27], [28].

**THEOREM 6.1.** *Let  $C$  be any class of languages that contains every language accepted deterministically in exponential time, i.e.,  $\text{DEXT} \subseteq C$ . Then for every  $k$  there is no sparse set that is  $\leq_{k-nt}^P$ -hard for  $C$ .*

Similarly, the proof of Theorem 4.3 is such that for every  $k > 0$  the set that witnesses the fact that  $P_{bnt}(\text{SPARSE}) \neq P_{nt}(\text{SPARSE})$  is a set that is in the class  $\text{DEXT}$ . Hence, there is no sparse set that can be  $\leq_{bnt}^P$ -hard for  $\text{DEXT}$ . This leads to the following result.

**THEOREM 6.2.** *Let  $C$  be any class of languages that contains every language accepted deterministically in exponential time, i.e.,  $\text{DEXT} \subseteq C$ . Then there is no sparse set that is  $\leq_{bnt}^P$ -hard for  $C$ .*

**COROLLARY.** *No sparse set is bounded truth-table hard for deterministic exponential time.*

**COROLLARY.** *No sparse set is bounded truth-table complete for deterministic exponential time.*

Results similar to Theorems 6.1 and 6.2 and the corollaries have been reported by Balcázar and Schöning [6] and by Berman and Hartmanis [7], both dealing with  $\leq_m^P$ . Watanabe [27], [28] has developed similar results for  $\leq_T^P$ -hard sets for  $\text{DEXT}$  and has shown that any such set must have density greater than  $\log \log n$ .

It is important to point out that all of the results presented here have to do with sets reducible to sparse sets. There are other results in the literature showing that the polynomial time truth-table reducibilities can be separated. Of particular interest are the results in an important new paper by Watanabe [26]. Recall that  $\text{DEXT}$  denotes the collection of all languages accepted deterministically in exponential time.

(1) For every integer  $k$  there exists a  $\leq_{(k+1)-nt}^P$ -complete set for  $\text{DEXT}$  which is not  $\leq_{k-nt}^P$ -complete for  $\text{DEXT}$ .

(2) There exists a  $\leq_{nt}^P$ -complete set for  $\text{DEXT}$  which is not  $\leq_{bnt}^P$ -complete for  $\text{DEXT}$ .

(3) There exists a  $\leq_T^P$ -complete set for  $\text{DEXT}$  which is not  $\leq_{nt}^P$ -complete for  $\text{DEXT}$ .

Thus, there is a properly infinite hierarchy of complete sets for  $\text{DEXT}$  based on the different (nonadaptive) bounded truth-table polynomial-time reducibilities.

## AN APPROXIMATION SCHEME FOR FINDING STEINER TREES WITH OBSTACLES\*

J. SCOTT PROVAN†

**Abstract.** We consider the problem of constructing a Steiner minimal tree connecting a given set  $K$  of points and lying inside a polygonally bounded, not necessarily simply connected region  $R$  in the plane. We first define the *path-convex hull* of  $K$  in  $R$ , which is a “sufficiently small” subregion of  $R$  guaranteed to contain the Steiner minimal tree. We then give an  $\epsilon$ -approximation scheme to find the Steiner minimal tree in  $R$  by reducing it to a Steiner tree problem on a “visibility graph” associated with  $K$  and the path-convex hull of  $R$ . This will be a fully polynomial approximation scheme when  $K$  is restricted to lie on a small number of interior points and boundary polygons of  $R$ . Several techniques are given which further reduce the region in which the Steiner minimal tree is known to lie, and which extend known results for the Steiner minimal tree problem without obstacles.

**Key words.** Steiner tree, approximation, polynomial algorithm, fully polynomial approximation, visibility graph

**AMS(MOS) subject classifications.** 05, 51, 90

**1. Introduction.** The *Steiner minimal tree with obstacles problem* (SMTO) studied in this paper is described as follows: Let  $R$  be a *polygonally bounded* region of the plane, that is, a connected (not necessarily simply connected) closed region of the plane whose boundary is made up of a finite number of straight-line segments, and let  $K$  be a set of *terminal points* lying in  $R$ . A *spanning graph* for  $K$  in  $R$  is a finite set of straight-line segments lying entirely in  $R$  and connecting all pairs of points in  $K$ . The *length* of  $T$ ,  $l(T)$ , is the sum of the Euclidean lengths of the line segments in  $T$ . SMTO is the problem of finding the *Steiner minimal tree* for  $K$  in  $R$ , that is, a spanning graph for  $K$  in  $R$  having minimum length, which must necessarily be a tree (see Fig. 1). The special case where  $R$  is the entire Euclidean plane is the classical

Steiner minimal tree problem, and has a long history [3], [4], [5], [8], [10], [12], [14], [18], [26]. SMTO has drawn less attention [15], [16], [25], although the related problem of shortest paths in the presence of obstacles has been fairly well studied [17], [22], [23], [28]. An important closely related problem is the *Steiner tree problem in graphs*. Here  $R$  is described as a graph  $G$  whose edges are given arbitrary lengths. The spanning graphs and Steiner minimal trees are drawn from the edges of  $G$ , with lengths defined accordingly. This problem has also been well studied [7], [13], [24], [27], [29], although little connection has been made between it and the Steiner minimal tree problem.

SMTO is known to be NP-hard [10], even in the case where  $R = \mathbb{R}^2$ . In fact even efficient approximation schemes are unlikely to exist, in the following sense. For a given instance  $(K, R)$  of SMTO, let  $T^*$  be the Steiner minimal for  $K$  in  $R$ . For  $\varepsilon > 0$ , an  $\varepsilon$ -approximation for  $T^*$  is a spanning graph  $T$  for  $K$  in  $R$  satisfying

$$l(T) \leq (1 + \varepsilon)l(T^*).$$

A *fully polynomial approximation scheme* for SMTO is an algorithm which, for any input  $(K, R)$  for SMTO and every  $\varepsilon > 0$ , gives an  $\varepsilon$ -approximation to the Steiner minimal tree for  $K$  in  $R$  in time which is bounded above by a polynomial in  $1/\varepsilon$  and the length of the input describing  $(K, R)$  (see [11, § 6.1], for a discussion of fully polynomial approximation schemes). The construction of [10] shows that a fully polynomial approximation scheme cannot exist for SMTO—even when  $R$  is restricted to be  $\mathbb{R}^2$ —unless  $P = NP$  (see [19, § 4], for details).

In a recent paper [19] the author studies the connection between the Steiner tree problem on graphs and the classical Steiner minimal tree problem. The notion of *path-convexity* is used to effectively restrict the region in which the Steiner minimal tree is known to lie. As a result, polynomial-time algorithms exist to find Steiner minimal trees, or  $\varepsilon$ -approximations thereof, when the terminals are located on the boundary of the restricted region. The purpose of this paper is to extend these results to SMTO, using some interesting recent results in the study of Steiner trees and obstacle-avoiding paths. The paper is organized as follows. In § 2 the notion of *path-convex hull* is introduced, and it is shown that a solution to SMTO always exists in any path-convex hull. An efficient algorithm is given to find a path-convex hull, which makes use of the *visibility graph* of Lozano-Perez and Wesley [17] and the results of Bienstock and Monma [1]. Section 3 gives a scheme for producing an  $\varepsilon$ -approximation to SMTO. By applying the method of Erickson, Monma, and Veinott [9] this scheme is shown to be a fully polynomial approximation scheme in the case where the set of terminals lies on a small number of boundary polygons and interior points of  $K$ . Section 4 shows how results of Bienstock and Monma [1], Gilbert and Pollak [12], Cockayne [5], and Hwang et al. [14] can be extended to shrink the size of a path-convex hull, and thus improve the complexity of the approximation scheme.

**2. The path-convex hull.** A typical input for SMTO consists of a list of terminal points, together with a description of the boundary  $\partial R$  of the enclosing region  $R$ . This latter set can be assumed to consist of a collection  $P_0, \dots, P_m$  of simple (not necessarily convex) polygons with  $P_0$  the exterior boundary of  $R$  and  $P_1, \dots, P_m$  the boundaries of the interior obstacles (see Fig. 1). If we denote by  $P_i^e$  and  $P_i^i$  the interior and exterior, respectively, of polygon  $i$ , then  $R = \mathbb{R}^2 - (P_0^e \cup P_1^i \cup \dots \cup P_m^i)$ . The  $P_1, \dots, P_m$  are assumed to have pairwise disjoint interiors and to be contained inside  $P_0$ . The  $P_i$  themselves need not be disjoint; indeed, an important special case is the Steiner tree problem on a plane graph with a given straight-line layout, where the  $P_i$  are the boundaries of the faces of the graph. It may also be that the exterior or interior boundaries are absent, as with the classical Euclidean minimal Steiner tree problem.

The most general description of a region with finite straight-line boundary also includes the case where the  $P_i$  are nonsimple, though having connected interior. We remark, however, that in this case  $R$  can be separated at the cutpoints of the  $P_i$  into regions with simple boundary polygons, and SMTO can be solved by solving smaller SMTOs separately on each subregion (see, for example, [19, § 2]).

In this paper we will actually treat the *discrete* minimal Steiner tree problem (see [10]); that is, we will assume that Euclidean distances are computed only to some predetermined number of digits' accuracy. Since the results in the paper concern  $\epsilon$ -approximations to SMTO anyway, this is not a serious restriction, although it allows intermediate complexity results to be stated without concern for the possible manipulation of irrational numbers.

Throughout the paper we will use  $V$  to denote the set of vertices in  $\cup_{i=1}^m P_i$ , and will use  $\nu$  and  $k$  to denote the cardinalities of  $V$  and  $K$ , respectively. We first describe a method for finding a "sufficiently small" subregion in which the Steiner tree is known to lie, and give properties of this region. Let  $\tilde{R}$  be a polygonally bounded, connected subregion of  $R$ . Then the exterior boundary of  $\tilde{R}$  can be traversed "clockwise" by a closed walk (a polygon with possibly repeated vertices and edges)  $\Gamma: v_0, e_1, v_1, \dots, v_{r-1}, e_r, v_r = v_0$ , where for  $i = 1, \dots, r$ ,  $e_i = [v_{i-1}, v_i]$  is the straight-line segment connecting  $v_{i-1}$  and  $v_i$ , and no point of  $\tilde{R}$  lies immediately to the left of  $e_i$  when traversed from  $v_{i-1}$  to  $v_i$ . The *perimeter* of  $\tilde{R}$  is defined to be

$$\rho(\tilde{R}) = \sum_{i=1}^r \|e_i\|,$$

where  $\|e_i\| = \|v_i - v_{i-1}\|$ . (See [19] for a more comprehensive discussion of these terms.) The region  $\tilde{R}$  is a *path-convex hull* of  $K$  in  $R$  if it contains  $K$  and has minimum perimeter over all such regions. Path-convex hulls correspond to convex hulls for the classical Steiner minimal tree problem [12, § 3.5] and to path-convex regions for the Steiner tree problem on graphs [1], [19]. Their significance in SMTO is given by the following result. Its proof is identical to that of Theorem 3 in [19].

**THEOREM 2.1.** *Let  $\tilde{R}$  be a path-convex hull of  $K$  in  $R$ . Then there exists a Steiner minimal tree for  $K$  in  $R$  which lies entirely in  $\tilde{R}$ .*

Next we turn to the problem of constructing a path-convex hull for  $K$  in  $R$ . Here we make use of a generalization of the notion of "visibility graph" introduced by Lozano-Perez and Wesley [17] (and by Shamos [22] under the name "viewability graph.") For any set  $S$  of points in  $R$ , define the *S-visibility graph* for  $R$  to be the graph whose vertices are  $V \cup S$  and whose edges consist of those pairs of vertices whose connecting straight-line segments lie entirely in  $R$  and contain no point of  $V \cup S$  in their interiors (see Fig. 2). Visibility graphs have been studied in relation to the shortest path problem [17], [23], [28], where the following theorem is implicit.

**THEOREM 2.2.** *The shortest Euclidean length path in  $R$  between any two points  $u$  and  $v$  can always be chosen to lie in the  $\{u, v\}$ -visibility graph for  $R$ .*

We also note that the  $S$ -visibility graph has  $n = |V \cup S|$  nodes and at most  $n^2$  edges, and the same methods for constructing visibility graphs (e.g., [23], § 2) can be applied to construct the  $S$ -visibility graph in time  $O(n^2 \log n)$ . We next prove a variant of Theorem 2.2 which will be useful for constructing the path-convex hull for  $K$  in  $R$ .

**LEMMA 2.3.** *Any path-convex hull  $\tilde{R}$  of  $K$  in  $R$  has its exterior boundary composed of edges of the  $K$ -visibility graph for  $R$ .*

*Proof.* Let  $\Gamma$  be the closed walk traversing the exterior boundary of  $\tilde{R}$ , specified so that the edges of  $\Gamma$  contain no points of  $V \cup K$  in their interior, and let  $v$  be a vertex of  $\Gamma$  at which two or more noncollinear edges of  $\Gamma$  meet. Suppose  $v$  is not in

FIG. 2. The  $K$ -visibility graph.

$V \cup K$ . By the choice of  $v$  there must exist a pair of successive edges  $[u, v], [v, w]$  in  $\Gamma$  which are noncollinear and whose convex angle contains no other edges of  $\Gamma$  passing through  $v$ . Now since  $v$  is not in  $V \cup K$ , there exists a point  $v'$  on  $[u, v]$  sufficiently close to  $v$  so that  $[v', w] \subseteq R$  and the triangle  $vv'w$  contains no element of  $K$  in its interior. It follows that the closed walk  $\Gamma'$  obtained by replacing  $[u, v], [v, w]$  by  $[u, v'], [v', w]$  in  $\Gamma$  has the property that  $\Gamma'$  lies entirely in  $R$ , encloses  $K$ , and has smaller length than  $\Gamma$ , a contradiction. Thus every such point  $v$  is in  $V \cup K$ , and the theorem follows.  $\square$

The problem of finding the path-convex hull now reduces to that of finding the minimum length closed walk surrounding  $K$  in the  $K$ -visibility graph  $G_K$  for  $R$ . This is facilitated by using two results. The first is due to Bienstock and Monma [1, Thm. 1] and, although it is stated in that paper for plane graphs, it applies as well to  $G_K$ . A *shortest path tree* for  $K$  in  $G_K$  rooted at  $r \in K$  is a tree consisting of a union of shortest paths, one from  $r$  to each of the other vertices of  $K$ .

**THEOREM 2.4** (Bienstock and Monma). *Let  $T$  be any shortest path tree for  $K$  in  $R$ . Then there exists a path-convex hull of  $K$  in  $R$  which contains  $T$ .*

The second result is proved in Theorem 1 of [20]. For path  $\Gamma$ , let  $\Gamma^{-1}$  be the path obtained by traversing  $\Gamma$  in reverse order.

**THEOREM 2.5.** *Let  $G' = (V', E')$  be a graph embedded (not necessarily in planar fashion) in the plane, and let  $P$  be a simple polygon in the plane such that no edge of  $G'$  crosses  $P$ . For  $s \in V'$  let  $\tau_s$  be the shortest path tree for  $V'$  in  $G'$  rooted at  $s$ . Then a minimum length walk in  $G'$  enclosing  $P$  and containing  $s$  can always be found in the form  $\Gamma_u \cup \{(u, v)\} \cup \Gamma_v^{-1}$ , where  $(u, v)$  is an edge of  $G$ , and  $\Gamma_u$ , and  $\Gamma_v$  are the paths in  $\tau_s$  from  $s$  to  $u$  and  $v$ , respectively.*

We are now in a position to give an algorithm to find the path-convex hull of  $K$  in  $R$ . An example is given in Fig. 3.

**PATH-CONVEX HULL ALGORITHM**

**Input:** Polygonally bounded plane region  $R$ , terminal set  $K \subseteq R$ .

FIG. 3. Path-convex hull algorithm.

**Output:** A path-convex hull of  $K$  in  $R$ .

**The algorithm:**

1. Construct the  $K$ -visibility graph  $G_K$  for  $R$ .
2. Find a shortest path tree  $T$  for  $K$  in  $G_K$ . Let  $P$  be a clockwise traversal of  $T$  (taken as a region). “Thicken”  $P$  by making each of its repeated vertices and edges distinct, and delete all edges of  $G_K$  which cross an edge of  $P$ . Call the new graph  $G' = (V', E')$ .
3. For each  $s \in V'$  construct a shortest path tree  $\tau_s$  for  $V'$  in  $G'$  rooted at  $s$ . Let  $C'_s = C'_s(e)$  be a minimum-length circuit enclosing  $P$  formed by adding a single edge  $e$  to  $\tau_s$ , and let  $C_s$  be the associated closed walk in  $G$ .
4. A path-convex hull of  $K$  in  $R$  is that region  $\tilde{R}$  enclosed by a minimum-length walk  $C_s$  among those found in step 3.

From Lemma 2.3, Theorems 2.4 and 2.5, and the fact that the shortest  $P$ -enclosing walk in  $G'$  will always be a circuit, it follows that the above algorithm finds a path-convex hull. For the complexity of the algorithm: the dominating computation is step 3, which involves finding  $|V'|$  shortest path trees in  $G'$ . Each tree can be found in time  $O(|V'|^2)$  using Dijkstra’s algorithm [6], and determining enclosure of  $P$  can be done directly using “winding angles” (see [20]). Since  $|V'| \leq 2(\nu + k)$  we have the following result.

**THEOREM 2.6.** *The path-convex hull algorithm correctly finds a path-convex hull of  $K$  in  $R$  in time  $O((\nu + k)^3)$ .*

**3. An approximation scheme for the Steiner tree problem with obstacles.** In this section we give a procedure which for any  $\epsilon > 0$  produces a graph  $G_\epsilon$ , containing  $K$  and contained in  $R$ , such that a Steiner tree for  $K$  in  $G_\epsilon$  is an  $\epsilon$ -approximation to the Steiner minimal tree for  $K$  in  $R$ . The following simple lemma is central to such a construction.

LEMMA 3.1. *Let  $\tilde{R}$  be a path-convex hull for  $K$  in  $R$ . Then any Steiner minimal tree  $T^*$  for  $K$  in  $R$  has  $l(T^*) \geq \frac{1}{2}\rho(\tilde{R})$ .*

*Proof.* Simply note that  $T^*$  itself is a connected subregion of  $R$  containing  $K$ , with  $\rho(T^*) = 2l(T^*)$ . Since  $\tilde{R}$  is a path-convex hull for  $K$  in  $R$ , the inequality follows.  $\square$

We next state three properties of a Steiner minimal tree for  $K$  in  $R$  which were noted by Gilbert and Pollak [12, §§ 3.3, 3.4, 8.2] for the classical Steiner tree problem, and whose generalization to SMTO is immediate. A *free Steiner point* in  $T^*$  is a vertex of  $T^*$  which is not in  $V \cup K$ .

*Free Steiner Point Property.* A free Steiner point in  $T^*$  has exactly three adjacent edges in  $T^*$ ; each pair of edges forms a  $120^\circ$  angle.

*Wedge Property.* Let  $\Delta$  be a triangle, one side of which is in  $\partial R$  and the opposite angle is at least  $120^\circ$ . If no point of  $V \cup K$  is in  $\Delta$ , then neither is any free Steiner point.

*Number of Steiner Points Property.* The maximum number of free Steiner points in  $T^*$  is at most  $k - 2$ .

The first two properties are used to prove the following important technical lemma. For any  $\delta > 0$ , define  $S_\delta$  to be that set of points in  $R$  of the form  $(i\delta, j\delta)$ , where  $i$  and  $j$  are integers.

LEMMA 3.2. *Let  $T^*$  be a Steiner minimal tree of  $K$  in  $R$ , and let  $u$  be any free Steiner point in  $T^*$ . Then for any  $\delta > 0$ , there is at least one point of  $V \cup K \cup S_\delta$  which is visible from  $u$ , and whose distance to  $u$  is at most  $2\delta$ .*

*Proof.* Suppose there is no point of  $S_\delta$  which satisfies the requirements of the theorem. Let  $v$  be a point of the form  $(i\delta, j\delta)$  which lies nearest to  $u$ . Then  $\|u - v\| < \delta < 2\delta$ , and so  $v$  is not visible from  $u$ . This means that the line segment  $[u, v]$  must cross some line segment  $[w, x]$  of  $\partial R$ , with  $w, x \in V$ , at a point  $v'$  visible from  $u$ . Sweep the line  $[u, y]$  along  $y \in [w, x]$  from  $y = v'$  toward  $x$  and  $w$ , respectively, until either a point of  $V \cup K$  is intercepted or else we arrive at points  $y = w'$  and  $y = x'$  with  $\|u - w'\| = \|u - x'\| = 2\delta$ . In the first case we have a point of  $V \cup K$  satisfying the requirements of the theorem. In the second case, since  $\|u - v'\| < \delta$  it must be that  $\sphericalangle w'ux' > 120^\circ$ . By the Free Steiner Point Property for  $u$  the triangle  $\Delta = w'ux'$  contains at least one of the edges of  $T^*$  adjacent to  $u$ , and hence at least one vertex of  $T^*$ . But since  $\Delta$  contains no element of  $V \cup K$ , then by the wedge property it can contain no free Steiner point either, a contradiction. Thus the theorem is proved.  $\square$

We can now give an approximation algorithm for SMTO which is similar to the procedure given in [19] for the Euclidean minimal Steiner tree problem.

APPROXIMATION ALGORITHM FOR SMTO

**Input:** Polygonally bounded plane region  $R$ , terminal set  $K \subseteq R$ ,  $\epsilon > 0$ .

**Output:** Spanning graph  $T$  in  $R$  with  $l(T) \leq (1 + \epsilon)l(T^*)$ .

**The algorithm:**

1. Find a path-convex hull  $\tilde{R}$  of  $K$  in  $R$ .
2. For  $\delta = (\rho(\tilde{R}) / (12k - 24))\epsilon$ , construct the  $S_\delta \cup K$ -visibility graph  $G_\epsilon = (V_\epsilon, E_\epsilon)$  for  $\tilde{R}$ .
3. Return the Steiner minimal tree  $T$  of  $K$  in  $G_\epsilon$ .

THEOREM 3.3. *The tree  $T$  given by the approximation algorithm for SMTO is an  $\epsilon$ -approximation to the Steiner minimal tree for  $K$  in  $R$ .*

*Proof.* Let  $T^*$  be the Steiner minimal tree for  $K$  in  $R$ , chosen by Theorem 2.1 to lie entirely in  $\tilde{R}$ . Choose, for each vertex  $v$  of  $T^*$ , the nearest vertex  $v'$  in  $V_\varepsilon = V \cup K \cup S_\delta$  which is visible from  $v$ , so that by Lemma 3.2  $\|v - v'\| \leq 2\delta$ . For each edge  $[u, v]$  of  $T^*$  let  $u'$  and  $v'$  be the associated vertices as chosen above and let  $\Gamma_{uv}$  be a shortest path from  $u'$  to  $v'$  in  $\tilde{R}$ , so that by Theorem 2.2  $\Gamma_{uv}$  can be found in the  $K \cup \{u', v'\}$ -visibility graph for  $\tilde{R}$  and hence it is in  $G_\varepsilon$ . Let  $T'$  be the union of the edges of  $\Gamma_{uv}$ , taken over all edges  $[u, v]$  in  $T^*$ . We claim that  $T'$  is an  $\varepsilon$ -approximation for  $T^*$ , and therefore so is the Steiner minimal tree for  $K$  in  $G_\varepsilon$ . First observe that for each edge  $[u, v]$  in  $T^*$ , the path  $\Gamma'_{uv}: u', [u', u], u, [u, v], v, [v, v'], v'$  is a path from  $u'$  to  $v'$  in  $\tilde{R}$ , and thus,

$$\begin{aligned} l(\Gamma_{uv}) &\leq l(\Gamma'_{uv}) \\ &= \|u' - u\| + \|u - v\| + \|v - v'\| \\ &\leq \|u - v\| + 2r\delta, \end{aligned}$$

where  $r = 0, 1,$  or  $2$ , depending on whether  $0, 1,$  or  $2$  of  $u$  and  $v$  are free Steiner points in  $T^*$ . Summing over all edges of  $T^*$ , and using the Number of Steiner Points Property and the  $120^\circ$  property for  $T^*$ , we get

$$\begin{aligned} l(T') &\leq l(T^*) + 6(k - 2)\delta \\ &= l(T^*) + \frac{\varepsilon}{2}\rho(\tilde{R}). \end{aligned}$$

But by Lemma 3.1 we have  $l(T^*) \geq \frac{1}{2}\rho(\tilde{R})$ . Thus  $l(T') \leq (1 + \varepsilon)l(T^*)$ , and this completes the proof of the theorem.  $\square$

Theorem 3.3 now allows us to solve SMTO—at least to within an  $\varepsilon$ -approximation—by reducing it to a Steiner tree problem on graphs. This reduction, moreover, has the following important property.

**COROLLARY 3.4.** *Let  $\mathcal{C}$  be any class of instances of SMTO having the property that there exists an algorithm to find the Steiner minimal tree for any of the associated graphs  $G_\varepsilon$  whose running time is polynomial in the size of  $G_\varepsilon$ . Then there exists a fully polynomial approximation scheme for SMTO on the class  $\mathcal{C}$ .*

*Proof.* Simply note that  $\tilde{R}$  can be enclosed by a square with sides of length at most  $\frac{1}{2}\rho(\tilde{R})$ , and so the number  $n_\varepsilon$  of vertices in  $G_\varepsilon$  is at most

$$\nu + k + \left(\frac{\frac{1}{2}\rho(\tilde{R})}{\delta}\right)^2 = \nu + k + \left(\frac{6k - 12}{\varepsilon}\right)^2$$

which is a polynomial in  $\nu, k,$  and  $1/\varepsilon$ . Since  $G_\varepsilon$  can be constructed in time  $O(n_\varepsilon^2 \log n_\varepsilon)$ , the theorem follows.  $\square$

Thus any algorithm for finding Steiner minimal trees in graphs that performs well on the graphs  $G_\varepsilon$  can be used to find efficient  $\varepsilon$ -approximations, or even fully polynomial approximation schemes, for SMTO. Several possibilities can be found in the literature. The most promising in this context, however, appears to be that of Erickson, Monma, and Veinott [9], since it can take advantage of the essentially planar nature of SMTO. In order to use their method, we first prove a preliminary result related to planarity and SMTO. Let  $G$  be a graph laid out in the plane such that the edges of  $G$  are represented by straight-line segments. For vertices  $u$  and  $v$  in  $G$ , denote by  $d(u, v)$  the Euclidean length of a shortest path in  $G$  from  $u$  to  $v$ . The graph  $G$  is *plane* if it contains no crossing edges, and *weight planar* if every pair  $(u, v)$  and  $(w, x)$  of

crossing edges has the property

$$\|u - v\| + \|w - x\| > d(u, w) + d(v, x).$$

LEMMA 3.5.  $G_\epsilon$  is weight-planar.

*Proof.* Since we assume that no edge of  $G_\epsilon$  contains any vertices of  $G_\epsilon$  in its interior, if the line segments  $[u, v]$  and  $[w, x]$  cross, the intersection point  $y$  must lie in the interior of  $\tilde{R}$ . This means that there must be a point  $y'$  in the interior of, say, segment  $[y, u]$  such that  $y'$  is visible from  $w$ . By using the triangle inequality, we have

$$\begin{aligned} \|u - v\| + \|w - x\| &= \|u - y'\| + \|y' - y\| + \|y - w\| + \|v - y\| + \|y - x\| \\ &> \|u - y'\| + \|w - y'\| + \|v - y\| + \|y - x\| \\ &\cong d(u, w) + d(v, x). \end{aligned} \quad \square$$

In Theorem 5 of [19] it is shown that the Steiner minimal tree for a weight-planar graph is plane. We thus have the following theorem.

THEOREM 3.6. *The Steiner minimal tree for  $G_\epsilon$  is plane.*

The method of Erickson, Monma, and Veinott applies to finding minimum-concave-cost flows in “ $k$ -planar” networks and is a significant generalization of the method of Dreyfus and Wagner [7] for finding Steiner trees in graphs. We restate their method here in the context of SMTO. We suppose that the terminal set lies on a subset  $Q_1, \dots, Q_l$  of boundary polygons of  $\tilde{R}$  and in addition comprises points  $Q_{l+1}, \dots, Q_r$  in the interior of  $\tilde{R}$ , which for simplicity we will take to be polygons with one vertex. Each terminal  $u$  is assigned to a unique  $Q_i$  on which it lies, and we use the phrase “ $u$  is on  $Q_i$ ” to denote this. For each  $Q_i$  and each pair  $u$  and  $v$  of terminal points on  $Q_i$ , define an *interval*  $[u, v)$  between vertices  $u$  and  $v$  to be the subset of terminal points on  $Q_i$ —including  $u$  but not including  $v$ —visited by traversing  $Q_i$  clockwise from  $u$  to  $v$ . We will let  $[u, u)$  denote all of the terminals on  $Q_i$ . Define a *multi-subinterval* of  $K$  to be any nonempty subset  $I$  of  $K$  of the form  $I = [a_1, b_1) \cup \dots \cup [a_p, b_p)$ , where each  $[a_j, b_j)$  is an interval for a distinct  $Q_{i_j}$ ,  $j = 1, \dots, p$ . Note that  $Q_{i_1}, \dots, Q_{i_p}$  do not necessarily comprise all of the  $Q_i$ . Denote by  $\mathcal{I}$  the collection of multi-subintervals.

It turns out that when the Steiner minimal tree for  $K$  in  $G_\epsilon$  is known to be plane, it can be built up from Steiner minimal trees in  $G_\epsilon$  for sets  $I \in \mathcal{I}$  by recursively “patching together” trees for smaller multi-subintervals into trees for larger ones. To be precise, for any  $I \in \mathcal{I}$  and vertex  $v$  of  $G_\epsilon$ , define  $C(v, I)$  to be the minimum cost of a spanning graph  $T$  for  $I \cup \{v\}$  in  $G_\epsilon$ , and if  $|I| \geq 2$  define  $B(v, I)$  to be the minimum cost of a spanning graph  $T$  for  $I \cup \{v\}$  in  $G_\epsilon$  having the property that  $v$  is either in  $K$  or has at least two adjacent edges of  $T$ . The following recursive equations linking  $C$  and  $B$  are exactly equations (2') and (3) in [9], when applied to SMTO (cf. also equations (1) and (2) in [19]):

$$\begin{aligned} (1) \quad C(v, I) &= \min_{u \in V_\epsilon} \{B(u, I) + d(u, v)\}, \\ (2) \quad B(v, I) &= \min_{\substack{I_1, I_2 \in \mathcal{I} \\ I_1, I_2 \text{ partition } I}} \{C(v, I_1) + C(v, I_2)\}. \end{aligned}$$

By initializing  $C(v, \{a\}) = d(v, a)$  for  $a \in K$  and then solving (2) and then (1) successively for  $I$  of increasing cardinality and  $v \in V_\epsilon$ , we obtain the length of the Steiner minimal tree for  $K$  in  $G_\epsilon$  as  $C(a, K - \{a\})$  for any  $a \in K$ . The actual Steiner tree can be obtained by an appropriate labeling.

To analyze the complexity of computing  $C(a, K - \{a\})$ , let  $n_\epsilon$  be the number of vertices in  $G_\epsilon$ . Let  $q_i$  be the number of terminal points on  $Q_i$ , with  $a$  taken to be on  $Q_1$ , and let  $q = q_1 \prod_{i=2}^r (q_i + 1)$ . Then each evaluation of equation (1) takes  $O(n_\epsilon)$  steps, each evaluation of (2) takes  $O(q)$  steps, and  $|\mathcal{I}| \leq q^2$ , for total time  $O(n_\epsilon q^2 (n_\epsilon + q))$  to

compute  $C(a, K - \{a\})$ , plus an additional  $O(n_\varepsilon^3)$  time to compute all shortest path distances. The important thing to note here is that the term  $q$  does not depend on  $\varepsilon$ , but only on the location of the terminals in  $\tilde{R}$ . We thus have the following result.

**THEOREM 3.7.** *For fixed  $c$ , there exists a fully polynomial approximation scheme for any instance  $(K, R)$  of SMTO, where  $K$  lies on at most  $c$  boundary polygons and interior points of  $R$ .*

*Proof.* If  $K$  lies on at most  $c$  boundary polygons and interior points of  $R$ , then it must do so for any path-convex hull  $\tilde{R}$  of  $K$  in  $R$  as well. Further  $q \leq k^c$ , and so the complexity of the above algorithm is  $O(n_\varepsilon k^{2c}(n_\varepsilon + k^c))$ . The theorem then follows from Corollary 3.4.  $\square$

**4. Improvements on the path-convex hull.** Theorem 3.7, although sufficient to give an a priori bound on the complexity of solving an instance of SMTO, can be strengthened considerably. For one thing, the set of  $c$  polygons on which  $K$  is required to lie is allowed to include the exterior polygons of the path-convex hull as well as the actual boundary polygons of  $R$ . It turns out, in fact, that in the sense of Theorem 3.7 it is *always* more efficient to work with the smallest possible region known to contain the Steiner minimal tree for  $K$  in  $R$ . To be precise, for any polygonally bounded region  $S$  containing  $K$  define  $b(K, S)$  to be the minimum number of boundary polygons and interior points of  $S$  whose union contains all points of  $K$ . Then  $b(K, S)$  essentially determines the exponent  $c$  in the procedure given in Theorem 3.7, and hence should be minimized in order to minimize the complexity of the procedure.

**LEMMA 4.1.** *Let  $(K, R)$  be any instance of SMTO and  $\tilde{R}$  any connected polygonally bounded subregion of  $R$  containing  $K$ . Then  $b(K, \tilde{R}) \leq b(K, R)$ .*

*Proof.* Let  $Q_1, \dots, Q_r$  be any set of boundary polygons and interior points of  $R$  containing all points of  $K$ . Take any  $Q_i$  and suppose that  $Q_i$  bounds an interior forbidden region  $Q_i^0$  (the case for the exterior forbidden region is symmetric). Since  $\tilde{R} \cap Q_i^0 = \emptyset$  and  $\tilde{R}$  is connected, then  $Q_i^0$  is entirely contained in  $\tilde{Q}_j^0$  for one of the boundary polygons  $\tilde{Q}_j$  defining  $\tilde{R}$ . But since  $K$  is contained in  $\tilde{R}$  then all of the points of  $K$  on  $Q_i$  must also be contained in  $\tilde{Q}_j$ . Thus by assigning, for  $i = 1, \dots, r$  all points of  $K$  on  $Q_i$  to be on the associated polygon  $\tilde{Q}_j$  we have  $K$  contained on at most  $r$  polygons and interior points of  $\tilde{R}$ . By taking  $r = b(K, R)$  the lemma follows.  $\square$

It is known [2] that the computation of  $b(K, S)$  is NP-hard. The proof of Lemma 4.1 tells us, however, that for *any* choice of boundary polygons and interior points of  $R$  whose union contains  $K$ , we can always find at least as few of the same in any subregion  $\tilde{R}$  also containing  $K$ . Thus the search for smaller regions containing a Steiner minimal tree can only offer an improvement even if a nonoptimal choice of boundary points and polygons is made.

The discussion thus far makes it clear that any method which can decrease the size of a subregion of  $R$  known to contain a Steiner minimal tree for  $K$  will increase the efficiency with which the Steiner tree can be found. The literature suggests several important ways this can be done for both the classical Steiner minimal tree problem and the Steiner tree problem on graphs, which have interesting extensions to SMTO. They can, moreover, be applied to any combination, since they require no particular global conditions on the region on which they are applied. In what follows, therefore, we let  $R$  loosely refer to any region known to contain a Steiner minimal tree for the given instance of SMTO.

**4.1. Minimal path-convex hulls.** The path-convex hull algorithm, as given in § 2, will not necessarily give the setwise minimal path-convex hull for  $K$  in  $R$ . Bienstock and Monma [1] give valuable insight concerning minimal path-convex hulls in the

context of planar graphs. We first summarize the results in § 2 of that paper (in particular, Theorem 2 and Lemma 3) as they apply to SMTO. The proof follows essentially the discussion in that paper.

**THEOREM 4.2** (Bienstock and Monma). *Let  $T$  be any shortest path tree for  $K$  in  $R$ . Then there is a unique (setwise) minimal path-convex hull  $\tilde{R}$  of  $K$  in  $R$  which contains  $T$ , and further,  $\tilde{R}$  contains the unique maximal set of terminal points on the exterior boundary of any path-convex hull of  $K$  in  $R$ .*

This means that the best we can do as far as placing points on the exterior boundary of a path-convex hull is to find the unique minimal path-convex region containing any arbitrarily chosen shortest path tree  $T$ . One such method is given in § 2 of [1]. When treating SMTO, however, we can do this by a simple modification of the path-convex hull algorithm given in § 2 of this paper. We first modify the circuits  $C'_s(e)$  found in step 3 by pushing their sides “inward” as much as possible. Specifically, let  $\Gamma_x$  be the unique  $s$ - $x$  path in  $\tau_s$ ,  $x \in V'$ , and let  $e = (u, v)$  be labeled such that  $\Gamma_u$  is to the “left” of  $\Gamma_v$  relative to the  $P$  found in step 2. Now form the “rightmost”  $s$ - $u$  path  $\Gamma'_u$ :  $s = u_0, u_1, \dots, u_k = u$  in  $G'$  passing to the left of  $P$  by setting  $u_{k+1} = v$  and for  $i = k, k = 1, \dots, 2$  recursively choosing the first edge  $(u_{i-1}, u_i)$  in a clockwise sweep from  $(u_i, u_{i+1})$  satisfying (a)  $l(\Gamma_{u_i}) = l(\Gamma_{u_{i-1}}) + d_{u_{i-1}u_i}$  and (b) the path  $\Gamma_{u_{i-1}}, u_i, \dots, u_k$  passes to the left of  $P$  with respect to  $\Gamma_v \cup \{e\}$ . Find the analogous “leftmost”  $s$ - $v$  path  $\Gamma'_v$ :  $s = v_0, v_1, \dots, v_j = v$ , passing to the right of  $P$  by the mirror image of the procedure given above. Then  $\Gamma'_u \cup \{e\} \cup (\Gamma'_v)^{-1}$  will contain a unique  $P$ -enclosing circuit  $C''_s(e)$ , with corresponding walk  $\tilde{C}_s(e)$  enclosing  $K$  in  $R$ . We now appeal to the following result.

**LEMMA 4.3.** *The boundary of a minimal path-convex hull of  $K$  in  $R$  is among the  $\tilde{C}_s(e)$  found in the modified procedure given above.*

*Proof.* Let  $C$  be the boundary of the minimal  $T$ -enclosing path-convex hull of  $K$  in  $R$ , so that the associated walk  $C'$  in  $G'$  is the innermost  $P$ -enclosing circuit in  $G'$ . Now choose any  $s$  in  $C'$  and let  $\tau_s$  be the tree found in step 2 of the procedure, with  $\Gamma_x, x \in V'$ , the associated  $s$ - $x$  paths in  $\tau_s$ . The weight-planarity of  $G'$  ensures that the  $\Gamma_x$  do not have crossing edges. Since  $C'$  encloses  $P$ , then there must be at least one edge  $e = (u, v) \in C' - \tau_s$  whose associated circuit  $C'_s(e)$  encloses  $P$ . Let  $C'' = C''_s(e)$  be the circuit produced from  $C'_s(e)$  by the modified procedure given above. When we construct  $C''$ , we find it has the same length as  $C'$ , and hence  $C''$  completely encloses  $C'$  as well as containing both  $e$  and  $s$ . Now suppose  $C' \neq C''$  and assume by symmetry that they differ on their “left-hand” sides with respect to  $e$  and  $s$ . Let  $\Gamma'_u$ :  $s = u_0, \dots, u_k = u$  be the left-hand path of  $C''$  and let  $i$  be the largest index for which  $(u_{i-1}, u_i)$  is not on  $C'$ . If  $(x, u_i), u_{i-1} \neq x \neq u_{i+1}$ , is the corresponding edge of  $C'$  adjacent to  $u_i$ , then  $(x, u_i)$  must occur in a clockwise sweep from  $(u_i, u_{i+1})$  to  $(u_{i-1}, u_i)$ . Further, since  $C'$  has minimal length,  $\Gamma_{u_i}$  and  $\Gamma_x$  have the same length as the corresponding sections of  $C'$ , and hence  $l(\Gamma_{u_i}) = l(\Gamma_x) + d_{x, u_i}$ . Finally, since  $\Gamma_x$  lies outside  $C'$  and does not cross  $\Gamma_u$ , the path  $\Gamma_x, u_i, \dots, u_k$  must pass to the left of  $P$  with respect to  $\Gamma_v \cup \{e\}$ , and this contradicts the choice of  $u_{i-1}$ . Thus  $C' = C''$  and so the corresponding walk  $\tilde{C}_s(e)$  is the boundary of a minimal path-convex hull of  $K$  in  $R$ .  $\square$

The modified procedure now chooses, in step 4, the unique innermost of the minimum length  $C''_s(e)$  found in the modified step 3. Since the (unique) innermost  $C''_s(e)$  for each  $s$  can be found in additional time  $O(|E'|) = O((\nu + k)^2)$  (again using “winding angles”), and the innermost of the  $C''_s(e)$  overall  $s \in V'$  can be found by a single pass through the  $|E'| |V'|$  edges of the set of these cycles, then there is no resulting increase in complexity using the modified procedure. We thus have the following result.

**COROLLARY 4.4.** *A path-convex hull of  $K$  in  $R$  containing the unique maximal set of vertices on the exterior boundary can be found in time  $O((\nu + k)^3)$ .*

**4.2. Path-convex hulls with respect to interior forbidden regions.** For the purpose of bounding the size of the region containing a Steiner minimal tree it is necessary to take a path-convex hull with respect to the exterior polygon (if one exists) of  $R$ . The results of § 2 apply as well, however, when the path-convex hull is taken with respect to *any* boundary polygon (cf. [1, § 3] for planar graphs). To be precise, for interior polygon  $P_i$  of  $R$ , conceptually turn the visibility graph  $G_K$  “inside-out,” so that  $P_i$  forms the exterior boundary. Now the  $P_i$ -path-convex hull of  $K$  in  $R$  is defined to be the path-convex hull with respect to the new layout, and both the results and the path-convex hull algorithm in § 2 apply in this context. Define the  $P_i$ -boundary of any polygonally bounded region  $\tilde{R} \subseteq R$  to be the boundary polygon of  $\tilde{R}$  enclosing  $P_i$  (or enclosed by  $P_i$  if  $P_i$  is the exterior boundary). Then generalizing to Corollary 4.4 we have the following result.

**COROLLARY 4.5.** *For any boundary polygon  $P_i$  of  $R$ , a  $P_i$ -path-convex hull of  $K$  in  $R$  containing the unique maximal set of vertices on its  $P_i$ -boundary can be found in time  $O((\nu + k)^3)$ .*

The modified path-convex hull algorithm can thus be applied successively to each boundary polygon  $P_0, \dots, P_m$ , resulting in a region  $R^*$  which, in a sense, contains the unique maximal set of terminals on its boundary polygons which can be achieved by using  $P_i$ -path-convexity alone.

**4.3. Convex hulls.** As a consequence of the discussion in § 2, we obtain a property of the region  $R^*$  which is analogous to the convex hull property given in [12], § 3.5. Let  $R$  be any polygonally bounded region, and let  $v$  be a point on boundary polygon  $P_i$  of  $R$ . Then  $v$  is called a *simple boundary point* of  $R$  if it is not a terminal point and is contained in no other boundary polygon of  $R$ . By applying the procedure given in § 2, we have the following result.

**COROLLARY 4.6.** *Let  $\tilde{R}$  be a  $P_i$ -convex hull of  $K$  in  $R$ . Then every simple boundary point of the  $P_i$ -boundary of  $\tilde{R}$  has its interior angle (with respect to  $\tilde{R}$ ) greater than or equal to  $180^\circ$ .*

**4.4. Steiner hulls and extensions.** Cockayne [5] and Hwang et al. [14], in the context of the classical Steiner tree problem, provide methods for further reducing the size of a region known to contain the Steiner minimal tree. The reduced regions are often much smaller than the path-convex hull, and the methods used are significantly different from those related to the construction of the path-convex hull. To extend these methods to SMTO, we first give the basic constructions of Cockayne and of Hwang et al. as they apply to SMTO. Let  $\Gamma$  be a path in some boundary polygon  $P_i$  connecting points (not necessarily vertices)  $u$  and  $v$  of  $P_i$ , and let  $\Lambda$  be a path in  $R$  connecting  $u$  to  $v$ , which is otherwise disjoint from  $\Gamma$ . Finally let  $S$  be the region enclosed by  $\Gamma \cup \Lambda$ . Both of the proposed criteria require the following common condition:

- (1)  $S - \Lambda$  contains neither  $P_i^0$  nor any point of  $K$ .

The criteria now differ depending on the precise structure of  $\Lambda$ . In what follows, angles will always refer to interior angles with respect to  $S$ .

**3-point criterion (Cockayne).**  $\Lambda = [u, a] \cup [a, v]$  such that (1) holds and

- (2)  $a \in K$ ;
- (3)  $\sphericalangle uav \geq 120^\circ$ .

- 4-point criterion** (Hwang et al.).  $\Lambda = [u, a] \cup [a, b] \cup [b, v]$  such that (1) holds and
- (2)  $a, b, \in K$  and  $[a, b]$  is a boundary edge of  $R$ ;
  - (3)  $\sphericalangle uab$  and  $\sphericalangle abv$  are both convex and at least  $120^\circ$ ;
  - (4) the point  $O$  of the intersection of  $[u, b]$  and  $[a, v]$  satisfies  $\sphericalangle uOv \geq \sphericalangle uab + \sphericalangle abv - 150^\circ$ .

To find  $\Gamma$  and  $\Lambda$  satisfying the 3- or 4-point criterion in  $O(k(\nu + k)^2)$  time, look at each terminal (or pair of terminals connected by a boundary edge) and check each pair of adjacent edges in the  $K$ -visibility graph to see whether or not the 3- (or 4-) point criterion is satisfied. Note that since  $\partial R$  forms a planar graph, the number of boundary edges connecting pairs of terminals is  $O(k)$ . The key results of Cockayne and Hwang et al. (Theorem 1 of [5] and the main theorem of [14]) can be extended to SMT0 via the following theorem.

**THEOREM 4.7.** *Let  $\Gamma$  and  $\Lambda$ , as described above, satisfy either the 3-point or 4-point criterion. Then the region  $S - \Lambda$  contains no part of a Steiner minimal tree for  $K$  in  $R$ .*

*Proof.* First, let  $T'$  be the Steiner minimal tree for  $K$  in the region  $R'$  obtained from  $R$  by removing all obstacles lying inside  $S$ . Then  $l(T') \leq l(T^*)$ , the length of the Steiner minimal tree in  $R$ , and so if  $T'$  can be shown to be shorter than any spanning graph passing through  $S - \Lambda$ , then  $T^*$  will also contain no part in  $S - \Lambda$ . Second, let  $\Gamma_0$  be the (unique) shortest path from  $u$  to  $v$  in  $S$  (without obstacles), and let  $S_0$  be the region enclosed by  $\Lambda \cup \Gamma_0$ . Then a simple convexity argument shows that  $T'$  must be contained entirely in  $S_0$ .

*Case 1.* Suppose that all angles of  $\Lambda$  are convex. Then  $\Gamma_0 = [u, v]$ , and we can apply the results of Cockayne and of Hwang et al. as cited above. The proofs of these theorems say, in effect, that if (i)  $a$  (and  $b$ , respectively) are in  $K$ , (ii)  $S_0 - \Lambda$  contains no elements of  $K$ , and (iii)  $T$  is a spanning graph for  $K$  which passes into  $S_0$  only via the edges  $[u, a]$  and  $[a, v]$  ( $[b, v]$ , respectively), then that part of  $T$  in  $S_0 - \Lambda$  can be replaced by appropriate segments of  $\Lambda$  to yield a smaller length spanning graph for  $K$ . (The requirement in these theorems that  $u$  and  $v$  belong to  $K$  is irrelevant here.) Since that is precisely the situation in this case,  $T'$  can contain no part in  $S - \Lambda$ .

*Case 2.* Suppose that  $\Gamma$  and  $\Lambda$  satisfy the 3-point criterion, with  $\sphericalangle uav \geq 180^\circ$ . Then  $S_0 = \Lambda$ , and we are done.  $\square$

Theorem 4.7 can be used to produce a region, similar to Cockayne's "Steiner hull," that is guaranteed to contain the Steiner minimal tree for  $K$  in  $R$ . Such a region, which will be called the *path-Steiner hull* for  $K$  in  $R$ , is obtained by successively performing the following operation until it can no longer be applied.

*Wedge operation.* Let  $\Gamma \subset P_i$  and  $\Lambda$  be paths as defined above which satisfy either the 2- or 3-point criterion, and let  $S$  be the region enclosed by  $\Gamma \cup \Lambda$ . Replace  $S$  by  $\Lambda$ , and take the  $P_i$ -path-convex hull of  $K$  in the resulting region.

Figure 4 shows the application of a wedge operation. Theorem 4.7 along with Theorem 2.1 immediately imply the following corollary.

**COROLLARY 4.8.** *A path-Steiner hull of  $K$  in  $R$  always contains a Steiner minimal tree for  $K$  in  $R$ .*

The next result gives the complexity of finding a path-Steiner hull.

**THEOREM 4.9.** *Let  $m$  be the number of boundary polygons for  $R$ . Then a path-Steiner hull for  $K$  in  $R$  can be found in  $O((m + k)(\nu + k)^3)$  steps.*

*Proof.* We first prove that the wedge operation can be applied at most  $6(m + k) - 12$  times. To show this, start with the graph  $G$  whose vertices are the points of  $K$ , together with a point  $v_i$  chosen in the interior of polygon  $P_i$ ,  $i = 1, \dots, m$ , and whose edges are of the form  $(u, v_i)$  where  $u \in K$  is on  $P_i$ . Then  $G$  is bipartite and planar, with  $m + k$

FIG. 4. Wedge operation.

vertices. Now each time a wedge operation is performed, we add an edge to  $G$  connecting the points  $a$  (and  $b$ ) in  $\Lambda$  to the vertex  $v_i$  such that  $\Gamma \subseteq P_i$ . The wedging operation may coalesce obstacles; in this case the points  $a$  (and  $b$ ) are connected to the appropriate  $v_i$  so as to preserve planarity in  $G$ . We also note that a point may be attached to the same boundary more than once, so that multiple edges are created. The 2- and 3-point criteria imply, however, that each time a point  $a$  (or  $b$ ) is attached to boundary  $P_i$ , it lies on an angle of at least  $120^\circ$  interior to  $P_i$ . Thus a point cannot be attached more than three times to the same boundary, and so edges in  $G$  can have multiplicity no greater than 3. The construction of  $G$  ensures that it always remains bipartite and planar, and has edge multiplicity at most 3. Since a bipartite planar graph with  $n$  vertices and no multiple edges can have no more than  $2n - 4$  edges,  $G$  can have at most  $6(m + k) - 12$  edges. Further, a new edge is added for each wedge operation, and so the number of wedge operations is at most  $6(m + k) - 12$ , as asserted.

For the complexity of the entire process, we note that the wedge operation will add no new vertices to  $V \cup K$ , since if either  $u$  or  $v$  in  $\Gamma$  is not a point of  $V \cup K$ , then replacing  $S$  by  $\Lambda$  will make this point a simple vertex of  $P_i$  with interior angle less than  $180^\circ$ . By Corollary 4.6, the  $P_i$ -path convex hull  $\tilde{R}$  will not contain this point, and hence by Lemma 2.3,  $\partial\tilde{R}$  will contain no new vertices. It follows that the  $P_i$ -path-convex hull can be computed in time  $O((\nu + k)^3)$ , and since this dominates the search for points satisfying the 2- and 3-point properties, then the overall complexity is  $O((m + k)(\nu + k)^3)$  as required.  $\square$

To end this section, we show how the 2- and 3-point criteria can be extended considerably by applying them in groups, so as to ignore obstacles which would prevent them from being applied individually. In particular, let  $\Gamma$  and  $\Lambda$  be paths as defined for the 2- and 3-point criteria, with  $S$  the enclosed region. Consider the following condition.

**$r$ -point criterion.**  $\Lambda = [u, a_1] \cup [a_1, a_2] \cup \dots \cup [a_r, v]$  such that (1) holds and

- (2) if all obstacles are removed from inside  $S$ , then there exists a series of wedging operations which can be performed to reduce  $S$  to  $\Lambda$ .

An example is given in Fig. 5, where the 3-point wedging operation can be applied successively with  $\Gamma_1 = \Gamma$ ,  $\Lambda = [u, a_1] \cup [a_1, v]$  and  $\Gamma_i = [u, a_{i-1}]$ ,  $\Lambda_i = [a_{i-1}, a_i] \cup [a_i, v]$   $i = 2, \dots, r$ . As an extension to Theorem 4.7 we have the following result.

**COROLLARY 4.10.** Let  $\Gamma$  and  $\Lambda$  as described above satisfy the  $r$ -point criterion. Then the region  $S - \Lambda$  contains no part of a Steiner minimal tree for  $K$  in  $R$ .

*Proof.* The proof follows from repeated applications of Theorem 4.7, when we use the argument in the first paragraph of the proof of that theorem.  $\square$

FIG. 5.  $r$ -point criterion.

As a simple application of Corollary 4.10, we can relax the requirement in the 4-point criterion that  $\sphericalangle uab$  and  $\sphericalangle abv$  be convex, for if either angle fails to be convex, then the  $r$ -point criterion applies by twice using the appropriate 3-point criterion. The wedging operation can now be extended to  $\Gamma$  and  $\Lambda$ , thus satisfying the  $r$ -point criterion to add to the repertoire of operations which reduce the region known to contain the Steiner minimal tree. It is immediate from the proof of Theorem 4.9 that the wedging operation continues to be limited to  $6(m+k)-12$  applications, with complexity  $O((\nu+k)^2)$  time per application. Unfortunately the complexity of finding  $\Gamma$  and  $\Lambda$  satisfying the  $r$ -point criterion now dominates the wedge operation itself. It is not even clear that the  $r$ -point criterion can be recognized in time which grows polynomial in  $r$ , although it is polynomial for fixed  $r$ .

**5. Summary and extensions.** As shown in this paper, SMTO provides a rich class of important Steiner tree problems whose solution methods draw from both graph theory and computational geometry. The results in § 4, moreover, show the areas where the greatest improvement in computational complexity can be achieved. Particularly intriguing are results extending the material in § 4, since this is where the specific geometry of the Steiner minimal tree pays a critical role. An interesting extension to the work in this paper is suggested by the work of Schäffer and Van Wyk [21]. Suppose the region  $R$  has boundaries made up not of straight-line segments, but rather of smooth non-self-intersecting curves. There exist straightforward analogues to most of the results in this paper, although the description and complexity of the corresponding procedures are significant unresolved issues. Little has been done even for the associated problem of shortest paths with obstacles, and so we leave this whole area as an interesting topic for future research.

**Acknowledgment.** The author would like to thank Dan Bienstock for pointing out a substantial error in the original Path-Convex Hull Algorithm of § 2.

## NONDETERMINISTIC SPACE IS CLOSED UNDER COMPLEMENTATION\*

NEIL IMMERMANT†

**Abstract.** In this paper we show that nondeterministic space  $s(n)$  is closed under complementation for  $s(n)$  greater than or equal to  $\log n$ . It immediately follows that the context-sensitive languages are closed under complementation, thus settling a question raised by Kuroda [*Inform. and Control*, 7 (1964), pp. 207–233].

**Key words.** nondeterministic space, context-sensitive language, complementation, first-order expressibility, computational complexity

**AMS(MOS) subject classification.** 68O25

**1. Introduction.** In this paper we show that nondeterministic space  $s(n)$  is closed under complementation for  $s(n)$  greater than or equal to  $\log n$ . It immediately follows that the context-sensitive languages are closed under complementation, thus settling a question raised by Kuroda in 1964 [9]. See Hartmanis and Hunt [4] for a discussion of the history and importance of this problem, and Hopcroft and Ullman [5] for all relevant background material and definitions.

The history behind the proof is as follows. In 1981 we showed that the set of first-order inductive definitions over finite structures is closed under complementation [6]. This holds with or without an ordering relation on the structure. If an ordering is present the resulting class is  $P$ . Many people expected that the result was false in the absence of an ordering. In 1983 we studied first-order logic, with ordering, with a transitive closure operator. We showed that NSPACE  $[\log n]$  is equal to (FO + pos TC), i.e., first-order logic with ordering, plus a transitive closure operation, in which the transitive closure operator does not appear within any negation symbols [7]. Now we have returned to the issue of complementation in light of the recent results on the collapse of the log space hierarchies [10], [2], [14]. We have shown that the class (FO + pos TC) is closed under complementation. Our main result follows. In this paper we give the proof in terms of machines and then state the result for transitive closure as Corollary 3. The question of whether (FO + pos TC) *without ordering* is closed under complementation remains open.

Our work in first-order expressibility led to our proof that nondeterministic space is closed under complementation. However, because first-order expressibility classes are not directly relevant to the proofs in this paper, we omit those definitions here. The interested reader should refer to [7] for all these definitions. Note that the proof of Theorem 3.3 in [7] is more complicated than the proof of Theorem 1, though it is quite similar to it. The same is true of the proof in [6] that the first-order inductive formulas are closed under complementation.

### 2. Results.

**THEOREM 1.** For any  $s(n) \geq \log n$ ,

$$\text{NSPACE}[s(n)] = \text{co-NSPACE}[s(n)].$$

*Proof.* We do this by two lemmas. We will show that counting the exact number of reachable configurations<sup>1</sup> of an NSPACE  $[s(n)]$  machine can be done in

\* Received by the editors August 6, 1987; accepted for publication (in revised form) November 2, 1987. This research was supported by National Science Foundation grant DCR-8603346.

<sup>1</sup> The *configuration* of a Turing machine is the contents of its work tapes, the positions of its heads, and its state. Note that for  $s(n) \geq \log n$ , the number of possible configurations is less than  $c^{s(n)}$  for some constant  $c$ , and thus can be written in  $O[s(n)]$  space.

NSPACE  $[s(n)]$  (Lemma 2). Lemma 1 says that once this number has been calculated we can detect rejection as well as acceptance. Note the similarity between Lemma 1 and a similar result about census functions in [12].

**LEMMA 1.** *Suppose we are given an NSPACE  $[s(n)]$  machine  $M$ , a size  $s(n)$  initial configuration, START, and the exact number  $N$  of configurations of size  $s(n)$  reachable by  $M$  from START. Then we can test in NSPACE  $[s(n)]$  if  $M$  rejects.*

*Proof.* Our NSPACE  $[s(n)]$  tester does the following. It initializes a counter to 0, and a target configuration to the lexicographically first string of length  $s(n)$ . For each such target either we guess a computation path of  $M$  from START to target and increment both counter and target, or we simply increment target. For each target that we have found a path to, if it is an accept configuration of  $M$  then we reject. Finally, if when we are done with the last target the counter is equal to  $N$ , we accept; otherwise we reject. Note that we accept if and only if we have found  $N$  reachable configurations, none of which is accepting. (Suppose that  $M$  accepts. In this case there can be at most  $N - 1$  reachable configurations that are not accepting, and our machine will reject. On the other hand, if  $M$  rejects then there are  $N$  nonaccepting reachable configurations. Thus our nondeterministic machine can guess paths to each of them in turn and accept.) That is, we accept if and only if  $M$  rejects.  $\square$

**LEMMA 2.** *Given START, as in Lemma 1, we can calculate  $N$ —the total number of configurations of size  $s(n)$  reachable by  $M$  from START—in NSPACE  $[s(n)]$ .*

*Proof.* Let  $N_d$  be the number of configurations reachable from START in at most  $d$  steps. The computation proceeds by calculating  $N_0, N_1$ , and so on. By induction on  $d$  we show that each  $N_d$  may be calculated in NSPACE  $[s(n)]$ . The base case  $d = 0$  is obvious.

*Inductive step.* Given  $N_d$  we show how to calculate  $N_{d+1}$ . As in Lemma 1 we keep a counter of the number of  $d + 1$  reachable configurations, and we cycle through all the target configurations in lexicographical order. For each target we do the following: Cycle through all  $N_d$  configurations reachable in at most  $d$  steps; again we find a path of length at most  $d$  for each reachable one, and if we do not find all  $N_d$  of them then we will reject. For each of these  $N_d$  configurations check if it is equal to target, or if target is reachable from it in one step. If so then increment the counter, and start on target +1. If we finish visiting all  $N_d$  configurations without reaching target, then just start again on target +1 without incrementing the counter. When we have completed this algorithm for all targets, our counter contains  $N_{d+1}$ . Since  $N$  is bounded above by  $c^{s(n)}$  for some constant  $c$ , the space needed is  $O[s(n)]$ .

To complete the proof of the lemma and the theorem note that  $N$  is equal to the first  $N_d$  such that  $N_d = N_{d+1}$ .  $\square$

*Remark.* In our original statement of Theorem 1 we made the assumption that  $s(n)$  is space-constructible. However, the standard definition of a nondeterministic Turing machine having space complexity  $s(n)$  is that, "...no sequence of choices enables it to scan more than  $s(n)$  cells ...," [5]. Thus, the above proof works even if  $s(n)$  is not space-constructible. We just let  $s(n)$  increase as needed.

The following corollary is immediate.

**COROLLARY 1.** *The class of context-sensitive languages is closed under complementation.*

*Proof.* Kuroda showed in 1964 that CSL = NSPACE  $[n]$  [9].  $\square$

The  $k$ th level of the log space alternating hierarchy ( $\Sigma_k$  ALOG) is defined to be the set of problems accepted by alternating log space Turing machines that make at most  $k - 1$  alternations and begin in an existential state. Recently Lange, Jenner, and Kirsig [10] showed that this hierarchy collapsed to the second level,  $\Sigma_2$  ALOG. This

result was then extended by several authors [2], [14] who showed that the log space oracle hierarchy collapses to  $L^{NL}$ . Here  $L = DSPACE[\log n]$ , and  $NL = NSPACE[\log n]$ . The logspace oracle hierarchy is given by  $\Sigma_1 OLOG = NL$ , and  $\Sigma_{k+1} OLOG = NL^{\Sigma_k OLOG}$ . In the case of the polynomial time hierarchy, the oracle and alternating hierarchies are identical, but they appeared to be different in the log space case. We knew that the log space oracle hierarchy is equal to  $(FO + TC)$ . This, together with the above results, led us to expect Theorem 1. The following is again immediate.

**COROLLARY 2.** *The log space alternating hierarchy and the log space oracle hierarchy both collapse to  $NSPACE[\log n]$ .*

In [7] we showed that  $NL$  is equal to  $(FO + \text{pos } TC)$ . In Theorem 3.3 of [7] we also showed that any problem in  $NL$  may be expressed in the form  $TC[\varphi](\bar{0}, \overline{\text{max}})$ , where  $\varphi$  is a quantifier-free first-order formula, and  $0$  and  $\text{max}$  are constant symbols. It now follows that the same is true for the class  $(FO + TC)$ .

**COROLLARY 3.** (1)  $NSPACE[\log n] = (FO + \text{pos } TC) = (FO + TC)$ .

(2) *Any formula in  $(FO + TC)$  may be expressed in the form  $TC[\varphi](\bar{0}, \overline{\text{max}})$ , where  $\varphi$  is a quantifier-free first-order formula.*

Michael Fischer has observed that we can now diagonalize nondeterministic space and thus easily prove a tight hierarchy theorem for nondeterministic space. Although Corollary 4 is not new, our techniques give a much simpler proof than was previously known. (See Chapter 12 in [5] for the old proof.)

**COROLLARY 4.** *For any tape-constructible  $s(n) \geq \log n$ ,*

$$\lim_{n \rightarrow \infty} \frac{t(n)}{s(n)} = 0$$

*implies*

$$NSPACE[t(n)] \neq NSPACE[s(n)].$$

**3. Conclusions and directions for future work.** Most of the interesting questions concerning the power of nondeterminism remain open. We still do not know whether nondeterministic space is equal to deterministic space, or whether Savitch's Theorem [15] is optimal. It is interesting to consider whether our proof method can be extended to answer these questions, or to tell us anything new about nondeterministic time.

Soon after we proved Theorem 1, Tompa et al. [1] gave two extensions: they proved that  $LOG(CFL)$ —the set of problems log space-reducible to a context-free language—is closed under complementation, and they showed that symmetric log space (cf. [11], [13]) is contained in  $ZPLP$ , "... the class of errorless probabilistic Turing machines running in  $O[\log n]$  space and polynomial expected time." We suggest the following open problems.

- (1) Is  $(FO \text{ without } \leq + \text{pos } TC)$  closed under complementation?
- (2) Is symmetric log space, equivalently  $(FO + \text{pos } STC)$ , closed under complementation?
- (3) Is  $NL$  equal to a complexity class that was previously known to be closed under complementation, e.g.,  $L$ ,  $AC^1$ , or  $DSPACE[\log^2 n]$ ?
- (4) In the proof of Theorem 1 we made use of the linear space compression theorem, Theorem 12.1 in [5]. Our actual construction multiplies the space bound by a factor of about eight. It is interesting to ask how much this can be reduced. Note in particular that if we could complement  $\log n$  times, while only increasing the space bound by a constant factor, then it would follow that  $NL = AC^1$ .

**Acknowledgments.** I thank Sam Buss, Mike Fischer, Lane Hemachandra, Steve Mahaney, and Joel Seiferas, all of whom contributed comments and corrections to this paper.

**Note added in proof.** See Róbert Szelepcsényi, *The method of forcing for nondeterministic automata*, Bull. Europ. Assoc. Theor. Comp. Sci., 33 (1987), pp. 96–100, for an independent proof of Theorem 1.

## VARIETIES OF ITERATION THEORIES\*

STEPHEN L. BLOOM† AND ZOLTAN ESIK‡

**Abstract.** The equational properties of iteration, when combined with composition and pairing, are captured by the notion of “iteration theory,” which was introduced in [*SIAM J. Comput.*, 9 (1980), pp. 26–45; 9 (1980), pp. 525–540]. We believe, although all of our evidence will not be exhibited here, that every iterative construction satisfies at least the properties of iteration theories. In this paper, axiomatizations are given for several varieties of iteration theories which occur naturally in the semantics of programming languages, i.e., those generated by theories of trees [*J. Comput. Sys. Sci.*, 16 (1978), pp. 362–399], theories of sequacious functions [Proc. 1973 Colloquium, Vol. 80, *Studies in Logic*, North Holland, Amsterdam, 1975, pp. 175–230], theories of partial functions, and theories of both sequacious and partial functions with distinguished predicates. We show which additional equations must be added to the axioms for iteration theories [*Comput. Ling. Comput. Lang.*, 14 (1980), pp. 183–207] in order to obtain a set of axioms for these subvarieties. Concrete descriptions of the free theories in each variety are given.

**Key words.** iteration, algebraic theories, varieties

**AMS(MOS) subject classifications.** 08B99, 18C05, 18C10

**Introduction.** Iteration plays a fundamental role in the theory of computation: for example, in the theory of automata, languages, formal power series, the semantics of flowchart algorithms, and in the solution of domain equations. Since iteration almost never occurs in isolation, but in conjunction with other basic operations such as function composition, it makes sense to study this operation in the context of algebraic theories, or clone of operations. The equational properties of iteration, when combined with composition and pairing, are captured by the notion of iteration theory, which was introduced in [BEW]. We believe, although all of our evidence will not be exhibited here, that every iterative construction satisfies at least the properties of iteration theories.

In this paper, axioms are given for several varieties of iteration theories that occur naturally in the semantics of programming languages, i.e., those generated by theories of trees [EBT], theories of sequacious functions [CCE], theories of partial functions, and theories of both sequacious and partial functions with distinguished predicates. Since a set of equational axioms for all iteration theories has already been found [Es80], we show which additional equations must be added to obtain a set of axioms for these subvarieties. If one is convinced that these varieties have some intrinsic interest, as we are, then the simple axioms for these varieties yield some important information as to their essential properties. It should be noted that the framework of iteration theories is purely algebraic; i.e., these theories make no use of order, metric, or other additional structure. Nevertheless, this framework is adequate for the treatment of the semantics of flowchart algorithms.

**I. Preliminaries.** Although we do not assume any acquaintance with iteration theories, we will assume the reader has some familiarity with the calculus of algebraic theories as presented in [CCE], and later in [BEW] and [Es80]. For some background information on iteration theories, see [CCE] or [BEW]. Other papers that make use of algebraic and/or iteration theories include the ADJ group [ADJ], Benson and Guessarian [BG], Courcelle [BC], Nelson [EN], Stefanescu [St] and Troeger [DT].

**0. Notation.** We will use  $\Sigma$  to denote a ranked set, i.e., a collection of pairwise disjoint set  $\Sigma_n, n \geq 0$ . The value of a function  $f: X \rightarrow Y$  on an element  $x \in X$  will be written variously as

$$xf, f(x), \langle x, f \rangle, f_x.$$

If  $A$  is a set,  $A^*$  is the set of all finite sequences of elements of  $A$ , including the empty sequence  $\lambda$ .  $A^+$  is  $A^* - \{\lambda\}$ . We let  $A^\infty$  denote the set of all finite and infinite sequences of elements of  $A$ . The set of nonnegative integers is denoted  $N$ , and for each  $n \in N, [n] = \{1, \dots, n\}$ . We will sometimes identify the set  $X$  with the set  $X \times [1]$ .

**1. Iteration theories.** An iteration theory is, briefly, an algebra which satisfies the same identities as the unfoldings of finite flowchart schemes (see [BE] for an analysis of the equational properties of flowchart schemes). Equational axioms for these algebras were given in [Es80]. As algebras, iteration theories are many-sorted, where the set of sorts is the set  $N \times N$  of ordered pairs of nonnegative integers. The algebras have several constants and three operations which correspond to three fundamental control structures in flowchart algorithms: composition (or sequencing), tupling (a case statement), and iteration (or looping).

An equivalent and somewhat simpler description of these structures is possible when we use the terminology of elementary category theory. An **algebraic theory**  $T$  [WL], [CCE] is a category whose objects are the nonnegative integers such that for each positive integer  $n$ , there are  $n$  distinguished “injections”

$$i_n : 1 \rightarrow n$$

$i = 1, 2, \dots, n$ , which make  $n$  the coproduct of 1 with itself  $n$ -times. More precisely, for any  $n$  morphisms  $g_i : 1 \rightarrow p, i = 1, \dots, n$ , there is a unique morphism  $g : n \rightarrow p$  such that

$$i_n \cdot g = g_i$$

for each  $i$ . (We will omit the subscript on  $i$  when the target is clear from context.) The uniquely determined morphism  $g$ , written  $\langle g_1, \dots, g_n \rangle$ , is called the **source tupling** of the morphisms  $g_i$ . In particular, for each  $n$  there is a unique morphism

$$0_n : 0 \rightarrow n.$$

We will assume that when  $n = 1$ , the co-product injection  $1_1$  is the identity morphism  $1 \rightarrow 1$ . A **theory morphism**  $\varphi : T \rightarrow T'$  between algebraic theories is a functor which preserves objects and the distinguished co-product injections.

It may be shown that the source tuplings of the distinguished injections correspond to functions  $[n] \rightarrow [p]$ , for all  $n$  and  $p$  in  $N$ . This correspondence is bijective whenever  $1_2 \neq 2_2$ , a condition satisfied whenever there are at least two morphisms  $1 \rightarrow p$ , for some  $p$ . From now on, we identify any such function with the corresponding morphism. These morphisms are called the base morphisms in any algebraic theory. In particular, the identity function  $[n] \rightarrow [n]$  corresponds to the identity morphism  $1_n : n \rightarrow n$  in  $T$ .

For any pair of morphisms  $f : n \rightarrow p, g : m \rightarrow p$  with the same target, there is a unique morphism  $\langle f, g \rangle : n + m \rightarrow p$  such that  $i_{n+m} \cdot \langle f, g \rangle = i_n \cdot f$ , for  $1 \leq i \leq n$ , and  $(n + j)_{n+m} \cdot \langle f, g \rangle = j_m \cdot g$ , for  $1 \leq j \leq m$ . The morphism  $\langle f, g \rangle$  is the **source pairing** of  $f$  and  $g$ .

If  $f_i : n_i \rightarrow p_i, i = 1, 2$ , the morphism

$$f_1 + f_2 : n_1 + n_2 \rightarrow p_1 + p_2,$$

called the **separated sum** of  $f_1$  and  $f_2$ , is defined as the source pairing of  $f_1 \cdot in_1$  and  $f_2 \cdot in_2$ , where  $in_1 : p_1 \rightarrow p_1 + p_2$  and  $in_2 : p_2 \rightarrow p_1 + p_2$  are base morphisms corresponding

to the inclusion and translated inclusion functions. The separated sum operation is associative.

The following useful identities concerning source pairing and sums were proved in [CCE], where we assume that the sources and targets of the indicated morphisms are appropriate:

$$(1.1) \quad (f_1 + g_1) \cdot (f_2 + g_2) = (f_1 \cdot f_2) + (g_1 \cdot g_2),$$

$$(1.2) \quad (f_1 + g_1) \cdot \langle f_2, g_2 \rangle = \langle f_1 \cdot f_2, g_1 \cdot g_2 \rangle,$$

$$(1.3) \quad \langle 0_p, g \rangle = g = \langle g, 0_p \rangle,$$

$$(1.4) \quad \langle f, g \rangle \cdot h = \langle f \cdot h, g \cdot h \rangle.$$

In [Es80] it is proved that an **iteration theory** may be defined as an algebraic theory equipped with an operation  $\dagger$ , which takes a morphism  $f: n \rightarrow p + n$  to a morphism  $f^\dagger: n \rightarrow p$ , and which satisfies the identities (1.5)–(1.8) below:

$$(1.5) \quad \textit{Left zero identity: } (0_n + f)^\dagger = 0_n + f^\dagger, \text{ where } f: m \rightarrow p + m.$$

$$(1.6) \quad \textit{Right zero identity: } (f + 0_m)^\dagger = f, \text{ where } f: m \rightarrow p.$$

$$(1.7) \quad \textit{Pairing identity: } \langle f, g \rangle^\dagger = \langle h^\dagger, g^\dagger \cdot \langle 1_p, h^\dagger \rangle \rangle, \text{ where } h = f \cdot \langle 1_{p+n}, g^\dagger \rangle, f: n \rightarrow p + n + m \text{ and } g: m \rightarrow p + n + m.$$

$$(1.8) \quad \textit{Commutative identity:}$$

$$\langle 1 \cdot \eta \cdot f \cdot (1_p + \eta_1), \dots, m \cdot \eta \cdot f \cdot (1_p + \eta_m) \rangle^\dagger = \eta \cdot (f \cdot (1_p + \eta))^\dagger,$$

where  $f: n \rightarrow p + m$ ,  $\eta: m \rightarrow n$  is a surjective base morphism, and  $\eta_i: m \rightarrow m$  are base with  $\eta_i \cdot \eta = \eta$ .

In any algebraic theory satisfying (1.5)–(1.7), the equation (1.8) is implied by the following implication:

$$(1.9) \quad \textit{Functorial dagger: } \text{ if } g: n \rightarrow p + n \text{ and } \eta: m \rightarrow n \text{ is a surjective base morphism such that } \eta \cdot g = f \cdot (1_p + \eta), \text{ for } f: m \rightarrow p + m, \text{ then } \eta \cdot g^\dagger = f^\dagger.$$

It is shown in [Es83] that the fixed-point identity

$$(1.10) \quad f^\dagger = f \cdot \langle 1_p, f^\dagger \rangle, f: n \rightarrow p + n$$

is a consequence of the other conditions.

An **iteration theory morphism**  $\varphi: I \rightarrow I'$  between iteration theories is a theory morphism which preserves dagger; i.e.,  $(f^\dagger)\varphi = (f\varphi)^\dagger$ , for all  $f: n \rightarrow p + n$  in  $I$ .

**2. Theories as algebras.** If we so wish, we might define an algebraic theory as an  $N \times N$  sorted algebra

$$T = \{T(n, p): n, p \geq 0\},$$

having, for each  $n \geq 1$ ,  $n$  distinguished constants  $i_n \in T(1, n)$ , for  $i \in [n]$ , and the following operations:

$$\textit{composition: } T(n, p) \times T(p, q) \rightarrow T(n, q),$$

$$f, g \mapsto f \cdot g;$$

$$\textit{source tupling: } T(1, p)^n \rightarrow T(n, p),$$

$$f_1, \dots, f_n \mapsto \langle f_1, \dots, f_n \rangle$$

which satisfy the following identities:

- (2.1)  $f \cdot (g \cdot h) = (f \cdot g) \cdot h$  for all  $f \in T(m, n)$ ,  $g \in T(n, p)$ ,  $h \in T(p, q)$ ,
- (2.2)  $\langle 1_n, \dots, n_n \rangle \cdot f = f$ ,  $g \cdot \langle 1_n, \dots, n_n \rangle = g$  for all  $f \in T(n, p)$ ,  $g \in T(m, n)$ ,
- (2.3)  $i_n \cdot \langle f_1, \dots, f_n \rangle = f_i$ ,  $i \in [n]$  for all  $f_j \in T(1, p)$ ,
- (2.4)  $\langle 1_n \cdot f, \dots, n_n \cdot f \rangle = f$  for all  $f \in T(n, p)$ ,
- (2.5)  $\langle 1_1 \rangle = 1_1$ .

The first two identities ensure that  $T$  is a category with  $T(n, p)$  as the set of morphisms  $n \rightarrow p$ , and with  $\langle 1_n, \dots, n_n \rangle: n \rightarrow n$  as the identity morphism; the next two make the distinguished morphisms co-product injections. Equation (2.5) identifies the identity morphism  $1 \rightarrow 1$  with the co-product injection  $1 \rightarrow 1$ . It should be noted that (2.1)–(2.5) are not independent. As an algebra, an iteration theory is an  $N \times N$  sorted algebra equipped with an additional family of operations

$$\begin{aligned} \dagger &: (n, p + n) \rightarrow T(n, p), \\ f &\mapsto f^\dagger \end{aligned}$$

which, in addition to the theory identities (2.1)–(2.5), also satisfy the dagger identities (1.5)–(1.8) above. An iteration theory morphism is just a homomorphism between the corresponding algebras. An iteration theory morphism is determined by its values on **scalar morphisms**, i.e., morphisms with source 1. An iteration theory morphism is injective if and only if it is injective on scalar morphisms.

We will feel free to treat iteration theories as either categories or many-sorted algebras, whichever seems more appropriate.

**3. Some special base morphisms.** In any theory, we denote the identity morphism  $s \rightarrow s$  as  $1_s$ . The base morphism  $1 \rightarrow p$  with value  $i$  is denoted  $i_p$ . This notation can be ambiguous when  $i = 1$ , but the context will prevent confusion. For positive integers  $k$  and  $s$ , we denote by  $\Psi_i^{k,s}: s \rightarrow ks$  the morphism

$$(3.1) \quad \Psi_i^{k,s} = 0_{(i-1)s} + 1_s + 0_{(k-i)s}: s \rightarrow ks,$$

for  $i = 1, \dots, k$ . Here,  $1_s$  must be the identity  $s \rightarrow s$  due to the fact that the source of the morphism  $\Psi_i^{k,s}$  is  $s$ . For example, when  $i = 2$ ,  $\Psi_i^{k,s}$  corresponds to the function mapping  $i \in [s]$  to  $s + i$ . For use in § V, note that for any morphism  $\Delta: 1 \rightarrow s$ , the  $k$ -fold sum

$$\Delta + \Delta + \dots + \Delta: k \rightarrow ks$$

may be written as the tuple

$$\langle \Delta \cdot \Psi_1^{k,s}, \dots, \Delta \cdot \Psi_k^{k,s} \rangle.$$

Note also that the base identity  $s^2 \rightarrow s^2$  is the tuple

$$\langle \Psi_1^{s,s}, \dots, \Psi_s^{s,s} \rangle: s^2 \rightarrow s^2.$$

**4. Trees.** Let  $\Sigma$  be a ranked set. We let  $X_p = \{x_1, \dots, x_p\}$ .

**DEFINITION 4.1.** A  $\Sigma$ -tree  $t: 1 \rightarrow p$  is a partial function

$$t: N^* \rightarrow \Sigma \cup X_p$$

such that  $\text{dom}(t)$ , the domain of  $t$ , is a prefix closed set containing the empty word  $\lambda$ . Furthermore, for each word  $w$  in  $N^*$ , we have the following:

$$(4.1.1) \quad \text{If } wt \in \Sigma_n, n > 0, \text{ then } wi \in \text{dom}(t) \text{ if and only if } i \in [n].$$

(4.1.2) If  $wt \in X_p \cup \Sigma_0$ , then for each  $i$ ,  $w_i$  is not in  $\text{dom}(t)$ , i.e.,  $w$  is a leaf of  $t$ . A  $\Sigma$ -tree  $n \rightarrow p$  is an  $n$ -tuple  $\langle t_1, \dots, t_n \rangle$  of  $\Sigma$ -trees  $1 \rightarrow p$ . The words in  $\text{dom}(t)$  are the vertices of  $t$ , and for  $v$  in  $\text{dom}(t)$ ,  $vt$  is the label of the vertex  $v$ .

Thus, there is a unique  $\Sigma$ -tree  $0 \rightarrow p$ , for any  $p$ . The **composite**  $t \cdot g$  of the tree  $t: 1 \rightarrow p$  with the tree  $g = \langle g_1, \dots, g_p \rangle: p \rightarrow q$  is the tree  $t \cdot g$  obtained by attaching a copy of  $g_i$  to each leaf of  $t$  labeled  $x_i$ . More precisely, for each  $w, v$  in  $N^*$ , if  $wt = x_i$  then  $\langle wv, t \cdot g \rangle$ , the value of  $t \cdot g$  on  $wv$ , is  $vg_i$ . The algebraic theory identities force the definition of the composite of  $\langle t_1, \dots, t_n \rangle: n \rightarrow p$  with  $g: p \rightarrow q$  to be

$$\langle t_1 \cdot g, \dots, t_n \cdot g \rangle.$$

The operation of composition is associative. (A rigorous discussion of the algebraic theory of trees can be found in [EBT].)

If  $t: 1 \rightarrow p+1$  is a  $\Sigma$ -tree the **iteration equation for  $t$**  is the equation in the variable  $z: 1 \rightarrow p$

$$z = t \cdot \langle 1_p, z \rangle.$$

For all trees  $t: 1 \rightarrow p$  except the tree with  $\lambda t = x_{p+1}$ , the iteration equation for  $t$  has a unique solution, denoted  $t^\dagger$ . In the case that  $\lambda t = x_{p+1}$ , if we define  $t^\dagger$  to be the tree

$$\Phi \cdot 0_p,$$

where  $\Phi: 1 \rightarrow 0$ , is any fixed tree, then the operation of **iteration**  $t \mapsto t^\dagger$  is a total operation on all scalar trees. The operation is extended to all vector trees  $t: n \rightarrow p+n$  using the pairing identity (1.7). Note that  $1_1^\dagger = \Phi$ . (See [BEW] for an analysis of how  $^\dagger$  can be defined in other theories when the iteration equation does not have a unique solution.)

**DEFINITION 4.2.** If  $t$  is a  $\Sigma$ -tree  $1 \rightarrow p$ , and  $w$  is a word in  $\text{dom}(t)$ , then  ${}_w t$  is the subtree of  $t$  at  $w$ , defined by the equation

$$\langle u, {}_w t \rangle = (wu)t,$$

for all  $u$  in  $N^*$ .

**DEFINITION 4.3.** For any  $\Sigma$ -tree  $\Phi: 1 \rightarrow 0$ ,  $(\Sigma\text{TR}, \Phi)$  is the algebraic theory of *all*  $\Sigma$ -trees. In this theory, the operation  $^\dagger$  is defined as above, so that  $1_1^\dagger = \Phi$ . We let  $\Sigma_\perp$  denote the ranked set obtained from  $\Sigma$  by the addition of a new letter  $\perp$  to  $\Sigma_0$ .  $(\Sigma_\perp\text{tr}, \perp)$  is the subtheory of  $(\Sigma_\perp\text{TR}, \perp)$  consisting of all  $\Sigma_\perp$ -trees  $t$  having only finitely many subtrees  ${}_w t$ ,  $w \in N^*$ . The trees in  $\Sigma_\perp\text{tr}$  are the “unfoldings” of finite flowchart schemes.

It is shown in [BEW] that both theories  $(\Sigma\text{TR}, \Phi)$  and  $(\Sigma_\perp\text{tr}, \perp)$  are iteration theories. Moreover,  $(\Sigma_\perp\text{tr}, \perp)$  is the free iteration theory freely generated by  $\Sigma$  (see [Es80], [BEW]). *From now on we will write “ $\Sigma\text{tr}$ ” instead of “ $(\Sigma_\perp\text{tr}, \perp)$ .”* The inclusion  $\Sigma \rightarrow \Sigma\text{tr}$  will usually be denoted  $\eta$ . In the sequel, we will identify any letter  $\sigma$  in  $\Sigma$  with the corresponding tree. Note that in  $\Sigma\text{tr}$  the distinguished morphism  $i_n: 1 \rightarrow n$  is the tree  $t$  with  $\lambda t = x_i$ . This tree will henceforth be denoted  $x_i$ .

**FACT 4.4.** It is proved in [Es80] that an algebraic theory  $T$  (equipped with a dagger operation) is an iteration theory if and only if  $T$  satisfies all of the identities valid in  $\Sigma\text{tr}$ , for each  $\Sigma$ .

**5. Sequacious functions.** Theories of sequacious functions were introduced in Elgot [CCE]. These functions model the sequence of states produced by the atomic actions occurring during the operation of a machine which follows a sequential flowchart algorithm. It may be easier to follow the formal Definition 5.1 if the reader interprets the set  $A$  in Definition 5.1 as the set of all possible states of the memory,

and interprets  $f: n \rightarrow p$  as a machine operating on  $A$  which takes inputs on any one of  $n$  input lines. If the computation is successful, a finite number of states will have been produced and the final state will determine one of  $p$  output lines. When the computation is unsuccessful (either nonterminating or abortive), a finite or infinite number of states will occur during the run of  $f$ , and no output line will be determined.

DEFINITION 5.1. Let  $A$  be any set. A **sequacious function**  $f: n \rightarrow p$  on  $A$  is a function

$$f: A^+ \times [n] \cup A^\infty \rightarrow A^+ \times [p] \cup A^\infty$$

such that the following conditions hold:

(5.1.1)  $vf = v$ , any  $v \in A^\infty$ .

(5.1.2) If  $(a, j)f = (v, i) \in A^+ \times [p]$ ,  $a \in A$ , then for all  $u$  in  $A^*$ ,  $(ua, j)f = (uv, i)$ ; similarly, if  $(a, j)f = w \in A^\infty$ , then  $(ua, j)f = uw$ , all  $u$  in  $A^*$ .

(5.1.3) If  $(a, j)f = (v, i) \in A^+ \times [p]$ , then  $v = av'$ , for some  $v'$  in  $A^*$ ; similarly, if  $(a, j)f = w \in A^\infty$ , then  $w = aw'$ , for some  $w' \in A^\infty$ .

The properties (5.1.1)–(5.1.3) imply the following.

**5.2.** A sequacious function is uniquely determined by its values on arguments of the form  $(a, i) \in A \times [n]$ .

If  $u$  and  $v$  are sequences in  $A^\infty$ , we sometimes write  $u^{\wedge}v$  for the sequence obtained by concatenating  $u$  and  $v$ ;  $u^{\wedge}v = u$  if  $u$  is infinite.

The **composite**  $f \cdot g$  of the sequacious functions  $f: n \rightarrow p$  and  $g: p \rightarrow q$  is obtained by standard function composition. The **source tupling** of sequacious functions  $f_i: 1 \rightarrow p$ ,  $i \in [n]$ , is the sequacious function  $n \rightarrow p$  whose value on  $(a, i)$  is the value of  $f_i$  on  $(a, 1)$ . If  $i_n: 1 \rightarrow n$  is the sequacious function determined by the requirement

$$(a, 1)i_n = (a, i),$$

it is easy to check that with the functions  $i_n$  as co-product injections,  $i \in [n]$ , the sequacious functions on  $A$  form an algebraic theory. We now define the operation of iteration in this theory.

Let  $f: n \rightarrow p + n$  be a sequacious function on  $A$ . We will define  $f^\dagger: n \rightarrow p$  by making use of some fixed element  $\perp$  in  $A^\infty$ . Given  $(a, i)$  in  $A \times [n]$ , we consider the sequence

$$(u_0, i_0), (u_1, i_1), \dots,$$

where  $(a, i) = (u_0, i_0)$ , and where, for all  $j$ ,  $(u_{j+1}, i_{j+1})$  is defined if

$$(u_j, i_j)f = (u_{j+1}, p + i_{j+1}).$$

Either  $(u_j, i_j)$  is defined for all  $j \geq 0$ , or not. If not, let  $j$  be least such that

$$(u_j, i_j)f \in A^+ \times [p] \cup A^\infty.$$

In this case we **define**

$$(a, i)f^\dagger = (u_j, i_j)f.$$

In the case where the sequence  $(u_j, i_j)$  is infinite, the sequence of words  $(u_j)$  is increasing, by (5.1.3), and has a limit, say,  $u$ . The word  $u$  is finite if and only if the sequence  $(u_j)$  is eventually constant. In this second case we **define**

$$(a, i)f^\dagger = u^{\wedge}\perp.$$

Now  $f^\dagger$  has been defined for all arguments in  $A \times [n]$ , and its values elsewhere are determined by the requirements (5.1.1)–(5.1.3). Note that  $1_1^\dagger$  is the sequacious function

taking  $(a, 1)$  to  $a^\wedge \perp$ . The resulting algebraic theory of sequacious functions is denoted  $(\text{Seq}(A), \perp)$ .

**THEOREM 5.3.** *The theory  $(\text{Seq}(A), \perp)$  is an iteration theory.*

It can be proved that, aside from satisfying the dagger identities (1.5)–(1.7), the sequacious functions satisfy the functorial dagger implication, and hence the commutative identity (1.8).

**6. Partial functions.** Given a nonempty set  $A$ , the theory  $\text{Pfn}(A)$  is defined as follows: a morphism  $f: n \rightarrow p$  is a partial function

$$f: A \times [n] \rightarrow A \times [p].$$

The distinguished morphism

$$i_n: A \times [1] \rightarrow A \times [n]$$

is the total function taking  $(a, 1)$  to  $(a, i)$ . Composition is standard function composition and the source tupling of the partial functions  $f_i: 1 \rightarrow n$  is the function  $f: n \rightarrow p$  defined by

$$(a, i)f = (a, 1)f_i.$$

It is easy to see that  $\text{Pfn}(A)$  is an algebraic theory. Moreover, in  $\text{Pfn}(A)$ , there is a unique morphism  $\perp: 1 \rightarrow 0$ , the function which is always undefined. We turn  $\text{Pfn}(A)$  into an iteration theory by defining  $f^\dagger$  as follows: given  $f: n \rightarrow p+n$  and an element  $(a, i)$  in  $A \times [n]$ , consider the sequence

$$(u_0, i_0), (u_1, i_1), \dots$$

defined by  $(u_0, i_0) = (a, i)$ , and  $(u_{j+1}, p+i_{j+1}) = (u_j, i_j)f$ . Now, either the sequence is defined for all  $j$ , or there is a least  $j$  such that either  $f$  is undefined on  $(u_j, i_j)$  or  $(u_j, i_j)f \in A \times [p]$ . In the latter case, we **define**  $(a, i)f^\dagger = (u_j, i_j)f$ . In the former, the value of  $f^\dagger$  on  $(a, i)$  is undefined.

**THEOREM 6.1.**  *$\text{Pfn}(A)$  is an iteration theory.*

One proof of this theorem may be found in [BEW].

**7. Congruences.** A congruence  $\approx$  on an algebraic theory  $T$  is a family of equivalence relations, one on each set  $T(n, p)$ ,  $n, p \geq 0$ , which is compatible with the theory operations of composition and source tupling; i.e., if  $f_i \approx g_i$ , then  $f_1 \cdot g_1 \approx f_2 \cdot g_2$ , and  $\langle f_1, \dots, f_n \rangle \approx \langle g_1, \dots, g_n \rangle$ . An **iteration theory congruence** is a theory congruence compatible with the dagger operation: i.e.,  $f^\dagger \approx g^\dagger$  whenever  $f \approx g$ . If  $\varphi: T \rightarrow T'$  is a morphism between iteration theories, then  $\ker(\varphi)$  is an iteration theory congruence on  $T$ , where  $f \approx g$  ( $\ker \varphi$ ) if  $f\varphi = g\varphi$ . Conversely, if  $\approx$  is an iteration theory congruence on  $T$ , the collection  $T/\approx$  of  $\approx$ -equivalence classes forms an iteration theory in the usual way, and the canonical map  $\kappa: T \rightarrow T/\approx$  is an iteration theory morphism, where  $f\kappa$  is the  $\approx$ -equivalence class of  $f$ . Congruences, as well as iteration theory morphisms, are determined by their scalar components.

**II. The method.** An iteration theory identity is an equation  $f = f'$  between terms built from a ranked set, say  $\Omega$ , with  $\Omega_k$  infinite for each  $k \geq 0$ , from constants  $i_n, i \in [n]$ ,  $n > 0$ , using the operation symbols for composition, source tupling, and iteration. We let  $\Omega\text{term}$  denote the  $N \times N$ -sorted algebra of terms. If  $T$  is an iteration theory, a rank-preserving function  $h: \Omega\text{term} \rightarrow T$  is a homomorphism if  $h$  preserves the constants and the operations. Thus, for example,  $(f \cdot g)h = fh \cdot gh$ . An identity  $f = f'$  is valid in  $T$  if  $fh = f'h$  for every homomorphism  $h: \Omega\text{term} \rightarrow T$ .

If  $K$  is a class of iteration theories, we let  $\text{id}(K)$  be the set of all identities true in  $T$  for each  $T$  in  $K$ . The variety generated by a class  $K$ ,  $V(K)$ , is the class of all iteration theories  $T$  such that each identity in  $\text{id}(K)$  is true in  $T$ .

In this paper, we are concerned with the problem of showing that for each of several classes  $K$  of iteration theories, some subset  $Ax$  of identities has the property that  $T \in V(K)$  if and only if each identity in  $Ax$  is valid in  $T$ . In other words, we want to show that  $Ax$  axiomatizes the variety  $V(K)$ .

Our method to prove that a set  $Ax$  (along with the axioms for iteration theories) correctly axiomatizes a variety  $V$  will be the same in each case. We will prove two facts. For any ranked set  $\Sigma$ , let  $\approx$  denote the least iteration theory congruence on  $\Sigma\text{tr}$  such that  $fh \approx f'h$  for each equation  $f = f'$  in  $Ax$  and each homomorphism  $h: \Omega\text{term} \rightarrow \Sigma\text{tr}$ . First we prove that if  $\varphi: \Sigma\text{tr} \rightarrow A$  is any iteration theory morphism from  $\Sigma\text{tr}$  into a theory  $A$  in  $V$ , then  $\approx$  is contained in  $\ker(\varphi)$ , the iteration theory congruence induced by  $\varphi$  on  $\Sigma\text{tr}$ . Second, we prove that the quotient theory  $\Sigma\text{tr}/\approx$  is itself in  $V$ . The Basic Theorem below shows that these facts are sufficient to show that  $\Sigma\text{tr}/\approx$  is freely generated by  $\Sigma$  in  $V$ , and thus the axioms are complete. The difficult part is proving that  $\Sigma\text{tr}/\approx$  is itself in the variety. We will do this in two steps: by finding an explicit description for representatives of the  $\approx$ -congruence classes, and then using this description to show how to embed the theory in one of the generating theories of the variety. Thus, *in each variety considered here, the free structures are subtheories of the generating theories.*

**BASIC THEOREM.** *Suppose that for a given variety  $V$  and set of equational axioms  $Ax$ , the following conditions hold:*

(1) *If  $A \in V$ , then for any iteration theory morphism  $\varphi: \Sigma\text{tr} \rightarrow A$ ,  $t\varphi = t'\varphi$  whenever  $t \approx t'$ .*

(2) *The quotient theory  $\Sigma\text{tr}/\approx$  is itself in  $V$ , where  $\approx$  is defined as above. Then  $\Sigma\text{tr}/\approx$  is freely generated in  $V$  by the composite  $\eta \cdot \kappa_{\approx}$ , where  $\eta: \Sigma \rightarrow \Sigma\text{tr}$  is the inclusion and  $\kappa_{\approx}: \Sigma\text{tr} \rightarrow \Sigma\text{tr}/\approx$  is the canonical map taking a tree  $t$  to its equivalence class. Further, an iteration theory  $T$  is in  $V$  if and only if each axiom is valid in  $T$ .*

*Proof.* Let  $\equiv$  be the intersection of all congruences on  $\Sigma\text{tr}$  of the form  $\ker(\varphi)$ , for  $\varphi: \Sigma\text{tr} \rightarrow A$  an iteration theory morphism whose target is in  $V$ . Then it is easy to see that  $\Sigma\text{tr}/\equiv$  is the free theory in  $V$  freely generated by

$$\eta \cdot \kappa_{\equiv}: \Sigma \rightarrow \Sigma\text{tr} \rightarrow \Sigma\text{tr}/\equiv.$$

By (1), there is a unique iteration theory morphism  $\alpha: \Sigma\text{tr}/\approx \rightarrow \Sigma\text{tr}/\equiv$  such that

$$\begin{array}{ccc} \Sigma\text{tr} & \xrightarrow{\kappa_{\equiv}} & \Sigma\text{tr}/\equiv \\ \kappa_{\approx} \downarrow & \nearrow \alpha & \\ \Sigma\text{tr}/\approx & & \end{array}$$

commutes. By (2), since  $\Sigma\text{tr}/\equiv$  is freely generated by  $\eta \cdot \kappa_{\equiv}: \Sigma \rightarrow \Sigma\text{tr} \rightarrow \Sigma\text{tr}/\equiv$ , there is a unique iteration theory morphism, say  $\beta$ , such that

$$\begin{array}{ccc} \Sigma\text{tr} & \xrightarrow{\kappa_{\equiv}} & \Sigma\text{tr}/\equiv \\ \kappa_{\approx} \downarrow & \nearrow \beta & \\ \Sigma\text{tr}/\approx & & \end{array}$$

commutes. But then both  $\alpha$  and  $\beta$  are necessarily isomorphisms, thus proving the first part of the theorem. The second statement follows from the fact that if each axiom is

valid in  $T$ , then  $T$  is a quotient of a theory of the form  $\Sigma\text{tr}/\approx$ , for a sufficiently large ranked set  $\Sigma$ . Thus  $T$  is in  $V$ , so the theorem is proved.

*Example. Tree varieties.* Let  $V$  denote the variety generated by the iteration theories  $(\Sigma\text{TR}, \perp)$ , for each  $\Sigma$ . We show that  $V$  is axiomatized by the set of axioms for all iteration theories, i.e.,  $Ax$  is empty and  $\approx$  is the identity congruence. Indeed, by our method, there is nothing to do to satisfy (1) above. And, since for any  $\Sigma$ , the theory  $\Sigma\text{tr}$  is a subtheory of  $(\Sigma_{\perp}\text{TR}, \perp)$ ,  $\Sigma\text{tr}$  is in  $V$ . Since the tree theories  $\Sigma\text{tr}$  are free in the class of all iteration theories [BEW],  $V$  is the variety of all iteration theories.

We will use a slight generalization of the above theorem as well. For each ranked set  $\Sigma$ , let  $\Gamma$  be a ranked set disjoint from  $\Sigma$  and let  $\Sigma_{\Gamma}$  denote the ranked set  $\Sigma \cup \Gamma$ . The corresponding set of terms over  $\Omega_{\Gamma}$  has constants for each letter in  $\Gamma$  as well. Suppose that  $K(\Gamma)$  is the class of iteration theories  $A$  such that for each  $\gamma \in \Gamma_n$  there is a distinguished morphism  $\gamma_A: 1 \rightarrow n$  in  $A$ . Morphisms between theories in  $K(\Gamma)$  preserve these distinguished morphisms. Homomorphisms from terms to theories in  $K(\Gamma)$  preserve constants in  $\Gamma$ . It is easy to see that  $\Sigma_{\Gamma}\text{tr}$  is freely generated in  $K(\Gamma)$  by  $\Sigma$ .

**COROLLARY.** *Suppose that for a given variety  $V$  of theories in  $K(\Gamma)$ , and a set of equational axioms  $Ax$ , written using terms in  $\Omega_{\Gamma}$ , the following two statements hold:*

- (3.1) *If  $A \in V$ , then for any iteration theory morphism  $\varphi: \Sigma_{\Gamma}\text{tr} \rightarrow A$ ,  $t\varphi = t'\varphi$  whenever  $t \approx t'$ .*
- (3.2) *The quotient theory  $\Sigma_{\Gamma}\text{tr}/\approx$  is itself in  $V$ , where  $\approx$  is as above. Then  $\Sigma_{\Gamma}\text{tr}/\approx$  is freely generated in  $V$  by the composite  $\eta \cdot \kappa$ , where  $\eta: \Sigma \rightarrow \Sigma_{\Gamma}\text{tr}$  is the inclusion and  $\kappa: \Sigma_{\Gamma}\text{tr} \rightarrow \Sigma_{\Gamma}\text{tr}/\approx$  is the canonical map taking a tree  $t$  to its  $\approx$ -equivalence class.*

**III. Axiomatizing sequacious functions.** In this section, we axiomatize the variety SEQ of iteration theories generated by the theories  $(\text{Seq}(A), \perp)$ , for each set  $A$ . The axioms turn out to be particularly simple: in addition to the axioms for iteration theories, we need add no new axioms. Thus, for each ranked set  $\Sigma$ , the congruence  $\approx$  in the Basic Theorem is the least congruence on  $\Sigma\text{tr}$ , the identity congruence. We need show only that  $\Sigma\text{tr}$  is in SEQ. This fact will follow immediately from the theorem below.

In the proof of Theorem 1 we will make use of sets  $B$  and  $A_0 = B^*$ , where

$$B = \cup (\Sigma_n \times [n]: n \geq 1) \cup \Sigma \cup \{\perp\}.$$

Recall that  $\perp$  is a letter not in  $\Sigma$  used to define  $1_1^{\dagger}$ . The use of  $A_0$  causes a notational problem. The elements of  $A_0$  are finite sequences of elements of  $B$ , and sequacious functions on  $A_0$  involve sequences of elements of  $A_0$ . We will denote concatenation of words on  $B$  by juxtaposition, and will use  $(a_1, \dots, a_k)$  to denote a finite sequence in  $A_0$ .

**THEOREM 1.** *For  $A_0$  as above, there is an injective iteration theory morphism*

$$\varphi_0: \Sigma\text{tr} \rightarrow (\text{Seq}(A_0), \perp).$$

*Proof.* Since this argument is a model for many to come, we will give a detailed proof. Since  $\Sigma\text{tr}$  is freely generated by  $\Sigma$ , to define  $\varphi_0$  we need specify the value of  $\varphi_0$  only on each letter in  $\Sigma$ .

We define  $\sigma\varphi_0$  when  $\sigma \in \Sigma_n$ ,  $n \geq 0$ , as the sequacious function determined by the following conditions (recall I.5.2). Let  $\gamma$  be a word on  $B$ , say  $\gamma = \delta_1\delta_2 \cdots \delta_k$ ,  $k \geq 0$ , where  $\delta_i \in B$ ,  $i = 1, \dots, k$ . Then, if  $k > 0$  and  $\delta_1 = (\sigma, i_1) \in \Sigma_n \times [n]$ ,  $n > 0$ ,

$$(1.1) \quad \langle \gamma, \sigma\varphi_0 \rangle = ((\gamma, \delta_2 \cdots \delta_k), i_1);$$

otherwise, if  $k$  or  $n$  is 0 or  $\delta_1 \neq (\sigma, j)$ ,

$$\langle \gamma, \sigma\varphi_0 \rangle = (\gamma, \sigma).$$

Thus, for all  $\gamma$  in  $A_0$ , all  $\sigma$  in  $\Sigma_n, n \geq 0$ , the value of  $\sigma\varphi_0$  on  $\gamma$  is an element  $A_0^2 \times [n] \cup A_0^2$ . The point of this construction is that the sequacious function  $F_t = t\varphi_0$  determined by the tree  $t$  determines the tree  $t$  itself in the following sense. If  $\gamma$  codes the label of a path in  $t$  to a vertex  $v$ ,  $F_t$  on  $\gamma$  will produce the sequence of words obtained from  $\gamma$  by deleting, from left to right, the letters in  $\gamma$  perhaps followed, at the end, by the element  $vt$ . On words that do not code a path in  $t$ ,  $F_t$  will abort.

*Example.* Let  $\sigma$  be a letter in  $\Sigma_1$  and suppose that  $\alpha$  and  $\beta$  are in  $\Sigma_2$ . Let  $t$  be the finite tree  $\sigma \cdot \beta : 1 \rightarrow 2$ . Then

and

$$\begin{aligned}
 (\sigma, 1)(\beta, 2)F_t &= (((\sigma, 1)(\beta, 2), (\beta, 2), \lambda), 2) \quad \text{in } A_0^3 \times [2], \\
 (\sigma, 1)(\alpha, 1)F_t &= ((\sigma, 1)(\alpha, 1), (\alpha, 1), \beta) \quad \text{in } A_0^3.
 \end{aligned}$$

In order to prove the resulting iteration theory morphism  $\varphi_0$  is injective, we restate some of the preceding definitions in the form of a proposition. In (2.3) below, when  $\gamma \in A_0$  and  $\delta = (\delta', j) \in A_0^+ \times [p]$ , we will understand  $(\gamma, \delta)$  to mean  $((\gamma, \delta'), j) \in A_0^+ \times [p]$ .

**PROPOSITION 2.** *Suppose that  $t : 1 \rightarrow p$  is a tree in  $\Sigma \text{tr}$ . Write  $F_t$  for  $t\varphi_0$ , and let  $\gamma$  be an element of  $A_0$ :*

- (2.1) *If  $t = x_j$ , then  $\gamma F_t = (\gamma, j)$ ;*
- (2.2) *If  $t = \sigma \cdot 0_n$ , for some  $\sigma$  in  $\Sigma_0 \cup \{\perp\}$ , then  $\gamma F_t = (\gamma, \sigma)$ ;*
- (2.3) *If  $t = \sigma \cdot \langle t_1, \dots, t_n \rangle$ , for some  $\sigma$  in  $\Sigma_n, n \geq 1$ , and if  $\gamma = (\sigma, i)^\wedge \gamma'$ , then  $\gamma F_t = (\gamma, \gamma' F_{t_i})$ ;*

*otherwise*

$$\gamma F_t = (\gamma, \sigma).$$

We now show that  $\varphi_0 : \Sigma \text{tr} \rightarrow \text{Seq}(A_0)$  is injective. Assume that  $t$  and  $t'$  are distinct trees  $1 \rightarrow p$  in  $\Sigma \text{tr}$ . We use induction on the length of the shortest word  $v$  such that  $vt \neq vt'$  to prove that  $\gamma F_t \neq \gamma F_{t'}$ , for some element  $\gamma$  in  $A_0$ .

*Case 1.*  $v = \lambda$ . In this case the labels of the roots of the two trees are distinct. Suppose, say, that  $t = \sigma \cdot \langle t_1, \dots, t_k \rangle$  and  $t' = \sigma' \cdot \langle t'_1, \dots, t'_j \rangle$ . One of the letters  $\sigma$  and  $\sigma'$  may be  $\perp$ . Then by (2.2) and (2.3),

$$\lambda F_t = (\lambda, \sigma) \neq (\lambda, \sigma') = \lambda F_{t'}.$$

If  $t' = x_j : 1 \rightarrow p$ , then

$$\lambda F_t = (\lambda, \sigma) \neq (\lambda, j) = \lambda F_{t'}.$$

If  $t$  is also a variable, say  $x_k, \lambda F_t = (\lambda, k)$ . The basis step is complete.

Case 2.  $v = iw$ ,  $t = \sigma \cdot \langle t_1, \dots, t_k \rangle$  and  $t' = \sigma \cdot \langle t'_1, \dots, t'_k \rangle$ , for some  $k \geq j$ . Suppose that  $t_i \neq t'_i$ , where  $1 \leq i \leq k$ . Then by the induction hypothesis there is some element  $\gamma'$  in  $A_0$  with

$$\gamma'F_{t_i} \neq \gamma'F_{t'_i}.$$

If we let  $\gamma = (\sigma, i)\gamma'$ , then

$$\gamma F_t = (\gamma, \gamma'F_{t_i}) \neq (\gamma, \gamma'F_{t'_i}) = \gamma F_{t'}.$$

The proof is complete.

We have completed the proof of the following theorem.

**THEOREM 3.** *For any ranked set  $\Sigma$ , the iteration theory  $\Sigma\text{tr}$  is in the variety SEQ, since it is isomorphic to a subtheory of a theory of the form  $(\text{Seq}(A_0), \perp)$ . Hence, the variety SEQ is the variety of all iteration theories.*

**IV. Partial functions.** In this section two main theorems are proved. First, an axiomatization is given (Theorem 12) for the variety PFN generated by the class of all iteration theories of the form  $\text{Pfn}(A)$ . In the course of the proof, the free iteration theories in this variety are explicitly exhibited. Second, it is proved (Theorem 13) that there is only one way to define the dagger operation  $\dagger$  in any theory  $\text{Pfn}(A)$  so that the resulting structure is an iteration theory. The latter result solves problem 3.9 in Part 2 of [BEW] and is analogous to Theorem 4.3 in [AM].

**PROPOSITION 1.** *There is a unique morphism  $1 \rightarrow 0$  in any iteration theory  $T$  in PFN.*

*Proof.* This condition is evidently an equational one, viz.,

$$(1.1) \quad f = g \quad \text{for all } f, g: 1 \rightarrow 0,$$

which is satisfied in any theory of the form  $\text{Pfn}(A)$  and hence in each theory in PFN. We now set out to show that this condition, together with the axioms for iteration theories, axiomatizes PFN. Let  $\approx$  denote the least iteration theory congruence on  $\Sigma\text{tr}$  such that

$$(2) \quad f \approx g,$$

for all  $f, g: 1 \rightarrow 0$ .

**PROPOSITION 3.** *If  $\varphi: \Sigma\text{tr} \rightarrow \text{Pfn}(A)$  is any iteration theory morphism, then  $\approx$  is contained in  $\ker(\varphi)$ .*

*Proof.* In  $\text{Pfn}(A)$ , a morphism  $f: 1 \rightarrow 0$  is a partial function

$$A \rightarrow \emptyset.$$

Thus  $f$  must be the empty function.

**FACT 4.** It is proved in [BT] that the least theory congruence such that (2) holds is also the least *iteration theory* congruence such that (2) holds.

**DEFINITION 5.** A tree  $t: 1 \rightarrow p$ ,  $p \geq 0$  in  $\Sigma\text{tr}$  is **co-accessible** if no leaf of  $t$  is labeled by a letter in  $\Sigma_0$  and, for each nonleaf vertex  $v$  in  $\text{dom}(t)$ , there is some  $u$  in  $N^*$  with  $(vu)t = x_i$ ; i.e., there is some path from  $v$  to a leaf of  $t$  labeled  $x_i$ , for some  $i \in [p]$ .

Thus a tree  $1 \rightarrow 0$  is coaccessible if and only if the root is a leaf labeled  $\perp$ .

We introduce additional terminology. If  $t: 1 \rightarrow p$  is a tree in  $\Sigma\text{tr}$ , and  $v \in N^*$  is a vertex in  $\text{dom}(t)$ , then we define the “label of the path to  $v$  in  $t$ ,”  $\text{lab}(v)$  for short, as follows.

**DEFINITION 6.** If  $v$  is a vertex in  $\text{dom}(t)$ , then  $\text{lab}(v)$  in  $t$  is the word on the alphabet  $\cup (\Sigma_n \times [n]: n \geq 1)$  defined by induction on the length of  $v$  as follows:

$$(6.1) \quad \text{If } v = \lambda, \text{ then } \text{lab}(v) = \lambda \text{ } (\lambda = \text{empty word}):$$

$$(6.2) \quad \text{If } v = iw, \text{ and } t = \sigma \cdot \langle t_1, \dots, t_n \rangle \text{ then } \text{lab}(v) = (\sigma, i)^\wedge \text{lab}(w), \text{ where } \text{lab}(w) \text{ is the label of } w \text{ in } t_i.$$

PROPOSITION 7. *If  $t$  and  $t'$  are distinct co-accessible trees  $1 \rightarrow p$  in  $\Sigma\text{tr}$ , then there is a leaf vertex  $v$  of  $t$ , say, labeled  $x_i$ , for some  $i \in [p]$ , such that  $\text{lab}(v)$  is not the label of a path to a leaf labeled  $x_i$  in  $t'$ .*

*Proof.* Since  $t$  and  $t'$  are distinct, there is some vertex  $w$  in the domain of both trees such that  $wt \neq wt'$ . We may assume that  $wt$  is not  $\perp$ . If  $w$  is not a leaf of  $t$  labeled  $x_i$  then some extension  $v = wu$  is a leaf vertex of  $t$  labeled  $x_i$ . But then  $\text{lab}(v) = \text{lab}(w) \wedge \text{lab}(u)$  and  $\text{lab}(v)$  is the required path label.

We will need the following terminology in the proof of the next proposition. In any theory, we say a morphism  $f: n \rightarrow p$  **factors through 0** if there is a morphism  $g: n \rightarrow 0$  such that  $f = g \cdot 0_p$ . In the theory  $\Sigma\text{tr}$ , if  $v$  is a vertex of the tree  $t: 1 \rightarrow p$ , we call  $v$  a **0-vertex** if  ${}_v t$  factors through 0 but for no proper prefix  $w$  of  $v$  does  ${}_w t$  factor through 0.

PROPOSITION 8. *For any tree  $t: 1 \rightarrow p, p \geq 1$ , in  $\Sigma\text{tr}$ , there is some co-accessible tree  $t'$  with  $t \approx t'$ .*

*Proof.* Let  $t_1, \dots, t_k$  be all subtrees of  $t$  which are distinct from  $\perp$  and which factor through 0. If  $k = 0$ , then  $t$  itself is co-accessible. Let  $X$  be the set of all 0-vertices  $v$  such that  ${}_v t = t_k$ . Let  $t^\wedge: 1 \rightarrow p+1$  denote the tree obtained from  $t$  by relabeling all vertices  $v$  in  $X$  as  $x_{p+1}$  and deleting the remaining vertices from the subtree  ${}_v t$ . Since  $t^\wedge$  has finitely many subtrees,  $t^\wedge$  is in  $\Sigma\text{tr}$ . Also, by construction,

$$(8.1) \quad t = t^\wedge \cdot \langle 1_p, t_k \rangle.$$

Let  $f = t^\wedge \cdot \langle 1_p, \perp \cdot 0_p \rangle$ . Then

$$(8.2) \quad t \approx f$$

and  $f$  has at least one fewer subtrees distinct from  $\perp$  which factor through 0. In this way, in finitely many steps we obtain a co-accessible tree  $t'$  with  $t' \approx t$ .

In the next argument, we give a construction similar to that used to prove Theorem III.1.

PROPOSITION 9. *There is a set  $A_0$  and a theory morphism  $\varphi_0: \Sigma\text{tr} \rightarrow \text{Pfn}(A_0)$  such that if  $t$  and  $t'$  are distinct co-accessible trees  $1 \rightarrow p$ , then  $t\varphi_0 \neq t'\varphi_0$ .*

*Proof.* Let  $B = \cup (\Sigma_n \times [n]: n \geq 1)$  and let  $A_0 = B^*$ , the set of all words on  $B$ . Again, to define  $\varphi_0$  we need only define the image  $\sigma\varphi_0$  of each letter in  $\Sigma$ . On  $\perp$  and the letters in  $\Sigma_0$  the value of  $\sigma\varphi_0$  is forced to be the empty function. Let  $w = (\delta_1, i_1) \cdots (\delta_k, i_k)$ ,  $k \geq 0$ . If  $\sigma$  is in  $\Sigma_n, n \geq 1$ , then if  $k \geq 1$  and  $\delta_1 = \sigma$ ,  $\sigma\varphi_0$  is defined by

$$(9.1) \quad \langle w, \sigma\varphi_0 \rangle = ((\delta_2, i_2) \cdots (\delta_k, i_k), i_1);$$

otherwise, if  $k = 0$  or  $\delta_1 \neq \sigma$ ,

$$\langle w, \sigma\varphi_0 \rangle \text{ is undefined.}$$

(Thus,  $\langle \lambda, \sigma\varphi_0 \rangle$  is undefined.)

CLAIM.

$$(9.2) \quad \text{If } w \text{ is } \text{lab}(v), \text{ where } v \text{ is a leaf of } t \text{ labeled } x_i, \text{ then } \langle w, t\varphi_0 \rangle = (\lambda, i).$$

$$(9.3) \quad \text{If } w \text{ is not the label of a path in } t \text{ to a leaf labeled by some } x_i, \langle w, t\varphi_0 \rangle \text{ is undefined.}$$

The claim is easily proved by induction on the length of  $w$ . Now the proof is completed by using Propositions 7 and 8.

*Example.* Let  $\sigma$  be a letter in  $\Sigma_1$  and suppose that  $\alpha$  and  $\beta$  are in  $\Sigma_2$ . Let  $t$  be the finite tree  $\sigma \cdot \beta : 1 \rightarrow 2$ . Then, writing  $t\varphi_0$  as  $F_t$ ,

and

$$\begin{aligned}
 (\sigma, 1)(\beta, 2)F_t &= (\lambda, 2), \\
 (\sigma, 1)F_t &= \lambda F_\beta \text{ is undefined.}
 \end{aligned}$$

PROPOSITION 10. For any tree  $t : 1 \rightarrow p$  there is a unique co-accessible tree  $t' : 1 \rightarrow p$  with  $t \approx t'$ .

*Proof.* The proof follows from Propositions 9, 3, and 8.

PROPOSITION 11.  $\Sigma\text{tr}/\approx$  belongs to PFN since  $\Sigma\text{tr}/\approx$  is isomorphic to a sub-iteration theory of  $\text{Pfn}(A_0)$ , where  $A_0$  is the set defined in Proposition 9.

By the Basic Theorem II.1, we obtain the desired result.

THEOREM 12.

(12.1)  $\Sigma\text{tr}/\approx$  is the free theory, freely generated by  $\Sigma$ , in the variety PFN;

(12.2) the axiom (1.1) axiomatizes PFN.

**Uniqueness.** In [BEW], it was asked whether there is more than one way to define the iteration operation  $\dagger$  so that the theory of partial functions  $\text{Pfn}(A)$  is an iteration theory. We devote the remainder of this section to answering the question negatively.

UNIQUENESS THEOREM 13. In each theory  $\text{Pfn}(A)$  there is only one way to define  $\dagger$  on partial functions  $f : n \rightarrow p + n$  in such a way that the operation  $\dagger$  satisfies all valid iteration theory identities.

We may not define  $f^\dagger$  arbitrarily on  $f : n \rightarrow p + n$ , since for example the fixed-point identity (14) must hold.

In view of the pairing identity (see below), we need only consider the case that  $f : 1 \rightarrow p + 1$ .

Let  $f : A \rightarrow A \times [p + 1]$  be a partial function in  $\text{Pfn}(A)$ . Let  $a \in A$ . We consider the following finite or infinite “ $f$ -sequence for  $a$ ”:

$$a = a_0, a_1, a_2, \dots$$

where

$$a_0 f = (a_1, p + 1), a_1 f = (a_2, p + 1), \dots$$

Either for some  $i$ ,  $a_i f$  is undefined (we say “ $f$  is eventually undefined on  $a$ ”) or  $a_i f = (b, j)$ , for some  $j \in [p]$  (we say “ $f$  is eventually successful on  $a$  with value  $(b, j)$ ”), or the sequence is infinite. In the last case, we say “ $f$  cycles on  $a$ .”

Let

$$\begin{aligned}
 S &= \{a \in A : \text{the } f\text{-sequence for } a \text{ is finite}\}, \\
 C &= A - S = \{a \in A : f \text{ cycles on } a\}.
 \end{aligned}$$

It is easy to see that the value of  $f^\dagger$  is determined on the elements of  $S$  by the fixed-point identity

$$(14) \quad f^\dagger = f \cdot \langle 1_p, f^\dagger \rangle.$$

Indeed, if  $a \in S$ , then  $f^\dagger$  is undefined on  $a$  if  $f$  is eventually undefined on  $a$ , and  $af^\dagger = (b, j)$  if  $f$  is eventually successful on  $a$  with value  $(b, j)$ . Thus, the only question unresolved by this particular identity is how  $f^\dagger$  behaves on elements in  $C$ . We wish to show that if  $f$  cycles on  $a$ ,  $f^\dagger$  must be undefined on  $a$ .

Using the following identity:

$$(15) \quad [f \cdot (\beta + 1_1)]^\dagger = f^\dagger \cdot \beta,$$

where  $f: 1 \rightarrow p+1$  and  $\beta: p \rightarrow 1$ , we see that we may also assume that  $p = 1$ , since  $f$  cycles on  $a$  if and only if  $f \cdot (\beta + 1_1)$  cycles on  $a$ .

In the discussion we will use two versions of the **pairing identity**: for  $f: n \rightarrow p + n + m$ ,  $g: m \rightarrow p + n + m$ ,

$$(16) \quad \langle f, g \rangle^\dagger = \langle h^\dagger, g^\dagger \cdot \langle 1_p, h^\dagger \rangle \rangle,$$

where  $h = f \cdot \langle 1_{p+n}, g^\dagger \rangle$ ;

$$(17) \quad \langle f, g \rangle^\dagger = \langle (f \cdot \rho)^\dagger \cdot \langle 1_p, k^\dagger \rangle, k^\dagger \rangle,$$

where  $k = g \cdot \langle 1_p + 0_m, (f \cdot \rho)^\dagger, 0_p + 1_m \rangle$ , and  $\rho: p + n + m \rightarrow p + m + n$  is the base permutation

$$\rho = 1_p + \langle 0_m + 1_n, 1_m + 0_n \rangle.$$

(See [BGR] or [BEW] for a derivation of the pairing lemmas.) Note that (16) is I.(1.7). We shall also use the following fact:

$$(18) \quad (f^2)^\dagger = f^\dagger,$$

for all  $f: n \rightarrow p + n$ , where

$$f^2 = f \cdot \langle 1_p + 0_n, f \rangle.$$

Now let  $f: A \rightarrow A \times [2]$  be a partial function. Define the partial function  $f': A \rightarrow A \times [3]$  as follows:

$$\begin{aligned} xf' &= (y, 3) \quad \text{if } xf = (y, 2) \text{ and } f \text{ cycles or is eventually undefined on } x, \\ &= xf \quad \text{if } f \text{ is eventually successful on } x, \\ &= \text{undefined,} \quad \text{otherwise.} \end{aligned}$$

Note that

$$(19) \quad \text{If } \beta: 3 \rightarrow 2 \text{ is the base morphism } \langle 1_1 + 0_1, 0_1 + 1_1, 0_1 + 1_1 \rangle \text{ then, } f' \cdot \beta = f; \text{ also, if } f' \text{ is eventually successful on } x, \text{ then } f' \text{ is "immediately successful on } x," \text{ i.e., } xf' = (y, j), \text{ for some } j \in [2].$$

Now, by the pairing identity (17) above,

$$(0_1 + 1_1) \cdot \langle 0_2 + 1_1, f' \rangle^\dagger = k^\dagger,$$

where

$$\begin{aligned} k &= f' \cdot \langle 1_1 + 0_1, (0_1 + 1_1 + 0_1)^\dagger, 0_1 + 1_1 \rangle \\ &= f' \cdot \langle 1_1 + 0_1, 0_1 + 1_1, 0_1 + 1_1 \rangle \\ &= f' \cdot \beta = f. \end{aligned}$$

But by (16),

$$(0_1 + 1_1) \cdot \langle 0_2 + 1_1, f' \rangle^\dagger = f'^\dagger \cdot \langle 1_1, h^\dagger \rangle,$$

for some  $h$ . Hence, if  $f$  cycles on  $x$ , so does  $f'$ , and if  $xf'^\dagger$  is defined, so is  $xf'^\dagger$ .

The previous discussion and the identity (15) allow us to assume that  $f: A \rightarrow A \times [2]$  is a partial function such that

- (20) If  $f$  is eventually successful on  $x$ , then  $xf = (y, 1)$  for some  $y$ ; i.e.,  $f$  is immediately successful on  $x$ . Further, there is some  $a_0 \in A$  such that  $f$  cycles on  $a_0$  and  $a_0f^\dagger$  is defined.

Suppose that

(21) 
$$a_0f^\dagger = (b, 1),$$

and let  $c \in A$  be some element such that  $c \neq b$ . Let  $h_c: A \rightarrow A$  be the constant function with value  $(c, 1)$ , and let

$$g = f \cdot (h_c + 1_1),$$

so that

$$g^\dagger = f^\dagger \cdot h_c.$$

Thus,  $a_0g^\dagger = a_1g^\dagger = (c, 1)$ , by the fixed-point identity (14), where  $a_0f = (a_1, 2)$ .

We now define the two partial functions  $f_1$  and  $f_2: 1 \rightarrow 3$  as follows:

$$f_1 = f \cdot (1_1 + 0_1 + 1_1) \quad \text{and} \quad f_2 = g + 0_1.$$

Using version (17) of the pairing identity, we see that

$$(1_1 + 0_1) \cdot \langle f_1, f_2 \rangle^\dagger = f \cdot \langle 1_1, (g^2)^\dagger \rangle,$$

by property (20) of  $f$ . Further,

$$(1_1 + 0_1) \cdot \langle f_1, f_2 \rangle^\dagger = f \cdot \langle 1_1, (g^2)^\dagger \rangle = f \cdot \langle 1_1, g^\dagger \rangle,$$

by (18) above. But using version (16) and property (20),

$$(1_1 + 0_1) \cdot \langle f_1, f_2 \rangle^\dagger = (f^2)^\dagger = f^\dagger.$$

But then,

$$a_0f^\dagger = a_0f \cdot \langle 1_1, g^\dagger \rangle = a_1g^\dagger;$$

and the value of the right-hand side is  $a_1g^\dagger = (c, 1)$ , contradicting (21).

We have thus proved the following: if the  $\dagger$ -operation is defined on  $\text{Pfn}(A)$  so that the resulting theory is an iteration theory, then there is only one way to define it on any given partial function  $f: 1 \rightarrow p + 1$ ; namely, if  $f$  cycles on  $x$ ,  $f^\dagger$  is undefined at  $x$ . Otherwise, the value  $xf^\dagger$  is determined by the fixed-point identity.

When defining the element  $c$  above (after (21)), we assumed that the set  $A$  contains at least two elements. In the case that  $A$  is a singleton, there is a much easier argument. Indeed, if  $f: 1 \rightarrow 2$  cycles on  $a_0$  but  $a_0f^\dagger$  is defined, consider the function

$$g = f \cdot (\perp \cdot 0_1 + 1_1).$$

Then  $g = f$ , since  $a_0f = (a_0, 2)$ , and  $a_0$  is the only element in  $A$ . But

$$g^\dagger = f^\dagger \cdot \perp \cdot 0_1,$$

by (15), so that  $a_0f^\dagger$  is undefined, a contradiction. The Uniqueness Theorem 13 is proved.

**V. Sequacious functions with predicates.**

**A. The theory of one generalized predicate.**

DEFINITION 1. Let  $T$  be the iteration theory  $(\text{Seq}(A), \perp)$  (i.e.,  $1_1^\dagger = \perp$ ). Let  $s$  be an integer greater than 1. A sequacious function  $\Delta : 1 \rightarrow s$  in  $T$  is a (generalized) predicate if, for all  $a \in A$ , there is some  $i \in [s]$  with

$$a\Delta = (a, i).$$

When we wish to emphasize that  $\Delta$  will have a fixed interpretation as a generalized predicate in  $T$  we will write

$$\text{Seq}(A, \perp, \Delta)$$

for this theory. Let  $\text{SEQ}(\Delta)$  be the variety of all iteration theories generated by theories  $\text{Seq}(A, \perp, \Delta)$ , for each  $A$ . In this section we will show that the identities (a.1)–(a.3) below axiomatize  $\text{SEQ}(\Delta)$ .

PROPOSITION 2. Any generalized predicate  $\Delta : 1 \rightarrow s$  satisfies the following identities in  $T$ .

(a.1)  $\Delta \cdot \langle 1_1, \dots, 1_1 \rangle = 1_1,$

(a.2)  $\Delta \cdot (\Delta + \dots + \Delta) = \Delta \cdot \rho,$

where there are  $s$   $\Delta$ 's in the sum and  $\rho : s \rightarrow s^2$  is the base function taking  $i \in [s]$  to  $(i-1)s + i$ ;

(a.3)  $(\Delta \cdot \gamma)^\dagger = \Delta \cdot \gamma \cdot (1_p + \perp),$

where  $\gamma : s \rightarrow p+1$  is any base function.

If  $\Sigma$  is any ranked set, let  $\Sigma_\Delta$  be the ranked set obtained by adding a new symbol  $\Delta$  of rank  $s$  to  $\Sigma$  (as well as the letter  $\perp$  to  $\Sigma_0$ ). Let  $\approx$  be the least iteration theory congruence on  $\Sigma_\Delta\text{tr}$  such that

(a.1')  $\Delta \cdot \langle 1_1, \dots, 1_1 \rangle \approx 1_1,$

(a.2')  $\Delta \cdot (\Delta + \dots + \Delta) \approx \Delta \cdot \rho,$

(a.3')  $(\Delta \cdot \gamma)^\dagger \approx \Delta \cdot \gamma \cdot (1_p + \perp),$

where  $\rho$  and  $\gamma$  are the base functions described in (a.2) and (a.3) above.

FACT 3.1. For each tree  $t : 1 \rightarrow p$ ,

$$t \approx \Delta \cdot \langle t, \dots, t \rangle.$$

FACT 3.2. Suppose that  $t = \Delta \cdot \langle \Delta \cdot u^1, \dots, \Delta \cdot u^s \rangle$ , where each  $u^i : s \rightarrow p$ . Then, writing  $u_j^i$  for the composite of the base  $j_s : 1 \rightarrow s$  with  $u^i : s \rightarrow p$ ,

$$t \approx \Delta \cdot \langle u_1^1, u_2^2, \dots, u_s^s \rangle.$$

We call a scalar tree  $t$  in  $\Sigma_\Delta\text{tr}$  “ $\Delta$ -separated” if for any word  $w$  in  $\text{dom}(t)$  and for each  $i \in [s]$ ,  $(wi)t \neq \Delta$  if  $wt = \Delta$ ;  $t$  is “alternating” if for each  $w$  in  $\text{dom}(t)$  of even length,  $wt = \Delta$ . Note that if  $t$  is both alternating and  $\Delta$ -separated then for  $w$  in  $\text{dom}(t)$ ,  $wt = \Delta$  if and only if the length of  $w$  is even. In particular,  $t$  is  $\Delta$ -rooted. The  $\Delta$ -separated alternating trees will be shown to be representatives of  $\approx$ -equivalence classes.

We state four lemmas, proved later, which are enough to prove the axiomatization theorem.

LEMMA 4. If  $\varphi : \Sigma_\Delta\text{tr} \rightarrow \text{Seq}(A, \perp, \Delta)$  is any iteration theory morphism mapping the letter  $\Delta : 1 \rightarrow s$  to the generalized predicate  $\Delta : 1 \rightarrow s$  in  $\text{Seq}(A, \perp, \Delta)$ , then  $t\varphi = t'\varphi$  whenever  $t \approx t'$ .

LEMMA 5. For every tree  $t:1 \rightarrow p$  in  $\Sigma_{\Delta}\text{tr}$  there is a  $\Delta$ -separated alternating tree  $t':1 \rightarrow p$  with  $t \approx t'$ .

LEMMA 6. There is a particular iteration theory morphism

$$\varphi_0: \Sigma_{\Delta}\text{tr} \rightarrow \text{Seq}(A_0, \perp, \Delta)$$

such that  $t\varphi_0 \neq t'\varphi_0$  if  $t$  and  $t'$  are distinct  $\Delta$ -separated, alternating trees.

LEMMA 7.  $\Sigma_{\Delta}\text{tr}/\approx$  is isomorphic to a subtheory of the theory  $\text{Seq}(A_0, \perp, \Delta)$  of the previous lemma.

Let  $\eta: \Sigma \rightarrow \Sigma_{\Delta}\text{tr}$  be the obvious inclusion function, and let  $\kappa_{\Delta}: \Sigma_{\Delta}\text{tr} \rightarrow \Sigma_{\Delta}\text{tr}/\approx$  be the canonical map taking a tree  $t$  to its  $\approx$ -congruence class.

THEOREM A.  $\Sigma_{\Delta}\text{tr}/\approx$  is freely generated by  $\eta \cdot \kappa_{\Delta}: \Sigma \rightarrow \Sigma_{\Delta}\text{tr}/\approx$  in  $\text{SEQ}(\Delta)$  and the identities (a.1)–(1.3) axiomatize  $\text{SEQ}(\Delta)$ .

Remark. From Lemmas 5–7 it follows that for each scalar tree  $t$  there is a unique  $\Delta$ -separated, alternating tree  $t'$  with  $t \approx t'$ , so that the free theories  $\Sigma_{\Delta}\text{tr}/\approx$  are concretely described by these trees.

We need only prove the lemmas.

*Proof of Lemma 5.* In fact, we show how to obtain a  $\Delta$ -separated alternating tree  $t'$  by an inductive procedure. The difficult part of the procedure ensures that no two  $\Delta$ -labeled vertices are adjacent. It will follow that if the procedure is applied to alternating trees, the result is also alternating. We know that any scalar tree in  $\Sigma_{\Delta}\text{tr}$  may be obtained from the atomic and base trees (i.e., those trees of height at most 1) using the operations of scalar iteration and composition in the form

$$t = t_0 \cdot \langle t_1, \dots, t_k \rangle,$$

where  $t_0:1 \rightarrow k$ , and  $t_i:1 \rightarrow p$ , for  $i = 1, \dots, k$ .

The base and atomic trees are clearly  $\Delta$ -separated. For each base  $\beta:1 \rightarrow p$

$$\beta \approx \Delta \cdot \langle \beta, \dots, \beta \rangle,$$

and the right-hand tree is alternating. If  $\sigma \in \Sigma_n$ , then

$$\sigma \approx \Delta \cdot \langle \sigma, \dots, \sigma \rangle \cdot (\Delta + \dots + \Delta) \cdot \gamma,$$

for an appropriate base  $\gamma$ , and again the right-hand tree is alternating. (There are  $s$   $\sigma$ 's and  $n$   $\Delta$ 's on the right-hand side.) The tree  $\Delta$  itself is  $\Delta$ -separated and alternating.

Now assume that  $t:1 \rightarrow p+1$  is  $\Delta$ -separated and alternating. We will show that there is a  $\Delta$ -separated alternating tree  $t'$ , with  $t' \approx t^{\dagger}$ .

Recall that  $t$  is  $\Delta$ -rooted. For notational simplicity, assume  $\Delta:1 \rightarrow 2$ , so that

$$t = \Delta \cdot \langle t_1, t_2 \rangle.$$

Case 1. One (or both) of  $t_i$ ,  $i = 1, 2$ , is the base  $x_{p+1}$ .

Suppose that just  $t_2$  is  $x_{p+1}$ . In this case, we use the fact that if

$$t = f \cdot \langle g, 0_p + 1_1 \rangle,$$

then  $t^{\dagger} = (f^{\dagger} \cdot g)^{\dagger}$ , and in this case  $f^{\dagger} \cdot g \approx \Delta \cdot \langle t_1, \perp \cdot 0_{p+1} \rangle$ . The details of the other cases are similar and are omitted.

Case 2. Otherwise (see Fig. 1 for an example). Call a leaf  $v$  of

$$t = \Delta \cdot \langle t_1, t_2 \rangle.$$

“ $i$ -bad” ( $i = 1, 2$ ) if  $v$  is labeled  $x_{p+1}$  and  $v$  is the  $i$ th successor of a vertex labeled  $\Delta$ . Let the trees  $\bar{t}, \bar{t}_1, \bar{t}_2:1 \rightarrow p+3$  be obtained from  $t, t_1, t_2$  by relabeling the  $i$ -bad leaves  $x_{p+1+i}$ ,  $i = 1, 2$ . Now define  $h:3 \rightarrow p+3$  by

$$h = \langle \bar{t}, \bar{t}_1, \bar{t}_2 \rangle.$$

FIG. 1

(Figure 2 indicates the triple  $h$  for the tree in Fig. 1.) Note. If  $\beta : 3 \rightarrow 1$  is the unique base morphism, then  $\bar{t} \cdot \langle 1_p + 0_1, 0_p + \beta \rangle = t$ . A similar statement holds for  $\bar{t}_i, i = 1, 2$ .

CLAIM 1.  $h^\dagger : 3 \rightarrow p$  is  $\Delta$ -separated (i.e., each component of  $h^\dagger$  is  $\Delta$ -separated), since  $\bar{t}_1$  and  $\bar{t}_2$  are not  $\Delta$ -rooted and there is no  $\Delta$ -labeled vertex in  $h$  having a leaf labeled  $x_{p+1}$  as an immediate successor (see Fig. 3 for the same example).

Let  $g : 3 \rightarrow p+3$  be the composite of  $h$  with

$$f = \langle 1_{p+1} + 0_2, 0_{p+1} + \Delta, 0_{p+1} + \Delta \rangle.$$

CLAIM 2.

$$(*) \quad g^\dagger = \langle t^\dagger, t_1 \cdot \langle 1_p, t^\dagger \rangle, t_2 \cdot \langle 1_p, t^\dagger \rangle \rangle.$$

*Proof.* It is easy to see that there is a unique solution to the iteration equation for  $g$ . Let  $k : 3 \rightarrow p$  denote the morphism on the right-hand side of (\*). We will show that

$$g \cdot \langle 1_p, k \rangle = k.$$

Indeed,

$$\begin{aligned} f \cdot \langle 1_p, k \rangle &= \langle 1_p, t^\dagger, \Delta \cdot \langle t_1 \cdot \langle 1_p, t^\dagger \rangle, t_2 \cdot \langle 1_p, t^\dagger \rangle \rangle, \Delta \cdot \langle t_1 \cdot \langle 1_p, t^\dagger \rangle, t_2 \cdot \langle 1_p, t^\dagger \rangle \rangle \rangle \\ &= \langle 1_p, t^\dagger, t^\dagger, t^\dagger \rangle, \end{aligned}$$

FIG. 2

FIG. 3

since  $t = \Delta \cdot \langle t_1, t_2 \rangle$  and  $t \cdot \langle 1_p, t^\dagger \rangle = t^\dagger$ . But then,

$$\begin{aligned} h \cdot f \cdot \langle 1_p, k \rangle &= \langle \bar{t}, \bar{t}_1, \bar{t}_2 \rangle \cdot \langle 1_p, t^\dagger, t^\dagger, t^\dagger \rangle \\ &= \langle \bar{t}, \bar{t}_1, \bar{t}_2 \rangle \cdot \langle 1_p + 0_1, 0_p + \beta \rangle \cdot \langle 1_p, t^\dagger \rangle \\ &= \langle t, t_1, t_2 \rangle \cdot \langle 1_p, t^\dagger \rangle \\ &= \langle t^\dagger, t_1 \cdot \langle 1_p, t^\dagger \rangle, t_2 \cdot \langle 1_p, t^\dagger \rangle \rangle. \end{aligned}$$

Thus  $g^\dagger = k$ , as claimed.

CLAIM 3.  $g \approx h$ .

Indeed,  $g$  is obtained from  $h$  by attaching the tree  $\Delta \cdot \langle x_{p+2}, x_{p+3} \rangle$  to any leaf of the components of  $h$  labeled  $x_{p+1+i}$ ,  $i = 1, 2$ . But such leaves have immediate predecessors labeled  $\Delta$ , by construction. Using Facts 3.1 and 3.2 and the fact that  $h$  has only finitely many  $\Delta$ -rooted subtrees such that some successor of the root is labeled  $x_{p+1+i}$ ,  $i = 1, 2$ , it follows that  $g \approx h$ .

By Claim 3, and the fact that  $\approx$  is an iteration theory congruence, it follows that  $h^\dagger \approx g^\dagger$ . Thus the first component of  $g^\dagger$ , namely  $t^\dagger$ , is congruent to the first component of  $h^\dagger$ , which is a  $\Delta$ -separated tree.

Note. Since  $t$  was already alternating, the first component of  $h^\dagger$  is also alternating.

A similar but much simpler argument shows that if each tree  $t_i, i = 0, \dots, k$  is  $\Delta$ -separated and alternating, and

$$t = t_0 \cdot \langle t_1, \dots, t_k \rangle$$

then we can construct a  $\Delta$ -separated alternating tree  $t'$  congruent to  $t$ .

Lemma 4 is obvious. Lemma 7 follows immediately from Lemmas 6 and 5.

We only sketch the proof of Lemma 6, since it is similar to previous arguments. Let  $Tv$  denote  $[s]^*$ , the collection of all finite sequences of elements in  $[s]$  (which we think of as "truth values"), including the empty sequence  $\lambda$ . Let  $B$  denote the union of the sets  $\Sigma_n \times [n], n \geq 1$ , with the set  $\Sigma \cup \{\perp\}$ . Let  $C$  be  $B^*$ . Finally let  $A_0 = Tv \times C$ . We consider the theory  $\text{Seq}(A_0, \perp, \Delta)$ , in which the generalized predicate  $\Delta$  is defined below. In the following definitions, let

$$\xi = (b_1 b_2 \dots b_k, c_1 \dots c_j) \in A_0.$$

We let  $\tilde{\perp}$  denote the pair  $(\lambda, \perp)$  in  $A_0$ . The predicate  $\Delta$  in  $\text{Seq}(A_0, \tilde{\perp}, \Delta)$  is defined as follows:

$$\begin{aligned} \xi \Delta &= (\xi, b_1) \quad \text{if } k \geq 1, \\ &= (\xi, 1) \quad \text{otherwise.} \end{aligned}$$

For  $\sigma \in \Sigma_n, n \geq 0$ , let  $\sigma\varphi_0$  be the sequacious function determined by the condition

$$\begin{aligned} \xi \sigma\varphi_0 &= (\xi^\wedge(b_2 \dots b_k, c_2 \dots c_j), j_1) \quad \text{if } k > 0, j > 0 \quad \text{and} \quad c_1 = (\sigma, j_1); \\ &= \xi^\wedge(\lambda, \sigma) \quad \text{otherwise.} \end{aligned}$$

It is not difficult to show that if  $t$  and  $t'$  are distinct  $\Delta$ -separated alternating trees then  $t\varphi_0 \neq t'\varphi_0$ .

This concludes the proof of the lemmas and Theorem A is established.

**B. The theory of several binary predicates.** In this section, we show that the variety  $\text{SEQ}(\Pi)$  generated by theories of sequacious functions equipped with a finite set  $\Pi$  of binary predicates is isomorphic to the variety  $\text{SEQ}(\Delta)$ , for a generalized predicate of the appropriate rank.

Let  $\Pi = \{\pi_1, \pi_2, \dots, \pi_r\}$  be a set of new letters and let  $\Sigma_\Pi$  denote the ranked set obtained from  $\Sigma$  by adding the set  $\Pi$  to  $\Sigma_2$ .

For  $i = 1, \dots, r$  we define trees in  $\Sigma_\Pi \text{tr}$  as follows.

DEFINITION 8.

$$\begin{aligned} \Delta_1 &= \pi_1 : 1 \rightarrow 2, \\ \Delta_{j+1} &= \pi_{j+1} \cdot (\Delta_j + \Delta_j) : 1 \rightarrow 2^{j+1}. \end{aligned}$$

For  $k = 1, \dots, r$ , let  $\beta_k : 2^k \rightarrow 1$  denote the unique base morphism and by induction we define the base maps  $\nu_i^k : 2^k \rightarrow 2$ , for  $1 \leq i \leq k \leq r$ , as follows.

DEFINITION 9.

$$\nu_1^1 = 1_1 + 1_1 (= 1_2 : 2 \rightarrow 2),$$

for  $i \leq k$ ,

$$\nu_i^{k+1} = \langle \nu_i^k, \nu_i^k \rangle,$$

when  $i = k + 1$ ,

$$\nu_{k+1}^{k+1} = \beta_k + \beta_k,$$

as an abbreviation, we omit the superscript,

$$(9.a) \quad \nu_k = \nu_k^r \quad \text{for } 1 \leq k \leq r.$$

Let  $\equiv$  denote the least iteration theory congruence on  $\Sigma_{\Pi}$  tr such that

- (c.1)  $\pi_i \cdot \langle 1_1, 1_1 \rangle \equiv 1_1$  for each  $i \in [r]$ ,
- (c.2)  $\pi_i \cdot (\pi_i + \pi_i) \equiv \pi_i \cdot (1_1 + 0_2 + 1_1)$  for each  $i \in [r]$ ,
- (c.3)  $\pi_i \cdot (\pi_j + \pi_j) \equiv \pi_j \cdot (\pi_i + \pi_i) \cdot (1_1 + \rho + 1_1)$  for each  $i, j \in [r]$ ,
- (c.4)  $[\Delta_r \cdot \gamma]^\dagger \equiv \Delta_r \cdot \gamma \cdot (1_p + \perp)$ .

In (c.3),  $\rho: 2 \rightarrow 2$  is the nontrivial base permutation, and in (c.4),  $\gamma: 2^r \rightarrow p + 1$  is any base morphism;  $\Delta_r: 1 \rightarrow 2^r$  was defined in Definition 8. Below, the axiom (c.3) is used only when  $i \neq j$ .

Let  $\text{SEQ}(\Pi)$  denote the variety of iteration theories generated by the theories  $\text{Seq}(A, \perp, \Pi)$  in which each letter  $\pi_i$  in  $\Pi$  is interpreted as a binary predicate. We will prove that  $\Sigma_{\Pi}\text{tr}/\equiv$  is freely generated in  $\text{SEQ}(\Pi)$  by  $\Sigma$ . The proof will be easy once we show that, in fact, if  $s = 2^r$  and  $\Delta: 1 \rightarrow s$  is a new letter, then the theories  $\Sigma_{\Delta}\text{tr}/\approx$  and  $\Sigma_{\Pi}\text{tr}/\equiv$  are isomorphic. (Here  $\approx$  is the congruence on  $\Sigma_{\Delta}\text{tr}$  defined § A.) We need some preliminary facts.

PROPOSITION 10. For each pair  $i, k$  with  $1 \leq i \leq k \leq r$ ,

- (10.1)  $\Delta_k \cdot \beta_k \equiv 1_1$ ,
- (10.2)  $\Delta_k \cdot \nu_i^k \equiv \pi_i$ ,
- (10.3)  $\Delta_r \cdot \nu_i \equiv \pi_i$ ,
- (10.4)  $\nu_i \cdot \langle 1_1, 1_1 \rangle = \beta_r$ .

*Proof.* The proofs of (10.1) and (10.2) are by induction on  $k$ . When  $k = 1$ ,  $\Delta_1 = \pi_1$  and  $\nu_1^1$  is the identity base morphism. Also,  $\pi_1 \cdot \beta_1 \equiv 1_1$ , by (c.1). Assume that (10.1) is true for  $k$ . Then,

$$\begin{aligned} \Delta_{k+1} \cdot \beta_{k+1} &= \pi_{k+1} \cdot (\Delta_k + \Delta_k) \cdot \langle \beta_k, \beta_k \rangle \\ &\equiv \pi_{k+1} \cdot \langle 1_1, 1_1 \rangle \\ &\equiv 1_1. \end{aligned}$$

Now for (10.2), if  $i \leq k$ ,

$$\begin{aligned} \Delta_{k+1} \cdot \nu_i^{k+1} &= \pi_{k+1} \cdot (\Delta_k + \Delta_k) \cdot \langle \nu_i^k, \nu_i^k \rangle \\ &\equiv \pi_{k+1} \cdot \langle \pi_i, \pi_i \rangle \text{ by the induction hypothesis,} \\ &\equiv \pi_i \cdot (\pi_{k+1} + \pi_{k+1}) \cdot \langle 1_1 + 0_1, 1_1 + 0_1, 0_1 + 1_1, 0_1 + 1_1 \rangle \\ &\equiv \pi_i \cdot (1_1 + 1_1) \\ &= \pi_i. \end{aligned}$$

If  $i = k + 1$ , then

$$\begin{aligned} \Delta_{k+1} \cdot \nu_{k+1}^{k+1} &= \pi_{k+1} \cdot (\Delta_k + \Delta_k) \cdot (\beta_k + \beta_k) \\ &\equiv \pi_{k+1} \cdot (1_1 + 1_1) \\ &= \pi_{k+1}. \end{aligned}$$

The proof (10.2) is complete. Clearly, (10.3) is a special case of (10.2). Equation (10.4) is obvious, since there is a unique base morphism  $n \rightarrow 1$ , for  $n \geq 1$ .

We define an iteration theory morphism  $\varphi : \Sigma_{\Pi} \text{tr} \rightarrow \Sigma_{\Delta} \text{tr}$  (where  $\Delta : 1 \rightarrow s, s = 2^r$ ), as the unique morphism extending the following function:

$$\begin{aligned} \sigma &\mapsto \sigma \quad \text{for each } \sigma \text{ in } \Sigma, \\ \pi_i &\mapsto \Delta \cdot \nu_i, \end{aligned}$$

for  $1 \leq i \leq r$ .

PROPOSITION 11. For each pair of trees  $t, t' : n \rightarrow p$  in  $\Sigma_{\Pi} \text{tr}$ ,

$$\text{if } t \equiv t' \text{ then } t\varphi \approx t'\varphi.$$

Thus, if  $\kappa_{\Pi} : \Sigma_{\Pi} \text{tr} \rightarrow \Sigma_{\Pi} \text{tr} / \equiv$  and  $\kappa_{\Delta} : \Sigma_{\Delta} \text{tr} \rightarrow \Sigma_{\Delta} \text{tr} / \approx$  are the canonical morphisms, there is a unique iteration theory morphism  $\varphi^{\wedge} : \Sigma_{\Pi} \text{tr} / \equiv \rightarrow \Sigma_{\Delta} \text{tr} / \approx$  such that the following diagram commutes:

$$\begin{array}{ccc} \Sigma_{\Pi} \text{tr} & \xrightarrow{\varphi} & \Sigma_{\Delta} \text{tr} \\ \kappa_{\Pi} \downarrow & & \downarrow \kappa_{\Delta} \\ \Sigma_{\Pi} \text{tr} / \equiv & \xrightarrow{\varphi^{\wedge}} & \Sigma_{\Delta} \text{tr} / \approx \end{array}$$

*Proof of the Proposition.* It is enough to prove that  $t_i\varphi \approx t'_i\varphi$ , where  $t_i$  is the term on the left-hand side of (c.i) for  $i \in [4]$ , and  $t'_i$  is the right-hand term, since  $\ker(\varphi \cdot \kappa_{\Delta})$  is an iteration theory congruence on  $\Sigma_{\Pi} \text{tr}$ . Thus, we must prove the following facts:

$$(11.1) \quad \Delta \cdot \nu_i \cdot \langle 1_1, 1_1 \rangle \approx 1_1,$$

$$(11.2) \quad \Delta \cdot \nu_i \cdot (\Delta \cdot \nu_i + \Delta \cdot \nu_i) \approx \Delta \cdot \nu_i \cdot (1_1 + 0_2 + 1_1),$$

$$(11.3) \quad \Delta \cdot \nu_i \cdot (\Delta \cdot \nu_j + \Delta \cdot \nu_j) \approx \Delta \cdot \nu_j \cdot (\Delta \cdot \nu_i + \Delta \cdot \nu_i) \cdot (1_1 + \rho + 1_1),$$

$i \neq j, \quad \rho : 2 \rightarrow 2$  the nontrivial permutation.

$$(11.4) \quad \begin{aligned} &[\Delta \cdot \nu_r \cdot (\Delta \cdot \nu_{r-1} + \Delta \cdot \nu_{r-1}) \cdot \dots \cdot (\Delta \cdot \nu_1 + \dots + \Delta \cdot \nu_1) \cdot \gamma]^{\dagger} \\ &\approx [\Delta \cdot \nu_r \cdot (\Delta \cdot \nu_{r-1} + \Delta \cdot \nu_{r-1}) \cdot \dots \cdot (\Delta \cdot \nu_1 + \dots + \Delta \cdot \nu_1) \cdot \gamma] \cdot (1_p + \perp), \end{aligned}$$

where  $\gamma : 2^r \rightarrow p + 1$  is any base morphism.

*Proof of 11.1.*  $\Delta \cdot \nu_i \cdot \langle 1_1, 1_1 \rangle = \Delta \cdot \langle 1_1, \dots, 1_1 \rangle \approx 1_1$ , by (a.1).

*Proof of 11.2.* We use the base morphisms  $\Psi_i^{k,s}$  defined in the preliminaries. First,  $\nu_i \cdot (\Delta \cdot \nu_i + \Delta \cdot \nu_i) = \nu_i \cdot (\Delta + \Delta) \cdot (\nu_i + \nu_i)$ , and for any base morphism  $\nu : s \rightarrow 2$ ,

$$\nu \cdot (\Delta + \Delta) = (\Delta + \dots + \Delta) \cdot (\Psi_{1\nu}^{2,s}, \dots, \Psi_{s\nu}^{2,s}).$$

But applying (a.2),

$$\Delta \cdot \nu_i \cdot (\Delta \cdot \nu_i + \Delta \cdot \nu_i) \approx \Delta \cdot \rho \cdot (\Psi_{1\nu}^{2,s}, \dots, \Psi_{s\nu}^{2,s}) \cdot (\nu_i + \nu_i).$$

Calculating, for  $j \in [s]$ , the value of the base function  $\rho \cdot (\Psi_{1\nu}^{2,s}, \dots, \Psi_{s\nu}^{2,s}) \cdot (\nu_i + \nu_i)$  on  $j$  is four if  $j\nu_i = 2$  and 1 if  $j\nu_i = 1$ . Thus this function is exactly the function  $\nu_i \cdot (1_1 + 0_2 + 1_1)$ .

The proof of (11.3) is similar and is omitted.

*Proof of 11.4.* For  $k = 1, \dots, r$ , we define morphisms  $E_k : 1 \rightarrow 2^k$  as follows:

$$E_1 = \Delta \cdot \nu_1,$$

$$E_{k+1} = \Delta \cdot \nu_{k+1} \cdot (E_k + E_k).$$

Then

$$E_r = \Delta \cdot \nu_r \cdot (\Delta \cdot \nu_{r-1} + \Delta \cdot \nu_{r-1}) \cdot \dots \cdot (\Delta \cdot \nu_1 + \dots + \Delta \cdot \nu_1).$$

We will show that for each  $k \in [r]$ , there is a base morphism  $\sigma_k : 2^r \rightarrow 2^k$  such that

$$E_k \approx \Delta \cdot \sigma_k.$$

Indeed, when  $k = 1$ ,  $\sigma_1 = \nu_1$ , by definition

$$\begin{aligned} E_{k+1} &= \Delta \cdot \nu_{k+1} \cdot (E_k + E_k) \\ &\approx \Delta \cdot \nu_{k+1} \cdot (\Delta \cdot \sigma_k + \Delta \cdot \sigma_k) \\ &= \Delta \cdot \nu_{k+1} \cdot (\Delta + \Delta) \cdot (\sigma_k + \sigma_k) \\ &= \Delta \cdot (\Delta + \dots + \Delta) \cdot \xi \cdot (\sigma_k + \sigma_k), \end{aligned}$$

for a base  $\xi$  (see the preliminaries)

$$\approx \Delta \cdot \rho \cdot \xi \cdot (\sigma_k + \sigma_k),$$

where  $\rho : 2^r \rightarrow 2^{r+r}$  is the base morphism given in (a.2). Let

$$\sigma_{k+1} = \rho \cdot \xi \cdot (\sigma_k + \sigma_k).$$

Now to prove (11.4), we have that

$$\begin{aligned} &[\Delta \cdot \nu_r \cdot (\Delta \cdot \nu_{r-1} + \Delta \cdot \nu_{r-1}) \cdot \dots \cdot (\Delta \cdot \nu_1 + \dots + \Delta \cdot \nu_1) \cdot \gamma]^\dagger \\ &= [E_r \cdot \gamma]^\dagger \approx [\Delta \cdot \sigma_r \cdot \gamma]^\dagger \\ &\approx \Delta \cdot \sigma_r \cdot \gamma \cdot (1_p + \perp) \end{aligned}$$

by (a.3),

$$\begin{aligned} &\approx E_r \cdot \gamma \cdot (1_p + \perp) \\ &= [\Delta \cdot \nu_r \cdot (\Delta \cdot \nu_{r-1} + \Delta \cdot \nu_{r-1}) \cdot \dots \cdot (\Delta \cdot \nu_1 + \dots + \Delta \cdot \nu_1) \cdot \gamma] \cdot (1_p + \perp), \end{aligned}$$

completing the proof.

With somewhat more work, we can show that in fact,  $\sigma_r$  is the identity, so that

$$(11.5) \quad E_r \approx \Delta.$$

Define an iteration theory morphism  $\psi : \Sigma_\Delta \text{tr} \rightarrow \Sigma_{\Pi} \text{tr}$  as the unique morphism extending the function

$$\begin{aligned} &\sigma \mapsto \sigma \quad \text{for each } \sigma \text{ in } \Sigma, \\ &\Delta \mapsto \Delta_r (= \pi_r \cdot (\pi_{r-1} + \pi_{r-1}) \cdot \dots \cdot (\pi_1 + \dots + \pi_1) : 1 \rightarrow 2^r). \end{aligned}$$

PROPOSITION 12. For each pair of trees  $t, t' : n \rightarrow p$  in  $\Sigma_\Delta \text{tr}$ ,

$$\text{if } t \approx t' \text{ then } t\psi \equiv t'\psi.$$

Thus, as in Proposition 11, there is a unique iteration theory morphism

$$\psi^\wedge : \Sigma_\Delta \text{tr} / \approx \rightarrow \Sigma_{\Pi} \text{tr} / \equiv$$

such that

$$\begin{array}{ccc}
 \Sigma_{\Delta}tr & \xrightarrow{\psi} & \Sigma_{\Pi}tr \\
 \kappa_{\Delta} \downarrow & & \downarrow \kappa_{\Pi} \\
 \Sigma_{\Delta}tr/\approx & \xrightarrow{\psi^{\wedge}} & \Sigma_{\Pi}tr/\equiv
 \end{array}$$

commutes.

*Proof.* It is enough to prove that  $t_i\psi \equiv t'_i\psi$ , where  $t_i$  is the term on the left-hand side of (a.i),  $i = 1, 2, 3$ , and  $t'_i$  is the right-hand term, since  $\ker(\psi \cdot \kappa_{\Pi})$  is an iteration theory congruence on  $\Sigma_{\Delta}tr$ . Thus we must show that

(12.1)  $\Delta_r \cdot \langle 1_1, \dots, 1_1 \rangle \equiv 1_1,$

(12.2)  $\Delta_r \cdot (\Delta_r + \dots + \Delta_r) \equiv \Delta_r \cdot \rho,$

where there are  $s = 2^r$   $\Delta$ 's in the sum and  $\rho : s \rightarrow s^2$  is the base function taking  $i \in [s]$  to  $(i-1)s + i$  and

(12.3)  $(\Delta_r \cdot \gamma)^{\dagger} \equiv \Delta_r \cdot \gamma \cdot (1_p + \perp),$

where  $\gamma : s \rightarrow p+1$  is any base function.

*Proof of 12.1.* This is the case that  $k = r$  in (10.1) of Proposition 10. Formula (12.3) is the axiom (c.4). In order to prove (12.2), we may prove the following by induction on  $k$ :

(12.a)  $\Delta_k \cdot (\Delta_k + \dots + \Delta_k) \equiv \Delta_k \cdot \rho_k, \quad k \in [r],$

where  $\rho_k : 2^k \rightarrow 2^{2k}$  is the base morphism defined by

(12.b)  $i\rho_k = (i-1)2^k + i.$

Note that  $\rho_r = \rho$ , so that (12.a) will imply (12.2). In the induction step of the proof, we use (12.c), established by repeated use of (c.3):

(12.c)  $\Delta_k \cdot (\pi_{k+1} + \dots + \pi_{k+1}) \equiv \pi_{k+1} \cdot (\Delta_k + \Delta_k) \cdot \tau_k, \quad k \in [r].$

where  $\tau_k : 2^{k+1} \rightarrow 2^{k+1}$  is the base morphism defined as follows:

$$\begin{aligned}
 i\tau_k &= 2i-1 \quad \text{if } 1 \leq i \leq 2^k \\
 &= 2(i-2^k) \quad \text{if } 2^k < i \leq 2^{k+1}.
 \end{aligned}$$

We omit the remaining details.

PROPOSITION 13. For any tree  $t$  in  $\Sigma_{\Delta}tr$  and  $t'$  in  $\Sigma_{\Pi}tr$ ,

(14)  $t \approx t\psi\varphi,$

(15)  $t' \equiv t'\varphi\psi.$

Thus, both  $\varphi$  and  $\psi$  induce iteration theory isomorphisms between  $\Sigma_{\Delta}tr/\approx$  and  $\Sigma_{\Pi}tr/\equiv$ .

*Proof.* We must prove the following facts:

(15.a)  $\Delta \cdot \nu_r \cdot (\Delta \cdot \nu_{r-1} + \Delta \cdot \nu_{r-1}) \cdot \dots \cdot (\Delta \cdot \nu_1 + \dots + \Delta \cdot \nu_1) \approx \Delta,$

$$(15.b) \quad \pi_i \equiv \Delta_r \cdot \nu_i,$$

for each  $i \in [r]$ . But (11.5) is the former assertion and (10.3) is the latter.

Now it is an easy matter to prove Theorem B.

**THEOREM B.**  $\Sigma_{\Pi}tr/\equiv$  is freely generated in SEQ (II) by

$$\eta \cdot \kappa_{\Pi} : \Sigma \rightarrow \Sigma_{\Pi}tr/\equiv$$

where  $\eta : \Sigma \rightarrow \Sigma_{\Pi}tr$  is the inclusion. Thus, (c.1)–(c.4) axiomatize SEQ (II).

Indeed,  $\Sigma_{\Pi}tr/\equiv$  is in the variety since  $\Sigma_{\Delta}tr/\approx$  is isomorphic to a subtheory of  $Seq(A_0, \Pi, \perp)$ , when  $\Delta$  is interpreted as  $\Delta_r$ . Using Propositions 11 and 12 and Theorem A, we see that any rank-preserving function  $\Sigma \rightarrow Seq(A, \Pi, \perp)$  extends to a unique iteration theory morphism

$$\Sigma_{\Pi}tr/\equiv \rightarrow Seq(A, \Pi, \perp).$$

*Remark 16.* If  $\Pi$  is infinite, it follows from the fact that  $\Pi$  is the direct limit of its finite subsets that the union of the identities (c.1)–(c.4) correctly axiomatizes the variety SEQ (II) generated by theories  $Seq(A, \perp, \Pi)$ .

**VI. The variety PFN ( $\Delta$ ).** Let  $\Delta : A \rightarrow A \times [s]$  be a partial function,  $s \geq 2$ .  $\Delta$  is a predicate on  $A$  if, for each  $a \in A$ , there is some  $i \in [s]$  such that  $a\Delta = (a, i)$ . We let  $Pfn(A, \Delta)$  denote the iteration theory of all partial functions  $A \times [n] \rightarrow A \times [p]$ , in which  $\Delta$  denotes some fixed predicate.  $PFN(\Delta)$  is the variety generated by all theories of the form  $Pfn(A, \Delta)$ . In this section we will axiomatize  $PFN(\Delta)$  and find all free theories, using the Basic Theorem.

