The initial challenge is on the output vertex. The game proceeds in rounds, with a round consisting of the following three parts. (a) If the game is not over at the currently challenged vertex u according to the conditions below, then Player 0 is the Challenger for this round if u is of challenge type 0 and the Pebbler otherwise. (b) In the *pebbling move*, the Pebbler picks up zero or more of its own pebbles from vertices already pebbled and places pebbles on any nonempty set of vertices. (c) In the *challenging move*, the Challenger either rechallenges the currently challenged vertex or challenges one of the vertices that acquired a pebble in the current round.

Player 1 wins the game if, immediately following the Challenger's move, the currently challenged vertex is a literal with value 1, or an OR gate at least one of whose immediate predecessors is 1-pebbled, or an AND gate all of whose immediate predecessors are 1-pebbled. Player 0 wins if, immediately following the Challenger's move, the currently challenged vertex is a literal with value 0, or an OR gate all of whose immediate predecessors are 0-pebbled, or an AND gate at least one of whose immediate predecessors is 0-pebbled. It is also possible to have a winner in an infinite play of the game, namely that player (if either) who is the Pebbler in only finitely many rounds. (The purpose of this last rule is to force each player to make progress as the Pebbler.)

These notions are defined more precisely below. Fix an augmented circuit α_n and its input x.

A *configuration* of the game is a tuple $(t, P_1, P_0, R_1, R_0, v)$, where
$t \in \{P, C\}$ indicates whether it is the Pebbler's or the Challenger's turn to move,
P_1 is the set of vertices with 1-pebbles on them from previous rounds,
P_0 is the set of vertices with 0-pebbles on them from previous rounds,
R_1 is the set of vertices 1-pebbled in the current round,
R_0 is the set of vertices 0-pebbled in the current round, and
v is the currently challenged vertex.

The initial configuration of the game is $(P, \varnothing, \varnothing, \varnothing, \varnothing, s)$, where s is the output of the circuit.

A configuration $(P, P_1, P_0, \varnothing, \varnothing, v)$ is *terminal* if v is a literal, or an OR (AND) gate with some (all) of its immediate predecessors in P_1 or all (some) of its immediate predecessors in P_0.

A *move* in the game is made in accordance with a binary relation $\vdash$ on configurations defined as follows (where P_0, P_1, S_0, and S_1 are arbitrary sets of vertices, and R_0 and R_1 are arbitrary nonempty sets of vertices):

$(P, P_1, P_0, \varnothing, \varnothing, v) \vdash (C, P_1 - S_1, P_0, R_1, \varnothing, v)$, for all configurations $(P, P_1, P_0, \varnothing, \varnothing, v)$ that are not terminal and where v is of challenge type 0,

$(P, P_1, P_0, \varnothing, \varnothing, v) \vdash (C, P_1, P_0 - S_0, \varnothing, R_0, v)$, for all configurations $(P, P_1, P_0, \varnothing, \varnothing, v)$ that are not terminal and where v is of challenge type 1,

$(C, P_1, P_0, R_1, \varnothing, v) \vdash (P, P_1 \cup R_1, P_0, \varnothing, \varnothing, v')$, for all $v' \in R_1 \cup \{v\}$,

$(C, P_1, P_0, \varnothing, R_0, v) \vdash (P, P_1, P_0 \cup R_0, \varnothing, \varnothing, v')$, for all $v' \in R_0 \cup \{v\}$.

The *game tree* T is a maximal rooted tree whose nodes are labeled by configurations of the game, whose root is labeled by the initial configuration, and whose edge relation is given by $\vdash$. Note that the leaves of the tree are labeled by terminal configurations.

A *finite play* of the game is a finite path in the game tree from the root to some leaf labeled by the terminal configuration $(P, P_1, P_0, \varnothing, \varnothing, v)$. It is a *winning finite play for Player* 1 if v is a literal with value 1, or if v is an OR gate at least one of whose immediate predecessors is in P_1, or if v is an AND gate all of whose immediate predecessors are in P_1; otherwise it is a *winning finite play for Player* 0. An infinite path Π in the game tree is a *winning infinite play* for the player (if either) that is the Pebbler in only finitely many configurations on Π.

A *winning strategy for Player* 1 (if it exists) is a subtree W of T such that:

(1) W contains the root of T;

(2) W contains exactly one child of every nonterminal node in W that is labeled by a configuration in which it is Player 1's turn to move;

(3) W contains all children of every nonterminal node in W that is labeled by a configuration in which it is Player 0's turn to move; and

(4) All paths in W are winning (finite or infinite) plays for Player 1.

A *winning strategy for Player* 0 is defined dually.

Let $\{\alpha_n\}$ accept the language L, where each member α_n of the family is an augmented circuit with n inputs. The game on α_n with input $x \in L \cap \{0, 1\}^n$ can be *played simultaneously in* $p(n)$ *space,* $r(n)$ *rounds, and* $s(n)$ *role switches* if and only if there is a winning strategy for Player 1 in which:

(1) Every pebbling configuration $(P, P_1, P_0, \varnothing, \varnothing, v)$ along every path satisfies $|P_1| \leqq p(n)$,

(2) On any path, there are at most $r(n)$ edges $(P, P_1, P_0, \varnothing, \varnothing, v) \vdash (C, P_1 - S_1, P_0, R_1, \varnothing, v)$ with v or challenge type 0, and

(3) On any path, there are at most $s(n)$ edges $(C, P_1, P_0, R_1, R_0, v) \vdash (P, P_1', P_0', \varnothing, \varnothing, v')$ having the challenge types of v and v' unequal.

Resources on inputs $x \notin L$ are defined dually, considering winning strategies for Player 0 in place of those for Player 1.

Finally, α_n is *pebbleable* simultaneously in $p(n)$ space, $r(n)$ rounds, and $s(n)$ role switches if and only if, for all x of length n, the game on α_n can be played simultaneously in $p(n)$ space, $r(n)$ rounds, and $s(n)$ role switches. Note that only the resources used by the winning player are counted.

Theorems 19 and 20 demonstrate the intimate relationship between layered circuits and pebbling.

THEOREM 19. *Suppose* $\{\alpha_n\}$ *is a family of* $(z, r, s+1, p)$*-circuits, where* z, r, s, *and* p *may be functions of* n. *Then there is an assignment of challenge types to the vertices of* α_n *such that* α_n *is pebbleable simultaneously in* p *space,* r *rounds, and* s *role switches.*

Proof. Any vertex in a layer with AND fan-in (OR fan-in) bounded by p is assigned challenge type 0 (respectively, 1). Suppose α_n outputs 1 on input x. A winning strategy for Player 1 follows from the claim below. The winning strategy for Player 0 when α_n outputs 0 is dual.

CLAIM. Let v be the currently challenged vertex of α_n. Suppose v evaluates to 1 on input x, no predecessor of v is 0-pebbled, and the subcircuit induced by v and its predecessors is a $(z', r', s'+1, p')$-circuit. Then Player 1 can win the game with p' pebbles, r' rounds, and s' role switches.

The claim is proved by induction on r'. The basis $r' = 0$ is immediate. The induction depends on the role of Player 1, as follows.

Case 1. The challenge type of v is 0; i.e., v is in a layer with bounded AND fan-in. Then Player 1 is the Pebbler, and begins by removing all 1-pebbles from the circuit.

Case 1.1. v is an OR gate. Then Player 1 pebbles any one immediate predecessor u of v that evaluates to 1. (Note that Player 1 does not lose immediately, as no predecessors of u are 0-pebbled.) Player 0 must move the challenge to u in order not to lose immediately. If the challenge type of u is 1, then a role switch occurs and s' decreases by at least 1. In any case, the claim now follows from the induction hypothesis.

Case 1.2. v is an AND gate with bounded fan-in. Then Player 1 pebbles every immediate predecessor of v. The claim follows as in Case 1.1.

Case 2. The challenge type of v is 1. Then Player 1 is the Challenger. If Player 0 never pebbles a predecessor of v that evaluates to 1, Player 1 retains its challenge on v and wins using no resources. Suppose Player 0 pebbles a predecessor of v that evaluates to 1. Consider the first such move. Let u be such a predecessor of minimum depth among the vertices that are pebbled. Player 1 moves its challenge to u. Notice that no predecessor of u is 0-pebbled. The depth of the challenged vertex is decreased without Player 1 using any resources (with the possible exception of a role switch), so the result again follows from the induction hypothesis. □

THEOREM 20. *Suppose a family* $\{\alpha_n\}$ *of augmented circuits of size* z *is pebbleable simultaneously in* p *space,* r *rounds, and* s *role switches, where* z, p, r, *and* s *may be functions of* n. *Then there is a family* $\{\beta_n\}$ *of* $((r+1)^2(s+1)z^{O(p)}, 4r+5, s+1, p+1)$*-circuits that recognizes the same language as* $\{\alpha_n\}$.

Proof. Construction. β_n has one vertex $g(A, r_1, r_0, \hat{s})$ for every $0 \leqq r_1, r_0 \leqq r$, every $0 \leqq \hat{s} \leqq s$, and every configuration $A = (t, P_1, P_0, R_1, R_0, v)$ with $\#(P_1 \cup R_1) \leqq p$ and $\#(P_0 \cup R_0) \leqq p$. $r_1(r_0)$ will be used to count the number of rounds in which Player 1 (respectively, 0) has been Pebbler, and $\hat{s}$ will be used to count the number of role switches that have occurred. If $A = (t, P_1, P_0, R_1, R_0, v)$ is terminal with v a literal x_j, then $g(A, r_1, r_0, \hat{s})$ is the literal x_j. If $A = (t, P_1, P_0, R_1, R_0, v)$ is terminal with appropriate immediate predecessors of the challenged gate v in P_i, then $g(A, r_1, r_0, \hat{s})$ is the constant i. Otherwise $g(A, r_1, r_0, \hat{s})$ is a gate of type OR (AND) if and only if in A it is the turn of Player 1 (respectively, 0). The output gate is $g(I, 0, 0, 0)$, where I is the initial configuration on α_n. Let $g(A, r_1, r_0, \hat{s})$ be a gate of β_n, where $A =$

$(t, P_1, P_0, R_1, R_0, v)$ and let $A' = (t', P_1', P_0', R_1', R_0', v')$ satisfy $A \vdash A'$. For $i \in \{0, 1\}$, let

$$r_i' = \begin{cases} r_i + 1, & \text{if } t = P \text{ and } v \text{ is of challenge type } 1 - i, \\ r_i, & \text{otherwise,} \end{cases}$$

$$\hat{s}' = \begin{cases} \hat{s} + 1, & \text{if the challenge types of } v \text{ and } v' \text{ are unequal,} \\ \hat{s}, & \text{otherwise.} \end{cases}$$

If $r_i' > r$ or $\#(P_i' \cup R_i') > p$, then there is a wire from the constant $1 - i$ to $g(A, r_1, r_0, \hat{s})$ (indicating that Player $1 - i$ must win from A', since the winner never exceeds its resources). If $\hat{s}' > s$, there is a wire from an arbitrary constant to $g(A, r_1, r_0, \hat{s})$. Otherwise, there is a wire from $g(A', r_1', r_0', \hat{s}')$ to $g(A, r_1, r_0, \hat{s})$.

Correctness. Suppose α_n evaluates to 1 on x. The fact that β_n evaluates to 1 on x is shown by arguing that there is an "accepting subcircuit" S of β_n, that is, a set of vertices including the output all of which evaluate to 1. (The proof when α_n evaluates to 0 is dual.)

Since α_n evaluates to 1 on x, there is a winning strategy W for Player 1 in which Player 1 uses at most p pebbles, r rounds, and s role switches. By construction, there is a corresponding subcircuit S of β_n that contains the output, and in which one immediate predecessor of each OR gate in S and all immediate predecessors of each AND gate in S are also in S. The major difference between W and S is that some plays (in particular, all infinite plays) in W are truncated in S due to the conditions $r_0 > r$ or $\#(P_0 \cup R_0) > p$. (Neither $r_1 > r$ nor $\#(P_1 \cup R_1) > p$ nor $\hat{s} > s$ ever occurs in S, since Player 1's strategy uses at most r rounds, at most p pebbles, and at most s role switches.) All literals or constants of S that correspond to leaves of W evaluate to 1, since Player 1 wins at all leaves of W. Furthermore, any literal or constant of S that does not correspond to a leaf of W is the constant 1 by construction, since it arises from a truncation due to $r_0 > r$ or $\#(P_0 \cup R_0) > p$. Thus, β_n outputs 1.

Analysis. The size bound of β_n follows from the fact that the number of configurations of the pebble game is $z^{O(p)}$. The depth bound of $4r + 5$ follows from the fact that either r_0 or r_1 increases each round, and there are two moves (one for each player) per round. The fan-in bound follows from the fact that, whenever it is the turn of Player 0 (1) who is the Challenger in A, the AND fan-in (respectively, OR fan-in) of $g(A, r_1, r_0, \hat{s})$ is at most $p + 1$, since only $p + 1$ configurations (corresponding to the possibilities for the next challenged vertex) follow from A by a move of the Challenger. Finally, there is one layer for each of the $s + 1$ values of $\hat{s}$, since the same player remains Challenger as long as $\hat{s}$ remains unchanged. □

Let *ROUNDS, SWITCHES*$(r(n), s(n))$ denote the set of languages each of which is accepted by a nonuniform family of polynomial-size circuits pebbleable simultaneously with $O(1)$ pebbles, $r(n)$ rounds, and $s(n)$ role switches.

COROLLARY 21.

$$\textit{ROUNDS, SWITCHES}(r(n), s(n)) \subseteq \textit{ROUNDS, SWITCHES}(O(r(n) + s(n) \log n), 0).$$

Proof. This follows from Theorems 17, 19, and 20, noting for the size bound that $r(n)$ and $s(n)$ are $n^{O(1)}$. □

The final corollary states an explicit threshold beyond which role switches appear to add power. Equations (1) and (3) are the nonuniform analogues of Theorems 4 and 5 in [38].

COROLLARY 22. *For any* $i \geqq 1$,

(1) $\quad$ *nonuniform* $SAC^i = ROUNDS, SWITCHES(O(\log^i n), 0)$

(2) $\quad = ROUNDS, SWITCHES(O(\log^i n), O(\log^{i-1} n))$;

(3) $\quad$ *nonuniform* $AC^i = ROUNDS, SWITCHES(O(\log^i n), O(\log^i n))$.

Proof. Equation (1) follows from Theorems 19 and 20, since nonuniform SAC^i is, by definition, the set of languages each of which is accepted by a family of $(n^{O(1)}, O(\log^i n), 1, O(1))$-circuits. Equation (3) follows by the same argument, since nonuniform AC^i is characterized similarly by $(n^{O(1)}, O(\log^i n), O(\log^i n), O(1))$-circuits. Equation (2) follows from Corollary 21. □

4. Open problems. Figure 1 indicates the relationships among space-bounded complexity classes between NC^1 and NC^2. Since it is still possible that $NC^1 = NC^2$ (or indeed $NC^1 = NP$), there are no proven proper inclusions or incomparability results among these classes.

In addition to the problems identified by Cook [7], we call attention to certain questions suggested by this paper:

(1) Is SL closed under complementation? If so, then the $\bigcup_k C\Sigma_k^{SL}$ hierarchy collapses to SL.

(2) Is RLP closed under complementation? If so, then $RLP = ZPLP$. If not, what is a new candidate for a language in RLP (or $BPLP$) that is not in $ZPLP$?

(3) Assuming that $RLP \neq NL = RL = ZPL$, we see that the expected polynomial-time bound is important in the case of errorless and one-sided error probabilistic $O(\log n)$ space computations, whereas $PL = PLP$ in the case of two-sided unbounded error. The case of two-sided bounded error remains open; that is, is $BPL = BPLP$? Is there a candidate for a language in $BPLP$ (or BPL) that is not in NL?

It seems surprising that the NC^1 AKS networks [1] provide the best known SAC^1 networks for Boolean sorting. An interesting question is whether we could exploit the availability of unbounded fan-in OR gates to get a simpler $O(n \log n)$ size monotone Boolean sorter, and/or one with a more favorable constant hidden in the big-O. Indeed, size $o(n \log n)$ is not out of the question for this model. See Friedman [11] and Valiant [35] for other recent approaches to threshold computation.

NOTE ON WEINTRAUB'S MINIMUM-COST CIRCULATION ALGORITHM*

FRANCISCO BARAHONA† AND ÉVA TARDOS‡

Abstract. In 1974 Weintraub [*Management Sci.*, 21 (1974), pp. 87-97] published an algorithm for the minimum-cost circulation problems with convex cost function. In this note Weintraub's algorithm is considered when applied to a minimum-cost circulation problem with linear objective function. It is shown that a minor variation of the algorithm runs in polynomial time. The resulting algorithm, although it is not strongly polynomial, does not rely on scaling. It is a generalization of the maximum flow algorithm due to Edmonds and Karp [*J. Assoc. Comput. Mach.*, 19 (1972), pp. 248-264] that augments along the fattest augmenting path in the residual graph.

The algorithm described here is slower than the fastest minimum-cost circulation algorithms known. The authors' interest in the algorithm is partially historical, a scaling free "almost polynomial time" algorithm was published in 1974, and partially due to the different ideas involved.

Key words. network flow, circulation, scaling, algorithms

C. R. subject classifications. F.2.2, G.2.2

1. Introduction. The circulation problem is one of the fundamental problems in the theory of algorithms. It is very often used in practice and has contributed considerably to our understanding of the efficiency of algorithms, especially of how the presence of numbers in a combinatorial problem affect the complexity of the problem.

An instance of the minimum-cost circulation problem is given by a directed graph $G=(V, E)$ and capacities $u: E \mapsto Z_+$ and costs $c: E \mapsto Z$ on the arcs. For notational convenience we assume that for every pair $v, w \in V$, there is at most one arc $e \in E$ with ends v and w. A *feasible circulation* is a vector $x \in R^E$ such that

$$0 \leqq x(e) \leqq u(e) \quad \text{for every } e \in E,$$

$$\sum_{w \in V} x(w, v) = \sum_{w \in V} x(v, w) \quad \text{for every node } v \in V.$$

The *cost of the circulation* x is

$$cx = \sum_{e \in E} c(e)x(e).$$

The *minimum-cost circulation problem* is to find a feasible circulation of minimum cost. We shall use n to denote the number of nodes, m to denote the number of arcs in G, and U and C to denote the maximum capacity and cost, respectively.

The problem was studied already as early as the 1940s. The first algorithm, the "out-of-kilter" method, was introduced in the early 60s (see Ford and Fulkerson [2]). The out-of-kilter method is a pseudo-polynomial algorithm and its running time is proportional to the unary size of the capacities.

* Received by the editors March 21, 1988; accepted for publication September 13, 1988. This research was partially supported by Air Force Office of Scientific Research contract AFOSR-86-0078.

The first polynomial time algorithm for the problem was discovered by Edmonds and Karp in 1972 [1]. This is the first so-called scaling algorithm. Since then, scaling algorithms have been widely studied and used for a variety of combinatorial optimization problems.

A theoretical disadvantage of scaling algorithms is that they are not strongly polynomial (that is, the number of arithmetic operations used by the algorithm depends on the size of the numbers involved, and not only on the number of nodes and arcs in the graph). In fact, scaling algorithms have a non-strongly polynomial "best case running time," since the algorithm handles each bit in the binary description of the capacities separately.

The first strongly polynomial algorithm for the minimum cost circulation problem was published thirteen years later in 1985 [8]. The current most efficient strongly polynomial algorithm is due to Orlin [7]. Goldberg and Tarjan [3] discovered a very elegant strongly polynomial algorithm. This algorithm is similar to the one studied in this paper in the sense that both are based on the same basic idea of canceling cycles (Klein [5]).

In this note, we consider an algorithm due to Weintraub [10] that was published two years after the Edmonds-Karp paper. The algorithm is based on the idea due to Klein [5] of repeatedly canceling negative cost cycles in the residual graph of a feasible circulation. Although Weintraub considers the circulation problem with convex costs, here we shall restrict our attention to the minimum-cost circulation problem with linear cost function. In the following, we shall refer to this special case as Weintraub's algorithm. In the paper [10] Weintraub proves that his cycle selection rule results in a minimum-cost circulation after canceling a polynomial number of cycles, but his algorithm takes superpolynomial time to find the right cycles to cancel. We show that the required cycle can be found in polynomial time. To make this note self-contained we shall describe the special case of Weintraub's algorithm in detail.

Weintraub's method relies on a subroutine that solves the assignment problem, and therefore its running time is worse than the fastest known minimum-cost circulation algorithms ([4], [7]). We find it still interesting to see how Weintraub's approach, which was published in 1974, can yield a fairly simple polynomial time algorithm.

2. A modification of Weintraub's algorithm. Given a circulation problem and a feasible circulation x we define the associated *residual graph* $G_x=(V, E_x)$, where $(v, w)\in E_x$ if either $(v, w)\in E$ and $x(v, w)<u(v, w)$ or $(w, v)\in E$ and $x(w, v)>0$. In the first case the arc (v, w) has *residual capacity* $u_x(v, w)=u(v, w)-x(v, w)$ and cost $c(v, w)$. In the second case $u_x(v, w)=x(w, v)$ and $c(v, w)=-c(w, v)$.

The algorithm is based on the following well-known fact (see, e.g., [6]).

LEMMA 1. *A feasible circulation x is of minimum cost if and only if the residual graph G_x contains no negative cost residual cycles.*

The main step of the algorithm is canceling negative cost cycles. We define the characteristic vector of a cycle C in the residual graph of a circulation as

$$\chi_C(e)=\begin{cases} 1 & \text{if } e=(v, w)\in C,\\ -1 & \text{if } e=(v, w) \text{ and } (w, v)\in C,\\ 0 & \text{otherwise.}\end{cases}$$

The amount of flow we can push around the cycle is $u_x(C)=\min_{(v,w)\in C} u_x(v, w)$. *Canceling* C results in a new feasible circulation $x'=x+u_x(C)\chi_C$.

Note that canceling a cycle C improves the cost of the circulation by

$$cx-cx'=-u_x(C)c\chi_C. \tag{1}$$

LEMMA 2. *For every feasible circulation x there exists a cycle C in the residual graph of x, canceling of which results in a feasible circulation x' with*

$$cx' - cx_{\text{opt}} \leqq \frac{m-1}{m}(cx - cx_{\text{opt}}),$$

where x_{opt} denotes the minimum-cost circulation.

Proof. Consider the circulation $x_{\text{opt}} - x$. This circulation can be decomposed into at most m conforming cycles. That is, there exists cycles C_i and positive scalars λ_i for $i = 1, \cdots, k$, such that $k \leqq m$ and $\sum_{i=1}^{k} \lambda_i \chi_{C_i} = x_{\text{opt}} - x$ and further $(v, w) \in C_i$ implies that either $(v, w) \in E$ and $x_{\text{opt}}(v, w) > x(v, w)$ or $(w, v) \in E$ and $x_{\text{opt}}(w, v) < x(v, w)$. Now C_i is a cycle in G_x for every $i = 1, \cdots, k$. Further $u_x(C_i) \geqq \lambda_i$. Therefore, the cycle C_i that maximizes $u_x(C_i) c\chi_{C_i}$ proves the lemma. □

As a corollary we can note that canceling the residual cycle that gives the biggest improvement in the cost of the circulation would give a polynomial-time algorithm (see the proof of Theorem 5). However, finding this cycle is NP-hard; it contains the Hamiltonian cycle problem as a special case.

Remark. The maximum flow problem can be reduced to the minimum-cost circulation problem by introducing a new arc (t, s) connecting the sink back to the source with infinite (very high) capacity and cost -1 and assigning cost 0 to all other arcs. A minimum cost circulation in this graph is equal to a maximum flow in the original graph with the arc (t, s) carrying the value of the flow. The circulation $x = 0$ is feasible. All negative cost cycles in the residual graph of any feasible circulation have cost -1 and go through the arc (t, s). Negative cost residual cycles correspond to augmenting paths for the maximum flow problem. The residual cycle whose canceling gives the maximum improvement in the cost is the cycle corresponding to the augmenting path with the minimum residual capacity along the path maximal. Such a path can be found in polynomial time. The resulting maximum flow algorithm is the polynomial time fattest path algorithm discovered by Edmonds and Karp [1].

Weintraub's main idea is that instead of solving the NP-hard problem of finding the best single cycle to cancel, we can look for a set of node-disjoint cycles and cancel them simultaneously. The following algorithm finds a set of node-disjoint cycles, canceling of which results in an improvement of the cost at least as big as the canceling of any single cycle. The algorithm will use a subroutine that solves the assignment problem (i.e., the minimum-cost matching problem in a bipartite graph) to find the right set of cycles.

Given a graph $G = (V, E)$ with a cost function c on its arcs, let us define a corresponding bipartite graph $B = (V' \cup V'', E')$ as follows.

Let V' and V'' denote two disjoint copies of V. Let v' and v'' denote the nodes in V' and V'', respectively, corresponding to node $v \in V$. Let $E' = \{v'w'' \mid \text{if either } v = w \text{ or } (v, w) \in E\}$. Define the costs on the edges of B as $c(v'w'') = c(v, w)$ if $v \neq w$ and 0 otherwise.

LEMMA 3. *For any directed graph G and the corresponding bipartite graph B the perfect matchings (assignments) of B are in one-to-one correspondence with the sets of node-disjoint cycles in G, and the two have the same cost.*

This lemma is the basis of the algorithm whose main step is described in Fig. 1. The subroutine takes a feasible circulation x as its input, and outputs a set of node-disjoint cycles that should be canceled. For feasible circulation x and a real number $\lambda \in R_+$ we use the graph $G(x, \lambda) = (V, E(x, \lambda))$, where $E(x, \lambda)$ denotes the set of arcs with residual capacity at least λ.

Step 1 Let $\lambda_1 > \cdots > \lambda_k > 0$ denote the different values of the residual capacities in G_x.

Step 2 For $i = 1, \cdots, k$ find the minimum cost set of node-disjoint cycles in $G(x, \lambda_i)$. This can be done using Lemma 3 and a subroutine to solve the resulting assignment problem. Let ν_i be equal to $-\lambda_i$ times the sum of the costs of the arcs in the set of cycles found.

Step 3 Choose the index i for which ν_i is maximal and output the set of cycles found in $G(x, \lambda_i)$.

FIG. 1. FIND CYCLES *subroutine.*

THEOREM 4. *Given a feasible circulation x, canceling the cycles found by the* FIND CYCLES *subroutine in Fig.* 1 *results in a new feasible circulation x', such that the improvement in the cost is at least as big as the improvement caused by canceling any single cycle in* G_x.

Proof. Let C denote the best residual cycle in G_x. Further, let λ_i denote the minimum residual capacity of the arcs in C. C is a cycle in $G(x, \lambda_i)$ and therefore (1) implies that the improvement in the cost caused by canceling C is at most ν_i. On the other hand, the cost improvement caused by canceling the cycles found by the subroutine is at least ν_i. □

THEOREM 5. *Starting with any feasible integer circulation x and repeatedly canceling the cycles found by the* FIND CYCLES *subroutine results in a minimum-cost circulation after at most* $O(m \log mUC)$ *calls to the subroutine.*

Proof. Let x_{opt} denote a minimum-cost circulation. Note that every intermediate feasible circulation x' found by this algorithm is integral, and therefore $cx' - cx_{\text{opt}} < 1$ implies that x' is of minimum cost. Further, any initial feasible circulation x_0 satisfies $cx_0 - cx_{\text{opt}} \leqq \sum_{e \in E} c(e)u(e) \leqq mCU$. Lemma 2 and Theorem 4 imply that the circulation x_k found after canceling k set of cycles given by the subroutine satisfies

$$cx_k - cx_{\text{opt}} \leqq (1 - 1/m)^k (cx_0 - cx_{\text{opt}}) \leqq (1 - 1/m)^k mCU.$$

For $k = m \log mUC$ we have that $cx_k - cx_{\text{opt}} < 1$ (since $(1 - 1/m)^m < e^{-1}$) and consequently x_k is optimal. □

THEOREM 6. *The above version of Weintraub's algorithm can be implemented to run in* $O(m^2(m + n \log m) \log mUC)$ *time.*

Proof. Theorem 5 implies that the FIND CYCLES subroutine will be used at most $O(m \log mUC)$ times. The cycles found by the subroutine can be canceled in $O(n)$ time. The most time-consuming part of the subroutine is solving the m assignment problems. Therefore, the running time can be bounded by $O(m^2 \log mUC)$ times the time required for solving a single assignment problem. This can be improved by noticing that the m assignment problems solved in one application of the subroutine are closely related: only one new edge is added to the old problem to create the new one. Having already found a solution to the previous problem, the new problem can be solved by a single call to a shortest path algorithm with nonnegative arclengths. Consequently, the FIND CYCLES subroutine can be implemented in $O(m(m + n \log n))$ time (see, e.g., [9]), and this gives an $O(m^2(m + n \log n) \log mUC)$ time minimum-cost circulation algorithm. □

Remark. Let us point out in what way the algorithm described by Weintraub differs from the one given above. Weintraub's algorithm has the same overall strategy,

and Weintraub has proved that the cycle selection rule implemented by the FIND CYCLES subroutine gives (in the case of a linear objective function) a minimum-cost circulation after canceling a polynomial number of cycles. The only difference lies in the choice of the set of values λ_i in Step 1 of the subroutine (Fig. 1). Weintraub was concerned with convex cost functions, where the number of different values of λ to be considered is even bigger than U. He did not notice that in the linear case m values suffice.

A scaling-like choice for the set of values λ_i that would also make the algorithm run in polynomial time has been pointed out to us by Plotkin and Orlin (personal communication). Namely, we can take the values λ_i in each application of the subroutine to be the different powers of 2 up to the maximum capacity U. In this case Theorem 4 has to be relaxed. This version of the subroutine finds a set of cycles, whose canceling improves the cost by at least half of the improvement possible by canceling any single cycle.

Open problem. It would be interesting to know if the minimum-cost circulation algorithm described here (or a minor modification of this algorithm) is actually strongly polynomial. Even Edmonds and Karp's fattest path maximum flow algorithm (that is, the same as our implementation of Weintraub's algorithm when applied to solve the maximum flow problem) is not known to run in strongly polynomial time.

FAST FOURIER TRANSFORMS FOR METABELIAN GROUPS*

MICHAEL CLAUSEN†

Abstract. Let G be a finite group . Then $L_s(G)$, the minimal number of arithmetic operations to evaluate a Fourier transform corresponding to G, is smaller than $2 \cdot |G|^2$. The fast Fourier transform algorithms improve this trivial upper bound by showing that for a cyclic group G, $L_s(G) \leqq c \cdot |G| \cdot \log |G|$. This last result is extended to metabelian groups, and it is shown that these groups also have fast inverse Fourier transforms. In particular there are fast algorithms for the (inverse) Fourier transforms for dihedral and generalized quaternion groups, as well as for all groups of square-free order.

Key words. fast Fourier transform, group algebras, metabelian groups, dihedral groups, quaternion groups

AMS(MOS) subject classifications. 68Q40, 20C15

1. Introduction. This paper is concerned with fast Fourier transforms (FFTs). For applications of such fast algorithms to signal and picture processing, coding theory, cryptography, and algorithmic circuit design, the interested reader is referred to [2], [3], [11], [13]. We start with a brief review of the mathematical background.

The set $\mathbf{C}G := \{a \mid a : G \to \mathbf{C}\}$ of all complex-valued functions on the finite group G becomes a $\mathbf{C}$-space by pointwise addition and scalar multiplication. Its $\mathbf{C}$-dimension equals the order $|G|$ of G. A natural $\mathbf{C}$-basis is given by the indicator functions of the group elements. By identifying each group element with its indicator function, $\mathbf{C}G$ can be viewed as the space of all formal sums $\sum_{g \in G} a_g g$ with complex coefficients. The multiplication in G can be bilinearly extended to $\mathbf{C}G$:

$$\left(\sum_{g \in G} a_g g\right) \cdot \left(\sum_{h \in G} b_h h\right) = \sum_{k \in G} \left(\sum_{(g,h):gh=k} a_g b_h\right) k.$$

Thus $\mathbf{C}G$ becomes a $\mathbf{C}$-algebra, the so-called *group algebra* of G over $\mathbf{C}$. For instance, the group algebra of the cyclic group C_n of order n can be identified with the algebra $\mathbf{C}[X]/(X^n - 1)$ of polynomials of degree $< n$ with multiplication modulo $X^n - 1$. By Chinese remaindering we know that $\mathbf{C}[X]/(X^n - 1)$ is isomorphic to the algebra of n-square diagonal matrices. This isomorphism, known as the (cyclic) *discrete Fourier transform* (DFT), can be viewed as a structural transition from the *signal domain* $\mathbf{C}C_n$ into the *spectral domain* $\mathbf{C}^n$; in particular, the DFT is multiplicative and thus links the convolution in $\mathbf{C}[X]/(X^n - 1)$ and the multiplication of n-square diagonal matrices. A fast multiplication of polynomials results from an FFT and the multiplication of diagonal matrices followed by a fast inverse Fourier transform.

Wedderburn's theorem, which generalizes the DFT for cyclic groups to arbitrary finite groups, says that the group algebra $\mathbf{C}G$ of a finite group G is isomorphic to a suitable algebra of block diagonal matrices:

$$\mathbf{C}G \simeq \bigoplus_{i=1}^{h} \mathbf{C}^{d_i \times d_i}.$$

The number h of blocks equals the number of conjugacy classes of G. Every such isomorphism is called a (*generalized*) *Fourier transform* for $\mathbf{C}G$. For the symmetric group S_3 it turns out that $\mathbf{C}S_3 \simeq \mathbf{C} \oplus \mathbf{C} \oplus \mathbf{C}^{2\times 2}$. The first two blocks correspond to the

† Fakultät für Informatik, Universität Karlsruhe, D-7500 Karlsruhe, Federal Republic of Germany.

representations ($S_3 \ni \pi \mapsto 1$) and ($S_3 \ni \pi \mapsto \operatorname{sgn}(\pi)$), whereas the last block represents S_3 as the symmetry group of a regular triangle. In general, the h blocks occurring in Wedderburn's theorem correspond to the h classes of inequivalent irreducible representations of $\mathbf{C}G$. A (*matrix*) *representation* D of $\mathbf{C}G$ of *degree* or *dimension* d is a $\mathbf{C}$-linear and multiplicative transformation $D: \mathbf{C}G \to \mathbf{C}^{d\times d}$ which maps 1 onto 1; it is *irreducible* if no proper linear subspace of $\mathbf{C}^d$ is invariant under the image of D. A change of bases in $\mathbf{C}^d$, described by an invertible d-square matrix T, leads to a new representation $D'(g) := T \circ D(g) \circ T^{-1}$, which, by definition, is *equivalent* to D. If $D_1, \cdots, D_h$ is a transversal of the equivalence classes of irreducible representations of $\mathbf{C}G$, then

$$\bigoplus_i D_i : a \mapsto \bigoplus_i D_i(a)$$

is a Fourier transform for $\mathbf{C}G$ and every algebra isomorphism $\mathbf{C}G \to \oplus_i \mathbf{C}^{d_i \times d_i}$ can be described in this way.

As a classical example we take the cyclic group $C_n = \langle x \rangle$ of order n. Let ω be a primitive nth root of unity. Then $\{D_k := (\sum_m a_m x^m \mapsto \sum_m a_m \omega^{mk}) \mid 0 \leqq k < n\}$ is the set of all irreducible $\mathbf{C}$-representations of $\mathbf{C}C_n$ and the Fourier transform for $\mathbf{C}C_n$ with respect to natural $\mathbf{C}$-bases is given by the n-square DFT matrix (ω^{mk}). Let us proceed with the general case. With respect to natural $\mathbf{C}$-bases in $\mathbf{C}G$ and $\oplus_{i \leqq h} \mathbf{C}^{d_i \times d_i}$, each Fourier transform can be viewed as a $|G|$-square complex matrix. The *linear complexity* $L_s(A)$ of a matrix $A \in \mathbf{C}^{r\times t}$ is the minimal number of $\mathbf{C}$-operations (= additions/subtractions/scalar multiplications) which are sufficient to compute $A \cdot x$ from x, where the input vector $x = (x_i)$ is a column vector of t indeterminates $x_1, \cdots, x_t$ over $\mathbf{C}$. Since a nonabelian group G has more than one Fourier transform, we define the *linear complexity* of the group G by $L_s(G) := \min L_s(W)$, where the minimum is taken over all possible Fourier transforms W for $\mathbf{C}G$. Trivially, $L_s(G) < 2 \cdot |G|^2$. For a cyclic 2-group G the Cooley-Tukey algorithm shows that $L_s(G) \leqq 3/2|G| \log |G| - |G| + 1$. (In this paper log will always mean $\log_2$.) Combining the variants of the FFT algorithms [1], [4], [5], [8], [12], [14], [15], [17], [18] we get for an arbitrary finite abelian group G

$$L_s(G) \leqq c \cdot |G| \log |G| - |G| + 1,$$

where $c \leqq 15$ depends on the prime divisors of $|G|$ and on the exponents of the Sylow subgroups of G (see the proof of Theorem 2.4).

The question is near at hand, whether an $O(|G| \log |G|)$ upper bound does also hold for the linear complexity of a wider class of groups. We answer this question in the affirmative by extending such an upper bound to all finite metabelian groups G (see Theorem 3.1). (Recall that G is metabelian if and only if G has an abelian normal subgroup A such that G/A is abelian. Dihedral and generalized quaternion groups are typical members of this class, as well as all p-groups G with $|G| \leqq p^5$. By a theorem of Hall, all groups of square-free order are also metabelian.) Furthermore we show that metabelian groups also have fast inverse Fourier transforms.

To prove this result we had to change the former strategies. Using a Fourier transform adapted to a composition series of G, Beth [2], [3] proved an $O(|G|^{3/2})$ upper bound for the linear complexity of soluble groups. This result can be essentially extended to arbitrary finite groups (see [6]) by choosing Fourier transforms adapted to a maximal chain of subgroups of G. In particular, for symmetric groups this technique yields the stronger estimate $L_s(S_n) = o(|S_n| \cdot \log^3 |S_n|)$ (see [6], [7]). To establish an FFT for metabelian groups we first fix a maximal abelian normal subgroup A of G containing the commutator subgroup G' of G. Then we evaluate the DFT corresponding

to A at $[G:A]$ suitable elements of $\mathbf{C}A$. By a result of Shoda [16] (see also Theorem 2.5), we know that every irreducible representation D of G is closely related to a one-dimensional representation (= linear character) of a normal subgroup B of G containing A. As a matter of fact, B depends only on the kernel of D. Choosing a DFT for $\mathbf{C}G$ that takes Shoda's theorem and the action of various character groups of type $X(B/A)$ into account, we get an FFT for $\mathbf{C}G$ along "global" FFTs for A and "local" FFTs for several groups B/A. Section 3 will make this statement more precise.

The major development of the paper is self-contained apart from some proof details of classical representation theory, which can be found in [9], [10].

2. Preliminaries. In the next section we will assume familiarity with some basic techniques of complexity and representation theory. The present section puts together the definitions and results we will need. The first lemma is concerned with the linear complexity of matrices. (When treating matrices the symbols $\oplus$ and $\otimes$ will always denote the direct sum and Kronecker product, respectively.)

LEMMA 2.1. *For $A \in \mathbf{C}^{a\times a}$, $B \in \mathbf{C}^{b\times b}$ and a-square permutation matrices P and Q we have*

(a) $L_s(A) = L_s(PAQ)$,

(b) $L_s(A \oplus B) \leqq L_s(A) + L_s(B)$,

(c) $L_s(A \cdot B) \leqq L_s(A) + L_s(B)$ *(assuming $a = b$)*,

(d) $L_s(A \otimes B) \leqq b \cdot L_s(A) + a \cdot L_s(B)$.

Proof. Claims (a), (b), and (c) are easy exercises. To prove (d), recall that the Kronecker product of matrices satisfies $A \otimes B = (A \otimes E_b) \cdot (E_a \otimes B)$, where E_a denotes the a-square unit matrix. Finally observe that $E_a \otimes B = B \oplus \cdots \oplus B$ (a times) and $A \otimes E_b = P(E_b \otimes A)Q$, for suitable permutation matrices P and Q. Claim (d) then follows from (a), (b), and (c). This proves Lemma 2.1.

The Kronecker product formula (d) yields an upper bound for the linear complexity of a direct product of finite groups.

LEMMA 2.2. *Let $G = G_1 \times \cdots \times G_r$ be the direct product of finite groups. Then*

$$L_s(G) \leqq \sum_{i=1}^{r} [G:G_i] L_s(G_i).$$

Proof. Let W_i be a Fourier transform for $\mathbf{C}G_i$ satisfying $L_s(G_i) = L_s(W_i)$. Then $W := W_1 \otimes \cdots \otimes W_r$ is a Fourier transform for $\mathbf{C}G$ (see [10, p. 516]). Hence Lemma 2.2 follows by induction from the Kronecker product formula, Lemma 2.1(d).

For $c > 0$ let FFT_c denote the class of all finite groups G that have a Fourier transform W satisfying $\max(L_s(W), L_s(W^{-1})) \leqq c \cdot |G| \cdot \log|G|$.

LEMMA 2.3. *FFT_c is closed under direct products.*

Proof. Let $G_1, \cdots, G_r \in FFT_c$, and let W_i be a Fourier transform for $\mathbf{C}G_i$ satisfying $\max(L_s(W_i), L_s(W_i^{-1})) \leqq c \cdot |G_i| \cdot \log|G_i|$. Then $W := W_1 \otimes \cdots \otimes W_r$ is a Fourier transform for $\mathbf{C}G$, $G := G_1 \times \cdots \times G_r$. By Lemma 2.2,

$$L_s(W) = L_s(W_1 \otimes \cdots \otimes W_r) \leqq \sum_i [G:G_i] L_s(W_i) \leqq c \cdot |G| \log|G|.$$

Since $W^{-1} = W_1^{-1} \otimes \cdots \otimes W_r^{-1}$, the same upper bound can be analogously derived for the linear complexity of W^{-1}. This proves Lemma 2.3.

Combining several variants of the classical FFT algorithms we get the following theorem.

THEOREM 2.4. (a) *$FFT_{3/2}$ contains all finite abelian 2-groups.*

(b) *$FFT_{2.2}$ contains all finite abelian 3-groups.*

(c) *FFT_{15} contains all finite abelian groups.*

Proof. (a) and (b). Every finite abelian group is a direct product of cyclic groups. Hence, by Lemma 2.3, it suffices to prove the statements for cyclic groups. Let C_n denote the cyclic group of order n, and let $\omega \in \mathbf{C}$ be a primitive nth root of unity. We have to estimate the linear complexity of the n-square DFT matrix $(\omega^{\mu\nu})_{0\leqq\mu,\nu<n}$ and its inverse

$$(\omega^{\mu\nu})^{-1} = \frac{1}{n}(\omega^{-\mu\nu}). \tag{1}$$

For every input vector $(a_\nu)_{0\leqq\nu<n}$ we thus have to compute

$$(A_\mu)_{0\leqq\mu<n} := (\omega^{\mu\nu})(a_\nu) \tag{2}$$

as well as

$$(B_\mu)_{0\leqq\mu<n} := \frac{1}{n}(\omega^{-\mu\nu})(a_\nu) \tag{3}$$

with at most $O(n \log n)$ **C**-operations. If $n = pq$, the indices μ and ν can be uniquely written as $\mu = kq + l (0 \leqq k < p,\ 0 \leqq l < q)$ and $\nu = ip + j (0 \leqq i < q,\ 0 \leqq j < p)$. Hence

$$\begin{aligned} A_{kq+l} &= \sum_{i<q} \sum_{j<p} a_{ip+j} \omega^{(ip+j)(kq+l)} \\ &= \sum_{j<p} \left(\sum_{i<q} a_{ip+j} (\omega^p)^{il} \right) \omega^{jl} (\omega^q)^{jk}. \end{aligned} \tag{4}$$

The last formula is the basis for the Cooley–Tukey algorithm [8] to compute the A_μ: first compute for all $j < p$ the expressions $b_{j,l} := \sum_{i<q} a_{ip+j}(\omega^p)^{il}$, $0 \leqq l < q$, by a cyclic DFT of order q. Then multiply the $b_{j,l}$ by the so-called twiddle factors ω^{jl} and finally compute for all $l < q$ the spectral coefficients $A_{kq+l} (0 \leqq k < p)$ by a cyclic DFT of order p. Altogether we get the recurrence relation $L_s(C_{pq}) \leqq p \cdot L_s(C_q) + q \cdot L_s(C_p) + pq - p - q + 1$. By induction, this yields for cyclic p-groups $L_s(C_{p^m}) \leqq (L_s(C_p) + p - 1)mp^{m-1} - p^m + 1$. Combining this with $L_s(C_2) = 2$ and $L_s(C_3) \leqq 8$ we get

$$G \simeq C_{2^m} \Rightarrow L_s(G) \leqq \tfrac{3}{2}|G| \log |G| - |G| + 1, \tag{5}$$

and

$$G \simeq C_{3^m} \Rightarrow L_s(G) \leqq 2.11|G| \log |G| - |G| + 1. \tag{6}$$

In order to get a fast algorithm that computes the B_μ (see (3)) we modify the right-hand side of equation (4) as follows. We replace ω by ω^{-1} and each twiddle factor ω^{jl} by ω^{-jl}/n. This proves (a) and (b).

(c) We partly follow the approach of Bluestein [4] (see also Büchi [5]) and show that for every n

$$L_s(C_n) \leqq 15n \log n - n + 1. \tag{7}$$

Furthermore we will prove that the same upper bound is valid for the inverse transformation. We are going to compute the spectral coefficients A_μ (see (2)) with a fast cyclic convolution of length a power of 2. First observe that $2\mu\nu = \mu^2 + \nu^2 - (\mu - \nu)^2$. Hence

$A_\mu = \omega^{\mu^2/2} \sum_{\nu<n} a_\nu \omega^{\nu^2/2} \omega^{-(\mu-\nu)^2/2}$ and with $u_j := a_j \omega^{j^2/2}$ and $v_k := \omega^{-k^2/2}$ we get

$$\omega^{-\mu^2/2} A_\mu = \sum_{0 \leqq \nu < n} u_\nu v_{(\mu-\nu) \bmod n}.$$

Let $C_N = \langle x \rangle$ denote the cyclic group of order $N := 2^{\lceil \log 2n \rceil}$. Then $U := \sum_{0 \leqq i < n} u_i (x^i + x^{N-n+i})$ as well as $V := \sum_{0 \leqq j < n} v_j x^j$ are elements of the group algebra $\mathbf{C}C_N$ and a straightforward computation shows that the first n coefficients of the product $U * V$ are equal to $\omega^{-\mu^2/2} A_\mu$, $(0 \leqq \mu < n)$. These coefficients can be computed along the formula $U * V = DFT_N^{-1}(DFT_N(U) \cdot DFT_N(V))$. Now observe that V is independent of the input. Thus we can precompute $DFT_N(V)$ and store it as a constant vector. To compute U we need at most $n-1$ operations. According to the special form of U we can save $2(N-2n)$ operations in the first level of the computation of $DFT_N(U)$; thus, according to (5), after at most $\frac{3}{2}N \log N - 3N + 5n$ steps we know $DFT_N(U)$. After the pointwise multiplication of the two transformed vectors we compute only the first n coefficients of the inverse of the resulting vector. Combining the final multiplications with $\omega^{\mu^2/2}$ and the factor N^{-1} corresponding to DFT_N^{-1}, this transformation needs at most $\frac{3}{2}N \log N - 2N + 2n + 1$ arithmetic operations. Now let $n \geqq 41$. (If $n \leqq 40$ then the trivial upper bound $2n^2 - 3n + 1$ does not exceed $15n \log n - n + 1$.) Since $N = cn$ for some $2 \leqq c \leqq 4$, we altogether get

$$L_s(G) \leqq 3cn \log n + 3cn \log c - 4cn + 7n + 1.$$

As $3c \log c - 4c$ is monotonically increasing in the relevant interval $2 \leqq c \leqq 4$, we get

$$L_s(G) \leqq 12n \log n + 16n - n + 1 \leqq 12n \log n + \frac{16}{\log 41} n \log 41 - n + 1$$

$$\leqq 15n \log n - n + 1.$$

Recalling that $(\omega^{\mu\nu})^{-1} = 1/n(\omega^{-\mu\nu})$ and multiplying in the final step by the precomputed values $\omega^{\mu^2/2} N^{-1} n^{-1}$ we see that the same upper bound is valid for the inverse transformation. This proves Theorem 2.4.

Now we begin our review of representation theory. In the introduction we already mentioned the notions of irreducibility and equivalence of representations of a group algebra. In the sequel it will sometimes be convenient for us to have a second concept at our disposal that is equivalent to the above concept. Let G be a finite group. A **C**-*representation* of G of *degree* or *dimension* d is a group morphism $D: G \to GL(d, \mathbf{C})$. By linear extension of D, we get a representation of the corresponding group algebra. By abuse of notation, this extension will also be denoted by D. D is *irreducible* if and only if its extension is. Two representations D and D' of G are *equivalent*, $D \sim D'$, if and only if the corresponding extensions are equivalent. By Maschke's theorem, every **C**-representation D of G is equivalent to a direct sum $D_1 \oplus \cdots \oplus D_r$ of irreducible **C**-representations D_i of G. This decomposition into irreducibles is essentially unique; in particular, the multiplicity $\langle D_i | D \rangle$, which is the number of j satisfying $D_j \sim D_i$, depends only on D and the equivalence class $[D_i]$ of D_i. By definition, D is *multiplicity-free* if and only if $\langle D_i | D \rangle \leqq 1$ for all i. Without explicitly knowing a decomposition of D into irreducibles, we can compute these multiplicities with the help of characters: Every representation D is associated with its *character* $\chi^D: G \to \mathbf{C}$, defined by $\chi^D(g) := \operatorname{trace}(D(g))$ for all $g \in G$. As a matter of fact, equivalent representations have the same character. The characters corresponding to the classes of irreducible representations are called *irreducible* characters. Characters are class functions on G, i.e., they are constant on the conjugacy classes of G. The set of all class functions on G becomes

a **C**-space under pointwise **C**-operations. It turns out that the irreducible characters form an orthonormal **C**-basis of this space under the inner product

$$\langle \phi \,|\, \psi \rangle := \frac{1}{|G|} \sum_{g \in G} \phi(g)\psi(g^{-1}).$$

According to this fact, the multiplicity $\langle D_i \,|\, D \rangle$ equals $\langle \chi^{D_i} \,|\, \chi^D \rangle$. If D is a d-dimensional representation of G, then G acts via D on $\mathbf{C}^d$. Let $\chi_1, \cdots, \chi_h$ be the irreducible characters of G. Then

$$\varepsilon_i := \frac{\chi_i(1)}{|G|} \sum_{g \in G} \chi_i(g^{-1})g$$

is a (primitive) idempotent of the center of $\mathbf{C}G$ and

$$\mathbf{C}^d = D(\varepsilon_1)\mathbf{C}^d \oplus \cdots \oplus D(\varepsilon_h)\mathbf{C}^d$$

is the decomposition of $\mathbf{C}^d$ into its *isotypic components*. If D_i is an irreducible representation of G with character χ_i then the action of G on $D(\varepsilon_i)\mathbf{C}^d$ affords a representation that is equivalent to $D_i \oplus \cdots \oplus D_i$ ($\langle D_i \,|\, D \rangle$ times). The simplest irreducible representations of G are those of degree 1. In this case the representation D is equal to its character χ^D. One-dimensional representations of G are usually called *linear characters* of G. They can be viewed as morphisms from G into the multiplicative group $\mathbf{C}^*$ of the complex field. Under pointwise multiplication, $(\chi \otimes \psi)(g) := \chi(g) \cdot \psi(g)$, the linear characters of G form an abelian group $X(G)$, the *character group* of G. If N is a normal subgroup of G, then $X(G/N)$ can be embedded into the character group $X(G)$ of G via the natural projection $G \to G/N$. Thus $X(G/N)$ "is" the set of all linear characters of G that have N in its kernel. For a subgroup U of G let $X(G)\downarrow U$ denote the subgroup of $X(U)$ consisting of all restrictions $\chi \downarrow U$, where χ is in $X(G)$. Using standard techniques it can be shown that

$$X(G)\downarrow U \simeq U/(G' \cap U). \tag{8}$$

In particular, $X(G)$ is isomorphic to the commutator factor group G/G'. Thus $X(G) \simeq G$ if and only if G is abelian. If G is not abelian, then G has at least one equivalence class of higher-dimensional irreducible representations. In case of a metabelian group G, every higher-dimensional irreducible representation D is closely related to a linear character of a subgroup U of G. To make this statement more precise, we need the concepts of induced and monomial representations. If U is a subgroup of the finite group G and F an f-dimensional **C**-representation of U, then the *induced representation* $F\uparrow G$ is a **C**-representation of G of degree $f \cdot [G : U]$. More precisely, let $u_1, \cdots, u_n$ be a transversal of the left cosets of U in G. Then, for all $g \in G$,

$$(F\uparrow G)(g) = [\dot{F}(u_i^{-1} g u_j)]_{1 \leqq i,j \leqq n} \tag{9}$$

where

$$\dot{F}(x) := \begin{cases} F(x) & \text{if } x \in U, \\ 0 & \text{if } x \in G \setminus U. \end{cases}$$

(The linear extension of $F\uparrow G$ to $\mathbf{C}G$ will sometimes be denoted by $F\uparrow \mathbf{C}G$.) Induction of representations is transitive up to permutational equivalence: If F is a representation of U and V is a subgroup of G containing U, then for some permutation matrix T and all $g \in G$ we have $T(F\uparrow G)(g)T^{-1} = ((F\uparrow V)\uparrow G)(g)$. Dual to induction is the concept of subduction (= restriction) of representations. Both concepts are linked by

the Frobenius Reciprocity Theorem (see, e.g., [10, p. 555]): If F and D are irreducible $\mathbf{C}$-representations of U and G, respectively, then the multiplicity of D in $F\uparrow G$ equals the multiplicity of F in the subduced representation $D\downarrow U$:

$$\langle D \mid F\uparrow G\rangle = \langle D\downarrow U \mid F\rangle.$$

If F is one-dimensional and $g\in G$ then, by (9), $(F\uparrow G)(g)$ is a *monomial* matrix, i.e., $(F\uparrow G)(g)$ has exactly one nonzero entry in each row and in each column. This fact justifies calling $F\uparrow G$ a *monomial* representation. A group G is called an *M-group* if and only if every irreducible representation of G is equivalent to a monomial one. The following result is essentially due to Shoda [16]. It shows that metabelian groups are M-groups and specifies the subgroups that are relevant for induction to get all equivalence classes of irreducible $\mathbf{C}$-representations of a metabelian group G represented by monomial representations.

THEOREM 2.5. *Let G be a finite metabelian group and let D be an irreducible $\mathbf{C}$-representation of G with kernel N. Let A be a subgroup of G containing $G'\cdot N$ such that A/N is a maximal abelian normal subgroup of G/N. Then D is equivalent to a monomial $\mathbf{C}$-representation $\alpha\uparrow G$ of G, where α is a linear character of A.*

Proof. Let D be an irreducible d-dimensional $\mathbf{C}$-representation of G with kernel N. If $d=1$ then $N\geqq G'$; thus $A=G$ and $\alpha=D$. Since all irreducible $\mathbf{C}$-representations of an abelian group G are one-dimensional, we are left with the case $G'\neq E$ and $d>1$. The rest of the proof is by induction on $|G|$.

Step 1. *Reduction to the case $N=E$.* If $N>E$, let ν be the projection $G\to G/N$. Then $D=D'\circ\nu$, for some *faithful* (i.e., injective) irreducible $\mathbf{C}$-representation D' of the metabelian group G/N. By induction, the theorem applies to D'. Thus there exists a subgroup A of G such that A/N is a maximal abelian normal subgroup of G/N containing $(G/N)'=G'N/N$. Furthermore, there is a linear character α' of A/N such that $D'\sim\alpha'\uparrow G/N$. Finally an easy computation shows that the linear character $\alpha:=\alpha'\circ(\nu\downarrow A)$ of A satisfies $D\sim\alpha\uparrow G$.

Step 2. Suppose $N=E$. Let A be a maximal abelian normal subgroup of G containing G'. Then, by Clifford's theorem (see, e.g., [10, p. 565]) G acts transitively on the isotypic constituents of $D\downarrow A$. Let $T\geqq A$ be the stabilizer (=inertia group) of such an isotypic constituent $\alpha\oplus\cdots\oplus\alpha$ of $D\downarrow A$. Again by Clifford's theorem, there exists an irreducible $\mathbf{C}$-representation τ of T such that $\tau\downarrow A=\alpha\oplus\cdots\oplus\alpha$ and $D\sim\tau\uparrow G$.

Case 1. $T=A$.

Then $\tau=\alpha$, $D\sim\alpha\uparrow G$, and $\deg(\alpha)=1$, since A is abelian. (We have to exclude the remaining cases.)

Case 2. $T=G$.

Since A is abelian and $D\downarrow A$ is isotypic, we have $D(a)=\alpha(a)\cdot E_d$ for all $a\in A$. Hence $D(A)$ is contained in the center of $D(G)$. As D is faithful, this implies that A is contained in the center $C(G)$ of G. Since $A\geqq G'$ is a maximimal abelian normal subgroup of G we get $G'\leqq A=C(G)<G$. Let $g\in G\backslash A$. Then the subgroup of G generated by A and g is an abelian normal subgroup of G, contradicting the maximality of A.

Case 3. $A<T<G$.

By induction, the theorem applies to the irreducible $\mathbf{C}$-representation τ of the metabelian group T. Thus for some subgroup B strictly containing A and for some one-dimensional representation β of B, we know that $\tau\sim\beta\uparrow T$. Since induction is transitive up to permutational equivalence, we get $D\sim\beta\uparrow G$. But then $N=\ker D=\bigcap_{g\in G} g\ker(\beta)g^{-1}\geqq B'>E$, contradicting the fact that D is a faithful representation of G. This proves Theorem 2.5.

3. FFT for metabelian groups. This section is devoted to the design and analysis of FFTs for metabelian groups. Our goal is to prove the following result.

THEOREM 3.1. (a) *$FFT_{3/2}$ contains all finite metabelian 2-groups.*

(b) *$FFT_{2.2}$ contains all finite metabelian 3-groups.*

(c) *FFT_{15} contains all finite metabelian groups.*

Proof. Let G be a finite metabelian group. By Theorem 2.4 we may assume that G is not abelian. Thus $G > G' > G'' = E$. Let A be a maximal abelian normal subgroup of G containing G'. We are going to specify a transversal $D_1, \cdots, D_h$ of irreducible $\mathbf{C}$-representations of G which will be the basis for a fast (inverse) Fourier transform. According to Theorem 2.5 we may assume that the D_i satisfy the following condition.

(i) For every i there exists a normal subgroup B_i of G containing A and a linear character β_i of B_i such that $D_i = \beta \uparrow G$.

To establish a second condition we let the character group $X(G/A)$ act on the set $\{[D_1], \cdots, [D_h]\}$ of equivalence classes of irreducible $\mathbf{C}$-representations of G by $\chi * [D_i] := [\chi \otimes D_i]$, where $(\chi \otimes D_i)(g) := \chi(gA) \cdot D_i(g)$ for all $\chi \in X(G/A)$ and all $g \in G$. Induction, subduction, and the tensor product of representations are related as follows:

$$\chi \otimes (\beta \uparrow G) = ((\chi \downarrow B) \otimes \beta) \uparrow G, \tag{10}$$

$\chi \in X(G/A)$, $A \leqq B \leqq G$, $\beta \in X(B)$. According to (8) and (10) we can postulate the following condition in addition to (i).

(ii) If $[D_i]$ and $[D_j]$ are in the same $X(G/A)$-orbit, then $B_i = B_j$ and $\beta_i = \psi \otimes \beta_j$, for some $\psi \in X(B_i/A)$.

If B is a normal subgroup of G then G acts via conjugation on $X(B)$ by $(g\beta)(b) := \beta(g^{-1}bg)$ ($g \in G$, $\beta \in X(B)$, $b \in B$). Since $g\beta = \beta$ for all $g \in B$, the G-orbits $G\beta$, $\beta \in X(B)$, have length at most $[G:B]$. The orbits of this length are of special interest for us: By (9) $\beta \uparrow G \downarrow B = \oplus_{gB \in G/B} (g\beta)$; applying the orthonormality of the irreducible characters and the Frobenius Reciprocity Theorem, we get for $\beta \in X(B)$

$$\begin{aligned} |G\beta| = [G:B] &\Leftrightarrow \beta \uparrow G \text{ is irreducible} \\ &\Leftrightarrow \beta \uparrow G \downarrow B \text{ is multiplicity-free.} \end{aligned} \tag{11}$$

Let $A \leqq b \leqq G$. We are going to combine the above group actions. To this end we define a semidirect product P of the normal subgroup $N := X(B/A) \trianglelefteq P$ and the subgroup $G < P$ by $(\psi, g)(\psi', g') := (\psi \otimes (g\psi'), gg')$. P acts on $X(B)$ by $(\psi, g)\beta := \psi \otimes (g\beta)$. According to (10) and (11), the set $\{\beta \in X(B) \mid \beta \uparrow G \text{ irreducible}\}$ is P-stable.

Now choose $\beta_1, \cdots, \beta_h$ according to (i) and (ii). Furthermore let P_i denote the semidirect product of $N_i := X(B_i/A)$ and G, as defined above. Then, by (10), (11), and condition (ii), the set of irreducible constituents of $\beta_1 \uparrow G \downarrow B_1, \cdots, \beta_h \uparrow G \downarrow B_h$ is the disjoint union of certain P_i-orbits; i.e., there is some index set $I \subseteq \{1, \cdots, h\}$ such that

$$\dot{\bigcup_{1 \leqq i \leqq h}} G\beta_i = \dot{\bigcup_{i \in I}} P_i\beta_i.$$

Every $P_i\beta_i$ further splits into N_i-orbits which are all of length $|N_i|$. More precisely, G acts on the set $\{N_i\gamma \mid \gamma \in P_i\beta_i\}$ by $g(N_i\gamma) := N_i(g\gamma)$. Let V_i be the stabilizer of the point $N_i\beta_i$ under this G-action. Then $V_i \geqq B_i$ and

$$P_i\beta_i = \dot{\bigcup_{u_iV_i \in G/V_i}} u_iN_i\beta_i = \dot{\bigcup_{u_iV_i \in G/V_i}} N_i(u_i\beta_i).$$

Our next goal is to evaluate (with a small number of **C**-operations) the Fourier transform $W := \oplus_i (\beta_i \uparrow \mathbf{C}G)$ of $\mathbf{C}G$ at an arbitrary element $y \in \mathbf{C}G$. To this end we first decompose G into the disjoint union of left cosets with respect to A: $G = \dot{\bigcup}_{1 \leqq k \leqq [G:A]} g_k A$. Then $y = \sum_k g_k a_k$, for suitable $a_k \in \mathbf{C}A$. Now let $B := B_i$ and $\beta := \beta_i$. If $G = \dot{\bigcup}_{1 \leqq j \leqq d} h_j B$ then, after renaming the g_k and a_k, we can achieve that $h_j = g_{j1}, \cdots, g_{jt} \in h_j B = \dot{\bigcup}_{1 \leqq l \leqq t} g_{jl} A$ with corresponding $a_{j1}, \cdots, a_{jt} \in \mathbf{C}A$. Thus $y = \sum_{j=1}^{d} \sum_{l=1}^{t} g_{jl} a_{jl}$. On the other hand there are $b_j \in \mathbf{C}B$ such that $y = \sum_{j=1}^{d} h_j b_j$. Combining the last three equations we have for all $j \leqq d$

$$b_j = \sum_{l=1}^{t} h_j^{-1} g_{jl} a_{jl}. \tag{12}$$

Altogether we get for the constituent $D = \beta \uparrow \mathbf{C}G$ of W evaluated at $y \in \mathbf{C}G$ the formula

$$D(y) = \sum_{j=1}^{d} D(h_j) D(b_j) = \sum_{j=1}^{d} D(h_j) \bigoplus_{gB \in G/B} (g\beta)(b_j). \tag{13}$$

Instead of evaluating D at $y \in \mathbf{C}G$ separately, it is of advantage to aim at a common evaluation of all representations in $\{\chi \otimes D \mid \chi \in X(G/A)\} \cap \{\beta_j \uparrow G \mid 1 \leqq j \leqq h\}$. With regard to (10), (12), and (13) we have to compute for any fixed j and for all $\chi \otimes \beta \in X(B/A) \otimes \beta$ the following expressions:

$$\begin{aligned}(\chi \otimes \beta)(b_j) &= \sum_{l=1}^{t} (\chi \otimes \beta)(h_j^{-1} g_{jl})(\chi \otimes \beta)(a_{jl}) \\ &= \sum_{l=1}^{t} \chi(h_j^{-1} g_{jl} A) \beta(h_j^{-1} g_{jl}) \beta(a_{jl}).\end{aligned}$$

Having computed for fixed j all products $b_{jl} := \beta(h_j^{-1} g_{jl}) \cdot \beta(a_{jl})$, we are left with the evaluation of

$$((\chi \otimes \beta)(b_j))_{\chi \in X(B/A)} = (\chi(h_j^{-1} g_{jl} A))_{\chi, l} (b_{jl})_{l \leqq t}. \tag{14}$$

The matrix $(\chi(h_j^{-1} g_{jl} A))$ is the character table of B/A; hence (14) is a DFT of the abelian group B/A of order t. Let W_A denote the Fourier transform of the abelian group A. After having computed all $W_A(a_k)$, the computation of all $(\chi \otimes \beta)(b_j)$, $\chi \in X(B/A)$, additionally costs $t-1$ multiplications (to get the b_{jl}) and $L_s(B/A)$ **C**-operations for the computation of *all* $(\chi \otimes \beta)(b_j)$. The proportion of **C**-operations to compute a single $(\chi \otimes \beta)(b_j)$ is thus $(L_s(B/A) + t - 1) t^{-1}$. (Note that according to our special choice of $D_1, \cdots, D_h$ and with regard to $P_i \beta_i = \dot{\bigcup}_{u_i} N_i(u_i \beta_i)$ *all* $(\chi \otimes \beta)(b_j)$ are really needed.) Thus , knowing all the $W_A(a_k)$, we can compute $D(b_1), \cdots, D(b_d)$ in $d^2(L_s(B/A) + t - 1) t^{-1}$ arithmetic steps, where $t = [B:A] = [G:A] \cdot d^{-1}$. Finally, knowing the $D(b_j)$, the computation of $D(y)$ via (13) additionally requires at most $(d-1) \cdot d$ multiplications. (To prove this last fact note that without loss of generality $h_1 = 1$, then use the monomiality of D, and finally observe that the concluding summation is free of costs since all the summands have their nonzero entries at pairwise disjoint positions: as D is irreducible we have $\dim D(\mathbf{C}G) = d^2$; on the other hand every $D(h_j) \cdot D(b_j)$ has its $\leqq d$ nonzero entries at the support of the monomial matrix $D(h_j)$.) Altogether the number of **C**-operations sufficient to compute $D(y)$ (knowing all the $W_A(a_k)$) is at most

$$d^2(L_s(B/A) + t - 1) t^{-1} + (d-1) \cdot d.$$

Let n_d denote the number of inequivalent irreducible representations of G of degree d. Furthermore, for every d let $t_d := [G:A] \cdot d^{-1}$. Let $m(t) := \max L_s(H)$, where the

maximum is over all abelian groups H of order t. Then, using (5), (6), (7), and the facts that $n_1 = [G:G']$ and $\sum_d n_d d^2 = |G|$ we get

$$L_s(W) \leqq [G:A]L_s(A) + \sum_d d^2 n_d \{(m(t_d) + t_d - 1)t_d^{-1} + 1 - d^{-1}\}$$

$$\leqq c|G| \log |G|,$$

with $c \leqq \frac{3}{2}$, $c \leqq 2.2$, and $c \leqq 15$ in cases (a), (b), and (c), respectively, of Theorem 3.1. This proves that metabelian groups have an FFT.

Our next goal is to show that the same upper bound does not hold for the linear complexity of W^{-1}. Given $W(y) = \oplus_i D_i(y)$, we thus have to recover $y \in \mathbf{C}G$. (The idea is to invert all local and global FFTs in the first half of the proof.) Again let $D := D_i$. As the summation over j in (13) is free of costs, the projection of $D(y)$ to the support of $D(h_j)$ equals $D(h_j) \oplus_{gB \in G/B} (g\beta)(b_j)$. By multiplying with the monomial matrix $D(h_j^{-1})$ we get $\oplus_{gB \in G/B} (g\beta)(b_j)$. Combining this information in an appropriate way, we know the left-hand side of (14). Inverting (14) with an inverse FFT we recover all the b_{jl}. Multiplying with $\beta(g_{jl}^{-1} h_j)^{-1}$ we get all the $\beta(a_{jl})$. Thus we know for all $\alpha \in X(A)$ the values $\alpha(a_k)$, $1 \leqq k \leqq [G:A]$. Finally with $[G:A]$ inverse FFTs we may recover all the a_k. Since $y = \sum_k g_k a_k$ and the above proof of the upper bound applies to the inverse of W as well, Theorem 3.1 is proved.

OPTIMAL AND SUBLOGARITHMIC TIME RANDOMIZED PARALLEL SORTING ALGORITHMS*

SANGUTHEVAR RAJASEKARAN† AND JOHN H. REIF†

Abstract. This paper assumes a parallel RAM (random access machine) model which allows both concurrent reads and concurrent writes of a global memory.

The main result is an optimal randomized parallel algorithm for INTEGER_SORT (i.e., for sorting n integers in the range $[1, n]$). This algorithm costs only logarithmic time and is the first known that is *optimal*: the product of its time and processor bounds is upper bounded by a linear function of the input size. Also given is a deterministic sublogarithmic time algorithm for *prefix sum*. In addition this paper presents a sublogarithmic time algorithm for obtaining a random permutation of n elements in parallel. And finally, sublogarithmic time algorithms for GENERAL_SORT and INTEGER_SORT are presented. Our sublogarithmic GENERAL_SORT algorithm is also optimal.

Key words. randomized algorithms, parallel sorting, parallel random access machines, random permutations, radix sort, prefix sum, optimal algorithms

1. Introduction.

1.1. Sequential sorting algorithms. Sorting is one of the most important problems not only of computer science but also of every other field of science. The importance of efficient sorting algorithms has been long realized by computer scientists. Many application programs like compilers, operating systems, etc., use sorting extensively to handle tables and lists. Due to both its practical value and theoretical interest, sorting has been an attractive area of research in computer science.

The problem of sorting a sequence of elements (also called *keys*) is to rearrange this sequence in either ascending order or descending order. When the keys to be sorted are *general*, i.e., when the keys have no known structure, a lower-bound result [1] states that any sequential algorithm (on the random access machine (RAM) and many other sequential models of interest) will require at least $\Omega(n \log n)$ time to sort a sequence of n keys. Many *optimal* algorithms like QUICK_SORT and HEAP_SORT, whose run times match this lower bound, can be found in the literature [1].

In computer science applications, more often, the keys to be sorted are from a finite set. In particular, the keys are integers of at most a polynomial (in the input size) magnitude. For keys with this special property, sorting becomes much simpler. If each one of the n elements in a sequence is an integer in the range $[1, n]$ we call these keys *integer keys*. The BUCKET_SORT algorithm [1] sorts n integer keys in $O(n)$ sequential steps. Notice that the run time of BUCKET_SORT matches the trivial $\Omega(n)$ lower bound for this problem.

In this paper we are concerned with randomized parallel algorithms for sorting both *general keys* and *integer keys*.

1.2. Known parallel sorting algorithms. The performance of a parallel algorithm can be specified by bounds on its principal resources viz., processors and time. If we

* Received by the editors January 17, 1987; accepted for publication (in revised form) August 19, 1987. A preliminary version of this paper appeared as "An optimal parallel algorithm for integer sorting" in the 18th IEEE Symposium of Foundations of Computer Science, Portland, Oregon, October 1985. This work was supported by National Science Foundation grant DCR-85-03251 and Office of Naval Research contract N00014-80-C-0647.

let P denote the processor bound, and T denote the time bound of a parallel algorithm for a given problem, the product PT is, clearly, lower bounded by the minimum sequential time, T_s, required to solve this problem. We say a parallel algorithm is *optimal* if $PT = O(T_s)$. Discovering optimal parallel algorithms for sorting both *general* and *integer keys* remained an open problem for a long time.

Reischuk [25] proposed a randomized parallel algorithm that used n synchronous PRAM processors to sort n *general keys* in $O(\log n)$ time. This algorithm, however, is impractical owing to its large word-length requirements. Reif and Valiant [24] presented a randomized sorting algorithm that ran on a fixed-connection network called *cube-connected cycles* (CCC). This algorithm employed n processors to sort n *general keys* in time $O(\log n)$. Since $\Omega(n \log n)$ is a sequential lower bound for this problem, their algorithm is indeed optimal. Simultaneously, Atai, Komlós, and Szemerédi [4] discovered a deterministic parallel algorithm for sorting n *general keys* in time $O(\log n)$ using a sorting network of $O(n \log n)$ processors. Later, Leighton [17] showed that this algorithm could be modified to run in $O(\log n)$ time on an n-node fixed-connection network.

As in the sequential case, many parallel applications of interest need only to sort *integer keys.* Until now, no optimal parallel algorithm existed for sorting n *integer keys* with a run time of $O(\log n)$ or less.

1.3. Some definitions and notations. Given a sequence of keys $k_1, k_2, \cdots, k_n$ drawn from a set S having a linear order $<$, the problem of *sorting* this sequence is to find a permutation σ such that $k_{\sigma(1)} < k_{\sigma(2)} < \cdots < k_{\sigma(n)}$.

By *general keys* we mean a sequence of n elements drawn from a linearly ordered set S whose elements have no known structure. The only operation that can be used to gain information about the sequence is the comparison of two elements.

GENERAL_SORT is the problem of sorting a sequence of general keys, and INTEGER_SORT is the problem of sorting a sequence of integer keys.

Throughout this paper we let $[m]$ stand for $\{1, 2, \cdots, m\}$.

A sorting algorithm is said to be *stable* if equal elements remain in the same relative order in the sorted sequence as they were in originally. In more precise terms, a sorting algorithm is stable if on input $k_1, k_2, \cdots, k_n$, the algorithm outputs a sorting permutation σ of $(1, 2, \cdots, n)$ such that for all $i, j \in [n]$, if $k_i = k_j$ and $i < j$ then $\sigma(i) < \sigma(j)$. A sorting algorithm that is not guaranteed to output a stable sorted sequence is called *nonstable.*

Just as the big-O function serves to represent the complexity bounds of deterministic algorithms, we employ $\tilde{O}$ to represent complexity bounds of randomized algorithms. We say a randomized algorithm has resource (like time, space, etc.) bound $\tilde{O}(g(n))$ if there is a constant c such that the amount of resource used by the algorithm (on any input of size n) is no more than $c\alpha g(n)$ with probability $\geqq 1 - 1/n^{\alpha}$ for any $\alpha > 1$.

1.4. Our model of computation. We assume the CRCW PRAM (concurrent-read concurrent-write parallel RAM) model proposed by Shiloach and Vishkin [26]. In a PRAM model, a number (say P) of processors work synchronously communicating with each other with the help of a common block of memory. Each processor is a RAM. A single step of a processor is an arithmetic operation, a comparison, or a memory access. CRCW PRAM is a version of PRAM that allows both concurrent writes and concurrent reads of shared memory. Write conflicts are resolved by priority.

All the algorithms given in this paper, except the prefix sum algorithm, are randomized. Every processor, in addition to the operations allowed by the deterministic version of the model, is also capable of making independent (n-sided) coin flips. Our

stated resource bounds will hold for the worst-case input with overwhelming probability.

1.5. Contents of this paper. Our main contributions in this paper are

1) An optimal parallel algorithm for INTEGER_SORT. This algorithm uses $n/\log n$ processors and sorts n integer keys in time $\tilde{O}(\log n)$, and
2) Sublogarithmic time algorithms for GENERAL_SORT and INTEGER_SORT. GENERAL_SORT algorithm employs $n(\log n)^{\varepsilon}$ (for any $\varepsilon > 0$) processors, and INTEGER_SORT algorithm employs $n(\log\log n)^2/\log n$ processors. Both these algorithms run in time $\tilde{O}(\log n/\log\log n)$.

The problem of optimal parallel sorting of n integers in the range $[n^{O(1)}]$ still remains an open problem. Our sublogarithmic time algorithm for GENERAL_SORT is optimal as implied by a recent result of Alon and Azar [2].

In our sublogarithmic time sorting algorithms we reduce the problem of sorting to the problem of *prefix-sum computation.* We show in this paper that *prefix sum* can be computed in time $O(\log n/\log\log(P\log n/n))$ using $P \geqq n/\log n$ processors. We also present a sublogarithmic time algorithm for computing a random permutation of n given elements with a run time of $\tilde{O}(\log n/\log\log n)$ using $n(\log\log n)^2/\log n$ processors.

Some of the results of this paper appeared in preliminary form in [22], but are substantially simplified in this manuscript. In § 2 we present some relevant preliminary results. Section 3 contains our optimal INTEGER_SORT algorithm. In § 4 we describe our sublogarithmic time algorithms.

2. Preliminary results.

2.1. Prefix circuits. Let Σ be a domain and let $\circ$ be an associative operation that takes $O(1)$ sequential time over this domain. The *prefix-computation problem* is defined as follows

- **input** $(X(1), X(2), \cdots, X(n)) \in \Sigma^n$
- **output** $(X(1), X(1)\circ X(2), \cdots, X(1)\circ X(2)\circ\cdots\circ X(n))$.

The special case of prefix computation when Σ is the set of all natural numbers and $\circ$ is integer addition is called *prefix-sum computation.* Ladner and Fischer [18] show that prefix computation can be done by a circuit of depth $O(\log n)$ and size n. The processor bound of this algorithm can be improved as follows.

LEMMA 2.1. *Prefix computation can be done in time* $O(\log n)$ *using* $n/\log n$ PRAM *processors.*

Proof. Given $X(1), X(2), \cdots, X(n)$, each one of the $n/\log n$ processors gets $\log n$ successive keys. Every processor sequentially computes the prefix sum of the $\log n$ keys given to it in $\log n$ time. Let $S(i)$ be the sum of all the $\log n$ keys given to processor i (for $i = 1, \cdots, n/\log n$). Then, $n/\log n$ processors collectively compute the prefix sum of $S(1), S(2), \cdots, S(n/\log n)$, using Ladner and Fischer's [18] algorithm. Using this prefix sum, each processor sequentially computes $\log n$ prefixes of the original input sequence. □

The above idea of processor improvement was originally used by Brent in his algorithm for expression evaluation, and hence we attribute Lemma 2.1 to him. Recently Cole and Vishkin [9] have proved the following lemma.

LEMMA 2.2. *Prefix-sum computation of* n *integers* ($O(\log n)$ *bits each*) *can be performed in* $O(\log n/\log\log n)$ *time using* $n \log\log n/\log n$ CRCW PRAM *processors.*

2.2. An assignment problem. We are given a set $Q = \{1, 2, \cdots, n\}$ of n indices. Each index belongs to exactly one of m groups $G_1, G_2, \cdots, G_m$. Let g_i stand for the

number of indices belonging to group G_i, $i=1, \cdots, m$. We are given a sequence $N(1), N(2), \cdots, N(m)$ where $\sum_{i=1}^{m} N(i) = O(n)$ and $N(i)$ is an upper bound for g_i, $i=1, 2, \cdots, m$. The problem is to find in parallel a permutation of $(1, 2, \cdots, n)$ in which all the indices belonging to G_1 appear first, all the indices belonging to G_2 appear next, and so on. (Assume that given an index i, the group $G_{i'}$ to which i belongs can be found in $O(1)$ time.)

As an example, if $n=5$, $m=2$, $G_1=\{2, 5\}$, $G_2=\{1, 3, 4\}$, then $(5, 2, 1, 3, 4)$ and $(2, 5, 3, 1, 4)$ are (two of the) valid answers.

LEMMA 2.3. *The above assignment problem can be solved in* $\tilde{O}(\log n)$ *parallel time using* $n/\log n$ PRAM *processors.*

Proof. We present an algorithm. We use a shared memory of size $2\sum_{i=1}^{m} N(i)$ $(=L$, say). This memory is divided into m blocks, $B_1, B_2, \cdots, B_m$ the size of B_i being $2N(i)$. A unique assignment for the indices belonging to G_i will be found in the block B_i, for $i=1, 2, \cdots, m$.

Each one of the $P(=n/\log n)$ processors is given $\log n$ successive indices. Precisely, processor π is given the indices $(\pi-1)\log n+1, (\pi-1)\log n+2, \cdots, \pi \log n$, for $\pi=1, 2, \cdots, P$. There are three phases of the algorithm. In the first phase, boundaries of the m blocks are computed. In the second phase every processor sequentially finds unique assignments for the $\log n$ indices given to it in their **respective** blocks. In the third phase, a prefix-sum computation is done to eliminate the unused cells, and the position of each index in the output is read. Details follow.

Step 1.

P processors collectively do a prefix sum of $(N(1), N(2), \cdots, N(m))$ and hence compute the boundaries of blocks in the common memory.

Step 2.

Each processor π is given a total time of $d \log n$ (d being a constant to be fixed) to find assignments for all its indices sequentially.

π starts with its first index (call it) l. If $G_{l'}$ is the group to which l belongs, π chooses a random cell in $B_{l'}$ and tries to write its identification in it. If the chosen cell did not contain the identification of any other processor and π succeeds in writing, then that cell is assigned to l. The probability of success in one trial is $\geqq \frac{1}{2}$. If π has failed in this trial, then it tries as many times as it takes to find an assignment for l and then it takes up the next index.

After $d \log n$ steps, even if there is a single processor that has not found assignments for all its keys, the algorithm is aborted and started anew.

Step 3.

Each processor π writes a 1 in the cells that have been assigned to its indices. Unassigned cells in the common memory will have 0's. P processors perform a prefix sum computation on the contents of the memory cells $(1, 2, \cdots, L)$. Finally, every processor reads out from the prefix sum the position of each one of its indices in the output.

Analysis. Steps 1 and 3 can be completed in $O(\log n)$ time in accordance with Lemma 2.1.

In Step 2, the probability that a particular processor π successfully finds an assignment for one of its keys in a single trial is $\geqq \frac{1}{2}$. Let Y be the random variable equal to the number of successes of π in $d \log n$ trials. We require Y to be $\geqq \log n$

for every processor. Clearly Y is lower bounded by a binomial variable (see Appendix A for definitions) with parameters $(d \log n, \frac{1}{2})$. It follows from the Chernoff bounds (see Appendix A, equation (3)) that the probability that there will be at least a single processor that has not found assignments for all of its indices after $d \log n$ trials can be made $\leqq n^{-\alpha}$ for any $\alpha \geqq 1$, if we choose a proper constant d. Therefore the whole algorithm runs in time $\tilde{O}(\log n)$. This completes the proof of Lemma 2.3. □

It should be mentioned here that when the number of groups, m, is 1, the above algorithm outputs a random permutation of $(1, 2, \cdots, n)$. An algorithm for this special case was given by Miller and Reif [19].

2.3. Some known results. We state here the existence of optimal sequential algorithms for INTEGER_SORT and optimal parallel algorithms for GENERAL_SORT.

LEMMA 2.4. *Stable* INTEGER_SORT *of n keys can be done in time* $O(n)$ *by a deterministic sequential* RAM [1].

LEMMA 2.5. GENERAL_SORT *of n keys can be performed in time* $O(\log n)$ *using n* PRAM *processors* ([4] *and* [8]).

3. An optimal INTEGER_SORT algorithm. In this section we present an optimal algorithm for INTEGER_SORT. This algorithm employs $n/\log n$ processors and runs in time $\tilde{O}(\log n)$.

3.1. Summary of the algorithm. The main idea behind our algorithm is radix sorting [15]. As an example of radix sorting, consider the problem of sorting a sequence of two-bit decimal integers. One way of doing this is to sort the sequence with respect to the least significant bits (LSB) of the keys and then to sort the resultant sequence with respect to the most significant bits (MSB) of the keys. This will work provided, in the second sort keys with equal MSBs will remain in the same relative order as they were in originally. In other words, the second sort should be stable.

We have a sequence of keys $k_1, k_2, \cdots, k_n \in [n]$, where each key is a $\log n$-bit integer. We first (nonstable) sort this sequence with respect to the $(\log n - 3 \log\log n)$ LSBs of the keys. (Call this sort *Coarse_Sort.*) In the resultant sequence we apply a stable sort with respect to the $3 \log\log n$ MSBs of the keys. (Call this sort *Fine_Sort.*)

Even though the sequential time complexity of stable sort is no different from that of nonstable sort, it seems that parallel stable sort is inherently more complex than parallel nonstable sort. This is the reason we have divided the bits of the keys unevenly.

In Coarse_Sort we need to (nonstable) sort a sequence of n keys, each key being in the range $[1, n/\log^3 n]$ and, in Fine_Sort we have to (stable) sort n keys in the range $[1, \log^3 n]$. In terms of notation, our algorithm can be summarized as follows.

Let $D = n/\log^3 n$ and $k_i' = \lfloor k_i/D \rfloor$ and $k_i'' = k_i - k_i' * D$ for all $i \in [n]$.

Coarse_Sort. Sort $k_1'', k_2'', \cdots, k_n'' \in [D]$. Let σ be the resultant permutation.

Fine_Sort. Stable-sort $k'_{\sigma(1)}, k'_{\sigma(2)}, \cdots, k'_{\sigma(n)} \in [\log^3 n]$. Let ρ be the resultant permutation.

Output. The permutation $\rho \cdot \sigma$, the composition of ρ and σ.

In §§ 3.2 and 3.3 we describe Fine_Sort and Coarse_Sort, respectively.

3.2. Fine_Sort. We give a deterministic algorithm for Fine_Sort. First we will show how to stable-sort n keys in the range $[\log n]$ using $n/\log n$ processors in time $O(\log n)$ and then apply the idea of radix sorting to prove that we can stable-sort n keys in the range $[(\log n)^{O(1)}]$ within the same resource bounds.

LEMMA 3.1. *n keys $k_1, k_2, \cdots, k_n \in [\log n]$ can be stable-sorted in $O(\log n)$ time using $P = n/\log n$ processors.*

Proof. In Fine_Sort algorithm, each processor π is given $\log n$ successive keys. Each one of the P processors starts by sequentially stable-sorting the keys given to it. Then, collectively, the P processors group all the keys with equal values. (There are $\log n$ groups in all.) Finally, they output a rearrangement of the given sequence in which all the 1's (i.e., keys with a value 1) appear first, all the 2's appear next, and so on. Throughout the algorithm the relative order of equal keys is preserved. More details follow.

To each processor $\pi \in [P]$ we assign the key indices $J(\pi) = \{j \mid (\pi - 1) \log n < j \leqq \min(n, \pi \log n)\}$. There are three steps in the algorithm.

Step 1.

Each processor π sequentially stable-sorts the keys $\{k_j \mid j \in J(\pi)\}$ in time $O(\log n)$ (see Lemma 2.4), and hence constructs $\log n$ lists $J_{\pi,k} = \{j \in J(\pi) \mid k_j = k\}$ for $k \in [\log n]$. Elements in $J_{\pi,k}$ are ordered in the same relative order as in the input.

Step 2.

The P processors collectively perform the prefix sum of

$$\begin{aligned}(&|J_{1,1}|, |J_{2,1}|, \cdots, |J_{P,1}|,\\ &|J_{1,2}|, |J_{2,2}|, \cdots, |J_{P,2}|,\\ &\cdots\\ &|J_{1,q}|, |J_{2,q}|, \cdots, |J_{P,q}|)\end{aligned}$$

where $q = \log n$. Call this sum

$$\begin{aligned}(&S_{1,1}, S_{2,1}, \cdots, S_{P,1},\\ &S_{1,2}, S_{2,2}, \cdots, S_{P,2},\\ &\cdots\\ &S_{1,q}, S_{2,q}, \cdots, S_{P,q}).\end{aligned}$$

Step 3.

Each processor π sequentially computes the position of each one of its keys in the output using the prefix sum. The position of keys in the list $J_{\pi,l}$ will be $S_{\pi-1,l}+1, S_{\pi-1,l}+2, \cdots, S_{\pi,l}$.

Analysis. It is easy to see that Steps 1 and 3 can be performed within the stated resource bounds. Step 2 also can be completed within the stated resource bounds as given in Lemma 2.1. □

LEMMA 3.2. *If n keys in the range $[R]$ (for any $R = n^{O(1)}$) can be stable-sorted in $O(\log n)$ time using $P = n/\log n$ processors, then n keys $k_1, k_2, \cdots, k_n \in [R^2]$ can be stable-sorted in time $O(\log n)$ using the same number of processors.*

Proof. Let $k'_i = \lfloor k_i / R \rfloor$ and $k''_i = k_i - k'_i * R$ for every $i \in [n]$. First, stable-sort $k''_1, k''_2, \cdots, k''_n$ obtaining a permutation σ. Then stable-sort $k'_{\sigma(1)}, k'_{\sigma(2)}, \cdots, k'_{\sigma(n)}$ obtaining a permutation ρ. Output $\rho \cdot \sigma$. Clearly both these sorts can be completed in time $O(\log n)$ using P processors. □

Lemmas 3.1 and 3.2 immediately imply the following lemma.

LEMMA 3.3. *n integer keys in the range $[(\log n)^{O(1)}]$ can be stable-sorted in time $O(\log n)$ using $n/\log n$ processors.*

3.3. Coarse_Sort. In this section we fix a key domain $[D]$, where $D = n/\log^3 n$. We assume, without loss of generality, that $\log^3 n$ divides n. Let the input keys be $k_1, k_2, \cdots, k_n \in [D]$. Define the *index sequence* for each key $k \in [D]$ to be $I(k) = \{i \mid k_i = k\}$. The randomized algorithm for Coarse_Sort to be presented in this section employs $P = n/\log n$ processors and runs in time $\tilde{O}(\log n)$. The sorted sequence is nonstable.

The main idea is to calculate the cardinalities of the index sequences $I(k)$, $k \in [D]$ approximately, and then to use the assignment algorithm of § 2.2 to rearrange the given sequence in sorted order.

LEMMA 3.4. *Given as input $k_1, k_2, \cdots, k_n \in [D]$ we can compute $N(1)$, $N(2), \cdots, N(D)$ in $\tilde{O}(\log n)$ time using $P = n/\log n$ processors such that $\sum_{k \in [D]} N(i) = O(n)$ and furthermore, with very high likelihood $N(k) \geqq |I(k)|$ for each $k \in [D]$.*

Proof. The following sampling algorithm serves as a proof.

Step 1.

Each processor $\pi \in [D \log n]$ in parallel chooses a random index $s_\pi \in [n]$. Let S be the sequence $\{s_1, s_2, \cdots, s_{D \log n}\}$.

Step 2.

The P processors collectively sort the keys with the chosen indices. That is, they sort $k_{s_1}, k_{s_2}, \cdots, k_{s_{D \log n}}$ and compute index sequences $I_S(k) = \{i \in S \mid k_i = k\}$ (for each $k \in [D]$).

Step 3.

D of the P processors in parallel set $N(k) = d(\log^2 n) \max(|I_S(k)|, \log n)$ for $k \in [D]$, d being a constant to be fixed in the analysis.

Output $N(1), N(2), \cdots, N(D)$.

Analysis. Trivially, Steps 1 and 3 can be performed in $O(1)$ time. Step 2 can be performed using any of the optimal GENERAL_SORT algorithms in $O(\log n)$ time (see Lemma 2.5). (Notice that we have to sort only $n/\log^2 n$ keys in step 2.) It remains to be shown that $N(i)$'s computed by the sampling algorithm satisfy the conditions in Lemma 3.4.

If $|I(k)| \leqq d \log^3 n$, then always $N(k) \geqq d \log^3 n \geqq |I(k)|$. So suppose $|I(k)| > d \log^3 n$. Then it is easy to see that $|I_S(k)|$ is a binomial variable with parameters $(n/\log^2 n, |I(k)|/n)$. The Chernoff bounds (see Appendix A, (2)) imply that for all $\alpha \geqq 1$, there exists a c such that

$$\text{Probability}\,(|I_S(k)| \leqq c\alpha |I(k)|/\log^2 n) \leqq \frac{1}{n^\alpha}.$$

Therefore, if we choose $d = (c\alpha)^{-1}$ then $N(k) \leqq |I(k)|$ (for every $k \in [D]$) with probability $\geqq 1 - n^{-\alpha}$. The Chernoff bounds (3) also imply that for all $\alpha \geqq 1$ there exists an h such that $N(k) \geqq (h\alpha)|I(k)|$ (for every $k \in [D]$) with probability $\geqq 1 - n^{-\alpha}$.

The bound on $\sum_{k \in [D]} N(k)$ clearly holds since

$$\sum_{k \in [D]} N(k) \leqq \sum_{k \in [D]} d \log^2 n[|I_S(k)| + \log n] = d \log^3 nD + d \log^2 n \sum_{k \in [D]} |I_S(k)|$$

$$= dn + d \log^2 nD \log n = 2dn.$$

This concludes the proof of Lemma 3.4. □

Having obtained the approximate cardinalities of the index sets, we apply the assignment algorithm of § 2.2. The set Q is the set of key indices viz., $\{1, 2, \cdots, n\}$. An index i belongs to group $G_{i'}$ if the value of the key with index i is i'. Under this definition, group G_j is the same as index sequence $I(j)$, $j = 1, 2, \cdots, D$. Since we can find approximate cardinalities of these groups (Lemma 3.4), we can use the assignment algorithm of § 2.2 to rearrange the given sequence in sorted order. Thus we have the following lemma.

LEMMA 3.5. *n keys $k_1, k_2, \cdots, k_n \in [D]$ can be sorted in time $\tilde{O}(\log n)$ using $n/\log n$ processors.*

Lemmas 3.3 and 3.5 together with the algorithm summary in § 3.1 prove the following theorem.

THEOREM 3.1. INTEGER_SORT *of n keys can be performed in randomized $\tilde{O}(\log n)$ time using $n/\log n$* CRCW PRAM *processors.*

4. Sublogarithmic time algorithms. In the previous section we presented an optimal algorithm for INTEGER_SORT. In this section we will be presenting nonoptimal sublogarithmic time algorithms for (1) prefix sum computation, (2) finding a random permutation of n elements, (3) GENERAL_SORT, and (4) INTEGER_SORT. Algorithms 3 and 4 are direct consequences of algorithms 1 and 2. Our prefix algorithm employs $P \leqq n/\log n$ processors and runs in time $O(\log n/\log\log(P \log n/n))$. Algorithms 2, 3, and 4 run in time $\tilde{O}(\log n/\log\log n)$. GENERAL_SORT uses $n(\log n)^{\varepsilon}$ processors and algorithms 2 and 4 use $n(\log\log n)^2/\log n$ processors.

4.1. A sublogarithmic prefix algorithm. We have a sequence of integers $X(1), X(2), \cdots, X(n)$. We need to find the prefix sum of this sequence. This problem can be solved in sublogarithmic time if we use more than $n/\log n$ processors as is stated by the following lemma.

LEMMA 4.1. *Prefix-sum computation can be performed in time $O(\log n/\log(P \log n/n))$ using $P \leqq n/\log n$* CRCW PRAM *processors.*

Proof. The algorithm can be summarized as follows: (1) divide the given sequence into blocks of d (to be determined later) successive keys; (2) sequentially compute prefix sums in each block; (3) apply prefix to the final prefixes in each block; and (4) compute prefixes in each block by using the result from 3 for the previous block.

More details follow. Let $n_1 = n/d$.

Step 1.

In $O(d)$ time using $n_1 \leqq P$ processors compute $X'(i, m)$, $i \in [n_1]$, $m \in [d]$, where $X'(i, m) = \sum_{j=(i-1)d+1}^{(i-1)d+m} X'(j)$.

Step 2.

Compute the prefix sum of the total sum of each part, i.e., compute $Y'(1), Y'(2), \cdots, Y'(n_1)$, where $Y'(i) = \sum_{j=1}^{i} X(j, d)$, for $i = 1, \cdots, n_1$.

Step 3.

In time $O(d)$, using n_1 processors compute

$$(X'(1,1), X'(1,2), \cdots, X'(1,d),$$
$$Y'(1) \circ X'(2,1), Y'(1) \circ X'(2,2), \cdots, Y'(1) \circ X'(2,d),$$
$$\cdots$$
$$Y'(n_1-1) \circ X'(n_1,1), Y'(n_1-1) \circ X'(n_1,2), \cdots, Y'(n_1-1) \circ X'(n_1,d))$$

which is the required output.

Analysis. Clearly, Steps 1 and 3 can be performed with n_1 processors in time $O(d)$. It remains to show that Step 2 can be performed within the same time using P processors.

Let $C_{n,2}$ be a circuit of size n and in-degree 2 that computes the prefix sum of n elements in depth $O(\log n)$. Obtain an equivalent circuit $C_{n_2,b}$ of size $n_2 = n/b$ ($n_2 \geqq n_1$) and in-degree b in the obvious way (by collapsing subcircuits of height $\log b$ into single nodes starting from the bottom of the circuit [11]). We will simulate $C_{n_2,b}$.

Each input key is a $\log n$ bit integer. Each one of the keys is divided into d parts, each comprising $\log n/d$ successive bits. The simulation proceeds in d stages. In the first stage, we input the $\log n/d$ least significant bits of the keys to the circuit $C_{n_2,b}$. In the second stage, we input the next most $\log n/d$ significant bits of the input keys to the circuit. Similarly we pipeline all the parts of the keys one part per stage. The computation in the circuit proceeds in a pipeline fashion.

At any stage, every node v of $C_{n_2,b}$ has to compute the sum of b integers that arrive at this node from its children and the carry it stored from the previous stage. v also has to store the carry from this stage to be used in the next. Each one of these b integers and the carry can be of at the most $2 \log n/d = s$ bits. Therefore, the computation at v can be made to run in time $O(1)$ if we replace v by a constant depth circuit of size $b2^{s(b+1)}$. The depth of $C_{n_2,b}$ is $\log_b n_2$. Thus, the run time of the circuit (and hence the simulation time) will be $\log_b n_2 + O(d)$. The size of the circuit is $n_2 b 2^{s(b+1)}$.

We require $b2^{s(b+1)} \leqq P/n_2$, $s = 2 \log n/d$, $n_1 = n/d$, $n_1 \leqq n_2$ and $\log_b n_2 = O(d)$. It is easy to see that choosing $s = \log \log (P \log n/n)$ will satisfy all the above constraints. This concludes the proof of Lemma 4.1. □

4.2. A sublogarithmic permutation algorithm. The problem is to compute a random permutation of $(1, 2, \cdots, n)$ in sublogarithmic parallel time. The algorithm presented in this section is very similar to the assignment algorithm of § 2.2. It employs $P = n(\log \log n)^2/\log n$ processors and runs in time $\tilde{O}(\log n/\log \log n)$.

A shared memory of size $2n$ is used. The main idea is to find unique assignments (in the common memory) for each one of the indices $i \in [n]$ and then to eliminate unused cells of common memory using a prefix sum computation. Processors are partitioned into groups of size $(\log \log n)^2$. Each group of $(\log \log n)^2$ processors gets $\log n$ successive indices. Detailed algorithm follows.

Step 1.

The $\log n$ indices given to each group of processors are partitioned into groups of size $(\log \log n)^2$. Step 1 consists of $\log n/(\log \log n)^2$ phases. In the ith phase ($i = 1, 2, \cdots, \log n/(\log \log n)^2$) each processor is given a distinct index from the group i of indices. Each processor spends $d \log \log n$ time (for some constant d) to find an assignment for its index (as explained in Step 2 of § 2.2). After $d \log \log n$ time the ith phase ends.

Step 2.

P processors perform a prefix-sum computation to determine the number (call it N) of indices that do not yet have an assignment. Let $z = \lfloor P/N \rfloor$.

Step 3.

A distinct group of z processors in parallel work to find an assignment for every index j that remains without an assignment. A group succeeds even if a single processor in the group succeeds. Each group is given $C \log n/\log \log n$ time (for some constant C).

After $C \log n/\log\log n$ time, even if a single index remains without an assignment the whole algorithm is aborted and started anew. (Grouping of processors in this step can easily be done using the prefix sum of Step 2.)

Step 4.

Finally, P processors perform a prefix-sum computation to eliminate unused cells and read the positions of their indices in the output.

Analysis. Consider the ith phase of Step 1. The probability that a given processor π succeeds in finding an assignment for its index in a single trial is $\geqq \frac{1}{2}$. Let Y be a random variable equal to the number of processors failing in the jth trial of phase i. Then Y is upperbounded by a binomial random variable with parameters $(N_i^j, \frac{1}{2})$ (where N_i^j is the number of processors that have not succeeded until the beginning of the jth trial of phase i). (Note that $N_i^1 = P$.) The Chernoff bounds (3) imply that Y is at the most a constant (<1) fraction of N_i^j with probability $\geqq 1 - 2^{-\varepsilon N_i^j}$ (for some fixed $\varepsilon < 1$). Therefore the number of unsuccessful processors at the end of phase i is $\tilde{O}(P/\log n)$. The number of keys without assignments at the end of Step 1 is $\sum_{i=1}^{\log n/(\log\log n)^2} N_i^{d \log\log n}$. Using additive property of binomial distributions and the Chernoff bounds we conclude that the number of keys without assignments at the end of Step 1 is $O(n/\log n)$ (and hence $z = \Omega((\log\log n)^2)$) with probability $\geqq 1 - n^{-\beta}$ for any $\beta \geqq 1$.

Step 2 runs in time $O(\log n/\log\log n)$ (Lemma 2.2). In Step 3, probability that a particular group fails in one trial is $\leqq (\frac{1}{2})^{\Omega((\log\log n)^2)}$. This implies that the probability that there is at least one unsuccessful group at the end of Step 3 can be made $\leqq n^{-\alpha}$, for any $\alpha \geqq 1$, if we choose a proper C.

Thus we conclude that the whole algorithm will run successfully in time $\tilde{O}(\log n/\log\log n)$. Clearly, this algorithm can also be used to solve the assignment problem of § 2.2. Thus we have the following lemma.

LEMMA 4.2. *The problem of computing a random permutation of n elements (and hence the assignment problem of* § 2.2*) can be solved in time* $\tilde{O}(\log n/\log\log n)$ *using* $P = n(\log\log n)^2/\log n$ *processors.*

4.3. An optimal sub-logarithmic GENERAL_SORT algorithm. Given as input $k_1, k_2, \cdots, k_n$, Reischuk's algorithm [25] for GENERAL_SORT samples $\sqrt{n}$ keys at random. If $l_1, l_2, \cdots, l_{\sqrt{n}}$ are the sampled keys in sorted order, these keys divide the input keys into $p \leqq \sqrt{n}+1$ collections $S_1, S_2, \cdots, S_p$, where $S_1 = \{q \mid q \leqq l_1\}$, $S_i = \{q \mid l_{i-1} < q \leqq l_i\}$ for $i = 2, 3, \cdots, (p, -1)$, and $S_p = \{q \mid q > k_{p-1}\}$. With very high likelihood [25], each one of these collections will be of size $O(\sqrt{n}\log n)$. (Reif and Valiant [24] give an algorithm for sampling $\sqrt{n}$ keys that will ensure that each one of these collections will be of size $O(\sqrt{n})$.) Having identified these collections, his algorithm sorts each one of them recursively and merges the results trivially.

As such, the algorithm in [25] requires a computer of word length $\Omega(\sqrt{n}\log n)$. This problem can be circumvented using the assignment algorithm of § 2.2. Moreover, such a modified algorithm can be made sublogarithmic if $n(\log n)^{\varepsilon}$ processors are used. A detailed algorithm follows.

Procedure sublog$GS(\{k_1, k_2, \cdots, k_n\})$;

Step 1. If n is a constant sort trivially.

Step 2. $\sqrt{n}$ processors in parallel each sample a random key.

Step 3. Sort the $\sqrt{n}$ keys sampled in Step 2 by comparing every pair of keys and computing the rank of each key. This can be done in $O(\log n/\log$

$\log n$) time using n processors. Let the sorted sequence be $l_1, l_2, \cdots, l_{\sqrt{n}}$.

Step 4. Processors are partitioned into groups of size $(\log n)^\epsilon$. Each group gets an index $i \in [n]$. In parallel each group does a $(\log n)^\epsilon$-ary search on $l_1, l_2, \cdots, l_{\sqrt{n}}$ to find out the collection $S_{i'}$ to which k_i belongs.

Step 5. n processors collectively compute $N(1), N(2), \cdots, N(p)$ such that $\sum_{j=1}^{p} N(j) = O(n)$ and $N(j) \geqq |S_j|$ for every $j \in [p]$. (Recall that $p \leqq \sqrt{n}+1$).

Step 6. n processors use the sublogarithmic assignment algorithm of § 4.2 to rearrange $k_1, k_2, \cdots, k_n$ such that all the elements of S_1 will appear first, all the elements of S_2 will appear next, and so on.

Step 7. Recursively sort $S_1, S_2, \cdots, S_p$. Here $O(\sqrt{n}(\log n)^\epsilon)$ processors work on each subproblem. Finally output sublog$GS(S_1), \cdots,$ sublog$GS(S_p)$.

Analysis. If $T'(n)$ is the time sublogGS takes to sort n general keys, Step 1 and Step 2 take $O(1)$ time each. Step 3, Step 4, and Step 6 take $\tilde{O}(\log n/\log\log n)$ time each. Step 7 takes time $T'(c\sqrt{n})$ (for some constant c) with probability $\geqq 1-n^{-\alpha}$ (for any $\alpha \geqq 1$). This is because no collection will be of size more than $O(\sqrt{n})$ with the same probability (if we employ Reif and Valiant's [24] sampling algorithm). Computing $N(1), N(2), \cdots, N(p)$ (Step 5) can be done in time $\tilde{O}(\log n/\log\log n)$ using n processors that employ a sampling algorithm very similar to the one given in § 3.2. (For details see Appendix B.) Therefore, the recurrence relation for $\bar{T}'(n)$, the expected value of $T'(n)$ can be written as

$$\bar{T}'(n) \leqq \bar{T}'(c\sqrt{n}) + \tilde{O}(\log n/\log\log n) + \tilde{O}(n^{-\alpha})\,\bar{T}'(n-\sqrt{n}+1).$$

By induction we can show that $\bar{T}'(n) \leqq \tilde{O}(\log n/\log\log n)$. Thus we have the following theorem.

THEOREM 4.1. GENERAL_SORT *can be done in time* $\tilde{O}(\log n/\log\log n)$ *with* $n(\log n)^\epsilon$ CRCW PRAM *processors.*

4.4. A sublogarithmic algorithm for INTEGER_SORT. In § 3, we presented an INTEGER_SORT algorithm that used $n/\log n$ processors to sort n integer keys in time $\tilde{O}(\log n)$. The same algorithm can be used to sort in time $\tilde{O}(\log n/\log\log n)$ if the number of processors used is $P = n(\log\log n)^2/\log n$. Here we will indicate only the modifications that need to be made.

The P processors are partitioned into groups of size $(\log\log n)^2$ and each group is given $\log n$ successive indices. In Fine_Sort Step 1, each group of $(\log\log n)^2$ processors stable sorts the $\log n$ keys given to it using any of the parallel optimal stable GENERAL_SORT algorithms, in time $O(\log n/\log\log n)$. Step 2 runs in time $O(\log n/\log\log n)$. In Step 3, each group of processors computes the position of each one of its $\log n$ keys in the output using the prefix sum of Step 2. The time needed for Step 3 is $\log n/(\log\log n)^2$.

In Coarse_Sort, while computing the $N(i)$'s, Steps 1 and 3 run in time $O(1)$. In Step 2, we need to sort $n/\log^2 n$ keys. The sublogarithmic algorithm of § 4.2 for GENERAL_SORT can be used to run Step 2 in time $\tilde{O}(\log n/\log\log n)$ using $< n/\log n$ processors. After computing $N(i)$'s, rearranging of the keys can be done using P processors in time $\tilde{O}(\log n/\log\log n)$ (Lemma 4.2). Therefore, both Coarse_Sort and Fine_Sort run in time $\tilde{O}(\log n/\log\log n)$. Thus we have the following theorem.

THEOREM 4.2. INTEGER_SORT *can be performed in* $\tilde{O}(\log n/\log\log n)$ *time using* $P = n(\log\log n)^2/\log n$ CRCW PRAM *processors.*

5. Conclusions. All the sorting algorithms appearing in this paper are nonstable. It remains an open problem to obtain stable versions of these algorithms. If we have a stable algorithm for INTEGER_SORT then the definition of integer keys can be extended to include integers in the range $[n^{O(1)}]$. Any deterministic algorithm for INTEGER_SORT using a polynomial number of CRCW PRAM processors will take at least $\Omega(\log n/\log\log n)$ time, as has been shown by Beam and Hastad [6]. However it is an open question whether there exists a randomized CRCW PRAM algorithm that uses a polynomial number of processors and runs in time $o(\log n/\log\log n)$.

A recent result of Alon and Azar [2] implies that our sublogarithmic time GENERAL_SORT algorithm is optimal. Their lower bound result is for a more powerful comparison tree model of Valiant and hence readily holds for PRAMs as well. Alon and Azar's theorem is that if P is the number of processors used, then the average time, T, required for sorting n elements by any randomized algorithm is $\Theta(\log n/\log(1+P/n))$ for $P \geqq n$, and the average time is $\Theta(\log n/(P/n))$ for $P \leqq n$. In particular, if $P = n(\log n)^{\epsilon}$, then $T = \Theta(\log n/\log\log n)$. It remains an open problem to prove or disprove the optimality of our sublogarithmic INTEGER_SORT algorithm.

Appendix A. Probabilistic bounds. We say a random variable X *upper bounds* another random variable Y (equivalently, Y *lower bounds* X) if for all x such that $0 \leqq x \leqq 1$, Probability $(X \leqq x) \leqq$ Probability $(Y \leqq x)$.

A *Bernoulli trial* is an experiment with two possible outcomes viz., *success* and *failure*. The probability of success is p.

A *binomial variable* X with parameters (n, p) is the number of successes in n independent Bernoulli trials, the probability of success in each trial being p.

The *distribution function* of X can easily be seen to be

$$\text{Probability}(X \leqq x) = \sum_{k=0}^{x} \binom{n}{k} p^n (1-p)^{n-k}.$$

Chernoff [7] and Angluin and Valiant [3] have found ways of approximating the tail ends of a binomial distribution. In particular, they have shown the following.

LEMMA A.1. *If X is binomial with parameters (n, p), and $m > np$ is an integer, then*

$$\text{Probability}(X \geqq m) \leqq \left(\frac{np}{m}\right)^m e^{m-np}. \tag{1}$$

Also,

$$\text{Probability}(X \leqq \lfloor (1-\varepsilon)pn \rfloor) \leqq \exp(-\varepsilon^2 np/2) \tag{2}$$

and

$$\text{Probability}(X \geqq \lceil (1+\varepsilon)np \rceil) \leqq \exp(-\varepsilon^2 np/3) \tag{3}$$

for all $0 < \varepsilon < 1$.

Appendix B. A sampling algorithm. We have an index set $Q = \{1, 2, \cdots, n\}$. Each index belongs to exactly one of $\sqrt{n}$ groups $G_1, G_2, \cdots, G_{\sqrt{n}}$. For any index i, in constant time we can find out the group $G_{i'}$ that i belongs to.

Problem. Compute $N(1), N(2), \cdots, N(\sqrt{n})$ such that $\sum_{i=1}^{\sqrt{n}} N(i) = O(n)$ and $N(i) \geqq |G_i|$ for each $i \in [\sqrt{n}]$, given that each $|G_i| \leqq \sqrt{n} \log n$.

LEMMA B.1. *The above problem can be solved in time $\tilde{O}(\log n/\log\log n)$ using n processors.*

Proof. We provide a sampling algorithm. A shared memory of size n is used. This shared memory is divided into $\sqrt{n}$ blocks $B_1, B_2, \cdots, B_{\sqrt{n}}$ each of size $\sqrt{n}$.

Step 1.

$n/\log n$ processors in parallel each choose a random index (in $[n]$).

Step 2.

Every processor $\pi \in [n/\log n]$ has to find an assignment for its index i in the block $B_{i'}$. It chooses a random cell in $B_{i'}$ and tries to write in it. If it succeeds, it increments the contents of that cell by 1. If it does not succeed in the first trial, it tries a second time to increment the **same** cell. It tries as many times as it takes.

A total of $h \log n/\log\log n$ (for some h to be determined) time is given.

Step 3.

n processors perform a prefix-sum computation on the contents of the shared memory and hence compute $L(1), L(2), \cdots, L(\sqrt{n})$ where $L(i)$ is the sum of the contents of block B_i, $i \in [\sqrt{n}]$.

Step 4.

$\sqrt{n}$ processors set in parallel $N(i) = d(\log n) \max(1, L(i))$ and output $N(i)$, $i \in [\sqrt{n}]$. d is a constant to be determined.

Analysis. Let $M(i)$, $i \in [\sqrt{n}]$ stand for the number of indices chosen in Step 1 that belong to G_i and let $R(i) = d(\log n) \max(1, M(i))$. Following the proof of Lemma 3.4, the $R(i)$'s satisfy the conditions $\sum_{i=1}^{\sqrt{n}} R(i) = O(n)$ and $R(i) \geqq |G_i|$, $i \in [\sqrt{n}]$. The proof will be complete if we can show that $L(i) = M(i)$ with very high probability.

Showing that $L(i) = M(i)$, $i \in [\sqrt{n}]$ is the same as showing that no cell in the common memory will be chosen by more than $h \log n/\log\log n$ processors in Step 1. Let Y be a random variable equal to the number of processors that have chosen a particular cell q. Following the proof of Lemma 3.4, no $M(i)$ will be greater than $c\beta\sqrt{n}$ with probability $\geqq 1 - n^{-\beta}$ for any $\beta \geqq 1$ and some fixed c. Therefore, Y is upperbounded by a binomial variable with parameters $(c\beta\sqrt{n}, 1/\sqrt{n})$. The Chernoff bounds (1) imply that $Y \leqq h \log n/\log\log n$ with probability $\geqq 1 - n^{-\alpha}$, for any $\alpha \geqq 1$ and a proper h. □

PRECISE ANALYSES OF THE RIGHT- AND LEFT-SHIFT GREATEST COMMON DIVISOR ALGORITHMS FOR $GF(q)[x]$*

G. H. NORTON†

Abstract. The precise average and worst-case running times of the right- and left-shift gcd algorithms for $GF(q)[x]$ are derived. A new approximate integer model for the binary greatest common divisor algorithm is obtained. The right-shift polynomial worst case differs markedly for $q=2$ and $q>2$. The method also yields an easy analysis of the Euclidean algorithm.

AMS(MOS) subject classifications. primary 68Q25, 68Q40; secondary 11A05, 12E99

Introduction. Let $q \geqq 2$ be a prime power. This paper derives the precise running times of the right-shift greatest common divisor (gcd) algorithm for $GF(q)[x]$ of [N] and the left-shift gcd algorithm of [BK] (by way of comparison). The method used to obtain the averages for uniformly distributed polynomials is similar to the lattice-point analysis of the binary gcd algorithm [K, p. 330 ff.], except that exact "transition probabilities" are derived. The first part of this paper (§§ 1-4) treats the right-shift gcd algorithm. Sections 5, 6, and 7 treat the left-shift algorithm. The case $q=2$ suggests a new approximate model for the binary gcd algorithm for integers. The worst-case polynomial running times, however, are quite different from the integer case, and were obtained by first computing upper bounds and then the polynomials which realise the upper bounds. Three families were found: one for $q=2$ and one for $q>2$ in part one, whereas one family suffices for the second part.

A polynomial is said to be (right) *normalized* if it does not vanish at zero. (This is no restriction in computing gcd's, since the number of common powers of x may be accumulated beforehand.) The right-shift gcd algorithm of [N] for normalized polynomials will be called "Algorithm B2" and the left-shift algorithm of [BK] will be called "Algorithm A2." Both algorithms perform a number of steps or iterations of the following form: each *iteration* has a pair (u, v) of polynomials as input, with $u \neq 0$ and replaces (u, v) by another pair (u', v') such that $\gcd(u', v') = \gcd(u, v)$ and either (i) $\deg u' < \deg u$ (continuation) or (ii) $u' = 0$ (termination). See Algorithms 1.2 and 5.1 for precise details. It is not hard to see that Algorithm A2 and Algorithm B2 compute the gcd of (normalized for Algorithm B2) polynomials of degree m, n over a field K in at most $m+n+1$ iterations. This paper improves this worst-case result for Algorithm B2 when $K = GF(2)$; it also determines coefficients α_q and β_q explicitly so that the average number of iterations is $\alpha_q m + \beta_q n + 0(1)$ when $K = GF(q)$.

The principal results for Algorithm B2 are the following theorems.

THEOREM A. *For uniformly distributed normalized $GF(q)$ polynomials of degree m, n, the average number of iterations of Algorithm* B2 *is*

$$\frac{q-1}{q} m + \frac{q-1}{q+1} n + 0(1) \quad \text{if } m \geqq n \geqq 0.$$

THEOREM B. *Let $N \geqq 1$. For uniformly and independently distributed $GF(q)$ polynomials with degree in the range* 0 *to* $N-1$, *the average number of iterations of*

* Received by the editors August 18, 1987; accepted for publication (in revised form) February 26, 1988.
† Department of Electrical Engineering, University of Bristol, Bristol, United Kingdom. Present address, Laboratoire d'Analyse Numérique, Mathématiques, Université Paul Sabatier, 31062 Toulouse, France.

Algorithm B2 *is*

$$\frac{2q+1}{q+1}\,\frac{q-1}{q}\,N+0(1).$$

THEOREM C. *Let* $m \geqq n \geqq 0$. *For* $u, v \in GF(q)[x]$ *with degree* m, n *respectively, the maximum number of iterations of Algorithm* B2 *is* $m+\lfloor n/2 \rfloor + 1$ *if* $q=2$ *and* $m+n+1$ *if* $q>2$. *In both cases, the maxima are attained.*

The proof of Theorem A proceeds by first obtaining the recurrence relations satisfied by the averages and then by solving these relations. This method readily yields the probability that two normalized polynomials are coprime and the general solution will also be used in a future paper to analyse a related gcd algorithm.

The approximate integer model suggested by Theorem A is discussed after Theorem 2, § 3.

The corresponding principal results for Algorithm A2 are the following theorems.

THEOREM D. *Let* $m \geqq n \geqq 0$. *For uniformly distributed* $GF(q)$ *polynomials of degree* m, n, *the average number of iterations of Algorithm* A2 *is* $(m+n+1)(1-1/q)+1/q^{n+1}$.

THEOREM E. *Let* $N \geqq 1$. *For uniformly distributed* $GF(q)$ *polynomials with degree in the range* 0 *to* $N-1$, *the average number of iterations of Algorithm* A2 *is* $(2(q-1)/q+\varepsilon)N+0(1)$, *where* ε *tends to zero with* q^{-N}.

THEOREM F. *Let* $m \geqq n \geqq 0$. *For* $u, v \in GF(q)[x]$ *performs with degree* m, n, *the maximum number of iterations of Algorithm* A2 *is* $m+n+1$ *and this maximum is attained.*

In conclusion, it can be seen that Algorithm B2 always performs faster (on the average) than Algorithm A2 and that the most improvement occurs over $GF(2)$.

The averages for A2 also satisfy a recurrence relation, and Theorem D was obtained by solving it. Indeed, the average analysis of the classical Euclidean algorithm (see [K, p. 417, #4]) may also be found by calculating certain transition probabilities and then by solving the associated recurrence relation; the reader may verify that this recurrence has the same characteristic equation as Algorithm A2.

The results of this paper were first announced at AAECC-4 in Karlsruhe and in [No].

Conventions. K denotes a field, not necessarily finite, and $q \geqq 2$ denotes a prime power. The zero polynomial has degree -1, to simplify the transition probabilities. $K[x]$ denotes the ring of polynomials with coefficients in K, that is, finite power series

$$\sum_{i=0}^{m} f_i x^i \text{ with } f_i \in K.$$

1. The right-shift algorithm. This section states the right-shift gcd algorithm for $GF(q)[x]$ of [N] for normalized polynomials, shows that uniformity is preserved, and determines the transition probabilities, an essential step in the precise average analysis.

DEFINITION 1. For non-zero g in $K[x]$

(a) let $L(g)$ be the leading coefficient of g

(b) define the symbol $g/\!/x$ to be g/x^k if for some $k \geqq 0$, x^k divides g but x^{k+1} does not

(c) g_o denotes the constant term of g.

ALGORITHM 2. GCD by Right shifting.

Input. Normalized $f, g \in K[x]$.

Output. gcd (f, g).

procedure B2 $\left(\sum_{i=0}^{m} f_i x^i, \sum_{j=0}^{n} g_j x^j\right)$;

while true do begin

if $\deg(f) < \deg(g)$ then swap (f, g);
$f := f - f_o g_o^{-1} g$;
if $f = 0$ then exit;
$f := f /\!/ x$;
end;
return $L(g)^{-1} g$.

Note that after one iteration of the algorithm, (i) g is normalized and (ii) either $f = 0$ or f is normalized.

EXAMPLE 3. Over GF(2), the iterations are

$$(x^5+x^2+1, x^4+x+1) = (x^4+x^3+x+1, x^4+x+1)$$
$$= (1, x^4+x+1) = (x^3+1, 1) = (1, 1) = (0, 1)$$

and the gcd 1 is returned.

An example using $GF(13)$ coefficients is given in [N, Ex. 2]. It is clear that the computation may be stopped if $\deg(f) = 0$, returning a gcd of 1 in this case.

We now show that Algorithm B2 preserves uniformity.

PROPOSITION 4. *Let $i \geqq 1$, let u, v be uniformly distributed normalized $GF(q)$ polynomials of degree $m \geqq n \geqq 0$ and let $1 \leqq k \leqq m+1$, $0 \leqq l \leqq n$. Suppose that after i iterations (u, v) is replaced by (u', v') of degree $m-k$, $n-l$, respectively. Then u', v' are uniformly distributed in degree $m-k$, $n-l$.*

Proof. It suffices to prove this with $i = 1$, so that $v' = v$, and $\deg u' = m-k$. Then $u = u(0)v(0)^{-1}v(x) + x^k u'(x)$ and so for given polynomials u', v there is a unique u, v with $u(0) = 1$ yielding u', v in one step. Since u, v are uniformly distributed so are u', v as required.

DEFINITION 5. For $m \geqq n \geqq 0$ and $1 \leqq k \leqq m+1$, let $P[(m, n) \to (m-k, n)]$ denote the probability that one iteration of Algorithm B2 replaces uniformly distributed, normalized polynomials of degree m, n by normalized polynomials of degree $m-k$, n, or terminates (if $k = m+1$).

THEOREM 6. (a) *For $m > n \geqq 0$*

$$P[(m, n) \to (m-k, n)] = \begin{cases} (q-1)q^{-k} & \text{if } 1 \leqq k \leqq m-1, \\ q^{1-m} & \text{if } k = m. \end{cases}$$

(b) *For $n \geqq 0$,*

$$P[(n, n) \to (n-k, n)] = \begin{cases} \dfrac{k(q-1)-1}{q^k} & \text{if } 1 \leqq k \leqq n-1,\ n \geqq 2, \\ \dfrac{n(q-1)-1}{(q-1)q^{n-1}} & \text{if } k = n,\ n \geqq 1, \\ (q-1)^{-1}q^{1-n} & \text{if } k = n+1,\ n \geqq 1, \\ 1 & \text{if } k = n+1,\ n = 0. \end{cases}$$

Proof. (a) Suppose that $m > n$ and let u, v be normalized polynomials of degree m, n, respectively. We begin with the case $k = m$. For the algorithm to produce an output of degree zero, there are $m-1$ constraints ($u_i = 0$ for $n+1 \leqq i \leqq m-1$ and $v_o u_i - u_o v_i = 0$ if $n > 0$ and $1 \leqq i \leqq n$) each of which occurs with probability $1/q$. To obtain an output of degree $m-k$ for $1 \leqq k \leqq m-1$, the argument is similar: there will be $k-1$ equalities and one inequality yielding $q^{1-k} \cdot (q-1)q^{-1} = (q-1)q^{-k}$. This proves part (a).

(b) The case $n=0$ is trivial, so suppose now that u and v are normalized polynomials of degree $n>0$. Then $v=\lambda(u+w)$, where $\lambda \in GF(q)$ is non-zero, $-1 \leqq \deg(w) \leqq n-1$ and $w_o \neq -u_o$. The first iteration produces $w_o u - u_o w = w_o u_n x^n + \sum_{i=0}^{n-1} (w_o u_i - u_o w_i) x^i$ (up to a scalar) and $P[w_o = 0] = 1/(q-1)$, $P[w_o u_i - u_o w_i = 0] = 1/q$ if $n \geqq 2$ and $1 \leqq i \leqq n-1$. The cases $k = n+1$, $k = n$, and $1 \leqq k \leqq n-1$ (if $n \geqq 2$) correspond to no, one or at least two non-zero coefficients of $w_o u - u_o w$, respectively, giving the stated probabilities.

2. A general recurrence relation. The method used in [K, p. 330 ff.] to analyse the binary gcd algorithm is adapted to Algorithm B2 for $GF(q)[x]$ in this section. Using the *exact* transition probabilities of Theorem 6, § 1, we define a set of double recurrence relations $A_{mn}(a, c, A_{00})$, from which a single recurrence relation (Theorem 8) is derived. This is then solved using generating functions and partial fractions, and leads to the general solution (Theorem 13). Two applications of this solution are given in the next section, and it will be shown in a future paper that $A_{mn}(q/(q-1), 0, 1)$ yields the uniform average for the algorithm discussed in [K, p. 618, #6].

DEFINITION 1. Let a, c be constants and let $A_{mn} = A_{mn}(a, c, A_{00})$ be given by

$$A_{mn}(a, c, A_{00}) = \begin{cases} A_{00} & \text{if } m = n = 0, \\ a + \sum_{k=1}^{m-1} \dfrac{k(q-1)-1}{q^k} A_{m-k,m} + \dfrac{m(q-1)-1}{(q-1)q^{m-1}} A_{0m} & \text{if } m = n \geqq 1, \\ c + (q-1) \sum_{k=1}^{m-1} \dfrac{A_{m-k,n}}{q^k} + \dfrac{A_{0n}}{q^{m-1}} & \text{if } m > n \geqq 0, \\ A_{nm} & \text{if } n > m \geqq 0. \end{cases}$$

The calculation of A_{mn} for $n=0$ is straightforward.

PROPOSITION 2.

(a) $A_{m+k,n} = \dfrac{q-1}{q} ck + A_{mn}$ if $m > n \geqq 0$, $k \geqq 0$

(b) $A_{m0} = \dfrac{q-1}{q} mc + \dfrac{c}{q} + A_{00}$ if $m > 0$.

Proof.

$$\begin{aligned} \text{(a)} \quad A_{m+1,n} &= c + \frac{q-1}{q} A_{mn} + \sum_{k=2}^{m} \frac{q-1}{q^k} A_{m+1-k,n} + \frac{1}{q^m} A_{0n}, \\ &= c + \frac{q-1}{q} A_{mn} + \sum_{k=1}^{m-1} \frac{q-1}{q^{k+1}} A_{m-k,n} + \frac{1}{q^m} A_{0n}, \\ &= c + \frac{q-1}{q} A_{mn} + \frac{1}{q}(A_{mn} - c) = \frac{q-1}{q} c + A_{mn}, \end{aligned}$$

and part (a) follows from a trivial induction.

(b) By part (a),

$$\begin{aligned} A_{mo} &= \frac{q-1}{q} c(m-1) + A_{10}, \\ &= \frac{q-1}{1} c(m-1) + c + A_{00} \end{aligned}$$

if $m > 0$.

For simplicity let $A_m = A_{mm}$ for $m \geqq 0$. Our next step is to find the recurrence satisfied by A_m. A key role is played by the terms S_m in Definition 3 below; S_m is used to express $A_{m+1,m}$ in terms of A_m (Lemma 6) and the recurrence of Theorem 8 below is derived from a recurrence satisfied by S_m (Lemma 7).

DEFINITION 3. For $m \geqq 2$, let

$$S_m = \sum_{k=1}^{m-1} \frac{A_{m+1,m-k}}{q^{k+1}} + \frac{A_{m+1,0}}{q^m}.$$

LEMMA 4. *For* $m \geqq 2$,

$$A_{m+1,m} = \frac{q-1}{q} A_m + (q-1)S_m - \frac{q-2}{q^m} A_{00} - \frac{(q-2)(q-1)}{q^{m+1}} mc + \left(1 - \frac{1}{q} + \frac{1}{q^2} - \frac{q-2}{q^m}\right) c.$$

Proof.

$$\begin{aligned} A_{m+1,m} &= c + \sum_{k=1}^{m} \frac{q-1}{q^k} A_{m+1-k,m} + \frac{A_{0m}}{q^m}, \\ &= c + \sum_{k=1}^{m+1} \frac{q-1}{q^k} A_{m+1-k,m} - \frac{q-1}{q^{m+1}} A_{0m} + \frac{A_{0m}}{q^m}, \\ &= c + \frac{q-1}{q} A_m + \sum_{k=1}^{m} \frac{q-1}{q^{k+1}} A_{m-k,m} + \frac{A_{0m}}{q^{m+1}}, \\ &= c + \frac{q-1}{q} A_m + \sum_{k=1}^{m} \frac{q-1}{q^{k+1}} \left(A_{m-k,m+1} - \frac{q-1}{q} c\right) + \frac{A_{0m}}{q^{m+1}} \end{aligned}$$

by Proposition 2(a). Now

$$\sum_{k=1}^{m} \frac{A_{m+1,m-k}}{q^{k+1}} = S_m - \frac{q-1}{q^{m+1}} A_{m+1,0}$$

so that

$$A_{m+1,m} = c + \frac{q-1}{q} A_m + (q-1)S_m - (q-1)^2 \frac{A_{m+1,0}}{q^{m+1}} - (q-1)^2 c \sum_{k=1}^{m} \frac{1}{q^{k+2}} + \frac{A_{0m}}{q^{m+1}}.$$

Expanding $A_{m+1,0}$ and A_{m0} via Proposition 2(b) and collecting terms gives the stated formula.

LEMMA 5. *For* $m \geqq 2$,

$$A_{m+1} = \frac{q-1}{q} a + \frac{A_m}{q} + (q-1)S_m + (q-2)\frac{A_{m+1,m}}{q} - \frac{A_{m0}}{q^m} + \left[\frac{q-1}{q^2} - \frac{(q-1)^2+2}{q^{m+1}} + \frac{1}{q^m}\right] c.$$

Proof.

$$A_{m+1} = a + \frac{q-2}{q} A_{m,m+1} + \sum_{k=2}^{m} \frac{q-2+(k-1)(q-1)}{q^k} A_{m+1-k,m+1} + \left(A_{0m} + c\frac{q-1}{q}\right) q^{-m}\left(m + \frac{q-2}{q-1}\right)$$

and by Proposition 2(a), the summation is, after re-indexing,

$$\frac{1}{q}\sum_{k=1}^{m-1} \frac{q-2+(k-1)(q-1)}{q^k}\left(A_{m,m-k} + c\frac{q-1}{q}\right) + \frac{1}{q}\sum_{k=1}^{m-1} \frac{q-1}{q^k}\left(A_{m,m-k} + c\frac{q-1}{q}\right).$$

The first term contributes

$$\frac{1}{q}\left(A_m - a - \frac{A_{0m}}{q^{m-1}}\left((m-1) + \frac{q-2}{q-1}\right)\right)$$

and the second contributes

$$(q-1)\left(S_m - \frac{A_{m+1,0}}{q^m}\right).$$

Applying Proposition 2(a) to $A_{m+1,0}$ and collecting terms completes the proof.

LEMMA 6. *For* $m \geqq 2$,

(a) $$\frac{2(q-1)^2}{q} S_m = A_{m+1} - \frac{A_m}{q^2}(q^2-2q+2) - \frac{q-1}{q} a + \frac{2(q-1)(q-2)}{q^{m+1}} A_{00} + \left\{\frac{2(q-2)(q-1)^2}{q^{m+2}} - 1 + \frac{2}{q}\left(1 - \frac{1}{q} + \frac{1}{q^2}\right) + \frac{1}{q^{m+1}}(2q^2-6q+5)\right\} c$$

(b) $$A_{m+1,m} = \frac{qA_{m+1}}{2(q-1)} + \frac{q-2}{2(q-1)} A_m - \frac{a}{2} + \frac{q}{q-1}\left(\frac{1}{2} - \frac{1}{q} + \frac{1}{q^2} + \frac{1}{2q^{m+1}}\right) c.$$

Proof. Part (a) follows by substituting the value for $A_{m+1,m}$ obtained in Lemma 4 in the expression for A_{m+1} of Lemma 5, and part (b) follows by using part (a) to eliminate S_m from Lemma 4.

LEMMA 7. *For* $m \geqq 3$,

$$S_m = \frac{A_{m,m-1}}{q^2} + \frac{1}{q} S_{m-1} + \left(\frac{1}{q^2} + \frac{1}{q^m} - \frac{2}{q^{m+1}}\right) c.$$

Proof.

$$\begin{aligned} S_m &= \sum_{k=1}^{m-1} \frac{A_{m+1,m-k}}{q^{k+1}} + \frac{A_{m+1,0}}{q^m} \\ &= \frac{1}{q}\sum_{k=1}^{m-1}\left(A_{m,m-k} + \frac{q-1}{q} c\right) q^{-k} + \left(A_{m0} + \frac{q-1}{q} c\right) q^{-m} \\ &= \frac{A_{m,m-1}}{q^2} + \frac{1}{q}\left(\sum_{k=1}^{m-2} \frac{A_{m,m-k-1}}{q^{k+1}} + \frac{A_{m0}}{q^{m-1}}\right) + c\frac{q-1}{q^2}\sum_{k=1}^{m-1}\frac{1}{q^k} + \frac{q-1}{q^{m+1}} c \\ &= \frac{A_{m,m-1}}{q^2} + \frac{1}{q} S_{m-1} + \left(\frac{1}{q^2} + \frac{1}{q^m} - \frac{2}{q^{m+1}}\right) c. \end{aligned}$$

THEOREM 8. *For* $m \geqq 2$,

$$A_{m+1} = \left(1+\frac{1}{q^2}\right)A_m - \frac{1}{q^2}A_{m-1} + \left(\frac{q-1}{q}\right)^3 a + \left\{1 - \frac{3}{q^2} + \frac{2}{q^3} + \frac{q-1}{q^{m+2}}\right\} c.$$

Proof. Lemmas 6(a) and 7 give two expressions for S_m. In the latter, $A_{m,m-1}$ may be expanded using Lemma 6(b), and S_{m-1} may be expanded by Lemma 6(a). What results is an equation (with left-hand side involving A_{m+1} and A_m and right-hand side involving A_m and A_{m-1}) which simplifies to the above.

We now solve the recurrence relation using the method of generating functions and partial fractions.

Let G be the generating function $G(z) = \sum_{m=0}^{\infty} A_m z^m$.

LEMMA 9.

$$(z-1)(z-q^2)G(z) = q^2A_0 + \{q^2A_1 - (q^2+1)A_0\}z + \{q^2A_2 - (q^2+1)A_1 + A_0\}z^2 + \left\{\frac{(q-1)^3}{q}a + \left(q^2 - 3 + \frac{2}{q}\right)c\right\}\frac{z^3}{1-z} + \frac{q-1}{q}c\frac{z^3}{q-z}.$$

Proof. This is a straightforward consequence of Theorem 8.

PROPOSITION 10.

$$A_{10} = A_{00} + c \quad A_{11} = a + \frac{q-2}{q-1}(A_{00}+c) \quad A_{20} = A_{00} + \frac{2q-1}{q}c,$$

$$A_{21} = \frac{q-1}{q}(a + A_{00}) + \frac{2q-1}{q}c,$$

$$A_{22} = \left\{1 + \frac{(q-2)(q-1)}{q^2}\right\}a + \left\{\frac{(q-2)(q-1)}{q^2} + \frac{2q-3}{q(q-1)}\right\}A_{00} + \left\{\frac{(q-2)(2q-1)}{q^2} + \frac{(2q-3)(2q-1)}{(q-1)q^2}\right\}c.$$

Proof. These follow directly from the definition of A_{mn}.

LEMMA 11.

$$G(z) = \left(\frac{1-2q}{q}a + \frac{2q-1}{q-1}A_0 + \frac{c}{q(q-1)}\right) + \frac{qc}{q-1}\frac{1}{z-q} + \left\{\frac{(q-1)^2a}{q(q+1)} + \frac{q^2-3+2/q}{q^2-1}c\right\}\frac{1}{(z-1)^2} + \left\{\frac{q^3-4q^2-q+2}{q(q+1)^2}a - \frac{q}{q+1}A_0 + \frac{q^4+2q^3-4q^2+3}{q(q+1)^2(q-1)}c\right\}\frac{1}{z-1} + \left\{\frac{-a}{(q+1)^2} + \frac{A_0}{q^2-1} - \frac{c}{(q-1)(q+1)^2}\right\}\frac{2q^4}{z-q^2}.$$

Proof. This follows from Lemma 9 using the method of partial fractions (see, e.g., [BM, pp. 79-81]) and also uses the values for A_1, A_2 of the previous proposition.

PROPOSITION 12. $A_{mn} = ((q-1)/q)(m-n-1)c + A_{n+1,n}$ *if* $m > n \geqq 0$.

Proof. This follows from Proposition 2(b) by a simple change of subscripts.

Finally, the general solution is given in Theorem 13.

THEOREM 13. (a) *For* $m \geqq 3$

$$A_m = \left\{\frac{(q-1)^2}{q(q+1)}a + \frac{q^2-3+2/q}{q^2-1}c\right\}m + \frac{3q^2-1}{q(q+1)^2}a + \frac{q}{q+1}A_0 - \frac{q^3-q^2+q+1}{q(q-1)(q+1)^2}c - \frac{c}{(q-1)q^m} + \left\{\frac{a}{q+1} - \frac{A_0}{q-1} + \frac{c}{q^2-1}\right\}\frac{2}{q+1}q^{2-2m}.$$

(b) *For* $m-1 \geqq n \geqq 2$

$$A_{mn} = \frac{q-1}{q}mc + \left\{\frac{(q-1)^2}{q(q+1)}a + \frac{q-1}{q(q+1)}c\right\}n + \frac{2q^2-1}{q(q+1)^2}a + \frac{q}{q+1}A_0 + \frac{1}{q(q+1)}c + \left\{\frac{a}{q+1} - \frac{A_0}{q-1} + \frac{c}{q^2-1}\right\}\frac{q-1}{q+1}q^{1-2n}.$$

Proof. Part (a) is an immediate consequence of the definition of G and Lemma 11. Lemma 6(b) and part (a) give a formula for $A_{m+1,m}$, and an application of Proposition 12 completes the proof of part (b).

3. The average analysis of Algorithm B2. Two average running times for Algorithm B2 are calculated in this section: one for uniformly distributed normalized polynomials in degree $m \geqq n \geqq 0$ (Theorem 2), which is then used to determine the average (up to 0(1) terms) for uniformly distributed polynomials with degree in the range 0 to $N-1$, $N \geqq 1$ (Theorem 7); we also compare a new approximate model for the binary integer algorithm with the lattice point model, and determine the probability that normalized polynomials are coprime (Theorem 8).

Recall that $A_{mn}(a, c, A_{00})$ is defined in Definition 1, § 2.

PROPOSITION 1. $A_{mn}(1, 1, 1)$ *is the average number of iterations of Algorithm* B2 *for uniformly distributed normalized polynomials of degree* $m \geqq n \geqq 0$.

Proof. By virtue of Theorem 6, § 1, it suffices to show that the average is equal to $1 + \sum_{k=1}^{m} P[(m, n) \to (m-k, n)]A_{m-k,n}$. This is proved by induction on $m+n$, the case $m+n=0$ being clear. For non-negative integers i, r, s, let $\pi_{r,s}(i)$ be the probability that i iterations of Algorithm B2 are required to calculate the gcd of uniformly distributed normalized polynomials of degree r, s and set $\pi_{-1,s}(i) = \delta_{i0}$. Then for $m+n>0$ and $i>0$,

$$\pi_{mn}(i) = \sum_{k=1}^{m+1} P[(m, n) \to (m-k, n)]\pi_{m-k,n}(i-1)$$

and the average in question can be written as

$$\begin{aligned}\sum_{i \geqq 1} i\pi_{mn}(i) &= \sum_{i \geqq 1}\sum_{k=1}^{m+1} P[(m, n) \to (m-k, n)](1+(i-1))\pi_{m-k,n}(i-1) \\ &= \sum_{k=1}^{m+1} P[(m, n) \to (m-k, n)]\left(1 + \sum_{i \geqq 0} i\pi_{m-k,n}(i)\right) \\ &= 1 + \sum_{k=1}^{m+1} P[(m, n) \to (m-k, n)] \sum_{i \geqq 1} i\pi_{m-k,n}(i) \\ &= 1 + \sum_{k=1}^{m} P[(m, n) \to (m-k, n)]A_{m-k,n}\end{aligned}$$

by the inductive hypothesis and the definition of $\pi_{-1,n}$.

Theorem A of the Introduction is an immediate consequence of the following result.

THEOREM 2. *For uniformly distributed normalized $GF(q)$ polynomials of degree m, n, the average number of iterations of Algorithm* B2 *needed to compute* $\gcd(u, v)$ *is*

$$\begin{cases} 1 & \text{if } m = n = 0, \\ \dfrac{q-1}{q}\, m + \dfrac{1}{q} + 1 & \text{if } m > n = 0, \\ \dfrac{(q-1)(2q+1)}{(q+1)q}\, m + \dfrac{q^3+2q^2-3q-2}{(q-1)(q+2)^2} - \dfrac{q^{-m}}{q-1} - \dfrac{2q^{2-2m}}{(q-1)(q+1)^2} & \text{if } m = n \geqq 1, \\ \dfrac{q-1}{q}\, m + \dfrac{q-1}{q+1}\, n + \dfrac{q^2+3q+1}{(q+1)^2} - \dfrac{q^{1-2n}}{(q+1)^2} & \text{if } m > n \geqq 1. \end{cases}$$

Proof. This follows from the preceding proposition and the results of § 2: for $m = n \geqq 3$ or $m > n \geqq 2$ from Theorem 2.13 and the remaining cases from Proposition 10, § 2.

Recall that there is an integer analogue of Algorithm B2, which repeatedly subtracts (non-negative) *odd* integers rather than normalized $GF(2)$ polynomials. Thus for 17 and 5, the iterations would be

$$(17, 5) = (5, 3) = (3, 1) = (1, 1) = (0, 1) = 1.$$

Further, the lattice-point model [*K*, p. 330 ff.] is similar to the above model for $q = 2$. Indeed, the lattice-point model uses the same probabilities as Theorem 6(a), § 1, for the case $m > n$ and differs only in the transition probabilities when $m = n$ and $0 \leqq k \leqq n-1$. It is therefore natural to compare the solutions of these two models *in abstracto.*

Thus, ignoring $o(1)$ terms and setting $q = 2$ in Theorem 2 gives $m/2 + n/3 + 11/9 - \delta_{mn}/3$ as another estimate of the average number of iterations of the binary gcd algorithm for uniformly and independently distributed odd $(m+1)$- and $(n+1)$-bit integers where m, n are both nonzero. This model was compared to the lattice point model as follows: fix m, n with $1 \leqq n \leqq m \leqq 7$. Compute the actual average a_{mn} using all 2^{m+n-2} possible pairs of $(m+1)$- and $(n+1)$-bit odd integers. This gives 28 actual averages. Now compute the error terms $(a_{mn} - A_{mn})^2$, where $A_{mn} = m/2 + n/3 + 11/9 - \delta_{mn}/3$. The average of these squares (the mean square error of the model) is 0.144, whereas the corresponding value for the lattice point model is 0.213. It would seem therefore that the transition probabilities of Theorem 1.6 are a slightly better approximation to the actual ones.

We now deal with the case where the inputs are uniformly distributed with degree in the range 0 to $N-1$, $N \geqq 1$. The approach is completely analogous to that used in [K, p. 335].

LEMMA 3. *Let $N \geqq 1$ and let u, v be $GF(q)$ polynomials, uniformly distributed with degree in the range* 0 *to* $N-1$. *Then, the average number of iterations C of Algorithm* B2 *satisfies*

$$\begin{aligned} (q^N-1)^2 C = {} & (q-1)^2 N^2 C_{00} + 2(q-1)N \sum_{n=1}^{N-1} (q-1)^2 q^{n-1} (N-n) C_{n0} \\ & + 2 \sum_{1 \leqq n < m < N} (q-1)^4 q^{m+n-2} (N-m)(N-n) C_{mn} \\ & + \sum_{n=1}^{N-1} \{(q-1)^2 q^{n-1} (N-n)\}^2 C_{nn} \end{aligned}$$

where C_{mn} denotes the average of Theorem 2.

Proof. There are $(q-1)N$ polynomials with degree in the range 0 to $N-1$ which can be shifted right until they have degree 0, and there are $(q-1)^2q^{m-1}(N-m)$ polynomials with degree in the range m to $N-1$ which can be shifted right until they have degree $m>0$.

LEMMA 4. (a) *For* $m \geqq 2$,

$$\sum_{n=1}^{m} nx^n = \frac{x}{(x-1)^2}[mx^{m+1}-(m+1)x^m+1].$$

(b) *For* $m \geqq 2$,

$$\sum_{n=1}^{m} n(n-1)x^n = \frac{x^2}{(x-1)^3}\{m(m-1)x^{m+1}-2(m-1)(m+1)x^m+m(m+1)x^{m-1}-2\}.$$

Proof. Part (a) is obtained in the standard way by differentiating the geometric series with ratio x, and part (b) follows from the series of part (a) in the same way.

LEMMA 5. *If* $C_{mn} = \alpha m+\beta n+\gamma$, $m \geqq n$, *then*

$$\text{(a)} \quad \sum_{1\leqq n<m<N} (N-m)(N-n)q^{m+n-2}C_{mn} = q^{2N}\left(\frac{2q^2+q+1}{(q-1)^4(q+1)^3}(\alpha+\beta)N+0(1)\right)$$

$$\text{(b)} \quad \sum_{1\leqq n<N} (N-n)^2q^{2n-2}C_{nn} = q^{2N}\left(\frac{q^2+1}{(q^2-1)^3}(\alpha+\beta)N+0(1)\right).$$

Proof. Both parts follow from Lemma 4 by a routine calculation similar to [K, p. 597].

THEOREM 6. *Let* $N \geqq 1$. *For uniformly and independently distributed* $GF(q)$ *polynomials with degree in the range* 0 *to* $N-1$, *the average number of iterations of Algorithm* B2 *is*

$$\frac{(q-1)(2q+1)}{(q+1)q}N+0(1).$$

Proof. By Lemmas 3 and 5 and by Theorem 2, the coefficient of N in the uniform average C is

$$(q-1)^4\left\{\frac{2(2q^2+q+1)}{(q-1)^4(q+1)^3}\left(\frac{q-1}{q}+\frac{q-1}{q+1}\right)+\frac{q^2+1}{(q^2-1)^3}\left(\frac{q-1}{q+1}\cdot\frac{2q+1}{q}\right)\right\}$$

and this simplifies to the stated value.

We conclude this section with another application of the results of § 2.

THEOREM 7. *Let* f, g *be uniformly distributed normalized* $GF(q)$ *polynomials of degree* m, n, *respectively. Then the probability that* f *and* g *are coprime is*

$$\begin{cases} 1 & \text{if } m \geqq n = 0, \\ \dfrac{q}{q+1}-\dfrac{2}{(q^2-1)q^{2m-2}} & \text{if } m = n \geqq 1, \\ \dfrac{q}{q+1}-\dfrac{1}{(q+1)q^{2n-1}} & \text{if } m > n \geqq 1. \end{cases}$$

Proof. As in the proof of Proposition 1, the required probability is clearly $A_{mn}(0, 0, 1)$, and, so for $m = n \geqq 3$ or $m > n \geqq 2$, the result follows from Theorem 13, § 2. The reader may check that in the remaining cases the stated formulae agree with Proposition 10 when $a = c = 0$ and $A_{00} = 1$.

Theorem 7 is also a simple consequence of the following result, which is due to an anonymous referee. First some notation is given:

for $m, n \geqq 0$, let
$P_m = \{u \in GF(q)[x]: \deg u = m, u \text{ monic and normalized}\}$
$R_{mn} = \{(u, v) \in P_m \times P_n : \gcd(u, v) = 1\}$
$r_{mn} = |R_{mn}|$.

THEOREM 8.

$$r_{mn} = \begin{cases} 1 & \text{if } m = n = 0, \\ q^{m-1}(q-1) & \text{if } m > n = 0, \\ \dfrac{q-1}{q+1}(q^{2n} - q^{2n-1} - 2) & \text{if } m = n > 0, \\ \dfrac{(q-1)^2}{q+1} q^{m-n-1}(q^{2n} - 1) & \text{if } m > n > 0. \end{cases}$$

Proof. The first two cases are trivial since $|P_0| = 1$ and for $m > 0$, $|P_m| = q^{m-1}(q-1)$. Fix $m \geqq n \geqq 1$, and for $1 \leqq k \leqq n$, define $\alpha_k : R_{m-k,n-k} \times P_k \to P_m \times P_n$ by $\alpha_k((u, v), w) = (uw, vw)$. To see that α_k is one-to-one onto its image, suppose that $(s, t) \in P_m \times P_n$ are *not* relatively prime. Put $g = \gcd(s, t)$, where $d = \deg g \geqq 1$. It is elementary that

$$\alpha_k^{-1}(s, t) = \begin{cases} \varphi & \text{if } k \neq d \\ ((s/g, t/g), g) & \text{if } k = d \end{cases}$$

so that each α_k is one-to-one and $P_m \times P_n = R_{mn} \cup \cup_{k=1}^{n} im(\alpha_k)$ is a disjoint union. Since $|P_m| = q^{m-1}(q-1)$, this gives the double recurrence relation

$$r_{mn} = q^{m+n-2}(q-1)^2 - \sum_{k=1}^{n} r_{m-k,n-k} q^{k-1}(q-1).$$

The remaining two formulae for r_{mn} are now straightforward verifications based on the first two cases.

We note in conclusion that the same argument shows that the probability that *unnormalized* polynomials (of positive degree) are relatively prime is $(q-1)/q$: (cf. [K, p. 417, #5]). To wit, let

$$Q_n = \{u \in GF(q)[x]: \deg u = n, u \text{ monic}\},$$
$$S_{mn} = \{(u, v) \in Q_m \times Q_n : \gcd(u, v) = 1\},$$
$$s_{mn} = |S_{mn}|.$$

THEOREM 9.

$$s_{mn} = \begin{cases} 1 & \text{if } m = n = 0, \\ q^m & \text{if } m > n = 0, \\ q^{m+n+1}(q-1) & \text{if } m \geqq n > 0. \end{cases}$$

Proof. As for Theorem 8, but using the fact that $|Q_m| = q^m$ for $m \geqq 0$.

4. The worst-case analysis of Algorithm B2. The worst-case analysis of Algorithm B2 for $GF(q)[x]$ differs when $q = 2$ and when $q > 2$. A more elaborate polynomial

construction, as well as a more elaborate argument, is needed in the former case. Both constructions incorporate a type of polynomial Fibonacci term.

PROPOSITION 1. *Let* $m \geqq n \geqq 0$. *If* $u, v \in K[x]$ *have degree* m, n, *respectively, then Algorithm* B2 *requires at most* $m+n+1$ *iterations to compute* $\gcd(u, v)$.

Proof. This is completely analogous to the proof of the integer case given in [N, § A] and is omitted.

If K is $GF(2)$, it is easy to check that the upper bound of Proposition 1 is the best possible if either polynomial has degree 0 or 1, but Algorithm B2 applied to $u(x) = x^2 + x + 1$ and $v(x) = x + 1$ requires three iterations, less than the expected upper bound of 4.

PROPOSITION 2. *If* $u, v \in GF(2)[x]$ *have degree* m, n, *respectively, where* $m \geqq n \geqq 0$, *then Algorithm* B2 *requires at most* $m + \lfloor n/2 \rfloor + 1$ *iterations to compute* $\gcd(u, v)$.

Proof. Without loss of generality, we may assume that u and v are normalized. We use induction on $m+n$. The result is clearly true for $m = n = 0$. Suppose that $m+n > 0$ and the first iteration yields polynomials of degree $m-k$, n for some k, $1 \leqq k \leqq m+1$. If $m = n$, at most $m + \lfloor (m-k)/2 \rfloor + 1$ further steps are required where $k \geqq 2$, since $u, v \in GF(2)[x]$. If $k = m+1$, the algorithm terminates and there is nothing to prove. If $m > n$, either $m - k + \lfloor n/2 \rfloor + 1$ or $n + \lfloor (m-k)/2 \rfloor + 1$ further steps are required, according as $m - k \geqq n$ or $m - k \leqq n$. In all cases, the inductive hypothesis implies that at most $m + \lfloor n/2 \rfloor + 1$ steps are needed.

Note that the preceding proof works because $m = n \Rightarrow k \geqq 2$ where $q = 2$. This fails for $q \geqq 3$ since there is no longer automatic cancellation of *leading* terms.

It will be shown that the following construction realises the previous upper bound; note that for m even, u_{mm} is defined in a way reminiscent of Fibonacci numbers.

DEFINITION 3. Define $u_{mn}, v_{mn} \in GF(2)[x]$ by $u_{00}(x) = v_{00}(x) = 1$ and

$$v_{m+1,n}(x) = \begin{cases} v_{mn}(x) & \text{if } n \text{ is even and } 0 \leqq n \leqq m, \\ x v_{m+1,n-1}(x) & \text{if } n \text{ is odd and } 1 \leqq n \leqq m+1; \end{cases}$$

$$u_{m+1,n}(x) = \begin{cases} x u_{mn}(x) + v_{m+1,n}(x) & \text{if } n \text{ is even and } 0 \leqq n \leqq m, \\ u_{m+1,n-1}(x) & \text{if } n \text{ is odd and } 1 \leqq n \leqq m+1; \end{cases}$$

$$v_{m+1,m+1}(x) = u_{m+1,m}(x) \quad \text{if } m \text{ is odd},$$

$$u_{m+1,m+1}(x) = u_{m+1,m}(x) + v_{m+1,m}(x) \quad \text{if } m \text{ is odd}.$$

The reader may check that $\deg(u_{mn}) = m$, $\deg(v_{mn}) = n$ by inducting on $m+n$.

LEMMA 4. (a) *For all* $m \geqq n \geqq 0$, $u_{mn}(0) \neq 0$,

(b) *If* n *is even*, $v_{nn}(0) \neq 0$.

Proof. This is trivial.

LEMMA 5. *Let* $m \geqq n \geqq 0$ *and let* $P(m, n)$ *be the proposition that Algorithm* B2 *requires* $m + \lfloor n/2 \rfloor + 1$ *steps to compute* $\gcd(u_{mn}, v_{mn})$.

(a) $P(n+1, n) \Rightarrow P(n+1, n+1)$

(b) if n is even, $P(m, n) \Rightarrow P(m+1, n)$

(c) if n is odd, $P(m, n-1) \Rightarrow P(m, n)$.

Proof. This follows from Definition 3 and from Lemma 4 using the parities of m and n, and is omitted.

PROPOSITION 6. *For* $m \geqq n \geqq 0$, *Algorithm* B2 *computes* $\gcd(u_{mn}, v_{mn})$ *in* $m + \lfloor n/2 \rfloor + 1$ *steps.*

Proof. The proof is by induction on $m+n$. $P(0, 0)$ is true. The case $m = n$ follows from part (a) of Lemma 5, and the case $m > n$ follows from part (b) or part (c) depending on whether n is even or odd.

The last topic is the worst case for $q>2$. This is easier than the case $q=2$, being independent of parity and attaining the first upper bound.

DEFINITION 7. For $q>2$ and $m>n\geqq 0$ define u_{mn}, $v_{mn}\in GF(q)[x]$ by

$$u_{00}(x)=v_{00}(x)=1,$$

$$u_{mn}(x)=xu_{m-1,n}(x)+v_{nn}(x),$$

$$v_{mn}(x)=v_{nn}(x),$$

$$v_{n+1,n+1}(x)=u_{n+1,n}(x),$$

$$u_{n+1,n+1}(x)=M(xv_{nn}(x)+tv_{n+1,n+1}(x)),$$

where $M(f)=L(f)^{-1}f$ makes $f\in GF(q)[x]$ monic, and $t\neq 0,-1$.

The condition on t easily implies that (a) $\deg(u_{mn})=m$ and $\deg(v_{mn})=n$ and (b) $u_{n+1,n}(0)\neq 0$, $v_{nn}(0)\neq 0$ for all $n\geqq 0$. This latter property and a simple induction establish the last result.

PROPOSITION 8. *For $q>2$, Algorithm* B2 *requires $m+n+1$ iterations to compute* $\gcd(u_{mn}, v_{mn})$.

It follows that for $q>2$, the upper bound $m+n+1$ of Proposition 1 is tight.

5. The left-shift algorithm. This section states the left-shift gcd algorithm for $GF(q)[x]$ and determines the transition probabilities. These in turn yield the recurrences to be solved for the average analyses. Recall that for non-zero $g\in K[x]$, $L[g]$ is the leading coefficient of g.

ALGORITHM 1. GCD by Left shifting.
Input. Polynomials f, $g\in K[x]$ with g non-zero.
Output. $\gcd(f, g)$.

procedure A2 $\left(\sum_{i=0}^{m} f_i x^i, \sum_{j=0}^{n} g_j x^j\right)$;

```
while f ≠ 0 do begin
    if deg(f) < deg(g) then swap (f, g);
    f := L(g)f − L(f)x^(deg(f)−deg(g)) g;
    end;
return L(g)^(−1) g.
```

EXAMPLE 2. Over $GF(2)$, the iterations are

$$(x^5+x^2+1, x^4+x+1)=(x^4+x+1, x+1)=(x^3+x+1, x+1)$$

$$=(x^2+x+1, x+1)=(x+1, 1)=(1, 1)=(0, 1)=1.$$

We now show that Algorithm A2 preserves uniformity.

PROPOSITION 3. *Let $i\geqq 1$, let u, v be uniformly distributed $GF(q)$ polynomials of degree $m\geqq n\geqq 0$, and let $1\leqq k\leqq m+1$, $0\leqq l\leqq n$. Suppose that after i iterations, (u, v) is replaced by (u', v') of degree $m-k$, $n-l$, respectively. Then u', v' are uniformly distributed in degree $m-k$, $n-l$.*

Proof. This is similar to Proposition 4, § 1, and is omitted.

DEFINITION 4. For $m\geqq n\geqq 0$ and $1\leqq k\leqq m+1$, let $P[(m, n)\to(m-k, n)]$ denote the probability that one iteration of Algorithm A2 replaces polynomials of degree m, n by polynomials of degree $m-k$, n, or terminates (if $k=m+1$).

PROPOSITION 5. *For* $m \geqq n \geqq 0$

$$P[(m, n) \to (m-k, n)] = \begin{cases} \dfrac{q-1}{q^k} & \text{if } 1 \leqq k \leqq m \\ \dfrac{1}{q^m} & \text{if } k = m+1. \end{cases}$$

Proof. Suppose that $m > n$ and let u, v be of degree m, n, respectively. The degree $m-k$ of the result falls into one of three cases: $m-n \leqq m-k \leqq m-1$, $0 \leqq m-k \leqq m-n-1$, and $m-k=-1$. The first case requires $v_n u_j = u_m v_{j+n-m}$ for $m-k+1 \leqq j \leqq m-1$ and $v_n u_{m-k} \neq u_m v_{n-k}$. The second requires $v_n u_j = u_m v_{j+n-m}$ for $m-n \leqq j \leqq m-1$, $u_j = 0$ for $m-k+1 \leqq j \leqq m-n-1$, and $u_{m-k} \neq 0$, whereas the last requires that $v_n u_j = u_m v_{j+n-m}$ for $m-n \leqq j \leqq m-1$ and $u_j = 0$ for $0 \leqq j \leqq m-n-1$. Each equality occurs with probability $1/q$, and each of the first two cases has $k-1$ equalities and one inequality, whereas the last case has m equalities.

The case $m = n$ is similar (requiring the first and last case only) without the zero conditions, and is omitted.

6. The average analysis of Algorithm A2. Two average running times for Algorithm A2 are calculated in this section: one for uniformly distributed polynomials in degree $m \geqq n \geqq 0$ (Corollary 5), which is then used to determine the average (up to 0(1) terms) for uniformly distributed polynomials with degree in the range 0 to $N-1$, $N \geqq 1$ (Theorem 8).

DEFINITION 1. Let A_{mn} be given by

$$A_{mn} = \begin{cases} 1 & \text{if } m = n = 0, \\ 1 + \sum_{k=1}^{m} \dfrac{q-1}{q^k} A_{m-k,n} & \text{if } m \geqq n \geqq 0, (m, n) \neq (0, 0), \\ A_{nm} & \text{if } n \geqq m \geqq 0, (m, n) \neq (0, 0). \end{cases}$$

As in Proposition 1, § 3, A_{mn} is the required average number of iterations of Algorithm A2. The following results are used to determine the recurrence satisfied by A_{nn} and to express A_{mn} in terms of A_{nn}.

PROPOSITION 2. *For* $m \geqq n \geqq 0$ *and* $k \geqq 0$,

$$A_{m+k,n} = A_{m,n} + k\left(\frac{q-1}{q}\right).$$

Proof.

$$\begin{aligned} A_{m+1,n} &= 1 + \sum_{k=1}^{m+1} \frac{q-1}{q^k} A_{m+1-k,n}, \\ &= 1 + \frac{q-1}{q} A_{mn} + \sum_{k=2}^{m+1} \frac{q-1}{q^k} A_{m+1-k,n}, \\ &= 1 + \frac{q-1}{q} A_{mn} + \frac{1}{q} \sum_{k=1}^{m} \frac{q-1}{q^k} A_{m-k,n}, \\ &= 1 + \frac{q-1}{q} A_{mn} + \frac{1}{q}(A_{mn} - 1), \\ &= A_{mn} + \frac{q-1}{q}. \end{aligned}$$

The general result now follows by induction on k.

For simplicity, let $A_m = A_{mm}$ for $m \geqq 0$.

PROPOSITION 3. *For* $m \geqq 0$,

$$A_{m+1} = A_m + \left(\frac{q-1}{q}\right)\left(2 - \frac{1}{q^{m+1}}\right).$$

Proof.

$$\begin{aligned}
A_{m+1} &= 1 + \sum_{k=1}^{m+1} \frac{q-1}{q^k} A_{m+1-k,m+1}, \\
&= 1 + \frac{q-1}{q} A_{m,m+1} + \sum_{k=2}^{m+1} \frac{q-1}{q^k} A_{m+1-k,m+1}, \\
&= 1 + \frac{q-1}{q}\left(A_m + \frac{q-1}{q}\right) + \frac{1}{q}\sum_{k=1}^{m} \frac{q-1}{q^k} A_{m-k,m+1}, \\
&= 1 + \frac{q-1}{q} A_m + \left(\frac{q-1}{q}\right)^2 + \frac{1}{q}\sum_{k=1}^{m}\left(\frac{q-1}{q^k} A_{m-k,m} + \frac{q-1}{q}\right), \\
&= 1 + \frac{q-1}{q} A_m + \frac{1}{q}(A_m - 1) + \left(\frac{q-1}{q}\right)^2 \sum_{k=1}^{m} \frac{1}{q^k}, \\
&= A_m + \frac{q-1}{q} + \left(\frac{q-1}{q}\right)^2 \frac{1-q^{m+1}}{q^{m+1}} \frac{q}{1-q}, \\
&= A_m + \frac{q-1}{q} - \frac{q-1}{q}\left(\frac{1}{q^{m+1}} - 1\right), \\
&= A_m + \left(\frac{q-1}{q}\right)\left(2 - \frac{1}{q^{m+1}}\right).
\end{aligned}$$

The recurrence of Proposition 3 is readily solved using the generating function (Proposition 4).

PROPOSITION 4. *For* $m \geqq 0$,

$$A_{m+1} = (2(m+1)+1)\left(\frac{q-1}{q}\right) + \frac{1}{q^{m+2}}.$$

Proof. Let $G(z) = \sum_{m=0}^{\infty} A_m z^m$. Proposition 3 implies that

$$G(z) - 1 - zG(z) = 2\left(\frac{q-1}{q}\right) z \sum_{m=0}^{\infty} z^m - \frac{q-1}{q}\frac{z}{q} \sum_{m=0}^{\infty} \left(\frac{z}{q}\right)^m,$$

and the method of partial fractions (see, e.g., [BM, pp. 79–81]) yields

$$G(z) = \sum_{m \geqq 0} z^m + 2\left(\frac{q-1}{q}\right) \sum_{m \geqq 0} (m+1) z^{m+1} - \frac{z}{q} \sum_{m \geqq 0} z^m + \frac{z}{q^2} \sum_{m \geqq 0} \left(\frac{z}{q}\right)^m.$$

Collecting terms on the right-hand side yields the formula for A_{m+1}.

COROLLARY 5. *Let* $m \geqq n \geqq 0$. *For uniformly distributed* $u, v \in GF(q)[x]$ *of degree* m, n, *respectively, the average number of iterations required to compute* $\gcd(u, v)$ *using Algorithm* A2 *is* $(m+n+1)(1-1/q)+1/q^{n+1}$.

Proof. By Proposition 2, $A_{mn} = (m-n)(1-1/q) + A_n$. Now $A_{00} = 1$ and if $n > 0$, A_n is given by Proposition 4. Combining these formulae yields the result.

The remainder of this section deals with the case where the inputs are uniformly distributed with degree in the range 0 to $N-1$, $N \geqq 1$.

LEMMA 6. *Let $N \geqq 1$ and let u, v be $GF(q)$ polynomials, independently and uniformly distributed with degree in the range 0 to $N-1$. Then C, the average number of iterations of Algorithm* A2 *satisfies*

$$(q^N-1)^2 C = \sum_{0 \leqq m,n < N} q^{m+n}(q-1)^2 C_{mn}$$

where C_{mn} denotes the average of Corollary 5.

Proof. There are $(q-1)q^t$ $GF(q)$ polynomials of degree $t \geqq 0$.

LEMMA 7. *If $m \geqq n \geqq 0$ and $C_{mn} = \alpha m + \beta n + \gamma$, then*

$$\text{(a)} \quad \sum_{0 \leqq n < m < N} q^{m+n}(q-1)^2 C_{mn} = q^{2N}\left(\frac{1}{q+1}(\alpha+\beta+\varepsilon)N + 0(1)\right)$$

$$\text{(b)} \quad \sum_{0 \leqq n < N} q^{2n}(q-1)^2 C_{nn} = q^{2N}\left(\frac{q-1}{q+1}(\alpha+\beta+\varepsilon)N + 0(1)\right)$$

where ε tends to zero with q^{-N}.

Proof. These are routine summations using the change of indices $r = N-m$, $s = N-n$.

THEOREM 8. *Let $N \geqq 1$. For uniformly and independently distributed $GF(q)$ polynomials with degree in the range 0 to $N-1$, the average number of iterations of Algorithm* A2 *is $(2(1-1/q)+\varepsilon)N + 0(1)$, where ε tends to zero with q^{-N}.*

Proof. By Lemmas 6 and 7 and by Corollary 5, the coefficient of N in the uniform average is

$$\left\{\frac{2}{q+1} + \frac{q-1}{q+1}\right\}\left(2\frac{q-1}{q} + \varepsilon\right)$$

as required.

7. The worst-case analysis of Algorithm A2. This short section gives a simple polynomial construction to realise the maximum number of iterations for Algorithm A2.

PROPOSITION 1. *Let $m \geqq n \geqq 0$. If u, $v \in K[x]$ have degree m, n, respectively, then Algorithm* A2 *requires at most $m+n+1$ iterations to compute* gcd (u, v).

Proof. This is a trivial induction on $m+n \geqq 0$.

DEFINITION 2. Define u_{mn}, $v_{mn} \in GF(q)[x]$ by

$$u_{00}(x) = v_{00}(x) = 1,$$

$$v_{mn}(x) = u_{n,n-1}(x) \quad \text{if } m \geqq n \geqq 1,$$

$$u_{nn}(x) = v_{n-1,n-1}(x) + u_{n,n-1}(x) \quad \text{if } n \geqq 1,$$

$$u_{mn}(x) = x^{m-n}v_{nn}(x) + u_{m-1,n}(x) \quad \text{if } m > n \geqq 0.$$

It is trivial to verify that deg $(u_{mn}) = m$, deg $(v_{mn}) = n$ and that each u_{mn}, v_{mn} is monic.

PROPOSITION 3. *For $q \geqq 2$ and $m \geqq n \geqq 0$, Algorithm* A2 *requires $m+n+1$ iterations to compute* gcd (u_{mn}, v_{mn}).

Proof. The result is true for $m = n = 0$. The general result follows by induction on $m+n$ since one iteration replaces (u_{mn}, v_{mn}) by $(u_{m-1,n}, v_{m-1,n})$ if $m > n$ and (u_{nn}, v_{nn}) by $(u_{n,n-1}, v_{n-1,n-1})$ otherwise.

It is not hard to see that the Euclidean algorithm requires $n+1$ steps to compute gcd (u_{mn}, v_{mn}).

Acknowledgments. I am indebted to the referees for their valuable comments and especially to "referee A" for his report on a first version of this paper. The first version

discussed the average number of subtraction steps as well as the average number of shifts, but for the case $q = 2$ only, and conjectured Theorem 3.7. Referee A kindly supplied a proof of this (see Theorem 3.8). His first report thus led to the current solution. The second reports of the referees also suggested many improvements. The time that they have spent is much appreciated.

EXPRESSIBILITY AND PARALLEL COMPLEXITY*

NEIL IMMERMAN†

Abstract. It is shown that the time needed by a concurrent-read, concurrent-write parallel random access machine (CRAM) to check if an input has a certain property is the same as the minimal depth of a first-order inductive definition of the property. This in turn is equal to the number of "iterations" of a first-order sentence needed to express the property.

The second contribution of this paper is the introduction of a purely syntactic uniformity notion for circuits. It is shown that an equivalent definition for the uniform circuit classes AC^i, $i \geq 1$ is given by first-order sentences "iterated" $\log^i n$ times. Similarly, uniform AC^0 is defined to be the first-order expressible properties (which in turn is equal to constant time on a CRAM by our main theorem). A corollary of our main result is a new characterization of the Polynomial-Time Hierarchy (PH): PH is equal to the set of languages accepted by a CRAM using exponentially many processors and constant time.

Key words. computational complexity, parallel complexity, first-order expressibility, polynomial-time hierarchy

AMS(MOS) subject classification. 68025

1. Introduction.

Parallel time on a random access machine has a surprisingly simple mathematical definition involving well-studied objects of mathematical logic. We show that the time needed by a concurrent-read, concurrent-write parallel random access machine (CRAM) to check if an input has a certain property is the same as the minimal depth of a first-order inductive definition of the property. This in turn is equal to the number of "iterations" of a first-order sentence needed to express the property.

We now state our main result. (See §2 for relevant definitions. In particular, the iteration of a first-order sentence is defined in §2.2, and the CRAM is defined in §2.3. The definition of the CRAM differs from the standard definition of the CRCW PRAM in [17] only in that a processor may shift a word of local memory by any polynomial number of bits in unit time. It follows from our results that for parallel time greater than or equal to $\log n$ there is no distinction between the models with and without the Shift instruction.)

THEOREM 1.1. *Let S be a set of structures of some vocabulary τ. For example, S is a set of boolean strings, or a set of graphs, etc. For all polynomially bounded, parallel time constructible $t(n)$, the following are equivalent:*

1. *S is recognizable by a* CRAM *in parallel time $t(n)$, using polynomially many processors.*

2. *There exists a first-order sentence φ such that the property S for structures of size at most n is expressed by φ iterated $t(n)$ times.*

3. *S is definable as a uniform first-order induction whose depth, for structures of size n, is at most $t(n)$.*

For $t(n) \geq \log n$, the equivalence of (1) and (2) in Theorem 1.1 may also be obtained by combining a result of Ruzzo and Tompa relating CRAMs to alternating Turing machines [17, Thm. 3], together with a result of ours relating alternating Turing machines to first-order expressibility [9, Thm. B.4]. In order to prove the

† Computer Science Department, Yale University, New Haven, Connecticut 06520.

theorem for $t(n) < \log n$, we were forced to modify the models slightly, adding the Shift operation to the CRAMs and adding BIT as a new logical relation to our first-order language (see §2). We believe that the naturalness of Theorem 1.1 justifies these modifications.

This paper is organized as follows. In §2 we give all relevant definitions. In §3 we prove our main result. In §4 we give a more detailed analysis of the bounds in Theorem 1.1. We show that the number of distinct variables in a first-order inductive definition is closely tied to the number of processors in the corresponding CRAM.

Until now, a principal unaesthetic feature of the theory of complexity via boolean circuits was that one had resorted to Turing machines to define the uniformity conditions for circuits [15]. As a corollary to Theorem 1.1, we obtain a purely syntactic uniformity notion for circuits. In §5 we describe this result as well as other relations between circuits and first-order complexity.

As another corollary to Theorem 1.1, we present in §6 a new characterization of the Polynomial-Time Hierarchy (PH): PH is equal to the set of languages recognized by a CRAM using exponentially many processors and constant time. In §7 we give some suggestions for future work in this area.

2. Background and definitions.

2.1. First-order logic. We begin this section by making some precise definitions concerning first-order logic. For more information see [4].

A *vocabulary* $\tau = \langle \underline{R}_1^{a_1}, \cdots, \underline{R}_k^{a_k}, \underline{c}_1, \cdots, \underline{c}_r \rangle$ is a tuple of relation symbols and constant symbols. $\underline{R}_i^{a_i}$ is a relation symbol of arity a_i. In the sequel we will usually omit the superscripts and the underlines to improve readability. A finite *structure* of vocabulary τ is a tuple, $\mathcal{A} = \langle \{0, 1, \cdots, n-1\}, R_1^{\mathcal{A}}, \cdots, R_k^{\mathcal{A}}, c_1^{\mathcal{A}}, \cdots, c_r^{\mathcal{A}} \rangle$, consisting of a universe $|\mathcal{A}| = n = \{0, \cdots, n-1\}$ and relations $R_1^{\mathcal{A}}, \cdots, R_k^{\mathcal{A}}$ of arities $a_1, \cdots, a_k$ on $|\mathcal{A}|$ corresponding to the relation symbols $\underline{R}_1^{a_1}, \cdots, \underline{R}_k^{a_k}$ of τ, and constants $c_1^{\mathcal{A}}, \cdots, c_r^{\mathcal{A}}$ from $|\mathcal{A}|$ corresponding to the constant symbols $\underline{c}_1, \cdots, \underline{c}_r$ from τ.

For example, a graph on n vertices, $G = \langle \{0 \cdots n-1\}, E \rangle$, is a structure whose vocabulary $\tau_0 = \langle \underline{E}^2 \rangle$ has a single binary relation symbol. Similarly, a binary string of length n is a structure $S = \langle \{0 \cdots n-1\}, M \rangle$, whose vocabulary $\tau_1 = \langle \underline{M}^1 \rangle$ consists of a single unary relation symbol. Here the ith bit of S is 1 if and only if $S \models M(i)$.

Let the symbol "$\leq$" denote the usual ordering on the natural numbers. We will include $\leq$ as a logical relation in our first-order languages. This seems necessary in order to simulate machines whose inputs are structures given in some order. It is convenient to include logical constant symbols, $0, 1, \cdots$, referring to the zeroth, first, etc., elements of the universe, respectively. (If the universe is smaller than a given constant, then interpret that constant as 0.) We also include the logical predicate BIT, where $\mathrm{BIT}(x, y)$ holds if and only if the xth bit in the binary expansion of y is a one.[1]

We now define the *first-order language* $\mathcal{L}(\tau)$ to be the set of formulas built up from the relation and constant symbols of τ and the logical relation and constant symbols, $=, \leq, \mathrm{BIT}, 0, 1, \cdots$, using logical connectives, $\wedge, \vee, \neg$, variables, $x, y, z, \cdots$, and quantifiers, $\forall, \exists$.

We will think of a *problem* as a set of structures of some vocabulary τ. It suffices to consider only problems on binary strings, but it is more interesting to be able to talk about other vocabularies, e.g., graph problems, as well. For definiteness, we will

[1] The relation BIT is crucial for the truth of Theorem 1.1, when $t(n) < \log n$, and for the plausibility of Definition 5.5.

fix a scheme for coding an input structure as a binary string. If $\mathcal{A} = \langle \{0, 1, \cdots, n-1\}, R_1^{\mathcal{A}} \cdots R_k^{\mathcal{A}}, c_1^{\mathcal{A}} \cdots c_r^{\mathcal{A}} \rangle$, is a structure of type τ, then $\mathcal{A}$ will be encoded as a binary string $\text{bin}(\mathcal{A})$ of length $I(n) = n^{a_1} + \cdots + n^{a_k} + r\lceil \log n \rceil$, consisting of one bit for each a_i-tuple, potentially in the relation R_i, and $\lceil \log n \rceil$ bits to name each constant, c_j. Thus we reserve n to indicate the size of the universe of the input structure. $I(n)$, the length of $\text{bin}(\mathcal{A})$, is polynomially related to n, and in the case where τ consists of a single unary relation – i.e., inputs are binary strings – $I(n) = n$.

Define the complexity class FO to be the set of all first-order expressible problems. We will see in §5 that FO is a uniform version of the circuit class AC^0. (See also [1], where it is shown that FO is equal to deterministic log time uniform AC^0.)

EXAMPLE 2.1. An example of a first-order expressible property is addition.[2] In order to turn addition into a yes/no question, we can let our input have the vocabulary $\tau_a = \langle A, B, k \rangle$ consisting of two unary relations and a constant symbol. In a structure $\mathcal{A}$ of vocabulary τ_a, the relations A and B are binary strings of length $n = |\mathcal{A}|$. We will say that $\mathcal{A}$ satisfies the addition property if the kth bit of the sum of A and B is one.

In order to express addition, we will first express the carry bit,

$$\text{CARRY}(x) \equiv (\exists y < x)[A(y) \wedge B(y) \wedge (\forall z.y < z < x)A(z) \vee B(z)] .$$

Then with $\oplus$ standing for exclusive or, we can express PLUS,

$$\text{PLUS}(x) \equiv A(x) \oplus B(x) \oplus \text{CARRY}(x) .$$

Thus the sentence expressing the addition property is $\text{PLUS}(k)$.

2.2. Iterating first-order sentences. To describe properties that are not in AC^0, we need languages that are more expressive than FO. We now recall the definition of the complexity classes $\text{FO}[t(n)]$[3]. Intuitively, $\text{FO}[t(n)]$ consists of those problems that may be described by a first-order sentence "iterated $t(n)$ times."

Let x be a variable and M a quantifier-free formula. We will use the notation $(\forall x.M)\psi$ – read, "for all x such that M, ψ," – to abbreviate $(\forall x)(M \rightarrow \psi)$. Similarly we will write $(\exists x.M)\psi$ – read, "there exists an x such that M, ψ," – to abbreviate $(\exists x)(M \wedge \psi)$. We will call the expressions $(\forall x.M)$ and $(\exists x.M)$ *restricted quantifiers.* Let a *quantifier block* be a finite sequence of restricted quantifiers: $\text{QB} = (Q_1 x_1.M_1) \cdots (Q_k x_k.M_k)$. We will use the notation $[\text{QB}]^t$ to denote the quantifier block QB repeated t times. I mean this literally:

$$[\text{QB}]^t = \underbrace{\text{QB}\,\text{QB}\,\text{QB} \cdots \text{QB}}_{t \text{ times}} .$$

Note that for any quantifier-free formulas $M_0, M_1, \cdots, M_k \in \mathcal{L}(\tau)$, and any $i \in \mathbf{N}$, the expression $[\text{QB}]^i M_0$ is a well-formed formula in $\mathcal{L}(\tau)$.

DEFINITION 2.2. Let $t : \mathbf{N} \rightarrow \mathbf{N}$ be any function, and let τ be any vocabulary. A set C of structures of vocabulary τ is a member of $FO[t(n)]$ if and only if there exists a quantifier block QB and a quantifier-free formula M_0 from $\mathcal{L}(\tau)$, such that if we let $\varphi_n = [\text{QB}]^{t(n)} M_0$, for $n = 1, 2, \cdots$, then for all structures G of vocabulary τ with $|G| = n$,

$$G \in C \Leftrightarrow G \models \varphi_n .$$

[2] This is a standard construction, see e.g., [17].

[3] The notation $\text{FO}[t(n)]$ was first used in [12]; however, the same classes were defined in [10] using the notation $\text{IQ}[t(n)]$, standing for "iterated queries." See [13] for a survey of descriptive complexity.

A more traditional way to iterate formulas is by making inductive definitions, [14], [10]. Let IND-DEPTH[$t(n)$] be the set of problems expressible as a uniform induction that requires depth of recursion at most $t(n)$ for structures of size n. In [7], Harel and Kozen introduce a programming language called IND, which is closely tied to inductive definitions. They prove that the execution time for their IND programs is equal to the depth of the inductive definitions that describe the programs' input output behavior. Let IND-TIME[$t(n)$] be the set of languages accepted by IND programs using $O[t(n)]$ steps for inputs of size n. Then:

FACT 2.3 ([7]). *For all $t(n)$,*

$$\text{IND-TIME}[t(n)] = \text{IND-DEPTH}[t(n)] .$$

This fact, together with Theorem 1.1, shows that there is a simple, high-level programming language for which time corresponds exactly to time on a CRAM. In the remainder of this paper we write IND[$t(n)$] to signify IND-TIME[$t(n)$] as well as IND-DEPTH[$t(n)$].

The following fact relates IND[$t(n)$] to FO[$t(n)$]. This fact follows easily from Moschovakis' Canonical Form for Positive Formulas, [14].

FACT 2.4 ([10], [14]). *For all $t(n)$,*

$$\text{IND}[t(n)] \subseteq \text{FO}[t(n)] .$$

(*In particular, a property in* IND[$t(n)$] *is expressible as a* FO[$t(n)$] *property in which* $M_0 \equiv$ *false, cf. Definition* 2.2.)

EXAMPLE 2.5. We show how to transfer a $\log n$ depth inductive definition of the transitive closure of a graph to an equivalent FO[$\log n$] definition.

Let E be the edge predicate for a graph G with n vertices. We can inductively define E^*, the reflexive, transitive closure of G, as follows:

$$E^*(x,y) \equiv x = y \vee E(x,y) \vee (\exists z)(E^*(x,z) \wedge E^*(z,y)) .$$

Let $P_n(x,y)$ mean that there is a path of length at most n from x to y. Then we can rewrite the above definition of E^* as:

$$P_n(x,y) \equiv x = y \vee E(x,y) \vee (\exists z)(P_{n/2}(x,z) \wedge P_{n/2}(z,y)) .$$

This can be rewritten:

$$P_n(x,y) \equiv (\forall z.M_1)(\exists z)(P_{n/2}(x,z) \wedge P_{n/2}(z,y)) ,$$

where $M_1 \equiv \neg(x = y \vee E(x,y))$. Note that there is no free occurrence of the variable z after the $\forall z$ quantifier. Thus, in this case $(\forall z.M_1)\alpha$ is equivalent to $(M_1 \rightarrow \alpha)$. Next,

$$P_n(x,y) \equiv (\forall z.M_1)(\exists z)(\forall uv.M_2)(P_{n/2}(u,v)) ,$$

where $M_2 \equiv (u = x \wedge v = z) \vee (u = z \wedge v = y)$. Now,

$$P_n(x,y) \equiv (\forall z.M_1)(\exists z)(\forall uv.M_2)(\forall xy.M_3)(P_{n/2}(x,y)) ,$$

where $M_3 \equiv (x = u \wedge y = v)$. Thus,

$$P_n(x,y) \equiv [\mathrm{QB}]^{\lceil \log n \rceil}(P_1(x,y)) ,$$

where $\mathrm{QB} = (\forall z.M_1)(\exists z)(\forall uv.M_2)(\forall xy.M_3)$. Note that

$$P_1(x,y) \equiv [\mathrm{QB}](\mathit{false}) .$$

It follows that

$$P_n(x,y) \equiv [\mathrm{QB}]^{\lceil 1+\log n \rceil}(\mathit{false}) ,$$

and thus $E^* \in \mathrm{FO}[\log n]$ as claimed.

2.3. Concurrent random access machines. We define the concurrent random access machine (CRAM) to be essentially the concurrent-read, concurrent-write parallel random access machine (CRCW PRAM) described in [17]. A CRAM is a synchronous parallel machine such that any number of processors may read or write into any word of global memory at any step. If several processors try to write into the same word at the same time, then the lowest-numbered processor succeeds.[4] In addition to assignments, the CRAM instruction set includes addition, subtraction, and branch on less than. Each processor also has a local register containing its processor number.

The difference between the CRAM and the CRCW PRAM described in [17] is that we also include a Shift instruction. Shift(x,y) causes the word x to be shifted y bits to the right. Without Shift, CRAM$[t(n)]$ would be too weak to simulate FO$[t(n)]$ for $t(n) < \log n$. The reason behind the Shift operation for CRAMs and the corresponding BIT predicate for first-order logic is that each bit of global memory should be available to every processor in constant time.

Let CRAM$[t(n)]$ be the set of problems accepted by a CRAM using polynomially many processors and time $O[t(n)]$. Recall that we encode an input structure $\mathcal{A} = \langle \{0,1,\cdots,n-1\}, R_1^{\mathcal{A}},\cdots,R_k^{\mathcal{A}}, c_1^{\mathcal{A}},\cdots,c_r^{\mathcal{A}} \rangle$, as the binary string $\mathrm{bin}(\mathcal{A})$ of length $I(n) = n^{a_1} + \cdots + n^{a_k} + r\lceil \log n \rceil$, Where a_i is the arity of the ith input relation. The input string is placed one bit at a time in the first $I(n)$ global memory locations.[5]

3. Proof of the main theorem. Theorem 1.1 follows immediately from three containments: Fact 2.4, and the following two lemmas.

LEMMA 3.1. *For any polynomially bounded $t(n)$ we have,*

$$\mathrm{CRAM}[t(n)] \subseteq \mathrm{IND}[t(n)] .$$

Proof. We want to simulate the computation of a CRAM M. On input $\mathcal{A}$, a structure of size n, M runs in $t(n)$ synchronous steps, using $p(n)$ processors, for some polynomial $p(n)$. Since the number of processors, the time, and the memory word size are all polynomially bounded, we need only a constant number of variables

[4] This is the "priority write" model. Our results remain true if instead we use the "common write" model, in which the program guarantees that different values will never be written to the same location at the same time. See Corollary 3.4.

[5] We show in Corollary 3.4 that if placement of the input is varied, e.g., if the first $I(n)/\log n$ words of memory contain $\log n$ bits each of the input, or even if all $I(n)$ bits are placed in the first word, then all our results remain unchanged. Note that this is not true of the models used in [2], for example. There processors are assumed to have unlimited power and thus the partition of the inputs is crucial.

$x_1, \cdots, x_k$, each ranging over the n element universe of $\mathcal{A}$, to name any bit in any register belonging to any processor at any step of the computation. We can thus define the contents of all the relevant registers for any processor of M, by induction on the time step.

We now specify the CRAM model more precisely. We may assume that each processor has a finite set of registers including the following: Processor, containing the number between 1 and $p(n)$ of the processor; Address, containing an address of global memory; Contents, containing a word to be written into or read from global memory; and Program_Counter, containing the line number of the instruction to be executed next. The instructions to be simulated are limited to the following:

- READ: Read the word of global memory specified by Address into Contents.
- WRITE: Write the Contents register into the global memory location specified by Address.
- OP $R_a\, R_b$: Perform OP on R_a and R_b, leaving the result in R_b. Here OP may be Add, Subtract, or Shift.
- MOVE $R_a\, R_b$: Move R_a to R_b.
- BLT $R\, L$: Branch to line L if the contents of R is less than zero.

It is straightforward to write a first-order inductive definition for the relation VALUE$(\overline{p}, \overline{t}, \overline{x}, r, b)$ meaning that bit $\overline{x}$ in register r of processor $\overline{p}$ just after step $\overline{t}$ is equal to b. Note that since the number of processors, the time, and the word size are all polynomially bounded, a constant number of variables ranging from 0 to $n-1$ suffice to specify each of these values.

The inductive definition of the relation VALUE$(\overline{p}, \overline{t}, \overline{x}, r, b)$ is a disjunction depending on the value of $\overline{p}$'s program counter at time $\overline{t}-1$. The most interesting case is when the instruction to be executed is READ. Here we simply find the most recent time $\overline{t'} < \overline{t}$ at which the word specified by $\overline{p}$'s Address register at time $\overline{t}$ was written into, and the lowest-numbered processor $\overline{p'}$ that wrote into this address at time $\overline{t'}$. In this way we can access the answer, namely, the $\overline{x}$th bit of $\overline{p'}$s Contents register at time $\overline{t'}$.

It remains to check that Addition, Subtraction, BLT, and Shift are first-order expressible, and that we can express the fact that each processor begins with its own processor number in its Processor register. Addition was done in Example 2.1. In a similar way we can express Subtraction, and Less Than. The main place we need the BIT relation is to express the fact that the initial contents of each processor's Processor register is its processor number. The relation BIT allows us to translate between variable numbers and words in memory. Using BIT we can also express addition on variable numbers and thus express the Shift operation.

Thus we have described an inductive definition of the relation VALUE, coding M's entire computation. Furthermore, one iteration of the definition occurs for each step of M. □

LEMMA 3.2. *For polynomially bounded, and parallel time constructible $t(n)$,*

$$\mathrm{FO}[t(n)] \subseteq \mathrm{CRAM}[t(n)] .$$

Proof. Let the FO$[t(n)]$ problem be determined by the following quantifier-free formulas and quantifier block,

$$M_0, M_1, \cdots, M_k, \quad \mathrm{QB} = (Q_1 x_1.M_1) \cdots (Q_k x_k.M_k) .$$

Our CRAM must test whether an input structure $\mathcal{A}$ satisfies the sentence,

$$\varphi_n \equiv [\mathrm{QB}]^{t(n)} M_0 .$$

The CRAM will use n^k processors and n^{k-1} bits of global memory. Note that each processor has a number $a_1 \cdots a_k$ with $0 \leq a_i < n$. Using the Shift operation it can retrieve each of the a_is in constant time.[6]

The CRAM will evaluate φ_n from right to left, simultaneously for all values of the variables $x_1, \cdots, x_k$. For $0 \leq r \leq t(n) \cdot k$, let

$$\varphi_n^r \equiv (Q_i x_i . M_i) \cdots (Q_k x_k . M_k)[\mathrm{QB}]^q M_0 ,$$

where $r = k \cdot (q+1) + 1 - i$. Let $x_1 \cdots \hat{x}_i \cdots x_k$ be the $k-1$-tuple resulting from $x_1 \cdots x_k$ by removing x_i. We will now give a program for the CRAM which is broken into rounds, each consisting of three processor steps such that:

(*) Just after the rth round, the contents of memory location $a_1 \cdots \hat{a}_i \cdots a_k$ is 1 or 0 according to whether $\mathcal{A} \models \varphi_n^r(a_1, \cdots, a_k)$.

Note that x_i is not free in φ_n^r! At the rth round, processor number $a_1 \cdots a_k$ executes the following three instructions according to whether $Q_i = \exists$ or $Q_i = \forall$:

$\{Q_i = \exists\}$

1. $b \leftarrow \mathrm{loc}(a_1 \cdots \hat{a}_{i+1} \cdots a_k)$;
2. $\mathrm{loc}(a_1 \cdots \hat{a}_i \cdots a_k) \leftarrow 0$;
3. if $M_i(a_1, \cdots, a_k)$ and b then $\mathrm{loc}(a_1 \cdots \hat{a}_i \cdots a_k) \leftarrow 1$;

$\{Q_i = \forall\}$

1. $b \leftarrow \mathrm{loc}(a_1 \cdots \hat{a}_{i+1} \cdots a_k)$;
2. $\mathrm{loc}(a_1 \cdots \hat{a}_i \cdots a_k) \leftarrow 1$;
3. if $M_i(a_1, \cdots, a_k)$ and $\neg b$ then $\mathrm{loc}(a_1 \cdots \hat{a}_i \cdots a_k) \leftarrow 0$;

It is not hard to prove by induction that (*) holds, and thus that the CRAM simulates the formula. □

REMARK 3.3. The proof of Lemma 3.2 provides a very simple network for simulating a FO[$t(n)$] property. The network has n^{k-1} bits of global memory and kn^k gates, where k is the number of distinct variables in the quantifier block. Each gate of the network is connected to two bits of global memory in a simple connection pattern. The blowup of processors going from CRAM to FO to CRAM seems large (cf. Corollary 4.1); however, it is plausible to build first-order networks with billions of processing elements, i.e., gates, thus accommodating fairly large n and moderately large k.

An immediate corollary of Theorem 1.1 is that the complexity class CRAM[$t(n)$] is not affected by minor changes in how the input is arranged, nor in the global memory word size, nor even by a change in the convention on how write conflicts are resolved.

COROLLARY 3.4. *For any function $t(n)$, the complexity class* CRAM[$t(n)$] *is not changed if we modify the definition of a* CRAM *in any consistent combination of the following ways. (By consistent we mean that we don't allow input words larger than the global word size, nor larger than the allowable length of applications of Shift.)*

1. *Change the input distribution so that either* (a) *the entire input is placed in the first word of global memory, or* (b) *the $I(n)$ bits of input are placed* $\log n$ *bits at a time in the first $I(n)/\log n$ words of global memory.*

2. *Change the global memory word size so that either* (a) *the global word size is one, i.e., words are single bits (local registers do not have this restriction so that*

[6] This is obvious if n is a power of 2. If not, we can just let each processor break its processor number into k $\lceil \log n \rceil$-tuples of bits. If any of these is greater than or equal to n, then the processor should do nothing during the entire computation.

the processor's number may be stored and manipulated); or (b) *the global word size is bounded by* $O[\log n]$.

3. *Modify the Shift operation so that shifts are limited to the maximum of the input word size and of the log base 2 of the number of processors.*

4. *Remove the polynomial bound on the number of memory locations, thus allowing an unbounded global memory.*

5. *Instead of the priority rule for the resolution of write conflicts, adopt the common write rule in which different processors never write different values into the same memory location at a given time step.*

Proof. The proof is that Lemmas 3.1 and 3.2 still hold with any consistent set of these modifications. This is immediate for Lemma 3.1. For Lemma 3.2, we must only show that processor number $a_1 \cdots a_k$ still has the power in constant time to evaluate the quantifier-free formula $M_i(a_1, \cdots, a_k)$, and to name the global memory location $a_1 \cdots \hat{a}_i \cdots a_k$, for $1 \leq i \leq k$. Recall that we are assuming that the input structure $\mathcal{A} = \langle \{0, 1, \cdots, n-1\}, R_1^{\mathcal{A}}, \cdots, R_p^{\mathcal{A}}, c_1^{\mathcal{A}}, \cdots, c_q^{\mathcal{A}} \rangle$ is coded as a bit string of length $I(n) = n^{r_1} + \cdots + n^{r_p} + q\lceil \log n \rceil$. It is clear that all of the consistent modifications above allow processor $a_1 \cdots a_k$ to test in constant time whether or not the relation $R(t_1, \cdots, t_r)$ holds, where R is an input or logical relation, and $t_j \in \{a_1, \cdots, a_k\} \cup \{c_j | 1 \leq j \leq q\}$. □

4. On the efficiency of the simulations. In this section we analyze the proof of Theorem 1.1 in more detail in order to give the following bounds for translating between CRAM and IND. After we prove Corollary 4.1, we discuss the cost of the simulation, and how these bounds can be improved. The proofs in this section involve counting how many variables are needed in various first-order formulas. This whole section should be omitted by the casual reader.

COROLLARY 4.1. *Let* CRAM$[t(n)]$-PROC$[p(n)]$ *be the complexity class* CRAM $[t(n)]$ *restricted to machines using at most* $O[p(n)]$ *processors. Let* IND$[t(n)]$-VAR$[v(n)]$ *be the complexity class* IND$[t(n)]$ *restricted to inductive definitions using at most* $v(n)$ *distinct variables. Assume for simplicity that the maximum size of a register word, and* $t(n)$ *are both* $o[\sqrt{n}]$, *and that* $\pi \geq 1$ *is a natural number. Then,*

$$\begin{aligned} &\text{CRAM}[t(n)]\text{-PROC}[n^{\pi}] \\ &\qquad \subseteq \quad \text{IND}[t(n)]\text{-VAR}[2\pi + 2] \\ &\qquad\qquad \subseteq \quad \text{CRAM}[t(n)]\text{-PROC}[n^{2\pi+2}]. \end{aligned}$$

Proof. We prove these bounds using the following two lemmas.

LEMMA 4.2. *If the maximum size of a register word, and* $t(n)$ *are both* $o[\sqrt{n}]$, *and if* M *is a* CRAM$[t(n)]$-PROC$[n^{\pi}]$ *machine, then the inductive definition of* VALUE *may be written using* $2\pi + 2$ *variables.*

Proof. We write out the inductive definition of VALUE in enough detail to count the number of variables used:

$$\text{VALUE}(\bar{p}, t, x, r, b) \equiv Z \vee W \vee S \vee R \vee M \vee B \vee A\,,$$

where the disjuncts have the following intuitive meanings:

Z: $t = 0$ and the initial value of r is correct.

W: $t \neq 0$ and the instruction just executed is WRITE, and the value of r is correct, i.e., unchanged unless r is Program_Counter.

S, R, M, B, A: Similarly for SHIFT, READ, MOVE, BLT, and, ADD or SUBTRACT, respectively.

It suffices to show that each disjunct can be written using the number of variables claimed. First we consider the disjunct Z. The only interesting part of Z is the case where r is "Processor". In this case we use the relation BIT to say that $b = 1$ if and only if the xth bit of $\overline{p}$ is 1. No extra variables are needed. Note that the number of free variables in the relation is $\pi + 1$ because we may combine the values t, x, r, and b into a single variable.

Next we consider the case of Addition. Recall that the main work is to express the carry bit:

$$C[A,B](x) \equiv (\exists y < x)[A(y) \wedge B(y) \wedge (\forall z.y < z < x)A(z) \vee B(z)] .$$

This definition uses two extra variables. Thus $\pi + 3 \leq 2\pi + 2$ variables certainly suffice. The cases S, M, and B are simpler.

The last, and most interesting case is R. Here we must say,

1. The instruction just executed is READ,
2. Register r is the Contents register,
3. There exists a processor $\overline{p'}$ and a time t' such that:
   (a) $t' < t$,
   (b) Address$(\overline{p'}, t')$ =Address$(\overline{p}, t)$,
   (c) VALUE$(\overline{p'}, t', x, r, b)$,
   (d) Processor $\overline{p'}$ wrote at time t',
   (e) For all $\overline{p''} < \overline{p'}$, if $\overline{p''}$ wrote at time t', then Address$(\overline{p''}, t') \neq$Address$(\overline{p'}, t')$,
   (f) For all t'' such that $t' < t'' < t$ and for all $\overline{p''}$, if $\overline{p''}$ wrote at time t'', then Address$(\overline{p''}, t'') \neq$Address$(\overline{p'}, t')$.

Let's count variables. On its face this formula uses three $\overline{p}$'s and three t's. However, two copies of each suffice. Observe that where we quantify $\overline{p''}$ in lines 3e and 3f, we no longer need $\overline{p}$, so we may use these variables instead. Similarly, when we quantify t'' on line 3f, we don't need $\overline{p''}$ so we may temporarily use one of its variables for t''. Finally, we would seem to need an extra variable to say "Address$(\overline{p''}, t'') \neq$Address$(\overline{p'}, t')$," in 3f. Here we use the fact that t is $o[\sqrt{n}]$, so t' and t'' can be coded into a single variable. Then with one more variable we can say that there exists a bit on which Address$(\overline{p''}, t'')$ and Address$(\overline{p'}, t')$ disagree. Thus $2\pi + 2$ variables suffice as claimed. □

The second lemma we need (Lemma 4.3) is a refinement of Lemma 3.2.

LEMMA 4.3. *Let $\varphi(R, \overline{x})$ be an inductive definition of depth $d(n)$. Let k be the number of distinct variables including $\overline{x}$ occurring in φ. Then the relation defined by φ is also computable in* CRAM$[d(n)]$-PROC$[O[n^k]]$.

Proof. This is very similar to the proof of Lemma 3.2. Let T be the parse tree of φ. The CRAM will have $n^k|T|$ processors: one for each value of the k variables and each node in T. Let δ be the depth of T. In rounds consisting of 3δ steps, the CRAM will evaluate an iteration of φ. Let $r =$ arity$(R) =$ the number of variables in $\overline{x}$; so $r \leq k$. The CRAM will have n^r bits of global memory to hold the truth value of $R_t = \varphi^t(\emptyset)$. It will use an additional $n^k|T|$ bits of memory to store the truth values corresponding to nodes of T. Thus $R_{d(n)}$, the least fixed point of φ, is computed in time $O[d(n)]$, using $O[n^k]$ processors, as claimed. □

This completes the proof of Corollary 4.1. □

The above proofs give us some information concerning the efficiency of our simulation of CRAMs with first-order inductive definitions. The main questions is, "Why is the number of variables needed to express a computation of n^π processors $2\pi + 2$,

instead of π?" We discuss the multiplicative factor of two, and the additional two variables, respectively in the next two paragraphs.

We need the 2π term for two reasons: we must specify $\overline{p}$ and $\overline{p'}$ at the same time in order to say that their Address registers are equal; and we need to say that no lower-numbered processor $\overline{p''}$ wrote into the same address as $\overline{p'}$. This term points out a difference between the CRAM model and the network described in Remark 3.3 that was used to simulate a FO$[t(n)]$ property. The factor of two would be eliminated if we adopted a weaker parallel machine model allowing only common writes[7], and such that the memory location accessed by a processor could be determined by a very simple computation on the processor number.

The additional two variables arise for various bookkeeping reasons. This term can be significantly reduced if we make the following two changes:

1. Rather than keeping track of all previous times, we can assume that every bit of global memory is written into at least every T time steps for some constant T.

2. The register size can be restricted to $O[\log n]$ so we need only $O[\log \log n]$ bits to name a bit of a word.

REMARK 4.4. The above observations show that the relation between the number of variables needed to give an inductive definition of a relation, and the logarithm to the base n of the number of processors needed to quickly compute the relation are nearly identical. The cost of programming with first-order inductive definitions rather than CRAMs is theoretically very small. More work and even some experimentation must be done before one can say whether or not this will turn out to be a practical approach.

5. NC versus FO. In this section we relate the uniform NC circuit classes to FO$[t(n)]$, and we derive a completely syntactic definition for circuit uniformity. We show that our definition is equivalent to the usual Turing machine-based definition in the range where the latter exists.

Let NC^i (respectively, AC^i) be the set of problems recognizable by a uniform sequence of polynomial size, bounded fan-in (respectively, unbounded fan-in) boolean circuits of depth $\log^i n$. Let $\mathrm{NC} = \mathrm{AC} = \bigcup_i \mathrm{NC}^i$. Ruzzo characterized these uniform circuit classes in terms of alternating Turing machines:

FACT 5.1 ([15]). *For $i \geq 1$,*

$$\begin{aligned} \mathrm{NC}^i &= \mathit{ASPACE\text{-}TIME}[\log n, \log^i n] , \\ \mathrm{AC}^i &= \mathit{ASPACE\text{-}ALT}[\log n, \log^i n] . \end{aligned}$$

Ruzzo and Tompa proved the following relationship between the uniform AC classes and the CRAM :

FACT 5.2 ([17]). *For $i \geq 1, \mathrm{AC}^i = \mathrm{CRAM}[\log^i n]$.*

The following corollary of Theorem 1.1 and Fact 5.2 shows that the uniformity condition for the AC^i circuit classes can be described in a syntactic way. A first-order sentence iterated $t(n)$ times is also an AC circuit "iterated" $t(n)$ times. Thus we no longer need to mention machines when discussing uniform circuit complexity.

COROLLARY 5.3. *For $i \geq 1$, $\mathrm{AC}^i = \mathrm{FO}[\log^i n]$.*

Before now there was no satisfactory definition for uniform AC^0. It is easy to see that a first-order sentence corresponds to a particularly simple sequence of AC^0

[7] See [6] for an earlier proof that a common write machine can simulate a CRAM with a linear increase in time and a squaring of the number of processors.

circuits. Each quantifier $\exists x$ (respectively, $\forall x$) is just an n-ary "or" (respectively, "and"). In [11] we showed that an appropriate way to make first-order sentences nonuniform is to add an arbitrary new logical relation. The following fact says that nonuniform AC^0 is equal to nonuniform FO.[8]

FACT 5.4 ([11]). *Given a problem S and an integer $d > 1$ the following are equivalent:*

1. *S is recognized by a sequence of depth $d+1$, polynomial-size circuits, with bounded fan-in at the bottom level.*

2. *There exists a new logical relation $R \subset \mathbf{N}^a$ and a first-order formula φ in which R occurs such that φ expresses S. The formula φ contains d alternating blocks of quantifiers.*

In view of the above results, we propose the following:

DEFINITION 5.5. Let (uniform) $AC^0 \stackrel{\text{def}}{=} FO[1] = CRAM[1]$.

Since we first made this suggestion, much evidence concerning the appropriateness of Definition 5.5 has appeared. In particular, see [1] for a study of low-level uniformity. It is shown there that FO is equal to deterministic log time uniform AC^0.

In [11] we introduced the notion of first-order translations. These reductions consist of a fixed first-order formula translating all instances of one problem to instances of another. (First-order translations are interpretations between theories, cf. [4], that are also reductions in the complexity theoretic sense.) It follows from Definition 5.5 that first-order translations are exactly uniform AC^0 reductions.

One way to evaluate the appropriateness of Definition 5.5 is to examine examples of AC^0 reductions in the literature and see whether or not they can be made uniform. Of those we have considered, the answer is yes, with the following interesting exception. (The UGAP problem is the set of undirected graphs for which there exists a path from vertex 0 to vertex $n-1$.)

FACT 5.6 ([3]). UGAP *is nonuniform* AC^0 *reducible to* UNDIR-CYCLE.

Now UNDIR-CYCLE is in DSPACE[$\log n$] [8], but UGAP is not known to be in DSPACE[$\log n$]. Of course,

REMARK 5.7. If UGAP is uniform AC^0 reducible to UNDIR-CYCLE, then UGAP is in DSPACE[$\log n$].

We mention one more interesting justification of Definition 5.5. In [3] it is shown that the obvious bounds,

$$\text{nonuniform } NC^i \subseteq \text{nonuniform } AC^i$$

can be improved to

FACT 5.8 ([3]).

$$\text{nonuniform } NC^i \subseteq \text{nonuniform AC-DEPTH}[\log^i n/\log\log n].$$

When $i = 1$ this bound is optimal because nonuniform AC-DEPTH[$\log n/\log\log n$] is necessary for Parity [18]. We next show that the same bound holds in the uniform case:

THEOREM 5.9. *For $t(n) \geq \log n$,*

$$\text{ASPACE}[\log n] - \text{TIME}[t(n)] \subseteq \text{FO}[t(n)/\log\log n].$$

[8] In [17] Stockmeyer and Vishkin showed that nonuniform AC^0 is equal to constant time on a nonuniform CRAM. This, together with Fact 5.4, gives a nonuniform version of Theorem 1.1.

Proof. This is a $\log\log n$ factor improvement of Theorem B.3 in [9]. There we showed how to code a log space Turing machine configuration using a constant number of variables, as well as how to write the predicate $M_1(\bar{x},\bar{y})$, meaning that $\langle \bar{x},\bar{y}\rangle$ is a valid move of the given alternating Turing machine. We could then inductively define the predicate $\text{Accept}_t(\bar{x})$, meaning that the configuration $\bar{x}$ leads to acceptance in the sense of alternating Turing machines in t steps:

$$\text{Accept}_t(\bar{x}) \equiv (\exists \bar{y}.M_1(\bar{x},\bar{y}))(\forall \bar{z}.M_2)\text{Accept}_{t-1}(\bar{z}) ,$$

where $M_2 \equiv (\bar{z}=\bar{y}) \vee (\text{“}\bar{x} \text{ is universal”} \wedge M_1(\bar{x},\bar{z}))$.

To improve this simulation by a $\log\log n$ factor, observe that a list of which existential moves to make in the event of each possible sequence of $(\log\log n)/2$ universal moves can be given in $\log n$ bits. Thus we can write

$$\text{Accept}_t(\bar{x}) \equiv (\exists e \forall u)(\exists \bar{z})(R \wedge \text{Accept}_{t-\log\log n}(\bar{z})) , \tag{1}$$

where R says that $\bar{z}$ follows from $\bar{x}$ in the $\log\log n$ moves determined by e and u.

Now it is easy to write an inductive definition of R whose depth is $\log\log n$. This definition uses the BIT predicate to decode from e and u which of the possible two moves the Turing machine makes at each of the $\log\log n$ steps. The simultaneous inductive definition of Accept is given in Equation 1. Obviously its depth is $\log n/\log\log n$. □

COROLLARY 5.10. *For $i \geq 1$, $\text{NC}^i \subseteq \text{FO}[\log^i n/\log\log n]$.*

6. The polynomial-time hierarchy. In second-order logic we have first-order logic, plus new relation variables over which we may quantify. Let A_i^j be a j-ary relation variable. Then $(\forall A_i^j)\varphi$ means that for all choices of j-ary relation A_i^j, φ holds. It is well known that second-order formulas may be transformed into prenex form, with all second-order quantifiers in front. Let SO be the set of second-order expressible properties, and let (SO $\exists$) be the set of second-order properties that may be written in prenex form with no universal second-order quantifiers. Fagin gave the following interesting characterization of nondeterministic polynomial-time (NP) in terms of logical expressibility:

FACT 6.1 ([5]). (SO$\exists$) = NP .

A few years later, when he defined the polynomial-time hierarchy (PH), Stockmeyer showed that it coincided with the set of second-order expressible properties:

FACT 6.2 ([16]). PH = SO.

As a corollary to Fact 6.2 and Theorem 1.1, we obtain the following characterization of PH as a parallel complexity class:

COROLLARY 6.3. PH *is equal to the set of properties checkable by a* CRAM *using exponentially many processors and constant time*[9]*:*

$$\text{PH} = \bigcup_{k=1}^{\infty} \text{CRAM[1]-PROC}[2^{n^k}] .$$

Proof. The inclusion $\text{SO} \subseteq \text{CRAM[1]-PROC}[2^{n^{O(1)}}]$ follows just as in the proof of Lemma 3.2. A processor number is now large enough to give values to all the

[9] Up to this point we had been assuming for notational simplicity that a CRAM has at most polynomially many processors. However, the class CRAM[$t(n)$]-PROC[$p(n)$] still makes sense for numbers of processors $p(n)$ that are not polynomially bounded.

relational variables as well as to all the first-order variables. Thus, as in Lemma 3.2, the CRAM can evaluate each first or second-order quantifier in three steps.

The inclusion CRAM[1]-PROC[$2^{n^{O(1)}}$] $\subseteq$ SO follows just as in the proof of Lemma 3.1. The only difference is that we use second-order variables to specify the processor number. □

7. Conclusions. To recapitulate, we have shown that parallel time has a simple mathematical definition: the minimal parallel time needed to compute a property using at most polynomially many processors is equal to the minimum depth of a first-order inductive definition of the property. Furthermore, the number of processors needed by the CRAM is closely tied to the number of variables needed in the inductive definition. We have also given purely syntactic definitions for uniformity of the circuit complexity classes AC^i, $i \geq 0$. Finally, we have given a striking, new characterization of the polynomial-time hierarchy. We believe that these results help to explain the nature of parallel complexity and will lead to an improved understanding of the subject.

There is much work to be done. The following general directions suggest themselves:

1. This paper provides a new way to think about parallel programming. The programmer provides efficient inductive definitions of the problem to be solved. Our simulation results then automatically give an efficient implementation on a CRAM. Much work is needed to explore whether or not this approach is practical.

2. We have given characterizations of parallel time and number of processors in terms of the depth and number of variables in inductive definitions. One should now develop upper and lower bounds on these parameters for all sorts of problems. We also feel that the analysis of the simulation in §4 can and should be improved.

3. There are many fascinating questions concerning uniformity and the power of precomputation. We hope that the notion of syntactic uniformity of circuits will help researchers determine when precomputation/nonuniformity can help; or, to prove lower bounds on what can be done by uniform circuits and formulas.

Acknowledgments. Thanks to Steve Cook, Steven Lindell, Ruben Michel, and Larry Ruzzo, who contributed comments and corrections to previous drafts of this paper.

MATRIX PADÉ FRACTIONS AND THEIR COMPUTATION*

GEORGE LABAHN† AND STAN CABAY‡

Abstract. For matrix power series with coefficients over a field, the notion of a matrix power series remainder sequence and its corresponding cofactor sequence are introduced and developed. An algorithm for constructing these sequences is presented.

It is shown that the cofactor sequence yields directly a sequence of Padé fractions for a matrix power series represented as a quotient $B(z)^{-1}A(z)$. When $B(z)^{-1}A(z)$ is normal, the complexity of the algorithm for computing a Padé fraction of type (m, n) is $O(p^3(m+n)^2)$, where p is the order of the matrices $A(z)$ and $B(z)$.

For a power series that are abnormal for a given (m, n), Padé fractions may not exist. However, it is shown that a generalized notion of Padé fraction, the Padé form, which is introduced in this paper, does always exist and can be computed by the algorithm. In the abnormal case, the algorithm can reach a complexity of $O(p^3(m+n)^3)$, depending on the nature of the abnormalities. In the special case of a scalar power series, however, the algorithm complexity is $O((m+n)^2)$, even in the abnormal case.

1. Introduction.

Let

$$A(z) = \sum_{i=0}^{\infty} a_i z^i, \tag{1.1}$$

where a_i, $i = 0, \cdots$, is a $p \times p$ matrix with coefficients from a field K, be a formal power series. Loosely speaking, a matrix Padé approximant of $A(z)$ is an expression of the form $U(z) \cdot V(z)^{-1}$, or $V(z)^{-1} \cdot U(z)$, where $U(z)$ and $V(z)$ are matrix polynomials of degree at most m and n, respectively, whose expansion agrees with $A(z)$ up to and including the term z^{m+n}.

The definition of a Padé approximant can be made more formal in a variety of ways. For example, Rissanen [17] restricts $V(z)$ to be a scalar polynomial and allows $U(z)$ to be a $p \times q$ matrix. Typically, however, $U(z)$ and $V(z)$ are $p \times p$ polynomial matrices, and $V(z)$ is further restricted by the condition that the constant term, $V(0)$, is invertible (cf., Bose and Basu [2], Bultheel [5], and Starkand [19]). In this paper, we call such approximants matrix Padé fractions, which is consistent with the scalar $(p = 1)$ case (cf., Gragg [12]).

For a particular m and n, however, matrix Padé fractions need not exist. Therefore, in this paper, we introduce the notion of a matrix Padé form, in which the condition of invertibility of $V(0)$ is relaxed. The definition is a generalization of a similar one given for the scalar case (cf., Gragg [12]). It is shown that matrix Padé forms always exist, but that they may not be unique. In general, matrix Padé forms need not have an invertible denominator, $V(z)$. However, for m and n given, by obtaining a basis for all the Padé forms, we are also able to construct a matrix Padé form with an invertible denominator, $V(z)$, in the case that one does exist.

Padé approximants have many applications in mathematics and in engineering-related disciplines. Applications include numerical computations for special power series such as the Gamma function (cf., Nemeth and Zimanyi [15]); algorithms in the field of numerical analysis (cf., Gragg [12]); triangulation of block Hankel and Toeplitz matrices (cf., Rissanen [18]); solving linear systems of equations with Hankel of Toeplitz coefficient matrices (cf., Rissanen [16]); in digital filtering theory (cf., Bultheel [7] and Brophy and Salazar [4]; and also in linear control theory (cf., Elgerd [11]).

In the one-dimensional case, examples of algorithms that calculate Padé approximants for normal power series (Gragg [12]) include the ε-algorithm of Wynn [21]; the Levinson–Durbin algorithm [10], [14]; and the algorithm of Trench [20]. Examples of algorithms that are successful in the degenerate nonnormal case include those given by Brent, Gustavson, and Yun [3]; Bultheel [6]; Cabay and Choi [8]; and Rissanen [16].

The matrix case parallels the scalar situation in that most algorithms are restricted to normal power series. Algorithms that require the normality condition include those of Bultheel [5], Bose and Basu [2], Starkand [19], and Rissanen [18]. An algorithm that calculates Padé approximants in a nonnormal case is given by Labahn [13]. However, in his algorithm there are still strict conditions that need to be satisfied by the power series before Padé approximants can be calculated.

The primary contribution of this paper is an algorithm, MPADE, for computing matrix Padé forms for a matrix power series. Central to the development of MPADE are the notions of a matrix power series remainder sequence and the corresponding cofactor sequence, which are introduced in § 4. These are generalizations of notions developed by Cabay and Kossowski [9] for power series over an integral domain. The cofactor sequence computed by MPADE yields a sequence of matrix Padé fractions along a specific off-diagonal path of the Padé table for $A(z)$.

Unlike other algorithms, there are no restrictions placed on the power series in order that MPADE succeed. For normal power series, the complexity of MPADE is $O(p^3 \cdot (m+n)^2)$ operations in K. This is the same complexity as some of the algorithms proposed by Bultheel [5], Bose and Basu [2], Starkand [19], and Rissanen [18]. In the abnormal case, the complexity of the algorithm can reach $O(p^3 \cdot (m+n)^3)$ operations in K, depending on the nature of the abnormalities.

2. Matrix Padé forms. Let $A(z)$ and $B(z)$ be formal power series

$$A(z) = \sum_{i=0}^{\infty} a_i z^i, \qquad B(z) = \sum_{i=0}^{\infty} b_i z^i \tag{2.1}$$

with coefficients from the ring of $p \times p$ matrices over some field K. Throughout this paper it is assumed that the leading coefficient, b_0, of $B(z)$ is an invertible matrix. For nonnegative integers m and n, let

$$U(z) = \sum_{i=0}^{m} u_i z^i, \qquad V(z) = \sum_{i=0}^{n} v_i z^i \tag{2.2}$$

denote $p \times p$ matrix polynomials.

DEFINITION 2.1. The pair of matrix polynomials $(U(z), V(z))$ is defined to be a **right matrix Padé form** (RMPFo) of type (m, n) for the pair $(A(z), B(z))$ if

I. $\partial(U(z)) \leqq m, \partial(V(z)) \leqq n$,†

(2.3) II. $A(z) \cdot V(z) + B(z) \cdot U(z) = z^{m+n+1} W(z)$, where $W(z)$ is a formal matrix power series, and

III. The columns of $V(z)$ are linearly independent over the field K. □

The matrix polynomials $U(z)$, $V(z)$, and $W(z)$ are usually called the right numerator, denominator, and residual (all of type (m, n)), respectively.

There is an equivalent definition for a **left matrix Padé form** (LMPFo). Condition II is replaced with an equivalent version with matrix multiplication by $U(z)$ and $V(z)$ being on the left. Condition III is replaced with the condition that the rows, rather than the columns, of the denominator are linearly independent over the base field K.

However, there is a one-to-one correspondence between RMPFo's and LMPFo's. By taking the transposes of the matrices on both sides of (2.3), it follows that

$$V^t(z) \cdot A^t(z) + U^t(z) \cdot B^t(z) = z^{m+n+1} W^t(z). \tag{2.4}$$

The degree and order conditions are identical. It is clear that if $(U(z), V(z))$ is a RMPFo for $(A(z), B(z))$, then $(U^t(z), V^t(z))$ is a LMPFo for $(A^t(z), B^t(z))$. Thus, any algorithm that calculates a right matrix Padé form of a certain type can also be used to calculate the left matrix Padé form of the same type.

For ease of discussion, we use the following notation. For any matrix polynomial

$$U(z) = u_0 + u_1 z + \cdots + u_k z^k, \tag{2.5}$$

we write U (i.e., the same symbol but without the z variable) to mean the $p(k+1)$ by p vector of matrix coefficients

$$U = \begin{bmatrix} u_0 \\ u_1 \\ \vdots \\ u_k \end{bmatrix} \tag{2.6}$$

or, equivalently, $U = [u_0^t, u_1^t, \cdots, u_k^t]^t$.

Let

$$S_{m,n} = \begin{bmatrix} a_0 & & & b_0 & & \\ & \ddots & & & \ddots & \\ \vdots & & a_0 & \vdots & & b_0 \\ & & \vdots & & & \vdots \\ a_{m+n} & \cdots & a_m & b_{m+n} & \cdots & b_n \end{bmatrix} \tag{2.7}$$

denote a Sylvester matrix for $A(z)$ and $B(z)$ of type (m, n). Then (2.3) can be written as

$$S_{m,n} \cdot \begin{bmatrix} V \\ U \end{bmatrix} = 0. \tag{2.8}$$

THEOREM 2.2 (Existence of matrix Padé forms). *For any pair of power series* $(A(z), B(z))$ *and any pair of nonzero integers* (m, n), *there exists a* RMPFo *of type* (m, n).

† $\partial(\ )$ denotes the degree of a matrix polynomial. This is the power of the largest nonzero coefficient of the polynomial.

Proof. Let X denote a vector of length $p(m+n+2)$, and consider the homogeneous system of linear equations

$$S_{m,n} \cdot X = 0. \tag{2.9}$$

Because $S_{m,n}$ has $p(m+n+1)$ rows, it follows that (2.9) has at least p linearly independent solutions. Let $[V^t, U^t]^t$ denote p such solutions arranged by columns. Then $[V^t, U^t]^t$ satisfies (2.8); consequently $U(z)$ and $V(z)$, determined according to the convention (2.5) and (2.6), satisfy (2.3). Clearly, the pair $(U(z), V(z))$ also satisfies conditions I in Definition 2.1. Finally, b_0 being nonsingular implies that the linear independence of the columns of $[V^t, U^t]^t$ is equivalent to the linear independence of the columns of $V(z)$. Thus condition III is satisfied. □

From the proof of Theorem 2.2, it follows that if $S_{m,n}$ has maximal rank, then Padé forms are unique up to multiplication of $U(z)$ and $V(z)$ on the right by a nonsingular matrix. On the other hand, if the rank of $S_{m,n}$ is less than maximal, then more than one independent Padé form exists.

Example 2.3. Let $B(z) = -I$ and

$$A(z) = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} + \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} z^2 + \begin{bmatrix} 2 & 0 \\ 0 & 1 \end{bmatrix} z^4 + \begin{bmatrix} -1 & 0 \\ -1 & 0 \end{bmatrix} z^5 + \cdots. \tag{2.10}$$

With $m = 2$ and $n = 3$, a basis for the solution space of (2.9) is given by the two vectors

$$X_1 = [0, 1, 0, 0, 0, -1, 0, 0, 0, 1, 0, 0, 0, 0]^t \tag{2.11}$$

and

$$X_2 = [0, 0, 0, 1, 0, 0, 0, -1, 0, 0, 0, 1, 0, 0]^t. \tag{2.12}$$

Thus,

$$V = \begin{bmatrix} 0 & 1 & 0 & 0 & 0 & -1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & -1 \end{bmatrix}^t \tag{2.13}$$

and

$$U = \begin{bmatrix} 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \end{bmatrix}^t \tag{2.14}$$

is a solution of (2.8), and the pair $(U(z), V(z))$, where

$$V(z) = \begin{bmatrix} 0 & 0 \\ 1-z^2 & z-z^3 \end{bmatrix} \quad \text{and} \quad U(z) = \begin{bmatrix} 0 & 0 \\ 1 & z \end{bmatrix} \tag{2.15}$$

is a Padé form of type (2.3) for $(A(z), B(z))$. □

In Example 2.3, note that the columns of $V(z)$ are linearly independent over the field K, but that they are linearly dependent over the ring of polynomials $K[z]$ (i.e., $V(z)$ is singular). Indeed, for this example, a RMPFo $(U(z), V(z))$ of type $(2, 3)$, for which $V(z)$ is nonsingular, cannot be found. The problem occurs because, although the solution space has dimension 2 when considered as a vector space over the field K, it has only dimension 1 when considered as a module over the ring $K[z]$.

We note that having an invertible denominator is highly desirable, since often the purpose of Padé forms is to approximate the infinite power series

$$-(B(z))^{-1} \cdot A(z) \tag{2.16}$$

by the finite rational form

$$U(z) \cdot (V(z))^{-1}, \tag{2.17}$$

where the approximation is to be exact for the first $m+n+1$ terms. When the denominator is singular, we cannot form this rational expression and this limits the usefulness of Padé approximation. For example, a singular denominator gives no information from the poles since every point is a pole in this case.

3. Matrix Padé fractions. One case when the denominator of a RMPFo is invertible is given by

DEFINITION 3.1. A pair $(U(z), V(z))$ of $p \times p$ matrix polynomials is said to be a **right matrix Padé fraction** (RMPFr) of type (m, n) for the pair $(A(z), B(z))$ if

I. $(U(z), V(z))$ is a RMPFo of type (m, n) for $(A(z), B(z))$, and

II. The constant term, $V(0)$, of the denominator is an invertible matrix. □

Condition II ensures that the denominator, $V(z)$ is an invertible matrix polynomial.

As in the case of Padé forms, there is an equivalent definition for a **left matrix Padé fraction** (LMPFr). Also, there is a correspondence between RMPFr for $(A(z), B(z))$ and LMPFr for $(A(z)', B(z)')$. It is interesting to note that a power series may have a matrix Padé fraction on one side but not on the other. In Example 2.3, the power series $A(z)$ does not have a right matrix Padé fraction of type $(2, 3)$, but it does have a left matrix Padé fraction of type $(2, 3)$. When a power series does have both a right and a left matrix Padé fraction of the same type, then the two resulting rational forms are equal (cf., Baker [1]).

The problem with Padé fractions, as mentioned in the previous section, is that they do not always exist. However, let

$$T_{m,n} = \left[\begin{array}{ccc|ccc} a_0 & & & b_0 & & \\ & \ddots & & & \ddots & \\ \vdots & & a_0 & \vdots & & b_0 \\ & & \vdots & & & \vdots \\ a_{m+n-1} & \cdots & a_m & b_{m+n-1} & \cdots & b_n \end{array}\right] \tag{3.1}$$

and define

$$d_{m,n} = \begin{cases} 1, & m = 0, \quad n = 0, \\ \det(T_{m,n}), & \text{otherwise.} \end{cases} \tag{3.2}$$

Then, a sufficient condition for the existence of a RMPFr is given by the Theorem 3.2.

THEOREM 3.2. *If $d_{m,n} \neq 0$, then every* RMPFo *of type (m, n) is an* RMPFr *of type (m, n). In addition, a* RMPFr *of type (m, n) is unique up to multiplication on the right by a nonsingular $p \times p$ matrix having coefficients from the field K.*

Proof. Equation (2.8) may be written as follows:

$$\left[\begin{array}{ccc|ccc} 0 & & & b_0 & & \\ a_0 & & & & \ddots & \\ & \ddots & & & & \\ \vdots & & a_0 & \vdots & & \\ & & \vdots & & & b_0 \\ a_{m+n-1} & \cdots & a_m & b_{b+n} & \cdots & b_n \end{array}\right] \cdot \left[\begin{array}{c} v_1 \\ \\ \\ v_n \\ u_0 \\ \\ u_m \end{array}\right] = - \left[\begin{array}{c} a_0 \\ \\ \\ \vdots \\ \\ \\ a_{m+n} \end{array}\right] \cdot v_0. \tag{3.3}$$

The matrix on the left of (3.3) is nonsingular, since $d_{m,n} \neq 0$ and b_0 is nonsingular. Thus, all the solutions of (3.3) can be obtained by assigning v_0 arbitrarily and solving (3.3) for the remaining components $v_1, \cdots, v_n, u_0, \cdots, u_m$. If v_0 is chosen to be a

singular matrix, then the solution obtained by solving (3.3) violates condition III in the definition of Padé form. Thus, in this case, all RMPFo's are RMPFr's.

To show uniqueness, suppose $(U(z), V(z))$ and $(U'(z), V'(z))$ are two RMPFr's for $(A(z), B(z))$. Then, v_0 and v_0' are both nonsingular matrices with coefficients from the field K. Thus, there exists a nonsingular matrix M with coefficients from K satisfying

$$v_0 = v_0' \cdot M. \tag{3.4}$$

It follows from (3.3) that

$$V(z) = V'(z) \cdot M \quad \text{and} \quad U(z) = U'(z) \cdot M, \tag{3.5}$$

and so uniqueness holds. □

In the next section we also require the following theorem.

THEOREM 3.3. *Let $A(z)$ and $B(z)$ be given by* (2.1). *If m and n are positive integers such that $d_{m,n} \neq 0$, then* RMPFo's $(P(z), Q(z))$ *of type* $(m-1, n-1)$ *for* $(A(z), B(z))$ *are unique up to multiplication of $P(z)$ and $Q(z)$ on the right by a nonsingular matrix from K. In addition, the leading term $R(0)$ of the residual in condition* II *for* RMPFo's,

$$A(z) \cdot Q(z) + B(z) \cdot P(z) = z^{m+n-1} R(z), \tag{3.6}$$

is a nonsingular matrix.

Proof. $S_{(m-1),(n-1)}$ can be obtained from $T_{m,n}$ by deleting the last block row (i.e., the last p rows). Since $T_{m,n}$ is of maximal rank $p(m+n)$, then $S_{(m-1),(n-1)}$ has rank $p(m+n-1)$. Consequently, the dimension of the solution space to

$$S_{(m-1),(n-1)} \cdot X = 0 \tag{3.7}$$

is exactly p. Then, $[Q', P']'$ is obtained by collecting by columns a basis for the solution space of (3.7). Clearly, if $[Q'', P'']'$ and $[Q', P']'$ are two such collections, then there exists a nonsingular matrix M from K such that

$$[Q', P']' = [Q'', P'']' \cdot M. \tag{3.8}$$

Thus, $P(z) = P'(z) \cdot M$ and $Q(z) = Q'(z) \cdot M$, proving uniqueness.

To prove the invertibility of $R(0)$ in (3.6), let $r_0 = R(0)$ and suppose that r_0 is a singular $p \times p$ matrix. Then, there is a nonzero $p \times 1$ vector X that satisfies

$$r_0 \cdot X = 0. \tag{3.9}$$

But, from (3.6) and (3.7), it follows that

$$T_{m,n} \cdot \begin{bmatrix} Q \\ P \end{bmatrix} = \begin{bmatrix} 0 \\ \vdots \\ 0 \\ r_0 \end{bmatrix}. \tag{3.10}$$

Thus,

$$T_{m,n} \cdot \begin{bmatrix} Q \\ P \end{bmatrix} \cdot X = 0. \tag{3.11}$$

Since the coefficient matrix for the above system is invertible, we deduce that

$$\begin{bmatrix} Q \\ P \end{bmatrix} \cdot X = 0. \tag{3.12}$$

But this contradicts the fact that the columns of $[Q', P']'$ are made up of linearly independent vectors. This implies that r_0 is invertible. □

The fact that Padé forms of type (m, n) and $(m-1, n-1)$ are uniquely determined after suitable normalizations, when $T_{m,n}$ is nonsingular, allows us to prove such properties as argument invariance (cf., Baker [1]) for the Padé forms computed by the algorithm MPADE given in § 5.

4. Matrix power series remainder sequences. We define a **right matrix Padé table** for $(A(z), B(z))$ to be any infinite two-dimensional collection of RMPFo's of type (m, n) for $(A(z), B(z))$ with $m = 0, 1, \cdots$ and $n = 0, 1, \cdots$. It is assumed that there is precisely one entry (i.e., one RMPFo) assigned to each position in the table. From Theorem 2.2, it follows that a right matrix Padé table exists for any given $(A(z), B(z))$. However, the table is not unique, because RMPFo's are not unique. This is unlike the definition of a Padé table for scalar power series (cf., Gragg [12]), since here a Padé table consists of a collection of Padé fractions, which are unique.

A matrix power series pair $(A(z), B(z))$ is said to be **normal** (cf., Bultheel [5]) if $d_{m,n} \neq 0$ for all m, n. For normal power series, it follows from Theorem 3.2 that every entry in the right matrix Padé table is a RMPFr. Consequently, from condition II in Definition 3.1 of RMPFr's a right-matrix Padé table for normal power series may be made unique by insisting that the constant term $V(0)$ in the denominator of any Padé fraction be the identity matrix.

Following the convention used in the scalar case (cf., Gragg [12]), we also define

$$(U(z), V(z)) = (z^m I, 0) \quad \text{for } m \geqq -1,\ n = -1, \tag{4.1}$$

and

$$(U(z), V(z)) = (0, z^n I) \quad \text{for } m = -1,\ n \geqq 0. \tag{4.2}$$

A right matrix Padé table appended with (4.1) and (4.2) is called an **extended right matrix Padé table**. The use of an extended table is strictly for initialization purposes. The entries given by (4.1) and (4.2) are not right matrix Padé forms (indeed, the $(-1, -1)$ entry is not even a matrix polynomial). However, they do satisfy property II of Definition 2.1. For example, for $m \geqq -1$ and $n = -1$, we have that

$$A(z)V(z) + B(z)U(z) = z^{m+n+1} W(z) \tag{4.3}$$

with

$$W(z) = B(z); \tag{4.4}$$

whereas, for $m = -1$ and $n \geqq 0$, we obtain (4.3) with

$$W(z) = A(z). \tag{4.5}$$

Given the power series (2.1) and any nonnegative integers m and n, we introduce a sequence of points

$$(m_0, n_0), (m_1, n_1), (m_2, n_2), \cdots \tag{4.6}$$

in the extended right matrix Padé table by setting

$$(m_0, n_0) = \begin{cases} (m-n-1, -1) & \text{for } m \geqq n \\ (-1, n-m-1) & \text{for } m < n \end{cases} \tag{4.7}$$

and

$$(m_{i+1}, n_{i+1}) = (m_i + s_i, n_i + s_i),\ i = 0, 1, 2, \cdots, \tag{4.8}$$

where $s_i \geqq 1$. Observe that

$$m_i - n_i = m - n, \qquad i = 0, 1, 2, \cdots, \tag{4.9}$$

and consequently the sequence (4.6) lies along the $m-n$ off-diagonal path of the extended right matrix Padé table. In (4.8), the s_i are selected so that

$$d_{m_{i+1},n_{i+1}} \neq 0 \tag{4.10}$$

and

$$d_{(m_i+j),(n_i+j)} = 0, \tag{4.11}$$

for $j = 1, 2, \cdots, s_i - 1$.

For $i = 1, 2, \cdots$, let $(U_i(z), V_i(z))$ be the unique RMPFr (cf., Theorem 3.2) of type (m_i, n_i) for $(A(z), B(z))$. Thus $[V_i^t, U_i^t]^t$ satisfies

$$S_{m_i,n_i} \cdot \begin{bmatrix} V_i \\ U_i \end{bmatrix} = 0, \tag{4.12}$$

and, according to (2.3), there exists a matrix power series $W_i(z)$ such that

$$A(z) \cdot V_i(z) + B(z) \cdot U_i(z) = z^{m_i+n_i+1} W_i(z). \tag{4.13}$$

Generalizing the notions of Cabay and Kossowski [9], we introduce the following definition.

DEFINITION 4.1. The sequence

$$\{W_i(z)\}, \qquad i = 1, 2, \cdots, \tag{4.14}$$

is called the **power series remainder sequence** for the pair $(A(z), B(z))$. The sequence of pairs

$$\{(U_i(z), V_i(z))\}, \qquad i = 1, 2, \cdots, \tag{4.15}$$

is called the corresponding **cofactor sequence**. The integer pairs $\{(m_i, n_i)\}$ are called **nonsingular nodes** along the $m-n$ off-diagonal path of the extended right matrix Padé table for $(A(z), B(z))$. □

We note that each term of a power series remainder sequence is unique up to multiplication on the right by a nonsingular matrix. This is also true for each term of the corresponding cofactor sequence.

Initially, when $m \geqq n$, observe that $m_1 = m - n$ and $n_1 = 0$ (i.e., $s_0 = 1$), because in (3.2) the nonsingularity of b_0 implies that $d_{(m-n),0} \neq 0$. Thus, $V_1(z)$ is some arbitrary nonsingular matrix from K and, using (4.12), $U_1(z)$ can be obtained by solving

$$\begin{bmatrix} b_0 & & \\ \vdots & \ddots & \\ b_{m_1} & \cdots & b_0 \end{bmatrix} U_1 = -\begin{bmatrix} a_0 \\ \vdots \\ a_{m_1} \end{bmatrix} V_1. \tag{4.16}$$

That is, $U_1(z)$ can be obtained by multiplying the first $m_1 + 1$ terms of the quotient power series $B^{-1}(z) \cdot A(z)$ on the right by $-V_1(z)$.

Initially, when $m < n$, depending on a_0 there are two cases to consider. The simple case, when $\det(a_0) \neq 0$, yields

$$d_{0,(n-m)} = \det \begin{bmatrix} a_0 & & \\ \vdots & \ddots & \\ a_{n-m-1} & \cdots & a_0 \end{bmatrix} \neq 0. \tag{4.17}$$

Thus, $s_0 = 1$, $m_1 = 0$, and $n_1 = n - m$. Then, the RMPFr $(U_1(z), V_1(z))$ of type (m_1, n_1) is determined by setting $U_1(z)$ to be an arbitrary nonsingular matrix from K and then solving

$$\begin{bmatrix} a_0 & & \\ \vdots & \ddots & \\ a_{n_1} & \cdots & a_0 \end{bmatrix} V_1 = -\begin{bmatrix} b_0 \\ \vdots \\ b_{n_1} \end{bmatrix} U_1. \tag{4.18}$$

That is, when $m < n$ and $\det(a_0) \neq 0$, $V_1(z)$ can be obtained from the first $n_1 + 1$ terms of the quotient power series $A^{-1}(z) \cdot B(z)$ multiplied on the right by $-U_1(z)$.

When $m < n$ and $\det(a_0) = 0$, we must first determine the smallest positive integer s_0 (i.e., the smallest $m_1 = m_0 + s_0$ and $n_1 = n_0 + s_0$) so that $d_{m_1,n_1} \neq 0$. Notice that here $s_0 > 1$. Once s_0 has been obtained, then $(U_1(z), V_1(z))$ is obtained by solving

$$S_{m_1,n_1} \cdot \begin{bmatrix} V_1 \\ U_1 \end{bmatrix} = 0. \tag{4.19}$$

In § 5, we give an algorithm which computes a RMPFo of type (m, n) for $(A(z), B(z))$ by performing a sequence of the above types of initializations (albeit, each for different power series).

When the power series pair $(A(z), B(z))$ is normal, only the initializations corresponding to (4.16) and (4.18) are required. Thus, for normal power series $s_i = 1$ for all $i \geqq 1$, and the algorithm reduces to a sequence of truncated power series divisions.

There are also some nonnormal power series that share this property. For each pair of integers m and n, let $r_{m,n}$ be the rank of the matrix $T_{m,n}$. Then normality is equivalent to

$$r_{m,n} = (m + n) \cdot p \tag{4.20}$$

for all m and n. A matrix power series pair $(A(z), B(z))$ is said to be **nearly normal** (cf., Labahn [13]) if, for all integers m and n,

$$r_{m,n} = k_{m,n} \cdot p \tag{4.21}$$

for some integer $k_{m,n}$. Clearly, every normal power series is also a nearly normal power series. In addition, all scalar power series are nearly normal.

For a nearly normal power series pair $(A(z), B(z))$ it is easy to see that when a_0 is singular, then $a_0 = 0$. This follows from the observation that the rank of a_0 is just $r_{0,1}$, which, if it is not p, must be zero. Also, if $a_0 = \cdots = a_{k-1} = 0$ and $a_k \neq 0$, then a_k must be a nonsingular matrix for similar reasons. When $k > m$ this implies that there are no nonsingular nodes along the $m - n$ off-diagonal path before and including the node (m, n). Otherwise, when $k \leqq m$, the initialization (4.19) becomes

$$\left[\begin{array}{ccc|ccc} 0 & & & b_0 & & \\ a_{m_1} & & & \vdots & \ddots & \\ \vdots & \ddots & & \vdots & & b_0 \\ a_{m_1+n_1} & \cdots & a_{m_1} & b_{m_1+n_1} & \cdots & b_{n_1} \end{array}\right] \cdot \begin{bmatrix} V_1 \\ U_1 \end{bmatrix} = 0, \tag{4.22}$$

where $s_0 = k + 1$, $m_1 = k$, and $n_1 = n - m + k$. Consequently the RMPFr $(U_1(z), V_1(z))$ of type (m_1, n_1) is obtained from (4.22) first by setting $U_1(z) = z^{m_1} \cdot U$, where U is any nonsingular matrix from K. Then, $V_1(z)$ is obtained by multiplying the first $n_1 + 1$ terms of the quotient power series $(z^{-m_1} \cdot A(z))^{-1} \cdot B(z)$ on the right by $-U$. Thus, also for

nearly normal power series (and therefore also for all scalar power series), all initializations reduce to truncated power series divisions.

Corresponding to the power series remainder sequence, we introduce Definition 4.2.

DEFINITION 4.2. The sequence

$$\{(P_i(z), Q_i(z))\}, \qquad i = 1, 2, \cdots, \tag{4.23}$$

where $(P_i(z), Q_i(z))$ is the $(m_i - 1, n_i - 1)$ entry in the extended matrix Padé table for $(A(z), B(z))$, is called a **predecessor sequence** of the power series remainder sequence. □

The pair $(P_i(z), Q_i(z))$ satisfies the equation

$$A(z) \cdot Q_i(z) + B(z) \cdot P_i(z) = z^{m_i + n_i - 1} \cdot R_i(z). \tag{4.24}$$

THEOREM 4.3. *For $i = 1, 2, \cdots$, the predecessors $(P_i(z), Q_i(z))$ are unique up to right multiplication by a nonsingular matrix from K. In addition, the leading term of the residual, $R_i(0)$, is nonsingular.*

Proof. For $m_i > 0$ and $n_i > 0$, the predecessors are right matrix Padé forms and the result is a direct consequence of Theorem 3.3. Thus, it remains only to show that the result holds when either m_1 or n_1 is zero.

When $n_1 = 0$, from (4.7) and (4.8) $m \geqq n$, and the predecessor node is the $(m - n - 1, -1)$ entry of the extended right matrix Padé table. By (4.1), this entry is given uniquely by

$$(P_1(z), Q_1(z)) = (z^{m-n-1} I, 0). \tag{4.25}$$

From (4.4), the residual $R_1(z)$ is $B(z)$ and the theorem therefore holds for $n_1 = 0$, since $\det(b_0) \neq 0$.

When $m_1 = 0$, then from (4.7) and (4.8) $n_1 = n - m > 0$, and the predecessor node is the $(-1, n - m - 1)$ entry of the extended table. By (4.2), this is uniquely given by

$$(P_1(z), Q_1(z)) = (0, z^{n-m-1} I). \tag{4.26}$$

From (4.5) the residual of this node, $R_1(z)$, is $A(z)$. But by (4.17), $(0, n - m)$ is the first nonsingular node if and only if $\det(a_0) \neq 0$. Hence the leading term of the residual is nonsingular. □

The main result of this section is given in Theorem 4.4.

THEOREM 4.4. *For any positive integer k, $(k - 1, k)$ is a nonsingular node in the Padé table for $(W_i(z), R_i(z))$ if and only if $(m_i + k, n_i + k)$ is a nonsingular node in the Padé table for $(A(z), B(z))$.*

Proof. Let M_{11}, M_{21}, M_{12}, and M_{22} be matrices of dimension $p(n_i + k) \times pk$, $p(m_i + k) \times pk$, $p(n_i + k) \times p(k - 1)$, and $p(m_i + k) \times p(k - 1)$, respectively, defined by

$$M_{11} = \begin{bmatrix} v_0 & & \\ v_{n_i} & \ddots & \\ & \ddots & v_0 \\ & & v_{n_i} \end{bmatrix}, \qquad M_{12} = \begin{bmatrix} 0 & & \\ 0 & & \\ q_0 & & \\ & \ddots & \\ q_{n_i - 1} & & q_0 \\ & \ddots & \\ & & q_{n_i - 1} \end{bmatrix}, \tag{4.27}$$

$$M_{21}=\begin{bmatrix} u_0 & & \\ u_{m_i} & \ddots & \\ & \ddots & u_0 \\ & & u_{m_i} \end{bmatrix}, \qquad M_{22}=\begin{bmatrix} 0 & & \\ p_{-1} & & \\ p_0 & \ddots & \\ & & p_{-1} \\ p_{m_i-1} & & \\ & \ddots & \\ & & p_{m_i-1} \end{bmatrix}. \tag{4.28}$$

In (4.28), $p_{-1}=0$ except when $m_1=0$ and $n_1=0$, in which case, according to (4.25), $p_{-1}=1$. Let M be

$$M=\begin{bmatrix} M_{11} & M_{12} \\ M_{21} & M_{22} \end{bmatrix}. \tag{4.29}$$

If we set

$$R_i(z)=\sum_{j=0}^{\infty} r_j z^j, \quad \text{with } \det(r_0)\neq 0, \quad \text{and } W_i(z)=\sum_{j=0}^{\infty} w_j z^j, \tag{4.30}$$

then, from (4.13) and (4.24), it follows that

$$T_{(m_i+k),(n_i+k)}\cdot M=\left[\begin{array}{ccc|ccc} 0 & \cdots & 0 & 0 & \cdots & 0 \\ 0 & \cdots & 0 & 0 & \cdots & 0 \\ w_0 & & & r_0 & & \\ & \ddots & & & \ddots & \\ \vdots & & w_0 & \vdots & & r_0 \\ & & \vdots & & & \vdots \\ w_{2k-2} & \cdots & w_{k-1} & r_{2k-2} & \cdots & r_k \end{array}\right] \tag{4.31}$$

$$=\begin{bmatrix} 0 \\ T'_{(k-1),k} \end{bmatrix},$$

where $\mathbf{0}$ represents a zero matrix of size $p(m_i+n_i+1)\times p(2k-1)$ and

$$T'_{(k-1),k}=\left[\begin{array}{ccc|ccc} w_0 & & & r_0 & & \\ & \ddots & & & \ddots & \\ & & w_0 & & & r_0 \\ w_{2k-2} & \cdots & w_{k-1} & r_{2k-2} & \cdots & r_k \end{array}\right]. \tag{4.32}$$

We are now in a position to prove the theorem. Assume $T_{(m_i+k),(n_i+k)}$ is nonsingular. We show that $T'_{(k-1),k}$ is then also nonsingular. Let

$$X=[X_1,\cdots,X_{2k-1}]^t \tag{4.33}$$

be a $p(2k-1)\times 1$ vector that satisfies

$$T'_{(k-1),k}\cdot X=0. \tag{4.34}$$

Since $T_{(m_i+k),(n_i+k)}$ is nonsingular, (4.31) implies

$$M\cdot X=0. \tag{4.35}$$

From (4.35), we then obtain that

$$v_0\cdot X_1=0, \tag{4.36}$$

and consequently $X_1 = 0$, because v_0 is nonsingular. The first block equation from (4.34) then implies

$$r_0 \cdot X_{k+1} = 0. \tag{4.37}$$

Thus, $X_{k+1} = 0$ because r_0 is nonsingular. In a similar fashion, it follows that $X_2 = 0$ and $X_{k+2} = 0$. Continuing in this way, we obtain that $X = 0$, that is, $T'_{(k-1),k}$ is nonsingular.

Conversely, suppose that $T'_{(k-1),k}$ is nonsingular. Let $X = (X_1, \cdots, X_{2k-1})$ be a $1 \times p(2k-1)$ vector, $Y = (Y_1, \cdots, Y_{m_i+n_i})$ a $1 \times p(m_i + n_i)$ vector, and Z a $1 \times p$ vector. Consider

$$(Z, Y, X) \cdot T_{(m_i+k),(n_i+k)} = 0. \tag{4.38}$$

Multiplying both sides of (4.38) on the right by M, and using equation (4.31), it follows that

$$X \cdot T'_{(k-1),k} = 0. \tag{4.39}$$

Since $T'_{(k-1),k}$ is nonsingular, then $X = 0$. Then, in (4.38), using block columns 2 through $n_i + 1$ and block columns $n_i + k + 2$ through to $m_i + n_i + k + 1$ of $T_{(m_i+k),(n_i+k)}$, we obtain

$$Y \cdot T_{m_i,n_i} = 0. \tag{4.40}$$

Since T_{m_i,n_i} is nonsingular, $Y = 0$. Finally, block column $n_i + k + 1$ of $T_{(m_i+k),(n_i+k)}$ now yields

$$Z \cdot b_0 = 0. \tag{4.41}$$

Since b_0 is nonsingular, $Z = 0$. Hence, $T_{(m_i+k),(n_i+k)}$ is nonsingular.

Theorem 4.4 allows us to calculate nonsingular nodes of a pair of power series by calculating nonsingular nodes of the residual pair of power series. This gives us an iterative method of calculating nonsingular nodes.

THEOREM 4.5. *The cofactor and predecessor sequences for* $(A(z), B(z))$ *satisfy*

$$\begin{bmatrix} U_{i+1}(z) & P_{i+1}(z) \\ v_{i+1}(z) & Q_{i+1}(z) \end{bmatrix} = \begin{bmatrix} U_i(z) & P_i(z) \\ V_i(z) & Q_i(z) \end{bmatrix} \cdot \begin{bmatrix} I & 0 \\ 0 & z^2 \cdot I \end{bmatrix} \cdot \begin{bmatrix} V'(z) & Q'(z) \\ U'(z) & P'(z) \end{bmatrix}, \tag{4.42}$$

where $(U'(z), V'(z))$ *is the* RMPFr *of type* $(s_i - 1, s_i)$ *for* $(W_i(z), R_i(z))$ *and* $(P'(z), Q'(z))$ *is its predecessor.*

Proof. Since $(U_i(z), V_i(z))$ and $(U_{i+1}(z), V_{i+1}(z))$ are successive elements of the cofactor sequence (4.14), then, according to (4.10) and (4.11), (m_i, n_i) and (m_{i+1}, n_{i+1}) are successive nonsingular nodes along the $m - n$ off-diagonal path of the Padé table for $(A(z), B(z))$. By Theorem 4.4, then s_i is the smallest positive integer for which $(s_i - 1, s_i)$ is a nonsingular node in the Padé table for $(W_i(z), R_i(z))$. Accordingly, we can determine $(U'(z), V'(z))$ to be the RMPFr of type $(s_1 - 1, s_i)$ for $(W_i(z), R_i(z))$ and $(P'(z), Q'(z))$ to be its predecessor.

Let $U(z)$, $V(z)$, $P(z)$, and $Q(z)$ be defined by

$$\begin{bmatrix} U(z) & P(z) \\ V(z) & Q(z) \end{bmatrix} = \begin{bmatrix} U_i(z) & P_i(z) \\ V_i(z) & Q_i(z) \end{bmatrix} \cdot \begin{bmatrix} I & 0 \\ 0 & z^2 \cdot I \end{bmatrix} \cdot \begin{bmatrix} V'(z) & Q'(z) \\ U'(z) & P'(z) \end{bmatrix}. \tag{4.43}$$

We shall first show that $(U(z), V(z))$ given by (4.43) is the RMPFr of type (m_{i+1}, n_{i+1}) for $(A(z), B(z))$. Because RMPFr's are unique, then $(U(z), V(z))$ must be the $(i+1)$st term in the cofactor sequence.

Since $(U'(z), V'(z))$ is a RMPFr of type $(s_i - 1, s_i)$ for $(W_i(z), R_i(z))$, it satisfies

$$W_i(z) \cdot V'(z) + R_i(z) \cdot U'(z) = z^{2s_i} W'(z), \tag{4.44}$$

where $V'(0)$ is nonsingular. Then, using (4.13), (4.24), (4.43), and (4.44), we get

$$\begin{aligned} & A(z)\cdot V(z)+B(z)\cdot U(z) \\ & \quad = A(z)\cdot\{V_i(z)\cdot V'(z)+z^2Q_i(z)\cdot U'(z)\} \\ & \qquad + B(z)\cdot\{U_i(z)\cdot V'(z)+z^2P_i(z)\cdot U'(z)\} \\ & \quad = \{A(z)\cdot V_i(z)+B(z)\cdot U_i(z)\}\cdot V'(z) \\ & \qquad + \{A(z)\cdot Q_i(z)+B(z)\cdot P_i(z)\}\cdot z^2U'(z) \\ & \quad = z^{m_i+n_i+1}\cdot\{W_i(z)\cdot V'(z)+R_i(z)\cdot U'(z)\} \\ & \quad = z^{(m_i+s_i)+(n_i+s_i)+1}\cdot W'(z). \end{aligned} \tag{4.45}$$

Thus, condition II for a RMPFo of type (m_i+s_i, n_i+s_i) for $(A(z), B(z))$ is satisfied.

To verify condition I, expanding (4.43) gives

$$U(z) = U_i(z)\cdot V'(z)+z^2P_i(z)\cdot U'(z), \tag{4.46}$$

so that

$$\begin{aligned} \partial(U(z)) &\leqq \max\,(m_i+s_i, 2+(m_i-1)+s_i-1) \\ &= m_i+s_i. \end{aligned} \tag{4.47}$$

Similarly,

$$\partial(V(z)) \leqq n_i+s_i. \tag{4.48}$$

Finally, to verify condition II for a RMPFr (and, thus, condition III for a RMPFo, as well), observe that

$$V(0) = V_i(0)\cdot V'(0), \tag{4.49}$$

and, consequently, $V(0)$ is invertible since both $V_i(0)$ and $V'(0)$ are invertible. Notice that we have a somewhat stronger result here, namely that if $V_i(z)$ and $V'(z)$ are both normalized with $V_i(0)=I$ and $V'(0)=I$, then so is $V(z)$.

Therefore, $(U(z), V(z))$ is a RMPFr of type (m_i+s_i, n_i+s_i) for $(A(z), B(z))$. Thus, it is the $(i+1)$st term in the cofactor sequence and $W'(z)$ is the $(i+1)$st term in the power series remainder sequence for $(A(z), B(z))$.

Notice that the above arguments also hold in the special case when $m=n$ and $i=1$. In this case $P_1(z)=z^{-1}I$ which is not a matrix polynomial. However, the right side of equation (4.43) immediately multiplies the predecessor by z^2 which subsequently results in a matrix polynomial.

A similar argument shows that $(P(z), Q(z))$ given in (4.43) is the predecessor of the nonsingular node (m_{i+1}, n_{i+1}). Hence the recurrence relation (4.42) holds. □

For purposes of the algorithm given in the next section, observe that if $(U'(z), V'(z))$ is a RMPFo of type $(s-1, s)$ for $(W_i(z), R_i(z))$ and $(P'(z), Q'(z))=(0, I)$ then in (4.43) $(U(z), V(z))$ yields a RMPFo (rather than a RMPFr) of type (m_i+s, n_i+s) for $(A(z), B(z))$ and $(P(z), Q(z))=(U_i(z), V_i(z))$.

5. The algorithm. Given nonnegative integers m and n, the algorithm MPADE below makes use of Theorem 4.5 to compute the cofactor and predecessor sequences

(4.10) and (4.18), respectively. Thus, intermediate results available from MPADE include those RMPFr's $(U_i(z), V_i(z))$ for $(A(z), B(z))$ at all the nonsingular nodes (m_i, n_i), $i = 1, 2, \cdots, k-1$, smaller than (m, n), along the off-diagonal path $m_i - n_i = m - n$. The output gives results associated with the final node (m_k, n_k). If (m, n) is also a nonsignular node, then the output $(U_k(z), V_k(z))$ is a RMPFr of type (m, n) for $(A(z), B(z))$, and $(P_k(z), Q_k(z))$ is a RMPFo of type $(m-1, n-1)$. If (m, n) is a singular node, then the output $(U_k(z), V_k(z))$ is simply a RMPFo of type (m, n) for $(A(z), B(z))$, and now $(P_k(z), Q_k(z))$ is set to be the RMPFr of type (m_{k-1}, n_{k-1}). An exception occurs in the latter case when $k = 0$ and $m < n$. Here, all nodes along the off-diagonal path must have been singular, and for $(P_k(z), Q_k(z))$ the algorithm returns instead the initial value $(0, z^{n-m-1}I)$.

Note that, when (m, n) is not a nonsingular node, a simple modification of MPADE allows the computation of all RMPFo's of type (m, n) for $(A(z), B(z))$. It is only necessary to arrange to compute q columns of $[V_k', U_k']$, rather than p, in order to form a basis for the solution space of the equation in step 3.1 of MPADE. From this basis, it is then possible to construct a $p \times p$ matrix $V(z)$, and a corresponding $U(z)$, for which $(U(z), V(z))$ is a RMPFo of type (m, n) for $(A(z), B(z))$ and has the property that $V(z)$ is an invertible matrix, assuming such a RMPFo exists. This enhancement is not included in MPADE primarily to simplify the presentation of the algorithm.

MPADE(A, B, m, n)

If $m \geqq n$

then

M1) $\begin{bmatrix} m_0 \\ n_0 \end{bmatrix} \leftarrow \begin{bmatrix} m-n-1 \\ -1 \end{bmatrix}$

M2) $\left(s_0, \begin{bmatrix} V_1(z) & Q_1(z) \\ U_1(z) & P_1(z) \end{bmatrix}\right) \leftarrow INITIAL\_PADE(B(z), A(z), n, m)$

else

M3) $\begin{bmatrix} m_0 \\ n_0 \end{bmatrix} \leftarrow \begin{bmatrix} -1 \\ n-m-1 \end{bmatrix}$

M4) $\left(s_0, \begin{bmatrix} U_1(z) & P_1(z) \\ V_1(z) & Q_1(z) \end{bmatrix}\right) \leftarrow INITIAL\_PADE(A(z), B(z), m, n)$

M5) $\begin{bmatrix} m_1 \\ n_1 \end{bmatrix} \leftarrow \begin{bmatrix} m_0 + s_0 \\ n_0 + s_0 \end{bmatrix}$

M6) $i \leftarrow 1$

M7) Do while $m_i < m$

M8) Compute $R_i(z)$ satisfying (4.24)

M9) Compute $W_i(z)$ satisfying (4.13)

M10) $\left(s_i, \begin{bmatrix} U'(z) & P'(z) \\ V'(z) & Q'(z) \end{bmatrix}\right) \leftarrow INITIAL\_PADE(W_i(z), R_i(z), m - m_i - 1, n - n_i)$

M11) $\begin{bmatrix} U_{i+1}(z) & P_{i+1}(z) \\ V_{i+1}(z) & Q_{i+1}(z) \end{bmatrix} \leftarrow \begin{bmatrix} U_i(z) & P_i(z) \\ V_i(z) & Q_i(z) \end{bmatrix} \cdot \begin{bmatrix} I & 0 \\ 0 & z^2 \cdot I \end{bmatrix} \cdot \begin{bmatrix} V'(z) & Q'(z) \\ U'(z) & P'(z) \end{bmatrix}$

M12) $\begin{bmatrix} m_{i+1} \\ n_{i+1} \end{bmatrix} \leftarrow \begin{bmatrix} m_i + s_i \\ n_i + s_i \end{bmatrix}$

M13) $i \leftarrow i + 1$

End do

M14) $k \leftarrow i$

M15) Return $\left(\begin{bmatrix} U_k(z) & P_k(z) \\ V_k(z) & Q_k(z) \end{bmatrix}\right)$

End MPADE

INITIAL_PADE(W(z), R(z), m', n')

I1) $s \leftarrow 0$

I2) $d \leftarrow 0$

I3) Do while $s \leqq m'$ and $d = 0$

I4) Compute $d \leftarrow \det(T_{s,n'-m'+s})$

I5) $s \leftarrow s+1$

End do

I6) Solve

$$S_{s-1,n'-m'+s-1} \cdot \begin{bmatrix} V' \\ U' \end{bmatrix} = 0$$

If $s > 1$ and $d \neq 0$

then

I7) Solve

$$S_{s-2,n'-m'+s-2} \cdot \begin{bmatrix} Q' \\ P' \end{bmatrix} = 0$$

else

I8) $$\begin{bmatrix} Q' \\ P' \end{bmatrix} \leftarrow \begin{bmatrix} z^{n'-m'-1} I \\ 0 \end{bmatrix}$$

I9) Return $\left(s, \begin{bmatrix} U' & P' \\ V' & Q' \end{bmatrix}\right)$

End INITIAL_PADE

THEOREM 5.1. *The* MPADE *algorithm is valid.*

Proof. The argument is by induction on i.

Initially, in step M2 of MPADE, where $m \geqq n$, the parameters input to INITIAL_PADE are $W(z) = B(z)$, $R(z) = A(z)$, $m' = n$ and $n' = m$. Consequently, INITIAL_PADE computes $s = 1$, since in step I5

$$d = \det(T_{0,m-n}) = \det \begin{bmatrix} b_0 & & \\ & \ddots & \\ b_{m-n-1} & & b_0 \end{bmatrix} \neq 0 \tag{5.1}$$

when $m > n$, and $d = 1$ when $m = n$. In step I6, the algorithm solves

$$S_{0,m-n} \begin{bmatrix} V' \\ U' \end{bmatrix} = \begin{bmatrix} b_0 & & & a_0 \\ & \ddots & & \\ b_{m-n} & & b_0 & a_{m-n} \end{bmatrix} \begin{bmatrix} V' \\ U' \end{bmatrix} = 0 \tag{5.2}$$

and step I8 yields

$$\begin{bmatrix} Q' \\ P' \end{bmatrix} = \begin{bmatrix} z^{m-n-1} I \\ 0 \end{bmatrix}. \tag{5.3}$$

Since the substitution in step M2 of MPADE yields $s_0 = s$ and

$$\begin{bmatrix} U_1 & P_1 \\ V_1 & Q_1 \end{bmatrix} = \begin{bmatrix} V' & Q' \\ U' & P' \end{bmatrix}, \tag{5.4}$$

it follows that the initialization for $m \geqq n$ is exactly that given by (4.16) and (4.25).

Alternately, when $m < n$, initialization is accomplished by step M4. In this case, the parameters input to INITIAL_PADE are $W(z) = A(z)$, $R(z) = B(z)$, $m' = m$, and $n' = n$. If $\det(a_0) \neq 0$, INITIAL_PADE again computes $s = 1$, since in step I5

$$d = \det(T_{0,n-m}) = \det \begin{bmatrix} a_0 & & \\ & \ddots & \\ a_{n-m-1} & & a_0 \end{bmatrix} \neq 0. \tag{5.5}$$

Step I6 then solves (4.18) with $U_1 = U'$ and $V_1 = V'$, and, with the substitution $(P_1, Q_1) = (P', Q')$, step I7 yields the required predecessor (4.26). If $\det(a_0) = 0$, then step I5 determines the smallest integer $s \geqq 2$, if one exists, for which $d = \det(T_{s-1,n-m+s-1}) \neq 0$. Consequently, step I6 solves exactly the system (4.19) and step I7 must then yield the correct predecessor.

Assume that, for $i \geqq 1$, MPADE calculates $(U_i(z), V_i(z))$ and $(P_i(z), Q_i(z))$ correctly. We shall show that one pass through the while loop M7 correctly computes $(U_{i+1}(z), V_{i+1}(z))$ and its predecessor.

In step M10 and MPADE, the parameters input to INITIAL_PADE are $W(z) = W_i(z)$, $R(z) = R_i(z)$, $m' = m - m_i - 1$, and $n' = n - n_i$. Noting (4.9), step I4 computes the smallest positive integer s, if one exists, for which $d = \det(T_{s-1,s}) \neq 0$. Clearly, then I6 computes a RMPFr of type $(s-1, s)$ for $(W_i(z), R_i(z))$, and steps I7 and I8 its predecessor. Thus, the matrix polynomials in step M11 correspond exactly to those of (4.42); that is, the algorithm correctly computes $(U_{i+1}(z), V_{i+1}(z))$ and its predecessor.

To complete the proof of algorithm validity, consideration must be given to the case for which there exists no s such that $d \neq 0$ in the while loop I3 of INITIAL_PADE. On exit from the while loop, observe that $s = m' + 1$. Step I6 then computes $(U'(z), V'(z))$ to be a RMPFo of type (m', n') for $(W(z), R(z))$ and sets $(P'(z), Q'(z)) = (0, z^{n-m-1}I)$.

The case where there exists no s such that $d \neq 0$ can occur when INITIAL_PADE is invoked in steps M4 and M10 of MPADE, only. If it occurs at step M4, then $(U_1(z), V_1(z))$ becomes a RMPFo of type (m, n) for $(A(z), B(z))$ as computed by INITIAL_PADE, and $(P_1(z), Q_{1(z)}) = (0, z^{n-m-1}I)$. Since step M5 next yields $(m_1, n_1) = (m, n)$, the algorithm immediately terminates. On the other hand, if it occurs at step M10, then $s_i = m - m_i$, $(U'(z), V'(z))$ is a RMPFo of type $(s_i - 1, s_i)$ for $(W_i(z), R_i(z)$ and $(P'(z), Q'(z)) = (0, I)$. Accordingly (cf., last paragraph of § 4), $(U_{i+1}(z), V_{i+1}(z))$ computed in step M11 is a RMPFo of type (m, n) for $(A(z), B(z))$ and $(P_{i+1}(z), Q_{i+1}(z)) = (U_i(z), V_i(z))$. Since step M12 yields $(m_{i+1}, n_{i+1}) = (m, n)$, the algorithm terminates. □

6. Complexity of the MPADE algorithm. Note that, in steps M8 and M9 of MPADE, only the first $m + n - m_i - n_i$ terms in $R_i(z)$ and $W_i(z)$ are required to ensure the subsequent success of step M10. Indeed, only the first $2s_i$ terms, $s_i \leqq m - m_i$, are sufficient, but unfortunately s_i is not known prior to step M10. Nevertheless, an efficient implementation can take advantage of this observation by delaying the computation of $R_i(z)$ and $W_i(z)$. Declaring $(A(z), B(z))$, $(U_i(z), V_i(z))$, $(P_i(z), Q_i(z))$ to be global variables, the coefficients of $R_i(z)$ and $W_i(z)$ can be computed in INITIAL_PADE only when they become necessary. The cost analysis below assumes that the algorithm has been implemented in such a fashion.

In assessing the costs of MPADE, it is assumed that classical algorithms are used for the multiplication of polynomials. Only the more costly steps are considered. For these steps, Table 6.1 below provides cruder upper bounds on the number of multiplications in K required. The table provides separate bounds for the normal and abnormal cases.

In step I5 of INITIAL_PADE, it is assumed that the Gaussian elimination method is used to obtain the LU decomposition of $T_{(s-1),n'-m'+s-1}$. In addition, it is assumed that Gaussian elimination is accompanied with bordering techniques. Thus, as s increases by 1 in step I4, the results of the previous pass through the while loop are used to achieve the current LU decomposition. The bound for step I5 in Table 6.1 for the abnormal case assumes we do not take any advantage of the special nature of $T_{(s-1),n'-m'+s-1}$. In the normal case $s=1$, and $T_{0,n'-m'}$ is already in triangular form, and so no computation is required in step I5.

For step I6, it is assumed that the LU decomposition of $T_{(s-1),n'-m'+s-1}$ from step I5, is used to simplify the triangulation of $S_{(s-1),n'-m'+s-1}$. The solution $[V', U']$ is obtained finally by solving this triangularized S. Similar observations apply to step I7 in the abnormal case.

Since steps M2, M4, and M10 simply invoke INITIAL_PADE, estimates of their costs are obtained by summing the costs of steps I5, I6, and I7 with appropriate substitutions of variables. Note that the cost of M2 is the same in both the normal and abnormal case, since for $m \geqq n$ it is always true that $s_0 = 1$.

An upper bound for the number of multiplications in K required by MPADE is obtained by summing the costs of the last six rows in Table 6.1 for $i = 0, 1, \cdots, k$. We use the fact that

$$\sum_{i=0}^{k} s_i = m, \text{ if } m \geqq n, \text{ and } \sum_{i=0}^{k} s_i = n, \text{ if } m < n. \tag{6.1}$$

In addition,

$$\sum_{i=0}^{k} m_i^{\alpha} s_i^{\beta} \leqq m^{\alpha+\beta} \text{ and } \sum_{i=0}^{k} n_i^{\alpha} s_i^{\beta} \leqq n^{\alpha+\beta}. \tag{6.2}$$

Then, steps M4 and M10 in the abnormal case have a complexity of $O(p^3(m+n)^3)$ and the remaining steps a complexity of $O(p^3(m+n)^2)$, at worst. When $(A(z), B(z))$ is normal, then due to the fact that $T_{s-1,n'-m'+s-1}$ is always in triangular form, the complexity of MPADE reduces to $O(p^3(m+n)^2)$. This is also true when $(A(z), B(z))$ is nearly normal. In this case s_i is often larger than 1, but the matrix $T_{s-1,n'-m'+s-1}$ is

TABLE 6.1
Bounds on operations per step.

Step	Normal case	Abnormal case
I5	0	$p^3(n'-m'-1+2(s-1))^3/3$
I6	$p^3(n'-m'+1)^2/2$	$p^3(n'-m'+2s-1)^2/2$
I7	0	$p^3(n'-m'+2s-1)^2/2$
M2	$p^3(m-n)^2$	$p^3(m-n)^2$
M4	$p^3(m-n)^2$	$p^3[(n-m-1+2(s_0-1))^3/3+(n-m+2s_0-1)^2]$
M8	$2p^3(m_i+n_i+2)$	$2p^3(m_i+n_i+2)s_i$
M9	$2p^3(m_i+n_i+2)$	$2p^3(m_i+n_i+2)s_i$
M10	0	$8p^3(s_i-1)^3/3$
M11	$8p^3(m_i+n_i+2)$	$8p^3(m_i+n_i+2)s_i$

also always in triangular form and so again the complexity is $O(p^3(m+n)^2)$. In particular, in the scalar case the complexity of MPADE is $O((m+n)^2)$.

The algorithm gives the worst performance when no nonsingular nodes are encountered along the $m-n$ off-diagonal path. In this case, with $m < n$, the algorithm reduces to solving one Sylvester system

$$S_{m,n}\begin{bmatrix} V_1 \\ U_1 \end{bmatrix} = 0 \tag{6.3}$$

in step M4 of MPADE. In Table 6.1, with $s_0 = m+1$, then the cost is simply that of Gaussian elimination, namely, approximately $p^3(m+n)^3/3$. Note that with the existence of even one nonsingular node the cost of MPADE can be dramatically reduced. If, for example, this one nonsingular node is $(m_1, n_1) = (m/2, n-m/2)$, where m is even, then $s_0 = 1+m/2$, $s_1 = m/2$ and the algorithm reduces essentially to solving (in steps M4 and M10) two Sylvester systems, each of approximately half the total size. This results in a saving of a factor of 4 over the simple use of Gaussian elimination. Algorithms requiring normality, on the other hand, break down when even one intermediate node is singular.

7. Conclusions. We have considered the problem of determining an adequate definition for a rational approximant of a formal matrix power series and also, given a suitable definition, the problem of computing it. We have restricted our attention to square matrix power series.

In attempting to extend the notion of Padé approximation to matrix power series, we have followed the classical theory of Padé approximants for scalar power series. We introduce the notion of a Padé form, which always exist but may not be unique, and also the notion of Padé fraction, which is unique but need not exist. The definition of Padé form is meant to be as broad as possible. By constructing all the Padé forms of type (m, n), it is always possible to determine ones for which the denominator is invertible, should one exist.

The notion of a matrix power series remainder sequence introduced in this paper is a generalization of one given by Cabay and Kossowski [9] for scalar power series. The cofactor sequence, which is shown to be associated with the remainder sequence, yields directly all the Padé fractions at the nonsingular nodes of a particular off-diagonal path of the Padé table. By determining also the (unique) Padé form at nodes preceding the nonsingular nodes, we are able to compute Padé fractions iteratively from one nonsingular node to the next. The resulting algorithm is at least as fast as other algorithms for computing matrix Padé fractions, and it is the only one that succeeds in the abnormal case.

The algorithm can be improved in a number of ways. We expect that the cost of the decomposition of $T_{s-1,n'-m'+s-1}$ in step I5 and, consequently, of $S_{s-1,n'-m'+s-1}$ in step I6 can be improved by taking advantage of the special structure of Sylvester matrices. The algorithm would also experience an improvement if it were possible to identify additional points between nonsingular nodes for which Theorem 4.5 is valid. This would improve the algorithm by decreasing the s_i. This, and in general the nature of Padé forms between nonsingular nodes, is a subject for further research. Finally, by appealing to fast methods for polynomial arithmetic, it is of interest to attempt to develop a recursive divide-and-conquer version of MPADE.

For normal and nearly normal power series, progressing from one nonsingular node to the next is equivalent to power series division of the residuals associated with the nonsingular nodes (because $S_{s-1,n'-m'+s-1}$ in step I5 of INITIAL_PADE, with the

exception of one column, reduces to a triangular matrix). Thus, in this case and in addition when $A(z)$ and $B(z)$ are matrix polynomials, there is a strong analogy between MPADE and Euclid's algorithm. It is a subject for future research to investigate the possibility of using MPADE to compute the greatest common divisor of two matrix polynomials in the abnormal case.

WORST-CASE COMPLEXITY BOUNDS ON ALGORITHMS FOR COMPUTING THE CANONICAL STRUCTURE OF FINITE ABELIAN GROUPS AND THE HERMITE AND SMITH NORMAL FORMS OF AN INTEGER MATRIX*

COSTAS S. ILIOPOULOS†

Abstract. An $O(s^5M(s^2))$ algorithm for computing the canonical structure of a finite Abelian group represented by an integer matrix of size s (this is the Smith normal form of the matrix) is presented. Moreover, an $O(s^3M(s^2))$ algorithm for computing the Hermite normal form of an integer matrix of size s is given.

The upper bounds derived on the computational complexity of the algorithms above improve the upper bounds given by Kannan and Bachem in [*SIAM J. Comput.*, 8 (1979), pp. 499-507] and Chou and Collins in [*SIAM J. Comput.*, 11 (1982), pp. 687-708].

Key words. Smith normal form, Hermite normal form, integer matrices, computational complexity

1. Introduction. Recently Chou and Collins [2] improved the results of Kannan and Bachem [6] on the computation of the Hermite and Smith normal form (abbreviated HNF and SNF, respectively) of an integer matrix. Reduction to the HNF and SNF can be done via integer row-column operations (abbreviated IRC operations; see [8]).

A closely related problem is the computation of the canonical structure [8] of a finite Abelian group G represented by a set of defining relations that is associated with an integer matrix. We can reduce the exponents of the generators in the set of defining relations modulo the order of the group, say d, and add to the set the relation $x^d = 1$, for every generator x, respecting the structure of the group. This fact allows the use of arithmetic modulo d for the IRC operations over the associated matrix (as formulated in § 2).

The computational complexity is measured in terms of elementary operations. An *elementary operation* is a Boolean operation on a single binary bit or pair of bits or an input or shift of a binary bit. $M(n)$ denotes an upper bound on the number of elementary operations required for multiplication of two integers of length n bits [10] and the size s of an $m \times n$ matrix A is the number $m+n+\log \|A\|$, with $\|A\| = \max_{i,j} \{|a_{ij}|\}$.

The main results of this paper are the following:

(i) An $O(s^3M(s^2))$ elementary operations algorithm for computing the HNF of a nonsingular integer matrix of size s.

(ii) An $O(s^5M(s^2))$ elementary operations algorithm for computing the SNF of a nonsingular integer matrix of size s.

The upper bounds found for (i) and (ii) improve the upper bounds given by Chou and Collins in [2] (see also Kannan and Bachem [6]). For (i) Chou and Collins proved an upper bound of $O(s^8)$ elementary operations and for (ii), using the Kannan-Bachem

method for reduction to SNF together with the improvements of Chou and Collins, we can derive an upper bound $O(s^{11})$ elementary operations.

The IRC operations performed on A in reduction to HNF matrix T are associated with a factorization of T as MA, where M is a square unimodular matrix. Similarly the IRC operations performed on A in reduction to SNF matrix D are associated with a factorization of D as BAC, where B and C are square unimodular matrices. Bounds on the complexity of the computation of the matrices M, B, C are also provided.

1.1. Preliminaries. Some upper bounds on the size of the determinant of an integer matrix and on the running time of algorithms for matrix multiplication and for computing the greatest common division (gcd) of two integers are exposed here.

THEOREM 1.1. (Hadamard). *Let A be an $n \times n$ matrix and let $d_i = \max_{1 \leqq j \leqq n} \{|\alpha_{ij}|\}$ for $1 \leqq i \leqq n$. Then*

$$|\det(A) \leqq \prod_{i=1}^{n} \left(\sum_{j=1}^{n} |a_{ij}|^2 \right)^{1/2}.$$

COROLLARY 1.2. *Let A be an $n \times n$ matrix with integer entries. Then we have the following*:

(i) $|\det(A)| \leqq n^{n/2} \|A\|^n$.

(ii) $\log(|det(A)|) = O(s^2)$, *where s is the size of A.*

THEOREM 1.3 (Gaussian elimination). *There exists an algorithm for computing the row-echelon form of an $m \times n$ matrix A with entries from a field in $O(mnrM(\log|d|))$ elementary operations, where $r = \operatorname{rank}(A)$, and d is the largest in absolute value determinant of a minor of A.*

Proof. It follows from the fact that the numerators and denominators of the rationals arising during the Gaussian elimination have modulos at most d, with d the maximum determinant of all square submatrices of A (see [4, p. 26]). □

The problems "computing the determinant of a square matrix," "computing the inverse of a nonsingular matrix," and "matrix multiplication" are computationally equivalent (for details see Strassen [12], Winograd [13], or Aho et al. [1]). In 1969 Strassen showed in [12] that matrix multiplication of 2×2 matrices can be done with seven multiplications instead of eight and, in general, the multiplication of $n \times n$ matrices can be done with $O(n^{\log 7}) = O(n^{2.81})$ multiplications instead of $O(n^3)$ multiplications required by the classical algorithm. This surprising result led to a series of improved algorithms for matrix multiplication, requiring even fewer multiplications. Currently the best upper bound on the number of multiplications required for matrix multiplication is the following.

THEOREM 1.4 (Coppersmith-Winograd [3]). *There exists an algorithm for multiplying two $n \times n$ matrices using $O(n^{\alpha})$ multiplications, where*

$$\alpha = 2.376.$$

In the sequel, when the time required for the "computation of the determinant" is not the bottleneck of the overall time complexity of the problem in investigation, we make use of the Gaussian elimination; otherwise we make use of the algorithm of Theorem 1.4. The reason is that the Coppersmith-Winograd algorithm is not practical, due to the very large hidden constant in the upper bound on the number of multiplications required.

The following theorem yields an upper bound on Knuth's algorithm (see [7]) for computing the greatest common divisor of two integers. This upper bound was proved by Schönhage in [9].

THEOREM 1.5 (Extended Euclidean Algorithm (EEA)). *There exists an algorithm for computing the greatest common divisor r of two n bit integers a_1 and a_2 and two integers x_1 and x_2 such that*

$$x_1a_1 + x_2a_2 = r$$

with

$$|x_1| \leqq |a_2|/2, \qquad |x_2| \leqq |a_1|/2$$

in $O(\log nM(n))$ elementary operations.

COROLLARY 1.6. *There exists an algorithm for computing r, the gcd of the integers $a_1, \cdots, a_k$ of length at most n binary bits and k integers $t_1, \cdots, t_k$ such that*

$$t_1a_1 + \cdots + t_ka_k = r$$

with

$$\log \|t\| := \max_i \{|t_i|\} = O(n \log k)$$

in $O(k \log nM(n))$ elementary operations.

Proof. Without loss of generality, assume that k is a power of 2. Let $a_1, \cdots, a_k$ be leaves of a balanced binary tree. Moreover let each parent node be the gcd of its children. Therefore the root of the tree is the gcd $(a_1, \cdots, a_k)$.

We can build up the tree using the EEA of Theorem 1.5. The t_i's can be computed by combining the expressions of the gcd's at each level of the tree.

The upper bounds can be found by a simple manipulation of the upper bounds of Theorem 1.5 and using the fact that the height of the tree is equal to $\log k$. □

2. The procedures ELIMINATECOL–ELIMINATEROW. Suppose that A is an $m \times n$ integer matrix associated with the set of defining relations of a finite Abelian group G. The matrix A has rank n and if B is an $n \times n$ nonsingular submatrix of A, then the determinant of B denoted $\det(B)$, is readily shown to be a multiple of the order $|G|$ of the group G. Moreover if I_n denotes the $n \times n$ identity matrix, then the $(m+n) \times n$ matrix

$$K = \begin{bmatrix} A \\ dI_n \end{bmatrix} \quad \text{with } d = \det(B) \tag{2.1}$$

presents the same group.

Matrix B and its determinant d can be computed by means of Gaussian elimination over the rationals.

ALGORITHM 2.1.

INPUT: The matrix K of (2.1) and an integer ρ such that $1 \leqq \rho \leqq n$.

OUTPUT: An $(m+n) \times n$ matrix K^* of the form

$$\begin{bmatrix} A^* \\ dI_n \end{bmatrix}$$

where the ρth column of A^* is of the form $(a^*_{1\rho}, \cdots, a^*_{\rho\rho}, 0, \cdots, 0)^T$ and K^* is a transformation of K via integer row operations.

Procedure ELIMINATECOL (K, d, ρ)

begin

if $k_{\rho\rho} \neq 0$ *then*
begin
(1) $r \leftarrow \gcd(k_{\rho\rho}, k_{\rho+1,\rho})$;
(2) compute integers x_1, x_2: $x_1 k_{\rho\rho} + x_2 k_{\rho+1,\rho} = r$;
comment Use the algorithm of Theorem 1.5.
(3) $y_1 \leftarrow k_{\rho+1,\rho}/r$;
(4) $y_2 \leftarrow -k_{\rho\rho}/r$;

$$L \leftarrow \left[\begin{array}{c|c|c} I_{\rho-1} & 0 & 0 \\ \hline 0 & \begin{matrix} y_1 & y_2 \\ x_1 & x_2 \end{matrix} & 0 \\ \hline 0 & 0 & I_{m+n-\rho-1} \end{array}\right];$$

comment Note that L is unimodular.
(5) $K \leftarrow L \cdot K$;
comment The result of step (5) is a matrix K having $k_{\rho\rho} = 0$ and $k_{\rho+1,\rho} = r$.
end
(6) $s \leftarrow \gcd(k_{\rho+1,\rho}, k_{\rho+2,\rho}, \cdots, k_{m\rho}, d)$;
(7) compute integers t_j for $\rho+1 \leqq j \leqq m+1$: $\sum_{j=\rho+1}^{m} t_j k_{j\rho} + t_{m+1} d = s$;
(8) $t_j \leftarrow t_j \pmod d$ for $\rho+1 \leqq j \leqq m$;
$t_{m+1} \leftarrow (s - \sum_{j+\rho+1}^{m} t_j k_{j\rho})/d$;
(9) ROW $(\rho) \leftarrow$ ROW $(\rho) + \sum_{j=\rho+1}^{m} t_j$ ROW $(j) + t_{m+1}$ ROW $(m+\rho)$;
comment The entry $k_{\rho\rho}$ of K is equal to s. Note that the computation of t_{m+1} is not necessary, since we can merely assign $k_{\rho\rho} = s$
(10) ROW $(i) \leftarrow$ ROW $(i) - (k_{i\rho}/s)$ ROW (i), for $\rho+1 \leqq i \leqq m$;
comment Now COL $(\rho) = (k_{1\rho}, \cdots, k_{\rho\rho}, 0, \cdots, 0, d, 0, \cdots, 0)^T$
(11) ROW $(i) \leftarrow$ ROW $(i) - (\lfloor k_{ij}/d \rfloor)$ ROW $(m+j)$, $1 \leqq i \leqq m$, $1 \leqq j \leqq n$;
comment At this step all the entries of K are reduced mod d.
return K;
end

Remark 2.1. We may speed up (in practice) the above procedure by making the following modifications:

(i) At the beginning of the procedure ELIMINATECOL we can check if there exists a $k_{i\rho}$ for some $\rho \leqq i \leqq m$ such that $k_{i\rho}$ divides $k_{j\rho}$ for every $\rho \leqq j \leqq m+\rho$ and if it exists, then interchange ROW (i) and ROW (ρ) and go to step (10) with $s = k_{i\rho}$.

(ii) At the beginning of the procedure we may check whether or not there exists a $k_{i\rho}$ for some $\rho \leqq i \leqq m$ such that $k_{i\rho} = 0$ and if it exists then interchange ROW (i) and ROW (ρ) and go to Step (6).

Note that the amount of computational time that can be saved with the above modifications does not effect the asymptotic worst-case time complexity.

Remark 2.2. Suppose that the matrix K of (2.1) is transformed to K^* after an application of the procedure ELIMINATECOL (K, d, ρ). Since every integer-row operation can be expressed as matrix multiplication of K by a unimodular matrix, we can easily modify ELIMININATECOL to compute a unimodular matrix L such that $LK = K^*$. Note that this can be done without an increase in asymptotic time complexity and $\log \|L\| = O(\log \|K\|)$.

PROPOSITION 2.2. *The procedure* ELIMINATECOL *terminates in*

$$O(mnM(\log(m\|K\|) + mM(\log \|K\|) \log\log \|K\|)$$

elementary operations in the worst-case and the norm $\|K^*\|$ *of the output matrix* K^* *is equal to* $|d|$.

Proof. Steps (1)-(2) require $O(M(\log \|A\|) \log\log \|A\|)$ elementary operations for an application of the EEA and

$$|x_1| \leqq |k_{\rho+1,\rho}|/2, \qquad |x_2| \leqq |k_{\rho\rho}|/2. \tag{2.2}$$

Steps (3)-(4) require $O(M(\log \|A\|))$ elementary operations for divisions.

In view of (2.2), step (5) requires at most $4n$ multiplications comprising $O(nM(\log \|A\|))$ elementary operations. If A' denotes the m top rows of K after step (5), then we can see that

$$\|A'\| = O(\|A\|^2). \tag{2.3}$$

Steps (6)-(7) require $O(mM(\log \|K\|) \log\log \|K\|)$ elementary operations for an application of the algorithm of Corollary 1.6, since, using (2.3), it follows that

$$\max\{k_{\rho+1,\rho}, \cdots, k_{m\rho}, d\} = O(\|A\|^2 + |d|) = O(\|K\|^2)$$

where K denotes the input matrix. (Note that $|d| = O(\|K\|)$.)

Step (8) requires $O(mM(\log \|K\|))$ elementary operations for divisions.

Step (9) requires $O(mnM(\log \|K\|))$ elementary operations for mn multiplications in the worst case. If A'' denotes the m top rows of K after Step (9) then

$$\|A''\| = O(m\|K\|^3). \tag{2.4}$$

Step (10) requires $O(mnM(\log \|A''\|)) = O(mnM(\log (m\|K\|)))$ elementary operations for divisions/multiplications when we use (2.4).

Step (11) requires $O(mnM(\log (m\|K\|)))$ elementary operations. The entries of K are reduced modulo d; hence the entries of the output matrix are bounded by $|d| = O(\|K\|)$. □

Remark 2.3. We can observe that the dominant complexity of the procedure is the computation in lines (9), (10), and (11) that require $O(mnM(\log (m\|K\|)))$ elementary operations, except in the case of A with enormous entries

$$\|A\| \geqq 2^{2^{m+\varepsilon}}.$$

ALGORITHM 2.3.

INPUT: The matrix K of (2.1) and an integer ρ such that $1 \leqq \rho \leqq m$.

OUTPUT: An $(m+n) \times n$ matrix K^* of the form

$$\begin{bmatrix} A^* \\ dI_n \end{bmatrix}$$

where the ρth row of A^* is of the form $(a^*_{\rho 1}, \cdots, a^*_{\rho\rho}, 0, \cdots, 0)$ and K^* is a transformation of K via IRC operations.

(Note that procedure ELIMINATEROW is almost symmetric with the procedure ELIMINATECOL; steps (6), (10), and (12) are the only nonsymmetries.)

Procedure ELIMINATEROW (K, d, ρ)
  begin
    if $k_{\rho\rho} \neq 0$ *then*
      begin

(1) $r \leftarrow \gcd(k_{\rho\rho}, k_{\rho,\rho+1})$;

(2) compute x_1, x_2: $x_1 k_{\rho\rho} + x_2 k_{\rho,\rho+1} = r$ with $|x_1| \leqq |k_{\rho,\rho+1}|/2$, $|x_2| \leqq |k_{\rho\rho}|/2$;

(3) $y_1 \leftarrow k_{\rho,\rho+1}/r$;

(4) $y_2 \leftarrow -k_{\rho\rho}/r$;

(5)
$$K \leftarrow K \begin{bmatrix} I_{\rho-1} & 0 & 0 \\ 0 & \begin{matrix} y_1 & x_1 \\ y_2 & x_2 \end{matrix} & 0 \\ 0 & 0 & I_{n-\rho-1} \end{bmatrix}.$$

(6) $k_{m+\rho,\rho} \leftarrow d$; $k_{m+\rho+1,\rho+1} \leftarrow d$; $k_{m+\rho+1,\rho} \leftarrow 0$; $k_{m+\rho,\rho+1} \leftarrow 0$;

comment The above operation can be expressed as a sequence of row operations. See Remark 2.4 below.

end

(7) $s \leftarrow \gcd(k_{\rho,\rho+1}, \cdots, k_{\rho n})$;

(8) Compute t_j for $\rho+1 \leqq j \leqq n$: $\sum_{j=\rho+1}^{n} t_j k_{\rho j} = s$;
$t_j \leftarrow t_j \bmod d$ for $\rho+1 \leqq j \leqq n$;

(9) $\mathrm{COL}(\rho) \leftarrow \mathrm{COL}(\rho) + \sum_{j=\rho+1}^{n} t_j \,\mathrm{COL}(j)$;

(10) $\mathrm{ROW}(m+j) \leftarrow \mathrm{ROW}(m+j) - t_j \,\mathrm{ROW}(m+\rho)$, for $\rho+1 \leqq j \leqq n$;

comment This step is not necessarily executed, since we can merely assign $k_{m+\rho+1,\rho} = \cdots = k_{m+n,\rho} = 0$.

(11) $\mathrm{COL}(j) \leftarrow \mathrm{COL}(j) - (k_{\rho j}/s)\,\mathrm{COL}(\rho)$, $\rho+1 \leqq j \leqq n$;

(12) $\mathrm{ROW}(m+\rho) \leftarrow \mathrm{ROW}(m+\rho) - \sum_{j=\rho+1}^{n} (k_{\rho j}/s)\,\mathrm{ROW}(m+j)$;

comment This step is not necessarily executed, since we can merely assign $k_{m+\rho,\rho+1} = \cdots = k_{m+\rho,n} = 0$

(13) $\mathrm{ROW}(i) \leftarrow \mathrm{ROW}(i) - (\lfloor k_{ij}/d \rfloor)\,\mathrm{ROW}(m+j)$, $\rho \leqq i \leqq n$, $\rho \leqq j \leqq m$;

return K;

end

Remark 2.4. If M is the inverse of

$$\begin{bmatrix} y_1 & x_1 \\ y_2 & x_2 \end{bmatrix},$$

then we can see that

$$\begin{bmatrix} I_{m+\rho-1} & 0 & 0 \\ 0 & M & 0 \\ 0 & 0 & I_{m+n-\rho-1} \end{bmatrix}.$$

K is equivalent to step (6), and thus it can be expressed as a sequence of row operations.

The row operations at steps (6), (10), and (12) are necessary in order to preserve the form of the n bottom rows of K as dI_n.

Remark 2.5. We may speed up the above procedure by modifying it in a way similar to the modification suggested for procedure ELIMINATECOL in Remark 2.1.

Remark 2.6. Suppose that K^* is the output matrix of ELIMINATEROW (K, d, ρ). Then it is not difficult to modify ELIMINATEROW in order to compute two unimodular matrices L and R such that

$$LKR = K^*.$$

PROPOSITION 2.4. *The procedure* ELIMINATEROW *terminates in*

$$O(mnM(\log(m\|K\|)) + nM(\log\|K\|)\log\log\|K\|)$$

elementary operations and the norm $\|K^*\|$ *of the output matrix* K^* *is equal to* $|d|$.

Remark 2.7. We can show that the computation of the matrices L and R of Remark 2.6 can be done without any asymptotic increase in the worst-case complexity of the procedure ELIMINATEROW and $\log(\max\{\|L\|, \|R\|\}) = O(\log \|K\|)$.

3. The main algorithm.

ALGORITHM 3.1.

INPUT: An $m \times n$ matrix representing a finite Abelian group G.

OUTPUT: The canonical structure of the group G.

begin

(1) $d \leftarrow$ The determinant of an $n \times n$ nonsingular submatrix of A;

(2) $K = \begin{bmatrix} A \\ dI_n \end{bmatrix}$;

(3) *for* $\rho = 1$ *to* n *do*
begin

(4) *repeat*

(5) ELIMINATEROW (K, d, ρ);

(6) ELIMINATECOL (K, d, ρ);

(7) *until* $k_{\rho\rho} | k_{\rho i}$ for $\rho + 1 \leqq i \leqq n$;
$k_{\rho i} \leftarrow 0$ for $\rho + 1 \leqq i \leqq n$;

(8) *end*
$A \leftarrow$ the n top rows of K;

(9) *for* $p = 1$ *to* n *do*
begin

(10) *for* $q = p + 1$ *to* n *do*
begin
$h \leftarrow a_p$;
$a_{pp} \leftarrow \gcd(a_{qq}, h)$;
$a_{qq} \leftarrow a_{qq} \cdot h / a_{pp}$;

(11) *end*

(12) *end*
return A;

end

PROPOSITION 3.2. *Algorithm* 3.1 *correctly computes a canonical basis for the Abelian group* G *in* $O(mn(n + \log\log \|K\|) \log \|K\| M(\log(m\|K\|)) + mn^2 M(\log d^*))$ *elementary operations, where* $\|K\| = \max\{|d|, \|A\|\}$ *and* $d^* = \max\{|\delta|: \delta$ *is the determinant of a square submatrix of* $A\}$.

Proof. The computation of a multiple of the order of the group G (Step (1)) requires $O(mn^2 M(\log d^*))$ elementary operations by Theorem 1.3.

Steps (5) and (6) require $O(mnM(\log m\|K\|) + mM(\log \|K\|) \log\log \|K\|)$ elementary operations; this follows from Propositions 2.4 and 2.2 and the facts

$$\|K^{(i)}\| \leqq |d| \leqq \|K\|, \qquad m \geqq n$$

where $K^{(i)}$ denotes the current matrix K at the ith iteration of the loop (4)-(7). The number of iterations required by loop (4)-(7) is at most $O(\log \|K\|)$ since

$$|k_{\rho\rho}^{(i)}| \leqq |k_{\rho\rho}^{(i-1)}|/2. \tag{3.1}$$

Hence loop (3)-(8) requires $O(n \log \|K\|)$ iterations.

Loop (9)-(12) requires $O(n^2)$ applications of EEA and $O(n^2)$ multiplications/divisions comprising $O(n^2M(\log|d|)\log\log|d|) = O(n^2M(\log\|K\|)\log\log\|K\|)$ elementary operations.

The proposition follows from the above analysis. □

COROLLARY 3.3. *Algorithm* 3.1 *terminates in* $O(mn^2[n+\log(n\log(n\|A\|))]\log(n\|A\|)M(n\log(mn\|A\|)))$ *elementary operations.*

Proof. We derive the proof from Proposition 3.2, using the fact that

$$\max\{\|K\|, d^*\} = \max\{\|A\|, |d|, d^*\} \leqq (n\|A\|)^n. \qquad \square$$

COROLLARY 3.4. *If a finite Abelian group is represented by a matrix of size s, then we can compute its canonical structure in* $O(s^5M(s^2))$ *elementary operations.* □

4. Hermite normal form.

THEOREM 4.1 (Hermite, see [5]). *Given a nonsingular* $n \times n$ *integer matrix A, there exists an* $n \times n$ *unimodular matrix M such that* $MA = T$ *is upper triangular with positive diagonal elements. Further, each off-diagonal element of T is nonpositive and strictly less in absolute value than the diagonal elements in its column.*

The algorithm below for computing the HNF of an integer matrix makes use of a version of the procedure ELIMINATECOL (K, d, ρ) with $K = \begin{bmatrix} A \\ dI_n \end{bmatrix}$, which eliminates all the entries below the diagonal element $k_{\rho\rho}$ of the ρth column of the matrix K. The modified version of ELIMINATECOL is as follows:

(i) Eliminate the entries $\alpha_{\rho+1,\rho}, \cdots, \alpha_{n,\rho}$ of K in a similar manner as ELIMINATECOL followed by reduction modulo d.

(ii) Do the row operation $\mathrm{ROW}(m+\rho) \leftarrow \mathrm{ROW}(m+\rho) - (d/k_{\rho\rho})\,\mathrm{ROW}(\rho)$ and let $A \leftarrow$ the n top rows of K and $\mathrm{ROW}(m+\rho)$ as last row.

(iii) The output matrix is of the form

$$\begin{bmatrix} & A & \\ dI_{\rho-1} & 0 & \\ & \vdots & 0 \\ 0 & 0 & dI_{n-\rho} \end{bmatrix}.$$

The above modified version of ELIMINATECOL will be called ELIMINATECOL* in the sequel.

Remark 4.1. The ρth column of the output matrix (say K^*) is of the form $(k_{1\rho}, \cdots, k_{\rho\rho}, 0, \cdots, 0)^T$. The running time of ELIMINATECOL* is asymptotically the same with the running time of ELIMINATECOL. Moreover, there exists a unimodular matrix L such that $L \cdot K = K^*$ and $\log\|L\| = O(\log\|K\|)$.

ALGORITHM 4.2.

INPUT: An $n \times n$ nonsingular matrix A.

OUTPUT: A matrix T the HNF of A and a matrix M such that $MA = T$.

begin

(1) $d \leftarrow \det(A)$;

(2) $K \leftarrow \begin{bmatrix} A \\ dI_n \end{bmatrix}$;

(3) *for* $i = 1$ *to* n *do*
begin
ELIMINATECOL* (K, d, i);

(4) *end*

$T^* \leftarrow [k_{ij}]$, $1 \leqq j \leqq n$, $1 \leqq i \leqq n$;

comment T^* is upper triangular now, but its off-diagonal entries do not satisfy the conditions of Theorem 4.1.

(4.1) $K \leftarrow \begin{bmatrix} T^* \\ dI_n \end{bmatrix}$;

ROW $(i) \leftarrow -$ROW (i) for each $k_{ii} < 0$;

(5) *for* $i = 2$ *to* n *do*

begin

(4.2) ROW $(j) \leftarrow$ ROW $(j) - (\lceil k_{ij}/k_{ii} \rceil)$ ROW (i) for $i \leqq j \leqq i$;

(4.3) ROW $(j) \leftarrow$ ROW $(j) - (\lfloor k_{jl}/d \rfloor)$ ROW $(n+l)$ for $1 \leqq j \leqq i$, $i \leqq l \leqq n$;

(6) *end*

comment The re-introduction of K at (4.1) was necessary, since the entries of K would grow exponentially at (4.2) without the reduction modulo d at (4.3).

$T \leftarrow [k_{ij}]$ for $1 \leqq i, j \leqq n$

(7) Solve the system: $X \cdot T = A$;

(8) return $M = X^{-1}$, T;

end

Remark 4.2. The employment of ELIMINATECOL* was necessary, since the use of ELIMINATECOL instead of ELIMINATECOL* would lead to an upper triangular of determinant qd, with q not necessarily equal to ± 1.

PROPOSITION 4.3. *Algorithm* 4.2 *correctly computes the* HNF *of* A *in* $O(n^2[n + \log(n \log(n\|A\|))]M(n \log(n\|A\|)))$ *elementary operations.*

Proof. First observe that there exists an integer matrix such that

$$WA = dI_n$$

and since every application of ELIMINATECOL* and every IRC operation corresponds to a multiplication of K by an $(m+n) \times (m+n)$ unimodular matrix, this implies the existence of a matrix L such that

$$L \begin{bmatrix} A \\ dI_n \end{bmatrix} = \begin{bmatrix} T^* \\ 0 \end{bmatrix},$$

and thus

$$L \begin{bmatrix} I_n & 0 \\ W & I_n \end{bmatrix} \begin{bmatrix} A \\ 0 \end{bmatrix} = \begin{bmatrix} T^* \\ 0 \end{bmatrix}.$$

Hence, if

$$\begin{bmatrix} Z_1 & Z_2 \\ Z_3 & Z_4 \end{bmatrix} := L \begin{bmatrix} I_n & 0 \\ W & I_n \end{bmatrix}$$

with Z_i matrices of dimension $n \times n$ for $1 \leqq i \leqq 4$, it then follows that

$$Z_1 A = T^*.$$

The matrices T^* and A represent the same group; hence $\det(T^*) = \det(A)$ and thus Z_1 is unimodular.

In a similar way we can show the existence of a unimodular matrix Z^* such that $Z^*T^* = T$ and thus prove that T is the HNF of A.

The computation of the determinant requires $O(n^3 M(n \log(n\|A\|)))$ elementary operations when we use Theorem 1.3 and Corollary 1.2(i).

Loop (3)-(4) requires $O(n^3M(\log n\|K\|)+n^2M(\log\|K\|)(\log\log\|K\|))$ elementary operations when we use Proposition 2.2.

We can show easily that loop (5)-(6) requires $O(n^3)$ multiplications comprising $O(n^3M(\log|d|))$ elementary operations.

The computation of X is not difficult since T is triangular and it requires $O(n^2)$ divisions comprising $O(n^2M(\log|d|))$ elementary operations.

The computation of the inverse of X requires $O(n^3M(n\log(n\|A\|)))$ elementary operations, by Theorem 1.3 and Corollary 1.2(i) (see the discussion below Theorem 1.3).

Hence, when we use

$$\|K\|\leqq\max\{\|A\|,|d|\}\leqq(n\|A\|)^n,$$

the proposition follows. □

COROLLARY 4.4. *There exists an algorithm for computing the* HNF *of a nonsingular matrix with integer entries of size s and the multiplier unimodular matrix M of Theorem* 4.1 *in* $O(s^3M(s^2))$ *elementary operations.*

In [2] Chou and Collins gave an $O(n^4(n+n\log(n\|A\|))^2)=O(s^8)$ elementary operations upper bound for computing the HNF of an integer matrix. This bound has been improved by a factor of $O(s^{3-\varepsilon})$ for any $\varepsilon>0$.

5. Smith normal form.

PROPOSITION 5.1 (Smith, see [11]). *Given a nonsingular* $n\times n$ *integer matrix A, there exist* $n\times n$ *unimodular matrices B, C such that* $D=BAC$ *is a diagonal matrix with positive diagonal elements such that* $d_{11}|d_{22}|\cdots|d_{nn}$.

From Corollary 3.3 we have the following.

PROPOSITION 5.2. *The* SNF *of an* $n\times n$ *matrix A can be computed in* $O(n^3[n+\log(n\log(n\|A\|))]\log(n\|A\|)M(n\log(n\|A\|)))$ *elementary operations.*

COROLLARY 5.3. *The* SNF *of a nonsingular matrix A of size s can be computed in* $O(s^5M(s^2))$ *elementary operations.*

PROPOSITION 5.4. *There exists an algorithm for computing the matrices B and C of Proposition* 5.1 *in* $O(n^{\alpha+2}\log(n\|A\|)\log(n\log(n\|A\|))M(n\log(n\|A\|)))$ *elementary operations, where* $O(n^\alpha)$ *multiplications are required for matrix multiplication.*

Proof. We can compute the matrix D the SNF of A using Algorithm 3.1. Each application of ELIMINATECOL in Algorithm 3.1 is equivalent to a pro-multiplication of K (as in (2.1)) by a unimodular matrix L_i (see Remark (2.2)) and each application of ELIMINATEROW is equivalent to L_jKR_i, where L_j, R_i are unimodular matrices (see Remark 2.6).

Hence there exist unimodular matrices $L_1,\cdots,L_\mu$ of dimension $2n\times 2n$ and $R_1,\cdots,R_\lambda$ of dimension $n\times n$ (corresponding to applications of ELIMINATEROW-ELIMINATECOL) such that

$$L_\mu\cdots L_1\begin{bmatrix}A\\ dI_n\end{bmatrix}R_1\cdots R_\lambda=\begin{bmatrix}D\\ dI_n\end{bmatrix}. \tag{5.1}$$

Let

$$L=L_\mu\cdots L_1=:\begin{bmatrix}\Lambda_1 & \Lambda_2\\ \Lambda_3 & \Lambda_4\end{bmatrix},$$

where Λ_i is an $n\times n$ matrix for $1\leqq i\leqq 4$, and $R=R_1\cdots R_\lambda$.

Moreover we can compute an $n\times n$ matrix W such that

$$WA=dI_n \tag{5.2}$$

by computing the inverse of A.

From (5.1), (5.2) it follows that

$$L\begin{bmatrix} I_n & 0 \\ W & I_n \end{bmatrix}\begin{bmatrix} A \\ 0 \end{bmatrix}, \qquad R = \begin{bmatrix} D \\ dI_n \end{bmatrix},$$

which implies that

$$(\Lambda_1 + \Lambda_2 W)AR = D$$

and the matrix $\Lambda_1 + \Lambda_2 W$ is unimodular, since $\det(R) = 1$ and $\det(A) = \det(D)$ (from Proposition 5.2). Hence in order to compute the matrices B and C, it suffices to compute the matrices L, R, and W.

Proposition 3.2 and Remarks 2.2, 2.6, and 2.7 yield the running time required for the computation of the L_i's and R_i's. Moreover the computation of W requires $O(n^\alpha)$ multiplications (see comments below Theorem 1.3).

Hence the analysis of the computation of L and R only remains. Using (3.1), we can show

$$\max\{\lambda, \mu\} = O(n \log |d|) = O(n^2 \log (n\|A\|)), \tag{5.3}$$

and using Remarks 2.2 and 2.7 we can show that

$$Q := \max_{i,j}\{\|L_i\|, \|R_j\|\} \leqq \max\{\|A\|, |d|\} \leqq (n\|A\|)^n. \tag{5.4}$$

The computation of L is done as follows. Let $L_\mu, \cdots, L_1$ be the leaves of a balanced binary tree and without loss of generality assume that μ is a power of 2. Moreover, let each parent node represent the product (in order) of its children. Then the root represents L.

We can observe that the entries of a matrix at the ith level of the tree is at most Q^{2^i} in absolute value, and the computation of the root requires $O(\sum_{i=1}^{h}(\mu/2^i))$ matrix multiplications, where $h = O(\log \mu)$ is the height of the tree. Therefore the computation of L requires

$$O\left(n^\alpha \sum_{i=1}^{h}\left(\frac{\mu}{2^i}\right)M(2^i \log Q)\right) \quad \text{elementary operations,}$$

comprising $O(n^{\alpha+2} \log (n\|A\|) \log (n \log (n\|A\|))M(n \log (n\|A\|)))$ elementary operations, using (5.3) and (5.4). The computation of R is done in a similar way.

COROLLARY 5.5. *Let the matrices A, B, and C be as in Proposition* 5.1. *Given A, there exists an algorithm for computing the matrices B and C in $O(s^{5.376} \log sM(s^2))$ elementary operations, where s is the size of A.*

Acknowledgments. The author owes a very significant debt to Dr. W. M. Beynon for his direct and indirect aid in this research. Thanks to J. D. Dixon for helpful discussions and for pointing out reference [2]. Thanks also to the referee for pointing out various inaccuracies in earlier versions of the paper and for his helpful suggestions.

WORST-CASE COMPLEXITY BOUNDS ON ALGORITHMS FOR COMPUTING THE CANONICAL STRUCTURE OF INFINITE ABELIAN GROUPS AND SOLVING SYSTEMS OF LINEAR DIOPHANTINE EQUATIONS*

COSTAS S. ILIOPOULOS†

Abstract. An $O(s^5M(s^2))$ elementary operations algorithm for computing the canonical structure of infinite Abelian groups represented by a matrix of size s is presented. Also given is an algorithm for solving systems of linear Diophantine equations (say, $Ax=b$) in $O(s^{3.376}\log sM(s^2)+s^2M(s^*))$ elementary operations, where s is the size of A and s^* is the size of b. The upper bounds mentioned above improve the results given by Chou and Collins in [SIAM *J. Comput.*, 11 (1982), pp. 687-708].

1. Introduction. Recently in [1] Chou and Collins gave an algorithm for transforming an integer matrix via integer row-column operations (abbreviated IRC operations) into a diagonal one whose nonzero diagonal entries have the property of a Smith normal form matrix. They make use of an improved version of the Kannan-Bachem polynomial algorithm (see [8]).

Here the equivalent problem of computing the canonical structure of an infinite Abelian group represented by a set of defining relations is considered. Let A be the $m\times n$ matrix of the coefficients of a set of defining relations for an Abelian group G and let $s=m+n+\log\|A\|$, with $\|A\|=\max_{i,j}\{|a_{ij}|\}$ be the size of A. An algorithm for computing the canonical structure of G in $O(s^5M(s^2))$ elementary operations is presented here, where $M(k)$ denotes an upper bound on the number of elementary operations required for multiplication of two integers of length of k bits (see [9]).

From [1] we can derive an upper bound of $O(s^{11})$ for computing the canonical structure of an infinite Abelian group; this bound has been improved by a factor of $O(s^{3-\varepsilon})$.

Moreover, in [1] an algorithm for solving a system of linear Diophantine equations (say, $Ax=b$) is given, which requires $O(s^8+s^4s^*)$ elementary operations, where s is the size of A and s^* is the size of b. An algorithm for solving the above system in $O(s^{3.376}\log sM(s^2)+s^2M(s^*))$ elementary operations is presented here; in this case the bound is improved by a factor of at least $O(s^2)$.

Both the algorithms presented here make use of procedures and algorithms given in [7].

2. Preliminaries. The algorithms and theorems presented in this section form the necessary background for proving the main results of this paper.

THEOREM 2.1 (see [7]). *Suppose that $m\times n$ integer matrix A with* rank $(A)=n$, *an integer ρ such that $1\leqq\rho\leqq n$ and d the determinant of an $n\times n$ nonsingular submatrix of*

A are given. Moreover, let

$$K = \begin{bmatrix} A \\ dI_n \end{bmatrix}.$$

Then there exists an algorithm (namely procedure ELIMINATECOL* (K, D, ρ)*) for transforming K, via integer row operations, into a matrix* K^* *of the form*

$$\begin{bmatrix} & A' & \\ dI_{\rho-1} & 0 & 0 \\ & \vdots & \\ 0 & 0 & dI_{n-\rho} \end{bmatrix}, \tag{2.1}$$

where the ρ*th column of* A' *is of the form* $(\alpha'_{1\rho}, \cdots, \alpha'_{\rho\rho}, 0, \cdots, 0)^T$*, that requires* $O(mnM(\log m \| K \|) + mM(\log \| K \|) \log\log \| K \|)$ *elementary operations and* $\| K^* \| = O(|d|)$*. It also computes a unimodular matrix L such that*

$$L \cdot K = K^* \quad \textit{with } \log \| L \| = O(\log \| K \|).$$

Now we consider the following problem.

Suppose that A is an $m \times n$ integer matrix with rank n. Compute a unimodular $(m+n) \times (m+n)$ matrix L such that

$$L \begin{bmatrix} A \\ 0_n \end{bmatrix} = \begin{bmatrix} T \\ 0 \end{bmatrix}, \tag{2.2}$$

where T is an upper triangular $n \times n$ matrix, and zero represents an $m \times n$ zero matrix.

ALGORITHM 2.2.

INPUT: An $m \times n$ matrix A with integer entries and rank $(A) = n$.

Output: A matrix L satisfying (2.2).

begin

(1) $B \leftarrow$ an $n \times n$ nonsingular submatrix of A;

(2) $d \leftarrow \det(B)$;

(3) Transform A via row interchanges to a matrix that the n top rows form the matrix B;

(4) Let L' be the unimodular matrix corresponding to the above transformation;

(5) $W \leftarrow (dI_n)B^{-1}$;

$$L^* \leftarrow \begin{bmatrix} I_n & 0 & 0 \\ 0 & I_{m-n} & 0 \\ W & 0 & I_n \end{bmatrix};$$

(6) $K \leftarrow L^* \begin{bmatrix} A \\ 0_n \end{bmatrix}$;

comment Note that $K = \begin{bmatrix} A \\ dI_n \end{bmatrix}$.

(7) *for* $i = 1$ *to* n *do*

begin

(8) ELIMINATECOL* $(K, d, 1)$

Let L_i be the corresponding unimodular matrix as in Theorem 2.1;

$$L_i \leftarrow \begin{vmatrix} I_{i-1} & 0 \\ 0 & L_i \end{vmatrix};$$

$K \leftarrow [K_{lj}]$ for $2 \leqq l \leqq n-i+1$, $2 \leqq j \leqq n-i+1$;

(9) *end*

(10) $L \leftarrow L_n L_{n-1} \cdots L_1 L^* L'$;
end

PROPOSITION 2.3. *Algorithm* 2.2 *correctly computes* L *in*

$$O(n[n^\alpha \log n + mn + m \log (n \log (n\|A\|))]M(n \log (m\|A\|)))$$

elementary operations, where $O(n^\alpha)$ *denotes an upper bound on the number of multiplications required for multiplication of two* $n \times n$ *matrices. Moreover,*

$$\log \|L\| = O(n^2 \log (n\|A\|)).$$

Proof. The computation of the determinant d and the matrix B can be done by means of the Gaussian elimination in $O(mn^2 M(\log d^*))$ elementary operations, where $d^* = \max\{|\delta|: \delta$ is the determinant of a square submatrix of $A\}$ (see Gantmacher [5, p. 26] and the remark below).

Step (3) requires at most $O(n^2)$ elementary operations for row interchanges and it is not difficult to show that

$$\|L'\| = 1.$$

Step (5) requires $O(n^3 M(\log d^*))$ elementary operations for computing the inverse of B and $W = dI_n B^{-1}$. Moreover, we can show that

$$\|W\| = O(d^*).$$

Therefore

$$\|L^*\| = O(d^*).$$

Step (6) merely introduces dI_n in the bottom n rows of the matrix $\begin{bmatrix} A \\ 0_n \end{bmatrix}$ of (2.2).

Using Theorem 2.1 we can find that loop (7)–(9) requires $O(mn^2 M(\log m\|K\|) + mnM(\log \|K\|)\log\log \|K\|)$ elementary operations.

The computation of L at Step (9) can be done as follows. Let the L_i's, L^*, and L' be the leaves of a balanced binary tree (without loss of generality we assume that the number of matrices is a power of two). Moreover, let each parent node represent the product of its children (in order). Then the root of the tree represents L. It is not difficult to see that the computation of all nodes of the tree require

$$O\left(\sum_{i=1}^{\lceil \log n \rceil} \left(\frac{n}{2^i}\right)\right)$$

matrix multiplications. From Theorem 2.1 it follows that $\|L_i\| = O(\|K\|^c)$ for some constant $c > 0$ for all i's; it is not difficult to show that the matrices of the ith level of the tree have entries of $O(\|K\|^{c2^i})$. Therefore the computation of L requires

$$O\left(n^\alpha \sum_{i=1}^{\lceil \log n \rceil} \left(\frac{n}{2^i}\right) M(2^i \log \|K\|)\right) = O(n^{\alpha+1} \log n M(nM(n \log (n\|A\|))))$$

elementary operations.

Now, using the fact that

$$\max\{\|K\|, d^*\} = O(n^n \|A\|^n),$$

the upper bound on the running time of Algorithm 2.2 follows and

$$\|L\| = O(\|K\|^{c2^{\log n}}) = O(\|K\|^{cn}) = O(n^{cn^2}\|A\|^{cn^2}).$$ □

Remark 2.1. Above we make use of the Gaussian elimination procedure for computing the determinant of a matrix and for computing the inverse of a matrix. Strassen in [11] and Coppersmith and Winograd in [2] give asymptotically faster methods for these computations. Here and in the sequel [7] we shall make use of the Gaussian elimination instead of the Coppersmith-Winograd algorithm (currently the fastest asymptotic method) when the computation of the determinant (or inverse) is not the bottleneck of the algorithm. This is because the Coppersmith-Winograd algorithm supersedes the Gaussian elimination only in the case of very large dimension matrices.

Remark 2.2. Suppose that A is the input matrix of Algorithm 2.2 and L is the output matrix. Let

$$L=\begin{bmatrix}\Lambda_1 & \Lambda_2\\ \Lambda_3 & \Lambda_4\end{bmatrix},$$

where Λ_1 is an $m\times m$ matrix, Λ_2 is an $m\times n$ matrix, Λ_3 is an $n\times m$ matrix, and Λ_4 is an $n\times n$ matrix.

Then

$$\Lambda_1 A=\begin{bmatrix}T\\ 0\end{bmatrix} \quad \text{where zero is an } m\times n \text{ zero matrix,}$$

but Λ_1 is not necessarily unimodular. The author is not aware of an efficient way of computing a unimodular matrix Λ such that

$$\Lambda A=\begin{bmatrix}T\\ 0\end{bmatrix} \quad \text{where zero is an } m\times n \text{ zero matrix.}$$

This will lead to some inelegancies in the presentation of algorithms for computing the structure of infinite Abelian groups and for solving systems of linear Diophantine equations.

PROPOSITION 2.4 (see [7, Cor. 3.3]). *There exists an algorithm for computing the canonical structure of a finite Abelian group G represented by an $m\times n$ integer matrix A in $O(mn^2(n+\log(n\log(n\|A\|)))\log(n\|A\|)M(n\log(mn\|A\|)))$ elementary operations.*

3. Infinite Abelian groups. An algorithm for computing the canonical structure of an infinite Abelian group represented by a matrix is presented below. The basic idea involved is the computation of a matrix representing the subgroup of all the finite-order elements of the group, and then the algorithm for computation of the canonical structure of finite Abelian groups given in [7] (see Proposition 2.4) is applied.

ALGORITHM 3.1.

INPUT: An $m\times n$ matrix A representing the infinite Abelian group G.

OUTPUT: The canonical structure of G.

begin

(1) $r\leftarrow \text{rank}(A)$;

(2) $B\leftarrow$ an $r\times r$ nonsingular submatrix of A;

(3) $A\leftarrow\begin{bmatrix}B & C\\ D & E\end{bmatrix}$;

comment The matrix D is an $(n-r)\times r$ matrix, C is an $r\times(n-r)$ matrix, and E is an $(m-r)\times(n-r)$ matrix. The transformation is done with column and row interchanges in such a way that the r top and the r

left-row columns form the matrix B in the left top corner of A.

$$A \leftarrow \left[\frac{A}{0_r 0}\right];$$

comment Note that the addition of trivial relations to the set of defining relations of G does not change its structure.

(4) Compute a unimodular $(m+r)\times(m+r)$ matrix L such that:

$$L\begin{vmatrix} B \\ D \\ 0_r \end{vmatrix} = \begin{vmatrix} V \\ 0 \end{vmatrix} \quad \text{where } V \text{ is an } r\times r \text{ upper triangular matrix;}$$

comment We can use Algorithm 2.2, since

$$\operatorname{rank}\left(\begin{vmatrix} B \\ D \\ 0_r \end{vmatrix}\right) = r.$$

(5) $A \leftarrow LA$;

(6) Let $A = \left[\begin{smallmatrix} V & M \\ 0 & 0 \end{smallmatrix}\right]$;

comment See the proof of Proposition 3.2, part (ii).

(7) *for* $i = r$ *down to* 1 *do*

begin

(8) $\mathrm{COL}(j) \leftarrow \mathrm{COL}(j) - (\lfloor m_{ij}/t_{ii} \rfloor)\,\mathrm{COL}(i)$ for $r+1 \leqq j \leqq n$;

comment We reduce M's entries modulo the diagonal elements

(9) *end*

(10) $A^* \leftarrow [V, M]^T$

comment A^* is an $n\times r$ matrix with rank r and thus represents a finite Abelian group, say, G^*.

(11) Compute the canonical structure of G^* using the algorithm of Proposition 2.4.

end

PROPOSITION 3.2. *Algorithm* 3.1 *correctly computes the canonical structure of* G.

Proof. (i) All steps are expressed in terms of IRC operations, which respect the structure of the group G.

(ii) In step (6) the bottom right corner $(m-r)\times(m-r)$ submatrix of A is a matrix where all of its entries are zeros, because if its jth column had a nonzero entry for some j, then A would have $r+1$ linearly independent columns (the first r columns of A and the jth of the submatrix), which contradicts the fact that $r = \mathrm{rank}(A)$.

(iii) In step (10), A^* represents the finite group G^*. Let G' be the maximal finite subgroup of G. It will be shown that G^* is isomorphic to G'. Let $A_1 = [V, M]$. Since A_1 represents G, there exists unimodular matrices L and R such that

$$LA_1R = D \tag{3.1}$$

where D represents the canonical structure of G. Moreover, let

$$G' = C(d_{11})\times\cdots\times C(d_{rr}), \tag{3.2}$$

where $C(k)$ represents a cyclic group of order k.

From (3.1) it follows that

$$R^T A_1^T L^T = D \quad \text{or} \quad R^T A^* L^T = D^T$$

and D^T represents the canonical structure of G^*. Therefore

$$G^* = C(d_{11}) \times \cdots \times C(d_{rr}),$$

and using (3.2) it follows that $G^* \approx G'$. □

PROPOSITION 3.3. *Algorithm* 3.1 *computes the canonical structure of* G *in*

$$O(r[r^\alpha \log r + mn + nr \log (r\|A\|)(r + \log (r \log (r\|A\|)))]$$
$$\cdot M(r \log (n\|A\|) + (r^2 n + mn) M(r^2 \log (r\|A\|))))$$

elementary operations.

Proof. Step (1)-(2) requires $O(mnrM(\log |d^*|))$ elementary operations by means of Gaussian elimination, where $|d^*| = \max \{|d|: d$ is the determinant of a square submatrix of $A\}$. Moreover using Hadamard's bound on the size of a determinant of a square matrix, it follows that

$$|d^*| \leqq (r\|A\|)^r.$$

The running time of step (4) is given by Proposition 2.3.

Step (5) requires $O(mn)$ multiplications comprising $O(mnM(r^2 \log (r\|A\|)))$ elementary operations, using that $\log \|L\| = O(r^2 \log (r\|A\|))$ by Proposition 2.3. Loop (7)-(9) requires $O(r^2 n)$ multiplications comprising $O(r^2 nM(r^2 \log (r\|A\|)))$ elementary operations.

Using Theorem 2.1 (bound on $\|T\|$), we can see that after the reduction modulo the t_{ii}'s, it follows that

$$\|A^*\| \leqq \|T\| \leqq (r\|A\|)^r. \tag{3.3}$$

From Proposition 2.4 and (3.3) we can derive the running time of step (11) comprising $O(nr^2 \log (r\|A\|)[r + \log (r \log (r\|A\|))]M(r \log (n\|A\|)))$ elementary operations. □

COROLLARY 3.4. *There exists an algorithm computing the canonical structure of an infinite Abelian group* G *represented by a matrix* A *of size* s, *in* $O(s^5 M(s^2))$ *elementary operations.*

Proof. From Proposition 3.3 and using the fact that $\alpha \leqq 3$ ($\alpha = 3$ in the classical algorithm for matrix multiplication). □

4. Linear Diophantine equations. Let A be an $m \times n$ matrix with integer entries and b an $n \times 1$ vector with entries from the integers. Then the system of equations

$$Ax = b, \qquad x \in \mathbb{Z}^{n \times 1} \tag{4.1}$$

is called a *system of linear Diophantine equations.*

The computation of a solution or all (if any) of the system (4.1) is closely related to the triangularization of the matrix A. If the matrix A of (4.1) is of rank n, then (4.1) has exactly one solution or none and this can be found by means of Gaussian elimination. In the case in which the rank r of A is less than n, the system (4.1) has an infinite number of solutions ($n - r$ linearly independent solutions) or the system is inconsistent. In this case the classical algorithm for solution of a system of linear Diophantine equations makes use of the classical triangularization algorithm (see Smith [10]) and therefore has the problem of "Intermediate expression swell."

The first polynomial algorithms for solution of (4.1) were given by Frumkin in [3] (see also [4]) in some special cases. Frumkin's algorithm for computing a *particular* solution of (4.1) or establishing that there is not one requires in the worst case

$$O(n^2 m^2 \log (n\|A\|) M(n \log (n\|A\|)) + n^2 M(n \log (n\|A\|) + \log \|b\|))$$
$$= O(s^5 M(s^2) + s^2 M(s^*)),$$

where s is the size of the matrix A and s^* is the size of the vector b. Moreover, in (4) Frumkin gave an algorithm for computing the set of all solutions (if any) of an *homogeneous system* of linear Diophantine equations (that is, (4.1) with $b=(0,\cdots,0)$), which requires

$$O(n^3 m \log(n\|A\|)M(m \log m \log(m\|A\|))) = O(s^5 M(s^2 \log s))$$

elementary operations.

The best-known polynomial algorithm for solving a general system of linear Diophantine equations is given by Chou and Collins in [1]. Their algorithm requires

$$O(n^3(m+n)[n+r\log(r\|A\|)]^2 + r(m+n)\log\|b\|[n+r\log(n\|A\|)]) = O(s^8 + s^4 s^*)$$

elementary operations for the computation of the set of all the solutions of (4.1), if any, where s is the size of A and s^* is the size of the vector b.

An algorithm for solving (4.1) whose upper bound improves the upper bounds of Frumkin and Chou and Collins is presented below.

ALGORITHM 4.1.

INPUT: The system of equations (4.1).

OUTPUT: A set of all integral solutions of the system (4.1), if any.

begin

(1) $r \leftarrow \text{rank}(A)$;

(2) $B \leftarrow$ an $r \times r$ nonsingular submatrix of A;

(3) $A \leftarrow [A \mid \begin{smallmatrix}0\\0\end{smallmatrix}_r]$;

(4) compute unimodular matrices L_1, R_1 such that $L_1 A R_1 = [\begin{smallmatrix}B & C\\D & E\end{smallmatrix}]$;

comment The matrix D is an $(m-r)\times r$ matrix, C is an $r\times(n-r)$ matrix, and E is an $(m-r)\times(n-r)$ matrix. The transformation is done with column and row interchanges in such a way that the top left $r\times r$ submatrix of A is the matrix B.

(5) $A \leftarrow L_1 A R_1$;

(6) $b \leftarrow L_1 \cdot b$;

(7) $H \leftarrow [B\ 0_r]^T$;

(8) Compute a square unimodular matrix L: $LH = |\begin{smallmatrix}U\\0\end{smallmatrix}|$,
where U is an $r\times r$ upper triangular matrix.

comment We may use Algorithm (2.2), since rank $(H)=r$ equal to the number of columns of H.

$R_2 \leftarrow L^T$;

(9) $A \leftarrow AR_2$;

(10) $U \leftarrow U^T$;

(11) Let $A = |\begin{smallmatrix}U & 0\\M & 0\end{smallmatrix}|$;

comment M denotes the $(n-r)\times r$ submatrix at the bottom left of the matrix A of Step (9).

(12) compute a particular solution $\vec{W}$ of the system $Ax=b$ over the rationals;

comment The computation of $\vec{W}$ is done by means of U^{-1} (note that U is triangular).

if $\vec{W}$ has noninteger entries *then*

return "The system (4.1) has not any integral solutions"

else

$\vec{V} \leftarrow$ the first n coordinates of $\vec{W}$;

(13) $R \leftarrow R_1 \cdot R_2$;

(14) $R' \leftarrow R^{-1}$;

$R^* \leftarrow [r_{ij}]$, $r+1 \leqq j \leqq n+r$, $1 \leqq i \leqq n$;

return $\{\vec{x} = R'\vec{V} + R^*(t_1, \cdots, t_n)$;
comment The t_i's are free variables.
end

PROPOSITION 4.2. *Algorithm* 4.1 *correctly computes a solution of the system* (4.1), *if any.*

Proof. Let A' denote the matrix A at Step (3) and let A'' denote the matrix A at Step (11). Then we have

$$A'' = A' \cdot R. \tag{4.2}$$

Let $\vec{z} = \vec{v} + (y_1, \cdots, y_r, t_1, \cdots, t_n)^T$ be the set of all integral solutions of the system

$$A'' \cdot \vec{z} = b. \tag{4.3}$$

Then we have

$$A''\vec{z} = A''\vec{v} + A''(y_1, \cdots, y_r, t_1, \cdots, t_n)^T. \tag{4.4}$$

When we use (4.3), (4.4), and the fact that $A\vec{v} = b$ follows

$$A''(y_1, \cdots, y_r, t_1, \cdots, t_n)^T = 0$$

or equivalently (see Step (11))

$$\begin{bmatrix} U & 0 \\ M & 0 \end{bmatrix} (y_1, \cdots, y_r, t_1, \cdots, t_n)^T = 0,$$

implies that $y_i = 0$ for $1 \leqq i \leqq r$.

Now let $\vec{x} = R'\vec{z}$. Then $\vec{x}$ yields the set of all integral solutions for the system

$$A'\vec{x} = b,$$

since $A'\vec{x} = A''RR^{-1}z = A''z = b$, when we use (4.2) and (4.3). Moreover,

$$\vec{x} = R'\vec{v} + R'(0, \cdots, 0, t_1, \cdots, t_n)^T = R'\vec{v} + R^*(t_1, \cdots, t_n)^T. \qquad \square$$

PROPOSITION 4.3. *Algorithm* 4.1 *correctly computes the set of all integral solutions of* (4.1) *in* $O(r[r^\alpha \log r + mn + n \log (r \log (r\|A\|))]M(r \log (n\|A\|)) + mnM(r^2 \log (r\|A\|) + \log \|b\|))$ *elementary operations.*

Proof. Steps (1)-(5), (7)-(11) require

$$O(r[r^\alpha \log r + mn + n \log (r \log (r\|A\|))]M(r \log (n\|A\|)) + mnM(r^2 \log (r\|A\|)))$$

elementary operations. Their analysis is the same as in Proposition 3.3 (Steps (1)-(5)).

Step (6) requires $O(n \log \|b\|)$ elementary operations when we use the fact that the rows of L_1 are of the form $(0, \cdots, 0, 1, 0, \cdots, 0)$.

Step (12) requires $O(mn)$ divisions/multiplications comprising $O(mnM(r^2(\log (r\|A\|)) + \log \|b\|)$ elementary operations, since if A^* denotes the matrix A at step (8) then

$$\log \|A^*\| = \log \|L_1 A R_1 R_2\| = O(r^2 \log (r\|A\|))$$

when we use $\|L_1\| = \|R_2\| = 1$ and $\|R_2\| \leqq \|A\|^{cr^2}$ by Proposition 2.3, for some constant $c > 0$.

Step (13) requires only $O(mn)$ elementary operations for column interchanges on R_2. Step (13) makes use of the Gaussian elimination (or the Coppersmith-Winograd algorithm).

The proposition follows from the above. $\square$

COROLLARY 4.4. *There exists an algorithm for computing the set of all solutions, if any, of a linear Diophantine system* (4.1) *in*

$$O(s^{\alpha+1} \log sM(s^2) + s^2 M(s^*))$$

elementary operations, where s is the size of A and s^* *is the size of b.*

Acknowledgment. I thank the referee for pointing out various errors and for his helpful suggestions.

ON THE COMPLEXITY OF PARTIAL ORDER PRODUCTIONS*

ANDREW CHI-CHIH YAO†

Abstract. Let $P=(<_P, Y)$ be a partial order on a set $Y=\{y_1, y_2, \cdots, y_n\}$ of n elements. The problem of *P-production* is as follows: Given an input of n distinct numbers $x_1, x_2, \cdots, x_n$, find a permutation σ of $(1, 2, \cdots, n)$ such that $y_i <_P y_j$ implies $x_{\sigma(i)} < x_{\sigma(j)}$. Let $C(P)$, $\bar{C}(P)$ be, respectively, the minimum number and the minimum average number of binary comparisons $x_i : x_j$ needed by any decision-tree algorithm to produce P. It is proved that $C(P)=\Theta(\bar{C}(P))$. As an intermediate result, it is shown that $C(P)=O(\log_2(n!/\mu(P))+n)$, where $\mu(P)$ is the number of permutations consistent with P, thus proving a conjecture of Saks.

1. Introduction. Sorting and median-finding of a set of n numbers are two of the classical problems in combinatorial computation. It is well known (see Knuth [Kn, § 5.3]) that sorting n numbers takes asymptotically $\Theta(n \log n)$ binary comparisons of the form $x_i : x_j$, both in the worst case and in the average case. For median-finding, it was first proved that the average-case complexity is $\Theta(n)$ (Floyd and Rivest [FR]), and later it was discovered that the worst-case complexity is also $\Theta(n)$ (Blum et al. [BFPRT]). Thus, in both problems, the worst-case complexity and the average-case complexity are of the same order of magnitude. Are they special cases of a general class of problems for which this phenomenon is true? In this paper we will show that this is indeed so.

Let $P=(<_P, Y)$ be a partial order on a set $Y=\{y_1, y_2, \cdots, y_n\}$. The *P-production problem* is the following. Given n distinct numbers $x_1, x_2, \cdots, x_n$, find a permutation σ of $(1, 2, \cdots, n)$ such that $y_i <_P y_j$ implies $x_{\sigma(i)} < x_{\sigma(j)}$. We are interested in the intrinsic complexity of this problem in the decision tree model. Clearly, sorting and median-finding are both special cases of the P-production problem.

A *decision tree* T is a binary tree, each of whose internal nodes u contains a comparison of the form $x_i : x_j$, and has two outgoing edges labeled by "$<$" and "$>$"; associated with each leaf l is a permutation σ_l of $(1, 2, \cdots, n)$. Given any input $\tilde{x}=(x_1, x_2, \cdots, x_n)$ of distinct numbers, we traverse a path $\xi(T, \tilde{x})$ in T from the root down, making comparisons and branching according to the outcomes, until a leaf $l_{\tilde{x}}$ is reached. We call T an *algorithm* for P-production if, for every $\tilde{x}$, $y_i <_P y_j$ implies $x_{\rho(i)} < x_{\rho(j)}$, where $\rho=\sigma_l$. Let cost $(T, \tilde{x})$ denote the number of comparisons made by T along the path $\xi(T, \tilde{x})$, and let cost (T) be $\max_{\tilde{x}}$ cost $(T, \tilde{x})$. Denote by $\mathscr{A}_P$ the family of all algorithms for P-productions. The *minimax complexity* $C(P)$ of P-production is defined as $\min\{\text{cost}(T) \mid T \in \mathscr{A}_P\}$.

Let Γ_n be the set of all permutations of $(1, 2, \cdots, n)$. A permutation ρ is said to be *consistent* with P, if $y_i <_P y_j$ implies $\rho(i) < \rho(j)$ for all i, j. Let $\Delta(P) \subseteq \Gamma_n$ be the set of all permutations consistent with P, and define $\mu(P)=|\Delta(P)|$.

The complexity problem of P-production was formulated and investigated by Schönhage [Sch], who showed by an information-theoretic argument that $C(P) \geqq \log_2(n!/\mu(P))$. Further results on this problem have been derived by Aigner [Ai].

Saks has conjectured [Sa] that Schönhage's lower bound can be achieved asymptotically, in the sense that $C(P) = O(\log_2(n!/\mu(P)) + n)$.

For any $T \in \mathscr{A}_P$, the *average cost* of T is defined as $\text{cost}'(T) = 1/n! \sum_{\rho \in \Gamma_n} \text{cost}(T, \tilde{x}_\rho)$, where $\tilde{x}_\rho = (\rho(1), \rho(2), \cdots, \rho(n))$. The *minimean complexity* of P-production is defined as $\bar{C}(P) = \min\{\text{cost}'(T) | T \in \mathscr{A}_P\}$.

A partial order $P = (<_P, Y)$ is said to be *connected*, if for every two distinct elements y and y' in Y, there exists a sequence $y = y_1, y_2, \cdots, y_m = y'$ such that $y_i <_P y_{i+1}$ or $y_i >_P y_{i+1}$ for all i. Every partial order P can be uniquely decomposed into the disjoint union of connected partial orders $P_i = (<_{P_i}, Y_i)$, where the sets Y_i form a partition of Y. Let $\beta(P)$ denote the number of connected components in this decomposition.

In this paper we will prove the following results.

THEOREM 1. *For all* P, $\bar{C}(P) = \Omega(n - \beta(P) + \log_2(n!/\mu(P)))$.

THEOREM 2. *For all* P, $C(P) = O(n - \beta(P) + \log_2(n!/\mu(P)))$.

THEOREM 3. *For all* P, $C(P) = \Theta(\bar{C}(P))$.

Theorem 2 proves the conjecture of Saks [Sa] mentioned earlier. Since $C(P) \geqq \bar{C}(P)$ by definition, Theorem 3 is an immediate consequence of Theorems 1 and 2. The rest of this paper is devoted to a proof of Theorem 1 and Theorem 2.

2. Proof of Theorem 1. We will prove two lemmas. The first is an extension of Schönhage's lower bound on the minimax complexity $C(P)$ to the minimean complexity.

LEMMA 1. $\bar{C}(P) \geqq \log_2(n!/\mu(P))$.

Proof. Let $T \in \mathscr{A}_P$. We will prove that

$$\text{cost}'(T) \geqq \log_2\left(\frac{n!}{\mu(P)}\right). \tag{1}$$

For each leaf l of T, let Q_l be the partial order on X generated by the constraints $x_i > x_j$ along the path from the root to l. As $T \in \mathscr{A}_P$, each Q_l contains an isomorphic copy of P as a subpartial order. This implies that $\mu(Q_l) \leqq \mu(P)$. Let $q_l = \mu(Q_l)/n!$ Then

$$q_l \leqq \frac{\mu(P)}{n!}. \tag{2}$$

If we consider a random input $\tilde{x}_\rho = (\rho(1), \rho(2), \cdots, \rho(n))$, where ρ is uniformly chosen from Γ_n, then q_l is the probability that the traversed path $\xi(T, \tilde{x}_\rho)$ in T will end in the leaf l. Let d_l be the distance from the root to l. Then,

$$\sum_l q_l = 1, \tag{3}$$

$$\text{cost}'(T) = \sum_l q_l d_l. \tag{4}$$

It follows from (3) and (4) that $\text{cost}'(T)$ is the expected length of a uniquely decipherable code for an alphabet with symbol frequencies q_l. It is a well-known fact (see, e.g., [Ab, § 4.1]) in information theory that a lower bound is given by the entropy, that is,

$$\text{cost}'(T) \geqq \sum_l q_l \log_2 \frac{1}{q_l}.$$

Inequality (1) now follows from (2) and (3). □

LEMMA 2. $\bar{C}(P) \geqq n - \beta(P)$.

Proof. Suppose the lemma is false. Then there exists $T \in \mathscr{A}_P$ and an input $\tilde{x} = (x_1, x_2, \cdots, x_n)$, such that $\text{cost}(T, \tilde{x}) < n - \beta(P)$. Let σ be the output permutation for $\tilde{x}$. We will derive a contradiction.

Let W be the sequence of inequalities $x_i < x_j$ generated along the path $\xi(T, \tilde{x})$; then $|W| < n - \beta(P)$. Denote by Q the partial order on X imposed by W. Then Q has more than $n-(n-\beta(P)) = \beta(P)$ connected components. Thus, there are integers r, s such that y_r, y_s are in the same component in P, while $x_{\sigma(r)}, x_{\sigma(s)}$ are in different components in Q.

Let $y_r = y_{i_1}, y_{i_2}, \cdots, y_{i_m} = y_s$ be such that, for each j, either $y_{i_j} <_P y_{i_{j+1}}$ or $y_{i_j} >_P y_{i_{j+1}}$. By the definition of $T \in \mathscr{A}_P$, every adjacent pairs in the sequence $x_{\sigma(r)} = x_{\sigma(i_1)}, x_{\sigma(i_2)}, \cdots, x_{\sigma(i_m)} = x_{\sigma(s)}$ must also be related in Q. This contradicts the assumption that $x_{\sigma(r)}$ and $x_{\sigma(s)}$ are in different components in Q. □

Theorem 1 follows immediately from Lemmas 1 and 2.

3. Reduction. In this section, we show that to prove Theorem 2, it suffices to prove the following result.

THEOREM 4. *There exists a constant $\lambda > 0$ such that*

$$C(P) \leqq \lambda \left(n - 1 + \log_2 \left(\frac{n!}{\mu(P)} \right) \right).$$

Assume that Theorem 4 is true. We will prove Theorem 2. Let $c = \beta(P)$. By definition, P can be written as the disjoint union of partial orders $P_i = (<_{P_i}, Y_i)$, $1 \leqq i \leqq c$, where the Y_i's form a partition of Y. Let $|Y_i| = n_i$. Then $n_i > 0$ for all i, and

$$\sum_i n_i = n, \tag{5}$$

$$\mu(P) = \left(\frac{n!}{n_1! n_2! \cdots n_c!} \right) \mu(P_1)\mu(P_2) \cdots \mu(P_c). \tag{6}$$

We now describe an algorithm T for P-production. Let $N_0 = 0$. Define $N_i = \sum_{1 \leqq k \leqq i} n_k$, and $I_i = \{j | N_{i-1} < j \leqq N_i\}$ for $1 \leqq i \leqq c$. Given any input set $X = \{x_i | 1 \leqq i \leqq n\}$, consider for each $1 \leqq i \leqq c$, the set X_i as input to P_i-production, where $X_i = \{x_j | j \in I_i\}$. Apply Theorem 4 to each P_i, and let $\sigma_i : I_i \to I_i$ be the permutation found for P_i-production. Then define the output permutation $\sigma \in \Gamma_n$ by $\sigma(j) = \sigma_i(j)$ if $j \in I_i$. It is clear that $T \in \mathscr{A}_P$, since the output permutation σ satisfies the constraint that $y_j <_P y_k$ implies $x_{\sigma(j)} < x_{\sigma(k)}$.

Using (5) and (6), we obtain

$$\begin{aligned} \text{cost}(T) &\leqq \lambda \sum_{1 \leqq i \leqq c} \left(n_i - 1 + \log_2 \left(\frac{n_i!}{\mu(P_i)} \right) \right) \\ &= \lambda \left(n - c + \log_2 \left(\frac{n_1! n_2! \cdots n_c!}{\mu(P_1)\mu(P_2) \cdots \mu(P_c)} \right) \right) \\ &= \lambda \left(n - c + \log_2 \left(\frac{n!}{\mu(P)} \right) \right). \end{aligned}$$

We have proved Theorem 2, assuming that Theorem 4 is true. In the next two sections we will prove Theorem 4.

4. An algorithm.

4.1. Preliminaries. Let $P = (<_P, Y)$ be a partial order. A subset $A \subseteq Y$ is an *independent set* of P, if $y \not<_P y'$ is true for all distinct $y, y' \in A$. The *width* of P, denoted by width (P), is the maximum size of any independent set of P. We associate with each P an independent set Y_P of maximum size. (Pick any one if there are several choices.)

Let $k \geqq 2$ be any integer. A *k-partition* of P is a k-tuple $(A_1, A_2, \cdots, A_k)$, where the A_i's are disjoint subsets of Y whose union equals Y, such that $y <_P y'$, $y \in A_i$ and $y' \in A_j$ imply $i \leqq j$. We are interested in two special k-partitions. Let $\mathscr{B}_P = (B_{P,1}, B_{P,2}, B_{P,3})$, where $B_{P,1} = \{y | y <_P y' \text{ for some } y' \in Y_P\}$, $B_{P,2} = Y_P$, and $B_{P,3} = Y - Y_P - B_{P,1}$. Clearly, $\mathscr{B}_P$ is a 3-partition. Note that some $B_{P,i}$ may be empty. To describe the second partition, let $\mathscr{M}_P$ be the set of all 2-partitions (A_1, A_2) of P such that $|A_1| = \lceil n/2 \rceil$ and $|A_2| = \lfloor n/2 \rfloor$. Let $\mathscr{D}_P = (D_{P,1}, D_{P,2})$ be a member of $\mathscr{M}_P$ such that $\mu(P_1)\mu(P_2)$ is maximum over all possible $(A_1, A_2) \in \mathscr{M}_P$, where P_i is the partial order P restricted to A_i.

Notation. For the rest of the paper, $P = (<_P, Y)$ will denote a partial order on $Y = \{y_1, y_2, \cdots, y_n\}$, and X will denote the input set $\{x_1, x_2, \cdots, x_n\}$. For any $J \subseteq \{1, 2, \cdots, n\}$, we will use Y_J to denote the set $\{y_j | j \in J\}$, and P_J to denote the partial order induced by P on Y_J; we agree that $\mu(P_J) = 1$ when $J = \varnothing$. Similarly, for any $I \subseteq \{1, 2, \cdots, n\}$, we use X_I to denote the set $\{x_i | i \in I\}$. For any two sets of numbers A, B, we write $A < B$ if $y < z$ for all $y \in A$ and $z \in B$. We adopt the convention that $0! = 1$, and we will employ two constants $c_2 = 40$ and $c_3 = 80$.

LEMMA 3. *Let $k \in \{2, 3\}$. Let I be a nonempty subset of $\{1, 2, \cdots, n\}$, and $n_1, n_2, \cdots, n_k$ be nonnegative integers satisfying $\sum_{1 \leqq i \leqq k} n_i = |I|$. Then there is a decision tree T of height $c_k|I|$ such that, given any input of n distinct numbers $X = \{x_1, x_2, \cdots, x_n\}$, T determines disjoint $I_1, I_2, \cdots, I_k$ satisfying* (a) $\cup_i I_i = I$, (b) $|I_i| = n_i$ *for all i, and* (c) $X_{I_1} < X_{I_2} < \cdots < X_{I_k}$.

Proof. If $k = 2$, the decision tree first finds the $(n_1 + 1)$st smallest element x_j in X_I, and then determines $I_1 = \{i | x_i < x_j\}$ and $I_2 = \{i | x_i \geqq x_j\}$. This can be done in less than $40n$ comparisons using the selection algorithm in [BFPRT]. Similarly, if $k = 3$, we can find the $(n_1 + 1)$st smallest and the $(n_1 + n_2 + 1)$st smallest elements in X_I, by applying the selection algorithm in [BFPRT] twice, and then find I_1, I_2, I_3. □

4.2. Procedure POPROD. The algorithm can be described as a recursive procedure. Depending on the width of P, we will either use comparisons to divide X into three parts X_I, satisfying $X_{I_1} < X_{I_2} < X_{I_3}$, or use comparisons to divide X into two parts X_{I_i} satisfying $X_{I_1} < X_{I_2}$. In the first case, we can match the elements $y_j \in B_{P,2}$ with elements in X_{I_2} in any fashion, and then recursively solve two subproblems: X_{I_1} as input to the production problem of P restricted to $B_{P,1}$, and X_{I_3} as input to the production problem of P restricted to $B_{P,3}$. This gives a valid final output, because $B_{P,2}$ is an independent set in P and $(B_{P,1}, B_{P,2}, B_{P,3})$ is a 3-partition. In the other case, we will simply solve recursively two subproblems: X_{I_1} as input to the production problem of P restricted to $D_{P,1}$, and X_{I_2} as input to the production problem of P restricted to $D_{P,2}$. Of course, the cardinality of the sets I_i needs to be chosen to match those of the 3-partitions and 2-partitions.

The criterion for deciding which case to use is whether the width of P is greater than a fraction of n. Intuitively, the first case is more like the median-finding problem and the second case is more like the sorting problem. In the first case, we would like to get immediately a large independent subset of the elements y_j in Y assigned, while in the second case, we rely on the technique of divide-and-conquer, and try to divide the problems into two subproblems of nearly equal size.

As an example, consider the partial order P shown in Fig. 1. The width of P is relatively large, and we have the first case. For this partial order, $B_{P,1} = \{y_1, y_2, y_3, y_4\}$, $B_{P,2} = \{y_5, y_8, y_{10}, y_{11}\}$, and $B_{P,3} = \{y_6, y_7, y_9, y_{12}, y_{13}\}$. We thus use comparisons to divide X into three parts X_{I_i} satisfying $X_{I_1} < X_{I_2} < X_{I_3}$, where $|I_1| = 4$, $|I_2| = 4$, and $|I_3| = 5$. The elements in $B_{P,2}$ can be assigned in a $1-1$ way to the x's in X_{I_2} without

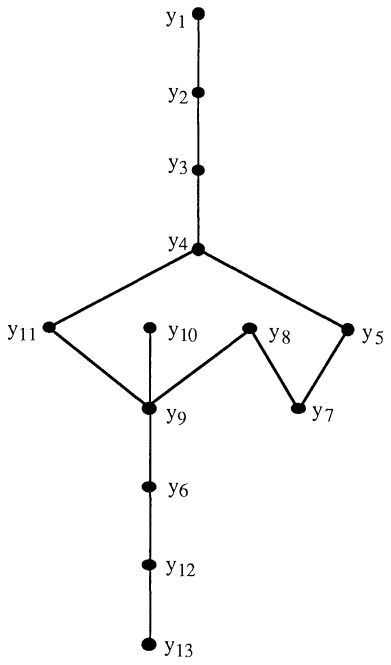

FIG. 1. *A partial order P; smaller elements on top, e.g.,* $y_2 <_P y_4$.

further comparisons. Of the two subproblems to be solved recursively, we will examine just the first one. To match the elements in $B_{P,1}$ with X_{I_1}, we observe that Q, the partial order P restricted to $B_{P,1}$, is $y_1 <_Q y_2 <_Q y_3 <_Q y_4$, which has width equal to 1. This means we have the second case for this subproblem. Clearly, $D_{Q,1} = \{y_1, y_2\}$ and $D_{Q,2} = \{y_3, y_4\}$. Therefore, we use comparisons to divide X_{I_1} into two parts A and A' with $A < A'$. Now we need to solve two subproblems: matching $D_{Q,1}$ to A, and $D_{Q,2}$ to A'.

We now specify the algorithm formally. Given an input set $X = \{x_1, x_2, \cdots, x_n\}$, the algorithm will output a permutation σ in the form of a set $\{(i, \sigma(i)) | 1 \leqq i \leqq n\}$; the correctness requirement is that $y_i <_P y_j$ implies $x_{\sigma(i)} < x_{\sigma(j)}$. We will give a recursive algorithm that takes as additional input arguments two sets $J \subseteq \{1, 2, \cdots, n\}$ and $I \subseteq \{1, 2, \cdots, n\}$ of equal size, and returns a *matching* between J and I, i.e., a set $V \subseteq J \times I$ such that each $j \in J$ appears exactly in one element $(j, k) \in V$, and each $i \in I$ appears exactly in one element $(m, i) \in V$. We will later prove that the matching produced satisfies the condition that, for $(j, m) \in V$ and $(j', m') \in V$, $y_j <_P y_{j'}$ implies $x_m < x_{m'}$. Thus, if we let $J = I = \{1, 2, \cdots, n\}$, we obtain the required permutation σ in the output.

PROCEDURE POPROD (X, J, I).

Case 1. $|J| \leqq 1$:

if $J = I = \varnothing$, then return $\varnothing$;
if $J = \{j\}$, $I = \{i\}$ then return $\{(j, i)\}$;

Case 2. $(|J| > 1) \wedge (\text{width}(P_J) > \lceil |J|/100 \rceil)$:

(a) Use $c_3|I|$ or less comparisons to divide I into disjoint I_1, I_2, I_3 such that $X_{I_1} < X_{I_2} < X_{I_3}$ and $|I_i| = |B_{P_{J,i}}|$ for $1 \leqq i \leqq 3$;
[Comments: This can be done by Lemma 3.]

(b) Suppose $B_{P_{J,i}} = \{y_j | j \in J_i\}$, for $1 \leqq i \leqq 3$;
let $V_2 \leftarrow \{(k_s, i_s) | 1 \leqq s \leqq |J_2|\}$, where k_s and i_s are the sth smallest elements in J_2 and I_2.
[Comments: No comparisons are used here.]
(c) $V_1 \leftarrow$ POPROD (X, J_1, I_1);
$V_3 \leftarrow$ POPROD (X, J_3, I_3);
(d) return $V \leftarrow V_1 \cup V_2 \cup V_3$;

Case 3. $(|J| > 1) \wedge (\text{width}(P_J) \leqq \lceil |J|/100 \rceil)$:
(a) Use $c_2|I|$ or less comparisons to divide I into disjoint I_1, I_2 such that $X_{I_1} < X_{I_2}$, $|I_1| = \lceil n/2 \rceil$, and $|I_2| = \lfloor n/2 \rfloor$;
[Comments: This can be done by Lemma 3.]
(b) Suppose $D_{P_{J,i}} = \{y_j | j \in J_i\}$, for $1 \leqq i \leqq 2$;
(c) $V_1 \leftarrow$ POPROD (X, J_1, I_1);
$V_2 \leftarrow$ POPROD (X, J_2, I_2);
(d) return $V \leftarrow V_1 \cup V_2$;

4.3. Correctness.

LEMMA 4. *In Procedure* POPROD, *the returned value V is a matching between J and I.*

Proof. We prove the lemma by induction on the size of J. The base case $|J| \leqq 1$ is obvious. Inductively, suppose $|J| > 1$, and that the first recursive call results in Case 2. Then V_2 constructed in step (b) is clearly a matching between J_2 and I_2. In step (c), by induction hypothesis, V_i is a matching between J_i and I_i for $i \in \{1, 3\}$. Thus, V is a matching between J and I. A similar argument can be given when the first recursive call results in Case 3. □

LEMMA 5. *Let V be the returned value in Procedure* POPROD, *when X, J, I are the input arguments. If* $(k, k') \in V$, $(m, m') \in V$ *and* $y_k <_P y_m$, *then* $x_{k'} < x_{m'}$.

Proof. We prove the lemma inductively on the size of the set J. The base case $|J| \leqq 1$ is obvious. Inductively, suppose $|J| > 1$, and that the first recursive call results in Case 2. Suppose that $(k, k') \in V_i$ and $(m, m') \in V_j$. As $y_k <_P y_m$, we have $i \leqq j$ (since $(B_{P_J,1}, B_{P_J,2}, B_{P_J,3})$ is a 3-partition of P_J by definition). If $i < j$, then $x_{k'} < x_{m'}$, as $x_{k'} \in X_{I_i}$, $x_{m'} \in X_{I_j}$, and $X_{I_i} < X_{I_j}$. If $i = j \in \{1, 3\}$, then the lemma holds by the induction hypothesis. The case $i = j = 2$ does not arise, since no two distinct y_k and y_m in $B_{P_J,2}$ are comparable in P_J. A similar argument can be given when the first recursive call results in Case 3. □

This proves that Procedure POPROD defines a decision tree algorithm for P-production, when we set $J = I = \{1, 2, \cdots, n\}$ in the input arguments. To complete the proof of Theorem 4, it remains to analyze the number of comparisons used in this procedure. This will be done in the next section.

5. Analysis of POPROD. Let $f_P(J)$ be the maximum number of comparisons used in POPROD (X, J, I) for any I and any relative ordering of the elements in X. Let $\lambda_2 = 5000c_2$, and $\lambda_3 = 100c_3$. In this section, we will prove

$$f_P(J) \leqq \lambda_2 n + \lambda_3 \log_2 \left(\frac{|J|!}{\mu(P_J)} \right). \tag{7}$$

This will complete the proof of Theorem 4.

5.1. Two lemmas. We digress to prove two auxiliary lemmas before proving (7). We need a classical theorem due to Dilworth [D].

DILWORTH'S THEOREM [D]. *Let* $P=(<_P, W)$ *be any partial order, and* width $(P)=m>0$. *Then* W *can be written as the disjoint union of* m *nonempty sets* $W_i=\{w_{i,1}, w_{i,2}, \cdots, w_{i,t_i}\}$, $1 \leqq i \leqq m$, *such that* $w_{i,1}<_P w_{i,2}<_P \cdots <_P w_{i,t_i}$ *for all* i.

Proof. See [D] for the proof. □

Let $P=(<_P, Y)$ be any partial order on a nonempty set $Y=\{y_1, y_2, \cdots, y_n\}$. Let $\mathscr{B}_P=(B_{P,1}, B_{P,2}, B_{P,3})$ and $\mathscr{D}_P=(D_{P,1}, D_{P,2})$ be the two special k-partitions defined in § 4.1.

LEMMA 6. *Let* J_1, J_2, J_3 *be such that* $B_{P,i}=\{y_j | j \in J_i\}$ *for* $i \in \{1,2,3\}$. *Then*

$$\frac{\mu(P_{J_1})}{|J_1|!}\frac{\mu(P_{J_3})}{|J_3|!} \geqq \frac{\mu(P)}{|Y|!}.$$

Proof. Take a random $\sigma \in \Gamma_n$. Let E be the event that $\sigma(j)<\sigma(k)$ for all $y_j <_P y_k$, and for $i \in \{1,3\}$, let E_i be the event that $\sigma(j)<\sigma(k)$ for all $y_j <_P y_k$ with $j, k \in J_i$. Thus, E is the event that $\sigma \in \Delta(P)$, and E_i is the event that σ is consistent with P_{J_i}.

Clearly, E implies $E_1 \wedge E_3$. Furthermore, E_1 and E_3 are independent events. It follows that

$$\begin{aligned}\frac{\mu(P)}{|Y|!} &= \Pr\{E\} \\ &\leqq \Pr\{E_1 \wedge E_3\} \\ &= \Pr\{E_1\} \cdot \Pr\{E_3\} \\ &= \frac{\mu(P_{J_1})}{|J_1|!}\frac{\mu(P_{J_3})}{|J_3|!}.\end{aligned}$$

This proves Lemma 6. □

LEMMA 7. *Suppose* $n>1$. *Let* J_1, J_2 *be such that* $D_{P,i}=\{y_j | j \in J_i\}$ *for* $i \in \{1,2\}$. *If* width $(P) \leqq \lceil n/100 \rceil$, *then*

$$\frac{\mu(P_{J_1})}{|J_1|!}\frac{\mu(P_{J_2})}{|J_2|!} \geqq (1.01)^{|Y|}\frac{\mu(P)}{|Y|!}.$$

Proof. Let $m=$ width (P). If $m=1$, then P is a linear order, and it is easy to see that the lemma is true in this case. We can thus assume that $m>1$. Since $\lceil n/100 \rceil \geqq m$, we have $n>100$. Clearly, both J_i are nonempty. By Dilworth's Theorem, P can be covered by m chains of lengths, say, $l_1, l_2, \cdots, l_m>0$. Thus, each 2-partition $(A_1, A_2) \in \mathscr{M}_P$ can be specified by integers $k_1, k_2, \cdots, k_m$, where k_i is the number of elements of A_1 on the ith chain. After standard manipulations for optimizing expressions, we obtain

$$\begin{aligned}|\mathscr{M}_P| &\leqq \prod_{1 \leqq i \leqq m}(1+l_i) \\ &\leqq \left(\frac{2n}{m}\right)^m \\ &\leqq (200)^{\lceil n/100 \rceil}.\end{aligned} \tag{8}$$

For each $\sigma \in \Delta(P)$, let $K_\sigma=\{y_j | 1 \leqq \sigma(j) \leqq \lceil n/2 \rceil\}$. Then $(K_\sigma, Y-K_\sigma) \in \mathscr{M}_P$. If we partition $\Delta(P)$ according to the value of K_σ, then there are $|\mathscr{M}_P|$ classes, each containing at most $\mu(P_{J_1})\mu(P_{J_2})\sigma$'s. Thus,

$$\mu(P) \leqq |\mathscr{M}_P|\mu(P_{J_1})\mu(P_{J_2}). \tag{9}$$

From (8), (9), and the fact $n > 100$, we obtain

$$\mu(P) \leqq (200)^{\lceil n/100 \rceil} \mu(P_{J_1}) \mu(P_{J_2})$$

$$\leqq \frac{1}{(1.01)^n} \binom{n}{\lceil n/2 \rceil} \mu(P_{J_1}) \mu(P_{J_2}).$$

Rearranging terms in the above expression gives the inequality to be proved in the lemma. □

5.2. The analysis. If $n = 1$, then $f_P(J) = 0$ and (7) is clearly true. We can thus assume $n \geqq 2$. In the algorithm POPROD, we can group the comparisons used into *steps*, each step performing either a 2-partition or a 3-partition of a subset of the input X. In our analysis, we will estimate separately the number of comparisons used for 2-partitions and for 3-partitions. To facilitate the analysis, we will utilize an auxiliary tree, with each internal node representing a step; the structure of the tree, together with information associated with the nodes, will contain enough details about the execution of the algorithm to permit an upper-bound estimate of the cost.

Given P, J, where $J \neq \emptyset$, we construct a *cost tree* $V_{P,J}$. Each node v will be associated with a triplet $\eta(v) = (\delta(v), \alpha(v), S(v))$, where $\delta(v) \in \{0, 2, 3\}$, $\alpha(v)$ is a nonnegative integer, and $S(v) \subseteq Y$. We will say that v is of *type* $\delta(v)$ and *weight* $\alpha(v)$.

The cost trees are recursively constructed. If $|J| = 1$ with, say, $J = \{j\}$, then $V_{P,J}$ consists of a single node v with $\eta(v) = (0, 0, \{y_j\})$.

If $(|J| > 1) \wedge (\text{width}(P_J) > \lceil |J|/100 \rceil)$, then the root v of $V_{P,J}$ has $\eta(v) = (3, c_3|J|, B_{P_{J,2}})$, and for each nonempty $B_{P_{J,i}}$, $i \in \{1, 3\}$, there is a son v_i of the root such that the subtree rooted at v_i is V_{P,J_i}, where J_i is the set of j with $y_j \in B_{P_{J,i}}$.

If $(|J| > 1) \wedge (\text{width}(P_J) \leqq \lceil |J|/100 \rceil)$, then the root v of $V_{P,J}$ has $\eta(v) = (2, c_2|J|, \emptyset)$, and for each $i \in \{1, 2\}$, there is a son v_i of the root such that the subtree rooted at v_i is V_{P,J_i}, where J_i is the set of j with $y_j \in D_{P_{J,i}}$. (Note that in this case both J_i are nonempty.)

We have defined the cost tree $V_{P,J}$. An example of $V_{P,J}$ is shown in Fig. 2, where P is the partial order in Fig. 1 and $J = \{1, 2, \cdots, n\}$; square nodes are of type 0, oval nodes with c_2 beside them are of type 2, and those with c_3 beside them are of type 3.

We now relate $f_P(J)$ to the cost tree. Let $a_i(P, J)$ be the total weight of type-i nodes in $V_{P,J}$. That is, let $a_i(P, J) = \sum_{v, \delta(v) = i} \alpha(v)$ for $i \in \{2, 3\}$.

LEMMA 8. $f_P(J) \leqq a_2(P, J) + a_3(P, J)$.

Proof. We prove the lemma by induction on the size of $|J|$. If $|J| = 1$, then $f_P(J) = a_2(P, J) = a_3(P, J) = 0$, and the lemma holds. Inductively, assume that $|J| = m > 1$, and that we have proved the lemma for all J with size less than m. If $\text{width}(P_J) > \lceil |J|/100 \rceil$, then in the execution of Procedure POPROD, for any I and X, Case 2 occurs at the top level, and thus

$$f_P(J) \leqq c_3|J| + \sum_{i \in \{1,3\}, J_i \neq \emptyset} f_P(J_i),$$

where J_i are the sets of j such that $y_j \in B_{P_{J,i}}$. Applying the induction hypothesis, we have

$$f_P(J) \leqq c_3|J| + \sum_{i \in \{1,3\}, J_i \neq \emptyset} (a_2(P, J_i) + a_3(P, J_i))$$

$$= a_2(P, J) + a_3(P, J).$$

A similar argument works when $\text{width}(P_J) \leqq \lceil |J|/100 \rceil$. This completes the inductive step of the proof. □

We now analyze $a_i(P, J)$.

LEMMA 9. $a_3(P, J) \leqq 100 c_3 |J|$.

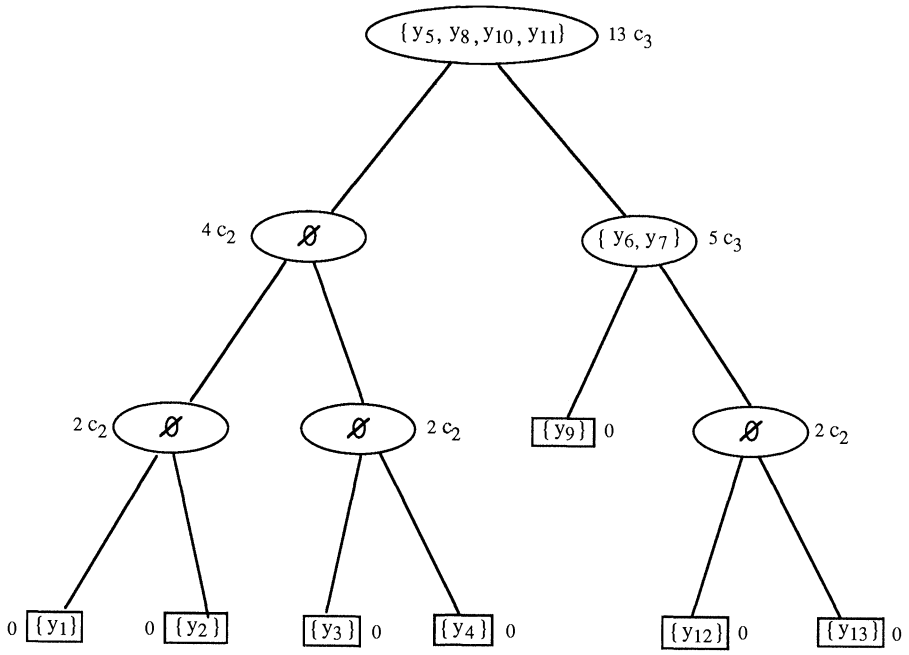

FIG. 2. *$V_{P,J}$ with the P in Fig. 1 and $J=\{1,2,\cdots,13\}$; $S(v)$ is shown inside the nodes v, and $\alpha(v)$ is shown just outside v.*

Proof. We first state two facts that can be easily verified. For all type-3 internal nodes v,

$$|S(v)|>\lceil\alpha(v)/(100c_3)\rceil. \tag{10}$$

For any two distinct internal nodes v and v',

$$S(v)\cap S(v')=\varnothing. \tag{11}$$

It follows from (10) and (11) that

$$\begin{aligned} a_3(P,J) &= \sum_{v,\delta(v)=3}\alpha(v) \\ &\leqq 100c_3\sum_{v,\delta(v)=3}|S(v)| \\ &\leqq 100c_3|Y_J| \\ &= 100c_3|J|, \end{aligned}$$

where the summation of v is over nodes in $V_{P,J}$. This proves the lemma. □

LEMMA 10. $a_2(P,J)\leqq 5000c_2\log_2(|J|!/\mu(P_J))$.

Proof. We prove the lemma inductively on the size of J. If $|J|=1$, then $a_2(P,J)=0$, $|J|=\mu(P_J)=1$, and the lemma is valid. Inductively, suppose that $|J|=m>1$ and that we have proved the lemma for all J, P with $|J|<m$.

If width $(P_J)>\lceil|J|/100\rceil$, then in the execution of Procedure POPROD, for any I and X, Case 2 occurs at the top level. Let J_i be the set of j with $y_j\in B_{P_{J,i}}$. Applying

the induction hypothesis to each son v_i, and keeping in mind that we employ the convention that $0! = \mu(P_\emptyset) = 1$, we obtain

$$a_2(P, J) = \sum_{i \in \{1,3\}, J_i \neq \emptyset} a_2(P, J_i)$$

$$\leqq 5000c_2 \sum_{i \in \{1,3\}} \log_2 \left(\frac{|J_i|!}{\mu(P_{J_i})} \right)$$

$$= 5000c_2 \log_2 \left(\frac{|J_1|!|J_3|!}{\mu(P_{J_1})\mu(P_{J_3})} \right).$$

Applying Lemma 6 to the partial order P_J, we then have

$$a_2(P, J) \leqq 5000c_2 \log_2 \left(\frac{|J|!}{\mu(P_J)} \right).$$

If width $(P_J) \leqq \lceil |J|/100 \rceil$, Case 3 occurs in the execution of POPROD. Let J_i be the set of j with $y_j \in D_{P_{J,i}}$. Both J_i are nonempty in this case. We have

$$a_2(P, J) \leqq c_2|J| + 5000c_2 \log_2 \left(\frac{|J_1|!}{\mu(P_{J_1})} \right) + 5000c_2 \log_2 \left(\frac{|J_2|!}{\mu(P_{J_2})} \right)$$

$$= c_2 m + 5000c_2 \log_2 \left(\frac{|J_1|!|J_2|!}{\mu(P_{J_1})\mu(P_{J_2})} \right).$$

Applying Lemma 7 to P_J, we obtain

$$a_2(P, J) \leqq c_2 m + 5000c_2 \log_2 \left(\frac{m!}{\mu(P_J)} \frac{1}{(1.01)^m} \right)$$

$$\leqq 5000c_2 \log_2 \left(\frac{m!}{\mu(P_J)} \right).$$

This completes the inductive step of the proof. □

Inequality (7), and hence Theorem 4, follows immediately from the preceding three lemmas. This completes the proof of Theorem 2.

6. Remarks. In this paper we have determined up to a constant factor the complexity of a class of problems involving partial orders, in terms of a familiar combinatorial quantity $\mu(P)$. It is of interest to explore the complexity of other classes of problems involving partial orders. An excellent survey of this topic can be found in Saks [Sa]. We list below some open problems directly related to our present discussion.

(a) Can we characterize the complexity of producing σ that satisfies more general constraints than a single partial order P? For example, let $P_1, P_2, \cdots, P_m$ be partial orders on $Y = \{y_1, y_2, \cdots, y_n\}$. What is the complexity of producing, for any input $X = \{x_1, x_2, \cdots, x_n\}$, a σ such that for some i, $y_j <_{P_i} y_k$ implies $x_{\sigma(j)} < x_{\sigma(k)}$ for all j, k?

(b) The results in this paper imply that the randomized decision tree complexity for P-production is asymptotically of the same order of magnitude as the worst-case complexity. Is this true for more general class of production problems, such as the one mentioned in (a)? It is also of interest to study the question of whether randomization helps for other types of partial order problems.

(c) The present paper gives an existence proof of a near-optimal height decision tree for P-production. If the partial order itself is also given as an input, is there a

polynomial time algorithm (counting all the bookkeeping steps) that uses a near-optimal number of comparisons for producing a partial order?

A FAST ALGORITHM FOR MULTIPROCESSOR SCHEDULING OF UNIT-LENGTH JOBS*

BARBARA B. SIMONS† AND MANFRED K. WARMUTH‡

Abstract. An efficient polynomial time algorithm for the problem of scheduling n unit length jobs with rational release times and deadlines on m identical parallel machines is presented. By using preprocessing, a running time of $O(mn^2)$ is obtained that is an improvement over the previous best running time of $O(n^3 \log\log n)$. The authors also present new NP-completeness results for two closely related problems.

1. Introduction. We present an efficient polynomial time algorithm for the problem of scheduling n unit length jobs with rational release times and deadlines on m identical parallel machines. The question of how the requirement that the jobs all have the same length affects the problem was first answered in [10], where a polynomial time algorithm with time complexity $O(n^2 \log n)$ is presented for the single machine case. An alternative algorithm with the same time complexity was subsequently obtained by [1]. Finally, an algorithm with time complexity $O(n \log n)$ for the single machine case was presented in [5].

In the multimachine case, the only previously known polynomial time algorithm has a worst-case running time of $O(n^3 \log\log n)$ [11]. We improve this running time to $O(mn^2)$ by doing some preprocessing before the jobs are actually scheduled. This speedup is obtained by generalizing to an arbitrary number of machines the notion of "forbidden regions," which was developed in [5].

If different integer job lengths are allowed, then by a simple reduction from 3 PARTITION [4], determining whether or not a schedule exists is strongly NP-complete, even if $m = 1$ and all release times and deadlines are integers. If m is arbitrary, then there is a similar reduction in which all jobs are released at time 0 and have the same integer deadline.

We strengthen the above NP-completeness result by allowing only a small number of integer job lengths:

(A) Three integer job lengths (1, 3, and q for some integer q), m machines, integer deadlines, but only one overall release time;

(B) Two integer job lengths (1 and q), m machines, integer release times and deadlines.

2. An overview. The algorithm, called BOUNDED_REGION, has two major sections. The first, called the BACKSEQUENCE Algorithm, is the preprocessing section. It determines a set BR of regions in which only a bounded number of jobs can be started in any feasible schedule. The actual scheduling of the jobs is done by SCHEDULE (BR). This procedure schedules jobs as early as possible subject to the restriction that the regions of BR are not violated. Below is a top level description of the algorithm.

3. Definitions. We shall assume that there is a set J of *n jobs*, $J(1), J(2), \cdots, J(n)$, and a set M of *m machines*. Each job $J(i)$ has a nonnegative integer *processing requirement*, $p(i)$, a nonnegative rational *release time*, $r(i)$, and a nonnegative rational *deadline*, $d(i)$, with $d(i) \geqq r(i)+p(i)$. When we speak of a job $J(i)$ being *released* by time t, we mean that $r(i) \leqq t$. If job $J(i)$ is *started* at time t, then it is *finished* at time $t+p(i)$ and occupies the interval $[t, t+p(i))$. A *schedule* SCH for a problem instance J and M is an assignment of a nonnegative start time $s(i)$ and a machine $m(i)$, $0 \leqq m(i) \leqq m-1$, for each $J(i) \in J$ such that the following conditions hold.

(1) No job is started before its release time or finished later than its deadline, i.e., $s(i) \geqq r(i)$ and $s(i)+p(i) \leqq d(i)$.

(2) No two jobs overlap, i.e., if job $J(i)$ is started at time t on machine $m(k)$, then no other job assigned to $m(k)$ is started in the interval $[t, t+p(i))$.

Note that in our definition of schedule *preemption* is not allowed, that is, once a job has begun execution it cannot be interrupted and consequently must run until it is completed.

Except for the section on NP-completeness, in which $p(i)$ is allowed to assume one of several integer values, we shall assume that $p(i)=1$. For this case a schedule consists of a *sequence* of start times, where a sequence S for n jobs and m machines is a nondecreasing list of n nonnegative start times with the additional constraint that for $i > m$ the ith start time of the sequence is at least one unit greater than the $(i-m)$th start time. This constraint guarantees that no more than m jobs are being processed simultaneously. We say that such a sequence S is of *length* n, i.e., $|S|=n$. If S is a sequence with $|S|=n$, then S_i, $1 \leqq i \leqq n$, denotes the ith start time counting forward from the beginning of the sequence. Likewise, S^i denotes the ith start time counting backward from the end of the sequence. Note that $S_i = S^{n+1-i}$, for $1 \leqq i \leqq n$, and that S_i is the ith smallest and S^i is the ith largest start time of S. Given a problem instance J and M, a sequence S of length n is an *r-sequence* if there exists a 1-1 mapping s (written $s(i)$ instead of $s(J(i))$) from jobs to elements of S such that $r(i) \leqq s(i)$. Similarly, a sequence S of length n is a *d-sequence* if there exists a 1-1 mapping s from jobs to elements of S such that $s(i) \leqq d(i)-1$. The aim is to produce an *rd-sequence* of length n for the set of n jobs, namely, a sequence for which there exists a 1-1 mapping s such that $r(i) \leqq s(i) \leqq d(i)-1$.

Given a schedule SCH for a problem instance J and M, then the sorted list of start times is clearly an *rd*-sequence. For the opposite direction, assume the m machines are numbered $0, 1, \cdots, m-1$. Given an *rd*-sequence of length n for J, the jobs in J can be assigned start times in SCH by applying the following Earliest Deadline Rule first to S_1, then S_2, then S_3, and so on: the unscheduled job with the smallest deadline from among all jobs released by time S_i is started at time S_i on machine i mod m.

4. Bounded and forced regions. If the release times are integers, the deadlines rationals, and the processing requirement one unit, then it is possible to construct a schedule in linear time if one exists [3], [7]. (Recall that our definition of schedule is an assignment of start times and machines to jobs.) A simple reduction from sorting

shows, however, that the construction of an *rd*-sequence requires $\Omega(n \log n)$ time. This time bound is attained by the Earliest Deadline Algorithm [8], which constructs an *rd*-sequence as well as a schedule for that sequence directly from the problem instance in $O(n \log n)$ time. The Earliest Deadline Algorithm computes start time S_i by setting S_i to be the minimum of the release times of the unscheduled jobs and $S_{i-m}+1$, for $i > m$. It then uses the Earliest Deadline Rule to select the job that is assigned start time S_i and machine $i \bmod m$.

This approach fails if arbitrary rational release times and deadlines are allowed. Intuitively, this happens for two reasons. First, jobs may be released during the time that other jobs are already running. (Note that this can be avoided if the release times are integers, since this implies that the start times can be constrained to be integers.) Second, there may be a set of jobs all of which are released on or after some release time, say $r(j)$, and have deadlines less than or equal to some deadline, say $d(i)$, such that the jobs in this set fill up almost the entire interval between $r(j)$ and $d(i)$. If "too many" jobs are started just before $r(j)$, then these jobs will extend into the interval $[r(j), d(i))$, and there will not be enough space in which to schedule all the jobs from the set. Consequently, it is necessary to bound the number of jobs that start less than one unit prior to $r(j)$. In the single machine case, it may be necessary to construct a forbidden region in which no job can start. Such a region has length no greater than one and has a release time as its right endpoint [5]. The m machine case becomes more complex because there can be up to m such intervals, each interval having a different length and a different restriction on the number of jobs that can start in its interior, but having the same release time as its right endpoint.

A *region* is defined to be an interval, either opened at both ends or closed at both ends. The length of a region is always no greater than one and can equal one only if the region is an open interval. The BACKSEQUENCE Algorithm computes regions in which at least k jobs *must* start in any *rd*-sequence. Because each job runs for one unit of time, this implies regions in which at most $m-k$ jobs *are allowed* to start in any *rd*-sequence. We refer to such a region as a *k-forced start region* and an $(m-k)$-*bounded start region*, respectively. We also say that k (respectively, $m-k$) is the *degree* of the k-forced (respectively, $(m-k)$-bounded) start region. If the region $[\alpha, \beta]$ is a k-forced start region, then the region $(\beta-1, \alpha)$ is an $(m-k)$-bounded start region. Note that if more than $m-k$ jobs start in the region $(\beta-1, \alpha)$, then k jobs cannot start in the region $[\alpha, \beta]$. (We require that the parameter k always lies in the range from one to m.) Lemma 0 below follows directly from the definitions of forced and bounded regions.

LEMMA 0. *If $[\alpha, \beta]$ is a k-forced region, then $(\beta-1, \alpha)$ is an $(m-k)$-bounded region.*

We say that an $(m-k)$-bounded start region is *correct* if there is no *rd*-sequence for the problem instance in which more than $(m-k)$ jobs start in the region. If a sequence or schedule has no more than $m-k$ jobs started in an $(m-k)$-bounded region, we say that the $(m-k)$-bounded region has been *avoided*. If more than $m-k$ jobs are scheduled to start in a $(m-k)$-bounded region, then we say that the $(m-k)$-bounded region is *violated*. The terms *correct*, *avoided*, and *violated* are defined similarly for k-forced regions.

Forced and bounded regions always come in pairs. The reader should bear in mind that we are concerned only with the number of jobs that actually start on all m machines in such a region (as opposed to those that have started earlier and are already running in the region). For reasons that will become apparent later, a k-forced region has a release time at its left endpoint and an $(m-k)$-bounded region has a release

time as its right endpoint. Bounded regions are open intervals and forced regions are closed intervals.

4.1. How to avoid bounded regions. We distinguish between two modes of constructing sequences. In the *backward* mode we select the latest possible start time by scanning backward starting from a deadline. In the *forward* mode we select the earliest possible start time for each job by scanning forward starting from a release time. BACKSEQUENCE constructs n sequences using the backward mode starting from each of the deadlines. At the end of each iteration, BACKSEQUENCE uses information from the sequences it has constructed to create a new set of up to m bounded regions. It then calls procedure ADD, which computes additional bounded regions implied by those already constructed. Finally, forward sequencing is used in the procedure SCHEDULE to construct the schedule for the problem instance.

Let S be a sequence, $|S| = v$. The subroutine NEXTFORWARD (S, BR, t), given below, returns the smallest start time S^0 such that $S^0 \geqq t$, $S^0 \geqq S^i$, $1 \leqq i \leqq v$, and all the bounded regions of BR are avoided by the start times of $S|S^0$, where | denotes "appended to." Note that if $S' = S|S^0$, then $S'^i = S^{i-1}$, for $1 \leqq i \leqq v+1$. Similarly, the subroutine NEXTBACKWARD (S, BR, t) returns the largest start time S_0 such that $S_0 \leqq t$, $S_0 \leqq S_i$, for $1 \leqq i \leqq v$, and all the bounded regions of BR are avoided by $S_0|S$. We use both procedures iteratively to construct sequences that avoid all bounded regions of BR. For examples of how bounded regions are avoided, see Figs. 3 and 4 in § 11.

SUBROUTINE NEXTFORWARD (S, BR, t) (* returns minimum start time $S^0 \geqq t$ such that the bounded regions of BR are avoided *)
(0) Let $|S| = v$;
  if $v < m$ then $S^m := t-1$; (* This prevents S^m from being undefined *)
(1) $S^0 := \max(t, S^1, S^m+1)$; (* This guarantees that $S|S^0$ is a sequence *)
(2) process the bounded regions of BR in order of nondecreasing left endpoints:
  let R be the next bounded region of BR, let $m-k$ be the degree of R, and let $\beta-1$ and α be the left and right endpoints, respectively, of R;
    if $m-k \leqq v$ then
    if $S^{m-k} \in (\beta-1, \alpha)$ then $S^0 := \max\{S^0, \alpha\}$; (* S^0 is increased by the minimum amount such that the $(m-k)$-bounded region $(\beta-1, \alpha)$ is avoided *)
(3) return (S^0).

SUBROUTINE NEXTBACKWARD (S, BR, t) (* returns maximum start time $S_0 \leqq t$ such that the bounded regions of BR are avoided *)
(0) Let $|S| = v$;
  if $v < m$ then $S_m := t+1$; (* This prevents S_m from being undefined *)
(1) $S_0 := \min(t, S_1, S_m-1)$; (* This guarantees that $S_0|S$ is a sequence *)
(2) process the bounded regions of BR in order of nonincreasing right endpoints:
  let R be the next bounded region of BR, let $m-k$ be the degree of R, and let $\beta-1$ and α be the left and right endpoints, respectively, of R;
    if $m-k \leqq v$ then
    if $S_{m-k} \in (\beta-1, \alpha)$ then $S_0 := \min(S_0, \beta-1)$; (* S_0 is decreased by the minimum amount such that the $(m-k)$-bounded region $(\beta-1, \alpha)$ is avoided *)
(3) return (S_0).

LEMMA 1. *Let S be a sequence with $|S| = v$ in which all bounded regions of* BR *are avoided. Then* NEXTFORWARD *computes the minimum start time $S^0 \geqq t$ such that $S|S^0$ is a sequence and the bounded regions of* BR *are avoided.*

Proof. Clearly, $S^0 \geqq t$. Since S is a sequence, $S^0 \geqq S^1$ implies that $S^0 \geqq S^i$, $1 \leqq i \leqq v$. Because $S^0 \geqq S^m + 1$ for $v \geqq m$, it follows that $S|S^0$ is a sequence. The regions are processed according to nondecreasing left endpoint; consequently, S^0 is never assigned a value that violates a region that has been previously processed. (We could have processed the bounded regions by right endpoint instead of left endpoint, as long as the approach was used consistently throughout the processing of the bounded regions.) Since S^0 is increased only if it falls within an $(m-k)$-bounded region already containing $m-k$ jobs, and since S^0 is increased the minimum amount required to avoid the region, S^0 is the minimum start time greater than or equal to t that avoids the bounded regions of BR. □

LEMMA 2. *Let S be a sequence, with $|S| = v$, in which all the bounded regions of* BR *are avoided. Then* NEXTBACKWARD *computes the maximum start time $S_0 \leqq t$ such that $S_0|S$ is a sequence and the bounded regions of* BR *are avoided.*

The proof is similar to the proof of Lemma 1.

5. Computing bounded regions by sequencing backward. Without loss of generality, assume that the jobs are sorted by release times and renamed, so that $r(1) \geqq r(2) \geqq \cdots \geqq r(n)$. In addition, let $d'(1), \cdots, d'(n)$ be the set of deadlines listed in sorted order so that $d'(1) \leqq d'(2) \leqq \cdots \leqq d'(n)$. Note that $r(i)$ remains the release time for $J(i)$ but that $d'(i)$ is almost certainly not the deadline for $J(i)$. We call i the *index* of $J(i)$.

Let $\Sigma(i, j)$ be the set of jobs with index less than or equal to j and deadlines less than or equal to $d'(i)$, $1 \leqq i, j \leqq n$, and let $n_{ij} := |\Sigma(i, j)|$. Note that all jobs in $\Sigma(i, j)$ have release times that are at least as large as $r(j)$. The BACKSEQUENCE Algorithm (presented below) iteratively constructs a set of n sequences, SE$[i]$, $1 \leqq i \leqq n$, and a set of bounded regions BR. SE$[i]$ corresponds to deadline $d'(i)$, and the jth iteration $(1 \leqq j \leqq n)$ corresponds to processing job $J(j)$ with release time $r(j)$. At the end of the jth iteration SE$[i]$ contains n_{ij} start times for the jobs $\Sigma(i, j)$. All these start times are at most $d'(i) - 1$ and are as late as possible subject to the constraint that all bounded regions already constructed are avoided. (Details are given in Theorem 1.) Since no job of $\Sigma(i, j)$ is released before $r(j)$, the algorithm stops in failure if SE$[i]_1 < r(j)$ for some i during the jth iteration. Also, if $r(j) < \text{SE}[i]_1$ and $\text{SE}[i]_1 - r(j) < 1$, for some i, then some job(s) of $\Sigma(i, j)$ must be started in the interval $[r(j), d'(i) - 1)$. This constraint triggers the creation of a bounded region with right endpoint $r(j)$. The bounded region guarantees that not too many jobs are started just prior to $r(j)$ such that they are running in the interval $[r(j), d'(i)]$ and interfering with the scheduling of $\Sigma(i, j)$.

```
SUBROUTINE BACKSEQUENCE
Initialize all sequences of SE[1..n] and BR to ∅;
(* SE[i] is the sequence ending at deadline d'(i) *)
(1) For j = 1 to n do (* Update SE[i] so that it contains precisely n_ij start times *)
Begin for loop
(2) For all i, 1 ≦ i ≦ n, such that d'(i) ≧ d(j) do
    (* d(j) is the deadline of the job with release time r(j) *)
      begin
      (* since each value of i corresponds to a different list, the order in which the
      d'(i)'s are processed is irrelevant *)
        S_0 := NEXTBACKWARD (SE[i], BR, d'(i) - 1);
        SE[i] := S_0|SE[i];
      end;
```

(3) For $1 \leqq k \leqq m$ do $f_k := \infty$;
    For $1 \leqq i \leqq n$ do
      $f_k := \min(f_k, \mathrm{SE}[i]_k)$;
(4) If $f_1 < r(j)$, then declare "infeasibility" and halt;
(5) For $k = 1$ to m do
      If $f_k - r(j) < 1$ then
        $\mathrm{BR} := \mathrm{BR} \cup \{$the $(m-k)$-bounded region $(f_k - 1, r(j))\}$.

End for loop;
Return BR;
End BACKSEQUENCE.

For the correctness proof below we use the notation BR$[j]$ to denote the set BR after the jth iteration of the global for loop of step (1). Examples of both the construction of the sequences and the creation of the bounded regions by BACKSEQUENCE are given in Figs. 1 and 2 in § 11.

THEOREM 1. *Let j be between one and n. The following statements are true at the completion of the processing of the jth iteration of the global for loop of* BACKSEQUENCE.

(i) *If* BACKSEQUENCE *does not halt in failure, then* $\mathrm{SE}[i]_1 \geqq r(j)$ *for all i such that* $\mathrm{SE}[i]_1$ *is not empty, and there is no d-sequence for $\Sigma(i, j)$ in which all regions of* BR$[j-1]$ *are avoided whose kth smallest start time is larger than* $\mathrm{SE}[i]_k$, $1 \leqq k \leqq |\mathrm{SE}[i]|$.

(ii) *All regions of* BR$[j]$ *are correct and are no more than one unit in length.*

(iii) *All regions of* BR$[j]$ *are avoided by* SE$[i]$ *for all i such that* $\mathrm{SE}[i]_1$ *is not empty.*

Proof. The proof is by induction on j. Let $j = 1$. Then clearly $\mathrm{SE}[i]_1 \geqq r(j)$ for all i such that $\mathrm{SE}[i]_1$ is not empty (which in this case is all i such that $d'(i) \geqq d(1)$). Otherwise, BACKSEQUENCE would have halted at step (4). Furthermore, any d-sequence could not have the last job in the sequence start later than $\mathrm{SE}[i]_1 = d'(i) - 1$. Since $\mathrm{BR}[0] = \varnothing$, there are no bounded regions for $\mathrm{SE}[i]_1$ to avoid. This proves condition (i) for the base case.

If $\mathrm{BR}[1] = \varnothing$, then conditions (ii) and (iii) also follow. So assume that $\mathrm{BR}[1] \neq \varnothing$. Then $f_1 - r(1) < 1$ in step (5), where $f_1 = d(1) - 1$ (since $\mathrm{SE}[i]_1 = d'(i) - 1$ for $d'(i) \geqq d(1)$). Thus, $[r(1), f_1]$ is a 1-forced region, which by Lemma 0 implies the correctness of the $(m-1)$-bounded region $(f_1 - 1, r(1))$. Note that the latter region is of length no greater than one, since otherwise we would have $f_1 < r(j)$, once again causing the algorithm to halt at step (4). This proves the correctness of (ii) for the base case. Finally, BR$[1]$ is avoided since $\mathrm{SE}[i]_1 \geqq \mathrm{SE}[1]_1 \geqq r(j)$ for all nonempty SE$[i]$, which proves the correctness of (iii).

Assume the lemma holds for $j' - 1$; we now prove it holds for j'.

(i) If SE$[i]$ is unchanged in iteration j', then $j' \notin \Sigma(i, j')$, i.e., $d(j') > d'(i)$ and by the induction assumption (i) holds for $j = j'$. Otherwise, it follows from the induction assumption together with Lemma 2 that the value of S_0 computed by NEXTBACKWARD is at least as large as the smallest feasible start time for SE$[i]$. Furthermore, if one of the other start times of SE$[i]$ were not to satisfy condition (i), then we would have a contradiction to the induction assumption that was made for $j' - 1$. Finally, since by (iii) all regions of BR$[j'-1]$ are avoided by SE$[i]$ after iteration $j' - 1$, it follows from Lemma 2 that (i) holds for $j = j'$.

(ii) Let $(f_k - 1, r(j))$ be an $(m-k)$-bounded region. Because of the way bounded regions are constructed, we have $r(j) \leqq f_k$, $f_k - r(j) < 1$, and $r(j) - (f_k - 1) < 1$. In addition, for some i, $\mathrm{SE}[i]_1 \leqq \mathrm{SE}[i]_2 \leqq \cdots \leqq \mathrm{SE}[i]_k = f_k$. (Note that $r(j) \leqq \mathrm{SE}[i]_1$.) Consequently, by condition (i), $[r(j), f_k]$ is a k-forced region, which implies by Lemma 0 the correctness of the $(m-k)$-bounded region $(f_k - 1, r(j))$.

(iii) By induction we know that all regions of BR$[j'-1]$ are avoided by SE$[i]$ after iteration $j'-1$ for nonempty SE$[i]_1$. From Lemma 2 we know that if a new start time is computed in step (2), it avoids the regions BR$[j'-1]$. Thus, SE$[i]$ avoids BR$[j'-1]$ after iteration j'. Now, any new regions added to BR$[j']$ have their right endpoints at $r(j')$. But by step (4) of BACKSEQUENCE, the values of SE$[i]$ are at least as large as $r(j')$. Consequently, these new regions are also avoided by SE$[i]$. □

Assume BACKSEQUENCE does not halt in failure. Consider the sequence SE$[i]$ after the completion of BACKSEQUENCE. As the following 1-machine example illustrates, the sequences SE$[i]$ are not necessarily d-sequences for $\Sigma(i, n)$. Let $r(1) = 1.2$, $d(1) = 4$, $r(2) = 1$, and $d(2) = 2.5$. Then SE$[2] = \{2, 3\}$. But if $J(2)$ is started at either time 2 or time 3, it will not be completed by its deadline. However, the sequences SE$[i]$ are r-sequences for $\Sigma(i, n)$, as the following trivial algorithm demonstrates. If $J(j) \in \Sigma(i, n)$, i.e., if $d'(i) \geqq d(j)$, then schedule job $J(j)$ at time S_0 computed in step (2) of BACKSEQUENCE during the jth iteration of the global for loop. Clearly, $J(j)$ will start no earlier than $r(j)$ in any of the SE$[i]$ that is updated in step (2), since otherwise BACKSEQUENCE would have halted in step (4).

COROLLARY 1. *For all bounded regions created by* BACKSEQUENCE, $(\beta-1, \alpha)$ *is an* $(m-k)$*-bounded region if and only if* $[\alpha, \beta]$ *is a* k*-forced region.*

Proof. If $[\alpha, \beta]$ is a k-forced region, then by Lemma 0, $(\beta-1, \alpha)$ is an $(m-k)$-bounded region. So suppose that $(\beta-1, \alpha)$ is an $(m-k)$-bounded region. Since all bounded regions are created in step (5) of BACKSEQUENCE, it follows that for some value of i, SE$[i]$ has k jobs starting in the region $[\alpha, \beta]$. By condition (i) of Theorem 1, it follows that it is necessary for k jobs to begin in the region $[\alpha, \beta]$. Hence, $[\alpha, \beta]$ is a k-forced region. □

COROLLARY 2. *If* BACKSEQUENCE *does not halt in failure, then after the* j*th iteration of the global loop,* SE$[i]$ *does not violate any bounded regions of the final set of bounded regions computed by* BACKSEQUENCE.

Proof. By (iii) of Theorem 1, SE$[i]$ avoids BR$[j]$; because BACKSEQUENCE does not halt in failure, SE$[i]_1 \geqq r(j)$. Since all bounded regions computed at iteration j or later have a right endpoint no greater than $r(j)$, SE$[i]$, as it is computed at the jth iteration, avoids all of BR$[n]$. □

COROLLARY 3. *If* BACKSEQUENCE *halts in failure, then there is no rd-sequence for the problem instance.*

Proof. If the algorithm halts in failure for $i = i^*$, $j = j^*$, then it follows from BACKSEQUENCE together with Theorem 1 that $r(j^*) > f_1 = \text{SE}[i^*]_1 = S_0$ (as computed in step (2) of BACKSEQUENCE). Combining the fact that all jobs in $\Sigma(i^*, j^*)$ have release time at least $r(j^*)$ together with the correctness of (i) of Theorem 1, we get that there is no *rd*-sequence for $\Sigma(i^*, j^*)$ and hence for the entire problem instance. □

6. Regions may imply additional regions. If two bounded regions overlap and together cover an interval of length greater than one, then they imply a new bounded region. We call the set of regions created by BACKSEQUENCE *original regions.*

LEMMA 3. *Let* $(\beta-1, \alpha)$ *be an original* $(m-k)$*-bounded region, and let* $(\beta'-1, \alpha')$ *be an original* $(m-k')$*-bounded region such that* $\beta-1 < \alpha' < \beta' < \alpha$. *Then* $[\alpha', \beta]$ *is a* $(k+k')$*-forced region,* $(\beta-1, \alpha')$ *is an* $(m-k-k')$*-bounded region, and both regions have length less than* 1.

Proof. Note that the $(m-k)$-bounded region $(\beta-1, \alpha)$ strictly contains the k'-forced region $[\alpha', \beta']$. By Corollary 1, $[\alpha, \beta]$ and $[\alpha', \beta']$ are k- and k'-forced regions, respectively. Since $\beta' < \alpha$, $[\alpha, \beta]$ and $[\alpha', \beta']$ do not overlap. $\beta-1 < \alpha'$ implies that

$\beta - \alpha' < 1$. Therefore, $[\alpha', \beta]$ is a $(k+k')$-forced region that, by Lemma 0, implies the $(m-k-k')$-bounded region $(\beta-1, \alpha')$ (see Fig. 4).

To prove that the regions are well defined, we must show that $k+k' \leqq m$. Assume for contradiction that $k' > m-k$. Then it follows from BACKSEQUENCE that at the completion of the iteration in which the $(m-k')$-bounded region $(\beta'-1, \alpha')$ is created there is some value I such that there are at least k' elements of SE$[I]$ within the interval $[\alpha', \beta']$. But then at least one of these start times will violate the $(m-k)$-bounded region $(\beta-1, \alpha)$. (Since $\alpha > \alpha'$, we know that the $(m-k)$-bounded region $(\beta-1, \alpha)$ is computed prior to the processing of release time α'.) Therefore, at least one value of SE$[I]$ will be set to $\beta-1$. But $(\beta-1) < \alpha'$, so BACKSEQUENCE will declare infeasibility and halt. Consequently, the region $(\beta'-1, \alpha')$ would not have been declared. Finally, the fact that α' lies between $\beta-1$ and β trivially implies that the regions $(\beta-1, \alpha')$ and $[\alpha', \beta]$ have length less than one. □

The bounded regions implied by Lemma 3 are computed by the subroutine ADD (BR), presented below. Note that the only overlapping regions that are examined by ADD are regions that are in the set BR.

SUBROUTINE ADD (BR) (* Computes the additional bounded regions implied by Lemma 3 *)
ADDITIONAL := ∅;
For all pairs of original bounded regions $(\beta-1, \alpha)$ and $(\beta'-1, \alpha')$ of BR such that $(\beta-1, \alpha)$ is an $(m-k)$-bounded region, $(\beta'-1, \alpha')$ is an $(m-k')$-bounded-region, and $\beta - 1 < \alpha' = r(j) < \beta' < \alpha$ do

ADDITIONAL := ADDITIONAL ∪ {the $(m-k-k')$-bounded region $(\beta-1, \alpha')$}.

BR := BR ∪ ADDITIONAL;
end ADD.

We call the set of regions created by ADD *additional regions.* It follows from the statement of Lemma 3 together with ADD that additional bounded regions are precisely those bounded regions that Lemma 3 proves correct. Note that to incorporate ADD into the algorithm, we need only add the following instruction to the global for loop of step (1) of BACKSEQUENCE.

(6) Call ADD (BR);

A more efficient routine for computing the regions implied by Lemma 3 called FASTADD is given in § 8.

Remark. It is easy to see that Theorem 1 and Corollaries 1, 2, and 3 still hold after the insertion of step (6) in BACKSEQUENCE. Observe that when an additional bounded region $(\beta-1, r(j))$ is created, all entries in the sequences SE[.] are at least $r(j)$. Thus, the additional regions are never violated when they are created, and they are avoided during later iterations in the same manner that the original regions are avoided.

An obvious question is whether or not the additional regions are necessary. As Figs. 3 and 4 in § 11 demonstrate, NEXTFORWARD might return a start time that violates an additional bounded region if the additional bounded regions are not incorporated into the algorithm. Consequently, the resulting sequence is not a d-sequence. Figure 4 in § 11 is an rd-sequence that does not violate the additional

bounded region. Thus, additional bounded regions are necessary if BACKSEQUENCE is used to create the regions that are used to construct r-sequences.

7. Producing the final schedule. In this section we show how to produce an rd-sequence and a schedule using the set of regions created by BACKSEQUENCE and ADD.

SUBROUTINE SCHEDULE (BR) (* constructs an rd-sequence by iteratively computing the earliest possible start time and then assigning a job to the newest start time *)
$S := \emptyset$;
For $i = 1$ to n do
(1) Let r be the minimum release time of all unscheduled jobs;
(2) $S_i :=$ NEXTFORWARD (S, BR, r); $S := S \mid S_i$;
(3) Use the Earliest Deadline Rule to select the job that starts at time S_i on machine $i \bmod m$;
end SCHEDULE.

LEMMA 4. SCHEDULE *produces an r-sequence in which all bounded regions are avoided.*

Proof. The selection of r in step (1) guarantees that there is always some unscheduled job that has been released by the time returned by NEXTFORWARD. In addition, by Lemma 1 all bounded regions are avoided. □

Let S be a sequence, and let $J(i)$ be the job that is assigned start time S_j by the Earliest Deadline Rule. We say that $J(i)$ is in *slot* j of sequence S. We also say that slot j *contains* $J(i)$ in sequence S. When speaking of slots, we shall omit the sequence name if the reference is unambiguous.

LEMMA 5. *Let S be the r-sequence produced by* SCHEDULE, *and let* $S_0 = -\infty$. *If some job in the schedule produced by* SCHEDULE *is completed after its deadline, then there exist v, w, i, and j such that*

(1) *The jobs in slots* $v, v+1, \cdots, w$ *consist exactly of the set* $\Sigma(i, j)$;
(2) $S_w + 1 > d'(i)$, *i.e., some job of* $\Sigma(i, j)$ *is finished after its deadline*;
(3) $S_{v-1} < r(j) \leqq S_v$.

Proof. Let X be the job in S that is finished later than its deadline and is in the largest numbered slot, say w, of all such jobs. That is, $d(X) = d'(i)$ for some i, and $S_w + 1 > d'(i)$. It follows from the choice of X that all jobs with deadlines no greater than $d'(i)$ are in slots numbered no greater than w.

If all jobs in slots 1 through w have deadlines no greater than $d'(i)$, then by setting $v = 1$ and $j = n$, we get that conditions (1)-(3) of the lemma are satisfied. Otherwise, let $v-1$ be the largest numbered slot less than w that contains a job with deadline greater than $d'(i)$. Let r be the minimum release time of the jobs in slots v through w, and let j be the maximum such that $r = r(j)$. Note that $\Sigma(i, j)$ consists of all jobs with release time at least $r(j)$ and deadline at most $d'(i)$. Since S is an r-sequence, it follows that $r(j) \leqq S_v$. Furthermore, since slot $v-1$ contains a job with a deadline larger than the deadlines of the jobs in slots v through w, it follows from the Earliest Deadline Rule that none of the jobs in slots v through w was available at time S_{v-1}. Therefore, $S_{v-1} < r(j) \leqq S_v$, and condition (3) of the lemma is proved. All the jobs in slots v through w are in $\Sigma(i, j)$, i.e., they must have deadlines at most $d'(i)$ (from the choice of v) and release time at least $r(j)$ (from the choice of j). Also no jobs of $\Sigma(i, j)$ are scheduled in slots 1 through $v-1$, since they are not yet released. Similarly, no jobs of $\Sigma(i, j)$ appear in slots $w+1, \cdots, n$: the jobs of $\Sigma(i, j)$ have deadlines at most

$d'(i)$, and thus they would be late if they were scheduled in slots $w+1$ through n; but w is the last slot with a late job. This shows that condition (1) holds, and completes the proof of the lemma. □

LEMMA 6. *If v, w, i, j are chosen as in Lemma 5 with the additional constraint that n_{ij} is minimal, then the following condition holds*:

(4) *If a job from slots v through w starts at its release time, then it starts at S_v.*

Proof. Assume that Lemma 5 holds for v, w, i, and j, with n_{ij} being minimal, and that condition (4) does not hold. In other words, there is some slot v', $v < v' \leqq w$, such that the job in slot v' has release time $S_{v'}$. Let j' be maximum such that $r(j') = S_{v'}$. Now conditions (1), (2), and (3) of Lemma 5 hold for v', w, i, and j', and $n_{ij'} < n_{ij}$. This contradicts the minimality of n_{ij}. □

For the remainder of this section we assume that S is the sequence constructed by SCHEDULE and that some job in the schedule produced by SCHEDULE is completed after its deadline. Let v, w, i, and j be chosen to satisfy Lemmas 5 and 6. Recall that SE$[i]$ corresponds to deadline $d'(i)$ and that the jobs in $\Sigma(i, j)$ all have deadlines less than or equal to $d'(i)$.

To simplify the notation, let F_{q-v+1} denote S_q, $0 \leqq q \leqq n$. Then the relevant start times in S for the jobs in $\Sigma(i, j)$ are $F_1, F_2, \cdots, F_{n_{ij}}$ instead of $S_v, S_{v+1}, \cdots, S_w$. Condition (3) of Lemma 5 now states that $F_0 < r(j) \leqq F_1$. (Recall that $S_0 = -\infty$.)

We compare the start times F_q to the start times of the sequence SE$[i]$ computed by BACKSEQUENCE in iteration j. Again for the sake of notation, let $B_k = \text{SE}[i]_k$ after iteration j, $1 \leqq k \leqq n_{ij}$. It follows from the construction of SE$[i]$ and from the fact that BACKSEQUENCE did not halt at step (4) that $r(j) \leqq B_1 \leqq B_2 \leqq \cdots \leqq B_{n_{ij}} \leqq d'(i) - 1$.

LEMMA 7. $F_q \leqq B_q$, $1 \leqq q \leqq n_{ij}$.

Before we prove Lemma 7, observe that since its correctness implies that $F_{n_{ij}} \leqq B_{n_{ij}} \leqq d'(i) - 1$, we get an immediate contradiction to the assumption that job X, which is scheduled in slot w in S, is finished later than its deadline of $d'(i)$. Therefore, Lemmas 4 and 7 imply the following theorem.

THEOREM 2. SCHEDULE *produces an rd-sequence and a schedule.*

Proof of Lemma 7. Assume q is the minimum value such that $F_q > B_q$. Since the value of F_q is assigned either in step (1) or in step (2) of NEXTFORWARD and there are three different possible assignments for step (1), we break the analysis into four cases.

Case 1. $F_q = F_{q-1}$ ($S^0 := S^1$ in step (1) of NEXTFORWARD). Since condition (3) of Lemma 5 implies that $F_1 > F_0$, we have in this case that $q > 1$. But $F_q > B_q \geqq B_{q-1}$ leads to $F_{q-1} > B_{q-1}$, and this contradicts the minimality of q.

Case 2. $F_q = F_{q-m} + 1$ ($S^0 := S^m + 1$ in step (1) of NEXTFORWARD). If $q - m \geqq 1$, then $F_{q-m} \leqq B_{q-m} \leqq B_q < F_q = F_{q-m} + 1$. This implies that $B_q - B_{q-m} < 1$, which contradicts the fact that SE$[i]$ is a sequence (Lemma 2).

If $q - m < 1$, then by condition (3) of Lemma 5, $F_{q-m} \leqq F_0 < r(j)$. Now, $F_q > B_q$ and $F_q = F_{q-m} + 1$ imply that $B_q < r(j) + 1$. Since $r(j) \leqq B_1 \leqq \cdots \leqq B_q < r(j) + 1$, $[r(j), B_q]$ is a q-forced region and $(B_q - 1, r(j))$ is an original $(m - q)$-bounded region. Since $B_q - 1 < F_q - 1 = F_{q-m}$ and since $F_0 < r(j)$, we have that $F_{q-m}, F_{q-m+1}, \cdots, F_0$ start in the $(m - q)$-bounded region $(B_q - 1, r(j))$. Therefore, there are $m - q + 1$ start times in the $(m - q)$-bounded region $(B_q - 1, r(j))$, and this region is violated by S. This contradicts Lemma 4, which states that the sequence produced by SCHEDULE does not violate any bounded regions.

Case 3. The job started at F_q in S has release time F_q ($S^0 := t$ and $t = r =$ minimum release time of all unscheduled jobs when NEXTFORWARD is called by

SCHEDULE). By condition (4) of Lemma 6, q can only be 1. Therefore, when NEXTFORWARD is called, all jobs of $\Sigma(i, j)$ are unscheduled. Thus, $r = F_q = r(j)$. Now the assumption that $F_1 > B_1$ implies $B_1 < r(j)$, contradicting condition (i) of Theorem 1.

Case 4. F_q received its final value in step (2) of NEXTFORWARD (to avoid violating a bounded region). This implies both that there exists an original p-bounded region $(\beta - 1, F_q)$ and that S has p start times within that region. These start times are $F_{q-p}, F_{q-p+1}, \cdots, F_{q-1}$. If $q > p$, then $F_{q-p} \leqq B_{q-p} \leqq B_{q-p+1} \leqq \cdots \leqq B_q < F_q$. This implies that SE $[i]$ violates a bounded region, which contradicts Corollary 2.

Assume that $q \leqq p$ which implies that $\beta - 1 < F_{q-p} < r(j)$. Recall that $(\beta - 1, F_q)$ is a p-bounded region. Since all $B_1, B_2, \cdots, B_q$ lie within $[r(j), B_q]$, $(B_q - 1, r(j))$ is an original $(m - q)$-bounded region. Combining inequalities, we have $\beta - 1 < r(j) < B_q < F_q$. Therefore, the conditions of Lemma 3 hold, with $\alpha = F_q$, $m - k = p$, $\beta' = B_q$, $\alpha' = r(j)$, and $k' = q$. Thus, $(\beta - 1, r(j))$ is a $(p - q)$ additional bounded region. We know that the interval $[r(j), F_q)$ contains $q - 1$ start times from S, namely $F_1, \cdots, F_{q-1}$, and that $F_0 < r(j)$. Because the p-bounded region $(\beta - 1, F_q)$ contains p start times from S, it follows that $(\beta - 1, r(j))$ contains $p - q + 1$ start times from S, which violates the additional $(p - q)$-bounded region $(\beta - 1, r(j))$. □

COROLLARY 4 (to Theorem 2). *There is no rd-sequence that has a qth smallest time smaller than the qth smallest time of the sequence S produced by* SCHEDULE, $1 \leqq q \leqq n$.

Proof. Suppose for contradiction that S' is an *rd*-sequence with start times $S'_1, S'_2, \cdots, S'_n$, and let q be the minimum value such that $S'_q < S_q$. As in Lemma 7, we analyze the four cases for the assignment of the value of S_q.

Case 1. $S_q = S_{q-1}$. This is contradicted by $S_{q-1} \leqq S'_{q-1} \leqq S'_q < S_q$.

Case 2. $q > m$ and $S_q = S_{q-m} + 1$. Again we get a contradiction since $S_{q-m} \leqq S'_{q-m} \leqq S'_q < S_q = S_{q-m} + 1$ implies that $S'_q < S'_{q-m} + 1$.

Case 3. S_q is the minimum release time of all the jobs in slots q through n in S. None of the jobs in slots q through n in S can be scheduled in slots 1 through q of S' since $S'_q < S_q$. But this is impossible since it is not possible to place $n - q + 1$ jobs in slots $q + 1$ through n of S'.

Case 4. There exists a k-bounded region $(\beta - 1, S_q)$ and there are k jobs starting in $(\beta - 1, S_q)$ in S. It follows from the definition of q that $S_{q-k} \leqq S'_{q-k} \leqq S'_{q-k+1} \leqq \cdots \leqq S'_q < S_q$, and hence $(\beta - 1, S_q)$ is violated by S', contradicting the assumption that S' is an *rd*-sequence. □

In particular, Corollary 4 implies that the output of SCHEDULE has minimum makespan over all schedules that observe the release time and deadline constraints.

8. An $O(mn^2)$ implementation of BACKSEQUENCE. We first indicate how to speed up the running time of ADD. For each value of j for which BR (j) has been computed by BACKSEQUENCE, only the largest of each of the (at most) m regions is recorded in step (5). Thus, the total number of regions is $O(mn)$. If $(\beta - 1, r(j))$ is an original k-bounded region, then all possible additional regions that are implied by $(\beta - 1, r(j))$ can be computed in $O(mn)$ time. However, since there might be m original regions computed by BACKSEQUENCE for $r(j)$, the running time could be $O(m^2n^2)$ for the entire algorithm. This can be avoided by methodically checking for overlapping regions.

Let B-REGION be an $m \times n$ array. When an original $(m - k)$-bounded region $(f_k - 1, r(j))$ is created by BACKSEQUENCE, set B-REGION $(m - k, j) := f_k - 1$, $1 \leqq k \leqq m$. Note that B-REGION $(m - 1, j) \leqq B$-REGION $(m - 2, j) \leqq \cdots \leqq B$-REGION $(0, j)$.

SUBROUTINE FASTADD (j) (* j is the j-value that has just been processed by BACKSEQUENCE *)
(1) $q := j-1$; (* start by comparing with B-REGION (*, $j-1$) *)
(2) while $q>0$ and $0<r(q)-r(j)<1$ do (* B-REGION (*, q) is the next one to check *)
(3) Compute K and W such that:
(3a) $K :=$ minimum value of k such that B-REGION $(m-k, q)<r(j)$;
(3b) $W :=$ minimum value of w such that B-REGION $(m-w, j)<r(q)-1$;
(4) If K and W are both defined then (* the necessary condition for additional bounded regions *)
for $k := K$ downto 1 do
If $f_{(m-W-k)}-1>B$-REGION $(m-k, q)$ then replace the $(m-W-k)$-bounded region $(f_{(m-W-k)}-1, r(j))$ with (B-REGION $(m-k, q)$, $r(j)$)
(* update $f_{(m-W-k)}$ because of additional region *)
(5) $q := q-1$; (* compare with the next set of regions *)
end while statement;
end FASTADD.

LEMMA 8. *The total amount of time required by all the calls to* FASTADD *is* $O(mn^2)$.

Proof. There are $O(n)$ calls to FASTADD. For each call to FASTADD there are at most $O(n)$ iterations of the while loop with each iteration requiring $O(m)$ time for step (3) and $O(m)$ time for step (4). □

The speedup of FASTADD depends on the following observation.

(*) If $(\beta-1, \alpha)$ is both an $(m-k)$-bounded region and an $(m-k')$-bounded region, for $k' \leqq k$, then the $(m-k')$-bounded region is redundant.

The correctness of (*) follows immediately from the definition of bounded regions and implies that the $(m-k')$-bounded region can be discarded.

LEMMA 9. *The additional bounded regions created by* FASTADD *are correct. Furthermore, all additional bounded regions created by* ADD *that are not created by* FASTADD *are redundant.*

Proof. Lemma 3 implies that any $(m-W-K)$-bounded region created by FASTADD for $k=K$ is correct. Since B-REGION $(m-k, q) \leqq B$-REGION $(m-K, q)$ for $k \leqq K$, it follows that B-REGION $(m-K, q)<r(j)$ implies that B-REGION $(m-k, q)<r(j)$, $k \leqq K$. Since B-REGION $(m-W, j)<r(q)-1$, the conditions of Lemma 3 hold for $k \leqq K$, and therefore the $(m-W-k)$-bounded regions created by FASTADD are correct. By (*) any bounded region implied by B-REGION $(m-w, j)$ for $w \leqq W$ is redundant. The definition of W implies that there are no additional regions created by B-REGION $(m-w, j)$ for $w>W$. □

We remind the reader that ALGORITHM BOUNDED_REGION, referred to below, is the main procedure that is presented at the beginning of this paper.

THEOREM 3. *The running time of* ALGORITHM BOUNDED_REGION *is* $O(mn^2)$.

Proof. We first show how to implement SCHEDULE in $O(mn \log n)$ time. Steps (1) and (3) of SCHEDULE cost only $O(n \log n)$ overall to implement. To implement step (2) efficiently, we make m sorted lists of bounded regions with each list containing no more than n regions as follows. For $0 \leqq k \leqq m-1$, sort the $O(n)$ k-bounded regions by their left endpoints, with ties being broken by the right endpoint. This takes $O(mn \log n)$ time. The ordered lists of regions are examined in step (2) of NEXTFORWARD starting from the 0-bounded regions and ending with the $(m-1)$-bounded regions. A pointer associated with each list of regions denotes the region most recently

examined. This pointer is updated to the next region on the list whenever a slot is moved through a region. If the start time of S^0 is increased because of a k-bounded region, step (1) of NEXTFORWARD guarantees that all start times that are subsequently computed will be at least as large as S^0. Therefore, once the start time of a slot is moved through a region, that region will never again have to be examined. Consequently, the total number of times that all regions are examined by NEXTFORWARD is $O(mn)$, and each region is examined in $O(1)$ time.

We now show that BACKSEQUENCE can be implemented in $O(mn^2)$ time. This is easy to verify for all but the calls to NEXTBACKWARD. Note that we have already shown how to implement ADD efficiently (Lemma 9). When we use the same technique as was used to implement step (2) of SCHEDULE, all calls associated with SE$[i]$ can be processed in $O(mn)$ time. Note that the bounded regions are created according to the sorted right endpoint, which is the order required by NEXTBACKWARD. For each of the n sequences SE$[i]$ the list of bounded regions needs to be scanned only once. Thus, BACKSEQUENCE has running time $O(mn^2)$. □

9. NP-completeness results. The NP-completeness proofs are reductions from the following problem that has been shown to be strongly NP-complete in [6].[1]

1/1/1 SCHEDULING.

Instance: Set T of triplets that are to be executed in the time interval $[0, 3f)$, with $|T| = t$. A triplet consists of three unit-length jobs, each of which has an integer release time that is at most $3f-1$.

Question: Is it possible to schedule f triplets of T on one machine in the time interval $[0, 3f)$ such that all $3f$ jobs are started no earlier than their release times?

For the sake of completeness of this paper we present an alternative reduction for the 1/1/1-scheduling problem to that given in [6].

THEOREM 4. 1/1/1 *scheduling is strongly* NP*-complete.*

Proof. The reduction is from the strongly NP-complete 3-partition problem [4].

3-PARTITION.

Instance: A multiset Q of $3m$ natural numbers $\{n_i: 0 \leqq i \leqq 3m-1\}$ and a natural number B, with $\sum_{i=0}^{3m-1} n_i = mB$.

Question: Can Q be partitioned into m 3-element multisets $Q_1, Q_2, \cdots, Q_m$ such that the numbers in each Q_i sum to B?

Given an arbitrary instance of 3-partition as defined above, we assume without loss of generality that $n_{p-1} \leqq n_p$, for $1 \leqq p \leqq 3m-1$. We define Q' to be the set of all possible combinations of three elements of Q that sum to B. Each triple of numbers (n_i, n_j, n_k) of Q' corresponds to a triplet of jobs $(J(i), J(j), J(k))$ with release times i, j, and k, respectively. Let T be all such corresponding triplets of jobs. The instance of 1/1/1 scheduling consists of T and the interval $[0, 3m)$, with $f = m$.

Note that $|T| < (3m)^3$ and $r(i) \leqq 3m-1$, for all jobs of T. Thus, even with a unary encoding of the release times this reduction is polynomial.

Given a solution to the 3-partition problem, it is easy to produce a schedule for the 1/1/1-scheduling problem. Each Q_i in the solution to the 3-partition instance corresponds to a triplet of T. We simply schedule the jobs in the corresponding triplets at their release times. The resulting schedule maps the jobs onto the start times $\{0, \cdots, 3m-1\}$.

[1] The definition of 1/1/1 scheduling given in [6] uses deadlines instead of release times as is done here. However, the definitions are symmetric.

Given triplets $T_1, \cdots, T_m$ and a one-processor schedule SCH of the corresponding $3m$ jobs onto $\{0, \cdots, 3m-1\}$, we have

$$\sum_{i=0}^{3m-1} n_i = \sum_{k=1}^{m} \sum_{J(i)\in T_k} n_{s(i)} = mB.$$

Since no job starts before its release time and since $n_{p-1} \leqq n_p$, it follows that

$$\sum_{J(i)\in T_k} n_{s(i)} \geqq \sum_{J(i)\in T_k} n_{r(i)} = B \quad \text{for } 1 \leqq k \leqq m.$$

We conclude that $\sum_{J(i)\in T_k} n_{s(i)} = B$, for $1 \leqq k \leqq m$, and thus the m sets $\{n_{s(i)}: J(i) \in T_k\}$ constitute a solution to the instance of 3-partition. □

PROBLEM A. *Instance*: m identical machines and n jobs, each job having a release time of 0, an integer deadline, and length 1, 3, or q, for some integer q.

Question: Does there exist a valid schedule for the set of jobs?

THEOREM 5. *Problem* A *is strongly* NP-*complete.*

Proof. Let $T = \{T(i): 0 \leqq i \leqq t-1\}$ and f be an instance of 1/1/1 scheduling. Denote the triplet $T(i)$ as $(T(i, 1), T(i, 2), T(i, 3))$, and the release time of $T(i, j)$ as $r(i, j)$. Without loss of generality we assume that $r(i, 1) < r(i, 2) < r(i, 3)$. (If $r(i, j) = r(i, k)$, then one of these release times can be increased by one since the jobs are identical.)

The corresponding instance of Problem A consists of t machines, numbered $0, 1, \cdots, t-1$, and the following set of jobs (see Fig. 5 in § 11):

(1) A set of *filler jobs* $F = \bigcup_{i=1}^{4(t-1)} F(i)$. The subset $F(i)$ contains $t - \lceil i/4 \rceil$ filler jobs $F(i, j)$ each of which has length one such that $d(F(i, j)) = i$, $1 \leqq j \leqq t - \lceil i/4 \rceil$.

(2) A set of *chain jobs* $C = \bigcup_{i=0}^{t-1} C(i)$. The ith chain $C(i)$ corresponds to the triplet $T(i)$. It contains $3f+2$ chain jobs $C(i, j)$, $1 \leqq j \leqq 3f+2$, each of which has length $q = 4t$ such that

$$\begin{aligned} d(C(i, j)) &= 4i + jq && \text{for } 1 \leqq j \leqq r(i, 1) + 1, \\ &= 4i + jq + 1 && \text{for } r(i, 1) + 1 < j \leqq r(i, 2) + 1, \\ &= 4i + jq + 2 && \text{for } r(i, 2) + 1 < j \leqq r(i, 3) + 1, \\ &= 4i + jq + 3 && \text{for } r(i, 3) + 1 < j \leqq 3f + 2. \end{aligned}$$

(3) A set of *interval jobs* $I = \{I(j): 1 \leqq j \leqq 3f\}$ each of which has length 1, with $d(I(j)) = (j+1)q - 1$. $I(j)$ corresponds to the interval $[j-1, j)$ in the 1/1/1 schedule.

(4) A set of *pusher jobs* $P = \{P(i): 1 \leqq i \leqq t-f\}$ all of which have length 3, and deadline $(3f+2)q - 1$. The pusher jobs correspond to the unscheduled triplets.

Let T' be a solution to the instance of 1/1/1 scheduling, that is, T' is a subset of f triplets of T for which there exists a schedule $\mathrm{SCH}_{1/1/1}$ on one machine with all jobs appearing in the interval $[0, 3f)$. We construct a schedule $\mathrm{SCH}_{\mathrm{A}}$ for the corresponding instance of Problem A. (See Fig. 5 in § 11.)

Machine i, $0 \leqq i \leqq t-1$, contains $4i$ filler jobs in the interval $[0, 4i)$. The chain $C(i)$, for $0 \leqq i \leqq t-1$, is scheduled on machine i. We distinguish between two cases:

Case $T(i) \notin T'$. Job $C(i, j)$, for $1 \leqq j \leqq 3f+1$, is scheduled on machine i finishing at $4i + jq$. The only exception is the last chain job $C(i, 3f+2)$ of $C(i)$. It finishes at $4i + (3f+2)q + 3$ instead of three time units earlier so that a pusher job can be scheduled in the interval $[4i + (3f+1)q, 4i + (3f+1)q + 3)$ on machine i.

Case $T(i) \in T'$. In this case three interval jobs of length 1 are scheduled on machine i instead of one pusher job. Without loss of generality we can assume that $T(i, 1)$ precedes $T(i, 2)$ and $T(i, 2)$ precedes $T(i, 3)$ in $\mathrm{SCH}_{1/1/1}$, since $r(i, 1) < r(i, 2) < r(i, 3)$. Otherwise, we could swap the jobs of $T(i)$ to make them appear in the above order.

Assume that $T(i, 1)$, $T(i, 2)$, and $T(i, 3)$ are scheduled in the intervals $[j-1, j)$, $[k-1, k)$, and $[l-1, l)$, respectively, in $\mathrm{SCH}_{1/1/1}$. Schedule the interval jobs $I(j)$, $I(k)$, and $I(l)$ on machine i such that they finish at times $4i+jq+1$, $4i+kq+2$, and $4i+lq+3$, respectively. Schedule the chain jobs of $C(i, r)$ on machine i such that they finish at the following times:

$$4i+rq \quad \text{for } 1 \leqq r \leqq j,$$

$$4i+rq+1 \quad \text{for } j < r \leqq k,$$

$$4i+rq+2 \quad \text{for } k < r < 3f+2,$$

$$4i+rq+3 \quad \text{for } r = 3f+2.$$

This completes the construction of SCH_A. Note that all jobs of the instance of A are completed before or at their deadlines.

To show the reverse, suppose we are given a schedule SCH_A for the instance of A. We want to show that SCH_A determines a subset T' of f triplets of T such that there exists a schedule $\mathrm{SCH}_{1/1/1}$ for T' on one machine in the interval $[0, 3f)$.

CLAIM A. (i) The jobs $C(i, 1)$, for $0 \leqq i \leqq t-1$, are scheduled on different machines in SCH_A. Without loss of generality, assume $C(i, 1)$ is scheduled on machine i.

(ii) The filler jobs are scheduled in SCH_A such that the interval $[0, 4i)$ of machine i is occupied with filler jobs and $C(i, 1)$ is scheduled on machine i such that it finishes at $4i+q$, $0 \leqq i \leqq t-1$. (See Fig. 5 in § 11.)

(iii) All jobs of the chain $C(i)$ are scheduled on the machine i in SCH_A. The job $C(i,j)$ can have one of at most four different finishing times in SCH_A: $4i+jq$, $4i+jq+1$, $4i+jq+2$, or $4i+jq+3$.

(iv) Machine i, $0 \leqq i \leqq t-1$, contains either three interval jobs of length one, or one pusher job of length 3.

(v) The set $T' = \{T(i)$: machine i in SCH_A contains interval jobs$\}$ is a solution of the instance of 1/1/1 scheduling. Assume SCH_A is normalized, where by normalized we mean that no interval job can be moved to the right by *swapping* it with the chain job or interval job that is following it on the same machine. Then $I(j)$, for $1 \leqq j \leqq 3f$, is scheduled in the interval $[jq, (j+1)q-1)$ in SCH_A. We can construct a schedule $\mathrm{SCH}_{1/1/1}$ for T' as follows. If $I(j)$ is the kth interval job on machine i, $1 \leqq k \leqq 3$, then schedule job $T(i, k)$ in the interval $[j-1, j)$ of $\mathrm{SCH}_{1/1/1}$.

Proof of (i). Assume two jobs $C(k, 1)$ and $C(k', 1)$, $k < k'$, are scheduled on the same machine in SCH_A. Since chain jobs have length q, the earliest time both jobs can finish is time $2q$. This contradicts the assumption that there is a feasible schedule for Problem A since, for $0 \leqq i \leqq t-1$, $d(C(i, 1)) \leqq d(C(t-1, 1)) = 4(t-1)+q < 2q$.

Proof of (ii). The job $C(0, 1)$ has to start at time 0 and finish at its deadline q. Assume $1 \leqq j \leqq 4$. Then, since $|F(j)| = t-1$, and the jobs of $F(j)$ have deadline j, the intervals $[j-1, j)$ of machines 1 through $t-1$ of SCH_A must be occupied with the filler jobs of $F(j)$. This implies that $C(1, 1)$ is started at time 4 in SCH_A and finished at its deadline $4+q$. Simple induction on j implies that the jobs of $F(j)$ are scheduled on machine $\lceil j/4 \rceil$ through t and that $C(i, 1)$ starts at $4i$ and finishes at its deadline $4i+q$.

Proof of (iii). We define the lexicographic order $\leqq$ on the tuples (i, j) as follows. If $i < t-1$, then (i, j) immediately precedes $(i+1, j)$; otherwise, $i = t-1$ and $(t-1, j)$

immediately precedes $(0, j+1)$. We use this lexicographic order to do an induction on the index tuple (i, j) of $C(i, j)$.

The base case that (iii) holds for $(i, j) \leqq (t-1, 1)$ follows from claim (ii). Assume that (iii) holds for all jobs $C(i, j)$ such that $(i, j) \leqq (i', j')$. Let (i^*, j^*) be the next tuple after (i', j') in the lexicographic ordering. By induction we know that machine i is busy in the interval $[4i+(j-1)q+3, 4i+jq)$, for $(i, j) \leqq (i', j')$, since it is executing $C(i, j)$. In particular, all machines i such that $i \neq i^*$ are busy in the interval $[4i^*+(j^*-1)q+3, 4i^*+(j^*-1)q+4)$. Since $d(C(i^*, j^*)) \leqq 4i^*+j^*q+3$, we conclude that $C(i^*, j^*)$ has to be executed on machine i^*. Clearly, $C(i^*, j^*)$ has to be completed by its deadline, since $\mathrm{SCH_A}$ is a valid schedule. The fact that $C(i^*, j^*)$ has to be finished at time $4i^*+j^*q$ or later follows by induction, since $C(i^*, j^*-1)$ is finished at time $4i^*+(j^*-1)q$ or later. This completes the proof of (iii).

Proof of (iv). From (i) and (iii), we know that machine i of $\mathrm{SCH_A}$ receives $4i$ filler jobs of length 1 and $3f+2$ chain jobs of length q. The deadlines of the pusher jobs and interval jobs are no greater than $(3f+2)q-1$. Therefore, the last job on machine i, for $0 \leqq i \leqq t-1$, is the chain job $C(i, 3f+2)$. Since $d(C(i, 3f+2)) = 4i+(3f+2)q+3$, it follows that there are exactly three units available on machine i for interval and pusher jobs. This gives us $3t$ time units for interval and pusher jobs on all t machines. Since there are $3f$ interval jobs of length 1 and $t-f$ pusher jobs of length 3, we conclude that each machine i of $\mathrm{SCH_A}$ contains either three interval jobs or one pusher job.

Proof of (v). Assume $\mathrm{SCH_A}$ is normalized and assume by contradiction that $I(j)$ is an interval job that is scheduled in the interval $[lq, (l+1)q-1)$, for some $l<j$. If $I(j)$ is scheduled on machine i, then by (iii), it has to be scheduled between the chain jobs $C(i, l)$ and $C(i, l+1)$ in the interval $[4i+lq, 4i+lq+3)$. Since $d(C(i, l+1)) \leqq d(C(t-1, l+1)) \leqq (l+2)q-1 \leqq d(I(j))$, we can move $I(j)$ past $C(i, l+1)$ as follows. Iteratively swap $I(j)$ with the interval jobs between $I(j)$ and $C(i, l+1)$, and finally, swap $I(j)$ with $C(i, l+1)$. The fact that $I(j)$ could be swapped with a chain or interval job to its right contradicts the fact that $\mathrm{SCH_A}$ is normalized. We conclude that $l=j$ and that $I(j)$ is scheduled in the interval $[jq, (j+1)q-1)$ in $\mathrm{SCH_A}$.

To complete the proof of (v), we need to show that the constructed schedule $\mathrm{SCH}_{1/1/1}$ is a valid schedule for T', that is $r(i, k) \leqq j-1$, for $1 \leqq k \leqq 3$. By (iii), we know that $I(j)$ is scheduled between $C(i, j)$ and $C(i, j+1)$ in the interval $[4i+jq, 4i+jq+3)$ on machine i. Since $k-1$ interval jobs are scheduled before $I(j)$ and $3-k$ after $I(j)$ on machine i, it follows that $I(j)$ is executed in the interval $[4i+jq+k-1, 4i+jq+k)$ on machine i. This implies that $d(C(i, j+1)) \geqq 4i+(j+1)q+k$ and therefore by the definition of the deadlines of the chain jobs, we have $r(i, k)+1<j+1$, which is equivalent to $r(i, k) \leqq j-1$. This completes the proof of Claim A and the theorem. □

In Problem B instead of having jobs of length 3 as in Problem A we have arbitrary integer release times as well as arbitrary integer deadlines.

PROBLEM B. *Instance*: m identical machines and n jobs, each job having a release time and deadline that are arbitrary integers, and having length 1 or q, for some integer q.

Question: Does there exist a valid schedule for the set of jobs?

The reduction for B is similar to the reduction for A. The jobs of length 3 in the reduction of A are replaced in B by an additional set of jobs R, all of which have length 1 or q.

THEOREM 6. *Problem* B *is strongly* NP*-complete.*

Proof. In Problem A the length-3 jobs were used to guarantee that either three or zero interval jobs were scheduled on a machine. In the latter case the machine received

a pusher job of length 3. In the reduction below the same set of jobs is used as in Theorem 5 except that the length-3 pusher jobs are replaced by R.

The *slack* $\Delta(J)$ of job J is defined to be the difference $d(J)-r(J)-p(J)$. The jobs of R have release time at least $(3f+2)q$. Thus, for any machine i, $0 \leqq i \leqq t-1$, in a valid schedule all jobs of R follow all other jobs. The set R consists of the following sets of jobs:

(1) A set of *frame jobs* $A=\{A(i): 0 \leqq i \leqq t-1\}$, with $r(A(i))=(3f+t+3)q+4i+3$, $d(A(i))=r(A(i))+q$, and $p(A(i))=q$. Note that $\Delta(A(i))=0$.

(2) A set of *glider jobs* $G=\bigcup_{i=1}^{t} G(i)$, with $G(i)=\{G(i,j): j \neq t-i, 0 \leqq j \leqq t-1\}$, $r(G(i,j))=(3f+2+j)q+4i$, $d(G(i,j))=r(G(i,j))+q+3$, and $p(G(i,j))=q$. Note that $\Delta(G(i,j))=3$.

(3) A set of *early jobs* $E=\{E(i): 0 \leqq i \leqq t-1\}$, with $r(E(i))=(3f+2)q+4i$, $d(E(i))=(3f+t-i+3)q+4i+3$, and $p(E(i))=q$.

(4) A set of *late jobs* $L=\{L(i): 0 \leqq i \leqq t-1\}$ with $r(L(i))=r(E(i))+3$, $d(L(i))=d(E(i))-3$, and $p(L(i))=q$.

(5) A set of *stuffer jobs* $U=\{U(i): 1 \leqq i \leqq 3(t-f)\}$, with $r(U(i))=(3f+t+3)q$, $d(U(i))=(3f+t+4)q-1$, and $p(U(i))=1$.

The jobs of R can be scheduled such that $A(i)$, $G(i)$, $E(i)$, and $L(i)$, for $0 \leqq i \leqq t-1$, appear on machine i in one of the following two ways. (See Fig. 6 in § 11.)

Case 1. $E(i)$ starts at $(3f+2)q+4i$ on machine i. $E(i)$ is followed by $G(i,1)$, $G(i,2), \cdots, G(i,t-i-1)$, $L(i)$, $G(i,t-i+1), \cdots, G(i,t)$, three stuffer jobs, and $A(i)$.

Case 2. $L(i)$ starts at $(3f+2)q+4i+3$ on machine i. $L(i)$ is followed by $G(i,1)$, $\cdots, G(i,t-i-1)$, $E(i)$, $G(i,t-i+1), \cdots, G(i,t)$, $A(i)$.

Since $|U|=3(t-f)$, case 1 occurs exactly $t-f$ times and case 2 occurs f times.

To show that R has to be scheduled as outlined above, we prove the following claim (see also Fig. 6 in § 11). Note that the jobs of R have the same function as the pusher jobs of the previous reduction.

CLAIM B. For $0 \leqq i \leqq t-1$, (i) Machine i receives $t+2$ jobs of length q of R. The last job of R of length q on machine i is $A(i)$.

(ii) The vth job of R of length q on machine i starts either at time $(3f+2+v-1)q+4i$ or no more than three time units later. The job $G(i,j)$, for $j \neq t-i$, $1 \leqq j \leqq t$, is the $(j+1)$st job of R of length q on machine i.

(iii) The jobs $E(i)$ and $L(i)$ share the first and $(t-i+1)$st position of the length q jobs of R on machine i.

(iv) The first job of R is an early job on eactly $(t-f)$ machines, and a late job on the remaining f machines. In the case where the first job on machine i is $E(i)$, the start time for $E(i)$ is $(3f+2)q+4i$, and three stuffer jobs are scheduled before $A(i)$. In the case where the first job on machine i is $L(i)$, $L(i)$ begins at $(3f+2)q+4i+3$.

Proof of (i). Since all frame jobs $A(i)$ start at $(3f+t+3)q+4i+3$ and run for $q=4t$ units of time, exactly one of the t frame jobs has to be scheduled on each of the t machines. In statement (iii) of Claim A (of the reduction for problem A), it was shown that the last job not in R on machine i finishes either at $(3f+2)q+4i$ or no more than three time units later. Thus, if machine i were to run more than $t+2$ jobs of R of length q, then the $(t+3)$rd job could not be finished earlier than time $(3f+t+5)q+4i$. Since all deadlines of the jobs of R are smaller than $(3f+t+5)q$, we conclude that each machine runs at most $t+2$ jobs of R of length q. Because R contains t^2+2t jobs of length q and there are t machines, each machine receives exactly $t+2$ jobs of R of length q.

From part (iii) of Claim A, we know that the first job of R of length q on machine i can start no earlier than $(3f+2)q+4i$. Thus the $(t+2)$nd such job can start no earlier

than $(3f+t+3)q+4i$. By a simple induction, it can be shown that this implies that $A(i)$ is scheduled on machine i.

Proof of (ii). Since $r(G(i,j))=(3f+j+2)q+4i$ and $\Delta(G(i,j))=3$, the second part of statement (ii) is implied by the first part. To prove the first part, note that by statement (iii) of Claim A the first job of length q of R can start no earlier than $(3f+2)q+4i$. Additionally, by statement (i) above, machine i receives $t+2$ jobs of R of length q, with the last such job starting at time $(3f+t+3)q+4i+3$.

Proof of (iii). By (i) and (ii) above, we know that every job of E and L is scheduled as the first or $(t-i+1)$st job of R of length q on some machine i. It is easy to see that the first and tth job of R of length q of machine 0 are $E(0)$ and $L(0)$. No other job of E and L is released early enough to be the first, and no job of E or L has a deadline large enough to be the $(t+1)$st job of machine i. By a simple induction it can be shown that $E(i)$ and $L(i)$ are the first and the $(t-i+1)$st jobs of R of length q on machine i.

Proof of (iv). If $L(i)$ is the first job of machine i, then by (ii) above, it must start at its release time of $(3f+2)q+4i+3$. In this case, no stuffer jobs can be scheduled on machine i.

If $L(i)$ is the $(t-i+1)$st job on machine i, then by (ii) above it must finish at its deadline of $(3f+t-i+3)q+4i$. This implies that $E(i)$ is started at its release time of $(3f+2)q+4i$ and that no more than three stuffer jobs can be scheduled in the interval $[(3f+t+3)q+4i,\ (3f+t+3)q+4i+3)$. Since there are $3(t-f)$ stuffer jobs of length 1, $E(i)$ must be the first job of R on at least $t-f$ machines.

Using arguments similar to the reduction of Problem A, the existence of $3f$ interval jobs implies that there are at least f machines whose last job finishes later than $(3f+2)q+4i$. We conclude that exactly $t-f$ machines start with a job from $E(i)$, and the remaining f machines start with a job from $L(i)$.

This completes the proof of Claim B. It follows from the proof for Problem A that the f machines starting with a job from $L(i)$ will contain the interval jobs. □

10. Open problems. (1) We conjecture that ALGORITHM BOUNDED_REGION can be modified to obtain a running time of $O(mn\log n)$. We have already shown that SCHEDULE runs in $O(mn\log n)$ time. It is also possible, using a technique of [5] to avoid computing the additional regions. This technique determines whether or not start times being computed by BACKSEQUENCE *might* violate a newly computed bounded region by comparing the start times mod 1. If the answer is determined to be yes, then the start times are decremented accordingly. It can be shown that this process will not cause a feasible problem instance to be incorrectly designated infeasible. It is also straightforward to show that this precomputation corresponds to the additional regions.

In [5], it was shown that the running time for the single machine version of this problem is $O(n\log n)$. This running time was obtained by eliminating the need to compute all sequences for those jobs with deadline at least as great as the deadline of the job whose release time is currently being processed. We believe that similar techniques should work for the general problem, but we have not been able to solve the problem of how to capture the notion of different degrees of boundedness, i.e., the fact that we have regions with restrictions on the number of jobs that can start within them.

(2) Can the NP-completeness proofs be made tighter, or are there polynomial time algorithms for the more constrained problems? In particular, what can be said about variations of Problems A and B in which there is only a single machine or there

are a constant number of machines. There ia polynomial time algorithm for the single machine version of Problem B [2], but we have been unable to generalize the algorithm to the case where the running time of a job is one of two arbitrary integers, as opposed to being either one or an arbitrary integer.

11. Figures. We use the example below to illustrate the BOUNDED_REGION Algorithm.

Example $m = 2$, $n = 7$. The release time and deadline of a job are listed as an ordered pair after the job:

$A(0, 4.4)$, $B(0.2, 2.2)$, $C(0.3, 2.3)$, $D(0.5, 1.8)$, $E(1.6, 3.4)$, $F(2.4, 3.6)$, $G(2.4, 4.0)$.

The table constructed for the above example is given in Fig. 2. In column j we list only those entries that are changed in iteration j.

$BR[1] = ((1.6, 2.4), \varnothing)$ $BR[2] = ((1.6, 2.4), (2, 2.4))$
$BR[3] = ((1, 1.6), \varnothing)$ $BR[4] = ((-0.2, 0.5), \varnothing)$
$BR[5] = ((-0.2, 0.3), \varnothing)$ $BR[6] = ((-0.7, 0.2), (0.0, 0.2))$
$BR[7] = ((-0.7, 0.0), \varnothing)$

FIG. 1. *The original bounded regions computed by* BACKSEQUENCE.

release times / deadlines		F	G	E	D	C	B	A
		2.4	2.4	1.6	0.5	0.3	0.2	0.0
D	1.8				0.8			
B	2.2				1.2		1.0 [3]	
C	2.3				1.3	1.0 [2]	0.3	
E	3.4			2.4	2.4	1.4	1.0 [4]	
F	3.6	2.6		2.6	1.6	1.6	0.6	
G	4.0	3.0	3.0	2.0	1.6 [1]	1.0	0.6	
A	4.4	3.4	3.4	2.4	2.4	1.4	1.0 [4]	0.4

[1] was 2.0
[2] was 1.3
[3] was 1.2
[4] was 1.4

FIG 2. *The sequences computed by* BACKSEQUENCE.

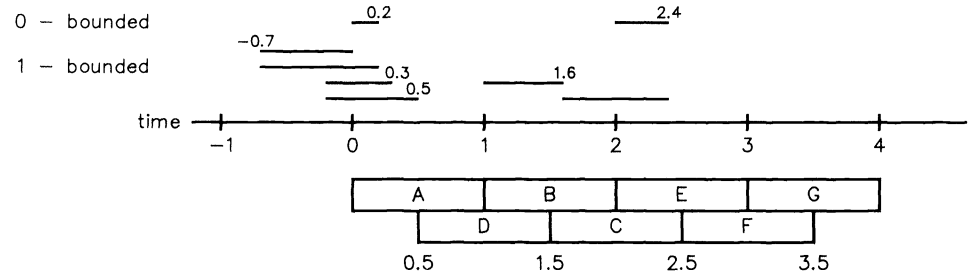

FIG 3. *Output of* SCHEDULE (BR), where BR *consists only of original regions.*

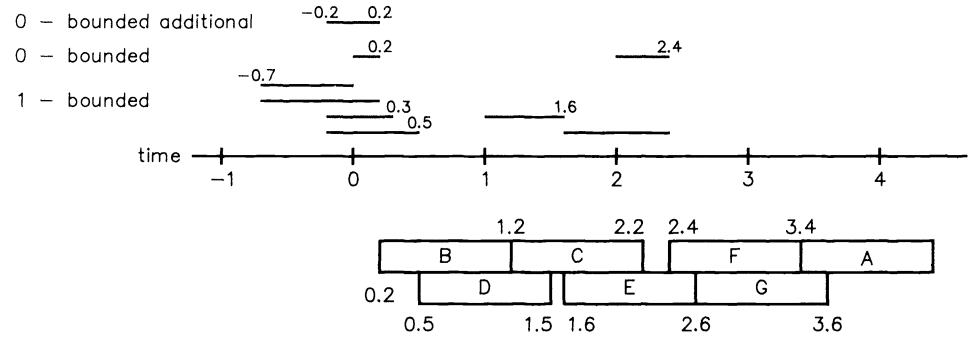

FIG. 4. *The final rd-sequence produced by* SCHEDULE (BR), *with additional regions included in* BR.

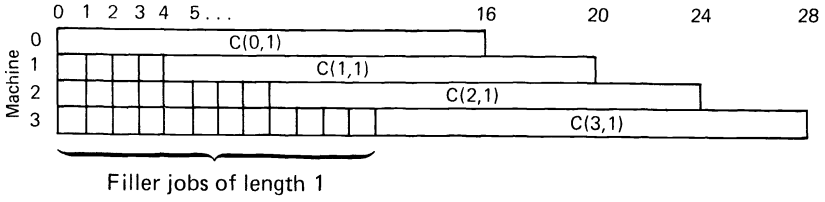
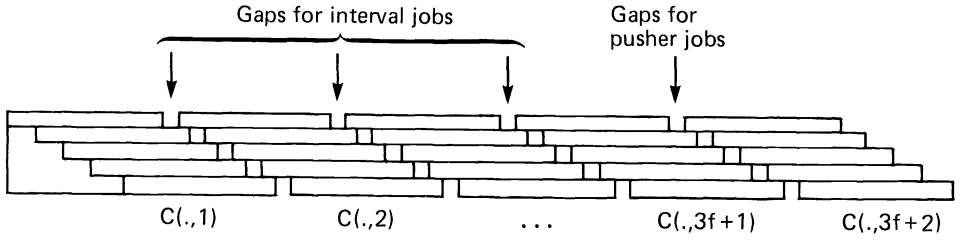
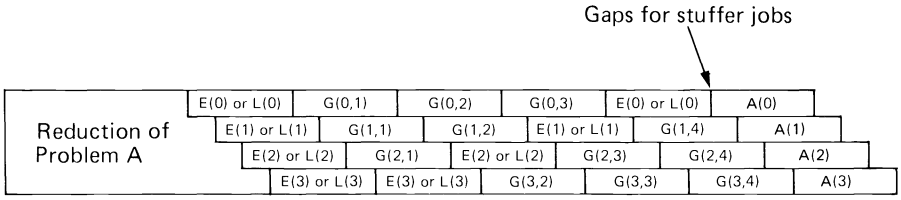


The beginning of a schedule for m = 4



Outline of SCH_A for m = 5

FIG. 5. SCH_A.



Outline of SCH_B for m = 4

FIG. 6. SCH_B.

The bounded regions computed at each iteration of the for loop of BACK-SEQUENCE are listed in Fig. 1. The first entry in the ordered pair is the 1-bounded region, the second is the 0-bounded region. The symbol $\varnothing$ is used when there is no bounded region.

Figure 3 shows how NEXTFORWARD avoids the original bounded regions. For the purpose of illustration, we ignore the additional regions. Observe that if only the original bounded regions listed above are used, C is completed later than its deadline, so the sequence is not a d-sequence. This follows because BR[4] and BR[6] satisfy the conditions of Lemma 3 and hence create the additional 0-bounded region $(-0.2, 0.2)$.

Acknowledgments. The authors are very grateful to Danny Dolev for the many hours he spent discussing the algorithm with us. We also are very appreciative of the comments and criticisms we received from the two very thorough referees.

MINIMUM-KNOWLEDGE INTERACTIVE PROOFS FOR DECISION PROBLEMS*

ZVI GALIL†¶, STUART HABER‡¶, AND MOTI YUNG§¶[1]

Abstract. Interactive communication of knowledge from the point of view of resource-bounded computational complexity is studied. Extending the work of Goldwasser, Micali, and Rackoff [*Proc. 17th Annual ACM Symposium on the Theory of Computing*, 1985, pp. 291-304; *SIAM J. Comput.*, 18 (1989), pp. 186-208], the authors define a protocol transferring the result of any fixed computation to be *minimum-knowledge* if it communicates no additional knowledge to the recipient besides the intended computational result. It is proved that such protocols may be combined in a natural way so as to build more complex protocols.

A protocol is introduced for two parties, a prover and a verifier, with the following properties:

(1) Following the protocol, the prover gives to the verifier a proof of the value, 0 or 1, of a particular Boolean predicate, which is (assumed to be) hard for the verifier to compute. Such a *deciding* "interactive proof-system" extends the interactive proof-systems of [*op. cit.*], which are used only to confirm that a certain predicate has value 1.

(2) The protocol is minimum-knowledge.

(3) The protocol is *result-indistinguishable*: an eavesdropper, overhearing an execution of the protocol, does not learn the value of the predicate that is proved.

The value of the predicate is a cryptographically secure bit, shared by the two parties to the protocol. This security is achieved without the use of encryption functions, all messages being sent in the clear. These properties enable one to define a cryptosystem in which each user receives exactly the knowledge he is supposed to receive, and nothing more.

Key words. zero knowledge, interactive proof systems, minimum knowledge cryptographic protocols, cryptography, security, probabilistic computations, factoring, quadratic residuosity, number theory

1. Introduction.

Transfer and exchange of knowledge is the basic task of any communication system. Recently, much attention has been given to the process of knowledge exchange in the context of distributed systems and cryptosystems. In particular, several authors have concentrated on problems associated with the interactive communication of proofs [17], [1], [24].

In [17] Goldwasser, Micali, and Rackoff developed a computational-complexity approach to the theory of knowledge: a message is said to convey knowledge if it contains information that is the result of a computation that is intractable for the receiver. They introduce the notion of an *interactive proof-system* for a language L. This is a protocol for two interacting probabilistic Turing machines, whereby one of them, the *prover*, proves to the other, the *verifier*, that an input string x is in fact (with

[1] The work of this author was supported in part by an IBM graduate fellowship.

very high probability) an element of L. The verifier is limited to tractable (i.e., probabilistic polynomial-time) computations. We do not limit the computational power of the prover; in the cryptographic context, the prover may possess some secret information—for example, the factorization of a certain integer N. (This is analogous to the following model of a "proof-system" for a language L in NP: given an instance $x \in L$, an NP *prover* computes a string y and sends it to a deterministic polynomial-time *verifier*, which uses y to check that indeed $x \in L$.)

Goldwasser, Micali, and Rackoff called an interactive proof-system for L *zero-knowledge* if it releases no additional knowledge—that is, nothing more than the one bit of knowledge given by the assertion that $x \in L$ [17]. Extending their definition, we consider all two-party protocols for the purpose of transferring from one party to the other the result of a specified computation—$y = f(x)$, say—depending on the input x, and call any such protocol *minimum-knowledge* if it releases nothing more than the assertion that $y = f(x)$. Naturally, such interactive protocols are of particular interest in a cryptographic setting where distrustful users with unequal computing power communicate with each other.

After giving our definition of minimum-knowledge protocols, we prove that the concatenation of two minimum-knowledge protocols is minimum-knowledge. This suggests the importance of the minimum-knowledge property for the modular design of complex protocols. In fact, it is by serially composing several minimum-knowledge subprotocols that we formulate the more complex minimum-knowledge protocol that we introduce in this paper.

In this paper we extend the ability of interactive proof-system protocols from *confirming* that a given string x is in a language L to *deciding* whether $x \in L$ or $x \notin L$. That is, we give the first (nontrivial) example of a language L so that both L and its complement have minimum-knowledge interactive proof-systems for confirming membership, where both the proof of membership in L and the proof of nonmembership in L are by means of the *same* protocol, which releases no more knowledge than the value of the membership bit ($x \in L$).

Furthermore, by following the protocol, the *prover* demonstrates to the *verifier* either that $x \in L$ or that $x \notin L$ in such a way that the two cases are indistinguishable to an eavesdropping third party that is limited to feasible computations. In fact, the protocol releases *no knowledge at all* to such an eavesdropper. As usual, we assume that the eavesdropper knows both the prover's and the verifier's algorithms, and we allow him access to all messages passed during an execution of the protocol. In spite of the fact that our protocol makes no use of encryption functions, the eavesdropper receives *no knowledge* about whether he has just witnessed an interactive proof of the assertion that $x \in L$ or of the assertion that $x \notin L$. We call this property of our protocol *result-indistinguishability.*

The proof that our protocol is minimum-knowledge with respect to the verifier and result-indistinguishable with respect to the eavesdropper relies on no unproved assumptions about the complexity of a number-theoretic problem.

The work of [17], [1], [24] concentrates on the knowledge transmitted by a prover to an active verifier. Introducing a third party to the scenario, we analyze the knowledge gained both by an active verifier and by a passive eavesdropper.

If membership or nonmembership in L is an intractable computation, then a result-indistinguishable minimum-knowledge proof-system for L can be used as a tool in building a cryptographic system. After an execution of our protocol, the string x can serve as a cryptographically secure encoding—shared only by the prover and the verifier—of the membership-bit ($x \in L$). The use of x as an encoding of the membership-

bit exemplifies what we may call "minimum-knowledge cryptography": it is a probabilistic encryption with the property that neither its specification (i.e., the interactive proof of the value encoded by x) nor its further use in communication can release any compromising knowledge, either to the verifier or to an eavesdropper. The minimum-knowledge property ensures that each party receives exactly the knowledge he is supposed to receive and nothing more. A cryptosystem based on such a minimum-knowledge protocol has the strongest security against passive attack that we could hope to prove; in particular, it is secure against both chosen-message and chosen-ciphertext attack.

The predicate that our protocol tests is that of being a quadratic residue or nonresidue modulo N for a certain number N (whose factorization may be the prover's secret information). We note that the language for which we show membership and nonmembership is in NP $\cap$ co-NP. A conventional membership proof for these languages releases the factorization of N, while in the interactive proof-system presented below no extra knowledge (about the factorization or about anything else) is given either to the verifier or to an eavesdropper.

An important motivation in our work on this protocol comes from our desire to guarantee the security of cryptographic keys, especially in situations where the generation of new keys is very costly or is otherwise limited by the context. If the integer N is the prover's public key in a public-key cryptosystem, then N is not compromised by polynomially many executions of our protocol; a polynomially bounded opponent knows no more after witnessing or participating in these executions than he knew before the key was used at all.

2. Preliminaries.

2.1. Interactive Turing machines. We specify the model for which we describe our protocol; this is an extension of the model used in [17]. Two probabilistic Turing machines A and B form an *interactive pair of Turing machines* if they share a read-only *input tape* and a pair of *communication tapes*; one of the communication tapes is exclusive-write for A, while the other is exclusive-write for B. (The writing heads are unidirectional; once a symbol has been written on a communication tape, it cannot be erased.) We model each machine's probabilistic nature by providing it with a read-only *random tape* with a unidirectional read-head; the machine "flips a coin" by reading the next bit from its random tape. The two machines take turns being *active*. While it is active, a machine can read the communication tapes, perform computation using its own work tape and consulting its random tape, and send a message to the other machine by writing the message on its exclusive-write communication tape. In addition, B has a private *output tape*; whatever is written on this tape when A and B halt is the *result* of their computation.

In order to model the fact that the system is not memory-less, we also assume that each machine has a *history tape*, with a unidirectional write-head, on which the following records are automatically written:

- When the machine flips a coin, the bit it reads from its random tape is recorded on its history tape.
- At the beginning of each active turn, when the machine reads a new message from the other machine's exclusive-write communication tape, it records this message on its history tape.
- At the end of each active turn, when the machine writes a message to the other machine on its own exclusive-write communication tape, it records this message on its history tape.

• The result written on B's output tape is also recorded on B's history tape.

These records are written on the history tape sequentially in order according to the machine's computation; for example, when the machine flips a coin several times while computing its next message, these random bits are recorded on the history tape immediately before the message. The input tape and communication tapes are public, or shared by the two machines; each machine's random tape, history tape, and work tape are private, as is B's output tape. This is not the only way to model the situation we would like to describe, and some of the records written on the history tape are redundant, but without loss of generality we may assume this mode of operation.

When A and B begin their computation, an infinite bit-string is written on each of their random tapes. The choice of these two bit-strings, independently and uniformly at random from the set of all infinite strings, defines a probability measure on the set of possible computation histories of (A, B) that begin in any particular configuration.

For any strings x, h we say that the interactive pair of Turing machines (A, B) begins its computation with input x and B's *initial history* h if in their initial configuration x is written on the common input tape and h is the written portion of B's history tape. (Throughout this paper, we are not concerned with the contents of A's history tape.) We use $(A, B)[x, h]$ to denote the set of computations that begin in this configuration. In each of the protocols that we present in this paper, B never consults its history tape. However, in discussing the properties of these protocols, we must be concerned with an arbitrary Turing machine that may take the role of B in an interaction with A, and that may make use of its history tape.

In what follows, B is limited to expected running time that is polynomial in the length of the common input x, while we make no limiting assumption about A's computational resources. (For cryptographic applications, A is also limited to feasible computation but possesses some trapdoor information.) Their messages to each other are in cleartext, though these messages may depend on their private coin flips, which remain hidden. We assume that both the length of B's initial history, as well as the total length of the messages written on the two communication tapes, are polynomial in $|x|$. For any input string x, we introduce the notation $H_x = \{h \mid h \in \{0, 1\}^*, |h| = O(|x|^{O(1)})\}$ for the set of associated initial histories that we allow.

Our scenario also includes a third probabilistic Turing machine, C, limited to expected polynomial-time computation, that can read the input and communication tapes of A and B and knows their algorithms. A is the *prover*, B is the *verifier*, and C is the *eavesdropper*.

2.2. Ensembles of strings. In order to speak precisely of the knowledge transmitted by communicated messages, we need the following definitions [17], [27], [6]. Let $I \subseteq \{0, 1\}^*$ be an infinite set of strings, and for each $x \in I$, let $\pi[x]$ be a probability distribution on a set of bit-strings. We call $\Pi = \{\pi[x] \mid x \in I\}$ an *ensemble* of strings (usually suppressing any mention of I).

For example, if M is a probabilistic Turing machine, then any input string x defines a probability distribution, according to the coin-tosses (i.e., the random tape) of M's computation, on the set $M[x]$ of possible outputs of M on input x. Thus, for any I, $\{M[x] \mid x \in I\}$ is an ensemble.

As a second example, suppose that (A, B) is an interactive pair of Turing machines. For any strings x, h, let $VIEW_B\{(A, B)[x, h]\}$ denote the set of private "histories" that may be written on B's history tape during a computation that begins with input x and B's initial history h; each of these is B's private view of the protocol execution. This

set has a natural probability distribution according to the random tapes of A and B. Thus, for any set I, $\{VIEW_B\{(A, B)[x, h]\} \mid x \in I, h \in H_x\}$ is an ensemble of strings.

As another example, for any string x let $COM\{(A, B)[x]\}$ denote the set of possible ordered sequences of messages written on the communication tapes of A and B during a computation that begins with input x. Each of these is the public view, and in particular that of the eavesdropper C, of a protocol execution of A and B. This set also has a natural probability distribution. (We assume that the specified computations do not make use of previous private or public history.) Thus, for any set I, $\{COM\{(A, B)[x]\} \mid x \in I\}$ is an ensemble of strings that we call the *communications ensemble* produced by the interactive system (A, B).

A *distinguisher* is a family $D = \{D_x \mid x \in I\}$ of circuits with a single Boolean output; we assume that there is a constant c so that circuit D_x has $|x|^c$ input gates and one output gate. D is *polynomial-size* if there is a constant d so that D_x has at most $|x|^d$ nodes. Suppose that $\Pi = \{\pi[x] \mid x \in I\}$ and $\Pi' = \{\pi'[x] \mid x \in I\}$ are ensembles of strings, and that D is a distinguisher (all with respect to the same constant c). Let $p_D(\pi[x])$ be the probability that D_x outputs a 1 when it is given as input a single sample string of length $|x|^c$, randomly selected according to probability distribution $\pi(x)$; and let $p_D(\pi'[x])$, depending on the distribution $\pi'[x]$, be defined similarly. We call the two ensembles (computationally) *indistinguishable* if for any polynomial-size distinguisher D, for all n and sufficiently long x,

$$|p_D(\pi[x]) - p_D(\pi'[x])| < |x|^{-n}.$$

This condition holds, of course, if the two ensembles are exactly identical. In this case, for *any* distinguisher D the difference $|p_D(\pi[x]) - p_D(\pi'[x])|$ is equal to zero.

Let π and π' be two probability distributions on strings, and suppose that the number δ satisfies $0 \leqq \delta \leqq 1$. We say that π *approximates* π' *with error probability* δ if

$$\sum_s |\text{prob}(\pi[x] = s) - \text{prob}(\pi'[x] = s)| \leqq \delta$$

(where the sum is taken over all strings s in $\{0, 1\}^*$). This implies that the difference $|p_D(\pi[x]) - p_D(\pi'[x])| \leqq \delta$ for any distinguisher D, even if the definition of "distinguisher" is relaxed to allow as inputs to D_x a set of many samples randomly chosen either according to $\pi[x]$ or according to $\pi'[x]$.

2.3. Interactive proof-systems and transfer protocols. This paper is mainly devoted to a special sort of two-party protocol, that of interactively proving or disproving membership in a language L. A protocol that achieves this is called an *interactive proof-system* for L [17]. The prover A and the verifier B share a common input x, the string whose membership is in question. We assume that x belongs to a fixed set I, $I \supseteq L$, of input strings for (A, B). Depending on $k = |x|$, the length of the (binary) representation of the input string, we allow an error probability $\delta(k)$ that vanishes with increasing k. (In fact, all of the examples in this paper satisfy the stronger requirement of an error probability that is exponentially vanishing in k.)

Extending the definition of [17], we distinguish between a *confirming* proof-system for L, whose purpose is that the verifier confirm membership in L for the input string, and a *deciding* proof-system for L, whose purpose is that the verifier decide whether or not the input string is in L. At the end of a confirming protocol, the verifier may either *accept* the proof that $x \in L$, or *reject* the proof; at the end of a deciding protocol, the verifier may either *accept* a proof that $x \in L$, or *accept* a proof that $x \notin L$, or *reject* the proof. The execution ends normally when all of B's messages appear as if B is

following the protocol; if this is so, then A ends the execution in a *success* state. A may halt the execution of the protocol if it detects that B is not following the protocol, ending the execution in a *failure* state.

For any input string x, let $k = |x|$. We say that $(A, B)_k$ is a *confirming interactive proof-system* for L with inputs I and error probability $\delta(k)$ if:

(1) For any $x \in L$ given as input to (A, B), B accepts the proof with probability at least $1 - \delta(k)$.

(2) For any interactive Turing machine A*, and for any $x \in I - L$ given as input to (A*, B), B accepts the proof with probability at most $\delta(k)$.

We say that (A, B) is a *deciding interactive proof-system* for L with inputs I and error probability $\delta(k)$ if:

(1) For any $x \in I$ given as input to (A, B), B accepts the proof, halting with the correct value of the predicate $(x \in L)$ on its output tape, with probability at least $1 - \delta(k)$.

(2) For any interactive Turing machine A*, and for any $x \in I$ given as input to (A*, B), B accepts a proof of the incorrect value of the predicate $(x \in L)$ with probability at most $\delta(k)$.

As part of the definition, we require that these conditions should hold independently of the choice of the initial-history string (of length polynomial in k) that may be written on B's history tape at the beginning of the computation.

In the first definition, we require that (with high probability) B correctly accept the proof for strings $x \in L$, and that no cheating adversary, no matter how powerful, can convince B incorrectly to accept the proof for strings $x \notin L$ (except with vanishingly small probability). In the second definition, we require that (with high probability), given *any* input string $x \in I$, B correctly decide whether $x \in L$ or $x \notin L$, and that no adversary can convince B to accept an incorrect proof (except with vanishingly small probability). The probability is taken over all sequences of coin-tosses (i.e., over all possible random-tape bit-strings) used by the probabilistic computations of the two Turing machines.

The two definitions above describe correctness for protocols that transfer to B the computed value of a Boolean predicate that supplies one bit of "knowledge" about the input string. We can also study a more general sort of *transfer protocol* whose purpose is to transfer the result $F(x)$ of any specified computation depending on the input string x. For example, a deciding interactive proof-system for the language L is a transfer protocol for the function $F(x)$ taking the value 1 or 0 according to whether or not $x \in L$. Because the interacting machines are probabilistic, the intended result may take values in a probability distribution whose value $F(x, r)$ depends on x as well as on a random input string r. As in the case of an interactive proof-system, B may either *accept* or *reject* an execution of an interaction with another Turing machine. We say that a given protocol (A, B) is *correct* for a specified probability distribution of outputs if B's computed result, when it interacts with A, has the intended distribution (with very high probability), and no machine A*, no matter how powerful, can bias the distribution of B's outputs (except with vanishingly small probability).

In order to define "correctness" more precisely, we observe that the computations of any interactive pair of Turing machines (A, B) determine a partial function $f_{A,B}$ as follows. Given strings x, r_A, and r_B, we define $f_{A,B}(x, r_A, r_B)$ to be the result written on B's output tape at the end of an accepting computation of (A, B) that begins with input x, when their random-tape strings begin with r_A and r_B (respectively); this value is well-defined, as long as r_A and r_B are sufficiently long. Notice that the choice of r_A and r_B defines a probability distribution $f_{A,B}(x, \cdot, \cdot)$.

We say that (A, B) is a *correct transfer protocol* for the probability distribution $F(x, r)$, with inputs I and error probability $\delta(\cdot)$, if:

(1) For each $x \in I$, the distribution $f_{A,B}(x, \cdot, \cdot)$ of B's computed outputs approximates, with error probability $\delta(|x|)$, the distribution $F(x, \cdot)$ of intended results.

(2) Let A* be any interactive Turing machine. We require that for any $x \in I$ and for any $s \in \{0, 1\}^*$, the probability that B accepts the computation of (A*, B) on input x and writes out the string s as its output is bounded by the quantity prob $(F(x, \cdot) = s) + \delta(|x|)$.

Note that, according to the second part of this definition, it may be possible for a malicious adversary A* to bias the distribution of the set of conversations of (i.e., the set of sequences of messages exchanged by) A* and B on a particular input string x. But A* cannot significantly increase the probability that any given result string is accepted by B; in particular, A* cannot force B to accept an erroneous result (one that occurs with probability zero in the distribution $F(x, \cdot)$) except with probability $\delta(|x|)$.

Observe that the probability threshold δ occurs twice in the above definition. In general, there may be protocols for which it makes sense to define correctness with two different δ's. In all our examples, the function $\delta(k)$ is exponentially vanishing in k; therefore, for simplicity, we use the same δ in both places.

3. Knowledge. In the setting of complexity theory, what do we mean by "knowledge"? Informally, a message conveys knowledge if it communicates the result of an intractable computation. A message that consists of the result of a computation that we can easily carry out by ourselves does not convey knowledge. In particular, a string of random bits—or a string of bits that is "indistinguishable" from a random string (as defined above)—does not convey knowledge, since we can flip coins by ourselves.

3.1. Minimum knowledge. Suppose that (A, B) is a confirming interactive proof-system for a language L, taking inputs from the set I. Following the definition in [17], we say that the system (A, B) is *minimum-knowledge* if, given any expected polynomial-time probabilistic Turing machine B*, there exists another probabilistic Turing machine M_{B^*}, running in expected polynomial time, such that the ensembles $\{M_{B^*}[x, h] \mid x \in L, h \in H_x\}$ and $\{VIEW_{B^*}\{(A, B^*)[x, h]\} \mid x \in L, h \in H_x\}$ are (computationally) indistinguishable. If the ensembles are identical, we say that the proof-system is *perfectly minimum-knowledge.*

The output of M_{B^*}, on input $x \in L$ and initial history h, is a simulation of B*'s view of the computation that A and B* would have on the same input and the same initial history. Note that, in this definition, we are not concerned with inputs that do not belong to L. When it takes part in a successful execution of the protocol with input x, B* learns that (with high probability) the predicate of language-membership associated with the protocol, $x \in L$, is true; however, it gains no more knowledge that this. Note that in our examples, B (the machine that acts according to the protocol specifications) does not use its initial history string at all; however, when we worry about the "knowledge" that a cheating machine B* may try to extract from A we have to consider the fact that B* can use its history string.

The authors of [17] called a confirming proof-system satisfying the above properties "zero-knowledge." We now show how to extend this definition so as to be able to say when a more general sort of protocol—for example, a two-party protocol whose purpose is to transfer to one of the parties the result of a hard computation—should be called "minimum-knowledge."

Let (A, B) be an interactive pair of Turing machines which constitute a correct transfer protocol for the probability distribution $F(x, r)$, with inputs I and error probability δ. We say that (A, B) is *minimum-knowledge* if, given any expected polynomial-time probabilistic Turing machine B*, there exists another probabilistic Turing machine M_{B^*}, running in expected polynomial time, such that:

(1) M_{B^*} has one-time access to an F-oracle, as follows. Given any input x and initial history h, M_{B^*} queries the oracle with input x; the oracle returns a value distributed according to $F(x, \cdot)$.

(2) The ensembles $\{M_{B^*}[x, h] | x \in I, h \in H_x\}$ and $\{VIEW_{B^*}\{(A, B^*)[x, h]\} | x \in I, h \in H_x\}$ are indistinguishable.

If the ensembles are identical, we say that the proof-system is *perfectly minimum-knowledge.*

In order to motivate this definition, we recall that we are trying to formalize the notion of the amount of knowledge transmitted by a sequence of messages. Speaking informally, one gains no knowledge from a message which is the result of a feasible computation that one could just as well have carried out by oneself. If the purpose of a protocol followed by two interacting parties A and B is that A transmit to B a value v chosen according to the probability distribution $F(x, r)$, we would like to be able to say exactly when the protocol transmits no more knowledge than this value. We might also demand that the protocol accomplish this even if B somehow tries to cheat—that is, even if the Turing machine B is replaced by another (polynomial-time, but possibly "cheating") machine B*. The simple transmission of the value v can be modelled by a single oracle query (with input x). If the provision of this oracle query makes it possible, by means of a feasible computation, to simulate B*'s view of the "conversation" that A and B* would have had on input x, then we can say that when A and B* actually have a conversation (i.e., follow the protocol) with the same input, there is no *additional* knowledge transmitted to B* besides the value v.