Let  $\Sigma$  be a fixed-ranked set, and let  $\Sigma_{\Delta}$  denote the ranked set obtained from  $\Sigma$  by adding a new letter  $\Delta$  to  $\Sigma_s$ . Let  $\approx$  be the least iteration theory congruence on  $\Sigma_{\Delta}tr$  such that 1) and 2) below hold.

1)  $\Delta$ -axioms:

$$(1.1) \quad \Delta \cdot \langle 1_1, \dots, 1_1 \rangle \approx 1_1,$$

$$(1.2) \quad \Delta \cdot (\Delta + \dots + \Delta) \approx \Delta \cdot \tau,$$

$$(1.3) \quad (\Delta \cdot \gamma)^{\dagger} \approx \Delta \cdot \gamma \cdot (1_p + \perp),$$

where  $\tau : s \rightarrow s^2$  is the base morphism taking  $i \in [s]$  to  $s(i-1) + i$ , and where  $\gamma : s \rightarrow p+1$  is any base morphism.

2)  $\perp$ -axiom:

$$(2.1) \quad f \approx \perp, \quad \text{all } f : 1 \rightarrow 0.$$

Note that 2) is equivalent to  $f \approx g$ , for all  $f, g : 1 \rightarrow 0$ . We show that the axioms corresponding to 1) and 2) suffice. The first lemma is obvious.

**LEMMA 3.** For any iteration theory morphism  $\varphi : \Sigma_{\Delta}tr \rightarrow Pfn(A, \Delta)$ , the congruence  $\approx$  is contained in  $\ker(\varphi)$ .

In order to show that  $\Sigma_{\Delta}tr/\approx$  is in the variety  $PFN(\Delta)$ , we introduce a slight variation of the notion of a “co-accessible tree.” Recall the definition of a  $\Delta$ -separated, alternating tree from § V.

**DEFINITION 4.** A  $\Delta$ -separated alternating tree  $t : 1 \rightarrow p$  is **almost co-accessible** if no leaf is labeled by an element of  $\Sigma_0$  and, for each nonleaf vertex  $v$  in  $\text{dom}(t)$  which is not labeled  $\Delta$ , there is an extension  $w = vu$  such that  $wt = x_i$ , for some  $i \in [p]$ .

Thus a  $\Delta$ -separated alternating tree  $1 \rightarrow 0$  is almost co-accessible if each successor of the root (which must be labeled  $\Delta$ ) is a leaf (labeled by  $\perp$ ). Further, if each subtree of the form  $\Delta \cdot \langle \perp \cdot 0_p, \dots, \perp \cdot 0_p \rangle$  is replaced by  $\perp$  in an almost co-accessible tree, the resulting tree is co-accessible. See Fig. 4 for an example of an almost co-accessible tree which is not co-accessible.

LEMMA 5. *For any tree  $t: 1 \rightarrow p$  in  $\Sigma_\Delta \text{tr}$  there is a  $\Delta$ -separated alternating almost co-accessible tree  $t'$  with  $t \approx t'$ .*

*Proof.* Using the  $\Delta$ -axioms, we can find a  $\Delta$ -separated alternating tree congruent to  $t$ , and using the  $\perp$ -axiom and only a slight modification of the argument in § IV, we can get an almost co-accessible tree congruent to  $t$ .

We again make use of the label  $\text{lab}(v)$  of a vertex of a tree in  $\Sigma_\Delta \text{tr}$  (see IV.(2)) to prove the following lemma. To avoid fatigue, in the next lemma we will say a tree  $t: 1 \rightarrow p$  is **admissible** if  $t$  is  $\Delta$ -separated, alternating, and almost co-accessible.

LEMMA 6. *There is a set  $A_0$  and a predicate  $\Delta_0$  on  $A_0$  and an iteration theory morphism  $\varphi: \Sigma_\Delta \text{tr} \rightarrow \text{Pfn}(A_0, \Delta_0)$  such that  $t\varphi \neq t'\varphi$  whenever  $t \neq t'$ , and both  $t$  and  $t'$  are admissible.*

*Proof.* Let  $B = \cup (\Sigma_n \times [n]: n \geq 1)$ , let  $C = \{\Delta\} \times [s]$  and define

$$A_0 = (C \cdot B)^* \cdot C,$$

the set of alternating words which begin and end with a letter of the form  $(\Delta, i)$  and every other letter has the form  $(\sigma, j)$ . Now we define the images  $\Delta\varphi = \Delta_0$  and  $\sigma\varphi$ , for each  $\sigma$  in  $\Sigma_n, n \geq 1$ .

Let  $w = (\Delta, i_1)v$ . The predicate  $\Delta_0$  is given by

$$w\Delta_0 = (w, i_1),$$

the partial function  $\sigma\varphi$  is defined by:

$$\begin{aligned} w\sigma\varphi &= (u, j) \quad \text{if } w = (\Delta, i)(\sigma, j)u \text{ for some } u \in A_0, \\ &= \text{undefined} \quad \text{otherwise.} \end{aligned}$$

FIG. 4

The point of these definitions is the following:

If  $w = \text{lab}(v)$ , where  $v$  is a leaf labeled  $x_i$  of an admissible tree  $t: 1 \rightarrow p$ , and if  $v$  is the  $j$ th successor of a vertex (labeled  $\Delta$ ) then

$$(6.1) \quad \langle w, t\varphi \rangle = ((\Delta, j), i);$$

otherwise,

$$(6.2) \quad \langle w, t\varphi \rangle \text{ is undefined.}$$

Both of these statements may be proved by induction on the length of  $w$ . But if  $t$  and  $t'$  are distinct admissible trees  $1 \rightarrow p$ , there is a word  $w$  which is a label of a path to a leaf  $v$  of  $t$ , say, labeled  $x_i$  and which is either not the label of a path to a leaf of  $t'$  or is the label of a path to a leaf of  $t'$  labeled  $\perp$  or  $x_j, j \neq i$ . Thus the lemma is proved.

Together, the lemmas yield a proof of the main result of this section.

**THEOREM 7.**  $\Sigma_{\Delta} \text{tr} / \approx$  is freely generated by

$$\eta \cdot \kappa_{=} : \Sigma \rightarrow \Sigma_{\Delta} \text{tr} \rightarrow \Sigma_{\Delta} \text{tr} / \approx$$

in  $\text{PFN}(\Delta)$ . The identities (1) and (2) axiomatize  $\text{PFN}(\Delta)$ .

Just as in § V, we may alternatively consider the variety  $\text{PFN}(\Pi)$  of iteration theories generated by theories of the form  $\text{Pfn}(A, \Pi)$ , where  $\Pi = \{\pi_1, \dots, \pi_r\}$  is a set of binary predicates on  $A$ . Using the same methods as in § V, it is possible to show that this variety is the same as  $\text{PFN}(\Delta)$ , where  $\Delta: 1 \rightarrow 2^r$ .

**VII. Summary of the axioms.** The variety  $\text{SEQ}$  is the variety of all iteration theories and is axiomatized by the identities listed in I.(1.5)–I.(1.8).

$\text{PFN}$  is axiomatized by the one axiom schema:

$$(1) \quad f = g \quad \text{all } f, g: 1 \rightarrow 0.$$

$\text{SEQ}(\Delta)$  is axiomatized by the three schema:

$$(2) \quad \Delta \cdot \langle 1_1, \dots, 1_1 \rangle = 1_1,$$

$$(3) \quad \Delta \cdot (\Delta + \dots + \Delta) = \Delta \cdot \rho,$$

where there are  $s$   $\Delta$ 's in the sum and  $\rho: s \rightarrow s^2$  is the base function taking  $i \in [s]$  to  $(i-1)s + i$ , and

$$(4) \quad (\Delta \cdot \gamma)^\dagger = \Delta \cdot \gamma \cdot (1_p + \perp),$$

where  $\gamma: s \rightarrow p+1$  is any base function.

$\text{SEQ}(\Pi)$  is axiomatized by

$$(5) \quad \pi_i \cdot \langle 1_1, 1_1 \rangle = 1_1 \quad \text{for each } i \in [r],$$

$$(6) \quad \pi_i \cdot (\pi_i + \pi_i) = \pi_i \cdot (1_1 + 0_2 + 1_1) \quad \text{for each } i \in [r],$$

$$(7) \quad \pi_i \cdot (\pi_j + \pi_j) = \pi_j \cdot (\pi_i + \pi_i) \cdot (1_1 + \rho + 1_1) \quad \text{for each } i, j \in [r],$$

$$(8) \quad [\Delta_r \cdot \gamma]^\dagger = \Delta_r \cdot \gamma \cdot (1_p + \perp).$$

In (7),  $\rho: 2 \rightarrow 2$  is the nontrivial base permutation, and in (8),  $\gamma: 2^r \rightarrow p+1$  is any base morphism;  $\Delta_r: 1 \rightarrow 2^r$  was defined in § V, Definition 8.

$\text{PFN}(\Delta)$  and  $\text{PFN}(\Pi)$  are axiomatized by adding the axiom (1) to the axioms for  $\text{SEQ}(\Delta)$  and  $\text{SEQ}(\Pi)$ , respectively.

**Acknowledgments.** We would like to thank the referees for an extremely meticulous job of proofreading and stylistic criticism. The result of their efforts is a better paper.

## ON THE COMPLEXITY OF COMPUTING THE VOLUME OF A POLYHEDRON\*

M. E. DYER† AND A. M. FRIEZE‡

**Abstract.** We show that computing the volume of a polyhedron given either as a list of facets or as a list of vertices is as hard as computing the permanent of a matrix.

**Key words.** volume, polyhedra, complexity, #P-complete

**AMS(MOS) subject classification.** 68A20

**1. Introduction.** Recently there has been some interest in establishing the computational complexity of determining the volume of convex bodies in  $\mathbb{R}^n$ . Elekes [2] and Bárány and Füredi [1] have shown that it is even difficult to closely approximate volumes of convex bodies defined by certain types of oracles. These hardness results complement the approximation algorithm of Lovász [4].

Lovász [4] also enquires about the complexity of computing the volume of a rational polytope given either by listing its facets or by listing its vertices. He conjectures that these problems are hard. In this paper we confirm Lovász's conjecture, and show that both problems are as hard as computing the matrix permanent, (see Valiant [6]). We cannot quite describe the problems as #P-complete, since they are not in the class #P as defined by Valiant [6]. However, since we have no wish to define yet another complexity class, we state our results relative to #P.

Let us now be more specific. Consider first Problem 1.

**Problem 1.** Let  $P = P(A, \mathbf{b}) = \{\mathbf{x} \in \mathbb{R}^n : A\mathbf{x} \leq \mathbf{b}\}$  be a polyhedron.  $A, \mathbf{b}$  have rational entries where  $A = (a_{ij}), i = 1, 2, \dots, m, j = 1, 2, \dots, n$ , and  $\mathbf{b} = (b_i), i = 1, 2, \dots, m$ . We shall use the notation of Schrijver [5] to describe problem size. Thus if  $x = p/q$  is rational where  $p, q > 0$  are relatively prime integers, then

$$\text{size}(x) = 1 + \lceil \log_2(|p| + 1) \rceil + \lceil \log_2(q + 1) \rceil$$

and

$$\text{size}(A, \mathbf{b}) = m(n + 1) + \sum_{i=1}^m \text{size}(b_i) + \sum_{i=1}^m \sum_{j=1}^n \text{size}(a_{ij}).$$

$L = \text{size}(A, \mathbf{b})$  will be used as our measure of problem size. Since we can (by linear programming) determine in polynomial time whether or not  $\text{vol}(P) = 0$  and whether or not  $\text{vol}(P) = \infty$ , we can assume without loss of generality that  $0 < \text{vol}(P) < \infty$ .

We shall prove two theorems. The first shows that computing  $\text{vol}(P)$  is #P-hard.

**THEOREM 1.** *Computing  $\text{vol}(P(A, \mathbf{b}))$  is #P-hard, even when  $A$  is totally unimodular.  $\square$*

There is a technical difficulty in stating the converse of this theorem. It may be encapsulated in the following problem.

**Problem.** Is  $\text{size}(\text{vol}(P))$  polynomially bounded in  $L$ ?  $\square$

It is not too difficult to show that  $\text{vol}(P)$  is a rational,  $p/q$ , say. We can also show that  $\text{vol}(P)$  cannot be too large. The difficulty is that  $q$  does not appear to have a

\* Received by the editors July 1, 1987; accepted for publication November 15, 1987.

† Department of Computer Studies, University of Leeds, Leeds LS2 9JT, United Kingdom.

‡ Department of Computer Science and Statistics, Queen Mary College, London E1 4NS, United Kingdom and the Department of Mathematics, Carnegie-Mellon University, Pittsburgh, Pennsylvania 15213.

bound polynomial in  $L$ . The problem stated above thus seems to be an open (and possibly difficult) question. We show later that the difficulty disappears if we restrict ourselves to any class of polyhedra whose vertices can be scaled to become integer lattice-points by a polynomial size transformation. We conjecture that the answer to our problem is in the affirmative, but we are at present only able to state the following result in terms of approximation.

**THEOREM 2.** *Let  $\varepsilon > 0$  be rational. Given a #P-complete oracle, in time polynomial in  $L$  and size  $(\varepsilon)$ , we can compute  $\hat{V}$  such that*

$$(1.1) \quad |\hat{V} - \text{vol}(P(\mathbf{A}, \mathbf{b}))| < \varepsilon. \quad \square$$

**COROLLARY 1.** *Suppose we restrict our attention in Theorem 2 to any class of polytopes for which  $\text{size}(\text{vol}(P))$  is bounded by a polynomial in  $L$ . Then, using a #P-complete oracle,  $\text{vol}(P)$  can be computed exactly in time polynomial in  $L$ .  $\square$*

Let us now consider Problem 2.

**Problem 2.** Let  $X = \{X_1, X_2, \dots, X_m\}$  be a set of rational points in  $\mathbb{R}^n$ . Let  $P(X)$  be the convex hull of  $X$ . We shall consider the problem of computing  $\text{vol}(P(X))$  when  $X$  is given as an  $n \times m$  matrix  $(x_{ij})$ ,  $i = 1, 2, \dots, n, j = 1, 2, \dots, m$ .  $\square$

**THEOREM 3.** *Computing  $\text{vol}(P(X))$  is #P-hard.  $\square$*

This time we have no difficulty in stating the converse result because, as we will show,  $\text{size}(\text{vol}(P(X)))$  is polynomially bounded in  $\text{size}(X)$ .

**THEOREM 4.** *Computing  $\text{vol}(P(X))$  is #P-easy.  $\square$*

**2. #P-hardness of Problem 1.** Let  $B = \{0, 1\}$  and  $C = B^n$ . We will consider a single linear inequality

$$(2.1) \quad \mathbf{a}^T \mathbf{x} \leq b$$

in  $\mathbb{R}^n$ , with  $\mathbf{a} > \mathbf{0}$  an integer vector. Define the polytope

$$(2.2) \quad P = \{\mathbf{x} \in \mathbb{R}^n : \mathbf{a}^T \mathbf{x} \leq b, \mathbf{0} \leq \mathbf{x} \leq \mathbf{e}\}$$

where  $\mathbf{e}^T = (1, 1, \dots, 1)$ , and let

$$(2.3) \quad K = C \cap P.$$

We shall wish to regard (2.1) as being parameterised by  $b$ , in which case we will write  $P(b)$  or  $K(b)$  for emphasis. The following problem is known to be #P-hard (see [3]).

**#KNAPSACK**

**Input.** Positive integers  $a_1, a_2, \dots, a_n, b$ .

**Problem.** Determine  $N = |K|$ .

We Turing reduce #KNAPSACK to computing the volumes of certain polyhedra. For  $\mathbf{x} \in C$ , let  $|\mathbf{x}| = \mathbf{e}^T \mathbf{x}$  denote the number of 1's in  $\mathbf{x}$ .

Now consider the following problem, which may appear rather artificial, but will be required later.

**#PARITY**

**Input.** As for #KNAPSACK.

**Problem.** For  $i = 0, 1$  let  $N_i = |\{\mathbf{x} \in K : |\mathbf{x}| \equiv i \pmod{2}\}|$ . Determine

$$(2.4) \quad D = N_0 - N_1.$$

**LEMMA 1.** #PARITY is #P-hard.

*Proof.* Suppose we have a procedure for #PARITY. Let  $M = \mathbf{e}^T \mathbf{a} + 1$ , and consider the set of  $(n + 1)$  #PARITY problems, as above, corresponding to the inequalities

$$(2.5) \quad (\mathbf{a} + M\mathbf{e})^T \mathbf{x} \leq b + rM \quad (r = 0, 1, \dots, n).$$

Let  $N^{(r)} = |\{\mathbf{x} \in K : |\mathbf{x}| = r\}|$ . It follows, by an easy analysis, that the  $r$ th #PARITY problem defined by (2.5) determines the value

$$D^{(r)} = (-1)^r N^{(r)} + \sum_{j=0}^{r-1} (-1)^j \binom{n}{j}.$$

A straightforward calculation now yields

$$N = 2^{n-1} + \sum_{r=0}^n (-1)^r D^{(r)}.$$

Thus a polynomial number of calls to the #PARITY procedure, plus polynomial additional time, would solve #KNAPSACK.  $\square$

We now turn to the proof of Theorem 1.

*Proof of Theorem 1.* Assume we have some procedure for determining  $\text{vol}(P)$ . Let  $\Delta = \{\mathbf{x} \in \mathbb{R}^n : \mathbf{a}^T \mathbf{x} \leq b, \mathbf{x} \geq \mathbf{0}\}$ . Note that  $\Delta$  is bounded with  $\text{vol}(\Delta) = b^n / (n! \prod_{j=1}^n a_j)$ . Let  $U$  be the uniform measure on subsets of  $\Delta$  such that  $U(\Delta) = b^n$ . Note that  $U$  is related to volume for a subset  $E$  of  $\Delta$  by the equation  $\text{vol}(E) / \text{vol}(\Delta) = U(E) / U(\Delta)$ . Thus our procedure for determining  $\text{vol}(P)$  can easily be modified to determine  $U(P)$ , and we will assume this has been done. Let  $E_j = \{\mathbf{x} \in \Delta : x_j \leq 1\}$  for  $j = 1, 2, \dots, n$  and  $\bar{E}_j = (\Delta - E_j)$ . Then clearly  $P = \bigcap_{j=1}^n E_j$ . Now, for each  $\mathbf{v} \in C$ , define

$$\bar{E}_{\mathbf{v}} = \{\mathbf{x} \in \Delta : \mathbf{x} > \mathbf{v}\} = \bigcap_{v_j=1} \bar{E}_j.$$

Note that  $\bar{E}_{\mathbf{v}}$  is either empty or is an  $n$ -simplex (actually its closure is). The well-known inclusion-exclusion formula (see, e.g., [7]) now yields

$$U(P) = \sum_{\mathbf{v} \in C} (-1)^{|\mathbf{v}|} U(\bar{E}_{\mathbf{v}}).$$

It is easy to show that

$$\begin{aligned} U(\bar{E}_{\mathbf{v}}) &= 0 && \text{if } \mathbf{a}^T \mathbf{v} > b \\ &= (b - \mathbf{a}^T \mathbf{v})^n && \text{if } \mathbf{a}^T \mathbf{v} \leq b. \end{aligned}$$

Thus

$$U(P) = \sum_{\mathbf{v} \in K} (-1)^{|\mathbf{v}|} (b - \mathbf{a}^T \mathbf{v})^n.$$

Suppose that  $b$  is an integer, and  $\beta$  real such that  $b \leq \beta < b + 1$ . The integrality of  $\mathbf{a}$  then implies that  $K(\beta) = K(b)$ . Thus, writing  $F(\beta) = U(P(\beta))$ , it follows that

$$(2.6) \quad F(\beta) = \sum_{\mathbf{v} \in K(b)} (-1)^{|\mathbf{v}|} (\beta - \mathbf{a}^T \mathbf{v})^n.$$

Let  $\beta$  be a rational  $p/q$  with  $p, q > 0$  relatively prime. It follows from (2.6) that  $q^n F(\beta)$  is an integer such that  $q^n F(\beta) \leq (2p)^n$ . Thus  $\text{size}(F(\beta)) \leq n(\text{size}(\beta) + 1)$ . Thus the procedure for calculating  $U(P)$  can be used to determine  $F(\beta)$ , provided  $\beta$  has size polynomial in  $L$ . Now, expanding the terms in (2.6), we see that

$$(2.7) \quad F(\beta) = \sum_{i=0}^n \alpha_i \beta^{n-i}$$

where

$$(2.8) \quad \alpha_i = (-1)^i \binom{n}{i} \sum_{\mathbf{v} \in K(b)} (-1)^{|\mathbf{v}|} (\mathbf{a}^T \mathbf{v})^i \quad (i = 0, 1, \dots, n).$$

Observe, in particular, that  $\alpha_0 = \sum_{\mathbf{v} \in K(b)} (-1)^{|\mathbf{v}|} = D$ , as defined in (2.4). This is #P-hard to compute (Lemma 1). It follows, a fortiori, that it is #P-hard to determine the coefficients of the polynomial  $F$ . But we may do this as follows:

(i) Determine  $F(\beta) = U(P(\beta)) = n! \prod_{j=1}^n a_j \text{vol}(P(\beta))$  for  $\beta = b + k/(n + 1)$ ,  $k = 0, 1, \dots, n$ .

(ii) Solve (in polynomial time) the resulting system of linear equations determined by (2.7).

We observe that none of the numbers involved in the computations is very large. For example, it follows from (2.8) that the  $\alpha_i$  are integers such that  $|\alpha_i| \leq (4e^T \mathbf{a})^n$ .

There is one final point. The statement of Theorem 1 claims that it remains true when  $A$  is totally unimodular. This follows by making the substitution

$$y_j = a_j x_j \quad (j = 1, 2, \dots, n)$$

in the system (2.2) defining  $P$ . The constraints are then easily transformed into a totally unimodular system. The theorem now follows.  $\square$

*Remark.* The problem we have proved hard may be viewed in either of the following ways:

(i) If  $\mathbf{X}$  is a point chosen randomly from the uniform probability distribution on the unit hypercube, then it is hard to compute the probability that  $\mathbf{X}$  satisfies a single linear inequality.

(ii) Integrating the step-function

$$\begin{aligned} \psi(\mathbf{x}) &= 1 && (b - \mathbf{a}^T \mathbf{x} \leq 0) \\ &= 0 && (b - \mathbf{a}^T \mathbf{x} > 0) \end{aligned}$$

over the unit hypercube is  $\#P$ -hard.

Note that the function  $\psi$  in (ii) is not even continuous. However, we may integrate  $\psi$  explicitly over  $k$  variables, using (2.6). This gives the piecewise polynomial function

$$\psi_k(\mathbf{x}) = \sum_{\hat{\mathbf{v}} \in \mathcal{K}(b - \mathbf{a}^T \mathbf{x})} (-1)^{|\hat{\mathbf{v}}|} (b - \mathbf{a}^T \mathbf{x} - \hat{\mathbf{a}}^T \hat{\mathbf{v}})^k$$

where  $\hat{\mathbf{a}}, \hat{\mathbf{v}} \in \mathbb{R}^k$  and  $\mathbf{a}, \mathbf{x} \in \mathbb{R}^{n-k}$ . This function is readily shown to be of class  $C^{k-1}$ . Hence we have the conclusion that it is hard to integrate such a function over the unit hypercube. In fact, since the description of  $\psi_k$  continues to be of polynomial size for  $k = O(\log n)$ , the conclusion can be strengthened further.

**3.  $\#P$ -easiness of Problem 1.** We will go straight into the proof of Theorem 2.

*Proof of Theorem 2.* Since  $P$  is bounded, we have [5, Thm. 10.2]

$$(3.1) \quad P \subseteq \Gamma = \{\mathbf{x} \in \mathbb{R}^n : |x_j| \leq D = 2^{4n^2 L} (j = 1, 2, \dots, n)\}.$$

Now let  $s = \lceil mn^2 2^{4n^3 L + n} / \varepsilon \rceil$ , and divide  $\Gamma$  into  $s^n$  subcubes of side  $\delta = 2D/s$ . These subcubes fall into three classes:

- (i) interior (wholly) to  $P$ ;
- (ii) exterior (wholly) to  $P$ ;
- (iii) boundary.

We will estimate  $V = \text{vol}(P)$  by the total volume of the interior cubes,  $\hat{V}$ . Thus  $\hat{V} = I\delta^n$ , where  $I$  is the number of interior cubes. Clearly  $V \geq \hat{V}$ , and the error  $E = V - \hat{V}$  is bounded above by  $J\delta^n$ , where  $J$  is the number of boundary cubes. We show later that

$$(3.2) \quad J \leq mn^2 s^{n-1},$$

and hence  $J\delta^n \leq \varepsilon$  as required.

The counting machine  $\phi$  [6] which computes  $I$  works as follows. Each copy chooses one of the integer vectors  $\mathbf{t}$ , where  $1 \leq t_j \leq s$  ( $j = 1, 2, \dots, n$ ) in time proportional to  $n$  size ( $s$ ). It then tests, in polynomial time, whether the subcube

$$\Gamma' = \{\mathbf{x} \in \mathbb{R}^n : -D + (t_j - 1)\delta \leq x_j \leq -D + t_j\delta, j = 1, 2, \dots, n\}$$

is interior. Note that this is equivalent to

$$\frac{1}{2} \delta \sum_{j=1}^n |a_{ij}| \leq b_i + \sum_{j=1}^n a_{ij} \{D - (t_j - \frac{1}{2})\} \delta \quad (i = 1, 2, \dots, m).$$

It is clear that the sizes of all numbers involved, in particular  $s$ , are polynomial in  $L$ . The output of  $\phi$  is  $I$ , from which  $\hat{V}$  is calculated.

It remains only to prove (3.2). If

$$P = \{x \in \mathbb{R}^n : a_i^T x \leq b_i (i = 1, 2, \dots, m)\}$$

then let  $H_i = \{x \in \mathbb{R}^n : a_i^T x = b_i\}$ . Call a subcube  $\Gamma'$  of  $\Gamma$  *intersected* if  $H_i \cap \Gamma' \neq \emptyset$  for some  $1 \leq i \leq m$ . Let  $K$  be the number of intersected subcubes. Clearly  $K \geq J$ . Each subcube  $\Gamma'$  projects onto  $n$  squares  $\Gamma'_j$  in the coordinate planes, i.e., if  $\Gamma' = \{x \in \mathbb{R}^n : u_k \leq x_k \leq u_k + \delta (k = 1, 2, \dots, n)\}$  then  $\Gamma'_j = \{x : x_j = 0 \text{ and } u_k \leq x_k \leq u_k + \delta (k \neq j)\}$ . The total number of distinct squares is clearly  $ns^{n-1}$ . Construct a mapping from the intersected cubes to the squares as follows.

For each intersected cube  $\Gamma'$  choose some  $i$  such that  $H_i \cap \Gamma' \neq \emptyset$  (e.g., the least such  $i$ ). Choose  $j$  so that

$$|a_{ij}| = \max_{1 \leq k \leq n} |a_{ik}|.$$

Suppose two intersected cubes map to the same square with the same value of  $i$ . Then there exist points  $x, x'$  within the two cubes such that

$$\begin{aligned} a_i^T x &= a_i^T x' = b_i, \\ x_j &\geq x'_j \quad \text{and} \quad |x_k - x'_k| \leq \delta \quad (k \neq j). \end{aligned}$$

Thus  $x_j - x'_j \leq \sum_{k \neq j} |a_{ik}| \delta / |a_{ij}| \leq (n-1)\delta$ . Therefore at most  $n$  cubes can map onto the same square for a given  $i$ . Since there are only  $m$  values of  $i$ , at most  $mn$  cubes map onto the same square. Hence  $K \leq mn \times ns^{n-1} = mn^2 s^{n-1}$ , and (3.2) follows.

*Proof of Corollary 1.* Suppose we know that  $\text{size}(\text{vol}(P)) \leq p(L)$  for some polynomial  $p(L)$ . Take  $\varepsilon = 1/3p(L)^2$  in Theorem 2. We know that  $V = a/b$  for integers  $a, b \leq 2^{p(L)}$ , and  $V - \hat{V} \leq \varepsilon$ . Having computed  $\hat{V}$ , we can use continued fractions to compute  $V$  exactly in polynomial time (see, e.g., [5, Cor. 6.3a]).  $\square$

Finally, we give a simple example of a class of polyhedra for which  $\text{vol}(P)$  has polynomial size.

LEMMA 2. *If  $P$  is integral, then  $\text{size}(\text{vol}(P)) = O(L^3)$ .*

*Proof.* Let  $P = \{x \in \mathbb{R}^n : a_i^T x \leq b_i (i = 1, 2, \dots, m)\}$  and be such that every vertex of  $P$  has integer coordinates. Now  $P$  has a triangulation using only its own vertices. If  $\sigma$  is a simplex of this triangulation, then

$$\text{vol}(\sigma) = \frac{1}{n!} \det \begin{pmatrix} 1 & 1 & & 1 \\ v_0 & v_1 & \dots & v_n \end{pmatrix} = \frac{\nu_\sigma}{n!}, \quad \text{say,}$$

where  $v_i (i = 0, 1, \dots, n)$  are vertices of  $P$ . Now  $\nu_\sigma$  is an integer. Hence  $\text{vol}(P) = \nu/n!$ , with  $\nu = \sum_\sigma \nu_\sigma$ , i.e.;  $n! \text{vol}(P)$  is an integer. Now (3.1) implies

$$\text{vol}(P) \leq 2^{8n^2L+n}.$$

Hence

$$\text{size}(\text{vol}(P)) \leq 8n^2L + n + \lceil \log_2(n! + 1) \rceil + 1,$$

and the result follows.  $\square$

**4. #P-hardness of Problem 2.** We shall again reduce the counting problem #KNAPSACK to volume computations of the relevant form. We will make the following two additional assumptions for #KNAPSACK:

$$(4.1) \quad \text{There are no 0-1 solutions to } \mathbf{a}^T \mathbf{x} = b.$$

We can ensure this simply by replacing  $a_j$  by  $2a_j$  ( $j = 1, 2, \dots, n$ ) and  $b$  by  $2b + 1$  in (2.1). This does not affect the value of  $N$ .

$$(4.2) \quad b > \frac{1}{2} \mathbf{e}^T \mathbf{a}.$$

If this is not true on input, then we can add a variable  $x_{n+1}$  with  $a_{n+1} = \mathbf{e}^T \mathbf{a} - b + 1$ , and replace  $b$  by  $b + a_{n+1}$ . This adds  $2^n$  to the value of  $N$ .

Now let  $P_1 = P = \{\mathbf{x} \in \mathbb{R}^n : \mathbf{a}^T \mathbf{x} \leq b, \mathbf{0} \leq \mathbf{x} \leq \mathbf{e}\}$ . Then (4.2) implies that  $\frac{1}{2} \mathbf{e} = (\frac{1}{2}, \frac{1}{2}, \dots, \frac{1}{2})$  is an interior point of  $P_1$ . Now, substituting  $\mathbf{y} = 2\mathbf{x} - \mathbf{e}$ , transform  $P_1$  to

$$P_2 = \{\mathbf{y} \in \mathbb{R}^n : \mathbf{a}^T \mathbf{y} \leq b', -\mathbf{e} \leq \mathbf{y} \leq \mathbf{e}\},$$

where  $b' = 2b - \mathbf{e}^T \mathbf{a} > 0$ . Note that  $\mathbf{x} \in \{0, 1\}^n \cap P_1 \leftrightarrow \mathbf{y} \in \{-1, +1\}^n \cap P_2$ . So we have reduced #KNAPSACK to computing  $N = |Y|$ , where

$$\begin{aligned} Y &= \{\mathbf{y} \in P_2 : y_j = \pm 1 \ (j = 1, 2, \dots, n)\} \\ &= \{\mathbf{y}^{(1)}, \mathbf{y}^{(2)}, \dots, \mathbf{y}^{(N)}\}, \text{ say.} \end{aligned}$$

The constraints defining  $P_2$  can be written as

$$(4.3) \quad \begin{aligned} &\mathbf{A}^T \mathbf{y} \leq 1, \\ &-y_j \leq 1, \quad y_j \leq 1 \quad (j = 1, 2, \dots, n) \end{aligned}$$

where  $\mathbf{A} = \mathbf{a}/b'$ . Now  $\mathbf{0}$  is an interior point of  $P_2$ . Consider the polar  $P_2^*$  [5, Chap. 9], where

$$(4.4) \quad \begin{aligned} P_2^* &= \{\mathbf{z} \in \mathbb{R}^n : \mathbf{z}^T \mathbf{u} \leq 1 \text{ for all } \mathbf{u} \in P_2\} \\ &= \text{conv}\{\mathbf{A}, \mathbf{e}_1, \mathbf{e}_2, \dots, \mathbf{e}_n, -\mathbf{e}_1, -\mathbf{e}_2, \dots, -\mathbf{e}_n\}. \end{aligned}$$

The second equality in (4.4) merely states the well-known relationship between the facets of  $P_2$  and the vertices of  $P_2^*$ .

We show that  $N$  can be computed from  $\text{vol}(P_2^*)$  and  $\text{vol}(\hat{P}_2^*)$ , where  $\hat{P}_2^*$  is the polyhedron obtained by using  $(b + \frac{1}{2})$  in place of  $b$  in the definition of  $P_1$  before transforming to  $P_2^*$ . Since  $P_2^*, \hat{P}_2^*$  are defined as convex hulls, Theorem 3 will follow.

Now polarity yields a one-to-one correspondence between the (*nondegenerate*) vertices of  $P_2$  not lying in facet  $\{\mathbf{y} \in P_2 : \mathbf{A}^T \mathbf{y} = 1\}$  (i.e., members of  $Y$ ) and the (*simplicial*) facets of  $P_2^*$  not containing the vertex  $\mathbf{A}$ . Observe that the facet corresponding to  $\mathbf{y}^{(t)}$  has vertex set  $\Lambda^{(t)} = \{y_i^{(t)} \mathbf{e}_i : i = 1, 2, \dots, n\}$  for  $t = 1, 2, \dots, N$ . Thus there is a decomposition of  $P_2^*$  into simplices  $\sigma_1, \sigma_2, \dots, \sigma_N$ , where  $\sigma_t = \text{conv}(\{\mathbf{A}\} \cup \Lambda^{(t)})$ . Hence

$$\begin{aligned} \text{vol}(P_2^*) &= \sum_{t=1}^N \text{vol}(\sigma_t) \\ &= \frac{1}{n!} \sum_{t=1}^N \left| \det \begin{pmatrix} 1 & 1 & \dots & 1 \\ \mathbf{A} & y_1^{(t)} \mathbf{e}_1 & \dots & y_n^{(t)} \mathbf{e}_n \end{pmatrix} \right| \\ &= \frac{1}{n!} \sum_{t=1}^N |1 - \mathbf{A}^T \mathbf{y}^{(t)}| \quad \text{since } y_i^{(t)} = \pm 1 \\ &= \frac{2}{n!} \sum_{t=1}^N \left| \frac{b - \mathbf{a}^T \mathbf{x}^{(t)}}{2b - \mathbf{e}^T \mathbf{a}} \right| \end{aligned}$$

where  $\mathbf{x}^{(t)} = \frac{1}{2}(\mathbf{e} + \mathbf{y}^{(t)})$  is the zero-one solution to (2.1) which corresponds to  $\mathbf{y}^{(t)}$ . Thus, using (4.2),

$$\begin{aligned} \frac{1}{2} n! \text{vol}(P_2^*) &= \sum_{t=1}^N \frac{b - \mathbf{a}^T \mathbf{x}^{(t)}}{2b - \mathbf{e}^T \mathbf{a}} \\ &= \frac{bN - S}{2b - \mathbf{e}^T \mathbf{a}} \end{aligned}$$

where  $S = \sum_{t=1}^N \mathbf{a}^T \mathbf{x}^{(t)}$ . Furthermore

$$\frac{1}{2} n! \text{vol}(\hat{P}_2^*) = \frac{(b + \frac{1}{2})N - S}{2(b + \frac{1}{2}) - \mathbf{e}^T \mathbf{a}}$$

where we have used, in the notation of § 2,  $K(b) = K(b + \frac{1}{2})$ , so that  $N$  and  $S$  are unchanged.

Now  $N$  can be easily computed from  $\text{vol}(P_2^*)$  and  $\text{vol}(\hat{P}_2^*)$ . Finally note that  $S$  is an integer with  $0 < S \leq 2^n b$ , so that the numbers involved are of polynomial size. Thus Theorem 3 has been proved.  $\square$

**5. #P-easiness of Problem 2.** Let us first show that  $\text{size}(\text{vol}(P(X)))$  is polynomially bounded. Indeed we can prove quite straightforwardly that, for  $m > n \geq 1$ ,

$$(5.1) \quad \tau = \text{size}(\text{vol}(P(X))) \leq 3mn^2L$$

where  $L = \text{size}(X)$ . To see this, let  $\lambda$  be the least common multiple of the denominators of entries of  $X$ . Then  $\text{size}(\lambda) \leq mnL$ . Now  $\lambda X$  contains integer vectors and  $\text{vol}(P(\lambda X)) = \lambda^n \text{vol}(P(X))$ . Since  $P(\lambda X)$  can be decomposed into simplices (see proof of Lemma 2), it follows that  $n! \text{vol}(P(\lambda X))$  is an integer. Hence

$$\text{vol}(P(X)) = \frac{n! \lambda^n \text{vol}(P(X))}{n! \lambda^n}$$

expresses  $\text{vol}(P)$  as a ratio of two integers. Noting that  $\text{vol}(P(X)) \leq 2^{nL}$ , (5.1) follows.

The proof of Theorem 4 is similar to that of Theorem 2, and so we will only give an outline. Now

$$P(X) \subseteq \Gamma_1 = \{\mathbf{x} \in \mathbb{R}^n : |x_j| \leq 2^L (j = 1, 2, \dots, n)\}.$$

Let  $s = \lceil m^n n^2 2^{6mn^2L + n(L+1)+2} \rceil$  and divide  $\Gamma_1$  into  $s^n$  subcubes of size  $\delta_1 = 2^{L+1}/s$ . Our counting machine computes the number  $I_1$  of subcubes which intersect  $P(X)$ . The estimate of volume is then  $I_1 \delta_1^m / m!$ . Note that this time we use an overestimate, rather than an underestimate, of the volume.

We can now reduce the testing for the intersection of an individual subcube with  $P(X)$  to the solution of a single linear program.

To establish this claim, for simplicity let us assume we translate and scale the problem to that of testing the intersection of the cube  $\Sigma = \{\mathbf{x} \in \mathbb{R}^n : -1 \leq x_j \leq 1 (j = 1, 2, \dots, n)\}$ , with the polytope  $P = \text{conv}\{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_m\}$ . Then  $\Sigma \cap P = \emptyset$  if and only if there exists a  $\boldsymbol{\gamma} \in \mathbb{R}^n$  such that

$$\sum_{i=1}^n |\gamma_i| < 1 \quad \text{and} \quad \boldsymbol{\gamma}^T \mathbf{x}_i \geq 1 \quad (i = 1, 2, \dots, m).$$

This can be tested by solving the linear program

$$\begin{aligned} &\text{minimise} \quad z = \mathbf{e}^T (\boldsymbol{\gamma}_1 + \boldsymbol{\gamma}_2) \\ &\text{subject to} \quad \mathbf{x}_i^T (\boldsymbol{\gamma}_1 - \boldsymbol{\gamma}_2) \geq 1 \quad (i = 1, 2, \dots, m) \end{aligned}$$

and by checking whether  $\min z < 1$ .

The error in the volume estimate is again bounded by the total volume of the subcubes which intersect the boundary of  $P(X)$ . Since  $P(X)$  has less than  $m^n$  facets, this is at most

$$m^n n^2 s^{n-1} \delta_1^n$$

(see the proof of Theorem 2 with  $m$  replaced by  $m^n$ ). By (5.1), this is at most  $2^{-2(\tau+1)}$ , and so  $\text{vol}(P(X))$  can be computed exactly using continued fractions.

**6. Remarks.** Our results leave open two interesting questions. The first is the problem raised in § 1 concerning the size of description of polyhedral volumes. The second is as to whether it remains hard to approximate the volume in either Problems 1 or 2; i.e., for some given  $\varepsilon > 0$ , is it hard to obtain an estimate  $\hat{V}$  of the volume  $V$  such that  $(1 - \varepsilon) < \hat{V}/V < (1 + \varepsilon)$ ? Our methods appear to shed little light on this issue, but we conjecture that this approximation problem is also hard. Finally, we observe that determining the volume of a polyhedron in *fixed* dimension is easy. We simply determine the complete face-lattice of the polyhedron, triangulate it, and then use the formula for the volume of a simplex.

## FAULT TOLERANCE IN NETWORKS OF BOUNDED DEGREE\*

CYNTHIA DWORK†, DAVID PELEG†, NICHOLAS PIPPENGER†, AND ELI UPFAL†

**Abstract.** Achieving processor cooperation in the presence of faults is a major problem in distributed systems. Popular paradigms such as Byzantine agreement have been studied principally in the context of a complete network. Indeed, Dolev [*J. Algorithms*, 3 (1982), pp. 14–30] and Hadzilacos [*Issues of Fault Tolerance in Concurrent Computations*, Ph.D. thesis, Harvard University, Cambridge, MA, 1984] have shown that  $\Omega(t)$  connectivity is necessary if the requirement is that *all* nonfaulty processors decide unanimously, where  $t$  is the number of faults to be tolerated. We believe that in foreseeable technologies the number of faults will grow with the size of the network while the degree will remain practically fixed. We therefore raise the question whether it is possible to avoid the connectivity requirements by slightly lowering our expectations. In many practical situations we may be willing to “lose” some correct processors and settle for cooperation between the vast majority of the processors. Thus motivated, we present a general simulation technique by which vertices (processors) in almost any network of bounded degree can simulate an algorithm designed for the complete network. The simulation has the property that although some correct processors may be cut off from the majority of the network by faulty processors, the vast majority of the correct processors will be able to communicate among themselves undisturbed by the (arbitrary) behavior of the faulty nodes.

We define a new paradigm for distributed computing, almost-everywhere agreement, in which we require only that almost all correct processors reach consensus. Unlike the traditional Byzantine agreement problem, almost-everywhere agreement can be solved on networks of bounded degree. Specifically, we can simulate any sufficiently resilient Byzantine agreement algorithm on a network of bounded degree using our communication scheme described above. Although we “lose” some correct processors, effectively treating them as faulty, the vast majority of correct processors decide on a common value.

**1. Preliminaries.** In 1982 Dolev [D] published the following damning result for distributed computing: “Byzantine agreement is achievable only if the number of faulty processors in the system is less than one-half of the connectivity of the system’s network.” Even in the absence of malicious failures connectivity  $t+1$  is required to achieve agreement in the presence of  $t$  faulty processors [H].

The results are viewed as damning because of the fundamental nature of the Byzantine agreement problem. In this problem each processor begins with an initial value drawn from some domain  $V$  of possible values. At some point during the computation, during which processors repeatedly exchange messages and perform local computations, each processor must irreversibly decide on a value, subject to two conditions. No two correct processors may decide on different values, and if all correct processors begin with the same value  $v$ , then  $v$  must be the common decision value. (See [F] for a survey of related problems.) The ability to achieve this type of coordination is important in a wide range of applications, such as database management, fault-tolerant analysis of sensor readings, and coordinated control of multiple agents.

A simple corollary of the results of Dolev and Hadzilacos is that in order for a system to be able to reach Byzantine agreement in the presence of up to  $t$  faulty processors, every processor must be directly connected to at least  $\Omega(t)$  others. Such high connectivity, while feasible in a small system, cannot be implemented at reasonable cost in a large system.

As technology improves, increasingly large distributed systems and parallel computers will be constructed. However, in any forthcoming technology, the number of

\* Received by the editors June 17, 1986; accepted for publication (in revised form) November 3, 1987.

faulty processors in a given system will grow with the size of the system, whereas the degree of the interconnection network by which the processors communicate will, for all practical purposes, remain fixed.

Despite these negative results, distributed systems are widely used and parallel computers are being built. This suggests that the correctness conditions for Byzantine agreement are too stringent to reflect practical situations. In particular, Byzantine agreement guarantees coordination among all correct processors, by necessarily omitting up to  $t$  faulty processors. In many situations it may suffice to guarantee agreement among all but  $O(t)$  processors. In other situations a simple majority consensus may suffice. Similarly, in clock synchronization, or in firing squad synchronization, it may suffice for a vast majority of the correct processors to be synchronized.

In the traditional paradigm for distributed computing described above, the correctness conditions describe the states of *all* nonfaulty processors. In this paper we propose a new paradigm for fault-tolerant computing in which correctness conditions are relaxed by “giving up for lost” those correct processors whose communication paths to the remainder of the network are excessively corrupted by faulty processors. Such a processor is called *poor*. While any network of bounded degree must contain some poor processors, in this paper we show that their number can often be kept quite small, even in networks of constant degree. Further, we argue that this type of cooperation may fit well most applications of, say, Byzantine agreement. All known algorithms guarantee only that if at most  $f \leq t < n/3$  processors fail then at least  $k \geq n - f$  processors will mutually agree on a value. Our results show that we can eliminate the costly connectivity condition requiring  $\Omega(nt)$  edges by employing an appropriately chosen bounded-degree network of  $n + O(t)$  processors and still guarantee agreement among  $n$  correct processors. Our paradigm admits deterministic solutions in networks of small constant degree to such fundamental problems as atomic broadcast, Byzantine agreement, and clock synchronization.

We present a general simulation technique by which for almost any regular graph  $G$ , the vertices (processors) of  $G$  can simulate an algorithm designed for a complete network in such a way that the number of poor processors in  $G$  is small. The crux of the simulation is a transmission scheme for simulating the point-to-point transmissions of the complete network by sending messages along several paths of  $G$  in such a way that there will always be a large set of correct processors capable of communicating among themselves as if they comprise a fully connected subnetwork, independent of the behavior of the faulty processors.

For consensus problems we can often do better than in the general simulation by employing a *compression procedure* based on the existence of *compressor graphs* [P]. This procedure is iterative and local in nature, and cannot by itself guarantee agreement. However, it can be used to “sharpen” dichotomies in that if a sufficiently large majority (e.g., all but  $O(t \log t)$ ) of the correct processors have the same value, then the procedure converges and strengthens this majority (e.g., to all but  $t + 1$ ).

Our model of computation is identical to that commonly used in the Byzantine literature. Specifically, each processor can be thought of as a (possibly infinite) state machine with special registers for communication with the outside world. The processors communicate by means of point-to-point links, which are assumed to be completely reliable. The entire system is synchronous, and can be thought of as controlled by a common clock. At each pulse of the common clock a processor may send a message on each of its incident communication links (possibly different messages on different links). Messages sent at one clock pulse are delivered before the next pulse.

For each of our transmission schemes there is a specific lower bound  $b$  on the number of clock pulses needed to simulate one complete round of message exchange

in the simulated network. For simplicity we assume that the common clock sends a “super-pulse” every  $b$  rounds. A processor simulates round  $r$  of the original algorithm at the  $r$ th super-pulse.

Since we cannot hope to solve the Byzantine agreement problem exactly on networks of bounded degree, we introduce the notion of *almost-everywhere agreement* (denoted a.e. agreement), in which all but a small number of the correct processors must choose a common decision value.

More precisely, a protocol  $P$  is said to achieve  $t$ -resilient  $X$  agreement, where  $X$  is any term, if in every execution of  $P$  in which at most  $t$  processors fail all but  $X$  of the correct processors eventually decide on a common value. Moreover, if all the correct processors share the same initial value then that must be the value chosen. Note that the traditional Byzantine agreement problem is just 0 agreement.

A protocol solves a.e. agreement if it solves  $X$  agreement for some  $X$  such that  $X/(n-t) \rightarrow 0$  as  $n \rightarrow \infty$ .

Our first result applies only to fail stop, omission, or authenticated Byzantine faults.

**THEOREM 1.** *For all  $r \geq 5$  there exists a constant  $\varepsilon = \varepsilon(r)$  such that for all  $t < \varepsilon n$  almost all  $r$ -regular graphs (i.e., all but a vanishingly small fraction of such graphs) admit a  $t$ -resilient algorithm for  $O(t)$  agreement.*

The remaining results apply to unauthenticated Byzantine failures.

**THEOREM 2.** *For all  $r \geq 5$ , almost all  $r$ -regular graphs admit a  $t$ -resilient algorithm for  $O(t)$  agreement, where  $t \leq n^{1-\varepsilon}$ , for some constant  $\varepsilon = \varepsilon(r)$ , where  $\varepsilon(r) \rightarrow 0$  as  $r \rightarrow n$ .*

The next theorems describe explicit graphs for which the set of poor processors is small.

**THEOREM 3.** *The  $n$  node butterfly network (degree 4; see § 2.3 for definition) admits a  $t$ -resilient  $O(t \log t)$ -agreement algorithm for  $t \leq cn/\log n$  for some constant  $c$ .*

The result of Theorem 3 can be improved for a family of networks obtained by superimposing a compressor of degree 5 on a butterfly network.

**THEOREM 4.** *There exists a constant  $c$  and a network of degree 9 that admits a  $t$ -resilient  $O(t)$ -agreement algorithm for  $t \leq cn/\log n$ .*

In the case of unauthenticated Byzantine failures, we achieve  $O(t)$  agreement only for  $t \leq cn/\log n$ . If  $t > O(n/\log n)$  then it is easy to show that the number of poor processors is linear in  $n$ . The existence problem for an  $O(t)$ -agreement algorithm in this case remains open. However, we solve this problem on graphs of unbounded but still relatively small degree.

**THEOREM 5.** *For every  $0 < \varepsilon < 1$  there exist a constant  $c = c(\varepsilon)$ , graphs  $G$  of degree  $O(n^\varepsilon)$ , and  $t$ -resilient  $O(t)$ -agreement algorithms for  $t \leq cn$ .*

Finally we present a purely combinatorial characterization of networks which admit  $p(t)$  agreement for any function  $p$ . When  $p(t) = 0$  our characterization coincides exactly with the  $(2t+1)$ -connectivity requirement for the traditional Byzantine agreement cited above [D].

**2. Simulation results.** In § 2.1 we describe a general strategy for simulating on one network any algorithm designed for another network, describing what we mean by “simulation.” In § 2.2 we discuss a general scheme for implementing our strategy, and in § 2.3 we make all of this more concrete by presenting the simulation of a complete network by a butterfly network. In § 2.4 we show that our general scheme can be implemented on almost all regular graphs of bounded degree. Finally, § 2.5 briefly discusses our results under more restrictive fault models.

**2.1. The general simulation.** For simplicity, we take the simulated network to be completely connected. Let  $A$  be an algorithm designed for a fully connected network  $H$ . Consider an arbitrary network  $G$  over the same set of vertices (processors) as in

$H$ , and suppose we wish to simulate  $A$  on  $G$ . We need only specify the simulation of communication between processors; a direct message from a processor  $u$  to its neighbor  $v$  in  $H$  can be simulated in  $G$  by sending the message from  $u$  to  $v$  through various paths, and supplying  $v$  with a method for determining the correct value of the message, e.g., by taking the value appearing in the majority of the paths. Taken together, the particular choice of paths and the supplied decision method constitute a *transmission scheme*. Of course, even if  $u$  and  $v$  are correct processors the faulty processors may be so placed that all or most of the paths from  $u$  to  $v$  are corrupted. Thus, even if a processor is correct, it may be unable to properly communicate with the other processors.

Let a transmission scheme for  $G$  be fixed. Let  $T$  be a subset of the vertices of  $G$  (think of  $T$  as the set of faulty processors). A pair of nodes  $(u, v) \in G$  is *successful* with respect to  $T$  if, whenever all the processors not in  $T$  follow the transmission scheme correctly, the simulation of a message transmission from  $u$  to  $v$  always succeeds (i.e.,  $v$  decides correctly on the value sent by  $u$ ). Let  $\text{POOR}(G, T)$  be a minimal set of correct nodes such that every pair of nodes,  $u, v \in T \cup \text{POOR}(G, T)$  is successful with respect to  $T$ . (Note that this set need not be unique.) Let  $p(G, t) = \max\{|\text{POOR}(G, T)| \text{ such that } T \subseteq V, |T| = t\}$ . As we will show in Theorem 2.1 there is a  $p(G, t)$ -agreement algorithm resilient to  $t$  failures for every graph  $G$  and suitable choice of  $t$ . We are therefore interested in finding graphs  $G$  for which  $p(G, t)$  is small. Such graphs are the subject of §§ 2.3 and 2.4.

**THEOREM 2.1.** *Let  $A$  be an algorithm for the traditional Byzantine agreement problem designed for network  $H$ , let  $G$  be a graph with the same number of vertices as  $H$ , and let  $TS$  be a transmission scheme for simulating on  $G$  message transmissions in  $H$ . Let  $A(TS)$  be the simulation of  $A$  on  $G$  using the transmission scheme  $TS$  to simulate messages sent on  $H$ . For every  $t$ , if  $A$  is guaranteed to work correctly on  $H$  in the presence of at most  $t + p(G, t)$  faults, then  $A(TS)$  achieves  $p(G, t)$  agreement on  $G$  in the presence of up to  $t$  faults.*

*Proof.* Let  $T$  be a set of faulty processors in  $G$ .  $A(TS)$  simulates the execution of  $A$  on  $H$  by simulating the processors in a one-one fashion. By definition, the processors not in  $\text{POOR}(G, T)$  can communicate among themselves as if they comprised a fully connected subnetwork, so the simulated communication among this set of processors is successful. The behavior of the correct processors in  $\text{POOR}(G, T)$  may appear to be faulty. These are the processors we give up for lost. Since  $A$  is guaranteed to work correctly even in the presence of  $t + p(G, t) \geq |\text{POOR}(G, T)|$  failures we are done.  $\square$

In order to use the transmission schemes described here the processors must have some knowledge of the topology of the system. The amount of knowledge needed, and how this quantity depends on the types of faults considered, are subjects for further research.

**2.2. A class of transmission schemes.** We now describe in more detail a specific class of transmission schemes, called *three-phase* transmission schemes. Let  $G$  be any network in which we may specify the following sets. For every node  $v$  we specify sets of processors  $\Gamma_{\text{in}}(v), \Gamma_{\text{out}}(v) \subseteq V$ , each of fixed (but not necessarily constant) size  $s$ . For each node  $w$  in  $\Gamma_{\text{in}}(v)$  ( $\Gamma_{\text{out}}(v)$ ) a path from  $w$  to  $v$  ( $v$  to  $w$ ) is specified. In addition, for each ordered pair of nodes  $(u, v)$  we specify  $s$  vertex-disjoint paths from  $\Gamma_{\text{out}}(u)$  to  $\Gamma_{\text{in}}(v)$ .

The transmission of a message  $x$  from  $u$  to  $v$  consists of three phases. In the first phase the message is broadcast from  $u$  to every node in  $\Gamma_{\text{out}}(u)$  through the specified paths. Thus, at the end of the first phase a copy of  $x$  is received by all nodes of  $\Gamma_{\text{out}}(u)$ .

(Those processors in  $\Gamma_{out}(u)$  whose path from  $u$  contains faults may have received an incorrect version of the message, or nothing at all.) In the second phase the  $s$  (possibly corrupted) copies of  $u$ 's message are sent along the vertex-disjoint paths from  $\Gamma_{out}(u)$  to  $\Gamma_{in}(v)$ . In the third phase these (possibly corrupted) copies of  $u$ 's message are routed to  $v$  along the specified paths from  $\Gamma_{in}(v)$  to  $v$ . Thus,  $v$  receives  $s$  (possibly corrupted) copies of  $u$ 's message. Finally,  $v$  takes the value appearing in the majority of the copies that arrived to be the actual message. (If no majority exists then a default value is taken.) Clearly,  $v$  could be making a mistake, even if it is a correct processor.

Let  $T$  be some set of nodes on the network (again, think of  $T$  as the set of faulty processors). A node  $u$  is said to be *out-bad* with respect to  $T$  if at least  $\frac{1}{8}$  of the specified paths to  $\Gamma_{out}(u)$  contain a vertex in  $T$ . Intuitively, if  $T$  is the set of faulty processors and  $u$  is out-bad with respect to  $T$ , then at least  $\frac{1}{8}$  of the processors in  $\Gamma_{out}(u)$  may receive a corrupted version of the message  $x$ . Similarly we say  $v$  is *in-bad* with respect to  $T$  if at least  $\frac{1}{8}$  of the paths from  $\Gamma_{in}(v)$  to  $v$  pass through some node of  $T$ . Let  $BAD(G, T)$  be the set of nodes in the network  $G$  which are (either out- or in-) bad with respect to  $T$ . Let  $b(G, t) = \max \{ |BAD(G, T)| \text{ such that } T \subseteq V, |T| = t \}$ . Recall that, informally,  $p(G, t)$  is an upper bound on the number of poor processors in  $G$  when no more than  $t$  processors fail. The next claim bounds the number of poor processors in terms of the number of bad processors.

CLAIM 2.2. *Let  $s$  be the size of the sets  $\Gamma$ . For all  $t < s/4$ ,  $p(G, t) \leq b(G, t)$ .*

*Proof.* We will prove that for any  $T \subseteq V$ ,  $POOR(G, T) \subseteq BAD(G, T)$ . The claim then follows immediately from the definitions. Let  $T$  be some subset of  $V$  of size at most  $t$ . We will show that for any two processors  $u$  and  $v$  not in  $BAD(G, T)$ , any message  $m$  sent from  $u$  to  $v$  according to the three-phase transmission scheme is correctly received by  $v$ . This follows from the following argument: since  $u$  is not out-bad,  $m$  will reach at least  $\frac{7}{8}$  of its first-phase destinations correctly. Thus at the end of the first phase, at most  $s/8$  copies of  $m$  have been corrupted. In the second phase, since every copy is transmitted along disjoint paths, at most  $t$  more copies might get hurt. Finally in the third phase, since  $v$  is not in-bad, at most an additional  $s/8$  copies can be corrupted. Over all, at most  $s/4 + t < s/2$  copies of the message might be lost. Therefore the majority of the copies will arrive intact, so  $v$  will recognize the message correctly.  $\square$

*Remark.* It will sometimes be necessary to consider a more relaxed type of three-phase transmission scheme in which each node  $v \in (\Gamma_{out}(u) \cup \Gamma_{in}(w))$  may appear on at most two of the paths between these two sets (once as an endpoint and at most once more as an intermediate node). The paths have to remain otherwise disjoint. For such a scheme we can prove that if  $s$  is the size of the sets  $\Gamma$ , then for all  $t < s/8$ ,  $p(G, t) \leq b(G, t)$ .

**2.3. Simulation of a complete network on the butterfly.** In this section we show how to simulate a complete network on a simple degree-4 network known as the butterfly [U]. All we have to do is specify a transmission scheme. This is done losing at most  $O(t \log t)$  processors in the presence of  $t$  faults (i.e., at most  $O(t \log t)$  processors will be bad as defined in § 2.2).

An  $m$ -butterfly is a communication graph  $G_m = (V_m, E_m)$  with  $V_m = \{(a, i) | 0 \leq a \leq m-1, 0 \leq i \leq 2^m-1\}$ . The set of edges  $E_m$  connects  $(a, i)$  to  $(b, j)$  if and only if  $b = (a+1) \pmod m$  and  $j$  is either identical to  $i$  or differs from it in the  $a$ th least significant bit.

On the butterfly we use a version of the three-phase scheme for transmitting a message from  $u = (a, i)$  to  $v = (b, j)$ . To do this we need only specify the out- and

in-sets and the three sets of paths. All messages are sent only through forward links (i.e., from a node  $(c, k)$  to a node  $((c+1) \pmod m, l)$  but not in the other direction). We take  $s = 2^m$  and define the sets  $\Gamma$  by  $\Gamma_{in}((c, k)) = \Gamma_{out}((c, k)) = \{(c, l) \mid 0 \leq l \leq 2^m - 1\}$ .

The paths are defined as follows. The forward edges of any node  $u$  span a full binary tree of height  $m$  whose leaves are all the nodes in  $\Gamma_{out}(u)$ , and the paths are chosen according to this tree. The second-phase paths connect every node  $(a, k)$  in  $\Gamma_{out}(u)$  to  $(b, k)$  in  $\Gamma_{in}(v)$  by  $(b - a) \pmod m$  edges connecting every intermediate node  $(c, k)$  to  $((c+1) \pmod m, k)$ . The third-phase paths from  $\Gamma_{in}(u)$  to  $u$  are defined in a way similar to the first-phase paths, using the dual tree based on the backward edges. More specifically, the path from a node  $(c, k)$  is directed to its neighbor  $((c+1) \pmod m, l)$  with the  $c$ th bit of  $l$  matching that of  $j$ .

This completes the description of a three-phase transmission scheme for the butterfly network. We now analyze the resiliency of this scheme.

CLAIM 2.3.  $b(G_m, t) = O(t \log t)$ .

*Proof.* Let us measure the amount of “damage” that a faulty processor  $p$  can cause to correct senders in the first phase. Keeping  $p$  fixed and looking at all possible senders  $u$  whose paths to  $\Gamma_{out}(u)$  contain  $p$  we see that  $p$  can block at most  $1/2^i$  of the outbound paths for its  $2^i$  “distance  $i$ ” neighbors. Summing up to distance  $\log 16t$ , the total damage caused by  $t$  faulty processors (measured in “number of dominated paths,” or “number of destroyed copies”) is

$$t \left( 2^{\frac{1}{2}} + 4^{\frac{1}{4}} + \dots + 2^{\log 16t} \frac{1}{2^{\log 16t}} \right) 2^m = t (\log 16t) 2^m.$$

The number of nodes that might lose  $\frac{1}{16}$  or more of their paths due to interruptions of distance  $\log 16t$  or less is therefore bounded by  $t \log 16t (2^m / (2^m / 16)) = 16t \log 16t$ . Now, let  $u$  be any processor for which less than  $\frac{1}{16}$  of the paths from  $u$  to  $\Gamma_{out}(u)$  contain a faulty processor at distance  $\log 16t$  or less from  $u$ . We claim  $u$  cannot be out-bad. This would imply that the number of out-bad nodes is also bounded by  $16t \log 16t$ . To prove the claim, note that if less than  $\frac{1}{16}$  of  $u$ 's out-bound paths are corrupted at distance  $\log 16t$  or less, then even if we assume the existence of up to  $t$  distinct faulty processes at distance  $\log 16t$  or more from  $u$ , these faults damage at most  $t 2^m / 2^{\log 16t} = 2^m / 16$  of the out-bound paths from  $u$ , so less than  $\frac{1}{8}$  of the paths from  $u$  to  $\Gamma_{out}(u)$  are corrupted, and by definition  $u$  is not out-bad. The analysis for the in-bad nodes is identical. Thus,  $b(G_m, t) \leq 32t \log 16t$ .  $\square$

COROLLARY 2.4.  $p(G_m, t) = O(t \log t)$ .

*Proof.* The proof is immediate from Claims 2.2 and 2.3.  $\square$

COROLLARY 2.5. For all  $m$ , there exists a  $t$ -resilient  $O(t \log t)$ -agreement algorithm running on  $G_m$  for  $t \leq cn / \log n$  for some constant  $c$ .

*Proof.* The proof is immediate from Claims 2.1 and 3.1.  $\square$

The next claim shows that this bound on almost-everywhere agreement is optimal for the butterfly network.

CLAIM 2.6.  $p(G_m, t) = \Omega(t \log t)$ .

*Proof.* Given  $t$ , let  $k = \lceil \log t \rceil$ , and choose the faulty nodes to be  $\{(i, j) \mid i = 0, k - 1, j = 0, \dots, 2^{k-1} - 1\}$ . This choice completely disconnects the set of nodes  $\{(a, b) \mid a = 0, \dots, k - 1, b = 0, \dots, 2^{k-1} - 1\}$ , which is of size  $\geq t \log t$ , from the remainder of the network.  $\square$

**2.4. Almost all regular graphs have good transmission schemes.** Let  $H(r, n)$  be the set of regular graphs of degree  $r$  and size  $n$ . Let  $h(r, n) = |H(r, n)| \geq (n/r)^{nr/2} [\text{Bo}]$ . We will show that for almost every  $r$ -regular graph  $G$ ,  $p(G, t) \in O(t^{1+\delta} \log t)$  for large

values of  $t$ . This is done by first showing that for all  $r \geq 5$  almost  $r$ -regular graphs  $G$  have three-phase transmission schemes for which  $b(G, t) \in O(t^{1+\delta} \log t)$  for  $t \in O(n^{1-\epsilon})$ , for appropriate  $\delta, \epsilon$ .

LEMMA 2.7. *For every  $r \geq 5$  there exists a constant  $\alpha = \alpha(r)$ ,  $0 < \alpha < 1$ , such that  $h(r, n)(1 - O(n^{-1/4}))$  of the  $h(r, n)$   $r$ -regular graphs have the following expansion property: Every subset of vertices  $U$  such that  $|U| \leq \alpha n$  has at least  $|U|(r - 3)$  neighbors outside  $U$ .*

*Proof.* We turn the set  $H(r, n)$  into a probability space by giving every graph  $G \in H(r, n)$  the same probability. A proof that a random graph  $G \in H(r, n)$  possesses the properties (1) and (2) with probability at least  $1 - O(n^{-1})$  implies Lemma 2.7.

The study of the probability space  $H(r, n)$  presents a special difficulty since no explicit representation of the set  $H(r, n)$  or a direct procedure for constructing a random element in  $H(r, n)$  are available. Recently, Bollobás [Bo] derived a method for studying  $H(r, n)$  through a related, more simple probability space  $\Phi(r, n)$ . Our proof is based on this new approach.

We start with a set,

$$W(r, n) = \{(v, i) | v = 1, \dots, n, i = 1, \dots, r\}.$$

A configuration  $F$  is a partition of  $W$  into  $rn/2$  pairs  $\{(v, i), (v', i')\}$ . Let  $\Phi(r, n)$  be the set of all configurations of  $W(r, n)$ . A configuration  $F$  defines an  $r$ -degree multigraph (with possible self loops), with vertex set  $V = \{1, \dots, n\}$  in which  $v$  is connected to  $v'$  if  $F$  includes a pair  $\{(v, i), (v', i')\}$  for some  $1 \leq i, i' \leq r$ .

Let  $\Psi(r, n)$  be the set of all configurations that define a proper  $r$ -regular graph. Bollobás was able to show that  $|\Psi(r, n)| \approx e^{(-r^2-1)/4} |\Phi(r, n)|$ . Thus, if we turn  $\Psi(r, n)$  and  $\Phi(r, n)$  into probability spaces by giving all their elements equal probability, an event that holds with probability  $1 - O(n^{-1})$  in  $\Psi(r, n)$  also holds with probability  $1 - O(n^{-1})$  in  $\Phi(r, n)$ . Furthermore, each graph  $G \in H(r, n)$  is obtained from precisely  $(r!)^n$  configurations. Thus, to prove that an event holds with probability  $1 - O(n^{-1})$  in  $H(r, n)$  it is enough to prove this result in the space  $\Phi(r, n)$ , where the analysis is substantially easier.

We first obtain a lower bound for the number of edges with at least one endpoint in a given set of vertices  $U$ . Let  $\beta = \frac{3}{2}$  and  $\alpha \leq e^{-2r} r^{-4}$ . Let  $E_1$  be the event: *There is a subset of vertices  $U$ ,  $|U| = k \leq \alpha n$ , that are endpoints of less than  $(r - \beta)k$  distinct edges.* The event  $E_1$  implies that at least  $\beta k$  edges in the graph connect two vertices of  $U$ . Thus,

$$\text{Prob}(E_1) \leq \sum_{k \leq \alpha n} \binom{n}{k} \binom{rk}{\beta k} \left(\frac{k}{n}\right)^{\beta k}.$$

Since

$$\binom{n}{k} \leq \left(\frac{ne}{k}\right)^k,$$

$$\text{Prob}(E_1) \leq \sum_{k \leq \alpha n} \left(\frac{en}{k}\right)^k (er)^{\beta k} \left(\frac{k}{n}\right)^{\beta k}.$$

For  $k \leq \log^3 n$ , each of the terms in the sum is bounded by  $O(n^{-1/2})$ ; thus, the sum of the first  $\log^3 n$  terms is bounded by  $O(n^{-1/3})$ . For  $k \geq \log^3 n$  each term in the sum is bounded by

$$(e^{(1+\beta)} r^\beta \alpha^{(\beta-1)})^k \leq n^{-2}$$

by the choice of  $\alpha$  and  $\beta$ . There are less than  $n$  terms in the sum; thus,  $\text{Prob}(E_1) = O(n^{-1/3})$ .

Let  $E_2$  be the event: *There exists a subset of vertices  $U, |U| \leq \alpha n$  that has less than  $|U|(r-3)$  neighbors outside  $U$ .* Conditioning on  $\bar{E}_1$ , the complement of the event  $E_1$ , we know that the vertices of  $U$  are endpoints of at least  $(r-\beta)|U|$  edges. We bound  $\text{Prob}(E_2|\bar{E}_1)$  by the probability that the other endpoints of all these edges are in a set of size  $(r-3)|U|$ . Thus,

$$\begin{aligned} \text{Prob}(E_2|\bar{E}_1) &\leq \sum_{k \leq \alpha n} \binom{n}{k} \binom{n}{(r-3)k} \left(\frac{k(r-3)}{n}\right)^{(r-\beta)k} \\ &\leq \left(\frac{ne}{k}\right)^k \left(\frac{ne}{(r-3)k}\right)^{(r-3)k} \left(\frac{(r-3)k}{n}\right)^{(r-\beta)k} \\ &\leq \left(e^{(r-2)}(r-3)^{(3-\beta)} \left(\frac{(r-3)k}{n}\right)^{(2-\beta)}\right)^k. \end{aligned}$$

Again we distinguish between two cases. If  $k \leq \log^3 n$  then since  $2-\beta = \frac{1}{2}$ , each term in the sum is bounded by  $O(n^{-1/2})$ . If  $k \geq \log^3 n$  then each term is bounded by  $(e^r r^{3/2} (r\alpha)^{1/2})^k$ , and thus, by the choice of  $\alpha$ , is bounded by  $O(n^{-2})$ .

Thus, the expansion property holds with probability  $\text{Prob}(\bar{E}_2) \geq \text{Prob}(\bar{E}_2|\bar{E}_1)$   $\text{Prob}(\bar{E}_1) \geq 1 - O(n^{-1/3})$ .  $\square$

**CLAIM 2.8.** *Let  $G = (V, E)$  be a graph satisfying the following expansion condition: Every subset of vertices  $U$  such that  $|U| \leq \alpha n$  has at least  $2|U|$  neighbors outside  $U$ . Then  $G$  has the following superconcentration property: Every two subsets of vertices  $U, W$  of size  $|U| = |W| \leq \alpha n$  are connected by  $|U|$  paths which are vertex-disjoint except that a node in  $U \cup W$ , in addition to being an endpoint, might appear as an intermediate node on one other path. item.*

*Proof.* We use the following extension of Menger’s theorem.

**THEOREM** [Br, p. 167]. *If  $a$  and  $b$  are two nonadjacent vertices of a simple graph  $G$ , then the maximum number of vertex-disjoint paths between  $a$  and  $b$  equals  $c_G(a, b) = \min_A |A|$ , where the minimization is taken over all vertex sets  $A$  that do not contain either  $a$  or  $b$  and whose removal disconnects  $a$  from  $b$ .*

Assume that our graph  $G = (V, E)$  contains a pair of sets  $U, W$  that do not satisfy the property. Let  $k = |U| = |W|$ . Consider the graph  $H = (V', E')$  obtained from  $G$  as follows: The set of vertices  $V' = V + U' + W' + \{s, t\}$ ,  $|U'| = |W'| = k$ . The vertex  $s$  is connected to all  $u', u' \in U'$  and the vertex  $t$  is connected to all  $w', w' \in W'$ . The connections between the vertices  $V$  are as in the graph  $G$ , and the vertices in  $U' \cup W'$  have the same connections as the corresponding vertices in  $U \cup W$ . Existence of  $k$  disjoint paths connecting  $s$  to  $t$  implies the superconcentration property. The above theorem implies that if there are no  $k$  vertex-disjoint paths connecting  $s$  to  $t$  then there is a set  $A, |A| < k$  that disconnects  $s$  from  $t$ .

We will prove that the existence of such a set in  $H$  violates the expansion property of  $G$ . Assume that a set  $A, |A| < k$  disconnects  $s$  from  $t$ . Let  $a = |U \cap A|$ ,  $b = |V \cap A|$  and  $c = |W \cap A|$ ,  $a + b + c < k$ . By the expansion property  $A \cap V$  can disconnect only a set of size  $\frac{1}{2}b$  from the rest of the set  $V$ . Thus, the set  $V - A$  has a connected component  $V'$  of size at least  $|V| - \frac{3}{2}b$ . By the expansion property the set  $U - A$  has at least  $2(k - a)$  neighbors in  $V$  and the set  $W - A$  at least  $2(k - c)$  neighbors in  $V$ . Since  $a + b + c < k$ ,  $2(k - a) > \frac{3}{2}b$  and  $2(k - c) > \frac{3}{2}b$ ; thus both  $U - A$  and  $W - A$  are connected to the connected component  $V'$  and there is a path connecting  $s$  to  $t$  that does not use the set  $A$ .  $\square$

**CLAIM 2.9.** *For all  $r \geq 5$ , for every graph  $G$  in  $H(r, n)$ , if  $G$  has the expansion and superconcentration properties, then there exists a three-phase transmission scheme for  $G$*

subject to  $p(G, t) \in O(t^{1+\delta} \log t)$  for  $t \in O(n^{1-\epsilon})$ , for some  $0 < \delta < \epsilon < 1$ ,  $\epsilon = \epsilon(r)$ , where  $\epsilon \rightarrow 0$  as  $r \rightarrow \infty$ .

*Proof.* In this proof all logarithms are to the base  $r-3$ . Let  $d = \lceil \log t \rceil$  and let  $\delta = \log((r-1)/(r-3))$ . For each vertex  $u$  in  $G$ , let  $D(u)$  denote the set of vertices in  $G$  at distance  $d+4$  from  $u$ . By the expansion property, and the fact that  $r-3 \geq 2$ ,  $|D(u)| \geq 16(r-3)^d$ . We choose  $\Gamma(u) = \Gamma_{\text{in}}(u) = \Gamma_{\text{out}}(u)$  to be an  $s = 9(r-3)^d \leq \alpha n$  element subset of  $D(u)$ . This leaves us free to use the same inbound paths as outbound paths. Specifically, we choose an arbitrary breadth-first search tree of  $G$  rooted at  $u$ , and use its branches to define paths between  $u$  and the elements of  $\Gamma(u)$ . Finally, by the superconcentration property there are  $s$  ‘‘almost vertex disjoint’’ paths between  $\Gamma(v)$  and  $\Gamma(w)$  for every two nodes  $v, w$  of  $G$ . For each pair of nodes we specify a particular set of such paths. This completes the specification of the transmission scheme.

It remains to analyze the damage that can be caused by the faulty processors and to show that it cannot be too large. Let  $u$  be an arbitrary correct processor and let  $p$  be a faulty processor at distance  $i$  from  $u$ . Then  $p$  can affect the paths from  $u$  to at most  $(r-1)^{d+4-i}$  elements of  $\Gamma(u)$ . At most  $r(r-1)^{i-1}$  vertices  $u$  are at distance  $i$  from  $p$ . Thus  $p$  can corrupt at most  $r(r-1)^{d+3}$  elements in sets  $\Gamma(u)$  for vertices  $u$  at distance  $i$  from  $p$ . Summing up for all distances  $i \leq d$  and all faulty processors we see that the faulty processors can corrupt at most  $tdr(r-1)^{d+3}$  paths in total. Therefore, assuming that this damage is distributed in a worst-case fashion for the transmission scheme (optimal for an adversary),

$$\begin{aligned} b(G, t) &\leq \frac{t \log tr(r-1)^{d+3}}{9(r-3)^d/8} \\ &= \frac{8r(r-1)^3}{9} t^{1+\delta} \log t. \end{aligned}$$

Finally note that by the remark following Claim 2.2 and the fact that  $s/8 > (r-3)^d \geq t$ , the same bound applies for  $p(G, t)$ . Note also that this bound limits the results to  $t \in O(n^{1-\epsilon})$  for an appropriate  $\delta < \epsilon < 1$ .  $\square$

**COROLLARY 2.10.** *For every  $r \geq 5$  almost every  $r$ -regular graph has a  $t$ -resilient  $O(t^{1+\delta} \log t)$ -agreement algorithm, for  $t \in O(n^{1-\epsilon})$ , for some  $0 < \delta < \epsilon < 1$ .  $\square$*

**2.5. Results for faults of restricted severity.** In this section we briefly mention our results for the failstop, omission, and authenticated Byzantine models. As with the unrestricted Byzantine failures (without authentication) our approach is to devise an appropriate transmission scheme. However, in the failure models considered here two correct processors can communicate provided they are connected by even one uncorrupted path. Thus the poor processors will be only those completely disconnected from the major portion of the graph. Now, if a graph has good expansion properties, then it is impossible for  $t$  processors to disconnect more than  $O(t)$  processors. Combining this with the fact that almost all regular graphs of degree at least 5 enjoy such properties (Lemma 2.7), we obtain the following result.

**THEOREM 2.11.** *Assuming an authentication mechanism or nonmalicious faults (failstop, omission), for all  $r \geq 5$  there exists a constant  $c = c(r)$  such that for all  $t \leq cn$ ,*

- (1) *almost all  $r$ -regular graphs have transmission schemes in which there are at most  $O(t)$  poor processors, and*
- (2) *almost all  $r$ -regular graphs admit a  $t$ -resilient algorithm for  $O(t)$  agreement.*

**3. Byzantine agreement on compressor graphs.** Until this point we have considered only techniques based on simulations of complete-network algorithms on our bounded

degree networks. A different approach to reaching agreement in a bounded degree network can be based on distributed protocols of a local nature. In this section we consider such an approach and analyze its behavior on a compressor graph.

A graph  $G$  is a  $\theta$ -compressor for constant  $\theta < 1$ , if for every subset of vertices  $U$  of size  $|U| \leq \theta n$ , the set  $\{v|v \text{ has at least half of its neighbors in } U\}$  has cardinality at most  $|U|/2$ . An explicit construction of compressors of a (very high) fixed degree (about  $8^{17}$ ) has been shown by Pippenger [P]. Using a recent result of Lubotzky, Phillips, and Sarnak [LPS] the degree of explicitly constructed compressors can be reduced to about 64.

Our interest in compressors follows from our ability to use the compression property to “sharpen” almost-everywhere agreement to achieve  $O(t)$  agreement (which is asymptotically optimal, as  $t$  faults can always completely disconnect  $\Omega(t)$  correct processors). Ultimately, our approach will be to use one of the simulation techniques of the previous section to obtain  $p(G, t)$  agreement and then to sharpen this to  $O(t)$  agreement by using the compressor properties of the graph.

We consider the following scheme for agreement, called the *compression procedure*. This procedure is based on simple rounds of the following form. In every round, every correct processor

- (1) sends its value to all its neighbors,
- (2) receives the values of all its neighbors, and
- (3) chooses as its new value the value held by a majority of its neighbors.

The procedure terminates after some fixed number of rounds.

Let  $G = (V, E)$  be a  $\theta$ -compressor of size  $n$ , and let  $T$  be the set of faulty processors in the network,  $|T| \leq t \leq \theta n/2$ .

LEMMA 3.1. *If there are  $(1 - \theta)n$  correct processors which share the same initial value  $x$ , then after applying the compression procedure for  $\log n$  rounds, at most  $t + 1$  correct processors will have a value different from  $x$ .*

*Proof.* Let  $V_k$  denote the set of correct processors whose value differs from  $v$  after  $k$  rounds of the majority procedure. Let  $A_k = ((2^k - 1)t + |V_0|)/2^k$ , for  $k \geq 0$ . We begin by bounding  $A_k$  in terms of  $n$  and  $t$ .

CLAIM 3.1.1. *For every  $k \geq 0$ ,  $A_k + t \leq \theta n$ .*

*Proof.* There are two cases. If  $|V_0| \leq t$  then for every  $k \geq 0$ ,  $A_k \leq ((2^k - 1)t + t)/2^k = t$  and we are done by the assumption on  $t$ . If  $|V_0| > t$  we prove the claim by induction on  $k$ . For  $k = 0$ ,  $A_k = |V_0|$ , and  $A_k + t = |V_0| + t \leq \theta n$  by the assumption on the initial state of the network. Assume the claim inductively for  $k$ . Since  $A_{k+1} = A_k + (t - |V_0|)/2^{k+1} < A_k$  we are done.  $\square$

We next bound  $V_k$  in terms of  $A_k$ .

CLAIM 3.1.2. *For every  $k \geq 0$ ,  $|V_k| \leq A_k$ .*

*Proof.* We prove the claim by induction on  $k$ . For  $k = 0$  the claim is trivial. Assume the claim for  $k$  inductively, and consider the case of  $k + 1$ . The set  $V_{k+1}$  will contain all correct processors whose majority of neighbors resides in  $T \cup V_k$ . By the inductive hypothesis this set has cardinality at most  $t + A_k$ , which, by Claim 3.1.1, is at most  $\theta n$ . We may therefore apply the compression property to obtain  $|V_{k+1}| \leq (t + A_k)/2 = A_{k+1}$ .

Taking  $k = \log n$  we obtain  $|V_k| \leq A_k \leq t + 1$ . This completes the proof of Claim 3.1.1.  $\square$

LEMMA 3.2. *For every  $r \geq 5$  there exists a constant  $0 < \theta < 1$ , such that  $h(r, n)(1 - O(n^{-1}))$  of the  $h(r, n)$   $r$ -regular graphs have the compression property for all subsets  $U$  of size  $|U| \leq \theta n$ .*

*Proof.* We use the same setting and notation as in the proof of Lemma 2.7. Define the event  $E_3$ : *There exists a set  $U$ ,  $|U| \leq \theta n$  and a set  $W$ ,  $|W| \leq |U|/2$  such that half of*

the edges incident on  $W$  have one endpoint in  $W$  and the other in the set  $U$ . Clearly if a graph has a set  $U$  that violates the compression property it is included in the event  $E_3$ . To estimate the probability of the event  $E_3$  we condition first on the complement of the event  $E_1$  (defined in the proof of Lemma 2.7). Under the condition  $\bar{E}_1$ , the vertices of the set  $W$  are incident to at least  $(r-\beta)|W|$  edges, and to satisfy the condition  $E_3$  at least half of these edges have their other endpoint in the set  $U$ :

$$\begin{aligned} \text{Prob}(E_3|\bar{E}_1) &\leq \sum_{k \leq \theta_n} \binom{n}{k} \binom{n}{k/2} \binom{(r-\beta)k}{((r-\beta)/2)k} \left(\frac{rk}{rn}\right)^{((r-\beta)/2)k} \\ &\leq \left(\frac{ne}{k}\right)^k \left(\frac{2ne}{k}\right)^{k/2} \left(\frac{(r-\beta)k}{((r-\beta)/2)k}\right)^{(r-\beta)k} \left(\frac{k}{n}\right)^{((r-\beta)/2)k} \\ &\leq \left(e^{3k/2} 2^{(r-\beta+1/2)} \left(\frac{k}{n}\right)^{(r-\beta-3/2)}\right)^k \end{aligned}$$

For  $k \leq \log^3 n$  each term in the sum is bounded by  $O(n^{-1})$ . For  $k \geq \log^3 n$  each term is bounded by  $(e^{r+1/2} \theta^{r-3/2})^k \leq n^{-2}$ , since  $\beta = \frac{3}{2}$  and  $e^{-2}$ . Thus,  $\text{Prob}(\bar{E}_3) \geq \text{Prob}(\bar{E}_3|\bar{E}_1) \text{Prob}(\bar{E}_1) \geq 1 - O(n^{-1})$ .  $\square$

Combining this with the transmission schemes described in § 2.4, we prove the following.

**COROLLARY 3.3.** *For every  $r \geq 5$ ,  $h(r, n)(1 - O(n^{-1}))$  of the  $h(r, n)$   $r$ -regular graphs admit  $O(t)$  agreement, where  $t \in O(n^{1-\epsilon})$  for some  $0 < \epsilon < 1$ .*

*Proof.* By Lemmas 2.7 and 3.2 almost every  $r$ -regular graph enjoys the expansion, compression, and superconcentration properties. Let  $G$  be any such graph. Using the three-phase transmission scheme of § 2.4 to simulate any standard Byzantine agreement designed for the complete network, we achieve  $O(t^{1+\delta} \log t)$  agreement, so at the end of the simulation at least  $1 - \theta$  of the correct processors agree on a value. Since this satisfies the conditions of Lemma 3.1 we may apply that lemma to obtain the desired  $O(t)$ -agreement.  $\square$

**COROLLARY 3.4.** *There exists a family of degree 9 networks that admit  $t$ -resilient  $O(t)$  agreement for  $t \leq \alpha n / \log n$ , for some constant  $\alpha$ .*

*Proof.* Since a butterfly has degree 4 and a compressor has degree 5, there exists a graph of degree 9 which is both a butterfly and a compressor. We first use the result of Corollary 2.5 to get an  $O(t \log t)$  agreement on the butterfly graph, then we use the compressor to sharpen this agreement.  $\square$

**4. Almost-everywhere agreement on networks of unbounded degree.** On a complete network,  $t$ -resilient agreement protocols exist for all  $t < n/3$ . In contrast, our previous algorithms can tolerate only  $O(n/\log n)$  failures. The situation for higher values of  $t$  on bounded degree networks remains open. In this section we present an approach for reaching agreement on networks of unbounded but small degree (which is nevertheless much lower than  $n$  or  $t$ ).

**THEOREM 4.1.** *For every  $\epsilon > 0$  there exist a constant  $c = c(\epsilon)$ , graphs  $G$  of degree  $O(n^\epsilon)$  and  $t$ -resilient  $O(t)$ -agreement algorithms for  $t \leq cn$ .*

*Proof.* For simplicity, we discuss only the case  $\epsilon = \frac{1}{2}$ . Let  $G = (V, E)$  be defined as follows.  $V$  contains  $n = m^2$  nodes, partitioned into  $m$  pairwise disjoint committees  $A_i, 1 \leq i \leq m$ , each of size  $m$ . Each committee forms a clique. In addition, every two committees  $A_i$  and  $A_j$  are connected by  $m$  edges which form a matching between them. On top of that, we optionally add edges so as to make the graph into a  $\theta$ -compressor. As discussed earlier, this property can be achieved by a graph of bounded degree. Thus the degree of any node in the resulting graph will be  $O(n^{1/2})$ .

Let  $P$  be any  $t$ -resilient protocol for the traditional Byzantine agreement problem on a complete network [DFFLS], [PSL], [LSP], guaranteeing agreement whenever the number of faulty processors is smaller than  $n/3$ .

The algorithm we give consists of two main stages plus an additional optional stage which uses the compressor edges. In the first stage, each committee privately runs  $P$  (appropriately scaled) among its own members. We say a committee is *good* if fewer than  $\frac{1}{4}$  of its members are faulty. Clearly the good committees will reach agreement among themselves. In the next stage, each committee acts as a single processor and the whole graph is viewed as a clique of  $m$  (composite) processors which simulate an execution of  $P$ . The final optional stage is a compression step, as described in § 3.

The communication between committees is performed by a special protocol COM which guarantees that processors within a good committee behave uniformly. According to this protocol a committee  $A$  sends a message  $x$  to  $B$  as follows. Every processor in  $A$  sends  $x$  to its neighbor in  $B$ . Every node in  $B$  now executes the following two steps:

- (1) Exchanges with all other processors in  $B$  the value received from  $A$ ;
- (2) Adopts as its updated value of  $x$  that message received from the majority of the nodes in  $B$  (ties are broken arbitrarily).

Finally, the nodes of  $B$  run  $P$  on the adopted values for  $x$ . The value agreed upon by the end of the run is taken to be the message sent by  $A$ .

We now analyze the behavior of this algorithm. Call a committee  $A_i$  *good* if  $t_i < m/4$ , where  $t_i$  is the number of actual faults in  $A_i$ , and *bad* otherwise.

CLAIM 4.2. *In every communication step (i.e., every execution of COM), if the committee  $A_i$  receiving a message is good then all the good processors in it will agree on the same received value.*

*Proof.* This follows from the properties of  $P$  and the fact that  $t_i < m/3$ .  $\square$

COROLLARY 4.3. *In every round of the second stage of the main algorithm, the elements of a good committee will have the same view and will send out the same messages.*  $\square$

CLAIM 4.4. *In every communication step COM, if the receiving committee  $A_i$  and the sending committee  $A_j$  are good, then all the good processors in  $A_j$  will agree on the value that was sent by (the good processors of)  $A_i$ .*

*Proof.* Since all the good processors of  $A_i$  send the same message  $X$ , and  $t_i, t_j < m/4$ , the number of good processes in  $A_j$  receiving  $X$  is at more than  $m/2$ . Therefore after the majority step of COM, all the correct processes in  $A_j$  will have the same value  $X$ . By the unanimity property of the algorithm  $P$ , all the correct processors in  $A_j$  will eventually agree on  $X$ .  $\square$

CLAIM 4.5. *If  $t < n/12$  then in the end of the basic main algorithm (without the final compression step), agreement will be reached between most of the good processors; at most  $3t$  good processors will reach a wrong decision.*

*Proof.* Denote the number of bad committees by  $b$ . Clearly  $b \leq 4t/m$  (otherwise, since every bad committee has at least  $m/4$  faults, there are more than  $t$  faults overall). Hence  $b < (4/m)(n/12) = m/3$ . Therefore the main algorithm will guarantee that all the good committees will reach agreement, where in every good committee all good processors will have the right value. The “confused” good processors are at most those in the bad committees, whose number is bounded by  $b(m - m/4) \leq (3m/4)(4t/m) = 3t$ .  $\square$

CLAIM 4.6. *If  $t < \theta n/4$  then in the end of the algorithm (with the final compression step), agreement will be reached between most of the good processors; at most  $t + 1$  good processors will reach a wrong decision.*

*Proof.* Upon termination of the basic algorithm, the number  $l$  of good processors holding a wrong value is bounded by  $3t$ , as shown in the previous claim. Thus  $t < \theta n/2$ , and  $l + t \leq 4t < \theta n$ , and by Claim 2.3, after the compression procedure at most  $t + 1$  good processors will have a wrong value.  $\square$

This algorithm can be naturally extended for graphs of degree  $O(n^{1/k})$  for  $k = 3, 4, \dots$ , by dividing the graph into committees of committees of committees, etc., with an appropriate definition of a good committee on every level. We omit the details.

**5. Combinatorial characterization of fault-tolerant networks.** There is a necessary and sufficient condition for a system to be  $t$ -resilient in terms of the combinatorial properties of its communication graph. In this section we derive a combinatorial characterization of graphs that admit  $p(t)$  agreement.

For any agreement protocol  $P$  let  $P(T)$  be any maximal set of correct processors that always reach agreement under the protocol  $P$ , independent of the behavior of the processors in  $T$  (thought of as faulty).

**THEOREM 5.1.** *Let  $G$  be a communication graph, let  $\{T_i\}_{i=1}^k$  be the family of all possible sets of faulty processors in  $G$ , and let  $\{A(T_i)\}_{i=1}^k$  be a family of sets of processors in  $G$ . There exists a protocol  $P$  subject to  $P(T_i) = A(T_i)$  for  $i = 1, \dots, k$ , if and only if for every pair of processors  $u, v \in A(T_i) \cap A(T_j)$ , the set  $T_i \cup T_j$  does not disconnect  $u$  from  $v$  in  $G$ .*

*Comment.* Note that if for all sets  $T$  of at most  $t$  processors  $A(T)$  is the complement of  $T$ , then our characterization yields the  $2t + 1$  connectivity condition for the traditional Byzantine agreement problem.

*Sketch of proof.* To prove necessity, we show that if there exist sets  $T_i$  and  $T_j$  which jointly (but not individually) can disconnect correct processors  $u$  and  $v$ , then there exist two scenarios, indistinguishable to  $v$ , such that in one scenario  $T_i$  is faulty and  $u$  decides on a value  $a$ , while in the second scenario  $T_j$  is faulty and  $u$  decides on a value  $b$ .

We prove sufficiency by constructing an algorithm with the desired properties. We briefly describe a few points of our construction.

A processor  $u$  transmits a message to  $v$  by sending it along all simple paths from  $u$  to  $v$ . As the message passes from site to site, each processor appends the name of the processor from which the message was received. Thus, a message that passes through faulty processors contains the name of at least one such processor (the last one). The processor  $v$  searches for a set  $T_i$  such that all the messages not passing through this set are consistent and both  $u$  and  $v$  are in  $A(T_i)$ . Let  $T$  be the set of faulty processors in a particular execution of our algorithm. If  $u$  and  $v$  are in  $A(T)$  then  $v$  will try this set and extract the correct value. Crucial to our algorithm is that  $v$  will never extract an incorrect value. This is because by assumption, for all other relevant sets  $T_j$ ,  $T \cup T_j$  will not disconnect  $u$  from  $v$ . Thus,  $v$  receives the message via at least one fault-free path. Therefore, the faulty processors can at most create an inconsistent set of values, from which  $v$  extracts nothing.  $\square$

**6. Conclusions and open problems.** We propose a new paradigm for fault-tolerant computing, in which correctness conditions are relaxed by accepting the loss of a small number of correct processors.

This paper concentrates on demonstrating the feasibility of this new approach and its advantages. In particular, we show that a simple distributed algorithm can achieve agreement among almost all the correct processors in circumstances in which Byzantine agreement is not achievable.

Many problems remain open for further investigation. We mention the following:

(1) What is the minimum number of steps and messages required to achieve  $X$  agreement? Can the efficiency of the algorithms presented in this paper be significantly improved?

(2) The algorithms presented in this work assume that all the processors know the topology of the communication network and the communication schemes used by all other processors. Is this requirement essential for achieving  $X$  agreement?

(3) Can  $X$  agreement be achieved on a network of bounded degree in the presence of more than  $n/\log n$  (malicious) faults? Note that in this case most of the communication paths between most pairs of processors include at least one faulty processor.

**Acknowledgment.** We wish to thank M. Ajtai for helpful discussions.

## NATURAL SELF-REDUCIBLE SETS\*

ALAN L. SELMAN†

**Abstract.** To every set  $A$  in NP we associate a (collection of) natural self-reducible set(s). We prove that every disjunctive-self-reducible set in NP is  $\cong_a^P$ -equivalent to one of these natural self-reducible sets and we show that if certain questions about these sets could be answered, then several significant open questions about the fine structure of NP would be solved.

**Key words.** NP, self-reducible, P-selective, P-separable, reducibilities, P-isomorphic

**AMS(MOS) subject classification.** 68Q15

**1. Introduction.** All “natural” NP-complete sets are self-reducible but it is not known whether *all* NP-complete sets are self-reducible. Self-reducibility is that property of sets which, for example, makes the problem of finding a satisfying assignment for a formula of propositional logic polynomially Turing equivalent to the problem of deciding whether a formula has a satisfying assignment. The theorems of Berman [Ber78] and Mahaney [Mah82] use the self-reducibility property extensively.

Our motivation is to reveal the mathematical structure of NP. Although hundreds of NP-complete problems are known, even elementary matters such as whether the union of every pair of disjoint NP-complete sets is NP-complete remains an open question. We suggest examination of self-reducible sets in order to gain insight into questions of this kind. To every set  $A$  in NP we associate a (collection of) natural self-reducible set(s), prefix  $(R_A)$ . Prefix  $(R_A)$  may be thought of as the set of all prefixes of accepting computations of some nondeterministic polynomial time-bounded Turing machine that accepts  $A$ . If we could answer certain questions about these sets, then several significant open problems about the fine structure of NP would be solved. Along the way some fundamental facts about self-reducible sets are obtained. We prove that every disjunctive-self-reducible set  $A$  is  $\cong_a^P$ -equivalent to an appropriate prefix  $(R_A)$ . (An immediate consequence is the known result that every disjunctive-self-reducible set belongs to NP [Ko83].)

**2. Preliminaries.** All languages considered are over the finite alphabet  $\Sigma = \{0, 1\}$ , and  $\#$  is a symbol that is not in the alphabet  $\{0, 1\}$ . The reader is assumed to be familiar with standard concepts and notation of polynomial time-bounded complexity theory [HU79], [GJ79], but a number of specialized notions are described below.

Let  $E = \cup_c \text{DTIME}(2^{cn})$ , and let  $NE = \cup_c \text{NTIME}(2^{cn})$ . It is not known whether  $E = NE$ , but it is a well-known fact that  $E \neq NE$  implies  $P \neq NP$  [Boo74a], [JS74]. A *tally language* is a subset of  $\{1\}^*$ . A set  $S$  is *sparse* if there is a polynomial  $p$  such that for every positive integer  $n$ ,

$$\|S \cap \{0, 1\}^n\| \leq p(n).$$

Obviously, tally languages are sparse sets. It is known that  $E = NE$  if and only if every tally language in NP belongs to P [Boo74b], [HHH74], and Hartmanis [Har83] has recently shown that  $E = NE$  if and only if every sparse set in NP belongs to P. Also, it is known that no NP-complete sets are sparse unless  $P = NP$  [Mah82].

**2.1. Reducibility concepts.** We use the notation  $\leq_T^P$  and  $\leq_m^P$  to denote polynomial time-bounded Turing and many-one reducibility, respectively. For an arbitrary polynomial time-bounded reducibility  $\leq_r^P$ , a set  $L$  is  $\leq_r^P$ -hard for complexity class  $C$  if every set in  $C$  is  $\leq_r^P$ -reducible to  $L$ , and a set  $L$  is  $\leq_r^P$ -complete for  $C$  if  $L$  is  $\leq_r^P$ -hard for  $C$  and  $L \in C$ . By consensus, “NP-complete” means  $\leq_m^P$ -complete for NP, and “NP-hard” means  $\leq_T^P$ -hard for NP.

It is known that  $\leq_T^P$  and  $\leq_m^P$  are not identical on the class of recursive sets [LLS75]. If  $P \neq NP$ , then there exist NP-hard sets that are not  $\leq_m^P$ -hard [Lon82]. However, it is not known whether there exist  $\leq_T^P$ -complete sets in NP that are not already NP-complete.

A number of specialized polynomial time-bounded reducibilities have been studied [LLS75]; of these we need to know disjunctive reducibility,  $\leq_d^P$ . A simple characterization follows:  $A \leq_d^P B$  if and only if there is a polynomial-time computable function

$$f: \{0, 1\}^* \mapsto (\neq \{0, 1\}^*)^*$$

such that for each input word  $x$ ,  $x \in A$  if and only if  $\{y_1, \dots, y_k\} \cap B \neq \emptyset$ , where  $f(x) = \#y_1 \dots \#y_k$ .

Reference will be made to truth-table and positive truth-table reducibilities also. The uninitiated reader need only be aware of the following inclusions:

$$\leq_m^P \subseteq \leq_d^P \subseteq \leq_{pt}^P \subseteq \leq_u^P \subseteq \leq_T^P.$$

**2.2. Self-reductions.** Self-reducibility notions have appeared in the literature in a variety of guises, but the most useful definition is due to Meyer and Paterson [MP79]. Their definition follows.

DEFINITION 1. A partial order  $<$  on  $\Sigma^*$  is OK if and only if

(i) every strictly decreasing chain is finite, and there is a polynomial  $p$  such that every finite  $<$ -decreasing chain is shorter than  $p$  of the length of its maximum element, and

(ii)  $x < y$  implies  $|x| \leq q(|y|)$ , for some polynomial  $q$ , and all  $x$  and  $y$  in  $\Sigma^*$ .

DEFINITION 2. A set  $A$  is self-reducible if and only if there is an OK partial order and a query machine  $M$  such that  $M$  accepts  $A$  in polynomial time with oracle  $A$ , and  $M$  is restricted so that on any input  $x$  in  $\Sigma^*$ ,  $M$  asks its oracle only about words strictly less than  $x$  in the partial order.

Our concern is with sets that are  $d$ -self-reducible, i.e., the query machine  $M$  also provides a  $\leq_d^P$ -reduction. This means that on every input word  $x$ , the query machine  $M$  either

(i) decides membership of  $x$  in  $A$  in polynomial time without queries to the oracle, or

(ii) computes a set of queries  $\{z_1, \dots, z_k\}$  in polynomial time so that

$$x \in A \Leftrightarrow \{z_1, \dots, z_k\} \cap A \neq \emptyset.$$

All of the known NP-complete combinatorial problems are  $d$ -self-reducible, and Meyer and Paterson [MP79] and Schnorr [Sch76] demonstrated  $d$ -self-reducibility of several problems in NP that are not known to be either in P or NP-complete.

**3. Natural self-reducible sets.** Given a set  $A \in NP$  there is an associated polynomial-time recognizable relation  $R_A$  and an associated polynomial  $p_A$  such that

$$(1) \quad A = \{x \mid \exists y |y| = p_A(|x|) \text{ and } R_A(x, y)\}.$$

A string  $y$  of length  $p_A(|x|)$  such that  $R_A(x, y)$  holds is called a *proof* that  $x \in A$ . We will be performing various manipulations on these proofs, and so for purely technical reasons it is convenient to assume that associated polynomial-time relations also satisfy the following condition:

$$(2) \quad \forall z_{|z| \geq p_A(|x|)} [R_A(x, z) \leftrightarrow R_A(x, y), \text{ where } y \text{ is the prefix of } z \text{ of length } p_A(|x|)].$$

We make this assumption without loss of generality because every polynomial-time recognizable relation  $R_A$  that satisfies property (1) can be extended so that it also satisfies condition (2).

DEFINITION 3.  $\text{Prefix}(R_A) = \{x \# u \mid \exists v \mid uv = p(|x|) \text{ and } R_A(x, uv)\}$ .

PROPOSITION 1. (i)  $\text{Prefix}(R_A)$  is *d-self-reducible*. (Namely,  $x \# u \in \text{Prefix}(R_A) \leftrightarrow (x \# u0 \in \text{Prefix}(R_A) \text{ or } x \# u1 \in \text{Prefix}(R_A)) \text{ or } R_A(x, u)$ .)

(ii)  $A \leq_m^P \text{Prefix}(R_A)$ . (Namely,  $x \in A \leftrightarrow x \# \in \text{Prefix}(R_A)$ .)

(iii) If  $A$  is NP-complete, then  $\text{Prefix}(R_A)$  is NP-complete.

(iv) If  $A$  is  $\leq_T^P$ -complete for NP, then  $\text{Prefix}(R_A)$  is  $\leq_T^P$ -complete for NP.

A number of open questions about  $\text{Prefix}(R_A)$  will be raised. From the possible answers to these questions, inferences will be drawn about structural properties of NP.

**3.1. Disjoint pairs of NP-sets.** The following are two well-known results about disjoint pairs of recursively enumerable sets (cf. [Sho71]).

(1) For every nonrecursive recursively enumerable set  $A$  there exist sets  $B_1$  and  $B_2$  such that  $A = B_1 \cup B_2$ ,  $B_1 \cap B_2 = \emptyset$  and  $B_1$  and  $B_2$  are both recursively enumerable and nonrecursive.

(2) If  $B_1$  and  $B_2$  are disjoint recursively enumerable sets, then  $\mathbf{d}(B_1 \cup B_2) = \mathbf{d}(B_1) \cup \mathbf{d}(B_2)$ . In particular,  $B_1 \leq_T B_1 \cup B_2$  and  $B_2 \leq_T B_1 \cup B_2$ .

Now the analogue of result (1) to polynomial-time complexity holds, for Ladner [Lad75] has shown that for every set  $A$  in NP-P, there exist disjoint sets  $B_1$  and  $B_2$  in NP-P such that  $A = B_1 \cup B_2$ .

Consider the proof of result (2): To decide  $B_1$  with oracle  $B_1 \cup B_2$ , on input  $x$ , if  $x \notin B_1 \cup B_2$ , then reject, else simultaneously enumerate  $B_1$  and  $B_2$  until  $x$  is output. Accept if the enumeration of  $B_1$  outputs  $x$  and reject if the enumeration of  $B_2$  outputs  $x$ .

The proof just given certainly suggests that the analogue of result (2) is false. More to the point perhaps, if  $B_1 \leq_T^P B_1 \cup B_2$  for every disjoint pair of sets  $B_1$  and  $B_2$  in NP, then  $\text{NP} \cap \text{co-NP} = \text{P}$ . (To see this assertion, let  $B_1 \in \text{NP} \cap \text{co-NP}$ , let  $B_2 = \overline{B_1}$ , and observe that  $B_1 \cup B_2 = \Sigma^*$  is in P.) Since it is unlikely that  $\text{NP} \cap \text{co-NP} = \text{P}$ , it seems reasonable to conjecture (assuming  $\text{P} \neq \text{NP}$ ) that there exist disjoint sets  $B_1$  and  $B_2$  in NP-P such that  $B_1 \cup B_2 \in \text{NP-P}$  and  $B_1 \not\leq_T^P B_1 \cup B_2$ . Neither Ladner's proof [Lad75] of the analogue of result (1) nor Schöning's elegant treatment [Sch82] yields a proof of this conjecture, for their techniques give  $B_1 \leq_m^P B_1 \cup B_2$  and  $B_2 \leq_m^P B_1 \cup B_2$ .

Let  $A$  and  $B$  be disjoint sets in NP-P. Let  $p_A$  and  $p_B$  be associated polynomials, and let  $R_A$  and  $R_B$  be any polynomial-time recognizable associated relations. Let  $p_{A \cup B} = \max\{p_A, p_B\}$ . Since  $R_A$  and  $R_B$  satisfy both of the defining conditions (1) and (2), it follows readily that  $A \cup B = \{x \mid \exists y \mid y = p_{A \cup B}(|x|) \text{ and } [R_A(x, y) \vee R_B(x, y)]\}$ . Furthermore,  $[R_A(x, y) \vee R_B(x, y)]$  satisfies condition (2), where  $p_{A \cup B}$  is the appropriate bound. Therefore,  $[R_A(x, y) \vee R_B(x, y)]$  is an associated relation for  $A \cup B$ . Hence, it is consistent with our notation to define  $R_{A \cup B}$  to be the relation  $R_A \cup R_B$ .

LEMMA 2.  $\text{Prefix}(R_A) \leq_T^P \text{Prefix}(R_{A \cup B})$ , if  $A \cap B = \emptyset$ .

*Proof.* The following procedure gives the reduction.

```

input  $x \# u$ ;
if  $x \# u \notin \text{prefix}(R_{A \cup B})$ 
  then reject
else begin
   $y := u$ ;
  while  $\neg R_{A \cup B}(x, y)$  do
    if  $x \# y0 \in \text{prefix}(R_{A \cup B})$ 
      then  $y := y0$ 
    else if  $x \# y1 \in \text{prefix}(R_{A \cup B})$ 
      then  $y := y1$ 
    end;
  if  $R_A(x, y)$ 
    then accept
  else reject

```

□

The following theorem follows from the lemma and Proposition 1(iv).

**THEOREM 3.** *If  $A$  and  $B$  are  $\leq_T^P$ -complete for NP,  $A \cap B = \emptyset$ , then  $\text{prefix}(R_{A \cup B})$  is  $\leq_T^P$ -complete for NP.*

**THEOREM 4.** *If  $\text{prefix}(R_A) \cap \text{prefix}(R_B) = \emptyset$ , then  $\text{prefix}(R_A) \leq_T^P \text{prefix}(R_A) \cup \text{prefix}(R_B)$ .*

Thus, the analogue of result (2) about disjoint pairs of recursively enumerable sets is true when restricted to prefix sets. For the proof, simply observe that  $\text{prefix}(R_A) \cup \text{prefix}(R_B) = \text{prefix}(R_{A \cup B})$  when  $\text{prefix}(R_A)$  and  $\text{prefix}(R_B)$  are disjoint. In particular, the analogue of result (2) for  $\leq_T^P$ -complete sets is true when attention is restricted to prefix sets, i.e., the union of two disjoint  $\leq_T^P$ -complete prefix sets is  $\leq_T^P$ -complete. We would like to know whether this is true in general. Because of the following easy-to-prove proposition, we caution that it probably would be difficult to prove, if it is true.

**PROPOSITION 5.** *If the union of every pair of disjoint sets  $\leq_T^P$ -complete for NP is a  $\leq_T^P$ -complete set for NP, then  $P \neq \text{NP}$  implies  $\text{NP} \neq \text{co-NP}$ .*

**3.2. P-inseparable sets in NP.** A disjoint pair of sets in NP,  $A$  and  $B$ , are *P-separable* if there exists a set  $L$  in P such that  $A \subseteq L$  and  $B \subseteq \bar{L}$ ; they are *P-inseparable* otherwise.

It is known that there exist public-key cryptosystems that cannot be cracked in polynomial time only if there exist NP-complete P-inseparable sets, and that  $P \neq \text{UP}$  implies the existence of NP-complete P-inseparable sets [GS84]. It is not known whether this condition follows from the (presumably) weaker hypothesis  $P \neq \text{NP}$ . The following proposition states that if there exist disjoint NP-complete ( $\leq_T^P$ -complete for NP) sets  $A$  and  $B$  such that  $A \cup B$  is not NP-complete (not  $\leq_T^P$ -complete, respectively), then  $A$  and  $B$  are P-inseparable. Thus, if the  $\leq_T^P$ -complete sets for NP are not closed under disjoint union, then that fact has an equally interesting structural implication (namely, the existence of  $\leq_T^P$ -complete for NP P-inseparable sets).

**PROPOSITION 6.** *Let  $A \cup B \neq \Sigma^*$ . If  $A$  and  $B$  are P-separable sets in NP, then  $A \leq_m^P A \cup B$  and  $\text{prefix}(R_A) \leq_m^P \text{prefix}(R_{A \cup B})$ . As a consequence, if  $A$  is NP-complete ( $\leq_T^P$ -complete for NP), then  $A \cup B$  is NP-complete ( $\leq_T^P$ -complete for NP, respectively).*

*Proof.* Let  $L \in P$  be a set that separates  $A$  and  $B$ ,  $A \subseteq L$  and  $B \subseteq \bar{L}$ . Let  $a$  be a string in the complement of  $A \cup B$ . Define  $f(x) = \text{if } x \in L \text{ then } x \text{ else } a$ . Then,  $x \in A \leftrightarrow f(x) \in A \cup B$  and so  $A \leq_m^P A \cup B$ . Noting that  $x \# u \in \text{prefix}(R_A) \leftrightarrow x \# u \in \text{prefix}(R_{A \cup B})$  and  $x \in A$ , it follows that  $x \# u \in \text{prefix}(R_A) \leftrightarrow f(x) \# u \in \text{prefix}(R_{A \cup B})$ . Thus,  $\text{prefix}(R_A) \leq_m^P \text{prefix}(R_{A \cup B})$ . □

The case that there exist disjoint NP-complete sets  $A$  and  $B$  whose union is  $\Sigma^*$  is easy to analyze. In this case  $A = \bar{B}$  and so it must be the case that  $\text{NP} = \text{co-NP}$ .

$A \cup B$  is not NP-complete regardless of whether  $A$  and  $B$  are P-inseparable because only  $\Sigma^*$  can be  $\leq_m^P$ -reducible to  $\Sigma^*$ . However, it remains true that if  $A$  and  $B$  are P-separable, then  $A \cup B$  is  $\leq_T^P$ -complete for NP. Namely,  $A$  and  $B$  are P-separable if and only if  $A \in P$ .  $A \in P$  implies  $P = NP$ , from which it follows that  $\Sigma^*$  is  $\leq_T^P$ -complete for NP.

**3.3. Disjunctive-self-reducible sets in NP.** How specialized are the  $d$ -self-reducible sets prefix  $(R_A)$ ? The answer is they are not very specialized—every  $d$ -self-reducible set can be put into this form.

**THEOREM 7.** *If  $A$  is  $d$ -self-reducible, then there is an associated polynomial-time relation  $R_A$  such that  $A \equiv_d^P \text{prefix}(R_A)$ .*

*Proof.* Let  $A$  be  $d$ -self-reducible, and let the reduction be given by the polynomial time computable function  $f$ . A self-reducing tree for each  $x \in \Sigma^*$  is constructed as follows (cf. [Ko83]). The root of the tree is  $x$ . For each node  $y$ , its children are the smaller strings  $z_1, \dots, z_k$ . Note that the self-reducing tree for  $x$  is polynomial depth-bounded and that  $x \in A$  if and only if this tree has a path all of whose nodes are in  $A$ . A path has all of its nodes in  $A$  if and only if the leaf is in  $A$ , and this occurs if and only if the self-reducing machine for  $A$  accepts the leaf without generating further queries.

Now define  $R_A(x, y) \equiv [y \text{ is a path in the self-reducing tree of } x \text{ such that the leaf is accepted by the self-reducing machine for } A]$ .  $R_A$  is clearly a polynomial-time recognizable relation, and

$$x \in A \leftrightarrow \exists y |y| = p_A(|x|) \text{ and } R_A(x, y),$$

for some polynomial  $p_A$ . (Existence of  $p_A$  is guaranteed since  $f$  computes relative to some OK partial order.) Recall that by definition  $R_A$  and  $p_A$  must satisfy two conditions in order for  $R_A$  to be an associated polynomial-time recognizable relation for  $A$ . We just showed that  $R_A$  and  $p_A$  satisfy condition (1). For this reason, without possibility of confusion, let  $R_A$  denote the extension of  $R_A$  that satisfies condition (2), so that the resulting relation  $R_A$  is then an associated polynomial-time recognizable relation for  $A$ .

We know already that  $A \leq_m^P \text{prefix}(R_A)$ .

A string  $x \neq u$  belongs to  $\text{prefix}(R_A)$  if and only if  $u$  is a prefix of an accepting path in the self-reducing tree of  $x$ . Thus, a string  $x \neq u$  belongs to  $\text{prefix}(R_A)$  if and only if the string  $u$  encodes a sequence  $y_1, \dots, y_k, y_{\text{short}}$  such that

- (i)  $y_1 = x$ ;
- (ii) for all  $i, i = 1, \dots, k-1, y_{i+1}$  is a string produced by  $f$  on input  $y_i$ ;
- (iii) if  $y_{\text{short}} = \lambda$ , then  $y_k \in A$ , and if  $y_{\text{short}} \neq \lambda$ , then there is a string  $z$  such that  $y_{\text{short}}$  is a prefix of  $z, z$  is a string produced by  $f$  on input  $y_k$ , and  $z \in A$ .

If  $y_{\text{short}} = \lambda$ , then  $y_k$  is the only oracle call to  $A$ . If  $y_{\text{short}} \neq \lambda$ , then the queries to  $A$  are all of the children of  $y_k$  in the self-reducing tree of  $x$  that start with  $y_{\text{short}}$ . Since  $x \in A$  if and only if one of these children is in  $A$ , it follows that  $\text{prefix}(R_A) \leq_d^P A$ .  $\square$

**COROLLARY 8 [Ko83]** *If  $A$  is  $d$ -self-reducible, then  $A$  belongs to NP.*

Now we will gain further insight by comparing  $d$ -self-reducibility with other properties of sets in NP. A set  $A$  is defined in [Sel79] to be  $p$ -selective if there is a function  $f: \Sigma^* \times \Sigma^* \mapsto \Sigma^*$  that satisfies each of the following:

- (1)  $f$  is computable in polynomial time;
- (2)  $f(x, y) = x$  or  $f(x, y) = y$ ;
- (3)  $x \in A$  or  $y \in A \rightarrow f(x, y) \in A$ .

The following proposition summarizes known results about  $p$ -selective sets that we will use.

PROPOSITION 9. (i) [Sel79] *For every tally language  $T$ , there exists a  $\leq_T^P$ -equivalent  $p$ -selective set  $A$ , and if  $T \in \text{NP}$ , then  $A \in \text{NP}$ . Therefore, if  $E \neq \text{NE}$ , then there exist  $p$ -selective sets in  $\text{NP} - \text{P}$ .*

(ii) [Sel82] *If a set is both  $p$ -selective and  $d$ -self-reducible, then it belongs to  $\text{P}$ .*

(iii) [Sel82] *If  $A \leq_{\text{PIT}}^P B$  and  $B$  is  $p$ -selective, then  $A$  is  $p$ -selective.*

(iv) [Sel82]  *$A \in \text{P}$  if and only if  $A \leq_{\text{PIT}}^P \bar{A}$  and  $A$  is  $p$ -selective.*

By assertions (i) and (ii) of Proposition 9, it is fairly clear that not all sets in  $\text{NP} - \text{P}$  are  $d$ -self-reducible. In [BB86] the notion of self-producible circuit is defined and it is proved that a set  $A$  has self-producible circuits if and only if  $A$  is  $\leq_T^P$ -equivalent to a tally language. Therefore,  $E \neq \text{NE}$  implies there is a  $p$ -selective set in  $\text{NP} - \text{P}$  that has self-producible circuits. Thus, it is fairly clear that not even all sets with self-producible circuits in  $\text{NP} - \text{P}$  are  $d$ -self-reducible. However, these remarks do not explain anything about the  $\text{NP}$ -complete sets because Ko [Ko83] has shown that  $\text{NP}$ -complete sets cannot be  $p$ -selective unless the polynomial hierarchy collapses to  $\Sigma_2^P$ . (Specifically, Ko showed that  $p$ -selective sets have sparse oracles. The conclusion follows from [KL80].)

The question of whether all  $\text{NP}$ -complete sets are  $d$ -self-reducible is somewhat related to the Isomorphism Conjecture of Berman and Hartmanis [BH77]. The following proposition is presented without proof, for its proof is straightforward and it is probably known to others.

PROPOSITION 10. *If  $A$  is  $d$ -self-reducible and  $A \equiv_{\text{iso}}^P B$ , then  $B$  is  $d$ -self-reducible.*

All of the known  $\text{NP}$ -complete combinatorial problems are paddable and every two paddable  $\text{NP}$ -complete sets are  $\text{P}$ -isomorphic [BH77], [MY85]. The Isomorphism Conjecture asserts that all  $\text{NP}$ -complete sets are  $\text{P}$ -isomorphic. The Satisfiability Problem, for example, is paddable and is  $d$ -self-reducible also. Hence, the following corollary follows.

COROLLARY 11. *Every paddable  $\text{NP}$ -complete set is  $d$ -self-reducible.*

Therefore, all of the known  $\text{NP}$ -complete combinatorial problems are  $d$ -self-reducible. If there exist  $\text{NP}$ -complete sets that are not  $d$ -self-reducible, then there exist  $\text{NP}$ -complete sets that are not paddable and so the Berman-Hartmanis conjecture is false.

Despite Theorem 7 and Corollary 11, we have not been able to extend Theorem 4 to arbitrary  $d$ -self-reducible sets. In particular, we do not know whether the union of every pair of disjoint  $d$ -self-reducible sets  $\leq_T^P$ -complete for  $\text{NP}$  is a  $\leq_T^P$ -complete set for  $\text{NP}$ . By Proposition 5 and Corollary 11, if the two problematic assertions hold, the Berman-Hartmanis conjecture is true and the union of every pair of disjoint  $d$ -self-reducible sets  $\leq_T^P$ -complete for  $\text{NP}$  is a  $\leq_T^P$ -complete set for  $\text{NP}$ , then  $\text{P} \neq \text{NP}$  implies  $\text{NP} \neq \text{co-NP}$ .

Joseph and Young [JY85] have invented a class of  $\text{NP}$ -complete sets which are not obviously  $d$ -self-reducible, and hence are not obviously paddable. Very few structural properties are known for these sets. But, it is proved in [JY85] that if one of these  $\text{NP}$ -complete sets is not  $d$ -self-reducible, then there exist one-way functions.

By the way,  $d$ -self-reducibility and paddability are not equivalent notions on  $\text{NP}$ . To see this, let  $A$  be any  $p$ -selective set in  $\text{NP} - \text{P}$ . By Proposition (iii), no  $d$ -self-reducible set can be  $\leq_m^P$ -equivalent to  $A$ , but  $A \equiv_m^P A \times \Sigma^*$ , which is paddable by definition.

Since not all sets in  $\text{NP}$  are  $d$ -self-reducible, let us raise the question of whether all sets in  $\text{NP}$  are  $\leq_T^P$ -equivalent to a  $d$ -self-reducible set. If this is so, then, assuming  $E \neq \text{NE}$ , reducibilities could be distinguished in  $\text{NP}$  in a very strong way.

PROPOSITION 12. *Statement (a) implies statement (b).*

- (a) Every set  $A$  that belongs to  $NP-P$  is  $\cong_T^P$ -equivalent to some  $d$ -self-reducible set.
- (b)  $E \neq NE$  implies

$$\exists C, D [C \in NP, D \in NP, C \cong_T^P D, \text{ and } C \not\cong_{pitt}^P D].$$

*Proof.* Apply Proposition 9(i) to obtain a  $p$ -selective set  $D$  that belongs to  $NP-P$ . Let  $C$  be a  $\cong_T^P$ -equivalent  $d$ -self-reducible set. Then, by Proposition 9(ii) and (iii),  $C \not\cong_{pitt}^P D$ .  $\square$

(Let us compare Proposition 12 with Corollary 16 of [Sel82]. The latter result uses a different hypothesis,  $NP \cap \text{co-}NP \neq P$ , to obtain essentially the same conclusion as in Proposition 12. That assumption is used in order to obtain a set  $C$  in  $NP \cap NP-P$  that is not  $p$ -selective. Then, letting  $D = \bar{C}$ ,  $C \cong_T^P D$  is trivial and  $C \not\cong_{pitt}^P D$  follows from assertion (iv) of Proposition 9. In contrast, the sets  $C$  and  $D$  that are obtained in Proposition 12 are by assumption two different  $\cong_T^P$ -equivalent sets that belong to  $NP$  and the conclusion follows from Proposition 9(iii).)

If  $NP$  contains disjoint sets  $A$  and  $B$  such that  $\text{prefix}(R_A) \not\cong_m^P \text{prefix}(R_{A \cup B})$ , then reducibilities could be distinguished on  $NP$ .

PROPOSITION 13 (i) *If there exist disjoint sets  $A$  and  $B$  in  $NP-P$  such that  $\text{prefix}(R_A) \not\cong_m^P \text{prefix}(R_{A \cup B})$ , then " $\cong_T^P$ " and " $\cong_m^P$ " differ on  $NP$ .*

(ii) *If there exist disjoint  $\cong_T^P$ -complete sets  $A$  and  $B$  such that  $\text{prefix}(R_A) \not\cong_m^P \text{prefix}(R_{A \cup B})$ , then " $\cong_T^P$ -complete" and " $\cong_m^P$ -complete" are distinct.*

*Proof.* The first claim follows from Lemma 2. For the second claim, by Theorem 3,  $\text{prefix}(R_{A \cup B})$  is  $\cong_T^P$ -complete for  $NP$ , but by the hypothesis, it is not  $\cong_m^P$ -complete.  $\square$

Is every set in  $NP-P$   $\cong_m^P$ -equivalent to a  $d$ -self-reducible set? We have already noted that the answer is *no*, for if  $E \neq NE$ , then  $NP-P$  contains a  $p$ -selective set  $A$  and no  $d$ -self-reducible set can be  $\cong_m^P$ -equivalent to  $A$ . It follows that for every associated relation  $R_A$ ,  $\text{prefix}(R_A) \not\cong_m^P A$ .

Perhaps every set  $A$  is  $\cong_T^P$ -equivalent to  $\text{prefix}(R_A)$  for *some* appropriate associated relation  $R_A$ . Is  $\text{prefix}(R_A) \cong_T^P A$  for every  $A$  and *every* associated relation  $R_A$ ? Assuming  $P \neq NP$ , the answer is *no*. The universal set  $\Sigma^*$  has an associated relation  $R_{\Sigma^*}$  that defines  $\Sigma^*$  as a member of  $NP$  such that  $\text{prefix}(R_{\Sigma^*})$  is  $NP$ -complete, and therefore  $\text{prefix}(R_{\Sigma^*}) \not\cong_T^P \Sigma^*$ . The proof is easy. Let  $SAT$  denote the  $NP$ -complete Satisfiability Problem. Let  $R_{\Sigma^*} = \{(x, y) | y = 0^{|x|^3} \text{ or } y = 1^{|x|^3 - |z|} z \text{ and } z \text{ is a satisfying assignment of } x\}$ .  $R_{\Sigma^*}$  is clearly an associated polynomial-time recognizable relation for  $\Sigma^*$ .  $\text{Prefix}(R_{\Sigma^*})$  is  $NP$ -complete because  $x \in SAT \leftrightarrow x \# 1 \in \text{prefix}(R_{\Sigma^*})$ .

The following theorem uses this construction in order to obtain a set  $A$  in  $NP-P$  and an associated polynomial-time recognizable relation  $R_A$  such that  $\text{prefix}(R_A)$  is  $\cong_T^P$ -complete for  $NP$  but  $A$  is not  $\cong_T^P$ -complete for  $NP$ .

THEOREM 14. *Assume  $NP \neq P$ . There exists a set  $A \in NP-P$  and an associated relation  $R_A$  such that  $\text{prefix}(R_A)$  is  $\cong_T^P$ -complete for  $NP$  and  $A$  is not  $\cong_T^P$ -complete for  $NP$ . Thus,  $\text{prefix}(R_A) \not\cong_T^P A$ .*

*Proof.* Choose  $L \in NP-P$ . Choose  $B \in NP-P$  such that  $B \cong_T^P L$  but  $L \not\cong_T^P B$  [Lad75]. Let  $B_0 = \{0x | x \in B\}$  and let  $B_1 = \{1x | x \in \Sigma^*\}$ . Let  $R_{\Sigma^*}$  be an associated polynomial-time recognizable relation for  $\Sigma^*$  such that  $\text{prefix}(R_{\Sigma^*})$  is  $NP$ -complete. Let  $R_{B_0}$  be any associated relation for  $B_0$  and define  $R_{B_1}$  so that

$$R_{B_1}(ax, y) \equiv [a = 1 \wedge R_{\Sigma^*}(x, y)].$$

Noting that  $B_0 \cap B_1 = \emptyset$ , define  $A = B_0 \cup B_1$  and let  $R_A = R_{B_0} \cup R_{B_1}$ .

Clearly  $A \cong_T^P B$ , because  $ax \in A \leftrightarrow (a = 0 \wedge x \in B) \vee a = 1$ , and  $x \in B \leftrightarrow 0x \in A$ . Therefore,  $A$  is not  $\cong_T^P$ -complete for  $NP$ .

Now we will show that  $\text{prefix}(R_{\Sigma^*}) \leq_T^P \text{prefix}(R_A)$ . Since  $\text{prefix}(R_{\Sigma^*})$  is NP-complete, this will complete the proof:

$$\begin{aligned} \text{prefix}(R_{\Sigma^*}) &\leq_T^P \text{prefix}(R_{B_1}) && \text{(by definition of } R_{B_1}) \\ &\leq_T^P \text{prefix}(R_{B_0 \cup B_1}) && \text{(by Lemma 2)} \\ &= \text{prefix}(R_A). \end{aligned}$$

## AXIOMATISING FINITE CONCURRENT PROCESSES\*

MATTHEW HENNESSY†

**Abstract.** We re-examine the well-known observational equivalence between processes with a view to modifying it so as to distinguish between concurrent and purely nondeterministic processes.

Observational equivalence is based on atomic actions or observations. In the first part of this paper we generalise these atomic observations so that arbitrary processes may act as observers. We show, for a particular language based on finite (CCS) terms, that the generalised equivalence coincides with observational equivalence; the more powerful observers do not lead to a finer equivalence.

In the second part of the paper we consider observers which can distinguish the beginning and ending of atomic actions. The resulting equivalence distinguishes a concurrent process from the purely nondeterministic process obtained by interleaving its possible actions. We give a complete axiomatisation for the congruence generated by the new equivalence.

**Key words.** concurrent processes, observational equivalence, noninterleaving

**CR classification.** F.3.2

**Introduction.** In [Mil1], [Mil2] Milner has developed a semantic theory of processes called observational or bisimulation equivalence. Intuitively two processes are deemed to be equivalent if there is no observational method for distinguishing them. We observe a process by communicating with it and this act of observation changes the subsequent behaviour of the process. A suitable formulation of these ideas leads to observational equivalence. It is the basis of a very elegant semantic theory of processes and has gained considerable popularity. When applied to algebraic languages for describing processes it can be characterised equationally [He]. This in turn leads to transformational proof techniques for showing that a process implementation meets its specification [Mil1].

However, this semantic theory does not treat concurrency as a primitive independent notion: every concurrent process is equivalent to a nondeterministic but sequential process. Consider, for example, the language CCS [Mil1]. Here  $p|q$  represents the process which consists of two subprocesses in parallel,  $p$  and  $q$ . As simple examples of such subprocesses consider  $aNIL$ ,  $bNIL$ , respectively. These are subprocesses which can only perform one action (called  $a$ ,  $b$ , respectively) and then die. The parallel process  $aNIL|bNIL$  is observationally equivalent to a sequential nondeterministic process, obtained by interleaving the possible atomic actions of the two subprocesses  $aNIL$ ,  $bNIL$ . In CCS this equivalent process is written as  $abNIL + baNIL$ . In general, no matter how complicated  $p$  and  $q$  might be, such a reduction is always possible although the resulting nondeterministic process may not be syntactically expressible in the description language under consideration.

The popularity of observational equivalence (and related equivalences) bears witness to the usefulness of a semantic theory based on interleaving, where concurrency is reduced to nondeterminism. Nevertheless, at an intuitive level the reduction of concurrency to nondeterminism seems unsatisfactory; surely one important property

---

of a concurrent process is the fact that it is composed of independent and possibly distributed processes.

The aim of this paper is to investigate semantic equivalences which do not reduce concurrency to nondeterminism. More specifically, we would like to use the basic paradigm of observational equivalence to develop behavioural equivalences which reflect in some way the concurrent nature of processes.

To continue this discussion it is necessary to describe in more detail observational equivalence. Let  $P$  denote a set of processes. The operational behaviour of these processes may be defined by describing the set of moves or actions which they can perform. By and large we will not be concerned with the nature of these actions nor with how we assign specific actions to specific processes, although we will see an example later in the paper. At this stage it suffices to say that for each action  $a$  there is a binary relation  $\overset{a}{\Rightarrow}$  over processes;  $p \overset{a}{\Rightarrow} q$  means that the process  $p$  may perform the action  $a$  and performing this action may transform it into the process  $q$ . In general  $\overset{a}{\Rightarrow}$  will be a relation because not every process can perform every action and individual processes may be capable of performing an action in various different ways.

Observational equivalence,  $\approx$ , is defined with respect to such a description of the operational behaviour of processes. It satisfies the following property:

(\*) if  $p \approx q$  and  $p \overset{a}{\Rightarrow} p'$ , then  $q \overset{a}{\Rightarrow} q'$  for some  $q'$  such that  $p' \approx q'$ .

Here  $p \overset{a}{\Rightarrow} p'$  may be termed an observation and so (\*) may be interpreted as saying that if  $p$  and  $q$  are observationally equivalent then they have similar observations. In fact  $\approx$  may be defined to be the largest symmetric relation which satisfies (\*). So, contrapositively, if  $p$  is not equivalent to  $q$  there is some observation of one which has no equivalent observation of the other.

When we apply this definition to languages such as CCS we are unable to distinguish concurrency from interleaving. Let us now look at how, while retaining the basic paradigm (\*), we might modify the definition so as to obtain a more discriminating equivalence. It uses the basic observations  $p \overset{a}{\Rightarrow} p'$  and we first consider the possibility of employing similar but more complex observations. The basic observation  $p \overset{a}{\Rightarrow} p'$  may be viewed as a successful communication between an unidentified external process and the process under observation,  $p$ . Indeed, in the usual formulation of the operational semantics of languages such as CCS, communication is defined as mutual observation. In this formulation  $p \overset{a}{\Rightarrow} p'$  is true exactly when a process such as  $aq$  can communicate with  $p$ . The effect of this communication on  $p$  is to transform it into  $p'$ . It also transforms the observer  $aq$  into  $q$ . So the total effect of the observation or communication may be described by

$$\langle p, aq \rangle \rightarrow \langle p', q \rangle.$$

However, in the definition of observational equivalence given above in (\*) no use is made of the residual of the observer. From the point of view of the definition we may take as observers the simple atomic processes  $aNIL$ ; the only observations used are of the form

$$\langle p, aNIL \rangle \rightarrow \langle p', NIL \rangle.$$

This reformulation of observational equivalence leads to the obvious generalisation where we allow as observers arbitrarily complicated processes. This includes observers which consist of many subprocesses each independently probing the process under observation.

Such a generalised observational equivalence is defined and investigated in § 1. The main theorem of this section states that this increase in the power of observers does not result in a more discriminating equivalence; the equivalence defined using arbitrary observers coincides with the equivalence defined using atomic observers only. This theorem is proved for a particular language based on CCS. However, the proof is so general that it should be widely applicable.

Faced with this setback we must examine more carefully the implicit assumptions underlying observational equivalence. One assumption is that observers, no matter how complicated, have only a monolithic view of the process under observation. They never get a separate view of subparts of the process nor are they allowed to experiment independently on these distinct subparts. In a separate paper we investigate generalisations of observational equivalence where observers are endowed with such powers. Here we weaken a different underlying assumption.

In the usual operational semantics of languages such as CCS, and the related observational equivalence, communication (or observation) is taken to be an instantaneous indivisible event. However it can be argued that there are at least two events: the communication as seen by the two processes in question. We postulate that these two events are different or that they take a certain amount of time. Rather than associate specific durations with actions, we introduce observers which can distinguish the initialisation of a communication from its termination. The observational equivalence based on these new observers is more discriminating. In particular, it can distinguish concurrency from nondeterminism.

The new equivalence is the topic of § 2. It is defined for a simple language for describing finite communicating processes, based on CCS. The main result of this section is that the related congruence can be completely characterised by a set of equations. An equational characterisation is one of the main attractions of the standard observational equivalence as such equations form the basis for transformational proof systems for processes. Thus our result provides a basis for a similar type of proof system which takes into consideration the concurrent nature of processes.

In a final section we briefly examine other formulations of our new equivalence and related work.

**1. Generalised observational equivalence.** In this section we reformulate the standard definition of observational equivalence so as to allow arbitrarily complex observers. The definition and some general consequences are given in § 1.1. In the next section it is applied to a CCS-like language and we prove that in this setting it is sufficient to consider simple atomic observers; the addition of the more complex observers does not add to the distinguishing power of the equivalence. In the final section we prove that our reformulation of observational equivalence does indeed coincide with the standard version of observational equivalence, as defined, say, in [Mil2]. We also provide an equational characterisation of the associated congruence.

**1.1.** A general notion of observation must take into account not only the effect the observation has on the observed but also on the observers themselves. Let  $O, P$  be sets of *observers*, *processes*, respectively. For the moment we are not interested in the composition of these objects. We use  $C$  to denote  $O \times P$  which we call the set of *configurations*. A set of observations is given by any relation  $\rightarrow \subseteq C \times C$ . We write  $\langle o, p \rangle \rightarrow \langle o', p' \rangle$  rather than  $\langle \langle o, p \rangle, \langle o', p' \rangle \rangle \varepsilon \rightarrow$  as it is more suggestive. It means that the act of  $o$  observing  $p$  changes the observer  $o$  into  $o'$  and the observed process  $p$  into  $p'$ . We define an equivalence of “indistinguishability” between processes,  $\sim_P$ , and a similar equivalence between observers,  $\sim_O$ . Intuitively  $p \sim_P p'$  means that there is no

way of observing any different behaviour between  $p$  and  $p'$  while  $o \sim_O o'$  means that both  $o$  and  $o'$  have exactly the same observational power. Following these intuitive ideas we would expect these relations to satisfy the following:

(a) If  $p \sim_P p'$ , then whenever  $\langle o, p \rangle \rightarrow \langle o', q \rangle$  there exists a configuration  $\langle o'', q' \rangle$  such that  $\langle o, p' \rangle \rightarrow \langle o'', q' \rangle$  where  $o' \sim_O o''$  and  $q \sim_P q'$ .

(b) If  $o \sim_O o'$ , then whenever  $\langle o, p \rangle \rightarrow \langle o'', q \rangle$  there exists a configuration  $\langle o''', q' \rangle$  such that  $\langle o'p \rangle \rightarrow \langle o''', q' \rangle$ , where  $o'' \sim_O o'''$  and  $q \sim_P q'$ .

In fact, we take (a), (b) (and their symmetric counterparts) to be the definitions of  $\sim_P, \sim_O$ . The inherent circularity of the definition is handled by using maximal fixpoints.

In the formal definition we use the following notation. For  $R_1 \subseteq O \times O, R_2 \subseteq P \times P$  let  $R_1 \times R_2 \subseteq C \times C$  be defined by  $\langle \langle o, p \rangle, \langle o', p' \rangle \rangle \in R_1 \times R_2$  if  $\langle o, o' \rangle \in R_1$  and  $\langle p, p' \rangle \in R_2$ .

DEFINITION 1.1.1. For  $R_1 \subseteq O \times O, R_2 \subseteq P \times P$  define  $D_1(R_1, R_2) \subseteq O \times O, D_2(R_1, R_2) \subseteq P \times P$  by the following:

(i)  $\langle o, o' \rangle \in D_1(R_1, R_2)$  if for every  $p$  in  $P$   $\langle o, p \rangle \rightarrow c$  implies  $\langle o', p \rangle \rightarrow c'$  for some configuration  $c'$  such that  $\langle c, c' \rangle \in R_1 \times R_2$ .

(ii)  $\langle p, p' \rangle \in D_2(R_1, R_2)$  if for every  $o$  in  $O$   $\langle o, p \rangle \rightarrow c$  implies  $\langle o, p' \rangle \rightarrow c'$  for some configuration  $c$  such that  $\langle c, c' \rangle \in R_1 \times R_2$ .  $\square$

Viewed as a tuple of functions over relations  $D_1, D_2$  are monotonic with respect to set inclusion. Therefore we may take  $\sim_O, \sim_P$  to be the maximal pair of symmetric relations which satisfies the equations

$$R_1 = D_1(R_1, R_2), \quad R_2 = D_2(R_1, R_2).$$

It is straightforward to show that both  $\sim_O$  and  $\sim_P$  are equivalence relations and by definition they satisfy (a) and (b) above. Readers familiar with the standard definition of observational equivalence should recognise that  $\sim_P, \sim_O$  are attempts at a straightforward generalisation to include more complicated observers. In § 1.3 we will actually see that the standard observational equivalence may be obtained from ours by restricting attention to what we will call atomic observers.

We first put a natural restriction on our systems of observations. We wish to examine how processes react in environments of other processes. Therefore we assume  $O = P$ . Further, we assume that “observing” and “being observed” are the same. So we assume that every observation relation  $\rightarrow$  satisfies

$$\langle o, p \rangle \rightarrow \langle o', p' \rangle \quad \text{if and only if} \quad \langle p, o \rangle \rightarrow \langle p', o' \rangle.$$

LEMMA 1.2. *If  $O = P$  and  $\rightarrow$  satisfies the above condition, then  $\sim_O$  and  $\sim_P$  coincide and are the maximal fixpoints of both of the equations*

$$R = D_1(R, R) \quad \text{and} \quad R = D_2(R, R).$$

*Proof.* Because of the symmetry of  $\rightarrow$  it is easy to show

$$(*) \quad \sim_O \subseteq D_2(\sim_P, \sim_O),$$

$$(**) \quad \sim_P \subseteq D_2(\sim_P, \sim_O),$$

from which it follows that  $\sim_O = \sim_P$ .

Let  $X$  denote the maximal fixpoint of  $R = D_1(R, R)$ . Because of (\*) it now follows that  $\sim_P \subseteq X$ . To show the converse, it is sufficient to prove  $X \subseteq D_1(X, X)$  which once again follows from the symmetry of  $\rightarrow$ .  $\square$

In the case when  $O$  and  $P$  coincide the resulting equivalence,  $\sim_O = \sim_P$ , is called *generalised bisimulation equivalence*, and will usually be denoted by  $\sim_O$ . We wish to

show that in fact there is no need to take observations with respect to the entire set of observers; a much smaller set will generate exactly the same equivalence. Note that the definition of  $\sim_O, \sim_P$  can be parameterised with respect to an arbitrary subset of observers. We are only interested in one particular subset, which we now explain.

An observer  $o$  is *blind* if for every  $p$  in  $P$   $\langle o, p \rangle \rightarrow \langle o', p' \rangle$  implies  $o'$  coincides with  $o$ ; a blind observer never changes state and therefore cannot perceive any difference in the process being observed. The observer  $o$  is *atomic* if for every  $p$  in  $P$   $\langle o, p \rangle \rightarrow \langle o', p' \rangle$  implies  $o'$  is blind. So atomic observers may make at most one observation. Let  $A \subseteq O$  denote the set of atomic observers. Definition 1.1.1 can now be modified so as to apply to  $A$  rather than  $O$ :

For  $R_1 \subseteq A \times A, R_2 \subseteq P \times P$  let  $E_1(R_1, R_2) \subseteq A \times A, E_2(R_1, R_2) \subseteq P \times P$  be defined by the following.

(i)  $\langle o, o' \rangle \in E_1(R_1, R_2)$  if for every  $p$  in  $P$   $\langle o, p \rangle \rightarrow c$  implies  $\langle o', p \rangle \rightarrow c'$  for some configuration  $c'$  such that  $\langle c, c' \rangle \in R_1 \times R_2$ .

(ii)  $\langle p, p' \rangle \in E_2(R_1, R_2)$  if for every  $o \in A$   $\langle o, p \rangle \rightarrow c$  implies  $\langle o, p' \rangle \rightarrow c'$  for some configuration  $c'$  such that  $\langle c, c' \rangle \in R_1 \times R_2$ .

Let  $\sim_{OA}, \sim_A$  be the maximal symmetric solutions to the pair of equations

$$R_1 = E_1(R_1, R_2), \quad R_2 = E_2(R_1, R_2).$$

The equivalence on observers  $\sim_{OA}$  is uninteresting but  $\sim_A$  is a formalisation of the idea that processes are equivalent unless they can be distinguished by atomic observers. In the next section we show  $\sim_P$  and  $\sim_A$  coincide, at least when applied to a particular language.

**1.2. A simple language.** The language used is a simple extension of “finite CCS.” The only innovation is an asymmetric version of the usual parallel combinator  $|$ , which we denote by  $\vdash$ . Intuitively  $p \vdash q$  acts in exactly the same way as  $p|q$  except that the very first action should involve the subprocess  $p$ .

Let  $\text{Act}$  be a set of actions which as usual we assume has the form  $\{\tau\} \cup \Lambda \cup \bar{\Lambda}$ , where

- $\Lambda$  is a given set of names,
- $\bar{\Lambda} = \{\bar{a}, a \in \Lambda\}$ , the complements of names in  $\Lambda$ ,
- $\tau$  is a distinguished action.

The distinguished action  $\tau$  is used to denote internal invisible actions and in our language these occur when subprocesses communicate with each other. Communication is modelled by the simultaneous occurrence of an action such as  $a$  with its complement  $\bar{a}$ . Notationally it is convenient to assume that complementation is symmetric, i.e.,  $\bar{\bar{a}} = a$ . We use  $\mu, \gamma$ , etc., to range over  $\text{Act}$  unless otherwise stated, and  $a, b$ , etc., to range over the restricted set of visible actions  $\Lambda \cup \bar{\Lambda}$ . We will sometimes use  $\text{VAct}$  to denote this set,  $\Lambda \cup \bar{\Lambda}$ . The language we use is given by the BNF definition

$$p := \text{NIL} \mid \mu p \mid p + q \mid p \mid q \mid p \vdash q.$$

For the remainder of the paper we let  $P$  denote the set of processes defined by this language. We assume prefixing,  $\mu$ -, binds stronger than  $\vdash, |$ , which in turn bind stronger than  $+$ . We also omit most occurrences of  $\text{NIL}$ , for example, rendering  $a\text{NIL} + b\text{NIL}$  simply as  $a + b$ .

We now define a system of observations based on this language. The processes to be observed are all those definable in the language and we use exactly the same processes as observers. Observation is simply a form of communication. Consequently the definition of observation relies mainly on what we mean by communication. This is defined in Fig. 1:  $p \xrightarrow{x} q$  means that  $p$  may be transformed into  $q$  by performing an

$$\begin{array}{ll}
\text{(I)} & \tau p \xrightarrow{\tau} p \\
\text{(II)} & p \xrightarrow{a} p', q \xrightarrow{\bar{a}} q' \text{ implies } p|q \xrightarrow{\tau} p'|q' \\
\text{(III)} & ap \xrightarrow{\mu} p \\
\text{(IV)} & p \xrightarrow{\mu} p' \text{ implies } p + q \xrightarrow{\mu} p' \\
& q + p \xrightarrow{\mu} p' \\
\text{(V)} & p \xrightarrow{\mu} p' \text{ implies } p|q \xrightarrow{\mu} p'|q \\
& p \uparrow q \xrightarrow{\mu} p'|q \\
& q|p \xrightarrow{\mu} q|p'
\end{array}$$

FIG. 1. *Communication.*

internal communication. To make the language more expressive we have included a direct syntactic representation of internal actions and this accounts for rule (I). The next rule is the principal one: communication is the simultaneous occurrence of complementary actions.  $p \xrightarrow{a} p'$  means that  $p$  may perform the action  $a$  and thereby be transformed into  $p'$ . So  $p|q$  may perform a communication to be transformed into  $p'|q'$  whenever  $p \xrightarrow{a} p'$  and  $q \xrightarrow{\bar{a}} q'$ , i.e., whenever  $p$  and  $q$  can perform complementary actions. The remaining rules merely state how external actions are produced and how actions, both external and internal communications, factor through the operators.

The definition of the observation relation  $\rightarrow$  is given in Fig. 2. It is the least relation which satisfies rules (I), (II), and (III). The essential rule is (I) which states that the basic method of observation is by communication. Rule (II) states that simultaneous observations are allowed. The final rule states that observation is asynchronous; an observation is not a simple discrete step but an indeterminate sequence of interactions between observations.

*Examples.*

$$(1) \quad \langle \bar{a}b\bar{o}, a(c+bp) | eq \rangle \rightarrow \langle o, p | eq \rangle.$$

This observation comes about by virtue of two communications between the observer and the observed, the first via the action  $a$ , the second via  $b$ .

$$(2) \quad \langle \bar{a}(cbo_1 | (\bar{c}o_2 + d)), a(c+bp) | eq \rangle \rightarrow \langle o_1 | o_2, p | eq \rangle.$$

$$\begin{array}{ll}
\text{(I)} & o|p \xrightarrow{\tau} o'|p' \text{ implies } \langle o, p \rangle \rightarrow \langle o', p' \rangle \\
\text{(II)} & \langle o_1, p_1 \rangle \rightarrow \langle o'_1, p'_1 \rangle, \langle o_2, p_2 \rangle \rightarrow \langle o'_2, p'_2 \rangle \\
& \text{implies } \langle o_1 | o_2, p_1 | p_2 \rangle \rightarrow \langle o'_1 | o'_2, p'_1 | p'_2 \rangle \\
\text{(III)} & \text{(a) } c \rightarrow c \\
& \text{(b) } c \rightarrow c', c' \rightarrow c'' \text{ implies } c \rightarrow c'
\end{array}$$

FIG. 2. *Observations.*

Here there are also two interactions, but this time they are separated by a communication internal to the observer.

$$(3) \quad \langle ao_1 | (bo_2 + co_3), \bar{a}p_1 | \bar{b}p_2 \rangle \rightarrow \langle o_1 | o_2, p_1 | p_2 \rangle.$$

This involves two independent simultaneous observations of different subprocesses of the observed process, the observer  $ao_1$  observing the subprocess  $\bar{a}p$  and the observer  $bo_2 + co_3$  observing  $\bar{b}p_2$ .

$$(4) \quad \langle ao_1 | bo_2 + do_3, \bar{a}p_1 | c\bar{b}p_2 | \bar{c}p_3 \rangle \rightarrow \langle o_1 | o_2, p_1 | p_2 | p_3 \rangle.$$

In this case the two independent observations are separated by a computation internal to the observed process.  $\square$

It is straightforward to prove that this particular observation relation  $\rightarrow$  is symmetric. First we can prove  $p | q \xrightarrow{x} p' | q'$  implies  $q | p \xrightarrow{x} q' | p'$ , using induction on the length of the proof of  $p | q \xrightarrow{x} p' | q'$ . Using the same inductive proof method, we can then show  $\langle o, p \rangle \rightarrow \langle o', p' \rangle$  implies  $\langle p, o \rangle \rightarrow \langle p', o' \rangle$ .

Following the general definition we therefore have a generalised bisimulation equivalence  $\sim_O$  over  $P$ . Following the restricted definition we also have  $\sim_A$  over  $P$ , observational equivalence. Superficially this looks much weaker but in fact we have the following.

**THEOREM 1.2.1.**  $p \sim_O q$  if and only if  $p \sim_A q$ .  $\square$

In effect, the weakness of the observers is compensated for by the power of the observational method.

One direction of the theorem is very straightforward.

**LEMMA 1.2.2.**  $p \approx_O q$  implies  $p \sim_A q$ .

*Proof.* Let  $\sim'$  denote  $\sim_O \cap (A \times A)$ . Then referring to the definitions in the previous section, it is sufficient to show

$$\sim' \subseteq E_1(\sim', \sim_O), \quad \sim_O \subseteq E_2(\sim', \sim_O).$$

This is immediate because  $\sim_O$  satisfies

$$\sim_O = D_1(\sim_O, \sim_O), \quad \sim_O = D_2(\sim_O, \sim_O)$$

and the set of atomic observers is a subset of the complete set of observers.  $\square$

Note that to carry out this proof we did not need to know the atomic observers. They are essentially of the form  $NIL$  or  $aNIL$ . To prove the converse we introduce the set of *sequential observers*, observers of the form  $a_1 \cdots a_k NIL$ ,  $k \geq 0$ . We will assume that the distinguished action  $\tau$  does not appear in any sequential observer. The complementation notation is also extended to these terms in the natural way:  $\bar{a}_1 \cdots \bar{a}_k NIL$  is the complement of  $a_1 \cdots a_k NIL$ .

The first result we need is that these new observers are no more powerful than simple atomic ones.

**LEMMA 1.2.3.** If  $p \sim_A q$  and  $\langle s, p \rangle \rightarrow \langle NIL, p' \rangle$  where  $s$  is a sequential observer, then  $\langle s, q \rangle \rightarrow \langle NIL, q' \rangle$  for some  $q'$  such that  $p' \sim_A q'$ .

*Proof.* The proof is induction on the length of  $s$ . If this is zero or one, then the result follows by the definition of  $\sim_A$ . So we may assume  $s$  has the form  $at$ .

We can now prove by induction on the length of the proof of  $\langle at, p \rangle \rightarrow \langle NIL, p' \rangle$  that  $p \xrightarrow{x}^* q$  for some  $q$  such that  $q \xrightarrow{\bar{a}} r$  and  $\langle t, r \rangle \rightarrow \langle NIL, p' \rangle$ . (Here  $\xrightarrow{x}^*$  is the reflexive transitive closure of  $\xrightarrow{x}$ .) This proof uses in turn the fact that  $\langle at, p \rangle \rightarrow \langle t, x \rangle$  implies  $p \xrightarrow{x}^* q \xrightarrow{\bar{a}} r$  for some terms  $q$  and  $r$ . This means we have the atomic observation  $\langle aNIL, p \rangle \rightarrow \langle NIL, r \rangle$ . By the definition of  $\sim_A$ , we therefore have that  $\langle aNIL, q \rangle \rightarrow \langle NIL, r' \rangle$  for some  $r'$  such that  $r \sim_A r'$ . Now using the inductive hypothesis on  $\langle t, r \rangle \rightarrow \langle NIL, p' \rangle$ , we may assume  $\langle t, r' \rangle \rightarrow \langle NIL, q' \rangle$  for some  $q'$  such that  $p' \sim_A q'$ . The atomic

observation  $\langle aNIL, q \rangle \rightarrow \langle NIL, r' \rangle$  can be modified to give the observation  $\langle at, q \rangle \rightarrow \langle t, r' \rangle$ , which when combined with  $\langle t, r' \rangle \rightarrow \langle NIL, q' \rangle$  gives the required observation  $\langle at, q \rangle \rightarrow \langle NIL, q' \rangle$ .  $\square$

The essential part of the proof of the main result is that all observations can be sequentialised. This is formalised as follows.

LEMMA 1.2.4. *If  $\langle o, p \rangle \rightarrow \langle o', p' \rangle$ , then there exists a sequential observer  $s$  such that  $\langle s, o \rangle \rightarrow \langle NIL, o' \rangle$  and  $\langle \bar{s}, p \rangle \rightarrow \langle NIL, p' \rangle$ .*

*Proof.* The proof is by induction on the length of the derivation of  $\langle o, p \rangle \rightarrow \langle o', p' \rangle$ .

(i)  $o | p \xrightarrow{x} o' | p'$ . This case requires a separate proof by induction on the length of the derivation of  $o | p \xrightarrow{x} o' | p'$ . This is straightforward and is left to the reader. Note that the resulting  $s$  will be of length at most one.

(ii)  $\langle o_1 | o_2, p_1 | p_2 \rangle \rightarrow \langle o'_1 | o'_2, p'_1 | p'_2 \rangle$  because  $\langle o_1, p_1 \rangle \rightarrow \langle o'_1, p_1 \rangle$  and  $\langle o_2, p_2 \rangle \rightarrow \langle o'_2, p'_2 \rangle$ . By induction we have two sequences  $s_1, s_2$  such that

$$\begin{aligned} \langle s_1, o_1 \rangle &\rightarrow \langle NIL, o'_1 \rangle, & \langle \bar{s}_1, p_1 \rangle &\rightarrow \langle NIL, p'_1 \rangle, \\ \langle s_2, o_2 \rangle &\rightarrow \langle NIL, o'_2 \rangle, & \langle \bar{s}_2, p_2 \rangle &\rightarrow \langle NIL, p'_2 \rangle. \end{aligned}$$

Let  $s$  denote  $s_1 s_2$ . (The sequence  $s_2 s_1$  could also be used.) The observation  $\langle s_1 o_1 \rangle \rightarrow \langle NIL, o'_1 \rangle$  can be transformed into the observation  $\langle s, o_1 | o_2 \rangle \rightarrow \langle s_2, o'_1 | o_2 \rangle$  and the observation  $\langle s_2, o_2 \rangle \rightarrow \langle NIL, o'_2 \rangle$  can be transformed into  $\langle s_2, o'_1 | o_2 \rangle \rightarrow \langle NIL, o'_1 | o'_2 \rangle$ . Therefore,  $\langle s, o_1 | o_2 \rangle \rightarrow \langle NIL, o'_1 | o'_2 \rangle$ .

In a similar fashion we can derive  $\langle \bar{s}, p_1 | p_2 \rangle \rightarrow \langle NIL, p'_1 | p'_2 \rangle$ .

(iii) (a)  $\langle o, p \rangle \rightarrow \langle o, p \rangle$ . The required  $s$  is  $NIL$ .

(b)  $\langle o, p \rangle \rightarrow \langle o'', p'' \rangle, \langle o'', p'' \rangle \rightarrow \langle o', p' \rangle$ . In this case the proof is similar to part (ii).  $\square$

The converse of this lemma is also true.

LEMMA 1.2.5. *If  $\langle s, o \rangle \rightarrow \langle NIL, o' \rangle, \langle \bar{s}, p \rangle \rightarrow \langle NIL, p' \rangle$  where  $s$  is a sequential observer, then*

$$\langle o, p \rangle \rightarrow \langle o', p' \rangle.$$

*Proof.* The proof is by induction on the length of  $s$ .

(i) If  $s$  is  $NIL$ . Here we have that  $\langle NIL, o \rangle \rightarrow \langle NIL, o' \rangle$  and  $\langle NIL, p \rangle \rightarrow \langle NIL, p' \rangle$ . As in the previous lemma, these can be transformed to  $\langle o, p \rangle \rightarrow \langle o', p \rangle$  and  $\langle o', p \rangle \rightarrow \langle o', p' \rangle$  respectively, which leads to  $\langle o, p \rangle \rightarrow \langle o', p' \rangle$ .

(ii)  $s$  is  $aNIL$ . In this case we must use induction on the combined length of the derivations of  $\langle aNIL, o \rangle \rightarrow \langle NIL, o' \rangle$  and  $\langle \bar{a}NIL, p \rangle \rightarrow \langle NIL, p' \rangle$ . The base case is when  $o \xrightarrow{a} o'$  and  $p \xrightarrow{\bar{a}} p'$ . In this case  $o | p \xrightarrow{x} o' | p'$  and therefore  $\langle o, p \rangle \rightarrow \langle o', p' \rangle$ .

There are a large number of induction cases, all of which are straightforward. A typical example is when

$$\begin{aligned} \langle aNIL, o \rangle &\rightarrow \langle aNIL, o_1 \rangle \rightarrow \langle NIL, o' \rangle, \\ \langle aNIL, p \rangle &\rightarrow \langle NIL, p_1 \rangle \rightarrow \langle NIL, p' \rangle. \end{aligned}$$

The required observation is obtained in this case by combining the sequence of observations:

$$\langle o, p \rangle \rightarrow \langle o_1, p \rangle \rightarrow \langle o', p_1 \rangle \rightarrow \langle o', p' \rangle.$$

In this sequence the first observation is obtained by transforming  $\langle aNIL, o \rangle \rightarrow \langle aNIL, o_1 \rangle$ , the second by the inductive hypothesis and the third by transforming  $\langle NIL, p_1 \rangle \rightarrow \langle NIL, p' \rangle$ .

(iii) More generally, suppose  $s$  has the form  $at$ . In this case we can apply induction and the previous case.

If  $\langle at, o \rangle \rightarrow \langle NIL, o' \rangle$ , then there exists some  $o''$  such that  $\langle at, o \rangle \rightarrow \langle t, o'' \rangle$  and  $\langle t, o'' \rangle \rightarrow \langle NIL, o' \rangle$ . (This requires a separate proof.) The first derivation  $\langle at, o \rangle \rightarrow \langle t, o'' \rangle$  gives rise to a derivation  $\langle aNIL, o \rangle \rightarrow \langle NIL, o'' \rangle$ . Similarly, the derivation  $\langle \bar{a}\bar{t}, p \rangle \rightarrow \langle NIL, p' \rangle$  may be decomposed into  $\langle \bar{a}\bar{t}, p \rangle \rightarrow \langle \bar{t}, p'' \rangle$  and  $\langle \bar{t}, p'' \rangle \rightarrow \langle NIL, p' \rangle$ , with the former also giving rise to  $\langle \bar{a}NIL, p \rangle \rightarrow \langle NIL, p'' \rangle$ .

Now case (ii) may be applied to the pair  $\langle \bar{a}NIL, p \rangle \rightarrow \langle NIL, p'' \rangle$ ,  $\langle aNIL, o \rangle \rightarrow \langle NIL, o'' \rangle$  to obtain  $\langle o, p \rangle \rightarrow \langle o'', p'' \rangle$ . Induction may be applied to  $\langle t, o'' \rangle \rightarrow \langle NIL, o' \rangle$  and  $\langle \bar{t}, p'' \rangle \rightarrow \langle NIL, p' \rangle$  to obtain  $\langle o'', p'' \rangle \rightarrow \langle o', p' \rangle$ . These two observations may now be combined to obtain the required

$$\langle o, p \rangle \rightarrow \langle o', o' \rangle. \quad \square$$

The result is now obtained by combining these three lemmas.

*Proof of Theorem 1.2.1.* It is sufficient to show  $p \sim_A q$  implies  $p \sim_o q$  and to do so we prove

$$\sim_A \subseteq D_2(\sim_A, \sim_A).$$

Suppose  $p \sim_A q$  and  $\langle o, p \rangle \rightarrow \langle o', p' \rangle$  for an arbitrary observer  $o$ . From Lemma 1.2.4 there is a sequential observer  $s$  such that  $\langle s, o \rangle \rightarrow \langle NIL, o' \rangle$  and  $\langle s, p \rangle \rightarrow \langle NIL, p' \rangle$ . Applying Lemma 1.2.3 we obtain a  $q'$  such that  $p' \sim_A q'$  and  $\langle s, q \rangle \rightarrow \langle NIL, q' \rangle$ . From Lemma 1.2.5 it follows that  $\langle o, q \rangle \rightarrow \langle o', q' \rangle$ .  $\square$

There is a wide variety of modifications which might be applied to the definition of generalised observational equivalence. However, the same result will apply to each of these modifications. The essential reason is that all interactions between observers and processes can be sequentialised and therefore, by Lemma 1.2.3, any attempt to obtain an equivalence finer than  $\sim_A$  is doomed to failure.

We now proceed to show that  $\sim_A$  coincides with the standard definition of observational equivalence, as defined, for example in [Mil2].

**1.3. Reduction to observational equivalence.** In the last section we have seen that we may confine our attention to atomic observers. We may take atomic observers to be processes of the form  $NIL$  or  $aNIL$  for some observable action  $a$ . There are other atomic observers such as  $NIL | NIL$ ,  $aNIL | NIL$ ,  $\tau NIL$ ,  $a(NIL | NIL)$ , but every observer is equivalent to one in the basic form.

The effect of these atomic observers may be defined directly on processes. This gives operational semantics for our language in the usual style of [M1], [He], etc. It is in terms of next-action relations for every  $\mu \in \text{Act}$ . These are defined to be the least relations which satisfy the rules in Fig. 3. These are slightly different than the relations defined in Fig. 1. We can show that for terms not involving  $\uparrow$   $p \stackrel{\mu}{\Rightarrow} q$  if and only if  $p \xrightarrow{\tau} p' \xrightarrow{\mu} q' \xrightarrow{\tau} q$  for some  $p', q'$ ;  $\stackrel{\mu}{\Rightarrow}$  allows silent actions before and after the simple action  $\xrightarrow{\mu}$ .

LEMMA 1.3.1. (a) For  $a \neq \tau$ ,  $p \stackrel{a}{\Rightarrow} q$  if and only if  $\langle aNIL, p \rangle \rightarrow \langle NIL, q \rangle$ .

(b)  $p \stackrel{\tau}{\Rightarrow} q$  if and only if  $\langle NIL, p \rangle \rightarrow \langle NIL, q \rangle$ , where  $q$  is different from  $p$ .

*Proof.* Each direction is a proof by induction on the length of derivations.  $\square$

Using these action relations we can now define observational equivalence in the standard way. As is normal, the relation  $\stackrel{\tau}{\Rightarrow}$  is too discriminating as  $p \stackrel{\tau}{\Rightarrow} q$  means that  $p$  has definitely made some internal computation. Instead we use the weaker relation  $\stackrel{\varepsilon}{\Rightarrow}$ :  $p \stackrel{\varepsilon}{\Rightarrow} q$  means  $p$  can evolve to  $q$  by making zero or more internal communications. Formally  $p \stackrel{\varepsilon}{\Rightarrow} q$  if  $p$  is  $q$  or  $p \xrightarrow{\tau} q$ .