Note that if F is computable in expected polynomial time, then the F-oracle adds no power to the machine M_{B^*}. In this case M_{B^*} can compute F without the assistance of A.

In all our examples, the simulating machine M_{B^*} uses the program of B* as a subprogram or subroutine. This subprogram makes use of the simulator's input tape (containing the input string x), a virtual history tape (which is initialized to contain the given initial history h), a virtual random tape, a virtual work tape, two virtual communication tapes, and a virtual output tape. Without loss of generality we supply the probabilistic machine M_{B^*} with two random tapes; one of these is B*'s virtual random tape. On its output tape—which is also the virtual history tape for the subprogram B*—the simulator uses the subprogram to write records that correspond to B*'s view of the simulated protocol execution.

While carrying on its computation, the machine M_{B^*} may back up a few steps in the simulated protocol and restore a previous machine configuration: It recovers the old state of B* and the old content of the virtual work tape, and resets both the virtual read-head of B*'s random tape and the write-head of its own output tape (the virtual history tape) to where they had been earlier; then it proceeds with its simulation, starting again from the old configuration but "flipping new coins" in its probabilistic computation.

The virtual communication tapes are used to simulate the communication activities of the simulated protocol. The simulator "sends" a message to B* by writing it on the appropriate virtual communication tape and then activating the subprogram. The subprogram operates for (the simulation of) one active turn and then writes a message

on the other virtual communication tape; this is the next message "received" from B*. Just as in the interaction of B* with A, the simulator's subprogram B* records random bits, messages read and written, and the computed result on the virtual history tape. The operation of the subprogram B* during a simulated active turn, beginning in a certain state with a certain configuration of the virtual tapes, is identical to the operation of the interactive Turing machine B* during an active turn, beginning in the same state with the same configuration of the actual tapes, of an actual protocol execution with A. This matter of the difference in B*'s operation, either as a subprogram of the simulator or as a Turing machine interacting with A, is discussed further in the remark at the end of the next section.

3.2. Concatenation of protocols. Next, we investigate how protocols may be concatenated in order to achieve modularity in protocol design and how properties of the resulting protocol can be derived from the properties of its subprotocols. The protocol presented in this paper is an example of such a modular design.

We write $s \cdot s'$ for the concatenation of the two strings s and s'.

Suppose that we are given two protocols $P_1 = (A_1, B_1)$ and $P_2 = (A_2, B_2)$. We define the *concatenation* of the two protocols, denoted $P = P_1; P_2$, to be the following two-stage protocol: Its first stage is P_1. If at the end of this stage A_1 is not in a failure state and B_1 has not rejected, the protocol continues with P_2; otherwise the protocol halts. We write $A_1; A_2$ and $B_1; B_2$ for the interacting machines of the concatenated protocol. At the end of an execution, the history tape of $B_1; B_2$ contains the initial history-string, followed by B_1's private view of the execution of P_1, followed by B_2's private view of the execution of P_2.

Assume that P_1 and P_2 are two transfer protocols for the probability distributions F_1 and F_2, respectively, both taking inputs from the set I. Then the concatenated protocol, on input $x \in I$, transfers to $B_1; B_2$ the combined result $[F_1(x, \cdot), F_2(x, \cdot)]$. As a special case, suppose that P_1 is a confirming interactive proof-system for L_1 with inputs I, and that P_2 is a confirming interactive proof-system for L_2 with inputs L_1. Then the concatenated protocol is a confirming interactive proof-system for $L_1 \cap L_2$, with inputs I.

It may not be surprising that the concatenation of two correct protocols gives the correct combined result. The more important observation is that, as we prove below, the concatenated protocol is minimum-knowledge if P_1 and P_2 are both minimum-knowledge.

LEMMA. *Given two protocols P_1 and P_2 as above, with error probabilities $\delta_1(k)$ and $\delta_2(k)$, respectively. Then the concatenation $P = P_1; P_2$ is a correct transfer protocol for the combined result $[F_1(x, \cdot), F_2(x, \cdot)]$ with error probability $\delta(k) = \delta_1(k) + \delta_2(k) + \delta_1(k) \cdot \delta_2(k)$. Furthermore, if P_1 and P_2 are both minimum-knowledge (or, respectively, both perfectly minimum-knowledge), then so is their concatenation.*

Proof. First we show that correctness of protocols is preserved by concatenation. It is clear that if the output distribution of (A_1, B_1) approximates the intended distribution F_1 with error probability δ_1, and the output of (A_2, B_2) approximates the intended distribution F_2 with error probability δ_2, then (A, B) approximates $[F_1, F_2]$ with error probability at most $\delta_1 + \delta_2$.

To show that the second correctness condition holds, let $x \in I$ and let s_1, s_2 be a pair of possible output strings, occurring with probabilities p_1 and p_2 in probability distributions $F_1(x, \cdot)$ and $F_2(x, \cdot)$, respectively. The pair (s_1, s_2) occurs with probability $p_1 p_2$ in the combined result distribution $[F_1(x, \cdot), F_2(x, \cdot)]$. Let us write $\delta_1 = \delta_1(|x|)$ and $\delta_2 = \delta_2(|x|)$. By the correctness of protocols P_1 and P_2, if A* is any interactive

Turing machine that interacts with $B = B_1; B_2$, then the probability that B writes out (s_1, s_2) is at most

$$(p_1 + \delta_1)(p_2 + \delta_2) = p_1 p_2 + \delta_1 p_2 + \delta_2 p_1 + \delta_1 \delta_2 \leqq p_1 p_2 + (\delta_1 + \delta_2 + \delta_1 \delta_2),$$

as required.

Next we show that concatenation maintains the minimum-knowledge property. Assume that P_1 and P_2 are both minimum-knowledge, and let B^* be any probabilistic interactive Turing machine, running in expected polynomial time, that interacts with $A_1; A_2$. We may write $B^* = B_1^*; B_2^*$ to denote the two parts of B^*'s program. For convenience, let us write $V_1[x, h] = VIEW_{B_1^*}\{(A_1, B_1^*[x, h]\}$ and $V_2[x, h] = VIEW_{B_2^*}\{(A_2, B_2^*)[x, h]\}$. Thus, for any input string x and any initial history h, we have $VIEW_{B^*}\{(A, B^*)[x, h]\} = \{v_1 \cdot v_2 \mid v_1 \in V_1[x, h],\ v_2 \in V_2[x, h \cdot v_1]\}$.

To show that the concatenated protocol P is minimum-knowledge we have to show the existence of a simulating expected polynomial-time probabilistic Turing machine $M = M_{B^*}$ whose output ensemble $\{M[x, h] \mid x \in I,\ h \in H_x\}$ is indistinguishable from the ensemble $\{VIEW_{B^*}\{(A, B^*)[x, h]\} \mid x \in I,\ h \in H_x\}$.

Our hypothesis on P_1 implies that, given B_1^*, there is a simulating machine M_1, running in expected polynomial time, with access to an F_1-oracle, so that the ensembles $\{M_1[x, h] \mid x \in I,\ h \in H_x\}$ and $\{V_1[x, h] \mid x \in I,\ h \in H_x\}$ are indistinguishable. Similarly, our hypothesis on P_2 implies that, given B_2^*, there is a simulating machine M_2, running in expected polynomial time, with access to an F_2-oracle, so that the ensembles $\{M_2[x, h] \mid x \in I,\ h \in H_x\}$ and $\{V_2[x, h] \mid x \in I,\ h \in H_x\}$ are indistinguishable. We specify M to be the machine that operates as follows, given any input string $x \in I$ and initial history $h \in H_x$. First, M runs machine M_1 on (x, h) to produce an output h_1. Second, if h_1 is the simulation of a successful execution of P_1, then M runs M_2 on (x, h_1) to produce its final output; otherwise, M simply writes out h_1.

For any $x \in I$, $h \in H_x$ we define the sets of strings

$$E_1[x, h] = VIEW_{B^*}\{(A, B^*)[x, h]\} = \{v_1 \cdot v_2 \mid v_1 \in V_1[x, h],\ v_2 \in V_2[x, h \cdot v_1]\}, \text{ and}$$

$$E_2[x, h] = M[x, h] = \{m_1 \cdot m_2 \mid m_1 \in M_1[x, h],\ m_2 \in M_2[x, h \cdot m_1]\}.$$

(As usual, the choices of the bit-strings that are written on these probabilistic machines' random tapes define a probability distribution on both of these sets.) We need to show that the ensembles $\bar{E}_1 = \{E_1[x, h] \mid x \in I,\ h \in H_x\}$ and $\bar{E}_2 = \{E_2[x, h] \mid x \in I,\ h \in H_x\}$ are indistinguishable. For this purpose, we introduce the intermediate ensemble $\bar{E}_3 = \{E_3[x, h] \mid x \in I,\ h \in H_x\}$, where

$$E_3[x, h] = \{v_1 \cdot m_2 \mid v_1 \in V_1[x, h],\ m_2 \in M_2[x, h \cdot v_1]\}.$$

Assume that $\bar{E}_1$ and $\bar{E}_2$ are not computationally indistinguishable. Then there is a polynomial-size distinguisher $D = \{D_{x,h} \mid x \in I,\ h \in H_x\}$ that distinguishes between the two ensembles. In other words, in the notation of § 2.2, for some n and for infinitely many pairs (x, h) (with $x \in I$, $h \in H_x$)

$$|p_D(E_1[x, h]) - p_D(E_2[x, h])| \geqq |x|^{-n}.$$

This implies, by the triangle equality, that at least one of the inequalities

$$|p_D(E_2[x, h]) - p_D(E_3[x, h])| \geqq \tfrac{1}{2}|x|^{-n} \tag{1}$$

$$|p_D(E_1[x, h]) - p_D(E_3[x, h])| \geqq \tfrac{1}{2}|x|^{-n} \tag{2}$$

holds infinitely often, i.e., that the circuit-family D distinguishes either between $\bar{E}_2$ and $\bar{E}_3$ or between $\bar{E}_1$ and $\bar{E}_3$ (or both.) We next show that either of these possibilities leads to a contradiction.

First, we show that if D distinguishes between $\bar{E}_2$ and $\bar{E}_3$ then we can construct a distinguisher D_1 that distinguishes between the ensembles $\{M_1[x, h] | x \in I, h \in H_x\}$ and $\{V_1[x, h] | x \in I, h \in H_x\}$, contradicting the hypothesis that P_1 is minimum-knowledge. Let I_1 be the infinite set of pairs (x, h) for which inequality (1) holds. Given as input a string s, chosen either from $M_1[x, h]$ or from $V_1[x, h]$, let $C_{x,h}$ be the (probabilistic) circuit that does the following: It simulates the operation of M_2 on input (x, s) for a suitable multiple of its expected running time to produce either a string m_2 or (for those few sequences of coin-flips which may cause M_2 to run too long) a null output, then passes $h \cdot m_2$ to the circuit $D_{x,h}$, which gives its output. Since the simulation of M_2 is polynomial in length, and D is polynomial-size, the circuit-family C is also polynomial-size. Inequality (1) shows that for all pairs $(x, h) \in I_1$, the circuit $C_{x,h}$ distinguishes between $M_1[x, h]$ and $V_1[x, h]$. Therefore, $C_{x,h}$ can be converted into a deterministic polynomial-size circuit $(D_1)_{x,h}$ that distinguishes between the same two sets.

Second, we show that if D distinguishes between $\bar{E}_1$ and $\bar{E}_3$ then we can construct a distinguisher D_2 that distinguishes between the ensembles $\{M_2[x, h] | x \in I, h \in H_x\}$ and $\{V_2[x, h] | x \in I, h \in H_x\}$, contradicting the hypothesis that P_2 is minimum-knowledge. Let I_2 be the infinite set of pairs (x, h) for which inequality (2) holds, and consider the infinite set $I_2' = \{(x, v) | v \in V_1[x, h], (x, h) \in I_2\}$. We define $(D_2)_{x,h}$ to be the circuit whose output, on input s (chosen either from $M_2[x, h]$ or from $V_2[x, h]$) is the output of $D_{x,h}$ on input $h \cdot s$. Since D is polynomial-size, it is clear that D_2 is polynomial-size, too. Inequality (2) shows that $(D_2)_{x,h}$ distinguishes between $M_2[x, h]$ and $V_2[x, h]$ for infinitely many pairs (x, h)—namely, for all pairs $(x, v) \in I_2'$.

We therefore conclude that the concatenated protocol is minimum-knowledge. Analogous arguments show that the concatenated protocol is perfectly minimum-knowledge if the same is true of both component protocols. □

REMARK. We mention here a special case of the above lemma that we use implicitly throughout the proofs in §§ 5 and 6. Suppose that a protocol (A, B) is given, and consider a certain point in the protocol execution when A has just sent a message and B is about to perform its next active turn. Let P_1 be the protocol up to this point, and let P_2 consist just of B's next active turn. The lemma implies that if P_1 and P_2 are minimum-knowledge, then so is the given protocol through the end of B's next turn. This allows us to specify a machine M_{B^*} for our proofs below, simply by having the machine activate a subprogram B* as explained at the end of the previous section: As long as the subprogram, when activated, has access to a virtual history tape whose contents are indistinguishable from the history tape of an actual protocol execution carried on with A, its operation within M_{B^*} is identical to its operation during an actual interaction.

3.3. Result indistinguishability. Next we introduce the eavesdropper C, as described above. Recall that $COM\{(A, B)[x]\}$ is the set of possibilities for C's view of the computation of A and B on input x. In all our examples of interactive pairs of Turing machines (A, B), neither machine uses its history tape. Thus, without loss of generality we can assume that A and B begin their computation with their history tapes initially empty.

We call an interactive pair of Turing machines (A, B) result-indistinguishable if an eavesdropper that has access to the communications of A and B on input x gains

no knowledge. More precisely, the system (A, B) is *result-indistinguishable* if there exists a probabilistic polynomial-time Turing machine M such that the ensembles $\{M[x] \mid x \in I\}$ and $\{COM\{(A, B)[x]\} \mid x \in I\}$ are indistinguishable. If the ensembles are exactly identical, we say that the proof-system is *perfectly result-indistinguishable.*

Suppose that (A, B) is a transfer protocol for the probability distribution $F(x, r)$. Observe that unlike the simulating machine in the definition of the minimum-knowledge property, this machine M does not have access to an oracle for F. In other words, M can simulate the communications of A and B on input x, regardless of the value $F(x, r)$ (even if computing F is intractable). Since this simulation is by means of a feasible computation that an eavesdropping adversary could carry out for itself, the adversary gains no knowledge if it is given the text of a "conversation" belonging to the set $COM\{(A, B)[x]\}$.

We remark that if two protocols are result-indistinguishable, then so is their concatenation. The simulating machine for the concatenated protocol is simply the concatenation of the two simulators for the component protocols; neither the interacting parties nor the simulator makes any computation that depends on the history tapes.

4. Specification of the language

4.1. Preliminaries. We assume that the reader is familiar with the following notions from elementary number theory. (See, for example, [19], [23] for the number theory, and [21] for a computational point of view.) We will be working in the multiplicative group $\mathbf{Z}_N^*$ of integers relatively prime to N. Any element $z \in \mathbf{Z}_N^*$ is called a *quadratic residue* if it is a square mod N (i.e., if the equation $x^2 \equiv z \bmod N$ has a solution); otherwise, z is a *quadratic nonresidue* mod N. Given N and $z \in \mathbf{Z}_N^*$, the quantity called the *Jacobi symbol* of z with respect to N, denoted $(\frac{z}{N})$, can be efficiently computed (in time polynomial in $\log N$) and takes on the values $+1$ and -1. If $(\frac{z}{N}) = -1$, then z must be a quadratic nonresidue mod N. On the other hand, if $(\frac{z}{N}) = +1$, then z may be either a residue or a nonresidue. Determining which is the case, without knowing the factorization of N, appears to be an intractable problem, namely the *quadratic residuosity* problem. (However, given the prime factorization of N, it is easy to determine whether or not z is a quadratic residue.) Several cryptographic schemes have been proposed that base their security on the assumed difficulty of distinguishing between residues and nonresidues modulo an integer N that is hard to factor [16], [3], [22].

We also make use of Bernstein's law of large numbers [25], [21]: Suppose that the event E occurs with probability p, and let $F_k(E)$ denote the frequency with which E occurs in k independent trials. Then for any $k \geqq 1$ and any positive $\varepsilon \leqq p(1-p)$,

$$\text{Prob}\{|F_k(E) - p| \geqq \varepsilon\} \leqq 2\, e^{-k\varepsilon^2}.$$

4.2. The language. The protocol introduced in [17] is a minimum-knowledge confirming interactive proof-system for the language

$$\{(N, z) \mid z \in \mathbf{Z}_N^*,\ z \text{ a quadratic nonresidue mod } N\}.$$

The protocol that we present below is a deciding interactive proof-system, which is both minimum-knowledge and result-indistinguishable, for a language based on the same problem.

We use the notation $\nu(N)$ to represent the number of distinct prime factors of an integer N.

Our protocol is concerned with integers of a special form, namely those with prime factorization $N = \prod_{i=1}^{k} p_i^{e_i}$ such that for some i, $p_i^{e_i} \equiv 3 \bmod 4$. Let ***BL*** (for Blum, who pointed out their usefulness in cryptographic protocols) denote the set of such integers. There are two equivalent formulations of membership in ***BL***: (1) $N \in \boldsymbol{BL}$ if

and only if for any quadratic residue mod N, half its square roots (mod N) have Jacobi symbol $+1$ and half its square roots have Jacobi symbol -1. (2) $N \in \boldsymbol{BL}$ if and only if there exists a quadratic residue mod N which has two square roots with different Jacobi symbols [2].

The special integers that we require form a subset of $\boldsymbol{BL}$, namely

$$\boldsymbol{N} = \{N \mid N \in \boldsymbol{BL},\ N \equiv 1 \bmod 4,\ \nu(N) = 2\}.$$

It is not hard to see that this set may be defined equivalently as

$$\boldsymbol{N} = \{p^i q^j \mid p \neq q \text{ prime},\ i, j \geqq 1,\ p^i \equiv q^j \equiv 3 \bmod 4\}.$$

Finally, we define the languages

$$I = \{(N, z) \mid N \in \boldsymbol{N},\ z \in \mathbf{Z}_N^*,\ (\tfrac{z}{N}) = +1\} \quad \text{and}$$

$$L = \{N, z) \in I \mid z \text{ a quadratic residue mod } N\}.$$

Taking I as the set of inputs, this paper gives a deciding interactive proof-system for L. Notice that $I - L = \{(N, z) \in I \mid z \text{ a quadratic nonresidue mod } N\}$.

4.3. Outline of the protocol. Our protocol is the concatenation of two subprotocols. The first part is a confirming interactive proof-system for I. If the first part is completed successfully (i.e., if A proves to B that the input string is in I), then A and B perform the second part of the protocol. The second part, taking inputs from the set I, is a deciding interactive proof-system for the language L; A proves to B either that the input string is in L or that it is not in L. Both parts are minimum-knowledge, and the second part is result-indistinguishable as well. The eavesdropper learns that, with high probability, the input is in I. But he gains no more knowledge than this—in particular, he gains no computational advantage in deciding whether the input is in L or in $I - L$, i.e., whether or not z is a quadratic residue mod N.

The confirmation that an input string (N, z) belongs to I in turn requires three stages, each of which confirms a property of N or of z; these stages are carried out in the following order:

(1) $N \equiv 1 \bmod 4$, $\nu(N) > 1$, $z \in \mathbf{Z}_N^*$, and $(\tfrac{z}{N}) = +1$.

(2) $N \in \boldsymbol{BL}$.

(3) $\nu(N) \leqq 2$.

While proving that our protocol has the properties that we desire, we make no limiting assumption about the computational power of Turing machine A. However, we remark that the protocol can be performed by a probabilistic polynomial-time Turing machine A which is given the factorization of the relevant integers N. (In the cryptographic applications that we discuss later, the party that performs A's role in our protocol chooses N along with its prime factorization.)

We now give the details of our protocol: the confirming first part in § 5, and the deciding second part in § 6.

5. Interactive confirmation of the input language. In each of the protocols that we describe, we use the notation "A → B: · · · " to indicate the transmission of a message from A to B.

5.1. Blum's coin-flip protocol. Our confirmation protocol requires that A and B jointly generate a sequence of bits. The verifier B has to be sure that A cannot bias these bits. They do this by following a protocol due to Blum [2].

An integer $N \in \boldsymbol{BL}$, $N \equiv 1 \bmod 4$, is given.

A and B generate a random bit b:

1. B chooses $u \in \mathbf{Z}_N^*$ at random, and computes $v := u^2 \bmod N$;
   B → A: v

2. A chooses $\sigma := +1$ or -1 at random, its guess for $(\frac{u}{N})$;
   $A \to B$: σ
3. $B \to A$: u
4. if $v \neq u^2 \bmod N$, then A halts the protocol in the FAILURE state;
   otherwise, if $\sigma = (\frac{u}{N})$ then $b := 1$ else $b := 0$

The message triple (v, σ, u) may be regarded as an encoding of the bit $b = \frac{1}{2} + \frac{1}{2}(\frac{u}{N})\sigma$.

This protocol is correct: Since B picks u at random and A picks the sign σ at random, the bit b chosen by the protocol is random. Furthermore, the first alternate characterization of ***BL*** (§ 4.2) implies that no interactive Turing machine A*, no matter what its computational power, can bias the bit produced, since it cannot guess the Jacobi symbol of the square root of v chosen by B with probability greater than $\frac{1}{2}$.

We remark that a cheating Turing machine B* could bias the bit solely by using its ability to produce two numbers u and u', both square roots (mod N) of v, with opposite Jacobi symbols; this capacity would enable B* to factor N simply by computing the greatest common divisor $(u - u', N)$.

The protocol is perfectly minimum-knowledge. The reason is that A's only task is to transmit a guess, $\sigma = +1$ or -1, for a sign, a task that may easily be carried out by a simulator interacting with B*. We formalize this argument below.

5.2. The confirmation protocol. This is a minimum-knowledge confirming interactive proof-system by which A proves to B that the input (N, z) is in the language I defined above. It consists of the concatenation of three subprotocols, each of which takes, as legal input, a string that has been confirmed (with high probability) by the preceding subprotocol. Let k denote the length of the input string.

First Stage: The easy properties of N and z

This stage involves no communications between A and B. Given (N, z) as input, B checks that $N \equiv 1 \bmod 4$, that N is not a prime power, and that $(\frac{z}{N}) = +1$. Each of these is easily accomplished in time polynomial in $\log N$ [21]. If any one of these conditions does not hold, then B REJECTS the proof (and halts the entire protocol).

Second Stage: N belongs to ***BL***

The following protocol is due to Blum [2]. The error probability of this proof-system is $\delta_2(k) = 2^{-k}$. This stage does not concern itself with z at all. The integer N must satisfy $N \equiv 1 \bmod 4$; this condition holds if the first stage has been completed successfully.

1. repeat k times:
   1.1 A chooses a quadratic residue $r \in \mathbf{Z}_N^*$ at random;
   $A \to B$: r
   1.2 B chooses $\sigma := +1$ or -1 at random;
   $B \to A$: σ
   1.3 if $\sigma \notin \{-1, +1\}$, then A halts the protocol in the FAILURE state;
   otherwise, A computes s such that $s^2 \equiv r \bmod N$ and $(\frac{s}{N}) = \sigma$;
   $A \to B$: s
   1.4 B checks to make sure that s satisfies the above conditions; if not, then B REJECTS the proof (and halts the entire protocol).
2. B ACCEPTS the proof.

Third Stage: N has two prime factors

This stage also does not concern itself with z.

Let us use $\mathbf{Z}_N^*(\pm 1)$ to denote the set of elements of $\mathbf{Z}_N^*$ with Jacobi symbol ± 1 (respectively). This protocol relies on the fact that if N has exactly i prime factors (i.e., $\nu(N) = i$), then exactly $1/2^{i-1}$ of the elements of $\mathbf{Z}_N^*(+1)$ are quadratic residues. A and B jointly pick random elements of $\mathbf{Z}_N^*(+1)$. If A can show that about half of them are residues (e.g., by producing their square roots mod N), then B should be convinced that $\nu(N) \leqq 2$. Since N is not a prime power, $\nu(N)$ must be equal to 2.

In order to pick a list of random elements of $\mathbf{Z}_N^*(+1)$, A and B follow Blum's coin-flip protocol, which requires that $N \in \boldsymbol{BL}$ and $N \equiv 1 \bmod 4$. These conditions hold (with very high probability) if the second stage has been completed successfully.

This proof-system has error probability $\delta_3(k) = 2e^{-k(1/8)^2}$.

1. A and B use Blum's coin-flip protocol to generate k random elements $r_1, \cdots, r_k \in \mathbf{Z}_N^*(+1)$:
   $i := 0$;
   do until $i = k$:
   a. generating it bit by bit using Blum's coin-flip protocol, A and B choose a number a, $0 < a < N$
   b. if g.c.d. $(a, N) \neq 1$ (which happens with vanishingly small probability) then HALT the protocol
   c. if $(\frac{a}{N}) = +1$ then $i := i + 1$; $r_i := a$
2. for each $i = 1, \cdots, k$ such that r_i is a quadratic residue, A computes s_i such that $r_i \equiv s_i^2 \bmod N$;
   A $\rightarrow$ B: (i, s_i)
3. B checks that at least $\frac{3}{8}$ of the r_i are quadratic residues; if so then B ACCEPTS the proof (and otherwise B REJECTS the proof and halts the entire protocol).

THEOREM 1. *This protocol is a perfectly minimum-knowledge confirming interactive proof-system for the language* $I = \{(N, z) \mid N \equiv 1 \bmod 4,\ N \in \boldsymbol{BL},\ \nu(N) = 2,\ (\frac{z}{N}) = +1\}$.

Proof. We treat each of the three subprotocol stages separately. As a consequence of the lemma of § 3.2, it then follows immediately that the concatenation of the three has the required properties.

First Stage

The first stage is, trivially, a confirming proof-system for the language

$$I_1 = \{(N, z) \mid N \equiv 1 \bmod 4,\ \nu(N) > 1,\ z \in \mathbf{Z}_N^*,\ (\tfrac{z}{N}) = +1\},$$

since each of these conditions is validated by B in polynomial time without interacting with A at all.

Second Stage

Given an integer $N \equiv 1 \bmod 4$ (in particular, given input that has been confirmed in the first stage), the second stage is a perfectly minimum-knowledge confirming interactive proof-system for the language $I_2 = \{(N, z) \mid N \in \boldsymbol{BL}\}$ with error probability $\delta_2(k) = 2^{-k}$.

This stage requires $O(k)$ communication rounds, during which $O(k^2)$ bits are exchanged.

The correctness of this stage depends on the alternate characterizations of membership in $\boldsymbol{BL}$ (§ 4.2). If $N \in \boldsymbol{BL}$, then each quadratic residue r sent by A has at least one square root mod N with Jacobi symbol $+1$ and at least one square root mod N with Jacobi symbol -1; no matter which sign σ B chooses, A can respond with a square root of the appropriate sign. B accepts the proof with probability 1. On the other hand, if $N \notin \boldsymbol{BL}$ then no quadratic residue mod N has two square roots with Jacobi symbols of opposite sign. In this case, it is very likely that there is some i for which A will be

unable to send an appropriate s_i, and B will halt the protocol. The only way for a cheating A* to convince B that $N \in \boldsymbol{BL}$ (by sending the appropriate elements s_i) is by guessing the entire sign-sequence $\sigma_1, \cdots, \sigma_k$; the probability that such a guess will be correct is at most $2^{-k} = \delta_2(k)$. Thus, this protocol is indeed a confirming interactive proof-system for ***BL***.

To prove the perfect minimum-knowledge property, choose any interactive Turing maching B*; we have to specify the computation of a Turing machine M_{B^*} whose output, on input $N \in \boldsymbol{BL}$ and initial history h, is a simulation of B*'s view of the computation that A and B* would have performed on the same input. This view includes a message-history that consists of triples (r, σ, s) satisfying the conditions implicitly defined by the specification of the protocol. As described above in § 3.1, M_{B^*} uses the program of B* as a subroutine. After initializing B*, M_{B^*} operates as follows:

1. repeat k times:
   1.1 save the current configuration of B*;
   1.2 choose $s \in \mathbf{Z}_N^*$ at random, compute $r := s^2 \bmod N$, "send" r to the simulated B^*, and "receive" σ in return;
   1.3 if $\sigma \notin \{-1, +1\}$ then append HALT to A's message-record in B*'s virtual history, write out the updated virtual history, and halt;
   otherwise if $(\frac{s}{N}) \neq \sigma$ then restore the saved configuration of B* and go back to step 1.1;
   (else $(\frac{s}{N}) = \sigma$ and the most recent exchange of messages recorded in B*'s virtual history is the triple (r, σ, s))
2. write out B*'s virtual history.

For each of the k iterations, the expected number of times the loop has to be repeated is 2, since for any value of r the probability that $(\frac{s}{N}) = \sigma$ is exactly $\frac{1}{2}$; thus the expected running time of M_{B^*} is polynomial in k.

The simulated messages "sent" to B* are drawn from the same probability distribution as the messages sent by A in an actual execution of the protocol, and the random communications triples (r, σ, s) produced by M_{B^*} satisfy the conditions $s^2 \equiv r \bmod N$ and $(\frac{s}{N}) = \sigma$. As explained in § 3.2, these messages are interleaved on the virtual history tape with the random-tape bits used by B*, exactly as they would be in an actual interaction with A. Therefore the sets $M_{B^*}[N, h]$ and $VIEW_{B^*}\{(A, B^*)[N, h]\}$ are identical. This completes the proof for the second stage.

Third Stage

Given an integer from the set

$$\{N \mid N \in \boldsymbol{BL},\ N \equiv 1 \bmod 4,\ \nu(N) > 1\}$$

(in particular, given input that has been confirmed in the first and second stages), the third stage is a perfectly minimum-knowledge confirming interactive proof-system for the language $I_3 = \{(N, z) \mid \nu(N) = 2\}$ with error probability $\delta_3(k) = 2e^{-k(1/8)^2}$.

This stage requires $O(k^2)$ communication rounds, during which $O(k^3)$ bits are exchanged.

During the third stage, A and B together choose random elements of $\mathbf{Z}_N^*(+1)$. Since they do this by means of Blum's coin-flip protocol, and no Turing machine A* can bias the bits produced by Blum's procedure, these elements are indeed produced at random. In order to prove that this stage is a proof-system, consider the experiment of choosing a random element of $\mathbf{Z}_N^*(+1)$, where the experiment is a success if the chosen element is a quadratic residue mod N; let $F_k(N)$ denote the frequency of

successes in k independent trials. Recall that B accepts N if the frequency $F_k(N) \geqq \frac{3}{8}$. As mentioned above, the probability of success in one trial is exactly $(\frac{1}{2})^{\nu(N)-1}$. (Since N is known to have at least two prime factors, this probability is at most $\frac{1}{2}$.) If $\nu(N)$ is exactly 2, then the probability that B does not accept N is, by Bernstein's law of large numbers,

$$\text{Prob}\{F_k(N) < \tfrac{3}{8}\} \leqq \text{Prob}\{|F_k(N) - \tfrac{1}{2}| \geqq \tfrac{1}{8}\} \leqq 2e^{-k(1/8)^2} = \delta_3(k).$$

On the other hand, if N has more than two prime factors, the probability of success in one trial is at most $\frac{1}{4}$, and thus the probability that B incorrectly accepts N (when interacting with a cheating A*) is

$$\text{Prob}\{F_k(N) \geqq \tfrac{3}{8}\} \leqq \text{Prob}\{|F_k(N) - \tfrac{1}{4}| \geqq \tfrac{1}{8}\} \leqq 2e^{-k(1/8)^2} = \delta_3(k).$$

To prove the minimum-knowledge property, given an interactive Turing machine B* we have to specify the computation of a simulating Turing machine M_{B^*}. The ensemble that M_{B^*} must simulate includes a sequence of Blum coin-flips, so we begin by showing that Blum's coin-flip protocol is perfectly minimum-knowledge. To prove this, we must specify the computation of a probabilistic polynomial-time Turing machine M_{coin}, whose output, on input N (satisfying $N \in \boldsymbol{BL}$ and $N \equiv 1 \bmod 4$), and initial history h, provides a simulation of the ensemble $VIEW_{B^*}\{(A, B^*)[N, h]\}$, which includes a message triple (v, σ, u) encoding a bit as described in § 5.1 above. Modelling the result oracle for the protocol, M_{coin} is given as additional input a (presumably random) bit b.

Given any bit b, M_{coin} (initializes B* and) proceeds as follows:

a. execute the protocol with B*:
   1. let B* "send" v (simulating step 1)
   2. save the current configuration of B*
   3. simulate A's action in step 2 by choosing $\sigma := \pm 1$ at random and "sending" it to B*
   4. let B* "send" u (simulating step 3)

b. if the bit encoded by (v, σ, u) is b, then write out B*'s virtual history (which includes the triple (v, σ, u)) and halt; otherwise:
   1. restore the saved configuration of B*
   2. simulating step 2 again, "send" $-\sigma$ (instead of σ) to B*
   3. let B* "send" u'
   4. write out B*'s virtual history (which includes the triple $(v, -\sigma, u')$)

Note that if B* does not follow the protocol, it may happen that the numbers u and u' are not the same; if their Jacobi symbol is the same the outcome of the protocol is the same random bit b and this has no effect on the output distribution of M_{coin} (since B*, when interacting with A, can decide to send either u or $-u$). On the other hand, if they have opposite Jacobi symbols mod N, then the outcome bit $1-b$ has been determined by B* and not chosen at random. As noted above, this can only happen if B* can factor N, in which case it indeed has the ability to dictate the outcome of the protocol, regardless of whether it is interacting with A or acting as a subroutine for M_{coin}.

Whether the virtual history of B* written out by M_{coin} was generated in step a or step b of the simulation, the distribution of its possible values (and thus the probability distribution of the bit encoded by the message triple) is identical to that of $VIEW_{B^*}\{(A, B^*)[N, h]\}$. Thus the coin-flip protocol is perfectly minimum-knowledge.

Next we describe the simulation by M_{B^*} of the third stage of our protocol. The set $VIEW_{B^*}\{(A, B^*)[N, h]\}$ that M_{B^*} must simulate begins with a sequence of Blum

coin-flips, which are used to generate random elements of $\mathbf{Z}_N^*$. This simulation can be performed by following the program M_{coin} as just described; the difficulty for M_{B^*}, a polynomial-time machine that may not be able to factor N, is that those elements which are quadratic residues must be randomly generated along with their square roots.

Given as input an integer N that has been confirmed by the first two stages and that satisfies $\nu(N)=2$, and given an initial history h, M_{B^*} proceeds as follows:

1. $i := 0$; $\Lambda :=$ the empty list
2. do until $i = k$:
   choose a random number a, $0 < a < N$;
   if g.c.d. $(a, N) \neq 1$ (which happens with vanishingly small probability) then FLAG the number a, adjoin it to Λ, and go to step 3;
   else:
   choose a random bit b (to decide the Jacobi symbol of the next element generated);
   if $b = 0$ then adjoin to Λ a random element of $\mathbf{Z}_N^*(-1)$;
   else:
   a. $i := i+1$
   b. choose $s_i \in \mathbf{Z}_N^*$ at random
   c. choose a random bit b_i (to decide whether the next element generated should be a quadratic residue);
      if $b_i = 0$ then $r_i := s_i^2 \bmod N$ (a random residue in $\mathbf{Z}_N^*(+1)$)
      else $r_i := -s_i^2 \bmod N$ (a random nonresidue in $\mathbf{Z}_N^*(+1)$)
   d. adjoin r_i to Λ
3. (simulate as many executions as needed of Blum's coin-flip in order to generate the sequence of bits in the list Λ)
   for each bit b in the representation of each number in Λ:
   follow the procedure above for M_{coin} (using B* as a subroutine), recording the numbers u (and possibly u') "sent" by B*;
   if the outcome of the coin-flip simulation is indeed b, then continue with the next bit in Λ;
   otherwise B* has "forced" the complementary outcome $1-b$ by "sending" u and u' with $(\frac{u}{N}) \neq (\frac{u'}{N})$, in which case:
   a. use u and u' to factor N
   b. discard the rest of Λ
   c. repeatedly execute Blum's coin-flip with B* (as originally specified, without backtracking to restore previous configurations of B*) in order to choose elements of $\mathbf{Z}_N^*$, bit by bit, until the resulting list contains k elements ($r_1, \ldots, r_k$, say) with Jacobi symbol $+1$; again let Λ denote the new list
4. if the last number in Λ is FLAGGED then halt
5. discard the elements in Λ with Jacobi symbol -1
6. if B* has not "forced" the outcome of any of the coin-flip simulations of step 3, then for each r_i in Λ such that $b_i = 0$ "send" (i, s_i) to B*;
   otherwise, use the factorization of N to test each r_i in Λ to see whether it is a quadratic residue; if it is, then compute s_i such that $r_i \equiv s_i^2 \bmod N$ and "send" (i, s_i) to B*
7. write out the virtual history of B*.

If $\nu(N)=2$, then a randomly chosen element of $\mathbf{Z}_N^*$—in particular, one that has been chosen by A interacting with a machine B* that does not "force" the outcome

of any Blum coin-flips—will have Jacobi symbol +1 with probability $\frac{1}{2}$; among these, quadratic residues will occur with probability $\frac{1}{2}$. If B*, as a subprogram of the simulator M_{B^*}, does not "force" any (simulated) Blum coin-flips, then the simulator generates elements of $\mathbf{Z}_N$ with exactly the same probabilities, and then perfectly simulates the generating coin-flips; on the other hand, if B* does "force" a coin-flip, then M_{B^*} simply performs with it a sequence of Blum coin-flips, exactly as in the specification of the protocol. Either way, M_{B^*} generates lists of elements of $\mathbf{Z}_N$ with the same distribution as do A and B*, and B* makes identical use of bits from its random tape, so that the sets $VIEW_{B^*}\{(A, B^*)[N, h]\}$ and $M[N, h]$ are identical. This completes the proof for the third stage.

Finally, to conclude the proof of Theorem 1, we see by the concatenation lemma that, given any input string at all, the concatenation of the three stages is a perfectly minimum-knowledge confirming interactive proof-system for the language $I_1 \cap I_2 \cap I_3 = I$. □

6. Interactive decision of quadratic residuosity. If the confirming part of our protocol has been successfully completed, then with high probability the input string (N, z) is in the language I. In particular, we know that $\nu(N) = 2$, that $z \in \mathbf{Z}_N^*$, and that $(\frac{z}{N}) = +1$; these are the properties that are required of the inputs to the next part of the protocol.

This part is a deciding interactive proof-system for L, taking inputs from I. The proof-system is both perfectly minimum-knowledge and perfectly result-indistinguishable. As noted above, a pair (N, z) that is known to belong to I either is or is not also a member of L according to whether or not z is a quadratic residue mod N.

To make the exposition clearer, we present three successive versions of our protocol.

Let $y \equiv -1 \bmod N$. Everything that follows holds for any nonresidue $y \in \mathbf{Z}_N^*$ that has Jacobi symbol +1. As long as $N \in \boldsymbol{BL}$ and $N \equiv 1 \bmod 4$, we can take $y = -1$. (*Remark.* If another nonresidue y is desired, A can prove to B, as a preliminary subprotocol stage, that y is a nonresidue by following the minimum-knowledge interactive proof-system of [17].)

Let us fix some notation. For any $x \in \mathbf{Z}_N^*$ we define the predicate:

$$\mathrm{RES}_N(x) = \begin{cases} 0 & \text{if } x \text{ is a quadratic residue mod } N, \\ 1 & \text{otherwise.} \end{cases}$$

Recall that $\mathbf{Z}_N^*(+1)$ denotes the set of elements of $\mathbf{Z}_N^*$ with Jacobi symbol +1. Since $\nu(N) = 2$, half of these are quadratic residues mod N, and half of them are nonresidues.

Our protocol relies on the fact that if $r \in \mathbf{Z}_N^*$ is chosen at random, then $r^2 \bmod N$ is a random quadratic residue in the set $\mathbf{Z}_N^*(+1)$ and $yr^2 \bmod N$ is a random quadratic nonresidue in $\mathbf{Z}_N^*(+1)$; similarly, $zr^2 \bmod N$ is either a random residue or a random nonresidue in $\mathbf{Z}_N^*(+1)$ according to whether or not z is a residue mod N.

This interactive proof-system has error probability $\delta(k) = 2e^{-4k/81}$.

First version: A deciding proof-system

i. Repeat k times:

1. B chooses $r \in \mathbf{Z}_N^*$ and $c \in \{1, 2, 3\}$ at random, and computes CASE c of:
   1: $x := r^2 \bmod N$
   2: $x := yr^2 \bmod N$
   3: $x := zr^2 \bmod N$
   B → A: x

2. A computes $b := \mathrm{RES}_N(x)$;
   A → B: b
3. B checks that if $c = 1$ then $b = 0$, if $c = 2$ then $b = 1$, and if $c = 3$ then b is consistent with any previous case-3 iterations; if not then B REJECTS the proof and halts the protocol

ii. B ACCEPTS the proof that $\mathrm{RES}_N(z)$ is equal to the consistent value of b for case-3 iterations.

As explained above, if z is a quadratic residue then x's constructed in case 1 are indistinguishable from x's constructed in case 3. If A acts as specified, then when the protocol finishes B will be convinced that z is a residue. The only way that a cheating A* can convince B that z is not a residue is by correctly guessing, among all iterations during which B has sent a residue x, which of these were constructed in case 1 and which of them in case 3; if there are ck such iterations in a particular execution of the protocol, then the probability of successful cheating is 2^{-ck}. Since c is very likely to be close to $\frac{2}{3}$, a simple calculation using Bernstein's law of large numbers shows that the probability of successful cheating is at most $2e^{-4k/81}$. Similarly if z is a quadratic nonresidue. Hence the above version is a deciding interactive proof-system for L.

However, this version is not result-indistinguishable. An observer of an execution of the protocol can easily tell whether he is watching an interactive proof that $\mathrm{RES}_N(z) = 1$ or a proof that $\mathrm{RES}_N(z) = 0$ by keeping a tally of the bits b sent by A in step 2 of each iteration.

Second version: A result-indistinguishable proof-system

A simple modification of the above protocol does hide the result from an eavesdropper. The only change is that at the beginning (before step i), A flips a fair coin in order to decide whether to use $R(x) = \mathrm{RES}_N(x)$ or $R(x) = 1 - \mathrm{RES}_N(x)$ as the bit b to be sent to B in step 2 of each iteration throughout the protocol. $R(x)$ can be regarded as an encoding, chosen at random for the entire protocol, of $\mathrm{RES}_N(x)$.

In step 3, B checks for consistency in the obvious way: B should receive the same bit b in all case-1 iterations and the complementary bit in all case-2 iterations; B should receive a consistent bit b in all case-3 iterations, and its value indicates to B whether or not z is a quadratic residue. As before, if in step 3 of any iteration B finds that the value of b is not consistent then B halts the protocol, REJECTing the proof.

With this modification, the protocol is still—arguing as above—a deciding interactive proof-system for L. Furthermore, it is result-indistinguishable. An eavesdropper expects to overhear one bit about $\frac{2}{3}$ of the time during step 2 of each iteration and the complementary bit the remaining $\frac{1}{3}$ of the time; whether the majority bit in a particular execution of the protocol is 0 or 1 gives him no knowledge. A formal proof of result-indistinguishability of the full protocol is presented below.

However, the version so far presented is not minimum-knowledge. For example, a cheating B* that wanted to find out whether a particular number—17, say—is a quadratic residue mod N could, during one of the iterations, send $x = 17$ in step 1 instead of an element x constructed at random according to B's program. A's response in step 2 will convey to B* the value $\mathrm{RES}_N(17)$, which is something that B* could not have computed by itself.

Third version: A minimum-knowledge result-indistinguishable proof-system

We can make this a minimum-knowledge protocol by refining step 1 of the version just presented; the refinement consists of several interactive substeps by which B gives to A what amounts to a minimum-knowledge proof that the element x that it sends

was constructed in one of the three ways specfied (without giving A any knowledge about which of the three ways). The rest of the protocol is unchanged.

1.0 B chooses $r \in \mathbf{Z}_N^*$ and $c \in \{1, 2, 3\}$ at random, and computes CASE c of:
1: $x := r^2 \bmod N$
2: $x := yr^2 \bmod N$
3: $x := zr^2 \bmod N$
B → A: x

1.1 B chooses $s_i \in \mathbf{Z}_N^*$ at random ($i = 1, \cdots, 4k$) and computes:
$T_1 = \{t_1, \cdots, t_k \mid t_i \equiv s_i^2 \bmod N\}$,
$T_2 = \{t_{k+1}, \cdots, t_{2k} \mid t_i \equiv ys_i^2 \bmod N\}$,
$T_3 = \{t_{2k+1}, \cdots, t_{3k} \mid t_i \equiv zs_i^2 \bmod N\}$,
$T_4 = \{t_{3k+1}, \cdots, t_{4k} \mid t_i \equiv yzs_i^2 \bmod N\}$;
taking this to be matrix of 4 rows $[T_1, T_2, T_3, T_4]$ and k columns (where column j contains the elements t_j, t_{k+j}, t_{2k+j}, t_{3k+j}), B randomly permutes each column of the matrix, resulting in a matrix T;
B → A: T

1.2 A chooses $S \subseteq \{1, \cdots, k\}$ at random (a *query* indicating a random subset of T's columns);
A → B: S

1.3 for each $j \in S$, for each $t_i \in$ column j, B → A: s_i
(These numbers show A that B has correctly computed the jth column of T for each $j \in S$ and convince A that it is very likely that at least one other column of T was also computed correctly.)

1.4 A verifies (for each such t_i) that $t_i \equiv$ either s_i^2, ys_i^2, zs_i^2, or $yzs_i^2 \bmod N$, with each congruence being satisfied once in each column $j \in S$;
if not, then A halts the protocol in the FAILURE state

1.5 for each $j \notin S$, for each $t_i \in$ column j, B computes w_i according to Table 1: if x was chosen as case c of step 1.0 and $t_i \in T_l$, then $w_i :=$ the table-entry in the lth row and cth column;

TABLE 1. (Step 1.5.)
(*All computations of table entries are modulo N.*)

	$x = \cdots$		
$t_i = \cdots$	r^2 ($c = 1$)	yr^2 ($c = 2$)	zr^2 ($c = 3$)
$s_i^2 \in T_1$	$rs_i = \sqrt{(xt_i)}$	$yrs_i = \sqrt{y(xt_i)}$	$zrs_i = \sqrt{z(xt_i)}$
$ys_i^2 \in T_2$	$yrs_i = \sqrt{y(xt_i)}$	$yrs_i = \sqrt{(xt_i)}$	$yzrs_i = \sqrt{yz(xt_i)}$
$zs_i^2 \in T_3$	$zrs_i = \sqrt{z(xt_i)}$	$yzrs_i = \sqrt{yz(xt_i)}$	$zrs_i = \sqrt{(xt_i)}$
$yzs_i^2 \in T_4$	$yzrs_i = \sqrt{yz(xt_i)}$	$yzrs_i = \sqrt{z(xt_i)}$	$yzrs_i = \sqrt{y(xt_i)}$

(For each $j \notin S$, these four numbers show A that if B has correctly computed the jth column of T, then B has correctly computed x.)
for each such t_i, B → A: w_i.

1.6 A verifies (for each such t_i) that $w_i^2 \equiv$ either (xt_i), $y(xt_i)$, $z(xt_i)$, or $yz(xt_i) \bmod N$, with each congruence being satisfied once in each column $j \notin S$;
if not, then A halts the protocol in the FAILURE state.

The protocol now continues as before. A sends $b = R(x)$ to B (step 2), and B checks b for consistency (step 3); and then they continue with step 1 of the next iteration. Note that it is in A's "interest" to choose S at random in step 1.2, so that with overwhelming probability both S and $\{1, \cdots, k\} - S$ are reasonably large (and thus the probability that any particular column of T will be queried is close to $\frac{1}{2}$).

The idea is that any machine playing the role of B (and desiring that the protocol succeed) must follow the protocol, because if it tries to cheat during any iteration—either by sending a number x in step 1.0 for which it does not "know" the corresponding number r, or by sending numbers t_i in step 1.1 for which it does not "know" the corresponding numbers s_i—then A will, with overwhelming probability, detect its cheating either in step 1.6 or in step 1.4. This is formalized in the following proof.

THEOREM 2. *Given input belonging to* $I = \{(N, z) \mid N \equiv 1 \bmod 4,\ N \in \mathbf{BL},\ \nu(N) = 2,\ (\frac{z}{N}) = +1\}$, *this protocol is a perfectly minimum-knowledge and perfectly result-indistinguishable deciding interactive proof-system for* $L = \{(N, z) \in I \mid z$ *a quadratic residue* $\bmod N\}$.

Proof. First we prove that the protocol is a deciding proof-system for L. Since we have already shown that the second version presented above is a proof-system, it suffices to show that the refinement of step 1 preserves this property.

Suppose that z is a quadratic residue. The question is whether a cheating A*—even if it does not choose S at random in step 1.2—can use the numbers sent by B during step 1 to distinguish correctly between case-1 iterations ($x = r^2 \bmod N$ for a random r) and case-3 iterations ($x = zr^2 \bmod N$). Since B has chosen them at random, A* is unable to distinguish between residues t_i of the form s_i^2 and residues t_i of the form zs_i^2. Table 2, the subtable of Table 1 corresponding to these four possibilities, has rows that are permutations of each other, and thus A* is not able to tell whether B is using column $c = 1$ or column $c = 3$ of the whole table.

TABLE 2
A subtable of Table 1.

		$c = 1$	$c = 3$
$t_i = \cdots$	s_i^2	$\sqrt{(xt_i)}$	$\sqrt{z(xt_i)}$
	zs_i^2	$\sqrt{z(xt_i)}$	$\sqrt{(xt_i)}$

Similarly for nonresidues t_i of the form ys_i^2 or yzs_i^2. A like analysis holds if z is a nonresidue mod N. Hence the protocol is indeed a deciding interactive proof-system for L.

In order to prove the minimum-knowledge property, we choose an interactive Turing machine B* that runs in expected polynomial time; we must describe the computation of a simulating machine $M = M_{B^*}$.

M has one-time access to an oracle for the result of the protocol, as explained in § 3.1. M begins by querying the oracle on the input string (N, z), and learns (with very high probability) the value of $\mathrm{RES}_N(z)$. The rest of the simulation is similar to that of the proof that the protocol of [17] is minimum-knowledge.

As its next step, M flips a coin to simulate A's choice of whether to compute $R(x) = \mathrm{RES}_N(x)$ or $R(x) = 1 - \mathrm{RES}_N(x)$ during the protocol.

In each iteration, M carries on the protocol through the end of (the refinement of) step 1 in a straightforward manner: M uses B* to perform its own version of B's role, and M easily simulates A's role, choosing a random query S in step 1.2 and

checking several congruences mod N in steps 1.4 and 1.6. If these congruences do satisfy the check, the difficulty comes in simulating A's communication in step 2, which consists of the bit $R(x)$; how can M quickly calculate the correct value of $\mathrm{RES}_N(x)$? M accomplishes this by following the EXTRACTION procedure described below.

After B* has performed its computations in the simulation of step 1.1 and "sent" the matrix T, M saves the current configuration C_0 of B*. At this point, given C_0 (which includes a fixed random-tape string) and any fixed query-set $S \subseteq \{1, \cdots, k\}$ that A might choose in step 1.2, the lists of numbers that B* would "send" in steps 1.3 and 1.5 in answer to the query S are determined. Let us call S a *satisfiable* query if these answers would satisfy A's verifying checks of steps 1.4 and 1.6, causing the protocol to continue with step 2. (A query that is not satisfiable would cause A to halt the protocol in its failure state.) It is easy to check whether or not a query S is satisfiable, by setting B*'s configuration to C_0, "sending" S to B*, and checking the numbers that B* "sends" in return.

In its simulation, M makes use of an auxiliary matrix T' that contains two data fields for each entry t_i of the matrix T, one for the number s_i and one for the number w_i (where s_i and w_i are related to t_i as in the specification of the protocol). Note that if M succeeds in filling both fields for any single entry t_i, then M can easily deduce the value $R(x)$ that it needs in order to simulate step 2: M can use s_i to see how t_i was computed in step 1.1 (i.e., which set T_j contains t_i, and hence which row of the table B* must use in step 1.5); next M can use w_i to see which column c of the table B* must use; and then the choice of column gives M the value of $\mathrm{RES}_N(x)$, and hence of $R(x)$.

Next we describe the EXTRACTION procedure that M performs in each iteration following the simulation of step 1.1.

1. save the current machine configuration C_0
2. choose a query $S \subseteq \{1, \cdots, k\}$ at random, store it, and "send" it to B* (simulating step 1.2)
3. let B* "send" its answers to S (the numbers s_i of step 1.3 and $w_{i'}$ of step 1.5), and check the congruences of steps 1.4 and 1.6;
   if the congruences do not check, then halt the simulation;
   otherwise, store B*'s answers in the auxiliary matrix T' and repeat the following two loops concurrently until *success*:
   a. sampling the query space (without repetition):
      i. restore configuration C_0
      ii. choose a new query $S' \subseteq \{1, \cdots, k\}$ at random that has not already been chosen (if there is one; if none exists, then halt the sampling loop);
      store S' and "send" it to B*
      iii. let B* "send" its answers to S'
      iv. for each $j = 1 \cdots k$ if B*'s answers for column j of the matrix T satisfy the congruences of 1.4 (if $j \in S'$) or of 1.6 (if $j \notin S'$), then enter them in the auxiliary matrix T';
      if any of these new entries is an s_i for which T' already contains w_i or vice versa, then (as explained above) use s_i, w_i to compute $R(x)$ and set *success* := TRUE
   b. use any factoring algorithm F to factor N:
      i. until (*success* or {F has successfully factored N}) do the next step of F
      ii. use the prime factors of N to compute $\mathrm{RES}_N(x)$ and $R(x)$, and set *success* := TRUE

4. restore configuration C_0 and "send" to B* the original query S
5. let B* "send" its answers and update its history tape (exactly as it did the first time it received the query S)

Simulating step 2, M sets $b := R(x)$ (as computed either in a or b of the last inner loop) and "sends" b to B*, which performs its version of step 3 of the protocol. If B* is following the instructions of step 3, then it is indeed "expecting" the computed value of b, and the simulation continues with the next iteration.

We need to show that M's expected running time is polynomial (in k, the length of the input) and that its output ensemble is identical to B*'s view. To bound the running time, it suffices to prove a polynomial bound on the expected time required by each of the k iterations of M's program. First observe that the outer loop of the EXTRACTION procedure takes polynomial time. The same is true for any single execution of the inner loop: queries may be stored in a lexicographically ordered tree (so that choosing a new one costs $O(k)$); the rest of the sampling loop is polynomial-time, and in each inner loop only one step of the factoring algorithm is performed. Therefore, it is enough to show that, for any fixed configuration C_0, the expected number of repetitions of the inner loop is polynomial in k.

In fact, we show that this number is constant. In configuration C_0, let p $(0 \leqq p \leqq 2^k)$ be the number of queries that are satisfiable. When M performs the EXTRACTION procedure, with probability $1 - p/2^k$ its first query S will not be satisfiable, in which case the inner loop is not executed at all. If $p = 0$, we have no other case to consider; so assume $p \geqq 1$. With probability $p/2^k$, S is satisfiable, and the inner loop is repeated until *success* is set to TRUE (either in the sampling process or after factoring N). Each sampling loop begins with the choice of a new random query. Of the $2^k - 1$ possible queries, at least the $p - 1$ satisfiable queries (besides S) lead to *success*; that is, the probability of a successful inner loop is at least $(p-1)/(2^k - 1)$. Hence if $p > 1$, the expected number of attempts after choosing a satisfiable original query is at most $(2^k - 1)/(p-1)$; overall, the expected number of repetitions of the inner loop is at most $(p/2^k) \cdot (2^k - 1)/(p-1) \leqq 2$. We consider below the special case $p = 1$.

Next, we show that the sets $VIEW_{B^*}\{(A, B^*)[(N, z), h]\}$ and $M[(N, z), h]$ are identical; following the Remark of § 3.2, it suffices to show that this is so for any one of the k iterations of the protocol. Consider, therefore, an iteration—either of an actual protocol execution by A and B* or of the simulation by M—at the beginning of which B* sends the matrix T, and let p $(0 \leqq p \leqq 2^k)$ be the number of satisfiable queries. With probability $1 - p/2^k$ a randomly chosen query is not satisfiable, causing either the protocol execution or the simulation to halt; in this case, the actual history and the virtual history are identical. If $p = 0$, then this is the only case that occurs. Otherwise, with probability $p/2^k$, the original query S is satisfiable, and both the actual protocol and the simulation continue with step 2. As long as $p \geqq 2$, there is at least one other query that leads to *success* in the inner loop of M's EXTRACTION procedure, enabling M to "send" in its simulation of step 2 the correct value of $b = R(x)$, the same one that A would send during an actual execution. The factoring algorithm may be faster then the sampling process, in which case the correct value of b is computed directly. Either way, the actual history and the virtual history are identical.

If $p = 1$, then the probability that M's original query is satisfiable is only 2^{-k}. In this rare case, the sampling process in the inner loop of the EXTRACTION procedure might never lead to *success*; the inner loop might not terminate until after N has been factored. Since the cost of factoring N is less than $O(2^k)$, the total expected number of repetitions of the inner loop when $p = 1$ is less than $2^{-k} \cdot 2^k = 1$. In this case, as

before, the actual history and the virtual history are identical. This concludes the proof that the protocol is perfectly minimum-knowledge.

In order to prove that the protocol is result-indistinguishable, we must specify the computation of a probabilistic Turing machine M′, running in expected polynomial time, that simulates the communications ensemble $COM\{(\mathrm{A}, \mathrm{B})[N, z]\}$. (Recall that M′ does not have access to any oracle.) M′ begins by flipping a coin to decide whether to simulate the choice $R(z)=0$ or the choice $R(z)=1$. Then in each iteration M′ simulates the specified computations of A and B, except for the following changes. In (simulated) step 1.0, M′ chooses $x := zr^2 \bmod N$ with probability $\frac{2}{3}$ and $x := yzr^2 \bmod N$ with probability $\frac{1}{3}$. In (simulated) step 2, M′ outputs $b = R(z)$ if $x = zr^2$ and $b = 1 - R(z)$ if $x = yzr^2$. (Here the simulation of step 2 is much simpler than in the minimum-knowledge proof above, since M′ "knows" how each x was constructed.) In (simulated) step 1.5, M′ outputs w_i computed according to Table 3.

TABLE 3

	$x = \cdots$	
$t_i = \cdots$	zr^2	yzr^2
s_i^2	$zrs_i = \sqrt{z(xt_i)}$	$yzrs_i = \sqrt{yz(xt_i)}$
ys_i^2	$yzrs_i = \sqrt{yz(xt_i)}$	$yzrs_i = \sqrt{z(xt_i)}$
zs_i^2	$zrs_i = \sqrt{(xt_i)}$	$yzrs_i = \sqrt{y(xt_i)}$
yzs_i^2	$yzrs_i = \sqrt{y(xt_i)}$	$yzrs_i = \sqrt{(xt_i)}$

The numbers x output by M′ have the same distribution as the numbers x output by B; the same is true of the s_i and the w_i. Hence, as required, the set of outputs $\mathrm{M}'[N, z]$ is identical to the set $COM\{(\mathrm{A}, \mathrm{B})[N, z]\}$, so the protocol is perfectly result-indistinguishable.

As presented, the protocol takes $O(k)$ communication rounds during which $O(k^3)$ bits are exchanged. However, all k iterations of the main loop can be performed in parallel, taking $O(1)$ rounds. The simulator M can perform in parallel all k iterations of its main loop, and its expected running time is still polynomial in k. Similarly, M′ can operate in parallel. Thus the parallelized version of the protocol is also perfectly minimum-knowledge and perfectly result-indistinguishable. This concludes the proof of Theorem 2. □

We note that there is another modification of the first version of our protocol that also achieves result-indistinguishability. A can always respond in step 2 with the true value of $\mathrm{RES}_N(x)$ if B computes each x in step 1 according to a random choice among four varieties: to the types r^2, yr^2, and $zr^2 \bmod N$ we add the fourth type $yzr^2 \bmod N$. If the protocol is to be minimum-knowledge as well, we can refine step 1 as in the third version of our protocol, adding an appropriate fourth column to the table used to compute w_i.

7. Cryptographic applications. In all our applications, we let N be the public key of a user A who knows its factorization. Within the set $\boldsymbol{N}$, it is most advantageous to

A to choose N to be of the form $N = pq$, with p and q of approximately the same size. A can follow our confirming protocol in order to prove to any other user that $N \in \boldsymbol{BL}$ and $\nu(N) = 2$. For these applications, we assume that the residuosity problem is intractable.

When A communicates with another user B, any element $z \in \mathbf{Z}_N^*(+1)$ can serve as an encoding of the bit $\mathrm{RES}_N(z)$, as soon as A has used our protocol to prove to B the value of this bit. According to need, z can be chosen by A or by both A and B together (say, by flipping coins). Because of the result-indistinguishability of the protocol, this encoding is cryptographically secure.

In contrast, the conventional approach to hiding knowledge from an eavesdropper is to use encryption. (For example, given two different protocols, one for membership in a language L and the other for nonmembership in L, one could "pad" the protocols so that they both caused messages of the same length to be sent at each round of communications, and then encrypt all messages.) However, in this approach, proving a theorem about the security of the protocol against eavesdroppers usually requires an assumption about the security of the encryption scheme used.

The result-indistinguishability of our protocol suggests two different ways that it can be used in a public-key encryption scheme that is secure against chosen-ciphertext attack.

(1) A sequence of random elements $z_1, z_2, \cdots$ can serve as a probabilistic encryption [16] of the bit-sequence $\mathrm{RES}_N(z_1), \mathrm{RES}_N(z_2), \cdots$, which in turn can be used as a one-time pad to encode a message sent either from A to B or from B to A.

(2) Instead of using the z_i directly to encrypt the bits $\mathrm{RES}_N(z_i)$, we can define a much more efficient scheme for probabilistic encryption by using a short bit-sequence $\mathrm{RES}_N(z_1), \mathrm{RES}_N(z_2), \cdots$ as the random seed for a cryptographically secure pseudorandom bit generator [5], [27], [6] whose security may be based on the unknown factorization of N (e.g., [3], [4]). Sharing the seed, A and B can efficiently generate polynomially many bits and use them as a (very long) one-time pad with which to send messages back and forth. The pad bits alone are secure against any polynomially bounded adversary; furthermore, the adversary gains no computational advantage in guessing any pad bit when he is given probabilistic encryptions of the bits of the seed, nor when he is allowed to overhear the protocol interactions that define these encrypted bits. Because our protocol is only used in order to initialize the system, this scheme has low amortized cost.

Whether the bits $\mathrm{RES}_N(z_i)$ are used directly or to form the seed of a pseudorandom bit generator, the resulting schemes have the minimum-knowledge property with respect to B as well as with respect to an eavesdropper C. In particular, they are provably secure against both chosen-message and chosen-ciphertext attack. For precise definitions of levels of cryptographic security, and for further study of the power that interaction seems to add to public-key cryptography, see [13], [10].

Another application of our protocol gives a new private unbiased coin-flip, generated jointly by A and B. The two users simply choose z at random—for example, choosing its bits by means of Blum's coin-flip. Note that the bits of z are public; it is $\mathrm{RES}_N(z)$, the result of the coin-flip, which is private.

In certain applications we can omit the confirming proof that N is of the required form. Suppose in fact that N has more than two prime factors. For any $z \in \mathbf{Z}_N^*(+1)$, A can carry out the deciding protocol as before. Now, however, if y and z—both quadratic nonresidues in $\mathbf{Z}_N^*(+1)$—have different quadratic character modulo several

of the prime factors of N, then A can distinguish numbers of the form r^2 from numbers of the form $yr^2 \bmod N$ and can distinguish each of these from numbers of the form $zr^2 \bmod N$. (This is not true if $\nu(N) = 2$; recall that for such N any nonresidue in $\mathbf{Z}_N^*(+1)$ is a nonresidue modulo both prime factors of N.) Thus A can, at will, use our deciding protocol to "prove" to B either that z is a residue or that z is a nonresidue. In either case, the interactively proved value of $\mathrm{RES}_N(z)$—whether or not it is the true value—is cryptographically secure. This value gives B no knowledge whatever. The "proof" only convinces B that A can distinguish between numbers with different quadratic characters mod N, without releasing to B any information about the quadratic character mod N of any particular number. (This can be formalized in terms of a simulator $\mathrm{M} = \mathrm{M}_{\mathrm{B}^*}$ for any given verifier B*. Note that at the beginning of the program for M given in the proof of Theorem 2, we can replace the oracle query for $\mathrm{RES}_N(z)$ with a simple coin-flip; then exactly as in that proof, the two sets

$$VIEW_{\mathrm{B}^*}\{(\mathrm{A}, \mathrm{B})[(N, z), h]\}$$

and

$$\mathrm{M}[(N, z), h]$$

are identical.) Thus, we may say that in this case, the protocol is result-indistinguishable even with respect to B.

In this situation, when N has more than two prime factors, we can define the following game: A picks a random nonresidue z with quadratic character different from that of y. A then "proves" to user B_1 that $\mathrm{RES}_N(z) = b_1$, and "proves" to user B_2 that $\mathrm{RES}_N(z) = b_2$. The "proven" value of $\mathrm{RES}_N(z)$ in each execution of the protocol is shared only by the prover A and the verifier B_1 or B_2. In fact, user B_1 has absolutely no computational advantage in deciding whether or not $b_1 = b_2$, and neither does user B_2.

8. Conclusions. Approaching knowledge from the point of view of computational complexity, we have studied the interactive transmission of computational results. The protocol that we introduce gives a proof of the value, 0 or 1, of a number-theoretic predicate, $\mathrm{RES}_N(\cdot)$. In a sense that we make precise (extending the definitions of [17]), the verifier gains no more knowledge from an execution of the protocol than this value; this is the "minimum-knowledge" property of the protocol. Furthermore, we are able to analyze the difference between the knowledge gained by the active verifier and that gained by a passive eavesdropper of equal computational power; the protocol is "result-indistinguishable," in that an eavesdropper gains no knowledge at all by overhearing the messages passed during an execution.

Recent work on minimum-knowledge protocols has taken several different directions. Feige, Fiat, and Shamir adapted the result-indistinguishable protocol of this paper (originally presented in [11]) and the protocols of [17] in order to give an efficient minimum-knowledge (and therefore cryptographically secure) identification scheme [9]. Their paper proposes a formalization, similar to that of Tompa and Woll [26], of the notion that a protocol can supply a "proof" that the prover knows some fact or possesses some computational ability, while completely hiding this piece of knowledge. (For example, in case N has more than two prime factors, our deciding proof-system for $\mathrm{RES}_N(\cdot)$ may be regarded as demonstrating the prover's ability to distinguish between numbers with different quadratic characters mod N; see § 7.)

Goldreich, Micali, and Wigderson proved that, under the assumption that one-way functions exist, every language in NP has a minimum-knowledge confirming interactive proof-system; this result has important consequences for the design of cryptographic

protocols [14]. Under the assumption that certain number-theoretic computations are infeasible, a similar result was proved by Brassard and Crepeau, both for prover and verifier as described in this paper [7], and for the dual situation in which a resource-bounded prover interacts with a verifier of unlimited computational power [8]. (Our formalization of the requirement that a two-party transfer protocol be minimum-knowledge applies to protocols that depend on such "cryptographic assumptions;" and under the appropriate assumption, the concatenation lemma of § 3.2 holds in the cryptographic setting.) Impagliazzo and Yung gave a construction for the direct minimum-knowledge transfer of the result of any given computation (both for the usual and for the dual model of the computational power of the prover and the verifier); the dual protocol is implemented under the more general assumption that any of a large class of one-way functions exist [20]. Their construction applies to probabilistic as well as deterministic computations, and in particular it provides a minimum-knowledge interactive proof-system for any language possessing a confirming interactive proof-system at all (i.e., for any language in the complexity class IP [1], [18]).

In a recent paper, instead of considering only protocols for transferring a computational result from one party to another, Yao studied a broad class of two-party protocols for what may be called "crytographic computation," in which the (polynomially bounded) users combine their private inputs in order to compute private outputs in a minimum-knowledge fashion, preserving the privacy of these inputs and outputs and hiding partial computational results as much as possible; it may also be required that both users compute their final results simultaneously [28]. Under the asssumption that factoring is hard, Yao showed how to design such a protocol for any given cryptographic computation problem. Continuing this work, Goldreich, Micali, and Wigderson proved similar results for multiparty protocols, assuming that one-way trapdoor functions exist, and showed how such protocols could be made to tolerate faults [15]. Galil, Haber, and Yung simplified and extended these constructions for cryptographic computation, giving new methods for the design of fault-tolerant multiparty cryptographic protocols [12].

In summary, the complexity-theoretic approach to measuring and controlling the knowledge transmitted in various distributed and cryptographic settings has proved to be a useful tool in protocol design.

Acknowledgments. We would like to thank Silvio Micali and Charles Rackoff for their helpful discussions, and Paul Beame, Gilles Brassard, Joan Feigenbaum, Shafi Goldwasser, David Lichtenstein and Adi Shamir for their insightful remarks.

Note added in proof. The concatenation lemma of § 3.2 was proved independently in Y. Oren, *On the cunning power of cheating verifiers: Some observations about zero-knowledge proofs*, Proc. 28th Annual IEEE Symposium on the Foundations of Computer Science, 1987, pp. 462–471, and in [26].

AN OPTIMAL SYNCHRONIZER FOR THE HYPERCUBE*

DAVID PELEG† AND JEFFREY D. ULLMAN‡

Abstract. The synchronizer is a simulation methodology introduced by Awerbuch [*J. Assoc. Comput. Math.*, 32 (1985), pp. 804-823] for simulating a synchronous network by an asynchronous one, thus enabling the execution of a synchronous algorithm on an asynchronous network. In this paper a novel technique for constructing network synchronizers is presented. This technique is developed from some basic relationships between synchronizers and the structure of a *t-spanning subgraph* over the network. As a special result, a synchronizer for the hypercube with optimal time and communication complexities is obtained.

Key words. distributed computation, networks, synchronization, spanners

AMS(MOS) subject classifications. 68R10, 68M10

1. Introduction. Algorithms for synchronous networks are easier to design, debug, and test than similar algorithms for asynchronous networks. Consequently, it is desirable to have a uniform methodology for transforming an algorithm for synchronous networks into an algorithm for asynchronous networks. This tool will enable one to design an algorithm for a synchronous network, test it and analyze it in that simpler environment, and then use the standard methodology to transform the algorithm into an asynchronous one, and use it in the asynchronous network.

This general approach for handling asynchrony was introduced by Awerbuch in [A1], and referred to as a *synchronizer.* His paper proposes several specific methods for implementing a simulation of this type, and studies their complexities. Later Awerbuch [A2] demonstrated the surprising fact that despite the inevitable overheads involved in such a simulation, asynchronous algorithms designed in this way are sometimes more efficient than any previously known. This is mainly due to the inherent difficulty in reasoning about an asynchronous network, which sometimes makes it hard to reach an optimal solution for a problem directly in such an environment. This phenomenon was demonstrated on several graph problems, such as breadth-first-search and maximum flow [A2], for which algorithms obtained by combining a standard synchronous algorithm with a synchronizer yield an asynchronous algorithm with better performance (in terms of time and/or number of messages) than all previously known ones.

It is clear that every synchronizer incurs some time and communication costs for the synchronization of every round. Let us denote the time and communication requirements added by a synchronizer ν for each pulse (timestep) of the synchronous algorithm by $T(\nu)$ and $C(\nu)$, respectively. Clearly, an efficient synchronizer should keep these costs as low as possible. In [A1], Awerbuch presents three synchronizers, α, β, and γ. These synchronizers demonstrate a certain trade-off between their communication and time requirements.

The first two simple synchronizers represent the two endpoints of this trade-off. Synchronizer α is time optimal, i.e., $T(\alpha) = O(1)$, but its communication complexity is $C(\alpha) = O(|E|)$. On the other hand, synchronizer β achieves an optimal number of messages (i.e., $C(\beta) = O(|V|)$), but its time requirement may be high, namely, $T(\beta) = O(D)$. Here V, E, and D denote the set of vertices, the set of edges, and the diameter of the network, respectively. (Note that these complexities are crucial since they represent the overhead *per pulse* of the synchronous algorithm.) The third, more involved synchronizer γ is a combination of the two previous ones, which achieves some reasonable middle points on this scale. In particular, it is possible to achieve $C(\gamma) = O(k|V|)$ and $T(\gamma) = O(\log_k |V|)$, where k is a parameter taken from the range $2 \leqq k < |V|$.

Awerbuch also proves some lower bounds which demonstrate that for some networks, the best possible improvements are within constant factors from synchronizer γ [A1], [A3]. However, this lower bound is not global, and for various networks one can do better. For example, note that for the class of bounded-degree networks, synchronizer α is optimal in both time and messages, since $|E| \in O(|V|)$. This covers many common architectures proposed for parallel computing, such as meshes, butterflies and cube-connected cycles, rings, etc. The same holds also for the class of trees and planar graphs in general. Likewise, for bounded-diameter networks, synchronizer β is optimal. Thus the problem remains interesting only for graph classes that are in between.

A notable example of a network for which the current solutions are not satisfactory is the hypercube (cf. [P], [U]). It is possible to construct synchronizers of type α, β or γ for the hypercube using the constructions of [A1], but the resulting complexities are not optimal. Furthermore, in the sequel we note that the hypercube has an even better synchronizer of type γ, which can be obtained by direct construction (rather than by using the algorithm of [A1]) and whose complexities are $T = O(\log \log V)$ and $C = O(V)$, which is still not optimal. The main result of this paper is the construction of an optimal synchronizer (with $T = O(1)$ and $C = O(|V|)$) for the hypercube.

On our way toward this goal, we introduce a novel general methodology for a synchronizer (that we term δ, for purposes of consistency). This methodology is developed by exploiting the close connection between synchronizers and the structure of a *t-spanner* on a network. Given a network $G = (V, E)$, a subgraph $G' = (V, E')$ is a *t-spanner* of G if for every $(u, v) \in E$, the distance between u and v in G' is at most t.

In the sequel we derive the following basic connections between t-spanners and synchronizers.

THEOREM 1. (1) *If the network G has no t-spanner with at most m edges, then every synchronizer ν for G requires either $T(\nu) \geqq t+1$ or $C(\nu) \geqq m+1$.*

(2) *If the network G has a t-spanner with m edges, then it has a synchronizer δ with $T(\delta) = O(t)$ and $C(\delta) = O(tm)$.* □

In fact, the lower bounds of [A1], [A3] implicitly use part (1) of Theorem 1.

We then proceed to prove the existence of a 3-spanner with a linear ($O(2^n)$) number of edges for the hypercube of dimension n (henceforth, the n-cube). This yields the desired optimal synchronizer for the hypercube.

THEOREM 2. *For every $n \geqq 0$, the n-cube has a synchronizer of type δ with optimal time and communication complexities $T(\delta) = O(1)$ and $C(\delta) = O(2^n)$.* □

Spanners turn out to have other applications in the area of communication networks, e.g., in designing memory-efficient routing strategies (cf. [PU]). Additional results on the existence of spanners for various graph classes can be found in [PS].

The rest of the paper is organized as follows. Section 2 contains the definitions of the synchronous and asynchronous models, and § 3 gives an overview of the basic structure of a synchronizer. Finally, in § 4 we discuss the relationships between synchronizers and t-spanners and prove Theorem 1, and in § 5 we construct an optimal synchronizer of type δ for the hypercube and thus prove Theorem 2.

2. The model. We consider the standard model of an asynchronous point-to-point communication network (e.g., [A1], [GHS]). The network is described by an undirected graph $G=(V, E)$. The nodes of the graph represent the processors of the network and the edges represent bidirectional communication channels between the processors.

All the processors have distinct identities. There is no common memory, and algorithms are event-driven (i.e., processors cannot access a global clock in order to decide on their action). Messages sent from a processor to its neighbor arrive within some finite but unpredictable time. Each message contains a fixed number of bits, and therefore carries only a bounded amount of information.

A synchronous network is a variation of the above model in which all link delays are bounded. More precisely, each processor keeps a local clock, whose pulses must satisfy the following property. A message sent from a processor v to its neighbor u at pulse p of v must arrive at u before pulse $p+1$ is generated by u.

Our complexity measures are defined as follows. The *communication complexity* of an algorithm A, C_A, is the worst-case total number of messages sent during the run of the algorithm. The *time complexity* of an algorithm A, T_A, is defined as follows. For a synchronous algorithm, T_A is the number of pulses generated during the run. For an asynchronous algorithm, T_A is the worst-case number of time units from the start of the run to its completion, assuming that each message incurs a delay of at most one time unit. This assumption is used only for performance evaluation, and does not imply that there is a bound on delay in asynchronous networks.

Next, let us formally define the hypercube of dimension n, $H_n=(V_n, E_n)$. This network is defined by $V_n=\{0, 1\}^n$ and

$$E_n=\{(x, y)\,|\,x, y\in V_n, x \text{ and } y \text{ differ in exactly one bit}\}.$$

The network has $|V_n|=2^n$ nodes, $|E_n|=n\cdot 2^{n-1}$ edges, and diameter n.

Finally, let us define the *Cartesian product* of two graphs. Let $G_1=(V_1, E_1)$ and $G_2=(V_2, E_2)$. The Cartesian product of G_1 and G_2, denoted $G_1\times G_2$, is defined as

$$G_1\times G_2=(V_1\times V_2, E)$$

where

$$E=\{((u_1, v_1), (u_2, v_2))\,|\,(u_1=u_2 \text{ and } (v_1, v_2)\in E_2) \text{ or } (v_1=v_2 \text{ and } (u_1, u_2)\in E_1)\}.$$

Hence $G_1\times G_2$ is constructed by substituting a copy of G_2 for each vertex in G_1 and drawing in edges between corresponding nodes of adjacent copies.

The H_n hypercube can be viewed as the Cartesian product graph $H_n=H_{n-k}\times H_k$, for any $0\leqq k\leqq n$. Later, we make use of this characterization of the cube.

3. Synchronizers. Th synchronizer is intended to enable any synchronous algorithm to run on any asynchronous network. The goal of the simulation is to generate a sequence of local clock pulses at each processor of the network, satisfying the following property: pulse number p is generated by a processor only after it received all the messages of the algorithm sent to it by its neighbors during their pulse number $p-1$.

This property is easy to guarantee as long as we restrict our attention to synchronous algorithms with complete communication, i.e., algorithms that require every processor to send messages to every neighbor at every time pulse. The obvious problem with

partial communication algorithms is that in the case where processor v does not send any message to its neighbor u at a certain pulse, u is obliged to wait forever for a message, as link delays in the asynchronous network are unpredictable.

The conceptual solution proposed in [A1] consists of two additional phases of communication. The first phase simply requires every processor receiving a message from a neighbor to send back an acknowledgment. This way, every processor learns, within finite time, that all the messages it sent during a particular pulse have arrived. Such a processor is said to be *safe* with respect to that pulse. Note that introducing this phase does not increase the message complexity or the time complexity of the algorithm by more than a constant factor.

A processor may generate a new pulse whenever it learns that all its neighbors are safe with respect to the current pulse. Thus the second and main phase of the synchronizer involves delivering this "safety" information. This phase is thus responsible for the additional time and message requirements, denoted earlier by $C(\nu)$ and $T(\nu)$, for a synchronizer ν.

The complexities of a synchronous algorithm S are related to those of the asynchronous algorithm A resulting from combining S with a synchronizer ν by $C_A = C_S + T_S \cdot C(\nu)$ and $T_A = T_S \cdot T(\nu)$. (We ignore, for the purposes of the present discussion, any additional costs of an initialization phase that may be needed for setting up the synchronizer.)

Let us demonstrate these ideas by giving a brief description of the three synchronizers introduced in [A1]. Synchronizer α is the simplest. After the execution of a certain pulse, when a processor learns that it is safe, it simply reports this fact directly to all its neighbors. Thus the behavior and complexity of this synchronizer boil down to those of an algorithm in which every processor sends messages to every neighbor in every pulse, so $C(\alpha) = O(|E|)$ and $T(\alpha) = O(1)$.

For synchronizer β we assume the existence of a rooted spanning tree in the network. After the execution of a certain pulse, the safety information is collected "bottom-up" on the tree, by means of a communication pattern termed *convergecast*; whenever a processor learns that it and all its descendants in the tree are safe, it reports this fact to its parent. Eventually the root learns that all the processors in the network are safe, and then it broadcasts this fact along the tree, letting the processors start a new pulse. Since the process is carried out on the tree, the complexities of synchronizer β are $C(\beta) = O(|V|)$ and $T(\beta) = O(H)$, where H is the height of the tree. In the worst case $H = O(|V|)$ too.

The last synchronizer, γ, ahieves a certain trade-off between the previous ones. For synchronizer γ we assume that the network is partitioned into *clusters*. The partition is defined by a rooted spanning forest of the graph, where each tree in the forest defines a cluster. Between any two neighboring clusters there is one designated *preferred link* that serves for communication between them.

The safety information is handled by synchronizer γ in three steps. In the first step, each cluster separately applies the synchronizer β. By the end of this step, every processor knows that its cluster is safe (i.e., every processor in the cluster is safe). In the second step, every processor incident to a preferred link sends a message to the other cluster, saying that its cluster is safe. Finally, the third step is a repetition of the first, except the convergecast performed in each cluster carries a different information: whenever a processor learns that all the clusters neighboring it or any of its descendants are safe, it reports this fact to its parent. Again, when the root learns that all the neighboring clusters are safe, it broadcasts this fact along the tree, letting the processors of the cluster start a new pulse.

The complexities of synchronizer γ are $C(\gamma) = O(E_p)$ and $T(\gamma) = O(H_p)$, where E_p is the number of all tree links and all preferred links in a partition P, and H_p is the maximum height of a tree in the forest of P. Thus our goal is to find partitions with small values of E_p and H_p.

Let us now describe a simple partition for product graphs, and state the resulting complexities of a synchronizer γ based on this partition. Partition a product graph $G_1 \times G_2$ by defining each copy of G_2 as a cluster. Let D_2 denote the diameter of G_2. Then G_2 has a spanning tree of depth D_2. This spanning tree can be used to define the whole forest, as all the clusters have identical structure. Between every two clusters there are $|V_2|$ edges, but only one of them need be chosen as a preferred link. Thus an overall of $|E_1|$ preferred links are used. The number of edges used in the trees is $|V_1|(|V_2|-1)$. Thus, the time and communication complexities of the resulting synchronizer of type γ are $T = O(D_2)$ and $C = O(|E_1| + |V_1| \cdot |V_2|)$, respectively. (Alternatively, noting the symmetric role of G_1 and G_2 in the definition of the Cartesian product, we may reverse our view of the two graphs and obtain another partition, yielding the complexities $T = O(D_1)$ and $C = O(|E_2| + |V_1| \cdot |V_2|)$.)

The construction described above immediately suggests a way to handle the hypercube. For any chosen k, $0 \leqq k \leqq n$, view H_n as the product $H_n = H_{n-k} \times H_k$ and partition H_n as described earlier. This yields a synchronizer of type γ for H_n with time and communication complexities $T = O(k)$ and $C = O((n-k)2^{n-k} + 2^n)$, respectively. In particular, selecting $k = \lfloor \log n \rfloor$, we get $T = O(\log \log |V_n|)$ and $C = O(|V_n|)$. This complexity is already better than that of a synchronizer γ based on any partition obtained by using the partitioning algorithm of [A1]. However, it is still not optimal. To achieve an optimal synchronizer we need to develop a new technique, discussed in the next section.

4. Synchronizers and t-spanners. In this section we prove the two parts of Theorem 1. This amounts to showing two complementary relationships between t-spanners and synchronizers. On the one hand, the nonexistence of a t-spanner of a certain size implies a lower bound on the complexities of any synchronizer for the network. On the other hand, the existence of a t-spanner can be used for constructing a synchronizer of a new type, δ.

THEOREM 1 (Part (1)). *If the network G has no t-spanner with at most m edges, then every synchronizer ν for G requires either $T(\nu) \geqq t+1$ or $C(\nu) \geqq m+1$.*

Proof. Let us assume that the network $G = (V, E)$ has no t-spanner of m edges, and yet it has a synchronizer ν with $C(\nu) \leqq m$, i.e., using m or fewer messages per pulse. The argument is similar to that of the lower bounds of [A1], [A2]. The requirement from the synchronizer is to ensure that a processor does not produce a new pulse before it gets all the messages sent to it in the previous pulse. Thus, between every two consecutive pulses there must be some transfer of information between each pair of neighbors in the network. Otherwise, the completely asynchronous nature of the network will force these neighbors to wait forever for a message that may still be on its way. Consider the set E' of edges through which the messages of the synchronizer were sent. The information flow between every pair of neighbors in G has to go through the edges of E'. Since only m or fewer messages were sent, the number of these edges is at most m. Therefore by hypothesis, the subgraph $G' = (V, E')$ is not a t-spanner. This implies that there is an edge $(u, v) \in E$ such that the distance between u and v in G' is at least $t+1$. Thus, the information flow between u and v may require $t+1$ time units, so the time complexity of the synchronizer ν is at least $t+1$. □

THEOREM 1 (Part (2)). *If the network G has a t-spanner with m edges, then it has a synchronizer δ with $T(\delta) = O(t)$ and $C(\delta) = O(tm)$.*

Proof. Assume that the network $G=(V, E)$ has a t-spanner $G'=(V, E')$ of m edges. The synchronizer δ for G is constructed as follows. The safety information is transmitted over the spanner in rounds which may be viewed as "subpulses." When a processor v learns that it is safe, it sets a counter c to 0 and sends the message "safe" to all its neighbors *in the spanner.* Then it waits to hear a similar message from all these neighbors. Upon receiving a "safe" message from all neighbors (again—in the spanner), it increases its counter and repeats the process (i.e., it sends the message "safe" again, and then waits for similar messages and so on). This is done for t rounds. When $c=t$, the processor v may generate its next pulse. □

LEMMA 4.1. *When v holds $c=i$, every processor u at distance i or less from v in G' is safe.*

Proof. By induction on i. For $i=0$ the claim is immediate, as v reaches this stage of the synchronizer only after it is safe itself. Now consider the time when v increases c to $i+1$. This is done after v received $i+1$ "safe" messages from every neighbor in G'. These neighbors each sent the $(i+1)$st message only after having $c=i$. Thus, by the inductive hypothesis, for every such neighbor u, every processor w at distance i or less from u in G' is safe. Thus every processor w at distance $i+1$ or less from v in G' is safe too. □

COROLLARY 4.2. *When v holds $c=t$, every neighbor of v in G is safe.*

Proof. By the lemma, when v holds $c=t$, every processor u at distance i from v in G' is safe. By the definition of t-spanners, every neighbor of v in G is at distance t or less from v in G'. Thus every such neighbor is safe. □

It is clear that the time delay of synchronizer δ is at most $O(t)$, and the number of additional messages is $O(mt)$. Thus the proof is complete. □

The synchronizers of [A1] do not use spanners explicitly, and their formulations are quite different from our synchronizer δ. Nevertheless it is interesting to note that their underlying structure is strongly related to the notion of spanners. For instance, synchronizer α is based essentially on the fact that every graph is its own 1-spanner, and the construction algorithm of [A1] for synchronizer γ establishes the fact that every graph has an $O(\log_k |V|)$-spanner with $O(k|V|)$ edges, where $1<k<|V|$ is a parameter.

5. An optimal synchronizer δ for the hypercube. In this section we show how to construct a 3-spanner for the hypercube H_n with a linear $[O(2^n)]$ number of edges. This in turn implies an optimal synchronizer δ and thus proves our Theorem 2.

A *dominating set* for a graph G is a subset U of vertices with the property that for every vertex v of G, U contains either v itself or some neighbor of v.

To construct dominating sets, we make use of the notion of a Hamming code, a well-known idea from coding theory (cf. [H]). Since the Hamming code is so central to what we do, we review its definition and properties. The reader familiar with Hamming codes can skip directly to Lemma 5.1.

A string of 0's and 1's is a *word.* The *product* of two code words of the same length is their bitwise logical "and;" their *sum* is their bitwise exclusive "or." For example, the product of 0011 and 0101 is 0001, and their sum is 0110. The *weight* of a code word is the number of 1's in the word.

For any integer r, the Hamming code $HC(r)$ is defined by making reference to a matrix of 0's and 1's with r rows and 2^r-1 columns. The columns are all the binary integers from 1 up to 2^r-1. For example, here is the matrix used to define $HC(3)$:

$$M_3=\begin{bmatrix}0&0&0&1&1&1&1\\0&1&1&0&0&1&1\\1&0&1&0&1&0&1\end{bmatrix}.$$

The *code words* in $HC(r)$ are all those words of length 2^r-1 whose product with each of the rows of the defining matrix M_r has even weight. For example, 0000000 and 0101010 are code words of $HC(3)$. Word 0000000 has a product with each row of M_r that has weight 0, while 0101010 has products of weight 2, 2, and 0, respectively.

The *distance* between two words is the weight of their sum. Put another way, the distance is the number of positions in which the two words differ. For example, each pair of rows of M_r has distance 4.

An important and easily proved fact about Hamming codes is that the sum of two code words is also a code word. As a consequence, the Hamming codes have minimum distance 3; that is, no two code words have distance less than 3. In proof, let u and v be code words, and let w be their sum, which is also a code word. If the weight of w were 1, then since the product of w with every row of M_r has even weight, those products would have to have weight 0; i.e., the one column in which w has a 1 would have all 0's in M_r. Since there is no such column, w cannot have weight 1. Similarly, if w had weight 2, we could argue that two columns of M_r would have to be identical, which is not the case.

Now, let the *neighborhood* of a code word be that word plus all words of distance 1. Then in $HC(r)$, all neighborhoods have 2^r members. No word can be in the neighborhood of two code words, or else those code words would be of distance 2.

The last fact we need about Hamming codes is that $HC(r)$ has exactly 2^{2^r-1-r} members. The argument is that the rows of M_r can be thought of as independent vectors in the vector space of 2^r-1 dimensions over the field of two elements. $HC(r)$ is thus the null space of the vector space (of dimension r) whose basis is the rows of M_r, and therefore $HC(r)$ is of dimension 2^r-1-r.

The number of words in the neighborhood of some code word of $HC(r)$ is thus $2^r \times 2^{2^r-1-r}$, or 2^{2^r-1}. This is exactly the number of binary words of length 2^r-1. Thus, every binary word of length 2^r-1 is in the neighborhood of exactly one code word of $HC(r)$. Put another way, $HC(r)$ is a dominating set for the hypercube H_{2^r-1}.

LEMMA 5.1. *For every $n \geqq 1$, the n-cube has a dominating set of at most $2^{n+1}/n$ nodes.*

Proof. Let us first consider the case of $n = 2^r-1$ for some $r \geqq 1$. Let U be the Hamming code $HC(r)$. As we have argued above, U is a dominating set for the n-cube, and $|U| = 2^n/(n+1) \leqq 2^{n+1}/n$.

Now consider an arbitrary $n \geqq 1$. Let r be the integer satisfying $2^r-1 \leqq n < 2^{r+1}-1$ and let $d = 2^r-1$. Note that $n/2 \leqq d$. Let U_d be a dominating set for the d-cube. View the n-cube as the Cartesian product $H_n = H_{n-d} \times H_d$, and let $U = \{(x, y) \mid x \in V_{n-d}, y \in U_d\}$, where V_{n-d} is the set of vertices of H_{n-d}. Clearly U is a dominating set for the n-cube, and its size is

$$2^{n-d}|U_d| = 2^{n-d}\frac{2^d}{d+1} = \frac{2^n}{d+1} \leqq \frac{2^{n+1}}{n}. \qquad \square$$

We finally construct a spanner for the n-cube. The cases $n = 1, 2$ can easily be verified directly, so assume $n \geqq 3$. Our construction uses dominating sets for some of the subcubes of our hypercube. Consider an n-cube H_n, and let $p = \lfloor n/2 \rfloor$ and $q = \lceil n/2 \rceil$. View H_n as the Cartesian product $H_p \times H_q$. Let U_1 and U_2 be minimum-size dominating sets for H_p and H_q, respectively.

We define the subgraph $G' = (V_n, E')$ by choosing the following sets of edges:

(1) Every edge $((x, y), (x, y'))$ subject to $(y, y') \in E_q$ and $y' \in U_2$.
(2) Every edge $((x, y), (x', y))$ subject to $(x, x') \in E_p$ and $x' \in U_1$.
(3) Every edge $((x, y), (x, y'))$ subject to $(y, y') \in E_q$ and $x \in U_1$.
(4) Every edge $((x, y), (x', y))$ subject to $(x, x') \in E_p$ and $y \in U_2$.

LEMMA 5.2. *G' has fewer than $7 \cdot 2^n$ edges.*

Proof. By the previous lemma $|U_1| \leqq 2^{p+1}/p$ and $|U_2| \leqq 2^{q+1}/q$. Therefore the number of edges $(y, y') \in E_q$ with $y' \in U_2$ is at most $q|U_2| \leqq 2^{q+1}$, and so the number of edges of the first type is at most $2^p 2^{q+1} = 2^{n+1}$. Similarly the number of edges of the second type is at most 2^{n+1}. For the third type we get the bound $|U_1| \cdot |E_q| \leqq (2^{p+1}/p) \cdot q \cdot 2^{q-1} \leqq (q/p) \cdot 2^n$, and similarly of the fourth type there are at most $|U_2| \cdot |E_p| \leqq (p/q) \cdot 2^n$ edges. (This simple counting ignores multiple occurrences of certain edges in the various types, which in fact implies a slightly smaller bound.) Since $n \geqq 3$, $p/q + q/p < 3$, so overall we get a bound of fewer than $7 \cdot 2^n$ edges ($6 \cdot 2^n$ for even n). □

LEMMA 5.3. *G' is a 3-spanner of the n-cube.*

Proof. Consider two neighboring vertices u, v in H_n. Let $u = (x, y)$ where $x \in \{0, 1\}^p$. Then either $v = (x, y')$ for some neighbor y' of y in H_q or $v = (x', y)$ for some neighbor x' of x in H_p. Suppose the first case holds. If $x \in U_1$ then G' contains the edge (u, v) itself (type 3). Otherwise, G' contains the following edges:

(1) $e_1 = ((x, y), (x', y))$ for some $x' \in U_1$ (type (2)).

(2) $e_2 = ((x', y), (x', y'))$ (type (3)).

(3) $e_3 = ((x', y'), (x, y'))$ (type (2)).

These three edges constitute a path of length 3 in G' connecting u and v. The second case is handled similarly, using edges of types (1) and (4). □

COROLLARY 5.4. *For every $n \geqq 0$ the n-cube has a 3-spanner of fewer than $7 \cdot 2^n$ edges.* □

Finally, using Theorem 1 together with the last corollary, we have Theorem 2, which we restate below.

THEOREM 2. *For every $n \geqq 0$, the n-cube has a synchronizer of type δ with optimal time and communication complexities $T(\delta) = O(1)$ and $C(\delta) = O(2^n)$.* □

We note that the relatively large constant involved in the construction implies that the new synchronizer improves on the simple synchronizer α only for large n. A more careful analysis of Lemma 5.2 reveals improvements for some values of n beginning around $n \geqq 18$.

Acknowledgments. We wish to thank Alex Schäffer for helpful discussions.

SPACE-TIME TRADE-OFFS FOR ORTHOGONAL RANGE QUERIES*

PRAVIN M. VAIDYA†

Abstract. This paper investigates the question of (storage) space-(retrieval) time trade-off for orthogonal range queries on a static data base. Each record in the data base consists of a key that is a d-tuple of integers, and a data value that is an element in a commutative semigroup G. An orthogonal range query is specified by a d-dimensional parallelepiped (box). Two types of response to such a query are considered: one where the output is the semigroup sum of the data values whose keys are located in the query parallelepiped, and the other where the output is a list of all the records whose keys lie in the query parallelepiped. This paper studies two models, the arithmetic model and the tree model and obtains lower bounds on the product of retrieval time and storage space in both models.

Key words. range queries, space-time trade-offs, lower bounds

1. Introduction.

Consider a data base that contains a collection of records, each with a key and a number of data fields. Given a range query, which is specified by a set of constraints on the keys, the data base system is expected to return the set of records, or a function of the set of records whose keys satisfy all the constraints. If the data base is static the collection of records may be preprocessed to achieve a balance between the storage utilized and the time required to answer a query. There is an extensive literature [1], [2], [4], [8], [9], [11], [12] on algorithms for range query, and the space and time requirements have traditionally been used as performance measures for such algorithms. In this paper, we investigate the question of (storage) space-(retrieval) time trade-off for orthogonal range queries on a static data base.

Let G be a commutative semigroup with an addition operation $+$. Let d be a fixed positive integer. Let $N=\{1, 2, \cdots, n\}$ and let N^d denote the set of all d-tuples of positive integers less than or equal to n. A record $(k, f(k))$ is a pair of key $k \in N^d$ and datum $f(k) \in G$. The data base consists of n such records. Let $k=(k_1, k_2, \cdots, k_d)$. An orthogonal range query is specified by a $2d$-tuple $(x_{11}, x_{12}, x_{21}, x_{22}, \cdots, x_{d1}, x_{d2})$ of positive integers satisfying $x_{i1} < x_{i2}$, $1 \leqq i \leqq d$. Alternately, the query region for an orthogonal range query is a parallelepiped (box) b, defined by the product $[x_{11}, x_{12}) \times [x_{21}, x_{22}) \times \cdots \times [x_{d1}, x_{d2})$ of d-semiclosed intervals with positive integer endpoints. A key k is said to be located in a box $b=[x_{11}, x_{12}) \times [x_{21}, x_{22}) \times \cdots \times [x_{d1}, x_{d2})$ if and only if $x_{i1} \leqq k_i < x_{i2}$, $1 \leqq i \leqq d$. We consider two types of response to such a query, one where the output is the sum of the data $f(k)$ whose keys k are located in the query parallelepiped (box) b, and the other where the output is a list of all the records whose keys lie in the query parallelepiped b.

Let $Q(b)$ denote the input $2d$-tuple corresponding to query box b, and let K denote the set of keys in the data base. As we shall be studying space-time requirements for orthogonal range query only, we shall assume that the set of query regions is fixed to be the set of boxes.

A space-time trade-off seeks to answer questions such as what is the minimum amount of storage needed to ensure a certain query time? The trade-off between space

and time is dependent on the model of data structure and the set of records in the data base. We fix the data structure model and then try to obtain a set of records that makes this trade-off as bad as possible. Thus the lower bounds on space-time products are to be interpreted as worst-case bounds, i.e., there exists a set of n records whose space-time product has the said bounds.

We study two models. In Model A, we work in the general framework defined by Fredman [5]-[7], and consider only data structures and manipulation algorithms that are independent of the choice of the semigroup G. So the set K of keys in the data base together with the set of query regions completely specifies the problem. Given a query box b, the query answering algorithm is expected to return the semigroup sum of the data values whose keys are located in b. Model A is an arithmetic model with unit cost for each arithmetic operation but no cost for memory retrieval. In this model, we show that for orthogonal range query on a static database with n records, there is a space-time trade-off $(\log T)^{d-1}TS \geqq \Omega(n(\log n)^{d-\theta})$, where $\theta = 1$ for $d = 2$, and $\theta = 2$ for $d \geqq 3$. Space-time trade-offs for circular range query and interval query in this model are studied by Yao in [13] and [14]. We note that for $d = 2$ the results of Yao [14] are considerably stronger for this model; specifically he shows that for a restricted type of range query $T = \Omega(\log n/(\log(S/n) + \log\log n))$ for $d = 2$. The complexity of dynamic range queries in this model is discussed by Fredman in [5]-[7].

In Model B (tree model), we study a broad class of tree data structures. In this model, a data structure is a rooted tree, and with each edge in the tree is associated a condition. Given a query, the query answering algorithm starts with the root, and visits a vertex v if and only if the given query satisfies the conjunction of the conditions on the path from the root to v. The output corresponding to a given query is a function of the data associated with the visited vertices. Several standard data structures, such as linked lists, range trees, etc. [1], [2], [4], [8], [9], [11], [12], fit into this model. In Model B, we investigate the orthogonal reporting problem where the response to a query is a list of all the records in the data base whose keys are located in the query box. Since the output size is query dependent, the time required to answer a query is not the correct measure of the overhead involved in producing the desired response to the query. So we define a scaled query time T' that measures the overhead for producing one unit of output. For the orthogonal reporting problem on a static data base with n records, we show that there is a space-time trade-off $(\log T' + \log\log n)^{d-1}T'S \geqq \Omega(n(\log n)^{d-\theta})$, where $\theta = 1$ for $d = 2$, and $\theta = 2$ for $d \geqq 3$.

The results in this paper for Model A (arithmetic model) have been significantly strengthened by Chazelle using a different technique [3].

2. An overview.

2.1. Model A. Arithmetic model. In this model [5], [6], [7], a data structure is an infinite array Z of variables $z_0, z_1, z_2, \cdots$, that stores elements from the commutative semigroup G. Given any input query, the query answering algorithm chooses a collection of at most T variables in the array and returns their semigroup sum as the response to the query. Since only arithmetic operations are charged, the query time is T. The data structure is assumed to be independent of the specific semigroup G and so the mapping between elements in G and variables in Z is determined solely by the set K of n keys in the data base. With each variable z_i in Z is associated a subset h_i of K, and the data value $\sum_{k \in h_i} f(k)$ is stored in z_i, where $f(k)$ is the data value associated with k. Let $H \subseteq 2^K$ such that every set in H is associated with some variable in Z and every variable in Z is associated with some set in H. Let R be the set of all possible query boxes, and let $P(K, H, T)$ be the property that for each $b \in R$, $b \cap K$ is expressible

as the disjoint union of at most T sets in H. (The lower bounds in this paper are valid even if disjoint union is replaced by union in the definition of $P(K, H, T)$.) The query answering algorithm works correctly if and only if $P(K, H, T)$ is satisfied. The storage space S is defined by

$$S = \max_{K} \min_{H \text{ satisfying } P(K,H,T)} |H|.$$

The following theorem summarizes the results in this model.

THEOREM 1. *In Model* A, *for orthogonal range query on a static database with n records, there is a space-time trade-off* $(\log T)^{d-1} TS \geq \Omega(n(\log n)^{d-\theta})$, *where* $\theta = 1$ *for* $d = 2$, *and* $\theta = 2$ *for* $d \geq 3$.

The proof is based on Lemma 1 given below. The lemma asserts that there exists a set K of n keys and a large enough set $B(T, n)$ of query parallelepipeds such that the subsets of K induced by members of $B(T, n)$ satisfy certain intersection conditions. The proof of Lemma 1 is given in § 4.

LEMMA 1. *There is a set K of n keys and a set $B(T, n)$ of boxes satisfying the following properties*:

(1) $(\log T)^{d-1} T|B(T, n)| = \Omega(n(\log n)^{d-\theta})$, *where* $\theta = 1$ *for* $d = 2$, *and* $\theta = 2$ *for* $d \geq 3$.

(2) *For distinct* b_1, b_2, *in* $B(T, n)$, $|b_1 \cap b_2 \cap K| < 1/T \min\{|b_1 \cap K|, |b_2 \cap K|\}$.

Using property (2) in Lemma 1, we show that for any H satisfying $P(K, H, T)$, we must have $|H| \geq |B(T, n)|$. Then Theorem 1 follows from the lower bound on $|B(T, n)|$ given by property (1) in Lemma 1. Let b_1, b_2, be distinct boxes in $B(T, n)$. As $b_1 \cap K$ is expressible as the union of at most T sets in H, there exists $h_1 \in H$ such that $|h_1| \geq (1/T)|b_1 \cap K|$ and $h_1 \subseteq (b_1 \cap K)$. Since $|(b_1 \cap K) \cap (b_2 \cap K)| < (1/T)|b_1 \cap K|$, h_1 cannot appear in the decomposition of $b_2 \cap K$ as the union of members of H. So with each b_i in $B(T, n)$ we can associate a distinct h_i in H.

2.2. Model B. Tree model. In the case of the reporting problem the output size is dependent on the given query, and so the arithmetic model is not suitable for investigating this problem. So we study the tree model for data structures. In this model, the data structure is assumed to be a rooted tree. With each vertex v is associated a set of data items and we let $data(v)$ denote the set of data items associated with vertex v. With each edge in the tree is associated a condition. Given an input query in the form of a tuple of numbers, the query answering algorithm first visits the root. A vertex v is visited if and only if it is a son of some vertex u that has already been visited and the input tuple satisfies the condition associated with edge uv. We define $cond(v)$ to be the conjunction of all the conditions on the path from the root to vertex v. Thus for any query box b, on being given the corresponding tuple $Q(b)$ as input, the query answering algorithm visits vertex v if and only if $Q(b)$ satisfies $cond(v)$. The response to a query is a function of the data at the visited vertices.

In the tree model, we investigate the orthogonal reporting problem where the response to a given query is a list of all the records in the data base whose keys lie in the query box. Let $\hat{G}$ be a semigroup consisting of a single element. We shall restrict the universe of records so that the data in each record is the unique element from $\hat{G}$. We shall only consider sets of records which are such that no two records in a set have the same key. Then the set K of keys completely specifies the set of records, and the orthogonal reporting problem is to produce a list of all the keys in K that lie in the given query box. Note that considering this special case does not cause any loss of generality as the lower bounds obtained in the special case trivially extend to the general case. Let r be a fixed constant. We restrict ourselves to trees where every vertex

has degree at most r. The condition associated with each edge in the tree is restricted to be a disjunction of at most r binary comparisons. Thus $cond(v)$, the conjunction of the conditions on the path from the root to v, is now a conjunction of disjunctions of comparisons. For each vertex v, $data(v)$ is a set of keys. Vertices may share storage, so $data(v)$ is effectively the set of records accessed via vertex v.

Consider a fixed set K of keys, and a fixed tree for K. For a query box b, let $U(b)$ be the set of all those vertices v such that $Q(b)$ satisfies $cond(v)$. Given a query box b, the query answering algorithm visits all the vertices in $U(b)$, and extracts the set of keys $\bigcup_{v \in U(b)} data(v)$. The set of keys $b \cap K$ is then obtained by explicitly testing for each key in $\bigcup_{v \in U(b)} data(v)$ whether the key is located in b. Thus filtering search [2] is included in this model. Let $T(b)$ be the time required to answer the query corresponding to b. $T(b)$ is lower bounded by $|U(b)| + |\bigcup_{v \in U(b)} data(v)|$. Since the output size is query dependent, the time required to answer a query is not the correct measure of the overhead involved in producing the desired response to the query. With respect to a fixed set K of keys, and a fixed tree for K, we define a scaled query time T' as follows:

$$T' = \max_{1 \leqq |b \cap K| \leqq \log_2 n} \frac{T(b)}{|b \cap K|}.$$

For a fixed set of keys, the storage S is defined to be the minimum number of vertices a corresponding tree must have to ensure a scaled query time of T'.

At this point we remark that several common data structures, such as linked lists, range trees, etc. [1], [2], [4], [8], [9], [11], [12], fit into the tree model. Also note that the tree model restricts the manner in which data records are accessed; it does not place a restriction on how the data is stored. As long as there is a fixed tree that defines how the data in the data structure is accessed, and a node in this tree corresponds to a distinct unit of storage in the data structure, the data structure would still fit into the tree model; it would not matter that the data structure itself was not a tree.

THEOREM 2. *In the tree model, for the orthogonal reporting problem on a static data base with n records, there is a space-time trade-off* $(\log T' + \log\log n)^{d-1} T' S \geqq \Omega(n(\log n)^{d-\theta})$, *where* $\theta = 1$ *for* $d = 2$, *and* $\theta = 2$ *for* $d \geqq 3$.

The proof of Theorem 2 is based on Lemma 2 below. A proof of Lemma 2 is given in § 4.

LEMMA 2. *Let c_1 and c_2 be constants dependent on the dimension d. There exists a set of K of n keys that has a subset K' satisfying the following properties*:

(1) $|K'| \geqq c_1 n$.

(2) *With respect to a particular tree for K, let $V(k)$ be the set of all those vertices v that satisfy the conditions* (i) *key* $k \in data(v)$; *and* (ii) *there is a box b such that $Q(b)$ satisfies $cond(v)$ and* $1 \leqq |b \cap K| \leqq \kappa(d, n)$, *where* $\kappa(d, n) = 1$ *for* $d = 2$ *and* $\kappa(d, n) = \log_2 n$ *for* $d \geqq 3$. *Then for each tree for K, for each key* $k \in K'$, $|V(k)| \geqq (\log_2 n)^{d-1} / c_2 (\log_2 T' + \log_2 \log_2 n)^{d-1}$.

Let K be a set of n keys and K' be a subset of K such that K and K' satisfy the conditions in Lemma 2. Consider a fixed tree for K. For a key k, let $V(k)$ be as defined in Lemma 2. We must have that

$$\sum_{k \in K'} |V(k)| \leqq \sum_{v \in \bigcup_{k \in K'} V(k)} |data(v)|.$$

For each vertex v in $\bigcup_{k \in K'} v(k)$, $|data(v)| \leqq \kappa(d, n) T'$, since v is visited by a query corresponding to a box containing at most $\kappa(d, n)$ keys. Then from properties (1) and

(2) in Lemma 2 it follows that

$$\left| \bigcup_{k \in K'} V(k) \right| \geq \frac{c_1 n (\log_2 n)^{d-1}}{c_2 \kappa(d, n) T' (\log_2 T' + \log_2 \log_2 n)^{d-1}}.$$

Thus the storage S for a set K of n keys satisfying the conditions in Lemma 2 must obey the following constraint:

$$S \geq \frac{c_1 n (\log_2 n)^{d-1}}{c_2 \kappa(d, n) T' (\log_2 T' + \log_2 \log_2 n)^{d-1}}.$$

3. Canonical parallelepipeds and almost uniform distributions. We shall utilize a special class of parallelepipeds (boxes) in obtaining the desired space-time trade-offs. Let n be a power of 2 and let $I_l = \{[j2^l + 1, (j+1)2^l + 1): 0 \leq j < (n/2^l)\}$. I_l is the set of intervals obtained by breaking up $[1, n+1)$ into $n/2^l$ semiclosed intervals of equal size, each interval being closed on the left and open on the right. Let $I = I_0 \cup I_1 \cup \cdots \cup I_{\log_2 n}$. Then I is defined to be the set of canonical intervals, and I^d is defined to be the set of canonical parallelepipeds, or equivalently canonical boxes.

For a box b, we use $[\pi_{i1}(b), \pi_{i2}(b))$ to denote the interval that is the projection of box b onto to the ith coordinate axis. Equivalently, for $1 \leq i \leq d$, $\pi_{i1}(b)$ and $\pi_{i2}(b)$ denote the $(2i-1)$st and the $(2i)$th components of the $2d$-tuple $Q(b)$ corresponding to box b. For a box b, *dimensions*(b) is defined to be the d-tuple $((\pi_{12}(b) - \pi_{11}(b)), (\pi_{22}(b) - \pi_{21}(b)), \cdots, (\pi_{d2}(b) - \pi_{d1}(b)))$. We note that since I contains intervals of $\log_2 n + 1$ distinct lengths, the total number of choices possible for the dimensions of a canonical box is $(\log_2 n + 1)^d$. Let *vol*(b) denote the volume of a box b, and let $p(x) = 2^{\lceil \log_2 x \rceil}$. Let J be the canonical parallelepiped $J_0 \times J_1 \times \cdots \times J_{d-1}$ where $J_i = [2i(2p(d))^{-1} n + 1, (2i+1)(2p(d))^{-1} n + 1)$, for $0 \leq i \leq d-1$. The following lemmas list the properties of canonical boxes that we shall require.

LEMMA 3. *The number of canonical boxes of identical dimensions and of volume* 2^i *is* $n^d / 2^i$.

LEMMA 4. *Let* $0 \leq i \leq (\log_2 n / d^2)$. *Then the number of possibilities for the dimensions of a canonical box of volume* $2^i n^{d-1}$ *is* $\Omega((\log_2 n / d^2)^{d-1})$, *and at most* $(\log_2 n + d)^{d-1}$.

Proof. The number of nonnegative integer solutions to

$$j_1 + j_2 + \cdots + j_d = i + (d-1) \log_2 n,$$

$$\text{subject to} \quad 0 \leq j_l \leq \log_2 n, \quad 1 \leq l \leq d, \quad i \leq (\log_2 n / d^2)$$

is at least $(\log_2 n / d^2)^{d-1}$ for large enough n, and at most $(\log_2 n + d)^{d-1}$ for any i in the desired range. That gives the required bound on the number of possibilities for the dimensions of a canonical box of volume $2^i n^{d-1}$. □

LEMMA 5. *Let* $b_1, b_2, \cdots, b_\rho$ *be canonical boxes of volume* α *such that* $\bigcap_{i=1}^{\rho} b_i \neq \emptyset$. *Then* $vol(\bigcap_{i=1}^{\rho} b_i) \leq \alpha 2^{1 - \rho^{1/(d-1)}}$.

Proof. For $1 \leq m \leq d$, let

$$L_m = \{[\pi_{m1}(b_j), \pi_{m2}(b_j)): 1 \leq j \leq \rho\}.$$

The intervals in L_m can be ordered by containment, and the ratio of the lengths of the largest and the smallest intervals in L_m is $2^{|L_m|-1}$. Let $|L_m^*| = \max_m |L_m|$. By pigeonholing, $|L_m^*| \geq \rho^{1/(d-1)}$. Then

$$vol\left(\bigcap_{i=1}^{\rho} b_i \right) \leq \alpha 2^{1 - |L_m^*|} \leq \alpha 2^{1 - \rho^{1/(d-1)}}.$$

□

LEMMA 6. *Let $\hat{b}$ be a fixed canonical box of volume α. Then the number of canonical boxes b of volume α which satisfy the condition $vol(b \cap \hat{b}) \geqq 2^{-j} vol(\hat{b})$ is at most $(2j+d+1)^{d-1}$.*

Proof. Since $vol(b \cap \hat{b}) \geqq 2^{-j} vol(\hat{b})$ and $vol(b) = vol(\hat{b})$, for each m, $1 \leqq m \leqq d$, either $[\pi_{m1}(b), \pi_{m2}(b))$ contains $[\pi_{m1}(\hat{b}), \pi_{m2}(\hat{b}))$ or $[\pi_{m1}(\hat{b}), \pi_{m2}(\hat{b}))$ contains $[\pi_{m1}(b), \pi_{m2}(b))$, and

$$2^{-j} \leqq \frac{\pi_{m2}(b) - \pi_{m1}(b)}{\pi_{m2}(\hat{b}) - \pi_{m1}(\hat{b})} \leqq 2^{j}.$$

Thus for $1 \leqq m \leqq d$, there are at most $(2j+1)$ possibilities for the mth interval defining box b, and as the volume of the boxes b is fixed to be α the total number of possibilities for the boxes b is bounded by $(2j+d+1)^{d-1}$. □

Having described canonical boxes, we shall proceed to almost uniform distributions of n keys. The distributions are termed almost uniform because the number of keys in a canonical box does not deviate too far from the volume of the box divided by n^{d-1}. For $d=2$, we can explicitly construct such distributions, and thereby get Theorem 3. For $d \geqq 3$, we have to resort to counting arguments and show that the number of distributions of n keys, which do not satisfy the properties in Theorem 4, is less than the total of n^{dn} possible distributions.

THEOREM 3. *For $d=2$, there is a set K of n keys such that for each canonical box b,*

$$\left\lfloor \frac{vol(b)}{n^{d-1}} \right\rfloor \leqq |b \cap K| \leqq \left\lceil \frac{vol(b)}{n^{d-1}} \right\rceil.$$

Proof. It is adequate to obtain a set K of n keys such that each canonical box of volume n contains exactly one key. We use an inductive construction. Let x_1 and x_2 denote the two attributes of a key. Let K_m denote a set of m keys satisfying the conditions in Theorem 3. We shall obtain K_{2m} from K_m. Let

$$K'_m = \{(2x_1 - 1, x_2) : (x_1, x_2) \in K_m\}$$

and

$$K''_m = \{(2x_1, x_2 + m) : (x_1, x_2) \in K_m\}.$$

We let $K_{2m} = K'_m \cup K''_m$. A canonical box of volume $2m$ and x_1 dimension equal to 1 contains exactly one key, as each key has a distinct value for x_1. Let $b = [x_{11}, x_{12}) \times [x_{21}, x_{22})$ be a canonical box of volume m corresponding to $n = m$, and let $b_1 = [2x_{11} - 1, 2x_{12} - 1) \times [x_{21}, x_{22})$ and $b_2 = [2x_{11} - 1, 2x_{12} - 1) \times [x_{21} + m, x_{22} + m)$. Then b_1 and b_2 are canonical boxes of volume $2m$ corresponding to $n = 2m$. If $(x_1, x_2) \in b \cap K_m$ then $(2x_1 - 1, x_2) \in b_1 \cap K'_m$ and $(2x_1, x_2 + m) \in b_2 \cap K''_m$, and b_1, b_2 do not contain any other key in K_{2m}. Furthermore, all canonical boxes corresponding to $n = 2m$, of volume $2m$ and x_1 dimension at least 2, may be derived in this manner from canonical boxes of volume m corresponding to $n = m$. □

THEOREM 4. *Let σn^{dn} be the number of distinct sets K of n keys, each key in N^d, that satisfy the three properties given below. Then σ tends to 1 as n tends to ∞ and $\sigma = (1 - o(1/n))$.*

(1) *Let $a(n) = 2p(\log_2 n)$. For each canonical box b,*

$$\left\lfloor \frac{vol(b)}{a(n) n^{d-1}} \right\rfloor \leqq |b \cap K| < 6a(n) \left\lceil \frac{vol(b)}{a(n) n^{d-1}} \right\rceil.$$

(2) *Each canonical box of volume n^{d-1} contains at most $\log_2 n$ keys.*

(3) $|J \cap K| \geqq (n/(4(2p(d))^{2d})) = n/4(c_3)^2$.

Proof. The total number of possible key distributions (sets) K is n^{dn}. Let F_1, F_2, and F_3, be the fraction of distributions that do not satisfy properties (1), (2), and (3), in Theorem 4, respectively. We shall show that each of F_1, F_2, and F_3, is $o(1/n)$.

To bound F_1 note that, if there is a canonical box whose volume is not equal to $a(n)n^{d-1}$ and that violates property (1) above, then there is necessarily a canonical box of volume $a(n)n^{d-1}$ that violates property (1) in the same manner. Let F_{11} be the fraction of distributions K such that there is a canonical box of volume $a(n)n^{d-1}$ that does not contain a key in K, and let F_{12} be the fraction of distributions K such that some canonical box of volume $a(n)n^{d-1}$ contains at least $6a(n)$ keys in K. Then $F_1 \leqq F_{11} + F_{12}$. A bound on F_{11} may be obtained by noting that there are at most $n(\log_2 n + d)^{d-1}$ choices for a canonical box of volume $a(n)n^{d-1}$ and all the keys in K must lie outside the chosen canonical box. Thus

$$\begin{aligned} F_{11} &\leqq n(\log_2 n + d)^{d-1}\left(1 - \frac{a(n)}{n}\right)^n \\ &\leqq O(n(\log n)^{d-1} e^{-a(n)}) \\ &= o\left(\frac{1}{n}\right). \end{aligned}$$

An upper bound on F_{12} is obtained by observing that we may choose a canonical box of volume $a(n)n^{d-1}$ in at most $n(\log_2 n + d)^{d-1}$ ways, and we may choose $6a(n)$ keys to lie in the chosen box and then let the remaining keys be located anywhere in $[1, n+1)^d$. Then

$$\begin{aligned} F_{12} &\leqq n(\log_2 n + d)^{d-1}\binom{n}{6a(n)}\left(\frac{a(n)}{n}\right)^{6a(n)} \\ &\leqq n(\log_2 n + d)^{d-1}\frac{(a(n))^{6a(n)}}{6a(n)!} \\ &\leqq n(\log_2 n + d)^{d-1}\left(\frac{e}{6}\right)^{6a(n)} \cdots \quad \text{(using Stirling's approximation)} \\ &= o\left(\frac{1}{n}\right). \end{aligned}$$

Thus

$$F_1 \leqq F_{11} + F_{12} = o(1/n) + o(1/n) = o(1/n).$$

A bound F_2 is obtained as follows. A canonical box of volume n^{d-1} may be chosen in at most $n(\log_2 n + d)^{d-1}$ ways; then $\log_2 n$ keys may be selected to lie in the chosen box, and the remaining keys may lie anywhere in $[1, n+1)^d$. Thus,

$$\begin{aligned} F_2 &\leqq n(\log_2 n + d)^{d-1}\binom{n}{\log_2 n} n^{-\log_2 n} \\ &\leqq \frac{n(\log_2 n + d)^{d-1}}{(\log_2 n)!} \\ &= o\left(\frac{1}{n}\right). \end{aligned}$$

To bound F_3, we choose $(1-4^{-1}c_3^{-2})n$ points to lie outside the canonical box J, and let the remaining points be located anywhere in $[1, n+1)^d$. Furthermore, the volume of J is n^d/c_3. Thus

$$F_3 \leqq \left(\frac{n}{(1-4^{-1}c_3^{-2})n}\right)\left(1-\frac{1}{c_3}\right)^{n(1-4^{-1}c_3^{-2})}.$$

Using Stirling's approximation for factorials and taking logarithms we get

$$\log_e F_3 \leqq \frac{n}{4c_3^2}\left(\log_e (4c_3^2)+(4c_3^2-1)\log_e\left(1-\frac{4c_3-1}{4c_3^2-1}\right)\right)+O(\log n).$$

Then noting that $\log_e (1-x) \leqq -x$ for $0 < x \leqq 1$, we get

$$\log_e F_3 \leqq \frac{n}{4c_3^2}(\log_e (4c_3^2)+1-4c_3)+O(\log n)$$

$$\leqq -\frac{7n}{4c_3^2}+O(\log n) \quad \text{as } c_3 \geqq 16.$$

Thus $F_3 = o(1/n)$. □

4. Proofs of lemmas. In this section we give proofs of Lemmas 1 and 2 used to prove Theorems 1 and 2 in §§ 2.1 and 2.2, respectively. For the purposes of this section we shall let the set K of keys be fixed. For $d=2$ let K be a fixed set of n keys as specified by Theorem 3, and for $d \geqq 3$ let K be a fixed set of n keys as specified by Theorem 4. We assume that n is a power of 2. Let $\beta(\alpha)$ denote the set of canonical boxes of volume α, and let β_J denote the set of those canonical boxes that are also subboxes of J (for definition of J see § 3).

Proof of Lemma 1. We shall give a proof for $d \geqq 3$, the proof for $d=2$ is similar. Let $\chi(T) = (64T(2p(d))^{2d})$. Let $B(T, n)$ be the largest set of boxes satisfying the following conditions:

(1) For all $b \in B(T, n)$, $b \in \beta(\chi(T)a(n)n^{d-1})$, and $|b \cap K| \geqq 6Ta(n)$.

(2) For any two boxes b_1 and b_2 in $B(T, n)$, $vol(b_1 \cap b_2) \leqq a(n)n^{d-1}$.

By Theorem 4, the number of keys in K located in a canonical box of volume $\chi(T)a(n)n^{d-1}$ is at most $6\chi(T)a(n)$. It is then easily shown that the number of boxes in $\beta(\chi(T)a(n)n^{d-1})$ that have identical dimensions and that contain at least $6Ta(n)$ keys is $\Omega(n/(T\log_2 n))$. Then from Lemmas 4 and 6 in § 3, we can conclude that $|B(T, n)| = \Omega(n/T\log_2 n(\log_2 n/\log_2 T)^{d-1})$. The intersection of any two distinct boxes b_1, b_2 in $B(T, n)$ is a canonical box of volume at most $(a(n)n^{d-1})$ and so by Theorem 4, $|b_1 \cap b_2 \cap K| < 6a(n) < (1/T)\min\{|b_1 \cap K|, |b_2 \cap K|\}$. □

In Model B, as we restrict ourselves to binary comparisons, the only possible comparisons are those between two components of the input tuple, and those between a component of the input tuple and a constant. We shall focus on canonical boxes that are subboxes of the canonical box J. For each box $b \subseteq J$, the input tuple $Q(b) = (x_{11}, x_{12}, x_{21}, x_{22}, \cdots, x_{d1}, x_{d2})$ is such that $x_{11} < x_{12} < x_{21} < x_{22} < \cdots < x_{d1} < x_{d2}$, and so a comparison between two components of the input tuple has the same outcome for each subbox b of J. Then, in Model B we need to analyze only comparisons between a component of the input tuple and a constant. We note that, if the input tuple satisfies a comparison between x_j, the (j)th component of the tuple, and a constant, when x_j takes on the value z_1 as well as when x_j takes on the value z_2, then the input tuple satisfies the comparison whenever x_j takes on any value between z_1 and z_2. The following lemma follows directly from these observations.

LEMMA 7. *Let b_1 and b_2 be subboxes of J. Let C be a conjunction of binary comparisons, and let both $Q(b_1)$ and $Q(b_2)$ satisfy C. Let b be a subbox of J such that either $\pi_{ij}(b_1) \leqq \pi_{ij}(b) \leqq \pi_{ij}(b_2)$ or $\pi_{ij}(b_2) \leqq \pi_{ij}(b) \leqq \pi_{ij}(b_1)$, for $1 \leqq i \leqq d$, $1 \leqq j \leqq 2$. Then the tuple $Q(b)$ also satisfies C.* □

LEMMA 8. *Let t be an integer greater than 1, let γ be an integer greater than 0, and let m be an integer such that $1 \leqq m \leqq d$. Let $C = \neg(C_1 \vee C_2 \vee \cdots \vee C_{t-1})$, where each of C_i, $1 \leqq i \leqq t-1$, is a conjunction of comparisons. Let $b_1, b_2, \cdots, b_{t+1}$ be distinct canonical boxes satisfying the following conditions:*

(1) *For all i, $1 \leqq i \leqq t+1$, $b_i \in (\beta_J \cap \beta(\alpha))$.*

(2) *Each of the tuples $Q(b_1), Q(b_2), \cdots, Q(b_{t+1})$ satisfies condition C.*

(3) *For all i, $1 \leqq i \leqq t+1$, $\pi_{m2}(b_i) - \pi_{m1}(b_i) = \pi_{m2}(b_1) - \pi_{m1}(b_1)$.*

(4) *For all i, $1 \leqq i \leqq t$, $\pi_{m1}(b_{i+1}) - \pi_{m2}(b_i) \geqq \gamma(\pi_{m2}(b_1) - \pi_{m1}(b_1))$.*

Then there are at least γ boxes b in $\beta_J \cap \beta(\alpha)$ such that $Q(b)$ satisfies condition C.

Proof. Let $\lambda([y_1, y_2), m, b)$ be the box obtained by replacing the mth interval defining box b by the interval $[y_1, y_2)$. Note that I is the set of canonical intervals. For $1 \leqq i \leqq t$, let

$$A_i = \{\lambda([y_1, y_2), m, b_i) : [y_1, y_2) \in I, y_2 - y_1 = \pi_{m2}(b_1) - \pi_{m1}(b_1), \pi_{m2}(b_i) \leqq y_1 < y_2 \leqq \pi_{m1}(b_{i+1})\}.$$

Then $|A_i| \geqq \gamma$, and each box in A_i is a subbox of J and a canonical box of volume α. There exists an i such that for each box b in A_i, $Q(b)$ satisfies C. Suppose this is not true. Then there exist boxes $\hat{b}_{i_1} \in A_{i_1}$, $\hat{b}_{i_2} \in A_{i_2}$, $1 \leqq i_1 < i_2 \leqq t$, such that both $Q(\hat{b}_{i_1})$ and $Q(\hat{b}_{i_2})$ satisfy C_l, for some l, $1 \leqq l \leqq t-1$. Then by Lemma 7 it follows that $Q(b_{i_2})$ must satisfy C_l and thereby not satisfy C which is a contradiction. □

Proof of Lemma 2. We shall give a proof for $d \geqq 3$, the proof for $d = 2$ may be constructed along similar lines. Fix a tree for the set of keys K. For the purposes of the proof we shall restrict ourselves to canonical boxes that are subboxes of J. Note that as K satisfies the conditions in Theorem 4 in § 3, a canonical box in $\beta(n^{d-1})$ contains at most $\log_2 n$ keys in K, and so the query time T for such a box cannot exceed $T' \log_2 n$. We shall show that if the conditions in Lemma 2 do not hold then there must be a canonical box $b \in \beta(n^{d-1})$ such that $Q(b)$ satisfies $cond(v)$ for more than $T' \log_2 n$ vertices v. Then the query time for b would exceed $T' \log_2 n$, and that would be a contradiction.

Let $|J \cap K| = c_5 n$, by Theorem 4 we know that such a c_5 exists. For each key $k \in J \cap K$, there are at least $c_4(\log_2 n)^{d-1}$ boxes in $\beta_J \cap \beta(n^{d-1})$ that contain k, for some constant c_4 dependent on d. Let $\delta = 2^d (T' \log_2 n + 1)^d (\log_2 n + 1)^{d+2}$, and let $\psi(T', n) = 2rc_5^{-1}(T')^2 \log_2 n + d)^{d+3}\delta$. Let c_6 be a large enough constant such that $(T' \log_2 n)^{c_6^{1/(d-1)}} \geqq 2^d (4\psi(T', n) + 6)^d$. The constants c_1 and c_2 in Lemma 2 are given by $c_1 = c_5/2$ and $c_2 = c_6/c_4$.

For each key $k \in K$, let

$$\tau(k) = \{b : b \in (\beta_J \cap \beta(n^{d-1})), k \in (b \cap K)\},$$

and let

$$\hat{V}(k) = \{v : k \in data(v), \exists b \in \tau(k) \quad \text{s.t.} \quad Q(b) \text{ satisfies } cond(v)\}.$$

We note that for each box $b \in \tau(k)$ there exists a vertex $v \in \hat{V}(k)$ such that $Q(b)$ satisfies $cond(v)$. For each $k \in J \cap K$, $|\tau(k)| \geqq c_4(\log_2 n)^{d-1}$, and $\hat{V}(k) \subseteq V(k)$, where $V(k)$ is the set of boxes defined in Lemma 2 in § 2.2.

Let K' be the largest subset of $J \cap K$ such that

$$\forall k \in K' \quad |\hat{V}(k)| \geq \frac{c_4(\log_2 n)^{d-1}}{c_6(\log_2 T' + \log_2 \log_2 n)^{d-1}}.$$

If $|K'| \geq c_5 n/2$ then the conditions in Lemma 2 are satisfied. So assume that $|(J \cap K) - K'| \geq c_5 n/2$. With each key k in $(J \cap K) - K'$ we can associate a distinguished vertex $\mu(k)$ and a distinguished set of canonical boxes $A(k)$ satisfying the following conditions:

(1) $|A(k)| \geq c_6(\log_2 T' + \log_2 \log_2 n)^{d-1}$.
(2) $A(k) \subseteq \tau(k)$.
(3) $\mu(k) \in \hat{V}(k)$.
(4) For all $b \in A(k)$, $Q(b)$ satisfies $cond(\mu(k))$.

The query time for a box in $\beta(n^{d-1})$ cannot exceed $T' \log_2 n$, and hence for all $k \in ((J \cap K) - K')$, $|data(\mu(k))| \leq T' \log_2 n$. Then $|\{\mu(k): k \in ((J \cap K) - K')\}| \geq c_5 n/2T' \log_2 n$. Let η be the set of all vertices v such that there are at least δ vertices in the set $\{\mu(k): k \in ((J \cap K) - K')\}$ that are also present in the subtree rooted at v. As the degree of each vertex in the tree is at most r (r a fixed constant), $|\eta| \geq c_5 n/2r\delta T' \log_2 n$.

For a vertex u, let $num(u)$ be the number of canonical boxes b such that $b \in \beta(n^{d-1})$ and $Q(b)$ satisfies $cond(u)$. Suppose we can show that for each vertex u in η, $num(u) \geq \psi(T', n)$. From the lower bound on the number of vertices in η it would follow that

$$\sum_{u \in \eta} num(u) \geq |\eta| \psi(T', n) > n(\log_2 n + d)^{d+1} T'.$$

Since $|\beta(n^{d-1})| \leq n(\log_2 n + d)^{d-1}$, we could then conclude that there is a $b \in \beta(n^{d-1})$ such that $Q(b)$ satisfies $cond(u)$ for at least $T' \log_2 n + 1$ vertices u in η, and that would be a contradiction.

Let u be an arbitrary vertex in η other than the root. We have to show that $num(u) \geq \psi(T', n)$. With u one can associate distinct keys $k_1, k_2, \cdots, k_\delta$ in $(J \cap K) - K'$, such that for each box b in $\bigcup_{i=1}^{\delta} A(k_i)$, $Q(b)$ satisfies $cond(u)$. Let $b(k_i) = \bigcap_{b \in A(k_i)} b$. Then for $1 \leq i \leq \delta$, $b(k_i) \in \beta_J$, and $b(k_i)$ contains key k_i. By Lemma 5, each of $b(k_i)$ has volume at most $n^{d-1}/(4\psi(T', n) + 6)^d$.

Among $b(k_1), b(k_2), \cdots, b(k_\delta)$ we can find $2^d(T' \log_2 n + 1)^d(\log_2 n + 1)$ distinct boxes of identical dimensions, say $b_1, b_2, \cdots, b_l$. This is possible since the number of possibilities for the dimensions of a canonical box is at most $(\log_2 n + 1)^d$, and by Theorem 4 each of $b(k_i)$ can contain at most $\log_2 n$ keys in K. Corresponding to $b_1, b_2, \cdots, b_l$, for $1 \leq m \leq d$, let

$$L_m = \{[\pi_{m1}(b_j), \pi_{m2}(b_j)): 1 \leq j \leq l\}.$$

All the intervals in L_m are of the same length, and any two intervals in L_m do not overlap. Let $t = T' \log_2 n$. Suppose that for some m, $1 \leq m \leq d$, there exist $t+1$ intervals $[\pi_{m1}(b_{j_1}), \pi_{m2}(b_{j_1})), [\pi_{m1}(b_{j_2}), \pi_{m2}(b_{j_2})), \cdots, [\pi_{m1}(b_{j_{t+1}}), \pi_{m2}(b_{j_{t+1}}))$, in L_m such that for $1 \leq q \leq t$, $\pi_{m1}(b_{j_{q+1}}) - \pi_{m2}(b_{j_q}) \geq \psi(T', n)(\pi_{m2}(b_{j_1}) - \pi_{m1}(b_{j_1}))$. To each of these $t+1$ intervals $[\pi_{m1}(b_{j_q}), \pi_{m2}(b_{j_q}))$ there corresponds a distinct box $\hat{b}_q$ such that $[\pi_{m1}(\hat{b}_q), \pi_{m2}(\hat{b}_q)) = [\pi_{m1}(b_{j_q}), \pi_{m2}(b_{j_q}))$, $\hat{b}_q \in (\beta_J \cap \beta(n^{d-1}))$, and $Q(\hat{b}_q)$ satisfies $cond(u)$. The pathlength from the root to u does not exceed $t-1$, and so we may apply Lemma 8 to these $t+1$ boxes and conclude that there are at least $\psi(T', n)$ boxes b in $\beta(n^{d-1})$ such that $Q(b)$ satisfies $cond(u)$.

We shall now show that there exists a required collection of $T' \log_2 n + 1$ intervals in some set L_m. Assume that such a collection of intervals does not exist. Then for each m, $1 \leqq m \leqq d$, all the intervals in the set L_m can be covered by $T' \log_2 n$ intervals, each of length at most $(2\psi(T', n)+3)(\pi_{m2}(b_1) - \pi_{m1}(b_1))$. Each of the $dT' \log_2 n$ covering intervals is closed on the left and open on the right, and has integer end points in the range 1 to $n+1$. It then follows that the boxes $b_1, b_2, \cdots, b_l$, are themselves contained in the union of $(T' \log_2 n)^d$ boxes, each of volume at most $(2\psi(T', n)+3)^d vol(b_1)$. As each of $b_1, b_2, \cdots, b_l$ contains a distinct key, and $l \geqq 2^d (T' \log_2 n + 1)^d (\log_2 n + 1)$, and $vol(b_1) \leqq (4\psi(T', n)+6)^{-d} n^{d-1}$, it follows that there is a box of volume at most n^{d-1} that contains at least $2^d(\log_2 n + 1)$ keys in K. This box of volume at most n^{d-1} can be covered by 2^d canonical boxes of volume n^{d-1}. Thus there must be a canonical box of volume n^{d-1} that contains at least $\log_2 n + 1$ keys in K, and since K is a set of keys satisfying the conditions in Theorem 4 this is not possible. □

5. Conclusion. We have obtained space-time trade-offs for orthogonal range query in two models, the arithmetic model and the tree model. Most data structures used in practice are rooted trees and so it may be worth studying more problems in the context of Model B. We conclude by raising questions related to the tree model.

(1) Drawing an analogy with decision trees, what happens when the conditions associated with tree edges are allowed to be comparisons involving linear or higher order polynomial functions of the input? Do the bounds weaken in such a situation?

(2) What kind of bounds can one obtain for queries other than orthogonal range query, say circular range query or polyhedral query?

(3) Can the lower bounds in the tree model be extended to data structures that are directed acyclic graphs?

A LOWER BOUND FOR MATRIX MULTIPLICATION*

NADER H. BSHOUTY†

Abstract. This paper proves that computing the product of two $n \times n$ matrices over the binary field requires at least $2.5\,n^2 - o(n^2)$ multiplications.

Key words. matrix multiplication, arithmetic complexity, lower bounds, linear codes

AMS(MOS) subject classifications. 15A63, 15A03, 68Q40

1. Introduction. Let $\mathbf{x} = (x_1, \cdots, x_n)^T$ and $\mathbf{y} = (y_1, \cdots, y_m)^T$ be column vectors of indeterminates. A straight-line algorithm for computing a set of bilinear forms in $\mathbf{x}$ and $\mathbf{y}$ is called *quadratic* (respectively, *bilinear*), if all its nonscalar multiplication are of the shape $l(\mathbf{x}, \mathbf{y}) \cdot l'(\mathbf{x}, \mathbf{y})$, (respectively, $l(\mathbf{x}) \cdot l'(\mathbf{y})$), where l and l' are linear forms of the indeterminates.[1]

In this paper we establish the new $2.5n^2 - o(n^2)$ lower bound on the multiplicative complexity of quadratic algorithms for multiplying $n \times n$ matrices over the binary field $\mathbf{Z}_2$. Let $M_{\mathbf{F}}(n, m, k)$ and $\bar{M}_{\mathbf{F}}(n, m, k)$ denote the number of multiplications required to compute the product of $n \times m$ and $m \times k$ matrices by means of quadratic and bilinear algorithms, respectively, over the field $\mathbf{F}$. It is known from [18], [19], and [7] that the complexity of quadratic algorithms for matrix multiplication is lower than that of bilinear algorithms, namely, $M_{\mathbf{Z}_2}(n, 2, 2) \leqq 3n + 2$, whereas $\bar{M}_{\mathbf{Z}_2}(n, 2, 2) \geqq 3.5n$. It has been proved in [1] that for any field $\mathbf{F}$

$$M_{\mathbf{F}}(n, n, n) \geqq 2n^2 - 1,$$

and for the case of binary field, it has been shown in [11] that

$$\bar{M}_{\mathbf{Z}_2}(n, n, n) \geqq 2n^2 + \left\lceil \frac{3}{46} n \right\rceil - 2.$$

Our bound on $M_{\mathbf{Z}_2}(n, n, n)$ is given by Theorem 1 below.

THEOREM 1. *We have*

$$M_{\mathbf{Z}_2}(n, n, n) \geqq 2.5n^2 - 0.5n \log n - O(n).$$

Obviously, the above bound holds for the ring of integers as well.

The rest of the paper is organized as follows. In the next section we give some basic definitions and preliminary results. The proof of Theorem 1 is presented in § 3.

2. Basic definitions and preliminary results. Let $\mathbf{A} = \{A_1, \cdots, A_p\}$ be a set of matrices. A *characteristic matrix of* $\mathbf{A}$ is the matrix $\mathbf{A}(\mathbf{z}) = \sum_{i=1}^{p} A_i z_i$ where $\mathbf{z} = (z_1, \cdots, z_p)^T$ is a vector of indeterminates. Conversely, let $\mathbf{A}(\mathbf{z}) = \sum_{i=1}^{p} z_i A_i$ be a matrix whose entries are linear combinations of $\{z_1, \cdots, z_p\}$. The set of matrices $\{A_1, \cdots, A_p\}$ will be denoted by $\mathbf{A}$. We denote by $\mu_{\mathbf{F}}(\mathbf{A}(\mathbf{z}))$ or $\mu_{\mathbf{F}}(\mathbf{A})$ the minimal number of nonscalar multiplications required to compute $\mathbf{x}^T A_1 \mathbf{y}, \cdots, \mathbf{x}^T A_p \mathbf{y}$ by a quadratic algorithm.

[1] It is known from [17] that over infinite fields we can restrict ourselves to quadratic algorithms without increasing the multiplicative complexity of a set of quadratic forms. For the finite fields, quadratic algorithms are optimal in the family of algorithms without division, (see [21]).

The characteristic matrix of the bilinear forms defined by the product of the $n \times m$ and $m \times k$ matrices

$$X_{n\times m} \cdot Y_{m\times k} = \begin{bmatrix} x_1 & x_{n+1} & \cdots & x_{(m-1)n+1} \\ x_2 & x_{n+2} & \cdots & x_{(m-1)n+2} \\ \vdots & \vdots & \vdots & \vdots \\ x_n & x_{2n} & \cdots & x_{mn} \end{bmatrix} \begin{bmatrix} y_1 & y_2 & \cdots & y_k \\ y_{k+1} & y_{k+2} & \cdots & y_{2k} \\ \vdots & \vdots & \vdots & \vdots \\ y_{(m-1)k+1} & y_{(m-1)k+2} & \cdots & y_{mk} \end{bmatrix}$$

is

$$\mathbf{A}_{n,m,k}(\mathbf{z}) = \left.\begin{bmatrix} \Phi_{n,k}(\mathbf{z}) & & \mathbf{0} \\ & \ddots & \\ \mathbf{0} & & \Phi_{n,k}(\mathbf{z}) \end{bmatrix}\right\} m \text{ times},$$

where

$$\Phi_{n,k}(\mathbf{z}) = \begin{bmatrix} z_1 & z_2 & \cdots & z_k \\ z_{k+1} & z_{k+2} & \cdots & z_{2k} \\ \vdots & \vdots & \vdots & \vdots \\ z_{(n-1)k+1} & z_{(n-1)k+2} & \cdots & z_{nk} \end{bmatrix}$$

(see [2]).

In [9] Hopcroft and Munsinski showed that

$$\bar{M}_{\mathbf{F}}(n, m, k) = \bar{M}_{\mathbf{F}}(n, k, m) = \bar{M}_{\mathbf{F}}(m, n, k).$$

Since $X_{n\times m} Y_{m\times k} = (Y^T_{m\times k} X^T_{n\times m})^T$ we have

$$M_{\mathbf{F}}(n, m, k) = M_{\mathbf{F}}(k, m, n).$$

Below we assume that $\mathbf{F} = \mathbf{Z}_2$ and omit the subscript $\mathbf{Z}_2$.

Let n be an integer. A *binary linear code* of length n is a linear subspace $\mathbf{C}$ of $\mathbf{Z}_2^n$. If $\dim \mathbf{C} = k$ then $\mathbf{C}$ is called $[n, k]$ code. For $c \in \mathbf{C}$ the *weight* of c, denoted by $\mathrm{wt}(c)$, is the number of the nonzero components of c. The *minimal weight* of $\mathbf{C}$ in $\min\{\mathrm{wt}(c) \mid c \in \mathbf{C} - \{\mathbf{0}\}\}$. We say that $\mathbf{C}$ is a *binary* $[n, k, d]$ *code* if $\mathbf{C} \subseteq \mathbf{Z}_2^n$ is a code of dimension k and minimal weight d. Let $N(k, d)$ be the smallest integer such that there exist a binary $[N(k, d), k, d]$ code. The connection between binary linear codes and the complexity of quadratic forms over $\mathbf{Z}_2$ is given in the following lemma.

LEMMA 1. *Let* $\mathbf{A} = \{A_1, \cdots, A_p\}$ *be a set of binary matrices and let* $L(\mathbf{A})$ *be the linear space spanned by* $\mathbf{A}$. *Let* $d = \min_{A \in L(\mathbf{A})} \operatorname{rank} A$ *and* $k = \dim L(\mathbf{A})$. *Then*

$$\mu_{\mathbf{F}}(\mathbf{A}) \geqq N(k, d).$$

In [2] Brockett and Dobkin proved Lemma 1 for bilinear algorithms. (See also [15].) The same proof is true for quadratic algorithms. This lemma was used in [3]–[12], and [14] to obtain lower bounds for some tensors rank.

Lemma 2 below gives a bound on $N(k, d)$.

LEMMA 2 (Griesmer Bound [13, p. 59]). *We have*

$$N(k, d) \geqq \sum_{i=0}^{k-1} \left\lceil \frac{d}{2^i} \right\rceil.$$

Another lower bound technique for quadratic algorithms is as follows.

LEMMA 3 ([21], [20], [10]). *Let* $\mathbf{A}(\mathbf{z}) = \mathbf{A}_1(\mathbf{z}_1) + \mathbf{A}_2(\mathbf{z}_2)$, *where* $\mathbf{z}_1$ *and* $\mathbf{z}_2$ *are distinct vectors of indeterminates of length* d_1 *and* d_2, *respectively. Then*

$$\mu_{\mathbf{F}}(\mathbf{A}(\mathbf{z})) \geqq \min_{N \in \mathcal{N}} \mu_{\mathbf{F}}[\mathbf{A}_1(\mathbf{z}_1) + \mathbf{A}_2(N\mathbf{z}_1)] + \dim L(\mathbf{A}_2),$$

where $\mathcal{N}$ *is the set of all* $d_2 \times d_1$ *matrices.*

For the polynomial $p(\lambda)=\lambda^n+a_{n-1}\lambda^{n-1}+\cdots+a_0\in \mathbf{Z}_2[\lambda]$ the *companion matrix* C_p of $p(\lambda)$ is defined by

$$C_p=\begin{bmatrix}0 & 0 & \cdots & 0 & -a_0\\ 1 & 0 & \cdots & 0 & -a_1\\ 0 & 1 & \cdots & 0 & -a_2\\ \vdots & \vdots & \vdots & \vdots & \vdots\\ 0 & 0 & \cdots & 1 & -a_{n-1}\end{bmatrix}.$$

We define the set of $n\times n$ matrices $\mathbf{A}^p$ by

$$\mathbf{A}^p=\{C_p^0, C_p^1, \cdots, C_p^{n-1}\}.$$

If $p(\lambda)$ is an irreducible polynomial, then $L(\mathbf{A}^p)=\{f(C_p)\,|\,f\in \mathbf{Z}_2[\lambda],\ \deg f\leqq n-1\}$, every matrix in $L(\mathbf{A}^p)$ is of rank n, and dim $L(\mathbf{A}^p)=n$. Let $p(\lambda)$ and $q(\lambda)$ be irreducible polynomials over $\mathbf{Z}_2$ of degree n and m, respectively, where $m\geqq n$. Let $\mathbf{0}_{j\times k}$ denote the zero $j\times k$ matrix.

Consider the matrix

$$\mathbf{C}(\mathbf{z})=\begin{bmatrix}\mathbf{A}^p(\mathbf{z}_0) & \mathbf{0}_{n\times n} & \cdots & \mathbf{0}_{n\times n} & \mathbf{0}_{n\times m}\\ \mathbf{E}_{1,1}(\mathbf{z}_{1,1}) & \mathbf{A}^p(\mathbf{z}_0) & \cdots & \mathbf{0}_{n\times n} & \mathbf{0}_{n\times m}\\ \mathbf{E}_{2,1}(\mathbf{z}_{2,1}) & \mathbf{E}_{2,2}(\mathbf{z}_{2,2}) & \cdots & \mathbf{0}_{n\times n} & \mathbf{0}_{n\times m}\\ \vdots & \vdots & \vdots & \vdots & \vdots\\ \mathbf{E}_{k-1,1}(\mathbf{z}_{k-1,1}) & \mathbf{E}_{k-1,2}(\mathbf{z}_{k-1,2}) & & \mathbf{A}^p(\mathbf{z}_0) & \mathbf{0}_{n\times m}\\ \mathbf{G}_1(\mathbf{z}_{k,1}) & \mathbf{G}_2(\mathbf{z}_{k,2}) & \cdots & \mathbf{G}_k(\mathbf{z}_{k,k}) & \mathbf{A}^q(\mathbf{z}_0)\end{bmatrix},$$

where $\mathbf{z}_0, \mathbf{z}_{1,1}, \cdots, \cdots, \mathbf{z}_{k,k}$ are distinct vectors of indeterminates $\mathbf{z}_0=(z_{0,1}, \cdots, z_{0,m})$,

$$\mathbf{A}^p(\mathbf{z}_0)=\sum_{i=1}^{n} C_p^{i-1}z_{0,i}, \qquad \mathbf{A}^q(\mathbf{z}_0)=\sum_{i=1}^{m} C_q^{i-1}z_{0,i},$$

$$\mathbf{E}_{i,j}(\mathbf{z}_{i,j})=\begin{bmatrix}z_{i,j,1,1} & \cdots & z_{i,j,1,n}\\ \vdots & \vdots & \vdots\\ z_{i,j,n,1} & \cdots & z_{i,j,n,n}\end{bmatrix}, \qquad \mathbf{G}_i(\mathbf{z}_{k,i})=\begin{bmatrix}z_{k,i,1,1} & \cdots & z_{k,i,1,n}\\ \vdots & \vdots & \vdots\\ z_{k,i,m,1} & \cdots & z_{k,i,m,n}\end{bmatrix}.$$

Let

$$\mathbf{C}^*(\mathbf{z})=I_w\otimes\mathbf{C}(\mathbf{z})=\begin{bmatrix}C(\mathbf{z}) & & & \mathbf{0}\\ & \ddots & & \\ & & w \text{ times} & \\ & & & \ddots\\ \mathbf{0} & & & C(\mathbf{z})\end{bmatrix},$$

where I_w is the identity matrix of order w and $\otimes$ is the Kronecker product of matrices. Then $L(\mathbf{C}^*)\subseteq L(\mathbf{A}_{nk+m,w,nk+m})$ and therefore

$$\mu_{\mathbf{F}}(\mathbf{C}^*)\leqq M(nk+m, w, nk+m). \tag{1}$$

The characteristic matrix $\mathbf{C}^*(\mathbf{z})$ can be written as

$$\begin{aligned}\mathbf{C}^*(\mathbf{z})&=\mathbf{C}'(\mathbf{z}^{(1)})+\mathbf{E}'(\mathbf{z}^{(2)})+\mathbf{G}'(\mathbf{z}^{(3)})+\mathbf{H}'(\mathbf{z}^{(4)})\\ &=I_w\otimes(\tilde{\mathbf{C}}(\mathbf{z}^{(1)})+\tilde{\mathbf{E}}(\mathbf{z}^{(2)})+\tilde{\mathbf{G}}(\mathbf{z}^{(3)})+\tilde{\mathbf{H}}(\mathbf{z}^{(4)})),\end{aligned}$$

where

$$\tilde{\mathbf{C}}(\mathbf{z}^{(1)}) = \begin{bmatrix} I_k \otimes \mathbf{A}^p(\mathbf{z}_0) & \mathbf{0} \\ \mathbf{0} & \sum_{i=1}^{n} z_{0,i} C_q^{i-1} \end{bmatrix},$$

$$\tilde{\mathbf{E}}(\mathbf{z}^{(2)}) = \begin{bmatrix} \mathbf{0}_{n\times n} & \mathbf{0}_{n\times n} & \cdots & \mathbf{0}_{n\times n} & \mathbf{0}_{n\times m} \\ \mathbf{E}_{1,1}(\mathbf{z}_{1,1}) & \mathbf{0}_{n\times n} & \cdots & \mathbf{0}_{n\times n} & \mathbf{0}_{n\times m} \\ \mathbf{E}_{2,1}(\mathbf{z}_{2,1}) & \mathbf{E}_{2,2}(\mathbf{z}_{2,2}) & \cdots & \mathbf{0}_{n\times n} & \mathbf{0}_{n\times m} \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ \mathbf{E}_{k-1,1}(\mathbf{z}_{k-1,1}) & \mathbf{E}_{k-1,1}(\mathbf{z}_{k-1,1}) & \cdots & \mathbf{E}_{k-1,k-1}(\mathbf{z}_{k-1,k-1}) & \mathbf{0}_{n\times m} \\ \mathbf{0}_{m\times n} & \mathbf{0}_{m\times n} & \cdots & \mathbf{0}_{m\times n} & \mathbf{0}_{m\times m} \end{bmatrix},$$

$$\tilde{\mathbf{G}}(\mathbf{z}^{(3)}) = \begin{bmatrix} \mathbf{0}_{n\times n} & \cdots & \mathbf{0}_{n\times n} & \mathbf{0}_{n\times m} \\ \vdots & \vdots & \vdots & \vdots \\ \mathbf{0}_{n\times n} & \cdots & \mathbf{0}_{n\times n} & \mathbf{0}_{n\times m} \\ \mathbf{G}_{k,1}(\mathbf{z}_{k,1}) & \cdots & \mathbf{G}_{k,k}(\mathbf{z}_{k,k}) & \mathbf{0}_{m\times m} \end{bmatrix},$$

and

$$\tilde{\mathbf{H}}(\mathbf{z}^{(4)}) = \begin{bmatrix} I_k \otimes \mathbf{0}_{n\times n} & \mathbf{0} \\ \mathbf{0} & \sum_{i=n+1}^{m} z_{0,i} C_q^{i-1} \end{bmatrix}.$$

By Lemma 3, we have

$$\begin{aligned} \mu_{\mathbf{F}}(\mathbf{C}^*) \geqq \min \mu_{\mathbf{F}}[\mathbf{C}'(\mathbf{z}^{(1)}) + \mathbf{E}'(W_1\mathbf{z}^{(1)}) + \mathbf{G}'(W_2\mathbf{z}^{(1)}) + \mathbf{H}'(W_3\mathbf{z}^{(1)})] \\ + \dim L(\mathbf{E}') + \dim L(\mathbf{G}') + \dim L(\mathbf{H}'), \end{aligned} \tag{2}$$

where the minimum is over all the matrices W_1, W_2 and W_3. We shall therefore estimate all the terms appearing in the right-hand side of (2). We have

$$\dim L(\mathbf{E}') = \dim L(\tilde{\mathbf{E}}) = \sum_{s=1}^{k-1} \sum_{r=1}^{s} \dim L(\mathbf{E}_{s,r}) = \frac{k^2-k}{2} n^2, \tag{3}$$

$$\dim L(\mathbf{G}') = \dim L(\tilde{\mathbf{G}}) = \sum_{r=1}^{k} \dim L(\mathbf{G}_{k,r}) = kmn, \tag{4}$$

and

$$\dim L(\mathbf{H}') = \dim L(\tilde{\mathbf{H}}) = m - n. \tag{5}$$

Let

$$\mathbf{D}'(\mathbf{z}^{(1)}) = \mathbf{C}'(\mathbf{z}^{(1)}) + \mathbf{E}'(W_1\mathbf{z}^{(1)}) + \mathbf{G}'(W_2\mathbf{z}^{(1)}) + \mathbf{H}'(W_3\mathbf{z}^{(1)}).$$

Every nonzero matrix in $L(\mathbf{D}')$ is of the shape $D' = I_w \otimes D$, where

$$D = \begin{bmatrix} f(C_p) & \mathbf{0}_{n\times n} & \cdots & \mathbf{0}_{n\times n} & \mathbf{0}_{n\times m} \\ E_{1,1} & f(C_p) & \cdots & \mathbf{0}_{n\times n} & \mathbf{0}_{n\times m} \\ E_{2,1} & E_{2,2} & \cdots & \mathbf{0}_{n\times n} & \mathbf{0}_{n\times m} \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ E_{k-1,1} & E_{k-1,2} & \cdots & f(C_p) & \mathbf{0}_{n\times m} \\ G_1 & G_2 & \cdots & G_k & f(C_q) + \sum_{r=n+1}^{m} \delta_r C_q^{r-1} \end{bmatrix}$$

for some polynomial $f(\lambda) \in \mathbf{Z}_2[\lambda]$ of degree less than n. Thus

$$\det D' = (\det D)^w = (\det f(C_p))^{kw}\left(\det\left(f(C_q)+\sum_{r=n+1}^{m}\delta_r C_q^{r-1}\right)\right)^w \neq 0.$$

Therefore every matrix in $L(\mathbf{D}')$ is of rank $(kn+m)w$. Since, obviously, dim $L(\mathbf{D}') = n$, by Lemma 1, for any W_1, W_2 and W_3 we have

$$\mu_{\mathbf{F}}[\mathbf{C}'(\mathbf{z}^{(1)})+\mathbf{E}'(W_1\mathbf{z}^{(1)})+\mathbf{G}'(W_2\mathbf{z}^{(1)})+\mathbf{H}'(W_3\mathbf{z}^{(1)})] \geqq N(n,(kn+m)w).$$

This in conjunction with (1)-(5) gives the following in equality.

LEMMA 4. *We have*

$$M(nk+m, w, nk+m) \geqq \frac{k^2-k}{2}n^2+kmn+m-n+N(n,(kn+m)w).$$

Note that the only property of the companion matrix of an irreducible polynomial we use is that every nonsingular space spanned by $\{C_p^0, \cdots, C_p^{n-1}\}$ is of rank n. Actually, every set $\mathbf{A}=\{A_0, \cdots, A_{n-1}\}$ of n independent matrices with the above property is available for our proof.

LEMMA 5 [2]. *We have*

$$\bar{M}(n, m, k) \geqq \bar{M}(n-j, m, k)+j\max(m, k), \quad M(n, m, k) \geqq M(n-j, m, k)+jk.$$

LEMMA 6. *If $m \geqq n \geqq k$, then for every $1 \leqq j \leqq k$*

$$\bar{M}(n, m, k) \geqq (n-k)m+(\lfloor k/j\rfloor -1)(k-0.5j\lfloor k/j\rfloor)j+(k-j\lfloor k/j\rfloor)+N(j, km).$$

If $n \geqq k$, then

$$M(n, m, k) \geqq (n-k)k+(\lfloor k/j\rfloor -1)(k-0.5j\lfloor k/j\rfloor)j+(k-j\lfloor k/j\rfloor)+N(j, km).$$

Proof. By Lemma 5 with $j = n-k$, we have

$$\bar{M}(n, m, k) \geqq (n-k)m+\bar{M}(k, m, k).$$

Then substituting m, $\lfloor k/j\rfloor -1$, j, and $k-(\lfloor k/j\rfloor -1)j$ for w, k, n and m, respectively, in Lemma 4, we obtain

$$\bar{M}(k, m, k) \geqq (\lfloor k/j\rfloor -1)(k-0.5j\lfloor k/j\rfloor)j+(k-j\lfloor k/j\rfloor)+N(j, km)$$

for any $1 \leqq j \leqq k$. The bound on $M(n, m, k)$ can be proved in the same manner. □

3. Proof of the Theorem 1.

By Lemma 5 we have

$$M(n, n, n) \geqq \left(\left\lfloor\frac{n}{j}\right\rfloor -1\right)\left(n-\frac{\lfloor n/j\rfloor}{2}j\right)j+\left(n-j\left\lfloor\frac{n}{j}\right\rfloor\right)+N(j, n^2).$$

Let t be the minimal positive integer such that j divide $n-t$, then $t<j$ and

$$\left\lfloor\frac{n}{j}\right\rfloor = \frac{n-t}{j}.$$

Therefore

$$\begin{aligned} M(n, n, n) &\geqq (n-t-j)\left(\frac{n+t}{2}\right)+t+N(j, n^2) \\ &= \frac{n^2}{2}+N(j, n^2)-j\frac{n}{2}-\frac{t^2}{2}-j\frac{t}{2}+t \\ &\geqq 2.5n^2-\left(\frac{n^2}{2^{j-1}}+\frac{jn}{2}\right)-j^2, \end{aligned}$$

where the last inequality follows from Lemma 2. Now for $j = \lceil \log n \rceil + 1$ we obtain

$$M(n, n, n) \geqq 2.5n^2 - 0.5n \log n - O(n). \qquad \square$$

Other results concerning $\bar{M}(n, m, k)$ and $M(n, m, k)$ are summarized in Theorem 2 below.

THEOREM 2. *If* $n \geqq k$, *then*

$$M(n, m, k) \geqq \begin{cases} nk + 2km - k^2 + k - \log km & \text{if } km \leqq 2^{k-1}, \\ nk + 2km - k^2 - (km/2^{k-1}) & \text{if } km \geqq 2^{k-1}, \\ nk + 2km - 0.5k^2 - 0.5k \log m - O(k) - O(\log^2 m) & \text{if } \log m = o(k). \end{cases}$$

If $m \geqq n \geqq k$, *then*

$$\bar{M}(n, m, k) \geqq \begin{cases} nm + km + k - \log km & \text{if } km \leqq 2^{k-1}, \\ nm + km - (km/2^{k-1}) & \text{if } km \geqq 2^{k-1}, \\ nm + km + 0.5k^2 - 0.5k \log m - O(k) - O(\log^2 m) & \text{if } \log m = o(k). \end{cases}$$

Proof. The first two bounds on $\bar{M}$ are obtained if we put $j = k$ in Lemma 6 and the last bound is obtained if we put $j = \lceil \log m \rceil$. The bound on $M(n, m, k)$ can be shown in a similar manner. $\square$

The bounds compare favorably with the bound $m(n+k) + (k-m) + 1$ established in [2] and [6]. We must note, however, that the bound in [2] and [6] holds over any field.

Acknowledgments. I am grateful to Michael Kaminski for introducing me to the subject and for many helpful discussions, to Ron M. Roth for checking the proofs, to my brother Daoud Bshouty and Michael Kaminski for correcting my very poor English, and to my wife Nadera Bshouty for encouraging me.

TIME/SPACE TRADE-OFFS FOR REVERSIBLE COMPUTATION*

CHARLES H. BENNETT†

Abstract. A reversible Turing machine is one whose transition function is 1:1, so that no instantaneous description (ID) has more than one predecessor. Using a pebbling argument, this paper shows that, for any $\varepsilon > 0$, ordinary multitape Turing machines using time T and space S can be simulated by reversible ones using time $O(T^{1+\varepsilon})$ and space $O(S \log T)$ or in linear time and space $O(ST^{\varepsilon})$. The former result implies in particular that reversible machines can simulate ordinary ones in quadratic space. These results refer to reversible machines that save their input, thereby insuring a global 1:1 relation between initial and final IDs, even when the function being computed is many-to-one. Reversible machines that instead erase their input can of course compute only 1:1 partial recursive functions and indeed provide a Gödel numbering of such functions. The time/space cost of computing a 1:1 function on such a machine is equal within a small polynomial to the cost of computing the function and its inverse on an ordinary Turing machine.

Key words. reversibility, invertibility, time, space, Turing machine, TISP

1. Introduction. A deterministic computer is called reversible if it is also backwards deterministic, having no more than one logical predecessor for each whole-machine state. Reversible computers must avoid such common irreversible operations as assignments and transfers of control that throw away information about the previous state of the data or program. Reversible computers of various kinds (Turing machines, cellular automata, combinational logic) have been considered [1], [11], [12], [13], [6], [2], [14] especially in connection with the physical question of the thermodynamic cost of computation; and it has been known for some time that they can simulate the corresponding species of irreversible computers in linear time [1] (or linear circuit complexity [13]), provided they are allowed to leave behind at the end of the computation a copy of the input (thereby rendering the mapping between initial and final states 1:1 even though the input-output mapping may be many-to-one).

The physical significance of reversible simulation stems from the fact [7], [1] that many-to-one data operations have an irreducible thermodynamic cost, while one-to-one operations do not. The ability to program any computation as a sequence of 1:1 operations therefore implies that, using appropriate hardware, an arbitrarily large amount of "computational work" (in conventional units of time/space complexity) can in principle be performed per unit of physical energy dissipated by the computer. This result contradicted an earlier widely held belief [15] that any computer operating at temperature T must dissipate at least $kT \ln 2$ (the heat equivalent to one bit of entropy, approximately equal to the kinetic energy of a gas molecule at temperature T) per elementary binary operation performed. Needless to say, most real computing equipment, both electronic and biological, is very inefficient thermodynamically, dissipating many orders of magnitude more than kT per step. However, a few thermodynamically efficient data processing systems do exist, notably genetic enzymes such as RNA polymerase, which, under appropriate reactant concentrations, can transcribe information from DNA to RNA at a thermodynamic cost considerably less than kT per step.

The old linear-time simulation [1] is not at all economical of space: in the worst case, it uses exponentially more space than the irreversible computation being simulated.

Here we review this old result and present some new results on more space-efficient reversible computation using the formalism of multitape Turing machines. For simplicity we consider (deterministic) machines whose input tape and output tape, like the work tapes, are two-way, read-write, and included in the space accounting. As usual we restrict ourselves to "well-formed" machines (a recursive subset of machines) whose computations, if started in a standard initial ID will either fail to halt or will halt in a standard final ID. A standard initial ID is one with the Turing machine's control unit in the designated start state, with the input in standard format (input head scanning the blank square just left of a finite input string containing no embedded blanks) and with work and output tapes blank. A standard final ID is one in which the control unit is in a single designated terminal state, all work tapes are blank and all heads have been restored to their original locations, and the output tape contains a single string in standard format. Let $\{\varphi_i\}$ be a Gödel numbering of well-formed machines, and let $T_i(x)$ and $S_i(x)$ denote the time and space used by machine i on input x, the partial functions T_i and S_i having the same domain as φ_i.

A machine φ_i is *reversible* if its quintuples have disjoint ranges, thereby rendering the transition function 1 : 1. We define two special kinds of standard, reversible machine:

Input-saving machines whose input head is read-only, so that the input string remains unchanged throughout the computation.

Input-erasing machines in which the input tape, like the work tapes, is required to be blank at the end of any halting computation on standard input.

These requirements, like the well-formedness requirements for ordinary Turing machines, can be enforced through recursive constraints on the quintuples, so that the input-saving and input-erasing reversible machines can be Gödel-numbered as recursives subsets of $\{\varphi_i\}$.

2. Input-saving reversible computations. As a preliminary to the new results we restate the old, linear-time simulation of [1].

LEMMA 1. *Each conventional multitape Turing machine running in time T and space S can be simulated by a reversible input-saving machine running in time $O(T)$ and space $O(S+T)$. More precisely, there exists a constant c such that for each ordinary Turing machine φ_i, an index j can be found effectively from i, such that φ_j is reversible and input-saving, $\varphi_j = \varphi_i$, and $T_j < c + c \cdot T_i$, and $S_j < c + c \cdot (S_i + T_i)$.*

Proof. As illustrated by Table 1 below, the simulation proceeds by three stages. The first stage uses an extra tape, initially blank, to record all the information that would have been thrown away by the irreversible computation being simulated. This history-taking renders the computation reversible, but also leaves a large amount of unwanted data on the history tape (hence the epithet "untidy"). The second stage copies the output produced by the first stage onto a separate output tape, an action that is intrinsically reversible (without history-taking) if the output tape is initially blank. The third stage exactly reverses the work of the first stage, thereby restoring the whole machine, except for the now-written output tape, to its original condition. This cleanup is possible precisely because the first stage was reversible and deterministic. An apparent problem in constructing the cleanup stage, viz. that conventional read/write/shift quintuples have inverses of a different form (shift/read/write), can be avoided by expressing each read/write/shift of the untidy stage as a product of nonshifting read/writes and oblivious shifts, then inverting these. For more details, see the Appendix and [1].

TABLE 1

Basic linear-time reversible simulation using an extra tape to record, temporarily, a history of the irreversible computation being simulated (underbars denote head positions).

Stage	Input tape	Work tape(s)	History tape	Output tape
Untidy	_INPUT	–	–	–
	INPUT	WORK	HIST_	–
	_INPUT	_OUTPUT	HISTORY_	–
Copy output	_INPUT	_OUTPUT	HISTORY_	–
	_INPUT	OUTPUT	HISTORY_	OU_
	_INPUT	OUTPUT_	HISTORY_	OUTPUT_
	_INPUT	_OUTPUT	HISTORY_	_OUTPUT
Cleanup	_INPUT	_OUTPUT	HISTORY_	_OUTPUT
	INPUT	WORK	HIST_	_OUTPUT
	_INPUT	–	–	_OUTPUT

Note in passing that the operation of copying onto a blank tape serves in stage 2 as a substitute for ubiquitous assignment operation $a := b$, which is not permitted in reversible programming. Similarly, the inverse of copying onto blank tape, which reversibly erases one of two strings known to be identical, can take the place of the more general but irreversible operation of erasure. If the natural number 0 is identified with the empty string, reversible copying and erasure can be represented as incrementation and decrementation, with $a := a + b$ having the same effect as $a := b$, if $a = 0$ initially, and $a := a - b$ having the same effect as $a := 0$, if $a = b$ initially.

The above scheme for reversible simulation runs in linear time but sometimes uses as much as exponential space. The following theorem shows that by allowing slightly more than linear time a much more space-efficient simulation can be obtained.

THEOREM 1. *For any $\varepsilon > 0$, any multitape Turing machine running in time T and space S can be simulated by a reversible input-saving machine using time $O(T^{1+\varepsilon})$ and space $O(S \cdot \log T)$.*

Proof. This space-efficient simulation is obtained by breaking the original computation into segments of m steps, where $m \approx S$, then doing and undoing these segments in a hierarchical manner as shown in Table 2. This table shows that by hierarchically iterating the simulation of 2 segments of original computation by 3 stages of reversible computation, 2^n segments of the original computation can be simulated in 3^n stages of reversible computation. More generally, for any fixed $k > 1$, k^n segments of irreversible computation can be simulated by $(2k-1)^n$ stages of reversible computation. Each stage of reversible computation invokes the linear-time reversible simulation of Lemma 1 to create or destroy a checkpoint (a complete intermediate ID of the simulated computation) from the preceding, m-steps earlier, checkpoint, using time and space $O(S)$. Taking $n \approx \log(T/m)/\log(k)$, the number of intermediate checkpoints in storage at any one time is at most $n(k-1)$, which for fixed k is $O(\log T)$, and since each checkpoint uses storage $O(S)$, the space requirement is $O(S \cdot \log T)$, while the time requirement is $O(S \cdot (2k-1)^n) = O(T^{(1+1/\log k)})$. The simulation is applied to segments of length $m \approx S$ rather than to single steps ($m = 1$) to insure that the time $O(S)$ of copying or erasing a checkpoint does not dominate the time $O(m)$ of computing it from the previous checkpoint. The extra space $O(m)$ required for the history tape in

TABLE 2
Reversible simulation in time $O(T^{\log 3/\log 2})$ and space $O(S \cdot \log T)$.

Stage	Action	Checkpoints in storage (0 = initial ID, checkpoint $j = (jm)$th step ID)								
0	Start	0								
1	Do segment 1	0	1							
2	Do segment 2	0	1	2						
3	Undo segment 1	0		2						
4	Do segment 3	0		2	3					
5	Do segment 4	0		2	3	4				
6	Undo segment 3	0		2		4				
7	Do segment 1	0	1	2		4				
8	Undo segment 2	0	1			4				
9	Undo segment 1	0				4				
10	Do segment 5	0				4	5			
11	Do segment 6	0				4	5	6		
12	Undo segment 5	0				4		6		
13	Do segment 7	0				4		6	7	
14	Do segment 8	0				4		6	7	8
15	Undo segment 7	0				4		6		8
16	Do segment 5	0				4	5	6		8
17	Undo segment 6	0				4	5			8
18	Undo segment 5	0				4				8
19	Do segment 1	0	1			4				8
20	Do segment 2	0	1	2		4				8
21	Undo segment 1	0		2		4				8
22	Do segment 3	0		2	3	4				8
23	Undo segment 4	0		2	3					8
24	Undo segment 3	0		2						8
25	Do segment 1	0	1	2						8
26	Undo segment 2	0	1							8
27	Undo segment 1	0								8

the linear-time simulation between checkpoints does not increase the order of the overall space bound $O(S \cdot \log T)$.

To complete the proof, it remains to be shown how the reversible machine causes the above operations to be performed in correct sequence, how it organizes the storage of the checkpoints on tape, and finally how it arrives at satisfactory values for m and n without knowing T and S beforehand. The hierarchical sequencing of operations is conveniently performed by a recursive subroutine that, given m and n, reversibly calculates the $m \cdot k^n$th successor of an arbitrary ID, using $k-1$ local variables (each restricted to m squares of tape) at each lower level of recursion in n to store the necessary intermediate checkpoints. At the $n = 0$ level of recursion, the mth successor is calculated by the method of Lemma 1. The search for the correct m and n values is performed by a main procedure, which calls the recursive subroutine for successively larger m and n until the time $m \cdot k^n$ and space m allowances prove sufficient, meanwhile keeping a history of the sequence of m and n values to preserve reversibility. When the desired output has been obtained and copied onto the output tape, the search for m and n is undone to dispose of the history of this search. (For more details, see the Appendix.) □

Remark. The reversible creation and annihilation of checkpoints illustrated in Table 2 may be regarded as a case of *reversible pebbling* of a one-dimensional graph. In ordinary pebbling, addition of a pebble to a node requires that all predecessors of

the node already have pebbles, but removal of a pebble can be performed at any time. In reversible pebbling, both the addition and the removal of a pebble require that the predecessors have pebbles.

COROLLARY. *Each ordinary Turing machine running in space S can be simulated by a reversible, input-saving machine running in space $O(S^2)$.*

Related results. Using the same construction, but with k increasing as a function of T (and consequently having n increase less rapidly than $\log T$), one can obtain reversible simulations using less time and more space. For example, using fixed n, k increases linearly with T and one obtains a reversible simulation in time $O(T)$ and space $O(ST^{\varepsilon})$. Intermediate trade-offs can also be obtained, e.g., time $O(T \cdot 2^{\sqrt{\log T}})$ and space $O(S \cdot 2^{(\sqrt{\log T})+O(\log\log T)})$.

The usual linear tape-compression and time speedup theorems apply to reversible machines; therefore, if $T(x)$ and $S(x)$ are total functions bounded below by $3|x|+3$ and $|x|+2$, respectively, then

$$\mathbf{TISP}(T, S) \subseteq \mathbf{RTISP}(T^{1+\varepsilon}, S \log T),$$

where **TISP** (T, S) denotes the class of languages accepted by ordinary Turing machines in time T and space S, and **RTISP** (T, S) denotes the analogous class for input-saving reversible machines. Similarly, the class **TISP** (T, S) is contained in

$$\mathbf{RTISP}(T, ST^{\varepsilon}),$$

and in

$$\mathbf{RTISP}(T \cdot 2^{\sqrt{\log T}}, S \cdot 2^{(\sqrt{\log T})+O(\log\log T)}).$$

It is interesting to compare the time/space trade-off in reversible simulation of ordinary Turing machines with the analogous depth/width trade-off in reversible simulation of ordinary combinatorial logic circuits. A depth-efficient construction due to Fredkin and Toffoli [6], paralleling Lemma 1, simulates ordinary circuits of depth d and width w, in an input-saving manner, by reversible circuits of depth $O(d)$ and width $O(dw)$, composed of reversible gates with no more than three inputs and outputs. A construction parallel to Theorem 1 above would yield a more width-efficient simulation, by reversible circuits of depth $O(d^{1+\varepsilon})$ and width $O(w \cdot \log d)$.

However, a still more width-efficient simulation is possible, based on Coppersmith and Grossman's result [5] that any even permutation on the space of n-bit strings can be computed by a circuit of width n, and depth exponential in n, composed of the reversible gates of $\leqq 3$ inputs and outputs. Width n is insufficient to realize odd permutations, but these can be computed by circuits of width $n+1$, using an extra "garbage" bit whose initial value does not matter, and which is returned unmodified in the output.

Accessing such garbage during a reversible computation might at first appear useless, like renting space in a warehouse already full of someone else's belongings, but in fact it serves the purpose of allowing the odd permutation to be embedded in an even permutation of higher order (any permutation on strings that is oblivious to the values of one or more bits is perforce even) [3]. In particular, any m-bit function of an n-bit argument, $F_m(X_n)$, can be embedded in an even permutation of the form $(X_n, 0^m, g) \to (X_n, F_m(X_n), g)$, where g is a garbage bit, and computed reversibly in width $n+m+1$. Cleve [4] has explored other aspects of the depth/width trade-off for reversible circuits.

The extreme width-efficiency of the Coppersmith–Grossman circuits suggests the possibility of more space-efficient reversible Turing machine simulations using, say,

linear space rather than $S \cdot \log T$. However, this may not be possible, since a deep-but-narrow logic circuit can perform a sequence of *different* transformations, while a Turing machine is forced to apply the *same* transition function at each step.

3. Input-erasing reversible computations. The schemes described so far achieve global reversibility by saving the input, in effect embedding an arbitrary partial recursive function $\varphi(x)$ into the 1:1 partial recursive function $\langle x, \varphi(x)\rangle$. We now consider reversible machines that destroy their input, as well as clearing all working storage, while producing the desired output. Because of unique terminal state of the finite control, such machines cannot destroy or hide even a finite amount of the information present in the input, and so can compute only 1:1 functions. We show that such machines provide a Gödel numbering of the 1:1 partial recursive functions and that the time/space cost of computing a 1:1 function on such a machine is polynomially related to the cost of computing and inverting the function on ordinary Turing machines.

First we need a definition of the cost of inverting a function. Let T^* and S^* be arbitrary partial recursive functions. A 1:1 partial recursive function $f(x)$ will be said to be *invertible in time* $T^*(x)$ *and space* $S^*(x)$ if and only if there exists an (in general irreversible) multitape Turing machine for computing f^{-1} that, for all x in the domain of f, uses time $\leqq T^*(x)$ and space $\leqq S^*(x)$ to compute x from $f(x)$. The theorem below extends an analogous but space-inefficient result [1], [2] on reversible computation of 1:1 functions.

THEOREM 2 (on input-erasing reversible computations). (a) *A function is partial recursive and* 1:1 *if and only if it is computed by an input-erasing reversible multitape Turing machine. These machines thus provide a Gödel-numbering of* 1:1 *partial recursive functions.*

(b) *If f is a* 1:1 *partial recursive function computable in time T and space S, and invertible in time T^* and space S^*, then f can be computed in time $O(T + T^*)$ and space $O(\max\{S \cdot T^{\varepsilon}, S^* \cdot T^{*\varepsilon}\})$ on an input-erasing reversible machine.*

(c) *If f is a* 1:1 *partial recursive function computable in time T and space S, and invertible in time T^* and space S^*, then f can be computed in time $O(T^{1+\varepsilon} + T^{*1+\varepsilon})$ and space $O(\max\{S \log T, S^* \log T^*\})$ on an input-erasing reversible machine.*

(d) *If f is computable by an input-erasing reversible machine in time T and space S, then f is computable by an ordinary machine in time T and space S, and f is invertible by an ordinary machine in time $O(T)$ and space $S + O(1)$.*

Proof. The "if" of part (a) above is immediate from the nature of an input-erasing reversible machine. The "only if" of (a) and the time/space bounds (b) and (c) depend on the construction below (Table 3), in which irreversible algorithms for f and f^{-1} are combined to yield an input-erasing reversible algorithm for f. The "only if" of part (a) in addition depends on the fact noted by McCarthy [10] that, if f is 1:1, then an algorithm for f^{-1} can be obtained effectively from an algorithm for f. (Levin's optimal inverting algorithm [8], [9] is a refinement of this idea). Part (d) is immediate from the fact that an input-saving reversible Turing machine is already a Turing machine, and the fact that the inverse of a reversible machine (obtained by inverting its quintuples as explained in the proof of Lemma 1) runs in the same space and linear time as the original reversible machine.

Table 3 shows how two irreversible algorithms, for a 1:1 partial recursive function f and its inverse f^{-1}, can be combined to perform an input-erasing reversible computation of f. In the first half of the computation the irreversible algorithm for f is used in the manner of Table 1 or Table 2 to construct a temporary bridge (history or checkpoints) from x to $f(x)$, thereby allowing a copy of $f(x)$ to be left on the output

TABLE 3

Input-erasing reversible computation of a 1:1 *function f, given irreversible algorithms for f and* f^{-1}.

Action	Input tape	History tape	Work tapes	Output tape
Do then undo f, via	x			
history or checkpoints,	x	f-HISTORY	$f(x)$	
to create $f(x)$ reversibly	x	f-HISTORY	$f(x)$	$f(x)$
in presence of x	x			$f(x)$
Do then undo f^{-1}, via	x			$f(x)$
history or checkpoints,	x	f^{-1}-HISTORY	x	$f(x)$
to destroy x reversibly		f^{-1}-HISTORY	x	$f(x)$
in presence of $f(x)$				$f(x)$

tape after the bridge is removed. In the last half of the computation the algorithm for f^{-1} is used similarly to generate a bridge from $f(x)$ back to x, but in this case the bridge is used to delete the copy of x already present on the input tape before the bridge was constructed. The time and space required are evidently as stated in (b) and (c) above. □

Remark. Theorem 2 implies Theorem 1, since for any function φ computable in time T and space S, the function $f(x) = x * \varphi(x)$, where $*$ is a distinctive punctuation, is 1:1 and both computable and invertible in time $O(T)$ and space $O(S)$.

Appendix. Details of proofs. Here we give further details of the proofs of Lemma 1 and Theorem 1.

Lemma 1. Here we describe the construction of the reversible machine's Untidy Stage and Cleanup Stage quintuples corresponding to a typical quintuple

$$q_j, S_j \to S_k, \sigma, q_l$$

of the irreversible machine being simulated. The elements of the quintuple before the arrow represent, respectively, the initial control state and scanned tape symbol(s); those after the arrow represent the written tape symbol(s), shift, and final control state. In the Untidy Stage, each execution of such a quintuple should leave a record on the history tape sufficient to undo the operation in the subsequent Cleanup Stage. Since a deterministic Turing machine's quintuples have disjoint domains, it is sufficient to write $\langle i, j \rangle$ on the history tape. This can be achieved by replacing the above quintuple by the following quintuples:

(1) A nonshifting quintuple of the form

$$q_j, (S_j, b) \to (S_k, b), (0, 0), q'_{ij},$$

which executes the original quintuple's read/write operation while reading and writing blank on the history tape (second element in parentheses), and remembering i and j in a special control state;

(2) A quintuple of the form

$$q'_{ij}, X \to X, (\sigma, +), q''_{ij}$$

for each scanned-symbol combination X. Together these quintuples implement an oblivious shift, in which the history tape is right-shifted (+), while the other tapes perform the shift σ called for by the simulated computation. The memory of i and j is passed on via another special control state.

(3) A quintuple of the form

$$q''_{ij}, (Y, b) \rightarrow (Y, \langle i, j \rangle), (0, 0), q_l$$

for each scanned symbol combination Y on the nonhistory tapes. Together these quintuples implement a nonshifting read/write on the history tape, in which a blank is read and the information $\langle i, j \rangle$ representing the quintuple just executed is left in its place. Since each of these quintuples of types (1)-(3) has an inverse of the same form as itself, and since the history-taking and special starred control states guarantee disjointness of the quintuples' ranges, all operations of the Untidy Stage can be undone in the Cleanup Stage.

Theorem 1. We describe in more detail how the reversible machine causes operations to be performed in correct sequence, how it organizes the storage of the checkpoints on tape, and finally how it arrives at the satisfactory values for m and n without knowing T and S beforehand. We describe the case $k = 2$; generalization to larger k is straightforward. For the moment assuming m and n to be given, the hierarchical simulation is conveniently performed by a recursive routine such as RS(z,x,n,m,d) below, whose effect is to cause argument z, representing an ID of the simulated computation, to be incremented or decremented (according to whether argument d is +1 or −1) by the (m 2^n)th successor of argument x under the simulated computation's transition rule.

```
procedure RS(z,x,n,m,d)
 if (n=0)
  LINSIM(z,x,m,d)
 fi (n=0)
 if (n>0)
  RS(y,x,n-1,m,+1)
  RS(z,y,n-1,m,d)
  RS(y,x,n-1,m,-1)
 fi (n>0)
```

It should be noted that in reversible programs, the paths entering a merge point, like those leaving a branch point, must be labeled with mutually exclusive conditions. For example, in RS, the statement `fi (n=0)` denotes a merge point in which control may pass *from* the preceding block of code only if n=0. All assignments are done reversibly, presuming a knowledge of the previous value of the variable (initially zero).

All the actual simulation in RS above is done by the procedure LINSIM(z,x,m,d) below, which, according to the sign of d, increments or decrements argument z by the mth successor of argument x, computed by the method of Lemma 1, i.e., by creating, then clearing, an m-step history on a worktape reserved for that purpose.

```
procedure LINSIM(z,x,m,d)
 if (x is terminal or |x|>m-1)
  z:=z+d*x
 fi (x is terminal or |x|>m-1)
 if (x nonterminal and |x|<m)
  z:=z+d*[mth successor of x]
 fi (x nonterminal and |x|<m)
```

Note that LINSIM suspends forward computation, treating x as its own successor, when the computation being simulated terminates, or when the size of argument x exceeds the space bound m. This convention enables the main procedure, to be described later, to find the right segment size m $\approx S$ and recursion depth n $\approx \log(T/S)$.

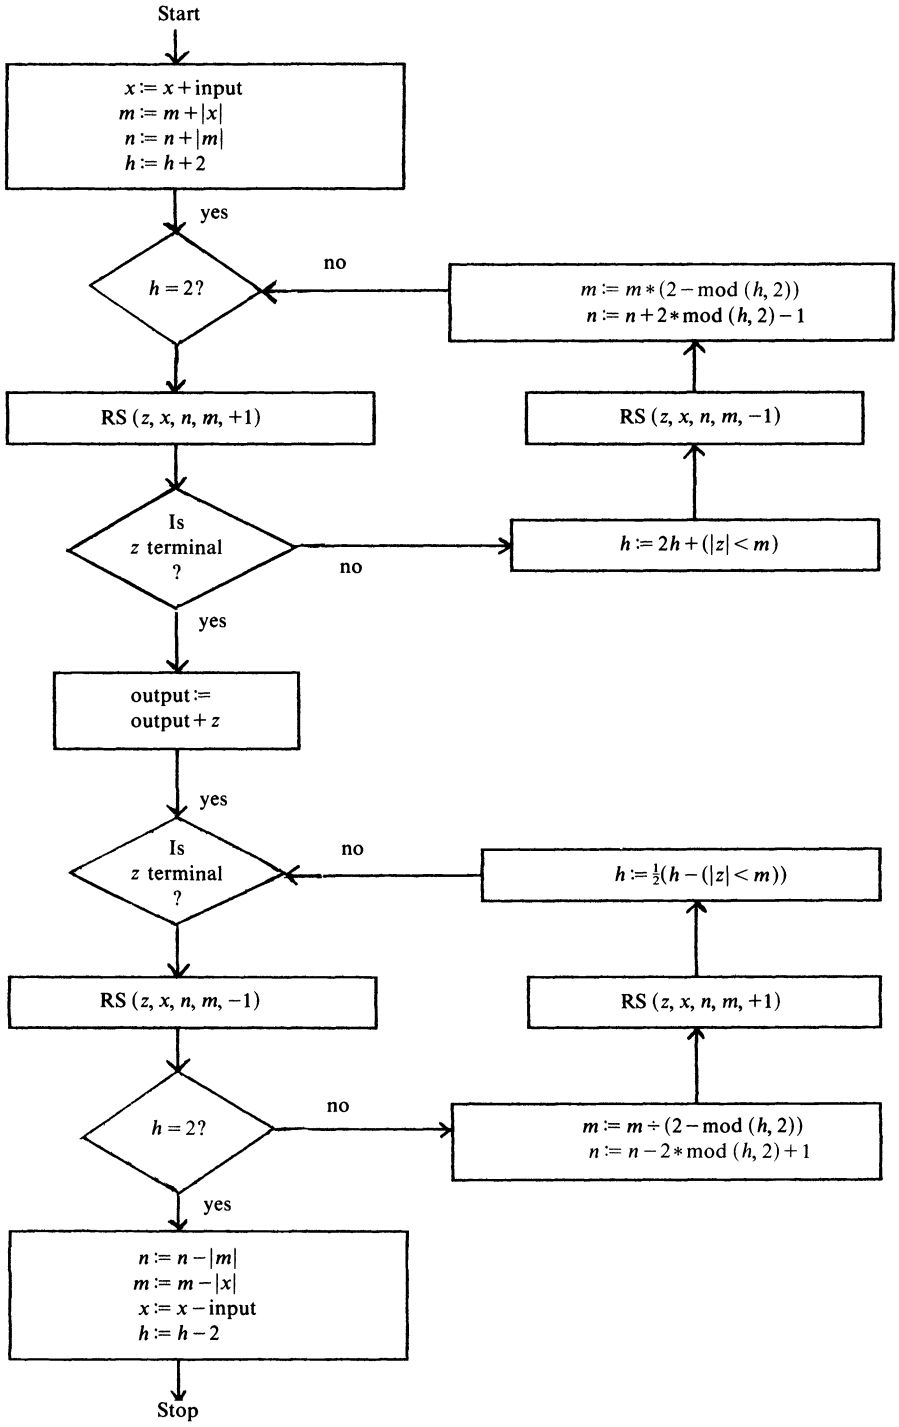

FIG. 1. MAIN *procedure for space-efficient reversible computation using recursive subroutine* "RS."

Proceeding now to the organization of data on tape, it can be seen that the procedure RS needs separate storage $O(\mathtt{m})$ at each level of recursion, for its arguments and for the local variable y. This storage can conveniently be organized as a sequence of n blocks of size $O(\mathtt{m})$ on a single "checkpoint" tape, demarcated by appropriate punctuation. Each call to RS would then involve reversibly passing arguments of size $O(\mathtt{m})$ back and forth between adjacent blocks, a job that can be done in time $O(\mathtt{m})$ if an extra blank tape is used as a buffer. The level of recursion would not have to be passed as an explicit argument, since that information would already be encoded by the head position on the checkpoint tape. At the 0 level of recursion, the linear time computation of each checkpoint from its predecessor would proceed using all the tapes of the original machine being simulated, plus an additional history tape.

We now go on to describe the main procedure, which tries successively larger m and n until the correct values are found, writes the final output (if the computation being simulated indeed terminates), and then reversibly disposes of all intermediate data generated in the course of the simulation. This procedure can be represented by a flow chart (Fig. 1). Here diamonds are used to represent both branch points and merge points since, as remarked before, it is necessary in reversible programming to label alternative paths into a merge point, like the paths out of a branch point, with mutually exclusive conditions. Note that the whole bottom half of the flow chart is devoted to undoing the work of the top half, so that all intermediate data are restored to their initial states after the desired output has been obtained.

In more detail, the main procedure begins by initializing m, n, and x, as well as a variable h, which will be used to encode the history of the search for correct m and n values. Each turn around the main loop in the upper half of the chart either increases n by one (thereby doubling the time allowance if it was exceeded before the space allowance), or doubles m and decreases n by one (thereby doubling the space allowance while keeping the time allowance fixed if the space allowance was exceeded first). In the former case a 0 is pushed into the least significant bit of h (regarded as a binary string); in the latter case a 1 is pushed. Since LINSIM simulates m steps of computation between space tests, the final m value may be less than S, but lies between $S/2$ and $2S$. The final n value is similarly equal to $\log(T/S)$ within a term of order unity. When the final m and n are found, the ID z generated by RS will be found to be terminal. It is then copied onto the output tape, and the entire computation up to that point is undone in the bottom half of the chart.

The space used by the algorithm is dominated by the $O(\mathtt{mn}) \leqq O(S \log(T))$ squares used on the checkpoint tape, all other terms being $O(S)$ or less. The time used in one turn around the main loop depends on m and n as $O(\mathtt{m} \cdot (2k-1)^{\mathtt{n}})$, from $O((2k-1)^{\mathtt{n}})$ recursive invocations of RS and $O((2k-1)^{\mathtt{n}})$ m-step linear-time simulations. Since n may be decreased at some turns around the loop (recall that when the space bound is exceeded, m is doubled and n is decreased by 1), the largest time cost is not necessarily associated with the last turn. Nevertheless, the total time cost of all the turns is bounded by a convergent geometric series

$$O\left((2k-1)^{\log T} \sum_i \left(\frac{k}{(2k-1)}\right)^i\right).$$

Executing the bottom half of the flow chart of course only introduces a factor of order unity, so the total time cost remains $O(T^{1+1/(\log k)})$ as claimed. □

Acknowledgments. I wish to thank Leonid Levin for urging and helping me to strengthen a previous, much weaker version of Theorem 1 and Martin Tompa for pointing out how to reduce the time exponent from 1.585 to $1+\varepsilon$.

Note added in proof. Robert Y. Levine and Alan T. Sherman, in a recent preprint, "A Note on Bennett's Time-Space Trade-off for Reversible Computation" (Department of Computer Science, Tufts University, Medford, Massachusetts 02155), give tighter time and space bounds for the reversible simulation as $\Theta(T^{1+\epsilon}/S^{\epsilon})$ and $\Theta(S \ln(T/S))$, respectively; and they point out that the space bound contains a constant factor diverging with small ϵ approximately as $\epsilon 2^{1/\epsilon}$.

ULTIMATE CHARACTERIZATIONS OF THE BURST RESPONSE OF AN INTERVAL SEARCHING ALGORITHM: A STUDY OF A FUNCTIONAL EQUATION*

PHILIPPE JACQUET† AND WOJCIECH SZPANKOWSKI‡

Abstract. The interval searching algorithm for broadcast communications of Gallager and Tsybakov and Mikhailov is analyzed. Ultimate characterizations of the burst response of the algorithm, that is, when the number of collided packets becomes large is presented. Three quantities are of interest: the *conflict resolution interval* (CRI); the fraction of the *resolved interval* (RI); and the number of *resolved packets* (RP). If n is the multiplicity of a conflict, then it is proved that the mth moments of CRI, RI, and RP are $O(\log^m n)$, $O(n^{-m})$, and $O(1)$, respectively. In addition, for the first two moments of these parameters precise asymptotic approximations are presented. The methodology proposed in this paper is applicable to asymptotic analysis of any problem that can be reduced to a solution of the *functional equation* $f(x)=2^s\cdot f(x/2)\cdot a(x)+b(x)$, where s is an integer and $a(x)$, $b(x)$ are given functions.

Key words. interval searching algorithms, analysis of algorithms, digital trees and other data structures, asymptotic analysis, functional equations, Mellin transform

1. Introduction.

In a broadcast packet-switching network a number of distributed users share a common communication channel. Since the channel is the only means of communication among the users, packet collisions are inevitable if a central coordination is not provided. The problem is to find an efficient distributed algorithm for retransmitting conflicting packets. In recent years *conflict resolution algorithms* (CRA) [1], [2], [5]-[7], [9], [14]-[16] have become increasingly popular, mainly due to a nice stability property. The basic idea of CRA is to solve each conflict by splitting it into smaller conflicts (divide-and-conquer algorithm). This is possible if each user observes the channel and learns whether in the past it was idle, success, or collision transmissions. The partition of a conflict can be made on the basis of a random variable (flipping a coin) [2], [6], [7], [15] or on the basis of the time a user became active [2], [5], [9], [14], [16]. The former algorithm is known as the Capetanakis-Tsybakov-Mikhailov algorithm [2], [15] (the stack algorithm) while the latter as the Gallager-Tsybakov-Mikhailov algorithm [5], [16] known also as an interval-searching algorithm.

For interval searching algorithms, three parameters are of interest: the *conflict resolution interval* (CRI), the fraction of the *resolved interval* (RI), and the number of *resolved packets* (RP). For the initial multiplicity of a conflict n (i.e., n packets collide) the mth moments of the above parameters are denoted as T_n^m, W_n^m and C_n^m, respectively. We prove that $T_n^m=O(\log^m n)$, $W_n^m=O(n^{-m})$, and $C_n^m=O(1)$ for large n. However, for the first two moments, which are the most important from a practical viewpoint, we offer precise estimations. In particular, we show that asymptotically $W_n^1\sim a/(n+1)+P(\log n)$, $C_n^1\sim a+P(\log n)$, and $T_n^1\sim\log n+c+P(\log n)$, where a and c are constants that are determined in our Proposition, and $P(\log n)$ is a fluctuating

function with a small amplitude. For the variance, we obtain $\operatorname{var}\mathbf{W}_n \sim a'/(n+1)^2$, $\operatorname{var}\mathbf{C}_n \sim a''$ and $\operatorname{var}\mathbf{T}_n \sim c'$, respectively. Our results are useful in characterizing the "burst response" of the algorithm. Indeed, it seems to be interesting to evaluate the ability of a communication protocol to resolve an initial collision of large multiplicity (e.g., a "bursty" access to the channel of several stations). It is known that the algorithm does not completely resolve the initial collision in one session, and it needs several sessions for successful transmissions of n initially collided packets. Our results show (for more details see also Remark (ii) at the end of § 2) that the algorithm needs on the average $n(\log_2 n - 1)/a + nc/a$ slots to resolve the initial collision of size n.

To the best of the authors' knowledge, previous research has been restricted only to the first moments of CRI, RI, and RP, however, the exact asymptotic expansions have not been achieved [14] (see also [9], [16]). The methodology presented in this paper can be easily extended to analyze other interval searching algorithms as well as some other data structures such as digital search trees [12]. Moreover, conflict resolution algorithms find applications in typical computer science problems such as semaphore conflicts and batch retrieval algorithms for databases [17], [18].

2. Problem statement and main results. Let us start with a short description of the Gallager-Tsybakov-Mikhailov algorithm with ternary feedback [5], [16]. Assume a channel is slotted and a slot duration is equal to a packet transmission time. The algorithm defined below allows the transmission of the packets on the basis of their generation times and we assume that packets are generated according to a Poisson point process with rate λ. Access to the channel is controlled by a window based on the current age of packets. This window will be referred to as the *enabled interval* (EI). Let s_i denote the starting point for the ith EI, and t_i is the corresponding starting point for the *conflict resolution interval* (CRI), where CRI represents the number of slots needed to resolve a collision. Initially, the enabled interval is set to be $[s_i, \min\{s_i+\tau, t_i\}]$, where τ is a constant that will be further optimized. At each step of the algorithm, we compute the endpoints of the EI based on the outcome of the channel. If at most one packet falls in the initial EI, then the conflict resolution interval ends immediately, and $s_{i+1} = s_i + \min\{\tau, t_i - s_i\}$. Otherwise, the EI is split into two halves, and three cases must be considered:

(i) All users whose current age of packets fall into the first (left) half are allowed to transmit packets. If it causes next *collision*, all knowledge about the second half is erased, and the first half is immediately split into two halves;

(ii) If enabling the first half causes an *idle* slot, the second half is immediately split into two halves;

(iii) If the first half gives a *success*, the entire second half is enabled.

A CRI that begins with a collision, continues until enabling the second half of some pairs gives a success.

Assume that an initial collision of a CRI is of multiplicity n, that is, n packets collide in the first slot of a CRI. Then all packets whose generation times fall into an interval (s_i, s_{i+1}) are successfully sent in the ith CRI. The interval (s_i, s_{i+1}) is called the ith *resolved interval* (RI) and its length is at most τ. The parameters of interest are: the length of a CRI, $\mathbf{T}$; the fraction of the resolved interval (i.e., the ratio of the resolved interval and τ), $\mathbf{W}$; and the number of resolved packets (successfully transmitted) in an enabled interval, $\mathbf{C}$. Let also $\mathbf{N}$ denote the multiplicity of a conflict. Then the mth conditional moments of the above quantities are defined as $T_n^m = E\{\mathbf{T}^m | \mathbf{N} = n\}$, $W_n^m = E\{\mathbf{W}^m | \mathbf{N} = n\}$, and $C^m = E\{\mathbf{C}^m | \mathbf{N} = n\}$, respectively. For $m = 0$, we define $T_n^0 = W_n^0 = C_n^0 = 1$. Then we have Theorem 1.

THEOREM 1. (i) *The mth conditional moment of* $\mathbf{T}$ *satisfies the following recurrence*:

$$T_0^m = T_1^m = 1,$$

$$(2.1)\quad (2^n-2)T_n^m = 2^n + n(2^m-2) + \sum_{i=1}^{m-1}\binom{m}{i}[T_n^i + n2^{m-i}T_{n-1}^i] + \sum_{j=2}^{n}\sum_{i=1}^{m-1}\binom{n}{j}\binom{m}{i}T_j^i + nT_{n-1}^m + \sum_{j=1}^{n-1}\binom{n}{j}T_j^m, \qquad n \geqq 2.$$

(ii) *The recurrence for* W_n^m *is*

$$W_0^m = W_1^m = 1,$$

$$(2.2)\quad (2^{n+m}-2)W_n^m = 1 + \sum_{j=1}^{m-1}\binom{n}{j}[W_n^i + nW_{n-1}^i] + nW_{n-1}^m + \sum_{j=1}^{n-1}\binom{n}{j}W_j^m, \qquad n \geqq 2.$$

(iii) *The recurrence for the mth conditional moment of* $\mathbf{C}$ *becomes*

$$C_0^m = 0, \qquad C_1^m = 1,$$

$$(2.3)\quad (2^n-2)C_n^m = n\sum_{j=1}^{m-1}\binom{m}{j}C_{n-1}^i + nC_{n-1}^m + \sum_{j=1}^{n-1}\binom{n}{j}C_j^m, \qquad n \geqq 2.$$

Proof. Note that an n-conflict is resolved by splitting n into two groups, and according to the algorithm description three basic cases must be considered: (1) $n \to (0, n)$; (2) $n \to (1, n-1)$; (3) $n \to (j, n-j)$, $j \geqq 2$. The probabilities of these cases are equal to 2^{-n}, $n2^{-n}$, and $\binom{n}{j}2^{-n}$, respectively. For example,

$$C_n^m = 2^{-n}E\{\mathbf{C}^m|\mathbf{N}=n\} + n2^{n-1}E\{(1+\mathbf{C})^m|\mathbf{N}=n-1\} + 2^{-n}\sum_{j=2}^{n}\binom{n}{j}E\{\mathbf{C}^m|\mathbf{N}=j\}.$$

After some algebraic manipulations, we prove the recurrences (2.1), (2.2), and (2.3). □

We now give a summary of the main results, delaying more complicated proofs to the next two sections. Let $W_m(x)$, $C_m(x)$, and $T_m(x)$ represent the exponential generating functions of W_n^m, C_n^m, and T_n^m, respectively, e.g., $T_m(x) = \sum_{n=0}^{\infty} T_n^m x^n/n!$. It turns out that to analyze recurrences (2.1)-(2.3), it is more convenient to deal with modified generating functions defined as $w_m(x) = W_m(x)\, e^{-x}$, $c_m(x) = C_m(x)\, e^{-x}$, and $t_m(x) = T_m(x)\, e^{-x} - 1$. Recurrences (2.1)-(2.3) can be transformed into functional equations for $w_m(x)$, $c_m(x)$, and $t_m(x)$. For example, from Theorem 1 we can easily prove that the generating functions $w_1(x)$, $c_1(x)$, and $t_1(x)$ satisfy the following functional equations:

$$w_1(x) = 2^{-1}[1 + (1+x/2)\, e^{-x/2}]w_1(x/2),$$

$$c_1(x) = [1 + (1+x/2)\, e^{-x/2}]c_1(x),$$

$$t_1(x) = [1 + (1+x/2)\, e^{-x/2}]t_1(x/2) + 1 - (1+3x/2)\, e^{-x} + 0.5x\, e^{-x/2}.$$

Note the generic form for these functional equations is

$$(2.4)\qquad f(x) = 2^s f(x/2)a(x) + b(x),$$

where s is an integer, $a(x) = \frac{1}{2}[1 + (1+x/2)\, e^{-x/2}]$, and the nonhomogeneous term $b(x)$ depends on the particular recurrence (see §§ 3 and 4). The general solution for (2.4) is given in the next lemma.

LEMMA 1. (i) *Functional equation* (2.4) *possesses the following solution*:

$$(2.5)\qquad f(x) = f^*(x) + \sum_{n=0}^{\infty} 2^{sn} b(x2^{-n}) \prod_{k=0}^{n-1} a(x2^{-k}),$$

where

$$f^*(x) = \lim_{n\to\infty} 2^{sn} f(x2^{-n}) \prod_{k=0}^{n-1} a(x2^{-k}) \tag{2.6}$$

assuming $f^*(x)$ exists and the series in (2.5) *is convergent.*

(ii) *Let $w(x) = \prod_{k=0}^{\infty} a(x2^{-k})$ exist and $f(0) = f'(0) = \cdots = f^{(s-1)} = 0$, $f^{(s)}(0) \neq 0$. Then*

$$f^*(x) = \begin{cases} 0 & s < 0, \\ x^s w(x) f^{(s)}(0)/s! & s \geqq 0, \end{cases} \tag{2.7}$$

where $f^{(s)}(0)$ denotes the sth derivative of $f(x)$ at $x = 0$.

(iii) *If $a(0) < 2$ and $b(x) = O(x^{s+1})$ for $x \to 0$, then the series in* (2.5) *is convergent.*

Proof. Part (i) follows immediately from formal iteration of (2.4). For (ii) assume first $s \geqq 0$. Let $u = x2^{-n}$; then

$$f^*(x) = x^s w(x) \lim_{u\to 0} \frac{f(u)}{u^s}. \tag{2.8}$$

Applying l'Hopital rule s-times, we prove (2.7). The case $s < 0$ is easy and left to the reader. For part (iii), we use D'Alembert's criterion, that is, to prove that $\sum_{n\geqq 0} \alpha_n$ is convergent, it is sufficient to show that $\lim_{n\to\infty} \alpha_{n+1}/\alpha_n < 1$. In our case, assuming $u = x2^{-n}$,

$$\lim \frac{\alpha_{n+1}}{\alpha_n} = a(0)2^s \lim_{u\to 0} \frac{b(u/2)}{b(u)} = \frac{a(0)}{2} < 1,$$

where the last equality follows from the assumption $b(x) = O(x^{s+1})$ for $x \to 0$. □

Direct use of Lemma 1 leads to very complicated formulas. Nevertheless, based on the lemma and using the Mellin transform, we can reduce these formulas to very simple asymptotics, as summarized in the following proposition.

PROPOSITION. *For $x \to \infty$ the following hold.*

(i) *The first two modified generating functions for the resolved interval are*

$$w_1(x) \sim \frac{a}{x} + \frac{a}{x} P(\log x), \tag{2.9}$$

$$w_2(x) \sim \frac{a(2+b)}{x^2} + P(\log x) \cdot \frac{a}{x^2}, \tag{2.10}$$

where $P(\log x)$ is a fluctuating function with a very small amplitude, and

$$a = \exp[\alpha/\log 2 + \log 2/2] \approx 2.505, \qquad b = \beta/\log 2 \approx 1.692, \tag{2.11}$$

where

$$\alpha = \int_0^\infty \frac{x e^{-x} \log x}{1+(1+x)e^{-x}}\, dx \approx 1.496, \qquad \beta = \int_0^\infty \frac{e^{-x/2}}{1+(1+x/2)e^{-x/2}}\, dx \approx 1.17. \tag{2.12}$$

(ii) *The modified generating functions for the number of resolved packets become*

$$c_1(x) = x w_1(x) \sim a + aP(\log x), \tag{2.13}$$

$$c_2(x) \sim a(1+b) + aP(\log x). \tag{2.14}$$

(iii) *The first two modified generating functions for the conflict resolution interval satisfy*

$$t_1(x) \sim \log_2 x + c + aP(\log x), \tag{2.15}$$

$$t_2(x) \sim \log_2^2 x + 2c \log_2 x + d + aP(\log x), \tag{2.16}$$

where

$$c = 2 - \frac{\mu a}{(\log 2)^2} \approx 4.149, \qquad d = \frac{5}{6} + 3(c-1) - c^2 - \frac{a\nu}{(\log 2)^2} \approx 17.169, \tag{2.17}$$

and

$$\mu = \int_0^\infty f_1(x) \frac{\log x}{x}\, dx \approx -0.41, \qquad \nu = -\frac{1}{2}\int_0^\infty f_2(x) \log^2 x\, dx \approx -1.484, \tag{2.18}$$

where the functions $f_1(x)$ and $f_2(x)$ depend on $a(x)$, $b(x)$, and $w_1(x)$; they are given in the next sections. □

The next stage consists of translating the expansions of $T_m(x)$, $W_m(x)$, and $C_m(x)$ for $x \to \infty$ into information about the asymptotics of their coefficients. That is, if $F(x) = f(x)\, e^x$ is the exponential generating function and $f(x) = \sum_{n=0}^\infty f_n x^n / n!\, e^{-x}$, then by the Cauchy formula [8] the coefficient f_n is given by

$$f_n = \frac{n!}{2\pi i} \oint f(x)\, e^x \frac{dx}{x^{n+1}}, \tag{2.19}$$

where the integration is done on the circle with center 0 and radius n. It should be stressed that $f(x) \sim g(x)$ does not necessarily imply $f_n \sim g_n$. Note, however, that the leading factor in the asymptotics for the generating functions of the quantities of interest is of the form $x^p (\log x)^q$ for some p and q. The next lemma establishes conditions under which this factor can be transformed into information on the coefficients (see also [11]).

LEMMA 2. *Let $f(x) = F(x)\, e^{-x}$ and S_θ be a cone $S_\theta = \{x: |\arg x| < \theta, 0 < \theta < \pi/2\}$. If for x in the cone, that is, for $x \in S_\theta$, and $x \to \infty$*

$$f(x) \sim x^p (\log x)^q \tag{2.20}$$

for some p and q, and for x outside the cone S_θ

$$|F(x)| < B\, e^{\alpha |z|} \tag{2.21}$$

for some B and $0 < \alpha < 1$, then for large n the coefficient f_n of $F(x)$ asymptotically satisfies

$$f_n = f(n) \cdot \left\{ 1 + O\left(\frac{1}{\sqrt{n} \log n} \right) \right\} = n^p (\log n)^q + O(n^{p-1/2} \log^{q-1} n). \tag{2.22}$$

Proof. The coefficient f_n is computed by Cauchy formula (2.19), where the integration is done along the circle $|x| = n$. Two cases are considered: $x \in S_\theta$ and x outside the cone S_θ. In the latter case, using (2.21) and Stirling's formula [7] we find that f_n defined in (2.19) can be upper bounded as $|f_n| < B\, e^{-(1-\alpha)n}$, that is, for large n the contribution of the integral outside the cone S_θ is negligible.

Now assume that $x \in S_\theta$. Using substitution $x = n\, e^{iv}$ in (2.19) and applying again Stirling's formula, one finds $f_n = I_n[1 + O(n^{-1})] + O(e^{-(1-\alpha)n})$, where

$$I_n = \sqrt{\frac{n}{2\pi}} \int_{-\theta}^{\theta} f(n\, e^{iv})\, e^{ne^{iv}}\, e^{-inv}\, dv. \tag{2.23}$$

The last integral can be further simplified by developing e^{iv} and the change of variable $y = \sqrt{n}\, v$. Then

$$I_n = \frac{1}{\sqrt{2\pi}} \int_{-\theta\sqrt{n}}^{\theta\sqrt{n}} f(n\, e^{iy\sqrt{n}})\, e^{n^{i\sqrt{n}}}\, e^{-i\sqrt{n}y}\, dy. \tag{2.24}$$

But the following is easy to establish: $f(n\,e^{iy\sqrt{n}})/f_n \to 1$, and $e^{ne^{iy\sqrt{n}}}\,e^{-i\sqrt{n}y} \to e^{-y^2/2}$ as $n \to \infty$. Then, by the *Lebesgue Dominated Convergence* theorem we show that

$$\frac{I_n}{f(n)} \to \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} e^{-y^2/2} = 1.$$

Finally, we note that a refinement in the evaluation of the order of convergence in the latter derivation leads to $f_n/f(n) = 1 + O(n^{-1/2}\log^{-1} n)$. This readily gives (2.22). □

Now we are prepared to state our second main result. Direct application of Lemma 2 to Proposition leads to Theorem 2.

THEOREM 2. *For large n the following hold*:

(i) *The fraction of the resolved interval becomes*

$$W_n^1 = \frac{a}{n+1} + \frac{1}{n+1} P(\log n) + O(n^{-3/2}) \approx \frac{2.505}{n+1}, \tag{2.25}$$

$$\begin{aligned} \operatorname{var} \mathbf{W}_n &= \frac{a(2+b)}{(n+1)(n+2)} - \frac{a^2}{(n+1)^2} + \frac{1}{(n+1)^2} P_1(\log n) + O(n^{-3/2}) \\ &\approx \frac{a(2+b)-a^2}{(n+1)^2} + \frac{1}{(n+1)^2} P_1(\log n) + O(n^{-3/2}) \approx \frac{2.97}{(n+1)^2}, \end{aligned} \tag{2.26}$$

$$W_n^m = O(n^{-m}). \tag{2.27}$$

(ii) *The number of resolved packets satisfies*

$$C_n^1 = a + P(\log n) + O(n^{-1/2}) \approx 2.505, \tag{2.28}$$

$$\operatorname{var} \mathbf{C}_n = a + ab - a^2 + P_2(\log n) + O(n^{-1/2}) \approx 0.47, \tag{2.29}$$

$$C_n^m = O(1). \tag{2.30}$$

(iii) *The conflict resolution interval can be represented as*

$$T_n^1 = \log_2 n + c + P(\log n) + O(n^{-1/2}) \approx \log_2 n + 4.144, \tag{2.31}$$

$$\operatorname{var} \mathbf{T}_n = \frac{5}{6} + 3(c-1) - c^2 - \frac{a\nu}{(\log 2)^2} + P_3(\log n) + O(n^{-1/2}) \approx 4.7, \tag{2.32}$$

$$T_n^m = O(\log^m m). \tag{2.33}$$

Remarks. (i) *Maximum throughput for the algorithm.* Let $x = \lambda\tau$, where λ is the input rate from the Poisson arrival process, and τ is the algorithm parameter defined in § 2. The *maximum throughput*, $\lambda_{\max}$, is defined as the maximum rate of successful transmissions that assures that the average packet delay is finite. In other words, for $\lambda < \lambda_{\max}$ the algorithm is stable. But, the throughput is also the ratio of the average number of successful transmissions to the average conflict resolution length, hence (see [1], [16])

$$\lambda_{\max} = \sup_x \frac{C_1(x)}{T_1(x)} = \sup_x \frac{x W_1(x)}{T_1(x)}. \tag{2.34}$$

It is easy to compute $\lambda_{\max}$ numerically for some values of x, and taking the first eight or nine values of T_n^1 and W_n^1 reveals $\lambda_{\max} = 0.48771$ for $x = 1.26$. This comes from the

fact that the maximum in (2.34) occurs for small values of x. Thus, from the numerical point of view, there is nothing to add. From the mathematical viewpoint, however, there is some interest in finding an analytical solution for $\lambda_{\max}$, e.g., to show whether some maximizing x is a global or a local maximum. Using the Proposition, we immediately see that for large x

$$\lambda_{\max} \sim \sup_x \frac{a}{\log_2 x + c}$$

and $\lambda_{\max}$ is a decreasing function of x. Thus, $x_{\text{op}} = 1.26$ is a global one.

(ii) *Average number of slots needed to resolve the initial collision.* Let us assume that one injects n packets into the system. How long does it take on the average to resolve completely this initial collision? It is well known that the Gallager-Tsybakov-Mikhailov algorithm does not solve the entire collision in one session. By Theorem 2(ii) we know that for large initial multiplicity n of a collision, only a packets are transmitted on the average in a conflict resolution session. Thus, n/a sessions are necessary to resolve the contention. According to Theorem 2(iii) each session with initial multiplicity n requires $\log_2 n + c$ slots. Therefore, on the average the algorithm with the initial multiplicity n needs $c + \log_2 n + c + \log_2 (n-a) + c + \log_2 (n-2a) + \cdots$ slots to resolve the conflict. This is roughly equal to $n/a \times (\log_2 n - 1) + nc/a$ slots. This can be compared with $\alpha \cdot n$ slots required to solve initial conflict for stack algorithms [2], [7], where α is a parameter of the system.

(iii) *Non-Poisson arrival processes and limiting distribution.* The reason why the asymptotic behavior of T_n^1 and W_n^1 is not essential for the algorithm follows from the fact that the probability of more than four packets collide is less than 0.01 if x is near the optimal value. This, however, holds only for the Poisson assumption model. If this assumption is dropped and the input process is more biased (e.g., multimodal or the peak of the distribution is for large values), then the asymptotic behavior, i.e., burst response, becomes more important. Although in general our recurrences (2.1)-(2.3) do not work for non-Poisson models, we can slightly change the algorithm (this change, anyhow, is required in practice) to assure that the recurrences are valid. Namely, in a non-Poisson model we spread randomly over a window all packets that fall into the window. Then, for such a randomized algorithm our recurrences hold since the binomial distribution of packets in each half of a window is preserved. Moreover, note that for such a randomized non-Poisson model limiting distributions for T_n^1 play a role. From our analysis (Theorem 2(iii)) we know that T_n^1 is *not* normally distributed, since $T_n^1 = O(\log n)$ and $\operatorname{var} T_n = O(1)$ (see [11]). At last, the burst response becomes increasingly important for extreme behaviors of the algorithm (even within the Poisson model) since in such situations the Poisson assumption is no longer true. In other words, the average behavior is well described by the throughput and the delay of the algorithm, but for dynamic behavior we need to study burst response.

(iv) *Other applications of our analysis.* Finally, we note that the interval searching algorithm motivated our study of a general functional equation of the form $f(x) = 2^s f(x/2) \cdot a(x) + b(x)$ (see Eq. (2.4)). In particular, we have investigated the asymptotic behavior of the coefficient f_n of the Taylor expansion of $f(x)$ (see (2.19)). Such a general approach has its own advantage in the fact that a class of problems can be solved in a unified manner. For example, noting that the conflict resolution session T_n can be represented as a path in an appropriate digital tree [16] we can easily apply our analysis to study some other properties of digital search trees. Note also that our methodology enables us to compute the asymptotics *without* exact solution of the recurrences (2.1)-(2.3). For example, the following recurrence is often met in the

analysis of digital search trees (radix trees, Patricia trees, etc. [12], [13]):

$$x_n = a_n + \sum_{k=0}^{n} \binom{n}{k} 2^{-n} (l_{n-k} x_k + r_k x_{n-k}), \tag{2.35}$$

where x_n is the numerical value of a given property of the tree, a_n is the amount of the property possessed by the root, and l_k, r_k are weights of the left and right subtrees. For instance, if $l_k = r_k = 1$, then (2.35) models (for appropriate a_n) the successful search time (all moments) of radix tries and Patricia tries [13]; if $l_k = r_k = 1 - \delta_{n,k}$, where $\delta_{n,k}$ is the Kronecker delta, then (2.35) represents the unsuccessful search in a Patricia tree. For the Gallager algorithm we have to assume $l_k = \frac{1}{2}$ and $r_k = \frac{1}{2}(1 + 2\delta_{n-1,k})$. Introduction of the general (additive) term a_n in (2.35) enables to study a class of properties instead of a particular one. For example, another version of Gallager's algorithm, namely Berger's protocol [2], is analyzed in exactly the same manner except that for T_n^1 the additive term is equal to $a_n = 2 + n2^{-n} - 2^{-n}$ instead of $a_n = 1 - 2^{-n}$.

3. Analysis of the first moments. In this section we concentrate on derivations of the asymptotics for W_n^1, C_n^1, and T_n^1. From the methodological viewpoint, we mention here the crucial role of the generating function $W_1(x)$ of W_n^1. This is a consequence of the fact that $w_1(x) = W_1(x)\, e^{-x}$ satisfies homogeneous functional equation of type (2.4), that is, $b(x) \equiv 0$ in (2.4). We shall see that all other generating functions, which satisfy nonhomogeneous functional equation (2.4), can be expressed in terms of $w_1(x)$. In the derivations we extensively use the Mellin transform. A good reference for properties of the Mellin transform is [4] and [3]. Some details of the derivations can also be found in [10].

3.1. The fraction of the resolved interval. The first moment of the fraction of resolved interval W_n^1 satisfies recurrence (2.2) with $m = 1$. Let $W_1(x)$ be the exponential generating function of W_n^1, and define $w_1(x) = W_1(x)\, e^{-x}$. Multiplying both sides of (2.2) by $x^n/n!$ and summing, we find

$$w_1(x) = \tfrac{1}{2}[1 + (1 + x/2)\, e^{-x/2}] w_1(x/2). \tag{3.1}$$

This functional equation falls into (2.4) with $b(x) \equiv 0$ (homogeneous equation) and $a(x) = \frac{1}{2}[1 + (1 + x/2)\, e^{-x/2}]$. Let us also define $a_1(x) = a(2x)$. Then, by Lemma 1 and $w_1(0) = 1$ the solution of (3.1) is

$$w_1(x) = \prod_{k=1}^{\infty} a_1(x2^{-k}) = \prod_{k=0}^{\infty} a(x2^{-k}). \tag{3.2}$$

Let $l(x) = \log w_1(x)$ and $g_1(x) = \log a_1(x)$. Then (3.2) becomes

$$l(x) = \sum_{k=1}^{\infty} g_1(x2^{-k}). \tag{3.3}$$

Equation (3.3) is used to derive asymptotics for $l(x)$ for $x \to \infty$. At this stage, we start plunging into complex analysis, that is, into the Mellin transform. First we give an overview of the methodology. We use the following facts about Mellin transform [4], [3].

PROPERTY 1. If $f(x)$ is piecewise continuous on $[0, \infty]$, and

$$f(x) = O(x^{\alpha}), \quad x \to 0, \qquad f(x) = O(x^{\beta}), \quad x \to \infty, \tag{3.4a}$$

then the Mellin transform of $f(x)$ defined as [4], [3]

$$f^*(s) = \int_0^{\infty} f(x) x^{s-1}\, dx \tag{3.4b}$$

exists in the *fundamental strip*

$$-\alpha < \operatorname{Re} s < -\beta.$$

PROPERTY 2. A *harmonic sum* of the form

$$F(x) = \sum_{k=0}^{\infty} f(\mu_k x) \tag{3.5a}$$

has a simple Mellin transform:

$$F^*(s) = f^*(s) \sum_{k=0}^{\infty} \mu_k^{-s}. \tag{3.5b}$$

PROPERTY 3. The following holds for $x \to \infty$.

$$f(x) \sim -\sum_{-\beta < \operatorname{Re}(s_k) < M} \operatorname{Res}\{f^*(s)x^{-s};\ s = s_k\} + O(x^{-M}) \tag{3.6a}$$

where s_k are the singularities of $f^*(s)$ lying in the strip $-\beta < \operatorname{Re}(s) < M$, and M is an arbitrary large number, and $\operatorname{Res}\{f(s);\ \delta = s_k\}$ is the residue of $f(s)$ at $s = s_k$.

PROPERTY 4. If for $x \to \infty$ the function $f(x)$ satisfies $f(x) \sim dx^{\beta}$, then

$$f^*(s) \sim -\frac{d}{s+\beta}, \qquad s \to -\beta. \tag{3.6b}$$

□

The plan for dealing with a sum such as (3.3) follows: Noting that (3.3) falls into the harmonic sum (3.5a) in Property 2, we first compute the Mellin $l^*(s)$ transform of $l(x)$ as suggested in (3.5b). The fundamental strip of $l^*(s)$ is defined in Property 1. Then, by Property 4 we find the asymptotic expansion for $l^*(s)$, and by the inversion formula (3.6a) in Property 3 we determine asymptotics for $l(x)$.

Note that (3.3) is of the form (3.5a), and hence for $\operatorname{Re} s < 0$ the Mellin transform of (3.3) is

$$l^*(s) = \frac{2^s}{1-2^s} g_1^*(s). \tag{3.7}$$

But $g_1(x) = O(x^2)$ for $x \to 0$ and $g_1(x) = -\log 2$ for $x \to \infty$. Hence, $g_1^*(s)$ exists in the strip $-2 < \operatorname{Re} s < 0$. Note also that by (3.6b) $g_1^*(s)$ has a pole at $s = 0$ and $g_1^*(s) \sim \log 2/s$. But, the first factor in (3.7), that is, $2^s/(1-2^s)$, has poles at $\chi_k = 2\pi ik/\log 2$, $k = 0, \pm 1, \cdots$. The singularity at $k = 0$, i.e., $\chi_0 = 0$ is the most difficult to treat, since it is a double pole, and it determines the leading component of the asymptotics [4], [12]. Let us first consider $k = 0$. Note that

$$\frac{2^s}{1-2^s} = -\frac{1}{\log 2} \cdot \frac{1}{s} - \frac{1}{2} + O(s), \tag{3.8a}$$

$$g_1^*(s) = \frac{\log 2}{s} + \alpha + O(s). \tag{3.8b}$$

To determine the constant α we integrate $g_1^*(s)$ by parts, and hence

$$g_1^*(s) = \int_0^{\infty} \log \frac{1}{2}[1 + (1+x)\, e^{-x}] x^{s-1}\, dx = \frac{1}{s} \int_0^{\infty} \frac{x\, e^{-x}}{1 + (1+x)\, e^{-x}} x^s\, dx. \tag{3.9}$$

Using $x^s = 1 + s \log x + O(s^2)$, we immediately find

$$\alpha = \int_0^{\infty} \frac{x\, e^{-x} \log x}{1 + (1+x)\, e^{-x}}\, dx \tag{3.10}$$

or in another form

$$\alpha = \sum_{n=0}^{\infty} (-1)^n \int_0^{\infty} x\, e^{-x}(1+x)^n\, e^{-nx} \log x\, dx$$

$$= \sum_{n=0}^{\infty} (-1)^n \sum_{k=0}^{n} \binom{n}{k} \frac{(k+1)!}{(n+1)^{k+2}} [H_{k+1} - \gamma - \log(n+1)]. \tag{3.11}$$

As a side effect, we also prove that

$$\int_0^{\infty} \frac{x\, e^{-x}}{1+(1+x)\, e^{-x}} = \log 2. \tag{3.12}$$

The rest is easy. Multiplying (3.8a) and (3.8b) and taking into account additional simple poles at $s = \chi_k = 2\pi ik/\log 2$, $k \neq 0$, we obtain

$$l^*(s) = -\frac{1}{s^2} - \left(\frac{\alpha}{\log 2} + \frac{\log 2}{2}\right) \cdot \frac{1}{s} + \sum_{\substack{k=-\infty \\ k\neq 0}}^{\infty} \frac{g_1^*(s)}{s-\chi_k} + O(1). \tag{3.13}$$

Property 3 applied to (3.13) implies [4], [7]

$$l(x) = -\log x + \left(\frac{\alpha}{\log 2} + \frac{\log 2}{2}\right) + P(\log x) + O(x^{-M}) \tag{3.14}$$

where M is a large positive constant, and

$$P(u) = \frac{1}{\log 2} \sum_{\substack{k=-\infty \\ k\neq 0}}^{\infty} g_1^*\left(\frac{2\pi ik}{\log 2}\right) \exp\left[-\frac{2\pi iku}{\log 2}\right]. \tag{3.15}$$

The series in (3.15) converges since $g_1^*(iy) = O(y^{-M})$ for $y \to \infty$. Note also that the fluctuating function $P(\log x)$ can be safely ignored in practice, since it has a very small amplitude. Indeed, this follows from the fact that $g_1^*(s)$ can be developed as a factorization of $\Gamma(s)$ and $\Gamma(2\pi i/\log 2) \approx 10^{-6}$. Finally, (3.14) implies

$$w_1(x) = \exp[l(x)] \sim \frac{a}{x} + \frac{a}{x} P(\log x), \tag{3.16}$$

where $a = \exp[\alpha/\log 2 + \log 2/2]$.

This proves (2.9) of Proposition (i). To estimate coefficient W_n^1 of $W_1(x)$, we apply Lemma 2, and for this we must prove that $|W_1(x)| < e^{\alpha|z|}$ holds for $\alpha \in (0,1)$ outside the cone S_θ. Since $W_1(x) = \frac{1}{2}(e^{x/2} + 1 + (x/2))\, W_1(x/2)$, hence $|W_1(x)| < e^{|x|/2} |W_1(x/2)|$. This implies $W_1(x) = (1 + O(x^2))\, e^x$, and for $x \in S_\theta$ $|W_1(x)| = (1 + O(x^2))\, e^{\alpha|x|}$, where $\alpha = \cos\theta$. Thus, $|W_1(x)| < e^{(\alpha+\varepsilon)|z|}$ and condition (2.21) in Lemma 2 holds. Thus, with (3.16) and (2.22) this proves (2.25) in Theorem 2(i).

3.2. The number of resolved packets. The first moment of the number of resolved packets, C_n^1, satisfies recurrence (2.3) with $m = 1$. Then, after simple algebra, we check that the modified generating function $c_1(x) = C_1(x)\, e^{-x}$ satisfies the functional equation

$$c_1(x) = [1 + (1 + x/2)\, e^{-x/2}] c_1(x/2) = 2a(x) c_1(x/2). \tag{3.17}$$

Let $c_1(x) = xF_1(x)$ for some function $F_1(x)$. Then (3.17) is transformed into $F_1(x) = a(x)F_1(x/2)$, which is exactly the same as the functional equation for $w_1(x)$ (see (3.17)). Thus, $c_1(x) = xW_1(x)$ and $C_n^1 = nW_{n-1}^1$. Proposition (ii), (2.13), and (2.28) of Theorem 2(ii) follow immediately.

3.3. The conflict resolution interval. The recurrence for T_n^1 is given in (2.1) with $m=1$. Let $T_1(x)$ be the exponential generating function for T_n^1, and define $t_1(x)=T_1(x)\,e^{-x}-1$. Then $t_1(x)$ satisfies recurrence

$$\begin{aligned} t_1(x) &= \left[1+\left(1+\frac{x}{2}\right)e^{-x/2}\right]t_1\frac{x}{2}+1-\left(1+\frac{3}{2}x\right)e^{-x}+\frac{x}{2}e^{-x/2} \\ &= 2a(x)t_1\frac{x}{2}+b(x) \end{aligned} \tag{3.18}$$

where $a(x)=\frac{1}{2}[1+(1+x/2)\,e^{-x/2}]$ and

$$b(x)=1-\left(1+\frac{3}{2}x\right)e^{-x}+\frac{x}{2}e^{-x/2}. \tag{3.19}$$

The recurrence (3.18) falls into (2.4) and by Lemma 1 it has solution (2.5). Note that our definition of $t_1(x)$ implies that $t_1(0)=0$; thus the solution of (3.18) is

$$t_1(x)=\sum_{n=0}^{\infty}2^n b(x2^{-n})\prod_{k=0}^{n-1}a(x2^{-k}). \tag{3.20}$$

The series is convergent since $b(x)=O(x^2)$ for $x\to 0$, as required in Lemma 1(iii). Define

$$w_1(x)=\prod_{k=0}^{\infty}a(x2^{-k}), \tag{3.21}$$

which falls into our solution of the homogeneous equation (3.2) on the fraction of the resolved interval. Noting that $\prod_{k=0}^{n-1}a(x2^{-k})=w_1(x)/w_1(x2^{-n})$ we transform (3.21) into

$$\frac{t_1(x)}{w_1(x)}=\sum_{n=0}^{\infty}2^n\frac{b(x2^{-n})}{w_1(x2^{-n})}. \tag{3.22}$$

Finally, defining

$$Q_1(x)=\frac{t_1(x)}{xw_1(x)},\qquad q_1(x)=\frac{b(x)}{xw_1(x)} \tag{3.23}$$

we obtain from (3.22)

$$Q_1(x)=\sum_{n=0}^{\infty}q_1(x2^{-n}). \tag{3.24}$$

This falls into our general harmonic sum discussed in Property 2, and by (3.5), the Mellin transform of (3.24) is

$$Q_1^*(s)=\frac{q_1^*(s)}{1-2^s} \tag{3.25}$$

for $-1<\operatorname{Re} s<0$. Unfortunately, straightforward application of the same trick as in § 3.1 does not work here, since the appropriate integrals do not exist. This follows from the fact that $w_1(x)$ involved in the definition of $q_1(x)$ has infinity many poles for $\operatorname{Re} s=0$. To avoid this problem, we define a new function:

$$f_1(x)=q_1(x)-q_1\left(\frac{x}{2}\right)=\frac{b(x)-2b(x/2)a(x)}{xw_1(x)}. \tag{3.26}$$

Note now that $f_1(x) = O(e^{-x})$ for $x \to \infty$ and the Mellin transform $f_1^*(s)$ exists in the strip $-1 < \operatorname{Re} s < \infty$. For, $f_1^*(s) = q_1(s)/(1-2^s)$, (3.25) becomes

$$Q_1^*(s) = \frac{f_1^*(s)}{(1-2^s)^2}. \tag{3.27}$$

But $f_1^*(s)$ is analytical at $s=0$, and hence $f_1^*(0) = f_1^*$ and $(d/ds)f^*(s)|_{s=0} = \mu$ exist. Trivial computations show

$$f_1^* = \int_0^\infty f_1(x)\frac{dx}{x}, \qquad \mu = \int_0^\infty f_1(x)\frac{\log x}{x}\,dx. \tag{3.28}$$

The second integral must be evaluated numerically, while the first reduces to

$$\begin{aligned} f_1^* &= \int_0^\infty \left[\frac{q_1(x)}{x} - \frac{q_1(x/2)}{x}\right] dx = \lim_{k\to\infty} \int_0^{2^{k+1}} \frac{q_1(x) - q_1(x/2)}{x}\,dx \\ &= \lim_{k\to\infty} \int_{2^k}^{2^{k+1}} \frac{q_1(x)}{x}\,dx = \frac{\log 2}{a} \end{aligned} \tag{3.29}$$

where the last equality follows from (3.14) and (3.23), noting that $\lim_{x\to\infty} q_1(x) = 1/a$.

The rest is really simple and standard. Using the following expansions:

$$\frac{1}{(1-2^s)^2} = \frac{1}{s^2(\log 2)^2} - \frac{1}{s\log 2} + \mathrm{O}(1),$$

$$f_1^*(s) = \frac{\log 2}{a} + s\mu + O(s^2),$$

we obtain:

$$Q_1^*(s) = \frac{1}{a\log 2}\cdot\frac{1}{s^2} - \frac{1}{s}\left[\frac{1}{a} - \frac{1}{(\log 2)^2}\right] + O(1). \tag{3.30}$$

Taking additional poles of $(1-2^s)^2$ at $\chi_k = 2\pi ik/\log 2$, $k \neq 0$, and translating (3.30) into $Q_1(x)$ through Property 3, we find for $x \to \infty$ that

$$Q_1(x) = \frac{\log x}{a\log 2} + \left(\frac{1}{a} - \frac{\mu}{\log^2 2}\right) + P(\log x).$$

Finally, definition (3.23) of $Q_1(x)$ and estimation (3.14) for $w_1(x)$ imply that for $x \to \infty$

$$T_1(x)\, e^{-x} \sim \log_2 x + 2 - \frac{\mu a}{(\log 2)^2} + aP(\log x) \tag{3.31}$$

which proves formula (2.15) of Proposition (iii). Application of Lemma 2 (in the same manner as for $w_1(x)$) to (3.31) establishes (2.31) in Theorem 2(iii).

4. Analysis of variances and higher moments. In the previous section, we have established methodology for studying nonhomogeneous functional equations of type (2.4). It consists of two parts: first the solution to a homogeneous equation is found, then using it and properties of the Mellin transform, we obtain asymptotics for the nonhomogeneous one as was done, for example, in § 3.3. Finally, we appeal to Lemma 2 to establish asymptotics for the coefficients of the generating function. The same plan is adopted in this section, however, this time we present only sketches of proofs. For more details see [10].

4.1. The fraction of the resolved interval. Let us compute first the second moment W_n^2 of the fraction of the resolved interval, that is, we deal now with recurrence (2.3) for $m=2$. It is easy to see that the modified generating function $w_2(x)$ satisfies

$$w_2(x)=2^{-1}a(x)w_2(x/2)+b(x), \tag{4.1}$$

where $a(x)$ is defined as before (see (3.1)), and

$$b(x)=w_1(x)-\tfrac{1}{2}w_1(x/2) \tag{4.2}$$

with $w_1(x)$ defined in (3.1). The functional equation (4.1) falls into (2.4) with $s=-1$ and $a(0)=\frac{1}{2}$. Since $b(x)=O(1)$ for $x\to 0$ the recurrence (4.1) has the solution of form (2.5). Define

$$Q_2(x)=\frac{xw_2(x)}{w_1(x)}, \qquad q_2(x)=\frac{xb(x)}{w_1(x)}; \tag{4.3}$$

then the Mellin transform of (4.3) is

$$Q_2^*(s)=\frac{q_2^*(s)}{1-2^s}$$

for $-1<\operatorname{Re} s<0$, and after simple algebra we show that

$$Q_2^*(s)=-\frac{2\log 2+\beta}{\log 2}\cdot\frac{1}{s}+\sum_{\substack{k=-\infty\\ k\neq 0}}^{\infty}\frac{q_2^*(s)}{s-\chi_k}+O(1), \tag{4.4}$$

where β is defined in (2.12). Alternatively, β can be computed as

$$\beta=2\sum_{n=0}^{\infty}(-1)^n\sum_{k=0}^{n}\binom{n}{k}\frac{k!}{(n+1)^{k+1}}.$$

Formula (4.4) can be translated into

$$w_2(x)\sim a(2+b)\frac{1}{x^2}+\frac{a}{x^2}P(\log x), \tag{4.5a}$$

where $b=\beta/\log 2$, and

$$P(u)=\frac{1}{\log 2}\sum_{\substack{k=-\infty\\ k\neq 0}}^{\infty}q_2^*\left(\frac{2\pi ik}{\log 2}\right)\exp\left[-\frac{2\pi iku}{\log 2}\right]. \tag{4.5b}$$

This proves (2.10) in Proposition (i), and by Lemma 2 it also establishes (2.26) of Theorem 2.

To obtain ultimate asymptotic analysis for $\mathbf{W}_n$, we need only to prove (2.27) for the mth moment of the fraction of the resolved interval. Using (2.2) for general m, we show that the modified generating function $w_m(x)$ satisfies

$$w_m(x)=2^{-m+1}a(x)w_m(x/2)+b(x),$$

where $b(x)=O(e^{-x})$ for $x\to\infty$. Then, generalizing (4.3), we define

$$Q(x)=\frac{x^{m-1}w_m(x)}{w_1(x)}, \qquad q(x)=\frac{x^{m-1}b(x)}{w_1(x)};$$

then $Q^*(s)=q^*(s)/(1-2^s)$. But $q^*(s)=O(1)$ for $s\to 0$, hence $Q^*(s)=O(s^{-1})$, and finally by (4.12), $W_m(x)=O(x^{-m})$. Using Lemma 2, we prove (2.27).

4.2. The number of resolved packets. The corresponding functional equation for the modified generating function $c_2(x)$ satisfies

$$c_2(x) = 2a(x)c_2\frac{x}{2} + b(x), \tag{4.6}$$

where

$$b(x) = x\,e^{-x/2}c_1\frac{x}{2} = \frac{x^2}{2}\,e^{-x/2}w_1\frac{x}{2}$$

and the last equality follows from $c_1(x) = xw_1(x)$ proved in § 3.2. Then by Lemma 1, the functional equation (4.6) possesses the solution $c_2(x) = c_2'(x) + c_2''(x)$, where by (2.7) of Lemma 1, $c_2'(x) = xw_1(x)$. The second term $c_2''(x)$ has the infinite series solution of form (2.5). Therefore, the same derivation as in § 4.1 leads finally to (2.14) of Proposition (ii). The proof of (2.30) of Theorem 2(ii) follows the same arguments as in the end of § 4.1 and is left to the reader.

4.3. The conflict resolution interval. The analysis of T_n^2 is much more intricate. Define $t_2(x) = T_2(x)\,e^{-x} - 1$; then the modified generating function $t_2(x)$ satisfies

$$t_2(x) = 2a(x)t_2\frac{x}{2} + b(x) \tag{4.7}$$

where

$$b(x) = 2t_1(x) + x\,e^{-x/2}t_1\frac{x}{2} + \frac{x}{2}\,e^{-x/2} - \frac{5}{2}\,x\,e^{-x/2} - 1.$$

We split $b(x)$ into two functions, $b(x) = b_1(x) + b_2(x)$, where $b_1(x)$ is given by (3.19) and

$$b_2(x) = 2t_1(x) - 2 + x\,e^{-x/2}t_1\frac{x}{2} - x\,e^{-x}. \tag{4.8}$$

Then, $t_2(x) = t_1(x) + t_2''(x)$, where $t_1(x)$ is evaluated in § 3.3, and $t_2''(x)$ satisfies our general functional equation (2.4) with the solution given by (2.5). Therefore, our general approach from the previous sections can be used. Define $Q_4(x) = t_2''(x)/xw_1(x)$ and $q_4(x) = b_2(x)/xw_1(x)$; then the Mellin transform is $Q_4^*(s) = q_4^*(s)/(1-2^s)$, and it exists only for $-1 < \operatorname{Re} s < -\varepsilon$. As in the case of $t_1(x)$, the transform $Q_4^*(s)$ needs a special treatment to find an asymptotic expansion. We follow the approach from § 3.3 and define a new function

$$f_2(x) = q_4(x) - q_4\frac{x}{2} = \frac{b_2(x) - 2b_2(x/2)a(x)}{xw_1(x)} \tag{4.9}$$

for which the Mellin transform $f_2^*(s)$ exists for $-1 < \operatorname{Re} s < 0$. The function $f_2^*(s)$ has pole at $s = 0$; hence $f_2^*(s) = -2/(s\alpha) + f_2^* + s\nu + O(s^2)$, where f_2^* and ν can be computed in the same manner as before and are given by

$$f_2^* = -\int_0^\infty f_2'(x)\log x\,dx, \qquad \nu = -\frac{1}{2}\int_0^\infty f_2'(x)\log^2 x\,dx. \tag{4.10}$$

Using the same arguments as in the derivation of (3.29), we can prove that

$$f_2^* = \frac{2}{\alpha}(c-1)\log 2 - \frac{\log 2}{\alpha}. \tag{4.11}$$

Finally, the Mellin transform of $Q_4(x)$ can be expressed as

$$Q_4^*(s) = \frac{-2}{a \log^2 2} \cdot \frac{1}{s^3} + \frac{1}{s^2}\left[\frac{f_2^*}{\log^2 2} + \frac{2}{a \log 2}\right] - \frac{1}{s}\left[\frac{5}{6a} + \frac{f_2^*}{\log 2} - \frac{\nu}{\log^2 2}\right] + O(1) \tag{4.12}$$

so (2.16) of Proposition (iii) is proved. By Lemma 2, the following also holds:

$$T_n^2 = \log_2^2 n + 2c \log_2 n + \frac{5}{6} + 3(c-1) - \frac{a\nu}{\log^2 2} + P(\log n) + O(n^{-1/2}) \tag{4.13}$$

and (2.32) of Theorem 2(iii) follows from $\operatorname{var} \mathbf{T}_n = T_n^2 - (T_n^1)^2$. The rest is simple and is left to the reader (see also [10]).

Acknowledgment. We thank an anonymous referee for very careful reading of our paper and several suggestions for improvement of the presentation.

AN OPTIMAL-TIME ALGORITHM FOR SLOPE SELECTION*

RICHARD COLE†, JEFFREY S. SALOWE‡, W. L. STEIGER§, AND ENDRE SZEMERÉDI¶§

Abstract. Given n points in the plane and an integer k, the problem of selecting that pair of points that determines the line with the kth smallest or largest slope is considered. In the restricted case, where k is $O(n)$, line sweeping gives an optimal, $O(n \log n)$-time algorithm. For general k the parametric search technique of Megiddo is used to describe an $O(n(\log n)^2)$-time algorithm. This is modified to produce a new, optimal $O(n \log n)$-time selection algorithm by incorporating an approximation idea.

Key words. computational geometry, selection, slopes

1. Introduction. Given n distinct points in the plane, $(x_1, y_1), \cdots, (x_n, y_n)$, write $N = \binom{n}{2}$ and consider the N (not necessarily distinct) lines they determine, $y = a_{ij}x + b_{ij}$, $1 \leqq i < j \leqq n$, one for each pair of points. In [4], Chazelle mentions the problem of selecting one of these lines according to the rank of its slope: given $1 \leqq k \leqq N$ we seek the kth smallest element of $S = \{a_{ij}, 1 \leqq i < j \leqq n\}$.

When $k = N/2$, the median slope is the Theil estimator [13] of the slope of the regression line through the data. In [12], Shamos enquires about the complexity of computing the Theil estimator and wonders whether it might be $o(N)$. Chazelle [4] studies several interesting geometric selection problems but does not give any results for the selection of slopes. In this paper, we describe some facts relating to the problem that may not be widely known and give a new, optimal-time algorithm for the slope selection task. The algorithm is applicable to other geometric selection problems [10] and may also have wider interest.

If we were to just present S, the fast selection algorithm of Blum et al. [3] would use $O(N)$ comparison steps for any rank, k. However, if we exploit the geometric information embodied by the n points, we may be able to (i) avoid computing all N slopes and consequently (ii) find the rank k line in $o(N)$ steps. From now on we take a *step* to mean any arithmetic operation, comparison, pointer manipulation, or read to/write from memory.

The paper is organized as follows. In § 2, the shallow selection problem is studied. In shallow selection, k is nearly 1 or N. In § 3, an $O(n(\log n)^2)$-time algorithm is presented for the general selection problem. This algorithm is improved in § 4 to yield an optimal $O(n \log n)$-time algorithm. Section 5 contains general remarks and a summary of the results.

2. Shallow selection. In the slope selection problem, we are given n points, $(x_1, y_1), \cdots, (x_n, y_n)$. Throughout the paper, assume that the points are in general position. In this context, general position means that no three points are collinear and

that no two of the induced lines have the same slope; this assumption simplifies the arguments without affecting the asymptotic complexity of the algorithms.

Consider the selection problem when $k = 1$. It is easy to show that $\Omega(n \log n)$ time is a lower bound for this problem in the algebraic decision tree model of computation. It is known that $\Omega(n \log n)$ time is needed to determine if a set of n numbers are distinct in the algebraic decision tree model [8]. This problem is known as ELEMENT UNIQUENESS. In linear time, we can transform an instance of the ELEMENT UNIQUENESS problem to the problem of selecting the smallest slope. Given as input a set of n numbers H, map each number h_i in H to point (h_i, i) in the plane. If the smallest slope is finite, then input points are distinct; otherwise, some pair h_i and h_j have the same value.

In fact, $O(n \log n)$ steps are sufficient to find either the smallest or the largest slope (the extreme slopes). Sort the input points $(x_1, y_1), \cdots, (x_n, y_n)$ by x-coordinate. It is easy to see that the extreme slopes are determined by a line incident to points having adjacent x-coordinates. By computing the relevant $n-1$ slopes and finding the minimum, we see that extremal selection can be done in $O(n \log n)$ steps. The idea is easily adapted to cover optimal shallow selection.

LEMMA 1. *If $k = O(\log n)$, the rank k slope may be found in $O(n \log n)$ steps.*

Proof. Let $p_1 = (x_1, y_1)$ and $p_2 = (x_2, y_2)$, $x_1 \leqq x_2$, be the pair of points determining line l, whose slope has rank k. We claim that there are at most $k-1$ other points whose x-coordinates lie between x_1 and x_2. Each intervening point bears witness to the presence of an additional line with slope smaller than l. For any point p between x_1 and x_2 lying below l, the line incident to p_1 and p has slope less than that of l. For any point p between x_1 and x_2 lying above l, the line incident to p_2 and p has slope smaller than that of l. Since no three points are collinear, these are the only possibilities.

The algorithm to select slope k would sort the input points by x-coordinate, consider pairs of points that are separated by at most $k-1$ other points, and use the linear time selection algorithm to find the kth smallest slope. Since $k = O(\log n)$, this algorithm uses $O(n \log n)$ steps. □

It is easy to see that Lemma 1 can also be used to select slopes with rank $N - k + 1$, where $k = O(\log n)$.

To make more progress in designing selection algorithms, we transform the slope selection problem into a more convenient form using a point-line duality. This is defined by a mapping T that takes the point $p = (a, b)$ to the line Tp given by $y = ax + b$ and the line l given by $y = cx + d$ to the point $Tl = (-c, d)$. It is well known that T preserves incidence. That is, if points p_1 and p_2 are incident with line l, Tl is the point of intersection of the lines Tp_1 and Tp_2; similarly, if l_1 and l_2 intersect at point p, Tp is the line incident with the points Tl_1 and Tl_2.

Under T, the n given points map to lines $l_1, \cdots, l_n$ whose points of intersection, $l_i \cap l_j \equiv (u_{ij}, v_{ij})$, correspond to the lines incident with the ith and jth original points. Furthermore, $-u_{ij}$ is the slope of this line. Thus, the dual of the problem of selecting slope k is the following, equivalent selection problem: **Given distinct lines $l_1, \cdots, l_n$, find the intersection point whose x-coordinate is the $N - k + 1$th smallest element of the set $TS = \{u_{ij}, 1 \leqq i < j \leqq n\}$.** We will consider the general problem of selecting elements in TS in the remainder of the paper.

For ease of exposition, we will abuse notation by blurring the distinction between intersection points and their x-coordinates. This is justified because the y-coordinates provide no information for the selection problem. We write $t_1 < \cdots < t_N$ for the $\binom{n}{2}$ elements of TS is sorted order. Note that the t_i's are distinct because the input points are in general position. Given k, we seek t_k.

In this dual problem, optimal *shallow* selection ($k = O(n)$) can be effected by the line sweep technique of Bentley and Ottmann [2]. The sweep starts at $x = a$, $a < t_1$. Let π be the permutation that sorts the slopes in ascending order. Thus $m_{\pi_1} < \cdots < m_{\pi_n}$, where we write $y = m_i x + b_i$ as the equation of l_i. If $a < t_1$, the vertical line $x = a$ meets $l_1, \cdots, l_n$ at $y_1(a), \cdots, y_n(a)$ and $y_{\pi_1}(a) > \cdots > y_{\pi_n}(a)$. For each adjacent pair of lines, find the x-coordinate $z_i = (b_{\pi_{i+1}} - b_{\pi_i})/(m_{\pi_i} - m_{\pi_{i+1}})$ of their intersection point and place these $n-1$ numbers in a (min) heap. Clearly $t_1 = \min(z_i)$. It has been obtained in time $O(n \log n)$.

Suppose z_p is the smallest z_i. It is currently at the top of the heap. We sweep just beyond $t_1 = z_p$. When $a > t_1$, $y_{\pi_p}(a) < y_{\pi_{p+1}}(a)$ because lines l_{π_p} and $l_{\pi_{p+1}}$ have crossed at t_1. We compute the two new intersection points $z' = (b_{\pi_{p+1}} - b_{\pi_{p-1}})/(m_{\pi_{p-1}} - m_{\pi_{p+1}})$ and $z'' = (b_{\pi_{p+2}} - b_{\pi_p})/(m_{\pi_p} - m_{\pi_{p+2}})$ (if $p = n-1$, only compute z'; if $p = 1$, only compute z''). Delete z_p from the heap, insert z' and z'', and exchange π_p with π_{p+1}. We may now obtain $t_2 = \min(z_i)$ having expended $O(\log n)$ steps. The two new z's were computed in constant time, and the deletion and two insertions took $O(\log n)$ time. Continuing in the same fashion by sweeping through to t_k, we have Lemma 2.

LEMMA 2. *Given n lines $l_1, \cdots, l_n$ and an integer k, the cost of sweeping to the intersection point $l_i \cap l_j$ with the kth smallest x-coordinate is $O(n \log n + k \log n)$.*

When $k = O(n)$, the total effort would be $O(n \log n)$, and this is optimal. In the primal problem we achieve optimal selection for slopes of rank $k = N - O(n) + 1$. By symmetry, we can select slopes with $k = O(n)$ in optimal time as well.

When $k \neq O(n)$, a more powerful technique is required for efficient slope selection. In the next section we give an $O(n(\log n)^2)$ time algorithm for selecting elements in *TS*.

3. The general selection algorithm. Write $\pi(a)$ for the permutation that orders the intercepts of $l_1, \cdots, l_n$ in descending order at $x = a$. Thus, under obvious notation, $y_{\pi_1(a)}(a) > \cdots > y_{\pi_n(a)}(a)$. Renumber $l_1, \cdots, l_n$ so that for $a < t_1$, $\pi(a)$ is the identity. At the intersection points t_i, we disambiguate π by defining $\pi(t_i) = \pi(t_i + \varepsilon)$, where $0 < \varepsilon < \min(t_{j+1} - t_j)$. The permutation $\pi(t_1)$ has one inversion (exactly one pair of lines crossed at t_1), $\pi(t_2)$ has two, etc. In fact the function

$$I(\pi(x)) = \#\text{ inversions in } \pi(x)$$

is a monotone step function in x with unit jumps at the t_i's. $I(\pi(x)) = j$ if and only if $t_j = \max(t_i : t_i \leqq x)$. For a given k, the problem of finding t_k may be viewed as an unusual sorting problem to which we apply Megiddo's ingenious technique [7], improved by Cole [5], of building sequential algorithms from parallel ones. An implicit binary search over the t_i's is performed, each step taking $O(n \log n)$ time. This will give an $O(n(\log n)^2)$-time algorithm.

In seeking t_k, we will attempt to sort $y_1(a^*), \cdots, y_n(a^*)$ at $a^* = t_k + \varepsilon$. We know that this sort may be achieved in $O(n \log n)$ "comparisons," each answering a question Q_{ij} of the form "$y_i(a^*) \leqq y_j(a^*)$?". The $O(n \log n)$ answers yield the permutation π^* that sorts these intercepts: $y_{\pi_1^*}(a^*) > \cdots > y_{\pi_n^*}(a^*)$. Once π^* has been found,

$$t_k = \max[u_{\pi_i^*, \pi_{i+1}^*} : \pi_i^* > \pi_{i+1}^*];$$

the kth inversion must have just reversed a pair of adjacent intercepts in the permutation $\pi(t_{k-1})$.

The control structure for the sort will come from the $O(\log n)$-depth sorting network of Ajtai, Komlós, and Szemerédi [1]. At each level, $n/2$ of the questions

Q_{ij}: "$y_i(a^*) \leqq y_j(a^*)$?" are answered. The network is just a guide for blocking these comparisons into groups of size $n/2$; the comparisons are actually performed in series. The sort is complete once the $O(n \log n)$ answers are obtained and we have determined π^*.

Even though we do not know a^*, we can answer the question "$y_i(a^*) \leqq y_j(a^*)$?" in time $O(n \log n)$ by ranking. We find u_{ij}, the *x-coordinate of* $l_i \cap l_j$, $i<j$, in constant time and then obtain its rank among the t_i's as follows. Sort the n intercepts at u_{ij} in decreasing order to get $\pi(u_{ij})$. The rank of u_{ij} is the number of inversions in $\pi(u_{ij})$, $I(\pi(u_{ij}))$. If $I(\pi(u_{ij}))>k$ we know that $u_{ij}>t_k$ so the answer is "no;" lines i and j have not yet crossed at t_k. Similarly if $I(\pi(u_{ij}))<k$, $u_{ij}<t_k$ and the answer is "yes." If $I(\pi(u_{ij}))=k$, $t_k=u_{ij}$. I may be computed in time $O(n \log n)$ as explained in Knuth [6]: if $\pi(u_{ij})=(r_1, \cdots, r_n)$, we use merge-sort to sort the slopes $m_{r_1}, \cdots, m_{r_n}$ and count the inversions that were performed.

If we actually answered all $n/2$ questions $Q_{i_1 j_1}, \cdots, Q_{i_{n/2} j_{n/2}}$ on a level of the network by counting inversions, the complexity would be $O(n^2 \log n)$ for that level and $O((n \log n)^2)$ overall. The trick is to resolve the $n/2$ questions on a level by actually counting inversions only $O(\log n)$ times.

As mentioned, each question Q_{ij} determines an intersection point of a distinct pair of lines, and the answer to Q_{ij} is obtained by comparing the rank of that intersection point with k. On a given level of the sequentialized version of the parallel sorting network, denote the x-coordinates of these points by $z_{i_1}, \cdots, z_{i_{n/2}}$. We can compute the median of these intersection points, z_{med}, in time $O(n)$. It costs time $O(n \log n)$ to rank z_{med}, and this answer resolves half the questions. For example, if $z_{\text{med}}<t_k$, then $z_{i_j}<t_k$ for all the $z_{i_j} \leqq z_{\text{med}}$. Continuing with the $n/4$ unresolved questions on this level, we again find the median z and rank it in time $O(n \log n)$, etc. After $O(\log n)$ inversions counts, all $n/2$ questions on this level are resolved. Since each inversion count takes $O(n \log n)$ steps and there are $O(\log n)$ levels, the algorithm has time complexity $O(n(\log n)^3)$.

In [5], Cole shows how this result may be improved by a factor of $\log n$. Each question in the network has two inputs. On level 1, all inputs are prescribed. The inputs to each question on level $j>1$ depend on the answers to some pair of questions from level $j-1$. A question is "active" if both its inputs have been determined but it is not yet answered. The idea is to resolve questions as they become active. A weight of $1/4^{j-1}$ is assigned to active questions on level j. At each "stage" the weighted median, z_{wmed}, of intersection points of active questions is determined in linear time [9] and resolved in time $O(n \log n)$ by ranking z_{wmed}. As before, this resolves either all questions for which $z \leqq z_{\text{wmed}}$ or all questions for which $z \geqq z_{\text{wmed}}$. Once resolved, questions are no longer active. Cole shows that the weight of the active questions is reduced by a factor of at least $\frac{1}{4}$ after ranking z_{wmed}. In total, $O(\log n)$ inversion counts are sufficient to resolve all the questions asked by the network. This argument proves the following assertion:

THEOREM 3. *Given n lines* $l_1, \cdots, l_n$ *and an integer k, the intersection point* $l_i \cap l_j$ *with the kth smallest x-coordinate may be found in time* $O(n(\log n)^2)$.

4. Improvement with approximate ranking. The previous sections showed that for any given k, the worst-case time complexity to select the intersection point with the kth smallest x-coordinate is in the interval $(cn \log n, dn(\log n)^2)$. In this section we show that the lower bound is sharp or equivalently:

THEOREM 4. *Given n lines* $l_1, \cdots, l_n$ *and an integer k, the complexity of finding the intersection point* $l_i \cap l_j$ *with the kth smallest x-coordinate is* $O(n \log n)$.

The proof will describe an explicit algorithm, argue its correctness, and demonstrate the time complexity assertion. The algorithm is superimposed on the one used in Theorem 3, and it is presented in five sections. Section 4.1 presents the general strategy, §§ 4.2–4.4 describe the three essential procedures in the algorithm, and § 4.5 completes the analysis and proves Theorem 4.

4.1. The approximation algorithm. The new idea is to use an approximate rank for each point chosen by the sorting network. Let sign (x) be $+1$ if x is positive, 0 if x is zero, and -1 if x is negative. The algorithm discussed in § 3 expended time $O(n \log n)$ to find rank (z_{wmed}) for each of the $O(\log n)$ weighted median points given by the network. This rank determined sign $(z_{\text{wmed}} - t_k)$, and we could resolve all the z_i for which sign $(z_i - z_{\text{wmed}}) = \text{sign}\,(z_{\text{wmed}} - t_k)$. In the improved algorithm, we will use $O(n)$ (amortized) time to develop an approximation ρ_z to the rank of z. Let e_z denote the error of the approximation:

$$e_z = |\text{rank}\,(z) - \rho_z|.$$

If the error is small enough, ρ_z can tell us the relative ordering of z and t_k. By definition, rank (z) must lie inside the closed interval $[\rho_z - e_z, \rho_z + e_z]$. If k lies outside the interval $[\rho_z - e_z, \rho_z + e_z]$, then sign $(z - t_k) = \text{sign}\,(\text{rank}\,(z) - k) = \text{sign}\,(\rho_z - k)$; in this case, the relative ordering of z and t_k can be deduced from ρ_z and k, and we may resolve the relevant z_i's. On the other hand, if k lies inside the interval $[\rho_z - e_z, \rho_z + e_z]$, the approximation will not be accurate enough to distinguish the relative positions of z and t_k, so we cannot use z resolve any other questions. To account for this, we will do some extra comparisons to refine ρ_z and reduce e_z until k lies outside the interval $[\rho_z - e_z, \rho_z + e_z]$. It turns out that at most $O(n \log n)$ extra work will be done to refine rank approximations throughout the entire course of the algorithm.

The key structure used in the approximation is the following. Suppose we have a "reference" intersection point at $x = r$ and we know sign $(r - t_k)$. Also suppose that we have partitioned the n lines into $\tau = \lceil n/T \rceil$ groups $G_1, \cdots, G_\tau$ of size T (maybe G_τ is smaller) with the property that if $i_1 \in G_i$, $i_2 \in G_j$, and $i < j$, then $y_{i_1}(r) \geqq y_{i_2}(r)$, where T is an integer to be specified later. Thus, G_1 refers to the lines with the T largest intercepts at $x = r$, G_2 the lines with the next T largest intercepts, etc. The groups are therefore sorted, but within any particular group, we have no ordering information. Such a structure is called a *partition of size T at r*. We maintain partitions of size T at the current "reference" points as an invariant. The occasional refinements will divide T by 2 and restore the invariant in time $O(n)$ per refinement, $O(n \log n)$ overall.

A partition of size T at r is represented by a permutation $p(r, T) = (p_1(r, T), \cdots, p_n(r, T))$, where $p_1(r, T), \cdots, p_T(r, T)$ are the lines in G_1, $p_{T+1}(r, T), \cdots, p_{2T}(r, T)$ the lines in G_2, etc. Partition $p(r, T)$ is thus an approximation to $\pi(r)$, the permutation that correctly orders the intercepts $y_i(r)$. We define the approximate rank $\rho_{(r,T)}$ to be the number of inversions in $p(r, T)$:

$$\rho_{(r,T)} = I(p(r, T)). \tag{1}$$

Because $p(r, T)$ represents the partition, it can differ from $\pi(r)$ only with respect to inversions between pairs of lines within the same group. Since there are at most $\binom{T}{2}$ such inversions in a group, $\rho_{(r,T)}$ differs from rank (r) by less than $nT/2$. Therefore, for any given value of T,

$$e_r < nT/2. \tag{2}$$

If the value of T is clear from the context, we will remove the parameter T from $p(r, T)$ and $\rho_{(r,T)}$.

To prove the correctness and derive the time complexity of the approximation algorithm, we will choose T to be a power of 2 for which

$$|\rho_{(r,T)} - k| \leqq nT, \tag{3}$$

$$|\rho_{(r,T/2)} - k| > nT/2. \tag{4}$$

Because (2) implies that $\rho_{(r,T/2)} - nT/4 < \text{rank}\,(r) < \rho_{(r,T/2)} + nT/4$ and (4) implies that k lies outside the open interval $(\rho_{(r,T/2)} - nT/2,\ \rho_{(r,T/2)} + nT/2)$, $\text{sign}\,(\rho_{(r,T/2)} - k) = \text{sign}\,(\text{rank}\,(r) - k) = \text{sign}\,(r - t_k)$. From condition (4), we are able to determine the relative position of r and t_k, so our approximation correctly reveals whether the current point r lies on the left or right of t_k. If (3) and (4) should fail for the current value of T, we would halve T and create the partition for the new smaller groups. The impact of (3) and (4) is indicated in the following lemma.

LEMMA 5. *Let $p(r, T)$ be a partition of size T at r, and assume that* (3) *and* (4) *hold for $p(r, T)$. Then $nT/4 < |\text{rank}\,(r) - k| < 3nT/2$.*

Proof. By (2), $|\text{rank}\,(r) - \rho_{(r,T)}| < nT/2$, and by (3), $|\rho_{(r,T)} - k| \leqq nT$. Therefore, $|\text{rank}\,(r) - k| < 3nT/2$. By (4), $|\rho_{(r,T/2)} - k| > nT/2$, and by (2), $|\text{rank}\,(r) - \rho_{(r,T/2)}| < nT/4$. Therefore, $|\text{rank}\,(r) - k| > nT/4$. □

We now describe the flow of control in the approximation algorithm. The algorithm maintains *two reference points*: $r_L \leqq t_k$ and $r_R \geqq t_k$. We maintain orderings $p(r_L)$ and $p(r_R)$ and calibrated partition sizes T_L and T_R for both reference points. The reference point with the smaller value of T is "active." (From this point in the paper until § 4.5, we will abbreviate $p(r, T)$ by $p(r)$ because the value of T will be clear from the context.) When the network gives a new query point $x = q$, if $q \notin (r_L, r_R)$, the relative position of q with respect to t_k may be deduced by transitivity. We can immediately resolve this point and the relevant z_i's (of which q was the weighted median). Otherwise, we construct the partition at $x = q$. If $q < t_k$, the partition of size T at q is a modification of the partition of size T at r_L. If $q > t_k$, the partition of size T at q is a modification of the partition of size T at r_R. Since we do not know the relative ordering of q and t_k, an attempt is made to modify the partition at r, the active reference point. The attempt will be aborted if $|\text{rank}\,(r) - \text{rank}\,(q)|$ is "large;" in this case, the other reference point r' then becomes active and the partition at r' is modified to give the partition at q. Position q then replaces the appropriate reference point (on the same side of t_k as q) and the reference point with the smallest value of T becomes the new active reference point.

Figure 1 contains a description of the selection algorithm. To initialize the algorithm, we find any $r_L < t_1$ and $r_R > t_N$ in $O(n \log n)$ steps by the shallow selection technique and use $p(r_L) = (1, \cdots, n)$ and $p(r_R) = (n, \cdots, 1)$ regardless of the initial values of T_L and T_R. To calibrate T_L, we know $k - \rho_{(r_L,T)} = k - \rho_{(r_L,T/2)} = k$, and from (3) and (4), $k/n \leqq T_L < 2k/n$. Therefore, $T_L = 2^{\lceil \log(k/n) \rceil}$; similarly, $T_R = 2^{\lceil \log((N-k)/n) \rceil}$. In the algorithm, the variable SIDE indicates which reference point is active: SIDE $= -1$ means r_L is active and SIDE $= 1$, that r_R is.

We shall briefly explain the above steps and analyze them in detail in subsequent sections. The lines ⟨0⟩-⟨3⟩ initialize the active reference point. The algorithm will continue to make approximations until T is within a constant. When T is less than or equal to 10, the error bound and the properties of the partition imply that the maximum number of intervening vertices between q and t_k is less than $5n$, so the sweepline algorithm used in Lemma 2 can be slightly modified to find t_k in $O(n \log n)$ additional steps. At line ⟨5⟩, the next vertex to be compared with t_k is delivered; this vertex has x-coordinate q. If q is outside the interval from r_L to r_R, it may be resolved immediately

```
⟨0⟩  IF T_L ≦ T_R THEN
⟨1⟩    T ← T_L; SIDE ← −1; r ← r_L; ρ_r ← 0; p(r) = (1, 2, ···, n)
⟨2⟩  ELSE
⟨3⟩    T ← T_R; SIDE ← 1; r ← r_R; ρ_r ← n(n−1)/2; p(r) = (n, n−1, ···, 1)
⟨4⟩  WHILE T > 10

FIG. 1. *Algorithm description.*

by transitivity. Therefore, RESOLVE q in line ⟨7⟩ should be interpreted to mean "answer q and all z_i (of which q is the weighted median) for which sign $(z_i - q) =$ sign $(q - t_k)$."

If q is inside the interval from r_L to r_R, more work must be done. As stated earlier, if $q < t_k$, the partition of size T at q must be obtained by modifying the partition of size T_L at r_L. If $q > t_k$, the partition of size T at q must be obtained by modifying the partition of size T_R at r_R. (The rationale for this restriction will be explained in § 4.2.) The important procedures are PARTITION, COUNT, and HALVE.

The procedure PARTITION is the heart of the algorithm and will be described in detail in § 4.2. For now, it is enough to take the following statements on faith: (i) whenever $|\text{rank}\,(r) - \text{rank}\,(q)| < 3nT/2$, it will use $p(r)$ to construct a partition of size T at q, $p'(q)$, in linear time. (ii) If $3nT/2 \leqq |\text{rank}\,(r) - \text{rank}\,(q)|$, PARTITION will halt in linear time either with TOOFAR = 1 or with a partition of size T at q, $p'(q)$.

If TOOFAR = 1 in line ⟨10⟩, then $|\text{rank}\,(q) - \text{rank}\,(r)| \geqq 3nT/2$. By Lemma 5, this implies that q and r are on opposite sides of t_k, so control proceeds to line ⟨17⟩.

The procedure COUNT computes ρ'_q, the number of inversions in $p'(q)$, given ρ_r, $p'(q)$, $p(r)$, and SIDE. (The reader should observe that ρ'_q never appears in Fig. 1 since ρ_q is always updated on the fly. We introduce ρ'_q so that the action of procedure COUNT is clear.) In linear time COUNT either returns the correct value of ρ'_q or the message that $|\rho_r - \rho'_q| \geqq 3nT/2$. In the latter case, it will set TOOFAR to 1 since it is known that q and r cannot be on the same side of t_k. (This claim will be justified in § 4.4.) If TOOFAR is set to 1 in line ⟨11⟩, then control proceeds to line ⟨17⟩, as above.

If TOOFAR = 0 at the time line ⟨12⟩ is executed, $p'(q)$ defines a partition of size T at q. If the condition in line ⟨12⟩ is true, then (3) and (4) do not hold. The procedure HALVE converts the partition of size T into one of size $T/2$ and corrects ρ_q. The WHILE loop can end in one of two ways. Either T has been correctly calibrated and $p(q)$ has been formed, or sign $(\rho_q - k) \neq$ sign $(\rho_r - k)$. In the latter case, this will indicate that r and q are on opposite sides of t_k. (This claim will be justified in § 4.5.)

At line ⟨17⟩, the algorithm has either succeeded in computing a new partition at q, the flag TOOFAR has been set to 1, or sign $(\rho_q - k) \neq$ sign $(\rho_r - k)$. The test in line ⟨17⟩ decides whether q is on the same side of t_k as r. If the test is false, q is on the same side of t_k as r and the partition has already been computed. If the test in line ⟨17⟩ is true, q is on the opposite side of t_k as r, so q is on the same side of t_k as the other reference point r'. In this case, the partition of size T at q is computed with respect to r' in lines ⟨18⟩-⟨23⟩. Procedure CHANGESIDES in line ⟨18⟩ changes the value of variable SIGN, switches the reference point, and resets T to the value corresponding to the new reference point.

Since the relative position of q with respect to t_k is known when line ⟨25⟩ is executed, RESOLVE q can be performed. Actually, the partition of size T at q may not be accurate enough to determine the relative positions of q and t_k; as is stated in (4), it is the next smaller size of T that permits the resolution of q. To set up the variables for the next iteration, a procedure called FIXREFS sets $r_L \leftarrow q$, $p(r_L) \leftarrow p(q)$, and $T_L \leftarrow T$ if SIDE $= -1$ or $r_R \leftarrow q$, $p(r_R) \leftarrow p(q)$, and $T_R \leftarrow T$ otherwise. It then sets $T \leftarrow \min(T_L, T_R)$ and makes the reference point with the smaller value of T the active reference point.

4.2. The procedure PARTITION. At reference point $x = r$ (r is either r_L or r_R), the permutation $p(r)$ defines a partition of the n lines into $\tau = \lceil n/T \rceil$ groups $G_1 \geqq \cdots \geqq G_\tau$ of size T ($|G_\tau|$ may be $< T$). Recall that the inequalities mean that if $c \in G_i$, $d \in G_j$, and $i < j$, then $y_c(r) \geqq y_d(r)$. We wish to construct a new partition of size T' at q, $p(q)$, where $T' = T/2^s$ for some $s \geqq 0$. Procedure PARTITION performs the first step in this process. With respect to the active reference point, procedure PARTITION will, in linear time, either construct a partition of size T at q, $p'(q)$, or deduce that $|\text{rank}(r) - \text{rank}(q)| \geqq 3nT/2$. In the former case, procedure HALVE will, if necessary, form $p(q)$ by refining $p'(q)$ until (3) and (4) are reestablished. In the latter case, Lemma 5 implies that r and q are on opposite sides of t_k.

To make the selection algorithm correct, constraints must be placed on the partitions $p'(q)$ and $p(q)$. First, we require that the partition $p(q)$ is derived from the partition at the reference point r that satisfies sign $(q - t_k) =$ sign $(r - t_k)$. Second, we insist that when $r < q$:

(5) Lines appearing in any particular group in $p(q)$ or $p'(q)$ are in the same order as they were in $p(r)$.

There are two reasons to constrain the partition in the manner described above. First, the constraints simplify the maintenance of invariants (3) and (4). Specifically, a partition of size T at r may be in error by at most $nT/2$. At reference line r, $|\rho_r - k| \leqq nT$. To ensure that T cannot increase during the course of the algorithm, we insist that $|\rho'_q - k| \leqq |\rho_r - k| \leqq nT$ if q and r are on the same side of t_k. Here, ρ'_q is the number of inversions present in $p'(q)$. We will prove this result in Lemma 12.

The second motivation for (5) is to simplify the design of the counting procedures COUNT and HALVE. Suppose that a new partition $p'(q)$ is constructed by procedure PARTITION. Procedure COUNT will compute the number of inversions ρ'_q in $p'(q)$ by comparing the partition $p(r)$ with $p'(q)$. If the approximation ρ'_q is not sufficiently

accurate, procedure HALVE will be run. If no constraints are imposed within groups of the partition $p'(q)$, it is possible that PARTITION might invert a pair of lines between $x = r$ and $x = q$ and then HALVE reverses this inversion. The problem is that our COUNT and HALVE procedures will account twice for an inversion that does not appear in $p(q)$.

In the description of the algorithm, the groups in partition $p'(q)$ are denoted by $G'_1 \geqq \cdots \geqq G'_\tau$. When convenient, $p'(q)$ will be referred to as as $\{G'_i\}$. The groups in $p(r)$ are denoted by $G_1 \geqq \cdots \geqq G_\tau$ and will sometimes be referred to as $\{G_i\}$. Various intermediate groups are created during the construction of $p'(q)$; these groups are designated by $\{G_i^j\}$ and are distinguished by the superscript j.

PARTITION begins by *blocking intercepts at* $x = q$. That is, PARTITION puts the first 20 groups $G_1, \cdots, G_{20}$ into block 1, the next 20 into block 2, etc. The lines in each block are *regrouped* according to their intercepts $y_s(q)$ at q. Thus G^1_{20i-19} contains the T largest intercepts at q among the block i lines, G^1_{20i-18} the next T largest intercepts at q among the block i lines.

LEMMA 6. *Let* $\{G_i\}$ *be a partition of size* T *at* r. *The cost of forming* $\{G_i^1\}$ *is* $O(|\{G_i\}|)$.

Proof. In each block we find the Tth largest $y_i(q)$, the $(2T)$th largest, and so on up to the $(19T)$th largest, each in time $O(T)$. Once these 19 group dividers are determined, each element in the block may be placed into the correct group in constant time, and since there are $O(n/T)$ blocks, the linear time bound holds. □

Furthermore, since lines are blocked in the order in which they appear in $p(r)$, lines in the same group at $x = q$ satisfy (5). With each line j, we will maintain $\gamma(j)$, its index at $x = r$ (i.e., line j is the $\gamma(j)$th line in descending order in $p(r)$).

Here is a quick overview of how PARTITION will continue after blocking. Within each block, the groups $\{G_i^1\}$ are correctly ordered at q. This is a good start in constructing $p'(q)$. Call a pair of groups G_i^1 and G_j^1 *out of order* if G_i^1 is above G_j^1 at r (i.e., every line in G_i^1 is above every line in G_j^1), but G_j^1 is above G_i^1 at q. The idea is that not too many pairs of groups from different blocks can be out of order, unless q is far from r. If groups G_i^1 and G_j^1 were in the same block at r, their images at q "should" differ by less than one block; that is, few groups should be out of order according to the definition above. If the group images differ by more than one block, then many groups are out of order and $|\text{rank}\,(r) - \text{rank}\,(q)|$ would have to be large. Thus we may (A) *extract* a large subset $\{G_i^2\}$ of the groups $\{G_i^1\}$ which are already properly ordered at q. The remaining elements, comprising at most $3n/5$ lines, may be (B) *reblocked* and treated in the same manner, recursively, until they are all in groups $\{G_i^3\}$ which are properly ordered at q. Then we (C) *merge* these two collections of ordered groups of size T into one collection $\{G_i^4\}$ of ordered groups of size at most $2T$, all in linear time. Finally, using another $O(n)$ steps, we can (D) *reorganize* the groups in $\{G_i^4\}$ to form $p'(q)$. We now give the details.

(A) *The procedure* EXTRACT $(\{G_i^1\}, T)$ takes ordered groups of size T which are blocked at $x = q$ and, in linear time, extracts a collection $\{G_i^2\}$ of groups of size T which are ordered at q. If less than two-fifths of the groups $\{G_i^1\}$ are extracted, $|\text{rank}\,(r) - \text{rank}\,(q)|$ must be at least $3nT/2$ and TOOFAR is set to 1.

The procedure EXTRACT will first construct two lists. One list contains the lines in the odd-numbered blocks, and the other list contains the lines in the even-numbered blocks. The lists are formed by stack operations. Each partially formed list has the property that the groups appearing in it are correctly ordered at $x = q$. Consider the list corresponding to the odd-numbered blocks; the even-numbered blocks are handled similarly. The groups in the odd-numbered blocks are examined from the lowest-numbered group to the highest-numbered group. The group on the top of the stack

has the highest index and corresponds to the lines currently in the stack with the T smallest intercepts at q. The group on the bottom has the lowest index and corresponds to the T lines with the largest intercepts. For each group G_i^1, compute

$$\phi_i = \min(y_s(q), s \in G_i^1), \qquad \Phi_i = \max(y_s(q), s \in G_i^1).$$

This takes linear time because in each of $\tau = \lceil n/T \rceil$ groups, we are selecting from T elements.

Starting with blocks 1 and 3, push block 1 onto the stack. We compare the current top of the stack, group G_{20}^1, to G_{41}^1. If $\phi_{20} \geqq \Phi_{41}$, not only are these groups correctly ordered at q, but all pairs of groups in these two blocks are correctly ordered as well. We push block 3 onto the stack and move on to block 5. Otherwise, these groups may not be correctly ordered. We pop the group on the top of the stack, discard group G_{41}^1, and next compare group G_{19}^1 with group G_{42}^1. This process continues until we either find a pair of groups in correct order or the stack is emptied. In the former case, we push the remainder of the block onto the stack, so we now have a stack of (at most 40) undeleted groups which are correctly ordered at $x = q$ and can process block 5. In the latter case, block 5 is pushed on the stack and block 7 is considered.

We process the next odd block, say $2i+1$, comparing group G_{40i+1}^1 (the first group of block $2i+1$) with the group G_j' on the top of the stack. If $\Phi_{40i+1} \leqq \phi_j'$, block $2i+1$ is pushed on the top of the stack and we move on to the next odd block, $2i+3$. Otherwise, these groups may not be correctly ordered at q. We pop G_j' from the stack, discard G_{40i+1}^1 from the block, and compare the group on the current top of the stack with the next group in block $2i+1$. Whenever the line in the group on the top of the stack with minimum intercept crosses the line in the current group in block $2i+1$ with maximum intercept, the stack is popped and the current group is block $2i+1$ is deleted. If a pair is found to be correctly ordered, that group and the rest of its block are pushed on the stack and we move to the lowest-indexed group in the next odd block. If the last group in block $2i+1$ is deleted, we move on to block $2i+3$. If the stack is ever emptied, either the remainder of the current odd block or the entire next odd block is pushed on the stack, whichever is appropriate.

The "odd" stack forms a collection of groups, $\{G_i^o\}$, which were not deleted from odd blocks and which are properly ordered with respect to each other at q, and the "even" stack forms a collection, $\{G_j^e\}$, of groups which were not deleted from even blocks and which are properly ordered with respect to each other at q. The time taken to form these two lists is clearly $O(n)$. If we started with 20 groups or fewer, no deletion would have been necessary. Block 1 is $\{G_i^o\}$ and the groups in block 2 comprise $\{G_j^e\}$. In the second phase of EXTRACT, these two lists are merged into one list whose groups are properly ordered at q.

LEMMA 7. *$\{G_i^0\}$ and $\{G_j^e\}$ can be merged into a collection $\{G_i^m\}$ of groups in time $O(|G_i^o\}|+|\{G_j^e\}|)$, where each group in $\{G_i^m\}$ has size at most $2T$, and if $c \in G_i^m$, $d \in G_j^m$ and $i<j$, then $y_c(q) \geqq y_d(q)$. Furthermore, $\{G_i^m\}$ satisfies invariant* (5).

Proof. A procedure MERGE $(\{G_i^o\}, \{G_j^e\})$ combines $\{G_i^o\}$ and $\{G_j^e\}$ into one collection $\{G_i^m\}$ of ordered groups of size at most $2T$. Comparing G_i^0 with G_j^e, there are three cases, (i) the groups do not overlap, (ii) one group is "inside" the other, and (iii) they partly overlap. In case (i) suppose $\max(y_s(q), s \in G_i^o) \leqq \min(y_s(q), s \in G_j^e)$. Then G_j^e is taken next into the merge and $j \leftarrow j+1$. If G_i^o is above G_j^e, G_i^o is taken next into the merge and $i \leftarrow i+1$.

In case (ii), G_j^e is "inside" G_i^o if $\max(y_s(q), s \in G_i^o) \geqq \max(y_s(q), s \in G_j^e)$ and $\min(y_s(q), s \in G_i^o) \leqq \min(y_s(q), s \in G_j^e)$. We take next G_j^e and all those $s \in G_i^0$ for which $y_s(q) \geqq \min(y_s(q), s \in G_j^e)$ as the group G which will be added to the merge.

To satisfy (5), lines must appear in G in the order in which they appear in $p(r)$. Therefore we form G by merging the lines in G_j^e with those that were selected from G_i^o according to the index γ at $x=r$. Line $u \in G_j^e$ is taken into G before $v \in G_i^o$ only if $\gamma(u) < \gamma(v)$. It takes $O(T)$ steps to form G and add it to the merge. We now remove the elements that were selected from G_i^o, set $j \leftarrow j+1$ and continue merging. The case where G_i^o is inside G_j^e is similar. In both instances, the group G added to the merge is of size at most $2T$. Also, at least a full-sized group or the remainder of a full-sized group must be added to the merge at each step, so the number of merge steps is bounded by the number of groups.

Finally, for case (iii) suppose that G_i^o has both a larger max $(y_s(q))$ and a larger min $(y_s(q))$ than G_j^e. Then we take next into the merge G_i^o and all those $s \in G_j^e$ for which $y_s(q) \geqq \min(y_s(q), s \in G_i^o)$, modify G_j^e accordingly, and set $i \leftarrow i+1$. Once again the group G taken next into the merge has lines ordered by the group indices at $x=r$. If G_j^e is partly above G_i^o, the processing is similar. As in case (ii), the number of merge steps is bounded by the number of groups involved in case (iii) merges. In both cases the set taken into the merge has size at most $2T$. The merge compared $O(n/T)$ groups, each in time $O(T)$, so it took linear time in all. □

At this point we have a collection $\{G_i^m\}$ of groups of size at most $2T$ which are ordered at $x=q$ and which maintain the invariant in (5). Within each group, i precedes j only if $\gamma(i) < \gamma(j)$. The final phase of EXTRACT is to form $\{G_i^2\}$ from $\{G_i^m\}$, where the groups in $\{G_i^2\}$ all have size T. Some care is required to adjust these groups in linear time to form the ordered groups $\{G_i^2\}$, principally because of the invariant in (5). The procedure SIZET$(T, \{G_i^m\})$ performs this task. Its action is described by the following lemma.

LEMMA 8. *$\{G_i^m\}$ may be reorganized into $\{G_i^2\}$ in time $O(|\{G_i^m\}|)$, where each group in $\{G_i^2\}$ has size exactly T, $\{G_i^2\}$ satisfies invariant (5), and if $c \in G_i^2$, $d \in G_j^2$ and $i<j$, then $y_c(q) \geqq y_d(q)$.*

Proof. Procedure SIZET forms groups of size T in the following way. In general, the ith group in $\{G_i^2\}$, G_i^2, is formed from the s lines in G_{j-1}^m with the smallest $y(q)$, in order, a whole group G_j^m of size s', and the $T-s-s'$ lines from G_{j+1}^m with largest $y(q)$, in order. To preserve (5) for G_i^2, we use order in $p(r)$ to decide how to organize the lines in G_{j-1}^m, G_j^m, and G_{j+1}^m. Since only three adjacent groups in $(G_i^m\}$ need to be examined to form each new group in $\{G_i^2\}$ and each group in $\{G_i^m\}$ has size at most $2T$, SIZET runs in time $O(|\{G_i^m\}|)$.

To see that only three groups are sufficient, we show that every pair of adjacent groups G_j^m and G_{j+1}^m in $\{G_i^m\}$ satisfies $|G_j^m|+|G_{j+1}^m| \geqq T$. Recall that the algorithm MERGE compares group fragments G_{au}^o with G_{bu}^e. (The u in the subscript indicates that these fragments are involved in the uth step of MERGE.) We first claim that one of G_{au}^o and G_{bu}^e must have been a full-sized group.

When the merge begins, both G_{a1}^o and G_{b1}^e are full-sized groups. Suppose that at the time of the uth merging step, at least one of G_{au}^o and G_{bu}^e is a full-sized group. In the $(u+1)$th step of the merge, either all of G_{au}^o will be taken or all of G_{bu}^e will be taken, and the other group may be fragmented. Without loss of generality, suppose G_{au}^o is taken; then $G_{a(u+1)}^o$ is a full-sized group, justifying the claim.

If a full-sized group is taken next into the merge, $|G_j^m| \geqq T$, so $|G_j^m|+|G_{j+1}^m| \geqq T$. If a full-sized group G' is not taken into the merge, then G' may be fragmented. On the next step, either the remains of G' are taken or a full-sized group is taken. In either case, $|G_j^m|+|G_{j+1}^m| \geqq T$. □

An important property of EXTRACT is that *at least $2n/5$ lines are represented in the collection $\{G_i^2\}$ of groups, correctly orderd at q*, unless the ranks of r and q differ

by at least $3nT/2$. Let n_j be the number of groups that were deleted from block j, $0 \leqq n_j \leqq 20$. A group G_i^1 is deleted only if a line in G_i^1 crosses a line in a group G_j^1 at least 2 blocks away (i.e., separated by at least one block). Suppose that both G_i^1 and G_j^1 are not the top or bottom groups of their blocks, where we assume that the top group has the largest intercepts at q and the bottom group has the smallest intercepts. For example, let G_i^1 be separated from the bottom of its block by sub-block A and let G_j^1 be separated from the top of its block by sub-block B. Then all the $20T$ lines in the intervening block between G_i^1 and G_j^1 must either cross all of the lines in A, all of the lines in B, or both. This implies that if n_j is 3, we may account for $10T^2$ inversions; we have divided 20 by 2 because it pertains to the two groups, G_i^1 and G_j^1. Therefore the total number of inversions between $p(r)$ and $p'(q)$ must be at least

$$I = \sum_{j=1}^{n/(20T)} (n_j - 2)5T^2;$$

here we have divided 10 by 2 to adjust for double counting of inversions with lines in the intervening block. If at least $3n/(5T)$ groups $\{G_i^1\}$ were deleted, $I \geqq 5nT/2$. Since $p(r)$ and $p'(q)$ are in error by less than $nT/2$ each, this implies that $|\text{rank}\,(r) - \text{rank}\,(q)| \geqq 3nT/2$. It is useful to make a slightly more general statement.

LEMMA 9. *Let i be a positive integer between 0 and $\lfloor \log n/T \rfloor$. Suppose h_i lines, ordered according to $p(r)$, are reblocked into a partition $\{H_i\}$ of size 2^iT with respect to ordering at q by the procedure described in Lemma 6. In time $O(h_i)$,* EXTRACT $(\{H_i\}, 2^iT)$ *will determine groups $\{H_i^*\}$ of size 2^iT that are ordered at $x = q$ and eliminate h_{i+1} lines. Furthermore, if $|\text{rank}\,(r) - \text{rank}\,(q)| < 3nT/2$, then*

$$h_{i+1} < \frac{n}{2^{i+1}} + \frac{h_i}{10}.$$

Proof. The time bound to construct $\{H_i^*\}$ was justified in the description of the "odd" and "even" stacks along with Lemmas 7 and 8. If $|\text{rank}\,(r) - \text{rank}\,(q)| < 3nT/2$, then $|\rho_r - \rho_q'| < 5nT/2$. As before, n_j denotes the number of groups deleted from block j. The number of inversions I between $p(r)$ and $p'(q)$ is bounded so that

$$I = \sum_{j=1}^{h_i/(20(2^iT))} (n_j - 2)5(2^iT)^2 \leqq |\rho_r - \rho_q'| < 5nT/2.$$

However,

$$I = 5(2^iT)\left[(2^iT)\sum_{j=1}^{h_i/(20(2^iT))} n_j\right] - 10h_i(2^iT)^2/(20(2^iT))$$

$$= 5(2^iT)h_{i+1} - h_i(2^iT)/2 < 5nT/2.$$

This inequality can be simplified to give

$$h_{i+1} < \frac{n}{2^{i+1}} + \frac{h_i}{10}.$$

□

If procedure PARTITION is called on a list of size h_i but h_{i+1} does not satisfy the inequality, TOOFAR is set to 1 because $|\text{rank}\,(r) - \text{rank}\,(q)| \geqq 3nT/2$.

(B) So far EXTRACT has organized at least $2n/5$ of the lines into groups $\{G_i^2\}$ of size T, ordered at $x = q$, or set TOOFAR = 1. In the latter case PARTITION halts (see Fig. 2), but in the former, we use PARTITION recursively.

For $i = 1, \cdots, \tau$ let G_i^d denote those lines in G_i in the original order in $p(r)$ that have been deleted; clearly $0 \leqq |G_i^d| \leqq T$. This collection is easily obtained by marking