- (I)  $\mu p \stackrel{\mu}{\Rightarrow} p$
- (II)  $p \stackrel{\mu}{\Rightarrow} p'$  implies  $p + q \stackrel{\mu}{\Rightarrow} p'$   
 $q + p \stackrel{\mu}{\Rightarrow} p'$
- (III)  $p \stackrel{\mu}{\Rightarrow} p'$  implies  $p | q \stackrel{\mu}{\Rightarrow} p' | q$   
 $q | p \stackrel{\mu}{\Rightarrow} q | p'$   
 $p \upharpoonright q \stackrel{\mu}{\Rightarrow} p' | q$
- (IV)  $p \stackrel{\alpha}{\Rightarrow} p', q \stackrel{\alpha}{\Rightarrow} q'$  implies  $p | q \stackrel{\tau}{\Rightarrow} p' | q'$   
 $p \upharpoonright q \stackrel{\tau}{\Rightarrow} p' | q'$
- (V)  $p \stackrel{\tau}{\Rightarrow} p', p' \stackrel{\mu}{\Rightarrow} q$  implies  $p \stackrel{\mu}{\Rightarrow} q$   
 $p \stackrel{\mu}{\Rightarrow} p', p' \stackrel{\tau}{\Rightarrow} q$  implies  $p \stackrel{\mu}{\Rightarrow} q$

FIG. 3. Asynchronous actions.

DEFINITION 1.3.2. For  $R \subseteq P \times P$  let  $F(R) \subseteq P \times P$  be defined by

$$\langle p, p' \rangle \in F(R) \text{ if for every } \mu \text{ in } V\text{Act} \cup \{\varepsilon\} \text{ } p \stackrel{\mu}{\Rightarrow} q$$

implies  $p' \stackrel{\mu}{\Rightarrow} q'$  for some  $q'$  such that  $\langle p', q' \rangle \in R$ .  $\square$

Let  $\approx$  be the maximal solution to the equation

$$R = F(R).$$

THEOREM 1.3.3.  $p \sim_A q$  if and only if  $p \approx q$ .

*Proof.* It is sufficient to show

$$\begin{aligned} \sim_A &\subseteq F(\sim_A) \quad \text{and} \\ \approx' &\subseteq E_1(\approx', \approx), \\ \approx &\subseteq E_2(\approx', \approx) \quad \text{where } \approx' = \approx \cap A \times A. \end{aligned}$$

These follow in a straightforward manner from Lemma 1.3.1.  $\square$

We end this section with an equational characterisation of this relation. As usual  $\sim_A$  is not a congruence as it is not preserved by the operator  $+$ . Therefore we characterise the largest congruence contained in  $\sim_A, \sim_A^c$ . This is defined formally by

$$p \sim_A^c q \text{ if and only if for every context } C[\ ], C[p] \sim_A C[q].$$

THEOREM 1.3.4.  $\approx_A^c$  is the least congruence generated by the equations in Fig. 4.

There are many similar results in the literature. See for example [He], [DeN], [Mil3]. The only novelty here is the presence of the asynchronous parallel operator  $\upharpoonright$ .

A similar operator has been used in [Be] and related works. One advantage of this operator is that it gives a more powerful set of equations.

(A1)	$(x + y) + z = x + (y + z)$
(A2)	$x + y = y + x$
(A3)	$x + x = x$
(A4)	$x + NIL = x$
(B1)	$(x + y) \upharpoonright z = x \upharpoonright z + y \upharpoonright z$
(B2)	$(x \upharpoonright y) \upharpoonright z = x \upharpoonright (y \upharpoonright z)$
(B3)	$x \upharpoonright NIL = x$ $NIL \upharpoonright x = NIL$
(I1)	$x + \tau x = \tau x$
(I2)	$\mu \tau x = \mu x$ $\mu(x + \tau y) = \mu(x + y) + \mu y$
(X1)	$x   y = x \upharpoonright y + y \upharpoonright x$
(X2)	Let $y$ denote $\sum \{\lambda_j y_j, j \in J\}$ , $J$ a finite index set. $\mu x \upharpoonright y = \mu(x   y) + \sum \{\tau(x   y), \mu = \bar{\lambda}_j\}$

FIG. 4. A complete set of equations.

*Example 1.*  $(x | y) | z = x | (y | z)$ . This follows by repeated use of (B1), (B2):

$$\begin{aligned}
 (x | y) | z &= (x | y) \upharpoonright z + z \upharpoonright (x | y) \\
 &= (x \upharpoonright y + y \upharpoonright x) \upharpoonright z + z \upharpoonright (x | y) \\
 &= (x \upharpoonright y) \upharpoonright z + (y \upharpoonright x) \upharpoonright z + z \upharpoonright (x | y) \\
 &= x \upharpoonright (y | z) + y \upharpoonright (x | z) + z \upharpoonright (x | y) \\
 &= x \upharpoonright (y | z) + (y \upharpoonright z) \upharpoonright x + (z \upharpoonright y) \upharpoonright x \\
 &= x \upharpoonright (y | z) + (y \upharpoonright z + z \upharpoonright y) \upharpoonright x \\
 &= x \upharpoonright (y | z) + (y | z) \upharpoonright x \\
 &= x | (y | z).
 \end{aligned}$$

Note that this cannot be derived using the axioms in [He] even though such a particular instance is derivable.  $\square$

*Example 2.* The summand notation used in (X2) is justified by the equations (A1)–(A4): if  $J$  is the set  $\{1, \dots, n\}$ , then  $\sum \{p_j, j \in J\}$  stands for the term  $p_1 + \dots + p_n$ ; if  $J$  is empty it stands for  $NIL$ . The equation X2 gives rise to the more usual interleaving axiom from [Mil1], [He], which is also expressed using this summation notation:

$$\text{let } x, y \text{ denote } \sum \{\mu_i p_i, i \in I\}, \quad \sum \{\lambda_j q_j, j \in J\}$$

where both  $I$  and  $J$  are finite sets. Then

$$x | y = \sum \{\mu_i (p_i | y), i \in I\} + \sum \{\lambda_j (x | q_j), j \in J\} + \sum \{\tau(x_i | y_j), \mu_i = \bar{\lambda}_j\}.$$

This follows because

$$\begin{aligned}
 \text{(X1)} \quad x | y &= x \upharpoonright y + y \upharpoonright x \\
 \text{(B1)} \quad &= \sum \{\mu_i x_i \upharpoonright y, i \in I\} + \sum \{\lambda_j y_j \upharpoonright x, j \in J\} \\
 &= \sum \{\mu_i (x_i | y), i \in I\} + \sum \{\tau(x_i | y_j), \mu_i = \lambda_j\} \\
 &\quad + \sum \{\lambda_j (y_j | x), j \in J\} + \sum \{\tau(x_i | y_j), \mu_i = \lambda_j\}
 \end{aligned}$$

by (X2) and reorganisation.  $\square$

This example shows that the reduction of concurrency to nondeterminism occurs via the equation (X2). In the next section, where we develop a semantic equivalence for which this reduction no longer holds, this equation is no longer valid.

We will merely outline the proof of this characterisation theorem as the proofs of many similar theorems already appear in the literature. We use  $=_1$  to denote the least congruence generated by the equations.

(1) The first step is to obtain a simple characterisation of  $\sim_A^c$ .

Let  $p \approx^+ q$  if  $aNIL + p \approx aNIL + q$  for some  $a$  not appearing in  $p, q$ . Then we can show that  $p \sim_A^c q$  if and only if  $p \approx^+ q$ .

(2) *Soundness.* We can now show that each of the equations satisfies  $\approx^+$  from which it follows that  $p =_1 q$  implies  $p \sim_A^c q$ .

(3) *Derivation lemma.* If  $p \xrightarrow{\mu} q$  then  $p =_1 p + \mu q$ . This is proved by induction on the derivation of  $p \xrightarrow{\mu} q$ .

(4) The characterisation of  $\sim_A^c$  above makes it easy to show that  $p \sim_A q$  implies (i)  $p \sim_A^c q$ , or (ii)  $\tau p \sim_A^c q$ , or (iii)  $p \sim_A^c \tau q$ .

(5) *Completeness.* Using the equations (B1)-(B4), (X1) and (X2) all occurrences of  $|, \uparrow,$  may be eliminated from terms. Such terms are called *sumforms* and it is sufficient to show  $p \sim_A^c q$  implies  $p =_1 q$  when  $p$  and  $q$  are sumforms. Let  $q$  be of the form  $\sum \mu_i q_i$ . Then by symmetry it is sufficient to show  $p =_1 p + \mu_i q_i$  for each index  $i$ . Now  $q \xrightarrow{\mu_i} q_i$  and so  $p \xrightarrow{\mu_i} p'$  for some  $p'$  such that  $q_i \sim_A p'$ . From (4) and induction  $p' =_1 q'$ ,  $\tau p' =_1 q'$  or  $p' =_1 \tau q'$ . Applying Axiom (I2) if necessary, we have in each case that  $\mu p' =_1 \mu_i q_i$ . By (3) above it follows that  $p =_1 p + \mu_i q_i$ .  $\square$

**2. Adding time.** In this section we develop a version of bisimulation equivalence based on actions or communications which are not necessarily instantaneous. The result will be a semantic theory in which concurrency is not reducible to nondeterminism. The basic idea has already been outlined in the Introduction. Rather than assigning specific lengths of time to actions, we simply assume that there are observers which can detect the beginnings and endings of actions. We could use these basic observers to develop a general theory of observation as in § 1.1. However, a theorem similar to Theorem 1.2.1 would show once again that atomic observers suffice. Accordingly we develop the new equivalence along the lines of standard observational equivalence, as in § 1.3. This is the topic of § 2.1, where the main theorem is also stated. This is an equational characterisation of the new equivalence. The next section is devoted to the proof of this result. In the final section we discuss variations on the new definition of equivalence and address some natural questions which arise.

**2.1.** We now assume that the beginning of an action and the termination of an action are two distinct events. Moreover these distinct events may be observed. Let  $S(a)$  be an observer which can detect the start of the action  $a$  and  $F(a)$  one which can detect its termination. Referring to § 1.3 we can simply view  $S(a), F(a)$  as a new class of events and define an operational semantics in terms of next-event relations  $\xrightarrow{S(a)}, \xrightarrow{F(a)}$ . We will also continue to use complete actions, as given by  $\xrightarrow{\mu}$ .

When we assumed actions were instantaneous, the language used to describe processes was also sufficiently expressive to also describe possible states which a process might reach. This is no longer the case. For example, we cannot describe the state  $ap|bq$  attains when it initiates an  $a$  action but before the action terminates.

We propose a simple solution to this problem. For each visible action  $a$  we add a new prefixing operator  $a_s$ . For example,  $a_s p | b_s q$  denotes a process which has initiated an  $a$  action and a  $b$  action but has terminated neither. We will continue to use  $p, q$ , etc., to range over processes, terms in the basic language, and  $s, s'$ , etc., to range over the extended language of states. Let  $E = \{S(a), F(a), a \in VAct\} \cup Act$ ;  $E$  is the set of events. We use  $\forall E$  to denote the related set  $(E - \{\tau\}) \cup \{\varepsilon\}$ . The operational semantics is given in terms of a set of next-event relations  $\xrightarrow{e}$ , one for each  $e$  in  $E$ . They are

defined to be the least relations over states which satisfy the rules in Fig. 5. Rule (I) is the important new case. The process  $ap$  can initiate an  $a$  action and thereby be transformed into the intermediate state  $a_s p$ . This intermediate state can terminate the  $a$  action and thereby be transformed into  $p$ . The remaining rules are taken from Fig. 3.

A standard observational equivalence may now be defined using these event-relations. If  $R$  is a relation over states, define  $G(R)$  by:

$$\langle s, s' \rangle \in G(R) \text{ if for every } e \text{ in } VE \text{ } s \xrightarrow{e} t \text{ implies } s' \xrightarrow{e} t \text{ for some } t' \text{ such that } \langle t, t' \rangle \in R.$$

Let  $\approx_T$  be the maximal symmetric solution to the equation

$$R = G(R).$$

This equivalence relation we call *t-observational equivalence*. We are of course only interested in it as it applies to processes but, as we have seen, states are necessary to describe intermediate configurations.

We now give some examples of equivalent and inequivalent processes.

*Example 1.*  $aNIL|bNIL \not\approx_T abNIL + baNIL$ . This follows intuitively because  $aNIL|bNIL$  can initiate an  $a$  action and subsequently can initiate a  $b$  action without having terminated the  $a$  action; this is not possible of  $abNIL + baNIL$ . Formally  $aNIL|bNIL \xrightarrow{S(a)} a_s NIL|bNIL$  and  $abNIL + baNIL$  cannot perform a similar  $S(a)$ -move. The only possible  $S(a)$ -move is  $abNIL + baNIL \xrightarrow{S(a)} a_s bNIL$  and obviously  $a_s NIL|bNIL \not\approx_T a_s bNIL$ ; one can perform an  $S(b)$ -move which is impossible of the other.  $\square$

*Example 2.* Let  $p$  denote the process

$$p_1|(q_1 + q_2) + p_2|(q_1 + q_2) + (p_1 + p_2)|q_1 + (p_1 + p_2)|q_2$$

where  $p_1, p_2, q_1, q_2$  are arbitrary process then  $p \approx_T p + (p_1 + p_2)|(q_1 + q_2)$ .

- |       |  |
|-------|--|
| (I)   | $ap \xrightarrow{S(a)} a_s p$  |
|       | $a_s p \xrightarrow{F(a)} p$   |
| (II)  | $\mu p \xrightarrow{\mu} p$  |
| (III) | $s_1 \xrightarrow{e} s'_1 \text{ implies } s_1 + s_2 \xrightarrow{e} s'_1$   |
|       | $s_2 + s_1 \xrightarrow{e} s'_2$   |
| (IV)  | $s_1 \xrightarrow{e} s'_1 \text{ implies } s_1   s_2 \xrightarrow{e} s'_1   s_2$                                     |
|       | $s_2   s_1 \xrightarrow{e} s_2   s'_1$   |
|       | $s_1 \uparrow s_2 \xrightarrow{e} s'_1   s_2$  |
| (V)   | $s_1 \xrightarrow{a} s'_1, s_2 \xrightarrow{\bar{a}} s'_2 \text{ implies } s_1   s_2 \xrightarrow{\tau} s'_1   s'_2$ |
|       | $s_1 \uparrow s_2 \xrightarrow{\tau} s'_1   s'_2$  |
| (VI)  | (a) $s \xrightarrow{e} s$  |
|       | (b) $s_1 \xrightarrow{\tau} s'_1, s'_1 \xrightarrow{e} s_2 \text{ implies } s_1 \xrightarrow{e} s_2$                 |
|       | (c) $s_1 \xrightarrow{e} s'_1, s'_1 \xrightarrow{\tau} s_2 \text{ implies } s_1 \xrightarrow{e} s_2.$                |

FIG. 5. Events.

Note that this equality follows from the axioms (X1), (B2), (A1)–(A3).  $\square$

*Example 3.*  $abNIL + aNIL | bNIL \not\approx_{\tau} aNIL | bNIL$ . Intuitively the left-hand side can, by starting an  $a$ -action, get into a state in which it cannot perform a  $b$ -action without first terminating the  $a$ -action. This is impossible of the right-hand side.

*Example 4.*  $aNIL | (bNIL + cNIL) \not\approx_{\tau} aNIL | bNIL + aNIL | cNIL + a(bNIL + cNIL)$ . Intuitively this follows because in the right-hand side the decision to perform a  $b$ -action or a  $c$ -action must be taken either before the action  $a$  has commenced or after it has finished. This restriction does not apply to the left-hand side. Formally this can perform an  $S(a)$ -move to be transformed into the state  $a_sNIL | (bNIL + cNIL)$  and the right-hand side cannot be transformed into an equivalent state.  $\square$

The equivalence  $\approx_{\tau}$  is not a congruence for the usual reasons associated with the nondeterministic operator  $+$ :  $aNIL \approx_{\tau} \tau aNIL$  but  $bNIL + aNIL \not\approx_{\tau} bNIL + \tau aNIL$ . So when wishing to associate the new equivalence with equational theories we consider as usual the largest congruence contained in  $\approx_{\tau}$ , denoted  $\approx_{\tau}^c$ . This also has the following usual characterisation.

LEMMA 2.1.1.  $p \approx_{\tau}^c q$  if and only if  $p + aNIL \approx_{\tau} q + aNIL$  for some visible action  $a$  not occurring in  $p, q$ .  $\square$

A useful corollary to this characterisation is that if  $p \approx_{\tau}^c q$ , then both  $p$  and  $q$  must have matching  $\tau$ -moves:  $p \xrightarrow{\tau} p'$  implies  $q \xrightarrow{\tau} q'$  for some  $q'$  such that  $p' \approx_{\tau} q'$ , and vice versa for  $q$ . This will be useful in the sequel.

We now turn our attention to the problem of providing an equational characterisation of  $\approx_{\tau}^c$ . A natural place to start is with the equations in Fig. 4. As might be expected, (X2) is *not* satisfied by  $\approx_{\tau}^c$ . For example

$$aNIL \upharpoonright bNIL \approx_{\tau} a(NIL | bNIL)$$

as may be readily checked. Condition (X2) is the basis of “interleaving” or the reduction of concurrency to nondeterminism, associated with the standard observational equivalence. So its failure is not surprising. However, it remains true when  $\mu$  is  $\tau$ :

$$\tau x \upharpoonright y = \tau(x | y).$$

A related equation satisfied by  $\approx_{\tau}^c$  is

$$x \upharpoonright \tau y = x \upharpoonright y.$$

These two, together with (X1), imply the natural equation

$$\tau x | y = \tau(x | y).$$

All the other equations in Fig. 4 remain satisfied by  $\approx_{\tau}^c$  *except* (I3). For example,

$$a(bNIL + \tau cNIL) \not\approx_{\tau} a(bNIL + \tau cNIL) + acNIL.$$

The right-hand side can perform an  $S(a)$ -move to the state  $a_s cNIL$ ; no equivalent state can be reached by the left-hand side. Once more (I3) remains satisfied when  $\mu$  is  $\tau$ :

$$\tau(x + \tau y) = \tau(x + \tau y) + \tau y.$$

However this is already derivable from (I1), using (A1)–(A3):

$$\begin{aligned} \tau(x + \tau y) &= \tau(x + \tau y) + x + \tau y \\ &= \tau(x + \tau y) + x + \tau y + \tau y \\ &= \tau(x + \tau y) + \tau y. \end{aligned}$$

However there is an equation very similar in style to (I3) which is true of  $\approx_T^c$ :

$$x \upharpoonright (y + \tau z) = x \upharpoonright (y + \tau z) + x \upharpoonright z.$$

This revised set of equations is not complete for  $\approx_T^c$  as it ignores the possibility of communication between subprocesses. A natural additional equation would be

$$(*) \quad ax \mid \bar{a}y = ax \mid \bar{a}y + \tau(x \mid y).$$

Unfortunately, the addition of this equation will still not give a complete theory. As (X1) shows,  $\upharpoonright$  plays a more fundamental role than does  $\mid$ . What is required is a reformulation of (\*) in terms of  $\upharpoonright$ . The additional equation we use is

$$(C) \quad ax_1 \upharpoonright (\bar{a}x_2 \upharpoonright y + z) = ax_1 \upharpoonright (\bar{a}x_2 \upharpoonright y + z) + \tau(x_1 \mid x_2 \mid y).$$

We collect all the required equations in Fig. 6. Let  $\equiv$  denote the generated congruence. The main result of the paper may now be stated.

**THEOREM 2.1.2.**  *$P \approx_T^c q$  if and only if  $p \equiv q$ .*

The proof of this theorem is the subject of the next section.

**2.2. Proof of the equational characterisation.** We take for granted the alternative characterisation of  $\approx_T^c$  given in Lemma 2.1.1, although checking this would involve the reader in very tedious calculations. For example, it is necessary to check that  $\approx_T$  is preserved by all the operators except  $+$ . However, all of the calculations are straightforward and are simple variations on those found in references such as [He], [Mil1], [Mil2].

(A1)	$(x + y) + z = x + (y + z)$
(A2)	$x + y = y + x$
(A3)	$x + x = x$
(A4)	$x + NIL = x$
(B1)	$(x + y) \upharpoonright z = x \upharpoonright z + y \upharpoonright z$
(B2)	$(x \upharpoonright y) \upharpoonright z = x \upharpoonright (y \upharpoonright z)$
(B3)	$x \upharpoonright NIL = x$ $NIL \upharpoonright x = NIL$
(I1)	$x + \tau x = \tau x$
(I2)	$\mu \tau x = \mu x$
(NI3)	$x \upharpoonright (y + \tau z) = x \upharpoonright (y + \tau z) + x \upharpoonright z$
(X1)	$x \mid y = x \upharpoonright y + y \upharpoonright x$
(NX2)	$\tau x \upharpoonright y = \tau(x \mid y)$ $x \upharpoonright \tau y = x \upharpoonright y$
(C)	$ax_1 \upharpoonright (\bar{a}x_2 \upharpoonright y + z) = ax_1 \upharpoonright (ax_2 \upharpoonright y + z) + \tau(x_1 \mid x_2 \mid y)$

FIG. 6. Complete equations for  $\approx_T^c$ .

We also leave it to the reader to use this characterisation to check that all the equations are satisfied by  $\approx_T^c$ . Once more the calculations are straightforward. We therefore concentrate on completeness, showing  $p \approx_T^c q$  implies  $p \equiv q$ . This proof follows the general outline (given at the end of § 1.3) of the previous completeness proof but in this case the details are more difficult. However the following ingredient is still straightforward.

LEMMA 2.2.1.  $p \approx_T q$  implies

- (i)  $p \approx_T^c q$ , or
- (ii)  $\tau p \approx_T^c q$ , or
- (iii)  $p \approx_T^c \tau q$ .

*Proof.* Let us assume that  $p \approx_T q$  and let  $a$  be a visible action not occurring in  $p, q$ .

(a) Suppose that  $p \xrightarrow{\tau} p'$  for some  $p'$  such that  $p' \approx_T q$ . In this case we can show that  $a + p \approx_T a + q$ .

(b) By symmetry if  $q \xrightarrow{\tau} q'$  for some  $q'$  such that  $q' \approx_T p$ , we can show that  $a + \tau p \approx_T a + q$ .

(c) If neither (a) nor (b) is possible it follows directly that  $a + p \approx_T a + q$ .  $\square$

This result will be used in a manner similar to that of the completeness proof of § 1.3.

We also need a corresponding derivation lemma. However it will be more straightforward to establish this for only a subset of process terms. This subset of terms, called the simple forms, will play the role of the sumforms in the previous completeness proof. These are now explained.

The axiom (X1) enables us to eliminate all occurrences of the parallel operator  $|$  from terms, at the expense of introducing the asymmetric operator. This cannot be eliminated; otherwise we could once more reduce concurrency to nondeterminism. However we can always reduce terms to a particularly simple form.

DEFINITION 2.2.2. (i) *NIL* is a *simple form* (sf).

(ii) If each  $p_i, p'_i, p_j$  are sfs, then

$$\sum \{a_i p_i \upharpoonright p'_i, i \in I\} + \sum \{\tau p_j, j \in J\}$$

is also an sf where  $I, J$  are finite index sets.  $\square$

PROPOSITION 2.2.3. *Every process term can be reduced to a simple form, i.e., for every  $p$  there exists an sf  $\text{sf}(p)$  such that  $p \equiv \text{sf}(p)$ .*

*Proof.* The proof is by induction on the size of  $p$ . We proceed by case analysis on the structure of  $p$ .

(i)  $p$  is  $ap'$ . The required sf is  $ap' \upharpoonright \text{NIL}$ .

(ii)  $p$  is  $p' \upharpoonright p''$ . By induction suppose  $\text{sf}(p')$  is  $\sum a_i q_i \upharpoonright q'_i + \sum \tau q_j$ . Then

$$\begin{aligned} p &= {}_2 \sum (a_i q_i \upharpoonright q'_i) \upharpoonright p'' + \sum (\tau q_j) \upharpoonright p'' \quad \text{by repeated use of (B1)} \\ &= {}_2 \sum a_i q_i \upharpoonright (q'_i | p'') + \sum \tau (q_j | p'') \quad \text{by repeated use of (B2), (I4)}. \end{aligned}$$

By induction we may assume  $\text{sf}(q'_i | p'')$  and  $\text{sf}(q_j | p'')$  exists for each  $i, j$ . Therefore the required sf is

$$\sum a_i q_i \upharpoonright \text{sf}(q'_i | p'') + \sum \tau \text{sf}(q_j | p'').$$

(iii) The remaining cases are similar.  $\square$

We now proceed to state an appropriate version of the Derivation Lemma. In the actual completeness proof we are only interested in derivations with respect to  $\tau$ -actions and  $S(a)$ -actions; in the proof we will only need to absorb these kinds of derivatives. We therefore only need a derivation lemma for these kinds of actions. Moreover the definition of  $\xrightarrow{\tau}$  is completely independent of that of  $\xrightarrow{S(a)}$ . So we first prove the required result for  $\xrightarrow{\tau}$  and then we prove the corresponding result for  $\xrightarrow{S(a)}$ .

PROPOSITION 2.2.4 (Derivation Lemma). *If  $p$  is a simple form*

$$p \xrightarrow{\tau} p' \quad \text{implies } p \equiv p + \tau q.$$

*Proof.* The proof is by induction on the length of the derivation of  $p \xrightarrow{\tau} p'$ . Let us assume that  $p$  has the form  $\sum a_i p_i \upharpoonright p'_i + \sum \tau p'_j$ .

- (a)  $p'$  is  $p_j''$  for some  $j$ . Using the equations (A1)-(A4), the proof is immediate.  
 (b)  $p_j'' \xrightarrow{\tau} p'$ , for some  $j$ . By induction  $p_j'' \equiv p_j'' + \tau p'$ . It follows from (I1) that  $\tau p_j'' \equiv \tau p_j'' + \tau p'$  from which  $p \equiv p + \tau p'$  is immediate.  
 (c)  $a_i p_i \uparrow p_i' \xrightarrow{\tau} p'$  for some  $i$ . In this case  $p'$  has the form  $x|y$ , where  $p_i \xrightarrow{\varepsilon} x$  and  $p_i' \xrightarrow{\bar{a}_i} y$ .

There are two subcases, which we examine separately.

(i)  $x$  is  $p_i$ . Here we have a further inductive argument. This time we prove  $a_i p_i \uparrow p_i' \equiv a_i p_i \uparrow p_i' + \tau(x|y)$  by induction on the number of applications of rule (VI) in the derivation of  $p_i' \xrightarrow{\bar{a}_i} y$ . Let us assume  $p_i'$  has the form  $\sum b_j q_j \uparrow q_j' + \sum \tau q_k'$ .

(a) The number of applications is zero. In this case  $y$  is  $q_j|q_j'$  for some  $j$  such that  $b_j$  is  $\bar{a}_i$ . We may now apply the new equation (C) to obtain

$$a_i p_i \uparrow \bar{p}_i' \equiv a_i p_i \uparrow \bar{p}_i' + \tau(p_i|q_j|q_j').$$

(b) Otherwise  $q_k' \xrightarrow{\bar{a}_i} y$  for some  $k$  and also  $p_i' + q_k' \xrightarrow{\bar{a}_i} y$ . Moreover the number of applications of rule (VI) in this derivation is strictly less than in the derivation of  $p_i' \xrightarrow{\bar{a}_i} y$ . So we may apply induction to obtain

$$a_i p_i \uparrow (p_i' + q_k') \equiv a_i p_i \uparrow (p_i' + q_k') + \tau(x|y).$$

However  $p_i' \equiv p_i' + \tau q_k'$  from which it follows that  $p_i' \equiv p_i' + q_k'$  by (I1). The required result now follows.

(ii) The second case is when  $p_i \xrightarrow{\tau} x$ .

By case (i) we know

$$a_i p_i \uparrow p_i' \equiv a_i p_i \uparrow p_i' + \tau(p_i|y).$$

To complete the proof we now show

$$\tau(p_i|y) \equiv \tau(p_i|y) + \tau(x|y).$$

By induction we know  $p_i \equiv p_i + \tau x$ . Therefore

$$\begin{aligned} p_i|y &\equiv p_i|y + p_i \uparrow y && \text{by (X1)} \\ &\equiv p_i|y + (p_i + \tau x) \uparrow y \\ &\equiv p_i|y + (\tau x) \uparrow y && \text{by (B1)} \\ &\equiv p_i|y + \tau(x|y) && \text{by (NX2)} \end{aligned}$$

By applying (I1) we now obtain the required  $\tau(p_i|y) \equiv \tau(p_i|y) + \tau(x|y)$ .  $\square$

The proof of the corresponding result for  $\xrightarrow{S(a)}$  is much more straightforward.

**COROLLARY 2.2.5 (Derivation Lemma).** *If  $p$  is a simple form  $p \xrightarrow{S(a)} a_s p_1 | p_2$  implies  $p \equiv p + a p_1 \uparrow p_2$ .*

*Proof.* The proof is by induction on why  $p \xrightarrow{S(a)} a_s p_1 | p_2$ . Let us assume that  $p$  has the form  $\sum a_i p_i \uparrow p_i' + \sum \tau p_j$ .

(i) For some  $i$ ,  $a_i p_i \uparrow p_i' \xrightarrow{S(a)} a_s p_1 | p_2$ . Then  $a_i p_i$  is  $a p_1$  and  $p_i' \xrightarrow{\varepsilon} p_2$ . If  $p_i'$  is  $p_2$  we are finished, so assume  $p_i' \xrightarrow{\tau} p_2$ . By the previous result  $p_i' \equiv p_i' + \tau p_2$ . Therefore by (NI3)  $a_i p_i \uparrow p_i' \equiv a_i p_i \uparrow p_i' + a p_1 \uparrow p_2$ .

(ii) For some  $j$ ,  $p_j \xrightarrow{S(a)} a_s p_1 | p_2$ . By induction  $p_j \equiv p_j + a p_1 \uparrow p_2$  and from (I1) it follows that  $\tau p_j \equiv \tau p_j + a p_1 \uparrow p_2$ .  $\square$

We need one subsidiary, technical result before proving the Completeness Theorem. What we actually want to show is

$$(*) \quad a_s p | p' \approx_{\tau} a_s q | q' \text{ implies } p \approx_{\tau} q \text{ and } p' \approx_{\tau} q'.$$

However, in order to use induction, we will prove a stronger result. Its statement requires the introduction of some new notation. If  $X$  is a multi-set of terms  $\{t_1, \dots, t_k\}$ , we use  $\prod X$  to denote the product term  $t_1 | t_2 \cdots | t_k$ . Because of the commutativity and associativity of  $|$ , the exact enumeration of  $X$  does not matter. Also if  $k = 0$ , then  $\prod X$  denotes  $NIL$ . If  $X, Y$  denote multi-sets of the form  $\{a_{is}p_i, i \in I\}, \{a_{js}q_j, j \in J\}$ , respectively, we write  $X < Y$  to mean there is a one-to-one correspondence  $f: I \rightarrow J$  such that for every  $i$  in  $I$   $p_i \approx_{\tau} y_i$  for some  $i$  such that  $q_{f(i)} \xrightarrow{\varepsilon} y_i$ . We abbreviate  $\{t\} < \{s\}$  to  $t < s$  and it is simple to show that  $<$  is transitive on terms. This transitivity is used to prove the following general result about  $<$ .

LEMMA 2.2.6. *If  $X, Y$  are multi-sets, then  $Y < X$  and  $X \cup \{s\} < Y \cup \{t\}$  implies  $s < t$ .*

*Proof.* The proof is by induction on the size of  $X$  (and therefore also of  $y$ ). If  $X = \emptyset$ , then the result is immediate. If  $X = \{x\}$  then  $Y = \{y\}$  and  $y < x$ . There are two possible correspondences between  $\{x, s\}$  and  $\{y, t\}$ . One immediately gives  $s < t$ ; the other gives  $s < y, x < t$  and, by transitivity, we obtain  $s < t$ . Otherwise  $X$  contains at least two elements. Let  $y_i \rightarrow x_i$  be the correspondence from  $Y$  to  $X$ . Consider the correspondence from  $X \cup \{s\}$  to  $Y \cup \{t\}$ . If this maps  $s$  to  $t$  we immediately have  $s < t$ . Otherwise, by renaming, if necessary, we can assume  $s$  is mapped to  $y_1$ . If  $x_1$  is mapped to  $t$  we have  $s < t$ , again by transitivity. Otherwise assume  $x_1$  is mapped to  $y_2$ . Let  $X', Y'$  denote  $X - \{x_1, x_2\}, Y - \{y_1, y_2\}$ , respectively. Then  $X' \cup \{x_2\} < Y' \cup \{t\}$  and  $Y' < X'$ . By induction we have  $x_2 < t$  and therefore, once more by transitivity, we have  $s < t$ .  $\square$

LEMMA 2.2.7.  $\prod \{a_{is}p_i, i \in I\} | p \approx_{\tau}^c \prod \{b_{js}q_j, j \in J\} | q$  implies  $\{a_{is}p_i, i \in I\} < \{b_{js}q_j, j \in J\}$  and  $p \approx_{\tau} q$ .

*Proof.* The proof is by induction on the combined size of the terms. We use the alternative characterisation of  $\approx_{\tau}^c$  and the characterisation of  $\approx_{\tau}$  in Lemma 2.2.1. For convenience we denote the multi-sets  $\{a_{is}p_i, i \in I\}, \{b_{js}q_j, j \in J\}$  by  $X, Y$ , respectively, and the corresponding product terms by  $x, y$ .

(a)  $p \approx_{\tau}^c NIL$ . Then  $q \approx_{\tau} NIL$ , for otherwise the right-hand side could perform a complete action which could not be matched by the left-hand side. It follows that  $x \approx y$ . We must show  $X < Y$ .

Let  $a$  denote  $a_1$  for some  $1 \in I$ . Then  $x \xrightarrow{F(a)} p_1 | x'$ , where  $x'$  is  $\prod \{a_i, i \in I - \{1\}\}$ . So for some  $k \in J$ , such that  $b_k$  is  $a, y \xrightarrow{F(a)} q' | y'$ , where  $y'$  is defined in the obvious way from  $y$  and  $k, q_k \xrightarrow{\varepsilon} q'$  and  $p_1 | x' \approx q' | y'$ . Applying Lemma 2.2.1, we have three possibilities of which we will consider only one:  $p_1 | x' \approx_{\tau}^c \tau(q' | y')$ . Using the equation  $\tau(x | y) = x | \tau y$  this may be rewritten as  $p_1 | x' \approx_{\tau}^c \tau q' | y'$ . We may now apply induction because the combined size of the terms has decreased. We obtain  $X' < Y'$  and  $p_1 \approx \tau q'$ , where the sets  $X', Y'$  are defined in the obvious manner. Now  $p_1 \approx \tau q' \approx q'$  implies  $a_s p_1 < a_s q_k$  from which  $X < Y$  follows.

(b)  $p \not\approx_{\tau}^c NIL$ . Then for some action  $\mu, p \xrightarrow{\mu} p'$ . So  $x | p \xrightarrow{\mu} x | p'$ . Because  $x | p \approx_{\tau}^c y | q$ , it follows that  $p \xrightarrow{\mu} q'$  for some  $q'$  such that  $x | q' \approx y | p'$ . Applying Lemma 2.2.1 and induction we obtain, at least,  $X < Y$ . We must show  $p \approx q$ .

The argument we have just completed shows that every complete action of  $p$  (and by symmetry of  $q$ ) may be matched by a corresponding action of  $q$  (respectively  $p$ ). It remains to consider initial events. This argument may also be used, by considering a complete action from  $q$ , to show  $Y < X$ . In the final argument about initial events this fact is used. Suppose  $p \xrightarrow{S(a)} z$ . It is not too difficult to show  $z$  must be of the form  $a_s r | r'$ . Then  $x | p \xrightarrow{S(a)} x | a_s r | r'$ . So  $q \xrightarrow{S(a)} a_s w | w'$  such that  $y | a_s w | w' \approx_{\tau} x | a_s r | r'$ . We must show  $a_s w | w' \approx_{\tau} a_s r | r'$ . We do this by applying induction to  $y | a_s w | w' \approx_{\tau} x | a_s r | r'$ . Lemma 2.2.1 gives three possibilities of which we examine one. Suppose  $\tau(y | a_s w | w') \approx_{\tau}^c x | a_s r | r'$ , i.e.,  $y | a_s w | \tau w' \approx_{\tau}^c x | a_s r | r'$ . By induction  $\tau w' \approx_{\tau} r'$  and  $X \cup$

$\{a_s r\} < Y \cup \{a_s w\}$ . By the previous lemma  $a_s r < a_s w$ . However induction may also be applied to obtain  $Y \cup \{a_s w\} < X \cup \{a_s r\}$ . Since  $X < Y$  we also have  $a_s w < a_s r$ . The two facts  $a_s r < a_s w$  and  $a_s w < a_s r$  imply  $a_s w \approx_T a_s r$  and therefore  $a_s w | w' \approx_T a_s r | r'$ .

A symmetrical argument will show that every initial event of  $q$  may be matched by one from  $p$ . It follows that  $p \approx_T q$ .  $\square$

After this rather delicate proof the following is now straightforward.

**PROPOSITION 2.2.8.**  $a_s p | p' \approx_T a_s q | q'$  implies  $p \approx_T q$  and  $p' \approx_T q'$ .

*Proof.* The proof is by a direct application of the previous lemma, if we first apply Lemma 2.2.1. For example, this might give  $a_s p | p' \approx_T^c a_s q | \tau q'$  from which we obtain  $a_s p < a_s q$ ,  $a_s q < a_s p$ , and  $p' \approx_T \tau q'$ , i.e.,  $p' \approx_T q'$ . The first result implies  $q \xrightarrow{e} q''$  for some  $q''$  such that  $p \approx_T q''$  and the second implies  $p \xrightarrow{e} p''$  for some  $p''$  such that  $p'' \approx_T q$ . These two imply in turn that  $p \approx_T q$ .  $\square$

We are now ready for the completeness theorem.

**THEOREM 2.2.9 (Completeness).**  $P \approx_T^c q$  implies  $p \equiv q$ .

*Proof.* We may assume both  $p$  and  $q$  are simple forms and the proof is by induction on the combined size of the terms. We show  $p + q \equiv q$ . By symmetry  $p \equiv q$  will follow.

Suppose  $p$  has the form  $\sum a_i p_i | p'_i + \sum \tau p_j$ . We show  $q \equiv q + a_i p_i | p'_i$  and  $q \equiv q + \tau p_j$ .

(a)  $p \xrightarrow{S(a)} a_{is} p_i | p'_i$  so  $q \xrightarrow{S(a)} x$  for some  $x$  such that  $x \approx_T a_{is} p_i | p'_i$ . Using the operational semantics we can prove that  $x$  must have the form  $a_{is} q_1 | q_2$ . Applying the previous proposition we have  $p_i \approx_T q_1$  and  $p'_i \approx_T q_2$ . Now using Lemma 2.2.1, possibly (I2), and induction, we obtain  $a_i p_i \equiv a_i q_1$ . Applying Lemma 2.2.1 to  $p'_i \approx_T q_2$  one typical possibility is that  $\tau p'_i \approx_T q_2$ . Applying induction we obtain  $\tau p'_i \equiv q_2$  and by (NX2) we obtain  $a_i p_i | p'_i \equiv a_i q_1 | q_2$ .

It remains to show that  $q \equiv q + a_i q_1 | q_2$ . However, this follows by the second Derivation Lemma.

(b)  $p \xrightarrow{\tau} p_j$ . So  $q \xrightarrow{\tau} q'$  for some  $q'$  such that  $p_j \approx_T q$ . Again applying Lemma 2.2.1, induction, and possibly (I2), we have  $\tau p_j \equiv \tau q'$ . From the first Derivation Lemma we have  $q \equiv q + \tau q'$  and therefore  $q \equiv q + \tau p_j$ .  $\square$

**2.3. Remarks.** The equations in Fig. 6 are robust in the sense that if we make various changes to the notion of observation they remain complete. We look briefly at two possibilities. The observational equivalence  $\approx_T$  is based on the partitioning of time into three distinct phases with respect to a particular action: before the action, during the action, and after the action. This can be generalised to an arbitrary number of phases. In this generalisation we are allowed to examine a process an arbitrary number of times during the execution of an action. This is formalised by adding to the alphabet new prefixing operators  $a_n$ , for every visible action  $a$  and for every  $n > 0$ . The operational semantics is given by the rules

$$\begin{aligned} ap &\xrightarrow{S(a)} a_n p \quad \text{for any } n > 0 \\ a_1 p &\xrightarrow{F(a)} p \\ a_{n+2} p &\xrightarrow{D(a)} a_{n+1} p \end{aligned}$$

together with the usual rules for complete actions, communication and  $+$  and  $|$ . Let  $\sim_T$  be the observational equivalence generated in the usual way using this operational semantics. Then we can prove that for processes  $p, q$   $p \approx_T^c q$  if and only if  $p \sim_T q$ ; the extra increase in the power of observation does not lead to a finer congruence.

Another possibility is to allow observers to perform multiple experiments. This is formalised by defining relations  $\xrightarrow{M}$ , where  $M$  is a multiset of events. We omit the

details of the definition as they are rather complicated and tedious. However, the resulting observational congruence coincides once more with  $\approx_T^c$ .

The hypothesis that each action has a beginning and an end which are distinct from each other seems to be the simplest way of associating time with actions. These two examples indicate that this gives us considerable descriptive power, making redundant more detailed analysis of the time-dependent behaviour of processes.

For the time-based equivalence  $\approx_T$  the “interleaving axiom” no longer holds for processes. However, this was achieved by hypothesising observers which are more discriminating than processes. These observers are more discriminating in that they can find differences where processes cannot. At this more elementary level we can investigate observers observing observers, using instantaneous actions once more to define an equivalence, as in § 1. At this level “interleaving” will once more be valid. We can then consider processes as particular kinds of observers and at least for simple processes  $\approx_T$  can be derived from the more elementary interleaving equivalence on observers,  $\sim_A$ . The basic idea is to translate processes into observers by

$$\begin{aligned} \text{tr}: ap &\rightarrow S(a)F(a) \text{tr}(p) \\ p + p' &\rightarrow \text{tr}(p) + \text{tr}(p') \\ p | p' &\rightarrow \text{tr}(p) | \text{tr}(p'). \end{aligned}$$

In the special case where we do not allow communication we can then prove

$$p \approx_T q \text{ iff } \text{tr}(p) \sim_A \text{tr}(q).$$

It is not known if this is true when communication is allowed. However it seems that in this way “interleaving semantics” will often be sufficient to explain more complex notions of behaviour of processes.

Although it is sufficient it may be unnecessary and inconvenient. It would be preferable to be able to manipulate processes without having to examine their behaviour at more detailed levels. In the case examined in this paper we have shown that this is possible. The axioms of Fig. 6 are sufficient to derive all pairs of observationally congruent, ( $\approx_T^c$ ), processes. It is therefore unnecessary to translate them into the observer language and use the axioms at this more elementary level. Proofs using this method would in general be long since they involve expansion of terms using interleaving. Moreover each variation in the semantics, for example as outlined above, would necessitate new translations into new observer languages and new axioms for these underlying languages.

Finally, let us refer to some related work. Many models of concurrent processes have been proposed where concurrency is independent of nondeterminism. Perhaps the best known are Petri nets [Re]. However, this is a very operationally oriented model and it is difficult to impose on it an algebraic framework. Some attempts have been made (see [Go], for example), but the resulting equivalence on terms is very weak; although concurrency and nondeterminism are differentiated processes, such as  $aNIL + aNIL$  and  $aNIL$ , are also distinguished. The resulting model of processes is not very abstract. Similar remarks may be made of the work of Mazurkiewicz [Ma]. The related work on event structures [Wi] is very much concerned with developing algebraic models for concurrency but no attempt has yet been made to introduce into these structures a notion of abstract behaviour.

Recently there have been other attempts at generalising observational equivalence to take concurrency into account. The works known to the author in this direction are [De], [BO], [Ca], and [Gl]. In the first paper a general definition of observational

equivalence is given for nondeterministic measurement systems. This can be instantiated to give the usual observational equivalence on CCS or a more discriminating equivalence called partial-ordering observational equivalence. Partial orders are also used in [Bo] to generalise observational equivalence and the resulting equivalence is axiomatised. The basic technique used is to transfer much of the structure of processes onto the set of actions. Our equivalence can be shown to be strictly finer than theirs. In [Ca] observational equivalence is generalised by using the notion of locality; the resulting equivalence, called *distributed bisimulation*, is also axiomatised. Unlike  $\approx_{\tau}$  it satisfies

$$\mu(x + \tau y) = \mu(x + y) + \mu y.$$

Once more  $\approx_{\tau}$  is more discriminating. Finally, [G1] is a good survey of the area of “interleaving” versus “true concurrency” for processes. A variety of new equivalences are defined but, unlike the other papers, the algebraic language used is ACP, [Be].

**Acknowledgments.** The author thanks L. Mejia for many useful discussions at l’Ecole des Mines, Sophia-Antipolis, France. The author also thanks F. Williams for typing this difficult manuscript.

## A LINEAR ALGORITHM FOR TOPOLOGICAL BANDWIDTH IN DEGREE-THREE TREES\*

ZEVI MILLER†

**Abstract.** Let  $G$  be a graph, and  $f$  a one-to-one map of  $G$  into the positive integers. The *bandwidth* of  $G$  is  $B(G) = \min_f \max \{|f(x) - f(y)| : xy \in E(G)\}$ , where the max is taken over all edges  $xy$  in  $G$  and the min over all maps  $f$ .  $B(G)$  is related to the matrix bandwidth  $B(M)$  for a symmetric matrix  $M$ , and knowledge of the latter parameter is important for the efficient execution of certain matrix operations. The problem of determining  $B(G)$  for arbitrary  $G$  was shown by Papadimitriou to be NP-complete, and it was subsequently proved NP-complete even when  $G \in \Omega$ , where  $\Omega$  is the set of trees with maximum degree 3. Let  $B^*(G)$  be the minimum possible bandwidth of any subdivision of  $G$ , i.e., any graph obtained from  $G$  by inserting degree-2 points along edges of  $G$ . We present an  $O(n)$  algorithm for computing  $B^*(G)$  when  $G \in \Omega$ .

**Key words.** topological bandwidth

**AMS(MOS) subject classification.** 05C99

**1. Introduction.** Let  $G = (V, E)$  be a finite graph with no loops or multiple edges. A one-to-one map  $f: V(G) \rightarrow \mathbb{Z}$  of the vertex set of  $G$  into the integers will be called a *layout* of  $G$ . We let  $|f| = \max \{|f(v) - f(w)| : vw \in E(G)\}$ , and we define the *bandwidth* of  $G$ ,  $B(G)$ , to be  $B(G) = \min_f |f|$ . For convenience, we adopt the convention  $B(K_1) = 1$ , where  $K_1$  is the singleton graph.

The problem of determining  $B(G)$  for any  $G$  has importance in the theory of sparse matrices. Given an  $n \times n$  matrix  $A = (a_{ij})$ , define a graph  $G(A)$  by letting  $V(G(A)) = \{1, 2, \dots, n\}$  and declaring that  $ij$  is an edge if and only if  $a_{ij} \neq 0$  or  $a_{ji} \neq 0$ . Suppose we can find a symmetric permutation of the rows and columns of  $A$  so that all nonzero entries lie within the first  $k$  superdiagonals or the first  $k$  subdiagonals about the main diagonal. Then clearly  $B(G(A)) \leq k$ . Conversely if  $B(G(A)) \leq k$ , then the stated permutation exists. The problem of finding the permutation with the smallest  $k$ , equivalently, finding  $B(G(A))$ , is important in efficiently operating on and storing matrices, e.g., for Gaussian elimination, systolic processes, etc. Relevant work can be found in [1], [3], [9].

Recently the importance of bandwidth for complexity theory has been demonstrated in the work of Sudborough and Monien [1], [15]. The main kind of result has been that when certain well-known graph problems which are complete for some complexity class  $C$  are restricted to graphs with bounded bandwidth, the resulting problem is complete for space-bounded or simultaneous space- and time-bounded subclasses of  $C$ . Of course the bandwidth problem for arbitrary graphs [13], and even for trees of maximum degree 3 [6], is known to be NP-complete.

The problem of given a graph  $G$  to determine whether  $B(G) \leq k$  when  $k$  is fixed was proved polynomial time solvable in [14], with an improvement in [7].

The subject of this paper is the following topological version of bandwidth, attributed in [3] to R. Graham. For any graph  $G$ , let  $S(G)$  be the set of all subdivisions of  $G$ , i.e., the set of all graphs obtainable from  $G$  by finitely many compositions of the operation, called elementary subdivision, of replacing some edge  $xz$  by two edges  $xy$  and  $yz$ , where  $y$  is a vertex not previously in the graph. Obviously any  $H \in S(G)$

† Department of Mathematics and Statistics, Miami University, Oxford, Ohio 45056.

is homeomorphic with  $G$  and hence has the same underlying topology as  $G$ . The *topological bandwidth* of  $G$ ,  $B^*(G)$ , is defined by  $B^*(G) = \min \{B(H) : H \in S(G)\}$ .

Topological bandwidth is related to sparse matrices as follows. Given the system  $Ax = b$ , construct an equivalent system by replacing some term  $a_{ij}x_j$  by the new variable  $y$  and add a new equation  $a_{ij}x_j = y$ . This operation is equivalent to inserting a point of degree 2 in the edge  $ij$  of  $G(A)$ . Clearly  $B^*(G(A))$  is the smallest  $k$  such that for some system  $A'x = b'$  equivalent to  $Ax = b$  by a sequence of the above operations there is a permutation of the rows and columns which yields a  $2k + 1$  band form. The new system may be more efficient to work with if it is not too large, i.e., if the number of additional degree-2 vertices is not too large.

Another application is in regarding a graph  $G$  as a circuit with gates (corresponding to points of  $G$ ) laid out linearly for automation purposes [12], [16]. Inserting degree-2 points along edges of  $G$  corresponds to inserting drivers along wires of the circuit. Hence  $B^*(G)$  is the minimum length of the longest connection over all linear layouts allowing drivers. This minimum gives a lower bound on the time delay in transmission between elements of the circuit.

The cutwidth,  $cw(G)$ , of a graph  $G$  is defined as the minimum, over all layouts  $f$ , of  $\max_i |\{uv \in E(G) : f(u) \leq i < f(v)\}|$ . The relation between  $B^*(T)$  and  $cw(T)$  for trees  $T$  was explored by Chung in [5]. It was shown that  $cw(T)$  and  $B^*(T)$  can be arbitrarily far apart, but that  $cw(T) \leq B^*(T) - \log_2 B^*(T) + 2$ . Recently Yannakakis has found an  $O(n \log n)$  algorithm for  $cw(T)$  for arbitrary trees  $T$  [17].

The relation between  $cw(G)$  and  $B^*(G)$  was also investigated by Makedon, Papadimitriou, and Sudborough in [10]. They show that for any graph  $G$  we have  $B^*(G) \leq mcw(G) + 1$ , where  $mcw$  is the "modified cutwidth" considered in [10] and defined earlier by Lengauer in [18]. Since for any graph  $G$  we have  $mcw(G) \leq cw(G) - 1$ , it follows that  $B^*(G) \leq cw(G)$ . Makedon et al. also show that for any graph with maximum degree 3,  $B^*(G) = mcw(G) + 1$ . Thus an algorithm for topological bandwidth in trees of maximum degree 3 is also an algorithm for  $mcw$  in such trees.

The main result of this paper is an  $O(n)$  algorithm for computing  $B^*(T)$ , where  $T$  is any tree of maximum degree 3. First we develop an  $O(n \log n)$  algorithm which contains all the essential graph-theoretic ideas. Some additional data structure then leads to the  $O(n)$  solution. Our result is a contrast to the NP-completeness of bandwidth for trees of maximum degree 3, and hence shows that topological structure "alone" is not the reason for this NP-completeness.

We remark that an  $O(n \log n)$  algorithm for  $B^*(T)$  in degree-3 trees is obtained independently by Makedon, Papadimitriou, and Sudborough, in [10]. They show that the topological bandwidth problem for arbitrary graphs is NP-complete, they characterize graphs with topological bandwidth two, and they explore relations with pebbling and searching.

We follow standard graph-theoretic notation, as may be found in [2] or [8] for example. In particular, if  $G = (V, E)$  is a graph and  $H$  is a subgraph of  $G$ , then  $G - H$  is the graph obtained from  $G$  by deleting all points of  $H$  and all edges of  $G$  incident on those points.

**2. The main algorithm.** Let  $P$  be a path joining two end vertices of  $T$ . A subtree  $\alpha$  of  $T$  is called a *hanging from  $P$*  if it is one of the connected components of  $T - P$ . Thus each such  $\alpha$  contains a unique vertex  $x_\alpha$  such that  $x_\alpha y \in E(T)$  for some  $y \in P$ . We denote by  $Z(P)$  the set of all hangings from  $P$ . Let  $\|P\|$ , the *norm of  $P$  in  $T$* , be defined by  $\|P\| = 1 + \max \{B^*(\alpha) : \alpha \in Z(P)\}$ . To emphasize the role of  $T$ , we sometimes

write this as  $\|P\|_T$ . We let  $K_{1,2}$  (respectively,  $K_{1,3}$ ) be the tree with a central point joined to two (respectively, three) endpoints.

We begin with some lemmas.

LEMMA 1. *For any tree  $T$  there exists a layout of  $T$  satisfying  $|f| = B(T)$  such that  $f^{-1}(\min f(x))$  and  $f^{-1}(\max f(x))$  are both end vertices of  $T$ .*

*Proof.* Let  $g$  be a layout of  $T$  such that  $|g| = B(T)$ . Let  $p = g^{-1}(\min g(x))$  and  $q = g^{-1}(\max g(x))$ . We may suppose that at least one of  $p$  and  $q$  is not an end vertex (or leaf). Let  $P$  be the path in  $T$  joining  $p$  and  $q$ , and let  $Y_p$  (respectively,  $Y_q$ ) be the set of branches at  $p$  (respectively,  $q$ ) having empty intersection with  $P$ . Now define a new layout  $g_1$  of  $T$  as follows:

$$g_1(x) = \begin{cases} g(x), & x \in V(T) \setminus [Y_p \cup Y_q], \\ 2g(p) - g(x), & x \in Y_p, \\ 2g(q) - g(x), & x \in Y_q. \end{cases}$$

Notice that  $g_1$  just reflects  $Y_p$  and  $Y_q$  about  $p$  and  $q$ , respectively, and  $|g_1| = |g|$ . If  $g_1^{-1}(\min g_1(x))$  and  $g_1^{-1}(\max g_1(x))$  are both end vertices, then we are done. If not, then repeat the above process with  $g_1$  in place of  $g$ . Eventually we obtain a layout for  $T$  of the required kind.  $\square$

A path  $P$  joining two end vertices of the tree  $T$  is called a *backbone* of  $T$ . If  $f$  is a layout of  $T$  such that  $z_1 = f^{-1}(\min f(x))$  and  $z_2 = f^{-1}(\max f(x))$  are both end vertices of  $T$ , then the backbone  $P$  joining  $z_1$  and  $z_2$  is called a *backbone of  $f$* . We also say that  $f$  has backbone  $P$ .

Let  $T^* \in \mathcal{S}(T)$ , and let  $P$  be a backbone of  $T$ . A layout  $f$  of  $T^*$  will be called a *t-layout* of  $T$  ( $t$  for topological). We call  $P$  an *optimal backbone of  $T$*  if there exists such an  $f$  and  $T^*$  satisfying

- (i)  $|f| = B^*(T)$ , and
- (ii) the path joining  $f^{-1}(\min f(x))$  and  $f^{-1}(\max f(x))$  corresponds to  $P$  under the subdivision operation (so that  $f^{-1}(\min f(x))$  and  $f^{-1}(\max f(x))$  are endpoints of  $T^*$  corresponding to the endpoints of  $P$ ).

COROLLARY 1.1. *Every tree  $T$  has an optimal backbone.*

*Proof.* Let  $f$  be a  $t$ -layout of  $T$  with  $|f| = B^*(T)$ . By Lemma 1 we can find a  $t$ -layout  $g$  such that  $g^{-1}(\min g(x))$  and  $g^{-1}(\max g(x))$  are end vertices  $v_1$  and  $v_2$  (respectively) while  $|g| = B^*(T)$ . The path in  $T$  joining the vertices  $v_1$  and  $v_2$  is the required optimal backbone.  $\square$

Given a layout  $f$  of  $G$  and  $H \subseteq G$ , the layout of  $H$  induced by  $f$  is the layout  $f_H: V(H) \rightarrow \{1, 2, \dots, |V(H)|\}$  which maps the points of  $H$  in the same order as they are mapped by  $f$ .

LEMMA 2. *Let  $T$  be a nontrivial tree of maximum degree 3,  $P$  be an optimal backbone of  $T$ , and  $Z(P) = \{H_1, H_2, \dots, H_k\}$ . Then  $B^*(T) = \|P\| \equiv 1 + \max B^*(H_j)$ .*

*Proof.* We start with the lower bound  $B^*(T) \geq \|P\|$ . Consider a  $t$ -layout of  $T$ , say  $f: T^* \rightarrow \mathbb{Z}$  for some  $T^* \in \mathcal{S}(T)$ , such that  $|f| = B^*(T)$ . Let  $\bar{H}_i \in \mathcal{S}(H_i)$ ,  $1 \leq i \leq k$ , be the hanging from  $P^*$  (the subdivision of  $P$  in  $T^*$ ) corresponding to  $H_i$ . Let  $f_i$  be the layout of  $\bar{H}_i$  induced by  $f$ . Clearly  $|f_i| \geq B(\bar{H}_i) \geq B^*(H_i)$ , so there exist  $c, d \in V(H_i)$  (say with  $f(c) < f(d)$ ) such that  $f_i(d) - f_i(c) \geq B^*(H_i)$ . After translating  $f_i$  to correspond to the restriction of  $f$  to  $\bar{H}_i$ , we find that there is an edge  $ab \in E(P^*)$  such that without loss of generality either

- (i)  $f(a) < f_i(c)$  and  $f(b) > f_i(d)$ , or
- (ii)  $f_i(c) < f(a) < f_i(d)$ .

In either case we get  $|f| \geq 1 + B^*(H_i)$ , so by the arbitrariness of  $i$  we get  $|f| \geq \|P\|$ .

The bound  $B^*(T) \leq \|P\|$  follows from the layout indicated in Fig. 1. For each  $i$ ,  $1 \leq i \leq k$ , we take a layout  $f_i$  of some  $\bar{H} \in S(H_i)$  satisfying  $|f_i| = B^*(H_i)$ . Assuming without loss of generality that the  $H_i$  occur along  $P$  in indicial order, we place the layouts  $f_i$  along  $\mathbb{Z}$  in the same order so that  $f_i$  and  $f_{i+1}$  have no overlap for all  $i$ . We then lay out some  $P^* \in S(P)$  so that consecutive points on  $P^*$  are  $\|P\|$  units apart,  $\min\{P^*\} < \min f_1(x)$ , and  $\max\{P^*\} > \max f_k(x)$  (where we identify  $P^*$  with points of  $\mathbb{Z}$ ). Of course this requires us to “squeeze in” points of  $P^*$  into the range of the layouts  $f_i$ . We make room for this by iteratively translating values  $f_i(x)$  greater than the squeezed-in point one unit to the right. Since consecutive points on  $P^*$  are  $\|P\|$  units apart, and since  $B^*(H_i) < \|P\|$ , we will never have to stretch any pair  $f_i(x), f_i(y), xy \in E(\bar{H}_i)$ , more than  $\|P\|$  units apart. This defines a layout  $f: T^* \rightarrow \mathbb{Z}$  for some  $T^* \in S(T)$ . By construction we have  $|f(x) - f(y)| \leq \|P\|$  for any  $xy \in E(P^*) \cup (\cup E(\bar{H}_i))$ . Now for each  $i$  there is a unique edge  $w_i p_i \in E(T)$ ,  $w_i \in H_i, p_i \in P$ . We choose a  $w_i \in \bar{H}_i$  (to correspond to  $w_i$  and  $B_i$ ), and then find a  $p_i \in P^*$  (to correspond to  $p_i \in P$ ) that is at most distance  $\|P\|$  from  $w_i$ . Letting these  $w_i p_i$  be the remaining edges of  $T^*$ , we get  $|f| \leq \|P\|$  as required.  $\square$

In order to make use of the lemma in the algorithm we need some further notation.

Let  $T$  be a tree of maximum degree 3. If the vertices of  $T$  are numbered in the order of a depth-first search (DFS) starting at  $r$ , then the resulting numbers  $s$  can be used to define the usual relations on rooted trees: if  $x$  and  $y$  belong to the same branch at  $r$  and the path in  $T$  from  $r$  to  $y$  passes through  $x$ , then we write  $x \leq y$ . If  $x \leq y$  then we call  $x$  an *ancestor* of  $y$  and we call  $y$  a *descendant* of  $x$ . If  $y$  is a descendant of  $x$  and  $xy \in E(T)$ , then  $y$  is a *son* of  $x$  and  $x$  is a *father* of  $y$ . If  $Q$  is a subtree of  $T$ , then we define *head*( $Q$ ) to be the vertex  $x \in Q$  such that  $x \leq y$  for all  $y \in Q \setminus \{x\}$ . For  $x \in V(T)$ , let  $B_x(T)$  denote the subtree of  $T$  consisting of  $x$  and all descendants of  $x$  in  $T$ . We write  $B_x$  instead of  $B_x(T)$  when  $T$  is understood by context. For any subtree  $\gamma \subseteq T$  with *head*( $\gamma$ ) =  $s$ , we let  $(\gamma)_s$  be the tree with vertex set  $V(\gamma) \cup \{\bar{s}\}$ , where  $\bar{s}$  is a new symbol, and edge set  $E(\gamma) \cup \{s\bar{s}\}$ . Thus  $(\gamma)_s$  is obtained by attaching a new endpoint to  $s$ . Accordingly, if  $\beta$  is a backbone of  $\gamma$  which remains a backbone of  $(\gamma)_s$ , then we let  $\|\beta\|_s$  be the norm of  $\beta$  in  $(\gamma)_s$ . We say that  $B_x$  is *k-primitive* (or just primitive when  $k$  is understood) if  $B^*(B_x) = k$  and  $B^*(B_y) < k$  for all  $y \in B_x$ . Note that if  $B_x$  and  $B_z$  are distinct  $k$ -primitive branches, then  $B_x \cap B_z = \emptyset$ . If  $P$  is a path in  $T$ , we say that  $P$  *threads* the branch  $B_x$  if  $P$  passes through  $x$  and some end vertex of  $B_x$ .

COROLLARY 2.1. (a) Let  $B_x$  and  $B_y$  be branches of  $T$  such that  $B_x \cap B_y = \emptyset$  and  $B^*(B_x) = B^*(B_y) = B^*(T)$ . Then any optimal backbone of  $T$  threads both  $B_x$  and  $B_y$ .

(b) If  $T$  has three branches  $B_{x1}, B_{x2}, B_{x3}$  having pairwise empty intersection, then  $B^*(T) \geq 1 + \min_i B^*(B_{xi})$ .

*Proof.* (a) Let  $P$  be an optimal backbone of  $T$  violating the conclusion. Then at least one of  $B_x$  or  $B_y$  is contained in some hanging  $C$  of  $P$ . Thus by the lemma  $B^*(T) \geq 1 + B^*(C) \geq 1 + B^*(B_x) > B^*(T)$ , a contradiction.

FIG. 1. The optimal  $t$ -layout of  $T$  from Lemma 2.

(b) By Corollary 1.1 we know that  $T$  must have an optimal backbone  $P$ . Now observe that for any optimal backbone  $P$  of  $T$  one of the  $B_{x_i}$ , say  $B_{x_1}$ , must be contained in a hanging from  $P$ . Hence  $B^*(T) \geq 1 + B^*(B_{x_1}) \geq 1 + \min B^*(B_{x_i})$ .  $\square$

**COROLLARY 2.2.** *For any backbone  $\beta$  of  $T$  we have  $B^*(T) \leq \|\beta\|$ . Hence by Corollary 1.1 and Lemma 2,  $B^*(T) = \min \{\|\beta\| : \beta \text{ a backbone of } T\}$ .*

*Proof.* Let  $Z(\beta) = \{B_j : 1 \leq j \leq k\}$ . Using the proof of the upper bound in the lemma we can construct a  $t$ -layout  $g$  of  $T$  such that  $|g| = \|\beta\|$ .  $\square$

Thus a backbone  $\beta$  of  $T$  is *optimal* (in the sense defined previously) if and only if  $\|\beta\|$  is a minimum among all backbones of  $T$ .

Before proceeding to the algorithm we introduce some notation. Let  $A$  and  $C$  be trees on which a DFS has been performed with roots  $x$  and  $y$ , respectively. Denote by  $A \vee C$  the tree with  $V(T) = V(A) \cup V(C) \cup \{r\}$ ,  $E(T) = E(A) \cup E(C) \cup \{rx, ry\}$ . The basic idea in our main procedure LABEL( $A, C, r$ ) is to use an inductive knowledge of  $B^*(A)$ ,  $B^*(C)$  and some additional information (described below) to find an optimal backbone  $\beta$  of  $A \vee C$  and compute  $B^*(A \vee C) = \|\beta\|$ .

Now let  $\tau$  be any tree of maximum degree 3 rooted at a point  $u$ . Define  $h(\tau)$  to be the point of  $\tau$  closest to  $u$  which can be on an optimal backbone of  $\tau$ . Also let  $\nu(\tau)$  be the number of  $B^*(\tau)$ -primitive branches of  $\tau$ . Thus  $\nu(\tau)$  equals 1 or 2 by Corollary 2.1(b).

**COROLLARY 2.3.** *Let  $\tau$  be a tree of maximum degree 3 rooted at  $u$ .*

(a) *If  $\nu(\tau) = 1$  then  $h(\tau) = u$ .*

(b) *Suppose  $\nu(\tau) = 2$ , and let  $B_x$  and  $B_y$  be the  $B^*(\tau)$ -primitive branches of  $\tau$ . Then  $h(\tau)$  is the point closest to  $u$  on the unique path in  $\tau$  joining  $x$  and  $y$ .*

*Proof.* (a) Let  $B_z$  be the unique  $B^*(\tau)$ -primitive branch of  $\tau$ . Clearly there exists a backbone  $\beta$  of  $\tau$  threading  $B_z$  and passing through  $u$ . Let  $\alpha$  be any hanging of  $\beta$ . If  $\alpha \subset B_z$ , then  $B^*(\alpha) \leq B^*(\tau) - 1$  by primitivity of  $B_z$ . If  $\alpha \subset \tau - B_z$  then  $B^*(\alpha) \leq B^*(\tau) - 1$  since otherwise  $B^*(\alpha) = B^*(\tau)$  and hence  $\alpha$  would contain a  $B^*(\tau)$ -primitive branch, contradicting the uniqueness of  $B_z$ . Thus  $\|\beta\| \leq B^*(\tau)$  so  $\beta$  is optimal and  $h(\tau) \leq \text{head}(\beta) = u$ . But  $h(\tau) \geq u$  since  $u$  is the root, so  $h(\tau) = u$ .

(b) By Corollary 2.1 any optimal backbone  $\beta$  must thread  $B_x$  and  $B_y$ . Hence  $\beta$  passes through  $x$  and  $y$  and the claim follows.  $\square$

We illustrate the conclusion of the lemma in Fig. 2. The curled line indicates an optimal backbone.

For any  $s \in \tau$ , let  $\tau/s$  be the tree  $\tau - B_s(\tau)$ . We will be interested in  $\tau/h(\tau)$ . We define the *signature* of  $\tau$ ,  $\text{sign}(\tau)$ , to be the 4-tuple  $(B^*(\tau), \nu(\tau), h(\tau), B^*((\tau)_u))$ .

We define a nested sequence Tree( $\tau$ ) of subtrees  $\{\tau_i\}$  of  $\tau$ , where  $u \in \tau_i$  for all  $i$ , as follows. Let  $\tau_1 = \tau$ . If  $\tau$  is a path, then  $\text{Tree}(\tau) = \{\tau_1\}$ . Otherwise assume inductively

FIG. 2.  $h(\tau)$  depending on  $\nu(\tau)$ .

that  $\tau_1, \tau_2, \dots, \tau_i$  have been defined. If  $h(\tau_i) = u$ , then  $\text{Tree}(\tau) = \{\tau_1, \tau_2, \dots, \tau_i\}$ . Otherwise let  $\tau_{i+1} = \tau_i/h(\tau_i)$ . Note that if  $u$  has only one son, then  $\tau_{|\text{Tree}(\tau)|}$  is a path with endpoint  $u$ . We define  $\text{deck}(\tau)$  as the ordered list  $\text{deck}(\tau) = \{\text{sign}(\tau_1), \text{sign}(\tau_2), \dots, \text{sign}(\tau_{|\text{Tree}(\tau)|})\}$ , where  $\text{sign}(\tau_1)$  is the top and  $\text{sign}(\tau_{|\text{Tree}(\tau)|})$  is the bottom. If  $L = (l_1, l_2, \dots, l_m)$  and  $N = (n_1, n_2, \dots, n_j)$  are two ordered lists, we let  $L \oplus N$  be the ordered list  $(l_1, l_2, \dots, l_m, n_1, n_2, \dots, n_j)$ . Typically  $L$  and  $N$  will be of the form  $\text{deck}(\tau)$  for some  $\tau$ . If  $k \leq m$ , we let  $L_k = (l_1, l_2, \dots, l_k)$ , so  $\text{deck}(\tau)_k$  refers to the top  $k$  entries of  $\text{deck}(\tau)$ . We call these entries *frames*.

We now introduce the two procedures used in our algorithm. The main one LABEL  $(A, C, r)$  had  $\text{deck}(A)$  and  $\text{deck}(C)$  as input, where  $A$  and  $C$  are nonempty trees, and  $\text{deck}(A \vee C)$  as output. We use it in working our way up  $T$  in postorder, where  $A = B_s, C = B_t$  for  $s, t \in T$ , and  $A \vee C = B_u$ , where  $u$  is the father of  $s$  and  $t$ . The second, MAKEDECK  $(T, r)$  has  $\text{deck}(T)$  as input, where  $T$  is rooted  $r$ , and  $\text{deck}((T)_r)$  as output. It is called by LABEL in a certain case. The validity of LABEL will be proved in its description while that of MAKEDECK will follow from some later lemmas.

Procedure LABEL  $(A, C, r)$ .

*Input.*  $\text{deck}(A), \text{deck}(C)$       *Output.*  $\text{deck}(A \vee C)$

We let  $\text{Tree}(A) = \{\tau_1, \tau_2, \dots, \tau_k\}$ , and  $\text{Tree}(C) = \{\mu_1, \mu_2, \dots, \mu_l\}$ . Initially we scan  $\text{sign}(\tau_1) = \text{sign}(A)$  and  $\text{sign}(\mu_1) = \text{sign}(C)$  in  $\text{deck}(A)$  and  $\text{deck}(C)$ , respectively.

*Case 1.*  $B^*(A) = B^*(C) \equiv b$ .

Since  $\nu(A) + \nu(C) \geq 2$ , we have  $\nu(A) + \nu(C) \geq 3$  or  $\nu(A) = \nu(C) = 1$ . We consider these subcases in turn.

*Subcase 1(a).*  $\nu(A) + \nu(C) \geq 3$ .

By Corollary 2.1(b) it follows that  $B^*(A \vee C) \geq 1 + b$ . But any backbone  $\beta$  of  $A \vee C$  containing  $r$  satisfies  $\|\beta\| \leq 1 + b$  since any hanging  $\alpha$  of  $\beta$  is a subtree of  $A$  or  $C$  so by monotonicity of  $B^*$  satisfies  $B^*(\alpha) < b$ . Hence by Corollary 2.2 we have  $B^*(A \vee C) = 1 + b$ . Clearly  $\nu(A \vee C) = 1$  since  $A \vee C$  is its own  $(1 + b)$ -primitive branch, and  $h(A \vee C) = r$  since (as remarked above) any backbone containing  $r$  is optimal. The same  $\beta$  satisfies  $\|\beta\|_r \leq 1 + b$  since the only additional hanging it has in  $(A \vee C)_r$  is the single point  $\bar{r}$ . Thus  $B^*((A \vee C)_r) \leq 1 + b$ . The opposite inequality follows from  $(A \vee C)_r \supset A \vee C$  and monotonicity of  $B^*$ . The procedure thus ends with  $\text{deck}(A \vee C) = \{(1 + b, 1, r, 1 + b)\}$ .

*Subcase 1(b).*  $\nu(A) = \nu(C) = 1$ .

Let  $B_x \subset A$  and  $B_y \subset C$  be the unique  $b$ -primitive branches of  $A$  and  $C$ , respectively. Consider any backbone  $\beta$  of  $A \vee C$  which threads both  $B_x$  and  $B_y$ . Each of its hangings  $\alpha$  is either properly contained in  $B_x$  or  $B_y$ , or contains no  $b$ -primitive branches. Hence  $B^*(\alpha) \leq b - 1$ , so  $\|\beta\| \leq b$  and thus  $B^*(A \vee C) \leq b$  by Corollary 2.2. The opposite inequality is immediate by monotonicity of  $B^*$ . Thus  $B^*(A \vee C) = b$ . Obviously  $\nu(A \vee C) = 2$  since  $B_x$  and  $B_y$  are two  $b$ -primitive branches, and  $h(A \vee C) = r$  since any optimal backbone must thread  $B_x$  and  $B_y$  and hence contains  $r$ .

As for  $B^*((A \vee C)_r)$  we have two cases. If  $B^*(A) = 1$ , then the assumption  $\nu(A) = \nu(C) = 1$  implies that each of  $A$  and  $C$  has only one endpoint in  $A \vee C$ , and hence that  $A \vee C$  is a subdivision of a path. Thus  $(A \vee C)_r$  is a subdivision of  $K_{1,3}$ , so  $B^*((A \vee C)_r) = 2$ . We then return  $\text{deck}(A \vee C) = \{(1, 2, r, 2)\}$ . If  $B^*(A) \geq 2$ , then the same  $\beta$  above satisfies  $\|\beta\|_r \leq b$ , so  $B^*((A \vee C)_r) \leq b$ . The opposite inequality again follows from monotonicity of  $B^*$ . Hence we return  $\text{deck}(A \vee C) = \{(b, 2, r, b)\}$ .

Case 2.  $b = B^*(A) > B^*(C)$ .

Subcase 2(a).  $\nu(A) = 1$ .

Here we can find a backbone  $\beta$  of  $A \vee C$  which threads the unique  $b$ -primitive branch  $B$  of  $A$  and passes through  $r$ . Such a  $\beta$  satisfies  $\|\beta\| \leq b$ , so that  $B^*(A \vee C) = b$  and  $h(A \vee C) = r$ . Also  $\nu(A \vee C) = 1$  since  $B$  is unique. Again the same  $\beta$  satisfies  $\|\beta\|_r \leq b$  so  $B^*((A \vee C)_r) \leq b$  and by monotonicity  $B^*((A \vee C)_r) = b$ . We then return  $\text{deck}(A \vee C) = \{(b, 1, r, b)\}$ .

Subcase 2(b).  $\nu(A) = 2$ .

Let  $B_x$  and  $B_y$  be the two  $b$ -primitive branches of  $A$ . Clearly any backbone  $\beta$  of  $A \vee C$  satisfying  $\|\beta\| = b$  (if such exists) must thread both  $B_x$  and  $B_y$ , and  $\text{head}(\beta) = h(A)$ . Also, its hanging  $(A \vee C)/h(A)$  must have  $B^*$  value  $\leq b - 1$ .

It follows that if  $B^*((A \vee C)/h(A)) = b$  then  $B^*(A \vee C) \geq b + 1$ . Equality follows since for any backbone  $\delta$  of  $A \vee C$  containing  $r$  the hangings  $\alpha$  all satisfy  $B^*(\alpha) \leq \max\{B^*(A), B^*(C)\} = b$  so such a  $\delta$  satisfies  $\|\delta\| \leq b + 1$ . Also  $\|\delta\|_r \leq b + 1$  since the only additional hanging is a single point, and  $\nu(A \vee C) = 1$  since  $A \vee C$  is its own  $(b + 1)$ -primitive branch. Thus we output  $\text{deck}(A \vee C) = \{(b + 1, 1, r, b + 1)\}$ .

Suppose on the other hand that  $B^*((A \vee C)/h(A)) \leq b - 1$ . Take any backbone  $\beta$  of  $A \vee C$  threading the two  $b$ -primitive branches  $B_x$  and  $B_y$  of  $A$ . Then every hanging  $\alpha$  of it satisfies exactly one of the following:

- (a)  $\alpha \subset B_x$  or  $\alpha \subset B_y$  with proper containment.
- (b)  $\alpha$  contains no  $b$ -primitive branches.
- (c)  $\alpha = (A \vee C)/h(A)$ .

Each of these implies that  $B^*(\alpha) \leq b - 1$  so  $\|\beta\| \leq b$  and hence  $B^*(A \vee C) = b$ . Also  $\text{head}(\beta) = h(A)$  since any optimal backbone of  $A$  threads  $B_x$  and  $B_y$  and thus has a uniquely determined head which must therefore be the same as  $\text{head}(\beta)$ . Clearly  $\nu(A \vee C) = 2$ . As for  $B^*((A \vee C)_r)$ , the argument given above for  $A \vee C$  can be repeated for  $(A \vee C)_r$  to show that if  $B^*((A \vee C)_r/h(A)) \leq b - 1$ , then  $B^*((A \vee C)_r) = b$  while if  $B^*((A \vee C)_r/h(A)) = b$ , then  $B^*((A \vee C)_r) = b + 1$ . We conclude that  $\text{sign}(A \vee C) = (b, 2, h(A), z)$ , where  $z = B^*((A \vee C)_r)$  depends on  $B^*((A \vee C)_r/h(A))$  as indicated. Thus the first frame of  $\text{deck}(A \vee C)$  is  $\text{sign}(A \vee C)$  as given, so  $\text{deck}(A \vee C) = (b, 2, h(A), z) \oplus \text{deck}((A \vee C)/h(A))$ .

To summarize, we see that in Subcase 2(b) if  $B^*((A \vee C)/h(A)) = b$ , then  $\text{deck}(A \vee C) = \{(b + 1, 1, r, b + 1)\}$  while if  $B^*((A \vee C)/h(A)) \leq b - 1$ , then  $\text{deck}(A \vee C) = (b, 2, h(A), z) \oplus \text{deck}((A \vee C)/h(A))$ . Hence the output of LABEL( $A, C$ ) is given directly in the first case, while in the second the procedure must still produce  $\text{deck}((A \vee C)/h(A))$ . When this is done  $z$  is determined from the last entry, corresponding to  $B^*((A \vee C)_r/h(A))$ , of the top frame of  $\text{deck}((A \vee C)/h(A))$ , and the given  $\text{deck}(A \vee C)$  is returned.

Consider then the construction of  $\text{deck}((A \vee C)/h(A))$  which, since  $(A \vee C)/h(A) = (A/h(A)) \vee C$ , is  $\text{deck}((A/h(A)) \vee C)$ . If  $A/h(A) \neq \emptyset$ , then we do this by making a recursive call on LABEL( $A/h(A), C, r$ ) = LABEL( $\tau_2, \mu_1, r$ ) after popping  $\text{sign}(\tau_1) = \text{sign}(A)$  from the top of  $\text{deck}(A)$  so that  $\text{sign}(\tau_2) = \text{sign}(A/h(A))$  is available for scanning. We get as output the required  $\text{deck}((A/h(A)) \vee C)$ . If  $A/h(A) = \emptyset$  we cannot make this call and instead use procedure MAKEDECK as follows.

Suppose then that  $A/h(A) = \emptyset$ . Then  $(A/h(A)) \vee C = (C)_y$ , where  $y$  is the root of  $C$ , i.e., the son of  $r$  in  $C$ . Hence we get  $\text{deck}((A/h(A)) \vee C)$  by calling on procedure MAKEDECK( $C, y$ ).

This completes procedure LABEL( $A, C, r$ ).

We illustrate the Subcase 2(b) requiring recursion in Figs. 3 and 4. The pointers in Fig. 4 show the entries to be scanned in the indicated calls to LABEL.

FIG. 3. Determining  $B^*(\tau_1 \vee \gamma_1)$  from  $B^*(\tau_2 \vee \gamma_1)$ .

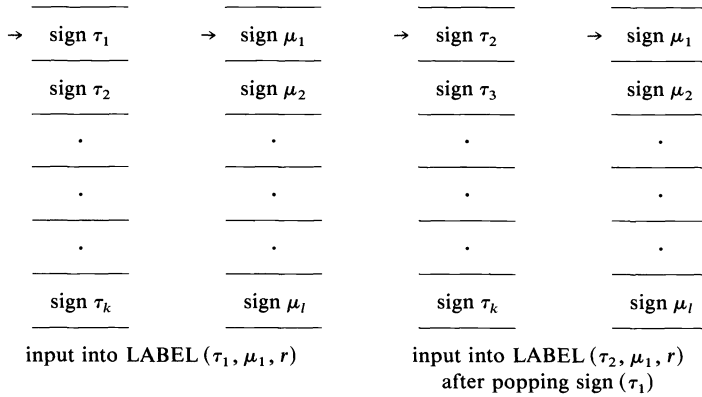

FIG. 4. The deck structure in recursion.

The procedure may continue calling itself through possibly  $k + l$  levels in recursion (after popping a sign ( $\tau_i$ ) or sign ( $\mu_j$ ) in preparation each time) until either Case 1 or Subcase 2(a) obtains, where of course  $A$  and  $C$  are replaced by some  $\tau_i$  or  $\mu_j$ . At this point the answer cascades back up as in the discussion of Subcase 2(b) to give the final output of LABEL ( $A, C, r$ ).

We must now develop the procedure MAKEDECK ( $T, r$ ) for an arbitrary tree  $T$  of maximum degree 3 rooted at a point  $r$  of degree 1 or 2. We begin with some lemmas.

A *pendant path* in  $T$  is a path  $P$  in  $T$  with endpoints  $x$  and  $y$  at least one of which is an endpoint in  $T$  and such that  $\deg(z, T) = 2$  for all  $z \in P \setminus \{x, y\}$ .

LEMMA 3. Let  $T$  be a tree. Let  $P$  be a pendant path in  $T$  from  $x$  to  $y$  such that  $\deg_T(x) = 1$ . Suppose  $T_p$  is a copy of  $T$  except that edges in  $P$  may be subdivided. Then  $B^*(T) = B^*(T_p)$ .

*Proof.* First note that  $B^*(T_p) \cong B^*(T)$  because any subdivision of  $T_p$  is also a subdivision of  $T$ . Thus we need only show the other direction, which we will do by induction on  $|T|$ . Let  $Q$  be an optimal backbone of  $T$ .

Case 1.  $P \cap Q = \emptyset$ . Then  $P$  is contained in  $H$ , a hanging of  $Q$ . By the induction hypothesis,  $B^*(H_p) = B^*(H)$  since  $H$  is smaller than  $T$ . Also the hangings of  $Q$  other than  $H$  do not contain  $P$ , so they have the same  $B^*$  values whether viewed as subtrees of  $T$  or  $T_p$ . Thus, all the hangings of  $Q$  in  $T_p$  have the same  $B^*$  values as the hangings of  $Q$  in  $T$ . Hence by Lemma 2 there is a  $t$ -layout of  $T_p$  having bandwidth  $\|Q\| = B^*(T)$ .

Case 2.  $P \cap Q = (y)$ . Let  $H = P' = P - y$ , so that  $H$  is a hanging of  $Q$  and  $P'$  is a pendant path in  $H$  (which happens to be all of  $H$ ). This gives the same situation as Case 1 with  $B^*(H) = B^*(H_p) = 1$ . The same argument as in Case 1 then gives  $B^*(T_p) \cong B^*(T)$ .

Case 3.  $P \subset Q$ . Then  $P$  is the tail of  $Q$  and it has no hangings, so by the construction of the optimal layout of  $T$  given by Lemma 2, the points on  $P$  will be numbered with integers spaced  $\|Q\|$  apart at the high end (or low end—it does not matter) of the range of the layout. But then it is easy to push out the high end of the range in order to fit in the additional points of  $T_p$ . This does not change the bandwidth.

Note that there can be no other way for  $P$  and  $Q$  to intersect because  $P$  is pendant. The proof is thereby completed.  $\square$

We now pass to a description of deck  $((T)_r)$  in terms of deck  $(T)$ . As notation we let  $\text{Tree}(T) = (\gamma_1, \gamma_2, \dots, \gamma_m)$  and  $\text{Tree}((T)_r) = (\gamma'_1, \gamma'_2, \dots, \gamma'_p)$ . We recall that  $\bar{r}$  is the endpoint not in  $T$  attached to  $r$ . We view it as the father of  $r$  in a depth-first search of  $(T)_r$ .

LEMMA 4. *Suppose  $T$  is rooted at a point  $r$  satisfying  $\text{deg}(r, T) = 1$ . Then  $\text{deck}((T)_r) = \text{deck}(T)_{m-1} \oplus (1, 1, \bar{r}, 1)$ .*

*Proof.* We begin by showing that  $\gamma'_i = (\gamma_i)_r$ ,  $1 \leq i \leq m$ , and that  $m = p$ . For the first claim we proceed by induction on  $i$ . It is trivially true for  $i = 1$ . Suppose it is true for all  $i \leq i_0$ , where  $i_0 < m$ . If  $h(\gamma_{i_0}) \neq r$ , then  $\gamma_{i_0}$  has two  $B^*(\gamma_{i_0})$ -primitive branches. Since  $\gamma'_{i_0} = (\gamma_{i_0})_r$  by induction, we have  $B^*(\gamma'_{i_0}) = B^*(\gamma_{i_0})$  by Lemma 3 and hence any optimal backbone of  $\gamma'_{i_0}$  must thread the same two branches. Thus  $h(\gamma'_{i_0}) = h(\gamma_{i_0})$  and hence  $\gamma'_{i_0+1} = (\gamma_{i_0+1})_r$ , so the induction is completed. The fact that  $m = p$  follows immediately since  $\gamma'_m = (\gamma_m)_r$  and  $h(\gamma_m) = r$  imply that  $h(\gamma'_m) = \bar{r}$ . Thus  $\gamma'_{m+1} = \emptyset$  so  $\gamma'_m$  is the last element of  $\text{Tree}((T)_r)$ .

We can now complete the proof. First we show that  $\text{sign}(\gamma'_j) = \text{sign}(\gamma_j)$  for  $j < m$ . The conditions  $\text{deg}(r, T) = 1$ ,  $\gamma'_j = (\gamma_j)_r$ , and Lemma 3 imply that  $B^*((\gamma'_j)_r) = B^*(\gamma'_j) = B^*((\gamma_j)_r) = B^*(\gamma_j)$ , and that the  $B^*(\gamma'_j)$ -primitive branches of  $\gamma'_j$  are identical to the  $B^*(\gamma_j)$ -primitive branches of  $\gamma_j$ . The condition  $\gamma'_j = (\gamma_j)_r$  for all  $j$  implies  $h(\gamma'_j) = h(\gamma_j)$  for  $j < m$ . It follows that  $\text{sign}(\gamma'_j) = \text{sign}(\gamma_j)$  for  $j < m$ .

For  $j = m$ , just observe that  $\gamma_m$  is a path with endpoint  $r$  so  $\gamma'_m = (\gamma_m)_r$  is a path with endpoint  $\bar{r}$ . Thus  $\text{sign}(\gamma'_m) = \{(1, 1, \bar{r}, 1)\}$ .

The lemma is thus proved.  $\square$

We now make some observations that lead to a description of deck  $((T)_r)$ , where  $r$  has degree 2.

LEMMA 5. *Suppose that for some integer  $j < m$  we have  $B^*(\gamma_q) = B^*((\gamma_q)_r)$  for  $1 \leq q \leq j$ . Then*

- (1)  $\gamma'_q = (\gamma_q)_r$  for  $1 \leq q \leq j + 1$ , and
- (2)  $\text{sign}(\gamma'_q) = \text{sign}(\gamma_q)$  for  $1 \leq q \leq j$ .

*Proof.* We start with (1). Proceeding by induction, suppose there is an integer  $q_0 \leq j$  for which (1) is true for all  $q \leq q_0$ , the case  $q_0 = 1$  being trivially true. Since  $q_0 < m$  we have  $h(\gamma_{q_0}) \neq r$ . Thus any optimal backbone of  $\gamma_{q_0}$  threads two  $B^*(\gamma_{q_0})$ -primitive branches of  $\gamma_{q_0}$ , and since  $B^*(\gamma_{q_0}) = B^*((\gamma_{q_0})_r)$ , any optimal backbone of  $(\gamma_{q_0})_r$  must thread these same two branches. Hence  $h(\gamma'_{q_0}) = h((\gamma_{q_0})_r) = h(\gamma_{q_0})$ , so  $\gamma'_{q_0+1} = (\gamma_{q_0+1})_r$  and the inductive step is done.

Now consider (2). We may suppose that  $m > 1$  since otherwise the statement is vacuously true. Take any  $q$  in the range  $1 \leq q \leq j$ . By hypothesis  $B^*(\gamma_q) = B^*((\gamma_q)_r)$  and by (1) we have  $B^*(\gamma'_q) = B^*((\gamma_q)_r)$ , so  $B^*(\gamma'_q) = B^*(\gamma_q)$ . By Lemma 3 we have  $B^*((\gamma'_q)_{\bar{r}}) = B^*(\gamma'_q) = B^*((\gamma_q)_r)$ . Hence the first and last entries of  $\text{sign}(\gamma'_q)$  are identical to those of  $\text{sign}(\gamma_q)$ . Since  $q < m$  we have  $h(\gamma_q) < m$ , and the argument in (1) can be

repeated to give  $h(\gamma'_q) = h(\gamma_q)$  and  $\nu(\gamma'_q) = \nu(\gamma_q) = 2$ . Hence  $\text{sign}(\gamma'_q) = \text{sign}(\gamma_q)$ . Part (2) is proved and we are done.  $\square$

LEMMA 6. *Suppose  $T$  is rooted at a point  $r$  satisfying  $\text{deg}(r, T) = 2$ .*

(1) *Let  $j$  be the first index, if it exists, such that  $B^*((\gamma_j)_r) \neq B^*(\gamma_j)$  (so that  $B^*((\gamma_j)_r) = B^*(\gamma_j) + 1$ ). Then*

$$\text{deck}((T)_r) = \text{deck}(T)_{j-1} \oplus (B^*(\gamma_j) + 1, 1, \bar{r}, B^*(\gamma_j) + 1).$$

(2) *If no such  $j$  exists, then*

(2a) *If  $\text{deg}(r, \gamma_m) = 1$ , then*

$$\text{deck}((T)_r) = \text{deck}(T)_{m-1} \oplus (B^*(\gamma_m), 1, \bar{r}, B^*(\gamma_m)).$$

(2b) *If  $\text{deg}(r, \gamma_m) = 2$ , then*

(2b') *If  $\nu(\gamma_m) = 1$ , then*

$$\text{deck}((T)_r) = \text{deck}(T)_{m-1} \oplus (B^*(\gamma_m), 1, \bar{r}, B^*(\gamma_m)).$$

(2b'') *If  $\nu(\gamma_m) = 2$ , then*

$$\text{deck}((T)_r) = \text{deck}(T) \oplus (1, 1, \bar{r}, 1).$$

*Proof.* (1) Suppose that the stated  $j$  exists. Then by Lemma 5  $\gamma'_q = (\gamma_q)_r$  for  $1 \leq q \leq j$  and  $\text{sign}(\gamma'_q) = \text{sign}(\gamma_q)$  for  $1 \leq q \leq j - 1$ . As for  $\text{sign}(\gamma'_j)$ , note that any backbone  $\beta$  of  $\gamma'_j = (\gamma_j)_r$  containing  $\bar{r}$  satisfies  $\|\beta\| \leq B^*(\gamma_j) + 1$  since all its hangings  $\alpha$  satisfy  $\alpha \subset \gamma_j$  and hence  $B^*(\alpha) \leq B(\gamma_j)$ . Thus  $h(\gamma'_j) = \bar{r}$ , so  $\text{sign}(\gamma'_j)$  is the last frame of  $\text{deck}((T)_r)$ . We have by Lemma 3 and hypothesis  $B^*((\gamma'_j)_{\bar{r}}) = B^*(\gamma'_j) = B^*((\gamma_j)_r) = B^*(\gamma_j) + 1$ . Finally  $\nu(\gamma'_j) = 1$  since  $\gamma'_j$  is its own  $B^*(\gamma_j)$ -primitive branch. Thus  $\text{sign}(\gamma'_j) = (B^*(\gamma_j) + 1, 1, \bar{r}, B^*(\gamma_j) + 1)$  and hence  $\text{deck}((T)_r) = \text{deck}(T)_{j-1} \oplus (B^*(\gamma_j) + 1, 1, \bar{r}, B^*(\gamma_j) + 1)$  as required.

(2) Suppose no such  $j$  exists. Since  $\gamma_m$  is the last tree in  $\text{Tree}(T)$ , it follows that  $h(\gamma_m) = r$ . Hence there is an optimal backbone  $\beta$  of  $\gamma_m$  containing  $r$ . We also have  $\text{sign}(\gamma'_q) = \text{sign}(\gamma_q)$  for  $q < m$  by Lemma 5.

Case 2(a). We can extend  $\beta$  to  $\bar{r}$  thereby obtaining a backbone  $\bar{\beta}$  of  $(\gamma_m)_r$ . Clearly  $\|\bar{\beta}\| = \|\beta\|$  since  $\bar{\beta}$  has the same hangings as  $\beta$ . Thus  $B^*((\gamma_m)_r) = B^*(\gamma_m)$ . By Lemma 5 we have  $\gamma'_m = (\gamma_m)_r$  so  $B^*(\gamma'_m) = B^*(\gamma_m)$ , and by Lemma 3,  $B^*((\gamma'_m)_{\bar{r}}) = B^*(\gamma'_m) = B^*(\gamma_m)$ . Finally  $h(\gamma'_m) = \text{head}(\bar{\beta}) = \bar{r}$ , and  $\nu(\gamma'_m) = 1$  since otherwise  $h(\gamma'_m) \neq \bar{r}$ . Thus  $\text{sign}(\gamma'_m) = (B^*(\gamma_m), 1, \bar{r}, B^*(\gamma_m))$ . Clearly  $\gamma'_m$  is the last element of  $\text{Tree}((T)_r)$ . Thus  $\text{deck}((T)_r) = \text{deck}(T)_{m-1} \oplus (B^*(\gamma_m), 1, \bar{r}, B^*(\gamma_m))$ .

Case 2(b). Assume first that  $\nu(\gamma_m) = 1$ . Then any backbone  $\bar{\beta}$  of  $\gamma'_m = (\gamma_m)_r$  which threads the unique  $B^*(\gamma_m)$ -primitive branch of  $\gamma_m$  satisfies  $\|\bar{\beta}\| = B^*(\gamma_m)$ . We can choose such a  $\bar{\beta}$  which contains  $\bar{r}$ . Hence we get  $B^*(\gamma'_m) = B^*(\gamma_m)$  and  $h(\gamma'_m) = \bar{r}$ . As above  $B^*((\gamma'_m)_{\bar{r}}) = B^*(\gamma'_m)$ , and  $\nu(\gamma'_m) = 1$  since  $\gamma'_m$  has the same unique  $B^*(\gamma_m)$ -primitive branch as  $\gamma_m$ . Thus  $\text{deck}((T)_r) = \text{deck}(T)_{m-1} \oplus (B^*(\gamma_m), 1, \bar{r}, B^*(\gamma_m))$ .

Now suppose  $\nu(\gamma_m) = 2$ . Since  $B^*(\gamma'_m) = B^*(\gamma_m)$  any optimal backbone  $\bar{\beta}$  of  $\gamma'_m$  must thread the same two  $B^*(\gamma_m)$ -primitive branches of  $\gamma_m$  as does  $\beta$ . Hence  $h(\gamma'_m) = \text{head}(\bar{\beta}) = \text{head}(\beta) = r$ . Clearly  $\nu(\gamma'_m) = \nu(\gamma_m) = 2$ , and  $B^*((\gamma'_m)_r) = B^*(\gamma'_m)$  as before. Thus  $\text{sign}(\gamma'_m) = \text{sign}(\gamma_m)$ . Also we have  $\gamma'_{m+1} = \{\bar{r}\}$ , so  $\text{sign}(\gamma'_{m+1}) = (1, 1, \bar{r}, 1)$ . Thus  $\text{deck}((T)_r) = \text{deck}(T) \oplus (1, 1, \bar{r}, 1)$ . The lemma is therefore proved.  $\square$

The procedure MAKEDECK  $(T, r)$  is now essentially given by Lemmas 4 and 6. For completeness we describe it explicitly.

Procedure MAKEDECK  $(T, r)$ .

*Input.*  $\text{deck}(T)$ , where  $T$  is a tree of maximum degree 3 rooted at  $r$ .

*Output.*  $\text{deck}((T)_r)$

(1) determine  $\text{deg}(r, T)$

(2) If  $\text{deg}(r, T) = 1$ , then

$$\text{deck}((T)_r) \leftarrow \text{deck}(T)_{m-1} \oplus (1, 1, \bar{r}, 1).$$

(3) If  $\text{deg}(r, T) = 2$ , then

(a) Search  $\text{deck}(T)$  from top to bottom until you find the minimum  $j$ , if it exists, such that  $B^*((\gamma_j)_r) \neq B^*(\gamma_j)$ .

(b) If such a  $j$  exists, then

$$\text{deck}((T)_r) \leftarrow \text{deck}(T)_{j-1} \oplus (B^*(\gamma_j) + 1, 1, \bar{r}, B^*(\gamma_j) + 1).$$

(c) If no such  $j$  exists, then determine  $\text{deg}(r, \gamma_m)$ . Depending on the answer, output  $\text{deck}((T)_r)$  according to the conditions defining cases (2a), (2b'), and (2b'') of Lemma 6.

This completes  $\text{MAKEDECK}(T, r)$ .

We remark that to determine  $\text{deg}(r, T)$  and  $\text{deg}(r, \gamma_m)$  we must maintain a new fifth entry, having value “1” or “2” to denote  $\text{deg}(r, \gamma_j)$  in  $\text{sign}(\gamma_j)$  for all  $\gamma_j \in \text{Tree}(T)$ . We describe the updating of  $\text{deg}(r, \gamma_j)$  here, omitting its formal inclusion in the lemmas and procedures to simplify their presentations.

We suppose then that in procedure  $\text{LABEL}(A, C, r)$  each frame  $\text{sign}(\tau_i)$  and  $\text{sign}(\mu_j)$  in  $\text{deck}(A)$  and  $\text{deck}(C)$ , respectively, has the additional bit  $\text{deg}(x, \tau_i)$  or  $\text{deg}(y, \mu_j)$  (respectively), where  $x$  and  $y$  are the roots of  $A$  and  $C$  (and thus the sons of  $r$  in  $T$ ). Our goal is to describe  $\text{deg}(r, \gamma_j)$  in all frames  $\text{sign}(\gamma_j)$  of  $\text{deck}(A \vee C)$ .

Suppose first that any of Subcases 1(a), 1(b), or 2(a) in  $\text{LABEL}(A, C, r)$  holds. Then the output  $\text{deck}(A \vee C)$  has a single frame. Since  $A$  and  $C$  are nonempty we have  $\text{deg}(r, A \vee C) = 2$ , so we insert “2” for  $\text{deg}(r, A \vee C)$  in the single frame.

Suppose then that Subcase 2(b) holds. The possible outputs are

(a)  $\text{deck}(A \vee C) = \{(b+1, 1, r, b+1)\}$ .

(b)  $\text{deck}(A \vee C) = (b, 2, h(A), B^*((A \vee C)_r)) \oplus \text{deck}((A \vee C)/h(A))$ .

In case (a) we again insert “2” for  $\text{deg}(r, A \vee C)$  as above. Suppose (b) holds. For the topmost frame we insert “2” again since  $A$  and  $C$  are nonempty so  $\text{deg}(r, A \vee C) = 2$ . The remaining frames (those in  $\text{deck}((A \vee C)/h(A))$ ) are handled as follows. If  $A/h(A) \neq \emptyset$ , then a call to  $\text{LABEL}(A/h(A) \vee C)$  was made and hence the degree entries in the frames of  $\text{deck}(A/h(A) \vee C) = \text{deck}((A \vee C)/h(A))$  have been inserted by recursion. If  $A/h(A) = \emptyset$ , then a call is made to  $\text{MAKEDECK}(C, y)$ . We then insert “1” in all frames of the resulting  $\text{deck}((C)_y)$ . The reason is that  $r$  (which plays the role of  $\bar{y}$  in  $\text{MAKEDECK}(C, y)$ ) is an endpoint of  $(C)_y$ , attached to  $y$  and hence has degree 1 in each element of  $\text{Tree}((C)_y)$ .

**3. Complexity.** We now discuss the complexity of procedures  $\text{LABEL}(A, C, r)$  and  $\text{MAKEDECK}(T, r)$  and the complexity of the resulting algorithm for  $B^*(T)$  in trees  $T$  of maximum degree 3.

Let  $T$  be any tree of maximum degree 3 rooted at a point  $r$ . We assume a DFS on  $T$  with associated branches  $B_x$  for all  $x \in T$ . Let  $|\text{deck}(T)|$  denote the number of frames (or signatures) in  $\text{deck}(T)$ , so  $|\text{deck}(T)| = |\text{Tree}(T)|$ . Our first goal is to estimate  $|\text{deck}(T)|$ .

For the next lemma we recall that a tree  $T$  is  $k$ -primitive if and only if it is its own (and hence unique)  $k$ -primitive branch, i.e.,  $B^*(T) = k$  and  $B^*(T') < k$  for any proper subtree  $T'$  with  $r \notin T'$ .

LEMMA 7. Let  $T$  be a  $k$ -primitive tree. Then  $|T| \geq 2^{k-1}$ .

*Proof.* Let  $f_k = \min \{p : |T| = p, T \text{ is } k\text{-primitive}\}$ . We show  $f_k \geq 2^{k-1}$  by induction on  $k$ .

For  $k = 1$ , the one-point tree is  $k$ -primitive by convention and has minimum order. Thus  $f_1 \geq 1 = 2^0$ . Now suppose  $f_j \geq 2^{j-1}$  for  $j < s$ .

Let  $T$  be  $s$ -primitive and have minimum possible order. We claim  $T$  must have at least two  $(s-1)$ -primitive branches. Suppose first that  $T$  has no  $(s-1)$ -primitive branches. Then any backbone  $\beta$  of  $T$  through  $r$  satisfies  $\|\beta\| \leq s-1$ , so  $B^*(A) \leq s-1$ , a contradiction. Similarly if  $T$  has only one  $(s-1)$ -primitive branch  $B_z$ , then any backbone  $\beta$  of  $T$  threading  $B_z$  and passing through  $r$  satisfies  $\|\beta\| \leq s-1$ , again a contradiction. Hence  $T$  has at least two  $(s-1)$ -primitive branches, so by induction  $|T| = f_s \geq 2f_{s-1} \geq 2^{s-1}$ .  $\square$

A sequence of trees  $T_1, T_2, \dots, T_k$  is called *monotone* if  $B^*(T_i) > B^*(T_{i+1}), i \geq 1$ .

LEMMA 8. For any tree  $T$ ,  $\text{Tree}(T)$  is *monotone*.

*Proof.* Let  $\text{Tree}(T) = \{\tau_1, \tau_2, \dots, \tau_l\}$ . Now by definition  $\tau_i/h(\tau_i) = \tau_{i+1}, 1 \leq i \leq l-1$ , and  $B^*(\tau_i) = \|\beta_i\|$  where  $\beta_i$  is a  $t$ -backbone of  $\tau_i$  with head  $(\beta_i) = h(\tau_i)$ . It follows that  $\tau_{i+1}$  is a hanging of  $\beta_i$  in  $\tau_i$ . Hence  $B^*(\tau_{i+1}) \leq \|\beta_i\| - 1 = B^*(\tau_i) - 1$ .  $\square$

COROLLARY 8.1. Let  $T$  be a tree on  $n$  points. Then  $|\text{deck}(T)| \leq B^*(T) \leq O(\log n)$ .

*Proof.* Since  $|\text{deck}(T)| = |\text{Tree}(T)|$  it suffices to prove the inequalities with  $|\text{deck}(T)|$  replaced by  $|\text{Tree}(T)|$ .

Let  $\text{Tree}(T) = \{\tau_1, \tau_2, \dots, \tau_l\}$ . Clearly  $B^*(\tau_1) = B^*(T)$ , so  $\tau_1$  contains a  $B^*(T)$ -primitive branch, and hence  $n = |\tau_1| \geq 2^{B^*(T)-1}$ . It follows that  $B^*(T) \leq O(\log n)$ . Also  $l < B^*(T)$  since  $\text{Tree}(T)$  is monotone.  $\square$

LEMMA 9. Let  $A$  and  $C$  be trees with  $|A| + |C| = n$ . Then  $\text{LABEL}(A, C, r)$  has complexity  $O(\log n)$ .

*Proof.* We may divide the running time of the algorithm into two parts. In the first part LABEL makes nested calls on itself of the form  $\text{LABEL}(\tau_i, \mu_j)$ . In the second part, which may not occur, LABEL calls on MAKEDECK  $(\mu_{j_0}, y)$  or MAKEDECK  $(\tau_{i_0}, x)$  for some  $j_0 \leq |\text{deck}(C)|$  or  $i_0 \leq |\text{deck}(A)|$ . Without loss of generality let this call be MAKEDECK  $(\mu_{j_0}, y)$ .

Consider the first part. Each call requires  $O(1)$  time since it consists in scanning  $\text{sign}(\tau_i)$  and  $\text{sign}(\mu_j)$  and then defining  $\text{deck}(\tau_i \vee \mu_j)$  as a single frame or the result of pushing a single frame onto the recursively computed  $\text{deck}(\tau_{i+1} \vee \mu_j)$  or  $\text{deck}(\tau_i \vee \mu_{j+1})$ . The call pops either  $\text{sign}(\tau_i)$  or  $\text{sign}(\mu_j)$  before the next call begins. The total number of calls is the number of times a frame is popped before the call to MAKEDECK  $(\mu_{j_0}, y)$ . Hence this number is  $|\text{deck}(A)| + j_0$ , so the time spent on the first part is  $O(|\text{deck}(A)| + j_0)$ .

In the second part MAKEDECK processes from top to bottom all the remaining  $|\text{deck}(C)| - j_0$  frames of  $\text{deck}(C)$ . It spends at most  $O(1)$  time on each frame since it only scans for the condition  $B^*((\gamma)_r) \neq B^*(\gamma_j)$  or inserts a new frame at the bottom of the ones it has already checked. The time for the second part is thus  $O(|\text{deck}(C)| - j_0)$ .

It follows that the total time of LABEL  $(A, C, r)$  is  $O(|\text{deck}(A)| + |\text{deck}(C)|) \leq O(\log |A| + \log |C|) \leq O(\log (|A||C|)) \leq O(\log(n^2)) = O(\log n)$ .  $\square$

LEMMA 10. Let  $A$  be a tree with  $|A| = n$  rooted at  $r$ . Then MAKEDECK  $(A, r)$  has complexity  $O(\log n)$ .

*Proof.* The proof is essentially the same as the second part of the proof of Lemma 9.  $\square$

We can now give an  $O(n \log n)$  algorithm for  $B^*(T)$ . Later we sketch how it can be refined to linear time.

THEOREM 1. Let  $T$  be a tree of maximum degree 3. Then  $B^*(T)$  can be computed

in  $O(n \log n)$  time.

*Proof.* Suppose first that  $t$  has a point  $r$  of degree 2.

Now view  $r$  as the root of  $T$ . Now order  $V(T)$  in reverse depth-first search from endpoints “up” to  $r$  (i.e., in postorder). If  $e$  is an endpoint, then  $\text{deck}(\{e\}) = \{(1, 1, e, 1)\}$ , (where we recall the convention  $B^*(\{e\}) = 1$ ). Now for some  $x \in T$ , assume inductively that  $\text{deck}(B_y)$  is known for each of (the at most two) sons of  $x$ . If  $x$  has only one son  $y$ , then  $\text{deck}(B_x)$  can be obtained from  $\text{deck}(B_y)$  by calling on MAKEDECK( $B_y, y$ ). Suppose then that  $x$  has sons  $y_1$  and  $y_2$ . We then apply LABEL( $B_{y_1}, B_{y_2}, x$ ) and get  $\text{deck}(B_x)$  as output.

Continuing to work our way up we eventually apply LABEL( $B_{s_1}, B_{s_2}, r$ ), where  $s_i$  are the sons of  $r$ . The output,  $\text{deck}(B_r) = \text{deck}(T)$ , has in its first entry the required  $B^*(T)$ . The algorithm then halts.

If  $T$  has no point of degree 2, then let  $r$  be a point of degree 1. We proceed as above, calling on either LABEL or MAKEDECK as we work our way up  $T$  (rooted at  $r$ ). Eventually we call on MAKEDECK( $B_s, s$ ), where  $s$  is the unique son of  $r$ . The output,  $\text{deck}((B_s)_s) = \text{deck}(T)$ , gives  $B^*(T)$  and the algorithm halts.

In either case there are a total of  $n$  calls of the form LABEL( $B_{y_1}, B_{y_2}, x$ ) or MAKEDECK( $B_y, y$ ), each requiring at most  $O(\log n)$  time by Lemmas 9 and 10. Hence the total time is bounded by  $O(n \log n)$ .  $\square$

**4. A  $O(n)$  time bound.** In this section we describe informally a way of lowering the complexity of our algorithm to  $O(n)$ .

Let  $\text{Tree}(A) = \{\tau_i : 1 \leq i \leq l\}$  and  $\text{Tree}(C) = \{\gamma_j : 1 \leq j \leq k\}$ . The main idea is to modify procedure LABEL( $A, C, r$ ). In the worst case it processes all  $|\text{deck}(A)| + |\text{deck}(C)| \leq \log |A| + \log |C|$  signatures in  $\text{deck}(A)$  and  $\text{deck}(C)$ , giving a time bound  $O(\log n)$ ,  $n = |A \vee C|$ . We indicate how the addition of new decks that point to gaps in the sequences  $\{B^*(\tau_i)\}$  and  $\{B^*(\gamma_j)\}$  permits an  $O(\min\{\log |A|, \log |C|\})$  implementation of the procedure.

As motivation, suppose that LABEL( $A, C, r$ ) performs in recursion LABEL( $\tau_c, \gamma_d, r$ ), say with  $B^*(\tau_c) > B^*(\gamma_d)$ . Suppose also that for some  $e > c$  we have  $B^*(\tau_e) = B^*(\gamma_d)$  and  $B^*(\tau_{i+1}) = B^*(\tau_i) - 1$  for  $c \leq i \leq e - 1$ . Then we have the equivalences  $B^*(\tau_c \vee \gamma_d) \leq B^*(\tau_c) \Leftrightarrow B^*(\tau_{c+1} \vee \gamma_d) \leq B^*(\tau_c) - 1 \Leftrightarrow \dots \Leftrightarrow B^*(\tau_e \vee \gamma_d) \leq B^*(\tau_c) - (e - c)$ . Of course the falsity of the above inequalities yields  $B^*(\tau_c \vee \gamma_d) = B^*(\tau_c) + 1$  in which case  $\text{deck}(\tau_c \vee \gamma_d)$  has only one frame. Thus the result of LABEL( $\tau_e, \gamma_d, r$ ) telescopes up to decide the result of LABEL( $\tau_c, \gamma_d, r$ ). As now constituted, LABEL( $A, C, r$ ) performs the  $O(e - c)$  operations for achieving the telescoping. Our goal is to do this in  $O(1)$  time by using a pair of successive pointers from a separate deck, one to  $B^*(\tau_c)$  and the other to  $B^*(\tau_e)$ . When the inequalities are false, we advance the pointer to  $B^*(\tau_c)$  one unit and delete the one to  $B^*(\tau_e)$ , and when they are true we leave both pointers stationary. In this way we can treat entire segments of  $\text{deck}(A)$  (or  $\text{deck}(C)$ ), i.e., a sequence of successive frames having successive  $B^*$  values, in  $O(1)$  time. The result will be that the time spent by LABEL in processing  $\text{deck}(A)$  and  $\text{deck}(C)$  becomes proportional to the number of gaps in the sequence of  $B^*$  values occurring in whichever of  $\text{deck}(A)$  or  $\text{deck}(C)$  has fewer frames.

To be precise, we define two additional decks, GAP( $A$ ) and GAP( $C$ ), as follows. Suppose  $R_{jm} = \{\tau_j, \tau_{j+1}, \dots, \tau_m\}$  is a subsequence of  $\text{Tree}(A)$  satisfying  $B^*(\tau_{i+1}) = B^*(\tau_i) - 1$ ,  $j \leq i \leq m - 1$ ,  $B^*(\tau_{j-1}) > 1 + B^*(\tau_j)$ , and  $B^*(\tau_{m+1}) < B^*(\tau_m) - 1$ . We call  $R_{jm}$  a *run* of  $\text{Tree}(A)$  (and also of  $\text{deck}(A)$  under the correspondence between  $\text{deck}(A)$  and  $\text{Tree}(A)$ ). For any  $\tau \in \text{Tree}(A)$ , let  $\text{run}(\tau)$  denote the run of  $\text{Tree}(A)$  to which  $\tau$  belongs. For each run  $R_{jm}$  there will be two consecutive elements  $b(R_{jm}), t(R_{jm})$  in

the list  $GAP(A)$ . We let  $t(jm)$  point to  $B^*(\tau_j)$  in  $sign(\tau_j)$  and  $b(jm)$  point to  $B^*(\tau_m)$  in  $sign(\tau_m)$ . If  $R_{jm}$  and  $R_{qr}$  are runs with  $m < q$ , then the pointers to  $R_{jm}$  come before (i.e., above) those to  $R_{qr}$ . The deck  $GAP(C)$  is constructed similarly.

Our new procedure  $\overline{LABEL}(A, C, r)$  can be described informally as follows. It has input deck  $(A)$ , deck  $(C)$ ,  $GAP(A)$ ,  $GAP(C)$ , and output deck  $(A \vee C)$  and  $GAP(A \vee C)$ . Without loss of generality we take  $B^*(A) \cong B^*(C)$ . For brevity we consider only the first case where  $\log|C| \leq \log|A|$ ; the case  $\log|C| > \log|A|$  is done with straightforward but tedious changes. We let  $bottomdeck(T)$  be the bottommost entry of deck  $(T)$  for a tree  $T$ .

(I) Work your way up deck  $(A)$  from  $bottomdeck(A)$  to  $sign(\tau_u)$ , where  $u = \min\{j: B^*(\tau_j) \cong B^*(\gamma_1)\}$  if  $B^*(\tau_l) \cong B^*(\gamma_1)$  and  $u = l$  otherwise. Also work up  $GAP(A)$  until you reach  $b(run(\tau_u))$ .

(II) Perform  $\overline{LABEL}(\tau_u, \gamma_1, r)$ .

(III) Construct deck  $((A \vee C)_r)$  and  $GAP((A \vee C)_r)$  as follows.

(A) Suppose  $B^*(\tau_u \vee \gamma_1) = 1 + B^*(\gamma_1)$ , so that deck  $(\tau_u \vee \gamma_1)$  is the single frame  $sign(\tau_u \vee \gamma_1) = (1 + B^*(\gamma_1), 1, r, B^*(\gamma_1))$ .

(1) Check if there is a run  $R_{ab}$  in  $Tree(A)$  one of whose members  $\tau$  satisfies  $B^*(\tau) = 1 + B^*(\gamma_1)$ . (Note. Such an  $R_{ab}$  must be  $run(\tau_u)$  or the run preceding  $run(\tau_u)$  in  $Tree(A)$ .)

(2) If there is, then move up to  $t(R_{ab})$  in  $GAP(A)$  (up  $\leq 2$  pointers) and follow  $t(R_{ab})$  to the top frame  $sign(\tau_a)$  of  $R_{ab}$ . Now do  $sign(\tau_a \vee \gamma_1) \leftarrow (1 + B^*(\gamma_1), 1, r, 1 + B^*(\gamma_1))$ . Now deck  $(A \vee C)$  is given by  $deck(A \vee C) = deck(A)_{a-1} \oplus sign(\tau_a \vee \gamma_1)$ . Note that the list  $deck(A)_{a-1}$  may now be regarded as  $\{sign(\tau_j \vee \gamma_1)\}$ .

(3) If there is no  $R_{ab}$ , then let  $deck(A \vee C) = deck(A)_{u-1} \oplus sign(\tau_u \vee \gamma_1)$ . Again, the entries  $\{sign(\tau_j)\}$ ,  $1 \leq j \leq u-1$ , may be regarded as  $\{sign(\tau_j \vee \gamma_1)\}$ .

(4)  $GAP(A \vee C)$  is obtained by making corresponding changes in  $GAP(A)$ . Suppose for example that (2) holds, and let  $run(\tau_a \vee \gamma_1) = R_{\alpha\beta}$  in deck  $(A \vee C)$ . If  $R_{\alpha\beta}$  is not a singleton, then  $R_{\alpha\beta}$  corresponds to a run  $R_{\alpha(\beta-1)}$  in deck  $(A)$  with  $\tau_a \vee \gamma_1$  appended at the end. Hence we let  $t(R_{\alpha\beta}) = t(R_{\alpha(\beta-1)})$  while  $b(R_{\alpha\beta})$  points to  $sign(\tau_a \vee \gamma_1)$ . Naturally  $b(R_{\alpha(\beta-1)})$  in  $GAP(A)$  is deleted. All elements of  $GAP(A)$  corresponding to runs about  $R_{\alpha\beta}$  are retained in  $GAP(A \vee C)$ . We omit here the changes appropriate to (3) since similar changes are described below.

(B) Suppose  $B^*(\tau_u \vee \gamma_1) = B^*(\gamma_1)$ . Then deck  $(A \vee C)$  is given by  $deck(A \vee C) = deck(A)_{u-1} \oplus deck(\tau_u \vee \gamma_1)$ . Now  $GAP((A \vee C)_r)$  is constructed as follows.

(1) Create  $GAP(\tau_u \vee \gamma_1)$  by processing deck  $(\tau_u \vee \gamma_1)$  top to bottom and forming the pointers appropriate to each run.

(2) Attach  $GAP(\tau_u \vee \gamma_1)$  to  $GAP(A)$  as follows.

Let  $GAP'(A)$  be the subdeck of  $GAP(A)$  of pointers corresponding to  $run(\tau_{u-1})$  and all runs above  $run(\tau_{u-1})$ .

(a) If  $B^*(\tau_{u-1}) > 1 + B^*(\gamma_1)$ , then just append  $GAP(\tau_u \vee \gamma_1)$  to the bottom of  $GAP'(A)$  and retain the pointer structure in each.

(b) If  $B^*(\tau_{u-1}) = 1 + B^*(\gamma_1)$ , then append as above but remove  $b(run(\tau_{u-1}))$  from  $GAP'(A)$  and  $t(run(\tau_u \vee \gamma_1))$  from  $GAP(\tau_u \vee \gamma_1)$ . (This has the effect of merging the runs  $run(\tau_{u-1})$  and  $run(\tau_u \vee \gamma_1)$  into one in  $GAP(\tau_u \vee \gamma_1)$ .)

We now examine the complexity of our procedure.

**THEOREM 2.**  $\overline{\text{LABEL}}(A, C, r)$  has complexity  $O(\min\{\log|C|, \log|A|\})$ .

*Proof.* For brevity we again restrict ourselves to the case  $B^*(A) \geq B^*(C)$  and  $\log|C| \leq \log|A|$  treated above.

First, (I) and (II) each require  $O(\log(C))$  time since each processes at most  $O(B^*(\gamma_1)) = O(\log|C|)$  frames. The construction of deck  $(A \vee C)$  takes  $O(1)$  time since it consists in just appending deck  $(\tau_u \vee \gamma_1)$  below a certain position in deck  $(A)$ . This position is accessed in  $O(1)$  time since after performing (I) and (II) we are just below the pointer in  $\text{GAP}(A)$  that leads to this position.

$\text{GAP}(A \vee C)$  is constructed in  $O(1)$  time in case (A), and in  $O(\log|C|)$  time in case (B). In (A) we simply adjust one or two pointers at the position of  $\text{GAP}(A)$  reached after (I) and (II). In (B) we first construct  $\text{GAP}(\tau_u \vee \gamma_1)$ . This takes  $O(\log|C|)$  time since we are just scanning frames  $\text{sign}(\tau_i \vee \gamma_j)$  of deck  $(\tau_u \vee \gamma_1)$  all with  $B^*$  values  $\leq B^*(\gamma_1)$ . The number of such frames is at most  $B^*(\gamma_1)$  by monotonicity of  $\text{Tree}(\tau_u \vee \gamma_1)$  from Lemma 8, and  $B^*(\gamma_1) \leq O(\log|\gamma_1|) = O(\log|C|)$  by Corollary 8.1. We then splice together  $\text{GAP}(\tau_u \vee \gamma_1)$  and  $\text{GAP}'(A)$  by at worst deleting two pointers (the position below which we have already accessed), and this is  $O(1)$  time. Hence the total time of  $\overline{\text{LABEL}}(A, C, r)$  is  $O(\log|C|)$ , as required.  $\square$

In a similar way we can define a new procedure  $\overline{\text{MAKEDECK}}(T, r)$  which does the same job as the old procedure  $\text{MAKEDECK}(T, r)$ ; that is, it constructs deck  $((T), r)$  from deck  $(T)$ . By creating additional pointer structure, we can make the new procedure run in time  $O(1)$  instead of the worst-case  $O(\log n)$  for the old procedure. A brief sketch of how this is done follows.

As motivation, recall that  $\text{MAKEDECK}(T, r)$  constructs deck  $((T), r)$  from deck  $(T)$  by doing one of the following operations:

- (op1) inserting a frame at the bottom of deck  $(T)$ ,
- (op2) replacing the bottom frame of deck  $(T)$  by a different frame, or
- (op3) finding the topmost frame of deck  $(T)$  in which  $B^*((\gamma_j), r) \neq B^*(\gamma_j)$  (if such a frame exists), and replacing it and the frames under it (i.e., those associated with  $\gamma_i$ , where  $i > j$ ) by the single frame  $(B^*(\gamma_j) + 1, 1, \bar{r}, B^*(\gamma_j) + 1)$ .

Notice that to do any one of these operations we need only access an “extreme” frame of some type: either the bottom frame in deck  $(T)$ , or the topmost relative to the property  $B^*((\gamma_j), r) \neq B^*(\gamma_j)$ .

This suggests the construction of a new deck; call it  $\text{FRAME}(T)$ . The elements of  $\text{FRAME}(T)$  will be pointers to those frames of deck  $(T)$  in which  $B^*((\gamma_j), r) \neq B^*(\gamma_j)$ , and, if not already present among the elements just mentioned, an additional pointer to the bottom frame of deck  $(T)$ . These elements will be ordered top to bottom in  $\text{FRAME}(T)$  in the same relative order as the frames of deck  $(T)$  to which they point. We can then access the required frame of deck  $(T)$  in each case by using either the topmost or bottommost element of  $\text{FRAME}(T)$ . Finding either of these elements takes  $O(1)$  time since they are at the top or bottom of  $\text{FRAME}(T)$ .

Now the procedure  $\overline{\text{MAKEDECK}}(T, r)$  operates by invoking  $\text{MAKEDECK}(T, r)$  and using  $\text{FRAME}(T)$  to access the frame in deck  $(T)$  under which the insertion specified by  $\text{MAKEDECK}$  will take place. The resulting construction of deck  $((T), r)$  takes  $O(1)$  time since it involves placing a single frame under or at the accessed frame of deck  $(T)$ .

Finally we sketch how the time required to maintain  $\text{FRAME}(T)$  is dominated by the complexity of procedures already in use, so that the total complexity of our algorithm is unaffected (up to a constant term) by the additional pointer structure. To update  $\text{FRAME}(T)$  we need to do the following:

(1) Construct  $\text{FRAME}((T)_r)$  from  $\text{FRAME}(T)$  (after  $\overline{\text{MAKEDECK}}(T, r)$  has constructed deck  $((T)_r)$  from deck  $(T)$ ).

(2) Construct  $\text{FRAME}(A \vee C)$  from  $\text{FRAME}(A)$  and  $\text{FRAME}(C)$  (after  $\overline{\text{LABEL}}(A, C, r)$  has constructed deck  $(A \vee C)$  from deck  $(A)$  and deck  $(C)$ ).

Upon starting task (1), note that we would have already performed one of the operations (op1), (op2), or (op3) during  $\overline{\text{MAKEDECK}}(T, r)$ . If (op2) was performed then  $\text{FRAME}((T)_r)$  is obtained from  $\text{FRAME}(T)$  by reorienting the bottom element of  $\text{FRAME}(T)$  to point to the bottom of deck  $((T)_r)$ . The remaining elements of  $\text{FRAME}(T)$  remain the same, except now regarded as members of  $\text{FRAME}((T)_r)$ . If (op3) was performed, then  $\text{FRAME}((T)_r)$  is just a single element pointing to the bottom frame of deck  $((T)_r)$ . If (op1) was performed, then the updating depends on whether

- (i) the bottom element of deck  $(T)$  has the property  $B^*((\gamma_m)_r) \neq B^*(\gamma_m)$ , or
- (ii) the bottom element of deck  $(T)$  does not have this property.

If (i) holds then  $\text{FRAME}((T)_r)$  is gotten by inserting a new element at the bottom of  $\text{FRAME}(T)$ , and pointing this element to the bottom of deck  $((T)_r)$ . If (ii) holds, then  $\text{FRAME}((T)_r)$  is obtained by reorienting the bottom element of  $\text{FRAME}(T)$  to point to the bottom of deck  $((T)_r)$ .

Notice that any of these updates requires at most  $O(1)$  time since it involves a  $O(1)$  manipulation (insertion and orientation of a pointer to the bottom of some deck) at or directly below an element of  $\text{FRAME}(T)$  already accessed in  $O(1)$  time. It is also easily checked that the deck  $\text{FRAME}((T)_r)$  so produced has the necessary properties, namely, elements pointing to the frames of deck  $((T)_r)$  in which  $B^*((\gamma_j)_r) \neq B^*(\gamma_j)$  and ordered in the natural way, and a bottom element (if not already present) pointing to the bottom of deck  $((T)_r)$ .

We can achieve (2) in a manner analogous to the construction of  $\text{GAP}(A \vee C)$  from  $\text{GAP}(A)$  and  $\text{GAP}(C)$  outlined previously. This requires time  $O(\min\{\log|A|, \log|C|\})$  which is already required by the procedure  $\overline{\text{LABEL}}$ . Details of the construction and time bound in (2) are omitted here since they are nearly identical with the above-mentioned construction and time analysis for  $\text{GAP}(A \vee C)$ .

Our procedures  $\overline{\text{LABEL}}$  and  $\overline{\text{MAKEDECK}}$  can now be used to give our linear algorithm.

**THEOREM 3.** *Let  $T$  be a tree of maximum degree 3 on  $n$  points. Then  $B^*(T)$  can be computed in  $O(n)$  time.*

*Proof.* We carry out our procedures in the order specified by the proof of Theorem 1. That is, we work our way up  $T$  from bottom to top in postorder. Thus we start by defining deck  $((e))$  for each endpoint  $e$  as before. Now as we meet each new point  $x \in T$  in postorder, our job is to compute deck  $(B_x)$  given deck  $(B_y)$  for each of the (at most) two children  $y$  of  $x$ . If  $x$  has two children  $y_1$  and  $y_2$ , then we apply  $\overline{\text{LABEL}}(B_{y_1}, B_{y_2}, x)$  to get deck  $(B_x)$  at a cost of  $\log(\min(|B_{y_1}|, |B_{y_2}|))$  time by Theorem 2. If  $x$  has one child  $y$ , then we apply  $\overline{\text{MAKEDECK}}(B_y, y)$  to get deck  $(B_x)$  at a cost of  $O(1)$  time by the above discussion. At the end we finally obtain deck  $(B_r) = \text{deck}(T)$ , where  $r$  is the root of  $T$  and from that we get  $B^*(T)$  by scanning the topmost frame of this deck.

Now let  $T(n)$  be the total time required by the algorithm described in the above paragraph. It follows from the description that  $T(n+1) \leq \max_{1 \leq k \leq n/2} \{T(k) + T(n-k) + \log(k)\}$ .

We now claim that  $T(n)$  satisfies

$$T(n) \leq An - B \log(n) + C$$

for some constants  $A$ ,  $B$ , and  $C$ . Of course, the theorem follows from this claim. Proceeding by induction, suppose the inequality holds for all  $n \leq p$ . Using the inductive assumption we then have

$$\begin{aligned}
 T(p+1) &\leq \max_{1 \leq k \leq p/2} \{T(k) + T(n-k) + \log(k)\} \\
 (*) \quad &\leq \max_{1 \leq k \leq p/2} \{Ak - B \log(k) + A(p-k) - B \log(p-k) + \log(k) + 2C\} \\
 &= \max_{1 \leq k \leq p/2} \{Ap - \log(k^{B-1}(p-k)^B) + 2C\}.
 \end{aligned}$$

We now show that there are constants  $B$  and  $C$  such that the inequality

$$(**) \quad \max_{1 \leq k \leq p/2} \{-\log(k^{B-1}(p-k)^B) + 2C\} \leq -B \log(p+1) + C$$

holds for  $p$  sufficiently large. Clearly (\*\*) is equivalent to  $\min_{1 \leq k \leq p/2} \{k^{B-1}(p-k)^B\} \geq (p+1)^{B-2} C$ . Choosing  $B=2$ , we find that for  $p \geq 4$  the minimum in the left-hand side is achieved at  $k=1$  and is therefore  $(p-1)^2$ . Now with  $C=-2$  we get (\*\*) to hold for  $p \geq 4$ . Thus (\*\*) holds with  $B=2$  and  $C=-2$  for all  $p \geq 4$ .

Now combining (\*) and (\*\*) and observing that  $Ap < A(p+1)$  we see that the inductive step is completed. It remains only to choose  $A$  sufficiently large relative to  $B=2$  and  $C=-2$  ( $A \geq 20$  will do) so that the claimed bound for  $T(n)$  holds for  $n \leq 3$ , thereby providing the base for the induction. The theorem is thus proved.  $\square$

**Acknowledgments.** The author thanks I. H. Sudborough and J. Ellis for discussions which stimulated the idea for the additional data structure used in the last section, and Robert Tarjan for suggesting the method of proving that the linear time bound follows from the recurrence satisfied by the time complexity. Thanks also go to Ruth Engel for executing the drawings.

## OPTIMAL BOUNDS FOR SOLVING TRIDIAGONAL SYSTEMS WITH PRECONDITIONING\*

PAOLO ZELLINI†

**Abstract.** Let (1)  $T\mathbf{x} = \mathbf{f}$  be a linear tridiagonal system of  $n$  equations in the unknowns  $x_1, \dots, x_n$ . It is proved that  $3n - 2$  (nonscalar) multiplications/divisions are necessary to solve (1) in a straight-line program excluding divisions by elements of  $\mathbf{f}$ . This bound is optimal if the cost of preconditioning of  $T$  is not counted. Analogous results are obtained in case (i)  $T$  is bidiagonal and (ii)  $T$  and  $\mathbf{f}$  are both centrosymmetric. The existence of parallel algorithms to solve (1) with preconditioning and with minimal multiplicative redundancy is also discussed.

**Key words.** multiplicative complexity, LU factorization, straight-line algorithms, parallel algorithms, tridiagonal systems, rational preconditioning

**AMS(MOS) subject classifications.** 68Q25, 65F05

**1. Introduction.** It is well known that the inverse  $S$  of a tridiagonal matrix  $T$  has a special structure which can be described in terms of a few vectors [2], [3], [7], [9], [24]. More precisely, if  $T$  has dimension  $n \times n$  and  $\det T \neq 0$ , then two  $n$ -vectors  $\mathbf{u} = [u_1, \dots, u_n]^T$  and  $\mathbf{v} = [v_1, \dots, v_n]^T$ , and one  $(n-1)$ -vector  $\mathbf{w} = [w_1, \dots, w_{n-1}]^T$  are sufficient to define  $S = T^{-1}$  (for more details see § 2). The amount of information to define  $T^{-1}$  can also be reduced in case  $T$  has a special structure: in particular if  $T$  is symmetric or centrosymmetric (see [7], [9], and § 2).

Observe that a general tridiagonal  $n \times n$  matrix  $T$  is a linear combination of  $3n - 2$  rank-one  $(0, 1)$  matrices. Thus  $3n - 2$  is the multiplicative complexity of a matrix-vector product  $T\mathbf{f}$ , even if all entries (indeterminates) in  $T$  and in  $\mathbf{f}$  commute with each other (this is a trivial consequence of the first results on the multiplicative complexity of a set of bilinear forms stated in [8], [10], [15], [20], [6]). Now, by the special structure of  $S = T^{-1}$ , we suspect that the same multiplicative complexity ( $3n - 2$  multiplicative operations) is in a special sense relevant to the "inverse" problem of computing the vector  $T^{-1}\mathbf{f} = S\mathbf{f}$ , or, equivalently, for solving a system of linear equations  $T\mathbf{x} = \mathbf{f}$ . More specifically, it will be proved in the next sections that  $3n - 2$  is an optimal lower bound to solve, with preconditioning, a general  $n \times n$  tridiagonal system  $T\mathbf{x} = \mathbf{f}$ . This bound holds for all straight-line programs, relative to a ground field  $G$  and to the set of indeterminates present in  $T$  and in  $\mathbf{f}$ ; the only restriction is excluding divisions by polynomials in the  $f_i$ 's. This last restriction does not seem to be serious since in all best known sequential and parallel algorithms for solving  $T\mathbf{x} = \mathbf{f}$  (LU decomposition, Cramer's rule, cyclic odd-even reduction, QR algorithms, methods using explicit formulas for the entries of  $T^{-1}$ ) there is no division by such polynomials. Analogous results can easily be stated for bidiagonal systems and for systems  $T\mathbf{x} = \mathbf{f}$ , where  $T$  is centrosymmetric and  $f_i = f_{n-i+1}$ .

**2. Preliminaries.** Let  $T = (t_{ij})$  be a general, i.e., with indeterminate entries,  $n \times n$  tridiagonal matrix,  $\det T \neq 0$ ,

$$(2.1) \quad t_{ij} = \begin{cases} a_i, & i = j, \\ b_i, & j - i = 1, \\ c_j, & i - j = 1, \\ 0 & \text{otherwise} \end{cases}$$

\* Received by the editors December 2, 1985; accepted for publication (in revised form) November 3, 1987.

† Dipartimento di Matematica e Informatica, Università di Udine, 6-33100 Udine, Italy.

and let  $S = (s_{ij})$  be a general matrix,  $\det S \neq 0$ , defined by

$$(2.2) \quad s_{ij} = \begin{cases} v_i u_j \prod_{q=i}^{j-1} w_q, & i < j, \\ u_i v_j, & i \cong j. \end{cases}$$

The relationship between (2.1) and (2.2) and an explicit formula for  $\det S$  are stated in the following proposition.

PROPOSITION 1 [9].

- (i)  $T^{-1}$  has the form (2.2).
- (ii)  $S^{-1}$  is tridiagonal.
- (iii)  $\det S = v_1 u_n \prod_{q=1}^{n-1} (u_q v_{q+1} - w_q u_{q+1} v_q)$ .

Observe that the  $3n - 2$  entries of  $T = S^{-1}$  are given, in explicit form, by [9]:

$$(2.3) \quad \begin{aligned} a_1 &= v_2 q_1 / v_1, & b_1 &= -w_1 q_1, \\ c_{i-1} &= -q_{i-1}, \\ a_i &= -p_i q_{i-1} q_i, \\ b_i &= -w_i q_i, & i &= 2, 3, \dots, n-1, \\ c_{n-1} &= -q_{n-1}, & a_n &= u_{n-1} q_{n-1} / u_n \end{aligned}$$

where

$$q_j = 1 / (u_j v_{j+1} - u_{j+1} v_j w_j), \quad p_j = u_{j+1} v_{j-1} w_{j-1} w_j - u_{j-1} v_{j+1}.$$

Observe that if  $w_q = 1$  in (2.2), then both  $S$  and  $S^{-1}$  are symmetric. Also, if  $w_q = 0$ , then  $S^{-1}$  is bidiagonal and the inverse of a bidiagonal  $n \times n$  has the form (2.2) with  $w_k = 0$ . The results in Proposition 1 are to be modified slightly in case  $T$  is centrosymmetric, i.e.,  $a_i = a_{n-i+1}$  and  $c_j = b_{n-j}$  in (2.1). More precisely, let  $M = (m_{ij})$  be a general centrosymmetric matrix ( $\det M \neq 0$ ) defined by

$$(2.4) \quad m_{ij} = \begin{cases} u_i v_{n-j+1}, & i \leq j, \\ u_{n-i+1} v_j, & i \geq j, \end{cases}$$

with  $u_i v_{n-i+1} \equiv u_{n-i+1} v_i$ .

Then we have the following proposition.

PROPOSITION 2.

- (i) If  $T$  in (2.1) is centrosymmetric, then  $T^{-1}$  has the form (2.4).
- (ii)  $M^{-1}$  is tridiagonal and centrosymmetric.
- (iii)  $\det M = u_1 v_1 \prod_{q=1}^{n-1} (u_{n-q+1} v_{q+1} - u_q v_{n-q})$ .

*Proof.* We can see Proposition 2 as a consequence of Proposition 1; in fact (2.2) and (2.4) can be made identical by reindexing the indeterminates  $u$  in (2.4) and by giving proper values to  $w_q$  in (2.2), i.e.,  $w_q = u_{n-q+1} u_{q+1}^{-1} v_{n-q} v_q^{-1}$ . The explicit formulas for the entries of  $M^{-1}$  are given by

$$(2.5) \quad \begin{aligned} a_1 &= -v_2 z_{n-1} / v_1, \\ b_i &= z_i, & i &= 1, 2, \dots, n-1, \\ a_i &= -t_i z_{i-1} z_i, & i &= 1, 2, \dots, \lfloor n/2 \rfloor, \\ a_m &= -(v_{m-1} + v_{m+1}) / u_m v_m (v_{m-1} - v_{m+1}) \quad (\text{for } n \text{ odd}), \end{aligned}$$

where  $m = \lfloor n/2 \rfloor + 1$  and

$$z_j = 1 / (u_{n-j} v_j - u_{j+1} v_{n-j+1}), \quad t_j = u_{n-j} v_{j-1} - u_{j+1} v_{n-i+2}.$$

Observe that the previous results can be extended to block tridiagonal matrices (though we do not develop this extension here in detail).

**3. Tridiagonal and bidiagonal systems.** Let

$$(3.1) \quad T\mathbf{x} = \mathbf{f}, \quad \mathbf{x} = \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{bmatrix}, \quad \mathbf{f} = \begin{bmatrix} f_1 \\ f_2 \\ \vdots \\ f_n \end{bmatrix}$$

be a system of linear equations where  $T$  is an  $n \times n$  general tridiagonal matrix of the form (2.1). In solving (3.1) we consider all (direct) straight-line algorithms in  $F[f_1, f_2, \dots, f_n]$  (thus excluding divisions by the  $f_i$ 's) where  $F = G(a_1, \dots, a_n, b_1, \dots, b_{n-1}, c_1, \dots, c_{n-1})$ ,  $G$  is a subfield of  $F$  and  $a_i, b_i, c_j, f_i$  are indeterminates. An operation  $\omega_1 \odot \omega_2$ , where  $\odot$  is a multiplication or a division, is said to be *active*, if none of the following conditions is satisfied:

- (i)  $\omega_2 \in G$ .
- (ii)  $\omega_1 \in G$  and  $\odot$  is a multiplication.
- (iii)  $\omega_1 \in F$  and  $\omega_2 \in F$ .

Thus the *inactive* operations are either scalar multiplications or involve only elements of  $G(\mathbf{a}, \mathbf{b}, \mathbf{c})$  [6]. The cost of the operations in  $G(\mathbf{a}, \mathbf{b}, \mathbf{c})$  is the cost of rational preconditioning of  $T$ .

Also in computing the vector

$$(3.2) \quad \mathbf{Sf} \quad \mathbf{S} \text{ defined by (2.2)}$$

with a straight-line algorithm in  $F[f_1, f_2, \dots, f_n]$ ,  $F = G(u_1, \dots, u_n, v_1, \dots, v_n, w_1, \dots, w_{n-1})$ ,  $G \subseteq F$ , an *active* operation (multiplication or division) is defined exactly as in the case of (3.1), except for replacing  $a_i, b_i, c_j$  by  $u_i, v_i, w_q$ .

The following result then holds.

**THEOREM 1.** *Every straight-line program solving (3.1) with preconditioning in  $F[f_1, f_2, \dots, f_n]$  uses at least  $3n - 2$  active operations. This bound is optimal.*

*Proof.* Solving (3.1) with the classical LU decomposition (where  $L$  and  $U$  are bidiagonal and the diagonal entries of either  $L$  or  $U$  are equal to 1) costs, exactly,  $3n - 2$  active operations in  $F[\mathbf{f}]$  [13]. Now let  $A'$  be an algorithm solving (3.1) with  $t$  active operations. Then we are able to define an algorithm  $A$  in  $F[\mathbf{f}]$ ,  $F = G(\mathbf{u}, \mathbf{v}, \mathbf{w})$ , computing  $\mathbf{Sf}$  in (3.2) with  $t$  active operations. In fact the two main steps of  $A$  are:

- (i) Compute  $T = S^{-1}$  according to (2.3) using only inactive operations in  $G(\mathbf{u}, \mathbf{v}, \mathbf{w})$ .
- (ii) Solve the system  $T\mathbf{x} = \mathbf{f}$  in  $F[f_1, f_2, \dots, f_n]$ , with  $F = G(\mathbf{u}, \mathbf{v}, \mathbf{w})$ , by exploiting the steps of  $A'$ .

Let  $G[[y_1, \dots, y_k]]$  denote the ring of power series in  $y_1, \dots, y_k$  with coefficients in  $G$  and let  $J(y_1, \dots, y_k)$ , or  $J(\mathbf{y})$ , be the ideal spanned by the third-order terms in  $y_1, \dots, y_k$ . Now every computation in  $F[\mathbf{f}]$ ,  $F = G(\mathbf{u}, \mathbf{v}, \mathbf{w})$  can be simulated by a computation in  $G[[\tilde{u}_1, \dots, \tilde{u}_n, \tilde{v}_1, \dots, \tilde{v}_n, \tilde{w}_1, \dots, \tilde{w}_{n-1}, f_1, \dots, f_n]]$ , without divisions, where

$$(3.3) \quad \begin{aligned} \tilde{u}_i &= u_i - k_i, \\ \tilde{v}_i &= v_i - h_i, \quad 1 \leq i \leq n, \\ \tilde{w}_q &= w_q - l_q, \quad 1 \leq q \leq n - 1, \end{aligned}$$

with  $k_i, h_i, l_q \in G$ . As usual [5], [6], [21], the change of indeterminates (3.3) is necessary to guarantee that only divisions by units in  $G[[\tilde{\mathbf{u}}, \tilde{\mathbf{v}}, \tilde{\mathbf{w}}, \mathbf{f}]]$  occur. Here we suppose also

that  $k_i, h_i, l_q$  are all different from zero. Call  $S'$  the matrix obtained from  $S$  by the substitution (3.3), so each entry of  $S'$  is a nonhomogeneous polynomial, including linear terms, in the new indeterminates  $\tilde{u}_i, \tilde{v}_i, \tilde{w}_q$ . Now reduce the computation in  $G[[\tilde{\mathbf{u}}, \tilde{\mathbf{v}}, \tilde{\mathbf{w}}, \mathbf{f}]]$  modulo  $J(\tilde{\mathbf{u}}, \tilde{\mathbf{v}}, \tilde{\mathbf{w}}, \mathbf{f})$  to obtain an algorithm  $B$  computing only the quadratic and linear part of  $S'\mathbf{f}$ . As each term in each entry of  $S'\mathbf{f}$  is linear in the  $f_i$ 's, the vector computed by  $B$  has no quadratic entry only in the indeterminates  $\tilde{u}_i, \tilde{v}_i, \tilde{w}_q$ . Thus  $B$  computes a vector

$$(3.4) \quad \tilde{S}\mathbf{f} + \mathbf{g}$$

where the elements of  $\tilde{S}$  are linear homogeneous functions in  $\tilde{u}_i, \tilde{v}_i, \tilde{w}_q$  and each entry of  $\mathbf{g}$  is linear in the  $f_i$ 's. It is well known [21], [5], [6], that the reduction mod  $J(\tilde{\mathbf{u}}, \tilde{\mathbf{v}}, \tilde{\mathbf{w}}, \mathbf{f})$  can be performed so that  $B$  uses only  $t$  active multiplications in  $G(\tilde{\mathbf{u}}, \tilde{\mathbf{v}}, \tilde{\mathbf{w}}, \mathbf{f})$ , whose factors are linear homogeneous functions in  $\tilde{u}_i, \tilde{v}_i, \tilde{w}_q, f_i$ . The explicit form of  $\tilde{S} = (\tilde{s}_{ij})$  is given by

$$(3.5) \quad \tilde{s}_{ij} = \begin{cases} h_i k_j \sum_{\mu=i}^{j-1} \xi_\mu \tilde{w}_\mu + \xi_{ij}(h_i \tilde{u}_j + k_j \tilde{v}_i), & i < j, \\ h_j \tilde{u}_i + k_i \tilde{v}_j, & i \geq j \end{cases}$$

where  $\xi_\mu = \prod_{\nu \neq \mu} l_\nu$ ,  $\xi_{ij} = \prod_{\nu=i}^{j-1} l_\nu$ . Now, according to the rank-immunity criterion [16], [14], [4], observe that the matrix  $S$  satisfies the following conditions: (i) replacing any subset  $\Gamma'$  of  $\Gamma = \{\tilde{v}_2, \dots, \tilde{v}_n, \tilde{w}_1, \dots, \tilde{w}_{n-1}\}$  by a  $G$ -linear combination of the remaining indeterminates of  $S$  cannot make any of the  $\{\tilde{v}_2, \dots, \tilde{v}_n, \tilde{w}_1, \dots, \tilde{w}_{n-1}\} \setminus \Gamma'$  disappear in  $\tilde{S}$ ; (ii) the row-rank of the matrix (3.5) is  $n$  even if each indeterminate in the set  $\Gamma$  is replaced by a  $G$ -linear combination of  $\tilde{u}_1, \tilde{u}_2, \dots, \tilde{u}_n$ . In other words,  $S$  is "n-immune" in  $\tilde{v}_2, \dots, \tilde{v}_n, \tilde{w}_1, \dots, \tilde{w}_{n-1}$ . (This is shown even more directly by setting  $v_1 = 1$  in  $S$ , without loss of generality, which forces the first column of  $\tilde{S}$  to become  $[\tilde{u}_1, \tilde{u}_2, \dots, \tilde{u}_n]^T$ .) As  $\Gamma$  has  $2(n-1)$  elements, we obtain  $t \geq n + 2(n-1) = 3n - 2$ .

A last remark is needed for the cardinality of  $G$ . We have tacitly assumed that the number of elements in  $G$  is infinite. But there is no loss of generality in this assumption: in fact, by introducing an extra indeterminate  $y$  and using  $F' = F(y)$  and  $G' = G(y)$  instead of  $F$  and  $G$ , respectively, we obtain that the ground field  $G'$  has infinitely many elements (essentially the same argument is used, for instance, in [23]). Thus the theorem holds for any field  $G$ .

*Remark 1.* Excluding divisions by polynomials in the  $f_i$ 's has the following justification: allowing such divisions forces us to extend to  $f_i$  the change of indeterminates (3.3). This modifies the task (3.4) by the addition of quadratic terms only in the  $\tilde{u}_i, \tilde{v}_i, \tilde{w}_q$ 's so that the rank-immunity criterion [15] can no longer be applied.

*Remark 2.* In the previous proof it is correct to assume that the leading principal minors of a general matrix  $T$  (or  $S^{-1}$ ) are nonzero (so the above-mentioned decomposition LU holds for  $T$ . Otherwise the degrees of freedom in  $T$  (or in  $S$ ) would be reduced and Theorem 1 would not be true (for example, five active operations would suffice to solve (3.1) with  $n = 3$  and  $a_1 a_2 - b_1 c_1 = 0$ ).

An analogous result can be stated if  $T$  is bidiagonal (say,  $b_i = 0$  in (3.1)). In this case a lower bound of  $2n - 1$  operations is obtained which is optimal for all straight-line algorithms solving  $T\mathbf{x} = \mathbf{f}$  in  $F[\mathbf{f}]$ , with  $F = G(\mathbf{a}, \mathbf{c})$ .

**THEOREM 2.** *Every straight-line algorithm solving an  $n \times n$  bidiagonal system  $T\mathbf{x} = \mathbf{f}$  in  $F[\mathbf{f}]$ ,  $F = G(\mathbf{a}, \mathbf{c})$ , requires  $2n - 1$  active operations. This bound is optimal.*

*Proof.* The proof is analogous to that of Theorem 1. The matrix  $\tilde{S}$  in (3.4), with  $v_1 = 1$  (without loss of generality) and  $w_j = 0$  in (2.2), has elements  $\tilde{s}_{ij}$  defined by

$$\tilde{s}_{ij} = \begin{cases} \tilde{u}_i, & j = 1, \\ h_j \tilde{u}_i + k_i \tilde{v}_j, & i \geq j > 1, \\ 0 & \text{elsewhere.} \end{cases}$$

Clearly this matrix is  $n$ -immune in  $\tilde{v}_2, \tilde{v}_3, \dots, \tilde{v}_n$ . The trivial algorithm by forward-substitution employs exactly  $2n - 1$  (active) operations.

The LU decomposition is not the unique best preconditioning. In fact, for a given tridiagonal  $T \ n \times n$ , we can easily calculate three diagonal matrices  $D_1 = \text{diag}(\alpha_1, \alpha_2, \dots, \alpha_n)$ ,  $D_2 = \text{diag}(\beta_1, \beta_2, \dots, \beta_n)$ , and  $D = \text{diag}(d_1, d_2, \dots, d_n)$  such that

$$(3.6) \quad D_1 T D_2 = R D R^T$$

where  $R = (r_{i,j})$  is defined by

$$(3.7) \quad r_{ij} = \begin{cases} 1, & i = j, \\ -1, & i - j = 1, \\ 0 & \text{elsewhere.} \end{cases}$$

It is easy to see that  $\alpha_i, \beta_i$ , which are supposed to be different from zero, satisfy the second-order linear recurrences (for  $b_i, c_i \neq 0$ )

$$(3.8) \quad \alpha_i = -\frac{a_{i-1}\alpha_{i-1} + b_{i-2}\alpha_{i-2}}{c_{i-1}}, \quad i = 2, 3, \dots, n$$

$$\beta_i = -\frac{a_{i-1}\beta_{i-1} + c_{i-2}\beta_{i-2}}{b_{i-1}},$$

where  $\alpha_1$  and  $\beta_1$  are arbitrary ( $\alpha_1, \beta_1 \neq 0$ ) and  $\alpha_2 = -a_1\alpha_1/c_1, \beta_2 = -a_1\beta_1/b_1$ .

We can see that  $\alpha_i, \beta_i$  are proportional to the leading principal minors of  $T$ , so  $\alpha_i, \beta_i \neq 0$  in case these minors are nonzero or  $T$  is diagonally dominant.

By (3.8) we can solve (3.1) with  $3n - 2$  active operations by the sequence of matrix-vector products indicated by the formula

$$(3.9) \quad \mathbf{x} = D_2(R^T)^{-1}D^{-1}R^{-1}D_1\mathbf{f}$$

where  $R^{-1}$  is the lower-triangular matrix whose nonzero entries are all equal to 1.

Observe that (3.8) and (3.9) produce a parallel algorithm  $P$  in an SIMD model to solve (3.1) in  $O(\log n)$  steps with  $O(n)$  processors. (Recall that SIMD is the abbreviation for "Single Instruction Multiple Data," which means roughly that all processors interpret the same instructions and execute them on different data.) The number of active operations in this algorithm is still  $3n - 2$ , so  $P$  has minimal multiplicative redundancy if the cost of preconditioning is not counted.  $P$  should be compared with other known parallel algorithms: the modified LU method of Stone [19] employs  $O(n \log n)$  active operations to solve two bidiagonal systems. The methods of odd-even reduction [12], [17] and Swarztrauber's algorithm [22] have low redundancy but employ more than  $3n - 2$  active operations. The cyclic odd-even reduction also extends to block tridiagonal matrices, but the blocks have to be commuting [11]. The formulas (3.6)–(3.9) extend to block matrices on condition that the nondiagonal square blocks of  $T$  and the leading block submatrices of both  $T$  and its (block) transpose are nonsingular. In other words the previous algorithm is block-extensible if all the blocks

of  $T$  are nonsingular (not necessarily commuting) and both  $T$  and its (block) transpose are diagonally dominant [11]. Thus the algorithm  $P$  could be applied, in principle, to a wide class of linear (tridiagonal, block-tridiagonal or band) systems arising in the discretization of ordinary differential equations, elliptic partial differential problems, or spline interpolation.

**4. The case of centrosymmetric tridiagonal matrices.** By Theorem 1, LU decomposition defines an optimal preconditioning to solve a general tridiagonal system  $T\mathbf{x} = \mathbf{f}$ . But the LU method is insensitive to some special properties which may belong, in many applications, to  $T$  or to  $\mathbf{f}$ . In problems concerning the cubic splines or the discretization of ordinary differential equations,  $T$  is more often symmetric or centrosymmetric (or differs from a symmetric or centrosymmetric matrix by a low-rank correction). Moreover, in these problems, we may have a centrosymmetry property for  $\mathbf{f}$ , i.e.,  $f_i = f_{n-i+1}$ . Also, if  $T$  is centrosymmetric, a centrosymmetry of  $\mathbf{f}$  could be assumed for the approximation, through the power method, of the (possible) dominant eigenvalue of  $T^{-1}$  (that gives the minimal eigenvalue of  $T$ ): in fact, for any eigenvector  $\mathbf{y} = [y_1, y_2, \dots, y_n]^T$  of a centrosymmetric matrix the entries  $y_i$  of  $\mathbf{y}$  satisfy the equality  $y_i = y_{n-i+1}$  [1].

**THEOREM 3.** Any algorithm solving  $T\mathbf{x} = \mathbf{f}$ , where  $T$  is a tridiagonal, centrosymmetric matrix of dimension  $n \times n$  and  $f_i = f_{n-i+1}$ , requires  $3\lfloor n/2 \rfloor - 2$  active operations in  $F[\mathbf{f}]$ ,  $F = G(a, b)$ . This bound is optimal.

*Proof.* To prove that  $3\lfloor n/2 \rfloor - 2$  active operations are necessary, follow the same argument in the proof of Theorem 1. Observe that in (2.4) there are only  $\lfloor n/2 \rfloor + n$  free indeterminates because  $u_i v_{n-i+1} \equiv u_{n-i+1} v_i$ . Assume these indeterminates are  $u_1, u_2, \dots, u_{\lfloor n/2 \rfloor}, v_1, \dots, v_n$ . Now put  $u_i = u_{n-i+1} v_i v_{n-i+1}^{-1}$  in (2.4) and let  $A$  be an algorithm solving the system  $T\mathbf{x} = \mathbf{f}$  with  $t$  active operations in  $F[\mathbf{f}]$ . Then we have implicitly defined a bilinear program that computes a vector  $\tilde{M}\mathbf{f}_1 + \mathbf{g}_1$ , where  $\mathbf{f}_1^T = [f_1, f_2, \dots, f_{\lfloor n/2 \rfloor}]$ ,  $\mathbf{g}_1$  is an  $\lfloor n/2 \rfloor$ -vector whose entries are linear functions of the  $f_i$ 's and the elements of the  $\lfloor n/2 \rfloor \times \lfloor n/2 \rfloor$  matrix  $\tilde{M}$  are linear functions of new indeterminates  $\tilde{u}_1, \tilde{u}_2, \dots, \tilde{u}_{\lfloor n/2 \rfloor}, \tilde{v}_1, \dots, \tilde{v}_n$ .

In particular, for  $u_1 = 1$  (without loss of generality) and for proper choice of nonzero  $G$ -coefficients  $k$  and  $h$ , the last column of  $\tilde{M}$  is an  $\lfloor n/2 \rfloor$ -vector whose  $i$ th entry is  $k_i \tilde{v}_{\lfloor n/2 \rfloor + 1} + h_{\lfloor n/2 \rfloor} \tilde{u}_i$  for  $1 < i \leq \lfloor n/2 \rfloor$  and  $\tilde{v}_{\lfloor n/2 \rfloor}$  for  $i = 1$ . For  $n = 7$ ,  $\tilde{M}$  has the explicit form

$$\begin{bmatrix} \tilde{v}_7 + \tilde{v}_1 & \tilde{v}_6 + \tilde{v}_2 & \tilde{v}_5 + \tilde{v}_3 & \tilde{v}_4 \\ \theta_1 \tilde{v}_1 + \theta_2 \tilde{v}_2 + & k_2 \tilde{v}_6 + h_6 \tilde{u}_2 + & k_2 \tilde{v}_5 + h_5 \tilde{u}_2 + & k_2 \tilde{v}_4 + h_4 \tilde{u}_2 \\ \theta_3 \tilde{v}_6 + \theta_4 \tilde{u}_2 & k_2 \tilde{v}_2 + h_2 \tilde{u}_2 & k_2 \tilde{v}_3 + h_3 \tilde{u}_2 & \\ \varepsilon_1 \tilde{v}_1 + \varepsilon_2 \tilde{v}_3 + & \xi_1 \tilde{v}_2 + \xi_2 \tilde{v}_3 + & k_3 \tilde{v}_5 + h_5 \tilde{u}_3 + & k_3 \tilde{v}_4 + h_4 \tilde{u}_3 \\ \varepsilon_2 \tilde{v}_5 + \varepsilon_4 \tilde{u}_3 & \xi_4 \tilde{v}_5 + \xi_5 \tilde{u}_3 & k_3 \tilde{v}_3 + h_3 \tilde{u}_3 & \\ 2(h_1 \tilde{u}_4 + k_4 \tilde{v}_1) & 2(k_4 \tilde{v}_2 + h_2 \tilde{u}_4) & 2(k_4 \tilde{v}_3 + h_3 \tilde{u}_4) & k_4 \tilde{v}_4 + h_4 \tilde{u}_4 \end{bmatrix}$$

where the coefficients  $k_i, h_i$  are assumed to be nonzero and the coefficients  $\theta, \varepsilon, \xi$  depend on  $k_i, h_i$ . In general, for  $n$  odd (the case  $n$  even is left to the reader),  $u_1 = 1$ ,  $\tilde{M}$  is  $\lfloor n/2 \rfloor$ -immune in  $\tilde{v}_1, \tilde{v}_2, \dots, \tilde{v}_{\lfloor n/2 \rfloor - 1}, \tilde{v}_{\lfloor n/2 \rfloor + 1}, \dots, \tilde{v}_n$ . Then  $\lfloor n/2 \rfloor + n - 1$  (active) multiplications are necessary to compute  $\tilde{M}\mathbf{f}_1 + \mathbf{g}_1$  and  $t \geq 3\lfloor n/2 \rfloor - 2$ .

Now observe that neither LU decomposition nor trivial halving of the dimension of the system and using Sherman-Morrison formula for inverting "modified" matrices [18] define an algorithm with  $3\lfloor n/2 \rfloor - 2$  active operations. To reach this bound,

consider all nonsingular centrosymmetric  $n \times n$  matrices of the form

$$(4.1) \quad \begin{bmatrix} R & 0 \\ 0 & R^T \end{bmatrix} \text{diag}(x_1, \dots, x_{n/2}, x_{n/2}, \dots, x_1) \begin{bmatrix} R^T & 0 \\ 0 & R \end{bmatrix} \quad (n \text{ even}), \quad \text{or} \\ \begin{bmatrix} R & \beta & 0 \\ \alpha^T & 1 & \delta^T \\ 0 & \gamma & R^T \end{bmatrix} \text{diag}(x_1, \dots, x_{\lfloor n/2 \rfloor}, \dots, x_1) \begin{bmatrix} R^T & \alpha & 0 \\ \beta^T & 1 & \gamma^T \\ 0 & \delta & R \end{bmatrix} \quad (n \text{ odd})$$

where  $\alpha^T = [0, \dots, 0, -1]$ ,  $\delta^T = [-1, 0, \dots, 0]$ ,  $\beta = \mathbf{0}$ ,  $\gamma = \mathbf{0}$ , and  $R \equiv (r_{ij})$  is defined as in (3.7) for  $i, j = 1, \dots, \lfloor n/2 \rfloor$ . Now compute diagonal, centrosymmetric matrices  $D_1 = \text{diag}(\alpha_1, \dots, \alpha_{\lfloor n/2 \rfloor}, \dots, \alpha_1)$ ,  $D_2 = \text{diag}(\beta_1, \beta_{\lfloor n/2 \rfloor}, \dots, \beta_1)$ , and  $D = \text{diag}(d_1, \dots, d_{\lfloor n/2 \rfloor}, \dots, d_1)$  such that  $D_1 T D_2$  has the form (4.1) ( $\alpha_i$  and  $\beta_i$  are computable through second-order linear recurrences, as in (3.8)). As  $\alpha_i, \beta_i$  are arbitrary, this preconditioning produces an algorithm of  $3 \lfloor n/2 \rfloor - 2$  active operations to solve  $T\mathbf{x} = \mathbf{f}$ . Obviously,  $\alpha_i$  and  $\beta_i$  must be different from zero, which is verified if the leading principal submatrices of  $T$  are nonsingular (or if  $T$  is diagonally dominant).

The above preconditioning suggests a parallel algorithm that works in  $O(\log n)$  steps with  $O(n)$  processors and has (apart from the cost of preconditioning) minimal multiplicative redundancy. This algorithm extends to block-tridiagonal matrices, where the nondiagonal blocks of  $T$  and the leading block submatrices of both  $T$  and its (block) transpose are nonsingular.

**Acknowledgment.** The author thanks the referee for his useful suggestions.

## AVERAGE-CASE LOWER BOUNDS FOR SEARCHING\*

COLIN MCDIARMID†

**Abstract.** Lower bounds are given for certain average search times in a set with a random linear order about which there is partial information. These bounds extend various recent worst-case and average-case results, in particular those of Alt and Mehlhorn, Borodin et al., and Mairson concerning searching “semi-sorted” tables and trade-offs between presorting time and search time. We make fuller use of the framework of information theory than have previous investigations.

**Key words.** searching, sorting, average case, lower bound, trade-off, information, uncertainty

**AMS(MOS) subject classifications.** 86P10, 60C05

**1. Introduction.** *Searching.* We consider problems related to “searching semi-sorted tables” [2] and “data location for partially ordered structures” [5], [8].

Suppose that a set  $X$  of  $n$  ( $\geq 2$ ) elements has an unknown linear order  $\pi$  about which we may have partial information. We let  $\pi$  be given as a bijection from  $X$  to  $N = \{1, \dots, n\}$ . Also there is an order-preserving injection  $s$  from  $X$  into the real numbers  $R$ ; that is,  $s(x) < s(x')$  if  $\pi(x) < \pi(x')$ . We think of the number  $s(x)$  being stored at the location  $x$  in our partly ordered data structure. For an (unrevealed) query  $y \in R$  we must determine if  $y$  is one of the numbers stored, and if so at which location. We adopt a “decision-tree” approach. The basic steps allowed are comparisons  $y: s(x)$  for  $x \in X$  and comparisons  $s(x): s(x')$  for  $x, x' \in X$ . Observe that if we have determined that  $y$  is one of the numbers stored, then we must actually have found the location  $x$  in  $X$  such that  $y = s(x)$ .