```
PARTITION (s, T, {G_i}, {G'_i}, TOOFAR)
⟨1⟩  h_s ← |{G_i}|
⟨2⟩  {G_i^1} ← BLOCK-REGROUP at q
⟨3⟩  {G_i^2} ← EXTRACT ({G_i^1}, T)
⟨4⟩  IF h_s − |{G_i^2}| ≧ n/2^{s+1} + h_s/10 THEN
⟨5⟩    TOOFAR ← 1
⟨6⟩  ELSE
⟨7⟩    {G_i^D} ← lines deleted from {G_i^1}, partitioned at r
⟨8⟩    T' ← 2T
⟨9⟩    PARTITION (s+1, T', {G_i^D}, {Ḡ_i^3}, TOOFAR)
⟨10⟩   IF TOOFAR ≠ 1 THEN
⟨11⟩     {G_i^3} ← HALVE ({Ḡ_i^3})
⟨12⟩     {G_i^4} ← MERGE ({G_i^2}, {G_i^3})
⟨13⟩     {G'_i} ← SIZET(T, {G_i^4})
⟨14⟩   END IF
⟨15⟩ END IF
```

FIG. 2. *The Procedure* PARTITION.

deleted items in the EXTRACT process and removing unmarked lines from permutation $p(r)$. If $i=0$ and $h_0=n$ in Lemma 9, then

$$h_1 \equiv \sum_{i=1}^{\tau} |G_i^d| < \frac{3n}{5}.$$

We can reorganize these lines into $h_1/(2T)$ groups of size $2T$ that are properly ordered according to $p(r)$. These reorganized groups, denoted by $\{G_i^D\}$, form a partition of deleted lines of size $2T$ at r. We invoke PARTITION $(s+1, 2T, \{G_i^D\}, \{\bar{G}_i^3\}, \text{TOOFAR})$. Parameter $s+1$ indicates that the recursion is one level deeper. The groups in $\{\bar{G}_i^3\}$ form a partition of size $2T$ at q of the lines not included in $\{G_i^2\}$, or else TOOFAR $=1$. In the latter case $|\text{rank}(q)-\text{rank}(r)| \geqq 3nT/2$ and PARTITION is aborted. In the former case, procedure HALVE is applied to $\{\bar{G}_i^3\}$ to form $\{G_i^3\}$, a partition of the lines that were deleted from $\{G_i^1\}$ of the original size T, at $x=q$. (In this case, the number of inversions counted by HALVE is ignored. The number of inversions induced by PARTITION will be counted entirely by procedure COUNT.)

(C) Merging $\{G_i^2\}$ and $\{G_i^3\}$ gives a collection $\{G_i^4\}$ consisting of groups of size at most $2T$, correctly ordered at q. As with the merge of $\{G_i^o\}$ and $\{G_j^e\}$, the current one is simplified by the structure of the sets involved. The MERGE procedure described earlier may be used here as well.

(D) The final step of the procedure PARTITION is to reorganize $\{G_i^4\}$ into $\{G'_i\}=p'(q)$. This task can be done by procedure SIZET$(T, \{G_i^4\})$ in $O(n)$ time.

A simplified description of this algorithm is presented in Fig. 2. The only portion of procedure PARTITION that still needs to be described is procedure HALVE.

4.3. The procedure HALVE. The procedure HALVE converts the partition $p'(q)$ of size T at q into a partition $p''(q)$ of size $T/2$ at q and computes the number of additional inversions in $p''(q)$. For each group G'_i in $p'(q)$, we find $\mu=$ median $(y_s(q), s \in G'_i)$ and then assign each line to the correct subgroup depending on whether $y_s(q)$ is less or greater than μ, using the following strategy. Let $i_1, \cdots, i_T$ be the T lines in G'_i in the order in which they appear in $p'(q)$. The elements in group G'_i will be redistributed into two groups in $p''(q)$. These groups will be denoted by A and B; group A will have index $2i-1$ in $p''(q)$, and group B will have index $2i$. If $y_{i_1}(q)$ is greater than μ, it is placed in position j_1 (initially 1), the first available position in the upper half, A, and j_1 is increased by 1. Otherwise $y_{i_1}(q)$ is placed in position j_2

(initially 1), the first available position in the lower half, B, and j_2 is increased by 1, etc., until all T lines have been placed into the correct half. The group G_i' has now been replaced by groups A and B of size $T/2$ each, and they are correctly ordered at q.

While modifying $p'(q)$ in this way, the count of the number of inversions at q is updated to reflect these changes. Specifically, if line i_s is assigned to position j_2 in the lower half, it can only be involved in inversions with lines in G_i' that were below it but which will now be assigned to the upper half-group A. There are exactly $T/2-j_1+1$ such lines, so we change ρ_q by

$$(T/2-j_1+1)/2.$$

Similarly, line i_s that is assigned to position j_1 in the upper half can only be involved in inversions with lines in G_i' that were orginally above it but which have just been assigned to the lower half-group, B. As there are exactly j_2-1 such lines, we change ρ_q by

$$(j_2-1)/2.$$

The change is an increase when SIDE $=-1$ and a decrease otherwise. Division by 2 reflects the double counting of each inversion. For each group, the cost of finding the median, partitioning, and adjusting ρ_q is $O(T)$, or $O(n)$ overall.

This proves the following lemmas.

LEMMA 10. *A partition $p'(q)$ of size T at q can be converted into a partition $p''(q)$ of size $T/2$ at q in linear time. Furthermore, the number of additional inversions between $p'(q)$ and $p''(q)$ can be computed in linear time.*

LEMMA 11. *Let r be an active reference point, let $p(r)$ be a partition of size T at r, and let q be the query point. If* $|\text{rank}(r)-\text{rank}(q)|<3nT/2$, *procedure* PARTITION *will construct $p'(q)$, a partition of size T at q, in linear time. If* $|\text{rank}(r)-\text{rank}(q)|\geqq 3nT/2$, *procedure* PARTITION *will halt in linear time with either $p'(q)$ or* TOOFAR *set to* 1.

Proof. The correctness of the algorithm follows from Lemmas 6-10. To apply Lemma 9, note that whenever PARTITION $(s, T', \{G_i\}, \{G_i'\}, \text{TOOFAR})$ is invoked, $T'=2^sT$, T being the size of the partition in the original call. This is clear when $s=0$, and inductively it is true because the partition size is doubled before each recursive call.

For the time complexity, suppose that $|\text{rank}(r)-\text{rank}(q)|<3nT/2$. Each statement in PARTITION has been shown to have cost $O(h)$ (Lemmas 6-10), where h is the current size of the list. Initially, PARTITION is called for a list of size $h_0=n$. By Lemma 9, the size of the list in the $(i+1)$th recursive call statisfies

$$h_{i+1}<\frac{n}{2^{i+1}}+\frac{h_i}{10}.$$

As a result, the total cost of the algorithm is bounded by $H=c\sum_{i=0}^{\infty}h_i<20cn/9$.

If $|\text{rank}(r)-\text{rank}(q)|\geqq 3nT/2$, procedure PARTITION will either construct a partition of size T at q, or it will set TOOFAR to be 1. TOOFAR is set to 1 as soon as the recurrence relation in Lemma 9 is not satisfied for the first time. Consequently, PARTITION will have made at most a linear number of steps when TOOFAR is set to 1, and it will make no more recursive calls. If TOOFAR is not set to 1, the algorithm successfully constructs a partition of size T at q in linear time. □

4.4. The procedure COUNT. The purpose of procedure COUNT is to count p_q' the number of inversions in $p'(q)$. It will do this by computing $\Delta=|\rho_q'-\rho_r|$ if $|\rho_q'-\rho_r|<3nT/2$. In this section, we assume that $r=r_L$; analogous lemmas and algorithms can be devised when $r=r_R$.

LEMMA 12. (i) *Every inversion in* $p(r_L)$ *also occurs in both* $p(q)$ *and* $p'(q)$; *and* (ii) *inversions present in either* $p(q)$ *or* $p'(q)$ *actually occur between the corresponding* $y_s(q)$. *Furthermore,* (iii) *if* $\text{rank}(q) < k$, $|\rho'_q - k| \leqq nT$.

Proof. When $p(r_L) = (1, 2, \cdots, n)$, property (5) implies that (i) and (ii) are true for the first $p(q)$ and $p'(q)$. Assume that (i) and (ii) are true at $p(r)$, and let $a < b$ be two lines in $p(r)$. By (5), if a and b appear in the same group of $p(q)$, they are in the same order as in $p(r)$. Therefore, (i) and (ii) must still hold for a and b at $p(q)$. If a and b appear in different groups of $p(q)$, there are two possibilities. First, a and b may be in the same relative order in $p(q)$ as in $p(r)$. In this case, an inversion was neither created nor destroyed, so (i) and (ii) are maintained. In the second case, a and b have inverted between $p(r)$ and $p(q)$. Properties (i) and (ii) at $p(r)$ imply that a and b invert in $p(q)$ for the first time. Claim (ii) holds for $p(q)$ because the ordering information given by the partition implies that a and b must have crossed. In fact, since properties (i) and (ii) are true at $p(r)$, a similar argument shows that (i) and (ii) also hold for $p'(q)$ as well.

Since $p'(q)$ contains all of the inversions in $p(r)$, $\rho'_q \geqq \rho_r$. If both ρ'_q and ρ_r are less than k, then $|\rho'_q - k| \leqq |\rho_r - k| \leqq nT$. If ρ'_q exceeds k, then (2) implies that ρ'_q cannot exceed k by more than $nT/2$ if $\text{rank}(q) < k$. Therefore, $|\rho'_q - k| \leqq nT$. □

By Lemma 12, if SIDE $= -1$, then $\rho'_q = \rho_r + \Delta$ since every inversion in $p(r)$ also occurs in $p'(q)$.

LEMMA 13. *If* $|\rho'_q - \rho_r| \geqq 3nT/2$, *then* q *and* r *must be on opposite sides of* t_k.

Proof. Lemma 12 implies that $\rho'_q \geqq \rho_r$, so $\rho'_q - \rho_r \geqq 3nT/2$. By (3), $|\rho_r - k| \leqq nT$, so $\rho'_q - k \geqq 3nT/2 + \rho_r - k \geqq nT/2$. By (2), $|\text{rank}(q) - \rho'_q| < nT/2$, so $\text{rank}(q) - k > 0$ and $\text{sign}(r - t_k) \neq \text{sign}(q - t_k)$. □

Lemma 12 shows that the invariant (5) simplifies the counting procedure by allowing us to calculate the number of inversions in $p'(q)$ by computing Δ. Let $\xi(i)$ be the index of the group in $p'(q)$ containing line i. The value of $\xi(i)$ was found by procedure PARTITION. By the invariant (5), an inversion involving i and j between $p(r)$ and $p'(q)$ can occur only if $\xi(i) \neq \xi(j)$.

Procedure COUNT will examine the lines in $p(r)$ in descending order, and it can be separated into four stages. First, COUNT uses a data structure that must be (A) *initialized.* This data structure contains a collection of "bins" of size of at least T but less than $3T$; each individual bin is ordered according to $p(r)$, but different bins are ordered according to q. For each line $p(r)$, we (B) *find* its correct location in the data structure and place it into the appropriate bin. When a bin reaches capacity $3T$, we (C) *split* the bin into two new bins, each with size at least T. After all lines are processed, we (D) *finish* by redistributing the elements in the bins to form $p'(q)$. Inversions are counted in steps (B), (C), and (D).

(A) As stated in the previous paragraph, COUNT will use a data structure. This data structure $u(q)$ is called the binned partition at q, and it consists of a series of bins U_1, U_2, etc. A bin can either be empty or contain at least T but less than $3T$ lines ordered according to $p(r)$. As with partitions, if $c \in U_i$ and $d \in U_j$, $i < j$, then $y_c(q) \geqq y_d(q)$. If there are k nonempty bins, they must have index $1, 2, \cdots, k$.

Each bin in $u(q)$ has three parameters associated with it. The *size* of a bin is the number of elements it contains. Variable *min* contains the smallest $\xi(i)$ in the bin (the only possible exception is $\min(U_1)$, which is always defined to be 1). For each U_j, the closed interval from $\min(U_j)$ to $\min(U_{j+1}) - 1$ is called the *range* (if U_k is the highest numbered bin, its range extends from $\min(U_j)$ to τ). Finally, each bin U_j contains a pointer *nextbin* to U_{j-1}. The binned partition $u(q)$ is simply a linked list which is entered at the highest-numbered nonempty bin.

In addition to the three parameters associated with each bin, a variable Δ_u is associated with $u(q)$. Intuitively, Δ_u contains the current number of inversions induced by forming $u(q)$ from $p(r)$. Throughout the procedure COUNT, two invariants will hold: (a) the ranges in the nonempty bins are disjoint and the union of the ranges is 1 to τ; and (b) lines in a particular bin are positioned according to order in $p(r)$.

To initialize $u(q)$, the elements in G_1 in $p(r)$ are placed into U_1, the size of U_1 is set to T, min is set to 1 and Δ_u is set to 0. The initialization clearly takes $O(T)$ time.

(B) Let i be the next line examined by the procedure COUNT. At the time line i is examined, all the lines preceding i in $p(r)$ have been placed into $u(q)$, and no bin has size $3T$. Let $u(q) = U_1 U_2 \cdots U_k$. If $\xi(i)$ is in the range of U_k, then line i is placed at the bottom of U_k. Otherwise, $\xi(k)$ is less than min (U_k), and U_{k-1} is examined. If U_{k-1} is examined, line i must have crossed every line in U_k, so Δ_u is incremented by size (U_k). If $\xi(i)$ lies in the range of U_{k-1}, then line i is placed at the bottom of U_{k-1}. Otherwise, Δ_u is incremented by size (U_{k-1}) and U_{k-2} is examined. In general, $\xi(i)$ is compared with the range of U_j. If $\xi(i)$ is inside the range of U_j, then it is placed at the bottom of U_j and the find routine halts. If $\xi(i)$ is less than min (U_j), then Δ_u is incremented by size (U_j) and U_{j-1} is examined. It is important to note that at least T inversions are counted each time $\xi(i)$ is outside the range of U_j.

Once line i is placed into bin U_j, the size condition may be violated because size $(U_j) = 3T$. In this case, the split routine is performed.

(C) The split routine is intended to separate a bin of size $3T$ into two bins of size at least T. It is very similar to the procedure HALVE. An element l can be used to split bin U_j into two bins, U_{j1} and U_{j2}. U_{j1} contains the lines v in U_j for which $\xi(v) < \xi(l)$, and they appear in their order at $p(r)$. U_{j2} contains the remaining lines in their order at $p(r)$. Since there are $3T$ lines in U_j, U_j must contain at least 3 distinct values of ξ.

The partitioning element is chosen in the following manner. Once size $(U_j) = 3T$, the median line μ in U_j with respect to the ordering at q is computed. U_j will be partitioned by one of two lines, l_1 or l_2. Line l_1 is the line in U_j with smallest index in $p(r)$ satisfying $\xi(l_1) = \xi(\mu)$, and line l_2 is the line in U_j with largest index in $p(r)$ satisfying $\xi(l_2) = \xi(\mu)$. Since at most T lines in U_j can be in group $\xi(\mu)$, at least one of l_1 and l_2 splits U_j into two bins of size at least T. The number of inversions induced by split is counted in the same way as the inversions detected in HALVE. Note that the split routine did not separate any lines in U_j with the same value of ξ, so the invariants are maintained.

(D) After all lines have been placed in $u(q)$, the binned partition has the following form. Each bin U_j contains at least T but less than $3T$ lines. By invariant (a), lines with the same value of ξ must appear in the same bin. Consequently, size (U_j) must be a multiple of T, so U_j contains either T or $2T$ lines. In the former case, the number of inversions with respect to lines in U_j has already been computed in steps (B) and (C). In the latter case, U_j must be split and inversions counted in the same manner as part (C). This routine takes at most $O(T)$ time per bin, and $O(n)$ time overall.

LEMMA 14. *If* $|\rho_r - \rho'_q| < 3nT/2$, *the* COUNT *procedure correctly computes the number of inversions between* $p(r)$ *and* $p'(q)$ *in linear time.*

Proof. By the invariants (a) and (b), correctness follows from a straightforward induction on the number of applications of find and split. The time complexity requires a bit more care.

Parts (A) and (D) have already been shown to take $O(n)$ time. For part (B), the cost of each examination of U_j is $O(1)$ because $u(q)$ is implemented as a linked list. Call such an examination a *find operation.* Suppose that the find operation is performed

n_i times for line i. All but the first find operation guarantees T inversions, so

$$\sum_{i=1}^{n} (n_i - 1)T < \frac{3nT}{2}.$$

Therefore,

$$\sum_{i=1}^{n} n_i < \frac{5n}{2}.$$

The total time spent on the find operations is $O(n)$.

For part (C), each split operation takes $O(T)$ time and increases the number of nonempty bins by one. Since each bin must have size T, there are at most n/T nonempty bins. At most n/T split operations can be done, so the total time for the splits is $O(n)$. □

4.5. The proof of Theorem 4. We first show that the algorithm presented in Fig. 1 correctly finds t_k. If the test at ⟨6⟩ fails, procedure PARTITION is applied. At the active reference point r, say r_L (similar arguments can be made if $r = r_R$),

$$|\rho_{(r,T)} - k| \leqq nT, \qquad |\rho_{(r,T/2)} - k| > nT/2.$$

If the new query point q is on the same side of t_k as r, then Lemma 11 implies that PARTITION will succeed in finding $p'(q)$. By Lemma 14, COUNT will determine the number of inversions in $p'(q) = p(q, T)$, $\rho_{(q,T)}$. Lemma 12(iii) implies that $|\rho_{(q,T)} - k| \leqq nT$, so (3) is satisfied. Procedure HALVE will be run to see if (4) is satisfied as well. If (4) is satisfied, then $p(q) = p(q, T)$ and q can be resolved. If (4) is not satisfied, then $|\rho_{(r,T/2)} - k| \leqq nT/2$. HALVE will be executed until some T satisfies both (3) and (4). Note that unless $|\text{rank}(q) - k| \leqq n/2$, some T will satisfy (4) since there is some separation between q and t_k. Therefore, if r and q are on the same side of t_k, $p(q)$ will be determined in line ⟨15⟩.

The new query point q can be on the opposite side of t_k from r. There are several ways that this can be detected. First, Lemma 11 implies that PARTITION may detect that $|\text{rank}(r) - \text{rank}(q)|$ is large and set TOOFAR = 1. Lemma 14 shows that COUNT will either succeed in determining the number of inversions in $p(q, T)$, or it will halt if there are at least $3nT/2$ inversions between $p(r, T)$ and $p(q, T)$. By Lemma 13, $3nT/2$ inversions implies that r and q are on opposite sides of t_k. If both PARTITION and COUNT succeed in constructing and counting $p(q, T)$, then we will determine the relative order of q and t_k by the approximation.

Since we are assuming that the partition $p'(q)$ was computed by modifying the partition at r_L, invariant (5) implies that the number of inversions present in each refinement cannot decrease as T decreases. That is, $\rho_{(q,T/2)} \geqq \rho_{(q,T)}$. This implies that once there are more than k inversions present in an approximation, q and r_L must be on opposite sides of t_k. The number of executions of HALVE to detect that $\rho_{(q,T/2)} > k$ cannot be greater than the number of executions of HALVE to satisfy (3) and (4). This explains the third condition in line ⟨12⟩ as a stopping condition for the calibration loop.

If r and q are on the same side of t_k, $p(q)$ is determined in line ⟨15⟩. If r and q are not on the same side of t_k, then the test in ⟨17⟩ is true, and $p(q)$ is determined in line ⟨23⟩. In conclusion, the algorithm correctly computes the partition $p(q)$ and uses (4) to answer the question delivered by the network.

The procedures PARTITION, HALVE, and COUNT all took linear time. By the construction of the algorithm, PARTITION and COUNT are invoked at most twice

for any given q. Therefore, the total amount of work done by PARTITION and COUNT over the entire algorithm is $O(n \log n)$ steps. HALVE is invoked immediately after PARTITION to evaluate invariant (4). However, the procedure HALVE may be run many more times for any particular q. Suppose that r_L is the active reference point and that HALVE is called $s > 0$ times in line ⟨13⟩ of the algorithm in Fig. 1. If q and r_L are on the same side of t_k, then the new value of T_L is $T_L/2^s$. In the remainder of the algorithm, Lemma 12(iii) implies that T_L can never be increased because the upper bound in (3) is satisfied. If q and r_L are on opposite sides of t_k, then the partition $p(q)$ is computed with respect to r_R. Since the number of executions of HALVE to establish (3) and (4) is greater than or equal to the number of executions of HALVE actually used to determine the relative positions of q and t_k, consider the value of T_L when $|\rho_{(q,T_L/2)} - k| > nT_L/2$ and $|\rho_{(q,T_L)} - k| \leqq nT_L$. From the latter equation, we can deduce that $|\text{rank}\,(q) - k| < 3nT_L/2$.

The new value of T_R must satisfy both (3) and (4). Lemma 5 implies that properly calibrated values of T_R must satisfy $|\text{rank}\,(q) - k| > nT_R/4$. Therefore, $nT_R/4 < 3nT_L/2$, so $T_R < 6T_L$. Recall that $T_R \geqq T_L$ since r_L is the active reference point. For invariants (3) and (4) to be established, HALVE must be run at least $s-2$ times until $T_R < 6T_L$.

This shows that if line ⟨13⟩ is executed s times and r and q are on opposite sides of t_k, then line ⟨21⟩ will be executed at least $s-2$ times. Either T_L or T_R is reduced by a factor of at least 2^{s-2}, implying that the number of calls to procedure HALVE is at most $O(\log n)$. This proves the asserted $O(n \log n)$ time bound and Theorem 4.

5. General remarks. This paper presented an optimal-time algorithm to compute the kth largest or smallest slope determined by a set of points in the plane. The control structure of the algorithm is based on the parametric search technique devised by Megiddo. To obtain the optimal-time algorithm, however, an approximation idea was incorporated. This general paradigm may be useful for other problems to which Megiddo's technique is amenable.

The ideas behind the algorithm described have also been applied successfully to other selection problems [10]. In particular, the kth smallest interdistance between n points in d-space, using the L_∞ metric, may be found in time $O(n(\log n)^d)$ [11]. Unfortunately nontrivial lower bounds are not known for this problem.

FULLY DYNAMIC POINT LOCATION IN A MONOTONE SUBDIVISION*

FRANCO P. PREPARATA† AND ROBERTO TAMASSIA‡

Abstract. In this paper a dynamic technique for locating a point in a monotone planar subdivision, whose current number of vertices is n, is presented. The (complete set of) update operations are insertion of a point on an edge and of a chain of edges between two vertices, and their reverse operations. The data structure uses space $O(n)$. The query time is $O(\log^2 n)$, the time for insertion/deletion of a point is $O(\log n)$, and the time for insertion/deletion of a chain with k edges is $O(\log^2 n + k)$, all worst-case. The technique is conceptually a special case of the chain method of Lee and Preparata and uses the same query algorithm. The emergence of full dynamic capabilities is afforded by a subtle choice of the chain set (separators), which induces a total order on the set of regions of the planar subdivision.

1. Introduction.

A fundamental and classical problem in computational geometry, *planar point location*, is an instrument in a wide variety of applications. In a geometric context, it is naturally viewed as the extension to two dimensions of its one-dimensional analogue: search in a total ordering. It is formulated as follows. Given a planar subdivision **P** with n vertices (a planar graph embedded in the plane with straight-line edges), determine to which region of **P** a query point q belongs. The repetitive use of **P** and the on-line requirement on the answers call for a preprocessing of **P** that may ease the query operation, just as sorting and binary search intervene in one-dimensional search. The history of planar point location research spans more than a decade and is dense in results; the reader is referred to the extensive literature on this subject: [DL], [EKA], [EGS], [Ki], [LP], [LT], [P1], [P2], [PS], and [ST].

Most of the past research on the topic has focused on the *static* case of planar point location, where the planar subdivision **P** is fixed. For this instance of the problem, several practical techniques are available today (e.g., [EKA], [EGS], [LP], [P1], [ST]), some of which are provably optimal in the asymptotic sense [EGS], [ST]. The analogy with one-dimensional search, for which both static and dynamic optimal techniques have long been known, naturally motivates the desire to develop techniques for *dynamic* planar point location, where the planar subdivision can be modified by insertions and deletions of points and segments. In this setting, the three traditional measures of complexity for the static problem—preprocessing time, space for the data structure, and query time—are supplemented by measures of pertinent update times, and preprocessing time is no longer relevant if the data structure is dynamically built.

Work on dynamic point location is a rather recent undertaking. Overmars [O] proposed a technique for the case where the n vertices of **P** are given, the boundary of each region has a bounded number of edges, and only edges can be easily inserted or deleted. The basic entities used in Overmars's method are the edges themselves;

each edge currently in **P** is stored in a segment tree defined on the fixed set of vertex abscissae, and the edge fragments assigned to a given node of the segment tree form a totally ordered set and are therefore efficiently searchable. This approach yields $O(n \log n)$ space, and $O(\log^2 n)$ query and update times (worst-case). Note that these measures are unrelated to the current number of edges in **P**. This technique can be extended to support insertions and deletions of vertices in $O(\log^2 n)$ amortized time, at the expense of deploying a rather complicated and not very practical data structure.

Another interesting dynamic point location technique, allowing both edge and vertex updates, is presented by Fries, Mehlhorn, and Naeher [F], [FMN], [M]. Their approach achieves $O(n)$ space, $O(\log^2 n)$ query time, and $O(\log^4 n)$ amortized update time. If only insertions are considered, the update time is reduced to $O(\log^2 n)$ (amortized) [M, pp. 135–143]. This technique is suited for general subdivisions, and is based on the static point location algorithm of Lee and Preparata [LP].

In a recent paper [ST], Sarnak and Tarjan indicated as one of the most challenging problems in computational geometry the development of a fully dynamic point location data structure whose space and query time performance are of the same order as that of the best known static techniques for this problem. In this paper we make significant progress toward this goal, as expressed by the following theorem, which represents the central result of this paper.

THEOREM A. *Let* **P** *be a monotone planar subdivision with n vertices. There exists a dynamic point location data structure with* $O(n)$ *space requirement and* $O(\log^2 n)$ *query time that allows for insertion/deletion of a vertex in time* $O(\log n)$ *and insertion/deletion of a chain of k edges in time* $O(\log^2 n + k)$, *all time bounds being worst-case.*

It must be underscored that our method allows for arbitrary insertions and deletions of vertices and edges, the only condition being that monotonicity of the subdivision be preserved. The restriction to monotone subdivisions prevents the achievement of a more general goal. However, the class of monotone subdivisions is very important in applications, since it includes convex subdivisions, triangulations, and rectangular dissections. Moreover, from a methodological standpoint, the presented dynamic technique does not use bizarre data structures and is based on the same geometric objects, the separating chains, that yielded the first practical, albeit suboptimal, point location technique of Lee and Preparata [LP], and later the practical and optimal algorithm of Edelsbrunner, Guibas, and Stolfi [EGS].

The paper is organized as follows. In § 2 we review the technical background and precisely formulate the problem. We recall the static point location technique of Lee and Preparata that consists essentially of performing binary search on a set of monotone chains, called separators, sorted from left to right. Also, we introduce a complete repertory of update operations.

In § 3 we define a total ordering $<$ on the set of regions of **P** and define a subclass of monotone subdivisions, called regular subdivisions, for which the ordering $<$ is induced by the left-to-right adjacency of the regions. We show that the separators of a regular subdivision have a simple structure that allows for an efficient dynamic maintenance. We then transform an arbitrary subdivision **P** into a regular subdivision **P*** by (virtually) duplicating the edges along some monotone chains, called "channels." The regions of **P***, called "clusters," are sets of regions of **P** (consecutive in the order $<$) connected by channels. The formal underpinning of the order $<$ can be found in the theory of planar *st*-graphs [LEC], [TP] and planar lattices [KR].

In § 4, we present the dynamic technique. The data structure is based on organizing the separators of **P*** into a balanced tree, called "separator tree." We show that the insertion/deletion of a chain causes the ordering $<$ of the regions of **P** to be modified

in a simple way. Namely, the transformation consists of partitioning the sorted sequence of regions into four subsequences and swapping the two middle ones. Regarding $\mathbf{P}^*$, we show that only $O(1)$ channels are affected by the update. These properties are the basis of the algorithms for the insertion/deletion of chains. At the end of the section we describe the simpler algorithms for the insertion/deletion of vertices.

Finally, § 5 concludes the paper with some open problems.

2. Preliminaries. The geometric objects to be defined below are readily motivated if we view a point of the plane as the central projection of a point of a hemisphere to whose pole this plane is tangent.

A *vertex* v in the plane is either a finite point or a point at infinity (the latter is the projection of a point on the hemisphere equator). An *edge* $e=(u, v)$ is the portion of the straight line between u and v, with the only restriction that u and v be not points at infinity associated with the same direction. Thus e is either a segment or a straight-line ray, but not a whole straight-line. When both u and v are at infinity, then e is an edge at infinity, i.e., a portion of the line at infinity (the projection of an arc of the equator). A (*polygonal*) *chain* γ is a sequence $(e_i: e_i=(v_i, v_{i+1}), i=1, \cdots, p-1)$ of edges; it is *simple* if nonself-intersecting; it is *monotone* if any line parallel to the x-axis intersects γ in at most a point or a segment. The notions of "left" and "right" are referred to a bottom-up orientation of the involved entity (a chain, or, later on, a separator, an edge, etc.). A *simple polygon* r is a region of the plane delimited by a simple chain with $v_p=v_1$, called the *boundary* of r. Note that r could be unbounded; in this case the boundary of r contains one or more edges belonging to the line at infinity. A polygon r is monotone if its boundary is partitionable into two monotone chains γ_1 and γ_2, called the *left chain* and *right chain* of r, respectively (see Fig. 1). Chains γ_1 and γ_2 share two vertices referred to as $HIGH(r)$ and $LOW(r)$, respectively, with $y(HIGH(r))>y(LOW(r))$. In other words, $HIGH(r)$ and $LOW(r)$ are, respectively, points of maximum and minimum ordinates in polygon r; each is unique unless it is the extreme of either a horizontal edge or an edge at infinity, in which case the selection between the two edge extremes is arbitrary.

A *monotone subdivision* $\mathbf{P}$ is a partition of the plane into monotone polygons called the *regions* of $\mathbf{P}$ (see Fig. 2(a)). It is easily realized (see also [EGS]) that a monotone subdivision of $\mathbf{P}$ is determined by a planar graph G embedded in the plane whose edges are either segments or rays of straight lines (referred to as a "planar

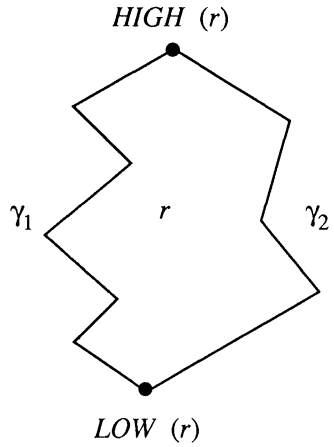

FIG. 1. *Nomenclature for a monotone polygon. Left chain*: γ_1; *right chain*: γ_2.

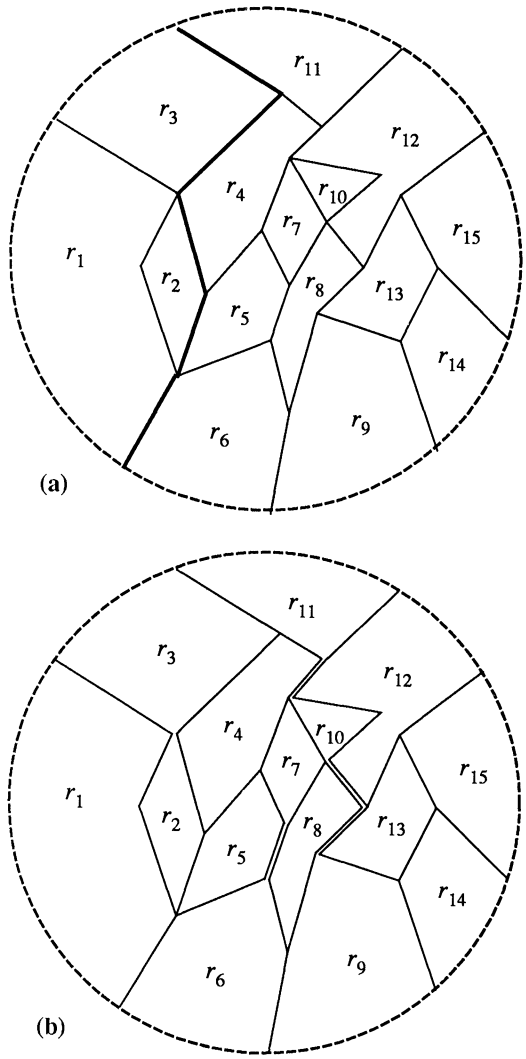

FIG. 2. (a) *A monotone subdivision* **P**. - - - *line at infinity*; ——— *separator.* (b) *The regular subdivision* **P*** *obtained from* **P** *by forming all maximal clusters.*

straight-line graph" in [LP]): edges, vertices, and chains of G are referred to as edges, vertices, and chains of **P**. The vertices of **P** are both the finite ones and those at infinity. This ensures the validity of the well-known Euler's formula and its corollaries:

$$|E| = O(|V|), \quad |R| = O(|V|),$$

where V, E, and R, respectively, are the set of vertices, edges, and regions of **P**.

Given a monotone subdivision **P**, a *separator* σ of **P** is a monotone chain $(v_1, \cdots, v_p)$ of **P** with the property that v_1 and v_p are points at infinity (hence, each horizontal line intersects a separator either in a point or in a segment). A separator of **P** is illustrated with bold line segments in Fig. 2(a). Given separators σ_1 and σ_2 of **P**, we say that σ_1 *is to the left of* σ_2, denoted $\sigma_1 < \sigma_2$, if, for any horizontal line l intersecting σ_1 and σ_2 in distinct points, l intersects σ_1 to the left of σ_2. A *partial subdivision* is the portion of a monotone subdivision contained between two distinct separators σ_1

and σ_2, with $\sigma_1 < \sigma_2$. A *complete family of separators* Σ for **P** is a sequence $(\sigma_1, \sigma_2, \cdots, \sigma_t)$ with $\sigma_1 < \sigma_2 < \cdots < \sigma_t$, such that every edge of **P** is contained in at least one separator of Σ. Notice that from Euler's formula $t = O(n)$. As shown in [LP], every monotone subdivision admits a complete family of separators.

Given a complete family of separators Σ for **P**, it is well known [LP] how to use Σ to perform planar point location in **P**. If n is the number of vertices of **P**, then in time $O(\log n)$ we can decide on which side of a separator the query point q lies; applying this operation as a primitive, a bisection search on Σ determines, in time $O(\log t \cdot \log n)$, two consecutive separators between which lies q. This process can be adapted or supplemented to determine the actual region r to which q belongs.

Since Σ is used in a binary search fashion, each separator is assigned to a node of a binary search tree, called the *separator tree* **T**. With a minor abuse of language, we call "node σ" the node of **T** to which σ has been assigned. An edge e of **P** belongs, in general, to a nonempty interval $(\sigma_i, \sigma_{i+1}, \cdots, \sigma_j)$ of separators. Let node σ_k, $i \leqq k \leqq j$ be the least common ancestor of nodes $\sigma_i, \sigma_{i+1}, \cdots, \sigma_j$; then e is called a *proper edge* of σ_k and is stored only once at node σ_k. We denote by $proper(\sigma_k)$ the set of proper edges of σ_k, i.e., the edges of σ_k stored at node σ_k. This yields $O(n)$ storage space while guaranteeing the correctness of the technique (see [EGS], [LP]). Note that edges whose extremes are both at infinity need not be stored.

We now illustrate that a planar subdivision **P** can be constructed by an appropriate sequence of the following operations.

INSERTPOINT $(v, e; e_1, e_2)$:
Split the edge $e = (u, w)$ into two edges $e_1 = (u, v)$ and $e_2 = (v, w)$ by inserting vertex v.

REMOVEPOINT $(v; e)$:
Let v be a vertex of degree 2 whose incident edges, $e_1 = (u, v)$ and $e_2 = (v, w)$, are on the same straight line. Remove v and replace e_1 and e_2 with edge $e = (u, w)$.

INSERTCHAIN $(\gamma, v_1, v_2, r; r_1, r_2)$:
Add the monotone chain $\gamma = (v_1, w_1, \cdots, w_{k-1}, v_2)$, with $y(v_1) \leqq y(v_2)$, inside region r, which is decomposed into regions r_1 and r_2, with r_1 and r_2, respectively, to the left and to the right of γ, directed from v_1 to v_2.

REMOVECHAIN $(\gamma; r)$:
Let γ be a monotone chain whose nonextreme vertices have degree 2. Remove γ and merge the regions r_1 and r_2 formerly on the two sides of γ into region r. (The operation is allowed only if the subdivision **P**′ so obtained is monotone.)

With the above repertory of operations, we claim that a monotone subdivision **P** can always be transformed into a monotone subdivision **P**′ having either fewer vertices or fewer edges. Then by $O(n)$ such transformations, we obtain the trivial subdivision whose only region is the entire plane (bounded by the line at infinity).

Indeed, let σ be a separator of **P**, and imagine traversing σ from $-\infty$ to $+\infty$. Let $\deg^-(v)$ and $\deg^+(v)$ denote the numbers of edges incident on v and lying in the halfplanes $y < y(v)$ and $y > y(v)$, respectively. (For simplicity, we assume here that no edge is horizontal. In the general case, a horizontal edge is conventionally directed from left to right.) Let $(v_1, \cdots, v_p)$ be the sequence of finite vertices of σ with $\deg^+(v_i) + \deg^-(v_i) \geqq 3$, as encountered in the traversal of σ. If this sequence is empty, the entire chain can be trivially removed. Therefore, assume $p \geqq 1$. If there are two consecutive vertices v_i and v_{i+1} such that $\deg^+(v_i) \geqq 2$ and $\deg^-(v_{i+1}) \geqq 2$, then the chain γ (of degree-2 vertices) between v_i and v_{i+1} can be deleted by *REMOVECHAIN* while preserving monotonicity. Suppose that there are no two such vertices. If

$\deg^-(v_1) \geqq 2$, then the portion of σ from $-\infty$ to v_1 can be deleted. Otherwise, $\deg^-(v_1) = 1$, and the preceding conditions give rise to the following chain of implications:

$$(\deg^-(v_1) = 1) \Rightarrow (\deg^+(v_1) \geqq 2) \Rightarrow (\deg^+(v_2) \geqq 2) \Rightarrow \cdots \Rightarrow (\deg^+(v_p) \geqq 2);$$

the latter shows that the portion of σ from v_p to $+\infty$ can be deleted. This establishes our claim.

When all finite vertices have disappeared, the resulting subdivision consists of a closed chain of edges whose union is the line at infinity. Removal of the vertices at infinity completes the transformation. Since all of the above operations are reversible, this shows that any monotone subdivision **P** with n vertices can be constructed by $O(n)$ operations of the above repertory.

THEOREM 1. *An arbitrary planar subdivision* **P** *with n vertices can be assembled starting from the empty subdivision by a sequence of* $O(n)$ *INSERTPOINT and INSERTCHAIN operations, and can be disassembled to obtain the empty subdivision by a sequence of* $O(n)$ *REMOVEPOINT and REMOVECHAIN operations.*

Although the above operations are sufficient to assemble and disassemble any monotone subdivision, the following operation is also profitably included in the repertory.

MOVEPOINT $(v; x, y)$:

Translate a degree-2 vertex v from its present location to point (x, y). (The operation is allowed only if the subdivision $\mathbf{P}'$ so obtained is monotone and topologically equivalent to **P**.)

3. Ordering the regions of a monotone subdivision. Let **P** be a monotone subdivision, and assume for simplicity that none of its finite edges is horizontal. Given two regions r_1 and r_2 of **P**, we say that r_1 is *left-adjacent to* r_2, denoted $r_1 \ll r_2$, if r_1 and r_2 share an edge e, and any separator of **P** containing e leaves r_1 to its left and r_2 to its right. Note that relation $\ll$ is trivially antisymmetric. But we can also show Lemma 1.

LEMMA 1. *Relation* $\ll$ *on the regions of* **P** *is acyclic.*

Proof. Assume $r_1 \ll r_2 \ll \cdots \ll r_k \ll r_1$. Let Σ be a complete family of separators and let $\{\sigma_1, \cdots, \sigma_{k-1}\} \subseteq \Sigma$ be such that σ_i separates r_i and r_{i+1}, so that $\sigma_1 < \sigma_2 < \cdots < \sigma_{k-1}$. If $\sigma \in \Sigma$ leaves r_k to its left and r_1 to its right, we have $\sigma_{k-1} < \sigma$ and $\sigma < \sigma_1$, a contradiction since the separators are ordered. □

Thus, the transitive closure of $\ll$ is a partial order, referred to as "*to the left of*," and denoted by $\rightarrow$. Specifically, $r_1 \rightarrow r_2$ if there is a path from r_1 to r_2 in the directed graph of the relation $\ll$ on the set of regions. Correspondingly, given two regions r_1 and r_2 of **P**, we say that r_1 *is below* r_2, denoted $r_1 \uparrow r_2$, if there is a monotone chain from $HIGH(r_1)$ to $LOW(r_2)$. Obviously, $\uparrow$ is a partial order on the set of regions. The following lemma shows that these two partial orders are complementary, and it is the geometric counterpart of a topological property of planar lattices [B, ex. 7(c), p. 32], [Ka], [KR].

LEMMA 2. *Let* r_1 *and* r_2 *be two regions of a monotone subdivision* **P**. *Then one and only one of the following holds*:

$$r_1 \rightarrow r_2, \quad r_2 \rightarrow r_1, \quad r_1 \uparrow r_2, \quad r_2 \uparrow r_1.$$

Proof. Let σ_L be the leftmost separator that contains the left chain of the boundary of r_1 and, analogously, let σ_R be the rightmost separator containing the right chain of the boundary of r_1. These separators partition **P** into five portions, each a partial subdivision: one of them is r_1 itself, and the others are denoted L, R, B, and T (see Fig. 3). Now, we consider four mutually exclusive cases for r_2, one of which must occur:

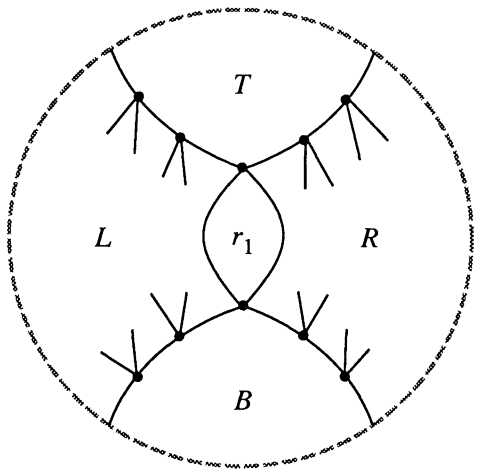

FIG. 3. **P** *partitioned into five portions, each a partial subdivision (for the proof of Lemma* 2).

(1) $r_2 \in L$. Consider any sequence of regions $(r'_1, \cdots, r'_s)$ such that $r_2 \to r'_1$, $r'_i \to r'_{i+1}$ for $i = 1, \cdots, s-1$, and the right chain of r'_s has a nonempty intersection with σ_L. If the right chain of r'_s has an edge that is also on the left boundary of r_1, then $r_2 \to r_1$. Otherwise, by the definition of σ_L, there is a sequence $r'_{s+1}, \cdots, r'_p$ of regions such that $r'_j \to r'_{j+1}$ for $j = s, \cdots, p-1$, and $r'_p \to r_1$. Thus, in all cases, $r_2 \to r_1$.

(2) $r_2 \in R$. Arguing as in (1), we establish $r_1 \to r_2$.

(3) $r_2 \in B$. Since $LOW(r_1)$ is the highest ordinate vertex in B, there is a monotone chain from any vertex in B to $LOW(r_1)$, and, in particular, from $HIGH(r_2)$ to $LOW(r_1)$. Thus $r_2 \uparrow r_1$.

(4) $r_2 \in T$. Arguing as in (3), we establish $r_1 \uparrow r_2$. □

We say that r_1 *precedes* r_2, denoted $r_1 < r_2$, if either $r_1 \to r_2$ or $r_1 \uparrow r_2$.

THEOREM 2. *The relation* $<$ *on the regions of* **P** *is a total order.*

As an example, the region subscripts in Fig. 2(a) reflect the order $<$.

DEFINITION 1. A *regular subdivision* is a monotone subdivision having no pair (r_1, r_2) of regions such that $r_1 \uparrow r_2$.

For example, in Fig. 2(a) we have $r_9 \uparrow r_{10}$, which shows that the illustrated monotone subdivision is not regular. An example of regular subdivision is given in Fig. 4(a).

The significance of regular subdivisions is expressed by Theorem 3 below. It is easily realized that there is a unique complete family $\Sigma = (\sigma_1, \cdots, \sigma_t)$ of separators for a regular subdivision **P**. By the definition of separator, all regions to the left of σ_j precede all those to its right in the order $<$. Let **T** be a separator tree for the above family Σ. Recalling the rule for storing the edges of separator σ in **T**, as reviewed in § 2, we have Theorem 3.

THEOREM 3. *In a regular subdivision* **P**, *the edges of proper*(σ) *in* **T** *form a single chain* (*see Fig.* 4(b)).

Proof. Assume for a contradiction that σ contains a chain γ that is the bottom-to-top concatenation of three nonempty chains γ_1, γ_2, and γ_3, where γ_1 and γ_3 consist of proper edges of σ, and γ_2 contains no such edge. Let v_1 and v_2 be the bottom and top vertices, respectively, of γ_2, and let $e' \in \gamma_1$ and $e'' \in \gamma_2$ be the edges of σ incident on v_1. Since $e'' \notin proper(\sigma)$, we must have $e'' \in proper(\sigma')$, where node σ' is an ancestor of node σ in **T**. We claim there is a region r_1 such that $v_1 = HIGH(r_1)$. Otherwise, each separator containing e''—and so σ'—also contains e', contrary to the hypothesis

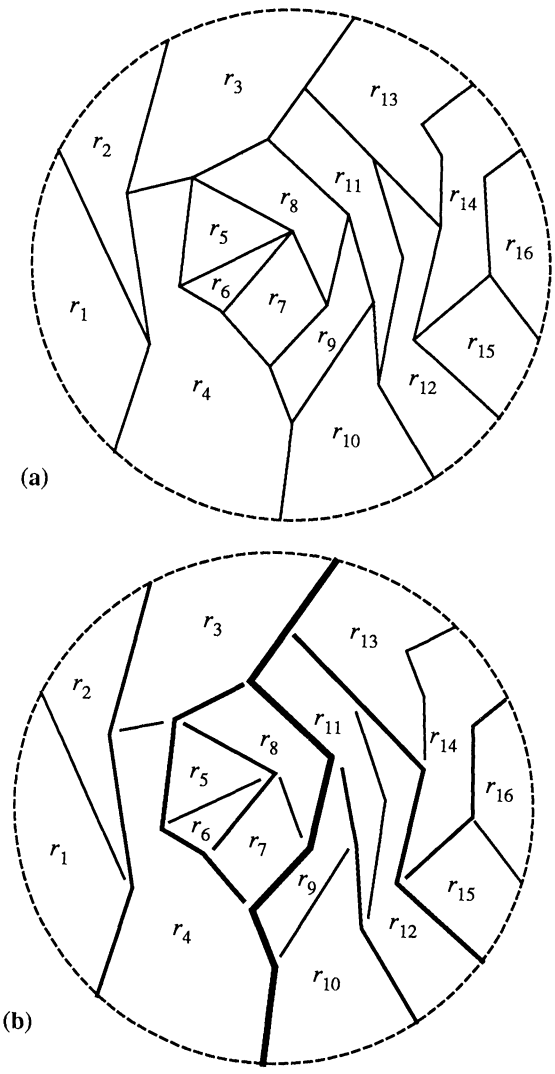

FIG. 4. (a) *A regular subdivision.* (b) *Its chains* $\{proper(\sigma)\colon \sigma \in \Sigma\}$.

that node σ is closest to the root among the nodes whose separator contains e'. Analogously, we show that there is a region r_2 for which $v_2 = LOW(r_2)$. Since γ_2 is a monotone chain from $HIGH(r_1)$ to $LOW(r_2)$, then $r_1 \uparrow r_2$, whence a contradiction. □

This theorem shows that a regular subdivision has a particularly simple separator tree. In the next section we shall show that the property expressed by Theorem 3 is crucial for the efficient dynamization of the chain method for point location. We now slightly generalize the notion of region in a way that will enable us to show that any monotone subdivision embeds a unique regular subdivision. We say that two regions r_1 and r_2 consecutive in $<$ with $r_1 \uparrow r_2$ are *vertically consecutive.* We then have Lemma 3.

LEMMA 3. *If r_1 and r_2 are two vertically consecutive regions of a monotone subdivision* **P**, *then the monotone chain from $HIGH(r_1)$ to $LOW(r_2)$ is unique.*

Proof. The lemma holds trivially if $HIGH(r_1) = LOW(r_2)$. Thus, assume the contrary. Since $r_1 \uparrow r_2$, there is a monotone chain γ from $HIGH(r_1)$ to $LOW\ (r_2)$.

Suppose now, for a contradiction, that there is a monotone chain γ' from $HIGH\ (r_1)$ to $LOW\ (r_2)$ distinct from γ. Then $\gamma \cup \gamma'$ defines the boundary of a partial subdivision that contains at least one region of **P**. For any region r inside this partial subdivision, there are (possibly empty) chains from $HIGH(r_1)$ to $LOW(r)$ and from $HIGH(r)$ to $LOW(r_2)$, so that $r_1 \uparrow r \uparrow r_2$, contrary to the hypothesis that r_1 and r_2 are consecutive in $<$. □

DEFINITION 2. Given two vertically consecutive regions, r_1 and r_2, in **P**, with $r_1 \uparrow r_2$, the unique monotone chain from $HIGH(r_1)$ to $LOW(r_2)$ is called a *channel.*

LEMMA 4. *All channels are pairwise vertex-disjoint.*

Proof. Assume, for a contradiction, that there are two channels γ_1 and γ_2 that are not vertex-disjoint, where γ_1 connects regions r_1 and r_2, γ_2 connects regions r_3 and r_4, and $r_1 < r_2 < r_3 < r_4$ (see Fig. 5). Since γ_1 and γ_2 share a vertex x, there is a chain from $HIGH(r_3)$ to $LOW(r_2)$ consisting of the portion of γ_2 from $HIGH(r_3)$ to x, and the portion of γ_1 from x to $LOW(r_2)$. Hence, we have $r_3 < r_2$, a contradiction. □

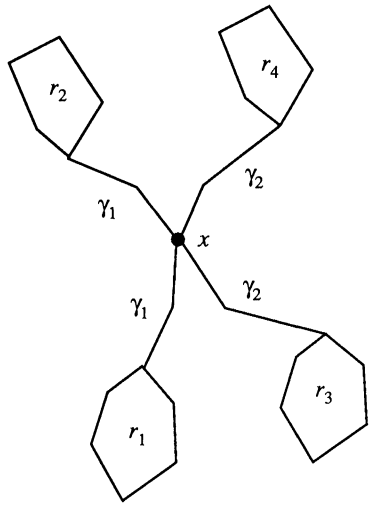

FIG. 5. *Two channels γ_1 and γ_2 that are not vertex-disjoint, where γ_1 connects regions r_1 and r_2, γ_2 connects regions r_3 and r_4, and $r_1 < r_2 < r_3 < r_4$ (for the proof of Lemma 4).*

Given two vertically consecutive regions r_1 and r_2, with $r_1 \uparrow r_2$, we imagine duplicating the channel from r_1 to r_2 and view the measure-zero region delimited by the two replicas as a degenerate polygon joining r_1 and r_2 and merging them into a new region $r_1 \cup r_2$ (see Fig. 6). Clearly, we can merge in this fashion any sequence of vertically consecutive pairs. This is formulated in the following definition.

DEFINITION 3. *Clusters* are recursively defined as follows:

(1) An individual region r is a cluster;

(2) Given two vertically consecutive clusters χ_1 and χ_2, with $\chi_1 \uparrow \chi_2$, their union is a cluster χ, denoted χ_1-χ_2 (the horizontal bar denotes the channel).

A *maximal cluster* χ is one that is not properly contained in any other cluster.

The unique subdivision resulting by forming all maximal clusters of **P** is denoted **P***. Figure 2(b) illustrates the regular subdivision **P*** corresponding to the subdivision **P** of Fig. 2(a). Note the clusters r_2-r_3, r_6-r_7, and r_9-r_{10}-r_{11}.

The above definition leads us to a convenient string notation for the order $<$, as well as for the cluster structure where appropriate. Normally, we shall use lowercase

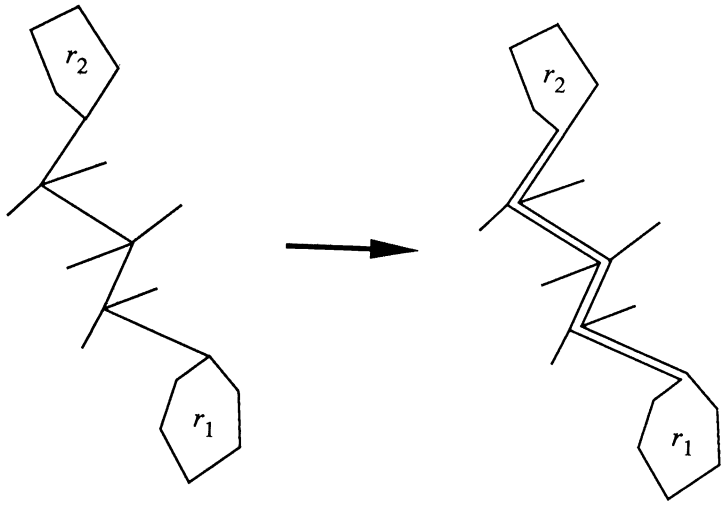

FIG. 6. *Creation of a channel between two vertically consecutive regions.*

roman letters for individual regions, lowercase Greek letters for clusters, and uppercase roman letters otherwise (i.e., for collections of consecutive regions not forming a single cluster). Specifically, we have:

(1) A cluster (possibly, a region) is a string.

(2) Given two strings A and B, such that the rightmost cluster of A and the leftmost cluster of B are consecutive (contiguity), then AB is a string.

A subdivision may be represented by means of its structural decomposition. For example, the subdivision of Fig. 2(b) is described by the following string:

$$r_1\chi_1 r_4 r_5 \chi_2 r_8 \chi_3 r_{12} r_{13} r_{14} r_{15},$$

where $\chi_1 = r_2 - r_3$, $\chi_2 = r_6 - r_7$, and $\chi_3 = r_9 - r_{10} - r_{11}$.

Later we will find it convenient to explicitly indicate that two consecutive regions r_1 and r_2 may or may not form a cluster. We shall denote this with the string notation $r_1 - - r_2$, where "--" means "potential channel."

We conclude this section with the following straightforward observation.

THEOREM 4. *The subdivision* $\mathbf{P}^*$ *obtained by forming all maximal clusters of a monotone subdivision* $\mathbf{P}$ *is regular.*

Note that in the transformation of $\mathbf{P}$ to $\mathbf{P}^*$ only the edges of channels are duplicated. By Lemma 4, each edge is duplicated at most once, thereby ensuring that the number of edges remains $O(n)$.

4. Dynamic point location in a monotone subdivision.

4.1. Data structure. In the following description, we assume that all sorted lists are stored as *red-black trees* [GS], [T]. We recall the following properties of red-black trees that are important in the subsequent time complexity analyses.

(1) Only $O(1)$ rotations are needed to rebalance the tree after an insertion/deletion.

(2) The data structure can be used to implement concatenable queues. Operations *SPLICE* and *SPLIT* of concatenable queues take $O(\log n)$ time and need $O(\log n)$ rotations each for rebalancing.

The search data structure consists of a main component, called the *augmented separator tree*, and an auxiliary component, called the *dictionary*. The *augmented*

separator tree **T** has a primary and secondary structure. The *primary structure* is a separator tree for $\mathbf{P}^*$, i.e., each of its leaves is associated with a region of $\mathbf{P}^*$ (a maximal cluster of **P**), and each of its internal nodes is associated with a separator of $\mathbf{P}^*$. (The left-to-right order of the leaves of the primary structure of **T** corresponds to the order $<$ on the regions of $\mathbf{P}^*$.) The *secondary structure* is a collection of lists, each realized as a search tree. Specifically, node σ points to the list $proper(\sigma)$ sorted from bottom to top, and the leaf associated with cluster χ (briefly called "leaf χ") points to the list $regions(\chi)$ of the regions that form cluster χ, also sorted from bottom to top.

Given two regions r_1 and r_2 consecutive in $<$, the separator σ between r_1 and r_2 is associated with the least common ancestor of the leaves associated with the respective clusters of r_1 and r_2 in **T**. By the definition of separator tree, the edges of σ are stored in the secondary structures of nodes along the path from node σ to the root of **T**; by Theorem 3, in a regular subdivision each extreme vertex of $proper(\sigma)$ splits $proper(\sigma')$, for some ancestor node σ' of node σ, into two chains. More precisely, the following simple lemma, stated without proof, makes explicit the allocation of the edges of σ to the nodes of **T**.

LEMMA 5. *Let σ be a separator of $\mathbf{P}^*$, and $\sigma_1, \cdots, \sigma_h$ be the sequence of nodes of* **T** *on the path from the root $(=\sigma_1)$ to σ. Then*

$$\sigma = (\alpha_1, \alpha_2, \cdots, \alpha_h, proper(\sigma), \beta_h, \beta_{h-1}, \cdots, \beta_1),$$

where α_i and β_i are (possibly empty) subchains of $proper(\sigma_i)$, $i = 1, \cdots, h$.

To dynamically maintain the channels, it is convenient to keep two representatives e' and e'' of each edge e that are created when e is inserted into **P**. If e does not belong to a channel, e' and e'' are joined into a *double edge* and belong to the same $proper(\sigma)$. If instead e is part of a channel, then e' and e'' are *single edges* and belong to distinct $proper(\sigma')$ and $proper(\sigma'')$. In the latter case e' and e'' are on the boundary of the same cluster χ so that nodes σ' and σ'' are on the path from leaf χ to the root of **T**. Therefore we represent $proper(\sigma)$ by means of two lists: $strand1(\sigma)$ and $strand2(\sigma)$. List $strand1(\sigma)$, called *primary strand*, stores a representative for each edge of $proper(\sigma)$ in bottom-to-top order. List $strand2(\sigma)$, called *secondary strand*, stores a representative for each double edge of $proper(\sigma)$ in bottom-to-top order.

Moreover, associated with each chain $proper(\sigma)$ there are two boolean indicators $t(\sigma)$ and $b(\sigma)$, corresponding, respectively, to the topmost and bottommost vertices of $proper(\sigma)$. Specifically, let σ' be the ancestor of σ such that the topmost vertex of $proper(\sigma)$ is an internal vertex of the chain $proper(\sigma')$ (for the special case where the topmost vertex of σ is at infinity, we let σ' be the father of σ). We define $t(\sigma) = left$ if σ is to the left of σ', and $t(\sigma) = right$ if σ is to the right of σ'. Parameter $b(\sigma)$ is analogously defined.

The *dictionary* contains the sorted lists of the vertices, edges, and regions of **P**, each sorted according to the alphabetic order of their names. With each vertex v we store pointers to the representatives of v in the (at most two) chains $proper(\sigma)$ and $proper(\sigma')$ of which v is a nonextreme vertex. With each edge e we store pointers to the two representatives of e in the data structure. Finally, with each region r we store the vertices $HIGH(r)$ and $LOW(r)$, and a pointer to the representative of r in the list $regions(\chi)$ such that χ is the maximal cluster containing r. The dynamic maintenance of the dictionary in the various operations can be trivially performed in $O(\log n)$ time, and will not be explicitly mentioned in the following.

To analyze the storage used by the data structure, we note the following: the primary structure of **T** has $O(n)$ nodes, since there are $O(n)$ regions (by Euler's formula) and therefore $O(n)$ separators; the secondary structure of **T** also has size

$O(n)$, since there are $O(n)$ edges in $\{proper(\sigma): \sigma \in \mathbf{T}\}$ and $O(n)$ regions in $\{regions(\chi): \chi \in \mathbf{T}\}$ (again, by Euler's formula); the auxiliary component has one record of bounded size per vertex, edge, and region. Therefore, we conclude with the following theorem.

THEOREM 5. *The data structure for dynamic point location has storage space* $O(n)$.

Note that the above data structure is essentially *identical* with the one originally proposed for the static version of the technique [LP]. What is remarkable is that the single-chain structure of the proper edges of any given separator, due to our specific choice of the separator family, is the key for the emergence of full dynamic capabilities.

We now show that the property expressed by Theorem 3 allows us to establish an important dynamic feature of the data structure. According to standard terminology, a *rotation at node* μ of a binary search tree is the restructuring of the subtree rooted at μ so that one of the children of μ becomes the root thereof. A rotation is either *left* or *right* depending on whether the right or left child of μ becomes the new root, respectively. We then have Lemma 6.

LEMMA 6. *A rotation at a node of* $\mathbf{T}$ *can be performed in* $O(\log n)$ *time.*

Proof. Without loss of generality, we consider a left rotation as illustrated in Fig. 7. Clearly, the separators stored at nodes outside the subtree rooted at σ_2 in Fig. 7(a) are not affected by the rotation, nor are those in the subtrees rooted at σ_1, σ_3, and σ_5. Hence, the only alterations involve separators σ_2 and σ_4. If $\sigma_4 \cap proper(\sigma_2) = \emptyset$, then the modification is trivial. Suppose then that $\sigma_4 \cap proper(\sigma_2) \neq \emptyset$. In this case the set $\sigma_4 \cap proper(\sigma_2)$ forms either the initial or the final segment of the chain $proper(\sigma_2)$, or both, for otherwise, regular subdivision $\mathbf{P}^*$ would contain vertically consecutive regions. Thus the update is accomplished by: (1) splitting $proper(\sigma_2)$ into $\gamma_2 = \sigma_4 \cap proper(\sigma_2)$ and its relative complement γ_1: (2) splicing γ_2 with $proper(\sigma_4)$ to form the updated $proper(\sigma_4)$; and (3) setting the updated $proper(\sigma_2)$ equal to γ_1. Note that the extreme vertices of $proper(\sigma_4)$ are obtained in time $O(1)$, and the splitting vertices of $proper(\sigma_2)$ are determined in time $O(\log n)$. Since data structures for $proper(\sigma_2)$ and $proper(\sigma_4)$, (i.e., the red-black trees associated with lists $strand1$ and $strand2$) are also concatenable queues, the splitting and splicing operations are executed in time $O(\log n)$ as well. The parameters $t(\sigma)$ and $b(\sigma)$ for the resulting separators are updated in $O(1)$ time by means of straightforward rules. □

Hereafter, the red-black tree $\mathbf{T}$ is assumed to be balanced. The rest of this section is devoted to the discussion of the algorithms to perform searches, insertions, and deletions.

4.2. Query. To perform point location search for a query point q, we use essentially the same method as in [LP]. The search consists of tracing a path from the root to a leaf χ of $\mathbf{T}$. At each internal node σ we discriminate q against separator σ. Three cases may occur:

(1) $q \in \sigma$: we return the edge of σ that contains q and stop;
(2) q is to the left of σ: we proceed to the left child of σ;
(3) q is to the right of σ: we proceed to the right child of σ.

Once we reach a leaf χ, we know that q belongs to a region of χ. Since the regions of χ are sorted from bottom to top, such region is determined by searching in the list $regions(\chi)$. The above technique can be viewed as a "horizontal" binary search in the set of separators of $\mathbf{P}^*$, followed by a "vertical" binary search in the set of regions of the leaf χ.

Let e be the edge of σ whose vertical span contains $y(q)$. When $e \in proper(\sigma)$, the discrimination of q against σ is a conventional search in $strand1(\sigma)$. When

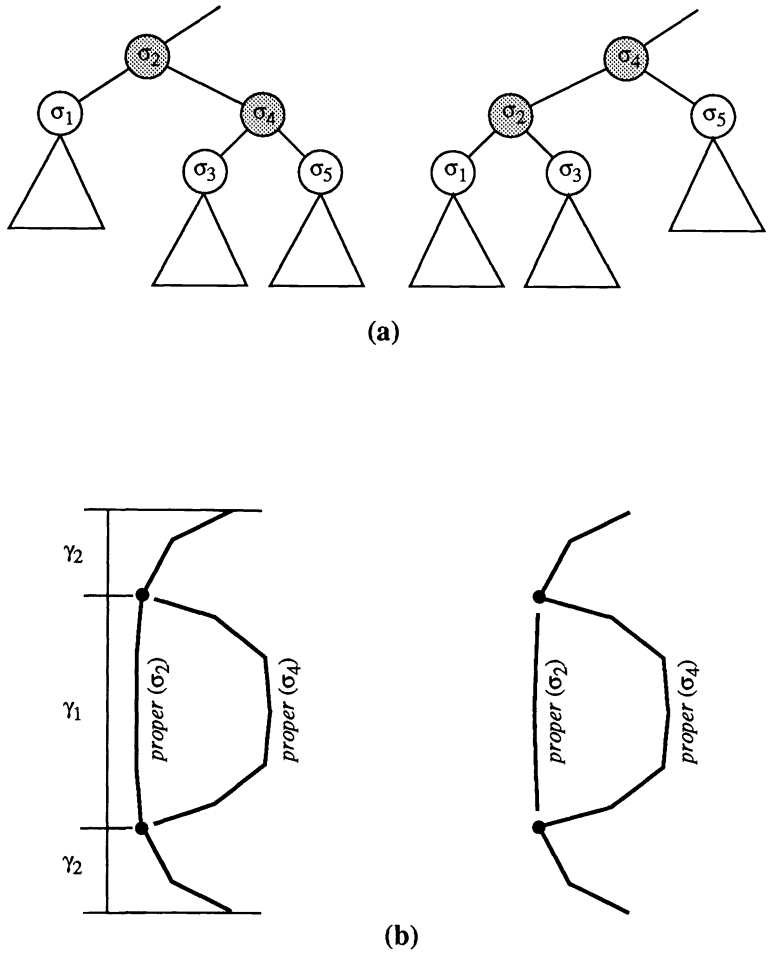

FIG. 7. *Illustration of a (left) rotation. Shaded regions are nodes involved in the update.* (a) *Separator tree.* (b) *Chains of proper edges.*

$e \notin proper(\sigma)$ then we use the pair $(t(\sigma), b(\sigma))$: for example, when e is above $proper(\sigma)$, if $t(\sigma) = left$, then q is discriminated to the right of σ, and to its left otherwise. (This is a minor variant of the criterion adopted in [LP].) The case when e is below $proper(\sigma)$ is treated analogously. This simple analysis confirms that the time spent at each node is $O(\log n)$. We have Theorem 6 [LP].

THEOREM 6. *The time complexity of the query operation is* $O(\log^2 n)$.

4.3. Insertion. We shall first show that the effect of operation *INSERT-CHAIN*$(\gamma, v_1, v_2, r; r_1, r_2)$ on the order $<$ of the regions of **P** can be expressed as a syntactical transformation between the strings expressing the order before and after the update. The situation is illustrated in Fig. 8.

On the boundary of r there are two distinguished vertices: $HIGH(r_1)$ and $LOW(r_2)$. Note that $HIGH(r_1) = HIGH(r)$ if v_2 is on the right chain of the boundary of r (and similarly $LOW(r_2) = LOW(r)$ if v_1 is on the left chain). Thus, in general, $HIGH(r_1)$ is on the left chain of the boundary of r, and $LOW(r_2)$ is on the right chain. Using the string notation introduced in § 3, let L and R be the strings corresponding to the

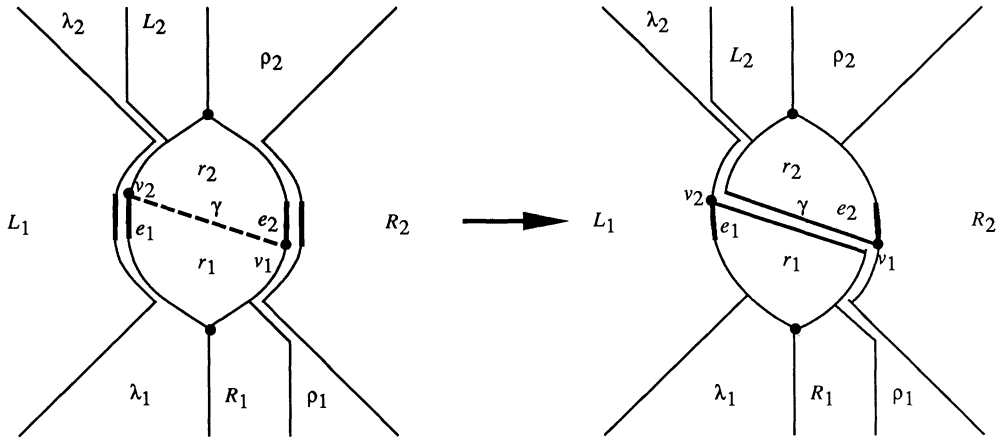

FIG. 8. (a) *Canonical partition of subdivision* $\mathbf{P}^*$ *with reference to region r and vertices* v_1 *and* v_2. (b) *The restructured subdivision after the insertion of chain* γ *between* v_1 *and* v_2.

regions that, respectively, precede and follow r in $<$. Thus, the subdivision $\mathbf{P}^*$ is described by the string LrR.

Let e_1 be the edge of $\mathbf{P}^*$ on the left boundary of r incident on $HIGH(r_1)$ from below, and let χ be the maximal cluster on the left of e_1. In general, this cluster consists of two portions, χ_1 and χ_2 (such that χ_1-χ_2), where χ_2 consists exactly of the regions q' of χ for which $y(LOW(q')) \cong y(HIGH(r_1))$. Thus, we have $L = L'\chi L''$. We now distinguish three cases and define substrings λ_1, λ_2, L_1, and L_2 as follows.

(1) $\chi_2 \neq \varnothing$. Let $\lambda_1 = \chi_1$, $\lambda_2 = \chi_2$, $L_1 = L'$, $L_2 = L''$, so that $L = L_1\lambda_1\text{-}\lambda_2 L_2$.

(2) $\chi_2 = \varnothing$. Let q be the region preceding r (note q could form a cluster with r). We further distinguish:

(2.1) $y(LOW(q)) \cong y(HIGH(r_1))$. In this case we let $L = L_1\lambda_2 L_2$, where λ_2 is the maximal cluster immediately following χ.

(2.2) $y(LOW(q)) < y(HIGH(r_1))$. In this case we let $L = L_1\lambda_1\text{--}$, where λ_1 is the rightmost maximal cluster of L (but not necessarily a maximal cluster in $\mathbf{P}^*$).

The three cases are conveniently encompassed by the notation

$$L = L_1\lambda_1\text{--}\lambda_2 L_2.$$

Note that some of the symbols may denote empty strings.

Analogously, string R can be reformulated as

$$R = R_1\rho_1\text{--}\rho_2 R_2$$

with straightforward meanings of the symbols.

Thus, in general, for any given region r and choice of v_1 and v_2 on its boundary, we have the following canonical string decomposition of $\mathbf{P}^*$:

$$L_1\lambda_1\text{--}\lambda_2 L_2 r R_1\rho_1\text{--}\rho_2 R_2.$$

The corresponding partition of the subdivision is illustrated in Fig. 8(a). Examples of configurations corresponding to cases (2.1) and (2.2) are shown in Fig. 9. Namely, Fig. 9(a) shows case (2.1) for L and case (1) for R, Fig. 9(b) shows case (2.2) for L and R, and Fig. 9(c) shows case (2.2) for L and case (1) for R.

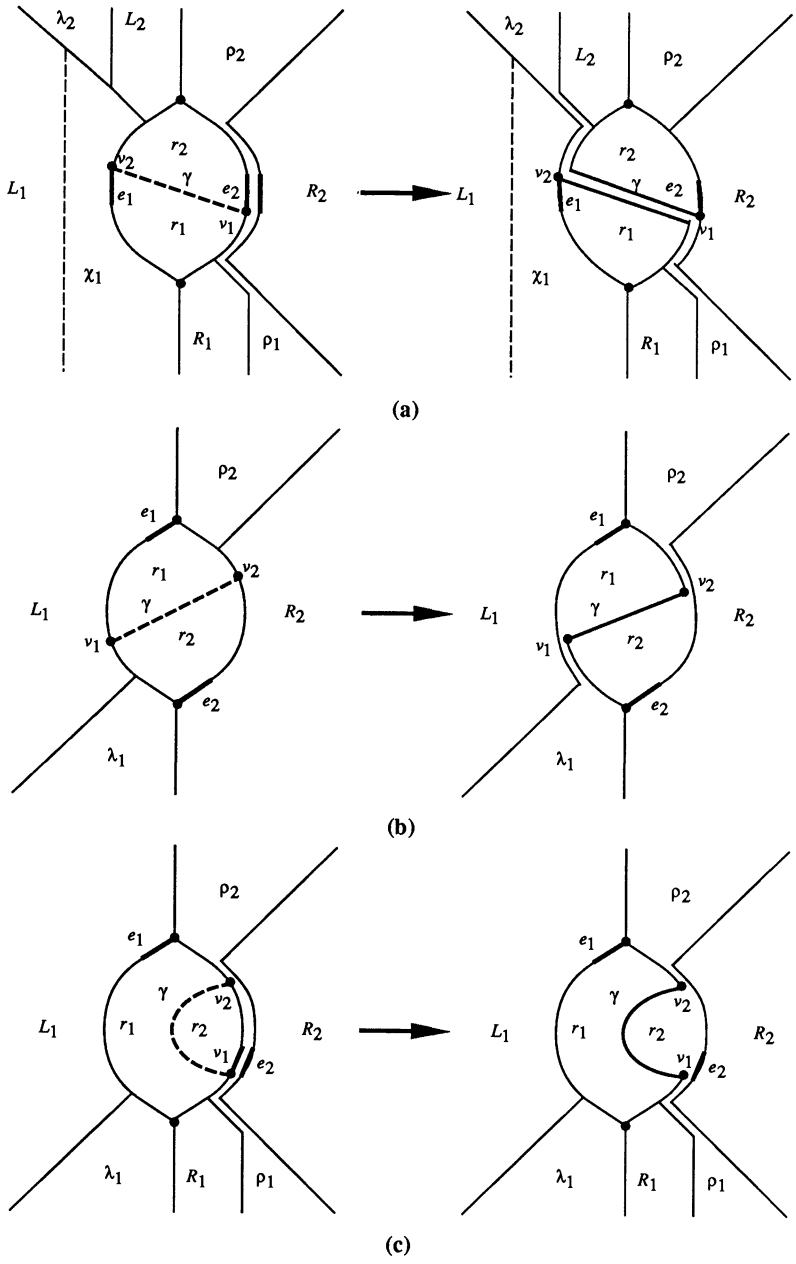

FIG. 9. *Special cases of the structural partition of Fig.* 8. (a) *Case* (2.1) *for L and case* (1) *for R.* (b) *Case* (2.2) *for both L and R.* (c) *Case* (2.2) *for L and case* (1) *for R.*

We now investigate the rearrangement of this order caused by the insertion of chain γ into r. Referring to Fig. 8(b), it is immediately observed that the order after the update is as follows:

$$L_1 < \lambda_1 < r_1 < R_1 < \rho_1 < \lambda_2 < L_2 < r_2 < \rho_2 < R_2.$$

To obtain the string description of the updated subdivision we must determine whether any new channel has been created. Any such channel can only arise in correspondence

with a new adjacency caused by the update, specifically for the following pairs: (λ_1, r_1), (ρ_1, λ_2), and (r_2, ρ_2). The channel from λ_1 to r_1 exists only if $y(HIGH(\lambda_1)) \leqq y(LOW(r_1))$, and analogously for the channel from r_2 to ρ_2. Instead, since $y(HIGH(\rho_1)) < y(LOW(\lambda_2))$, the cluster ρ_1-λ_2 always exists. Therefore, the order caused by the insertion of γ is represented by the string

$$L_1\lambda_1\text{--}r_1R_1\rho_1\text{-}\lambda_2L_2r_2\text{--}\rho_2R_2.$$

(In purely syntactic terms, this transformation corresponds to rewriting r as $r_2 - r_1$ and then exchanging substrings $r_1R_1\rho_1$ and $\lambda_2L_2r_2$.) This is summarized as follows.

THEOREM 7. *Let* $L_1\lambda_1\text{--}\lambda_2L_2rR_1\rho_1\text{--}\rho_2R_2$ *be the string description of the order of* $\mathbf{P}^*$, *where* L_1, r, *and* R_2 *are nonempty. After operation* $INSERTCHAIN(\gamma, v_1, v_2, r; r_1, r_2)$ *the new order is described by* $L_1\lambda_1\text{--}r_1R_1\rho_1\text{-}\lambda_2L_2r_2\text{--}\rho_2R_2$.

The algorithm for the $INSERTCHAIN(\gamma, v_1, v_2, r; r_1, r_2)$ operation implements the syntactical transformation of the string description by decomposing the subdivision $\mathbf{P}$ into its components L_1, λ_1, λ_2, L_2, r, R_1, ρ_1, ρ_2, and R_2, which are subsequently reassembled according to the new order given by Theorem 7.

To formally describe the algorithm, we denote by $\mathbf{P}(S)$ the partial subdivision associated with a string S of consecutive regions of $\mathbf{P}$. We can represent $\mathbf{P}(S)$ with essentially the same data structure described in § 4.1, and we denote with $\mathbf{T}(S)$ the augmented separator tree for S. Note that $\mathbf{T}(S)$ does not store the edges which form the boundary of S (in the same way as $\mathbf{T}$ does not store the edges at infinity). Partial subdivisions can be cut and merged with the same rules as for the decomposition and concatenation of the corresponding strings.

Let $\mathbf{P}(S_1)$, $\mathbf{P}(S_2)$, and $\mathbf{P}(S)$ be partial subdivisions such that $S = S_1S_2$. We show in the following how to *merge* $\mathbf{T}(S_1)$ and $\mathbf{T}(S_2)$ into $\mathbf{T}(S)$, and how to *cut* $\mathbf{T}(S)$ to produce $\mathbf{T}(S_1)$ and $\mathbf{T}(S_2)$. The merge operation needs also the separator σ forming the common boundary between the two (open) partial subdivisions $\mathbf{P}(S_1)$ and $\mathbf{P}(S_2)$; σ is represented by its primary and secondary strands. The cut operation returns the separator σ. These operations can be implemented by means of the following six primitives.

PROCEDURE $MERGE1(S_1, \sigma, S_2; S)$. (It merges partial subdivisions $\mathbf{P}(S_1)$ and $\mathbf{P}(S_2)$, with $S_1 \to S_2$; σ is the separator between $\mathbf{P}(S_1)$ and $\mathbf{P}(S_2)$.)

(1) Construct a separator tree $\mathbf{T}(S)$ for $\mathbf{P}(S)$, by placing σ at the root, and making $\mathbf{T}(S_1)$ and $\mathbf{T}(S_2)$ the left and right subtrees of σ, respectively.
($\mathbf{T}(S)$ is a legal separator tree for $\mathbf{P}(S)$, but might be unbalanced.)

(2) Rebalance $\mathbf{T}(S)$ by means of rotations.

PROCEDURE $MERGE2(\chi_1, \alpha, \chi_2; \chi)$. (It merges partial subdivisions $\mathbf{P}(\chi_1)$ and $\mathbf{P}(\chi_2)$ such that $\chi_1 \uparrow \chi_2$ into $\mathbf{P}(\chi)$, where $\chi = \chi_1\text{-}\chi_2$, and α is the channel between γ_1 and χ_2.)

(1) Separate the two strands of α, and make the secondary strand become a new primary strand.

(2) Splice $regions(\chi_1)$ and $regions(\chi_2)$ to form $regions(\chi)$.

LEMMA 7. *Operations* $MERGE1(S_1, \sigma, S_2; S)$ *and* $MERGE2(\chi_1, \alpha, \chi_2; \chi)$ *have time complexity* $O(\log^2 n)$ *and* $O(\log n)$, *respectively.*

Proof. The time bound for operation $MERGE2$ follows immediately from the properties of concatenable queues. With regard to $MERGE1$, Step (1) consists of forming $\mathbf{T}(S)$ by joining the primary structures of $\mathbf{T}(S_1)$ and $\mathbf{T}(S_2)$ through node σ, which takes $O(1)$ time. Since we use red-black trees, we can rebalance $\mathbf{T}(S)$ with

$O(\log n)$ rotations [GS], [T, pp. 52–53]. By Lemma 6, each such rotation takes $O(\log n)$ time, so that the total time complexity is $O(\log^2 n)$. □

PROCEDURE $CUT1(S, \chi_1, \chi_2; S_1, \sigma, S_2)$. (It cuts partial subdivision $\mathbf{P}(S)$ into $\mathbf{P}(S_1)$ with rightmost cluster χ_1 and $\mathbf{P}(S_2)$ with leftmost cluster χ_2, such that $\chi_1 \to \chi_2$, and also returns the separator σ between $\mathbf{P}(S_1)$ and $\mathbf{P}(S_2)$.)

(1) Find the node σ of $\mathbf{T}(S)$ that is the least common ancestor of leaves χ_1 and χ_2.
(2) Perform a sequence of rotations to bring σ to the root of $\mathbf{T}(S)$, where after each rotation we rebalance the subtree of σ involved in the rotation, namely, the left subtree for a left rotation and the right subtree for a right rotation (see Fig. 10).
(3) Set $\mathbf{T}(S_1)$ as the left subtree of σ and $\mathbf{T}(S_2)$ as the right subtree of σ. Return the chain $proper(\sigma)$.

PROCEDURE $CUT2(\chi; \chi_1, \alpha, \chi_2)$. (It cuts partial subdivision $\mathbf{P}(\chi)$ into $\mathbf{P}(\chi_1)$ and $\mathbf{P}(\chi_2)$, where $\chi = \chi_1 - \chi_2$ and α is the channel between χ_1 and χ_2.)

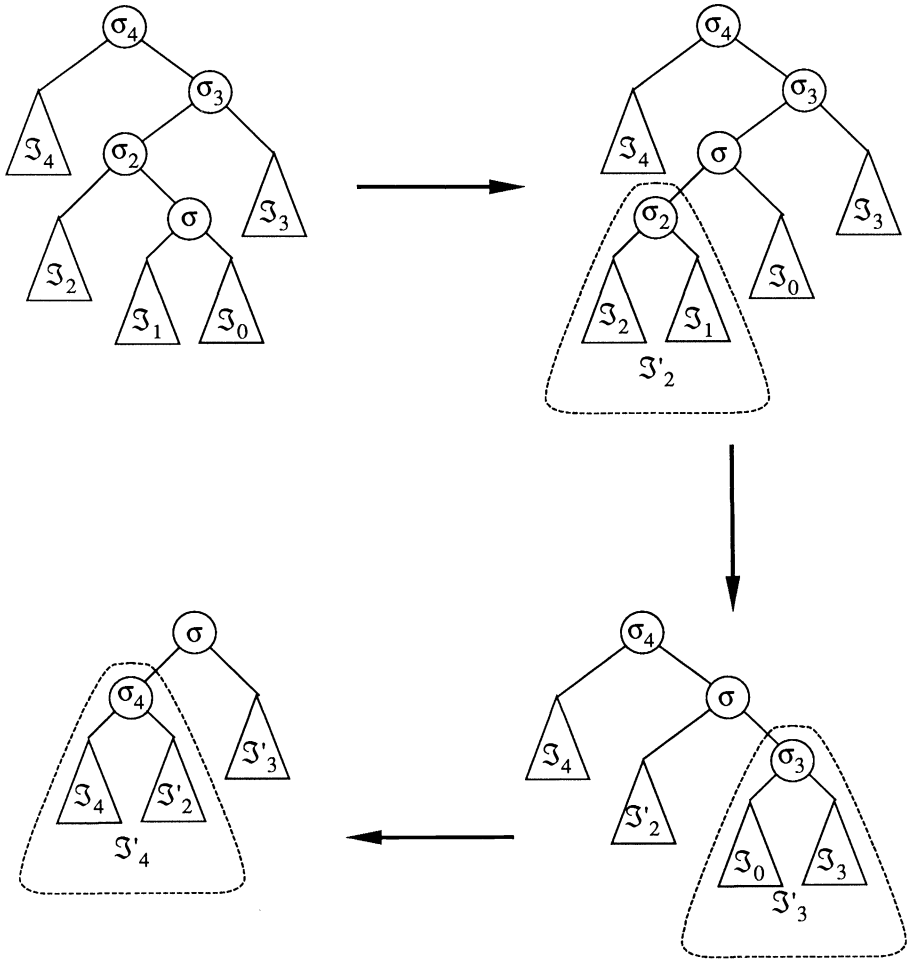

FIG. 10. *Example for step* (2) *of Procedure CUT*1.

(1) Join the two previously separated strands of α, so that the rightmost one becomes the secondary strand of the other.
(2) Split *regions*(χ) into *regions*(χ_1) and *regions*(χ_2).

LEMMA 8. *Operations* $CUT1(S, \chi_1, \chi_2; S_1, \sigma, S_2)$ *and* $CUT2(\chi; \chi_1, \gamma, \chi_2)$ *have time complexity* $O(\log^2 n)$ *and* $O(\log n)$, *respectively.*

Proof. The time bound for operation $CUT2$ is immediate. With regard to operation $CUT1$, step (1) takes $O(height(\mathbf{T}(S))) = O(\log n)$ time. In step (2), we perform no more than *height*($\mathbf{T}(S)$) rotations to bring σ to the root. After each such rotation, we have to rebalance a subtree $\mathbf{T}'$, whose left and right subtrees are already balanced, so that the number of rotations required for rebalancing is proportional to the difference of height of the subtrees of $\mathbf{T}'$. Such differences form a sequence whose sum is proportional to *height*($\mathbf{T}(S)$) [GS], [T, p. 53]. By Lemma 6, each such rotation takes $O(\log n)$ time, so that the total time complexity is $O(\log^2 n)$. □

PROCEDURE *FINDLEFT*($e; \chi$). (It finds the cluster χ to the left of edge e. If e is part of a channel, then χ is the cluster that contains such channel.)
(1) Perform a point location search for (any point of) edge e. The search will stop at a node σ of $\mathbf{T}$ that stores (a representative of) e.
(2) If e is a double edge of σ (i.e., e does not belong to a channel), resume the point location search in the left subtree of σ and return the leaf χ where the search terminates. (This corresponds to searching for a point p^- immediately to the left of edge e.)
(3) Otherwise (i.e., e is a single edge of σ and belongs to a channel) resume the point location search in both subtrees of σ. (This corresponds to searching for points p^- and p^+ immediately to the left and right of edge e, respectively.) One of the two searches, say the left one, will terminate in a leaf, while the other search, say the right one, will stop at a node σ' that stores the other representative of e. (Recall that the two nodes storing e are on the path from leaf χ to the root of $\mathbf{T}$.) We resume the search in the left subtree of σ' and return the leaf χ where the search terminates. (The case where the right search out of σ terminates in a leaf is analogous.)

PROCEDURE *FINDRIGHT*($e; \chi$). (It finds the cluster χ to the right of edge e. If e is part of a channel, then χ is the cluster that contains such channel.)
(Analogous to *FINDLEFT*.)

LEMMA 9. *Operations* $FINDLEFT(e; \chi)$ *and* $FINDRIGHT(e; \chi)$ *have each time complexity* $O(\log^2 n)$.

Proof. Since each edge has two representatives, there are at most two nodes of $\mathbf{T}$ where we proceed to both children. Hence, we visit a total of $O(\log n)$ nodes, spending $O(\log n)$ time at each node. □

The complete algorithm for operation $INSERTCHAIN(\gamma, v_1, v_2, r; r_1, r_2)$ is as follows.

ALGORITHM $INSERTCHAIN(\gamma, v_1, v_2, r; r_1, r_2)$.
(1) Find regions q and s immediately preceding and following r, respectively; also, find clusters χ_L and χ_R by means of $FINDLEFT(e_1; \chi_L)$ and $FINDRIGHT(e_2; \chi_R)$. From these obtain λ_1, λ_2, ρ_1, and ρ_2.
(2) Perform a sequence of $CUT1$ and $CUT2$ operations to decompose $\mathbf{P} = \mathbf{P}(L_1\lambda_1\text{--}\lambda_2 L_2 r R_1 \rho_1\text{--}\rho_2 R_2)$ into $\mathbf{P}(L_1)$, $\mathbf{P}(\lambda_1)$, $\mathbf{P}(\lambda_2)$, $\mathbf{P}(L_2)$, $\mathbf{P}(r)$, $\mathbf{P}(R_1)$, $\mathbf{P}(\rho_1)$, $\mathbf{P}(\rho_2)$, and $\mathbf{P}(R_2)$. The primary and secondary strands returned by each such

operation, which form the boundaries of the above partial subdivisions, are collected into a list **L**.

(3) Construct the primary and secondary strands of chain γ and add them to **L**.

(4) Destroy $\mathbf{P}(r)$ and create $\mathbf{P}(r_1)$ and $\mathbf{P}(r_2)$.

(5) Test for channels λ_1–r_1 and r_2–ρ_2, and perform a sequence of *MERGE*1 and *MERGE*2 operations to construct the updated subdivision $\mathbf{P}(L_1\lambda_1\text{--}r_1R_1\rho_1\text{-}\lambda_2L_2r_2\text{--}\rho_2R_2)$. The separators and channels needed to perform each such merge are obtained by splitting and splicing the appropriate strands of **L**.

THEOREM 8. *The time complexity of operation INSERTCHAIN*$(\gamma, v_1, v_2, r; r_1, r_2)$, *where* γ *consists of* k *edges, is* $O(\log^2 n + k)$.

Proof. In step (1), finding q and s takes $O(\log n)$ time. In fact, q is either in the cluster of r or in the cluster immediately preceding the one of r, and analogously for s. By Lemma 9, finding χ_L and χ_R takes $O(\log^2 n)$ time. The remaining computation of λ_1, λ_2, ρ_1, and ρ_2 can be done in $O(\log n)$ time. By Lemma 8, step (2) takes $O(\log^2 n)$ time. Note that the list **L** has $O(1)$ elements. Step (3) can be clearly performed in time $O(k)$. Step (4) takes $O(1)$ time since r, r_1, and r_2 are single-region structures. In step (5), testing for channels λ_1--r_1 and r_2--ρ_2 takes $O(1)$ time. Since the list **L** has $O(1)$ elements, we can construct in $O(\log n)$ time the separators and channels needed for each merge operation of step (5). By Lemma 7 the total time for such merges is $O(\log^2 n)$. □

With regard to the *INSERTPOINT* operation, we locate the edge e in the dictionary, and replace each of the two representatives of e in the data structure with the chain (e_1, v, e_2). This corresponds to performing two insertions into sorted lists, so that we have Theorem 9.

THEOREM 9. *The time complexity of operation INSERTPOINT*$(v, e; e_1, e_2)$ *is* $O(\log n)$.

A similar argument shows Theorem 10.

THEOREM 10. *The time complexity of operation MOVEPOINT*$(v; x, y)$ *is* $O(\log n)$.

4.4. Deletion. The transformations involved in a *REMOVECHAIN* operation are exactly the reverse of the ones for the *INSERTCHAIN* operation. We observe that all the updates performed in the latter case are totally reversible, which establishes Theorem 11.

THEOREM 11. *The time complexity of operation REMOVECHAIN*$(\gamma; r)$, *where* γ *consists of* k *edges, is* $O(\log^2 n + k)$.

The same situation arises with respect to the *INSERTPOINT* and *REMOVEPOINT* operations, so that we have Theorem 12.

THEOREM 12. *The time complexity of operation REMOVEPOINT*$(v; e)$ *is* $O(\log n)$.

Theorem A stated in § 1 results from the combination of the above Theorems 5, 6, 8, 9, 11, and 12.

5. Conclusion and open problems. The above technique represents a reasonably efficient solution of the dynamic point location problem. It requires no new sophisticated or bizarre data structures, and it appears eminently practical.

It remains an open problem whether $O(\log n)$ optimal performance is achievable for query/update times; in particular, whether the technique of fractional cascading, which achieved optimality for its suboptimal static predecessor [EGS], can also be successfully applied to the presented technique.

Another challenging open question is to extend our technique to general planar subdivisions.

ON THE LIMIT SETS OF CELLULAR AUTOMATA*

KAREL CULIK II†, JAN PACHL‡, AND SHENG YU§

Abstract. The limit sets of cellular automata, defined by Wolfram, play an important role in applications of cellular automata to complex systems. A number of results on limit sets are proved, considering both finite and infinite configurations of cellular automata. The main concern of this paper is with testing membership and (essential) emptiness of limit sets for linear and two-dimensional cellular automata.

Key words. cellular automaton, limit set, limit language, decidability, bi-infinite words

AMS(MOS) subject classification. 68D20

1. Introduction. Recently, cellular automata (CA) have been intensively studied as models of complex systems, especially systems containing a large number of simple components with local interactions [11], [12], [13]. An important role in these models is played by the limit sets of CA. The limit set of a CA consists of those configurations that might occur after arbitrarily many computation steps of the automaton. They correspond to the concept of attractors in the chaos theory in physics.

Many problems concerning CA limit sets are open [6], [11], [13]. In this paper, we study several versions of the "emptiness problem" for CA limit sets. We show that for $k \geq 2$ it is undecidable whether the limit set of a given k-dimensional cellular automaton consists of the quiescent configuration only. We also show that for all $k \geq 1$ it is undecidable whether the limit set of a given k-dimensional cellular automaton contains a finite configuration. The first problem for $k = 1$ is still open. However, we show that if the limit set of a given cellular automaton contains the quiescent configuration only, then all the configurations map to the quiescent configuration in a bounded number of steps. The methodology of this work is of interest. Besides automata theoretical techniques we also use, as Hurd did [6], the product topology on the space of configurations; we use the fact that this topological space is compact.

In §2 we define cellular automata and their limit sets. In §3 we endow the set of states of a CA cell with the discrete topology and observe that the space of all the configurations of the CA with the product topology is compact by Tychonoff's theorem. We then use compactness to prove several properties of the limit sets, including nonemptiness. We also use Baire's category theorem to derive a classification of cellular automata.

In the following section we prove two results about the relationship between the limit sets and the limit languages of linear (one-dimensional) automata.

In §5 we use the undecidability of the tiling problem to prove that for $k \geq 2$ it is undecidable whether the limit set of a given k-dimensional cellular automaton is a singleton.

A configuration of a CA is called finite if all but finite (nonzero) number of cells are quiescent. In §6 we study the limit sets of finite configurations, i.e., the intersection of the limit set with the set of finite configurations. Our main result here is that it is undecidable whether the limit set of finite configurations is empty even for linear CA. The set of all finite subwords of the configurations in a limit set is called a limit language. We show that the membership problem for CA limit languages, i.e., whether a given string is in the limit language of a given linear CA, is undecidable. Using the existence of a universal CA [1], we prove that there exists a CA whose limit language is not recursive. Similar results were proved by Hurd [6]. In §6 it is explained how our results relate to those in [6].

There are simple regular languages that are not CA limit languages. On the other hand, since the complement of any CA limit language is recursively enumerable, a limit language is recursive if and only if it is recursively enumerable. Thus the result mentioned above implies that not all limit languages are recursively enumerable [6]. Moreover, there is no obvious effective translation between the description of a recursive limit set by its CA and the description by a Turing machine. For more detailed proofs of the results in §§4–6 see [4].

2. Cellular automata: Basic definitions. Let Z be the set of integers, and Z^k the set of k-tuples of integers. A *cellular automaton*, abbreviated CA (or, more specifically, a *k-dimensional cellular automaton*, kD CA), is an infinite array, indexed by Z^k, of *cells*. Each cell is identified by its *location* $I \in Z^k$.

At any time, each cell has a *state*, which belongs to a finite set S. The dynamic behavior of the CA is determined by a rule that describes the state of each cell at time $t+1$ as a function of the states of some neighboring cells at time t. The rule is invariant with respect to translations (shifts) of Z^k.

Formally, a cellular automaton is a quadruple $A = (k, S, N, f)$, where $k \geq 1$ is the dimension, S is the finite set of states, N is the *neighborhood*, and f is the *local function* of A. The dimension k is an integer, $k \geq 1$. The (relative) neighborhood N is a sequence $(I_1, I_2, \cdots, I_h)$ of relative locations $I_j \in Z^k$, $1 \leq j \leq h$. The local function is a total function $f : S^h \to S$.

A *configuration* c of the CA is a function $c : Z^k \to S$, which assigns a state in S to each cell of the CA. The set of configurations is denoted S^{Z^k}. The local function f is extended to the *global function*

$$G_f : S^{Z^k} \to S^{Z^k}$$

of the set of configurations into itself. By definition, for $c_1, c_2 \in S^{Z^k}$,

$$G_f(c_1) = c_2$$

if and only if

$$c_2(I) = f(c_1(I + I_1), c_1(I + I_2), \cdots, c_1(I + I_h))$$

for all $I \in Z^k$.

The function G_f describes the dynamic behavior of the CA: The CA moves from the configuration c at time t to the configuration $G_f(c)$ at time $t+1$. The state of the cell I at time $t+1$ depends only on the states of the cells in the neighborhood $(I + I_1, I + I_2, \cdots, I + I_h)$ at time t. Notice that besides being locally defined, the global function G_f is total and translation invariant.

Example 1. Let $A = (1, S, N, f)$ be a one-dimensional CA, where $S = \{0, 1\}$, $N = (-2, -1, 0, 1, 2)$, and

$$f(x_1, x_2, x_3, x_4, x_5) = \begin{cases} 1 & \text{if } x_1 + x_2 + x_3 + x_4 + x_5 = 4; \\ 0 & \text{otherwise.} \end{cases}$$

If c is a configuration consisting of all 1's and c' is a configuration consisting of all 0's, then $G_f(c) = c'$.

For $c \in S^{Z^k}$, the sequence $(c, G_f(c), {G_f}^2(c), {G_f}^3(c), \cdots)$ is called the *orbit of* c.

Frequently, a state $\tilde{q}$ with the property

$$f(\tilde{q}, \tilde{q}, \cdots, \tilde{q}) = \tilde{q}$$

is distinguished and called the *quiescent state*. In a CA, there may be more than one state with the above property, but at most one of them is distinguished as the quiescent state. The configuration with all cells in the quiescent state is called the *quiescent configuration*, denoted by $\tilde{Q}$.

Let $A = (k, S, N, f)$ be a CA. Define

$$\begin{aligned} \Omega^{(0)} &= S^{Z^k}, \text{ and} \\ \Omega^{(i)} &= G_f(\Omega^{(i-1)}) \text{ for } i \geq 1 . \end{aligned}$$

Then

$$\Omega = \bigcap_{i=0}^{\infty} \Omega^{(i)}$$

is called the *limit set* of A.

Define

$$\Phi = \{ c \in S^{Z^k} \mid G_f(c) = c \}$$

(this is the set of "fixed points" of G_f). Obviously $\Phi \subseteq \Omega$.

3. The product topology on configurations. The configuration space S^{Z^k} is a product of infinitely many finite sets S. When S is endowed with the discrete topology, the *product topology* on S^{Z^k} is compact by Tychonoff's theorem [7, Thm. 5.13]. A subbasis of open sets for the product topology consists of all sets of the form

$$\{ c \in S^{Z^k} \mid c(i) = a \}, \tag{1}$$

where $i \in Z^k$ and $a \in S$. A subset of S^{Z^k} is open if and only if it is a union of finite intersections of sets of the form (1). It is easy to show that the global function G_f defined in the previous section is continuous from S^{Z^k} to S^{Z^k}. (Thus the pair (S^{Z^k}, G_f) is a classical dynamical system, in the sense of [3].)

THEOREM 3.1. *For every G_f the limit set Ω is nonempty.*

Proof. Since G_f is continuous, each $\Omega^{(i)}$, $i \geq 0$ is a continuous image of the compact space S^{Z^k}. Hence $\Omega^{(i)}$ are nonempty compact subsets of S^{Z^k}, and $\Omega^{(0)} \supseteq \Omega^{(1)} \supseteq \Omega^{(2)} \supseteq \cdots$. Therefore the intersection $\Omega = \bigcap_{i=0}^{\infty} \Omega^{(i)}$ is nonempty. □

The theorem has also an easy nontopological proof.

An alternative proof. Let $c : Z^k \to S$ be a constant function (i.e., there is $a \in S$ such that $c(I) = a$ for all $I \in Z^k$). In the orbit $(c, c_1, c_2, \cdots)$ of c, each c_j is a constant function. Since the set S is finite, there are only finitely many constant functions from Z to S, and thus there exists m such that $c_m = c_j$ for infinitely many j. Hence $c_m \in \Omega^{(i)}$ for all $i \geq 0$, and $c_m \in \Omega$. □

For some CA, the limit set Ω contains only one configuration. In particular, for a CA with a special quiescent state $\tilde{q}$, it is possible that the limit set contains only the quiescent configuration $\tilde{Q}$. It was open whether the problem $\Omega \stackrel{?}{=} \{\tilde{Q}\}$ is decidable for k-dimensional CA for $k \geq 1$. It is still open for $k = 1$.

Now we are going to use Baire's category theorem to classify cellular automata by the limit behavior of their orbits. A subset of a topological space is called a G_δ set if it is the intersection of a countable family of open sets.

THEOREM 3.2. *Let C be a closed translation-invariant subset of S^{Z^k}. Exactly one of these two conditions is true:*

(i) *There exists an integer $i \geq 0$ such that $G_f{}^i(S^{Z^k}) \subseteq C$.*

(ii) *There exists a dense G_δ set $D \subseteq S^{Z^k}$ such that*

$$C \cap \bigcup_{i=0}^{\infty} G_f{}^i(D) = \emptyset.$$

Proof. For $i = 0, 1, 2, \cdots$, let

$$F_i = \{\, c \in S^{Z^k} \mid G_f{}^i(c) \in C \,\}.$$

The sets F_i are closed and translation invariant. Let

$$D = S^{Z^k} - \bigcup_{i=0}^{\infty} F_i \ .$$

Thus D is a G_δ set in S^{Z^k} and

$$C \cap \bigcup_{i=0}^{\infty} G_f{}^i(D) = \emptyset.$$

If D is dense in S^{Z^k}, then condition (ii) holds.

If D is not dense, then $\bigcup_{i=0}^{\infty} F_i$ contains a nonempty open subset E of S^{Z^k}. The set E is locally compact; therefore, by Baire's theorem [7, Thm. 6.34], there exists i such that F_i contains a nonempty open subset of E, which is an open subset of S^{Z^k}. Since F_i is translation invariant, it follows that F_i contains a nonempty open *translation-invariant* subset of S^{Z^k}. However, every nonempty open translation-invariant subset of S^{Z^k} is dense in S^{Z^k}. Since F_i is closed, it follows that $F_i = S^{Z^k}$, and therefore (i) holds. □

In the notation of §2, $\Omega^{(i)} = G_f{}^i(S^{Z^k})$. The set $\{\tilde{Q}\}$ (the singleton set containing only the quiescent configuration) and the limit set Ω are closed and translation invariant. Thus we obtain Corollaries 1 and 2.

COROLLARY 3.3. *If $\Omega \neq \{\tilde{Q}\}$, then there exists a configuration whose orbit does not contain $\tilde{Q}$.*

Proof. If there exists i such that $\Omega^{(i)} \subseteq \{\tilde{Q}\}$, then $\Omega = \{\tilde{Q}\}$. Therefore, by Theorem 3.2, if $\Omega \neq \{\tilde{Q}\}$, then condition (ii) holds with $C = \{\tilde{Q}\}$. If $c \in D$, then the orbit of c does not meet $\{\tilde{Q}\}$. □

COROLLARY 3.4. *For each* CA, *exactly one of these two conditions is true:*

(i) *There exists an integer* $i \geq 0$ *such that* $\Omega^{(i)} = \Omega$.
(ii) *There exists a dense* G_δ *set* $D \subseteq S^{Z^k}$ *such that*

$$\Omega \cap \bigcup_{i=0}^{\infty} {G_f}^i(D) = \emptyset.$$

It is easy to find CA satisfying condition (i) in Corollary 3.4. For instance, (i) holds whenever G_f is surjective (because in that case $\Omega = \Omega^{(i)} = S^{Z^k}$ for every i). On the other hand, the CA in the following example does not satisfy (i) (and therefore it satisfies (ii)).

Example 2. Let $A = (1, S, N, f)$ be a one-dimensional CA such that $S = \{0, 1\}$, $N = (-1, 0, 1)$, and

$$f(a_{-1}, a_0, a_1) = \begin{cases} 1 & \text{if } a_{-1} = a_0 = a_1 = 1; \\ 0 & \text{otherwise.} \end{cases}$$

In this example,

$$\Omega = \{\, {}^{\omega}1^{\omega} \,\} \cup \{\, {}^{\omega}01^n0^{\omega} \mid n = 0, 1, 2, \cdots \}.$$

However,

$${G_f}^i({}^{\omega}01^{2i+1}01^{2i+1}0^{\omega}) = {}^{\omega}010^{2i+1}10^{\omega}$$

and therefore $\Omega^{(i)} \neq \Omega$ for every i, which means that condition (i) in Corollary 3.4 does not hold.

Now we prove that condition (ii) in Corollary 3.4 never holds when $\Omega = \{\tilde{Q}\}$.

THEOREM 3.5. $\Omega = \{\tilde{Q}\}$ *if and only if there exists an integer* $i \geq 0$ *such that* $\Omega^{(i)} = \{\tilde{Q}\}$.

Proof. The *if* part is trivially true. To prove the *only if* part, assume that $\Omega = \{\tilde{Q}\}$. Choose one cell $I_0 \in Z^k$, and define

$$C = \{\, c \in S^{Z^k} \mid c(I_0) \neq \tilde{q} \,\}.$$

Then C is a closed set and

$$\bigcap_{i=0}^{\infty} \left(\Omega^{(i)} \cap C\right) = \{\tilde{Q}\} \cap C = \emptyset.$$

By compactness, $\Omega^{(i)} \cap C = \emptyset$ for some i. Since $\Omega^{(i)}$ is translation invariant,

$$\Omega^{(i)} \cap \{\, c \in S^{Z^k} \mid c(I) \neq \tilde{q} \,\} = \emptyset$$

for every $I \in Z^k$. Hence $\Omega^{(i)} = \{\tilde{Q}\}$. □

Theorem 3.5 yields a semi-procedure for demonstrating that Ω contains only the quiescent configuration. To define the semi-procedure, we extend the global function G_f to operate on partial configurations. If $W \subseteq Z^k$, define

$$N^{-1}(W) = \{\, I \in Z^k \mid I + I_j \in W \text{ for } 1 \leq j \leq h \,\}$$

and for a function $c_1 : W \to S$ define

$$G_f(c_1) = c_2,$$

where $c_2 : N^{-1}(W) \to S$ is such that

$$c_2(I) = f(c_1(I + I_1), c_1(I + I_2), \cdots, c_1(I + I_h))$$

for all $I \in N^{-1}(W)$.

For $r \geq 0$, define the k-dimensional interval W_r to be the product of one-dimensional intervals $[-r, r]$; that is,

$$W_r = \{ (i_1, i_2, \cdots, i_k) \in Z^k \mid -r \leq i_j \leq r \text{ for } j = 1, 2, \cdots, k \}.$$

Denote by I_0 the origin in Z^k, i.e., the k-tuple of zeros.

COROLLARY 3.6. *Let $r \geq 0$ be such that $N \subseteq W_r$. Then $\Omega = \{\tilde{Q}\}$ if and only if there exists an integer $i \geq 0$ such that for every function $c : W_{ir} \to S$ the function ${G_f}^i(c)$ maps I_0 to $\tilde{q}$.*

Proof. The corollary follows from the theorem and from this observation, which can be proved by induction in i: If $c : W_{ir} \to S$ and $c' : Z^k \to S$ agree on W_{ir}, then ${G_f}^i(c)$ and ${G_f}^i(c')$ agree at I_0. □

The following semi-procedure determines that $\Omega = \{\tilde{Q}\}$: Let $A = (k, S, N, f)$ be the given CA. Find r such that $N \subseteq W_r$. For $i = 1, 2, \cdots$, generate all functions $c : W_{ir} \to S$, and for each such c compute the value of ${G_f}^i(c)$ at I_0. Stop when, for some i, all the values are $\tilde{q}$. This is only a semi-procedure, because it never halts when $\Omega \neq \{\tilde{Q}\}$.

We conjecture that the problem $\Omega \stackrel{?}{=} \{\tilde{Q}\}$ is decidable for *linear* (i.e., one-dimensional) CA. In §5 we show that the problem is undecidable for two-dimensional CA, and therefore also for k-dimensional CA when $k \geq 2$. In the remainder of this section, we show that the same problem for Φ (the set of fixed points of G_f, defined at the end of §2) is decidable for linear CA, although (as will be proved in Theorem 5.3) it is undecidable for dimensions $k \geq 2$.

A configuration $c : Z \to S$ is called *periodic* if there is $m > 0$ (called a *period of* c) such that $c(j + m) = c(j)$ for every $j \in Z$.

LEMMA 3.7. *For a linear CA $(1, S, N, f)$, let $r > 0$ be such that $N \subseteq [-r, r]$, and let n be the cardinality of S. If $\Phi \neq \{\tilde{Q}\}$ then there exists a periodic configuration $c \in \Phi$, $c \neq \tilde{Q}$, with period at most n^{2r+1}.*

Proof. Choose any $c' \in \Phi - \{\tilde{Q}\}$. Find the smallest $j > 0$ such that for some j_0 the restrictions of c' to the intervals $[j_0, j_0 + 2r]$ and $[j_0 + j, j_0 + j + 2r]$ are identical (modulo a shift) and $c'(j_1) \neq \tilde{q}$ for some j_1 in $[j_0, j_0 + j]$. Since there are n^{2r+1} different partial configurations $d : [-r, r] \to S$, it follows that $j \leq n^{2r+1}$. Define c to be the (unique) configuration that is equal to c' on the interval $[j_0, j_0 + j + 2r]$ and periodical with period j. □

THEOREM 3.8. *The problem $\Phi \stackrel{?}{=} \{\tilde{Q}\}$ is decidable for $k = 1$.*

Proof. In view of Lemma 3.7, the following algorithm decides whether $\Phi = \{\tilde{Q}\}$: Generate all partial configurations $c : [-r, n^{2r+1} + r] \to S$, and for each such c check whether there exists an integer m, $0 < m \leq n^{2r+1}$, such that $G_f(c)(j) = c(j)$ for $0 \leq j \leq n^{2r+1}$, $c(j) = c(j + m)$ for $-r \leq j \leq r$, and $c(0) \neq \tilde{q}$. If there is at least one c for which the test is positive, then $\Phi \neq \{\tilde{Q}\}$. Otherwise, $\Phi = \{\tilde{Q}\}$. □

4. The limit languages of linear cellular automata. In this section we assume that $A = (1, S, N, f)$; that is, A is a linear CA.

We treat a configuration of A as a bi-infinite word over the alphabet S. With every set of configurations we associate a set of finite words (strings) over S, as follows:

For a bi-infinite word $c \in S^Z$, define (as in [6])

$$L[c] = \{ w \in S^* \mid w \text{ is a finite subword of } c\},$$

and, for $C \subseteq S^Z$, define

$$L[C] = \bigcup_{c \in C} L[c].$$

$L[C]$ is called the *language of* C. If Ω is the limit set of the CA A, then we call $L[\Omega]$ the *limit language of* A.

The next theorem gives an alternative definition of the limit language $L[\Omega]$.

THEOREM 4.1. $L[\Omega] = \bigcap_{i=0}^{\infty} L[\Omega^{(i)}]$.

Proof. Since $\Omega \subseteq \Omega^{(i)}$ for every i, it follows that $L[\Omega] \subseteq \bigcap_i L[\Omega^{(i)}]$. To prove the opposite inclusion, choose any $w \in \bigcap_i L[\Omega^{(i)}]$. Let j be the length of w. Define

$$C = \{ c \in S^Z \mid c(1)c(2)\cdots c(j) = w \}.$$

Then C is a closed set and $C \cap \Omega^{(i)} \neq \emptyset$ for every i, by the choice of w and the translation invariance of $\Omega^{(i)}$. By compactness,

$$\Omega \cap C = \bigcap_{i=0}^{\infty} \left(\Omega^{(i)} \cap C\right) \neq \emptyset ,$$

which means that w is a subword of some $c \in \Omega$, hence $w \in L[\Omega]$. □

Wolfram [12] shows that the set $L[\Omega^{(i)}]$ is regular for each $i \geq 0$. This result can be proved using the fact that regular sets are closed under general sequential machine (GSM) mappings [5]. Indeed for each local function f it is easy to construct the GSM T_f that maps each word w in $L[\Omega^{(i)}]$ with $|w| \geq r$, where r is the span of the neighborhood, into the successor string of length $|w| - r$ in $L[\Omega^{(i+1)}]$. The set $L[\Omega^{(0)}] = S^*$ is regular, therefore for each $i > 0$, $L[\Omega^{(i+1)}] = T_f(L[\Omega^{(i)}])$ is regular as well. We omit the details of this proof.

A natural extension of finite automata (FA) to bi-infinite words ($\omega\omega$-words), called $\omega\omega$-FA, is described in [4]. The set of bi-infinite words recognized by an $\omega\omega$-FA is called an *$\omega\omega$-regular set.*

In [4] we prove that

(i) the sets $\Omega^{(i)}$ are $\omega\omega$-regular;

(ii) the set Ω is $\omega\omega$-regular if and only if the language $L[\Omega]$ is regular.

Hurd [6] shows that $L[\Omega]$ need not be regular.

As a corollary of the next theorem, we shall give a characterization of Ω in terms of $L[\Omega]$.

THEOREM 4.2. *If $C \subseteq S^Z$ is translation invariant, then the set $\{ c \in S^Z \mid L[c] \subseteq L[C] \}$ is the closure of C in the product topology.*

Proof. Let $D = \{ c \in S^Z \mid L[c] \subseteq L[C] \}$. The complement of D in S^Z is open. Indeed, if $c' \notin D$ then $c'(i)\cdots c'(j) \notin L[C]$ for some $i, j \in Z, i \leq j$. In that case the set

$$\{ c \in S^Z \mid c(i)\cdots c(j) = c'(i)\cdots c'(j) \},$$

which is a neighborhood of c' in the product topology, does not intersect D.

Since D is closed and $C \subseteq D$, it follows that the closure $\bar{C}$ of C is a subset of D. To prove that $D \subseteq \bar{C}$, choose any $d \in D$. Then for every $j \geq 0$ the word

$d(-j)\cdots d(j)$ is a subword of some $c_j \in C$. Since C is translation invariant, we can choose c_j so that $d(-j)\cdots d(j) = c_j(-j)\cdots c_j(j)$. But then d is the limit of the sequence $(c_j \mid j = 0, 1, \cdots)$ in the product topology, which proves that $d \in \bar{C}$. □

COROLLARY 4.3. *A configuration $c \in S^Z$ belongs to the limit set Ω if and only if $L[c] \subseteq L[\Omega]$.*

Proof. By Theorem 4.2, $\Omega = \{ c \in S^Z \mid L[c] \subseteq L[\Omega] \}$. □

5. The limit sets of two-dimensional cellular automata. In contrast to the conjecture we made for linear CA in §3, we are now going to show that it is undecidable, whether or not the limit set of a given two-dimensional CA consists of the quiescent configuration only. Consequently, the same problem for k-dimensional CA limit sets is undecidable for any $k \geq 2$. The proof is based on a well-known deep result, the undecidability of the tiling problem. The tiling problem was raised by Wang [10], and proved to be undecidable five years later by Berger [2]. Robinson gave a more readable proof in [9].

THEOREM 5.1. *It is recursively undecidable whether or not the limit set Ω of a given two-dimensional* CA *consists of $\tilde{Q}$ only.*

Proof. We show that the tiling problem can be transformed into our problem. We are given a set of tiles

$$T = \{ (l_i, r_i, u_i, d_i) \mid 1 \leq i \leq n \},$$

where l_i, r_i, u_i, and d_i denote the colors of the left, right, upper, and lower edges, respectively. In the following, we use $l(t), r(t), u(t)$, and $d(t)$ to denote the colors of the four edges of a tile t; that is, $t = (l(t), r(t), u(t), d(t))$. We construct a CA $A = (2, Q, N, f)$, where

$Q = T \cup \{\tilde{q}\}$;

$N = ((0,0), (-1,0), (1,0), (0,1), (0,-1))$;

and

$$f(t_o, t_l, t_r, t_u, t_d) = \begin{cases} t_o & \text{if } l(t_o) = r(t_l), r(t_o) = l(t_r), \\ & u(t_o) = d(t_u), \text{ and } d(t_o) = u(t_d); \\ \tilde{q} & \text{otherwise.} \end{cases}$$

Now we show that there is a valid tiling of the plane if and only if the limit set of A is not $\{\tilde{Q}\}$, where $\tilde{Q}$ denotes the quiescent configuration. If the plane can be tiled with the given tiles, then all the valid tilings are configurations in the limit set of A. If the plane cannot be tiled with the given tiles, then there is an integer $i \geq 1$ such that the square of size i cannot be tiled (this follows from König's infinity lemma [8, pp. 381-383]). By the definition of f, $G_f{}^i(c) = \tilde{Q}$ for all $c \in S^{Z^2}$. This implies that $\Omega^{(i)} = \{\tilde{Q}\}$, and the limit set Ω is equal to $\{\tilde{Q}\}$.

Since the tiling problem is undecidable, the problem $\Omega \stackrel{?}{=} \{\tilde{Q}\}$ for two-dimensional CA is also undecidable. □

COROLLARY 5.2. *It is recursively undecidable, whether or not the limit set of a given k-dimensional* CA *consists of the quiescent configuration only, for any $k \geq 2$.*

Proof. Define the local function such that only two dimensions are actually effective. A cell remains in the same nonquiescent state if its four neighbors in two specific dimensions satisfy the rule of tiling. □

The same technique does not work for linear CA because the tiling problem in one dimension is trivially decidable.

Observe that, for the given set of tiles and the cellular automaton constructed in the proof of Theorem 5.1, there is a valid tiling of the plane if and only if the set $\Phi \subseteq S^{Z^k}$ (defined at the end of §2) contains some configuration different from the quiescent configuration $\tilde{Q}$. Thus the proof of Theorem 5.1 also proves the following result.

THEOREM 5.3. *For $k \geq 2$ it is recursively undecidable whether $\Phi = \{\tilde{Q}\}$.*

6. Limit sets of finite configurations. A configuration is *finite* if the number of nonquiescent cells is finite but not zero. Let $\mathcal{F}$ denote the set of all finite configurations of a CA A. We define the *limit set of finite configurations* of A as

$$\Omega_F = \Omega \cap \mathcal{F}.$$

In this section, we show that, given an arbitrary CA, it is undecidable whether Ω_F is empty. The difficulty in transforming the Turing machine halting problem into this problem is that CA do not distinguish input symbols from working symbols. Note also that the limit set of finite configurations may be nonempty, even if every finite configuration eventually becomes quiescent. This is shown by Example 3.

Example 3. Let $A = (1, S, N, f)$ be the linear CA defined in Example 2. That is, $S = \{0, 1\}$, $N = (-1, 0, 1)$, and

$$f(a_{-1}, a_0, a_1) = \begin{cases} 1 & \text{if } a_{-1} = a_0 = a_1 = 1; \\ 0 & \text{otherwise.} \end{cases}$$

In this example, either "0" or "1" can be distinguished as the quiescent state. If "0" is the quiescent state, then the limit set of finite configurations is the set of all configurations that have exactly one substring of the form "011 $\cdots$ 10". If "1" is the quiescent state, then the limit set of finite configurations is empty.

Now, we show that given a CA it is undecidable whether Ω_F is empty. To prove this is much harder than it appears at first. One might think that since a CA can easily simulate a Turing machine (TM), we can reduce the TM halting problem to this problem using a rather standard approach. However, this does not work since the CA we are considering do not distinguish input symbols from work symbols (i.e., tape symbols for a TM). Assume that a CA A simulates a TM M. Then every configuration of M may appear as an initial string of A including the halting configurations which may never be reached by M. Two distinctive technique are used in the following proof. One is the repeated initialization of the simulation of a TM on a blank tape. The other is the continuous decreasing, rather than increasing, of the size of the simulation.

THEOREM 6.1. *Given a* CA, *it is undecidable whether $\Omega_F = \emptyset$.*

Proof. In this proof we consider linear CA only. The result can be easily extended to multidimensional CA.

Given a Turing machine M operating on a one-way infinite tape, we construct a CA A as follows. Besides the quiescent state, the state set of A consists of a left boundary state, l; a right boundary state, r; the left- and right-moving signals s_l and s_r; a yellow state, y; a destroyer, d; and a set of blue states, $B = \{b_1, b_2, \cdots, b_t\}$. The blue states are used to encode the computation of M. Before describing how A operates, we first introduce the notion of valid segments. A *segment* is the finite, consecutive, nonquiescent part of a configuration, that is surrounded by quiescent cells. A segment is *valid* if

(i) its left and right boundaries are l and r, respectively;
(ii) it has a signal symbol $s \in \{s_l, s_r\}$ between l and r ;
(iii) every cell between l and s is in a blue state;
(iv) all cells between s and r are in the yellow state.

A segment is *invalid* otherwise. The validity of a segment can be checked locally in one step. If a configuration contains an invalid segment, the destroyer d is generated and spreads. It is not difficult to prove that every finite configuration that contains an invalid segment is not in the limit set. This statement is even true for infinite configurations. A valid segment evolves as follows. See Fig. 1. The left boundary l

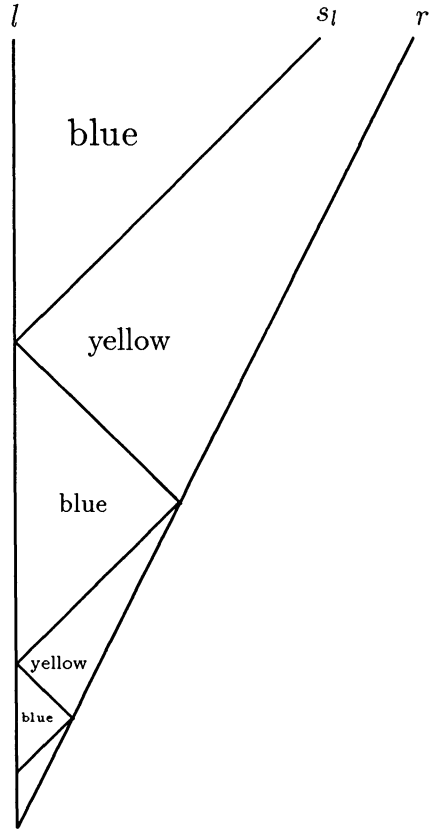

FIG. 1. *A computation of* CA *A*.

stays unchanged. The right boundary moves to the left at half speed (one cell each two steps). The signal s_l moves left at full speed (one cell each step) until it meets l. Then it changes to s_r and moves right. The signal s_r changes back to s_l when it meets r. And this repeats. Each time s_l meets l, a simulation of M starts. Each simulation is restricted to a triangle-shaped region labeled *blue* in the time-space diagram in Fig. 1. The simulation may repeatedly start and terminate until l and r meet. If a halting configuration of M is simulated, the destroyer d is generated and spreads. Then the

simulation is aborted by the spreading destroyers.

Now, we show that M starting with the blank tape halts if and only if the limit set of A does not contain a finite configuration.

If M never halts, then we can have arbitrarily large blue triangles. The configuration

$$c_0 = \cdots q\, q\, q\, l\, r\, q\, q\, q \cdots,$$

where q is the quiescent state, has an infinite history, i.e., for any integer $i \geq 0$, there exists a configuration of A such that it maps to c_0 in exactly i steps. Therefore, c_0 is in the limit set of A.

If M halts in n steps, then no blue triangle that allows the simulation of M to operate for more than n steps exists. Only the first blue triangle which has a missing upper corner can be an exception. So, it is not difficult to show that no configuration with a valid segment is in the limit set. Since, as we mentioned, no other finite configurations are possible in the limit set, the limit set of A contains no finite configurations. □

The following theorem was proved by Hurd [6, Thm. 4].

THEOREM 6.2. *Given a* CA $A = (1, S, N, f)$ *and a string* $w \in S^*$, *it is undecidable whether* w *is in the limit language of* A.

Proof. For the cellular automaton A constructed in the proof of Theorem 6.1, the string lr is in the limit language if and only if $\Omega_F \neq \emptyset$. □

Our next result (Corollary 6.3) has been stated in [6] as a direct consequence of a theorem equivalent to our Theorem 6.2. However, we feel that Corollary 6.3 does not *immediately* follow from Theorem 6.2. In order to find a nonrecursive limit language, one must show that for *one particular* CA A it is undecidable whether a given string is in the limit language of A.

COROLLARY 6.3. *There exists a linear cellular automaton such that its limit language is not recursive.*

Proof. The corollary follows from Theorem 6.2 with the help of a universal CA. A universal CA is given in [1], where any CA is simulated by encoding its local function in the states of the universal CA. Given a CA A and a string w of A, there is a string w' of the universal CA such that w' encodes both A and w. Now, the problem of whether w is in the limit language of A is transformed to the problem of whether w' (the encoding of A and w) is in the limit language of the universal CA. Since the former is undecidable, the latter is undecidable, too. □

EFFICIENT MESSAGE ROUTING IN PLANAR NETWORKS *

GREG N. FREDERICKSON † AND RAVI JANARDAN ‡

Abstract. The problem of routing messages along near-shortest paths in a distributed network without using complete routing tables is considered. It is assumed that the nodes of the network can be assigned suitable short names at the time the network is established. Two space-efficient near-shortest-path routing schemes are given for the class of planar networks. Both schemes use the separator property of planar networks in assigning the node names and performing the routings. For an n-node network, the first scheme uses $O(\log n)$-bit names and a total of $O(n^{4/3})$ items of routing information, each $O(\log n)$ bits long, to generate routings that are only three times longer than corresponding shortest routings in worst case[1]. For any constant ϵ, $0 < \epsilon < 1/3$, the second scheme achieves the better space bound of $O(n^{1+\epsilon})$ items, each $O((1/\epsilon)\log n)$ bits long, but at the expense of $O((1/\epsilon)\log n)$-bit node names and a worst-case bound of 7 on the routings.

1. Introduction.

One of the primary functions in a distributed network is the routing of messages between pairs of nodes. Assuming that a nonnegative cost, or distance, is associated with each edge, it is desirable to route along shortest paths. While this can be accomplished using a complete routing table at each of the n nodes in the network, such tables are expensive for large networks, storing a total of $\Theta(n^2)$ items of routing information, where each item is a node name. Thus, recent research has focused on identifying classes of network topologies for which the shortest paths information at each node can be stored succinctly. It is assumed that the nodes can be assigned suitable short names at the time the network is established. The idea behind naming nodes is to encode useful information about the network into the node names and then to make use of this information when performing the routing. Shortest-path routing schemes that use $O(\log n)$-bit node names and a total of $\Theta(n)$ items of routing information have been given for networks such as trees, unit-cost rings [12],[13], unit-cost complete networks, unit-cost grids [14], and networks at the lower end of a hierarchy identified in [5] (the simplest of which are the outerplanar networks [7]). Unfortunately, the approach in the research cited above becomes expensive even for very simply defined classes of networks such as, for instance, the series-parallel networks [3]. However, by shifting our focus to consider schemes that route along near-shortest paths, we have been able to design space-efficient routing schemes for much broader classes of network topologies.

The issue of saving space in routing tables by settling for near-shortest path routings was first raised in [8]. (Indeed, this is the first reported work on the problem

[1] Unless stated otherwise, all logarithms are to the base 2.

of space-efficient routing.) Networks of general topology were studied in [8], and a clustering approach was proposed for naming the nodes. Unfortunately, no indication was given of how to do the clustering. Furthermore, the routings produced depended crucially on certain strong assumptions about the structure of the clusters, and, in worst case, could be $O(n)$ times longer than shortest routings. In this paper, and in related work [6], we consider various classes of networks that exhibit a certain separator property and show how to take advantage of this property to design space-efficient near-shortest routing schemes. All our schemes achieve routings that are, in worst case, only a small constant times longer than corresponding shortest routings. More recently, general networks with unit-cost edges have been considered in [11], and a trade-off has been established between the space used and the quality of the routings generated. Both upper and lower bounds are given for this trade-off.

In this paper we present near-shortest-path routing schemes for planar networks. A *planar network* is a network that can be embedded in the plane such that edges do not cross [7]. We measure the quality of the routings achieved by our schemes on a network by the *performance bound*, defined as the maximum ratio $\hat{\rho}(u,v)/\rho(u,v)$ taken over all pairs of nodes u, v in the network, where $\rho(u,v)$ is the length of a shortest path from u to v and $\hat{\rho}(u,v)$ is the length of the routing from u to v. We give a routing scheme that for any constant ϵ, $0 < \epsilon < 1/3$, can be set up to use $O((1/\epsilon)\log n)$-bit names and $O(n^{1+\epsilon})$ items of routing information, each $O((1/\epsilon)\log n)$ bits long, and achieve a performance bound of 7. Our approach makes use of separator strategies [9],[10] to decompose the network hierarchically and generate names for the nodes. However, using only the Lipton–Tarjan separator algorithm [9], the best we are able to achieve is a scheme that uses $O(n^{4/3})$ items, each $O(\log n)$ bits long, although with a better performance bound of 3. To reduce the storage to $O(n^{1+\epsilon})$ items, we employ a combination of very sparse routing tables and interval routing [5] to route in succession to a number of intermediate destinations carefully placed at higher levels of the decomposition. We show how Miller's algorithm [10] can be applied to generate the structured separators necessary for encoding the interval routing information.

In [6], we give a near-shortest-path routing scheme for any class of *c-decomposable networks*, i.e., networks that can be decomposed recursively by separators of size at most a constant c, where $c \geq 2$. Examples of such networks are the series-parallel networks [3], for which $c = 2$, and the k-outerplanar networks [1], for $k > 1$ a constant, for which $c = 2k$. A basic scheme is given which uses $O(cn \log n)$ items of routing information, each $O(\log n)$ bits long, and $O(\log n)$-bit names, generated from a separator-based hierarchical decomposition of the network, to achieve a performance bound of 3. We then show how to generate improved routings by including in the node names $O(c \log c \log n)$ additional bits of information about relative distances in the network. The resulting scheme has a performance bound of $(2/\alpha) + 1$, where α, $1 < \alpha \leq 2$, is the root of the equation $\alpha^{\lceil (c+1)/2 \rceil} - \alpha - 2 = 0$. Thus, the performance bound is 2 for $c \leq 3$ and ranges up to strictly less than 3 for increasing values of c.

The decomposition technique used in [6] for c-decomposable networks does not yield a space-efficient solution for planar networks, since the latter have separators of size $O(\sqrt{n})$. Instead, we take advantage of a different approach for planar graph decomposition, which is presented in [4]. This result is reviewed briefly in §2.1. The remainder of §2 describes the $O(n^{4/3})$-space scheme, called Scheme I, while §3 discusses the $O(n^{1+\epsilon})$-space scheme, called Scheme II.

2. A basic routing scheme: Scheme I.

2.1. Multilevel division and naming in Scheme I. Throughout the paper we model our network by an undirected planar graph G. (For graph-theoretic terms not defined here, see [2],[7].) For the purposes of assigning the node names and setting up the routing information, we perform a multilevel division of G into regions. A *division* of a planar graph is a grouping of its nodes into subsets called *regions*. A region contains two types of nodes, namely, interior nodes and boundary nodes. An *interior node* is contained in exactly one region and is adjacent only to nodes contained in the region, whereas a *boundary node* is contained in two or more regions.

For any parameter $f(n) < n$, an $f(n)$-*division* of a planar graph is a division of the graph into $\Theta(n/f(n))$ regions with a total of $O(n/\sqrt{f(n)})$ boundary nodes, where each region contains no more than $f(n)$ nodes and $O(\sqrt{f(n)})$ boundary nodes. An $f(n)$-division of a planar graph exists for any $f(n) < n$. An algorithm for performing an $f(n)$-division of a planar graph, based on the planar separator algorithm of [9], is given in [4]. Briefly, the $f(n)$-division algorithm involves careful, repeated application of the planar separator algorithm to G until no region has more than $f(n)$ nodes. We take the boundary nodes of the regions to be the separator nodes generated by the separator algorithm. The division has the property that any path between boundary nodes that are interior to different regions must contain a boundary node of each of these regions. We will make use of this property to do the routing. The reader is referred to [4] for more details of the $f(n)$-division algorithm. We note that although the algorithm in [4] is based on the planar separator algorithm of Lipton and Tarjan [9], it can easily be adapted to use the separator algorithm of Miller [10] as well.

The regions at various levels in the multilevel division are defined inductively as follows. The level 0 region R_1 consists of the nodes of G, with all nodes interior. In general, the name of a region is of the form R_γ, where γ is a sequence of positive integers. Let $f(n) < n$ be a parameter to be specified later. For $i \geq 1$, let R_γ be a level $i-1$ region with n' nodes. If R_γ has a nonzero number of interior nodes, then the $f(n')$-division algorithm of [4], based on the separator algorithm of [9], is applied to it to generate the level i regions $R_{\gamma 1}, R_{\gamma 2}, \cdots, R_{\gamma r}$, for some positive integer $r > 1$.

While performing the division of R_γ, we treat the boundary nodes of R_γ as boundary nodes of the resulting level i regions also. From the arguments in [4] it can be shown that, for the choice of $f(\cdot)$ to be made, the division is still an $f(\cdot)$-division. A node v that is interior to R_γ and first becomes a boundary node during its division is a *level i node*. Any other level i node generated by the division of R_γ is a *sibling* of v. A boundary node u of a level j region, $j < i$, to which v is interior is an *ancestor of v for level j*. We call v a *descendant* of u. Two nodes are *related* if one is an ancestor of the other or if they are siblings. Otherwise, they are *unrelated*.

Each level i node resulting from the division of R_γ is assigned the name γ, with an integer distinguisher appended to make the names distinct. This naming has the property that for unrelated nodes v and u, the length l of the longest common prefix of the distinguisher-free portions of their names is the smallest integer for which the nodes are in different level l regions. We call level l the *separating level for v and u*.

For the purposes of doing the routing, additional information is encoded into the name of a level i node v, identifying the closest ancestor of v for each level $j < i$. An integer, called a *level j designator*, is associated with each boundary node of the level j regions that result from the division of the level $j-1$ region to which v is interior. The level j designator of the closest ancestor of v for level j is recorded in v's name, in the jth field following the distinguisher.

The length of the names depends on the parameter $f(\cdot)$. We will show in §2.2

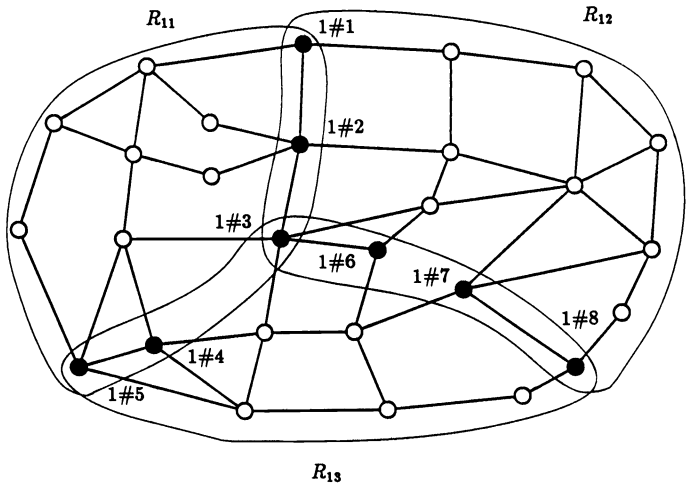

FIG. 1. *Illustration of the first level in the multilevel division and naming of a planar graph.*

that, for the choice of $f(\cdot)$ to be made, the names are $O(\log n)$ bits long.

We illustrate the decomposition and naming using Fig. 1. The given graph, constituting the level 0 region R_1, is divided into three level 1 regions: R_{11}, R_{12}, and R_{13}. The level 1 nodes, which are the boundary nodes resulting from the division, are shown filled in. The names assigned to these nodes are also shown. The "#" symbol is a delimiter and the integer following it is the distinguisher. No designators are encoded into the names of the level 1 nodes, as they do not have any ancestors.

2.2. Routing information stored at the nodes in Scheme I. Once the nodes have been assigned suitable names, based on their position in the decomposition, appropriate information is stored at them to do the routing. We first give an overview of the routing strategy in order to motivate the routing information stored. Let s be any source and d any destination. The strategy for routing from s to d depends on whether or not s and d are related. As we will see, it is not too expensive, in terms of total storage used in the network, to store a routing table at s to route to all related nodes d. However, this approach is expensive for routing between unrelated nodes, as the total number of pairs of unrelated nodes is large. Instead, the routing from s to an unrelated node d is done in three stages, as follows. Let l be the separating level for s and d; let $\hat{s}$ be the closest ancestor of s for level l; and let $\hat{d}$ be the closest ancestor of d for level l. In the first stage, the message is routed from s to $\hat{s}$, in the second stage from $\hat{s}$ to $\hat{d}$, and in the third stage from $\hat{d}$ to d. Note that since the source and destination for each stage are related nodes, routing information for each stage is available in the routing tables stored. For this approach to work, s must have available the name $\hat{s}$, and $\hat{s}$ must have available the name $\hat{d}$. The former is accomplished by storing at s the name of its closest ancestor for each level. The latter is accomplished by storing at $\hat{s}$ a table mapping the designators of certain nodes to their names. The name $\hat{d}$ is determined by $\hat{s}$ by indexing into this table using the designator of the closest ancestor of d for level l, which has been encoded in d's name.

One problem that can arise in the routing strategy described is the following.

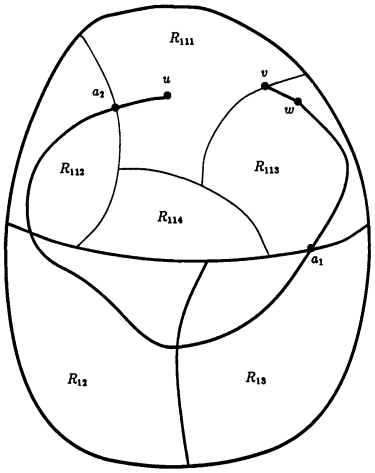

FIG. 2. *Illustration of the next milestone, a_1, and the final milestone, a_2, for u at v.*

Consider the routing from some node v to a related node u during some phase in the routing from s to d, where v and u are possibly s and d, respectively. Let w be the node to which v must send the message, as determined by v from its routing table. Now, if w and u are unrelated, then w will not be able to continue the routing to u. The problem is overcome by having v make available to w, in the message header, the names a_1 and a_2 of a pair of related nodes on a shortest (v,u)-path through w, where a_1 is an ancestor of w and a_2 an ancestor of u. The routing from w to u proceeds through a_1 and a_2, in that order. The nodes a_1 and a_2, called *the next milestone for u at v* and *the final milestone for u at v*, respectively, are defined as follows. Let R be the region such that w and u are both in R but are in different regions R' and R'' that result from the division of R. Then a_1 and a_2 are, respectively, the first boundary nodes of R' and R'' on a shortest (v,u)-path through w.

Figure 2 illustrates schematically a two-level division of a planar graph. A shortest (v,u)-path is shown in bold, where the neighbor w of v on this path and node u are unrelated. Both w and u are in region R_{11}, but in different regions, R_{113} and R_{111}, which result from the division of R_{11}. Nodes a_1 and a_2 are the first boundary nodes of R_{113} and R_{111}, respectively, on the shortest (v,u)-path.

We can now describe the routing information stored at any node v in the network. A routing table is maintained at v, giving for each related node u the name $next\_node_v(u)$ of the next node on a shortest (v,u)-path in G. To route to u, v sends the message to $next\_node_v(u) = w$ over edge $\{v,w\}$. In addition, v also has two tables containing the next and final milestone information. If w and u are unrelated, then the names of the next milestone for u at v and the final milestone for u at v are stored at v in $next\_milestone_v(u)$ and $final\_milestone_v(u)$, respectively.

The following information is stored at v to enable it to route to unrelated nodes. Let v be a level i node. Then, for each level $j < i$, the name of the closest ancestor of v for level j is stored at v in a table. Furthermore, consider the division of the level $i-1$ region to which v is interior into level i regions. A table is stored at v, mapping the

level i designator of each boundary node of the level i regions to its name.

The amount of routing information in the network depends on $f(\cdot)$. As the following theorem shows, the appropriate choice for $f(n)$ is $n^{2/3}$.

THEOREM 2.1. *For any n-node planar graph, Scheme* I *uses a total of $O(n^{4/3})$ items of routing information, where each item is $O(\log n)$ bits long.*

Proof. Each item of routing information held at a node is a node name. As will be seen in Theorem 2.2, each node name in Scheme I is $O(\log n)$ bits long.

We bound the number of items of routing information as follows. We first bound the total number of items of routing information held by all level 1 nodes for the other nodes, as well as the number of items of routing information held by all the other nodes for the level 1 nodes. We then use this to develop a recurrence that gives the total number of items of routing information held by all the nodes in the network.

Since there are $O(n/\sqrt{f(n)})$ level 1 nodes, the level 1 nodes together maintain a total of $O((n/\sqrt{f(n)})^2)$ items of shortest paths information for siblings. As there are $\Theta(n/f(n))$ level 1 regions, each containing $O(f(n))$ nodes and $O(\sqrt{f(n)})$ boundary nodes, the level 1 nodes store a total of $O(\sqrt{f(n)}f(n)n/f(n))$, i.e., $O(n\sqrt{f(n)})$ items of shortest paths information for descendants. The descendants of the level 1 nodes store $O(\sqrt{f(n)}f(n)n/f(n))$, i.e., $O(n\sqrt{f(n)})$ items of shortest paths information overall for the level 1 nodes (ancestors for level 1). Thus the number of items of routing information stored by level 1 nodes for related nodes and vice versa is $O((n/\sqrt{f(n)})^2 + n\sqrt{f(n)})$. The number of items of milestone information held by the level 1 nodes for the other nodes and vice versa is of this same order.

The size of the table of designators of a level 1 node is $O(n/\sqrt{f(n)})$, so that the space used by the designator tables of all level 1 nodes is $O((n/\sqrt{f(n)})^2)$. Finally, the descendants of the level 1 nodes store $O(f(n)n/f(n))$, i.e., $O(n)$ items of information identifying nearest level 1 nodes.

Let $S(n)$ be the total number of items of information stored in an n-node network. Then, for positive constants a, b, and c, we have $S(n) \leq an^2/f(n) + bn\sqrt{f(n)} + c(n/f(n))S(f(n))$, where the last term accounts for the information stored at lower levels in the decomposition. We choose $f(n) = n^{2/3}$ to make the opposing terms $an^2/f(n)$ and $bn\sqrt{f(n)}$ equal to within a constant factor. Thus $S(n) \leq dn^{4/3} + cn^{1/3}S(n^{2/3})$ for some positive constant d. We choose the range of n, for which the above recurrence holds, as $n \geq (2c)^9$. Thus we have,

$$S(n) \leq dn^{4/3} + cn^{1/3}S(n^{2/3}), \quad \text{for } n \geq (2c)^9.$$

For some positive constant e, we may write the basis cases as

$$S(n) \leq e, \quad \text{for } 1 \leq n < (2c)^9.$$

Then we claim that $S(n) \leq gn^{4/3}$, where $g = \max\{e, 2d\}$. The claim can be shown by induction on n. The claim clearly holds for the basis. For the induction step, for which $n \geq (2c)^9$, we require $dn^{4/3} + cn^{1/3}gn^{8/9} \leq gn^{4/3}$, i.e., $d + cgn^{-1/9} \leq g$, i.e., $d + g/2 \leq g$, which is true. The theorem follows.

Note that our choice of the threshold for n as $(2c)^9$ was arbitrary. A threshold of $((1+\delta)c)^9$ for any $\delta > 0$ will do. Correspondingly, $g = \max\{e, (1+1/\delta)d\}$. □

We next show that for the above choice of $f(n) = n^{2/3}$ the node names are only $O(\log n)$ bits long. With Scheme II in mind, we prove a more general result. We show that for $f(n) = n^{1-\epsilon}$, where ϵ is any constant, $0 < \epsilon < 1$, the node names are $O((1/\epsilon)\log n)$ bits long.

THEOREM 2.2. *Consider the naming of the nodes of an n-node planar graph from a multilevel division, performed with respect to a parameter $f(n) = n^{1-\epsilon}$, where ϵ is any constant, $0 < \epsilon < 1$. The node names are $O((1/\epsilon)\log n)$ bits long.*

Proof. At level 0 in the decomposition there is just one region of size n and no boundary nodes. It is easy to show by induction that the division of a level $j-1$ region into level j regions, $j \geq 1$, results in $O(n^{(1-\epsilon)^{j-1}\epsilon})$ level j regions and $O(n^{(1-\epsilon)^{j-1}(1+\epsilon)/2})$ boundary nodes of these level j regions. Furthermore, the highest level number L in the decomposition is at most $1 + \log_{1/(1-\epsilon)} \log n$, which is $1 + \log\log n/\log(1/(1-\epsilon))$. This can be seen as follows. Since a level j region has at most $n^{(1-\epsilon)^j}$ nodes, the level number at which all regions have at most two nodes is at most $\log_{1/(1-\epsilon)} \log n$. At most one node of each region with two nodes can be an interior node. Thus at most one additional level is needed to get regions with no interior nodes, at which point the decomposition terminates.

For $i \geq 1$, the name of a level i node v consists of $2i$ fields: i integers that constitute the name of the level $i-1$ region to which v is interior; an integer distinguisher; and $i-1$ integers, each a level j designator, $0 \leq j \leq i-1$. These fields are separated by $2i-1$ delimiters. The delimiter and the bits 0 and 1 used in the binary representation of the fields can be encoded using two bits each.

The number of bits needed to encode the region name is at most

$$\begin{aligned} 2\Big(1 + \sum_{j=1}^{i-1}\big(\lceil \log n^{(1-\epsilon)^{j-1}\epsilon}\rceil + O(1)\big)\Big) &= O\Big(i + \sum_{j=1}^{i-1} \log n^{(1-\epsilon)^{j-1}\epsilon}\Big) \\ &= O(i + (1-(1-\epsilon)^{i-1})\log n) \\ &= O(i + \log n). \end{aligned}$$

The number of bits needed for the distinguisher is at most

$$\begin{aligned} 2\lceil \log n^{(1-\epsilon)^{i-1}(1+\epsilon)/2}\rceil + O(1) &= O(\log n^{(1-\epsilon)^{i-1}(1+\epsilon)/2}) \\ &= O((1-\epsilon)^{i-1}((1+\epsilon)/2)\log n) \\ &= O(\log n), \quad \text{since } \epsilon < 1. \end{aligned}$$

The number of bits needed to encode all the designators is at most

$$\begin{aligned} 2\sum_{j=1}^{i-1}\big(\lceil \log n^{(1-\epsilon)^{j-1}(1+\epsilon)/2}\rceil + O(1)\big) &= O\Big(i + \sum_{j=1}^{i-1} \log n^{(1-\epsilon)^{j-1}(1+\epsilon)/2}\Big) \\ &= O(i + (((1+\epsilon)/2)(1-(1-\epsilon)^{i-1})/\epsilon)\ \log n) \\ &= O(i + (1/\epsilon)\log n). \end{aligned}$$

Finally, the delimiters can be encoded using $2(2i-1)$, i.e., $O(i)$ bits in all.

Summing these and simplifying, the total number of bits needed to encode the name of v is

$$\begin{aligned} O(i + (1 + (1/\epsilon))\log n) &= O(i + (1/\epsilon)\log n), \quad \text{since } 0 < \epsilon < 1 \text{ implies } (1/\epsilon) > \epsilon \\ &= O((1/\epsilon)\log n + \log\log n/\log(1/(1-\epsilon))), \quad \text{since } i \leq L \\ &= O((1/\epsilon)\log n), \quad \text{noting that } \log(1/(1-\epsilon)) > \epsilon. \end{aligned}$$

This proves the theorem. □

2.3. The routing strategy in Scheme I. A message is routed from a source s to a destination d as follows. The message header contains separate fields for the next milestone, final milestone, and the destination, all initially set to d. The next and final milestone fields alone are reset, as necessary, during the routing. Let d' and d'', respectively, denote the current names in the next milestone and final milestone fields. Each node v participating in the routing performs a *routing action* as follows. It sets $w = next\_node_v(d')$, and resets d'' to $final\_milestone_v(d')$, and d' to $next\_milestone_v(d')$ if these entries for d' are stored at v. It then sends the message to w.

The routing begins with s searching its routing table for d', which is initially d. If found, then s and d are related, and s performs a routing action. Otherwise, let l be the separating level for s and d (l can be determined from the names s and d), and let $\hat{s}$ be the closest ancestor of s for level l. Then s resets d' and d'' to $\hat{s}$ and performs a routing action.

Let v be any node that the message arrives at subsequently. If $v \neq d'$, then v performs a routing action.

If $v = d' \neq d''$, then v sets d' to d'' and performs a routing action.

Suppose that $v = d' = d'' \neq d$. If v and d are related, then v sets d' and d'' to d and performs a routing action. Otherwise, v must be $\hat{s}$, and $\hat{s}$ must be a level l node (Lemma 2.3 below). Using its table of level l designators and the lth field designator in d's name, v determines the closest ancestor $\hat{d}$ of d for level l. It then sets d' and d'' to $\hat{d}$ and performs a routing action.

If $v = d' = d'' = d$, then the routing terminates.

LEMMA 2.3. *Let l be the separating level for source s and destination d, and let $\hat{s}$ be the closest ancestor of s for level l. In the routing from s to d, let v be any final milestone different from d. If v and d are unrelated, then v must be $\hat{s}$, and $\hat{s}$ must be a level l node.*

Proof. Clearly, if s and d are related, then so are v and d. Thus, assume that s and d are unrelated. We first show that for each v, v and d are related, except possibly when v is $\hat{s}$.

In the routing from s to $\hat{s}$, v is always $\hat{s}$, since $\hat{s}$ is an ancestor of every node in the routing. If $\hat{s}$ and d are related, the routing is from $\hat{s}$ to d. Thus every v in this routing is an ancestor of d. However, if $\hat{s}$ and d are unrelated, then the routing is from $\hat{s}$ to $\hat{d}$. Every v in this phase is an ancestor of $\hat{d}$, and hence an ancestor of d. The message eventually reaches a final milestone that is either $\hat{d}$, or an ancestor of $\hat{d}$. Thus, in the routing from this node to d, every v is an ancestor of d. Every v in this routing is an ancestor of d.

Thus, if v and d are unrelated, then v must be $\hat{s}$. Suppose that $\hat{s}$ is a level $j < l$ node. Thus $\hat{s}$ is a boundary node of the level $l-1$ region to which s is interior. But, since s and d are interior to the same level $l-1$ region, $\hat{s}$ must be an ancestor of d, a contradiction. Thus $\hat{s}$ must be a level l node. □

We now establish an upper bound on the length of the routings generated by Scheme I. First, we obtain in the following lemma a lower bound on the distance between nodes s and d in the case that they are unrelated.

LEMMA 2.4. *Let s and d be unrelated nodes in the multilevel division of a planar graph. Let $\hat{s}$ be the closest ancestor for s, and let $\hat{d}$ be the closest ancestor of d for the separating level of s and d. Then $\rho(s,d) \geq \rho(s,\hat{s}) + \rho(d,\hat{d})$.*

Proof. Let s' and d' be the ancestors of s and d, respectively, on a shortest (s,d)-path. Thus $\rho(s,d) \geq \rho(s,s') + \rho(d,d')$. But $\rho(s,s') \geq \rho(s,\hat{s})$ and $\rho(d,d') \geq \rho(d,\hat{d})$, by

our choice of $\hat{s}$ and $\hat{d}$. The lemma follows. □

THEOREM 2.5. *For any planar graph, the performance bound of Scheme* I *is* 3.

Proof. Let s be any source and d any destination. If s and d are related, then the routing is along a shortest (s,d)-path. This is because every node participating in the routing performs a routing action with respect to d', which is always on a shortest (s,d)-path. Otherwise, s routes to ancestor $\hat{s}$, and if $\hat{s}$ and d are related, then $\hat{s}$ routes to d. As both routings are along shortest paths, we have

$$\begin{aligned}\hat{\rho}(s,d) &= \rho(s,\hat{s}) + \rho(\hat{s},d)\\ &\leq \rho(s,\hat{s}) + \rho(\hat{s},s) + \rho(s,d)\\ &\leq 3\rho(s,d), \text{ as } \rho(s,\hat{s}) \leq \rho(s,d) \quad \text{by Lemma 2.4.}\end{aligned}$$

If $\hat{s}$ and d are unrelated, then $\hat{s}$ routes to $\hat{d}$, where $\hat{d}$ is a sibling or an ancestor. Consider the first occasion that a final milestone $\hat{d}'$ is reached, where $\hat{d}'$ is either $\hat{d}$, or an ancestor of $\hat{d}$, and hence an ancestor of $\hat{s}$ and d. The message is routed from $\hat{d}'$ to d. The routings from $\hat{s}$ to $\hat{d}'$ and from $\hat{d}'$ to d are both along shortest paths. Thus,

$$\begin{aligned}\hat{\rho}(s,d) &= \rho(s,\hat{s}) + \rho(\hat{s},\hat{d}') + \rho(\hat{d}',d)\\ &\leq \rho(s,\hat{s}) + \rho(\hat{s},\hat{d}') + \rho(\hat{d}',\hat{d}) + \rho(\hat{d},d)\\ &= \rho(s,\hat{s}) + \rho(\hat{s},\hat{d}) + \rho(\hat{d},d), \text{ since } \hat{d}' \text{ is on a shortest } (\hat{s},\hat{d})\text{-path}\\ &\leq \rho(s,\hat{s}) + \rho(\hat{s},s) + \rho(s,d) + \rho(d,\hat{d}) + \rho(\hat{d},d)\\ &\leq 3\rho(s,d), \text{ as } \rho(s,\hat{s}) + \rho(\hat{d},d) \leq \rho(s,d) \quad \text{by Lemma 2.4.}\end{aligned}$$

Thus $\hat{\rho}(s,d)/\rho(s,d) \leq 3$ for any nodes s and d, and the theorem follows. □

3. Improving the space bound: Scheme II.

3.1. Multi-level division and naming in Scheme II. We now give Scheme II, in which the storage is reduced to $O(n^{1+\epsilon})$ items, where ϵ is any constant, $0 < \epsilon < 1/3$. The scheme uses $O((1/\epsilon)\log n)$-bit names and has a performance bound of 7. To reduce the storage, we maintain at each node a routing table for only certain closest ancestors and descendants. However, the previous routing strategy will not work now, since the routing tables are very sparse. To overcome this problem, we introduce an additional phase in the routing, in which the message is routed to a pair of intermediate destinations carefully placed at a higher level in the decomposition. We show how to choose a good, though not necessarily optimal, path for this phase, for which the multi-interval labeling scheme from [5] can be used to encode succinctly the routing information in interval form.

The network is decomposed essentially as in Scheme I. However, in order to set up the multi-interval routing information, the boundary nodes of each region must lie on one or more cycles. For a triangulated planar graph, Miller's algorithm [10] yields an $O(\sqrt{n})$-separator that is a simple cycle. The desired regions can be generated by using this, instead of the Lipton–Tarjan separator algorithm [9], in the $f(\cdot)$-division algorithm. The graphs induced on the regions at each level are first triangulated. The cost of the triangulating edges is chosen large enough (for instance, greater than the sum of the costs of all edges in G) so that shortest paths are unaffected. (We remark that the triangulation is done only so that Miller's algorithm can be applied. These edges will not be used in the routing itself, and they do not have to be added physically to the network.) The faces of each graph are then assigned zero weight (as Miller's algorithm requires that faces be weighted), and the $f(\cdot)$-algorithm is then

applied to generate the regions at the next level. As in Scheme I, the boundary nodes of each region are considered to be boundary nodes of the regions resulting from its division. The nodes are named as in Scheme I. As seen later, in Scheme II we choose $f(n) = n^{1-\epsilon}$, where ϵ is any constant, $0 < \epsilon < 1/3$. Thus Theorem 2.2 applies and the node names are $O((1/\epsilon)\log n)$ bits long.

3.2. Routing information in Scheme II. Let v be a level j node, $j \geq 1$. For each level $i \geq j$, shortest paths information is maintained at v for only those of its descendants for which it is the closest ancestor for level i. Let T be a tree of shortest paths from v to these descendants. Starting at v, depth-first numbers are assigned to the nodes of T, and at each node, the edge joining it to a child is labeled by a subinterval of depth-first numbers, representing all nodes in the subtree rooted at the child. A table is stored at v, mapping node names to depth-first numbers. A shortest routing from v to any node u in T is performed by having each node on the path use the depth-first number of u, recorded in the message header by v, to choose the appropriate edge over which to route.

For each level $i < j$, the closest ancestor of v for level i is identified, and the name of the parent of v in the tree rooted at that ancestor is stored at v. Thus v can perform a shortest routing to this ancestor.

For any level $i \geq j$, let R be a level i region for which v is a boundary node. Let R' be the level $i-1$ region containing R; let B be the set of boundary nodes associated with the division of R'. The following information maintained at v enables it to route to the nodes in B.

A table of designators is stored at v, mapping the level i designator of each node u in B to its name.

For each u, a level number $\bar{i}$ is maintained at v, where $\bar{i} \leq i$ is the largest integer for which there is a shortest (v,u)-path in G wholly in the level $\bar{i}-1$ region $\bar{R}$ containing R.

Furthermore, consider each u for which there is at least one (v,u)-path in G wholly in R', and let P be a least-cost such path. The name $next\_milestone_v(u)$ of the first node from B on P (in the direction from v to u) is stored at v. The routing from v to u is performed along P. Path P consists of segments, each of which is wholly in some level i region resulting from the division of R', and whose endpoints are boundary nodes of the level i region. Furthermore, each segment is a shortest such segment. For instance, the first segment has endpoints v and $next\_milestone_v(u)$, and, without loss of generality, lies wholly in region R. Each intermediate node on this segment routes to $next\_milestone_v(u)$. The routing information for this segment can be set up using the multi-interval labeling scheme from [5], as follows.

In the decomposition, the boundary nodes of each region lie on cycles. Let region R have t boundary nodes lying on $p \geq 1$ cycles. Associate an integer between 1 and t, called an *interval name*, with each boundary node by proceeding around each cycle in turn, as described in [5].

The following lemma shows that the routing information for the boundary nodes of R can be encoded succinctly at each node of R as subintervals of interval names labeling each incident edge.

LEMMA 3.1. *At any node w of R, the ends of all the edges incident with w can be labeled with at most $3p + degree(w) - 2$ subintervals of $[1,t]$ such that the following is true. Let z be any boundary node of R reachable from w by a path in G that is wholly contained in R. Then, the first edge on a shortest such (w,z)-path is the one whose label at w contains the interval name of z.*

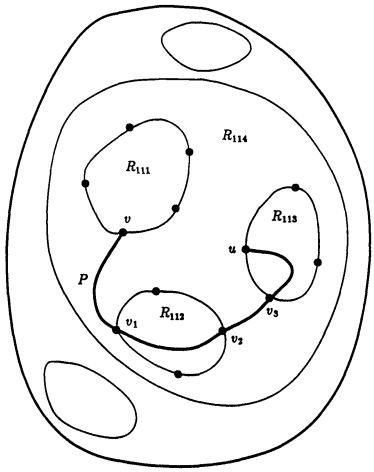

FIG. 3. *Multi-interval routing from v to u in Scheme* II.

Proof. Consider the graph G_R defined by the nodes and edges of R. A shortest (w, z)-path in G that is wholly contained in R is a shortest (w, z)-path in G_R. The lemma then follows from Corollary 5.1 in [5], since all the boundary nodes z lie on at most p faces in G_R. □

The edges incident with each node of R are labeled with subintervals of interval names. At boundary node v, a table mapping the names of the other boundary nodes of R to their respective interval names with respect to R, is stored. The routing from v to $next\_milestone_v(u)$ is performed by having each participating node use the interval name of $next\_milestone_v(u)$, recorded in the message header by v, to choose the appropriate edge over which to route.

The multi-interval routing is illustrated schematically in Fig. 3, which shows four regions, R_{111}, R_{112}, R_{113}, and R_{114}, resulting from the division of level 1 region R_{11}. (For clarity, the figure is not drawn to scale and not all regions and region names are shown. Also, all interior nodes have been omitted.) The boundary nodes resulting from the division are shown filled in. For boundary nodes v and u, a least cost (v, u)-path P contained wholly in R_{11} is shown bold. The routing over P consists of four phases of multi-interval routing, as follows: from v to $v_1 = next\_milestone_v(u)$; from v_1 to $v_2 = next\_milestone_{v_1}(u)$; from v_2 to $v_3 = next\_milestone_{v_2}(u)$; and finally, from v_3 to u.

The following theorem bounds the number of items of routing information used by Scheme II.

THEOREM 3.2. *For any n-node planar graph, Scheme* II *can be set up to use $O(n^{1+\epsilon})$ items of routing information, where ϵ is any constant, $0 < \epsilon < 1/3$. Each item is $O((1/\epsilon)\log n)$ bits long.*

Proof. Each item of routing information stored at a node in Scheme II is one of the following: a node name, a level number, a depth-first number, or an interval name. From Theorem 2.2, the length of a node name is $O((1/\epsilon)\log n)$ bits. Each depth-first number and interval name is an integer in the range 1 to n, and so $O(\log n)$ bits suffice

for these. Each level number is an integer of magnitude $O(\log\log n/\log(1/(1-\epsilon)))$, i.e., $O((1/\epsilon)\log\log n)$. Thus, $O(\log((1/\epsilon)\log\log n))$, i.e., $O(\log(1/\epsilon)+\log\log\log n)$ bits are needed for a level number. It follows that an item is $O((1/\epsilon)\log n+\log(1/\epsilon))$ bits long, which is $O((1/\epsilon)\log n)$, since $(1/\epsilon)>\log(1/\epsilon)$.

We count the number of items of routing information by levels. The level 1 nodes claim, in the role of closest ancestors for level 1, disjoint subsets of the level $j>1$ nodes. Thus the tables at the level 1 nodes, which map node names to depth-first search numbers, use a total of $O(n)$ space. Furthermore, the total number of subintervals of depth-first search numbers maintained for level 1 is proportional to the number of edges of G, which is $O(n)$.

Each level $j>1$ node maintains a constant number of items for its closest ancestor for level 1. Thus the level j nodes maintain a total of $O(n)$ items about nearest ancestors for level 1.

Each boundary node of a level 1 region maintains a constant number of items (a level 1 designator, a level number, and *next_milestone*$(\cdot)$) for each of the other boundary nodes. Since there are $O(n/\sqrt{f(n)})$ boundary nodes of level 1 regions, a total of $O((n/\sqrt{f(n)})^2)$, i.e., $O(n^2/f(n))$ items is stored.

The storage used by the multi-interval routing scheme for level 1 is as follows. Each boundary node of a level 1 region maintains, for each of the other boundary nodes of the region, an entry in the table that maps node names to interval names. Since there are $O(\sqrt{f(n)})$ boundary nodes per level 1 region, a total of $O((\sqrt{f(n)})^2)$, i.e., $O(f(n))$ items are stored per level 1 region. Thus, as there are $\Theta(n/f(n))$ level 1 regions, a total of $O(f(n)n/f(n))$, i.e, $O(n)$ items are stored for all level 1 regions. By Lemma 3.3 below, $O(n)$ intervals are used to encode the multi-interval routing information.

Thus the total number of items of routing information associated with level 1 is $O(n^2/f(n)+n)$, i.e., $O(n^2/f(n))$, since $f(n)<n$. Let $S(n)$ be the total number of items stored in an n-node network. Then, for positive constants c and d we have $S(n)\le dn^2/f(n)+c(n/f(n))S(f(n))$. We choose $f(n)=n^{1-\epsilon}$, for any constant ϵ, $0<\epsilon<1/3$, and the range of n for which the above recurrence holds as $n\ge(2c)^{1/\epsilon^2}$. Thus,

$$S(n)\le dn^{1+\epsilon}+cn^{\epsilon}S(n^{1-\epsilon}),\quad \text{for } n\ge(2c)^{1/\epsilon^2}.$$

For e a positive constant, we may write the basis cases as

$$S(n)\le e,\quad \text{for } 1\le n<(2c)^{1/\epsilon^2}.$$

We claim that $S(n)\le gn^{1+\epsilon}$, where $g=\max\{e,2d\}$. The proof is by induction and is similar to that in Theorem 2.1. Remarks analogous to those in Theorem 2.1 apply here as well, for the choice of the threshold for n. □

The multi-interval routing scheme at level 1 enables routing between the boundary nodes of the various level 1 regions that result from the division of the level 0 region, which has n nodes. We show in the following lemma that this scheme uses a total of $O(n)$ intervals. (In general, for any level $i\ge1$, there are a number of multi-interval routing schemes. Each scheme is associated with a level $i-1$ region and enables routing between certain boundary nodes of the level i regions resulting from the division of the level $i-1$ region. The number of intervals used for each scheme is proportional to the size of the corresponding level $i-1$ region.)

LEMMA 3.3. *The multi-interval labeling scheme at level* 1 *uses a total of* $O(n)$ *intervals.*

Proof. We first derive an upper bound on the number of cycles on the boundaries of the level 1 regions, counting separately each occurrence of a cycle on a level 1 region boundary. In worst case the cycles are all vertex-disjoint, so that the number of cycles is one less than the number of level 1 regions, which is $\Theta(n/f(n))$. Since each cycle is on the boundary of two level 1 regions, the desired upper bound is $\Theta(n/f(n))$.

Let R be any level 1 region. Let p_R be the number of cycles on the boundary of R, and let w be any node of R. From Lemma 3.1 it follows that the total number of intervals maintained for R by all nodes w of R is less than

$$\sum_{w \in R} (3p_R + degree(w)) \leq 3p_R cf(n) + 2(3cf(n) - 6),$$

since R has at most $cf(n)$ nodes for some constant c, and the induced subgraph of G on R is planar. Thus the total number of intervals for all level 1 regions R is less than

$$\sum_{\text{all } R} (3p_R cf(n) + 6cf(n)) = 3cf(n) \sum_{\text{all } R} p_R + 6cf(n) \sum_{\text{all } R} 1,$$

which is $O(n)$, since, from the first part of the lemma, $\sum_{\text{all } R} p_R$ is $\Theta(n/f(n))$, and since there are $\Theta(n/f(n))$ level 1 regions. □

3.3. The routing strategy in Scheme II. The routing from s to d is as follows. Irrespective of whether or not s and d are related, the routing is always performed via the closest ancestor $\hat{s}$ of s and the closest ancestor $\hat{d}$ of d for level l, where l is the length of the longest common prefix of the distinguisher-free portions of the names of s and d. The routing from s to $\hat{s}$ is along a shortest-path tree rooted at $\hat{s}$. Using its table of designators and the lth field designator in d's name, $\hat{s}$ determines $\hat{d}$. Unfortunately, unlike Scheme I, it is now not possible to perform shortest paths routing from $\hat{s}$ to $\hat{d}$, since, in general, this information will not be available at $\hat{s}$. Instead, the routing from $\hat{s}$ to $\hat{d}$ is performed along a near-shortest path as follows.

Let $\bar{l} \leq l$ be the level number maintained at $\hat{s}$ for $\hat{d}$. Thus there is a shortest $(\hat{s}, \hat{d})$-path in G that is wholly contained in the enveloping level $\bar{l} - 1$ region. Let $\hat{\hat{s}}$ and $\hat{\hat{d}}$ be the closest ancestors of $\hat{s}$ and $\hat{d}$, respectively, for level $\bar{l}$. If $\bar{l} = l$, then we take $\hat{\hat{s}}$ and $\hat{\hat{d}}$ to be just $\hat{s}$ and $\hat{d}$, respectively. The routing from $\hat{s}$ to $\hat{d}$ is performed in three stages, as follows. Node $\hat{s}$ records $\bar{l}$ and $\hat{d}$ in the message header and routes to $\hat{\hat{s}}$ along a shortest $(\hat{s}, \hat{\hat{s}})$-path. Using its table of designators and the $\bar{l}$th field designator in $\hat{d}$'s name, $\hat{\hat{s}}$ determines $\hat{\hat{d}}$. It then uses interval routing information to route to $\hat{\hat{d}}$ along a path P of least cost from among those that are wholly contained in the level $\bar{l} - 1$ region. Note that at least one such path exists, namely, the one consisting of the shortest paths from $\hat{\hat{s}}$ to $\hat{s}$, from $\hat{s}$ to $\hat{d}$, and from $\hat{d}$ to $\hat{\hat{d}}$. Node $\hat{\hat{d}}$ then routes to $\hat{d}$ along a shortest $(\hat{\hat{d}}, \hat{d})$-path. Finally, the message is routed from $\hat{d}$ to d along a shortest $(\hat{d}, d)$-path.

An example of a routing from s to d is shown schematically in Fig. 4. (Again, the figure is not drawn to scale, and not all regions and region names are shown.) Since s and d are in different level 4 regions, R_{11111} and R_{11112}, but in the same level 3 region, R_{1111}, l is 4. As level 1 region R_{11} is the first enveloping region to completely contain a shortest $(\hat{s}, \hat{d})$-path in G, shown dashed, $\bar{l}$ is 2. The message path is shown in bold.

The following theorem establishes the performance bound of the routing.

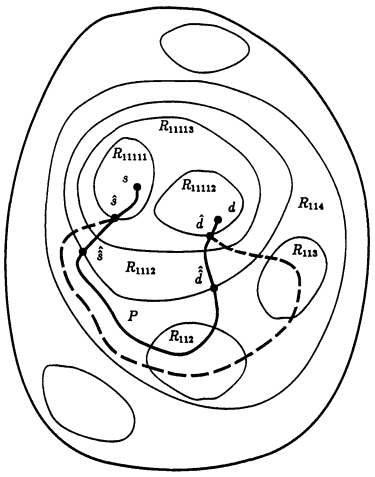

FIG. 4. *An example of a routing from s to d in Scheme* II. *The message path is shown bold.*

THEOREM 3.4. *For any planar graph, the performance bound of Scheme* II *is* 7.

Proof. Let s be any source and d any destination. If $\bar{l} = l$, then $\hat{s}$ and $\hat{\hat{d}}$ are just $\hat{s}$ and $\hat{d}$, respectively, and it follows that P is a shortest $(\hat{s}, \hat{d})$-path in G. Thus

$$\begin{aligned}\hat{\rho}(s,d) &= \rho(s,\hat{s}) + \rho(\hat{s},\hat{d}) + \rho(\hat{d},d) \\ &\leq \rho(s,\hat{s}) + \rho(\hat{s},s) + \rho(s,d) + \rho(d,\hat{d}) + \rho(\hat{d},d) \\ &\leq 3\rho(s,d), \text{ as } \rho(s,\hat{s}) + \rho(d,\hat{d}) \leq \rho(s,d) \quad \text{by Lemma 2.4.}\end{aligned}$$

Otherwise, $\bar{l} < l$ is the highest-numbered level for which a shortest $(\hat{s}, \hat{d})$-path in G is not contained in the enveloping level $\bar{l}$ region, but is contained in the enveloping level $\bar{l} - 1$ region. The path thus leaves the level $\bar{l}$ region for the first time and reenters it for the last time via two of its boundary nodes, b_1 and b_2, respectively. Thus $\rho(\hat{s},\hat{d}) \geq \rho(\hat{s},b_1) + \rho(\hat{d},b_2) \geq \rho(\hat{s},\hat{\hat{s}}) + \rho(\hat{d},\hat{\hat{d}})$, by our choice of $\hat{\hat{s}}$ and $\hat{\hat{d}}$ as the closest ancestors of $\hat{s}$ and $\hat{d}$ for level $\bar{l}$, respectively. Let $| P |$ be the length of P. Then $| P | \leq \rho(\hat{\hat{s}},\hat{s}) + \rho(\hat{s},\hat{d}) + \rho(\hat{d},\hat{\hat{d}}) \leq 2\rho(\hat{s},\hat{d})$. The length of the routing from $\hat{s}$ to $\hat{d}$ is then $\rho(\hat{s},\hat{\hat{s}}) + | P | + \rho(\hat{\hat{d}},\hat{d}) \leq 3\rho(\hat{s},\hat{d})$. Thus

$$\begin{aligned}\hat{\rho}(s,d) &\leq \rho(s,\hat{s}) + 3\rho(\hat{s},\hat{d}) + \rho(\hat{d},d) \\ &\leq \rho(s,\hat{s}) + 3(\rho(\hat{s},s) + \rho(s,d) + \rho(d,\hat{d})) + \rho(\hat{d},d) \\ &= 4(\rho(s,\hat{s}) + \rho(d,\hat{d})) + 3\rho(s,d) \\ &\leq 7\rho(s,d), \quad \text{by Lemma 2.4.}\end{aligned}$$

Thus $\hat{\rho}(s,d)/\rho(s,d) \leq 7$ for any nodes s and d, and the theorem follows. □

POLYNOMIAL TIME ALGORITHMS FOR FINDING INTEGER RELATIONS AMONG REAL NUMBERS*

J. HASTAD†, B. JUST‡¶, J. C. LAGARIAS§, AND C. P. SCHNORR‡

Abstract. This paper considers variants and generalizations of the following computational problem. Given a real input $\mathbf{x} \in \mathbb{R}^n$, find a small integer relation $\mathbf{m}$ for x that is a nonzero vector $\mathbf{m} \in \mathbb{Z}^n$ orthogonal to $\mathbf{x}$, or prove that no integer relation $\mathbf{m}$ exists with $\|\mathbf{m}\| \leqq 2^k$. An algorithm is presented that solves this problem in $O(n^3(k+n))$ arithmetic operations over real numbers. The algorithm is a variation of the multidimensional Euclidean algorithm proposed by Ferguson and Forcade [*Bull. Amer. Math. Soc.*, 1 (1979), pp. 912-914] and Bergman [*Notes on Ferguson and Forcade's Generalized Euclidean Algorithm*, University of California, Berkeley, CA, 1980]. A connection between such multidimensional Euclidean algorithms and the Lattice Basis Reduction Algorithm of Lenstra, Lenstra Jr., and Lovász [*Math. Ann.*, 21 (1982), pp. 515-534] is shown. Polynomial time solutions are also established for finding linearly independent sets of small integer relations and for finding small simultaneous integer relations for several real vectors, using real input vectors and counting arithmetic operations over real numbers at unit cost. For integer input vectors $\mathbf{x}$ a different algorithm is given for finding integer relations (that always exist) that uses at most $O(n^3 \log \|x\|)$ arithmetic operations on $O(n + \log \|\mathbf{x}\|)$ bit integers.

1. Introduction.

Given a real vector $\mathbf{x} = (x_1, \cdots, x_n) \in \mathbb{R}^n$, an *integer relation* for $\mathbf{x}$ is a nonzero vector $\mathbf{m} = (m_1, \cdots, m_n) \in \mathbb{Z}^n$ such that $\langle \mathbf{m}, \mathbf{x} \rangle = \sum_{i=1}^n m_i x_i = 0$. This paper studies the following computational problem. Given a real vector $\mathbf{x} \in \mathbb{R}^n$, either find a small integer relation $\mathbf{m}$ for $\mathbf{x}$ or prove that no small integer relation exists.

The problem of finding integer relations for two numbers (x_1, x_2) can be solved by applying the Euclidean algorithm to x_1, x_2, or, equivalently, by computing the ordinary continued fraction expansion of the real number x_1/x_2. The problem of finding good algorithms for $n \geqq 3$ has been studied under the names *generalized Euclidean algorithm* and *multidimensional continued fraction algorithm.* Quite a few of these algorithms have been proposed, many of which are surveyed in Brentjes (1981) and Bernstein (1971).

In geometric terms the task is to approximate a line $\mathbf{x}\mathbb{R} \subset \mathbb{R}^n$, consisting of scalar multiples of $\mathbf{x}$, by a sequence of integer lattice bases of $\mathbb{Z}^n$. The convergence of a sequence of lattice bases $\mathbf{b}_1^{(\nu)}, \cdots, \mathbf{b}_n^{(\nu)}$ for $\nu = 1, 2, \cdots$ to the line $\mathbf{x}\mathbb{R}$ has the following consequences. The $(n-1)$-vector $(b_{i2}^{(\nu)}/b_{i1}^{(\nu)}, \cdots, b_{in}^{(\nu)}/b_{i1}^{(\nu)})$ associated with $\mathbf{b}_i^{(\nu)} = (b_{i1}^{(\nu)}, \cdots, b_{in}^{(\nu)})$ is a good simultaneous Diophantine approximation to the vector $(x_2/x_1, \cdots, x_n/x_1)$ associated with $\mathbf{x} = (x_1, \cdots, x_n)$. The lattice basis $\mathbf{c}_1^{(\nu)}, \cdots, \mathbf{c}_n^{(\nu)}$ that is *dual* to $\mathbf{b}_1^{(\nu)}, \cdots, \mathbf{b}_n^{(\nu)}$ consists of the row vectors of the inverse of the matrix

¶ The maiden name of B. Just is B. Helfrich.

$[\mathbf{b}_1^{(\nu)}, \cdots, \mathbf{b}_n^{(\nu)}]$ with column vectors $\mathbf{b}_1^{(\nu)}, \cdots, \mathbf{b}_n^{(\nu)}$, i.e., $[\mathbf{c}_1^{(\nu)}, \cdots, \mathbf{c}_n^{(\nu)}]^\top = [\mathbf{b}_1^{(\nu)}, \cdots, \mathbf{b}_n^{(\nu)}]^{-1}$. If the basis $\mathbf{b}_1^{(\nu)}, \cdots, \mathbf{b}_n^{(\nu)}$ converges (in various ways) to $\mathbf{x}\mathbb{R}$ then the vectors $\mathbf{c}_i^{(\nu)}$ for $1 \leqq i \leqq n$ converge to $(\mathbf{x}\mathbb{R})^\perp$. If in particular $\mathbf{c}_i^{(\nu)}$ is orthogonal to $\mathbf{x}$ then $\mathbf{c}_i^{(\nu)}$ is an *integer relation* for $\mathbf{x}$; if such a vector $\mathbf{c}_i^{(\nu)}$ occurs it is said that an integer relation has been detected.

Jacobi (1868) proposed a continued fraction algorithm for $n = 3$ and Perron (1907) extended it to general n. The Jacobi–Perron algorithm generates a sequence of integer lattice bases $\mathbf{b}_1^{(\nu)}, \cdots, \mathbf{b}_n^{(\nu)}$ of $\mathbb{Z}^n$ that *weakly converges* to $\mathbf{x}\mathbb{R}$, i.e., the angles between $\mathbf{b}_i^{(\nu)}$ and $\mathbf{x}$ converge to 0, which means $\lim_\nu (\mathbf{b}_i^{(\nu)}/\|\mathbf{b}_i^{(\nu)}\| - \mathbf{x}/\|\mathbf{x}\|) = \mathbf{0}$ for $1 \leqq i \leqq n$. Ferguson and Forcade (1979) presented the first continued fraction algorithm for arbitrary n that is guaranteed to detect integer relations when they exist. If no integer relations exist this algorithm is *strongly convergent*, i.e., the distances of $\mathbf{b}_i^{(\nu)}$ to $\mathbf{x}\mathbb{R}$ converge to 0, which means $\lim_\nu (\mathbf{b}_i^{(\nu)}\|\mathbf{x}\| - \mathbf{x}\|\mathbf{b}_i^{(\nu)}\|) = 0$ for $1 \leqq i \leqq n$. Ferguson and Forcade's algorithm is inductive. The n-dimensional version of the algorithm repeatedly uses lower-dimensional versions of the algorithm as a subroutine (see Ferguson and Forcade (1982), Ferguson (1986).) A noninductive algorithm that incorporates the basic Ferguson–Forcade ideas but which is different in detail was developed by Bergman (1980). Ferguson (1987) presents a similar noninductive algorithm and proves an exponential running time bound for it. Bergman's algorithm is surprisingly similar to the Lovász algorithm for lattice basis reduction. Both algorithms perform the same type of basis transformations, reduction in size and exchange steps according to similar but slightly different exchange rules.

This paper studies the problem of finding integer relations via generalized Euclidean algorithms. It considers the following computational problem, the *integer relation problem*. Given a real vector $\mathbf{x} \in \mathbb{R}^n$ and a bound 2^k, either find an integer relation $\mathbf{m}$ for $\mathbf{x}$ with $\|\mathbf{m}\| \leqq 2^{n+k}$ or prove there is no integer relation $\mathbf{m}$ with $\|\mathbf{m}\| < 2^k$. A gap between the upper bounds 2^{n+k} and 2^k is unavoidable because efficient lattice basis reduction algorithms only find a nearly shortest lattice vector. We distinguish two versions of this problem: one in which the input vector $\mathbf{x}$ consists of arbitary real numbers, and the other in which the input vector is an integer vector. The algorithms for the real input version use the following arithmetic operations on real numbers at unit cost: addition, subtraction, multiplication, division, comparison of two numbers ($<$), and the nearest integer function ($\lceil \rfloor$). On the other hand, the algorithms for the integer input version are studied using the bit complexity model in which we count bit operations. We present algorithms for both the real and the integer versions of the problem, and we prove running time bounds that are polynomial in n, k, and the bit length of the integer inputs. The algorithms for the real input version of the problem are similar to the algorithms of Bergman (1980) and Ferguson (1987). For the integer input version of the problem we present an algorithm that is close to the Lovász basis reduction algorithm.

The problem dual to the integer relation problem is the problem of finding good simultaneous Diophantine approximations. Algorithms for the integer relation problem do not necessarily find good Diophantine approximations. Just (1987) has established a class of continued fraction algorithms that use both the Bergman and Lovász exchange rule and that find reasonably good simultaneous Diophantine approximations in all dimensions.

Now we describe the contents of the paper in more detail. Section 2 presents a version of the generalized Euclidean algorithm of Bergman (1980) and Ferguson (1987) and the Lovász Lattice Basis Reduction Algorithm of Lenstra, Lenstra, Jr., and Lovász

(1982). These algorithms are presented in a form that illustrates their striking similarity; this was not apparent in the original papers. We call our version of the "Bergman, Ferguson, Forcade-type" algorithm the *Basic Integer Relation Algorithm.* This algorithm exhibits the main features of the polynomial time algorithms to solve the real input version of various integer relation problems presented in §§ 3–5. The Basic Integer Relation Algorithm and the Lovász Lattice Basis Reduction Algorithm use different rules for exchanging basis vectors. This difference is crucial to obtaining a polynomial running time bound for the real input version of the Basic Integer Relation Algorithm. The Lovász exchange rule does not find integer relations among real numbers in polynomial time.

Section 3 presents the *Small Integer Relation Algorithm* that is derived from the Basic Relation Algorithm by adding a suitable termination test. The Small Integer Relation Algorithm takes as input a real vector $\mathbf{x}=(x_1,\cdots,x_n)\neq\mathbf{0}$ and a positive integer k. We prove it has the following properties.

(1) It either finds an integer relation $\mathbf{m}$ for $\mathbf{x}$ with $\|\mathbf{m}\|^2\leqq 2^{n-2}\min\{\lambda(\mathbf{x})^2, 2^{2k}\}$ or proves $\lambda(\mathbf{x})\geqq 2^k$, where $\lambda(\mathbf{x})$ is the length of the shortest, nonzero integer relation for $\mathbf{x}$.

(2) It halts after at most $O(n^3(k+n))$ arithmetic operations on real numbers.

The arithmetic model of computation on real numbers, with the operations addition, subtraction, multiplication, division, comparison ($<$), and the nearest integer function ($\lceil\,\rfloor$) at unit cost, is not compatible with the usual Turing machine model since it allows infinite precision arithmetic at each step. In the Turing machine model we cannot prove the existence of integer relations for real numbers since this would require infinite precision arithmetic. However in the Turing machine model we can prove, by computations on rational numbers, the nonexistence of small integer relations for given real numbers $x_1,\cdots,x_n$. For this we apply the Small Integer Relation Algorithm to a rational vector $\bar{\mathbf{x}}$ that is sufficiently close to $\mathbf{x}=(x_1,\cdots,x_n)$. We cannot say beforehand how close $\bar{\mathbf{x}}$ has to be to $\mathbf{x}$ but Theorem 3.5 defines the term "sufficiently close" a posteriori.

Section 4 describes an algorithm used to find several small linearly independent integer relations if they exist. The resulting algorithm, the *Several Relations Algorithm,* takes as input a vector $\mathbf{x}\neq 0$ in $\mathbb{R}^n$, and positive integers k and r satisfying $1\leqq r\leqq n-1$. Its output is either a set of r linearly independent integer relations $\{\mathbf{m}_i: 1\leqq i\leqq r\}$ with all $\|\mathbf{m}_i\|\leqq 2^{n+k}$ or a proof that there do not exist r linearly independent integer relations with all $\|\mathbf{m}_i\|\leqq 2^k$. Its running time is $O(n^3(k+n))$ arithmetic operations. Let $L_{\mathbf{x}}\subset\mathbb{Z}^n$ be the lattice of integer relations for $\mathbf{x}$. The Several Relations Algorithm can be used to approximate the successive minima of $L_{\mathbf{x}}$. It can also be used to find a basis of a sublattice L of the lattice $L_{\mathbf{x}}$ that contains all shortest vectors in $L_{\mathbf{x}}$.

Section 5 presents an algorithm that finds simultaneous integer relations for linearly independent vectors $\mathbf{x}_1,\cdots,\mathbf{x}_q\in\mathbb{R}^n$. The *Simultaneous Relations Algorithm* incorporates all the previous algorithms as special cases. When given as input $\mathbf{x}_1,\cdots,\mathbf{x}_q\in\mathbb{R}^n$ and r, $k\in\mathbb{N}$ this algorithm halts after at most $O(n^3(k+n))$ arithmetic operations with real numbers and either finds r independent simultaneous integer relations $\mathbf{m}$ for $\mathbf{x}_1,\cdots,\mathbf{x}_q$ or proves there does not exist such a set of relations $\mathbf{m}$ with $\|\mathbf{m}\|<2^k$. This algorithm can be used to find r independent integer dependencies among a set of real vectors $\mathbf{y}_1,\cdots,\mathbf{y}_t\in\mathbb{R}^n$.

Section 6 studies integer relation algorithms in the bit complexity model of computation. In this case the input is a vector $\mathbf{x}$ in $\mathbb{Z}^n$, and integer relations always exist. We describe an algorithm based on ideas from the Lattice Basis Reduction

Algorithm. This algorithm finds a basis for the $(n-1)$-dimensional lattice $L_{\mathbf{x}}$ of integer relations for $\mathbf{x}$. It essentially applies the Lovász algorithm to the linearly dependent vectors $\mathbf{b}_0 = \mathbf{x}, \mathbf{b}_1, \cdots, \mathbf{b}_n$, where $\mathbf{b}_1, \cdots, \mathbf{b}_n$ is the standard basis of $\mathbb{Z}^n$. This algorithm finds short basis vectors for the lattice $L_{\mathbf{x}}$, and it terminates after at most $O(n^3 \log \|\mathbf{x}\|)$ arithmetic steps using $O(n + \log \|\mathbf{x}\|)$-bit integers. The performance of this algorithm should be compared with that of the efficient reduction algorithms by Schönhage (1984) and Schnorr (1986, 1988).

The results of this paper were obtained independently by Hastad and Lagarias and by Just and Schnorr. Just and Schnorr rediscovered the Basic Integer Relation Algorithm independently of Bergman, Ferguson, and Forcade as a modification of the Lovász algorithm.

2. The Basic Integer Relation Algorithm and the Lovász Lattice Basis Reduction Algorithm. We will use the following notation throughout the paper. Let $\mathbb{R}^n$ be the n-dimensional real vector space, $n > 1$ with inner product $\langle , \rangle$ and let $\|\mathbf{y}\| = \langle \mathbf{y}, \mathbf{y} \rangle^{1/2}$ be the length of the vector $\mathbf{y} \in \mathbb{R}^n$. All vectors are column vectors unless otherwise specified. For a linear subspace $E \subset \mathbb{R}^n$ we let $E^{\perp} \subset \mathbb{R}^n$ be the orthogonal complement of E, i.e., the subspace consisting of all vectors that are orthogonal to E. For $\mathbf{b}_1, \cdots, \mathbf{b}_r \in \mathbb{R}^n$ let $\langle \mathbf{b}_1, \cdots, \mathbf{b}_r \rangle$ be the additive closure of $\mathbf{b}_1, \cdots, \mathbf{b}_r$, i.e., the set of all vectors $\sum_{i=1}^{r} m_i \mathbf{b}_i$ with $m_i \in \mathbb{Z}$. The $n \times r$ matrix with column vectors $\mathbf{b}_1, \cdots, \mathbf{b}_r \in \mathbb{R}^n$ is denoted $[\mathbf{b}_1, \cdots, \mathbf{b}_r]$. Let span $(\mathbf{b}_1, \cdots, \mathbf{b}_r)$ be the linear space generated by the vectors $\mathbf{b}_1, \cdots, \mathbf{b}_r$. The transpose of matrix A is $A^{\top}$.

A lattice $L \subset \mathbb{R}^n$ is a discrete, additive subgroup of $\mathbb{R}^n$. Every lattice is the additive closure of a set $\mathbf{b}_1, \cdots, \mathbf{b}_r$ of linearly independent vectors in $\mathbb{R}^n$, i.e., $L = \langle \mathbf{b}_1, \cdots, \mathbf{b}_r \rangle$. The vectors $\mathbf{b}_1, \cdots, \mathbf{b}_r$ are called a *basis* of L, and r is the *rank* of the lattice L. The *determinant* of L is the volume of the r-dimensional parallelepiped generated by the basis $\mathbf{b}_1, \cdots, \mathbf{b}_r$. The rank and the determinant do not depend on the choice of basis. The ith *successive minimum* $\lambda_i(L)$ of lattice L is the smallest radius of a ball with center $\mathbf{0}$ that contains i linearly independent lattice vectors.

All algorithms of this paper that take real numbers for input will use the following arithmetic operations on real numbers at unit cost: addition, subtraction, multiplication, division, comparison ($<$), and the nearest integer function ($\lceil \rfloor$). We call this the *arithmetic model of computation.* (It differs from the arithmetic model of computation used in Frank and Tardös (1985) because it includes $\lceil \rfloor$ as a basic arithmetic operation.)

An *integer relation* $\mathbf{m} \in \mathbb{Z}^n$ for $\mathbf{x}$ is a nonzero vector $\mathbf{m} \in \mathbb{Z}^n$ satisfying $\langle \mathbf{x}, \mathbf{m} \rangle = 0$. We associate with a nonzero vector $\mathbf{x} \in \mathbb{R}^n$ the lattice $L_{\mathbf{x}} \subset \mathbb{Z}^n$ of all integer relations for $\mathbf{x}$ together with $\mathbf{0}$, i.e.,

$$L_{\mathbf{x}} = \{\mathbf{m} \in \mathbb{Z}^n : \langle \mathbf{x}, \mathbf{m} \rangle = 0\}.$$

For general real vectors $\mathbf{x}$ the lattice $L_{\mathbf{x}}$ may have rank from 0 to $n-1$, while for rational vectors its rank is always $n-1$. For real vectors $\mathbf{x}$ the rank of $L_{\mathbf{x}}$ cannot be computed in the arithmetic model of computation. Babai, Just, and Meyer auf der Heide (1988) have shown that it cannot even be decided in the arithmetic model of computation whether there exists an integer relation for $\mathbf{x}$, i.e., whether rank $(L_{\mathbf{x}}) \geqq 1$. Let $\lambda(\mathbf{x}) = \lambda_1(\mathbf{x}) \leqq \lambda_2(\mathbf{x}) \leqq \cdots \leqq \lambda_r(\mathbf{x})$, with $r = \text{rank}\,(L_{\mathbf{x}})$, be the successive minima of the lattice $L_{\mathbf{x}}$. Then $\lambda(\mathbf{x})$ is the length of the shortest integer relation for $\mathbf{x}$ provided that some integer relation exists. If there is no integer relation for $\mathbf{x}$ we let $\lambda(\mathbf{x}) = \infty$.

With a sequence of vectors $\mathbf{b}_1, \cdots, \mathbf{b}_n \in \mathbb{R}^n$ and the fixed vector $\mathbf{b}_0 = \mathbf{x} \in \mathbb{R}^n$, we associate the orthogonal system $\mathbf{b}_0^*, \cdots, \mathbf{b}_n^*$ where $\mathbf{b}_i^*$ is the component of $\mathbf{b}_i$ that is orthogonal to $\mathbf{b}_1, \cdots, \mathbf{b}_{i-1}$ and $\mathbf{b}_0$. The vectors $\mathbf{b}_0^*, \cdots, \mathbf{b}_n^*$ can be computed by the

process of Gram-Schmidt orthogonalization using $O(n^3)$ arithmetic operations:

$$\mathbf{b}_0^* = \mathbf{x},$$

$$\mathbf{b}_i^* = \mathbf{b}_i - \sum_{j=0}^{i-1} \mu_{i,j}\mathbf{b}_j^*, \qquad i = 1, \cdots, n,$$

where $\mu_{i,j} = \langle \mathbf{b}_i, \mathbf{b}_j^* \rangle \|\mathbf{b}_j^*\|^{-2}$ if $\mathbf{b}_j^* \neq 0$, and $\mu_{i,j} = 0$ if $\mathbf{b}_j^* = 0$. This process gives the usual Gram-Schmidt orthogonalization for $\mathbf{b}_1, \cdots, \mathbf{b}_n$ when $\mathbf{b}_0 = \mathbf{x} = \mathbf{0}$. We denote by $\lceil r \rfloor$ the integer nearest to $r \in \mathbb{R}$, with $\lceil r \rfloor = r - \frac{1}{2}$ if r is a half-integer.

Both the Basic Integer Relation Algorithm and the Lovász Lattice Basis Reduction Algorithm perform a sequence of elementary basis exchange operations on a current ordered basis $\mathbf{b}_1, \cdots, \mathbf{b}_n$ of a given lattice. These consist of two types of steps:

(1) *Exchange steps.* Interchange $\mathbf{b}_i$ and $\mathbf{b}_{i+1}$ for some i.

(2) *Size-reduction step.* Replace $\mathbf{b}_i$ with $\mathbf{b}_i - l\mathbf{b}_j$ where $l \in \mathbb{Z}$ for some i and j with $1 \leqq j < i$.

Both types of steps produce a new basis matrix B^{new} with $B^{\text{new}} = BU$ for some matrix $U \in \mathrm{GL}(n, \mathbb{Z})$, where $B = [\mathbf{b}_1, \cdots, \mathbf{b}_n]$.

The purpose of a size-reduction step is to make the Gram-Schmidt quantity $\mu_{i,j}^{\text{new}}$ in the new basis satisfy $|\mu_{i,j}^{\text{new}}| \leqq \frac{1}{2}$. This uniquely determines the integer l in the size-reduction step by $l = \lceil \mu_{i,j}^{\text{old}} \rfloor$. A basis $\mathbf{b}_1, \cdots, \mathbf{b}_n$ of a lattice is *size-reduced* if all $|\mu_{i,j}| \leqq \frac{1}{2}$ in its Gram-Schmidt orthogonalization. Given any basis we can obtain a size-reduced basis having the same Gram-Schmidt orthogonal system $\mathbf{b}_1^*, \cdots, \mathbf{b}_n^*$ by applying a sequence of $n(n-1)/2$ size-reduction steps. These steps have to be applied in a suitable order that does not change the $|\mu_{i,j}| \leqq \frac{1}{2}$ produced in previous steps.

The Basic Integer Relation Algorithm is a variant of the algorithms of Bergman (1980) and Ferguson (1987), which are themselves based on ideas of the Ferguson-Forcade Algorithm (1979), (1982).

BASIC INTEGER RELATION ALGORITHM. (On input $\mathbf{x} \in \mathbb{R}^n$ this algorithm produces infinite sequences $M^{(t)}$, $P^{(t)}$ of matrices in $\mathrm{GL}(n, \mathbb{Z})$. The column vectors $\mathbf{b}_1^{(t)}, \cdots, \mathbf{b}_n^{(t)}$ of $P^{(t)}$ form a basis of $\mathbb{Z}^n$ and these bases approach span $(\mathbf{x})$ as t increases. The row vectors of $M^{(t)} = (P^{(t)})^{-1}$ are the dual basis, and these converge to span $(\mathbf{x})^{\perp}$.)

1. *Initiation.* For the vectors $\mathbf{b}_0 = \mathbf{x}$ and standard basis $\mathbf{b}_1, \cdots, \mathbf{b}_n$ of $\mathbb{Z}^n$ compute the Gram-Schmidt quantities $\mu_{i,j}$ and $\|\mathbf{b}_i^*\|^2$ for $0 \leqq j$, $i \leqq n$. Set iteration count $t := 0$.

2. *Exchange step.* $t := t+1$. Choose for $1 \leqq i \leqq n$ that i that maximizes $2^i \|\mathbf{b}_i^*\|^2$. Size-reduce $\mathbf{b}_{i+1}$ with respect to $\mathbf{b}_i$ by setting $\mathbf{b}_{i+1} := \mathbf{b}_{i+1} - \lceil \mu_{i+1,i} \rfloor \mathbf{b}_i$. Exchange $\mathbf{b}_i$ and $\mathbf{b}_{i+1}$. Now update the Gram-Schmidt data $\|\mathbf{b}_r^*\|^2$, $\mu_{r,j}$, $\mu_{j,r}$ for $r = i$, $i+1$ and $1 \leqq j \leqq n$. Output $P^{(t)} = [\mathbf{b}_1, \cdots, \mathbf{b}_n]$ and $M^{(t)} = [\mathbf{b}_1, \cdots, \mathbf{b}_n]^{-1}$. Go to 2.

For completeness we include formulae for updating the Gram-Schmidt numbers $\mu_{i,j}$, $\|\mathbf{b}_i^*\|^2$. For the transformation $\mathbf{b}_{i+1} := \mathbf{b}_{i+1} - \lceil \mu_{i+1,i} \rfloor \mathbf{b}_i$ we obtain the new $\mu_{i+1,j}$ by setting

$$\mu_{i+1,j} := \mu_{i+1,j} - \lceil \mu_{i+1,i} \rfloor \mu_{i,j} \quad \text{for } j = 1, \cdots, i,$$

and the other Gram-Schmidt quantities do not change. Explicit formulae for updating an exchange step $\mathbf{b}_i \leftrightarrow \mathbf{b}_{i+1}$ with $\|\mathbf{b}_i^*\|$, $\|\mathbf{b}_{i+1}^*\| \neq 0$ are given by Lenstra, Lenstra Jr., and Lovász (1982). We extend their formulae to include the case $\|\mathbf{b}_{i+1}^*\| = 0$.

Updating $\|\mathbf{b}_\nu^*\|$, $\mu_{\nu,j}$, $\mu_{j,\nu}$ *for* $\nu = i$, $i+1$ *and* $j = 1, \cdots, n$ *in case of an exchange* $\mathbf{b}_i \leftrightarrow \mathbf{b}_{i+1}$.

$\mu := \mu_{i+1,i}$;

$\|\mathbf{b}_i^*\|_{\text{new}}^2 := \|\mathbf{b}_{i+1}^*\|^2 + \mu^2 \|\mathbf{b}_i^*\|^2$;

if $\|\mathbf{b}_i^*\|_{\text{new}} \neq 0$ *then* $(\|\mathbf{b}_{i+1}^*\|^2 := \|\mathbf{b}_i^*\|^2 \|\mathbf{b}_{i+1}^*\|^2 / \|\mathbf{b}_i^*\|_{\text{new}}^2,\ \mu_{i+1,i} := \mu \|\mathbf{b}_i^*\| / \|\mathbf{b}_i^*\|_{\text{new}}^2)$
else $(\|\mathbf{b}_{i+1}^*\|^2 := \|\mathbf{b}_i^*\|^2,\ \mu_{i+1,i} := 0)$.
$\|\mathbf{b}_i^*\|^2 := \|\mathbf{b}_i^*\|_{\text{new}}^2$;

$$\begin{pmatrix} \mu_{i,j} \\ \mu_{i+1,j} \end{pmatrix} := \begin{pmatrix} \mu_{i+1,j} \\ \mu_{i,j} \end{pmatrix} \quad \text{for } j = 1, \cdots, i-1.$$

$$\begin{pmatrix} \mu_{j,i} \\ \mu_{j,i+1} \end{pmatrix} := \begin{pmatrix} 1 & \mu_{i+1,i} \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 0 & 1 \\ 1 & -\mu \end{pmatrix} \begin{pmatrix} \mu_{j,i} \\ \mu_{j,i+1} \end{pmatrix} \quad \text{for } j = i+2, \cdots, n.$$

We remark that this algorithm keeps $\mathbf{b}_0 = \mathbf{x}$ fixed throughout; all the operations are on the remaining $n \times n$ matrix of basis vectors $\mathbf{b}_1, \cdots, \mathbf{b}_n$. Theorem 3.2 below proves that this algorithm eventually detects an integer relation if one exists. If no integer relation exists the algorithm does not stop and the sequence of output bases $[\mathbf{b}_1^{(\nu)}, \cdots, \mathbf{b}_n^{(\nu)}]$ converges strongly to $\mathbf{x}\mathbb{R}$, i.e., $\lim_\nu (\mathbf{b}_i^{(\nu)} \|\mathbf{x}\| - \mathbf{x} \|\mathbf{b}_i^{(\nu)}\|) = \mathbf{0}$ for $1, \cdots, n$. The strong convergence has been proved by Ferguson and Forcade (1979). It follows from $\lim_\nu \|\mathbf{b}_i^{(\nu)*}\| = 0$ for $i = 1, \cdots, n$.

The Basic Integer Relation Algorithm coincides essentially with the algorithms of Bergman (1980) and Ferguson (1987). The particular exchange rule used in the Basic Integer Relation Algorithm was proposed by Bergman (1980), so we call it the *Bergman exchange rule.* We have however used a somewhat different language than Ferguson (1987) to describe the algorithm, and our algorithm also differs from his in that in the exchange step it only size-reduces $\mu_{i+1,i}$ and not $\mu_{i+1,1}, \cdots, \mu_{i+1,i-1}$. The size-reduction of $\mu_{i+1,1}, \cdots, \mu_{i+1,i-1}$ is not necessary for finding integer relations in the real number model of computation. This size-reduction keeps the entries in the matrix $M^{(t)}$ small, which is important in the bit complexity model.

It is interesting to compare the Basic Integer Relation Algorithm with the Lovász Lattice Basis Reduction Algorithm that appears in Lentra, Lenstra Jr., and Lovász (1982). We outline a variant of the latter algorithm that takes for input an arbitrary sequence $\mathbf{b}_1, \cdots, \mathbf{b}_n$ of vectors in $\mathbb{R}^n$, possibly linearly dependent. In this description $\mathbf{b}_1^*, \cdots, \mathbf{b}_n^*$ is the ordinary Gram-Schmidt orthogonalization system arising when $\mathbf{b}_0 = \mathbf{x} = \mathbf{0}$.

BASIC LOVÁSZ ALGORITHM.

1. *Initiation.* Input $\mathbf{b}_1, \cdots, \mathbf{b}_n$ in $\mathbb{R}^n$ and compute the Gram-Schmidt quantities $\mu_{i,j}$ and $\|\mathbf{b}_i^*\|$ for $1 \leqq j,\ i \leqq n$.
2. *Termination condition.* If $\|\mathbf{b}_i^*\|^2 \leqq 2\|\mathbf{b}_{i+1}^*\|^2$ for $1 \leqq i \leqq n-1$, then size-reduce the basis, output it, and halt.
3. *Exchange step.* Choose the smallest $i < n$ with $\|\mathbf{b}_i^*\|^2 > 2\|\mathbf{b}_{i+1}^*\|^2$. Size reduce $\mathbf{b}_{i+1}$ with respect to $\mathbf{b}_i$, setting $\mathbf{b}_{i+1} = \mathbf{b}_{i+1} - \lceil \mu_{i+1,i} \rfloor \mathbf{b}_i$. Exchange $\mathbf{b}_i$ and $\mathbf{b}_{i+1}$. Update the Gram-Schmidt quantities. Go to 2.

This algorithm differs from the usual Lattice Basis Reduction Algorithm by omitting extra size-reduction steps used to keep integers small, which are not relevant in the real-number model of computation. It also differs in that we have replaced in the Lovász algorithm the reduction condition $\frac{3}{4}\|\mathbf{b}_i^*\|^2 \leqq \|\mathbf{b}_{i+1}^*\|^2 + \mu_{i+1,i}^2 \|\mathbf{b}_i^*\|^2$ by the essentially equivalent *Siegel reduction condition* $\|\mathbf{b}_i^*\|^2 \leqq 2\|\mathbf{b}_{i+1}^*\|^2$. If the input vectors are linearly independent, then this algorithm eventually halts and produces a basis reduced in the Lovász sense. (The arguments in Lenstra, Lenstra Jr., and Lovász (1982) are easily adapted to prove this.) If the input vectors are linearly dependent the algorithm may never halt.

A great similarity in the form of the Basic Integer Relation Algorithm and the Basic Lovász Algorithm is apparent. Both algorithms have an exchange rule that

exchanges $\mathbf{b}_i$ and $\mathbf{b}_{i+1}$ where $\|\mathbf{b}_i^*\|^2 > 2\|\mathbf{b}_{i+1}^*\|^2$: the Lovász algorithm chooses the smallest such i while the Basic Integer Relation Algorithm chooses an i that maximizes $\|\mathbf{b}_i^*\|^2 2^i$. The subtle difference in the form of the Bergman exchange rule relative to the Lovász exchange rule is critical in obtaining a polynomial running time bound for the Basic Integer Relation Algorithm. If the Lovász exchange rule is inserted in the Basic Integer Relation Algorithm, the resulting algorithm can be proved to detect an integer relation if one exists, but in the real number model the number of steps it takes to find a relation of size less than or equal to 2^k cannot be bounded in terms of n and k alone.

We can also use the Lovász algorithm to eliminate integer dependencies from a generator system $\mathbf{b}_1, \cdots, \mathbf{b}_n$ of a lattice $L = \langle \mathbf{b}_1, \cdots, \mathbf{b}_n \rangle$. Because L is discrete all sufficiently small vectors in L must be $\mathbf{0}$. We have the following theorem.

THEOREM 2.1. *Suppose $\bar{\mathbf{b}}_1, \cdots, \bar{\mathbf{b}}_s \in \mathbb{R}^n$ is a set of generators for the lattice $L = \langle \bar{\mathbf{b}}_1, \cdots, \bar{\mathbf{b}}_s \rangle$ of rank r. Then the Lovász Algorithm transforms the input vectors $\bar{\mathbf{b}}_1, \cdots, \bar{\mathbf{b}}_s$ into vectors $\mathbf{b}_1, \cdots, \mathbf{b}_s$ such that $\mathbf{b}_1 = \cdots = \mathbf{b}_{s-r} = \mathbf{0}$ and $\mathbf{b}_{s-r+1}, \cdots, \mathbf{b}_s$ form a basis of the lattice L. This basis has the properties*

$$\|\mathbf{b}_i^*\|^2 \leqq 2\|\mathbf{b}_{i+1}^*\|^2 \quad \text{for } s-r+1 \leqq i \leqq s-1,$$
$$|\mu_{i,j}| \leqq \tfrac{1}{2} \quad \text{for } s-r+1 \leqq j < i \leqq s.$$

For integer input vectors with $B = \max_i \|\bar{\mathbf{b}}_i\|$ this algorithm terminates after at most $O(n^4 \log B)$ arithmetic steps on $O(n \log B)$-integers.

The proof is a straightforward extension of the analysis of the Lovász algorithm (see Lenstra, Lenstra, Jr., and Lovász (1982)) and is left to the reader. Theorem 2.1 asserts that the Lovász algorithm finds integer dependencies between the generators of a lattice whenever an integer dependency exists. On the other hand, if the input vectors $\bar{\mathbf{b}}_1, \cdots, \bar{\mathbf{b}}_s$ do not generate a lattice then the Lovász algorithm may fail to find integer dependencies. This occurs, e.g., if $\bar{\mathbf{b}}_2 = \alpha \bar{\mathbf{b}}_1$ for some irrational α and $\bar{\mathbf{b}}_1 = \bar{\mathbf{b}}_3$. Then the Lovász algorithm successively reduces and exchanges $\bar{\mathbf{b}}_1, \bar{\mathbf{b}}_2$ an infinite number of times, so that the vector $\bar{\mathbf{b}}_1$ converges to $\mathbf{0}$ but it does not achieve $\bar{\mathbf{b}}_1 = \mathbf{0}$. It never detects the integer dependency $\mathbf{b}_1 = \mathbf{b}_3$. We present an algorithm to find integer dependencies in § 5.

3. Finding integer relations. The Basic Integer Relation Algorithm can be adapted to detect small integer relations and also to rule out the existence of small integer relations by adding a suitable termination test to the algorithm. We call the resulting algorithm the Small Integer Relation Algorithm.

SMALL INTEGER RELATION ALGORITHM. (On input $\mathbf{x} \in \mathbb{R}^n$ and $k \in \mathbb{N}$ this algorithm either finds an integer relation $\mathbf{c}_n$ for $\mathbf{x}$ satisfying $\|\mathbf{c}_n\|^2 \leqq 2^{n-2}\lambda(\mathbf{x})^2$ or it proves $\lambda(\mathbf{x}) \geqq 2^k$.)

1. *Initiation.* For the vectors $\mathbf{b}_0 = x$ and standard basis $\mathbf{b}_1, \cdots, \mathbf{b}_n$ of $\mathbb{Z}^n$ compute the Gram-Schmidt quantities μ_{ij} and $\|\mathbf{b}_i^*\|^2$ for $0 \leqq i, j \leqq n$.
2. *Termination test.* If $\|\mathbf{b}_n^*\| \neq 0$ then an integer relation is found. Compute the matrix $[\mathbf{c}_1, \cdots, \mathbf{c}_n]^\top = [\mathbf{b}_1, \cdots, \mathbf{b}_n]^{-1}$, output the integer relation $\mathbf{c}_n$, and stop. If $\|\mathbf{b}_i^*\| \leqq 2^{-k}$ for $1 \leqq i \leqq n$, then no small integer relation exists. Output "$\lambda(\mathbf{x}) \geqq 2^k$" and stop.
3. *Exchange step.* Choose for $1 \leqq i \leqq n$ that i that maximizes $2^i\|\mathbf{b}_i^*\|^2$. Size-reduce $\mathbf{b}_{i+1}$ with respect to $\mathbf{b}_i$ by setting $\mathbf{b}_{i+1} := \mathbf{b}_{i+1} - \lceil \mu_{i+1,i} \rfloor \mathbf{b}_i$. Exchange $\mathbf{b}_i$ and $\mathbf{b}_{i+1}$. Now update $\|\mathbf{b}_\nu^*\|^2$, $\mu_{\nu,j}$, $\mu_{j,\nu}$ for $\nu = i, i+1$ and $1 \leqq j \leqq n$. Go to 2.

Instead of computing, on termination, the inverse matrix $[\mathbf{c}_1, \cdots, \mathbf{c}_n]^\top = [\mathbf{b}_1, \cdots, \mathbf{b}_n]^{-1}$, we can compute it incrementally. Initially $[\mathbf{c}_1, \cdots, \mathbf{c}_n]$ is the unit matrix. A reduction step $\mathbf{b}_{i+1} := \mathbf{b}_{i+1} - \lceil \mu_{i+1,i} \rfloor \mathbf{b}_i$ changes the vectors $\mathbf{c}_1, \cdots, \mathbf{c}_n$ as $\mathbf{c}_i := \mathbf{c}_i + \lceil \mu_{i+1,i} \rfloor \mathbf{c}_{i+1}$. For an exchange $\mathbf{b}_i \leftrightarrow \mathbf{b}_{i+1}$ we have to exchange $\mathbf{c}_i$ and $\mathbf{c}_{i+1}$.

In analyzing this algorithm, we first prove that the termination test gives a correct answer when it applies. (We defer until later a proof that the termination condition will eventually hold for any input.)

PROPOSITION 3.1 (Correctness of Small Integer Relation Algorithm).

(1) *The output* $\mathbf{c}_n$ *in step* 2 *is an integer relation for* $\mathbf{x}$.

(2) $\lambda(\mathbf{x}) \geqq 1/\max_i \|\mathbf{b}_i^*\|$ *holds for every basis* $\mathbf{b}_1, \cdots, \mathbf{b}_n$ *of the lattice* $\mathbb{Z}^n$.

(3) *The output* $\mathbf{c}_n$ *satisfies* $\|\mathbf{c}_n\|^2 \leqq 2^{n-2} \min\{\lambda(\mathbf{x})^2, 2^{2k}\}$.

Proof. In the proof i ranges over $1 \leqq i \leqq n$ only.

(1) Let $\mathbf{b}_n^* \neq \mathbf{0}$; then $\mathbf{b}_i^* = \mathbf{0}$ holds for some $i < n$. The vectors $\mathbf{b}_1, \cdots, \mathbf{b}_i$ are linearly independent but linearly dependent mod $(\mathbf{x}\mathbb{R})$, and thus $\mathbf{x} \in \text{span}(\mathbf{b}_1, \cdots, \mathbf{b}_i)$. Since $\langle \mathbf{b}_j, \mathbf{c}_k \rangle = 0$ holds for $k > j$ this implies $\langle \mathbf{x}, \mathbf{c}_k \rangle = 0$ for $k > i$ and in particular $\langle \mathbf{x}, \mathbf{c}_n \rangle = 0$. The vector $\mathbf{c}_n$ is integral since it is part of the inverse of the unimodular matrix $[\mathbf{b}_1, \cdots, \mathbf{b}_n]$.

(2) Let $\mathbf{m}$ be any integer relation for $\mathbf{x}$. Since $\mathbf{m} \in (\mathbf{x}\mathbb{R})^{\perp} = \text{span}(\mathbf{b}_1^*, \cdots, \mathbf{b}_n^*)$ there exists i with $\langle \mathbf{m}, \mathbf{b}_i^* \rangle \neq 0$. For the smallest such i we have $\langle \mathbf{m}, \mathbf{b}_i^* \rangle = \langle \mathbf{m}, \mathbf{b}_i \rangle \in \mathbb{Z}$, and hence $|\langle \mathbf{m}, \mathbf{b}_i^* \rangle| \geqq 1$, and thus $\|\mathbf{m}\| \geqq \|\mathbf{b}_i^*\|^{-1}$. This shows that the Small Integer Relation Algorithms correctly claims "$\lambda(\mathbf{x}) \geqq 2^k$" in step 2.

(3) The integer relation $\mathbf{c}_n$ found by the algorithm is determined by

$$[\mathbf{c}_1, \cdots, \mathbf{c}_n]^{\top} = [\mathbf{b}_1, \cdots, \mathbf{b}_n]^{-1}$$

where $\mathbf{b}_1, \cdots, \mathbf{b}_n$ is the terminal basis of lattice $\mathbb{Z}^n$. Since both $\mathbf{b}_n^*$ and $\mathbf{c}_n$ are orthogonal to $\mathbf{x}, \mathbf{b}_1, \cdots, \mathbf{b}_{n-1}$ we have $\text{span}(\mathbf{b}_n^*) = \text{span}(\mathbf{c}_n)$, and it follows from $\langle \mathbf{b}_n, \mathbf{c}_n \rangle = 1$ that

$$\mathbf{c}_n = \pm \mathbf{b}_n^* \|\mathbf{b}_n^*\|^{-2}, \qquad \|\mathbf{c}_n\| = \|\mathbf{b}_n^*\|^{-1}. \tag{3.1}$$

Let $\bar{\mathbf{b}}_1, \cdots, \bar{\mathbf{b}}_n$ be the basis of lattice $\mathbb{Z}^n$ before the last exchange $\mathbf{b}_n \leftrightarrow \mathbf{b}_{n-1}$. (If there is no such exchange then $\|\mathbf{c}_n\| = 1$ and the claim holds.) We have $\max_i \|\bar{\mathbf{b}}_i^*\|^2 2^i = \|\bar{\mathbf{b}}_{n-1}^*\|^2 2^{n-1}$, which implies

$$\|\bar{\mathbf{b}}_i^*\|^2 \leqq 2^{n-i-1} \|\bar{\mathbf{b}}_{n-1}^*\|^2 = 2^{n-i-1} \|\mathbf{b}_n^*\|^2 \quad \text{for } i = 1, \cdots, n-1.$$

From this we conclude that

$$\|\mathbf{c}_n\|^2 = \|\mathbf{b}_n^*\|^{-2} \leqq 2^{n-2} / \max_i \|\bar{\mathbf{b}}_i^*\|^2.$$

From (2) and since the algorithm did not terminate previously we see

$$1/\max_i \|\bar{\mathbf{b}}_i^*\|^2 \leqq \min\{\lambda(\mathbf{x})^2, 2^{2k}\}.$$

Thus the claim follows from the two latter inequalities. □

This proposition reveals the underlying motivation for Bergman's exchange rule: it is designed to prove there is no short integer relation as quickly as possible. Since we have $\lambda(\mathbf{x}) \geqq 1/\max_i \|\mathbf{b}_i^*\|$ it is reasonable to minimize $\max_i \|\mathbf{b}_i^*\|$. Bergman's exchange rule strives to minimize $\max_i 2^i \|\mathbf{b}_i^*\|^2$, where the extra powers of two are included so that we can make a profitable exchange.

Now we prove a running time bound for the Small Integer Relation Algorithm.

THEOREM 3.2. *The Small Integer Relation Algorithm halts after at most* $O(n^3(k+n))$ *arithmetic steps on real numbers. It either finds an integer relation* $\mathbf{c}_n$ *for* $\mathbf{x}$ *satisfying* $\|\mathbf{c}_n\|^2 \leqq 2^{n-2} \min\{\lambda(\mathbf{x})^2, 2^{2k}\}$ *or else it proves* $\lambda(\mathbf{x}) \geqq 2^k$.

Proof. We measure the progress of the algorithm using the quantity

$$D = \prod_{i=1}^{n-1} \alpha(\mathbf{b}_i^*)^{n-i} \quad \text{where } \alpha(\mathbf{b}_i^*) = \max\{\|\mathbf{b}_i^*\|^2 2^n, 2^{-2k}\}.$$

LEMMA 3.3. *Every exchange step of the Small Integer Relation Algorithm achieves*

$$D_{\text{new}} \leqq \tfrac{3}{4} D_{\text{old}}.$$

The lemma extends the time analysis of the Lovász algorithm to the Small Integer Relation Algorithm. It holds for arbitrary positive numbers k. Lemma 3.3 holds for Bergman's exchange rule, but does not hold if, in the algorithm, the Lovász exchange rule is used instead. However in the particular case $k=\infty$, i.e., $\alpha(\mathbf{b}_i^*) = \|\mathbf{b}_i^*\|^2 2^n$, the lemma does hold for the Lovász exchange rule. The Lovász exchange rule performs well provided that the numbers $\|\mathbf{b}_i^*\|$ cannot become arbitrarily small and nonzero, as is the case for reduction of a generator system of a lattice (Theorem 2.1). The lemma shows that Bergman's exchange rule performs well in some sense even if some of the numbers $\|\mathbf{b}_i^*\|$ become arbitrarily small and nonzero during the computation. There is a subtle interplay between the termination condition $\max_{i=1,\cdots,n-1} \|\mathbf{b}_i^*\| \leqq 2^{-k}$ and Bergman's exchange rule. Bergman's exchange rule strives to make this termination condition valid as soon as possible.

Proof. Since i has been chosen to maximize the number $2^i \|\mathbf{b}_i^*\|^2$, we have

$$\|\mathbf{b}_{i+1}^{\text{old}^*}\|^2 \leqq \tfrac{1}{2} \|\mathbf{b}_i^{\text{old}^*}\|^2.$$

From this and $|\mu_{i+1,i}| \leqq \frac{1}{2}$ we see

$$\|\mathbf{b}_i^{\text{new}^*}\|^2 = \|\mathbf{b}_{i+1}^{\text{old}^*}\|^2 + \mu_{i+1,i}^2 \|\mathbf{b}_i^{\text{old}^*}\|^2 \leqq \tfrac{3}{4} \|\mathbf{b}_i^{\text{old}^*}\|^2. \tag{3.2}$$

Since the algorithm did not previously terminate in step 2 some j satisfies $\|\mathbf{b}_j^{\text{old}^*}\| > 2^{-k}$. Since i has been chosen to maximize $2^i \|\mathbf{b}_i^*\|^2$ we have

$$2^n \|\mathbf{b}_i^{\text{old}^*}\|^2 \geqq 2^i \|\mathbf{b}_i^{\text{old}^*}\|^2 \geqq 2^j \|\mathbf{b}_j^{\text{old}^*}\|^2 \geqq 2^{-2k+j} \geqq 2^{-2k+1}. \tag{3.3}$$

We conclude from $\|\mathbf{b}_i^{\text{old}^*}\| \geqq \|\mathbf{b}_{i+1}^{\text{new}^*}\|$ that

$$\alpha(\mathbf{b}_i^{\text{old}^*}) \geqq \alpha(\mathbf{b}_{i+1}^{\text{new}^*}). \tag{3.4}$$

We are going to prove the inequality

$$\frac{\alpha(\mathbf{b}_i^{\text{new}^*})\alpha(\mathbf{b}_{i+1}^{\text{new}^*})}{\alpha(\mathbf{b}_i^{\text{old}^*})\alpha(\mathbf{b}_{i+1}^{\text{old}^*})} \leqq 1. \tag{3.5}$$

If $\alpha(\mathbf{b}_i^{\text{new}^*}) = 2^{-2k}$, then (3.5) follows from (3.4) and $\alpha(\mathbf{b}_{i+1}^{\text{old}^*}) \geqq 2^{-2k}$. If $\alpha(\mathbf{b}_{i+1}^{\text{new}^*}) = 2^{-2k}$, the inequality (3.5) follows from $\alpha(\mathbf{b}_{i+1}^{\text{old}^*}) \geqq 2^{-2k}$ and $\alpha(\mathbf{b}_i^{\text{new}^*}) \leqq \alpha(\mathbf{b}_i^{\text{old}^*})$, which follows from (3.2). If $\alpha(\mathbf{b}_i^{\text{new}^*}) = \|\mathbf{b}_i^{\text{new}^*}\|^2 2^n$ and $\alpha(\mathbf{b}_{i+1}^{\text{new}^*}) = \|\mathbf{b}_{i+1}^{\text{new}^*}\|^2 2^n$ the inequality (3.5) holds by virtue of

$$\|\mathbf{b}_i^{\text{new}^*}\| \, \|\mathbf{b}_{i+1}^{\text{new}^*}\| = \|\mathbf{b}_i^{\text{old}^*}\| \, \|\mathbf{b}_{i+1}^{\text{old}^*}\|.$$

From the inequality (3.5) we finally conclude

$$\frac{D_{\text{new}}}{D_{\text{old}}} = \frac{\alpha(\mathbf{b}_i^{\text{new}^*})^{n-i} \alpha(\mathbf{b}_{i+1}^{\text{new}^*})^{n-i-1}}{\alpha(\mathbf{b}_i^{\text{old}^*})^{n-i} \alpha(\mathbf{b}_{i+1}^{\text{old}^*})^{n-i-1}}$$

$$\overset{(3.5)}{\leqq} \alpha(\mathbf{b}_i^{\text{new}^*}) / \alpha(\mathbf{b}_i^{\text{old}^*}) \overset{(3.3)}{=} 2^{-n} \alpha(\mathbf{b}_i^{\text{new}^*}) \|\mathbf{b}_i^{\text{old}^*}\|^{-2} \overset{(3.2),(3.3)}{\leqq} \frac{3}{4}. \qquad \square$$

To complete the proof of Theorem 3.2, it suffices to observe that the algorithm starts with $D \leqq 2^{n^3}$, and $D \geqq 2^{-kn^2}$ holds on termination. Thus by Lemma 3.3 there can be at most $O(n^2(k+n))$ exchange steps. Each exchange step uses at most $O(n)$

arithmetic steps; this includes the steps to update $\mu_{i,j}$, $\mu_{i+1,j}\mu_{j,i}$, $\mu_{j,i+1}$ for $j=1,\cdots,n$ and $\|\mathbf{b}_i^*\|^2$, $\|\mathbf{b}_{i+1}^*\|^2$. The initial computation of the numbers $\mu_{i,j}$, $\|\mathbf{b}_i^*\|^2$ for $1<j<i\leqq n$ can be done using $O(n^3)$ arithmetic operations. This shows that the algorithm halts after at most $O(n^3(k+n))$ arithmetic operations on real numbers.

The second part of the theorem follows immediately from Proposition 3.1. □

Theorem 3.2 implies that the Basic Integer Relation Algorithm always detects an integer relation in $O(n^3 \log \lambda(\mathbf{x})+n)$ arithmetic operations if one exists; simply apply the Small Integer Relation Algorithm with $k=2^j$ for $j=1, 2, \cdots$, until an integer relation is found.

An interesting feature of the integer relation problem is that it contains a gap between the largest size 2^{n+k} of an integer relation found and the size 2^k of an integer relation proved not to exist. Some sort of gap like this seems necessary in order to obtain polynomial time algorithms. It is unreasonable to expect that there exists a fast algorithm to answer the question: "Does there exist an integer relation $\mathbf{m}$ for $\mathbf{x}$ with $\|\mathbf{m}\|\leqq 2^k$?" This problem contains the shortest vector problem for integer lattices, i.e., the problem to decide for a given lattice basis whether there exists a lattice vector $\mathbf{y}$ with $\|\mathbf{y}\|\leqq 2^k$. This problem is believed to be hard and is known to be NP-complete for the version in which the Euclidean norm $\|\mathbf{y}\|$ is replaced by the sup-norm $\|\mathbf{y}\|_{\sup}$ (see Van Emde Boas (1981)).

The Small Integer Relation Algorithm can also be applied starting with a basis $\mathbf{b}_1,\cdots,\mathbf{b}_n\in\mathbb{R}^n$ of an arbitrary lattice $M=\langle\mathbf{b}_1,\cdots,\mathbf{b}_n\rangle$ of rank n, possibly distinct from $\mathbb{Z}^n$. In this case the row vectors $\mathbf{c}_1,\cdots,\mathbf{c}_n$ of the matrix

$$[\mathbf{c}_1,\cdots,\mathbf{c}_n]^{\top}=[\mathbf{b}_1,\cdots,\mathbf{b}_n]^{-1}$$

form a basis of the *dual (or reciprocal, or polar) lattice* M^*, defined as

$$M^*=\{\mathbf{y}\in \operatorname{span}(\mathbf{b}_1,\cdots,\mathbf{b}_n)\,|\,\langle\mathbf{b}_i,\mathbf{y}\rangle\in\mathbb{Z} \text{ for } i=1,\cdots,n\}.$$

(In the case $M=\mathbb{Z}^n$ we have $M=\mathbb{Z}^n=M^*$.) In this case we consider the lattice

$$L_{\mathbf{x},M}=\{\mathbf{y}\in M^*\,|\,\langle\mathbf{y},\mathbf{x}\rangle=0\}$$

of relations $\mathbf{y}$ for $\mathbf{x}$ that are in M^*. Let $\lambda_M(\mathbf{x})$ be the length of the shortest, nonzero relation in $L_{\mathbf{x},M}$. Proposition 3.1 holds for arbitrary lattices $M\subset\mathbb{R}^n$ of rank n provided that relations for $\mathbf{x}$ are in $M^*$and $\lambda(\mathbf{x})$ is replaced by $\lambda_M(\mathbf{x})$. The time analysis of Lemma 3.3 remains valid, too. This observation proves the following result.

THEOREM 3.4. *Suppose the Small Integer Relation Algorithm is run with input* $\mathbf{x}\in\mathbb{R}^n$ *and starting with a basis* $\mathbf{b}_1,\cdots,\mathbf{b}_n$ *of lattice* $M\subset\mathbb{R}^n$. *Then the Small Integer Relation Algorithm halts after at most* $O(n^3(k+n))$ *arithmetic steps. It either finds a relation* $\mathbf{c}_n\in M^*$ *for* $\mathbf{x}$ *satisfying* $\|\mathbf{c}_n\|^2\leqq 2^{n-2}\min\{\lambda_M(\mathbf{x})^2, 2^{2k}\}$ *or it proves* $\lambda_M(\mathbf{x})\geqq 2^k$.

The arithmetic complexity model describes computations with real numbers although on actual computers we can only approximate computations with real numbers. In particular, it is an undecidable problem to test the equality of two computable real numbers specified by computer programs that compute them to arbitrary accuracy. In consequence on an actual computer (Turing machine) we cannot prove the existence of an integer relation for a set of real numbers. However we *can* prove the nonexistence of a small integer relation using only computations on rational numbers. We can prove $\lambda(\bar{\mathbf{x}})\geqq 2^k$ for a given real vector $\bar{\mathbf{x}}$ by applying the Small Integer Relation Algorithm to a sufficiently close rational approximation $\mathbf{x}$ to $\bar{\mathbf{x}}$. We cannot say beforehand how close $\mathbf{x}$ has to be to $\bar{\mathbf{x}}$, but the term "sufficiently close" can be defined a posteriori. We can certify that a given $\mathbf{x}$ is "sufficiently close" to $\bar{\mathbf{x}}$ by the following theorem.

THEOREM 3.5. *Suppose that the Small Integer Relation Algorithm claims "*$\lambda(\mathbf{x}) \geqq 2^k$*." Then* $\lambda(\bar{\mathbf{x}}) \geqq 2^{k-1}$ *holds for every vector* $\bar{\mathbf{x}} \in \mathbb{R}^n$ *such that* $\max_i \|\mathbf{b}_i\| \|\mathbf{x} - \bar{\mathbf{x}}\| \leqq 2^{-k} \min\{\|\mathbf{x}\|, \|\bar{\mathbf{x}}\|\}$ *where* $\mathbf{b}_1, \cdots, \mathbf{b}_n$ *is the basis on termination.*

Proof. Let $\mathbf{b}^*_{i,\mathbf{x}}$, ($\mathbf{b}^*_{i,\bar{\mathbf{x}}}$, respectively) be the component of $\mathbf{b}_i$ that is orthogonal to $\mathbf{b}_1, \cdots, \mathbf{b}_{i-1}$, $\mathbf{x}$ (to $\mathbf{b}_1, \cdots, \mathbf{b}_{i-1}$, $\bar{\mathbf{x}}$, respectively), and let $\pi_{\mathbf{x}}$, $\pi_{\bar{\mathbf{x}}}$ be the orthogonal projection to $(\mathbf{x}\mathbb{R})^\top$, $(\bar{\mathbf{x}}\mathbb{R})^\top$. It is sufficient to prove $\|\mathbf{b}^*_{i,\bar{\mathbf{x}}}\| \leqq 2^{-k+1}$ for $i = 1, \cdots, n$, which implies $\lambda(\bar{\mathbf{x}}) \geqq 2^{k-1}$ by Proposition 3.1. Below we show the inequality

$$\|\pi_{\mathbf{x}}(\mathbf{b}) - \pi_{\bar{\mathbf{x}}}(\mathbf{b})\| \leqq \|\mathbf{b}\| \|\mathbf{x} - \bar{\mathbf{x}}\| \text{ for all } \mathbf{b}, \mathbf{x}, \bar{\mathbf{x}} \text{ satisfying } \|\mathbf{x}\|, \|\bar{\mathbf{x}}\| \geqq 1. \tag{3.6}$$

This implies for all vectors $\mathbf{x}$, $\bar{\mathbf{x}}$

$$\|\mathbf{b}^*_{i,\mathbf{x}} - \mathbf{b}^*_{i,\bar{\mathbf{x}}}\| \leqq \|\mathbf{b}_i\| \|\mathbf{x} - \bar{\mathbf{x}}\| / \min\{\|\mathbf{x}\|, \|\bar{\mathbf{x}}\|\} \leqq 2^{-k}$$

by the assumptions on $\mathbf{x}$, $\bar{\mathbf{x}}$, and $\mathbf{b}_i$. Since on termination the Small Integer Relation Algorithm has $\|\mathbf{b}^*_{i,\mathbf{x}}\| \leqq 2^{-k}$ for $i = 1, \cdots, n$ the inequality above yields $\|\mathbf{b}^*_{i,\bar{\mathbf{x}}}\| \leqq 2^{-k+1}$ for $i = 1, \cdots, n$, which proves the theorem.

Proof of equation (3.6). We prove this in three cases.

Case $\|\mathbf{x}\| = \|\bar{\mathbf{x}}\| = 1$ and $\mathbf{b} \in \text{span}(\mathbf{x}, \bar{\mathbf{x}})$. Without loss of generality let $\mathbf{x}$, $\bar{\mathbf{x}}$, $\mathbf{b} \in \mathbb{R}^2$, and $\mathbf{x} = (x_1, x_2)$, $\bar{\mathbf{x}} = (1, 0)$, $\mathbf{b} = (b_1, b_2)$. Then we have

$$\begin{aligned}
\|\pi_{\mathbf{x}}(\mathbf{b}) - \pi_{\bar{\mathbf{x}}}(\mathbf{b})\|^2 &= \|\langle \mathbf{x}, \mathbf{b}\rangle \mathbf{x} - \langle \bar{\mathbf{x}}, \mathbf{b}\rangle \bar{\mathbf{x}}\|^2 \\
&= ((x_1 b_1 + x_2 b_2) x_1 - b_1)^2 + (x_1 b_1 + x_2 b_2)^2 x_2^2 \\
&= b_1^2 - 2 b_1 x_1 (x_1 b_1 + x_2 b_2) + (x_1 b_1 + x_2 b_2)^2 \quad (\text{since } x_1^2 + x_2^2 = 1) \\
&= b_1^2 + x_2^2 b_2^2 - x_1^2 b_1^2 = \|\mathbf{b}\|^2 x_2^2 \leqq \|\mathbf{b}\|^2 \|\mathbf{x} - \bar{\mathbf{x}}\|^2.
\end{aligned}$$

Case $\|\mathbf{x}\| = \|\bar{\mathbf{x}}\| \geqq 1$. Let $\bar{\mathbf{b}}$ be the component of $\mathbf{b}$ in span $(\mathbf{x}, \bar{\mathbf{x}})$. Then

$$\|\pi_{\mathbf{x}}(\mathbf{b}) - \pi_{\bar{\mathbf{x}}}(\mathbf{b})\| = \|\pi_{\mathbf{x}}(\bar{\mathbf{b}}) - \pi_{\bar{\mathbf{x}}}(\bar{\mathbf{b}})\| \leqq \|\bar{\mathbf{b}}\| \|\mathbf{x} - \bar{\mathbf{x}}\| \leqq \|\mathbf{b}\| \|\mathbf{x} - \bar{\mathbf{x}}\|$$

follows from the previous case.

General Case. We assume without loss of generality that $\|\bar{\mathbf{x}}\| \geqq \|\mathbf{x}\| \geqq 1$. Application of the previous case to $\tilde{\mathbf{x}} = \bar{\mathbf{x}}\|\mathbf{x}\| / \|\bar{\mathbf{x}}\|$ gives $\|\pi_{\mathbf{x}}(\mathbf{b}) - \pi_{\bar{\mathbf{x}}}(\mathbf{b})\| = \|\pi_{\mathbf{x}}(\mathbf{b}) - \pi_{\tilde{\mathbf{x}}}(\mathbf{b})\| \leqq \|\mathbf{b}\| \|\mathbf{x} - \tilde{\mathbf{x}}\| \leqq \|\mathbf{b}\| \|\mathbf{x} - \bar{\mathbf{x}}\|$. □

4. Finding linearly independent integer relations. There is a natural adaptation of the Small Integer Relation Algorithm to find several small linearly independent integer relations. We modify the exchange rule and the termination test accordingly. The following algorithm either finds r small linearly independent integer relations or proves they do not exist.

SEVERAL RELATIONS ALGORITHM. (On input $\mathbf{x} \in \mathbb{R}^n$ and r, $k \in \mathbb{N}$ this algorithm either finds r linearly independent integer relations $\mathbf{c}_{n-r+1}, \cdots, \mathbf{c}_n$ for $\mathbf{x}$ or it proves that $\lambda_r(\mathbf{x}) \geqq 2^k$.)

1. *Initiation.* For $\mathbf{b}_0 = \mathbf{x}$ and the standard basis $\mathbf{b}_1, \cdots, \mathbf{b}_n$ of $\mathbb{Z}^n$ compute the Gram-Schmidt numbers $\mu_{i,j}$, $\|\mathbf{b}^*_i\|^2$ for $1 \leqq i, j \leqq n$. Find the unique $s \leqq n$ such that $\mathbf{b}^*_s = \mathbf{0}$.
2. *Termination test.* If $s \leqq n - r$ then r linearly independent integer relations are found; size-reduce $\mathbf{b}_1, \cdots, \mathbf{b}_n$, set $[\mathbf{c}_1, \cdots, \mathbf{c}_n]^\top := [\mathbf{b}_1, \cdots, \mathbf{b}_n]^{-1}$, output $\mathbf{c}_{n-r+1}, \cdots, \mathbf{c}_n$ and stop. If $\|\mathbf{b}^*_i\| \leqq 2^{-k}$ for $1 \leqq i \leqq n - r + 1$ then r small independent relations do not exist, output "$\lambda_r(\mathbf{x}) \geqq 2^k$" and stop.
3. *Exchange step.* Choose that i with $1 \leqq i < s$ that maximizes $\|\mathbf{b}^*_i\|^2 2^i$. Size-reduce $\mathbf{b}_{i+1}$ with respect to $\mathbf{b}_i$ by setting $\mathbf{b}_{i+1} := \mathbf{b}_{i+1} - \lceil \mu_{i+1,i} \rfloor \mathbf{b}_i$. Exchange $\mathbf{b}_i$ and $\mathbf{b}_{i+1}$.

Update the Gram-Schmidt quantities $\|\mathbf{b}_\nu^*\|^2, \mu_{\nu,j}, \mu_{j,\nu}$ for $\nu = i, i+1$ and $1 \leqq j \leqq n$. If $\mathbf{b}_i^* = \mathbf{0}$ then set $s := i$. Go to 2.

There are two features that distinguish this algorithm from the Small Integer Relation Algorithm. First, the exchange rule only allows exchanges $\mathbf{b}_i \leftrightarrow \mathbf{b}_{i+1}$ such that i is smaller than that s for which $\mathbf{b}_s^* = \mathbf{0}$. This exchange rule strives to minimize $\max_{j=1,\cdots,s} \|\mathbf{b}_j^*\|^2 2^j$ where $s \geqq n-r$ holds throughout the algorithm. This rule is justified by fact (4.1) proved below that $1/\max_{j=1,\cdots,n-r+1} \|\mathbf{b}_j^*\|$ is a lower bound for $\lambda_r(\mathbf{x})$. The termination condition is modified accordingly so that the algorithm stops if $\max_{i=1,\cdots,n-r+1} \|\mathbf{b}_i^*\| \leqq 2^{-k}$. Second, in the termination step before computing the inverse matrix $[\mathbf{c}_1, \cdots, \mathbf{c}_n]^\top = [\mathbf{b}_1, \cdots, \mathbf{b}_n]^{-1}$, the basis $\mathbf{b}_1, \cdots, \mathbf{b}_n$ is size-reduced. This size-reduction makes the output relations $\mathbf{c}_{n-r+1}, \cdots, \mathbf{c}_n$ small as is proved in Theorem 4.2 below. The resulting basis $\mathbf{b}_1, \cdots, \mathbf{b}_n$ has the same $\mathbf{b}_i^*$ as before and $|\mu_{i,j}| \leqq \frac{1}{2}$ holds for all $1 \leqq j < i \leqq n$.

THEOREM 4.1. *When given for input a vector $\mathbf{x} \in \mathbb{R}^n$ and r, $k \in \mathbb{N}$ then the Several Relations Algorithm either finds r linearly independent integer relations $\mathbf{c}_{n-r+1}, \cdots, \mathbf{c}_n$ for $\mathbf{x}$ or proves $\lambda_r(\mathbf{x}) \geqq 2^k$. It halts after at most $O(n^3(k+n))$ arithmetic operations on real numbers.*

Proof. Correctness. The algorithm has two possibilities for termination. First, if $\mathbf{b}_s^* = \mathbf{0}$ occurs with $s \leqq n-r$ then $\mathbf{x} \in \text{span}(\mathbf{b}_1, \cdots, \mathbf{b}_{n-r})$. Since $\mathbf{c}_{n-r+1}, \cdots, \mathbf{c}_n$ are orthogonal to span $(\mathbf{b}_1, \cdots, \mathbf{b}_{n-r})$ they are r linearly independent integer relations for $\mathbf{x}$. Second, we must show that $\|\mathbf{b}_i^*\| \leqq 2^{-k}$ for $i = 1, \cdots, n-r+1$ implies $\lambda_r(\mathbf{x}) \geqq 2^k$. This follows from the claim that

$$\lambda_r(\mathbf{x}) \geqq 1/\max_{1 \leqq i \leqq n-r+1} \|\mathbf{b}_i^*\|. \tag{4.1}$$

To prove this inequality let $\mathbf{m}_1, \cdots, \mathbf{m}_r \in L_\mathbf{x}$ be linearly independent vectors such that $\|\mathbf{m}_i\| = \lambda_i(\mathbf{x})$ for $i = 1, \cdots, r$. Then there exists $i \leqq n-r+1$ and $j \leqq r$ such that $\langle \mathbf{m}_j, \mathbf{b}_i \rangle \neq 0$. For fixed j let i be minimal with $\langle \mathbf{m}_j, \mathbf{b}_i \rangle \neq 0$. This yields

$$|\langle \mathbf{m}_j, \mathbf{b}_i \rangle| = |\langle \mathbf{m}_j, \mathbf{b}_i^* \rangle| \geqq 1.$$

Hence $\|\mathbf{m}_j\| \geqq 1/\|\mathbf{b}_i^*\|$, which proves (4.1).

Running time bound. We use the quantity $D = \prod_{i=1}^n \max\{\|\mathbf{b}_i^*\|^2 2^n, 2^{-2k}\}^{n-i}$ used in the proof of Theorem 3.2. We claim that at each exchange step we have

$$D_{\text{new}} \leqq \tfrac{3}{4} D_{\text{old}}. \tag{4.2}$$

This follows by the argument of Lemma 3.3, with two modifications to reflect the new exchange rule. The new algorithm exchanges $\mathbf{b}_i$ and $\mathbf{b}_{i+1}$ where $2^i \|\mathbf{b}_i^*\|^2$ is maximized over $1 \leqq i \leqq s-1$, and $\mathbf{b}_s^* = \mathbf{0}$. Thus

$$\|\mathbf{b}_{i+1}^{\text{old}^*}\|^2 \leqq \tfrac{1}{2} \|\mathbf{b}_i^{\text{old}^*}\|^2$$

still holds. Since the algorithm did not previously halt there is some j with $1 \leqq j \leqq s-1$, $\|\mathbf{b}_j^{\text{old}^*}\| > 2^{-k}$, and the inequality

$$2^n \|\mathbf{b}_i^{\text{old}^*}\|^2 \geqq 2^i \|\mathbf{b}_i^{\text{old}^*}\|^2 \geqq 2^j \|\mathbf{b}_j^{\text{old}^*}\|^2 \geqq 2^{-2k+j} \geqq 2^{-2k+1} \tag{3.3}$$

still holds.

The $O(n^3(n+k))$ arithmetic operation bound now follows from (4.2) exactly as in Theorem 3.2. □

THEOREM 4.2. *If the Several Relations Algorithm finds r integer relations $\mathbf{c}_{n-r+1}, \cdots, \mathbf{c}_n$ for $\mathbf{x}$ then these satisfy $\|\mathbf{c}_{n-i+1}\|^2 \leqq 1.5^{2i-2} 2^{n-1} \lambda_i(\mathbf{x})^2$ for $i = 1, \cdots, r$.*

Proof. If the initiation step finds s with $s \leqq n-r$ then we have $\mathbf{c}_{n-i+1} = \mathbf{e}_{n-i+1}$ for $i = 1, \cdots, r$ and the claim holds. Now assume that initially we have $s > n-r$. Let $\mathbf{b}_1, \cdots, \mathbf{b}_n$ be the basis of lattice $\mathbb{Z}^n$ on termination of the Several Relations Algorithm. Since we have found r integer relations we have $\mathbf{b}_s^* = \mathbf{0}$ with $s = n-r$ and

$$[\mathbf{b}_1, \cdots, \mathbf{b}_n] = [\mathbf{b}_1^*, \cdots, \mathbf{b}_{s-1}^*, \mathbf{x}, \mathbf{b}_{s+1}^*, \cdots, \mathbf{b}_n^*] W^{\top},$$

holds for the matrix $W = [w_{i,j}]_{1 \leqq i,j \leqq n}$ with entries

$$w_{i,j} = \begin{cases} \langle \mathbf{b}_i, \mathbf{x} \rangle \|\mathbf{x}\|^{-2}, & j = s, \\ \mu_{i,j}, & j \neq s. \end{cases}$$

We have $w_{i,i} = 1$ for $i \neq s$ and, by the size-reduction in step 2, $|w_{i,j}| \leqq 1/2$ for $1 \leqq j < i \leqq n$ with $j \neq s$. The matrix W is lower triangular for all except the sth column, i.e., $w_{i,j} = 0$ for $i < j \neq s$. From the definition of $\mathbf{c}_1, \cdots, \mathbf{c}_n$ and since the vectors $\mathbf{x}, \mathbf{b}_1^*, \cdots, \mathbf{b}_n^*$ are orthogonal we conclude

$$\begin{aligned} [\mathbf{c}_1, \cdots, \mathbf{c}_n] &= ([\mathbf{b}_1, \cdots, \mathbf{b}_n]^{-1})^{\top} \\ &= [\mathbf{b}_1^*, \cdots, \mathbf{b}_{s-1}^*, \mathbf{x}, \mathbf{b}_{s+1}^*, \cdots, \mathbf{b}_n^*] \begin{bmatrix} \|\mathbf{b}_1^*\|^{-2} & & & & 0 \\ & \ddots & & & \\ & & \|\mathbf{x}\|^{-2} & & \\ & & & \ddots & \\ 0 & & & & \|\mathbf{b}_n^*\|^{-2} \end{bmatrix} W^{-1}. \end{aligned}$$

Let the matrix $V := W^{-1}$ have entries $v_{i,j}$. Since V is lower triangular for the last r columns we have

$$\|\mathbf{c}_{n-i+1}\|^2 = \sum_{j \geqq n-i+1} v_{j,n-i+1}^2 \|\mathbf{b}_j^*\|^{-2} \quad \text{for } i = 1, \cdots, r. \tag{4.3}$$

We prove below the inequalities

$$|v_{i,j}| \leqq 1.5^{i-j} \quad \text{for } s < j \leqq i \leqq n, \tag{4.4}$$

$$\|\mathbf{b}_{n-i+1}^*\|^{-2} \leqq \lambda_i(\mathbf{x})^2 2^{n-i-1} \quad \text{for } i = 1, \cdots, r. \tag{4.5}$$

The desired bounds follow from (4.3), (4.4), and (4.5):

$$\begin{aligned} \|\mathbf{c}_{n-i+1}\|^2 &\overset{(4.3),(4.4)}{\leqq} \sum_{j=1}^{i} 1.5^{2(i-j)} \|\mathbf{b}_{n-j+1}^*\|^{-2} \\ &\overset{(4.5)}{\leqq} \sum_{j=1}^{i} 1.5^{2(i-j)} 2^{n-j-1} \lambda_j(\mathbf{x})^2 \\ &\leqq \begin{cases} \lambda(\mathbf{x})^2 2^{n-2}, & i = 1, \\ \lambda_i(\mathbf{x})^2 1.5^{2i-2} 2^{n-1}, & i = 2, \cdots, r. \end{cases} \end{aligned}$$

It remains to prove the inequalities (4.4), (4.5). The inequality (4.4) follows from $|w_{i,j}| \leqq \frac{1}{2}$ for $s < j < i \leqq n$, $w_{i,i} = 1$ for $i > s$, together with the fact that the matrix W is lower triangular for the last r columns. We prove the inequality (4.4) by induction on $q = i - j$. If $q = 0$ we have $i = j$ and $v_{i,i} = 1$ holds for $i = s+1, \cdots, n$ since the matrix $V^{-1} = W$ is lower triangular, for the last $n-s$ columns, and has ones in the diagonal. For the induction step $q-1 \to q$ consider the equation

$$\sum_{t=j}^{i} \mu_{i,t} v_{t,j} = 0 \quad \text{for } s < j < i,$$

which follows from $V = W^{-1}$. We see that

$$v_{i,j} = -\sum_{t=j}^{j+q-1} \mu_{i,t} v_{t,j}$$

and the induction hypothesis implies

$$|v_{i,j}| \leqq \sum_{\nu=0}^{q-1} \frac{1}{2} 1.5^{\nu} \leqq 1.5^{q}.$$

To prove (4.5) consider the basis $\bar{\mathbf{b}}_1, \cdots, \bar{\mathbf{b}}_n$ of $\mathbb{Z}^n$ before the last exchange $\mathbf{b}_{n-r} \leftrightarrow \mathbf{b}_{n-r+1}$. The maximum of $\|\bar{\mathbf{b}}_j^*\|^2 2^j$ for $j \leqq n-r$ is at $j = n-r$, and $\bar{\mathbf{b}}_{n-r+1}^* = \mathbf{0}$. Thus we have for $j = 1, \cdots, n-r+1$:

$$\|\bar{\mathbf{b}}_j^*\|^2 \leqq \|\bar{\mathbf{b}}_{n-r}^*\|^2 2^{n-r-j} = \|\mathbf{b}_{n-r+1}^*\|^2 2^{n-r-j}.$$

Hence

$$\lambda_r(\mathbf{x}) \overset{(4.1)}{\geqq} 1/\max_{\nu \leqq n-r+1} \|\bar{\mathbf{b}}_\nu^*\| \geqq \|\mathbf{b}_{n-r+1}^*\|^{-1} 2^{(-n+r+1)/2}.$$

This proves (4.5) for $i = r$. The inequality (4.5) for $i < r$ follows in the same way from the basis of $\mathbb{Z}^n$ before the last exchange $\mathbf{b}_{n-i} \leftrightarrow \mathbf{b}_{n-i+1}$. □

The Several Relations Algorithm can also be modified to find a basis of a lattice L of integer relations for $\mathbf{x}$ that contains all shortest vectors in $L_{\mathbf{x}}$.

The *Shortest Relations Algorithm*, which takes as input $\mathbf{x} \in \mathbb{R}^n$, is just the Several Integer Relations Algorithm with a new termination test.

New termination test. If $s < n$ and $\|\mathbf{b}_j^*\| < \|\mathbf{b}_n^*\|$ holds for $1 \leqq j \leqq s-1$ then size-reduce $\mathbf{b}_1, \cdots, \mathbf{b}_n$, compute $[\mathbf{c}_1, \cdots, \mathbf{c}_n]^{\top} := [\mathbf{b}_1, \cdots, \mathbf{b}_n]^{-1}$, output $\mathbf{c}_{s+1}, \cdots, \mathbf{c}_n$, and stop.

The algorithm will not halt unless $\mathbf{x}$ has at least one integer relation. We show that if $L_{\mathbf{x}} \neq \{\mathbf{0}\}$ then the algorithm halts in time polynomial in n and $\log \lambda(\mathbf{x})$ and finds a lattice containing all shortest integer relations.

THEOREM 4.3. *When given for input a vector* $\mathbf{x}$ *with* $L_{\mathbf{x}} \neq \{\mathbf{0}\}$, *the Shortest Relations Algorithm finds integer relations* $\mathbf{c}_{s+1}, \cdots, \mathbf{c}_n$ *for* $\mathbf{x}$ *such that*:

(1) *The lattice* $\langle \mathbf{c}_{s+1}, \cdots, \mathbf{c}_n \rangle$ *contains all shortest integer relations for* $\mathbf{x}$,

(2) $\|\mathbf{c}_i\| \leqq 3^n \lambda(\mathbf{x})$ *for* $i = s+1, \cdots, n$.

The Shortest Relations Algorithm halts after at most $O(n^4 + n^3 \log \lambda(\mathbf{x}))$ *arithmetic operations on real numbers.*

Proof. Let $\mathbf{b}_1, \cdots, \mathbf{b}_n$ be the basis of lattice $\mathbb{Z}^n$ on termination of the Several Relations Algorithm. On termination we have $\mathbf{b}_s^* = \mathbf{0}$ and thus $\mathbf{x} \in \operatorname{span}(\mathbf{b}_1, \cdots, \mathbf{b}_s)$. Therefore the vectors $\mathbf{c}_{s+1}, \cdots, \mathbf{c}_n$ are integer relations for $\mathbf{x}$.

Next we show that the lattice

$$L = \langle \mathbf{c}_{s+1}, \cdots, \mathbf{c}_n \rangle$$

contains all $\mathbf{w} \in L_{\mathbf{x}}$ satisfying $\|\mathbf{w}\| \leqq \lambda(\mathbf{x})$. If $\mathbf{w}$ is not in the span of $\mathbf{c}_{s+1}, \cdots, \mathbf{c}_n$ there exists an integer $i \leqq s$ such that $\langle \mathbf{w}, \mathbf{b}_i \rangle \neq 0$ and consequently the smallest such i satisfies

$$|\langle \mathbf{w}, \mathbf{b}_i^* \rangle| = |\langle \mathbf{w}, \mathbf{b}_i \rangle| \geqq 1.$$

Since the new termination condition holds we have

$$\|\mathbf{w}\| \geqq \|\mathbf{b}_i^*\|^{-1} > \|\mathbf{b}_n^*\|^{-1} = \|\mathbf{c}_n\| \geqq \lambda(\mathbf{x}).$$

If however $\mathbf{w}$ is in the span of $\mathbf{c}_{s+1}, \cdots, \mathbf{c}_n$ then $\mathbf{w}$ must be in L since $\mathbf{c}_1, \cdots, \mathbf{c}_n$ is a basis of the lattice $\mathbb{Z}^n$.

We next establish property (2). Let $\mathbf{b}_1, \cdots, \mathbf{b}_n$ be the basis of lattice $\mathbb{Z}^n$ on termination of the Shortest Relations Algorithm. We have

$$\|\mathbf{c}_i\|^2 = \sum_{j=i}^{n} v_{j,i}^2 \|\mathbf{b}_j^*\|^{-2} \quad \text{for } i = s+1, \cdots, n$$

where $|v_{j,i}| \leqq 1.5^{j-i}$. Therefore the inequality (2) follows from

$$\|\mathbf{b}_j^*\|^{-2} \leqq \lambda(\mathbf{x})^2 2^{n+j-3} \quad \text{for } j = s+1, \cdots, n. \tag{4.6}$$

Proof of equation (4.6). The inequality holds for $\mathbf{b}_n^*$ since the output vector $\mathbf{c}_n = \pm \mathbf{b}_n^* \|\mathbf{b}_n^*\|^{-2}$ of the Shortest Relations Algorithms, by Proposition 3.1(3), satisfies $\|\mathbf{b}_n^*\|^{-2} = \|\mathbf{c}_n\|^2 \leqq 2^{n-2}\lambda(\mathbf{x})^2$. To prove the inequality for $\mathbf{b}_j^*$ with $s+1 \leqq j < n$, we consider the basis $\bar{\mathbf{b}}_1, \cdots, \bar{\mathbf{b}}_n$ before the last exchange step $\mathbf{b}_{j-1} \leftrightarrow \mathbf{b}_j$ of the Shortest Relations Algorithm. We have $\bar{\mathbf{b}}_n^* = \mathbf{b}_n^*$ and the exchange achieves $\mathbf{b}_{j-1}^{\text{new}^*} = \mathbf{0}$ and $\mathbf{b}_j^* = \mathbf{b}_j^{\text{new}^*} = \bar{\mathbf{b}}_{j-1}^*$. Before this exchange there exists $i < j$ satisfying $\|\bar{\mathbf{b}}_i^*\| > \|\bar{\mathbf{b}}_n^*\| = \|\mathbf{b}_n^*\|$, since the termination condition does not yet hold. From this and $\max_{i<j} \|\bar{\mathbf{b}}_i^*\|^2 2^i = \|\bar{\mathbf{b}}_{j-1}^*\|^2 2^{j-1}$ we conclude

$$\|\mathbf{b}_j^*\|^2 = \|\bar{\mathbf{b}}_{j-1}^*\|^2 \geqq \|\bar{\mathbf{b}}_i^*\|^2 2^{i-j+1} > \|\mathbf{b}_n^*\|^2 2^{i-j+1}.$$

This implies

$$\|\mathbf{b}_j^*\|^{-2} \leqq \|\mathbf{b}_n^*\|^{-2} 2^{j-i-1} \leqq \lambda(\mathbf{x})^2 2^{n-2} 2^{j-1},$$

which finishes the proof of (4.6).

Running time bound. We use the quantity

$$D = \prod_{i=1}^{n-1} \max\{\|\mathbf{b}_i^*\|^2 2^n, 2^{-n}\lambda(\mathbf{x})^{-2}\}^{n-i}.$$

It is the quantity of Lemma 3.3 except that 2^k is replaced by $2^{n/2}\lambda(\mathbf{x})$. We adjust the proof of Lemma 3.3 to show that each exchange step $\mathbf{b}_i \leftrightarrow \mathbf{b}_{i+1}$ achieves

$$D_{\text{new}} \leqq \tfrac{3}{4} D_{\text{old}}.$$

It is sufficient to show that the inequality (3.3) holds with 2^k replaced by $2^{n/2}\lambda(\mathbf{x})$, i.e., that $2^n \|\mathbf{b}_i^{\text{old}^*}\|^2 \geqq 2 \cdot 2^{-n}\lambda(\mathbf{x})^{-2}$ holds for each exchange $\mathbf{b}_i \leftrightarrow \mathbf{b}_{i+1}$.

We first show that there exists $j < s$ such that $\|\mathbf{b}_j^{\text{old}^*}\| \geqq 2^{-n/2}\lambda(\mathbf{x})^{-1}$. If $s < n$ this holds because $\mathbf{b}_n^{\text{old}}$ is the vector $\mathbf{b}_n$ on termination; since the algorithm did not previously halt there exists j with $1 \leqq j \leqq s-1$ such that $\|\mathbf{b}_j^{\text{old}^*}\| \geqq \|\mathbf{b}_n^{\text{old}^*}\| = \|\mathbf{c}_n\|^{-1} \geqq 2^{-n/2}\lambda(\mathbf{x})^{-1}$, where the latter inequality holds by Proposition 3.1(3). If $s = n$ we see from Proposition 3.1(2) that there exists $j \leqq n$ such that $\|\mathbf{b}_j^{\text{old}^*}\| \geqq \lambda(\mathbf{x})^{-1}$ and we have $j < n$ since $\|\mathbf{b}_n^{\text{old}^*}\| = 0$.

Since i with $1 \leqq i \leqq s-1$ was chosen such that $\|\mathbf{b}_i^{\text{old}^*}\|^2 2^i$ is maximal for $i < s$ we have for the above j that

$$2^n \|\mathbf{b}_i^{\text{old}^*}\|^2 \geqq 2^i \|\mathbf{b}_i^{\text{old}^*}\|^2 \geqq 2^j \|\mathbf{b}_j^{\text{old}^*}\|^2 \geqq 2 \cdot 2^{-n}\lambda(\mathbf{x})^{-2}.$$

From this we prove $D_{\text{new}} \leqq \frac{3}{4} D_{\text{old}}$ exactly as in the proof of Lemma 3.3 with 2^k replaced by $2^{n/2}\lambda(\mathbf{x})$.

Using the relation $D_{\text{new}} \leqq \frac{3}{4} D_{\text{old}}$ the claimed time bound is straightforward. Initially we have for the Shortest Relations Algorithm that $D \leqq 2^{n^3}$ and $D \geqq 2^{-2n^3}\lambda(\mathbf{x})^{-2n^2}$ holds on termination. Therefore the Shortest Relations Algorithm performs at most $O(n^3 + n^2 \log \lambda(\mathbf{x}))$ exchange steps. Since each exchange step uses at most $O(n)$ arithmetic operations the total number of arithmetic steps of the Shortest Relations Algorithm is at most $O(n^4 + n^3 \log \lambda(\mathbf{x}))$. □

Remarks. (i) If on termination of the Shortest Relations Algorithm we have $s = n-1$, then the output $\mathbf{c}_n$ is a shortest integer relation for $\mathbf{x}$. If $\dim(L_{\mathbf{x}}) = 1$, then the terminal value of s must be $n-1$, and thus the Shortest Relations Algorithm proves that the output $\mathbf{c}_n$ is a shortest vector in $L_{\mathbf{x}}$. In case $\dim(L_{\mathbf{x}}) = 1$, the Basic Integer Relation Algorithm also finds a shortest integer relation for $\mathbf{x}$ but it does not prove that $\mathbf{c}_n$ is shortest since $\dim(L_{\mathbf{x}})$ may be unknown.

(ii) The Shortest Relations Algorithm reduces the problem of finding a shortest (short, respectively) integer relation for $\mathbf{x}$ to the problem of finding a shortest (short, respectively) vector in the lattice $L = \langle \mathbf{c}_{s+1}, \cdots, \mathbf{c}_n \rangle$ where $\mathbf{c}_{s+1}, \cdots, \mathbf{c}_n$ are the output vectors of the Shortest Relations Algorithm. We have shown that these vectors are already reasonably short. By applying Lovász basis reduction to the vectors $\mathbf{c}_{s+1}, \cdots, \mathbf{c}_n$ we obtain an integer relation $\mathbf{m}$ for $\mathbf{x}$ satisfying $\|\mathbf{m}\|^2 \leqq 2^{n-s-1}\lambda(\mathbf{x})^2$. A shortest integer relation for $\mathbf{x}$ can be found by Kannan's Algorithm *Shortest* that performs Korkine-Zolotareff reduction, see Kannan (1983). An improved version of Kannan's Algorithm and a hierarchy of polynomial time lattice basis reduction algorithms stretching from LLL-reduction toward Korkine-Zolotareff reduction has been given by Schnorr (1987).

5. Finding simultaneous integer relations. We describe an algorithm used to find simultaneous integer relations for real vectors $\mathbf{x}_1, \cdots, \mathbf{x}_l \in \mathbb{R}^n$, i.e., we search for linearly independent nonzero vectors $\mathbf{m} \in \mathbb{Z}^n$ such that $\langle \mathbf{x}_i, \mathbf{m} \rangle = 0$ for $i = 1, \cdots, l$. The *Simultaneous Relations Algorithm* resembles the Small Integer Relation Algorithm, but uses a more general exchange rule and a corresponding termination test. The Simultaneous Relations Algorithm includes the Small Integer Relation Algorithm and the Several Relations Algorithm as special cases.

Let the vectors $\mathbf{x}_1, \cdots, \mathbf{x}_l$ be fixed, and for a basis $\mathbf{b}_1, \cdots, \mathbf{b}_n$ of lattice $\mathbb{Z}^n$ let $\mathbf{b}_j^*$ be the component of $\mathbf{b}_j$ that is orthogonal to $\mathbf{x}_1, \cdots, \mathbf{x}_l, \mathbf{b}_1, \cdots, \mathbf{b}_{j-1}$. The number of integers i, such that $\mathbf{b}_i^* = \mathbf{0}$, is the rank of the matrix $[\mathbf{x}_1, \cdots, \mathbf{x}_l]$. The general exchange rule is as follows.

GENERAL EXCHANGE RULE. Choose i with $1 \leqq i \leqq s$ that maximizes $2^{\tau_i}\|\mathbf{b}_i^*\|^2$ where $\tau_i = \#\{j: 1 \leqq j < i, \mathbf{b}_j^* \neq \mathbf{0}\}$ and $s = \max\{i \mid \mathbf{b}_i^* = \mathbf{0}\}$.

It includes the previous exchange rules, including the Bergman exchange rule, as special cases.

Let $L(\mathbf{x}_1, \cdots, \mathbf{x}_l)$ denote the lattice of simultaneous integer relations in $\mathbb{Z}^n$ for $\mathbf{x}_1, \cdots, \mathbf{x}_l$, i.e., $L(\mathbf{x}_1, \cdots, \mathbf{x}_l) = \{\mathbf{m} = (m_1, \cdots, m_n) \in \mathbb{Z}^n \mid \langle \mathbf{m}, \mathbf{x}_i \rangle = 0 \text{ for } 1 \leqq i \leqq l\}$. This lattice has rank $t = t(\mathbf{x}_1, \cdots, \mathbf{x}_l)$ where t may take any value in the range from 0 to $n - \operatorname{rank}[\mathbf{x}_1, \cdots, \mathbf{x}_l]$. Let $\lambda_i(\mathbf{x}_1, \cdots, \mathbf{x}_l)$ denote the ith successive minimum of the lattice $\langle \mathbf{x}_1, \cdots, \mathbf{x}_l \rangle$ for $1 \leqq i \leqq t$ and set $\lambda_i(\mathbf{x}_1, \cdots, \mathbf{x}_l) = \infty$ for $t+1 \leqq i \leqq n$.

SIMULTANEOUS RELATIONS ALGORITHM. (On input the real vectors $\mathbf{x}_1, \cdots, \mathbf{x}_l \in \mathbb{R}^n$ and $k, r \in \mathbb{N}$ this algorithm either finds r independent simultaneous integer relations $\mathbf{c}_{n-r+1}, \cdots, \mathbf{c}_n$ for $\mathbf{x}_1, \cdots, \mathbf{x}_l$ or it proves $\lambda_r(\mathbf{x}_1, \cdots, \mathbf{x}_l) \geqq 2^k$.)

1. *Initiation.* For the standard basis $\mathbf{b}_1, \cdots, \mathbf{b}_n$ of $\mathbb{Z}^n$ compute the Gram-Schmidt quantities $\|\mathbf{b}_i^*\|^2$, $\mu_{i,j} = \langle \mathbf{b}_i, \mathbf{b}_j^* \rangle \|\mathbf{b}_j^*\|^{-2}$ for $1 \leqq i, j \leqq n$, where $\mathbf{b}_i^*$ is the component of $\mathbf{b}_i$ that is orthogonal to $\mathbf{x}_1, \cdots, \mathbf{x}_l, \mathbf{b}_1, \cdots, \mathbf{b}_{i-1}$. Set $s := \max\{i: \mathbf{b}_i^* = \mathbf{0}\}$.
2. *Termination test.* If $s < n - r + 1$ then r simultaneous integer relations are found. Size-reduce the basis $\mathbf{b}_1, \cdots, \mathbf{b}_n$. Compute $[\mathbf{c}_1, \cdots, \mathbf{c}_n]^{\mathrm{T}} := [\mathbf{b}_1, \cdots, \mathbf{b}_n]^{-1}$, output $\mathbf{c}_{n-r+1}, \cdots, \mathbf{c}_n$, and stop. If $\|\mathbf{b}_i^*\| < 2^{-k}$ for $1 \leqq i \leqq n - r + 1$, then output "$\lambda_r(\mathbf{x}_1, \cdots, \mathbf{x}_l) \geqq 2^k$" and stop.
3. *Exchange step.* Choose i with $1 \leqq i \leqq s - 1$ that maximizes $2^{\tau_i}\|\mathbf{b}_i^*\|^2$ where $\tau_i = \#\{j \mid 1 \leqq j \leqq i, \mathbf{b}_j^* \neq \mathbf{0}\}$. Size-reduce $\mathbf{b}_{i+1}$ with respect to $\mathbf{b}_i$ by setting $\mathbf{b}_{i+1} := \mathbf{b}_{i+1} - \lceil \mu_{i+1,i} \rfloor \mathbf{b}_i$. Exchange $\mathbf{b}_i$ and $\mathbf{b}_{i+1}$. Update the Gram-Schmidt quantities

$\|\mathbf{b}_\nu^*\|^2$, $\mu_{j,\nu}$, $\mu_{\nu,j}$ for $\nu = i$, $i+1$ and $j = 1, \cdots, n$. If $i = s-1$ and $\mathbf{b}_i^{\text{new}^*} = \mathbf{0}$, set $s := s-1$. Go to 2.

We prove the following result.

THEOREM 5.1. *When given vectors $\mathbf{x}_1, \cdots, \mathbf{x}_l \in \mathbb{R}^n$ and k, $r \in \mathbb{N}$ as input, the Simultaneous Relations Algorithm either finds r independent simultaneous integer relations $\mathbf{c}_{n+r+1}, \cdots, \mathbf{c}_n$ for $\mathbf{x}_1, \cdots, \mathbf{x}_l$, with*

$$\|\mathbf{c}_n\|^2 \leqq 2^{n-d+1}\lambda_1(\mathbf{x}_1, \cdots, \mathbf{x}_l)^2,$$

where $d = \operatorname{rank}[\mathbf{x}_1, \cdots, \mathbf{x}_l]$, or else it proves $\lambda_r(\mathbf{x}_1, \cdots, \mathbf{x}_l) \geqq 2^k$. It halts after at most $O(n^3(k+n))$ arithmetic operations on real numbers.

In addition to the upper bound on $\|\mathbf{c}_n\|^2$ we can extend the results of Theorem 4.2. Using the proof of Theorem 4.2 the reader can verify that the following holds.

If the Simultaneous Relations Algorithm finds integer relations $\mathbf{c}_{n-r+1}, \cdots, \mathbf{c}_n$ then we have $\|\mathbf{c}_{n-i+1}\|^2 \leqq 1.5^{2i-2}2^{n-d+1}\lambda_i(\mathbf{x}_1, \cdots, \mathbf{x}_l)$ for $i = 1, \cdots, r$.

Proof. Correctness. Suppose first that the algorithm gives output $\mathbf{c}_{n-r+1}, \cdots, \mathbf{c}_n$. We prove that $\langle \mathbf{x}_i, \mathbf{c}_{n-r+j}\rangle = 0$ for $i = 1, \cdots, l$ and $j = 1, \cdots, r$. Since $\mathbf{b}_{n-r+j}^* \neq \mathbf{0}$ for $1 \leqq j \leqq r$ we have $\dim(\operatorname{span}(\mathbf{x}_1, \cdots, \mathbf{x}_l, \mathbf{b}_1^*, \cdots, \mathbf{b}_{n-r}^*)) = n-r$ and this implies that $\mathbf{x}_1, \cdots, \mathbf{x}_l \in \operatorname{span}(\mathbf{b}_1, \cdots, \mathbf{b}_{n-r})$. The row vectors $\mathbf{c}_{n-r+1}, \cdots, \mathbf{c}_n$ of the inverse matrix

$$[\mathbf{c}_1, \cdots, \mathbf{c}_n]^\top = [\mathbf{b}_1, \cdots, \mathbf{b}_n]^{-1}$$

satisfy $\langle \mathbf{b}_i, \mathbf{c}_{n-r+j}\rangle = 0$ for $1 \leqq i \leqq n-r$ and $j = 1, \cdots, r$, which yields the desired result that the vectors $\mathbf{c}_{n-r+j}$ are simultaneous integer relations.

To prove the claim that

$$\|\mathbf{c}_n\|^2 \leqq 2^{n-d+1}\lambda_1(\mathbf{x}_1, \cdots, \mathbf{x}_l)^2 \tag{5.1}$$

we use the special case $r = 1$ of the inequality

$$\lambda_r(\mathbf{x}_1, \cdots, \mathbf{x}_l) \geqq 1/\max_{1 \leqq i \leqq n-r+1} \|\mathbf{b}_i^*\| \quad \text{for } 1 \leqq r \leqq n-1, \tag{5.2}$$

which is proved by exactly the same argument that proves (4.1). Now the vector $\mathbf{c}_n$ is given by the inverse of the matrix $[\mathbf{b}_1, \cdots, \mathbf{b}_n]$ that occurs just after the last exchange $\mathbf{b}_{n-1} \leftrightarrow \mathbf{b}_n$. This exchange produces $\mathbf{b}_n^* \neq \mathbf{0}$, and the vectors $\mathbf{b}_{n-1}$ and $\mathbf{b}_n$ are never exchanged after that point and hence the last row $\mathbf{c}_n$ of the inverse matrix is never changed subsequently. Let $\mathbf{b}_1, \cdots, \mathbf{b}_n$ be the basis of $\mathbb{Z}^n$ before the last exchange $\mathbf{b}_n \leftrightarrow \mathbf{b}_{n-1}$. We have

$$\mathbf{c}_n = \pm\mathbf{b}_{n-1}^*\|\mathbf{b}_{n-1}^*\|^{-2}, \qquad \|\mathbf{c}_n\| = \|\mathbf{b}_{n-1}^*\|^{-1}. \tag{5.3}$$

The exchange rule says that the numbers $\|\mathbf{b}_i^*\|^2 2^{\tau_i}$ have a maximum at $i = n-1$, and we have $\tau_{n-1} - \tau_i \leqq n - \operatorname{rank}[\mathbf{x}_1, \cdots, \mathbf{x}_l] + 1 = n-d+1$ for $i = 1, \cdots, n-1$. This implies

$$\|\mathbf{b}_i^*\|^2 \leqq 2^{\tau_{n-1}-\tau_i}\|\mathbf{b}_{n-1}^*\|^2 \leqq 2^{n-d+1}\|\mathbf{b}_{n-1}^*\|^2 \quad \text{for } i = 1, \cdots, n-1$$

and thus

$$\|\mathbf{b}_{n-1}^*\|^{-2} \leqq 2^{n-d+1}\|\mathbf{b}_i^*\|^{-2}.$$

Therefore the claim (5.1) follows from

$$\lambda_1(\mathbf{x}_1, \cdots, \mathbf{x}_l)^2 \overset{(5.2)}{\geqq} 1/\max_{1 \leqq i \leqq n-1} \|\mathbf{b}_i^*\|^2 \geqq 2^{-n+d-1}\|\mathbf{b}_{n-1}^*\|^{-2} \overset{(5.3)}{=} 2^{-n+d-1}\|\mathbf{c}_n\|^2.$$

The correctness of the part of the termination test asserting "$\lambda_r(\mathbf{x}_1, \cdots, \mathbf{x}_l) \geqq 2^k$" follows immediately from (5.2).

Running time bound. We measure the progress of the algorithm using the quantity

$$D = \prod_{i=1}^{n} \max\{\|\mathbf{b}_i^*\|^2 2^n, 2^{-2k}\}^{n-i}.$$

We claim that at any exchange step we have

$$D_{\text{new}} \leqq \tfrac{3}{4} D_{\text{old}}. \tag{5.4}$$

This has been proved in the case $\tau_i = i$ for all $i \leqq n-1$, by Lemma 3.3. We prove (5.4) analogously to Lemma 3.3 with the change $\alpha(\mathbf{b}_i^*) = \max\{\|\mathbf{b}_i^*\|^2 2^n, 2^{-2k}\}$. If the Simultaneous Relation Algorithm exchanges $\mathbf{b}_i$ and $\mathbf{b}_{i+1}$, then $\|\mathbf{b}_i^*\| \neq 0$, $\tau_{i+1}^{\text{old}} = \tau_i^{\text{old}} + 1$ and $\tau_j^{\text{new}} \leqq \tau_j^{\text{old}}$ for all j. Since i has been chosen to maximize the number $\|\mathbf{b}_j^*\|^2 2^{\tau_j}$ for $1 \leqq j < s$ we have $\|\mathbf{b}_{i+1}^{\text{old}*}\|^2 \leqq \frac{1}{2}\|\mathbf{b}_i^{\text{old}*}\|^2$, and thus the inequality

$$\|\mathbf{b}_i^{\text{new}*}\|^2 \leqq \tfrac{3}{4}\|\mathbf{b}_i^{\text{old}*}\|^2 \tag{3.2}$$

still holds. Since the algorithm did not previously terminate in step 2 we have $\|\mathbf{b}_j^{\text{old}*}\| \geqq 2^{-k}$ for some $j < s$ so that the inequality

$$2^n\|\mathbf{b}_i^{\text{old}*}\|^2 \geqq 2^{\tau_i+1}\|\mathbf{b}_i^{\text{old}*}\|^2 \geqq 2^{\tau_j+1}\|\mathbf{b}_j^{\text{old}*}\|^2 \geqq 2^{-2k+\tau_j+1} \geqq 2^{-2k+1} \tag{3.3}$$

still holds. Now the claim (5.4) follows by imitating the rest of the proof of Lemma 3.3.

Since we have $D \leqq 2^{n^3}$ at the start of the algorithm, while $D \geqq 2^{-kn^2}$ always holds, it follows that the number of exchange steps is at most $O(n^2(k+n))$, hence $O(n^3(k+n))$ arithmetic operations are used. □

Remarks. (i) A particular instance of the simultaneous relation problem is the problem of finding the minimal polynomial of an algebraic number. Let $\alpha = (\text{Re}(\alpha), \text{Im}(\alpha)) \in \mathbb{C}$ be an algebraic number with degree at most n. Then every simultaneous relation $m = (m_0, \cdots, m_n)$ for $x_1 = (\text{Re}(\alpha^0), \cdots, \text{Re}(\alpha^n))$, $x_2 = (\text{Im}(\alpha^0), \cdots, \text{Im}(\alpha^n))$ yields a multiple $p(x) = \sum_{i=0}^{n} m_i x^i$ of the minimal polynomial for α. The minimal polynomial can be found by repeating this process with smaller values of n. The degree of the minimial polynomial is the smallest n for which a simultaneous relation exists. Algorithms which determine the minimial polynomial of an algebraic number have been proposed by Schönhage (1984) and Kannan, Lenstra, and Lovász (1984, 1988).

(ii) Another instance of the simultaneous relation problem is to find an *integer dependency* $\mathbf{m} = (m_1, \cdots, m_s) \in \mathbb{Z}^s$ for the real vectors $\mathbf{y}_1, \cdots, \mathbf{y}_s \in \mathbb{R}^n$, i.e., a nonzero integer vector $\mathbf{m}$ satisfying $\sum_{i=1}^{s} m_i \mathbf{y}_i = 0$. An integer dependency for $\mathbf{y}_1, \cdots, \mathbf{y}_s$ is a simultaneous relation for the row vectors $\mathbf{x}_1, \cdots, \mathbf{x}_n$ of the matrix with column vectors $\mathbf{y}_1, \cdots, \mathbf{y}_s$, i.e., $[\mathbf{x}_1, \cdots, \mathbf{x}_n]^\top = [\mathbf{y}_1, \cdots, \mathbf{y}_s]$.

6. Finding short integer relations among integers. The problem to find short integer relations for an integer vector $\mathbf{x} \in \mathbb{Z}^n$ is particularly interesting since it is closely related to the *Knapsack problem*, which is known to be NP-complete. The *Knapsack problem* is to decide for given integers $a_1, \cdots, a_n, b$ whether the equation $\sum_{i=1}^{n} a_i m_i = b$ has a $\{0, 1\}$-solution $(m_1, \cdots, m_n) \in \{0, 1\}^n$. This means to decide whether there is a $\{0, 1\}$-relation $\mathbf{m} \in \{0, 1\}^{n+1}$ for the integer vector $\mathbf{x} = (a_1, \cdots, a_n, -b) \in \mathbb{Z}^{n+1}$ satisfying $m_{n+1} = 1$. Polynomial time algorithms for integer programming with a fixed number of variables have been given by Lenstra (1983) and Kannan (1983), (1987).

While we cannot expect to find a $\{0, 1\}$-relation in polynomial time, it is shown that we can find a basis of the lattice $L_{\mathbf{x}}$ of integer relations in polynomial time. The

following algorithm when given $\mathbf{x}$ as input finds a basis of short vectors of $L_{\mathbf{x}}$ within $O(n^3 \log \|\mathbf{x}\|)$ arithmetic operations in $O(n+\log \|\mathbf{x}\|)$-bit integers. It essentially applies the original Lovász algorithm to the set of linearly dependent vectors $\mathbf{b}_0, \mathbf{b}_1, \cdots, \mathbf{b}_n$ where $\mathbf{b}_0$ is the primitive vector $\mathbf{x}/\gcd(x_1, \cdots, x_n)$ and $\mathbf{b}_1, \cdots, \mathbf{b}_n$ is the standard basis of $\mathbb{Z}^n$. It uses the Lovász exchange rule, which exchanges $\mathbf{b}_i$ and $\mathbf{b}_{i+1}$ for the smallest i such that $\|\mathbf{b}_i^*\|^2 > 2\|\mathbf{b}_{i+1}^*\|^2$. Here the vector $\mathbf{b}_i^*$ is the component of $\mathbf{b}_i$ that is orthogonal to $\mathbf{b}_0, \cdots, \mathbf{b}_{i-1}$. Now the Lovász exchange rule is efficient since the numbers $\|\mathbf{b}_i^*\|^2$ cannot become arbitrarily small and nonzero. We analyze this algorithm in the bit complexity model. This analysis would not work when using Bergman's exchange rule. Because of its great similarity to the original Lovász algorithm we call this algorithm the *Lovász Integer Relation Algorithm.*

LOVÁSZ INTEGER RELATION ALGORITHM. (On input $\mathbf{x} \in \mathbb{Z}^n$ this algorithm finds a basis $\mathbf{c}_2, \cdots, \mathbf{c}_n$ of lattice $L_{\mathbf{x}}$ such that $\|\mathbf{c}_{n-i+1}\|^2 \leqq 1.5^{2i-2}2^{n-1}\lambda_i(\mathbf{x})^2$ for $i = 1, \cdots, n-1$.)

1. *Initiation.* $\mathbf{b}_0 := \mathbf{x}/\gcd(x_1, \cdots, x_n)$.
   For the standard basis $\mathbf{b}_1, \cdots, \mathbf{b}_n$ of $\mathbb{Z}^n$ compute the Gram-Schmidt numbers $\|\mathbf{b}_i^*\|^2$, $\mu_{i,j}$ for $0 \leqq n$, $i := 1$ (i is the *stage*).
2. *Termination test.* If $i = n$ then
   $([\mathbf{c}_1, \cdots, \mathbf{c}_n]^\top := [\mathbf{b}_0, \mathbf{b}_2, \cdots, \mathbf{b}_n]^{-1}$, output $(\mathbf{c}_2, \cdots, \mathbf{c}_n)$ and stop).
3. *Reduction in size.* For $j = i$ down to 0 do
   $(\mathbf{b}_{i+1} := \mathbf{b}_{i+1} - \lceil \mu_{i+1,j} \rfloor \mathbf{b}_j$, for $\nu = 0, \cdots, j$ do $\mu_{i+1,\nu} := \mu_{i+1,\nu} - \lceil \mu_{i+1,j} \rfloor \mu_{j,\nu})$.
   If $\|\mathbf{b}_i^*\|^2 \leqq 2\|\mathbf{b}_{i+1}^*\|^2$ then ($i := i+1$, goto 2).
4. *Exchange step.* Exchange $\mathbf{b}_i$ and $\mathbf{b}_{i+1}$. Update $\|\mathbf{b}_\nu^*\|^2$ and $\mu_{\nu,j}$ for $\nu = i, i+1$ and $j = 0, \cdots, i$.
   If $i > 1$ then $i := i-1$.
   Goto 3.

Note that this algorithm leaves the vector $\mathbf{b}_0$ fixed throughout and that it performs a complete size-reduction after each exchange step, which seems necessary to obtain good running time bounds in the bit complexity model.

THEOREM 6.1. *When given an integer vector $\mathbf{x} \in \mathbb{Z}^n$, the Lovász Integer Relations Algorithm finds a basis $\mathbf{c}_2, \cdots, \mathbf{c}_n$ of the lattice $L_{\mathbf{x}}$ satisfying $\|\mathbf{c}_{n-i+1}\|^2 \leqq 1.5^{2i-2}2^{n-1}\lambda_i(\mathbf{x})^2$ for $i = 1, \cdots, n-1$. Here $\lambda_1(\mathbf{x}), \cdots, \lambda_{n-1}(\mathbf{x})$ are the successive minima of the lattice $L_{\mathbf{x}}$ of integer relations for $\mathbf{x}$. It terminates after at most $O(n^3 \log \|\mathbf{x}\|)$ arithmetic operations on $O(n+\log \|\mathbf{x}\|)$ bit integers.*

Proof. We show that the output vectors $\mathbf{c}_2, \cdots, \mathbf{c}_n$ form a basis of lattice $L_{\mathbf{x}}$. Throughout the computation the vectors $\mathbf{b}_0, \mathbf{b}_1, \cdots, \mathbf{b}_n$ generate the lattice $\mathbb{Z}^n$. The vector $\mathbf{b}_0$ is never exchanged. On termination we have $\|\mathbf{b}_i^*\|^2 \leqq 2\|\mathbf{b}_{i+1}^*\|^2$ for $i = 1, \cdots, n-1$. This implies $\mathbf{b}_1^* = \mathbf{0}$ and thus $\mathbf{b}_1 \in \operatorname{span}(\mathbf{b}_0)$. Since $\mathbf{b}_0$ is a primitive vector we see that the vectors $\mathbf{b}_0, \mathbf{b}_2, \cdots, \mathbf{b}_n$, on termination, form a basis of lattice $\mathbb{Z}^n$. Therefore the output vectors $\mathbf{c}_2, \cdots, \mathbf{c}_n$ that are the row vectors of the inverse matrix $[\mathbf{c}_1, \cdots, \mathbf{c}_n]^\top = [\mathbf{b}_0, \mathbf{b}_2, \cdots, \mathbf{b}_n]^{-1}$ form a basis of the lattice $L_{\mathbf{x}}$.

The inequalities $\|\mathbf{c}_{n-i+1}\|^2 \leqq 1.5^{2i-2}2^{n-1}\lambda_i(\mathbf{x})^2$ for $i = 1, \cdots, n-1$ have been shown in Theorem 4.2. This proof is still valid since the equalities (4.3) and the inequalities (4.4), (4.5) hold for $r = n-1$, $s = 1$ and for the output vectors $\mathbf{b}_2, \cdots, \mathbf{b}_n$ of the Lovász Integer Relation Algorithm. While this is obvious for (4.3) and (4.4) we remark that the inequalities

$$\|\mathbf{b}_{n-i+1}^*\|^{-2} \leqq \lambda_i(\mathbf{x})^2 2^{n-i-1} \quad \text{for } i = 1, \cdots, n-1 \tag{4.5}$$

follow from

$$\lambda_i(\mathbf{x}) \overset{(4.1)}{\geqq} 1/\max_{j=1,\cdots,n-i+1} \|\mathbf{b}_j^*\|$$

and

$$\|\mathbf{b}_j^*\|^2 \leqq 2\|\mathbf{b}_{j+1}^*\|^2 \quad \text{for } j = 1, \cdots, n-1.$$

Running time bound. We measure the progress of the algorithm using the quantity

$$D := \prod_{i=1, \mathbf{b}_i^* \neq \mathbf{0}}^{n} \|\mathbf{b}_i^*\|^{2(n-\tau(i))} \quad \text{where } \tau(i) = \#\{j \mid 1 \leqq j \leqq i, \mathbf{b}_j^* \neq \mathbf{0}\}.$$

We first show that every exchange $\mathbf{b}_i \leftrightarrow \mathbf{b}_{i+1}$ achieves

$$D_{\text{new}} \leqq \tfrac{3}{4} D_{\text{old}} \quad \text{if } \mathbf{b}_i^{\text{new}^*} \neq \mathbf{0}, \tag{6.1}$$

$$D_{\text{new}} = D_{\text{old}} \quad \text{if } \mathbf{b}_i^{\text{new}^*} = \mathbf{0}. \tag{6.2}$$

If $\mathbf{b}_i^{\text{new}^*} \neq \mathbf{0}$, then (6.1) follows from (3.2) $\|\mathbf{b}_i^{\text{new}^*}\|^2 \leqq \frac{3}{4}\|\mathbf{b}_i^{\text{old}^*}\|^2$. If $\mathbf{b}_i^{\text{new}^*} = \mathbf{0}$, then $\mathbf{b}_{i+1}^{\text{new}^*} = \mathbf{b}_i^{\text{old}^*}$ and we have $D_{\text{new}} = D_{\text{old}}$. Obviously there is for each i at most one exchange $\mathbf{b}_i \leftrightarrow \mathbf{b}_{i+1}$ such that $\mathbf{b}_i^{\text{new}^*} = \mathbf{0}$.

Upon entry of the algorithm the number D is at most 1, and now we bound from below the number D on termination. We know that $\mathbf{b}_1^* = \mathbf{0}$ holds on termination and thus

$$D = \prod_{i=2}^{n} \|\mathbf{b}_i^*\|^{2(n-i+1)}.$$

Since the vectors $\mathbf{b}_0, \mathbf{b}_2, \cdots, \mathbf{b}_n$ generate the lattice $\mathbb{Z}^n$ we have

$$1 = \|\mathbf{b}_0\| \prod_{i=2}^{n} \|\mathbf{b}_i^*\|.$$

It can easily be seen that the inequalities $\|\mathbf{b}_i^*\| \leqq 1$ for $i = 2, \cdots, n$ hold throughout the computation. This implies

$$\prod_{i=2}^{j} \|\mathbf{b}_i^*\|^2 = \|\mathbf{b}_0\|^{-2} \prod_{i=j+1}^{n} \|\mathbf{b}_i^*\|^{-2} \geqq \|\mathbf{b}_0\|^{-2} \geqq \|\mathbf{x}\|^{-2}.$$

Thus, on termination we have

$$D = \prod_{j=2}^{n} \prod_{i=2}^{j} \|\mathbf{b}_i^*\|^2 \geqq \|\mathbf{b}_0\|^{-2n+2} \geqq \|\mathbf{x}\|^{-2n+2}.$$

These bounds and the inequalities (6.1), (6.2) show that the number of exchange steps is at most

$$n + (2n-2)\log_{4/3} \|\mathbf{x}\| = O(n \log \|\mathbf{x}\|).$$

Each exchange step costs $O(n^2)$ arithmetic operations, the reduction in size of $\mathbf{b}_{i+1}$ included. From this we see that the total number of arithmetic steps is at most $O(n^3 \log \|\mathbf{x}\|)$, which also covers the steps for the initial computation of the Gram-Schmidt numbers $\mu_{i,j}$, $\|\mathbf{b}_i^*\|^2$.

The size of the integers involved. For $j = 1, \cdots, n$ let $d_j = \prod_{i=0}^{j} \|\mathbf{b}_i^*\|^2 = \det[\langle \mathbf{b}_i, \mathbf{b}_l \rangle]_{0 \leqq i,l \leqq j}$ where i and l only range over integers satisfying $\mathbf{b}_i^*, \mathbf{b}_l^* \neq \mathbf{0}$. The integer d_j is the square of the determinant of the lattice $\langle \mathbf{b}_0, \cdots, \mathbf{b}_j \rangle$. It is known from Lenstra, Lenstra Jr., and Lovász (1982, formulae (1.28), (1.29)) that the vector $\mathbf{b}_j^* d_{j-1}$ and the numbers $\mu_{i,j} d_j$ are integral. Therefore all numbers involved with the Lovász

Integer Relations Algorithm are rational with denominator not larger than $\max_j d_j$. We have $\max_j d_j \leqq \|\mathbf{x}\|^2$ since $\|\mathbf{b}_0^*\| \leqq \|\mathbf{x}\|$ and $\|\mathbf{b}_i^*\| \leqq 1$ for $i = 1, \cdots, n$.

Next we show that the following inequalities always hold upon entry of stage i:

$$\|\mathbf{b}_0\| \leqq \|\mathbf{x}\|, \|\mathbf{b}_k^*\| \leqq 1 \quad \text{for } k = 1, \cdots, n, \tag{6.3}$$

$$\|\mathbf{b}_k\|^2 \leqq \|\mathbf{x}\|^2 + n \quad \text{for } k = 1, \cdots, n, \tag{6.4}$$

$$|\mu_{k,j}| \leqq \|\mathbf{x}\|^2 + n \quad \text{for } 0 \leqq j \leqq k \text{ and } i \leqq k \leqq n. \tag{6.5}$$

Proof of equation (6.3). Throughout the computation we have $\mathbf{b}_0 = \mathbf{x}/\gcd(x_1, \cdots, x_n)$ and $\max_k \|\mathbf{b}_k^*\| \leqq 1$. This is because an exchange $\mathbf{b}_i \leftrightarrow \mathbf{b}_{i+1}$ does not increase the maximum of $\|\mathbf{b}_1^*\|, \cdots, \|\mathbf{b}_n^*\|$.

Proof of equation (6.4). Initially $\|\mathbf{b}_k\| \leqq 1$ holds for $k = 1, \cdots, n$. During the computation we only permute the vectors $\mathbf{b}_1, \cdots, \mathbf{b}_n$, and on stage i we reduce the vector $\mathbf{b}_{i+1}$ in size. After the reduction of $\mathbf{b}_{i+1}$ we have

$$\|\mathbf{b}_{i+1}\|^2 \leqq \sum_{j=0}^{i+1} \mu_{i+1,j}^2 \|\mathbf{b}_j^*\|^2 \overset{(6.3)}{\leqq} \frac{(\|\mathbf{x}\|^2 + i + 1)}{4}.$$

Proof of equation (6.5). We have

$$\begin{aligned} |\mu_{k,j}| &\leqq \|\mathbf{b}_k\| \, \|\mathbf{b}_j^*\|^{-1} \\ &\overset{(6.4)}{\leqq} (\|\mathbf{x}\|^2 + n)^{1/2} (d_{j-1}/d_j)^{1/2} \\ &\leqq (\|\mathbf{x}\|^2 + n)^{1/2} d_{j-1}^{1/2} \leqq \|\mathbf{x}\|^2 + n. \end{aligned}$$

We next prove bounds for the other integers occurring with the algorithm. During the reduction of the vector $\mathbf{b}_{i+1}$ at stage i the numbers $\mu_{i+1,l}$ are transformed as

$$\mu_{i+1,l} := \mu_{i+1,l} - \lceil \mu_{i+1,j} \rfloor \mu_{j,l} \quad \text{for } l = 0, \cdots, j-1$$

for $j = i$ down to 0. Since $|\mu_{j,l}| \leqq \frac{1}{2}$ these steps at most double the number $M := \max_l |\mu_{i+1,l}|$ for each j. From (6.5) we know that $M \leqq \|\mathbf{x}\|^2 + n$, when the reduction of $\mathbf{b}_{i+1}$ starts, and thus $M \leqq 2^n(\|\mathbf{x}\|^2 + n)$ holds throughout the reduction of $\mathbf{b}_{i+1}$. So far we see that the numerators and denominators of the rational numbers d_j, $\mu_{i,j}$, $\|\mathbf{b}_j^*\|^2$ are at most $2^n(\|\mathbf{x}\|^2 + n)\|\mathbf{x}\|^2$ in absolute value.

The cost of the final matrix inversion. We consider the computation of the output vectors $\mathbf{c}_2, \cdots, \mathbf{c}_n$ along the matrix inversion $[\mathbf{c}_1, \cdots, \mathbf{c}_n]^\top := [\mathbf{b}_0, \mathbf{b}_2, \cdots, \mathbf{b}_n]^{-1}$. We know from (4.3) that

$$\|\mathbf{c}_{n-i+1}\|^2 = \sum_{j \geqq n-i+1} v_{j,n-i+1}^2 \|\mathbf{b}_j^*\|^{-2} \quad \text{for } i = 1, \cdots, n-1$$

holds with $|v_{j,n-i+1}| \leqq 1.5^n$ and $\|\mathbf{b}_j^*\|^{-2} = d_{j-1}/d_j \leqq d_{j-1} \leqq \|\mathbf{x}\|^2$. This implies $\|\mathbf{c}_{n-i+1}\| \leqq \sqrt{n} 1.5^n \|\mathbf{x}\|$ for $i = 1, \cdots, n-1$.

This shows that the coordinates of the output vectors $\mathbf{c}_2, \cdots, \mathbf{c}_n$ have at most $\lceil \log_2(\sqrt{n} 1.5^n \|\mathbf{x}\|) \rceil$ bits. Therefore it is sufficient to compute the inverse matrix $[\mathbf{c}_1, \cdots, \mathbf{c}_n]^\top = [\mathbf{b}_0, \mathbf{b}_2, \cdots, \mathbf{b}_n]^{-1}$ modulo 2^e with $e = 1 + \lceil \log_2(\sqrt{n} 1.5^n \|\mathbf{x}\|) \rceil$. The inverse matrix $[\mathbf{b}_0, \mathbf{b}_2, \cdots, \mathbf{b}_n]^{-1}$ exists modulo 2^e since the vectors $\mathbf{b}_0, \mathbf{b}_2, \cdots, \mathbf{b}_n$ generate the lattice $\mathbb{Z}^n$, and thus $\det[\mathbf{b}_0, \mathbf{b}_2, \cdots, \mathbf{b}_n] = 1$. This matrix inversion can be done using $O(n^3)$ arithmetic steps (i.e., additions, multiplications, divisions) modulo 2^e. The matrix inversion requires at most n divisions modulo 2^e and each division can be done via the extended Euclidean algorithm using $O(e)$ arithmetic steps with $O(e)$-bit integers. From this we see that the matrix inversion costs at most $O(n^3 + n \log \|\mathbf{x}\|)$ arithmetical steps with $O(n + \log \|\mathbf{x}\|)$-bit integers. Thus the cost of the matrix inversion is covered by the time bound of Theorem 6.1. □

It is an interesting idea to replace in the above algorithm the Lovász exchange rule by Bergman's exchange rule. Will the resulting algorithm be equally efficient? The inequalities (6.1), (6.2) still hold for every exchange $\mathbf{b}_i \leftrightarrow \mathbf{b}_{i+1}$, and thus the number of arithmetic operations is still $O(n^3 \log \|\mathbf{x}\|)$. Moreover, the inequalities (6.3), (6.4), and (6.5) still hold after each exchange $\mathbf{b}_i \leftrightarrow \mathbf{b}_{i+1}$ using Bergman's exchange rule. However, during size-reduction of the vector $\mathbf{b}_{i+1}$ where the numbers $\mu_{i+1,l}$ are transformed by

$$\mu_{i+1,l} := \mu_{i+1,l} - \lceil \mu_{i+1,j} \rfloor \mu_{j,l} \quad \text{for } l = 0, \cdots, j-1$$

from $j = i$ down to 0, the vector $\mathbf{b}_j$ need not to be size-reduced. So we only know $|\mu_{j,l}| \leqq \|\mathbf{x}\|^2 + n$ instead of $|\mu_{j,l}| \leqq \frac{1}{2}$ in case of the Lovász exchange rule. Thus in case of Bergman's exchange rule we only see that

$$\max_l |\mu_{i+1,l}| \leqq (\|\mathbf{x}\|^2 + n)^{n+1} \|\mathbf{x}\|^2$$

holds throughout size-reduction of the vector $\mathbf{b}_{i+1}$.

We can obtain upper bounds for the successive minima $\lambda_1(\mathbf{x}), \cdots, \lambda_{n-1}(\mathbf{x})$ of the lattice $L_{\mathbf{x}}$ in terms of $\mathbf{x}$ and Hermite's constant γ_{n-1}. For each n Hermite's constant γ_n is the maximal value of $\lambda_1(L)^2 \det(L)^{-2/n}$ where l ranges over all lattices of rank n, $\lambda_1(L)$ is the first successive minimum, and $\det(L)$ the determinant of the lattice L. It is known that $\gamma_n \leqq (4/\pi)\Gamma(1 + n/2)^{2/n}$ (see Cassels (1971, Chap. IX.7)), and this implies $\gamma_n \leqq \frac{2}{3}n$ for $n \geqq 2$.

THEOREM 6.2. *Let $\mathbf{x} \in \mathbb{Z}^n$ be a nonzero integer vector, $L_{\mathbf{x}}$ the lattice of integer relations for $\mathbf{x}$ and $\lambda_1(\mathbf{x}), \cdots, \lambda_{n-1}(\mathbf{x})$ the successive minima of lattice $L_{\mathbf{x}}$. We have*

(1) $\det L_{\mathbf{x}} = \|\mathbf{x}\| / \gcd(x_1, \cdots, x_n)$;

(2) $\lambda_1(\mathbf{x}) \leqq \sqrt{\gamma_{n-1}} (\|\mathbf{x}\| / \gcd(x_1, \cdots, x_n))^{1/(n-1)}$;

(3) $\prod_{i=1}^{n-1} \lambda_i(\mathbf{x}) \leqq \gamma_{n-1}^{(n-1)/2} \|\mathbf{x}\| / \gcd(x_1, \cdots, x_n) \leqq (n-1)^{(n-1)/2} \|\mathbf{x}\| / \gcd(x_1, \cdots, x_n)$.

Proof. (1) The rank of lattice $L_{\mathbf{x}}$ is $n-1$. Let $\mathbf{c}_1, \cdots, \mathbf{c}_n$ be a basis of the lattice $\mathbb{Z}^n$ such that $\mathbf{c}_2, \cdots, \mathbf{c}_n$ is a basis of the lattice $L_{\mathbf{x}}$. (Every basis $\mathbf{c}_2, \cdots, \mathbf{c}_n$ of $L_{\mathbf{x}}$ can be extended to a basis of $\mathbb{Z}^n$ since $\operatorname{span}(L_{\mathbf{x}}) \cap \mathbb{Z}^n = L_{\mathbf{x}}$.) The component of $\mathbf{c}_1$ that is orthogonal to $\mathbf{c}_2, \cdots, \mathbf{c}_n$ is $\langle \mathbf{c}_1, \mathbf{x} \rangle \|\mathbf{x}\|^{-2} \mathbf{x}$ and has length $\langle \mathbf{c}_1, \mathbf{x} \rangle \|\mathbf{x}\|^{-1}$. This implies

$$1 = \det \mathbb{Z}^n = (\det L_{\mathbf{x}}) \quad |\langle \mathbf{c}_1, \mathbf{x} \rangle| \, \|\mathbf{x}\|^{-1}.$$

On the other hand, $\langle \mathbf{c}_1, \mathbf{x} \rangle$ is the minimal positive integer in $\{\langle \mathbf{m}, \mathbf{x} \rangle \mid \mathbf{m} \in \mathbb{Z}^n\}$, and thus $\langle \mathbf{c}_1, \mathbf{x} \rangle = \gcd(x_1, \cdots, x_n)$. From this we see that $\det L_{\mathbf{x}} = \|\mathbf{x}\| / \gcd(x_1, \cdots, x_n)$. The inequalities (2) and (3) are direct consequences of (1) by the Minkowski inequality

$$\prod_{i=1}^{n-1} \lambda_i(L) \leqq \gamma_{n-1}^{(n-1)/2} \det L$$

where L is a lattice with dimension $n-1$ and with successive minima $\lambda_1(L), \cdots, \lambda_{n-1}(L)$ (see Cassels (1971), Chap. VIII.2)). □

The upper bound $\lambda(\mathbf{x}) \leqq \sqrt{\gamma_{n-1}} \|\mathbf{x}\|^{1/(n-1)}$ in Theorem 6.2 is optimal for rank $n = 2$. The shortest integer relation for $\mathbf{x} = (x_1, x_2) \in \mathbb{Z}^2$ is $(-x_2, x_1)/\gcd(x_1, x_2)$ that has length $\|\mathbf{x}\| / \gcd(x_1, x_2) = \sqrt{\gamma_1} \|\mathbf{x}\| / \gcd(x_1, x_2)$.

RANKING THE BEST BINARY TREES*

S. ANILY† AND R. HASSIN‡

Abstract. The problem of ranking the K-best binary trees with respect to their weighted average leaves' levels is considered. Both the alphabetic case, where the order of the weights in the sequence $w_1, \cdots, w_n$ must be preserved in the leaves of the tree, and the nonalphabetic case, where no such restriction is imposed, are studied.

For the alphabetic case a simple algorithm is provided for ranking the K-best trees based on a recursive formula of complexity $O(Kn^3)$. For nonalphabetic trees two different ranking problems are considered, and for each of them it is shown that the next best tree can be solved by a dynamic programming formula of low complexity order.

Key words. binary trees, alphabetic and nonalphabetic trees, ranking of solutions

AMS(MOS) subject classifications. 94B45, 68E99

1. Introduction. Let $w_1, \cdots, w_n$ be given "weights." This paper deals with the problem of computing the best, second best, $\cdots$, K-best binary trees with respect to these weights. The problem arises when we want to construct the best tree satisfying certain constraints, and no efficient algorithm is known to find this tree. We may then rank the best trees ignoring these additional constraints starting from the best to the next best until the best tree obeying the constraints is reached.

We consider both the alphabetic case, where the order the weights are given must be preserved in the leaves of the tree, and the nonalphabetic case where no such constraints are imposed. The techniques we present can be used however in other problems of ranking trees. For example, ranking binary search trees is done almost in the same way as for the alphabetic case.

Ranking alphabetic trees is relatively a straightforward task. The problem is solvable by dynamic programming, and thus partitioning of the solution set can be obtained by introducing constraints on the decisions made while executing the computations. In this regard the problem is similar to the well-solved problem of ranking the shortest paths between a pair of nodes in a network. In § 2 we show how this can be done efficiently, and the K-best trees can be computed in $O(Kn^3)$-time.

Nonalphabetic trees are useful in the context of binary encoding of a set of words where each word v_i has a given frequency w_i in which it appears in the language. In a given code each word is written as a string of zeros and ones, and the length of a word is defined as the length of the string. The main objective is to find a binary encoding of minimum average length. Here we distinguish between two different problems:

(a) The language is viewed as a collection of n objects (words); we say that two codes are different if there exists a word v_i, $1 \leqq i \leqq n$ that is associated with strings of different lengths in these codes (see § 5).

(b) Here we do not distinguish between words of identical weights, i.e., given a code for a language containing two words v_i and v_j for which $w_i = w_j$, then exchanging

between the strings associated with v_i and v_j does **not** induce a new code even if their lengths (=levels) are different. In other words, the set of words $\{v_1, v_2, \cdots, v_n\}$ is partitioned into disjoint subsets according to their weights. A code is identified by the corresponding subsets of the strings' lengths where the order in which the levels of a particular subset are assigned to the words in that subset, is unimportant (see § 3).

We note that if all the weights are different from each other, then the two problems coincide; otherwise, the number of different codes is larger in the problem defined in (a). In both cases care must be taken to avoid repetition of solutions (where "repetition" is defined differently in the two cases), as a solution is uniquely identified by the length of the words and thus may be represented in many ways by different topological trees with different orderings of the weights.

Ranking the nonalphabetic trees is not as straightforward as ranking the alphabetic trees since no order is defined on the problem's elements. We note that the set of all alphabetic trees corresponding to a given order of leaves is only a subset (of a **much smaller** size) of the set of all nonalphabetic trees with the same number of leaves. (For example, in all alphabetic trees with three leaves v_1, v_2, and v_3 the second leaf of the trees is of level two while in the set of nonalphabetic trees using the same leaves, v_2 may also be of level one.) Therefore, the task of ranking the nonalphabetic trees cannot be achieved by applying the corresponding algorithm for alphabetic trees on any specific order of the leaves. Moreover, since the leaves can be ordered in $n!$ **different ways**, a direct application of the ranking procedure for alphabetic trees to the nonalphabetic case may result in an unefficient algorithm and an enormous number of repetitions of solutions. The main objective of this paper is in developing efficient ranking algorithms for nonalphabetic trees.

We show that the best nonalphabetic tree (i.e., the "Huffman tree") can be computed by any algorithm for **alphabetic** trees. We then extend this property to rank nonalphabetic trees using ranking schemes for alphabetic trees: in § 3 we introduce another algorithm for alphabetic trees (with a higher complexity order-$O(kn^4)$) that is modified in § 4 to rank the solutions for the nonalphabetic problem (b) defined above. In § 5, we present an $O(kn^3)$ algorithm that ranks the solutions for the nonalphabetic problem (a) by combining a procedure for ranking solutions for the assignment problem.

We assume that the reader is familiar with the basic concepts involved with binary trees as described, for example, in [K].

2. Alphabetic trees: Algorithm A. An alphabetic tree with n leaves $v_1, \cdots, v_n$ is represented by the sequence of levels of its leaves, ordered from left to right. We denote this sequence by $(l_1, \cdots, l_n)$. For a given sequence of **weights** we define the cost of the tree $T=(l_1, \cdots, l_n)$ as $C(T)=\sum_{i=1}^{n} w_i l_i$. The optimal tree, i.e., the one of minimum cost, can be found in $O(n \log n)$-time by the algorithm of Hu and Tucker [HT]; however, we do not know of any method that will use this algorithm to rank the K-best trees. In this section and in the next we describe, instead, two methods for ranking the best trees that are based on the recursive algorithm suggested by Gilbert and Moore [GM]. The first computes the K-best trees in $O(Kn^3)$-time by modifying the above algorithm in a way similar to that used by Dreyfus [Dre] and Lawler [L2] to rank the K shortest s-t paths in a network. The second requires $O(Kn^4)$-time and will serve later to rank the best (nonalphabetic) binary trees.

Let T_{ij}^k and C_{ij}^k denote the k-best tree and its cost for a problem consisting of the weights $w_i, w_{i+1}, \cdots, w_j$ and define $W_{ij}=\sum_{r=i}^{j} w_r$. Then $C_{ii}^1=0$ $i=1, \cdots, n$, and

$$C_{ij}^1=\min_{i\leq r\leq j-1}\{C_{ir}^1+C_{r+1,j}^1\}+W_{ij}, \qquad i<j. \tag{1}$$

For $k>1$, C_{ij}^k is given by $C_{ir}^u + C_{r+1,j}^v + W_{ij}$ for some $i \leqq r < j$ and $u, v \leqq k$. Thus C_{ij}^k is fully characterized by the triple (r, u, v) and we denote $T_{ij}^k = (r_{ij}^k, u_{ij}^k, v_{ij}^k)$.

Let

$$U(i, j, r, K) = \max \{u \mid r_{ij}^k = r \text{ and } u_{ij}^k = u, \text{ for some } k = 1, \cdots, K-1\},$$

$$\text{LAST}(i, j, r, K, u) = \max \{v \mid v_{ij}^k = v, u_{ij}^k = u, r_{ij}^k = r \text{ for some } k = 1, \cdots, K-1\}.$$

Both U and LAST are set to zero when the maximization is over an empty set. U and LAST focus on the subset of the $(K-1)$st-best solutions for $v_i, v_{i+1}, \cdots, v_j$ in which the left subtree consists of the leaves $v_i, v_{i+1}, \cdots, v_r$ and the right subtree consists of the leaves $v_{r+1}, \cdots, v_j$, i.e., the set $\{T_{ij}^k \mid T_{ij}^k = (r, u_{ij}^k, v_{ij}^k), k = 1, \cdots, K-1\}$. The operator U provides us with the maximum u_{ij}^k in the set that represents the rank value of the worse left subtree used among these solutions. The operator LAST, on the other hand, has an additional parameter u and is applied on a subset of the above set, namely, $\{T_{ij}^k \mid T_{ij}^k = (r, u, v_{ij}^k), k = 1, \cdots, K-1\}$ consisting only of those solutions using the uth best tree for $v_i, v_{i+1}, \cdots, v_r$ as their left subtree. LAST is assigned the maximum v_{ij}^k in this set, i.e., the rank value of the worse right subtree consisting of the leaves $v_{r+1}, \cdots, v_j$ used together with T_{ir}^u among the $(K-1)$st-best solutions for $v_i, \cdots, v_j$. The operators U and LAST are used in the design of Algorithm A.

Let

$$M_n = \frac{1}{n}\binom{2n-2}{n-1}$$

be the number of distinct alphabetic binary trees with n leaves [RH]. For a given sequence of weights $w_1, \cdots, w_n$ and $K \leqq M_n$, we propose an algorithm, based on a dynamic programming formulation that we explain in the sequel, for computing the K-best trees:

ALGORITHM A.
Compute C_{ij}^1 for all $1 \leqq i \leqq j \leqq n$ using recursion (1).
For $m = 1, \cdots, n-1$ do begin
For $i = 1, \cdots, n-m$ do begin
For $k = 2, \cdots, \min(K, M_{m+1})$ do

$$C_{i,i+m}^k = W_{i,i+m} + \min_{i \leqq r < i+m} \left\{ \min_{1 \leqq u \leqq U(i,i+m,r,k)+1} \{C_{ir}^u + C_{r+1,i+m}^{\text{LAST}(i,i+m,r,k,u)+1}\} \right\} \tag{2}$$

end
end

In (2) it is assumed that $C_{ij}^k = \infty$ for $k > M_{j-i+1}$. It is also assumed that some tie-breaking rule is applied whenever $C_{ij}^{k+1} = C_{ij}^k$. For example, we may require in such a case that either $r_{ij}^k < r_{ij}^{k+1}$, or $r_{ij}^k = r_{ij}^{k+1}$ and $u_{ij}^k < u_{ij}^{k+1}$, or $r_{ij}^k = r_{ij}^{k+1}$, $u_{ij}^k = u_{ij}^{k+1}$ and $v_{ij}^k < v_{ij}^{k+1}$.

Formula (2) can be explained as follows. $T_{i,i+m}^K$ can be viewed as combined of two subtrees emanating from its root; the left one consisting of the leaves $v_i, v_{i+1}, \cdots, v_r$ and the right one consisting of the leaves $v_{r+1}, \cdots, v_{i+m}$ for some $i \leqq r < i+m$. Among the $(K-1)$st-best trees for the leaves $v_i, \cdots, v_{i+m}$ consider only those combined of two subtrees in which v_r is the highest indexed leaf in the left subtree. The best such solution is, of course, consisting of the subtrees T_{ir}^1 and $T_{r+1,i+m}^1$. The second best such solution may either consist of the subtrees T_{ir}^2 and $T_{r+1,i+m}^1$ or the subtrees T_{ir}^1

and $T^2_{r+1,i+m}$, etc. By the same reason with respect to $T^K_{i,i+m}$ we distinguish between the following cases:

(a) $T^K_{i,i+m}$ consists of a subtree T^u_{ir} that already has been used in one of the trees $T^k_{i,i+m}$, $1 \leqq k \leqq K-1$, i.e., $u \leqq U(i, i+m, r, K)$. In that case the right subtree must be the **best** tree for $v_{r+1}, \cdots, v_{i+m}$ that has not been used previously together with T^u_{ir} in one of the solutions $T^k_{i,i+m}$, $1 \leqq k \leqq K-1$, thus the right subtree is given by $T^{\mathrm{LAST}(i,i+m,r,K,u)+1}_{r+1,i+m}$.

(b) If the left subtree T^u_{ir} has not been used in one of the solutions $T^k_{i,i+m}$, $1 \leqq k \leqq K-1$, then it is easily verified that u must be equal to $U(i, i+m, r, K)+1$ and the right subtree must be the optimal one, i.e., $T^1_{r+1,i+m}$. We observe that for $u > U$ the operator LAST is equal to zero by definition. In addition, since the costs of T^u_{ir} and $T^v_{r+1,i+m}$, i.e., C^u_{ir} and $C^v_{r+1,i+m}$ are computed relative to **their** roots, we must adjust the leaves' levels that results in adding the sum of the weights $W_{i,i+m}$ to $C^u_{ir}+C^v_{r+1,i+m}$.

Formula (2) follows immediately from the above observations.

Maintaining an appropriate data structure of $\{C^u_{ir}+C^{\mathrm{LAST}(i,i+m,r,K,u)+1}_{r+1,i+m} \mid r = i, \cdots, i+m-1, u = 1, \cdots, K\}$ for each (i, m) pair, the $O(K)$ minimizations in the inner loop require $O(n+K \log (n+K))$-time. Since $\log K \leqq \log M_n = O(n)$, the overall complexity of the algorithm is $O(Kn^3)$.

3. Alphabetic trees: Algorithm B. We do not know of any efficient modification of Algorithm A to solve for the best binary (nonalphabetic) trees. Next we describe an $O(Kn^4)$ algorithm for alphabetic trees, for which such a modification is possible as will be described in the next section. This algorithm that we call Algorithm B uses a partitioning procedure of the solution set, similar to that of Murty [M] and Lawler [L1]. (See also [KIM2], [KIM3] and the extensive bibliographies on ranking the K-best shortest paths.)

Let A_n be the set of alphabetic trees with n leaves.

Let $T^k = (l^k_1, \cdots, l^k_n)$ be the K-best tree in A_n. Suppose that T_1 is known. For $i = 1, \cdots, n-1$ let $S_i(S'_i)$ be the subset of A_n satisfying $l_1 = l^1_1, \cdots, l_{i-1} = l^1_{i-1}$, $l_i < l^1_i$ $(l_i > l^1_i)$. The union of all these sets is $A_n - \{T^1\}$, so that if we can solve for the best tree in each set then we can obtain T^2 by comparing these trees and selecting the one with minimum cost.

Suppose, without loss of generality, that $T^2 \in S_i$. To compute T^3 we first partition $S_i - \{T^2\}$ to subsets $R_j(R'_j)$ $j = i, \cdots, n-1$ satisfying new constraints in addition to those defining S_i. Specifically,

$$R_i = \{T \in A_n \mid l_1 = l^1_1, \cdots, l_{i-1} = l^1_{i-1}, l_i < l^2_i\},$$

$$R'_i = \{T \in A_n \mid l_1 = l^1_1, \cdots, l_{i-1} = l^1_{i-1}, l^2_i < l_i < l^1_i\}, \text{ and for } j = i+1, \cdots, n-1,$$

$$R_j = \{T \in A_n \mid l_1 = l^1_1, \cdots, l_{i-1} = l^1_{i-1}, l_i = l^2_i, \cdots, l_{j-1} = l^2_{j-1}, l_j < l^2_j\},$$

$$R'_j = \{T \in A_n \mid l_1 = l^1_1, \cdots, l_{i-1} = l^1_{i-1}, l_i = l^2_i, \cdots, l_{j-1} = l^2_{j-1}, l_j > l^2_j\}.$$

If we could solve for the best tree in each of these sets, then we could compute T^3 as the tree of minimum cost among these trees and the best trees of S'_i, S_j, and S'_j $j \neq i$. By repeating this procedure $K-1$ times we could compute the K-best trees in A_n.

To apply such a procedure we need an algorithm that computes the best tree satisfying constraints of the following type: $l_1 = \bar{l}_1, \cdots, l_{i-1} = \bar{l}_{i-1}$, $D_1 \leqq l_i \leqq D_2$. We

denote the set of trees satisfying these constraints by F_i. All these trees share a common left part consisting of the paths from the root to the $(i-1)$st most left leaves $v_1, \cdots, v_{i-1}$.

DEFINITION. The **front** of the trees in F_i consists of the subgraph of a tree $T \in F_i$ induced by the paths from the root to the i leftmost leaves, where the path to v_i is extended from the leaf so that its total length is D_2. This extended path is called the **stem** of the front.

We note that the front is uniquely defined and is independent of the choice of the tree T. The front is also independent of D_1, so that it is characterized by the level sequence $(\bar{l}_1, \cdots, \bar{l}_{i-1}, D_2)$.

The nodes on the front, except those on the stem, are either leaves or parents to two sons. The nodes on the stem fall into three categories:

(i) Parents to two sons. We call them **closed** nodes.

(ii) Parents to a single son. We call them **open** nodes.

(iii) The leaf. We classify it also as an open node.

We name the open nodes in order from the leaf to the root by $O_1, \cdots, O_m$ as in Fig. 1, and denote their levels by $l(O_1), \cdots, l(O_m)$, respectively.

Let $q = \max\{j \mid l(O_j) \geqq D_1$ and there are no closed nodes below $O_j\}$, i.e., O_q is the open node closest to the root whose level is at least D_1 such that all the closed nodes on the stem have lower levels. In other words, the ith leaf of the trees in F_i must be one of the nodes $O_q, O_{q-1}, \cdots, O_1$.

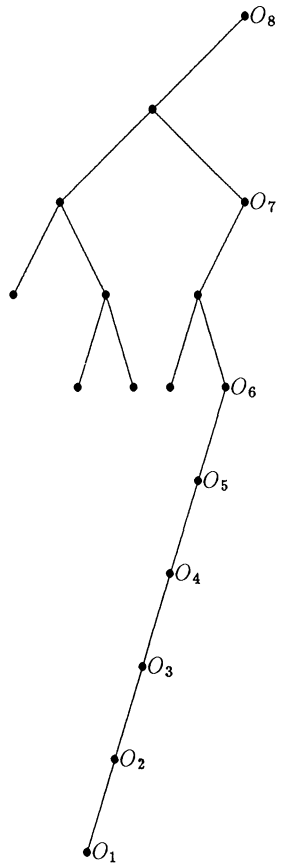

FIG. 1. *The front* (3, 4, 4, 4, 9).

Any tree in F_i is constructed from the front of F_i by assigning v_i to an open node O_p, $p \leqq q$, deleting $O_1, \cdots, O_{p-1}$, and joining $v_{i+1}, \cdots, v_n$ to $O_{p+1}, \cdots, O_m$ through **nonempty** alphabetic trees whose leaves are consecutive subsequences of $v_{i+1}, \cdots, v_n$, and whose roots are connected to the open nodes. For example, suppose $F_i = \{T \in A_n \mid l_1 = 3,\ l_2 = 4,\ l_3 = 4,\ l_4 = 4,\ 5 \leqq l_5 \leqq 9\}$. Then the front of F_i is as in Fig. 1, and $O_q = O_5$. Figure 2 illustrates the construction of a member of F_i from the front of F_i.

We now show how to solve the problem of computing the best tree in F_i by dynamic programming.

Let V_{jl}, $j \geqq 1$, $l \geqq 1$ denote the minimum cost involved with attaching leaves $v_i, \cdots, v_l$ to subtrees connected to $O_1, \cdots, O_j$. Let C_{rl} denote the cost of an optimal alphabetic tree with leaves $v_r, v_{r+1}, \cdots, v_l$. Note that if we attach this tree to the front through an edge from O_j to its root, then the actual cost is $C_{rl} + W_{rl}(l(O_j)+1)$. Therefore,

$$V_{jl} = \min_{i \leqq r \leqq l-1} \{V_{j-1,r} + C_{r+1,l} + W_{r+1,l}(l(O_j)+1)\}, \qquad l > i, \quad j > 2,$$

$$V_{1l} = \infty, \qquad l > i,$$

$$V_{ji} = \begin{cases} w_i l(Oj), & 1 \leqq j \leqq q, \\ \infty, & j > q. \end{cases} \tag{3}$$

The costs C_{rl}, $1 \leqq r < l \leqq n$ can be computed in $O(n^3)$-time by (1). Then (3) can be computed for a given front and q (determined by a lower bound D_1) and for all relevant j and l in $O(n^3)$.

To apply (3) we must first determine the levels of the open nodes on the stem. For this purpose we make the following definitions:

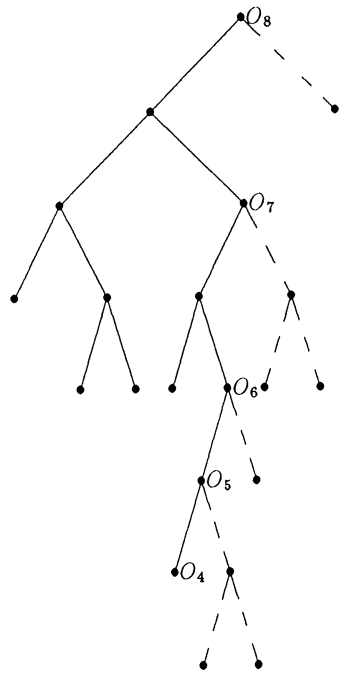

FIG. 2. *A possible completion for the tree in Fig.* 1.

For a sequence $a_1, \cdots, a_n$ let $k = \min\{i \mid a_{i-1} = a_i\}$. Then the sequence $a_1, \cdots, a_{i-2}, a_i - 1, a_{i+1}, \cdots, a_n$ is the **reduction from the left** of the original sequence. The **left-reduced sequence** for $a_1, \cdots, a_n$ is obtained by repeating the process of reduction from the left until $a_{i-1} \neq a_i$, $i = 2, \cdots, n$. For example, the sequence (3, 4, 4, 4) generates (3, 3, 4) and then (2, 4). No further reduction is possible and thus (2, 4) is the left reduced sequence.

LEMMA 1 [HT]. *A sequence $l_1, \cdots, l_n$ defines a tree in A_n if and only if its left reduced sequence is* (0).

In a similar way we can prove the following theorem.

THEOREM 2. *Let $(l_1^*, \cdots, l_p^*)$ be the left reduced sequence of $(\bar{l}_1, \cdots, \bar{l}_{i-1})$. Then*

(a) *F_i is nonempty if and only if $D_2 \geqq l_p^*$ and $\max\{D_1, l_p^*\} - p \leqq n - i + 1$.*

(b) *If F_i is nonempty then the stem of the front of the trees in F_i, defined by $(\bar{l}_1, \cdots, \bar{l}_{i-1}, D_2)$, contains exactly p closed nodes, at levels $l_1^* - 1, \cdots, l_p^* - 1$.*

The costs $C_{rl} \leqq r < l \leqq n$ used in (3) can be computed in $O(n^3)$-time by (1). For a given front the open nodes can be computed with the aid of Theorem 2, and q is determined by the front and the lower bound D_1. Then (3) can be computed for all relevant j and l in $O(n^3)$-time. For each value of k, $1 \leqq k \leqq K$ we apply (3) at most $2n$ times using the above partitioning procedure, and then select the best of the solutions obtained for the $O(Kn)$ subsets of the partition. Therefore the time required to compute the next best tree is $O(n^4 + n \log Kn) = O(n^4)$, and the overall complexity of computing the K-best trees is $O(Kn^4)$.

4. Nonalphabetic trees: Algorithm C. In this section and the subsequent one, we describe two algorithms for computing the K-best binary trees for the leaves $v_1, v_2, \cdots, v_n$. In contrast to the previous section, the order of the leaves is not prespecified. The optimal tree can be computed in $O(n \log n)$-time by the algorithm due to Huffman [Huf]. Alternatively, the leaves can be numbered in ascending order of their weights $w_1, \cdots, w_n$ and then the best alphabetic tree for $v_1, v_2, \cdots, v_n$ can be computed by the Hu-Tucker Algorithm [HT] that also requires $O(n \log n)$ time. It is known that the resulting tree is indeed optimal.

As mentioned in § 1 we consider two different ranking problems on the set of nonalphabetic trees. In this section we provide a ranking algorithm of complexity $O(Kn^4)$ according to (b) defined in § 1. In this problem a solution $(l_1, l_2, \cdots, l_n)$ is characterized by the set $\{(l_i, w_i) \mid 1 \leqq i \leqq n\}$, i.e., interchanging the levels of two words with identical weights will **not** create a new solution.

We first modify the partitioning algorithm of § 3 to rank nonalphabetic trees. To reduce the time complexity we modify the partitioning scheme so that when computing the next best solution each subset is replaced by just two new ones, rather than $O(n)$ new ones. As in [G], [Der], [KIM1] and [KIM3] this requires knowledge of both the best and the second-best solution in each subset of the partition.

Without loss of generality we assume that $w_1 \leqq w_2 \leqq \cdots \leqq w_n$ and let l_i denote the level of v_i. A **tree** is uniquely defined by the sequence $(l_1, \cdots, l_n)$ for which there exists a permutation $(l_1', \cdots, l_n')$ defining an alphabetic tree. It is well known that a necessary and sufficient condition for integers $(l_1, \cdots, l_n)$ to define a tree is that

$$\sum_{i=1}^{n} 2^{-l_i} = 1. \tag{4}$$

The cost of the tree $(l_1, \cdots, l_n)$ is $\sum_{i=1}^{n} w_i l_i$. Trees $(l_1, \cdots, l_n)$ and $(l_1', \cdots, l_n')$ are said to be isomorphic if one sequence is a permutation of the other. Trees $T = (l_1, \cdots, l_n)$

and $T' = (l'_1, \cdots, l'_n)$ are distinct if the ordered sequences $(l_1, \cdots, l_n)$ and $(l'_1, \cdots, l'_n)$ are different. As before, we denote by $T^k = (l_1^k, \cdots, l_n^k)$ the k-best tree.

Clearly there exists an optimal binary tree $(l_1, l_2, \cdots, l_n)$ satisfying $l_1 \geqq l_2 \geqq \cdots \geqq l_n$ and without loss of generality we call it T^1. The next lemma shows that T^1 is also the best alphabetic tree with respect to the nondecreasing weight sequence $w_1, \cdots, w_n$, and thus can be computed by the Hu-Tucker Algorithm or by (1).

LEMMA 3 [Has]. *Any nonincreasing sequence* $(l_1, \cdots, l_n)$ *satisfying* (4) *represents an alphabetic tree.*

The following theorem uses this property and will be used to compute the second-best tree in every subset of the partition.

THEOREM 4. *Either* T^2 *is the second-best alphabetic tree with respect to* $w_1, \cdots, w_n$, *or* T^2 *is isomorphic to* T^1 *and* $(l_1^2, \cdots, l_n^2) = (l_1^1, \cdots, l_{r-2}^1, l_r^1, l_{r-1}^1, l_{r+1}^1, \cdots, l_n^1)$ *for some* $r \geqq 2$ *such that* $l_{r-1}^1 > l_r^1$ *and* $w_r \neq w_{r-1}$.

Proof. Clearly if T^1 and T^2 are not isomorphic then $l_1^2 \geqq l_2^2 \geqq \cdots \geqq l_n^2$. By Lemma 3, T^2 is an alphabetic tree, thus it is the second-best alphabetic tree. Suppose now that T^1 and T^2 are isomorphic. Since $l_1^1 \geqq l_2^1 \geqq \cdots \geqq l_n^1$, there must exist indices $j < r$ such that $l_j^1 > l_r^1$ and $l_r^2 = l_j^1$. Moreover, we can assume $l_{r-1}^1 > l_r^1$ and $w_{r-1} < w_r$. Then T^2 is the best tree satisfying $l_r = l_j^1$, which means that except for l_r the levels are nondecreasing: $l_1^2 \geqq l_2^2 \geqq \cdots \geqq l_{r-1}^2 \geqq l_{r+1}^2 \geqq \cdots \geqq l_n^2$. Consequently, $(l_1^2, \cdots, l_n^2) = (l_1^1, \cdots, l_{j-1}^1, l_{j+1}^1, \cdots, l_r^1, l_j^1, l_{r+1}^1, \cdots, l_n^1)$, so that T^2 is obtained from T^1 by a cyclic permutation of a subsequence $(l_j, \cdots, l_r)$. The difference in the costs of T^2 and T^1 is

$$\sum_{i=1}^{n} w_i(l_i^2 - l_i^1) = -\sum_{i=j}^{r-1} w_i(l_i^1 - l_{i+1}^1) + w_r(l_j^1 - l_r^1)$$

$$\geqq -w_{r-1} \sum_{i=j}^{r-1} (l_i^1 - l_{i+1}^1) + w_r(l_j^1 - l_r^1) = (w_r - w_{r-1})(l_j^1 - l_r^1)$$

$$\geqq (w_r - w_{r-1})(l_{r-1}^1 - l_r^1).$$

The last term is the change in costs obtained with respect to the tree $(l_1^1, \cdots, l_{r-2}^1, l_r^1, l_{r-1}^1, l_{r+1}^1, \cdots, l_n^1)$. Hence this tree is the second-best tree as claimed. □

Let B_n denote the set of nonalphabetic trees with n leaves. We now consider the problem of computing the best tree in B_n satisfying $l_i = \bar{l}_i$, $i \in Q$. Let $i_1, \cdots, i_{|Q|}$ be a permutation of $i \in Q$ such that $\bar{l}_{i_1} \leqq \bar{l}_{i_2} \leqq \cdots \leqq \bar{l}_{i_{|Q|}}$. Let $i_{|Q|+1}, \cdots, i_n$ be a permutation of $i \in \{1, \cdots, n\} \backslash Q$ such that $w_{i_{|Q|+1}} \leqq w_{i_{|Q|+2}} \leqq \cdots \leqq w_{i_n}$. Clearly there exists an optimal nonalphabetic tree $(\tilde{l}_1, \cdots, \tilde{l}_n)$ with respect to the constraints $l_i = \bar{l}_i$, $i \in Q$ satisfying $\tilde{l}_{i_{|Q|+1}} \geqq \tilde{l}_{i_{|Q|+2}} \geqq \cdots \geqq \tilde{l}_{i_n}$. Theorem 5 below shows that the sequence $\tilde{l}_{i_1}, \cdots, \tilde{l}_{i_n}$ defines an **alphabetic** tree, and obviously this implies that $(\tilde{l}_{i_1}, \cdots, \tilde{l}_{i_n})$ is the optimal alphabetic tree with respect to $w_{i_1}, \cdots, w_{i_n}$. Therefore the best **nonalphabetic** tree under the constraints $l_i = \bar{l}_i$, $i \in Q$ can be computed by applying (3) to $w_{i_1}, \cdots, w_{i_n}$.

THEOREM 5. *A sequence of integers* $(l_1, \cdots, l_n)$ *satisfying conditions* (a) *and* (b) *represents an alphabetic binary tree*:

(a) $\sum_{i=1}^{n} 2^{-l_i} = 1$

(b) *For some* m, $1 \leqq m \leqq n$, $l_1 \leqq l_2 \leqq \cdots \leqq l_{m-1} < l_m$, *and* $l_m \geqq l_{m+1} \geqq \cdots \geqq l_n$.

Proof. The proof is by induction on n. For $n = 2$ the only sequence (l_1, l_2) satisfying (a) and (b) is $(1, 1)$, which also represents an alphabetic tree. Suppose the conclusion holds for a sequence of k elements with $k \leqq n-1$ and assume the sequence $(l_1, \cdots, l_n)$

satisfies (a) and (b). Clearly $l_m = \max_{1 \leqq j \leqq n} l_j$ and as $\sum_{j=1}^{n} 2^{-l_j} = 1$ there must exist an even number of indices for which $l_j = l_m$. Without loss of generality assume $l_m = l_{m+1} = \cdots = l_{m+k_1}$ for some odd number $k_1 \geqq 1$. Let j^* and j^*+1 be the most left pair of indices for which $l_{j^*} = l_{j^*+1}$. Clearly, $j^* \leqq m$. The first step of reduction from the left of the sequence l will generate the sequence $(l_1, \cdots, l_{j^*-1}, l_{j^*} - 1, l_{j^*+2}, \cdots, l_n)$. It is easily verified that the last sequence of $n-1$ elements satisfies both (a) and (b), thus by the assumption it represents an alphabetic tree T with $n-1$ leaves. The alphabetic tree for the sequence l is obtained by adding two sons to the j^*th leaf of T. □

We now describe the partitioning scheme. Suppose $T^1 = (l_1^1, \cdots, l_n^1)$ has been computed. T^2 is then either the second-best tree in $F_1 = \{T \mid l_1 = l_1^1\}$ or the optimal tree in $F_2 = \{T \mid l_1 \neq l_1^1\}$.

To compute the optimal tree in F_2 we could imitate the partitioning procedure described in § 2 also here. However, we do not know how to solve a problem with constraints of the type $l_i \leqq D_2$ except for by solving $D_2 = O(n)$ problems with $l_i = l$, $l = q, \cdots, D_2$. The scheme requires solving $O(Kn)$ such problems, and each requires $O(n^3)$-time, so the overall complexity is $O(Kn^5)$. We now describe a modified partitioning scheme, relying on our ability to compute the two best solutions to constrained problems, that results in $O(Kn^4)$ time complexity.

The optimal tree in F_2 is obtained by solving $O(n)$ problems, each with a constraint of the form $l_1 = \hat{l}$, for $\hat{l} \in \{1, \cdots, n\} \backslash \{l_1^1\}$. Altogether the two best solutions are computed in $O(n^4)$ time complexity.

At the beginning of the kth iteration of the algorithm, we have a partition $\tilde{F}$ of $B_n \backslash \{T^1, \cdots, T^{k-1}\}$ into subsets. In each subset $F \in \tilde{F}$ we are given the best and second-best trees $T^1(F)$ and $T^2(F)$. We define $T(F)$ to be $T^1(F)$ if $T^1(F) \notin \{T^1, \cdots, T^{k-1}\}$. Otherwise we define $T(F) = T^2(F)$, and in this case $T^2(F) \notin \{T^1, \cdots, T^{k-1}\}$. The next best tree T^k, is therefore the best of all trees $\{T(F) \mid F \in \tilde{F}\}$.

Suppose $T^k = T(F^*)$. If $T^k = T^1(F^*)$ then we do not change the partition and set $T(F^*) = T^2(F^*)$. If $T^k = T^2(F^*)$ then there exist $j < k$ such that $T^j = T^1(F^*)$. Suppose $F^* = \{T \in B_n \mid l_i = l_i^j, i \in Q\}$. Since $T^k \neq T^j$ there exist $m \notin Q$ such that $l_m^k \neq l_m^j$. We replace F^* by new subsets, $F_r = \{T \in B_n \mid l_i = l_i^j, i \in Q, l_m = r\}$ for all $r = 1, \cdots, n-1$. For each of these new subsets we compute both the best and the second-best solutions. This requires $O(n^3)$-time for each subset.

We note that $\bigcup_{r=1}^{n-1} F_r = F^*$ and these sets are disjoint. For $r = l_m^j$, $T^1(F_r) = T^j$ and for $r = l_m^k$ $T^1(F_r) = T^k$. Thus for these values of r we set $T(F_r)$ to $T^2(F_r)$. For the other sets F_r we set $T(F_r)$ to $T^1(F_r)$. This requires $O(n^3)$-time for each set and $O(n^4)$ in total. Thus the overall complexity per iteration is $O(n^4)$ and for ranking K-best trees it amounts to $O(Kn^4)$.

5. Nonalphabetic trees: Algorithm D. In this section we propose an $O(Kn^3)$ algorithm for ranking the K-best nonalphabetic trees for problem (a) defined in § 1. Here a solution is defined by the sequence $(l_1, \cdots, l_n)$, i.e., interchanging the lengths of two words with identical weights **will** create a new solution of the same cost. The algorithm uses a two-stage partitioning scheme. First B_n—the set of nonalphabetic trees—is partitioned into subsets characterised by the (unordered) level set $\{l_1, \cdots, l_n\}$. Then these sets are further partitioned by an algorithm for ranking a special type of transportation problems adopted from that of Murty [M] and Weintraub [W].

Let $w_1, \cdots, w_n$ be given in ascending order $w_1 \leqq w_2 \leqq \cdots \leqq w_n$, and $T_a^1, \cdots, T_a^K$ be the K-best alphabetic trees for $w_1, \cdots, w_n$. For $k = 1, \cdots, K$, let S_{kl} be the set of

leaves of T_a^k whose level is l. Let $T_A^1, \cdots, T_A^R$ be the subsequence of $T_a^1, \cdots, T_a^K$ obtained by deleting all trees T_a^k for which there exists $j<k$ such that $|S_{jl}|=|S_{kl}|$, $l=1, \cdots, n-1$.

For $r=1, \cdots, R$ consider the following transportation problem P_r that assigns the weights $w_1, \cdots, w_n$ to the level sets S_{rl} of T_A^r:

$$
\begin{aligned}
(P_r) \qquad \text{minimize} \quad & \sum_{i,l} l w_i X_{il} \\
\text{subject to} \quad & \sum_{l} X_{il} = 1 \qquad \forall i, \\
& \sum_{i} X_{il} = |S_{rl}| \qquad \forall l, \\
& X_{il} \geqq 0 \qquad \forall i, l.
\end{aligned}
$$

Let X^{kr} be the k-best solution to (P_r) and let Y^k be the k-best solution among $\{X^{jr} | j=1, \cdots, K, r=1, \cdots, R\}$. Let T^k be the tree defined by Y^k.

THEOREM 6. *T^k is the k-best nonalphabetic tree.*

Proof. X^{rk} defines the k-best solution when the tree is restricted to have the level sets defined by S_{rl}, $l=1, \cdots, n-1$. Therefore, Y^k defines the k-best nonalphabetic tree, under the restriction that it has $|S_{rl}|$ leaves of level l, $l=1, \cdots, n-1$, for some $r \in \{1, \cdots, R\}$. We now show that this restriction is legitimate. Assume otherwise that the list $T^1, \cdots, T^k$ contains a tree that does not obey the above restriction. Let k^* be the smallest index of such a tree. Clearly in T^{k^*} the weights are assigned to leaves in a nonincreasing order, i.e., $l(w_i) \geqq l(w_j)$ for $i<j$. By Lemma 3 there exists an alphabetic tree with the same level set and where the levels of the leaves are nonincreasing. Therefore T^{k^*} is an alphabetic tree with respect to $w_1, \cdots, w_n$ and $T^{k^*} = T_A^r$ for some r, $1 \leqq r \leqq R$, in contradiction to the assumption. □

Each problem (P_r) is a transportation problem that can be reformulated as an assignment problem (P_r'):

$$
\begin{aligned}
(P_r') \qquad \text{minimize} \quad & \sum_{i} \sum_{l} \sum_{e \in S_{rl}} l w_i X_{ie} \\
\text{subject to} \quad & \sum_{e} X_{ie} = 1 \qquad \forall i \\
& \sum_{i} X_{ie} = 1 \qquad \forall e.
\end{aligned}
$$

The next best solution of (P_r) can therefore be obtained by solving $O(n)$ problems of this type, as described by Murty [M] and Weintraub [W].

The complexity of producing $T_a^1, \cdots, T_a^K$, and deleting trees to obtain $T_A^1, \cdots, T_A^R$ is of order $O(Kn^3)$. Weintraub [W] in his interesting paper presents an $O(Kn^3)$ algorithm for ranking the K-best assignments. By using his procedure to rank the solutions of (P_r') our algorithm for calculating $Y^1, \cdots, Y^K$ requires an overall complexity of $O(Kn^3)$.

It is worth pointing out that for the special case where $w_1 < w_2 < \cdots < w_n$ the two last algorithms solve the same problem. In view of the differences in their order complexities, we should prefer to use Algorithm D.

AN ANALYSIS OF THE RATIONAL EXPONENTIAL INTEGRAL*

G. W. CHERRY†

Abstract. In this paper an algorithm is presented for integrating expressions of the form $\int ge^f dx$, where f and g are rational functions of x, in terms of a class of special functions called the special incomplete Γ functions. This class of special functions includes the exponential integral, the error function, the sine and cosine integrals, and the Fresnel integrals. The algorithm presented here is an improvement over those published previously for integrating with special functions in the following ways: (i) This algorithm combines all the above special functions into one algorithm, whereas previously they were treated separately. (ii) Previous algorithms require that the underlying field of constants be algebraically closed. This algorithm, however, works over any field of characteristic zero in which the basic field operations can be carried out. (iii) This algorithm does not rely on Risch's solution of the differential equation $y'+fy=g$. Instead, a more direct method of undetermined coefficients is used.

Key words. Liouville's theorem, integration in finite terms, special functions, logarithmic integrals, exponential integrals, error functions

AMS(MOS) subject classifications. 68Q40, 12H05

1. Background. It is well known that if C is the field of complex numbers and g is a rational function in $C(x)$, then $\int g\,dx$ can be written in terms of elementary functions. Specifically, the integral can be written as the sum of a rational function and a linear combination of logarithms. There are, however, algorithmic difficulties encountered if we try to factor the denominator of g (or any part of this denominator) into linear factors to determine the logarithms. Only recently (cf. [Roth76], [Trag76]) have the algorithmic details been worked out.

In this paper we present a similar analysis of the *rational exponential integrals*—integrals of the form $\int ge^f dx$ where f and g are rational functions of x. Our algorithm will determine whether a given rational exponential integral can be written in terms of a class of functions called the *special incomplete* Γ *functions* [Bate53]. This class includes, in addition to the elementary functions, a number of well-known special functions such as the exponential integral

$$\operatorname{ei}(u) = \int \frac{u'}{u} e^u\,dx$$

and the error function[1]

$$\operatorname{erf}(u) = \int u'e^{u^2}\,dx.$$

Examples of integrations performed by our algorithm are

$$\int e^{1/x}\,dx = xe^{1/x} - \operatorname{ei}\left(\frac{1}{x}\right)$$

and

$$\int \left(\frac{1}{x}+\frac{1}{x^2}\right) e^{1/x^2}\,dx = -\frac{1}{2}\operatorname{ei}\left(\frac{1}{x^2}\right) - \operatorname{erf}\left(\frac{1}{x}\right).$$

[1] The usual error function, $\operatorname{Erf}(x) = \int_0^x e^{-t^2}\,dt$ [Bate53], differs from our definition, which is denoted as Erfi in [Bate53], as follows: $\operatorname{Erf}(x) = 1/i \operatorname{Erfi}(ix)$. Also see the Appendix.

As these examples indicate, there are many integrals that cannot be written in terms of elementary functions but can be written in terms of special incomplete Γ functions. Another, more general example of this is the integral $\int ge^x\,dx$. It is elementary only if g is a polynomial, but it can always be integrated in terms of elementary functions and exponential integrals.

Algorithms for integrating in terms of special functions have been reported in [Ssc85], [Cher83], [Cher85], and [Cher86] where separate procedures have been given for integrating transcendental elementary functions in terms of exponential integrals and error functions. This work was later extended in [Know86a] and [Know86b]. The algorithm presented in this paper can be viewed as a synthesis and refinement of the so-called "base cases" of these procedures. In addition to the synthesis we have made two improvements to the original algorithms. The first concerns algebraic constants. If we are interested in expressing rational exponential integrals only in terms of elementary functions, then it is not necessary to introduce new algebraic constants (e.g., if the integrand is composed of rational functions f and g that lie in $Q(x)$, then an elementary integral, if it exists, will be of the form he^f where h is in $Q(x)$). However, when integrating in terms of special incomplete Γ functions new algebraic constants may arise. For example,

$$\int \frac{e^x}{x^2-2}\,dx = e^{\sqrt{2}}\,\mathrm{ei}\,(x+\sqrt{2}) + e^{\sqrt{2}}\,\mathrm{ei}\,(x+\sqrt{2}).$$

In [Cher83], and again in [Know86a], [Know86b], it is assumed that the field of constants over which the integrand is defined is algebraically closed. Under this assumption it is not necessary to introduce "new" algebraic constants to express the integral. It is necessary, however, to perform all operations such as partial fraction decompositions over an algebraically closed field such as the algebraic closure of the rationals. Although theoretically sound (cf. [DaTr81]) there are difficulties with this approach. The algorithm presented here works over any constant field of characteristic zero, provided the basic field operations can be performed. Also, any new algebraic constants that are necessary for expressing the integral will be expressed in a field of lowest possible degree. In fact, it will be shown that any algebraic constants occurring in the error functions are quadratic over the constant field.

The second improvement presented here concerns the overall structure of the algorithm. In previous algorithms a two step strategy has been employed: first we generate a finite set of special functions

$$\left\{\int h_1 e^f, \cdots, \int h_n e^f\right\}$$

such that if the integral can be resolved, then the special functions that appear in the result are from this set. For the class of special functions we are considering here, this implies that there exist constants c_i and a rational function y such that

$$\int ge^f + c_1 \int h_1 e^f + \cdots + c_n \int h_n e^f = ye^f.$$

The second step is to apply an algorithm of Risch's [Risch69, Main Theorem, part (b)] that reduces the calculation of the elements $y, c_1, \cdots, c_n$ to the solution of a linear system of equations. We observe, however, that the actual construction of this linear system is often not necessary. In fact, it has recently been shown [Dav86] that in the base case of Risch's algorithm (the only part needed in this paper) it is never necessary to explicitly solve a linear system of equations. Instead, by examining the partial

fraction decompositions of f and g, we can directly solve for y. The algorithm presented here uses similar techniques to those in [Dav86] to directly solve for the elementary part y and then for the exponential integrals and error functions.

The paper is organized as follows. In §2 we give a formal definition of the special incomplete Γ functions and prove two results concerning the structure of integrals that can be expressed in terms of these functions. In §3 we examine the problem of completing squares of rational functions, which is a basic problem encountered when integrating with error functions. The algorithm is described in §4 and examples are given in §5.

2. The special incomplete Γ functions. Let F be a differential field[2] of characteristic zero with derivation $'$. A differential extension E of F is called a *special incomplete* Γ *extension of* F if there exists a tower of fields $F = F_0 \subset F_1 \subset \cdots \subset F_n = E$ such that for each i, $1 \leqq i \leqq n$, $F_i = F_{i-1}(\theta_i)$ and one of the following holds:

(i) θ_i is algebraic over F_{i-1}.

(ii) θ_i is logarithmic over F_{i-1} (i.e., $\theta_i' = u'/u$ for some nonzero u in F_{i-1}, and we write $\theta_i = \log(u)$).

(iii) θ_i is an exponential over F_{i-1} (i.e., $\theta_i' = u'\theta_i$ for some u in F_{i-1}, and we write $\theta_i = e^u$).

(iv) θ_i is an error function over F_{i-1} (i.e., $\theta_i' = u'v$ for some u and v in F_{i-1} such that $v' = (u^2)'v$, and we write $\theta_i = \operatorname{erf}(u)$).

(v) θ_i is an exponential integral over F_{i-1} (i.e., $\theta_i' = (u'/u)v$ for some nonzero u and v in F_{i-1} such that $v' = u'v$, and we write $\theta_i = \operatorname{ei}(u)$).

We note that (v) could be replaced by the equivalent statement (v′):

(v′) θ_i is a logarithmic integral over F_{i-1} (i.e., $\theta_i' = u'/v$ for some nonzero u and v in F_{i-1} such that $v' = u'/u$, and we write $\theta_i = \operatorname{li}(u)$).

The following theorem is a synthesis of two results that have appeared in [Ssc85] and [Cher83]. The proof relies on the following lemma (that also can be found in [Cher83]).

LEMMA 2.1. *Let k be a field containing the nth roots of unity and let K be an algebraic extension of k. If v is an element of K such that v^n is in k, then either v is in k or the trace of v in K with respect to k is zero.*

Proof. First note that v satisfies a pure equation and therefore has a cyclic Galois group: $\{\sigma, \sigma^2, \cdots, \sigma^r\}$ [Vdw50]. Next, let $\sigma(v) = \xi^k v$ where ξ is a primitive nth root of unity and write the conjugates of v as

$$\begin{aligned} \sigma(v) &= \xi^k v \\ \sigma^2(v) &= \xi^{2k} v \\ &\vdots \\ \sigma^r(v) &= \xi^{rk} v. \end{aligned}$$

Now since $\sigma = \sigma^{r+1}$, ξ^k is an rth root of unity and so either $r = 1$ or

$$\operatorname{Tr}(v) = (\xi^k + \cdots + \xi^{rk})v = 0 \cdot v = 0. \qquad \square$$

THEOREM 2.2. *Let E be a Liouvillian extension of $C(x)$ where C is a field of constants, x is transcendental over C, and $x' = 1$. Assume C is algebraically closed and has characteristic zero, and let γ be an element of E that has an integral in some special*

[2] We shall assume the reader is familiar with the basic terminology of differential algebra (cf. [Kap57]).

incomplete Γ*-extension of* E. *Then there exist constants* b_i, c_i, *and* d_i *in* C, *elements* w_i, u_i, *and* v_i *in* E *and* $\tilde{u}_i$ *and* $\tilde{v}_i$ *algebraic over* E *such that*

$$\gamma = w_0' + \sum b_i \frac{w_i'}{w_i} + \sum c_i \frac{u_i'}{u_i} v_i + \sum d_i \tilde{u}_i' \tilde{v}_i \tag{2.1}$$

where $v_i' = u_i' v_i$, $\tilde{v}_i' = (\tilde{u}_i^2)' \tilde{v}_i$, *and* $\tilde{u}_i^2$, $\tilde{v}_i^2$, *and* $\tilde{u}_i' \tilde{v}_i$ *are in* E.

Proof. A direct application of the main theorem from [Ssc85][3] implies that there exist constants b_i, c_i, and d_i and elements w_i, u_i, v_i, $\tilde{u}_i$, and $\tilde{v}_i$ algebraic over E satisfying (2.1). Now for each i, since $v_i' = u_i' v_i$, we have by the lemma on p. 338 of [RoSi77] that u_i is in E and some positive power of v_i is in E. Therefore some positive power of $(u_i'/u_i)v_i$ is in E. Similarly, for each i, we have $\tilde{u}_i^2$ and some positive power of $\tilde{v}_i$ in E. Moreover, $(\tilde{u}_i')^2 = \frac{1}{4}((\tilde{u}_i^2)')^2/\tilde{u}_i^2$, and so $(\tilde{u}_i')^2$ is in E and some positive power of $\tilde{u}_i' \tilde{v}_i$ is in E. Next let $\bar{E}$ be a normal extension of E containing the w_i, u_i, v_i, $\tilde{u}_i$, and $\tilde{v}_i$ and take the trace in $\bar{E}$ on both sides of (2.1) over the field E. This yields

$$m\gamma = (\operatorname{Tr}(w_0))' + \sum c_i \frac{(N(w_i))'}{N(w_i)} + \sum c_i \operatorname{Tr}\left(\frac{u_i'}{u_i} v_i\right) + \sum d_i \operatorname{Tr}(\tilde{u}_i' \tilde{v}_i)$$

where m is a positive integer and $N(w_i)$ is the norm of w_i. Now Lemma 2.1 implies that, for each i, $\operatorname{Tr}((u_i'/u_i)v_i) = 0$ unless $(u_i'/u_i)v_i$ is in E and $\operatorname{Tr}(\tilde{u}_i' \tilde{v}_i) = 0$ unless $\tilde{u}_i' \tilde{v}_i$ is in E. In the first case u_i is in E and so v_i is in E. In the second case $(\tilde{u}_i')^2$ is in E and so $\tilde{v}_i^2 = (\tilde{u}_i' \tilde{v}_i)^2/(\tilde{u}_i')^2$ is in E. This completes the proof. □

We now examine the case where F is a field of constants, f and g are in $F(x)$, and E is the differential field $\bar{F}(x, e^f)$.

THEOREM 2.3. *Let* F *be a field of constants and let* x *be transcendental over* x *with* $x' = 1$. *Let* f *and* g *be elements of* $F(x)$ *and suppose that* ge^f *has an integral in some special incomplete* Γ*-extension of* $F(x, e^f)$. *Then there exist constants* c_i *and* d_i *in* $\bar{F}$, *an element* y *in* $F(x)$, *and elements* u_i *and* $\tilde{u}_i$ *in* $\bar{F}(x)$ *such that*

$$g = y' + f'y + \sum c_i \frac{u_i'}{u_i} + \sum d_i \tilde{u}_i' \tag{2.2}$$

where

(i) *For each* u_i *there exists an* α_i *algebraic over* F *such that* $u_i = f + \alpha_i$; *and*

(ii) *For each* $\tilde{u}_i$ *there exists a* β_i *algebraic over* F *such that* $\tilde{u}_i^2 = f + \beta_i$.

Proof. Let θ denote the exponential e^f and apply the above theorem (where E is the field $\bar{F}(x, \theta)$). This yields constants b_i, c_i, and d_i algebraic over F, w_i, u_i, and v_i in $\bar{F}(x, \theta)$, and $\tilde{u}_i$ and $\tilde{v}_i$ algebraic over $\bar{F}(x, \theta)$ such that

$$g\theta = w_0' + \sum b_i \frac{w_i'}{w_i} + \sum c_i \frac{u_i'}{u_i} v_i + \sum d_i \tilde{u}_i' \tilde{v}_i \tag{2.3}$$

where $v_i' = u_i' v_i$, $\tilde{v}_i' = (\tilde{u}_i^2)' \tilde{v}_i$ and $\tilde{u}_i^2$, $\tilde{v}_i^2$ and $\tilde{u}_i' \tilde{v}_i$ are in $\bar{F}(x, \theta)$. Since, for each i, v_i is an exponential of u_i, Theorem 3.1 of [RoCa79] implies that there exist rational numbers δ_i and constants α_i in $\bar{F}$ so that $u_i = \delta_i f - \alpha_i$. Thus θ^{δ_i} and v_i are both exponentials of u_i and, since two exponentials of a fixed element of a differential field must differ by a multiplicative constant, we have $v_i = \theta^{\delta_i} \eta_i$ where η_i is in $\bar{F}$. Note that since v_i is in $\bar{F}(x, \theta)$, δ_i is an integer. Similarly, there exist rational numbers $\tilde{\delta}_i$ and constants β_i and $\tilde{\eta}_i$ in $\bar{F}$ so that $\tilde{u}_i^2 = \tilde{\delta}_i f + \beta_i$ and $\tilde{v}_i = \theta^{\tilde{\delta}_i} \tilde{\eta}_i$. Here $\tilde{\delta}_i$ must be an integer since $\tilde{u}_i' \tilde{v}_i$ is in

[3] Where the alternative definition (v') is used for the special incomplete Γ-extensions.

$\bar{F}(x, \theta)$ and $\tilde{u}_i'$ does not involve θ. This now implies that $\tilde{u}_i'$ is in $\bar{F}(x)$ and hence, $\tilde{u}_i = (\tilde{u}_i^2)'/2\tilde{u}_i'$ is in $\bar{F}(x)$. Now, absorbing η_i into c_i and $\tilde{\eta}_i$ into d_i, write (2.3) as

$$g\theta = w_0' + \sum b_i \frac{w_i'}{w_i} + \sum c_i \frac{u_i'}{u_i}\theta^{\delta_i} + \sum d_i \tilde{u}_i' \theta^{\tilde{\delta}_i} \tag{2.4}$$

and compare the partial fraction decompositions in the variable θ over the field $\bar{F}(x)$ on both sides of (2.4). This yields $\delta_i = \tilde{\delta}_i = 1$, $w_i = 0$ for $i \geqq 1$, and $w_0 = y\theta$ for some y in $\bar{F}(x)$. Equation (2.4) becomes

$$g\theta = (y\theta)' + \sum c_i \frac{u_i'}{u_i}\theta + \sum d_i \tilde{u}_i' \theta$$

and dividing by θ yields

$$g = y' + f'y + \sum c_i \frac{u_i'}{u_i} + \sum d_i \tilde{u}_i'. \tag{2.5}$$

Now let E be a normal extension of $F(x)$ containing y and the constants α_i, c_i, β_i, and d_i, and let σ be an automorphism of E that fixes the field $F(x)$. Then from (2.5) we have

$$g = (\sigma y)' + f'(\sigma y) + \sum \sigma(c_i) \frac{\sigma(u_i')}{\sigma(u_i)} + \sum \sigma(d_i)\sigma(\tilde{u}_i)'$$

where $\sigma(u_i) = f + \sigma(\alpha_i)$ and $\sigma(\tilde{u}_i)^2 = f + \sigma(\beta_i)$. Summing over all such automorphisms, we have

$$mg = \left(\sum_\sigma y\right)' + f'\left(\sum_\sigma y\right) + \sum_\sigma \sum \sigma(c_i) \frac{\sigma(u_i')}{\sigma(u_i)} + \sum_\sigma \sum \sigma(d_i)\sigma(\tilde{u}_i)'$$

where m is a positive integer. Since $\sum_\sigma y$ is in $F(x)$, dividing this equation by m yields an equation in the same form as (2.2) and the proof is complete. □

The theorem implies that

$$\int g e^f \, dx = y e^f + \sum c_i e^{-\alpha_i} \operatorname{ei}(u_i) + \sum d_i e^{-\beta_i} \operatorname{erf}(\tilde{u}_i).$$

3. Completing squares of rational functions. In Theorem 2.3 we have shown that if error functions appear in the integral, then there exist algebraic constants β_i such that

$$f + \beta_i = \tilde{u}_i^2. \tag{3.1}$$

In this section we show that there can be at most two such values for β_i and that these values are either in F or are quadratic conjugates over F.

In the case where f is in $F[x]$ we have the familiar problem of completing squares of polynomials. Here the basic result is well known. If f is a nonconstant polynomial, then there can be at most one constant β such that $f + \beta$ is a perfect square. We state and prove here an equivalent statement that shall be useful in the next section.

THEOREM 3.1. *Let F be a constant field of characteristic zero and let f and g be two nonconstant polynomials in $F[x]$ such that $f^2 - g^2 = c$ where c is a constant. Then $c = 0$.*

Proof. Assume there are nonconstant polynomials f and g and a nonzero constant c such that $f^2 - g^2 = c$. Then f and g must be of the same degree and relatively prime. Now differentiate both sides of the equation $f^2 - g^2 = c$. This yields the equality $f'f = g'g$. Since f and g have no common factors, this implies $f = \delta g'$ where δ is in F. This, however, is impossible since $\partial f = \partial g$ (where ∂f denotes the degree of f). □

The more general problem of completing squares of rational functions and its connection to error functions was first treated in [Ssc85]. Since then the problem has been pursued in [CoTr82], [Cher83], and [Zwil84]. The results below were originally stated in the unpublished manuscript [CoTr82], although the proofs presented here are new.

THEOREM 3.2. *Let F be a constant field of characteristic zero and let f be a nonconstant element of $F(x)$. Then there are at most two constants β_i in $\bar{F}$ such that $f+\beta_i = g_i^2$ for some g_i in $\bar{F}[x]$.*

Proof. Let $f = p/q$ where p and q are relatively prime and q is monic, and for each i let $g_i = r_i/s_i$ where r_i and s_i are relatively prime and s_i is monic. Now note that for all β_i, $p+\beta_i q$ and q are relatively prime. Therefore $q = s_i^2$ and $p+\beta_i q = r_i^2$. This determines s_i uniquely and therefore we drop the subscript on s_i. We first claim that any two solutions r_i and r_j, corresponding to distinct β_i and β_j are relatively prime. To show this let β_i and β_j be distinct elements of $\bar{F}$ and r_i and r_j be elements of $\bar{F}[x]$ so that $p+\beta_i q = r_i^2$ and $p+\beta_j q = r_j^2$. Subtraction yields the equality $(\beta_i-\beta_j)q = r_i^2 - r_j^2$. This implies that if a common factor of r_i and r_j exists, then it must divide q. But from $p+\beta_i q = r_i^2$, this common factor of q and r_i also divides p. This contradicts the assumption that p and q are relatively prime and proves our claim. Now let $\max\{\partial p, \partial q\} = m$ for some integer m. Clearly, if $\partial q \geqq \partial p$, then $m = 2\partial s$ is even. On the other hand, if $\partial p > \partial q$ then $m = \partial p$ must be even if there is to be a solution r to $p+\beta q = r^2$. Therefore let $m = 2n$. Now consider the possibility that $\partial r_i < n$ for some i. This can only happen if (i) $\partial p = \partial q$ and $\beta_i = -lc(p)$ (where $lc(p)$ denotes the leading coefficient of p) or (ii) $\partial p < \partial q$ and $\beta_i = 0$. Since these situations are mutually exclusive we know that there can be at most one r_i such that $\partial r_i < n$. For the remainder of the proof we will label such an r_i as r_1. Thus, $\partial r_1 \leqq n$ and $\partial r_j = n$ for $j > 1$.

Now differentiating both sides of the equation $p/q + \beta_i = (r_i/s)^2$, we obtain $sp' - 2ps' = 2r_i(sr_i' - r_i s')$. Thus for distinct i and j we have $r_i(sr_i' - r_i s') = r_j(sr_j' - r_j s')$, and, in particular, $r_1(sr_1' - r_1 s') = r_j(sr_j' - r_j s')$ for $j > 1$. This implies, since r_1 and r_j are relatively prime, that $r_j | (sr_1' - r_1 s')$ for all $j > 1$. But $\partial(sr_1' - r_1 s') \leqq 2n-1$, implying that there can be at most one solution r_j where $j > 1$ and a maximum of two solutions. □

COROLLARY 3.3. *Let F, f, g, β_1, and β_2 be as in Theorem 3.2. Then, if solutions β_1 and β_2 are not in F, they are quadratic conjugates over F.*

Proof. This follows directly from the observation that if β is a solution to (3.1), i.e., $f+\beta = g^2$ for some g in $\bar{F}[x]$, and if $\sigma(\beta)$ is an automorphic image over F of β, then $\sigma(\beta)$ is also a solution to (3.1). □

Solutions to (3.1) can be computed by calculating the resultant, resultant $(p+\beta q, p'+\beta q')$, with respect to x. This will be a polynomial, say $h(\beta)$, in the variable β of degree $3n-1$ where n is as above. Observe that $\hat{\beta}$ is a root of h if and only if $p+\hat{\beta}q$ has multiple factors. We can therefore find all the linear and quadratic roots of $h(\beta)$ and test for perfect squares. However, in the next section we will see that it is not necessary to perform this computation to integrate with error functions. Instead it will be possible to find constants U and V such that the solutions to (3.1) are roots of the quadratic polynomial $\beta^2 - U\beta + V$.

4. The algorithm. In § 2 it has been shown that computing the indefinite integral $\int ge^f$ is equivalent to finding suitable y, c_i, u_i, d_i, and $\tilde{u}_i$ such that

$$g = y' + f'y + \sum c_i \frac{u_i'}{u_i} + \sum d_i \tilde{u}_i'. \tag{4.1}$$

The algorithm presented in this section solves first for the elementary part y, then for the exponential integrals, and finally for the error functions.

First we introduce some notation. We will assume that $f = p/q$ where p and q are relatively prime polynomials and q is monic. Then for each i, since $f + \alpha_i = u_i$, we can write $u_i = p_i/q$ where $p_i = p + \alpha_i q$ is relatively prime to q. Also for each $i, f + \beta_i = \tilde{u}_i^2$ implies that there exist polynomials r_i in $\bar{F}[x]$ such that $\tilde{u}_i = r_i/s$, where s is the unique monic square root of q, $r_i^2 = p + \beta_i q$, and r_i and s are relatively prime. We note here that no error functions can appear in the integral if q is not a perfect square.

We will also make use of the following definitions. For an arbitrary element f in $F(x)$ we define the *degree* of f, denoted ∂f, to be $\partial(\text{num}(f)) - \partial(\text{den}(f))$. Now write $f = f_p + f_n/f_d$ where f_p, f_n, and f_d are in $F[x]$, $\partial f_n < \partial f_d, f_n$, and f_d are relatively prime, and f_d is monic. We define the *leading coefficient* of f, denoted $lc(f)$, to be the leading coefficient of f_p. Finally we borrow an idea from [Dav86]. For f not in $F[x]$ write f_n in the form $c_{r-1}x^{r-1} + \cdots + c_0$ where r is the degree of f_d. We then refer to the constant c_{r-1} as the *proper fraction coefficient* of f and denote it f_∞. We also define f_∞ to be zero for all f in $F[x]$. Note that $f_\infty = 0$ if $\partial f_n < r - 1$. It is easy to show that (i) $(f')_\infty = 0$ for all f in $F(x)$, and (ii) $(f+g)_\infty = f_\infty + g_\infty$ for all f and g in $F(x)$.

4.1. The elementary part. To compute y we can use the same strategy that is used in [Dav86, Thm. 1]. We repeat the steps here to show that the partial fraction arguments presented in [Dav86] are not hampered by the special function terms in (4.1). First write $g = \bar{G}/g_1 g_2$ where $\bar{G}$, g_1, and g_2 are in $F[x]$, g_1 and g_2 are monic, g_2 is the product of all the irreducible factors of the denominator of g that divide q, and g_1 is the product of all the irreducible factors of the denominator of g that do not. Next perform a partial fraction decomposition of g

$$g = G + \frac{\tilde{g}_1}{g_1} + \frac{\tilde{g}_2}{g_2} \tag{4.2}$$

where $G, \tilde{g}_1$, and $\tilde{g}_2$ are in $F[x], \partial(\tilde{g}_1) < \partial(g_1)$, and $\partial(\tilde{g}_2) < \partial(g_2)$. We now divide the computation of y into three steps. Steps E1 and E2 will solve for the "fractional part" of y, and Step E3 will solve for the "polynomial part" of y.

Step E1. Perform a squarefree decomposition of g_1, $g_1 = h_r^r \cdots h_1$, and a partial fraction decomposition

$$\frac{\tilde{g}_1}{g_1} = \sum_{i=1}^{r} \sum_{j=1}^{i} \frac{G_{ij}}{h_i^j} \tag{4.3}$$

where $\partial(G_{ij}) < \partial(h_i)$. Combining (4.2) and (4.3), we have the following decomposition for g:

$$g = G + \sum_{i=1}^{r} \sum_{j=1}^{i} \frac{G_{ij}}{h_i^j} + \frac{\tilde{g}_2}{g_2}. \tag{4.4}$$

Now suppose that y is written in the same format

$$y = Y + \sum_{i=1}^{n} \sum_{j=1}^{i} \frac{Y_{ij}}{z_i^j} + \frac{\tilde{y}_2}{y_2} \tag{4.5}$$

and substitute (4.4) and (4.5) into (4.1). This yields

$$G + \sum_{i=1}^{r} \sum_{j=1}^{i} \frac{G_{ij}}{h_i^j} + \frac{\tilde{g}_2}{g_2} = \left(Y + \sum_{i=1}^{n} \sum_{j=1}^{i} \frac{Y_{ij}}{z_i^j} + \frac{\tilde{y}_2}{y_2} \right)' + \left(\frac{p}{q} \right)' \left(Y + \sum_{i=1}^{n} \sum_{j=1}^{i} \frac{Y_{ij}}{z_i^j} + \frac{\tilde{y}_2}{y_2} \right) + \sum c_i \left(\frac{p_i'}{p_i} - \frac{q'}{q} \right) + \sum d_i \left(\frac{r_i}{s} \right)'. \tag{4.6}$$

Performing the differentiations and comparing terms on both sides of this equation, we see that $r=n+1$, $z_n=h_r$, and $G_{rr}\equiv -nY_{nn}h_r'(\text{modulo } h_r)$. Since h_r and h_r' are relatively prime, this congruence can be solved uniquely for Y_{nn}. With Y_{nn} known we can make the substitution $y=\bar{y}-Y_{nn}/h_r^r$ in (4.1). This will result in an equation in the same form of (4.1) (with $\bar{y}$ replacing y) where the multiplicity of h_r in g_1 is reduced. After a sequence of such substitutions g_1 becomes squarefree, implying that each irreducible factor of the denominator of y divides q. Note that we have reduced n to zero—the variable n will be reused below in Step E2.

Step E2. We now make the following observations concerning any irreducible factors of y_2. Let ϕ be such an irreducible factor and suppose $\phi^n\|\text{den}(y)$ and $\phi^m\|q$.[4] By assumption, $n, m>0$. Then $\phi^{n+1}\|\text{den}(y')$, $\phi^{m+1}\|\text{den}(f')$ and $\phi^{n+m+1}\|\text{den}(f'y)$. For the special function terms we have, for each i, $\phi\|\text{den}(u_i'/u_i)$, and if $s\neq 1$ then $\phi^{(m/2)+1}\|\text{den}(\tilde{u}_i')$. Now examine the partial fraction decompositions on both sides of (4.1). Since $m>0$, the $f'y$ term dominates with respect to ϕ and $\phi^{n+m+1}\|g_2$. Our strategy, therefore, is to apply substitutions of the form $y=\bar{y}-\delta$ that reduce the multiplicities in g_2 until the above degree argument implies that $y_2=1$. This will happen when the highest multiplicity in g_2 is $m+1$ or less.

Following the strategy outlined in [Dav86, Lemma 4.3], we first find a squarefree polynomial h such that $h^r\|g_2$, $h^m\|q$, and such that g_2/h^r and q/h^m are relatively prime to h. h can be generated easily from the squarefree factors of g_2 and q. If $r\leqq m+1$ then the above observations imply that h is relatively prime to y_2. Therefore assume that $r>m+1$. Then the above observations applied to the irreducible factors of h imply that $h^{r-(m+1)}\|y_2$. Now write the partial fraction decompositions of $\tilde{g}_2/g_2$, $\tilde{y}_2/y_2$ and f' as

$$\frac{\tilde{g}_2}{g_2}=\frac{\hat{g}}{h^r}+\cdots,$$

$$\frac{\tilde{y}_2}{y_2}=\frac{\hat{y}}{h^{r-(m+1)}}+\cdots,$$

$$f'=\frac{\hat{f}}{h^{m+1}}+\cdots$$

where $\hat{g}$, $\hat{y}$, and $\hat{f}$ are relatively prime to h with degrees less than h. We then have $\hat{g}\equiv\hat{f}\hat{y}(\text{modulo } h)$. This congruence can be uniquely solved for $\hat{y}$ and the substitution $y=\bar{y}-\hat{y}/h^{r-(m+1)}$ will reduce the multiplicity of h in g_2. After a finite number of such substitutions we can assume that y is a polynomial.

Step E3. When y is written as a polynomial, $y=y_nx^n+\cdots+y_0$, (4.1) becomes

$$g=(y_nx^n+\cdots+y_0)'+f'(y_nx^n+\cdots y_0)+\sum c_i\frac{u_i'}{u_i}+\sum d_i\tilde{u}_i'. \tag{4.7}$$

Now we consider two cases.

Case (i). $\partial p>\partial q$. Here $lc(f')=0$ and we compare leading coefficients on both sides of (4.7). First note that, for each i, $\partial(u_i'/u_i)=-1$ and, since $\tilde{u}_i^2=f+\beta_i$, $\partial(\tilde{u}_i')=\frac{1}{2}\partial f-1=\frac{1}{2}(\partial f'-1)$. Therefore

$$\partial(y'+f'y)=\partial(f'y)>\partial\left(\sum c_i\frac{u_i'}{u_i}+\sum d_i\tilde{u}_i'\right),$$

[4] The notation $u^r\|v$, for polynomials u and v and a nonnegative integer r, means that u^r divides v but u^{r+1} does not.

which implies $lc(g) = lc(f')y_n$. Solving for y_n and making the substitution $y = \bar{y} - y_n x^n$ will reduce the degree of g. Repeating this procedure will eventually yield all of y.

Case (ii). $\partial p \leqq \partial q$. Here $\partial f' \leqq -2$ and, for all i, $\partial(u_i'/u_i) = -1$ and $\partial(\tilde{u}_i') \leqq -2$. In the subcase where $n > 0$, we have

$$\partial(y' + f'y) = \partial(y') > \partial\left(\sum c_i \frac{u_i'}{u_i} + \sum d_i \tilde{u}_i'\right),$$

which implies $lc(g) = ny_n$ and we can solve for y_n and reduce the degree of g. Next consider the subcase where $n = 0$. Choose any squarefree factor of q, say h, such that $h^m \| q$ and q/h^m is relatively prime to h. Again we have $h^{m+1} \| \text{den}(f')$, and for each i, $h \| \text{den}(u_i'/u_i)$ and $h^{m/2+1} \| \text{den}(\tilde{u}_i')$. Next we form the partial fraction expansions of g and f'

$$g = \frac{\hat{g}}{h^r} + \cdots, \qquad f' = \frac{\hat{f}}{h^{m+1}} + \cdots,$$

and compare partial fraction expansions on both sides of (4.1). This yields $r = m+1$ and $y_0 = \hat{g}/\hat{f}$.

4.2. The exponential integrals. When we assume that y has been calculated, (4.1) becomes

$$g = \sum c_i \left(\frac{p_i'}{p_i} - \frac{q'}{q}\right) + \sum d_i \left(\frac{r_i}{s}\right)'.$$

Comparing this equation with the decomposition of g in (4.2), we obtain

$$\frac{\tilde{g}_1}{g_1} = \sum_{p_i \notin \bar{F}} c_i \frac{p_i'}{p_i} \tag{4.8}$$

and

$$G + \frac{\tilde{g}_2}{g_2} = -\frac{q'}{q} \sum_{p_i \notin \bar{F}} c_i - \sum_{p_i \in \bar{F}} c_i \frac{q'}{q} + \sum d_i \left(\frac{r_i}{s}\right)'. \tag{4.9}$$

We will consider each of these two equations separately.

Step P1. To resolve (4.8) compute the resultant of g_1 and $p + \alpha q$ with respect to x. This will be a polynomial in the variable α, say $h(\alpha)$. The roots of $h(\alpha)$ will each yield a factor $p_i = p + \alpha_i q$ of g_1. We now have a factorization of g_1, $g_1 = \Pi p_i$, and can perform a partial fraction decomposition of $\tilde{g}_1/g_1$:

$$\frac{\tilde{g}_1}{g_1} = \sum \frac{\tilde{p}_i}{p_i}. \tag{4.10}$$

Comparison of (4.8) and (4.10) determines whether constants c_i exist satisfying equation (4.8). If no such constants exist, then the integral does not exist in a special incomplete Γ-extension and the algorithm terminates.

Step P2. Now consider (4.9) and note that there are only two mutually exclusive cases where $p_i = p + \alpha_i q$ is in $\bar{F}$ for some i. These are (i) $\partial p = \partial q$ and $\alpha_i = lc(p)$, and (ii) p is in F and $\alpha_i = 0$. In either case there can only be one term in the sum $\sum_{p_i \in \bar{F}} c_i(q'/q)$. We therefore write this sum as $c(q'/q)$ and, transposing the known quantity $-q'/q \sum_{p_i \notin \bar{F}} c_i$ to the left-hand side, we rewrite (4.9) as

$$\gamma = -c\frac{q'}{q} + \sum d_i \left(\frac{r_i}{s}\right)'$$

where γ is a known element in $F(x)$. Now if $q \neq 1$ we have, by comparing proper fraction coefficients on both sides of this equation, that $c = -\gamma_\infty/\partial q$. This concludes the calculation of the exponential integrals.

4.3. The error functions. We have reduced the original problem to the calculation of constants d_i and polynomials r_i such that

$$g = \sum d_i \left(\frac{r_i}{s}\right)' \tag{4.11}$$

where, for each i, there exists a constant β_i so that $p/q + \beta_i = (r_i/s)^2$. It is easy to determine whether q is a perfect square and, if so, to compute s such that $q = s^2$. Clearly if no such s exists, then there can be no error functions and the algorithm halts.

Now note, for each i, that

$$\left(\frac{p}{q} + \beta_i\right)' = \left(\frac{p}{q}\right)' = 2\left(\frac{r_i}{s}\right)\left(\frac{r_i}{s}\right)',$$

and therefore

$$\left(\frac{r_i}{s}\right)' = \frac{1}{2}\frac{s}{r_i}\left(\frac{p}{q}\right)'.$$

Thus (4.11) can be written

$$\frac{2g}{s(p/q)'} = \sum \frac{d_i}{r_i}. \tag{4.12}$$

We have, since r_i and r_j are relatively prime for distinct i and j, that the monic denominator of the left side of this equation is the unique monic associate of the product Πr_i. Denoting this denominator by h we have

$$ch = \Pi r_i \tag{4.13}$$

where c is an unknown constant in $\bar{F}$.

Now Theorem 3.2 implies that there can be only one or two terms in the above sum. Thus our strategy is to first attempt to satisfy (4.11) with one error function. If this fails, then two error functions will be tried. Again we label the two steps as follows.

Step R1. If we assume there is one term in (4.11), then (4.13) implies that $ch = r_1$ and, therefore, $p = c^2h^2 - \beta_1 q$. Since h and q are relatively prime (a common divisor would also divide p, an impossibility), we can determine if there exist constants R and S such that $p = Rh^2 + Sq$. If such constants exist, then they must be unique and we have $\beta_1 = -S$. This yields r_1. The constant d_1 can then be calculated from (4.12). Of course, if R and S do not exist or (4.12) does not yield a constant for d_1, then the remaining integral is not a single error function.

Step R2. Next we consider the case where there are two error functions. Here (4.13) yields $ch = r_1 r_2$ and we have

$$c^2h^2 = (p + \beta_1 q)(p + \beta_2 q) \tag{4.14}$$

or

$$p^2 = c^2h^2 - [(\beta_1 + \beta_2)p + (\beta_1\beta_2)q]q.$$

We now claim that $\partial(h^2) > n$ where $n = \max\{\partial(p), \partial(q)\}$. This follows from (4.14) as follows. First note that $\partial(p + \beta q) < n$ only if (i) $\partial p = \partial q$ and $\beta = -lc(p)$, or (ii) $\partial p < \partial q$ and $\beta = 0$. In the first case (4.14) implies that $\partial(h^2) > n$ unless $p + \beta_i q$ is a constant for $i = 1$ or 2. Without loss of generality assume $p + \beta_1 q = \delta$ where δ is a constant and subtract $p + \beta_1 q = \delta$ from $p + \beta_2 q = r_2^2$. This yields $(\beta_2 - \beta_1)q = r_2^2 - \delta$, contradicting Theorem 3.1, since $q = s^2$. In the second case, $\partial(h^2) > n$ unless p is a constant. But if p is a constant, then the equation $p + \beta_2 q = r_2^2$ again contradicts Theorem 3.1.

Now since $\partial[(\beta_1+\beta_2)p+(\beta_1\beta_2)q] \leqq n$, we have $\partial[(\beta_1+\beta_2)p+(\beta_1\beta_2)q] < \partial(h^2)$. We therefore calculate unique polynomials R and S such that $p^2 = Rh^2 + Sq$ where $\partial(R) < \partial(q)$ and $\partial(S) < \partial(h^2)$. This implies that

$$-S = (\beta_1+\beta_2)p+(\beta_1\beta_2)q.$$

We then determine if there exist constants U and V such that $-S = Up + Vq$. If these constants exist, then β_1 and β_2 are roots of the quadratic equation $\beta^2 - U\beta + V$. From here we can calculate r_1 and r_2. Finally, comparing the numerators of (4.12), we obtain an equation of the form $k = d_1r_2 + d_2r_1$ where k is known. From this equation we can determine if constants d_1 and d_2 exist satisfying (4.11).

5. Examples.

Example 5.1. Consider the integral

$$\int e^{1/x}\,dx.$$

Since there are no error functions here (q is not square), (4.1) becomes

$$1 = y + \frac{-1}{x^2}\,y + \sum c_i\left(\frac{p_i'}{p_i} - \frac{q'}{q}\right). \tag{5.1}$$

Since $g = 1$, the elementary part of the integral, if it exists, must be of the form $y = y_1x + y_0$. Substituting this into (5.1), we obtain $y_1 = 1$ and so $y = x + y_0$, which we substitute again into (5.1). This yields an equation of the form

$$\frac{1}{x} = y_0' + \frac{-1}{x^2}\,y_0 + \sum c_i\left(\frac{p_i'}{p_i} - \frac{q'}{q}\right).$$

Comparing partial fraction decompositions, we obtain $y_0 = 0$, thus completing the determination of y. We now have

$$\frac{1}{x} = \sum c_i\left(\frac{p_i'}{p_i} - \frac{q'}{q}\right). \tag{5.2}$$

Since the denominator of $1/x$ does not contain a factor relatively prime to q, we go directly to Step P2. Here $\gamma = 1/x$, $c = -\gamma_\infty/\partial q = -1$, and so

$$\int e^{1/x}\,dx = xe^{1/x} - \mathrm{ei}\left(\frac{1}{x}\right). \qquad \square$$

Example 5.2. Consider the integral

$$\int \left(\frac{1}{x} + \frac{1}{x^2}\right) e^{1/x^2}\,dx.$$

In this case Steps E1, E2, and E3 reveal that there is no elementary part, i.e., $y = 0$, and we go to Step P2 where we have

$$c = -\frac{(1/x + 1/x^2)_\infty}{\partial q} = \frac{-1}{2}.$$

Now consider the error function problem. Equation (4.12) becomes

$$-1 = \sum \frac{d_i}{r_i}.$$

Applying Step R1, we find R and S such that $1 = R + Sq$. This yields $S = 0$, and so $\beta_1 = 0$ and $r_1^2 = 1$. Thus $r_1 = 1$, $d_1 = -1$, and

$$\int \left(\frac{1}{x} + \frac{1}{x^2}\right) e^{1/x^2}\,dx = -\frac{1}{2}\,\mathrm{ei}\left(\frac{1}{x^2}\right) - \mathrm{erf}\left(\frac{1}{x}\right). \qquad \square$$

Example 5.3. Consider the integral

$$\int \frac{x^4-1}{x^5+x}\, e^{(x^2+1)/x}\, dx.$$

Here (4.8) becomes

$$\frac{x^4-1}{x^5+x} = \frac{2x^3}{x^4+1} - \frac{1}{x},$$

and so Step P1 applies. From the resultant $h(\alpha) = \alpha^4 - 4\alpha^2 + 4$ we get $\alpha_1 = \sqrt{2}$ and $\alpha_2 = -\sqrt{2}$. Thus $p_1 = x^2 + \sqrt{2}x + 1$ and $p_2 = x^2 - \sqrt{2}x + 1$, leading to the partial fraction decomposition

$$\frac{2x^3}{x^4+1} = \frac{x - \sqrt{2}/2}{x^2 - \sqrt{2}x + 1} + \frac{x + \sqrt{2}/2}{x^2 + \sqrt{2}x + 1}.$$

Comparing this to (4.8), we obtain $c_1 = c_2 = \frac{1}{2}$. Subtracting

$$\frac{1}{2}\frac{p_1'}{p_1} + \frac{1}{2}\frac{p_2'}{p_2} - \frac{1}{x}\left(\frac{1}{2} + \frac{1}{2}\right)$$

from g, we obtain zero and so

$$\int \frac{x^4-1}{x^5+x}\, e^{(x^2+1)/x}\, dx = \frac{e^{\sqrt{2}}}{2}\,\mathrm{ei}\left(\frac{x^2 - \sqrt{2}x + 1}{x}\right) + \frac{e^{-\sqrt{2}}}{2}\,\mathrm{ei}\left(\frac{x^2 + \sqrt{2}x + 1}{x}\right). \qquad \square$$

Example 5.4. Consider the integral

$$\int e^{(x^4+a)/x^2}\, dx.$$

Here the constant field F contains the parameter a (i.e., $F = Q(a)$). The left side of (4.12) becomes $x^2/(x^4 - a)$, and so $h = x^4 - a$. Solving $p^2 = Rh^2 + Sq$, we obtain $R = 1$ and $S = 4ax^2$. Solving $-4ax^2 = Up + Vq$, we obtain $U = 0$ and $V = -4a$. The roots of $\beta^2 - 4a$ are $2\sqrt{a}$ and $-2\sqrt{a}$, yielding $r_1 = x^2 + \sqrt{a}$ and $r_2 = x^2 - \sqrt{a}$. Calculating d_1 and d_2, we obtain

$$\int e^{(x^4+a)/x^2}\, dx = \frac{1}{2}\, e^{-2\sqrt{a}}\,\mathrm{erf}\left(\frac{x^2 + \sqrt{a}}{x}\right) + \frac{1}{2}\, e^{2\sqrt{a}}\,\mathrm{erf}\left(\frac{x^2 - \sqrt{a}}{x}\right). \qquad \square$$

Appendix. The incomplete Γ functions [Bate53, Chap. 9] are functions that can be expressed in the form

$$\gamma(a, x) = \int_0^x e^{-t} t^{a-1}\, dt, \qquad \mathrm{Re}\, a > 0$$

or

$$\Gamma(a, x) = \int_x^\infty e^{-t} t^{a-1}\, dt = \Gamma(a) - \gamma(a, x).$$

Bateman refers to the extensively studied members of this class as the *special* incomplete Γ functions. Of these, the exponential integral and error function correspond to the parameter values $a = 0$ and $a = \frac{1}{2}$, respectively. Although our algorithm only explicitly handles exponential functions and error functions, each of the other special functions discussed in [Bate53] can be expressed in terms of these two as follows:

(i) The logarithmic integral:

$$\mathrm{li}\,(u) = \int \frac{u'}{\log u}\, dx = \mathrm{ei}\,(\log\,(u)).$$

(ii) The sine and cosine integrals:

$$\operatorname{si}(u) = \int \frac{u' \sin(u)}{u}\, dx = \frac{1}{2i}[\operatorname{ei}(iu) - \operatorname{ei}(-iu)],$$

$$\operatorname{ci}(u) = \int \frac{u' \cos(u)}{u}\, dx = \frac{1}{2}[\operatorname{ei}(iu) + \operatorname{ei}(-iu)].$$

(iii) The Fresnel integrals:

$$S(u) = \int u' \sin\left(\frac{\pi}{2} u^2\right) dx = \frac{-1}{\sqrt{2\pi i}}[\operatorname{erf}(\sqrt{-\pi i/2}\, u) + \operatorname{erf}(\sqrt{\pi i/2}\, u)],$$

$$C(u) = \int u' \cos\left(\frac{\pi}{2} u^2\right) dx = \frac{1}{\sqrt{2\pi i}}[\operatorname{erf}(\sqrt{\pi i/2}\, u) - \operatorname{erf}(\sqrt{-\pi i/2}\, u)].$$

Acknowledgments. I thank D. Coppersmith and B. Trager for the insight I received from their unpublished note on completing squares [CoTr82]. This paper is dedicated to the memory of Dr. Hatem Khalil.

AN ANALYSIS OF A GOOD ALGORITHM FOR THE SUBTREE PROBLEM, CORRECTED*

RAKESH M. VERMA† AND STEVEN W. REYNER‡

Abstract. It is shown that the proof of the main result in Reyner's paper, similarly titled, is incorrect. Interestingly, by combining a simple modification of the algorithm with tighter analysis, one can obtain the original result with a minor improvement.

Key words. algorithm, algorithm analysis, bipartite graphs, computational complexity, matching, subtree

AMS(MOS) subject classification. 68Q25

1. Introduction. The rooted subtree isomorphism[1] problem has several applications in computer science, besides being one of the known subcases of subgraph isomorphism in the complexity class *P*. The main contribution of [2] was the analysis of a very simple algorithm for subtree isomorphism in terms of the complexity of bipartite matching. The result of this analysis had the following important implication: Improvements in the upper bound for bipartite matching would yield corresponding improvements in the upper bound for subtree isomorphism. Unfortunately, however, we show that the proof of Theorem 1 in [2] is incorrect (for the benefit of the reader we include the statement of Theorem 1). More importantly, by modifying the algorithm given by Reyner we are able to prove this theorem. At the same time, our modification preserves the simplicity of the algorithm. The proof of Theorem 2 in [2] is not affected, except that in the last line of the proof for Theorem 2, $0+m-1$ should be $0+n-1$. The statement of Theorem 2 can be obtained from the statement of Theorem 1 by replacing rs^u by rs, omitting $u>1$, and replacing nm^u by $nm \ln n$.

2. Main results.

THEOREM 1 (Reyner [2]). *Given an algorithm for bipartite matching that requires at most $O(rs^u)$ operations where $r \leqq s$ and $u>1$, the subtree algorithm will require at most $O(nm^u)$ operations.*

The original proof is erroneous. The proof starts off by choosing a b large enough so that the matching algorithm requires at most brs^u operations, and so that the subtree algorithm requires at most bnm^u operations whenever n and m satisfy $(n-1)\cdot((m-1)^u+m-1)>nm^u$. It was claimed in [2] that *such a b exists since only finitely many m and n satisfy the above inequality*, and the marriage algorithm is $O(rs^u)$. We show that for all real values of u, $1<u<2$ there are *infinitely* many positive integers n and m such that the inequality holds. Note that since n and m denote the number of vertices of the trees S and T, respectively, the set of positive integers is the only domain of interest for n, m. For convenience, we choose $n=m$, which corresponds to the tree isomorphism problem.

THEOREM 2. *For all $1<u<2$ there is an $m_0(u)$ such that the inequality $(m-1)^{u+1}+(m-1)^2-m^{u+1}>0$ holds for all $m>m_0(u)$ or almost everywhere (a.e.).*

Proof. Expanding $(m-1)^{u+1}$ by the binomial theorem, we need to show that

$$(m-1)^2-m^{u+1}+\sum_{k=0}^{\infty}\binom{u+1}{k}(-1)^k m^{u+1-k}>0 \text{ a.e.}$$

or that

$$m^2-2m+1+\binom{u+1}{2}m^{u-1}-\binom{u+1}{1}m^u+\sum_{k=3}^{\infty}\binom{u+1}{k}(-1)^k m^{u+1-k}>0 \text{ a.e.}$$

Observe that since $1<u<2$, the terms in the last summation are all negative and since $|\binom{u+1}{k}|\leqq 1$ for $k\geqq 3$, the last summation is less in absolute value than $\sum_{k=3}^{\infty} m^{u+1-k}=m^{u-2}(\sum_{k=0}^{\infty} m^{-k})=m^{u-1}/(m-1)<1+\binom{u+1}{2}m^{u-1}$. Therefore it suffices to show that $m^2-2m-(u+1)m^u>0$ almost everywhere. As $2m<2m^u$, we need only prove that $m^2>(u+3)m^u$ almost everywhere. Since $u<2$, the last inequality is true almost everywhere and we are done. □

Remark. The above theorem can also be proved by showing that the more general inequality $1+x^{\varepsilon-1}>(1+1/x)^{k-\varepsilon}$ holds for all real ε $0<\varepsilon<1$, positive integers k, and sufficiently large x [3].

What is more interesting and useful is that by making some modifications to the algorithm originally described by Matula [1], we can prove a slightly stronger theorem than Reyner's main result. If G is any graph, let $v(G)$ denote the number of vertices of G. The basic idea is that the subtree isomorphism problem is trivial when $v(S)$ is 1 or 2. In that case, S is a subtree of any rooted tree T, provided $v(S)\leqq v(T)$. Therefore, we determine for each vertex v in S, T the number of its children $c(v)$, the number of its descendants $d(v)$, and the number of its subtrees with at least two vertices $o(v)$. It should be clear that this takes only $3(n+m)\leqq 6m$ operations. A high-level description of the modified algorithm is as follows. It is assumed that the algorithm is given the roots (root of a tree G is denoted r_g) of the trees to be checked and invoked for trees having at least three vertices.

Algorithm: Rooted Subtree Isomorphism (r_s, r_t)

(1) If $d(r_s)\leqq d(r_t)$ and $c(r_s)\leqq c(r_t)$ and $o(r_s)\leqq o(r_t)$, then delete r_s and r_t to obtain rooted subtrees $S_1,\cdots,S_p$ and $T_1,\cdots,T_q$, else return 0. Here $p=c(r_s)$ and $q=c(r_t)$.

(2) (Recursively) For each S_i such that $v(S_i)>2$ (decide whether S_i is a rooted subtree of T_j with $v(T_j)>2$ and form a $k\times l$ matrix M with $m_{ij}=1(0)$ if S_i is (not) a rooted subtree of T_j). k is the number of such S_i's and l is the number of such T_j's. Relabel the S_i's and T_j's if necessary.

(3) Apply an algorithm for obtaining a maximal matching in the bipartite graph corresponding to M. If there is no such matching, then return 0 else return 1.

We can now prove a slightly stronger theorem than the one given by Reyner.

Proof. Choose c large enough so that the matching algorithm requires at most crs^u for each r and s and $c\geqq 1$. Let d and f be the number of S_i's and T_j's of size at least 3. Then the total number of operations of algorithm Rooted Subtree Isomorphism is given by five comparisons, operations in step 3, and the operations contributed by the recursive calls. Hence the total number of operations is bounded by

$$5+cdf^u+\sum_{i=1}^{d}\sum_{j=1}^{f} cn_i m_j^u\leqq 5+cdf^u+c(n-1)\sum_{j=1}^{f} m_j^u.$$

Since $1\leqq d\leqq \lfloor (n-1)/3\rfloor$ and $m_j\geqq 3$ for $1\leqq j\leqq f$,

$$5+c(n-1)\left(f^u/3+\sum_{j=1}^{f} m_j^u\right)\leqq 5+c(n-1)(f^u/3+(f-1)3^u+(m+2-3f)^u)=g(f).$$

On showing that $g(f)\leqq cnm^u$ we will be done. Also since $1\leqq f\leqq \lfloor (m-1)/3\rfloor$ and the second derivative of $g(f)$ is positive ($u>1$), the maximum occurs at an endpoint.

Therefore an upper bound is the larger of $g(1)$ or $g((m-1)/3)$. Now $g(1) = 5 + c(n-1)(1/3 + (m-1)^u) \leqq cnm^u$ for $m > 2 (n \leqq m, u > 1)$. Also $g((m-1)/3) = 5 + c(n-1)((1/3)((m-1)/3)^u + (m-1)3^{u-1})$ is less than cnm^u if either $u \geqq 1.03$ or $u < 1.03$ and m large. To see this consider $h(m) = 5 + c(n-1)((m-1)^u 3^{-u-1} + (m-1)3^{u-1}) - cnm^u$. After careful analysis it can be shown that the second derivative of $h(m)$ is negative, and its first derivative is negative if $u \geqq 1.03$ or $u < 1.03$ and m is large. □

The entire algorithm (including processing) therefore takes $6m + cnm^u$ operations or about $(c+2)nm^u$ (no preprocessing required if $n < 3$) operations overall (observe that the preprocessing operations are done only once; hence, it is still correct to use $cn_i m_j^u$ for the recursive calls). This is an improvement of the result in Reyner's original article. In the event that a bipartite matching algorithm is obtained with $1 < u < 1.03$, further analysis along these lines might be appropriate.

3. Conclusion. Thus we have been able to show that improving the exponent u in the upper bound for bipartite matching will improve the exponent for subtree isomorphism. The advantage of the algorithm is its obvious simplicity, and when there is a hierarchical structure involved (e.g., trees representing terms), this may be the only algorithm of interest.

THE COMPLETE CONVERGENCE OF BEST FIT DECREASING*

WANSOO T. RHEE† AND MICHEL TALAGRAND‡

Abstract. Consider a probability measure μ on $[0, 1]$ and an independent sequence of random variables $X_1, \cdots, X_n, \cdots$ distributed according to μ. No regularity assumptions are made on μ. Denote by $B(X_1, \cdots, X_n)$ the number of unit-size bins that are used by Best Fit Decreasing to pack items of size $X_1, \cdots, X_n$. The existence of a constant $b(\mu)$ is proven such that for each $\varepsilon > 0$,

$$\sum_{n \geq 1} P(|n^{-1}B(X_1, \cdots, X_n) - b(\mu)| \geq \varepsilon) < \infty.$$

Key words. probabilistic analysis, approximation algorithm, bin packing

AMS(MOS) subject classifications. 90B99, 60K30

1. Introduction. The bin-packing problem requires finding the minimum number of unit-size bins needed to pack a given collection of items with sizes in $[0, 1]$. The problem has many applications and has been shown to be NP-complete. There is a growing literature devoted to the analysis of stochastic models for bin packing (see [1]). Most authors have analyzed approximation algorithms under a model of items drawn independently from a special distribution, e.g., uniform on some subinterval of $[0, 1]$. In that case, most approximation algorithms will pack few items in a typical bin and will never produce complicated patterns. Thus, the choice of a restrictive stochastic model may ignore most of the inherent complexity of the algorithm. For example, it is known that many approximation algorithms exhibit anomalous behavior [3]. This behavior does not seem to occur for typical lists drawn at random from the uniform distribution. One way to deepen our understanding could be to consider more general models, where the items are drawn independently according to a distribution μ, on which no restriction is made. (This approach has met some success in [4], [6], [7].) In that case, the typical list can produce very complicated packing patterns. In this paper, we are interested in the algorithm Best Fit Decreasing (BFD). In BFD, we first order the items according to decreasing size. Each item is then packed in the bin in which it fits the best, i.e., in which the remaining space is minimal after adding the item, using a new bin whenever necessary. We refer the reader to [2] for the deterministic analysis of BFD.

We denote by $B(x_1, \cdots, x_n)$ the number of bins used by BFD to pack items of size $x_1, \cdots, x_n$. Our main result is the following convergence property.

THEOREM 1. *For each probability measure μ on $[0, 1]$, there exists a constant $b(\mu)$, such that if $(X_i)_{i \geq n}$ are independent and identically distributed like μ, for each $\varepsilon > 0$, we have*

$$\sum_{n \geq 1} P\left(\left|\frac{1}{n} B(X_1, \cdots, X_n) - b(\mu)\right| \geq \varepsilon\right) < \infty. \tag{1}$$

It might be worth mentioning that while many results in the literature reach a conclusion stronger than (1) they either deal with specific distributions or with much better-behaved algorithms [5], [9].

‡ Equipe d'Analyse-Tour 46, Université de Paris VI, 4 Place Jussieu, 75230, Paris, France, and Department of Mathematics, Ohio State University, Columbus, Ohio 43210. The research of this author was supported in part by National Science Foundation grant DMS-8801180.

The problem of complete convergence, i.e., of proving a result corresponding to Theorem 1, seems of interest for all approximation algorithms. In a companion paper [8], we investigate the case of First Fit Decreasing (FFD), which turns out to be considerably deeper. Interestingly enough, there is a considerable difference between these two algorithms. Using the methods of [8], one can show that the pattern BFD produces when packing a typical random list exhibits some kind of convergence. However, this is not needed to prove Theorem 1, which is a simple consequence of the following deterministic result.

PROPOSITION 1. *There exists a function* $\varphi(\delta, n)$ *such that* $\lim_{n\to\infty,\delta\to 0}\varphi(\delta, n)=0$ *with the following property. Consider two lists of items,* $x_1, \cdots, x_n$, *and* $y_1, \cdots, y_{n'}$. *Let*

$$\delta = \sup_{t\geqq 0}\left|\frac{1}{n}\,card\{i\leqq n;\ x_i\geqq t\}-\frac{1}{n'}\,card\{i\leqq n';\ y_i\geqq t\}\right|. \tag{2}$$

Then

$$\left|\frac{1}{n}B(x_1, \cdots, x_n)-\frac{1}{n'}B(y_1, \cdots, y_{n'})\right|\leqq\varphi(\delta, \min(n, n')). \tag{3}$$

It would be of interest to know what is the best possible order of decrease of the function φ. Our method shows that for $n\geqq\delta^{-1}$, one can take $\varphi(\delta, n)=K(\log(1/\delta))^{-1}$ for some universal constant K, and the proof of Theorem 1 given below shows that this implies

$$\left|\frac{1}{n}B(X_1, \cdots, X_n)-b(\mu)\right| = O((\log n)^{-1})\text{a.s.}$$

We see no reason why these estimates would be sharp.

It might be worthwhile to point out that the two-sided control in (2) is essential. Examples in [3] show that we can have $n=n'$, and

$$\forall t\geqq 0,\quad card\{i\leqq n;\ x_i\geqq t\}\geqq card\{i\leqq n;\ y_i\geqq t\},$$

but $B(y_1, \cdots, y_n)=(43/42)B(x_1, \cdots, x_n)$.

Proposition 1 can be interpreted as a kind of *uniform* continuity of BFD. The great difference in nature between BFD and FFD is that such a result does not seem to hold for FFD. (Thus one has to establish a property of (nonuniform) continuity instead.)

Proof of Theorem 1. For $1\leqq i\leqq n'$, define

$$y_i^{n'}=\sup\left\{y;\ 0\leqq y\leqq 1,\ \mu([y, 1])\geqq\frac{i}{n'}\right\}.$$

Then, for each $t\in[0, 1]$,

$$\left|\frac{1}{n'}\,card\{i;\ 1\leqq i\leqq n',\ y_i^{n'}\geqq t\}-\mu([t, 1])\right|\leqq\frac{1}{n'}.$$

Thus, by Proposition 1, the sequence $b_{n'}=B(y_1^{n'}, \cdots, y_{n'}^{n'})$ is a Cauchy sequence. Denote by $b(\mu)$ its limit. Using (3) for $x_i=X_i$, $y_i=y_i^{n'}$, n' large enough, and letting $n'\to\infty$ gives

$$\left|\frac{1}{n}B(X_1, \cdots, X_n)-b(\mu)\right|\leqq\varphi(2\delta(X_1, \cdots, X_n), n),$$

where

$$\delta(X_1, \cdots, X_n)=\sup_{t\geqq 0}\left|\frac{1}{n}\,card\{i\leqq n;\ X_i\geqq t\}-\mu([t, 1])\right|.$$

Consider now $\varepsilon > 0$, and let $\delta_0 > 0$, n_0, such that $\delta \leqq \delta_0$, $n \geqq n_0 \Rightarrow \varphi(2\delta, n) \leqq \varepsilon$. To prove (2), it suffices to show that

$$\sum_{n \geqq 1} P(\delta(X_1, \cdots, X_n) \geqq \delta_0) < \infty.$$

But it is a well-known property of the Kolmogorov-Smirnov statistics that

$$P(\delta(X_1, \cdots, X_n) \geqq t) \leqq 2 \exp(-2nt^2).$$

2. The basic matching procedure. The space left in a bin at any point of the packing procedure is called its vacancy. We agree that we begin the procedure with a sufficient number of size-one bins (say, as many as items). Bins having not yet received an item have a vacancy one. The number of bins having actually received items is the number of vacancies less than 1. The difficulty in analyzing the algorithm BFD is that the packing of any item changes the list of vacancies, and thus influences the sequel of the packing. This difficulty will be solved by dividing the packing into stages in which it has a simpler structure. In order to do that, we need to analyze a simpler procedure called *basic matching*. In this procedure, a list of items $x_1 \geqq \cdots \geqq x_p$ is attributed to a list of (bins with) vacancies $v_1 \leqq \cdots \leqq v_q$. Each x_i is attributed (=matched) in turn, starting by x_1, to the smallest unattributed $v_j \geqq x_i$. The procedure stops when either the list of items or the list of vacancies is exhausted. (For definiteness, say that ties are broken by the index, but this is irrelevant since only the sizes of the items matter.) The following simple lemma will be essential.

LEMMA 1. *Consider the basic matching of two lists* $x_1, \cdots, x_p$, $v_1, \cdots, v_q$. *Then for* $0 \leqq t \leqq u \leqq 1$,

(i) *The number of items* $x_i \geqq t$ *that are attributed to a bin* $v_j \leqq u$ *is given by*

$$\inf_v (card\{i \leqq p;\ t \leqq x_i \leqq v\} + card\{j \leqq q;\ v < v_j \leqq u\})$$

$$= \inf_v (card\{i \leqq p;\ t \leqq x_i < v\} + card\{j \leqq q;\ v \leqq v_j \leqq u\}),$$

where v *is allowed to take any value in* $\mathbf{R}$.

(ii) *The number of items* $x_i \geqq t$ *that are not attributed to a vacancy* $v_j \leqq u$ *is given by*

$$\sup_{t \leqq v \leqq u} (card\{i \leqq p;\ v \leqq x_i \leqq u\} - card\{j \leqq q;\ v \leqq v_j \leqq u\}).$$

(iii) *The number of vacancies less than or equal to* u *that are not attributed an item* $x_i \geqq t$ *is given by*

$$\sup_{t \leqq v \leqq u} (card\{j \leqq q;\ t \leqq v_j \leqq v\} - card\{i \leqq p;\ t \leqq x_i \leqq v\}).$$

Proof. These statements are equivalent and well known (e.g., see [5] for the proof of (ii)).

The main result of the section is as follows.

PROPOSITION 2. *Consider two lists of items,* $x_1, \cdots, x_p$, $x'_1, \cdots, x'_{p'}$, *and two lists of vacancies* $v_1, \cdots, v_q$, $v'_1, \cdots, v'_{q'}$. *Consider* n, n' *(to be thought of as normalizing factors) and* $\delta > 0$. *Assume that*

$$\forall t \geqq 0, \left| \frac{1}{n} card\{i \leqq p;\ x_i \geqq t\} - \frac{1}{n'} card\{i \leqq p';\ x'_i \geqq t\} \right| \leqq \delta, \tag{4}$$

$$\forall t \geqq 0, \left| \frac{1}{n} card\{j \leqq q;\ v_j \geqq t\} - \frac{1}{n'} card\{j \leqq q';\ v'_j \geqq t\} \right| \leqq \delta. \tag{5}$$

For $s \geqq 0$, denote by $M(s)$ (respectively, $M'(s)$) the number of couples (x_i, v_j), $v_j \geqq x_i + s$ (respectively, (x'_i, v'_j), $v'_j \geqq x'_i + s$) that are matched by the basic matching of the lists $x_1, \cdots, x_p$ and $v_1, \cdots, v_q$ (respectively, $x'_1, \cdots, x'_{p'}$ and $v'_1, \cdots, v'_{q'}$). Then

$$\left| \frac{1}{n} M(s) - \frac{1}{n'} M'(s) \right| \leqq \left(10 + \frac{32}{s} \right) \delta. \tag{6}$$

Proof. Denote by S the set of couples (x_i, v_j) that are matched in the basic matching of the lists $x_1, \cdots, x_p$ and $v_1, \cdots, v_q$. By induction, we define a sequence (t_i) as follows. We set $t_0 = 0$, and we define by induction

$$t_{r+1} = \sup \{ t;\ t_r < t \leqq 1,\ S \cap \{(x, v);\ x < t,\ t_r + s < v < x + s\} = \varnothing \}.$$

Obviously, there is a matched couple $(x_{i(r+1)}, v_{j(r+1)})$ such that $x_{i(r+1)} = t_{r+1}$ and $t_r + s < v_{j(r+1)} < t_{r+1} + s$. Thus

$$t_r + s < v_{j(r+1)} < t_{r+1} + s < v_{j(r+2)}.$$

Since $x_{i(r+1)} = t_{r+1} \leqq x_{i(r+2)} = t_{r+2}$ is matched later than $x_{i(r+2)}$ and is matched with $v_{j(r+1)}$, this means that the vacancy $v_{j(r+1)}$ has not yet received an item right after $x_{i(r+2)}$ is packed. Since $t_{r+2} = x_{i(r+2)}$ is matched with $v_{j(r+2)} > v_{j(r+1)}$, we have $t_{r+2} > v_{j(r+1)}$, and hence $t_{r+2} > t_r + s$. This shows that the construction of the points t_r stops with a last point $t_h = 1$, where $h \leqq 1 + 2/s$. Let

$$A = (\{(x, v) \in [0, 1]^2;\ \exists r,\ 0 \leqq r < h;\ t_r < x < t_{r+1},\ t_r + s < v \text{ or } \exists r,\ 0 \leqq r \leqq h,\ x = t_r,\ t_r + s \leqq v\}).$$

First we show that

$$A \supset \{(x, v) \in [0, 1]^2;\ v \geqq x + s\}.$$

Consider (x, v) with $v \geqq x + s$. Let $r < h$ be the smallest such that $x < t_{r+1}$. Then if $x = t_r$, we have $(x, v) \in A$. Otherwise, $x > t_r$, so $v \geqq x + s > t_r + s$ and again $(x, v) \in A$.

Next, we show that each matched couple (x_i, v_j) that belongs to A satisfies $v_j \geqq x_i + s$. This is obvious if $x_i = t_r$. Otherwise, if $t_r < x_i < t_{r+1}$, the definition of t_{r+1} shows that $v_j \geqq x_i + s$. Thus, we have

$$M(s) = card\{(x_i, v_j);\ (x_i, v_j) \text{ is matched},\ (x_i, v_j) \in A\}$$

$$M'(s) \leqq card\{(x'_i, v'_j);\ (x'_i, v'_j) \text{ is matched},\ (x'_i, v'_j) \in A\}.$$

The set A is a disjoint union $A = \bigcup_{i \leqq 2h+1} B_i$ of $2h + 1$ sets of either type

$$B = \{(x, v);\ x = t_r,\ v \geqq t_r + s\} \quad \text{or} \quad B = \{(x, v);\ t_r < x < t_{r+1},\ v > t_r + s\}.$$

For a subset X of $[0, 1]^2$, denote by $N(X)$ (respectively, $N'(X)$) the number of matched couples (x_i, v_j) (respectively, (x'_i, v'_j)) that belong to X. If X is of the type $\{(x, v);\ t \leqq x,\ v \leqq u\}$, it follows from Lemma 1(i), (4), and (5) that

$$\left| \frac{1}{n} N(X) - \frac{1}{n'} N'(X) \right| \leqq 2\delta.$$

It follows that if X is the product of two intervals (that may contain their endpoints or not), we have

$$\left| \frac{1}{n} N(X) - \frac{1}{n'} N'(X) \right| \leqq 8\delta.$$

This holds in particular if X is one of the sets B_i. Thus

$$\frac{1}{n'}M'(s) \leqq \frac{1}{n'}N'(A) \leqq (2h+1)8\delta + \frac{1}{n}N(A)$$

$$\leqq \left(10+\frac{32}{s}\right)\delta + \frac{1}{n}N(A) = \frac{1}{n}M(s) + \left(10+\frac{32}{s}\right)\delta$$

from which (6) follows by symmetry.

Comment. It is easy to improve on the constants 10 and 32. However, we make no attempt at giving sharp constants, but we always give the simplest estimates suitable for our purpose.

3. Stages of packing. We decompose the packing of a list (according to the BFD rule) into "stages" where BFD has a simpler structure. In the first stage, we put all items of size greater than 1/2 each in a single bin. If no such item exists, we do nothing.

After the $(k-1)$th stage has been completed, the largest unpacked item x_1 has a size $2^{-l-1} < x_1 \leqq 2^{-l}$ for some $l = l(k) \geqq 0$. If w_2 denotes the *second* smallest of the vacancies greater than 2^{-l}, it satisfies $rx_1 \leqq w_2 < (r+1)x_1$ for some $r = r(k) \geqq 1$. Denote by $x_1 \geqq x_2 \geqq \cdots \geqq x_a$ the unpacked items greater than 2^{-l-1}. Denote by $v_1 \geqq \cdots \geqq v_q$ the vacancies less than or equal to 2^{-l}, and by $w_1 \leqq \cdots \leqq w_m$ the vacancies greater than 2^{-l}. We now pack in turn $x_1, \cdots, x_a$, following the BFD rule. If an item x_i is attributed to one of the vacancies v_j, we call it an *ordinary* item and an *excess* item otherwise. For an ordinary item, the new vacancy $v_j - x_i$ created by its packing is less than 2^{-l-1}, and thus does not have to be taken into account when packing $x_1, \cdots, x_a$. The first excess item $x_{i(1)}$ (if such an item exists) will be attributed to w_1. If no excess items exists, the kth stage of packing finishes with the packing of x_a. In the sequel of this discussion, we will not mention anymore the case when the items $x_1, \cdots, x_a$ are all packed before the event described occurs. It is understood that in this case, the kth stage finishes with the packing of x_a. The vacancy created by attributing $x_{i(1)}$ to w_1 is $w_1 - x_{i(1)}$.

Case 1. $w_1 < rx_1$. We attribute consecutive excess items $x_{i(1)}, \cdots, x_{i(s)}$ to w_1 until either of the following happens.

Case 1a. For some $s \leqq r$, $w_1 - x_{i(1)} - \cdots - x_{i(s)} \leqq 2^{-l}$. When $x_{i(s)}$ is attributed, we end the kth stage. The first item not packed at the kth stage is $x_b = x_{i(s)+1}$. For the $(k+1)$th stage, w_2 is the smallest vacancy greater than 2^{-l}, and $w_2 \geqq rx_1 \geqq rx_b$. In particular, $r(k+1) \geqq r(k)$.

Case 1b. $w_1' = w_1 - x_{i(1)} - \cdots - x_{i(r)} > 2^{-l}$. When $x_{i(r)}$ is attributed, we end the kth stage. The first item not packed at the kth stage is $x_b = x_{i(r)+1}$. Since $w_1' > 2^{-l} \geqq x_b$, we have $w_1 \geqq (r+1)x_b$, so $w_2 \geqq (r+1)x_b$. Since w_2 is the second largest vacancy greater than 2^{-l} at the $(k+1)$th stage, we have $r(k+1) \geqq r(k)+1$.

Case 2. $w_1 \geqq rx_1$. After r excess items have been attributed to w_1, we obtain a vacancy $u_1 = w_1 - x_{i(1)} - \cdots - x_{i(r)}$ that we call the first *added* vacancy. (The name suggests that this is the first vacancy added to our list that might make the packing of $x_1, \cdots, x_a$ different from the basic matching of the lists $x_1, \cdots, x_a$ and $v_1, \cdots, v_q$.) In a similar fashion, we create our second added vacancy u_2, etc. The first time we meet an item x_b for which there exists an added vacancy $u \geqq x_b$, we do *not* pack x_b, and we declare that the kth stage is finished. (This occurs in particular if we create an added vacancy greater than or equal to 2^{-l}). If w_m is the first vacancy greater than 2^{-l} that received no item during the kth stage, and if x_b is the first item greater than 2^{-l-1} not packed during that stage, we have $x_b \leqq u$, where u is of the type $w_{m_1} - (x_{i(1)} + \cdots + x_{i(r)})$ for $i(1) < \cdots < i(r) < b$, $m_1 < m$, so that $(r+1)x_b \leqq w_{m_1} \leqq w_m$. Since

there is at most one vacancy $2^{-l} < w < w_m$ (it is of the type $w_{m-1} - x_{i(1)} - \cdots - x_{i(s)}$ for $s \leqq r$), we have $r(k+1) \geqq r(k)+1$.

Observation 1. We show that at most 2^{l+2} stages are needed to pack the items of size between 2^{-l} and 2^{-l-1}.

Since $r(k) \leqq 2^{l(k)+1}$, it suffices to show that if $l(k+2) = l(k) = l$, we have $r(k+2) > r(k)$. □

We have shown that $r(k+1) > r(k)$ except possibly in Case 1a, where nonetheless $r(k+1) \geqq r(k)$. Thus it suffices to observe that either $w_3 \geqq (r+1)x_b$, and then $r(k+1) > r(k)$, or that $(r+1)x_b > w_3 \geqq w_2 \geqq rx_b$, and then Case 2 occurs at stage $k+1$, so that $r(k+2) > r(k+1) \geqq r(k)$.

Observation 2. We set $p = b-1$, so that x_p is the last item $> 2^{l-1}$ packed at the kth stage. An alternative way to look at the packing of the items $x_1, \cdots, x_p$ is as follows. We perform the basic matching of the lists $x_1, \cdots, x_p$ and of the list $v_1, \cdots, v_q$ of vacancies less than 2^{-l}. The unmatched items (excess items) are then attributed to the vacancies $w_1 \leqq w_2 \leqq \cdots$ that are greater than or equal to 2^{-l}, putting in each w_j as many consecutive excess items as will fit. In the first case, only w_1 receives excess items. In the second case, all the vacancies $w_1, w_2, \cdots$ that receive excess items receive exactly $r(k)$ items, with the possible exception of the last one.

Thus, if $h+1$ denotes the number of vacancies w_i that receive excess items, we have at most $(h+1)r$ excess items, and the first rh of these items, that we call $g_1, \cdots, g_{rh}$, fit r at a time in turn in the vacancies $w_1, w_2, \cdots, w_h$. Moreover, since x_p is larger than the last added vacancy, we have

$$\begin{aligned} x_p &> w_h - (g_{(r-1)h+1} + \cdots + g_{rh}) \\ &\geqq w_h - rg_{(r-1)h}. \end{aligned}$$

Proposition 3 is the crucial part of our proof. In this proposition, we keep the notations of Observation 2. We consider a list of items $2^{-l} \geqq x_1 \geqq \cdots \geqq x_p > 2^{-l-1}$ that are packed during one stage of the packing in bins with vacancies $(z_i)_{i \leqq n}$.

PROPOSITION 3. *Consider a list of items $x'_1, \cdots, x'_{p'}$ and a list of vacancies $z'_1, \cdots, z'_{n'}$. For $u \geqq 0$, let*

$$\delta(u) = \sup_{t \geqq u} \left| \frac{1}{n} \operatorname{card}\{i \leqq n;\ z_i \geqq t\} - \frac{1}{n'} \operatorname{card}\{i \leqq n';\ z'_i \geqq t\} \right|. \tag{7}$$

Consider a number $\delta \geqq \max(1/n, 1/n')$, such that $\delta \geqq \delta(2^{-l-1})$, and that

$$\delta \geqq \sup_{t \geqq 0} \left| \frac{1}{n} \operatorname{card}\{i \leqq p;\ x_i \geqq t\} - \frac{1}{n'} \operatorname{card}\{i \leqq p';\ x'_i \geqq t\} \right|. \tag{8}$$

Denote by $\bar{z}_1, \cdots, \bar{z}_n$ (respectively, $\bar{z}'_1, \cdots, \bar{z}'_{n'}$) the list of vacancies after the items $x_1, \cdots, x_p$) (respectively, $x'_1, \cdots, x'_{p'}$) are attributed according to the BFD *rule to the vacancies $z_1, \cdots, z_n$ (respectively, $z'_1, \cdots, z'_{n'}$). Let*

$$\bar{\delta}(u) = \sup_{t \geqq u} \left| \frac{1}{n} \operatorname{card}\{i \leqq n;\ \bar{z}_i \geqq t\} - \frac{1}{n'} \operatorname{card}\{i \leqq n';\ \bar{z}'_i \geqq t\} \right|.$$

Then for some universal constant K, we have

$$\begin{aligned} &\bar{\delta}(u) \leqq K\delta \text{ for } u \geqq 2^{-l-1} \text{ and} \\ &\bar{\delta}(u) \leqq K(\max(\delta(u), \delta/u)) \text{ for } u < 2^{-l-1}. \end{aligned} \tag{9}$$

Proof. We will denote by K a universal constant, not necessarily the same in each occurrence. The idea of the proof is to show that within a small perturbation, the

packing of $x'_1, \cdots, x'_{p'}$, according to the BFD rule, has the same structure as the packing of that list by the following procedure. We perform the basic matching of $x'_1, \cdots, x'_{p'}$ with the vacancies $z'_j \leqq 2^{-l}$. The unmatched items are then attributed to the vacancies $z'_j > 2^{-l}$, putting in turn as many items as possible in each such vacancy (which is the procedure by which the items $x_1, \cdots, x_p$ are packed). First we observe that there are at most $n'\delta$ items x'_i that are greater than x_1. BFD packs these items first. Packing them will affect at most $n'\delta$ vacancies. Thus if we consider the list of items and vacancies after these items are packed, (7) and (8) still hold with $\delta(u)+\delta$ and 2δ, respectively, instead of $\delta(u)$ and δ. Thus one can assume that $x'_i \leqq x_1$ for all i. A similar argument shows that we can assume $x_p \leqq x'_i$. We say that an item x'_i is an *excess* item if it is unmatched in the basic matching of the list of items $(x'_i)_{i \leqq p'}$ and of the list of vacancies $\{z'_i;\ i \leqq n',\ z'_i \leqq 2^{-l}\}$. From Lemma 1(iii), (7), and (8), we see that the numbers n_1 (respectively, n_2) of excess items greater than or equal to $g_{r(h-1)}$ (respectively, $< g_{r(h-1)}$) satisfy

$$\frac{n_1}{n'} \leqq \frac{r(h+1)}{n} + K\delta; \qquad \frac{n_2}{n'} \leqq \frac{2h}{n} + K\delta. \tag{10}$$

In the process of packing, items are added to bins. Call a bin *irregular* if at some point of the packing of $x'_1, \cdots, x'_{p'}$ after it has received at least one of these items, its vacancy falls in the interval $[x_p, x_1[$. Call a bin *regular* if it is not irregular.

After a bin becomes irregular, it can accept at most one item. Call these items *irregular*. Call an item *regular* if it is not irregular.

We now observe that the final list of the regular vacancies in the BFD packing of $x'_1, \cdots, x'_{p'}$ is identical to the list of vacancies obtained by the following procedure. We perform the BFD packing of the list $y'_1, \cdots, y'_{p_1}$ of regular items with the list of vacancies z'_i, removing a bin from the list whenever it becomes irregular. Equivalently, we first perform the basic matching of the list $y'_1, \cdots, y'_{p_1}$ with the list of vacancies less than or equal to 2^{-l}. Call the unmatched items the *special* items. As many of the special items as will fit are attributed in turn to the bins with vacancies greater than 2^{-l}, starting with the smallest vacancy.

Our first task is to bound the number of irregular bins, and hence, of irregular items. An irregular bin can be created only when a special item is attributed to a vacancy greater than $2^{-\ell}$. If a special item is attributed to a bin whose original vacancy was in the interval $]2^{-l}, w_1[$, it might create an irregular bin. There are at most $2n'\delta$ such vacancies, so at most that many irregular bins will arise this way.

We recall the inequalities $w_1 \geqq rx_1$, $w_h - rg_{r(h-1)} < x_p$. From (7), we have at least $n'(h/n - 2\delta)$ vacancies in the interval $[w_1, w_h]$. When attributing to these vacancies special items of size greater than of equal to $g_{r(h-1)}$, we never create irregular vacancies. Indeed, if we attribute $(r-1)$ items, we create a vacancy greater than or equal to $w_1 - (r-1)x_1 \geqq x_1$, but if we attribute r items, the vacancy will be less than x_p. Thus in these bins, there is enough room to accept $r\lfloor n'(h/n - 2\delta)\rfloor$ special items greater than or equal to $g_{r(h-1)}$. Observing that special items are excess items, from (10), we see that there is at most $rK\delta n'$ special items left. These might be attributed to vacancies greater than w_h. They will create a maximum of $K\delta n'$ irregular bins. Thus we have at most $K\delta n'$ irregular bins, and hence, at most $K\delta n'$ irregular items. From (7), we see that

$$\forall t \geqq 0, \left| \frac{1}{n} \operatorname{card}\{i \leqq p;\ x_i \geqq t\} - \frac{1}{n'} \operatorname{card}\{i \leqq p_1;\ y'_i \geqq t\} \right| \leqq K\delta. \tag{11}$$

Thus, we have reduced the problem to the case where we do not pack the items $x'_1, \cdots, x'_{p'}$ packed according to the BFD but where we first perform the basic matching

of these items with the vacancies less than or equal to 2^{-l}, and then attribute the excess (=unmatched) items to the vacancies greater than 2^{-l}. (This is the procedure by which the items $x_1, \cdots, x_p$ are packed.) We can still assume $x_p \leqq x'_i \leqq x_1$ for $i \leqq p'$. In that procedure, vacancies are produced in four different manners, and we will show that for each of the sources of vacancies, an estimate of the type (9) holds. First, there are those of the vacancies of size in $]2^{-l-1}, 2^{-l}]$ that receive no item. For this class, the result follows from Lemma 1(iii). Second, there are the vacancies less than 2^{-l-1}, none of which receive items. For this class, the result is obvious. Third, there are the vacancies created by matching an item and a vacancy less than 2^{-l}. These are all less than 2^{-l-1}. For this class, the result follows from Proposition 2.

Finally, there are the vacancies created by packing the excess items in the vacancies greater than 2^{-l}. If we denote by $g_1 \geqq \cdots \geqq g_b$; $g'_1 \geqq \cdots \geqq g'_{b'}$ the excess items in the basic matching of $x_1, \cdots, x_p$ (respectively, $x'_1, \cdots, x'_{p'}$) and of the vacancies $z_i \leqq 2^{-l}$ (respectively, $z'_i \leqq 2^{-l}$) we see from Lemma 1, (ii), that

$$\forall t \geqq 0, \left| \frac{1}{n} \operatorname{card}\{i \leqq b;\ g_i \geqq t\} - \frac{1}{n'} \operatorname{card}\{i \leqq b';\ g'_i \geqq t\} \right| \leqq K\delta. \tag{12}$$

Recall also that $rh \leqq b \leqq r(h+1)$. Also, the lists $w_1 \leqq \cdots \leqq w_m$, $w'_1 \leqq \cdots \leqq w'_{m'}$ of vacancies greater than 2^{-l} satisfy

$$\forall t \geqq 0, \left| \frac{1}{n} \operatorname{card}\{i \leqq m;\ w_i \geqq t\} - \frac{1}{n'} \operatorname{card}\{i \leqq m';\ w'_i \geqq t\} \right| \leqq K\delta. \tag{13}$$

From (12) and (13), we get easily that

$$g_{b(i)} \geqq g'_i \geqq g_{a(i)},\ w_{a(i)} \geqq w'_i \geqq w_{b(i)},$$

where $a(i) = \lceil ni/n' + K\delta \rceil$, $b(i) = \lfloor ni/n' - K\delta \rfloor$, whenever all the quantities are defined. A vacancy $w' \leqq w_h$ will accept at most r excess items greater than or equal to $g_{r(h-1)}$, while a vacancy $w' \geqq w_1$ will accept at least r excess items. Consider a bin with vacancy w'_i. We will have no control of what happens in the bin if either $w'_i < w_1$ or $w'_i > w_h$, or $g'_{ri} \leqq g_{r(h-1)}$, but since $g'_{ri} \geqq g_{a(ri)}$, there are at most $K\delta n'$ such bins. Otherwise, the smallest excess item that fits in the bin is larger than g'_{ri}, so the final vacancy $\bar{w}'_i$ in this bin will be greater than or equal to $w'_i - rg'_{ri}$. Also, if $ni > n'K\delta$, the largest excess item that fits in the bin is less than or equal to $g'_{r(b(i)-1)}$, so the final vacancy $\bar{w}'_i$ is less than or equal to $w'_i - rg'_{r(b(i)-1)}$. For $k \leqq h$, the kth final vacancy produced by the packing of $g_1, \cdots, g_b$ is $\bar{w}_k = w_k - (g_{k(r-1)+1} + \cdots + g_{kr})$. The sequence $\bar{w}_k$ increases. For $t > 0$, the number $n(t)$ of final vacancies in the packing of $g_1, \cdots, g_b$ that are less than t is such that $|n(t) - k| \leqq 1$, where k is the largest such that $\bar{w}_k < t$ (recall that we do not control what happens in the bin w_{h+1}). Thus $\bar{w}'_i < t$ whenever $w'_i \leqq w_k$, $g'_{r(b(i)-1)} \geqq g_{k(r-1)+1}$, and this occurs as soon as $a(i) \leqq k$, $a(r(b(i)-1)) \leqq k(r-1)+1$. Also, $\bar{w}'_i \geqq t$ as soon as $w'_i > w_{k+1}$, $g'_{ri} \leqq g_{(k+1)r}$, and this occurs as soon as $b(i) \geqq k+1$, $a(ri) \geqq (k+1)r$. The conclusion follows easily.

4. Proof of Proposition 2. Consider two lists of items $x_1 \geqq \cdots \geqq x_n$, $x'_1 \geqq \cdots \geqq x'_{n'}$. Set

$$\delta' = \sup_{t \geqq 0} \left| \frac{1}{n} \operatorname{card}\{i \leqq n;\ x_i \geqq t\} - \frac{1}{n'} \operatorname{card}\{i \leqq n';\ x'_i \geqq t\} \right|.$$

We divide the packing of $x_1, \cdots, x_n$ in stages, as described in § 3. Let $x_{b(k)}$ be the first element that is packed at stage k. Let

$$m(k) = \min\left(\lfloor n'b(k)/n \rfloor, \operatorname{card}\{i \leqq n';\ x'_i \geqq x_{b(k)}\}\right).$$

It is easy to see that for each $k \geqq 0$

$$\sup_{t \geqq 0} \left| \frac{1}{n} card\{b(k) \leqq i < b(k+1);\ x_i \geqq t\} - \frac{1}{n'} card\{m(k) \leqq i < m(k+1);\ x'_i \geqq t\} \right| \leqq \delta,$$

where $\delta = 2(\delta' + 1/n + 1/n')$.

We start the packing of $x_1, \cdots, x_n$ (respectively, $x'_1, \cdots, x'_{n'}$) with n (respectively n') empty bins. Denote by $z_{1,k}, \cdots, z_{n,k}$ (respectively, $z'_{1,k}, \cdots, z'_{n',k}$) the list of vacancies after the items $x_1, \cdots, x_{b(k)-1}$ (respectively, $x'_1, \cdots, x'_{m(k)-1}$) have been packed according to the BFD rule. Set

$$\delta_k(u) = \sup_{t \geqq u} \left| \frac{1}{n} card\{i \leqq n;\ z_{i,k} \geqq t\} - \frac{1}{n'} card\{i \leqq n';\ z'_{i,k} \geqq t\} \right|.$$

Denote by K the constant of Proposition 3. We recall that when the last element of size in $]2^{-l-1}, 2^{-l}]$ is packed, a new stage begins. Consider the following statement:

$H(l, m)$: If k is such that m stages have occurred since the last item x_i of size greater than 2^{-l} was packed, then

$$\delta_k(u) \leqq K^{m+2^{l+2}} 2^{(l+1)(l+2)/2} \delta \quad \text{if } u \geqq 2^{-l-1},$$
$$\delta_k(u) \leqq u^{-1} K^{m+2^{l+2}} 2^{(l+1)(l+2)/2} \delta \quad \text{if } u < 2^{-l-1}.$$

When l is fixed, this statement follows by induction over m from Proposition 3. Since 2^{l+2} stages are enough to pack all the items of size in $]2^{-l-1}, 2^{-l}]$ and after all these items are packed, we have

$$\delta_k(u) \leqq K^{2^{l+3}} 2^{(l+1)(l+2)/2} \delta \quad \text{if } u \geqq 2^{-l-1},$$
$$\delta_k(u) \leqq u^{-1} K^{2^{l+3}} 2^{(l+1)(l+2)/2} \delta \quad \text{if } u < 2^{-l-1}.$$

Thus in particular

$$\delta_k(u) \leqq K^{2^{l+3}} 2^{(l+2)(l+3)/2} \delta \quad \text{if } u \geqq 2^{-l-2}, \tag{14}$$
$$\delta_k(u) \leqq u^{-1} K^{2^{l+3}} 2^{(l+2)(l+3)/2} \delta \quad \text{if } u < 2^{-l-2},$$

which is $H(l+1, 0)$. Thus the statement $H(l, 0)$ follows by induction over l.

Let $k(p)$ be the smallest such that $x_{b(k(p))} \leqq 2^{-p}$. Then by definition of $m(k)$, $x'_{m(k(p))} \leqq x_{b(k(p))} \leqq 2^{-p}$. Now (14) shows that for $n, n' \geqq \delta'^{-1}$, $\delta_{k(p)}(2^{-p}) \leqq K^{2^p} \delta'$ (for a new constant K). Denote by $B(p)$ (respectively, $B'(p)$) the number of bins that have received items before $x_{b(k(p))}$ (respectively, $x'_{m(k(p))}$) is packed. Since $B(p) = n - card\{i \leqq n;\ z_{i,k(p)} < 1\}$, and since a similar formula holds for $B'(p)$, we have

$$\left| \frac{B(p)}{n} - \frac{B'(p)}{n'} \right| \leqq K^{2^p} \delta'.$$

Obviously $B(p) \leqq B(x_1, \cdots, x_n) \leqq B(p) + \lceil 2^{-p} n \rceil$. A similar formula for $B'(p)$ implies

$$\left| \frac{1}{n} B(x_1, \cdots, x_n) - \frac{1}{n'} B'(x'_1, \cdots, x'_n) \right| \leqq K^{2^p} \delta' + 2^{-p} + \frac{1}{n} + \frac{1}{n'}.$$

This concludes the proof. (The choice of p such that $2^p \sim \alpha(\log 1/\delta')$ for α small enough gives the quantitative estimate mentioned in the Introduction.)

THE COMPLETE CONVERGENCE OF FIRST FIT DECREASING*

WANSOO T. RHEE† AND MICHEL TALAGRAND‡

Abstract. Consider a probability measure μ on $[0, 1]$ and an independent sequence of random variables $X_1, \cdots, X_n, \cdots$ distributed according to μ. No regularity assumptions are made on μ. Denote by $F_n(X_1, \cdots, X_n)$ the number of unit-size bins that are used by First Fit Decreasing to pack $X_1, \cdots, X_n$. The existence of a constant $f(\mu)$ is proven such that for each $\varepsilon > 0$, we have

$$\sum_{n \geqq 1} P(|n^{-1}F_n(X_1, \cdots, X_n) - f(\mu)| \geqq \varepsilon) < \infty.$$

Key words. probabilistic analysis, approximation algorithm, bin packing

AMS(MOS) subject classifications. 90B99, 60K30

1. Introduction. The bin-packing problem requires finding the minimum number of unit-size bins needed to pack a given collection of items with sizes between zero and one. The problem has many applications and has been shown to be NP-complete. There is a growing literature devoted to the analysis of stochastic models for bin packing (see the survey paper [2]). Most authors have analyzed approximation algorithms under a model of items drawn independently from a special distribution, e.g., uniform on some subinterval of $[0, 1]$. In this paper, we are interested in the algorithm First Fit Decreasing (FFD). In FFD, we first order the items according to decreasing sizes. We start with an ordered collection of unit-size bins, and we put each item in turn in the first bin in which it fits. We refer the reader to [4] for the worst-case analysis of FFD. In the model where the items are drawn independently from the uniform distribution on $[0, 1]$, it is easy to see that the expected wasted space by FFD is $\Theta(\sqrt{n})$ [6]. When the distribution has a decreasing density on $[0, 1/2]$, deep recent results show that the expected wasted space is bounded [1], [3]. Two challenging aspects of FFD are (1) that it can produce very complicated patterns and (2) that it has erratic behavior, in the sense that the packing of a list with smaller items can use more bins. These interesting aspects completely disappear in the two models mentioned above, where the patterns are simple and where the good behavior of FFD is obtained by showing that it uses fewer bins than a much better behaved algorithm called mFFD. The algorithm mFFD has been analyzed by Rhee [9] in the same model as the present paper, and we refer the reader to [9] to fully appreciate the dramatic difference in complexity between mFFD and FFD. In our model, the items will be distributed according to a distribution μ, on which no restriction whatsoever is made. Thus, it can happen that the packing by FFD of a typical random list is very complicated. Nonetheless, our proof will show that the packing pattern of a typical random list exhibits some kind of convergence. This is not obvious beforehand, since one can find lists for which a tiny decrease in the size of a single item produces a quite long packing. Such lists are, however, exceptional and, on average, FFD behaves reasonably well.

The complete convergence result claimed in the abstract is an immediate consequence of the properties of the Kolmogorov statistic and of the following deterministic result.

THEOREM 1. *For each probability measure μ on $[0, 1]$, there exists a number $f(\mu)$, such that for each $\varepsilon > 0$, there exists $\delta > 0$, $N_0 \geqq 1$, such that for each sequence $(z_1, \cdots, z_N)$ of items, $N \geqq N_0$, that satisfies*

$$(1) \qquad \forall t \leqq 1, \quad \left| \frac{1}{N} \operatorname{card}\{i \leqq N;\ z_i \geqq t\} - \mu([t, 1]) \right| \leqq \delta,$$

we have

$$\left| \frac{1}{N} F_N(z_1, \cdots, z_N) - f(\mu) \right| \leqq \varepsilon.$$

Our proof will contain explicit constructions that allow, at least in principle, us to compute $f(\mu)$ when μ is given.

One can look at Theorem 1 as a continuity property of FFD. It should be noted that, given $\varepsilon > 0$, the choice of δ given by our proof will critically depend on μ. The existence of the pathological lists mentioned above shows that given ε, δ cannot be chosen independently of μ. This is an interesting contrast with the case of Best Fit Decreasing that is studied in the companion paper [10].

The principle of the approach is very simple. The first step is to define for measures a "packing" operation that mimicks FFD. Then one shows that the packing of lists of items that satisfy (1) proceeds very much as the "packing" of measure. To complete this program, we will, however, have to develop new tools and to proceed to an in-depth study. This might not be suprising in view of the delicate nature of FFD. (Working with measures instead of lists of items was the philosophy of [7], [8], and [9].)

2. The basic matching procedure. The space left in a bin at any point of the packing is called its vacancy. For our purposes, only the vacancies matter. Thus, for simplicity, we will talk of the list of vacancies and use expressions such as "attribute an item to a vacancy," which has the obvious meaning. We will denote items and their sizes by the same letter.

Each time a bin receives an item, the list of vacancies changes, which influences the way in which later items are packed. This difficulty will be solved in § 3 by dividing the packing into steps that have a simpler structure. Our first task is to analyze a simpler procedure that we call basic matching. In this procedure, we have a sorted list of items $z_1 \geqq \cdots \geqq z_p$ and a number $\alpha \geqq z_1$. We have an ordered list of vacancies $v_1, v_2, \cdots, v_N$. For each vacancy, we define its *multiplicity* by $m_j = \lfloor v_j/\alpha \rfloor$ if $v_j \geqq 2\alpha$ and $m_j = 1$ otherwise. To each vacancy v_j, we attribute in turn the largest unattributed item $z_i \leqq v_j$ if $m_j = 1$ and the m_jth largest unattributed item z_i otherwise.

Comment. (1) To see the relevance of such a procedure, let us recall the following fact brought to light in [1]. When attributing the sorted items $z_1, \cdots, z_p$ to the vacancies $v_1, \cdots, v_N$ by the FFD rule, one can think of the bins being filled in turn. To fill each bin, the remaining items are examined in turn, and each item that fits is put in the bin.

(2) Basic matching is rather different from FFD. In particular, a vacancy v_i of size $2\alpha - \varepsilon$ is always attributed at most one item, while if, when its turn comes to be filled, the largest unattributed item is of size less than or equal to $v_i/2$, FFD should attribute to it at least two items. But the basic matching will be used only on suitably restricted lists for which this difference plays no role.

Our starting point is the following lemma which is probably known.

LEMMA 1. *The number of items of size greater than or equal to t that are attributed to a vacancy v_j, $j \leqq k$ is given by*

$$(2) \qquad \inf_{u \geqq t} \{\operatorname{card}\{i \leqq p;\ t \leqq z_i < u\} + \sum \{m_j;\ j \leqq k,\ v_j \geqq u\}\}.$$

In this formula, values of $u > 1$ are allowed, giving a value card$\{i \leqq p;\ t \leqq z_i\}$.

Proof. By replacing in the list each vacancy $v_j > \alpha$ by m_j consecutive vacancies of size α, we can assume that $m_j = 1$ for each j. If the sequence $(v_j)_{j \leqq k}$ decreases, (2) is proved, e.g., in [9, Lem. 1]. For the general case, it suffices to show that transposing two consecutive vacancies v_i, v_{i+1}, $i+1 \leqq k$, does not change the collection of items that are attributed to vacancies of index less than or equal to k. Indeed, we can go from the decreasing case to the general case by performing a finite number of such transpositions. If, when v_i is attributed its item, there remains one item of size s such that $\min(v_i, v_{i+1}) < s \leqq \max(v_i, v_{i+1})$, the transposition changes nothing. Otherwise, it simply exchanges the items attributed to v_i and v_{i+1}. □

Consider a positive measure ν on $[0, 1] \times [0, 1]$. For simplicity, set $H(x, t) = \nu([0, x] \times [t, 1])$. The idea is that for a long sequence of vacancies, $(v_i)_{i \leqq N}$, $NH(x, t)$ is the sum of the multiplicities of the vacancies of index less than or equal to N_x and size greater than or equal to t. Consider a positive measure μ on $[0, 1]$. The idea is that $N\mu([t, 1]) = card\{i \leqq p;\ z_i \geqq t\}$ for our list of items under consideration.

We observe the following immediate properties. The first expresses the fact that $\nu(]x, y] \times [a, b[) \geqq 0$.

$$0 \leqq x \leqq y \leqq 1,\ 0 \leqq a \leqq b \leqq 1, \Rightarrow H(y, a) + H(x, b) \geqq H(x, a) + H(y, b). \tag{3}$$

$H(x, t)$ increases in x, decreases in t. If $t_n \nearrow t$, $x_n \searrow x$, we have

$$H(x, t) = \lim_{n \to \infty} H(x_n, t_n). \tag{4}$$

In view of (2), it is natural to consider the function

$$G(x, t) = \inf_{u \geqq t} (H(x, u) + \mu([t, u[)).$$

In this formula, values of $u > 1$ are allowed, giving a right-hand side $\mu([t, 1])$.

LEMMA 2. (a) *G increases in x, decreases in t.*

(b) *For $s \geqq t$,*

$$G(x, t) \leqq \mu([t, s[) + G(x, s). \tag{5}$$

Proof. Lemma 2(a) is obvious. For (b), observe that for any $u \geqq s$,

$$G(x, t) \leqq H(x, u) + \mu([t, u[) = \mu([t, s[) + H(x, u) + \mu([s, u[),$$

which implies (5).

LEMMA 3. *If $x_n \searrow x$, $t_n \nearrow t$, then $G(x, t) = \lim_{n \to \infty} G(x_n, t_n)$.*

Proof. Let $u \geqq t$. Then, since $u \geqq t_n$,

$$G(x_n, t_n) \leqq H(x_n, u) + \mu([t_n, u[)$$

so that by (4)

$$\limsup_{n \to \infty} G(x_n, t_n) \leqq H(x, u) + \mu([t, u[)$$

and hence

$$\limsup_{n \to \infty} G(x_n, t_n) \leqq G(x, t).$$

Since $G(x, t) \leqq G(x_n, t_n)$, the proof is complete.

From Lemmas 2 and 3, we see that we can define a positive measure μ_z by

$$\mu_z([t, s[) = \mu([t, s[) + G(z, s) - G(z, t). \tag{6}$$

This represents the distribution of items that have not been attributed to vacancies of index less than or equal to Nz.

A nice feature of basic matching is that the items attributed to the vacancies of index greater than k depend only on the list of items that have not been attributed to the vacancies of index less than or equal to k. We now prove a result of the same nature. This useful technical point will be of much help. We define, for $x \geqq z$,

$$H_z(x, t) = H(x, t) - H(z, t) = \nu(]z, x] \times [t, 1]),$$

and we set

$$G_z(x, t) = \inf_{u \geqq t} (H_z(x, u) + \mu_z([t, u[)). \tag{7}$$

PROPOSITION 1. *For* $x \geqq z$,

$$G(x, t) = G(z, t) + G_z(x, t).$$

Proof. In (7), we substitute the values of μ_z and H_z. After cancellation, we obtain

$$G(z, t) + G_z(x, t) = \inf_{u \geqq t} (\mu([t, u[) + H(x, u) + G(z, u) - H(z, u)).$$

By definition of $G(z, u)$, we obtain

$$G(z, t) + G_z(x, t) = \inf_{v \geqq u \geqq t} (\mu([t, v[) + H(x, u) - H(z, u) + H(z, v)).$$

Taking $v = u$, we get

$$G(z, t) + G_z(x, t) \leqq \inf_{u \geqq t} (\mu([t, u[) + H(x, u)) = G(x, t).$$

On the other hand, since $z \leqq x$, $u \leqq v$, (3) shows that

$$H(x, u) - H(z, u) + H(z, v) \geqq H(x, v),$$

and thus

$$G(z, t) + G_z(x, t) \geqq \inf_{v \geqq u \geqq t} (\mu([t, v[) + H(x, v)) = G(x, t). \qquad \square$$

In the sequel, we will always assume that $\nu(\{x\} \times [0, 1]) = 0$ for all x. In particular, $\mu_0 = \mu$, $G(0, t) = 0$ for all t.

COROLLARY 1. (a) *For* $y \leqq z$, $\mu_z \leqq \mu_y$.

(b) *For* $y \leqq z$, $s \leqq t$,

$$G(y, s) - G(y, t) \leqq G(z, s) - G(z, t). \tag{8}$$

(c) *For* $y \leqq z$,

$$G(z, 0) - G(y, 0) \leqq H(z, 0) - H(y, 0). \tag{9}$$

Proof. By Proposition 1, it suffices to consider the case $y = 0$, in which case this is obvious. $\square$

From Lemma 3, and (8), we conclude that there exists a positive measure η on $[0, 1] \times [0, 1]$ such that $G(x, t) = \eta([0, x] \times [t, 1])$ (see [5, §§ 4-5]). We note the formula

$$\eta(]x, y] \times [s, t[) = G(y, s) + G(x, t) - G(y, t) - G(x, s). \tag{10}$$

From (9), we observe that

$$\eta(]x, y] \times [0, 1]) \leqq \nu(]x, y] \times [0, 1]) \tag{11}$$

for $x \leqq y$. In particular, since we assume $\nu(\{x\} \times [0, 1]) = 0$, we have $\eta(\{x\} \times [0, 1]) = 0$ for all x. Thus, when computing with η, we can always disregard any set that is contained in a countable union of vertical lines, since such a set is negligible.

The measure η can be thought of as the distribution of the couple $(j/N, x_j)$, where x_j is the size of the item(s) attributed to the vacancy v_j. Unfortunately, we are not interested in that, but in the new list of vacancies after the basic matching has been completed. Although this information is contained in η, to extract it in a useful way will require the development of more tools.

We define

$$\varphi(x, t) = \inf \{u;\ 0 \leqq u < t,\ \mu_x(]u, t]) = 0\}$$

when this set is not empty, and $\varphi(x, t) = t$ otherwise. Thus we have

$$\mu_x(]\varphi(x, t), t]) = 0; \qquad \forall u < t,\ \mu_x(]u, t]) > 0. \tag{12}$$

LEMMA 4. *Consider $y > x$. Then*

$$u > \varphi(x, t);\ t \geqq \varphi(y, u) \Rightarrow \varphi(y, u) \leqq \varphi(x, t).$$

Proof. From (12), and Corollary 1, we have

$$\mu_y(]\varphi(x, t), t]) \leqq \mu_x(]\varphi(x, t), t]) = 0,$$

and from (12) we also have

$$\mu_y(]\varphi(y, u), u]) = 0.$$

Hence, since $u > \varphi(x, t)$, $t \geqq \varphi(y, u)$, we have

$$\mu_y(]\varphi(x, t), u]) = 0,$$

so $\varphi(y, u) \leqq \varphi(x, t)$ by definition of $\varphi(y, u)$. □

We will prove later that "the item size attributed to a vacancy v_i of size t is either t or $\varphi(i/N, t)$." The following is the main step toward that result.

LEMMA 5. *Let $0 \leqq b < d \leqq 1$. Then*

$$\nu(\{(x, t);\ t < d,\ \varphi(x, t) > b\}) \leqq \mu(]b, d[). \tag{13}$$

Proof. Step 1. We define

$$h(x) = \sup \{t;\ \mu_x(]b, t[) = 0\}$$

if this set is not empty, $h(x) = b$ otherwise. Then

$$\mu_x(]b, h(x)[) = 0,$$

and

$$\forall u > h(x), \qquad \mu_x(]b, u[) > 0. \tag{14}$$

If $\varphi(x, t) > b$, by definition of $\varphi(x, t)$, we have $\mu_x(]b, t]) > 0$, and hence $\mu_x([h(x), t]) > 0$ if $h(x) > b$. So we have

$$\begin{aligned} &\{(x, t);\ t < d,\ \varphi(x, t) > b\} \\ &\qquad = \{(x, t);\ h(x) = b,\ t > b \text{ or } h(x) > b,\ \mu_x([h(x), u]) \geqq 0\} \\ &\qquad \subset A' =: \{(x, t);\ t > h(x) \text{ or } t = h(x) > b,\ \mu_x(\{h(x)\}) > 0\}. \end{aligned}$$

Hence, it is enough to prove that $\nu(A') \leqq \mu(]b, d[)$. It might happen that ν charges (i.e., gives positive measure to) the set of points $(x, h(x))$ for which $\mu_x(\{h(x)\}) > 0$. Since a careful accounting of these points is needed, this makes the proof very tedious.

Step 2. Fix x such that $h(x) > b$. Let $t = h(x)$. Consider a sequence $v_n \geqq t$ such that

$$G(x, t) = \lim_{n\to\infty} \mu([t, v_n[) + H(x, v_n).$$

Without loss of generality, we can assume that (v_n) converges. We claim that $\lim_{n\to\infty} v_n = t$. For, otherwise, taking w with $t < w < \lim_{n\to\infty} v_n$, we would have

$$G(x, t) = \mu([t, w[) + \lim_{n\to\infty} (\mu([w, v_n[+ H(x, v_n))) \geqq \mu([t, w[) + G(x, w),$$

i.e., $\mu_x([t, w[) = 0$, so that $\mu_x(]b, w[) = 0$, which contradicts (14).

Since $t = \lim_{n\to\infty} v_n$, we get

$$G(x, t) = \min(H(x, t), \mu(\{t\}) + H^+(x, t)), \tag{15}$$

where, for simplicity, we set $H^+(x, t) = \lim_{u\to t^+} H(x, u) = \nu([0, x] \times]t, 1])$. Thus, for $u > t$,

$$\min(H(x, t) - H(x, u), \mu(\{t\}) + H^+(x, t) - H(x, u)) = G(x, t) - H(x, u)$$
$$\leqq G(x, t) - G(x, u) \leqq \mu([t, u[)$$

or, equivalently,

$$\nu([0, x] \times]h(x), u[) + \min(\nu([0, x] \times \{h(x)\}), \mu(\{h(x)\})) \leqq \mu([h(x), u[). \tag{16}$$

This holds for all $u > t$, and hence

$$\nu([0, x] \times]h(x), u]) + \min(\nu([0, x] \times \{h(x)\}), \mu(\{h(x)\})) \leqq \mu([h(x), u]). \tag{17}$$

Step 3. When $\mu_x(\{h(x)\}) > 0$, we have (still with $t = h(x)$) $G(x, t) - G^+(x, t) < \mu(\{t\})$. Since $G^+(x, t) \leqq H^+(x, t)$, by (15), we have

$$\mu(\{t\}) > G(x, t) - G^+(x, t)$$
$$\geqq G(x, t) - H^+(x, t) = \min(H(x, t) - H^+(x, t), \mu(\{t\})),$$

and then $H(x, t) - H^+(x, t) < \mu(\{t\})$. So

$$A' \subset A =: \{(x, t);\ t > h(x) \quad \text{or } t = h(x) > b,\ H(x, t) - H^+(x, t) < \mu(\{t\})\}.$$

Hence, it is enough to prove that $\nu(A) \leqq \mu(]b, d[)$.

Step 4. Suppose now (with $t = h(x)$) that $H^+(x, t) + \mu(\{t\}) \leqq H(x, t)$. Hence, by (5), (15), for $u > t$,

$$H^+(x, t) + \mu(\{t\}) = G(x, t) \leqq \mu([t, u[) + G(x, u).$$

Thus, $H^+(x, t) \leqq \mu(]t, u[) + G(x, u)$, and letting $u \to t$, we have $H^+(x, t) \leqq G^+(x, t)$, so $G^+(x, t) = H^+(x, t)$, since $G \leqq H$. Hence for $u > t$, by (5),

$$H^+(x, t) - H(x, u) = G^+(x, t) - H(x, u)$$
$$\leqq G^+(x, t) - G(x, u) \leqq \mu(]t, u[)$$

or, equivalently

$$\nu([0, x] \times]h(x), u[) \leqq \mu(]h(x), u[). \tag{18}$$

Since this holds for $u > t$, we also have

$$\nu([0, x] \times]h(x), u]) \leqq \mu(]h(x), u]). \tag{19}$$

Step 5. Consider $k>1$. We denote by $h_1<\cdots<h_{m-1}$ the *different* values taken by h at the points $i2^{-k}$, $0\leqq i\leqq 2^k$, and we set $h_m=d$. For $l\leqq m-1$, we set $X_l=\{x;\ h(x)=h_l\}\neq\varnothing$, and $x_l=\inf X_l$, $x'_l=\sup X_l$, so that $x'_{l-1}\leqq x_l\leqq x'_l\leqq x_{l+1}$. For $0\leqq l\leqq m-1$, we set

$$y_l=\sup\{y\leqq 1;\ H(y,h_l)-H^+(y,h_l)<\mu(\{h_l\})\}$$
$$=\sup\{y\leqq 1;\ \nu([0,y]\times\{h_l\})<\mu(\{h_l\})\}.$$

Setting $x'_0=0$, for $1\leqq l\leqq m-1$, we define

$$z_l=\begin{cases}\min(y_l,x'_l) & \text{if } y_l>x_l\\ x'_{l-1} & \text{otherwise.}\end{cases}$$

We set

$$A_k=\{(x,t);\ \exists l,\ 1\leqq l<m,\ t>h_l,\ x<x'_l \text{ or } t=h_l>b,\ x<z_l\}.$$

The sequence (A_k) obviously increases, and $A\backslash\bigcup_k A_k$ is contained in the countable collection of vertical line whose abscissa n has one of the following properties:

$$x=\sup\{z;\ H(z,t)-H^+(z,t)<\mu(\{t\})\},\quad \text{where } \mu(\{t\})>0,$$

or

$$h \text{ is not continuous at } x.$$

Thus, $\nu(A\backslash\bigcup A_k)=0$, and hence it is enough to show that for each k, we have $\nu(A_k)\leqq\mu(]b,d[)$.

Step 6. We define, for $0\leqq l<m-1$,

$$B'_l=\{(x,t);\ h_l<t<h_{l+1},\ x<x'_l\}$$

$$C_l=\begin{cases}\{(x,t);\ t=h_l,\ x<z_l\} & \text{if } y_l>x_l,\ h_l>b\\ \varnothing & \text{otherwise}\end{cases}$$

$$D_l=\begin{cases}\{(x,t);\ t=h_l,\ x<x'_{l-1}\} & \text{if } y_l\leqq x_l,\ h_l<d\\ \varnothing & \text{otherwise.}\end{cases}$$

Observe that by definition of y_l,

$$C_l\neq\varnothing\Rightarrow\nu(C_l)\leqq\min(\mu(\{h_l\}),\nu([0,x'_l]\times\{h_l\})). \tag{20}$$

Let $B_l=C_l\cup B'_l\cup D_{l+1}$, so that $A_k=\bigcup_{l=1}^{m-1}B_l$. Define, for $l\leqq m+1$,

$$\gamma_l=\mu(]b,h_l]) \quad \text{if } C_l=\varnothing,\ D_l\neq\varnothing,$$

and

$$\gamma_l=\mu(]b,h_l[) \quad \text{if } D_l=\varnothing,\ C_l\neq\varnothing.$$

To prove that $\nu(A_k)\leqq\mu(]b,d[)$ it is enough to show that $\nu(B_l)\leqq\gamma_{l+1}-\gamma_l$. In the case $C_l\neq\varnothing$, $D_{l+1}\neq\varnothing$ (respectively $C_l\neq\varnothing$, $D_{l+1}=\varnothing$; $C_l=\varnothing$, $D_{l+1}\neq\varnothing$; $C_l=\varnothing$, $D_{l+1}=\varnothing$) this follows from (20) and (17) (respectively (16), (19), (18)) applied with $u=h_{l+1}$, $x\in X_l$, and having $x\to x'_l$. □

We now consider a positive measure λ on $[0,1]$ and a Borel measurable map $\theta:[0,1]\to[0,1]$. We suppose that ν is the image of λ by the map $x\to(x,\theta(x))$. This means that for each Borel subset G of $[0,1]^2$ we have

$$\nu(G)=\lambda(\{x\in[0,1];\ (x,\theta(x))\in G\}).$$

We define $\psi(x)=\varphi(x,\theta(x))$.

THEOREM 2. *When ν is as above, η is supported by the union of the graph of θ and of the graph of ψ.*

Proof. Consider $\gamma > 0$. By Lusin's theorem [12, p. 56], we can find a compact subset K of $[0, 1]$ such that $\lambda([0, 1]\backslash K) \leqq \gamma$, and that θ and ψ are continuous on K. Thus, we can find a sequence $x_0 = 0 < x_1 < x_2 < \cdots < x_n = 1$, and numbers $(a_i)_{i\leqq n}$, $(b_i)_{i\leqq n}$ such that $x_{i-1} < x < x_i$, $x \in K \Rightarrow a_i < \theta(x) < a_i + \gamma$; $b_i < \psi(x) < b_i + \gamma$. Since $\varphi \leqq \theta$, we can assume that $b_i \leqq a_i$. Let $\gamma_i = \lambda([x_{i-1}, x_i]\backslash K)$. Hence $\sum_{i=1}^n \gamma_i \leqq \gamma$. The main point in the proof is to show that

$$\eta([x_{i-1}, x_i] \times ([0, 1]\backslash [b_i, b_i + \gamma] \cup [a_i, a_i + \gamma])) \leqq 3\gamma_i. \tag{21}$$

Indeed, this implies that

$$\eta(\{(x, t), t \notin [\psi(x) - \gamma, \psi(x) + \gamma] \text{ or } t \notin [\theta(x) - \gamma, \theta(x) + \gamma]\}) \leqq 5\gamma,$$

and letting $\gamma \to 0$ proves the theorem.

To prove (21), we can assume by Proposition 1 that $x_{i-1} = 0$, $i = 1$. We have

$$\begin{aligned} \eta([0, x_1] \times [a_1 + \gamma, 1]) &= G(x_1, a_1 + \gamma) \leqq H(x_1, a_1 + \gamma) \\ &= \lambda(\{x \leqq x_1;\ \theta(x) \geqq a_1 + \gamma\}) \leqq \gamma_1. \end{aligned} \tag{22}$$

It may or may not be the case that $b_1 + \gamma < a_1$. If $b_1 + \gamma < a_1$, we estimate $\eta([0, x_1] \times]b_1 + \gamma, a_1[)$. Let $\tau = \inf K$, so that $\lambda([0, \tau]) \leqq \gamma_1$. Since $\varphi(\tau, \theta(\tau)) = \psi(\tau) < b_1 + \gamma$, $\theta(\tau) > a_1$, we must have $\mu_\tau(]b_1 + \gamma, a_1[) = 0$, so that $\mu_{x_1}(]b_1 + \gamma, a_1[) = 0$. Hence

$$\eta(]\tau, x_1] \times]b_1 + \gamma, a_1[) = \mu_\tau(]b_1 + \gamma, a_1[) - \mu_{x_1}(]b_1 + \gamma, a_1[) = 0$$

and thus, by (11),

$$\begin{aligned} \eta([0, x_1] \times]b_1 + \gamma, a_1[) &\leqq \eta([0, \tau] \times [0, 1]) + \eta(]\tau, x_1] \times]b_1 + \gamma, a_1[) \\ &\leqq \lambda([0, \tau]) \leqq \gamma_1. \end{aligned} \tag{23}$$

We finally evaluate $\eta([0, x_1] \times [0, b_1[)$. By Lemma 5, whenever $c > b_1$, we have

$$\begin{aligned} \lambda(\{x;\ \theta(x) < c, \psi(x) > b_1\}) &= \nu(\{(x, t);\ t < c, \varphi(x, t) > b_1\}) \\ &\leqq \mu(]b_1, c[) \end{aligned}$$

and thus

$$\begin{aligned} \nu(\{(x, t);\ x \leqq x_1, t < c\}) &= \lambda(\{x;\ x \leqq x_1, \theta(x) < c\}) \\ &\leqq \lambda(\{x;\ \theta(x) < c, \psi(x) > b_1\}) + \lambda(\{x;\ x \leqq x_1, x \notin K\}) \\ &\leqq \mu(]b_1, c[) + \gamma_1, \end{aligned}$$

which means

$$H(x_1, 0) \leqq H(x_1, c) + \mu(]b_1, c[) + \gamma_1.$$

Since this holds for all $c > b_1$, we have

$$H(x_1, 0) \leqq G(x, b_1) + \gamma_1,$$

and hence

$$G(x_1, 0) \leqq H(x_1, 0) \leqq G(x, b_1) + \gamma_1$$

so that

$$\eta([0, x_1] \times [0, b_1[) \leqq \gamma_1. \tag{24}$$

Since (20) follows from (22) to (24), the proof is complete. □

We are now ready to construct the distribution of vacancies after the items have been attributed. Consider again a Borel-measurable map $\theta : [0, 1] \to [0, 1]$. Consider a

positive measure λ' on $[0, 1]$. The image ν' of λ' under the map $x \to (x, \theta(x))$ will be our distribution of vacancies. The reader would expect that in a correct model we would have $\nu([a, b] \times [0, 1]) = b - a$ for all $a \leqq b$. However, it is more convenient not to keep track of the vacancies of size zero, which are irrelevant for the packing. If λ_L denotes Lebesgue's measure, we will have $\lambda' \leqq \lambda_L$, and we can think of having unaccounted (irrelevant) vacancies of size zero of distribution $\lambda_L - \lambda'$.

Consider a parameter $\alpha > 0$ that will play a role similar to what it did in the definition of basic matching. We define $s(t, \alpha) = 1$ if $t < 2\alpha$, $s(t, \alpha) = \lfloor t/\alpha \rfloor$ if $t \geqq 2\alpha$. We consider the measure ν on $[0, 1]^2$ that has density $s(t, \alpha)$ at the point (x, t) with respect to ν'. The idea is that ν represents the distribution of the multiplicities of the vacancies. Consider the measure λ of density $s(\theta(x), \alpha)$ with respect to λ'. Then ν is the image of λ by the map $x \to (x, \theta(x))$.

We will assume that μ has a large enough mass at zero (larger than $\|\lambda\|$ is enough). Thus, all vacancies will receive items, and we will not have to consider separately those vacancies that receive no item. Of course, receiving a size zero item is the same as receiving nothing. We leave to the reader to check that the claim "all vacancies receive items" can be formalized by the equality

$$\eta([0, x] \times [0, 1]) = G(x, 0) = H(x, 0) = \nu([0, x] \times [0, 1]).$$

We will not use this fact directly. Actually, the fact that "all vacancies receive items" is mentioned at this point solely for the purpose of convincing the reader that the correct model is being developed. It will remain completely implicit in the rest of this section and will be used only in the proof of the (crucial) Theorem 3.

We assume that $[0, \alpha]$ supports μ. We set $A = \{x;\ \theta(x) \geqq 2\alpha\}$, $C = [0, 1] \backslash A$. We denote by λ'' the measure of $[0, 1]$ given by

$$\lambda''(B) = \eta((B \times [0, 1]) \cap (\text{Graph } \psi \backslash \text{Graph } \theta))$$

for each Borel set B of $[0, 1]$. We define the measure $\bar{\nu}_1$ on $[0, 1] \times [0, 1]$ as the image of λ' by the map $x \to \theta(x) - s(\theta(x), \alpha)\psi(x)$ *restricted to* A. The idea is that, in the basic matching, the vacancies of size $\theta(x) > \alpha$ receive $s(\theta(x), \alpha)$ items of the largest size left, i.e., $\psi(x)$. We define the measure $\bar{\nu}_2$ on $[0, 1] \times [0, 1]$ as the image of λ'' by the map $x \to \theta(x) - \psi(x)$ *restricted to* C. The idea is that (as Theorem 2 expresses) a vacancy of size $\theta(x)$ receives an item of size either $\theta(x)$ or $\psi(x)$. The measure λ'' takes in account the fact that only some vacancies of size $\theta(x)$ receive an item of size $\psi(x)$. The other bins of size $\theta(x)$ receive an item of size $\theta(x)$, so actually we create vacancies of size zero represented by the distribution $\lambda' - \lambda''$. Vacancies of size zero are irrelevant for our purposes, so we do not take this piece into account, and we set $\bar{\nu} = \bar{\nu}_1 + \bar{\nu}_2$. Given ν', μ, and α that satisfy the above conditions, the construction of $\bar{\nu}$, and of the related objects ν, η, μ_x, λ'', etc., will be called "performing the basic matching of μ and ν' with parameter α." When we need to be specific, we will write $\bar{\nu} = \bar{\nu}(\mu, \nu', \alpha)$.

We end this section with technical results that will be needed to stay in control when we iterate the constructions. We say that a measure ν on $[0, 1]^2$ is *decomposable* if it is the image of a measure λ on $[0, 1]$ by the map $x \to (x, \theta(x))$ that has the following property:

$\forall \varepsilon > 0$, there is a partition $L_0, L_1, \cdots, L_n$ (n depending on ε) of $[0, 1]$ in Borel sets such that

(25) $$L_0 = \{\theta < \varepsilon\} \quad \text{and} \quad \forall i \geqq 1,\ x, y \in L_i,\ x \leqq y \Rightarrow \theta(x) \leqq \theta(y).$$

If the map θ satisfies (25), we will call it decomposable.

PROPOSITION 2. *If ν is decomposable, then $\bar{\nu}$ is decomposable.*

Proof. Consider $\varepsilon > 0$ and a Borel set L such that

$$x, y \in L \Rightarrow \varepsilon \leqq \theta(x) \leqq \theta(y).$$

We can partition L into a finite number of (Borel) pieces $(L_j)_{j \leqq p}$ such that

$$x, y \in L_j \Rightarrow |\theta(y) - \theta(x)| < \varepsilon.$$

If $x, y \in L_j$, $x \leqq y$, $\theta(x) - \psi(x) \geqq \varepsilon$, $\theta(y) - \psi(y) \geqq \varepsilon$, we have $\psi(y) < \theta(x)$, and so, by Lemma 4, we have $\psi(y) \leqq \psi(x)$, so that $\theta(x) - \psi(x) \leqq \theta(y) - \psi(y)$. The same holds with $\theta - s\psi$. This completes the proof.

Let us say that a decomposable measure ν has the property $P(y)$ if the following holds:

$P(y)$: for $x < y$, we have $\theta(x) < 1$; for $x > y$, we have $\theta(x) = 1$; and the restriction of λ' to $[y, 1]$ is Lebesgue's measure.

PROPOSITION 3. *If ν has property $P(y)$, then $\bar{\nu}$ has property $P(\bar{y})$, where $y \leqq \bar{y} \leqq y + \|\mu\|/\lfloor 1/\alpha \rfloor$.*

Proof. The decomposable map $\bar{\theta}$ corresponding to $\bar{\nu}$ obviously satisfies $\bar{\theta}(x) < 1$ for $x < y$. Thus, by Proposition 1, we can replace μ by μ_y and suppose that ν has property $P(0)$, i.e., ν is the one-dimensional measure on $[0, 1] \times \{1\}$. But the result is obvious in that case. □

We observe that when ν has property $P(y)$, we have $1 - y = \nu([0, 1] \times \{1\})$, i.e., $y = 1 - \nu([0, 1] \times \{1\})$.

When performing the basic matching of μ and ν' with parameter α, we will say that μ *is packed at* x_0 if $\mu_{x_0} = 0$. (In that definition, we do not insist on x_0 being the smallest possible.)

3. FFD matching. We mentioned earlier that basic matching would be an adequate representation of "small portion" of FFD. Our task in this section is to develop that idea. Consider a distribution ν' on $[0, 1] \times [0, 1]$ that is the image of a positive measure $\lambda' \leqq \lambda_L$ by the map $x \to (x, \theta(x))$, where $\theta(x)$ is a decomposable map. Consider a positive measure μ on $[0, 1]$. Let $\alpha = \inf\{a; \mu(]a, 1])\} = 0$. We will, in that section, assume that μ is supported by the set $\{0\} \cup [\beta, \alpha]$, where $\beta \geqq \alpha/2$. We allow μ to have a (large) mass at zero for the reasons mentioned in § 2. The use of this will soon become apparent. Define, as before, $s(t, \alpha) = \lfloor t/\alpha \rfloor$ for $t \geqq 2\alpha$, $s(t, \alpha) = 1$ otherwise. We perform the basic matching of μ and ν' with parameter α, and we use the notations of § 2. Our whole approach relies on the following theorem.

THEOREM 3. *Suppose that for some $0 \leqq x_1 \leqq 1$ the following occur:*

$$\forall s \geqq 2, \qquad \nu'([0, x_1] \times]s\beta, s\alpha[) = 0. \tag{26}$$

$$\mu \text{ is packed at } x_1. \tag{27}$$

$$\mu \text{ is supported by } \{0\} \cup]\beta, \alpha]. \tag{28}$$

Then, given any $\varepsilon > 0$, $0 < t_0 < \beta$, we can find $\delta > 0$ and $N_0 > 0$ with the following properties. Consider $N \geqq N_0$ and a list of items $z_1, \cdots, z_p$ that satisfies

$$\forall t > 0, \qquad \left| \frac{1}{N} \operatorname{card}\{i \leqq p;\ z_i \geqq t\} - \mu([t, 1]) \right| \leqq \delta. \tag{29}$$

Consider a list of vacancies $(v_i)_{i \leqq N}$ that satisfies

$$\forall x \leqq 1, \quad \forall t \geqq t_0, \qquad \left| \frac{1}{N} \operatorname{card}\{i \leqq xN, v_i \geqq t\} - \nu'([0, x] \times [t, 1]) \right| \leqq \delta. \tag{30}$$

Then, if $(w_i)_{i \leqq N}$ *is the list of vacancies after the items* z_i *are attributed to the vacancies* v_i *following the* FFD *rule, we have*

$$(31) \qquad \forall x \leqq 1, \qquad \forall t \geqq t_0, \qquad \left| \frac{1}{N} \operatorname{card}\{i \leqq xN;\ w_i \geqq t\} - \bar{\nu}([0, x] \times [t, 1]) \right| \leqq \varepsilon.$$

Proof. Step 1. At most δN items z_i are greater than α. Packing them will modify at most δN vacancies. If we delete these items from our list of items, (29) still holds with 2δ instead of δ. Thus we can assume that all items are less than or equal to α. In a similar fashion, we can assume that all items are greater than β.

Step 2. We show that it is enough to prove (31) for $x \leqq x_1$ and to prove the following:

(32) The number of items z_i that are not packed in bins of index less than Nx_1 is less than or equal to εN.

Since ν' and $\bar{\nu}$ coincide on $[x_1, 1]$, from (30) we get that for $t \geqq 0$, $x \geqq x_1$,

$$\left| \frac{1}{N} \operatorname{card}\{i;\ x_1 N < i \leqq xN,\ v_i \geqq t\} - \bar{\nu}(]x_1, x] \times [t, 1]) \right| \leqq 2\delta.$$

On the other hand, since at most εN items z_i have not been packed in bins of index less than Nx_1, for at most εN indices $i > x_1 N$, we can have $w_i \neq v_i$. Thus,

$$\left| \frac{1}{N} \operatorname{card}\{i;\ x_1 N < i \leqq xN,\ w_i \geqq t\} - \bar{\nu}(]x_1, x] \times [t, 1]) \right| \leqq 2\delta + \varepsilon.$$

Together with (31) for $x = x_1$, this implies

$$\left| \frac{1}{N} \operatorname{card}\{i;\ i \leqq xN,\ w_i \geqq t\} - \bar{\nu}([0, x] \times [t, 1]) \right| \leqq 2\delta + 2\varepsilon$$

for $x_1 \leqq x \leqq 1$ and give (31) for all $0 \leqq x \leqq 1$ (with $2\varepsilon + 2\delta$ instead of ε).

In the sequel, we assume $x_1 = 1$, which changes nothing but simplifies notations. Thus (26) becomes now

$$(33) \qquad \forall s \geqq 2, \qquad \nu'([0, 1] \times]s\beta, s\alpha[) = 0.$$

Step 3. We show now that we can assume that the items z_i are attributed to the vacancies v_i according to basic matching of parameter α instead of the FFD rule. Say that a vacancy v_i is *abnormal* (respectively, *normal*) if it belongs to some (does not belong to any) interval $]s\beta, s\alpha[$, $s \geqq 2$. From (33), $\nu'([0, 1] \times]s\beta, s\alpha[) = 0$ for $s \geqq 2$. Since it is enough to consider the case $s \leqq 1/\beta$, by (30) we have at most $2\delta N/\beta$ abnormal vacancies. Thus, if we modify our list of vacancies by replacing the abnormal vacancies by 0, (30) still holds with $\delta(1 + 2/\beta)$ instead of δ. Any vacancy can receive at most $1/\beta$ items, thus the abnormal vacancies can receive at most $2\delta N/\beta^2$ items. Hence, the list of items attributed to the normal vacancies satisfies (29) with $\delta(1 + 2/\beta^2)$ instead of δ. If we attribute these items to the modified list of vacancies following the FFD rule, the ith vacancy w_i' obtained is w_i whenever v_i is normal. Thus if the sequence (w_i') satisfies (31), the sequence w_i will satisfy it with $\varepsilon + 2\delta/\beta^2$ instead of ε. Thus, we see that it is enough to prove the result under the extra assumption that there are no abnormal vacancies. However, in that case the basic matching with parameter α and the attribution of items following the FFD rule coincide, as is seen, e.g., by induction on the number of items, the point being that a vacancy $v_i \geqq \alpha$ is attributed $s = \lfloor v_i/\alpha \rfloor$ consecutive largest items by the FFD rule, since it satisfies $v_i < (s+1)\alpha$, and thus $v_i \leqq (s+1)\beta$ and hence cannot accept $s+1$ items of size greater than β.

Step 4. It is convenient to use the same conventions for our list of vacancies v_i as we do for ν'. Recall that we allow a "defective" ν', i.e., $\nu'([a,b]\times[0,1]) \leqq b-a$. The corresponding idea for the list of vacancies v_i is to allow some indices i to have no vacancy v_i attached to them, or if one prefers, one can achieve the same effect by formally setting this vacancy equal to -1. For the purpose of counting the vacancies w_i, it is very convenient to assume that all the v_i receive items. This is done by adding enough items of size zero to the list (z_i). It is at this point that our hypothesis that μ has a large enough mass at zero is explicitly used, since we can add the size zero items and assume that (29), which is valid for $t>0$, also becomes valid for $t=0$ (provided that $N^{-1} \leqq \delta$).

Consider the restriction ν_1' of ν' to $[0,1]\times[0,\beta[$. Then

$$\forall t \geqq t_0, \qquad \left| \frac{1}{N} \, card\{i;\, i \leqq xN,\, t \leqq v_i < \beta\} - \nu_1'([0,x]\times[t,1]) \right| \leqq 2\delta.$$

By construction of $\bar{\nu}$, if we replace ν' by $\nu' - \nu_1'$ (e.g., by replacing λ' by its restriction to the set $\{\theta \geqq \beta\}$), we replace $\bar{\nu}$ by $\bar{\nu} - \nu_1'$. On the other hand, the vacancies $v_i < \beta$ are not changed by the packing. Thus, to prove the theorem, one can replace ν' by $\nu' - \nu_1'$ and remove the vacancies $v_i < \beta$ from the list (i.e., setting them equal to -1). Hence, we can assume that (30) holds for all $t \geqq 0$.

Step 5. We have

$$\nu([0,x]\times[t,1]) = s\nu'([0,x]\times[t,1]) + \sum_{i>s} \nu'([0,x]\times[i\alpha,1]),$$

where $s = s(t,\alpha)$, and a similar formula holds for the multiplicities m_i of the vacancies. From (30), (which now holds for all $t \geqq 0$), it follows that

$$\forall t \geqq 0, \qquad \left| \frac{1}{N} \sum \{m_i;\, i \leqq xN,\, v_i \geqq t\} - \nu([0,x]\times[t,1]) \right| \leqq \frac{\delta}{\alpha}. \tag{34}$$

To simplify notations, for a subset X of $[0,1]^2$, we set

$$V'(X) = \frac{1}{N} \, card\left\{ i \leqq N;\, \left(\frac{i}{N}, v_i\right) \in X \right\},$$

$$V(X) = \frac{1}{N} \sum \left\{ m_i;\, \left(\frac{i}{N}, v_i\right) \in X \right\},$$

$$Z(X) = \frac{1}{N} \, card\{\text{items attributed to a vacancy } v_i,\, (i/N, v_i) \in X\},$$

$$\bar{V}(X) = \frac{1}{N} \, card\left\{ i \leqq N;\, \left(\frac{i}{N}, w_i\right) \in X \right\}.$$

Thus, (30) and (34) become

$$\forall t \geqq 0, \qquad |V'([0,x]\times[t,1]) - \nu'([0,x]\times[t,1])| \leqq \delta$$

$$\forall t \geqq 0, \qquad |V([0,x]\times[t,1]) - \nu([0,x]\times[t,1])| \leqq \delta/\alpha.$$

From (29), (2), and the definition of G, we see that for $t \geqq 0$,

$$|Z([0,x]\times[t,1]) - \eta([0,x]\times[t,1])| \leqq \delta(1+(1/\alpha)).$$

It follows that if R is a rectangle $I\times J$, where I, J are intervals (that may contain their endpoints or not), we have

$$|Z(R) - \eta(R)| \leqq 4\delta(1+(1/\alpha)).$$

A similar statement holds for V' and ν' and V and ν. For simplicity, we set $\delta' = 4\delta(1+1/\alpha)$. If X is the union of k disjoint rectangles, then $|Z(X)-\eta(X)| \leqq k\delta'$.

Step 6. We are already in position to prove (32). Since μ is packed at $x_1 = 1$, we have $\mu_1([\beta, 1]) = 0$, i.e., $\eta([0,1]\times[\beta,1]) = \mu([\beta,1])$. Thus,

$$Z([0,1]\times[\beta,1]) \geqq \eta([0,1]\times[\beta,1]) - \delta' = \mu([\beta,1]) - \delta'$$

$$\geqq \frac{1}{N}\, card\{i;\, z_i \geqq \beta\} - \delta - \delta'$$

and thus at most $N(\delta+\delta')$ nonzero items are not attributed to the vacancies v_i. Since we can always assume $\delta+\delta' \leqq \varepsilon$, this proves (32).

Step 7. Since θ is decomposable, we can find a finite Borel partition $M_0, \cdots, M_n$ of $[0,1]$, where $M_0 = \{\theta < \beta\}$, such that

$$\forall i \geqq 1, \qquad x, y \in M_i,\ x < y \Rightarrow \theta(x) \leqq \theta(y). \tag{35}$$

Let $\bar{\gamma}$ be a positive number to be determined later. We can approximate the sets $M_i \cap \{\theta - \psi \geqq t_0\}$, $M_i \cap \{\theta - \psi < t_0\}$ by finite unions of intervals. That is, we can find a partition $(I_j)_{j \leqq m}$ of $[0,1]$ in intervals, and for each $j \leqq m$ there is a measurable subset L_j of I_j such that for some $i = i(j)$, $0 \leqq i \leqq n$, we have

$$L_j = I_j \cap M_i \cap \{\theta - \psi \geqq t_0\} \quad \text{or} \quad L_j = I_j \cap M_i \cap \{\theta - \psi < t_0\}$$

and such that if we set

$$\gamma_j = \lambda'(I_j \backslash L_j),$$

we have $\sum_{j \leqq m} \gamma_j \leqq \bar{\gamma}$ (see [11, Prop. 15, p. 63). When $L_j \subset M_i$ for $i \geqq 1$, we can moreover assume from (35) that

$$\sup_{L_j} \theta(x) - \inf_{L_j} \theta(x) < t_0/2, \tag{36}$$

by cutting I_j in at most $2/t_0$ subintervals. When $L_j \subset \{\theta - \psi \geqq t_0\}$, it follows from Lemma 4 (as in the proof of Proposition 3) that

$$x, y \in L_j,\ x \leqq y \Rightarrow \psi(y) \leqq \psi(x). \tag{37}$$

Thus, we can also assume

$$\sup_{L_j} \psi(x) - \inf_{L_j} \psi(x) < t_0/2, \tag{38}$$

but splitting again I_j in at most $2/t_0$ subintervals. A further splitting ensures that on each L_j either $\beta \leqq \theta \leqq 2\alpha$ or $s_j\alpha \leqq \theta < (s_j+1)\alpha$ for some integer $s_j \geqq 2$.

Step 8. Let $t \geqq t_0$ be fixed. We can split each of our intervals I_j in at most two pieces in such a way that for all j, one of the following occurs:

$$L_j \subset M_0, \text{ i.e., } x \in L_j \Rightarrow \theta(x) < \beta; \tag{39}$$

$$x \in L_j \Rightarrow \beta \leqq \theta(x) \leqq 2\alpha,\ \theta(x) - \psi(x) < t; \tag{40}$$

$$x \in L_j \Rightarrow \beta \leqq \theta(x) \leqq 2\alpha,\ \theta(x) - \psi(x) \geqq t; \tag{41}$$

$$x \in L_j \Rightarrow s_j\alpha \leqq \theta(x) < (s_j+1)\alpha,\ \theta(x) - s_j\psi(x) < t; \tag{42}$$

$$x \in L_j \Rightarrow s_j\alpha \leqq \theta(x) < (s_j+1)\alpha,\ \theta(x) - s_j\psi(x) \geqq t. \tag{43}$$

Our family of intervals $(I_j)_{j \leqq m}$ now depends on t, but its cardinality m is bounded independently of t. Also if $\gamma_j = \lambda'(I_j \backslash L_j)$, we have $\sum_{j \leqq m} \gamma_j \leqq \bar{\gamma}$, independently of t.

Step 9. In all the preceding five cases, we are going to show

$$|\bar{V}(I_j\times[t,1])-\bar{\nu}(I_j\times[t,1])|\leqq\frac{10}{\alpha}(\delta+\gamma). \tag{44}$$

Since we can assume that $\bar{\nu}(I_j\times[0,1])\leqq\bar{\gamma}$ for all j, we get by summation over $j\leqq m$ that for all $x\leqq 1$,

$$\left|\frac{1}{N}\,card\{i;\, xN\leqq i,\, w_j\geqq t\}-\bar{\nu}([0,x]\times[t,1])\right|\leqq\frac{10}{\alpha}\,m\delta+\frac{11}{\alpha}\,\bar{\gamma}.$$

We choose $\bar{\gamma}=\alpha\varepsilon/22$ (which determines m) and then $\delta=\alpha\varepsilon/22m$ to obtain (31) (in which N_0 is any integer $\geqq 1/\delta$).

We turn to the proof of (44). We fix $j\leqq m$. We denote J and J' respectively, the smallest intervals such that $x\in L_j\Rightarrow\theta(x)\in J$, $\psi(x)\in J'$. We observe that by (36) J is of length less than $t_0/2$ unless (39) occurs and that J' is of length less than $t_0/2$ if (41) occurs. For simplicity of notation, we set $I=I_j$, $L=L_j$, $\gamma=\gamma_j$. The most interesting of the following cases will be the third one.

Case 1. (39) holds. In Step 4 we have reduced the proof to the case where $\lambda'(M_0)=0$. Thus,

$$\bar{\nu}(I\times[0,1])\leqq\lambda'(I)=\lambda'(I\backslash M_0)\leqq\lambda'(I\backslash L)\leqq\gamma.$$

Also

$$\bar{V}'(I\times[0,1])\leqq V'(I\times[0,1])\leqq\nu'(I\times[0,1])+\delta'\leqq\gamma+\delta'$$

so that (44) holds.

Case 2. (40) holds. We set $J-J'=\{u-u';\, u\in J,\, u'\in J'\}$. We first show that $J-J'\subset[0,t[$. Since $\theta(x)-\psi(x)<t$ on L, and since θ increases and ψ decreases on L, we have $\sup_L\theta-\inf_L\psi\leqq t$. If $\sup_L\theta-\inf_L\psi=t$, since $\theta(x)-\psi(x)<t$ for $t\in L$, either $\sup_L\theta$ or $\inf_L\psi$ is not attained and thus does not belong to J (respectively, J'). Thus $J-J'\subset[0,t[$. Since $\theta(x)-\psi(x)<t$ for $x\in L$, we have

$$\bar{\nu}(I\times[t,1])\leqq\lambda'(I\backslash L)\leqq\gamma.$$

Since $\theta(x)\in J$ for $x\in L$, we have

$$\nu'(I\times([0,1]\backslash J))\leqq\lambda'(I\backslash L)\leqq\gamma,$$

and hence, since $I\times([0,1]\backslash J)$ is the union of at most two disjoint rectangles,

$$V'(I\times([0,1]\backslash J))\leqq\gamma+2\delta'. \tag{45}$$

Since η is supported by the union of the graphs of θ and ψ, we have

$$\eta(I\times([0,1]\backslash(J\cup J')))\leqq\lambda(I\backslash L)\leqq\frac{\gamma}{\alpha},$$

and thus, since $I\times([0,1]\backslash(J\cup J'))$ is the union of at most three disjoint rectangles,

$$Z(I\times([0,1]\backslash(J\cup J')))\leqq 3\delta'+\frac{\gamma}{\alpha}. \tag{46}$$

Attributing an item of size in $J\cup J'$ to a vacancy in J creates a vacancy in $J-(J\cup J')$. Since J has length less than $t_0/2$, we have $J-J'\subset[0,t_0[\subset[0,t[$, thus $J-(J\cup J')\subset[0,t[$. Thus

$$\bar{V}(I\times[t,1])\leqq 5\delta'+\frac{2\gamma}{\alpha}$$

and (44) holds again.

Case 3. (41) holds. In that case, both J and J' have length less than $t_0/2$. Thus they must be disjoint, for otherwise $x \in L \Rightarrow \theta(x) - \psi(x) < t_0$. Since $\theta(x) - \psi(x) \geqq t$ on L, we have $\inf_L \theta - \sup_L \psi \geqq t$, so that $J - J' \subset [t, 1]$.

Since η is supported by the union of the graphs of θ and ψ, and since for $x \in L$, we have $\theta(x) \notin J'$, $\psi(x) \in J'$, we have

$$\bar{\nu}(L \times [t, 1]) = \lambda''(L) = \eta(L \times [0, 1] \cap \mathit{graph}\ \psi) = \eta(L \times J').$$

We also have

$$\eta(L \times J') \geqq \eta(I \times J') - \eta((I \backslash L) \times [0, 1]) \geqq \eta(I \times J') - \gamma,$$