We shall investigate average-case lower bounds on the number of comparisons required. Note that given the linear order  $\pi$  the actual mapping  $s$  is not important; and we may as well assume that  $s = \pi$ . Thus, we may simplify the statement of the problem as follows: for an unrevealed linear order  $\pi$  on  $X$  and query  $y \in R$  we must determine if  $y \in N$  by making comparisons  $y: \pi(x)$  or  $\pi(x): \pi(x')$ . Given some decision-tree algorithm as above the search time  $S = S(\pi, y)$  taken on the (unrevealed) input  $(\pi, y)$  is defined to be the number of comparisons required.

If we know the linear order  $\pi$ , then binary search yields a worst-case time of about  $\log n$ , and this is best possible. (Throughout the paper  $\log$  denotes logarithm to the base 2.) At the other extreme, if any linear order  $\pi$  is possible, then clearly we need worst-case time equal to  $n$ .

We shall consider both “unsuccessful” search, when the query  $y \notin N$ , and the more interesting case of “successful” search, when  $y \in N$ . Unsuccessful search is the easier to analyse. When  $y \notin N$  we shall actually give lower bounds for  $S'(\pi, y)$ , which we define to be the smallest possible number of questions as above to prove that  $y \notin N$ . Of course we always have  $S(\pi, y) \geq S'(\pi, y)$ . Equivalently, for each pair  $(\pi, y)$  we could define  $S'(\pi, y)$  to be the minimum over all allowed decision-trees of the search time  $S(\pi, y)$ . Results concerning  $S'$  may also be phrased in terms of “nondeterministic” search algorithms [2]. For successful search we shall consider also a hybrid quantity

$S^*$ , where for  $y \in N$  we define  $S^*(y)$  to be the maximum value of  $S(\pi, y)$  over all possible linear orders  $\pi$ .

We shall assume that a random linear order  $\pi$  on  $X$  and an independent random query  $y \in R$  are input according to certain distributions of interest, and give lower bounds concerning the random search times  $S$ ,  $S^*$ , and  $S'$ . When analysing a successful search we assume that the random query  $y$  is uniformly distributed over the set  $N = \{1, 2, \dots, n\}$ . When analysing an unsuccessful search we assume that the random query  $y$  is uniformly distributed over the set  $N' = N - \frac{1}{2} = \{\frac{1}{2}, \frac{3}{2}, \dots, n - \frac{1}{2}\}$ . Our investigation falls into two parts: "restricted search" and "general search."

In restricted search only comparisons involving the query  $y$  are allowed, as in [2], [5]. Let us consider an arbitrary probability distribution  $\mathbf{p} = (p_\pi: \pi \in \Pi)$  on a set  $\Pi$  of linear orders on  $X$ . Recall that the *uncertainty*  $H = H(\mathbf{p})$  of the random linear order  $\pi$  is defined to be  $-\sum_{\pi \in \Pi} p_\pi \log p_\pi$ . Also, if each member of  $\Pi$  is equally likely then  $H = \log |\Pi|$ . We give lower bounds concerning the random search times  $S$ ,  $S^*$ , and  $S'$  in terms of the quantity  $H$ . The results for  $S^*$  and  $S'$  extend the work of Alt and Mehlhorn [2] on searching semi-sorted tables. As noted in [2] the lower bounds are sometimes, but not always, sharp. For tight bounds of a different nature see [5].

In general search we also allow comparisons  $\pi(x): \pi(x')$  for  $x, x' \in X$ . We now must restrict the probability distributions considered for the random linear order  $\pi$ . We shall assume that  $\Pi$  is the set of linear extensions of a partial order, and that  $p_\pi > 0$  for each  $\pi \in \Pi$ . In order to investigate successful general search we also analyse the problem of searching for the minimum element in a random linear extension of a partial order.

The two combinations for which we here give good lower bounds on search times are thus (a) restricted search with arbitrary distributions on linear orders, and (b) general search with certain special distributions. Feldman (see [10]) has very recently given an elegant construction for a large set of linear orders that can be searched quickly when we allow comparisons  $\pi(x): \pi(x')$ . This example shows that there are no corresponding lower bounds for general search with arbitrary distributions of linear orders, and throws our results here into sharp relief.

For both restricted and general search there are interesting "trade-off" lower bounds concerning sorting or preprocessing times and searching times.

*Sorting or preprocessing.* Suppose that the set  $X$  with its unknown linear order  $\pi$  is to be partially sorted or preprocessed so that subsequent searches as above can be performed quickly. In the preprocessing stage only (binary) questions concerning  $\pi$  may be asked. If only comparisons  $\pi(x): \pi(x')$  for  $x, x' \in X$  are allowed we call this *restricted sorting*. We use the phrase general sorting when arbitrary binary questions are allowed. Denote by  $P = P(\pi)$  the time taken, that is the number of questions asked, on input  $\pi$ . With each leaf of the decision tree corresponding to the preprocessing stage we associate a search algorithm as above.

*Trade-offs.* Let us consider restricted sorting and general searching. There are similar results below concerning general sorting and restricted searching.

If we do no preprocessing we require worst-case search time  $n$ . At the other extreme it takes worst-case time about  $n \log n$  to sort completely, and then search requires worst-case time about  $\log n$ . As an intermediate strategy we can make  $n/k$  lists of length about  $k$  in worst-case time about  $n \log k$ , and then search in worst-case time about  $(n/k) \log k$ . There is clearly a trade-off between worst-case preprocessing or sorting times and searching times.

**THEOREM 1.1** [4]. *For any restricted sorting and general searching algorithms as above, the maximum over all linear orders  $\pi$  of  $X$  and all (successful) queries  $y \in N$  of the quantity  $P(\pi) + n \log S(\pi, y)$  is at least  $n \log n + O(n)$ .*

We shall give related trade-offs in the average case which extend this worst-case result and extend also the results stated in Mairson [6], [7].

*Plan of the paper.* In the next section, we present our main results. Then in § 3 we give a brief discussion on uncertainty and random linear orders. Section 4 contains the main proofs, apart from that of the theorem on searching for the minimum which is postponed to the last section, § 5.

## 2. Statement of results.

**2.1. Restricted search.** In this section we allow the search algorithms only to make comparisons involving the unknown query  $y$ , as in [2], [5], that is, to ask questions “ $y: \pi(x)?$ ” for  $x \in X$ . The random linear order  $\pi$  on  $X$  may have an arbitrary probability distribution. Let  $\Pi$  be the set of linear orders that occur with positive probability. Denote the uncertainty associated with  $\pi$  by  $H = H(\pi)$ . The main result on restricted search is the following theorem.

**THEOREM 2.1.** *For any restricted search algorithm*

- (i)  $E[n \log S^*] \geq \log |\Pi|$ ,
- (ii)  $E'[n \log S'] \geq H$ ,
- (iii)  $E[n \log S] \geq H - n \log \log n$ .

Here we use  $E\{E'\}$  to denote expectation over the random linear order  $\pi$  and the independent random query  $y$  uniformly distributed over  $N\{N'\}$ .

**COROLLARY 2.2.** *If each linear order  $\pi$  in  $\Pi$  is equally likely, then*

- (i)  $E[S^*] \geq |\Pi|^{1/n}$ ,
- (ii)  $E'[S'] \geq |\Pi|^{1/n}$ ,
- (iii)  $E[S] \geq |\Pi|^{1/n} / \log n$ .

Parts (i) and (ii) of Corollary 2.2 contain the theorems of Alt and Mehlhorn [2]. Now let us consider “trade-off” results. Recall that  $P = P(\pi)$  denotes time spent in the sorting or preprocessing stage.

**COROLLARY 2.3.** *For any general sorting and restricted searching algorithms*

- (i)  $E[P + n \log S^*] \geq H$ ,
- (ii)  $E'[P + n \log S'] \geq H$ ,
- (iii)  $E[P + n \log S] \geq H - n \log \log n$ .

**2.2. General search.** Suppose now that as well as comparisons involving the query  $y$  we may make comparisons  $\pi(x): \pi(x')$ , where  $x, x' \in X$ . We shall consider only “well-behaved” distributions for the random linear order  $\pi$  on  $X$ . Let  $\Pi$  denote the set of linear orders that occur with positive probability. We shall always assume when considering general search that  $\Pi$  is the set of linear extensions of some partial order, and sometimes we shall further assume that each linear order  $\pi$  in  $\Pi$  is equally likely. We consider first the quantities  $S^*$  and  $S'$  and postpone briefly the more difficult full average-case analysis for successful search.

**THEOREM 2.4.** *If  $\Pi$  is the set of linear extensions of a partial order, then for any general searching algorithm*

- (i)  $E[n \log S^*] \geq \log |\Pi|$ ,
- (ii)  $E'[n \log S'] \geq H$ .

**COROLLARY 2.5.** *If  $\Pi$  is the set of linear extensions of a partial order, then for any restricted sorting algorithm and general searching algorithms*

- (i)  $E[P + n \log S^*] \geq H$ ,
- (ii)  $E'[P + n \log S'] \geq H$ .

**COROLLARY 2.6.** *If all  $n!$  linear orders on  $X$  are equally likely, then both  $E[P + n \log S^*]$  and  $E'[P + n \log S']$  are at least  $n \log n + O(n)$ .*

Both of the inequalities in Corollary 2.6 extend the worst-case result Theorem 1.1 of Borodin et al. [4]. This is of course immediate for the mixed worst-case average-case

result concerning  $S^*$ , and it will be shown easily for the result concerning unsuccessful search.

All the results above follow naturally from the general discussion in § 3 below on uncertainty and random linear orders. However, we cannot prove such strong average-case results for successful search, when we also average over the random linear order  $\pi$ , and we must work harder. In order to prove Theorem 2.7 below we shall investigate carefully the problem of searching for the minimum element in a random linear extension of a partial order (see § 2.3).

**THEOREM 2.7.** *Let  $\Pi$  be the set of linear extensions of a partial order, and suppose that each linear order  $\pi$  in  $\Pi$  is equally likely. Then for any general search algorithm*

$$E[S] \geq (1/2n)|\Pi|^{2/n}.$$

This theorem gives weaker bounds than Theorem 2.4, and we can deduce correspondingly weaker trade-off results. We give two forms of trade-off result.

**COROLLARY 2.8.** *Let  $\Pi$  be the set of linear extensions of a partial order, and suppose that each linear order  $\pi$  in  $\Pi$  is equally likely. Then for any restricted sorting algorithm and general searching algorithms,*

- (i)  $2E[P] + n \log E[S] \geq 2 \log |\Pi| - n \log 2n,$
- (ii)  $E[4^{P/n}S] \geq |\Pi|^{2/n}/2n.$

The most interesting case of Corollary 2.8 is when  $\Pi$  is the set of all linear orders on  $X$ .

**COROLLARY 2.9.** *Suppose that all  $n!$  linear orders on  $X$  are equally likely. Then for any restricted sorting algorithm and general searching algorithms,*

- (i)  $2E[P] + n \log E[S] \geq n \log n - n \log 2e^2,$
- (ii)  $E[4^{P/n}S] \geq n/2e^2.$

Part (i) of this result is perhaps the more attractive. It extends a result proposed and partially proved by Mairson [6], [7] (who has  $3E[P]$  instead of  $2E[P]$ ). Indeed the present investigation was inspired by hearing Mairson present this result. However, this part has the unsatisfactory feature that it does not seem to yield any worst-case result, whereas part (ii) at least yields half the lower bound in Thm. 1.1. Corollary 2.9 represents only partial progress towards investigating the following conjecture.

**Conjecture 2.10.** With premises as in Corollary 2.9

$$E[P + n \log S] \geq (1 + o(1))n \log n.$$

**2.3. Searching for the minimum.** Let  $Q$  be a partial order on the set  $X$  of  $n \geq 2$  elements and let  $\Pi$  be the set  $L(Q)$  of linear extensions of  $Q$ . Suppose that these linear orders  $\pi$  occur randomly with each equally likely, and we wish to find the minimum element  $\pi^{-1}(1)$  quickly. The basic steps allowed are questions “Is  $x$  the minimum?” where  $x \in X$  and comparisons  $\pi(x) : \pi(x')$  where  $x, x' \in X$ . We may stop only when we receive a positive answer to a question of the former type. Given a decision-tree search algorithm as described, let  $T(\pi)$  be the time taken (number of questions) on input  $\pi \in \Pi$ . The following result is a main step in proving Theorem 2.7 above.

**THEOREM 2.11.** *If the partial order  $Q$  has  $m$  minimal elements, then*

$$E[T] \geq 1 + m(m - 1)/2n.$$

It is straightforward to check that this result is the best possible, in the sense that for any  $1 \leq m \leq n$  there is a suitable partial order  $Q$  and search algorithm such that the expected search time  $E[T]$  equals  $1 + m(m - 1)/2n$ . Indeed we may let  $Q$  consist of a set  $Z$  of  $n - m$  elements with any partial order, an element  $x_1$  less than each  $z \in Z$ , and  $m - 1$  “independent” elements  $x_2, \dots, x_m$ ; and then search for the minimum by testing in the fixed order  $x_1, x_2, \dots, x_m$ .

To see that  $E[T]$  is as stated, let  $\Pi_i$  denote the set of linear extensions  $\pi$  in  $\Pi$  with  $x_i$  the minimum, for each  $i = 1, \dots, m$ . Then by considering last where to put  $x_i$  we see that  $|\Pi_i| = |\Pi|/n$  for each  $i = 2, \dots, m$ . Hence

$$\begin{aligned} E[T] &= (1/|\Pi|) \sum_{j=1}^m j|\Pi_j| \\ &= 1 + m(m-1)/2n. \end{aligned}$$

Theorem 2.11 above is related to the ‘‘accounting game’’ claim proposed by Mairson [6], [7].

**3. Uncertainty and random linear orders.** We start with a brief general discussion on uncertainty (see for example Ash [3]).

We consider only random variables taking finitely many values. Let the random variable  $Y$  take values in the set  $\{x_1, \dots, x_n\}$ , with  $P\{Y = x_i\} = p_i$  for  $i = 1, \dots, n$  and  $\mathbf{p} = (p_1, \dots, p_n)$ . The *uncertainty* (or *entropy*)  $H(Y)$  or  $H(\mathbf{p})$  is defined to be  $-\sum_{i=1}^n p_i \log p_i$ . (We take  $t \log t = 0$  if  $t = 0$ .) Thus  $H(\mathbf{p}) \geq 0$ , with equality if and only if we have the trivial case that some  $p_i = 1$ .

We note first a very useful inequality. Let  $q_1, \dots, q_n > 0$  with  $\sum_{i=1}^n q_i = 1$ . Then

$$(3.1) \quad -\sum_{i=1}^n p_i \log p_i \leq -\sum_{i=1}^n p_i \log q_i$$

with equality if and only if  $p_i = q_i$  for each  $i$ .

To prove (3.1) note that for  $t > 0$ ,  $\ln t \leq t - 1$  with equality if and only if  $t = 1$ . Here  $\ln$  denotes natural logarithm. Thus

$$\sum_{i=1}^n p_i \ln (q_i/p_i) \leq \sum_{i=1}^n (q_i - p_i) = 0,$$

and (3.1) follows easily. (Lemma 4.1 of [5] is essentially the above inequality again.)

If we set  $q_i = 1/n$  in (3.1) we find that

$$(3.2) \quad H(\mathbf{p}) \leq \log n, \text{ with equality if and only if the } p_i \text{ are all equal.}$$

For a pair  $(Y, Z)$  of random variables let us write  $H(Y, Z)$  for  $H((Y, Z))$ . Thus if  $P\{(Y, Z) = (y, z)\} = p(y, z)$ , then the uncertainty is

$$H(Y, Z) = -\sum_y \sum_z p(y, z) \log p(y, z).$$

Denote the conditional probabilities for  $Z = z$  given  $Y = y$  by  $p(z|y)$ . Then the conditional uncertainty of  $Z$  given that  $Y = y$  is

$$H(Z | Y = y) = -\sum_z p(z|y) \log p(z|y).$$

The *conditional uncertainty of  $Z$  given  $Y$* ,  $H(Z | Y)$ , is the appropriate weighted average of the above quantities, which yields

$$H(Z | Y) = -\sum_y \sum_z p(y, z) \log p(z|y).$$

From this definition we easily find the basic property

$$(3.3) \quad H(Y, Z) = H(Y) + H(Z | Y).$$

(3.4) It follows from (3.3) that the average number of binary questions required to determine the value of a random variable  $Y$  is at least the uncertainty  $H(Y)$ .

One way to prove this is by induction on the depth of the corresponding decision tree. The result is clear if we need no questions, for then  $H(Y) = 0$ . Consider a nontrivial decision tree such that the result holds for any shallower tree. Let the binary random variable  $Z$  specify the answer to the first question. Then  $H(Z) \leq 1$  by (3.2) and so by the induction hypothesis the expected number of steps to determine the value of  $Y$  is at least

$$1 + H(Y|Z) = 1 + H(Y, Z) - H(Z) \geq H(Y).$$

Given a random variable  $Y$  we define a distribution for a random variable  $\tilde{T} = \tilde{T}(Y)$  as follows. List the quantities  $P\{Y = x\}$  in nonincreasing order, as  $p'_1 \geq p'_2 \geq \dots \geq p'_n$ , say. Then let  $P\{\tilde{T} = i\} = p'_i$  for each  $i = 1, \dots, n$ .

Suppose that we wish to determine the value of  $Y$  by asking questions of the form "Is  $Y = x$ ?", until we receive the answer "yes." Given an appropriate list of questions let  $T$  be the random number of questions required. Clearly for any  $t = 1, 2, \dots, n$

$$P\{T \leq t\} \leq \sum_{i=1}^t p'_i.$$

Thus

$$(3.5) \quad T \geq \tilde{T} \text{ in distribution.}$$

Now let  $g(n) = 1 + 1/2 + \dots + 1/n$ . Then

$$\begin{aligned} H(Y) &= - \sum_{i=1}^n p'_i \log p'_i \\ &\leq - \sum_{i=1}^n p'_i \log (ig(n))^{-1} \quad \text{by the inequality (3.1)} \\ &= E[\log \tilde{T}] + \log g(n) \\ &\leq E[\log T] + \log g(n) \quad \text{by (3.5).} \end{aligned}$$

Hence we have

$$(3.6) \quad E[\log T] \geq H(Y) - \log g(n).$$

Now let us consider the uncertainty of a random vector  $\mathbf{Y} = (Y_1, \dots, Y_n)$ . By (3.3),

$$H(\mathbf{Y}) = H(Y_1) + H(Y_2, \dots, Y_n | Y_1),$$

and thus we obtain

$$(3.7) \quad H(\mathbf{Y}) = \sum_{k=1}^n H(Y_k | Y_l \text{ for each } l < k).$$

Denote by  $A$  the set of vectors  $\mathbf{y} = (y_1, \dots, y_n)$  such that  $P\{\mathbf{Y} = \mathbf{y}\} > 0$ . For each  $\mathbf{y} \in A$  and  $k \in N$  let

$$h(\mathbf{y}, k) = H(Y_k | Y_l = y_l \text{ for each } l < k).$$

Then averaging over  $\mathbf{Y}$  we have that for each  $k \in N$

$$E[h(\mathbf{Y}, k)] = H(Y_k | Y_l \text{ for each } l < k)$$

and so by (3.7)

$$(3.8) \quad \sum_{k=1}^n E[h(\mathbf{Y}, k)] = H(\mathbf{Y}).$$

Now for each  $y \in A$  and  $k \in N$  let us also define  $m(y, k)$  to be the number of different possible values for  $Y_k$  given that  $Y_l = y_l$  for each  $l < k$ . Then by (3.2)

$$h(y, k) \leq \log m(y, k).$$

Hence by (3.8)

$$(3.9) \quad \sum_{k=1}^n E[\log m(Y, k)] \geq H(Y).$$

Suppose that we have a random linear order  $\pi$  on a set  $X$  of  $n$  elements. Recall that we think of  $\pi$  as a bijection from  $X$  to  $N = \{1, \dots, n\}$ . Thus the inverse  $\pi^{-1}$  may be thought of as a random vector  $(\pi^{-1}(1), \dots, \pi^{-1}(n))$ . We shall use (3.9) with  $Y$  replaced by  $\pi^{-1}$ . Note that  $H(\pi^{-1}) = H(\pi)$ . Note also that if  $\pi_0$  is a possible linear order and  $k \in N$ , then  $m(\pi_0^{-1}, k)$  is the number of different possible  $k$ th elements in linear orders  $\pi$  that agree with  $\pi_0$  in the first  $k - 1$  elements. Let us state this particular case of (3.9) as

$$(3.10) \quad \sum_{k=1}^n E[\log m(\pi^{-1}, k)] \geq H(\pi).$$

We now note one easy corollary of the result (3.10). Suppose that each linear order  $\pi$  in a set  $\Pi$  is equally likely, so that by (3.2)  $H(\pi) = \log |\Pi|$ . Now recall that since  $\log(x)$  is concave, for any random variable  $Z \geq 1$  we have Jensen's inequality that

$$(3.11) \quad \log E[Z] \geq E[\log Z].$$

Hence

$$\begin{aligned} \log \left\{ (1/n) \sum_{k=1}^n E[m(\pi^{-1}, k)] \right\} &\geq (1/n) \sum_{k=1}^n \log E[m(\pi^{-1}, k)] \\ &\geq (1/n) \sum_{k=1}^n E[\log m(\pi^{-1}, k)] \\ &\geq (1/n) \log |\Pi| \quad \text{by (3.10).} \end{aligned}$$

Thus

$$(3.12) \quad (1/n) \sum_{k=1}^n E[m(\pi^{-1}, k)] \geq |\Pi|^{1/n}.$$

These last results (3.10) and its corollary (3.12) may be visualised in terms of the "permutation trees" of Alt and Mehlhorn [2]. We have used elementary information theory to replace the detailed inductive proof in [2] essentially of (3.12) (see also Theorem 3.7.1 of Mairson [6], [7]).

**4. Main proofs.** In this section, we use the general results on uncertainty given in the last section to deduce the results of restricted and unrestricted search given in § 2. For the proof of Theorem 2.7 on unrestricted search we shall also need Theorem 2.11 on searching for the minimum. This last result is proved in the next (and last) section.

*Proof of Theorem (2.1).* Let us start with some notation. Given  $\pi_0 \in \Pi$  and  $k_0 \in N$  let

$$\Pi_0 = \Pi_0(\pi_0, k_0) = \{\pi \in \Pi: \pi^{-1}(l) = \pi_0^{-1}(l) \text{ for each } l < k_0\},$$

$$A_0 = A_0(\pi_0, k_0) = \{x \in X: \pi_0(x) \geq k_0\},$$

$$M_0 = M_0(\pi_0, k_0) = \{x \in X: \pi(x) = k_0 \text{ for some } \pi \in \Pi_0\}.$$

Thus  $M_0 \subseteq A_0$  and  $|M_0| = m(\pi_0^{-1}, k_0)$  in the notation of (3.10).

Let us prove part (i) first. Let  $k_0 \in N$  and suppose that  $y = k_0$ . Reveal  $k_0$  and that  $y = k_0$  or  $k_0 - \frac{1}{2}$ . Consider any  $\pi_0 \in \Pi$ , and restrict  $\pi$  to  $\Pi_0$ . Of course

$$S^*(k_0) \geq \max \{S(\pi, k_0) : \pi \in \Pi_0\}.$$

Now suppose that we reveal  $\Pi_0$  and that  $\pi \in \Pi_0$ . Then we still have

$$(4.1) \quad \max \{S(\pi, k_0) : \pi \in \Pi_0\} \geq |M_0|.$$

For clearly we can restrict attention to questions of the form “Is  $\pi(x) = y$ ?” for  $x \in M_0$ ; and given any sequence of less than  $|M_0|$  such questions an adversary could answer “no” each time, and we would not know whether  $y = k_0$  or  $k_0 - \frac{1}{2}$ . Thus we have shown that for any  $\pi_0 \in \Pi$

$$(4.2) \quad S^*(k_0) \geq m(\pi_0^{-1}, k_0).$$

Hence

$$\begin{aligned} E[n \log S^*] &= \sum_{k_0=1}^n \log S^*(k_0) \\ &\geq \sum_{k_0=1}^n E[\log m(\pi^{-1}, k_0)] \\ &\geq H \quad \text{by (3.10).} \end{aligned}$$

But as far as  $S^*$  is concerned the precise distribution of the random linear order  $\pi$  is not relevant, only the set  $\Pi$ . Thus by (3.2) we may replace the last  $H$  by  $\log |\Pi|$ .

Now consider part (ii) of Theorem 2.1. Let  $k_0 \in N$  and  $\pi_0 \in \Pi$ , and suppose that  $y = k_0 - \frac{1}{2}$  and  $\pi = \pi_0$ . Reveal  $k_0$  and that  $y = k_0$  or  $k_0 - \frac{1}{2}$ ; and reveal also  $\Pi_0$  and that  $\pi \in \Pi_0$ . Then still

$$(4.3) \quad S'(\pi_0, k_0 - \frac{1}{2}) \geq m(\pi_0^{-1}, k_0).$$

For as above we may restrict attention to questions of the form “Is  $\pi(x) = y$ ?” for  $x \in M_0$ . The answer to each such question of course will be “no,” but we cannot know that  $y \notin N$  until we have asked such a question for each  $x \in M_0$ .

Hence by (4.3)

$$\begin{aligned} E'[n \log S'] &= \sum_{k_0=1}^n E[\log S'(\pi, k_0 - \frac{1}{2})] \\ &\geq \sum_{k_0=1}^n E[\log m(\pi^{-1}, k_0)] \\ &\geq H \quad \text{by (3.10).} \end{aligned}$$

Finally let us prove part (iii) of Theorem 2.1. Let  $k_0 \in N$  and  $\pi_0 \in \Pi$ , and suppose that  $y = k_0$  and  $\pi = \pi_0$ . Reveal  $k_0$  and that  $y = k_0$  or  $k_0 - \frac{1}{2}$ ; and reveal  $\Pi_0$  and that  $\pi \in \Pi_0$ . Again we may restrict attention to questions of the form “Is  $\pi(x) = y$ ?” for  $x \in M_0$ , but now we must continue until we receive the answer “yes.” Since here  $\pi(x) = y$  if and only if  $\pi^{-1}(k_0) = x$  we are identifying the value of the random variable  $Y = \pi^{-1}(k_0)$  as considered in the discussion preceding the inequalities (3.5) and (3.6). Here  $Y$  ranges over the set  $M_0$ , and  $|M_0| \leq n - k_0 + 1$ . Hence by (3.6)

$$\begin{aligned} E[\log S(\pi, k_0) | \pi \in \Pi_0] &\geq H(\pi^{-1}(k_0) | \pi \in \Pi_0) - \log g(n - k + 1) \\ &= h(\pi_0^{-1}, k_0) - \log g(n - k + 1) \end{aligned}$$

in the notation of (3.8).

Now keep  $k_0$  fixed but consider different possible  $\pi_0$ . Then

$$\begin{aligned} E[\log S(\pi, k_0)] &= \sum_{\pi_0 \in \Pi} E[\log S(\pi, k_0) | \pi \in \Pi_0(\pi_0, k_0)] P(\pi = \pi_0) \\ &\geq \sum_{\pi_0 \in \Pi} h(\pi_0^{-1}, k_0) P(\pi = \pi_0) - \log g(n - k_0 + 1) \\ &= E[h(\pi^{-1}, k_0)] - \log g(n - k_0 + 1). \end{aligned}$$

Hence

$$\begin{aligned} E[n \log S] &= \sum_{k_0=1}^n E[\log S(\pi, k_0)] \\ &\geq \sum_{k_0=1}^n E[h(\pi^{-1}, k_0)] - \sum_{k=1}^n \log g(n - k + 1) \\ &= H - \sum_{k=1}^n \log g(k) \quad \text{by (3.8)}. \end{aligned}$$

We shall see below that

$$(4.4) \quad \sum_{k=1}^n \log g(k) \leq n \log \log n \quad \text{for } n \geq 3.$$

This will then establish part (iii) of the theorem for  $n \geq 3$ . The case  $n = 2$  is easy to check separately, since then

$$E[n \log S] \geq 1 \geq H.$$

It remains then only to prove (4.4). Now for each  $k \geq 1$

$$g(k) \leq 1 + \int_1^k (1/x) dx = 1 + \ln k.$$

Hence since  $\ln(x)$  is concave

$$(1/n) \sum_{k=1}^n g(k) \leq 1 + (1/n) \sum_{k=1}^n \ln k \leq 1 + \ln \frac{n+1}{2}.$$

But the function

$$f(x) = \log x - \left( 1 + \ln \frac{x+1}{2} \right) \quad \text{for } x > 0$$

is increasing, and  $f(4) > 0$ . Hence

$$1 + \ln \frac{n+1}{2} < \log n \quad \text{for } n \geq 4.$$

Thus

$$(1/n) \sum_{k=1}^n g(k) < \log n \quad \text{for } n \geq 4,$$

and it is easy to check separately that this inequality holds also for  $n = 3$ . Hence, since  $\log(x)$  is concave,

$$\begin{aligned} (1/n) \sum_{k=1}^n \log g(k) &\leq \log \left\{ (1/n) \sum_{k=1}^n g(k) \right\} \\ &< \log \log n \quad \text{for } n \geq 3. \end{aligned}$$

This completes the proof of (4.4), and thus of Theorem 2.1.  $\square$

Corollary 2.2 follows easily from Theorem 2.1 using (3.2) and Jensen’s inequality (3.11).

In each of the three parts of Corollary 2.3, the case when there is no preprocessing is just the corresponding part of Theorem 2.1 (where we have replaced the  $\log |\Pi|$  by  $H$  again): and the result may now be proved exactly as was (3.4) by induction on the depth of the preprocessing decision tree.

*Proof of Theorem 2.4.* Let us use notation from the proof of Theorem 2.1. Consider the following condition on a set  $\Pi$  of linear orders on  $X$ .

- (4.5) Given  $\pi_0 \in \Pi$ ,  $k_0 \in N$ ,  $x_0 \in M_0$ , and a partial order  $Q$  on  $A_0$  with  $x_0$  minimal, if some  $\pi \in \Pi_0$  has restriction  $\pi|_{A_0}$  in the set  $L(Q)$  of linear extensions of  $Q$  then some  $\pi \in \Pi_0$  has  $\pi|_{A_0}$  in  $L(Q)$  and has  $\pi(x_0) = k_0$ .

Clearly the set of linear extensions of a partial order satisfies this condition. For given  $\pi \in \Pi_0$  with  $\pi|_{A_0}$  in  $L(Q)$ , if the rank  $\pi(x_0) \neq k_0$  then  $x_0$  has rank  $> k_0$ , and we may simply move  $x_0$  down to rank  $k_0$  and “shuffle up” other elements as required. (This also holds for any set  $\Pi$  consisting of those linear extensions of a partial order which satisfy further conditions of the form  $\pi(x) = k$  or  $\pi(x) \geq k$ .)

We shall see that Theorem 2.4 in fact holds for any set  $\Pi$  of linear orders which satisfies the condition (4.5), by showing that both the inequalities (4.2) and (4.3) from the proof of Theorem 2.1 still hold.

In order to prove that (4.2) still holds we shall show that (with the information revealed as before) the inequality (4.1) still holds. Now we may restrict attention to questions of the form “Is  $\pi(x) = y$ ?” for  $x \in M_0$  and of the form “ $\pi(x) : \pi(x')$ ?” for  $x, x' \in A_0$ .

Consider a sequence of  $q < |M_0|$  such questions. An adversary could say “no” to each question of the former kind, and respond to questions of the latter kind by picking an arbitrary  $\hat{\pi} \in \Pi_0$  and answering according to  $\hat{\pi}$ . Let  $B$  be the set of elements  $x \in M_0$  mentioned in questions of the former kind, and let  $C$  be the set of elements  $x \in M_0$  for which there is a question “ $\pi(x) : \pi(x')$ ?” which received the answer “ $\pi(x) > \pi(x')$ .” Then  $|B| + |C| = q < |M_0|$  and there is some  $x_0 \in M_0 \setminus (B \cup C)$ . Now the answers to the questions of the latter kind yield a partial order  $Q$  on  $A_0$ , and the linear order  $\hat{\pi}$  in  $\Pi_0$  is such that  $\hat{\pi}|_{A_0}$  is in  $L(Q)$ . Hence by the condition (4.5) there is some  $\pi \in \Pi_0$  with  $\pi(x_0) = k_0$  which yields all the answers given. Thus it is still possible that  $y = k_0$ , and thus also possible that  $y = k_0 - \frac{1}{2}$ .

This completes the proof that the inequality (4.1) still holds and thus also the inequality (4.2).

Finally we must show that the inequality (4.3) still holds. But consider any sequence of  $q < |M_0|$  questions as above, and let  $B$  and  $C$  be as defined there. Chance now takes the role of the adversary. Just as above there is some  $x_0 \in M_0 \setminus (B \cup C)$  and some  $\pi \in \Pi_0$  with  $\pi(x_0) = k_0$  which would yield all the answers given. Hence it is still possible that  $y \in N$ , and the inequality (4.3) follows.  $\square$

Corollary 2.5 follows from Theorem 2.4 just as Corollary 2.3 followed from Theorem 2.1. Also, Corollary 2.6 follows immediately from Corollary 2.5 and (3.2).

To see that the result in Corollary 2.6 concerning unsuccessful search yields the worst-case result Theorem 1.1 note that we may assume that for each leaf  $v$  of the sorting decision tree the corresponding search algorithm  $S_v$  is minimal in the following sense. Let  $\Pi_v$  denote the set of linear orders  $\pi$  that reach leaf  $v$ . If a node in the decision tree for  $S_v$  cannot be reached by any pair  $(\pi, y)$ , where  $\pi \in \Pi_v$  and  $y \in N$  then that node must be a leaf, labelled “ $y \notin N$ .” But now consider any pair  $(\pi_1, y_1)$ , where  $\pi_1 \in \Pi_v$  and  $y_1 \in N'$ . Some pair  $(\pi_2, y_2)$ , where  $\pi_2 \in \Pi_v$  and  $y_2 \in N$  must reach the father

of the leaf reached by  $(\pi_1, y_1)$ , and must then reach a different son of that father. Thus  $S_v(\pi_1, y_1) \cong S_v(\pi_2, y_2)$ . Now it is clear that the maximum search time over  $\pi \in \Pi_v, y \in N'$  is at most the maximum search time over  $\pi \in \Pi_v, y \in N$  (and it is not hard to see that in fact equality holds).

In order to prove Theorem 2.7 we shall use Theorem 2.11, which is proved in the next section.

*Proof of Theorem 2.7.* Let us again use the notation from the proof of Theorem 2.1. Let  $k_0 \in N$  and  $\pi_0 \in \Pi$ , and suppose that  $y = k_0$  and  $\pi = \pi_0$ . Reveal  $k_0$  and that  $y = k_0$  or  $k_0 - \frac{1}{2}$ ; and reveal also  $\Pi_0$  and that  $\pi \in \Pi_0$ . By Theorem 2.11

$$E[S(\pi, k_0) | \pi \in \Pi_0] \cong m(\pi_0^{-1}, k_0)^2 / 2n.$$

But by (3.12)

$$E[m^2] \cong E[m]^2 \cong |\Pi|^{2/n}.$$

Hence

$$E[S] \cong E[m^2] / 2n \cong |\Pi|^{2/n} / 2n. \quad \square$$

*Proof of Corollary 2.8.* Both of these inequalities may be proved from Theorem 2.7 along the lines of the proof of (3.4), by induction on the depth of the preprocessing decision tree. We spell out proofs below (though no new ideas are involved).

If there is no preprocessing, each inequality reduces to Theorem 2.7. For each inequality we then consider a nontrivial decision tree such that the result holds for any shallower tree. Suppose that the first question asked is the comparison  $\pi(x) : \pi(x')$ , where  $x, x' \in X, x \neq x'$ . Let  $\Pi_1, \Pi_2$  be the sets of linear orders  $\pi$  in  $\Pi$  with  $\pi(x) < \pi(x')$ ,  $\pi(x) > \pi(x')$ , respectively. For  $i = 1, 2$  let  $t_i = |\Pi_i| / |\Pi|$ , and let  $P_i, S_i$  refer to  $\Pi_i$ .

Now consider the inequality (i). We have

$$\begin{aligned} 2E[P] + n \log E[S] &= 2(1 + t_1 E(P_1) + t_2 E(P_2)) + n \log (t_1 E[S_1] + t_2 E[S_2]) \\ &\cong 2 + \sum_{i=1}^2 t_i (2E(P_i) + n \log E[S_i]) \\ &\qquad\qquad\qquad \text{by the concavity of the log function} \\ &\cong 2 + \sum_{i=1}^2 t_i 2 \log (t_i |\Pi|) - n \log 2n \\ &\qquad\qquad\qquad \text{by the induction hypothesis} \\ &= 2 \log |\Pi| - n \log 2n + 2(1 + t_1 \log t_1 + t_2 \log t_2) \\ &\cong 2 \log |\Pi| - n \log 2n \quad \text{by (3.2).} \end{aligned}$$

This completes the proof of inequality (i).

Now consider the inequality (ii). We have

$$\begin{aligned} E[4^{P/n} S] &= 4^{1/n} \left( \sum_{i=1}^2 t_i E[4^{P_i/n} S_i] \right) \\ &\cong 4^{1/n} \left( \sum_{i=1}^2 t_i (t_i |\Pi|)^{2/n} / 2n \right) \\ &\qquad\qquad\qquad \text{by the induction hypothesis} \\ &= (|\Pi|^{2/n} / 2n) \{ 4^{1/n} (t_1^{1+2/n} + t_2^{1+2/n}) \} \\ &\cong |\Pi|^{2/n} / 2n. \end{aligned}$$

To see the last inequality note that if  $\delta \geq 0$  the function  $f(x) = x^{1+\delta}$  is convex for  $x > 0$ .  $\square$

Corollary 2.9 of course follows immediately from Corollaries 2.8 and 3.2.

Since the proofs of our results on successful general search rest on Theorem 2.11 and thus on Lemma 5.6 below it will be seen that these results actually hold for more general models of computation (see for example Yao [9]).

**5. Searching for the minimum.** In this section, we prove Theorem 2.11 on searching for the minimum element in a random linear extension of a partial order. We make a careful investigation which may also be of help in resolving Conjecture 2.10. We shall need to consider more general sets of linear orders, and we shall also “assist” the search algorithms.

Given a set  $\Pi$  of linear orders on  $X$ , a partial order  $Q$  on  $X$  and a subset  $Y$  of the minimal elements in  $Q$  let us call  $\Pi$  *good* (with respect to  $Q$  and  $Y$ ) if for any fixed  $\tilde{\pi}$  in  $\Pi$

$$\Pi = \{ \pi \in L(Q) : \pi^{-1}(1) \in Y, \pi(x) = \tilde{\pi}(x) \text{ for each } x \in X \setminus Y \}.$$

Recall that  $L(Q)$  denotes the set of linear extensions of  $Q$ . Here we shall always deal with good sets of linear orders.

We shall assist the search algorithm by giving away certain information for free (and thus assist our analysis). Consider a comparison “ $\pi(x) : \pi(x')$ ?”: if say the result is “ $\pi(x) > \pi(x')$ ” (so that certainly  $x$  is not the minimum) then the rank  $\pi(x)$  of  $x$  is revealed for free. Similarly, the question “Is  $x$  the minimum?” is answered by revealing  $\pi(x)$ . (See also the comment following the proof of the lemma below.) Note that if  $\Pi$  is good with respect to  $Q$  and  $Y$  then the only questions an assisted algorithm need ever use are of the form “Is  $x$  the minimum?” for  $x \in Y$ , and “ $\pi(x) : \pi(x')$ ?” for  $x, x' \in Y$ .

LEMMA 5.1. *Suppose that the set  $\Pi$  of linear extensions is good with respect to  $Q$  and  $Y$ , and that each linear order  $\pi \in \Pi$  is equally likely. Then for any assisted search algorithm as above the random time  $T$  taken satisfies  $T \geq \tilde{T}$  in distribution, where  $\tilde{T} = \tilde{T}(\pi^{-1}(1))$  is as defined in § 3.*

This result says that it is optimal to order the elements of  $X$  by decreasing size of  $|\Pi(x)|$  and repeatedly to ask questions “Is  $x$  the minimum?” in this fixed order, ignoring any extra information gained and never making any comparisons (see (3.5)). Here  $\Pi(x)$  is the set of linear orders  $\pi \in \Pi$  with  $\pi(x) = 1$ .

*Proof.* Let  $Z = X \setminus Y$ . For each  $y \in Y$  let  $b(y)$  be the least  $k \in \mathbb{N}$  such that there is a  $z \in Z$  with  $y < z$  in  $Q$  and rank  $\pi(z) = k$  for some (or each)  $\pi \in \Pi$ . If there is no such  $z$  then set  $b(y) = \infty$ . The key observation is that, with the natural conventions regarding  $\infty$

$$(5.2) \quad \text{if } y, y' \in Y \text{ and } b(y) \geq b(y') \text{ then } |\Pi(y)| \leq |\Pi(y')|.$$

For the map  $\pi \rightarrow \pi' = (y, y')\pi$  gives an injection from  $\Pi(y)$  into  $\Pi(y')$ . To see this, note that if  $\pi \in \Pi(y)$  then  $\pi' \in L(Q)$  and so  $\pi' \in \Pi$ .

Let us order the elements of  $Y$  as  $x_1, \dots, x_m$ , say, so that  $b(x_1) \leq \dots \leq b(x_m)$ .

We shall prove the lemma by induction on the depth  $d$  of the decision tree. The case  $d = 1$  (one question) is trivial, so consider an instance with  $d > 1$ , and such that the lemma holds for any shallower decision tree. Clearly we may assume that  $m = |Y| > 1$ .

Let  $t \in \{1, \dots, m\}$ , and let  $R_t = R_t(\Pi)$  denote the set of linear orders  $\pi \in \Pi$  which reach leaves of the decision tree at depth at most  $t$ . Then  $P\{T \leq t\} = |R_t|/|\Pi|$ , and we must show that

$$(5.3) \quad |R_t| \leq \sum_{k=1}^t |\Pi(x_k)|.$$

This is clearly true if  $t = 1$ , so suppose  $t \geq 2$ . There are two cases to consider.

*Case (a).* The first question is “Is  $x$  the minimum?” for some  $x \in Y$  (or equivalently, “What is  $\pi(x)$ ?”). The root of the decision tree has one son which is a leaf and is reached by the linear orders  $\pi$  in  $\Pi(x)$  (if  $\Pi(x)$  is not empty). It also has a nonleaf son  $s$  for each possible value of  $\pi(x) \neq 1$ . For each such  $s$  let  $\Pi^s$  be the set of linear orders  $\pi \in \Pi$  that reach it. Then  $\Pi^s$  is good with respect to  $Q$  and  $Y \setminus \{x\}$ . Hence we may use the induction hypothesis to bound  $|R_t \cap \Pi^s|$ .

Note that by the key observation (5.2) the sets  $\Pi^s(x_1), \Pi^s(x_2), \dots$ , other than  $\Pi^s(x)$  are nonincreasing in size (and perhaps are empty from some point on). There are two subcases, depending on whether or not  $x$  is in the set  $Y_t = \{x_1, \dots, x_{t-1}\}$ .

(a1) Suppose that  $x \in Y_t$ . Then for each nonleaf son  $s$

$$|R_t \cap \Pi^s| \leq \sum \{|\Pi^s(x_k)| : k = 1, \dots, t, x_k \neq x\}.$$

Hence

$$\begin{aligned} |R_t| &\leq |\Pi(x)| + \sum \{|\Pi(x_k)| : k = 1, \dots, t, x_k \neq x\} \\ &= \sum_{k=1}^t |\Pi(x_k)|. \end{aligned}$$

(a2) Suppose that  $x \in Y \setminus Y_t$ . Then for each nonleaf son  $s$ ,

$$|R_t \cap \Pi^s| \leq \sum_{k=1}^{t-1} |\Pi^s(x_k)|,$$

and so

$$\begin{aligned} |R_t| &\leq |\Pi(x)| + \sum_{k=1}^{t-1} |\Pi(x_k)| \\ &\leq \sum_{k=1}^t |\Pi(x_k)|. \end{aligned}$$

*Case (b).* The first question is a comparison  $\pi(x) : \pi(x')$ , where  $x, x' \in Y$ . Let

$$\Pi_l = \{\pi \in \Pi : \pi(x) < \pi(x')\}, \quad \Pi_r = \Pi \setminus \Pi_l.$$

Let the partial orders  $Q_l, Q_r$  be obtained from  $Q$  by adding the inequalities  $x < x', x > x'$ , respectively.

The root of the decision tree has a collection of left sons corresponding to  $\Pi_l$  and right sons corresponding to  $\Pi_r$ . Each left son  $s$  corresponds to a possible value for  $\pi(x')$ . Consider such a left son  $s$ . Let  $\Pi_l^s$  be the set of linear orders  $\pi \in \Pi_l$  that reach it. Then  $\Pi_l^s$  is good with respect to  $Q_l$  and  $Y \setminus \{x'\}$ . Also note that by the key observation (5.2) the sets  $\Pi_l^s(x_1), \Pi_l^s(x_2), \dots$ , other than  $\Pi_l^s(x)$  and  $\Pi_l^s(x') (= \emptyset)$  are nonincreasing in size. Similar comments hold for each right son  $s$ , with corresponding set  $\Pi_r^s$  of linear orders. Thus we may use the induction hypothesis much as in Case (a).

Note that if  $x$  or  $x'$  is in  $Y_t$ , then by (5.2) for each left son  $s$   $|\Pi_l^s(x)| \leq |\Pi_l^s(x_t)|$ , and similarly for each right son  $s$   $|\Pi_r^s(x')| \leq |\Pi_r^s(x_t)|$ . There are now three subcases.

(b1) Suppose that  $x, x' \in Y_t$ . For each left son  $s$

$$|R_t \cap \Pi_l^s| \leq \sum_{k=1}^t |\Pi_l^s(x_k)|,$$

since the  $t$  sets  $\Pi_l^s(x_1), \dots, \Pi_l^s(x_t)$  contain  $(t-1)$  largest sets of the form  $\Pi_l^s(x_i)$  (together with the set  $\Pi_l^s(x')$  which is empty). Hence

$$|R_t \cap \Pi_l| \leq \sum_{k=1}^t |\Pi_l(x_k)|.$$

Similarly

$$|R_t \cap \Pi_r| \leq \sum_{k=1}^t |\Pi_r(x_k)|,$$

and so (5.3) holds.

(b2) Suppose that  $x \in Y_t, x' \in Y \setminus Y_t$ . For each left son  $s$ ,

$$|R_t \cap \Pi_l^s| \leq \sum_{k=1}^{t-1} |\Pi_l^s(x_k)|$$

since  $\Pi_l^s(x_1), \dots, \Pi_l^s(x_{t-1})$  are  $(t-1)$  largest sets of the form  $\Pi_l^s(x_i)$ ; and so

$$|R_t \cap \Pi_l| \leq \sum_{k=1}^{t-1} |\Pi_l(x_k)|.$$

Also, for each right son  $s$

$$|R_t \cap \Pi_r^s| \leq \sum_{k=1}^{t-1} |\Pi_r^s(x_k)| + |\Pi_r^s(x')|$$

since  $|\Pi_r^s(x')| \geq |\Pi_r^s(x_t)|$  and so the  $t$  sets  $\Pi_r^s(x_1), \dots, \Pi_r^s(x_{t-1}), \Pi_r^s(x')$  contain  $(t-1)$  largest sets of the form  $\Pi_r^s(x_i)$  (together with the set  $\Pi_r^s(x)$  which is empty). Hence

$$|R_t \cap \Pi_r| \leq \sum_{k=1}^{t-1} |\Pi_r(x_k)| + |\Pi_r(x')|.$$

Thus

$$\begin{aligned} |R_t| &\leq \sum_{k=1}^{t-1} (|\Pi_l(x_k)| + |\Pi_r(x')|) \\ &\leq \sum_{k=1}^t |\Pi_l(x_k)| \quad \text{as required for (5.3).} \end{aligned}$$

(b3) Suppose that  $x, x' \in Y \setminus Y_t$ . This is the most interesting subcase. Let  $b = b(x_{t-1})$ . Consider a left son  $s$ . By the key observation (5.2), if  $\pi(x') \geq b$  (for each  $\pi \in \Pi_l^s$ ) then  $\Pi_l^s(x_1), \dots, \Pi_l^s(x_{t-1})$  are  $(t-1)$  largest sets of the form  $\Pi_l^s(x_i)$ ; and if  $\pi(x') < b$ , then  $\Pi_l^s(x_1), \dots, \Pi_l^s(x_{t-2}), \Pi_l^s(x)$  are  $(t-1)$  largest sets of this form. Hence

$$|R_t \cap \Pi_l^s| \leq \begin{cases} \sum_{k=1}^{t-1} |\Pi_l^s(x_k)| & \text{if } \pi(x') \geq b, \\ \sum_{k=1}^{t-2} |\Pi_l^s(x_k)| + |\Pi_l^s(x)| & \text{if } \pi(x') < b. \end{cases}$$

Thus

$$\begin{aligned} |R_t \cap \Pi_l| &\leq \sum_{k=1}^{t-2} |\Pi_l(x_k)| + |\{\pi \in \Pi_l(x_{t-1}): \pi(x') \geq b\}| \\ &\quad + |\{\pi \in \Pi_l(x): \pi(x') < b\}|. \end{aligned}$$

Similarly

$$|R_t \cap \Pi_r| \leq \sum_{k=1}^{t-2} |\Pi_r(x_k)| + |\{\pi \in \Pi_r(x_{t-1}): \pi(x) \geq b\}| + |\{\pi \in \Pi_r(x'): \pi(x) < b\}|.$$

Hence

$$|R_t| \leq \sum_{k=1}^{t-2} |\Pi(x_k)| + |\{\pi \in \Pi(x_{t-1}): \max(\pi(x), \pi(x')) \geq b\}| + |\{\pi \in \Pi(x): \pi(x') < b\}| + |\{\pi \in \Pi(x'): \pi(x) < b\}|.$$

Now  $b = b(x_{t-1}) \leq b(x)$ . Let  $\pi \in \Pi(x)$ , and let  $\pi' = (x, x_{t-1})\pi$ . Then  $\pi' \in L(Q)$  since  $x_{t-1}$  is minimal in  $Q$ , and if  $x < z$  in  $Q$ , then  $\pi'(z) = \pi(z) \geq b(x) \geq b > \pi(x_{t-1}) = \pi'(x)$ . It follows that  $\pi' \in \Pi$ . Thus the map  $\pi \rightarrow \pi'$  yields an injection from  $\{\pi \in \Pi(x): \pi(x') < b\}$  into  $\{\pi \in \Pi(x_{t-1}): \pi(x), \pi(x') < b\}$ . Also by (5.2)

$$|\{\pi \in \Pi(x'): \pi(x) < b\}| \leq |\Pi(x')| \leq |\Pi(x_t)|.$$

Hence

$$\begin{aligned} |R_t| &\leq \sum_{k=1}^{t-2} |\Pi(x_k)| + |\{\pi \in \Pi(x_{t-1}): \max\{\pi(x), \pi(x')\} \geq b\}| \\ &\quad + |\{\pi \in \Pi(x_{t-1}): \max\{\pi(x), \pi(x')\} < b\}| + |\Pi(x_t)| \\ &= \sum_{k=1}^t |\Pi(x_k)|. \end{aligned}$$

This completes the proof of Lemma 5.1.  $\square$

Suppose that in case (a) of the proof above the set  $\Pi(x)$  is empty. Then arguing as above, we see that

$$|R_t| \leq \sum_{k=1}^{t-1} |\Pi(x_k)|.$$

Hence the lemma will still hold if we do not charge for questions “Is  $x$  the minimum?” when  $\Pi(x)$  is empty. Thus the assistance given to the search algorithm may now take the simple form: whenever it is not possible for an element  $x$  to be the minimum, then its rank  $\pi(x)$  is revealed for free (and this process may be repeated).

Let  $Q$  be a partial order on  $X$ , with set  $Y$  of minimal elements. For each  $y \in Y$  let the “above-set”  $A(y)$  be the set of  $z \in X$  such that  $y < z$  in  $Q$ . We shall be interested in the case that the sets  $A(y)$  for  $y \in Y$  are “nested,” that is, we can list  $Y$  as  $x_1, \dots, x_m$ , say, so that  $A(x_1) \supseteq \dots \supseteq A(x_m)$ . This is certainly the case if the set  $Z = X \setminus Y$  is linearly ordered by  $Q$ .

**LEMMA 5.4.** *Let  $\Pi$  be the set of linear extensions of a partial order  $Q$  on  $X$  such that the above-sets  $A(y)$  of the minimal elements  $y$  are nested. Suppose that each linear order  $\pi$  in  $\Pi$  is equally likely. Then for any assisted search algorithm as above the random search time  $T$  satisfies  $T \geq \tilde{T}$  in distribution, where  $\tilde{T} = \tilde{T}(\pi^{-1}(1))$ .*

*Proof.* Suppose that revealing the rank  $\pi(z)$  of the nonminimal elements  $z$  partitions  $\Pi$  into nonempty sets  $\Pi^s$  of linear orders. Then each set  $\Pi^s$  is good with respect to  $Q$  and  $Y$ . Also by the key observation (5.2),  $|\Pi^s(x_1)| \geq \dots \geq |\Pi^s(x_m)|$ . Hence by Lemma 5.1, for any  $1 \leq t \leq m$

$$|R_t(\Pi^s)| \leq \sum_{k=1}^t |\Pi^s(x_k)|,$$

and so

$$|R_t(\Pi)| = \sum_s |R_t(\Pi^s)| \leq \sum_{k=1}^t |\Pi(x_k)|. \quad \square$$

*Proof of Theorem 2.11.* Note first that it is sufficient to prove the theorem for the case when the set  $X \setminus Y$  is linearly ordered by  $Q$ . For we could assist the search algorithm by first revealing the linear order on this set; then for each subproblem the expected search time would be at least  $1 + m(m - 1)/2n$ . And so, the overall expected (assisted) search time would be at least this value.

Let us assume then that the set  $X \setminus Y$  is linearly ordered by  $Q$ . The key observation now is that for each  $x \in Y$

$$(5.5) \quad |\Pi(x)| \geq |\Pi|/n.$$

To see this, define a function  $\phi$  from  $\Pi$  into  $\Pi(x)$  as follows. For each linear order  $\pi \in \Pi$  let  $\phi(\pi)$  be the linear order in  $\Pi$  obtained by moving  $x$  to be the minimum. Then for each  $\pi_0 \in \Pi(x)$  we have  $|\{\pi \in \Pi: \phi(\pi) = \pi_0\}| \leq n$ . Hence  $|\Pi| \leq n|\Pi(x)|$ , as required. (See also Theorem 3.3.4 of Mairson [6], [7].)

Now by Lemma 5.4  $E[T] \geq E[\tilde{T}]$ . But  $E[\tilde{T}] = \sum_j j p_j$ , where the summation is over  $j = 1, \dots, m$  and  $p_1, \dots, p_m$  are the values  $|\Pi(x)|/|\Pi|$  arranged in nonincreasing order. Also the minimum value of the linear program  $\min \sum_j j p_j$  subject to  $\sum_j p_j = 1, p_j \geq 1/n$  ( $j = 1, \dots, m$ ) clearly occurs at  $p_2 = \dots = p_m = 1/n, p_1 = 1 - (m - 1)/n$ , and the value equals

$$1 - (m - 1)/n + (1/n) \sum_{j=2}^m j = 1 + m(m - 1)/2n.$$

Hence we have shown that

$$E[T] \geq E[\tilde{T}] \geq 1 + m(m - 1)/2n$$

as required.  $\square$

*Remark.* Lemma 5.4 does *not* hold for an arbitrary partial order  $Q$ .

*Example 5.6.* Let  $X = \{x_1, \dots, x_6\}$  and let the partial order  $Q$  consist of the relations  $x_1 < x_3, x_2 < x_3, x_4 < x_6, x_5 < x_6$ , as shown in Fig. 1.

FIG. 1

A decision tree yielding the random search time  $\tilde{T}$  is shown in Fig. 2. Here the notation “ $x_i?$ ” means “Is  $x_i$  the minimum?”, and  $y, n$  stand for yes and no. The numbers at the leaves are the numbers of linear extensions of  $Q$  reaching them. Note that

$$P\{\tilde{T} \leq 3\} = 60/80.$$

A decision tree with initial query the comparison  $\pi(x_1): \pi(x_4)$  is shown in Fig. 3. Note that here

$$P\{T \leq 3\} = 62/80.$$

FIG. 2

FIG. 3

Perhaps for any partial order  $Q$  we still have  $E[\log T] \cong E[\log \tilde{T}]$ . If this is so, then we could deduce as for Theorem 2.1 (iii) that

$$E[n \log S] \cong \log |\Pi| - n \log \log n,$$

and Conjecture 2.10 would follow.

## EFFICIENT SOLUTION OF CONNECTIVITY PROBLEMS ON HIERARCHICALLY DEFINED GRAPHS\*

THOMAS LENGAUER† AND EGON WANKE†

**Abstract.** Using hierarchical definitions we can describe very large graphs in small spaces. In this paper we discuss how such succinct graph descriptions can be used to speed up the solution of graph problems. We present the bottom-up method that solves graph problems without expanding the hierarchical description. This allows solutions that are efficient in terms of the hierarchical graph description instead of the size of the expanded graph. We exemplify the method by giving efficient solutions to connectivity problems on hierarchical graphs. Our results have applications in computer-aided design for integrated circuit design and other engineering problems.

**Key words.** connectivity, biconnectivity, hierarchical graphs, succinct graph descriptions, query

**AMS(MOS) subject of classification.** 05C40

**1. Introduction.** Graph algorithms have many applications in engineering, e.g., in the areas of mechanical and electrical engineering. As the technology in these areas advances, the sizes of graphs to be processed increases dramatically. Perhaps the best example for this development is the area of very large-scale integration (VLSI) design. Today's integrated circuits have up to several hundred thousand transistors. Processing such designs requires the internal representation of graphs with up to over a million vertices.

On the other hand large engineering designs always have some regular structure. This is because they are developed with relatively small resources, e.g., a few people in a relatively short time. Therefore most computer-aided design (CAD) systems for engineering design allow for some mechanism of succinct design description. This enables the designer to describe a large design in a small space. The complete explicit design description is generated by the computer in a data-expansion step.

Traditionally this data expansion was the first action taken by the CAD system for design processing. It involves the generation of large amounts of data that with today's applications generally do not fit into the address space of the computer. Thus processing the expanded data is both complicated (since it involves secondary storage management) and inefficient (because of large amounts of input/output on secondary storage). Even if the expanded design fits into the address space of the computer and secondary storage management can be avoided, page swapping is usually extensive. The resulting performance problems often are the critical obstacle to the acceptance of CAD tools.

In this paper we will present a method that circumvents these problems, when design processing is done on the basis of graph algorithms. The regularity of an engineering design is reflected by the regularity of the graph representing it. Thus such a graph can also be described succinctly. We will present a method that allows us to process succinctly described graphs *before* they are expanded. Thus the data-expansion step may only be needed to generate the final output of the processing. As a consequence, working storage requirements for design processing are dramatically reduced, and secondary storage management as well as expensive page-swapping overhead can be avoided. However, this is only possible if we choose an appropriate model for succinct graph description.

The remainder of the paper is organized as follows: Section 2 gives a short summary of models for succinct graph description presented in the literature, and introduces the graph model we use in this paper. Section 3 introduces the *bottom-up method* for hierarchical graph processing and applies it to the connectivity problem of undirected graphs. Sections 4 and 5 present the hierarchical solution of the biconnectivity, respectively, strong connectivity problem. Section 6 gives conclusions.

**2. The graph model.** Several approaches towards succinct graph description have been pursued in the literature. In [GW83] graphs are succinctly described by Boolean circuits computing their adjacency matrix. Thus a graph  $G = (V, E)$  with  $n$  vertices ( $V = \{0, \dots, N-1\}$ ) is defined by a Boolean circuit computing a predicate  $\phi(i, j) \in \{0, 1\}$ ,  $0 \leq i, j \leq N-1$ , where  $\phi(i, j) = 1$  if and only if  $\{i, j\} \in E$ . For example, the square grid of  $N \times N$  nodes is defined by the predicate

$$\phi(i, j) \Leftrightarrow (|x_i - x_j| = 1 \text{ and } y_i = y_j) \text{ or } (|y_i - y_j| = 1 \text{ and } x_i = x_j), i, j \in \{0, N^2 - 1\}$$

where  $x_i = i \bmod N$ ,  $y_i = i \text{ div } N$ . (For simplicity assume that  $n$  is a power of 2.) Note that the Boolean circuit size of  $\phi(i, j)$  is  $O(\log N)$  in this case. Unfortunately, [GW83] shows that this data compression cannot be significantly exploited when processing the graph: Even the simplest graph problems, e.g., connectivity, minimum or maximum degree, etc. become NP-hard when the graph is defined in this form.

Reference [BOW83] introduces an explicit hierarchical specification for sets of iso-oriented rectangles in the Euclidean plane. Their notion of hierarchy is taken from mask data formats for VLSI layouts (see [MC80]). Reference [BOW83] shows that many simple problems on rectangle sets (e.g., intersection questions) become NP-complete if the set is defined hierarchically. Reference [Wa84] translates the results of [BOW83] into graph theory. Bentley et al. hierarchically describe graphs whose vertices are points in  $d$ -dimensional Euclidean space. Here a graph is built up out of primitive components (edges, denoted by sets of pairs of vertices) and copies of previously defined subgraphs (cells).

A cell can be copied by translating it along a specified vector. The copy of the cell is specified by an identifying number of the cell and the point in space defining the vector of translation. Thus the  $N \times N$  square grid that is placed into the plane such that all edges have unit length and the lower left corner is placed at the origin can be defined by the following sequence of subcells. The cell  $G_k$  defines a  $(2^k + 1) \times (2^k + 1)$  grid.

$G_0$ :	primitive edges:	$\{(0, 0)(0, 1)\}, \{(0, 0)(1, 0)\},$ $\{(1, 0)(1, 1)\}, \{(0, 1)(1, 1)\}$
	no subcells	
$G_k$ ( $k > 0$ ):	no primitive edges	
	subcells	$(G_{k-1}, (0, 0)), (G_{k-1}, (0, 2^{k-1})),$ $(G_{k-1}, (2^{k-1}, 0)),$ $(G_{k-1}, (2^{k-1}, 2^{k-1}))$

(The fact that each interior edge of the grid is represented twice here is technical and insignificant for our discussion.) In this way we can describe an  $N \times N$  grid with a specification of length  $O((\log N)^2)$  (logarithmic cost measure).

Reference [Wa84] shows that in this model even the simplest graph problems become NP-hard. The intuitive reason is that two subcells can be placed such that they overlap each other. This placement can be described in space  $O(1)$ , but it can make a large number of "implicit" connections in the region of overlap. Thus in order to make the graph model amenable to hierarchical processing we have to explicitly define a "boundary" of a subcell, i.e., a set of vertices at which the environment can connect to the cell. We call such vertices *pins*.

Reference [S182] shows that if connections to subcells are restricted to pins, and if there are only a few pins in a subcell, then certain problems become easy. Thus our graph model will be a certain restricted type of context-free graph grammar.

DEFINITION 1. A hierarchical (un-) directed graph  $\Gamma = (G_1, \dots, G_k)$  is a finite sequence of (un-) directed simple graphs  $G_i$  called cells. Here the graph  $G_i$  has  $n_i$  vertices and  $m_i$  edges.  $p_i$  of the vertices are distinguished and called pins. The other  $n_i - p_i$  vertices are called inner vertices.  $r_i$  of the inner vertices are distinguished and called nonterminals. The other  $n_i - r_i$  vertices are called terminals or proper vertices.

Each pin has a unique label, its name. Without loss of generality we can assume that the pins are named with numbers between 1 and  $p_i$ . Each nonterminal has two labels, a name and a type. The type is a symbol from  $\{G_1, \dots, G_{i-1}\}$ . If a nonterminal  $v$  has type  $G_j$  then  $v$  has degree  $p_j$  and each proper vertex that is a neighbor of  $v$  has a label  $(v l)$  such that  $1 \leq l \leq p_j$ . We say that the neighbor of  $v$  labeled  $(v, l)$  matches the  $l$ th pin of  $G_j$ . (All neighbors of a nonterminal must be terminals.)

We assume that  $\Gamma$  is not redundant in the sense that each  $G_i$  is the type of some nonterminal  $\nu$  in some  $G_j, j > i$ . The size of  $\Gamma$  is  $n := \sum_{1 \leq i \leq k} n_i$ , the edge number is  $m := \sum_{1 \leq i \leq k} m_i$ . Note that with  $\Gamma = (G_1, \dots, G_k)$  also each prefix  $\Gamma_i = (G_1, \dots, G_i), i < k$  is a hierarchical graph.

Definition 1 essentially describes a context-free graph grammar with axiom  $G_k$ , where each nonterminal only has one production. Thus the language of the graph grammar has one word. This word is called the expansion of  $\Gamma$ .

DEFINITION 2. The *expansion*  $E(\Gamma)$  of the hierarchical graph  $\Gamma$  is obtained as follows:

$k = 1$ :  $E(\Gamma) = G_1$ . The pins of  $E(\Gamma)$  are the pins of  $G_1$ .

$k > 1$ : Repeat the following step for each nonterminal  $\nu$  of  $G_k$ , say, of type  $G_j$ :  
Delete  $\nu$  and its incident edges. Insert a copy of  $E(\Gamma_j)$  by identifying the  $l$ th pin of  $E(\Gamma_j)$  with the node in  $G_k$  that is labeled  $(\nu, l)$ .

The size of  $E(\Gamma)$ , i.e., its number of vertices, is denoted by  $N$ . The number of edges of  $E(\Gamma)$  is denoted by  $M$ .

The expansion of  $\Gamma$  naturally has a tree structure, namely the parse tree for the word  $E(\Gamma)$  in the graph grammar  $\Gamma$ .

DEFINITION 3. With  $\Gamma$  and  $E(\Gamma)$  we associate the so-called *hierarchy tree*  $T$  that is defined as follows. Each node in  $T$  has two labels, a name and a type. (The root of  $T$  has no name.) A node  $x$  of type  $G_i$  in  $T$  has  $r_i$  sons. Each son of  $x$  has the name and type of one of the nonterminals in  $G_i$ .  $T$  is defined inductively:

$k = 1$ :  $T$  has one node with type  $G_1$ .

$k > 1$ :  $T$  has a root of type  $G_k$ . The son of the root that has the name and type of the nonterminal  $\nu$  of type  $G_j$  in  $G_k$  is the root of a copy of the hierarchy tree for  $\Gamma_j = (G_1, \dots, G_j)$ .

$T$  is the parse tree of the unique word generated by the context-free graph grammar. Clearly each node of type  $G_i$  in the hierarchy tree  $T$  corresponds to a copy of  $E(\Gamma_i)$  in  $E(\Gamma)$ . (In the context of  $T$  we will use exclusively the term node. In the context of  $\Gamma$  or  $E(\Gamma)$  we will use exclusively the term vertex.)

The terminology in the above three definitions is taken partly from the area of graph grammars (nonterminals) and partly from the area of CAD for VLSI design (cells, pins).

Let us define the  $N \times N$  grid hierarchically using the above definition. This time we choose  $N = 2^k$ , again for technical reasons.  $\Gamma = (G_1, \dots, G_k)$ , where  $\Gamma_i$  defines the  $2^i \times 2^i$  grid. We define  $G_i$  pictorially. Hereby we denote pins by squares, nonterminals by circles labeled with the type of subcells they represent, and terminals that are not

FIG. 1

pins by dots.  $\Gamma$  is defined as in Fig. 1. The labels on the neighbors of nonterminals are omitted for the sake of readability of Fig. 1. The correspondence is clear from the position of the vertices in the figure.

Note that  $\Gamma$  has length  $O(N)$ , as opposed to  $O((\log N)^2)$  in the model of [Wa84]. This is because the boundary of a grid grows as the square root of the size of the grid. There are hierarchical graphs such that  $n = O(\text{polylog}(N))$ , but in general this model is weaker than the model of [Wa84] in that hierarchical descriptions can be longer. However, the model presented here allows us to solve a large number of interesting and important graph problems before data expansion. Furthermore the model is quite natural and corresponds to the actual representation of data in a number of CAD systems.<sup>1</sup>

The following example will accompany us through the remainder of the paper.

*Example 1.* Let  $\Gamma = (G_1, G_2, G_3, G_4)$  be the hierarchical graph shown in Fig. 2. The expansion  $E(\Gamma)$  is shown in Fig. 3; the hierarchy tree is shown in Fig. 4.

In Fig. 4, we again omitted labels on the vertices. The correspondence between pins of  $G_j$  and neighbors of a nonterminal of type  $G_j$  in cell  $G_i$  is clear by the positions of the vertices in the figure. Each edge in  $E(\Gamma)$  belongs to a unique node  $x$  in  $T$ . For example, the edge  $e_1$  in Fig. 3 belongs to the unique node in  $T$  that is of type  $G_3$ . Similarly a vertex in  $E(\Gamma)$  belongs to a unique node  $x$  in  $T$ , where that vertex appears as a terminal that is not a pin. For example, the vertex  $v_1$  belongs to the same node  $x$  in  $T$  as the edge  $e_1$ . (This is even though the vertex  $v_1$  is also represented by pins in three descendants of  $x$  in  $T$ .) Thus an edge (vertex) in  $E(\Gamma)$  can be identified by providing the path from the root of  $T$  to the node  $x$  in  $T$  to which the edge (vertex) belongs, and then identifying the edge (vertex) inside  $x$ . In general, a pathname is a sequence of nonterminals  $v_1, \dots, v_{i-1}$  followed by a terminal node  $v$  or an edge  $e$ . Here,  $v_1$  is a nonterminal in  $G_k$  and if  $v_k$  is a nonterminal of type  $G_j$ , then  $v_{k+1}$  is a nonterminal in  $G_j$ . For technical reasons we assume pathnames start with a dummy nonterminal of type  $G_k$ . Note that  $E(\Gamma)$  can have multiple edges, in general, even though  $G_i$  has no multiple edges, for all  $i$ . However, the results in this paper also generalize to the case that  $G_i$  may be a multigraph.

<sup>1</sup> Reference [Ga82] presents a hierarchical graph model that is based on the abutment of subcells at lists of pins. This model allows some degree of hierarchical processing but in general some expansion is necessary, because pin lists can also be composed hierarchically.

FIG. 2

FIG. 3

**3. The bottom-up method.** For certain graph problems the solution on a subgraph can in some sense be done independently of the environment in which the subgraph is placed. Such problems can be solved hierarchically in a bottom-up fashion.

The bottom-up method is based on the concept of replaceability. Let  $P$  be a binary question that can be asked about graphs, e.g., the question “Is  $E(T)$  connected?”

DEFINITION 4. Let  $G, G'$  be two cells with pins  $p_1, \dots, p_n$  and no nonterminal vertices. Let  $H$  be a cell with no pins and exactly one nonterminal vertex  $v$ . Vertex  $v$  has degree  $n$ . Let the neighbors of  $v$  be marked as defined in Definition 1.  $G, G'$  are *replaceable* with respect to  $P$  if for each such  $H$  the answer to  $P$  is the same no matter whether we substitute  $G$  or  $G'$  for  $v$  in  $H$ .

The aim of the bottom-up method is to find small graphs  $G_i^b$  that are replaceable with  $E(\Gamma_i)$  and to find such graphs fast. In order to do so, the bottom-up method fills a table of graphs, the so-called BU-table (see Fig. 5 for the BU-table for the connectivity of Example 1.) Row  $i$  of the BU-table corresponds to cell  $G_i$ . The BU-table has three columns. (We will discuss a fourth column that may be added to the BU-table later.) The first column contains the cells  $G_1, \dots, G_k$ . All other columns are empty initially.

The bottom-up method fills the second and third columns of the table row-wise from top to bottom with graphs  $\tilde{G}_i$ , respectively,  $G_i^b$  that are replaceable with  $E(\Gamma_i)$  but smaller than  $E(\Gamma_i)$ .  $\tilde{G}_i$  (in column 2) is obtained by substituting  $G_j^b$  instead of  $E(\Gamma_j)$  for all nonterminals of type  $G_j$  in  $G_i$ . Since the  $G_j^b$  and  $E(\Gamma_j)$  are replaceable by assumption,  $\tilde{G}_i$  and  $E(\Gamma_i)$  are also replaceable (with respect to question  $P$ ). We call  $\tilde{G}_i$  the *fooled* graph.  $\tilde{G}_i$  is then further reduced in size by a shrinking procedure,

FIG. 4

called *burning*, that depends on the question  $P$ . The result  $G_i^b$  is put in column 3 and called the *burnt graph*.

The correctness of the bottom-up method is ensured if the burning process produces replaceable graphs (with respect to question  $P$ ). This is so because if we attach replaceable graphs to the same environment we get replaceable graphs again. The efficiency of the bottom-up method depends on two things. First, the burning process must be efficient. Second, the burning process must yield small graphs, such that the graphs in the BU-table do not become too large. In particular, if every  $G_i^b$  has at most  $O(p_i)$  vertices and edges, then every  $\tilde{G}_i$  has at most  $O(m_i + n_i)$  vertices and edges. In this case, we can fill the BU-table with a linear time burner in linear time in the size of the hierarchical description.

After the BU-table has been filled the answer to the question can then usually be obtained by a quick inspection of its contents.

In order to apply the bottom-up method to the question  $P$ : “*Is  $E(\Gamma)$  connected?*”, we only have to find an appropriate burning procedure. For connectivity this is especially simple: To burn  $\tilde{G}_i$  down to  $G_i^b$  we find the connected components of  $\tilde{G}_i$ . We reserve a vertex  $c$  for each connected component that contains a pin. If there are connected components without pins we also reserve an additional vertex representing all of them. (If  $\tilde{G}_i$  does not have pins and is not connected we need two such vertices.) These vertices and the pins of  $\tilde{G}_i$  are the vertices of  $G_i^b$ . The edges in  $G_i^b$  connect each pin with the vertex representing the connected component containing this pin. The proof of the following lemma is straightforward.

FIG. 5

LEMMA 1.  $\tilde{G}_i$  is replaceable with  $G_i^b$  with respect to connectivity.

An inductive application of Lemma 1 yields Theorem 1.

THEOREM 1.  $E(\Gamma)$  is connected if and only if  $\tilde{G}_k$  is connected.

Since the size of  $G_i^b$  is  $O(p_i)$  and  $G_i^b$  can be constructed in linear time in the size of  $\tilde{G}_i$ , connectivity of  $E(\Gamma)$  can be decided in time  $O(m+n)$ . Figure 5 gives the bottom-up table for the connectivity of Example 1.

The burning process above answer the decision problem: “Is  $E(\Gamma)$  connected?” By augmenting the BU-table appropriately we can also solve other problems pertaining to connectivity. The augmentation adds a fourth column that contains a hierarchical graph  $\Gamma'$  such that  $E(\Gamma') = E(\Gamma)$ , but  $\Gamma'$  explicitly describes the connected components of  $E(\Gamma)$ . Figure 5 shows  $\Gamma'$  for Example 1. Figure 6 gives the hierarchy tree  $T'$  or  $\Gamma'$ . In order to find  $\Gamma'$  we scan through column 2 of the BU-table. When processing row  $i$  we make a new *component* cell out of each connected component of  $\tilde{G}_i$ . Nonterminals whose types are these component cells replace the vertices of  $G_i^b$  representing the connected components later on in the hierarchy. The component cell  $G_{il}$  for the  $l$ th component of  $\tilde{G}_i$  consists of the graph of this component, where all vertices representing connected components in some copy of  $G_j^b$  inside  $\tilde{G}_i$  are replaced with nonterminals of the appropriate component cell types. A vertex that represents several isolated components of  $\tilde{G}_j$  without pins inside a copy of  $G_j^b$  is replaced with a nonterminal, whose type is a cell that consists just of isolated nonterminals representing each of the components. Such a cell is called *disconnected*. All other cells are called *connected*. The names of disconnected cells are underscored in Figs. 5 and 6. Finally, if  $G_k^b$  has several components we create a disconnected root cell joining all of them. Components containing only a nonterminal and its pins with no additional vertex or edges cause no creation of component cells. Rather, the component cell type of the nonterminal is reused higher up in the hierarchy. (In Fig. 5  $G_{11}$  is reused for a component of  $G_3$  inside  $G_{41}$  in this way.)

THEOREM 2. (a)  $E(\Gamma') = E(\Gamma)$

(b)  $m', n' = O(m+n)$ . The depth of the hierarchy tree  $T'$  of  $\Gamma'$  is at most  $k+1$ .

(c) A cell in  $\Gamma'$  is connected exactly if its expansion is connected.

FIG. 6

(d) *The hierarchy tree  $T'$  of  $\Gamma'$  has a top part consisting exclusively of nodes whose type is a disconnected cell. The bottom part of  $T'$  consists exclusively of nodes whose type is a connected cell. The connected components of  $\Gamma$  are represented by the maximal subtrees of  $T'$  that are rooted at nodes whose type is a connected cell.*

*Proof.* The proof of part (a) is obvious.

(b)  $m', n' = O(m+n)$  since  $\tilde{G}_i$  has size  $O(m_i + n_i)$ . To see that  $T'$  has depth at most  $k+1$ , note that as we scan a path from a node  $x$  to the root in  $T'$  we move downward in column 4 of the BU-table. Here we scan at most one cell per row of the BU-table, except when we encounter the first disconnected cell. There we scan two cells out of the same row. (In the example this row is row 4.)

(c) The proof is by induction on the number of the row containing the cell in column 4 that contains the cell.

(d) The proof follows from (c).  $\square$

Because of Theorem 2(d) the pathnames in  $T'$  start with a segment of nonterminals whose type is disconnected, then continue with a segment of nonterminals whose type is connected, and finish with a terminal vertex or edge. Pathnames in  $\Gamma'$ , respectively,  $\Gamma$  can be translated into each other by scanning the pathname backwards and substituting between corresponding cells in column 1, respectively 4, of the BU-table.

We can solve a large variety of problems pertaining to connectivity on  $\Gamma'$ . For example, consider the problem of producing the adjacency structure for the connected component of  $E(\Gamma)$  containing vertex  $v$  given by its pathname in  $\Gamma$ . The solution to this problem may be a large data structure; thus the running time will be large. We call such problems construction problems. But we can produce the output using only as much working storage as needed by the BU-table. We just translate the pathname of  $v$  in  $\Gamma$  into its pathname in  $\Gamma'$  and expand the leftmost cell  $G_j$  in the pathname that is connected. If a hierarchical description of the connected component suffices we only select the cells of  $\Gamma'$  that occur inside the hierarchy tree rooted at  $G_j$ . These cells can be identified in time  $O(n)$  by scanning through the BU-table from bottom to top.

In many applications we need more information than that given by the decision problem but less information than is provided by the construction problem. Especially in interactive CAD tools we want to selectively query critical parts of the design. This corresponds, for instance, to the following query problem: Q1 ( $v, w$ ): *Given two vertices  $v, w$  in  $E(\Gamma)$ , are they connected?* Such a query can also be answered easily on  $\Gamma'$ . We just translate the pathnames of  $v, w$  in  $\Gamma$  into pathnames in  $\Gamma'$  and ask whether in both pathnames the beginning segment up to the first nonterminal whose type is connected is identical. This takes time  $O(m+n)$  for preprocessing and time  $O(k)$  for answering each query, by Theorem 2(a).

**4. Biconnectivity.** In this section we will show how to decide biconnectivity of a hierarchical graph in time  $O(m+n)$ . We will also solve construction and query problems pertaining to biconnectivity. We will not make the assumption that  $E(\Gamma)$  is connected, and answer the question  $P$ : *“Is  $E(\Gamma)$  connected and biconnected?”*

The biconnectivity burner starts on  $\Gamma$  with some graph  $\tilde{G}_i$ , and manipulates the following kind of tree structures (see [Ha69] for the basic definitions of biconnectivity).

**DEFINITION 5.** The *biconnectivity forest* for a graph  $G$  is a bipartite forest  $T^b$ , with two kinds of labeled nodes, a-nodes and b-nodes. Each a-node  $a$  is labeled with an articulation point  $v_b$  of  $G$ . Each b-node  $b$  is labeled with a block  $C_b$  of  $G$ . There is an edge between  $a$  and  $b$  if  $v_a \in C_b$ . The biconnectivity forest  $T$  is said to *represent*  $G$ .

In order to keep the biconnectivity burner simple we will sometimes mark a graph  $G_i^b$  after burning. Marking  $G_i^b$  will mean that  $G_i^b$  is not biconnected and can never

be biconnected in any environment. When a marked graph  $G_i^b$  is substituted into some  $G_i$  to yield  $\tilde{G}_i$ ,  $\tilde{G}_i$  is marked too. When  $\tilde{G}_i$  is marked,  $G_i^b$  is marked automatically. Replaceability will be shown with respect to the question  $P'$ : “Is  $G$  connected and biconnected, or is  $G$  marked?” The biconnectivity burner is defined as follows.

- (1) *Construct biconnectivity forest.* Construct the biconnectivity forest  $T^b$  for the resulting graph  $G$ .
- (2) *Delete leafblocks not containing pins.* Delete a leaf  $b$  in a tree of  $T^b$  representing a connected component of  $G$  such that  $b$  is a b-node, and the only pin of  $C_b$ , if any, is the unique relevant articulation point in  $C_b$  (if any). If now an a-node becomes a leaf, delete the a-node as well. Repeat this step until no more deletions are possible. (Do not delete the last b-node of  $T^b$ .)
- (3) *Collapse long paths.* Let  $a_1, b_1, \dots, a_{n-1}, b_{n-1}, a_k (k > 3)$  be a path of maximal length in  $T^b$  with the following properties:
  - (a) The  $a_i$  are a-nodes, the  $b_i$  are b-nodes;
  - (b) All nodes on the path have degree two;
  - (c) No labels of nodes on the path are pins or contain pins.
 Replace the path  $b_1, a_2, \dots, b_{k-1}$  with a new b-node  $b'$  in  $T^b$ . Connect  $b'$  to  $a_1$  and  $a_k$ . Label  $b'$  with the graph consisting just of  $v_{a_1}$  and  $v_{a_2}$  and the edge between them. (We call this edge a *collapsed edge*.) Repeat this step until no more changes are possible.
- (4) *Reduce blocks.* Consider all b-nodes  $b$  in  $T$  that are still labeled with blocks of  $\tilde{G}_i$ . Replace  $C_b$  with the following graph  $C'_b$ , which is chosen via a case distinction with respect to the size of the set  $S_b$  of pins and relevant articulation points inside  $C_b$  after Step (2).
  - Case 1.*  $|S_b| \geq 3$ .  $C'_b$  is a simple cycle containing all vertices in  $S_b$ .
  - Case 2.*  $|S_b| = 2$ .  $C'_b$  is the graph containing the two vertices in  $S_b$  and an edge between them.
  - Case 3.*  $|S_b| = 1$ . In this case  $S_b$  contains one pin. (All other parts were deleted in Step (2).)
  - Case 3.1.* If  $C_b$  contains at least one edge then  $C'_b$  is the graph consisting of the vertex in  $S_b$ , an additional new vertex, and an edge between them.
  - Case 3.2.* Otherwise  $C_b = C'_b$ , i.e.,  $C_b$  consists of only the pin in  $S_b$ .
  - Case 4.*  $|S_b| = 0$ .  $C'_b$  consists of a single vertex with no edges.
 All edges created in this step are called *cycle edges*.
- (5) *Mark  $G_i^b$ .* If any deletions have been made in Step (2) or if  $\tilde{G}_i$  was marked, mark  $G_i^b$ .

The tree  $T^b$  resulting after completion of the reduction represents  $G_i^b$ . Figure 7 shows an example of an application of the biconnectivity burner. Note that all reduction steps yield valid biconnectivity forests for graphs of decreasing size.

Figure 8 shows the BU-table for biconnectivity for Example 1.

Let us first bound the size of  $G_i^b$ .

LEMMA 2.  $G_i^b$  has size  $O(p_i)$ .

*Proof.* In Step (2) the graph  $\tilde{G}_i$  is reduced such that each leaf of  $T^b$  is a bold node. After Step (3) we meet a bold node at least every fourth node along a path of degree-2 nodes in  $T^b$ . Since each pin labels only one bold node, the size of  $T^b$  is  $O(p_i)$  after Step (3). Thus  $G_i^b$  has size  $O(p_i)$ , as well.  $\square$

Since the biconnectivity forest of  $\tilde{G}_i$  can be generated in linear time, generating the BU-table takes time  $O(m + n)$ . In order to show the correctness of the biconnectivity burner we prove the following theorem.

FIG. 7(a). A graph  $\tilde{G}_i$  with eight pins.

FIG. 7(b). The biconnectivity forest  $T^b$  for  $G$  constructed in Step (1). In Figs. 7(b), (c), (d): \*—a-node that does not represent a pin; \*—a-node that represents a pin;  $\bigcirc$ —b-node representing a block that has no pins that are not articulation points in  $T^b$ ;  $\bullet$ —b-node representing a block that has pins that are not articulation points in  $T^b$ .

FIG. 7(c). The forest  $T^b$  after Step (2).

FIG. 7(d). The forest  $T^b$  after Step (3).

FIG. 7(e). The graph  $G_i^b$ .

FIG. 8. Marks in the lower right corner of an entry show that a graph is marked.

THEOREM 3. (a)  $\tilde{G}_i$  and  $G_i^b$  are replaceable with respect to  $P'$ .

(b)  $E(\Gamma)$  is connected and biconnected if and only if  $G_k^b$  is not marked.

*Proof.* (a) We show that each step of the reduction transforms a graph  $G$  into a new graph  $G'$  that is replaceable with  $G$  with respect to  $P'$ . Step (1) does not change  $G$ . Step (2) deletes parts of  $G$  without pins that are attached at some articulation point and thus can never be biconnected in any environment. The rest of  $G$  is not changed. Marking  $G'$  if any deletions occur ensures replaceability. Steps (3) and (4) yield replaceable graphs since paths through  $G$  can be simulated by paths through  $G'$  and vice versa, even if a given vertex has to be circumvented. Case 3.1 in Step (4) ensures that the single pin  $p$  in  $S_b$  remains an articulation point in  $G'$  for any environment  $H$  that has an edge incident to  $p$ .

(b) By Step (5) of the burning process  $G_i^b$  is marked only if some deletion of material from  $\tilde{G}_i$  occurred that could never be biconnected in any environment. Since  $G_k^b$  always is a single vertex ( $G_k$  has no pins), (b) follows from part (a).  $\square$

As in § 3 we augment the BU-table with a fourth column containing a hierarchical graph  $\Gamma'$  such that  $E(\Gamma') = E(\Gamma)$  but the blocks of  $E(\Gamma)$  are represented explicitly in

$\Gamma'$ . We construct the portion of  $\Gamma'$  belonging to row  $i$  when burning  $\tilde{G}_i$  down to  $G_i^b$ . Parts cut off during Step (2) of the burning process are represented by so-called *branch* cells. Paths collapsed in Step (3) are represented by *path* cells. Blocks shrunk in Step (4) are represented by *block* cells. The details of this process are as follows.

In Step (2) we create a block cell for each deleted b-node. This is done as described for Step (4) below. The pins of a block cell are the relevant articulation points of the block. Finally, for each connected part cut off from the tree we create a branch cell recreating it. This cell has nonterminals whose types are the block cells representing cut off blocks in the component. These nonterminals are connected as the cutoff part of the tree prescribes. Each branch cell has one pin, namely the articulation point at which the part was cut off. There is an additional branch cell representing all connected components of the biconnectivity tree that have no pins. An identical branch cell already existing can be reused, but a block cell must not be reused as a branch cell.

During Step (3) we create a new block cell for each block on the collapsed path as described below (Step (4)). Then a new path cell is created that recreates the collapsed path and the parts of  $\tilde{G}_i$  attached to it that were deleted in Step (2). To this end, nonterminals whose types are the block, path, and branch cells representing the parts of the collapsed path are created and connected appropriately. The resulting path cell represents the collapsed edge in  $G_i^b$ .

During Step (4) we create for each reduced block a block cell. This block cell has the same general structure as the block in  $\tilde{G}_i$  but parts from some copy of  $G_j^b$  are represented by their corresponding block cells. If a block consists of a single edge that is a path edge, no block cell is created for this block, but the corresponding path cell is reused higher up in the hierarchy. The pins of a block cell are all pins and all relevant articulation points of the corresponding block.

The result of this process is shown in Fig. 9 for Example 1. Figure 10 shows the hierarchy tree  $T'$  of  $\Gamma'$ . Composed cells are underlined in Fig. 10.

THEOREM 4. (a)  $E(\Gamma) = E(\Gamma')$ .

(b)  $m', n' = O(m + n)$ . The depth of the hierarchy tree  $T'$  of  $\Gamma'$  is  $O(k)$ .

(c) Each block in  $E(\Gamma)$  is represented by a subtree of  $T'$  with the following properties:

(c.1) The type of the root  $x$  of the subtree is a block cell, and when going from  $x$  towards the root of  $T'$  we meet first (perhaps) a few path cells and then a branch cell.

(c.2) From the subtree rooted at  $x$  in  $T'$  all subtrees are deleted that are rooted at branch cells.

In Fig. 10 the subtrees of  $T'$  that represent blocks of  $E(\Gamma)$  are circled with dotted lines.

*Proof.* (a) The proof is by induction on the cell number in  $\Gamma'$ .

(b) Since  $\tilde{G}_i$  has size  $O(m_i + n_i)$ ,  $m', n' = O(m + n)$ .  $T'$  has depth  $O(k)$  since on each path from a node  $x$  in  $T'$  to the root at most four cells in each row entry of column 4 of the BU-table can occur, namely two block cells, one branch cell, and one path cell.

(c) The proof holds because of the following facts. First, when cutting off parts of  $E(\Gamma)$  in Step (2) we cut off blocks that can never be enlarged in any environment. A branch cell represents the part of  $E(\Gamma)$  being cut off. Second, branch cells and path cells represent compositions of blocks, in which each block is also represented by a separate block cell. Third, because path cells are reused, cells representing chains of blocks collapsed in Step (3) remain path cells, until the chain of blocks is absorbed into a single block by biconnecting it higher up in the hierarchy.  $\square$

Theorem 4 enables us to use  $\Gamma'$  for solving a variety of problems pertaining to biconnectivity.

FIG. 9. Branch cells are underscored; there are no path cells.

Consider the following construction problem: *Given an edge  $e$  in  $E(\Gamma)$ , produce its biconnected component.* We can solve this problem by first translating the pathname of  $e$  into  $\Gamma'$ . Then we look for the root of the block containing  $e$ . To this end we scan the pathname of  $e$  right-to-left until we find a branch cell. Then we go left-to-right in the pathname until we find a cell that is a block cell. The resulting node  $x$  is the root of the block containing  $e$ . To produce the adjacency structure we just expand the subtree  $T_x$ , but whenever we find a nonterminal whose type is a branch cell we do not expand it. This procedure may take a lot of time if much output has to be produced, but it only needs working space  $O(m+n)$ , because of Theorem 4(b). A hierarchical representation of the block containing  $e$  can be obtained by first finding the root of the block as above and then scanning bottom-up through the BU-table selecting the

FIG. 10

rows of the table describing cells in the subtree of  $T'$  rooted at  $x$ . Here we cut off nodes representing branch cells. The whole process takes time  $O(m + n)$ . Other construction problems can be solved similarly.

The query Q2 ( $e_1, e_2$ ): *Given two edges  $e_1 \neq e_2$  in  $E(\Gamma)$  are they on a common simple cycle?* can be answered simply by comparing the pathnames for the roots of the blocks containing  $e_1$  and  $e_2$ . If they are identical the answer to the query is yes.

In order to answer the query Q3 ( $v$ ): *Given a vertex  $v$  in  $E(\Gamma)$ , is  $v$  an articulation point?* we augment  $\Gamma'$  some more. We mark a vertex in  $G_i$ , respectively,  $\tilde{G}_i, G_i^b$  if some deletions occur at this vertex during some execution of Step (2). Vertices retain their marks when some copy of  $G_j^b$  is substituted into some  $\tilde{G}_i$ . Now, obviously a vertex is an articulation point if the vertex denoted by the last symbol in the pathname of  $v$  is marked.

The only other vertices in  $E(\Gamma)$  that can be articulation points are vertices that are relevant articulation points on some path just before collapsing it in some  $G_i$ , such that the path does not get biconnected higher up in the hierarchy tree.

The pathnames of such vertices have the property that as we scan the pathname backwards we find a sequence of path cells followed by a branch cell. Thus query Q3 ( $v$ ) can also be answered in time  $O(k)$ .

Other query problems can be solved in a similar manner. It should be noted that an appropriate modification of the above construction yields a modified hierarchy on which connectivity and biconnectivity problems can be answered efficiently.

**5. Strong connectivity.** In this section we remark on how to hierarchically answer the question: *“Is  $E(\Gamma)$  strongly connected?”* given a hierarchical directed graph  $\Gamma$ .

The burning process is quite straightforward.  $G_i^b$  is just the reduction of the transitive closure of  $\tilde{G}_i$  to the pins of  $G_i$ . If  $\tilde{G}_i$  will never yield a strong connected result in any environment, we add an isolated vertex to  $G_i^b$ . (If  $\tilde{G}_i$  does not have pins we need two such vertices.) There are two problems with this burning process. First, it does not take linear time, but in general it takes time  $O(n^{2.39} \dots)$  (as of today

[CW86]). Second it may produce dense graphs with  $O(p_i^2)$  edges. Thus the substitution of the  $G_j^b$  into  $G_i$  to yield  $\tilde{G}_i$  may take  $\Omega(n_i^3)$  time. The resulting graph (after deleting multiple edges) may have size  $\Omega(n_i^2)$ . Thus filling the BU-table in general takes time  $O(\sum_{i=1}^k n_i^3)$ . If the hierarchy is *efficient* in the sense that there are many small cells, this can still be close to linear. In general, we do not know how to achieve a linear time hierarchical strong connectivity test. Indeed the following argument shows that we will probably not achieve such a test with the bottom-up method.

**THEOREM 5.** *There are at least  $2^{p^{2/4}}$  different equivalence classes of replaceable graph with  $p$  pins with respect to strong connectivity.*

*Proof.* The  $2^{p^{2/4}}$  different burnt graphs that can be produced by the above strong connectivity burner are not replaceable pairwise.  $\square$

Thus any strong connectivity burner has to produce at least  $2^{p^{2/4}}$  different burnt graphs with  $p$  pins. Since each graph is unambiguously described by its adjacency structure, and this structure has size  $O((m+n) \log n)$  for a graph with  $m$  edges and  $n$  vertices in the logarithmic cost measure, we must have  $m+n = \Omega(p^2/\log p)$ . This can only yield strong connectivity tests with time  $O(\sum_{i=1}^k (n_i^3/\log n_i))$ . We could circumvent this argument by labeling graphs appropriately and thus increasing their variety in an efficient way. However, we know of no helpful scheme for doing so.

There is another problem with strong connectivity. We do not know how to construct a hierarchical graph  $\Gamma'$  explicitly representing the strong components of  $\Gamma$ . We can identify the strong components in  $\tilde{G}_i$  during the burning process and provide special cells for them. But  $G_i^b$  does not specify how to use these cells later on. On the other hand, any burnt graph that might provide explicit locations for nonterminals whose types are these cells seems to become very large. Having no  $\Gamma'$  makes it more difficult to solve query problems pertaining to strong connectivity. We can still efficiently solve construction problems such as the following: *For each vertex in  $E(\Gamma)$  give the number of its strong component.* This is done by first generating the BU-table and then performing a preorder traversal on the hierarchy tree. When visiting the root all component numbers for vertices belonging to the root are output. Then the sons of the root are processed recursively. When a node  $x$ , say, of type  $G_i$ , in  $T$  is processed the component numbers for its pins are known. We connect all pins in the same component up into a circuit in  $\tilde{G}_i$ . Then we find the strong components resulting graph. The vertices belonging to  $x$  that are in a component with pins receive the number of that component. The other components are numbered with new numbers. The traversal takes a long time but only uses space  $O(m+n)$ .

The query Q4 ( $v, w$ ): *Given two vertices  $v, w$  in  $T$ , are  $v, w$  strongly connected?* can be answered by doing the above preorder traversal just on the subtree of  $T$  consisting of the paths from the two nodes to which  $v, w$  belong to the root. This takes time  $O(\sum_{i=1}^k n_i^2)$  since a strong connectivity check on a potentially dense graph must be performed on each node in the subtree.

How to improve on these algorithms is an open question.

**6. Conclusions, further results, and open problems.** We introduced a model for the succinct hierarchical representation of graphs that is widely applicable in areas of engineering, e.g., in CAD for integrated circuits. The model is a strongly restricted version of a context-free grammar that generates exactly one word. We efficiently solved connectivity problems on this model. For decision problems we achieved solutions with linear (connectivity, biconnectivity), respectively, cubic (strong connectivity) running time in the size of the hierarchical description. For construction and query problems we achieved large savings of working space and preprocessing time.

We also generated short hierarchical descriptions for the output of construction problems.

The graph problems we discussed are all relevant to integrated circuit design. Connectivity tests are used in electrical checking; biconnectivity tests occur in testability analysis. The results on strong connectivity generalize to the single source shortest path problem which is at the basis of many one-dimensional compaction algorithms [Le82], [U184] and also occurs in wire-routing applications. The hierarchical compaction algorithm has been implemented [Ki84]. Reference [Le82] contains some results showing that it is difficult in general to construct short hierarchical descriptions of the shortest path tree.

Reference [HS84] presents a hierarchical compaction algorithm with low page fault complexity. This algorithm processes the hierarchical description of the graph top-down, and uses  $O(N)$  space. The definition of hierarchy is a little different in [HS84]. There a graph is only partitioned into a collection of cells without the notion of a hierarchy tree. Here we exploit the presence of a hierarchy tree with many identical subtrees to reduce the space requirement of the hierarchical compaction.

Another application of the hierarchical strong connectivity algorithm is the solution of hierarchical linear systems, as occur in finite element modeling of mechanical structures [LW87].

A hierarchical solution to the minimum spanning forest problem in almost-linear time is given in [Le87]. The minimum spanning forest problem is relevant in wire routing for integrated circuit layouts. Reference [Le87] solves construction and query problems without resorting to a short hierarchical description of the minimum spanning tree. But such a description along the lines presented here is also possible in that case. The complexities of the solutions to the construction and query problems are the same as those given in §§ 3 and 4 of this paper. Reference [Le86b] discusses a linear time hierarchical planarity test. Reference [Le86a] gives an overview of the application of hierarchical processing in CAD for VLSI design.

There are also problems that cannot be solved hierarchically using this model. A thorough discussion is given in [LW87]. There it is also shown that the complexity of the hierarchical version of a graph problem cannot in general be deduced from the complexity of its nonhierarchical version. Two examples of hard problems are the circuit value problem and the network flow problem. Both become PSPACE complete in their hierarchical version. This is unfortunate as the circuit value problem is at the basis of most simulation algorithms for integrated circuits.

All hierarchical solutions to graph problems mentioned in this paper have the property that they use a nonhierarchical algorithm for the same graph problem as a subroutine. Thus they do not depend on a specific nonhierarchical solution method; any nonhierarchical algorithm will do. This is important for practicality, since often asymptotically worse algorithms are superior in practice for small graphs, and the subcells can be expected to be small. For this reason the BU-method is not only a tool for proving asymptotic results on hierarchical graphs, but it should serve as a powerful basis for bringing hierarchical graph algorithms on the computer.

We believe that the bottom-up method introduced in this paper is a powerful method for speeding up the processing of hierarchically defined graphs such as arise in many areas of application, notably in VLSI design. The hierarchical graph model is still rather restricted, and extensions should be possible that are useful in several areas of application while preserving the efficient solvability of a large number of important graph problems. The hierarchical graph model discussed in this paper is used in the HILL (Hierarchical Layout Language) system [LM84].

## A FAST PARALLEL ALGORITHM FOR DETERMINING ALL ROOTS OF A POLYNOMIAL WITH REAL ROOTS\*

MICHAEL BEN-OR<sup>†</sup>, EPHRAIM FEIG<sup>‡</sup>, DEXTER KOZEN<sup>§</sup>, AND PRASOON TIWARI<sup>¶</sup>

**Abstract.** Given a polynomial  $p(z)$  of degree  $n$  with  $m$  bit integer coefficients and an integer  $\mu$ , the problem of determining all its roots with error less than  $2^{-\mu}$  is considered. It is shown that this problem is in the class NC if  $p(z)$  has all real roots. Some very interesting properties of a Sturm sequence of a polynomial with distinct real roots are proved and used in the design of a fast parallel algorithm for this problem. Using Newton identities and a novel numerical integration scheme for evaluating a contour integral to high precision, this algorithm determines good approximations to the linear factors of  $p(z)$ .

**Key words.** parallel algorithms, polynomial, roots, Sturm sequences, numerical integration, root separation, zeros

**AMS(MOS) subject classifications.** 12D10, 68Q99

**1. Introduction.** Determining the set of all roots of a polynomial is a classical problem with applications in many branches of engineering. Although many sequential algorithms have been designed for this problem (see, for example, [H74] and [S82]), to date no fast parallel algorithm is known. In this paper we show that this problem is in NC if all roots of the given polynomial are real. Moreover, the problem of determining if all the roots of a given polynomial are real is also in NC. The best previous result for this root-finding problem appears in [P85] and has worst-case running time  $O(n \log n)$  using  $n$  processors. Here  $n$  is the degree of the given polynomial and each processor is capable of performing arithmetic operations on operands having polynomially many bits in one step. Our results achieve considerable improvement in the parallel running time at the expense of polynomially many processors.

We use an exclusive read exclusive write PRAM (parallel random access machine) as the model of parallel computation [FW78]. In addition, we assume that a processor can perform arithmetic operations  $+$ ,  $-$ ,  $\times$ , and  $/$  in time polylog in the length (of the binary representation) of the operands.

The Sturm sequences of a polynomial were defined by C. Sturm in 1829 and have been studied for over 150 years [BP60]. We prove some very interesting properties of a Sturm sequence of a polynomial with distinct real roots and use these properties in the design of our algorithm. In particular, these properties imply that we can quickly compute a point on the real line such that at least a fraction of the roots of the polynomial lie on either side of the point.

We factor the given polynomial into its approximate linear factors, and hence approximately determine all its roots. This approximate factorization is achieved by recursively factoring the given polynomial into two approximate factors of almost

equal degree. These two factors are in turn obtained by numerically evaluating a contour integral and then using the Newton identities.

Finally, in the last section, we also prove that the problem of determining all real roots in the presence of complex roots is in NC if and only if the problem of determining all roots is in NC.

The numerical integration scheme is based on a suggestion by Franco Preparata. This work has been inspired by the work of Schönhage [S82], and complements recent work of the first and the third authors on algebraic cell decomposition of  $\mathbf{R}^d$  [BKR84], [KY85]. The algorithm presented here also appears in [T86].

**2. The basic strategy.** In this section we give an overview of our algorithm for simultaneously determining all roots of a polynomial  $h(z)$ , which has distinct real roots. The major steps of the algorithm are given below.

#### ALGORITHM ROOTS.

**Input.** A polynomial  $h(z)$  of degree  $n$  having  $m$  bit integer coefficients, distinct real roots, and an error tolerance  $\mu$ .

**Output.** Approximations  $\tilde{z}_1, \tilde{z}_2, \dots, \tilde{z}_n$  to the roots  $z_1, z_2, \dots, z_n$  of  $h(z)$  such that  $|z_i - \tilde{z}_i| < 2^{-\mu}$ .

#### Method.

*Step 1.* Divide  $h(z)$  by its leading coefficient. Let  $p(z)$  be the resulting polynomial. The leading coefficient of  $p(z)$  is 1.

*Step 2.* Factor  $p(z)$  recursively in the following manner until all monic linear factors are found.

*Step 2(a).* Find a point  $w$  that separates the roots of  $p(z)$  into two sets  $L$  and  $R$ , those to the left and to the right of  $w$ , respectively, each containing between  $\frac{1}{4}$  and  $\frac{3}{4}$  of all roots of  $p(z)$ . In addition,  $w$  is not too close to any root of  $p(z)$ .

*Step 2(b).* Using a numerically evaluated contour integral and the Newton identities, determine approximations to the two monic factors  $p_1(z)$  and  $p_2(z)$  of  $p(z)$  with roots  $L$  and  $R$ , respectively.

In case the given polynomial has repeated roots, well-known methods (see, for example, [vG83a]) can be used to reduce the problem to that of determining the roots of a polynomial with distinct roots. An alternate method of performing this reduction appears in [T86]. This method has the advantage that it only uses integer addition and multiplication.

In order to show that ROOTS can be implemented in  $\log^{O(1)}(m+n+\mu)$  steps using  $(m+n+\mu)^{O(1)}$  processors, we must show that: (i) ROOTS can be implemented in  $\log^{O(1)}(m+n+\mu)$  steps using  $(m+n+\mu)^{O(1)}$  processors on a PRAM, where each processor is also capable of performing a real arithmetic operation in one step; and (ii) the operands of each (real) arithmetic operation can be expressed using  $(m+n+\mu)^{O(1)}$  bits.

It is not difficult to check that all real numbers computed by our algorithm are bounded in absolute value by  $2^{(m+n+\mu)^{O(1)}}$ . Therefore, in order to prove assertion (ii) of the last paragraph, we show that all these real numbers need not be computed exactly, but that we can approximate them to within  $2^{-(m+n+\mu)^{O(1)}}$  of their correct value and still ensure a correct output.

First, following Schönhage [S82], we show that it is sufficient to compute the coefficients of all polynomials constructed during an execution of ROOTS to within  $2^{-(m+n+\mu)^{O(1)}}$  of their correct value. The following theorem will be useful in proving this fact.

**THEOREM 2.1** [C29], [H70]. *Let  $h(z)$  be a polynomial of degree  $n$  with  $m$  bit integer coefficients. Then all roots of  $h(z)$  are less than  $2^m$  in absolute value.*

Since the roots of  $p(z)$  are the same as the roots of  $h(z)$ , all roots of  $p(z)$  are also bounded in absolute value by  $2^m$ . If  $h(z) = \sum_{i=0}^n h_i z^i$  has distinct roots  $z_1, z_2, \dots, z_n$ , then define the *height* of  $h(z)$ , denoted  $|h|$ , to be the sum  $\sum_{i=0}^n |h_i|$ . Also define the *minimum root separation*  $\Delta(h) = \min_{i \neq j} |z_i - z_j|$ . Unless stated otherwise, logarithms in this paper are to base 2.

**THEOREM 2.2** [M64]. *If  $h(z)$  is a univariate polynomial with integer coefficients, of degree  $n \geq 2$ , and distinct roots, then the minimum root separation  $\Delta(h)$  is at least  $\sqrt{3} n^{-(n+2)/2} |h|^{-(n-1)}$ .*

**COROLLARY 2.3.** *Let  $h(z)$  be a polynomial with  $m$  bit integer coefficients, degree  $n \geq 2$ , and distinct roots  $z_1, z_2, \dots, z_n$ , then  $\Delta = \min_{i \neq j} |z_i - z_j| > 2^{-\sigma}$ , where  $\sigma = 2n \log n + mn$ .*

We also need a bound on perturbation induced on the zeros of a polynomial as a result of perturbation of its coefficients. We will frequently use a perturbation bound which is a corollary to the following well-known theorem of Ostrowski.

**THEOREM 2.4** [H70]. *Let  $f(z) = z^n + a_1 z^{n-1} + \dots + a_n$  and  $g(z) = z^n + b_1 z^{n-1} + \dots + b_n$ . Let  $\gamma = 2 \max(|a_j|^{1/j}, |b_j|^{1/j})$ , and define  $\epsilon > 0$  by  $\epsilon^n = \sum_{j=1}^n |b_j - a_j| \gamma^{n-j}$ . Then the zeros  $z_j$  and  $w_k$  of  $f$  and  $g$ , respectively, can be ordered so that  $|z_j - w_j| < 2n\epsilon$ .*

**COROLLARY 2.5.** *Consider the polynomial  $p(z)$  of degree  $n$  with real coefficients, leading coefficient 1, and roots  $z_1, z_2, \dots, z_n$  such that  $|z_i| < 2^m$ . Let  $\tilde{p}(z)$  be an approximation to  $p(z)$  such that the corresponding coefficients of  $\tilde{p}(z)$  and  $p(z)$  differ by at most  $2^{-\pi}$ . Then there is an ordering of the roots  $\tilde{z}_i$  of  $\tilde{p}(z)$  such that  $|z_i - \tilde{z}_i| < n^2 2^{m+4-\pi/n}$ , for all  $i$ .*

**COROLLARY 2.6.** *If  $\pi > n(m + \mu + 2 \log n + 4)$ , then the roots of  $\tilde{p}_0(z)$  approximate the roots of  $p(z)$  with error less than  $2^{-\mu}$ .*

As a consequence of this corollary, all roots of  $\tilde{p}(z)$  are bounded in absolute value by  $2^{m+1}$  whenever  $\pi$  is chosen appropriately. The following corollary is important for establishing the correctness of our algorithm.

**COROLLARY 2.7.** *If  $p(z)$  has distinct real roots,  $\Delta(p) > 2^{-\sigma}$ ,  $\mu \geq \sigma + 2$ ,  $\pi > n(m + \mu + 2 \log n + 4)$ , and all coefficients of  $\tilde{p}(z)$  are real, then  $\tilde{p}(z)$  has distinct real roots.*

*Proof.* Since all coefficients of  $\tilde{p}(z)$  are real, its roots are either real or appear in complex conjugate pairs. Suppose  $\tilde{z}_i$  and  $\tilde{z}_j$  is a pair of complex conjugate roots of  $\tilde{p}(z)$ . By Corollary 2.6, we have  $|z_i - \tilde{z}_i| < 2^{-\mu}$ ,  $|z_j - \tilde{z}_j| < 2^{-\mu}$ , and therefore the imaginary part of each of  $\tilde{z}_i$  and  $\tilde{z}_j$  is less than  $2^{-\mu}$ . This implies that  $|\tilde{z}_i - \tilde{z}_j| < 2^{-\mu+1}$ . But,  $|z_i - z_j| > 2^{-\sigma}$  implies  $|\tilde{z}_i - \tilde{z}_j| > |z_i - z_j| - |\tilde{z}_i - z_i| - |z_j - \tilde{z}_j| > 2^{-\sigma} - 2^{-\mu+1}$ . For  $\mu \geq \sigma + 2$ , we have  $|\tilde{z}_i - \tilde{z}_j| > 2^{-\mu+1}$ —a contradiction. Hence, all roots  $\tilde{p}(z)$  are real. The fact that they are distinct can also be proved using a similar argument.  $\square$

In the following discussion we will assume that  $\mu \geq \sigma + 2$ . Also in view of Corollary 2.6, let  $\pi = n(m + \mu + 2 \log n + 4) + 1$ . We wish to determine approximate linear factors  $L_1, L_2, \dots, L_n$  of  $p(z)$  such that

$$(2.1) \quad |p(z) - L_1 L_2 \dots L_n| < 2^{-\pi}.$$

Then Corollary 2.6 would imply that the easily available zeros of  $L_i$  are sufficiently good approximation to the zeros of  $p(z)$ . However, in order to achieve  $2^{-\pi}$  precision in (2.1), we may need precision of more than  $\pi$  bits beyond the binary point in all intermediate computations.

Next we determine the precision required during the factorization in Step 2 in order to satisfy the above requirements. Suppose that the precision of  $\lambda$  bits beyond

the binary point is sufficient for all intermediate computations in order to finally compute the approximate linear factors which satisfy (2.1). We approximate the coefficients of  $p(z)$  to within  $2^{-\lambda}$  in order to obtain an approximation  $p_0(z)$  to  $p(z)$ . Then we factor  $p_0(z)$  recursively to obtain all linear factors  $L_i$ , always computing the factors to  $\lambda$  bit precision beyond the binary point. Choice of the precision  $\lambda$  ensures that at any stage of the recursive factorization of  $p(z)$ , we have a set of polynomials  $p_1(z), p_2(z), \dots, p_l(z)$  whose product is a good approximation to  $p(z)$ .

**LEMMA 2.8.** *Given a monic polynomial  $p(z)$  of degree  $n$ , all of whose roots are bounded in absolute value by  $2^m$ , suppose  $p_1(z), p_2(z), \dots, p_l(z)$  are monic polynomials such that  $g(z) = p(z) - p_1(z)p_2(z) \cdots p_l(z)$  is of degree at most  $n - 1$  and  $|g(z)| < 2^{-\pi}$ . Then each coefficient of  $p_i(z)$ ,  $1 \leq i \leq l$ , is less than  $2^{2n+mn}$  in absolute value and therefore  $|p_i| < (n + 1)2^{2n+nm}$ .*

*Proof.* Let  $\tilde{p}(z) = p_1(z)p_2(z) \cdots p_l(z)$ . By the comment after Corollary 2.6 and the choice of  $\pi$ , each root of  $\tilde{p}(z)$ , and hence each root of  $p_i(z)$  for  $1 \leq i \leq l$ , is less than  $2^{m+1}$ . Therefore, each coefficient of  $p_i(z)$  is less than  $2^n(2^{m+1})^n$ .  $\square$

Suppose  $p_i(z)$  is monic,  $\deg(p_i) > 1$ , and let  $p_j(z)$  and  $p_k(z)$  be the two monic factors of  $p_i(z)$  computed during its factorization. Recall that the coefficients of these factors are truncated beyond the  $\lambda$ th bit after the binary point. Then, we have the following.

**LEMMA 2.9.**  $|p_i(z) - p_j(z)p_k(z)| < (n + 1)^2 2^{1+2n+nm-\lambda}$ .

*Proof.* Observe that  $p_i(z) = (p_j(z) + \gamma(z))(p_k(z) + \xi(z))$  where each coefficient of  $\gamma(z)$  and  $\xi(z)$  is less than  $2^{-\lambda}$ . Then,  $|\gamma(z)|, |\xi(z)| < n2^{-\lambda}$ , and hence  $|p_i - p_jp_k| = |p_i\xi + p_k\gamma + \gamma\xi|$ , and the assertion in the statement of the lemma follows from Lemma 2.8.  $\square$

A corollary to the following theorem specifies the precision  $\lambda$  sufficient for the recursive factorization routine.

**THEOREM 2.10.** *Let  $p_1(z), p_2(z), \dots, p_l(z)$  be the known factors of  $p(z)$  at an intermediate stage such that  $|p - p_1p_2 \cdots p_l| < \theta$ ,  $\theta \leq 2^{-\pi}$ , and  $\deg(p_1) > 1$ . Suppose  $p_1(z)$  is approximately factored into  $p_j(z)$  and  $p_k(z)$  whose coefficients are determined only to  $\lambda$  bits beyond the binary point. Then,  $|p - p_jp_kp_2p_3 \cdots p_l| < \theta + (n + 1)^3 2^{1+4n+2mn-\lambda}$ .*

*Proof.*  $|p - p_jp_kp_2p_3 \cdots p_l| = |p - p_1p_2 \cdots p_l + p_1p_2 \cdots p_l - p_jp_kp_2p_3 \cdots p_l| < \theta + |p_2p_3 \cdots p_l| |p_1 - p_jp_k|$ . Application of Lemmas 2.8 and 2.9 proves the theorem.  $\square$

**COROLLARY 2.11.** *Let  $L_1(z), L_2(z), \dots, L_n(z)$  be the approximate factors of  $p(z)$  obtained by the recursive factorization using precision of  $\lambda \geq \pi + \log n$  bits beyond the binary point. Then,  $|p(z) - L_1L_2 \cdots L_n| < n2^{-\lambda} + (n + 1)^4 2^{1+4n+2mn-\lambda}$ .*

*Proof.* For the purpose of establishing this lemma, we can assume that our algorithm works as follows. To begin, we have a set of polynomials  $F = \{p_0(z)\}$  such that  $|p(z) - p_0(z)| < n2^{-\lambda}$ . Our algorithm can be viewed as selecting a polynomial of degree at least two, and replacing it with its approximate factors. By Theorem 2.10, each such operation increases the error between  $p(z)$  and the product of polynomials by at most  $(n + 1)^3 2^{1+4n+2mn-\lambda}$ .  $\square$

Equation (2.1) and Corollary 2.11 imply that  $\lambda = \pi + 2 + 4 \log(n + 1) + 4n + 2mn$  is sufficient precision in order to obtain the desired approximations to the roots of  $p(z)$ . Substituting for  $\pi$ , we get  $\lambda = O(n(\log n + m + \mu))$ .

**3. Computing the factors using the Newton identity.** Consider a polynomial  $p(z)$  of degree  $n$  having distinct real roots, leading coefficient 1, and all other coefficients having at most  $\lambda$  bits beyond the binary point. Let  $z_1 < z_2 < \dots < z_n$  be the distinct real zeros of  $p(z)$ ,  $|z_i| < 2^{m+1}$ ; and let  $p_1(z) = \sum_{i=0}^k c_i z^i$  be the factor of  $p(z)$  with roots

$z_1, z_2, \dots, z_k$ . In this section, we present a fast parallel algorithm for determining good approximations to coefficients  $c_i$ 's using good approximations to  $s_j = \sum_{i=1}^k z_i^j$ , for  $j=1, \dots, k$ . More precisely, we show that  $c_i$ 's can be computed correct to  $\lambda$  bits beyond the binary point, if approximations  $\tilde{s}_j$  to  $s_j$  are given such that  $|\tilde{s}_j - s_j| < 2^{-\tau}$ , where  $\tau$  is polynomially bounded. In the next section, we will present a fast parallel algorithm for computing  $\tilde{s}_j$  to the required precision.

We will use the well-known relation between the  $s_i$ 's and the  $c_i$ 's given by the Newton identity:

$$(3.1) \quad \begin{bmatrix} 1 & & & & & \\ s_1 & 2 & & & & \\ s_2 & s_1 & 3 & & & \\ s_3 & s_2 & s_1 & 4 & & \\ \vdots & \vdots & \vdots & \vdots & \ddots & \\ s_{k-1} & s_{k-2} & s_{k-3} & s_{k-4} & \dots & k \end{bmatrix} \begin{bmatrix} c_{k-1} \\ c_{k-2} \\ c_{k-3} \\ \vdots \\ c_0 \end{bmatrix} = - \begin{bmatrix} s_1 \\ s_2 \\ s_3 \\ \vdots \\ s_k \end{bmatrix}.$$

Let  $\mathbf{M}$  denote this  $k \times k$  lower triangular matrix and let us denote this equation by  $\mathbf{M}\mathbf{c} = -\mathbf{s}$ . We compute  $\mathbf{M}^{-1}$  using Csanky's adaptation of Leverrier's method [C76]:

$$(3.2) \quad \mathbf{M}^{-1} = - \frac{\mathbf{M}^{k-1} + d_1\mathbf{M}^{k-2} + \dots + d_{k-1}\mathbf{I}}{d_k},$$

where  $d_i$  is the coefficient of  $x^{k-i}$  in  $\prod_{i=0}^k (x - i)$ . Since we use approximations  $\tilde{s}_i$  to  $s_i$  in these computations, the result may not be the exact value of  $c_j$  but an approximation  $\tilde{c}_j$ . In the rest of this section, our aim is to determine a reasonable upper bound on the deviation  $|c_j - \tilde{c}_j|$ . The following sequence of claims leads to the error estimate of Theorem 3.3 in the entries of the computed inverse in terms of the approximation error in the entries of the original matrix.

**LEMMA 3.1.** *Let  $A = (a_{ij})$  be a  $k \times k$  matrix, and suppose that  $\tilde{A}$  is given such that  $\tilde{A} = A + E$ , where  $E = (e_{ij})$  and  $|e_{ij}| \leq \varepsilon$ . Let  $A^m = (a_{ij}^{(m)})$ , and  $\alpha = \max\{1, \max_{ij}\{a_{ij}\}\}$ . Suppose  $\tilde{A}^m = (\tilde{a}_{ij}^{(m)})$  is the  $m$ th power of  $\tilde{A}$  obtained when all intermediate computations are carried out with error less than  $2^{-\kappa}$ . If  $2^{-\kappa+1} + 4k^2\varepsilon^2 < \varepsilon\alpha$  then  $\tilde{A}^m$ , for  $1 \leq m \leq k$ , can be computed such that  $|a_{ij}^{(m)} - \tilde{a}_{ij}^{(m)}| \leq (2^{q+1} - 1)(\alpha k)^{2^q - 1} \varepsilon$  where  $q = \lceil \log m \rceil$ .*

*Proof.* Let us arrange the computation of  $A^m$  as a binary tree  $T$  of height  $\lceil \log m \rceil$ . Each vertex of  $T$  is associated with a result matrix. The result associated with each leaf of  $T$  is  $A$ . The result associated with any other vertex is the product, computed using real arithmetic, of matrices associated with all its children. Observe that any vertex of height  $i$  is labeled with  $A^l$ , where  $l \leq 2^i$ . In this manner, the root of  $T$  is labeled with  $A^m$ .

We will bound the change in each of the entries of the result matrices if we replace  $A$  by  $\tilde{A}$  at the leaves, and use arithmetic operations with error at most  $2^{-\kappa}$  instead of real arithmetic. Observe that in order to derive a worst-case estimate, we can assume that all errors are additive, all entries of  $A$  are nonnegative, and that  $\tilde{A} = A + \varepsilon J$ , where  $J$  is a  $k \times k$  matrix of all 1's. Since our error estimate is a monotonically increasing function of  $m$ , we can bound the error in the entries of all result matrices at height  $q$  by the error bound for the corresponding entries of  $A^{2^q}$  and  $\tilde{A}^{2^q}$ . We will also use the fact that  $|a_{ij}^{(l)}| \leq \alpha^l k^{l-1}$ .

It is not difficult to check that  $|a_{ij}^{(2)} - \tilde{a}_{ij}^{(2)}| < k[2\varepsilon\alpha + \varepsilon^2 + 2^{-\kappa}] + k2^{-\kappa}$ . But  $2^{-\kappa+1} < \varepsilon[\alpha - 4k^2\varepsilon]$  implies that  $k[2\varepsilon\alpha + \varepsilon^2 + 2^{-\kappa+1}] < k[3\varepsilon\alpha]$ . Inductively, if  $|a_{ij}^{(2^{q-1})} - \tilde{a}_{ij}^{(2^{q-1})}| < k^{2^{q-1}-1}[(2^q - 1)\varepsilon\alpha^{2^{q-1}-1}]$ , then  $|a_{ij}^{(2^q)} - \tilde{a}_{ij}^{(2^q)}| < k^{2^q-1}[2(2^q - 1)\varepsilon\alpha^{2^q-1} + (2^q - 1)^2\varepsilon^2\alpha^{2^q-2} + 2^{-\kappa}] + k2^{-\kappa}$ . But  $2^{-\kappa+1} + 4k^2\varepsilon^2 < \varepsilon\alpha$  implies that  $[(2^q - 1)^2\varepsilon^2\alpha^{2^q-2} + 2^{-\kappa+1}] < \varepsilon\alpha^{2^q-1}$ , and the lemma follows.  $\square$

Returning to the problem of solving (3.1), we can state the following.

**COROLLARY 3.2.** *Given approximations  $\tilde{s}_i$  to  $s_i$  such that  $|s_i - \tilde{s}_i| < 2^{-\tau}$ ,  $\tau \geq 1$ , an approximation  $\tilde{\mathbf{R}} = (\tilde{r}_{ij})$  to  $\mathbf{R} = (r_{ij}) = \mathbf{M}^{-1}$  can be computed such that  $|r_{ij} - \tilde{r}_{ij}| \leq (2k)^{k+2} \{4k(\alpha k)^{2k} 2^{-\tau}\}$ , where  $\alpha = k2^{k+mk}$ .*

*Proof.* In (3.2),  $1 \leq |d_i| \leq (2k)^k$  and can be computed exactly. Let  $\mathbf{B} = (b_{ij})$  be the numerator of the right side of (3.2). Since  $|s_i| < k2^{k+mk} = \alpha$ ,  $|b_{ij}| \leq k(2k)^k (\alpha k)^k$ . Compute the approximations to the powers of  $\mathbf{M}$  using the algorithm suggested in Lemma 3.1, with  $\alpha = k2^{k+mk}$  and  $\kappa = \tau$ . These are then used in computing an approximation  $\tilde{\mathbf{B}} = (\tilde{b}_{ij})$  to  $\mathbf{B}$ . Then  $|b_{ij} - \tilde{b}_{ij}| \leq (2k)^{k+1} \{4k(\alpha k)^{2k} 2^{-\tau}\}$ , provided the scalar multiplication and addition in (3.2) are carried out to reasonable precision. Next, compute  $1/d_k$  to  $\tau$  bits beyond the binary point and then compute the product  $\tilde{\mathbf{R}} = (1/d_k)\tilde{\mathbf{B}}$ . Then  $|r_{ij} - \tilde{r}_{ij}| \leq (2k)^{k+2} \{4k(\alpha k)^{2k} 2^{-\tau}\}$ .  $\square$

**THEOREM 3.3.** *Given approximations  $\tilde{s}_i$  to  $s_i$  such that  $|s_i - \tilde{s}_i| < 2^{-\tau}$ , approximations  $\tilde{c}_i$ 's to the coefficients  $c_i$  can be correctly computed to  $\tau - 17mk^2$  bits.*

*Proof.* Approximate the vector  $\mathbf{c}$  by the product  $\tilde{\mathbf{R}}\tilde{\mathbf{s}}$ , using the matrix  $\tilde{\mathbf{R}}$  computed in Corollary 3.2.  $\square$

**COROLLARY 3.4.** *In order to compute the coefficients  $c_i$  correct to the  $\lambda$  bits beyond the binary point, it is sufficient to compute  $s_i$  correct to  $\tau = \lambda + 17mk^2$  bits.*

Substituting for  $\lambda$  from § 2, we get  $\tau = O(mn^2 + n\mu)$ . In the next section we describe a way to compute the  $s_i$ 's to sufficient accuracy by numerically evaluating a contour integral.

**4. Evaluating a contour integral to high precision.** Let  $p(z) = \sum_{i=0}^n p_i z^i$ ,  $p_n = 1$  be a polynomial of degree  $n$  with simple real roots  $z_1 < z_2 < z_3 < \dots < z_n$  such that  $|z_i| < 2^m + 1$ . Then  $|p_i| < 2^{2n+mn}$ . Suppose that at most  $\lambda$  bits are given for any  $p_i$  after the binary point. In addition, a point  $W$  with coordinates  $(w, 0)$  is given such that  $|w - z_j| > 2^{-\beta} = d$  for all  $1 \leq j \leq n$  and  $z_k < w < z_{k+1}$ . In order to compute  $s_l$  with error less than  $2^{-\tau}$  (see § 3), we wish to evaluate the following integral to  $\tau$  significant bits beyond the binary point:

$$\sum_{i=1}^k z_i^l = s_l = \frac{1}{2\pi i} \int_{\Gamma} \frac{z^l p'(z) dz}{p(z)}$$

Here  $\Gamma$  can be chosen as the boundary of the rectangle with vertices  $A, B, C$ , and  $D$ , traversed in the counterclockwise direction, where  $A, B, C$ , and  $D$  are points in the complex plane with coordinates  $(w, -2^{m+1}), (w, 2^{m+1}), (-2^{m+1}, 2^{m+1})$ , and  $(-2^{m+1}, -2^{m+1})$ , respectively (see Fig. 1).

For convenience, the contour  $\Gamma$  is partitioned into four segments  $AB, BC, CD$ , and  $DA$ . This gives the following expression for the contour integral:

$$(4.1) \quad \int_{\Gamma} = \int_A^B + \int_B^C + \int_C^D + \int_D^A$$

We will only discuss a scheme for computing the first term on the right-hand side of (4.1). A similar scheme can be used to compute the third integral on the right-hand side of (4.1). The second and the fourth integrals are much simpler to compute. These are discussed towards the end of this section.

The integral  $\int_A^B$  can be further partitioned into two symmetric parts about the point  $W$  with coordinates  $(w, 0)$  in the complex plane, i.e.,  $\int_A^B = \int_A^W + \int_W^B$ . Let  $I_{WB}$  denote the integral  $\int_W^B (z^l p'(z) dz / p(z))$  and let  $\tilde{I}_{WB}$  denote the computed approximation to  $I_{WB}$ . We require that the error  $|I_{WB} - \tilde{I}_{WB}|$  be bounded by  $2^{-(\tau+3)}$  so that the total error in the right-hand side of (4.1) does not exceed  $2^{-\tau}$ . In [S82], Schönhage uses a numerical

FIG. 1. The contour of integration.

integration scheme which is based on properties of the sums of the roots of unity and requires that all poles of the integrand be relatively far from the contour of integration (which is a circle). However, we cannot use Schönhage’s scheme because some poles of the integrand under consideration may be too close to the contour of integration  $\Gamma$ . The following scheme for evaluating  $I_{WB}$  is based on a suggestion by Franco Preparata to “increase the spacing of samples on  $C$  geometrically as one goes away from the real axis.”

Define two sequences  $y_j$  and  $a_j$  for  $j = -1, 0, 1, \dots, q$ , where  $q = \lceil \log_{3/2} 2^{m+1} - \log_{3/2} (d/2) \rceil$ , as follows:  $y_{-1} = 0, y_0 = (d/2), y_1 = (3/2)(d/2), \dots, y_j = (3/2)^j (d/2), \dots, y_{q-1} = (3/2)^{q-1} (d/2)$ ; and  $a_j = w + iy_j$  for all  $-1 \leq j \leq q-1$  (here  $i = \sqrt{-1}$ ). In addition, let  $y_q = 2^{m+1}$  and  $a_q = w + iy_q$ . Observe that, in the complex plane, the points  $a_j$  are all on the segment from  $W$  to  $B$ .

Let  $f(z) = z^l p'(z)/p(z)$ . The Taylor series of  $f(z)$  about  $a_j$  is given by

$$f(z) = f(a_j) + f'(a_j)(z - a_j) + \dots + \frac{f^{(t)}(a_j)}{t!} (z - a_j)^t + R_t(z),$$

where

$$|R_t(z)| \leq \frac{M y_j}{y_j - r} \left( \frac{r}{y_j} \right)^{t+1}, \quad r = |z - a_j| < y_j$$

[C48], and  $M$  is the maximum value of  $f(z)$  in the closed disc of radius  $y_j$  centered

at  $a_j$ . Observe that the radius of convergence of the above series is greater than  $y_j = (3/2)^j(d/2)$ , for  $j \geq 0$  and is  $> d$  for  $j = -1$ . Let  $T_j(z)$  be the series consisting of the first  $t + 1$  terms of the Taylor series of  $f(z)$  about  $a_j$ . We would approximate the integral  $I_{WB}$  as follows:

$$I_{WB} = \int_{a_{-1}}^{a_q} f(z) dz = \sum_{j=-1}^{q-1} \int_{a_j}^{a_{j+1}} f(z) dz \cong \sum_{j=-1}^{q-1} \int_{a_j}^{a_{j+1}} T_j(z) dz = \tilde{I}_{WB}.$$

Then,

$$(4.2) \quad \tilde{I}_{WB} = \sum_{j=-1}^{q-1} \sum_{u=0}^t \frac{\alpha_{uj}}{u+1} (a_{j+1}^{u+1} - a_j^{u+1}),$$

where  $\alpha_{uj}$  is the coefficient of  $z^u$  in  $T_j(z)$ . In order to estimate the error  $|I_{WB} - \tilde{I}_{WB}|$ , we need to find an upper estimate on  $M$  in the vicinity of the segment  $WB$ :

$$\begin{aligned} M &= \max_j \max_{z: |z-a_j| \leq y_j} \left| \frac{z'p'(z)}{p(z)} \right| \leq n \max_{z, z_i} \left| \frac{z'}{z-z_i} \right| \\ &\leq \frac{n2^{2(m+1)l}}{d} < 2^{2ml+2l+\beta+\log n}. \end{aligned}$$

Consequently, for  $z$  belonging on the segment from  $a_j$  to  $a_{j+1}$

$$|R_t(z)| \leq \frac{My_j}{y_j - r} \left(\frac{r}{y_j}\right)^{t+1} < 2^{2ml+2l+\beta+\log n-t}.$$

Suppose the powers of  $a_j$  are computed exactly (note that this requires only polynomial precision) while evaluating the right-hand side of (4.2), and approximations  $\tilde{\alpha}_{uj}$  to  $\alpha_{uj}$ , such that  $|\alpha_{uj} - \tilde{\alpha}_{uj}| < 2^{-\nu}$ , are used in computing  $\tilde{I}_{WB}$ . Then,

$$|I_{WB} - \tilde{I}_{WB}| \leq \int_W^B R_t(z) dz + 2^{-\nu} \sum_{i=1}^{t+1} 2^{i(m+1)} < 2^{2ml+2l+\beta+\log n+m+1-t} + 2^{(m+1)(t+2)-\nu}.$$

In order to ensure  $|I_{WB} - \tilde{I}_{WB}| \leq 2^{-(\tau+3)}$ , it is sufficient to require that  $2^{2ml+2l+\beta+\log n+m+1-t} < 2^{-(\tau+4)}$  and  $2^{(m+1)(t+2)-\nu} < 2^{-(\tau+4)}$ . Hence  $t = \tau + O(mn + \beta)$  and  $\nu = O(m(\tau + mn + \beta))$ . Substituting for  $\tau$ , we get  $t = O(mn^2 \log n + n\mu + \beta)$  and  $\nu = O(m^2 n^2 \log n + mn\mu + m\beta)$ .

The integral  $\int_A^W$  can also be evaluated in a similar manner. This completes the evaluation of the integral  $\int_A^B$ . The integral  $\int_C^D$  in (4.1) can also be evaluated in a similar manner. The remaining two integrals  $\int_B^C$  and  $\int_D^A$  of (4.1) can also be computed using the above method. However, in case of these integrals, we can get away with using only five sample points. For example, in order to compute  $\int_B^C$ , we need to consider only the five sampling points  $(w, 2^{m+1})$ ,  $(2^m, 2^{m+1})$ ,  $(0, 2^{m+1})$ ,  $(-2^m, 2^{m+1})$ , and  $(-2^{m+1}, 2^{m+1})$ , if  $w > 2^m$ .

The Taylor coefficients required by this integration scheme can be determined quickly using an algorithm due to von zur Gathen [vG83b]. An alternate method of computing these coefficients based on Kung's [K74] power series inversion method, with complete error analysis, appears in [T86].

**5. Separating the roots.** The integration scheme described in the last section requires a point  $w$  such that  $|w - z_i| > 2^{-\beta}$ , where  $z_i, i = 1, 2, \dots, n$  are the distinct real roots of  $p(z)$ , and  $z_l < w < z_{l+1}$ . Moreover, for algorithm ROOTS to have only  $O(\log n)$  depth of recursion, we require that  $n/4 \leq l \leq 3n/4$ . In the following paragraphs, we describe a fast algorithm to determine one such point  $w$ .

Given the polynomial  $p(z)$ , let us define the sequence of polynomials  $f_0(z), f_1(z), \dots, f_n(z)$  such that  $f_0(z) = p(z), f_1(z) = p'(z)$ , and  $f_{i+2}(z)$  is defined as the negative of the remainder obtained on dividing  $f_i(z)$  by  $f_{i+1}(z)$ :

$$f_i = q_i(z)f_{i+1}(z) - f_{i+2}(z).$$

It is well known (see, for example, [H71]) that  $f_i$ 's form a Sturm sequence for the polynomial  $p(z)$  over the interval  $(-\infty, \infty)$ . Fast parallel algorithms for computing  $f_i$  are implicit in [C66] and [C67]. We will show that if  $p(z)$  has distinct real roots, then  $f_i(z)$ 's have degree  $n - i$ , and therefore  $q_i(z)$ 's are linear in  $z$ . Let  $r_i$  be the real root of  $q_i$ . In this section we prove that  $w_i$  can be chosen close to one of the  $r_i$ 's. A fast parallel algorithm for determining  $r_i$ 's appears in [vG83a].

Let  $z_{ij}, j = 1, 2, \dots$ , be the roots of  $f_i$  such that  $z_{ij} \leq z_{i,j+1}$ . Let  $R_i$  be the set of roots of the polynomial  $f_i$  and let  $S_i, i > 1$ , be the (multi) set  $R_i \cup \{r_{i-2}\}$ . If  $A$  and  $B$  are two subsets of the set of real numbers, then we say that  $A$  (strictly) interleaves  $B$  if the (open) closed interval defined by any two points of  $B$  contains a point  $A$ . The following properties of the sets  $R_i$  and  $S_i$  play an important role in locating  $w$ .

**LEMMA 5.1.** *If  $f_0$  has distinct real roots, then  $R_{i+1}$  strictly interleaves  $R_i$ , for  $i = 0, 1, \dots, n - 2$ .*

*Proof.* We prove the assertion in the lemma by induction on  $i$ .

*Induction Hypothesis.*  $R_{i+1}$  strictly interleaves  $R_i$ , and  $R_i$  has  $n - i$  distinct elements.

*Basis.* For  $i = 0$ , the hypothesis reduces to Rolle's theorem [M66]. In case the polynomial has distinct real roots, Rolle's theorem implies that roots of the derivative strictly interleave the roots of the polynomial.

*Induction Step.* Suppose the hypothesis holds for  $0 \leq i \leq k - 1$ . Then  $z_{k-1,j}$  and  $z_{k,j}$  are all real and distinct. Let  $z_{k-1,1} < z_{k,1} < z_{k-1,2} < z_{k,2} < \dots < z_{k-1,n-k} < z_{k,n-k} < z_{k-1,n-k+1}$ . From the defining equation:

$$f_{k-1} = q_{k-1}f_k - f_{k+1}$$

we conclude that  $f_{k+1}(z_{kj}) = -f_{k-1}(z_{kj})$ , for  $1 \leq j \leq n - k$ . But since  $R_k$  strictly interleave  $R_{k-1}$ ,  $\text{sign}\{f_{k-1}(z_{kj})\} = -\text{sign}\{f_{k-1}(z_{k,j+1})\}$ . Therefore,  $\text{sign}\{f_{k+1}(z_{kj})\} = -\text{sign}\{f_{k+1}(z_{k,j+1})\}$  and  $f_{k+1}$  must have a zero between  $z_{kj}$  and  $z_{k,j+1}$ . This argument, along with the degree constraint on  $f_{k+1}(z)$ , proves the assertion for  $i = k$ .  $\square$

This lemma implies that  $\text{deg}(f_i(z)) = n - i$ . Therefore, it also implies that each  $q_i(z)$  is linear in  $z$ .

**LEMMA 5.2.** *If  $f_0$  has distinct real roots and  $z, z'$  are two adjacent roots of  $f_{i-1}, 1 \leq i < n$ , then either  $r_{i-1} \in [z, z']$  or there is a root of  $f_{i+1}$  in the open interval  $(z, z')$ .*

*Proof.* Consider the equation

$$(5.1) \quad \frac{f_{i+1}}{f_{i-1}} = q_{i-1} \frac{f_i}{f_{i-1}} - 1.$$

By Lemma 5.1,  $f_i$  has exactly one root in the interval  $[z, z']$  which is also in the interval  $(z, z')$ . The shape of the plot of the rational function  $f_i/f_{i-1}$  is one of those shown in

Fig. 2. If  $r_{i-1} \notin [z, z']$ , then  $q_{i-1}$  does not change sign on the interval  $[z, z']$ . By (5.1), we conclude that the plot of  $f_{i+1}/f_{i-1}$  also has one of the shapes shown in Fig. 2. Hence  $f_{i+1}(z)$  must have a zero in the interval  $(z, z')$ .  $\square$

**COROLLARY 5.3.** *If  $f_0$  has distinct real roots, then  $S_{i+1}$  interleaves  $R_{i-1}$ , for  $i = 1, 2, \dots, n - 1$ .*

*Proof.* As in the proof of Lemma 5.1, let  $z_{k-11} < z_{k1} < z_{k-12} < z_{k2} < \dots < z_{k-1n-k} < z_{kn-k} < z_{k-1n-k+1}$ . Recall that  $r_{k-1}$  is the only zero of  $q_{k-1}$ . If  $r_{k-1}$  is not in the interval  $[z_{k-11}, z_{k-1n-k+1}]$ , then by Lemma 5.2,  $f_{k+1}(z)$  must have at least  $n - k$  zeros, one in each of the  $n - k$  intervals  $(z_{k-1j}, z_{k-1j+1})$ ,  $1 \leq j \leq n - k$ . But this contradicts the fact that  $\deg(f_{k+1}) = n - k - 1$ . Therefore  $r_{k-1}$  must lie in the interval  $[z_{k-11}, z_{k-1n-k+1}]$ .

If  $r_{k-1}$  equals either  $z_{k-11}$  or  $z_{k-1n-k+1}$  then  $r_{k-1}$  is also a root of  $f_{k+1}$ . This contradicts the fact that  $R_{k+1}$  strictly interleaves  $R_k$ . Therefore,  $r_{k-1}$  lies in the open interval  $(z_{k-11}, z_{k-1n-k+1})$ .

Next, suppose that  $r_{k-1}$  coincides with one of the other roots of  $f_{k-1}$ , say  $r_{k-1} = z_{k-1\alpha}$ ,  $1 < \alpha < n - k + 1$ . Then  $z_{k-1,\alpha}$  is also a root of  $f_{k+1}(z)$ . By Lemma 5.2, each of the intervals  $(z_{k-1j}, z_{k-1j+1})$ ,  $1 \leq j < \alpha - 1$  and  $\alpha < j < n - k + 1$ , contains one root of  $f_{k+1}(z)$ . This accounts for all the  $n - k - 1$  roots of  $f_{k+1}(z)$ . Therefore  $z_{k-11} < z_{k+11} < z_{k-12} < z_{k+12} < \dots < z_{k-1\alpha-1} < z_{k+1\alpha-1} = z_{k-1\alpha} = r_{k-1} < z_{k-1\alpha+1} < z_{k+1\alpha} < \dots < z_{k-1n-k} < z_{k+1n-k-1} < z_{k-1n-k+1}$ . Hence the assertion in the corollary holds in this case.

In case  $r_{k-1}$  does not coincide with any root of  $f_{k-1}(z)$ , the corollary immediately follows from Lemma 5.2. Hence  $S_{k+1}$  interleaves  $R_{k-1}$ .  $\square$

The main result of this section follows as a corollary to the following theorem.

**THEOREM 5.4.** *There exists a  $k$ ,  $0 \leq k \leq n - 2$ , such that  $r_k$  splits the real line into two semi-infinite intervals,  $I_1 = (-\infty, r_k)$  and  $I_2 = [r_k, \infty)$ , with the property that  $|R_0 \cap I_i|$  is in the range  $[n/4, 3n/4]$ , for  $i = 1, 2$ .*

In order to prove this theorem, we need the following lemma:

**LEMMA 5.5.** *Any subinterval  $I$  of the real line which contains  $l > \lfloor (n + 1)/2 \rfloor$  roots of  $f_0$  contains at least one  $r_k$  for some  $k$ :  $0 \leq k \leq n - 2$ .*

*Proof.* The proof of the lemma is by contradiction. Suppose an interval  $I$  contains  $l > \lfloor (n + 1)/2 \rfloor$  roots of  $f_0$  and none of the  $r_k$ 's. In order to prove the lemma, we first prove by induction that  $I$  contains at least  $l - \lfloor (m + 1)/2 \rfloor$  roots of  $f_m$ .

*Basis.* Trivially true for  $f_0$  and  $f_1$ .

*Induction Step.* Suppose  $I$  contains  $l - \lfloor (m - 1)/2 \rfloor$  roots of  $f_{m-2}$ . Since  $r_{m-2}$  is not in  $I$ , by Corollary 5.3, the roots of  $f_m$  in  $I$  interleave the roots of  $f_{m-2}$  in  $I$ . Hence  $f_m$  has at least  $l - \lfloor (m - 1)/2 \rfloor - 1 = l - \lfloor (m + 1)/2 \rfloor$  roots in the interval  $I$ .

But  $f_n$  is of degree 0 and therefore has no root in  $I$ —a contradiction.  $\square$

FIG. 2. Possible shapes of the plots of  $f_i/f_{i-1}$  and  $f_{i+1}/f_{i-1}$ .

*Proof of Theorem 5.4.* Consider the interval  $I$  containing the middle  $\lfloor (n+3)/2 \rfloor$  roots of  $f_0$ . By Lemma 5.5,  $I$  contains some  $r_k$ .  $\square$

The above theorem proves that there exists a  $k$  such that at least  $n/4$  roots of  $p(z)$  are on either side of  $r_k$  on the real line. For convenience, let us denote this distinguished  $r_k$  by  $v$ . There may be a root of  $f_0$  which is very close to  $v$ . Therefore, the choice of  $v$  as the point  $w$  in the description of the numerical integration scheme is not suitable. We get around this problem by choosing  $w$  very close to  $v$  as follows:

$$w = \begin{cases} v & \text{if } s_- = s_+ = s_0, \\ v - 2^{-(\sigma+2)} & \text{if } s_+ \neq s_0 \neq 0, \\ v + 2^{-(\sigma+2)} & \text{if } s_- \neq s_0 \neq 0, \\ v + 2^{-(\sigma+1)} & \text{if } s_0 = 0, \end{cases}$$

where  $\sigma$  is as defined in Corollary 2.3 and  $s_-$ ,  $s_0$ , and  $s_+ \in \{-, 0, +\}$  are the signs of  $p(v - 2^{-(\sigma+2)})$ ,  $p(v)$ , and  $p(v + 2^{-(\sigma+2)})$ , respectively.

**6. Determining real roots in the presence of complex roots is as hard as determining all roots.** In this section, we reduce the problem of determining all roots of a polynomial to the problem of determining all real roots of two related polynomials. The reduction uses some well-known techniques from the *Theory of Equations* (see, for example, [U48]). The size of the two related polynomials is polynomially bounded by the size of the initial polynomial and the reduction is in NC. This establishes that the problem of determining all real roots of a polynomial is in NC if and only if the problem of determining all roots (real and complex) of a polynomial is in NC.

Suppose we wish to determine all roots of a polynomial  $h(z)$  of degree  $n$  with  $m$  bit integer coefficients. Replace  $z$  by  $x + iy$ ,  $x, y$  real, and  $i = \sqrt{-1}$ . Also write  $h(x + iy) = f(x, y) + ig(x, y)$ , where  $f(x, y)$  and  $g(x, y)$  are the real and imaginary parts of  $h(x + iy)$ , respectively. Let  $f(x, y) = \sum_{j=0}^n \psi_j(x)y^j = \sum_{j=0}^n \omega_j(y)x^j$  and  $g(x, y) = \sum_{j=0}^n \phi_j(x)y^j = \sum_{j=0}^n \chi_j(y)x^j$ . Define  $X$  to be the  $2n \times 2n$  matrix as follows:

$$\begin{aligned} X(i, j) &= \psi_{n+i-j}(x), & 1 \leq i \leq n, \\ X(i, j) &= \phi_{i-j}(x), & n \leq i \leq 2n. \end{aligned}$$

Similarly, define a  $2n \times 2n$  matrix  $Y$  using  $\omega_i(y)$  and  $\chi_i(y)$  instead of  $\psi_i(x)$  and  $\phi_i(x)$ , respectively. Then  $\det(X)$  and  $\det(Y)$  are polynomials of degree at most  $n^2$ . The real and imaginary parts of any root of  $h(z)$  are real roots of  $\det(X)$  and  $\det(Y)$ , respectively. Thus, by finding all real roots of  $\det(X)$  and  $\det(Y)$ , we can determine all the roots of  $h(z)$ .

**Acknowledgments.** We would like to thank Franco Preparata for suggesting the “geometric spacing” of samples in order to evaluate various contour integrals to high precision and Don Coppersmith for making many useful suggestions during the course of this work. We would also like to thank Alok Aggarwal, Ashok Chandra, Ming-Deh Huang, Barry Trager, and Victor Miller for helpful discussions, and a referee for suggestions that have improved this manuscript. The referee also pointed out an error in the proof of Lemma 3.1 in the original version of this manuscript. In addition, the last author wishes to thank Tamer Basar, Dan Grayson, Michael Loui, Kameshwar Poolla, Sanjeev Rao, and Vasant Rao for helpful discussions on the general root-finding problem.

The IBM Thomas J. Watson Research Center, Yorktown Heights, provided the creative atmosphere in which this work began.

## A LOWER BOUND ON THE COMPLEXITY OF THE UNION-SPLIT-FIND PROBLEM\*

KURT MEHLHORN<sup>†</sup>, STEFAN NÄHER<sup>‡</sup>, AND HELMUT ALT<sup>‡</sup>

**Abstract.** We prove a  $\Theta(\log \log n)$  (i.e., matching upper and lower) bound on the complexity of the Union-Split-Find problem, a variant of the Union-Find problem. Our lower bound holds for **all** pointer machine algorithms and does not require the separation assumption used in the lower-bound arguments of Tarjan [*J. Comput. Systems Sci.*, 18 (1979), pp. 110–127] and Blum [*SIAM J. Comput.*, 15 (1986), pp. 1021–1024]. We complement this with a  $\Theta(\log n)$  bound for the Split-Find problem under the separation assumption. This shows that the separation assumption can imply an exponential loss in efficiency.

**Key words.** complexity, interval splitting, lower bound, pointer machine, priority queue, union

**AMS(MOS) subject classification.** 68

**1. Introduction.** We consider the following three operations on a linear list  $x_1, x_2, \dots, x_n$  of items, some of which are marked:

- UNION ( $x_i$ ): given a pointer to the marked item  $x_i$  unmark this item;
- SPLIT ( $x_i$ ): given a pointer to the unmarked item  $x_i$  mark this item;
- FIND ( $x_i$ ): given a pointer to the item  $x_i$  return a pointer to  $x_j$ ,  
where  $j = \min \{l \mid l \geq i \text{ and } x_l \text{ is marked}\}$ .

Note that the marked items partition the linear list  $x_1, \dots, x_n$  into intervals of unmarked items. Then FIND ( $x_i$ ) returns (a pointer to) the right endpoint of the interval containing  $x_i$ , SPLIT ( $x_i$ ) splits the interval containing  $x_i$ , and UNION ( $x_i$ ) joins the two intervals having  $x_i$  as a common endpoint. We call the problem above the **Union-Split-Find problem**; P. v. Emde Boas et al. [EKZ77] called it a priority queue problem. They referred to the three operations as Insert, Delete, and Successor, and exhibited an  $O(\log \log n)$  solution for it. We will also consider the **Split-Find problem** and the **Union-Find problem** (only operations split, find and union, find, respectively). Note that our Union-Find problem is a restriction of the usual Union-Find problem (here called the general Union-Find problem) because we allow only adjacent intervals to be joined. The Union-Split-Find problem is important for a number of applications, e.g., dynamic fractional cascading [MN86] and computing shortest paths [M84b, p. 47].

We study the complexity of the Union-Split-Find problem in the pointer machine model of computation (Kolmogorov [Ko53], Knuth [Kn68], Schönhage [S73], Tarjan [T79]). A pointer machine captures the list-processing capabilities of computers; its storage consists of records connected by pointers. Previously, lower bounds in a restricted pointer machine model (the term “restricted” is explained below) were obtained by Tarjan [T79] and Blum [B86]. Tarjan proved a  $\Theta(\alpha(n))$  bound on the amortized cost of the general Union-Find problem and Blum proved a  $\Theta(\log n / \log \log n)$  bound on the worst-case cost. Tarjan’s and Blum’s lower bounds rely heavily on the following **separation assumption** (quoted from Tarjan [T79]):

At any time during the computation, the contents of the memory can be partitioned into collections of records such that each collection corresponds to a currently existing

\* Received by the editors December 31, 1986; accepted for publication (in revised form) December 9, 1987. This research was supported by the Deutsche Forschungsgemeinschaft, grant SPP ME 620/6-1.

<sup>‡</sup> FB Mathematik, WE3, Freie Universität Berlin, D-1000 Berlin 33, Federal Republic of Germany.

set,  $\dots$  and no record in one collection contains a pointer to a record in another collection.

Because of this assumption we call their model **restricted**. If we view pointers as undirected edges in a graph, then the separation assumption states that every currently existing set corresponds to a component of the graph.

The main results of this paper are as follows.

(1) The complexity of the Union-Split-Find problem in the pointer machine model is  $\Theta(\log \log n)$ . Here, the upper bound is on the worst-case cost of the three operations and the lower bound is on the amortized cost of the three operations, i.e., there are arbitrarily large  $m$  and sequences of  $m$  SPLIT, FIND, and UNION operations having a total cost of  $\Omega(m \log \log n)$ .

The upper bound can be found in [EKZ77], [Ka84], and [MN86]. The solution of [MN86] supports two additional operations ADD and ERASE which allow us to modify the underlying linear list; the solution does not satisfy the separation assumption. The lower bound will be proved in § 2 of this paper.

(2) In the restricted pointer machine model the worst-case complexity of the Split-Find problem is  $\Theta(\log n)$  and the amortized complexity of the Union-Split-Find problem is  $\Theta(\log n)$ .

This will be shown in § 3.

**2. The lower bound.** In this section we will show that each solution for the Union-Split-Find problem on a pointer machine requires  $\Omega(\log \log n)$  computational steps, even in the amortized sense. More precisely, we show that there are arbitrarily large  $m$  and sequences of  $m$  UNION, FIND, SPLIT operations having a total cost of  $\Omega(m \log \log n)$ .

Our machine model is a pointer machine as described in [T79]. Its memory  $M$  consists of an unbounded collection of records, each containing two pointers to other records and an arbitrary amount of additional information. Thus  $M$  can be regarded as a directed graph with outdegree 2. We assume that the set of items  $S$  is realized by two sets of records in  $M$ , a set of input records  $I = \{x_1^*, x_2^*, \dots, x_n^*\}$ , and a set of output records  $O = \{y_1^*, y_2^*, \dots, y_n^*\}$ . (The distinction between input and output records is merely a notational convenience.)

FIND( $x$ ) is executed as follows. The machine starts with a pointer to input Record  $x^*$  (corresponding to item  $x \in S$ ) in some register  $r$ . It stops with a pointer to the output record  $y^*$  in  $r$  which corresponds to item  $y = \text{FIND}(x)$ . Since it can access records in  $M$  only by pointers contained in one of its registers, there must be a path  $p$  formed by records and pointers in  $M$  starting in  $x^*$  and ending in  $y^*$  such that pointers to all records on  $p$  have been loaded into a register during the execution of the FIND. In addition to traversing a path from  $x^*$  to  $y^*$  the FIND operation may change some number of pointers. The cost of the FIND operation is certainly bounded from below by the length of a shortest path from  $x^*$  to  $y^*$  in  $M$  plus the number of pointers changed.

When executing the operation SPLIT( $y$ ) the machine starts with a pointer to record  $y^*$  in some register. After the operation record  $y^*$  is reachable via pointers in  $M$  for all records  $x^*$  corresponding to items  $x$  with  $\text{FIND}(x) = y$ . To achieve this the machine changes certain pointers in  $M$ . The number of pointers changed is the cost of SPLIT( $y$ ). The cost of UNION( $y$ ) is defined similarly.

In order to model the actions of the pointer machine on its memory  $M$  in a more abstract way we consider FIND and SPLIT as operations on a directed graph  $G$  as follows:

Let  $G = (V, E)$  be a directed graph with the following:

- (1) For all  $v \in V$ :  $\text{outdegree}(v) = 2$ .
- (2) There is a set of  $n$  input nodes  $I = \{x_1, x_2, \dots, x_n\} \subseteq V$ .
- (3) There is a set of  $n$  output nodes  $O = \{y_1, y_2, \dots, y_n\} \subseteq V - I$  which may be marked (we call  $y_i$  the output node corresponding to input node  $x_i$ ,  $1 \leq i \leq n$ ).

FIND ( $x_i$ ),  $x_i \in I$ , returns output node  $y_j$  such that  $j \geq i$ , and  $j$  is minimal with  $y_j$  marked. In addition, it may replace some edges of  $G$  by new edges. The complexity of FIND ( $x_i$ ) is the length of the shortest path from  $x_i$  to  $y_j$  in  $G$  plus the number of edges replaced.

SPLIT ( $y$ ),  $y \in O$ , marks output node  $y$  and replaces some edges of  $G$  by new edges such that every marked output node  $y$  is reachable from all input nodes  $x$  with  $\text{FIND}(x) = y$ . The complexity of SPLIT ( $y$ ) is the number of edges replaced.

UNION ( $y$ ),  $y \in O$ , unmarks output node  $y$  and replaces some edges of  $G$  with new edges. The complexity of UNION ( $y$ ) is the number of edges replaced.

LEMMA 1. *Let  $k$  be any integer, let  $L = 2^{2k+1} + 1$ , let  $n \geq 2^{(5k)2^k}$ , and let  $G_0 = (V, E)$  be a directed graph with all output nodes unmarked. Then there is a sequence of  $L$  SPLIT operations followed by  $L$  FIND operations, followed by  $L$  UNION operations such that we have the following:*

- (1) *The total cost of the sequence is at least*

$$\min \left( k \cdot L, \frac{1}{2^{2k+4}} n^{1/2^k} \right).$$

- (2) *All output nodes are unmarked after executing the sequence.*

*Proof.* We call a graph  $G$  a  $k$ -structure if and only if for every input node  $x$  there is a path of length at most  $k$  from  $x$  to the output node  $y = \text{FIND}(x)$ .

The idea of the proof is as follows. We first execute a sequence of  $L$  SPLIT instructions (this sequence is constructed below) which leaves us with a data structure  $G_1$ . We next execute a hardest FIND on  $G_1$ , i.e., an operation  $\text{FIND}(x)$  where the shortest path from  $x$  to  $\text{FIND}(x)$  has maximal length. Execution of this FIND instruction yields the data structure  $G_2$ . Again we perform a hardest FIND,  $\dots$ . In this way we perform a total of  $L$  FINDs, each FIND being a hardest FIND in the present data structure. Finally, we perform a sequence of UNIONS which undo all the SPLITS. This yields a data structure  $G'_0$  (generally different from  $G_0$ ) in which all output nodes are unmarked.

In order to estimate the cost of this sequence of instructions we distinguish two cases. Assume first that no  $G_i$ ,  $1 \leq i \leq L$ , is a  $k$ -structure. Then each FIND costs at least  $k$  time units for a total cost of  $k \cdot L$  time units. Assume next that some  $G_i$  is a  $k$ -structure. We will show that it takes at least  $(1/2^{2k+4}) \cdot n^{1/2^k}$  edge changes to construct  $G_i$  from  $G_0$ ; more precisely, we show the following claim.

CLAIM. *Let  $G_0$  be an arbitrary data structure with all output nodes unmarked. Then there is a set  $\{z_1, \dots, z_L\} \subseteq O$  of output nodes such that no  $k$ -structure  $G'$  with exactly  $z_1, \dots, z_L$  marked can be constructed from  $G_0$  with fewer than  $(1/2^{2k+4}) \cdot n^{1/2^k}$  edge replacements.*

*Proof.* For all  $v \in V$  and  $l \geq 1$  let  $R_l(v)$  denote the set of all input nodes  $w$  such that  $v$  is reachable from  $w$  on a path of length at most  $l$ .

Let  $c_0, c_1, \dots, c_{2^k}$  be a sequence of positive constants with

$$n = c_0 \geq c_1 \geq \dots \geq c_{2^k-1} \geq c_{2^k} = 1.$$

Then the following lemma holds for  $G_0$ .

LEMMA 2. *There is an  $l$ ,  $0 \leq l \leq 2^k - 1$ , and  $l$  distinct nodes  $v_1, \dots, v_l$  such that we have the following:*

- (1) *Either  $l = 0$ , or  $|\bigcap_{1 \leq i \leq l} R_{k-1}(v_i)| \geq c_l$ .*

(2) For each  $w \in V - \{v_1, \dots, v_l\}$ :  $|I^* \cap R_{k-1}(w)| < c_{l+1}$ , where  $I^* = \bigcap_{1 \leq i \leq l} R_{k-1}(v_i)$  ( $I^* = I$  if  $l=0$ ).

*Proof.* Let  $l_0$  be maximal such that there are distinct nodes  $v_1, \dots, v_{l_0}$  with  $|\bigcap_{1 \leq i \leq l_0} R_{k-1}(v_i)| > c_0$ . We only have to show that  $l_0 < 2^k$ . Assume  $l_0 \geq 2^k$ . Then there are  $2^k$  distinct nodes  $v_1, \dots, v_{2^k}$  with  $\bigcap_{1 \leq i \leq 2^k} R_{k-1}(v_i) \neq \emptyset$ . But for every  $x \in I$  there are at most  $2^k - 1$  nodes  $v \in V$  with  $x \in R_{k-1}(v)$ , a contradiction.  $\square$

Now let  $l \geq 0$  and let  $v_1, v_2, \dots, v_l$  be nodes satisfying the conditions of Lemma 2.. We give a sequence of  $2^{2^{k+1}} + 1$  SPLIT operations which require at least  $(c_l/2L - 2^{k+1})/c_{l+1}$  edge replacements. First we divide  $I^* = \bigcap_{1 \leq i \leq l} R_{k-1}(v_i)$  into  $2L$  intervals  $A_1, A_2, \dots, A_{2L}$  of about equal size.  $A_1$  consists of the  $\lfloor I^*/2L \rfloor$  smallest indexed items in  $I^*$ ,  $A_2$  consists of the next  $\lfloor I^*/2L \rfloor$  smallest indexed items in  $I^*$ , and so forth. Clearly,

$$|A_i| \geq \frac{c_l}{2L} - 1 \quad \text{for all } i.$$

Let  $A'_1, A'_2, \dots, A'_{2L}$  be the corresponding intervals of output nodes.

LEMMA 3. In every  $A'_j$ ,  $j \in \{2, 4, 6, \dots, 2L\}$ , there is an output node  $y_j$  that is reachable in  $G_0$  from at most  $2^{k+1}$  input nodes in  $A_{j-1}$  on a path of length  $\leq k$ .

*Proof.* For all  $x \in A_{j-1}$  we have  $|\{v \in V \mid x \in R_k(v)\}| \leq 2^{k+1} - 1$ . Thus we conclude

$$\begin{aligned} \sum_{x \in A_{j-1}} |\{v \in V \mid x \in R_k(v)\}| &\leq |A_{j-1}| \cdot (2^{k+1} - 1) \\ &= |A'_j| \cdot (2^{k+1} - 1). \end{aligned} \quad \square$$

Let  $y_j \in A'_j$ ,  $j \in \{2, 4, \dots, 2L\}$  be defined as in Lemma 3. Then there exists for each  $j$  a set  $B_{j-1} \subseteq A_{j-1}$  such that  $|B_{j-1}| \geq |A_{j-1}| - 2^{k+1}$  and such that for each  $x \in B_{j-1}$  there is no path of length at most  $k$  from  $x$  to  $y_j$  in  $G_0$ . Next consider any  $k$ -structure  $G'$  in which exactly the  $y_j$ 's defined above are marked. In  $G'$  there must be a path of length at most  $k$  from any  $x \in B_{j-1}$  to  $y_j$ . Let  $p(x)$  be any such path from  $x$  to  $y_j$  and let  $e(x)$  denote the first new edge on  $p(x)$ . Let the edge  $e(x)$  start in vertex  $v(x)$ . We have the following lemma.

LEMMA 4. (1)  $|\{x \in B_{j-1} \mid v(x) = w\}| \leq c_{l+1}$  for every node  $w \notin \{v_1, v_2, \dots, v_l\}$  and every  $j$ .

(2) There is a  $j \in \{2, 4, 6, \dots, 2L\}$  such that  $v(x) \notin \{v_1, v_2, \dots, v_l\}$  for all  $x \in B_{j-1}$ .