and

$$\begin{aligned} \bar{\nu}(I \times [t, 1]) &\leqq \bar{\nu}((I \backslash L) \times [0, 1]) + \bar{\nu}(L \times [0, 1]) \\ &\leqq \lambda'(I \backslash L) + \lambda''(L) \leqq \gamma + \eta(I \times J') \end{aligned}$$

so that

$$|\bar{\nu}(I \times [t, 1]) - \eta(I \times J')| \leqq \gamma. \tag{47}$$

We note that (45) and (46) still hold. An item of size in J' that is attributed to a vacancy in J creates a vacancy greater than or equal to t. Then, from (45),

$$\bar{V}(I \times [t, 1]) \geqq Z(I \times J') - \gamma - \delta'.$$

On the other hand, an item of size in J that is attributed to a vacancy in J creates a vacancy less than t_0. Thus vacancies greater than or equal to t can come only from item sizes not in J or vacancies not in J and hence

$$\begin{aligned} \bar{V}(I \times [t, 1]) &\leqq Z(I \times ([0, 1] \backslash J)) + V'(I \times ([0, 1] \backslash J)) \\ &\leqq Z(I \times J') + Z(I \times ([0, 1] \backslash (J \cup J')) + V'(I \times ([0, 1] \backslash J)) \\ &\leqq Z(I \times J') + 5\delta' + \frac{2\gamma}{\alpha}, \end{aligned}$$

and thus

$$|\bar{V}(I \times [t, 1]) - Z(I \times J')| \leqq 5\delta' + \frac{2\gamma}{\alpha}.$$

Since $|\eta(I \times J') - Z(I \times J')| \leqq \delta'$, (47) shows that (44) holds again.

Case 4. (42) holds. We set $s = s_j$, $J - sJ' = \{u - su';\ u \in J,\ u' \in J'\}$. As in Case 2, we see that $J - sJ' \subset [0, t[$, and thus, by definition of $\bar{\nu}$,

$$\bar{\nu}(I \times [t, 1]) \leqq \lambda'(I \backslash L) \leqq \gamma.$$

Since $\theta(x) \in J$ for $x \in L$, we have

$$\nu'(I \times ([0, 1] \backslash J)) \leqq \lambda'(J \backslash L) \leqq \gamma$$

and hence

$$V'(I \times ([0, 1] \backslash J)) \leqq \gamma + 2\delta'. \tag{48}$$

Since η is supported by the union of the graphs of θ and ψ, and also by $[0, \alpha]\times[0, 1]$, and since $\theta \geqq 2\alpha$ on L, on $L\times[0, 1]$, η is supported by the graph of ψ, hence by $L\times J'$ and thus

$$\eta(I\times([0, 1]\backslash J')) \leqq \lambda(I\backslash L) \leqq \frac{\gamma}{\alpha}.$$

So we have

$$Z(I\times([0, 1]\backslash J')) \leqq 2\delta' + \frac{\gamma}{\alpha}. \tag{49}$$

To vacancies in J the basic matching attributes s consecutive largest unpacked items. If all these items belong to J', one checks easily that the resulting vacancy belongs to $J - sJ' \subset [0, t[$. Thus

$$\bar{V}(I\times[t, 1[) \leqq 4\delta' + \frac{2\gamma}{\alpha}$$

and (44) holds again.

Case 5. (43) holds. Using the notation of Case 5, we see as in Case 3 that $J - sJ' \subset [t, 1]$. By definition of $\bar{\nu}$,

$$\lambda'(I) - \gamma \leqq \lambda'(L) \leqq \bar{\nu}(I\times[t, 1]) \leqq \lambda'(I).$$

We observe that (48) and (49) still hold. Also we have

$$\nu'(I\times J) \geqq \lambda'(L) \geqq \lambda'(I) - \gamma,$$

so that

$$V'(I\times J) \geqq \lambda'(I) - \gamma - 2\delta'.$$

To vacancies in J the basic matching attributes s consecutive largest unpacked items. If all these items belong to J', the resulting vacancy belongs to $J - sJ' \subset [t, 1]$. Thus,

$$\bar{V}(I\times[t, 1[) \geqq V'(I\times J) - \left(2\delta' + \frac{\gamma}{\alpha}\right) \geqq \lambda'(I) - 4\delta' - \frac{2\gamma}{\alpha}$$

$$\geqq \bar{\nu}(I\times[t, 1]) - 4\delta' - \frac{2\gamma}{\alpha}.$$

Also

$$\bar{V}(I\times[t, 1[) \leqq V'(I\times[0, 1]) \leqq \nu'(I\times[0, 1]) + \delta'$$

$$= \lambda'(I) + \delta' \leqq \bar{\nu}(I\times[t, 1]) + \delta' + \gamma.$$

Thus, (44) holds again and the proof is complete.

The proof of Theorem 3 needs only obvious modifications to give Theorem 4.

THEOREM 4. *Same as Theorem* 3, *with* (26) *and* (27) *replaced, respectively, by*

$$\forall s \geqq 2, \qquad \nu'([0, 1]\times[s\beta, s\alpha[) = 0, \tag{50}$$

$$\mu \text{ is supported by } \{0\}\cup[\beta, \alpha]. \tag{51}$$

4. Definition of $f(\mu)$ and proof of Theorem 1. Our last significant task will be to prove Theorem 5.

THEOREM 5. *Given a probability measure μ on $[0,1]$, one can find four sequences $(u_k)_{k\geqq 1}$, $(u'_k)_{k\geqq 1}$, $(x_k)_{k\geqq 1}$, $(y_k)_{k\geqq 1}$ of numbers, a sequence $(\nu'_k)_{k\geqq 0}$ of decomposable measures on $[0,1]^2$, and a sequence $(\mu_k)_{k\geqq 1}$ of positive measures on $[0,1]$, with the following properties*:

(52) ν'_0 *is the one-dimensional Lebesgue measure on* $[0,1]\times\{1\}$,

(53) ν'_k *is the measure* $\bar{\nu}(\mu_k, \nu'_{k-1}, u_k)$, *and* μ_k *is packed at* x_k.

(54) ν'_k *has the property* $P(y_k)$ *for* $k\geqq 1$.

$$\mu = \sum_{k\geqq 1} \mu_k \tag{55}$$

$$\lim_{k\to\infty} u_k = 0;\ u_{k+1} \leqq u'_k \leqq u_k \tag{56}$$

(57) *For each* $k\geqq 1$, *either of the following occurs*:

(58) $]u_{k+1}, u'_k]$ *supports* μ_k, *and* $\nu'_k([0, x_k]\times]su_{k+1}, su'_k[) = 0$ *whenever* $s\geqq 2$.

(59) $[u_{k+1}, u'_k]$ *supports* μ_k, *and* $\nu'_k([0, x_k]\times[su_{k+1}, su'_k[) = 0$ *whenever* $s\geqq 2$.

Before we prove this theorem, we turn to the definition of $f(\mu)$ and the proof of Theorem 1. From Proposition 3, we see that the sequence (y_k) increases and that $y_{k+1}\leqq y_k + \|\mu_{k+1}\|/\lfloor 1/u_{k+1}\rfloor$. Thus, for $l\geqq 1$,

$$y_{k+l} \leqq y_k + \sum_{0\leqq i\leqq l} \frac{\|\mu_{k+i}\|}{\lfloor 1/u_{k+i}\rfloor} \leqq y_k + \sum_{1\leqq i\leqq l} \frac{\|\mu_{k+i}\|}{\lfloor 1/u_{k+1}\rfloor}.$$

We set $f(\mu) = \lim_{k\to\infty} y_k$. Thus, for all k,

$$f(\mu) \leqq y_k + \left(\left\lfloor \frac{1}{u_{k+1}}\right\rfloor\right)^{-1}. \tag{60}$$

We should observe that the quantities involved in Theorem 5 have no reason to be uniquely determined. It is a priori unclear that $f(\mu) = \lim_{k\to\infty} y_k$ depends on μ only, and not on these quantities. But we are going to show that Theorem 1 holds for this value of $f(\mu)$, thereby proving that it depends on μ only. Consider a list of items $z_1\geqq\cdots\geqq z_N$, and let

$$\tau = \sup_{0\leqq t\leqq 1} \left| \frac{1}{N} \operatorname{card}\{i\leqq N;\ z_i\geqq t\} - \mu([t,1])\right|. \tag{61}$$

We define $i_k = \lfloor N\|\sum_{i\leqq k}\mu_i\|\rfloor$. Thus, it is clear that

$$\sup_{0\leqq t\leqq 1} \left| \frac{1}{N} \operatorname{card}\{i;\ i_k\leqq i < i_{k-1},\ z_i\geqq t\} - \mu_k([t,1])\right| \leqq 2\tau + \frac{2}{N}. \tag{62}$$

Consider now N empty unit-size bins, and denote by $v_1^k, \cdots, v_N^k$ the list of vacancies after the items $(z_i)_{i\leqq i_k}$ have been packed according to the FFD rule.

Claim. Given $k\geqq 1$, $\varepsilon > 0$, $t_0 > 0$, there exists N_0 and $\delta > 0$, such that if (61) holds for $\tau\leqq\delta$, and if $N\geqq N_0$, then for all $x\leqq 1$ and $t\geqq t_0$, we have

$$\left| \frac{1}{N} \operatorname{card}\{i;\ i\leqq Nx,\ v_i^k\geqq t\} - \nu'_k([0,x]\times[t,1])\right| \leqq \varepsilon. \tag{63}$$

This statement is proved by induction over k, using (62) and using in the induction step, Theorem 3 when (58) holds and Theorem 4 when (59) holds.

Denote by F_k the number of bins that have received items after z_{i_k} is packed. Thus,

$$F_k = N - card\{i \leqq N;\ v_i^k = 1\}.$$

From (63), with $x = t = 1$, we have

$$\left| \frac{1}{N} card\{i \leqq N;\ v_i^k = 1\} - \nu_k'([0,1]\times\{1\}) \right| \leqq \varepsilon$$

so that we have $|N^{-1}F_k - y_k| \leqq \varepsilon$, since $y_k = 1 - \nu_k'([0,1]\times\{1\})$. Denote by F the total number of bins needed to pack $z_1, \cdots, z_N$. Then $F_k \leqq F \leqq F_k + 1 + N(\lfloor 1/u_{k+1} \rfloor)^{-1}$, since new bins accept at least $\lfloor 1/u_{k+1} \rfloor$ items of size $\leqq u_{k+1}$. Thus, with (60) we have

$$|N^{-1}F - f(\mu)| \leqq \varepsilon + N^{-1} + 2(\lfloor 1/u_{k+1} \rfloor)^{-1}.$$

Since $\lim_{k\to\infty} u_{k+1} = 0$, given $\varepsilon' > 0$, we can first pick k such that $2(\lfloor 1/u_{k+1} \rfloor)^{-1} \leqq \varepsilon'/3$; we then pick δ such that (63) holds for $\varepsilon' = \varepsilon/3$, then, if needed, N large enough that $1/N \leqq \varepsilon'/3$. This completes the proof of Theorem 1.

To prove Theorem 5, it suffices to apply inductively the following to the restriction of μ to the interval $]2^{-l-1}, 2^{-l}]$, $l \geqq 0$.

THEOREM 6. *Given a positive measure μ on $[0,1]$, supported by $]2^{-l-1}, 2^{-l}]$ $(l \geqq 0)$, and a decomposable measure ν' on $[0,1]^2$ that has property $P(y)$, we can find a finite sequence $2^{-l} = u_1 \geqq u_1' \geqq u_2 \geqq u_2' \geqq \cdots \geqq u_{p+1} = 2^{-l-1}$, increasing sequences $(y_k)_{k\leqq p}$, $(x_k)_{k\leqq p}$ of numbers, a sequence $(\nu_k')_{0\leqq k\leqq p}$ of decomposable measures on $[0,1]^2$, and a sequence $(\mu_k)_{k\leqq p}$ of positive measures on $[0,1]$ with the following properties*:

$$\nu_0' = \nu', \tag{64}$$

$$\nu_k' \text{ is the measure } \bar{v}(\mu_k, \nu_{k-1}', u_k'), \text{ and } \mu_k \text{ is packed before } x_k. \tag{65}$$

$$\nu_k' \text{ has property } P(y_k), \tag{66}$$

$$\mu = \sum_{1\leqq k\leqq p} \mu_k. \tag{67}$$

$$\text{For each } 1 \leqq k \leqq p, \text{ either of the following occurs:} \tag{68}$$

$$]u_{k+1}, u_k'] \text{ supports } \mu_k \text{ and } \nu_k'([0, x_k]\times]su_{k+1}, su_k'[) = 0 \tag{69}$$

whenever $s \geqq 2$, or

$$[u_{k+1}, u_k'] \text{ supports } \mu_k \text{ and } \nu_k'([0, x_k]\times[su_{k+1}, su_k'[) = 0 \tag{70}$$

whenever $s \geqq 2$.

Proof. Since ν' is decomposable, we can find a finite Borel partition $L_1, \cdots, L_n$ of the set $\{\theta \geqq 2^{-l-1}\}$, such that for $i \leqq n$,

$$x, y \in L_i \Rightarrow \theta(x) \leqq \theta(y).$$

The procedure we will define will take at most $n2^{l+1}$ steps. We define, for $i \leqq n$,

$$\theta_i(x) = \inf(\{\theta(y);\ y \geqq x,\ y \in L_i\}).$$

Thus θ_i is increasing, and $\theta_i(x) = \theta(x)$ if $x \in L_i$.

We define $u_1' = \inf\{a > 0;\ \mu(]a, 1]) = 0\}$. We use u_1' as a parameter for the basic matching, and we consider the measure ν of density $s(t, u_1')$ with respect to ν'. We perform the basic matching of μ and ν. Define

$$\Gamma_1(x) = \inf\{a > 0;\ \mu_x(]a, 0]) = 0\}.$$

This is a decreasing function. It is right continuous, as follows from the relation (see (8)) for $x \leqq y$.

$$\mu_x(]a, 0]) - \mu_y(]a, 0]) \leqq \eta([x, y] \times [0, 1]) \leqq \lambda([x, y]) \leqq 2^{l+1}(y - x).$$

For $i \leqq n$, we define $s_i^! = \inf(\{s(\theta_i(y), u_1'), y > 0\})$. Since θ is increasing, $\theta_i(y) < (s_i^! + 1)u_1'$ for y small enough. Since Γ_1 is right continuous, we have $\lim_{y \to 0^+} \Gamma_1(y) = u_1'$, so we can find $y > 0$ such that $\theta_i(y) < (s_i^! + 1)\Gamma_1(y)$ for $i \leqq n$. Define

$$x_1 = \sup\{y > 0; \forall i \leqq n, \theta_i(y) < (s_i^! + 1)\Gamma_1(y)\}$$

so that $x_1 > 0$. We define $u_2 = \lim_{x \to x_1^-} \Gamma_1(x)$.

Case 1. $\Gamma_1(x) > u_2$ for $x < x_1$. Let $x < x_1$. For $x < x' < x_1$, we have $\theta_i(x) \leqq \theta_i(x') \leqq (s_i^! + 1)\Gamma_1(x')$. Letting $x' \to x_1$ gives $\theta_i(x) \leqq (s_i^! + 1)u_2$. Since $s_i^! u_1' \leqq \theta_i(x) \leqq (s_i^! + 1)u_2$ for $0 < x < x_1$, we have $\nu'([0, x_1] \times]su_2, su_1'[) = 0$ for all $s \geqq 2$. We define μ_1 as the restriction of μ to $]u_2, u_1]$. It is supported by $]u_2, u_1']$, since $(\mu_1)_{x_1} \leqq \mu_{x_1}$, $(\mu_1)_{x_1}$ is supported by $[0, u_2]$. Since $(\mu_1)_{x_1} \leqq \mu_1$, it is supported by $]u_2, u_1']$, so we have $(\mu_1)_{x_1} = 0$. This shows that μ_1 is packed before x_1 and that (69) holds.

Case 2. For some $x_0 < x_1$, we have $\Gamma_1(x_0) = u_2$. For $x < x_1$, we have

$$\theta_i(x) \leqq \theta_i(\max(x, x_0)) < (s_i^! + 1)\Gamma_1(\max(x, x_0)) = (s_i^! + 1)u_2.$$

Thus, $\nu'([0, x_1] \times [su_2, su_1']) = 0$ for $s \geqq 2$.

We define μ_1 as the restriction of μ to $]u_2, u_1]$, to which we add the mass $\mu(\{\mu_2\}) - \mu_{x_1}(\{u_2\})$ at u_2. It is supported by $[u_2, u_1']$. To finish this case, we prove that μ_1 is packed before x_1. Since μ_1 is supported by $[u_2, u_1']$, so is $(\mu_1)_{x_1}$. Since $(\mu_1)_{x_1} \leqq \mu_{x_1}$, $(\mu_1)_{x_1}$ is supported by $\{u_2\}$. If $\mu_{x_1}(\{u_2\}) = 0$, the proof is finished. So suppose $h = \mu_{x_1}(\{u_2\}) > 0$. For $t > u_2$, we have $\mu_{x_1}([t, 1]) = 0$. Thus, for $u > u_2$,

$$\mu([t, 1]) = G(x_1, t) \leqq \mu([t, u[) + \nu([0, x_1] \times [u, 1]).$$

So $\mu([u, 1]) \leqq \nu([0, x_1] \times [u, 1])$ for $u > u_2$. This shows that

$$\inf_{u > u_2} (\mu([u_2, u[) + \nu([0, x_1] \times [u, 1])) \geqq \mu([u_2, 1]). \tag{71}$$

Since $\mu_{x_1}(]u_2, 1]) = 0$, we have

$$h = \mu_{x_1}(\{u_2\}) = \mu_{x_1}([u_2, 1]) = \mu([u_2, 1]) - G(x_1, u_2)$$

so that

$$\mu([u_2, 1]) - h = G(x_1, u_2) = \inf_{u \geqq u_2} (\mu([u_2, u[) + \nu([0, x_1] \times [u, 1])).$$

By (71), we have $G(x_1, u_2) = \nu([0, x_1] \times [u_2, 1])$, and thus, for $u > u_2$, by (71) again

$$\begin{aligned} \nu([0, x_1] \times [u_2, 1]) &= G(x_1, u_2) = \mu([u_2, 1]) - h \\ &\leqq \mu([u_2, u[) + \nu([0, x_1] \times [u, 1]) - h. \end{aligned}$$

Thus, replacing μ by μ_1 replaces $\mu([u_2, 1])$ by $\mu([u_2, 1]) - h$ but does not change $G(x_1, u_2)$. Thus, $(\mu_1)_{x_1}([u_2, 1]) = 0$, and this finishes the proof that μ_1 is packed before x_1.

For $x < x_1$, we have $\theta_i(x) < (s_i^! + 1)\Gamma_1(x)$, so that $\theta_i(x) - s_i^! \Gamma(x) \leqq \Gamma_1(x) \leqq u_1$. When $x \in L_i$ and $\theta(x) > u_1'$, we have $\Gamma_1(x) = \psi(x)$, and thus $\theta_i(x) - s(\theta(x), u_1')\psi(x) \leqq u_1 = 2^{-l}$. When $\theta(x) < u_1$, we also have $\theta(x) - \psi(x) \leqq 2^{-l}$. The definition of $\bar{\nu}$ shows that $\nu_1' = \bar{\nu}(\mu_1, \nu_0', u_1')$ does not charge $[0, x_1] \times]2^{-l}, 1]$. Also, ν_1' and ν' coincide on $[x_1, 1] \times [0, 1]$.

Consider $\mu_1' = \mu - \mu_1$. We perform the basic matching of μ_1' and ν_1' with parameter 1. Define

$$\Gamma_2'(x) = \inf\{a > 0;\ (\mu_1')_x(]a, 1]) = 0\}.$$

Obviously $\Gamma_2'(x) \leqq u_2$. We set $u_2' = \Gamma_2'(x_1)$, so $u_2' \leqq u_2$. We now perform the basic matching of μ_1' and ν_1' with parameter u_2', and we define

$$\Gamma_2(x) = \inf\{a > 0;\ (\mu_1')_x(]a, 1]) = 0\}.$$

Obviously, since ν_1' does not charge $[0, x_1] \times [2^{-l}, 1]$, Γ_2 and Γ_2' coincide on $[0, x_1]$, thus $u_2' = \Gamma_2(x_1)$. We define, for $i \leqq n$,

$$s_i^2 = \inf(\{s(\theta_i(y), u_2'), y > x_1\}).$$

We note that, by definition of x_1, there exists one $i \leqq n$ such that $\theta_i(y') \geqq (s_i^1 + 1)\Gamma_1(y')$ whenever $y' \geqq x_1$. So, if $x_1 < y' < y$, $\theta_i(y) \geqq \theta_i(y') \geqq (s_i^1 + 1)\Gamma_1(y')$. Letting $y' \to x_1$, since Γ_1 is right continuous, we get $\theta_i(y) \geqq (s_i^1 + 1)u_2 \geqq (s_i^1 + 1)u_2'$. Thus we have $s_i^2 \geqq s_i^1 + 1$.

We define

$$x_2 = \sup\{y > 0; \quad \forall i \leqq n,\ \theta_i(y) < (s_i^2 + 1)\Gamma_2(y)\}$$

$$u_3 = \lim_{x \to x_2^-} \Gamma_2(y),$$

and we proceed as in the first step of the construction to define μ_2. The measure $\nu_2' = \bar{\nu}(\mu_2, \nu_1', u_2')$ is then such that $\nu_2'([0, x_2] \times]2^{-l}, 1]) = 0$.

We continue this procedure until μ is exhausted. At each step k of the procedure there is one $i \leqq n$ such tht $s_i^{k+1} \geqq s_i^k + 1$. The numbers s_i^k are always less than $1/2^{-l-1} = 2^{l+1}$. This shows that the procedure terminates in at most $n2^{l+1}$ steps. The proof of Theorem 6 (and thus of Theorem 1) is complete.

IMPROVED TIME BOUNDS FOR THE MAXIMUM FLOW PROBLEM*

RAVINDRA K. AHUJA†‡, JAMES B. ORLIN†, AND ROBERT E. TARJAN§

Abstract. Recently, Goldberg proposed a new approach to the maximum network flow problem. The approach yields a very simple algorithm running in $O(n^3)$ time on n-vertex networks. Incorporation of the dynamic tree data structure of Sleator and Tarjan yields a more complicated algorithm with a running time of $O(nm \log (n^2/m))$ on m-arc networks. Ahuja and Orlin developed a variant of Goldberg's algorithm that uses scaling and runs in $O(nm + n^2 \log U)$ time on networks with integer arc capacities bounded by U. In this paper possible improvements to the Ahuja-Orlin algorithm are explored. First, an improved running time of $O(nm + n^2 \log U/\log\log U)$ is obtained by using a nonconstant scaling factor. Second, an even better bound of $O(nm + n^2(\log U)^{1/2})$ is obtained by combining the Ahuja-Orlin algorithm with the wave algorithm of Tarjan. Third, it is shown that the use of dynamic trees in the latter algorithm reduces the running time to $O(nm \log((n/m)(\log U)^{1/2}+2))$. This result shows that the combined use of three different techniques results in speed not obtained by using any of the techniques alone. The above bounds are all for a unit-cost random access machine. Also considered is a semilogarithmic computation model in which the bounds increase by an additive term of $O(m \log_n U)$, which is the time needed to read the input in the model.

1. Introduction.

We consider algorithms for the classical maximum network flow problem [5], [6], [13], [15], [20]. We formulate the problem as follows. Let $G = (V, E)$ be a directed graph with vertex set V and arc set E. The graph G is a *flow network* if it has two distinct distinguished vertices, a *source* s and a *sink* t, and a nonnegative real-valued *capacity* $u(v, w)$ on each arc $(v, w) \in E$. We assume that G is *symmetric*, i.e., $(v, w) \in E$ if and only if $(w, v) \in E$. We denote by n, m, and U the number of vertices, the number of arcs, and the maximum arc capacity, respectively. For ease in stating time bounds, we assume $m \geqq n$ and $U \geqq 4$. Bounds containing U are subject to the assumption that all arc capacities are integral. All logarithms in the paper are base two unless an explicit base is given.

A *flow* f on a network G is a real-valued function f on the arcs satisfying the following constraints:

$$f(v, w) \leqq u(v, w) \text{ for all } (v, w) \in E \text{ (capacity constraint);} \tag{1}$$

$$f(v, w) = -f(w, v) \text{ for all } (v, w) \in E \text{ (antisymmetry constraint);} \tag{2}$$

$$\sum_{(v,w)\in E} f(v, w) = 0 \text{ for all } w \in V - \{s, t\} \text{ (conservation constraint).} \tag{3}$$

The *value* $|f|$ of a flow f is the net flow into the sink:

$$|f| = \sum_{(v,t)\in E} f(v, t).$$

A *maximum flow* is a flow of maximum value. The *maximum flow problem* is that of finding a maximum flow in a given network.

Remark. We assume that all arc capacities are finite. If some arc capacities are infinite but no path of infinite-capacity arcs from s to t exists, then each infinite capacity can be replaced by the sum of the finite capacities without affecting the problem. □

The maximum flow problem has a long, rich history, and a series of faster and faster algorithms for the problem has been developed. (See [10] for a brief survey.) Until now the fastest known algorithms have been the one of Goldberg and Tarjan [9], [10] (running in time $O(nm \log (n^2/m))$) and the one of Ahuja and Orlin [1] (running in time $O(nm + n^2 \log U)$). Both of these algorithms are refinements of a generic method proposed by Goldberg [8], which we shall call the *preflow algorithm.* For networks with $m = \Omega(n^2)$, the Goldberg-Tarjan bound is $O(n^3)$, which matches the bound of several earlier algorithms [12], [14], [16], [21]. For networks with $m = O(n^{2-\varepsilon})$ for some constant $\varepsilon > 0$, the Goldberg-Tarjan bound is $O(nm \log n)$, which matches the bound of the earlier Sleator-Tarjan algorithm [17], [18]. Under the *similarity assumption* [7], namely, $U = O(n^\gamma)$ for some constant γ, the Ahuja-Orlin bound beats the Goldberg-Tarjan bound unless $m = O(n)$ or $m = \Omega(n^2)$.

The Goldberg-Tarjan and Ahuja-Orlin algorithms obtain their speed from two different techniques. The former uses a sophisticated data structure, the dynamic tree structure of Sleator and Tarjan [18], [19], [20], whereas the latter uses scaling. In this paper we explore improvements in the Ahuja-Orlin algorithm obtained by incorporating other ideas, including the use of dynamic trees. We begin in § 2 by reviewing the generic preflow algorithm [8], [9], [10]. In § 3, we develop a version of the Ahuja-Orlin algorithm that uses a stack-based vertex selection rule and a nonconstant scaling factor to obtain a time bound of $O(nm + n^2 \log U/\log\log U)$. In § 4, we describe an even faster variant that uses a constant scaling factor but combines the scaling idea with the *wave algorithm* of Tarjan [21]. This algorithm has a running time of $O(nm + n^2 (\log U)^{1/2})$. In § 5, we add dynamic trees to the method of § 4, thereby obtaining a running time of $O(nm \log ((n/m)(\log U)^{1/2}+2))$. The results in §§ 3-5 rely on the assumption that pointer manipulations and arithmetic operations on integers of magnitude U take $O(1)$ time. In § 6, we consider the effect on our time bounds of a weaker assumption, namely, that arithmetic on integers of magnitude n takes $O(1)$ time. The extra time needed by our algorithms in this *semilogarithmic computation model* is an additive term of $O(m \log_n U)$, which is the same as the time needed to read the input. We conclude in § 7 with some final remarks.

2. The preflow algorithm. In contrast to the classical *augmenting path method* of Ford and Fulkerson [6] that moves flow along an entire path from s to t at once, the preflow method moves flow along a single arc at a time. The key concept underlying the algorithm is that of a *preflow*, introduced by Karzanov [12]. A preflow f is a real-valued function on the arcs satisfying constraints (1), (2), and a relaxation of (3). For any vertex w, let the *flow excess* of w be $e(w) = \sum_{(v,w)\in E} f(v, w)$. The required constraint is the following:

$$e(w) \geqq 0 \quad \forall w \in V - \{s\} \text{ (preflow constraint).} \tag{4}$$

We call a vertex v *active* if $v \neq t$ and $e(v) > 0$. Observe that the preflow constraint implies that $e(s) \leqq 0$.

The *residual capacity* of an arc (v, w) with respect to a preflow f is $u_f(v, w) = u(v, w) - f(v, w)$. An arc is *saturated* if $u_f(v, w) = 0$ and *unsaturated* otherwise. (The capacity constraint implies that any unsaturated arc (v, w) has $u_f(v, w) > 0$.)

The preflow algorithm maintains a preflow and moves flow from active vertices through unsaturated arcs toward the sink, along paths estimated to contain as few arcs as possible. Excess flow that cannot be moved to the sink is returned to the source, also along estimated shortest paths. Eventually the preflow becomes a maximum flow.

As an estimate of path lengths, the algorithm uses a *valid labeling* that is a function d from the vertices to the nonnegative integers such that $d(s) = n$, $d(t) = 0$, and $d(v) \leqq d(w) + 1$ for every unsaturated arc (v, w). A proof by induction shows that, for any valid labeling d, $d(v) \leqq \min\{d_f(v, s) + n, d_f(v, t)\}$, where $d_f(v, w)$ is the minimum number of arcs on a path from v to w consisting of arcs unsaturated with respect to the flow f. We call an arc (v, w) *eligible* if (v, w) is unsaturated and $d(v) = d(w) + 1$.

The algorithm begins with an initial preflow f and a valid labeling d defined as follows:

$$f(v, w) = \begin{cases} u(v, w) & \text{if } v = s, \\ -u(w, v) & \text{if } w = s, \\ 0 & \text{if } v \neq s \text{ and } w \neq s, \end{cases}$$

$$d(v) = \min\{d_f(v, s) + n, d_f(v, t)\}.$$

The algorithm consists of repeating the following two steps, in any order, until no vertex is active:

Push(v, w).

Applicability: Vertex v is active and arc (v, w) is eligible.

Action: Increase $f(v, w)$ by $\min\{e(v), u_f(v, w)\}$. The push is *saturating* if (v, w) is saturated after the push and *nonsaturating* otherwise.

Relabel(v).

Applicability: Vertex v is active and no arc (v, w) is eligible.

Action: Replace $d(v)$ by $\min\{d(w) + 1 \mid (v, w) \text{ is unsaturated}\}$.

When the algorithm terminates, f is a maximum flow. Goldberg and Tarjan [10] derived the following bounds on the number of steps required by the algorithm:

LEMMA 2.1 [10]. *Relabeling a vertex v strictly increases $d(v)$. No vertex label exceeds $2n - 1$, and the total number of relabelings is $O(n^2)$.*

LEMMA 2.2 [10]. *There are at most $O(mn)$ saturating pushes and at most $O(n^2m)$ nonsaturating pushes.*

Efficient implementations of the above algorithm require a mechanism for selecting pushing and relabeling steps to perform. Goldberg and Tarjan proposed the following method: For each vertex, construct a (fixed) list $A(v)$ of the arcs out of v. Designate one of these arcs, initially the first on the list, as the *current arc* out of v. To execute the algorithm, repeat the following step until there are no active vertices:

Push/Relabel(v).

Applicability: Vertex v is active.

Action: If the current arc (v, w) of v is eligible, perform *push*(v, w). Otherwise, if (v, w) is not the last arc on $A(v)$, make the next arc after (v, w) the

current one. Otherwise, perform *relabel*(v) and make the first arc on $A(v)$ the current one.

With this implementation, the algorithm runs in $O(nm)$ time plus $O(1)$ time per nonsaturating push. This gives an $O(n^2m)$ time bound for any order of selecting vertices for push/relabel steps. Making the algorithm faster requires reducing the time spent on nonsaturating pushes. The number of such pushes can be reduced by selecting vertices for push/relabel steps carefully. Goldberg and Tarjan showed that first-in, first-out selection (first active, first selected) reduces the number of nonsaturating pushes to $O(n^3)$. Cheriyan and Maheshwari [3] showed that highest label selection (always pushing flow from a vertex with highest label) reduces the number of nonsaturating pushes to $O(n^2m^{1/2})$. (The latter rule was first proposed by Goldberg [8], who gave an $O(n^3)$ bound.) Ahuja and Orlin proposed a third selection rule, which we discuss in the next section.

3. The scaling algorithm. The intuitive idea behind the Ahuja-Orlin algorithm, henceforth called the *scaling algorithm*, is to move large amounts of flow when possible. The same idea is behind the maximum capacity augmenting path method of Edmonds and Karp [4] and the capacity scaling algorithm of Gabow [7]. One way to apply this idea to the preflow algorithm is to always push flow from a vertex of large excess to a vertex of small excess, or to the sink. The effect of this is to reduce the maximum excess at a rapid rate.

Making this method precise requires specifying when an excess is large and when it is small. For this purpose the scaling algorithm uses an *excess bound* Δ and an integer *scaling factor* $k \geqq 2$. A vertex v is said to have *large excess* if its excess exceeds Δ/k and *small excess* otherwise. As the algorithm proceeds, k remains fixed, but Δ periodically decreases. Initially, Δ is the smallest power of k such that $\Delta \geqq U$. The algorithm maintains the invariant that $e(v) \leqq \Delta$ for every active vertex v. This requires changing the pushing step to the following:

Push (v, w).

Applicability: Vertex v is active and arc (v, w) is eligible.

Action: If $w \neq t$, increase $f(v, w)$ by $\min\{e(v), u_f(v, w), \Delta - e(w)\}$. Otherwise, $(w = t)$, increase $f(v, w)$ by $\min\{e(v), u_f(v, w)\}$.

The algorithm consists of a number of *scaling phases*, during each of which Δ remains constant. A phase consists of repeating push/relabel steps, using the following selection rule, until no active vertex has large excess, and then replacing Δ by Δ/k. The algorithm terminates when there are no active vertices.

Large excess, smallest label selection: Apply a push/relabel step to an active vertex v of large excess; among such vertices, choose one of smallest label.

If the edge capacities are integers, the algorithm terminates after at most $\lfloor \log_k U + 1 \rfloor$ phases. After $\lfloor \log_k U + 1 \rfloor$ phases, $\Delta < 1$, which implies that f is a flow, since the algorithm maintains integrality of vertex excesses. Ahuja and Orlin derived a bound of $O(kn^2 \log_k U)$ on the total number of nonsaturating pushes. We repeat the analysis here, since it provides motivation for our first modification of the algorithm.

LEMMA 3.1 [1]. *The total number of nonsaturating pushes in the scaling algorithm is* $O(kn^2(\log_k U + 1))$.

Proof. Consider the function $\Phi = \sum_{v \text{ active}} e(v)\, d(v)/\Delta$. We call Φ the *potential* of the current preflow f and labeling d. Since $0 < e(v)/\Delta \leqq 1$ and $0 \leqq d(v) \leqq 2n$ for every active vertex v, $0 \leqq \Phi \leqq 2n^2$ throughout the algorithm. Every pushing step decreases Φ. A nonsaturating pushing step decreases Φ by at least $1/k$, since the push is from a

vertex v with excess more than Δ/k to a vertex w with $d(w) = d(v) - 1$, and $e(w) \leqq \Delta/k$ or $w = t$. The value of Φ can increase only during a relabeling or when Δ changes. A relabeling of a vertex v increases Φ by at most the amount $d(v)$ increases. Thus the total increase in Φ due to relabelings, over the entire algorithm, is at most $2n^2$. When Δ changes, Φ increases by a factor of k, to at most $2n^2$. This happens at most $\lfloor \log_k U + 1 \rfloor$ times. Thus the total increase in Φ over the entire algorithm is at most $2n^2 \lfloor \log_k U + 2 \rfloor$. The total number of nonsaturating pushes is at most k times the sum of the initial value of Φ and the total increase in Φ. This is at most $2kn^2 \lfloor \log_k U + 3 \rfloor$. □

Choosing k to be a constant independent of n gives a total time bound of $O(nm + n^2 \log U)$ for the scaling algorithm, given an efficient implementation of the vertex selection rule. One way to implement the rule is to maintain an array of sets indexed by vertex label, each set containing all large excess vertices with the corresponding label, and to maintain a pointer to the nonempty set of smallest index. The total time needed to maintain this structure is $O(nm + n^2 \log U)$.

Having described the scaling algorithm, we consider the question of whether its running time can be improved by reducing the number of nonsaturating pushes. The proof of Lemma 3.1 bounds the number of nonsaturating pushes by estimating the total increase in the potential Φ. Observe that there is an imbalance in this estimate: $O(n^2 \log_k U)$ of the increase is due to phase changes, whereas only $O(n^2)$ is due to relabelings. Our plan is to improve this estimate by decreasing the contribution of the phase changes, at the cost of increasing the contribution of the relabelings. Making this plan work requires changing the algorithm.

We use a nonconstant scale factor k and a slightly more elaborate method of vertex selection. We make use of the *stack-push/relabel* step defined below, which performs a sequence of push and relabel steps using a stack. The stack provides an alternative way of avoiding pushes to large-excess vertices (other than t).

Stack-Push/Relabel(r).

Applicability: Vertex r is active.

Action: Initialize a stack S to contain r. Repeat the following step until S is empty:

Stack Step. Let v be the top vertex on S and let (v, w) be the current arc out of v. Apply the appropriate one of the following cases:

Case 1: (v, w) *is not eligible.*

Case 1a: (v, w) *is not last on* $A(v)$. Replace (v, w) as the current arc out of v by the next arc on $A(v)$.

Case 1b: (v, w) *is last on* $A(v)$. Relabel v and pop it from S. Replace (v, w) as the current arc out of v by the first arc on $A(v)$.

Case 2: (v, w) *is eligible.*

Case 2a: $e(w) > \Delta/2$ and $w \neq t$. Push w onto S.

Case 2b: $e(w) \leqq \Delta/2$ or $w = t$. Perform *push*(v, w) (modified as at the beginning of this section to maintain $e(w) \leqq \Delta$ if $w \neq t$). If $e(v) = 0$, pop v from S.

Some remarks about *stack-push/relabel* are in order. Let us call a nonsaturating push *big* if it moves at least $\Delta/2$ units of flow and *little* otherwise. During an execution of *stack-push/relabel*, every vertex pushed onto S, except possibly the first, has an excess of at least $\Delta/2$ when it is added to S. A vertex v can be popped from S only after it is relabeled or its excess is reduced to zero. Of the pushes from v while v is on S, at most two are nonsaturating, only the last of which can be little.

Our variant of the scaling algorithm, called the *stack scaling algorithm*, consists of phases just as in the scaling algorithm. A phase consists of repeatedly applying the *stack-push/relabel* step to a large-excess active vertex of highest label; a phase ends when there are no large-excess active vertices.

LEMMA 3.2. *The total number of nonsaturating pushes made by the stack scaling algorithm is* $O(kn^2+n^2(\log_k U+1))$.

Proof. To bound the number of nonsaturating pushes, we use an argument like the proof of Lemma 3.1, but with two potentials instead of one. The first potential is that of Lemma 3.1, namely, $\Phi=\sum_{v \text{ active}} e(v)\, d(v)/\Delta$. By the analysis in the proof of Lemma 3.1, every push decreases Φ, the total increase in Φ over all phases is $O(n^2 \log_k U)$, and the difference between the initial and the final values of Φ is $O(n^2)$. Each big push moves at least $\Delta/2$ units of flow and hence decreases Φ by at least $\frac{1}{2}$. Thus the number of big pushes is $O(n^2(\log_k U+1))$.

To count little pushes, we divide them into two kinds, those that result in an empty stack S, called *emptying pushes*, and those that do not, called *nonemptying pushes*. A nonemptying push from a vertex v is such that $e(v)$ was at least $\Delta/2$ when v was added to S, and the push results in $e(v)$ decreasing to zero. We can charge such a push against the cumulative decrease of at least $\frac{1}{2}$ in Φ resulting from moving the original excess on v to vertices of smaller label. Hence there can be only $O(n^2(\log_k U+1))$ nonemptying pushes.

An emptying push from a vertex v can be associated with a decrease of at least $1/k$ in Φ, namely, the drop in Φ caused by the movement of the original excess on v, which is at least Δ/k, to smaller labeled vertices. But using this drop gives a bound on the number of emptying pushes of only $O(kn^2(\log_k U+1))$. We count emptying pushes more carefully by using a second potential, Φ_2. The definition of Φ_2 involves two parameters, an integer l and a set P. The value of l is equal to the minimum of $2n$ and the smallest label of a vertex added to S while S was empty during the current phase. Observe that $l=2n$ at the beginning of a phase and that l is nonincreasing during a phase. The set P contains all vertices that have label greater than l, and also all vertices that have label equal to l and from which an emptying push has been made during the current phase. Observe that P is empty at the beginning of a phase and P never loses a vertex during a phase. The definition of Φ_2 is

$$\Phi_2=\sum_{v\in P:e(v)>0} e(v)(d(v)-l+1)/\Delta. \text{ (If } P=\varnothing, \text{ then } \Phi_2=0.)$$

Observe that $0\leqq\Phi_2\leqq 2n^2$. Any emptying push can be associated either with an addition of a vertex to P or with a decrease in Φ_2 of at least $1/k$. (If the push is from v, either $v\notin P$ when v is added to S but $v\in P$ after the push, or $v\in P$ when v is added to S and Φ_2 drops by at least $1/k$ because of pushes from v while v is on S.) The number of vertices added to P is at most $n\lfloor\log_k U+1\rfloor$ over all phases, and hence so is the number of emptying pushes not associated with decreases in Φ_2.

To bound the number of emptying pushes associated with decreases in Φ_2, we bound the total increase in Φ_2. Increases in Φ_2 are due to relabelings and to decreases in l. (A vertex added to P because of an emptying push has zero excess and hence adds nothing to Φ_2.) A relabeling of a vertex v increases Φ_2 by at most the increase in $d(v)$ plus one; the "plus one" accounts for the fact that the relabeling may add v to P. Thus relabelings contribute at most $4n^2$ to the growth of Φ_2.

There are at most $2n$ decreases in l per phase. A decrease in l by one adds at most n/k to Φ_2, since when the decrease occurs every vertex in P has small excess. (Such a decrease occurs because some vertex v of label less than l is added to S while

S is empty. The label of v becomes the new value of l. When this happens, P contains only vertices of label exceeding the new value of l, all of which must have small excess.) Thus the total increase in Φ_2 due to decreases in l is at most $2n^2\lfloor \log_k U+1\rfloor/k$ over all phases.

The total number of emptying pushes associated with decreases in Φ_2 is at most k times the total increase in Φ_2, since Φ_2 is initially zero. Thus the total number of such pushes is at most $4kn^2+2n^2\lfloor \log_k U+1\rfloor$. □

As in the Goldberg-Tarjan and Ahuja-Orlin algorithms, the time to perform saturating pushes and relabeling operations and to examine ineligible arcs is $O(nm)$. The only significant remaining issue is how to choose vertices to add to S when S is empty. For this purpose, we maintain a data structure consisting of a collection of doubly linked lists: $list(j)=\{i\in N: e(i)>\Delta/k \text{ and } d(i)=j\}$ for each $j\in\{1, 2, \cdots, 2n-1\}$. We also maintain a pointer to indicate the largest index j for which $list(j)$ is nonempty. Maintaining this structure requires $O(1)$ time per push operation plus time to maintain the pointer. Each pointer increase is due to a relabeling (the increase is at most the amount of change in label) or due to a phase change (the increase is at most $2n$). Consequently, the number of times the pointer needs to be incremented or decremented is $O(n^2+n(\log_k U+1))$. The overall running time of the algorithm is thus $O(nm+kn^2+n^2(\log_k U+1))$. Choosing $k=\lceil \log U/\log\log U\rceil$ gives the following result:

THEOREM 3.3. *The stack scaling algorithm, with an appropriate choice of k, runs in* $O(nm+n^2\log U/\log\log U)$ *time.*

4. The wave scaling algorithm. Another way to reduce the number of nonsaturating pushes in the scaling algorithm is to keep track of the *total excess*, defined to be the sum of the excesses of all active vertices. The key observation is that if the total excess is sufficiently large, the algorithm can make significant progress by applying *stack-push/relabel* to each active vertex in turn, processing vertices in topological order with respect to the set of eligible arcs. Even though some vertices of very small excess are processed, the overall benefits of this approach yield an even better running time than that of the stack scaling algorithm. The idea of processing vertices in topological order originated in the *wave algorithm* of Tarjan [20], [21]; therefore, we call the new algorithm the *wave scaling algorithm.*

The wave scaling algorithm seems to derive no benefit from using a nonconstant scaling factor; therefore, we fix $k=2$. The algorithm uses another parameter, $l\geqq 1$, whose exact value we shall choose later. A phase of the wave scaling algorithm consists of two parts. First, the *wave step* below is repeated until the total excess is less than $n\Delta/l$. Then *stack-push/relabel* steps are applied to large-excess active vertices in any order until there are no large-excess active vertices.

Wave: Construct a list L of the vertices in $V-\{s, t\}$ in topological order with respect to the set of eligible arcs. (Ordering L in nonincreasing order by vertex label suffices.) For each vertex v on L, if v is active and v has not been relabeled during the current wave, then perform *stack-push/relabel*(v).

Observe that the total excess is a nonincreasing function of time. Constructing L at the beginning of a wave takes $O(n)$ time using a radix sort by vertex label. The time spent during a single wave is $O(n)$ plus time for the relabelings and pushes. Thus the total time required by the wave scaling algorithm is $O(nm)$ plus $O(n)$ per wave plus $O(1)$ per nonsaturating push. We complete the running time analysis with two lemmas.

LEMMA 4.1. *The number of nonsaturating pushes done by the wave scaling algorithm is* $O(n^2+(n^2/l)\log U)$ *plus* $O(n)$ *per wave.*

Proof. We count big pushes (those that move at least $\Delta/2$ units of flow) and little pushes separately. The analysis in the proof of Lemma 3.1 applies to bound the number of big pushes, with the following improvement. At the end of a phase, the total excess is less than $n\Delta/l$. Thus the potential at the beginning of the next phase is at most $4n^2/l$. (The new value of Δ is half of the old; each vertex label is at most $2n$.) Thus the sum of the increases in Φ caused by changes in Δ is $O((n^2/l)\log U)$, which implies that the number of big pushes is $O(n^2+(n^2/l)\log U)$. The same argument gives the same bound on the number of little pushes from vertices that have large excess when added to the stack S, since as in the proof of Lemma 3.2 each such push can be charged against a drop of at least $\frac{1}{2}$ in Φ. The remaining little pushes consist of at most one per vertex to which *stack-push/relabel* is applied during waves, totaling at most n per wave. □

LEMMA 4.2. *The number of waves in the wave scaling algorithm is* $O(\min\{nl+\log U, n^2\})$.

Proof. Consider any wave except the last in a phase. At the end of the wave, the total excess is at least $n\Delta/l$. The only way for excess to remain on a vertex x at the end of a wave is for x to have been relabeled during the wave; once x is relabeled, $e(x)$ remains constant until the end of the wave. The maximum excess on any single vertex is Δ. It follows that at least n/l relabelings must have occurred during the wave. Since the total number of relabelings is $O(n^2)$, the total number of waves is $O(nl+\log U)$. Furthermore, a wave during which no relabeling occurs causes all vertices to become inactive, and hence terminates the entire algorithm. Thus the number of waves is $O(n^2)$. □

THEOREM 4.3. *The running time of the wave scaling algorithm is* $O(nm+n^2(\log U)^{1/2})$ *if* l *is chosen equal to* $(\log U)^{1/2}$.

Proof. By Lemmas 4.1 and 4.2, the running time of the wave scaling algorithm is $O(nm+(n^2/l)\log U+\min\{n^2l+n\log U, n^3\})$. Choosing $l=(\log U)^{1/2}$ gives a bound of $O(nm+n^2(\log U)^{1/2}+\min\{n\log U, n^3\})$. But $\min\{n\log U, n^3\}\leqq n^2(\log U)^{1/2}$, since $n\log U\geqq n^2(\log U)^{1/2}$ implies $(\log U)^{1/2}\geqq n$. □

5. Use of dynamic trees. The approach taken in §§ 3 and 4 reduced the total number of pushes. An orthogonal approach is to reduce the total time of the pushes without necessarily reducing their number. This can be done by using the dynamic tree data structure of Sleator and Tarjan [18], [19], [20]. We conjecture that, given a version of the preflow algorithm with a bound of $p\geqq nm$ on the total number of pushes, the running time can be reduced from $O(p)$ to $O(nm\log((p/nm)+1))$ by using dynamic trees. Although we do not know how to prove a general theorem to this effect, we have been able to obtain such a result for each version of the preflow algorithm that we have considered. As an example, the $O(nm\log(n^2/m))$ time bound of Goldberg and Tarjan results from using dynamic trees with the first-in, first-out selection rule; the bound on the number of pushes in this case is $O(n^3)$. In this section we shall show that the same idea applies to the wave scaling algorithm of § 4, resulting in a time bound of $O(nm\log((n/m)(\log U)^{1/2}+2))$. This idea can also be applied to the stack scaling algorithm of § 3, giving a bound of $O(nm\log((n\log U/m\log\log U)+2))$; we omit a description of the latter result since the former bound is better.

The dynamic tree data structure allows the maintenance of a collection of vertex-disjoint rooted trees, each arc of which has an associated real value. We regard each tree arc as being directed from child to parent, and we regard every vertex as being

both an ancestor and a descendant of itself. The data structure supports the following seven operations:

find-root(v):	Find and return the root of the tree containing vertex v.
find-size(v):	Find and return the number of vertices in the tree containing vertex v.
find-value(v):	Find and return the value of the tree arc leaving v. If v is a tree root, the value returned is infinity.
find-min(v):	Find and return the ancestor w of v with minimum *find-value*(w). In case of a tie, choose the vertex w closest to the tree root.
change-value(v, x):	Add real number x to the value of every arc along the path from v to the root of its tree.
link(v, w, x):	Combine the trees containing v and w by making w the parent of v and giving the arc (v, w) the value x. This operation does nothing if v and w are in the same tree or if v is not a tree root.
cut(v):	Break the tree containing v into two trees by deleting the arc joining v to its parent; return the value of the deleted arc. This operation breaks no arc and returns infinity if v is a tree root.

A sequence of h tree operations, starting with an initial collection of singleton trees, takes $O(h \log (z+1))$ time if z is the maximum tree size [10], [18], [19], [20].

In the network flow application, the dynamic tree arcs are a subset of the current arcs out of the vertices. Only eligible arcs are tree arcs. The value of a tree arc is its residual capacity. The dynamic tree data structure allows flow to be moved along an entire path at once, rather than along a single arc at a time. We shall describe a version of the wave scaling algorithm, which we call the *tree scaling algorithm*, that uses this capability. Two parameters govern the behavior of the algorithm, a variable bound Δ on the maximum excess at an active vertex and a fixed bound z, $1 \leqq z \leqq n$, on the maximum size of a dynamic tree. The algorithm is identical to the wave scaling algorithm except that it uses the following step in place of *stack-push/relabel*:

Tree-Push/Relabel(r)

Applicability: Vertex r is active.

Action: Initialize a stack S to contain r. Repeat the following step until S is empty.

Stack Step. Let v be the top vertex on S and let (v, w) be the current arc out of S. Apply the appropriate one of the following cases:

Case 1: (v, w) *is not eligible.*

Case 1a: (v, w) *is not last on* $A(v)$. Replace (v, w) as the current arc out of v by the next arc on $A(v)$.

Case 1b: (v, w) *is last on* $A(v)$. Relabel v and pop it from S. Replace (v, w) as the current arc out of v by the first arc on $A(v)$. For every tree arc (y, v), perform *cut*(y).

Case 2: (v, w) *is eligible.* Let $x =$ *find-root*(w).

Case 2a: $e(x) > \Delta/2$ *and* $x \neq t$. Push x onto S.

Case 2b: $e(x) \leqq \Delta/2$ *or* $x = t$. Let $\varepsilon = \min \{e(v), u_f(v, w),$ *find-min*$(w)\}$. Let $\delta = \varepsilon$ if $x = t$, $\delta = \min \{\varepsilon, \Delta - e(x)\}$ if $x \neq t$. Send δ units of flow from v to x by increasing $f(v, w)$ by δ and performing *change-value*$(w, -\delta)$. (This is called a *tree push* from v to x. The tree push is *saturating* if $\delta = \min \{u_f(v, w),$ *find-min*$(w)\}$ before the push and *nonsaturating* otherwise.) While it is the case that *find-value*(*find-*

min$(w)) = 0$, perform *cut*(*find-min*(w)). If $e(v) = 0$, pop v from S, and if in addition $u_f(v, w) > 0$ and *find-size*(w) + *find-size*$(v) \leqq z$, perform *link*$(v, w, u_f(v, w))$.

The tree scaling algorithm stores flow in two different ways; explicitly for arcs that are not dynamic tree arcs and implicitly (in the dynamic tree data structure) for arcs that are dynamic tree arcs. After each cut, the flow on the arc cut must be restored to its correct current value. In addition, when the algorithm terminates, the correct flow value on each remaining tree arc must be computed. For arcs cut during the computation, the desired flow values are returned by the corresponding *cut* operations. Computing correct flow values on termination can be done using at most $n-1$ *find-value* operations. We have omitted these bookkeeping steps from our description of the algorithm.

The algorithm maintains the following invariants: every active vertex is a tree root, every tree arc is eligible, no excess exceeds Δ, and no tree size exceeds z. Let us call a nonsaturating tree push *big* if it moves at least $\Delta/2$ units of flow, and *little* otherwise. Of the pushes from a given vertex v while v is on S, at most two are nonsaturating and at most one (the last) is small.

The tree scaling algorithm is a variant of the dynamic tree algorithm of Goldberg and Tarjan [9], [10]. Their analysis applies to give the following result:

LEMMA 5.1 [10]. *The total time required by the tree scaling algorithm is* $O(nm \log (z+1))$ *plus* $O(\log (z+1))$ *time per tree push plus the time needed to construct and scan the list* L *during wave steps. The number of links, cuts, and saturating tree pushes is* $O(nm)$.

Making the tree scaling algorithm efficient requires careful implementation of the list L used in *wave* steps. For the moment we shall ignore the time spent manipulating L. The remaining issue in analyzing the algorithm is bounding the number of nonsaturating pushes. To do this we need two lemmas:

LEMMA 5.2. *The number of waves in the tree scaling algorithm is* $O(\min\{nl + \log U, n^2\})$.

Proof. Identical to the proof of the same result for the wave scaling algorithm (Lemma 4.2). □

LEMMA 5.3. *The number of nonsaturating tree pushes done by the tree scaling algorithm is* $O(nm + (n^2/l) \log U)$ *plus* $O(n/z)$ *per wave.*

Proof. The potential function Φ used in § 3, as applied in the proof of Lemma 3.3, serves to bound the number of big tree pushes by $O(n^2 + (n^2/l) \log U)$. We count little tree pushes as follows. Any little tree push, say from a vertex v, reduces $e(v)$ to zero. We shall count such a push against the most recent previous push that made $e(v)$ nonzero; or, if there is no such previous push, against the preflow initialization. We call the event of $e(v)$ becoming nonzero an *activation* of v. We shall derive a bound of $O(nm + (n^2/l) \log U)$ plus $O(n/z)$ per wave on the number of activations, thereby proving the lemma.

Initializing the preflow f at the beginning of the entire algorithm causes $O(n)$ vertex activations. Every other activation is due to a tree push (Case 2b of *tree-push/relabel*). If such a tree push results in a link or cut, we charge the activation against the corresponding link or cut. Similarly, if the tree push is saturating, we charge the activation against the arc saturation. Such charges account for $O(nm)$ activations.

Any remaining activation, say of a vertex x, is produced by a tree push through an arc (v, w) to $x =$ *find-root*(w), after which *find-size*(v) + *find-size*$(w) > z$, since no

link is performed. Let T_v and T_w be the dynamic trees containing v and w, respectively. We call a dynamic tree *large* if it contains more than $z/2$ vertices and *small* otherwise. Just after the push, one of T_v and T_w must be large.

If the tree push is big, we charge the activation of x against the push. By the argument above counting big tree pushes, this accounts for $O(n^2+(n^2/l)\log U)$ activations. Otherwise, the push is little, and thus it reduces $e(v)$ to zero. There can be at most one such push from v per wave. If T_v has changed between the beginning of the most recent wave and the push, we charge the activation of x to the link or cut that most recently changed T_v. There are $O(nm)$ such charges, at most one per link and at most two per cut, since vertex v is the root of T_v when the push occurs. Similarly, if T_w has changed between the beginning of the most recent wave and the push, we charge the activation of x to the link or cut that most recently changed T_w. There are $O(nm)$ such charges, since a vertex x can be activated at most once per wave, and x is the root of T_w when the push occurs. If neither T_v nor T_w has changed, we charge the activation of x to whichever of T_v or T_w is large. Each large tree existing at the beginning of a wave can be charged at most twice (once as a T_v, once as a T_w). Since there are fewer than $2n/z$ large trees at the beginning of any wave, the total number of such charges is $O(n/z)$ per wave. Combining all our estimates gives the claimed bound on vertex activations. □

THEOREM 5.4. *The number of tree pushes done by the tree scaling algorithm is* $O(nm)$ *if* z *is chosen equal to* $\min\{n, \max\{1, (n^2/m^2)\log U\}\}$, *and* l *is chosen equal to* m/n *if* $z=1$, $(n/m)\log U$ *if* $1<z\leqq n$.

Proof. By Lemmas 5.2 and 5.3, the number of tree pushes done by the algorithm is $O(nm+(n^2/l)\log U+(n/z)\min\{nl+\log U, n^2\})$. We consider three cases:

Case 1. $(n^2/m^2)\log U\leqq 1$. Then $z=1$ and $l=m/n\geqq 1$. The number of tree pushes is $O(nm+(n^3/m)\log U+n\min\{m+\log U, n^2\})$. Since $\log U\leqq m^2/n^2$, the bound on tree pushes is $O(nm+\min\{m^2/n, n^3\})=O(nm)$, because $m^2/n\leqq n^3$ implies $m\leqq n^2$, which means $m^2/n\leqq nm$, and $m^2/n\geqq n^3$ implies $m\geqq n^2$, which means $n^3\leqq nm$. (This analysis allows for the possiblity of multiple arcs in G, i.e., the possibility that $m>n^2$.)

Case 2. $1<(n^2/m^2)\log U<n$. Then $z=(n^2/m^2)\log U$ and $l=(n/m)\log U\geqq 1$. The number of tree pushes is $O(nm+(m^2/n\log U)\min\{(n^2/m)\log U+\log U, n^2\})=O(nm+\min\{m^2/n, m^2n/\log U\})=O(nm+\min\{m^2/n, n^3\})$, since $\log U>m^2/n^2$. Since $\min\{m^2/n, n^3\}\leqq nm$ (see Case 1), the number of tree pushes is $O(nm)$. (As in Case 1, this analysis allows for the possiblity that $m>n^2$.)

Case 3: $(n^2/m^2)\log U\geqq n$. Then $z=n$ and $l=(n/m)\log U\geqq 1$. The number of tree pushes is $O(nm+\min\{(n^2/m)\log U+\log U, n^2\})=O(nm)$. □

Observe that if z is chosen as in Theorem 5.4, i.e., equal to $\min\{n, \max\{1, (n^2/m^2)\log U\}\}$, the time per dynamic tree operation is $O(\log(z+1))=O(\log((n/m)(\log U)^{1/2}+2))$. Thus the running time of the tree scaling algorithm, with k and z chosen as in Theorem 5.4, is $O(nm\log((n/m)(\log U)^{1/2}+2))$ (ignoring time spent manipulating L).

All that remains is to show that the manipulations of the list L in *wave* steps can be performed in $O(nm\log((n/m)(\log U)^{1/2}+2))$ time. It is not sufficient to represent L simply as a linked list, for then the time spent scanning L will be $O(n)$ per wave, and this scanning time will dominate the time for the rest of the computation. Instead, we represent L as follows. For each integer i in the range $1\leqq i\leqq 2n-1$, we maintain the set $K(i)$ of active vertices with label i that have not been relabeled during the current wave. For each integer j in the range $1\leqq j\leqq\lceil(2n-1)/z\rceil$, we maintain a heap (priority queue) $H(j)$ of the integers i with $K(i)\neq\varnothing$ and $\lceil i/z\rceil=j$. We also maintain a current index j^*, initially equal to $\lceil(2n-1)/z\rceil$.

During a wave, we find the next vertex v to which to apply a *tree-push/relabel* step by decrementing j^* until $H(j^*) \neq \emptyset$, then finding the maximum integer $i \in H(j^*)$, and finally selecting v to be any vertex in $K(i)$. During each *tree push/relabel* step, the sets $K(i)$ and heaps $H(j)$ are updated as vertices become active or inactive and labels change. Each insertion or deletion in a set $K(i)$ takes $O(1)$ time. The heaps $H(j)$ are implemented using any standard heap implementation (see [20]), so that insertion or deletion in a heap $H(j)$ takes $O(\log(z+1))$ time, as does finding the maximum integer in a given heap $H(j)$. (The maximum number of elements in any heap $H(j)$ is z.) A set $K(i)$ or a heap $H(j)$ can change only as the result of a tree push or a relabeling, and the time required for the associated updating of sets and heaps is $O(\log(z+1))$. Thus we obtain the following result:

LEMMA 5.5. *The total time spent maintaining the sets $K(i)$, the heaps $H(j)$, and the index j^* during the tree scaling algorithm is $O(nm \log(z+1))$, if z and l are chosen as in Theorem* 5.4.

Proof. The number of relabelings is $O(nm)$, as is the number of tree pushes by Theorem 5.4. There is $O(n/z)$ time per wave spent decrementing j^*, but this amount of time is included in the $O(nm)$ bound of Theorem 5.4. □

THEOREM 5.6. *The tree scaling algorithm runs in $O(nm \log((n/m)(\log U)^{1/2}+2))$ time if z is chosen equal to $\min\{n, \max\{1, (n^2/m^2)\log U\}$ and l is chosen equal to m/n if $z=1$ or to $(n/m)\log U$ if $z>1$.*

Proof. Immediate from Theorem 5.4 and Lemma 5.5, since $\log(z+1) = O(\log((n/m)(\log U)^{1/2}+2))$. □

6. Bounds in a semilogarithmic computation model. The time bounds derived in §§ 3–5 are all based on the assumption that addition and comparison of integers of magnitude at most U takes $O(1)$ time. If U is huge, this assumption may be unjustified. In this section we explore the consequences to our results of using a semilogarithmic computation model in which each computer word is allowed to hold $O(\log n)$ bits, and any operation involving $O(1)$ words takes $O(1)$ time. In this model, all the elementary graph and list manipulation operations needed by our algorithms take $O(1)$ time each, but adding or comparing two capacity or flow values can take $O(\log_n U)$ time if an exact answer is required. Thus a straightforward translation of our results into the semilogarithmic model increases each of the time bounds by a factor of $O(\log_n U)$.

By suitably modifying the algorithms, however, it is possible to reduce the extra time each of our algorithms requires in the semilogarithmic model to an additive term of $O(m \log_n U)$. Thus, for example, the running time of the tree scaling algorithm becomes $O(nm \log((n/m)(\log U)^{1/2}+2) + m \log_n U)$. Note that the time needed to read all the arc capacities is $\Theta(m \log_n U)$ in this model. Thus, as U grows exponentially large, the total running time becomes linear in the size of the input.

The general approach is to approximately solve a sequence of $O(\log_n U)$ closer-and-closer approximations to the original problem. Each approximation uses as a starting point the approximate solution to the previous problem. Solving each problem requires manipulation of integers of only $O(\log n)$ bits.

Making this approach work involves a number of messy technical details. Since the result is mainly of theoretical interest, we shall merely sketch the ideas involved in modifying the algorithms of §§ 4 and 5. We assume (without loss of generality) that n is a power of two and that U is a power of n. For $k = 1, 2, \cdots, \log_n U$, we define *problem k* to be the maximum flow problem on the graph G with arc capacities $u_k(v, w)$ defined by $u_k(v, w) = \lceil u(v, w)/\delta_k \rceil \delta_k$, where $\delta_k = U/n^k$. Observe that for $k = \log_n U$,

$\delta_k = 1$; thus, problem $\log_n U$ is the original problem. Also, for a general value of k, all capacities in problem k are divisible by δ_k; and, for every arc (v, w), $0 \leqq u_{k-1}(v, w) - u_k(v, w) \leqq \delta_{k-1}$.

We solve problem k for $k = 1, 2, \cdots, \log_n U - 1$ approximately and then solve problem $\log_n U$ exactly. Throughout the computation we maintain a preflow f and a valid labeling d for the current problem. Preflow f satisfies the following constraint:

$$(5) \qquad e(v) \geqq \min \left\{ \sum_{f(u,v)>0} f(u, v), n(\delta_k - 1) \right\} \forall v \neq s \text{ (flow holdback constraint).}$$

(In inequality (5), the sum over $f(u, v)$ is taken to be zero if $f(u, v) \leqq 0$ for all arcs (u, v).)

For a vertex v, the *available excess* at v, which is the amount actually allowed to be pushed from v, is $a(v) = \max\{0, e(v) - n(\delta_k - 1)\}$. Throughout the computation, the available excesses are used in place of the actual excesses to determine when vertices are active and how much flow can be pushed.

The flow holdbacks are needed to maintain the preflow property when converting a solution for one problem into a good initital preflow for the next problem. For the first problem, the preflow f and valid labeling d are initialized exactly as in § 2 (using the arc capacities $u_1(v, w)$). Once a solution to problem $k-1$ is computed, it is converted into an initial preflow for problem k by replacing the current preflow f by the preflow f' defined by $f'(v, w) = \min\{f(v, w), u_k(v, w)\}$. Since $0 \leqq u_{k-1}(v, w) - u_k(v, w) \leqq \delta_{k-1}$, f' is obtained from f by decreasing the flow on each arc (v, w) by an amount between zero and $\min\{f(v, w), \delta_{k-1}\}$ (inclusive). Since $\delta_{k-1} = n\delta_k$, the validity of the flow holdback constraint for f in problem $k-1$ implies the validity of the flow holdback constraint for f' in problem k. The flow holdback constraint implies that f' is a preflow, since f' satisfies the capacity constraint by construction. Since every arc saturated by f in problem $k-1$ remains saturated by f' in problem k, d is a valid labeling for f' in problem k.

For $1 \leqq k < \log_n U$, a preflow f and valid labeling d constitute a solution to problem k if $a(v) \leqq 2n(\delta_k - 1)$ for every active vertex v. Thus a solution to problem $\log_n U$ gives a maximum flow in the original network. After the initialization of the preflow for problem k, every active vertex has an excess of at most $4n^2\delta_k$, of which $3n^2\delta_k = 3n\delta_{k-1}$ comes from the excess on v in problem $k-1$ (since $a(v) \leqq 2n(\delta_{k-1} - 1)$), and $n^2\delta_k = n\delta_{k-1}$ comes from the changes made to f in initializing the preflow for problem k. (These are overestimates.) The initial value of Δ (the bound on maximum available excess) for problem k is $4n^2\delta_k$. Problem k is solved by performing a number of phases, continuing until the maximum available excess is at most $2n(\delta_k - 1)$, which happens by the time Δ is reduced to $n\delta_k$ (or to $\frac{1}{2}$ if $k = \log_n U$). If $k < \log_n U$, the number of phases needed is at most $\log n + 2$; if $k = \log_n U$, the number of phases needed is at most $2 \log n + 3$. Thus each problem requires $O(\log n)$ phases, and the total number of phases over all subproblems is $O(\log n \log_n U) = O(\log U)$.

During the solution of problem k, the preflow f is maintained so that $f(v, w)$ is a multiple of δ_k for each arc (v, w). (This happens automatically, since Δ, the initial flow values, and all capacities are multiples of δ_k.) Thus the flow values and capacities can be represented in units of δ_k. Furthermore, the flow values and capacities are not represented explicitly, but rather as differences from the initial flow values. To be more precise: let f_{k-1} be the final preflow for problem $k-1$; let $f_0 = 0$. Then the current preflow f is represented by the value $f(v, w) - f_{k-1}(v, w)$ for each arc (v, w). The capacity function u_k is represented by the value $\min\{u_k(v, w) - f_{k-1}(v, w), 9n^5\delta_k\}$ for each arc (v, w). We claim that the amount by which the flow on an arc can change during the

solution of problem k and subsequent problems is at most $8n^5\delta_k$. This claim implies that if $u_k(v, w) - f_k(v, w) > 9n^5\delta_k$, the extra residual capacity (beyond $9n^5\delta_k$) on arc (v, w) will never be used and can be ignored. To prove the claim, we note that between relabelings at most $n\Delta \leq 4n^3\delta_k$ units of flow can be moved through any given arc, and there are at most $2n^2$ relabelings over the entire algorithm. This accounts for $8n^5\delta_k$ units of change. The change on an arc due to modifying f between subproblems is at most $\sum_{j=k-1}^{\log_n U} \delta_j \leq 2\delta_{k-1} = 2n\delta_k$. Thus the claim is true.

Storing f and u_k in such a difference form, in units of δ_k, allows the algorithm to manipulate numbers consisting of only $O(\log n)$ bits, and all necessary additions and comparisons of flows and capacities take $O(1)$ time. Constructing the final preflow is merely a matter of adding together the successive flow differences $f_1 - f_0, f_2 - f_1, \cdots$ computed when solving successive problems. By adding these differences from right to left, the time per addition can be made $O(m)$, and the total time is $O(m \log_n U)$. This is also the total time required for initializing the preflow for each problem ($O(m)$ time per problem).

If the wave scaling algorithm is used, the bounds in § 4 remain valid almost without modification and apply to the calculations involved in solving all $\log_n U$ problems. Specifically, the number of relabelings is $O(n^2)$, the number of saturating pushes is $O(nm)$, the number of nonsaturating pushes is $O(n^2 + (n^2/l) \log U)$ plus $O(n)$ per wave, and the number of waves is $O(\min\{nl + \log U, n^2 + \log_n U\})$. The bound on waves is the only one that changes, in that n^2 becomes $n^2 + \log_n U$; this occurs because a wave without relabelings terminates only the solution of the current problem and not the entire algorithm. Choosing $l = (\log U)^{1/2}$ gives an overall bound of $O(nm + n^2(\log U)^{1/2} + m \log_n U)$ time.

Use of the tree scaling algorithm of § 5 results in a time bound of $O(nm \log((n/m)(\log U)^{1/2} + 2) + m \log_n U)$. To obtain this bound, we must verify that the extra time required for initializing the sets $K(i)$, the heaps $H(j)$, and the dynamic trees for each problem, and the extra time for tree pushes associated with vertices that become active at the beginning of a new problem, is $O(m)$ per problem.

We need two extra facts about the dynamic tree data structure. By traversing the entire data structure, the flow values for all the dynamic tree arcs can be computed in $O(n)$ time. Furthermore, a new set of flow values for all these arcs can be installed in the data structure in $O(n)$ time. These facts can easily be verified by checking the description of the data structure [19], [20].

When the flow f is modified at the beginning of a new problem, new vertices with available excess are created, possibly as many as $n - 2$. Handling these newly active vertices is the hardest part of the initialization of the new problem. To begin a new problem, the current flow on all dynamic tree arcs is computed explicitly. (This takes $O(n)$ time as noted above.) Then the flow and capacities are modified to their initial values for the new problem. The bound on maximum available excess is set equal to $4n^3\delta_k$. (This is n times the value proposed earlier in this section and is greater than the total excess on all active nodes.)

Next, the vertices of G are scanned in topological order with respect to the set of eligible arcs. A vertex v is scanned by applying to it a *push/relabel* step of the kind defined in § 2. Such a step either relabels v or reduces its available excess to zero. After all vertices have been scanned, all the available excess is on vertices that have been relabeled during the scanning. The current flow values for dynamic tree arcs are reinstated in the dynamic tree data structure, and every dynamic tree arc that has been saturated during the scanning or that has had one of its end vertices relabeled is cut. Finally, the sets $K(i)$ and heaps $H(j)$ are reinitialized, which takes $O(n)$ time.

(A heap can be initialized in linear time [20].) Then the tree scaling algorithm is begun.

Because the starting value of Δ for each problem is increased, the number of phases increases, but only by $\log n$ per subproblem, or $\log U$ overall. The time to carry out all the scanning in the initialization is $O(m)$. The time to initialize the dynamic tree data structure is $O(m)$ plus $O(\log(z+1))$ per cut; the time for a cut can be charged against the corresponding arc saturation or vertex relabeling. The time to initialize the sets $K(i)$ and heaps $K(j)$ is $O(n)$. At the beginning of a subproblem, the only active vertices are those that have been relabeled during the initialization, and the timing analysis for the tree scaling algorithm is virtually the same as the analysis in § 5. Thus we obtain a total time bound of $O(nm \log((n/m)(\log U)^{1/2}+2)+m \log_n U)$.

The techniques discussed above can also be applied to the maximum flow algorithm of Goldberg and Tarjan [10], resulting in a time bound in the semilogarithmic model of $O(nm \log(n^2/m)+m \log_n U)$. The details are straightforward.

7. Remarks. The algorithms of §§ 3–4 not only have good theoretical time bounds, but they may be very efficient in practice. We hope to conduct experiments to determine whether either of these algorithms is competitive with previously known methods. The tree scaling algorithm of § 5 is perhaps mainly of theoretical interest, although for huge networks there is some chance that the use of dynamic trees may be practical.

The two obvious open theoretical questions are (1) whether further improvement in the time bound for the maximum flow problem is possible and (2) whether our ideas extend to the minimum cost flow problem. It is not unreasonable to hope for a bound of $O(nm)$ for the maximum flow problem; note that the bounds of Theorems 4.3 and 5.6 are $O(nm)$ for graphs that are not too sparse and whose arc capacities are not too large, i.e., $(\log U)^{1/2} = O(m/n)$. Obtaining a bound better than $O(nm)$ would seem to require major new ideas.

As a partial answer to the second question, we have been able to obtain a time bound of $O(nm \log\log U \log(nC))$ for the minimum cost flow problem, where C is the maximum arc cost, assuming all arc costs are integral [2]. This result uses some ideas in the present paper and some additional ones [11].

As a final remark, we note that in certain cases the bounds of our algorithms can be improved by substituting a smaller value for U. To be precise, suppose that f is a flow of value U_1 obtained by some fast heuristic and that U_2 is an upper bound on the maximum flow value, also obtained by some fast heuristic. Then all of our bounds can be improved by substituting $U^* = \max\{4, \min\{U, (U_2 - U_1)/n\}\}$ for U.

To see this, we first construct the residual network for the flow f. This network has the same graph as the original network, with the capacity of each arc (v, w) equal to $u_f(v, w)$. A flow of value x in the residual network corresponds to a flow of value $U_1 + x$ in the original network and vice-versa. It thus suffices to find a maximum flow in the residual network. For this network, $U_2 - U_1$ is an upper bound on the maximum flow value.

We now add to the network a new source s_0, new vertices $v_1, \cdots, v_n$, and arcs (s_0, v_i), (v_i, s), (v_i, s_0), and (s, v_i) for $1 \leqq i \leqq n$. We define $u(s_0, v_i) = u(v_i, s) = \lceil U^* \rceil$, $u(v_i, s_0) = u(s, v_i) = 0$ for $1 \leqq i \leqq n$. This augmented network has the same maximum flow value as the residual network. Then we run one of our excess-scaling algorithms on the augmented network, choosing as the original excess bound Δ the smallest possible allowed value exceeding U^*.

As an application of this result, we can take $U_1 = 0$ and $U_2 = \sum_{v \in V} u(s, v)$, giving a value for U^* of $\max\{4, \sum_{v \in V} u(s, v)/n\}$.

Acknowledgments. We thank Andrew Goldberg for inspiring ideas and stimulating conversations.

VERY FAST PARALLEL POLYNOMIAL ARITHMETIC*

WAYNE EBERLY†

Abstract. Parallel algorithms for polynomial arithmetic—multiplication of n polynomials of degree m, polynomial division with remainder, and polynomial interpolation—are presented. These algorithms can be implemented using polynomial time constructible families of Boolean circuits of polynomial size and optimal order depth, or log space constructible families of polynomial size and near optimal depth, for computations over $\mathbb{Z}$, $\mathbb{Q}$, finite fields, and several other domains. Arithmetic circuits of polynomial size and optimal order depth are obtained for polynomial arithmetic over arbitrary fields.

Key words. polynomial arithmetic, iterated product of polynomials, interpolation, polynomial division, parallel algorithms, circuit depth

AMS(MOS) subject classifications. 68Q40, 12E20, 68Q20

Introduction. A variety of efficient parallel algorithms have appeared in the recent literature. Computation of the product of n polynomials of degree m, polynomial division with remainder, and polynomial interpolation have received much attention, both as the main subject of research (see Reif [17] in particular) and as components in algorithms for related problems, including exponentiation and the factorization of polynomials over finite fields (see, for example, Fich and Tompa [10] and von zur Gathen [13]). Parallel algorithms whose running times are within a constant factor of optimal have been obtained for these problems, for arithmetic computations over fields supporting discrete Fourier transforms (see Bini [2] and Reif [17]). Efficient parallel algorithms for Boolean computations have been obtained for related integer problems, including the computation of the product of n k-bit integers, and integer division with remainder (see Reif [17] and Beame, Cook, and Hoover [1]).

In this paper, we generalize these results. We obtain (log space) NC^1-reductions from the computations for (integer) polynomials described above to the "Iterated Integer Product" problem—one of the integer problems discussed by Reif and by Beame, Cook, and Hoover. As a result, we obtain polynomial time constructible Boolean circuits of logarithmic depth and polynomial size, or log space constructible Boolean circuits of slightly larger depth and polynomial size, for all of these (integer) problems. Generalizing these still further, we obtain small depth Boolean circuits for polynomial arithmetic over finite fields and number fields. We generalize the arithmetic (rather than Boolean) results of Reif to show that the problems in polynomial arithmetic mentioned above can be solved, for polynomials over an arbitrary ground field F, using arithmetic circuits over F of logarithmic depth and polynomial size.

We first discuss Boolean computations. The model used to discuss these computations is a uniform family of Boolean circuits; algorithms are considered to be efficient if they can be implemented using a uniform family of circuits of size polynomial in N, and of depth polynomial in $\log N$, for input size N. We are interested in algorithms that are optimal (or near optimal)—algorithms for which the corresponding circuits

have depth $O(\log N)$ (or depth $O(\log^{1+\varepsilon} N)$ for small constants ε). Several definitions of circuit uniformity have been presented; since some algorithms can be implemented by "uniform" circuit families under some definitions of uniformity but (possibly) not for others, the complexity of a problem may depend on the definition used. Ruzzo [18] presents several commonly used definitions of uniformity and discusses relationships between the parallel complexity classes defined using them. Cook [8] gives an overview of parallel Boolean computation by uniform circuit families, including definitions of the model, complexity classes, and a survey of problems having efficient parallel solutions.

To discuss computations for polynomials with integer or rational coefficients, we must begin with algorithms for integer arithmetic—addition, multiplication, iterated product (multiplication of n integers, each of length n), and division with remainder of integers of length n. The sum or product of two n-bit integers can be computed by uniform circuit families using depth $O(\log n)$ and polynomial size (Savage [19], Borodin, Cook, and Pippenger [6]). Applying these results, it is not difficult to obtain uniform circuit families with depth $O(\log^2 n)$ and polynomial size for iterated product and division with remainder. Reif [17] improved this result, obtaining log space constructible families of circuits with depth $O(\log n \log\log n)$ and polynomial size for iterated integer product and integer division with remainder. Beame, Cook, and Hoover [1] get smaller depth using a weaker definition of circuit uniformity: they obtain polynomial time constructible circuit families of depth within a constant factor of optimal ($O(\log n)$) and polynomial size for these problems.

Efficient arithmetic circuits for polynomial arithmetic have been obtained (and will be discussed later). Reasonably efficient Boolean circuits for arithmetic for polynomials with integer coefficients can be obtained if we replace each field operation (indicated by a node) in such an arithmetic circuit by a Boolean circuit implementing that operation (over $\mathbb{Q}$). However, by doing this we increase the depth of the original circuit by a small multiplicative factor; we will not obtain optimal order depth Boolean circuits. Circuits with optimal depth (to within a constant factor) have been obtained: Eberly [9] presents such circuits for computation of the iterated product of polynomials with integer coefficients, for (integer) polynomial division with remainder, and for (integer) polynomial interpolation. Bini and Pan [5] have subsequently used a different method to obtain similar results for (integer) polynomial division with remainder. Their Boolean circuits for this problem are smaller, and hence more efficient, than ours; the circuit depths obtained are the same to within a constant factor. The same technique is used in each case: integer computations are used to obtain the value of a polynomial at a sufficiently large power of two; this value is then used to recover the coefficients of the desired polynomial using circuits of small depth. We will review the reduction from the problem "Iterated Product of Integer Polynomials" to "Iterated Integer Product," and the reductions from other computations for integer polynomials to the latter problem. Applying the results of Reif and Beame, Cook, and Hoover for the integer problem, we conclude that small depth circuits exist for all these problems. We obtain uniform circuit families of the same order depth for arithmetic for polynomials with coefficients in finite fields and in number fields.

We next consider arithmetic computations. As stated above, efficient arithmetic circuits have been obtained for polynomial arithmetic over many fields. Bini [2] presents an optimal order depth algorithm for inversion of a triangular Toeplitz matrix; as indicated by Bini and Pan [3]–[5], Bini's algorithm can be applied to compute the quotient and remainder of polynomials over a large class of fields. Reif [17] presents optimal order depth circuits for computation of the iterated product of polynomials,

interpolation, evaluation of elementary symmetric polynomials, polynomial division with remainder, and for some Taylor series computations. Reif, Bini, and Bini and Pan all assume that the ground field F supports a discrete Fourier transform: that is, F includes nth primitive roots of unity for arbitrarily large n. The assumption is not necessary: Eberly [9] modifies the algorithm presented by Reif to obtain circuits for polynomial arithmetic over arbitrary fields, while Bini and Pan [4] modify Bini's algorithm to obtain such circuits for polynomial division with remainder. We discuss the generalization of Reif's algorithm to computations over arbitrary fields.

As we note above, the definition of uniformity used for Boolean circuits affects the results obtained for these problems. The importance of "uniformity" for arithmetic circuits is less clear—in part, because this has not received much attention. Von zur Gathen [14] presents a survey of results for parallel arithmetic computation, and proposes several definitions of uniformity for arithmetic circuits. We consider two of these definitions. The first is quite generous; we show that our algorithms can be implemented using "uniform" families of circuits when this definition is used. The second definition is much more restrictive; using this definition, we obtain uniform families of arithmetic-Boolean circuits of near optimal depth for these problems, and a reduction to the "Boolean" problem "Iterated Integer Product."

In § 1 we introduce the problems in polynomial arithmetic to be discussed, and describe the representations of field elements to be used for Boolean computations. In §§ 2 and 3 we present results for Boolean computations: for polynomials with integer coefficients in § 2, and for more general domains in § 3. We discuss arithmetic computations in the next sections. "Nonuniform" computations over arbitrary fields are discussed in § 4. We discuss definitions of "uniformity" for arithmetic circuits, and apply them to our algorithms, in § 5. Section 6 includes extensions and open problems.

1. Definitions of problems. We begin with the definition of the "Iterated Integer Product" problem—that to which all others will be reduced. We continue with definitions of problems in polynomial arithmetic over arbitrary domains. These definitions are sufficient for discussions of arithmetic computations. To discuss Boolean computations, however, we must consider "Boolean" representations of elements of various domains. We conclude with a discussion of these representations.

Our "basic" problem for Boolean computations is the following.

ITERATED INTEGER PRODUCT.
Input. Binary representations of integers $n, k > 0$, and of integers $a_1, a_2, \cdots, a_n$ such that $|a_i| < 2^k$ for all i.
Output. Binary representation of the product $\prod_{i=1}^{n} a_i$.

Next we define the problems "Iterated Product of Polynomials," "Polynomial Interpolation," "Evaluation of Elementary Symmetric Polynomials," and "Polynomial Division with Remainder" as computational problems for polynomials with coefficients in a commutative integral domain D. The definitions are made as general as possible to avoid redefining the problems for various domains later.

ITERATED PRODUCT OF POLYNOMIALS (D).
Input. Binary representations of integers $n > 0$, and $m \geqq 0$.
Coefficients $a_{ij} \in D$ (for $0 \leqq j \leqq m$) of polynomials

$$f_i = a_{i0} + a_{i1}x + \cdots + a_{im}x^m \in D[x] \quad \text{for } 1 \leqq i \leqq n.$$

Output. Coefficients $b_0, b_1, \cdots, b_{mn} \in D$ of the product

$$g = b_0 + b_1 x + \cdots + b_{mn} x^{mn} = \prod_{i=1}^{n} f_i \in D[x].$$

POLYNOMIAL INTERPOLATION (D).
Input. Binary representation of an integer $n > 0$. Distinct values $a_1, a_2, \cdots, a_n \in D$, and values $b_1, b_2, \cdots, b_n \in D$ (not necessarily distinct).
Output. Values $d = \prod_{1 \leqq j < i \leqq n} (a_i - a_j) \in D$ and $c_0, c_1, \cdots, c_n \in D$ such that

$$f = c_0 + c_1 x + \cdots + c_{n-1} x^{n-1} \in D[x]$$

is the (unique) interpolating polynomial such that $f(a_i) = db_i$ for $1 \leqq i \leqq n$.

EVALUATION OF ELEMENTARY SYMMETRIC POLYNOMIALS (D).
Input. Binary representations of integers $n \geqq m \geqq 0$. Values $a_1, a_2, \cdots, a_n \in D$.
Output.

$$\alpha_{nm}(a_1, a_2, \cdots, a_n) = \sum_{\substack{J \subseteq \{a_1, a_2, \cdots, a_n\} \\ |J| = m}} \prod_{j \in J} a_j.$$

DIVISION WITH REMAINDER OF POLYNOMIALS (D).
Input. Binary representations of integers $n \geqq m \geqq 0$.
Values $a_0, a_1, \cdots, a_n \in D$ and $b_0, b_1, \cdots, b_m \in D$ such that $b_m \neq 0$.
Output. Values $d = b_m^{n-m+1} \in D$ and $q_0, q_1, \cdots, q_{n-m}, r_0, r_1, \cdots, r_{m-1} \in D$ such that $df = qg + r$ for the polynomials

$$f = a_0 + a_1 x + \cdots + a_n x^n \in D[x], \qquad g = b_0 + b_1 x + \cdots + b_m x^m \in D[x],$$

$$q = q_0 + q_1 x + \cdots + q_{n-m} x^{n-m} \in D[x], \qquad r = r_0 + r_1 x + \cdots + r_{m-1} x^{m-1} \in D[x].$$

We have actually defined "pseudodivision" of polynomials instead of "division," because the former problem is well defined over arbitrary commutative integral domains, while the latter problem is not, as follows: Suppose $f, g \in D[x]$ such that the degree of f is greater than the degree of g, and that the leading coefficient of g is not a unit in D. Then the coefficients of the quotient q and remainder r (such that $f = qg + r$ and r has degree less than that of g) will lie in the quotient field of D, but not in D itself. We have given a nonstandard definition of the problem "Polynomial Interpolation" for the same reason. Note that the "standard" outputs for these problems—coefficients of the quotient and remainder for "Division," and of the interpolating polynomial for "Interpolation"—can be computed efficiently from the outputs of our generalized problems if the domain D is a field and the operation "Division over D" is inexpensive.

We have also included binary representations of integer parameters as inputs for our "arithmetic" problems. These actually specify the size of the input; if desired, they can be left out or, for models allowing elements of the domain D as the only inputs, they can be represented as strings of 0's and 1's (where 0 and 1 represent the arithmetic and multiplicative identify of D, respectively).

These definitions are sufficient for discussions of arithmetic computations. To define Boolean problems, we must describe Boolean representations of elements of the domain D. We also add extra inputs, describing the length of the values used as input or the structure of the domain D. We conclude this section with a discussion of the Boolean representations and additional parameters for the domains to be considered.

$D = \mathbb{Z}$. We use binary representations of integers, with an additional sign bit. We add an additional parameter k, identifying the length of the integers used as coefficients for our input polynomials: each input coefficient a has absolute value less than 2^k.

$D = \mathbb{F}_p$. Each element of the field $\mathbb{F}_p = \mathbb{Z}/(p)$ corresponds to an integer between zero and $p-1$. We use the binary representation of this integer to represent the element of $\mathbb{F}_p$. We add the binary representation of the prime p as an additional parameter.

$D = \mathbb{Q}$. We represent a rational number a by binary representations of an integer numerator and denominator α and β such that $a = \alpha/\beta$ and $\beta > 0$. We do not require that α and β be relatively prime. We add an additional parameter k, identifying the maximum length of the integer numerators and denominators given as input.

$D = \mathbb{Z}[y]$. We use a dense representation of polynomials: a polynomial $\gamma_0 + \gamma_1 y + \cdots + \gamma_k y^k$ (with $\gamma_i \in \mathbb{Z}$ for $0 \leqq i \leqq k$) is represented using binary representations of each of the coefficients $\gamma_0, \gamma_1, \cdots, \gamma_k$. We add two additional parameters, k_1 and k_2. The first is the maximum length of any of the integer coefficients of the elements of D included in the input; the second is the maximum degree (in the indeterminate y) of any of these elements of D.

$D = \mathbb{F}_p[y]$. We use a dense representation of polynomials, as above. We add as additional parameters the prime p and the maximum degree in y of any of the elements of D given as input.

$D = \mathbb{Q}[y]$. Again, we use a dense representation for polynomials. A polynomial

$$\frac{\alpha_0}{\beta_0} + \frac{\alpha_1}{\beta_1} y + \cdots + \frac{\alpha_k}{\beta_k} y^k,$$

with $\alpha_i, \beta_i \in \mathbb{Z}$, and $\beta_i > 0$ for $0 \leqq i \leqq k$, is represented using binary representations of numerators and denominators $\alpha_0, \beta_0, \alpha_1, \beta_1, \cdots, \alpha_k, \beta_k$. As above, we add two parameters: the maximum length of any of the integer numerators and denominators in the input, and the maximum degree (in y) of any of the elements of D used as input.

$D = \mathbb{F}_{p^k}$. We use the fact that $\mathbb{F}_{p^k} \cong \mathbb{F}_p[y]/(\phi)$ for a monic irreducible polynomial $\phi \in \mathbb{F}_p[y]$ with degree k. To each element of $\mathbb{F}_{p^k}$ there corresponds a unique polynomial in $\mathbb{F}_p[y]$ with degree less than k; we use a representation of this polynomial (as described above) to represent the field element. We add as additional parameters binary representations of p and k, and the coefficients of the polynomial $\phi \in \mathbb{F}_p[y]$.

D is a finite algebraic extension of $\mathbb{Q}$. We use the fact that each of these extensions is isomorphic to $\mathbb{Q}[y]/(\phi)$, for some polynomial $\phi \in \mathbb{Z}[y]$ that is irreducible in $\mathbb{Q}[y]$. Each element of the field corresponds to a unique polynomial in $\mathbb{Q}[y]$ with degree less than that of ϕ; we use the representation of the polynomial (described above) to represent the field element. We use as additional parameters the additional parameters described for the domain $\mathbb{Q}[y]$, as well as the degree and coefficients of the polynomial ϕ.

For the sake of completeness, we note here that we will also need to describe the representation of finite algebraic extensions of finite fields to discuss some algorithms for our computational problems. We will state these details in §§ 4 and 5, where they are applied.

2. Boolean computations for integer polynomials. We begin by reducing the problem "Iterated Product of Polynomials ($\mathbb{Z}$)" to "Iterated Integer Product." We use this reduction, and techniques that previously have been used to reduce arithmetic problems to "Iterated Product of Polynomials (D)," to show that the Boolean problems "Polynomial Interpolation ($\mathbb{Z}$)," "Evaluation of Elementary Symmetric Polynomials ($\mathbb{Z}$)," and "Division with Remainder of Polynomials ($\mathbb{Z}$)" can also be reduced to "Iterated Integer Product."

We use uniform families of Boolean circuits as our model for parallel Boolean computation. We consider "log space" uniformity (and call families of circuits "uniform"), and "polynomial time" uniformity (and use the term "P-uniform"). The reductions we state are "NC^1-reductions," as defined by Cook [8].

Our reduction from "Iterated Product of Polynomials ($\mathbb{Z}$)" to "Iterated Integer Product" is based on the fact that the coefficients of an integer polynomial g can be computed from the integer $g(2^L)$ for sufficiently large L. This idea, "Interpolation via Binary Segmentation," has been applied for the sequential computation of polynomials in a number of settings (see Fischer and Paterson [11], Pan [16], [24, § 4], Schönhage [20]). It has also been used to obtain other NC^1-reductions from computations for integer polynomials to integer computations (Eberly [9], Bini and Pan [5]). Bini and Pan include a short history of the use of this method. While it has been presented elsewhere, the method must be modified (slightly) to be used for parallel reductions. Hence we present it in detail.

Suppose now that the polynomial $g \in \mathbb{Z}[x]$ has degree at most d, so that

$$g = g_0 + g_1 x + \cdots + g_d x^d \quad \text{for } g_0, g_1, \cdots, g_d \in \mathbb{Z}.$$

Suppose also that $|g_i| < 2^l$ for $l \geqq 0$, $l \in \mathbb{Z}$, for all i. Let $L = l + 1$.

LEMMA 2.1. *Let d, l, $L \in \mathbb{Z}$, and $g \in \mathbb{Z}[x]$ be as above, and suppose $h_0, h_1, \cdots, h_d \in \mathbb{Z}$. Then the following are equivalent:*

(i) $|h_i| \leqq 2^l$ *for* $0 \leqq i \leqq d$, *and* $g(2^L) = h_0 + h_1 2^L + \cdots + h_d 2^{Ld}$;

(ii) $g_i = h_i$ *for* $0 \leqq i \leqq d$.

Proof. Clearly (ii)$\Rightarrow$(i). We show that (i)$\Rightarrow$(ii) by induction on d. The case $d = 0$ is trivial. For positive d we note that condition (i) implies

$$(h_0 - g_0) + (h_1 - g_1)2^L + \cdots + (h_{d-1} - g_{d-1})2^{L(d-1)} = (g_d - h_d)2^{Ld}.$$

Since $|h_i - g_i| \leqq 2^{l+1} - 1 = 2^L - 1$ for all i, it is easy to show that the value of the left-hand side has magnitude less than 2^{dL}. Since the value of the right-hand side is divisible by 2^{dL}, it is clear that both values equal zero; hence $g_d = h_d$, and the result follows by the inductive hypothesis. □

We compute the coefficients of g from the value $g(2^L)$ by using the binary representation of this number to find a set of integers satisfying the first condition in this lemma, as shown below.

EXTRACTION OF COEFFICIENT ALGORITHM.

Input. Integers G and L, $L > 0$, and $d \geqq 0$, such that $G = g(2^L)$ for some polynomial $g \in \mathbb{Z}[x]$ with degree at most d and whose coefficients have absolute value less than 2^{L-1}.

Output. Coefficients $g_0, g_1, \cdots, g_d$ of the polynomial g.

(1) Compute the values

$$s = \begin{cases} 1 & \text{if } G \geqq 0, \\ -1 & \text{if } G < 0, \end{cases} \quad \text{and } H = sG.$$

Note that $H \geqq 0$.

For $0 \leqq i \leqq d$ in parallel, perform steps (2)-(4).

(2) Compute $k_i = (H \operatorname{div} 2^{Li}) \bmod 2^L$.
(Note. $H = \sum_{i=0}^{d} k_i 2^{Li}$, $0 \leqq k_j < 2^L$ for all j, and $k_d < 2^{L-1}$.)

(3) Compute

$$c_i = \begin{cases} 0 & \text{if } i = 0, \\ 0 & \text{if } i > 0 \text{ and } 0 \leqq k_{i-1} < 2^{L-1}, \\ 1 & \text{if } i > 0 \text{ and } 2^{L-1} \leqq k_{i-1} < 2^L. \end{cases}$$

Let $c_{d+1} = 0$.

(4) Compute $g_i = s(c_i + k_i - 2^L c_{i+1})$.

LEMMA 2.2. *The algorithm "Extraction of Coefficients" is correct and can be used to compute the coefficients of the polynomial g from the value $G = g(2^L)$, using a (log space) uniform family of Boolean circuits of depth $O(\log dL)$ and size $(dL)^{O(1)}$.*

Proof. It is easy to verify that $|g_i| \leqq 2^{L-1}$ for all i and that $g(2^L) = \sum_{i=0}^{d} g_i 2^{Li}$. Correctness then follows by Lemma 2.1. The depth and size bounds are also obvious, assuming that a binary representation of the integer G is given as input. □

For the problem "Iterated Product of Polynomials ($\mathbb{Z}$)," we consider the polynomial $g = \prod_{i=1}^{n} f_i$, where each polynomial f_i has degree at most m and has coefficients with magnitude less than 2^k, for integers $m \geqq 0$ and $k > 0$. Lemma 2.3 gives us a reasonably small upper bound for the magnitude of the coefficients of g.

LEMMA 2.3. *Let $g = \prod_{i=1}^{n} f_i \in \mathbb{Z}[x]$, for integer polynomials $f_i = \sum_{j=0}^{m} a_{ij} x^j$ with degree at most m and with coefficients a_{ij} with magnitude less than 2^k, for all i. Then $g = \sum_{i=0}^{nm} g_i x^i$ for integers $g_0, g_1, \cdots, g_{nm}$ such that $|g_i| < 2^l$ for $0 \leqq i \leqq nm$, where $l = n(k + \lceil \log_2 (m+1) \rceil)$.*

Proof. This follows immediately from the equation

$$g_i = \sum_{\substack{j_1, j_2, \cdots, j_n \geqq 0 \\ j_1 + j_2 + \cdots + j_n = i}} \prod_{h=1}^{n} a_{hj_h},$$

relating the coefficients of g to those of f, the bound $|a_{ij}| < 2^k$, and the fact that there are fewer than $(m+1)^n$ possible choices of the integers $j_1, j_2, \cdots, j_n$ for each value of i. □

We can now state the algorithm that reduces "Iterated Product of Polynomials ($\mathbb{Z}$)" to "Iterated Integer Product."

ITERATED PRODUCT OF POLYNOMIALS ($\mathbb{Z}$) VIA ITERATED INTEGER PRODUCT ALGORITHM.

Input. Binary representations of integers $n > 0$, $m \geqq 0$ and $k > 0$.
Binary representations of coefficients $a_{ij} \in \mathbb{Z}$ (for $0 \leqq j \leqq m$) of polynomials

$$f_i = a_{i0} + a_{i1} x + \cdots + a_{im} x^m \in \mathbb{Z}[x]$$

such that $|a_{ij}| < 2^k$ for $0 \leqq j \leqq m$, $1 \leqq i \leqq n$.

Output. Binary representations of coefficients $b_0, b_1, \cdots, b_{mn}$ of the product

$$g = b_0 + b_1 x + \cdots + b_{mn} x^{mn} = \prod_{i=1}^{n} f_i \in \mathbb{Z}[x].$$

(1) Compute $L = n(k + \lceil \log_2 (m+1) \rceil) + 1$.

(2) For all i, in parallel, compute

$$F_i = f_i(2^L) = a_{i0} + a_{i1} 2^L + \cdots + a_{im} 2^{Lm}.$$

(3) (*Iterated integer product.*) Compute $G = \prod_{i=1}^{n} F_i$. (Note. $G = g(2^L)$.)

(4) (*Extraction of coefficients.*) Use the value G to compute the coefficients of g.

THEOREM 2.4. *The problem "Iterated Product of Polynomials* $(\mathbb{Z})$*" is* NC^1*-reducible to "Iterated Integer Product."*

Proof. It is sufficient to note that the above algorithm is correct (by Lemmas 2.2 and 2.3) and that steps (1), (2), and (4) can be implemented using depth logarithmic, and size polynomial, in the input size. □

We reduce the remaining integer problems to "Iterated Integer Product" by reducing them to "Iterated Integer Product" and "Iterated Product of Polynomials $(\mathbb{Z})$," and applying the above theorem. It is sufficient to adapt the arithmetic reductions of Reif (see [17, §§ 2.4–2.5]) to obtain division-free (Boolean) algorithms in order to do this; we sketch the resulting methods below.

(i) *Polynomial interpolation.* Given integers $n \geqq 0$ and distinct integers $a_1, a_2, \cdots, a_n \in \mathbb{Z}$, the integer

$$d = \prod_{1 \leqq j < i \leqq n} (a_i - a_j)$$

and the polynomials

$$L_h = \left(\prod_{\substack{i=2 \\ i \neq h}}^{n} \prod_{\substack{j=1 \\ j \neq h}}^{i-1} (a_i - a_j) \right) \cdot \left(\prod_{j=1}^{h-1} (x - a_j) \right) \cdot \left(\prod_{i=h+1}^{n} (a_i - x) \right)$$

are computed using instances of "Iterated Integer Product" and "Iterated Product of Polynomials $(\mathbb{Z})$" in parallel. It is clear that, for $1 \leqq i, j \leqq n$,

$$L_i(a_j) = 0 \quad \text{if } i \neq j \quad \text{and} \quad L_i(a_i) = d.$$

Given integers $b_1, b_2, \cdots, b_n$, we set $f = \sum_{i=1}^{n} b_i L_i$; then $f(a_i) = db_i$ for $1 \leqq i \leqq n$, as desired.

(ii) *Evaluation of elementary symmetric polynomials.* It can be verified by a straightforward expansion that

$$\prod_{i=1}^{n} (x + a_i) = \sum_{m=0}^{n} \sigma_{n,m}(a_1, a_2, \cdots, a_n) x^{n-m}.$$

Thus we can compute $\sigma_{nm}(a_1, a_2, \cdots, a_n)$ by computing the product of the polynomials $(x + a_1), (x + a_2), \cdots, (x + a_n)$ and selecting the coefficient of x^{n-m} in the result.

(iii) *Division with remainder of polynomials.* Given integers $n \geqq m \geqq 0$ and polynomials

$$f = a_n x^n + a_{n-1} x^{n-1} + \cdots + a_0 \quad \text{and} \quad g = b_m x^m + b_{m-1} x^{m-1} + \cdots + b_0,$$

with $a_n, a_{n-1}, \cdots, a_0, b_m, b_{m-1}, \cdots, b_0 \in \mathbb{Z}$ and $b_m \neq 0$, we compute the ("pseudo") quotient and remainder obtained by dividing $df = b_m^{n-m+1} f$ by g, by considering the "reversals"

$$F = x^n f\left(\frac{1}{x}\right) = a_n + a_{n-1} x + \cdots + a_0 x^n \quad \text{and} \quad G = x^m g\left(\frac{1}{x}\right) = b_m + b_{m-1} x + \cdots + b_0 x^m.$$

Set $H = b_{m-1} + b_{m-2} x + \cdots + b_0 x^{m-1}$, so that $G = b_m + xH$. Solving instances of "Iterated Product of Polynomials $(\mathbb{Z})$" and "Iterated Integer Product" in parallel, we (first) compute the powers $H, H^2, H^3, \cdots, H^{n-m}$ and $b_m, b_m^2, \cdots, b_m^{n-m}$, and (then) the polynomials $Q_0, Q_1, \cdots, Q_{n-m}$ in $\mathbb{Z}[x]$ with degree at most $n - m$ such that

$$Q_j \equiv b_m^j x^j \sum_{k=0}^{n-m-j} ((-1)^k b_m^{n-m-j-k} x^k H^k) \bmod x^{n-m+1}.$$

Then, $Q_j \cdot G = Q_j \cdot (b_m + xH) \equiv b_m^{n-m+1} x^j = dx^j \bmod x^{n-m+1}$, for $0 \leqq j \leqq n-m$. Setting $Q = a_0 Q_0 + a_1 Q_1 + \cdots + a_{n-m} Q_{n-m} \in \mathbb{Z}[x]$, we find that Q has degree at most $n-m$ (since each Q_j does), and that $dF \equiv d(a_0 + a_1 x + \cdots + a_{n-m} x^{n-m}) \equiv Q \cdot G \bmod x^{n-m+1}$.

Now, setting $q = x^{n-m} Q(1/x) \in \mathbb{Z}[x]$, and $r = df - qg \in \mathbb{Z}[x]$, we find that r has degree less than m and $df = qg + r$: that is, q and r are the (pseudo) quotient and remainder we require.

Note. Reif includes this basic reduction (in a form suitable for computations over fields) as well as a variation that eliminates the need to compute most of the powers H^i and b_m^i (for $1 \leqq i \leqq n-m$) explicitly—producing circuits of smaller size for this reduction. See § 2.5 of Reif [17] for details.

THEOREM 2.5. *The problems "Polynomial Interpolation ($\mathbb{Z}$)," "Evaluation of Elementary Symmetric Polynomials ($\mathbb{Z}$)," and "Division with Remainder of Polynomials ($\mathbb{Z}$)" are all NC^1-reducible to "Iterated Integer Product."*

Proof. Each of the algorithms sketched above can be implemented using (log space) uniform families of Boolean circuits, with oracles for "Iterated Integer Product," of polynomial size and logarithmic depth. □

Now we are ready to apply the results of Reif [17] and Beame, Cook, and Hoover [1] stated below.

FACT 2.6 (Reif [17]). *The problem "Iterated Integer Product" can be solved using a* (log space) *uniform family of Boolean circuits of depth $O(\log N \log\log N)$ and size $N^{O(1)}$, for input size N.*

FACT 2.7 (Beame, Cook, and Hoover [1]). *The problem "Iterated Integer Product" can be solved using a* P*-uniform family of Boolean circuits of depth $O(\log N)$ and size $N^{O(1)}$, for input size N.*

Combining the results of Theorems 2.4–2.5 and Facts 2.6–2.7, we obtain the following.

COROLLARY 2.8. *Each of the problems stated in Theorems* 2.4 *and* 2.5 *can be solved using a uniform family of Boolean circuits of depth $O(\log N \log\log N)$ and size $N^{O(1)}$, or a* P*-uniform family of Boolean circuits of depth $O(\log N)$ and size $N^{O(1)}$, for input size N.*

The results in this section were first presented in Eberly [9]. Bini and Pan [5] have subsequently shown that the problem "Division with Remainder of Polynomials ($\mathbb{Z}$)" is reducible to the problem "Integer Division with Remainder"—also using "Interpolation via Binary Segmentation" to obtain their reduction. Since the integer problems "Integer Division with Remainder" and "Iterated Integer Product" are equivalent with respect to log space reducibility, they also establish the reduction for "Division with Remainder of Polynomials ($\mathbb{Z}$)" stated in Theorem 2.5. As they note, their more direct algorithm produces smaller (hence, more efficient) circuits than those that would be obtained using the reduction stated here; the depths of their (log space) uniform circuits and P-uniform circuits are the same as ours, to within a constant factor.

3. Boolean computations over other domains. The results of § 2 for computations of integer polynomials can be extended to computations of polynomials over more general domains. In this section we consider Boolean computations of polynomials with coefficients in a domain D, for each of the domains discussed in § 1. We assume that elements of these domains are represented as described in that section. We apply the techniques that have been described in § 2 to exhibit NC^1-reductions from computations over these domains to our "basic" problem, "Iterated Integer Product."

THEOREM 3.1. *For each of the domains $D = \mathbb{F}_p$, $\mathbb{Q}$, $\mathbb{Z}[y]$, $\mathbb{F}_p[y]$ $\mathbb{Q}[y]$, $\mathbb{F}_{p^k}$, and $\mathbb{Q}[y]/(\phi)$ (for ϕ irreducible in $\mathbb{Q}[y]$), the problems "Iterated Product of Polynomials*

(D)," "Polynomial Interpolation (D)," "Evaluation of Elementary Symmetric Polynomials (D)," and "Division with Remainder of Polynomials (D)" are all NC^1-reducible to "Iterated Integer Product."

Proof. We first reduce "Iterated Product of Polynomials (*D*)" to "Iterated Integer Product," for each of these domains *D*. We then adapt Reif's reductions (in [17]; used here to prove Theorem 2.5) to reduce the remaining problems to "Iterated Integer Product." We make repeated use of Theorems 2.4 and 2.5, and the fact that "Integer Division with Remainder" is NC^1-reducible to "Iterated Integer Product" (see Beame, Cook, and Hoover [1, Thm. 3.1 and Cor. 6.2.]).

(i) The result is straightforward for the case $D=\mathbb{F}_p$, since the elements of $\mathbb{F}_p$ are represented using integers between zero and $p-1$. We simply treat the input as a set of binary representations of integer polynomials, compute their product, and compute the residue (modulo p) of each coefficient of the result to obtain a representation of the product (in $\mathbb{F}_p[x]$) to be generated.

(ii) For the case $D=\mathbb{Q}$, we note that by computing a small number of products of integers in parallel, we can "rewrite" each input polynomial so that its coefficients have the same integer denominator: that is,

$$f_i=\frac{1}{\beta_i}(\alpha_{i0}+\alpha_{i1}x+\cdots+\alpha_{im}x^m)=\frac{1}{\beta_i}\hat{f}_i$$

for $\beta_i, \alpha_{i0}, \alpha_{i1}, \cdots, \alpha_{im}\in\mathbb{Z}$, $\beta_i>0$, and for $\hat{f}_i\in\mathbb{Z}[x]$, for $1\leqq i\leqq n$. Solving instances of "Iterated Product of Polynomials ($\mathbb{Z}$)" and "Iterated Integer Product," we compute $\beta=\prod_{i=1}^m\beta_i$ and the coefficients of $\hat{g}=\prod_{i=1}^m\hat{f}_i$ separately. We then use the binary representations of these values to obtain a representation of the polynomial $g=\beta^{-1}\hat{g}$.

(iii)-(v) For the case $D=\mathbb{Z}[y]$ we can use either of two simple methods to reduce our problem to "Iterated Product of Polynomials ($\mathbb{Z}$)." The coefficients of the product to be computed are integer polynomials in the indeterminate y; we can use "Interpolation via Binary Segmentation" to compute these coefficients by replacing y by a suitably large power of two, computing the product of the resulting univariate integer polynomials, and then extracting the coefficients (in y) as described in § 2. Alternatively, we can replace y by a suitably large power of x (x^{mn+1} is sufficient)—and again recover our coefficients after computing the product of univariate integer polynomials. We use the latter method to reduce our problems for $D=\mathbb{F}_p[y]$ and $D=\mathbb{Q}[y]$ to the problems for $D=\mathbb{F}_p$ and $D=\mathbb{Q}$, respectively.

(vi) We next consider the case $D=\mathbb{F}_{p^k}$. As stated in § 2, we are given an irreducible polynomial $\phi\in\mathbb{F}_p[y]$ with degree k, such that $\mathbb{F}_{p^k}\cong\mathbb{F}_p[y]/(\phi)$. An instance of "Iterated Product of Polynomials ($\mathbb{F}_{p^k}$)" includes the polynomial ϕ, and polynomials $\hat{f}_1,\hat{f}_2,\cdots,\hat{f}_n\in(\mathbb{F}_p[y])[x]$; the latter polynomials "represent" the polynomials $f_1=(\hat{f}_1 \bmod \phi), f_2=(\hat{f}_2 \bmod \phi),\cdots,f_n=(\hat{f}_n \bmod \phi)$ whose product we wish to compute.

Set $g=\prod_{i=1}^n f_i\in\mathbb{F}_{p^k}[x]$ and $\hat{g}=\prod_{i=1}^n\hat{f}_i\in(\mathbb{F}_p[y])[x]$; then it is clear that $g=(\hat{g} \bmod \phi)$. We compute g in two steps: We first use an instance of "Iterated Product of Polynomials ($\mathbb{F}_p[y]$)" to compute the polynomial $\hat{g}$. We then use instances of "Division with Remainder of Polynomials ($\mathbb{F}_p$)" in parallel, dividing each of the coefficients of $\hat{g}$ (for powers of x) by ϕ to obtain the coefficients of g.

We have already seen that "Iterated Product of Polynomials ($\mathbb{F}_p[y]$)" is NC^1-reducible to "Iterated Integer Product." It is clear that we can solve an instance of "Division with Remainder of Polynomials ($\mathbb{F}_p$)" by performing (pseudo) division of integer polynomials, and then computing residues (modulo p) of the resulting coefficients. Applying Theorem 2.5, and the NC^1-reduction of "Integer Division with Remainder" to "Iterated Integer Product" ([1, Thm. 3.1]), we conclude that "Division

with Remainder of Polynomials ($\mathbb{F}_p$)" is NC^1-reducible to "Iterated Integer Product." Thus "Iterated Product of Polynomials ($\mathbb{F}_{p^k}$)" is NC^1-reducible to "Iterated Integer Product," as well.

(vii) The case $D = \mathbb{Q}[y]/(\phi)$ is analogous to the case $D = \mathbb{F}_{p^k}$: we compute the desired product by solving instances of the problems "Iterated Product of Polynomials ($\mathbb{Q}[y]$)" and "Division with Remainder of Polynomials ($\mathbb{Q}$)." Again, we can reduce the last problem to "Iterated Integer Product" by extracting the denominators of coefficients (as in (ii), above) and performing pseudodivision of integer polynomials.

For each domain D stated above, we use the division-free forms of the reductions to "Iterated Product of Polynomials (D)" given by Reif [17] (and used here already to prove Theorem 2.5) to reduce our (Boolean) problems "Polynomial Interpolation (D)," "Evaluation of Elementary Symmetric Polynomials (D)," and "Division with Remainder of Polynomials (D)" to "Iterated Product of Polynomials (D)" and "Iterated Integer Product," and hence to "Iterated Integer Product" alone. We cannot apply Reif's reductions directly. We leave it to the reader to verify that the versions of the reductions given in § 2 are division-free and correct for arbitrary commutative integral domains. It is also easily checked that these "modified" reductions can be used to produce (Boolean) NC^1-reductions from each of these problems to "Iterated Integer Product" (see Eberly [9] for a more detailed presentation). □

Applying Facts 2.6 and 2.7 again, we obtain Corollary 3.2.

COROLLARY 3.2. *Each of the problems stated in Theorem* 3.1 *can be solved using a uniform family of Boolean circuits of depth* $O(\log N \log\log N)$ *and size* $N^{O(1)}$, *or a* P*-uniform family of Boolean circuits of depth* $O(\log N)$ *and size* $N^{O(1)}$, *for input size* N.

For fields $D = \mathbb{Q}$, $\mathbb{F}_p$, $\mathbb{F}_{p^k}$ and $\mathbb{Q}[y]/(\phi)$, it is clear that we do not need the denominator d included in the output for our division and interpolation problems: polynomial division and interpolation (rather than pseudodivision and our "nonstandard" interpolation problem) are well-defined problems for computations over fields.

Unfortunately, we do not obtain NC^1-reductions from these "standard" problems to "Iterated Integer Product"—for we do not have log depth circuits for division of field elements for fields $\mathbb{F}_p$, $\mathbb{F}_{p^k}$ and $\mathbb{Q}[y]/(\phi)$, using our representations.

For the field $\mathbb{F}_p = \mathbb{Z}/(p)$, and representations we are using, we must compute the binary representation of an integer s such that $su \equiv 1 \pmod p$ if we are to invert the element u. We can do this sequentially by using the extended Euclidean algorithm to compute $\gcd(u, p)$ as well as integers s and t such that $su + tp = \gcd(u, p) = 1$. However, no efficient parallel algorithm for this computation is known.

For the field extensions $\mathbb{F}_{p^k}$ and $\mathbb{Q}[y]/(\phi)$ and the representations we use, we again compute inverses sequentially by using the extended Euclidean algorithm—but for polynomials, rather than integers. This method can be implemented using Boolean circuits of depth $O(\log^2 N)$ and size $N^{O(1)}$ for input size N—using a "redundant notation" (as above) for elements of $\mathbb{F}_p$ or of $\mathbb{Q}$ (see Borodin, von zur Gathen, and Hopcroft [7], von zur Gathen [13]). Recently, the problem "Inversion in $\mathbb{F}_{p^k}$" has been reduced (with respect to log space or NC^1 computations) to "Inversion in $\mathbb{F}_p$" for arbitrary primes p (see Litow and Davida [23] and von zur Gathen [22]). However, this is not sufficient for the problem at hand.

4. Nonuniform arithmetic computations. We discuss results for two models of parallel arithmetic computation. *Arithmetic circuits* use elements of a commutative integral domain D for inputs and constants, and return elements of D as outputs. We execute one arithmetic operation over D (that is, one of $+$, $-$, $\times$, or the selection of an input or constant in D) at each node of the circuit; if D is a field, we also allow

nodes for division ($\div$). *Arithmetic-Boolean circuits* include these operations as well as a Boolean component: we include nodes for selection of Boolean constants (**T**, **F**), operations ($\wedge, \vee, \neg$), *zero tests* (using an input from D and producing a Boolean output), and *selections* (of one of two inputs from D on the basis of a third Boolean input—branching).[1] This second model of arithmetic computation is strictly stronger than the first: Fich and Tompa [10] present a problem that has an efficient parallel solution in the second model, but that has no such solution in the first. We will not define "uniform" families of arithmetic-Boolean circuits in this section; hence we call the circuit families we discuss "nonuniform."

Henceforth we consider polynomial arithmetic over a field (F). We begin with a discussion of computations for infinite fields. Bini [2] and Reif [17] have presented circuits with optimal depth (to within a constant factor) for a problem that is clearly equivalent to "Division with Remainder of Polynomials (F)," and for "Iterated Product of Polynomials (F)," respectively, for fields F containing nth primitive roots of unity for infinitely many n. Reif also notes that a variety of other problems (including those discussed here) are reducible to "Iterated Product of Polynomials (F)."

Reif [17] computes the "Iterated Product of Polynomials (F)" by implementing a discrete Fourier transform as follows. Given polynomials $f_1, f_2, \cdots, f_n$, whose product g is to be computed, he uses a discrete Fourier transform to compute the values of each of the f_i's at a set of roots of unity. He then uses multiplication in F to compute the value of g at each of these roots, and, finally, uses the inverse Fourier transform to recover the coefficients of g from this set of values. We obtain an optimal order depth algorithm for "Iterated Product of Polynomials (F)" that is correct for an arbitrary infinite field F, but that is implemented using circuits of larger size than those obtained by Reif, by replacing the roots of unity used (as evaluation points) in his method by any sufficiently large set of distinct elements of F. The resulting algorithm is stated below.

ITERATED PRODUCT OF POLYNOMIALS VIA EVALUATION-INTERPOLATION ALGORITHM.

Input. Binary representations of integers $n > 0$, and $m \geqq 0$.
Coefficients $a_{ij} \in F$ (for $0 \leqq j \leqq m$) of polynomials

$$f_i = a_{i0} + a_{i1}x + \cdots + a_{im}x^m \in F[x] \quad \text{for } 1 \leqq i \leqq n.$$

Output. Coefficients $b_0, b_1, \cdots, b_{mn} \in F$ of the product

$$g = b_0 + b_1 x + \cdots + b_{mn}x^{mn} = \prod_{i=1}^{n} f_i \in F[x].$$

Constants used. Distinct $\gamma_0, \gamma_1, \cdots, \gamma_{mn} \in F$;
the entries of the *inverse* of the Vandermonde matrix
$V(\gamma_0, \gamma_1, \cdots, \gamma_{mn})$ of order $mn+1$ defined by

$$V(\gamma_0, \gamma_1, \cdots, \gamma_{mn})_{ij} = \gamma_{i-1}^{j-1} \quad \text{for } 1 \leqq i, j \leqq mn+1.$$

(1) For all i and j, $1 \leqq i \leqq n$, $0 \leqq j \leqq mn$, compute

$$f_i(\gamma_j) = \sum_{l=0}^{m} a_{il}\gamma_j^l.$$

(2) For all j, $0 \leqq j \leqq mn$, compute $g(\gamma_j) = \prod_{i=1}^{n} f_i(\gamma_j)$.

[1] Arithmetic-Boolean circuits have been called *arithmetic networks* in some papers.

(3) Use the values computed in step (2) and the entries of $V(\gamma_0, \gamma_1, \cdots, \gamma_{mn})^{-1}$ (supplied as constants) to compute the coefficients $b_0, b_1, \cdots, b_{mn}$ such that

$$\begin{bmatrix} b_0 \\ b_1 \\ \vdots \\ b_{mn} \end{bmatrix} = V(\gamma_0, \gamma_1, \cdots, \gamma_{mn})^{-1} \begin{bmatrix} g(\gamma_0) \\ g(\gamma_1) \\ \vdots \\ g(\gamma_{mn}) \end{bmatrix}.$$

Return these coefficients as output.

THEOREM 4.1. *Let F be an infinite field. Then the problem "Iterated Product of Polynomials (F)" can be solved using a (nonuniform) family of arithmetic circuits of depth $O(\log N)$ and size $N^{O(1)}$, for input size N.*

Proof. It is sufficient to show that the above algorithm is correct and efficient, when the field F is infinite.

It is easily checked that

$$V(\gamma_0, \gamma_1, \cdots, \gamma_{mn}) \begin{bmatrix} b_0 \\ b_1 \\ \vdots \\ b_{mn} \end{bmatrix} = \begin{bmatrix} g(\gamma_0) \\ g(\gamma_1) \\ \vdots \\ g(\gamma_{mn}) \end{bmatrix},$$

and that $\det V(\gamma_0, \gamma_1, \cdots, \gamma_{mn}) = \prod_{i=1}^{mn} \prod_{j=0}^{i-1} (\gamma_i - \gamma_j) \neq 0$, so that the matrix $V(\gamma_0, \gamma_1, \cdots, \gamma_{mn})$ is invertible. It follows that the values $b_0, b_1, \cdots, b_{mn}$ returned by this algorithm are the coefficients we want: that is, the algorithm is correct.

The only operations used in the algorithm are the evaluation of polynomials with small degree (in step (1)); multiplication of elements in F (in step (2)); and the multiplication of a matrix by a vector (in step (3)). It is clear, then, that the algorithm can be implemented using arithmetic circuits of the stated depth and size. □

We obtain corresponding results for the problems "Polynomial Interpolation (F)," "Evaluation of Elementary Symmetric Polynomials (F)," and "Division with Remainder of Polynomials (F)," by applying Theorem 4.1 and arithmetic reductions from each of these problems to "Iterated Product of Polynomials (F)." We use the definition of "NC^1_F-reduction" stated by von zur Gathen [14], and state these reductions in a general form suitable for their use in the rest of §§ 4–5.

FACT 4.2 (Reif [17]). *Let F be an arbitrary field. Then each of the problems "Polynomial Interpolation (F)," "Evaluation of Elementary Symmetric Polynomials (F)," and "Division with Remainder of Polynomials (F)" is NC^1_F-reducible to "Iterated Product of Polynomials (F)."*

Proof. The reductions stated by Reif [17, §§ 2.4–2.5] are sufficient. We leave it as an exercise for the reader to verify that these are (log space uniform) "NC^1_F-reductions," as defined in [14]. □

Combining Theorem 4.1 and Fact 4.2, we obtain Corollary 4.3.

COROLLARY 4.3. *Let F be an infinite field. Then each of the problems "Iterated Product of Polynomials (F)," "Polynomial Interpolation (F)," "Evaluation of Elementary Symmetric Polynomials (F)," and "Division with Remainder of Polynomials (F)" can be solved using a (nonuniform) family of arithmetic circuits of depth $O(\log N)$ and size $N^{O(1)}$, for input size N.*

We now consider computations over the finite field $F = \mathbb{F}_q = \mathbb{F}_{p^k}$, for prime p and positive k. As above, we first consider the problem "Iterated Product of Polynomials (F)." Suppose m and n are as defined in the statement of this problem. If $q \geqq mn+1$ then our algorithm for infinite fields can be used directly, because F includes a suitable

set of constants. Otherwise, we must construct a field extension and perform arithmetic over the extension if we are to use this algorithm. A direct simulation, in which we simulate each operation over the extension individually using arithmetic over F, is not sufficient: the circuit depth is increased by a small multiplicative factor, so circuits of optimal depth (to within a constant factor) are not obtained. In the rest of this section we describe a slightly more complicated simulation that we use to obtain optimal order depth circuits for this problem.

We begin by describing our representation of finite fields $F = \mathbb{F}_q$ and $E = \mathbb{F}_r = \mathbb{F}_{q^l} \supseteq F$ (the extension used by our algorithm). Since all finite fields of size r are isomorphic, $E \cong F[y]/(\phi)$ for every irreducible polynomial $\phi \in F[y]$ with degree l. Hence we could represent elements of E as the residues modulo ϕ of polynomials in $F[y]$ for any such polynomial ϕ. Embedding F in E is trivial: the elements of the smaller field correspond to the residues of constant polynomials (and we convert between representations of inputs and outputs as "elements of F" and "elements of E" using constant depth). Addition and multiplication in E are also straightforward. To multiply elements of E (represented as residues of polynomials) we multiply the corresponding (small degree) polynomials in $F[y]$ and then compute the remainder (resulting from division by ϕ) to obtain a representation of the product. This last step can be implemented using circuits with size polynomial in l and depth $O(\log^2 l)$. (Note that one of our goals is to prove that polynomial division with remainder can be performed using circuits of polynomial size and logarithmic depth. We "charge" depth $\Theta(\log^2 l)$ for the division mentioned here to avoid the use of a result we have yet to prove.) If the residues y^i modulo ϕ are "precomputed," for $0 \leqq i \leqq 2l$, then the depth for subsequent multiplications in E can be reduced to $O(\log l)$. Addition in E requires "coefficient-wise" addition in $F[y]$, and can be implemented using circuits of depth one and size $O(l)$. Division and exponentiation in E are (slightly) more expensive: each can be implemented using polynomial size circuits, with depth $O(\log^2 l)$ for division and depth $O(\log n \log l)$ for computation of the nth power of an element of E. Using these costs, we find that evaluation of a polynomial of degree n with coefficients in F at an element of E can be performed using depth $O(\log n \log l)$ and polynomial size. We can compute the product of n polynomials with degree m and coefficients in $F = \mathbb{F}_q$ by implementing our algorithm over an extension $E = \mathbb{F}_{q^l}$, for $l = \lceil \log_q (mn+1) \rceil = O(\log mn)$, using circuits of polynomial size and depth $O(\log mn \log\log mn)$.

Examining the algorithm "Iterated Product of Polynomials via Evaluation–Interpolation," implemented over a fixed extension E, we see that the only steps using depth $\omega(\log mn)$ are the evaluations of products of $O(mn)$ elements of E. We can perform these computations quickly using a different representation of E. Since the multiplicative subgroup of any finite field is cyclic, there exists some nonzero $\zeta \in E$ such that

$$E = \{0\} \cup \{\zeta^i : 0 \leqq i \leqq |E| - 2 = q^l - 2\}.$$

We can represent a nonzero element α of E by its (discrete) logarithm with respect to base ζ—that is, by the unique integer i such that $0 \leqq i < q^l - 1$ and $\zeta^i = \alpha$. Using this representation, we can compute the product of n nonzero elements by adding their logarithms and dividing this sum by $q^l - 1$ (we know $\zeta^{q^l - 1} = 1$). The remainder of this division is the discrete logarithm of the product. Division in E is also straightforward, since the inverse of ζ^i is $\zeta^{q^l - 1 - i}$ if $i \neq 0$, or ζ^0 otherwise. We use circuits of polynomial size and depth $O(\log n + \log l)$ to multiply n elements of E, and circuits of depth $O(\log l)$ to divide. Unfortunately, it is not easy to add elements of E represented by

discrete logarithms, or to convert between the "standard" representation of $\alpha \in F$ and its representation by a discrete logarithm in E.

As noted above, however, we only need to perform computations over a field extension when F is very small. Furthermore, we can solve our problem using an extension $E \supseteq F$ such that E has size less than $(mn+1)^2$. Under this condition, we can combine the two representations for $E = \mathbb{F}_{q^l}$ by choosing a monic irreducible polynomial $\phi \in F[y]$ with degree l such that the element y modulo ϕ is a generator of the multiplicative subgroup of $E = F[y]/(\phi)$. That is,

$$E = \left\{ \sum_{i=0}^{l-1} c_i y^i : c_0, c_1, \cdots, c_{l-1} \in F \right\} = \{0\} \cup \{ y^i : 0 \leqq i < q^l - 1 \}.$$

We know a suitable polynomial ϕ exists: E must contain some generator of its multiplicative subgroup, and we choose ϕ to be the minimal polynomial (over F) of (any) generator. Since E is small, we can "hardwire" a table, listing the two representations of every nonzero element of E, into our circuit. We use the "small degree polynomial" representation of elements for most computations. To perform multiplications of $m > 2$ elements of E, we perform a "table lookup" to compute discrete logarithms, compute the logarithm of the product, then perform another lookup to obtain the "polynomial" representation of this product. Using this combined representation, we can evaluate polynomials of degree n over E, compute products of m elements of E, and divide elements of E, using circuits of depth $O(\log mn)$ and polynomial size. It can then be easily checked that we can implement our algorithm over a small field extension E using arithmetic-Boolean circuits of polynomial size and depth $O(\log mn)$ (with arithmetic over F at unit cost), as required. We apply Reif's reductions once again to obtain small depth circuits for the other problems in polynomial arithmetic being discussed.

THEOREM 4.4. *Let F be a finite field; then there exist nonuniform families of arithmetic-Boolean circuits of depth $O(\log N)$ and size $N^{O(1)}$ solving each of the problems "Iterated Product of Polynomials (F)," "Polynomial Interpolation (F)," "Evaluation of Elementary Symmetric Polynomials (F), and "Division with Remainder of Polynomials (F)."* □

Finally, we note again that the techniques we describe for computations over infinite fields fail us only when our ground field F is very small—specifically, when $|F| < N^c$, where N is our input size, and c is a small constant. We leave it to the reader to verify that under this condition, a "zero test" in F can be simulated by the evaluation of a fixed polynomial of small degree; "selection gates," $\wedge$, $\vee$ and $\neg$ gates can also be simulated by small arithmetic circuits. Hence, we can strengthen Theorem 4.4 by replacing "arithmetic-Boolean circuits" by "arithmetic circuits" in the statement of the result (at the cost of complicating the proof slightly). Using this observation, together with Corollary 4.3 and Theorem 4.4, we obtain Corollary 4.5.

COROLLARY 4.5. *Let F be an arbitrary field. Then each of the problems "Iterated Product of Polynomials (F)," "Polynomial Interpolation (F)," "Evaluation of Elementary Symmetric Polynomials (F)," and "Division with Remainder of Polynomials (F)" can be solved using a (nonuniform) family of arithmetic circuits (over F) of depth $O(\log N)$ and size $N^{O(1)}$, for input size N.*

These results first appeared in Eberly [9]. Bini and Pan [4] have independently generalized Bini's algorithm for "Division with Remainder of Polynomials (F)" to obtain optimal order depth circuits for this problem over arbitrary infinite fields, and over each finite field. Hence they independently prove the results stated for "Division" in Corollary 4.3 and Theorem 4.4. As they note, their more direct algorithms can be

implemented using smaller (and hence more efficient) circuits than are obtained using the method described here.

5. Arithmetic computations: Adding uniformity. The circuits we have discussed in the last section have been called "nonuniform"—mainly because we have yet to define "uniform" families of arithmetic (or arithmetic-Boolean) circuits. In this section we discuss several definitions of uniformity proposed recently (von zur Gathen [14]). Our algorithms can be used (with minor modifications) to produce uniform families of arithmetic-Boolean circuits for each of these definitions.

It can be argued that a precise definition of "uniformity" for families of arithmetic circuits is not really necessary, provided that we consider algorithms that are reasonably simple, and that can be implemented using uniform families of Boolean circuits (for computations over $\mathbb{Q}$ and finite fields). It is clear that our algorithms have these properties; we will not improve our Boolean results by showing that the algorithms can be implemented using "uniform" families of arithmetic-Boolean circuits. On the other hand, it is clear that the arithmetic problems we have discussed are closely related. We make this statement more precise by adopting formal definitions of arithmetic uniformity, complexity classes, and reductions—and exhibiting reductions between the problems.

The definitions we use were proposed in von zur Gathen [14]; to our knowledge, they have not been used anywhere else. It is conceivable that they will be replaced by a different set of uniformity criteria; we regard them as provisional. They also include technical details beyond the scope of this paper. Consequently, we give a less formal presentation of uniformity. Precise statements of our results and a sketch of their proofs are given at the end of this section.

The criteria for uniformity proposed by von zur Gathen are similar to criteria for uniformity of families of Boolean circuits: families of arithmetic-Boolean circuits are considered to be "uniform" if the circuits have "descriptions" that can be computed quickly (using a deterministic Turing machine). Unfortunately, the task of defining a "circuit description" for an arithmetic-Boolean circuit over an arbitrary field is nontrivial. Encoding nodes for arithmetic operations $(+, -, \times, \div)$, Boolean operations, and connections between these nodes is not difficult. However, we must also encode arithmetic constants—elements of the field F. If F is uncountable then we cannot avoid "missing" some elements completely, or using encodings that do not identify unique field elements. We need a method for describing elements of F, and arithmetic-Boolean circuits, that is simple enough to be usable, but also general enough so that "reasonable" algorithms can be implemented using families of arithmetic-Boolean circuits that we can encode easily.

Von zur Gathen presents two encoding methods and develops definitions for "uniform" families, complexity classes, and reductions for each. One of these is quite generous: it is not difficult to show that the constants (and circuits) for our algorithms can be encoded using this method, and that the encodings can be computed using a deterministic Turing machine using space logarithmic in the number of inputs. That is, our algorithms can be implemented using "L-L-uniform" families of arithmetic-Boolean circuits.

Unfortunately, this first encoding method and definition of uniformity may be too generous. For example, we would like to be able to take (as "input") an encoding of an arithmetic-Boolean circuit over $\mathbb{Q}$ or over a finite field, and produce (as "output") an encoding of a Boolean circuit. This process is nontrivial, because it is not clear how to obtain binary representations of constants from their "encodings" efficiently.

Von zur Gathen proposes a second method for encoding circuits that is simpler, but also much more restrictive. Under this method, the only constants that can be encoded (hence the only constants used in "uniform" families of arithmetic-Boolean circuits) are the arithmetic constants 0 and 1 and the Boolean constants **T** and **F**.[2] Elements of the prime field of F can be computed from these using size linear and depth logarithmic in the lengths of their binary representations; no other constants can be supplied or computed. Now the task of defining circuit encodings, and uniformity, is straightforward. However, showing that an algorithm can be implemented using a "uniform" family of arithmetic-Boolean circuits is much more difficult.

We do not expect that this second scheme will be adopted as a criterion for uniformity—it is clearly much too restrictive. We use it here to make our statements as strong as possible: we view these results as evidence that our algorithms are uniform for *any* reasonable definition of uniformity.

In fact, we do not obtain log space constructible families of arithmetic-Boolean circuits for our algorithms when this restrictive encoding method is used. Instead, we obtain a formal reduction from our arithmetic problems to the Boolean problem "Iterated Integer Product." For each problem, we therefore have "L-uniform" (log space constructible) families of arithmetic-Boolean circuits of depth $O(\log N \log \log N)$ and size $N^{O(1)}$, and "P-uniform" (polynomial time constructible) families of arithmetic-Boolean circuits of depth $O(\log N)$ and size $N^{O(1)}$, for input size N. In some sense we have reversed the usual roles of "arithmetic" and "Boolean" computations: we have shown that any improvement in the known results for a (concrete) Boolean problem yields a corresponding improvement in results for a set of (abstract) arithmetic problems.

In the rest of this section we give a precise statement of our results for "uniform" arithmetic computations and sketch their proof. For the sake of brevity we omit most of the details and leave it as an exercise for the reader to develop the full proof using this sketch and the results in von zur Gathen [14]. The reader who is not interested in these details can skip ahead to § 6.

THEOREM 5.1. *Let F be a field.*

(1) *Each of the problems "Iterated Product of Polynomials (F)," "Polynomial Interpolation (F)," "Evaluation of Elementary Symmetric Polynomials (F)," and "Division with Remainder of Polynomials (F)" can be solved using an* L-L*-uniform family of arithmetic-Boolean circuits of depth $O(\log N)$ and size $N^{O(1)}$, for input size N.*

(2) *Each of the above problems is reducible to "Iterated Integer Product." Hence each can be solved using an* L*-uniform family of arithmetic-Boolean circuits of depth $O(\log N \log \log N)$ and size $N^{O(1)}$, or a* P*-uniform family of arithmetic-Boolean circuits of depth $O(\log N)$ and size $N^{O(1)}$, for input size N.*

Proof. We consider the problem "Iterated Product of Polynomials (F)." Reif's reductions can be used to prove the results stated for the other problems.

(1) We first note that it is sufficient to consider descriptions of constants for our algorithms; the rest of the circuit descriptions can clearly be computed efficiently.

Let K be the prime field of F ($\mathbb{F}_p$ if F has characteristic $p > 0$, or $\mathbb{Q}$ otherwise). Von zur Gathen proposes that we "describe" constants in F using encodings of division free straightline programs computing polynomials with coefficients in K, together with a small amount of extra information indicating how these polynomials are to be used.

[2] In fact, von zur Gathen only allows the arithmetic constant one. However, we note that the constants 0, **T**, and **F** are easily obtained as well by using subtraction in F to obtain zero, and zero tests to obtain the Boolean constants.

Since K is countable, it is easy to define encodings of these straightline programs. A family of arithmetic-Boolean circuits is "L-L-uniform" if the circuit description (including encodings of straightline programs describing constants) for the circuit for M inputs can be computed using a deterministic Turing machine using space $O(\log M)$. We illustrate the use of straightline programs to describe constants in F using the constants required by our algorithms for "Iterated Product of Polynomials." We leave it to the reader to verify that encodings of the straightline programs described here comprise "standard encodings of descriptions of constants" for the constants we need (see von zur Gathen [14] for the definitions required).

Suppose F is infinite. For n input polynomials each with degree at most m, our algorithm requires the following constants:

(i) $N=(mn+1)$ distinct field elements $\gamma_1, \gamma_2, \cdots, \gamma_N$;

(ii) The entries of the nonsingular Vandermonde matrix $V(\gamma_1, \gamma_2, \cdots, \gamma_N)$;

(iii) The entries of $V(\gamma_1, \gamma_2, \cdots, \gamma_N)^{-1}$.

We simplify the problem of describing these constants by requiring that $\gamma_i = \gamma^{i-1}$ for some $\gamma \in F$ (so $\gamma_1 = 1$, $\gamma_2 = \gamma$, $\gamma_3 = \gamma^2$, etc.). We can use as γ any element of F that is not a root of the polynomial

$$g = \prod_{i=1}^{N-1} (y^i - 1) \in K[y],$$

for K the prime field of F.[3]

We will supply as constants the entries of adj $V(\gamma_1, \gamma_2, \cdots, \gamma_N)$ and det $V(\gamma_1, \gamma_2, \cdots, \gamma_N)$, instead of the entries of $V(\gamma_1, \gamma_2, \cdots, \gamma_N)^{-1}$; note that the latter values can be computed easily from the former. Now each of the constants γ_i and $V(\gamma_1, \gamma_2, \cdots, \gamma_N)_{st}$ (for $1 \leqq s, t \leqq N$) is a small power of γ. For $1 \leqq i \leqq N$, the entries of the ith column of adj $V(\gamma_1, \gamma_2, \cdots, \gamma_N)$ are the coefficients of the polynomial

$$(-1)^{N-i} \prod_{\substack{j=1 \\ j \neq i}}^{N} (x - \gamma_j) \prod_{\substack{k=2 \\ k \neq i}}^{N} \prod_{\substack{h=1 \\ h \neq i}}^{k-1} (\gamma_k - \gamma_h);$$

det $V(\gamma_1, \gamma_2, \cdots, \gamma_N) = \prod_{i=2}^{N} \prod_{j=1}^{i-1} (\gamma_i - \gamma_j)$. Each of these values can be computed from γ using a log space constructible straightline program of size $N^{O(1)}$. The polynomial g describing γ can also be computed using a log space constructible straightline program. Hence we have established the first part of the theorem, for infinite fields.

We next consider computations over the finite field $F = \mathbb{F}_{p^k} = \mathbb{F}_q$. If $|F| = p^k > N$ then we use the constants we have just described—and these have log space computable descriptions. Otherwise, we must supply the constants described in § 4. That is, we include the following:

(i) The coefficients of the minimal polynomial ψ (over F) of a generator γ of the multiplicative subgroup of an extension $E \supseteq F$ of size greater than N ($\psi \in F[y]$, $\psi(\gamma) = 0$, and $E = F(\gamma) = F[y]/(\psi)$).

(ii) A table of discrete logarithms (for base γ) for E: that is, the coefficients of the polynomials $(y^i \bmod \psi)$, for $0 \leqq i \leqq |E| - 2$.

(iii) Representations of the entries of the matrices $V(1, \gamma, \gamma^2, \cdots, \gamma^{N-1})$ and adj $V(1, \gamma, \gamma^2, \cdots, \gamma^{N-1})$, and of det $V(1, \gamma, \gamma^2, \cdots, \gamma^{N-1})$. Each of the elements δ of E can be represented by a vector of coefficients (in F) of a polynomial $h \in F[y]$

[3] In fact, the resulting circuit description describes a *set* of circuits, corresponding to different choices for this constant γ. The description of constants is correct because this set is nonempty, and because *any* circuit in the set can be used to solve our problem.

such that $h(\gamma) = \delta$. We use this method to represent the entries of these matrices (using constants in F).

We also include as a constant a generator α of F over $\mathbb{F}_p$. The description of the constant α is an encoding of a straightline program encoding the minimal polynomial of α over $\mathbb{F}_p$. As a description of any other constant β (in F), we use an encoding of a straightline program computing a polynomial $k \in \mathbb{F}_p[y]$ such that $k(\alpha) = \beta$.

It is actually easy to compute "descriptions" for the generator α and for the constants listed in (i) and (ii), because the fields F and E are very small. The minimal polynomial of α over $\mathbb{F}_p$ and the minimal polynomial ψ of γ over $F = \mathbb{F}_p(\alpha)$ have binary representations with length $O(\log N)$; we can use an exhaustive search to find these polynomials. Since ψ is small, we can also compute descriptions for the constants in (ii) using space $O(\log N)$ by a straightforward method. We obtain log space constructible straightline programs computing the constants in (iii) using the expressions for the determinant and entries of the adjoint of the Vandermonde matrix $V(\gamma_1, \gamma_2, \cdots, \gamma_N)$ stated in the proof of part (1) for infinite fields.

(2) As we have noted, we can only use "constants" from the prime field K of F when using this more restrictive definition of uniformity. We cannot assume K will include a suitable set of constants. Instead, we compute the value γ (described above) as an element of $G = K(\alpha_1, \alpha_2, \cdots, \alpha_M)$ where $\alpha_1, \alpha_2, \cdots, \alpha_M$ are the inputs for our circuit; or, if G is small, we choose γ from a field extension of G. This method is correct for our problems because our outputs are all rational functions of our inputs: hence we can "assume" $G = F$. Note that this assumption could not be made safely for all problems. For example, we could not make this assumption when describing circuits for factorization of polynomials over F.

While nontrivial, it can be shown that the element γ can be computed using (log space constructible) circuits of size $N^{O(1)}$ and depth $O(\log N)$. We can also compute a table of discrete logarithms for a small extension E of G at this cost, if G is small. We must also compute the determinant and adjoint of the Vandermonde matrix $V(1, \gamma, \gamma^2, \cdots, \gamma^{N-1})$; this requires the inversion of an integer Vandermonde matrix (if we are to use "uniform" circuits for the computation). While the rest of the computation can be performed using depth $O(\log N)$, this step is reducible to "Iterated Integer Product." Hence we obtain the reduction stated in the theorem. □

We obtain different bounds when using the different methods of describing constants because the first method is much more generous: we are only required to show that we can *encode* straightline programs using space $O(\log N)$. It is *not* required that these programs can be implemented using circuits wiith depth $O(\log N)$. We have algorithms for our problems that use constants whose descriptions can be computed using small space, but we do not know how to compute the constants from their descriptions using circuit depth $O(\log N)$. When using the second definition of uniformity, we must "construct" these constants as part of our circuits, and the depth of the circuits increases.

6. Extensions and open problems. We conclude with some extensions of our results and suggestions for further work.

The set of domains D over which we can perform polynomial arithmetic using small depth Boolean circuits is easily extended to include rings of polynomials in h indeterminates (for any fixed integer h) over $\mathbb{Z}$ or any of the fields $\mathbb{F}_p$, $\mathbb{Q}$, $\mathbb{F}_{p^k}$, or number fields. The methods used in § 3 can be applied to obtain these extensions.

We have not emphasized the size of the circuits we obtained. While they have size $N^{O(1)}$ for input size N, we have a substantial increase over the size of the best

sequential algorithms. With some effort, we can reduce this increase for arithmetic computations over infinite fields. Bini and Pan [3]–[5] obtain optimal order depth parallel algorithms for "Polynomial Division with Remainder" for infinite fields that have asymptotically smaller size than can be obtained by our methods. No such "optimal depth, size efficient" algorithms for computations over finite fields are known.

Von zur Gathen [14] includes a precise definition for "NC^1_F-reducibility" of arithmetic problems. Since we did not obtain optimal order depth circuits for our arithmetic problems, using the strictest definition of uniformity proposed, reductions between the problems are of some interest. If F is a field with characteristic 0 then all of the arithmetic problems (over F) listed in § 1 are NC^1_F-equivalent. For an arbitrary field F, they are all NC^1_F-reducible to "Iterated Product of Polynomials (F)." However, it is not known whether the problem "Iterated Product of Polynomials (F)" is NC^F_1-reducible to "Division with Remainder of Polynomials (F)," if F is a field with positive characteristic.

Having seen that our problems are all solvable using (polynomial time constructible) families of bounded fan-in circuits of polynomial size and logarithmic depth, it seems natural to ask whether they can also be solved using *unbounded fan-in* circuits of constant depth and polynomial size. As we show below, we can answer part of this question by applying the results of Furst, Saxe, and Sipser [12] and Smolensky [21] in a fairly direct way.

For the Boolean case, it is easy to see that the answer to this question is "no"—at least, for our integer problems. That is, these problems *cannot* be solved using unbounded fan-in Boolean circuits of constant depth and polynomial size: Furst, Saxe, and Sipser show that *parity* cannot be computed using Boolean circuits of this type and give a "constant depth, polynomial size" reduction from *parity* to the computation of the (binary representation of the) product of two n-bit integers (see [12]). It is a simple matter to show that this *multiplication* problem is "constant depth, polynomial size" reducible to each of our integer polynomial problems—so that none of them can be solved using constant depth, polynomial size Boolean circuits. It is possible that some of the Boolean computations for polynomials over finite field that are discussed in this paper can be performed using unbounded fan-in Boolean circuits of constant depth and polynomial size.

The arithmetic case is quite different. If we allow unbounded fan-in gates for both addition and multiplication, then it is easy to show that the computations for polynomials over an *infinite* field F discussed in § 4 can be performed using unbounded fan-in arithmetic circuits over F of polynomial size and constant depth: we need only implement the algorithms presented in that section. It is almost as easy to show that this is *not* the case when $F=\mathbb{F}_2$: we simply note that, given $\alpha_1, \alpha_2, \cdots, \alpha_n \in \mathbb{F}_2$, we can determine whether the majority of these values is one by examining the coefficients of $\prod_{i=1}^{n}(x-\alpha_i)$. Thus *majority* is "constant depth, polynomial size" reducible to the problem "Iterated Product of Polynomials ($\mathbb{F}_2$)." Now if $F=\mathbb{F}_2$, and we identify elements of $\mathbb{F}_2$ with the Boolean values zero and one, then an unbounded fan-in $\times$-gate is equivalent to an unbounded fan-in $\wedge$-gate, and an unbounded fan-in $+$-gate is equivalent to a *parity*- or MOD_2-gate. Hence the statement that "Iterated Product of Polynomials ($\mathbb{F}_2$)" *cannot* be solved using unbounded fan-in arithmetic (or even arithmetic-Boolean) circuits of constant depth and polynomial size is a direct result of the corollary of Theorem 2 of Smolensky (see [21]). It is conceivable, however, that "Division with Remainder of Polynomials ($\mathbb{F}_2$)," or some of our problems for polynomial arithmetic over finite fields other than $\mathbb{F}_2$, can be solved using unbounded fan-in arithmetic circuits of constant depth and polynomial size.

Finally, we ask whether the above (positive) results for computations over infinite fields by unbounded fan-in arithmetic circuits remain valid if we consider circuits with unbounded fan-in gates for addition, but with fan-in 2 gates for multiplication. Conventional wisdom, and our own intuition, would suggest that the answer is "no." However, Kung has shown that exponentiation (computing x^n given $x \in F$ and $n \in \mathbb{N}$) can be performed using constant depth, polynomial size (in n) arithmetic circuits over F, with gates of this type—provided that the field F contain an nth primitive root of unity (see [15, Algorithm 3.1]). We do not know whether this result can be generalized, either to the problems we have discussed, or to exponentiation over a more general class of ground fields.

Acknowledgments. Many thanks go to my advisor, Joachim von zur Gathen, who suggested the problem and made many contributions. I also thank Alan Borodin and Faith Fich for much helpful advice.

TOPOLOGICAL COMPLETENESS IN AN IDEAL MODEL FOR POLYMORPHIC TYPES*

ERNST-ERICH DOBERKAT†

Abstract. The topological structure underlying the ideal model of recursive polymorphic types proposed by MacQueen, Plotkin, and Sethi are examined. It is shown that their central argument in establishing a well-defined semantical function, viz., completeness with respect to a metric obtained from the construction of their domain, is a special case of complete uniformities, which arise in a natural way from the study of closeness of ideals on domains. These uniformities are constructed and studied, and a general fixed-point theorem is derived for maps defined on these ideals.

Key words. polymorphic topological type models, domain theory, fixed points

1. Introduction. MacQueen, Plotkin, and Sethi discuss in [6] the semantics of types and propose σ-ideals over domains as a formalization of the naive view of types as sets of values. This is based on the following observations. Naively, one may tend to model types as sets of values: saying that the variable a has the type τ means that a always will be a member of the set modeling τ. Since types are thought to preserve structural similarity, and since this latter property should be preserved by approximations (i.e., it is closed *downward*) and by taking least upper bounds of consistent sets of values (i.e., it is closed *upward*), the formulation of a type as a set of values having all the properties of a σ-ideal is quite attractive (see [6, § 1] for a more detailed account).

In their model, self-application and recursion is possible, i.e., a type τ may be described by an expression such as $\tau = f(\tau)$, e.g., $\tau = \tau \to \sigma$. Hence, it has to be established that types of this kind do exist. This is not too difficult if the type constructor f has pleasant mathematical properties, monotonicity and continuity among them. In the case of type constructors, however, these properties cannot be guaranteed (cf., the zig-zag example in [6, pp. 98-99]). Hence, other ways of establishing the existence of a fixed point have to be found, and MacQueen, Plotkin, and Sethi propose using Banach's celebrated fixed point theorem.

This theorem is a tool that is long established in numerical mathematics to make sure that numerical iterations converge. Under proper conditions, the machinery associated with this theorem works as follows: if the convergence of an iteration has to be established, this iteration is formulated in terms of a function, mapping the search space into itself in such a way that the wanted value appears as a fixed point of the mapping. If the map can be shown to be a contraction, then convergence of the iterates to the fixed point follows from Banach's theorem. The underlying mathematical structure for the Banach theorem is a complete metric space, and the map to be considered must be a contraction, i.e., the distance between the image of two points must be by a proportionality factor smaller than the distance of these points. MacQueen,

Plotkin, and Sethi establish such a complete metric on the space of all σ-ideals, which is used in that paper as a type model. This metric is introduced using an arbitrary witness function, and a closer look at the situation and at the completeness proof suggests that this scenario may indeed be a special case of a far more general one, since nature as well as properties of the witness function are rather negligible—the only interesting thing here is that the witness function exists.

In this note we demonstrate that the case considered in [6] is a special case from a topological point of view. We consider the usual generalization of metric spaces—uniform spaces—and show that the method to define a metric space may be applied to a more general one yielding complete uniform spaces.

We characterize those uniformities on the set of all σ-ideals of a domain that are generated by a rank function. Completeness was only a tool for establishing fixed points, so we discuss fixed points in greater detail, establishing from Landes's Fixed Point Theorem [5] for uniform spaces a characterization of those maps for which a unique fixed point exists. This is done first in the general uniform setting over the space of all ideals, and then a special case including the metric situation is derived from this.

The main technical innovation of this paper is to impose a uniform structure on a set of types and to establish existence of recursively defined types using a rather general fixed-point theorem. Thus, we propose replacing the metric arguments introduced by MacQueen, Plotkin, and Sethi with uniform ones, when it comes to using completeness results and in particular fixed-point arguments. Arguments from the theory of uniform spaces are usually easier to apply from a technical point of view and have the advantage of not involving the use of real numbers, since uniformities may be formulated using intrinsic properties of the objects under consideration. In addition, we expect that the results here may ease the application of fixed-point arguments without having to struggle through the technical details of metric or uniform spaces. Such fixed-point constructions seem to occur in mathematical semantics quite frequently (apart from [6], see e.g., [1]).

The present note is organized as follows: § 2 collects some notations from domain theory and from uniform spaces, and § 3 deals with Landes's fixed-point theorem. In § 4, we generalize the metric investigated by MacQueen, Plotkin, and Sethi to specific uniformities, and we study the question under which conditions the uniformity may be generated by a metric. Section 5 contains some results on fixed points, and in § 6 we indicate how the methods and results obtained may be used in the situation studied in [6].

2. Some preliminaries. For easier reference and to make the paper self-contained, we collect some notations. The standard reference for topological and uniform spaces is [4], and for domains we refer to [7].

A complete partial order (cpo) is a partial order $\leqq$ on a set D which has a smallest element $\perp$ such that each increasing sequence has its supremum in D. An element $x \in D$ is said to be *compact* if for each increasing sequence $(y_n)_{n\in\mathbb{N}}$ in D with $x \leqq \sup_{n\in\mathbb{N}} y_n$ there is an index k such that $x \leqq y_k$ holds. D is *algebraic* if there are countably many compact elements, and if for each $x \in D$ the set

$$L_x := \{a \in D;\ a \text{ is compact with } a \leqq x\}$$

is directed such that $x = \sup L_x$ holds (as usual, here we call a set L *directed* if two elements in L have an upper bound in L). Denote by A^o all compact elements in A, hence $A^o = A \cap D^o$. D is called a *domain* if it is an algebraic cpo such that each subset

bounded from above has a supremum. We fix a domain D for the rest of this paper.

A nonempty set $I \subset D$ is said to be an *ideal* if it is downward closed; hence, if $x \leqq y \in I$ implies $x \in I$ for each $x \in D$, $y \in I$; denote by $\mathscr{I}(D)$ the set of all ideals in D. An ideal is called a *σ-ideal* if it is closed with respect to taking suprema of increasing sequences; denote by $\mathscr{I}_\sigma(D)$ the set of all σ-ideals in D and by $\mathscr{I}_\sigma^*(D)$ the augmented set $\mathscr{I}_\sigma(D) \cup \{\varnothing\}$. The map $I \mapsto I^o$ is a bijection from $\mathscr{I}_\sigma(D)$ to $\mathscr{I}(D^o)$, the inverse of which is given by

$$\mathscr{I}(D^o) \ni I \mapsto \{\sup_{n\in\mathbb{N}} x_n;\ (x_n)_{n\in\mathbb{N}} \subset I \text{ is increasing}\}$$

([6], Proposition 1).

A subset $\mathscr{A}$ of the power set $\mathscr{P}(S)$ of a set S is a *filterbase* if $\varnothing \notin \mathscr{A}$, $\mathscr{A} \neq \varnothing$, and if we may find for each $A_1, A_2 \in \mathscr{A}$ an element $A \in \mathscr{A}$ with $A \subset A_1 \cap A_2$. A *filter* $\mathscr{A}$ is a filterbase that is a dual ideal, i.e., if the following implication holds:

$$A \in \mathscr{A}, \qquad A \subset B \Rightarrow B \in \mathscr{A}.$$

A filter $\mathscr{G}$ on $S \times S$ is said to be a *uniformity* if

(1) $\forall G \in \mathscr{G}$: $G^{-1} := \{(y, x);\ (x, y) \in G\} \in \mathscr{G}$ (G^{-1} is called the inverse of G).

(2) $\Delta \in \mathscr{G}$, where $\Delta := \{(x, x);\ x \in S\}$ is the diagonal.

(3) $\forall G \in \mathscr{G}\ \ \exists H \in \mathscr{G}$: $H \circ H \subset G$
(here the composition operator is defined as usual by $I \circ J := \{(x, z);$
$\exists y$: $(x, y) \in I$ and $(y, z) \in J\}$).

We then call $(S, \mathscr{G})$ a *uniform space.*

A filterbase generating a uniformity is called a *base* for this uniformity. If d is a metric on S (i.e., if $d : S \times S \to \mathbb{R}_\oplus$ with $\forall y\ \ \forall y$: $d(x, y) = d(y, x)$; $\forall x \forall y$: $d(x, y) = 0 \Leftrightarrow x = y$; $\forall x \forall y \forall z$: $d(x, z) \leqq d(x, y) + d(y, z)$), then it is easily seen that the smallest filter $\mathscr{G}_d$ on $S \times S$ that contains all the sets $\{(x, y);\ d(x, y) \leqq r\}$ is a uniformity. In a metric space, we may numerically evaluate the closeness of two points x, y by computing $d(x, y)$; in a uniform space, closeness of x and y is expressed in terms of the elements of $\mathscr{G}$: x and y are close with respect to $H \in \mathscr{G}$ if and only if $(x, y) \in H$. Thus, uniform spaces generalize metric spaces; they are, in turn, less general than topological spaces.

We will use two constructions from the theory of uniform spaces, viz., the product of two uniformities and the Hausdorff uniformity on the space $\mathscr{CL}(\mathscr{S})$ of all nonempty closed subsets of a uniform space. Both constructions will be needed later when we show that under certain topological conditions, fixed points do exist. This will be described in terms of the Hausdorff uniformity on the space $\mathscr{CL}(\mathscr{S} \times \mathscr{S})$ for a suitably chosen uniform space $\mathscr{S}$. Let (S, G) be a uniform space. First, let $W \subset \mathscr{S}^4$, then define the shuffle

$$\langle W \rangle := \{(a, c, b, d);\ (a, b, c, d) \in W\}.$$

Then the set of all shuffled rectangles

$$\mathscr{G} \boxtimes \mathscr{G} := \{\langle A \times B \rangle;\ A, B \in \mathscr{G}\}$$

defines the basis for the *product uniformity* $\mathscr{G} \otimes \mathscr{G}$ on $S \times S$ (intuitively, a pair is close if and only if both components are close to each other). If $\mathscr{G}$ has a base $\mathscr{G}_o$, $\mathscr{G}_o \boxtimes \mathscr{G}_o$ forms a base for $\mathscr{G} \otimes \mathscr{G}$. Turning to $\mathscr{CL}(S)$, we define for $A \subset S$, $U \in \mathscr{G}$ the U-neighborhood $U(A)$ of A by

$$U(A) := \{y \in S;\ (x, y) \in U \quad \text{for some } x \in A\};$$

two sets $C, D \in \mathscr{SL}(S)$ are U-close if and only if they lie in the U-neighborhoods of each other. Formally,

$$[U] := \{(C, D);\ C, D \in \mathscr{CL}(S) \quad \text{with } C \subset U(D),\ D \subset U(C)\}$$

then $\{[U];\ U \in \mathscr{G}\}$ defines the basis for a uniformity on $\mathscr{CL}(S)$, the so called *Hausdorff uniformity* (see [2, § II]).

$(S, \mathscr{G})$ is called *separated* (or *Hausdorff*) if and only if $\bigcap \mathscr{G} = \Delta$; so two distinct points can always be separated by an element of $\mathscr{G}$. The space is called *complete* if and only if each Cauchy net converges. This means the following: a *net* $(n_r)_{r \in R}$ in S is a map $R \ni r \mapsto n_r \in S$ such that R is a set that is directed by a transitive and reflexive relation (which is usually omitted in the notation; the natural numbers $\mathbb{N}$ are a directed set under the natural order; hence, each sequence is a net). The net $(n_r)_{r \in R}$ *converges to* n if and only if elements of the net are eventually close to n; hence if and only if

$$\forall U \in \mathscr{G} \quad \exists r_o \in R \quad \forall R \ni r \geqq r_o\colon (n_r, n) \in U$$

and it is a *Cauchy net* if and only if

$$\forall U \in \mathscr{G} \quad \exists r_o \in R \quad \forall r, s \geqq r_o\colon (n_r, n_s) \in U,$$

hence if and only if the elements of the net are eventually close to each other.

It is not too difficult to see that $(S \times S, \mathscr{G} \otimes \mathscr{G})$ is a Hausdorff space, if $(S, \mathscr{G})$ is one, and that this space is complete if $(S, \mathscr{G})$ is. In addition, $\mathscr{CL}(S)$ with the Hausdorff uniformity is a separated space whenever $(S, \mathscr{G})$ is [2, Thm. II-12, p. 45].

Finally, if $A, B \subset S$, define the symmetric difference $A \triangle B$ of A and B by $(A \cup B) - (A \cap B)$. It is rather easy to see that $(\mathscr{P}(S), \triangle)$ is an Abelian group, and that for all $A, B, C \subset S$

$$A \triangle B \subset (A \triangle C) \cup (C \triangle B)$$

as well as

$$(A \triangle B) \cap C = (A \cap C) \triangle (B \cap C)$$

hold (see, e.g., [3, p. 6]).

3. Fixed points. Since we will study fixed points over uniform structures on the set of all σ-ideals of a domain as a generalization of [6], we need an extension of the fixed-point arguments of the Banach type. Recently, Thomas Landes gave a suitable generalization of Banach's celebrated theorem that fits into the framework considered here and that will be of considerable use in the arguments below. Since this result has not been published yet, and in order to make the present paper self-contained, we give Landes's result in greater detail and sketch its proof (for technical reasons the arrangement is a bit different from the one given by Landes; however, the proofs are entirely due to Landes).

For this section fix a uniform space $(S, \mathscr{G})$ with a complete and separated uniformity $\mathscr{G}$ having $\mathscr{G}_o$ as a base. We begin with some definitions.

DEFINITION 3.1. A map $F\colon \mathscr{G}_o \to \mathscr{G}_o$ is said to be an *attractor* if and only if the following condition holds

(A-1) $$\forall U \in \mathscr{G}_o\colon F(U) \subset U.$$

(A-2) $$\forall U \in \mathscr{G}_o \quad \exists N = N(U) \in \mathbb{N} \quad \forall k \in \mathbb{N}\colon F^N(U) \circ \cdots \circ F^{N+k}(U) \subset U.$$

This notion of an attractor simulates contractions in a metric space in the following sense: suppose (X, d) is a complete metric space, and $f\colon X \to X$ has a contracting

property, viz., there is $0<\beta<1$ such that $d(f(x),f(y))\leqq\beta d(x,y)$ always holds. Taking the set of balls $\{K_r(x);\ r>0,\ x\in X\}$ (with $K_r(x):=\{y;\ d(x,y)<r\}$), it is easy to see that the map $K_r(x)\mapsto f[K_r(x)]$ furnishes an attractor.

DEFINITION 3.2. A map $f: M\to M$ is called a *contraction* if

(A-3) there exists an attractor F_f with the property that for all $U\in\mathcal{G}_o$ the following holds: $(f(x),f(y))\in F_f(U)$, whenever $(x,y)\in U$.

(A-4) $$\forall x\in M\quad \forall U\in\mathcal{G}_o\quad \exists m\in\mathbb{N}\colon (f^m(x),f^{m+1}(x))\in U.$$

If in addition the condition (A-5) holds, then we call f a *strong contraction*:

(A-5) $$\forall x\neq y\quad \exists U\in\mathcal{G}_o\quad \exists m\in\mathbb{N}\colon (x,y)\notin U \text{ and } (f^m(x),f^m(y))\in U.$$

The fixed-point theorem due to Landes then reads as follows:

THEOREM 3.3. (1) *Any contraction f has a fixed point x^*, and $x^*=\lim_{n\to\infty}f^n(x)$ holds, where $x\in S$ is arbitrary.*

(2) *If f is a strong contraction, then x^* is the unique fixed point.*

Proof. (1) Uniqueness is easily established for a strong contraction, once we know that x^* exists.

(2) Fix $x\in S$, then it is enough to show that the sequence $(f^n(x))_{n\in\mathbb{N}}$ is a Cauchy sequence; completeness will then establish a limit for this sequence, which in turn is easily seen to be a fixed point. Given $U\in\mathcal{G}_o$, we may find $m\in\mathbb{N}$ such that

$$(f^m(x),f^{m+1}(x))\in U.$$

Now let $k\geqq 1$, $n\geqq N+m$, where N is chosen according to condition (A-2) for the attractor F_f, then

$$(f^n(x),f^{n+k}(x))\in F_f^N(U)\circ\cdots\circ F_f^{N+k}(U)\subset U.$$

This establishes the theorem. □

We will need to extend the notion of a contraction to several dimensions, and for the sake of demonstrating techniques we will focus on the case of two dimensions. We call a map $f: M\times M\to M$ a (*strong*) *contraction* if and only if for each $s,t\in M$ the maps $f_s:=\lambda t\cdot f(s,t)$ and $f^t:=\lambda s\cdot f(s,t)$ are (strong) contractions, where the attractors belonging to F_{f_s} and F_{f^t}, respectively, are uniformly equal, i.e., $\forall s,t\in M\colon F_{f_s}=F_{f^t}$.

4. Constructing uniformities. When defining a uniformity $\mathcal{G}$, one has to specify which elements are considered to be close to each other. If, in addition, closeness can be specified in numeric terms, i.e., in terms of a distance function, a metric space is defined.

Let $r: D^o\to\mathbb{N}$ be a rank function on the compact elements of a domain; then the closeness $c(x,y)$ for $x,y\in\mathcal{I}_\sigma(D)$ is defined by

$$c(x,y):=\begin{cases}\infty, & \text{if } x=y\\ \min\{r(k);\ k\in x^o\triangle y^o\}, & \text{otherwise.}\end{cases}$$

Hence, x and y are the closer the later one realizes that there is a witness $x^o\triangle y^o$, since $x=y$ iff $x^o=y^o$ iff $x^o\triangle y^o=\varnothing$.

The distance associated with the rank function r is then defined by

$$d(x,y):=2^{-c(x,y)}.$$

This makes $(\mathcal{I}_\sigma(D),d)$ a complete (ultra-) metric space.

The use of $c(x, y)$ suggests that in the general situation the closer the two ideals, the less distinguishable their compact elements are, i.e., the smaller $x^o \triangle y^o$ is. Taking an arbitrary set $\mathscr{A} \subset \mathscr{D}^o$ as a yardstick, we say that the ideals x and y are *$\mathscr{A}$-close* if the difference of their compact elements is witnessed by $\mathscr{A}$. This is stated formally in Definition 4.1.

DEFINITION 4.1. For $A \subset D^o$, define

$$G_A := \{(x, y);\ x, y \in \mathscr{I}_\sigma(D),\ x^o \triangle y^o \subset A\}.$$

Thus two σ-ideals are close to each other with respect to A if the difference of the trace they leave on the compact elements is contained in A. Now we will demonstrate that this constitutes a basis for a uniformity on $\mathscr{I}_\sigma(D)$.

LEMMA 4.2. *Let $\mathscr{A} \subset P(D^o)$ be a filter base, then we have the following properties*:

(a) $\mathscr{G}_{\mathscr{A}} := \{G_A;\ A \in \mathscr{A}\}$ *is the base for a uniformity $\mathscr{G}^*_{\mathscr{A}}$ (thus $\mathscr{G}^*_{\mathscr{A}}$ is the smallest uniformity containing $\mathscr{G}_{\mathscr{A}}$)*;

(b) *if $\mathscr{B}$ is another filter base with $\mathscr{A} \subset \mathscr{B}$, then $\mathscr{G}^*_{\mathscr{A}} \subset \mathscr{G}^*_{\mathscr{B}}$*;

(c) *if $\mathscr{F}(\mathscr{A})$ denotes the filter generated by $\mathscr{A}$, then $\mathscr{G}^*_{\mathscr{F}(\mathscr{A})} = \mathscr{G}^*_{\mathscr{A}}$*;

(d) *$\mathscr{G}^*_{\mathscr{A}}$ is Hausdorff, provided that $\bigcap \mathscr{A} = \varnothing$.*

Proof. (a) It is enough to demonstrate that we can find for any $A \in \mathscr{A}$ an element $B \subset \mathscr{A}$ with $G_B \circ G_B \subset G_A$. In fact, we will show that B may be chosen as A itself. Now, let $(x, y) \in G_A \circ G_A$, then we know that we can find z with $x^o \triangle z^o \subset A$ and $z^o \triangle y^o \subset A$. But because

$$x^o \triangle y^o \subset (x^o \triangle z^o) \cup (z^o \triangle y^o) \subset A,$$

we see that $(x, y) \in G_A$. The other properties of a uniformity are straightforward.

(b) Property (b) follows from the observation that $C \in \mathscr{G}^*_{\mathscr{A}}$ if and only if $G \subset C$ for some $G \in \mathscr{G}_{\mathscr{A}}$.

(c) Property (c) is established similarly: Since $F \in \mathscr{F}(\mathscr{A})$ iff $A \subset F$ for some $A \in \mathscr{A}$, and since $B \mapsto G_B$ is an increasing map, the assertion is immediate.

(d) Let $(x, y) \in \bigcap \mathscr{G}^*_{\mathscr{A}}$ be a pair of ideals, then $x^o \triangle y^o \subset \bigcap \mathscr{A}$; so we may infer that $(x, y) \in \bigcap \mathscr{G}^*_{\mathscr{A}}$ if and only if $x = y$, provided $\bigcap \mathscr{A} = \varnothing$. But this means that in the latter case $\bigcap \mathscr{G}^*_{\mathscr{A}}$ reduces to the diagonal. □

The metric defined in [6] falls rather naturally into the realm of the uniformity defined above. As indicated, let d be derived from a rank function r, then

$$d(x, y) < \varepsilon$$

iff

$$r(k) \geqq \left\lceil \log_2 \frac{1}{\varepsilon} \right\rceil$$

for each $k \in x^o \triangle y^o$, provided the σ-ideals x and y are different. It is then easily seen that the metric uniformity $\mathscr{G}_r$ coincides with $\mathscr{G}^*_{\mathscr{A}}$ where

$$\mathscr{A} := \{A_n;\ n \in \mathbb{N} \quad \text{and } A_n \neq \varnothing\}$$

with

$$A_n := \{r \geqq n\} := \{t \in D^o;\ r(t) \geqq n\}.$$

We will return to the question under which conditions $\mathscr{G}^*_{\mathscr{A}}$ equals $\mathscr{G}_r$ for some r in due course.

We are interested in the completeness of $\mathscr{G}^*_{\mathscr{A}}$. Recall that a uniform space is complete if each Cauchy net has a limit. We are going to represent the limit in terms

of the following set-theoretical construction. Let $(A_r)_{r\in R}$ be a net of sets, then

$$\liminf_{r\in R} A_r := \bigcup_{r\in R} \bigcap_{r_o \geqq r} A_{r_o}$$

is said to be the *limit inferior* of this net and is the set of all elements which are eventually in all A_r, and

$$\limsup_{r\in R} A_r := \bigcap_{r\in R} \bigcup_{r_o \geqq r} A_{r_o}$$

is called the *limit superior* of this net and is the set of all elements which are frequently in A_r.

It is rather easy to verify the following technical lemma.

LEMMA 4.3. *Let $(x_r)_{r\in R}$ be a net of ideals in D^o, then we have the following*:

(a) $\liminf_{r\in R} x_r$ *and* $\limsup_{r\in R} x_r$ *are both ideals in* D^o;

(b) $\liminf_{r\in R} x_r \subset \limsup_{r\in R} x_r$;

(c) *for every* $s \in R$, *the following inclusions hold*

$$\liminf_{s\leqq r\in R} x_r \subset \liminf_{r\in R} x_r$$

and

$$\limsup_{s\leqq r\in R} x_r \supset \limsup_{r\in R} x_r.$$

This allows the representation of a limit in purely set-theoretical terms, provided one knows that it exists. Recall that a sequence in a Hausdorff space has at most one limit.

PROPOSITION 4.4. *Let $(x_r)_{r\in R} \subset \mathcal{I}_\sigma(D)$ be a net with $\mathcal{G}^*_{\mathcal{A}} - \lim_{r\in R} x_r = x \in \mathcal{I}_\sigma(D)$, and assume that $\mathcal{G}^*_{\mathcal{A}}$ is Hausdorff. Then we have*

$$x^o = \liminf_{r\in R} x_r^o = \limsup_{r\in R} x_r^o.$$

Proof. (0) $\mathcal{G}^*_{\mathcal{A}} - \lim_{r\in R} x_r = x$ means that we can find for every $A \in \mathcal{A}$ an index $r_o = r_o(A)$ such that $x_r^o \triangle x^o \subset A$ holds for every $r \geqq r_o$.

(1) Fix $A \in \mathcal{A}$ and select r_o for A according to part 0. If $r \geqq r_o$, we have $x^o \triangle x_r^o \subset A$, or, equivalently, $x^o - A \subset x_r^o - A$. Consequently,

$$x^o - A \subset \liminf_{r\in R} x_r^o - A.$$

Because $\mathcal{G}^*_{\mathcal{A}}$ is Hausdorff, hence $\bigcap \mathcal{A} = \varnothing$, we may infer

$$E \subset F$$

from

$$\forall A \in \mathcal{A}\colon E - A \subset F - A.$$

Thus we may conclude that

$$x^o \subset \liminf_{r\in R} x_r^o.$$

Similarly, we see that

$$\limsup_{r\in R} x_r^o \subset x^o.$$

Now the conclusion follows from 4.3(b). □

From 4.4, we infer completeness for the uniformity.

PROPOSITION 4.5. *If $\mathcal{G}^*_{\mathcal{A}}$ is Hausdorff, then it is complete.*

Proof. (0) We show that each Cauchy net $(x_r)_{x\in R}$ of σ-ideals converges with respect to $\mathcal{G}^*_A$. Fix for the moment $A\in\mathcal{A}$, then we find an index $r_o\in R$ such that $x^o_r \triangle x^o_s \subset A$ whenever $r, s \geqq r_o$.

(1) From the latter inclusion we see that

$$\forall s, t \geqq r_o\colon x^o_s - A \subset x^o_t - A,$$

hence we have for any $s \geqq r_o$ the inclusion

$$x^o_s - A \subset \liminf_{s\leqq r\in R} x^o_r - A \subset \liminf_{r\in R} x^o_r - A.$$

Similarly, we see that

$$x^o_s - A \supset \limsup_{r\in R} - A.$$

Now let $x\in\mathcal{I}_\sigma(D)$ be determined by the equation

$$x^o = \liminf_{r\in R} x^o_r,$$

then we see that $x^o_s - A = x^o - A$, whenever $s \geqq r_o$. □

Let us illustrate Proposition 4.5 and our constructions with an example. It is well known that $D := \mathcal{P}(\mathbb{N})$ is a domain, using set inclusion as the order relation and that the compact elements are just the finite subsets. Count D^o using the bijection

$$\varphi : a \mapsto \sum_{t\in a} 2^t.$$

Putting

$$\mathcal{A} := \{\{\varphi \geqq n\};\ n\in\mathbb{N}\}$$

we obtain a complete Hausdorff uniformity $\mathcal{G}^*_{\mathcal{A}}$ on $\mathcal{I}^*_\sigma(D)$. Now define

$$x_n := \{a\in D;\ k\geqq n \quad \text{holds for all } k\in a\},$$

then x_n is easily seen to be a σ-ideal.

CLAIM. *$(x_n)_{n\in\mathbb{N}}$ is a Cauchy sequence.*

Proof. Given $N\in\mathbb{N}$, select k with $2^k > N$. If $s, t\in\mathbb{N}$, let

$$a \in x^o_{k+s} \triangle x^o_{k+s+t} \subset x^o_{k+s},$$

thus

$$\varphi(a) = \sum_{m\in a} 2^m > \operatorname{card}(a) 2^{k+s} > N,$$

so $(x_{k+s}, x_{k+s+t}) \in G_{\{\varphi\geqq N\}}$. Since s and t have been chosen arbitrarily, the above claim is established. □

Consequence. $\mathcal{G}^*_{\mathcal{A}} - \lim_{n\to\infty} x_n = \varnothing$.

This has been the reason for including the empty set into the set of σ-ideals that we wanted to consider. Usually, one considers only the set of nonempty σ-ideals; this is justified by the fact that the bottom element in a domain constitutes an ideal.

Let us remark that φ may serve as a ranking function, so that on one hand we have the uniform space $(\mathcal{I}_\sigma(\mathcal{P}(\mathbb{N})), \mathcal{G}^*_{\mathcal{A}})$, and on the other we have the metric space $(\mathcal{I}_\sigma(\mathcal{P}(\mathbb{N})), d)$ with the metric d as defined by MacQueen, Plotkin, and Sethi. It is not

difficult to see that the uniformity defined by the metric is just the same as $\mathcal{G}^*_{\mathcal{A}}$. We will denote the uniformity that is generated from the metric obtained from the rank function r by $\mathcal{G}_r$. Now we will discuss conditions under which the uniformity $\mathcal{G}^*_{\mathcal{A}}$ is actually generated by a rank function. Since a rank function has the property that its uniformity is generated by some countable sets, it is worthwhile to investigate countability conditions.

If $\mathcal{B}$ is a filter, then $\mathcal{B}$ is said to be *countably based* if there exists a countable filter base $\mathcal{A}$ such that $\mathcal{B}$ equals $\mathcal{F}(\mathcal{A})$. It is the countably based filters which constitute the special case of metrizable uniformities. We return to the case of a general D for an investigation of this question.

PROPOSITION 4.6. *Let $\mathcal{A}$ be a filter base with $\cap\, \mathcal{A} = \varnothing$. There exists a rank function $r: D^o \to \mathbb{N}$ with $\mathcal{G}^*_{\mathcal{A}} = \mathcal{G}^*_r$ if and only if $\mathcal{F}(\mathcal{A})$ is countably based.*

Proof. (1) If $\mathcal{G}^*_{\mathcal{A}} = \mathcal{G}^*_r$ for some rank function r, then

$$\{A_n;\ n \in \mathbb{N},\ A_n \neq \varnothing\}$$

with

$$A_n := \{r \geqq n\}$$

constitutes a countable base for $\mathcal{F}(\mathcal{A})$.

(2) If $\mathcal{F}(\mathcal{A})$ has a countable base

$$\mathcal{B} = \{B_t;\ t \in \mathbb{N}\},$$

we may assume without loss of generality that the B_t form a descending chain

$$B_1 \supset B_2 \supset \cdots$$

(otherwise, force this condition without losing the properties of $\mathcal{B}$). Let for $v \in D^o$ the rank function be defined by

$$r(v) := \operatorname{card}(\{t;\ v \in B_t\}).$$

Then r is a finite function, because $\cap\, \mathcal{B} = \varnothing$, and $B_t = \{r \geqq t\}$ is easily seen. This implies the desired equality $\mathcal{G}^*_{\mathcal{A}} = \mathcal{G}_r$. □

5. Fixed points. Completeness is only a necessary condition for establishing the existence of a fixed point for a map of a metric or a uniform space into itself. The technical condition used in [6] was that the maps in question are contractions, so that the distance between the image of two points is bounded by a constant factor times the distance between the points themselves; the constant being strictly smaller than unity. This is shown to have the effect that successive applications of the map will eventually result in closer and closer points, thus yielding a Cauchy sequence that must converge to the fixed point.

A similar strategy is employed in the case of a complete uniform space. Since here numerical measurements of distances are not possible, one has to use other techniques in establishing the convergence of the iterates of the map in question. This has been discussed in § 3, and we will show how to utilize this result in the context of σ-ideals over a domain.

It will be convenient to consider a general situation first. Let M be a complete uniform space with uniformity $\mathcal{G}$ and let $\mathcal{G}_o$ be a base for $\mathcal{G}$. Assume that $\varphi: M \to M$ is a contraction, and define for $V \in \mathcal{G}_o$

$$R_m(\varphi, V) := \operatorname{closure}((\varphi^m \times \varphi^{m+1})[V]),$$

where

$$(\varphi^m \times \varphi^{m+1})[V] := \{(\varphi^m(a), \varphi^{m+1}(b));\ (a, b) \in V\}$$

is the image of the basic neighborhood $V \subset M \times M$ under the map $(\varphi^m \times \varphi^{m+1})$, the closure being topological in the product space $M \times M$, where M is endowed with the topology canonically generated by the uniformity that is based on $\mathcal{G}_o$. Thus $(x, y) \in M \times M$ is in $R_m(\varphi, V)$ if and only if there exists a net $((a_n, b_n)_{n \in R}) \subset V$ such that

$$(x, y) = \lim_{n \in R} (\varphi^m \times \varphi^{m+1})(a_n, b_n).$$

$R_m(\varphi, \cdot)$ maps basic neighborhoods into closed and nonempty subsets of the Cartesian product. A useful condition for a fixed point may be derived from this observation: if applying two subsequent iterations of φ to an arbitrary pair in V renders the images more and more indistinguishable, or, topologically speaking, if $R_m(\varphi, V)$ is absorbed eventually by the diagonal, then condition (A-4) establishing a fixed point is satisfied.

This condition is intuitively rather clear, and in order to formulate it we need the topological framework which is sketched in § 2.

PROPOSITION 5.1. *If* $\lim_{m \to \infty} R_m(\varphi, V)$ *exists for each* $V \in \mathcal{G}_o$ *and is a subset of the diagonal, then* φ *has a fixed point.*

Proof. 0. According to Theorem 3.3 it is enough to show that given $x \in M$, and $U_1 \in \mathcal{G}_o$, there exists $m \in \mathbb{N}$ such that

$$(\varphi^m(x), \varphi^{m+1}(x)) \in U_1.$$

Since $\mathcal{G}_o$ is a base for $\mathcal{G}$, there exists for U_1 a neighborhood $U \in \mathcal{G}_o$ that is symmetric (i.e., for which $U^{-1} = U$), holds, such that $U \circ U \subset U_1$, and for x there exists a basic neighborhood V with the property that $(x, \varphi(x)) \in V$. Consequently,

$$\forall k \in \mathbb{N}: (\varphi^k(x), \varphi^{k+1}(x)) \in R_k(\varphi, V)$$

holds.

(1) Let $\Delta^* := \lim_{n \to \infty} R_n(\varphi, V)$ be the limit with respect to the Hausdorff uniformity. Since the sequence $(R_n(\varphi, V))_{n \in \mathbb{N}}$ converges, we know that there exists an index n_o such that

$$\forall n \geqq n_o: R_n(\varphi, V) \subset \langle U \times U \rangle(\Delta^*).$$

Thus $(z, z, \varphi^n(x), \varphi^{n+1}(x)) \in \langle U \times U \rangle$ for a suitably chosen $z \in M$ and all such n. This implies the desired property. □

The condition given above is a bit strong and not very practical. First, the proof shows that one need not insist on the convergence of the closures of $(\varphi^m \times \varphi^{m+1})[V]$. This has been done to assure a proper topological formulation of the sufficient condition (otherwise, one would have to have resorted to a topology on the space of all subsets of $M \times M$, a space that is too large to be topologized properly). Second, the convergence is not easily checked, so the condition is not really useful, although it applies to the situation in question as well.

Let us return to the space $\mathcal{I}_\sigma(D)$ of all σ-ideals of the domain D (note that now we can do without the empty set). Assume that we have a contraction φ defined on $\mathcal{I}_\sigma(D)$ and that furthermore a rank function $r: D^o \to \mathbb{N}$ is defining the uniformity. Let $\mathcal{A}$ be the base determined by r, then $\mathcal{G}^*_{\mathcal{A}}$ is Hausdorff. Define for each subset $A \subset D$ its weight

$$r^*(A) := \min \{r(d);\ d \in A \cap D^o\}$$

(we adopt the convention that $r^*(\varnothing) = +\infty$).

The next lemma will be an auxiliary statement establishing the existence of a fixed point. Intuitively, it describes what happens when the map φ makes the difference of

the images of two ideals harder to discern than the ideals themselves. Call a map $\varphi : \mathcal{J}_\sigma(D) \to \mathcal{J}_\sigma(D)$ *discerning* if $r^*(\varphi(x) \triangle \varphi(y)) > r^*(x \triangle y)$ holds whenever $x \neq y$.

LEMMA 5.2. *If φ is discerning, then we can find for every $A, B \in \mathcal{A}$ an index m_o such that*

$$R_m(\varphi, G_B) \subset G_A$$

holds whenever $m \geqq m_o$.

Proof. (0) We show first that

$$T := \min \{r^*(a_1 \triangle a_2); (a_1, a_2) \in (\mathrm{id} \times \varphi)[G_B]\}$$

is a finite quantity. Assume on the contrary that $T = +\infty$, then $a_1 = a_2$, whenever $(a_1, a_2) \in (\mathrm{id} \times \varphi)[G_B]$. But this means that $G_B = \{(x, x)\}$ for some $x \in \mathcal{J}_\sigma(D)$. But since the diagonal on $\mathcal{J}_\sigma(D)$ is a subset of G_B by definition, there is only one σ-ideal x on D, thus the domain is trivial, and φ is not discerning. Hence we have arrived at a contradiction.

(1) Now an inductive argument will show that

$$(+) \qquad \forall (a_1, a_2) \in (\varphi^m \times \varphi^{m+1})[G_B]: r^*(a_1 \triangle a_2) \geqq T + m.$$

This is trivial for $m = 0$ by construction of T. Now assume that $(+)$ holds for m, and consider $(a_1, a_2) \in (\varphi^{m+1} \times \varphi^{m+2})[G_B]$, thus $a_p = \varphi(b_p)$ for some $(b_1, b_2) \in (\varphi^m \times \varphi^{m+1})[G_B]$, consequently

$$\begin{aligned} r^*(a_1 \triangle a_2) &= r^*(\varphi(b_1) \triangle \varphi(b_2)) \\ &> r^*(b_1 \triangle b_2) \\ &\geqq T + m. \end{aligned}$$

(2) In $(+)$ we may substitute $R_m(\varphi, G_B)$ for $(\varphi^m \times \varphi^{m+1})[G_B]$, since the former is the topological closure of the latter, and we can find for each element in $R_m(\varphi, G_B)$ a net in $(\varphi^m \times \varphi^{m+1})[G_B]$ converging to it. Hence Proposition 4.4 actually justifies the substitution.

(3) Since we may assume that $A = \{r \geqq t\}$ for some suitably chosen value t, Lemma 5.2 now follows from relation $(+)$. □

We are now in a position allowing us to formulate a fixed-point theorem adequate for the considered situation.

PROPOSITION 5.3. *Let $\varphi : \mathcal{J}_\sigma(D) \to \mathcal{J}_\sigma(D)$ be discerning. Then φ has a fixed point.*

Proof. (1) We infer from Lemma 5.2 that for any $x \in \mathcal{J}_\sigma(D)$ and for any $B \in \mathcal{A}$ there exists $m \in \mathbb{N}$ with

$$(\varphi^m(x), \varphi^{m+1}(x)) \in G_B,$$

thus condition (A-4) is satisfied. To establish the existence of a unique fixed point, it has to be shown that the condition (A-5) is satisfied, too. For this, let x and y be σ-ideals. Because $\mathcal{G}^*_{\mathcal{A}}$ is Hausdorff, we can find $C \in \mathcal{A}$ so that G_C does not contain the pair (x, y), and we may find $B \in \mathcal{A}$ with $(\varphi(x), y) \in G_B$. From Lemma 5.2 we see that eventually $R_m(\varphi, G_B) \subset G_C$ holds, so we find m such that

$$(\varphi^{m+1}(x), \varphi^{m+1}(y)) = (\varphi^m \times \varphi^{m+1})(\varphi(x), y) \in G_C,$$

thus condition (A-5) indeed holds.

(2) It remains to be shown that φ is a quasi contraction. Define for $U \in \mathcal{A}$ the map $F : \mathcal{A} \to \mathcal{A}$ by setting

$$F(U) := \{(\varphi(x), \varphi(y)); (x, y) \in U\}$$

then by construction $(\varphi(x), \varphi(y)) \in F(U)$ holds whenever $(x, y) \in U$. We have, however, to establish the properties (A-1) as well as (A-2). Since φ is discerning, we have for $A := \{r \geqq n\}$ the property

$$x^o \triangle y^o \subset A \quad \text{implies } \varphi(x)^o \triangle \varphi(y)^o \subset A,$$

which in turn establishes (A-1). In order to establish (A-2), we first observe that

$$F(U_1 \circ U_2) = F(U_1) \circ F(U_2);$$

hence F is a homomorphism with respect to composing relations. From this, (A-2) is easily inferred, since from what we have shown it is plain that

$$U^N \subset U$$

holds for each $U \in \mathscr{A}$. □

6. Discussion. So far we have demonstrated that the metric completeness result and the application of Banach's fixed-point theorem in [6] are special cases of a situation that may more generally be described by uniformities and by a fixed-point theorem due to Landes. The metric defined in [6] was defined using a rank function, and in turn the value of this function is determined by the construction of the special kind of domain that MacQueen, Plotkin, and Sethi use. This domain is constructed using a limiting process [6, § 2.3] in which an increasing sequence of approximating domains is built up. The rank of an element is then its height in that sequence.

The results proposed here suggest that one does not need to make use of this limiting process, but that rather intrinsic properties of the uniformity are sufficient for the constructions employed in [6] as far as the semantics of type expressions are concerned. We want to demonstrate this with a simple example; rather than going through the formalism of specifying a language with recursive types, we show how one of the central specific results in [6] may be obtained using the framework sketched in this note. For this, we assume that the domain D under consideration satisfies the domain equation

$$D = Y + D \times D$$

for some domain Y, where the equality actually is an order isomorphism. Thus $D^o = Y^o + D^o \times D^o$ holds, and we may identify $(s, t) \in \mathscr{I}_\sigma(D) \times \mathscr{I}_\sigma(D)$ with the σ-ideal $s \times t \subset D \times D$. We will consider the map induced by this identification; hence, the map

$$p: \begin{cases} \mathscr{I}_\sigma(D) \times \mathscr{I}_\sigma(D) \to \mathscr{I}_\sigma(D \times D) \\ (s, t) \qquad\qquad\quad \mapsto s \times t, \end{cases}$$

and show that this is a strong contraction for a wide class of uniformities $\mathscr{G}^*_{\mathscr{A}}$ on $\mathscr{I}_\sigma(D)$.

DEFINITION 6.1. Let $A \subset \mathscr{P}(D^o)$ be a filter basis, then

(a) $\mathscr{A}$ is *p-closed* iff $\forall A \in \mathscr{A}\ \forall t \in \mathscr{I}(D^o)$: $A \times t \cup t \times A \subset A$;

(b) $\mathscr{A}$ is *absorbing* iff $\forall s, t \in \mathscr{I}(D^o)\ \forall A \in \mathscr{A} \exists m \in \mathbb{N}$: $s^m \times t \cup t \times s^m \subset A$;

(c) $\mathscr{A}$ is *suitable* iff $\mathscr{A}$ is p-closed as well as absorbing.

Suppose for the moment that $\mathscr{A}$ is determined by a ranking function r which has the additional property that

$$r(a, b) > \max\{r(a), r(b)\}$$

holds, whenever $a, b \in D$; this is the case, e.g., in [6]. Hence,

$$\mathscr{A} = \{\{r \geqq n\}; \{r \geqq n\} \neq \varnothing, n \in \mathbb{N}\}$$

holds. It is immediate that $\mathscr{A}$ is suitable.

Now fix for the general case an absorbing filterbase $\mathscr{A}$. We will show now that p is a strong contraction for the uniformity $\mathscr{G}^*_{\mathscr{A}}$, where the attractor on $\mathscr{G}_{\mathscr{A}}$ is the identity. For the sake of not duplicating arguments, we will restrict our attention to $p_s = \lambda t \cdot p(s, t)$ for some arbitrarily chosen $s \in \mathscr{I}_\sigma(D)$. Since the conditions (A-1) and (A-2) are obvious for the identity on $\mathscr{G}_{\mathscr{A}}$, and since (A-3) holds because $\mathscr{A}$ is suitable, we will have to focus on the conditions (A-4) and (A-5). Since $\mathscr{A}$ is absorbing, we may find for $A \in \mathscr{A}$, $t \in \mathscr{I}_\sigma(D)$ an exponent m such that

$$(s^o)^m \times t^o \subset A.$$

Consequently,

$$(s^o)^m \times (s^o \triangle s^o \times t^o) \subset A,$$

which is equivalent to

$$(p_s^m(t), p_s^{m+1}(t)) \in G_A.$$

(Here we have used the identity

$$P \times (Q \triangle R) = (P \times Q) \triangle (P \times R),$$

which is easily established using the indicator function 1_M of a set M:

$$1_M(g) := \textit{if } g \in M \quad \textit{then } 1 \textit{ else } 0 \textit{ fi}$$

by observing the identities

$$1_{M \times N}(g, h) = 1_M(g) \cdot 1_N(h)$$

and

$$1_{M \triangle N}(g) = |1_M(g) - 1_M(h)|.$$

The argumentation above shows that p_s satisfies (A-4), and the identity

$$((s^o)^m \times t_1^o) \triangle ((s^o)^m \times t_2^o) = (s^o)^m \times (t_1^o \triangle t_2^o)$$

immediately yields condition (A-5).

Acknowledgment. Benno Fuchssteiner, Thomas Landes, and Marcel Erné provided some insight into fixed points. The referees' comments helped to clarify the presentation and to remove some obscure points.

THE DISTRIBUTED FIRING SQUAD PROBLEM*

BRIAN A. COAN†, DANNY DOLEV‡, CYNTHIA DWORK§¶, AND LARRY STOCKMEYER§

Abstract. The distributed firing squad problem is defined in the context of a synchronous distributed system where the correct processors operate in lock-step synchrony but do not share a global clock. If one or more correct processors receive a command to start a firing squad synchronization, then at some future time all correct processors must "fire" (formally, enter a special state) at exactly the same step. For various fault models, upper and lower bounds are proved on the number of faulty processors that can be tolerated and on the number of rounds of communication required between the reception of the start command and firing. For example, if a firing squad protocol is resilient to t fail-stop faults, then at least $t+1$ rounds are necessary and sufficient. For the case of Byzantine faults with authentication where the faulty processors can take steps in between the synchronous steps of the correct processors, the firing squad problem can be solved in $t+5$ rounds, provided that $n>3t$, where n is the number of processors and t is the number of faults, and the problem cannot be solved at all if $n \leqq 3t$. Moreover, in the case that $n \leqq 3t$, the impossibility of a firing squad protocol holds even for a weaker "timing fault model" where all processors generate messages correctly according to the protocol, but the faulty processors can affect the system by slightly slowing down or speeding up messages.

Key words. firing squad problem, Byzantine generals problem, synchronization, coordination, fault tolerance, distributed computing

1. Introduction.

Many fault-tolerant distributed algorithms assume a *synchronous system*, in which processing is divided into synchronous unison "steps" separated by rounds of message exchange (see, e.g., [11], [20], [25]). A message sent at step s from a correct processor p to a correct processor q is received by q at step $s+1$. This assumption is motivated by the impossibility results of [15] and [8], which show that if the system is asynchronous then there is no protocol for distributed agreement tolerant to even one benign processor failure. There are various ways to maintain synchronous steps in an unreliable distributed system. For example, one can have hardware that sends a periodic signal to all processors. Another common assumption is that all processors begin the algorithm simultaneously, i.e., at the same step. Typically, however, an algorithm is executed in response to a request from some specific processor that may in turn be responding to some external request. If the given processor is correct then all correct processors learn of the request simultaneously, so they can indeed begin the algorithm in unison. However, if the processor is faulty then the correct processors may learn of the request at different steps.

¶ This work was performed in part while the author was a Bantrell Postdoctoral Fellow at the Laboratory for Computer Science, Massachusetts Institute of Technology, Cambridge, Massachusetts.

In this paper we justify the design assumption of simultaneous starts. Specifically, we provide algorithms to solve the associated synchronization problem that we call the *distributed firing squad* problem. An algorithm for the distributed firing squad problem has two properties:

(1) If any correct processor receives a message to start a firing synchronization, then at some future time all correct processors will "fire" (formally, enter a special state); and

(2) The correct processors all fire at exactly the same step.

Our principal results, which are summarized in this Introduction, are for the case in which the processors, although operating in lock-step, are not assumed to share a common view of the current "global" time. We also present a simpler algorithm for the case in which such a common view is assumed.

The two complexity measures we study are *fault tolerance*, the maximum number of faulty processors that can be tolerated, and *time*, the maximum number of rounds of message exchange taken by the algorithm, starting with the step at which some correct processor receives a message to start a firing synchronization and ending with the step at which all correct processors fire. We are also interested in the *communication complexity* of an algorithm, that is, the total number of message bits sent by correct processors, but only to the extent of distinguishing polynomial from exponential communication complexity. Below, n denotes the number of processors in the system; t denotes the maximum number of faults that can be tolerated by a particular algorithm, and any such algorithm is said to be *t-resilient.*

In the case of fail-stop faults (the most benign type of fault usually studied, in which a faulty processor follows its algorithm correctly but simply stops at some point), it is easy to find a t-resilient distributed firing squad algorithm for any number $t \leqq n$ of faults that halts in $t+1$ rounds. This was observed independently by Burns and Lynch [3]. By reducing the Weak Byzantine Agreement (WBA) problem to the distributed firing squad problem, we can use a lower bound of Lamport and Fischer [18] on the time complexity of the WBA problem to show that any t-resilient algorithm for the distributed firing squad problem requires $t+1$ rounds for fail-stop faults, and therefore also for more malicious types of faults. Thus, the situation for fail-stop faults is well understood. Burns and Lynch [4] give a distributed firing squad algorithm for the case of Byzantine faults without authentication (the most serious type of fault usually studied, where faulty processors can exhibit arbitrary behavior); we say more about this case below. The main results in this paper concern Byzantine faults with authentication. Byzantine processors can exhibit arbitrary behavior, but we assume that every processor can sign messages in such a way that the signature of a correct processor cannot be forged by a faulty processor (see, e.g., [11]), and the signatures are common knowledge.

In trying to determine the maximum fault tolerance of the distributed firing squad problem in the authenticated Byzantine case, we found it necessary to distinguish between several types of faulty behavior, since these distinctions affect the fault tolerance. In *rushing*, a Byzantine faulty processor can receive, process, and resend messages "between" the synchronous steps of other processors. Figure 1(a) shows a normal communication round involving three correct processors A, B, and C, with A sending messages to B and C. Fig. 1(b) shows a similar round in which processor C is faulty, takes a step between the steps of the correct A and B, computes its response to the message it received from A, and then "rushes" this response to B in the same round. A special case of rushing is the *timing fault* model, where faulty processors never fail and always follow their algorithms correctly, but may take steps at irregular

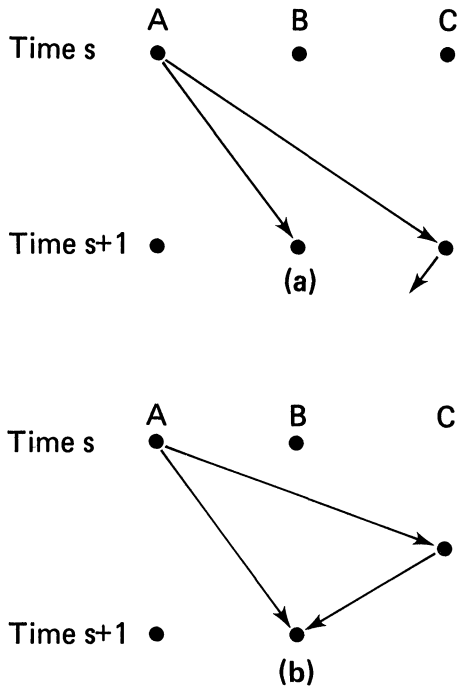

FIG. 1. (a) *A communication round with three correct processors. For simplicity, only the messages sent by A at time s are shown.* (b) *The processor C rushes.*

times and may experience slight delays or accelerations in communicating with the other processors. Rushing and timing faults are realistic types of faults whenever there is sufficient uncertainty in message transmission time. The length of a communication round must be chosen as large as the maximum possible transmission time between correct processors, but if a message happens to be delivered to a faulty processor in time less than this maximum, the faulty processor has the opportunity to rush.

We must also distinguish the case where faulty processors can sign messages using the signature functions of other faulty processors, which we call *collusion*, and the case where a faulty processor has only its own signature function. Collusion is unlikely to occur as a result of a random failure, but it could occur if the faulty processors were controlled by a malevolent intelligence that allowed faulty processors to share signature keys.

Table 1 summarizes our results and the results of [4] for the different fault models. Each entry gives $n_{\min}$, the smallest number n ($n \geqq 2$) of processors for which there exists a t-resilient distributed firing squad algorithm ($t \geqq 1$). Unless otherwise indicated, all algorithms require at most $t+c$ rounds, where $c \leqq 5$ is a constant independent of n and t, and the total number of bits of communication sent by correct processors is polynomial in n. In proving lower bounds on the minimum n, we make the usual assumption that the receiver of a message knows the identity of the sender; however, this assumption is not needed by our algorithms because the necessary deductions about the sender's identity can be made in the fault models we consider.

There are several interesting things to note about these results. First we should emphasize that the lower bound $n \geqq 3t+1$ holds for the timing fault model in which *all processors follow the algorithm correctly.* The only way faulty processors can affect the system is by taking steps at irregular times and unknowingly delaying and speeding up certain messages by small amounts. Second, even though our bounds on the

TABLE 1

Fault	$n_{\min}$ for t-resiliency	Remarks
fail-stop	t	1
Byzantine with authentication

collusion, no rushing	$5t/3 < n_{\min} \leqq 2t+1$	2
rushing, no collusion	$3t+1$	
rushing and collusion	$3t+1$	
timing faults	$3t+1$	
Byzantine without authentication	$3t+1$	3

Remarks. (1) *Due independently to Burns and Lynch* [3]. (2) *Lower bound* $5t/3 < n_{\min}$ *proved only for* $t \geqq 3$; *algorithm with* $2t+1$ *processors takes* $2t+1$ *rounds.* (3) *Algorithm due to Burns and Lynch* [4]; *algorithm uses either exponential communication or more than* $t+O(1)$ *rounds. Except as noted in* 2 *and* 3, *running time of all algorithms is* $t+c$, $c \leqq 5$, *and communication complexity is polynomial in n.*

minimum n in the case of collusion but no rushing are presently not tight, the bounds are sufficient to show that collusion does decrease fault tolerance when compared to the case of no collusion and no rushing, and rushing alone admits less fault tolerance than collusion alone. The distinction thus shown between these three fault models is (to us) an unexpected result of this work.

Burns and Lynch [4] solve the distributed firing squad problem in the unauthenticated Byzantine case essentially by adapting an agreement protocol. Since all known unauthenticated agreement protocols either use exponential communication, use more than $t+O(1)$ rounds, or require $n > 8t$ [2], [5], [9], [10], [20], [24], their distributed firing squad solution has the same property. Recently, Moses and Waarts [24] have devised a new unauthenticated agreement protocol; together with the work of Burns and Lynch, this gives an unauthenticated distributed firing squad protocol using polynomial communication, $n > 8t$ processors, and the optimal time $t+1$. By using signatures, we achieve polynomial communication, time $t+5$, and the maximum resiliency $t = \lfloor (n-1)/3 \rfloor$. Our lower bounds $n > 3t$ ($n > 5t/3$) for rushing (collusion) suggest that the approach of directly adapting agreement protocols to the distributed firing squad problem will not work in the authenticated case, since there are authenticated agreement protocols tolerant to any number of failures [11]. For the same reason, the distributed firing squad problem seems to be different from the clock synchronization problem studied in [16], [19], [21], [26], where the object is to bring the clocks of correct processors "close" together: in the authenticated Byzantine case, there is a clock synchronization algorithm tolerant to any number of failures [16]. Our problem is also different from the version of the firing squad problem that was proposed in the late 1950s [23]. That version of the problem was interesting because the processors were finite state machines which were connected in a linear array so each processor could count only to some fixed constant independent of n; however, faults were not considered. In our version of the problem, the difficulty arises not from limitations on the processors or communication network (we assume a completely connected system of powerful processors) but rather from the possibility of processor and timing faults.

In § 2 we give definitions. Section 3 contains results (firing squad algorithm and lower bound) for the case of no collusion and no rushing, § 4 gives results for rushing and timing faults, and § 5 considers the case of collusion but no rushing. In § 6 we mention some related results, such as the application of firing squad ideas to the

problem of Byzantine Agreement in the case that the processors do not all start at the same round, and results concerning the distributed firing squad problem where the processors share a common view of global time.

2. Definitions. For simplicity we give definitions for a single occurrence of a firing squad synchronization. Let $p_1, p_2, \cdots, p_n$ denote the processors in the system. For technical reasons we introduce another "processor" w, whose only purpose is to start a synchronization; w does not receive messages from the p_i's. In reality w might be another process running within one of the p_i. Formally a distributed firing squad algorithm is specified by an infinite set of messages M and for each processor p_i an infinite set of states Q_i, a state transition function σ_i, and a sending function β_i, where

$$\sigma_i : Q_i \times M^{n+1} \to Q_i,$$
$$\beta_i : Q_i \times M^{n+1} \to M^n.$$

The inputs to σ_i and β_i are the current state and an $(n+1)$-tuple of received messages, one from each processor $p_1, \cdots, p_n, w$. The function σ_i gives the new state, and β_i gives an n-tuple of messages $(m_1, \cdots, m_n)$ such that m_j is sent to p_j for each j. There are special messages $\varnothing$, the null message, and "Awake", the awake message, which is sent by w to start a synchronization. For each i there are states q_0 and q_f in Q_i, the *quiescent state* and the *firing state*, respectively, where $q_0 \neq q_f$. In addition,

$$\sigma_i(q_0, \varnothing, \cdots, \varnothing) = q_0,$$
$$\beta_i(q_0, \varnothing, \cdots, \varnothing) = (\varnothing, \cdots, \varnothing).$$

We introduce the concept of *global time* as an expositional convenience. The individual processors have no knowledge of global time. We assume that processors take steps at global times specified by nonnegative real numbers. A *run* is specified by giving, for each processor $p_1, \cdots, p_n$, w (including both correct and faulty processors), a list of nonnegative real numbers that specifies the times at which the processor takes steps. A message sent from a processor p to a processor q at time s is received by q at time s', where s' is the smallest $s' > s$ such that q takes a step at s'. (If q receives more than one message from some p at some step, then the message sent at the latest time is used by the transition functions; since this occurs only if either p or q is faulty, this convention is not critical.) Whenever w takes a step, it sends the awake message to some (possibly empty) subset of the p_i's and it sends the null message to the rest.

A processor p_i is *correct* in a run R if

(1) p_i takes its first step at time 0 in state q_0 receiving messages $(\varnothing, \varnothing, \cdots, \varnothing)$, and thereafter takes steps at successive integer times 1, 2, 3, $\cdots$;

(2) p_i executes its algorithm (transition functions) correctly; and

(3) if authentication is assumed (see below), then no other processor p_j signs any message using the signature function of p_i.

A run R is *active* if some correct processor receives a non-null message at some step; define $awake(R)$ to be the earliest such time (necessarily integer). If a correct p_i receives a non-null message for the first time at time s, we say that p_i *awakens* at time s. Define $fire_i(R)$ to be the time of the first step in R during which p_i makes a transition into state q_f (undefined if p_i does not enter q_f).

A distributed firing squad algorithm is *t-resilient* with respect to a given type of faulty behavior if for any active run R in which at most t of the processors $p_1, \cdots, p_n$ are faulty and in which the faulty processors conform to the given type of faulty behavior, there is a (necessarily integer) time $fire(R) \geqq awake(R)$ such that $fire_i(R) = fire(R)$ for all i such that p_i is correct in R. The *time complexity* of the algorithm is

the maximum of $fire(R) - awake(R)$ over all such runs R. (Note that w is not counted among the t faulty processors no matter how it behaves.)

Since the definitions above consider a processor to be faulty throughout a run if it fails at any time in the run, the definitions would seem to allow a scenario S where some processor p_i first fails after time $fire(R)$; thus, the definitions do not require p_i to fire with the other processors even though it is actually "correct" throughout execution of the algorithm. It is sufficient to note, however, that any such scenario can be modified to a scenario S', where p_i is correct throughout the entire (infinite) run, and all processors behave exactly as they do in S from time 0 through time $fire(R)$. In the modified S', p_i violates the definition of correctness. We find it convenient, both for definitions and for proofs of correctness, to consider a processor to be either correct or faulty throughout an entire run rather than to define the first time when a faulty processor actually exhibits faulty behavior.

We now define various types of faulty behavior. A faulty processor p_i is *fail-stop* if it operates as a correct processor up to some time s, at time s some nonempty subset of the messages p_i is supposed to send are replaced by null messages, and for all subsequent steps p_i sends only null messages. A processor is *Byzantine* if its behavior can deviate in any way from the behavior specified by its transition functions. A special case of Byzantine faultiness is Byzantine faults with authentication, where each processor p can sign messages using a private signature function E_p in such a way that the signature of a correct processor cannot be forged by any other processor. In this case, if processor q receives a message $E_p(m)$ from a third processor r, then q knows that if p is correct then p actually sent the message $E_p(m)$ at some previous time. We also let E_i denote the signature function of processor p_i. A Byzantine faulty processor *rushes* if it takes some step at a noninteger time. In this case, messages to and from faulty processors may take less than one round to be delivered. Faulty processors p and q *collude* if p signs a message using the signature function of q. In this case q is considered faulty, even though the messages it sends may be correct.

Finally we define the *timing fault model.* Runs in this model have the following properties:

(1) all processors execute the algorithm correctly;

(2) correct processors take steps at times $0, 1, 2, \cdots$;

(3) faulty processors take steps at times $\frac{1}{2}, \frac{3}{2}, \frac{5}{2}, \cdots$;

(4) messages between two correct processors or between two faulty processors take one unit of time to be delivered; and

(5) messages between a correct and a faulty processor take either $\frac{1}{2}$ unit of time or $\frac{3}{2}$ units of time to be delivered.

It is not hard to see that the timing fault model is a special case of authenticated Byzantine faultiness with rushing (but no collusion). The model with rushing can simulate a delivery time of $\frac{3}{2}$ simply by having a Byzantine processor either delay sending or delay receiving the message. For example, if in the timing fault model the faulty processor p sends a message m at time $\frac{3}{2}$ which the correct q should receive at time 3, then in the model with rushing the (now Byzantine) p simply holds m and sends it to q at time $\frac{5}{2}$. Therefore, giving an algorithm for the model with rushing yields a result for both models, as does proving a lower bound on n for the timing fault model.

The *communication complexity* of an algorithm is the maximum total number of message bits sent by correct processors, between the time when a correct processor first awakens and the time when all correct processors fire. The communication complexity is expressed as a function of n. Of course, there is no way to bound the number of bits sent by Byzantine faulty processors. For each of our algorithms it is

easy to see that exceedingly long messages sent by faulty processors never cause a correct processor to send exceedingly long messages. This is true because each correct processor has, at each step of the algorithm, a bound on the length of messages it expects to receive. Once the length of a message exceeds that bound, the message can be ignored.

As the firing squad problem is defined above, any single Byzantine faulty processor can initiate a firing synchronization. One way to limit the ability of faulty processors to start extraneous synchronizations in models with authentication is to have w sign the awake message with its own unforgeable signature. A correct processor considers as null any received message that does not contain w's signature. The necessary changes to our algorithms are trivial (in algorithms that count the number of signatures on a message, the signature of w is not counted). This still allows a faulty w to start extraneous synchronizations, but this is unavoidable in any model where we allow a single processor or an external agent to start a synchronization.

Processors as defined above are deterministic. Coan and Dwork [6] have studied probabilistic protocols for firing squad synchronization and have found that probabilistic protocols are essentially no better than deterministic ones for the firing squad problem.

3. No rushing and no collusion.

3.1. Upper bound. We begin with a simple algorithm that tolerates any number of fail-stop or authenticated Byzantine faults. It does not tolerate rushing, timing faults, or collusion. This algorithm was discovered independently by Burns and Lynch [3]. The basic idea is that since any processor, faulty or otherwise, can add at most one signature per round, we can use the number of signatures on a message as a clock, giving a lower bound on the time elapsed since the protocol was initiated. A correct processor fires as soon as it knows that at least $t+1$ rounds have elapsed. The details of the algorithm and its proof of correctness are similar to those of the Dolev–Strong algorithm for authenticated Byzantine agreement [11].

THEOREM 3.1. *In the model with authenticated Byzantine failures (but no rushing or collusion) there is a t-resilient distributed firing squad algorithm for any number $n \geqq t$ of processors. The algorithm has time complexity of $t+1$ rounds, and it uses an amount of communication polynomial in n.*

Proof. Each processor p participating in the protocol has a private clock c_p that is completely under the control of p. Initially, $c_p = -1$. A message m is *proper* if it has the form

$$m = E_{i_1}(E_{i_2}(\cdots E_{i_k}(\text{Awake})\cdots))$$

where E_{i_j} is the signature function of p_{i_j}, and the k signatures are by distinct processors. The *length* of the proper message m, denoted $|m|$, is the number of signatures appearing in m (i.e., k above). The awake message has length 0. A proper message m is *acceptable* to p if and only if $|m| > c_p$. A proper message m is *new* to p if and only if p's signature does not appear in m.

Upon first awakening, p sets its clock to $|m|$, where m is any acceptable message of maximum length received by p. If $c_p = t+1$, then p fires; otherwise, p signs m and broadcasts the result $E_p(m)$. If all messages received by p in this first step are unacceptable, then p sets its clock to 0 and broadcasts $E_p(\text{Awake})$.

At each subsequent step, if p receives any acceptable message, p arbitrarily chooses one such message m of maximum length and sets c_p to $|m|$. If $c_p \geqq t+1$, then p fires; if $c_p < t+1$ and m is new to p, then p signs m and broadcasts the result $E_p(m)$. If no acceptable message is received, p increments c_p by one. Again, if $c_p \geqq t+1$ then p fires.

This completes the description of the protocol for a correct p.

LEMMA 3.1.1. *For all k with $k \geqq 0$ and for any message m, at least k rounds are required to add k distinct signatures to m.*

Proof. Each processor knows at most one signature function and there is no rushing. □

LEMMA 3.1.2. *In any execution of the protocol resulting in a firing, all correct processors fire simultaneously.*

Proof. Let r be the earliest step at which some correct processor fires, and let p be a correct processor that fires at step r. We will show that for all correct processors q, $c_q \geqq t+1$ by the end of step r, so q fires at r.

There are two cases to consider, according to whether or not p receives an acceptable message at step r. If p receives an acceptable message m at step r, then m has at least $t+1$ signatures. Without loss of generality, let $m = E_k(E_{k-1}(\cdots E_1(\text{Awake})\cdots))$, where $k = |m| \geqq t+1$. Clearly, if p_k is correct then all correct processors receive m at r, and so all correct clocks have value at least $t+1$ by the end of step r. If p_k is faulty, then let p_i be the last correct processor whose signature appears in a substring $m_i = E_i(\cdots E_1(\text{Awake})\cdots)$ of m, and let $s-1$ be the step at which m_i is sent by p_i. By Lemma 3.1.1 at most one signature can be added to m_i in each step, so $r - s \geqq |m| - |m_i|$. Furthermore, since p_i is correct, the clocks of all correct processors have value at least $|m_i|$ by the end of step s. Since the clock of a correct processor is incremented by at least 1 at each step, by the end of step r the clocks of all correct processors will have value at least

$$|m_i| + (r-s) \geqq |m_i| + (|m| - |m_i|) = |m| \geqq t+1$$

so all correct processors will fire at step r.

In the second case where p receives no acceptable message at step r, let i be such that step $r-i$ is the last step at which p broadcasts. (Since this happens when p first awakens, i is well defined.) Let $E_p(m)$ be the message broadcast by p at $r-i$. Since this message has length $|m|+1$ and since all correct processors receive this message at step $r-i+1$, by the end of step $r-i+1$ all correct processors have clock value at least $|m|+1$. Therefore, the clocks of all correct processors have value at least $|m|+i$ by the end of step r. We now want to argue that p increments its clock by exactly 1 at each step j with $r-i+1 \leqq j \leqq r$. Suppose otherwise that p increments its clock by more than 1 at step j, and let m' be the acceptable message received at step j which causes this increment. Since p receives no acceptable message at step r, we must have $j < r$. If m' is not new to p at step j, then using Lemma 3.1.1 as in the preceding paragraph, it is easy to show that m' could not cause p to increment its clock by more than 1. If m' is new to p, then by definition of the algorithm p would broadcast at step j, contradicting the choice of i. Therefore, such a j and m' cannot exist. Having bounded p's clock increment at each step j with $r-i+1 \leqq j \leqq r$, it follows that $c_p = |m|+i$ at the end of step r. Since p fires at r, we have $|m|+i \geqq t+1$. Thus all correct processors fire at step r. □

LEMMA 3.1.3. *Let R be any active run and let s be the earliest time when some correct processor p awakens in R. Then p fires at time $s+t+1$ or earlier.*

Proof. Upon awakening, p sets its clock to some value $c_p \geqq 0$. At every step c_p is incremented by at least one, and p fires when $c_p \geqq t+1$. □

It is now easy to complete the proof of Theorem 3.1. By Lemma 3.1.3, if any correct processor awakens there is a firing, and by Lemma 3.1.2 all correct processors fire simultaneously. Lemma 3.1.3 also implies that the time complexity of the algorithm

is at most $t+1$ rounds. Furthermore, at each step each correct processor broadcasts at most one message. Since this message is proper, it requires only polynomial in n bits. Thus the communication required is polynomial in n. □

Obviously, the algorithm of Theorem 3.1 also works for fail-stop faults: instead of signing a message m with the signature function E_p, the processor p simply attaches its name to m.

3.2. Lower bound. We now show that the time complexity of this algorithm is optimal by reducing the Weak Byzantine Agreement problem (WBA) [17] to the distributed firing squad problem. Optimality follows from the fact that WBA requires at least $t+1$ rounds [18].

In the WBA problem, all processors start the algorithm at the same global time (say, time 0), and each processor has a binary initial value. By maintaining a counter, all correct processors have a common notion of global time. A protocol solves WBA if (1) every correct processor eventually reaches a decision; (2) no two correct processors reach different decisions; and (3) if all initial values are the same, say v, and there are no failures, then v is the value decided. The following result shows that WBA reduces to distributed firing squad at no cost in running time.

THEOREM 3.2. *Let A be a distributed firing squad algorithm that is t-resilient to fail-stop faults (respectively, unauthenticated Byzantine faults) and that requires k rounds between awakening and firing in the execution in which all the processors awaken simultaneously and no failure occurs (note that k is unique since the system is completely deterministic in this case). Then there exists an algorithm for* WBA *that is t-resilient to fail-stop faults (respectively, unauthenticated Byzantine faults) and that always halts in k rounds.*

Proof. Consider an instance of WBA in which processor p_i has initial value v_i. If $v_i = 0$, then p_i begins simulating A at time 0. That is, p_i acts as if it received the awake message from w and null messages from the rest. If $v_i = 1$, then p_i begins simulating A at time 1. That is, p_i sends null messages during the first round and acts as though it received the awake message from w at time 1 (p_i could receive non-null messages from other processors at time 1 in this case if other processors had initial value 0). If the simulation of A causes p_i to fire at time k or earlier, then p_i decides 0 at time k; otherwise, p_i decides 1 at time k.

Correctness of A immediately implies that all correct processors decide on the same value, since either all correct processors simulate a firing at a time $\leqq k$ or none do. If all processors begin with value 0 and there are no failures, then by choice of k each processor will simulate a firing at time k, so the decision will be 0. However, if all begin with 1 and there are no failures, then all processors will simulate a firing at time $k+1$, so the decision will be 1. □

COROLLARY 3.3. (1) *Let $t \leqq n-2$. Any distributed firing squad algorithm resilient to t fail-stop faults requires at least $t+1$ rounds. Moreover, this is true even if the order in which processors are sent to in a round is fixed a priori. It is also true even in all executions in which all processors are correct.*

(2) *Any distributed firing squad algorithm resilient to t unauthenticated Byzantine faults requires at least $3t+1$ processors.*

Proof. The proof is immediate from the preceding theorem and the corresponding bounds for WBA [13], [14], [17], [18], [22]. □

Remark. To close the gap between Theorem 3.1 and Corollary 3.3(1) for $n-1 \leqq t \leqq n$, note that if we take $t = n-2$ in the algorithm of Theorem 3.1, then the algorithm is in fact n-resilient. If there is only one correct processor p, then p will fire within $t+1$

$(=n-1)$ steps after awakening, since c_p is incremented by at least 1 at each step. If there are no correct processors, then there is nothing to prove.

In the next section the lower bound of Corollary 3.3(2) is strengthened to hold in the model with authentication and rushing.

4. Rushing and timing faults.

4.1. Upper bound. This section contains tight bounds on fault tolerance for timing faults and authenticated Byzantine faults with rushing. The following result gives the principal algorithm of the paper.

THEOREM 4.1. *In the model with Byzantine failures and authentication, in which faulty processors can both rush and collude, there is a t-resilient distributed firing squad algorithm requiring* $t+5$ *rounds,* $n \geq 3t+1$ *processors, and communication polynomial in n.*

Before giving the details of the algorithm and its proof of correctness, we begin with an informal discussion of the principal ideas. Our protocol is composed of a set of identical subprotocols executed independently and in parallel. A processor initiates a subprotocol by broadcasting its signature. Let p be an arbitrary (possibly faulty) initiator, and consider a set of processors all receiving p's signature at the same step. In some sense these processors are synchronized, in that they share a common idea of when they first heard from p, although no processor in the set knows which other processors are in the set. If the set of synchronized processors is sufficiently large, then *because they are synchronized* these processors can run an agreement protocol similar to the Dolev and Strong protocol [11] that assumes synchronous start. The processors are essentially agreeing on the members of the set. If the agreed upon set is sufficiently large, then correct processors will order a firing. In particular, a correct processor in the set orders a firing only if there are at least $n-t \geq 2t+1$ processors in the agreed upon set. Of these, at least $t+1$ are correct, synchronized processors. Thus a correct processor orders a firing only if at least $t+1$ correct processors do so simultaneously. Now, consider a processor q receiving at least $t+1$ commands to fire. Since q knows at least one of these messages is from a correct processor, it knows at least $t+1$ are. Thus q knows that every processor receives at least $t+1$ commands to fire, and therefore that every processor knows every processor has received these commands, and so on. In short, it becomes *common knowledge* that every processor has received $t+1$ commands to fire, so it is safe to fire.

Proof of Theorem 4.1. As stated above, the protocol is composed of a set of identical subprotocols executed independently and in parallel. Specifically, as each correct processor awakens it initiates a *core protocol.* If the core protocol is successfully completed, then the correct processors fire upon completion. An execution of the core protocol initiated by a correct processor will complete successfully, unless a firing occurs earlier due to the completion of a different execution of the core protocol. An execution of the core protocol initiated by a faulty processor may not cause a firing, but if it does then all correct processors fire simultaneously. (Thus, it would be sufficient to have any $t+1$ processors initiate the core protocol.) In the following, if a correct processor receives the same message at different times, all receptions but the first are ignored; this prevents a faulty processor from doing any damage by taking a message that was broadcast by a correct processor and resending it at a later time.

A processor p initiates a core protocol by broadcasting its signature, $E_p(p)$. Each processor (including p itself) that receives $E_p(p)$ signs it and broadcasts it. Each processor q then attempts to form a *core for p,* that is, a list of the form

$$\langle E_{i_1}(E_p(p)), \cdots, E_{i_k}(E_p(p))\rangle$$

where $k \geqq n-t$ and each of the k copies of $E_p(p)$ is signed by a distinct processor. The signatures $E_{i_1}, \cdots, E_{i_k}$ *belong* to the core, and the core *contains* these signatures. Intuitively, a core is a set of processors which claim to have received $E_p(p)$ at the same time.

A *notarized core for p* is a list of the form

$$\langle E_{i_1}(C_1), \cdots, E_{i_k}(C_k)\rangle$$

where $k \geqq n-t$ and the C's are (possibly different) cores for p, each signed by a distinct processor.

We now describe how a processor q participates in the core protocol initiated by p. (Processor p participates in the core protocol initiated by itself.) Let s be the global time when q receives $E_p(p)$. Then q tries to form a core for p at time $s+1$. This is done by looking for a set of messages $\{E_{i_1}(E_p(p)), \cdots, E_{i_k}(E_p(p))\}$ received at time $s+1$ where $k \geqq n-t$ and where each of the k copies of $E_p(p)$ is signed by a distinct processor. This is the only time at which q tries to form a core for p, and q includes in the core only messages received at time $s+1$. If q forms a core then q includes in the core all messages of the form signature$(E_p(p))$ received at time $s+1$. If a core is formed, q signs it and broadcasts it. Processor q also tries to form a notarized core for p at time $s+2$. This is the only time when q tries to form a notarized core for p. A notarized core, if formed, contains all messages of the form signature(core for p) received at time $s+2$. If a notarized core N is formed by q at this step, then N is considered to have been "received" at this step. Starting with the second step after $E_p(p)$ was received, each correct processor q does the following (regardless of whether or not q formed a core for p or a notarized core for p).

If q receives message m, q checks if m is *acceptable* in the following sense:

(1) $m = E_{j_1}(E_{j_2}(\cdots E_{j_k}(N)\cdots))$, where N is a notarized core for p and each of the k signatures ($k \geqq 0$) is distinct (m is said to have *length* k, denoted $|m|$);

(2) q's signature belongs to at least $n-2t$ of the cores in N (we say that q *supports* N); and

(3) q first received $E_p(p)$ $k+2$ steps back (this condition implies that at any given step of q, messages of only one particular length are acceptable).

An acceptable message m as in (1) is *new* to q if none of the signatures $E_{j_1}, E_{j_2}, \cdots, E_{j_k}$ is by q. If q finds one or more messages of length k that are new and acceptable, q chooses one such message m arbitrarily and broadcasts $E_q(m)$, ignoring the rest. Finally, if q receives an acceptable message m of length $t+1$, then q signs and broadcasts "fire$_p$". A correct processor fires at step f if and only if at step f it receives at least $t+1$ commands "fire$_p$" signed by different processors.

Lemmas 4.1.1–4.1.4 show that the core protocol causes a firing if the initiator is correct. For these lemmas, let p be a correct processor initiating a core protocol at time r.

LEMMA 4.1.1. *At time $r+2$ all correct processors can form a core for p containing the signature of every correct processor, and at time $r+3$ all correct processors can form a notarized core for p.*

Proof. Since p is correct, all correct processors receive $E_p(p)$ at time $r+1$. All correct processors q broadcast $E_q(E_p(p))$ at time $r+1$, and these messages are received at time $r+2$. Since there are at least $n-t$ correct processors, every processor receives at least $n-t$ messages of the form $E_q(E_p(p))$ signed by distinct processors. Thus all correct processors can form a core at time $r+2$. Furthermore, since a correct processor puts all messages $E_i(E_p(p))$ received into the core, for every correct processor q the message $E_q(E_p(p))$ appears in the cores formed by the correct processors.

A similar argument shows that every correct processor can form a notarized core for p at time $r+3$. □

LEMMA 4.1.2. *Let N be any notarized core for p. Then every correct processor q supports N.*

Proof. A notarized core contains at least $n-t$ cores, each signed by distinct processors, so at least $n-2t$ of the cores contained in N were formed by correct processors. By Lemma 4.1.1 all these $n-2t$ cores contain the signature of every correct processor. □

LEMMA 4.1.3. *For all i, $0 \leqq i \leqq t$, at time $r+3+i$ at least one correct processor receives a new acceptable message of length i.*

Proof. The proof is by induction on i.

Basis $i=0$. By the previous two lemmas every correct processor forms a notarized core which it supports at time $r+3$. By convention, this notarized core is a new acceptable message "received" at time $r+3$.

Assume the lemma is true inductively for $i-1$ ($i \geqq 1$). Thus at time $r+3+(i-1) = r+i+2$ some correct processor receives a new acceptable message of length $i-1$. It signs this message and broadcasts the resulting message m of length i with notarized core N. The message m is received at time $r+i+3$ by all correct processors. Since there are $n-t \geqq 2t+1$ correct processors, at most t of which have signed m, and since by Lemma 4.1.2 every correct processor supports N, m is acceptable to some correct processor that has not yet signed it, so the induction holds. □

LEMMA 4.1.4. *If a correct processor p initiates a core protocol at time r, then the core protocol runs to completion and the correct processors fire at time $r+t+5$.*

Proof. By Lemma 4.1.3, at time $r+3+t$ at least one correct processor receives a new acceptable message m. Thus by time $r+4+t$ every correct processor receives an acceptable message of length $t+1$, so all correct processors broadcast "fire$_p$". Since there are at least $n-t > t+1$ correct processors, every processor receives at least $t+1$ commands to fire at time $r+5+t$, so a firing will indeed take place at time $r+5+t$. □

We now show that for an arbitrary initiator p, the core protocol never causes two correct processors to fire at different times. Let p be a possibly faulty processor initiating a core protocol. If S is a set of processors, we say that *S forms a core for p* if any processor in S forms a core for p. A *group* is a maximal set of correct processors receiving $E_p(p)$ at the same time. Let G be a group and let s be the time at which the members of G receive $E_p(p)$. Let H be the set of correct processors not in G.

LEMMA 4.1.5. *If G forms a core for p, then H does not form a core for p.*

Proof. First we observe that if G forms a core, then the core contains no signatures of processors in H. Similarly, no signature of a processor in G is contained in a core formed by any processor in H.

If G forms a core for p, then there exists some g in G that received at least $n-t$ messages of the form $E_q(E_p(p))$ at time $s+1$. Since none of those messages were sent by processors in H, we have $|H| \leqq t$. Thus even if the processors in H form a group and t faulty processors cooperate in helping H to form a core, the total number of cooperating processors is $2t < n-t$, so H cannot form a core. □

LEMMA 4.1.6. *If G forms a core for p and if any processor forms a notarized core N for p, then every processor in G supports N.*

Proof. Every notarized core N contains at least $n-t$ cores, at least $n-2t$ of which were formed by correct processors. Since no processor in H forms a core at least $n-2t$ of the cores in N were formed by processors in G and therefore contain all the signatures of all the processors in G. □

LEMMA 4.1.7. *Let N be a notarized core for p. If some g in G supports N then*
(1) *all processors in G support N, and*
(2) *no processor in H supports N.*

Proof. We will show that if g belongs to $n-2t$ of the cores in N, then G forms a core for p. It follows by Lemma 4.1.6 that every processor in G supports N. This will give us (1). Furthermore, by Lemma 4.1.5 if G forms a core, then H does not. Since neither processors in G nor in H form cores containing signatures of processors in H, the only cores that contain processors in H are formed by faulty processors. Thus, there can be at most $t < n-2t$ of them, so we have (2).

It remains to show that if g belongs to at least $n-2t > t$ of the cores in N, then G forms a core. This is immediate from the fact that no processor in H forms a core containing elements of G. Thus, if g appears in more than t cores, at least one of these was formed by some processor in G. □

LEMMA 4.1.8. *If any processor in G ever finds a message acceptable, then G contains at least $n-2t$ processors.*

Proof. Let m be acceptable to some g in G and let N be the notarized core of m. Of the $n-2t \geqq t+1$ cores in N containing g, at least one is signed by a correct processor. Let q be such a correct processor and let C be the core in N signed by q; i.e., $E_q(C)$ has the form

$$E_q(C) = E_q(\langle \cdots, E_g(E_p(p)), \cdots \rangle).$$

Of the $n-t$ processors whose signatures belong to C, at least $n-2t$ are correct. These $n-2t$ correct processors (one of which is g) all wrote to q at the same time, indicating that they received $E_p(p)$ at that time. Since no processor in H received $E_p(p)$ at the same time as g, no processor in H belongs to C. Since the correct processors are in either G or H, it follows that G contains at least $n-2t$ processors. □

LEMMA 4.1.9. *Let m be a message that is new and acceptable to processor g in group G at time z. Then $E_g(m)$ is acceptable to all processors in G at time $z+1$.*

Proof. Let N be the notarized core of m. One of the conditions of acceptability is that g supports N. By Lemma 4.1.7, every processor in G supports N. By condition (3) of acceptability, g first received $E_p(p)$ at time $z-|m|-2$, as did all other processors in G (by definition of a group), so every processor in G first received $E_p(p)$ at time $(z+1)-|E_g(m)|-2$. Thus every processor in G finds $E_g(m)$ acceptable at time $z+1$. □

LEMMA 4.1.10. *Let f be the earliest time at which some correct processor q fires (as a result of the core protocol initiated by p). Then all correct processors fire at time f.*

Proof. Since q fires only if it simultaneously receives at least $t+1$ messages "fire$_p$", some correct processor g sent "fire$_p$" at time $f-1$. Therefore, g received an acceptable message m of length $t+1$ at time $f-1$. Let G be the group of g. Without loss of generality, let

$$m = E_{t+1}(E_t(\cdots E_1(N)\cdots)).$$

Let $c = p_j$ be a correct processor among the $t+1$ processors that signed N. Let

$$m' = E_{j-1}(\cdots E_1(N)\cdots).$$

Since c finds m' acceptable, c supports N. Since g finds m acceptable, g supports N. It follows from Lemma 4.1.7(2) that c belongs to G. Let z be the time when c receives m'. By Lemma 4.1.9, all processors in G find $E_c(m')$ acceptable at time $z+1$. Furthermore, by Lemma 4.1.8, G contains at least $n-2t \geqq t+1$ processors, so there will be

some processor in G that has not yet signed N, provided $|E_c(m')| \leqq t$. By repeated application of Lemmas 4.1.9 and 4.1.8, all processors in G receive an acceptable message of length $t+1$ at time $f-1$, so they all broadcast "fire$_p$" at time $f-1$. Recall that G contains at least $t+1$ processors. It follows from the definition of the core protocol that all correct processors fire at time f. □

The proof of Theorem 4.1 follows directly from Lemmas 4.1.4 and 4.1.10. It is clear from the definition of the protocol that the number of bits of communication is polynomial in n. □

4.2. Lower bound. We next give a matching lower bound, $n \geqq 3t+1$, for the timing fault model. As noted in § 2, the lower bound of Theorem 4.2 holds also for the fault model of Theorem 4.1 (even without collusion).

THEOREM 4.2. *In the timing fault model there is a t-resilient distributed firing squad algorithm only if* $n \geqq 3t+1$.

Proof. Consider first the proof that there is no algorithm for $t=1$ and $n=3$. We consider four scenarios with three processors, A, B, and C, in each. Processor C is faulty in Scenarios 1 and 4, B is faulty in Scenario 2, and A is faulty in Scenario 3. It is possible to fix the wake-up times and the message transmission times (see Fig. 2) so that the following lemmas hold.

LEMMA 4.2.1. *If A fires at time z in Scenario* 1, *then A fires at time $z+1$ in Scenario* 4.

Proof. This follows since Scenarios 1 and 4 are identical except that all processors wake up exactly one time unit later in Scenario 4. □

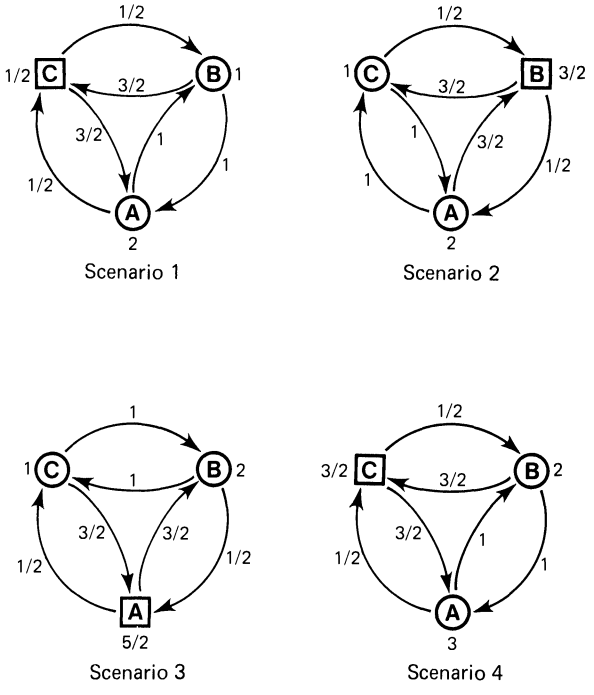

FIG. 2. *The scenarios used to prove Theorem* 4.2. *The number on the edge directed from processor X to processor Y is the message transmission time from X to Y. The number written next to processor X is the time when processor X wakes up. Correct (faulty) processors are drawn as circles (squares).*

For the next lemma it is convenient to introduce the "local step number" of a processor. A processor executes its first local step at the time it wakes up, and the local step number is incremented by one at each subsequent step. For example, in Scenario 1 in Fig. 2, A is executing its first step at global time 2, whereas B is executing its second step at global time 2. Letting p denote a processor, two scenarios are *p-equivalent* if the message history of p, i.e., messages received and messages sent at each local step of p, are the same in the two scenarios. Two scenarios are *strongly p-equivalent* if they are p-equivalent and p wakes up at the same global time in both scenarios.

LEMMA 4.2.2. *For $i=1,2,3$, Scenarios i and $i+1$ are strongly p-equivalent where p is the processor that is correct in both scenarios.*

Proof. By inspection of the scenarios in Fig. 2, one can easily verify that the following two facts hold for all four scenarios and for all integers $s \geqq 1$:

(1) for all messages sent from A to B, from B to C, or from A to C, the message sent at local step s of the sender is received at local step $s+2$ of the receiver; and

(2) for all messages sent from B to A, from C to B, or from C to A, the message sent at local step s of the sender is received at local step s of the receiver.

It follows easily from these facts (formally by induction on the local step number) that any two scenarios are p-equivalent where p is any of the three processors. The lemma then follows immediately from the choice of the wake-up times. □

These lemmas easily give a contradiction. Say that A fires at time z in Scenario 1. By strong A-equivalence of Scenarios 1 and 2, A fires at time z in Scenario 2. Since A and C are correct in Scenario 2, C also fires at z in Scenario 2. By a similar argument, B fires at z in Scenario 3, and A fires at z in Scenario 4, which contradicts Lemma 4.2.1.

The impossibility proof for general n and t with $n \leqq 3t$ is done as usual (cf. [25]) by replacing each processor by a group of at least one and at most t processors. The intragroup transmission times are all 1. The intergroup transmission times and the wake-up times are chosen as in Fig. 2. This completes the proof of Theorem 4.2. □

5. Collusion.

5.1. Upper bound. In this section we examine the distributed firing squad problem in the authenticated Byzantine model, in which faulty processors may share signature functions but they cannot rush messages.

THEOREM 5.1. *In the model with Byzantine failures and authentication where faulty processors can collude but cannot rush, there exists a t-resilient distributed firing squad algorithm requiring $n \geqq 2t+1$ processors, $2t+1$ rounds, and an amount of communication polynomial in n.*

We describe the main ideas informally before giving the formal proof. As in the other protocols, correct processors attempt to build messages signed by several processors and to use the length of these messages to synchronize. Since faulty processors can add several signatures at a given step, we wish to obtain a sort of "notarization" for each signature in a string of signatures guaranteeing that a specific amount of time was spent adding the signature.

In the straightforward approach, a processor p requests notarization of a signed message $E_p(m)$ by broadcasting $E_p(m)$. Then all processors attempt to obtain at least $t+1$ acknowledgments of the form $E_q(E_p(m))$. The list

$$m' = \langle E_{q_1}(E_p(m)), \cdots, E_{q_{t+1}}(E_p(m)) \rangle$$

is the notarization of $E_p(m)$. If the length of a message is the number of notarizations

it has undergone, then a message of length k requires exactly $2k$ steps to be constructed, even if the k signers of the message are faulty. Although conceptually simple, this approach leads to an algorithm with communication complexity exponential in t, since each notarization increases the size of a message by at least the factor $t+1$. Our algorithm uses the idea of notarization with an implementation that is harder to prove correct but that requires communication only polynomial in n. The basic idea is as follows. Suppose that p has received a notarized message m in the form of at least $t+1$ signatures of m by distinct processors. Then p "requests support" of $E_p(m)$ by broadcasting $E_p(m)$ together with a "proof" that m was notarized. This proof consists of $t+1$ signatures of m by distinct processors. Any correct processor q receiving $E_p(m)$, together with such a proof, "supports" $E_p(m)$ by signing $E_p(m)$ and broadcasting the result. The key fact is that the proof that m was notarized can be thrown away by q at this point, so message length does not grow exponentially. The idea of notarization and its implementation below is similar to the fault-tolerant distributed clocks described in [1], [12]. Similar ideas were also used in [27].

Proof of Theorem 5.1. We first define certain types of messages. A *proper* message has the form

$$E_{i_1}(E_{i_2}(\cdots E_{i_k}(p_{i_k})\cdots))$$

where the k signatures are by distinct processors. Such a message is called an α_k*-message.*

At various times in the protocol, processors may request support for a message m. A processor p *supports* m by sending a *support message* of the form $E_p(\text{support } m)$. We let $S(m)$ denote a support message for m.

A *proof* of a message m is a list of $t+1$ support messages for m, each signed by a distinct processor. We let $P(m)$ denote a proof for message m.

A processor p *requests support* for a message $E_p(m)$ by broadcasting a message of the form $\langle E_p(m), P(m)\rangle$. We let $R(E_p(m))$ denote a request for support of $E_p(m)$. When $E_p(m)$ has the form α_k, $k>1$, we call this request an R_k*-message.* An R_1-message has the form $\langle E_p(p), \lambda\rangle$, where λ denotes the empty string.

We now describe the protocol for a correct processor p. At every step p may issue both support messages and requests for support. In particular, after receiving at each step, p does the following.

(1) p chooses the maximum i such that p can form an R_i-message, $R(E_p(m)) = \langle E_p(m), P(m)\rangle$, where $E_p(m)$ is proper and p could not form an R_i-message at any previous step. If such an i exists then p broadcasts an R_i-message. If it can construct several syntactically distinct R_i-messages, then it arbitrarily chooses one to broadcast.

(2) For each processor q, p chooses the maximum j such that p receives an R_j-message $\langle E_q(m), P(m)\rangle$ from q. If $j<t+1$, then p broadcasts the corresponding support message $E_p(\text{support } E_q(m))$.

(3) If p receives an R_j-message for some $j\geqq t+1$, then p fires.

Viewing the number of signatures on a message as a clock, the two key lemmas state that the faulty processors cannot increment the clock faster than by 1 within two steps (Lemma 5.1.1) and that the correct processors can increment the clock at least that quickly (Lemma 5.1.2).

LEMMA 5.1.1. *Let $R(m)$ be an R_i-message and let s be the earliest time at which some correct processor sends $R(m)$. Let s' be the earliest time at which some (possibly faulty) processor q sends $R(m')$, where m' is an α_j-message of the form $E_b(E_c(\cdots(m))$. Then $s'\geqq s+2(j-i)$.*

Proof. The proof is by induction on $j-i$.

Basis $j-i=0$. Since $R(m)$ is sent by a correct processor, m is of the form $E_p(m'')$ for some correct processor p. Since $m'=m$ in this case, and since q cannot forge p's signature, q cannot construct $R(m')$ before time s.

Assume the lemma inductively for $j-i \leqq k$. Let $j=i+k+1$. Let $m''=E_c(\cdots(m))$ be such that $E_b(m'')=m'$. By the inductive hypothesis $R(m'')$ can be constructed no sooner than step $s+2(j-i-1)$.

If q constructs $R(m')$ at s', then q constructs $P(m'')$ at s', so q receives $t+1$ $S(m'')$ messages no later than time s'. Thus some correct processor received $R(m'')$ at $s'-1$, so $R(m'')$ was sent not later than $s'-2$. We therefore have $s'-2 \geqq s+2(j-i-1)$ by the inductive hypothesis, so $s' \geqq s+2(j-i)$ and the induction holds. □

LEMMA 5.1.2. *Fix a time s. Let i be the maximum i such that a correct processor broadcasts an R_i-message at time s, and let p be such a processor. If $i<t+1$, then by time $s+2$ some correct processor q forms and broadcasts an R_j-message for some $j \geqq i+1$.*

Proof. Without loss of generality, we may assume s is the first time at which p can construct an R_i-message. In this case p broadcasts $R(E_p(m))=\langle E_p(m), P(m)\rangle$ at s ($\langle E_p(m), \lambda\rangle$ if $i=1$), where $E_p(m)$ is an α_i-message, and every processor receives $R(E_p(m))$ at time $s+1$. Since this is the only request for support sent by p at s, every correct processor responds by broadcasting $S(E_p(m))$ at $s+1$. Thus all processors receive $n-t \geqq t+1$ $S(E_p(m))$ messages at $s+2$, each signed by a distinct processor, so at time $s+2$ every correct processor can construct a proof for $E_p(m)$. By signing $E_p(m)$ to obtain an α_{i+1}-message and combining this with the proof for $E_p(m)$, any processor that has not already signed $E_p(m)$ can construct an R_{i+1}-message. Because $i<t+1$, there is at least one such correct processor, say, q. If q has already broadcast an R_j-message for some $j \geqq i+1$, then the lemma holds trivially. Otherwise, by Step 1 of the protocol and the fact that it can construct an R_{i+1}-message, q will broadcast an R_j-message for some $j \geqq i+1$ at time $s+2$. □

LEMMA 5.1.3. *If any correct processor awakens, then every correct processor eventually fires. Moreover, if s is the earliest time when some correct processor awakens, then every correct processor fires by time $s+2t+1$.*

Proof. Upon awakening, each correct processor forms and broadcasts an R_j-message, for some $j \geqq 1$, since the proof of an R_1-message is the empty string. Let p be the first correct processor to awaken, and let s be the time at which it awakens. By t applications of Lemma 5.1.2, some correct processor constructs and broadcasts an R_j-message for some $j \geqq t+1$ by time $s+2t$. Thus every correct processor fires by $s+2t+1$. □

LEMMA 5.1.4. *In any execution of the protocol resulting in a firing, all correct processors fire simultaneously.*

Proof. Let p be the first correct processor to fire and let f be the time at which p fires. If p fires at f then, for some $k \geqq t+1$, p receives an R_k-message at f. Let $R(m')$ be such a message. Without loss of generality let $m'=E_k(\cdots E_2(E_1(p_1)))$. Let i be the maximum i, $1 \leqq i \leqq k$, such that p_i is correct. (Since there are at most t faulty processors, some such p_i exists.) If $p_i=p_k$, then all processors receive $R(m')$ at f so all fire simultaneously at f.

If $i<k$, then at some round $f'<f$, p_i broadcast an R_i-message. This message was received by all correct processors no later than round $f'+1 \leqq f$. If $i \geqq t+1$, then by Step 3 of the protocol all correct processors fire at $f'+1$. Since f is the first round at which any correct processor fires, we have $f'+1=f$, and all correct processors fire simultaneously.

We now consider the case $i<t+1$. Let s be the time at which p_i broadcasts $R(m)$, where $m=E_i(\cdots(E_1(p_1)))$. Since p_i is correct, s is the earliest time at which $R(m)$ is

sent. By Lemma 5.1.1, no processor can construct $R(m')$ before step $s+2(t+1-i)$, so $f \geqq s+2(t+1-i)+1$. By $t+1-i$ applications of Lemma 5.1.2, some correct processor constructs and broadcasts an R_j-message for some $j \geqq t+1$ by time $s+2(t+1-i)$, so every correct processor receives such an R_j-message by time $s+2(t+1-i)+1$. Thus all correct processors fire by time $s+2(t+1-i)+1$. Since p is the first correct processor to fire and p fires at f, we have $f \leqq s+2(t+1-i)+1$. Thus all correct processors fire simultaneously at f. □

It is now easy to complete the proof of Theorem 5.1. By Lemmas 5.1.3 and 5.1.4, the algorithm is t-resilient. By Lemma 5.1.3, every correct processor fires within $2t+1$ rounds after the first correct processor awakens. Finally, at each step a correct processor broadcasts at most one request for support and n support messages, so at each step the number of bits sent by any correct processor is polynomial in n. Since there are n processors and $O(n)$ steps, the total amount of communication is polynomial in n. □

5.2. Lower bound.

THEOREM 5.2. *In the fault model of Theorem* 5.1 (*Byzantine faults with authentication, collusion, but no rushing*), *if* $t \geqq 3$, *there is a t-resilient distributed firing squad algorithm only if* $n \geqq \lfloor 5t/3 \rfloor + 1$.

Proof. The general outline of the proof is similar to the proof of Theorem 4.2. Consider the impossibility proof for $t=3$ and $n=5$. We consider six scenarios, with three faulty and two correct processors in each. Figure 3 shows the message transmission

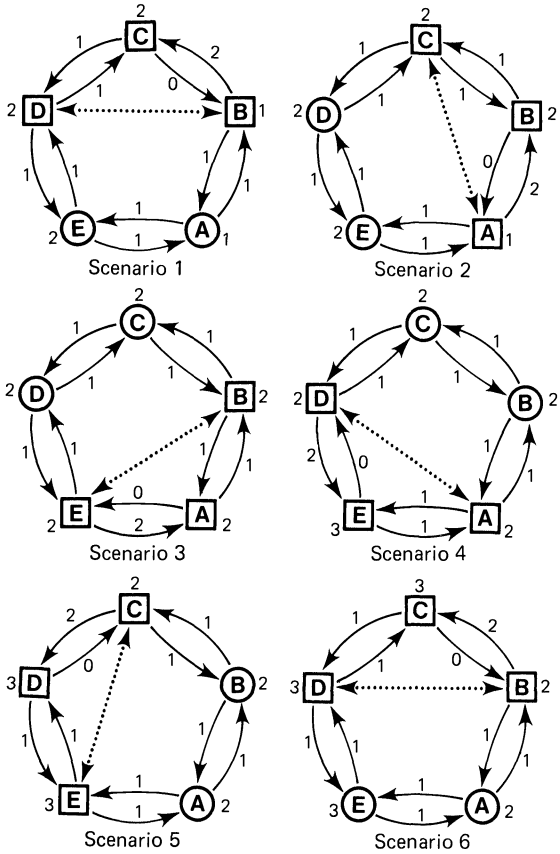

FIG. 3. *The scenarios used to prove Theorem* 5.2.

times, wake-up times, and which processors are faulty in each scenario. A link that is not drawn in these scenarios means that the faulty processor at one end of the link does not communicate along that link; i.e., no messages are sent along that link by the faulty processor, and messages received along that link are ignored. The link drawn as a dotted line is used only by faulty processors. Therefore, in each scenario the network is essentially a ring from the point of view of a correct processor. In each scenario, two of the faulty processors simulate a "timing fault" where messages in one direction take time 2 and messages in the other direction take time 0. The only nonobvious part is simulating a transmission time of zero. To see how this is done focus, for example, on Scenario 1, where messages from C to B take zero time. Note that D is also faulty in Scenario 1. Whenever D takes a step at some time x in which it should send the message m to C, it sends m to B also. At time $x+1$, B has enough information to do the processing that C would do at time $x+1$ to find the message m' that C should send to B at time $x+1$ (the ability of B to sign messages with C's signature is necessary here). But B has m' during the step it is executing at time $x+1$, thus simulating the transmission of m' from C to B in zero time. Message transmission time of 0 is simulated similarly in the other scenarios.

By following the proof of Theorem 4.2, it is straightforward to show that analogues to Lemmas 4.2.1 and 4.2.2 hold. (Formally, in defining equivalence of scenarios, only messages sent along the ring links are included in message histories; the messages sent over dotted links are not included.)

The proof for general n and t is done by replacing each processor by a group of at most $\lfloor t/3 \rfloor$ or at most $\lfloor t/3 \rfloor + 1$ processors in such a way that the total number of faulty processors never exceeds t in any of the scenarios. □

Remark. Regarding the condition $t \geqq 3$ in Theorem 5.2, by using the assumption that the receiver of a message knows the identity of the sender, it is not hard to find a 2-resilient distributed firing squad algorithm for any number $n \geqq 2$ of processors. Briefly, the algorithm is a modification of the algorithm used to prove Theorem 3.1 in the case of no collusion and no rushing. In the modified algorithm, whenever a processor p sends a message m to a processor q, p attaches a header to m that says "the next signer of this message should be processor q". When checking acceptability of a proper message

$$m = E_{i_1}(E_{i_2}(\cdots E_{i_k}(\text{Awake})\cdots))$$

p also checks that m was received from processor p_{i_1} and that each signature in m matches the header of the message being signed. This effectively prevents two faulty processors from adding two signatures in one step, even if they collude. Given this observation, the correctness proof is identical to that of Theorem 3.1, and details are left to the reader. (Note, however, that the modification does not prevent three faulty processors from adding three signatures in two steps, so this method does not generalize to $t \geqq 3$.)

Remark. We can close the fault-tolerance gap between Theorems 5.1 and 5.2 by adding the requirement that each correct processor must broadcast one message at each step (formally, if $(m_1, m_2, \cdots, m_n)$ is in the range of some sending function β_i, then $m_1 = m_2 = \cdots = m_n$). Note that the algorithm of Theorem 5.1 meets this requirement. With this requirement, the proof of the lower bound, Theorem 5.2, can be done with a ring of four processors, two of which are faulty, thus improving the lower bound to $n \geqq 2t+1$. This can be done because the broadcast condition prevents the correct processors from hiding from the faulty processors signed text that these faulty processors would otherwise have to forge. Details are left to the reader. (Note that this

result applies to communication systems like the Ethernet, in which eavesdropping cannot be avoided.)

6. Related results.

6.1. Byzantine agreement with nonunison start. Suppose we want to solve authenticated Byzantine agreement when the correct processors do not all awaken at the same time and the faulty processors can rush. For simplicity, we consider the version of the Byzantine agreement problem as in [11], where the protocol is initiated by a single "sender" processor p that wants to send a "value" v to all the processors. If the sender p is correct, then p sends $E_p(v)$ to all processors at exactly the same step; in this case, we require that all correct processors eventually decide that v was the value sent by p. If the sender p is faulty, it can initially send different values to different processors, and it can send values at different times; in this case, we require that if any correct processor decides on a value u, then all correct processors must decide on u. The second type of faulty behavior, initiating the protocol at different times with respect to different processors, is not considered in Dolev and Strong [11], and their efficient ($t+1$ round) algorithm does not work in this case. An obvious solution would be to first run the firing squad algorithm of Theorem 4.1 to synchronize the processors and then run the Dolev-Strong algorithm for a total time of $2t+6$. This time can be improved to $t+5$ by modifying the algorithm of Theorem 4.1 to solve agreement directly.

THEOREM 6.1. *In the model with Byzantine failures and authentication, in which faulty processors can both rush and collude, there is a t-resilient protocol for Byzantine agreement with nonunison start, requiring $t+5$ rounds, $n \geqq 3t+1$ processors, and communication polynomial in n.*

Proof. The algorithm of Theorem 4.1 is modified by associating a value with every core and with every notarized core. Let h be a function that maps a set of values to a single value as follows: $h(\{v\}) = v$; if S is not a singleton set, then $h(S) = 0$. The value associated with the core

$$\langle E_{i_1}(E_p(v_1)), \cdots, E_{i_k}(E_p(v_k))\rangle$$

is $h(\{v_1, \cdots, v_k\})$. The value of the notarized core

$$\langle E_{i_1}(C_1), \cdots, E_{i_k}(C_k)\rangle$$

is h applied to the set containing the values of the cores $C_1, \cdots, C_k$. Each processor q remembers the set V_q of values of notarized cores that it has seen in acceptable messages. In addition to the previous algorithm for signing and forwarding acceptable messages, whenever q receives an acceptable message m containing the notarized core N, and if the value of N is not currently in V_q, then that value is added to V_q and q signs m and broadcasts the result $E_q(m)$. At the point where q receives an acceptable message of length $t+1$, q signs and broadcasts "decide$_p$ $h(V_q)$". A processor decides v if it receives, at the same step, at least $t+1$ messages "decide$_p$ v" signed by different processors. The correctness proof is very similar to the correctness proof given in § 4; only Lemma 4.1.10 requires modification. Details are left to the reader. □

A similar modification to the algorithm solves the version of the agreement problem where each processor begins the algorithm with an initial value.

A drawback in modifying a distributed firing squad algorithm to solve agreement is that it requires $n > 3t$. By adapting an algorithm of Cristian, Aghili, Strong, and Dolev [7] to the model used in this paper, there is a completely different solution, not using firing squad ideas, which tolerates any number $t \leqq n$ of faults but which takes

$2t+2$ rounds. It is an open question whether arbitrary fault tolerance and time $t+O(1)$ can be obtained simultaneously.

6.2. Distributed firing squad with a global clock. At this point, one might suspect that the difficulty of the distributed firing squad problem is due to the processors having no common notion of global time. We show now, however, that the problem does not become trivial, even with a common clock, although for one fault model the problem does become easier. Informally, a common clock means that at each integer time s, all correct processors taking their unison step at time s know that it is time s. (More formally, the state set Q_i of p_i is partitioned into sets $Q_{i,j}$ for integer $j \geqq 0$, and all transitions from a state in $Q_{i,j}$ must go to states in $Q_{i,j+1}$. Each set $Q_{i,j}$ contains a copy $q_{0,j}$ of the quiescent state. The initial state of p_i is $q_{0,0}$. If p_i is in state $q_{0,j}$ and receives only null messages, then p_i next enters state $q_{0,j+1}$.)

Let the *clocked distributed firing squad* problem be defined like the distributed firing squad problem, but in the model with a common clock. We first give a reduction similar to that of Theorem 3.2. As corollaries of this reduction, clocked distributed firing squad still requires $t+1$ rounds for fail-stop faults, and $n \geqq 3t+1$ is needed in the unauthenticated Byzantine case.

THEOREM 6.2. *Let A be an algorithm for clocked distributed firing squad that is t-resilient to fail-stop faults (respectively, unauthenticated Byzantine faults) and that has time complexity of k rounds. Then there exists an algorithm for* WBA *that is t-resilient to fail-stop faults (respectively, unauthenticated Byzantine faults) and that always halts in k rounds.*

Proof. Given A, define the function f on the natural numbers as follows. For a given integer $r \geqq 0$, consider the run of A in which all processors wake up at (common) time r and there are no faults; then $f(r)$ is the (common) time when all processors fire. Since $f(r) \geqq r$ for all r, there must be a time s such that $f(s+1) > f(s)$.

Now consider an instance of WBA in which processor p_i has initial value v_i. If $v_i = 0$, then p_i begins simulating A as though it were time s. That is, at time 0 of the WBA algorithm, p_i acts as though it were in state $q_{0,s}$ receiving the awake message from w and null messages from the rest. If $v_i = 1$, then p_i waits one step during the WBA algorithm and begins simulating A as though it were awakened at time $s+1$. (In general, time i in the WBA algorithm corresponds to time $s+i$ in the simulation of A.) Let $m = f(s) - s$. If the simulation of A causes p_i to fire within m steps after the beginning of the WBA algorithm, then p_i decides 0 at time m; otherwise, p_i decides 1 at time m. Since A has time complexity k, we have $m \leqq k$. The correctness proof for this WBA algorithm is very similar to the proof of Theorem 3.2 and is left to the reader. □

The next result concerns the case of Byzantine faults with authentication and rushing and shows that the clocked version of the problem is easier for this fault model; specifically, the fault-tolerance improves to any $t \leqq n$, and the time is optimal.

THEOREM 6.3. *In the model with Byzantine failures and authentication, in which faulty processors can both rush and collude, there is a t-resilient clocked distributed firing squad protocol requiring $t+1$ rounds, $n \geqq t$ processors, and communication polynomial in n.*

Proof. In this algorithm, a *proper* message has the form

$$m = E_{i_1}(E_{i_2}(\cdots E_{i_k}(\text{“fire at } c\text{”})\cdots))$$

where c is a natural number modulo $t+1$, where $k \geqq 1$, and where the k signatures are by distinct processors; the *length* of m is k and the *content* of m is c. Such a

message is *acceptable* at common time r if and only if $r \equiv c + k \bmod (t+1)$. This message is *new* to p if p's signature does not appear in m.

A processor p that is awakened by the Awake message at common time s computes $c = s \bmod (t+1)$ and broadcasts E_p("fire at c"). If any processor q receives one or more new acceptable messages with content c at some time, q arbitrarily chooses one, say m, and broadcasts $E_q(m)$. A processor q fires at common time z if q has received, at time z or earlier, an acceptable message m with content c, where $c \equiv z \bmod (t+1)$ such that message m has not caused q to fire at any time earlier than z.

It is clear that if some correct processor awakens at common time s, then all correct processors fire on or before common time $s+t+1$. To argue that all correct processors fire together, we note that if m is new and acceptable to some correct p at time r, then $E_p(m)$ is acceptable to all correct processors at time $r+1$. Let z be the earliest time when some correct processor fires, and let p be a correct processor that fires at z. Therefore, p received an acceptable message m with content c, where $c \equiv z \bmod (t+1)$. If m was received before time z, then all correct processors receive an acceptable message with content c on or before time z, because p must have broadcast such a message before time z. If m is received by p at time z, then $z \equiv c + k \bmod (t+1)$ where k is the length of m, because m is acceptable at time z. Since $c \equiv z \bmod (t+1)$ and $k \geqq 1$, it follows that $k \geqq t+1$. So m must contain the signatures of $t+1$ processors, at least one of which is correct, and again it is easy to argue that all correct processors received an acceptable message with content c by common time z. □

Acknowledgment. We are grateful to Nancy Lynch for saving an extra round in our reduction of the WBA problem mentioned in § 3.2.

FASTER SCALING ALGORITHMS FOR NETWORK PROBLEMS*

HAROLD N. GABOW† AND ROBERT E. TARJAN‡

Abstract. This paper presents algorithms for the assignment problem, the transportation problem, and the minimum-cost flow problem of operations research. The algorithms find a minimum-cost solution, yet run in time close to the best-known bounds for the corresponding problems without costs. For example, the assignment problem (equivalently, minimum-cost matching in a bipartite graph) can be solved in $O(\sqrt{n}m \log(nN))$ time, where n, m, and N denote the number of vertices, number of edges, and largest magnitude of a cost; costs are assumed to be integral. The algorithms work by scaling. As in the work of Goldberg and Tarjan, in each scaled problem an approximate optimum solution is found, rather than an exact optimum.

1. Introduction.

Many problems in operations research involve minimizing a cost function defined on a bipartite or directed graph. A simple but fundamental example is the assignment problem. This paper gives algorithms for such problems that run almost as fast as the best-known algorithms for the corresponding problems without costs. For the assignment problem, the corresponding problem without costs is maximum cardinality bipartite matching.

The results are achieved by scaling the costs. This requires the costs to be integral-valued. Further, for the algorithms to be efficient, costs should be polynomially bounded in the number of vertices, i.e., at most $n^{O(1)}$. These requirements are satisfied by a large number of problems in both theoretical and practical applications.

Table 1 summarizes the results of the paper. The parameters describing the input are specified in the caption and defined more precisely below. The first column gives the problem and the best-known strongly polynomial time bound. Such a bound comes from an algorithm with running time independent of the size of the numbers (assuming the uniform cost model of computation [AHU]). The second column gives the time bounds achieved in this paper by scaling. The table shows that significant speedups can be achieved through scaling. Further, it will be seen that the scaling algorithms are simple to program. Now we discuss the specific results.

The assignment problem is to find a minimum-cost perfect matching in a bipartite graph. The strongly polynomial algorithm is the Hungarian algorithm [K55], [K56] implemented with Fibonacci heaps [FT]. This algorithm can be improved significantly when all costs are zero. Then the problem amounts to finding a perfect matching in a bipartite graph. The best-known cardinality matching algorithm, due to Hopcroft and Karp, runs in time $O(\sqrt{n}m)$ [HK]. The new time bound for the assignment problem is

just a factor of $\log(nN)$ more than this. The algorithm is similar to the Hopcroft–Karp cardinality algorithm and appears simple enough to be useful in practice.

TABLE 1
Bounds for network problems.

Strongly Polynomial Bound	New Scaling Bound
Assignment problem $O(n(m + n\log n))$ [FT]	$O(\sqrt{n}m\log(nN))$
Shortest paths (single-source, directed graph, possibly negative lengths) $O(nm)$ [Bel]	$O(\sqrt{n}m\log(nN))$
Minimum cost degree-constrained subgraph of a bipartite multigraph $O(U(m + n\log n))$ [FT], [G83]	$O(\min\{\sqrt{U}, n^{2/3}M^{1/3}\}\overline{m}\log(nN))$
Transportation problem (uncapacitated or capacitated) $O(\min\{U, n\log U\}(m + n\log n))$ [FT], [EK], [L]	$O((\min\{\sqrt{U}, n\}m + U\log U)\log(nN))$
Minimum cost flow $O(n^2(m + n\log n)\log n)$ [GalT]	$O(nm\log n\log(nN)\log M)$ convex cost functions allowed $O(n(m + n\log n)\log M)$ lower bounds only

Parameters: n = number of vertices; m = number of edges; $\overline{m}$ = number of edges counting multiplicities; U = total degree constraints; N = maximum cost magnitude; and M = maximum flow capacity or lower bound, or edge multiplicity.

The new algorithm improves the scaling algorithm of [G85], which runs in time $O(n^{3/4}m\log N)$. The improvement comes from a different scaling method. The algorithms of [G85] compute an optimum solution at each of $\log N$ scales. The new method computes an approximate optimum at each of $\log(nN)$ scales; using $\log n$ extra scales ensures that the last approximate optimum is exact. The appropriate definition of approximate optimum is due to Tardos [Tard] and independently to Bertsekas [Ber79], Ber86]. The new approach to scaling was recently discovered by Goldberg and Tarjan for the minimum-cost flow problem [Go], [GoT87a], [GoT87b]. Their minimum-cost flow algorithm solves the assignment problem in time $O(nm\log(nN))$, which this paper improves. Bertsekas [Ber87] gives an algorithm for the assignment problem that

also runs in sequential time $O(nm \log(nN))$ and has a distributed asynchronous implementation.

The assignment algorithm extends to other network problems. This paper presents extensions to problems on bipartite graphs and directed graphs. For algorithms on general graphs (and bidirected graphs) and other extensions, see § 4. Throughout this paper all undirected graphs are bipartite (we usually mention this explicitly).

Variants of minimum-cost perfect bipartite matching (such as minimum-cost bipartite matching) can be done in the same time bound. The linear programming dual variables for perfect bipartite matching can be found from the algorithm. This gives a solution to the shortest path problem when negative edge lengths are allowed. The table entry for the degree-constrained subgraph problem is just a factor of $\log(nN)$ more than the bound of [ET] for the corresponding problem without costs, namely, the problem of maximum flow in a 0-1 network. These bounds improve [G85] in a manner analogous to the assignment problem.

The table entry for the transportation problem is a good bound when total supply and demand (U) is small. The key fact for this bound is the low total augmenting path length for the assignment algorithm; this fact generalizes the bounds of [ET] for cardinality matching and 0-1 network flow. The entry for minimum-cost flow is a double scaling algorithm — it scales edge capacities, and at each scale solves a small transportation problem by the above cost-scaling algorithm. This algorithm is not as good asymptotically as the recent bound of Goldberg and Tarjan, $O(nm \log(n^2/m) \log(nN))$ [GoT87b]. The latter is just a factor of $\log(nN)$ more than the best bound for maximum value flow [GoT86]. The double scaling algorithm may be more useful in practice, however, since it requires fewer data structures. The double scaling algorithm generalizes to find a minimum-cost integral flow when the cost of each edge is an arbitrary convex function of its flow. The time bound is unchanged, as long as the cost for a given flow value can be computed in $O(1)$ time. The last bound of the table improves the previous one for problems where edges have a lower bound on the flow and infinite capacity (more generally, $O(n)$ finite capacities are allowed). Such problems arise as covering problems. We illustrate how this bound leads to an efficient strongly polynomial bound for the directed Chinese postman problem.

Section 2 presents the matching algorithm and its analysis, including facts used in the generalizations. Section 3 presents the extensions to more general network flow problems. Section 4 gives some concluding remarks. This section closes with definitions from graph theory; more thorough treatments are in [L], [PS], [Tarj].

We use interval notation for sets of integers: for integers i and j, define $[i..j] = \{k | k \text{ is an integer}, i \leq j \leq k\}$, $[i..j) = \{k | k \text{ is an integer}, i \leq j < k\}$, etc. The *symmetric difference* of sets S and T is denoted by $S \oplus T$. The function $\log n$ denotes logarithm to the base two.

For a graph G, $V(G)$ and $E(G)$ denote the vertex set and edge set, respectively. The given graph G is bipartite and has bipartition V_0, V_1 (so $V(G)$ is the disjoint union of V_0 and V_1, and any edge joins V_0 to V_1). The given graph G has m edges; in § 2, $n = |V_0| = |V_1|$ (we assume without loss of generality that the two sets of the bipartition have equal cardinality); in § 3, $n = |V(G)|$. If H is a subgraph of G, an *H-edge* is an edge in H and a *non-H-edge* is not in H. When an auxiliary graph G' is constructed from the given graph G, *G-edge* refers to an edge of G' that represents an edge of G. We use this term without explicit comment only when the representation is obvious (i.e., $vw \in E(G)$ is represented by $v'w'$, where v' and w' are obvious representatives of v and w). We say *path P ends with edge vw* if vw is at an end of P and further, v is an endpoint of P.

A *matching* in a graph is a set of vertex-disjoint edges. Thus a vertex v is in at most one matched edge vv'; v' is the *mate* of v. A *free* vertex has no mate. A *maximum cardinality matching* has the greatest number of edges possible; a *perfect matching* has no free vertices (and is clearly maximum cardinality). An *alternating path* (*cycle*) for a matching is a simple path (cycle) whose edges are alternately matched and unmatched. An *augmenting path* P is an alternating path joining two distinct free vertices. *Augmenting* the matching along P means enlarging the matching M to $M \oplus P$, thus giving a matching with one more edge. Suppose each edge e has a numeric *cost* $c(e)$; in this paper costs are integers in $[-N..N]$, unless stated otherwise. The cost $c(S)$ of a set of edges S is the sum of the individual edge costs. A *minimum* (*maximum*) *perfect matching* is a perfect matching of smallest (largest) possible cost. The *assignment problem* is to find a minimum perfect matching in a bipartite graph. More generally, a *minimum-cost maximum cardinality matching* is a matching that has the greatest number of edges possible, and subject to that restriction has minimum cost possible. (The phrase "minimum-cost maximum cardinality set" can be interpreted ambiguously. In this paper it refers to a set that has maximum cardinality subject to any other restrictions that have been mentioned, and among such sets has minimum cost possible.) A *minimum-cost matching* is a matching of minimum cost (its cardinality can be any value, including zero).

A *multigraph* has a set of edges $E(G)$, where each edge e has an integral *multiplicity* $u(e)$ (i.e., there are $u(e)$ parallel copies of e). The size parameter m is the number of edges, $m = |E(G)|$; $\overline{m}$ counts multiplicities, i.e., $\overline{m} = \sum\{u(e) | e \in E(G)\}$; M is the maximum edge multiplicity. (In a graph $M = 1$.) When each vertex v has associated nonnegative integers $\ell(v)$ and $u(v)$, a *degree-constrained subgraph* (DCS) is a subgraph such that each vertex has degree in $[\ell(v)..u(v)]$. It is convenient to use both set notation and functional notation for a DCS. Thus we use a capital letter D to denote a DCS, and the corresponding lowercase letter d to denote two functions defined by D: for an edge e, $d(e)$ denotes the multiplicity of e in D, and for a vertex v, $d(v)$ denotes the degree of v in D, i.e., $d(v) = \sum\{d(vw) | vw \in E(G)\}$. Hence $d(e) \leq u(e)$ and $\ell(v) \leq d(v) \leq u(v)$. The *deficiency* of DCS D at vertex v is $\phi(v, D) = u(v) - d(v)$. In a *perfect* DCS each deficiency is zero. The size of the DCS is measured by $U = \sum\{u(v) | v \in V\}$ (so U is twice the number of edges in a perfect DCS). When edges e have costs, the usual assumption is that each copy of e has the same cost, denoted $c(e)$. When this assumption fails, we use cost functions, defined in the text. Other definitions for DCS — e.g., *minimum perfect* DCS, *minimum-cost maximum cardinality* DCS, etc., follow by analogy with matching.

The *transportation problem* is to find a minimum-cost perfect DCS in a bipartite multigraph in which all edges have infinite multiplicity; alternatively, if M is the maximum degree constraint, all multiplicities are M. If some multiplicities are less than M, the problem is a *capacitated transportation problem.* The usual definition of the transportation problem allows nonnegative real-valued degree constraints and edge multiplicities (both given multiplicities and those in the solution). This paper deals with the integral case of this problem. Note that if the given degree constraints and multiplicities are rational, they can be scaled up to integers. Also note that no loss of generality results from the constraint in this paper that the solution to the transportation problem has integral multiplicities — such an optimum solution always exists when the given degree constraints and multiplicities are integral [L]. Finally note that in our terminology the minimum perfect DCS problem is the same as the capacitated transportation problem.

2. Matching and extensions. Section 2.1 presents our algorithm to find a minimum perfect matching in a bipartite graph. Section 2.2 gives extensions to other versions of matching, some facts about the algorithm needed in § 3, and our shortest path algorithm. In this section n denotes the number of vertices in each vertex set V_0, V_1 of the given bipartite graph.

2.1. The assignment algorithm. For convenience assume that the given graph G has a perfect matching (the algorithm can detect graphs not having a perfect matching, as indicated below).

The plan for the algorithm is to combine the Hungarian algorithm for weighted matching with the Hopcroft–Karp algorithm for cardinality matching. Recall that the Hungarian algorithm always chooses an augmenting path of smallest net cost. The Hopcroft–Karp algorithm always chooses an augmenting path of shortest length. Both of these rules can be approximated simultaneously *if* the costs are small integers. Arbitrary costs can be replaced by small integers by scaling. Thus our algorithm scales the costs. At each scale it computes a perfect matching. The computation is efficient because it is similar to the Hopcroft–Karp algorithm; the matching is close to optimum because the computation is similar to the Hungarian algorithm. Now we give the details.

Each scale of the algorithm finds a close-to-minimum matching, defined as follows. Every vertex v has a *dual variable* $y(v)$. A 1-*feasible matching* consists of a matching M and dual variables $y(v)$ such that for any edge vw,

$$y(v) + y(w) \le c(vw) + 1,$$
$$y(v) + y(w) = c(vw), \quad \text{for } vw \in M.$$

A 1-*optimal matching* is a perfect matching that is 1-feasible. If the $+1$ term is omitted from the first inequality, these are the usual complementary slackness conditions for a minimum perfect matching [L], [PS]. The following result is due to Bertsekas [Ber79], [Ber86].

LEMMA 2.1. *Let M be a 1-optimal matching.*

(a) *Any perfect matching P has $c(P) \ge c(M) - n$.*

(b) *If some integer k, $k > n$, divides each cost $c(e)$, then M is a minimum perfect matching.*

Proof. Part (a) follows because

$$c(M) = \sum \{c(e) | e \in M\} = \sum \{y(v) | v \in V(G)\} \le c(P) + n.$$

Part (b) follows from (a) and the fact that any matching has cost a multiple of k. □

This lemma is the basis for the *main routine* of the algorithm, which does the scaling. The routine starts by computing a new cost $\bar{c}(e)$ for each edge e, equal to $n+1$ times the given cost. Consider each $\bar{c}(e)$ to be a signed binary number $\pm b_1 b_2 \cdots b_k$ having $k = \lfloor \log(n+1)N \rfloor + 1$ bits. The routine maintains a variable $c(e)$ for each edge e, equal to its cost in the current scale. The routine initializes each $c(e)$ to 0 and each dual $y(v)$ to 0. Then it executes the following loop for index s going from 1 to k:

Step 1. For each edge e, $c(e) \leftarrow 2c(e) +$ (signed bit b_s of $\bar{c}(e)$). For each vertex v, $y(v) \leftarrow 2y(v) - 1$.

Step 2. Call the *scale_match* routine to find a 1-optimal matching. □

Lemma 2.1(b) shows that the routine halts with a minimum perfect matching. Each iteration of the loop is called a *scale*. We give a *scale_match* routine that runs in $O(\sqrt{n}m)$ time. Since there are $O(\log(nN))$ scales, this achieves the desired time bound.

It is most natural to work with small costs. The *scale_match* routine transforms costs to achieve this. Specifically, *scale_match* changes the cost of each edge vw to $c(vw) - y(v) - y(w)$; then it calls the *match* routine on these costs to find a 1-optimal matching M with duals $y'(v)$; then it adds $y'(v)$ to each dual $y(v)$ ($y(v)$ is the dual value before the call to *match*).

Clearly, M with the new duals is a 1-optimal matching for cost function c. Further, since Step 1 of the main routine changes costs and duals so that the empty matching is 1-feasible, the costs input to *match* are integers -1 or larger. If vw is an edge in the 1-optimal matching found in the previous scale, then after Step 1, $y(v) + y(w) \geq c(vw) - 3$. Hence vw costs at most three in the costs for *match*. Thus there is a perfect matching of cost at most $3n$. (This is true even in the first scale). We will show that if every edge costs at least -1 and a minimum perfect matching costs $O(n)$, *match* finds a 1-optimal matching in $O(\sqrt{n}m)$ time. This gives the desired time bound.

Note that the transformation done by *scale_match* is for conceptual convenience only. An actual implementation would not transform costs; rather *match* would work directly on the untransformed costs.

The *cost-length* of an edge e with respect to a matching M is

$$cl(e) = c(e) + (\textbf{if } e \notin M \textbf{ then } 1 \textbf{ else } 0).$$

The *net cost-length* of a set of edges S with respect to M is

$$cl(S) = \sum\{cl(e) | e \in S - M\} \; - \sum\{cl(e) | e \in S \cap M\}.$$

This quantity equals the net cost of S (with respect to M) plus the number of unmatched edges in S. Hence an augmenting path with smallest net cost-length approximates both the smallest net cost augmenting path and the shortest augmenting path; this is in keeping with our plan for the algorithm.

An edge vw is *eligible* if $y(v) + y(w) = cl(vw)$, i.e., the 1-feasibility constraint for vw holds with equality. (Note that a matched edge is always eligible.) It follows from the analysis below that an augmenting path of eligible edges has the smallest possible net cost-length. Hence the algorithm augments along paths of eligible edges. If no such path exists, it adjusts the duals to create one. The details are as follows.

Assume the costs given to *match* are integers that are at least -1, and there is a perfect matching costing at most an. (In the scaling algorithm $a = 3$.)

procedure *match*.
Initialize all duals $y(v)$ to 0 and matching M to $\emptyset$. Then repeat the following steps until Step 1 halts with the desired matching:

Step 1. Find a maximal set $\mathcal{A}$ of vertex-disjoint augmenting paths of eligible edges. For each path $P \in \mathcal{A}$, augment the matching along P, and for each vertex $w \in V_1 \cap P$, decrease $y(w)$ by 1. (This makes the new matching 1-feasible.) If the new matching M is perfect, halt.

Step 2. Do a Hungarian search to adjust the duals (maintaining 1-feasibility) and find an augmenting path of eligible edges. □

We now give the details of Steps 1 and 2 that are needed to analyze *match*. (A full description of these steps is given below, in the paragraphs preceding the statement of Theorem 2.1. The reader may prefer to examine these details now, although this is not necessary.) Both steps can be implemented in $O(m)$ time. Step 2 is a Hungarian search (essentially Dijkstra's shortest path algorithm, see e.g., [L], [PS]). The search does a number of *dual adjustments*. Each dual adjustment calculates a positive integer δ and increases or decreases various dual values by δ, so as to preserve 1-feasibility and eventually create an augmenting path of eligible edges. (The dual adjustment is defined more precisely below.) At any point in the algorithm define

F = the set of free vertices in V_0;

Δ = the sum of all dual adjustment quantities δ in all Hungarian searches so far.

The Hungarian search maintains the duals so that any free vertex $v \in F$ has $y(v) = \Delta$ and any free vertex $v \in V_1$ has $y(v) = 0$.

To analyze the *match* routine, first observe that it is correct: The changes to the matching (in Step 1) and to the duals (in Steps 1–2) keep M a 1-feasible matching. If M is not perfect but G has a perfect matching, the Hungarian search creates an augmenting path of eligible edges. Hence the algorithm eventually halts with M a 1-optimal matching, as desired. (Note that if G does not have a perfect matching, this is eventually detected in Step 2.)

To analyze the run time, consider any point in the execution of *match*. Let M be the current matching, and define F and Δ as above. Let M^* be a minimum perfect matching. For any set of edges S let $cl(S)$ denote net cost-length with respect to M.

$M^* \oplus M$ consists of an augmenting path P_v for each $v \in F$, plus alternating cycles C_w. Thus

$$n + c(M^*) - c(M) \geq cl(M^* \oplus M) = \sum_{v \in F} cl(P_v) + \sum_{w} cl(C_w). \tag{1}$$

To estimate the right-hand side, consider an alternating path P from $u \in V_0$ to $m \in V_0$, where u is on an unmatched edge of P and m is on a matched edge of P (m stands for "matched"; no confusion should result from the double usage of m). Then

$$y(u) \leq y(m) + cl(P). \tag{2}$$

This follows since for edges $uv \notin M$ and $vm \in M$, $y(u) + y(v) \leq cl(uv)$ and $y(v) + y(m) = cl(vm)$, so $y(u) \leq y(m) + cl(uv) - cl(vm)$. Inequality (2) implies that any alternating cycle C has $cl(C) \geq 0$. It also implies that any augmenting path P_v from some $v \in F$ to some free vertex $t \in V_1$ has $y(v) + y(t) \leq cl(P_v)$. Recall that the Hungarian search keeps $y(v) = \Delta$ and $y(t) = 0$. Hence $\Delta \leq cl(P_v)$, and the right-hand side of (1) is at least $|F|\Delta$.

By assumption on the input to *match*, $c(M^*) \leq an$ and $c(M) \geq -n$. Hence the left-hand side of (1) is at most bn for $b = a + 2$. Thus we have shown

$$|F|\Delta \leq bn. \tag{3}$$

This implies there are $O(\sqrt{n})$ iterations of the loop of *match*. To see this, note that each execution of Step 1 (except possibly the first) augments along at least one path because of the preceding Hungarian search. Hence at most $\sqrt{bn} + 1$ iterations start with $|F| \leq \sqrt{bn}$. From (3), $|F| \geq \sqrt{bn}$ implies $\Delta \leq \sqrt{bn}$. The next paragraph

shows that each Hungarian search increases Δ by at least one. This implies that at most $\sqrt{bn}+1$ iterations start with $\Delta \leq \sqrt{bn}$, giving the desired bound.

Now we show that a Hungarian search $\mathcal{S}$ increases Δ by at least one. It suffices to show that $\mathcal{S}$ does a dual adjustment (since any dual adjustment quantity δ is a positive integer). Search $\mathcal{S}$ does a dual adjustment unless there is an augmenting path P of eligible edges when it starts. Clearly, P intersects some augmenting path found in Step 1. It is easy to see that P contains an unmatched edge vw, with w but not v in an augmenting path of Step 1, and $w \in V_1$. But vw is ineligible after the Step 1 decreases $y(w)$. So P does not exist, and $\mathcal{S}$ does a dual adjustment.

In summary, *match* does $O(\sqrt{n})$ iterations. Each iteration takes time $O(m)$, giving the desired time bound $O(\sqrt{n}m)$.

It remains to give the details of Steps 1 and 2. Step 1 finds the augmenting paths P by depth-first search. To do this, it marks every vertex reached in the search. It initializes a path P to a free unmarked vertex of V_0. To grow P, it scans an eligible edge xy from the last vertex x of P (x will always be in V_0). If y is marked, the next eligible edge from x is scanned; if none exists, the last two edges of P (one matched and one unmatched) are deleted from P; if P has no edges, another path is initialized. If y is free, another augmenting path has been found; in this case y is marked, the path is added to $\mathcal{A}$, and the next path is initialized. The remaining possibility is that y is matched to a vertex z. In this case y and z are marked; edges xy, yz are added to P; and the search is continued from z.

It is clear that this search uses $O(m)$ time. To show that it halts with $\mathcal{A}$ maximal, first observe that for any marked vertex $x \in V_0 - V(\mathcal{A})$, every eligible edge xy has y marked and matched, or y in $V(\mathcal{A})$. (Note that $V(\mathcal{A})$ is the set of vertices in paths of $\mathcal{A}$.) Hence an easy induction shows that an alternating path of eligible edges, starting at a free vertex of V_0 and vertex-disjoint from $\mathcal{A}$, has all its V_0 vertices marked and is not augmenting.

Step 2 is the Hungarian search. It grows a forest $\mathcal{F}$ of eligible edges, from roots F. An eligible edge vw with $v \in V_0 \cap \mathcal{F}$ and $w \notin \mathcal{F}$ is added to $\mathcal{F}$ whenever possible. If w is free, $\mathcal{F}$ contains an augmenting path of eligible edges. Otherwise, the matched edge ww' is added to $\mathcal{F}$. Eventually either $\mathcal{F}$ contains an augmenting path or $\mathcal{F}$ cannot be enlarged.

In the latter case a *dual adjustment* is done. It changes duals in a way that preserves 1-feasibility and allows $\mathcal{F}$ to be enlarged, as follows. It computes the dual adjustment quantity

$$\delta = \min\{cl(vw) - y(v) - y(w) | v \in V_0 \cap \mathcal{F}, w \notin \mathcal{F}\}.$$

Each $v \in \mathcal{F}$ gets $y(v)$ increased by $\delta \times$ (**if** $v \in V_0$ **then** 1 **else** -1). It is easy to see that this achieves the goal of the dual adjustment (an edge vw achieving the above minimum becomes eligible and so can be added to $\mathcal{F}$).

After the dual adjustment, the search continues by enlarging $\mathcal{F}$. Eventually $\mathcal{F}$ contains the desired augmenting path of eligible edges and the Hungarian search halts.

Note that, as claimed above, at any point in the algorithm a free vertex v has $y(v) = \Delta$ if $v \in F$ (since every dual adjustment increases $y(v)$) and $y(v) = 0$ if $v \in V_1$ (no dual adjustment changes $y(v)$).

A Hungarian search can be implemented in $O(m)$ time. This depends on two observations. First, the proper data structure allows a dual adjustment to change all duals $y(v)$ in $O(1)$ time total. Specifically the algorithm keeps track of Δ (defined above). When a vertex v is added to $\mathcal{F}$, its current dual value and the current value

of Δ are saved as $y^0(v)$ and $\Delta(v)$, respectively. Then at any time the current value of $y(v)$ can be calculated as

$$y^0(v) + (\Delta - \Delta(v)) \times (\textbf{if } v \in V_0 \textbf{ then } 1 \textbf{ else } -1).$$

Hence the dual adjustment is accomplished by simply increasing the value of Δ.

The second observation is how to compute δ in a dual adjustment. The usual implementation of a Hungarian search does this with a priority queue that introduces a logarithmic factor into the time bound (e.g., [FT]). This can be avoided when, as in our case, costs are small integers (this was observed in [D], [W] for Dijkstra's shortest path algorithm). The details are as follows. The next value of δ is the amount that the next value of Δ increases from its current value. Hence it suffices to calculate the next value of Δ. The next value of Δ is the smallest possible value such that some edge vw with $v \in V_0 \cap \mathcal{F}$ and $w \notin \mathcal{F}$ becomes eligible (when duals are adjusted by δ). Thus the next value of Δ equals

$$\min\{cl(vw) - y^0(v) - y(w) + \Delta(v) | v \in V_0 \cap \mathcal{F}, w \notin \mathcal{F}\}.$$

Since any Hungarian search has $|F| \geq 1$, inequality (3) implies $\Delta \leq bn$. The algorithm maintains an array $Q[1..bn]$. Each entry $Q[r]$ points to a list of edges vw that can make $\Delta = r$, i.e., $v \in V_0 \cap \mathcal{F}$, $w \notin \mathcal{F}$, and $r = cl(vw) - y^0(v) - y(w) + \Delta(v)$. The algorithm scans down Q and chooses the next value of Δ as the smallest value r with $Q[r]$ nonempty. This gives the next value of δ, and the newly eligible edges, as desired. The total overhead for scanning is $O(n)$, since Q has bn entries. (Note that an edge vw with $v \in V_0 \cap \mathcal{F}$, $w \notin \mathcal{F}$ does not get entered in this data structure if $cl(vw) - y^0(v) - y(w) + \Delta(v) > bn$.)

Only one detail of the derivation remains: We have assumed that the dual values $y(v)$ do not grow too large, so that arithmetic operations use $O(1)$ time. To justify this, we show that each $y(v)$ has magnitude $O(n^2N)$. It suffices to do this for $v \in V_0$. Define Y_s as $\max\{|y(v)||v \in V_0\}$ after the sth scale. Then $Y_0 = 0$ and $Y_{s+1} \leq 2Y_s + bn - 1$ (since $\Delta \leq bn$). Thus $Y_k \leq (2^k - 1)(bn - 1) = O(n^2N)$, as desired. Note that the input uses a word size of at least $\max\{\log N, \log n\}$ bits. Hence at worst the algorithm uses triple-word integers for the dual variables.

THEOREM 2.1. *A minimum perfect matching in a bipartite graph can be found in* $O(\sqrt{n}m \log(nN))$ *time and* $O(m)$ *space.* □

A heuristic that may speed up the algorithm in practice is to prune the graph at the start of each scale. Specifically, *scale_match* can delete any edge whose new cost is $6n$ or more. In proof, recall that in the costs computed by *scale_match* there is a perfect matching M costing at most $3n$; taking into account the low-order bits of cost that are not included in the current scale, the true cost of M is less than $4n$. In the costs computed by *scale_match* every edge costs at least -1; again taking into account low order bits, the true cost is more than -2. Hence a matching containing an edge of new cost $6n$ or more has true cost more than $4n$ and so is not minimum.

2.2. Extensions of the assignment algorithm. The bounds of Theorem 2.1 also apply to finding a minimum-cost matching. To see this, let G be the given graph. Form $\overline{G}$ by taking two copies of G; for each $v \in V(G)$ join the two copies of v by a cost zero edge. Then $\overline{G}$ is bipartite, and a minimum perfect matching in $\overline{G}$ gives a minimum-cost matching in G.

A similar result holds for minimum-cost maximum cardinality matching. The construction is the same except that the edges joining two copies of v cost nN. The

problem of finding a minimum-cost matching of given cardinality can also be solved in the same bounds; it is most convenient to use Theorem 3.2 below.

Returning to perfect matching, several properties of *match* are needed for § 3. Define

$$A = \text{ the total length of all augmenting paths found by } match.$$

We first derive a bound on A. Let P_i denote the ith augmenting path found by *match*. Let ℓ_i be its length, measured as its number of unmatched edges; let Δ_i denote the value of Δ when P_i is found; let M_i be the matching after augmenting along P_i. Recall that in the Hopcroft–Karp algorithm, for some constant c, $\ell_i \le cn/(n-i+1)$. Thus the total augmenting path length is $\sum_{i=1}^{n} \ell_i = O(n \log n)$ [ET]. In *match*, ℓ_i does not have a similar bound. However, it is bounded in an amortized sense, as follows.

LEMMA 2.2. *For any* $k \in [1..n]$, $c(M_k) + \sum_{i=1}^{k} \ell_i = \sum_{i=1}^{k} \Delta_i$.

Proof. A calculation similar to (2) shows that for any i, $\Delta_i = cl(P_i)$. It is easy to see that $cl(P_i) = \ell_i + c(M_i) - c(M_{i-1})$ (assume $c(M_0) = 0$). Summing these relations gives the lemma. □

COROLLARY 2.1. $A = O(n \log n)$.

Proof. Since $|M_k| = k$, the entry conditions for *match* imply $c(M_k) \ge -k$. Hence $A \le n + \sum_{i=1}^{n} \Delta_i$. By (3), $\Delta_i \le bn/(n-i+1)$. Summing these inequalities gives the lemma. □

The second property shows that the depth-first search of Step 1 never encounters a cycle. A similar property for network flows is used in [GoT87a].

LEMMA 2.3. *In* match *there is never an alternating cycle of eligible edges.*

Proof. Initially there are no matched edges, so there are no alternating cycles of eligible edges. In a Hungarian search, whenever the duals of a matched edge vw are changed, $w \in V_1$ gets $y(w)$ decreased. Hence any edge joining w to a vertex not in the search forest $\mathcal{F}$ is ineligible. This implies that the Hungarian search does not create an alternating cycle of eligible edges. Similar reasoning applies when an augment creates a new matched edge and changes duals. □

Some applications of matching require the optimal linear programming dual variables. The dual variables $y(v)$ are *optimal* if there is a perfect matching M such that every edge vw has $y(v) + y(w) \le c(vw)$, with equality for every $vw \in M$. (This implies that M is a minimum perfect matching.) Such duals exist for any bipartite graph having a perfect matching [L], [PS]. The scaling algorithm halts with duals that are 1-optimal but not necessarily optimal. Optimal duals can be found as follows.

Let G^+ be G with an additional vertex $s \in V_0$ and an edge sv for each $v \in V_1$. Extend the given cost function c to G^+ by defining $c(sv)$ as an arbitrary integer; the cost function used by the matching algorithm extends to G^+ by its definition, $\bar{c} = (n+1)c$. To specify a cost function on G^+, we write $G^+; c$ or $G^+; \bar{c}$. Let M be a minimum perfect matching in G; for vertex v, let v' denote its mate, i.e., $vv' \in M$. For $v \in V_0$, let M_v be a minimum perfect matching in $G^+ - v; c$. (Such a matching exists, for instance, $M - vv' + sv'$.) Set

$$y(v) = \textbf{if } v \in V_0 \textbf{ then } -c(M_v) \textbf{ else } c(vv') - y(v').$$

These duals are optimal on G. (This can be proved by an argument similar to the algorithm given below. Alternatively, see [G87] for a proof from first principles.)

Suppose a Hungarian search (as in *match*) is done on $G^+; \bar{c}$. It halts with a tree T of eligible edges, rooted at s. Clearly T is a spanning tree. For any $v \in V_0$, augmenting along the sv-path in T gives a 1-optimal matching N_v in $G^+ - v; \bar{c}$. N_v is a minimum

perfect matching in $G^+ - v; c$. This follows from Lemma 2.1, since $G^+ - v$ and G have the same number of vertices. Hence N_v qualifies as M_v.

In summary, the following procedure finds optimal duals. Given is the output of the matching algorithm, i.e., a 1-optimal matching in $G; \bar{c}$ with duals y. Form $G^+; \bar{c}$, defining $c(sv) = \lceil y(v)/(n+1) \rceil$ for each $v \in V_1$; also set $y(s) \leftarrow 0$ (this gives 1-feasible duals). Do a Hungarian search to construct a spanning tree T of eligible edges rooted at s. Do a depth-first search of T to find $c(M_v)$ for each $v \in V_0$. Define optimal duals $y(v)$ by the above formula.

The time for this algorithm is $O(m)$. This is clear, except perhaps for the time for the Hungarian search. The choice of $c(sv)$ ensures that $\Delta \leq n$. Hence, as in *match*, the Hungarian search can be implemented using an array Q. This gives $O(m)$ time.

COROLLARY 2.2. *Optimal dual variables on a bipartite graph can be found in* $O(\sqrt{n}m \log(nN))$ *time and* $O(m)$ *space.* □

This implies the next result. Consider a directed graph with n vertices, m edges, and arbitrary (possibly negative) edge lengths.

THEOREM 2.2. *The single-source shortest path problem on a directed graph with arbitrary integral edge lengths can be solved in* $O(\sqrt{n}m \log(nN))$ *time and* $O(m)$ *space.*

Proof. This problem can be solved by finding optimal duals on a bipartite graph whose costs are the edge lengths and then running Dijkstra's algorithm [G85]. □

Obviously the same bound holds for $O(\sqrt{n})$ sources.

3. Degree-constrained subgraphs and extensions. This section extends the assignment algorithm to derive the last three bounds of Table 1. Section 3.1 gives an algorithm for the minimum perfect degree-constrained subgraph problem, deriving time bounds for finding a degree-constrained subgraph and for solving the transportation problem. Section 3.2 discusses scaling edge multiplicities, which improves the bounds when edge multiplicities are large. Section 3.3 extends the results to network flow. Throughout § 3, n denotes the number of vertices in the input graph. The problems of §§ 3.1–3.2 are defined on a multigraph. Recall that for a multigraph m denotes the number of edges and $\overline{m}$ the number of edges counting multiplicities.

3.1. The degree-constrained subgraph algorithm. This section gives an algorithm for the perfect degree-constrained subgraph problem. Note that a perfect DCS problem on a multigraph of n vertices and $\overline{m}$ edges can be reduced in linear time to a perfect matching problem on a graph of $O(\overline{m})$ vertices and edges [G87]. Hence Theorem 2.1 immediately implies a bound of $O(\overline{m}^{3/2} \log(\overline{m}N))$ for the DCS problem. We now derive the better bound given in Table 1.

For a DCS D, the *cost-length* of edge e is

$$cl(e) = c(e) + (\textbf{if } e \notin D \textbf{ then } 1 \textbf{ else } 0).$$

A 1-*feasible* DCS is a DCS D and dual variables $y(v)$ for each vertex v, such that for any edge vw,

$$y(v) + y(w) \leq cl(vw), \qquad \text{for } vw \notin D,$$
$$y(v) + y(w) \geq cl(vw), \qquad \text{for } vw \in D.$$

A 1-*optimal* DCS is a perfect DCS that is 1-feasible. (Note that the definition of a 1-feasible matching is slightly different — the second relation holds with equality. The difference is not significant: if we treat a matching problem as a DCS problem, a 1-feasible DCS gives a 1-feasible matching, by lowering duals as necessary to achieve the desired equalities.)

As in Lemma 2.1, if every cost is divisible by k, $k > n/2$, then a 1-optimal DCS is a minimum perfect DCS. This is essentially a result of Bertsekas [Ber79], [Ber86]. In proof, note that a perfect DCS D has minimum cost if any alternating (simple) cycle C has $c(C \cap D) \leq c(C - D)$. This condition can be verified for a 1-optimal DCS D by a calculation similar to Lemma 2.1.

Now we describe the algorithm. Many details are exactly as in § 2, so we elaborate only on the parts that change. All data structures have size $O(m)$ (not $O(\overline{m})$). Clearly the multigraph G can be represented by such a structure.

The main routine works in (at most) $\lfloor \log(n+2)N \rfloor$ scales. (This is justified by the above analog of Lemma 2.1; each original cost is multiplied by $\lceil (n+1)/2 \rceil$.) Steps 1–2 and *scale_match* are unchanged. Let D_0 be the 1-optimal DCS of the previous scale. Note that the *match* routine is called with integral costs $c(e)$ that are at least -1 for $e \notin D_0$ and at most three for $e \in D_0$.

The *match* routine initializes all duals $y(v)$ to 0 and D to $\{e | c(e) < -1\}$. (Clearly D does not violate any degree constraint.) The definition of an *eligible* edge vw is still $y(v) + y(w) = cl(vw)$. Step 1 of *match* finds a maximal set of edge-disjoint augmenting paths of eligible edges such that any vertex v is an end of at most $\phi(v, D)$ paths. (In a multigraph, "edge-disjoint" means a given copy of an edge is in at most one path.) It augments the DCS along each path. Unlike § 2, no duals are changed after an augment; the new DCS is 1-feasible, and the edges on an augmenting path become ineligible. Step 2 does a Hungarian search to adjust duals and find an augmenting path of eligible edges.

Note that this algorithm is correct: Since the Hungarian search maintains 1-feasiblity, the algorithm halts with a 1-optimal DCS (assuming a perfect DCS exists).

Step 1 is implemented by a depth-first search similar to that of § 2, modified for degree constraints larger than one: Each augmenting path P is initialized to a vertex $x \in V_0$ with positive deficiency; x is used to initialize paths P until its deficiency becomes zero or it is deleted from P. P is grown as an alternating path, so that when its last vertex x is in V_0 an edge not in D is scanned, and when x is in V_1 an edge of D is scanned. Instead of vertex marks, each vertex has a pointer to its last unscanned edge. The last edge of P gets deleted if x has no more unscanned edges. It is easy to see the time for Step 1 is $O(\overline{m})$. (As shown below, each augmenting path is simple, although this fact is not needed for correctness.)

The details of the Hungarian search are similar to § 2. The main differences stem from the fact that the search forest $\mathcal{F}$ is grown edge by edge, rather than in pairs of unmatched and matched edges. The time for the search is $O(m)$. This assumes that, as in § 2, an array $Q[1..dn]$ is used to compute minima; here d is the constant of Lemma 3.3, which justifies using the array.

This completes the description of the DCS algorithm. The discussion shows that it is correct. The efficiency analysis uses three inequalities, each analogous to (3) of § 2. To state the inequalities, we use notation similar to that of § 2: D is the DCS at any point in *match*. D_0 is the 1-optimal DCS of the previous scale; hence each of its edges costs at most $a = 3$. F is the set of vertices in V_0 with positive deficiency; Φ is their total deficiency,

$$\Phi = \sum \{\phi(v, D) | v \in F\}.$$

Δ is the sum of all dual adjustment quantities δ in all Hungarian searches so far. Each $x \in F$ has $y(x) = \Delta$. P_x denotes any one of the augmenting paths in $D_0 \oplus D$ that contains x.

LEMMA 3.1. *For some constant b, at any point in* match, $\Phi\Delta \leq bU$.

Proof. The argument of § 2 gives an analog of (1),

$$cl(D_0 \oplus D) \geq \sum\{\phi(v, D)y(v) | v \in F\}.$$

An edge of $D_0 - D$ has cost-length at most $a + 1$; an edge of $D - D_0$ has cost-length at least -1. Hence the lemma holds with $b = (a + 2)/2$. □

The second inequality is for graphs with bounded multiplicity. It generalizes [ET]. Recall that M denotes the maximum multiplicity of an edge in the multigraph.

LEMMA 3.2. *For some constant c, at any point in* match, $\Delta\sqrt{\Phi} \leq cn\sqrt{M}$.

Proof. Set $b = a + 2$. For each integer j define

$$U_j = \{u \in V_0 | y(u) \in [b(j-1)..bj)\},$$
$$W_j = \{w \in V_1 | y(w) - a - 1 \in (-bj.. - b(j-1)]\}.$$

We will show that for any $j \in [1..\lceil \Delta/b + 1 \rceil]$, each P_x has an edge uw with $u \in U_j$, $w \in W_j$. This implies $M|U_j||W_j| \geq \Phi$. Thus $|U_j|$ or $|W_j|$ is at least $\sqrt{\Phi/M}$. Hence $n \geq \sqrt{\Phi/M}(\Delta/b)$, as desired.

To find the desired edge uw of P_x, let the edges in $P_x - D$ be $u_i w_i$, $i = 1, \cdots, k$ (thus $u_1 = x$, and $u_{i+1}w_{i+1}$ follows $u_i w_i$). Since $P_x \subseteq D_0 \oplus D$,

$$\begin{aligned} y(u_i) + y(w_i) &\leq a + 1, \\ y(w_i) + y(u_{i+1}) &\geq -1. \end{aligned} \tag{4}$$

Note that $y(u_1) = \Delta$; $y(u_k) < b$ (by (4) and $y(w_k) = 0$); and $y(u_{i+1}) \geq y(u_i) - b$ (also by (4)). These three inequalities imply that for any $j \in [1..\lceil \Delta/b + 1 \rceil]$, P_x has some $u_i \in U_j$. For a given j, choose the last such i. Then $u_{i+1} \in U_{j-1}$. Together with (4) this implies $w_i \in W_j$, since

$$-bj < -y(u_{i+1}) - b \leq y(w_i) - a - 1 \leq -y(u_i) \leq -b(j-1).$$

We have shown that $w_i \in W_j$ and $u_i \in U_j$, as desired. □

Before giving the third inequality, we note a useful refinement of Lemma 3.2. Let X be a matching such that every edge not in X has multiplicity at most M_X.

COROLLARY 3.1. *For some constant c, at any point in* match, $\Delta\sqrt{\Phi} \leq cn\sqrt{M_X}$.

Proof. The proof is similar to the lemma. We show that for any $j \in [1..\lceil \Delta/b + 1 \rceil]$, each P_x has an edge uw not in X with $u \in U_j \cup U_{j-1}$, $w \in W_j$. This implies $M_X|U_j \cup U_{j-1}||W_j| \geq \Phi$, which leads to the desired conclusion.

To find the desired edge uw for a path P_x, proceed exactly as in the lemma to find an index i with $u_i \in U_j$, $u_{i+1} \in U_{j-1}$, and $w_i \in W_j$. One of the edges $u_i w_i$, $w_i u_{i+1}$ is not in X and can be taken as uw. □

Another bound on Δ is useful for large multiplicities. It is similar to the bound used in [GoT87a]. It justifies using the array $Q[1..dn]$ to compute minima in the Hungarian search.

LEMMA 3.3. *For some constant d, at any point in* match, $\Delta \leq dn$.

Proof. The proof of Lemma 3.2 shows that for any $j \in [1..\lceil \Delta/b + 1 \rceil]$, P_x has some $u \in U_j$. □

COROLLARY 3.2. *The number of iterations of* match *is* $O(\min\{\sqrt{U}, n^{2/3}M^{1/3}, n\})$.

Proof. Each execution of Step 1 (except possibly the first) augments along at least one path, i.e., it decreases Φ by at least one. The definition of Step 1 implies that each Hungarian search (except the last) increases Δ by at least one. Now the

first two bounds of the lemma follow because at any point in the algorithm Δ or Φ is at most B, where Lemma 3.1 gives $B = \sqrt{bU}$ and Lemma 3.2 gives $B = (cn)^{2/3}M^{1/3}$. The third bound follows from Lemma 3.3. □

The corollary implies the following time estimates. The estimates are good for graphs or multigraphs of very small multiplicity.

THEOREM 3.1. *A minimum perfect* DCS *on a bipartite multigraph can be found in* $O(\min\{\sqrt{U}, n^{2/3}M^{1/3}\}\overline{m}\log(nN))$ *time. The space is* $O(m)$. □

For example, in a bipartite graph a minimum perfect DCS can be found in $O(\min\{\sqrt{m}, n^{2/3}\}m\log(nN))$ time.

The bounds of the theorem also apply to finding a minimum-cost DCS. To see this let G be the given multigraph or graph. Form $\overline{G}$ by taking two copies of G and adding a set of edges X, where for each $v \in V(G)$, X contains an edge joining the two copies of v, with multiplicity $u(v) - \ell(v)$ and cost zero. It is easy to see that $\overline{G}$ is bipartite, and a minimum perfect DCS on $\overline{G}$ gives a minimum-cost DCS on G. Furthermore, X is a matching, so Corollary 3.1 applies with $M_X = M$. This implies the time bound of the theorem for minimum-cost DCS.

A similar reduction can be used to find a minimum-cost maximum cardinality DCS. The only difference is that an X-edge costs nN rather than zero. A minimum perfect DCS on this graph $\overline{G}$ induces the desired DCS on (either copy of) G. (In proof, let $\overline{D}$ be a minimum perfect DCS on $\overline{G}$. We can assume that $\overline{D}$ contains the same subgraph D in the two copies of G. Suppose D does not have maximum cardinality. Let P be an augmenting path. Then an alternating cycle C is formed by the two copies of P plus two edges of $\overline{D} \cap X$ that are incident to the two ends of P. Furthermore, $c(\overline{D} \oplus C) < c(\overline{D})$, a contradiction.)

Now we derive bounds that are good for multigraphs with moderately sized multiplicities. First observe that Lemma 2.3 still holds: in *match* there is no alternating cycle of eligible edges. The proof is essentially the same: There is no such cycle initially, since the edges initially in D are ineligible. A Hungarian search does not create such a cycle, since immediately after a dual adjustment a cycle leaving $\mathcal{F}$ on a new eligible edge reenters $\mathcal{F}$ on an ineligible edge.

This fact ensures that the time for a depth-first search in Step 1 is $O(m)$ plus the total augmenting path length. Thus the total time for *match* is $O(mB + A)$, where B is the number of iterations and A is the total augmenting path length. Corollary 3.2 bounds B; now we estimate A.

LEMMA 3.4. $A = O(\min\{U\log U, n\sqrt{MU}\})$.

Proof. As in Corollary 2.1, $A \le U + \sum_{i=1}^{U}\Delta_i$. For the first bound, estimate the summation as in Corollary 2.1, using Lemma 3.1. For the second bound, Lemma 3.2 shows that the summation is at most $\sum_{i=1}^{U} cn\sqrt{M/i} = O(n\sqrt{MU})$. □

THEOREM 3.2. *The transportation problem (capacitated or not) can be solved in* $O((\min\{\sqrt{U}, n^{2/3}M^{1/3}, n\}m + \min\{U\log U, n\sqrt{MU}\})\log(nN))$ *time. The space is* $O(m)$. □

To understand this rather involved time bound, first note that the terms containing M are relevant only in the capacitated transportation problem. The main use of the theorem in this paper is when $U = O(nm)$, in which case the time is $O(nm\log n\log(nN))$; this bound is used in § 3.2 to solve transportation problems with larger U. For further applications we concentrate on the range $M = O(n)$. In this case the above bound for $U = O(nm)$ holds, and also the bound $O(n^2\sqrt{m}\log(nN))$; hence in this range the performance is competitive with [GoT87a]. In most of the range $M = O(n)$, the bounds of Theorem 3.2 are those of Theorem 3.1, with $\overline{m}$ replaced by m: Using $U\log U$ as the second term of the time bound and writing Bm

as the first term, the first term dominates if $U = O(Bm/\log n)$. Hence the bound is $O(n^{2/3}M^{1/3}m\log(nN))$ if $U = O(n^{2/3}M^{1/3}m/\log n)$, e.g., $M = O(n/(\log n)^{3/2})$; the bound is $O(\sqrt{mM}m\log(nN))$ if $U = O(\sqrt{mM}m/\log n)$, e.g., $M = O(m/(\log n)^2)$; the bound is $O(\sqrt{nM}m\log(nN))$ if $U = O(\sqrt{nM}m/\log n)$, e.g., all degree constraints are $O(M)$ and $M = O(m^2/(n(\log n)^2))$.

As in Theorem 3.1, the same bounds hold for networks where each node has an upper and lower bound on its desired degree, and the objective is minimum cost or minimum-cost maximum cardinality.

3.2. Scaling edge multiplicities. In multigraphs with large multiplicities, efficiency is gained by scaling the multiplicities. Let D be a DCS. Recall that for an edge e, $u(e)$ and $d(e)$ denote the multiplicities of e in G and D, respectively; for a vertex v, $u(v)$ and $d(v)$ denote the degree constraint of v and the degree of v in D, respectively. The term *u-value* refers to a multiplicity $u(e)$ or a degree constraint $u(v)$. The approach is to scale u-values. The "closeness lemma" needed for scaling is the following.

Let G be a multigraph with u-values for which D is a minimum-cost maximum cardinality DCS. Form u^+ by adding one to the u-values of an arbitrary subset of vertices and edges (in particular a u-value can increase from zero to one). Let I be the number of increased u-values (so $I \leq m + n$). Let D^+ be a minimum-cost maximum cardinality DCS for u^+. Let $D^+ \oplus D$ denote the subgraph that is the direct sum of subgraphs D^+ and D (i.e., for any edge e, $D^+ \oplus D$ has $|d^+(e) - d(e)|$ copies of e). Choose D^+ so that $|D^+ \oplus D|$ is as small as possible. $\phi^+(v, D)$ denotes the deficiency of D at v for u-values u^+.

LEMMA 3.5. *$D^+ \oplus D$ can be partitioned into at most I simple alternating paths and cycles (where "alternating" means with respect to D and D^+).*

Proof. Since both D^+ and D are DCSs for u^+, $D^+ \oplus D$ can be partitioned into simple alternating paths and cycles; for each vertex v, at most $\phi^+(v, D^+)$ paths end at v on a D-edge, and similarly for a D^+-edge. Call an edge vw with $d^+(vw) > d(vw)$ *new* if either

(i) $d(vw) = u(vw)$, or

(ii) vw is an end of a path of $D^+ \oplus D$ and $d(v) = u(v)$.

There are at most I new edges. (A type (i) new edge clearly has an increased u-value. For a type (ii) new edge vw, v has an increased u-value and $\phi^+(v, D) = 1$, so vw is the only type (ii) edge associated with v.) Thus it suffices to show that any alternating path or cycle P of $D^+ \oplus D$ contains a new edge.

P does not begin and end with a D-edge, since D^+ has maximum cardinality. Suppose P does not contain a new edge. Then $D \oplus P$ is a feasible DCS for u. (This follows, since a D^+-edge vw of P has $d(vw) < u(vw)$; further, if this edge vw is an end of P, then $d(v) < u(v)$.) P does not begin and end with a D^+-edge, since D has maximum cardinality. Thus P is an even length alternating path or cycle. This implies that P has zero net cost (with respect to D or D^+). But this contradicts the fact that $|D^+ \oplus D|$ is as small as possible. □

It is convenient to define a new cost function $c_N(e) = c(e) - nN$. Here, as usual, N denotes the largest magnitude of an edge cost. Observe that D^+ is a minimum-cost DCS for c_N. (To prove this, we show that any DCS F with fewer edges than D^+ is not minimum: F has an augmenting path P. The DCS $F \oplus P$ has $c_N(F \oplus P) \leq c_N(F) + (n-1)N - nN < c_N(F)$.)

Lemma 3.5 indicates that $D^+ \oplus D$ can be found in a multigraph G' that models alternating paths. More precisely G' is defined as follows. A vertex $v \in V(G)$ corre-

sponds to v_1, $v_2 \in V(G')$; G' has an edge v_1v_2 of cost 0 and multiplicity I. An edge $vw \in E(G)$ corresponds to edges v_1w_1, $v_2w_2 \in E(G')$, with multiplicities and costs

$$u'(v_1w_1) = u^+(vw) - d(vw), \quad c'(v_1w_1) = c_N(vw);$$
$$u'(v_2w_2) = d(vw), \quad c'(v_2w_2) = -c_N(vw).$$

Finally, each $v \in V(G)$ has upper- and lower-degree constraints $u'(v_1) = u'(v_2) = I$, $\ell'(v_1) = 0$, $\ell'(v_2) = I - \phi^+(v, D)$.

Edges of type v_1v_2 are called *non-G-edges*, and all other edges are *G-edges*; edges of type v_2w_2 are called *D-edges*, and type v_1w_1 are *non-D-edges*. Observe that G' is bipartite, since a cycle has an even number of non-G-edges and the G-edges give a (not necessarily simple) cycle of G.

The desired subgraph D^+ can be chosen as $D' \oplus D$, where D' is a minimum-cost DCS on G'. To prove this, we will show two properties:

(a) A DCS D^+ for u^+ gives a DCS D' on G' of cost $c_N(D^+) - c_N(D)$.

(b) A minimum-cost DCS D' on G' gives a DCS for u^+ of c_N-cost $c_N(D) + c'(D')$.

To see that (a) and (b) suffice, observe that (a) implies $c_N(D^+) - c_N(D) \geq c'(D')$, (b) implies $c_N(D) + c'(D') \geq c_N(D^+)$, implying equality in both relations.

For (a), D' consists of the D-edges of $D - D^+$ and the non-D-edges of $D^+ - D$; additionally, for each vertex v, D' has $I - k$ copies of edge v_1v_2, where v is on k of the I paths and cycles of $D^+ \oplus D$ given by Lemma 3.5. Note that the lower bound constraint for v_2 is satisfied, since D^+ has at most $\phi^+(v, D)$ more non-D-edges than D-edges.

Part (b) follows from the observation that the G-edges of D' can be partitioned into at most I paths and cycles that are alternating for D, and that $D \oplus D'$ is a feasible DCS. The lower bounds $\ell'(v_2)$ ensure that $D \oplus D'$ satisfies all upper bounds u^+.

Now we can state the *capacity-scaling algorithm* for finding a minimum perfect DCS. Given a DCS problem on a multigraph G, let $\overline{u}$ denote the given u-values, with M the largest $\overline{u}$-value. (Without loss of generality, M is the $\overline{u}$-value of a vertex.) Consider each $\overline{u}$-value to be a binary number $b_1 \cdots b_k$ of $k = \lfloor \log M \rfloor + 1$ bits. The routine maintains u as the u-values in the current scale. Each scale constructs a minimum-cost maximum cardinality DCS D for u; d is the function corresponding to D. The routine initializes each $u(e)$, $d(e)$ and each $u(v), d(v)$ to zero. Then it executes the following loop for scale index s going from 1 to k:

Step 1. For each edge e, $d(e) \leftarrow 2d(e)$ and $u(e) \leftarrow 2u(e)+$ (bit b_s of $\overline{u}(e)$). For each vertex v, $u(v) \leftarrow 2u(v)+$ (bit b_s of $\overline{u}(v)$).

Step 2. Form the multigraph G' defined above. (Note that the function u^+ in the definition of G' is given by the function u constructed in Step 1; increased u-values correspond to bits b_s that are one in Step 1.)

Step 3. Let D' be a minimum-cost DCS on G'. Set $D \leftarrow D \oplus D'$, and let d be the function corresponding to D. □

To see that this algorithm is correct, note that the subgraph D constructed in Step 3 is a minimum-cost maximum cardinality DCS for u, by the above discussion. Hence in the last scale, D is the desired minimum perfect DCS. (Note that the algorithm works on both bipartite and general graphs.)

To estimate the running time, assume that Step 3 uses the cost-scaling algorithm of Theorem 3.2 to find the minimum-cost DCS. Noting that $U = O(nm)$ gives the following.

THEOREM 3.3. *The transportation problem (capacitated or not) can be solved in* $O(nm \log n \log(nN) \log M)$ *time. The space is* $O(m)$. □

This result extends to the variants of the perfect DCS problem mentioned above.

Next consider the *transportation problem with cost functions.* This problem allows parallel copies of an edge to have different costs. Specifically the cost of the pth copy of an edge e, $1 \le p \le u(e)$, is given by $c(e,p)$, a nondecreasing function of p that can be evaluated in $O(1)$ time. As usual, these costs are in $[-N..N]$, and each vertex v has a desired degree $u(v)$. The problem is to find a minimum-cost perfect DCS for these degree constraints. Note that the desired DCS can still be represented by an integral function on the edges $d(e)$, where $0 \le d(e) \le u(e)$, since we can assume that the DCS contains the $d(e)$ smallest cost copies of e.

As examples of this problem, $c(e,p) = \lfloor a_e p \rfloor + b_e$ is the original DCS problem for $a_e = 0$, and a simple example of diminishing returns to scale for $a_e > 0$. Alternatively, $c(e,p)$ could be, say, a piecewise quadratic function; in this case evaluating $c(e,p)$ for arbitrary p would probably involve a binary search on the breakpoints. (Note that in the definition of the transportation problem with cost functions, the restriction to nondecreasing cost functions $c(e,p)$ is crucial: without it the problem is NP-hard [GJ, p. 214]. Also note that the solution to the problem is a multigraph with integral multiplicities, by definition. This assumption of integrality is also crucial. This issue is discussed further after Theorem 3.5 for network flows, where real-valued flows make sense.)

In a trivial sense, the algorithm of Theorem 3.3 solves the transportation problem with cost functions — just treat parallel copies of an edge with different costs as different edges. The disadvantage of this approach is that in the time bound, the term m must count each edge e according to the number of distinct costs $c(e,p)$. We show how to avoid this: We extend the capacity-scaling algorithm to the transportation problem with cost functions, preserving the time bound of Theorem 3.3.

First we modify the cost-scaling algorithm to preserve the time bounds of Theorems 3.1–3.2. The derivation of those theorems remains valid for cost functions and gives the desired time bounds, provided all individual steps are implemented to run in essentially the same time as before. This means implementing Step 1 of the main routine and *scale_match* in time $O(m)$ (even though they modify every cost) and similarly for *match.* This can be done because of the following observation. When there are cost functions, the conditions for a DCS D to be 1-feasible are equivalent to a system involving only two inequalities per edge $e = vw$,

$$c(e, d(e)) \le y(v) + y(w) \le c(e, d(e) + 1) + 1.$$

Furthermore, the only copies of e that can be eligible are D-edges costing $c(e, d(e))$ and non-D-edges costing $c(e, d(e) + 1) + 1$.

Step 1 of the main routine and *scale_match* do not explicitly modify edge costs. Instead, *match* computes the cost of an edge when it is needed, in $O(1)$ time using arithmetic operations. Specifically, the pth cost for vw is

$$\bar{c}(vw, p) \div 2^{k-s} - y_0(v) - y_0(w), \tag{5}$$

where $\div$ denotes integer division, $k = \lfloor \log(n+2)N \rfloor$ is the number of cost scales, s is the index of the current cost scale, and y_0 denotes duals at the start of scale s.

The *match* routine starts by initializing D to contain all edges costing less than -1. This is done by examining each edge and adding smallest cost copies to D until

the cost reaches -1. The time is $O(m+U)$, which suffices for the bounds of Theorems 3.1–3.2.

In the depth-first search of Step 1, it is unnecessary to know the multiplicity of each eligible edge when the search begins. Rather, costs $c(e, d(e))$ and $c(e, d(e)+1)$ are used to determine which edges have at least one eligible copy. When the depth-first search finds an augmenting path P, the next cost for each edge $e \in P$ is used to see if there is another eligible copy of e (i.e., for $e \in P \cap D$, another copy of e is eligible if $c(e, d(e) - 1) = c(e, d(e))$, and similarly for $e \in P - D$). Thus the time for the depth-first search is still $O(m)$ plus the total augmenting path length. It is obvious that the Hungarian search, given costs $c(e, d(e))$ and $c(e, d(e) + 1)$, uses time $O(m)$. Thus the bounds of Theorems 3.1–3.2 apply.

Now we modify the capacity-scaling algorithm of Theorem 3.3. The new version works by scaling the domain of the cost functions. The closeness lemma (Lemma 3.5) generalizes as follows. Let G be a multigraph with cost functions c and u-values for which D is a minimum-cost maximum cardinality DCS. Form u^+ by adding one to the u-values of an arbitrary set of vertices and edges. Form c^+ so that for each edge e and $p \in [0..u^+(e))$,

$$c(e, p+1) \geq c^+(e, p+1) \geq c(e, p). \tag{6}$$

(Here $c(e, 0) = -\infty$, $c(e, u(e) + 1) = \infty$.) Let I be the number of vertices with an increased u-value plus the number of edges with an increased u-value or some decreased c-value (so that $I \leq m + n$). Let D^+ be a minimum-cost maximum cardinality DCS for c^+ and u^+, chosen so that $|D^+ \oplus D|$ is minimum ($D^+ \oplus D$ has the obvious interpretation).

LEMMA 3.6. *$D^+ \oplus D$ can be partitioned into at most I simple alternating paths and cycles.*

Proof. The argument is an expanded version of Lemma 3.5. We will explicitly state only the new material. The definition of *new edge* is expanded to include a type (iii) new edge e, defined to have $d^+(e) > d(e)$ and $c(e, d(e) + 1) > c^+(e, d(e) + 1)$, where by definition only the $d(e) + 1$st copy of e is new. (Note that $d^+(e) - d(e)$ may be larger than one.)

The argument remains unchanged until the end, when P is an even length alternating path or cycle not containing a new edge, and we must show that it has zero net cost (with respect to c^+ and D^+). The net cost of P with respect to c^+ and D^+ is nonnegative, by the minimum-cost property of D^+. Hence it suffices to show that the net cost of P with respect to c^+ and D is nonnegative.

This follows from the minimum-cost property of D if for every edge e whose pth copy is in $P \cap D^+$, $c^+(e, p) \geq c(e, d(e) + 1)$. We prove this inequality as follows. The pth copy of e is not new and $p \geq d(e) + 1$. Consider two cases: If $p = d(e) + 1$ then $c^+(e, p) = c(e, d(e) + 1)$, as desired. If $p > d(e) + 1$ then $c^+(e, p) \geq c(e, d(e) + 1)$ by (6), as desired. □

This lemma justifies an algorithm similar to the capacity-scaling algorithm. The main differences are as follows. Step 1, in addition to scaling d and u, scales the cost function domain. Specifically let c_0 denote the given cost function. Then for each e and $p \in [1..u(e)]$ (where $u(e)$ is the new u-value) Step 1 sets $c(e, p) \leftarrow c_0(e, 2^{k-s}p)$, where $k = \lfloor \log M \rfloor + 1$ is the number of capacity scales and s is the index of the current capacity scale. Observe that the DCS corresponding to the new (scaled) d is a minimum-cost maximum cardinality DCS for the new (scaled) u-values rounded down to even numbers and the new costs c with $c(e, 2p - 1)$ increased to $c(e, 2p)$. So

Lemma 3.6 applies and justifies the remaining steps: Step 2 defines G' as before but with costs changed in the obvious way to take cost functions into account. Step 3 computes D' using the cost-scaling algorithm described above.

For efficiency, these three steps are not done explicitly. (For instance, doing Step 2 explicitly would use $\Theta(m^2)$ time, since an edge can be in G' with multiplicity $m+n$.) Step 1 computes only two new costs for each edge e, $c(e, d(e))$ (already known) and $c(e, d(e)+1)$. To do Step 2, G' is initialized to contain only the cheapest copy of each edge of type v_1w_1, v_2w_2. This is the copy that will be added to the DCS D' first. Each copy comes from a cost computed in Step 1. When the cost-scaling algorithm checks to see if there is another eligible copy of an edge e (in the depth-first search), the next higher (or lower) cost copy of e is computed (by the formula of Step 1) and the cost is scaled down using (5).

THEOREM 3.4. *The transportation problem (capacitated or not) with cost functions can be solved in $O(nm \log n \log(nN) \log M)$ time. The space is $O(m)$.* □

We close this section with a variant of the capacity-scaling algorithm of Theorem 3.3. It will be useful in the next section for flow problems with lower bounds. The variant is essentially the (capacity scaling) mincost flow algorithm of Edmonds and Karp [EK]. For completeness we sketch this algorithm, which we call EK (capacity) scaling.

It is convenient to describe EK scaling in terms of two well-known ideas, which we now summarize. The algorithm could be given in terms of 1-feasibility, but it is more natural to use optimal dual variables. Analogous to § 2.2 for matching, optimal duals satisfy the 1-feasible inequalities with cost-length *cl* replaced by cost c. Specifically, variables $y(v)$, $v \in V$, are *optimal* for a DCS D if for any edge vw, $y(v)+y(w) \le c(vw)$ if $vw \notin D$ and $y(v)+y(w) \ge c(vw)$ if $vw \in D$. Any graph with a perfect DCS has a minimum perfect DCS with corresponding optimal duals. (Optimal duals correspond to the optimal linear programming dual variables.)

The classic Hungarian search for the Hungarian matching/DCS algorithm works with such optimal dual variables (see [L], [PS]). In contrast, the Hungarian search of § 3.1 uses 1-feasible duals. The difference in the two Hungarian searches is essentially the definition of "eligible": § 3.1 uses cost-length in the definition of eligible where the standard Hungarian search uses cost. In either case, the purpose of the Hungarian search is to adjust duals, preserving 1-feasibility or optimality as appropriate, and find an augmenting path of eligible edges. A Hungarian search (with optimal duals) can be done in time $O(m + n \log n)$ using Fibonacci heaps [FT].

Hungarian search can be used to do sensitivity analysis for the DCS problem. We will need two sensitivity problems: Given is a minimum perfect DCS D with corresponding optimal duals y. The first problem is to increase the degree constraints of two vertices v, w each by one, and update D and y (if a perfect DCS exists). The second problem is to add an edge vw to the multigraph and update D and y. Both problems can be solved in the time for one Hungarian search. We briefly sketch the algorithms.

First, suppose $u(v)$ and $u(w)$ are each increased by one. Do a Hungarian search from v. Eventually the search finds an augmenting path P of eligible edges from v to w. (The augmenting path can only end at w. If no such path is found, there is no perfect DCS for the new degree constraints.) The algorithm augments along P.

Next, suppose edge vw is added. If $y(v) + y(w) \le c(vw)$, then D and y remain optimal. Suppose $y(v) + y(w) > c(vw)$. Add new vertices v', w', and new edges vv', ww' with $c(vv') = c(ww') = 0$; set $y(v') = -y(v)$, $y(w') = -y(w)$. Do a Hungarian search from v', to adjust duals and find an augmenting path of eligible edges. Note that

the search lowers $y(v)$. If at some point $y(v)$ is lowered so that $y(v) + y(w) \leq c(vw)$ the search stops, since now vw can be added to the graph. Otherwise, the search finds an augmenting path P of eligible edges from v' to w'. (Note that if there is no augmenting path from v' to w', the Hungarian search can eventually lower $y(v)$ so that the first case holds.) The algorithm augments along P and adds vw to the DCS. (This is permissible, since $y(v) + y(w) > c(vw)$.) Finally, the new vertices and edges are deleted.

The EK-scaling algorithm scales capacities similar to the capacity-scaling algorithm. Since it works with optimal duals, it modifies the graph of each scale to ensure that a perfect DCS exists. This is done by using the graph $\overline{G}$ (defined in § 3.1): $\overline{G}$ consists of two copies of G plus edges X, where for each $v \in V(G)$, X contains an edge joining the two copies of v, with multiplicity $u(v)$ and cost nN. Note that (as in § 3.1) a minimum perfect DCS on $\overline{G}$ induces a minimum-cost maximum cardinality DCS on G. Hence in the last scale, the desired minimum perfect DCS is found.

Now we present the EK-*scaling algorithm.* It finds a minimum perfect DCS. Given a DCS problem on a multigraph G, define $\overline{u}$, M, k as in the capacity-scaling algorithm. The routine maintains u as the u-values in the current scale. Each scale constructs a minimum perfect DCS D for the graph $\overline{G}$; d is the function corresponding to D. The routine initializes each $u(e)$, $d(e)$, and each $u(v)$ to zero. Then it executes the following loop for scale index s going from 1 to k:

Step 1. For each $e \in E(\overline{G})$, $d(e) \leftarrow 2d(e)$ and $u(e) \leftarrow 2u(e)$. For each $v \in V(\overline{G})$, $u(v) \leftarrow 2u(v)$.

Step 2. For each $e \in E(G)$ such that the binary expansion of $\overline{u}(e)$ has bit $b_s = 1$, do the following: For each copy of G, add one to the copy of $u(e)$ and add another copy of e, updating D and y using the above routine for adding an edge.

Step 3. For each $v \in V(G)$ such that the binary expansion of $\overline{u}(v)$ has bit $b_s = 1$, do the following: Add another copy of the edge joining both copies of v to $\overline{G}$. Update D and y using the above routine for adding an edge. Then add one to both copies of $u(v)$, and update D and y using the above routine for increasing upper bounds. □

The correctness of EK scaling follows from the fact that it maintains a set of optimal duals on $\overline{G}$ for u and D. Note that in Step 3 in the update routine for increasing upper bounds, an augmenting path always exists: If the edge vv was added to D in the routine for adding an edge, the augmenting path that was used can now be reused.

In problems where each scale has $I = O(n)$, the total time for EK scaling is $O(n(m + n \log n) \log M)$, slightly improving Theorem 3.3. We will encounter such problems in the next section.

3.3. Network flow. This section extends the results to integral network flows. It is convenient to work with the problem of finding a minimum-cost circulation, defined as follows [L]. Let G be a directed graph where each vertex v has a nonnegative integral capacity $u(v)$, and each edge e has a nonnegative integral capacity $u(e)$, a lower bound $\ell(e)$ and a cost $c(e)$. The *minimum circulation problem* is to find a feasible circulation with smallest possible cost. (If vertex capacities are not given, setting $u(v) = \sum_{vw} u(vw)$ does not change the problem. The circulation problem includes the minimum-cost flow problem as a special case. As already mentioned, the usual definition of the circulation (network flow) problem allows real-valued parameters. However, note that if all capacities and lower bounds are integral, an optimum

circulation (flow) that is integer-valued always exists [L].)

A minimum circulation problem on a network G can be transformed to a minimum perfect DCS problem on a bipartite multigraph B, as follows. A vertex $v \in V(G)$ corresponds to v_1, $v_2 \in V(B)$; B has an edge v_1v_2 of cost 0 and multiplicity $u(v)$. An edge $vw \in E(G)$ corresponds to $v_1w_2 \in E(B)$ with cost $c(vw)$ and multiplicity $u(vw) - \ell(vw)$. The degree constraints on B are

$$u(v_1) = u(v) - \sum\{\ell(vw) | vw \in E(G)\},$$
$$u(v_2) = u(v) - \sum\{\ell(wv) | wv \in E(G)\}.$$

A circulation on G corresponds to a perfect DCS on B costing less by exactly $\sum\{\ell(e)c(e) | e \in E(G)\}$. Thus the flow problem can be solved using the DCS algorithms given above. Note that B has n vertices in each vertex set, $O(m)$ edges, $U = O(\sum\{u(v) | v \in V(G)\})$ and $\overline{m} = O(U + \sum\{u(e) | e \in E(G)\})$. In part (a) below, $\overline{m}$ is the number of edges, with each edge counted according to its capacity.

THEOREM 3.5. *A minimum-cost circulation on a network with all edge capacities and lower bounds in* $[0..M]$ *can be found in the following time bounds (and space* $O(m)$*):*

(a) $O(\min\{\sqrt{\overline{m}}, n^{2/3}M^{1/3}\}\overline{m}\log(nN))$.

(b) $O((\min\{\sqrt{mM}, n^{2/3}M^{1/3}, n\}m + \min\{mM\log(mM), n^2\sqrt{m}\})\log(nN))$.

(c) $O(nm\log n\log(nN)\log M)$.

These bounds also hold when each edge cost is a convex function of its flow.

Proof. These bounds follow essentially from Theorems 3.1–3.4. Note that M does not necessarily bound the multiplicities in B, since we assume no bound on vertex capacities in G. Nonetheless, the bound for part (b) holds. To show this, use Corollary 3.1, with matching X containing all edges of the form v_1v_2; note that $M_X = M$. Also the bound for part (c) holds: There are $\log(mM)$ capacity scales, but the time bound involves the factor $\log M$, because each of the first $\log m$ scales is trivial. □

Note that in Theorem 3.5(c), the algorithm for convex cost functions finds an optimal integral-valued flow. However, this flow need not be the global optimum, which may involve real-valued flow values. Finding this solution appears to be much harder. For instance, if the cost of an edge is a quadratic function of its flow, finding a minimum-cost flow is NP-hard [GJ], [H].

Next, consider a minimum circulation problem in which $O(n)$ vertices and edges have finite capacity. As usual, every edge has a lower bound, perhaps zero. Such problems arise as covering problems; a common special case is circulations with lower bounds but no upper bounds (e.g., the aircraft scheduling problem of [L, p. 139]).

THEOREM 3.6. *A minimum circulation on a network with lower bounds but only* $O(n)$ *finite capacities, all lower bounds and finite capacities in* $[0..M]$*, can be found in* $O(n(m + n\log n)\log(nM))$ *time and* $O(m)$ *space.*

Proof. Without loss of generality assume that no cycle has negative cost and infinite capacity. (Such a cycle can be detected in time $O(nm)$ using Bellman's algorithm [Bel].) Recall that a circulation can be decomposed into flows around cycles [Tarj]. Hence it is easy to see that all infinite capacities (on edges or vertices) can be replaced by any number that is at least $S = \sum\{\textbf{if } c(e) \text{ is finite } \textbf{then } c(e) \textbf{ else } \ell(e) | e \in E(G)\} + \sum\{c(v) | v \in V(G),\ c(v) \text{ is finite}\}$.

The algorithm is as follows: Find S and set $k = \lceil \log S \rceil$. For each infinite capacity vertex v, redefine its capacity to S; for each infinite capacity edge e, redefine its

capacity to $\ell(e) + 2^{k+1}$. Transform the new circulation problem into a DCS problem, as above, and solve the DCS problem using EK scaling.

The correctness of this algorithm follows from the definition of S. To estimate the efficiency, note that in the DCS problem, every infinite capacity edge of G has multiplicity 2^{k+1} and every vertex v_1, v_2 has degree constraint at most $S \leq 2^k$. Hence the first scale is trivial — no edges are in the DCS, and the duals can be set to any sufficiently small values (say $\min\{c(e)/2 | e \in E\}$). Every scale after the first has $I = O(n)$ (recall that I is the number of increased u-values), since the u-values of infinite capacity edges double. Hence the total time is $O(n(m + n \log n) \log S)$, implying the desired bound. □

The term $\log(nM)$ in the time bound can be replaced by $\log M$, or more precisely, $(1 + \log(S/n))$. This modified bound is an asymptotic improvement for S very close to n. The modified bound follows because, although there are $\log S$ scales, the first $\log n$ scales do $O(n)$ augmentations. (This in turn holds, since every unit of I in the first $\log n$ scales contributes at least S/n to the sum for S. Actually, to achieve this requires a slight modification to the algorithm: the capacity of an infinite capacity vertex v is changed to $2^k + \sum\{\ell(e) | e \text{ is incident to } v\}$.) Bounds similar to this are in [EK], [AL].

As an example of an application of these bounds, consider the directed Chinese postman problem. A complete definition of the problem is given in [EJ], [PS]; it is a special case of the above problem with $S = O(m)$. The theorem gives time $O(n(m+n \log n) \log n)$ for this problem; the modified bound is slightly better, $O(n(m+n \log n) \log(m/n))$. (For instance, it is easy to see that the modified bound is no worse than $O(nm \log n)$.) Aho and Lee [AL] give a complete discussion of covering problems such as this one.

4. Concluding remarks. Table 1 shows that in terms of asymptotic estimates, many network problems can be solved efficiently by scaling. Scaling algorithms also tend to be simple to program. For instance, the assignment algorithm consists of an outer scaling loop plus an inner loop that does a depth-first search, followed by a Dijkstra calculation. We believe that such algorithms will run efficiently in practice. Note that in the experiments done by Bateson [Ba] the scaling algorithm of [G85] ran faster than the Hungarian algorithm as long as the cost of the matching could be stored in a machine integer. Our assignment algorithm has even simpler code than [G85] and so should do even better.

We have extended the assignment algorithm in three other directions. The first direction is parallel computation. Almost-optimum speedup can be achieved for a large number of processors. Specifically, the time bound for the assignment problem improves by a factor of $(\log(2p))/p$ for a version of the algorithm running on an EREW PRAM with p processors, for $p \leq m/(\sqrt{n} \log^2 n)$. Details are in [GabT88]. The second direction is matroid generalizations of bipartite matching, such as the independent assignment problem and weighted matroid intersection. As in this paper, time bounds very close to the best-known bounds for the cardinality versions of the problems can be achieved; see [GX89a], [GX89b]. The third direction is matching on general graphs. The time bound for finding a minimum perfect matching on a general graph is $O(\sqrt{n\alpha(m,n) \log n}\ m \log(nN))$. The algorithm is more complicated than the assignment algorithm because of "blossoms" that occur in general matching. Blossoms compound the error due to scaling. Details are in [GabT89].

Since the initial writing of this paper several related results have also been obtained by others. Orlin and Ahuja [OA] discovered an alternative $O(\sqrt{nm} \log(nN))$-

time algorithm for the assignment problem. Their algorithm uses our scaling approach in combination with a hybrid inner loop that uses the Goldberg–Tarjan "preflow-push" method in a first phase and single augmentations in a second phase. (We chose not to use this approach because of the conceptual and practical advantages of a uniform algorithm.) Orlin and Ahuja also show how to use their assignment algorithm (or ours) to find a minimum average cost cycle in a directed graph with edge costs, in the same time bound. Ahuja, Goldberg, Orlin, and Tarjan [AGOT] have studied other double scaling algorithms for the minimum-cost flow problem. Their fastest algorithm runs in $O(nm \log(nN) \log\log M)$ time with sophisticated data structures or $O(nm \log M(1 + \log(nN)/\log\log M))$ time with simple data structures. Aho and Lee [AL] have investigated the use of Edmonds–Karp scaling in covering problems, as already mentioned in § 3.3.

Acknowledgment. We thank Andrew Goldberg for sharing his ideas, which inspired this work.

A NEW BASE CHANGE ALGORITHM FOR PERMUTATION GROUPS *

CYNTHIA A. BROWN†, LARRY FINKELSTEIN†, AND PAUL W. PURDOM, JR. ‡

Abstract. The computation of a strong generating set for a permutation group acting on a set Ω of n points is the fundamental operation that underlies most of the algorithms in computational group theory. Sims gave a *change of basis* algorithm that transforms a strong generating set relative to one ordering of Ω into a strong generating set relative to a different ordering. Base change is crucial for many of the important algorithms that have been implemented in the Cayley system, and is also important for many applications of computational group theory to combinatorial and search problems. Sims's base change has worst-case time $O(n^5)$. The main result of this paper is a new change of basis algorithm that has worst-case time $O(n^3)$.

1. Introduction.

Let G be a permutation group acting on a set Ω, and let $\pi = \pi_1, \pi_2, \cdots, \pi_n$ be an ordering of the points of Ω. Define $G^{(i)}$ to be the subgroup of G consisting of all elements of G that fix each of the points $\pi_1, \pi_2, \cdots, \pi_{i-1}$, $1 \leq i \leq n$. The *point stabilizer sequence* for G relative to π is the chain of subgroups

$$G = G^{(1)} \supseteq G^{(2)} \supseteq \cdots \supseteq G^{(n-1)} \supseteq G^{(n)} = \{e\}.$$

A set S of generators for G is said to be a *strong generating set* for G relative to π, if

$$G^{(i)} = \langle S \cap G^{(i)} \rangle,$$

i.e., those *generators* in S that fix $\pi_1, \pi_2, \cdots, \pi_{i-1}$ generate $G^{(i)}$.

The computation of a strong generating set for G relative to an ordering π is the fundamental operation that underlies many important algorithms in computational group theory. Sims [11] developed the first algorithm for constructing a strong generating set, using the *Schreier vector* data structure for storing the resulting generators. Sims also gave an efficient *change of basis* algorithm that transforms a strong generating set relative to one ordering of Ω into a strong generating set relative to a different ordering. Butler and Lam [5] have shown that Sims's base change algorithm has worst-case time $O(n^5)$. This paper presents a change of basis algorithm that has worst-case time $O(n^3)$.

Base change is crucial for an efficient application of Sims's backtracking method for performing fundamental group computations. This method underlies many of the algorithms implemented in the Cayley system [6] and is also important for applications of computational group theory to combinatorial and search problems [3], [5], [10].

Sims's method involves a systematic search through the elements of G in order to compute a subgroup H of G satisfying a certain property (such as centralizing an element of G). If any subgroup K of H is known in advance, or is computed in the course of the search, the algorithm uses K to prune the search space for G. In order to do the pruning efficiently, it is necessary to be able to rapidly compute K_Γ, the pointwise stabilizer in K of an arbitrary subset Γ of Ω [4]. With an efficient change of basis algorithm, strong generators for K relative to an ordering of Ω for which Γ forms a prefix can be computed, and so generators for K_Γ are readily available.

Our base change algorithm is also useful for the pointwise stabilizer problem. Recently, Babai, Luks, and Seress [1] have described an $O(n^4(\log(n)^c))$ algorithm for obtaining a strong generating set for a permutation group. Their method requires an initial ordering of the points to be compatible with an "extended structure tree" determined by the action of the permutation group. Thus the Babai-Luks-Seress algorithm can find the pointwise stabilizer for a set of points that are the leftmost consecutive leaves of the structure tree. As they state, the method can be extended to obtain the pointwise stabilizer of an arbitrary subset of Ω within the same asymptotic worst-case time. However, a simple alternative for the general pointwise stabilizer problem is to use a structure tree to obtain a strong generating set in $O(n^4(\log(n)^c))$ time, and then use our change of basis algorithm to obtain a strong generating set relative to a suitable reordering of the points in time $O(n^3)$.

Our change of basis algorithm uses the *labeled branching* data structure to represent a strong generating set for a permutation group. This data structure was introduced by Jerrum [8] as a compact way of (implicitly) storing a coset table for the point stabilizer chain of subgroups relative to an ordering π. The labeled branching for G requires the storage of at most $n-1$ permutations and can be used to compute a coset representative for $G^{(i+1)}$ in $G^{(i)}$ with a single permutation multiplication. The permutations in the labeled branching for G also constitute a set of strong generators for G relative to π. A labeled branching occupies $O(n^2)$ storage, versus the $O(n^3)$ storage required for the Schreier vector method, and can be computed directly in $O(n^5)$ time using an algorithm described by Jerrum [8]. (See also [7] for a description of an efficient implementation of this algorithm.) Alternatively, a labeled branching for G relative to π can easily be computed in $O(n^3)$ time once a strong generating set for G relative to π is known.

Let $\mathcal{B}$ be a labeled branching for G relative to an ordering $\pi = \pi_1, \pi_2, \cdots, \pi_n$. The key step in our algorithm is a fast method for constructing a labeled branching $\mathcal{B}'$ for G relative to a new ordering $\pi_1, \cdots, \pi_{r-1}, \pi_s, \pi_r, \pi_{r+1}, \cdots, \pi_{s-1}, \pi_{s+1}, \cdots, \pi_n$, where $r < s$. This step, which amounts to a "right cyclic shift" of the points $\pi_r, \cdots, \pi_s$, can be performed in $O(n^2)$ time. The ordering $\pi_1, \pi_2, \cdots, \pi_n$ can be transformed into an arbitrary ordering $\pi'_1, \pi'_2, \cdots, \pi'_n$ by performing at most $n-1$ such shifts, giving a total time of $O(n^3)$. (There are some applications where a fast algorithm for a single cyclic right shift is of direct interest [3].) In Sims's original formulation, the key step is to use an elegant trick to get a strong generating set for G relative to a new ordering of the form $\pi_1, \cdots, \pi_{i-1}, \pi_{i+1}, \pi_i, \cdots, \pi_n$ without performing any "sifting" operations. It then takes $O(n^2)$ transpositions to reach the final ordering. Our method generalizes Sims's trick for transpositions to a right cyclic shift, still without requiring any sifting operations.

2. Labeled branchings. Let permutation group G act on $\Omega = \{1, 2, \cdots, n\}$, and let $\pi = \pi_1, \pi_2, \cdots, \pi_n$ be an ordering of the points of Ω. A *branching* on Ω relative to π is a directed forest in which each edge has the form (π_i, π_j) for $i < j$. A branching

$\mathcal{B}$ is said to be a *labeled branching for* G relative to π if each edge (π_i, π_j) is labeled by a permutation σ_{ij} so that the following properties hold:

(i) $\sigma_{ij} \in G^{(i)}$ and moves π_i to π_j, i.e., $\pi_k^{\sigma_{ij}} = \pi_k$ for $1 \leq k < i$ and $\pi_i^{\sigma_{ij}} = \pi_j$.

(ii) The set of edge labels of $\mathcal{B}$ generates G.

A labeled branching $\mathcal{B}$ is said to be *complete* if the following additional property holds:

(iii) If π_k is in the $G^{(i)}$ orbit of π_i, then there is a directed path in $\mathcal{B}$ from π_i to π_k.

Criterion (iii) ensures that the edge labels of $\mathcal{B}$ form a strong generating set for G relative to the ordering π.

Labeled branchings can be implemented as an array of structures using $O(n^2)$ storage. Although we have described the labeled branching in terms of the edge labels σ, the actual permutations stored in the branching data structure are products of the edge labels. Let π_r be the root of the connected component of $\mathcal{B}$ containing π_j. Associate with each node a *node label* $\tau(j)$, where $\tau(j)$ is the product of the edge labels from the root π_r to π_j if $\pi_r \neq \pi_j$, and is the identity if $\pi_r = \pi_j$. Since $\tau(j)^{-1}$ moves π_j to its root π_r, we may recover the label for edge (π_i, π_j), σ_{ij}, as $\sigma_{ij} = \tau(i)^{-1}\tau(j)$. Thus, the node labels are an implicit way of storing the edge labels, as they allow an edge label to be recovered at the cost of one permutation multiply. Furthermore, if there is a path from π_k to π_j in $\mathcal{B}$, then $\tau(k)^{-1}\tau(j)$ is the product of the edge labels along the path from π_k to π_j. This means that coset representatives can also be recovered from the data structure at the cost of one multiply, as opposed to $O(n)$ multiplies if edge labels were stored.

In addition to the τ field, each node π_j of $\mathcal{B}$ has a *parent* field, where $parent(j) = k$ if (π_k, π_j) is an edge, and -1 (a value less than any point) otherwise. When a constant factor of time is more important than a constant factor of space, one should also store $\tau(j)^{-1}$. For some applications, it is useful to keep a list of the children for each node.

The main operation on a labeled branching is "sifting" a permutation. This is the key step in all algorithms for finding a strong generating set. The basic idea behind sifting is to see if a given permutation g can be written in the form $g = g_{n-1}g_{n-2}\cdots g_1$, where g_i is an element of a fixed set $U^{(i)}$ of coset representatives for $G^{(i+1)}$ in $G^{(i)}$, $1 \leq i \leq n-1$. If g cannot be written in this form, then there exists an index i such that $g' = gg_1^{-1}\cdots g_{i-1}^{-1}$, where $g_j \in U^{(j)}$, for $1 \leq j \leq i-1$, $g' \in G^{(i)}$, and there does not exist a path in $\mathcal{B}$ from i to $j = i^{g'}$. Sift then attempts to create a new edge (i, j) with edge label g'. If $indegree(j) = 0$, then this can be done directly. However, if $indegree(j) = 1$, then care must be taken to preserve both the branching property as well as "connectivity" and "generational" properties already built into the current branching (see [8] and [2, Prop. 8.1, 8.2]).

Jerrum proved that a complete labeled branching for a permutation group can be computed in $O(n^5)$ time using $O(n^2)$ storage. The basic idea of the algorithm is to sift into an empty labeled branching generators for G, and then to sift in "Schreier generators" for $G^{(i+1)}$, $i = 1, \cdots, n-2$, successively. Schreier generators for $G^{(i+1)}$ can be built from a set of generators for $G^{(i)}$ and a set of coset representatives for $G^{(i+1)}$ in $G^{(i)}$ that are available from the branching and were entered in the previous iteration. Knuth [9] also has an $O(n^5)$ time algorithm for computing a strong generating set, but his algorithm requires $O(n^3)$ storage.

3. The base change algorithm. Let $\mathcal{B}$ be a labeled branching for G with respect to the ordering

$$\pi = \pi_1, \cdots, \pi_{r-1}, \pi_r, \cdots, \pi_s, \pi_{s+1}, \cdots, \pi_n,$$

let $\Omega = \{1, 2, \cdots, n\}$, and let

$$\pi' = \pi_1, \cdots, \pi_{r-1}, \pi_s, \pi_r, \pi_{r+1}, \cdots, \pi_{s-1}, \pi_{s+1}, \cdots, \pi_n$$

(i.e., $\pi'_i = \pi_i$, for $1 \leq i < r$, $s < i \leq n$, and $\pi'_r = \pi_s$, $\pi'_i = \pi_{i-1}$, for $r < i \leq s$). Permutation π' is obtained from π by a *cyclic shift of values* (the values between r and s). In this case, the labeled branching $\mathcal{B}'$ with respect to π' is said to be obtained from $\mathcal{B}$ by a *cyclic shift of base points.* We describe a function *Cycle-node*, which transforms $\mathcal{B}$ to $\mathcal{B}'$.

The function Cycle-node has as input the labeled branching $\mathcal{B}$ for G relative to π and a new ordering π' obtained from π by a cyclic shift of values. It returns a labeled branching $\mathcal{B}'$ for G relative to π'. We start with a trivial labeled branching $\mathcal{B}'$ and build $\mathcal{B}'$ into a complete labeled branching for G with respect to π' from the leaves to the root. In the course of building $\mathcal{B}'$, it is convenient to store the edge label connecting π'_j to its parent π'_i (i.e., σ'_{ij}) in the τ'_j field. After all the appropriate edge labels have been constructed, we restore the τ' fields to their original purpose in $O(n^2)$ time. We do this to avoid the necessity of constantly updating the τ fields as new connections are made. Since we are building $\mathcal{B}'$ from leaves to the root, we always introduce new edges of the form (π'_i, π'_j) where π'_j is the current root of a subtree of $\mathcal{B}'$. If we used the standard interpretation of τ, then we would have to update the τ fields of each descendant π'_k of π'_j each time we added an edge, and this takes $O(n^2)$ time. In order to compensate for not using the standard interpretation of τ, we maintain an array *root* of length n with the property that if $i = root[j]$, then π'_i is the root of the subtree containing π'_j.

Let $G_{ab\cdots c}$ be the subgroup of G that fixes the points $a, b, \cdots, c$ of Ω. We denote $G^{(i)} = G_{\pi_1 \cdots \pi_{i-1}}$, the subgroup that fixes the first $i-1$ points, $\pi_1, \cdots, \pi_{i-1}$ and $\Delta^{(i)} = \pi_i^{G^{(i)}}$, the orbit of point π_i in $G^{(i)}$. $G'^{(i)} = G_{\pi'_1 \cdots \pi'_{i-1}}$ and $\Delta'^{(i)} = \pi_i'^{G'^{(i)}}$ are used for the transformed points. We use primes for distinguishing between node fields of $\mathcal{B}$ and $\mathcal{B}'$.

Before performing Cycle-node, we initialize $\mathcal{B}'$ to the empty branching and set $root[i] = i$, $1 \leq i \leq n$. Set the fields of nodes $s+1, \cdots, n$ of $\mathcal{B}'$ to reflect the fact that $\pi_j = \pi'_j$ for j in the range $s+1, \cdots, n$. For each j in the range from $s+1$ to n, if π_i is the parent of π_j and $s+1 \leq i$, we set $parent'(j) = i$, $\tau'(j) = \tau(i)^{-1}\tau(j)$, and $root[j] = root[i]$. If $i < s+1$, then $\tau'(j)$, $parent'(j)$, and $root[j]$ are unmodified from their initial values. After this step is completed, $\mathcal{B}'$ is a labeled branching for $G'^{(s+1)}$ relative to π', subject to adjusting the τ fields.

The next step is the crucial one. We successively fill in the edge labels of $\mathcal{B}'$ that emanate from π'_j as j goes from s to r. This requires computing

$$\Delta'^{(j)} = \pi_j'^{G'^{(j)}}.$$

Now, $\pi'_j = \pi_{j-1}$ for $r < j \leq s$, and $\pi'_r = \pi_s$. Furthermore, for $r < j \leq s$

$$G^{(j)} = G_{\pi'_1 \cdots \pi'_{j-1}} = G_{\pi_1 \cdots \pi_{j-2} \pi_s},$$

and

$$G'^{(r)} = G^{(r)}.$$

Thus, for $r < j \leq s$,

$$\Delta'^{(j)} = \pi_{j-1}^{G_{\pi_1 \cdots \pi_{j-2} \pi_s}}$$

and

$$\Delta^{(r)} = \pi_s^{G^{(r)}}.$$

Since it is straightforward to compute $\Delta'^{(r)}$, we concentrate on the case where $r < j \leq s$. For these values of j, $\Delta'^{(j)} \subseteq \Delta^{(j-1)}$. It is easy to compute $\Delta^{(j-1)}$, so we need a criterion for deciding whether a point of $\Delta^{(j-1)}$ is in $\Delta'^{(j)}$. The following is a generalization of a result of Sims [11].

LEMMA 3.1. *Let $r < j \leq s$ and let $\pi_m = \pi_{j-1}^{\alpha} \in \Delta^{(j-1)}$ for some $\alpha \in G^{(j-1)}$. Then*

$$\pi_m \in \Delta'^{(j)} \iff \pi_s^{\alpha^{-1}} \in \pi_s^{G^{(j)}}.$$

Proof. Suppose that $\pi_m \in \Delta'^{(j)}$. Then $\pi_m = \pi_{j-1}^{\beta}$ for some $\beta \in G'^{(j)} = G_{\pi_1 \cdots \pi_{j-2} \pi_s}$. Now, $\beta\alpha^{-1}$ fixes π_{j-1}, and so $\beta\alpha^{-1} \in G^{(j)}$. Furthermore, β fixes π_s. Thus,

$$\pi_s^{\alpha^{-1}} = \pi_s^{\beta\alpha^{-1}} \in \pi_s^{G^{(j)}}.$$

Conversely, suppose that $\pi_s^{\alpha^{-1}} \in \pi_s^{G^{(j)}}$. Let $\pi_s^{\alpha^{-1}} = \pi_s^{\beta}$ for some $\beta \in G^{(j)}$. Then $\beta\alpha \in G'^{(j)}$ and

$$\pi_m = \pi_{j-1}^{\alpha} = \pi_{j-1}^{\beta\alpha} \in \Delta'^{(j)}$$

as required. □

In preparation for inserting the edge labels of $\mathcal{B}'$ that emanate from π'_j for $r \leq j \leq s$, we construct a Boolean array *orbit* of length n where $orbit[i] = 1$ if and only if $\pi_i \in \pi_s^{G^{(s)}}$. Additionally, we construct an array *cosetrep* of length n where $cosetrep[i]$ is a permutation of $G^{(s)}$ that moves π_s to π_i if $orbit[i] = 1$, and $cosetrep[i]$ is *nil* if $orbit[i] = 0$.

Now assume that we have inserted into $\mathcal{B}'$ the edges that emanate from π'_i, for $r < j < i \leq s+1$, so that $\mathcal{B}'$ is a labeled branching for $G'^{(j+1)}$ relative to π' (subject to adjusting the τ' fields). Further, assume that we have updated *root* and extended *orbit* and *cosetrep* to reflect the fact that *orbit* and *cosetrep* are defined for $\pi_s^{G^{(j+1)}}$. We describe how to insert the edges of $\mathcal{B}'$ that emanate from π'_j.

The first step is to extend *orbit* and *cosetrep* for the orbit $\pi_s^{G^{(j)}}$. This amounts to throwing into the pool of generators for the previous orbit and coset calculations those edge labels of $\mathcal{B}$ that move π_j. Each of these new generators must be applied to each point currently in the orbit, and all generators for $G^{(j)}$ must then be applied against all new points discovered. The total cost of updating *orbit* and *cosetrep* for $r \leq j \leq s$ is thus equal to the cost of computing *orbit* and *cosetrep* for $\pi_s^{G^{(r)}}$ using generators for $G^{(r)}$ available from $\mathcal{B}$.

We now apply Lemma 3.1. Let $\Gamma = \Delta^{(j-1)}$. For each point $\pi_m = \pi_{j-1}^{\alpha} \in \Gamma$, we use *orbit* to find out whether $\pi_s^{\alpha^{-1}} \in \pi_s^{G^{(j)}}$. If it is, we then find q such that $\pi_m = \pi'_q$ and check whether $root[q] = q$. We only want to connect π'_j to a node of $\mathcal{B}'$ that is a root of a subtree. Thus if π'_q is not a root, we move on to the next point of Γ, knowing that the connection will eventually be made between π'_j and π'_q via the root of the subtree containing π'_q. If π'_q is a root, we use *cosetrep* to find β, as in Lemma 3.1, so that for $\gamma = \alpha\beta \in G'^{(j)}$, $\pi_m = \pi_{j-1}^{\gamma}$, and hence $\pi'_q = \pi_j'^{\gamma}$. We now set $\tau'(q) = \gamma$, $parent'(q) = j$. Furthermore, we set $root[q] = j$ and modify *root* so that if $root[i] = q$ then set $root[i] = j$. After examining all points of Γ, $\mathcal{B}'$ will be a labeled branching for $G'^{(j)}$.

We continue decrementing j and constructing $\mathcal{B}'$ in this way until $j = r$. Since $\Delta'^{(r)} = \pi_s^{G^{(r)}}$, for $j = r$ we extend *orbit* and *cosetrep* as before, but this time we do

not require the use of Lemma 3.1. We simply check each point $\pi_m \in \Delta^{(r)}$ to see if its corresponding value π'_q is a root of $\mathcal{B}'$ or not. If it is, then we use *cosetrep* to find an element $\gamma \in G^{(r)} = G'^{(r)}$ that moves π'_r to π'_q. We then install a new edge from π'_r to π'_q and update both $\mathcal{B}'$ and *root* as is done above.

At this point, $\mathcal{B}'$ is a labeled branching for $G'^{(r)}$ relative to π'. Since $\pi'_i = \pi_i$ for $1 \le i \le r-1$, the remaining data for $\mathcal{B}'$ may be filled in using a slight modification of the procedure above. This time we may use the information stored in $\mathcal{B}$ instead of relying on *orbit* and *cosetrep*. In particular, suppose that the data for $\mathcal{B}'$ have been entered for all nodes π'_j such that $i < j$. For each $\pi_m \in \Delta^{(i)} - \{\pi_i\}$, we check if π'_q is a root of $\mathcal{B}'$. If it is, we set $\tau'(q) \leftarrow \tau^{-1}(i)\tau(m)$, $parent'(q) \leftarrow i$, and update *root*. Once this is done, $\mathcal{B}'$ is a labeled branching for $G'^{(i)}$. We then continue decrementing i until $i = 1$.

The final step in the process is to modify all the τ' fields so that $\tau'(i)$ is the product of the edge labels along the path from the root π'_r of the subtree containing π'_i to π'_i. This is easily done, starting from roots of subtrees of $\mathcal{B}$ and working down.

We now give a pseudocode version of Cycle-node. The work of Cycle-node is performed by three main functions, which partition the work along the lines just described. These are Cycle-node-bottom, Cycle-node-middle, and Cycle-node-top. We present pseudocode for each function in sufficient detail to allow for a simple proof of correctness and an analysis of the running time. It is assumed that arrays are always passed by reference.

Cycle-node. *Input Parameters*: $\mathcal{B}$, π, π', r and s, where $\mathcal{B}$ is a labeled branching for G with respect to π, and π' is a new ordering obtained from π by a cyclic shift of values in the range r to s. *Returned Value*: A labeled branching $\mathcal{B}'$ for G with respect to π'. *Notation*: $\pi = \pi_1, \cdots, \pi_n$, and $\pi' = \pi'_1, \cdots, \pi'_n$ where $\pi'_i = \pi_i$, $1 \le i < r$, $s < i \le n$, and $\pi'_r = \pi_s$, $\pi'_i = \pi_{i-1}$, $r < i \le s$.

Set $\mathcal{B}'$ to the identity branch on n points.
Set *root* so that each point is its own root.
Cycle-node-bottom($\mathcal{B}, \mathcal{B}', root, s$) (enter data in $\mathcal{B}'$ for nodes π'_{s+1} to π'_n, and update *root*).
Cycle-node-middle($\mathcal{B}, \mathcal{B}', \pi, \pi', root, r, s$) (enter data in $\mathcal{B}'$ for nodes π'_r to π'_s, and update *root*).
Cycle-node-top($\mathcal{B}, \mathcal{B}', \pi, \pi', root, r$) (enter data in $\mathcal{B}'$ for nodes π'_1 to π'_{r-1}).
(Complete $\mathcal{B}'$ by modifying the τ' fields for nodes π'_1 to π'_n to reflect path products.)
For $j \leftarrow 1$ to n
    set $i \leftarrow parent'(j)$
    if $i \neq -1$ then set $\tau'(j) \leftarrow \tau'(i)\tau'(j)$.
Return($\mathcal{B}'$).

Cycle-node-bottom. *Input Parameters*: $\mathcal{B}, \mathcal{B}', root, s$. *Purpose*: Modify $\mathcal{B}'$ by copying the edge labels from $\mathcal{B}$ for nodes $\pi'_{s+1}, \cdots, \pi'_n$.

For $j \leftarrow s+1$ to n
    let $i = parent(j)$
    if $(s < i)$ then
        set $parent'(j) \leftarrow i$, $root[j] \leftarrow root[i]$ and $\tau'(j) \leftarrow \tau^{-1}(i)\tau(j)$
            (in this case, $\tau'(j)$ is an edge label from π'_i to π'_j).

Cycle-node-middle. *Input Parameters*: $\mathcal{B}, \mathcal{B}', \pi, \pi', root, r, s$. *Purpose*: Build $\mathcal{B}'$ for nodes π'_r to π'_s by implementing Lemma 3.1. *Local Variables*: *orbit* and *cosetrep* are used to define $\pi_s^{G^{(j)}}$, $r \le j \le s$ in the sense that *orbit* is an n-dimensional Boolean

array with $orbit[i] = 1$ if and only if $\pi_i \in \pi_s^{G^{(j)}}$ and *cosetrep* is an n-dimensional array with $cosetrep[i]$, an element of $G^{(j)}$ that moves π_s to π_i if $orbit[i] = 1$; *genlist* is a list of edge labels of $\mathcal{B}$ which generate $G^{(j)}$ and *orbitlist* is a list of points in $\pi_s^{G^{(j)}}$.

Initialize *orbit*, *cosetrep*, *orbitlist*, and *genlist* for $\pi_s^{G^{(s)}}$ using $\mathcal{B}$.
For $j \leftarrow s$ down to $r+1$
    set $\Delta \leftarrow \Delta^{(j-1)} = \pi_{j-1}^{G^{(j-1)}}$ (this can be computed using $\mathcal{B}$)
    for each $\pi_m \in \Delta$
        let $\pi_p = \pi_s^{\tau^{-1}(m)\tau(j-1)}$ ($\tau^{-1}(j-1)\tau(m)$ is the path product from π_{j-1} to π_m)
        if $orbit[p] = 1$ ($\pi_p \in \Delta^{(j-1)}$), then
            let $\pi'_q = \pi_m$
            if $q \neq j$ and π'_q is a root of $\mathcal{B}'$, then (connect π'_j to π'_q in $\mathcal{B}'$)
                set $\tau'(q) \leftarrow cosetrep[p]\tau^{-1}(j-1)\tau(m)$
                    (in Lemma 3.1, $\beta = cosetrep[p]$ and $\alpha = \tau^{-1}(j-1)\tau(m)$)
                for $i \leftarrow j+1$ to n (update *root*)
                    if $root[i] = q$, then set $root[i] \leftarrow j$
    (Extend *orbit* and *cosetrep* to $\pi_s^{G^{(j-1)}}$.)
    if π_{j-2} is not a leaf (otherwise, the data for the orbit is unchanged), then
        (*orbitlist*, *genlist*) $\leftarrow$
            update-orbit($\mathcal{B}, \pi$, *orbit*, *cosetrep*, *genlist*, *orbitlist*, $s, j-2$).
(Now *orbit* and *cosetrep* are defined for $\pi_s^{G^{(r)}}$. Enter the data for node π'_r.)
Set $\Delta \leftarrow \pi_s^{G^{(r)}}$.
For each $\pi_m \in \Delta$
    let $\pi'_q = \pi_m$
    if $root[q] = q$ and $q \neq r$ (π'_q is a root of $\mathcal{B}'$), then
        (Connect π'_r to π'_q.)
        set $\tau'(q) \leftarrow cosetrep[m]$ ($cosetrep[m] \in G^{(r)}$ and moves $\pi_s = \pi'_r$ to $\pi_m = \pi'_q$)
        for $i \leftarrow r+1$ to n (update *root*)
            if $root[i] = q$, then set $root[i] \leftarrow r$.

Cycle-node-top. *Input Parameters*: $\mathcal{B}, \mathcal{B}', \pi, \pi', root, r$. *Purpose*: Modify $\mathcal{B}'$ by inserting the data for nodes π'_1 to π'_{r-1}.

For $i \leftarrow r-1$ to 1 do
    set $\Delta \leftarrow \Delta^{(i)} = \pi_i^{G^{(i)}}$
    for each $\pi_m \in \Delta$
        let $\pi'_q = \pi_m$
        if $root[q] = q$, then
            set $\tau'(q) \leftarrow \tau^{-1}(i)\tau(m)$ and $parent'(q) \leftarrow i$
            for $k \leftarrow i+1$ to n (update *root*)
                if $root[k] = q$, then set $root[k] \leftarrow i$.

We complete this part of the discussion by presenting pseudocode for the procedure update-orbit in Cycle-node-middle.

Update-orbit. *Input Parameters*: $\mathcal{B}, \pi$, *orbit*, *cosetrep*, *genlist*, *orbitlist*, s, j. *Return value*: The list (*orbitlist*, *genlist*). *Purpose*: Extend *orbit*, *cosetrep*, *genlist*, *orbitlist* from $\pi_s^{G^{(j+1)}}$ to $\pi_s^{G^{(j)}}$. *Local variables*: A list *newpoints* for holding new points in the orbit; a temporary list of points, *pointlist*; and a list *newgens* for holding the edge labels of $\mathcal{B}$ in $G^{(j)}$ that move π_j.

Set *newpoints* $\leftarrow$ *nil* and *newgens* $\leftarrow$ the edge labels of $\mathcal{B}$ in $G^{(j)}$ that move π_j.
For each $g \in$ *newgens* (apply each new generator against each old point)

for each $p \in$ *orbitlist*
let $\pi_q = \pi_p^g$
if *orbit*$[q] \neq 1$ (a new point in $\pi_s^{G^{(j)}}$ has been found), then
set *orbit*$[q] \leftarrow 1$, *cosetrep*$[q] \leftarrow$ *cosetrep*$[p] * g$, and append q to *newpoints*.
(Append *newgens* to *genlist* and apply each generator in *genlist* to each point in *newpoints*.)
While *newpoints* $\neq$ *nil*
append *newpoints* to *orbitlist*, set *pointlist* $\leftarrow$ *newpoints* and *newpoints* $\leftarrow$ *nil*
for each $g \in$ *genlist* (apply each generator against each old point)
for each $p \in$ *pointlist*
let $\pi_q = \pi_p^g$
if *orbit*$[q] \neq 1$ (a new point in $\pi_s^{G^{(j)}}$ has been found), then
set *orbit*$[q] \leftarrow 1$, *cosetrep*$[q] \leftarrow$ *cosetrep*$[p] * g$, and append q to *newpoints*.
Return(*orbitlist*, *genlist*).

4. Proof of correctness of the base change algorithm. In this section we give a straightforward proof that base-change performs correctly, namely, that it returns a labeled branching for G relative to the new ordering π'. This will follow directly once we have established the same result for the procedure Cycle-node.

PROPOSITION 4.1. *Let $\mathcal{B}$ be a labeled branching for G relative to the ordering π and let π' be a new ordering obtained from π by a cyclic shift of values. Then Cycle-node($\mathcal{B}, \pi, \pi'$) returns a labeled branching for G relative to π'.*

Proof. Let $\pi = \pi_1, \cdots, \pi_n$, and $\pi' = \pi'_1, \cdots, \pi'_n$ where $\pi'_i = \pi_i$, $1 \leq i < r, s < i \leq n$, and $\pi'_r = \pi_s$, $\pi'_i = \pi_{i-1}$, $r < i \leq s$. In addition, let $G'^{(j)} = G_{\pi'_1 \cdots \pi'_{j-1}}$ for $1 \leq j \leq n$.

Consider the state of the labeled branching $\mathcal{B}'$ created by Cycle-node just after Cycle-node-top returns. We will prove by induction on i for $i = n$ down to 1 that if

$$\pi'_j \in \Delta'^{(i)} = \pi_i'^{G'^{(i)}},$$

then there exists a path in $\mathcal{B}'$ from π'_i to π'_j, and that the product of the edge labels from π'_i to π'_j is an element of $G'^{(i)}$ that moves π'_i to π'_j. Once this has been shown, it follows directly that the last step of Cycle-node creates a labeled branching for G relative to π' in which the τ fields have the correct values.

The result is clearly true when $i = n$, so assume that $i < n$ and the result holds for all k such that $i < k \leq n$. The entries for node π'_i are set in one of the functions Cycle-node-bottom, Cycle-node-middle, or Cycle-node-top. In all cases, we examine a complete set of points that contains all possible candidates for $\pi'_j \in \Delta'^{(i)}$. This follows from Lemma 3.1 in the case where $r < j \leq s$ and directly in the remaining cases. If π'_j is such a candidate, then we first check if π'_j is currently a root of $\mathcal{B}'$. If so, then we connect π'_i to π'_j and label the edge by a permutation in $G'^{(i)}$ that moves π'_i to π'_j. Otherwise, we do nothing. To see why this works, assume that $\ell = root[j] < j$, so that there is a path from π'_ℓ to π'_j in $\mathcal{B}'$. Assume first that $i = \ell$. This could happen if π'_j is not a root of $\mathcal{B}'$ at the end of the previous iteration, but its root π'_m is connected to π'_i, and hence *root* updated before π'_j is encountered. But then, by induction, there is a path product from π'_i to π'_j through π'_m and the composition of the path products from π'_i to π'_m and π'_m to π'_j moves π'_i to π'_j and is an element of $G'^{(i)}$. Otherwise, $i < \ell$, and we may invoke our inductive assumption to conclude that the path product σ from π'_ℓ to π'_j moves π'_ℓ to π'_j and lies in $G'^{(\ell)}$. But since $\pi'_j \in \Delta'^{(i)}$ and $\sigma \in G'^{(i)}$,

it then follows that $\pi'_\ell \in \Delta'^{(i)}$ as well. Hence, we are certain of choosing π'_ℓ as one of our candidates. When this occurs, we connect π'_i to π'_ℓ with edge label $\rho \in G'^{(i)}$ that moves π'_i to π'_ℓ. But then $\rho\sigma \in G'^{(i)}$ and moves π'_i to π'_j. Therefore, the result holds for i and hence for all nodes by induction. □

5. Analysis of the base change algorithm. The main result of this section is an analysis of the running time for Cycle-node.

PROPOSITION 5.1. *Cycle-node has running time* $O(n^2)$.

Proof. We will first show that each of Cycle-node-bottom, Cycle-node-middle, and Cycle-node-top have running time $O(n^2)$.

The running time for Cycle-node-bottom is dominated by at most $n - s$ permutation multiplies of the form $\tau^{-1}(i)\tau(j)$. Thus Cycle-node-bottom takes time $O(n^2)$.

The analysis of Cycle-node-middle is a little more complex. Let us first compute the total cost for adding new edges and updating *root*. Each time we add a new edge, it costs $O(n)$ time to enter the data and $O(n)$ time to update *root*. However, at most $O(n)$ edges can ever be entered since a labeled branching on n nodes has at most $n-1$ edges. Thus the total cost incurred for adding new edges and updating *root* is $O(n^2)$.

Consider the cost of updating *cosetrep* and *orbit*. These data structures are initialized for $\Delta^{(s)}$ using the edge labels of $\mathcal{B}$ that lie in $G^{(s)}$. Each time we call update-orbit as j goes from s down to r, we extend *orbit* and *cosetrep* to $\pi_s^{G^{(j-1)}}$ by adding to the generators for $G^{(j)}$ those edge labels that move π_{j-1}. Each generator is applied exactly once to each point in the orbit. Furthermore, the union of all generators added incrementally yields a set of edge labels that generate $G^{(r)}$, and hence has cardinality at most $n - 1$. Thus, the cumulative cost of all the calls to update-orbit is equal to the cost of building *orbit* and *cosetrep* for $\pi_s^{G^{(r)}}$, and hence is $O(n^2)$. Doing the orbit calculation in time $O(n^2)$ is perhaps the most delicate part of the algorithm. We considered several alternate ways of doing this part of the calculation, but the alternate ways always resulted in larger running times.

We now incorporate these two observations into the analysis of Cycle-node-middle. Consider the first "for" loop on j for j goes from s down to $r + 1$. The first step is to compute $\Delta = \Delta^{(j-1)}$ from $\mathcal{B}$. This step takes $O(n)$ time since it simply involves determining all points in $\mathcal{B}$ that can be reached from π_j. For each point $\pi_m \in \Delta$, we compute the image

$$\pi_p = \pi_s^{\tau^{-1}(m)\tau(j)}$$

and check if

$$\pi_p \in \pi_s^{G^{(j)}}.$$

This takes constant time. If $\pi_p \notin \pi_s^{G^{(j)}}$, then we continue. Otherwise, we enter the data for node π'_q where $\pi'_q = \pi_m$. This takes a constant amount of time plus the time to compute $\tau'(q)$ and update *root*. Thus the cost of each iteration of the for loop on Δ is $O(1)$ plus the cost of computing new edge labels and updating *root* each time a new edge label is added. We can then summarize the total work on the for loop on j as $O((s - r)n)$ + (the cost of adding new edge labels and updating *root*) + (the cost of updating *orbit* and *cosetrep*) = $O(n^2)$. Finally, consider the last for loop on Δ used to fill in the edges of $\mathcal{B}'$ which emanate from π'_r. The orbit Δ has already been computed through the process of updating *orbit* and *cosetrep*. As before, the cost of executing this loop is $O(1)$ per iteration plus the cost of adding new edge labels and updating *root*. Combining this with the previous computation results in a running time Cycle-node-middle of $O(n^2)$.

Using the same reasoning, the running time for Cycle-node-top can be computed to be $O(n)$+(the cost of adding new edge labels and updating*root*) $= O(n^2)$. Finally, the cost of completing $\mathcal{B}'$ is dominated by $O(n)$ permutation multiplies and hence is $O(n^2)$. Since Cycle-node-bottom, Cycle-node-middle, Cycle-node-top, and the final completion of $\mathcal{B}'$ each have running times of $O(n^2)$, the same holds for Cycle-node and the proof is completed. □

Since at most $O(n)$ calls to Cycle-node are made by our base change algorithm, we have the following result as a corollary.

COROLLARY 5.2. *The base change algorithm runs in time* $O(n^3)$.

6. Implementation issues. The pseudocode presented in §3 for Cycle-node was designed to give a clean exposition of the algorithm and to facilitate the analysis and proof of correctness. In this section, we indicate how a more complex version of Cycle-node can avoid much of the duplication inherent in the earlier version. This more complex version is the one we actually programmed.

The main difference in the new version of Cycle-node occurs after we have built the labeled branching $\mathcal{B}'$ for nodes π'_r, π'_{r+1}, $\cdots$, π'_n. The idea is to integrate the information stored in $\mathcal{B}'$ back into $\mathcal{B}$ and return the labeled branching for G relative to π' in $\mathcal{B}$. There are two reasons for doing this. First, $\tau'(i) = \tau(i)$ and $parent(i) = parent'(i)$ for $1 \leq i \leq r-1$, so the top of the branching is unchanged. Second, as r increases, most of the edge labels in the new branching will emanate from nodes π'_1, $\cdots$, π'_{r-1}; i.e., most of the nodes of $\mathcal{B}'$ at the end of Cycle-node-middle will be roots. When the edges emanating from nodes with index less than r terminate in a root π'_q, with $r \leq q$, then $\tau'(q) = \tau(m)$ where $\pi_m = \pi'_q$. Therefore $\tau'(q)$ has already been computed in $\mathcal{B}$.

We briefly describe how we weave into $\mathcal{B}$ the knowledge gained from the structure of $\mathcal{B}'$ in order to produce the new branching. Consider the state of $\mathcal{B}'$ at the time just after the edge labels emanating from π'_r are inserted, and let $\mathcal{R}$ be a list of the roots of $\mathcal{B}'$, excluding nodes π'_i, $i < r$. We use a routine insert-roots to connect edges from nodes $\pi_i = \pi'_i$, $i < r$, to nodes π'_j, $j \geq r$, where π'_j is a root of $\mathcal{B}'$.

For each $\pi'_j \in \mathcal{R}$, let $\pi_m = \pi'_j$ and follow π_m backwards in $\mathcal{B}$ until we come to the first node π_i, if any, such that $i < r$. If such a node is not found, then π'_j is a root in the new branching and we set $\tau(j) \leftarrow identity$ and $parent(j) \leftarrow -1$. Otherwise, we connect π_i to π'_j. Note that $\tau^{-1}(i)\tau(m)$ is the path product from $\pi_i = \pi'_i$ to $\pi_m = \pi'_j$ and so moves π'_i to π'_j. Thus, $\tau(j) \leftarrow \tau(i)(\tau^{-1}(i)\tau(m)) = \tau(m)$. By manipulation of pointers, the proper τ value can be transferred from node m to j in a single assignment, avoiding unnecessary copying. When insert-root returns, the node fields of $\mathcal{B}$ are complete for all nodes π'_i such that either π'_i is a root or $parent'(i) < r$. The fields for nodes that are children of roots in $\mathcal{B}'$ can now be entered in $\mathcal{B}$ in a straightforward manner.

An extra measure of efficiency can be obtained by recognizing situations where the correct information is already stored in $\mathcal{B}$ and need not be copied from $\mathcal{B}'$. If, at the end of Cycle-node-middle, a node $\pi_j > s$ is a root in $\mathcal{B}'$, then the τ fields for itself and its descendants are the same in the new branching as in the old, and so no modifications need be considered for them. If π_j is not a root in $\mathcal{B}$, its parent in the new branching is unchanged from that in $\mathcal{B}$. If there is a component of $\mathcal{B}$ whose root π_j is greater than s, that component will never be affected by the base change algorithm at all. If $\mathcal{B}'$ is used only to update those parts of $\mathcal{B}$ that are changed, additional savings result. These modifications do not affect the worst-case performance of the algorithm, but they can greatly increase its speed in many practical situations where

the base change affects only a few points of Ω.

RATIO ESTIMATORS ARE MAXIMUM-LIKELIHOOD ESTIMATORS FOR NON-CONTEXT-FREE GRAMMARS*

KEITH HUMENIK†

Abstract. This paper shows that straightforward ratio estimators for the production probabilities of non-context-free unambiguous probabilistic grammars are maximum-likelihood estimators. These ratio estimates are obtained by analyzing the derivations of the strings in a random sample of strings taken from the language derived by the grammar.

Key words. probabilistic grammars, ratio estimators, maximum-likelihood estimators, random sample, unambiguous grammar

AMS(MOS) subject classifications. 60J99, 62F10, 68Q50, 68Q75

1. Introduction. The structure of most programming languages can be described by context-free grammars. However, many other interesting questions regarding the actual usage of programming languages can only be answered by adding the notion of probability to a language. One method of accomplishing this task is to define a probabilistic grammar by assigning probabilities to each production in the grammar, G. Once this is done, the probability of a word in $L(G)$ can be calculated [3].

Often the grammar, G, and the language, $L(G)$, are known, but the production probabilities are not. Humenik and Pinkham [4],[5] have shown that these production probabilities can be estimated for context-free grammars, by taking a random sample of strings from $L(G)$ and parsing the strings to obtain the relative frequency with which each production in G is used. The probabilities are then estimated by using simple ratio estimators. A random sample of 40 or more strings yields excellent results. Maryanski and Booth [6] have shown that these ratio estimators are the maximum-likelihood estimates for the production probabilities in G. Chaudhuri and Rao [3] have shown that the true probabilities may be obtained as the limit of the estimates inferred from an increasing sequence of randomly drawn samples from $L(G)$.

There are many structures, however, that cannot be adequately described by context-free grammars. In this paper we review the notion of probabilistic grammars that are not context-free and prove that ratio estimators remain maximum-likelihood estimates of the production probabilities of an unambiguous non-context-free grammar. This result is not surprising, since we would expect the frequency of production use to provide much of the necessary information to estimate the production probabilities.

2. Preliminaries. A *probabilistic grammar* (*p-grammar*) is a 5-tuple, $G=(V_T, V_N, R, P, \alpha_1)$, where V_T is a finite set of *terminals*; V_N is a finite set of *nonterminals*; R is a mapping $(V_N \cup V_T)^* V_N (V_N \cup V_T)^* \times (V_N \cup V_T)^*$, where each element of R is of the form $\alpha_i \rightarrow \beta_{ij}$, $i=1,\cdots,m$, $j=1,\cdots,m_i$, and is called a *production* or *rule*;

*Received by the editors October 26, 1987; accepted for publication (in revised form) January 3, 1989.

†Department of Computer Science, University of Maryland– Baltimore County, Baltimore, Maryland 21228.

$\alpha_1 \in V_N$ is the *start symbol*; and P is a set of *production probabilities* such that the probability associated with $\alpha_i \to \beta_{ij}$ is p_{ij}. The set R and, hence, the set P are finite. α_i is called the *premise* of the production $\alpha_i \to \beta_{ij}$; β_{ij} is called the *consequence*.

A probabilistic grammar in which all productions in R satisfy $|\alpha_i| \leq |\beta_{ij}|$ is called a *context-sensitive p-grammar* (CSPG). A p-grammar that is not context-sensitive is called an *unrestricted p-grammar* (UPG).

In this paper we shall assume that all p-grammars are unambiguous, using the definition of Aho and Ullman [1]. That is, let G be an unrestricted p-grammar. Let D be the set of all derivations of the form $\alpha_1 \overset{+}{\Rightarrow} w$. That is, elements of D are sequences of the form $(\beta_1, \beta_2, \cdots, \beta_n)$, such that $\beta_1 = \alpha_1$, $\beta_n \in V_T^*$, and $\beta_{i-1} \Rightarrow \beta_i$, $1 \leq i \leq n$.

Define a relation R_0 on D by $(\beta_1, \beta_2, \cdots, \beta_n) R_0 (\gamma_1, \gamma_2, \cdots, \gamma_n)$ if and only if there exists some i between 1 and n such that

(1) $\beta_j = \gamma_j$ for all $1 \leq j \leq n$ such that $j \neq i$.

(2) We can write $\beta_{i-1} = \delta_1\delta_2\delta_3\delta_4\delta_5$ and $\beta_{i+1} = \delta_1\epsilon\delta_3\eta\delta_5$ such that $\delta_2 \to \epsilon$ and $\delta_4 \to \eta$ are in R; and either $\beta_i = \delta_1\epsilon\delta_3\delta_4\delta_5$ and $\gamma_i = \delta_1\delta_2\delta_3\eta\delta_5$, or conversely.

Let R be the smallest equivalence relation containing R_0. Each equivalence class of R represents the essentially similar derivations of a given sentence.

A p-grammar is *unambiguous* if each w in $L(G)$ appears as the last component of a derivation in one and only one equivalence class under R.

Example 1.

- Let G_1 be given by the following

$$S \to abC \mid aB$$
$$B \to bc$$
$$bC \to bc$$

where the four productions have probabilities p_{11}, p_{12}, p_{21}, and p_{31}, respectively. G_1 is an ambiguous grammar, since the sequences (S, abC, abc) and (S, aB, abc) are in two distinct equivalence classes.

- Let G_2 be given by

$$S \to aSBC \mid aBC$$

with probabilities p_{11} and p_{12}, respectively, and

$$p_{21} : aB \to ab$$
$$p_{31} : bB \to bb$$
$$p_{41} : CB \to BC$$
$$p_{51} : bC \to bc$$
$$p_{61} : cC \to c$$

Then G_2 is an unambiguous grammar.

We shall assume herein that the probabilities associated with the productions of R depend only on the deterministic properties of the grammar, G, and not upon the sequence in which the productions are applied during the generation of a given string of the language [2]. That is, the use of a production to expand a sentential form β_i depends only on β_i itself and not upon how β_i was derived in G. We shall call a grammar that has this property a *Markov grammar*.

We shall assume that all grammars are *proper*, that is

$$\sum_{j=1}^{m_i} p_{ij} = 1$$

for all $i=1,\cdots,m$.

The probability of $w \in L(G)$ is given by the product of the production probabilities associated with the productions used in the derivation of w. That is,

$$P(w) = \prod_{k=1}^{K} p_k,$$

where K is the number of steps in the derivation of w and $p_k \in P$ is the probability of the production used at the kth step. Note that since G is unambiguous, there is only one essentially distinct derivation of w, and this derivation can always be found, since there are a finite number of productions in R.

A grammar that satisfies $\sum_{w\in L(G)} P(w) = 1$ is called a *consistent grammar*. Not every grammar is consistent.

A *random sample*, RS, of size M from $L(G)$ is a multiset of M strings from $L(G)$, obtained by drawing a string from $L(G)$ such that each string is equally likely to be drawn. Thus a string is drawn randomly, its derivation is determined, and it is replaced [3].

Example 2. For the grammar G_2 in Example 1, the derivation of the string $a^ib^ic^i$ is given by

$$S \overset{i-1}{\Rightarrow} a^{i-1}S(BC)^{i-1} \Rightarrow a^i(BC)^i \overset{(i-1)i/2}{\Rightarrow} a^iB^iC^i$$

$$\Rightarrow a^ibB^{i-1}C^i \overset{i-1}{\Rightarrow} a^ib^iC^i \Rightarrow a^ib^icC^{i-1} \overset{i-1}{\Rightarrow} a^ib^ic^i.$$

Then $P(a^ib^ic^i)= p_{11}^{i-1}p_{12}p_{41}^{(i-1)i/2}p_{21}p_{31}^{i-1}p_{51}p_{61}^{i-1}$. But if G_2 is proper, then $p_{j1} = 1$ for $2 \le j \le 6$, and $P(a^ib^ic^i)= p_{11}^{i-1}p_{12}$. Note that

$$\sum_{i=1}^{\infty} P(a^ib^ic^i) = \sum_{i=1}^{\infty} p_{11}^{i-1}p_{12} = p_{12}\frac{1}{1-p_{11}} = 1,$$

so G_2 is consistent.

3. Main result. Consider a probabilistic, unambiguous grammar, $G = (V_T, V_N, R, P, \alpha_1)$, and assume that we know everything except the values for the rule probabilities P. Using the information in the sample RS, these values are to be estimated. The sets R and P of G look like the following:

$$\begin{array}{lcccccc} & & p_{11} & & p_{12} & \cdots & p_{1m_1} \\ \alpha_1 & \rightarrow & \beta_{11} & | & \beta_{12} & | \ \cdots \ | & \beta_{1m_1} \end{array}$$

$$\begin{array}{lcccccc} & & p_{21} & & p_{22} & \cdots & p_{2m_2} \\ \alpha_2 & \rightarrow & \beta_{21} & | & \beta_{22} & | \ \cdots \ | & \beta_{2m_2} \end{array}$$

$$\begin{matrix} & p_{m1} & p_{m2} & \cdots & p_{mm_m} \\ \alpha_m \rightarrow & \beta_{m1} & \beta_{m2} & \cdots & \beta_{mm_m} \end{matrix}$$

Partition R and P so that

$$R = R_1 \cup R_2 \cup \cdots \cup R_m$$

and

$$P = P_1 \cup P_2 \cup \cdots \cup P_m$$

such that R_i and P_i are the rules and their associated probabilities that have α_i as premise.

According to G, let n_{ij} be the number of times that rule r_{ij} with premise α_i and probability p_{ij} is used in the parsing of the M strings of RS. This rule is $p_{ij} : \alpha_i \rightarrow \beta_{ij}$.

Also let $N(\alpha_i)$ be the total number of times that an α_i production is used in the parsing of the M strings of RS according to G.

THEOREM 1. *The maximum-likelihood estimate $\hat{p}_{ij}$ of the rule probability $p_{ij} \in P$ (the probability of the production $\alpha_i \rightarrow \beta_{ij}$) given RS is*

$$\hat{p}_{ij} = \frac{n_{ij}}{N(\alpha_i)}.$$

Proof. Let $x_k \in L(G)$. Then, if G is unambiguous,

$$p(x_k) = \prod_{i=1}^{m} \prod_{j=1}^{m_i} p_{ij}^{c_{ijk}},$$

where $p_{ij} \in P$ and c_{ijk} is the number of times that production $\alpha_i \rightarrow \beta_{ij}$ is used in the derivation of x_k.

Note. We are assuming that $p(x_k)$ is equal to the product of the probabilities of the individual productions used in the derivation of x_k.

Since the strings making up RS are statistically independent,

$$p(RS) = \prod_{k=1}^{u} p(x_k)^{f_k} = \prod_{k=1}^{u} \left[\prod_{i=1}^{m} \prod_{j=1}^{m_i} p_{ij}^{c_{ijk}} \right]^{f_k},$$

where f_k is the number of times that string x_k, $k = 1, 2, \cdots, u$ appears in the sample.

Taking the log of both sides and collecting terms yields

$$\log(p(RS)) = \sum_{k=1}^{u} f_k \left[\sum_{i=1}^{m} \sum_{j=1}^{m_i} c_{ijk} \log(p_{ij}) \right] = \sum_{k=1}^{u} \left[\sum_{i=1}^{m} \sum_{j=1}^{m_i} f_k c_{ijk} \log(p_{ij}) \right].$$

But

$$n_{ij} = \sum_{k=1}^{u} f_k c_{ijk},$$

and thus

$$\log(p(RS)) = \sum_{i=1}^{m} \sum_{j=1}^{m_i} n_{ij} \log(p_{ij}).$$

The maximum-likelihood estimate of the probabilities is obtained when

$$\frac{\partial \log p(RS)}{\partial p_{ij}} = 0, \ i = 1, \cdots, m; \ j = 1, \cdots, m_i.$$

However, let

$$P_i = \{p_{i1}, p_{i2}, \cdots, p_{im_i}\}$$

be one of the subsets of P. Since

$$\sum_{\nu=1}^{m_i} p_{i\nu} = 1,$$

only $m_i - 1$ of the elements of P_i can be specified independently. Therefore, for $\nu = 1, 2, \cdots, m_i - 1$,

$$\frac{\partial \log p(RS)}{\partial p_{i\nu}} = \frac{\partial}{\partial p_{i\nu}} \left[\sum_{i=1}^{m} \sum_{j=1}^{m_i} n_{ij} \log(p_{ij}) \right] = \frac{n_{i\nu}}{p_{i\nu}} + \frac{n_{im_i}}{p_{im_i}} \frac{\partial p_{im_i}}{\partial p_{i\nu}}.$$

But

$$\frac{\partial p_{im_i}}{\partial p_{i\nu}} = -1,$$

so

$$\frac{n_{i\nu}}{p_{i\nu}} = \frac{n_{im_i}}{p_{im_i}} = g, \tag{1}$$

where g is a constant and $\nu = 1, 2, \cdots, m_i - 1$. By the law of equal proportions,

$$g = \frac{\sum_{\nu=1}^{m_i} n_{i\nu}}{\sum_{\nu=1}^{m_i} p_{i\nu}} = \sum_{\nu=1}^{m_i} n_{i\nu} = N(\alpha_i).$$

But $N(\alpha_i)$ is the total number of α_i productions used in the generation of the M strings of RS. Using (1) gives

$$\hat{p}_{i\nu} = \frac{n_{i\nu}}{N(\alpha_i)},$$

which yields the general form

$$\hat{p}_{ij} = \frac{n_{ij}}{N(\alpha_i)}.$$

Conclusion. Ratio estimators are maximum-likelihood estimators for unambiguous grammars.

4. Examples and numerical results. This section provides two examples that illustrate the application of the theorem in §3. Random samples are generated by using a Pascal program to simulate the derivation of strings in the specific grammar. The program uses a standard random number generator to produce random values, which are then used to select the appropriate production. Of course, for some strings within the derivation only one production is applicable and is applied immediately.

TABLE 1
G_2 *with* M=40 *and* M=100.

Sample	Actual values		Estimated values M=40		Estimated values M=100	
	p_{11}	p_{12}	$\hat{p}_{11}$	$\hat{p}_{12}$	$\hat{p}_{11}$	$\hat{p}_{12}$
1	0.01	0.99	0.0000	1.0000	0.0099	0.9901
2	0.10	0.90	0.0909	0.9091	0.0991	0.9009
3	0.25	0.75	0.2857	0.7143	0.2424	0.7576
4	0.50	0.50	0.4805	0.5195	0.4624	0.5376
5	0.75	0.25	0.7701	0.2299	0.7590	0.2410
6	0.90	0.10	0.8730	0.1270	0.9063	0.0937
7	0.99	0.01	0.9895	0.0105	0.9902	0.0098

Example 3. Random samples consisting of 40 strings and 100 strings were generated using the grammar G_2 given in Example 1. Table 1 shows the actual values of p_{11} and p_{12} and the estimated values of p_{11} and p_{12}, $\hat{p}_{11}$ and $\hat{p}_{12}$, respectively. Since G_2 is proper, all other probabilities are equal to one and, hence, need not be estimated. The estimates were calculated using maximum-likelihood ratio estimation. Thus, $\hat{p}_{11}$ was calculated by dividing the total number of times that rule r_{11} was used in derivations of the M strings in RS by the total number of times that both rules in R_1 (i.e., r_{11} and r_{12}) were used to derive all strings in RS. That is,

$$\hat{p}_{11} = \frac{n_{11}}{n_{11} + n_{12}} = \frac{n_{11}}{n_{11} + M},$$

since $n_{12} = 1$ for each string derived in G_2. Similarly,

$$\hat{p}_{12} = \frac{M}{n_{11} + M} = 1 - \hat{p}_{11}.$$

For example, random sample 2 with M=40 contained 36 occurrences of the string abc and 4 occurrences of the string $a^2b^2c^2$. Hence,

$$\hat{p}_{11} = \frac{4}{4 + 40} = 0.0909.$$

Example 4. Random samples consisting of 40 strings and 100 strings were generated using the unambiguous UPG, G_3, given below:

$$p_{11} : S \to aS$$
$$p_{21} : aS \to aaS$$
$$p_{22} : aS \to aA$$
$$p_{31} : aA \to abA$$
$$p_{41} : bA \to bbA$$
$$p_{42} : bA \to b$$

Table 2 shows the actual values of all production probabilities not equal to one (since G_3 is assumed to be proper) and the corresponding maximum-likelihood ratio estimates for the random samples, with M=40. Data for random samples of 100 strings is given in Table 3.

The percentage errors for random samples of size 40 range from 0 to 100 percent, with the average percentage error equal to 24.63. For random samples of size 100, percentage errors range from 0 to 96 percent, with the average error equal to 8.76.

8	0.90	0.10	0.55	0.45	0.8957	0.1043	0.6154	0.3846
9	0.99	0.01	0.99	0.01	0.9900	0.0100	0.9903	0.0097

In general, the average error is skewed by large percentage errors in cases where the actual production probabilities are small. Thus, a random sample of at least 100 strings is needed for reasonable estimates. The Law of Large Numbers tells us that even larger sample sizes will provide better estimates, and this is indeed the case.

5. Conclusions. It has been shown that ratio estimators are maximum-likelihood estimators for unambiguous probabilistic grammars. This result is a generalization of the proof for unambiguous context-free probabilistic grammars. The conclusion verifies the intuitive notion that the values of production probabilities can be estimated by comparing the number of times each production is used to parse a given sample of strings.

Several questions remain open. Statistical properties such as means and variances have not been computed for the ratio estimators in the non-context-free case. The author believes that this can be done using Markov chains to describe derivations. Other open problems include the following:

(1) How does ambiguity affect the results obtained in this paper?

(2) Can this method be modified to estimate production probabilities that vary in time?

(3) Given a random sample of strings, can production probability estimation be combined with inference techniques to develop a method for inferring non-context-free probabilistic grammars?

ANALYSIS OF PREFLOW PUSH ALGORITHMS FOR MAXIMUM NETWORK FLOW*

J. CHERIYAN†‡ AND S. N. MAHESHWARI†

Abstract. The class of preflow push algorithms recently introduced by Goldberg and Tarjan for solving the maximum flow problem on a weighted digraph with n vertices and m edges is studied. Goldberg and Tarjan's $O(n^3)$ time bound for the highest distance preflow push algorithm is improved to $O(n^2\sqrt{m})$, and it is shown that this bound is tight by constructing a parametrized worst-case network. It is also shown that the $O(n^3)$ time bound is tight for the FIFO preflow push algorithm, and the $O(n^2m)$ time bound is tight for the LIFO preflow push algorithm. The maximal excess preflow push algorithm is then developed, and it is shown that it performs $O(n^2\sqrt{m})$ pushes and that this bound is tight. Based on this, the authors develop a maximum flow algorithm for the synchronous distributed model of computation that uses $O(n^2\sqrt{m})$ messages and $O(n^2)$ time, thereby improving upon the best previously known algorithms for this model.

1. Introduction.

The problem of finding a maximum flow in a network is one of the most important problems in the area of combinatorial optimization. Besides having many practical applications it is also closely related to theoretical topics such as graph connectivity and matchings.

Dinic [D70] has shown that the problem can be solved by repeatedly extracting a layered subnetwork of the given network and solving the simpler problem of finding a blocking flow for the layered subnetwork. All subsequent research has been directed at developing faster algorithms for the blocking flow subproblem. Recently, Goldberg [Go85] has introduced a new maximum flow algorithm, namely, the FIFO preflow push algorithm that does away with the blocking flow subproblem. Goldberg's approach was later generalised by Goldberg and Tarjan [GT88]. They introduced a class of algorithms called *preflow push algorithms.* A preflow push algorithm consists of a general scheme together with a rule for selecting a vertex having flow excess. Different algorithms can be obtained by using different rules. A *push step* is applied to the selected vertex. The most important attribute of a preflow push algorithm is the number of push steps performed by it since this is what determines the time complexity of the algorithm.

In this paper we are interested in studying preflow push algorithms. One of the motivating factors is the intrinsic appeal of simple heuristics that lead to surprisingly good performance. Indeed, a good deal of research in the area of algorithms has focused on giving tight time bounds for algorithms based on simple heuristics that solve important problems. We will give tight time bounds for several preflow push algorithms. Another motivating factor is that, due to their simplicity, preflow push algorithms are likely to dominate asymptotically faster algorithms for networks of moderate size. Furthermore, preflow push algorithms are not dependent on centralized resources and so work very well in distributed models of computation.

In what follows, we will use n to denote the number of vertices of the network for which the maximum flow has to be found, m to denote the number of (directed) edges, and U to denote the largest absolute value of the edge capacities.

Goldberg and Tarjan [GT88] have shown that two of these algorithms, namely, the FIFO preflow push algorithm and the highest distance preflow push algorithm, perform $O(n^3)$ pushes and so achieve an $O(n^3)$ time bound.

We first show that the actual time bound for the highest distance preflow push algorithm is $O(n^2\sqrt{m})$. Although this is $O(n^3)$ for dense graphs, it is $O(n^{2.5})$ for sparse graphs. Our analysis is based on ideas used previously by Cherkasky [Ch77] and Galil [Ga80] to analyze their respective maximum flow algorithms. We then show that this bound is tight by constructing a parametrized worst-case network. Given two numbers n and m such that n is sufficiently large and m is greater than kn, where k is a constant, this network has at most n vertices and m edges, and the highest distance preflow push algorithm performs $\Theta(n^2\sqrt{m})$ pushes on it. Our construction uses techniques introduced by Galil [Ga81] to construct a parametrized worst-case network for many of the earlier maximum flow algorithms. We also show that the bounds of $O(n^3)$ and $O(n^2m)$ are tight for the FIFO and LIFO preflow push algorithms, respectively, by constructing parametrized worst-case networks for these algorithms. We then develop the maximal excess preflow push algorithm that combines the best features of the FIFO preflow push algorithm and the highest distance preflow push algorithm. We show that this algorithm performs $O(n^2\sqrt{m})$ pushes and we also construct a parametrized worst-case network on which this algorithm performs $\Theta(n^2\sqrt{m})$ pushes.

The maximal excess preflow push algorithm leads us to a maximum flow algorithm for the synchronous distributed model of computation that uses at most $O(n^2\sqrt{m})$ messages and $O(n^2)$ time. This improves on the $O(n^3)$ messages and $O(n^2)$ time algorithms of Awerbuch [Aw85b], Goldberg [Go85], and Goldberg and Tarjan [GT88]. Recently, Marberg and Gafni [MG87] have developed a maximum flow algorithm for the asynchronous distributed model of computation that uses $O(n^2\sqrt{m})$ messages and $O(n^2\sqrt{m})$ time. Clearly, this gives an algorithm for the synchronous distributed model of computation that uses $O(n^2\sqrt{m})$ messages and $O(n^2\sqrt{m})$ time. Although our distributed algorithm works only for the synchronous model, note that our time bound is better than that of [MG87] for this model.

We mention other interesting results pertaining to preflow push algorithms. Goldberg and Tarjan [GT88] have improved the FIFO preflow push algorithm to $O(nm \log n^2/m)$ by using the dynamic trees data structure. This is asymptotically the fastest known algorithm. Later, Ahuja and Orlin [AO87] developed an $O(nm + n^2 \log U)$ algorithm that was based on the scaling technique. Subsequently, Ahuja, Orlin, and Tarjan [AOT89] obtained an $O(nm \log (n/m(\log U)^{1/2}+2))$ algorithm that uses scaling and the dynamic trees data structure.

In § 2 we describe preflow push algorithms following Goldberg [Go87] and Goldberg and Tarjan [GT88], and give a few definitions. Section 3 has the $O(n^2\sqrt{m})$ bound for the highest distance preflow push algorithm. Section 4 has the parametrized worst-case network showing that this bound is tight. The $O(n^3)$ time bound for the FIFO preflow push algorithm and the $O(n^2m)$ time bound for the LIFO preflow push algorithm are also shown to be tight in § 4. Section 5 considers the maximal excess preflow push algorithm. The synchronous distributed algorithm is developed in § 6. Section 7 has conclusions.

2. Preflow push algorithms. Let $G(V, E)$ be a digraph with two distinguished vertices, a source s and a sink t, and a positive real-valued capacity $c(v, w)$ on every

edge (v, w). (By an "edge" we mean a directed edge; so (v, w) is the directed edge with tail-vertex v and head-vertex w.) For convenience define $c(v, w) = 0$ if (v, w) is not an edge. A flow on G is a real-valued function f on vertex pairs having the following three properties:

(2.1) *Skew symmetry*: $f(v, w) = -f(w, v)$ for all vertex pairs v, w.

(2.2) *Capacity constraint*: $f(v, w) \leqq c(v, w)$ for all vertex pairs v, w.

(2.3) *Flow conservation*: $\sum_w f(v, w) = 0$ for every vertex v in $V - \{s, t\}$.

The value $|f|$ of a flow is the net flow into the sink, $\sum_v f(v, t)$. The maximum flow problem is that of finding a flow of maximum value.

A preflow push algorithm computes a maximum flow in a given network by manipulating a preflow f on the network. A preflow f is a real-valued function on vertex pairs satisfying (2.1) and (2.2) above, as well as the following weaker form of (2.3):

(2.4) *Nonnegativity constraint*: $\sum_u f(u, v) \geqq 0$ for every vertex v in $V - \{s\}$.

The *flow excess* $e(v)$ of a vertex v is defined to be the net flow into v, $\sum_u f(u, v)$. A vertex v is said to be *active* if v is in $V - \{s, t\}$ and $e(v) > 0$. The *residual capacity* $r(v, w)$ of a vertex pair (v, w) with respect to a preflow f is given by $r(v, w) = c(v, w) - f(v, w)$. The residual graph with respect to a preflow f has vertex set V and has an edge (v, w) if and only if $r(v, w) > 0$.

A preflow push algorithm also maintains a valid distance labeling, where a *valid distance labeling* d is a function from the vertices to the nonnegative integers, such that $d(s) = n$, $d(t) = 0$, and $d(v) \leqq d(w) + 1$ for every edge (v, w) in the residual graph. The intent is that if $d(v) < n$ then $d(v)$ is a lower bound on the actual distance from v to t in the residual graph, and if $d(v) \geqq n$ then $d(v) - n$ is a lower bound on the actual distance to s in the residual graph. In the latter case it will turn out that there is no path from v to t in the residual graph.

A valid distance labeling is called *exact* if $d(v)$ equals the actual distance from v to t (or from v to s) in the residual graph for every vertex v with $d(v) < n$ (or $d(v) \geqq n$). Otherwise, the distance labeling is called *approximate*. The generic preflow push algorithm given below uses an exact distance labeling. This is because the worst-case networks given in §§ 4 and 5 are constructed for preflow push algorithms that use an exact distance labeling.

At each iteration of the generic algorithm an active vertex, say v, with (positive) flow excess is selected, and its excess is sent closer to the sink by making use of the distance labels of v and its neighbours in the residual graph. If the flow excess cannot be sent to vertices with smaller distance labels, then the distance label of v is increased. The algorithm terminates when every vertex in $V - \{s, t\}$ has zero flow excess. An outline of the generic algorithm follows.