*Proof.* (1) If  $v(x) = w$  then  $w$  was reachable from  $x$  in the data structure  $G_0$  in at most  $k - 1$  steps. Thus the claim follows immediately from the definition of  $v_1, \dots, v_l$ .

(2) For every  $v \in \{v_1, v_2, \dots, v_l\}$  we have  $|\{y \in O \mid v \in R_k(y)\}| \leq 2^{k+1}$  and thus

$$\begin{aligned} \sum_{v \in \{v_1, \dots, v_l\}} |\{y \in O \mid v \in R_k(y)\}| &\leq l 2^{k+1} \\ &\leq 2^{2^{k+1}} \quad \text{since } l \leq 2^k. \end{aligned}$$

That is, all paths of length at most  $k$  using nodes from  $\{v_1, \dots, v_l\}$  cannot lead to more than  $2^{2^{k+1}} = L - 1$  output nodes. Since we marked  $L$  nodes in  $O$  there must be one  $y_j$  such that  $v(x) \notin \{v_1, \dots, v_l\}$  for all  $x \in B_{j-1}$ .  $\square$

Now consider any  $j \in \{2, 4, \dots, 2L\}$  satisfying condition (2) of Lemma 4; i.e.,  $v(x) \notin \{v_1, \dots, v_l\}$  for all  $x \in B_{j-1}$ . Next observe that by (1) of Lemma 4 for any node  $w \notin \{v_1, \dots, v_l\}$  there are at most  $c_{l+1}$  nodes  $x \in B_{j-1}$  with  $v(x) = w$ . Thus

$$\frac{|B_{j-1}|}{c_{l+1}} = \frac{|A_{j-1}| - 2^{k+1}}{c_{l+1}} \geq \frac{c_l/2L - 1 - 2^{k+1}}{c_{l+1}} \geq \frac{c_l/(2^{2^{k+2}} + 2) - 1 - 2^{k+1}}{c_{l+1}}$$

edges must be changed to obtain  $G'$  from  $G_0$ . With

$$c_i = n^{1-i/2^k}, \quad 0 \leq i \leq 2^k$$

we conclude further that

$$\begin{aligned} \frac{c_l / (2^{2k+2} + 2) - (2^{k+1} + 1)}{c_{l+1}} &\cong \frac{n^{1/2^k}}{2^{2k+2} + 2} - (2^{k+1} + 1) \\ &\cong \frac{n^{1/2^k}}{2 \cdot (2^{2k+2} + 2)} \quad \text{since } n \cong 2^{(5k)2^k} \\ &\cong \frac{n^{1/2^k}}{2^{2k+4}}. \end{aligned}$$

This completes the proof of the claim and of Lemma 1.  $\square$

**THEOREM 1.** (a) *The single operation worst-case complexity of the Split-Find problem is  $\Omega(\log \log n)$ .*

(b) *The amortized complexity of the Union-Split-Find problem is  $\Omega(\log \log n)$ ; i.e., there are arbitrarily large  $m$  and sequences of  $m$  UNION, SPLIT, and FIND operations having a total cost of  $\Omega(m \log \log n)$ .*

*Proof.* (a) Let  $k$  be maximal such that  $n \cong 2^{(5k)2^k}$ . Then  $k = \Omega(\log \log n)$  and

$$\begin{aligned} \frac{1}{2^{2k+1} + 1} \cdot \frac{1}{2^{2k+4}} n^{1/2^k} &\cong \frac{2^{5k}}{2^{2k+4}(2^{2k+1} + 1)} \\ &= \Omega(2^k) \\ &= \Omega(\log n) \\ &= \Omega(\log \log n). \end{aligned}$$

Consider the sequence of  $2L$  SPLITs and FINDs constructed in the proof of Lemma 1. The cost of this sequence is

$$\Omega\left(\min\left(k \cdot L, \frac{1}{2^{2k+4}} \cdot n^{1/2^k}\right)\right) = \Omega(L \cdot \log \log n),$$

and hence at least one operation of the sequence has cost  $\Omega(\log \log n)$ .

(b) Let  $k$  be maximal such that  $n \cong 2^{(5k)2^k}$  and let  $m = 3 \cdot L \cdot s$  for some  $s$ . Let  $G_0$  be any data structure with all output nodes unmarked. By part (a) and Lemma 1 there is a sequence of  $3 \cdot L$  instructions such that

- (1) the total cost of the sequence is  $\Omega(L \log \log n)$ ;
- (2) all output nodes are unmarked after executing the sequence.

Thus again by part (a) and Lemma 1 there is another sequence of  $3 \cdot L$  instructions  $\dots$ . Using this argument  $s$  times yields a sequence of  $m$  instructions with total cost  $\Omega(m \log \log n)$ .  $\square$

**3. A lower bound in the restricted model.** In this section we prove a  $\Omega(\log n)$  lower bound for the worst-case complexity of the Split-Find problem and a  $\Omega(\log n)$  lower bound for the amortized complexity of the Union-Split-Find problem in the restricted pointer machine model. We consider pointer machine algorithms satisfying the following **separation condition**:

The memory can be partitioned into subgraphs such that each subgraph corresponds exactly to a current interval. There exists no edge from a node in such a subgraph to a node outside the subgraph [B86], [T79].

As in the previous section we define a  $k$ -structure.

DEFINITION. Let  $G = (V, E)$  be a directed graph with input nodes  $I = \{x_1, \dots, x_n\}$  and output nodes  $O = \{y_1, \dots, y_n\}$  some of which may be marked.  $G$  is called a  **$k$ -structure** if and only if for every  $x \in I$  there is a path of length at most  $k$  to  $\text{FIND}(x)$  and  $G$  fulfills the separation condition; i.e., for every  $x_i, x_j \in I$  with  $\text{FIND}(x_i) \neq \text{FIND}(x_j)$  there is no  $v \in V$  that is reachable from both  $x_i$  and  $x_j$ .  $\square$

LEMMA 5. Let  $n \geq (4k)^k/k!$ . In any  $k$ -structure with output nodes  $y_1, \dots, y_{n-1}$  unmarked and  $y_n$  marked satisfying the separation condition there is a SPLIT operation requiring at least  $k/12 \cdot n^{1/k}$  edge replacements.

*Proof.* Since  $y_n$  is the only marked output node there is, for each input node  $x$ , a path of length at most  $k$  to  $y_n$ . Let  $T$  be the subgraph of  $G$  formed by all shortest paths from input nodes to  $y_n$ . Then  $T$  is a tree with root  $y_n$ , leaves  $\{x_1, \dots, x_n\}$ , and height at most  $k$ . For any node  $v$  in  $T$  let  $I(v)$  denote the set of input nodes which are the leaves of the subtree rooted at  $v$ . At each internal node  $v$  of  $T$  the incoming edges can be ordered  $(w_1, v), (w_2, v), \dots, (w_m, v)$  such that the minimal index of any input node in  $I(w_i)$  is smaller than the minimal index of any input node in  $I(w_j)$  for all  $1 \leq i < j \leq m$ . (We call  $w_i$  the  $i$ th child of  $v$ .)

Now assume that SPLIT( $x$ ) is executed for some  $x \in I$ . Let

$$p: x = v_0 \rightarrow v_1 \rightarrow \dots \rightarrow v_l = y_n$$

be the path from  $x$  to the root  $y_n$  in  $T$ . For any  $v_i, 1 \leq i \leq l$ , on this path let  $w_1^i, \dots, w_j^i = v_{i-1}, \dots, w_m^i$  be the children of  $v_i$  in the order defined above. Before the split operation  $v_i$  is reachable from all input nodes of both of the following sets:

$$L_i = \{u \mid u \text{ is the node with minimal index in } I(w_k^i), 1 \leq k \leq j-1\},$$

$$R_i = \{u \mid u \text{ is the node with minimal index in } I(w_k^i), j+1 \leq k \leq m\}.$$

After the split  $\text{FIND}(a) \neq \text{FIND}(b)$  for all  $a \in L_i, b \in R_i$  and by the separation condition  $v_i$  is not reachable from any node of at least one of the sets  $L_i$  or  $R_i$ . Thus the execution of SPLIT( $x$ ) requires at least

$$\min(|L_i|, |R_i|) = \min\{j-1, \text{indegree}(v_i) - j \mid v_{i-1} \text{ is the } j\text{th child of } v_i\}$$

edge replacements for each node  $v_i, 1 \leq i \leq l$ , on path  $p$ .

The total cost for SPLIT( $x$ ) is at least

$$c(p) = \sum_{i=1}^l \min\{j-1, \text{indegree}(v_i) - j \mid v_{i-1} \text{ is the } j\text{th child of } v_i\}.$$

We prove a lower bound for  $c(p)$ .

LEMMA 6. Let  $T$  be any tree of height  $k$  with  $n$  leaves and root  $r$ . Then there is a leaf  $x$  in  $T$  such that the path  $p$  from  $x$  to  $r$  has cost

$$c(p) \geq \frac{k}{12} \cdot n^{1/k}.$$

*Proof.* Define  $l(k, j)$  as the maximal number of leaves in any tree  $T$  of height  $k$ , such that  $c(p) \leq j$  for every path  $p$  from a leaf to the root of  $T$ .

Then we have

$$l(0, j) = 1 \quad \text{for } j \geq 0$$

$$\ell(2, 2) = 24$$

FIG. 2

The term  $2^k$  accounts for the fact that in every vertex each label can be used twice:

$$\begin{aligned} l(k, j) &\leq 2^k \cdot \binom{k+j-1}{k-1} \\ &\leq 2^k \cdot \frac{(k+j-1)^{k-1}}{(k-1)!} \\ &\leq 2^k \cdot \frac{(k+j-1)^k}{k!} \\ &\leq 2^k \cdot \frac{(k+j)^k}{k!}. \end{aligned}$$

We conclude that in any tree of height  $k$  with  $n$  leaves there exists a path  $p$  from some leaf to the root such that

$$\begin{aligned} n &\leq 2^k \cdot \frac{(c(p) + k)^k}{k!} \\ &\leq 2^k \cdot \frac{(2 \cdot c(p))^k}{k!} \quad \text{since } n \geq \frac{(4k)^k}{k!} \text{ and hence } c(p) \geq k, \end{aligned}$$

and finally

$$\begin{aligned} c(p) &\geq \frac{1}{2} \left( \frac{n \cdot k!}{2^k} \right)^{1/k} \\ &\geq \frac{k}{12} \cdot n^{1/k} \quad \text{since } (k!)^{1/k} \geq \frac{k}{3} \text{ if } k \geq 6. \end{aligned}$$

This completes the proof of Lemma 5.  $\square$

**THEOREM 2.** *In the restricted pointer machine model we have the following:*

- (a) *The single-operation worst-case complexity of the Split-Find problem is  $\Omega(\log n)$ .*
- (b) *The amortized complexity for the Union-Split-Find problem is  $\Omega(\log n)$ ; i.e., there are arbitrarily large  $m$  and sequences of  $m$  UNION, SPLIT, FIND operations having a total cost of  $\Omega(m \log n)$ .*

*Proof.* (a) Let  $k$  be maximal such that  $n \geq (4k)^k/k!$ . Then  $k = \Omega(\log n)$ . Let  $G$  be any data structure with all output nodes except  $y_n$  unmarked. By Lemma 5 there is either a FIND operation which costs more than  $k$  time units or there is a SPLIT operation having a cost of

$$\frac{k}{12} \cdot n^{1/k} \geq \frac{\log n}{12} \cdot n^{1/\log n} = \frac{\log n}{6} = \Omega(\log n).$$

(b) Let  $G$  be any structure with all output nodes except  $y_n$  unmarked. Define  $k$  as in part (a). If  $G$  is not a  $k$ -structure then we perform a hardest FIND in  $G$ ; this FIND has cost  $k = \Omega(\log n)$  and leaves us with a structure  $G'$  where all output nodes except  $y_n$  are unmarked. If  $G$  is a  $k$ -structure then there is a SPLIT operation of cost  $k/12 \cdot n^{1/k} = \Omega(\log n)$ . We perform it and immediately undo it by the corresponding UNION operation. This leaves us with a structure  $G'$ , where all output nodes except  $y_n$  are unmarked. At this point we are in the initial situation and we have forced the algorithm to spend  $\Omega(\log n)$  time units on at most two operations. Part (b) follows.  $\square$

We want to point out that  $O(\log n)$  is clearly also an upper bound for the complexity of the Union-Split-Find problem in the restricted model. We only have to represent each interval by a balanced tree (cf., e.g., [M84a, § III.5.3.1]).

We close this section with the following corollary.

**COROLLARY 1.** *Pointer machines obeying the separation assumption are exponentially weaker than pointer machines without the separation assumption. This is true for the worst-case complexity and for the amortized complexity.*

*Proof.* This follows immediately from Theorems 1 and 2.  $\square$

**4. Conclusions and open problems.** In this paper we proved several new lower bounds for the Union-Split-Find problem. In particular, we presented an  $\Omega(\log \log n)$  lower bound on the amortized complexity of the Union-Split-Find problem valid for **all** pointer machine algorithms and an  $\Omega(\log n)$  lower bound for restricted (in the sense of Tarjan [T79] and Blum [B86]) pointer machine algorithms. Our lower bounds match known upper bounds. Thus our results reveal that the separation assumption of Tarjan and Blum can imply an exponential loss in efficiency.

Table 2 summarizes all known bounds for the complexity of pointer machine algorithms for the Union-Split-Find problem on intervals including the results of this paper.

There are still several open problems in both models. We have no lower bounds on the amortized complexity of Union-Find and Split-Find and for the worst-case

TABLE 2

Problem	General model		Restricted model	
Union-Find worst case amortized	$O(\log \log n)$ —	[EKZ77]	$O(\log n/\log \log n)$ $\Theta(\alpha(n))$	[B86] [T79]
Split-Find worst case amortized	$\Theta(\log \log n)$ —	<b>new</b>	$\Theta(\log n)$ $O(\log^* n)$	<b>new</b> [HU73]
Union-Split-Find worst case amortized	$\Theta(\log \log n)$ $\Theta(\log \log n)$	<b>new</b> <b>new</b>	$\Theta(\log n)$ $\Theta(\log n)$	<b>new</b> <b>new</b>

complexity of Union-Find in the general model. In the restricted model it remains an open problem to determine whether the Split-Find algorithm of Hopcroft and Ullman [HU73], whose amortized running time is  $O(\log^* n)$ , is optimal. We suppose that Blum's lower bound proof for the general Union-Find problem cannot be modified to work also for the interval problem.

We want to point out that the Union-Find problem and the Split-Find problem considered in this paper have amortized complexity  $\Theta(1)$  on random access machines. This was shown by Gabow and Tarjan [GT83] for the Union-Find problem and by Imai and Asano [IA84] for the Split-Find problem.

## A SHORT-TERM NEURAL NETWORK MEMORY\*

ROBERT J. T. MORRIS† AND WING SUNG WONG†

**Abstract.** Neural network memories with storage prescriptions based on Hebb's rule are known to collapse as more words are stored. By requiring that the most recently stored word be remembered precisely, a new simple short-term neural network memory is obtained and its steady state capacity analyzed and simulated. Comparisons are drawn with Hopfield's method, the delta method of Widrow and Hoff, and the revised marginalist model of Mezard, Nadal, and Toulouse.

**Key words.** neural networks, associative memory, short-term memory, machine learning, adaptive systems

**AMS(MOS) subject classifications.** 68Q05, 68T05

**1. Introduction.** In a paper [1] which attracted considerable attention, Hopfield proposed a neural network model consisting of  $N$  neurons taking values  $e^1, \dots, e^N \in \{-1, 1\}$ , and interconnected by a synaptic matrix  $T$ , where  $T_{ij}$  represents the synaptic efficacy by which neuron  $j$  influences neuron  $i$ . The collective behavior of the neurons is described by the equation

$$(1.1) \quad e^i \leftarrow \operatorname{sgn} \left( \sum_{j=1}^N T_{ij} e^j - u^i \right), \quad i = 1, \dots, N,$$

where  $\operatorname{sgn}(x) = x/|x|$ ,  $x \neq 0$ , and from now on we will assume  $u^i = 0$ . Equation (1.1) is a simplified, discrete version of the McCullough-Pitts physiological model. Hopfield required that the neurons' values be updated *randomly* and *asynchronously*. He showed that this model had the *autoassociative* property, as defined by Kohonen [2], i.e., it was able to retrieve a previously stored word from part of its specification. The prescription for storage of words  $e_s = (e_s^1, \dots, e_s^N)$ ,  $s = 1, 2, \dots, m$  was obtained from the equation

$$(1.2) \quad T_{ij} = \begin{cases} \sum_{s=1}^m e_s^i e_s^j, & i \neq j, \\ 0, & i = j. \end{cases}$$

This equation has frequently been called Hebb's rule and is simple and attractive, partly because of its property of *locality*; i.e., the synapse  $T_{ij}$  is updated with the storage of new word  $e_s$  according to a simple function of  $e_s^i$  and  $e_s^j$  only, and so all elements of the matrix  $T_{ij}$  can be updated asynchronously and in parallel. Hopfield gave a simple explanation as to why Hebb's rule (1.2) tends to result in the stored words being fixed points for the dynamics of (1.1):

$$\sum_{j=1}^N T_{ij} e^j = \sum_{s=1}^m e_s^i \left[ \sum_{j \neq i} e_s^j e_s^j \right] \approx e_s^i (N-1),$$

where the last approximation appeals to the argument that the stored vectors are expected to be "pseudo-orthogonal," i.e., the square-bracketed term is approximately  $(N-1)\delta_{st}$ . Furthermore, since  $T_{ij}$  is symmetric it is readily verified that the "energy function"  $-\sum_i e^i \sum_j T_{ij} e^j$  is decreased by the substitution (1.1) whenever  $e^i$  changes

(provided individual neurons are updated one at a time and are left unchanged when the argument of  $\text{sgn}(\cdot)$  is zero). Thus (1.1) must converge to a fixed point. This constitutes an error-correcting property in the sense that patterns close to a fixed point are attracted to that point through the iteration of (1.1).

These ideas are closely related to schemes developed and/or analyzed by Widrow and Hoff [3], Kohonen [2], [4], and Stone [5] (see [6] for extensive references). Most of these rules were stated for the more general *heteroassociative* storage problem in which “keys and contents” or “inputs and targets” are associated; however, we will rephrase these results here in the autoassociative theme. An appealing learning rule in place of (1.2) has been called the Widrow-Hoff, or delta, rule and is described by<sup>1</sup>

$$(1.3) \quad T_n = T_{n-1} + \eta \delta_n e'_n,$$

where  $T_n$  is the synaptic matrix after word  $e_n$  has been stored and  $\eta$  is a scalar. The term  $\delta_n$  is given by

$$(1.4) \quad \delta_n = e_n - T_{n-1} e_n$$

and so represents the deviation between a new word and its image under the synaptic matrix just before it is stored. The most important result about these methods [2], [5] is that as the number of stored words increases, the  $T$  matrix converges to the matrix that (when applied to the input vector) results in minimal least square error for the estimation of the target vector from the input vector. In the autoassociative case this matrix is just the identity matrix. Kohonen [4] describes algorithms that do even more—they recursively produce the  $T_n$  matrix which for every  $n$  is the optimal estimator, although they are considerably more complex than the simple Hebb or delta rules. In exchange for the simplicity of the Hebb rule, these rules (including the delta rule) do not impose any requirement of orthogonality or even linear independence in achieving their properties. To place Hopfield’s work in perspective with prior and contemporary work, it should be noted that it is more the retrieval process of (1.1) that is unusual in that it specifies iterated (or feedback) threshold dynamics, as opposed to a retrieval process which is typically a single application of the synaptic matrix to the input vector, often without any thresholding. For more complete surveys of neural and associative learning models, see [1], [4], [6], [7].

There have been numerous variations on the memories described by (1.1) and (1.2). Soulie [8] and Soulie and Weisbuch [9] consider variations of (1.1) according to how points lying on the discontinuity of the  $\text{sgn}(\cdot)$  are treated and the order in the updating of the neurons. Definitions are given for *parallel iteration*, where all the neurons are updated simultaneously, *sequential iteration*, where all the neurons are repeatedly updated in the order of a permutation of  $\{1, \dots, N\}$ , and *random iteration*, as in Hopfield [1].

Personnaz, Guyon, and Dreyfus [10] consider variations on (1.2) which also mitigate the pseudo-orthogonality requirement of the Hebb rule. They note that for a state  $e_s$  to be stable with respect to (1.1) it is necessary and sufficient that

$$(1.5) \quad T e_s = A e_s,$$

for some  $A$  a diagonal matrix with nonnegative elements. For the simplest case of  $A = I$  and  $e_s$ ,  $s = 1, \dots, m$  linearly independent, (1.3) can be solved by taking

$$T = \Sigma(\Sigma'\Sigma)^{-1}\Sigma'$$

<sup>1</sup> We use the notation that  $T_{ij}$  represents the  $(i, j)$ th element of matrix  $T$ , whereas  $T_n$  represents the  $n$ th matrix in a sequence. As above,  $e_n$  refers to the  $n$ th column vector in a sequence and  $e'_i$  the  $i$ th component of vector  $e$ .

where  $\Sigma$  is the matrix with columns  $e_1, \dots, e_m$ . They referred to this prescription for storage as the Generalized Hebb rule.  $T$  is one form of a pseudo-inverse, and so this method is closely related to the other methods described above. One further distinction between [1] and the other work cited above is the use of zero diagonal elements of  $T$ ; we will return to the role of diagonal elements in § 2.

The memories described above have limited capacities, and as new words continue to be stored, reach a point where no words can be reliably retrieved or corrected. This collapse in capacity can occur in two distinct ways. One way, exhibited by Hopfield's method ((1.1), (1.2)), is that "pseudo-orthogonality" between all pairs of stored words becomes less likely. In addition, the unbounded growth of the  $T$  matrix typically implies decreasing relatively smaller contributions of any stored word. This results in the inability to retrieve any, including recently stored, words at steady state. A second method of degeneracy which is exhibited, for example, by the delta method of storage ((1.3), (1.4)), is the convergence of  $T$  to the identity matrix after the input of a long sequence of random vectors. As pointed out above, this is by design in the sense that with  $T = I$  the memory optimally recalls any vector offered to it. But the identity matrix fails to exhibit any capability to correct errors or produce a word from its partial presentation, and arguably has degenerated to a state of zero storage capacity. These two modes of collapse are discussed more precisely in § 2 and demonstrated experimentally in § 3.

If a neural network memory is to be used on an ongoing basis, it either needs to be reset to the *tabula rasa* ( $T = 0$ ) state periodically, or old words need to be removed or "forgotten" in some way. Besides physiological evidence that short-term memories, called *palimpsests*, exist in nature, perhaps the most common application of associative memories in computers is in hierarchical memory systems. These cache memories are often found between CPU and pinout on a chip, between CPU and backplane bus on single board computers, in memory management units and in disk buffer caches. In these caches it is desirable that words that have not been used for some time be replaced by current words according to the long recognized principle of locality of reference [11]. Additionally, the capability of neural memories to provide rapid, highly parallel but sometimes imperfect retrieval, and the presence of backup copies of data in lower levels of memory hierarchies suggest a possible role for neural architectures in hierarchical memory systems.

In the original paper by Hopfield [1] it was proposed that a short-term memory could be obtained by limiting the range of values  $T_{ij}$  could assume. This idea was pursued further by Nadal et al. [12] who called it "learning within bounds." Both [1] and [12] required that changes in  $T_{ij}$  satisfy a constraint such as  $|T_{ij}| \leq A$ . The experiments in [12] suggested that for optimal choice of parameters, about  $.016N$  words could be stored in this memory before the bit error rate (probability that an arbitrary bit of a retrieved word is in error) exceeded 1.5 percent. The paper [12] also proposed another scheme called "marginalist learning," but that scheme resulted in exponential growth of synaptic values causing the authors to regard it as somewhat unrealistic for use on an ongoing basis. Subsequently Mezard, Nadal, and Toulouse [13] revised the marginalist scheme by requiring that the average squared synaptic efficacy remain constant and obtained an update rule

$$(1.6) \quad T_{n+1} = (1 + \varepsilon^2/N)^{-1/2}[(\varepsilon/N)e_{n+1}e'_{n+1} + T_n]$$

where  $T_n$  is the synaptic matrix after learning  $e_1, \dots, e_n$ , and  $\varepsilon$  is a tuning parameter. Using this scheme and  $\varepsilon = 4$ , they observed a capacity of approximately  $.06N$  at a bit error rate of 1.5 percent.

In this paper we describe and analyze a short-term neural network memory that is based on a simple modification to Hopfield's model. The storage rule is simply described and implemented: the new word is impressed on the memory with sufficient intensity that it is memorized. This provides an automatic forgetting of older words in the memory. We present a detailed analysis and comparison of this scheme with Hopfield's memory, the delta method, and the revised marginalist method. Several important insights emerge regarding the role of the diagonal elements and a number of techniques are developed that allow approximation of various error rates.

**2. A new short-term memory.** In this section we present a mathematical analysis of the new update model. We break the analysis into two parts depending on whether the diagonal elements in the  $T$  matrix are present.

**2.1. New model without diagonal terms.** To make the analysis precise, we assume we have a sequence of independent words,  $e_1, e_2, e_3, \dots$ , each of which is an  $N$ -dimensional vector of *uniform signary* random variables. By a uniform signary random variable we mean a random variable that attains values 1 and  $-1$  with equal probability of one half. We represent the synaptic matrix after storing  $n$  words by  $T_n$ . Define the  $i$ th bit *impression* of the word  $e_k$  on  $T_n$ ,  $I_i(n, k)$ , by the relation

$$\begin{bmatrix} I_1(n, k) & & 0 \\ & \ddots & \\ 0 & & I_N(n, k) \end{bmatrix} = \langle T_n e_k e_k' \rangle,$$

where  $e'$  denotes the transpose of  $e$  and  $\langle \cdot \rangle$  is a linear operator on the space of  $N \times N$  matrices defined by

$$\langle X \rangle_{ij} = \begin{cases} 0, & i \neq j, \\ X_{ii} & \text{otherwise.} \end{cases}$$

Thus, the word  $e_k$  is correctly stored in  $T_n$  if and only if the impression  $I_i(n, k) > 0$ , for  $1 \leq i \leq N$ .

The new method of update requires that  $\langle T_n \rangle = 0$ , and  $I_i(n, n) = r$ , where  $r > 0$  is a storage threshold, for all  $i$  and  $n$ . That is, the latest word is always stored to precisely impression  $r$  on each coordinate. We will see that  $r > 0$  is purely a scale factor and does not affect the results in any qualitative way. Let  $S_n = e_n e_n'$ , and  $M = N - 1$ , and assume  $M > 0$ . The update rules are

$$(2.1a) \quad \begin{aligned} T_1 &= \frac{r}{M} (S_1 - I_N), \\ T_n &= T_{n-1} + D_n (S_n - I_N), \quad n \geq 2, \end{aligned}$$

where  $D_n$  is the diagonal matrix defined by

$$(2.1b) \quad D_n = \frac{r}{M} I_N - \frac{1}{M} \langle T_{n-1} S_n \rangle$$

and  $I_N$  is the  $N$ -by- $N$  identity matrix.

Note that the complexity of updating the synaptic matrix,  $T_n$ , is of order  $N^2$ , which is the same order as that of the Hebb or delta rule. Moreover, the update rule given by (2.1) has a very simple interpretation and implementation. An individual neuron  $e^i$  can be considered merely to update its incoming weights  $T_{ij}$ ,  $j \neq i$ , at a rate

proportional to  $e^i e^j$  until the threshold condition is met. Thus, like Hebb's rule, the update can be accomplished simply and in parallel, with all neurons revising their corresponding row of the  $T$  matrix simultaneously and independently.

PROPOSITION 1. For  $n \geq 1$ ,  $T_n e_n = r e_n$ .

Proof. By direct substitution and the observation that  $S_n e_n = N e_n$  and  $\langle T_{n-1} S_n \rangle e_n = T_{n-1} e_n$ .  $\square$

From (2.1) it is easy to see that the threshold,  $r$ , is simply a scaling factor and can be taken equal to  $M$ . Unlike the Hopfield case,  $T_n$ , for  $n \geq 2$ , is in general nonsymmetric. Let  $\alpha = 1 - 1/M$ ,  $\gamma = 1 - 2/M + 2/M^2$ . In the Appendix, we prove the following theorem.

THEOREM 1.

- (i)  $\mathbf{E} T_k = 0$ ,  $k \geq 1$ ,
- (ii)  $\mathbf{E} T_k T'_k = M^2(1 - \alpha^k) I_N$ ,  $k \geq 1$ ,
- (iii)  $\mathbf{E} T_{n+k} S_{n+1} = M \alpha^{k-1} I_N$ ,  $n \geq 0$ ,  $k \geq 1$ ,
- (iv)  $\mathbf{E} e'_{n+1} T'_{n+k} T_{n+k} e_{n+1} = \mathbf{E} \text{tr} T_{n+k} S_{n+1} T'_{n+k} = M^2 N(1 - \alpha^{n+1}(\alpha^{k-1} - \gamma^{k-1}))$ ,  $n \geq 0$ ,  $k \geq 1$ .

Theorem 1 implies that for all  $i$ ,  $\mathbf{I}_i(n+k, n+1)$  has a mean of  $m(n+k, n+1) = M \alpha^{k-1}$ , and a standard deviation of

$$(2.2) \quad \sigma(n+k, n+1) = M \sqrt{1 - \alpha^{2k-2} - \alpha^{n+1}(\alpha^{k-1} - \gamma^{k-1})}.$$

Define the last element stored as having lag 0, and so the  $k$ th last element stored has lag  $k-1$ . The residual impression  $\mathbf{I}_i(n+k, n+1)$  is of interest because it is nonnegative if and only if the  $i$ th bit of a word at lag  $k-1$  is stable under (1.1) after the storage of  $n+k$  words. In the transient case starting from the initial condition  $T=0$  at  $n=0$ , (called the tabula rasa case), the standard deviation for the residual impression of the  $(k-1)$ th lag work after  $k$  words are stored is  $\sigma(k, 1) \approx M \sqrt{1 - \alpha^k}$ . At steady state, the standard deviation for the residual impression of the  $(k-1)$ th lag is  $\lim_{n \rightarrow \infty} \sigma(n+k, n+1) \approx M \sqrt{1 - \alpha^{2k-2}}$ . So even if the lag is fixed, the new model shows some degradation as it approaches steady state. However, unlike the Hopfield case, the capacity does not degenerate to zero at any time.

To better understand the capacity of the new model in storing words, notice that if  $N$  is large,  $\mathbf{I}_i(n+k, n+1)$  can be approximated by a Gaussian random variable. If the word  $e_{n+1}$  is presented for retrieval after storing the  $(n+k)$ th word, one of three things may happen: (1) the system may stabilize at  $e_{n+1}$ ; (2) the system may stabilize at a state different from  $e_{n+1}$ ; (3) the system may cycle through a chain of states. Only the first case corresponds to error-free recall. The condition that  $e_{n+1}$  is a stable point is equivalent to  $\mathbf{I}_i(n+k, n+1)$  positive for all  $i$ . Let  $\phi_b$  be the  $(100b)$ th percentile point of the standard normal distribution. Let  $\text{ber}_1(n+k, n+1)$  denote the probability that  $\mathbf{I}_i(n+k, n+1)$  is negative. (By symmetry, it is easy to see that the probability is independent of  $i$ .) The term  $\text{ber}_1(n+k, n+1)$  can be thought of as the bit error rate of the word  $e_{n+1}$  if all neurons update exactly once synchronously. Under the Gaussian assumption,  $1 - \text{ber}_1(n+k, n+1) = b$  when

$$(2.3) \quad \frac{m(n+k, n+1)}{\sigma(n+k, n+1)} = \phi_b.$$

For the tabula rasa case with  $b = 0.95$ , this implies

$$\sqrt{\frac{\alpha^{2k-2}}{1 - \alpha^k}} \approx 1.64,$$

or  $\alpha^{k-1} \approx 0.78$ . At steady state, the formula becomes

$$\sqrt{\frac{\alpha^{2k-2}}{1-\alpha^{2k-2}}} \approx 1.64,$$

or  $\alpha^{k-1} \approx 0.85$ .

These expressions can be solved to yield the maximum number of words that can be stored with  $\text{ber}_1(n+k, n+1) = 0.05$ . For the tabula rasa case the result is roughly  $0.25N$ , and roughly  $0.15N$  at steady state.

Assuming the  $I_i$ 's are independent, the probability that the  $(k-1)$ th lag word stabilizes with an error,  $\text{BER}(n+k, n+1)$ , is simply

$$\text{BER}(n+k, n+1) = 1 - (1 - \text{ber}_1(n+k, n+1))^N.$$

It is clear that  $\text{BER}(n+k, n+1) \rightarrow 1$  as  $N \rightarrow \infty$ . Another quantity of interest is the probability that an arbitrary bit is in error when the retrieval process has settled to a fixed point, or that the retrieval process is oscillating, denoted  $\text{ber}_\infty(n+k, n+1)$ . The quantity  $\text{ber}_\infty(n+k, n+1)$  is hard to compute theoretically, but will be simulated and approximated in § 3.

**2.2. New model with diagonal contribution.** The new model discussed previously does not allow self-excitation ( $T_{ii}$ ) terms. Here, we want to examine their effects. Consider a second model with synaptic matrix updated by the following rules:

$$(2.4) \quad T_1^d = \frac{r}{N} S_1, \quad T_n^d = T_{n-1}^d + \frac{1}{N} (rI_N - T_{n-1}^d) S_n.$$

Then it is easy to show that  $T_n^d e_n = r e_n$ . Again, it is clear that  $r$  is simply a scaling factor, and so we choose  $r = N$ . Let  $Q_n = I_N - (S_n/N)$ . Then the update rule can be rewritten as

$$(2.5) \quad T_n^d = (T_{n-1}^d - NI_N) Q_n + NI_N.$$

Let  $\alpha_d = 1 - 1/N$ , and  $\gamma_d = 1 - 2/N + 2/N^2$ . Then the following results can be proved using techniques similar to the proof of Theorem 1.

**THEOREM 2.**

- (i)  $\mathbf{E} T_k^d = N(1 - \alpha_d^k) I_N, k \geq 1,$
- (ii)  $\mathbf{E} T_k^d T_k^{d'} = N^2(1 - \alpha_d^k) I_N, k \geq 1,$
- (iii)  $\mathbf{E} T_{n+k}^d S_{n+1} = NI_N, n \geq 0, k \geq 1,$
- (iv)  $\mathbf{E} \text{tr} T_{n+k}^d S_{n+1} T_{n+k}^{d'} = N^3(1 + \alpha_d^{n+1}(\alpha_d^{k-1} - \gamma_d^{k-1})), n \geq 0, k \geq 1.$

Theorem 2 implies that at steady state, (as  $n$  tends to infinity),  $\mathbf{E}(T_n^d - NI_N)$  ( $T_n^{d'} - NI_N$ ) =  $N^2 \alpha_d^n I_N \rightarrow 0$ . Since for a matrix  $A$ ,

$$\text{tr} AA' = \sum_{ij=1}^N A_{ij}^2,$$

this implies that  $T_n^d$  converges to  $NI_N$  with probability 1. Hence, the new model with diagonal entries collapses in the long run under the assumption of a long stream of uniform signary inputs. On the other hand, for transient use, a scheme of this type may be practical (see [2] for illustrations). It is interesting to observe that choosing  $r = 1$  and  $\eta = 1/N$  causes the new method with diagonal to coincide with the delta method of (1.3) and (1.4). Thus the result shown here regarding the convergence of  $T_n^d$  to a multiple of the identity matrix is the same as the phenomenon discussed in § 1.

**2.3. Hopfield's model.** In order to facilitate the discussion in comparing the models, we recapitulate here some results concerning Hopfield's model. The synaptic

matrix of Hopfield's model can be represented as

$$T_n^H = \sum_{i=1}^n (S_i - I_N).$$

THEOREM 3.

- (i)  $\mathbf{E} T_k^H = 0, k \geq 1,$
- (ii)  $\mathbf{E} T_k^H T_k^{H'} = kMI_N, k \geq 1,$
- (iii)  $\mathbf{E} T_{n+k}^H S_{n+1} = MI_N, n \geq 0, k \geq 1,$
- (iv)  $\mathbf{E} \text{tr} T_{n+k}^H S_{n+1} T_{n+k}^{H'} = M(M+n+k-1)N, n \geq 0, k \geq 1.$

Theorem 3 implies that the variance of  $I_i(n+k, n+1)$  is  $M(n+k-1)$ , which goes to infinity as  $n \rightarrow \infty$ . Hence, the capacity of Hopfield's model degenerates to zero for large  $n$ .

**3. Experimental results and discussion.** We now describe the experimental results, which were obtained by simulation. Three memory-storage rules were simulated: Hopfield's model (1.2), the new methods of §§ 2.1 and 2.2 (2.1) and (2.4), and the revised marginalist model ((1.6) with zero diagonal terms). In each case the model was required to store a sequence of words that were independently generated, uniform signary random strings. The state evolution rule in each case was (1.1), and the individual neurons were updated randomly and asynchronously until a fixed point or cycle was observed.

The following performance measures were instrumented as a means of relating the experimental results to the analytical results of § 2:

$\text{ber}_1(n+k, n+1)$ : The probability that the impression of an arbitrary bit is negative before any bits of the word are updated, when retrieval of the  $(n+1)$ th word stored is attempted after storage of the  $(n+k)$ th word, (i.e., lag  $k-1$ ).

$\text{ber}_\infty(n+k, n+1)$ : The probability that an arbitrary bit is recalled with error after the memory has settled to a fixed point, or that the retrieval process is oscillating (i.e., (1.1) cycles), when retrieval of the  $(n+1)$ th word stored is attempted after storage of the  $(n+k)$ th word.

$\text{BER}(n+k, n+1)$ : The block error rate, or probability that any bit of word is in error, when retrieval of the  $(n+1)$ th word stored is attempted after storage of the  $(n+k)$ th word.

Note that when the memory is presented with an exact version of a stored vector for retrieval and any bit of the word is returned in error after an application of (1.1), then the memory will either retrieve the word incorrectly or it will cycle. We count both of these events as a block error.

Figure 1 shows a transient study of the case of  $N = 100$  neurons, with 7, 10, and 15 words stored, starting from tabula rasa. We show the block error rates at lags ranging from the last word stored back to the first. The results are shown for Hopfield's and the new method (without diagonal). As expected it is seen that Hopfield's method maintains an error rate independent of the lag, but increasing sharply as more words are stored. The new method shows errors that, as expected for a short-term memory, increase as a function of lag. The new method significantly outperforms Hopfield's for recent lags and is superior except for the most distant three or four words. The results were obtained using 1000-5000 ensemble averages.

Figure 2 is another transient study where the lag is fixed at 2 (i.e., the third last word stored is attempted for retrieval),  $N = 30$  neurons, and 80 words are stored. In this case both  $\text{BER}$  and  $\text{ber}_\infty$  results are shown. These results verify the statement in § 2 that as more words are stored, Hopfield's method quickly collapses ( $\text{BER}$

FIG. 1. Transient block error rates as a function of lag, starting from tabula rasa, for Hopfield and new methods. ( $N = 100$  neurons.)

approaches 1 when 25 words have been stored), whereas the new method settles to a bit error rate of about 5 percent and a block error rate of about 30 percent. For these results 1000 ensemble averages were used for each point.

As discussed in § 1, a second type of collapse of a short-term autoassociative memory is exhibited by the new method with diagonal, or the delta method. Figure 3 demonstrates this behavior. In this case, since the synaptic matrix is converging towards a multiple of the identity matrix (Theorem 2) it is necessary to test the ability of the memory to correct errors, or to perform autoassociative recall from the presentation of part of a word. In Fig. 3 we show results from the attempted retrieval of a word with  $b = 1, 2,$  or  $3$  bit errors introduced (at random). Shown is the probability that the iteration (1.1) (random and asynchronous updates) fails to converge to the exact initially stored word. This is denoted in Fig. 3 as  $BER_{\infty}$ , to emphasize the fact that (1.1) is iterated. Again, cycles are recorded as block errors and 1000 ensemble averages are used. It is seen that the new method with diagonal, which is equivalent to the delta method, is initially quite effective but quickly reaches a point where it is unable to correct any bit errors and consequently has  $BER_{\infty} = 1$ . In contrast, the new method without diagonal is able to correct errors at steady state.

Figures 4(a) and 4(b) concentrate on short-term memories at steady state ( $n \rightarrow \infty$ ) and compare the performance of the new method with the revised marginalist method ([13] with  $\varepsilon = 4.108$ ). These results do not utilize ensemble averages but instead use

FIG. 2. Transient error rates at lag two (i.e., third last element stored), as a function of number of words stored, for the Hopfield and new methods. ( $N = 30$  neurons.)

running averages collected over long runs (allowing 200,000 to 1,000,000 observations) but after first discounting a warming-up period. Figure 4a considers the case of  $N = 30$  neurons and shows BER and  $ber_{\infty}$  for the new and revised marginalist method. Both show good performance as short-term memories. The new method exhibits smaller settled bit errors except at lags 1 and 2 and smaller block errors except at lag 1. Figure 4b repeats the experiment for  $N = 100$  and shows results for BER and  $ber_{\infty}$ , although in this case the new method was observed to have smaller settled bit error rates except at lags 2 through 6, and uniformly smaller block error rates. (See also Note Added in Proof.)

In the remainder of this section we discuss experimental results that relate back to the analysis carried out in § 2. We compare the  $ber_1$  results observed in the simulations with the results predicted using the assumption of a Gaussian distribution as proposed in § 2. The Tables 1, 2, and 3 for cases  $N = 10, 30,$  and  $100,$  respectively, report the results in their columns 1 and 2. It is seen that the approximation works well when ( $ber_1$ ) bit error rates are at least 10 percent for the case of  $N = 10,$  down to at least 2 percent for the case of  $N = 100.$  Thus this approximation might be stated to be quite accurate for the case of a large number of neurons, and particularly when the threshold bit error rate which is associated with “nominal capacity” is not too small. However, for small numbers of neurons and/or very low error rate regimes the error might be significant. It could be argued that the case of a small number of neurons is not as challenging to the investigator since these systems are easily simulated to high accuracy.

FIG. 3. Transient error rates at lag one (i.e., second last element stored), as a function of number of words stored, when the word presented for retrieval has  $b$  bit errors. Shown are the new method without and with diagonal, the latter being a delta storage rule. ( $N = 30$  neurons.)

The second analytical approximation we investigate in the tables refers to the computation of block error rates, or BER. As described in § 2, if we are willing to make an assumption of independence between bit errors in a word, the result  $BER = 1 - (1 - ber_1)^N$  is obtained. The quality of this approximation is shown in columns 3 and 4 of the tables, with and without the effect of the Gaussian approximation. That is, column 4 uses the independence assumption on the observed  $ber_1$  values, whereas column 3 uses it on the theoretically predicted  $ber_1$  values. Column 5 shows the observed values. It is seen that the independence assumption does introduce some errors at the lower error rates. The agreement between the theoretical (column 3) and observed (column 5) is seen to be fairly good, partly due to a fortuitous cancellation of errors. It should also be noted that the methodology of § 2 allows the theoretical BER results to be calculated without recourse to the independence assumption. However, this procedure involves the numerical evaluation of a multidimensional integral (first orthant probability of a Gaussian distribution), which we decided to avoid.

Our final topic in this section discusses the prospects for the computation of the  $ber_\infty$ , or settled bit error rate, statistics. Let  $ber_\infty(j)$  denote  $\lim_{n \rightarrow \infty} ber_\infty(n+j+1, n+1)$ , and  $BER(j)$  denote  $\lim_{n \rightarrow \infty} BER(n+j+1, n+1)$ . Then,

$$ber_\infty(j) = E[\text{settled bit errors at lag } j | \text{block error at lag } j] BER(j) / N.$$

We observed that the above conditional error rate was quite large, implying that when

FIG. 4(a). Steady state error rates as a function of lag, for revised marginalist and new methods. ( $N = 30$  neurons.)

a block error occurred the model settled to a point far from the stored value we were trying to retrieve, i.e., the stored word was completely or almost completely lost from the memory, and convergence to another quite different stored word or spurious state occurred. The ranges of observed values are recorded in Table 4; the ranges noted are those observed as the lag varies. A simple explanation for and estimate of these observed values can be obtained as follows. If we were to ignore the erroneous and spurious words stored, then the expected number of words stored would be  $p$  pairs, where  $p = \sum_{i=0}^{\infty} (1 - \text{BER}(i))$ —the pairs arise from the observation that a word and its complement are always both fixed points of (1.1). Then when a block error occurs, we assume that the word stored is completely lost and that the memory settles to the nearest in Hamming distance of  $p$  randomly chosen words. Thus the expected number of bit errors  $Q$  given that a block error occurs is given by

$$Q = \sum_{k=0}^{\lfloor N/2 \rfloor - 1} \left( 1 - 2 \sum_{j=0}^k \binom{N}{j} \left( \frac{1}{2} \right)^N \right)^p.$$

Computational experience suggests that this expression is relatively insensitive to  $p$  in the neighborhood of its estimate given above. The values of  $Q/N$  are given in Table 4 and show a rough approximation to the observed rates. Thus combining this with

FIG. 4(b). Steady state error rates as a function of lag, for revised marginalist and new methods. ( $N = 100$  neurons.)

the previous methodology for finding the block error rate BER we obtain a rough method of calculation of the settled bit error rate  $\text{ber}_{\infty}$ .

**4. Conclusion.** The proposed neural network memory exhibits the behavior required of a short-term memory and its capacity compares favorably with previously proposed approaches. Its derivation is based on the simple and intuitive principle that the last word stored should be remembered correctly. The model's qualitative behavior is well explained by an analysis based on the mean and variance of the bit impression. Further work is needed to investigate the potential role of memories such as these in hierarchical memory systems and connectionist architectures.

**Appendix.** To prove Theorem 1, we need some simple algebraic formulas summarized in the following lemma.

LEMMA A: Let  $z' = (z_1, \dots, z_N)$ , where  $z_i$ 's are independent uniform signary random variables,  $S = zz'$  and  $R = I_N - (1/M)S$ . Let  $X, Y$  be  $N$ -by- $N$  matrices with coefficients independent of the  $z_i$ 's. Let  $E_z$  denote the expectation taken with respect to variables  $z_1, \dots, z_N$  only. Then

- (i)  $E_z R X R = (1 - 1/M)^2 X + (1/M^2)(X' + (\text{tr } X)I_N - 2\langle X \rangle)$ .
- (ii)  $E_z \langle X R \rangle Y R = E_z \langle R X' \rangle Y R = (1 - 2/M + 1/M^2)\langle X \rangle Y + (1/M^2)(\langle Y \rangle X + \langle X Y' \rangle - 2\langle X \rangle \langle Y \rangle)$ .
- (iii)  $E_z \langle X R \rangle^2 = (1 - 2/M)\langle X \rangle^2 + (1/M^2)\langle X X' \rangle$ .

*Proof.* To prove (i), note that

$$E_z R X R = \left(1 - \frac{2}{M}\right) X + \frac{1}{M^2} E_z S X S,$$

$$E_z S X S = \left(E_z z_i z_j \sum_{k,l=1}^N X_{kl} z_k z_l\right).$$

Part (i) follows from

$$E_z z_i z_j \sum_{k,l=1}^N X_{kl} z_k z_l = \begin{cases} X_{ij} + X_{ji}, & i \neq j, \\ \sum_{k=1}^N X_{kk}, & i = j. \end{cases}$$

The other results can be proved similarly.  $\square$

From now on we assume the symbols and notation defined in § 2. For  $k \geq 1$ , define  $\tilde{T}_k = T_k - M I_N$  and  $R_k = I_N - (1/M)S_k$ . Then, (2.1) can be rewritten as

$$T_k = \tilde{T}_{k-1} R_k - \langle \tilde{T}_{k-1} R_k \rangle.$$

Let  $E_k$  represent expectation taken with respect to variables  $e_k^1, \dots, e_k^N$  only.

*Proof of Theorem 1(i).* Clearly  $E T_1 = 0$ . The result follows by induction, since if  $E T_{k-1} = 0$ , then

$$E T_k = E \tilde{T}_{k-1} R_k - E \langle \tilde{T}_{k-1} R_k \rangle = \left(1 - \frac{1}{M}\right) (E \tilde{T}_{k-1} - E \langle \tilde{T}_{k-1} \rangle) = \left(1 - \frac{1}{M}\right) E T_{k-1} = 0. \quad \square$$

*Proof of Theorem 1(ii).* It is easy to see that  $E T_1 T_1' = M I_N = M^2(1 - \alpha) I_N$ . For  $k > 1$ ,

$$(A1) \quad \begin{aligned} E \tilde{T}_k \tilde{T}_k' &= E T_k T_k' + M^2 I_N \\ &= E \tilde{T}_{k-1} R_k^2 \tilde{T}_{k-1}' - E \langle \tilde{T}_{k-1} R_k \rangle R_k \tilde{T}_{k-1}' - E \tilde{T}_{k-1} R_k \langle R_k \tilde{T}_{k-1}' \rangle + E \langle \tilde{T}_{k-1} R_k \rangle^2 + M^2 I_N. \end{aligned}$$

Since  $E R_k^2 = (1 - 1/M + 1/M^2) I_N$ , the first term of the right-hand side of (A1) simplifies to  $(1 - 1/M + 1/M^2) \tilde{T}_k \tilde{T}_k'$ . Now let  $Y$  in Lemma A(ii) be the identity matrix. It follows that

$$\begin{aligned} E \langle \tilde{T}_{k-1} R_k \rangle R_k \tilde{T}_{k-1}' &= E (E_k \langle \tilde{T}_{k-1} R_k \rangle R_k) \tilde{T}_{k-1}' \\ &= \left(1 - \frac{2}{M}\right) E \langle \tilde{T}_{k-1} \rangle \tilde{T}_{k-1}' + \frac{1}{M^2} E \tilde{T}_{k-1} \tilde{T}_{k-1}' \\ &= \left(1 - \frac{2}{M}\right) M^2 I_N + \frac{1}{M^2} E \tilde{T}_{k-1} \tilde{T}_{k-1}'. \end{aligned}$$

Since  $\tilde{T}_{k-1}R_k\langle R_k\tilde{T}'_{k-1}\rangle$  is the transpose of  $\langle\tilde{T}_{k-1}R_k\rangle R_k\tilde{T}'_{k-1}$ , the second and third term of the right-hand side of (A1) are equal. Applying Lemma A(iii) to the fourth term, we have the following equation:

$$\mathbf{E}\tilde{T}_k\tilde{T}'_k = \left(1 - \frac{1}{M} - \frac{1}{M^2}\right)\mathbf{E}\tilde{T}_{k-1}\tilde{T}'_{k-1} + \frac{1}{M^2}\mathbf{E}\langle\tilde{T}_{k-1}\tilde{T}'_{k-1}\rangle + 2MI_N.$$

Using this relation, it is easy to show by induction that  $\mathbf{E}\tilde{T}_k\tilde{T}'_k = \mathbf{E}\langle\tilde{T}_k\tilde{T}'_k\rangle$  for all  $k$ . Hence, letting  $\alpha = 1 - 1/M$ , we have

$$\begin{aligned} \mathbf{E}\tilde{T}_k\tilde{T}'_k &= \left(1 - \frac{1}{M}\right)\mathbf{E}\tilde{T}_{k-1}\tilde{T}'_{k-1} + 2MI_N \\ &= \alpha^{k-1}\mathbf{E}\tilde{T}_1\tilde{T}'_1 + 2M(1 + \dots + \alpha^{k-2})I_N \\ &= M^2(2 - \alpha^k)I_N. \end{aligned} \quad \square$$

*Proof of Theorem 1(iii).* For  $k > 1$ ,

$$\begin{aligned} \mathbf{E}\tilde{T}_{n+k}S_{n+1} &= \mathbf{E}\tilde{T}_{n+k-1}R_{n+k}S_{n+1} - \mathbf{E}\langle\tilde{T}_{n+k-1}R_{n+k}\rangle S_{n+1} - MI_N \\ &= \left(1 - \frac{1}{M}\right)\mathbf{E}\tilde{T}_{n+k-1}S_{n+1} + \left(M\left(1 - \frac{1}{M}\right) - M\right)I_N \\ &= \alpha^{k-1}\mathbf{E}\tilde{T}_{n+1}S_{n+1} - (1 + \dots + \alpha^{k-2})I_N \\ &= M(\alpha^{k-1} - 1)I_N, \end{aligned}$$

since  $\mathbf{E}T_{n+1}S_{n+1} = MI_N$ . It follows for  $k \geq 1$  that

$$\mathbf{E}T_{n+k}S_{n+1} = M\alpha^{k-1}I_N. \quad \square$$

*Proof of Theorem 1(iv).* The result clearly holds for  $k = 1$ . For  $k > 1$ ,

$$\begin{aligned} \mathbf{E} \operatorname{tr} T_{n+k}S_{n+1}T'_{n+k} &= \mathbf{E} \operatorname{tr} T'_{n+k}T_{n+k}S_{n+1} \\ &= \mathbf{E} \operatorname{tr} R_{n+k}\tilde{T}'_{n+k-1}\tilde{T}_{n+k-1}R_{n+k}S_{n+1} \\ \text{(A2)} \quad &\quad - \mathbf{E} \operatorname{tr} \langle R_{n+k}\tilde{T}'_{n+k-1}\rangle\tilde{T}_{n+k-1}R_{n+k}S_{n+1} \\ &\quad - \mathbf{E} \operatorname{tr} R_{n+k}\tilde{T}'_{n+k-1}\langle\tilde{T}_{n+k-1}R_{n+k}\rangle S_{n+1} + \mathbf{E} \operatorname{tr} \langle\tilde{T}_{n+k-1}R_{n+k}\rangle^2 S_{n+1}. \end{aligned}$$

Applying Lemma A(i) to the first term, we have

$$\begin{aligned} \text{First term} &= \mathbf{E} \operatorname{tr} \tilde{T}_{n+k-1}(\mathbf{E}_k R_{n+k}S_{n+1}R_{n+k})\tilde{T}'_{n+k-1} \\ &= \left(1 - \frac{2}{M} + \frac{2}{M^2}\right)\mathbf{E} \operatorname{tr} \tilde{T}_{n+k-1}S_{n+1}\tilde{T}'_{n+k-1} + \left(\frac{1}{M} - \frac{1}{M^2}\right)\mathbf{E} \operatorname{tr} \tilde{T}_{n+k-1}\tilde{T}'_{n+k-1}. \end{aligned}$$

Applying Lemma A(ii) and Theorem 1(iii), we have

$$\begin{aligned} &\mathbf{E} \operatorname{tr} \langle R_{n+k}\tilde{T}'_{n+k-1}\rangle\tilde{T}_{n+k-1}R_{n+k}S_{n+1} \\ &= \left(1 - \frac{2}{M} + \frac{2}{M^2}\right)\mathbf{E} \operatorname{tr} \langle\tilde{T}_{n+k-1}\rangle\tilde{T}_{n+k-1}S_{n+1} \\ &\quad + \frac{1}{M^2}(\mathbf{E} \operatorname{tr} \langle\tilde{T}_{n+k-1}\tilde{T}'_{n+k-1}\rangle S_{n+1} - 2\mathbf{E} \operatorname{tr} \langle\tilde{T}_{n+k-1}\rangle^2 S_{n+1}) \\ &= (M-2)MN - (M^2 - 2M + 2)N\alpha^{k-2} + \frac{1}{M^2}\mathbf{E} \operatorname{tr} \tilde{T}_{n+k-1}\tilde{T}'_{n+k-1}. \end{aligned}$$

Since the third term on the right-hand side of (A2) is equal to  $\mathbf{E} \operatorname{tr} S_{n+1} R_{n+k} \tilde{T}'_{n+k-1} \langle \tilde{T}_{n+k-1} R_{n+k} \rangle$ , it is equal to the second term. Finally, by applying Lemma A(iii), we have

$$\text{Fourth term} = (M-2)MN + \frac{1}{M^2} \mathbf{E} \operatorname{tr} \tilde{T}_{n+k-1} \tilde{T}'_{n+k-1}.$$

So, letting  $\gamma = 1 - 2/M + 2/M^2$ , and using Theorem 1(ii),

$$\begin{aligned} \mathbf{E} \operatorname{tr} T'_{n+k} T_{n+k} S_{n+1} &= \gamma \mathbf{E} \operatorname{tr} \tilde{T}'_{n+k-1} \tilde{T}_{n+k-1} S_{n+1} + \left( \frac{1}{M} - \frac{2}{M^2} \right) M^2 (2 - \alpha^{n+k-1}) N \\ &\quad + (2\gamma M^2 \alpha^{k-2} - (M-2)M) N \\ &= \gamma \mathbf{E} \operatorname{tr} T'_{n+k-1} T_{n+k-1} S_{n+1} + (2 + (M-2)(2 - \alpha^{n+k-1})) N \\ &= \gamma^{k-1} \mathbf{E} \operatorname{tr} T'_{n+1} T_{n+1} S_{n+1} + 2(M-1)N(1 + \dots + \gamma^{k-2}) \\ &\quad - (M-2)N(\alpha^{n+k-1} + \alpha^{n+k-2}\gamma + \dots + \alpha^{n+1}\gamma^{k-2}) \\ &= M^2 N(1 - \alpha^{n+1}(\alpha^{k-1} - \gamma^{k-1})). \quad \square \end{aligned}$$

**Acknowledgments.** The authors thank S. Solla for her careful reading of this paper. We are also greatly indebted to a conscientious referee who made numerous suggestions that resulted in a much better paper.

**Note Added in Proof.** A generalization of the above new method which exhibits further improved performance is described in "A Decentralized Tunable Short Term Neural Network Memory and Application to Tracking", R. J. T. Morris, L. D. Rubin, and W. S. Wong, Second International Conference on Neural Networks, San Diego, CA, July 24-27, 1988.

## TRANSITIVE ORIENTATIONS OF GRAPHS\*

BÉLA BOLLOBÁS<sup>†‡</sup> AND GRAHAM BRIGHTWELL<sup>†</sup>

**Abstract.** Suppose that we have a set  $X$  of  $n$  objects in some unknown total order  $<$ . For  $G$  a graph on  $X$ , we ask, for each edge  $xy$ , "Is  $x < y$ ?" On processing the information thus gained we may be able to deduce more comparisons. The information we have is then in the form of a partial order  $P(G; <)$ . Let  $t(G)$  denote the maximum, over all linear orders  $<$  on  $X$ , of the number of pairs *not* related in  $P(G; <)$ ; and let  $t(n, p)$  denote the minimum of  $t(G)$  over all graphs  $G$  with  $n$  vertices and  $\lfloor pn^2/2 \rfloor$  edges. We find upper and lower bounds for  $t(n, p)$  throughout the range of  $p = p(n)$ .

**Key words.** graph, sorting algorithm, comparison sorting, orientations

**AMS(MOS) subject classifications.** 68R10, 68Q20, 05C80

**1. Introduction.** We are concerned with 2-round sorting problems of the following type. Suppose that we have a set  $V$  of size  $n$  in an unknown order  $<$ . We wish to ask a set of  $\lfloor pn^2/2 \rfloor$  questions all at once, such that no matter what answers we get we can deduce all but at most  $t(n, p)$  of the  $\binom{n}{2}$  relations. We can then, in the second round, complete our sort by asking at most  $t(n, p)$  questions. How large need  $t(n, p)$  be? Here a *question* or *probe* is a pair  $(a, b)$  of objects, and the answer reveals whether  $a < b$  or  $b < a$ .

As the probes have to be made simultaneously, the set of probes can be thought of as a graph on  $V$ . We can thus reformulate our problem in terms of graphs. Given a graph  $G = (V, E)$  of order  $n = |G|$  and size  $e(G)$ , say, consider an acyclic orientation of the edges. Let  $\vec{G} = (V, \vec{E})$  be the directed graph obtained in this way and let  $C(\vec{G})$  be the *acyclic closure* of  $\vec{G}$ :  $\vec{xy}$  is an arc of  $C(\vec{G})$  if  $\vec{G}$  contains a directed path from  $x$  to  $y$ . As every acyclic orientation of  $G$  is induced by a total order on  $V$ , we may assume that  $\vec{E}$  is induced by a total order  $<$  on  $V$ . The arcs of  $C(\vec{G})$  define a partial order  $P(G; <)$ ; we call  $P(G; <)$  the *transitive orientation* of  $G$  associated with  $<$ . So  $x < y$  in  $P(G; <)$  if there are elements  $x_1, x_2, \dots, x_r$  of  $V(G)$  such that  $x = x_1 < x_2 < \dots < x_r = y$  and  $x_i x_{i+1}$  is an edge of  $G$  for  $1 \leq i < r$ .

Thus we are interested in graphs  $G$  such that every transitive orientation of  $G$  contains many relations. Let  $r(G; <)$  denote the number of relations in  $P(G; <)$ , and let  $t(G) = \max_{<} \{ \binom{n}{2} - r(G; <) \}$ ; i.e.,  $t(G)$  is the maximum over all orders  $<$  of the number of pairs not related in  $P(G; <)$ . The question we are interested in is the following. For a graph  $G$  with  $n$  vertices and  $\lfloor pn^2/2 \rfloor$  edges, how small can  $t(G)$  be? Accordingly, let  $t(n, p) = \min \{ t(G) : |G| = n, e(G) = \lfloor pn^2/2 \rfloor \}$ . Our aim is to give bounds on  $t(n, p)$  throughout the range of  $p$ . (The notation  $t(n, p)$  is intended to suggest that the problem is closely related to random graphs, and a random graph of order  $n$ , with probability  $p$  of an edge, has about  $pn^2/2$  edges.)

One particular version of this problem is the following. How many questions do we have to ask in order to ensure that, when we know the answers to these questions, we will know all but  $o(n^2)$  of the relations? In other words, how large must  $p(n)$  be before  $t(n, p)$  becomes  $o(n^2)$ ? This question was proposed by Rabin (see [7]), and considered by the present authors [6] as well as by Ajtai et al. [1], and by Alon, Azar, and Vishkin [4].

<sup>‡</sup> The work of this author was partially supported by MCS grant 8104854.

Related problems have been studied by Bollobás and Rosenfeld [8], Häggkvist and Hell [12]–[14], Ajtai, Komlós, and Szemerédi [2], [3], Bollobás and Thomason [9], and others (see Bollobás and Hell [7] and Bollobás [5]).

A slightly extended version of this paper, together with [6], occurs as § 8 of the second author’s thesis [10].

Before embarking on the results, we recall the concept of a random graph. Let  $G_{n,p} \equiv G_p$  denote a random graph on  $n$  vertices, with each pair of vertices joined by an edge with probability  $p = p(n)$ , each pair considered independently. We say that *almost every*  $G_p$  has property  $Q$ , or that  $Q$  holds *almost surely*, if the probability that  $G_{n,p}$  has  $Q$  tends to 1 as  $n \rightarrow \infty$ . For the general theory of random graphs, the reader is referred to Bollobás [5].

We note here one more piece of terminology: if  $x_1 x_2 \cdots x_r$  is a chain in  $P(G; <)$ , we say that the chain *spans*  $s$  vertices if there are precisely  $s$  vertices between  $x_1$  and  $x_r$  in  $<$ .

**2. Summary of results.** The function  $t(n, p)$  exhibits very different behaviour in three different ranges of  $p = p(n)$ . Of course, the boundaries of these ranges are chosen somewhat arbitrarily. We deal first with the middle range, with  $\frac{1}{3} \cong p \cong c \log n \log \log n / n \log \log \log n$ , it seems that almost every  $G_{n,p}$  has  $t(G_{n,p})$  close to  $t(n, p)$ . In this range, we shall prove the following general bound.

$$(1) \quad c_1 n p^{-1} \log n \leq t(n, p) \leq c_2 n p^{-1} \log(np) \log(p^{-1}).$$

(Here and throughout  $c, c_1, c_2$ , etc., are unspecified absolute constants.) It seems likely that, at any rate for most of this range, the correct order of magnitude of  $t(n, p)$  is  $n p^{-1} \log(np) \log(p^{-1}) / \log \log(np)$ . We offer several pieces of evidence in support of this conjecture: see also the remark after Theorem 8. First, we prove that, if  $p > (\log n)^3 / n$  and  $p(n) \rightarrow 0$  then, for almost every  $G_p$ ,

$$(2) \quad t(G_{n,p}) \cong \frac{c n p^{-1} \log(np) \log(p^{-1})}{\log \log(np)}.$$

In [6, Thms. 1 and 5] we proved that, for the special case  $p = \alpha \log n \log \log n / n \log \log \log n$ , with  $\alpha > 100$  a constant, that, for almost every  $G_p$ ,

$$(3) \quad \frac{n^2}{4\alpha^2} \leq t(G_{n,p}) \leq \frac{4n^2}{\alpha^{1/2}},$$

which fits in with our conjecture, and for the other end of the range we prove in this paper that our estimate is correct: if  $\frac{1}{3} \cong p \cong c_2^{-1} \log \log n / \log n$ , then

$$(4) \quad c_1 n p^{-1} \log n \leq t(n, p) \leq c_2 n p^{-1} \log n.$$

Alon, Azar, and Vishkin [4, Thm. 3.3] assert, essentially, that for  $p = c_1 n^{-1/2} \log n / (\log \log n)^{1/2}$ , we have

$$(5) \quad t(n, p) \leq \frac{c_2 n^{3/2} \log n}{(\log \log n)^{1/2}},$$

which serves to provide evidence in favour of our conjecture.

Let us give two special cases of (1). If  $p = n^{-r}$ , where  $r$  is a constant strictly between 0 and 1, we have:

$$(6) \quad c_1 n^{1+r} \log n \leq t(n, p) \leq c_2 n^{1+r} (\log n)^2,$$

and if  $p = r \log n / n$ , where  $\log \log n \leq r \leq (\log n)^s$ , then our “gap” is just  $O(\log \log n)$ :

$$(7) \quad \frac{c_1 n^2}{r} \leq t(n, p) \leq (s+1) c_2 \frac{n^2}{r} \log \log n.$$

In [10], we proved that if  $p \geq \alpha(n) \log n \log \log n / n \log \log \log n$ , where  $100 \leq \alpha(n) \leq (\log \log n)^{1/4}$ , then

$$(8) \quad t(n, p) \leq \frac{4n^2}{\alpha^{1/2}},$$

whereas ([6, Thm. 6], also Alon, Azar, and Vishkin [4, Prop. 3.5(i)], and Ajtai et al. [1, Thm. 2]), if  $p \leq c \log n / n$ , then

$$(9) \quad t(n, p) \geq \binom{n}{2} \max \left\{ \frac{4}{3c+5}, \left(1 - \frac{c}{2}\right) \left|1 - \frac{c}{2}\right| (1 - \varepsilon) \right\}.$$

Thus for smaller  $p$  the nature of the question changes, and we ask instead for the order of magnitude of  $r(n, p) = \binom{n}{2} - t(n, p)$ , the maximum number of relations a graph with  $n$  vertices and  $\lfloor pn^2/2 \rfloor$  edges can guarantee us. Here the graphs giving our lower bound are of the following form. We use about half of the edges to form a random graph on a set  $R$  of the vertices, with  $|R| = r$ , with  $r$  chosen just small enough to guarantee that, in every transitive orientation of  $G[R]$ , at least  $(8/9)\binom{r}{2}$  of the pairs of vertices of  $R$  are related. Other vertices of  $G$  have degree 1, sending one edge to  $R$ . Thus, in every transitive orientation, most of these vertices are related to a positive proportion of the vertices of  $R$ . By considering graphs of the above form, we prove the following results. For  $\frac{1}{4} \log n / n \geq p \geq 4/n$ , we have

$$(10) \quad \frac{c_1 n^3 p}{\log n} \geq \binom{n}{2} - t(n, p) \geq \frac{c_2 n^3 p \log \log \log n}{\log n \log \log n},$$

and for  $m = \lfloor pn^2/2 \rfloor \leq 2n$ , we have

$$(11) \quad \frac{c_1 m^2}{\log m} \geq \binom{n}{2} - t(n, p) \geq \frac{c_2 m^2 \log \log \log m}{\log m \log \log m}.$$

The final case we have to consider is the range  $p \geq \frac{1}{3}$ . This is covered by the following result. We prove that there are absolute constants  $d_1$  and  $d_2$  such that, whenever  $m \leq \frac{2}{3}\binom{n}{2}$ , we have

$$(12) \quad d_1 m^{1/2} \log m \leq t\left(n, 1 - m / \binom{n}{2}\right) \leq d_2 m^{1/2} \log m.$$

Also in this case random graphs  $G_p$  almost surely do not have  $t(G_{n,p})$  attaining the bound  $t(n, p)$ , up to a constant. Rather, we prove the upper bound in (12) by considering graphs where the  $m$  non-edges form a random graph on a set of  $cm^{1/2}$  vertices, and every other vertex has degree  $n - 1$ .

There are thus a variety of results in this paper, and it might be hoped that some of the ‘‘gaps’’ between our lower and upper bounds could be closed.

**3. The middle range.** Our first step in proving the results is to investigate a technique which gives a good lower bound for  $t(G)$  for many graphs  $G$ . If we have a set  $X$  of  $n$  objects,  $s$  of which are red, and we totally order  $X$  by  $<$ , then a *run* of red objects is simply an interval in  $(X, <)$  all elements of which are red. If a vertex  $x$  of our graph has many non-neighbours (the red vertices) in a set  $X$ , then, on taking a random ordering  $<$  of  $X$ , we shall find, with high probability, a longish run of non-neighbours; we can then find an extension of  $<$  to  $V(G)$  in which  $x$  is not related to any of these non-neighbours. What is more, we can do this simultaneously for many vertices  $x$  of our graph, thus yielding many pairs unrelated in  $P(G; <)$ . We first need an elementary

lemma concerning the existence of a long run. This is, of course, a well-known combinatorial problem, and variations of Lemma 1 can be found in several textbooks (for instance, David and Barton [11]). Some details are omitted in the proof.

LEMMA 1. *Suppose  $0 \leq l \leq s < n$  and  $2l + 1 < n$ . Let  $X$  be a set of  $n$  objects,  $s$  of which are red. If we take a random total ordering  $<$  of  $X$ , all orderings being equiprobable, then the probability that there is a run of  $l$  red objects in  $(X, <)$  is at least*

$$1 - \left(\frac{n-l}{s-l}\right)^l (n-s)^{-1} - \frac{2l+1}{n-2l-1}.$$

Furthermore, there is an  $n_0$  such that if  $n \geq n_0$  and  $l \leq \lfloor \log(\frac{1}{5}(n-s))/\log(n/s) \rfloor$ , then this probability is at least  $\frac{1}{2}$ .

*Proof.* Without loss of generality  $X$  is the set  $[n] = \{1, 2, \dots, n\}$ , the ordering  $<$  is the usual total ordering of  $[n]$ , and we are selecting the  $s$  red elements at random from  $[n]$ . Let  $M$  be the number of elements  $m \in [n]$  such that  $m$  is not red but  $m+1, m+2, \dots, m+l$  are. The random variable  $M$  thus depends on the set of red elements of  $[n]$ .

We see that

$$\mathbb{E}M = (n-l) \binom{n-l-1}{s-l} / \binom{n}{s},$$

and

$$\mathbb{E}M^2 \leq \mathbb{E}M + (n-l)^2 \binom{n-2l-2}{s-2l} / \binom{n}{s},$$

where  $\mathbb{E}$  denotes expectation. Hence by Chebyshev's inequality

$$\begin{aligned} P(M=0) &\leq \frac{\mathbb{E}M^2 - (\mathbb{E}M)^2}{(\mathbb{E}M)^2} \\ &\leq \frac{1}{\mathbb{E}M} + \left[ \binom{n}{s} \binom{n-2l-2}{s-2l} / \binom{n-l-1}{s-l}^2 - 1 \right]. \end{aligned}$$

Expanding the binomial coefficients and rearranging, we find that

$$\begin{aligned} P(M=0) &\leq \frac{1}{\mathbb{E}M} + \left[ \frac{(n-1)(s-l)}{(n-l-1)s} \cdot \frac{(n-2)(s-l-1)}{(n-l-2)(s-1)} \right. \\ &\quad \left. \dots \frac{(n-l)(s-2l+1)}{(n-2l)(s-l+1)} \cdot \frac{n}{n-2l-1} - 1 \right] \\ &\leq \frac{1}{\mathbb{E}M} + \frac{2l+1}{n-2l-1}. \end{aligned}$$

But

$$\mathbb{E}M \geq (n-s) \binom{s-l}{n-l}.$$

So

$$P(M=0) \leq \left(\frac{n-l}{s-l}\right)^l (n-s)^{-1} + \frac{2l+1}{n-2l-1},$$

as desired.

It is straightforward but tedious to check the second assertion, namely that for  $n$  sufficiently large and  $l = \lfloor \log(\frac{1}{5}(n-s))/\log(n/s) \rfloor$ , the expression above is at most  $\frac{1}{2}$ . For details see [10].  $\square$

Now we show how Lemma 1 can be used to find transitive orientations  $<$  of our graph  $G$  in which many pairs are unrelated.

**THEOREM 2.** *Let  $G$  be any graph. Suppose there are subsets  $U$  and  $W$  of  $V(G)$  of sizes  $|U| = u$  and  $|W| = w$ , respectively, such that every vertex of  $U$  sends at least  $\gamma$  non-edges to  $W$  (i.e., sends at most  $w - \gamma$  edges to  $W$ ) and  $w \geq n_0$ . Then  $t(G) \geq \frac{1}{2}ul(w, \gamma)$ , where*

$$l = l(w, \gamma) = \left\lfloor \frac{\log(\frac{1}{3}(w - \gamma))}{\log(w/\gamma)} \right\rfloor.$$

*Proof.* Consider a random total ordering of  $W$  (all orderings equiprobable), and let  $x$  be a vertex in  $U$ . By Lemma 1, with the “red” vertices as the elements of  $W$  which are non-neighbours of  $x$ , the probability that there is a run of  $l$  non-neighbours is at least  $\frac{1}{2}$ . Hence the expected number of vertices of  $U$  with a run of at least  $l$  non-neighbours is at least  $u/2$ . We now fix an ordering  $<$  of  $W$  such that the set  $X$  of vertices in  $U$  which do have a run of  $l$  non-neighbours in  $(W, <)$  has order at least  $u/2$ . Without loss of generality  $(W, <) = [w]$ . For each  $x \in X$ , fix some  $k(x)$  such that  $x$  is adjacent to  $k(x)$  but to none of  $k(x) + 1, \dots, k(x) + l$ .

We now extend  $<$  to a total order of  $V(G)$  as follows:

- (i) The order  $<$  remains unaltered on  $W$ .
- (ii) We choose any total order on  $V(G) \setminus (W \cup X)$ , and set  $(V(G) \setminus (W \cup X)) < W \cup X$ .
- (iii) For each  $x \in X$ , we set  $k(x) < x < k(x) + 1$ .
- (iv) We order each of the sets  $\{x \in X : k(x) = k\}$  in any way.

This is clearly an extension of  $<$  to a total order of  $V(G)$ . Also, each  $x \in X$  is incomparable with all of  $k(x) + 1, \dots, k(x) + l$  in  $P(G; <)$ . Indeed, if  $y \in X$  is above  $x$  in  $<$ , then  $k(y) \geq k(x)$ , and so  $y$  is not less than any vertex of  $W$  below  $k(y) + l$ , which is at least  $k(x) + l$ .

Therefore the  $|X|l$  relations  $x < k(x) + j$ , for  $x \in X$  and  $1 \leq j \leq l$ , are in  $<$  but not in  $P(G; <)$ , and therefore  $t(G) \geq |X|l \geq \frac{1}{2}ul$ , as desired.  $\square$

We shall make use of Theorem 2 both for large and medium values of  $p$ . We shall first consider the middle range, with  $p \leq \frac{1}{3}$  and  $pn/\log n \geq \frac{1}{2}$ . In this range, as mentioned earlier, it turns out that the upper bounds given by considering random  $G_p$ 's are at least close to best possible. Let us first prove the lower bound for  $t(n, p)$  given by (1). This in fact requires two quite different techniques, useful for different ranges of  $p$ . The first bound we prove, using Theorem 2, is good for fairly large  $p$ . Here and throughout, we omit integrality signs, which do not affect the argument. All our inequalities are claimed to hold only for  $n$  sufficiently large, even when this is not explicitly stated.

**THEOREM 3.** *If  $np \rightarrow \infty$ , and  $p \leq \frac{1}{3}$ , then  $t(n, p) \geq (1/30)np^{-1} \log(np)$ , for  $n$  sufficiently large, say  $n \geq n_1$ .*

*Proof.* Let  $G$  be any graph with  $n$  vertices and  $pn^2/2$  edges.

We consider first random partitions of  $V(G)$  into two components  $V_1$  and  $V_2$  of size  $m = n/2$ . The expected number of  $V_1 - V_2$  edges is  $pn^2/4$ . We fix one such partition with at most  $pn^2/4$  edges from  $V_1$  to  $V_2$ . At most  $n/4$  vertices of  $V_1$  send more than  $pn$  edges to  $V_2$ , and so there is a subset  $U$  of  $V_1$  with  $|U| \geq n/4$  such that no vertex of  $U$  sends more than  $pn$  edges to  $V_2$ . Hence the conditions of Theorem 2 are satisfied with  $W = V_2$  and  $\gamma = (\frac{1}{2} - p)n$ . Therefore

$$t(G) \geq \frac{1}{2} \frac{n}{4} \left\lfloor \frac{\log(\frac{1}{3}pn)}{\log((1-2p)^{-1})} \right\rfloor.$$

Since  $p \leq \frac{1}{3}$ , we have  $\log(1 - 2p) \geq -2p - 4p^2 \geq -(10/3)p$ , and hence

$$t(G) \geq \frac{n}{8} \left\lfloor \frac{3 \log(pn/5)}{10p} \right\rfloor$$

$$\geq \frac{1}{30} np^{-1} \log(pn),$$

for sufficiently large  $n$ .  $\square$

Let us note that a special case of Theorem 3 gives a result of Alon, Azar, and Vishkin [4], which is an improvement of a result of Bollobás and Thomason [9] and Häggkvist and Hell [13]. It proves that, to sort  $n$  objects in two rounds, at least  $(1/12)n^{3/2}(\log n)^{1/2}$  parallel processors are required. Bollobás and Thomason proved that  $n^{3/2} \log n$  processors suffice; this will also follow, up to a constant factor, from the upper bound on  $t(n, p)$  given by (1). In [4], Alon, Azar, and Vishkin announced that, in fact,  $n^{3/2} \log n / (\log \log n)^{1/2}$  processors suffice.

**COROLLARY 4.** *Let  $G$  be any graph with  $n$  vertices and  $(1/12)n^{3/2}(\log n)^{1/2}$  edges. If  $n$  is sufficiently large, then there is a transitive orientation of  $G$  with at most*

$$\binom{n}{2} - (1/12)n^{3/2}(\log n)^{1/2}$$

*relations.*

*Proof.* Set  $p = \frac{1}{6}n^{-1/2}(\log n)^{1/2}$  in Theorem 3.  $\square$

The drawback of the method used in the proof of Theorem 3 is that it considers only “short-range” implications, in the sense that if  $x < y$  in  $P(G; <)$  and  $y < z$ , we do not look to see whether the relation  $x < z$  is missing from  $P(G; <)$ . If  $p$  is small, this is obviously a serious restriction, and in fact we can improve on Theorem 3 by just taking a random ordering of  $V(G)$  and counting chains spanning fairly few vertices. This proof is essentially the same as one sketched in [6].

**THEOREM 5.** *Suppose that  $p(n) \rightarrow 0$  and  $(pn/\log n) \geq \frac{1}{2}$ . Then  $t(n, p) \geq (1/64)np^{-1} \log(p^{-1})$ .*

*Proof.* Let  $G$  be any graph with  $n$  vertices and  $pn^2/2$  edges. There are at most  $n/2$  vertices of degree greater than  $2pn$ . We place these vertices at the top of the ordering, and ignore them. The graph  $G'$  spanned by the remaining vertices has order  $m \geq n/2$  and maximal degree at most  $2pn$ .

We next take a random ordering  $<$  of  $V(G)$ , and calculate the expected number of chains spanning at most  $l = \frac{1}{3}p^{-1} \log(p^{-1}) \leq n/4$  vertices.

The number of chains of length  $k$  in  $G'$  is at most  $n(2pn)^k$ , and the probability that such a chain spans at most  $l$  vertices is at most

$$n \binom{l}{k} \frac{(m - k - 1)!}{m!}.$$

Hence the expected number of chains spanning at most  $l$  vertices is at most

$$\sum_{k=0}^l n^2(2pn)^k \binom{l}{k} \frac{(m - k - 1)!}{m!} \leq n \sum_{k=0}^l (2p)^k \binom{l}{k} \frac{2n^{k+1}}{m^{k+1}}$$

$$\leq 4n \sum_{k=0}^l (4p)^k \binom{l}{k}$$

$$= 4n(1 + 4p)^l.$$

Thus there is an ordering of  $G'$  such that at least  $(m-l)l-4n(1+4p)^l$  relations are omitted. But  $(1+4p)^l \leq e^{4pl} = p^{-1/2} \leq l/32$  and  $(m-l)l \geq nl/4$ , so

$$t(G) \geq t(G') \geq (m-l)l-4n(1+4p)^l \geq \frac{nl}{8} = \frac{1}{64} np^{-1} \log(p^{-1}),$$

as required.  $\square$

Combining Theorems 3 and 5, we obtain the desired lower bound for  $t(n, p)$ .

**THEOREM 6.** *Suppose  $pn/\log n \geq \frac{1}{2}$  and  $p \leq \frac{1}{3}$ . Then  $t(n, p) \geq (1/100)np^{-1} \log n$ .*

*Proof.* The maximum of  $(1/64) \log(p^{-1})$  and  $(1/30) \log(pn)$  is always at least  $(1/100) \log n$ .  $\square$

The lower bounds for  $t(n, p)$  in (1), (4), (6), and (7) follow from Theorem 6. We now turn our attention to an upper bound. As mentioned earlier, we shall prove this using the techniques of random graphs. We first give properties of a graph  $G$  which imply that  $t(G)$  is small, and then prove that almost every  $G_p$  has these properties, for appropriate values of the parameters.

**THEOREM 7.** *Suppose  $l \leq n$ , and let  $G$  be a graph on  $n$  vertices. Let  $(Q_1)$  and  $(Q_2)$  be the following properties of graphs, depending on  $l$ .*

$(Q_1)$  *For every pair  $(U, V)$  of subsets of  $V(G)$  with  $|U|=|V|=l$ , there is a  $U-V$  edge.*

$(Q_2)$  *Every triple  $(A, B, C)$  of disjoint subsets of  $V(G)$  with  $|A|=|B|=|C|=6l$  has the following property. For at most  $l^2$  pairs  $(x, y)$  with  $x \in A, y \in C$  there is no  $z \in B$  with  $xzy$  a path in  $G$ .*

(i) *If  $G$  has  $(Q_1)$ , then  $t(G) \leq 8nl \log l$ .*

(ii) *If, in addition,  $G$  has  $(Q_2)$ , then  $t(G) \leq 11nl$ .*

*Proof.* Let  $G$  be any graph on  $n$  vertices satisfying  $(Q_1)$ , and let  $<$  be any ordering of  $V(G)$ . Without loss of generality  $(V(G), <)= [n]$  with its natural order. We split  $V(G)$  into  $s = n/6l$  sets,  $V_1, \dots, V_s$ , where  $|V_i|=6l$  for each  $i$ , and  $V_1 < V_2 < \dots < V_s$ .

Suppose first that  $G$  has property  $(Q_1)$ , and it may or may not have  $(Q_2)$ . We shall find many implications in  $P(G; <)$  using just  $(Q_1)$ . Our method is to construct subsets  $W_i$  of the  $V_i$ , each of order at least  $5l$ , such that every subset  $Y$  of  $W_i$  of order at most  $l$  has at least  $2|Y|$  neighbours in  $W_{i-1}$ , for each  $i$ . Thus a vertex  $x$  in  $W_i$  will be above many vertices in  $W_{i-k}$ , for large  $k$ . Our final step will be to show that the vertices we discard in the construction of the  $W_i$  do not contribute excessive numbers of relations not in  $P(G; <)$ .

We define the  $W_i$  inductively, beginning with  $W_1 = V_1$ . Given  $W_{i-1}$  as required, set

$$\mathcal{A} = \{A \subseteq V_i: |\Gamma(A) \cap W_{i-1}| < 2|A|\}.$$

Clearly  $\mathcal{A}$  is closed under disjoint unions. We claim that  $\mathcal{A}$  contains no set of size between  $l$  and  $2l$ . Indeed, suppose that  $A \in \mathcal{A}$  and  $l \leq |A| \leq 2l$ . Then  $|W_{i-1} \setminus \Gamma(A)| > 5l - 4l = l$ , and so, since  $G$  has  $(Q_1)$ , there is an  $A - (W_{i-1} \setminus \Gamma(A))$  edge, which is not possible.

Let  $X_i$  be an element of  $\mathcal{A}$  which is maximal subject to  $|X_i| < l$ , and set  $W_i = V_i \setminus X_i$ . If  $Y \subset W_i$  has order at most  $l$ , and  $Y \in \mathcal{A}$ , then  $X_i \cup Y \in \mathcal{A}$ , but  $|X_i \cup Y| < 2l$  and so  $|X_i \cup Y| < l$ , contradicting the maximality of  $X_i$ . Therefore  $|\Gamma(Y) \cap W_{i-1}| \geq 2|Y|$  for every small subset  $Y$  of  $W_i$ , and so  $W_i$  is as desired.

Set  $W = \bigcup_{i=1}^s W_i$  and  $X = \bigcup_{i=1}^s X_i$ , so that  $V(G)$  is the disjoint union of  $W$  and  $X$ . We claim that, for every vertex  $x$  in  $W$ , there are at most  $7l \log l$  vertices  $y \in V(G)$  with  $y < x$  but  $y \not< x$  in  $P(G; <)$ . Indeed, suppose that  $x \in W_k$ , where we may assume that  $k \geq \log l$ . By induction on  $j$ , we see that for  $1 \leq j \leq \lceil \log_2 l \rceil$ , there are  $2^j$  vertices  $v$

in  $W_{k-j}$  with  $v < x$  in  $P(G; <)$ , and therefore in particular there are at least  $l$  vertices  $v$  in  $W_{k-\lceil \log_2 l \rceil}$  with  $v < x$  in  $P(G; <)$ . All but at most  $l$  vertices of  $G$  send an edge to one of these  $l$  vertices, since  $G$  has  $(Q_1)$ , and therefore there are at most  $6l(1 + \lceil \log_2 l \rceil) + l \leq 7l \log l$  vertices  $y \in V(G)$  with  $y < x$  but  $y \not\prec x$  in  $P(G; <)$ , as claimed.

Now we suppose that  $G$  also has property  $(Q_2)$ . In this case, we shall show that rather more is true: we can select a large subset  $W$  of  $V(G)$  such that, for every vertex  $x$  of  $W$ , there are at most  $8l$  vertices  $y$  of  $V(G)$  with  $y < x$  but  $y \not\prec x$  in  $P(G; <)$ .

We construct subsets  $W_i$  of  $V_i$  of size at least  $5l$  with the property that, for all  $x \in W_i$ , there are at least  $5l$  vertices  $y$  in  $V_{i-2}$  with  $y < x$  in  $P(G; <)$ . We set  $W_1 = V_1$  and  $W_2 = V_2$ . For  $k \geq 2$ , let  $A = V_{k+1}$ ,  $B = V_k$ , and  $C = V_{k-1}$ , and use  $(Q_2)$ . If  $xzy$  is a path in  $G$ , for  $x \in A$ ,  $z \in B$ , and  $y \in C$ , then  $y < x$  in  $P(G; <)$ , and so there are at most  $l^2$  pairs  $(x, y)$  with  $x \in A$ ,  $y \in C$ , and  $y \not\prec x$  in  $P(G; <)$ . Hence the set

$$X_{k+1} = \{x \in V_{k+1} : y \not\prec x \text{ in } P(G; <) \text{ for at least } l \text{ vertices } y \in V_{k-1}\}$$

has order at most  $l$ . The set  $W_{k+1} = V_{k+1} \setminus X_{k+1}$  then has the desired properties.

Every vertex  $x$  of  $W = \bigcup_{i=1}^s W_i$ , say  $x \in W_k$  with  $k \geq 3$ , has at least  $5l$  vertices  $y$  in  $V_{k-2}$  which are less than  $x$  in  $P(G; <)$ , and as before at most  $l$  vertices of  $G$  do not send an edge to one of these  $5l$  vertices. Thus at most  $8l$  vertices  $y < x$  are such that  $y \not\prec x$  in  $P(G; <)$ , as claimed.

In both cases, we have found sets  $W_i \subseteq V_i$  such that  $|W_i| \geq 5l$ , and every vertex  $x$  of  $W = \bigcup_{i=1}^s W_i$  has at most  $m$  vertices  $y$  below  $x$  with  $y \not\prec x$  in  $P(G; <)$ , where  $m \leq 7l \log l$ , and if  $(Q_2)$  holds, then  $m \leq 8l$ .

Now let us turn our attention to the vertices  $x$  in  $X = V(G) \setminus W$ . For such  $x$ , define

$$r_x = \max \{r : \{x-1, x-2, \dots, x-r\} \cap \Gamma(x) \cap W = \emptyset\},$$

so that  $x$  is joined to  $x - r_x - 1$  by an edge of  $G$ , and  $x - r_x - 1 \in W$ , but this is not true for any smaller  $r$ . There are at most  $m$  vertices below  $x - r_x - 1$  which are not less than  $x - r_x - 1$  in  $P(G; <)$ , and hence there are at most  $r_x + m$  vertices  $y$  such that  $y < x$  but  $y \not\prec x$  in  $P(G; <)$ .

Thus  $t(G)$ , the total number of pairs not related in  $P(G; <)$ , is at most  $mn + \sum_{x \in X} r_x$ . It remains to be shown that  $\sum_{x \in X} r_x$  cannot be too large.

For  $x \in X$ , let  $I_x = W \cap \{x-1, \dots, x-r_x\}$ . We note that, for  $r_x > 4l$ , we have  $|I_x| > r_x/2$ , and so

$$\sum_{x \in X} r_x \leq \frac{2}{3}nl + \sum_{x \in X} |I_x|.$$

Each  $I_x$  is an interval in  $(W, <|_W)$ , and we know that, for any subset  $Y$  of  $X$  of size  $l$ , the intersection of the  $I_x$  for  $x \in Y$  is not too large:  $|\bigcap_{x \in Y} I_x| < l$ , since otherwise  $(Y, \bigcap_{x \in Y} I_x)$  is a pair of subsets of  $V(G)$  which violates  $(Q_1)$ .

We relabel  $W$  so that  $(W, <|_W) = [l, 2l, \dots, sl] \in W$ , where  $s = |W|/l$ . Now consider the set

$$J = \{(x, j) : x \in X, \{jl, (j+1)l\} \subseteq I_x\}.$$

Essentially, we count  $|J|$  in two ways. First,  $|J| \leq (s-1)(l-1) < |W|$  since, for each  $j$ , there are at most  $l-1$  vertices  $x$  with  $(x, j) \in J$ .

But also  $|I_x| \leq l(2 + |\{j : (x, j) \in J\}|)$ , and so

$$\sum_{x \in X} |I_x| \leq l(2|X| + |J|) \leq 2ln.$$

So  $t(G) \leq mn + 3ln$ , for  $n$  sufficiently large. Therefore if  $(Q_1)$  holds, then  $t(G) \leq 8nl \log l$ , and if  $(Q_2)$  also holds, then  $t(G) \leq 11nl$ , which is as required.  $\square$

To use Theorem 7 to find bounds on  $t(n, p)$ , we need to show that there are graphs  $G$  with  $n$  vertices and  $pn^2/2$  edges with properties  $(Q_1)$  and  $(Q_2)$ , for appropriate  $l$ . As usual, we in fact show that *almost every*  $G_{n,p}$  will do.

THEOREM 8. (i) *If  $\alpha \geq 2$ ,  $p > \alpha^{-1} \log \log n / \log n$ , and  $n$  is sufficiently large, then  $t(n, p) \leq \alpha np^{-1} \log n$ .*

(ii) *If  $pn \rightarrow \infty$ , and  $n$  is sufficiently large, then  $t(n, p) \leq 50np^{-1} \log(np) \log(p^{-1})$ .*

*Proof.* We first show that, for  $l = \alpha p^{-1} \log(np)$  and  $\alpha$  any constant at least 2, almost every  $G_{n,p}$  has  $(Q_1)$ , provided  $np \rightarrow \infty$ .

Indeed, the expected number of pairs  $(U, V)$  of subsets with  $|U| = |V| = l$  and no  $U - V$  edge is at most

$$\begin{aligned} \binom{n}{l}^2 (1-p)^{l^2} &\leq \left(\frac{en}{l}\right)^{2l} e^{-pl^2} \\ &= \exp \left\{ l \left[ 2 \log \left( \frac{en}{l} \right) - pl \right] \right\} \\ &\leq \exp \left\{ l \left[ 2 \log \left( \frac{enp}{\alpha \log(np)} \right) - \alpha \log(np) \right] \right\} \\ &\rightarrow 0 \quad \text{as } n \rightarrow \infty. \end{aligned}$$

Next we show that, if  $p > \alpha^{-1} \log \log n / \log n$ , and  $l = \alpha p^{-1} \log n$ , then almost every  $G_{n,p}$  has property  $(Q_2)$ .

Indeed, the probability that  $(A, B, C)$  violates  $(Q_2)$  is at most

$$\sum_{j=l^2}^{36l^2} \binom{36l^2}{j} q^{36l^2-j} (1-q)^j,$$

where  $q = 1 - (1-p^2)^{6l}$  is the probability that there is a vertex  $z$  of  $B$  with  $xzy$  a path in  $G$ , for fixed vertices  $x$  and  $y$ . Hence the expected number of triples violating  $(Q_2)$  is rather crudely, at most

$$\begin{aligned} n^{18l} 36l^2 (36l^2)^{l^2} (1-p^2)^{6l^3} &\leq \exp \{ 18\alpha p^{-1} (\log n)^2 + 5\alpha^2 p^{-2} (\log n)^2 \log \log n \\ &\quad - 6\alpha^3 p^{-1} (\log n)^3 \} \\ &\leq \exp \{ \frac{1}{2} \alpha^3 p^{-1} (\log n)^3 + 5\alpha^3 p^{-1} (\log n)^3 - 6\alpha^3 p^{-1} (\log n)^3 \} \\ &\rightarrow 0 \quad \text{as } n \rightarrow \infty. \end{aligned}$$

Thus almost every  $G_{n,p}$  does have  $(Q_2)$ .

Applying Theorem 7(ii) with  $l = \alpha p^{-1} \log n$ , we obtain that, if  $p > \alpha^{-1} \log \log n / \log n$ , then  $t(G_{n,p}) \leq \alpha np^{-1} \log n$  almost surely, and so certainly  $t(n, p) \leq \alpha np^{-1} \log n$ , thus proving part (i) of the theorem.

We now apply Theorem 7(i) with  $l = 3p^{-1} \log(np)$ , and we find that

$$t(G_{n,p}) \leq 25np^{-1} \log(np) \log(p^{-1} \log(np)).$$

But by part (i) we may assume that  $\log(np) < p^{-1}$  and so, for  $n$  sufficiently large,

$$t(n, p) \leq 50np^{-1} \log(np) \log(p^{-1}),$$

as desired.  $\square$

Thus we have shown that inequalities (1), (4), (6), and (7) hold.

Theorem 8(ii) is probably not the best possible result. In the proof, all we use is that most small sets “spread” by a factor of 2 from one  $V_i$  to the next. In fact, it is almost certain that most sets spread by a factor of, say,  $(\log(np))^{1/2}$ . This would suggest that  $t(n, p) \leq cnp^{-1} \log(np) \log(p^{-1})/\log \log(np)$ , for some constant  $c$  and sufficiently large  $n$ . Our next result, establishing inequality (2), shows that, for random graphs, this would be best possible: almost every  $G_{n,p}$  has  $t(G_{n,p})$  at least as large as this bound.

**THEOREM 9.** *Suppose that  $p > 3 \log n \log \log n/n \log \log \log n$ , and that  $p(n) \rightarrow 0$ . Then almost every  $G_{n,p}$  has  $t(G_{n,p}) \geq np^{-1} \log(np) \log(p^{-1})/1000 \log \log(np)$ .*

*Proof.* We shall use the following elementary facts concerning random graphs, all of which can be found in Bollobás [5]. Almost every  $G_{n,p}$  has maximal degree at most  $2pn$  and chromatic number  $\chi(G_{n,p}) \leq 2pn/\log(np)$ , and almost no  $G_{n,p}$  has an independent set of size larger than  $2p^{-1} \log(np)$ .

Combining the last two facts, we see that almost every  $G_{n,p}$  has  $l \geq pn/4 \log(np)$  colour classes of size at least  $\frac{1}{4}p^{-1} \log(np)$ . The union  $H$  of these classes has order  $m$  at least  $n/16$ .

We consider orderings  $<$  of  $H$  in which colour classes appear one after the other, so that the only chains we need to consider are ones with vertices in separate colour classes. Such chains give rise to relations in  $P(G; <)$  if and only if the colour classes are in the “right” order in  $<$ .

We take a random permutation of the  $l$  colour classes of  $H$  and consider the expected number of chains of length  $k$  which span at most  $r = \log(p^{-1})/3 \log \log(np)$  classes, for  $k \leq r$ .

This is at most

$$m(2pn)^k l \binom{r}{k} \frac{(l-k-1)!}{l!} \leq 2m \left(\frac{2pn}{l}\right)^k \binom{r}{k}.$$

Thus the expected number of chains spanning at most  $r$  classes is at most

$$2m \left(1 + \frac{2pn}{l}\right)^r \leq 2m(9 \log(np))^r \leq 2mp^{-1/2}.$$

Therefore there are at least  $\frac{1}{2}mr\frac{1}{4}p^{-1} \log(np) - 2mp^{-1/2}$  relations omitted in some ordering of this form. Thus

$$t(G_{n,p}) \geq \frac{1}{1000} \frac{np^{-1} \log(np) \log(p^{-1})}{\log \log(np)},$$

as desired.  $\square$

**4. Sparse graphs.** In this section we consider graphs with fewer than  $\frac{1}{4}n \log n$  edges. As mentioned in the introduction, we are interested now in the approximate size of  $r(n, p) = \binom{n}{2} - t(n, p)$ , which is the maximum number of relations a graph of order  $n$  and size  $m \equiv \lfloor pn^2/2 \rfloor$  can guarantee us. We prove the following result, establishing inequalities (10) and (11).

**THEOREM 10.** *Let  $m = \lfloor pn^2/2 \rfloor$ .*

(i) *If  $\frac{1}{4}n \log n \geq m \geq 2n$ , then*

$$\frac{5nm}{\log n} \geq r(n, p) \geq \frac{nm \log \log \log n}{5 \times 10^5 \log n \log \log n}.$$

(ii) If  $m \leq 2n$ , then

$$\frac{10m^2}{\log m} \geq r(n, p) \geq \frac{m^2 \log \log \log m}{10^6 \log m \log \log m}.$$

*Proof.* First we suppose that  $\frac{1}{4}n \log n \geq m \geq 2n$ , and define  $r = m \log \log \log n / 6000 \log n \log \log n$ . Let  $X$  be a set of  $n$  vertices, and  $R \subseteq X$  be a subset of order  $r$ , which without loss of generality we take to be  $[r]$ . We construct a graph  $G$  on  $X$  as follows. We know from Theorem 1 of [6] (inequality (8) of this paper) with  $\alpha = 72^2$  that there is a graph  $H$  on  $R$  with at most  $2600r \log r \log \log r / \log \log \log r \leq m/2$  edges such that, for every transitive orientation  $<$  of  $H$ , there are at least  $\frac{8}{9}\binom{r}{2}$  relations in  $P(H; <)$ . We define  $G[R]$  to be equal to such an  $H$ . Next we partition the  $n - r$  vertices of  $X \setminus R$  into  $r$  sets  $S_1, \dots, S_r$  of equal size, and join  $x$  to every vertex of  $S_x$ , for  $x \in R$ . This uses at most  $n \leq m/2$  edges, and so our resulting graph  $G$  has at most  $m$  edges.

Now let  $<$  be any transitive orientation of  $G$ . We claim that there is a set  $W$  consisting of at least  $r/9$  vertices of  $R$  such that, for every vertex  $x$  of  $W$ , there are at least  $r/9$  vertices of  $R$  above  $x$  in  $P(G; <)$  and at least  $r/9$  vertices of  $R$  below  $x$  in  $P(G; <)$ . This will imply that, for every  $x \in W$  and every  $y \in S_x$ , whatever the orientation of the edge  $xy$  in  $<$ , the vertex  $y$  will be related to at least  $r/9$  elements of  $R$  in  $P(G; <)$ , and hence  $P(G; <)$  contains at least  $(n - r)/9 \cdot r/9 \geq nm \log \log \log n / 5 \times 10^5 \log n \log \log n$  relations, which gives the lower bound in (i).

Suppose then that our claim is false. For every vertex  $x \notin W$  with  $r/9 < x < 8r/9$ , there are at least  $\min\{x - r/9, 8r/9 - x\}$  vertices  $y \in R$  with  $x$  not related to  $y$  in  $P(H; <)$ . An elementary calculation now shows that there are at least  $r^2/9$  ordered pairs  $(x, y)$  of vertices of  $R$  not related in  $P(H; <)$ , which is a contradiction. Thus the lower bound in (i) is proven. (If we use some facts established in the proof of [6, Thm. 1], we can obtain rather better constants here.)

The lower bound in (ii) is obtained by putting a graph of the form described above on a subset of the vertices of order  $m/2$ , giving every other vertex degree 0, and applying part (i).

The upper bounds are fairly straightforward. We suppose first that  $\frac{1}{4}n \log n \geq m \geq n/2$ . At most  $4m/\log n$  vertices have degree at least  $\frac{1}{2} \log n$ . Consider the graph  $H$  spanned by the vertices of smaller degree, and consider a random ordering  $<$  of  $V(H)$ . The expected number of chains in  $(H; <)$  is at most

$$\sum_{l=1}^n n \left( \frac{1}{2} \log n \right)^l \frac{1}{(l+1)!} \leq ne^{(1/2) \log n} = n^{3/2}.$$

Thus there is an ordering of  $H$  with fewer than  $n^{3/2}$  chains. We take such an ordering of  $H$  and place all vertices of higher degree at the top, so that our graph has at most  $4m/\log n \cdot n + n^{3/2} < 5mn/\log n$  relations in this ordering, which gives the upper bound in (i). For (ii), we simply note that at most  $2m$  vertices have non-zero degree, and so we can delete all vertices of degree 0 and apply the above result to the remaining graph.  $\square$

**5. Dense graphs.** Finally, we turn our attention to very dense graphs, i.e., graphs with more than  $\frac{1}{3}\binom{n}{2}$  edges.

For very large values of  $p$ , a random  $G_p$  is not likely to be a good choice, i.e.,  $t(G_p)$  is almost surely much larger than the minimum of  $t(G)$  over all graphs of order  $n$  and size  $pn^2/2$ . To see this, let us consider the extreme case when  $p$  is so large that

the non-edges of  $G_p$  are almost surely independent (i.e., there is no triple  $x, y, z$  of vertices with neither  $xy$  nor  $yz$  an edge). In this case, by taking an ordering  $<$  of  $V(G)$  such that, whenever  $xy$  is a non-edge of  $G$ ,  $x$  and  $y$  are consecutive in  $<$ , we can arrange that  $t(G_p) = \binom{n}{2} - e(G_p)$ , the lowest possible value, almost surely.

We can do considerably better as follows. Let  $m$  be the (given) number of non-edges. Let  $V$  be a set of size  $n$  and  $X$  be a subset of  $V$  of size  $(3m)^{1/2} \leq n$ . We form a graph with vertex set  $V$  and  $m$  non-edges as follows. If  $x$  and  $y$  are in  $V$ , not both in  $X$ , we join  $x$  and  $y$  by an edge. We know by Theorem 3 that there is a graph  $H$  with vertex set  $X$ ,  $m$  non-edges, and  $t(H) \leq 6(3m)^{1/2} \log(3m^{1/2}) \leq 6m^{1/2} \log m$ , provided  $m$  is sufficiently large. We set  $G[X] = H$ . Our graph  $G$  thus has  $m$  non-edges, and clearly  $t(G) = t(H) \leq 6m^{1/2} \log m$ .

In fact, graphs of this type, with all vertices except those in a set  $W$  of order  $m^{1/2}$  having codegree 0, and those vertices in  $W$  having codegree about  $\frac{2}{3}m^{1/2}$ , are apparently not extremal. For instance, if we take a graph of this type and, for every vertex in  $W$ , delete  $\log m$  edges from that vertex to  $V(G) \setminus W$ , selecting different vertices each time, then the “best” ordering of  $V(G)$  still has the vertices of  $W$  appearing consecutively, so  $t(G)$  is not significantly increased. However, as shown by the next result, the bound  $6m^{1/2} \log m$  is, up to a constant factor, best possible.

**THEOREM 11.** *There are absolute constants  $\lambda, \eta > 0$  such that, whenever  $\binom{n}{2} \geq m$ , we have*

$$\lambda m^{1/2} \log m > t\left(n, 1 - m / \binom{n}{2}\right) > \eta m^{1/2} \log m.$$

*Proof.* We have already seen that the upper bound holds for  $\lambda > 6$ . We now consider the lower bound.

Let  $m_0$  be sufficiently large that every  $m \geq m_0$  satisfies the following inequalities.

- (i)  $m \geq 2n_1^2$ ;
- (ii)  $\log(m/3)/\log m > \sqrt{3}/2$ ;
- (iii)  $m^{1/2} \log m \leq m/12$ ;
- (iv)  $m \geq n_0^2$ ;
- (v)  $m^{1/4}/(\log m)^{3/2} > \frac{1}{5}$ ;
- (vi)  $\log(m^{1/2}/15) > \frac{1}{4} \log m$ .

Here  $n_0$  and  $n_1$  are the constants in Lemma 1 and Theorem 3, respectively. We shall make use of inequalities (i) to (vi) in the course of the proof, without always making explicit reference to the fact.

Our aim is to prove the result by induction on  $n$  and  $m$ . To get this induction started, we first need a few very simple facts.

We may assume that  $G$  has no vertex  $x$  of codegree at least  $m^{1/2} \log m$ , since otherwise we can place  $x$  at the top of our ordering  $<$ , and its non-neighbours immediately below it, thus forming a transitive orientation of  $G$  with at least  $m^{1/2} \log m$  pairs unrelated. Similarly, if there are  $m^{1/2} \log m$  independent non-edges  $x_i y_i$  in  $G$ , we make each pair  $(x_i, y_i)$  adjacent in  $<$ , and again we are done. Hence we may assume that there are at most  $2m(\log m)^2$  vertices of non-zero codegree in  $G$ . Furthermore, if  $G'$  is the graph obtained from  $G$  by deleting all vertices of codegree 0, then clearly  $t(G) = t(G')$ . Therefore we may assume that  $G$  has no vertices of codegree 0, and hence that  $n \leq 2m(\log m)^2$ .

We take  $\eta$  sufficiently small that  $t(n, 1 - m/\binom{n}{2}) > \eta m^{1/2} \log m$  for every  $m \leq m_0$  and  $n \leq 2m_0(\log m_0)^2$ . We also insist that  $\eta < 1/160$ .

Next we note that if  $m \geq m_0 \geq 2n_1^2$  and  $n \leq (3m)^{1/2}$ , then we are done by Theorem 3, since  $\eta < 1/30$ .

We have thus chosen a value of  $\eta$  such that our result is true for every pair  $(n, m)$  with  $m \leq m_0$  or  $n \leq (3m)^{1/2}$ . We now suppose that  $G$  has  $n > (3m)^{1/2}$  vertices,  $m > m_0$  non-edges, and that the result is true for all strictly smaller values of  $(n, m)$ .

We now eliminate the case when the non-edges of  $G$  tend to fall into two separate "components." Suppose there is a partition  $V_1 \cup V_2$  of  $V(G)$  such that  $\bar{e}(V_1), \bar{e}(V_2) \geq m/3$ . By induction there are orderings of  $G[V_1]$  and  $G[V_2]$  each omitting at least  $\eta(m^{1/2}/\sqrt{3}) \log(m/3)$  relations. So, by concatenating these orders, we see that there is an orientation of  $G$  omitting

$$\frac{2}{\sqrt{3}} \frac{\log(m/3)}{\log m} \eta m^{1/2} \log m \geq \eta m^{1/2} \log m$$

relations, since  $m > m_0$ . Therefore we may assume that there is no such partition.

We now begin the main part of the proof. We wish to apply Theorem 2, and so we need a fairly small set of vertices with many incident non-edges. Let  $W$  be a subset of  $V(G)$  of minimum order satisfying  $\bar{e}(W) \geq m/3$ , and also take  $W$  such that  $\bar{e}(W)$  is maximum subject to  $W$  being of this order  $w$ . Note that  $\bar{e}(W) \leq m/3 + m^{1/2} \log m \leq m/2$ , as we are assuming that there is no vertex of codegree greater than  $m^{1/2} \log m$ . Let  $d_w(x)$  denote the  $W$ -codegree of  $x$ , the number of non-neighbours of  $x$  which are in  $W$ . We see that  $d_w(x) \geq d_w(y)$  for every  $x \in W$  and  $y \in V(G) \setminus W$ , since otherwise  $\bar{e}(W \cup \{y\} \setminus \{x\}) > \bar{e}(W)$ . Let  $\gamma_0$  be the minimum of  $d_w(x)$  over  $x \in W$ .

Also, by our assumption on partitions of the vertex set,  $\bar{e}(V(G) \setminus W) < m/3$ , and hence there are at least  $m/3 - m^{1/2} \log m \geq m/4$  edges between  $W$  and  $V(G) \setminus W$ .

Let us give some fairly simple bounds for  $w$  and  $\gamma_0$ . First we check that  $\gamma_0$  cannot be too close to  $w$ . Indeed, if  $\gamma_0 \geq \frac{2}{3}w$ , then  $m/2 \geq \bar{e}(W) \geq \frac{1}{2}w\gamma_0 \geq w^2/3$ , so  $w \leq m^{1/2}$  and, as before, we are done by Theorem 3 applied to  $G[W]$ . Hence we may assume that  $\gamma_0 < \frac{2}{3}w$ . If, on the other hand,  $w$  is large, say  $w \geq m^{1/2} \log m$ , then consider  $U = \{y \in V(G) \setminus W : \exists x \in W \text{ with } xy \notin E(G)\}$ , the set of "coneighbours" of  $W$ . We have

$$\frac{m}{w} \geq \frac{1}{w} \sum d_w(x) \geq \gamma_0 \geq \frac{1}{|U|} \sum d_w(y) \geq \frac{m}{4|U|},$$

and so  $|U| > w/4 \geq \frac{1}{4}m^{1/2} \log m$ . For every  $y \in U$ , take a vertex  $x \in W$  with  $xy \notin E(G)$ , and say that  $y$  belongs to  $x$ . Form an ordering of  $V(G)$  in which each  $x \in W$  is immediately preceded by those  $y$  belonging to  $x$ . In such an ordering  $<$ , none of the relations  $xy$  with  $y \in U$  belonging to  $x \in W$ , are in  $P(G; <)$ , and so  $t(G) \geq \frac{1}{4}m^{1/2} \log m$ , and we are done. Thus we may and shall assume that

$$m^{1/2} \leq w \leq m^{1/2} \log m \quad \text{and} \quad \gamma_0 \leq \min \left\{ \frac{2}{3}w, \frac{m}{w} \right\}.$$

Now we shall apply Theorem 2 to  $(U, W)$  for all values of  $\gamma$  up to  $\gamma_0$ . If  $r(\gamma)$  vertices of  $U$  send at least  $\gamma$  non-edges to  $W$ , where  $15 \leq \gamma \leq \gamma_0$ , then Theorem 2 tells us that

$$\begin{aligned} t(G) &\geq \frac{1}{2} r(\gamma) \left[ \frac{\log(\frac{1}{5}(w-\gamma))}{\log(w/\gamma)} \right] \\ &\geq \frac{1}{2} r(\gamma) \left[ \frac{\log(w/15)}{\log(w/\gamma)} \right], \end{aligned}$$

since  $\gamma \leq \gamma_0 \leq \frac{2}{3}w$ . Hence if  $r(\gamma) \geq 2\eta m^{1/2} \log m [\log(w/15)/\log(w/\gamma)]^{-1}$  for any value of  $\gamma$  ( $15 \leq \gamma \leq \gamma_0$ ), we are done.

If  $\gamma \geq 4w^{1/2}$ , then  $\lceil \log(w/15)/\log(w/\gamma) \rceil \geq 2$ , so  $\lceil \log(w/15)/\log(w/\gamma) \rceil^{-1} \leq 2 \log(w/\gamma)/\log(w/15)$ .

But for  $\gamma < 4w^{1/2}$ , we certainly have the bound  $t(G) \geq r(\gamma)$ , and indeed we are done unless  $r(\gamma) \leq \eta m^{1/2} \log m$  for all  $\gamma > 0$ .

Thus we may and shall assume that the total number of  $U - W$  edges is at most

$$\begin{aligned} & 4w^{1/2} \eta m^{1/2} \log m + \sum_{\gamma=1}^{\gamma_0} 4\eta m^{1/2} \log m \frac{\log(w/\gamma)}{\log(w/15)} \\ &= 4w^{1/2} \eta m^{1/2} \log m + 4\eta m^{1/2} \frac{\log m}{\log(w/15)} [\gamma_0 \log w - \log(\gamma_0!)] \\ &\leq 4w^{1/2} \eta m^{1/2} \log m + 4\gamma_0 \eta m^{1/2} \frac{\log m}{\log(w/15)} \log(ew/\gamma_0). \end{aligned}$$

It now remains only to be shown that this quantity is always less than  $m/4$ , as that will imply that there are fewer than  $m/4$  edges from  $U$  to  $V$ , a contradiction. Thus we shall have proved the result for every pair  $(n, m)$ , and we shall be done.

The first term in the above expression is at most  $4\eta m^{3/4} (\log m)^{3/2} < m/8$ , and so it remains to be shown that  $m/8 \geq 4\gamma_0 \eta m^{1/2} (\log m / \log(w/15)) \log(ew/\gamma_0)$ , or in other words that

$$(13) \quad \frac{m^{1/2}}{\log m} \geq 32\eta \frac{\gamma_0 \log(ew/\gamma_0)}{\log(w/15)},$$

for all feasible values of  $w$  and  $\gamma_0$ .

For each fixed  $w$ , the right-hand side of (13) is increasing for  $\gamma_0 < w$ . We have that  $\gamma_0 \leq m/w \leq w$ , and so, setting  $\gamma_0 = m/w$  in (13), it is sufficient to show that

$$\frac{w \log(w/15)}{\log(ew^2/m)} \geq 32\eta m^{1/2} \log m.$$

Certainly  $\log(w/15) \geq \log(m^{1/2}/15) > \frac{1}{4} \log m$ , and  $w/\log(ew^2/m)$  is minimised at  $w = (em)^{1/2}$ . Therefore

$$\begin{aligned} \frac{w \log(w/15)}{\log(ew^2/m)} &\geq e^{1/2} m^{1/2} \frac{1}{4} \log m \frac{1}{2} \\ &\geq 32\eta m^{1/2} \log m, \end{aligned}$$

as desired, since  $\eta \leq 1/160$ . Therefore there are fewer than  $m/4$   $U - W$  edges, which is a contradiction. Thus the result is true for every pair  $(n, m)$  and we are done.  $\square$

## READIES AND FAILURES IN THE ALGEBRA OF COMMUNICATING PROCESSES\*

J. A. BERGSTRA†, J. W. KLOP‡, AND E.-R. OLDEROG§

**Abstract.** Readiness and failure semantics are studied in the setting of Algebra of Communicating Processes (ACP). A model of process graphs modulo readiness equivalence, respectively, failure equivalence, is constructed, and an equational axiom system is presented which is complete for this graph model. An explicit representation of the graph model is given, the failure model, whose elements are failure sets. Furthermore, a characterisation of failure equivalence is obtained as the maximal congruence which is consistent with trace semantics. By suitably restricting the communication format in ACP, this result is shown to carry over to subsets of Hoare's Communicating Sequential Processes (CSP) and Milner's Calculus of Communicating Systems (CCS). Also, the characterisation implies a full abstraction result for the failure model. In the above we restrict ourselves to finite processes without  $\tau$ -steps. At the end of the paper a comment is made on the situation for infinite processes with  $\tau$ -steps: notably we obtain that failure semantics is incompatible with Koomen's fair abstraction rule, a proof principle based on the notion of bisimulation. This is remarkable because a weaker version of Koomen's fair abstraction rule is consistent with (finite) failure semantics.

**Key words.** process algebra, concurrency, readiness semantics, failure semantics, bisimulation semantics

**AMS(MOS) subject classifications.** 68Q05, 68Q10, 68Q55, 68Q45

**Introduction.** This paper is concerned with the *failure semantics* for communicating processes as introduced by Brookes, Hoare, and Roscoe [BHR84] (see also Rounds and Brookes [RB81].) This notion of failure semantics is based on the assumption that all possible knowledge about a process takes the form of a set of pairs  $[\sigma, X]$ , where  $\sigma$  is a linear history of events (actions) in which the process has engaged in cooperation with its environment, and where  $X$  is a set of events which are impossible after  $\sigma$ . Thus failure semantics can be seen as a linear history semantics enriched by "local branching information."

Two further semantic models of processes will play an auxiliary role in our paper: Milner's model based on the notion of *observational equivalence* [Mi80] or *bisimulation* (see Park [Pa83]) and the *readiness semantics* described in [OH83]. Processes which are equivalent in the sense of bisimulation semantics are also failure equivalent, but failure semantics identifies more processes. Intermediate between bisimulation and failure semantics is the readiness semantics; here positive information  $(\sigma, Y)$  is given about a process:  $Y$  is a set of possible actions after the history  $\sigma$ .

Related to the study of failure semantics which was done by Brookes, Hoare, and Roscoe [BHR84] and Brookes [Br83] in the context of Communicating Sequential Processes (CSP) (see [Ho78], [Ho80]) is the work of De Nicola and Hennessy [DH84], where some equivalences, based on the notion of *test*, are introduced, one of which

coincides on a class of simple expressions with failure equivalence. The work of De Nicola and Hennessy [DH84] takes place in the context of Milner's Calculus of Communicating Systems (CCS). Connections between CCS and CSP, in regard to failure semantics, were given by Brookes [Br83].

Most of the work just mentioned was carried out in a context where both recursion and hiding (abstraction from silent  $\tau$ -steps) were present. This combination has complicated matters significantly. The aim of our paper is therefore to investigate the "pure" failure semantics *without recursion* and *hiding* (except for an interesting digression in its final section where the intricate interplay of these phenomena is highlighted). Our context will be ACP, the axiomatic system for the *Algebra of Communicating Processes* as introduced and studied in the series of papers [BK83], [BK84a], [BK84b], [BK84c], [BK85], [BBK85], [BK86a], [BK86b]. (For an introductory survey see [BK86b].) As we shall see, one advantage of this choice is that the different communication concepts of CSP and CCS can be treated in a uniform way (cf. also Milner [Mi83] and Winskel [Wi83]). In fact, to achieve this uniformity we will work here with a mild extension of ACP, where *renaming operators* are present. This system is called  $ACP_r$  and is displayed in Table 1. Note that  $ACP_r$  is purely equational and, for a finite alphabet of actions, it is a finite axiom system.

It turns out that in our restricted setting readiness and failure semantics have a neat *axiomatisation*, by means of two equations R1,2, which on top of  $ACP_r$  yield readiness semantics, and a "saturation" axiom S which, when added to  $ACP_r + R1,2$ , yields failure semantics.  $ACP_r$  alone corresponds to bisimulation semantics. These results are established in the first part of the paper. In §§ 1-3 we construct models for these axiom systems, starting from a domain of finite process graphs on which equivalences  $\Leftrightarrow, =_{\mathcal{R}}, =_{\mathcal{F}}$  (bisimulation equivalence, readiness equivalence, failure equivalence, respectively) are divided out. Next, in § 4, the axiom systems for these quotient structures are presented and shown to be complete. The extra axioms R1,2 and S are not new; in a form disguised by many  $\tau$ 's they appear already in [Br83], and they are derivable from the axioms given in [DH84] (see our comparison in Remark 7.3.3). The definitions of  $\Leftrightarrow, =_{\mathcal{R}}, =_{\mathcal{F}}$  are also standard. What seems new in our treatment is the strategy of the completeness proofs by means of a decomposition of  $\Leftrightarrow, =_{\mathcal{R}}, =_{\mathcal{F}}$  on process graphs in a small number of very simple *process graph transformations* (§ 3).

So we obtain a "graph model" for  $ACP_r$  satisfying failure semantics. In § 5, an *explicit representation* of this graph model, called the *failure model* is constructed directly from the failure sets. This links our work with that of [BHR84]. The graph model and the failure model are shown to be isomorphic. In § 6 we restrict the general communication format of  $ACP_r$  to one-to-one communication. We show that subsets of CSP and CCS can be interpreted within this framework. This serves as a preparation for § 7, where we prove that for  $ACP_r$  with one-to-one communication failure equivalence is the *maximal trace respecting congruence*. Here traces are understood as *complete* histories recording all communications up to a final process state. This simple characterisation of failure equivalence seems new. In the proof we use the readiness semantics as a "stepping stone" towards failure equivalence. The characterisation is shown to carry over to the subsets of CSP and CCS introduced in § 6. For CCS we relate our result to the notion of testing introduced in [DH84]. Further on, the characterisation implies that for  $ACP_r$  with one-to-one communication the failure model is *fully abstract* with respect to trace equivalence.

The paper concludes in § 8 with a digression in which processes under failure semantics are considered in the context of recursion and hiding. The main point made here is that the proof principle *Koomen's Fair Abstraction Rule* (KFAR), which is

$a_H(xy) = a_H(x) \cdot a_H(y)$	RN4

important in system verification and which can be justified in bisimulation semantics, is not valid in any extension of (finite) failure semantics. As far as we know this observation, which is supported by deriving a formal inconsistency, is new. Remarkably, a weaker version of KFAR turns out to be both useful for verification and consistent with finite failure semantics (see [BKO86]).

**1. The domain  $\mathbb{H}_\delta$  of finite acyclic process graphs.** In order to build a “graph model” for the axiomatisation ACP<sub>r</sub> (see Introduction, Table 1) which also satisfies failure semantics, we start by introducing a domain of process graphs ( $\mathbb{H}_\delta$ ) enriched with a number of operations  $+$ ,  $\cdot$ ,  $\parallel$ ,  $\llbracket \_ \rrbracket$ ,  $|$ ,  $\partial_H, a_H (a \in A)$  corresponding to the operators in ACP<sub>r</sub>. It should be emphasized that this structure  $\mathbb{H}_\delta(+, \cdot, \parallel, \llbracket \_ \rrbracket, |, \partial_H, a_H, a, \delta) (a \in A)$  is not yet a model of ACP<sub>r</sub>; it becomes so after dividing out by a suitable equivalence on  $\mathbb{H}_\delta$  (which, of course, should be a congruence with respect to the operations). For example, dividing out by bisimulation equivalence (as defined in § 2.3 below) yields a model of ACP<sub>r</sub>, and in fact one that is isomorphic to the initial model of ACP<sub>r</sub>. This

matter does not, however, concern us in this paper. What we are interested in is the quotient structure obtained by dividing out by readiness equivalence or failure equivalence, respectively (defined below in 2.2), that is, what we will call (in analogy with “term model”) the graph model for  $ACP_r$ , satisfying readiness semantics or failure semantics, respectively.

**1.1. Finite acyclic process graphs in  $\delta$ -normal form.** A process graph over a set is a rooted, directed multigraph whose edges are labeled by elements of this set. Let  $\mathbb{H}$  be the collection of *finite acyclic* process graphs over the alphabet  $A_\delta = A \cup \{\delta\}$  (here  $\delta \notin A$ ) consisting of actions  $a, b, \dots \in A$  and the constant  $\delta$  denoting deadlock. In the sequel we will work with  $\mathbb{H}_\delta \subseteq \mathbb{H}$ , the subset of  $\delta$ -normal process graphs. A process graph  $g \in \mathbb{H}$  is  $\delta$ -normal if whenever an edge  $s \xrightarrow{\delta} t$  occurs in  $g$ , then the node  $s$  has outdegree 1 and the node  $t$  has outdegree 0. In anthropomorphic terminology, let us say that an edge  $s \rightarrow t$  is an *ancestor* of  $s' \rightarrow t'$  if it is possible to move along edges from  $t$  to  $s'$ ; likewise the latter edge will be called a *descendant* of the former. Edges having the same initial node are *brothers*. So, a process graph  $g$  is  $\delta$ -normal if all its  $\delta$ -edges have no brothers and no descendants.

Note that for  $g \in \mathbb{H}$  the ancestor relation is a partial order on the set of edges of  $g$ .

We will now associate to a process graph  $g \in \mathbb{H}$  a unique  $g'$  in  $\delta$ -normal form, by the following procedure:

- (1) *nondeterministic  $\delta$ -removal* is the elimination of a  $\delta$ -edge having at least one brother.
- (2)  *$\delta$ -shift* of a  $\delta$ -edge  $s \xrightarrow{\delta} t$  in  $g$  consists of deleting this edge, creating a fresh node  $t'$ , and adding the edge  $s \xrightarrow{\delta} t'$ .

Now it is not hard to see that the procedure of repeatedly applying (in arbitrary order) (1), (2) in  $g$  will lead to a unique graph  $g'$  which is  $\delta$ -normal; this  $g'$  is the  *$\delta$ -normal form* of  $g$ . It is understood that pieces of the graph which have become inaccessible from the root, are discarded.

*Example 1.1.1.* See Fig. 1, where  $g'$  is the  $\delta$ -normal form of  $g$ .

**1.2. Operations on process graphs.** On  $\mathbb{H}_\delta$  we define the operations  $+, \cdot, \parallel, \llbracket, \lceil, \partial_H$ , as in [BK85], [BK86a], and moreover rename operators  $a_H$ . The constants  $a, \delta (a \in A)$  are represented by graphs consisting of a single arrow labeled by  $a, \delta$ , respectively. For the sake of completeness we repeat the definitions briefly:

FIG. 1

(i) The *sum*  $g + h$  is the graph obtained by identifying the roots of  $g, h$  and taking the  $\delta$ -normal form (this is necessary if  $g$  or  $h$  is the graph consisting of a single step labeled with  $\delta$ ).

(ii) The *product*  $g \cdot h$  is obtained by appending  $h$  at all terminal nodes which are not terminal nodes of a  $\delta$ -step.

(iii) The *merge*  $g \parallel h$  consists of the  $\delta$ -normal form of the process graph obtained as the Cartesian product of  $g, h$  augmented with diagonal edges for successful communications.

(iv) The *left-merge*  $g \underline{\parallel} h$  is the subgraph of  $g \parallel h$ , where an initial step must be one from  $g$ .

(v) The *communication merge*  $g | h$  is the subgraph of  $g \parallel h$ , where an initial step must be a communication result of an initial step in  $g$  and an initial step in  $h$ .

(vi) The *encapsulation*  $\partial_H(g)$  is the result of renaming all (labels of) steps in  $H \subseteq A$  by  $\delta$ , and taking the  $\delta$ -normal form.

(vii) The *renaming*  $a_H(g)$  is the result of renaming all (labels of) steps in  $H \subseteq A$  by  $a$ . We have renamings  $a_H$  for each  $a \in A$ .

*Example 1.2.1.* Let  $g$  be the process graph in Fig. 2(a) and  $h$  the process graph in Fig. 2(b). Let the communication function  $|\cdot| : A_\delta \times A_\delta \rightarrow A_\delta$  be such that  $a | c = e$  and  $b | d = f$ , all other communications equal  $\delta$ . Then  $g + h$  is the graph in Fig. 2(c);  $g \cdot h$  is the graph in Fig. 2(d);  $g \parallel h$  is the  $\delta$ -normal form of the graph in Fig. 2(e), which is the graph in Fig. 2(f);  $g \underline{\parallel} h$  is the graph in Fig. 2(g);  $g | h$  is the graph in Fig. 2(h);  $\partial_{\{a,d\}}(g)$  is the graph in Fig. 2(i);  $\partial_{\{a,d\}}(h)$  is the graph in Fig. 2(j); and  $a_{(b)}(g)$  is the graph in Fig. 2(k).

**2. Equivalences on process graphs.** Though in this paper our main interest is in the *ready equivalence* and the *failure equivalence*, we also will consider trace equivalence and bisimulation equivalence. In this section these notions are introduced and compared. At the end of the section the concept of a *convexly saturated* process graph is introduced, which illuminates the relationship between ready and failure equivalence and which will play an important role in establishing the completeness of the axiom systems for ready and failure equivalence, respectively, presented in § 4.

**2.1. Trace equivalence.** Consider a process graph  $g \in \mathbb{H}_\delta$ . Every path in  $g$  from the root of  $g$  to some node in  $g$  determines a word  $s \in A_\delta^*$  formed by concatenating the labels in the consecutive steps in the path. Any such word  $\sigma$  will be called a *history* of (the path in)  $g$ . We are particularly interested in *complete histories*, i.e., words determined by paths ending in a terminal node. Throughout this paper complete histories will be called *traces*. By *trace* ( $g$ ) we denote the set of all traces of  $g$ . *Trace equivalence*  $\sim_{\text{tr}}$  of process graphs  $g, h \in \mathbb{H}_\delta$  is defined as follows:

$$g \sim_{\text{tr}} h \quad \text{iff} \quad \text{trace}(g) = \text{trace}(h).$$

Note that there are two types of traces: *successful traces*  $\sigma \in A^*$  ending in a successful termination node (see § 2.2) and *deadlocking traces*  $\sigma \cdot \delta \in A^* \cdot \{\delta\}$  ending in  $\delta$ .

**2.2. Ready equivalence and failure equivalence.** We will distinguish four types of nodes of  $g \in \mathbb{H}_\delta$ .

- (i) End nodes of  $\delta$ -steps in  $g$  are *improper*.
- (ii) Begin nodes of  $\delta$ -steps are called *deadlock nodes*.
- (iii) Termination nodes of  $g$  other than those in (i) are *successful termination nodes*.
- (iv) Nonterminal nodes which are not deadlock nodes.

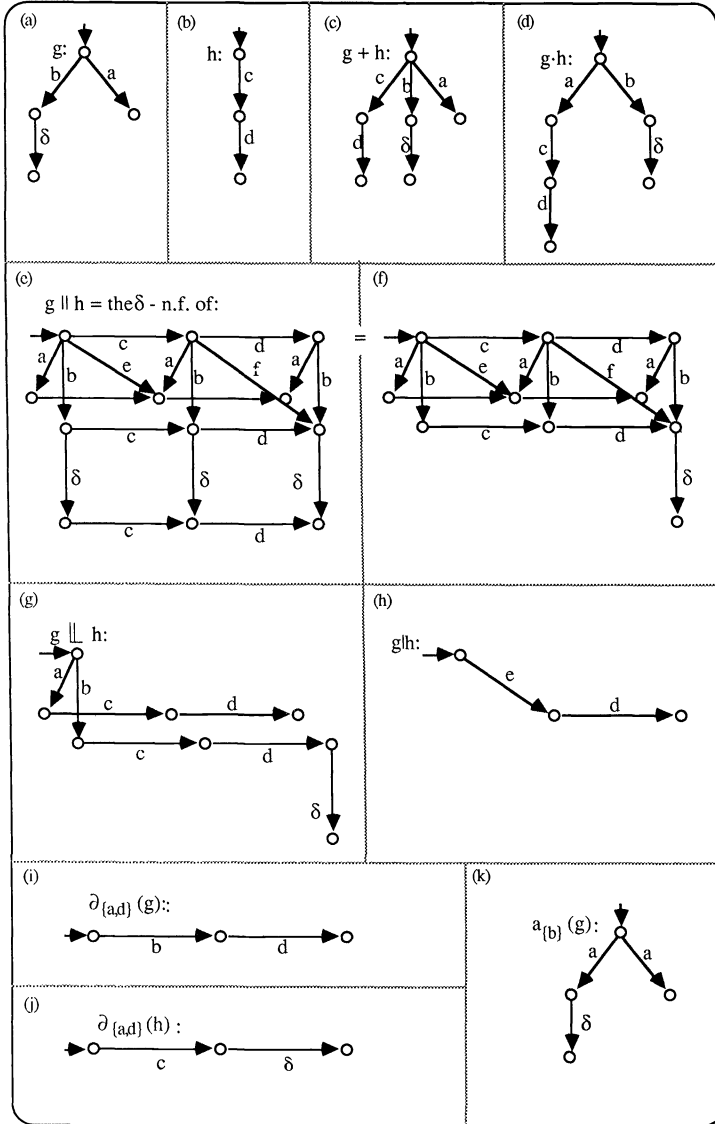

FIG. 2

The *successor set* of node  $s$  as in (ii) is, by definition,  $\emptyset$ . The successor set of a node  $s$  as in (iv) is the set of labels  $\in A$  of edges with begin node  $s$ . A node as in (i) or (iii) has no successor set.

Now  $(\sigma, X)$  where  $\sigma \in A^*$ ,  $X \subseteq A$  is a *ready pair* of  $g$  if there is a path from root  $s_0$  to some proper node  $s$  which is not a successful termination node, with history  $\sigma$  and  $X$  as the successor set of  $s$ . The *ready set* of  $g$  is the set of all ready pairs of  $g$  together with all successful traces. Notation:  $\mathcal{R}[g]$ .

The *failure set* of  $g$ , notation:  $\mathcal{F}[g]$ , is defined as follows. If  $(\sigma, X) \in \mathcal{R}[g]$ , then  $[s, Y]$  is a *failure pair* of  $g$  if  $Y \subseteq X^c$ , and  $Y$  is called a *refusal set*. Here and in the sequel we use the following notation:  $X^c = A - X$ . Now  $\mathcal{F}[g]$  is the set of all failure

pairs of  $g$ , together (again) with the successful traces of  $g$ . Thus we have

$$\mathcal{R}[g] = \{\sigma \mid \sigma \text{ is a successful trace of } g\} \cup \{(\sigma, X) \mid (\sigma, X) \text{ is a ready pair of } g\},$$

$$\mathcal{F}[g] = \{\sigma \mid \sigma \text{ is a successful trace of } g\} \cup \{[\sigma, Y] \mid Y \subseteq X^c \text{ for some } (\sigma, X) \in \mathcal{R}[g]\}.$$

Note that  $\delta$  does not appear anywhere in  $\mathcal{R}[g]$  and  $\mathcal{F}[g]$ .

*Example 2.2.1.* Consider  $g$  as in Fig. 3; at each node its type (i)–(iv) is indicated. Moreover Table 2 contains the contribution of each node to the failure and ready set of  $g$ .

*Example 2.2.2.* (i) Let  $\delta$  be the graph consisting of one  $\delta$ -step. Then  $\mathcal{R}[\delta] = \{(\varepsilon, \emptyset)\}$  and  $\mathcal{F}[\delta] = \{[\varepsilon, Y] \mid Y \subseteq A\}$ .

(ii) Let  $a \in A$ . Then  $\mathcal{R}[a] = \{(\varepsilon, \{a\}), a\}$  and  $\mathcal{F}[a] = \{a\} \cup \{[\varepsilon, Y] \mid Y \subseteq A - \{a\}\}$ .

(iii) Let  $a\delta$  be the graph consisting of a consecutive  $a$ - and  $\delta$ -step. Then  $\mathcal{R}[a\delta] = \{(\varepsilon, \{a\}), (a, \emptyset)\}$  and  $\mathcal{F}[a\delta] = \{[\varepsilon, Y] \mid Y \subseteq A - \{a\}\} \cup \{[a, Z] \mid Z \subseteq A\}$ .

**DEFINITION 2.2.3.** Let  $g, h \in \mathbb{H}_\delta$ . Then  $g \equiv_{\mathcal{R}} h$  if  $\mathcal{R}[g] = \mathcal{R}[h]$  and  $g \equiv_{\mathcal{F}} h$  if  $\mathcal{F}[g] = \mathcal{F}[h]$ . In other words,  $g, h$  are *ready equivalent*, and *failure equivalent*, respectively.

**2.3. Bisimulation equivalence.** For the sake of completeness we include the definition of the well-known notion of a bisimulation.

FIG. 3

TABLE 2

	$\mathcal{R}[g]$	$\mathcal{F}[g]$
$s_0$	$(\varepsilon, \{a, b\})$	$[\varepsilon, Y], Y \subseteq A - \{a, b\}$
$s_1$	$(a, \emptyset)$	$[a, Y], Y \subseteq A$
$s_2$	$(a, \{c\})$	$[a, Y], Y \subseteq A - \{c\}$
$s_3$	$b$	$b$
$s_4$		
$s_5$	$ac$	$ac$

DEFINITION 2.3.1. Let  $g, h \in \mathbb{H}_\delta$ . Let  $\text{ROOT}(g)$ ,  $\text{ROOT}(h)$  denote the root of  $g, h$ , respectively, and let  $\text{NODES}(g)$ ,  $\text{NODES}(h)$  denote the set of nodes of  $g, h$ , respectively.

Then  $R \subseteq \text{NODES}(g) \times \text{NODES}(h)$  is a *bisimulation* from  $g$  to  $h$  if:

- (i)  $(\text{ROOT}(g), \text{ROOT}(h)) \in R$ ;
- (ii) If  $(s, t) \in R$  and  $s \xrightarrow{u} s'$  (where  $u \in A_\delta$ ) is an edge in  $g$ , then  $(s', t') \in R$  for some  $t'$  such that  $t \xrightarrow{u} t'$ ;
- (iii) If  $(s, t) \in R$  and  $t \xrightarrow{u} t'$  (where  $u \in A_\delta$ ) is an edge in  $h$ , then  $(s', t') \in R$  for some  $s'$  such that  $s \xrightarrow{u} s'$ .

Notation:  $g \Leftrightarrow h$  ( $g, h$  are *bisimulation equivalent*, or *bisimilar*) if there is a bisimulation from  $g$  to  $h$  (or vice versa).

As we will want to model the axiom  $\delta \cdot x = \delta$  later, we profit here from the fact that only  $\delta$ -normal process graphs are considered. Otherwise the definition of bisimulation would be more involved.

**2.4. Comparing the equivalences.** It is not hard to compare the four equivalences  $\sim_{\text{tr}}$ ,  $\equiv_{\mathcal{R}}$ ,  $\equiv_{\mathcal{F}}$ , and  $\Leftrightarrow$ : for  $g, h \in \mathbb{H}_\delta$  we have

$$g \Leftrightarrow h \Rightarrow g \equiv_{\mathcal{R}} h \Rightarrow g \equiv_{\mathcal{F}} h \Rightarrow g \sim_{\text{tr}} h$$

and in general none of these implications can be reversed as some of the following examples (e.g., Example 2.4.2) show. Lemma 2.5.5 states a sufficient condition for reversing the second implication.

In the sequel we will prove (Proposition 4.2.3) that  $g \equiv_{\mathcal{R}} h$  and  $g \equiv_{\mathcal{F}} h$  are *congruences* with respect to the operations defined above in § 1.2. Also  $\Leftrightarrow$  is a congruence; see Theorem 2.5 of [BK85] for the more complicated situation where  $\tau$ -steps are present. Trace equivalence however is *not* a congruence with respect to these operations, as the following example shows.

Example 2.4.1. Let  $\mathcal{C}[\xi]$  be the context  $\partial_{\{b,c\}}(\xi \parallel c)$ , and let  $a, b, b^o, c, c^o$  be atoms with communications  $b \mid b = b^o, c \mid c = c^o$  and all other communications resulting in  $\delta$ . Consider the trace equivalent processes  $a(b + c)$  and  $ab + ac$ . Then  $\mathcal{C}[a(b + c)] = ac^o \uparrow_{\text{tr}} ad + ac^o = \mathcal{C}[ab + ac]$ .

Example 2.4.2. See Fig. 4.

**2.5. Convexly saturated process graphs.** Following [Br83] and [DH84] we introduce the following notion of convexity.

DEFINITION 2.5.1.  $\mathcal{X} \subseteq \mathcal{P}(A)$  is *convex* if

- (i)  $X, Y \in \mathcal{X} \Rightarrow X \cup Y \in \mathcal{X}$ ;
- (ii)  $X, Y \in \mathcal{X}, X \subseteq Z \subseteq Y \Rightarrow Z \in \mathcal{X}$ .

(Here  $\mathcal{P}(A)$  is the power set of  $A$ . In particular,  $\emptyset \subseteq \mathcal{P}(A)$  is convex.)

DEFINITION 2.5.2. (i) Let  $g \in \mathbb{H}_\delta$  and  $\sigma \in A^*$ . Then  $g \mid \sigma = \{X \mid (\sigma, X) \in \mathcal{R}[\![g]\!]\}$ .

(ii)  $g$  is *convexly saturated* (or just “convex” or “saturated”) if  $g \mid \sigma$  is convex, for all  $\sigma \in A^*$ .

Example 2.5.3. In Fig. 5,  $g_1, g_2$  are not convexly saturated, but their “convex saturations”  $g'_1, g'_2$  are.

PROPOSITION 2.5.4. Let  $\mathcal{X} \subseteq \mathcal{P}(A)$  be convex, and let  $Y \subseteq A$  be a finite set such that  $Y \notin \mathcal{X}, Y \subseteq \cup \mathcal{X}$ . Then for no  $X \in \mathcal{X}$  we have  $Y^c \subseteq X^c$ .

Proof. Consider a finite  $Y$  such that  $Y \notin \mathcal{X}, Y \subseteq \cup \mathcal{X}$ . Suppose that there is an  $X \in \mathcal{X}$  such that  $Y^c \subseteq X^c$ , or equivalently  $X \subseteq Y$ . Clearly,  $Y$  is covered by finitely many members from  $\mathcal{X}$ , hence (since  $\mathcal{X}$  is convex) by some  $Z \in \mathcal{X}$ . From  $X \subseteq Y \subseteq Z$  it follows that  $Y \in \mathcal{X}$ , a contradiction.  $\square$

FIG. 4

LEMMA 2.5.5. *Let  $g, h \in \mathbb{H}_\delta$  be convexly saturated. Then*

$$g \equiv_{\mathcal{R}} h \Leftrightarrow g \equiv_{\mathcal{F}} h.$$

*Proof.* Only to prove ( $\Leftarrow$ ). So, we suppose  $g \not\equiv_{\mathcal{R}} h$  and we want to prove  $g \not\equiv_{\mathcal{F}} h$ . Furthermore, we may suppose that  $g, h$  have the same trace set; otherwise  $g \not\equiv_{\mathcal{F}} h$  is immediate. Now there is a ready pair  $(\sigma, X)$  in (say)  $\mathcal{R}[[g]]$  but not in  $\mathcal{R}[[h]]$ . By  $(\sigma, X) \in \mathcal{R}[[g]]$  we have the failure pair  $[\sigma, X^c] \in \mathcal{F}[[g]]$ . Now consider  $h \upharpoonright \sigma$ , which is by assumption convex. Since  $g \sim_{\text{tr}} h$ , we have  $X \subseteq \cup (h \upharpoonright \sigma)$ . Furthermore,  $(\sigma, X) \notin \mathcal{R}[[h]]$  entails  $X \not\subseteq h \upharpoonright \sigma = \{X_i \mid i \in I\}$ . So, by Proposition 2.5.4: for no  $i \in I$  we have  $X^c \subseteq X_i^c$ . But then  $[\sigma, X^c] \notin \mathcal{F}[[h]]$  and we have  $g \not\equiv_{\mathcal{F}} h$ .  $\square$

**3. Transformations on process graphs.** We now introduce four *elementary transformations* on process graphs  $\in \mathbb{H}_\delta$  with the following property: the first two of them generate, when applied on  $g \in \mathbb{H}_\delta$ , all process graphs  $g'$  *bisimilar* to  $g$ ; further, the first three generate the *ready equivalence* class of  $g$ ; and finally, the four together generate the *failure equivalence* class of  $g$ .

FIG. 5

**3.1. The transformations double edge, sharing, cross, and fork.**

[i] **Double edge.** This process graph transformation step removes in a *double edge* as in Fig. 6 (where  $a \in A$ ), one of the edges. Notation:  $g \Rightarrow_{[i]} h$ .

[ii] **Sharing.** Suppose  $g \in \mathbb{H}_\delta$  contains two nodes  $s, t$  determining isomorphic subgraphs  $(g)_s, (g)_t$ . Then the nodes  $s, t$  may be identified. Notation:  $g \Rightarrow_{[ii]} h$ .

[iii] **Cross.** If  $s$  is a node of  $g \in \mathbb{H}_\delta$ ,  $\sigma$  is a *history* of  $s$  if there is a path from the root of  $g$  to  $s$  yielding the word  $\sigma$ . Furthermore,  $\text{history}(s)$  is the set of all histories of  $s$ . Now let  $g \in \mathbb{H}_\delta$  contain a part as in Fig. 7(a), where  $\text{history}(s_1) = \text{history}(s_2)$ . Then edges, as in Fig. 7(b), may be inserted. Notation:  $g \Rightarrow_{[iii]} h$ .

Note that the condition on histories is fulfilled when  $g$  is a process tree. Furthermore, note that the condition on histories is necessary: it is easy to give an example where this requirement is violated and such that after insertion of the two new steps we have new ready pairs or new completed traces.

[iv] **Fork.** Let  $g \in \mathbb{H}_\delta$  contain a part as in Fig. 8(a), where all successor steps  $b_1, \dots, b_n$  of the left  $a$ -step are displayed. Then a part as indicated in Fig. 8(b) may be inserted. Notation:  $g \Rightarrow_{[iv]} h$ .

Here it is not required that all steps  $b_1, \dots, b_n, c_1, \dots, c_m$  have different end nodes. If  $n = 1, b_1$  may be  $\delta$ ; likewise  $c_1$  may be  $\delta$ . In such a case, after inserting the fork we have to  $\delta$ -normalise the resulting graph again. We emphasize that a fork connects all of the successor steps of the left  $a$ -step with some of those of the right  $a$ -step.

FIG. 6

FIG. 7

Notation 3.1.1. (i)  $\Rightarrow$  is  $\Rightarrow_{[i]} \cup \dots \cup \Rightarrow_{[iv]}$ ;

(ii)  $\Rightarrow^*$  is the transitive reflexive closure of  $\Rightarrow$ ;

(iii)  $\Leftrightarrow^*$  is the equivalence relation generated by  $\Rightarrow$ .

Example 3.1.2. (i) See Fig. 9. Note how  $\Rightarrow_{[iii]}$  enables us to switch subgraphs  $x, y$  at the end of paths with the same history ( $abc$  in Fig. 9(b)).

(ii) (See Fig. 10.) Figure 10(a) contains an example of a fork transformation. Figure 10(b) contains an example of a fork transformation involving a  $\delta$ -step. Figure 10(c) shows that complete branches can be pruned by successive transformations.

FIG. 8

FIG. 9

DEFINITION 3.1.3. (i) A transformation step  $g \Rightarrow_{[iii]} h$  is called *restricted* if  $g$  is a process tree (i.e., a process graph without sharing of subgraphs).

(ii) Let  $\Leftrightarrow$  be the symmetric closure of  $\Rightarrow$ . A transformation  $g \Leftrightarrow \dots \Leftrightarrow h$  is restricted if every  $[iii]$ -step in the transformation is restricted.

**3.2. Connecting process graph equivalences with process graph transformations.**

PROPOSITION 3.2.1. Let  $g, h \in H_\delta$ . Then we have the following:

- (i)  $g \Rightarrow_{[i-iii]} h$  implies  $g \equiv_{\mathcal{R}} h$ ;
- (ii)  $g \Rightarrow_{[i-iv]} h$  implies  $g \equiv_{\mathcal{F}} h$ .

*Proof.* Item (i) follows at once from the definitions.

(ii) We must only prove that the new node  $s$  introduced in a fork does not generate new failure pairs (see Fig. 8(b)).

Case 1. Let  $(\sigma a, \{b_1, \dots, b_n\})$  be the ready pair contributed by node  $t_1$ , where  $n \geq 1$  and the  $b_i$  are not  $\delta$ . The ready pair of the new node  $s$  is  $(\sigma a, \{b_1, \dots, b_n, c_1, \dots, c_m\})$ . Hence the failure pairs contributed by  $s$  are among those of  $t_1$ .

Case 2.  $n = 1$  and  $b = \delta$ . Then  $(\sigma a, \emptyset)$  is the ready pair of  $t_1$  so the failure pairs of  $t_1$  are  $[\sigma a, X]$ ,  $X \subseteq A$  and again these cover the failure pairs of  $s$ .

Case 3. The cases where  $m = 1, c_1 = \delta$  are trivial.

So in all cases the *new* failure pairs (of  $s$ ) were already present as failure pairs of  $t_1$ . The part of  $\mathcal{F}[g]$  that consists of successful traces is invariant.  $\square$

We will now prove the reverse implications in Proposition 3.2.1. To this end the *ready normal form*  $\mathcal{R}(g)$  and the *failure normal form*  $\mathcal{F}(g)$  will be defined. First we define a map  $\gamma$  from the collection of ready sets  $\{\mathcal{R}[g] \mid g \in H_\delta\}$  to  $H_\delta$ .

DEFINITION 3.2.2. (i) Let  $g \in H_\delta$  have ready set  $\mathcal{R}[g]$ . Then  $\gamma(\mathcal{R}[g])$  is the process graph with  $\mathcal{R}[g] \cup \{o\}$  as set of nodes, with  $(\varepsilon, X) \in \mathcal{R}[g]$  as root, and with edges

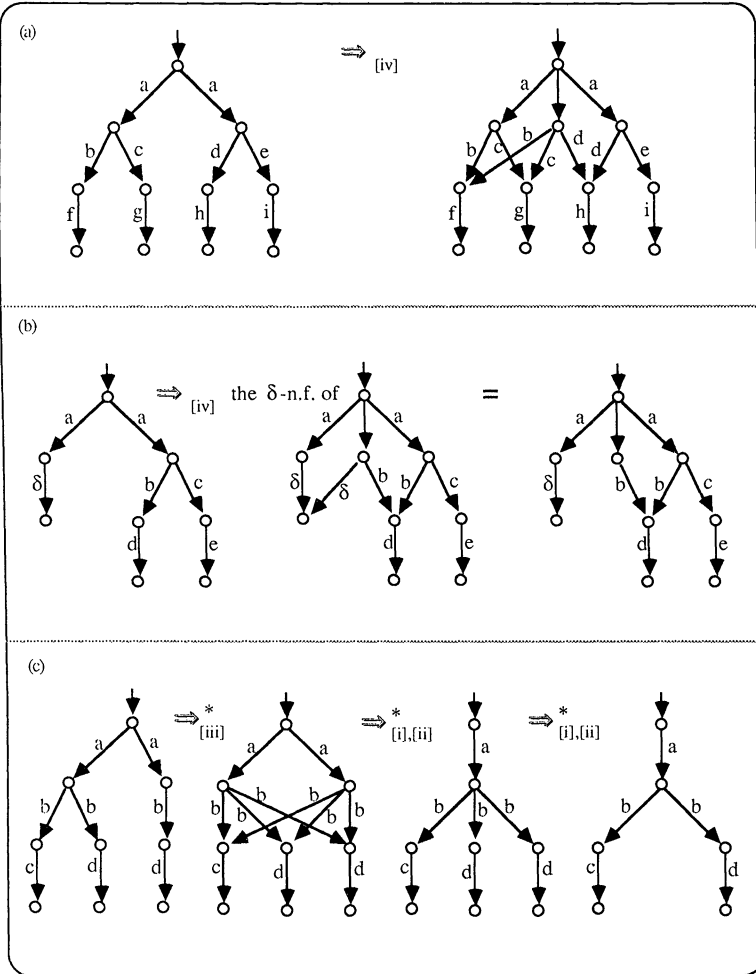

FIG. 10

given by

$$\begin{aligned}
 (\sigma, \{a\} \cup X) &\xrightarrow{a} (\sigma a, Y), \\
 (\sigma, \{a\} \cup X) &\xrightarrow{a} \sigma a, \\
 (\sigma, \emptyset) &\xrightarrow{\delta} o
 \end{aligned}$$

(whenever the left-hand side, right-hand side  $\in \mathcal{R}[[g]] \cup \{o\}$ ).

(ii)  $\mathcal{R}(g) = \gamma(\mathcal{R}[[g]])$  is the *ready normal form* of  $g$ .

(iii) The *convex closure*  $\text{cl}(\mathcal{R}[[g]])$  of  $\mathcal{R}[[g]]$  is obtained as the smallest set containing  $\mathcal{R}[[g]]$  and satisfying

$$(\sigma, X), (\sigma, Y \cup Z) \in \text{cl}(\mathcal{R}[[g]]) \Rightarrow (\sigma, X \cup Y) \in \text{cl}(\mathcal{R}[[g]]).$$

(iv)  $\mathcal{F}(g) = \gamma(\text{cl}(\mathcal{R}[[g]]))$  is the *failure normal form* of  $g$ .

*Example 3.2.3.* Let  $g$  be as in Fig. 11(a). Then  $\mathcal{R}(g)$ ,  $\mathcal{F}(g)$  are as in Fig. 11(b), 11(c), respectively.

**PROPOSITION 3.2.4.**

- (i)  $g \Leftrightarrow_{[i-iii]}^* \mathcal{R}(g)$  via a restricted transformation;
- (ii)  $g \Leftrightarrow^* \mathcal{F}(g)$  via a restricted transformation;

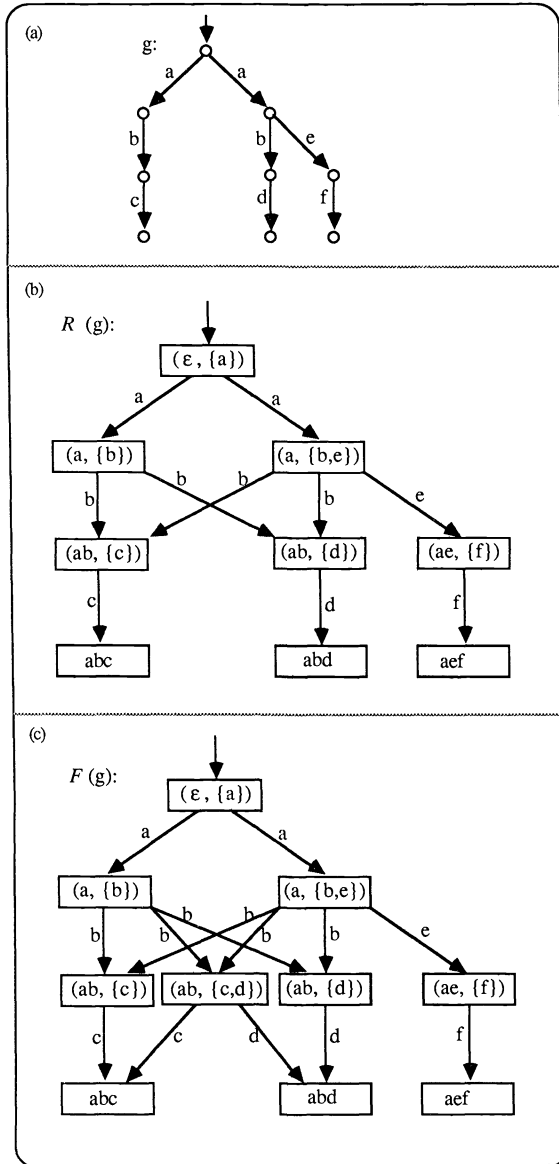

FIG. 11

- (iii)  $g \equiv_{\mathcal{R}} \mathcal{R}(g)$ ;
- (iv)  $g \equiv_{\mathcal{F}} \mathcal{F}(g)$ ;
- (v)  $\mathcal{R}(\mathcal{F}(g)) = \mathcal{F}(g)$ ;
- (vi)  $g \equiv_{\mathcal{R}} h \Rightarrow \mathcal{R}(g) = \mathcal{R}(h)$ ;
- (vii)  $g \equiv_{\mathcal{F}} h \Rightarrow \mathcal{F}(g) = \mathcal{F}(h)$ .

*Proof.* (i) (The following proof was kindly provided to us by R. J. van Glabbeek (personal communication).) Let  $g \in \mathbb{H}_\delta$  be given. We will transform  $g$  via a restricted transformation to a process graph  $g^*$  such that  $g^* \Leftrightarrow \mathcal{R}(g)$ . Since  $\Leftrightarrow$  coincides with  $\Leftrightarrow_{\{i,iii\}}^*$  (see Corollary 3.2.5(i)) this suffices.

If each node in  $g$  has a unique history,  $g$  is called *history unambiguous*. So in particular, process trees are history unambiguous. For a history-unambiguous process graph  $g$ , the *level* of node  $s$  in  $g$  is the length in symbols of the history of  $s$ . The root of  $g$ , therefore, has level 0. We will use the following notation: if  $s$  is a node of  $g$ ,  $\text{ready}(s)$  is the ready contribution of  $s$  to the ready set of  $g$ ; so  $\text{ready}(s) = (\sigma, X)$  or  $\sigma$  for some  $\sigma, X$ . If  $s, t$  are nodes of  $g$ , we write  $s \Leftrightarrow t$  to indicate that the subgraphs with  $s, t$  as roots, respectively, are bisimilar.

The transformation of  $g$  to  $g^*$  such that  $g^* \Leftrightarrow \mathcal{R}(g)$  will be done in stages, level by level, starting from the top level (level 0). The induction hypothesis for the transformation is that after the  $n$ th stage  $g$  ( $=g_0$ ) is transformed to  $g_n$  satisfying the following property  $\mathbb{H}_n$ : *Suppose  $p, q$  are nodes of  $g_n$  such that  $p$  has level  $n$ ,  $\text{ready}(p) = (\sigma, X \cup \{a\})$  and  $\text{ready}(q) = (\sigma a, Y)$  or  $\sigma a$ . Then  $g_n$  contains a node  $r$  such that  $q \Leftrightarrow r$  and  $p \rightarrow_a r$ .*

For  $g_0$  we have indeed  $\mathbb{H}_0$ ;  $p$  is then the root and for  $r$  we just take  $q$ . Now suppose  $g_n$  is constructed such that  $\mathbb{H}_n$  holds. We will construct  $g_{n+1}$  such that  $\mathbb{H}_{n+1}$  holds. So consider a node  $p$  of level  $n+1$  in  $g_n$  admitting an  $a$ -step (see Fig. 12) with  $\text{ready}(p) = (\sigma b, X \cup \{a\})$ , and a node  $q$  with  $\text{ready}(q) = (\sigma b a, Y)$ . Hence there is a node  $p'$  on level  $n$  such that  $p' \rightarrow_b p$ ; say  $\text{ready}(p') = (\sigma, X')$ . Also there must be a node  $q'$  such that  $q' \rightarrow_a q$  and, say,  $\text{ready}(q') = (\sigma b, Z)$ . By  $\mathbb{H}_n$ , therefore, there is a node  $r'$  such that  $q' \Leftrightarrow r'$  and  $p' \rightarrow_b r'$ . By the definition of  $\Leftrightarrow$ , there is a node  $r$  such that  $r' \rightarrow_a r$  and  $q \Leftrightarrow r$ . Now we insert a cross (i.e., two  $a$ -steps) as in the figure. The result is unshared by backward application of  $\Rightarrow_{(iii)}$  to a process tree. This unsharing does not increase the number of nodes of level  $n+1$ , and also does not increase the number of nodes of level  $n+2$  modulo  $\Leftrightarrow$ . The procedure is repeated for all  $p$  of level  $n+1$  and equivalence classes  $q/\Leftrightarrow$ . As there are only finitely many such pairs  $p, q/\Leftrightarrow$  the procedure stops eventually; the resulting tree is  $g_{n+1}$ . Clearly  $g_{n+1}$  satisfies  $\mathbb{H}_{n+1}$ . The construction of the sequence  $g_0, g_1, \dots, g_n$  stops when  $n$  is equal to the depth of  $g$ . The result is called  $g^*$ , and we claim that  $g^* \Leftrightarrow \mathcal{R}(g)$  via the bisimulation that relates nodes  $s, t$  in  $g^*, \mathcal{R}(g)$ , respectively, such that  $\text{ready}(s) = \text{ready}(t)$ .

*Proof of the Claim.* Suppose  $s, t$  are nodes in  $g^*, \mathcal{R}(g)$ , respectively, such that  $\text{ready}(s) = \text{ready}(t) = (\sigma, X \cup \{a\})$ . Let  $s \rightarrow_a s'$ . Then take the unique node  $t'$  in  $\mathcal{R}(g)$  with  $\text{ready}(t') = \text{ready}(s')$ . This must be  $(\sigma a, Y)$  or  $\sigma a$ . By definition of the edges in  $\mathcal{R}(g)$  we have  $t \rightarrow_a t'$ ; and indeed  $s' \Leftrightarrow t'$  because  $\text{ready}(s') = \text{ready}(t')$ . The other side of the bisimulation requirements: Let  $s, t$  be as before, and let  $t \rightarrow_a t'$  with  $\text{ready}(t') = (\sigma a, Y)$  or  $\sigma a$ . Let  $s^*$  be a node in  $g^*$  such that  $\text{ready}(s^*) = \text{ready}(t')$ . By construction

FIG. 12

of  $g^*$  there is a node  $s'$  in  $g^*$  with  $s^* \Leftrightarrow s'$  and  $s \rightarrow_a s'$ . Clearly,  $\text{ready}(s') = \text{ready}(s^*) = \text{ready}(t')$ , hence  $s' \Leftrightarrow t'$ .

(ii) Let  $g$  be given. According to (i) there is a restricted transformation of  $g$  to  $\mathcal{R}(g)$ . We will transform (via a restricted transformation)  $\mathcal{R}(g)$  further into  $\mathcal{F}(g)$ , as follows. Take nodes  $(\sigma, X)$ ,  $(\sigma, Y \cup Z)$  from  $\mathcal{R}(g)$  such that  $(\sigma, X \cup Y)$  is not yet a node of  $\mathcal{R}(g)$ . (If such nodes do not exist then  $\mathcal{R}(g)$  is already equal to  $\mathcal{F}(g)$ .) Now it is easy to see that there are paths in  $\mathcal{R}(g)$  from the root to the nodes  $(\sigma, X)$ ,  $(\sigma, Y \cup Z)$  such that these paths coincide in all but their last step, i.e., the paths split up as late as possible. At the split-up node we now insert a fork into  $\mathcal{R}(g)$ , with central node  $(\sigma, X \cup Y)$ , which is a new node. Call the result:  $\mathcal{R}(g)^+$ . Next,  $\mathcal{R}(g)^+$  is transformed (according to (i)) to  $\mathcal{R}(\mathcal{R}(g)^+)$ . Iteration of this procedure, via  $\mathcal{R}(\mathcal{R}(g)^+)^+$ ,  $\mathcal{R}(\mathcal{R}(\mathcal{R}(g)^+)^+)$ , etc., obviously will stop in  $\mathcal{F}(g)$ .

Parts (iii) and (iv) are left to the reader.

(v) By Definition 3.2.2,  $\mathcal{R}(\mathcal{F}(g)) = \mathcal{F}(g)$  means

$$\gamma(\mathcal{R}[\gamma(\text{cl}(\mathcal{R}[\mathcal{R}(g)]))]) = \gamma(\text{cl}(\mathcal{R}[\mathcal{R}(g)])),$$

which is equivalent to

$$\mathcal{R}[\gamma(\text{cl}(\mathcal{R}[\mathcal{R}(g)]))] = \text{cl}(\mathcal{R}[\mathcal{R}(g)]).$$

So we must check that the set of ready pairs of the graph determined by the set of ready pairs  $\text{cl}(\mathcal{R}[\mathcal{R}(g)])$  is just  $\text{cl}(\mathcal{R}[\mathcal{R}(g)])$ ; this seems obvious.

(vi)  $g \equiv_{\mathcal{R}} h$  by definition means  $\mathcal{R}[g] = \mathcal{R}[h]$ . Hence  $\mathcal{R}(g) = \gamma(\mathcal{R}[g]) = \gamma(\mathcal{R}[h]) = \mathcal{R}(h)$ .

(vii) Suppose  $g \equiv_{\mathcal{F}} h$ . Then by (iv)  $g \equiv_{\mathcal{F}} \mathcal{F}(g)$ ,  $h \equiv_{\mathcal{F}} \mathcal{F}(h)$ , so  $\mathcal{F}(g) \equiv_{\mathcal{F}} \mathcal{F}(h)$ . Since both  $\mathcal{F}(g)$ ,  $\mathcal{F}(h)$  are convexly closed, we have  $\mathcal{F}(g) \equiv_{\mathcal{R}} \mathcal{F}(h)$  (by Lemma 2.5.5). So

(vi)  $\mathcal{R}(\mathcal{F}(g)) = \mathcal{R}(\mathcal{F}(h))$ . Hence by (v):  $\mathcal{F}(g) = \mathcal{F}(h)$ .  $\square$

**COROLLARY 3.2.5.** *Let  $g, h \in \mathbb{H}_\delta$ . Then we have the following:*

- (i)  $g \Leftrightarrow h$  if and only if  $g \Leftrightarrow_{\{\text{ii}, \text{iii}\}}^* h$ ;
- (ii)  $g \equiv_{\mathcal{R}} h$  if and only if  $g \Leftrightarrow_{\{\text{i}-\text{iii}\}}^* h$ ;
- (iii)  $g \equiv_{\mathcal{F}} h$  if and only if  $g \Leftrightarrow^* h$ .

*Proof.* Item (i) is (essentially) proved in the Appendix of [BK83] and also in Corollary 2.13 of [BK85]: the proofs there also take  $\tau$ -steps into account; after leaving out all mention of  $\tau$ -steps, the result follows.

(ii) The implication from right to left follows from Proposition 3.2.1(i). The other direction follows from Proposition 3.2.4(i), (vi).

(iii) The proof is similar to (ii).  $\square$

**4. Axiomatising the equivalences on process graphs.** We will now use our analysis of  $\equiv_{\mathcal{R}}, \equiv_{\mathcal{F}}$  on the graph domain  $\mathbb{H}_\delta$  to formulate complete axiom systems for these notions. First this will be done for the signature of  $+, \cdot$  alone, later on (in § 4.2) also  $\parallel, \ll, \mid, \partial_H$  will be taken into account.

**4.1. The case without communication.** We start with the observation (whose proof is simple and omitted) that  $\equiv_{\mathcal{R}}, \equiv_{\mathcal{F}}$  are congruences on  $\mathbb{H}_\delta(+, \cdot)$ , and hence can be factored out to yield  $\mathbb{H}_\delta(+, \cdot)/\equiv_{\mathcal{R}}$  and  $\mathbb{H}_\delta(+, \cdot)/\equiv_{\mathcal{F}}$ , respectively. These are the structures which we will now axiomatise.

We will prove that the axiom system  $\text{BPA}_\delta + \text{R1}, 2 + \text{S}$  in Table 3 is a complete axiomatisation for  $\mathbb{H}_\delta(+, \cdot)/\equiv_{\mathcal{F}}$ ; after leaving out axiom *S* we have a complete axiomatisation for  $\mathbb{H}_\delta(+, \cdot)/\equiv_{\mathcal{R}}$ . Here  $a, b$  vary over  $A \cup \{\delta\}$ ;  $x, y, z, u, v$  are variables

for processes. Note that R2 is not derivable from R1 because in  $\text{BPA}_\delta + \text{R1}, 2 + \text{S}$  there is no process  $x$  satisfying  $bx = b$  when  $b \neq \delta$ . On the other hand,  $x$  should be present in axiom S as the equation

$$a + a(y + z) = a + a(y + z) + ay$$

would yield the failure-inconsistent equation

$$a + ab = a + ab + a\delta.$$

*Remark 4.1.1.* (i) The axioms R1, 2 and S (R for readiness, S for saturation), which are specific for failure equivalence, appear already in [Br83] in a slightly different form. [Br83] considers also  $\tau$ -steps and presents as laws valid for failure equivalence in Proposition 1.3.6:

$$(1) \quad \tau(\mu x + u) + \tau(\mu y + v) = \tau(\mu x + \mu y + u) + \tau(\mu x + \mu y + v),$$

$$(2) \quad \mu x + \mu y = \mu(\tau x + \tau y)$$

(here  $\mu \in A_\delta \cup \{\tau\}$ ;  $x, y, u, v$  are arbitrary processes), and in Proposition A.3 in [Br83]:

$$(3) \quad \tau x + \tau y = \tau x + \tau y + \tau(x + y),$$

$$(4) \quad \tau x + \tau(x + y + z) = \tau x + \tau(x + y) + \tau(x + y + z).$$

Clearly (1), (2) imply R1 in Table 3; and using the  $\tau$ -law  $x\tau = x$ , also valid in failure semantics, we also derive R2. Further, (3), (4) together with (2) yield the pair

$$ax + ay = ax + ay + a(x + y),$$

$$ax + a(x + y + z) = ax + a(x + y) + a(x + y + z)$$

(where  $a \in A_\delta$ ), which is equivalent to axiom S in Table 3.

TABLE 3  
 $\text{BPA}_\delta + \text{R1}, 2 + \text{S}$

$x + y = y + x$	A1
$(x + y) + z = x + (y + z)$	A2
$x + x = x$	A3
$(x + y)z = xz + yz$	A4
$(xy)z = x(yz)$	A5
$x + \delta = x$	A6
$\delta x = \delta$	A7
$a(bx + u) + a(by + v) = a(bx + by + u) + a(bx + by + v)$	R1
$a(b + u) + a(by + v) = a(b + by + u) + a(b + by + v)$	R2
$ax + a(y + z) = ax + a(y + z) + a(x + y)$	S

(ii) The axioms R1, 2 and S are also immediate consequences of the proof system of De Nicola and Hennessy [DH84] for strong testing equivalence  $\approx_2$ , to be discussed and related with failure equivalence later in Remark 7.3.3. This can be seen as follows:

(1) *Axiom S* in Table 3:  $ax + a(y + z) = ax + a(y + z) + a(x + y)$  implies

$$ax + ay = ax + ay + a(x + y)$$

by taking  $z = y$ ; this is (D5) in [DH84]. Further, (S) implies

$$ax + a(x + y + z) = ax + a(x + y + z) + a(x + y)$$

by replacing  $y$  in (S) by  $x+y$ . This is (D6) in [DH84]. Vice versa, (S) follows from (D5), (D6):

$$ax + a(y+z) \tag{D5}$$

$$= ax + a(y+z) + a(x+y+z) \tag{D6}$$

$$= ax + a(y+z) + a(x+y+z) + a(x+y) \tag{D5}$$

$$= ax + a(y+z) + a(x+y).$$

(2) *Axiom R1*:  $a(bx+u) + a(by+v) = a(bx+by+v) + a(bx+by+u)$  is derived from the axiom system in [DH84] as follows:

$$bx + \tau(by+v) = \tau(bx+by+v) \tag{N3},$$

$$by + \tau(bx+u) = \tau(bx+by+u) \tag{N3},$$

$$bx + by + \tau(by+v) + \tau(bx+u) = \tau(bx+by+v) + \tau(bx+by+u)$$

$$bx + \tau(bx+u) = \tau(bx+u) \tag{D9},$$

$$by + \tau(by+v) = \tau(by+v) \tag{D9},$$

$$\tau(by+v) + \tau(bx+u) = \tau(bx+by+v) + \tau(bx+by+u),$$

$$a[\tau(by+v) + \tau(bx+u)] = a[\tau(bx+by+v) + \tau(bx+by+u)],$$

$$a(by+v) + a(bx+u) = a(bx+by+v) + a(bx+by+u) \tag{N1}.$$

Here (N1), (N3), and (D9) are axioms in [DH84].

(3) *Axiom R2*:  $a(b+u) + a(by+v) = a(b+by+u) + a(b+by+v)$  is not needed in [DH84] because a process  $b$ , which first performs action  $b$  and then successfully terminates, is not considered there. Note that the process  $b\text{NIL}$  of [DH84] corresponds to  $b \cdot \delta$  and is thus different from  $b$ .

**4.1.2. Connecting terms with process graphs.** Let  $\text{Ter}(\text{BPA}_\delta)$  be the set of closed terms in the signature of  $\text{BPA}_\delta$  (=the signature of  $\text{BPA}_\delta + \text{R1, 2+S}$ ). We define the following translations:

$$\text{graph: } \text{Ter}(\text{BPA}_\delta) \rightarrow \mathbb{H}_\delta,$$

$$\text{ter: } \mathbb{H}_\delta \rightarrow \text{Ter}(\text{BPA}_\delta).$$

Here  $\text{graph}(T)$  is the process graph obtained by first normalizing  $T$  with respect to A4, A6, A7 in Table 3 and second by interpreting  $a, +, \cdot$  as the corresponding ‘‘one-edge graphs’’ and operators  $+, \cdot$  on  $\mathbb{H}_\delta$ .

Further, to define  $\text{ter}(g)$  we first define  $\text{tree}(g)$  as the tree obtained from  $g$  by ‘‘unsharing.’’ Now we define  $\text{ter}(g)$  as the term corresponding in the obvious way to  $\text{tree}(g)$ .

*Example 4.1.2.1.* (i)  $\text{graph}(a(b+c+d)d+de+ed) = \text{graph}(a(bd+cd)+ed)$  is the graph in Fig. 13(a).

(ii) If  $g$  is as in Fig. 13(b), then  $\text{tree}(g)$  is as in Fig. 13(c).

(iii) If  $g$  is as in (ii), then  $\text{ter}(g) = ace + b(de + ab)$ .

*Remark 4.1.3.* Note that  $\text{ter}, \text{graph}$  are ‘‘almost’’ inverse to each other:

$$\text{BPA}_\delta \vdash (\text{ter} \circ \text{graph})(T) = T,$$

$$(\text{graph} \circ \text{ter})(g) \Leftrightarrow g$$

where  $\Leftrightarrow$  (bisimilarity) coincides with  $\Leftrightarrow_{\text{III,III}}^*$ .

TRANSFER LEMMA 4.1.4 (see diagram). Let  $g, h \in \mathbb{H}_\delta$  be such that  $g \Rightarrow h$ . In case  $\Rightarrow$  is  $\Rightarrow_{(iii)}$  we require moreover that  $g$  be a process tree. Then

*Proof.* A transformation  $g \Rightarrow_{(ii)} h$  (removing a double edge) “translates” into some applications of A3:  $x + x = x$ .

A transformation  $g \Rightarrow_{(iii)} h$  is invisible on the level of terms, i.e.,  $\text{ter}(g)$  and  $\text{ter}(h)$  are identical terms. Next consider a transformation  $g \Rightarrow_{(iii)} h$ , which consists of adding two edges in  $g$  as in Fig. 14. (Note that in this case  $g$  is assumed to be a tree.) This translates to an application of R1 if the subtrees  $x, y$  are nonempty, and to R2 if one of these subtrees is empty. In case both subtrees  $x, y$  are empty we have an application of axiom A3.

Finally, a transformation  $g \Rightarrow_{(iv)} h$  (see also Fig. 8) translates into some applications of axiom S in Table 3.  $\square$

THEOREM 4.1.5. (i)  $\text{BPA}_\delta + \text{R1}, 2 \vdash T_1 = T_2 \Leftrightarrow \text{graph}(T_1) \equiv_{\mathcal{G}} \text{graph}(T_2)$ .

(ii)  $\text{BPA}_\delta + \text{R1}, 2 + \text{S} \vdash T_1 = T_2 \Leftrightarrow \text{graph}(T_1) \equiv_{\mathcal{F}} \text{graph}(T_2)$ .

*Proof.* We prove (ii); the proof of (i) is similar.

Checking the soundness ( $\Rightarrow$ ) is routine and will not be done here. As to the completeness ( $\Leftarrow$ ): suppose  $\text{graph}(T_1) \equiv_{\mathcal{F}} \text{graph}(T_2)$ . Then by Proposition 3.2.4(ii), (vii):  $\text{graph}(T_1) \Leftrightarrow^* \text{graph}(T_2)$  via a restricted transformation. Now by the Transfer Lemma 4.1.4 we have

$$\text{BPA}_\delta + \text{R1}, 2 + \text{S} \vdash (\text{ter} \circ \text{graph})(T_1) = (\text{ter} \circ \text{graph})(T_2)$$

and by Remark 4.1.3:

$$\text{BPA}_\delta + \text{R1}, 2 + \text{S} \vdash T_1 = T_2. \quad \square$$

FIG. 13

*Notation 4.1.6.* (i) If  $(\Sigma, E)$  is a specification (sometimes only written as  $E$  if the signature  $\Sigma$  is clear), then  $I(\Sigma, E)$  is its initial algebra.

(ii)  $\cong$  denotes isomorphism between algebras.

COROLLARY 4.1.7. (i)  $\mathbb{H}_\delta(+, \cdot, a, \delta) / \equiv_{\mathcal{F}} \cong I(\text{BPA}_\delta + \text{R1}, 2)$ .

(ii)  $\mathbb{H}_\delta(+, \cdot, a, \delta) / \equiv_{\mathcal{F}} \cong I(\text{BPA}_\delta + \text{R1}, 2 + \text{S})$ .  $\square$

**4.2. The case with communication: the graph model of  $\text{ACP}_r$ .** Finally we will prove the results above in the presence of communication. The operators  $\parallel, \llbracket, \cdot, |, \partial_H, a_H (a \in A)$  on  $\mathbb{H}_\delta$  were already introduced in § 1.2. They are the semantical counterparts of the same operators in the axiom system  $\text{ACP}_r$ , as in the upper part of Table 4, which presents the axiom system  $\text{ACP}_r + \text{R1}, 2 + \text{S}$ , and which extends our earlier axiom system  $\text{BPA}_\delta + \text{R1}, 2 + \text{S}$  in Table 3.

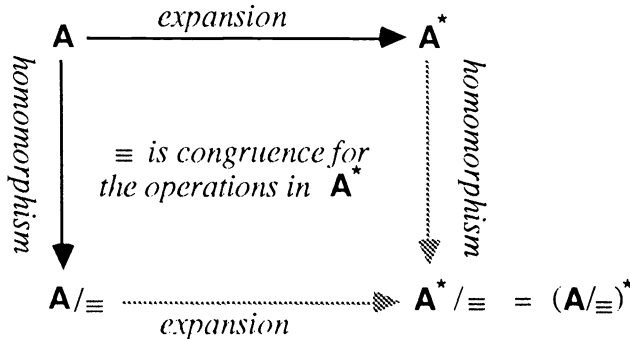

As before, in Table 4 a, b, c vary over  $A \cup \{\delta\}$ , and  $x, y, z, u, v$  vary over processes.

We want to prove that the initial algebra of  $\text{ACP}_r + \text{R1}, 2 + \text{S}$  is isomorphic to the model of finite acyclic graphs modulo failure equivalence  $\equiv_{\mathcal{F}}$ , called the *graph model* for  $\text{ACP}_r + \text{R1}, 2 + \text{S}$ . To this end we have first to prove that  $\equiv_{\mathcal{F}}$  is a *congruence* with respect to also the new operators. Once we have this, and knowing from [BK85], [BK86a] (after leaving out all reference to  $\tau$ -steps) that there is the isomorphism

$$I(\text{ACP}_r) \cong \mathbb{H}_\delta(+, \cdot, \parallel, \llbracket, \cdot, |, \partial_H, a_H, a, \delta) / \Leftrightarrow$$

where  $\Leftrightarrow$  is bisimulation (which coincides with  $\Leftrightarrow_{\{\text{III}, \text{III}\}}^*$ ; Corollary 3.2.5(i)), the derived isomorphism is a consequence from some general facts which we will state now.

**4.2.1. General intermezzo.** Let  $\mathbf{A}$  be an algebra that on the one hand can be expanded to  $\mathbf{A}^*$  (i.e., enriched with new functions; the domain is invariant) and on the other hand can be factored out via  $\equiv$ , a congruence on  $\mathbf{A}$ , to  $\mathbf{A}/\equiv$ . Suppose moreover that  $\equiv$  is also a congruence on  $\mathbf{A}^*$ . (See the following diagram.)

Then this expansion and factorisation are compatible (or commuting):  $\mathbf{A}^*/\equiv$  equals  $(\mathbf{A}/\equiv)^*$ . Now let  $\mathbf{A}, \mathbf{A}^*, \mathbf{A}/\equiv$  be isomorphic respectively to the initial algebras of the equational specifications  $(\Sigma, E), (\Sigma \cup \Delta, E \cup D), (\Sigma, E \cup F)$ . Then it follows that  $(\Sigma \cup \Delta, E \cup D)$  is

- (1) a conservative extension of the “base” specification  $(\Sigma, E)$  (i.e., no new identities between closed terms in the base signature  $\Sigma$  are provable from  $(\Sigma \cup \Delta, E \cup D)$ ), and
- (2) moreover, the extra operators in  $\Delta$  can be *eliminated*:

FIG. 14

TABLE 4  
ACP<sub>r</sub>+R1, 2+S

$x + y = y + x$	A1
$x + (y + z) = (x + y) + z$	A2
$x + x = x$	A3
$(x + y)z = xz + yz$	A4
$(xy)z = x(yz)$	A5
$x + \delta = x$	A6
$\delta x = \delta$	A7
$a b = b a$	C1
$(a b) c = a (b c)$	C2
$\delta a = \delta$	C3
$x  y = x  y + y  x + x y$	CM1
$a  x = ax$	CM2
$ax  y = a(x  y)$	CM3
$(x + y)  z = x  z + y  z$	CM4
$ax b = (a b)x$	CM5
$a bx = (a b)x$	CM6
$ax by = (a b)(x  y)$	CM7
$(x + y) z = x z + y z$	CM8
$x (y + z) = x y + x z$	CM9
$\partial_H(a) = a \quad \text{if } a \notin H$	D1
$\partial_H(a) = \delta \quad \text{if } a \in H$	D2
$\partial_H(x + y) = \partial_H(x) + \partial_H(y)$	D3
$\partial_H(xy) = \partial_H(x) \cdot \partial_H(y)$	D4
$a_H(b) = b \quad \text{if } b \notin H$	RN1
$a_H(b) = a \quad \text{if } b \in H$	RN2
$a_H(x + y) = a_H(x) + a_H(y)$	RN3
$a_H(xy) = a_H(x) \cdot a_H(y)$	RN4
$a(bx + u) + a(by + v) = a(bx + by + u) + a(bx + by + v)$	R1
$a(b + u) + a(by + v) = a(b + by + u) + a(b + by + v)$	R2
$ax + a(y + z) = ax + a(y + z) + a(x + y)$	S

Furthermore (and this is what we are interested in) we may conclude from the given isomorphisms that

$$\mathbf{A}^*/\equiv = (\mathbf{A}/\equiv)^* \cong I(\Sigma \cup \Delta, E \cup D \cup F)$$

where the last algebra is the initial algebra of the *union* of  $(\Sigma, E \cup F)$  and  $(\Sigma \cup \Delta, E \cup D)$ .

(In the statement of the next theorem, as well as in its proof and Table 5, we have suppressed mention of the constants  $a, \delta$  in, e.g.,  $\mathbb{H}_\delta(+, \cdot)$ , which actually should read  $\mathbb{H}_\delta(+, \cdot, a, \delta)(a \in A)$ .)

**THEOREM 4.2.2.** *Let the initial algebras  $I(\text{BPA}_\delta)$  etc. as in Table 5(ii) of the axiom systems  $\text{BPA}_\delta$  etc. as in Table 5(i) be given. Furthermore, consider the graph models  $\mathbb{H}_\delta(+, \cdot) / \cong$  etc. as in Table 5(iii).*

*Then corresponding initial models and graph models are isomorphic. In particular:*

$$I(\text{ACP}_r + \text{R1}, 2 + \text{S}) \cong \mathbb{H}_\delta(+, \cdot, \parallel, \llbracket, \lrcorner, \partial_H, a_H) / \equiv_{\mathcal{F}}$$

*Proof.* Consider, for example,

$$\begin{array}{ccc} \text{BPA}_\delta & \longrightarrow & \text{ACP}_r \\ \downarrow & & \\ \text{BPA}_\delta + \text{R1}, 2 + \text{S} & & \end{array}$$

and the corresponding initial algebras

$$\begin{array}{ccc} I(\text{BPA}_\delta) & \longrightarrow & I(\text{ACP}_r) \\ \downarrow & & \\ I(\text{BPA}_\delta + \text{R1}, 2 + \text{S}) & & \end{array}$$

and furthermore (by position in the diagram in Table 5) the corresponding graph models

$$\begin{array}{ccc} \mathbb{H}_\delta(+, \cdot) / \cong & \xrightarrow{\text{exp}} & \mathbb{H}_\delta(+, \cdot, \parallel, \llbracket, \lrcorner, \partial_H, a_H) / \cong \\ \downarrow \text{hom} & & \\ \mathbb{H}_\delta(+, \cdot) / \equiv_{\mathcal{F}} & & \end{array}$$

By Corollary 4.1.7(ii) we have  $I(\text{BPA}_\delta + \text{R1}, 2 + \text{S}) \cong \mathbb{H}_\delta(+, \cdot) / \equiv_{\mathcal{F}}$ , and by results in [BK85], [BK86a], [BK86b] we have  $I(\text{BPA}_\delta) \cong \mathbb{H}_\delta(+, \cdot) / \cong$  and  $I(\text{ACP}_r) \cong \mathbb{H}_\delta(+, \cdot, \parallel, \llbracket, \lrcorner, \partial_H, a_H) / \cong$ .

Therefore, by 4.2.1, it suffices to prove that  $\equiv_{\mathcal{F}}$  is a congruence with respect to the “new” operators on  $\mathbb{H}_\delta$  in order to conclude that

$$I(\text{ACP}_r + \text{R1}, 2 + \text{S}) \cong \mathbb{H}_\delta(+, \cdot, \parallel, \llbracket, \lrcorner, \partial_H, a_H) / \equiv_{\mathcal{F}}$$

This is proved in the next proposition.  $\square$

**PROPOSITION 4.2.3.** (i) *Failure equivalence is a congruence with respect to the operators  $\parallel, \llbracket, \lrcorner, \partial_H, a_H$  on  $\mathbb{H}_\delta$ .*

(ii) *The same holds for ready equivalence.*

*Proof.* (i) We consider some typical cases.

*The case of  $\partial_H$ .* To prove  $g \equiv_{\mathcal{F}} h \Rightarrow \partial_H(g) \equiv_{\mathcal{F}} \partial_H(h)$ . By Corollary 3.2.5 it suffices to check that  $g \Rightarrow h$  implies  $\partial_H(g) \equiv_{\mathcal{F}} \partial_H(h)$ . The cases that  $\Rightarrow$  is  $\Rightarrow_{[i]}$  or  $\Rightarrow_{[ii]}$  present no problem. As to  $\Rightarrow_{[iii]}$ : it is easy to verify that

$$g \Rightarrow_{[iii]} h \text{ implies } \partial_H(g) = \partial_H(h) \text{ or } \partial_H(g) \Rightarrow_{[iii]} \partial_H(h).$$

As to  $\Rightarrow_{[iv]}$ , as in the previous case, the effect of  $\partial_H$  (renaming some atoms in  $g, h$  into  $\delta$  and  $\delta$ -normalising the resulting graphs again) is such that either the “same” fork can be inserted or  $\partial_H(g) = \partial_H(h)$ .

TABLE 5

(i)	
$BPA_\delta$	$\longrightarrow$ $ACP_r$
$\downarrow$	$\downarrow$
$BPA_\delta + R1, 2$	$\longrightarrow$ $ACP_r + R1, 2$
$\downarrow$	$\downarrow$
$BPA_\delta + R1, 2 + S$	$\longrightarrow$ $ACP_r + R1, 2 + S$
(ii)	
$I(BPA_\delta)$	$\xrightarrow{\text{exp}}$ $I(ACP_r)$
$\downarrow \text{hom}$	$\downarrow \text{hom}$
$I(BPA_\delta + R1, 2)$	$\xrightarrow{\text{exp}}$ $I(ACP_r + R1, 2)$
$\downarrow \text{hom}$	$\downarrow \text{hom}$
$I(BPA_\delta + R1, 2 + S)$	$\xrightarrow{\text{exp}}$ $I(ACP_r + R1, 2 + S)$
(iii)	
$\mathbb{H}_\delta(+, \cdot) / \simeq$	$\xrightarrow{\text{exp}}$ $\mathbb{H}_\delta(+, \cdot, \parallel, \perp,  , \partial_H, a_H) / \simeq$
$\downarrow \text{hom}$	$\downarrow \text{hom}$
$\mathbb{H}_\delta(+, \cdot) / \equiv_{\mathcal{R}}$	$\xrightarrow{\text{exp}}$ $\mathbb{H}_\delta(+, \cdot, \parallel, \perp,  , \partial_H, a_H) / \equiv_{\mathcal{R}}$
$\downarrow \text{hom}$	$\downarrow \text{hom}$
$\mathbb{H}_\delta(+, \cdot) / \equiv_{\mathcal{F}}$	$\xrightarrow{\text{exp}}$ $\mathbb{H}_\delta(+, \cdot, \parallel, \perp,  , \partial_H, a_H) / \equiv_{\mathcal{F}}$

(Note here that it is crucial that process graphs  $g, h$  as in Fig. 15 are not failure equivalent, since  $\partial_{\{b\}}$  would yield a trace  $a\delta$  in  $h$  but not in  $g$ .)

The case of  $\parallel$ . It suffices to prove

$$g \Rightarrow g' \text{ implies } g \parallel h \equiv_{\mathcal{F}} g' \parallel h.$$

As above, only the cases [iii], [iv] (cross and fork, respectively) are of interest. In fact we will prove the following:

- (1)  $g \Rightarrow_{\text{[iii]}} g'$  implies  $g \parallel h \Rightarrow_{\text{[iii]}} g' \parallel h$ .
- (2)  $g \Rightarrow_{\text{[iv]}} g'$  implies  $g \parallel h \equiv_{\mathcal{F}} g' \parallel h$ .

*Proof of (1).* Due to the construction of a merge as a Cartesian product with diagonal edges for communications (Fig. 16), it is “geometrically” clear (see Fig. 17) that inserting a cross in  $g$  amounts to inserting several crosses (also possibly diagonal ones, depending on the communication function) in the merge  $g \parallel h$ . So  $g \parallel h \Rightarrow_{\text{[iii]}} g' \parallel h$ . (It is not hard to see that the condition on histories, which is stated in the definition

FIG. 15

FIG. 16

of  $\Rightarrow_{(iii)}$ , stays satisfied in such a way that insertion of these crosses in  $g \parallel h$  is indeed legitimate.)

*Proof of (2).* Under the assumption  $g \Rightarrow_{(iv)} g'$  we now prove  $g \parallel h \equiv_{\mathcal{F}} g' \parallel h$  directly from the definition  $\equiv_{\mathcal{F}}$ . So consider the addition in  $g$  of a fork that connects all successors of  $s_1$  (see Fig. 18) to some of those of  $s_3$ . That is, the failure pairs contributed by the new node  $s_2$  are contained in those of  $s_1$ . Then we must check that the new

FIG. 17

FIG. 18

nodes  $(s_2, t)$  in  $g' || h$  caused by this addition, contribute no new failure pairs. It is not hard to check that indeed the failure pairs of  $(s_2, t)$  are contained in those of  $(s_2, t)$  by some consideration of the outgoing edges of  $(s_1, t)$  and  $(s_2, t)$ . The precise verification is omitted here.

The proof of part (ii) of the proposition is as for (i)—but simpler. It is omitted here.  $\square$

**5. The failure model of  $ACP_r$ .** In the previous sections the notion of failure equivalence was introduced for the process graph domain  $\mathbb{H}_\delta$ , and it was shown to be a congruence with respect to the operators of  $ACP_r$  in  $\mathbb{H}_\delta$ . The quotient  $\mathbb{H}_\delta / \equiv_{\mathcal{F}}$  was shown to be a model of  $ACP_r$ , called the graph model of  $ACP_r$ . Furthermore, a complete axiomatisation  $ACP_r + R1, 2 + S$  was given for  $\equiv_{\mathcal{F}}$  in the sense of

$$I(ACP_r + R1, 2 + S) \cong \mathbb{H}_\delta / \equiv_{\mathcal{F}}.$$

Here  $\mathbb{H}_\delta / \equiv_{\mathcal{F}}$  is short for  $\mathbb{H}_\delta(+, \cdot, \parallel, \lfloor \_ \rfloor, \lfloor \_ \rfloor, \partial_H, a_H, a, \delta) / \equiv_{\mathcal{F}}$ . In this section we will provide an *explicit representation* of the quotient structure  $\mathbb{H}_\delta(+, \cdot, \parallel, \lfloor \_ \rfloor, \lfloor \_ \rfloor, \partial_H, a_H, a, \delta) / \equiv_{\mathcal{F}}$ , called the *failure model* of  $ACP_r$ . The model will shed more light into the structure of failures, and—in connection with § 6.2—it will link our definitions with the original work on failures in [BHR84].

**5.1. The domain  $\mathbb{F}$  of failure sets.** First we introduce the domain of failure sets, denoted by  $\mathbb{F}$ . It consists of all finite subsets

$$F \subseteq A^+ \cup (A^* \times \mathcal{P}(A))$$

(where  $A^*$  is the set of finite words over  $A$ ,  $A^+$  is the set of nonempty finite words

over  $A$ , and  $\mathcal{P}(A)$  is the power set of  $A$ ) which satisfy the following closure properties:

- (i)  $[\varepsilon, \emptyset] \in F$ ;
- (ii)  $[\sigma_1 \sigma_2, \emptyset] \in F \Rightarrow [\sigma_1, \emptyset] \in F$ ;
- (iii)  $X \subseteq Y$  and  $[\sigma, Y] \in F \Rightarrow [\sigma, X] \in F$ ;
- (iv)  $[\sigma, X] \in F$  and  $[\sigma, X \cup \{a\}] \notin F \Rightarrow \sigma a \in F$  or  $[\sigma a, \emptyset] \in F$ ;
- (v)  $\sigma a \in F \Rightarrow [\sigma, \emptyset] \in F$ ;
- (vi)  $[\varepsilon, X] \in F \ \& \ a \in X \Rightarrow [a, \emptyset] \notin F$ .

The conditions (i)-(iv) on failure sets are exactly as in [BHR84]. Condition (v) deals with traces  $\sigma \in A^+$  which allow a direct definition of sequential composition without using (and later hiding again) an extra action  $\surd$  coding the event of successful termination as in [BHR84]. In § 6.2 on CSP we will restrict ourselves to CSP without successful termination. Then this difference is irrelevant. Condition (vi) is needed because we do not consider  $\tau$ -steps and hence no initial nondeterminism.

**5.2. Operations on failure sets.** Now we define the constants  $\delta, a (a \in A)$  and the operations  $+, \cdot, \parallel, \llbracket, \partial_H, a_H$  of ACP, directly on  $F$ . For  $F, G \in \mathbb{F}$  we put the following:

- (i)  $\delta = \{[\varepsilon, X] \mid X \subseteq A\}$ .
- (ii)  $a = \{[a, X] \mid X \subseteq A - \{a\}\} \cup \{a\}$ .  
Initially “ $a$ ” can refuse anything except “ $a$ .” After “ $a$ ” has occurred, the process successfully terminates.

- (iii)  $F + G = \{[\varepsilon, X] \mid [\varepsilon, X] \in F \cap G\} \cup \{\sigma \mid \sigma \in F \cup G\} \cup \{[\sigma, X] \mid \sigma \neq \varepsilon \wedge [\sigma, X] \in F \cup G\} \cup \{\sigma \mid \sigma \in F \cup G\} \cup \{[\sigma, X] \mid \sigma \neq \varepsilon \wedge [\sigma, X] \in F \cup G\}$ .

In its first step  $F + G$  can refuse only those actions which can be refused by both  $F$  and  $G$ . In all subsequent steps  $F + G$  behaves as  $F \cup G$ .

- (iv)  $F \cdot G = \{[\sigma, X] \mid [\sigma, X] \in F\} \cup \{\sigma_1 \sigma_2 \mid \sigma_1 \in F \wedge \sigma_2 \in G\} \cup \{[\sigma_1 \sigma_2, X] \mid \sigma_1 \in F \wedge [\sigma_2, X] \in G\}$ .

$F \cdot G$  first behaves like  $F$  and after successful termination of  $F$  in a trace  $\sigma_1$  continues to behave as  $G$ .

- (v) (1)  $F \parallel G = \{\sigma \mid \exists \sigma_1 \in F, \sigma_2 \in G: \sigma \in \sigma_1 \parallel \sigma_2\} \cup \{[\sigma, X] \mid \exists [\sigma_1, X_1] \in F, [\sigma_2, X_2] \in G: \sigma \in \sigma_1 \parallel \sigma_2 \wedge X \subseteq (X_1 \cap X_2) - \{(a \mid b) \mid a \notin X_1 \wedge b \notin X_2\}\}$
- (2)  $\wedge X \subseteq (X_1 \cap X_2) - \{(a \mid b) \mid a \notin X_1 \wedge b \notin X_2\}$
- (3)  $\cup \{[\sigma, X] \mid \exists \sigma_1 \in F, [\sigma_2, X_2] \in G: \sigma \in \sigma_1 \parallel \sigma_2 \wedge X = X_2\}$
- (4)  $\cup \{[\sigma, X] \mid \exists [\sigma_1, X_1] \in F, \sigma_2 \in G: \sigma \in \sigma_1 \parallel \sigma_2 \wedge X = X_1\}$

where  $\sigma_1 \parallel \sigma_2$  is the set of traces in  $A^*$  defined inductively by

$$\varepsilon \parallel \sigma = \sigma \parallel \varepsilon = \{\sigma\},$$

$$a \sigma_1 \parallel b \sigma_2 = a \cdot (\sigma_1 \parallel b \sigma_2) \cup b \cdot (a \sigma_1 \parallel \sigma_2) \cup [a \mid b] \cdot (\sigma_1 \parallel \sigma_2)$$

with  $[a \mid b] = \{(a \mid b)\}$  if  $a \mid b \neq \delta$  and  $\emptyset$  if  $a \mid b = \delta$ .

Thus  $\sigma_1 \parallel \sigma_2$  is the set of successful traces obtained by merging and communicating between  $\sigma_1$  and  $\sigma_2$ . For all traces  $\sigma_1 \in F$  and  $\sigma_2 \in G$  this set is included in  $F \parallel G$  (clause (1)). Besides traces  $F \parallel G$  contains certain failure pairs  $[\sigma, X]$ . If either  $F$  or  $G$  have already terminated,  $X$  is just the refusal set of the other, not-yet-terminated component  $G$  or  $F$  (clauses (3) and

(4)). If neither  $F$  nor  $G$  have terminated,  $X$  contains only actions that both  $F$  and  $G$  can refuse. This suggests  $X \subseteq X_1 \cap X_2$ , where  $X_1$  and  $X_2$  are the refusal sets of  $F$  and  $G$ . However,  $F \parallel G$  cannot refuse the possible communications between  $F$  and  $G$ . These communications can only be of the form  $(a|b)$  with  $a \notin X_1$  and  $b \notin X_2$ . This explains the condition

$$X \subseteq X_1 \cap X_2 - \{(a|b) \mid a \notin X_1 \wedge b \notin X_2\}$$

for the refusal set  $X$  of  $F \parallel G$  (clause (2)). Note that in case of  $(a|b) = \delta$  nothing is deduced from  $X_1 \cap X_2$ .

Clearly,  $F \parallel G$  and  $F|G$  are just variations of  $F \parallel G$  differing only in their first actions.

$$(vi) \quad F \parallel G = \{\sigma \mid \exists \sigma_1 \in F, \sigma_2 \in G: \sigma \in \sigma_1 \parallel \sigma_2\}$$

$$\cup \{[\varepsilon, X] \mid [\varepsilon, X] \in F\}$$

$$\cup \{[\sigma, X] \mid \sigma \neq \varepsilon \wedge \exists [\sigma_1, X_1] \in F, [\sigma_2, X_2] \in G: \sigma \in \sigma_1 \parallel \sigma_2 \\ \wedge X \subseteq (X_1 \cap X_2) - \{(a|b) \mid a \notin X_1 \wedge b \notin X_2\}\}$$

$$\cup \{[\sigma, X] \mid \sigma \neq \varepsilon \wedge \exists \sigma_1 \in F, [\sigma_2, X_2] \in G: \sigma \in \sigma_1 \parallel \sigma_2 \wedge X = X_2\}$$

$$\cup \{[\sigma, X] \mid \sigma \neq \varepsilon \wedge \exists [\sigma_1, X_1] \in F, \sigma_2 \in G: \sigma \in \sigma_1 \parallel \sigma_2 \wedge X = X_1\}$$

where  $\sigma_1 \parallel \sigma_2$  is the set of traces in  $A^*$  defined inductively by

$$\varepsilon \parallel \sigma = \emptyset,$$

$$a\sigma_1 \parallel \sigma_2 = a \cdot (\sigma_1 \parallel \sigma_2).$$

Until the completion of its first communication  $F \parallel G$  behaves as  $F$ . This explains why  $F \parallel G$  inherits all initial failure pairs  $[\varepsilon, X]$  of  $F$ . Afterwards  $F \parallel G$  behaves as  $F \parallel G$ .

$$(vii) \quad F|G = \{\sigma \mid \exists \sigma_1 \in F, \sigma_2 \in G: \sigma \in \sigma_1 | \sigma_2\}$$

$$\cup \{[\varepsilon, X] \mid \exists [\varepsilon, X_1] \in F, [\varepsilon, X_2] \in G: X \subseteq A \\ - \{(a|b) \mid a \notin X_1 \wedge b \notin X_2\}\}$$

$$\cup \{[\sigma, X] \mid \sigma \neq \varepsilon \wedge \exists [\sigma_1, X_1] \in F, [\sigma_2, X_2] \in G: \sigma \in \sigma_1 | \sigma_2 \\ \wedge X \subseteq (X_1 \cap X_2) - \{(a|b) \mid a \notin X_1 \wedge b \notin X_2\}\}$$

$$\cup \{[\sigma, X] \mid \sigma \neq \varepsilon \wedge \exists \sigma_1 \in F, [\sigma_2, X_2] \in G: \sigma \in \sigma_1 | \sigma_2 \wedge X = X_2\}$$

$$\cup \{[\sigma, X] \mid \sigma \neq \varepsilon \wedge \exists [\sigma_1, X_1] \in F, \sigma_2 \in G: \sigma \in \sigma_1 | \sigma_2 \wedge X = X_1\}$$

where  $\sigma_1 | \sigma_2$  is the set of traces in  $A^*$  defined inductively by

$$\varepsilon | \sigma_2 = \sigma_1 | \varepsilon = \emptyset,$$

$$a\sigma_1 | b\sigma_2 = [a|b] \cdot (\sigma_1 \parallel \sigma_2).$$

In its first step  $F|G$  requires a communication between  $F$  and  $G$ . Here initially  $F|G$  can refuse every set  $X$  of actions not containing possible communications between  $F$  and  $G$ . This explains the condition

$$X \subseteq A - \{(a|b) \mid a \notin X_1 \wedge b \notin X_2\}$$

for the failure pairs  $[\varepsilon, X]$ . After its first step  $F|G$  behaves like  $F \parallel G$ .

- (viii)  $\partial_H(F) = \{\sigma \mid \sigma \in F \text{ does not contain any } a \in H\}$   
 $\cup \{[\sigma, X \cup Y] \mid [\sigma, X] \in F, s \text{ does not contain any } a \in H, \text{ and } Y \subseteq H\}.$

In  $\partial_H(F)$  only those traces that do not contain any  $a \in H$  are successful, and the actions in  $H$  can be refused at any moment.

- (ix)  $a_H(F) = \{a_H(\sigma) \mid \sigma \in F\}$   
 $\cup \{[a_H(\sigma), X] \mid a \in X \wedge [\sigma, X \cup H] \in F\}$   
 $\cup \{[a_H(\sigma), X] \mid a \notin X \wedge [\sigma, X - H] \in F\}$

where the renaming operator  $a_H$  is applied pointwise to the elements in  $\sigma$ . A set  $X$  can be refused by  $a_H(F)$  if  $a_H^{-1}(X) = \{b \mid \exists c \in X: a_H(b) = c\}$  can be refused by  $F$ .

Except for the different representation of successful termination, the definitions of  $\delta, a, +, \cdot, a_H$  are as for STOP,  $a \rightarrow$  SKIP,  $\square, ;$  and direct image in [BHR84]. The definition of  $\parallel$  differs from the parallel composition operators in [BHR84]. In § 6.2 we will show how to interpret in  $ACP_r$  synchronous parallel composition of [BHR84]. The operators  $\parallel, |, \partial_H$  are not present in [BHR84].

**5.3. The failure model.** The *failure model* of  $ACP_r$  is now given by the structure  $\mathbb{F}(+, \cdot, \parallel, \llcorner, |, \partial_H, a_H, a, \delta)(a \in A)$ .

**THEOREM 5.3.1.** *The failure model of  $ACP_r$  is isomorphic to the graph model of  $ACP_r$ :*

$$\mathbb{H}_\delta(+, \cdot, \parallel, \llcorner, |, \partial_H, a_H, a, \delta) / \equiv_{\mathcal{F}} \cong \mathbb{F}(+, \cdot, \parallel, \llcorner, |, \partial_H, a_H, a, \delta).$$

*Proof.* Consider the mapping  $\mathcal{F}: \mathbb{H}_\delta \rightarrow \mathbb{F}$  introduced in § 2.2. It is clear that  $\mathcal{F}$  is well defined, i.e., that  $\mathcal{F}[g] \in \mathbb{F}$  holds for every  $g \in \mathbb{H}_\delta$ . Also, by Definition 2.2.3,  $g \equiv_{\mathcal{F}} h$  if and only if  $\mathcal{F}[g] = \mathcal{F}[h]$  for all  $g, h \in \mathbb{H}_\delta$ . Thus  $\mathcal{F}$  is also well defined and injective as a mapping:

$$\mathcal{F}: \mathbb{H}_\delta / \equiv_{\mathcal{F}} \rightarrow \mathbb{F}$$

(which, by abuse of language, we denote also with  $\mathcal{F}$ ). Now  $\mathcal{F}$  is surjective and behaves homomorphically over the operations  $+, \cdot, \parallel, \llcorner, |, \partial_H$ , and  $a_H$ . The proofs of these facts are tedious but follow in a straightforward way from the definitions of these operators on graphs (in § 1.2) and the definitions of the corresponding operators on  $\mathbb{F}$  (in § 5.1). We will not spell out these proofs. Thus  $\mathcal{F}$  is the required isomorphism from  $\mathbb{H}_\delta(\dots)$  to  $\mathbb{F}(\dots)$ .  $\square$

**6.  $ACP_r$  with one-to-one communication.** As a preparation for the subsequent section we now introduce some additional structure on the alphabet  $A_\delta$  and the communication function  $|: A_\delta \times A_\delta \rightarrow A_\delta$  of  $ACP_r$ .

**6.1. One-to-one communication.** First we assume that  $A$  (with typical elements  $a, b \in A$ ) is partitioned into  $A = C \cup I$ , where  $C$  (with typical elements  $c, d \in C$ ) is the set of *communicating* actions and  $I$  (disjoint from  $C$  and with typical elements  $i, j \in I$ ) is the set of *internal* actions. The set  $I$  will serve as an auxiliary tool for the communication function  $|$ .

Second, we denote by  $\alpha(x)$ , the *alphabet* of  $x$ , the set of non- $\delta$  actions occurring in the closed  $ACP_r$ -term  $x$ . For example,  $\alpha(a\delta + cd) = \{a, c, d\}$ . In subsequent results we will usually be interested in terms  $x$  with  $\alpha(x) \subseteq C$ , i.e., not involving internal,

auxiliary actions. Formally, the alphabet of a closed  $ACP_r$ -term  $x$  is defined by first eliminating the operators  $\parallel$ ,  $\ll$ ,  $|$ ,  $\partial_H$ , and  $a_H$  from  $x$ , using the axioms of  $ACP_r$ . (This is possible by virtue of an elimination theorem to this effect proved in [BK84a] for  $ACP$ ; the extra operators  $a_H$  in  $ACP_r$  present no problem.) The resulting closed term  $x'$  contains only the “basic constructors”  $+$  and  $\cdot$ , and we may further suppose that  $x'$  contains no subterm of the form  $(p+q)r$  (by some applications of axiom A4 of  $ACP_r$ , see Table 1); that is,  $x'$  uses only prefix multiplication. Now we define  $\alpha(x)$  to be  $\alpha(x')$ , where  $\alpha(x')$  is defined by the following clauses, using induction on the structure of  $x'$ :

$$\begin{aligned}\alpha(\delta) &= \emptyset, \\ \alpha(a) &= \{a\} \quad (a \in A), \\ \alpha(\delta x) &= \emptyset, \\ \alpha(ax) &= \{a\} \cup \alpha(x) \quad (a \in A), \\ \alpha(x+y) &= \alpha(x) \cup \alpha(y).\end{aligned}$$

(That  $\alpha(x)$  is indeed well defined in this way, follows from the confluence property of the rewriting procedure used in obtaining  $x'$  from  $x$ . This fact is for  $ACP$  also proved in [BK84a] and is easily carried over to  $ACP_r$ .)

LEMMA 6.1.1. *For closed terms  $x, y$  over  $ACP_r$ , with  $\alpha(x), \alpha(y) \subseteq C$  we have*

$$\partial_C(x \parallel y) = \partial_C(x | y).$$

*Proof.* It suffices to show that  $\partial_C(x \ll y) = \delta$ . Recall that  $x$  can be normalized in  $ACP_r$  to

$$x = \sum_i c_i x_i + \sum_j d_j$$

with  $c_i, d_j \in C$ , and with the empty sum  $\Sigma$  denoting  $\delta$ . Thus

$$x \ll y = \sum_i c_i (x_i \parallel y) = \sum_j d_j y$$

which implies  $\partial_C(x \ll y) = \delta$ .  $\square$

DEFINITION 6.1.2. Assuming the above partition of the alphabet  $A$  we say  $ACP_r$  has *one-to-one communication* if for the communication merge  $|$  there exists a bijection  $\varphi: C \rightarrow C$  such that  $c | \varphi(c) \in I$  for every  $c \in C$ , and  $a | b = \delta$  otherwise.

Note that  $c | \varphi(c) \in I$  implies  $c | \varphi(c) \neq \delta$ . Next, we show that the definitions of parallel composition used in CSP and CCS are typical examples of one-to-one communication.

**6.2. Hoare's parallel composition  $\parallel_{\mathscr{H}}$  in CSP.** In [BHR84] Hoare et al. propose an operation  $x \parallel_{\mathscr{H}} y$  modelling the full synchronization of processes  $x$  and  $y$ . We shall consider  $\parallel_{\mathscr{H}}$  here within a small subset of the language CSP [BHR84] which we call “CSP.” The signature of “CSP” is given by

- the constant STOP,
- unary prefix operators  $c \rightarrow$ , for  $c \in C$ ,
- the binary infix operators  $\square$  and  $\parallel_{\mathscr{H}}$ .

Here  $C$  is a given set of communication actions, contained in the overall alphabet  $A$ .

The semantics of “CSP” is determined by the failures model of [BHR84]. It is based on the failures domain  $F_{\text{BHR}}$  consisting of all subsets

$$F \subseteq A^* \times \mathcal{P}(A)$$

satisfying the closure properties (i)–(iv) discussed in § 5.1. The additional closure property (v) on traces is not needed here since the failure sets  $F \in \mathbb{F}_{\text{BHR}}$  contain only failure pairs  $[\sigma, X]$ .

The failure model assigns to each closed ‘‘CSP’’ term  $x$  a failure set  $\mathcal{F}_{\text{BHR}}\llbracket x \rrbracket$  in the domain  $\mathbb{F}_{\text{BHR}}$ . According to [BHR84] the definition is as follows:

- (i)  $\mathcal{F}_{\text{BHR}}\llbracket \text{STOP} \rrbracket = \{[\varepsilon, X] \mid X \subseteq A\}$ ;
- (ii)  $\mathcal{F}_{\text{BHR}}\llbracket c \rightarrow x \rrbracket = \{[\varepsilon, X] \mid X \subseteq A - \{c\}\} \cup \{[c \cdot \sigma, X] \mid [\sigma, X] \in \mathcal{F}_{\text{BHR}}\llbracket x \rrbracket\}$ ;
- (iii)  $\mathcal{F}_{\text{BHR}}\llbracket x \square y \rrbracket = \{[\varepsilon, X] \mid [\varepsilon, X] \in \mathcal{F}_{\text{BHR}}\llbracket x \rrbracket \cap \mathcal{F}_{\text{BHR}}\llbracket y \rrbracket\}$   
 $\cup \{[\sigma, X] \mid \sigma \neq \varepsilon \wedge [\sigma, X] \in \mathcal{F}_{\text{BHR}}\llbracket x \rrbracket \cup \mathcal{F}_{\text{BHR}}\llbracket y \rrbracket\}$ ;
- (iv)  $\mathcal{F}_{\text{BHR}}\llbracket x \parallel y \rrbracket = \{[\sigma, X \cup Y] \mid [\sigma, X] \in \mathcal{F}_{\text{BHR}}\llbracket x \rrbracket \wedge [\sigma, Y] \in \mathcal{F}_{\text{BHR}}\llbracket y \rrbracket\}$ .

The failure model induces the following failure equivalence  $\equiv_{\mathcal{F}, \text{BHR}}$  on closed ‘‘CSP’’ terms  $x$  and  $y$ :

$$x \equiv_{\mathcal{F}, \text{BHR}} y \quad \text{iff} \quad \mathcal{F}_{\text{BHR}}\llbracket x \rrbracket = \mathcal{F}_{\text{BHR}}\llbracket y \rrbracket.$$

We now link these definitions of [BHR84] to our present setting by interpreting ‘‘CSP’’ in  $\text{ACP}_r$  with one-to-one communication. Let  $C = \{c_1, \dots, c_n\}$ . Then we take  $A = C \cup I$  with

$$I = \{\hat{c}_1, \dots, \hat{c}_n\}$$

where the  $\hat{c}_i (i = 1, \dots, n)$  are new copies of the actions  $c_i$  in  $C$ . Furthermore, one-to-one communication is introduced by putting  $\varphi(c) = c$  and  $c \mid c = \hat{c}$  for every  $c \in C$ . The interpretation of ‘‘CSP’’ in  $\text{ACP}_r$  is given by a mapping  $\mathcal{I}$  from closed ‘‘CSP’’ terms into closed  $\text{ACP}_r$  terms defined as follows:

- (i)  $\mathcal{I}(\text{STOP}) = \delta$ ;
- (ii)  $\mathcal{I}(c \rightarrow x) = c \cdot \mathcal{I}(x)$ ;
- (iii)  $\mathcal{I}(x \square y) = \mathcal{I}(x) + \mathcal{I}(y)$ ;
- (iv)  $\mathcal{I}(x \parallel y) = C_I(\partial_C(\mathcal{I}(x) \parallel \mathcal{I}(y)))$

where  $C_I$  abbreviates the composite operator  $(c_i)_{\{\hat{c}_i\}} \circ \dots \circ (c_n)_{\{\hat{c}_n\}}$ , built from the renaming operators  $(c_i)_{\{\hat{c}_i\}} (i = 1, \dots, n)$  that rename  $c_i$  into  $\hat{c}_i$ .

This interpretation is justified by the following result.

**PROPOSITION 6.2.1.** *For closed ‘‘CSP’’ terms  $x$*

$$\mathcal{F}_{\text{BHR}}\llbracket x \rrbracket = \mathcal{F}\llbracket \mathcal{I}(x) \rrbracket \subseteq C^* \times \mathcal{P}(A)$$

*holds where  $\mathcal{F}$  is the  $\text{ACP}_r$  failures model of § 5. In particular  $\mathcal{F}\llbracket \mathcal{I}(x) \rrbracket$  does not contain any traces  $\sigma$  signaling successful termination, only failure pairs  $[\sigma, X]$ .*

*Proof.* By induction on the structure of  $x$ . The cases (i)–(iii) are immediate. Case (iv), parallel composition, is more tedious. It is easy to see that both

$$\mathcal{F}_{\text{BHR}}\llbracket x \parallel y \rrbracket, \mathcal{F}\llbracket C_I(\partial_C(\mathcal{I}(x) \parallel \mathcal{I}(y))) \rrbracket \subseteq C^* \times \mathcal{P}(A).$$

Hence the closure properties of the failure domains  $\mathbb{F}_{\text{BHR}}$  and  $\mathbb{F}$ , respectively, imply

$$\begin{aligned} [\sigma, X] \in \mathcal{F}_{\text{BHR}}\llbracket x \parallel y \rrbracket & \quad \text{iff} \quad [\sigma, X \cup Y] \in \mathcal{F}_{\text{BHR}}\llbracket x \parallel y \rrbracket, \\ [\sigma, X] \in \mathcal{F}\llbracket C_I(\partial_C(\mathcal{I}(x) \parallel \mathcal{I}(y))) \rrbracket & \quad \text{iff} \quad [\sigma, X \cup Y] \in \mathcal{F}\llbracket C_I(\partial_C(\mathcal{I}(x) \parallel \mathcal{I}(y))) \rrbracket \end{aligned}$$

for arbitrary  $Y \subseteq A - C$ . Thus it suffices to show

$$[\sigma, X] \in \mathcal{F}_{\text{BHR}}\llbracket x \parallel y \rrbracket \quad \text{iff} \quad [\sigma, X] \in \mathcal{F}\llbracket C_I(\partial_C(\mathcal{I}(x) \parallel \mathcal{I}(y))) \rrbracket$$

for  $\sigma \in C^*$  and  $X \subseteq C$ .

Let  $\hat{\sigma}$  and  $\hat{X}$  result from  $\sigma$  and  $X$  by replacing pointwise each action  $c$  by  $\hat{c}$ . In particular, we have  $\hat{C} = A - C$ . Then for  $\sigma \in C^*$  and  $X \subseteq C$

$$[\sigma, X] \in \mathcal{F}_{\text{BHR}}[x \parallel_{\neq} y]$$

if and only if (induction hypothesis, definition of  $\parallel_{\neq}$ )

$$\exists X_1 \subseteq C, X_2 \subseteq C:$$

$$[\sigma, X_1] \in \mathcal{F}[\mathcal{I}(x)] \wedge [\sigma, X_2] \in \mathcal{F}[\mathcal{I}(y)] \wedge X \subseteq X_1 \cup X_2$$

if and only if (definition  $\hat{X}$ )

$$\exists X_1 \subseteq C, X_2 \subseteq C:$$

$$[\sigma, X_1] \in \mathcal{F}[\mathcal{I}(x)] \wedge [\sigma, X_2] \in \mathcal{F}[\mathcal{I}(y)] \wedge \hat{X} \subseteq \{\hat{c} \mid c \in X_1 \cup X_2\}$$

if and only if (closure properties of the failure domain F)

$$\exists X_1, X_2: \hat{C} \subseteq X_1 \subseteq A \wedge \hat{C} \subseteq X_2 \subseteq A$$

$$\wedge [\sigma, X_1] \in \mathcal{F}[\mathcal{I}(x)] \wedge [\sigma, X_2] \in \mathcal{F}[\mathcal{I}(y)]$$

$$\wedge \hat{X} \subseteq X_1 \cap X_2 - \{\hat{c} \mid c \notin X_1 \cup X_2\}$$

if and only if (one-to-one communication, definition  $\parallel$ )

$$[\hat{\sigma}, \hat{X}] \in \mathcal{F}[\mathcal{I}(x) \parallel \mathcal{I}(y)]$$

if and only if (definition  $C_I, \partial_C$ )

$$[\sigma, X] \in \mathcal{F}[C_I(\partial_C(\mathcal{I}(x) \parallel \mathcal{I}(y)))]$$

This finishes our proof.  $\square$

Consequently, for ‘‘CSP’’ the original failure equivalence  $\equiv_{\mathcal{F}_{\text{BHR}}}$  of [BHR84] coincides with our definition of failure equivalence  $\equiv_{\mathcal{F}}$  in § 2. More precisely we have the following corollary:

**COROLLARY 6.2.2.** *For closed ‘‘CSP’’ terms  $x$  and  $y$*

$$x \equiv_{\mathcal{F}_{\text{BHR}}} y \quad \text{iff} \quad \mathcal{I}(x) \equiv_{\mathcal{F}} \mathcal{I}(y).$$

For closed ‘‘CSP’’ terms  $x$  and  $y$  the notions of trace and trace equivalence are defined via the interpretation in ACP<sub>r</sub>:

$$\text{trace}(x) = \text{trace}(\mathcal{I}(x)),$$

$$x \sim_{\text{tr}} y \quad \text{iff} \quad \mathcal{I}(x) \sim_{\text{tr}} \mathcal{I}(y).$$

(Actually, trace is in § 2.1 only defined on graphs; using the operation graph from § 4.1.2 we now define for a term  $x$ , trace( $x$ ) as trace(graph( $x$ )).) Using Proposition 6.2.1 the trace set of a term  $x$  can also be computed directly from its failure set  $\mathcal{F}_{\text{BHR}}[x]$ :

$$\text{trace}(x) = \{\sigma \cdot \delta \mid [\sigma, A] \in \mathcal{F}_{\text{BHR}}[x]\}.$$

Recall that in our paper we only consider *complete* traces, either leading to a deadlock  $\delta$  or to successful termination (not possible for ‘‘CSP’’). In [BHR84] the word ‘‘trace’’ is used as well, but it refers to any sequence  $\sigma$  with

$$[\sigma, \emptyset] \in \mathcal{F}_{\text{BHR}}[x].$$

Such sequences were called *histories* in § 2.

**6.3. Milner's parallel composition  $\parallel_{\mathcal{M}}$  in CCS.** Since the parallel composition  $\parallel$  in  $ACP_r$  can be seen as a generalization of Milner's operation  $\parallel_{\mathcal{M}}$  in CCS [Mi80], it is easy to regain the original definition. As for CSP, we do this within a small subset of CCS which we call "CCS." Milner stipulates that the set  $C$  of communicating actions is equipped with a bijection  $\bar{\cdot} : C \rightarrow C$  satisfying  $\bar{\bar{c}} = c$ . Here  $\bar{c}$  is called the *matching* action of  $c$ . In addition to communicating actions Milner uses a symbol  $\tau$  denoting the so-called *silent* action. We will write  $\hat{\tau}$  because we work here without Milner's  $\tau$ -laws that make  $\tau$  silent or invisible (see the discussion below and § 8). Hence the alphabet for "CCS" will be  $A = C \cup \{\hat{\tau}\}$ .

The signature of "CCS" consists of the following:

- the constant NIL;
- unary prefix operators  $a \cdot$ , for  $a \in A$ ;
- unary postfix operators  $\setminus H$ , for  $H \subseteq C$ ;
- the binary infix operators  $+$  and  $\parallel_{\mathcal{M}}$ .

Informally,  $x \parallel_{\mathcal{M}} y$  denotes the nondeterministic interleaving of  $x$  and  $y$ , plus the communication of  $x$  and  $y$  via matching actions which then yield  $\hat{\tau}$  as a result. Following [Mi80], this can be expressed by the infinite axiom scheme:

$$(*) \quad (\sum_i a_i x_i) \parallel_{\mathcal{M}} (\sum_j b_j y_j) = \sum_i a_i (x_i \parallel_{\mathcal{M}} y) + \sum_j b_j (x \parallel_{\mathcal{M}} y_j) + \sum_{a_i = \bar{b}_j} \hat{\tau} \cdot (x_i \parallel_{\mathcal{M}} y_j)$$

where  $x = \sum_i a_i x_i$  and  $y = \sum_j b_j y_j$ .

We shall define the semantics of  $\parallel_{\mathcal{M}}$  via an interpretation  $\mathcal{F}$  of "CCS" in  $ACP_r$ , with one-to-one communication. To this end, take  $I = \{\hat{\tau}\}$  and define

$$\varphi(c) = \bar{c} \text{ and } c | \bar{c} = \hat{\tau}.$$

Then  $\mathcal{F}$  is rather trivial:

- (i)  $\mathcal{F}(\text{NIL}) = \delta$ ;
- (ii)  $\mathcal{F}(a \cdot x) = a \cdot \mathcal{F}(x)$ ;
- (iii)  $\mathcal{F}(x \setminus H) = \partial_H(\mathcal{F}(x))$ ;
- (iv)  $\mathcal{F}(x + y) = \mathcal{F}(x) + \mathcal{F}(y)$ ;
- (v)  $\mathcal{F}(x \parallel_{\mathcal{M}} y) = \mathcal{F}(x) \parallel \mathcal{F}(y)$ .

Note that the auxiliary operations  $\parallel$  and  $|$  in  $ACP_r$  serve to replace the infinite axiom scheme (\*) by finitely many  $ACP_r$  axioms.

In [Mi80] Milner studies CCS terms under the (weak) bisimulation equivalence [Pa83]; however, here we shall study "CCS" under the failure equivalence. For closed "CCS" terms  $x$  and  $y$  we define the notions of failure equivalence, trace equivalence and alphabet via the interpretation  $\mathcal{F}$  in  $ACP_r$ :

$$\begin{aligned} x \equiv_{\mathcal{F}} y & \text{ iff } \mathcal{F}(x) \equiv_{\mathcal{F}} \mathcal{F}(y), \\ x \sim_{\text{tr}} y & \text{ iff } \mathcal{F}(x) \sim_{\text{tr}} \mathcal{F}(y), \\ \alpha(x) & = \alpha(\mathcal{F}(x)). \end{aligned}$$

In general, these definitions are not quite appropriate for CCS because  $\tau$  should be silent or invisible; more formally  $\tau$  should be subject to Milner's  $\tau$ -laws. In the above interpretation of "CCS"  $\hat{\tau}$  remains visible, i.e., recorded in the traces and failure pairs. The reason for this clash is that CCS indivisibly couples parallel composition  $\parallel_{\mathcal{M}}$  and  $\tau$ , whereas we decided to separate failure equivalence  $\equiv_{\mathcal{F}}$  from  $\tau$ .

However, we can regain the spirit of CCS if we restrict the failure equivalence to  $\hat{\tau}$ -free "CCS" terms  $x$  and  $y$ , i.e., with

$$\hat{\tau} \notin \alpha(x), \alpha(y).$$

Unfortunately,  $\hat{\tau}$ -free “CCS” terms are not closed under parallel composition  $\parallel_{\mathcal{M}}$ . Therefore we shall consider also a modified trace set

$$\text{trace}_{\hat{\tau}}(x)$$

for “CCS” terms  $x$  which results from  $\text{trace}(x)$  by deleting in every trace  $\sigma \cdot \delta \in \text{trace}(x)$  all occurrences of  $\hat{\tau}$  in  $\sigma$ . Then  $\text{trace}_{\hat{\tau}}(x)$  represents the set of complete traces in the sense of CCS. For example,

$$\begin{aligned} \text{trace}(c\text{NIL} \parallel_{\mathcal{M}} \bar{c}\text{NIL}) &= \{c\bar{c}\delta, \bar{c}c\delta, \hat{\tau}\delta\}, \\ \text{trace}_{\hat{\tau}}(c\text{NIL} \parallel_{\mathcal{M}} \bar{c}\text{NIL}) &= \{c\bar{c}\delta, \bar{c}c\delta, \delta\}. \end{aligned}$$

**7. The maximal trace respecting congruence.** In § 4 (Proposition 4.2.3) it was shown that failure equivalence  $\equiv_{\mathcal{F}}$  is a congruence with respect to the operators of  $\text{ACP}_r$ . In this section we will prove that for  $\text{ACP}_r$  with one-to-one communication failure equivalence is in fact the maximal trace respecting congruence. This implies a full abstraction result for the failure model of § 5. But first let us introduce the relevant concepts.

**7.1. Preliminaries.** Let  $\Sigma$  be a signature with  $\text{Ter}(\Sigma)$  denoting the set of closed terms over  $\Sigma$ . By  $\text{Ter}(\Sigma)[\xi]$  we denote the set of terms over  $\Sigma$  with  $\xi$  as free variable. These terms are called *contexts* and are typically written as  $\mathcal{C}[\xi]$ .

Let  $\mathcal{T} \subseteq \text{Ter}(\Sigma)$ . A *congruence for  $\mathcal{T}$*  is an equivalence relation  $\equiv$  on  $\mathcal{T}$ , such that

$$x \equiv y \text{ implies } \mathcal{C}[x] \equiv \mathcal{C}[y]$$

for all terms  $x, y \in \mathcal{T}$  and contexts  $\mathcal{C}[\xi] \in \text{Ter}(\Sigma)[\xi]$  with  $\mathcal{C}[x], \mathcal{C}[y] \in \mathcal{T}$ . A congruence  $\equiv$  for  $\mathcal{T}$  is *trace respecting* if

$$x \equiv y \text{ implies } \text{trace}(x) = \text{trace}(y)$$

for all  $x, y \in \mathcal{T}$ . A trace respecting congruence  $\equiv$  for  $\mathcal{T}$  is called *maximal* if for all  $x, y \in \mathcal{T}$ ,  $x \not\equiv y$  implies that there exists some context  $\mathcal{C}[\xi] \in \text{Ter}(\Sigma)[\xi]$  with  $\mathcal{C}[x], \mathcal{C}[y] \in \mathcal{T}$  and  $\text{trace}(\mathcal{C}[x]) \neq \text{trace}(\mathcal{C}[y])$ .

**PROPOSITION 7.1.1.** *For each  $\mathcal{T} \subseteq \text{Ter}(\Sigma)$  the maximal trace respecting congruence for  $\mathcal{T}$  exists and is unique.*

*Proof. Uniqueness.* Suppose  $\equiv_1$  and  $\equiv_2$  are different maximal trace respecting congruences on  $\mathcal{T}$ . Then for some  $x, y \in \mathcal{T}$  we have

$$x \equiv_1 y, \text{ but } x \not\equiv_2 y.$$

Since  $\equiv_1$  is a trace respecting congruence on  $\mathcal{T}$ ,  $\text{trace}(\mathcal{C}[x]) = \text{trace}(\mathcal{C}[y])$  holds for every context  $\mathcal{C}[\xi] \in \text{Ter}(\Sigma)[\xi]$  with  $\mathcal{C}[x], \mathcal{C}[y] \in \mathcal{T}$ . But this contradicts the maximality of  $\not\equiv_2$ .

*Existence.* Define  $\equiv$ , a binary relation on  $\mathcal{T}$ , as follows:  $x \equiv y$  if and only if for every context  $\mathcal{C}[\xi] \in \text{Ter}(\Sigma)[\xi]$  with  $\mathcal{C}[x], \mathcal{C}[y] \in \mathcal{T}$ ,  $\text{trace}(\mathcal{C}[x]) = \text{trace}(\mathcal{C}[y])$  holds.

It is easy to see that  $\equiv$  is a trace respecting congruence for  $\mathcal{T}$ ; maximality follows from its definition.  $\square$

**7.2. A characterisation of failure equivalence.** Let us now turn to  $\text{ACP}_r$ . We write  $\text{Ter}(\text{ACP}_r)$  instead of  $\text{Ter}(\Sigma)$ . From § 4 we know that failure equivalence  $\equiv_{\mathcal{F}}$  is a trace respecting congruence for  $\text{Ter}(\text{ACP}_r)$ . (For the sake of convenience, we have identified here the semantical notion  $\equiv_{\mathcal{F}}$  with the equivalence induced by  $\equiv_{\mathcal{F}}$  on  $\text{Ter}(\text{ACP}_r)$  via the correspondence between process graphs and terms, explained in § 4.1.) Thus for  $\text{ACP}_r$ , in general, we have

$$\equiv_{\mathcal{F}} \subseteq \equiv_{\max}$$

with  $\equiv_{\max}$  denoting the maximal trace respecting congruence for  $\text{Ter}(\text{ACP}_r)$ . If we specialize  $\text{ACP}_r$  to the case of one-to-one communication, we can actually prove that

$$\equiv_{\mathcal{F}} = \equiv_{\max},$$

and thus arrive at a very pleasing characterization of failure equivalence.

**THEOREM 7.2.1.** *Consider  $\text{ACP}_r$  with one-to-one communication. Then failure equivalence  $\equiv_{\mathcal{F}}$  is the maximal trace respecting congruence for the set  $\mathcal{T}_C$  of all closed terms  $x$  over  $\text{ACP}_r$  with alphabet  $\alpha(x) \subseteq C$ .*

*Proof.* Suppose  $x \not\equiv_{\mathcal{F}} y$ ; i.e.,  $\mathcal{F}[x] \neq \mathcal{F}[y]$  holds for  $x, y \in \mathcal{T}_C$ . If  $\text{trace}(x) \neq \text{trace}(y)$ , the trivial context  $\mathcal{C}[\xi] = \xi$  will do. Now suppose that  $\text{trace}(x) = \text{trace}(y)$  holds. Because of  $x \not\equiv_{\mathcal{F}} y$  we can assume without loss of generality that there exists a failure pair  $[\sigma, X]$  with

$$[\sigma, X] \in \mathcal{F}[x], [\sigma, X] \notin \mathcal{F}[y].$$

By the definition of  $\mathcal{F}$ ,  $[\sigma, X] \in \mathcal{F}[x]$  implies that there exists some ready pair  $(\sigma, Z) \in \mathcal{R}[x]$  with  $X \subseteq Z$ . Note that  $Z \neq \emptyset$ . Suppose we had  $(\sigma, \emptyset) \in \mathcal{R}[x]$ . Then  $\sigma\delta \in \text{trace}(x) = \text{trace}(y)$  and  $(\sigma, \emptyset) \in \mathcal{R}[y]$ . Thus  $[\sigma, C] \in \mathcal{F}[y]$  and therefore also  $[\sigma, X] \in \mathcal{F}[x]$ , a contradiction.

Trace equivalence of  $x$  and  $y$  implies that there exists a ready pair  $(\sigma, Y) \in \mathcal{R}[y]$  with  $Y \neq \emptyset$ . Again by the definition of  $\mathcal{F}$ ,  $[\sigma, X] \notin \mathcal{F}[y]$  implies that for every such ready pair  $(\sigma, Y) \in \mathcal{R}[y]$  there exists some  $d \in X \cap Y$ . Now consider a context of the form

$$\mathcal{C}[\xi] = (c_{1\{i_1\}} \circ \dots \circ c_{n\{i_n\}} \circ \partial_C)(x \parallel \varphi(\sigma) \cdot \Sigma \varphi(d) \cdot \delta)$$

where the sum  $\Sigma$  is taken over all  $d \in X \cap Y$  such that  $(\sigma, Y) \in \mathcal{R}[y]$ . Furthermore  $I = \{i_1, \dots, i_n\}$ ,  $c_1, \dots, c_n \in C$ ,  $\varphi$  is the bijection describing the one-to-one communication in  $\text{ACP}_r$  and  $\varphi(\sigma)$  is the result of applying  $\varphi$  pointwise to  $\sigma$ . Note that  $\mathcal{C}[\xi]$  is uniquely determined by  $x$  and  $y$  except for the choice of the  $c_1, \dots, c_n$  in the renaming operators. Note that indeed  $\mathcal{C}[x], \mathcal{C}[y] \in \mathcal{T}_C$  due to the presence of operators  $\partial_C$  and  $c_{j\{i_j\}}$  in  $\mathcal{C}[\xi]$ . We now claim that

$$(c_{1\{i_1\}} \circ \dots \circ c_{n\{i_n\}})(\sigma \mid \varphi(\sigma)) \cdot \delta \in \text{trace}(\mathcal{C}[x]), \notin \text{trace}(\mathcal{C}[y])$$

where  $\sigma \mid \varphi(\sigma)$  is understood by applying  $\mid$  pointwise to  $\sigma$  and  $\varphi(\sigma)$ .

To prove this claim we first state a general observation about ready sets  $\mathcal{R}[z]$  of closed terms  $z$  over  $\text{ACP}_r$ . Let  $\sigma = a_1 \dots a_m$  and  $Z = \{b_1, \dots, b_n\}$ . Then  $(\sigma, Z) \in \mathcal{R}[z]$  if and only if there exist  $x_1, \dots, x_m, y_1, \dots, y_n \in \text{Ter}(\text{ACP}_r)$  with

$$\text{ACP}_r \vdash x = a_1(a_2 \dots (a_m(b_1y_1 + \dots + b_ny_n) + x_m) \dots + x_2) + x_1.$$

This observation is obvious from §§ 3 and 4.

Next we recall from Lemma 6.1.1 that due to the encapsulation  $\partial_C$  we can replace the general parallel composition  $\parallel$  in  $\mathcal{C}[\xi]$  by the communication operator  $\mid$  which enforces synchronization.

Combining these two facts, it is easy to calculate that  $(\sigma, Z) \in \mathcal{R}[x]$  with  $X \subseteq Z$  yields

$$(c_{1\{i_1\}} \circ \dots \circ c_{n\{i_n\}})(\sigma \mid \varphi(\sigma)) \cdot \delta \in \text{trace}(\mathcal{C}[x]).$$

Now suppose that this trace is also present in  $\text{trace}(\mathcal{C}[y])$ . Since  $\text{ACP}_r$  allows only one-to-one communication, there exists a history  $\sigma \in C^*$  such that every ready pair  $(\sigma, Y) \in \mathcal{R}[y]$  satisfies  $X \cap Y = \emptyset$ . This is a contradiction. This finishes our proof.  $\square$

**7.3. Application to CSP and CCS.** The characterization of failure equivalence for  $ACP_r$  yields corresponding results for the subsets “CSP” and “CCS” or [BHR84] and [Mi80].

**COROLLARY 7.3.1.** *For closed “CSP” terms the failure equivalence  $\equiv_{\mathcal{F},\text{BHR}}$  of [BHR84] is the maximal trace respecting congruence.*

*Proof.* Via the interpretation  $\mathcal{I}$  the failure equivalence  $\equiv_{\mathcal{F},\text{BHR}}$  is a trace respecting congruence for “CSP.” To show maximality, suppose  $x \not\equiv_{\mathcal{F},\text{BHR}} y$  for closed terms  $x$  and  $y$ . Then  $\mathcal{I}(x) \not\equiv_{\mathcal{F}} \mathcal{I}(y)$  by Corollary 6.2.2. Since  $\alpha(\mathcal{I}(x)), \alpha(\mathcal{I}(y)) \subseteq C$ , Theorem 7.2.1 applies and yields a context  $\mathcal{C}[\xi]$  in  $ACP_r$  with

$$\mathcal{C}[\mathcal{I}(x)] \not\sim_{\text{tr}} \mathcal{C}[\mathcal{I}(y)].$$

Looking at the proof of Theorem 7.2.1 we see that  $\mathcal{C}[\xi]$  can be expressed in “CSP”; i.e., there exists a context  $\mathcal{C}'[\xi]$  in “CSP” with

$$I(\mathcal{C}')[\xi] = \mathcal{C}[\xi]$$

where we stipulate  $\mathcal{I}(\xi) = \xi$ . Thus

$$\mathcal{I}(\mathcal{C}')[\mathcal{I}(x)] \not\sim_{\text{tr}} \mathcal{I}(\mathcal{C}')[\mathcal{I}(y)].$$

Since  $\mathcal{I}$  is defined by structural induction, we have  $\mathcal{I}(\mathcal{C}')[\mathcal{I}(x)] = \mathcal{I}(\mathcal{C}'[x])$  and likewise for  $y$ . Thus

$$\mathcal{C}'[x] \not\sim_{\text{tr}} \mathcal{C}'[y]$$

by the definition of trace equivalence for “CSP.”  $\square$

Due to the differences of  $\tau$  and  $\hat{\tau}$  in CCS and  $ACP_r$  (see § 6.3), we can characterize failure equivalence only for  $\hat{\tau}$ -free “CCS” terms.

**COROLLARY 7.3.2.** *On the subset of closed,  $\hat{\tau}$ -free “CCS” terms failure equivalence  $\equiv_{\mathcal{F}}$  coincides with the maximal trace respecting congruence defined for full “CCS.” This result holds for both notions of trace introduced for “CCS” terms, viz.,  $\text{trace}(\cdot)$  and  $\text{trace}_{\hat{\tau}}(\cdot)$ .*

*Proof.* Via the interpretation  $\mathcal{I}$  failure equivalence  $\equiv_{\mathcal{F}}$  is a trace respecting congruence for “CCS.” This holds for the original definition of  $\text{trace}(\cdot)$ , however, since

$$\text{trace}(x) = \text{trace}(y) \quad \text{implies} \quad \text{trace}_{\hat{\tau}}(x) = \text{trace}_{\hat{\tau}}(y),$$

it holds for  $\text{trace}_{\hat{\tau}}(\cdot)$  as well.

Now consider two closed,  $\hat{\tau}$ -free “CCS” terms  $x, y$  such that  $x \not\equiv_{\mathcal{F}} y$ , i.e.,  $\mathcal{I}(x) \not\equiv_{\mathcal{F}} \mathcal{I}(y)$ . Since  $\hat{\tau}$ -freeness means  $\alpha(\mathcal{I}(x)), \alpha(\mathcal{I}(y)) \subseteq C$ , the proof technique for Theorem 7.2.1 applies and yields an  $ACP_r$  context of the form

$$\mathcal{C}[\xi] = \partial_C(\xi \parallel \mathcal{I}(z))$$

where  $z$  is a closed,  $\hat{\tau}$ -free “CCS” term such that for some  $n \geq 0$

$$\hat{\tau}^n \cdot \delta \in \text{trace}(\mathcal{C}[\mathcal{I}(x)]), \notin \text{trace}(\mathcal{C}[\mathcal{I}(y)]).$$

Note that in the definition of  $\mathcal{C}[\xi]$  we deviate slightly from Theorem 7.2.1 and omit the renaming operator, which would yield here  $c_{\{\hat{\tau}\}}$  for some  $c \in C$ . The reason is that  $\tau$  (respectively,  $\hat{\tau}$ ) cannot be renamed in Milner’s [Mi80] (and hence “CCS”).

The above  $\mathcal{C}[\xi]$  can be translated back into the “CCS” context

$$\mathcal{C}'[\xi] = (\xi \parallel_{\mathcal{M}} z) \setminus C,$$

which yields

$$\hat{\tau}^n \cdot \delta \in \text{trace}(\mathcal{C}'[x]), \notin \text{trace}(\mathcal{C}'[y]),$$

and thus

$$\delta \in \text{trace}_{\hat{\tau}}(\mathcal{C}'[x]), \notin \text{trace}_{\hat{\tau}}(\mathcal{C}'[y]).$$

This proves the maximality of failure equivalence for  $\hat{\tau}$ -free ‘‘CCS’’ terms with respect to both notions of trace.  $\square$

Thus the (proof of) Theorem 7.2.1 gives a uniform argument for the communication mechanisms of both ‘‘CSP’’ and CCS.’’

*Remark 7.3.3.* (Comparison with the work of De Nicola and Hennessy [DH84].) We have proved that (under a restricted communication format) processes are failure equivalent if and only if they cannot be separated by any context where ‘‘separated’’ refers to the criterion of having different traces. This characterisation is easy to understand, as it involves only the notions of *trace* and *context*. It is interesting to compare our result with a result in [DH84]. Since the settings are quite different (here finite processes in  $ACP_r$ , there CCS with recursion,  $\tau$ -steps and an additional constant  $\Omega$  denoting the undefined state), we state the comparison for the greatest common denominator of  $ACP_r$  and CCS, viz., the language ‘‘CCS’’ of § 6.3.

De Nicola and Hennessy [DH84] set up a notion of *testing* and consider two processes  $p$  and  $q$  as equivalent if and only if they pass exactly the same tests. This idea of testing is very appealing, but the formal definitions are somewhat more technical. Both processes and tests are just terms over the signature of ‘‘CCS.’’ However, in the alphabet  $A$  we assume a distinguished action  $\omega$ , which may appear in tests only. The action  $\omega$  is interpreted as reporting success; it is needed in the definition of a process passing a test. Due to the restriction to ‘‘CCS,’’ we can phrase De Nicola and Hennessy’s definition as follows.

For ‘‘CCS’’ terms  $p, q, r$  and actions  $a \in A$  we write

$$p \xrightarrow{a} q \quad \text{if } \exists r: \text{‘‘CCS’’} \vdash p = a \cdot q + r,$$

$$p \xrightarrow{a} \quad \text{if } \exists q: p \xrightarrow{a} q.$$

Intuitively,  $p \xrightarrow{a} q$  states that  $p$  can perform an action  $a$  and then behave like  $q$ . A *computation* is a sequence of ‘‘CCS’’ terms of the form

$$p_1 \xrightarrow{\hat{\tau}} p_2 \xrightarrow{\hat{\tau}} \cdots \xrightarrow{\hat{\tau}} p_n;$$

it is called *maximal* if there is no ‘‘CCS’’ term  $q$  with  $p_n \xrightarrow{\hat{\tau}} q$ . Since ‘‘CCS’’ does not include recursion, any computation is finite here.

There are two forms of a process  $p$  passing a test  $t$ :

- (i)  $p$  may pass  $t$  if there exists a computation

$$p \parallel_{\mathcal{M}} t = p_1 \parallel_{\mathcal{M}} t_1 \xrightarrow{\hat{\tau}} \cdots \xrightarrow{\hat{\tau}} p_n \parallel_{\mathcal{M}} t_n$$

with  $t_n \xrightarrow{\omega}$ , or equivalently if there exists some  $n \geq 0$  with

$$\hat{\tau}^n \cdot \omega \in \text{trace}(p \parallel_{\mathcal{M}} t),$$

- (ii)  $p$  must pass  $t$  if whenever

$$p \parallel_{\mathcal{M}} t = p_1 \parallel_{\mathcal{M}} t_1 \xrightarrow{\hat{\tau}} \cdots \xrightarrow{\hat{\tau}} p_n \parallel_{\mathcal{M}} t_n$$

is a *maximal computation* then there exists some  $m$  with  $1 \leq m \leq n$  and  $t_m \xrightarrow{\omega}$ .

Thus a term  $t_n$  that can perform an  $\omega$ -action serves as a criterion for success. For examples of (i) and (ii) we refer to [DH84].

Then De Nicola and Hennessy [DH84] introduce three so-called *testing equivalences* on processes  $p, q$ :

- (i)  $p \approx_1 q$  if for every test  $t$ :  $p$  may pass  $t$  if and only if  $q$  may pass  $t$ .

- (ii)  $p \approx_2 q$  if for every test  $t$ :  $p$  must pass  $t$  if and only if  $q$  must pass  $t$ .
- (iii)  $p \approx_3 q$  if  $p \approx_1 q$  and  $p \approx_2 q$ .

It is now very interesting that for  $\hat{\tau}$ -free “CCS” the strong testing equivalence coincides with the failure equivalence  $\equiv_{\mathcal{F}}$ . This is an immediate consequence of Corollary 6.2.6 of [DH84] stated for the class of so-called strongly convergent CCS terms, which in particular includes all  $\hat{\tau}$ -free “CCS” terms. Thus at least for  $\hat{\tau}$ -free “CCS” terms we have a pleasing convergence of ideas:

*strong testing equivalence = failure equivalence = maximal trace respecting congruence.*

Conceptually, we find the notion of a maximal trace respecting congruence simpler than the definition of passing a test.

**7.4. Full abstraction.** The notion of *full abstraction* is due to Milner [Mi77] (see also [HP79], [Pl77]). It is a relationship between models (of an axiomatic system) and equivalence relations (on the terms of that system) whose definition is motivated by the following question:

*Under what circumstances can we replace a term  $x$  by a term  $y$  without noticing this change by a given equivalence  $\equiv$ ?*

Using the notion of a context introduced above, this question amounts to:

*Under what conditions on  $x$  and  $y$  do we have  $\mathcal{C}[x] \equiv \mathcal{C}[y]$  for every context  $\mathcal{C}[\xi]$ ?*

Full abstraction can be seen as looking for a sufficient and necessary condition that answers this question. Formally, we state the following definition.

**DEFINITION 7.4.1.** A model  $\mathcal{M}$  for  $\mathcal{T} \subseteq \text{Ter}(\Sigma)$  is called *fully abstract with respect to an equivalence relation  $\equiv$  on  $\mathcal{T}$*  if for all terms  $x, y \in \mathcal{T}$ :

$$\mathcal{M}[x] = \mathcal{M}[y] \text{ iff } \mathcal{C}[x] \equiv \mathcal{C}[y] \text{ holds for every context } \mathcal{C}[\xi] \in \text{Ter}(\Sigma)[\xi] \text{ with } \mathcal{C}[x], \mathcal{C}[y] \in \mathcal{T}.$$

Thus a fully abstract model  $\mathcal{M}$  optimally fits the equivalence  $\equiv$  in the sense that it just makes the identifications on terms that are forced by  $\equiv$ . Usually, it is quite difficult to discover fully abstract models (see [HP79], [Mi77], [Pl77]), but for the failure model  $\mathcal{F} = \mathcal{F}(+, \cdot, \parallel, \llbracket, \lrcorner, \partial_H, a_H, a, \delta)(a \in A)$  of § 5 and the trace equivalence  $\sim_{\text{tr}}$  of § 2 we can now state such a result.

**THEOREM 7.4.2.** *Consider  $\text{ACP}_r$  with one-to-one communication. Then for the set  $\mathcal{T}_C$  of all closed terms  $x$  over  $\text{ACP}_r$  with alphabet  $\alpha(x) \subseteq C$  the failure model  $\mathcal{F}$  is fully abstract with respect to the trace equivalence  $\sim_{\text{tr}}$ .*

*Proof.* By Definition 7.4.1, it suffices to show that for all  $x, y \in \mathcal{T}_C$ :

$$\mathcal{F}[x] = \mathcal{F}[y] \quad \text{iff } x \equiv_{\max} y$$

where  $\equiv_{\max}$  is the maximal trace respecting congruence. But this is immediate from Theorem 7.2.1.  $\square$

**COROLLARY 7.4.3.** *For the set of closed “CSP” terms the failure model  $\mathcal{F}_{\text{BHR}}$  of [BHR84] is fully abstract with respect to the trace equivalence  $\sim_{\text{tr}}$ .*

For “CCS” we cannot state the analogous result due to the  $\hat{\tau}$  mismatch discussed above.

## 8. Processes with recursion and abstraction: bisimulation versus failure equivalence.

**8.1. Preliminaries.** In the preceding sections we have been exclusively concerned with the failure semantics for finite processes without abstraction, i.e., not involving  $\tau$ -steps. In this section we will set aside that restriction and comment also on infinite

(recursive) processes with abstraction, in regard to bisimulation and failure equivalence. The crucial point is the way in which infinite sequences of  $\tau$ -steps in a process are treated.

In the failure semantics proposed in [BHR84], all processes having an infinite  $\tau$ -sequence from the root are set equal (to the process CHAOS). The notion of bisimulation is more discriminating. The advantage is that models obtained by bisimulation equivalence satisfy a useful abstraction principle: *Koomen's Fair Abstraction Rule* (KFAR), as introduced in [BK84b]. Roughly, this rule gives a way of simplifying processes by elimination of (some) infinite  $\tau$ -sequences. This elimination can be understood as *fairness* of (visible) actions over silent  $\tau$ -steps. A more precise description is given below. (Of course, setting all processes having an infinite  $\tau$ -sequence from the root equal to CHAOS also eliminates infinite  $\tau$ -sequences, but then all information is lost.)

Since KFAR is a very useful tool for system verification (e.g., in [BK84b] it was used to verify an alternating bit protocol), it is natural to ask whether  $\text{KFA}_{\kappa}$  is also compatible with the somewhat simpler failure semantics. More precisely, we can ask whether there exists a process model which for finite processes agrees with the failure semantics and for infinite processes satisfies KFAR. Interestingly, it turns out that such a model does not exist. To prove this result, we will formulate a set of assumptions embodying failure semantics and KFAR, and derive an inconsistency. Formally, the inconsistency arises from the following extension of the axiom system considered above:

$$\begin{aligned} & \text{ACP}_r + \text{R1}, 2 + \text{S} \\ & \quad + \text{Milner's } \tau\text{-laws} + \text{axioms for abstraction operators} \\ & \quad + \text{KFAR} \\ & \quad + \text{RSP (recursive specification principle)}. \end{aligned}$$

Here RSP is the assumption that guarded systems of recursion equations have a solution, which is moreover unique.

Now by virtue of our axiomatic approach we can pinpoint the origin of the inconsistency derived below with some accuracy. It turns out that the failure of KFAR in failure semantics holds already in ready semantics, and moreover that communication does not play a role in the inconsistency. That is, the inconsistency already appears in the subsystem

$$\text{BPA} + \text{T1} + \text{TI1} - 5 + \text{R1} + \text{KFAR} + \text{RSP}$$

which we will explain now. BPA, for *basic process algebra*, consists of the axioms A1-5 of  $\text{ACP}_r$ , which specify the properties of  $+$  and  $\cdot$ . T1 is the simplest of Milner's  $\tau$ -laws [Mi80] (see Table 6). In addition, Table 6 contains axioms TI1-TI5; these specify the abstraction operators  $\tau_I$ , where  $I \subseteq A$  is a set of *internal* actions as simple renaming operators (cf. [BK84c] and [BK86a], [BK86b]).

R1 is the axiom for the readiness semantics (see Tables 3 and 4):

$$a(bx + u) + a(by + v) = a(bx + by + u) + a(bx + by + v).$$

The *recursive specification principle* RSP states that guarded systems  $E$  of recursive equations have unique solutions (see [BK84b] or [BBK85]):

$$\frac{E(x_1, \dots, x_n), E(y_1, \dots, y_n), \quad E \text{ guarded}}{x_i = y_i}.$$

Informally, "guarded" means that every recursive occurrence of  $x_i$  in  $E$  is preceded

TABLE 6  
BPA+T1+TI1-5

$x + y = y + x$	A1
$(x + y) + z = x + (y + z)$	A2
$x + x = x$	A3
$(x + y)z = xz + yz$	A4
$(xy)z = x(yz)$	A5
$x\tau = x$	T1
$\tau_i(\tau) = \tau$	TI1
$\tau_i(a) = a \text{ if } a \notin I$	TI2
$\tau_i(a) = \tau \text{ if } a \in I$	TI3
$\tau_i(x + y) = \tau_i(x) + \tau_i(y)$	TI4
$\tau_i(xy) = \tau_i(x) \cdot \tau_i(y)$	TI5

by an action different from  $\tau$ . For example, the system

$$\begin{aligned} x_1 &= ax_2 + bx_2, \\ x_2 &= c(x_1 + x_2) + d \end{aligned}$$

is guarded and thus has a unique solution.

We will now explain KFAR. For each  $n \geq 1$ , we have a version  $\text{KFAR}_n$ .  $\text{KFAR}_1$  is as follows:

$$\frac{x = ix + y \quad (i \in I)}{\tau_I(x) = \tau \cdot \tau_I(y)}$$

The premise of  $\text{KFAR}_1$  says that  $x$  has an infinite  $i$ -trace (see Fig. 19). Now  $\text{KFAR}_1$  expresses the fact that  $x$  makes *fair* choices along its infinite  $i$ -trace, i.e., performing  $x$  entails at most finitely many choices against  $y$ . We may note here the necessity of the abstraction operator  $\tau_i$  in  $\text{KFAR}_1$ : From  $x = \tau x + y$  it does *not* follow that  $x = \tau \cdot \tau_i(y)$ , since the equation  $x = \tau x + y$  has infinitely many solutions (see [BK84c] or [BK86a]).

FIG. 19

The version of KFAR for  $n = 2$  is

$$\frac{x_1 = ix_2 + y_1, \quad x_2 = jx_1 + y_2 \quad (i, j \in I)}{\tau_I(x_1) = \tau \cdot \tau_I(y_1 + y_2)}.$$

In the general formulation of  $\text{KFAR}_n$  the premise displays an “ $I$ -cycle” of length  $n$ . For a precise formulation we refer to [BK84b] or [BBK85].

Note that except for KFAR all assumptions in  $\text{BPA}_\tau + \text{TI1-TI5} + \text{R1} + \text{RSP}$  are valid for failure semantics. To see that the  $\tau$ -laws TI1-TI3 (of which only the first one is needed for the derivation of the contradiction below) are valid for failure semantics, we refer to [Br83], which gives axioms describing failure semantics for finite processes involving  $\tau$ -steps; these axioms imply the  $\tau$ -laws.

**8.2. The inconsistency of failure semantics with KFAR.** We will now derive the announced contradiction. It is important to notice that this contradiction is entirely insensitive to how failure semantics works with processes that contain  $\tau$ -steps.

Consider the following systems of guarded recursion equations:

$$E_1 \begin{cases} x = ax_1 + ax_2, \\ x_1 = c + bx_2, \\ x_2 = d + bx_1, \end{cases}$$

and

$$E_2 \begin{cases} y = ay_1 + ay_2, \\ y_1 = c + by_2, \\ y_2 = d + by_1. \end{cases}$$

The systems  $E_1, E_2$  have solutions  $x, y$  which can be depicted as in Fig. 20.

CLAIM:  $x$  and  $y$  are failure equivalent.

Intuitively this may be clear since (as demonstrated in § 3.1) axiom R1 amounts to placing “crosses”; from the graphs for  $x, y$  we can thus obtain equivalent graphs as in Fig. 21. These two graphs are in fact identical.

*Proof of the Claim (Formally).* Consider the system  $E_3$  of guarded recursion equations:

$$E_3 \begin{cases} z = az_1 + az_2, \\ z_1 = c + bz_1 + bz_2, \\ z_2 = d + bz_1 + bz_2. \end{cases}$$

(This system corresponds with the graph in Fig. 21.) Now

$$\begin{aligned} x &= ax_1 + ax_2 = a(c + bx_2) + a(d + bx_1) \quad (\text{by R1}) \\ &= a(c + bx_2 + bx_1) + a(d + bx_1 + bx_2) = az'_1 + az'_2 \end{aligned}$$

where

$$z'_1 = c + bx_2 + bx_1 \quad \text{and} \quad z'_2 = d + bx_1 + bx_2.$$

Further,

$$\begin{aligned} z'_1 &= c + bx_2 + bx_1 = c + b(d + bx_1) + b(c + bx_2) \quad (\text{by R1}) \\ &= c + b(c + bx_2 + bx_1) + b(d + bx_1 + bx_2) \\ &= c + bz'_1 + bz'_2 \end{aligned}$$

FIG. 20

and likewise

$$z'_2 = d + bz'_1 + bz'_2.$$

So  $(x, z'_1, z'_2)$  satisfies  $E_3$ . A similar computation shows that  $(y, z''_1, z''_2)$ , where

$$z''_1 = c + by_1 + by_2, \quad z''_2 = d + by_1 + by_2$$

satisfies  $E_3$ . Hence by RSP,

$$(x, z'_1, z'_2) = (y, z''_1, z''_2) = (z, z_1, z_2),$$

in particular  $x = y$ . This proves the claim.

FIG. 21

In order to derive the inconsistency we will abstract from  $b$ , by means of  $\tau_{\{b\}}$ , in  $x$  and  $y$ . This yields corresponding process graphs as in Fig. 22. Next we apply KFAR on  $\tau_{\{b\}}(x)$  and  $\tau_{\{b\}}(y)$  and obtain  $a(c+d)$  and  $ac+ad$ , respectively. This can be seen graphically: KFAR shrinks the infinite  $\tau$ -traces to a point, obtaining the graphs as in Fig. 23.

Formally:

$$(*) \quad \tau_{\{b\}}(x) = \tau_{\{b\}}(ax_1 + ax_2) = a \cdot \tau_{\{b\}}(x_1) + a \cdot \tau_{\{b\}}(x_2).$$

Further,

$$x_1 = bx_2 + c, \quad x_2 = bx_1 + d$$

yields by KFAR<sub>2</sub>:

$$\tau_{\{b\}}(x_1) = \tau \cdot \tau_{\{b\}}(c+d) = \tau(c+d),$$

$$\tau_{\{b\}}(x_2) = \tau \cdot \tau_{\{b\}}(c+d) = \tau(c+d).$$

Hence from (\*)

$$\begin{aligned} \tau_{\{b\}}(x) &= a\tau(c+d) + a\tau(c+d) \quad (\text{by T1 in Table 6}), \\ &= a(c+d) + a(c+d) = a(c+d). \end{aligned}$$

Next consider  $y$ :

$$(**) \quad \tau_{\{b\}}(y) = a \cdot \tau_{\{b\}}(y_1) + a \cdot \tau_{\{b\}}(y_2).$$

Now  $y_1 = by_1 + c$  yields by KFAR<sub>1</sub>:  $\tau_{\{b\}}(y_1) = \tau c$ ; similarly  $\tau_{\{b\}}(y_2) = \tau d$ . Hence from (\*\*)

$$\tau_{\{b\}}(y) = a\tau c + a\tau d = ac + ad.$$

So, since  $x = y$ , we have proved  $a(c+d) = ac + ad$ . But  $a(c+d)$  and  $ac + ad$  are not failure equivalent.

**8.3. Further results.** The above inconsistency proves that the advantages of Koo-  
men's fair abstraction rule, KFAR, cannot be combined with the simplicity of failure  
semantics. We investigated this dichotomy further and were pleased to find a weaker

FIG. 22

FIG. 23

fair abstraction rule, called  $\text{KFAR}^-$ , which is consistent with (finite) failure semantics, and which is still useful for many process verifications. More precisely, the new rule is consistent with a version of Brookes, Hoare, and Roscoe's failure semantics [BHR84] without catastrophic divergence, i.e., that does not identify processes having an infinite  $\tau$ -sequence from the root with the process CHAOS. The details and applications of the new rule  $\text{KFAR}^-$  can be found in [BKO86].

**Acknowledgment.** We thank R. van Glabbeek and one of the referees for pointing out some inconsistencies in a previous version of this paper and for many detailed suggestions and corrections.

## THE AVERAGE COMPLEXITY OF DETERMINISTIC AND RANDOMIZED PARALLEL COMPARISON-SORTING ALGORITHMS\*

N. ALON†‡ AND Y. AZAR†

**Abstract.** In practice, the average time of (deterministic or randomized) sorting algorithms seems to be more relevant than the worst-case time of deterministic algorithms. Still, the many known complexity bounds for parallel comparison sorting include no nontrivial lower bounds for the average time required to sort by comparisons  $n$  elements with  $p$  processors (via deterministic or randomized algorithms). We show that for  $p \geq n$  this time is  $\Theta(\log n / \log(1 + p/n))$  (it is easy to show that for  $p \leq n$  the time is  $\Theta(n \log n / p) = \Theta(\log n / (p/n))$ ). Therefore even the average-case behaviour of randomized algorithms is not more efficient than the worst-case behaviour of deterministic ones.

**Key words.** parallel sorting, comparison algorithms, randomized sorting

**AMS(MOS) subject classification.** 68E05

**1. Introduction.** Sorting is one of the central problems in computer science. For extensive lists of publications dealing with serial and parallel sorting algorithms see, e.g., [Ak85], [BHe85], [Kn73], and [Th83].

Most of the fastest serial and parallel sorting algorithms are based on binary comparisons. In these algorithms the number of comparisons is typically the primary measure of time complexity. Any lower bound on the number of comparisons required for a problem clearly implies a time lower bound for such algorithms.

It is well known that  $\Theta(n \log n)$  binary comparisons are both necessary and sufficient for sorting  $n$  elements in the serial comparison tree model. The situation is somewhat more complicated for parallel algorithms. The common parallel comparison model here is the one introduced by Valiant [Va75] (see also [BH085]), where only comparisons are counted.

In measuring time complexity within this model, we do not count steps in which communication among the processors, movement of data, and memory addressing are performed. We also avoid counting steps in which consequences are deduced from comparisons that were performed.

Note that any lower bound in this model implies the same bound for all algorithms, based on comparisons, in any parallel random access machine (PRAM), including PRAMs that allow simultaneous access to the same common memory location for read and write purposes.

In a serial decision-tree model, we wish to minimize the number of comparisons. The goal of an algorithm in a parallel comparison model is to minimize the number of comparison rounds as well as the total number of comparisons performed.

Let  $k$  stand for the number of comparison rounds (time) of an algorithm in the parallel comparison model. Let  $c(k, n)$  denote the *minimum total* number of comparisons required to sort any  $n$  elements in  $k$  rounds (over all possible algorithms).

Upper and lower bounds for  $c(k, n)$  appear in [AA87], [AAV86], [AKS83a], [AKS83b], [AV87], [BT83], [BHe85], [Bo86], [BH085], [HH80], [HH81], [Pi87]. The

best-known bounds for fixed  $k$  are (see [AA87], [AAV86], [BHe85])

$$\Omega(n^{1+1/k}(\log n)^{1/k}) \leq c(k, n) \leq O(n^{1+1/k} \log n)$$

and for general  $k \leq \log n$  (see [AV87], [AAV86])

$$(1.1) \quad \Omega(kn^{1+1/k}) \leq c(k, n) \leq kn^{1+b/k}$$

where  $b > 0$  is a constant. These bounds imply that the time required for sorting  $n$  elements, if  $p$  comparisons are performed in each time unit, is  $\Theta(\log n/(p/n))$  for  $p \leq n$  and  $\Theta(\log n/\log(1+p/n))$  for  $p \geq n$ .

These results determine up to a constant factor the (worst-case) time complexity of sorting in the parallel comparison tree model. However, the problem of estimating the *average* (over all orders) running time of the best sorting algorithm, as well as that of determining the time complexity of the best randomized sorting algorithm, is far from being settled. In fact, besides the relatively easy  $\Omega(n \log n)$  lower bound for randomized (or average) serial sorting (see, e.g., [AHU74]), there are no known lower bounds for the worst-case or average-time complexity of randomized sorting algorithms at all. Such bounds appear to be important, since in practical situations we are naturally interested in the average running time, and not necessarily in the worst-case behaviour. Similarly, fast randomized parallel sorting algorithms could be extremely helpful in practice.

Proving lower bounds for the average time of (deterministic or randomized) comparison algorithms appears to be much more complicated than obtaining lower bounds for the worst-case time of deterministic ones. In fact, there are several known results that show that for various comparison algorithms the average time, as well as the worst-case time of randomized algorithms, differs asymptotically from the worst-case time of their deterministic counterparts. One such result is due to Reischuk [Re81], who gave a randomized comparison parallel algorithm for selection, whose expected running time is bounded by a constant, using  $n$  processors. Together with the  $\Omega(\log \log n)$  lower bound of [Va75] for finding the maximum among  $n$  elements using  $n$  processors, we conclude that there exists a randomized algorithm for selection that performs better than any of its deterministic counterparts. The results of [BHe85] on approximate sorting in one round, those of [Rei85] on integer sorting and those of [AAV86] on sorting in a fixed number of rounds supply several other examples of parallel randomized comparison algorithms that perform better than the corresponding best-known deterministic ones. In view of these examples we might expect that randomized parallel sorting algorithms could work asymptotically faster than deterministic ones. Our main result in this paper is that this is not the case. In fact we prove the following theorem.

**THEOREM 1.1.** *The average time required for sorting  $n$  elements in the best randomized algorithm with  $p$  processors, (i.e., the best algorithm that performs  $p$  comparisons in each time unit), is  $\Theta(\log n/\log(1+p/n))$  for  $p \geq n$  (and is, easily,  $\Theta(\log n/(p/n))$  for  $p \leq n$ ).*

This matches, up to a constant factor, the worst-case running time for the deterministic case for all values of  $p$ .

To prove the lower bound we prove the following proposition.

**PROPOSITION 1.2.** *The average number of comparisons in the best deterministic algorithm that sorts  $n$  elements in  $k$  rounds is*

$$\Omega(kn^{1+1/k}) \quad \text{for all } k \leq \log n.$$

Note that for  $k = \Theta(\log n)$  this coincides with the known bound for the serial case.

A parallel algorithm is said to achieve average *optimal speedup* if its average running time is proportional to  $\text{Seq}(n)/p$ , where  $\text{Seq}(n)$  is the lower bound on the average serial running time,  $n$  is the size of the problem being considered, and  $p$  is the number of processors used.

An immediate consequence of Theorem 1.1 is that if the number  $p$  of processors is larger than  $n$  by an order of magnitude then it is impossible to design an average optimal speedup randomized comparison sorting algorithm. Note that, for  $p = O(n)$ , there is an optimal speedup (deterministic and therefore randomized or average deterministic) algorithm, given by the [AKS83a], [AKS83b] sorting network. These results enable us to identify asymptotically the parallelism average break point of sorting, which is the minimum average time that can be achieved by an average optimal speedup algorithm. Specifically,  $\Theta(\log n)$  is the average break point for sorting  $n$  elements, which is the same break point as that of deterministic algorithms (see [AAV86], [AV87]).

Note that for finding the maximum the average break point is better than the worst-case break point. Reference [Va75] proved that  $\Theta(\log \log n)$  is the break point for finding the maximum among  $n$  elements but [Re81] proved that  $\Theta(1)$  is the average break point of that problem.

The proof of Theorem 1.1 differs considerably and is far more complicated than that of the corresponding result for the worst-case time of deterministic algorithms (which, obviously, follows from it). The main difficulty lies in the proof of Proposition 1.2. As we are dealing with the average-case behaviour, we cannot use the traditional adversary way for choosing the unknown order; we need a new method. Since a direct proof seems elusive, we must prove a stronger result, which implies, e.g., that our bound holds for algorithms that allow, in addition to usual comparisons, questions of the form “is rank  $(x) \leq i$ ?” For the exact statement of the stronger result see § 2. We are unable to prove Proposition 1.2 without proving this stronger assertion.

The derivation of Theorem 1.1 from Proposition 1.2 is much easier than the proof of Proposition 1.2; however, it is not straightforward. It combines certain probabilistic arguments with a well-known observation of Yao [Ya77] and the upper bound in inequality (1.1). This is described in § 3. The final section, 4, contains concluding remarks, together with an application of our method to selection problems.

## 2. The average number of comparisons in deterministic algorithms.

**2.1. The parallel computation model.** Let  $N$  be a set of  $n$  elements taken from a totally ordered domain. The *parallel comparison model of computation* equivalent to the parallel computation tree model of [BHo85] allows algorithms that work as follows. The algorithm consists of timesteps called *rounds*. In each round binary comparisons are performed simultaneously. The input for each comparison is two elements of  $N$ . The output of each comparison is one of the following two:  $<$  or  $>$ . Each item may take part in several comparisons during the same round.

Our discussion uses the following correspondence between each round and a graph. The elements are the vertices. Each comparison to be performed is an undirected edge that connects its input elements. Each computation results in orienting this edge from the largest element to the smallest. Thus in each round we get an acyclic orientation of the corresponding graph, and the transitive closure of the union of the  $r$  oriented graphs obtained until round  $r$  represents the set of all pairs of elements whose relative order is known at the end of round  $r$ .

Suppose we performed  $r$  rounds where  $r > 0$  is some integer. The comparisons performed in round  $r + 1$  are chosen, of course, according to the results in all previous rounds.

Recall that  $c(k, n)$  denotes the minimum *total* worst-case number of comparisons required to sort  $n$  elements in  $k$  rounds (over all possible algorithms).

Let  $r(k, n)$  denote the *average* total number of comparisons, over all orders, required to sort  $n$  elements in  $k$  rounds, in the best algorithm (that necessarily stops after  $k$  rounds). Clearly  $r(k, n) \leq c(k, n)$ . Our objective is to prove Proposition 1.2, which supplies a lower bound for  $r(k, n)$ , where  $k$  is possibly a function of  $n$ .

**2.2. Legal situations.** We prove a stronger result that implies Proposition 1.2. We consider the following situation, called a *legal situation*: We have  $s + 1$  disjoint sets of elements, denoted  $Z$  and  $Y_1, \dots, Y_s$ , with a set  $E$  of edges (comparisons) between them.

The set  $Z$ ,  $|Z| = m$ ,  $0 \leq m \leq n$ , is a set of  $m$  elements such that the rank of each  $z \in Z$  in the total  $n$ -order is known.  $Y_1, \dots, Y_s$ ,  $|Y_i| = y_i > 0$ ,  $1 \leq i \leq s$  are  $s \geq 0$  sets of elements such that, for each  $i$ , the set of  $y_i$  ranks of the  $i$ th set in the total  $n$ -order is known, but all the  $y_i!$  orders of the elements of the sets are equally likely. The existing edges (comparisons) we have are only for this round and are only between pairs of elements of the same  $Y_i$ , for some  $i$ , or between an element of  $Y_i$  and an element of  $Z$ . The answers to these comparisons are known, but depend, of course, on the actual orders inside the sets  $Y_i$ . Let  $e_i$  be the number of edges in  $Y_i$ . Let  $\bar{e}_i$  be the number of edges between an element of  $Y_i$  and an element outside  $Y_i$ , whose relative order does not follow from the known information about the sets of ranks. Denote  $f_i = e_i + \frac{1}{2}\bar{e}_i$  and call it the “ $f$ -number” of the set  $Y_i$  in this situation.

The following facts are worth noting:

(1) The number of edges  $|E|$  satisfies

$$|E| \geq \sum_{i=1}^s \left( e_i + \frac{1}{2} \bar{e}_i \right) = \sum_{i=1}^s f_i.$$

(2) The number of elements  $n$  satisfies

$$n = m + \sum_{i=1}^s y_i.$$

(3) The (known) set of ranks of each  $Y_i$  is not necessarily a block of  $y_i$  consecutive ranks, and there are no edges between an element of  $Y_i$  and an element of  $Y_j$  for  $i \neq j$ . Before the next round of comparisons, all the information about the relative order of an element of  $Y_i$  and an element of  $Y_j$  is a consequence of either the known sets of ranks of  $Y_i$  and  $Y_j$  or the results of comparisons to elements of  $Z$  and transitivity.

(4) If for some set  $Y_i$ ,  $f_i = 0$  then all the  $y_i!$  orders in this set are equally likely for each possibility of the results of the comparisons of the present round (and independently of these results).

**2.3. The lower bound.** Let  $A$  denote the above legal situation. Denote by  $F(k, A)$  the average, over all the  $\prod_{i=1}^s (y_i!)$  possible orders, of the “ $f$ -number” of comparisons that are needed to sort the  $n$  elements in  $k$  more rounds, starting from situation  $A$ . Here the “ $f$ -number” means that a comparison between an element of  $Y_i$  and an element of  $Y_j$  ( $i$  can be equal to  $j$ ) is counted as one comparison and a comparison between an element of  $Y_i$  and an element of  $Z$  is counted as  $\frac{1}{2}$  a comparison.

Define

$$g_k(y, f) = \begin{cases} 1, & f = 0, \\ \left(\frac{c}{4}\right)^{1/k}, & 0 < \frac{f}{y} \leq \frac{1}{4}, \\ \left(\frac{cf}{y}\right)^{1/k}, & \frac{f}{y} \geq \frac{1}{4}, \end{cases}$$

where  $c$  is some positive constant to be chosen later. Define also

$$\varphi_k(y, f) = k \left[ \frac{y^{1+1/k}}{cg_k(y, f)} - y \right].$$

Note that  $\varphi_k$  is a monotone nonincreasing function of  $f$ . The key inequality is the following.

**THEOREM 2.1.** *In the above notation*

$$(2.1) \quad F(k, A) \geq \sum_{i=1}^s \varphi_k(y_i, f_i)$$

for every  $k \geq 1$ , and every legal situation  $A$ .

The (rather lengthy) proof of Theorem 2.1 is given below. It is based on moving from one legal situation to another by finding properties that hold for all orders (and not just for a special one chosen by an adversary). Some inequalities for convex functions and some statistical behaviour of random orders are used as well, together with a reduction of nonlegal situations that are created during the algorithm to legal ones.

Proposition 1.2 for  $k \leq \log n / (\log 2c)$  is the special case of Theorem 2.1 in which  $A$  is the legal situation with  $Z = \phi$ ,  $s = 1$ ,  $Y_1$  is the set of all elements, and  $f_1 = 0$ . For  $k = \Theta(\log n)$ , Proposition 1.2 follows immediately from the serial bound. Another special case of Theorem 2.1 corresponds to algorithms that allow queries of the form “is rank ( $x$ )  $\leq i$ ” besides usual comparisons. Indeed, suppose we have  $2n - 1$  elements. Let  $A$  be the legal situation in which  $|Z| = n - 1$ , the set of ranks of  $Z$  is  $\{2, 4, \dots, 2n - 2\}$ ,  $s = 1$ , the set of ranks of  $Y_1$  is  $\{1, 3, \dots, 2n - 1\}$  and  $f_1 = 0$ . Applying Theorem 2.1 to this situation we conclude that  $\Omega(kn^{1+1/k})$  comparisons are needed to sort  $Y_1$  in  $k$  ( $\leq \log n$ ) rounds, where here, clearly, a comparison to an element of  $Z$  corresponds to a query of the form “is rank( $x$ )  $\leq i$ ?”

*Proof of Theorem 2.1.* We prove the theorem for every fixed  $n \geq 2$  by induction on  $k$  and on the parameters of  $A$  with  $c = 256e$ . (We make no effort here to obtain the best possible  $c$ .) The base case is left to the end. Our induction hypothesis is that the assertion of Theorem 2.1 holds for any  $k'$  and any legal situation  $A'$  with sets  $Z'$ ,  $|Z'| = m'$  and  $Y'_1, \dots, Y'_{s'}$ ,  $|Y'_i| = y'_i > 0$ , where

$$m' + \sum_{i=1}^{s'} y'_i = n,$$

provided at least one of the following three cases holds:

- (a)  $k' < k$ .
- (b)  $k' = k$  and  $\sum_{i=1}^{s'} y'_i < \sum_{i=1}^s y_i$ .
- (c)  $k' = k$ ,  $\sum_{i=1}^{s'} y'_i \leq \sum_{i=1}^s y_i$  and  $s < s'$ . (Note that always  $s, s' \leq n$ .)

We have to prove the theorem for  $k$  and  $A$ . We consider two possible cases.

*Case 1.* There is a set  $Y_i$ , with  $f_i > 0$ .

*Case 2.* For all  $i$ ,  $1 \leq i \leq s$ ,  $f_i = 0$ , and  $k > 1$ . (The case  $k = 1$  and  $f_i = 0$  for all  $i$  will be the base case.)

In Case 1 we can assume, without loss of generality, that  $f_s > 0$ . Denote  $Y = Y_s$ ,  $|Y| = y = y_s$ ,  $f = f_s$ .

*Subcase 1a.*  $f \geq (1/c^{k+1})y^2$ . In this case  $\varphi_k(y, f) \leq k(y^{1+1/k}/c(cf/y)^{1/k} - y) \leq 0$ . For each order of  $Y$ , let the algorithm know this order for free; i.e., let  $A'$  be the legal situation obtained from  $A$  by replacing  $Z$  by  $Z \cup Y$ . Since  $\sum y'_i < \sum y_i$  and  $k' = k$  it follows from the induction hypothesis (case (b)) that

$$F(k', A') \geq \sum_{i=1}^{s'} \varphi_k(y'_i, f'_i) = \sum_{i=1}^{s-1} \varphi_k(y_i, f_i) \geq \sum_{i=1}^s \varphi_k(y_i, f_i).$$

Averaging over all orders of  $Y$  we conclude that  $F(k, A) \geq \sum_{i=1}^s \varphi_k(y_i, f_i)$ , as needed. (Note that each comparison that is counted as one comparison in  $F(k', A')$  is also counted as 1 in  $F(k, A)$  and each comparison that is counted as  $\frac{1}{2}$  in  $F(k', A')$  is counted either as  $\frac{1}{2}$  or as 1 in  $F(k, A)$ .)

*Subcase 1b.*  $0 < f \leq y/4$ . Since  $2f = 2e_s + \bar{e}_s$  there are at most  $2f$  elements in  $Y$ , which are compared to some other elements (in  $Y$  or in  $Z$ ). Let  $Y'_s \subseteq Y$  be a set of  $2f \leq y/2$  elements containing all those that are compared to members of  $Y \cup Z$ . Also define  $Y'_{s+1} = Y \setminus Y'_s$ . We let the algorithm know for free the set of ranks of  $Y'_s$  and  $Y'_{s+1}$ . This corresponds to the legal situation  $A'$  obtained from  $A$  by splitting  $Y_s$  into the two sets  $Y'_s$  and  $Y'_{s+1}$ . For  $A'$ ,  $s' = s + 1$ ,  $f'_s \leq f_s$ ,  $f'_{s+1} = 0$ . As  $s' > s$  we can apply the induction hypothesis (case (c)) to  $A'$  and conclude that

$$F(k, A') \geq \sum_{i=1}^{s+1} \varphi_k(y'_i, f'_i) \geq \sum_{i=1}^s \varphi_k(y_i, f_i) - \varphi_k(y, f) + \varphi_k(2f, f) + \varphi_k(y - 2f, 0).$$

In Appendix 1 below we show that for  $0 < f \leq y/4$ ,  $\varphi_k(2f, f) + \varphi_k(y - 2f, 0) \geq \varphi_k(y, f)$ . Thus, for each  $A'$  that arises as above  $F(k, A') \geq \sum_{i=1}^s \varphi_k(y_i, f_i)$ . Averaging over all possible assignments of the two sets of ranks to the elements in  $Y'_s$  and in  $Y'_{s+1}$ , we conclude that  $F(k, A)$ , which is at least this average, is at least  $\sum_{i=1}^s \varphi_k(y_i, f_i)$ , as needed.

*Subcase 1c.* (The main case.)  $y/4 < f < y^2/c^{k+1}$ . Define  $t = \lceil 4f/y \rceil (> 1)$ ,  $\beta = \lfloor y/t \rfloor$ . Note that  $2 \leq t \leq 8f/y$ , and  $y/t \geq y^2/8f > c^{k+1}/8$ , and hence  $\beta \geq 1$  and

$$(2.2) \quad \beta = \left\lfloor \frac{y}{t} \right\rfloor \geq \frac{y}{t} \left( 1 - \frac{8}{c^{k+1}} \right).$$

Randomly partition  $Y$  into  $t + 1$  blocks  $B_1, \dots, B_t, C$  where  $|B_i| = \beta$ , and  $|C| = y - t\beta$  (possibly  $|C| = 0$ ). For each such partition choose a random permutation  $\pi$  of  $[1, 2, \dots, t]$ . Assume that each element of  $C$  is greater than each element of  $Y \setminus C$ , and that each element of  $B_i$  is greater than each element of  $B_j$  if and only if  $\pi(i) > \pi(j)$ . These choices, together with the assumption that all the orders inside each block are equally likely, give each of the possible  $y!$  orders of  $y$  with equal probability. For each choice of  $B_i, C$ , and  $\pi$ , there are  $t$  pairwise disjoint sets  $Z_1, \dots, Z_t$  whose ranges of ranks lie inside those of  $B_1, \dots, B_t$ . Let  $g'_i$  be the number of comparisons between two elements of  $B_i$ , and let  $g''_i$  be the number of comparisons between an element of  $B_i$  and an element of  $Z_i$ . Also define  $g_i = g'_i + \frac{1}{2}g''_i$ . Note that  $g'_i, g''_i$ , and  $g_i$  are random variables (whose values depend on the choice of the partition and of  $\pi$ ), that  $2g_i$  is an integer, and that  $g_i$  is the  $f$ -number of  $B_i$  (since the result of each comparison between members of  $B_i$  and members of  $N \setminus (B_i \cup Z_i)$  follows from the assumptions on the sets of ranks of each  $B_i$ ). If  $2g_i < \beta$ , let  $G_i$  be a subset of  $B_i$ ,  $|G_i| = 2g_i$  that contains every member of  $B_i$ , which is compared to a member of  $B_i \cup Z_i$ . (Clearly there are at most  $2g_i$  such elements.) If  $2g_i \geq \beta$ , define  $G_i = B_i$ . Also define  $N_i = B_i \setminus G_i$ . We let our algorithm know for free the sets of ranks of each  $G_i$  and each  $N_i$ . By the definition of  $G_i$  there are no comparisons between  $G_i$  and  $N_i$ . Hence we now have, for each choice of  $B_i, C$ , and  $\pi$ , a new legal situation  $A'$ , which is obtained from  $A$

by replacing  $Z$  by  $Z \cup C$  and by replacing  $Y = Y_s$  by all the nonempty  $G_i$  and  $N_i$  (of which there are at least  $t \geq 2$ ). Note that for  $A'$ ,  $k' = k$ ,  $\sum y'_i \leq \sum y_i$ , and  $s' > s$ . Note also that the  $f$ -number of  $N_i$ ,  $f_{N_i} = 0$  for each nonempty  $N_i$ ,  $1 \leq i \leq t$ . Let  $h_i = f_{G_i}$  be the  $f$ -number of  $G_i$ . Note that  $h_i \leq g_i$ . By applying case (c) of the induction hypothesis to  $A'$  (and by the fact that  $\varphi_k(0, 0) = 0$ ) it suffices to prove that

$$\psi = \psi_1 - \psi_2 \geq 0 \quad \text{where}$$

$$(2.3) \quad \psi_1 = E\left(\sum_{i=1}^t \varphi_k(|N_i|, 0) + \sum_{i=1}^t \varphi_k(|G_i|, h_i)\right), \quad \psi_2 = \varphi_k(y, f),$$

and where the expected value is over all choices of the partition  $B_i$ ,  $C$ , and the permutation  $\pi$ . By the symmetry of the sets  $B_i$

$$E\left(\sum_{i=1}^t \varphi_k(|N_i|, 0) + \sum_{i=1}^t \varphi_k(|G_i|, h_i)\right) = tE(\varphi_k(|N_1|, 0) + \varphi_k(|G_1|, h_1))$$

$$\geq tE(\varphi_k(|N_1|, 0) + \varphi_k(|G_1|, g_1)).$$

Denote  $g = g_1$ . Let  $A_1$  be the event  $2g < \beta$  and let  $p = P(A_1)$  be its probability. Put  $\bar{p} = 1 - p$ . In this notation the right-hand side of the last inequality is simply

$$tpE_{A_1}(\varphi_k(\beta - 2g, 0) + \varphi_k(2g, g)) + t\bar{p}E_{\bar{A}_1}(\varphi_k(\beta, g)),$$

where  $E_{A_1}$ ,  $E_{\bar{A}_1}$  are the expectations given  $A_1$ ,  $\bar{A}_1$ , respectively. Hence

$$\psi_1 \geq tpE_{A_1}\left(k\left[\frac{(\beta - 2g)^{1+1/k}}{c} - (\beta - 2g)\right] + k\left[\frac{(2g)^{1+1/k}}{c(c/2)^{1/k}} - 2g\right]\right)$$

$$+ t\bar{p}E_{\bar{A}_1}\left(k\left[\frac{\beta^{1+1/k}}{c(cg/\beta)^{1/k}} - \beta\right]\right)$$

$$= \frac{tk}{c}\left[pE_{A_1}\left((\beta - 2g)^{1+1/k} + \frac{(2g)^{1+1/k}}{(c/2)^{1/k}}\right) + \bar{p}E_{\bar{A}_1}\frac{\beta^{1+1/k}}{(cg/\beta)^{1/k}}\right] - kt\beta(p + \bar{p}).$$

Put  $E_{A_1}(2g) = a_1$ ,  $E_{\bar{A}_1}(2g) = a_2$ ,  $E(2g) = a$ . Note that  $a_2 \geq \beta$ ,  $pa_1 + \bar{p}a_2 = a$ ,  $p + \bar{p} = 1$ , and  $\beta t \leq y$ . By the convexity of the functions  $x^{1+1/k}$  and  $1/x^{1/k}$  we can apply Jensen's inequality (see, e.g., [HLP59]) to get

$$\psi_1 \geq \frac{kt}{c}\left[p\left((\beta - a_1)^{1+1/k} + \frac{a_1^{1+1/k}}{(c/2)^{1/k}}\right) + \bar{p}\frac{\beta^{1+1/k}}{(\frac{1}{2}ca_2/\beta)^{1/k}}\right] - ky.$$

Put  $\alpha_1 = a_1/\beta$ ,  $\alpha_2 = a_2/\beta$ ,  $\alpha = a/\beta$ . Clearly

$$(2.4) \quad \alpha_2 \geq 1, \quad p\alpha_1 + \bar{p}\alpha_2 = \alpha,$$

and

$$\psi_1 \geq \frac{kt\beta^{1+1/k}}{c}\left[p\left((1 - \alpha_1)^{1+1/k} + \frac{\alpha_1^{1+1/k}}{(c/2)^{1/k}}\right) + \bar{p}\frac{1}{((c/2)\alpha_2)^{1/k}}\right] - ky.$$

Hence

$$\psi = \psi_1 - \psi_2 \geq \frac{kt\beta^{1+1/k}}{c}\left[p\left((1 - \alpha_1)^{1+1/k} + \frac{\alpha_1^{1+1/k}}{(c/2)^{1/k}}\right) + \frac{\bar{p}}{((c/2)\alpha_2)^{1/k}}\right]$$

$$- ky - k\left[\frac{y^{1+1/k}}{c(cf/y)^{1/k}} - y\right].$$

Since  $t < 8f/y$  we conclude, by (2.2), that

$$\psi \cong \frac{ky^{1+1/k}(1-8/c^{k+1})^{1+1/k}}{ct^{1/k}} \left[ p \left( (1-\alpha_1)^{1+1/k} + \frac{\alpha_1^{1+1/k}}{(c/2)^{1/k}} \right) + \frac{\bar{p}}{((c/2)\alpha_2)^{1/k}} - \frac{1}{(c/8)^{1/k}(1-8/c^{k+1})^{1+1/k}} \right].$$

As  $c = 256e$  we can check that  $(1-16/c^{k+1})^k \cong 1-16k/c^{k+1} \cong \frac{1}{2}$ , and hence

$$\left(1 - \frac{8}{c^{k+1}}\right)^{1+1/k} \cong \left(1 - \frac{8}{c^{k+1}}\right)^2 \cong 1 - \frac{16}{c^{k+1}} \cong \left(\frac{1}{2}\right)^{1/k}.$$

Therefore

$$\psi \cong \frac{ky^{1+1/k}(1-8/c^{k+1})^{1+1/k}}{ct^{1/k}} \left[ p \left( (1-\alpha_1)^{1+1/k} + \frac{\alpha_1^{1+1/k}}{(c/2)^{1/k}} \right) + \frac{\bar{p}}{((c/2)\alpha_2)^{1/k}} - \frac{1}{(c/16)^{1/k}} \right].$$

To establish (2.3) it suffices to show that

(2.5) 
$$h \cong 0 \quad \text{where}$$

$$h = p \left[ (1-\alpha_1)^{1+1/k} + \frac{\alpha_1^{1+1/k}}{(c/2)^{1/k}} \right] + \frac{\bar{p}}{((c/2)\alpha_2)^{1/k}} - \frac{1}{(c/16)^{1/k}}.$$

In Appendix 2 we prove that (2.5) holds, subject to the constraints (2.4) and

(2.6) 
$$\alpha \leq \frac{1}{2}.$$

In Appendix 3 we establish (2.6). Therefore  $\psi \cong 0$  and (2.3) holds, completing the proof of Subcase 1c and that of Case 1.

*Case 2.* For all  $i, 1 \leq i \leq s, f_i = 0$  and  $k > 1$ . Here the next round of comparisons ( $k$ th from the end) is performed. Let  $F$  be the set of these comparisons. Note that (if  $s > 1$ )  $F$  may contain comparisons between members of distinct sets  $Y_i$ , and hence the present situation is not necessarily a legal one. Let  $f_1, \dots, f_s$  be the new “ $f$ -numbers” of  $Y_1, \dots, Y_s$  (i.e.,  $f_i = e_i + \frac{1}{2}\bar{e}_i$ , where  $e_i, \bar{e}_i$  are as in the definition of a legal situation given in § 2.2). Clearly  $|F| \cong \sum_{i=1}^s f_i$ .

*Subcase 2a.*  $s = 1$ . In this case the present situation  $A'$  is a legal one. For  $A'$ , the number of remaining rounds is  $k' = k - 1$ , and there is a set  $Y = Y_1$  with  $f$ -number  $f = f_1$ , and  $|Y| = y$  elements and a set  $Z$ . By case (a) of the induction hypothesis  $F(k', A') \cong \varphi_{k-1}(y, f)$ . Therefore, to complete the proof for this subcase it suffices to check that

$$f + \varphi_{k-1}(y, f) \cong \varphi_k(y, 0).$$

If  $0 \leq f < y/4$  then

$$\begin{aligned} f + \varphi_{k-1}(y, f) &\cong \varphi_{k-1}(y, f) \cong (k-1) \left( \frac{y^{1+1/(k-1)}}{c(c/4)^{1/(k-1)}} - y \right) \\ &= ky \left[ \left( 1 - \frac{1}{k} \right) \frac{y^{1/(k-1)}}{c(c/4)^{1/(k-1)}} + \frac{1}{k} \cdot 1 \right] - ky. \end{aligned}$$

By the Arithmetic-Geometric Inequality  $\alpha a + \beta b \cong a^\alpha b^\beta$  for all  $\alpha, \beta, a, b \geq 0, \alpha + \beta = 1$ . Applying it with  $\alpha = 1 - 1/k, \beta = 1/k$  we get

$$\begin{aligned} f + \varphi_{k-1}(y, f) &\cong ky \left[ \frac{y^{(1/(k-1))(k-1/k)}}{c^{(k-1)/k} c^{1/k} (\frac{1}{4})^{1/k}} \cdot 1^{1/k} \right] - ky \\ &= \frac{ky^{1+1/k} \cdot 4^{1/k}}{c} - ky \cong \frac{ky^{1+1/k}}{c} - ky = \varphi_k(y, 0), \end{aligned}$$

as needed. Otherwise  $f > y/4$  and then, by a similar application of the Arithmetic-Geometric Inequality,

$$\begin{aligned}
 f + \varphi_{k-1}(y, f) &= f + (k-1) \left( \frac{y^{1+1/(k-1)}}{c(cf/y)^{1/(k-1)}} - y \right) \\
 &= ky \left[ \frac{1}{k} \left( \frac{f}{y} \right) + \left( 1 - \frac{1}{k} \right) \frac{y^{1/(k-1)}}{c^{1+1/(k-1)}(f/y)^{1/(k-1)}} \right] - (k-1)y \\
 &\geq ky \left( \frac{f}{y} \right)^{1/k} \frac{y^{(1/(k-1))((k-1)/k)}}{c^{(k/(k-1))((k-1)/k)}(f/y)^{1/k}} - (k-1)y \\
 &= \frac{ky^{1+1/k}}{c} - (k-1)y \geq k \left( \frac{y^{1+1/k}}{c} - y \right) = \varphi_k(y, 0).
 \end{aligned}$$

This completes the proof of Subcase 2a.

*Subcase 2b.*  $s > 1$ . Here the situation is not necessarily legal, as there may be comparisons between distinct sets  $Y_i$ . We will show that the average value of the  $f$ -number of comparisons of each set  $Y_i$  is at least  $\varphi_k(y_i, f_i)$ . As the total  $f$ -number is simply the sum of the  $f$ -numbers of the sets  $Y_i$ , this will give the desired result. Fix  $i$ ,  $1 \leq i \leq s$ . Let  $A_i''$  be the legal situation obtained from (the possibly nonlegal one)  $A'$  by defining  $Z'' = N \setminus Y_i$ , i.e., by giving the exact rank of each element outside  $Y_i$ . (Note that there are many distinct such  $A_i''$ , depending on the actual ranks of the elements in  $\cup_{j \neq i} Y_j$ .) As  $y_i < \sum_{j=1}^s y_j$ , we can apply case (b) of the induction hypothesis and conclude that  $F(k-1, A_i'') \geq \varphi_{k-1}(y_i, f_i)$ . It follows that any algorithm that sorts in  $k-1$  rounds, starting from the situation  $A'$  performs on the average at least  $\varphi_{k-1}(y_i, f_i)$  ( $f$ -number of) comparisons for  $Y_i$ , averaging only on those orders in which the ranks outside  $Y_i$  are as in the specific choice of  $A_i''$ . Averaging over all possible  $A_i''$  and summing over  $i$ ,  $1 \leq i \leq s$ , we conclude that

$$\begin{aligned}
 F(k, A) &\geq \sum_{i=1}^s f_i + \sum_{i=1}^s \varphi_{k-1}(y_i, f_i) \\
 &= \sum_{i=1}^s (f_i + \varphi_{k-1}(y_i, f_i)) \geq \sum_{i=1}^s \varphi_k(y_i, 0),
 \end{aligned}$$

where the last inequality follows from the computation of the previous subcase. This completes the proof of Case 2, and the proof of the induction step.

To complete the proof of Theorem 2.1, it remains to establish the base case of the induction. Clearly this case corresponds to a legal situation  $A$  with  $k = 1$ , with a set  $Z$  and sets  $Y_1, \dots, Y_s$ , where  $f_i = 0$  for all  $i$  (otherwise we are in either Case 1 or Case 2, and can apply the induction hypothesis). By the arguments given in the proof of Subcase 2b, we can reduce the case  $s > 1$  to the case  $s = 1$  (otherwise we bound the  $f$ -number for each  $Y_i$  separately, as in Subcase 2b). Hence we may assume that for  $A$ ,  $k = 1$ ,  $s = 1$ ,  $Y = Y_1$ ,  $|Y| = y$ ,  $f_1 = 0$ , and  $Z$  is a set of elements with known ranks. We must sort  $Y$  in one round. Note that since we must complete the sorting in one round we actually have to prove here a worst-case lower bound. If there are two successive ranks in the (known) set of ranks of  $Y$ , we must compare each pair of elements of  $Y$ . Indeed, suppose that a dispensed comparison is between such two successive elements of  $Y$  in the sorted order. The algorithm will clearly fail to determine their relative order. Hence, in this case,  $F(1, A) \geq \binom{y}{2} \geq \varphi_1(y, 0)$ , as needed. Therefore, we may assume that there is at least one element of  $Z$  between any two successive elements of  $Y$ . Clearly we can assume that there is precisely one element of  $Z$  between any two

successive elements of  $Y$  and that there are no elements of  $Z$  that are greater than all members of  $Y$  (or smaller than all members of  $Y$ ), as no additional information can be derived from comparisons to such elements. We can thus assume that  $|Z| = |Y| - 1 = y - 1$ , the (known) set of ranks of  $Z$  is  $\{2, 4, \dots, 2y - 2\}$ , and the (known) set of ranks of  $Y$  is  $\{1, 3, \dots, 2y - 1\}$ .

Let  $F$  be the set of comparisons performed by the algorithm. Suppose  $F = F' \cup F''$ , where  $F'$  are the comparisons between elements of  $Y$  and  $F''$  are those between elements of  $Y$  and elements of  $Z$ . We claim that if  $a, b$  are two distinct members of  $Y$  and the comparison (= edge)  $\{a, b\}$  satisfies  $\{a, b\} \notin F'$  then there are at least  $y - 1 = |Z|$  comparisons in  $F''$  that involve  $a$  or  $b$ . Indeed, if this is false, then there is an element  $z \in Z$  such that  $\{a, z\}, \{b, z\} \notin F''$ . If  $\text{rank}(z) = l$ , then the algorithm clearly will fail to distinguish between any order in which  $\text{rank}(a) = l - 1$  and  $\text{rank}(b) = l + 1$  and the order obtained from it by replacing the ranks of  $a$  and  $b$ . Thus the claim holds. Summing these comparisons of  $F''$  over all  $a, b$  with  $\{a, b\} \notin F'$ , we obtain at least  $(y - 1) \cdot (\binom{y}{2} - |F'|)$ . In this sum each comparison in  $F''$  is counted at most  $y - 1$  times, as for every  $a \in Y$  there are at most  $y - 1$   $b \in Y, b \neq a$  such that  $\{a, b\} \notin F'$ . Hence

$$(y - 1)|F''| \geq (y - 1) \left( \binom{y}{2} - |F'| \right), \quad \text{i.e., } |F'| + |F''| \geq \binom{y}{2}.$$

We conclude that the  $f$ -number of  $Y$  satisfies  $f = |F'| + \frac{1}{2}|F''| \geq \frac{1}{2}\binom{y}{2} \cong \varphi_k(y, 0)$ . This completes the proof of the base case of the induction and establishes Theorem 2.1.  $\square$

**3. Time lower bounds for randomized parallel sorting algorithms.** In this section we derive Theorem 1.1 from Proposition 1.2. The easy fact that for  $p \leq n$  the average time is  $\Theta(\log n / (p/n))$  follows from the existence of the sorting network [AKS83a], [AKS83b], together with the  $\Omega(n \log n)$  known bound for serial average randomized algorithms. The upper bound in inequality (1.1) implies that for every  $p \geq n$  time  $O(\log n / \log(1 + p/n))$  is sufficient, even for the worst case of deterministic algorithms. It remains to prove the lower bound  $\Omega(\log n / \log(1 + p/n))$  for  $p \geq n$ . As observed by Yao [Ya77], since any randomized algorithm is simply a probability distribution on deterministic ones, it suffices to establish the same lower bound for the average time of deterministic sorting algorithms with  $p$  processors. This does not follow immediately from Proposition 1.2, since in this proposition we considered only algorithms that necessarily stop after  $k$  rounds. Hence we need to do some more work. We first need the following simple probabilistic lemma. Let  $S_n$  denote the group of all permutations on  $n$  elements. For  $A \subseteq S_n$  and  $g_0 \in S_n$  define  $g_0A = \{g_0g \mid g \in A\}$ . Also define  $q(A) = |A|/|S_n| = |A|/n!$

**LEMMA 3.1.** *If  $A \subseteq S_n$  and  $q(A) \leq \frac{1}{2}$  then for every  $s \geq 1$  there are  $g_1, g_2, \dots, g_s \in S_n$  such that  $q(\bigcap_{i=1}^s g_iA) \leq 1/2^s$ .*

*Proof.* Choose, independently,  $s$  (not necessarily distinct) random elements  $g_1, g_2, \dots, g_s$  of  $S_n$ . If  $h \in S_n$ , the probability that  $h \in \bigcap_{i=1}^s g_iA$ , is precisely  $q(A)^s$ . Thus, the expected number of elements in  $\bigcap_{i=1}^s g_iA$  is  $n!q(A)^s \leq n!/2^s$ , and there are  $g_1, \dots, g_s \in S_n$  satisfying the conclusion of Lemma 3.1.  $\square$

**PROPOSITION 3.2.** *Suppose there is a deterministic algorithm  $M$  that sorts  $n$  elements with  $p$  processors in expected time  $T$ . Then, for every  $s \geq 1$ , there is a deterministic algorithm that sorts  $n$  elements in  $2T + \lceil T \rceil \leq 4T$  rounds (and necessarily stops after these  $4T$  rounds) with at most  $2Tps + 1/2^s \lceil T \rceil n^{1+b/T}$  average number of comparisons, where  $b > 0$  is the constant from (1.1).*

*Proof.* Let  $N$  be the set of elements we have to sort. Let  $A$  be the set of all permutations of  $N$  that  $M$  fails to sort in  $\leq 2T$  rounds. Clearly,  $q(A) \leq \frac{1}{2}$ . By Lemma 3.1 there exist  $g_1, \dots, g_s \in S_n$  such that  $q(\bigcap_{i=1}^s g_iA) \leq 1/2^s$ . Let  $M''$  be the algorithm

in which  $s$  copies of  $M$  run simultaneously for  $\lceil 2T \rceil$  rounds, where the  $i$ th copy runs on the elements of  $N$  permuted according to  $g_i^{-1}$ . Clearly  $M''$  finds the order of  $N$ , unless this order corresponds to a permutation in  $B = \bigcap_{i=1}^s g_i A$ . But this happens only on a  $1/2^s$ -fraction of the orders. Let  $M'$  be the algorithm that consists of  $M''$ , and if  $M''$  fails it uses the best deterministic algorithm for sorting  $N$  in  $\lceil T \rceil$  rounds. By (1.1) this part takes, in the worst case, at most  $\lceil T \rceil n^{1+b/T}$  additional comparisons. This completes the proof.  $\square$

*Proof of Theorem 1.1.* As observed in the beginning of this section, we only have to establish an  $\Omega(\log n / \log(1 + p/n))$  lower bound for the average time of deterministic algorithms for sorting  $n$  elements with  $p \geq n$  processors. By Proposition 1.2 there exists a (small) constant  $\frac{1}{2} > c > 0$  such that the average number of comparisons in any deterministic algorithm that sorts  $n \geq 2$  elements in  $k \leq \log n$  rounds is at least

$$(3.1) \quad ckn^{1+1/k}.$$

Let  $b \geq 1$  be the (large) constant from inequality (1.1). Let  $d$  be the (small) positive constant defined by

$$(3.2) \quad \frac{1}{16d} = 1 + \log(16b) + \log(1/2c).$$

(Notice that the right-hand side is positive, as  $c < \frac{1}{2}$ ,  $b \geq 1$ .)

Let  $M$  be a deterministic algorithm that sorts  $n$  elements with  $p \geq n$  processors in expected time  $T$ . To complete the proof we show that

$$(3.3) \quad T \geq d \log n / \log(1 + p/n).$$

If  $T \geq d \log n$  then (3.3) holds (for every  $p \geq n$ ). Hence, we may assume that  $T < d \log n (< b \cdot \log n)$ . Define  $s = \lceil b \log n / T \rceil$ . Clearly  $b \log n / T \leq s \leq 2b \log n / T$ . By Proposition 3.2, there is a deterministic algorithm that sorts  $n$  elements in at most  $4T$  rounds with at most

$$2Tps + \frac{1}{2^s} \lceil T \rceil n^{1+b/T} \leq 4Tp \frac{b \log n}{T} + 2Tn$$

average number of comparisons. Hence, by (3.1)

$$4Tp \frac{b \log n}{T} + 2Tn \geq c \cdot 4Tn^{1+1/(4T)},$$

i.e.,

$$4 \frac{p}{n} \frac{b \log n}{T} \geq 4cn^{1/(4T)} - 2 \geq 2cn^{1/(4T)},$$

where the last inequality holds since  $\log n / 4T > 1/4d > -\log(c)$ . By taking logarithms we obtain

$$\log \left( \frac{p}{n} \right) \geq \frac{\log n}{4T} - \log \left( \frac{\log n}{4T} \right) + \log(2c) - \log(16b).$$

As  $\log n / 4T > 1/4d > 4$  we have

$$\frac{\log n}{4T} - \log \left( \frac{\log n}{4T} \right) \geq \frac{\log n}{8T}.$$

Also, by (3.2),

$$\frac{\log n}{16T} > \frac{1}{16d} > \log(16b) - \log(2c).$$

These three inequalities imply

$$\log(p/n) > \frac{\log n}{16T},$$

and hence, for  $p \geq n$  the inequality

$$T > \frac{1}{16} \frac{\log n}{\log(p/n)} > d \log n / \log(1 + (p/n))$$

holds (provided our assumption  $T < d \log n$  holds). This establishes (3.3) and completes the proof.  $\square$

**4. Concluding remarks.** We have shown that the average running time of any comparison (deterministic or randomized) algorithm for sorting  $n$  elements with  $p$  processors is  $\Theta(\log n / \log(1 + p/n))$ , for all  $p \geq n$ , (and is  $\Theta(\log n / (p/n))$  for  $p \leq n$ .)

This is the first known nontrivial bound for randomized parallel comparison sorting algorithms. It shows that the average time of the best randomized algorithm is not smaller than the worst-case time of the best deterministic algorithm for all  $p$  and  $n$ , up to a constant factor.

We note that although Proposition 1.2 is mainly used as a tool for deriving this result, it actually gives additional information. This proposition shows that the average number of comparisons in any deterministic algorithm that sorts  $n$  elements in  $k \leq \log n$  rounds is  $\Omega(kn^{1+1/k})$ . As shown in [AAV86] this result is sharp for any fixed  $k$ . Note also that as shown in [AA87], the worst-case number of comparisons for such an algorithm is  $\Omega(n^{1+1/k}(\log n)^{1/k})$ , i.e., it is bigger for every fixed  $k$ . Thus we conclude that the average behaviour is somewhat different from the worst-case one for parallel comparison sorting algorithms. Our main result (Theorem 1.1) shows that this difference is, however, very small and shrinks to a constant factor if we fix the number of processors and estimate the running time. It is more than a constant factor if we fix the time and estimate the number of processors.

Our methods supply some results for randomized selection algorithms as well. In particular, we can show that the average number of comparisons needed in any randomized algorithm for finding the maximum of  $n$  elements in two rounds is  $\Theta(n^{4/3})$ , and for doing so in three rounds is  $\Theta(n)$ . We omit the details.

**Appendix 1.** We have to show that for  $0 < f \leq y/4$ ,  $\varphi_k(2f, f) + \varphi_k(y - 2f, 0) \geq \varphi_k(y, f)$ . That is,

$$k \left( \frac{(2f)^{1+1/k}}{c(c/2)^{1/k}} - 2f \right) + k \left( \frac{(y-2f)^{1+1/k}}{c} - (y-2f) \right) \geq k \left( \frac{y^{1+1/k}}{c(c/4)^{1/k}} - y \right),$$

or

$$(y-2f)^{1+1/k} + \frac{(2f)^{1+1/k}}{(c/2)^{1/k}} - \frac{y^{1+1/k}}{(c/4)^{1/k}} \geq 0.$$

Put  $\alpha = 2f/y$  and  $h(\alpha) = (1 - \alpha)^{1+1/k} + \alpha^{1+1/k}/(c/2)^{1/k} - 1/(c/4)^{1/k}$ . We have to show that  $h(\alpha) \geq 0$  for all  $0 < \alpha \leq \frac{1}{2}$ . This is done by checking that  $h$  is convex,  $h'(\frac{1}{2}) \leq 0$ , and  $h(\frac{1}{2}) \geq 0$ . Hence for all  $0 < \alpha \leq \frac{1}{2}$   $h'(\alpha) \leq 0$  and therefore  $h(\alpha) \geq h(\frac{1}{2}) \geq 0$ .

$h$  is convex, as it is a sum of convex functions.  $h'(\frac{1}{2}) = -(k+1)/k[(\frac{1}{2})^{1/k} - (1/2)^{1/k}/(c/2)^{1/k}] \leq 0$ , as  $c \geq 2$ .

$$\begin{aligned} h\left(\frac{1}{2}\right) &= \left(\frac{1}{2}\right)^{1+1/k} \left[ 1 + \left(\frac{2}{c}\right)^{1/k} - 2\left(\frac{8}{c}\right)^{1/k} \right] \\ &= \left(\frac{1}{2}\right)^{1+1/k} \left[ \left(1 - \left(\frac{8}{c}\right)^{1/k}\right)^2 + \left(\frac{64}{c^2}\right)^{1/k} \left(\left(\frac{c}{32}\right)^{1/k} - 1\right) \right] \geq 0, \end{aligned}$$

as  $c \geq 32$ .

**Appendix 2.** We have to show that

(2.5)  $h \geq 0$  where

$$h = p \left[ (1 - \alpha_1)^{1+1/k} + \frac{\alpha_1^{1+1/k}}{(c/2)^{1/k}} \right] + \frac{\bar{p}}{((c/2)\alpha_2)^{1/k}} - \frac{1}{(c/16)^{1/k}}$$

subject to

(2.4)  $\alpha_2 \geq 1, \quad p\alpha_1 + \bar{p}\alpha_2 = \alpha$

and

(2.6)  $\alpha \leq \frac{1}{2}$ .

(Recall that  $p, \bar{p}, \alpha, \alpha_1, \alpha_2 \geq 0, p + \bar{p} = 1, c = 256e$ .) Consider  $h$  as a function of  $\alpha_1$ , where  $\alpha, p, \bar{p}$  are constants and  $\alpha_2 = (\alpha - p\alpha_1)/\bar{p}$ . Since  $\alpha_2 \geq 1, \alpha \leq \frac{1}{2}$  we have  $0 \leq \alpha_1 \leq (\alpha - \bar{p})/p = 1 - (1 - \alpha)/p$ . Clearly  $h(\alpha_1)$  is a convex function of  $\alpha_1$ , i.e.,  $h''(\alpha_1) \geq 0$  for all admissible  $\alpha_1$ . Here we prove that  $h'(1 - (1 - \alpha)/p) \leq 0$  and hence, as  $h'(\alpha_1)$  is nonincreasing, we have  $h(\alpha_1) \geq h(1 - (1 - \alpha)/p)$ . We next show that  $h(1 - (1 - \alpha)/p) \geq 0$  and complete the proof. To check that  $h'(1 - (1 - \alpha)/p) \leq 0$ , observe that

$$\begin{aligned} h'(\alpha_1) &= p \left[ -\frac{k+1}{k} (1 - \alpha_1)^{1/k} + \frac{k+1}{k} \frac{\alpha_1^{1/k}}{(c/2)^{1/k}} \right] - \bar{p} \frac{c/2(-p/\bar{p})}{k((c/2)\alpha_2)^{1+1/k}} \\ &= \frac{p}{k} \left[ -(k+1)(1 - \alpha_1)^{1/k} + (k+1) \frac{\alpha_1^{1/k}}{(c/2)^{1/k}} + \frac{c}{2((c/2)\alpha_2)^{1+1/k}} \right]. \end{aligned}$$

For  $\alpha_1 = 1 - (1 - \alpha)/p$  we have  $\alpha_2 = 1$ ; hence (since  $0 \leq p \leq 1, \alpha \leq \frac{1}{2}$ )

$$\begin{aligned} h\left(1 - \frac{1 - \alpha}{p}\right) &= \frac{p}{k} \left[ -(k+1) \left(\frac{1 - \alpha}{p}\right)^{1/k} + (k+1) \left( \left(1 - \frac{1 - \alpha}{p}\right)^{1/k} / (c/2)^{1/k} \right) + \left(\frac{2}{c}\right)^{1/k} \right] \\ &\geq \frac{p}{k} \left[ -(k+1)(1 - \alpha)^{1/k} + (k+1)\alpha^{1/k} \left(\frac{2}{c}\right)^{1/k} + \left(\frac{2}{c}\right)^{1/k} \right] \\ &= -\frac{p}{k} \left[ (k+1) \left( (1 - \alpha)^{1/k} - \alpha^{1/k} \left(\frac{2}{c}\right)^{1/k} \right) - \left(\frac{2}{c}\right)^{1/k} \right] \\ &\geq -\frac{p}{k} \left[ (k+1) \left( \left(\frac{1}{2}\right)^{1/k} - \left(\frac{1}{2}\right)^{1/k} \left(\frac{2}{c}\right)^{1/k} \right) - \left(\frac{2}{c}\right)^{1/k} \right] \\ &= -\frac{p}{k} \left(\frac{1}{2}\right)^{1/k} \left[ (k+1) \left( 1 - \left(\frac{2}{c}\right)^{1/k} \right) - \left(\frac{4}{c}\right)^{1/k} \right]. \end{aligned}$$

The last quantity is clearly negative for  $k = 1$  (as  $c = 256e$ ). For  $k \geq 2$ ,  $(2/c)^{1/k} \leq (\frac{1}{4})^{1/k} \leq 1 - 1/k$ , and hence we have

$$h\left(1 - \frac{1-\alpha}{p}\right) \leq -\frac{p}{k} \left(\frac{1}{2}\right)^{1/k} \left[ (k+1) \left(1 - \left(1 - \frac{1}{k}\right)\right) - 1 \right] = -\frac{p}{k} \left(\frac{1}{2}\right)^{1/k} \leq 0,$$

as needed. It remains to check that  $h(1 - (1 - \alpha)/p) \geq 0$ . Indeed

$$h\left(1 - \frac{1-\alpha}{p}\right) = p \left[ \left(\frac{1-\alpha}{p}\right)^{1+1/k} + \left(1 - \frac{1-\alpha}{p}\right)^{1+1/k} / (c/2)^{1/k} \right] + \frac{\bar{p}}{(c/2)^{1/k}} - \left(\frac{16}{c}\right)^{1/k}.$$

Since  $(1-x)^\gamma \geq 1 - \gamma x$  for  $0 \leq x \leq 1$ ,  $\gamma \geq 1$  this implies

$$\begin{aligned} h\left(1 - \frac{1-\alpha}{p}\right) &\geq \frac{(1-\alpha)^{1+1/k}}{p^{1/k}} + p \frac{1 - ((1+1/k)(1-\alpha)/p)}{(c/2)^{1/k}} + \frac{1-p}{(c/2)^{1/k}} - \left(\frac{16}{c}\right)^{1/k} \\ &= \frac{(1-\alpha)^{1+1/k}}{p^{1/k}} + \frac{1 - (1+1/k)(1-\alpha)}{(c/2)^{1/k}} - \left(\frac{16}{c}\right)^{1/k}. \end{aligned}$$

As  $p \leq 1$  we conclude

$$\begin{aligned} h\left(1 - \frac{1-\alpha}{p}\right) &\geq \left(\frac{2}{c}\right)^{1/k} \left[ \left(\frac{c}{2}\right)^{1/k} (1-\alpha)^{1+1/k} + 1 - \left(1 + \frac{1}{k}\right)(1-\alpha) - 8^{1/k} \right] \\ &= \left(\frac{2}{c}\right)^{1/k} \left\{ (1-\alpha) \left[ \left(\frac{c(1-\alpha)}{2}\right)^{1/k} - \left(1 + \frac{1}{k}\right) \right] + 1 - 8^{1/k} \right\}. \end{aligned}$$

Since  $\alpha \leq \frac{1}{2}$  and  $c = 256e$  implies  $[(c/2)(1-\alpha)]^{1/k} \geq (c/4)^{1/k} = (64e)^{1/k} \geq 64^{1/k}$ .  $(1+1/k)$  we have

$$\begin{aligned} h\left(1 - \frac{1-\alpha}{p}\right) &\geq \left(\frac{2}{c}\right)^{1/k} \left\{ \frac{1}{2} \left[ \left(\frac{c}{4}\right)^{1/k} - \left(1 + \frac{1}{k}\right) \right] + 1 - 8^{1/k} \right\} \\ &= \frac{1}{2} \left(\frac{2}{c}\right)^{1/k} \left[ \left(\frac{c}{4}\right)^{1/k} + 1 - \frac{1}{k} - 2 \cdot 8^{1/k} \right] \\ &= \frac{1}{2} \cdot \left(\frac{2}{c}\right)^{1/k} \left[ (1 - 8^{1/k})^2 + \left(\frac{c}{4}\right)^{1/k} - 64^{1/k} - \frac{1}{k} \right] \\ &\geq \frac{1}{2} \cdot \left(\frac{2}{c}\right)^{1/k} \left[ (1 - 8^{1/k})^2 + 64^{1/k} \left(1 + \frac{1}{k}\right) - 64^{1/k} - \frac{1}{k} \right] \\ &= \frac{1}{2} \cdot \left(\frac{2}{c}\right)^{1/k} \left[ (1 - 8^{1/k})^2 + \frac{1}{k} (64^{1/k} - 1) \right] \geq 0. \end{aligned}$$

This completes the proof of (2.5).

**Appendix 3.** Here we show  $\alpha \leq \frac{1}{2}$ . Recall that  $\alpha = a/\beta$ , where  $a = E(2g) = E(2g' + g'')$ ,  $g'$  is the number of comparisons inside  $B_1$  and  $g''$  is the number of comparisons between  $B_1$  and  $Z_1$ . Let  $F'$  be the set of all comparisons (= edges) between elements of  $Y$  and let  $F''$  be the set of all comparisons between  $Y$  and  $Z$  whose results do not follow from the known information about the ranks. Put  $|F'| = e$ ,  $|F''| = \bar{e}$  and let  $f = e + \frac{1}{2}\bar{e}$  be the “ $f$ -number” of  $Y$ . As the members of  $B_1$  are  $\beta$  random elements of  $Y$  we have

$$E(g') = \binom{\beta}{2} / \binom{y}{2} |F'| \leq \frac{\beta^2}{y^2} e.$$

Consider a fixed edge (= comparison) in  $F''$ . Such a comparison compares some member  $m_y \in Y$  to some member  $m_z \in Z$ . The probability that the  $m_y$  will be in  $\cup_{i=1}^t B_i$  is, clearly,  $\beta t/y$ . As the permutation  $\pi$  is chosen randomly, the probability that  $m_y \in B_i$ , given that  $m_z \in Z_i$  (and that  $m_y \in \cup_{i=1}^t B_i$ ), is  $1/t$ . Therefore, the expected number of edges from  $F'$  that join members of  $B_i$  to members of  $Z_i$  for some  $1 \leq i \leq t$  is at most  $|F''| \cdot \beta t/y \cdot 1/t = \beta \bar{e}/y$ . By the symmetry of the sets  $B_i$  this gives  $E(g'') \leq \beta \bar{e}/y$ . Therefore, since  $\beta t \leq y$ ,

$$a = E(2g) = E(2g' + g'') \leq 2 \frac{\beta^2}{y^2} e + \frac{\beta \bar{e}}{yt} \leq 2 \frac{\beta}{yt} \left( e + \frac{1}{2} \bar{e} \right) = 2 \frac{b}{yt} f.$$

Recall that  $t \geq 4f/y$ , i.e.,  $f \leq ty/4$ . This implies  $\alpha = a/\beta \leq 2f/yt \leq \frac{1}{2}$ , as needed.

## P-PRINTABLE SETS\*

ERIC W. ALLENDER† AND ROY S. RUBINSTEIN‡

**Abstract.** P-printable sets arise naturally in the studies of generalized Kolmogorov complexity and data compression, as well as in other areas. We present new characterizations of the P-printable sets and present necessary and sufficient conditions for the existence of sparse sets in P that are not P-printable. As a corollary to one of our results, we show that the class of sets of small generalized Kolmogorov complexity is exactly the class of sets which are P-isomorphic to a tally language.

**Key words.** Kolmogorov complexity, sparse sets, P-isomorphisms, AuxPDAs, computational complexity

**AMS(MOS) subject classifications.** 68Q15, 68Q30, 68Q05, 03D15, 03D30

**1. Introduction.** Sparse sets have the useful property that for every  $n$  there is a table of size polynomial in  $n$  that lists the elements of the set of size less than or equal to  $n$ . Letting  $S$  be an arbitrary sparse set, it is conceivable that by storing a polynomial size table for sufficiently large  $n$ , we might have immediate access to all the information about  $S$  that we might ever need, despite the fact that the uniform complexity of  $S$  may be very high. Unfortunately, the complexity of producing such a table may be much greater than the complexity of recognizing the set  $S$ . If the complexity of producing a table for  $S$  is not much greater than the complexity of recognizing  $S$ , i.e., the complexity of producing a table for  $S$  is polynomial-time Turing reducible to  $S$ , then  $S$  is said to be *self P-printable*. If the complexity of producing a table for  $S$  is easy, i.e., a table for  $S$  can be produced in polynomial time without using  $S$  as an oracle, then  $S$  is *P-printable*. (Formal definitions for this and other concepts are given in § 2.) Obviously, P-printable sets belong to P. The notion of P-printability was introduced in [HY84] and was further explored in [HIS85].

The idea of generalized Kolmogorov complexity was introduced in [Har83] and [Sip83], and the connection between it and P-printability has been studied independently in [BB86], [HH86], and [Rub86b]. Generalized Kolmogorov complexity is a measure of how far a string can be compressed and how fast it can be restored. The relativized version of generalized Kolmogorov complexity allows the use of an oracle in the restoration. Sets containing only strings that can be greatly compressed and quickly restored (to be defined more precisely in the next section) are said to have *small generalized Kolmogorov complexity*. The papers [BB86] and [HH86] show that a set is self-P-printable if and only if it has small generalized Kolmogorov complexity relative to itself. This has the corollary (independently proved in [Rub86b]) that a set is P-printable if and only if it is in P and has small generalized Kolmogorov complexity.

P-printable sets are also shown here to have close connections with tally sets. Section 3 presents the result that a set is P-printable if and only if it is P-isomorphic to a tally language in P, if and only if it is in P and has small generalized Kolmogorov complexity. This has the important corollary that sets of small generalized Kolmogorov complexity are precisely those that are P-isomorphic to a tally language. This improves

upon a result in [BB86] that the sets of small generalized Kolmogorov complexity are those that are “semi-isomorphic” to a tally language. Since most of the properties of sets studied in complexity theory are invariant under P-isomorphisms, the significance of this corollary is that the sets of small generalized Kolmogorov complexity are essentially identical to the tally languages from the point of view of complexity theory.

It is also shown that a set is P-printable if and only if it is sparse and has a ranking function computable in polynomial time. A ranking function is a function that maps an element of a set to its index in the lexicographic ordering of the set. They are presented in the context of data compression in [GS85] and are of independent interest [All85] and [Hem87].

Section 4 presents machine-based characterizations of the P-printable sets. It is shown there that a set is P-printable if and only if it is sparse and accepted by a deterministic one-way logspace-bounded AuxPDA, if and only if it is sparse and accepted by a nondeterministic one-way logspace-bounded AuxPDA. This presents a parallel to the result of Cook [Coo71] that a set is in P if and only if it is accepted by a (two-way) logspace-bounded AuxPDA. It is surprising that restricting AuxPDAs to have a one-way input head leads to a characterization of P-printable sets.

One-way AuxPDAs are not very powerful machines, as it was shown in [Bra77b] that some relatively “natural” languages in P are not accepted by one-way AuxPDAs of sublinear space complexity. With this result, any argument showing the existence of a sparse set in P (or even PSPACE) that is not accepted by any one-way logspace-bounded AuxPDA is strong enough to settle several outstanding problems in complexity theory, since, for example,  $P = PSPACE$  implies all sparse sets in PSPACE are P-printable [HY84].

Section 5 addresses some structural questions concerning P-printable sets. While it is clear that every P-printable set is sparse and in P, it is not known whether or not there is a sparse set in P that is not P-printable. Here we present the result that there is a sparse set in P that is not P-printable if and only if there is a sparse set in DLOG that is not P-printable, if and only if there is a sparse set in FewP – P. FewP was introduced in [All86b] as a class of sets between UP and NP (see § 2 for more details). This section concludes with the results that there are infinite sparse sets of time complexity arbitrarily close to polynomial that have finite intersection with every P-printable set, and that every infinite set in P has an infinite P-printable subset if and only if every infinite set in NP has an infinite P-printable subset.

**2. Preliminaries.** While it is assumed that the reader is familiar with the basic concepts and structures from complexity theory (such as P, NP, and DLOG), some of the more important and not universally known ones are presented here, along with notation.

We use the standard lexicographic ordering  $\leq$  on strings, and  $|w|$  denotes the length of the string  $w$ . All strings here are elements of  $\{0, 1\}^*$ , and all sets are subsets of  $\{0, 1\}^*$ . Although a language may be referred to as a subset of  $\{0, 1, \#\}^*$ , this is merely a notational convenience; such a language should be thought of as a subset of  $\{00, 11, 01\}^*$ . A tally language is a subset of  $\{0\}^*$ .

Strings are sometimes used to denote numbers (and vice versa) by letting the string  $w$  denote the number whose binary representation is  $1w$ . This preserves the ordering and allows us to write, for example,  $|w| = \lfloor \log w \rfloor$ . All logarithms are base two. We use EXPTIME to denote  $DTIME(2^{O(n)})$  and NEXPTIME to denote  $NTIME(2^{O(n)})$ .

**DEFINITION 1.** A set  $A$  is *sparse* if there exists a polynomial  $p$  such that the

number of strings in  $A$  of length less than or equal to  $n$  is less than or equal to  $p(n)$ .