```
BEGIN
preprocess: Let the initial preflow f be equal to the edge capacity on each edge emanating
from the source and zero on all other edges. Let d(s) = n and compute d(v) for all
other vertices by doing a backward breadth-first search starting from t.
WHILE there is an active vertex v DO
    BEGIN
    select: Select an active vertex, say v, using a particular rule;
    push: WHILE e(v) > 0 and there is an edge (v, w) with d(v) = d(w) + 1 and
    r(v, w) > 0 DO
        push on edge (v, w):
```

Send min $\{r(v, w), e(v)\}$ units of flow from v to w and update $e(v)$, $e(w)$, $f(v, w)$, and $f(w, v)$ accordingly;
IF there is no edge (v, w) with $d(v) = d(w) + 1$ and $r(v, w) > 0$
THEN
BEGIN
relabel: Replace $d(v)$ by min $\{1 + d(w) | r(v, w) > 0\}$;
Propagate the relabel backward in the residual graph, i.e., if there is a vertex u with $d(u) = d(v) + 1$ and v is the unique successor of u with distance label $d(v)$ then relabel u, and so on;
END;
END;
END.

Note that if the distance label $d(v)$ of a vertex v becomes greater than $n-1$ after a relabel step then there is no path from v to the sink in the residual graph. When this happens the remaining flow excess at v is pushed back along shortest available paths to the source.

The correctness and termination of the generic preflow push algorithm is proved by using the max-flow min-cut theorem [FF56]. (The proofs of the lemmas in this section can be found in [Go87] and [GT88].)

LEMMA 2.1. *The algorithm maintains the invariant that d is a valid distance labeling.*

LEMMA 2.2. *Suppose that the algorithm terminates. Then the preflow f is a maximum flow.*

The termination of the generic algorithm is shown by proving that the number of push steps and relabel steps performed by the algorithm is finite. An edge (v, w) is said to be *saturated* if $r(v, w) = 0$, i.e., if $f(v, w) = c(v, w)$, and an edge (v, w) is said to be *cleared* if $f(v, w) = 0$. A push on edge (v, w) is called a *saturating push* if $r(v, w) = 0$ after the push, otherwise, the push is called a *nonsaturating push.* We say that a push on edge (v, w) is a *nonzeroing push* if this is the first push on (v, w) after either v or w has been relabeled.

LEMMA 2.3. *For any vertex v, an application of a relabel step to v increases $d(v)$. The number of relabel steps is at most $2n-1$ per vertex and at most $2n^2$ overall.*

LEMMA 2.4. *The number of saturating push operations on edges is at most $2nm$. The number of nonzeroing push operations on edges is at most $2nm$. The number of nonsaturating push operations on edges is at most $4n^2m$.*

LEMMA 2.5. *The generic algorithm terminates after $O(n^2m)$ push and relabel steps.*

The generic algorithm can be implemented so that the total time spent in relabel steps is $O(nm)$ and the total time spent in saturating pushes is $O(nm)$. Furthermore, each nonsaturating push can be implemented in $O(1)$ time. When we use Lemma 2.5, it follows that any preflow push algorithm based on the generic algorithm runs in $O(n^2m)$ time.

Several specific algorithms can be obtained from the generic algorithm above depending on the rule used in the select step.

The FIFO *preflow push algorithm* selects all active vertices in the round-robin order. The algorithm maintains all active vertices in a FIFO queue. In the select step it selects the vertex at the front of the queue and applies a push step to it; if this creates flow excesses at any new vertices then these newly active vertices are added to the rear of the queue. Goldberg [Go85] has proved the following lemma.

LEMMA 2.6. *The* FIFO *preflow push algorithm performs $O(n^3)$ pushes, and hence it runs in $O(n^3)$ time.*

In § 4 we will show that the $O(n^3)$ bound is tight for the FIFO algorithm.

The *highest distance preflow push algorithm* selects a vertex having flow excess that is furthest from the sink in each select step. In other words, if we let $d_{\max} = \max\{d(v) | e(v) > 0\}$ then a vertex v with $d(v) = d_{\max}$ and $e(v) > 0$ is selected.

In addition to the above two algorithms, Goldberg and Tarjan also suggested that the scaling technique could be used with preflow push algorithms, and they mentioned two other preflow push algorithms.

The *maximum-value excess preflow push algorithm* selects a vertex having the maximum value of flow excess at each select step.

The LIFO *preflow push algorithm* maintains all active vertices in a stack and selects a vertex for a select step according to the last-in first-out rule. In § 4 we will show that the naive bound of $O(n^2 m)$ is tight for the LIFO algorithm.

Note that when a push step of the generic algorithm terminates (i.e., the inner while loop in the outline above) then the last push, say on edge (v, w), may have been a nonsaturating push. In this case, (v, w) becomes the *current-edge* of v. The importance of the current-edge is that, the next time v is selected for a push step, the current-edge is the first edge on which a push is done, provided that $d(v)$ is still equal to $d(w)+1$.

It is easy to see that at every step of the algorithm the current-edges, at most one edge emanating from each vertex, form a spanning forest of the residual graph. We take each tree in the forest to be rooted at the unique vertex in the tree with minimum distance label. A flow excess at vertex v is called a *maximal excess* if the subtree rooted at v has no other flow excesses.

Occasionally we will regard a flow excess as a "physical entity" originated by either a saturating push or a nonzeroing push. The reason for saying that a nonzeroing push originates a new flow excess is as follows. Suppose a vertex v having flow excess is relabeled and the next push step at v does not saturate any edge. Then we can associate only a nonzeroing push with the resulting flow excess. Each flow excess is identified (i.e., tagged) by the saturating push or nonzeroing push that originated it. When two flow excesses coalesce the resulting flow excess is identified with the constituent that was most recently pushed. We mention that the approach of regarding a flow excess as a physical entity has been used before by Shiloach and Vishkin [SV82], Goldberg [Go85], and others.

We also need the notion of a clock pulse. Consider an implementation of a preflow push algorithm in the synchronous distributed computation model (this model is described in § 6). A clock pulse of a distributed preflow push algorithm consists of all push steps that can be performed simultaneously. For example, during a clock pulse of the distributed FIFO algorithm, a push step is simultaneously performed on each active vertex, and during a clock pulse of the distributed highest distance algorithm, a push step is simultaneously performed on each active vertex v that has $d(v) = d_{\max}$. The notion of a clock pulse carries over to a sequentaial preflow push algorithm as follows. We assume that the algorithm maintains a set of active vertices called SELECTED that is initially empty. At any select step, if the algorithm finds that the set SELECTED is empty, then it uses the rule in the select step to simultaneously insert as many active vertices as possible into the set. At each subsequent select step the algorithm selects any vertex in SELECTED and deletes it from the set. Each pass over the set SELECTED is said to be a *clock pulse* of the preflow push algorithm. The notion of a clock pulse has been used before by Goldberg [Go85] and others.

In the following, we sometimes say that an edge has infinite capacity. This should be interpreted as mU or more, where U is the largest absolute value of the edge capacities.

3. An $O(n^2\sqrt{m})$ bound for the highest distance preflow push algorithm. An example network on which the highest distance preflow push algorithm is superior to the FIFO preflow push algorithm may be constructed as follows (see Fig. 1). The network consists of a path of length $n-2$ together with the source vertex s joined to alternate vertices along the path by edges of unit capacity. The sink t is located at the head of the path, and each edge in the path has infinite capacity. The FIFO algorithm performs $O(n^2)$ pushes on this network since it does $O(n)$ pushes per clock pulse and there are $O(n)$ clock pulses. The highest distance algorithm performs only $O(n)$ pushes since it does only one push per clock pulse. The highest distance algorithm has the desirable feature that it never pushes a nonmaximal flow excess, thereby saving on the total number of pushes.

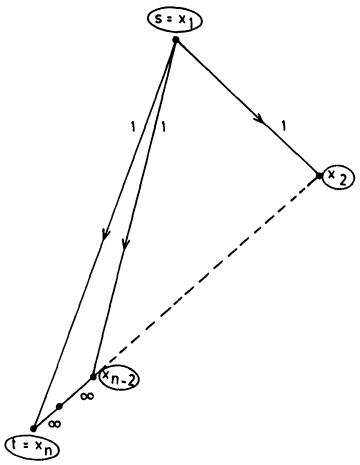

FIG. 1. *Example network on which the highest distance algorithm performs* $\Theta(n)$ *pushes and the* FIFO *algorithm performs* $\Theta(n^2)$ *pushes.*

To determine the number of nonsaturating pushes performed by the highest distance preflow push algorithm, we divide the computation into phases. A *phase* consists of all pushes that occur between two consecutive relabel steps. Note that during a phase the flow excesses that are most distant from the sink are pushed down one level at a time. The $O(n^3)$ bound is easily obtained using the following observation. Any vertex does at most one nonsaturating push per phase, and since there are $O(n^2)$ phases, the total number of nonsaturating pushes is $O(n^3)$.

At any step of the algorithm, let $d_{\max}$ be the distance of the furthest flow excess from the sink. Note that the total increase in $d_{\max}$ over the whole algorithm sums to $O(n^2)$ because each increase is caused by some vertex updating its distance label during a relabel step. The length, l_i, of phase i, is the difference between $d_{\max}$ at the start of the phase and $d_{\max}$ at the end of the phase. Goldberg and Tarjan have shown that the sum of the lengths of all phases $\sum_i l_i$ is $O(n^2)$. This follows because $\sum_i l_i$ is just the total decrease in $d_{\max}$ over the whole algorithm, and hence is bounded by $O(n)$ plus the total increase in $d_{\max}$.

We need the notion of *originating edge* of a maximal excess to improve the time bound below $O(n^3)$. Consider any step of the algorithm. Starting from a maximal excess at a vertex v, we can backtrace along a path of current-edges till we reach an edge, say (x, y), such that the last push along (x, y) was either a saturating push or a nonzeroing push. (If there is more than one such edge then an arbitrary choice can

be made.) In other words, the last push on (x, y) originated a flow excess that is now contained in the flow excess at v. The edge (x, y) is called the originating edge of the flow excess at v. The path of current-edges from (x, y) to v is called a *trajectory.*

During a phase, each nonsaturating push leaves behind a current-edge. At the end of the phase these current-edges constitute a forest, since each vertex has at most one outgoing edge. We partition these current-edges among trajectories that are vertex disjoint, except possibly for the end vertices of some trajectories. We shall account for the nonsaturating pushes by the originating edges of these trajectories.

THEOREM 3.1. *The highest distance preflow push algorithm performs at most* $O(n^2\sqrt{m})$ *nonsaturating pushes, and its time bound is* $O(n^2\sqrt{m})$.

Proof. We partition the nonsaturating pushes into two kinds of pushes and show that over the whole algorithm there are $O(n^2\sqrt{m})$ pushes of each kind.

The nonsaturating pushes that occur along a trajectory within a distace of $n/\sqrt{m}$ from the originating edge of the trajectory are called *short trajectory pushes,* and the remaining pushes that occur along a trajectory at a distance greater than $n/\sqrt{m}$ from the originating edge are called *long trajectory pushes.*

It is easily seen that over the whole algorithm there are $O(n^2\sqrt{m})$ short trajectory pushes because each trajectory starts with either a saturating push or a nonzeroing push and over the whole algorithm the total number of saturating pushes and nonzeroing pushes is $O(nm)$.

The long trajectory pushes are accounted for as follows. Observe that during any phase the trajectories are vertex disjoint and hence the number of "long" trajectories (i.e., longer than $n/\sqrt{m}$) is at most $\sqrt{m}$. Thus the number of long trajectory pushes in a phase of length l_i is at most $\sqrt{m}l_i$. Summed over all phases this is $O(n^2\sqrt{m})$.

The algorithm maintains all vertices having flow excess in a data structure so that it can easily select the highest distance vertex. This can be done at a cost of $O(1)$ per selected vertex by using a list based buckets data structure. The theorem follows. □

4. Parametrized worst-case networks for the FIFO, LIFO, and highest distance preflow push algorithms. Let n and m be two given numbers such that n is sufficiently large and m is greater than $5n$. We construct a worst-case network having at most n vertices and m edges on which the FIFO algorithm performs $\Theta(n^3)$ pushes. We also sketch how this network may be modified to obtain a worst-case network having at most n vertices and m edges on which the LIFO algorithm performs $\Theta(n^2m)$ pushes. Then we construct a worst-case network having at most n vertices and m edges on which the highest distance algorithm performs $\Theta(n^2\sqrt{m})$ pushes.

We will construct the worst-case networks by using gadgets A, B, C, D, F, and G. Each of these gadgets is a one-input one-output gadget, i.e., each gadget has one input vertex and one output vertex. When we draw a figure to illustrate a gadget (Figs. 2–7) then the input vertex of the gadget is the vertex adjacent to s and the output vertex is the vertex adjacent to t. Note that vertices s and t do not belong to the gadget.

Each finite capacity edge that we use in a gadget or in a network is a directed edge, i.e., if edge (v, w) has finite capacity then the vertex pair (w, v) has zero capacity. The direction of a finite capacity edge belonging to a gadget is given by the direction in which that edge is traversed by a shortest path from the input vertex of the gadget to the output vertex through that edge. Each infinite capacity edge (i.e., an edge of capacity at least mU) that we use is an undirected edge, i.e., it represents a pair of oppositely-oriented directed edges, both of which have infinite capacity. If the capacity of an edge is not shown in a figure then that edge has infinite capacity. The direction of a finite capacity edge belonging to a gadget may not be shown in a figure; the

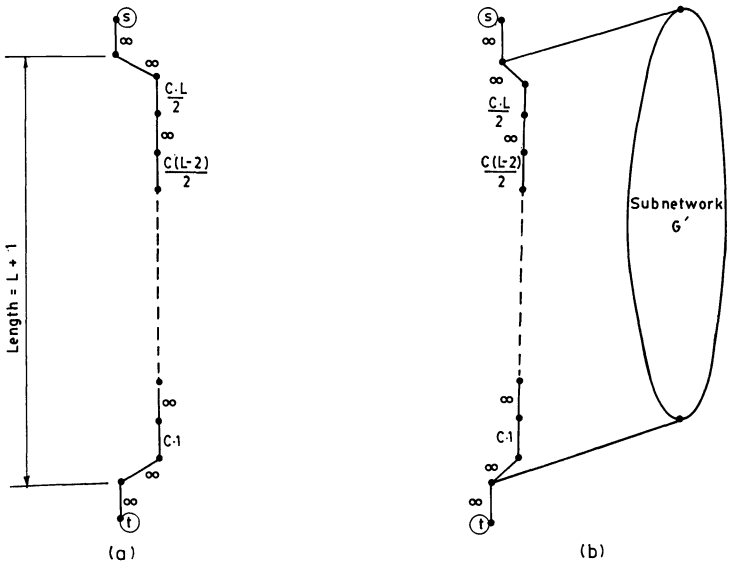

FIG. 2. (a) *Gadget A.* (b) *Gadget A being used by the highest distance algorithm to send a sequence of $L/2$ flow excesses into G'.*

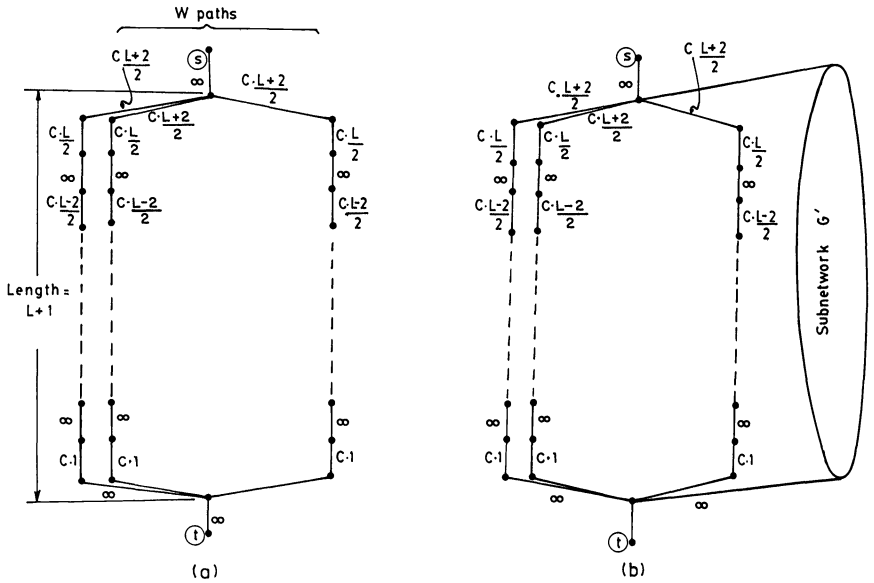

FIG. 3. (a) *Gadget B.* (b) *Gadget B being used by the highest distance algorithm to send a sequence of $WL/2$ flow excesses into G'.*

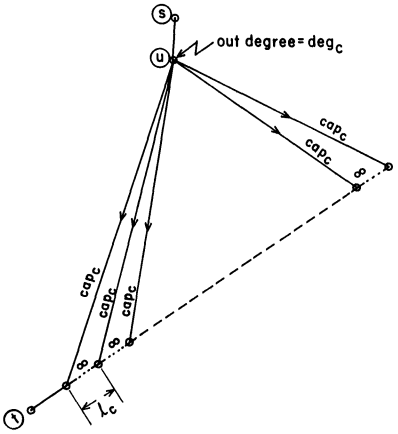

FIG. 4. *Gadget C. The distance label of input vertex u increases by l_c each time a flow excess of value* cap_c *is pushed in at u.*

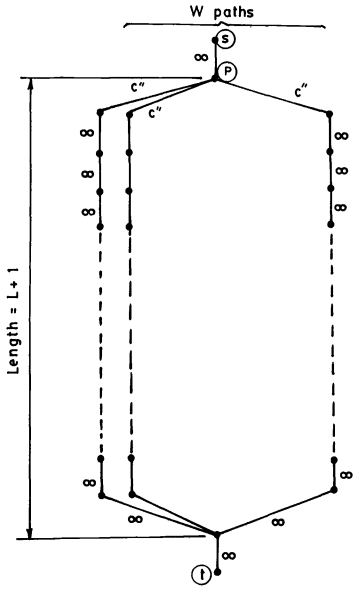

FIG. 5. *Gadget D. WL nonsaturating pushes occur in the gadget each time a flow excess of value c″W is pushed in at p.*

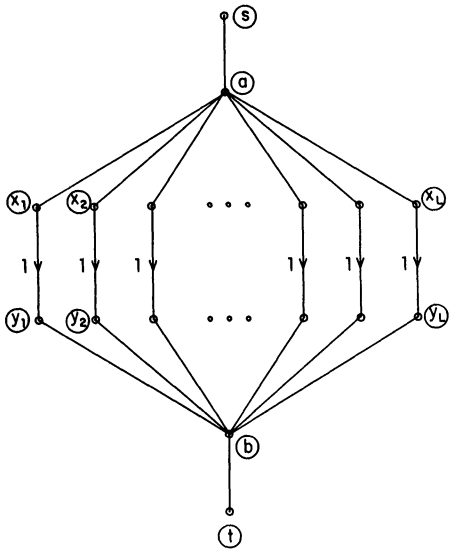

FIG. 6. *Gadget F. Suppose a large flow excess enters the gadget, then leaves it only after a delay of* $2L$ *clock pulses.*

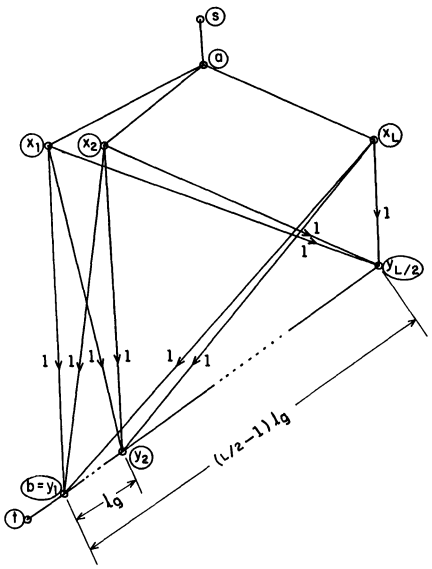

FIG. 7. *Gadget G. Suppose a large flow excess enters the gadget, then leaves it only after a delay of* $2L$ *clock pulses, and this can be repeated a total of* $L/2$ *times.*

direction of such an edge is given by the above convention. We define the *outdegree* of a vertex v to be the number of finite capacity edges with tail-vertex v.

Gadgets A and B are used only in the worst-case network for the highest distance algorithm, and gadgets F and G are used only in the worst-case network for the maximal excess algorithm (§ 5). The values of the parameters used in the gadgets and in the networks are fixed later.

Gadget A (Fig. 2(a)) is a path with $L/2$ finite capacity edges that have telescoping edge capacities. Suppose the highest distance algorithm is run on the network in Fig. 2(b); then a relabel step occurs whenever flow is pushed into an edge of capacity ic, $1 \leqq i \leqq L/2$; it can be seen that a sequence of $L/2$ flow excesses is sent into subnetwork G'.

Putting together W copies of gadget A, we get gadget B (Fig. 3(a)). Suppose the highest distance algorithm is run on the network in Fig. 3(b); then a sequence of $WL/2$ flow excesses is sent into subnetwork G'.

Gadget C (Fig. 4) contains an infinite capacity path of length l_c $(\deg_c - 1)$ and an input vertex u. There are $\deg_c$ edges, each of capacity cap_c, emanating from u. The head-vertices of the edges emanating from u lie in the path, and the head-vertices of two consecutive edges are located at a distance of l_c apart. If a sequence of flow excesses, each of value cap_c, is pushed into u then the distance of u from the sink increases in jumps of l_c.

Gadget D (Fig. 5) contains W vertex disjoint paths, where each path has length $L+1$. The first edge in each path has capacity c'' and the remaining edges have infinite capacity. If a flow excess of value $c''W$ is pushed into vertex p, it gives rise to WL nonsaturating pushes on the collection of paths.

Gadget F is shown in Fig. 6. It consists of two vertices a and b, and L vertex disjoint paths between a and b. Each path is of length three. The middle edge in each path has unit capacity while the other two edges in each path have infinite capacity.

Gadget G (Fig. 7) is constructed as follows. Let $\{x_1, x_2, \cdots, x_L\}$ be a set of L vertices and let $\{y_1, y_2, \cdots, y_{L/2}\}$ be a set of $L/2$ vertices. A complete bipartite graph is constructed on the vertex partition $\{x_1, x_2, \cdots, x_L\}$ and $\{y_1, y_2, \cdots, y_{L/2}\}$. Each edge in the bipartite graph has unit capacity and is directed from x_i to y_j. The input vertex a of gadget G is joined to all the vertices $\{x_1, x_2, \cdots, x_L\}$ by infinite capacity edges. A path of infinite residual capacity is constructed on the vertices $\{y_1, y_2, \cdots, y_{L/2}\}$ such that there is a distance of l_g between two consecutive vertices y_i and y_{i+1}, $1 \leqq i < L/2$, in the path. For convenience, we will refer to the output vertex of gadget G as b (instead of y_1).

When we describe the working of a preflow push algorithm on a network that contains a particular gadget, then we also use the name of that gadget to denote a shortest path from the input vertex of the gadget to the output vertex at a particular step in the running of the algorithm. For example, "Gadget C" initially denotes a path of length one, but after the first edge emanating from the input vertex u is saturated, "Gadget C" denotes a path of length $1+l_c$.

Recall that each push step performed by a preflow push algorithm either moves some flow closer to the sink or moves some flow closer to the source. The latter kind of push step occurs when the distance label of the selected vertex, say v, is greater than n, i.e., all paths leading from v to the sink have been saturated. When we describe the working of a preflow push algorithm on a network, we will completely ignore the pushes that move some flow closer to the source.

For some of the networks described below, we will see that the sequence of steps performed by a particular preflow push algorithm running on the network can be

partitioned into a number of *periods* such that the sequence of steps constituting the first period is similar to the sequence of steps constituting the second period, and so on. This allows us to describe the working of that algorithm on the network just by describing the sequence of steps that occur in the first period and by specifying the total number of periods.

In each of the networks that we construct for either the FIFO algorithm or the maximal excess algorithm, there is only one edge emanating from the source, and this edge has a sufficiently large finite capacity M. When we describe the working of the FIFO algorithm or the maximal excess algorithm on one of these networks, then we will see that, at each step of the algorithm, there is one flow excess whose value is greater than M/2. We will refer to this as "the large flow excess," and, for expository reasons, we will regard it as the same flow excess moving through the network.

4.1. Parametrized worst-case networks for the FIFO and LIFO algorithms. First consider the network in Fig. 8 on which the FIFO algorithm performs $\Theta(n^2)$ pushes.

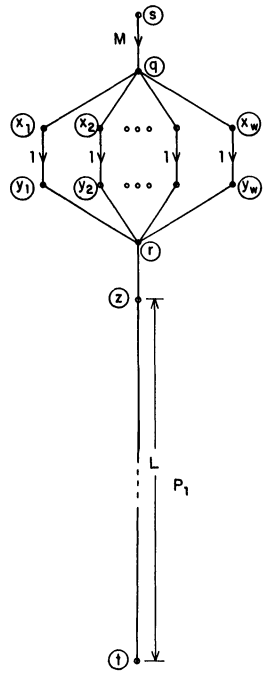

FIG. 8. *Network on which the* FIFO *algorithm performs* $\Theta(n^2)$ *pushes. The parameters are* $L = n/4$ *and* $W = n/4$.

This network contains two sets of vertices $X = \{x_1, x_2, \cdots, x_w\}$ and $Y = \{y_1, y_2, \cdots, y_w\}$ with W vertices each. For every i, $1 \leqq i \leqq W$, vertex x_i has a unit-capacity directed edge (x_i, y_i) to the corresponding vertex y_i. Note that these edges induce a bipartite graph $G'(X, Y, E')$. Each vertex in X is joined to a new vertex q by an infinite capacity edge, and each vertex in Y is joined to a new vertex r by an infinite capacity edge. There is an infinite capacity edge from r to a new vertex z, and z is joined to the sink by a path P_1 of length L with infinite residual capacity.

When the FIFO algorithm is run on this network it first creates a single large flow excess (with value M) at vertex q. The large flow excess then moves from q to vertex

x_1 and performs a saturating push on edge (x_1, y_1), thus creating a unit-capacity flow excess at y_1. (Actually, the large flow excess could move to any vertex x_i and create a unit-capacity flow excess at y_i, but the exact order in which the large flow excess visits the vertices in X does not matter.) The FIFO algorithm then pushes the unit-capacity flow excess at y_1 to the sink along the path $y_1 r z P_1 t$ and this requires $L+1$ nonsaturating pushes. Meanwhile, the large flow excess moves from x_1 to x_2 through vertex q, and then performs a saturating push on edge (x_2, y_2), thus creating a unit-capacity flow excess at y_2. Again the FIFO algorithm requires $L+1$ pushes to move the unit-capacity flow excess from y_2 to the sink. In this manner, the large flow excess visits the vertices $x_1, x_2, \cdots, x_w$, in sequence and saturates all the edges (x_i, y_i), $1 \leqq i \leqq W$, in the bipartite graph, thus creating a unit-capacity flow excess at each vertex y_i. The FIFO algorithm requires $L+1$ pushes to move each unit-capacity flow excess to the sink.

It follows that the FIFO algorithm performs $W(L+1) = \Theta(WL)$ pushes on this network. Taking $W = n/4$ and $L = n/4$, we see that the FIFO algorithm performs $\Theta(n^2)$ pushes on this network.

Let us briefly consider the LIFO preflow push algorithm. It can be seen that the LIFO algorithm also works as described above on the network in Fig. 8, and hence it performs $\Theta(n^2)$ pushes. The number of pushes performed by the LIFO algorithm can be increased to $\Theta(nm)$ by modifying the network in Fig. 8 as follows. We replace the bipartite graph $G'(X, Y, E')$ by the complete bipartite graph $G''(X, Y, E'')$. Each edge in $G''(X, Y, E'')$ has unit capacity and is directed from x_i to y_j. Also, we take $|X| = |Y| = W = \sqrt{m}/4$. It can be seen that the LIFO algorithm performs $\Theta(Lm) = \Theta(nm)$ pushes on this network (by taking $L = n/4$). This concludes the discussion on the LIFO algorithm.

Note that in the network in Fig. 8 a single large flow excess is used to create W unit-capacity flow excesses by saturating all the edges (x_i, y_j) of the bipartite graph. (The FIFO algorithm then performs $\Theta(L) = \Theta(n)$ pushes on each of these unit-capacity flow excesses.) The essential idea for obtaining a worst-case network on which the FIFO algorithm performs $\Theta(n^3)$ pushes is as follows. We clear the edges in the bipartite graph and then use it again to create W unit-capacity flow excesses. This process of creating W unit-capacity flow excesses and then clearing the bipartite graph is repeated a total of $\Theta(n)$ times. We first give an intuitive sketch of how this is done and give the details later (see Figs. 9(a)-(d)). Note that a path P_3 between q and z of length seven has been added to the network in Fig. 8. After all the edges (x_i, y_i) in the bipartite graph have been saturated, the FIFO algorithm moves the large flow excess to vertex r (Fig. 9(b)). When the large flow excess reaches r, it finds that a shortest path from r to the sink is a path $r y_i x_i q P_3 z P_1 t$. Hence, the large flow excess visits the vertices $y_1, y_2, \cdots, y_w$, in sequence and pushes back one unit of flow on each of the edges $(y_1, x_1), (y_2, x_2), \cdots, (y_w, x_w)$ (Fig. 9(c)). This achieves the aim of clearing the edges in the bipartite graph. After this, the FIFO algorithm moves the large flow excess back to q (Fig. 9(d)).

The construction of the complete worst-case network is somewhat complicated because we have to add four copies C_1, C_2, C_3, and C_4 of gadget C and several paths to the network in Fig. 8 to ensure that the large flow excess indeed moves as shown in Fig. 9. We will construct the complete network in four steps and at each step we will indicate the function of the newly added component of the network.

The network in Fig. 10 is obtained from the network in Fig. 8 by replacing the edges (r, z) and (z, r) by gadget C_1 and by adding a path P_3 between q and z of length seven. The input vertex and output vertex of gadget C_1 coincide with r and z,

respectively. The parameters of gadget C_1 are $l_c = l'$, $\text{cap}_c = W = |X| = |Y|$, and $\deg_c = n/\Delta$, where l' and Δ are constants whose values are given later. When the FIFO algorithm is run on the network in Fig. 10, consider the step when the bipartite graph has been saturated and W units of flow have been sent into vertex r. At the next push step, the first edge in gadget C_1 gets saturated and the distance from r to the sink increases from $L+1$ to $L+1+l'$. Gadget C_1 is needed because when the large flow excess reaches r (see Fig. 9(b)), it should find that a path $ry_ix_iqP_3zP_1t$ is shorter than the path $r(\text{gadget } C_1)zP_1t$, and this can be ensured by taking l' to be sufficiently large.

The network in Fig. 11 is obtained from the network in Fig. 10 by adding a path P_2 between q and r of length six, and inserting gadget C_2 into this path such that the input vertex u_2 of gadget C_2 coincides with the neighbour of r in P_2. The output vertex of gadget C_2 coincides with z and the parameters of gadget C_2 are $l_c = l'$, $\text{cap}_c = 1$ and $\deg_c = n/\Delta$. Note that the initial distance label of u_2 equals the initial distance label of r. The path P_2 has infinite residual capacity. The path P_2 is used to move the large flow excess to r as follows. After the large flow excess saturates edge (x_w, y_w) (Fig. 9(a)), it finds that the shortest path from x_w to t is the path $x_wq \cdots u_2$ (gadget $C_2)zP_1t$ and so it moves to vertex u_2. After reaching u_2, the large flow excess saturates the first edge of gadget C_2 thereby increasing the distance label of u_2 by l'. After this, the large

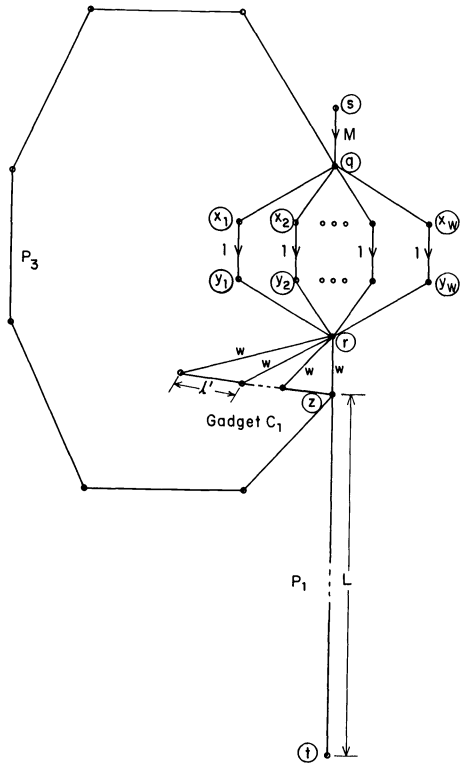

FIG. 10. *Step* 1 *in construction of worst-case network for the* FIFO *algorithm. Gadget* C_1 *and path* P_3 *have been added to the network in Fig.* 8.

flow excess finds that a shortest path from u_2 to the sink is a path $u_2 r y_i x_i q P_3 z P_1 t$ and so it moves to r. Thus the movement of the large flow excess shown in Fig. 9(b) is realized.

The network in Fig. 12 is obtained from the network in Fig. 11 by replacing path P_3 by the union of path P_3' and gadget C_3. P_3' has length six and has infinite residual capacity; the last vertex of P_3' coincides with the input vertex of gadget C_3. The output vertex of gadget C_3 coincides with z and the parameters of gadget C_3 are $l_c = l'$, $\text{cap}_c = W$ and $\deg_c = n/\Delta$. Path P_3' and gadget C_3 are needed to realize the movement of the large flow excess shown in Figs. 9(c)-(d).

Last, the network in Fig. 13 is obtained from the network in Fig. 12 by adding a path P_4 between r and q of length six and inserting gadget C_4 into this path such that the input vertex u_4 of gadget C_4 coincides with the neighbour of q in P_4. The path P_4 has infinite residual capacity. The output vertex of gadget C_4 is joined to z by a path P_5 of length six with infinite residual capacity. The parameters of gadget C_4 are $l_c = l'$, $\text{cap}_c = W$ and $\deg_c = n/\Delta$. The path P_4 is used to move the large flow excess back to q as follows. After the large flow excess saturates edge (y_w, x_w) (Fig. 9(c)), it can be seen that the distance label of u_4 equals the distance label of q, and the shortest path from y_w to t is the path $y_w r \cdots u_4$ (gadget C_4)$P_5 z P_1 t$. Hence, the large flow excess moves to vertex u_4 and saturates the first edge of gadget C_4, thereby increasing the distance label of u_4 by l'. Eventually, the large flow excess reaches q and finds that a shortest path from q to the sink is a path $q x_i y_i r$(gadget C_1)$z P_1 t$. Thus the movement of the large flow excess shown in Fig. 9(d) is realized.

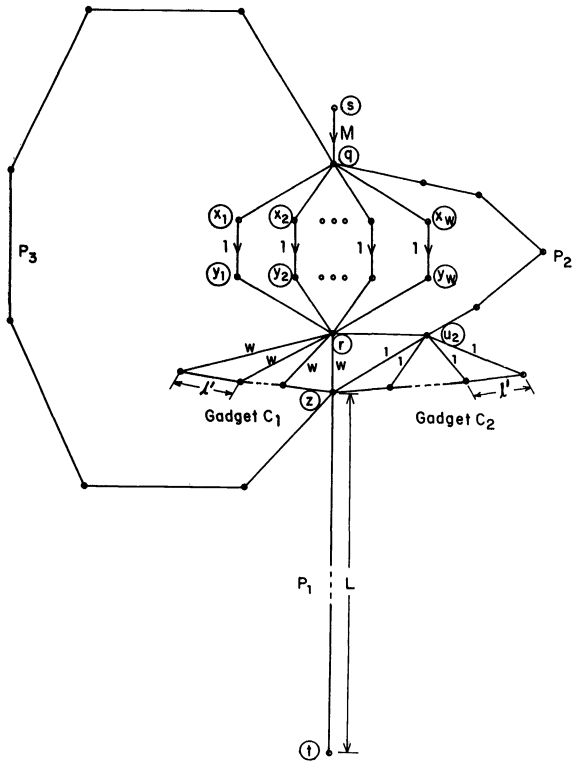

FIG. 11. *Step 2 in construction of worst-case network for the* FIFO *algorithm. Gadget C_2 and path P_2 have been added to the network in Fig.* 10.

The above sequence of steps (shown in Figs. 9(a)-(d)) constitutes one period of the FIFO algorithm running on the network in Fig. 13. The second period of the algorithm proceeds similarly. Note that in each period the FIFO algorithm performs $\Theta(WL)$ nonsaturating pushes. In each period, one edge in each of the gadgets C_1, C_2, C_3, and C_4 gets saturated. Hence, the number of periods over the whole algorithm equals the outdegree of the input vertex in any of these four gadgets, and this equals n/Δ.

We take the parameters to be $W = n/4$, $L = n/4$, $l' = 20$, and $\Delta = 320$. The capacity of the edge emanating from s is taken to be $M > 4(W+1)n/\Delta$. This gives us Theorem 4.1.

THEOREM 4.1. *There is a parametrized worst-case network on which the* FIFO *preflow push algorithm performs $\Theta(n^3)$ pushes.*

A similar construction for the LIFO algorithm gives us Theorem 4.2.

THEOREM 4.2. *There is a parametrized worst-case network on which the* LIFO *Preflow push algorithm performs $\Theta(n^2m)$ pushes.*

4.2. A parametrized worst-case network for the highest distance algorithm. First, consider the network in Fig. 14. This network contains two copies D_1 and D_2 of gadget D and two copies C_1 and C_2, of gadget C. The parameters for gadgets C_1 and C_2 are taken to be $l_c = l'$, $\text{cap}_c = c'$, and $\deg_c = L/2$, where l' is a constant whose value is fixed later. Let the neighbours of vertex P_1 in gadget D_1 be $x_1, x_2, \cdots, x_w$, and let the neighbours of vertex p_2 in gadget D_2 be $y_1, y_2, \cdots, y_w$. We construct a complete bipartite graph on the vertex partition $\{x_1, x_2, \cdots, x_w\}$ and $\{y_1, y_2, \cdots, y_w\}$ such that

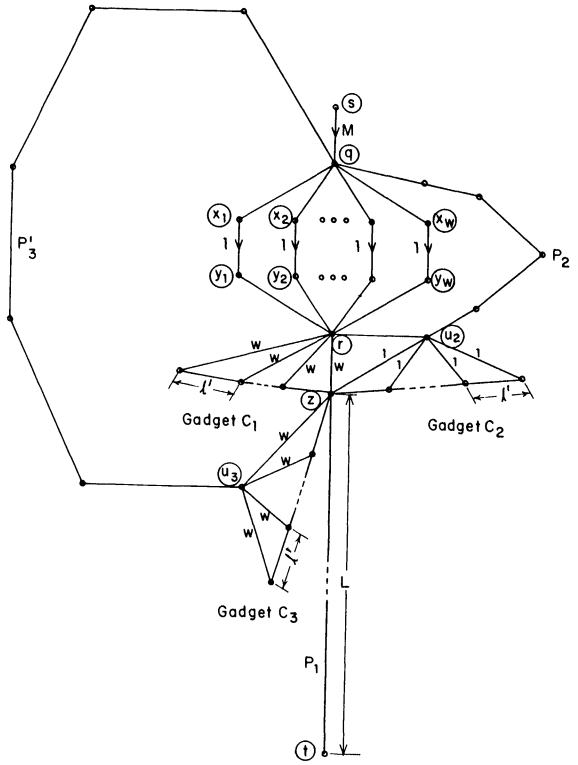

FIG. 12. *Step 3 in construction of worst-case network for the* FIFO *algorithm. Path P_3 in the network in Fig. 11 has been replaced by the union of gadget C_3 and path P'_3.*

each edge in the bipartite graph is directed from x_i to y_j and has capacity equal to c''. Note that the gadget C_1 is located $l'/2$ levels higher (with respect to distance from the sink) than gadget C_2, and gadget D_1 is located $l'/2$ levels higher than gadget D_2.

Consider the working of the highest distance algorithm on the network in Fig. 14. Suppose a sequence of W flow excesses, each of value $c''W$, is pushed into vertex p_1 then each of these flow excesses is routed through one of the vertices x_i and gives rise to WL nonsaturating pushes in gadget D_2. This sequence of flow excesses causes the first edge in gadget C_2 to saturate (we take $c' = c''W^2$ for ensuring this) and thus raises the level of gadget D_2 by l'. Now, suppose a sequence of W flow excesses, each of value $c''W$, is pushed into vertex p_2. Again each of these gives rise to WL nonsaturating pushes in gadget D_1. This process of alternately sending a sequence of flow excesses into p_1 and p_2 can be repeated $L/2$ times, until the gadgets C_1 and C_2 are completely saturated. The total number of nonsaturating pushes is $\Theta((WL)^2)$. Later we will fix the values of the parameters W and L such that $WL = \Theta(n)$; consequently, the total number of nonsaturating pushes is $\Theta(n^2)$.

Figure 15 shows a worst-case network on which the highest distance algorithm performs $\Theta(n^2)$ pushes. This network is obtained by adding two copies B_1 and B_2 of gadget B to the network in Fig. 14. Note that gadget B_1 is located one level higher (with respect to distance from the sink) gadget B_2.

When the highest distance algorithm is run on this network, it first creates a large flow excess at vertex g. The large flow excess then moves to vertex b_2 and saturates all the finite capacity edges emanating from b_2, thereby creating a flow excess of value

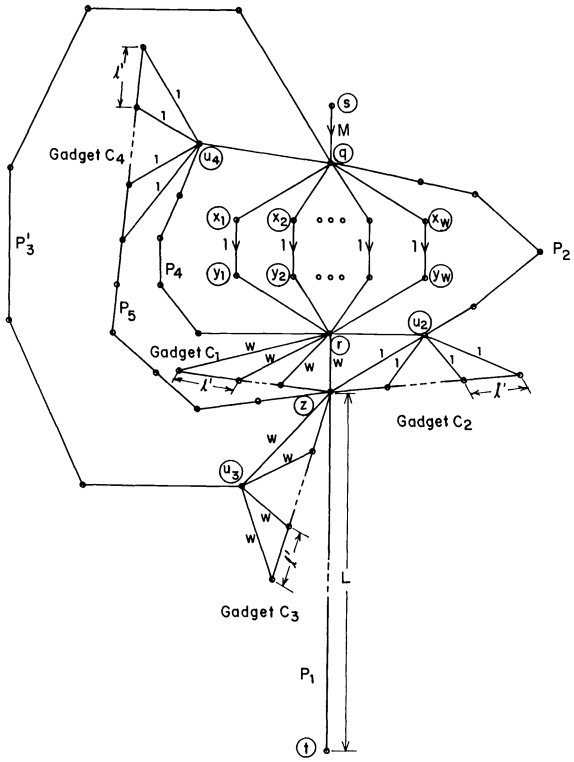

FIG. 13. *Parametrized worst-case network on which* FIFO *algorithm performs* $\Theta(n^3)$ *pushes. Gadget* C_4 *and paths* P_4 *and* P_5 *have been added to the network in Fig.* 12. *The input vertex in each of the gadgets* C_1, C_2, C_3, *and* C_4 *has outdegree* $= n/\Delta$, *where* $\Delta = 320$. *The parameters are* $L = n/4$, $W = n/4$, $l' = 20$, *and the capacity* $M > 4(W+1)n/\Delta$.

$c(L+2)/2$ at each neighbour of b_2 in gadget B_2. The remaining large flow excess at b_2 then moves along the path $b_2p_2gp_1b_1$ to b_1 and saturates all the finite capacity edges emanating from b_1, thereby creating a flow excess of value $c(L+2)/2$ at each neighbour of b_1 in gadget B_1.

At the next select step of the highest distance algorithm, one of the neighbours of b_1 in gadget B_1, say vertex v, is selected. The next push step saturates the unique outgoing edge from v and creates a flow excess with value $cL/2$ at the head-vertex of this edge. Then v gets relabeled and the remaining flow excess at v, with value c, is sent to vertex p_1. From p_1, the flow excess is routed through one of the vertices x_i and gives rise to WL nonsaturating pushes in gadget D_2 (we take $c = c''W$ for ensuring this). Similarly, each remaining neighbour of b_1 in gadget B_1 sends a flow excess with value c to vertex p_1, and each of these flow excesses gives rise to WL nonsaturating pushes in gadget D_2. After this, gadget B_2 sends a sequence of W flow excesses, each with value c, to vertex p_2, and each of these flow excesses gives rise to WL nonsaturating pushes in gadget D_1. This process of gadget B_1 sending a sequence of W flow excesses to p_1 and then gadget B_2 sending a sequence of W flow excesses to p_2 is repeated a total of $L/2$ times, until there are no more flow excesses left in gadgets B_1 and B_2.

Figure 16 shows a worst-case network on which the highest distance algorithm performs $\Theta(n^2\sqrt{m})$ pushes. It is obtained from the network in Fig. 15 by adding two copies C_3 and C_4 of gadget C. These gadgets are added because after gadget B_1 (or B_2) has sent $WL/2$ flow excesses into vertex p_1 (or p_2), all the finite capacity edges in

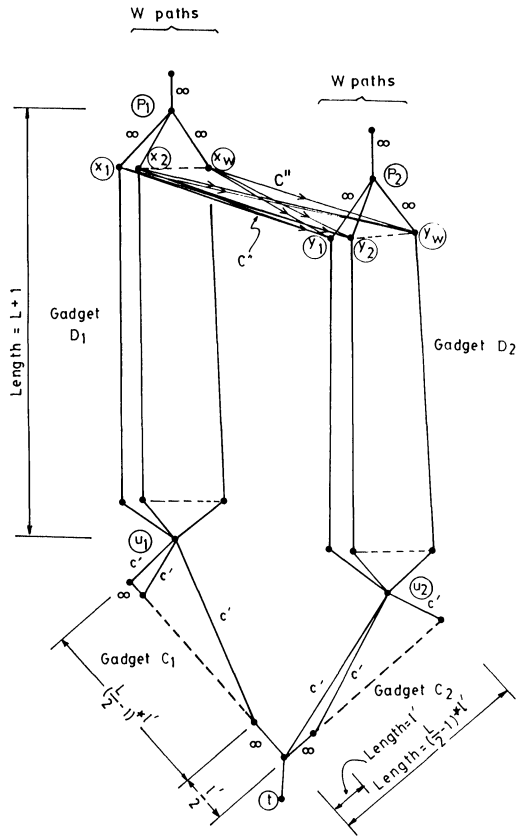

FIG. 14. *Suppose a sequence of W flow excesses, each of value c"W, is pushed in at p_1, then each flow excess causes WL nonsaturating pushes in Gadget D_2. Finally, the current edge of vertex u_2 is saturated and the distance label of u_2 increases by l'. The capacity $c' = c''W^2$.*

gadgets B_1 and B_2 and C_1 and C_2 become saturated. Gadgets C_3 and C_4 are needed to reverse flow through gadgets B_1 and B_2 and C_1 and C_2 to clear all the finite capacity edges in these gadgets. This allows us to reuse gadgets B_1 and B_2, and in fact, gadgets B_1 and B_2 are used repeatedly a total of $\Theta(n/L)$ times.

When we fix the value of l', it will turn out that the length of the longest path from vertex g to vertex z in the network in Fig. 16 is less than $6L+6$. We fix the distance from the output vertex of gadget C_4 to the sink to be $6L+6$. The parameters of gadgets C_3 and C_4 are taken to be $l_c = 12L+12$, $\text{cap}_c = 1$, and $\deg_c = W/12$.

When the highest distance algorithm runs on the network in Fig. 16, it first performs the same sequence of steps as the highest distance algorithm running on the network in Fig. 15. Consider the situation at the end of this sequence of steps. All the flow excess in the network has accumulated at vertex z to form a single large flow excess. The next push step saturates the first edge of gadget C_3. Hence, the distance label of z increases by $12L+12$ and now a path z(gadget B_2)b_2p_2g(gadget C_4) $\cdots$ t becomes a shortest path from z to the sink. It can be seen that the flow is then sent back through gadgets B_2, B_1, C_2 and D_2, and C_1 and D_1 to vertex g. Eventually, all the flow excess in the network (except the flow excess at t) accumulates at vertex g to form a single large flow excess. The next push step saturates the first edge of gadget C_4. Hence, the distance label of g increases by $12L+12$ and now a path gp_2b_2(gadget B_2)z(gadget

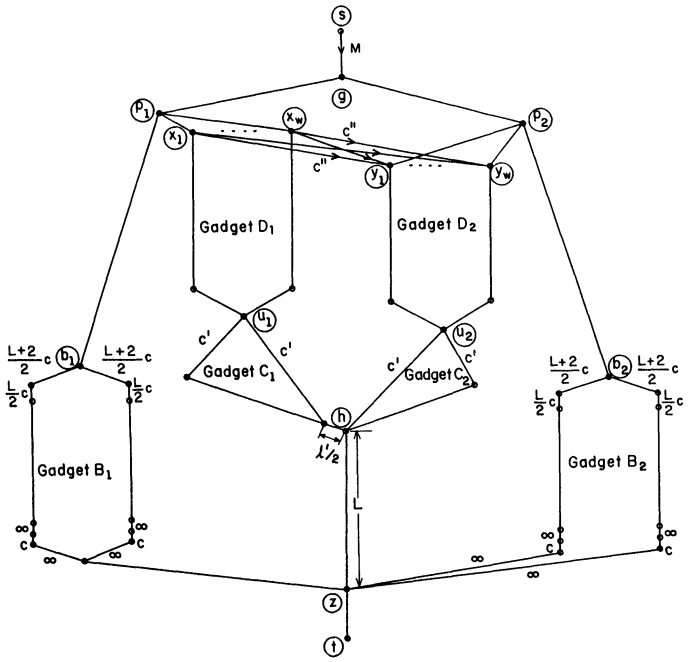

FIG. 15. *Network on which the highest distance algorithm performs* $\Theta(n^2)$ *pushes. Gadgets* B_1 *and* B_2 *have been added to the network in Fig.* 14. *The parameters are* $L = n/\sqrt{m}$, $W = \sqrt{m}/8$, *and* $l' = 8$. *The capacities are* $c'' = 4W^2$, $c = c''W$, $c' = c''W^2$, *and* $M = (L+2)Wc$.

$C_3)t$ becomes a shortest path from g to the sink. The sequence of steps from the start of the algorithm to the push step that saturates the first edge in gadget C_4 constitutes the first period of the highest distance algorithm running on the network in Fig. 16. The second period proceeds similarly. During each period the highest distance algorithm saturates one edge in each of the gadgets C_3 and C_4. Consequently, the number of periods equals the outdegree of vertex g (or z) and this equals $W/12$. When we take the parameters of the network to be $L = n/\sqrt{m}$, $W = \sqrt{m}/8$, and $l' = 8$, it follows that the highest distance algorithm performs $\Theta(n^2\sqrt{m})$ nonsaturating pushes on the network in Fig. 16.

One aspect of the working of the highest distance algorithm on the network in Fig. 16 remains to be discussed. At the beginning of the ith period, let $fsum_i$ denote the sum of the values of the first W flow excesses that are sent into vertex p_1 by gadget B_1. Clearly, $fsum_i$ should be greater than or equal to the capacity of the first edge in gadget C_2. Note that during each period, one unit of flow is pushed to the sink through each of gadgets C_3 and C_4. Consequently, the value of $fsum_i$ decreases by two in each period, i.e., $fsum_i = fsum_{i-1} - 2$, for $i > 1$. The worst-case network has been modified to compensate for this. The modifications are as follows. Let γ be greater than $2W/12$. In gadget C_2, there is one more edge, with capacity γ or more, emanating from the input vertex u_2, i.e., $\deg_c = L/2+1$ for gadget C_2; the capacity of one edge (x_i, y_j) is increased by γW; and the capacity of one edge emanating from vertex b_1 is increased by γ. The capacity of the edge emanating from s is taken to be $M = cW(L+2)+\gamma$. We do not go into further details, but it can be seen that the working of the highest distance algorithm remains essentially as explained above. This gives us the following theorem.

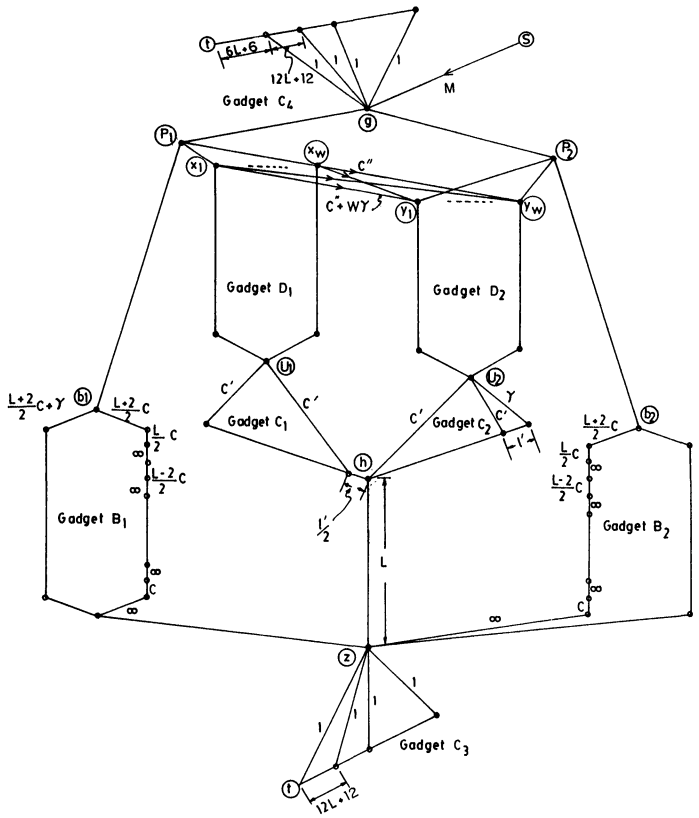

FIG. 16. *Parametrized worst-case network on which the highest distance algorithm performs* $\Theta(n^2\sqrt{m})$ *pushes. Gadgets* C_3 *and* C_4 *have been added to the network in Fig.* 15 *and in gadget* C_2 *there is one more edge emanating from* u_2. *The parameters are* $L = n/\sqrt{m}$, $W = \sqrt{m}/8$, *and* $l' = 8$. *The capacities are* $c'' = 4W^2$, $c = c''W$, $c' = c''W^2$, $\gamma > 2W/12$, *and* $M = (L+2)Wc + \gamma$.

THEOREM 4.3. *There is a parametrized worst-case network on which the highest distance preflow push algorithm performs* $\Theta(n^2\sqrt{m})$ *pushes.*

5. The maximal excess preflow push algorithm. Note that the highest distance algorithm and the FIFO algorithm are able to improve on the naive bound of $O(n^2m)$ for preflow push algorithms because they effectively exploit the mechanism of coalescing flow excesses. In this section we investigate how far the idea of coalescing flow excesses can be carried. Another motivation is to obtain an algorithm that is more suited to the distributed computation model than the highest distance algorithm.

The flow excesses can be coalesced together by pushing as many flow excesses as possible in the round-robin order while still retaining the desirable feature of the highest distance algorithm, namely, a nonmaximal excess is never pushed. This suggests that all active vertices v with maximal excesses (i.e., the current-edge subtree rooted at v contains no other flow excesses) should be selected in the round-robin order. The resulting algorithm is called the *maximal excess preflow push algorithm.*

There are two ways in which a maximal excess located at a vertex v becomes nonmaximal. The first is that some flow excess is pushed into the current-edge subtree rooted at v thereby causing the flow excess at v to become nonmaximal. Second, consider two maximal flow excesses that are moving down the current-edge tree. The one that reaches their nearest common ancestor earlier ceases to be a maximal excess.

Clearly, the maximal excess algorithm requires additional data structure overheads for detecting the above occurrences. We do not consider these overheads in detail but are primarily interested in the number of nonsaturating pushes performed by this algorithm.

The analysis given in Theorem 3.1 does not apply to the maximal excess algorithm because one vertex may do several nonsaturating pushes during a single phase (recall that a phase consists of all pushes between two consecutive relabel steps). However, we can still obtain an $O(n^2\sqrt{m})$ bound on the number of pushes by using an approach similar to that in Theorem 3.1.

THEOREM 5.1. *The maximal excess preflow push algorithm performs at most* $O(n^2\sqrt{m})$ *nonsaturating pushes.*

Proof. We partition the nonsaturating pushes into short trajectory pushes and long trajectory pushes, as in the proof of Theorem 3.1. It is easily seen that over the whole algorithm there are $O(n^2\sqrt{m})$ short trajectory pushes.

The number of long trajectory pushes is shown to be $O(n^2\sqrt{m})$ as follows. We assume that the algorithm operates in clock pulses, where during one clock pulse push steps are simultaneously performed on all maximal excesses. (Note that if the algorithm is implemented using a FIFO queue then a clock pulse corresponds to one pass over the queue.) It is easily seen that there are $O(n^2)$ clock pulses over the whole algorithm because during each clock pulse $d_{\max}$ (defined in § 2) either decreases by one or increases, and the total decrease in $d_{\max}$ over the whole algorithm is $O(n^2)$ and likewise for the total increase in $d_{\max}$.

Now we make the crucial observation that at any clock pulse the trajectories of all maximal excesses are vertex disjoint; otherwise, if the trajectories of two flow excesses overlap then either the two flow excesses have coalesced or one of the flow excesses is nonmaximal. It follows that at any clock pulse the number of long trajectory pushes is at most $\sqrt{m}$ because the number of maximal excesses having long trajectories (i.e., longer than $n/\sqrt{m}$) is at most $\sqrt{m}$. Hence, over the whole algorithm the number of long trajectory pushes is $O(n^2\sqrt{m})$. The theorem follows. □

5.1. A parametrized worst-case network for the maximal excess algorithm. Let n and m be two given numbers such that n is sufficiently large and m is greater than $140n$. We construct a worst-case network having at most n vertices and m edges on which the maximal excess algorithm performs $\Theta(n^2\sqrt{m})$ pushes. This worst-case network is similar to the worst-case network for the highest distance preflow push algorithm except that instead of using gadgets B_1 and B_2 to create flow excesses in gadgets D_1 and D_2, we take a different approach that uses $W-1$ copies of gadget F, and two copies of gadget G, and some additional paths. W and L are parameters whose values will be fixed later such that $WL=\Theta(n)$.

The gadgets D, C, F, and G are described in § 4. In the following, when we use a copy of gadget D we first delete the vertex p; this will not be mentioned explicitly.

We can use k copies of gadget F to construct a network on which the maximal excess algorithm performs $\Theta((k+1)n)$ nonsaturating pushes. Figure 17 illustrates this construction for $k=1$. The network in Fig. 17 contains a copy D_1 of gadget D, a copy F_1 of gadget F, and two new vertices x_1 and x_2. Each of the edges (x_i, y_j), $1 \leqq i \leqq 2$, $1 \leqq j \leqq W$, has unit capacity. The vertex a_1 of gadget F_1 is joined to x_1 by an edge and is joined to x_2 by a path of length four, and the vertex b_1 of gadget F_1 is joined to vertex y_1 by an edge.

The detailed working of the maximal excess algorithm on this network is as follows. A large flow excess is created at vertex x_1. Then the large flow excess performs saturating pushes on the edges (x_1, y_1), (x_1, y_2), $\cdots$, (x_1, y_w), thereby creating unit-capacity flow

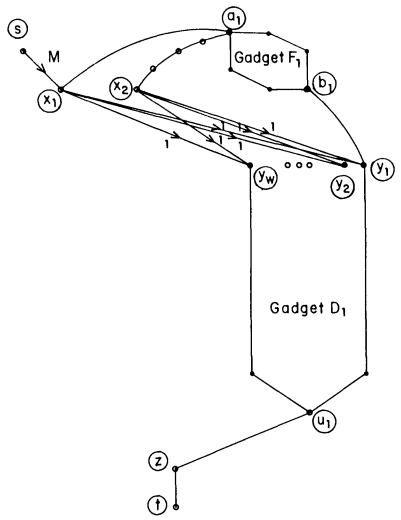

FIG. 17. *Network with one copy of gadget F on which the maximal excess algorithm performs* $\Theta(2WL)$ *pushes. This construction can be extended to give a network with k copies of gadget F on which the maximal excess algorithm performs* $\Theta((k+1)WL)$ *pushes.*

excesses at each of the vertices $y_1, y_2, \cdots, y_w$. The maximal excess algorithm then pushes these unit-capacity flow excesses to the sink and this gives rise to $\Theta(WL) = \Theta(n)$ nonsaturating pushes in gadget D_1. The large flow excess at x_1 should be moved to x_2 but it should reach x_2 only after $\Theta(n)$ nonsaturating pushes have occurred in gadget D_1, i.e., only after all the unit-capacity flow excesses in gadget D_1 have reached the sink. (Actually, when the large flow excess reaches x_2 the unit-capacity flow excess created at y_1 is still in gadget D_1; however, $\Theta(n)$ nonsaturating pushes would have occurred in gadget D_1 since the other unit-capacity flow excesses would have reached the sink.) In other words, there should be a delay of at least L clock pulses before the large flow excess reaches x_2.

Gadget F_1 is used to accomplish this delay. It can be seen that the large flow excess leaves gadget $F_1 2L$ clock pulses after entering the gadget because it saturates each of the unit-capacity edges in the gadget.

After the large flow excess reaches x_2 it again creates a unit-capacity flow excess at each of the vertices $y_1, y_2, \cdots, y_w$, and this gives rise to another $\Theta(n)$ nonsaturating pushes in gadget D_1. This completes the discussion on Fig. 17.

It can be seen that by adding vertices $x_3, x_4, \cdots, x_w$, edges (x_j, y_j) $3 \leqq i \leqq W$, $1 \leqq j \leqq W$, and $W-2$ more copies $F_2, \cdots, F_{w-1}$ of gadget F to the network in Fig. 17 and connecting gadget F_i to vertices x_i, x_{i+1}, and y_i, we obtain a network on which the maximal excess algorithm performs $\Theta(Wn)$ nonsaturating pushes.

The network in Fig. 18 contains two copies D_1 and D_2 of gadget D and $W-1$ copies $F_1, F_2, \cdots, F_{w-1}$ of gadget F, and these gadgets are connected together as shown in Fig. 18. Note that gadget D_2 is located $l'/2$ levels higher (with respect to distance from the sink) than gadget D_1, where l' is a constant whose value is fixed later. A complete bipartite graph is created on the vertex partition $\{x_1, x_2, \cdots, x_w\}$ and $\{y_1, y_2, \cdots, y_w\}$ (i.e., the "tail-vertices of paths" in gadget D_2 and the "tail-vertices of paths" in gadget D_1) by adding unit-capacity edges (x_i, y_j), for all $1 \leqq i \leqq W$ and $1 \leqq j \leqq W$. Also, a path P' between x_w and y_1 of length six and a path P'' between y_w and x_1 of length six are added to the network. Both P' and P'' have infinite residual

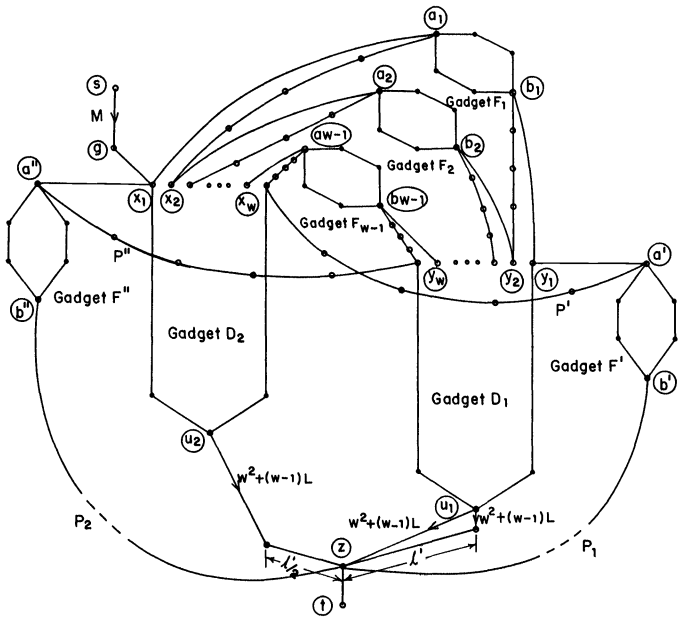

FIG. 18. *Network on which the maximal excess algorithm performs* $\Theta((W)WL)$ *pushes. Edges* (x_i, y_j) *have been omitted for clarity. Path* P' (P'') *and gadget* F' (F'') *are needed to move the large flow excess from* x_w *to* y_1 *(from* y_w *back to* x_1*). The lengths of paths* P_1 *and* P_2 *are* $L-2$ *and* $L-2+l'/2$.

capacity. Gadget F', a copy of gadget F, is inserted into path P' such that vertex a' of gadget F' coincides with the neighbour of y_1 in P'; similarly, gadget F'' is inserted into path P''. The output vertex b' of gadget F' and the output vertex b'' of gadget F'' are joined to vertex z by paths P_1 and P_2 having lengths $L-2$ and $L-2+l'/2$, respectively. The path lengths have been fixed such that $d(a')$ (the initial distance label of a') equals $d(y_1)$ and $d(a'')$ equals $d(x_1)$. Also, each finite capacity edge emanating from u_1 and from u_2 has capacity equal to $W^2+(W-1)L$.

When the maximal excess algorithm runs on this network, it moves the large flow excess to each of the vertices $x_1, x_2, \cdots, x_w$, in sequence, and for each vertex x_i the algorithm performs $\Theta(n)$ nonsaturating pushes in gadget D_1. After moving the large flow excess to x_w and saturating the edges $(x_W, y_1), \cdots, (x_W, y_W)$, the maximal excess algorithm finds that a shortest path from x_w to the sink is a path $x_w \cdots a'$ (gadget $F')b'P_1zt$, and so it moves the large flow excess from x_w along the path P' to gadget F'. The large flow excess is delayed in gadget F' for $2L$ clock pulses since it saturates each of the unit-capacity edges in gadget F'. Consider the step of the algorithm when all the unit-capacity edges in gadget F' have been saturated. All the flow excesses in gadget D_1 have reached the sink before this step, and also the edge (u_1, z) has been saturated. Hence, the maximal excess algorithm finds that a shortest path from a' to the sink is a path $a'y_1x_i$(gadget $D_2)u_2 \cdots zt$, and so it moves the large flow excess to y_1.

The large flow excess then saturates the edges $(y_1, x_1), \cdots, (y_1, x_w)$ and creates unit-capacity flow excesses at vertices $x_1, x_2, \cdots, x_w$, thereby giving rise to $\Theta(n)$ nonsaturating pushes in gadget D_2. The maximal excess algorithm then moves the large flow excess to each of the vertices $y_2, \cdots, y_w$, in sequence and for each y_i the algorithm performs $\Theta(n)$ nonsaturating pushes in gadget D_2.

After moving the large flow excess to y_w and saturating the edges $(y_w, x_1), \cdots, (y_w, x_w)$, the maximal excess algorithm moves the large flow excess from y_w along the path P'' to gadget F''. The large flow excess is then delayed in gadget F'' for $2L$ clock pulses since it saturates each of the unit-capacity edges in gadget F''. Finally, the large flow excess reaches vertex x_1. Before this step of the algorithm all flow excesses in gadget D_2 have reached the sink, and also the edge, with capacity $W^2+(W-1)L$, emanating from u_2 have been saturated.

Let us call the above sequence of steps a *macro-step*, i.e., when the maximal excess algorithm runs on the network in Fig. 18, it first performs a macro-step. Note that the maximal excess algorithm performs $\Theta(2nW)$ nonsaturating pushes during a macro-step.

The network in Fig. 19 is obtained from the network in Fig. 18 by adding two copies C_1 and C_2 of gadget C and replacing gadgets F' and F'' by two copies G' and G'' of gadget G. The parameters for gadgets C_1 and C_2 are taken to be $l_c = l'$, $\text{cap}_c = W^2+(W-1)L$, and $\deg_c = L/2$. For both gadgets G' and G'', the parameter l_g is taken to be l'. The output vertices b' and b'' of gadgets G' and G'' are joined to z by paths P_1 and P_2 of lengths $L-1$ and $L-1+l'/2$, respectively. Note that gadget C_2 is located $l'/2$ levels higher (with respect to distance from the sink) than gadget C_1, and gadget D_2 is located $l'/2$ levels higher than gadget D_1.

When the maximal excess algorithm runs on the network in Fig. 19, it first performs a macro-step. This constitutes one period of the maximal excess algorithm running on the network in Fig. 19. The second period proceeds similarly. Note that during the ith period the maximal excess algorithm saturates one edge in each of the gadgets C_1 and C_2 and also the algorithm saturates all the unit-capacity edges entering vertex y_i' in gadget G' and all the unit-capacity edges entering vertex y_i'' in gadget G'' (recall the

description of gadget G in § 4). It can be seen that the maximal excess algorithm performs $L/2$ periods, and so it performs $\Theta(nwL) = \Theta(n^2)$ pushes when it runs on the network in Fig. 19.

The $\Theta(n^2\sqrt{m})$ worst-case network for the maximal excess algorithm is shown in Fig. 20. This network is obtained from the network in Fig. 19 by adding two copies C_3 and C_4 of gadget C, and a path P_3 between the input vertex a'' of gadget G'' and vertex z. The gadgets C_3 and C_4 perform the same function as the gadgets C_3 and C_4 in the worst-case network for the highest distance algorithm (§ 4). Consider any shortest path from g to z that contains the longest path through gadget C_2; when we fix the value of l' it will turn out that the length of such a path is less than $11L$. We fix the distance from the output vertex of gadget C_4 to the sink to be $11L$. The parameters of gadgets C_3 and C_4 are taken to be $l_c = 22L$, $\text{cap}_c = 1$, and $\deg_c = W/22$. The path P_3 is needed to move the large flow excess to vertex z (this is discussed below); P_3 has length $L(1+l'/2)+2-l'/2$ and is longer than any longest path from a'' to z through gadget G''. Note that the path between g and x_1 has length four and the path between g and y_1 has length six.

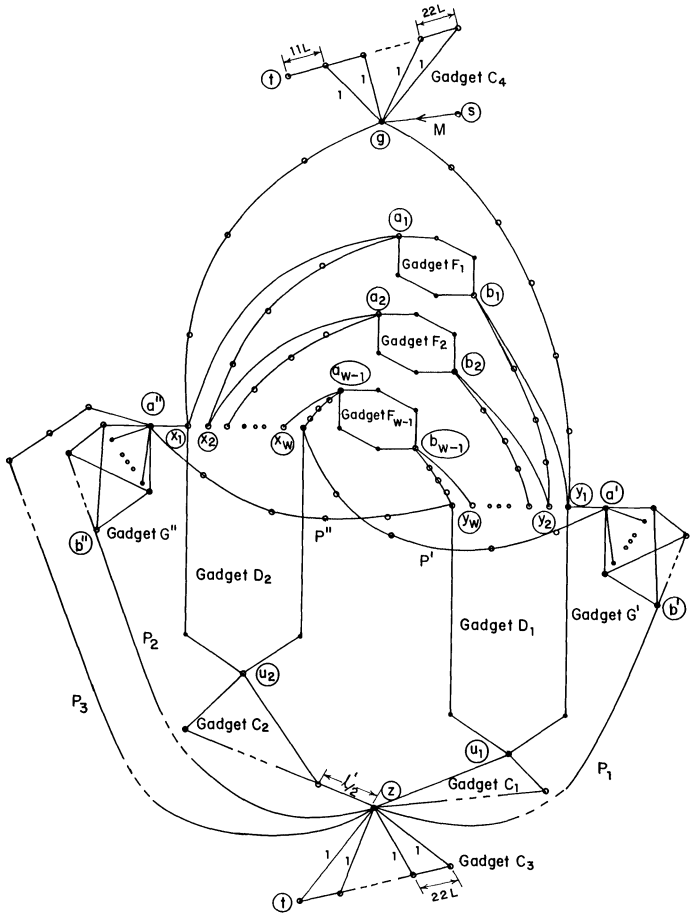

FIG. 20. *Parametrized worst-case network on which the maximal excess algorithm performs* $\Theta(n^2\sqrt{m})$ *pushes. Gadgets* C_3 *and* C_4 *and path* P_3 *have been added to the network in Fig.* 19. *Edges* (x_i, y_i) *have been omitted for clarity. The parameters are* $W = \sqrt{m}/64$, $L = 8n/\sqrt{m}$, $l' = 20$, *and the capacity is* $M > 2WL(W+L)$. *The lengths of paths* P_1, P_2, *and* P_3 *are* $L-1$, $L-1+l'/2$, *and* $L(1+l'/2)+2-l'/2$.

When the maximal excess algorithm runs on the network in Fig. 20, it first performs the same sequence of steps as the maximal excess algorithm running on the network in Fig. 19. At the end of this sequence of steps, all the finite capacity edges in gadgets C_1, C_2, G', and G'' have been saturated, and the large flow excess is at the input vertex a'' of gadget G''. Next, the large flow excess moves along path P_3 to z, and when it reaches z, all the flow excess in the network is located at z. The next push step saturates the first edge of gadget C_3. Hence, the distance label of z increases by $22L$ and now the path z(gadget C_1)(gadget D_1)$y_1 \cdots g$(gadget C_4)$\cdots t$ becomes the shortest path from z to the sink. It can be seen that the flow is then sent back through gadgets C_1 and D_1, C_2 and D_2, P_1 and G', P_2 and G'', and P_3 to vertex g. Eventually, all the flow excess in the network (except the flow excess at t) accumulates at vertex g to form a single large flow excess. The next push step saturates the first edge of gadget C_4. Hence, the distance label of g increases by $22L$ and now a path $g \cdots x_1 y_1$(gadget D_1)(gadget C_1)z(gadget C_3)t becomes a shortest path from g to the sink. The sequence of steps from the start of the algorithm to the push step that saturates the first edge in gadget C_4 constitutes the first period of the maximal excess algorithm running on the network in Fig. 20. The second period proceeds similarly. During each period the maximal excess algorithm saturates one edge in each of the gadgets C_3 and C_4. Consequently, the number of periods equals the outdegree of vertex g (or z) and this equals $W/22$. We take the parameters of the network to be $L = 8n/\sqrt{m}$, $W = \sqrt{m}/64$, and $l' = 20$, and the capacity of the edge emanating from s to be $M > 2WL(W+L)$. It follows that the maximal excess algorithm performs $\Theta(n^2\sqrt{m})$ nonsaturating pushes on the network in Fig. 20. This gives us the following theorem.

THEOREM 5.2. *There is a parameterized worst-case network on which the maximal excess preflow push algorithm performs* $\Theta(n^2\sqrt{m})$ *pushes.*

6. A distributed maximum flow algorithm. In this section, we develop a maximum flow algorithm for the synchronous distributed model of computation that uses at most $O(n^2\sqrt{m})$ messages and $O(n^2)$ time. This is a multiprocessor model with no shared memory. The graph underlying the network is realized as a processor network with one processor located at each vertex and all interprocessor communication occurs along the (bi-directional) edges of the graph. The processors are *synchronized.* The time required by each processor for its local computations is assumed to be negligible. The resource bounds of interest are the number of messages used by the algorithm and the total time taken (i.e., the number of clock pulses used). We will only use messages of length $O((\log n)+(\log U))$ bits.

The distributed maximum flow algorithm is based on the proof of Theorem 5.1. A *push message* is a message used by the algorithm to indicate the pushing of flow along some edge. Each flow excess keeps track of its originating edge and the distance it has moved since leaving the originating edge. A flow excess moves freely as long as its distance from its originating edge does not exceed $n/\sqrt{m}$.

Recall from Theorem 5.1 that, at each clock pulse, the number of long trajectory pushes (i.e., a nonsaturating push that occurs along a trajectory at a distance greater than $n/\sqrt{m}$ from the originating edge of the trajectory) is at most $\sqrt{m}$ because the long trajectories are vertex disjoint and so there are at most $\sqrt{m}$ maximal excesses that have long trajectories. To ensure that long trajectories in the distributed algorithm are vertex disjoint, each flow excess moves in *stages.* During stage i a flow excess moves for a distance of at most $(2^i n/\sqrt{m})$, i.e., it undergoes at most $(2^i n/\sqrt{m})$ nonsaturating pushes. When it has moved this distance, it stops and checks whether its trajectory is

overlapped by the trajectory of some other flow excess. For this purpose, it sends a *probe message* backward along its trajectory all the way to its originating edge. The originating edge echoes back the probe message along the trajectory to the flow excess. Upon receiving the echoed probe message the flow excess enters stage $i+1$ and resumes its movement. Of course, if a probe message is intercepted by a different flow excess, then the probe message is immediately destroyed.

THEOREM 6.1. *The above synchronous distributed algorithm for the maximum flow problem uses at most* $O(n^2\sqrt{m})$ *messages and* $O(n^2)$ *time.*

Proof. First, consider the number of clock pulses used by the distributed algorithm. Let us call a flow excess *dead* if it is waiting for its echoed probe message and its probe message has been intercepted by a different flow excess and destroyed; otherwise, the flow excess is called *alive.* Suppose the distributed algorithm maintains approximate distance labels and does lazy updates of the distance labels, i.e., a vertex v updates its distance label only immediately after a push step at v fails to reduce $e(v)$ to zero. Then a flow excess that is alive at a particular clock pulse was either alive at the preceding clock pulse or it was originated by another alive flow excess at the preceding clock pulse. Let us introduce a *token* into the distributed algorithm; the intention is that, at each clock pulse of the algorithm, the token is held by either an active vertex or by s or by t. Initially, the token is held by an active neighbour of s. At each clock pulse, the token is passed nondeterministically as follows. Suppose the token is held by a vertex v; then either the token is passed to a neighbour w of v such that a push is done on the edge (v, w) or the token continues to be held by v provided $e(v)$ remains greater than zero. It can be shown (using induction on the number of clock pulses) that there exists a token passing sequence such that the token is held by an alive flow excess at each clock pulse, and just before the algorithm terminates, the token is held by a flow excess that moves last. For this token passing sequence, it can be shown that the total distance moved by the token is $O(n^2)$, and the time required by the token to move a distance L is at most $5L$. It follows that the number of clock pulses is $O(n^2)$. The proof that the number of clock pulses for the distributed algorithm with exact distance labels is $O(n^2)$ is left to the interested reader.

Now consider the number of messages used by the algorithm. The number of push messages and probe messages used in stage zero and stage one, summed over all flow excesses originating in the algorithm, is at most $(2nm(11n/\sqrt{m}))$, which is $O(n^2\sqrt{m})$.

CLAIM. The number of stage i push messages at each clock pulse, summed over all i, $i>1$, is $O(\sqrt{m})$.

The $O(n^2\sqrt{m})$ bound on the number of messages would follow from the claim, because the total number of clock pulses is $O(n^2)$ and the number of probe messages is at most four times the number of push messages.

The essential idea for proving the claim is as follows. At each clock pulse, we associate with each stage i, $i>1$, push message a subpath of its trajectory having at least $(2^i-2)n/\sqrt{m}$ vertices such that for distinct stage i push messages the associated subpaths are vertex disjoint.

Let f_1 and f_2 be two flow excesses such that they give rise to two stage i, $i>1$, push messages that are transmitted at the same clock pulse. Suppose that the trajectories of f_1 and f_2 overlap, since otherwise there is nothing to prove. Assume that f_1 was originated earlier. Clearly, at any vertex v common to both trajectories, the (echoed) probe message that initiates stage i for f_1 precedes the push message for f_2. Let tv be the time at which the probe message for f_1 going toward f_1 passes through v, and let dv be the distance from v to the originating edge of f_1.

It can be seen that stage i for f_1 comes to an end at most $((2^i-1)n/\sqrt{m})-dv+(2^i n/\sqrt{m})$ clock pulses after tv. Similarly, stage i for f_2 can start only $2(2^i-1)n/\sqrt{m}$ clock pulses after tv. Thus dv is at most $n/\sqrt{m}$ since stage i push messages for f_1 and f_2 are transmitted at the same clock pulse.

Let p_1 denote f_1's trajectory at the end of stage $(i-1)$, and likewise for p_2. It can be seen that the suffix of p_1 obtained by deleting f_1's trajectory at the end of stage zero is vertex disjoint from the similar suffix of p_2. Hence, the number of stage i, $i>1$, push messages transmitted at any clock pulse is at most $\sqrt{m}/(2^i-2)$, and the claim follows. □

7. Conclusions. We have shown that the highest distance preflow push algorithm improves upon the $O(n^3)$ time bound and have examined several rules for selecting an active vertex in order to apply a push step to it.

We briefly consider the data structure required for implementing the maximal excess preflow push algorithm. The basic operation in this algorithm is to select an active vertex v such that the current-edge subtree rooted at v contains no other flow excesses. The basic operation corresponds to a nearest common ancestor query in a tree that changes in a "structured" way with respect to the distance labeling d. An $O(\log n)$ amortized time bound can be shown for the basic operation using the (self-adjusting) dynamic trees data structure [Ta83]. However, it is not clear that this is the most efficient data structure for this problem.

Recently, Ahuja and Orlin [AO87] have developed an $O(nm+n^2\log U)$ preflow push algorithm based on a novel use of the scaling technique. Their algorithm has $(1+\log U)$ stages. They do not exploit the mechanism of coalescing flow excesses. Rather, they control the coalescing and thereby restrict the value of the maximum flow excess that can be formed in stage i to $U/2^i$. At each stage, their algorithm moves only large enough flow excesses, by doing "restrained greedy" pushes. Subsequently, Safer [Sa88] has given an $O(nm+n^2\log U)$ message and an $O(n^2\log U)$ time distributed algorithm that was based on the above scaling algorithm.

Our work raises some questions. Note that every push on an edge is "greedy," i.e., as much flow as possible is pushed along it. Is there any advantage in doing "restrained greedy" pushes? Another possibility is to study heuristics for choosing the next outgoing edge during a push step. It is an open question whether the naive bound of $O(n^2m)$ is tight for Goldberg and Tarjan's maximum-value excess preflow push algorithm. Our $O(n^2\sqrt{m})$ messages and $O(n^2)$ time synchronous distributed algorithm does not seem to lead to an asynchronous distributed algorithm with comparable resource bounds. The straightforward approach of using Awerbuch's synchronizer [Aw85a] does not work because the synchronizer itself requires $\Theta(n^3)$ messages.

Finally, we comment on the performance of the highest distance preflow push algorithm in computational experiments. The performance of the basic algorithm (given in § 2) on random networks deteriorates due to the high overheads arising from too many relabel steps. Consider a network such that $|S|$ is $\Theta(n)$, where S denotes the set of vertices on the source side of the unique $s-t$ min-cut closest to s. Clearly, the highest distance algorithm (given in § 2) performs $\Theta(n^2)$ relabel steps on this network. Although this is not significant for worst-case networks (since the algorithm performs at least nm push steps on such networks), it does become significant on the average. Hence, an actual implementation should use some strategy to reduce the number of relabel steps. One way is to maintain approximate distance labels and to do periodical updates of the distance labels (in addition to the updates done in the relabel steps) by performing a breadth first search starting from the sink [Go87]. Another way is to

maintain the number of vertices $n(k)$ with distance labels equal to k; whenever $n(k)$ becomes zero for any k then all vertices with distance labels greater than k are disconnected from the sink, and so the algorithm avoids selecting these vertices until a maximum preflow to the sink has been found [AO87].

Acknowledgments. We thank the referees for their comments and also V. M. Malhotra, Sanjiv Kapoor, and Samar Singh for useful discussions.

POLYNOMIAL SPACE COUNTING PROBLEMS*

RICHARD E. LADNER†

Abstract. The classes of functions $\#PSPACE$ and $\natural PSPACE$ that are analogous to the class $\#P$ are defined. Functions in $\#PSPACE$ count the number of accepting computations of a nondeterministic polynomial space bounded Turing machine, and functions in $\natural PSPACE$ count the number of accepting computations of nondeterministic polynomial space bounded Turing machines that on each computation path make at most a polynomial number of nondeterministic choices. In contrast to what is known about $\#P$, exact characterizations of both $\#PSPACE$ and $\natural PSPACE$ are found. In particular, $\#PSPACE = FPSPACE$ (the class of functions computable in polynomial space) and $\natural PSPACE = FPSPACE(poly)$ (the class of functions computable in polynomial space with output length bounded by a polynomial). Both $\#PSPACE$ and $\natural PSPACE$ can be characterized by counting problems related to alternating Turing machines. Both $\#PSPACE$ and $\natural PSPACE$ have natural complete functions. It is an easy observation that $FP \subseteq \#P \subseteq \natural PSPACE$, where FP is the class of functions computable in polynomial time. Relativization to oracles is considered, as are approximation techniques for obtaining a better understanding of whether either of the above inclusions is proper.

Key words. computational complexity, polynomial space, alternating polynomial time, counting problems

AMS(MOS) subject classification. 68

1. Introduction. In this paper we consider counting problems that arise in nondeterministic polynomial space bounded ($NPSPACE$) computations and in alternating polynomial time bounded ($APTIME$) computations. For example, the class of functions $\#PSPACE$[1] is defined by $f: \Sigma^* \to N \in \#PSPACE$ if and only if there is a nondeterministic Turing machine M that runs in polynomial space with the property that $f(x)$ equals the number of accepting computation paths of M on input x. (N is the set of natural numbers, $\{0, 1, 2, \cdots\}$.) We assume that our polynomial space bounded Turing machines, both deterministic and nondeterministic always halt, avoiding the possibility that $f(x)$ is infinite. Similarly, we define the class of functions $\#APTIME$ by $f \in \#APTIME$ if and only if there is an alternating Turing machine M that runs in polynomial time with the property that $f(x)$ equals the number of accepting computation trees of M on input x. Finally, define $FPSPACE$ to be the class of functions computable in polynomial space. It is worth noting that our $FPSPACE$ functions output only binary strings that represent members of N in a natural way. The order of output, high- or low-order bits first, does not matter because if $f \in FPSPACE$ then $g \in FPSPACE$, where $g(x) = f(x)^R$ ($g(x)$ is the reversal of $f(x)$) for all x. One main result of this paper is the following theorem.

THEOREM 1. $\#PSPACE = \#APTIME = FPSPACE$.

This exact characterization of counting problems in polynomial space contrasts with our current knowledge about $\#P$ defined by Valiant [10], [11]. The class $\#P$ is defined as the class of counting problems in NP, that is, $f \in \#P$ if and only if there is a nondeterministic Turing machine M that runs in polynomial time with the property that $f(x)$ equals the number of accepting computation paths of M on input x. Although $\#P$ is defined in a simple way in terms of $NTIME$ Turing machines it does not

†Department of Computer Science, University of Washington, Seattle, Washington 98195.

[1] $\#PSPACE$ is pronounced "sharp p space."

seem that, in general, functions in $\#P$ are computable using an oracle in the polynomial time hierarchy. In fact, it is has been conjectured that complete functions in $\#P$ are not computable in polynomial time using an oracle in the polynomial time hierarchy. The best upper bound on $\#P$ is that it is contained in *FPSPACE*. However, it has been shown by Stockmeyer that every function in $\#P$ can be approximated by a function in $F\Delta_3^P$, the class of functions computable in polynomial time using an oracle from Σ_2^P [8]. Currently, we do not have any good characterization of $\#P$. One purpose of this paper is to try to gain more insight into $\#P$.

Because some functions in $\#PSPACE$ have exponential length and all functions in $\#P$ must have polynomial length, it is a simple observation that

$$\#P \neq \#PSPACE.$$

This inequality is a little artificial, leading us to consider restrictions of $\#PSPACE$ that might give us a more interesting comparison between $\#P$ and counting problems in polynomial space. Define the class of functions $\natural PSPACE$[2] by $f \in \natural PSPACE$ if and only if there is a nondeterministic Turing machine M that runs in polynomial space and that makes only a polynomial number of nondeterministic moves (while making potentially exponentially many moves) with the property that $f(x)$ equals the number of accepting computation paths of M on input x. With this restriction the length of $f(x)$ is bounded by a polynomial in $|x|$. Clearly, $\#P \subseteq \natural PSPACE$ and equality is not out of the question. However, $\natural PSPACE$ has some nice characterizations, which leads us to question the possibility that $\#P = \natural PSPACE$.

Let $\natural APTIME$ be the class of functions f such that there is an *APTIME* Turing machine M with the property that $f(x)$ equals the number of equivalence classes of accepting computation trees of M on input x, where two accepting computation trees are equivalent if the initial sequence of existential moves from the initial configuration to the first universal configuration is the same for both. At first glance, the class $\natural APTIME$ appears to be a bit bizarre. However, it turns out to be the natural counting class for alternating computations that corresponds to $\natural PSPACE$. Define $FPSPACE(poly)$ to be the class of functions that is computable in polynomial space and whose outputs are bounded in length by a polynomial. We can characterize $\natural PSPACE$ in Theorem 2.

THEOREM 2. $\natural PSPACE = \natural APTIME = FPSPACE(poly)$.

We define the notion of polynomial-time reducibility between counting problems that make it possible to compare one counting problem to another even though the counting problems may be functions that are exponential in length. We say that a function f is reducible to a function g in polynomial time ($f \leqq^P g$) if there is function h that is computable in polynomial time such that for all x, $f(x) = g(h(x))$. A function k is complete for a class of functions C if (i) $k \in C$ and (ii) for all $f \in C$, $f \leqq^P k$. There are natural counting problems that are complete for each of $\#PSPACE$ and $\natural PSPACE$. For example, let $\#NFA$ be the counting problem defined as follows: if M is a nondeterministic finite automaton, then $\#NFA(M)$ equals the number of input strings not accepted by M. In case the number of input strings not accepted by M is infinite, define $\#NFA(M)$ equal to $k = s^{2^q-1}+1$, where s is the number of input symbols of M and q is the number of states in M. The reason for this choice is that if the number of strings not accepted by M is finite, then the number of such nonaccepted strings must be $<k$. Then,

$$\#NFA \text{ is complete for } \#PSPACE.$$

Another example is $\natural QBF$, which is defined as follows. Let $A = \exists x_1 \forall x_2 \exists x_3 \cdots$

[2] $\natural PSPACE$ is pronounced "natural p space."

$Qx_mB(x_1, x_2, \cdots, x_m)$ be a quantified Boolean formula. Then $\natural QBF(A)$ equals the number of x_1's such that A is true. We have

$$\natural QBF \text{ is complete for } \natural PSPACE.$$

There are more natural complete problems that we describe later in the paper. Complete problems give us some information about the difficulty of $\#P$. For example, it can be shown that $\natural QBF \in \#P$ if and only if $\#P = \natural PSPACE$.

Let FP be the class of functions computable in polynomial time. The inclusions

$$FP \subseteq \#P \subseteq \natural PSPACE$$

are clear, and these inclusions relativize to an arbitrary oracle. It is an open question whether or not one or both of the inclusions are reversible. Using the techniques of Baker, Gill, and Solovay [1] we can construct computable oracles A, B, and C such that $FP^A = \natural PSPACE^A$, $FP^B \neq \#P^B$, and $\#P^C \neq \natural PSPACE^C$. These results indicate that more information about these inclusions may be very difficult to come by.

Stockmeyer has shown that functions in $\#P$ can be approximated by functions computable using an oracle in the polynomial hierarchy [8]. We give a generalization of this result to a class of counting problems defined by *APTIME* Turing machines with a bounded number of alternations. On the other hand, it is a fairly easy observation that if the functions in $\natural PSPACE$ can be approximated using an oracle in the polynomial hierarchy, then *PSPACE* is included in the polynomial hierarchy. This is some evidence that $\natural PSPACE$ is harder than $\#P$.

In § 2 we will clarify the definitions we have made so far and make new ones that will be used later in the paper. In § 3 we give proofs of Theorems 1 and 2. In § 4 we describe some complete problems and describe how they are useful. In § 5 we examine some relativized counting problems. Finally, in § 6 we discuss approximating counting problems.

2. Definitions. Our model of computation is the usual Turing machine. All our Turing machines will either be polynomial time or space bounded. As such, we can assume that our space bounded Turing machines always halt without looping. If the Turing machine has output, then the output is printed on a one-way, write-only output tape, and whatever space bound is put on the Turing machine does not apply to the output tape. Thus, if M is a *PSPACE* Turing machine that computes a function f, then $|f(x)|$ can be as long as $2^{|x|^k}$ for some k. For uniformity we assume that the output of a *PSPACE* Turing machine is a binary representation of a natural number ($N = \{0, 1, 2, \cdots\}$). Recall that *FPSPACE* is the class of functions computable in polynomial space and $FPSPACE(poly)$ are those $f \in FPSPACE$ with the property that there is a constant k such that $|f(x)| \leqq |x|^k$ for all x. We assume that readers are familiar with the polynomial-time hierarchy, $\Sigma_1^P, \Sigma_2^P, \cdots$ [7]. We will also want to consider functions computable in polynomial time FP, and functions computable in polynomial time using an oracle in the polynomial-time hierarchy. Define $F\Delta_k^P$ to be the class of functions computable in polynomial time using an oracle in Σ_{k-1}^P. By definition $FP = F\Delta_1^P$.

If M is a *NPSPACE* Turing machine and if x is an input, then there may be many different computations of M that can lead to the acceptance of x. Define $\#(M, x)$ to be the number of distinct accepting computation paths of M on input x. Naturally, if M does not accept x, then $\#(M, x) = 0$ and *vice versa*. Define $\#PSPACE$ to be the class of functions f such that there is a *NPSPACE* Turing machine M where $f(x) = \#(M, x)$. Note that functions in $\#PSPACE$ can be exponential in length. A natural restriction that limits the length of function in $\#PSPACE$ is to allow only a polynomial

number of nondeterministic moves on any accepting path. Hence, we have the following definition. $\natural PSPACE$ is the class of functions f such that there is a *NPSPACE* Turing machine M that makes only a polynomial number of nondeterministic moves on any computation path and $f(x) = \#(M, x)$. The machine M may still make exponentially many moves on input x, but only a polynomial number of them are nondeterministic, when a choice can be made between alternatives.

We will assume that the reader is familiar with alternating Turing machines [4]. If M is an alternating Turing machine and x is an input, then an accepting computation tree is a tree labeled with configurations satisfying the following conditions: (i) the root is labeled with the initial configuration; (ii) each nonleaf labeled with a universal configuration has a child labeled for each successive configuration; (iii) each nonleaf labeled with an existential configuration has exactly one child, which is labeled with a successive configuration; and (iv) all the leaves are labeled with accepting configuration. Define $\#(M, x)$ to be the number of accepting computation trees of M on input x. Further define $\natural(M, x)$ to be the number of equivalence classes of accepting computation trees, where two accepting computation trees are equivalent if the paths from the initial configuration to the first universal configuration are the same in both. Note that $\#(M, x)$ can have length exponential in $|x|$ while $\natural(M, x)$ can only have length polynomial in $|x|$.

Define $\#APTIME$ to be the class of functions f such that there is an *APTIME* Turing machine M such that $f(x) = \#(M, x)$. Further define $\natural APTIME$ to be the class of functions f such that there is an *APTIME* Turing machine M with $f(x) = \natural(M, x)$. By limiting the number of alternations we can, in a natural way, also define $\#\Sigma_k^P$ and $\natural\Sigma_k^P$. Note that $\natural\Sigma_1^P$ is simply another way of expressing $\#P$. Note further that $\#\Sigma_1^P = \natural\Sigma_1^P$ and $\#\Sigma_2^P = \natural\Sigma_2^P$, but for all $k > 2$, $\#\Sigma_k^P \neq \natural\Sigma_k^P$. This latter fact follows simply from that fact that some functions in $\#\Sigma_k^P$ are exponential in length for each $k > 2$.

3. Equivalence of function classes. In this section we sketch the proof of Theorem 1:

$$\#PSPACE = \#APTIME = FPSPACE.$$

We begin by showing $\#PSPACE \subseteq \#APTIME$. A variation of the standard simulation of a nondeterministic Turing machine that runs in space $s(n)$ by an alternating Turing machine that runs in time $s^2(n)$ [4] has the property that the number of accepting computation paths of the nondeterministic machine equals the number of accepting computation trees of the alternating machine. Let M be a *NPSPACE* Turing machine and let x be an input to M of length n. Without changing the number of accepting paths of M on x, we can pad all computations so they are all the same length $2^{p(n)}$ for some polynomial $p(n)$; we can also assume there is a unique accepting configuration. Consider the following alternating algorithm, *reach*(C, D, k), which accepts if and only if configuration D is reachable from configuration C in *exactly* 2^k steps.

definition *reach*(C, D, k):
begin
  if $k = 0$ then if D is reachable from C in one step then *accept* else *reject* else
    $\bigvee E$ [*reach*$(C, E, k-1) \wedge$ *reach*$(E, D, k-1)$]
end.

The notation $\bigvee E$ means existentially choose a configuration E. The notation $\wedge$ is a binary operator meaning universally choose one of its operands. It can be shown by induction on k that the number of computation paths from C to D of length exactly 2^k equals the number of accepting computation trees of *reach*(C, D, k). The alternating

algorithm that simulates M on input x is simply the call $reach(init, acc, p(n))$, where $init$ is the initial configuration of M on input x and acc is the unique accepting configuration. Hence, the number of accepting computations of M on input x equals the number of accepting computation trees of $reach(init, acc, p(n))$.

To show that $FPSPACE \subseteq \#PSPACE$, let $f \in FPSPACE$; let M be a $PSPACE$ Turing machine that computes f. We define a $NPSPACE$ machine M' with the property that $\#(M', x) = f(x)$ for all inputs x. Let x be fixed. We define a $PSPACE$ subroutine $bit(i)$ that returns the ith bit of $f(x)$, where $bit(0)$ is the lowest-order bit. We can assume without loss of generality that there are $m = 2^{|x|^k}$ bits in $f(x)$. If $f(x)$ is actually a small number, then there will be a large number of 0's as trailing bits. We define a nondeterministic recursive procedure, $check(i)$, which has the property that $\#check(i) = bit(i) + 2 \times \#check(i+1)$, where $\#check(i)$ refers to the number of accepting paths of $check(i)$. Hence, $\#check(0) = f(x)$. The machine M' simply runs $check(0)$.

definition $check(i)$:
begin
  if $i > m$ then *reject* else
    if $bit(i) = 0$ then $check(i+1) \vee check(i+1)$
    else $(bit(i) = 1)$ *accept* $\vee$ $check(i+1) \vee check(i+1)$
end.

To complete the proof, we show $\#APTIME \subseteq FPSPACE$. Let M be an alternating Turing machine that runs in polynomial time and let x be an input. Consider the full computation of tree T of M on input x. Unlike an accepting computation tree, each existential node in T may have more than one child, one child for each choice that can be made. $\#(M, x)$ can be computed, not in polynomial space, in the following way. Construct T and label each node in T with a number starting with the leaves of T. An accepting leaf is labeled with a one and a rejecting leaf is labeled with a zero. If a universal node has k children labeled $a_1, \cdots a_k$, respectively, then label the universal node with $\prod_{i=1}^{k} a_i$. If an existential node has k children labeled $a_1, \cdots, a_k$, respectively, then label the existential node with $\sum_{i=1}^{k} a_i$. The number labeled at the root is $\#(M, x)$.

There are two difficulties in trying to do this calculation of $\#(M, x)$ within polynomial space. The first is that the tree T requires exponential space to store it all, and the second is that the numbers labeled on the nodes of the tree can be exponentially long. Both these difficulties can be overcome by realizing that the whole tree and the number labels do not all have to be written down at once and that arithmetic on exponentially long numbers can be done in polynomial space. To be more specific, if C is a configuration, define $number(C)$ to be the number of accepting subtrees of M on input x when M is started in configuration C. We can define a recursive procedure $bit(i, C)$ that is the value of the ith bit of $number(C)$. Roughly, bit is defined recursively by:

definition $bit(i, C)$:
begin
  if C is accepting then if $i = 0$ then return 1 else return 0 else
  if C is rejecting then return 0 else
  if C is universal with children $D_1, \cdots, D_k$ then
    return the ith bit of $product(number(D_1), \cdots, number(D_k))$ else
  if C is existential with children $D_1, \cdots, D_k$ then
    return the ith bit of $sum(number(D_1), \cdots, number(D_k))$
end.

It is well known that there are procedures for *product* and *sum* that on inputs of length m run in log m space. This can be seen by taking standard logarithmic depth circuits for *product* and *sum* (see [6]) and converting them to logarithmic space Turing machines using a result of Borodin [3]. To compute the ith bit of $product(number(D_1), \cdots, number(D_k))$, run the logarithmic space Turing machine for *product* without actually writing any of the output. Keep a count of the number of output symbols that have been produced so far. When the count reaches i, the ith bit is produced. While *product* is running it may request a bit from its input. At that point a recursive call to *bit* is made. The full arguments of *product* are never written down all at once. A similar computation for *sum* can be made. The depth of recursion is bounded by the height of the computation tree, which is polynomial in $|x|$. The amount of space needed at each level of recursion is logarithmic in the length of $number(C)$, which again is polynomial in $|x|$. Hence, the computation of $bit(i, C)$ can be done in polynomial space. Clearly, the number of accepting subtrees of M on input x can be output by successive calls to $bit(i, init)$, where *init* is the initial configuration.

The proof of Theorem 2,

$$\natural PSPACE = \natural APTIME = FPSPACE(poly),$$

is a bit simpler than the result we have just proven.

We begin by showing that $\natural PSPACE \subseteq \natural APTIME$. Let M be a *PSPACE* Turing machine that makes at most a polynomial number of nondeterministic moves in a computation. There is a *PSPACE* Turing machine M' that takes two inputs x and y with the property that the number of accepting computations of M on input y is exactly the number of distinct x's such that M' accepts the pair (x, y). Furthermore, the length of x is bounded by a polynomial. Essentially, M' on input (x, y) simulates M on input y except when M reaches a nondeterministic move. The ith nondeterministic move is then determined by the ith character of x. By the standard alternating time theorem [4] M' can be simulated by an *APTIME* Turing machine M'' that begins in a universal configuration. Now, consider the alternating machine M''' that on input y first existentially guesses an x, then runs M'' on the input (x, y). We have $\#(M, y) = \natural(M''', y)$.

To show $FPSPACE(poly) \subseteq \natural PSPACE$ we can use the same nondeterministic procedure *check* used to prove $FPSPACE \subseteq \#PSPACE$. In the case that the function is polynomial length bounded, the nondeterministic procedure *check* makes only a polynomial number of nondeterministic moves on any computation path.

Finally, to show that $\natural APTIME \subseteq FPSPACE(poly)$ let M be an *APTIME* Turing machine. We define a new *PSPACE* machine M' that takes pairs (x, y) as input. On input (x, y), M' simulates the initial existential moves of M on input y with these moves determined by the characters of x, reaching a configuration C of M. That is, if M can make at most d moves from an existential configuration, then $x \in \{1, 2, \cdots, d\}^*$. Initially, M' sets a pointer to the first character of x. For each initial existential move of M, M' makes the move determined by the current character of x pointed to and moves the pointer one character to the right. If C is existential and x is exhausted, or C is universal and x is not yet exhausted, then M' rejects. Otherwise, a deterministic polynomial space simulation of the alternating machine M on input y starting in configuration C is used to discover if C is the root of an accepting computation tree of M on input y. If so, M' accepts (x, y). From M' we construct a Turing machine M'' that computes $\natural(M, y)$. The Turing machine M'' simply counts the number of x's

such that M' accepts (x, y). The number of such x's is bounded in length by a polynomial in $|y|$.

4. Complete functions. We would like to be able to classify the hardest problems in $\#PSPACE$ and $\natural PSPACE$ in a way similar to the way that the NP-complete problems are classified as the hardest problems in NP. To this end we define a generalization of the Karp reducibility [5] that extends it to a relation between functions. We say that f is reducible to g in polynomial time ($f \leqq^P g$) if there is function h that is computable in polynomial time such that for all $x, f(x) = g(h(x))$. It is easy to see that $\leqq^P$ is a reflexive and transitive relation between functions. If C is any of the classes of functions we have talked about so far, $FP, \#P, \#\Sigma_k^P, \natural\Sigma_k^P, \#PSPACE$, or $\natural PSPACE$, $g \in C$ and $f \leqq^P g$ then $f \in C$ also. Define a function k to be *complete* for a class of functions C if (i) $k \in C$ and (ii) for all $f \in C, f \leqq^P k$.

Since some functions in $\#PSPACE$ are exponential in length, it is a trivial observation that $\#PSPACE$ cannot equal any of $FP, \#P, \#\Sigma_2^P, \natural\Sigma_k^P$, or $\natural PSPACE$, each of which contains only polynomial length bounded functions. But it is not inconceivable that $\#PSPACE = \#\Sigma_k^P$ for some $k > 2$. The following proposition relates the complexity of complete functions in $\#PSPACE$ to whether $\#\Sigma_k^P = \#PSPACE$ for some k.

PROPOSITION 3. *Let f be complete for $\#PSPACE$. Then, $f \in \#\Sigma_k^P$ if and only if $\#\Sigma_k^P = \#PSPACE$.*

Functions in $\natural PSPACE$ are bounded in length by a polynomial so there is some chance that $\natural PSPACE$ could equal one of $FP, \#P$, or $\natural\Sigma_k^P$ for some k. Knowing the complexity of complete functions in $\natural PSPACE$ enables us to better characterize the class $\natural PSPACE$, and perhaps even $\#P$.

PROPOSITION 4. *Let f be complete for $\natural PSPACE$.*

(1) *$f \in FP$ if and only if $FP = \natural PSPACE$,*

(2) *$f \in \#P$ if and only if $\#P = \natural PSPACE$,*

(3) *$f \in \natural\Sigma_k^P$ if and only if $\natural\Sigma_k^P = \natural PSPACE$, for $k \geqq 2$.*

It is worth noting that if f is complete for $\natural PSPACE$ and $f \in FP$, then $P = PSPACE$.

The first complete counting functions we consider are derived from the *QBF* (quantified Boolean formulas) problem first considered by Stockmeyer and Meyer [9]. A quantified Boolean formula is one of the form

$$A = \exists x_1 \forall x_2 \exists x_3 \cdots Q x_m B(x_1, x_2, \cdots, x_m),$$

where x_i is a vector of Boolean variables for $1 \leqq i \leqq m$, B is a Boolean formula, and $Q = \forall$ if m is even and $Q = \exists$ if m is odd. If A is true, then its truth can be verified by constructing a *verifying tree*, the root of which is labeled with a truth assignment for x_1. The root has $2^{|x_2|}$ children, one for each possible truth assignment of x_2. Each child of the root has exactly one child labeled with a truth assignment for x_3. This process is carried on until all the variables are assigned. Thus, each leaf corresponds to an assignment of all the variables. For each leaf in the verifying tree the formula B must be true for the assignment associated with the leaf. Define $\#QBF$ to be the function that is defined by $\#QBF(A) =$ the number of verifying trees for A. We can also define $\natural QBF(A) =$ the number of x_1's such that there is a verifying tree for A with root labeled x_1.

THEOREM 5. (1) *$\#QBF$ is complete for $\#PSPACE$,*

(2) *$\natural QBF$ is complete for $\natural PSPACE$.*

The key idea in the proof of part (1) of Theorem 5 is that given a *NPSPACE* Turing machine M and an input x a quantified Boolean formula A can be constructed in polynomial time with the property that $\#(M, x) = \#QBF(A)$. This will demonstrate that the function f is defined by $f(x) = \#(M, x)$ satisfies $f \leqq^P \#QBF$. The construction

is a modification of the construction that shows *QBF* is complete for *PSPACE* [9]. To begin with, let us describe the more standard construction and explain why it does not work to get our result. We then modify the construction to get it to work.

Let M be a *NPSPACE* Turing machine and let x be an input of length n. We can assume that on input x, M makes exactly $2^{p(n)}$ moves on every computation path before halting, where $p(n)$ is a polynomial. A configuration of M on input x can be represented by a bit vector u of length $q(n)$ for some polynomial $q(n)$. We define a quantified Boolean formula $reach_k(u_k, v_k)$ that has $2q(n)$ free variables u_k, v_k and has the meaning "the configuration represented by v_k is reachable from the configuration represented by u_k in *exactly* 2^k moves of M." For $k>0$, define

$$reach_k(u_k, v_k) = \exists z_k \, \forall u_{k-1}, v_{k-1}$$
$$[(u_{k-1} \equiv u_k \wedge v_{k-1} \equiv z_k) \vee (u_{k-1} \equiv z_k \wedge v_{k-1} \equiv v_k) \Rightarrow reach_{k-1}(u_{k-1}, v_{k-1})].$$

In this context $u \equiv v$ means that u and v are pointwise equivalent. For $k=0$, $reach_0(u_0, v_0)$ is a quantifier-free formula expressing that v_0 follows from u_0 in exactly one move of M. The formula for $reach_k(u_k, v_k)$ can be easily rewritten so that all the quantifiers are leading quantifiers instead of embedded in the formula. Let c and d be specific bit vectors representing configurations of M. Unfortunately, the number of verifying trees of $reach_k(c, d)$ is in general larger than the number of computation paths of length 2^k from the configuration represented by c to the one represented by d. This is because in the definition of $reach_k(u_k, v_k)$ if $\neg[(u_{k-1} \equiv u_k \wedge v_{k-1} \equiv z_{k-1}) \vee (u_{k-1} \equiv z_k \wedge v_{k-1} \equiv v_k)]$, then the body of $reach_k(u_k, v_k)$ is true no matter what the values are of the rest of the variables. To overcome this difficulty we modify the formula to completely determine the values of the existentially quantified variables in all cases. To do this we define a formula $reach1_k$ that has free variables $u_0, \cdots, u_k, v_0, \cdots, v_k, z_1, \cdots, z_k$. If $k=0$, then $reach1_k = reach_k$. If $k>0$, then

$$reach1_k = [(u_{k-1} \equiv u_k \wedge v_{k-1} \equiv z_k) \vee (u_{k-1} \equiv z_k \wedge v_{k-1} \equiv v_k) \Rightarrow reach1_{k-1}] \wedge$$
$$[\neg[(u_{k-1} \equiv u_k \wedge v_{k-1} \equiv z_k) \vee (u_{k-1} \equiv z_k \wedge v_{k-1} \equiv v_k)] \Rightarrow \textstyle\bigwedge_{i=1}^{k-1} z_i \equiv 0].$$

In this context 0 represents the constant zero vector of length $q(n)$. Now $reach_k$ with free variables u_k, v_k is defined by

$$reach_k(u_k, v_k) = \exists z_k \, \forall u_{k-1}, v_{k-1} \, \exists z_{k-1} \, \forall u_{k-2}, v_{k-2} \cdots \exists z_1 \, \forall u_0, v_0 \, reach1_k.$$

With this definition of $reach_k$ it can be shown that if c and d are bit vectors representing configurations, then the number of verifying trees of $reach_k(c, d)$ equals the number of computation paths of length 2^k from the configuration represented by c to the one represented by d. Hence if *init* is the initial configuration and *acc* is the accepting configuration, then the formula $reach_{p(n)}(init, acc)$ has the number of verifying trees equal to the number of accepting computations of M on input x. Furthermore, the formula $reach_{p(n)}(init, acc)$ can be produced in time polynomial in n.

Part (2) of Theorem 5 can be shown using some of the ideas in the proof of $\natural PSPACE \subseteq \natural APTIME$ combined with the construction just given. Let M be a *PSPACE* Turing machine that makes at most a polynomial number of nondeterministic moves in a computation. There is a *PSPACE* Turing machine M' that takes two inputs x and y with the property that the number of accepting computations of M on input y is exactly the number x's such that M' accepts the pair (x, y). Furthermore, we can assume that for any y, if (x_1, y) and (x_2, y) are accepted by M', then $|x_1| = |x_2|$, $|x_1|$ is bounded by a polynomial, and x_1 is a binary string. From the machine M' we can construct $reach1_k$ just as before. In this case, for a particular input y to M there are

many inputs (x, y) to M'. Let $init(x)$ be the representation of the initial configuration corresponding to (x, y). Consider the following formula:

$$\exists x \, \forall w \, reach_{p(n)}(init(x), acc), \tag{1}$$

where M' runs in time $2^{p(n)}$ and w is a dummy Boolean variable. The number of x's such that there is a verifying tree for (1) is exactly the number of accepting computation paths of M on input y.

It is worth mentioning a couple of other functions that are complete for $\#PSPACE$. If M is a nondeterministic finite automaton, then $\#NFA(M)$ is the number of strings not accepted by M if the number of strings not accepted by M is finite and $\#PSPACE = s^{2^q-1}+1$ (where s is the number of symbols in the input alphabet and q is the number of states of M) otherwise. The number $s^{2^q-1}+1$ is chosen to be just larger than an upper bound on the number of strings which could be in the finite complement of a set accepted by a nondeterministic finite automaton with s input symbols and q states. If E is a regular expression, then $\#RE(E)$ is the number of strings not in the language defined by E if the number of string not in the language defined by E is finite and $\#RE(E) = s^{2^l-1}+1$ (where s is the number of symbols in the alphabet of E and l is the length of E) otherwise. The number $s^{2^l-1}+1$ is chosen to be just larger than an upper bound on the number of strings which could be in the finite complement of a language defined by a regular expression with s alphabet symbols and length l. Both $\#NFA$ and $\#RE$ are complete for $\#PSPACE$. It would be interesting to find more natural functions that are complete for either $\#PSPACE$ or $\natural PSPACE$.

5. Relativization. A good characterization of the complexity of $\#P$ is not known. We do have some interesting characterizations of $\natural PSPACE$ but for all we know $\natural PSPACE = FP$. The following inclusions are all we know for sure:

$$FP \subseteq \#P = \natural\Sigma_i^P \subseteq \natural\Sigma_2^P \subseteq \cdots \subseteq \natural PSPACE.$$

This sequence of inclusions also relativizes to any oracle so we have

$$FP^A \subseteq \#P^A = \natural\Sigma_1^{P,A} \subseteq \natural\Sigma_2^{P,A} \subseteq \cdots \subseteq \natural PSPACE^A.$$

In the definition of $\natural PSPACE^A$ we only allow strings of polynomial length to be written on the oracle tape. This makes the comparisons between the different classes of functions more fair. The following theorem gives the possible relationships between FP, $\#P$, and $\natural PSPACE$.

THEOREM 6. *There are computable oracles A, B, and C such that*:

(1) $FPA^A = \natural PSPACE^A$,

(2) $FP^B \neq \#P^B$,

(3) $\#P^C \neq \natural PSPACE^C$.

This result indicates it may be very difficult to separate FP from $\#P$ and $\#P$ from $\natural PSPACE$.

To show part (1) of Theorem 6, let A be any $PSPACE$-complete set. Suppose $f \in \natural PSPACE^A$. Since A is a member of $PSPACE$, it can be easily seen that $f \in FPSPACE(poly)$. The language $L = \{\langle x, i, b\rangle | i\text{th bit of } f(x) \text{ is } b\}$ is clearly a member of $PSPACE$. Since A is complete for $PSPACE$, L is polynomial time reducible to A. Hence, $f \in FP^A$ because, given x, the bits of $f(x)$ are encoded in the set L which can be computed in polynomial time using the set A as an oracle.

Part (2) of Theorem 6 holds for any B such that $P^B \neq NP^B$ [1]. Suppose $FP^B = \#P^B$. Let M be a $NPTIME$ oracle Turing machine that accepts L using oracle B. Let f be the function in $\#P^B$ defined by M. Thus, f is also a member of FP^B by assumption.

To check if $x \in L$ in polynomial time, compute $f(x)$ in polynomial time using the oracle B. We have $x \in L$ if and only if $f(x) > 0$. Hence, $P^B = NP^B$.

Part (3) of Theorem 6 holds for any C such that $NP^C \neq PSPACE^C$. Such sets C exist from the results of Baker and Selman [2] and Yao [12]. Suppose $\#P^C = \natural PSPACE^C$. Let M be a *PSPACE* oracle Turing machine which accepts L using oracle C. Let f be the function in $\natural PSPACE^C$ defined by M thinking of M as a nondeterministic machine. By assumption, $f \in \#P^C$. Let M' be the *NPTIME* oracle Turing machine which on oracle C defines f. The machine M' also accepts the set L. Hence, $NP^C = PSPACE^C$.

The proof technique of parts (2) and (3) of Theorem 6 combined with the result of Yao that the polynomial hierarchy can be separated using an oracle [12] can be used to show Theorem 7.

THEOREM 7. *There is an oracle A such that*

$$FP^A \subset \natural\Sigma_1^{P,A} \subset \natural\Sigma_2^{P,A} \subset \cdots \subset \natural PSPACE^A.$$

The notation $X \subset Y$ means that X is a proper subset of Y.

6. Approximation. Stockmeyer has shown that functions in $\#P$ can be approximated by functions in the polynomial hierarchy, namely by functions by $F\Delta_3^P$ [8]. This result can be generalized to functions in $\natural\Sigma_k^P$. We say that f is approximated by g if there is a constant $c \geqq 1$ such that for all $x, f(x)/c \leqq g(x) \leqq cf(x)$.

THEOREM 8. *For $k \geqq 2$, every function in $\natural\Sigma_k^P$ can be approximated by a function in $F\Delta_{k+1}^P$.*

A complete proof of Theorem 8 will not be given here since it follows immediately from an observation about a proof of Stockmeyer [8, Thm. 3.1, p. 858]. In Stockmeyer's proof a predicate of the form $z \in Acc_M(x)$, meaning "z is an accepting computation of M on input x," must be evaluated. In this context M is a *NPTIME* Turing machine so that this predicate can be checked in polynomial time. In our context this predicate would mean that "z is an initial sequence of configurations, the last of which is a universal configuration and all but the last of which are existential configurations, in an accepting computation tree of M on input x." In our context M is an *APTIME* Turing machine that starts in an existential configuration and makes at most $k-1$ alternations before halting. That is, M is a machine that defines a member of the class $\natural\Sigma_k^P$. Hence, in our context the predicate $z \in Acc_M(x)$ is computable in Π_{k-1}^P. Examining Stockmeyer's proof, we find this observation guarantees that a function in $F\Delta_{k+1}^P$ can approximate a function in $\natural\Sigma_k^P$.

Finally it is easy to show that functions in $\natural PSPACE$ are approximated by functions in the polynomial hierarchy if and only if *PSPACE* is contained in the polynomial hierarchy. To see this note that if $\{0, 1\}$-valued function f is approximated by g, then g essentially exactly computes f. This is evidence that the functions in $\natural PSPACE$ are harder to compute than those in $\#P$ or in $\natural\Sigma_k^P$ for any k.

Acknowledgments. The author thanks Sam Buss for the stimulating conversations that inspired some of these results. Thanks also go to Larry Stockmeyer for pointing out an easy way of finding oracles satisfying parts (2) and (3) of Theorem 6 and to an anonymous referee for pointing out an easy way to satisfy part (1) of Theorem 6. Also, the author thanks both referees for many useful suggestions.

SCHEDULING ARITHMETIC AND LOAD OPERATIONS IN PARALLEL WITH NO SPILLING*

DAVID BERNSTEIN†, JEFFREY M. JAFFE‡, AND MICHAEL RODEH§

Abstract. A machine model in which load operations can be performed in parallel with arithmetic operations by two separate functional units is considered. For this model, the evaluation of a set of expression trees is discussed. A dynamic programming algorithm for producing an approximate solution is described and analyzed. For binary trees its worse-case cost is at most $\min(1.091, 1+(2\log n)/n)$ times the optimal cost.

Key words. scheduling algorithms, code generation, parallel functional units

AMS(MOS) subject classifications. 68N20, 68Q25

1. Introduction. Optimal code generation for arithmetic expressions is the subject of many theoretical studies. In most previous papers the underlying machine model was assumed to be sequential. For sequential machines, linear algorithms have been designed that produce optimal code given a set of expression trees [N67], [Re69], [SU70]. Via dynamic programming wide classes of such machines may be handled [AJ76]. By contrast, generating optimal code for directed acyclic graphs is intractable [AJUa77], [BS76].

Modern computers are no longer sequential. Their design usually includes a certain degree of parallelism, most commonly by offering a number of functional units that may operate simultaneously—some units handle memory access while others manipulate (in registers) the data thus retrieved (for example, [Ru78]). We assume a machine model in which memory operations can be performed in parallel with arithmetic operations by two separate functional units. The parallelism of this kind appears in many existing computers, beginning with processors of RISC architecture [H84] to today's supercomputers, such as Cray-1 [Ru78] and Fujitsu VP-200 [HB84].

Allowing parallelism in a machine model introduces additional complications into code generation problems. In their seminal work [AJ76] Aho and Johnson proved that for a wide range of sequential machines an optimal evaluation of an expression tree can always be chosen from a class of *normal form* evaluations. This observation allowed them to use a linear time dynamic programming algorithm to provide an optimal solution to certain code generation problems. It turns out that for the proposed model of a parallel machine the Normal Form Theorem of [AJ76] does not hold, i.e., in an optimal evaluation of an expression tree it may be necessary to oscillate back and forth during the evaluation of various subtrees of certain expression trees.

This oscillatory phenomena was first investigated in [AJUb77] for sequential machines with multiregister operations, leaving open the questions of the existence of a polynomial time optimal algorithm and an efficient approximation algorithm. We continue in this direction learning more about the properties of bouncing (oscillating) evaluations. In a previous work [BJPR85], an efficient algorithm was developed to optimally schedule the operations of a forest of expression trees assuming that the number of registers in the parallel machine is unbounded. In this paper we consider

a more realistic model in which the number of registers is finite, but is sufficiently large to allow generating code with no stores.

As in [AJUb77], in this work the question of existence of a polynomial time optimal algorithm is not answered. Our main result is an approximation algorithm that schedules some of the load operations of a binary expression forest in parallel with the arithmetic operations so that the completion time is at most 9.1 percent worse than the optimal. The proposed algorithm is an extension of the dynamic programming scheme of Aho and Johnson [AJ76] making it suitable to our parallel machine. Performing tedious analysis of bouncing evaluations, we prove that for binary trees, if the difference between the completion time of the evaluation order generated by the algorithm and the shortest schedule is d then the expression tree must have at least 2^d vertices. This observation leads to the result that the ratio between the completion time of the generated and the shortest schedule tends to 1 as the size of the tree grows. Moreover, when a given expression tree has a small number of vertices ($n \leqq 16$), or the number of unary arithmetic operations in a tree is at most three, or a machine has only four registers or fewer, the proposed algorithm turns to be optimal. The algorithm can be implemented in such a way that its time complexity is bounded by $O(n \min(\log n, R))$, where R is the number of machine registers.

The rest of the paper is organized as follows. In § 2 we define the machine model, describe how an expression tree is computed on such machines, and present the dynamic programming scheme. In §§ 3–6 we perform full analysis of the algorithm. Then we conclude with the extensions and open problems. Note that to shorten the paper, some of the proofs are omitted; however, the reader is referred to [BJR87] for the full version of the paper.

2. Preliminaries.

2.1. The machine model. Our machine has R general purpose registers $r_1, \cdots, r_R$ and an unbounded number of memory cells $mem_1, mem_2, \cdots$. It supports the following operations, the execution times of which are all equal (in § 7 a generalization is considered):

(1) Load operation: $(mem_i) \to (r_j)$
(2) Store operation: $(r_i) \to (mem_j)$
(3) Unary arithmetic operation: $A((r_i)) \to (r_i)$
(4) Binary arithmetic operation: $A((r_i), (r_j)) \to (r_i)$.

The major parallel feature of the machine is that it can execute a load operation concurrently with an arithmetic operation. The only restriction on the registers participating in parallel instructions is that the result of the arithmetic operation should be directed to a register different from that of the load operation. As was mentioned in the Introduction, we assume that the given expression forests can be computed without storing intermediate results.

2.2. Computation forests and their evaluation. Following [AJ76] and [SU70], computations are represented by rooted forests. An example of a forest with one tree is given in Fig. 1. Throughout the paper we will use the tree of Fig. 1 as a running example.

The leaves $L(F)$ of a computation forest F represent load operations, and the internal vertices $A(F)$ represent arithmetic operations. Let $l(F) = |L(F)|$, $a(F) = |A(F)|$, $n(F) = l(F) + a(F)$. In the rest of the paper we use the following notation. Capital letters denote aggregates (sequences, evaluations, trees, forests), while lower case letters usually denote simple objects. A capital letter with a subscript denotes a particular element of an aggregate (a vertex of a tree, an operation of an evaluation, etc.) while an aggregate with a superscript designates an instance of this aggregate.

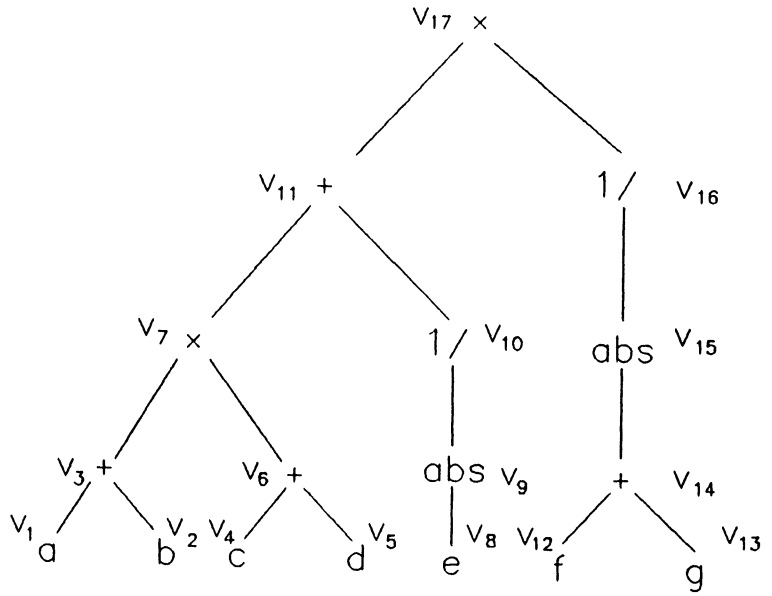

FIG. 1. *An expression tree for* $((a+b)\times(c+d)+1/\text{abs}(e))\times(1/\text{abs}(f+g))$.

However, we denote by F_v the subtree of F rooted at v. Also, let $l_v = l(F_v)$, $a_v = a(F_v)$, and $n_v = n(F_v)$.

A *sequential evaluation* $S = S_1, \cdots, S_n$ of a forest F is a linear ordering of the vertices of F such that if $i<j$ then S_i and S_j obey the precedence relation:

$$S_j \notin F_{S_i}.$$

For example, $S = 1\text{-}17$ (i is a shorthand for v_i and i-j stands for $i, i+1, \cdots, j$) is a legal evaluation of the tree of Fig. 1. S_i is the element of F computed (or loaded into memory) at *time slot i.* The *competion time* $c(S)$ of S is $|S| = n(F)$. Let S^1 and S^2 be two sequential evaluations of disjoint forests. The *concatenation* $S = S^1|S^2$ of S^1 and S^2 is simply a sequential evaluation S resulting from placing the first element of S^2 after the last element of S^1. Formally, for all $1 \leqq i \leqq |S^1|$, $S_i = S^1_i$, and for all $|S^1| < i \leqq |S^1|+|S^2|$, $S_i = S^2_{i-|S^1|}$.

A *parallel evaluation* $PQ = PQ_1, \cdots, PQ_{|PQ|}$ of a forest F is a sequence of pairs $PQ_i = (p_i, q_i)$ where $p_i \in L(F) \cup \{\text{NOP}\}$ (NOP stands for No OPeration) and $q_i \in A(F) \cup \{\text{NOP}\}$. If $p_i \neq \text{NOP}$ then p_i is loaded into memory at time slot i; otherwise i is an *empty load slot.* Similarly, if $q_i \neq \text{NOP}$ then q_i is computed at time slot i; otherwise i is an *empty arithmetic slot.* If both $p_i = \text{NOP}$ and $q_i = \text{NOP}$ then i is an *empty slot.* Thus, in the parallel evaluation PQ^1 of Fig. 2, time slots 7, 8, 10–13 are empty load slots while time slots 1, 2, 4 are empty arithmetic slots. For every $i<j$, PQ_i and PQ_j obey the *precedence relations*:

$$q_i \neq \text{NOP} \rightarrow p_j, \qquad q_j \notin F_{q_i}.$$

For a parallel evaluation PQ, the completion time $c(PQ) = |PQ|$.

The *width* $\rho_i(E)$ *of an evaluation* E (sequential or parallel) of a forest F *at time slot* i is the number of *useful intermediate results* (*registers*) of E which are available at time slot i. An intermediate result is *useful* at time slot i if the vertex representing it is either a root or a vertex that has already been computed at time slot i, and its parent has not been computed at time slot i. The *width* $\rho(E)$ *of an evaluation* E

i		1	2	3	4	5	6	7	8	9	10	11	12	13

FIG. 2. *Six parallel evaluations of the tree of Fig.* 1.

(sequential or parallel) of a forest F is the maximal value of $\rho_i(E)$ for all i. In Fig. 2, $\rho_i(PQ^1)=1$ for $i=1, 13$; $\rho_i(PQ^1)=2$ for $i=2, 3, 10\text{-}12$; and $\rho_i(PQ^1)=3$ for $4\leqq i\leqq 9$. Therefore, $\rho(PQ^1)=3$.

Any sequential evaluation may be viewed as a parallel evaluation of the same width by mapping every load operation p into a pair (p, NOP) and every arithmetic operation q into a pair (NOP, q). The other direction is also true: Given a parallel evaluation PQ, it can be transformed without increasing the width into a sequential evaluation by breaking every pair $PQ_i=(p_i, q_i)$ for which $p_i \neq \text{NOP}$ and $q_i \neq \text{NOP}$ into two pairs $(\text{NOP}, q_i)(p_i, \text{NOP})$ and then deleting all the NOPs from all pairs to yield a sequential evaluation. Transforming the parallel evaluation PQ^1 of Fig. 2 into a sequential, we obtain the sequential evaluation 1-6, 8, 7, 12, 9-11, 13-17.

Let E and E' be two (sequential or parallel) evaluations of a forest F. E and E' are *compatible* if the subsequences of load operations and the subsequences of arithmetic operations of E and E' are identical. For a given forest F let

$$\rho \min(E) = \min_{E'} [\rho(E') \mid E' \text{ is an evaluation of } F \text{ that is compatible with } E].$$

Also, let

$$\mu(F) = \min_{E} [\rho(E) \mid E \text{ is an evaluation of } F].$$

In other words, $\rho \min(E)$ is the minimal number of registers sufficient to compute F in an order compatible with E, and $\mu(F)$ is the minimal number of registers sufficient to compute F. In Fig. 2, $\rho \min(PQ^1)=3$, $\rho \min(PQ^5)=4$, while $\rho \min(PQ^6)=5$. For the tree T of Fig. 1, $\mu=3$. In the sequel, we will apply μ to a fixed tree T and use the following shorthand: $\mu=\mu(T)$ and $\mu_v=\mu(T_v)$.

2.3. The DP scheme. For the sequential case, the problem of finding an evaluation of minimum completion time is trivial, while the problem of finding an evaluation of minimum width is of interest. This problem has been solved efficiently by the *labelling*

algorithm of Sethi and Ullman [SU70]. Their algorithm labels the vertices of an expression tree with a minimal number of registers needed to compute the subtrees rooted at these vertices without store operations. In the following lemma we formalize their result without proof.

LEMMA 2.1. *Let T be a binary tree rooted at* root. *Then*

$$\mu = \begin{cases} 1 & \text{root } \textit{is the only vertex of } T, \\ \mu_u & \text{root } \textit{has one child } u, \\ \min(\max(\mu_u, \mu_w + 1), \max(\mu_u + 1, \mu_w)) & \text{root } \textit{has two children } u \textit{ and } w. \end{cases}$$ □

Before we start the discussion on parallel machines, we present a generic scheme derived from the dynamic programming algorithm of Aho and Johnson [AJ76]. For every vertex v of the input tree T the scheme computes $S_v[1], \cdots, S_v[R]$. If T_v cannot be computed with r registers, then $S_v[r] = \Lambda$, where Λ denotes the undefined evaluation sequence. Let $\Lambda | S = \Lambda$ and $S | \Lambda = \Lambda$ for every evaluation sequence S. Also, let Γ be a real-valued function defined over the set of evaluations (sequential or parallel) including the undefined evaluation sequence, so that $\Gamma(S) = \infty$ if and only if $S = \Lambda$.

THE DP SCHEME.
Visit the vertices of the tree in *postorder.* **For** every vertex v **do**;
if v is a leaf **then**
  for every $1 \leqq r \leqq R$ **do** $S_v[r] = (v)$
else if v has one child u **then**
  for every $1 \leqq r \leqq R$ **do** $S_v[r] = S_u[r]|(v)$
else /*v has two children */ **begin**
  let u, w be the children of v;
  $S_v[1] = \Lambda$;
  for every $2 \leqq r \leqq R$ **do**
L1: **if** $\Gamma(S_u[r]|S_w[r-1]|(v)) > \Gamma(S_w[r]|S_u[r-1]|(v))$ **then** $S_v[r] = S_w[r]|S_u[r-1]|(v)$
    else $S_v[r] = S_u[r]|S_w[r-1]|(v)$;
end;

All the decisions concerning the order of evaluation (line L1 in the DP scheme) depend on Γ. Given a specific function f, DP_f will stand for the algorithm obtained from the DP scheme by substituting f for Γ. In particular, consider DP_ρ and apply it to an input tree T. Let r be the smallest integer for which $S_{\mathrm{root}}[r] \neq \Lambda$. Then $r = \mu$ [AJ76]. For the tree of Fig. 1, DP_ρ yields $S_{\mathrm{root}}[r] = \Lambda$ for $r = 1, 2$ and $S_{\mathrm{root}}[r] = 1\text{-}17$ for $r \geqq 3$.

In the following theorem we state the correctness of the DP scheme. Notice that the proof (omitted here) is independent of Γ, and the only property that Γ must have is: $\Gamma(S) = \infty$ if and only if $S = \Lambda$.

THEOREM 2.2. *Let T be a binary tree and let v be a vertex of T.*
(i) *If $S_v[r] \neq \Lambda$, then $\rho(S_v[r]) \leqq r$.*
(ii) *For all $r \geqq \mu$, $S_{\mathrm{root}}[r] \neq \Lambda$.* □

In the following section a mapping P_r is developed that maps sequential to parallel evaluations whose width is bounded by r. $|P_r|$ is a function that, given a sequential computation S, finds the parallel completion time of $P_r(S)$. Assume that $\mathrm{DP}_{|P_r|}$ has been applied to a tree T. $P_R(S_{\mathrm{root}}[R])$ will be shown to be either undefined or use at most R registers. In addition it will be shown to be an efficient parallel evaluation that approximates the optimal one quite well.

2.4. From sequential to parallel evalution sequences. To develop the theory of parallel evaluations, let $P_r(S)$ be a shortest parallel evaluation of F compatible with

a sequential evaluation S that computes F such that $\rho(P_r(S)) \leqq r$. If no such evaluation exists, as $r < \rho \min(S)$, then $P_r(S) = \Lambda$. To fully describe $P_r(S)$ let L and A be the subsequences of S that consist of all the load and all the arithmetic operations of S, respectively.

THE P_r TRANSFORMATION.