The Kolmogorov complexity of finite strings was introduced independently by Kolmogorov [Kol65] and Chaitin [Cha66], [Cha75] as a way to measure the randomness of a finite string (or equivalently, the amount of information contained in a string). The Kolmogorov complexity of a finite binary string is the length of the shortest program that generates it. Intuitively it can be seen that if a string can be generated by a program shorter than itself (i.e., it can be *compressed*), it must contain some redundant information. A string is *random* if it cannot be compressed.

One limitation in using this as the definition of randomness is that it provides no limits or restrictions on the computation time to generate the original string from its smallest program. Time-bounded versions of Kolmogorov complexity have been considered by Ko [Ko86], Sipser [Sip83], and more recently by Hartmanis [Har83].

Hartmanis introduced a two-parameter version of Kolmogorov complexity (now called *generalized Kolmogorov complexity*) that includes information about not only how far a string can be compressed, but how fast it can be restored. This generalized Kolmogorov complexity is further explored in [All87], [BB86], [Huy86], [KOSW86], [Lon86], [Rub86b], and [Rub86a]. It is Hartmanis's definition of generalized Kolmogorov complexity that is presented here.

DEFINITION 2. For a Turing machine  $M_u$  and functions  $g$  and  $G$  mapping natural numbers to natural numbers, let

$$K_u[g(n), G(n)] = \{x \mid (\exists y)[|y| \leq g(|x|) \text{ and } M_u(y) = x \text{ in } G(|x|) \text{ or fewer steps}]\}.$$

We will refer to  $y$  as the *compressed string*,  $x$  as the *restored string*,  $g(n)$  as the *compression*, and  $G(n)$  as the *restoration time*. It was shown in [Har83] that there exists a Turing machine  $M_u$  (called a *universal Turing machine*) such that for any other Turing machine  $M_v$  there exists a constant  $c$  such that  $K_v[g(n), G(n)] \subseteq K_u[g(n) + c, cG(n) \log G(n) + c]$ . Dropping the subscript,  $K[g(n), G(n)]$  will actually denote  $K_u[g(n), G(n)]$ .

DEFINITION 3. A set is said to have *small generalized Kolmogorov complexity* if it is a subset of  $K[k \log n, n^k]$  for some  $k$ .

Clearly every set with small generalized Kolmogorov complexity is sparse. Note that the definition of small generalized Kolmogorov complexity is robust enough to handle the small difference between the universal machine mentioned above and any other machine.

We now give the definition of P-printability.

DEFINITION 4. A set  $S$  is *polynomial-time printable* (P-printable) if there exists a  $k$  such that all the elements of  $S$  up to size  $n$  can be printed by a deterministic machine in time  $n^k + k$ .

Clearly every P-printable set is necessarily sparse and in P.

Goldberg and Sipser [GS85] discuss compression of languages and ranking and present the following definitions.

DEFINITION 5. A function  $f: \Sigma^* \rightarrow \Sigma^*$  is a *compression* of language  $L$  if  $f$  is one-to-one on  $L$  and for all except finitely many  $x \in L$ ,  $|f(x)| < |x|$ .

DEFINITION 6. A language  $L$  is *compressible in time  $T$*  if there is a compression function  $f$  for  $L$  that can be computed in time  $T$ , and the "inverse" of  $f$ ,  $f^{-1}: f(L) \rightarrow L$ , such that for any  $x \in L$ ,  $f^{-1}(f(x)) = x$ , can be computed in time  $T$ .

This clearly relates to generalized Kolmogorov complexity in that compressible languages do not contain more than finitely many random strings, and the compression time (in this sense) relates to the second parameter of the generalized Kolmogorov complexity. Note that in this version, the compression time is a bound on both the

compression and restoration, whereas the time parameter of generalized Kolmogorov complexity refers only to the restoration time.

Reference [GS85] additionally presents the following definitions.

DEFINITION 7. A function  $f$  *optimally compresses* a language  $L$  if for any  $x \in L$  of length  $n$ ,  $|f(x)| \leq \lceil \log(\sum_{i=0}^n |L^i|) \rceil$ , where  $L^i$  is the set of strings in  $L$  of length  $i$ .

DEFINITION 8. For any set  $L \subseteq \Sigma^*$ , the *ranking function* for  $L$ ,  $r_L: \Sigma^* \rightarrow \mathbb{N}$ , is given by  $r_L(x) = |\{w \in L \mid w \leq x\}|$ .

The ranking is a special kind of optimal compression.

Allender [All86b] defined the complexity class FewP to be between UP and NP as follows.

DEFINITION 9. FewP is the class of languages that are accepted by nondeterministic polynomial-time Turing machines  $M$  for which there is a polynomial  $p$  such that for all inputs  $w$ , if  $M$  accepts  $w$ , there are fewer than  $p(|w|)$  accepting computations of  $M$  on  $w$ .

FewP is related to the class UP [Ber77], [Val76], [GS84] of languages in NP that are accepted by nondeterministic polynomial-time bounded Turing machines with unique accepting computations. Both UP and FewP are subclasses of NP defined by restricting the number of accepting computations. Densities of accepting computations were previously considered in [Mor82], but no class equivalent to FewP was introduced.

DEFINITION 10. A function  $f$  is a *P-isomorphism* if it is a bijection such that both  $f$  and  $f^{-1}$  are computable in polynomial time. Two sets  $A$  and  $B$  are *P-isomorphic* if there is some P-isomorphism  $f$  such that  $A = f(B)$ .

Auxiliary pushdown automata (AuxPDAs) are due to Cook [Coo71]. An AuxPDA is a Turing machine with a pushdown store in addition to a worktape. When we bound the space used by an AuxPDA, we bound only the space used on the worktape; the space used on the pushdown store is "free." Useful results about AuxPDAs are summarized in [HU79]. The fact that the languages accepted in time  $T(n)^{O(1)}$  are precisely the sets accepted by  $\log T(n)$  space-bounded deterministic and nondeterministic AuxPDAs [Coo71] will be used.

A one-way AuxPDA is an AuxPDA with a one-way input head. One-way AuxPDAs have been studied before in [Bra77b], [Bra77a], [Chy77], [WB79], and [Wec80]. In [BDG85] and [Huy85] one-way AuxPDAs were investigated in connection with restricted forms of nonuniform complexity. In most studies of one-way AuxPDAs, the machine starts its computation with  $\log n$  space marked off on its worktape; that is the model used here.

**3. Structural characterizations.** In this section the non-machine-based characterizations of the class of P-printable sets presented in the Introduction are proved.

THEOREM 1. *The following are equivalent:*

- (1)  $S$  is P-printable.
- (2)  $S$  is sparse and has a ranking function computable in polynomial time.
- (3)  $S$  is P-isomorphic to some tally set in P.
- (4)  $S \subseteq K[k \log n, n^k]$  and  $S \in P$ .

Note. The equivalence of (1) and (4) also appears in [BB86], [HH86], and [Rub86b].

*Proof.* [(1)  $\Rightarrow$  (2)]. The proof is immediate.

[(2)  $\Rightarrow$  (3)]. Let  $S$  have a ranking function  $r_1$  computable in polynomial time, and let there be fewer than  $p(n)$  strings of length  $n$  in  $S$ . Thus the function  $r_2$  given by  $r_2(w) = w - r_1(w)$  is a ranking function for the complement of  $S$ . (Recall that strings can represent numbers, as explained in § 2.) Also, the set  $T = \{0^{np(n)+i} \mid r_1(1^{n-1}) <$

$i \leq r_1(1^n)$  is a tally set in P; let  $r_3$  be a ranking function for the complement of  $T$ . As was noted in [GS85], all these ranking functions have inverses that are computable in time polynomial in the length of their output. It is now easy to show that the function that takes  $x$  of length  $n$  to  $0^{np(n)+r_1(x)}$  if  $x \in S$  and to  $r_3^{-1}(r_2(x))$  if  $x \notin S$  is a P-isomorphism mapping  $S$  onto  $T$ .

[(3)  $\Rightarrow$  (4)]. Let  $S$  be P-isomorphic to  $T \subseteq 0^*$  via some isomorphism  $f$  such that both  $f$  and  $f^{-1}$  are computable in time  $n^c$ . The compressed form of a string  $x \in S$  of length  $n$  is  $z$ , the binary representation of  $|f(x)|$ . Since  $f$  is computable in time at most  $n^c$ , it follows that  $|f(x)| \leq n^c$ , and thus  $|z| \leq c \log n$ . To get  $x$  back from  $z$ , simply compute  $f^{-1}(0^z)$ . Since  $|0^z| = |f(x)| \leq n^c$ , computing  $0^z$  from  $z$  takes time at most polynomial in  $n$ , call it  $n^l$ . Computing  $f^{-1}(0^z)$  takes time at most  $|0^z|^c \leq (n^c)^c = n^{c^2}$ . The computation time of  $x$  from  $z$  is thus  $\leq n^{c^2} + n^l \leq n^k$  for some  $k \geq c$ . Thus  $S \subseteq K[k \log n, n^k]$ . If  $T$  is in P, then  $S$  will also be in P since they are P-isomorphic.

[(4)  $\Rightarrow$  (1)]. Assume that  $S \in P$  and that for some  $k, S \subseteq K[k \log n, n^k]$ . On input  $n$ , for each of the  $n^{k+1} - 1$  strings of length  $\leq k \log n$ , run  $M_u$  for at most  $n^k$  steps and, if the computation has completed and the result is in  $S$ , print it. This process can clearly be done in time polynomial in  $n$ .  $\square$

It should be pointed out that results similar to those of Theorem 1 were presented in [BB86] as part of an investigation of sets of small generalized Kolmogorov complexity. In [BB86], Balcázar and Book define “semi-isomorphisms” and show that a set has small generalized Kolmogorov complexity if and only if it is semi-isomorphic to a tally set. Using Theorem 1 we can improve upon their result. First, however, we need the following easy result.

PROPOSITION 2. For all  $M_u$  and  $k, K_v[k \log n, n^k] \in P$ .

This proposition is readily seen to be true by the following procedure: to determine if a string  $x$  of length  $n$  is in  $K_v[k \log n, n^k]$ , run machine  $M_u$  on all strings of length less than or equal to  $k \log n$ , and accept if and only if  $M_u$  outputs  $x$  on one of these strings.

COROLLARY 3. There exists a  $k$  such that  $A \subseteq K[k \log n, n^k]$  if and only if  $A$  is P-isomorphic to a tally set.

Proof. The proof from right to left follows from the argument given in the proof of [(3)  $\Rightarrow$  (4)] of Theorem 1. For the forward direction, let  $A \subseteq K[k \log n, n^k]$ . By Theorem 1 and Proposition 2,  $K[k \log n, n^k]$  is P-isomorphic to some tally set  $T$  in P via some P-isomorphism  $f$ . It is now clear that  $A$  is P-isomorphic to  $f(A) \subseteq T \subseteq \{0^*\}$ .  $\square$

While no good upper bound is known for the generalized Kolmogorov complexity of sparse sets in P without assuming P-printability, it is not hard to show that every sparse set in P is a subset of  $K[O(\log n), 2^{O(n)}]$ . However, that is not very informative since every sparse set in EXPTIME is contained in  $K[O(\log n), 2^{O(n)}]$ .

We remark that, while it is not known whether or not there are sparse sets in P that are not subsets of  $K[k \log n, n^k]$  for any  $k$ , it is not hard to show that, for any time-constructible function  $T(n)$  that is greater than every polynomial, there is a sparse set in DTIME( $T(n)$ ) that is not a subset of  $K[k \log n, n^k]$  for any  $k$ . Also, there is a nonrecursive sparse set that is not a subset of  $K[S(n), T(n)]$  for any  $S(n) = o(n)$  and any recursive  $T(n)$ . As an example of such a set, consider a set consisting of exactly one Kolmogorov-random string of each length  $n$ . Sparse sets such as these are not P-isomorphic to any tally set.

**4. Machine-based characterizations.** We now present machine-based characterizations of the P-printable sets. Cook [Coo71] showed that a set is in P if and only if it is accepted by a (two-way) logspace-bounded AuxPDA. By restricting this machine

to be one way, we obtain a characterization of the P-printable sets.

**THEOREM 4.** *The following are equivalent:*

- (1)  $S$  is P-printable.
- (2)  $S$  is sparse and is accepted by a deterministic one-way logspace-bounded AuxPDA.
- (3)  $S$  is sparse and is accepted by a nondeterministic one-way logspace-bounded AuxPDA.

*Proof.* [(1)  $\Rightarrow$  (2)]. If  $S$  is P-printable, then there is a function  $f$  computable in polynomial time such that  $f(n)$  encodes the elements of  $S$  of length less than or equal to  $n$ . Thus the set  $A = \{n\#i \mid \text{the } i\text{th bit of } f(n) = 1\}$  is in EXPTIME and can thus be recognized by a deterministic AuxPDA that uses linear space. Equivalently, an AuxPDA with  $n\#i$  written on its worktape can determine if  $n\#i \in A$  without referencing its input tape (i.e., without moving its input head).

Using this trick, a one-way AuxPDA can easily check if the word on its input tape agrees with the  $i$ th word in the enumeration of  $S$ . If the  $i$ th word disagrees with the input in the  $j$ th position, it is not necessary to move the input head back to the start of the tape in order to compare the input with the  $(i+1)$ st word. Instead, find the next word in the enumeration which agrees with the  $i$ th word up to (and not including) the  $j$ th position. The following algorithm makes this precise. Let  $p$  be a polynomial such that for all  $n$  there are fewer than  $p(n)$  elements of  $S$  of length less than or equal to  $n$ . The following algorithm can be carried out by a deterministic logspace-bounded AuxPDA.

**begin**

At the start of the computation,  $w = w_1 \cdots w_n$  is on the input tape and  $\lfloor \log n \rfloor$  space is marked off on the worktape.

$r := 1^{\lfloor \log n \rfloor}$  //Note that the AuxPDA cannot know what  $n$  is until it has read the entire input. Clearly, however,  $n \leq r \leq 2n$ .

$i := 1$

$j := 0$  //The pair  $(i, j)$  will be maintained so that the word on the input tape will match the  $i$ th word in the enumeration of  $S$  up through position  $j$ .

**step one**

Increment  $j$  until a  $j$  is found (by repeated calls of the form  $r\#1 \in A?$ ,  $r\#2 \in A?$ ,  $\dots$ ) such that the  $j$ th input symbol differs from the  $j$ th symbol of the  $i$ th word of the enumeration of  $S$ , or until  $j = n$ .

If  $j = n$  and the first  $n$  symbols of the input match the first  $n$  symbols of the  $i$ th word of the enumeration and the  $i$ th word has length  $n$ , then halt and accept.

Otherwise go on to step two.

**step two**

By making repeated calls of the form  $r\#1 \in A?$ ,  $r\#2 \in A?$ ,  $\dots$ , find the least  $i'$  such that  $i < i' < p(r)$ , and such that the first  $j-1$  symbols of the  $i$ th and the  $i'$ th words of the enumeration of  $S$  agree.

If no such  $i'$  exists, halt and reject.

Otherwise set  $i := i'$  and go to step one.

**end**

The AuxPDA described above simply searches through the enumeration of  $S$  until some word is found that matches the input, and accepts if such a word is found. It is

easy to see that the algorithm is correct. Note that the only time the input head is moved is in step one, and that the input need only be read in one scan from left to right.

[(2)  $\Rightarrow$  (3)]. The proof is immediate.

[(3)  $\Rightarrow$  (1)]. Let  $S$  be sparse and accepted by a nondeterministic one-way logspace-bounded AuxPDA  $M$ . It is easy to construct another nondeterministic one-way AuxPDA accepting the set  $S' = \{0^n \# w \mid \text{there is a string } x \text{ such that } |wx| = n \text{ and } wx \in S\}$ . (This machine will store  $n$  in binary on its worktape and then simulate  $M$  on  $w$ . Then it will continue the simulation by guessing the  $n - |w|$  characters of  $x$ . Since  $M$  is one-way, only one bit of  $x$  needs to be stored at any time.) Thus  $S' \in P$ . By using  $S'$  it is now easy to construct the elements of  $S$ , bit by bit, and thus it follows that  $S$  is P-printable.

(This proof was pointed out to the first author by Osamu Watanabe, and simplifies the proof of the same result, which was presented in [All86b]).  $\square$

An interesting result somewhat related to Theorem 4 has recently been proved by Ibarra and Ravikumar; in [IR86] they show that all sparse CFLs are bounded.

The study of P-uniform circuit complexity is also related to the study of P-printable sets, and was part of the motivation for the present investigation of P-printable sets. A P-uniform family of circuits is a set of circuits  $\{C_n \mid n \geq 1\}$  such that the function  $n \rightarrow C_n$  is computable in time polynomial in  $n$ . P-uniform circuits are studied in [All85], [All86a], [BCH84], and [vzG84].

When studying circuit complexity classes, the class of functions that can be computed by very fast circuits (i.e., circuits of small depth) is of special interest. Thus, we are led to consider the class P-uniform NC (PUNC), the class of languages accepted by P-uniform circuits of depth  $\log^{O(1)} n$  [All86a].

Note that if  $\{C_n \mid n \geq 1\}$  is a P-uniform family of circuits, then it is a P-printable set. Thus in some sense, the sets in PUNC are those sets that can be computed very easily, relative to some P-printable set. For example, it is fairly easy to see that all P-printable sets are in PUNC.

Given this connection between P-printable sets and P-uniform circuit complexity, it is natural to consider the question of whether or not all sparse sets in PUNC are P-printable. It was shown in [All85], [All86a] that a set is in PUNC if and only if it is accepted by a logspace-bounded AuxPDA that moves its input head  $2^{\log^{O(1)} n}$  times. Thus both PUNC and the class of P-printable sets have characterizations in terms of AuxPDAs with restricted access to the input. On the other hand, we show in the next section that every sparse set in PUNC is P-printable if and only if every sparse set in P is P-printable.

**5. Some structural questions.** Questions relating to the existence and structure of non-P-printable sets are now presented.

While it is clear that all P-printable sets are sparse and in P, it is not known whether there are sparse sets in P that are not P-printable. The following theorem shows some equivalent conditions.

**THEOREM 5.** *The following are equivalent:*

- (1) *There is a sparse set in P that is not P-printable.*
- (2) *There is a sparse set in DLOG that is not P-printable.*
- (3) *There is a sparse set in FewP - P.*

*Proof.* If  $S$  is a sparse set in P that is not P-printable, then the set  $\{x \# 0^n \mid x \text{ is a prefix of a string of length } n \text{ in } S\}$  is a sparse set in FewP - P, thus proving [(1)  $\Rightarrow$  (3)]. [(3)  $\Rightarrow$  (2)] is proved by the observation that if  $S$  is sparse and in FewP - P, then the set of accepting computations of a machine accepting  $S$  is a sparse set in DLOG that is not P-printable. Because  $\text{DLOG} \subseteq P$ , the implication of (1) by (2) is clear.  $\square$

As a consequence of the fact that  $\text{DLOG} \subseteq \text{PUNC} \subseteq \text{P}$ , the above is also equivalent to the existence of a sparse set in  $\text{PUNC}$  that is not  $\text{P}$ -printable. This result provides a nice parallel to the result in [HY84] that there is a sparse set in  $\text{NP}$  that is not  $\text{P}$ -printable if and only if there is a sparse set in  $\text{NP-P}$ . While  $\text{NP}$  is the complexity class most closely related to the existence of non- $\text{P}$ -printable sparse sets in  $\text{NP}$ ,  $\text{FewP}$  is the complexity class most closely related to the existence of non- $\text{P}$ -printable sets in  $\text{P}$  and  $\text{DLOG}$ . As a side note, it is not known whether all sparse sets in  $\text{P}$  are in  $\text{PUNC}$ .

Turning now to the structure of non- $\text{P}$ -printable sets, we are interested in determining what they "look like." Can they be immune to the  $\text{P}$ -printable sets or must they have a  $\text{P}$ -printable subset? The following two theorems partially answer these questions.

**THEOREM 6.** *Let  $S$  be a set in  $\text{P}$  that is not  $\text{P}$ -printable, and let  $T(n)$  be a time-constructible function that grows faster than any polynomial. Then there is an infinite set  $A \in \text{DTIME}(T(n))$  such that  $A \subseteq S$  and  $A$  has finite intersection with every  $\text{P}$ -printable set.*

*Proof.* This is proved using techniques similar to those used in, e.g., [Orp86], where a result with a similar flavor concerning complexity cores was proved. Let  $M_1, M_2, \dots$  be an indexing of polynomial-time machines taking input from  $0^*$ ; each such machine can be viewed as taking  $0^n$  as input and producing a list of strings of length  $n$ . Thus  $\{M_i(0^*) \mid i \geq 1\}$  is a representation of all  $\text{P}$ -printable sets. Since the intersection of a set in  $\text{P}$  with a  $\text{P}$ -printable set is  $\text{P}$ -printable,  $S$  is not contained in  $M_i(0^*)$  for any  $i$ .

The idea of the proof is to find, for all  $i$ , a string  $x_i$  in  $S$  that is not in  $M_j(0^*)$  for any  $j \leq i$ . Such a string  $x_i$  must exist, or else  $S \subseteq M_1(0^*) \cup M_2(0^*) \cup \dots \cup M_i(0^*)$ , and thus  $S$  is  $\text{P}$ -printable.

Thus the function  $r(i) = \min \{n \mid \exists x \in S, |x| = n \text{ and } x \notin M_j(0^n) \text{ for all } j \leq i\}$  is total, monotone, and recursive. Let  $s$  be a total, monotone, recursive function that is greater than  $r$  and has the property that the function  $i \rightarrow s(i)$  can be computed in time linear in  $s(i)$ ; taking  $s$  to be the time complexity function for some machine computing  $r$  in unary will suffice.

We also require that our indexing satisfy the condition that machine  $M_i$  has running time bounded by  $T(n)/n$  on inputs of length  $n \geq i$ . Since  $T$  grows faster than any polynomial, this condition is easy to satisfy (see [Orp86]).

The following routine will run in time  $O(T(n))$  and will accept a subset  $A$  of  $S$  that has finite intersection with every  $\text{P}$ -printable set.

**begin** on input  $x$  of length  $n$

    Compute  $s(1), s(2), \dots$  until some  $i$  is found such that  $s(i) \leq n < s(i+1)$ .

    //This step takes  $O(n^2)$  time.

    Accept  $x$  iff  $x \in S - M_j(0^n)$  for all  $j \leq i$ .

    //This step takes  $\leq T(n)$  time, since (assuming without loss of generality that  $i < n$ ) each of the  $i$  simulations performed in this step requires at most  $T(n)/n$  steps.

**end**

It is clear that  $A \subseteq S$ , and that this routine runs in time  $O(T(n))$ . If  $x \in A$  then for some  $i$  such that  $s(i) \leq n < s(i+1)$ ,  $x$  is in  $S - M_j(0^n)$  for all  $j \leq i$ . Thus  $M_i(0^*)$  contains no elements in  $A$  of length  $\geq s(i)$ . It only remains to show that  $A$  is infinite.

Let  $i$  and  $i'$  be numbers such that  $s(i') \leq r(i) < s(i'+1)$ . By the definition of  $r$ , there is a string  $x_i \in S$  of length  $r(i)$  such that  $x_i \notin M_j(0^{|x_i|})$  for all  $j \leq i$ . In particular,  $x_i \notin M_j(0^{|x_i|})$  for all  $j \leq i'$ , since  $i' \leq i$ . Thus  $x_i \in A$  for all  $i$ , so  $A$  is infinite.  $\square$

It is natural to wonder whether the set  $A$  constructed in Theorem 6 can be made to be in  $\text{P}$ . A weaker form of this question asks whether every infinite set in  $\text{P}$  has an

infinite P-printable subset. While this is still undetermined, the following theorem, pointed out to the first author by David Russo, shows that the sets in NP have similar structure to the sets in P in this regard.

**THEOREM 7.** *Every infinite set in P has an infinite P-printable subset if and only if every infinite set in NP has an infinite P-printable subset.*

*Proof.* Assume that every infinite set in P has an infinite P-printable subset, and let  $L$  be an infinite set in NP. Thus there is an infinite set  $A$  in P such that  $L = \{x \mid \exists y, x \# y \in A\}$ . Without loss of generality, assume that there is some  $k$  such that  $x \# y \in A \Rightarrow |x \# y| = |x|^k$ . By assumption,  $A$  has an infinite P-printable subset  $S$ , so the set  $\{x \mid \exists y, x \# y \in S\}$  is an infinite P-printable subset of  $L$ .  $\square$

## SEARCH IN AN ORDERED ARRAY HAVING VARIABLE PROBE COST\*

WILLIAM J. KNIGHT†

**Abstract.** Steiglitz and Parks ["What Is the Filter-Design Problem?," *Proc. 1986 Princeton Conference on Information Science and Systems*, B. W. Dickenson, ed., Princeton University, Dept. of Electrical Engineering, Princeton, NJ, 1986] have shown that a problem in filter design gives rise to a related problem of how to search an ordered array in which the cost of a probe into the array varies with the location being probed. In this paper we prove that if probing in location  $k$  has cost  $k^p$ , where  $p$  is a positive integer, then the expected cost of a successful or unsuccessful search for a target element is at least  $(p+1)^{-1} n^p \lg n + O(n^p)$ . We also prove the somewhat surprising fact that ordinary binary search has this expected cost. However, for the case  $p=1$  we describe what appears to be a marginally better search algorithm.

**Key words.** binary search, search trees, array search

**AMS(MOS) subject classification.** 68P10

**1. Introduction.** In [3] Steiglitz and Parks describe a filter-design problem whose solution involves the following situation. For each positive integer  $k$  between two prescribed limits there is an associated linear programming (l.p.) problem of complexity  $k$ , the feasibility of which is not known; when the l.p. problem is feasible for some value of  $k$ , then all larger values of  $k$  have feasible associated problems; it is required that we find the smallest  $k$  whose associated l.p. problem is feasible. An interesting question immediately arises: What strategy should we use to find the smallest  $k$ ? Recall that the expected amount of time required to solve an l.p. problem is proportional to its complexity. Thus, in effect, we are confronted by an array of no's and yes's, with all the no's to the left of the yes's, in which a probe into location  $k$  has an associated cost proportional to  $k$ , and we must search the array for the location of the first yes. Steiglitz and Parks remark that because the probe cost grows with  $k$ , binary search might be expected to be inferior (as measured by expected cost) to a strategy that probes somewhere to the left of the midpoint of the remaining array at each step of the search. Computation of the optimal strategies, however, suggested to them that binary search is surprisingly near optimal. In this paper we give mathematical proofs that confirm this conjecture, but we also describe a search algorithm that appears to be marginally better than binary search.

**2. Preliminaries.** Let us generalize the investigation to any situation in which we confront an array of problems of some kind, one for each array subscript. We assume that solving the  $k$ th problem requires, on the average, an amount of time given by some penalty function  $P(k)$ . Each such problem has a yes or no answer, and when the answer is yes for some  $k$  it is yes for all larger subscripts  $k$ . We must find the smallest  $k$  for which the answer is yes, and we want to know the optimal search strategy, as measured by expected cost. We have no prior information about the location of the first yes, and so we assume that it is equally likely to be found in any of the  $n$  locations or not to be found at all. That is, each possibility has probability  $1/(n+1)$ . There is no loss in generality in assuming that the subscripts range from 1 to  $n$ , since any other range can be handled by translation of the subscripts and of the variable  $k$  in  $P(k)$ . In the Steiglitz-Parks problem,  $P(k)$  is a linear polynomial.

Every search strategy for this situation corresponds to a unique binary tree  $T_n$  with node labels  $1, 2, \dots, n$ , placed so that the inorder traversal of  $T_n$  finds the labels in increasing order. Conversely, every such binary tree corresponds to exactly one strategy. We shall call any such tree a *search tree*. The root of the tree gives the location of the first probe. We go left if we get a yes, right if we get a no, and repeat this with the corresponding subtree. Note that *we cannot stop until we reach an external node* (see [2, p. 239]), at which point we can identify the location of the first yes. Thus in this situation the search prescribed by the tree corresponds to an *unsuccessful search* of a conventional array, in which records with keys have been stored in increasing key order (see [2, p. 237]). It is this observation that prompted the title of this paper.

For a given probe penalty function  $P(k)$  the expected cost of an unsuccessful search using a search tree  $T_n$  is

$$(1) \quad \sum_{j=1}^{n+1} \frac{1}{n+1} \left\{ \sum_{\text{nodes } k \text{ from root to } j\text{th external node}} P(k) \right\},$$

where the inner sum in formula (1) is taken over all *internal* nodes  $k$  that lie on the path in  $T_n$  from the root down to the  $j$ th external node. We can write (1) in a more useful form by letting  $W_k(T_n)$  denote the number of internal nodes in that subtree of  $T_n$  whose root is  $k$ . The number of internal nodes in an extended binary tree is one less than the number of external nodes. It follows that  $W_k(T_n)$  is one less than the number of times that the term  $P(k)$  will occur when the value of formula (1) is computed. Thus the expected cost of our search, using  $T_n$ , is equal to

$$\frac{1}{n+1} \sum_{k=1}^n P(k) [W_k(T_n) + 1] = \frac{1}{n+1} \sum_{k=1}^n P(k) W_k(T_n) + \frac{1}{n+1} \sum_{k=1}^n P(k).$$

For computational convenience we discard the constant factor  $1/(n+1)$  and the constant term  $\sum P(k)$ , and we call the remaining sum the *search cost of  $T_n$*  for the given penalty function  $P(k)$ . We denote this by  $S_{P(k)}(T_n)$ . That is,

$$(2) \quad S_{P(k)}(T_n) = \sum_{k=1}^n P(k) W_k(T_n).$$

Thus, for example,  $S_1(T_n) = \sum W_k(T_n)$ ,  $S_{k+5}(T_n) = \sum (k+5) W_k(T_n)$ ,  $S_{\log(1+k)}(T_n) = \sum \log(1+k) W_k(T_n)$ , and so on. We note, parenthetically, that  $S_{P(k)}(T_n)$  is  $n$  times the expected cost of a *successful* search for a target record in a conventional ordered array having penalty  $P(k)$  for probing in location  $k$ .

Although our ultimate goal is to find all optimal search trees, extensive computer calculations indicate that even when  $P(k)$  is a rather tame function, the optimal trees do not organize themselves into simple patterns. For example, suppose  $P(k) = k$ . Then as  $n$  varies, the root of an optimal tree with  $n$  nodes wanders between  $n/4$  and  $n/2$  (approximately), with occasional sudden drops. For a fixed  $n$  there may be several optimal trees, the roots of which do not form a simple sequence. For example, when  $n = 33$  the optimal trees have roots 7, 10, and 11 (see the table at the end of the paper for more details). These cautionary findings suggest that it will not be easy to derive exact formulas for  $S_{P(k)}(T_n)$ , even when  $P(k)$  is simple, and in this paper we obtain mostly upper and lower bounds. For  $P(k) \equiv 1$ , however, we know the exact search cost in a *balanced* tree. Recall that a binary tree  $T$  of height  $h$  is called *balanced*, provided every external node of  $T$  is at level  $h$  or  $h+1$ .

LEMMA 1. Let  $T_n$  denote any balanced search tree with  $n$  nodes ( $n \geq 0$ ). Let  $p = \lfloor \lg(n+1) \rfloor$ , where as usual,  $\lg = \log_2$ . Then

$$S_1(T_n) = \sum_{k=1}^n W_k(T_n) = (n+1)(p+1) - 2^{p+1} + 1.$$

*Proof.* Let  $\text{Ext}(T_n)$  denote the external path length of  $T_n$  (see [2, pp. 239–243]). It is not hard to see that  $\sum W_k(T_n) = \text{Ext}(T_n) - n$ . By formula (5.10) in [2, p. 243]

$$\text{Ext}(T_n) - n = (n+1) \lg(n+1) + (n+1)[2 - \lg(n+1) + p - 2^{1-\lg(n+1)+p}] - n,$$

which reduces to the formula given in the lemma.  $\square$

The following corollary gives a lower bound for  $S_1(T_n)$  when  $T_n$  is any search tree, balanced or not. It is obtained from Lemma 1 by replacing  $p$  by  $\lg(n+1)$ .

LEMMA 2. For every search tree  $T_n$  with  $n$  nodes ( $n \geq 0$ ) we have

$$S_1(T_n) = \sum_{k=1}^n W_k(T_n) \geq (n+1)[\lg(n+1) - 1] + 1.$$

*Proof.* Let  $T_n$  be any search tree. First suppose  $T_n$  is not balanced. Then it is possible to move some leaf to a higher level (smaller level number). Doing so decreases the number of its ancestors, which decreases  $\sum W_k(T_n)$ . After a finite number of such leaf lifts, the tree is balanced. Thus it suffices to prove that the inequality holds for balanced trees. By Lemma 1 it then suffices to prove

$$(n+1)(p+1) - 2^{p+1} + 1 \geq (n+1)[\lg(n+1) - 1] + 1$$

for  $n = 0, 1, 2, \dots$ , where  $p = \lfloor \lg(n+1) \rfloor$ . This is equivalent to

$$(3) \quad (n+1)[p - \lg(n+1) + 2] \geq 2^{p+1}.$$

Let  $\theta = \lg(n+1) - p$ . Then  $0 \leq \theta < 1$ , and (3) is equivalent to

$$2^\theta(2 - \theta) \geq 2.$$

Denote the left side here by  $f(\theta)$  and note that  $f(0) = f(1) = 2$ . Moreover, the second derivative is

$$f''(\theta) = 2^\theta (\ln 2)[(-2)(1 - \ln 2) - \theta \ln 2] < 0$$

on the interval  $0 \leq \theta \leq 1$ , so  $f$  is concave down. These facts imply that  $f(\theta) \geq 2$  on the interval.  $\square$

There is a fundamental recursion formula that we shall use repeatedly. It arises from the following elementary fact: if  $T_n$  is a search tree with  $n$  nodes and root  $r$ , then the left subtree of  $r$  is a search tree with  $r-1$  nodes, while the right subtree is a search tree with  $n-r$  nodes, provided we decrease each node label by  $r$ . We denote the left subtree by  $T_{r-1}$ , and the right subtree with modified labels by  $T_{n-r}$ . Then for any probe penalty function  $P(k)$  whatsoever,

$$S_{P(k)}(T_n) = P(r) \cdot n + \sum_{k=1}^{r-1} P(k) \cdot W_k(T_n) + \sum_{k=r+1}^n P(k) \cdot W_k(T_n),$$

which gives us the important, perfectly general recursion formula

$$(4) \quad S_{P(k)}(T_n) = P(r) \cdot n + S_{P(k)}(T_{r-1}) + \sum_{k=1}^{n-r} P(k+r) \cdot W_k(T_{n-r}).$$

**3. Linear penalty functions.** In this section we derive upper and lower bounds for the search cost in an optimal tree when the probe penalty function is a linear polynomial.

These bounds are of interest in themselves, and they are also used to derive bounds for higher-order penalty functions. We begin with the special case where  $P(k) = k$  and where the search tree is *full*, by which we mean that it is balanced and has  $2^p - 1$  nodes for some integer  $p$ . Denote this tree by  $F_p$ .

LEMMA 3. For all integers  $p \geq 0$  and corresponding full binary trees  $F_p$  we have

$$(5) \quad S_k(F_p) = \sum_{k=1}^{2^p-1} k \cdot W_k(F_p) = 2(p-1)4^{p-1} + 2^{p-1}.$$

If we write  $n = 2^p - 1$  (the number of nodes in  $F_p$ ), then the formula takes the form

$$(6) \quad S_k(F_p) = \frac{1}{2}(n+1)^2[\lg(n+1) - 1] + \frac{1}{2}(n+1).$$

*Proof.* The proof is by induction. The formula is trivially true when  $p = 0$ . For  $p > 0$  we use (4), the fact that the root  $r$  of  $F_p$  is  $2^{p-1}$ , and the fact that the left and right subtrees of  $F_p$  are full trees with  $2^{p-1} - 1$  nodes. Thus

$$\begin{aligned} S_k(F_p) &= 2^{p-1}(2^p - 1) + S_k(F_{p-1}) + \sum_{k=1}^{2^{p-1}-2^{p-1}} (k + 2^{p-1})W_k(F_{p-1}) \\ &= 2^{2p-1} - 2^{p-1} + 2S_k(F_{p-1}) + 2^{p-1}S_1(F_{p-1}). \end{aligned}$$

By induction and (5),

$$S_k(F_{p-1}) = 2(p-2)4^{p-2} + 2^{p-2}.$$

By Lemma 1, with  $n = 2^{p-1} - 1$  and (consequently)  $p$  replaced by  $p - 1$ , we have

$$S_1(F_{p-1}) = 2^{p-1}p - 2^p + 1,$$

so

$$\begin{aligned} S_k(F_p) &= 2^{2p-1} - 2^{p-1} + 2[2(p-2)4^{p-2} + 2^{p-2}] + 2^{p-1}[2^{p-1}(p-2) + 1] \\ &= 2(4^{p-1}) - 2^{p-1} + (p-2)4^{p-1} + 2^{p-1} + 4^{p-1}(p-2) + 2^{p-1}. \end{aligned}$$

Algebraic reduction gives (5).  $\square$

Just as Lemma 1 suggests (2) of Lemma 2, so (6) of Lemma 3 suggests that for all search trees  $T_n$

$$(7) \quad S_k(T_n) \geq \frac{1}{2}(n+1)^2[\lg(n+1) - 1] + \frac{1}{2}(n+1).$$

Computer calculations verify (7) for all  $n$  up to 1084, but the best that the author can prove is the following slightly weaker inequality.

THEOREM 4. For every search tree  $T_n$  with  $n$  nodes ( $n \geq 0$ ) we have

$$(8) \quad S_k(T_n) \geq \frac{1}{2}(n+1)^2[\lg(n+1) - 1.070] + \frac{1}{2}(n+1).$$

*Proof.* We use induction to prove that for all search trees  $T_n$  with  $n$  nodes,

$$(9) \quad S_k(T_n) \geq \frac{1}{2}(n+1)^2[\lg(n+1) - K] + \frac{1}{2}(n+1)$$

for a constant  $K$  to be determined. When  $n = 0$  the formula holds, provided  $K \geq 1$ . Now suppose (9) holds for  $n = 0, 1, \dots, m - 1$ . Let  $T_m$  be a search tree with  $m$  nodes and root  $r$ . Then by (4) and induction we have

$$\begin{aligned} S_k(T_m) &= r \cdot m + S_k(T_{r-1}) + \sum_{k=1}^{m-r} (k+r) \cdot W_k(T_{m-r}) \\ &= r \cdot m + S_k(T_{r-1}) + S_k(T_{m-r}) + r \sum_{k=1}^{m-r} W_k(T_{m-r}) \\ &\geq r \cdot m + \frac{1}{2}r^2[\lg r - K] + \frac{1}{2}r + \frac{1}{2}(m-r+1)^2[\lg(m-r+1) - K] + \frac{1}{2}(m-r+1) \\ &\quad + r\{(m-r+1)[\lg(m-r+1) - 1] + 1\}, \end{aligned}$$

where the last line uses Lemma 2. We wish to prove that this expression is

$$\cong \frac{1}{2}(m+1)^2[\lg(m+1) - K] + \frac{1}{2}(m+1).$$

Write  $\lambda = r/(m+1)$ , so that  $0 < \lambda < 1$ . Then the inequality we seek to prove takes the form

$$\begin{aligned} & 2\lambda(m+1)m + \lambda^2(m+1)^2[\lg(\lambda(m+1)) - K] + \lambda(m+1) \\ & \quad + (1-\lambda)^2(m+1)^2[\lg((1-\lambda)(m+1)) - K] \\ & \quad + (1-\lambda)(m+1) + 2\lambda(m+1)\{(1-\lambda)(m+1)[\lg((1-\lambda)(m+1)) - 1] + 1\} \\ & \cong (m+1)^2[\lg(m+1) - K] + (m+1), \end{aligned}$$

which simplifies to

$$\begin{aligned} & \lambda^2(m+1)^2[\lg(m+1) + \lg \lambda] - \lambda^2(m+1)^2[\lg(m+1) + \lg(1-\lambda)] \\ & \quad + (m+1)^2 \lg(1-\lambda) + 2\lambda^2(m+1)^2 \cong -2K\lambda(1-\lambda)(m+1)^2, \end{aligned}$$

which further simplifies to

$$\frac{-2\lambda^2 - \lambda^2 \lg \lambda - (1-\lambda^2) \lg(1-\lambda)}{2\lambda(1-\lambda)} \leq K.$$

Mathematical analysis, combined with a computer search, shows that the maximum value of the expression on the left is less than 1.070 (for details, see the following paragraph). Thus we may take  $K$  to be 1.070.

Here is a sketch of the proof that the left side of the inequality above is less than 1.070. Denote the left side by  $f(\lambda)$  and use the identity  $\lg x = \ln x / \ln 2$  to write

$$f(\lambda) = \frac{-\lambda \lg \lambda}{2(1-\lambda)} + \frac{-2\lambda^2 - (1+\lambda)(1-\lambda) \ln(1-\lambda) / \ln 2}{2\lambda(1-\lambda)}.$$

We shall show that  $f(\lambda) < 1.070$  on each of the three intervals  $(0, 1/16)$ ,  $[1/16, 0.692]$ , and  $(0.692, 1)$ . First note that  $-\lambda \lg \lambda$  is increasing on the interval  $0 < \lambda < 1/e$ , and so is the fraction  $1/(2(1-\lambda))$ . Thus when  $0 < \lambda < 1/16$  we have

$$\frac{-\lambda \lg \lambda}{2(1-\lambda)} < \frac{-(1/16) \lg(1/16)}{2(15/16)} = \frac{2}{15}.$$

Also note that when  $|\lambda| < 1$  we have the Maclaurin expansions

$$-\ln(1-\lambda) = \lambda + \lambda^2/2 + \lambda^3/3 + \lambda^4/4 + \dots,$$

$$-(1-\lambda) \ln(1-\lambda) = \lambda - \lambda^2/(1 \cdot 2) - \lambda^3/(2 \cdot 3) - \lambda^4/(3 \cdot 4) + \dots.$$

Thus when  $0 < \lambda < 1$  we have the following three inequalities:

$$(10) \quad -\ln(1-\lambda) < \lambda + (\lambda^2/2)(1 + \lambda + \lambda^2 + \dots) = \lambda + (\lambda^2/2)/(1-\lambda),$$

$$(11) \quad -(1-\lambda) \ln(1-\lambda) < \lambda, \quad \text{and}$$

$$(12) \quad |\lambda + (1-\lambda) \ln(1-\lambda)| < (\lambda^2/2)(1 + \lambda + \lambda^2 + \dots) = (\lambda^2/2)/(1-\lambda).$$

From (11) we obtain

$$\frac{-2\lambda^2 - (1+\lambda)(1-\lambda) \ln(1-\lambda) / \ln 2}{2\lambda(1-\lambda)} < \frac{-2\lambda + (1+\lambda) / \ln 2}{2(1-\lambda)}.$$

In particular, when  $0 < \lambda < 1/16$  we have

$$f(\lambda) < \frac{2}{15} + \frac{0 + (17/16) / \ln 2}{2(15/16)} < 1.$$

Now consider  $f(\lambda)$  on the interval  $0.692 < \lambda < 1$ . First replace  $\lambda$  by  $1 - \lambda$  in (11) to get  $-\lambda \ln \lambda < 1 - \lambda$ , which gives us

$$\frac{-\lambda \ln \lambda}{2(1-\lambda)} < \frac{1}{2 \ln 2} = 0.7214.$$

Next use (10) and then  $1 - \lambda < 0.308$  to get

$$-(1 - \lambda^2) \ln (1 - \lambda) < \lambda + \frac{1}{2}(\lambda^2 - \lambda^3) < \lambda + \lambda^2(0.154).$$

This gives us

$$\frac{-2\lambda^2 - (1 - \lambda^2) \ln (1 - \lambda) / \ln 2}{2\lambda(1 - \lambda)} < \frac{-2\lambda^2 + [\lambda + \lambda^2(0.154)] / \ln 2}{2\lambda(1 - \lambda)} = \frac{0.7214 - 0.8889\lambda}{1 - \lambda}.$$

By elementary calculus, the last fraction above is decreasing when  $\lambda < 1$ , so on the interval  $0.692 < \lambda < 1$  its maximum value occurs at  $\lambda = 0.692$  and works out to be 0.3449. Thus  $f(\lambda) < 0.7214 + 0.3449 < 1.070$  on this interval. Finally, we investigate  $f(\lambda)$  on the interval  $1/16 \leq \lambda \leq 0.692$ . Here we have the derivative

$$f'(\lambda) = \frac{-1}{(1-\lambda)^2} + \frac{1}{2 \ln 2} \left[ \frac{-\ln \lambda}{(1-\lambda)^2} + \frac{\lambda + (1-\lambda) \ln (1-\lambda)}{\lambda^2(1-\lambda)} \right]$$

so by inequality (12) we have

$$\begin{aligned} |f'(\lambda)| &\leq \frac{1}{(1-\lambda)^2} + \frac{1}{2 \ln 2} \left[ \frac{|\ln \lambda|}{(1-\lambda)^2} + \frac{1}{2(1-\lambda)^2} \right] \\ &= \frac{1}{(1-\lambda)^2} \left[ 1 + \frac{|\lg \lambda|}{2} + \frac{1}{4 \ln 2} \right] \\ &< \frac{1}{(0.308)^2} \left[ 1 + \frac{|\lg (1/16)|}{2} + 0.3607 \right] < 35.43 \end{aligned}$$

because  $1/16 < \lambda < 0.692$ . It then follows from the Mean Value Theorem for derivatives that

$$(13) \quad f(\lambda) \leq f(b) + (35.43)(\lambda - b) \quad \text{when } 1/16 \leq b \leq \lambda \leq 0.692.$$

Computer examination of values of  $f(b)$  at finitely many points  $b$  spaced 0.00005 apart on the interval  $[1/16, 0.692]$  yields a maximum value  $f(0.36080) = 1.06822$ , so by (13)

$$f(\lambda) \leq 1.06822 + (35.43)(0.00005) < 1.070. \quad \square$$

Here is a lower bound for search cost for any linear penalty function  $P(k) = \alpha k + \beta$  in which the constants  $\alpha$  and  $\beta$  are nonnegative.

**COROLLARY 5.** *For all nonnegative constants  $\alpha$  and  $\beta$ , and for every search tree  $T_n$  with  $n$  nodes ( $n \geq 0$ ) we have*

$$S_{\alpha k + \beta}(T_n) \geq \frac{\alpha}{2}(n+1)^2[\lg(n+1) - 1.070] + \frac{\alpha}{2}(n+1) + \beta[(n+1) \lg(n+1) - n].$$

*Proof.* It easily follows from (2) that

$$S_{\alpha k + \beta}(T_n) = \alpha S_k(T_n) + \beta S_1(T_n).$$

Apply Theorem 4 and Lemma 2.  $\square$

We now prove that when  $P(k)$  is linear, ordinary binary search gives near-optimal results.

**THEOREM 6.** Let  $B_n$  denote the (balanced) search tree corresponding to binary search of an ordered array of length  $n$ . Then for all nonnegative constants  $\alpha$  and  $\beta$  we have

$$(14) \quad S_{\alpha k + \beta}(B_n) \leq \frac{\alpha}{2}(n+1)^2[\lg(n+1) - 0.9138] + \frac{\alpha}{2}(n+1) \\ + \beta[(n+1)(p+1) - 2^{p+1} + 1],$$

where  $p = \lfloor \lg(n+1) \rfloor$ .

*Proof.* It suffices to prove (14) in the case where  $\alpha = 1$  and  $\beta = 0$ ; the more general case follows from Lemma 1 and the equation in the proof of Corollary 5. We use induction on  $n$ . Unfortunately, the induction step leads to a rather messy inequality that turns out to be difficult to verify when  $n$  is small, but fairly easy when  $n$  is large enough that certain terms can be discarded. So as the first step of the proof we verify that inequality (14) holds for all  $n \leq 19999$ . This is done by using a computer and the recursion formula

$$(15) \quad S_k(B_n) = \begin{cases} m(2m) + S_k(B_{m-1}) + S_k(B_m) + m \cdot S_1(B_m) & \text{if } n = 2m, \\ (m+1)(2m+1) + 2 \cdot S_k(B_m) + (m+1)S_1(B_m) & \text{if } n = 2m+1 \end{cases}$$

derived from (4), to generate exact values for  $S_k(B_n)$ . Equation (15) arises from the fact that when  $n = 2m$  the root of  $B_n$  is  $m$  and the left and right subtrees are of the form  $B_{m-1}$  and  $B_m$ , but when  $n = 2m+1$  then both have the form  $B_m$ .

Now suppose (14) holds for  $n = 0, 1, \dots, 2m-1$ , where  $m \geq 10,000$ . We first examine the case where  $n = 2m$ , and later the case where  $n = 2m+1$ .

*Case 1.  $n = 2m$ .* Using (15), induction on (14), and Lemma 1 we find that

$$S_k(B_n) \leq 2m^2 + \frac{1}{2}m^2[\lg m - 0.9138] + \frac{1}{2}m + \frac{1}{2}(m+1)^2[\lg(m+1) - 0.9138] \\ + \frac{1}{2}(m+1) + m[(m+1)(p+1) - 2^{p+1} + 1],$$

where  $p = \lfloor \lg(m+1) \rfloor$ . We seek to prove that this expression is

$$\leq \frac{1}{2}(2m+1)^2[\lg(2m+1) - 0.9138] + \frac{1}{2}(2m+1) \quad \text{when } m \geq 10,000.$$

Write  $\lambda = 2^p/(m+1)$ . Then  $\frac{1}{2} < \lambda \leq 1$ , and the inequality we must prove can be written (after considerable algebra of the sort familiar from the proof of Theorem 4) in the form

$$m^2[\lg m - \lg(m+1)] + 2(0.9138)m(m+1) \\ \leq (2m+1)^2[\lg(2m+1) - \lg(m+1)] + 2m(m+1)[2\lambda - \lg \lambda] - 2m(3m+2).$$

By elementary calculus the minimum value of  $2\lambda - \lg \lambda$  on the interval  $\frac{1}{2} \leq \lambda \leq 1$  is 1.91393 (at  $\lambda = 1/(2 \ln 2)$ ). Since  $\lg m - \lg(m+1)$  is negative, it then suffices to prove that when  $m \geq 10,000$  we have

$$0.9138 \leq \frac{1}{2} \left( 2 + \frac{1}{m} \right) \left( \frac{2m+1}{m+1} \right) \lg \left( \frac{2m+1}{m+1} \right) - \frac{3m+2}{m+1} + 1.91393.$$

Since  $2 + 1/m > 2$  and  $(2m+1)/(m+1) \geq 1.9999$  and  $\lg((2m+1)/(m+1)) \geq 0.9999$  and  $-(3m+2)/(m+1) > -3$ , the inequality is satisfied.

*Case 2.  $n = 2m+1$ .* Using (15), induction on (14), and Lemma 1 we find that

$$S_k(B_n) \leq (m+1)(2m+1) + (m+1)^2[\lg(m+1) - 0.9138] + (m+1) \\ + (m+1)[(m+1)(p+1) - 2^{p+1} + 1],$$

where  $p = \lfloor \lg(m+1) \rfloor$ . We seek to prove that this expression is

$$\leq \frac{1}{2}(2m+1+1)^2[\lg(2m+1+1) - 0.9138] + \frac{1}{2}(2m+1+1).$$

Write  $\lambda = 2^p/(m+1)$ . Again  $\frac{1}{2} < \lambda \leq 1$ , and the inequality we must prove reduces to

$$(16) \quad 0.9138 \leq 2\lambda - \lg \lambda - 1 - 1/(m+1) \quad \text{for } m \geq 10,000.$$

As in Case 1,  $2\lambda - \lg \lambda \geq 1.91393$ , and the minimum value of  $-1/(m+1)$  when  $m \geq 10,000$  is  $-0.0001$ , so the minimum value of the right side of (16) is at least  $1.91393 - 1 + 0.0001$ .  $\square$

Extensive computer calculation has shown that the value 0.9138 that appears in Theorem 6 for classical binary search trees  $B_n$  cannot be significantly improved. However, as we shall now prove, there is another class of balanced search trees for which it is possible to get a better value, i.e., a value closer to the 1.070 that appears in Theorem 4 and Corollary 5. This has the double advantage of giving us a better upper bound on the search cost in the elusive *optimal* search trees and also exhibiting a slightly better search algorithm than classical binary search. The search trees we want to investigate are formed in the following way: take any balanced tree with  $n$  nodes and height  $h$ . Move all the leaves  $h$  as far to the right as possible. This produces what we shall call the (unique) *right-heavy balanced tree* of  $n$  nodes, denoted by  $R_n$ .

**THEOREM 7.** *For all right-heavy balanced search trees  $R_n$  and all nonnegative constants  $\alpha$  and  $\beta$  we have the upper bound*

$$S_k(R_n) \leq \frac{\alpha}{2}(n+1)^2[\lg(n+1) - 0.975] + \frac{\alpha}{2}(n+1) + \beta[(n+1)(p+1) - 2^{p+1} + 1],$$

where  $p = \lfloor \lg(n+1) \rfloor$ .

*Proof.* As in the proof of Theorem 6 it suffices to consider the case  $\alpha = 1$  and  $\beta = 0$ . We use induction to prove that

$$(17) \quad S_k(R_n) \leq \frac{1}{2}(n+1)^2[\lg(n+1) - K] + \frac{1}{2}(n+1)$$

for a constant  $K$  to be determined. When  $n = 0$  the formula holds, provided  $K \leq 1$ . Now suppose (17) holds for  $n = 0, \dots, m-1$ . Consider the right-heavy balanced tree  $R_m$ . Let  $p = \lfloor \lg(m+1) \rfloor$ , from which it follows that

$$(18) \quad 2^p \leq m+1 < 2^{p+1}.$$

Think of  $R_m$  as the full binary tree  $F_p$  with  $2^p - 1$  nodes, to which  $m - 2^p + 1$  "surplus" nodes have been attached at level  $p$ , as far to the right as possible. By (18) the number of surplus nodes must be less than  $2^p$ . If the number of surplus nodes is less than half of  $2^p$ , then they will all be attached to the right subtree of the root, which will be the node  $2^{p-1}$ . The left subtree will be the full tree  $F_{p-1}$ . The right subtree will be identical to the tree obtained by building the unique right-heavy balanced tree  $R_{m-2^{p-1}}$  and then increasing each of its node labels by  $2^{p-1}$ . However, if the number of surplus nodes is at least half of  $2^p$ , then the surplus nodes will fill out a full row at the bottom of the right subtree, and any that remain will spill over onto the left subtree of the root, which in this case will be the node numbered  $m - (2^p - 1)$ . Then the left subtree will be the right-heavy balanced tree  $R_{m-2^p}$ . The right subtree will be identical to the tree obtained by building the full tree  $F_p$  and then increasing each of its node labels by  $m - 2^p + 1$ . The calculations are slightly different in these two cases, so we consider them separately.

*Case 1.* The surplus is less than half of  $2^p$ ; that is,

$$(19) \quad m - 2^p + 1 < 2^p/2.$$

By (18) and (19),  $\lfloor \lg(m - 2^{p-1}) \rfloor = p - 1$ . Using Lemmas 3 and 1, (4), induction on

(17), and the discussion preceding Case 1 we obtain

$$\begin{aligned} S_k(R_m) &= 2^{p-1}m + S_k(F_{p-1}) + S_k(R_{m-2^{p-1}}) + 2^{p-1} \cdot S_1(R_{m-2^{p-1}}) \\ &\leq 2^{p-1}m + 2(p-2)4^{p-2} + 2^{p-2} + \frac{1}{2}(m-2^{p-1}+1)^2[\lg(m-2^{p-1}+1) - K] \\ &\quad + \frac{1}{2}(m-2^{p-1}+1) + 2^{p-1}[(m-2^{p-1}+1)(p-1+1) - 2^p + 1]. \end{aligned}$$

We seek to prove that this expression is

$$\leq \frac{1}{2}(m+1)^2[\lg(m+1) - K] + \frac{1}{2}(m+1).$$

Write  $\lambda = 2^{p-1}/(m+1)$ . By (18) and (19),

$$2^p \leq m+1 < 2^p + 2^{p-1} = 3(2^{p-1}),$$

so  $\frac{1}{3} < \lambda \leq \frac{1}{2}$ . Substitution and reduction show that we must prove

$$(2\lambda - \lambda^2) \lg \lambda + (1 - \lambda)^2 \lg(1 - \lambda) + 4\lambda - 7\lambda^2 + K(2\lambda - \lambda^2) \leq 0.$$

Since  $2\lambda - \lambda^2 > 0$ , we see that this is equivalent to

$$K \leq \frac{7\lambda^2 - 4\lambda}{2\lambda - \lambda^2} - \lg \lambda - \frac{(1 - \lambda)^2}{2\lambda - \lambda^2} \lg(1 - \lambda).$$

Denote the right side by  $f(\lambda)$ . Then straightforward calculation, together with the triangle inequality, shows that  $|f'(\lambda)| < 15$  when  $\frac{1}{3} \leq \lambda \leq \frac{1}{2}$ . Computer examination of values of  $f(b)$  at finitely many points  $b$  spaced 0.0001 apart yields a minimum value  $f(0.4385) = 0.9768$ , so by the Mean Value Theorem for derivatives,  $f(\lambda) \geq 0.9768 - 15(0.0001) > 0.975$  when  $\frac{1}{3} \leq \lambda \leq \frac{1}{2}$ . Thus for Case 1 it suffices to make  $K \leq 0.975$ .

*Case 2.* The surplus is at least half of  $2^p$ ; that is,

$$(20) \quad m - 2^p + 1 \geq 2^p/2.$$

By (18) and (20),  $[\lg(m - 2^p + 1)] = p - 1$ . Using Lemmas 3 and 1, (4), induction over (17), and the discussion preceding Case 1 we obtain

$$\begin{aligned} S_k(R_m) &= (m - 2^p + 1)m + S_k(R_{m-2^p}) + S_k(F_p) + (m - 2^p + 1)S_1(F_p) \\ &\leq (m - 2^p + 1)m + \frac{1}{2}(m - 2^p + 1)^2[\lg(m - 2^p + 1) - K] + \frac{1}{2}(m - 2^p + 1) \\ &\quad + 2(p-1)4^{p-1} + 2^{p-1} \\ &\quad + (m - 2^p + 1)[(2^p - 1 + 1)(p + 1) - 2^{p+1} + 1]. \end{aligned}$$

We seek to prove that this expression is

$$\leq \frac{1}{2}(m+1)^2[\lg(m+1) - K] + \frac{1}{2}(m+1).$$

Write  $\lambda = 2^p/(m+1)$ . By (18) and (20) we have

$$2^p/2 + 2^p \leq m+1 < 2^{p+1},$$

so  $\frac{1}{2} < \lambda \leq \frac{2}{3}$ . Substitution and a lengthy reduction show that we must prove that

$$K \leq -\lg \lambda + \lg(1 - \lambda) - \frac{\lambda^2 - 4\lambda + 2 + \lg(1 - \lambda)}{2\lambda - \lambda^2}.$$

Denote the right side by  $f(\lambda)$ . A laborious but straightforward calculation shows that

$$f''(\lambda) = \frac{-3 - 2\lambda(1 - \lambda)^2}{\lambda^2(1 - \lambda)^2(2 - \lambda)^2 \ln 2} + \frac{[-4 - 2 \lg(1 - \lambda)][3(1 - \lambda)^2 + 1] + 4\lambda^3}{(2\lambda - \lambda^2)^3} < 0$$

when  $\frac{1}{2} < \lambda \leq \frac{2}{3}$ , so  $f$  is concave down on this interval. Since  $f(\frac{1}{2}) = 1$  and  $f(\frac{2}{3}) > 1$ , it follows that the minimum value of  $f$  is 1. Thus for Case 2 it suffices to make  $K \leq 1$ .  $\square$

The proof of Theorem 7 shows how we can write a program to carry out the search prescribed by a right-heavy balanced tree. Given an array of no's and yes's occupying locations  $i, i + 1, \dots, j$ , with all no's to the left of all yes's, do the following:

- (a) (Initialize.) Set  $L = i$  and  $U = j$ . (Throughout the algorithm the number of locations remaining to be searched is  $U - L + 1$ , corresponding to  $m$  in the proof.)
- (b) (Find probe location  $K$ .) If  $U < L$ , the search ends and the leftmost yes is in location  $L$  (of  $L = n + 1$ , there are no yes's); otherwise, calculate  $P = \lfloor \lg(U - L + 1) \rfloor$ ; if  $U - L + 2 < 3(2^{P-1})$ , set  $K = (L - 1) + 2^{P-1}$ , else set  $K = (L - 1) + (U - L + 1) - (2^P - 1)$ .
- (c) (Adjust search limits.) If the probe at  $K$  finds a no, set  $L = K + 1$  and return to step (b), else set  $U = K - 1$  and return to step (b).

The only difference between this algorithm and binary search is that in step (b), binary search does not calculate  $P$ , but simply sets  $K = \lfloor (L + U) / 2 \rfloor$ .

Theorems 6 and 7 suggest, but do not prove, that search using a right-heavy balanced tree is less costly in general than binary search (of course, the two schemes coincide when the length of the array has form  $n = 2^p - 1$ , which gives a full tree). Although the author has not been able to prove this conjecture, computer calculation of the exact values (using the recursion relations such as (15)) validates the conjecture up to array length  $n = 5,000$ . At best, right-heavy balanced trees appear to have a cost advantage of only about 2 percent on the average.

**4. Higher-order penalty functions.** In this section we state upper and lower bounds for the search cost in an optimal tree when the probe penalty function is given by a nonlinear polynomial. We begin with a lower bound for the simple case when  $P(k) = k^p$ .

**THEOREM 8.** *For each fixed positive integer  $p$  and for every search tree  $T_n$  with  $n$  nodes ( $n \geq 0$ ) we have*

$$(21) \quad S_{k^p}(T_n) \geq \frac{1}{p+1} (n+1)^{p+1} \lg(n+1) - (n+1)^{p+1}.$$

*Proof.* The proof is by induction on  $p$ . The case  $p = 1$  is covered by Theorem 4, which gives a somewhat larger lower bound. For higher values of  $p$  the proof begins along the lines of the proof of Theorem 4, using induction over subtrees. Formula (4) is invoked and the term  $P(k+r) = (k+r)^p$  is expanded by the Binomial Formula. The details involve arguments similar to but more complicated than those in the proof of Theorem 4, and can be found in [1].  $\square$

Next we prove that ordinary binary search is nearly optimal when  $P(k) = k^p$ .

**THEOREM 9.** *Let  $B_n$  denote the search tree corresponding to binary search in an ordered array of length  $n$ . Then for any fixed positive integer  $p$ ,*

$$(22) \quad S_{k^p}(B_n) \leq \frac{1}{p+1} (n+1)^{p+1} [\lg(n+1) - 0.9138] + \frac{1}{2} (n+1)^p.$$

*Proof.* The proof is by induction on  $p$ . Theorem 6 covers the case  $p = 1$ . For larger  $p$  we use formula (4) and the Binomial Formula to write

$$S_{k^p}(B_n) = \binom{n}{2}^p (n) + S_{k^p}(B_{n/2-1}) + \sum_{j=0}^p \binom{p}{j} \left(\frac{n}{2}\right)^{p-j} S_{k^p}(B_{n/2})$$

when  $n$  is even, and a similar formula when  $n$  is odd (cf. formula (15)). Now we use induction over subtrees. The details, which are lengthy, can be found in [1].  $\square$

Theorems 8 and 9 deal with penalty functions of the simple form  $P(k) = k^p$ . For more general penalty functions of the form  $P(k) = \alpha_p k^p + \alpha_{p-1} k^{p-1} + \dots + \alpha_1 k + \alpha_0$ , formula (2) gives

$$S_{P(k)}(T) = \alpha_p S_{k^p}(T) + \alpha_{p-1} S_{k^{p-1}}(T) + \dots + \alpha_1 S_k(T) + \alpha_0 S_1(T),$$

to which we can apply Theorems 8 and 9 and Lemmas 1 and 2.

**5. Computation of exact optimal trees and costs.** It is possible to compute recursively the optimal trees and their search costs for any prescribed penalty function  $P(k)$  whatsoever. Assume that the array to be searched is indexed from 1 to  $n$ . Introduce a "displacement" parameter into (2) as follows:

$$S_{P(k)}(T_n, d) = \sum_{k=1}^n P(k+d) W_k(T_n),$$

which gives the search for a search tree of  $n$  nodes indexed from  $1+d$  to  $n+d$ . Then (4) takes the form

$$(23) \quad S_{P(k)}(T_n, d) = P(r+d) \cdot n + S_{P(k)}(T_{r-1}, d) + S_{P(k)}(T_{n-r}, r+d).$$

Write  $M_{P(k)}(n, d) = \min_{T_n} S_{P(k)}(T_n, d)$ , where for a fixed pair  $(n, d)$  the minimum is taken over all search trees  $T_n$  with  $n$  nodes. By the fundamental idea of dynamic programming, (23) gives

$$(24) \quad M_{P(k)}(n, d) = \min_{1 \leq r \leq n} \{P(r+d) \cdot n + M_{P(k)}(r-1, d) + M_{P(k)}(n-r, r+d)\}.$$

This recursion relation, together with the base equation  $M_{P(k)}(0, d) = 0$  for all  $d$ , allows us to calculate, for any pair  $(n, d)$ , the roots and search cost of all corresponding

optimal search trees. The entire trees can be constructed, provided we store for each  $(n, d)$  not only  $M_{P(k)}(n, d)$  but also the roots of all trees with this minimal cost. Note, however, that to calculate  $M_{P(k)}(n_0, d_0)$  by this method, we must calculate and store information for all  $(n, d)$  satisfying  $0 \leq n \leq n_0$  and  $0 \leq d \leq d_0 + n_0 - n$ . These enormous storage requirements can be dramatically reduced in some situations (e.g.,  $P(k) = k$ ) by storing, for fixed  $n$ , a linked list of cost-root pairs that are optimal over a wide range of  $d$  values. For more details, see [1].

Table 1 gives optimal search costs and roots of all the optimal trees for selected values of  $n$  when  $P(k) = k$ . These values were calculated using the recursive method outlined above.

## THE DECOMPOSITION OF A RECTANGLE INTO RECTANGLES OF MINIMAL PERIMETER\*

T. Y. KONG<sup>†</sup>, DAVID M. MOUNT<sup>‡</sup>, AND A. W. ROSCOE<sup>§</sup>

**Abstract.** We solve the problem of decomposing a rectangle  $R$  into  $p$  rectangles of equal area so that the maximum rectangle perimeter is as small as possible. This work has applications in areas such as flexible object packing and data allocation. Our solution requires only a constant number of arithmetic operations and integer square roots to characterize the decomposition, and linear time to print the decomposition. The discrete analogue of the problem in which the rectangle  $R$  is replaced by a rectangular array of lattice points is also considered, and three heuristic methods of solution are given. All of the heuristic methods operate by finding a discrete approximation to our optimal decomposition of  $R$ , but with different tradeoffs between the accuracy of the approximation and running time.

**Key words.** rectangle decomposition, flexible packing, digitization

**1. Introduction.** A fundamental problem in geometrical and combinatorial computing is how to decompose a large object into smaller objects subject to various constraints. By a *decomposition* of a region  $R$  we mean a finite set of closed regions whose union is  $R$  and whose interiors are pairwise disjoint. The regions of the decomposition need not be connected. Decomposition problems generally fall into one of two classes. In the first class, the objects have fixed dimensions, as in the knapsack and bin-packing problems [8], [11], [12]. In the second class the objects satisfy certain properties, as in decompositions of simple polygons into polygons that are star-shaped [2], convex [5], [17], triangular [7], or involve rectangles and rectilinear polygons [6], [9]. We consider a middle ground between these two classes in which the objects are of some specified area (or volume), but their shapes are not fully specified. In other words, the objects are flexible. The objective is to produce a decomposition in which the objects are not severely stretched; that is, they are nearly circular or square. More specifically, we consider the following problem involving the decomposition of a rectangle into rectangles of equal area or measure.

**RECTANGULAR DECOMPOSITION.** Given a rectangle  $R$  of height  $A$  and width  $B$ , and given an integer  $p$ , decompose  $R$  into  $p$  rectangles of equal area in such a way that the maximum rectangle perimeter is minimized.

Intuitively, the problem is to make the  $p$  rectangles in the decomposition of  $R$  as close to squares as we can. A special case of this problem in which  $R$  is a square was solved in [15]. The solution to the rectangular decomposition problem is a straightforward generalization of decomposition presented there, but the proof of optimality in the rectangular case is significantly more complex. A related problem with unconstrained areas was considered for the square in [1].

If we remove the restriction that  $R$  be decomposed into *rectangles* then we obtain another interesting problem. Define the *projection-perimeter* of a measurable plane set to be twice the sum of the lengths (measures) of its projections on the coordinate axes.

**GENERAL DECOMPOSITION.** Given a rectangle  $R$  on the Cartesian plane with sides parallel to the coordinate axes of height  $A$  and width  $B$ , and given a positive integer  $p$ , decompose  $R$  into  $p$  regions of equal measure in such a way that the maximum projection-perimeter is minimized.

Here the terms *height* and *width* denote the length of the projection onto the  $y$ - and the  $x$ -axis, respectively.

In this paper we solve the rectangular decomposition problem. We also show that for certain values of  $A$ ,  $B$ , and  $p$ , the optimal rectangular decomposition is, in fact, a solution to the general decomposition problem. For all values of  $A$ ,  $B$ , and  $p$ , we prove that the optimal rectangular decomposition is a solution to the following problem, which can be thought of as a compromise between the rectangular and general decomposition problems. Define a *pseudorectangle* to be any set that is congruent to a Cartesian product  $P \times Q$ , where  $P$  and  $Q$  are measurable subsets of the real line. (In particular, every rectangle is also a pseudorectangle.)

**PSEUDORECTANGULAR DECOMPOSITION.** Given a rectangle  $R$  on the Cartesian plane with sides parallel to the coordinate axes, of height  $A$  and width  $B$ , and given a positive integer  $p$ , decompose  $R$  into  $p$  pseudorectangles of equal measure in such a way that the maximum projection-perimeter is minimized.

We consider a model of computation in which unit charge is assessed for  $+$ ,  $-$ ,  $*$ ,  $/$ ,  $\leq$ ,  $\lfloor \rfloor$  and integer square root on rational numbers representable using  $O(\log(p + A + B))$  bits of precision. In this model of computation our optimal rectangular decomposition can be characterized in constant time and output in  $O(p)$  time.

These decomposition problems and their higher-dimensional counterparts have a number of applications:

- *Flexible object packaging.* There are  $p$  sacks of fluid that are to be placed in a box of volume  $A$ , and each sack is to fit into a rectangular box of volume  $A/p$ . The dimensions of the partitions may vary, but to minimize the stress on each sack, it is desirable to make the boxes as nearly cubical as possible.

- *Circuit decomposition.* Given a large circuit, laid out on an  $A \times B$  board (for example, a mesh of computer processors), decompose the circuit by slicing the board into  $p$  rectangles of equal area. To minimize the interboard communications, the perimeter of each board should be as small as possible.

- *Flexible circuit layout.* In VLSI layout, a designer wants to place  $p$  functionally identical circuits on a rectangular chip of area  $A$ . Each circuit can be deformed into an arbitrary rectangle, as long as the area is equal to  $A/p$ . However, highly eccentric rectangles lead to long wire lengths. It is desirable to reduce the length of the longest side of each rectangle, which implies that its perimeter is minimized.

An analogue of the general decomposition problem can be posed on a rectangular array of lattice points.

**LATTICE DECOMPOSITION.** Given positive integers  $A$ ,  $B$ , and  $p$ , partition an  $A \times B$  array of lattice points into  $p$  subsets each containing at most  $\lceil AB/p \rceil$  points, in such a way that the maximum projection-perimeter of a subset is minimized.

This arises in the following data-allocation problem for parallel computation of tables.

- *Data allocation for parallel computers.* We wish to compute all of the values of a binary function  $f$  on the Cartesian product  $S \times T$ , where  $|S| = A$  and  $|T| = B$ . The computation is to be performed in parallel on  $p$  identical processing units. The function values are computed as follows. The  $i$ th processor computes the values of  $f$  on some subset  $W_i$  of  $S \times T$ . The sets  $W_i$ ,  $1 \leq i \leq p$ , form a partition of  $S \times T$ . To minimize computation time, each processor is assigned at most  $\lceil AB/p \rceil$  function values to

compute. Each processor has a small amount of local memory used for storing its operands. The objective is to minimize this storage. The amount of storage used by the  $i$ th processor is equal to the number of operands needed to compute the values of  $W_i$ , which equals one half of the projection-perimeter of  $W_i$ .

The data allocation problem was in fact the initial motivation for this work [13], [15]. Although we will not present an exact solution to the lattice decomposition problem, we will give heuristic methods based on the idea of approximating our solution to the pseudorectangular decomposition problem on the discrete lattice. The quality of these approximate solutions will be good when  $A$  and  $B$  are large relative to  $p$ .

This paper is organized as follows. In § 2 we solve the rectangular decomposition problem and prove that the optimal rectangular decompositions are also optimal solutions to the pseudorectangular decomposition problem. This work is based on two interesting combinatorial lemmas that give lower bounds on the amount of stretching and compressing that must occur when  $p$  rectangles of equal area are packed into an  $A \times B$  rectangle. In § 3 we describe three procedures for approximating, or *digitizing*, the geometric decomposition described in § 2 on an integer lattice of height  $A$  and width  $B$ . These digitization procedures provide different tradeoffs between desirable characteristics of the digitization and running time. Ideally, the digitization should respect the geometric solution and preserve areas as closely as possible. We say that a digitization is *equitable* if it has the property that the area of each digitized region is at most the ceiling of the area of the original region. We give an algorithm for computing an equitable digitization by reduction to the problem of finding a feasible flow in a graph. This algorithm runs in time polynomial in  $A+B+p$ . We give two efficient algorithms that produce approximations to an equitable digitization.

**2. Optimal decomposition of a rectangle.** Let  $R$  be a rectangle in the Cartesian plane, with sides parallel to the coordinate axes, of height  $A$  and width  $B$ . Let  $p$  be any positive integer. In this section we solve the problem of how to decompose  $R$  into  $p$  rectangles  $R_1, R_2, \dots, R_p$  of equal area in such a way that the maximum of the perimeters of the  $R_i$ 's is as small as possible. Our solution actually minimizes the maximum projection-perimeter over all decompositions of  $R$  into pseudorectangles of equal measure.

If the rectangle  $R$  is sufficiently thin relative to  $p$ , in particular if  $p \leq \max(A/B, B/A)$ , then it is easy to see that the optimal decomposition results by simply partitioning the longer side of  $R$  into  $p$  equal parts. So we shall henceforth assume that  $p > \max(A/B, B/A)$ .

From now on, whenever we refer to a pseudorectangle we will assume that it is so oriented that its sides are parallel to the coordinate axes. Unless otherwise stated, the term *projection* will mean a projection on one of the coordinate axes. The two projections of a pseudorectangle are generally not connected sets. If a projection is a finite union of disjoint open and closed intervals then by the *length* of the projection we mean the sum of the lengths of those intervals. More generally the length of a projection is taken to mean its (Lebesgue) measure. Analogously, when we refer to the *area* of an arbitrary, measurable plane set, we mean its measure. When we speak of the *perimeter* of a pseudorectangle we mean its projection-perimeter, which is twice the sum of the lengths of its projections.

The sum of the lengths of the projections of a pseudorectangle of given area  $q$  (in our case  $q = AB/p$ ) is a strictly increasing function of the length of the longer of the two projections. (For if the longer projection has length  $(\sqrt{q} + h)$  where  $h \geq 0$  then

the sum of projections is  $(\sqrt{q+h}) + q/(\sqrt{q+h})$ , which is easily shown to be a strictly increasing function of  $h$  when  $h \geq 0$ .) So if we define the *cost* of a pseudorectangle to be the length of its longer projection, and the *cost* of a decomposition of  $R$  into  $p$  pseudorectangles to be the cost of the most costly pseudorectangle in the decomposition, then our optimization problems are equivalent to the problems of finding minimal cost decompositions of  $R$  into  $p$  rectangles and into  $p$  pseudorectangles of equal area.

Define a *row(column)* of rectangles to be a set of rectangles whose sides are parallel to the coordinate axes, all of which have the same projection onto the  $y$ -axis ( $x$ -axis). For any integer  $n$  such that  $1 \leq n \leq p$ , define an  $n$ -row decomposition ( $n$ -column decomposition) of  $R$  to be a decomposition consisting of just  $n$  rows (columns) of rectangles, each of which contains either  $\lfloor p/n \rfloor$  congruent rectangles or  $\lceil p/n \rceil$  congruent rectangles. Figure 1 shows a 4-row decomposition in the case  $p = 23$ , and a 5-column decomposition in the case  $p = 27$ .

FIG. 1. A 4-row decomposition and a 5-column decomposition.

If  $p/n$  is an integer then the  $n$ -row decomposition is an  $n$ -by- $(p/n)$  array of congruent rectangles with sides  $A/n$  and  $Bn/p$ . If  $p/n$  is not an integer then an  $n$ -row decomposition has  $p - n \lfloor p/n \rfloor$  rows of rectangles, each of which contains exactly  $\lceil p/n \rceil$  congruent rectangles, and  $n \lceil p/n \rceil - p$  rows of rectangles, each of which contains exactly  $\lfloor p/n \rfloor$  congruent rectangles. If we regard two  $n$ -row decompositions that are related by a permutation of rows to be the same, then for each  $1 \leq n \leq p$  there is just one  $n$ -row decomposition of  $R$ . Thus, we may refer to “the”  $n$ -row decomposition of  $R$ . The cost of an  $n$ -row decomposition is the maximum of the side lengths:  $B/\lfloor p/n \rfloor$ ,  $A\lfloor p/n \rfloor/p$ ,  $B/\lceil p/n \rceil$ ,  $A\lceil p/n \rceil/p$ . Clearly the maximum will be either the first or last of these values. Analogously the cost of an  $n$ -column decomposition is  $\max(A/\lfloor p/n \rfloor, B\lceil p/n \rceil/p)$ .

Intuitively, a decomposition into pseudorectangles of equal area has minimum cost when the pseudorectangles have horizontal and vertical projections that are nearly equal. Ideally, the rectangle would be divided exactly into squares with side lengths  $\sqrt{AB/p}$ , i.e., into  $\sqrt{Ap/B}$  rows and  $\sqrt{Bp/A}$  columns. This is possible only when these square roots are integers. However, we will show that one of four decompositions based on the floors and ceilings of these square roots must be a minimal-cost decomposition.

These four decompositions are the  $h_1$ -row,  $h_2$ -row,  $k_1$ -column, and  $k_2$ -column decompositions of  $R$ , where  $h_1 = \lfloor \sqrt{Ap/B} \rfloor$ ,  $h_2 = \lceil \sqrt{Ap/B} \rceil$ ,  $k_1 = \lfloor \sqrt{Bp/A} \rfloor$ , and  $k_2 = \lceil \sqrt{Bp/A} \rceil$ . (The four quantities  $h_1, h_2, k_1, k_2$  all lie between 1 and  $p$ , because we are assuming that  $p > \max(A/B, B/A)$ .)

From now on we shall use the term *principal decomposition* to denote an  $h_1$ -row,  $h_2$ -row,  $k_1$ -column, or  $k_2$ -column decomposition of  $R$ . The main objective of this section is to prove the following theorem.

**THEOREM 2.1.** *At least one of the four principal decompositions of  $R$  is an optimal decomposition of  $R$  into pseudorectangles of equal area.*

This theorem provides us with a simple algorithm for finding an optimal decomposition. The algorithm performs  $O(1)$  arithmetic operations. Once it is determined which decomposition is to be used, it is an easy matter to output the boundaries of the rectangles in  $O(p)$  time.

*Outline of the Proof of Theorem 2.1.* The key results on which the proof is based are Lemmas 2.3 and 2.4. Each implies a good lower bound on the cost of any decomposition of  $R$  into pseudorectangles. The lower bounds are explicitly stated in Lemma 2.5.

Plainly, any decomposition of  $R$  that attains one of these two lower bounds must be optimal. This simple observation is used to derive a variety of sufficient conditions on  $A$ ,  $B$ , and  $p$  for one of the four principal decompositions to be an optimal decomposition (Lemmas 2.8, 2.9, and 2.10). We establish Theorem 2.1 by verifying that whatever the values of  $A$ ,  $B$ , and  $p$  are, at least one of these sufficient conditions is sure to be satisfied.  $\square$

We begin by dealing with a trivial special case.

**LEMMA 2.1.** *If  $h_1 = h_2$  and  $k_1 = k_2$  then the four principal decompositions are the same, and this decomposition is optimal.*

*Proof.* If  $h_1 = h_2 = h$  and  $k_1 = k_2 = k$  then  $h = \sqrt{Ap/B}$  and  $k = \sqrt{Bp/A}$ , so  $hk = p$ , and  $A/h = \sqrt{AB/p} = B/k$ . Thus, all four of the decompositions yield an  $h$ -by- $k$  array of equal squares. It is clear from our definition of optimality that this decomposition is optimal.  $\square$

Our next goal is to derive the lower bounds on the cost of decompositions of  $R$ . We state these bounds in Lemma 2.5. One of our two bounds follows from a well-known result that is usually attributed to Chebyshev:

**LEMMA 2.2 (Chebyshev).** *If  $x_1 \leq \dots \leq x_n$  and  $y_1 \geq \dots \geq y_n$ , then the arithmetic mean of the sequence  $x_1 y_1, \dots, x_n y_n$  does not exceed the product of the arithmetic mean of the  $x_i$  and the arithmetic mean of the  $y_i$ .*

*Proof.* For all  $i > j$  the product  $(x_i - x_j)(y_i - y_j)$  is nonpositive, so the sum of all such products is nonpositive. But this sum is precisely  $n^2(W - UV)$ , where  $U$  is the mean of the  $x_i$ ,  $V$  is the mean of the  $y_i$ , and  $W$  is the mean of the  $x_i y_i$ .  $\square$

The next two lemmas imply the lower bounds we seek.

**LEMMA 2.3.** *Let  $h$  and  $k$  be positive integers such that  $(h - 1)(k - 1) < p$ . Let  $\{R_i \mid 1 \leq i \leq p\}$  be a collection of pseudorectangles each of area  $AB/p$  contained in  $R$  whose interiors are pairwise disjoint. Then there is some pseudorectangle  $R_i$  whose shortest projection has length at most  $\max(A/h, B/k)$ .*

*Proof.* Let  $a_i$  be the length of the projection of  $R_i$  on the  $y$ -axis, and let  $b_i$  be the length of the projection of  $R_i$  on the  $x$ -axis.

If some vertical line meets at least  $h$  of the  $R_i$  then there is  $i$  such that  $a_i \leq A/h$ . If some horizontal line meets at least  $k$  of the  $R_i$  then there is  $i$  such that  $b_i \leq B/k$ . In either case we are done.

Suppose towards a contradiction, that all horizontal lines meet at most  $k - 1$  of the  $R_i$ , and all vertical lines meet at most  $h - 1$  of the  $R_i$ . This implies that the sum of the  $a_i$  is at most  $A(k - 1)$  and the sum of the  $b_i$  is at most  $B(h - 1)$ . Therefore the product of the mean of the  $a_i$  and the mean of the  $b_i$  is at most  $AB(h - 1)(k - 1)/(p^2)$ , which in turn is less than  $AB/p$  by the hypotheses of the lemma.

Without loss of generality, assume that the  $a_i$  are arranged in ascending order. Since for each  $i$ ,  $a_i b_i = AB/p$ , the  $b_i$  are in descending order. It follows, by Lemma 2.2, that the mean of the product  $a_i b_i$  is at most the product of the means, which we showed to be less than  $AB/p$ . However, since  $a_i b_i = AB/p$ , the mean of the products is equal to  $AB/p$ , a contradiction.  $\square$

LEMMA 2.4. *Let  $h$  and  $k$  be positive integers such that  $p < (h+1)(k+1)$ . Let  $\{R_i \mid 1 \leq i \leq p\}$  be a collection of (possibly disconnected) regions of area  $AB/p$  whose union is  $R$ . Then there is some region  $R_i$  whose longest projection has length at least  $\min(A/h, B/k)$ .*

*Proof.* Let  $a_i$  be the length of the projection of  $R_i$  on the  $y$ -axis, and let  $b_i$  be the length of the projection of  $R_i$  on the  $x$ -axis.

If some vertical line meets at most  $h$  of the  $R_i$ , then there is  $i$  such that  $a_i \geq A/h$ . If some horizontal line meets at most  $k$  of the  $R_i$ , then there is  $i$  such that  $b_i \geq B/k$ . In either case we are done. Thus, we may assume that each vertical line passing through  $R$  meets at least  $h+1$  of the  $R_i$ , and each horizontal line passing through  $R$  meets at least  $k+1$  of the  $R_i$ .

First, we show that there is some  $i$  such that

$$(1) \quad a_i + b_i \geq \min(A/h + Bh/p, B/k + Ak/p).$$

Our assumption implies that the sum of the  $a_i$  is at least  $A(k+1)$ , and that the sum of the  $b_i$  is at least  $B(h+1)$ . Thus there is some  $i$  such that  $a_i + b_i \geq (A(k+1) + B(h+1))/p$ .

Next, we show that  $(A(k+1) + B(h+1))/p \geq \min(A/h + Bh/p, B/k + Ak/p)$ . Suppose not. Then we derive a contradiction as follows. Since  $p < (h+1)(k+1)$  we have

$$(2) \quad p - h(k+1) \leq k,$$

$$(3) \quad p - k(h+1) \leq h.$$

It follows from  $(A(k+1) + B(h+1))/p < A/h + Bh/p$  and (2) (by routine manipulations) that

$$Bh < A(p - h(k+1)) \leq Ak.$$

Symmetrically, from  $(A(k+1) + B(h+1))/p < B/k + Ak/p$  and (3) we have

$$Ak < B(p - k(h+1)) \leq Bh,$$

giving the required contradiction. Thus (1) is proved. If  $a_i + b_i \geq A/h + Bh/p$ , then since  $a_i b_i = AB/p = (A/h)(Bh/p)$ , it follows that  $\max(a_i, b_i) \geq \max(A/h, Bh/p) \geq \min(A/h, B/k)$ , as claimed. By symmetry, the same is true if  $a_i + b_i \geq B/k + Ak/p$ .  $\square$

To state the lower bounds implied by the last two lemmas, define the following values where the variables  $h$  and  $k$  range over positive integers:

$$C = \min \{ \max(A/h, B/k) \mid (h-1)(k-1) < p \},$$

$$S = \max \{ \min(A/h, B/k) \mid p < (h+1)(k+1) \}.$$

The reason for the names  $C$  and  $S$  is that we found it helpful to visualize the “bad” pseudorectangles  $R_i$  and  $R_j$  in parts (i) and (ii) of the next lemma as a *compressed* and a *stretched* pseudosquare, respectively.

LEMMA 2.5. *In any decomposition of  $R$  into pseudorectangles  $R_1, \dots, R_p$  of equal area:*

(i) *There is an  $R_i$  whose shortest projection has length at most  $C$ ; hence the cost of the decomposition is at least  $AB/(pC)$ .*

(ii) *There is an  $R_j$  whose longest projection has length at least  $S$ ; hence the cost of the decomposition is at least  $S$ .*

*Proof.* Assertion (i) follows from Lemma 2.3 and assertion (ii) from Lemma 2.4.  $\square$

By Lemma 2.5(ii) any decomposition of  $R$  in which the longer projection of every pseudorectangle has length at most  $S$  is optimal. Also, since the length of the shorter projection of a pseudorectangle of a given area determines the length of the longer projection, it follows from Lemma 2.5(i) that any decomposition of  $R$  in which the shorter projection of every pseudorectangle has length at least  $C$  is optimal. (Thus Lemma 2.5 generalizes Propositions 1 and 2 in [15].)

The next step in the proof is to establish a variety of sufficient conditions on  $A, B$ , and  $p$  for one of the four principal decompositions to attain one of the lower bounds on cost stated in Lemma 2.5. As it turns out, these sufficient conditions are most conveniently stated in terms of the following four quantities:

$$\begin{aligned} h_0 &= \lfloor p/k_2 \rfloor, & k_0 &= \lfloor p/h_2 \rfloor, \\ h_3 &= \lceil p/k_1 \rceil, & k_3 &= \lceil p/h_1 \rceil. \end{aligned}$$

Before deriving the sufficient conditions, we prove two useful technical lemmas.

LEMMA 2.6. (i)  $h_0 \leq h_1 \leq h_2 \leq h_3$ ;

(ii)  $k_0 \leq k_1 \leq k_2 \leq k_3$ ;

(iii) *Either  $k_2 = k_3$  or  $h_0 = h_1$ ;*

(iv) *Either  $h_2 = h_3$  or  $k_0 = k_1$ .*

*Proof.* Plainly,  $p/k_2 = p/\lfloor \sqrt{Bp/A} \rfloor \leq p/\sqrt{Bp/A} = \sqrt{Ap/B}$ . Hence  $h_0 \leq h_1$ . Similarly,  $h_3 \geq h_2$ . So (i) holds, and, by symmetry, so does (ii). Next, observe that if  $h_1 k_2 \leq p$  then  $h_1$  is an integer such that  $h_1 \leq p/k_2$ , so  $h_1 \leq \lfloor p/k_2 \rfloor = h_0$ , whence (i) implies that  $h_1 = h_0$ . If on the other hand  $h_1 k_2 \geq p$  then by an analogous argument  $k_2 = k_3$ . So (iii) holds, and by symmetry so does (iv).  $\square$

LEMMA 2.7. (i) *If  $h_1 = h_2$  and  $k_1 < k_2$  then  $h_0 < h_1 = h_2 < h_3$ .*

(ii) *If  $k_1 = k_2$  and  $h_1 < h_2$  then  $k_0 < k_1 = k_2 < k_3$ .*

*Proof.* If  $h_1 = h_2$  and  $k_1 < k_2$  then  $\sqrt{Ap/B}$  is an integer but  $\sqrt{Bp/A}$  is not, so  $h_0 \leq p/\lfloor \sqrt{Bp/A} \rfloor < p/\sqrt{Bp/A} = \sqrt{Ap/B} = h_1$ , and similarly  $h_3 > h_2$ . This proves (i), and (ii) follows by symmetry.  $\square$

If all the rectangles in a principal decomposition are congruent, then by Lemma 2.5 that decomposition is optimal if the longest (shortest) side of the rectangles has length at most  $S$  (at least  $C$ ). This simple observation yields the following sufficient conditions for one of the principal decompositions to be optimal.

LEMMA 2.8. (i) *If  $k_0 = k_1$  and  $h_2 = h_3$  then the  $h_2$ -row and  $k_1$ -column decompositions are the same. If, in addition,  $A/h_2 \geq C$  or  $B/k_1 \leq S$  then this decomposition is optimal.*

(ii) *If  $h_0 = h_1$  and  $k_2 = k_3$  then the  $k_2$ -row and  $h_1$ -column decompositions are the same. If, in addition,  $B/k_2 \geq C$  or  $A/h_1 \leq S$  then this decomposition is optimal.*

*Proof.* Suppose  $k_0 = k_1$  and  $h_2 = h_3$ . The first hypothesis implies  $k_1 = \lfloor p/h_2 \rfloor \leq p/h_2$  and the second implies  $h_2 = \lceil p/k_1 \rceil \geq p/k_1$ . Hence  $k_1 h_2 = p$ , so the  $h_2$ -row and  $k_1$ -column decompositions are the same; the decomposition is an  $h_2$ -by- $k_1$  array of congruent rectangles with sides of length  $A/h_2$  and  $B/k_1$ . A side of length  $A/h_2$  is a shortest side, and a side of length  $B/k_1$  is a longest side, so if  $A/h_2 \geq C$  or  $B/k_1 \leq S$  then the decomposition is optimal by Lemma 2.5. This proves (i); (ii) follows by a symmetrical argument.  $\square$

A principal decomposition usually contains exactly two different kinds of rectangles (see Fig. 1). If it is clear that one kind of rectangle is costlier than the other, and that the longest (shortest) side of the costlier rectangles has length at most  $S$  (at

least  $C$ ), then by Lemma 2.5 the decomposition is optimal. The following lemma gives sufficient conditions for one of the principal decompositions to be optimal, based on this idea.

- LEMMA 2.9. (i) *If  $k_0 < k_1$  and  $B/k_0 \leq S$  then the  $h_2$ -row decomposition is optimal.*  
 (ii) *If  $k_3 > k_2$  and  $B/k_3 \geq C$  then the  $h_1$ -row decomposition is optimal.*  
 (iii) *If  $h_0 < h_1$  and  $A/h_0 \leq S$  then the  $k_2$ -column decomposition is optimal.*  
 (iv) *If  $h_3 > h_2$  and  $A/h_3 \geq C$  then the  $k_1$ -column decomposition is optimal.*

*Proof.* Suppose  $k_0 < k_1$  and  $B/k_0 \leq S$ . Now each rectangle in an  $h_2$ -row decomposition either has a side of length  $B/\lfloor p/h_2 \rfloor$  or has a side of length  $B/\lceil p/h_2 \rceil$ . But (since we are assuming  $k_0 < k_1$ )  $\lceil p/h_2 \rceil \leq k_0 + 1 \leq k_1 \leq \sqrt{Bp/A}$ , so a side of length  $B/\lceil p/h_2 \rceil$  is the longest side of a rectangle of area  $AB/p$ , and (a fortiori) the same is true of a side of length  $B/\lfloor p/h_2 \rfloor$ . As  $B/k_0 \leq S$ ,  $B/\lfloor p/h_2 \rfloor \leq S$ , and (a fortiori)  $B/\lceil p/h_2 \rceil \leq S$ . So the  $h_2$ -row decomposition is optimal by Lemma 2.5 (assertion (ii)). This proves part (i) of Lemma 2.9. Part (ii) is proved by an analogous argument by making substitutions that are order-inverting. That is,  $k_i$  is replaced by  $k_{3-i}$ ,  $h_i$  by  $h_{3-i}$ ,  $\leq$  by  $\geq$ ,  $\lfloor \cdot \rfloor$  by  $\lceil \cdot \rceil$ ,  $S$  by  $C$ , and so on. Parts (iii) and (iv) are symmetrical with (i) and (ii).  $\square$

If the longest side of one kind of rectangle in a principal decomposition has length at most  $S$ , while the shortest side of the other kind of rectangle has length at least  $C$ , then by Lemma 2.5 the decomposition is optimal. Hence we have the following sufficient conditions for optimality.

- LEMMA 2.10. (i) *If  $h_0 = h_1$ ,  $A/h_1 \leq S$ , and  $A/h_2 \geq C$ , then the  $k_2$ -column decomposition is optimal.*  
 (ii) *If  $h_3 = h_2$ ,  $A/h_1 \leq S$ , and  $A/h_2 \geq C$ , then the  $k_1$ -column decomposition is optimal.*  
 (iii) *If  $k_0 = k_1$ ,  $B/k_1 \leq S$ , and  $B/k_2 \geq C$ , then the  $h_2$ -row decomposition is optimal.*  
 (iv) *If  $k_3 = k_2$ ,  $B/k_1 \leq S$ , and  $B/k_2 \geq C$ , then the  $h_1$ -row decomposition is optimal.*

*Proof.* Suppose  $h_0 = h_1$ ,  $A/h_1 \leq S$ , and  $A/h_2 \geq C$ . Then  $\lfloor p/k_2 \rfloor = h_1$ . There are two cases: either  $\lceil p/k_2 \rceil = h_1$  or  $\lceil p/k_2 \rceil = h_1 + 1$ .

In the first case the  $k_2$ -column decomposition consists of  $k_2$  columns, each of which contains  $h_1$  congruent rectangles. Each of these rectangles has a side of length  $A/h_1$ , and (since by definition  $h_1 \leq \sqrt{Ap/B}$ ) this is the longest side of the rectangles. Hence  $A/h_1 \leq S$  implies that the decomposition is optimal (by assertion (ii) of Lemma 2.5).

In the second case we note that, by Lemma 2.7(i),  $h_0 = h_1$  implies that either  $h_1 < h_2$  or  $k_1 = k_2$ . So we may assume that  $h_1 < h_2$ , for if  $k_1 = k_2$  and  $h_1 = h_2$  then Lemma 2.10 is certainly true (by Lemma 2.1). By hypothesis  $\lceil p/k_2 \rceil = h_1 + 1$ , so  $\lceil p/k_2 \rceil = h_2$ . Now each rectangle in the  $k_2$ -column decomposition either has a side of length  $A/\lfloor p/k_2 \rfloor (= A/h_1)$  or has a side of length  $A/\lceil p/k_2 \rceil (= A/h_2)$ . Since  $h_1 \leq \sqrt{Ap/B} \leq h_2$ , a side of length  $A/h_1$  is a longest side, and a side of length  $A/h_2$  is a shortest side. Recalling that  $A/h_1 \leq S$  and  $A/h_2 \geq C$ , we see that Lemma 2.10 now follows from Lemma 2.5. This proves assertion (i); the other assertions follow by symmetrical arguments.  $\square$

Finally, we need to show that for all values of  $A$ ,  $B$ , and  $p$  at least one of the sufficient conditions for optimality holds. The proof is by case analysis, based on the following lemma.

- LEMMA 2.11. (i) *If  $h_1 < h_2$  then  $\min(A/h_1, B/k_0) \leq S$  and  $\max(A/h_2, B/k_3) \geq C$ .*  
 (ii) *If  $k_1 < k_2$  then  $\min(B/k_1, A/h_0) \leq S$  and  $\max(B/k_2, A/h_3) \geq C$ .*

*Proof.* Suppose  $h_1 < h_2$ . Then  $k_0 = \lfloor p/(h_1 + 1) \rfloor$  and  $k_3 = \lceil p/(h_2 - 1) \rceil$ . Hence,  $(h_1 + 1)(k_0 + 1) > p$  implying that  $\min(A/h_1, B/k_0) \leq S$ , by definition of  $S$ . Similarly,  $(h_2 - 1)(k_3 - 1) < p$ ; thus  $\max(A/h_2, B/k_3) \geq C$ . This proves (i); as usual, (ii) follows by a symmetrical argument.  $\square$

*Proof of Theorem 2.1.* If  $h_1 = h_2$  and  $k_1 = k_2$  then we are done by Lemma 2.1. Suppose  $h_1 = h_2$  and  $k_1 < k_2$ . Then by Lemma 2.7  $h_0 < h_1 = h_2 < h_3$ , and so, by Lemma 2.6(iii),  $k_2 = k_3$ . Hence, we deduce Theorem 2.1 by combining Lemma 2.11(ii) with Lemma 2.10(iv) and Lemma 2.9 ((iii) and (iv)). By symmetry, Theorem 2.1 holds if  $h_1 < h_2$  and  $k_1 = k_2$ .

Now suppose  $h_1 < h_2$  and  $k_1 < k_2$ . On applying Lemma 2.11(i) we see that there are four possibilities:

- (a)  $A/h_1 \leq S$  and  $B/k_3 \geq C$ .
- (b)  $B/k_0 \leq S$  and  $B/k_3 \geq C$ .
- (c)  $A/h_1 \leq S$  and  $A/h_2 \geq C$ .
- (d)  $B/k_0 \leq S$  and  $A/h_2 \geq C$ .

Case (a). Case (a) need not be considered separately as it is symmetrical with Case (d).

Case (b). If  $k_0 < k_1$  or  $k_3 > k_2$  then Theorem 2.1 follows from Lemma 2.9((i) and (ii)). Otherwise  $k_0 = k_1$  and  $k_3 = k_2$ , and Theorem 2.1 follows from Lemma 2.10((iii) or (iv)).

Case (c). If  $h_0 = h_1$  or  $h_2 = h_3$  then Theorem 2.1 follows from Lemma 2.10((i) and (ii)). Otherwise  $h_0 < h_1$  and  $h_2 < h_3$ , and, by Lemma 2.6(iii),  $k_2 = k_3$ . Now apply Lemma 2.11(ii) to get the following four subcases:

- (c1)  $B/k_1 \leq S$  and  $A/h_3 \geq C$ .
- (c2)  $A/h_0 \leq S$  and  $A/h_3 \geq C$ .
- (c3)  $B/k_1 \leq S$  and  $B/k_2 \geq C$ .
- (c4)  $A/h_0 \leq S$  and  $B/k_2 \geq C$ .

Since, in the present case,  $h_0 < h_1$  and  $h_2 < h_3$ , Theorem 2.1 follows from Lemma 2.9 ((iii) and (iv)) in Cases (c1), (c2), and (c4). Since, in the present case,  $k_2 = k_3$ , Theorem 2.1 follows from Lemma 2.10(iv) in case (c3).

Case (d). We again apply Lemma 2.11(ii) to get the same four subcases (c1)–(c4) now renamed as Subcases (d1)–(d4).

*Subcase (d1).* Recall that  $A/h_2 \geq C$  and  $B/k_0 \leq S$  (from (d)). Now if  $k_0 < k_1$  or  $h_2 < h_3$  then Theorem 2.1 follows from Lemma 2.9((i) and (iv)); if, on the other hand,  $k_0 = k_1$  and  $h_2 = h_3$  then Theorem 2.1 follows from Lemma 2.8(i).

*Subcase (d2).* Symmetric with Case (b) above.

*Subcase (d3).* Symmetric with Case (c) above.

*Subcase (d4).* We have  $B/k_2 \geq C$  and (from (d))  $B/k_0 \leq S$ . Hence, if  $k_0 < k_1$  then Theorem 2.1 follows from Lemma 2.9(i), while if  $k_0 = k_1$  then Theorem 2.1 follows from Lemma 2.10(iii).  $\square$

We have proved that at least one of four principal decompositions is an optimal decomposition of  $R$  into pseudorectangles. But we conjecture that an optimal decomposition of  $R$  into pseudorectangles is in fact an optimal decomposition of  $R$  into arbitrary sets of equal area. In other words, the conjecture is that Theorem 2.1 solves the general decomposition problem as well as the pseudorectangular decomposition problem. We end this section with a simple argument which shows that the conjecture is true if  $S \geq AB/(pC)$ .

Observe, first of all, that in the statement of Lemma 2.4 the  $R_i$ 's need not be pseudorectangles. So we see that a decomposition of  $R$  into arbitrary measurable sets of area  $AB/p$  must contain a set whose  $x$ - or  $y$ -projection has length at least  $S$ . As was explained in our outline of the proof, we established Theorem 2.1 by showing that at least one of the four principal decompositions attains one of the two lower bounds stated in Lemma 2.5. In other words we showed that (at least) one of the

principal decompositions either has cost  $S$  or has cost  $AB/(pC)$ . Now suppose  $S \cong AB/(pC)$ . Then by Lemma 2.5(ii) none of the principal decompositions of  $R$  can have cost  $AB/(pC)$ . Therefore one of the principal decompositions has cost  $S$ , so that the sum of the height and width of any rectangle in that decomposition is at most  $S + AB/(pS)$ . The fact that a rectangular decomposition of  $R$  has cost  $S$  also implies that  $S \cong \sqrt{AB/p}$ . But we have seen that a decomposition of  $R$  into  $p$  arbitrary sets of equal area must contain a set whose  $x$ - or  $y$ -projection has length at least  $S$ ; the sum of the  $x$ - and  $y$ -projections of that set must be at least  $S + AB/(pS)$ .

**3. Digitizing a rectangular decomposition.** As noted in the Introduction, the lattice decomposition problem, is a discrete analogue to the region decomposition problem. Recall that the problem is to partition an  $A \times B$  rectangular array of integer lattice points into  $p$  subsets each of size at most  $\lceil AB/p \rceil$  such that the maximum projection-perimeter is minimized. We do not know of an efficient solution to the lattice decomposition problem, but when  $A$  and  $B$  are large relative to  $p$  the results of the previous section can be used to find an approximate solution. The problem reduces to approximating the decomposition of an  $A \times B$  rectangle on the lattice, so that areas and projection-perimeters are very nearly preserved.

In this section we consider how to compute this approximation, which, to borrow a term from computer graphics and vision, we call *digitization*. We present three digitization algorithms that provide tradeoffs between running time and the quality of the digitization. The second digitization algorithm is quite general, and operates on any decomposition into convex polygons. The other digitizations are significantly more efficient, but operate on a special class of rectangular decompositions which we call *row-major* decompositions. Consider the  $A \times B$  rectangle,

$$R = \{(x, y) \mid 0 \leq x \leq B, 0 \leq y \leq A\}.$$

A decomposition of  $R$  into rectangles is called *row-major* if it is of the following form.

(1)  $R$  is partitioned into  $r$  rows by a set of horizontal line segments running from  $x = 0$  to  $x = B$ . Let  $0 = h_0 < h_1 < \dots < h_r = A$  be the  $y$ -values of these segments.

(2) Each row is further decomposed by vertical segments into some number of columns. For the row bounded by  $h_{i-1}$  and  $h_i$  let  $0 = v_{i,0} < v_{i,1} < \dots < v_{i,s_i} = B$  be the  $x$ -values of these vertical segments.

Note that the decomposition produced by the algorithm of § 2 is either row-major, or can be made so by transposing rows and columns. In this section, we assume that  $A$  and  $B$  are positive integers. We assume that the line segments defining the decomposition are described using rational numbers representable using  $O(\log(p + A + B))$  bits each.

Consider the  $A \times B$  rectangular array of integer *lattice points*  $L$  superimposed on the rectangle  $R$ . That is,  $L = \{(i, j) \mid 0 \leq i < A, 0 \leq j < B\}$ . For each  $(i, j) \in L$ , let  $S_{i,j}$  denote the open unit square consisting of the points  $(x, y)$  for  $i < x < i + 1$  and  $j < y < j + 1$ . These are called the *lattice squares*. The rectangle  $R$  consists of  $A$  horizontal rows and  $B$  vertical columns of squares. Our aim is to approximate a decomposition of  $R$  into  $p$  regions by a partition of the lattice squares into  $p$  subsets. Although digitization is common in applications from computer vision and graphics, the goals of our digitization are rather special. We seek a partition of squares satisfying the following criteria: (1) the number of lattice squares assigned to a given region of the decomposition is nearly equal to the area of the region, and (2) the projection-perimeters of a region and its corresponding subset of lattice squares are nearly equal. We formalize these criteria by defining two properties of digitizations that we seek to produce through our algorithms.

DEFINITION. (1) A digitization is *overlapping* if each region is assigned only lattice squares  $S_{i,j}$  that overlap the region.

(2) A digitization is *equitable* if the number of lattice squares assigned to a given region does not exceed the ceiling of the area of the region.

All three of the digitization algorithms presented here produce overlapping digitizations; however, the first and third algorithms do not necessarily produce equitable digitizations. Define the *absolute excess* of a digitization to be the maximum signed difference between the number of lattice squares assigned to a region and the true area of the region. (Note that the absolute excess may be negative.) An equitable digitization has an absolute excess less than 1. The *relative excess* is defined to be the maximum ratio of these two values. The first digitization algorithm produces a digitization with relative excess approaching unity as  $\min(A, B)$  approaches infinity. The second procedure produces an equitable digitization by reducing the digitization problem to the problem of finding a feasible flow in a graph. This algorithm is the least efficient of the three. The third algorithm, is a compromise between these two. Like the first algorithm, it is very efficient with respect to running time but produces a digitization that has an absolute excess less than 2 for all input parameters.

The amount of time required to compute the digitization can be measured as the amount of time required to describe the boundaries of the digitization as a sequence of line segments. Our first and third algorithms can print the boundaries in  $O(p)$  time, and hence are optimal with respect to this criterion. Our second algorithm runs in polynomial time in  $A + B + p$ , although we do not attempt to find the most efficient implementation.

Our first algorithm is a simple naive digitization based on point containment. Stated simply, the set of lattice squares assigned to a region are those whose lower left corners are contained in the region. If a lattice point  $(i, j)$  lies on the boundary between two or more regions, then the corresponding square is assigned arbitrarily to one of the regions that overlaps the square. This is easily seen to be an overlapping digitization. It is also easy to see that as  $A$  and  $B$  increase relative to  $p$ , then the relative excess of the digitization approaches 1.

Note that the digitization of a given rectangle can be computed in constant time. This digitization algorithm has the property of mapping rectangles to rectangular arrays of squares. The other two digitizations that we present do not have this property.

**3.1. Absolutely equitable digitization.** The second algorithm works by reducing the digitization problem to a graph flow problem. This algorithm can be applied to any decomposition of  $R$  into convex polygonal regions. Let  $R_1, R_2, \dots, R_p$  denote a decomposition of  $R$  into  $p$  polygonal regions.

We define a bipartite flow graph with upper and lower vertex capacities,  $G = (V, E, L, U)$ , with vertex set  $V$ , edge set  $E$ , and lower and upper capacity functions  $L$  and  $U$ .  $V$  consists of the following elements:

- *region vertices*  $r_1, r_2, \dots, r_p$ , one for each region of the decomposition, and
- *lattice vertices*  $s_{i,j}$ , one for each of the lattice squares,  $S_{i,j}$  for  $0 \leq i < A$  and  $0 \leq j < B$ .

The edge set,  $E$ , consists of the following pairs:

- an edge from each region vertex  $r_k$  to each lattice vertex  $s_{i,j}$  whenever the unit square  $S_{i,j}$  overlaps the region  $R_k$ ,

The vertex capacities are expressed as pairs,  $(L(v), U(v))$ , representing the lower and upper flow capacity for each vertex  $v$ . These capacities are:

- $(1, 1)$  for each lattice vertex, and
- $(\lfloor a \rfloor, \lceil a \rceil)$  for each region vertex  $r_k$ , where  $a$  is the area of region  $R_k$ .

For example, Fig. 2 shows a decomposition of  $R$  and the corresponding flow graph.

Let  $\Gamma(v)$  denote the neighbors of a vertex  $v$ . A *feasible flow* is an assignment  $f$  of nonnegative integers to each edge of  $E$ , such that, for each vertex  $v \in V$

$$L(v) \leq \sum_{w \in \Gamma(v)} f(v, w) \leq U(v).$$

We say that a digitization is *absolutely equitable* if the number of lattice squares assigned to each region is either the floor or ceiling of the area of the region. An absolutely equitable digitization is, in some sense, the most equitable digitization that we can hope to achieve. The connection between the digitization problem and the graph  $G$  is established in our next lemma, which follows immediately from our construction.

LEMMA 3.1. *There exists an overlapping, absolutely equitable digitization if and only if the graph  $G$  has a feasible flow.*

Although the relationship between the feasible flow problem and the problem of absolutely equitable digitization gives a method of computing the digitization, it is not obvious that such a digitization need exist. Our next result applies a generalization of Hall's well-known theorem on complete matchings in bipartite graphs to show that such a digitization exists for all decompositions.

THEOREM 3.1. *Given any decomposition of  $R$  into regions with disjoint interiors, an absolutely equitable digitization of the decomposition exists.*

*Proof.* We make a straightforward adaptation of an existing result from the study of feasible flows in graphs with lower- and upper-edge capacities [10, p. 81], [3, p. 88], which generalizes Hall's theorem on the existence of complete matchings in graphs [4]. This result states that a necessary and sufficient condition for the existence of nonnegative feasible flow in  $G$  is that for all subsets  $U$  of region vertices and all subsets,  $T$ , of lattice vertices we have

$$(4) \quad \sum_{v \in U} L(v) \leq \sum_{w \in \Gamma(U)} U(w), \quad \sum_{w \in T} L(w) \leq \sum_{v \in \Gamma(T)} U(v).$$

The first half of (4) follows by noting that the sum of areas of a set of disjoint regions  $U$  is no greater than the number of unit squares  $\Gamma(U)$  that cover the set. The second half follows by noting that the number of disjoint unit squares in a set  $T$  is no greater than the sum of areas of the regions  $\Gamma(T)$  covering  $T$ .  $\square$

COROLLARY. *If the regions of the decomposition have integer areas, then there exists an overlapping digitization with an absolute excess of zero.*

FIG. 2. The flow graph of a decomposition.

Once the graph  $G$  has been constructed, the equitable digitization can be computed in  $O(|V|^3)$  time by any known algorithm for finding feasible flows in graphs [3], [18]. The number of vertices  $V$  is  $p + AB$  and the magnitude of the capacities is at most  $AB$ .

In the case where  $p$  is small relative to  $A$  and  $B$  we might hope to find a bound on the size of the vertex set of  $G$  that is independent of  $A$  and  $B$ . To do this we reduce the number of lattice vertices as follows. The lattice vertices can be partitioned into equivalence classes according to the set of regions that they overlap, that is according to  $\Gamma$ . The individual lattice vertices forming each equivalence class can then be replaced by a single aggregate vertex representing the entire class. The capacity of this aggregate vertex is the sum of the capacities of the individual vertices. It can be shown that if  $R$  is decomposed into  $p$  convex polygonal regions then the number of equivalence classes is  $O(p^2)$  [14]. This reduction can be computed easily in  $O(pAB)$  time, and the digitization can be computed in  $O(p^6)$  time by a feasible flow algorithm.

**3.2. Nearly equitable digitization.** In the previous section we showed that absolutely equitable digitizations exist, although they are somewhat expensive to compute. Next we present an efficient digitization algorithm that does not provide us with an equitable digitization, but does achieve an absolute excess less than 2. Figure 3 shows the result of this digitization of a seven-region decomposition on a lattice of size  $13 \times 13$ . This digitization has the property that, given a lattice square, the rectangle to which it is assigned can be determined in  $O(1)$  time. The boundary of a digitized region can be described by a collection of line segments in  $O(1)$  time. This is possible because the algorithm works *locally*, digitizing each rectangle of the decomposition without knowledge of the digitization of any other rectangles, as opposed to the graph flow method which operates *globally*.

FIG. 3. A 7-region digitization on a  $13 \times 13$  lattice.

This algorithm makes extensive use of the fact that the decomposition is a row-major decomposition. The algorithm operates in two phases. First, for each adjacent pair of horizontal lines  $h_i$  and  $h_{i-1}$  the digitized region lying between  $h_i$  and  $h_{i-1}$  is determined. In the second phase, within the digitized region between  $h_i$  and  $h_{i-1}$ , we digitize the region lying between the vertical lines  $v_j$  and  $v_{j-1}$ . In our discussion, we will make use of the following easily verified identity. For all numbers  $s$  and  $t$ :

$$(5) \quad \lfloor s - t \rfloor \leq \lceil s \rceil - \lfloor t \rfloor \leq \lceil s - t \rceil.$$

For the first phase of the algorithm, we show how to digitize the region between the horizontal lines  $y = h_i$  and  $y = h_{i-1}$ ,  $1 \leq i \leq r$ . For each  $i$  we digitize the region lying below  $h_i$ , denoted  $H_i$ , and then define the digitized region between  $h_i$  and  $h_{i-1}$  to be the set difference  $H_i - H_{i-1}$ .  $H_i$  consists of all lattice squares lying strictly below  $h_i$ , that is,  $S_{x,y}$  where  $y < \lfloor h_i \rfloor$ , and some subset of the horizontal row of squares  $S_{x,y}$ , where  $y = \lfloor h_i \rfloor$ . Consider the set of decomposition vertices lying in this row of squares. For each such vertex  $(g, h)$ , construct the vertical lines  $x = \lfloor g \rfloor$  and  $x = \lceil g \rceil$ . Let  $G_i$  denote the set of  $x$ -intercepts of these lines, and let  $0 = g_{i,0} < g_{i,1} < \dots < g_{i,m} = B$ , the sorted elements of  $G_i$ . These lines partition this horizontal row of lattice squares into  $m$  contiguous blocks. See Fig. 4.

FIG. 4. Allocation below a horizontal line.

The portion of this row, bounded above by  $h_i$  and lying to the left of  $g_{i,j}$  has area  $(h_i - \lfloor h_i \rfloor)g_{i,j}$ . Let  $C_{i,j}$  denote the ceiling of this value.  $C_{i,j}$  is the desired total number of squares to allocate to the left of  $g_{i,j}$ . For the block bounded by  $g_{i,j-1}$  and  $g_{i,j}$ , we allocate the leftmost  $C_{i,j} - C_{i,j-1}$  lattice squares to  $H_i$ . For example, in Fig. 4,  $h_i - \lfloor h_i \rfloor = \frac{1}{3}$ ; hence the number of squares allocated to  $H_i$  lying between  $g_{i,2} = 3$  and  $g_{i,3} = 7$  is  $\lceil 7/3 \rceil - \lceil 3/3 \rceil = 2$ . The allocated squares are shaded in Fig. 4.

Using (5), we have

$$0 \leq C_{i,j} - C_{i,j-1} \leq \lceil (g_{i,j} - g_{i,j-1})(h_i - \lfloor h_i \rfloor) \rceil \leq g_{i,j} - g_{i,j-1}.$$

Hence, there are enough lattice squares between  $g_{i,j-1}$  and  $g_{i,j}$  to satisfy this allocation scheme. It is an easy consequence of our definition that  $H_{i-1} \subseteq H_i$ , for  $1 \leq i \leq r$ . Thus, the digitization of the row between  $h_i$  and  $h_{i-1}$  can be defined to be  $H_i - H_{i-1}$ . It is clear by our construction that each square of  $H_i - H_{i-1}$  overlaps the region between  $h_i$  and  $h_{i-1}$ . The next result states that the boundary of  $H_i$  can be computed in constant time within a fixed block of  $G_i$ .

CLAIM 3.1. For a lattice square  $S_{x,y}$ , where  $g_{i,j-1} \leq x < g_{i,j}$ , the membership of  $S_{x,y}$  in  $H_i$  can be tested in  $O(1)$  time. The boundary of  $H_i$  between  $g_{i,j-1}$  and  $g_{i,j}$  can be computed in  $O(1)$  time.

We now describe the second phase of the algorithm in which we complete the digitization of each rectangle by digitizing the vertical lines. Throughout, we will be considering the digitized region  $H_i - H_{i-1}$  for any fixed  $i$ ,  $1 \leq i \leq r$ . Let  $v_1, v_2, \dots, v_s$  denote the vertical segments between the horizontal lines  $h_i$  and  $h_{i-1}$ . Similar to the first phase, we determine the digitized region lying to the left of  $v_j$ , for each  $j$ , and then define the final digitized region by set difference. The process is slightly more

complex than the first phase because of the discontinuities in the boundary of  $H_i$  and  $H_{i-1}$ .

For an integer  $g, 0 \leq g \leq B$ , let  $L(g)$  denote the number of lattice squares in  $H_i - H_{i-1}$  that lie strictly to the left of the vertical line  $x = g$ . Intuitively,  $L(g)$  is a discrete approximation to the true area  $g(h_i - h_{i-1})$ . For example, in Fig. 4, the true area bounded by  $h_i = 3\frac{1}{3}$ ,  $h_{i-1} = 0$ , and  $g_{i,3} = 7$  is  $23\frac{1}{3}$  and  $L(g_{i,3}) = 24$ . In the special case that  $g$  is the floor or ceiling of a vertical line of the decomposition, then we can bound the value of  $L(g)$  as we now show.

CLAIM 3.2. *Let  $v_j$  be a vertical line of the decomposition between the horizontal lines  $h_i$  and  $h_{i-1}$ . Then*

- (i)  $L(\lfloor v_j \rfloor) \leq \lceil v_j(h_i - h_{i-1}) \rceil$ , and
- (ii)  $L(\lceil v_j \rceil) \geq \lfloor v_j(h_i - h_{i-1}) \rfloor$ .

*Proof.* By definition, both  $\lfloor v_j \rfloor$  and  $\lceil v_j \rceil$  are in  $G_i$  and  $G_{i-1}$ . From the definition of  $H_i$  and  $H_{i-1}$  it follows that  $L(\lfloor v_j \rfloor) = \lceil \lfloor v_j \rfloor h_i \rceil - \lceil \lfloor v_j \rfloor h_{i-1} \rceil$ . Part (i) follows by applying (5) and through simple manipulations. Part (ii) follows analogously.  $\square$

The digitized region to the left of  $v_j$ , denoted  $V_j$ , consists of all the squares  $S_{x,y} \in H_i - H_{i-1}$  for which  $x < \lfloor v_j \rfloor$  and a portion of the column of squares for which  $x = \lfloor v_j \rfloor$ . If  $v_j$  is not an integer, then the set of squares  $S_{x,y}$  with  $x \leq \lfloor v_j \rfloor$  is bounded on the right by the vertical line  $x = \lceil v_j \rceil$ . If  $v_j$  is an integer, then the overlapping constraint implies that we cannot allocate any squares to the right of  $v_j = \lceil v_j \rceil$ . Thus in either case the maximum number of such squares that can be allocated is  $L(\lceil v_j \rceil)$ . The digitization seeks to approximate the area bounded horizontally between  $h_i$  and  $h_{i-1}$  and on the left by  $v_j$ , that is,  $v_j(h_i - h_{i-1})$ . Thus, we define the size of  $V_j$ , denoted  $D_j$ , by combining these two values:

$$D_j = \min(\lceil v_j(h_i - h_{i-1}) \rceil, L(\lceil v_j \rceil)).$$

There are  $L(\lfloor v_j \rfloor)$  squares allocated strictly to the left of the column  $\lfloor v_j \rfloor$ , therefore, the number of squares  $S_{x,y}$  to be allocated where  $x = \lfloor v_j \rfloor$  is  $D_j - L(\lfloor v_j \rfloor)$ . We select the topmost squares of the column to be allocated. It follows from Claim 3.2(i) that  $0 \leq D_j - L(\lfloor v_j \rfloor)$ . It follows from the definition of  $D_j$  that there are enough squares in column  $\lfloor v_j \rfloor$  to satisfy this allocation. Finally, the digitized region between  $v_j$  and  $v_{j-1}$  is defined to be  $V_j - V_{j-1}$ . By definition of  $D_j$ , this digitization is overlapping.

For example, in Fig. 5, the true area bounded by  $h_i = 3\frac{1}{3}$ ,  $h_{i-1} = 0$ , and  $v_j = 7\frac{1}{2}$  is 25 and  $L(\lceil v_j \rceil) = 27$  and so  $D_j = 25$ . Since  $L(\lfloor v_j \rfloor) = 24$ , there is one square allocated in column  $\lfloor v_j \rfloor$ .

FIG. 5. Allocation to the left of a vertical line.

CLAIM 3.3. *The right-side boundary of  $V_j$  can be computed in  $O(1)$  time.*

*Proof.* The right-hand-side boundary is defined by the squares of column  $\lfloor v_j \rfloor$  that are in  $V_j$ . These squares can be computed in constant time once we know the topmost square of column  $\lfloor v_j \rfloor$  in  $H_i$ . However, since  $\lfloor v_j \rfloor \in G_i$ , the membership of this square in  $H_i$  can be determined in  $O(1)$  time by Claim 3.1.  $\square$

In summary, to digitize the rectangle bounded by horizontal lines  $h_i$  and  $h_{i-1}$  and vertical lines  $v_j$  and  $v_{j-1}$  we apply the first phase of the algorithm to digitize the horizontal region, and then apply the second phase to complete the digitization. We claim that this algorithm defines a digitization that is overlapping and has an absolute excess less than 2.

THEOREM 3.2. *Consider the digitization of each rectangle in a row-major decomposition of  $R$  described above.*

- (i) *The digitization defines a partition of the set of lattice squares in  $R$ .*
- (ii) *The digitization is overlapping.*
- (iii) *The digitization has an absolute excess less than 2.*

*Proof.* Parts (i) and (ii) follow from the preceding discussion. Details for both cases appear in [14]. To prove (iii), consider a digitized region bounded by vertical segments  $v_j$  and  $v_{j-1}$  between rows  $h_i$  and  $h_{i-1}$ . The size of the allocation is

$$\begin{aligned} D_j - D_{j-1} &= \min(\lceil v_j(h_i - h_{i-1}) \rceil, L(\lceil v_j \rceil)) - \min(\lceil v_{j-1}(h_i - h_{i-1}) \rceil, L(\lceil v_{j-1} \rceil)) \\ &\leq \lceil v_j(h_i - h_{i-1}) \rceil - \lfloor v_{j-1}(h_i - h_{i-1}) \rfloor \quad (\text{by Claim 3.2(ii)}) \\ &< \lceil (v_j - v_{j-1})(h_i - h_{i-1}) \rceil + 1 \quad (\text{by Equation (5)}) \\ &< (v_j - v_{j-1})(h_i - h_{i-1}) + 2. \end{aligned}$$

Thus, the digitization has absolute excess less than 2.  $\square$

The fact that the absolute excess may exceed 1 results from the min appearing in the definition of  $D_j$ . This seems to be an inherent consequence of the constraint that the digitization be overlapping and the locality exploited by the algorithm.

The running time of the algorithm follows from Claims 3.1 and 3.3 together with a few additional observations. By Claim 3.1, we can find the digitization of a rectangle, provided that the number of points in  $G_i$  is not too large. We can ignore all the vertices of the decomposition, except for those that appear within the set of unit squares that cover the rectangle, since the remaining vertices cannot affect the digitization here. The vertices to be considered will consist of the four corners of the rectangle, plus any other vertices along the horizontal edges of the rectangle. If the decomposition is generated by the algorithm presented in § 2, the widths of adjacent rectangles differ by at most a factor of  $\frac{1}{2}$ , from which it follows that the number of such vertices is never greater than 2. From this observation we have

CLAIM 3.4. *When the algorithm is applied to the  $n$ -row and  $n$ -column decompositions generated by the algorithm of § 2 and if  $p \leq AB$ , then we have the following:*

- (i) *The region containing a given lattice square can be determined in  $O(1)$  time.*
- (ii) *The boundary of a digitized region can be computed in  $O(1)$  time.*

**4. Further remarks.** We have given a simple algorithm for decomposing a rectangle into rectangles of equal area whose maximum perimeter is minimized. We have shown that this algorithm is optimal over the more general category of decompositions into pseudorectangles. We have also given an approximate solution to the discrete problem of partitioning grid squares into sets of equal size so that the maximum pseudoperimeter (sum of projections) is minimized.

There are a number of open questions remaining. In § 2, we showed that our decomposition is optimal over all decompositions into pseudorectangles. Is it true that

the decomposition is optimal even over all measurable, possibly disconnected, regions? The remark following Lemma 2.5 states that the algorithm is optimal (with respect to pseudoperimeter) for decomposition into arbitrary measurable sets, for certain input values. Also, the question of solving the rectangle decomposition problem in higher dimensions is open.

There is a wide class of similar partitioning problems that are related to the problems considered here. For example, given an  $A \times B$  rectangle  $R$  and a set of positive real numbers  $a_1, a_2, \dots, a_p$ , where  $\sum_i a_i = AB$ , decompose the rectangles into rectangles of area  $a_i$ , so that the maximum eccentricity (ratio of a rectangle's longer to shorter side) is minimized. It is also natural to consider alternate cost criteria, such as the sum of perimeters, rather than the maximum perimeter.

**Acknowledgments.** The authors thank Azriel Rosenfeld and Simon Kasif for drawing our attention to the data allocation problem, which was the motivation for this work. Stimulating conversations with Michael Werman are gratefully acknowledged. We would also like to thank the referees for their comments, which significantly improved the presentation.

## THE BOOLEAN HIERARCHY I: STRUCTURAL PROPERTIES\*

JIN-YI CAI†, THOMAS GUNDERMANN‡, JURIS HARTMANIS§, LANE A. HEMACHANDRA¶,  
VIVIAN SEWELSON<sup>1</sup>, KLAUS WAGNER<sup>2</sup>, AND GERD WECHSUNG‡

**Abstract.** In this paper, we study the complexity of sets formed by boolean operations (union, intersection, and complement) on NP sets. These are the sets accepted by trees of hardware with NP predicates as leaves, and together these form the boolean hierarchy.

We present many results about the structure of the boolean hierarchy: separation and immunity results, natural complete languages, and structural asymmetries between complementary classes.

We show that in some relativized worlds the boolean hierarchy is infinite, and that for every  $k$  there is a relativized world in which the boolean hierarchy extends exactly  $k$  levels. We prove natural languages, variations of VERTEX COVER, complete for the various levels of the boolean hierarchy. We show the following structural asymmetry: though no set in the boolean hierarchy is  $D^P$ -immune, there is a relativized world in which the boolean hierarchy contains  $\text{co}D^P$ -immune sets.

Thus, this paper explores the structural properties of the boolean hierarchy. A companion paper [J. Cai et al., *SIAM J. Comput.* 18 (1989), to appear] uses the boolean hierarchy to extend known results on small circuits [R. Karp and R. Lipton, *Proc. 12th Annual Symposium on the Theory of Computation*, 1980, pp. 302–309], sparse sets in NP-P [J. Hartmanis, N. Immerman, and V. Sewelson, *Proc. 15th Annual Symposium on the Theory of Computation*, 1983, pp. 382–391], and counting classes [A. Blass and Y. Gurevich, *Inform. and Control*, 55 (1982), pp. 80–88].

### 1. Introduction and overview of results.

**1.1. Introduction.** The class NP has long been central to computational complexity theory.  $D^P$ , the closure of  $\text{NP} \cup \text{coNP}$  under intersections, has recently been intensively studied [PY82], [PW85], [CM85]. In this paper, we study the natural completion of such structures—the closure of NP under boolean operations.

This closure, the boolean hierarchy (BH), has a clear “physical” interpretation. The sets in the boolean hierarchy are exactly those representable by *hardware over NP*. Each boolean hierarchy language is accepted by a hardware tree connecting NP machines (Fig. 1).

Each predicate is an NP predicate.

FIG. 1. Hardware over NP.

We present many results about the boolean hierarchy: separations and immunity results, natural complete languages, and structural asymmetries between complementary classes. Throughout, we emphasize the structure of the boolean hierarchy and its relationship to more familiar classes.

The boolean hierarchy appears in passing in many papers [PZ82], [R85], and was defined explicitly by Wagner and Wechsung [W85a]. Early results noted the location of the boolean hierarchy, i.e.,  $BH \subseteq P^{\#P}$  (in fact, a single call to a  $\#P$  oracle suffices), due to Papadimitriou and Zachos [PZ82] and  $BH \subseteq PP$ , due to Russo [R85]. This paper broadly investigates the structure of the boolean hierarchy itself. Related work of Köbler, Schöning, and Wagner [KSW86] explores the connection between the boolean hierarchy and sets that bounded truth-table reduce to SAT.

The boolean hierarchy has played a crucial role in the study of terseness and bounded query classes [AG87]. An important recent result is Kadin's proof that if the boolean hierarchy collapses then the polynomial hierarchy collapses [K87a]. This provides evidence that levels of the boolean hierarchy may be distinct.

**1.2. Definitions.** In § 2 we define the levels of the boolean hierarchy (Fig. 2). Each level of the boolean hierarchy consists of sets represented by a certain fixed structure of boolean operators on NP sets:

$$\begin{aligned}
 NP(0) &= P, \\
 NP(2i+1) &= \{L_A \cup L_B \mid L_A \in NP(2i), L_B \in NP\}, \\
 NP(2i+2) &= \{L_A \cap \overline{L_B} \mid L_A \in NP(2i+1), L_B \in NP\}, \\
 BH &= \bigcup_{i \geq 0} NP(i), \\
 coNP(i) &= \{S \mid \overline{S} \in NP(i)\}.
 \end{aligned}$$

For example,

$$NP(1) = NP, \quad NP(2) = D^P = \{L_1 \cap \overline{L_2} \mid L_1, L_2 \in NP\},$$

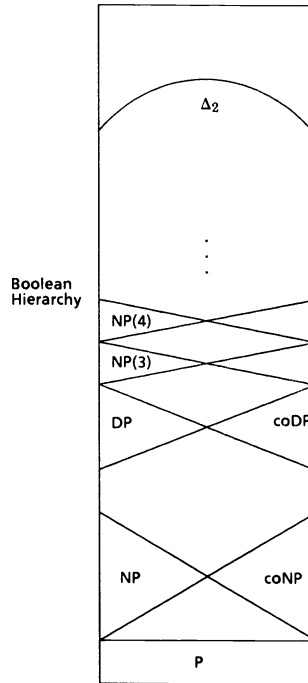

FIG. 2. Complexity hierarchies.

$$NP(3) = \{(L_1 \cap \overline{L_2}) \cup L_3 \mid L_1, L_2, L_3 \in NP\},$$

and

$$NP(4) = \{((L_1 \cap \overline{L_2}) \cup L_3) \cap \overline{L_4} \mid L_1, L_2, L_3, L_4 \in NP\}.$$

Sets in the boolean hierarchy have normal forms. Each can be written as a finite union of  $D^P$  sets. Indeed, the ubiquitous boolean hierarchy has many characterizations.

LEMMA. *The following are equivalent:*

- (1)  $T \in BH$ .
- (2)  $T$  is a finite union of  $D^P$  sets.
- (3)  $T$  is a finite intersection of  $coD^P$  sets.
- (4)  $T$  is in the boolean closure of  $NP$ .
- (5)  $T \equiv_{\text{bounded truth-table}}^P SAT$ .

**1.3. Relativized separations of the boolean hierarchy.** In § 3 we explore the relativized structure of the boolean hierarchy and present strong separation results. We show relativized worlds in which the boolean hierarchy is infinite. By comparison, oracles making the polynomial hierarchy infinite (see Yao [Y85]) are indirect, quite involved, and took many years to discover.

It follows from the relativizations of § 3 that  $BH$  is a natural complexity class that may lack many-one complete languages. Indeed, the boolean hierarchy in relativized worlds distinguishes between the power of many-one and bounded truth-table reducibilities; though the boolean hierarchy lacks many-one complete languages in some relativizations, it always has bounded truth-table complete sets.

To prove our infinite separation of the boolean hierarchy, we introduce the “sawing” technique. This method forms the basis of all the relativized results in the

boolean hierarchy of [CGII]. This technique places successively more stringent requirements on oracle extensions, while seeking to *force* a desired behavior.

Indeed, we can prove probabilistic separations. A well-known result of Bennett and Gill shows that  $P^A \neq NP^A$  with probability one (over randomly chosen  $A$ ) [BG81]. We can show that the boolean hierarchy is infinite with probability 1 [C86].

Heller's proof of Theorem 2 in [H84] shows that with appropriate relativization the polynomial hierarchy can be collapsed to  $D^P$  while separating NP from coNP. Recently, Ko [K87b] showed that for every  $k$  there is an oracle for which the polynomial hierarchy extends exactly  $k$  levels. For each  $k$ , we display worlds where the boolean hierarchy extends exactly  $k$  levels, with PSPACE collapsing to the  $k+1$ st level. In such worlds, understanding the boolean hierarchy is a prerequisite to understanding the structure of standard feasibly computable complexity classes, as the structure of the polynomial hierarchy degenerates exactly in the boolean hierarchy.

**THEOREM.** (1) *There exists recursive  $B$ , for all  $i \geq 1$ ,  $[NP^B(i) \neq NP^B(i+1)]$ .*

(2) *For all  $i \geq 0$ , there exists recursive  $B$   $[NP^B(1) \neq NP^B(2) \neq \dots \neq NP^B(i) \neq NP^B(i+1) = PSPACE^B]$ .*

**COROLLARY.** *Though the boolean hierarchy always has Turing (and even bounded truth-table) complete sets, there is an oracle  $B$  for which  $BH^B$  has no many-one complete sets.*

*Proof of the corollary.* SAT is bounded truth-table complete for the boolean hierarchy. If the boolean hierarchy has a many-one complete set, it is finite, i.e., it collapses to the level in which the complete set resides. Thus the oracle  $B$  from (1) of the above theorem guarantees that  $BH^B$  has no many-one complete sets.  $\square$

Since the method of (1) of the above theorem is central to the work of this paper, we now give a quick, informal proof. A much more detailed proof of a stronger version of this theorem appears as Theorem 3.1.1. However, the interested reader is urged to first peruse the following short proof.

*Proof of (1) of the theorem.* In the standard way, if we can separate a generic level of the boolean hierarchy by diagonalization, then by interleaving diagonalizations we can construct a single oracle, simultaneously separating the entire hierarchy. For concreteness, we show an oracle  $B$  so  $NP^B(17) \neq coNP^B(17)$ . In particular, we show that  $L_B$ , defined below, is in  $coNP^B(17)$ - $NP^B(17)$ :

$$L_B = \{0^{17j} | (\forall x, |x| = 17j)[x \notin B] \text{ AND} \\ \{(\exists x, |x| = 17j + 1)[x \in B] \text{ OR} \\ \{(\forall x, |x| = 17j + 2)[x \notin B] \text{ AND} \\ \{ \dots \text{ OR} \\ \{(\forall x, |x| = 17j + 16)[x \notin B] \} \dots \} \} \\ \}.$$

*Stage 0.* Let  $B_0 = \emptyset$ . We will have  $B = \cup B_i$ .

*Stage  $j$ .* Let  $H$  be the  $j$ th NP(17) machine. It is composed of nine NP machines ( $N_i$ 's) and eight coNP machines ( $A_j$ 's) so that (for simplicity, we use low numbers for the machines instead of indexing them):

$$L(H^B) =_{\text{def}} L(N_1^B) \cup \{L(A_1^B) \cap \{L(N_2^B) \cup \{ \dots \cup \{L(A_8^B) \cap L(N_9^B)\} \dots \}\}.$$

Without loss of generality each of the machines runs at most  $n^j + j$  steps. Recall that a coNP machine is a nondeterministic machine that rejects if and only if at least one

of its nondeterministic paths rejects. Choose  $w_j$  so large that we have the following: (1) no string of length  $\cong w_j$  has ever been queried or set before; (2)  $w_j > 18w_{j-1}$ ; and (3)  $17((w_j)^j + j) \ll 2^{w_j}$ . We now use our method of successive restriction (the “sawing” technique); we see-saw between pressuring NP machines to accept and pressuring coNP machines to reject. Throughout, we obey the constraint that in stage  $j$  we never add to our oracle any string of length less than  $w_j$ .

*Case 1.* There exists an extension  $C$  of  $B_{j-1}$  so that  $N_1^C(0^{17w_j})$  accepts (otherwise, go to Case 2). Freeze into  $B_j$  an accepting path of the machine; thus we know that  $H^B(0^{17w_j})$  accepts. Add an untouched string of length  $17w_j$  to  $B_j$ . Now we have ensured that  $0^{17w_j} \in L(H^B) - L_B$ . Thus, machine  $H$  fails to accept  $L_B$ .

*Case 2k* ( $1 \leq k \leq 8$ ). There exists an extension  $C$  of  $B_{j-1}$  so that  $C$  contains no length  $17w_j, \dots, 17w_j + 2k - 2$  strings and  $A_k^C(0^{17w_j})$  rejects (otherwise, go to case  $2k + 1$ ). Freeze into  $B_j$  a rejecting path of the machine; thus we know that  $H^B(0^{17w_j})$  rejects. Add an untouched string of length  $17w_j + 2k - 1$  to  $B_j$ . Now we have ensured that  $0^{17w_j} \in L_B - L(H^B)$ . Thus, machine  $H$  fails to accept  $L_B$ .

*Case 2k + 1* ( $1 \leq k \leq 8$ ). There exists an extension  $C$  of  $B_{j-1}$  so that  $C$  contains no length  $17w_j, 17w_j + 1, \dots, 17w_j + 2k - 1$  strings and  $N_{k+1}^C(0^{17w_j})$  accepts (otherwise, go to case  $2k + 2$ ). Freeze into  $B_j$  an accepting path of the machine; thus we know that  $H^B(0^{17w_j})$  accepts. Add an untouched string of length  $17w_j + 2k$  to  $B_j$ . Now we have ensured that  $0^{17w_j} \in L(H^B) - L_B$ . Thus, machine  $H$  fails to accept  $L_B$ .

*Case 18.* If we have made it to this case, we know that for any extension  $C$  of  $B_{j-1}$  that has no length  $17w_j, 17w_j + 1, \dots, 17w_j + 15$  strings,  $L(H^C)$  rejects  $0^{17w_j}$ . Let  $B_j := B_{j-1}$ , which safely avoids strings for the forbidden lengths. Thus  $0^{17w_j} \in L_B - L(H^B)$ .

In each case, we have seen that  $L(H^B) \neq L_B$ . Thus, by the preceding discussion, we are done.  $\square$

**1.4. Immunity results.** In § 4 we study the immunity structure of the boolean hierarchy. With appropriate relativization, we display a  $\Delta_2$  set that is BH-immune. Also, no set in the boolean hierarchy can be either NP bi-immune or coNP bi-immune. We show that no boolean hierarchy set is NP (2)-immune, yet there are worlds where the boolean hierarchy has a coNP (2)-immune set. Thus NP (2) and coNP (2) are structurally asymmetric. Such asymmetry between complementary classes is rare in the realm of feasible computations. The most notable previous example is the asymmetry between NP and coNP of Hartmanis, Immerman, and Sewelson [HIS83], which is extended in a companion paper [CGII].

**THEOREM.** *There is a recursive oracle  $A$  for which  $\Delta_2^A$  has a BH<sup>A</sup>-immune set.*

**THEOREM.** (1) *No set in the boolean hierarchy is NP bi-immune or coNP bi-immune.*

(2) *No set in the boolean hierarchy is NP (2)-immune, yet there is a relativized world in which NP (2) has coNP (2)-immune sets.*

**1.5. Complete languages for the boolean hierarchy.** Though certain complexity classes may lack complete languages [S82], [HI85], [HH86b], most standard classes have complete languages. Complete languages mark the upper limit of the complexity of a class, and are useful in proving new languages complete for the class [GJ79].

In § 5 we present natural complete languages for the levels of the boolean hierarchy. Related work on complete languages appears in [W86]. We show variations of SAT that provide canonical complete languages for the levels of the boolean hierarchy. For example,  $SAT(3) = \{\langle f_1, f_2, f_3 \rangle \mid (f_1 \in SAT \wedge f_2 \in UNSAT) \vee f_3 \in SAT\}$  is easily seen to be NP (3)-complete, and we can similarly define  $SAT(k)$ , complete for NP ( $k$ ), by mimicking the definitions of § 2. By reductions from these languages, we show many problems

to be complete for the levels of the boolean hierarchy. For example, the following theorem shows the completeness of versions of graph colorability.

**THEOREM.** COLORABILITY ( $k$ ) is NP ( $k$ )-complete, where

$$\text{COLORABILITY } (k) = \{G \mid \chi(G) \text{ is odd} \wedge 3k \leq \chi(G) \leq 4k\}, \quad k \text{ even}$$

$$\text{COLORABILITY } (k) = \{G \mid (\chi(G) \text{ is odd} \wedge 3k \leq \chi(G) \leq 4k) \vee \chi(G) < 3k\}, \quad k \text{ odd.}$$

**2. Definitions and representations.**

**2.1. The boolean hierarchy: definitions and algebraic characterizations.** In this section, we make precise the notation of fixing a certain amount of logic hardware over NP.

**DEFINITION 2.1.1.**

**Operator C:**

$$C(L_1) = L_1.$$

$$C(L_1, \dots, L_k) = \begin{cases} C(L_1, \dots, L_{k-1}) \cup L_k & \text{if } k \text{ is odd} \\ C(L_1, \dots, L_{k-1}) \cap \overline{L_k} & \text{if } k \text{ is even} \end{cases} \quad \text{for } k > 1.$$

**Operator D:**

$$D(L_1) = L_1.$$

$$D(L_1, \dots, L_k) = L_1 - D(L_2, \dots, L_k) \quad \text{for } k > 1.$$

**Operator E:**

$$E(L_1) = L_1.$$

$$E(L_1, L_2) = L_1 - L_2.$$

$$E(L_1, \dots, L_k) = \begin{cases} E(L_1, \dots, L_{k-1}) \cup L_k & \text{if } k \text{ is odd} \\ E(L_1, \dots, L_{k-2}) \cup (L_{k-1} - L_k) & \text{if } k \text{ is even} \end{cases} \quad \text{for } k > 2.$$

Thus,  $C(L_1, \dots, L_n)$  represents an alternating sum of the languages

$$(C^*) \quad L_1 - L_2 + L_3 \cdots + (-1)^{n-1} L_n$$

(where the expression is associated to the left, and  $+$ ,  $-$  stand for set theoretic union and difference, respectively). Similarly,  $D(L_1, \dots, L_n)$  represents the nested difference of the languages:

$$(D^*) \quad L_1 - (L_2 - (\dots (L_{n-1} - L_n) \dots)),$$

and  $E$  represents sums of differences of consecutive pairs:

$$(E^*) \quad E(L_1, \dots, L_n) = \begin{cases} (L_1 - L_2) \cup \dots \cup (L_{n-2} - L_{n-1}) \cup L_n & \text{if } n \text{ is odd,} \\ (L_1 - L_2) \cup \dots \cup (L_{n-1} - L_n) & \text{if } n \text{ is even.} \end{cases}$$

We consider the language classes generated by applying  $C$  to a fixed number of NP languages.

**DEFINITION 2.1.2.** For all  $n \geq 1$ , define

$$NP(n) = \{C(L_1, \dots, L_n) \mid L_i \in NP, 1 \leq i \leq n\}.$$

In particular,  $NP(1) = NP$  and  $NP(2) = D^P$ . For any oracle set  $X$ , the relativized version  $NP^X(n)$  is naturally defined.

These normal forms are analogous to normal forms developed by Hausdorff [H14], as noted in [W85a]. For detailed proofs see [H14], [W85a], [CH85].

**THEOREM 2.1.1** [H14], [W85a]. Each of the following classes is precisely  $NP(n)$ :

(1)  $\{C(L_1, \dots, L_n) \mid L_i \in NP, 1 \leq i \leq n\}$ .

(1')  $\{C(L_1, \dots, L_n) \mid L_1 \supseteq \dots \supseteq L_n, L_i \in NP, 1 \leq i \leq n\}$ .

- (2)  $\{\mathbf{D}(L_1, \dots, L_n) \mid L_i \in \text{NP}, 1 \leq i \leq n\}$ .
- (2')  $\{\mathbf{D}(L_1, \dots, L_n) \mid L_1 \supseteq \dots \supseteq L_n, L_i \in \text{NP}, 1 \leq i \leq n\}$ .
- (3)  $\{\mathbf{E}(L_1, \dots, L_n) \mid L_i \in \text{NP}, 1 \leq i \leq n\}$ .
- (3')  $\{\mathbf{E}(L_1, \dots, L_n) \mid L_1 \supseteq \dots \supseteq L_n, L_i \in \text{NP}, 1 \leq i \leq n\}$ .

DEFINITION 2.1.3.  $\text{coNP}(n) = \{\bar{L} \mid L \in \text{NP}(n)\}$ .

If we start from  $\text{coNP}$ , then the following theorem can be proved similarly.

THEOREM 2.1.1' [H14], [W85a]. *The following classes are identical:*

- (1)  $\{\mathbf{C}(L_1, \dots, L_n) \mid L_i \in \text{coNP}, 1 \leq i \leq n\}$ .
- (1')  $\{\mathbf{C}(L_1, \dots, L_n) \mid L_1 \supseteq \dots \supseteq L_n, L_i \in \text{coNP}, 1 \leq i \leq n\}$ .
- (2)  $\{\mathbf{D}(L_1, \dots, L_n) \mid L_i \in \text{coNP}, 1 \leq i \leq n\}$ .
- (2')  $\{\mathbf{D}(L_1, \dots, L_n) \mid L_1 \supseteq \dots \supseteq L_n, L_i \in \text{coNP}, 1 \leq i \leq n\}$ .
- (3)  $\{\mathbf{E}(L_1, \dots, L_n) \mid L_i \in \text{coNP}, 1 \leq i \leq n\}$ .
- (3')  $\{\mathbf{E}(L_1, \dots, L_n) \mid L_1 \supseteq \dots \supseteq L_n, L_i \in \text{coNP}, 1 \leq i \leq n\}$ .

Using Theorem 2.1.1' we can prove the following theorem, which will be useful later. (The proof is left to the reader.)

THEOREM 2.1.2.

$$\{\mathbf{C}(\bar{L}_1, \dots, \bar{L}_n) \mid \bar{L}_i \in \text{coNP}\} = \begin{cases} \text{NP}(n) & \text{if } n \text{ is even,} \\ \text{coNP}(n) & \text{if } n \text{ is odd.} \end{cases}$$

THEOREM 2.1.3 (Weak Hierarchy Theorem). *For every*

$$m < n, \text{NP}(m) \cup \text{coNP}(m) \subseteq \text{NP}(n) \cap \text{coNP}(n).$$

*Proof of Theorem 2.1.3.* Using normal form (3) from Theorem 2.1.1, we get  $\text{NP}(n) \subseteq \text{NP}(n+1)$ , since  $\mathbf{E}(L_1, \dots, L_n) = \mathbf{E}(L_1, \dots, L_n, \emptyset)$ . Using normal form (1), we have  $\mathbf{C}(L_1, \dots, L_n) = \mathbf{C}(\Sigma^*, \bar{L}_1, \bar{L}_2, \dots, \bar{L}_n)$ ; hence  $\text{NP}(n) \subseteq \text{coNP}(n+1)$ . Therefore,  $\text{NP}(n) \subseteq \text{NP}(n+1) \cap \text{coNP}(n+1)$ . Since the right-hand side is closed under complementation, the theorem follows.  $\square$

DEFINITION 2.1.4.  $\text{BH} = \bigcup_{k \geq 1} \text{NP}(k)$ . This defines the *boolean hierarchy*.

THEOREM 2.1.4.  $\text{BH} = \bigcup_{k \geq 1} \{\mathbf{C}(\bar{L}_1, \dots, \bar{L}_n) \mid \bar{L}_i \in \text{coNP}\}$ .

Whether the boolean hierarchy collapses (at some level, or entirely, or not at all) is unknown. We note that  $\text{P} = \text{NP} \Rightarrow \text{P} = \text{BH}$ ; hence a proof that the boolean hierarchy does not collapse entirely would entail  $\text{P} \neq \text{NP}$ . On the other hand, even assuming  $\text{P} \neq \text{NP}$ , a proof that the boolean hierarchy is infinite would still subsume such major open problems as  $\text{D}^{\text{P}} \neq \text{coD}^{\text{P}}$ . Therefore, settling whether the boolean hierarchy is a true hierarchy will be extremely difficult. Kadin [K87a] has shown that if the boolean hierarchy collapses then the polynomial hierarchy collapses, which suggests that the boolean hierarchy may be proper.

Note that  $\text{NP}(k) = \text{coNP}(k)$  implies that  $\text{NP}(k) = \text{BH}$ , using the normal forms. As a final remark, the boolean hierarchy sits between the first and second levels of the polynomial hierarchy, i.e.  $\text{NP} \subseteq \text{BH} \subseteq \text{P}^{\text{SAT}} = \Delta_2^{\text{P}}$ .

OBSERVATION 2.1.1 (Downward Separation). For all  $k \geq 1$ ,

$$\text{NP}(k) = \text{coNP}(k) \Rightarrow \text{NP}(k) = \text{BH}.$$

**2.2. The boolean hierarchy is the boolean closure of NP.** The boolean hierarchy is the boolean closure of NP. To prove this claim, we simply note that any amount of hardware over NP can be reshaped into a finite union of  $\text{D}^{\text{P}}$  sets. Thus two levels of hardware on top of  $\text{NP} \cup \text{coNP}$  are as powerful as  $n$  levels. Though every hardware tree has an equivalent two-level tree, we may need many more gates on the shallow tree.

LEMMA 2.2.1. *If  $S$  is expressible by hardware over NP predicates (i.e., if  $S$  is in the closure of NP with respect to {union, intersection, complement}), then  $S$  is a finite union of  $\text{D}^{\text{P}}$  sets and a finite intersection of  $\text{coD}^{\text{P}}$  sets.*

*Proof of Lemma 2.2.1.* To show  $S$  is the finite union of  $D^P$  sets, rewrite the tree describing  $S$  in disjunctive normal form over the predicates and their negations. We get the two-level logic tree of (Fig. 3), the leaves of which are NP and coNP predicates. Since any intersection of sets from  $NP \cup coNP$  is in  $D^P$ , we can write  $S$  as the finite union of  $D^P$  sets. Similarly, using conjunctive normal form,  $S$  is the finite intersection of  $coD^P$  sets.  $\square$

**THEOREM 2.2.1.** *The boolean hierarchy is the closure of NP under boolean operations.*

*Proof of Theorem 2.2.1.* Clearly every set in the boolean hierarchy is in the boolean closure of NP. By our lemma, every set  $S$  in the boolean closure of NP is the finite union of  $D^P$  sets. Thus for some  $k$  and  $\{L_i \in NP\}$ ,  $S$  is  $E(L_1, \dots, L_{2k})$ . Thus  $S$  is in  $NP(2k)$  by Theorem 2.1.1, so  $S$  is in the boolean hierarchy.  $\square$

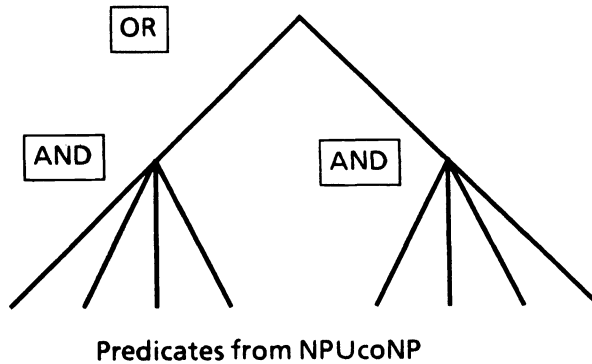

FIG. 3. Hardware tree of depth two.

The above theorems are NP versions of general theorems of Hausdorff about boolean closures of set rings [H14], [W85a].

We can give another characterization of our boolean hierarchy. The bounded truth-table reducibility of recursion theory has the following analogue among polynomial time computable classes [Y83]:

$A \leq_{btt}^P B \Leftrightarrow$  there are polynomial time transducers  $M_1$  and  $M_2$  and an integer  $n$  so that for every  $x$ ,  $M_1(x)$  prints a finite set of at most  $n$  elements and  $M_2(x)$  prints a finite collection of finite sets, such that  $x \in A \Leftrightarrow B \cap M_1(x)$  is present in  $M_2(x)$ .

We have the following theorem, which states that the boolean hierarchy is exactly the sets that are bounded truth-table reducible to SAT.

**THEOREM 2.2.2.**  $BH = \{T \mid T \leq_{btt}^P SAT\}$ .

*Proof of Theorem 2.2.2.*  $\Rightarrow (BH \subseteq \{T \mid T \leq_{btt}^P SAT\})$ : Let  $A \in BH$ , then there are sets  $L_1 \supseteq L_2 \supseteq \dots \supseteq L_k$  so that  $A = C(L_1, L_2, \dots, L_k)$ , where  $L_i \in NP$ . Let  $f_i$  be a many-one  $p$ -time reduction from  $L_i$  to SAT, a complete language for NP. Now for all  $x$ ,  $M_1(x)$  prints  $\{f_1(x), \dots, f_k(x)\}$  and  $M_2(x)$  prints the following sets  $\{f_1(x), \dots, f_{2i-1}(x)\}$ , where  $2i - 1 \leq k$ .

$\Leftarrow (BH \supseteq \{T \mid T \leq_{btt}^P SAT\})$ : Let  $A \leq_{btt}^P SAT$  via  $M_1$  and  $M_2$ . Without loss of generality,  $M_1(x)$  always prints  $k$  element sets. Let  $M_1(x) = \{f_1(x), \dots, f_k(x)\}$ , and  $L_i = \{x \mid f_i(x) \in SAT\}$ . Then  $L_i \in NP$ . Now it is easy to construct a union of  $2^k$  many  $D^P$  sets that equals  $A$ , using the definition of  $A \leq_{btt}^P SAT$ .  $\square$

**3. Separations.** Is the boolean hierarchy infinite or finite? If it is finite, how many levels does it extend before it collapses? This section shows that all reasonable answers

to these questions can be obtained in appropriately relativized worlds. In § 3.1 we give a detailed relativization that makes the boolean hierarchy infinite. In § 3.2 we show that, for each  $k$ , the boolean hierarchy can extend exactly  $k$  levels, with everything up to PSPACE collapsing into the  $(k + 1)$ st level.

**3.1. An infinite relativized boolean hierarchy.** This section proves the following strong separation theorem. As proven in § 1.3, a corollary of this theorem is that in some relativized worlds the boolean hierarchy does not have many-one complete sets—the fact that it *does* have bounded truth-table complete sets notwithstanding. The following proof combines the sawing argument of § 1.3 with other relativized separation techniques. Readers not interested in the details of oracle constructions may skip to § 3.2.

**THEOREM 3.1.1.** *There exists a recursive oracle  $X$  separating the entire boolean hierarchy. Specifically,*

$$\begin{aligned}
 & \subset \text{NP}^X \subset \\
 \text{P}^X \subset \text{NP}^X \cap \text{coNP}^X & \neq \text{NP}^X \cup \text{coNP}^X \subset \text{NP}^X(2) \cap \text{coNP}^X(2) \cdots \\
 & \subset \text{coNP}^X \subset \\
 & \subset \text{NP}^X(k) \subset \\
 \cdots \subset \text{NP}^X(k) \cap \text{coNP}^X(k) & \neq \text{NP}^X(k) \cup \text{coNP}^X(k) \\
 & \subset \text{coNP}^X(k) \subset \\
 & \subset \text{NP}^X(k+1) \cap \text{coNP}^X(k+1) \cdots .
 \end{aligned}$$

We first describe the strategies for  $X$  to achieve each of these separations.

(1)  $\text{P}^X \neq \text{NP}^X \cap \text{coNP}^X$  is done in the usual way: Allocate two “segments” of strings with exponentially many for each  $n$ . Diagonalize each  $p$ -time deterministic machine over a tally set  $L_1^\cap$ , where “ $1^n \in L_1^\cap$ ” is determined by the existence of some strings in the appropriate “segment.” To insure that  $L_1^\cap \in \text{NP}^X \cap \text{coNP}^X$ , we impose certain global constraints on  $X$ :  $X$  will have strings from exactly one segment of the two allocated, corresponding to any particular  $n$ . The oracle set  $X$  is constructed in stages  $\{X_s\}$ ; an extension of  $X_s$  is termed “admissible” only if it satisfies all these global constraints. (There are other constraints to be discussed later.)

To diagonalize, we pick  $n$  sufficiently large, and fix an extension  $\hat{X}_s$  of  $X_s$  that is “admissible” except for length  $n$ , where  $\hat{X}_s$  has no strings from either segments. Run the next  $p$ -time machine  $P_i$  on  $1^n$ , using  $\hat{X}_s$  to answer queries, and “freeze” to  $\bar{X}$  any string that is queried negatively. Since at most polynomially many strings are “frozen” when  $P_i$  halts, we may, according to whether  $P_i$  accepts or rejects  $1^n$ , choose the appropriate segment to enumerate a string (corresponding to length  $n$ ) into  $X$ . Then extend  $X_s$  according to  $\hat{X}_s$  so that, the computation of  $P_i$  on  $1^n$  is preserved. Thus, the final  $X$  will be “admissible” and  $\text{P}^X \neq \text{NP}^X \cap \text{coNP}^X$ .

The other requirements are of the following two types:

$$\text{NP}^X(k) \neq \text{coNP}^X(k), \quad \text{NP}^X(k) \cup \text{coNP}^X(k) \neq \text{NP}^X(k+1) \cap \text{coNP}^X(k+1)$$

for all  $k \geq 1$ .

Note that this is enough since

$$\begin{aligned}
 \text{NP}^X(k) \neq \text{coNP}^X(k) & \Rightarrow \text{NP}^X(k) \cap \text{coNP}^X(k) \subset \text{NP}^X(k) \subset \\
 & \subset \text{coNP}^X(k) \subset \\
 & \text{NP}^X(k) \cup \text{coNP}^X(k).
 \end{aligned}$$

Furthermore, for requirements  $\text{NP}^X(k) \neq \text{coNP}^X(k)$  it is enough to satisfy for all odd  $k$ .

(2) Strategies to insure  $NP^X(k) \neq coNP^X(k)$  for odd  $k$ . We will illustrate this with the case  $k=3$ . Let us fix three separate “segments”  $S_i$ ,  $1 \leq i \leq 3$ , each having an  $n$ th “block”  $S_i^n$  with exponentially many strings for every  $n$ . Define

$$L_3 = \{1^n \mid (\exists s_1 \wedge \neg \exists s_2) \vee \exists s_3\},$$

where “ $\exists s_i$ ” stands for  $\exists s_i \in X \cap S_i^n$ . Clearly  $L_3 \in NP^X(3)$ . We want to make sure that for each triple  $\langle N_i, N_j, N_k \rangle$ , the  $coNP^X(3)$  language  $W_3 = (L(N_i^X) \cup L(N_j^X)) \cap L(N_k^X)$  is not  $L_3$ ; hence  $L_3 \notin coNP^X(3)$ .

The following generic step embodies a “sawing” argument that is the key to our separation results, and can be readily generalized to the  $k > 3$  case.

Pick  $n$  sufficiently large so that the  $S_i^n$ ’s are all “clean,” in the sense that no string from these blocks has been committed to either  $X$  or  $\bar{X}$ .

*Case 1.* If  $N_k$  accepts  $1^n$  under some “admissible” extension of the current  $X_s$ , then we “freeze” an accepting computation and extend  $X_s$  “admissibly” (“freeze” those used negatively in the computation to  $\bar{X}$ ). Then enumerate an “unfrozen”  $s_3 \in S_3^n$  into  $X$ , (if there is none in  $X$  so far). We will see that there will always be some  $s_3$  “unfrozen,” if  $n$  is large, and  $s_3 \in X$  does not violate any global constraints. Thus  $1^n \notin W_3$  but  $1^n \in L_3$ .

*Case 2.*  $N_k$  never accepts  $1^n$  under any “admissible” extension. We will say an extension is *without*  $T$  if  $X \cap T^n = \emptyset$ . Consider all “admissible” extensions without  $S_3$  (i.e., extensions in which  $X \cap S_3^n = \emptyset$ ).

*Case 2.1.* If  $N_j$  accepts  $1^n$  under some such extension, then “freeze” an accepting computation and extend  $X_s$  “admissibly” without  $S_3$ . Enumerate an “unfrozen”  $s_2 \in S_2^n$  into  $X$  (if none exists in  $X$  so far). Thus  $1^n \in W_3$ , but  $1^n \notin L_3$ .

*Case 2.2.*  $N_j$  never accepts  $1^n$  under any admissible “without  $S_3$ ” extension. We consider all “admissible” extensions that are “without  $S_3$  and without  $S_2$ .”

*Case 2.2.1.* If  $N_i$  accepts  $1^n$  under one of such extension, “freeze” it. Extend  $X_s$  “admissibly” without  $S_3, S_2$ ; put an “unfrozen”  $s_1 \in S_1^n$  in  $X$ . Thus  $1^n \notin W_3$  but  $1^n \in L_3$ .

*Case 2.2.2.*  $N_i$  never accepts  $1^n$  under any “admissible without  $S_3, S_2$ ” extension. Then extend  $X_s$  “admissibly” without  $S_3, S_2, S_1$ . Thus  $1^n \in W_3$ , but  $1^n \notin L_3$ .

Hence, the final  $X$  will be admissible and  $NP^X(3) \neq coNP^X(3)$ .

(3) Strategies for  $NP^X(k) \cup coNP^X(k) \neq NP^X(k+1) \cap coNP^X(k+1)$ , for all  $k \geq 1$ .

We illustrate with  $k=2$ . Fix six separate “segments”  $S_i, S'_i, i=1, 2, 3$  as before. Denote  $S_i^n, S'_i^n$  their  $n$ th blocks. We impose the following global constraints on  $X$ :

For each  $n$ , either

(I) 
$$[(\exists s_1 \wedge \neg \exists s_2) \vee \exists s_3] \wedge [(\neg \exists s'_1 \vee \exists s'_2) \wedge \neg \exists s'_3]$$

or

(II) 
$$[(\neg \exists s_1 \vee \exists s_2) \wedge \neg \exists s_3] \wedge [(\exists s'_1 \wedge \neg \exists s'_2) \vee \exists s'_3]$$

where “ $\exists s_i$ ” “ $\exists s'_i$ ” are shorthands as before. For example, “ $\exists s_i$ ” means “ $\exists s_i \in S_i^n \cap X$ .”

Define

$$L_3^\cap = \{1^n \mid (\exists s_1 \wedge \neg \exists s_2) \vee \exists s_3\}.$$

Clearly, if  $X$  satisfies the above constraints, then  $L_3^\cap \in NP^X(3) \cap coNP^X(3)$ .

We need to insure for each tuple  $\langle N_i, N_j \rangle$  that neither  $L(N_i^X) \cap \overline{L(N_j^X)}$  nor  $L(N_i^X) \cup L(N_j^X)$  equals  $L_3^\cap$ , hence  $L_3^\cap \notin \text{NP}^X(2) \cup \text{coNP}^X(2)$ .

To insure this, we use the following variant of the “sawing” argument discussed before.

*Step (1).* For  $\overline{L(N_i^X)} \cup L(N_j^X)$ . Pick an  $n$  large enough so that the corresponding “blocks”  $S_i^n, S_i'^n$  are all “clean.”

Temporarily ignore global constraints (I), (II) for this particular  $n$ ; consider all “admissible” extensions of  $X_s$  without  $S_3, S_3'$  (that is, for which  $X \cap S_3^n = \emptyset$  and  $X \cap S_3'^n = \emptyset$ ).

*Case 1.* If  $N_j$  accepts  $1^n$  under such an extension, then we “freeze” an accepting computation. Extend  $X_s$  “admissibly,” and for this  $n$ , add an “unfrozen” member of  $S_2^n$  and an “unfrozen” member of  $S_3'^n$  to  $X$ , thus satisfying (II); therefore  $1^n \in L(N_j^X)$ , but  $1^n \notin L_3^\cap$ .

*Case 2.*  $N_j$  never accepts  $1^n$  under any such extension. Consider all “admissible” (again ignore (I), (II) for this  $n$ ) extensions of  $X_s$  without  $S_3, S_3', S_2, S_2'$ .

*Case 2.1.* If  $N_i$  accepts  $1^n$  for such an extension, then “freeze” one accepting computation and extend  $X_s$  “admissibly.” For this  $n$ , add to  $X$  an  $s_1$  and an  $s_2'$  “unfrozen” from the appropriate blocks  $S_1^n$  and  $S_2'^n$ , respectively. Thus satisfy (I), and  $1^n \notin \overline{L(N_i^X)} \cup L(N_j^X)$ , but  $1^n \in L_3^\cap$ .

*Case 2.2.*  $N_i$  never accepts  $1^n$  under such extensions. Then it rejects when we extend  $X_s$  “admissibly” without  $S_1$  and with some  $s_1' \in S_1'^n$ , and “without  $S_3, S_3', S_2, S_2'$ .” Then (II) is satisfied. Now  $1^n \in L(N_i^X)$ , but  $1^n \notin L_3^\cap$ .

This completes the diagonalization of Step (1).

*Step (2)* is similar, except we do it for  $L(N_i^X) \cap \overline{L(N_j^X)}$ .

A formal proof follows.

*Proof of Theorem 3.1.1.* We use a standard pairing function  $\langle \cdot, \cdot \rangle$ , for which  $|\langle x, y \rangle| \sim |x| + |y|$ . When convenient, we identify binary string  $x$  with integer  $1x$ . Define  $\langle a, b, c \rangle = \langle a, \langle b, c \rangle \rangle$ , etc.

Let  $\{P_i\}$  ( $\{N_i\}$ ) be standard enumerations of deterministic (nondeterministic) TMs with polynomial time clocks  $p_i$ .

Define  $S_{i,j,k}^n = \{\langle i, j, k, x \rangle \mid |x| = n\}$ . Note that  $S_{i,j,k}^n \cap S_{i',j',k'}^n = \emptyset$ , unless they are identical. Define propositions  $p_{i,j}^n \equiv S_{i,j,1}^n \cap X \neq \emptyset$ ,  $q_{i,j}^n \equiv S_{i,j,2}^n \cap X \neq \emptyset$ . We also use the operator  $C$  on propositions in a natural way.

FACT.  $\{1^n \mid C(q_1, \dots, q_t)\} \in \text{NP}(t)$ , provided  $\{1^n \mid q_s\} \in \text{NP}$ ,  $1 \leq s \leq t$ .

Define  $L_k = \{1^n \mid C(q_{k,1}^n, \dots, q_{k,k}^n)\}$  for odd  $k$ . Then  $L_k \in \text{NP}^X(k)$ .

We will impose the following global constraints  $GC_{k,n}$  on  $X$ :

$$(*) \quad C(p_{k,1}^n, \dots, p_{k,k}^n) \Leftrightarrow \neg C(p_{k,k+1}^n, \dots, p_{k,2k}^n).$$

Define  $L_k^\cap = \{1^n \mid C(p_{k,1}^n, \dots, p_{k,k}^n)\}$ .

FACT. If  $X$  satisfies  $GC_{k,n}$ , then  $L_k^\cap \in \text{NP}^X(k) \cap \text{coNP}^X(k)$ .

We have the following requirements (relativized to  $X$ ):

$$R_{\langle 0, i \rangle}: L(P_i) \neq L_1^\cap, \quad \text{for } k \geq 1,$$

$$R_{\langle 2k-1, i \rangle}: \overline{C(L(N_{i_1}), \dots, L(N_{i_{2k-1}}))} \neq L_{2k-1}, \quad \text{where } i = \langle i_1, \dots, i_{2k-1} \rangle,$$

$$R_{\langle 2k, i \rangle}: C(L(N_{i_1}), \dots, L(N_{i_k})) \neq L_{k+1}^\cap \quad \text{and} \quad \overline{C(L(N_{i_1}), \dots, L(N_{i_k}))} \neq L_{k+1}^\cap,$$

where  $i = \langle i_1, \dots, i_k \rangle$ .

Each  $S^n_{i,j,k}$  is called a “block.” Of importance to us are the blocks concerned in  $p^n_{i,j}$  and  $q^n_{i,j}$ . Specifically,  $S^n_{i,j,1}$  for  $1 \leq j \leq 2i$  and  $S^n_{i,j,2}$  for odd  $i$ ,  $1 \leq j \leq i$ . We call  $\cup_{j=1}^{2k} S^n_{k,j,1}$  and  $\cup_{j=1}^k S^n_{k,j,2}$  “large blocks.” Moreover, the former is called a “global constraint block,”  $GCB_{k,n}$ .

We further suppose a well-ordering  $\ll$  (of type  $\omega$ ) is defined, which “holds together” each block and large block (i.e., it induces a well-ordering on the block quotient space). This can be easily accomplished, e.g., imagine all integers on a line, then bring everything in  $S^n_{i,j,k}$  to just to the right of its leftmost member. That is, we will say that  $x_1 \ll x_2$  if (1) the smallest integer in the block to which  $x_1$  belongs is less than the smallest integer in the block to which  $x_2$  belongs, or (2)  $x_1$  and  $x_2$  are in the same block and  $x_1 < x_2$ . Also, do this for the large blocks.

$X$  is constructed in stages:  $X = \cup X_s$ . At the end of stage  $s$ , we have an initial (under  $\ll$ ) segment  $X_s$  of  $X$ . Membership in  $X$  or  $\bar{X}$  of any string in a block or a large block is determined in a single stage. If we define  $\text{block}(X_s)$  = the set of blocks on which  $X$  has been defined by stage  $s$ , then  $\text{block}(X_s)$  is an initial segment in the block quotient space and

$$(*) \quad X_s \cap \cup \text{block}(X_s) = X \cap \cup \text{block}(X_s).$$

An *admissible extension* of  $X_s$  is a set with  $X_s$  as initial segment (condition  $(*)$ ) and satisfies all  $GCB_{k,n}$ . We will maintain the condition that for each  $GCB_{k,n}$ , if  $GCB_{k,n} \cap \cup \text{block}(X_s) \neq \emptyset$ , then  $GCB_{k,n}$  is satisfied by  $X_s$ ; thus such admissible extensions always exist.

We say a block  $B$  is *clean* if  $B \cap \cup \text{block}(X_s) = \emptyset$ .

CONSTRUCTION OF  $X$ .

$$X_0 = \emptyset \quad s = 0; \quad n_0 = 0.$$

*Stage  $s + 1 = \langle 0, i \rangle + 1$ .* We satisfy  $R_{\langle 0, i \rangle}$ .

Let  $n_{s+1} = \min \{n \mid n > n_s \wedge GCB_{1,n} \text{ is clean} \wedge 2^n > p_i(n)\}$ . (Recall that  $p_i(\cdot)$  is the run time of deterministic polynomial time machine  $P_i$ .)

Take an extension  $\hat{X}_s$  of  $X_s$  satisfying  $\hat{X}_s \cap GCB_{1,n_{s+1}} = \emptyset$  and otherwise admissible. Run  $P_i$  on  $1^{n_{s+1}}$  using  $\hat{X}_s$ . “Freeze” into  $\bar{X}$  all strings not in  $\hat{X}_s$  that are queried by  $P_i$ . According to whether  $P_i(1^{n_{s+1}})$  accepts or rejects, enumerate an unfrozen  $x$  from  $S^n_{1,2,1}$  or  $S^n_{1,1,1}$ , respectively, into  $\hat{X}_s$ . (This satisfies  $GC_{1,n_{s+1}}$ .) Let  $B$  be the  $\ll$ -last (large) block that was queried, or  $GCB_{1,n_{s+1}}$ , whichever is later.

Set  $X_{s+1}$  to  $\hat{X}_s$  up to  $B$ .  $s := s + 1$ .

*Stage  $s + 1 = \langle 2k - 1, i \rangle + 1$ .* We satisfy  $R_{\langle 2k - 1, i \rangle}$ .

(Recall that  $i = \langle i_1, \dots, i_{2k-1} \rangle$ .)

Let  $n_{s+1} = \min \{n \mid n > n_s \wedge \cup_{j=1}^{2k-1} S^n_{2k-1,j,2} \text{ is clean} \wedge 2^n > \sum_{j=1}^{2k-1} p_{i_j}(n)\}$ .

$saw := 2k - 1$ ;  $done := false$ ;

Repeat

Consider all admissible extensions of  $X_s$ , satisfying  $\neg q^n_{2k-1,j}$ , for  $saw < j \leq 2k - 1$ . (If  $saw = 2k - 1$ , the previous condition is void.)

If  $N_{saw}(1^{n_{s+1}})$  has an accepting computation under such an extension  $\hat{X}_s$ , we will “freeze” an accepting computation as follows:

Extend  $X_s$  according to  $\hat{X}_s$  up to the  $\ll$ -last block for which there exists a queried string (round up to a large block if the block is a part of it) or  $\cup_{j=1}^{2k-1} S^n_{2k-1,j,2}$ , whichever is later.

Then enumerate an  $s_{saw} \in S_{2k-1, saw, 2}^{n_{s+1}}$  into  $X$  that is not queried negatively in the computation (if there does not exist one in  $X$  already).

$done := true$ ;

Else,  $saw := saw - 1$ .

Until ( $saw = 0$ ) or ( $done$ ).

If  $saw = 0$ , take any admissible extension  $\hat{X}_s$  of  $X_s$  satisfying  $\neg q_{2k-1, j}^{n_{s+1}}$ , for  $1 \leq j \leq 2k-1$ , then extend  $X_s$  according to  $\hat{X}_s$  up to large block  $\bigcup_{j=1}^{2k-1} S_{2k-1, j, 2}^{n_{s+1}}$ .

$s := s + 1$ .

**Stage  $s+1 = \langle 2k, i \rangle + 1$ .** We satisfy  $R_{\langle 2k, i \rangle}$ .

**Step 1.** Diagonalize  $\mathbf{C}(L(N_{i_1}), \dots, L(N_{i_k}))$ .

Let  $n_{s+1} = \min \{n \mid n > n_s \wedge GCB_{k+1, n} \text{ is clean} \wedge 2^n > \sum_{j=1}^k p_{i_j}(n)\}$

$saw := k$ ;  $done := false$ ;

**Repeat**

Consider all admissible extensions of  $X_s$  (except temporarily ignore  $GC_{k+1, n_{s+1}}$ ) satisfying  $(\neg p_{k+1, j}^{n_{s+1}}) \wedge (\neg p_{k+1, k+1+j}^{n_{s+1}})$ , for  $saw < j \leq k+1$ .

If  $N_{i_{saw}}(1^{n_{s+1}})$  has an accepting computation under such an extension  $\hat{X}_s$ , we will “freeze” an accepting computation as follows:

Extend  $X_s$  according to  $\hat{X}_s$  up to the  $\ll$ -last block for which there exists a queried string (round up to a large block if the block is part of it) or  $GCB_{k+1, n_{s+1}}$ , whichever is later.

Then enumerate an  $s_{saw+1} \in S_{k+1, saw+1, 1}^{n_{s+1}}$  and  $s'_{saw} \in S_{k+1, k+1+saw, 1}^{n_{s+1}}$  into  $X$  that are not queried negatively in the computation (if there do not exist such two strings in  $X$  already).

$done := true$ ;

Else,  $saw := saw - 1$

Until ( $saw = 0$ ) or ( $done$ ).

If  $saw = 0$  take any admissible extension of  $X_s$  that has no string from  $S_{k+1, j, 1}^{n_{s+1}}$ , for  $1 < j \leq k+1$ , and no string from  $S_{k+1, k+1+j, 1}^{n_{s+1}}$ , for  $1 \leq j \leq k+1$ , and has an  $s_1 \in S_{k+1, 1, 1}^{n_{s+1}}$  (this satisfies  $GC_{k+1, n_{s+1}}$ ). Then extend  $X_s$  up to large block  $GCB_{k+1, n_{s+1}}$ .

**Step 2.** Diagonalize  $\mathbf{C}(L(N_{i_1}), \dots, L(N_{i_k}))$ .

We omit the details since this step is symmetric to Step 1.

**End of construction**

Let us prove that stage  $\langle 2k-1, i \rangle + 1$  does satisfy requirement  $R_{\langle 2k-1, i \rangle}$ . The other parts are left to the reader.

Suppose the Repeat loop ends with  $saw > 0$ . Then clearly for some admissible extension  $\hat{X}_s$  of  $X_s$  satisfying  $\neg q_{2k-1, j}^{n_{s+1}}$ ,  $saw < j \leq 2k-1$ ,  $N_{i_{saw}}$  accepts  $1^{n_{s+1}}$ . Meanwhile  $N_{i_j}$ ,  $saw < j \leq 2k-1$ , reject  $1^{n_{s+1}}$  for all such admissible extensions of  $X_s$ .

There are at most  $p_{i_{saw}}(n_{s+1})$  strings being queried on the accepting computation path. Thus an  $s_{saw} \in S_{2k-1, saw, 2}^{n_{s+1}}$  can be found and enumerated into  $X$ . Therefore the accepting computation is preserved, and  $q_{2k-1, saw}^{n_{s+1}}$  is satisfied. Hence for the final  $X$ ,  $1^{n_{s+1}} \in \mathbf{C}(L(N_{i_{saw}}), \dots, L(N_{i_{2k-1}}))$ .

If  $saw$  is odd, then  $1^{n_{s+1}} \in L_{2k-1} - \overline{\mathbf{C}(L(N_{i_1}), \dots, L(N_{i_{2k-1}}))}$ .

If  $saw$  is even, then  $1^{n_{s+1}} \in \overline{\mathbf{C}(L(N_{i_1}), \dots, L(N_{i_{2k-1}}))} - L_{2k-1}$ .

Similarly, suppose the Repeat loop ends with  $saw = 0$ , then none of the  $N_{i_j}$ ,  $1 \leq j \leq 2k-1$ , will accept  $1^{n_{s+1}}$  for any admissible extensions with  $\neg q_{2k-1, j}^{n_{s+1}}$ ,  $1 < j \leq 2k-1$ . Since the final  $X$  has no string in  $\bigcup_{j=1}^{2k-1} S_{2k-1, j, 2}^{n_{s+1}}$ , we have  $1^{n_{s+1}} \in \overline{\mathbf{C}(L(N_{i_1}), \dots, L(N_{i_{2k-1}}))}$ , and  $1^{n_{s+1}} \notin L_{2k-1}$ .  $\square$

**3.2. Relativized boolean hierarchies extending exactly  $k$  levels.** In some relativized worlds, the boolean hierarchy separates at the  $k$ th level, yet PSPACE falls into the

$(k+1)$ st level. This fact opens the possibility that in the real world the structure of feasible computations degenerates exactly in the boolean hierarchy.

**THEOREM 3.2.1.** *For each  $k \geq 1$ , there is a recursive oracle  $A$  so that  $\text{NP}^A(k) \neq \text{coNP}^A(k)$ , yet  $\text{NP}^A(k+1) = \text{coNP}^A(k+1) = \text{PSPACE}^A$ .*

We state a proof for the case  $k=2$ , and show the form of the general proof. Our strategy is simple. While coding to ensure that  $\text{PSPACE}^A \subseteq \text{NP}^A(3)$ , we diagonalize so that  $\text{D}^P(A) \neq \text{coD}^P(A)$ .

*Proof of Theorem 3.2.1 ( $k=2$  case).* We display a recursive oracle  $A$  for which  $\text{D}^P(A) \neq \text{coD}^P(A)$  and  $\text{NP}^A(3) = \text{PSPACE}^A$ .

Let  $M_i$  be an enumeration of  $\text{PSPACE}$  machines. Without loss of generality,  $M_i$  runs in space at most  $n^i + i$  and queries strings of length at most  $n^i + i$ . By adopting polynomial length queries, we follow the standard model of relativized  $\text{PSPACE}$ [FSS81].

Let  $U = \{M_i \# x \# 1^{|x|^{i+1}} \mid M_i^A(x) \text{ accepts}\}$ . Note that  $U$  is  $\text{PSPACE}^A$  complete. We will encode to ensure that  $U \in \text{NP}^A(3)$ . In particular we will assure that if  $y$  is of length  $i$ :

$$(*) \quad y \in U \Leftrightarrow [(\exists z, |yz| = 5i+1)[yz \in A] \wedge (\forall z, |yz| = 5i+2)[yz \notin A]] \\ \vee (\exists z, |yz| = 5i+3)[yz \in A].$$

Let  $L = \{0^i \mid (\exists z, |z| = i)[z \in A]\} \cap \{0^i \mid (\forall z, |z| = i+1)[z \notin A]\}$ . Clearly  $L \in \text{D}^P(A)$ . We show that no  $\text{coD}^P(A)$  machine accepts  $L$ . The  $k$ th  $\text{coD}^P$  machine,  $H_k$ , will be such that  $L(H_k^A) = L(N_j^A) \cup L(A_l^A)$ ,  $\langle j, l \rangle = k$  and  $\{N_i\}, \{A_i\}$  are enumerations of  $\text{NP}$  and  $\text{coNP}$  machines, respectively. That is, to “run”  $H_k$ , we “run” both  $N_j$  and  $A_l$  and accept if either accepts.

Our oracle is built in stages. The following constraint applies throughout the construction: In stage  $5i+j$ ,  $1 \leq j \leq 5$ , no string of length less than  $5i+1$  can be added to the oracle.

#### ORACLE CONSTRUCTION.

*Stage “ $5i+1, 5i+2, 5i+3$ ” (Encoding).* For each  $y$  of length  $i$ , assure that equation  $(*)$  is satisfied. A possible problem is that our ability to control strings of lengths  $5i+1, 2, 3$  may be constrained by the effects of some previous diagonalization. Various cases of the diagonalizations put various types of constraints on us. Fortunately, for each type of constraint we retain the freedom of coding both possibilities,  $y \notin U$  or  $y \in U$ . After we list the diagonalization cases, we give a recipe for codings done under each case.

*Stage “ $5i+4, 5i+5$ ” (Diagonalization).* If strings of length greater than or equal to  $5i+1$  have been queried by any previous diagonalization phase, do nothing during this stage. Otherwise, let  $H_k$  be the first  $\text{coD}^P$  machine that still might accept  $L$ . Let us say  $k = \langle j, l \rangle$ ; so, informally speaking,  $H_k = N_j \cup A_l$ . If either  $N_j$  or  $A_l$  has run time (on inputs of length  $5i+4$ ) more than  $2^{\sqrt{i}}$ , do nothing.

Otherwise, run  $N_j(0^{5i+4})$  with, as oracles, all extensions of  $A$  that add no new string having length congruent to  $3 \pmod 5$ .

*Case 1.*  $N_j^A(0^{5i+4})$  accepts on some such extension. Freeze in  $A$  all elements along some accepting path. So  $H_k^A(0^{5i+4})$  accepts. Make it a liar by adding some unconstrained length  $5i+5$  string to  $A$ . We win, since  $0^{5i+4} \in L(H_k^A)$ , but  $0^{5i+4} \notin L$ .

*Case 2.*  $N_j^A(0^{5i+4})$  rejects on all such extensions. Then, as long as we make sure all strings of length congruent to  $3 \pmod 5$  remain out of  $A$ ,  $H_k$  is simply an overworked  $A_l$  trying to accept a hard language,  $L$ . So, run  $A_l(0^{5i+4})$

on all oracle extensions that (1) add no new string with length congruent to 3 mod 5, and (2) have no strings of lengths  $5i+2$  or  $5i+5$ .

- Case 2a.  $A_i^A(0^{5i+4})$  rejects on some such extension. Freeze in  $A$  elements along some rejecting path. So  $H_k^A(0^{5i+4})$  rejects. Make it a liar by putting an unconstrained length  $5i+4$  string into  $A$  (recall that by the conditions imposed, we have no length  $5i+5$  strings). We win, as  $0^{5i+4} \notin L(H_k^A)$ , but  $0^{5i+4} \in L$ .
- Case 2b.  $A_i^A(0^{5i+4})$  accepts on all such extensions. Then, in particular, it accepts on the extension that puts *no* strings of length  $5i+4$  or  $5i+5$  into  $A$ .  $H_k^A(0^{5i+4})$  accepts but  $0^{5i+4} \notin L$ , so we have again made  $H_k$  a liar.

End of cases

Finally, we must provide the promised coding strategies. Since our diagonalizations only take place when out of the range of any previous diagonalization, each time we code we are constrained by at most one case of the diagonalization. Figure 4 shows these strategies.

For example, consider trying to code  $y \in U$ , when our last diagonalization succeeded on Case 2a. Case 2 obligates us to keep strings of length congruent to 3 mod 5 out of  $A$ . Also, it may have fixed some strings of length  $5i+1$  in and out of  $A$ , and it may have fixed some strings of length  $5i+2$  out of  $A$ . Nonetheless, we have no problem here. We code  $y \in U$  by placing an unconstrained length  $5i+1$  string into  $A$ . Now we have no length  $5i+2$  strings in  $A$ ; by (\*) the new length  $5i+1$  string codes the fact that  $y \in U$ . Note that it does not interfere with the diagonalization.

Case	To code $y \in U$		To code $y \notin U$

FIG. 4. Encoding strategies under various restrictions.

This is a proof of the case  $k = 2$ . The general proof follows the same outline. To separate exactly  $k$  levels, we put  $L$  in  $NP^A(k) - coNP^A(k)$  and code  $U$  into  $NP^A(k + 1)$ . We will have  $k + 1$  encoding stages and  $k$  diagonalization stages.  $\square$

**4. Immunity results.** We first prove a theorem that shows the difficulty of finding immunity relations within the boolean hierarchy: No BH set is NP bi-immune or coNP bi-immune. Jockusch first proved the analogue for recursively enumerable sets of the following theorem.

**THEOREM 4.1.** *No set in the boolean hierarchy can be NP bi-immune. That is, for each  $S \in BH$  there is an infinite set  $L \in NP$  such that either  $L \subseteq S$  or  $L \subseteq \bar{S}$ . Similarly, no set in the boolean hierarchy is coNP bi-immune.*

*Proof of Theorem 4.1.* By definition,  $BH = \bigcup_{k \geq 1} NP(k)$ . We prove the first part; the second part is similar, using  $BH = \bigcup_{k \geq 1} \{C(\bar{L}_1, \dots, \bar{L}_k) \mid \bar{L}_i \in coNP\}$ .

Our proof is by induction on the level of  $S$  in the boolean hierarchy. Our base case is that  $S$  is in NP. If  $S$  is infinite, set  $L = S$ . If  $S$  is finite, set  $L = \bar{S}$ . In either case, we see that  $S$  is not bi-immune.

Suppose  $S \in NP(k)$ ,  $k > 1$ , and (inductively) no set in  $NP(k - 1)$  is NP bi-immune. By definition, there are NP sets  $L_i$ ,  $1 \leq i \leq k$ , for which  $S = C(L_1, \dots, L_k)$ . If  $k$  is odd, then  $S = S_1 \cup L_k$ , where  $S_1 \in NP(k - 1)$ . If  $L_k$  is infinite or  $S_1$  has an infinite NP subset, then so does  $S$ . Otherwise,  $L_k$  is finite and  $\bar{S}_1$  has an infinite NP subset  $X$ . Then  $\bar{S} = \bar{S}_1 \cap \bar{L}_k \supseteq X - L_k$ .  $X - L_k$  is an infinite NP set, so we are done.

A dual argument can be applied for  $k$  even.  $\square$

Is it possible for a set in a higher level of the boolean hierarchy to be immune to lower levels? We show the following theorem.

**THEOREM 4.2.** *There is a recursive oracle  $X$  such that  $NP^X(2)$  has a  $coNP^X(2)$ -immune set.*

*Proof of Theorem 4.2.* Define  $L = \{1^n \mid (\exists 0x \in X, |x| = n) \wedge \neg(\exists 1y \in X, |y| = n)\}$ . Clearly  $L$  is in  $NP^X(2)$ . We now diagonalize to ensure that  $L$  is  $coNP^X(2)$ -immune.

$X$  is constructed in stages. At each stage we keep a finite list of  $coNP(2)$  machines, represented as pairs of NP machines, that have not been “kicked out.” Recall  $coNP(2) = \{\bar{L}_i \cup L_j \mid L_i, L_j \in NP\}$ . At stage  $s$ , get a large  $n$ ; we achieve the following objective:

*Either* some machine on the list accepts  $1^n$  (this machine’s accepting computation will be preserved) and we will arrange to have  $1^n \notin L$  or no machine on the list accepts (this fact will also be preserved) and we will arrange to have  $1^n \in L$ .

In the former case, the “mistaken” machines, those we have fooled, are deleted from the list. In the latter, we append to the list one more  $\langle N_i, N_j \rangle$ . From stage  $s$  to  $s + 1$ , we will arrange to have some  $1y$  of the “skipped” length so that  $L$  is not enlarged.

Hence every  $\bar{L}(N_i) \cup L(N_j)$  once on the list will not accept any more members of  $L$ , unless it is “kicked out” later. Since at any moment the list is finite, we can only “kick out” a finite number of  $\langle N_i, N_j \rangle$ ’s consecutively. Thus the second possibility does occur infinitely often, so  $L$  is infinite and every  $\bar{L}(N_i) \cup L(N_j)$  is eventually considered. Therefore  $L$  only has finite subsets from  $coNP^X(2)$ .

The strategy to achieve that objective is the following:

Assume at some point there are  $k$  pairs  $\langle N_i, N_j \rangle$ ,  $1 \leq i \leq k$ , on the list. Construct NP machines  $N_\sigma, N_\tau$  such that

$$\bar{L}(N_\sigma) \cup L(N_\tau) = \bigcup_{1 \leq i \leq k} (\bar{L}(N_i) \cup L(N_j)).$$

Consider all extensions that contain no string previously frozen to  $\bar{X}$ , see if  $N_\tau$  accepts  $1^n$  under some such extension, and if so,

- Case 1. Freeze one accepting computation path of that extension. Choose a  $1y$  unfrozen with  $|y| = n$ ; put  $1y$  into  $X$ . Thus  $1^n \notin L$  and we may kick out all mistaken pairs (there is at least one). Otherwise,
- Case 2. Consider all extensions that have no string of the form  $1y$ ,  $|y| = n$ ; see if  $N_\sigma$  accepts  $1^n$  on one of these extensions. If so,
- Case 2a. Freeze one accepting computation and add an unfrozen string  $0x$ ,  $|x| = n$  to  $X$ . Thus  $1^n \in L$  and no pair on the list accepts  $1^n$ . Otherwise,
- Case 2b. Do nothing. At length  $n$ , we have neither  $0x$  nor  $1y$ ; hence  $1^n \notin L$ , but some  $\overline{L(N_i)}$  said yes to  $1^n$ .  $\square$

On the other hand, it follows from our normal form theorem that the situation is drastically different for NP(2). By Theorem 2.1.1, every set in the boolean hierarchy can be expressed as a finite union of NP(2) sets. Clearly, this implies the following theorem.

**THEOREM 4.3.** *No set in the boolean hierarchy is NP(2)-immune.*

Thus we have a *structural asymmetry among complementary classes*: though no boolean hierarchy set is  $D^P$ -immune, there are worlds where the boolean hierarchy does have  $\text{co}D^P$ -immune sets.

The argument used to prove Theorem 4.3 yields more. In fact, for every  $L$

$$L \text{ is NP(2)-immune} \Leftrightarrow L \text{ is BH-immune.}$$

The proof is immediate. If  $L$  has an infinite subset  $M$  from the boolean hierarchy then  $M$  in turn must have an infinite subset from NP(2). Thus  $L$  has an infinite NP(2) subset.

The above observation can be refined to prove the following theorem.

**THEOREM 4.4.** *There is a recursive oracle  $X$  so that  $\Delta_2^{P,X}$  has a set that is  $\text{BH}^X$ -immune.*

*Proof of Theorem 4.4.* Define predicates  $p_k^n \equiv \text{“}\exists x, |x| = n, 1^k 0x \in X\text{”}$ ,  $1 \leq k \leq 2n$ . (Note that  $1^k 0x = 1^l 0y \Rightarrow k = l, x = y$ .)

Consider  $L_\Delta = \{1^n \mid \mathbf{C}(p_1^n, \dots, p_{2n}^n)\}$ . Clearly  $L_\Delta \in \Delta_2^{P,X}$ .

We will construct  $X$ , so that  $L_\Delta$  is  $\text{BH}^X$ -immune.

$X$  is constructed in stages;  $X = \bigcup X_s$ . At each stage we keep a finite list of BH machines, represented by finite sequences of NP machine indices.  $\text{NP}(2k)$  consists of unions of  $k$  NP(2) sets. We may construct at stage  $s$  a finite sequence of NP indices  $\langle i_1, \dots, i_t \rangle$ , so that  $\mathbf{C}(L(N_{i_1}), \dots, L(N_{i_t}))$  is precisely the union of those on the list, relativized to any oracle set. Pick  $n$  sufficiently large, then apply our “sawing” argument to diagonalize.

CONSTRUCTION OF  $X$ .

$$X_0 = \emptyset; \quad X'_0 = \emptyset; \quad \text{list}_0 = \emptyset; \quad n_0 = 0; \quad s = 0.$$

Stage  $s + 1$ :

Construct  $\langle i_1, \dots, i_t \rangle$ , so that for every  $X$ ,

$$\mathbf{C}(L(N_{i_1}^X), \dots, L(N_{i_t}^X)) = \bigcup L(M^X);$$

the union is over all  $M \in \text{list}_s$ , represented as finite sequences of NP indices via  $\mathbf{C}$ . Let  $p$  be the sum of time bounds of  $N_{i_1}, \dots, N_{i_t}$ . Without loss of generality,  $t$  is even.

Let  $n_{s+1} = \min \{n \mid n > n_s \text{ and } 2n > t \text{ and } (\forall m \geq n)[m \text{ is “clean”}] \text{ and } (\forall m \geq n)[2^m > p(m)]\}$ .

$\forall n: n_s < n < n_{s+1}$ , keep  $1^n$  out of  $L_\Delta$  as follows:

{Find  $1^{2n} 0x \notin X'_s, |x| = n$ , set  $X_s := X_s \cup \{1^{2n} 0x\}$ .}

Set  $X'_s := X'_s \cup \{1^k 0x \mid |x| = n_{s+1}, t + 1 < k \leq 2n_{s+1}\}$

(This effectively strips away the last  $2n_{s+1} - (t + 1)$  quantifiers in the definition of  $L_\Delta$  for  $1^{n_{s+1}}$ .)

For some  $10x \notin X'_s$ ,  $|x| = n_{s+1}$  set  $X_s := X_s \cup \{10x\}$ .

$saw := 0$ ;  $done := false$ ;

repeat

{If there is an extension  $Y$  of  $X_s$ , so that  $X_s \subseteq Y$ ,  $Y \cap X'_s = \emptyset$ , and  $N_{i_t - saw}^Y(1^{n_{s+1}})$  has an accepting computation, we will freeze one accepting computation as follows:

$\{X_s := X_s \cup \{\text{those in } Y \text{ that are queried}\}$

$X'_s := X'_s \cup \{\text{those not in } Y \text{ that are queried}\}$

Pick a  $1^{t+1-saw}0x \notin X'_s$ ,  $|x| = n_{s+1}$ , and add it to  $X_s$ .

$done := true$ .

}

else  $\{X'_s := X'_s \cup \{1^{t+1-saw}0x \mid |x| = n_{s+1}\}$ ;  $saw := saw + 1\}$

}

until ( $saw = t$ ) or ( $done = true$ )

If  $saw$  is even then appended the next BH machine to  $list_s$

else delete all  $M \in list_s$  with  $1^{n_{s+1}} \in L(M^{X_s})$  (there must be one)

$X_{s+1} := X_s$ ,  $X'_{s+1} := X'_s$ ,  $list_{s+1} := list_s$ ,  $s := s + 1$

End of stage  $s + 1$

End of construction

We leave the proof that the construction works to the reader.  $\square$

**5. Complete languages for the boolean hierarchy.** Complete languages are important in the understanding of complexity class; a complete language marks the upper limit of a class's complexity. In this section we drive *natural* complete languages for the levels of the boolean hierarchy. However, our first complete languages will be universal and canonical ones.

**THEOREM 5.1.** For each  $k$ ,  $NP(k)$  has a complete language.

*Proof of Theorem 5.1.* Fix  $k \geq 1$ , we claim that the universal language

$$U = \{\langle i_1, i_2, \dots, i_k, x, 0^{p_i(|x|)} \rangle \mid x \in C(L(N_{i_1}), \dots, L(N_{i_k})), i = \langle i_1, \dots, i_k \rangle\},$$

is complete for  $NP(k)$  with respect to polynomial time reductions, where  $p_i(\cdot)$  is a sum of the polynomial time bounds for  $N_{i_1}, \dots, N_{i_k}$ . Clearly  $U$  is in  $NP(k)$ , owing to the padding  $0^{p_i(|x|)}$ . Given any  $L \in NP(k)$ , there exist  $i_1, \dots, i_k$ , so that  $L = C(L(N_{i_1}), \dots, L(N_{i_k}))$ . Let  $p_i(\cdot)$  be a sum of time bounds of  $N_{i_j}$ 's, then  $x \rightarrow \langle i_1, \dots, i_k, x, 0^{p_i(|x|)} \rangle$  is a one-to-one polynomial time reduction from  $L$  to  $U$ .  $\square$

Languages such as the one constructed in Theorem 5.1 are unnatural. Natural complete languages more forcefully demonstrate the usefulness of language classes. Natural complete languages exist for every level of the boolean hierarchy.

Define  $SAT(k) = \{\langle f_1, \dots, f_k \rangle \mid C(p_1, \dots, p_k)\}$ , where  $p_i \equiv \text{"}f_i \text{ is satisfiable.}"$  By the proof of Cook's theorem [C71] we have the following theorem.

**THEOREM 5.2.**  $SAT(k)$  is  $NP(k)$ -complete.

We continue our quest for natural complete languages, and display a family of variants of graph colorability that are complete for the levels of the boolean hierarchy.

**THEOREM 5.3.**  $COLORABILITY(k)$  is  $NP(k)$ -complete, where

$$COLORABILITY(k) = \{G \mid \chi(G) \text{ is odd} \wedge 3k \leq \chi(G) \leq 4k\}, \quad k \text{ even},$$

$$COLORABILITY(k) = \{G \mid (\chi(G) \text{ is odd} \wedge 3k \leq \chi(G) \leq 4k) \vee \chi(G) < 3k\}, \quad k \text{ odd}.$$

*Sketch of the proof of Theorem 5.3.* We reduce SAT( $k$ ) to COLORABILITY( $k$ ). Using the normal forms of boolean hierarchy sets [CH85, Props. 2.1.6, 2.1.3] we can efficiently transform  $\langle f_1, \dots, f_k \rangle$  to  $\langle g_1, \dots, g_k \rangle$  so that (1)  $\langle f_1, \dots, f_k \rangle \in \text{SAT}(k) \Leftrightarrow g(f) = \langle g_1, \dots, g_k \rangle \in \text{SAT}(k)$ , and (2) the  $g_i$  have the nice property that

$$(**) \quad (\forall i < j) \quad [g_j \in \text{SAT} \Rightarrow g_i \in \text{SAT}].$$

If  $G_i = (V_i, E_i)$ ,  $i = 1, 2$ , define  $G_1 \times G_2 = (V, E)$ , where  $V = V_1 \cup V_2$ , and  $E = E_1 \cup E_2 \cup \{\langle \nu_1, \nu_2 \rangle \mid \nu_i \in V_i\}$ . Clearly  $\chi(G_1 \times G_2) = \chi(G_1) + \chi(G_2)$ . Given  $\langle f_1, \dots, f_k \rangle$ , we transform this to  $\langle g_1, \dots, g_k \rangle$ , as explained in the previous paragraph. Let  $h$  be the polynomial time reduction from formulas to graphs of Cai and Meyer [CM85]. Crucially,  $\chi(h(F)) = 3$  if  $f \in \text{SAT}$  and  $\chi(h(F)) = 4$  if  $f \notin \text{SAT}$ . Let  $G_i = h(g_i)$ . Now, since the  $g_i$  satisfy (\*\*), the graph  $G = (\dots (G_1 \times G_2) \times G_3 \dots) \times G_k$  is just what we want;  $\langle f_1, \dots, f_k \rangle \in \text{SAT}(k) \Leftrightarrow G \in \text{COLORABILITY}(k)$ .  $\square$

Now, let  $f$  be a boolean formula. Then  $f$  is satisfiable  $\Leftrightarrow f' = (f \vee y) \wedge \bar{y}$  is satisfiable where  $y$  is a new variable. Furthermore,  $f'' = (f \vee y) \wedge z$  is always satisfiable. Using these observations, we can apply the standard transformation from SAT to 3SAT to Vertex Cover (VC) [GJ79]; we get a polynomial time transformation  $f \rightarrow (G_f, l_f)$ , so that if  $f$  is satisfiable, then the minimum size vertex cover for  $G_f$  is  $l_f$ ; otherwise, that minimum number is  $l_f + 1$ .

For each  $k \geq 0$ , define

$$\text{VC}(2k+2) = \{\langle G, l \rangle \mid \text{The minimum size VC of } G \text{ is } l+2i+1, 0 \leq i \leq k\},$$

$$\text{VC}(2k+1) = \{\langle G, l \rangle \mid \text{The minimum size VC of } G \text{ is } \leq l,$$

$$\text{or equal to } l+2i \text{ for some } 0 < i \leq k\}.$$

**THEOREM 5.4.** VC( $k$ ) is NP( $k$ )-complete.

*Proof of Theorem 5.4.* Start with formulae  $f_1, \dots, f_k$ . Using the normal forms of the boolean hierarchy [CH85, Props. 2.1.6, 2.1.3] we can without loss of generality assume that for all  $i < j$ ,  $[f_j \in \text{SAT} \Rightarrow f_i \in \text{SAT}]$  (see the proof of Theorem 5.3). Then apply the transformation described before to each  $f_i$  separately:  $f_i$  maps to  $\langle G_i, l_i \rangle$ . We get a graph  $G$  having  $k$  distinct components  $G_i$ ,  $1 \leq i \leq k$ . Let  $l = \sum l_i$ .

Clearly the minimum size of a vertex cover for  $G$  is  $l+j$ , where  $j$  = the number of  $f_i$ 's that are unsatisfiable. Hence,  $\langle f_1, \dots, f_k \rangle \in \text{SAT}(k) \Leftrightarrow \langle G, l \rangle \in \text{VC}(k)$ .  $\square$

We can prove similar completeness results for several variants of the Vertex Cover problem, such as independent set, clique, and others.

**6. Conclusions.** This paper explores the structure of the boolean hierarchy. The hierarchy responds flexibly to relativized control: there are worlds where the hierarchy is infinite and for every  $k$  there are worlds where it extends exactly  $k$  levels. It has only recently been discovered that the polynomial hierarchy can be similarly controlled [Y85], [K87b]. In relativized worlds the boolean hierarchy may have no complete languages, a behavior like that of UP, BPP, and  $\text{NP} \cap \text{coNP}$  [S82], [HI85], [HH86b] but unlike that of P, NP, and PSPACE [GJ79]. There are natural complete languages for the levels of the hierarchy and we have seen, via immunity, that the boolean hierarchy displays structural asymmetries between complementary classes.

These results supply a foundation of structural understanding for the boolean hierarchy. A companion paper [CGII] applies the hierarchy to extend the results of Karp and Lipton [KL80] on sparse oracles for NP, of Hartmanis, Immerman, and Sewelson [HIS83] on sparse sets in NP-P, and of Blass and Gurevich [BG82] of the weakness of counting classes.

## ON FINDING LOWEST COMMON ANCESTORS: SIMPLIFICATION AND PARALLELIZATION\*

BARUCH SCHIEBER† AND UZI VISHKIN‡

**Abstract.** We consider the following problem. Suppose a rooted tree  $T$  is available for preprocessing. Answer on-line queries requesting the lowest common ancestor for any pair of vertices in  $T$ . We present a linear time and space preprocessing algorithm that enables us to answer each query in  $O(1)$  time, as in Harel and Tarjan [*SIAM J. Comput.*, 13 (1984), pp. 338–355]. Our algorithm has the advantage of being simple and easily parallelizable. The resulting parallel preprocessing algorithm runs in logarithmic time using an optimal number of processors on an EREW PRAM. Each query is then answered in  $O(1)$  time using a single processor.

**Key words.** parallel algorithms, tree algorithms, lowest common ancestors

**AMS(MOS) subject classifications.** 05C05, 68Q10, 68Q20, 68R10

**1. Introduction.** We consider the following problem. Given a rooted tree  $T(V, E)$  for preprocessing, answer on-line LCA queries of the form, “Which vertex is the Lowest Common Ancestor (LCA) of  $x$  and  $y$ ?” for any pair of vertices  $x, y$  in  $T$ . (Let us denote such a query  $LCA(x, y)$ .) We present a preprocessing algorithm that runs in linear time and linear space on the serial RAM model. (For the definition of a random access machine (RAM) model see, e.g., [1].) Given this preprocessing, we show how to process each such LCA query in constant time.

We also consider parallelization of our algorithm. The model of parallel computation used is the exclusive-read exclusive-write (EREW) parallel random access machine (PRAM). A PRAM employs  $p$  synchronous processors all having access to a common memory. An EREW PRAM does not allow simultaneous access by more than one processor to the same memory location for either read or write purposes. See [11] for a survey of results concerning PRAMs.

Let  $\text{Seq}(n)$  be the fastest known worst-case running time of a sequential algorithm, where  $n$  is the length of the input for the problem at hand. A parallel algorithm that runs in  $O(\text{Seq}(n)/p)$  time using  $p$  processors is said to have *optimal speedup* or, more simply, to be *optimal*. A primary goal in parallel computation is to design optimal algorithms that also run as fast as possible.

Our preprocessing algorithm is easily parallelized to obtain an optimal parallel preprocessing algorithm that runs in  $O(\log n)$  time using  $n/\log n$  processors on an EREW PRAM, where  $n$  is the number of vertices in  $T$ . Parallelizing the query processing is straightforward, provided read conflicts are allowed:  $k$  queries can be processed in  $O(1)$  time using  $k$  processors.

---

In their extensive paper [5], Harel and Tarjan gave a serial algorithm for the same problem. The performance of their algorithm is the same as ours. However, our algorithm has two advantages: (1) It is considerably simpler in both the preprocessing stage and the query processing and (2) It leads to a simple parallel algorithm. Below, we discuss similarities and differences with respect to [5]. *Similarities*: Both algorithms use two basic observations: (1) It is possible to answer LCA queries in simple paths in constant time and (2) It is possible to answer LCA queries in complete binary trees in constant time. Both algorithms pack information regarding several vertices into a single  $O(\log n)$  bits number. *Differences*: The subtler part of both algorithms is to show how to use the above two observations for answering an LCA query. In this part, our approach is completely different. In the preprocessing stage we compute a mapping from the vertices of the input tree  $T$  to the vertices of a complete binary  $B$ . The mapping has two properties: (i) All the vertices of  $T$  mapped into the same vertex in  $B$  form a path and (ii) For each vertex  $v$  in  $T$ , the descendants of  $v$  are mapped into descendants of the image of  $v$  in  $B$ . This mapping, together with some additional information, enables us to answer an LCA query in constant time. In [5], on the other hand, the vertices of the input tree  $T$  are mapped to the vertices of an arbitrary tree of logarithmic height, called the compressed tree. The preprocessing consists of a quite involved manipulation of this compressed tree. This manipulation includes partitioning the compressed tree into three plies and preprocessing each ply separately and also embedding the compressed tree in a complete binary tree.

Consider a dynamic LCA problem which, interspersed with the LCA queries, are on-line deletions and insertions of edges. Reference [5] also gives algorithms for some cases of this problem. We do not consider this problem in the present paper.

Our parallel algorithm improves on the following results. Tsin [9] gave two parallel algorithms for the LCA problem. In his first algorithm both the preprocessing stage and the query processing take logarithmic time with a linear number of processors. In his second algorithm the preprocessing stage takes  $O(\log n)$  time using  $n^2$  processors and processing a query takes  $O(1)$  time using a single processor. Vishkin [12] includes a parallel algorithm for the LCA problem. The processing of an LCA query takes logarithmic time (as in the first algorithm of Tsin). The preprocessing stage takes  $O(\log n)$  time using  $n/\log n$  processors (as in the present paper).

Observe that using our parallel preprocessing algorithm we can process  $k$  off-line LCA queries in  $O(\log n)$  time using  $(n+k)/\log n$  processors, provided read conflicts are allowed. This affects the performance of parallel algorithms for three problems: (1) Given an undirected graph, orient its edges so that the resulting digraph is strongly connected (if such orientation is possible) [12]. (2) Computing an open-ear decomposition and  $st$ -numbering of a biconnected graph [8]. Using the new parallel connectivity and list-ranking algorithms of [3], it has become possible to solve each of these problems in logarithmic time using an optimal number of processors only when  $m \geq n \log n$ , where  $n$  is the number of vertices and  $m$  is the number of edges in the input graph. Our off-line LCA computation enables us to extend the range of optimal speedup logarithmic time parallel algorithms for these problems to sparser graphs, where  $m \geq n \log^* n$  as in the above connectivity algorithm. (3) Approximate string matching [6]. The new parallel suffix tree construction of [7] together with the present parallel LCA computation lead to a considerable simplification of the parallel algorithm of [6]. This simplification has already been described in [2].

The paper is organized as follows. Section 2 gives a high-level description of the algorithm. Section 3 describes the preprocessing stage. In § 4 we show how to process LCA queries in  $T$  using the outcome of the preprocessing stage. Section 5 presents parallelization of our preprocessing stage.

**2. High-level description.** The entire algorithm is based on the following two observations (made also in [5]): (1) Had our input tree been a simple path, it would have been possible to preprocess it (by way of computing the distance of each vertex from the root, as explained below) and later answer each LCA query in constant time. (2) Had our input tree been a complete binary tree, it would have been possible to preprocess it (by way of computing its inorder number, as explained below) and later to answer each LCA query in constant time.

The preprocessing stage assigns a number  $\text{INLABEL}(v)$  to each vertex  $v$  in  $T$ . Motivated by observation (1), these numbers satisfy the following *Path-Partition Property*: The  $\text{INLABEL}$  numbers partition the tree  $T$  into paths, called  $\text{INLABEL}$  paths. Each  $\text{INLABEL}$  path consists of the vertices that have the same  $\text{INLABEL}$  number.

Let  $B$  be the smallest complete binary tree having at least  $n$  vertices. Our description identifies each vertex in  $B$  by its inorder number. Motivated by observation (2), the  $\text{INLABEL}$  numbers also satisfy the following *Descendance-Preservation Property*: The  $\text{INLABEL}$  numbers map each vertex  $v$  in  $T$  into the vertex  $\text{INLABEL}(v)$  in  $B$ , such that the descendants of  $v$  are mapped into descendants of  $\text{INLABEL}(v)$  in  $B$  ( $v$  is considered both a descendant and an ancestor of itself).

Consider a vertex  $v$  in  $T$ . By the Descendance-Preservation Property all the ancestors of  $v$  are mapped into ancestors of  $\text{INLABEL}(v)$ . This implies that there are at most  $\log n$  distinct numbers among the  $\text{INLABEL}$  numbers of all the ancestors of  $v$ . Later, we show how to record all these  $\text{INLABEL}$  numbers using a single string of  $\log n$  bits. In the preprocessing stage we compute this string, for each vertex  $v$  in  $T$ , into  $\text{ASCENDANT}(v)$ .

In the preprocessing stage we also compute the table  $\text{HEAD}$ . It contains the highest vertex in every  $\text{INLABEL}$  path.

Section 4 describes how to process a query  $\text{LCA}(x, y)$  for any pair of vertices  $x, y$  in  $T$ . The processing breaks into two cases. The simpler case is where  $x$  and  $y$  belong to the same  $\text{INLABEL}$  path. In the preprocessing stage we compute for each vertex  $v$  in  $T$  its distance from the root into  $\text{LEVEL}(v)$ . So,  $\text{LCA}(x, y)$  is simply the vertex among  $x$  and  $y$  that is closer to the root. The more complicated case is where  $\text{INLABEL}(x) \neq \text{INLABEL}(y)$ . We proceed in four steps. In the first step, we find the  $\text{LCA}$  of  $\text{INLABEL}(x)$  and  $\text{INLABEL}(y)$  in the complete binary tree  $B$ , denoted by  $b$ . Let  $z = \text{LCA}(x, y)$  in  $T$ . In the second step, we find  $\text{INLABEL}(z)$ .  $\text{INLABEL}(z)$  is the lowest ancestor of  $b$  in  $B$  that is the  $\text{INLABEL}$  number of a common ancestor of  $x$  and  $y$  in  $T$ . For this, we use information provided by  $\text{ASCENDANT}(x)$  and  $\text{ASCENDANT}(y)$ . In the third and fourth steps we find  $z$  in the  $\text{INLABEL}$  path defined by  $\text{INLABEL}(z)$ . In the third step, we find the lowest ancestor of  $x$ , denoted  $\hat{x}$ , and the lowest ancestor of  $y$ , denoted  $\hat{y}$ , in the path defined by  $\text{INLABEL}(z)$  in  $T$ . This is done in an indirect fashion. Consider the path in  $B$  from  $\text{INLABEL}(z)$  to  $\text{INLABEL}(x)$ . We derive from  $\text{ASCENDANT}(x)$  the first  $\text{INLABEL}$  number (i.e., vertex of  $B$ ) of an ancestor of  $x$  in this path. Table  $\text{HEAD}$  gives the highest ancestor of  $x$  in  $T$  having this  $\text{INLABEL}$  number. Finally,  $\hat{x}$  is the father in  $T$  of this ancestor. We find  $\hat{y}$  similarly. In the fourth step we find  $z$ , which is simply the vertex among  $\hat{x}$  and  $\hat{y}$  that is closer to the root.

**3. The preprocessing stage.** The outcome of the preprocessing stage consists of labels that are assigned to the vertices of  $T$  and a look-up table, called  $\text{HEAD}$ . The label of each vertex  $v$  in  $T$  consists of three numbers:  $\text{INLABEL}(v)$ ,  $\text{ASCENDANT}(v)$ , and  $\text{LEVEL}(v)$ .

We start with computing  $\text{INLABEL}(v)$ , for each vertex  $v$  in  $T$ . This is done in two steps. After a discussion of these two steps we show how to implement them.

Let  $\text{PREORDER}(v)$  be the serial number of  $v$  in preorder traversal of  $T$  and  $\text{SIZE}(v)$  be the number of vertices in the subtree rooted at  $v$ . Definition of preorder traversal can be found, e.g., in [1, pp. 54–55].

*Step 1.* Compute  $\text{PREORDER}(v)$  and  $\text{SIZE}(v)$ .

We note that the  $\text{PREORDER}$  numbers of the vertices in the subtree rooted at  $v$  range between  $\text{PREORDER}(v)$  and  $\text{PREORDER}(v) + \text{SIZE}(v) - 1$ , and therefore, the closed interval  $[\text{PREORDER}(v), \text{PREORDER}(v) + \text{SIZE}(v) - 1]$  is called the *interval of  $v$* .

In Step 2 we consider the binary representation of the (integer) numbers in the interval of  $v$ . We remark that throughout this paper we alternately refer to numbers and to their binary representations. No confusion will arise.

*Step 2.* Find the (integer) number that has the maximal number of rightmost “0” bits in the interval of  $v$ . This number is assigned to  $\text{INLABEL}(v)$ .

For an example of computations described in this section see Fig. 3.1.

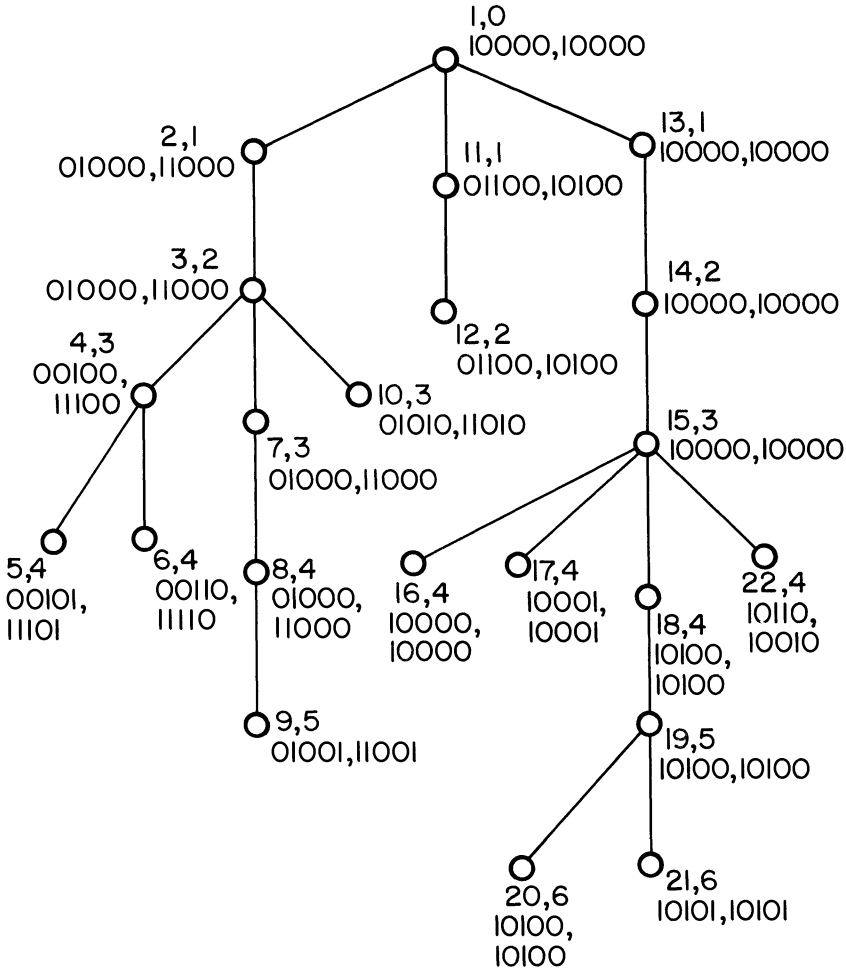

FIG. 3.1. Example. A tree with four numbers: PREORDER, LEVEL, INLABEL, and ASCENDANT at each vertex. (The last two numbers are given in binary representation.)

**Discussion.** We show that the INLABEL numbers satisfy the two properties defined in the high-level description of the previous section.

LEMMA 1. *The INLABEL numbers satisfy the Path-Partition Property.*

*Proof.* Observe that the intervals of the sons of  $v$  must be pairwise disjoint. Therefore, INLABEL( $v$ ) belongs to the interval of at most one son of  $v$ . Denote such a son by  $u$ . By the selection of the INLABEL numbers (Step 2), INLABEL( $u$ ) = INLABEL( $v$ ) (if  $u$  exists), and for any other son  $w$  of  $v$ , INLABEL( $w$ )  $\neq$  INLABEL( $v$ ). This implies the *Path-Partition Property* of the INLABEL numbers.  $\square$

LEMMA 2. *The INLABEL numbers satisfy the Descendance-Preservation Property.*

*Proof.* Let  $d$  be any descendant of  $v$  in  $T$ . We show that INLABEL( $d$ ) is a descendant of INLABEL( $v$ ) in the complete binary tree  $B$ . (Recall that our description identifies each vertex in  $B$  by its inorder number, thus proving the lemma.) Consider any two vertices  $b$  and  $c$  in  $B$ . We first give a necessary and sufficient condition for  $c$  to be a descendant of  $b$  in  $B$  and then show that INLABEL( $d$ ) and INLABEL( $v$ ) satisfy this condition. Let  $l = \lfloor \log n \rfloor + 1$  and  $i$  be the number of rightmost “0” bits in  $b$ . That is,  $b$  consists of  $l - i$  leftmost bits followed by a single “1” and  $i$  “0”s.

CLAIM. *A vertex  $c$  is a descendent of  $b$  if and only if (1) the  $l - i$  leftmost bits of  $c$  are the same as the  $l - i$  leftmost bits of  $b$ , and (2) the number of rightmost “0” bits in  $c$  is at most  $i$ .*

*Proof.* Let  $b_L$  and  $b_R$  be the left and right sons of  $b$ , respectively. It is not difficult to see the following: (i)  $b_L$  consists of the  $l - i$  leftmost bits of  $b$  followed by a single “0”, a single “1”, and  $i - 1$  “0”s; and (ii)  $b_R$  consists of the  $l - i$  leftmost bits of  $b$  followed by two “1”s and  $i - 1$  “0”s. These facts readily imply both directions of our claim.

For an example of a complete binary tree and its inorder numbering see Fig. 3.2.

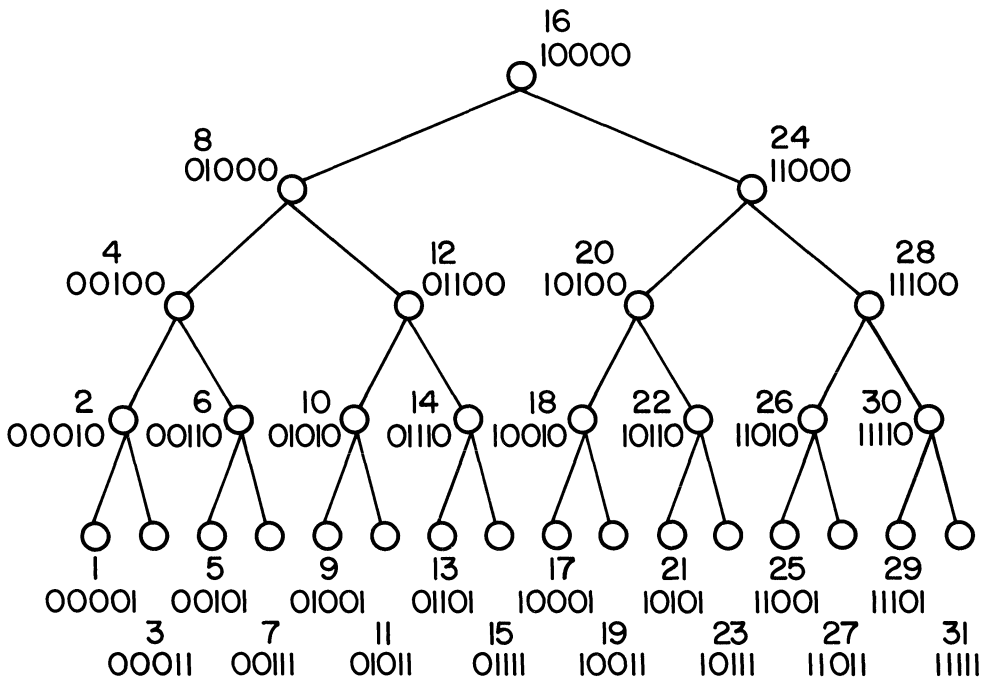

FIG. 3.2. Example. Inorder numbering of the complete binary tree with 31 vertices. (The numbers are given also in binary representation.)

<sup>1</sup> The base of all logarithms in this paper is two.

We return to the proof of Lemma 2. Let  $i$  be the number of rightmost “0” bits in  $\text{INLABEL}(v)$ . Since  $\text{INLABEL}(d)$  belongs to the interval of  $v$  and  $\text{INLABEL}(v)$  has the maximal number of rightmost “0” bits in this interval, the number of rightmost “0” bits in  $\text{INLABEL}(d)$  is at most  $i$ . The  $l-i$  leftmost bits are the same for all numbers in the interval. In particular, the  $l-i$  leftmost bits in  $\text{INLABEL}(d)$  are the same as the  $l-i$  leftmost bits in  $\text{INLABEL}(v)$ . This implies that  $\text{INLABEL}(d)$  is the descendant of  $\text{INLABEL}(v)$  in  $B$ . Lemma 2 follows.  $\square$

**Implementation.** Step (1) is implemented in linear time and linear space, using preorder traversal of  $T$ . Given  $\text{PREORDER}(v)$  and  $\text{SIZE}(v)$ , for each vertex  $v$  in  $T$ , Step (2) is implemented in constant time per vertex in two substeps.

*Step 2.1.* Compute  $\lfloor \log [(\text{PREORDER}(v)-1) \text{ xor } (\text{PREORDER}(v) + \text{SIZE}(v)-1)] \rfloor$  into  $i$ . Let us explain this. The bitwise logical exclusive OR (denoted **xor**) of  $\text{PREORDER}(v)-1$  and  $\text{PREORDER}(v)+\text{SIZE}(v)-1$  assigns “1” to each bit in which  $\text{PREORDER}(v)-1$  and  $\text{PREORDER}(v)+\text{SIZE}(v)-1$  differ. The floor of the (base two) logarithm gives the index of the leftmost bit of difference (counting from the rightmost bit whose index is zero). Note that the bit-indexed  $i$  must be “0” in  $\text{PREORDER}(v)-1$  and “1” in  $\text{PREORDER}(v)+\text{SIZE}(v)-1$ , since the second number is larger.

Step 2.2 shows how to “compose”  $\text{INLABEL}(v)$ . For this, we need two observations. (1) The  $l-i+1$  leftmost bits of  $\text{INLABEL}(v)$  are the same as the  $l-i+1$  leftmost bits in  $\text{PREORDER}(v)+\text{SIZE}(v)-1$ . (2) The  $i$  other bits in  $\text{INLABEL}(v)$  are “0”s.

*Step 2.2.* Compute  $2^i \lfloor (\text{PREORDER}(v)+\text{SIZE}(v)-1)/2^i \rfloor$  into  $\text{INLABEL}(v)$ . This assigns the  $l-i+1$  leftmost bits in  $\text{PREORDER}(v)+\text{SIZE}(v)-1$  to the  $l-i+1$  leftmost bits in  $\text{INLABEL}(v)$  and “0”s to the other bits of  $\text{INLABEL}(v)$ .

*Remark.* The above computation is based on  $\text{PREORDER}$  numbering of the vertices of  $T$ . This numbering has the property that the numbers assigned to the subtree rooted at any vertex of  $T$  provide a consecutive series of integers. In fact, any alternative numbering having this property (e.g.,  $\text{POSTORDER}$ ,  $\text{INORDER}$ ) will produce  $\text{INLABEL}$  numbers that will be suitable for our preprocessing stage.

We proceed to the computation of the  $\text{ASCENDANT}$  numbers. The general idea is that for each vertex  $v$ , the single number  $\text{ASCENDANT}(v)$  will record the  $\text{INLABEL}$  numbers of *all* the ancestors of  $v$  in  $T$ . We observe that, from the viewpoint of vertex  $v$  the  $\text{INLABEL}$  number of each of its ancestors can be fully specified by the index of its rightmost “1”. This is so because the bits that are to the left of this “1” are the same as their respective bits in  $\text{INLABEL}(v)$ . Like the  $\text{INLABEL}$  numbers,  $\text{ASCENDANT}(v)$  is also an  $(l+1)$ -bit number. Denote the binary representation of  $\text{ASCENDANT}(v)$  by the binary sequence  $A_l(v), \dots, A_0(v)$ . We set  $A_i(v) = 1$  only if  $i$  is the index of a rightmost “1” in the  $\text{INLABEL}$  number of an ancestor of  $v$  in  $T$ . To compute the  $\text{ASCENDANT}$  numbers, we scan the vertices of  $T$  from its root  $r$  down to its leaves (use, for instance, Breadth-First Search). We start with  $\text{ASCENDANT}(r) = 2^l$ . Consider an internal vertex  $v$  in  $T$  and let  $F(v)$  be the father of  $v$  in  $T$ . If  $\text{INLABEL}(v) = \text{INLABEL}(F(v))$  then we assign  $\text{ASCENDANT}(F(v))$  to  $\text{ASCENDANT}(v)$ ; otherwise, we assign  $\text{ASCENDANT}(F(v)) + 2^i$  to  $\text{ASCENDANT}(v)$ , where  $i$  is the index of the rightmost “1” in  $\text{INLABEL}(v)$ . It can be easily verified that  $i$  is given by  $\log(\text{INLABEL}(v) - [\text{INLABEL}(v) \text{ and } (\text{INLABEL}(v)-1)])$ , where **and** denotes bitwise logical AND.

Recall that  $\text{LEVEL}(v)$ , for each vertex  $v$  in  $T$ , is the distance, counting edges, of the path from  $v$  to the root  $r$ . Computation of the  $\text{LEVEL}$  numbers is straightforward and can be done using, e.g., Breadth-First Search.

Recall that Fig. 3.1 gives an example of the labels.

We conclude by describing how to compute the Table HEAD. HEAD( $k$ ) contains the vertex closest to the root in the path consisting of all vertices whose INLABEL number is  $k$ . HEAD( $k$ ) is sometimes called the *head* of the INLABEL path  $k$ . Computation of the table HEAD is trivial. For each vertex  $v$ , such that  $\text{INLABEL}(v) \neq \text{INLABEL}(F(v))$  we assign  $v$  to HEAD( $\text{INLABEL}(v)$ ). This, again, takes linear time and linear space.

*A general implementation remark.* The time bounds of both the preprocessing stage and the query processing depend on the ability to perform multiplication, division, powers-of-two computation, bitwise AND, base-two discrete logarithm, and bitwise exclusive OR in constant time. If these operations are not part of the machine's repertoire, look-up tables for each missing operation are prepared in linear time and linear space as part of the preprocessing stage. These tables will be used to perform the missing operations in  $O(1)$  operations in the repertoire.

**4. Processing LCA queries.** In this section we show how to answer LCA queries using the outcome of the preprocessing stage.

Consider a query LCA( $x, y$ ), for any pair of vertices  $x, y$  in  $T$ . (To illustrate the presentation the reader is referred to Fig. 3.1.) There are two cases.

*Case A.*  $\text{INLABEL}(x) = \text{INLABEL}(y)$ . It must be that  $x$  and  $y$  are in the same INLABEL path. We conclude that LCA( $x, y$ ) is  $x$  if  $\text{LEVEL}(x) \leq \text{LEVEL}(y)$  and  $y$  otherwise.

*Case B.*  $\text{INLABEL}(x) \neq \text{INLABEL}(y)$ . Let  $z$  be LCA( $x, y$ ). We find  $z$  in four steps:

*Step 1.* Find  $b$ , the LCA of INLABEL( $x$ ) and INLABEL( $y$ ) in the complete binary tree  $B$ , as follows. Let  $i$  be the index of the rightmost "1" in  $b$ . Since  $b$  is a common ancestor of INLABEL( $x$ ) and INLABEL( $y$ ) in  $B$ ,  $i$  must satisfy the following two conditions. (1) The  $l-i$  leftmost bits in INLABEL( $x$ ) and in INLABEL( $y$ ) are the same as these bits in  $b$ . (2) The index of the rightmost "1" in INLABEL( $x$ ) and in INLABEL( $y$ ) is at most  $i$ . Since  $b$  is the *lowest* common ancestor of INLABEL( $x$ ) and INLABEL( $y$ ) in  $B$ ,  $i$  is the *minimum* index satisfying both conditions. We distinguish three *cases*.

*Case (1).* INLABEL( $x$ ) is an ancestor of INLABEL( $y$ ). Let  $i_1$  be the index of the rightmost "1" in INLABEL( $x$ ). Note that in this case the  $l-i_1$  leftmost bits in INLABEL( $x$ ) and in INLABEL( $y$ ) are the same and that the index of the rightmost "1" in INLABEL( $y$ )  $< i_1$ . Hence,  $i$  equals  $i_1$ .

*Case (2).* INLABEL( $y$ ) is an ancestor of INLABEL( $x$ ). Similar to Case (1),  $i$  is the index of the rightmost "1" in INLABEL( $y$ ).

*Case (3).* Not cases (1) and (2). In this case  $i$  is the *minimum* index such that the  $l-i$  leftmost bits in INLABEL( $x$ ) and INLABEL( $y$ ) are the same.

We can deal with all three cases at once by simply taking  $i$  to be the maximum among the following: the index of the leftmost bit in which INLABEL( $x$ ) and INLABEL( $y$ ) differ; the index of the rightmost "1" in INLABEL( $x$ ); and the index of the rightmost "1" in INLABEL( $y$ ).  $b$  consists of the  $l-i$  leftmost bits in INLABEL( $x$ ) (or INLABEL( $y$ )) followed by a single "1" and  $i$  "0"s.

In Step 2 we find INLABEL( $z$ ) (where  $z$  is LCA( $x, y$ )). The Descendance-Preservation Property of the INLABEL numbers implies that INLABEL( $z$ ) is a common ancestor of INLABEL( $x$ ) and INLABEL( $y$ ). Notice that INLABEL( $z$ ) is not necessarily  $b$ , the *lowest* common ancestor of INLABEL( $x$ ) and INLABEL( $y$ ). This is so because the vertices in  $T$  mapped into  $b$  are not necessarily ancestors of  $x$

or  $y$ . However, it is not difficult to see that  $\text{INLABEL}(z)$  is the lowest ancestor of  $b$  in  $B$  that is the  $\text{INLABEL}$  number of an ancestor of both  $x$  and  $y$  in  $T$ .

*Step 2.* Find  $\text{INLABEL}(z)$ . For this we find the index of the rightmost “1” in  $\text{INLABEL}(z)$ , denoted by  $j$ . Since  $z$  is a common ancestor of  $x$  and  $y$  in  $T$ ,  $A_j(x) = 1$  and  $A_j(y) = 1$ . Since  $\text{INLABEL}(z)$  is the *lowest* ancestor of  $b$  that is a common ancestor of  $x$  and  $y$ , the index  $j$  must be the index of the *rightmost* “1” in  $A_l(x), \dots, A_i(x)$  and  $A_l(y), \dots, A_i(y)$ .  $\text{INLABEL}(z)$  consists of the  $l-j$  leftmost bits of  $\text{INLABEL}(x)$  (or  $\text{INLABEL}(y)$ ) followed by a single “1” and  $j$  “0”s.

In the next steps we find  $z$ , the lowest vertex in the path defined by  $\text{INLABEL}(z)$  that is a common ancestor of  $x$  and  $y$  in  $T$ . For this we find  $\hat{x}$ , the lowest ancestor of  $x$  in the path defined by  $\text{INLABEL}(z)$  and  $\hat{y}$ , the lowest ancestor of  $y$  in this same path.  $z$  is the highest vertex among these two vertices.

*Step 3.* Find  $\hat{x}$  and  $\hat{y}$ . We show how to find  $\hat{x}$ .  $\hat{y}$  is found similarly. If  $\text{INLABEL}(x) = \text{INLABEL}(z)$  then  $\hat{x} = x$  and nothing has to be done. Suppose  $\text{INLABEL}(x) \neq \text{INLABEL}(z)$ . We set the following intermediate goal, as the main step toward finding  $\hat{x}$ : Find the son of  $\hat{x}$  that is also an ancestor of  $x$ . Denote the vertex that we search by  $w$  and let  $k$  be the index of the rightmost “1” in  $\text{INLABEL}(w)$ . It is not difficult to verify that  $k$  is the index of the leftmost “1” in  $A_{j-1}(x), \dots, A_0(x)$ . So, we find  $k$ . Clearly,  $\text{INLABEL}(w)$  consists of the  $l-k$  leftmost bits of  $\text{INLABEL}(x)$  followed by a single “1” and  $k$  “0”s. Observe that  $w$  is the head of its  $\text{INLABEL}$  path (since the  $\text{INLABEL}$  number of its father  $\hat{x}$  is different from  $\text{INLABEL}(w)$ ). Therefore,  $w$  is  $\text{HEAD}(\text{INLABEL}(w))$  and our intermediate goal is achieved. Finally,  $\hat{x}$  is the father of  $w$ .

*Step 4.*  $\text{LCA}(x, y)$  is  $\hat{x}$  if  $\text{LEVEL}(\hat{x}) \leq \text{LEVEL}(\hat{y})$  and  $\hat{y}$  otherwise.

In the rest of this section we give additional implementation details required for the above processing.

*Step 1.* To find  $i$ , the index of the rightmost “1” in  $b$ , we do the following.

*Step 1.1.* Find  $i_1$ , the index of the rightmost “1” in  $\text{INLABEL}(x)$ , and  $i_2$ , the index of the rightmost “1” in  $\text{INLABEL}(y)$ . To find  $i_1$  we compute  $i_1 := \log(\text{INLABEL}(x) - [\text{INLABEL}(x) \text{ and } (\text{INLABEL}(x) - 1)])$ , as in the  $\text{ASCENDANT}$  numbers computation of the previous section.  $i_2$  is found similarly.

*Step 1.2.* Find  $i_3$ , the index of the leftmost bit in which  $\text{INLABEL}(x)$  and  $\text{INLABEL}(y)$  differ. To find  $i_3$  we compute  $i_3 := \lfloor \log[\text{INLABEL}(x) \text{ xor } \text{INLABEL}(y)] \rfloor$ . This is similar to Step 2.1 in the  $\text{INLABEL}$  numbers computation of the previous section.

$i$  is the maximum among  $i_1$ ,  $i_2$ , and  $i_3$ . Given  $i$ ,  $b$  can be computed similarly to Step 2.2 in the  $\text{INLABEL}$  numbers computation.

*Step 2.* To find  $j$  we do the following steps.

*Step 2.1.* Compute the bitwise logical AND of  $\text{ASCENDANT}(x)$  and  $\text{ASCENDANT}(y)$  into  $\text{COMMON}$ .

*Step 2.2.* Compute  $2^i \lfloor \text{COMMON} / 2^i \rfloor$  into  $\text{COMMON}_i$ .  $\text{COMMON}_i$  lists all the “1”s in both  $A_l(x), \dots, A_i(x)$  and  $A_l(y), \dots, A_i(y)$ .

*Step 2.3.*  $j$  is the index of the rightmost “1” in  $\text{COMMON}_i$ . To find  $j$  we compute  $j := \log(\text{COMMON}_i - [\text{COMMON}_i \text{ and } (\text{COMMON}_i - 1)])$ , as in the  $\text{ASCENDANT}$  numbers computation of the previous section.

The implementation of Step 3 uses the same techniques.

**5. The parallel preprocessing algorithm.** In this section we describe the parallel version of our preprocessing stage. It runs in  $O(\log n)$  time using  $n/\log n$  processors.

We make the following assumption regarding the representation of the input tree  $T$ . Its  $n - 1$  edges are given in an array, where the incoming edges of each vertex are grouped successively. By our definition of the tree  $T$ , its edges are directed towards the root.

*Computing the labels in parallel.* To compute the labels of the vertices in  $T$  we apply the Euler tour technique for computing tree functions, which was given in [10] and [12]. We will implement it, however, using the  $O(\log n)$  time optimal parallel list-ranking algorithm of [3]. This list-ranking algorithm is designed for an EREW PRAM. It is based on expander graphs and its  $O(\log n)$  time bound hides a constant that is not very small. We note that [4] recently gave an alternative list-ranking algorithm with the same time and processor efficiencies. This alternative algorithm is designed for a PRAM that allows simultaneous access to the same memory location for both read and write purposes (called CRCW PRAM). It is simpler and its  $O(\log n)$  time bound requires a small constant.

Below, we first recollect the construction required for the Euler tour technique. We then show how to use it for computing the labels. The only reason we were forced to present anew the Euler tour technique is that the computation of the ASCENDANT numbers has not appeared elsewhere.

*Step 1.* For each edge  $(v \rightarrow u)$  in  $T$  we add its antiparallel edge  $(u \rightarrow v)$ . Let  $H$  denote the new graph.

Since the indegree and outdegree of each vertex in  $H$  are the same,  $H$  has an Euler path that starts and ends in  $r$ . Step 2 computes this path into the vector of pointers  $D$ , where for each edge  $e$  of  $H$ ,  $D(e)$  will have the successor edge of  $e$  in the Euler path.

*Step 2.* For each vertex  $v$  of  $H$  we do the following: (Let the outgoing edges of  $v$  be  $(v \rightarrow u_0), \dots, (v \rightarrow u_{d-1})$ .)  $D(u_i \rightarrow v) := (v \rightarrow u_{(i+1) \bmod d})$ , for  $i = 0, \dots, d - 1$ . Now  $D$  has an Euler circuit. The “correction”  $D(u_{d-1} \rightarrow r) := \text{end-of-list}$  (where the outdegree of  $r$  is  $d$ ) gives an Euler path which starts and ends in  $r$ .

We show how to use the Euler path in order to find  $\text{PREORDER}(v)$ ,  $\text{PREORDER}(v) + \text{SIZE}(v) - 1$ , and  $\text{LEVEL}(v)$  for each vertex  $v$  in  $T$ .

*Step 3.* We assign two weights:  $W_1(e)$  and  $W_2(e)$  to each edge  $e$  in the Euler path as follows. (1)  $W_1(e) = 1$  if  $e$  is directed from  $r$  (that is, if  $e$  is not a tree edge), and  $W_1(e) = 0$  otherwise. (2)  $W_2(e) = 1$  if  $e$  is directed from  $r$ , and  $W_2(e) = -1$  otherwise.

*Step 4.* We apply twice an optimal logarithmic time parallel list-ranking algorithm to find for each  $e$  in  $H$  its (weighted) distance from the *start* of the Euler path: The first application is relative to the weights  $W_1$  and the result is stored in  $\text{DISTANCE}_1(e)$ ; the second application is relative to the weights  $W_2$  and the result is stored in  $\text{DISTANCE}_2(e)$ . Consider a vertex  $v \neq r$  and let  $u$  be its father in  $T$ .  $\text{PREORDER}(v)$  is  $\text{DISTANCE}_1(u \rightarrow v) + 1$ ,  $\text{PREORDER}(v) + \text{SIZE}(v) - 1$  is  $\text{DISTANCE}_1(v \rightarrow u) + 1$ , and  $\text{LEVEL}(v)$  is  $\text{DISTANCE}_2(u \rightarrow v)$ . (These claims can be readily verified by the reader.)

*Step 5.* Given  $\text{PREORDER}(v)$  and  $\text{PREORDER}(v) + \text{SIZE}(v) - 1$  for each vertex  $v$  in  $T$  we compute  $\text{INLABEL}(v)$  in constant time using  $n$  processors as in the serial algorithm.

Next, we show how to use the Euler path in order to find  $\text{ASCENDANT}(v)$  for each vertex  $v$  in  $T$ .

*Step 6.* We assign a (new) weight  $W(e)$  to each edge  $e$  in the Euler path as follows. For each vertex  $v \neq r$  we do the following. Let  $u$  be the father of  $v$  in  $T$  and let  $i$  be the index of the rightmost “1” in  $\text{INLABEL}(v)$ . If  $\text{INLABEL}(v) \neq \text{INLABEL}(u)$ , we assign  $W(u \rightarrow v) = 2^i$  and  $W(v \rightarrow u) = -2^i$ . The weight of all other edges is set to zero.

*Step 7.* We again apply a parallel list-ranking algorithm to find for each  $e$  in  $H$  its (weighted) distance from the start of the Euler path. Consider a vertex  $v \neq r$  and let  $u$  be its father in  $T$ .  $\text{ASCENDANT}(v)$  is the distance of the edge  $(u \rightarrow v)$  plus  $2^l$ . Clearly,  $\text{ASCENDANT}(r) = 2^l$ .

We note that, given the labels, the table HEAD can be computed in constant time using  $n$  processors.

*Complexity.* Each of steps 4 and 7 needs  $n/\log n$  processors and  $O(\log n)$  time. Each of Steps 1, 2, 3, 5, 6 and the computation of HEAD needs  $n$  processors and  $O(1)$  time and can be readily simulated by  $n/\log n$  processors in  $O(\log n)$  time. Thus, the parallel preprocessing stage can be done in a total  $O(\log n)$  time using  $n/\log n$  processors.

**Acknowledgments.** We are grateful to Noga Alon and Yael Maon for stimulating discussions. We also thank the anonymous referee for drawing our attention to [9].

## THE POLYNOMIAL TIME HIERARCHY COLLAPSES IF THE BOOLEAN HIERARCHY COLLAPSES\*

JIM KADIN†

**Abstract.** It is shown that if the Boolean hierarchy (BH) collapses, then there exists a sparse set  $S$  such that  $\text{co-NP} \subseteq \text{NP}^S$ , and therefore the polynomial time hierarchy (PH) collapses to  $\text{P}^{\text{NP}^{\text{NP}}[O(\log n)]}$ , a subclass of  $\Delta_3^{\text{P}}$ . Since the BH is contained in  $\text{P}^{\text{NP}}$ , these results relate the internal structure of  $\text{P}^{\text{NP}}$  to the structure of the PH as a whole. Other conditions that imply the collapse of the BH (and the collapse of the PH in turn) include  $\text{D}^{\text{P}} = \text{co-D}^{\text{P}}$ ,  $\text{P}^{\text{NP}[k]} = \text{P}^{\text{NP}[k+1]}$  for any  $k$ , and  $\text{P}^{\text{NP}\parallel[k]} = \text{P}^{\text{NP}\parallel[k+1]}$  for any  $k$ .  $\text{P}^{\text{NP}[i]}$  is the class of languages recognizable in polynomial time with at most  $i$  queries to an oracle from NP, and  $\text{P}^{\text{NP}\parallel[i]}$  is the class of languages recognizable with at most  $i$  parallel queries to an oracle from NP.

**Key words.** polynomial time hierarchy, Boolean hierarchy, polynomial time Turing reductions, oracle access, nonuniform algorithms, sparse sets

**AMS(MOS) subject classifications.** 68Q15, 03D15, 03D20

**1. Introduction.** Many different complexity hierarchies have recently been shown to collapse. Hemachandra showed that the strong exponential hierarchy collapses to its second level [7]. Several proofs appeared showing that the logarithmic space and linear space hierarchies collapse to their second levels [15], [23], [20]. Then Immerman and Szelepcsényi independently showed that nondeterministic space classes are closed under complementation which implies that the logarithmic and linear space hierarchies collapse all the way to their first levels, nondeterministic logarithmic and linear space, respectively [9], [22]. These results have greatly increased our understanding of resource-bounded computation and have simplified the complexity theory world.

In this paper we present strong evidence that three other lesser-known hierarchies, the Boolean hierarchy (BH), the query hierarchy (QH), and the parallel query hierarchy ( $\text{QH}_{\parallel}$ ), do not collapse. We show that if the BH, QH, or  $\text{QH}_{\parallel}$  collapses, then the polynomial time hierarchy (PH) collapses to  $\text{P}^{\text{NP}^{\text{NP}}[O(\log n)]}$ , the class of languages recognizable in deterministic polynomial time with  $O(\log n)$  queries to an oracle for  $\text{NP}^{\text{NP}}$ .  $\text{P}^{\text{NP}^{\text{NP}}[O(\log n)]}$  is a subclass of  $\Delta_3^{\text{P}}$ , the third level of the PH. If the PH is an infinite hierarchy as most researchers believe, then the BH, QH, and  $\text{QH}_{\parallel}$  are also infinite hierarchies.

The BH, QH, and  $\text{QH}_{\parallel}$  contain  $\text{NP} \cup \text{co-NP}$  and intertwine to form a rich structure inside  $\text{P}^{\text{NP}}$ . By relating these hierarchies to the PH, our results provide a deeper understanding of the PH. We see that the internal structure of  $\text{P}^{\text{NP}}$  and issues concerning how polynomial time machines can access the information from NP oracles are tied to the structure of the PH as a whole. This is also a downward structural result. We show that the structure of the BH above NP and co-NP affects the structure of the set of unsatisfiable Boolean formulas and thus co-NP itself.

The QH is  $\bigcup_k \text{P}^{\text{NP}[k]}$ , where  $\text{P}^{\text{NP}[k]}$  is the class of languages recognizable in deterministic polynomial time with at most  $k$  queries to an oracle in NP.

The  $\text{QH}_{\parallel}$  is  $\bigcup_k \text{P}^{\text{NP}\parallel[k]}$ , where  $\text{P}^{\text{NP}\parallel[k]}$  is the class of languages recognizable in

deterministic polynomial time with at most  $k$  parallel queries to an oracle in NP. A machine makes its queries in parallel if it computes all the strings that are to be queried before it receives any query answers from the oracle. The  $QH_{\parallel}$  equals  $BTT[NP]$ , the class of languages that are polynomial time bounded truth-table reducible to NP sets. Polynomial time bounded truth-table reducibilities are defined in [14].

The BH, defined by Cai, Gundermann, Hartmanis, Hemachandra, Sewelson, Wagner, and Wechsung [4] is a generalization of the class  $D^P$ .  $D^P$  was defined by Papadimitriou and Yannakakis to fully capture the complexity of several natural problems related to NP-optimization problems [19]. A language is in  $D^P$  if it is the difference of two NP languages:

$$D^P \stackrel{\text{def}}{=} \{L_1 - L_2 \mid L_1, L_2 \in NP\}.$$

Equivalently,  $L \in D^P$  if  $L = L_1 \cap \overline{L_2}$ , where  $L_1, L_2 \in NP$ . TSP facets, exact clique, and graph minimal uncolorability are  $\leq_m^P$ -complete for  $D^P$  [18], [19], [5].

The class  $\text{co-}D^P$  consists of the languages whose complements are in  $D^P$ . A language  $L$  is in  $\text{co-}D^P$  if  $L = \overline{L_1} \cup L_2$ , where  $L_1, L_2 \in NP$ . It is unknown whether  $D^P = \text{co-}D^P$ .

The first level of the BH,  $BH(1)$ , is defined to be NP. The second level,  $BH(2)$ , is  $D^P$ . Generalizing  $D^P$ , which is defined by one Boolean operator over NP predicates, the subsequent levels of the BH are defined by allowing more Boolean operations over NP predicates. See § 3 for a precise definition.  $BH \stackrel{\text{def}}{=} \bigcup_k BH(k)$ . For each  $k$ ,  $\text{co-}BH(k)$  is the class of languages whose complements are in  $BH(k)$ . It is unknown whether any level of the BH is closed under complementation, but it is shown in [4] that for all  $k$ ,

$$BH(k) = \text{co-}BH(k) \iff BH = BH(k).$$

The levels of the BH, QH, and  $QH_{\parallel}$  intertwine (see § 3). Therefore  $BH = QH = QH_{\parallel} = BTT[NP]$ , and either all three hierarchies collapse or all three are infinite hierarchies. All three hierarchies are contained in  $P^{NP}$ , the  $\Delta_2^P$  level of the PH:

$$NP \cup \text{co-NP} \subseteq P^{NP[1]} \subseteq D^P \subseteq P^{NP[2]} \subseteq P^{NP[2]} \subseteq \dots \subseteq QH = QH_{\parallel} = BH \subseteq P^{NP}.$$

Our proof that the collapse of these hierarchies causes the PH to collapse depends on the structure of the BH. We show that if the BH collapses, then there exist nonuniform NP algorithms for the languages in  $\text{co-NP}$ . That is, every language in  $\text{co-NP}$  can be recognized by an NP machine with access to a sparse oracle. A set  $S$  is sparse if the number of strings in  $S$  of each length is bounded by a polynomial.

**THEOREM.** *For all  $k$ , if  $BH(k) = \text{co-}BH(k)$ , then there exists a sparse set  $S \in NP^{NP}$  such that  $\text{co-NP} \subseteq NP^S$ .*

By the results of Yap in [26], the existence of a sparse set  $S$  such that  $\text{co-NP} \subseteq NP^S$  implies  $PH \subseteq NP^{NP^{NP}}$ , the  $\Sigma_3^P$  level of the PH. We relativize the main result in [10] to show that if the sparse set is in  $NP^{NP}$ , then the PH collapses further.

**THEOREM.** *If there exists a sparse set  $S \in NP^{NP}$  such that  $\text{co-NP} \subseteq NP^S$ , then  $PH \subseteq P^{NP^{NP}[O(\log n)]}$ .*

These two theorems together imply our main result.

**THEOREM.** *For all  $k$ , if  $BH(k) = \text{co-}BH(k)$ , then  $PH \subseteq P^{NP^{NP}[O(\log n)]}$ .*

**COROLLARY.** *If  $D^P = \text{co-}D^P$ , then  $PH \subseteq P^{NP^{NP}[O(\log n)]}$ .*

Since the collapse of the QH or the  $QH_{\parallel}$  implies the collapse of the BH, we also have the following corollaries.

COROLLARY. For all  $k$ , if  $P^{NP[k]} = P^{NP[k+1]}$ , then  $PH \subseteq P^{NP^{NP}[O(\log n)]}$ .

COROLLARY. For all  $k$ , if  $P^{NP\parallel[k]} = P^{NP\parallel[k+1]}$ , then  $PH \subseteq P^{NP^{NP}[O(\log n)]}$ .

Therefore the structure of the PH as a whole is closely related to the structure of  $P^{NP}$  and to the question of whether deterministic polynomial time machines can compute more if they are allowed to make more NP queries.

Our proof also shows that the structure within  $P^{NP}$  is related to co-NP itself. The existence of the sparse set  $S$  such that  $co-NP \subseteq NP^S$  is really quite a strong statement about the structure of unsatisfiable Boolean formulas. Indeed, the set  $S$  that we construct consists mainly of key unsatisfiable formulas, a constant number of each length, such that knowing these key formulas provides an NP algorithm for recognizing all unsatisfiable formulas of that length. In particular, if  $D^P = co-D^P$ , then there exists one key string of each length.

These results also relativize to the other  $\Delta_i^P$  levels of the PH. We can define a Boolean hierarchy and query hierarchy within each  $P^{\Sigma_i^P}$  and conclude that

$$PH \text{ collapses} \iff \exists i, k, P^{\Sigma_i^P[k]} = P^{\Sigma_i^P[k+1]}.$$

This work is also related to Krentel's results for classes of functions. He showed that for functions  $f(n)$  and  $g(n)$  with  $f(n) \leq \frac{1}{2} \log n$  and  $f(n) < g(n)$ , if  $FP^{NP[f(n)]} = FP^{NP[g(n)]}$ , then  $P = NP$  [13].  $FP^{NP[h(n)]}$  is the class of functions computable in polynomial time with  $h(n)$  queries to an oracle for NP. In particular,

$$FP^{NP[k]} = FP^{NP[k+1]} \implies P = NP.$$

Our result that

$$P^{NP[k]} = P^{NP[k+1]} \implies PH \text{ collapses}$$

has a weaker hypothesis and a weaker, yet similar, conclusion.

**2. Preliminaries.** The reader is assumed to be familiar with P, NP, oracle Turing machines, the NP-complete set SAT, the set of satisfiable Boolean formulas, and  $\overline{SAT}$ , the set of unsatisfiable Boolean formulas. All of these topics are covered in [8]. We also assume the reader is familiar with the PH defined in [21].

For any Turing machine  $N$ ,  $|N|$  is the size of the state transition table of  $N$ .

For any string  $x$ ,  $|x|$  is the length of  $x$ .

For any set of strings  $C$ ,  $C^{=n}$  is the set of strings in  $C$  of length  $n$ .  $C^{\leq n}$  is the set of strings in  $C$  of length less than or equal to  $n$ .

We write  $\|C\|$  for the cardinality of any set  $C$ .

For any two sets of strings  $B$  and  $C$ , the *disjoint union* of  $B$  and  $C$  is

$$B \oplus C \stackrel{\text{def}}{=} \{0x \mid x \in B\} \cup \{1x \mid x \in C\}.$$

For  $k$  sets  $B_1, \dots, B_k$ , this extends to

$$B_1 \oplus \dots \oplus B_k \stackrel{\text{def}}{=} \bigcup_i \{\underline{i}x \mid x \in B_i\},$$

where  $\underline{i}$  is the bit pattern of  $\lceil \log k \rceil$  bits representing  $i$  in binary.

DEFINITION 2.1. *A set of strings  $S$  is sparse if there exists a polynomial  $p(\cdot)$  such that for all  $n$ , the number of strings in  $S$  of length  $n$  is at most  $p(n)$ , i.e.,  $\|S^{\leq n}\| \leq p(n)$ .*

DEFINITION 2.2. *For any set of strings  $S$ , the census function of  $S$  gives the number of strings in  $S$  of length at most  $n$ :  $\text{Census}_S(n) \stackrel{\text{def}}{=} \|S^{\leq n}\|$ .*

There is a standard technique of using the prefixes of strings in a sparse set to find the strings in the set. For any sparse set  $S$ , let

$$\text{prefix}(S) \stackrel{\text{def}}{=} \{y\#^i \mid i \geq 0, \exists w \text{ with } |w|=i \text{ and } yw \in S\},$$

where “#” is a new alphabet symbol. The set  $\text{prefix}(S)$  is the set of *marked prefixes* of  $S$ . For every  $n$ ,  $\text{prefix}(S)$  contains at most  $n$  times as many strings of length  $n$  as  $S$  does. Therefore  $\text{prefix}(S)$  is sparse if  $S$  is. A deterministic polynomial time machine with an oracle for  $\text{prefix}(S)$  can generate all the strings in  $S^{\leq n}$  on input  $1^n$ . The machine builds up each string one character at a time by asking the oracle about longer and longer prefixes. A machine can actually generate all the strings in  $\text{prefix}(S)$  up to a given length this way. If we add all the strings in  $\text{prefix}(S)$  to  $S$ , we say  $S$  is *prefix marked*.

DEFINITION 2.3. *A set  $S$  is  $P^B$ -printable for an oracle  $B$  if there exists a  $P^B$  machine that prints all the strings in  $S^{\leq n}$  on input  $1^n$ .*

DEFINITION 2.4. *A set  $S$  is self-P-printable if  $S$  is  $P^S$ -printable.*

Thus if a sparse set  $S$  is prefix marked, then  $S$  is self-P-printable. Note that  $S \subseteq \text{prefix}(S)$ , and clearly  $\text{NP}^S \subseteq \text{NP}^{\text{prefix}(S)}$ .

**3. The hierarchies.** The query hierarchy, QH, and the parallel query hierarchy,  $\text{QH}_{\parallel}$ , arise quite naturally from questions about the structure of  $\text{P}^{\text{NP}}$  and the power of NP queries in general.

DEFINITION 3.1. *For  $k \geq 1$ ,  $\text{P}^{\text{NP}[k]}$  is the class of languages recognized by deterministic polynomial time oracle machines that make at most  $k$  queries to an oracle for NP.*

DEFINITION 3.2.  $\text{QH} \stackrel{\text{def}}{=} \bigcup_k \text{P}^{\text{NP}[k]}$ .

Unrestricted  $\text{P}^{\text{NP}}$  and  $\text{P}^{\text{NP}[k]}$  machines make their queries in a serial fashion: the answers to previous queries can be used to determine which string to query next. An alternative is to consider machines that are required to make their queries all at once, in parallel. Parallel query machines write down a list of query strings on their oracle tape and then enter the query state. The oracle replaces the query strings with a bit vector representing the answers to the queries. No further queries are permitted. Thus parallel query machines must compute all their queries in polynomial time without access to any oracle.

DEFINITION 3.3.  $\text{P}^{\text{NP}\parallel}$  is the class of languages recognizable by deterministic polynomial time machines that make (polynomially many) parallel queries to an oracle for NP.

DEFINITION 3.4. *For  $k \geq 1$ ,  $\text{P}^{\text{NP}\parallel[k]}$  is the class of languages recognized by deterministic polynomial time oracle machines that make at most  $k$  parallel queries to an oracle for NP.*

DEFINITION 3.5.  $\text{QH}_{\parallel} \stackrel{\text{def}}{=} \bigcup_k \text{P}^{\text{NP}\parallel[k]}$ .

Clearly,  $\text{P}^{\text{NP}\parallel} \subseteq \text{P}^{\text{NP}}$ , and for all  $k$ ,  $\text{P}^{\text{NP}\parallel[k]} \subseteq \text{P}^{\text{NP}[k]}$ .

Polynomial time truth-table and bounded truth-table reducibilities were defined in [14]. It is clear from the definitions that  $\text{P}^{\text{NP}\parallel} = \text{TT}[\text{NP}]$ , the class of languages polynomial time truth-table reducible to a language in NP. Similarly,  $\text{QH}_{\parallel} =$

BTT[NP], the class of languages that are bounded truth-table reducible to an NP language.

A related class is the set of languages recognizable with  $O(\log n)$  queries to an NP oracle.

DEFINITION 3.6.  $P^{NP[O(\log n)]}$  is the class of languages recognizable in deterministic polynomial time with  $O(\log n)$  queries to an NP oracle.

Clearly,  $QH \subseteq P^{NP[O(\log n)]}$ .

Since SAT is NP-complete, any queries made to an oracle for an NP language can be translated to queries to SAT without changing the number of queries made during the computation. Thus  $P^{SAT[k]} = P^{NP[k]}$ ,  $P^{SAT\parallel[k]} = P^{NP\parallel[k]}$ ,  $P^{SAT[O(\log n)]} = P^{NP[O(\log n)]}$ , etc.

It is easy to see that  $P^{NP[O(\log n)]} \subseteq P^{NP\parallel}$ . Given any  $P^{NP[O(\log n)]}$  machine and input  $x$ , we can run the machine on  $x$  trying both answers to each query and see what queries it asks with each answer sequence. Since the machine makes only  $O(\log n)$  queries no matter how the queries are answered, the number of different answer sequences and the number of possible queries is bounded by a polynomial in  $|x|$ . Therefore a polynomial time machine can generate all the possible queries and then determine if the  $P^{NP[O(\log n)]}$  machine accepts  $x$  by asking all the queries in parallel. Hence  $P^{NP[O(\log n)]} \subseteq P^{NP\parallel}$ . By a similar argument,  $P^{NP[k]} \subseteq P^{NP\parallel[2^k]}$ , and hence the QH and  $QH_{\parallel}$  intertwine, and  $QH = QH_{\parallel}$ .

Exploiting the NP-completeness of SAT, Hemachandra showed that  $P^{NP\parallel} \subseteq P^{NP[O(\log n)]}$  [7]. Therefore  $P^{NP\parallel} = P^{NP[O(\log n)]}$ .

In summary,

$$NP \cup \text{co-NP} \subseteq P^{NP[1]} \subseteq P^{NP[2]} \subseteq \dots \subseteq QH = QH_{\parallel} = \text{BTT[NP]} \\ \subseteq P^{NP[O(\log n)]} = P^{NP\parallel} \subseteq P^{NP}.$$

The BH is defined in [4]. It is a generalization of the class  $D^P$ , defined by Papadimitriou and Yannakakis [19].  $D^P$  has stirred a lot of interest because it contains many languages related to NP optimization problems. There are several ways of defining the BH and many normal forms for each level. We use the definition that most explicitly shows the structure that we will exploit later.

DEFINITION 3.7.  $BH(1) \stackrel{\text{def}}{=} NP$ . For  $i > 0$ ,

$$BH(2i) \stackrel{\text{def}}{=} \{L \mid L = L' \cap \overline{L_2}, \text{ where } L' \in BH(2i - 1), L_2 \in NP\},$$

$$BH(2i + 1) \stackrel{\text{def}}{=} \{L \mid L = L' \cup L_2, \text{ where } L' \in BH(2i), L_2 \in NP\}.$$

DEFINITION 3.8. For all  $i \geq 1$ ,  $\text{co-BH}(i)$  is the class of languages whose complements are in  $BH(i)$ .

DEFINITION 3.9.  $BH \stackrel{\text{def}}{=} \bigcup_k BH(k)$ .

Let  $L_i \in NP$ , then these definitions unwind as follows:

$$\begin{aligned} BH(1) &= NP, \\ BH(2) &= \{L_1 \cap \overline{L_2}\} (= D^P), \\ BH(3) &= \{(L_1 \cap \overline{L_2}) \cup L_3\}, \\ BH(4) &= \{((L_1 \cap \overline{L_2}) \cup L_3) \cap \overline{L_4}\}, \end{aligned}$$

$$\begin{aligned}
 \text{co-BH}(1) &= \text{co-NP}, \\
 \text{co-BH}(2) &= \{\overline{L_1} \cup L_2\} (= \text{co-D}^P), \\
 \text{co-BH}(3) &= \{(\overline{L_1} \cup L_2) \cap \overline{L_3}\}, \\
 \text{co-BH}(4) &= \{((\overline{L_1} \cup L_2) \cap \overline{L_3}) \cup L_4\}, \\
 &\vdots
 \end{aligned}$$

Many results about the BH are proven in [4]. For instance,

- (1)  $\text{BH}(k) \cup \text{co-BH}(k) \subseteq \text{BH}(k+1) \cap \text{co-BH}(k+1)$ .
- (2) The BH, QH, and  $\text{QH}_{\parallel}$  intertwine. Therefore

$$\text{BH} = \text{QH} = \text{QH}_{\parallel} = \text{BTT}[\text{NP}].$$

- (3) The BH has the upward collapse property:

$$\text{BH}(k) = \text{co-BH}(k) \iff \text{BH}(k) = \text{BH}.$$

The QH and  $\text{QH}_{\parallel}$  also have upward collapse properties:

$$\begin{aligned}
 \text{P}^{\text{NP}[k]} = \text{P}^{\text{NP}[k+1]} &\iff \text{P}^{\text{NP}[k]} = \text{QH}, \quad \text{and} \\
 \text{P}^{\text{NP}\parallel[k]} = \text{P}^{\text{NP}\parallel[k+1]} &\iff \text{P}^{\text{NP}\parallel[k]} = \text{QH}_{\parallel}.
 \end{aligned}$$

One way to see these properties is through the detailed examination of the intertwining of the hierarchies in [1], [2]. In [2], the following relationships are proven:

$$\begin{aligned}
 \text{BH}(k) \cup \text{co-BH}(k) &\subseteq \text{P}^{\text{NP}\parallel[k]} \subseteq \text{BH}(k+1) \cap \text{co-BH}(k+1), \\
 \text{BH}(2^k - 1) \cup \text{co-BH}(2^k - 1) &\subseteq \text{P}^{\text{NP}[k]} \subseteq \text{BH}(2^k) \cap \text{co-BH}(2^k).
 \end{aligned}$$

Therefore, if any two levels of the QH or  $\text{QH}_{\parallel}$  collapse, some level of the BH is closed under complementation, which implies that all three hierarchies collapse.

The intertwining, the upward collapse properties, and the fact that  $\text{P}^{\text{NP}[k]}$  and  $\text{P}^{\text{NP}\parallel[k]}$  are closed under complementation imply the following theorem.

**THEOREM 3.10.** *The following are equivalent:*

- (1) BH collapses.
- (2) QH collapses.
- (3)  $\text{QH}_{\parallel}$  collapses.
- (4)  $\exists k \text{ BH}(k) = \text{co-BH}(k)$ .
- (5)  $\exists j \text{ P}^{\text{NP}[j]} = \text{P}^{\text{NP}[j+1]}$ .
- (6)  $\exists j \text{ P}^{\text{NP}\parallel[j]} = \text{P}^{\text{NP}\parallel[j+1]}$ .
- (7)  $\exists j, k \text{ BH}(k) = \text{P}^{\text{NP}[j]}$ .
- (8)  $\exists j, k \text{ BH}(k) = \text{P}^{\text{NP}\parallel[j]}$ .
- (9)  $\exists j, k \text{ BH}(k) \cup \text{co-BH}(k) = \text{P}^{\text{NP}[j]}$ .
- (10)  $\exists j, k \text{ BH}(k) \cup \text{co-BH}(k) = \text{P}^{\text{NP}\parallel[j]}$ .

The equivalence of conditions (1) - (4) is also noted in [2].

To see that the structure of the BH is related to the structure of the PH, we need to understand the structure of the  $\leq_m^P$ -complete sets defined in [4]. For each  $k$ , a complete language,  $L_{\text{BH}(k)}$ , can be defined in terms of SAT and  $\overline{\text{SAT}}$ .

**DEFINITION 3.11.**  $L_{\text{BH}(1)} \stackrel{\text{def}}{=} \text{SAT}$ . For  $i > 0$ ,

$$\begin{aligned}
 L_{\text{BH}(2i)} &\stackrel{\text{def}}{=} \{(F_1, \dots, F_{2i}) \mid (F_1, \dots, F_{2i-1}) \in L_{\text{BH}(2i-1)} \text{ and } F_{2i} \in \overline{\text{SAT}}\}, \\
 L_{\text{BH}(2i+1)} &\stackrel{\text{def}}{=} \{(F_1, \dots, F_{2i+1}) \mid (F_1, \dots, F_{2i}) \in L_{\text{BH}(2i)} \text{ or } F_{2i+1} \in \text{SAT}\}.
 \end{aligned}$$

Similarly, for each  $k$ , we can define a complete language for  $\text{co-BH}(k)$ .

DEFINITION 3.12.  $L_{\text{co-BH}(1)} \stackrel{\text{def}}{=} \overline{\text{SAT}}$ . For  $i > 0$ ,

$$L_{\text{co-BH}(2i)} \stackrel{\text{def}}{=} \{ (F_1, \dots, F_{2i}) \mid (F_1, \dots, F_{2i-1}) \in L_{\text{co-BH}(2i-1)} \text{ or } F_{2i} \in \text{SAT} \},$$

$$L_{\text{co-BH}(2i+1)} \stackrel{\text{def}}{=} \{ (F_1, \dots, F_{2i+1}) \mid (F_1, \dots, F_{2i}) \in L_{\text{co-BH}(2i)} \text{ and } F_{2i+1} \in \overline{\text{SAT}} \}.$$

Unwinding these definitions a bit:

$$L_{\text{BH}(1)} \stackrel{\text{def}}{=} \text{SAT},$$

$$L_{\text{BH}(2)} \stackrel{\text{def}}{=} \text{SAT} \& \overline{\text{SAT}}$$

$$\stackrel{\text{def}}{=} \{ (F_1, F_2) \mid F_1 \in \text{SAT} \text{ and } F_2 \in \overline{\text{SAT}} \},$$

$$L_{\text{BH}(3)} \stackrel{\text{def}}{=} (\text{SAT} \& \overline{\text{SAT}}) \mid \text{SAT}$$

$$\stackrel{\text{def}}{=} \{ (F_1, F_2, F_3) \mid (F_1 \in \text{SAT} \text{ and } F_2 \in \overline{\text{SAT}}) \text{ or } F_3 \in \text{SAT} \},$$

$$L_{\text{BH}(4)} \stackrel{\text{def}}{=} ((\text{SAT} \& \overline{\text{SAT}}) \mid \text{SAT}) \& \overline{\text{SAT}}$$

$$\stackrel{\text{def}}{=} \{ (F_1, F_2, F_3, F_4) \mid ((F_1 \in \text{SAT} \text{ and } F_2 \in \overline{\text{SAT}}) \text{ or } F_3 \in \text{SAT}) \text{ and } F_4 \in \overline{\text{SAT}} \},$$

$$\vdots$$

$$L_{\text{co-BH}(1)} \stackrel{\text{def}}{=} \overline{\text{SAT}},$$

$$L_{\text{co-BH}(2)} \stackrel{\text{def}}{=} \overline{\text{SAT}} \mid \text{SAT}$$

$$\stackrel{\text{def}}{=} \{ (F_1, F_2) \mid F_1 \in \overline{\text{SAT}} \text{ or } F_2 \in \text{SAT} \},$$

$$L_{\text{co-BH}(3)} \stackrel{\text{def}}{=} (\overline{\text{SAT}} \mid \text{SAT}) \& \overline{\text{SAT}}$$

$$\stackrel{\text{def}}{=} \{ (F_1, F_2, F_3) \mid (F_1 \in \overline{\text{SAT}} \text{ or } F_2 \in \text{SAT}) \text{ and } F_3 \in \overline{\text{SAT}} \},$$

$$L_{\text{co-BH}(4)} \stackrel{\text{def}}{=} ((\overline{\text{SAT}} \mid \text{SAT}) \& \overline{\text{SAT}}) \mid \text{SAT}$$

$$\stackrel{\text{def}}{=} \{ (F_1, F_2, F_3, F_4) \mid ((F_1 \in \overline{\text{SAT}} \text{ or } F_2 \in \text{SAT}) \text{ and } F_3 \in \overline{\text{SAT}}) \text{ or } F_4 \in \text{SAT} \},$$

$$\vdots$$

Note the structure of  $L_{\text{BH}(k)}$  and  $L_{\text{co-BH}(k)}$ . For even  $k$ 's, the  $k$ -tuples in  $L_{\text{BH}(k)}$  have the form “ $(k-1\text{-tuple}) \& \overline{\text{SAT}}$ ”, where the  $k-1$ -tuple is in  $L_{\text{BH}(k-1)}$ , and the  $k$ th component is in  $\overline{\text{SAT}}$ . The  $k$ -tuples in  $L_{\text{co-BH}(k)}$  have the form “ $(k-1\text{-tuple}) \mid \text{SAT}$ ”, where the  $k-1$ -tuple is in  $L_{\text{co-BH}(k-1)}$ , or the  $k$ th component is in  $\text{SAT}$ . If  $k$  is odd,  $L_{\text{BH}(k)}$  and  $L_{\text{co-BH}(k)}$  have a similar structure, but  $\text{BH}(i)$  and  $\text{co-BH}(i)$  are reversed. It will become clear that this is the key that relates the collapse of the BH to the collapse of the PH.

For all  $k$ ,  $L_{\text{BH}(k)}$  and  $L_{\text{co-BH}(k)}$  are complements. Hence any function  $f$  that reduces  $L_{\text{BH}(k)}$  to  $L_{\text{co-BH}(k)}$  also reduces  $L_{\text{co-BH}(k)}$  to  $L_{\text{BH}(k)}$ .

**4. Generating the sparse oracle.** In this section we show that the collapse of the BH forces the existence of a sparse set  $S \in \text{NP}^{\text{NP}}$  such that  $\text{co-NP} \subseteq \text{NP}^S$ . By the results of Yap, the existence of a sparse set  $S$  such that  $\text{co-NP} \subseteq \text{NP}^S$  implies that

the PH collapses to  $\Sigma_3^P$  [26]. In § 5 we will show that the fact that the sparse set is in  $NP^{NP}$  actually implies that the PH collapses to  $P^{NP^{NP^{O(\log n)}}$ , the class of languages recognizable in polynomial time with  $O(\log n)$  queries to an oracle in  $NP^{NP}$ .

The basic idea is that if for some  $k$ ,  $BH(k) = \text{co-BH}(k)$ , and thus

$$L_{\text{co-BH}(k)} \leq_m^P L_{\text{BH}(k)},$$

then  $\overline{\text{SAT}}$  can be reduced to SAT by a polynomial time function that accesses a sparse oracle. The crux of the proof is in the construction of the sparse set. We will illustrate the main idea of the construction by showing how the argument works in the case where  $\text{BH}(2) = \text{co-BH}(2)$  ( $D^P = \text{co-D}^P$ ).

Suppose that  $\text{BH}(2) = \text{co-BH}(2)$ . Then  $L_{\text{BH}(2)} \leq_m^P L_{\text{co-BH}(2)}$ . That is, there is some polynomial time function  $h(\cdot, \cdot)$  such that

$$\text{SAT} \& \overline{\text{SAT}} \leq_m^P \overline{\text{SAT}} \mid \text{SAT} \text{ via } h.$$

The key is that  $h$  maps a conjunction to a disjunction. Both conditions of the conjunction are met if just one of the disjuncts is met. In the easy case, if the second component of the output of  $h$  is a satisfiable formula, then the first component of the input is satisfiable, and the second component is *not satisfiable*. This gives rise to an NP algorithm for recognizing some of  $\overline{\text{SAT}}$ .

Consider a formula  $F$  of length  $n$ . Suppose there exists a formula  $F'$  of length  $n$  such that

$$h(F', F) = (G', G), \text{ where } G \in \text{SAT}.$$

Then  $(G', G) \in \overline{\text{SAT}} \mid \text{SAT}$ , which implies  $F \in \overline{\text{SAT}}$  (and  $F' \in \text{SAT}$ ). Therefore an NP machine can recognize that  $F \in \overline{\text{SAT}}$  by guessing  $F'$ , computing  $h(F', F)$ , and verifying that  $G \in \text{SAT}$ . We call formulas such as  $F$  *easy* since an NP algorithm can recognize that  $F \in \overline{\text{SAT}}$ .

Let  $N_{\text{easy}}$  be the NP machine that executes this algorithm.  $L(N_{\text{easy}}) \subseteq \overline{\text{SAT}}$ , and clearly there is a polynomial time reduction from  $L(N_{\text{easy}})$  to SAT. Call this reduction  $h_{\text{easy}}$ . If all the strings in  $\overline{\text{SAT}}^n$  are easy, then  $h_{\text{easy}}$  reduces  $\overline{\text{SAT}}^n$  to SAT.

If not all the unsatisfiable strings of length  $n$  are easy, then some of them must be *hard*. A formula  $F$  of length  $n$  is *hard* if  $F \in \overline{\text{SAT}}$  and for all  $F'$  of length  $n$ ,

$$h(F', F) = (G', G), \text{ where } G \in \overline{\text{SAT}}.$$

Hard strings have a very useful property: given any hard string  $\hat{F}$  of length  $n$ ,  $h$  can be used to reduce  $\overline{\text{SAT}}^n$  to SAT. If  $F$  is any formula of length  $n$ , then

$$h(F, \hat{F}) = (G, \hat{G}), \text{ where } \hat{G} \in \overline{\text{SAT}}.$$

Since  $h$  is a reduction from  $\text{SAT} \& \overline{\text{SAT}}$  to  $\overline{\text{SAT}} \mid \text{SAT}$ ,

$$(F, \hat{F}) \in \text{SAT} \& \overline{\text{SAT}} \iff (G, \hat{G}) \in \overline{\text{SAT}} \mid \text{SAT}.$$

Since  $\hat{G} \notin \text{SAT}$ ,

$$(F, \hat{F}) \in \text{SAT} \& \overline{\text{SAT}} \iff G \in \overline{\text{SAT}}.$$

Since  $\hat{F} \in \overline{\text{SAT}}$ ,

$$F \in \text{SAT} \iff G \in \overline{\text{SAT}},$$

but this is equivalent to  $F \in \overline{\text{SAT}} \iff G \in \text{SAT}$ .

Let  $h_{\text{hard}(\hat{F})}$  be the polynomial time function that takes an input  $F$ , computes  $h(F, \hat{F}) = (G, \hat{G})$ , and outputs  $G$ . If  $|\hat{F}| = n$  and  $\hat{F}$  is hard, then  $h_{\text{hard}(\hat{F})}$  reduces  $\overline{\text{SAT}}^n$  to SAT. Note how each hard formula of length  $n$  is really a *key* string that gives rise to an NP algorithm for recognizing  $\overline{\text{SAT}}^n$  (accept  $F$  if  $h_{\text{hard}(\hat{F})}(F) \in \text{SAT}$ ).

Now it should be clear how to define a sparse set  $S$  and function  $g$  such that  $g^S$  reduces  $\overline{\text{SAT}}$  to SAT. For each length  $n$ , if some unsatisfiable formula of length  $n$  is hard, put the lexicographically least string and all of its marked prefixes into  $S$ . Then  $S$  is prefix marked so it is self-P-printable. Then  $g^S$  on input  $F$  of length  $n$  computes as follows:

- (1) Generate all the strings in  $S^n$ .
- (2) If  $S^n = \phi$ , then output  $h_{\text{easy}}(F)$ .
- (3) Otherwise, let  $\hat{F}$  be the hard string of length  $n$  in  $S$  (the only string in  $S^n$  that is not marked as a prefix), and output  $h_{\text{hard}(\hat{F})}(F)$ .

We can generalize this argument to show that there exists such a sparse set if any level of the BH is closed under complementation. The main lemma is that for any  $k$ , if there exist a sparse  $S$  and polynomial time function  $g$  such that  $g^S$  reduces  $L_{\text{BH}(k)}$  to  $L_{\text{co-BH}(k)}$ , then there exist another sparse set and function that reduces  $L_{\text{BH}(k-1)}$  to  $L_{\text{co-BH}(k-1)}$ . So if  $\text{BH}(k) = \text{co-BH}(k)$ , then for all  $i \leq k$ , there exist a sparse  $S$  and function  $g$  such that  $g^S$  reduces  $L_{\text{BH}(i)}$  to  $L_{\text{co-BH}(i)}$ . Thus if the BH collapses,  $\overline{\text{SAT}}$  can be reduced to SAT by a polynomial time function that accesses a sparse oracle. This implies  $\text{co-NP} \subseteq \text{NP}^S$  for some sparse set  $S$ , and therefore the PH collapses (see § 5).

The key that makes this work is the fine structure of the BH. Recall that a function is a reduction from  $L_{\text{BH}(k)}$  to  $L_{\text{co-BH}(k)}$  if and only if it is a reduction from  $L_{\text{co-BH}(k)}$  to  $L_{\text{BH}(k)}$ . Hence a reduction from  $L_{\text{BH}(k)}$  to  $L_{\text{co-BH}(k)}$  always maps  $k$ -tuples of the form

$$“(L_{\text{BH}(k-1)}) \& \overline{\text{SAT}}” \quad \text{to} \quad “(L_{\text{co-BH}(k-1)}) | \text{SAT}”,$$

or if  $k$  is odd:

$$“(L_{\text{co-BH}(k-1)}) \& \overline{\text{SAT}}” \quad \text{to} \quad “(L_{\text{BH}(k-1)}) | \text{SAT}”.$$

Thus we can define “easy” strings and “hard” strings as above and give a similar argument to define a reduction from  $L_{\text{BH}(k-1)}$  to  $L_{\text{co-BH}(k-1)}$ .

We need one technical refinement of the definitions of  $L_{\text{BH}(k)}$  and  $L_{\text{co-BH}(k)}$  before we prove the lemma. We will require that all  $k$  formulas in the  $k$ -tuples in  $L_{\text{BH}(k)}$  and  $L_{\text{co-BH}(k)}$  have the same length. This restricted version is still  $\leq_m^P$ -complete since the shorter formulas in any  $k$ -tuple can be padded up to the length of the longest formula in time that is polynomial in the length of the original  $k$ -tuple.

We will also need to talk about subsets of  $L_{\text{BH}(k)}$  and  $L_{\text{co-BH}(k)}$  for which all the formulas in each tuple have a fixed length.

DEFINITION 4.1. *For all  $k$  and  $n$ ,  $L_{\text{BH}(k),n}$  ( $L_{\text{co-BH}(k),n}$ ) is the finite subset of  $L_{\text{BH}(k)}$  ( $L_{\text{co-BH}(k)}$ ) where each  $k$ -tuple contains only formulas of length  $n$ .*

Clearly, for all  $k$ , any function  $f$  that reduces  $L_{\text{BH}(k)}$  to  $L_{\text{co-BH}(k)}$  also reduces  $L_{\text{BH}(k),n}$  to  $L_{\text{co-BH}(k)}$  and  $L_{\text{co-BH}(k),n}$  to  $L_{\text{BH}(k)}$ .

LEMMA 4.2. *For all  $k > 1$ , if there exist  $S_k, g_k$  where  $S_k$  is sparse and  $g_k^{S_k}$  is a polynomial time reduction of  $L_{\text{BH}(k)}$  to  $L_{\text{co-BH}(k)}$ , then there exist  $S_{k-1}, g_{k-1}$  where  $S_{k-1}$  is sparse and  $g_{k-1}^{S_{k-1}}$  is a polynomial time reduction of  $L_{\text{BH}(k-1)}$  to  $L_{\text{co-BH}(k-1)}$ .*

*Proof.* Suppose  $g_k^{S_k}$  reduces  $L_{\text{BH}(k)}$  to  $L_{\text{co-BH}(k)}$ . Assume, without loss of generality, that  $S_k$  is prefix marked so that  $S_k$  is self-P-printable.

As above, for each length  $n$ , there are two cases to distinguish: the case where all the unsatisfiable strings of length  $n$  are “easy” and the case where at least one is “hard.”

DEFINITION 4.3. *A formula  $F$  is  $k$ -easy if there exist  $F_1, \dots, F_{k-1}$  with  $|F_i| = |F|$  such that*

$$g_k^{S_k}(F_1, \dots, F_{k-1}, F) = (G_1, \dots, G_{k-1}, G), \text{ where } G \in \text{SAT}.$$

DEFINITION 4.4. *A formula  $F$  of length  $n$  is  $k$ -hard if  $F \in \overline{\text{SAT}}$  and for all  $F_1, \dots, F_{k-1}$  with  $|F_i| = n$ ,*

$$g_k^{S_k}(F_1, \dots, F_{k-1}, F) = (G_1, \dots, G_{k-1}, G), \text{ where } G \in \overline{\text{SAT}}.$$

Suppose  $F$  is  $k$ -easy. If  $k$  is even, and

$$g_k^{S_k}(F_1, \dots, F_{k-1}, F) = (G_1, \dots, G_{k-1}, G),$$

where  $G \in \text{SAT}$ , then

$$(G_1, \dots, G_{k-1}, G) \in L_{\text{co-BH}(k)}.$$

Since  $g_k^{S_k}$  is a reduction,

$$(F_1, \dots, F_{k-1}, F) \in L_{\text{BH}(k)},$$

which implies  $F \in \overline{\text{SAT}}$ . If  $k$  is odd, the same reasoning holds with  $\text{BH}(k)$  and  $\text{co-BH}(k)$  reversed. Therefore if  $F$  is  $k$ -easy,  $F \in \overline{\text{SAT}}$ , and there is an  $\text{NP}^{S_k}$  algorithm for recognizing  $F$  as unsatisfiable. On input  $F$ , guess  $F_1, \dots, F_{k-1}$ , compute  $g_k^{S_k}(F_1, \dots, F_{k-1}, F)$ , and accept if the last component of the output of  $g_k$  is satisfiable.

Call the machine that executes this  $\text{NP}^{S_k}$  algorithm  $N_{k\text{-easy}}$ ;

$$L(N_{k\text{-easy}}^{S_k}) \subseteq \overline{\text{SAT}}.$$

Since  $S_k$  is  $\text{P}^{S_k}$ -printable, there exists a polynomial time reduction  $r(\cdot)$  such that  $r^{S_k}$  reduces  $L(N_{k\text{-easy}}^{S_k})$  to  $\text{SAT}$ . On input  $F$ ,  $r^{S_k}$  first generates the subset  $S'_k$  of strings in  $S_k$  up to the length  $N_{k\text{-easy}}$  can ask on input  $F$ . Then since it is an  $\text{NP}$  question whether or not  $N_{k\text{-easy}}(F)$  accepts using oracle  $S'_k$ ,  $r$  can map  $\langle N_{k\text{-easy}}, F, S'_k \rangle$  to a formula that is satisfiable if and only if  $N_{k\text{-easy}}$  accepts.

Case 1. Suppose all the unsatisfiable formulas of length  $n$  are  $k$ -easy. Then

$$L(N_{k\text{-easy}}^{S_k})^n = \overline{\text{SAT}}^n,$$

and for all  $F$  of length  $n$ ,

$$r^{S_k}(F) \in \text{SAT} \iff F \in \overline{\text{SAT}}.$$

For such  $n$ 's, we can use  $r^{S_k}$  (and the fact that we can combine formulas with logical AND's and OR's) to reduce  $L_{\text{co-BH}(k-1), n}$  to  $\text{SAT}$ . Since  $\text{SAT} \leq_m^{\text{P}} L_{\text{BH}(k-1)}$ , we

can use  $r^{S^k}$  to reduce  $L_{\text{co-BH}(k-1),n}$  to  $L_{\text{BH}(k-1)}$ . Call the reduction that uses  $r$  in this way  $g_{k,\text{easy}}^{S^k}$ . For example, suppose  $k = 4$ , then

$$\begin{aligned} L_{\text{co-BH}(3)} &= (\overline{\text{SAT}} \mid \text{SAT}) \& \overline{\text{SAT}}, \quad \text{and} \\ L_{\text{BH}(3)} &= (\text{SAT} \& \overline{\text{SAT}}) \mid \text{SAT}. \end{aligned}$$

If there are no 4-hard strings of length  $n$ ,  $r^{S^4}$  reduces  $\overline{\text{SAT}}^n$  to SAT. Define

$$g_{4-\text{easy}}^{S^4}(F_1, F_2, F_3) \stackrel{\text{def}}{=} (\hat{G}_1, \hat{G}_2, (r^{S^4}(F_1) \vee F_2) \wedge r^{S^4}(F_3)),$$

where  $\hat{G}_1$  is FALSE padded up to the appropriate length, and  $\hat{G}_2$  is TRUE padded up to the appropriate length. Then

$$\begin{aligned} g_{4-\text{easy}}^{S^4}(F_1, F_2, F_3) \in (\text{SAT} \& \overline{\text{SAT}}) \mid \text{SAT} &\iff ((r^{S^4}(F_1) \vee F_2) \wedge r^{S^4}(F_3)) \in \text{SAT} \\ &\iff (F_1, F_2, F_3) \in (\overline{\text{SAT}} \mid \text{SAT}) \& \overline{\text{SAT}}. \end{aligned}$$

Similarly, if  $k$  is odd, then we can use  $r^{S^k}$  (and logical AND's and OR's) to reduce

$$L_{\text{BH}(k-1),n} \rightarrow \text{SAT} \rightarrow L_{\text{co-BH}(k-1)}.$$

Therefore, if all the formulas in  $\overline{\text{SAT}}^n$  are  $k$ -easy, then

$$g_{k,\text{easy}}^{S^k} \text{ reduces } L_{\text{co-BH}(k-1),n} \rightarrow L_{\text{BH}(k-1)} \text{ and } L_{\text{BH}(k-1),n} \rightarrow L_{\text{co-BH}(k-1)}.$$

For such lengths  $n$  and  $k - 1$ -tuples  $(F_1, \dots, F_{k-1})$  of formulas of length  $n$ , we will define  $S_{k-1}$  and  $g_{k-1}$  so that

$$g_{k-1}^{S_{k-1}}(F_1, \dots, F_{k-1}) = g_{k,\text{easy}}^{S^k}(F_1, \dots, F_{k-1}).$$

*Observation.* A subtle fact that we will use later is that, by defining  $g_{k-1}$  this way, if all the unsatisfiable formulas of length  $n$  are  $k$ -easy, then all the unsatisfiable formulas of length  $n$  are also  $k - 1$ -easy. That is, since  $g_{k-1}$  encodes all the  $k - 1$  formulas it takes as its input into the *last* component of its output, for any  $F \in \overline{\text{SAT}}^n$ , there exist  $(F_1, \dots, F_{k-2})$  all of length  $n$  such that

$$g_{k-1}^{S_{k-1}}(F_1, \dots, F_{k-2}, F) = (G_1, \dots, G_{k-2}, G), \text{ where } G \in \text{SAT}.$$

If  $k$  is even, any  $(F_1, \dots, F_{k-2}) \in L_{\text{co-BH}(k-2),n}$  will be such a tuple. If  $k$  is odd, any  $(F_1, \dots, F_{k-2}) \in L_{\text{BH}(k-2),n}$  will be such a tuple. Therefore, if all the unsatisfiable formulas of length  $n$  are  $k$ -easy, they are also all  $k - 1$ -easy. In other words, if there are no  $k$ -hard strings of length  $n$ , then there are no  $k - 1$ -hard strings of length  $n$ .

*Case 2.* Suppose there exists a formula  $\hat{F}$  of length  $n$  such that  $\hat{F}$  is  $k$ -hard. Suppose  $k$  is even. Let  $F_1, \dots, F_{k-1}$  be any formulas of length  $n$ , and let

$$g_k^{S^k}(F_1, \dots, F_{k-1}, \hat{F}) \stackrel{\text{def}}{=} (G_1, \dots, G_{k-1}, \hat{G}).$$

Then since  $\hat{F} \in \overline{\text{SAT}}$ ,

$$(F_1, \dots, F_{k-1}) \in L_{\text{BH}(k-1),n} \iff (F_1, \dots, F_{k-1}, \hat{F}) \in L_{\text{BH}(k),n}.$$

Since  $g_k^{S_k}$  is a reduction,

$$(F_1, \dots, F_{k-1}, \hat{F}) \in L_{\text{BH}(k),n} \iff (G_1, \dots, G_{k-1}, \hat{G}) \in L_{\text{co-BH}(k)}.$$

Since  $\hat{F}$  is  $k$ -hard,  $\hat{G} \notin \text{SAT}$ , and therefore

$$(G_1, \dots, G_{k-1}, \hat{G}) \in L_{\text{co-BH}(k)} \iff (G_1, \dots, G_{k-1}) \in L_{\text{co-BH}(k-1)}.$$

If  $k$  is odd, the same reasoning holds with  $\text{BH}(i)$  and  $\text{co-BH}(i)$  reversed. Hence there is a polynomial time function which, using  $S_k$ , can reduce  $L_{\text{BH}(k-1),n}$  to  $L_{\text{co-BH}(k-1)}$  (and  $L_{\text{co-BH}(k-1),n}$  to  $L_{\text{BH}(k-1)}$ ). Call this function  $g_{k\text{-hard}}(\hat{F})$ . On input  $F_1, \dots, F_{k-1}$ ,  $g_{k\text{-hard}}^{S_k}(\hat{F})$  computes  $g_k^{S_k}(F_1, \dots, F_{k-1}, \hat{F})$  and outputs the first  $k - 1$  components.

In summary, if all the strings of length  $n$  are  $k$ -easy, then  $g_{k\text{-easy}}^{S_k}$  reduces  $L_{\text{co-BH}(k-1),n}$  to  $L_{\text{BH}(k-1)}$ . If some formula  $\hat{F}$  of length  $n$  is  $k$ -hard, then  $g_{k\text{-hard}}^{S_k}(\hat{F})$  reduces  $L_{\text{co-BH}(k-1),n}$  to  $L_{\text{BH}(k-1)}$ .

Thus  $S_{k-1}$  can be defined as  $S_k$  plus enough strings to indicate which reduction works for each length  $n$ . Let  $\text{Lexhard}_k$  be the set consisting of the lexicographically least  $k$ -hard string of each length (if there is a  $k$ -hard string of that length). Then the set of marked prefixes of  $\text{Lexhard}_k$ ,  $\text{prefix}(\text{Lexhard}_k)$ , is self-P-printable. A polynomial time machine with access to oracle  $\text{prefix}(\text{Lexhard}_k)$  can determine if there are any  $k$ -hard strings of a given length, and it can get hold of the lexicographically least one if there are any. Therefore  $\text{prefix}(\text{Lexhard}_k)$  provides enough information to determine which reduction works for each length  $n$ .

Let

$$S_{k-1} \stackrel{\text{def}}{=} S_k \oplus \text{prefix}(\text{Lexhard}_k).$$

$S_{k-1}$  is sparse since  $S_k$  and  $\text{prefix}(\text{Lexhard}_k)$  are both sparse. Then  $g_{k-1}^{S_{k-1}}$  on input  $F_1, \dots, F_{k-1}$  (all of length  $n$ ) works as follows:

- (1) Generate all the strings in  $\text{prefix}(\text{Lexhard}_k)^{=n}$ .
- (2) If  $\text{Lexhard}_k^{=n} = \phi$ , output  $g_{k\text{-easy}}^{S_k}(F_1, \dots, F_{k-1})$ .
- (3) Otherwise let  $\hat{F}$  be the  $k$ -hard string in  $\text{Lexhard}_k^{=n}$ , and output

$$g_{k\text{-hard}}^{S_k}(\hat{F})(F_1, \dots, F_{k-1}).$$

For each  $n$ ,  $g_{k-1}^{S_{k-1}}$  reduces  $L_{\text{co-BH}(k-1),n}$  to  $L_{\text{BH}(k-1)}$  and hence reduces  $L_{\text{co-BH}(k-1)}$  to  $L_{\text{BH}(k-1)}$  and vice versa.  $\square$

**COROLLARY 4.5.** *For all  $k$ , if  $\text{BH}(k) = \text{co-BH}(k)$ , then there exist  $S, g$  such that  $S$  is sparse and  $g^S$  is a polynomial time reduction from  $\overline{\text{SAT}}$  to  $\text{SAT}$ .*

*Proof.* If  $\text{BH}(k) = \text{co-BH}(k)$ , then there exists a polynomial time reduction (that needs no oracle) from  $L_{\text{BH}(k)}$  to  $L_{\text{co-BH}(k)}$ . By  $k - 1$  repetitions of the above lemma, we can construct  $S$  and  $g$ .  $\square$

**LEMMA 4.6.** *If  $S$  is sparse and  $g^S$  is a polynomial time reduction from a language  $L$  to  $\text{SAT}$ , then  $L \in \text{NP}^S$ .*

*Proof.*  $L = L(\text{NP}^S)$ , where on input  $x$ ,  $N$  computes  $g^S(x) = y$  and accepts if  $y \in \text{SAT}$ .  $\square$

*Remark.* At first glance, the existence of a sparse  $S$  such that  $g^S$  reduces  $L$  to  $\text{SAT}$  seems to be a stronger condition than the existence of a sparse set  $S$  such that

$L \in \text{NP}^S$ . An  $\text{NP}^S$  machine can access  $S$  nondeterministically while the function  $g$  must ask queries deterministically. However, since any sparse set can be made self-P-printable by adding all of its marked prefixes, the following conditions are actually equivalent:

- (1) There exist sparse  $S$  and function  $g$  such that  $g^S$  is a polynomial time reduction from  $L$  to SAT.
- (2) There exists sparse  $S$  such that  $L \in \text{NP}^S$ .

Corollary 4.5 and Lemma 4.6 together imply the following theorem.

**THEOREM 4.7.** *For all  $k$ , if  $\text{BH}(k) = \text{co-BH}(k)$ , then there exists a sparse set  $S$  such that  $\overline{\text{SAT}} \in \text{NP}^S$  (i.e.,  $\text{co-NP} \subseteq \text{NP}^S$ ).*

By Theorem 4.7 and Yap’s result, we now know that the collapse of the BH implies the collapse of the PH (to  $\text{NP}^{\text{NP}^{\text{NP}}}$ ). In the rest of this section, we show that the sparse set  $S$  is in  $\text{NP}^{\text{NP}}$ . In § 5, we will prove that this fact implies  $\text{PH} \subseteq \text{P}^{\text{NP}^{\text{NP}}[O(\log n)]}$ .

We need the following easy lemma.

**LEMMA 4.8.** *If  $L \in \text{co-NP}$ , then*

$$L' \stackrel{\text{def}}{=} \{x \mid x \text{ is the lexicographically least string in } L^{|x|}\}$$

is in  $\text{co-NP}$ .

*Proof.* Since  $L \in \text{co-NP}$ , there exist a polynomial time predicate  $R(\cdot, \cdot)$  and a polynomial  $p(\cdot)$  such that

$$x \in L \iff \forall y \text{ with } |y| \leq p(|x|), R(x, y).$$

Then

$$x \in L' \iff \forall y, u, v \text{ such that } |y| \leq p(|x|), |u|=|x|, |v| \leq p(|x|), \\ R(x, y), \text{ and } R(u, v) \implies u \geq x \text{ lexicographically.}$$

Thus  $L' \in \text{co-NP}$ .  $\square$

Now we can show that the sparse oracle is in  $\text{NP}^{\text{NP}}$ .

**LEMMA 4.9.** *The sparse oracle  $S$  constructed in Corollary 4.5 is in  $\text{NP}^{\text{NP}}$ .*

*Proof.* We show that the set  $S$  defined by repeated applications of Lemma 4.2 is in  $\text{NP}^{\text{NP}}$ . Suppose  $\text{BH}(k) = \text{co-BH}(k)$  with  $g_k$  a polynomial time reduction from  $L_{\text{BH}(k)}$  to  $L_{\text{co-BH}(k)}$ . We define the set  $S$  from the hard strings at each level. For  $i$  backing down from  $k$  to 2, we define  $\text{Hard}_i$  to be the set of  $i$ -hard strings.  $\text{Lexhard}_i$  is the set consisting of the lexicographically least  $i$ -hard string of each length, and

$$S \stackrel{\text{def}}{=} \bigoplus_{i=2}^k \text{prefix}(\text{Lexhard}_i).$$

By backward induction, we will show that for each  $i$ ,  $\text{Lexhard}_i \in \text{NP}^{\text{NP}}$ . Therefore  $\text{prefix}(\text{Lexhard}_i) \in \text{NP}^{\text{NP}}$  which implies  $S \in \text{NP}^{\text{NP}}$ .

*Base Case.*  $\text{Lexhard}_k \in \text{co-NP} \subseteq \text{NP}^{\text{NP}}$ . Recall that a string  $F$  is  $k$ -easy if there exist  $F_1, \dots, F_{k-1}$  of length  $|F|$  such that

$$g_k(F_1, \dots, F_{k-1}, F) = (G_1, \dots, G_{k-1}, G), \text{ where } G \in \text{SAT}.$$

Hence the set of  $k$ -easy strings is in NP. Since

$$\text{Hard}_k = \overline{\text{SAT} \cup \{F \mid F \text{ is } k\text{-easy}\}},$$

$\text{Hard}_k \in \text{co-NP}$ . Then by Lemma 4.8,  $\text{Lexhard}_k \in \text{co-NP}$ .

*Inductive Step.* For  $i$  with  $2 \leq i < k$ ,  $\text{Lexhard}_i \in \text{NP}^{\text{NP}}$  if for all  $j$  with  $i < j \leq k$ ,  $\text{Lexhard}_j \in \text{NP}^{\text{NP}}$ . As we observed in the “easy” case of Lemma 4.2, there are no

$i$ -hard strings of length  $n$  if there are no  $i + 1$ -hard strings of length  $n$ . Therefore we know that a formula  $F$  of length  $n$  can be in  $\text{Lexhard}_i$  only if there are strings in  $\text{Lexhard}_{i+1}^{=n}, \dots, \text{Lexhard}_k^{=n}$ . If we are given the strings  $\hat{F}_{i+1}, \dots, \hat{F}_k$  that are in  $\text{Lexhard}_{i+1}^{=n}, \dots, \text{Lexhard}_k^{=n}$ , respectively, then we have enough information to compute  $g_i^{S_i}$ , the reduction from  $L_{\text{BH}(i),n}$  to  $L_{\text{co-BH}(i)}$  in polynomial time. Thus given  $\hat{F}_{i+1}, \dots, \hat{F}_k$ , a co-NP question can determine if  $F \in \text{Hard}_i$ :

$$“\forall F_1, \dots, F_{i-1}, g_i^{S_i}(F_1, \dots, F_{i-1}, F) = (G_1, \dots, G_{i-1}, G), \text{ where } G \in \overline{\text{SAT}}?”.$$

Similarly, a co-NP question can determine if  $F \in \text{Lexhard}_i$ .

Assuming the inductive hypothesis, on input  $F$ , an  $\text{NP}^{\text{NP}}$  machine can guess  $\hat{F}_{i+1}, \dots, \hat{F}_k$ , all of length  $|F|$ , and verify that  $\hat{F}_{i+1}, \dots, \hat{F}_k$  are in  $\text{Lexhard}_{i+1}^{=n}, \dots, \text{Lexhard}_k^{=n}$ , respectively. Then the  $\text{NP}^{\text{NP}}$  machine can verify that  $F \in \text{Lexhard}_i$  with one more query to NP.

Therefore by induction, the sparse set  $S$  is in  $\text{NP}^{\text{NP}}$ .  $\square$

**THEOREM 4.10.** *For all  $k$ , if  $\text{BH}(k) = \text{co-BH}(k)$ , then there exists a sparse set  $S \in \text{NP}^{\text{NP}}$  such that  $\text{co-NP} \subseteq \text{NP}^S$ .*

**5. Collapsing the polynomial time hierarchy.** We complete the proof that the collapse of the BH implies  $\text{PH} \subseteq \text{P}^{\text{NP}^{\text{NP}}[O(\log n)]}$  by showing that if there exists a sparse set  $S \in \text{NP}^{\text{NP}}$  such that  $\text{co-NP} \subseteq \text{NP}^S$ , then  $\text{PH} \subseteq \text{P}^{\text{NP}^{\text{NP}}[O(\log n)]}$ .

This result is really a relativization of the following theorem proved in [10].

**THEOREM 5.1.** *If there exists a sparse set  $S \in \text{NP}$  such that  $\text{co-NP} \subseteq \text{NP}^S$ , then  $\text{PH} \subseteq \text{P}^{\text{NP}[O(\log n)]}$ .*

The proof uses a technique called oracle replacement which is embedded in the proofs of the sparse oracle results of Karp and Lipton [12], Mahaney [17], Long [16], and Yap [26].

For oracles  $A$  and  $B$ , oracle replacement is a technique for mapping questions about whether an  $\text{NP}^B$  machine accepts an input to questions about whether some  $\text{NP}^A$  machine accepts an input. Let  $N$  be an  $\text{NP}^B$  machine. If we have two  $\text{NP}^A$  machines, one that accepts  $B$  and one that accepts  $\overline{B}$ , then we can construct an  $\text{NP}^A$  machine  $N_{\text{new}}$  such that

$$L(N^B) = L(N_{\text{new}}^A).$$

$N_{\text{new}}^A$  simulates  $N^B$ . When  $N$  would query  $B$ ,  $N_{\text{new}}$  runs the  $B$  and  $\overline{B}$  recognizers on the query string to determine the oracle answer. Thus, if there exist  $\text{NP}^A$  recognizers for  $B$  and  $\overline{B}$ , we can map  $\text{NP}^B$  questions to  $\text{NP}^A$  questions.

The technique can be used even if we cannot necessarily find  $\text{NP}^A$  machines that accept all of  $B$  and  $\overline{B}$ . For a given input  $x$ , if we can find  $\text{NP}^A$  machines that accept  $B^{\leq m}$  and  $\overline{B}^{\leq m}$ , where  $m$  is a bound on the length of the queries that  $N$  can make on input  $x$ , then the same trick works.

We will use the technique to map  $\text{NP}^S$  questions to  $\text{NP}^{\text{SAT}}$  questions. If  $S \in \text{NP}^{\text{NP}}$ , then there exists an  $\text{NP}^{\text{SAT}}$  machine that recognizes  $S$ . We will show that if  $S$  is also sparse, then a  $\text{P}^{\text{NP}^{\text{NP}}[O(\log n)]}$  machine can generate  $\text{NP}^{\text{SAT}}$  machines that recognize initial segments of  $\overline{S}$ . Hence a  $\text{P}^{\text{NP}^{\text{NP}}[O(\log n)]}$  machine can use oracle replacement to map a question of the form

$$“x \in L(N^S)?”$$

to a question of the form

$$“x \in L(N_{\text{new}}^{\text{SAT}})?”.$$

Then with one more query, the  $P^{NP^{NP}[O(\log n)]}$  machine can determine if  $x \in L(N_{new}^{SAT})$ . Therefore if  $S \in NP^{NP}$  and  $S$  is sparse, then  $NP^S \in P^{NP^{NP}[O(\log n)]}$ .

We need one more lemma before we prove the theorem.

LEMMA 5.2. *If  $S$  is sparse and prefix marked, and  $co-NP \subseteq NP^S$ , then  $NP^S = co-NP^S$ .*

*Proof.* Recall that if  $S$  is prefix marked, then  $S$  is  $P^S$ -printable. Let  $N$  be any  $NP^S$  machine. An  $NP^S$  algorithm for accepting  $x$ , if  $x \notin L(N^S)$ , starts by writing down the strings in  $S^{\leq m}$ , where  $m$  is a bound on the length of the queries  $N$  can make on input  $x$ . This can be done in polynomial time since  $S$  is  $P^S$ -printable. Of course  $x \in L(N^S) \iff x \in L(N^{S^{\leq m}})$ . With  $S^{\leq m}$  in hand, it is an NP question whether  $x \in L(N^{S^{\leq m}})$ , and thus  $\langle N, S^{\leq m}, x \rangle$  can be mapped to a Boolean formula  $F$  such that

$$F \in SAT \iff x \in L(N^{S^{\leq m}}).$$

Since  $\overline{SAT} \in NP^S$ , an  $NP^S$  machine can accept  $x$  if  $x \notin L(N^S)$ .  $\square$

THEOREM 5.3. *If there exists a sparse set  $S \in NP^{NP}$  such that  $co-NP \subseteq NP^S$ , then  $PH \subseteq P^{NP^{NP}[O(\log n)]}$ .*

*Proof.* If  $S \in NP^{NP}$  and  $co-NP \subseteq NP^S$ , then  $prefix(S) \in NP^{NP}$ , and  $co-NP \subseteq NP^{prefix(S)}$ . Therefore, without loss of generality, we can assume  $S$  is prefix marked. Then by the previous lemma,  $NP^S = co-NP^S$ . This implies that the polynomial time hierarchy relative to  $S$ ,  $PH^S$ , is contained in  $NP^S$  [26]. Hence

$$PH \subseteq PH^S \subseteq NP^S.$$

We will show  $PH \subseteq P^{NP^{NP}[O(\log n)]}$  by showing  $NP^S \subseteq P^{NP^{NP}[O(\log n)]}$ . This containment follows from oracle replacement.

Using the technique from [10], we will show that since  $P^{NP^{NP}[O(\log n)]}$  has the power to compute the census function of  $S$ , on an input of length  $m$ , a  $P^{NP^{NP}[O(\log n)]}$  machine can generate an  $NP^{SAT}$  machine,  $N_{\overline{S},m}$ , that accepts  $\overline{S}^{\leq m}$ .

The machines that accept  $\overline{S}^{\leq m}$  are based on the  $NP^{SAT}$  machine,  $N_{pseudo}$ , that accepts the *pseudo-complement* of  $S$ . The pseudo-complement of sparse sets was an important concept used in Mahaney's proof that the existence of a sparse  $\leq_m^P$ -complete set for NP implies  $P = NP$  [17]. On input  $(0^m, 1^j, y)$ ,  $N_{pseudo}^{SAT}$  guesses  $j$  strings of length at most  $m$ , verifies that the strings are in  $S$ , and accepts if  $|y| \leq m$  and  $y$  is not one of the guessed strings. If  $|y| \leq m$ , and  $j = Census_S(m)$ , then

$$(0^m, 1^j, y) \in L(N_{pseudo}^{SAT}) \iff y \in \overline{S}^{\leq m}.$$

Let  $c = Census_S(m)$ . Then  $N_{\overline{S},m}$  is  $N_{pseudo}$  with the first two arguments  $(0^m, 1^c)$  held constant. That is, on input  $y$ ,  $N_m$  writes  $(0^m, 1^c, y)$  on its tape and then runs like  $N_{pseudo}^{SAT}$ . Clearly  $L(N_{\overline{S},m}^{SAT}) = \overline{S}^{\leq m}$ .

On input  $1^m$ , a  $P^{NP^{NP}[O(\log n)]}$  machine can generate  $N_{\overline{S},m}$  since it can compute  $Census_S(m)$  by binary search. The binary search ranges over the numbers  $0 \cdots g(m)$ , where  $g(\cdot)$  is the polynomial that bounds  $Census_S$ . Each iteration of the binary search is a query of the form

“does  $N_{census}^{SAT}(0^m, 1^k)$  accept?”.

$N_{census}$  is the  $\text{NP}^{\text{SAT}}$  machine that takes an input  $(0^m, 1^k)$ , guesses  $k$  strings of length at most  $m$ , and accepts if they are all in  $S$ . Clearly,  $N_{census}^{\text{SAT}}$  accepts if and only if  $\text{Census}_S(m) \geq k$ . Thus the census value can be computed with  $O(\log g(m))$  queries to  $\text{NP}^{\text{SAT}}$ , and  $O(\log g(m))$  is  $O(\log m)$ . Therefore on input  $1^m$ , a  $\text{P}^{\text{NP}^{\text{NP}}[O(\log n)]}$  machine can generate  $N_{\bar{S},m}$ , an  $\text{NP}^{\text{SAT}}$  machine that accepts  $\bar{S}^{\leq m}$ .

These machines,  $\{N_{\bar{S},m}\}$ , that accept initial segments of  $\bar{S}$  can be used with  $N_S^{\text{SAT}}$ , the  $\text{NP}^{\text{SAT}}$  machine that accepts  $S$ , to replace the  $S$  oracle of any  $\text{NP}^S$  machine.

Let  $L = L(N^S)$  be any  $\text{NP}^S$  language. Let  $x$  be any string,  $|x| = n$ . Let  $m = p(n)$ , where  $p(\cdot)$  is the polynomial that bounds the running time of  $N$ . On input  $x$ , the  $\text{P}^{\text{NP}^{\text{NP}}[O(\log n)]}$  machine that recognizes  $L$  first generates  $N_{\bar{S},m}$ . Then using  $N_{\bar{S},m}$  and  $N_S$  to replace the oracle of  $N^S$ , it generates a machine  $N_{new}$  such that

$$x \in L(N_{new}^{\text{SAT}}) \iff x \in L(N^S).$$

Hence one more  $\text{NP}^{\text{NP}}$  query determines if  $x \in L(N^S)$ .

Therefore  $\text{NP}^S \subseteq \text{P}^{\text{NP}^{\text{NP}}[O(\log n)]}$ , and  $\text{PH} \subseteq \text{P}^{\text{NP}^{\text{NP}}[O(\log n)]}$ .  $\square$

Finally, we have all the pieces, and we have proved our main theorem.

**THEOREM 5.4.** *For all  $k$ , if  $\text{BH}(k) = \text{co-BH}(k)$ , then  $\text{PH} \subseteq \text{P}^{\text{NP}^{\text{NP}}[O(\log n)]}$ .*

Since the  $\text{BH}$ ,  $\text{QH}$ , and  $\text{QH}_{\parallel}$  are intertwined, we have the following corollaries.

**COROLLARY 5.5.** *If the  $\text{QH}$  collapses, then  $\text{PH} \subseteq \text{P}^{\text{NP}^{\text{NP}}[O(\log n)]}$ .*

**COROLLARY 5.6.** *If the  $\text{QH}_{\parallel}$  collapses, then  $\text{PH} \subseteq \text{P}^{\text{NP}^{\text{NP}}[O(\log n)]}$ .*

Since  $\text{P}^{\text{NP}[O(\log n)]} = \text{P}^{\text{NP}\parallel} = \text{TT}[\text{NP}]$ ,  $\text{BH} = \text{BTT}[\text{NP}]$ , and the  $\text{BH}$  collapses if  $\text{P}^{\text{NP}[O(\log n)]} = \text{BH}$ , we also have the following corollaries.

**COROLLARY 5.7.** *If  $\text{P}^{\text{NP}[O(\log n)]} = \text{BH}$ , then  $\text{PH} \subseteq \text{P}^{\text{NP}^{\text{NP}}[O(\log n)]}$ .*

**COROLLARY 5.8.** *If  $\text{P}^{\text{NP}\parallel} = \text{QH}_{\parallel}$ , then  $\text{PH} \subseteq \text{P}^{\text{NP}^{\text{NP}}[O(\log n)]}$ .*

**COROLLARY 5.9.** *If  $\text{TT}[\text{NP}] = \text{BTT}[\text{NP}]$ , then  $\text{PH} \subseteq \text{P}^{\text{NP}^{\text{NP}}[O(\log n)]}$ .*

Since Hemachandra’s result that  $\text{P}^{\text{NP}[O(\log n)]} = \text{P}^{\text{NP}\parallel} = \text{TT}[\text{NP}]$  relativizes to every level of the  $\text{PH}$ , we also have the following corollary.

**COROLLARY 5.10.** *If the  $\text{BH}$  collapses, then  $\text{PH} \subseteq \text{TT}[\text{NP}^{\text{NP}}]$ .*

Wagner has generalized Theorem 5.4 to show that for well-behaved functions  $r(n) < \log n$ , if  $r(n)$  queries to  $\text{NP}$  are as powerful as  $r(n) + 1$  queries, then the  $\text{PH}$  collapses to  $\text{P}^{\text{NP}^{\text{NP}}[O(\log n)]}$  [24]. Thus the techniques we have developed here apply to slow-growing functions in addition to constants. Let  $\text{P}^{\text{SAT}[r(n)]}$  and  $\text{P}^{\text{SAT}\parallel[s(n)]}$  be the classes of languages recognizable by machines that make no more than  $r(n)$  serial queries and no more than  $s(n)$  parallel queries, respectively.

**THEOREM 5.11 (WAGNER).** *For functions  $r(n) < \log n$ ,  $s(n) \leq n$ ,*

$$\begin{aligned} \text{P}^{\text{SAT}[r(n)]} = \text{P}^{\text{SAT}[r(n)+1]} &\implies \text{PH} \subseteq \text{P}^{\text{NP}^{\text{NP}}[O(\log n)]}, & \text{and} \\ \text{P}^{\text{SAT}\parallel[s(n)]} = \text{P}^{\text{SAT}\parallel[s(n)+1]} &\implies \text{PH} \subseteq \text{P}^{\text{NP}^{\text{NP}}[O(\log n)]}. \end{aligned}$$

*Proof sketch.* The proof is a generalization of the “easy-hard” argument of Lemma 4.2. In the constant case (Lemma 4.2), there is a fixed  $k$  such for each  $n$ , we can map

$$L_{\text{co-BH}(k),n} \text{ to } L_{\text{BH}(k)}.$$

Then by percolating down the  $k$  levels of the  $\text{BH}$ , we can define a sparse set with at most  $k$  hard strings of length  $n$  that lets us reduce  $\bar{\text{SAT}}$  to  $\text{SAT}$ .

In the generalization, instead of having one fixed level from which we can start to define the sparse set, for each length  $n$ , there is some  $m$  which is polynomial in  $n$  such that we can map

$$L_{\text{co-BH}(m),n} \text{ to } L_{\text{BH}(m)}.$$

Therefore for each length, we can define the sparse set by percolating down polynomially many levels.  $\square$

**6. Extensions and related results.**

**Other levels of the polynomial time hierarchy.** This work can be viewed as a study of oracle access mechanisms within the PH. The results given above generalize for every  $\Delta_i^P$  in the PH. Recall

$$\Delta_i^P \stackrel{\text{def}}{=} P^{\Sigma_{i-1}^P}.$$

A Boolean hierarchy and query hierarchy,  $P^{\Sigma_{i-1}^P[k]}$ , can be defined within each  $\Delta_i^P$ . If these hierarchies collapse, then there exists a sparse set  $S$  such that  $\Pi_{i-1}^P \subseteq \Sigma_{i-1}^{P,S}$ , and this collapses the PH to  $\Delta_{i+1}^P$ . In other words, for any  $\Delta_i^P$  and  $k$ , if  $k$  queries are as powerful as  $k + 1$  queries, the PH collapses.

**THEOREM 6.1.** *The PH collapses  $\iff$  there exist  $k, i$ ,  $P^{\Sigma_i^P[k]} = P^{\Sigma_i^P[k+1]}$ .*

In contrast, for each  $\Sigma_i^P$  in the PH, one query is enough. Recall

$$\Sigma_i^P \stackrel{\text{def}}{=} NP^{\Sigma_{i-1}^P}.$$

It is easy to prove from the quantifier structure of the PH [25] that for all  $i$ ,  $NP^{\Sigma_i^P} = NP^{\Sigma_i^P[1]}$ . This is a generalization of the result in [6] that  $NP^{NP} = NP^{NP[1]}$ . Thus for all the NP levels of the PH, one query is enough, yet if one query is enough at any of the P levels, then the PH collapses.

**Small machines for  $\overline{\text{SAT}}$ .** This work can also be viewed as a downward structural result. If the BH collapses, then the languages in co-NP are forced to have a certain structure.

A language  $L$  has *small NP (P) machines* if there exists a sequence of NP (P) machines  $\{N_i\}$  such that:

- (1)  $L(N_i) = L^{\leq i}$ .
- (2) There is a polynomial  $p_{\text{size}}(\cdot)$  such that for all  $i$ ,  $|N_i| \leq p_{\text{size}}(i)$ .
- (3) There is a polynomial  $p_{\text{run}}(\cdot)$  such that for all  $i$  and  $x$  with  $|x| \leq i$ ,  $p_{\text{run}}(i)$  bounds the running time of  $N_i(x)$ .

Small NP machines characterize nonuniform NP algorithms in much the same way that polynomial size circuits characterize nonuniform P algorithms. We show that a language  $L$  has small NP machines if and only if there exists a sparse  $S$  such  $L \in NP^S$ . As we saw in Theorem 5.3, this characterization ties in nicely with the oracle replacement technique. In fact, these two concepts are used in [11] to unify all the sparse oracle results of Karp and Lipton [12], Mahaney [17], Long [16], Yap [26], and Kadin [10].

**THEOREM 6.2.** *For all  $L$ , there exists a sparse set  $S$  such that  $L \in NP^S \iff$  there exist small NP machines for  $L$ .*

*Proof.* ( $\implies$ ) Let  $S$  be sparse, and let  $N$  be the NP machine such that  $L = L(N^S)$ .

Let  $p_1(\cdot)$  be a polynomial that bounds  $\|S^{\leq n}\|$ .

Let  $p_2(\cdot)$  be a polynomial that bounds the running time of  $N$ .

Define  $N_i$  to be  $N$  with  $S^{\leq p_2(i)}$  encoded as a table in  $N_i$ 's states and a routine to look up strings in the table in place of  $N$ 's query state. If the table is sorted by increasing length, then on an input  $x$  of length  $n \leq i$ , only the portion of the table containing strings of length less than or equal to  $p_2(n)$  has to be searched to find a query answer. This portion of the table contains at most  $p_1(p_2(n))$  strings, each of at most  $p_2(n)$  characters long. So each query takes  $N_i$  roughly  $p_2(n)p_1(p_2(n))$  steps to answer. Therefore

$$\begin{aligned} p_{run}(n) &= p_2(n)(p_2(n)p_1(p_2(n))), & \text{and} \\ p_{size}(i) &= |N| + p_2(i)p_1(p_2(i)) + c, \end{aligned}$$

which is the size of  $N$  plus the size of the table and lookup routine. Note that because the table is sorted,  $p_{run}$  actually bounds the running time of  $N_i$  on all inputs.

( $\Leftarrow$ ) Let  $\{N_i\}$  be the small machines for  $L$  with polynomials  $p_{run}$  and  $p_{size}$  as defined above. We can assume  $p_{size}$  is monotonically increasing. Add dummy states to each  $N_i$  so that it is exactly  $p_{size}(i)$  characters long. Let the sparse oracle  $S$  consist of the machines  $N_i$  themselves.  $S$  is sparse since it has at most one string of each length.

The  $NP^S$  machine  $N$  for recognizing  $L$  works as follows. On input  $x$  with  $|x|=n$ ,  $N$  guesses an NP machine of length  $p_{size}(n)$  and verifies with one query to  $S$  that it has guessed  $N_n$ . It then simulates  $N_n$  on  $x$ .  $\square$

Since the collapse of the BH implies the existence of a sparse set  $S$  such that  $co-NP \subseteq NP^S$ , we have the following corollary.

**COROLLARY 6.3.** *For all  $k$ , if  $BH(k) = co-BH(k)$ , then every language in  $co-NP$  has small NP machines.*

If  $\overline{SAT}$  has small NP machines, then there is a sequence of NP machines that recognize initial segments of  $\overline{SAT}$ . The sequence is uniform in the sense that a single polynomial bounds the running time of all the machines, and the difference in size from one machine to the next grows polynomially. The bound on the size of the machines implies that the machines do not simply contain tables of all the satisfiable or unsatisfiable strings of a certain length since there is no polynomial that bounds the number of such strings. Thus each machine in the sequence really executes some NP algorithm to recognize unsatisfiable strings. The existence of such machines would imply that nondeterminism is useful in recognizing  $\overline{SAT}$  and that  $co-NP$  is somehow close to NP.

In many ways, the collapse of the BH is similar to NP being closed under complementation. If the BH collapses, then there exists a polynomial time function relative to a sparse oracle that reduces  $\overline{SAT}$  to SAT, there exists a *nonuniform* NP algorithm for  $\overline{SAT}$ , and the PH collapses — in other words, after two quantifier alternations, polynomially bounded universal and existential quantifiers are equivalent.

Theorem 6.2 also goes through in the deterministic case.

**THEOREM 6.4.** *For all  $L$ , there exists a sparse set  $S$  such that  $L \in P^S \iff$  there exist small P machines for  $L$ .*

*Proof.* The proof is parallel to the proof of Theorem 6.2 except that when the small machines are put into the sparse oracle, a P machine cannot guess the small P machine for  $L$ . The prefixes of the small P machines must be encoded into the sparse oracle so that a deterministic machine can get hold of the small machines.  $\square$

There is a well-known result of Meyer published in [3] that relates sparse oracles for NP and polynomial size circuits for NP:

$$\exists \text{ sparse } S \text{ with } NP \subseteq P^S \iff NP \text{ has polynomial size circuits.}$$

Hence we know that the following are equivalent:

- (1) There exists sparse  $S$  such that  $SAT \in P^S$ .
- (2) There exist small P machines for SAT.
- (3) There exist polynomial size circuits for SAT.

**7. Conclusion.** The BH, QH, and  $QH_{||}$  intertwine to form a rich structure inside  $P^{NP}$ . This structure is strongly related to the structure of the PH itself.

Looking the other way, if these hierarchies within  $P^{NP}$  collapse, then there is a surprising structure among the unsatisfiable strings of each length: a small number of key unsatisfiable formulas must exist. These formulas can be put into a sparse oracle  $S$  such that  $co-NP \subseteq NP^S$ , or they can be encoded into a sequence of small NP machines that accept initial segments of  $\overline{SAT}$ .

There are still some open problems related to these results:

- (1) What about the collapse of  $P^{NP}$  to  $P^{NP^{O(\log n)}}$  or other classes above  $P^{NP^{O(\log n)}}$ ? It would seem that such a collapse should have some drastic implications. Krentel has shown that the collapse of the corresponding function classes,  $FP^{NP^{O(\log n)}} = FP^{NP}$ , implies  $P = NP$  [13].
- (2) The existence of the key (hard) unsatisfiable strings used in this paper seems unlikely. An interesting approach for further research would be to consider what kind of relationships of this type can and cannot exist among Boolean formulas. What other conditions (say collapses above  $P^{NP^{O(\log n)}}$ ) imply similar interplay among formulas?

**Acknowledgments.** I am grateful to Professor Juris Hartmanis for his support and guidance. It was partly through discussions with him that the formulation of the collapse in terms of sparse sets evolved. I am also grateful to Stuart Allen, Lane Hemachandra, Steve Mitchell, Geoff Smith, and Vijay Vazirani for helpful discussions.