```
i := 1;
j := 1;
PQ := ( );
while i ≦ |L| or j ≦ |A| do
  if |L| < i then for k := j to |A| do PQ := PQ, (NOP, A_k)
  else if |A| < j then for k := i to |L| do begin
    if ρ(PQ) = r then return (Λ);
    PQ := PQ, (L_k, NOP);
  end
  else if L_i ∈ F_{A_j} then
    if ρ(PQ) = r then return(Λ)
    else do begin
      PQ := PQ, (L_i, NOP);
      i := i+1;
    end
L1: else if ρ(PQ, (L_i, A_j)) ≦ r then begin
    PQ := PQ, (L_i, A_j);
    i := i+1;
    j := j+1;
  end
  else begin
    PQ := PQ, (NOP, A_j);
    j := j+1;
  end;
return(PQ);
```

Consider the evaluation $S = 1\text{-}17$ of the tree of Fig. 1. Then $P_1(S)$, $P_2(S) = \Lambda$, $P_3(S) = PQ^1$, and for $r \geqq 4$, $P_r(S) = PQ^2$ where PQ^1 and PQ^2 appear in Fig. 2. Given a sequential evaluation S, $P_r(S)$ is a shortest parallel evaluation compatible with S with the width less than or equal to r. We state that in the following lemma.

LEMMA 2.3. *Let PQ be a parallel evaluation of a forest F that is compatible with a sequential evaluation S. Then* $|P_{\rho(PQ)}(S)| \leqq |PQ|$. □

In § 3, additional properties of P_r are derived.

2.5. The analysis of the algorithm—An overview. The rest of the paper is devoted to the analysis of $\mathrm{DP}_{|P_r|}$. The DP scheme and the P_r transformation described above are all we need to implement $\mathrm{DP}_{|P_r|}$. However, in order to analyze the algorithm, several new concepts must be defined:

(1) In § 2.6, we define a class of *canonical* (sequential and parallel) evaluations. Informally, in canonical evaluations the arithmetic operations are scheduled as soon as possible after their operands have been computed. The evaluations produced by the DP scheme are always canonical. Also, we prove that an optimal evaluation can always be found among canonical evaluations. Therefore, in the rest of the paper, we restrict ourselves to considering canonical evaluations only.

(2) In § 3, several properties of parallel (canonical) evaluations are developed that enable us to define the *concatenation* of parallel evaluations. Intuitively, this concatenation operator allows to compute $|P_r(S_1|S_2)|$ from $|P_r(S_1)|$ and $|P_{r-1}(S_2)|$ in constant time. By employing the concatenation operator, the $DP_{|P_r|}$ algorithm is transformed into a dynamic programming algorithm (DPA) whose time complexity is linear. DPA is easier to analyze.

(3) Section 4 is devoted to the analysis of DPA. To this end, a subclass of canonical evaluations, called *normal form* (or simply *normal*) evaluations is defined. Evaluations produced by the DP scheme are always normal, and we prove that DPA produces shortest normal parallel evaluations.

(4) It turns out that certain trees do not have normal optimal evaluations. In § 5, we consider *bouncing* (nonnormal) evaluations and develop the conditions under which optimal evaluations necessarily bounce. Using these conditions, we prove that DPA is optimal when the number of registers is at most four and the number of vertices is at most 16.

(5) Finally, by performing elaborate analysis of DPA, we show in § 6 that the evaluations produced by DPA can be worse than the optimal by at most a factor of 1.091.

2.6. Canonical evaluations. Let S be a sequential evaluation of a forest F. Let $S_{j_1} \cdots S_{j_l}$ and $S_{i_1} \cdots S_{i_a}$ be the load and the arithmetic operations of S, respectively. For every $1 \leqq k \leqq l$, having S_{j_k} in a register enables a (possible empty) sequence B^k of arithmetic operations to be carried out that could not be computed without it. The *canonical evaluation derived from* S is $(S_{j_1})|B^1| \cdots |(S_{j_l})|B^l$. S is a *canonical evaluation* if it is identical to the canonical evaluation derived from S. Clearly, the canonical evaluation derived from S obeys the precedence constraints of F. Note that canonical evaluations are fully determined by the order among the load operations. Also, note that the arithmetic operations in a sequential evaluation S need not occupy the same positions in the canonical evaluation derived from it.

LEMMA 2.4. *Let $\bar{S}$ be the canonical evaluation derived from S. Then $\rho(\bar{S}) \leqq \rho(S)$.* □

Consider the evaluation $S = 1, 2, 4\text{-}6, 3, 7\text{-}17$ of the tree of Fig. 1 that has $\rho(S) = 4$. The canonical evaluation $\bar{S}$ derived from S is given by 1-17 and $\rho(\bar{S}) = 3$. Also, by Lemma 2.4, for every canonical evaluation S, $\rho \min(S) = \rho(S)$.

The notion of canonical evaluations may be extended to parallel evaluations. Let $PQ = (p_1, q_1) \cdots (p_{|PQ|}, q_{|PQ|})$ be a parallel evaluation of a forest F. Let $P = p_{j_1} \cdots p_{j_l}$ and $Q = q_{i_1} \cdots q_{i_a}$ be the non-NOP elements of PQ. As in the case of sequential evaluations, for every $1 \leqq k \leqq l$, having p_{j_k} in a register enables a (possibly empty) sequence B^k of arithmetic operations to be carried out that could not be computed without it. The concatenation $B = B^1|\cdots|B^l$ of $B^1, \cdots, B^l$ is a linear ordering of $A(F)$. Let $B = B_1, \cdots, B_a$. The *canonical parallel evaluation* $\overline{PQ}$ *derived from* PQ is obtained from PQ by replacing q_{i_k} with B_k for $1 \leqq k \leqq a$. We see that the arithmetic operations are permuted, but they occupy the same time slots (unlike the situation in the sequential case). The next lemma shows that canonical parallel evaluations fulfill the precedence relations.

LEMMA 2.5. *Let PQ be a parallel evaluation of a forest F. Then so is the canonical evaluation $\overline{PQ}$ derived from PQ.* □

In § 3, we show that for every parallel evaluation PQ compatible with a sequential evaluation S, there exists a parallel evaluation PQ', compatible with the canonical evaluation $\bar{S}$ derived from S, such that $c(PQ') \leqq c(PQ)$ and $\rho(PQ') \leqq \rho(PQ)$. Since PQ' is canonical, we will be interested only in canonical parallel evaluations.

3. Properties of parallel evaluations.

3.1. Basic properties. A binary arithmetic operation reduces by one the number of useful intermediate results in a parallel evaluation PQ while a unary arithmetic operation does not change it. Thus, if $p_i \neq \text{NOP}$ and q_i is a unary operation then $\rho_i(PQ) = \rho_{i-1}(PQ) + 1$ while if q_i is binary then $\rho_i(PQ) = \rho_{i-1}(PQ)$.

A time slot i is identified as a *load* (*arithmetic*) *hole* if in time slot i no load (arithmetic) operation is performed, while load (arithmetic) operations occur both before and after i. Consider the evaluation PQ^1 of Fig. 2. The time slots 7 and 8 are empty load holes while time slot 4 is an empty arithmetic hole.

Intuitively, the P_r procedure tries to execute the load and arithmetic operations of S as soon as possible without violating the precedence and the register constraints. Certain properties of the resultant parallel evaluations are derived from this observation. First, note that PQ has no empty slots. The following lemmas give additional properties of P_r.

LEMMA 3.1. *Let S be a sequential evaluation of a binary forest F and let $PQ = P_r(S) \neq \Lambda$. Then, all the load holes of PQ are occupied by unary arithmetic operations.* □

For example, consider evaluation PQ^1 of Fig. 2. The only empty load holes of PQ^1 are at time slots 7 and 8, and they are occupied by unary arithmetic operations that compute vertices 9 and 10 of the tree, respectively.

For sequential machines, ρ_i does not have to be a monotonic function of i; it increases as a result of several consecutive load operations and decreases when several binary arithmetic operations are performed in a row. This also may be true for parallel evaluations. However, if we concentrate on parallel evaluations generated by the P_r procedure, then ρ_i is a convex function of i. This is because if $\rho_i > \rho_{i+1}$ then a load operation could be scheduled at time slot $i+1$. Only when all the load operations have been scheduled may ρ_i decrease, but then it cannot increase again. Formally we get the following.

LEMMA 3.2. *Let the last load operation of an $PQ = P_r(S)$ be at time slot i. Then, $\rho_1(PQ) \leqq \cdots \leqq \rho_i(PQ) \geqq \rho_{i+1}(PQ) \geqq \cdots \rho_{|PQ|}(PQ)$.* □

COROLLARY 3.3. *Let S be a sequential evaluation of a binary forest F with k trees, and let $PQ = P_r(S)$. The number of binary arithmetic operations performed after the last load operation of PQ is $\rho(PQ) - k$. (However, there may be a few more unary operations.)* □

LEMMA 3.4. *Let $PQ = P_r(S)$, as above. Let the last arithmetic hole of PQ be at time slot i, and the first load hole at time slot j. Then, $j > i$.* □

The following lemma shows that the order of evaluation S of F determines the completion time of $P_r(S)$, independently of r (as long as $r \geqq \rho \min(S)$).

LEMMA 3.5. *Let S be a sequential evaluation of a forest F, and let $r_1, r_2 \geqq \rho \min(S)$. Then $|P_{r_1}(S)| = |P_{r_2}(S)|$.* □

Consider the tree T of Fig. 1. Computing T in the natural order $S = 1\text{-}17$, results in $P_3(S) = PQ^1$ and $P_4(S) = PQ^2$ where PQ^1 and PQ^2 appear in Fig. 2. Note that $c(PQ^1) = c(PQ^2) = 13$.

COROLLARY 3.6. *Let PQ be a parallel evaluation compatible with a sequential evaluation S. Let $\bar{S}$ be the canonical evaluation derived from S. Then*

(i) $|P_{\rho(\bar{S})}(\bar{S}) \leqq |PQ|$.

(ii) $\rho(P_{\rho(\bar{S})}(\bar{S})) \leqq \rho(PQ)$. □

Let S be a sequential (canonical) evaluation of a binary forest F. We define a (canonical) *ρ-efficient* evaluation PQ compatible with S to be $P_{\rho(S)}(S)$. As a consequence of Corollary 3.6, in the rest of the paper we consider canonical ρ-efficient evaluations only.

3.2. Consecutive evaluations. Let S be a sequential evaluation of a binary forest F and let $PQ = P_r(S)$. An evaluation PQ' that is identical to PQ, except that it has no arithmetic holes, is called *r-consecutive evaluation.* By Lemmas 3.2 and 3.4, we can iteratively delay all the arithmetic operations prior to the last arithmetic hole and leave all other operations in their original place to transform every parallel evaluation resulted from the P_r procedure into an r-consecutive evaluation of the same width and completion time. Let $P_r^*(S)$ denote the r-consecutive evaluation obtained from $P_r(S)$ in this fashion. Then, $\rho(P_r^*(S)) = \rho(P_r(S))$, and $|P_r^*(S)| = |P_r(S)|$. For example, PQ^3 of Fig. 2 is a 3-consecutive evaluation that corresponds to $PQ^1 = P_3(S)$ where $S = 1\text{-}17$. Also, PQ^4 is a 4-consecutive evaluation that corresponds to $PQ^2 = P_4(S)$. Since for all S and for every $r \geqq \rho \min(S)$, $|P_r^*(S)| = |P_r(S)|$, the properties of the algorithm $\mathrm{DP}_{|P_r^*|}$ are identical to those of $\mathrm{DP}_{|P_r|}$.

Given a parallel evaluation PQ and a sufficiently large r (e.g., $r > |PQ|$), an r-consecutive evaluation PQ' compatible with PQ will have no load holes. Such an evaluation PQ' is called ∞-*consecutive*, or simply *consecutive.* Thus, PQ^4 shown in Fig. 2 is the consecutive evaluation of the tree of Fig. 1 compatible with $S = 1\text{-}17$.

In line L1, the $\mathrm{DP}_{|P_r^*|}$ algorithm computes $|P_r^*(S_u[r]|S_w[r-1]|(v))|$ to make a decision concerning the order of evaluation. It turns out that $|P_r^*(S_u[r]|S_w[r-1]|(v))|$ can be computed directly from $|P_r^*(S_u[r])|$ and $|P_{r-1}^*(S_w[r-1])|$ rather than by applying P_r^* to $S_u[r]|S_w[r-1]|(v)$. Since, by Lemma 3.5, the cost of r-consecutive evaluations is independent of how large r can be, we can use P_∞^* rather than P_r^* and compute $|P_\infty^*(S_u[r]|S_w[r-1]|(v))|$ from $|P_\infty^*(S_u[r])|$ and $|P_\infty^*(S_w[r-1])|$. In the sequel, some properties of consecutive evaluations are developed. Then, using the concatenation of consecutive evaluations that will be defined, we develop a linear algorithm called DPA derived from the $\mathrm{DP}_{|P_\infty^*|}$ algorithm. DPA is easier to analyze than $\mathrm{DP}_{|P_r^*|}$.

Let F be a forest of k trees. Let PQ be a consecutive evaluation of F. A consecutive evaluation PQ is presented pictorially in Fig. 3(a). It is characterized by the following parameters:

(1) $c = |PQ|$ is the completion time of PQ;

(2) h is the *head*—the number of load operations that take place before the first arithmetic operation. Note that h is equal to the number of empty arithmetic slots in PQ. Using $a = a(F)$ we get

$$h = c - a; \tag{1}$$

(3) t is the *tail*—the number of arithmetic operations that take place after the last load operation. Note that t is equal to the number of empty load slots in PQ. Using $l = l(F)$ we get

$$t = c - l. \tag{2}$$

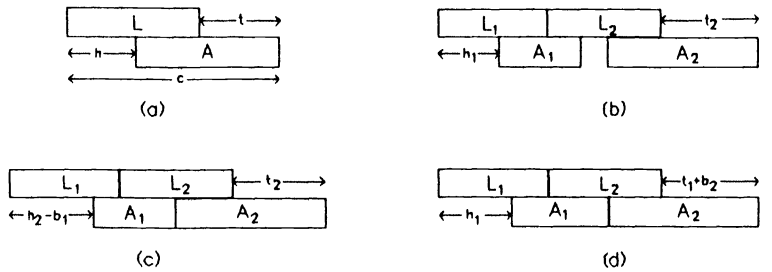

FIG. 3. *Pictorial presentation and concatenation of consecutive evaluations.*

The c, h, t parameters are a convenient, partial characterization of consecutive evaluations. To completely characterize consecutive evaluations that compute a forest F, both S and F are needed. In the sequel we present the c, h, t parameters of a consecutive evaluation PQ as a triple $\langle c, h, t\rangle$. For example, the consecutive evaluation of a single load operation is characterized by $\langle 1, 1, 0\rangle$, while a single arithmetic operation is characterized by $\langle 1, 0, 1\rangle$. Also, we assume that if $PQ = \Lambda$ then $c = \infty$, $h = \infty$, and $t = \infty$.

Since we assumed that there are no arithmetic leaves in expression trees, at least one load operation must be performed before a first arithmetic operation can be carried out. Therefore, in the rest of the paper we assume that $h \geqq 1$.

Below some key properties of the c, h, t parameters are derived. Let PQ be a consecutive evaluation which computes a forest F with k trees.

COROLLARY 3.7. $h(PQ) \geqq \rho(PQ)$. □

COROLLARY 3.8. $t(PQ) \geqq \rho(PQ) - k$. □

Another important concept is that of a *balance*. The *balance* of a consecutive evaluation PQ is defined by

$$b = t - h. \tag{3}$$

Substituting (1) and (2) into (3) we get $b = a - l$. Therefore, all forests with l load operations and a arithmetic operations have the same balance.

Let T be a binary tree. Since the number of arithmetic operations in T is at least one less than the number of load operations $a - l \geqq -1$. Therefore, for every binary tree T, $b \geqq u - 1$. Moreover, if T is a *full binary tree* (all the internal vertices of T have exactly two children) then $a = l - 1$, and $b = -1$.

Let PQ^1 and PQ^2 be two consecutive evaluations compatible with sequential evaluations S^1 and S^2 of F^1 and F^2, respectively. The *concatenation* $PQ^{1,2} = PQ^1 | PQ^2$ of PQ^1 *and* PQ^2 is defined as the consecutive evaluation of $F^1 \cup F^2$ compatible with $S^1 | S^2$. $PQ^{1,2}$ is obtained by shifting PQ^2 toward PQ^1, until either the load operations meet, as in Fig. 3(b) (and then shifting the arithmetic operations of PQ^1 to the right until they meet the arithmetic operations of PQ^2; see Fig. 3(c)), or until the arithmetic operations meet (and then shifting the load operations of PQ^2 to the left until they meet the load operations of PQ^1; see Fig. 3(d)). It turns out that to compute the c, h, and t parameters of $PQ^{1,2}$ only the c, h and t parameters of PQ^1 and PQ^2 are needed.

We use the concatenation operator defined above to present the following linear version of the $DP_{|P^*_\infty|}$ algorithm (DPA). Note that all the decisions in the DPA algorithm (line L1 below) are based solely on the c, h, and t parameters of consecutive evaluations.

THE DPA ALGORITHM.

Visit the vertices of the tree in *postorder*. **For** every vertex v **do**;
if v is a leaf **then**
  for every $1 \leqq r \leqq R$ **do** $PQ_v[r] = ((v, \text{NOP}))$
else if v has one child u **then**
  for every $1 \leqq r \leqq R$ **do** $PQ_v[r] = PQ_u[r] | ((\text{NOP}, v))$
else /* v has two children */ **begin**
  let u, w be the children of v;
  $PQ_v[1] = \Lambda$;
  for every $2 \leqq r \leqq R$ **do**
L1: **if** $c(PQ_u[r] | PQ_w[r-1] | ((\text{NOP}, v))) > c(PQ_w[r] | PQ_u[r-1] | ((\text{NOP}, v)))$
    then $PQ_v[r] = PQ_w[r] | PQ_u[r-1] | ((\text{NOP}, v))$
    else $PQ_v[r] = PQ_u[r] | PQ_w[r-1] | ((\text{NOP}, v))$
end;

It can be shown that the concatenation of two consecutive evaluations can be computed

in a constant time. Therefore, the complexity of DPA is linear in nR since every vertex is visited only once, and the time spent there is bounded by $O(R)$. Moreover, for large values of R ($R \geqq \log n$), DPA can be implemented in such a way that its complexity is bounded by $O(n \min(\log n, R))$. An example that shows how DPA processes the tree of Fig. 1 is shown in the Appendix.

4. Properties of DPA.

4.1. Properties of the concatenation operation. Below, certain properties of the concatenation of parallel consecutive evaluations are derived. The proofs of Lemmas 4.1–4.3 are essentially the same as those of [BJPR85] and are omitted here.

Let PQ^i, $i = 1, 2, \cdots$ be arbitrary consecutive evaluations with $\langle c_i, h_i, b_i \rangle$ parameters. Also, let $b_i = t_i - h_i$. Since $b = a - l$, we get

$$b_{1,2} = b_1 + b_2. \tag{4}$$

LEMMA 4.1. *Let* $PQ^{1,2} = PQ^1 | PQ^2$. *Then*

$$h_{1,2} = \max(h_1, h_2 - b_1). \tag{5}$$ □

The following lemma shows that the concatenation operator is associative. This will allow us to omit parenthesis where convenient.

LEMMA 4.2. (the associativity property). $(PQ^1 | PQ^2) | PQ^3 = PQ^1 | (PQ^2 | PQ^3)$. □

Lemma 4.3 below shows that if some subevaluation in the middle of a larger evaluation is locally improved, then the total cost may only decrease.

LEMMA 4.3 (the monotonicity property). *If* $b_2 = b_4$ *and* $h_2 \leqq h_4$ *then* $h_{1,2,3} \leqq h_{1,4,3}$. □

4.2. Normal form evaluations. A sequential canonical evaluation S of a tree T may be viewed as a visiting sequence of the vertices of T. S is a *normal form evaluation* (or simply *normal evaluation*) if for every $v \in T$ all the vertices of T_v are visited in a row such that v is the last one to be visited. A parallel evaluation is *normal* if it is compatible with a sequential normal evaluation S. For example, in Fig. 2, PQ^1 and PQ^5 are normal, while PQ^6 is not normal. Note that normal evaluations are always canonical. Also note that for all v and r, $PQ_v[r]$ is either normal or undefined.

THEOREM 4.4. $PQ_{root}[r]$ *has the shortest completion time among all normal evaluations that use at most* r *registers.*

Proof. The proof is by induction on $n = |T|$.

Basis. For a tree with one vertex the theorem trivially holds.

Induction hypothesis. Assume that for all trees with less than n vertices the theorem holds.

Induction step. Let T be a tree with n vertices rooted at *root*.

Case 1. *Root* has one immediate descendant u. By the induction hypothesis, $PQ_u[r]$ has the smallest completion time among all normal evaluations of T_u that use at most r registers. Therefore, so does $PQ_{\text{root}}[r] = PQ_u[r] | ((\text{NOP}, v))$.

Case 2. *Root* has two immediate descendants u and w. Consider the set of all normal evaluations of T that use at most r registers. They can be divided into two disjoint subsets $S^{u,w}$ and $S^{w,u}$, depending on the order in which they compute T. The evaluations of $S^{u,w}$ compute T_u first, while the evaluations of $S^{w,u}$ compute T_w first. Let $PQ = PQ^u | PQ^w | ((\text{NOP}, v))$ be an arbitrary evaluation in $S^{u,w}$ that uses at most r registers. PQ^u cannot use more than r registers. Therefore, by the induction hypothesis, $c(PQ_u[r]) \leqq c(PQ^u)$. Similarly, PQ^w cannot use more than $r-1$ registers. Again, by the induction hypothesis, $c(PQ_w[r-1]) \leqq c(PQ^w)$. By Lemma 4.3,

$$c(PQ_u[r] | PQ_w[r-1]) \leqq c(PQ_u[r] | PQ^w) \leqq c(PQ^u | PQ^w).$$

Therefore, $PQ_u[r]|PQ_w[r-1]|((\text{NOP}, v))$ has the smallest cost among all the evaluations in $S^{u,w}$. Similarly all the evaluations in $S^{w,u}$ have their completion time bounded below by $c(PQ_w[r]|PQ_u[r-1]|((\text{NOP}, v)))$. Since $c(PQ_{\text{root}}[r]) = \min(c(PQ_u[r]|PQ_w[r-1]|((\text{NOP}, v))), c(PQ_w[r]|PQ_u[r-1]|((\text{NOP}, v))))$, the theorem follows. □

The following lemma proves that $c(PQ_{\text{root}}[r])$ is a nonincreasing function of r, i.e., by increasing the number of registers it is possible only to reduce the completion time of the evaluation produced by DPA. Using (1) we can prove this result by showing that $h(PQ_{\text{root}}[r])$ never increases when r increases.

LEMMA 4.5. *Let T be a binary tree rooted at root. For every $r \geqq 2$, $h(PQ_{root}[r]) \leqq h(PQ_{root}[r-1])$.*

Proof. The proof is by induction on $n = |T|$.

Bases. For a tree with one vertex and for $r \geqq 2$, $h(PQ_{root}[r])$, $h(PQ_{root}[r-1]) = 1$. Therefore, the lemma trivially holds.

Induction hypothesis. Assume that for all trees with less than n vertices and for every $r \geqq 2$, $h(PQ_{root}[r]) \leqq h(PQ_{root}[r-1])$.

Induction step. Let T be a tree with n vertices.

Case 1. *Root* has one immediate descendant u. For every $r \geqq 1$, $h(PQ_{root}[r]) = h(PQ_u[r]|((\text{NOP}, root))$. Therefore, for every $r \geqq 2$, $h(PQ_{root}[r]) = h(PQ_u[r])$, and $h(PQ_{root}[r-1]) = h(PQ_u[r-1])$. By the induction hypothesis, for every $r \geqq 2$, $h(PQ_u[r]) \leqq h(PQ_u[r-1])$. Therefore, for every $r \geqq 2$, $h(PQ_{root}[r]) \leqq h(PQ_{root}[r-1])$.

Case 2. *Root* has two immediate descendants u and w. For $r = 2$, the lemma holds as $h(PQ_{root}[2]) \leqq h(PQ_{root}[1]) = \infty$. Therefore, assume that $r \geqq 3$. By the induction hypothesis,

$$\text{for all } r \geqq 2: \quad h(PQ_u[r]) \leqq h(PQ_u[r-1])$$

and

$$\text{for all } r \geqq 2: \quad h(PQ_w[r]) \leqq h(PQ_w[r-1]).$$

Therefore, by (5),

$$\begin{aligned} h(PQ_u[r-1]|PQ_w[r-2]|((\text{NOP}, root))) &= \max(h(PQ_u[r-1]), h(PQ_w[r-2]) - b_u) \\ &\geqq \max(h(PQ_u[r]), h(PQ_w[r-1]) - b_u) \\ &= h(PQ_u[r]|PQ_w[r-1]|((\text{NOP}, root))). \end{aligned}$$

Similarly,

$$h(PQ_w[r-1]|PQ_u[r-2]|((\text{NOP}, root))) \geqq h(PQ_w[r]|PQ_u[r-1]|((\text{NOP}, root))).$$

Substitution of these inequalities in the condition of line L1 of DPA yields

$$\begin{aligned} h(PQ_{root}[r]) &= \min(h(PQ_u[r]|PQ_w[r-1]|((\text{NOP}, root))), \\ &\quad h(PQ_w[r]|PQ_u[r-1]|((\text{NOP}, root)))) \\ &\leqq \min(h(PQ_u[r-1]|PQ_w[r-2]|((\text{NOP}, root))), \\ &\quad h(PQ_w[r-1]|PQ_u[r-2]|((\text{NOP}, root)))) \\ &= h(PQ_{root}[r-1]). \end{aligned}$$

□

The following lemma proves that DPA finds the minimal completion time (optimal) evaluation for a *full binary tree*—a tree in which all the internal vertices have exactly two children.

LEMMA 4.6. *Let T be a full binary tree rooted at root. For every $r \geqq \mu$, $h(PQ_{root}[r]) = \mu$.*

Proof. Consider the consecutive evaluation $PQ_{root}[\mu]$ of T. By Theorem 2.2, $PQ_{root}[\mu] \neq \Lambda$, and $\rho(PQ_{root}[\mu]) \leqq \mu$. Therefore, $\rho(PQ_{root}[\mu]) = \mu$. Let i and j be the time slots in which the first arithmetic operation and the last load operation of $PQ_{root}[\mu]$ are performed. Clearly, $\rho_{i-1}(PQ_{root}[\mu]) = h(PQ_{root}[\mu])$. By Lemma 3.3,, $\rho(PQ_{root}[\mu]) = \rho_j(PQ_{root}[\mu])$. But, since all the arithmetic operations of T are binary, for all $i \leqq k \leqq j$, $\rho_k(PQ_{root}[\mu]) = \rho_{i-1}(PQ_{root}[\mu])$. Therefore, $\mu = h(PQ_{root}[\mu])$.

For $r > \mu$, by Lemma 4.5, $h(PQ_{root}[r]) \leqq h(PQ_{root}[\mu])$. If for some r, $h(PQ_{root}[r]) < h(PQ_{root}[\mu])$ then the same argument shows that $\rho(PQ_{root}[r]) < \mu$, contradicting the definition of μ. Therefore, for every $r \geqq \mu$, $h(PQ_{root}[\mu]) = \mu$. □

LEMMA 4.7. *Let v be a binary vertex with two children u and w. If $h(PQ_v[\mu_v]) > h(PQ_u[\mu_u]), h(PQ_w[\mu_w])$, then T_v is a full binary tree.*

Proof. Without loss of generality, we assume that $\mu_u \geqq \mu_w$.

Case 1. $\mu_u = \mu_w$. By Lemma 2.1, $\mu_v = \mu_u + 1 = \mu_w + 1$. By line L1 of DPA,

$$h(PQ_v[\mu_v]) \leqq h(PQ_\mu[\mu_v] | PQ_w[\mu_v - 1]) = \max(h(PQ_u[\mu_v]), h(PQ_w[\mu_v - 1]) - b_u). \tag{6}$$

By Lemma 4.5, $h(PQ_u[\mu_u + 1]) \leqq h(PQ_u[\mu_u])$. Therefore, $h(PQ_v[\mu_v]) > h(PQ_u[\mu_v])$. Since $\mu_v - 1 = \mu_w$, $h(PQ_v[\mu_v]) > h(PQ_w[\mu_v - 1])$. Therefore, $b_u = -1$. Similarly, $b_w = -1$. Thus, T_v is a full binary tree.

Case 2. $\mu_v > \mu_w$.

We claim that this case cannot happen. Consider (6) again. By Lemma 2.1, $\mu_v = \mu_u$. Therefore, $h(PQ_v[\mu_v]) > h(PQ_u[\mu_v])$. Also, since $\mu_v - 1 \geqq \mu_w$, by Lemma 4.5, $h(PQ_v[\mu_v]) > h(PQ_w[\mu_v - 1])$. Therefore, $b_u = -1$, and T_u is a full binary tree. By Lemma 4.6, $h(PQ_u[\mu_u]) = \mu_u$. Also, by Theorem 2.2(i), $\rho(PQ_w[\mu_v - 1]) \leqq \mu_v - 1 = \mu_u - 1$, and by Corollary 3.7, $h(PQ_w[\mu_v - 1]) \leqq \mu_u - 1$. Therefore, by (6), $h(PQ_v[\mu_v]) \leqq \mu_u$, which would imply $h(PQ_v[\mu_v]) \leqq h(PQ_u[\mu_u])$ contradicting the assumption of the lemma. □

Let *bop* and *uop* be the number of binary and unary arithmetic operations of T, respectively. The following lemma establishes an upper bound on μ as a function of *bop*.

LEMMA 4.8. $bop \geqq 2^{\mu-1} - 1$.

Proof. The proof is by induction on $n = |T|$.

Basis. For a tree with one vertex $bop = 0$, and $\mu = 1$, and the lemma holds.

Induction hypothesis. Assume that for all trees with less than n vertices the lemma holds.

Induction step. Let T be a tree with n vertices rooted at *root*.

Case 1. *Root* has one immediate descendant u. By the induction hypothesis,

$$bop_u \geqq 2^{\mu_u - 1} - 1.$$

Since $bop = bop_u$ and by Lemma 2.1, $\mu = \mu_u$, the lemma holds.

Case 2. *Root* has two immediate descendants u and w. By the induction hypothesis,

$$bop_u \geqq 2^{\mu_u - 1} - 1 \quad \text{and} \quad bop_w \geqq 2^{\mu_w - 1} - 1.$$

Without loss of generality we assume that $\mu_u \geqq \mu_w$. If $\mu_u > \mu_w$ then, by Lemma 2.1, $\mu = \mu_u$. Therefore, $bop > bop_u \geqq 2^{\mu_u - 1} - 1 = 2^{\mu - 1} - 1$. If $\mu_u = \mu_w$ then, by Lemma 2.1, $\mu = \mu_u + 1$. Since $bop = bop_u + bop_w + 1$, we apply the induction hypothesis twice to get $bop \geqq 2^{\mu_u - 1} + 2^{\mu_w - 1} - 1$. By $\mu_u = \mu_w = \mu - 1$, we get $bop \geqq 2^{\mu_u} - 1 = 2^{\mu - 1} - 1$. □

COROLLARY 4.9. $h(PQ_{root}[\mu]) \leqq \lfloor \log(n - uop + 1) \rfloor$.

Proof. For arbitrary binary trees $l = (n - uop + 1)/2 = bop + 1$. Thus, by Lemma 4.8,

$$\lfloor \log (n - uop + 1) \rfloor = \lfloor \log 2(bop + 1) \rfloor \geqq \mu.$$

By Corollary 3.7, $h(PQ_{root}[\mu]) \leqq \mu$, and the statement is proved. □

COROLLARY 4.10. $a \geqq 2^{h(PQ_{root}[\mu])-1} + uop - 1$.

Proof. Since $a = bop + uop$, by Lemma 4.8, $a \geqq 2^{\mu-1} + uop - 1$. By Corollary 3.7, $h(PQ_{root}[\mu]) \leqq \mu$, and the statement is proved. □

5. Bouncing evaluations. In § 4 we have discussed the properties of normal evaluations, and have proved that DPA finds a normal parallel evaluation of minimum completion time. In this section we discuss arbitrary canonical ρ-efficient evaluations. By Corollary 3.6, no other parallel evaluations need be considered. In the sequel, whenever we mention sequential or parallel evaluations, we mean canonical sequential evaluations or canonical parallel ρ-efficient evaluations. Also, in the rest of the paper we use the following shorthand: $h(S) = h(P^*_\infty(S))$, $t(S) = t(P^*_\infty(S))$, and $b(S) = b(P^*_\infty(S))$. We start with some properties of ρ.

5.1. Properties of ρ. Let S be a sequential evaluation of a binary tree T, and let S^1 and S^2 be subevaluations of S such that $S = S^1 | S^2$. In the following lemmas we relate $\rho(S^1)$ and $\rho(S^2)$ to $\rho(S)$.

LEMMA 5.1. *Let $S = S^1 | S^2$, and let k be the number of useful results computed by S^1.*

(i) $\rho(S^1), \rho(S^2) \leqq \rho(S)$.

(ii) *If the results computed by S^1 are not used in S^2 then* $\rho(S) = \max(\rho(S^1), \rho(S^2) + k)$.

Proof. (i) $\rho(S^1) = \max_{1 \leqq i \leqq |S^1|} \rho_i(S) \leqq \rho(S) = \rho(S)$. Similarly, $\rho(S^2) \leqq \max_{|S^1| < i \leqq |S|} \rho_i(S) \leqq \rho(S)$. Therefore, (i) holds.

(ii) During the computation of S^2, k registers hold the results computed by S^1. Since they are not used in S^2, $\max_{|S^1| < i \leqq |S|} \rho_i(S) = \rho(S^2) + k$, and (ii) follows. □

LEMMA 5.2. *Let $S = S^1 | S^2$, and let k be the number of useful results computed by S^1 (some of them may be used in S^2). Then $h(S^2) \leqq \rho(S) - k$.*

Proof. Let $PQ = P_{\rho(S)}(S)$. Consider the time slot i of PQ at which the last arithmetic operation of S^1 is performed. Let the number of the load operations of S^2 that have been performed no later than i be h', and let the number of the arithmetic operations of S^2 be a.

CLAIM. $h' \geqq h(S^2)$.

Proof of Claim. Assume, by contradiction, that $h' < h(S^2)$. Consider the parallel evaluation PQ^2 that is compatible with S^2 in which all the operations are executed exactly in the same time slots as in PQ except that the first h' loads are consecutive at time slot $1, 2, \cdots, h'$ of PQ^2. PQ^2 is a legal parallel evaluation, and $|PQ^2| = h' + a < h(S^2) + a = |P^*_\infty(S^2)|$. This contradicts Lemma 3.5, and the claim follows. □

Now consider PQ again. At the end of slot i, k registers hold the results of S^1, and h' registers are loaded with elements needed to compute S^2. Therefore, $h' + k \leqq \rho(PQ)$. Since PQ is a ρ-efficient evaluation $\rho(PQ) = \rho(S)$, and the lemma follows. □

5.2. Properties of bouncing sequential evaluations. Let S be a sequential evaluation of a binary tree T. If S is not a normal evaluation then there exists at least one subtree T_v of T such that S starts to evaluate it, and without finishing the computation *bounces* to a disjoint subtree T_u of T. In this case we say that S *bounces* at v, and v is a *bouncing operation.* An operation computing $v \in T$ is *normal* in S if for every $u \in T_v$, the vertices of T_u are visited by S in a row and u is the last one to be visited. Note that if $v \in T$ is a bouncing operation of S then all the ancestors of v in T are not normal, but they are not necessarily bouncing. For example, consider the sequential evaluation $S = 8\text{–}10$,

12-16, 1-7, 11, 17 of the tree of Fig. 1 that is compatible with PQ^6 of Fig. 2. In S, v_7, v_{10}, and v_{16} are normal, v_{11} is bouncing, while v_{17} is neither normal nor bouncing. Also, note that all the operations that compute the leaves of a tree (load operations) are normal. If v has one child u then v is executed immediately after u in every canonical evaluation of T. In this case v is a normal operation if and only if u is normal. On the other hand, if v has two children u and w then there exist canonical evaluations in which u and w are normal while v is bouncing.

Let v be a bouncing operation of a sequential evaluation S whose children are normal. Then v has two children u and w. Assume that u is computed first, then v is executed immediately after w. Projecting S on the vertices of T_u and T_w yields subevaluations S^1 and S^2 of S, respectively. Let the vertices of T computed between S^1 and S^2, belong to some subforest F^v of T. We say that T_u, T_w and F^v *are induced by* v and S. Note that the operations of F^v may use some of the results that are computed in S before T_u, but since S is a canonical evaluation, for each such operation at least one of its two operands must be computed after T_u. In the following lemma, certain properties of T_u, T_w, and F^v are derived.

LEMMA 5.3. *Let S be a sequential evaluation of a tree T. Let v be a bouncing operation of S whose children are normal, and let T_u, T_w and F^v be induced by v and S. Let S^u be the projection of S on the vertices of T_u. Also, let m and k be the number of useful results that are computed by S before T_u and T_w, respectively. Let S' be a sequential evaluation of T that is identical to S except that F^v is computed after v. Let S'' be the sequential evaluation of T that is identical to S except that F^v is computed before T_u.*

(i) *If $k \geqq m+1$, then $\rho(S') \leqq \rho(S)$.*

(ii) *If $k < m+1$, then $\rho(S'') \leqq \rho(S)$.*

(iii) *If $\rho(S^u) \leqq \rho(S) - k + 1$, then $\rho(S'') \leqq \rho(S)$.*

Proof. (i) $\rho_i(S')$ may be greater than $\rho_i(S)$ only in time slots i in which T_w, v, and F^v are computed. Since T_u, T_w, and v construct a single subtree of T, during the computation of F^v the number of useful results in S and in S' is identical. Since $k \geqq m+1$, during the computation of T_w and v the number of useful results in S' is not greater than that in S.

(ii) Consider the part of S'' that computes F^v and T_u. During the computation of F^v the width cannot increase since T_u is computed after F^v in S'', while in S it is computed before F^v, and its result occupies one additional register. When T_u is computed in S, m registers hold previously computed results, while when T_u is computed in S'', only $k-1$ registers hold previously computed results. Since $m > k-1$, (ii) holds.

(iii) As in (ii), during the computation of F^v the width cannot increase since T_u is computed after F^v in S'', while in S it is computed before F^v, and its result occupies one additional register. When T_u is computed in S'', $k-1$ registers hold previously computed results. By the assumption, $\rho(S^u) \leqq \rho(S) - k + 1$. Therefore, by Lemma 5.1, (ii), (iii) holds. □

5.3. Properties of optimal parallel evaluations. The notion of bouncing evaluations can be extended to parallel evaluations. A parallel evaluation PQ of T is *bouncing* if it is compatible with a sequential bouncing evaluation S of T. This definition is proper since we are dealing with canonical evaluations only, and there is exactly one sequential canonical evaluation compatible with a parallel canonical evaluation.

Next let us develop some properties of optimal evaluations and derive the conditions under which a optiml evaluation may not be normal. Without loss of generality we consider only optimal bouncing ρ-efficient evaluations with a *minimal number of*

bouncing operations. Let PQ be such an optimal evaluation of a binary tree T compatible with a sequential evaluation S. Let T_v be a subtree of T normal in S. Let S^v be the projection of S on the vertices of T_v. Consider the parallel evaluation $PQ_v[\rho(S^v)]$ generated by DPA for T_v. By Theorem 2.2, $\rho(PQ_v[\rho(S^v)]) \leqq \rho(S^v)$, and by Theorem 4.4, $|PQ_v[\rho(S^v)]| \leqq |P^*_\infty(S^v)|$. Therefore, we can assume that for every $v \in T$, if v is normal in S, then T_v is computed in S in the same order of evaluation as the one generated by DPA.

To analyze bouncing evaluations, we permute them so as to get normal evaluations without increasing the number of registers used, and then assess the ratio between the completion time of the resultant normal evaluation and the completion time of the optimal bouncing evaluation.

LEMMA 5.4. *Let PQ be an optimal evaluation of a binary tree T compatible with a sequential evaluation S. Let v be a bouncing operation of S whose children are normal, and let T_u, T_w, and F^v be induced by v and S. Also, let m and k be the number of useful results computed by S before T_u and T_w, respectively, and assume that $k \geqq m+1$. Let S^1, S^2, and S^3 be the projection of S on the vertices of T_u, T_w, and F^v, respectively, and let PQ^1, PQ^2, and PQ^3 be the corresponding compatible consecutive evaluations.*

(i) $b_1, b_3 \geqq 1$ *and* $h_1 < h_3 < h_2$.

(ii) *Let $\bar{S}$ be the prefix of S computed before F^v. Then* $\rho(\bar{S}) \leqq \rho(S) - 1$.

(iii) $\rho(S^2) \leqq \rho(S) - 1$, $\rho(S^3) \leqq \rho(S) - 1$.

Proof. Let S' be a sequential evaluation of T identical to S except that F^v is computed after v. Since v is a normal operation in S', the number of bouncing operations of S' is strictly smaller than that of S. Let PQ' be a ρ-efficient evaluation compatible with S'. By Lemma 5.3(i), $\rho(S') \leqq \rho(S)$. We will use the fact that $|PQ'| > |PQ|$, since otherwise PQ could not have been an optimal evaluation with a minimal number of bouncing operations. Let $PQ^4 = PQ^2|((\text{NOP}, v))$. Therefore, $h_4 = h_2$ and $b_4 = b_2 + 1$.

Proof of (i) We compare $c_{1,3,4}$ with $c_{1,4,3}$. By Lemma 3.5, $|P^*_\infty(S)| = |PQ|$ and $|P^*_\infty(S')| = |PQ'|$. By Lemma 4.3, if $c_{1,4,3} \leqq c_{1,3,4}$ then $|P^*_\infty(S')| \leqq |P^*_\infty(S)|$ and therefore, $|PQ'| \leqq |PQ|$. Since this is impossible we assume that $c_{1,3,4} < c_{1,4,3}$, i.e., $h_{1,3,4} < h_{1,4,3}$. By (5), this leads to $h_{3,4} < h_{4,3}$.

CLAIM 1. $h_3 < h_4$.

Proof of Claim 1. Since T_w is a binary tree, $b_2 \geqq -1$. Therefore, $b_4 \geqq 0$, and by (5),

$$h_{4,3} = \max(h_4, h_3 - b_4) \leqq \max(h_4, h_3).$$

Also, by (5),

$$h_{3,4} = \max(h_3, h_4 - b_3).$$

If $h_3 \geqq h_4$ then

$$h_{4,3} \leqq h_3 \leqq \max(h_3, h_4 - b_3) = h_{3,4},$$

contradicting $h_{3,4} < h_{4,3}$, and Claim 1 is proved. □

CLAIM 2. $b_3 \geqq 1$.

Proof of Claim 2. If $b_3 \leqq 0$ then $h_{3,4} = \max(h_3, h_4 - b_3) \geqq h_4$. By Claim 1, $h_{4,3} \leqq \max(h_4, h_3) = h_4$. This leads to a contradiction to $h_{3,4} < h_{4,3}$. Therefore, Claim 2 is proved. □

CLAIM 3. $b_1 \geqq 1$ and $h_1 < h_3$.

Proof of Claim 3. The proof is by case analysis.

Case 3.1. $\rho(S^1) > \rho(S) - k + 1$.

We show that this leads to a contradiction. By Corollary 3.8, $t_1 \geqq \rho(S^1) - 1 \geqq \rho(S) - k + 1$. Let $\hat{S}$ be the prefix of S that ends just before v. Then, by Lemma 5.1(i),

$\rho(\hat{S}) \leqq \rho(S)$. Also by applying Lemma 5.2 to $\hat{S}$, $h_2 \leqq \rho(\hat{S}) - k \leqq \rho(S) - k$. Consider again the evaluation PQ'. By Lemma 5.3(i), $\rho(S') \leqq \rho(S)$. By (5),

$$h_{1,4,3} = \max(h_1, h_4 - b_1, h_3 - b_1 - b_4).$$

Since $h_4 - b_1 = h_2 + h_1 - t_1 \leqq (\rho(S) - k) + h_1 - (\rho(S) - k + 1) = h_1 - 1$ and $b_4 \geqq 0$, we get $h_{1,4,3} \leqq \max(h_1, h_3 - b_1)$. Also by (5),

$$h_{1,3,4} = \max(h_1, h_3 - b_1, h_4 - b_1 - b_3) \geqq \max(h_1, h_3 - b_1).$$

Thus, $h_{1,4,3} \leqq h_{1,3,4}$. By Lemmas 4.3 and 3.5, this leads to $|PQ'| \leqq |PQ|$, which is impossible.

Case 3.2. $\rho(S') \leqq \rho(S) - k + 1$.

By (5),

$$h_{1,3} = \max(h_1, h_3 - b_1) \quad \text{and} \quad h_{3,1} = \max(h_3, h_1 - b_3).$$

By Claim 2, $b_3 \geqq 1$. Therefore, $h_{3,1} \leqq \max(h_3, h_1)$. If $h_1 \geqq h_3$ then $h_{3,1} \leqq h_1 \leqq h_{1,3}$. Also, if $b_1 \leqq 0$ then $h_{1,3} \geqq \max(h_1, h_3) \geqq h_{3,1}$. In either case this leads to $h_{3,1} \leqq h_{1,3}$. Consider a sequential evaluation S'' that is identical to S except that F^v is computed before T_u. S'' has less bouncing operations than S. Let PQ'' be the ρ-efficient evaluation compatible with S''. By Lemma 5.3(ii), $\rho(S'') \leqq \rho(S)$. Since $h_{3,1} \leqq h_{1,3}$, by Lemmas 4.3 and 3.5, $|PQ''| \leqq |PQ|$ which is impossible. This completes the proof of Claim 3. □

Combining this with $h_2 = h_4$, (i) is proved.

Proof of (ii) By contradiction, assume that $\rho(\bar{S}) = \rho(S)$. Let $\overline{PQ} = P^*_\infty(\bar{S})$. We will show that this implies $h(\overline{PQ}|PQ^4|PQ^3) \leqq h(\overline{PQ}|PQ^3|PQ^4)$, leading to $|PQ'| \leqq |PQ|$. By (5),

$$\begin{aligned} h(\overline{PQ}|PQ^3|PQ^4) &= \max(h(\overline{PQ}), h_3 - b(\overline{PQ}), h_4 - b(\overline{PQ}) - b_3) \\ &\geqq \max(h(\overline{PQ}), h_3 - b(\overline{PQ})) \end{aligned}$$

and

$$h(\overline{PQ}|PQ^4|PQ^3) = \max(h(\overline{PQ}), h_4 - b(\overline{PQ}), h_3 - (\overline{PQ}) - b_4).$$

By Lemma 5.1(i) and (ii), $\rho(PQ^2) \leqq \rho(S) - 1$. Therefore, by Corollary 3.7, $h_4 = h_2 \leqq \rho(S) - 1$. By Corollary 3.8, $t(\overline{PQ}) \geqq \rho(S) - 1$. Thus, $h_4 - b(\overline{PQ}) = h_4 - t(\overline{PQ}) + h(\overline{PQ}) \leqq h(\overline{PQ})$. Therefore, $h(\overline{PQ}|PQ^4|PQ^3) = \max(h(\overline{PQ}), h_3 - b(\overline{PQ}) - b_4)$. Since $b_4 = b_2 + 1 \geqq 0$, $h(\overline{PQ}|PQ^4|PQ^3) \leqq h(\overline{PQ}|PQ^3|PQ^4)$.

Proof of (iii). Since u is not used in S^3, by Lemma 5.1(i) and (ii), $\rho(S^3) \leqq \rho(S) - 1$. Also, since the results of F^v are not used in T_w, $\rho(S^2) \leqq \rho(S) - 1$. □

THEOREM 5.5. DPA *produces an optimal evaluation for* T *if one of the following conditions is fulfilled*:

(i) *The number* uop *of unary arithmetic operations is at most three.*

(ii) *The number* R *of machine registers is at most four.*

(iii) T *has at most* 16 *vertices.*

Proof. (i) Let PQ be an optimal parallel evaluation of a tree T compatible with a sequential evaluation S having a minimal number of bouncing operations. By Theorem 4.4, we can assume that the number of bouncing operations in PQ is greater than zero. Let v be the leftmost bouncing operation of PQ, and let u and w be the normal children of v. Let T_u, T_w, and F^v be induced by v and S. Let the number of useful results computed in F^v be k. Let the projection of S on the vertices of T_u, T_w, and F^v be S^1, S^2, and S^3, respectively, and let PQ^1, PQ^2, and PQ^3 be the corresponding compatible consecutive evaluations. Since v is the leftmost bouncing operation of PQ, all the operations of F^v are normal, and therefore, we can apply Lemma 5.4(i) to PQ to get

$$b_1, b_3 \geqq 1 \quad \text{and} \quad h_1 < h_3 < h_2.$$

As $b_1, b_3 \geqq 1$, T_u and F^v must have at least two unary operations each. These unary operations are also unary in T. Therefore, $uop \geqq 4$.

(ii) By $h_2 > h_3 > h_1 \geqq 1$, $h_3 \geqq 2$ and $h_2 \geqq 3$. By applying Lemma 5.2 to $S^1|S^3$ and S^2, we get

$$h_2 \leqq \rho((S^1|S^3)|S^2) - k - 1.$$

Applying Lemma 5.1(i) twice we get $\rho(S) \geqq \rho((S^1|S^3)|S^2)$. Combining with $k \geqq 1$ and $h_2 \geqq 3$, we get $\rho(S) \geqq 5$, i.e., at least five registers are needed to compute S.

(iii) Since u and w are normal in S, $PQ^1 = PQ_u[\rho(S^1)]$ and $PQ^2 = PQ_w[\rho(S^2)]$. By Corollary 4.9,

$$h(PQ^1) \leqq \lfloor \log(n_u - uop_u + 1) \rfloor \quad \text{and} \quad h(PQ^2) \leqq \lfloor \log(n_w - uop_w + 1) \rfloor.$$

As $uop_u \geqq 2$ and $h_1 \geqq 1$, we get $n_u \geqq 3$. Also, since $h_2 \geqq 3$, $n_w - uop_w + 1 \geqq 8$. Therefore, $n_w \geqq 7$. Since $h_3 \geqq 2$ and $b_3 \geqq 1$, $t_3 \geqq 3$. Therefore, there are at least two loads and three arithmetic operations in PQ^3. Thus, $n(F^v) \geqq 5$. Taking into account v and the root of T (which is different than v as F^v and T_v are disjoint), we get $n \geqq 17$.

We see that PQ has one bouncing operation only if $uop \geqq 4$, $R \geqq 5$, and $n \geqq 17$. Otherwise there are no bouncing operations, and by Theorem 4.4, DPA yields an optimal schedule. □

The bounds on n, uop and R proved in Theorem 5.5 are tight. Consider, for example, the tree T of Fig. 1. It has $n = 17$ and $uop = 4$. The normal evaluation of T computed by DPA for $r \geqq 4$ is PQ^5 of Fig. 2 and its completion time is 12. PQ^6 of Fig. 2 is an optimal evaluation of T, its completion time is 11 and the number of registers that it uses is five.

LEMMA 5.6. *Let PQ be an optimal evaluation of T that is compatible with a sequential evaluation S. Let T' be a full binary subtree of T. Then, T' is normal in PQ.*

Proof. By contradiction, assume that T' is not normal in PQ. Let v be the leftmost bouncing operation of T'. Then, the children of v are normal. Let T_u, T_w, and F^v be induced by v and S. Also, let m and k be the number of useful results computed by S before T_u and T_w, respectively.

Case 1. $k \geqq m + 1$.

Then, we can apply Lemma 5.4(i) and get $b_1 \geqq 1$. Thus, $uop_u \geqq 2$, but this is impossible since T' is a full binary tree.

Case 2. $k < m + 1$.

Let S^1 and S^3 be the projection of S on the vertices of T_u and F^v, respectively, and let PQ^1 and PQ^3 be the corresponding compatible consecutive evaluations.

CLAIM 1. $b_3 \geqq 1$.

Proof of Claim 1. Let s be the number of results computed in S before T_u and used in F^v. Thus, F^v generates $k - 1 - (m - s)$ useful results. Since the balance of every tree in F^v is at least -1, we get $b_3 \geqq (-1)(k - 1 - (m - s)) = m - s - k + 1$. Since S is canonical, for each result computed before T_u and used in F^v a unary operation is generated in F^v. Since there are s such results, we get $b_3 \geqq m - k + 1 \geqq 1$. □

Now we complete the proof of Case 2. Consider a sequential evaluation S'' that is identical to S except that F^v is computed before T_u. Since v is normal in S'', the number of bouncing operations of S'' is strictly smaller than that of S. By Lemma 5.3(iii), $\rho(S'') \leqq \rho(S)$. Let PQ'' be the ρ-efficient evaluation that is compatible with S''. We will use the fact that $|PQ''| > |PQ|$, since otherwise PQ could not have been an optimal evaluation with a minimal number of bouncing operations. By (5),

$$h_{1,3} = \max(h_1, h_3 - b_1) \quad \text{and} \quad h_{3,1} = \max(h_3, h_1 - b_3).$$

By Claim 1, $b_3 \geq 1$. Therefore, $h_{3,1} \leq \max(h_3, h_1)$. If $b_1 \leq 0$ then $h_{1,3} \geq \max(h_1, h_3) \geq h_{3,1}$. However, if $h_{3,1} \leq h_{1,3}$ then by Lemmas 4.3 and 3.5, $|PQ''| \leq |PQ|$, which is impossible. Therefore, $b_1 \geq 1$. Thus, $uop_u \geq 2$, but this is impossible since T' is a full binary tree. □

Let T be a fixed binary tree, let $v \in T$, and let $T^0 = T_v$. By iteratively deleting the vertices $parent(v) = v_1, v_2, \cdots, root$ on the path from v to the root of T, we create subtrees $T^1, T^2, \cdots$ of T in addition to T^0 (some of these trees may be empty). We denote the forest composed of $T^1, T^2, \cdots$ by $F(v)$. Let S^i be a sequential evaluation of T^i, $i \geq 0$, and assume that for $i \geq 1$, S^i is normal, while S^0 may contain bouncing operations. For a given sequential evaluation S^0, let $\Omega(S^0)$ be the set of all possible evaluations of the form $S^0|S^1|(v_1)|S^2|(v_2)|\cdots|(root)$. Note that if S^0 is a normal evaluation of T_v, then all $S \in \Omega(S^0)$ are normal. Applying Lemma 5.1(ii) several times, we get

$$\rho(S) = \max(\rho(S^0), 1 + \max_{i \geq 1} \rho(S')). \tag{7}$$

Since for every tree T there exists a normal evaluation that computes T with no more than μ registers (Theorem 2.2), there exists $S' \in \Omega(S^0)$ such that

$$\rho(S') = \max(\rho(S^0), 1 + \max_{X \in F(v)} \mu(X)). \tag{8}$$

Let $PQ' = P^*_\infty(S^i)$. Since $P^*_\infty(S') = P^*_\infty(S^0)|P^*_\infty(S^1)|(\text{NOP}, v_1)|\cdots|(\text{NOP}, root)$, by (5),

$$h(S') = \max(h_0, \max_{i \geq 0}(h_{i+1} - b_{v_i})). \tag{9}$$

Note that for all i, $b_{v_i} \geq b_v$.

LEMMA 5.7. *Let PQ be an optimal evaluation of T having a minimal number of bouncing operations, and let S be a compatible sequential evaluation. Let $v \in T$ be a normal vertex in S, and let S^v be the projection of S on the vertices of T_v. If there exists a bouncing operation in S that is executed later than v, then there exists a normal evaluation $\hat{S} \in \Omega(S^v)$ such that $\rho(\hat{S}) \leq \rho(S)$.*

Proof. Applying Lemma 5.1 twice we show that $\rho(S^v) \leq \rho(S)$. Therefore, by (8), to prove the lemma it suffices to show that for every tree $X \in F(v)$, $\mu(X) \leq \rho(S) - 1$. Assume, by contradiction, that there exists a tree $T_u \in F(v)$ such that $\mu_u \geq \rho(S)$. By Lemma 2.1, $\mu \geq \mu_u$, implying $\mu_u \leq \rho(S)$. Therefore, we assume that $\mu_u = \rho(S)$.

Let S^0 be the projection of S on the vertices of T_u. By (8), there exists a sequential evaluation $S' \in \Omega(S^0)$ such that

$$\rho(S') = \max(\rho(S^0), 1 + \max_{X \in F(u)} \mu(X)).$$

Let PQ' be the ρ-efficient evaluation compatible with S'. We wish to prove the following:

(i) The number of bouncing operations in S' is strictly smaller than that of S.

(ii) $\rho(S') \leq \rho(S)$.

(iii) $|P^*_\infty(S')| \leq |P^*_\infty(S)|$.

Since, by Lemma 3.5, $|P^*_\infty(S')| \leq |P^*_\infty(S)|$ implies that $|PQ'| \leq |PQ|$, this will contradict the assumption that PQ is an optimal evaluation with a minimal number of bouncing operations.

Proof of (i). First note that the only bouncing operations of S' are those of S^0 and that u does not bounce. Furthermore, all the operations of S^0 that are bouncing in S', are also bouncing in S. Therefore, if u is bouncing in S then (i) follows. If u is not bouncing in S then, by Lemma 5.1, T_u is the first subtree of T computed by S. Therefore, T_v is computed in S later than T_u. Since there exists a bouncing operation in S computed later than T_v, there exists a bouncing operation computed later than T_u. Since this operation is not bouncing in S', (i) follows.

Proof of (ii). Since $\rho(S^0)=\rho(S)$, we only have to prove that for all $X\in F(u)$, $\mu(X)\leqq\rho(S)-1$. If, by contradiction, there exists $T_w\in F(u)$ such that $\mu_w=\rho(S)$, then T must contain two disjoint subtrees T_u and T_w such that $\mu_u=\mu_w=\rho(S)$. By Lemma 2.1, this leads to $\mu\geqq\mu_u+1=\rho(S)+1$, which is impossible.

Proof of (iii). Let i be the earliest time slot in which some $S_i\notin T_u$ is computed. (If $S_1\notin T_u$ then $i=1$.) Let $\bar{S}=S_1,\cdots,S_{i-1}$, and let $\underline{S}=S_i^0,\cdots,S_{|S^0|}^0$. (If $i=1$, then $\bar{S}$ is empty.) Note that $\bar{S}=S_1^0,\cdots,S_{i-1}^0$.

CLAIM 1. $\rho(\bar{S})=\mu_u$.

Proof of Claim 1. As $\mu_u=\rho(S)$, $\rho(\bar{S})$ cannot be larger than μ_u. Assume, by contradiction, that $\rho(\bar{S})<\mu_u$. By the choice of i, $\bar{S}$ computes a (possible empty) part of T_u. Since $\rho(S^0)=\mu_u$ and $\rho(\bar{S})<\mu_u$, there exists $j\geqq i$ such that $\rho_j(S_0)=\mu_u$. In time slot i, $S_i\notin T_u$ is computed. Therefore, by Lemma 5.1(ii), there exists $j>i$ such that $\rho_j(S)=\mu_u+1$, which is impossible. □

CLAIM 2. $\rho(\underline{S})<\mu_u$.

Proof of Claim 2. If $\rho(\underline{S})=\mu_u$ then since $S_i\notin T_u$ is computed, by Lemma 5.1(ii), there exists $j>i$ such that $\rho_j(S)=\mu_u+1$, which is impossible. □

CLAIM 3. $h(S)\geqq h(S^0)$.

Proof of Claim 3. Since $\bar{S}$ is a prefix of S, by (5), $h(S)\geqq h(\bar{S})$. Also, $P_\infty^*(S^0)=P_\infty^*(\bar{S})|P_\infty^*(\underline{S})$. Therefore, by (5),

$$h(S^0)=\max\,(h(\bar{S}),\,h(\underline{S})-b(\bar{S}))=\max\,(h(\bar{S}),\,h(\underline{S})-t(\bar{S})+h(\bar{S})).$$

By Claim 1, $\rho(\bar{S})=\mu_u$. Therefore, by Corollary 3.8, $t(\bar{S})\geqq\rho(\bar{S})-1=\mu_u-1$. By Claim 2, $\rho(\underline{S})<\mu_u$. Therefore, by Corollary 3.7, $h(\underline{S})\leqq\rho(\underline{S})\leqq\mu_u-1$. Therefore, $h(\underline{S})\leqq t(\bar{S})$ yielding $h(S^0)=h(\bar{S})$, and Claim 3 follows. □

Now we complete the proof of (iii). Let S^i be the projection of S' on the vertices of $T^i\in F(u)$. Since $S'\in\Omega(S^0)$, S' has the form $S^0|S^1|(u_1)|S^2|\cdots|(root)$. Therefore,

$$P_\infty^*(S')=P_\infty^*(S^0)|P_\infty^*(S^0)|P_\infty^*(S^1)|(\mathrm{NOP},\,u_1)|P_\infty^*(S^2)|\cdots|(\mathrm{NOP},\,root).$$

Note that, by the associativity property of concatenation (Lemma 4.2), the parentheses are not needed here. Let $h_i=h(S^i)$, $t_i=t(S^i)$, and $b_i=b(S^i)$. By Corollary 3.7, $h_i\leqq\rho(S^i)$. By the choice of S', $\rho(S^i)=\mu(T^i)$. As in (ii) above, for every subtree $X\in F(u)$, $\mu(X)\leqq\rho(S)-1$. Therefore, for all $i\geqq1$, $h_i\leqq\rho(S)-1$. Also, by Corollary 3.8, $t_0\geqq\rho(S^0)-1=\rho(S)-1$. By (5),

$$h_{0,1}=\max\,(h_0,\,h_1-b_0)=\max\,(h_0,\,h_1-t_0+h_0).$$

Since $t_0\geqq h_1$, $h_{0,1}=h_0$. Also, since $\rho(S^0|S^1)=\rho(S)$, by Corollary 3.8, $t_{0,1}\geqq\rho(S)-1$. We can continue this argument with $S^0|S^1$ and u_1 and iteratively with the rest of S' to show that $h(S')=h_0$. Since, by Claim 3, $h(S)\geqq h_0$, we get $h(S')\leqq h(S)$, and (iii) is proved. □

LEMMA 5.8. *For $v\in T$ let S^v be a normal evaluation of T_v. Then there exists a normal evaluation $S'\in\Omega(S^v)$ of T such that $\rho(S')\leqq\max\,(\rho(S^v),1+\mu)$.*

Proof. By (8), there exists $S'\in\Omega(S^v)$ such that

$$\rho(S')=\max\,(\rho(S^v),1+\max_{X\in F(v)}\mu(X)).$$

Since for every $X\in F(v)$, $\mu(X)\leqq\mu$, the lemma holds. □

6. Worse-case analysis of DPA. As proved in § 5, DPA does not always find optimal evaluations. Let T be a fixed binary tree rooted at *root*, and assume that DPA is not optimal for T. Let PQ be a fixed optimal ρ-efficient evaluation of T that has a minimal number (greater than zero) of bouncing operations, and let S be a compatible

sequential evaluation. Let $copt = |PQ|$ and $hopt = h(S)$. Also, let $cdpa = c(PQ_{root}[\rho(S)])$ and $hdpa = h(PQ_{root}[\rho(S)])$. In this section we derive upper bounds on

$$B = \frac{cdpa}{copt} = \frac{hdpa + a}{hopt + a} = 1 + \frac{hdpa - hopt}{hopt + a}. \tag{10}$$

6.1. Proof of 1.091 bound. It follows from (10) that if we increase *hdpa*, or decrease *hopt*, or decrease *a*, an upper bound for B is obtained. By Lemma 4.5, $hdpa \leqq h(PQ_{root}[\mu])$. Therefore, by Corollary 4.9, $hdpa \leqq \lfloor \log(n - uop + 1) \rfloor$. Since DPA is not optimal, we get $hopt < hdpa$. By Theorem 5.5 this implies that $uop \geqq 4$. Therefore, $hdpa < \log n$, and $a = (n + uop - 1)/2 > n/2$. Substituting into (10) and using $hopt \geqq 1$, we get

$$B < \frac{\log n + n/2}{1 + n/2} < 1 + \frac{2 \log n}{n}.$$

It follows that as n grows, B converges to one. To analyze (10) more precisely, let $hmax = \max_v h(PQ_v[\mu_v])$. By definition, $hmax \geqq h(PQ_{root}[\rho(S)]) = hdpa$.

LEMMA 6.1. $hmax \geqq hdpa + 1$.

Proof. By contradiction, assume that $hmax = hdpa$. Let v be the leftmost bouncing operation of S. Let T_u, T_w, and F^v be induced by v and S. Let the projection of S on the vertices of T_u and T_w be S^u and S^w, respectively. Let $PQ^u = P^*_\infty(S^u)$ and $PQ^w = P^*_\infty(S^w)$. By Lemma 5.4(i), $b_u \geqq 1$ and $h_u \leqq h_w - 2$. Since we can assume that every normal subtree of T is computed in S in the order of evaluation determined by DPA, $h_w \leqq hmax = hdpa$. Therefore, $h_u \leqq hdpa - 2$. By Lemma 5.7, there exists a sequential evaluation $S' \in \Omega(S^u)$ such that $\rho(S') \leqq \rho(S)$. Since S^u is a normal evaluation of T_u, S' is a normal evaluation of T. Let S^i be the projection of S' on the vertices of $T^i \in F(u)$, and let $PQ^i = P^*_\infty(S^i)$. Since S^i is a normal evaluation, $h_i \leqq hmax$. By (9), using $h_0 = h_u \leqq hdpa - 2$, $b_{v_i} \geqq b_u \geqq 1$, and $h_i \leqq hmax = hdpa$, we get $h(S') \leqq hdpa - 1$. Since $\rho(S') \leqq \rho(S)$, this contradicts Theorem 4.4 and completes the proof. □

Consider the vertex v of T at which $h(PQ_v[\mu_v]) = hmax$. We say that T_v is a *maximal subtree of* T if there does not exists a vertex $w \in T_v$ other than v such that $h(PQ_w[\mu_w]) = hmax$. By Lemma 4.7, a maximal subtree of T is a full binary tree. Thus, by Lemma 5.6, maximal subtrees of T are normal in S. In the sequel we denote maximal subtrees by *TMAX*. In the next lemma we establish the lower bound on the number a of the arithmetic operations of T as a function of *hmax*.

LEMMA 6.2. $a \geqq 2^{hmax-1} + 6$.

Proof. Let *TMAX* be a maximal subtree of T. Then, by Lemma 4.7, *TMAX* is a full binary tree. Also, by Corollary 4.10, $a(TMAX) \geqq 2^{hmax-1} - 1$. Let v be the leftmost bouncing operation of S. Let T_u, T_w, and F^v be induced by v and S. Note that by Lemma 5.6, $v \notin TMAX$ since v is bouncing. Also, the root of T cannot belong to *TMAX* as T cannot be a full binary tree. Let the projection of S on the vertices of T_u, T_w, and F^v be S^1, S^2, and S^3, respectively. Let $PQ^1 = P^*_\infty(S^1)$, $PQ^2 = P^*_\infty(S^2)$, and $PQ^3 = P^*_\infty(S^3)$. By Lemma 5.4(i), $b_1, b_3 \geqq 1$ and $h_2 > h_3 > h_1$. Therefore, $h_3 \geqq 2$ and $h_2 \geqq 3$. Since $b_1 \geqq 1$, $a_u \geqq 2$. By Corollary 4.10, $h_2 \geqq 3$ implies $a_w \geqq 3$. Since $h_3 \geqq 2$ and $b_3 \geqq 1$, $t_3 \geqq 3$. Therefore, $a(F^v) \geqq 3$. Since *TMAX* may belong to either T_u, T_w, or F^v, taking into account v and the root of T, we get

$$a \geqq a(TMAX) + a_u + a_w + a(F^v) + 2 - \max(a_u, a_w, a(F^v)) \geqq 2^{hmax-1} + 6. \qquad \square$$

By substituting the result of Lemma 6.2 into (10) we obtain

$$B \leqq 1 + (hdpa - hopt)/(hopt + 2^{hmax-1} + 6). \tag{11}$$

Assume that $hmax \geqq hdpa+2$. B achieves the largest value when $hmax = hdpa+2$. Substituting this into (11) results in

$$B \leqq 1+\frac{hdpa-hopt}{hopt+2^{hdpa+1}+6}$$

where the maximum value of B is 1.087 when $hopt = 1$ and $hdpa = 3$. In what follows we assume that $hmax = hdpa+1$, and thus (11) reduces to

$$B \leqq 1+\frac{hdpa-hopt}{hopt+2^{hdpa}+6}. \tag{12}$$

Assume that $hopt \geqq 2$. The largest value of B is achieved for $hopt = 2$. Substituting this into (12), we obtain

$$B \leqq 1+\frac{hdpa-2}{2^{hdpa}+8}$$

and B is bounded by 1.083. Therefore, hereafter we assume that $hopt = 1$. Substituting this into (12), we obtain

$$B \leqq 1+\frac{hdpa-1}{2^{hdpa}+7}.$$

For $hdpa \geqq 6$ and $hdpa = 2$, $B \leqq 1.091$. Therefore, in the sequel we can assume $3 \leqq hdpa \leqq 5$. We summarize the assumptions that will be used in the rest of this section:

(A1) $hopt = 1$.

(A2) $hmax = hdpa+1$.

(A3) $3 \leqq hdpa \leqq 5$.

LEMMA 6.3. *Let $u \in T$ be a normal vertex in S. Let S^u be the projection of S on the vertices of T_u. If S has at least one bouncing operation computed after u and $h(S^u) \leqq hdpa-1$ then $b_u \leqq 1$.*

Proof. Assume, by contradiction, that such vertex u exists, but $b_u \geqq 2$. Since there is at least one bouncing operation in S performed after u, by Lemma 5.7, there exists a normal sequential evaluation $S' \in \Omega(S^u)$ such that $\rho(S') \leqq \rho(S)$. By (9), using $h_0 = h(S^u) \leqq hdpa-1$, $b_{v_i} \geqq b_u \geqq 2$ and $h_i \leqq hmax = hdpa+1$, we get $h(S') \leqq hdpa-1$, contradicting Theorem 4.4. □

LEMMA 6.4. *Let TMAX be a maximal subtree of T. If TMAX is computed in S before the leftmost bouncing operation then*:

(i) $uop \geqq 6$.

(ii) $\rho(S) \geqq 3+\mu(TMAX)$.

(iii) *There exist two disjoint subtrees T_x and T_y of T computed before TMAX such that*:

(a) $b_x, b_y = 1$.

(b) *Let S^x and S^y be the projection of S on the vertices of T_x and T_y, respectively. Then $h(S^x)$, $h(S^y) \leqq hdpa-1$.*

Proof. *TMAX* cannot be the first tree to be computed in S since otherwise, $hopt \geqq hmax$ would contradict assumption (A1). Let $\bar{S}$ be the prefix of S ending just

before *TMAX*. Let *SMAX* be the projection of S on the vertices of *TMAX*. $h(P^*_\infty(\bar{S})|P^*_\infty(SMAX)) \leqq hopt = 1$. However, by (5), $h(P^*_\infty(\bar{S})|P^*_\infty(SMAX)) \geqq h(SMAX) - b(\bar{S})$, leading to $1 \geqq hmax - b(\bar{S})$. Therefore, $b(\bar{S}) \geqq hmax - 1 \geqq 3$. Thus, there are at least four unary operators before *TMAX* in S. Let these unary operators be $u_1, u_2, \cdots$ and assume that they appear in the same order as in S. For every vertex u_i there exists a unique subtree T^i of T rooted at $root_i$ such that $u_i \in T^i$ and $parent(root_i)$ is not scheduled before *TMAX*. Let $\bar{T}^1, \bar{T}^2, \cdots, \bar{T}^k$ be the subsequence of $T^1, T^2, \cdots$ such that $b(\bar{T}^i) > 0$. Let $\bar{S}^i$ be the projection of S on $\bar{T}^i$ and let $\underline{S}^i$ be the prefix of S that ends just before $\bar{T}^i$.

CLAIM 1. $\bar{T}^1$ and $\bar{T}^2$ exist and $b(\bar{T}^1) = b(\bar{T}^2) = 1$.

Proof of Claim 1. We repeat the following argument for $j = 1$ and $j = 2$. If $h(\bar{S}^j) \leqq hdpa - 1$ then the claim follows from Lemma 6.3. Otherwise, $h(\bar{S}^j) \geqq hdpa$. Since by (A3), $hdpa \geqq 3$, $\bar{S}^j$ cannot be a prefix of S. Therefore, $\underline{S}^j$ is not empty. By (5), $h(P^*_\infty(\underline{S}^j)|P^*_\infty(\bar{S}^j)) \geqq h(\bar{S}^j) - b(\underline{S}^j)$. (A1) implies

$$1 \geqq h(\bar{S}^j) - b(\underline{S}^j) \geqq hdpa - b(\underline{S}^j). \tag{13}$$

Since $\bar{T}^1$ is the leftmost tree with positive balance and $\underline{S}^1$ precedes $\bar{T}^1$, $b(\underline{S}^1) = 0$, and a contradiction to (A3) is obtained. Therefore, $b(\bar{T}^1) = 1$. Now we can plug $b(\underline{S}^2) = b(\bar{S}^1) = 1$ into (13) to obtain a contradiction to (A3). Therefore, $b(\bar{T}^2) = 1$. □

Note that $\bar{T}^1$ and $\bar{T}^2$ fulfill the conditions of (iii), and therefore, this proves (iii).

CLAIM 2. $\bar{T}^3$ exists.

Proof of Claim 2. By Claim 1, $\bar{T}^1$ and $\bar{T}^2$ contribute a total balance of 2. Since $b(\bar{S}) \geqq 3$, a third tree of positive balance must exist. □

Now we complete the proof of (i) and (ii). Since $\bar{T}^1$, $\bar{T}^2$, and $\bar{T}^3$ are disjoint trees with positive balance, each has two unary operations, proving (i). Also, at least three registers must hold the results computed those trees before *TMAX* is computed, proving (ii). □

LEMMA 6.5. *Let TMAX be a maximal subtree of T. If* $B > 1.091$ *then* $\mu = \mu(TMAX)$.

Proof. Assume, by contradiction, that $\mu > \mu(TMAX)$. Then, by Lemma 2.1, there exists at least one subtree T_x of T that is disjoint of *TMAX* and such that $\mu_x \geqq \mu(TMAX)$. By Lemma 4.8, $bop(TMAX)$, $bop_x \geqq 2^{\mu(TMAX)-1} - 1$. Since by Lemma 4.7, *TMAX* is a full binary tree, by Lemma 4.6, $hmax = \mu(TMAX)$. Also, by (A2), $hmax = hdpa + 1$. Therefore, $bop(TMAX)$, $bop_x \geqq 2^{hdpa} - 1$. We proceed by case analyses.

Case 1. $hdpa = 3$. By (10), to achieve $B > 1.091$ we need $a \leqq 20$. $bop(TMAX)$, $bop_x \geqq 7$. Let v be the leftmost bouncing operation of S. Since by Lemma 4.7, *TMAX* is a full binary tree, $v \notin TMAX$. If *TMAX* is computed before v then by Lemma 6.4(i), $uop \geqq 6$, leading to $a \geqq 21$. Therefore, we may assume that *TMAX* is computed after v.

Let T_u, T_w, and F^v be induced by v and S. Let S^1, S^2, and S^3 be the projection of S on the vertices of T_u, T_w, and F^v, respectively. Let $PQ^1 = P^*_\infty(S^1)$, $PQ^2 = P^*_\infty(S^2)$, and $PQ^3 = P^*_\infty(S^3)$. Since $b_1, b_3 \geqq 1$, we get $uop_u \geqq 2$ and $uop(F^v) \geqq 2$. Since the root of T belongs neither to *TMAX* nor T_x, we get

$$a \geqq bop(TMAX) + bop_x + 1 + uop_u + uop(F^v) \geqq 19. \tag{14}$$

We want to show that T has at least two more arithmetic vertices, contradicting $a \leqq 20$. First, consider $a(F^v)$. By Lemma 5.4(i), $h_1 < h_3$ and $b_3 \geqq 1$. Therefore, $h_3 \geqq 2$ and $t_3 \geqq 3$, implying $a(F^v) \geqq 3$. Second, consider a_w. Using Lemma 5.4(i) again we get $h_2 \geqq 3$ and by Corollary 4.10, $a_w \geqq 3$.

CLAIM 1. $v \in T_x$.

Proof of Claim 1. Otherwise, v is not counted in the above 19 vertices, and we have 20 vertices already. Since $a_w \geqq 3$ and *TMAX* is computed after v, $w \in T_x$. But then only two operations of F^v have been counted in (14). Since $a(F^v) \geqq 3$, we would get $a \geqq 21$. □

CLAIM 2. F^v is a subforest of T_x.

Proof of Claim 2. By Claim 1, F^v cannot contain T_x. Therefore, we have to show that T_x and F^v cannot be disjoint. If they are disjoint, then by $a(F^v) \geqq 3$, one of the vertices of F^v is not counted in (14), and we get $a \geqq 20$. However, T now contains three disjoint subforests, T_x, *TMAX* and F^v. The root of T can combine at most two of them, and we need at least one additional vertex that has not been counted before to build a single tree out of T_x, *TMAX*, and F^v, proving Claim 2. □

Consider $F(u)$. It consists of at least three trees, namely, T_w, F^v, and *TMAX*. Therefore, there are at least three binary vertices of T that do not belong to any of the trees of $F(u)$. By Lemma 5.7, there exists a normal evaluation $S' \in \Omega(S^1)$ such that $\rho(S') \leqq \rho(S)$.

CLAIM 3. Let $T_y \in F(u)$ be such that *TMAX* is not a subtree of T_y. Then $\mu_y < hmax$.

Proof of Claim 3. Otherwise, by Lemma 4.8, $bop_y \geqq 7$. Therefore, counting three for the binary vertices of T that belong to the path from u to the root of T, we get $a \geqq bop_y + bop(TMAX) + 3 + uop_u + uop(F^v) \geqq 21$. □

Now we complete the proof of Case 1. Remember that T_x and *TMAX* are disjoint. By Claim 1, $v \in T_x$, and therefore, $u \in T_x$. Since S' starts by evaluating T_u, the computation of T_x in S' is completed before *TMAX* even starts. By Claim 1, $v \in T_x$, and by Claim 2, F^v is a subforest of T_x. Therefore, $b_x \geqq b_u + b(F^v) \geqq 2$. Also, since by Lemma 5.4(i), $h_1 < h_3 < h_2 \leqq hmax$, by (A2), we get $h_1 \leqq hdpa - 1$. Also, by Claim 3, for every $T_y \in F(u)$ other than the one containing *TMAX*, $\mu_y \leqq hmax - 1 = hdpa$. Therefore, by Corollary 3.7, for every evaluation S^y of T_y, $h(S^y) \leqq \mu_y \leqq hdpa$. Summarizing the information needed to apply (9), we get the following:

(a) For T_u, $h_1 \leqq hdpa - 1$.

(b) For every $T^i \in F(u)$ such that *TMAX* is not a subtree of T^i, $h_i \leqq hdpa$, and $b_{v_i - 1} \geqq b_u \geqq 1$.

(c) For $T^j \in F(u)$ such that *TMAX* is a subtree of T^j, $h_j \leqq hmax = hdpa + 1$, and $b_{v_{j-1}} \geqq b_x \geqq b_u + b(F^v) \geqq 2$.

Thus, we can apply (9) and get $h(S') \leqq hdpa - 1$, contradicting Theorem 4.4.

Case 2. $hdpa = 4$. By (10), to achieve $B > 1.091$ we need $a \leqq 31$. Since $bop(TMAX)$, $bop_x \geqq 15$, and by Theorem 5.5, $uop \geqq 4$, we get $a \geqq 34$, a contradiction.

Case 3. $hdpa = 5$. By (10), to achieve $B > 1.091$ we need $a \leqq 42$. Since $bop(TMAX)$, $bop_x \geqq 31$, we get $a \geqq 62$, a contradiction. □

Since by Lemma 4.7, *TMAX* is a full binary tree, by Lemma 4.6, $\mu(TMAX) = hmax$. Therefore, if more than one maximal subtree of T would exist then, by Lemma 2.1, $\mu \geqq hmax + 1 = \mu(TMAX) + 1$ contradicting Lemma 6.5. Therefore, we can make the following additional assumptions:

(A4) T has a unique maximal tree, denoted *TMAX*.

(A5) $\mu = \mu(TMAX)$.

LEMMA 6.6. *Let v be the leftmost bouncing operation of S. Let T_u, T_w, and F^v be induced by v and S. Assume that TMAX and T_u are disjoint. There exists a subtree T_x of T with the following properties*:

(i) *T_x is computed in S before v.*

(ii) *T_x and TMAX are disjoint.*

(iii) *T_x and T_u are disjoint.*

(iv) $b_x \geqq 1$.

Let S^x be the projection of S on the vertices of T_x:

(v) $\rho(S^x) \leqq \rho(S) - 1$.

(vi) $h(S^x) \leqq hdpa - 1$.

Proof. Let S^1, S^2, and S^3 be the projection of S on the vertices of T_u, T_w, and F^v, respectively. Let $PQ^1 = P^*_\infty(S^1)$, $PQ^2 = P^*_\infty(S^2)$, and $PQ^3 = P^*_\infty(S^3)$. By Lemma 5.4(i), $b_1, b_3 \geqq 1$ and $h_1 < h_3 < h_2$. Since $h_2 \leqq hmax$, (A2) implies $h_1 \leqq hdpa - 1$.

Case 1. *TMAX* is computed in S after v.

By (A4), T_w cannot be maximal, and therefore, $h_2 < hmax$. By (A2), $h_3 \leqq h_2 - 1 \leqq hmax - 2 = hdpa - 1$. F^v is a forest with one or more trees. Since $b_3 = b(F^v) \geqq 1$, at least one of these trees has positive balance. Let $x \in F^v$ be the leftmost vertex of S such that $b_x \geqq 1$. Part (iv) holds by the construction. Also, since $x \in F^v$, (i), (ii), and (iii) hold. Since, by Lemma 5.4(iii), $\rho(S^x) \leqq \rho(S) - 1$, (v) holds. To prove (vi) let $\bar{S}$ be the (possibly empty) prefix of S^3 that is computed before T_x. By the choice of T_x, $b(\bar{S}) \leqq 0$. By (5), we get

$$hdpa - 1 \geqq h_3 \geqq \max(h(\bar{S}), h(S^x) - b(\bar{S})) \geqq h(S^x).$$

Therefore, (vi) holds.

Case 2. *TMAX* is computed in S before v.

By Lemmas 5.4(i) and 6.3, $b_1 = 1$. By Lemma 6.4(iii), there exist two disjoint subtrees T_x and T_y of T satisfying (i), (ii), (iv), and (vi). They cannot both be subtrees of T_u since $b_1 = 1$. Therefore, at least one of them satisfies (iii). Let this subtree be T_x. Since T_x is computed in S before v, it may be computed in S before F^v, or $x \in F^v$, or $x \in T_w$. By Lemma 5.4(ii) and (iii), in either case $\rho(S^x) \leqq \rho(S) - 1$. Therefore, (v) holds, and we are done. □

THEOREM 6.7. $B = cdpa/copt \leqq 1.091$.

Proof. Assume, by contradiction, that $B > 1.091$. Let v be the leftmost bouncing operation of S. Let T_u, T_w, and F^v be induced by v and S. Let S^u and S^w be the projection of S on the vertices of T_u and T_w, respectively. Let $PQ^u = P^*_\infty(S^u)$ and $PQ^w = P^*_\infty(S^w)$. By Lemma 5.4(i), $b_u \geqq 1$ and $h_w - 1 > h_u \geqq 1$. Therefore, by (A2), $h_u \leqq hdpa - 1$. By (A4), T has a unique maximal subtree *TMAX*.

CLAIM 1. *TMAX* and T_u are disjoint.

Proof of Claim 1. Otherwise, *TMAX* is a subtree of T_u. By Lemma 5.7, there exists a normal evaluation $S' \in \Omega(S^u)$ such that $\rho(S') \leqq \rho(S)$. Summarizing the information needed to apply (9), we get the following:

(a) $h_u \leqq hdpa - 1$.

(b) By (A4), no $T^i \in F(u)$ is maximal. Therefore, by (A2), $h_i \leqq hmax - 1 = hdpa$. Also, $b_{v_{i-1}} \geqq b_u \geqq 1$. Therefore, we can apply (9) and get $h(S') \leqq hdpa - 1$, contradicting Theorem 4.4. □

Let $T_y \in F(u)$ be a subtree of T such that *TMAX* is a subtree of T_y. Let $z = parent(y)$, and let s be the second child of z. There exists a subtree T_x of T that satisfies conditions (i)-(vi) of Lemma 6.6. Let the projection of S on the vertices of T_x be S^x.

Case 1. $x \in T_z$.

Subcase 1.1. $x \in T_s$. Since T_x is disjoint of T_u, $b_u \geqq 1$, $b_x \geqq 1$, $b_s \geqq 2$. By Lemma 5.7, there exists a normal evaluation $S' \in \Omega(S^1)$ such that $\rho(S') \leqq \rho(S)$. In S', T_s is completed before *TMAX* starts. Again, summarizing the information needed to apply (9), we get the following:

(a) $h_u \leqq hdpa - 1$.

(b) For every $T^i \in F(u)$, $T^i \neq T_y$, by (A2) and (A4), $h_i \leqq hmax - 1 = hdpa$, and $b_{v_{i-1}} \geqq b_u \geqq 1$.

(c) Let $T_y = T^i$. Then $h_i \leqq hmax = hdpa + 1$, and $b_{v_{i-1}} = b_s \geqq b_u + b_x \geqq 2$.

Therefore, we can apply (9) and get $h(S') \leqq hdpa - 1$, contradicting Theorem 4.4.

Subcase 1.2. $x \in T_y$. By (A5), $\mu_y = \mu(TMAX)$. Let us apply Lemma 5.8 to T_y. It follows that there exists a normal evaluation S^y of T_y that computes T_x first by S^x such that $\rho(S^y) \leqq \max(\rho(S^x), 1 + \mu_y)$. If *TMAX* is computed in S before v then, by Lemma 6.4(ii), $\rho(S) \geqq 3 + \mu(TMAX)$. Otherwise, $\rho(S) \geqq 2 + \mu(TMAX)$, since by Lemma 6.6(i) both T_u and T_x are computed in S before v and therefore, before *TMAX*. Therefore, $1 + \mu_y \leqq \rho(S) - 1$. By Lemma 6.6(v), $\rho(S^x) \leqq \rho(S) - 1$. Together, we get $\rho(S^y) \leqq \rho(S) - 1$. By (8), there exists a normal evaluation $S' \in \Omega(S^1)$ such that

$$\rho(S') = \max(\rho(S^u), 1 + \max_{X \in F(u)} \mu(X)).$$

However, we would like to make a stronger assumption on the evaluation of T_y in S', namely, that it is identical to S^y. Then we get

$$\rho(S') = \max(\rho(S^u), 1 + \rho(S^y), 1 + \max_{X \in F(u), X \neq T_y} \mu(X)).$$

By Lemma 5.7, $\rho(S^u)$ and $1 + \max_{X \in F(u), X \neq T_y} \mu(X)$ are both bounded by $\rho(S)$. Since $\rho(S^y) \leqq \rho(S) - 1$, we get $\rho(S') \leqq \rho(S)$.

CLAIM 2. $h(S^y) \leqq hdpa$.

Proof of Claim 2. Note that S^y computes first T_x by S^x and then proceeds with the rest of T_y. Let $\hat{S} \in \Omega(S^x)$ be a sequential evaluation of T whose projection on T_y is S^y. Let S^i be the projection of $\hat{S}$ on the vertices of $T^i \in F(x)$. By Lemma 6.6(vi), $h(S^x) \leqq hdpa - 1$. Also, by Lemma 6.6(iv), $b_x \geqq 1$. Since for every S^i, $h(S^i) \leqq hmax = hdpa + 1$, using (9), we get $h(\hat{S}) \leqq hdpa$. However, since S^y is a prefix of $\hat{S}$, $h(S^y) \leqq h(\hat{S}) \leqq hdpa$. □

Now we complete the proof of Subcase 1.2. Summarizing the information needed to apply (9), we get the following:

(a) $h_u \leqq hdpa - 1$.

(b) Since *TMAX* is a unique maximal subtree of T and by Claim 2, for every $T^i \in F(u)$, $h_i \leqq hmax - 1 = hdpa$.

(c) $b_{v_{i-1}} \geqq b_u \geqq 1$.

Therefore, we can apply (9) and get $h(S') \leqq hdpa - 1$, contradicting Theorem 4.4.

Case 2. $x \notin T_z$. x cannot be an ancestor of z since by the choice of x, T_x, and *TMAX* are disjoint and *TMAX* is a subtree of T_z. Let $T_t \in F(x)$ be the subtree that contains z. By (A5), $\mu_t = \mu(TMAX)$. Let us apply Lemma 5.8 to T_t. It follows that there exists a normal evaluation S^t of T_t that computes T_u first by S^u and $\rho(S^t) \leqq \max(\rho(S^u), 1 + \mu_t)$. If *TMAX* is computed in S before v then, by Lemma 6.4(ii), $\rho(S) \geqq 3 + \mu(TMAX)$. Otherwise, $\rho(S) \geqq 2 + \mu(TMAX)$ since by Lemma 6.6(i), both T_u and T_x are computed in S before v and therefore, before *TMAX*. Therefore, $1 + \mu_t \leqq \rho(S) - 1$. By Lemma 5.4(ii), $\rho(S^u) \leqq \rho(S) - 1$. Together, we get $\rho(S^t) \leqq \rho(S) - 1$. By (8), there exists a normal evaluation $S' \in \Omega(S^x)$ such that

$$\rho(S') = \max(\rho(S^x), 1 + \max_{X \in F(x)} \mu(X)).$$

However, as in Subcase 1.2, we would like to make a stronger assumption on the evaluation of T_t in S', namely, that it is identical to S^t. Then we get

$$\rho(S') = \max(\rho(S^x), 1 + \rho(S^t), 1 + \max_{X \in F(x), X \neq T_t} \mu(X)).$$

By Lemma 5.7, $\rho(S^x)$ and $1+\max_{X\in F(x),X\neq T_t}\mu(X)$ are both bounded by $\rho(S)$. Since $\rho(S')\leqq\rho(S)-1$, we get $\rho(S')\leqq\rho(S)$. Also, note that, by Lemma 6.6(vi), $h_x\leqq hdpa-1$.

CLAIM 3. $h(S')\leqq hdpa$.

Proof of Claim 3. Note that S' first computes T_u by S^u and then proceeds with the rest of T_t. Let $\hat{S}\in\Omega(S^u)$ be a sequential evaluation of T whose projection on T_t is S'. Let S^i be the projection of $\hat{S}$ on the vertices of $T^i\in F(u)$. By Lemma 5.4(i), $h(S^u)\leqq hdpa-1$, and $b_u\geqq 1$. Since for every S^i, $h(S^i)\leqq hmax=hdpa+1$, using (9), we get $h(\hat{S})\leqq hdpa$. However, since S' is a prefix of $\hat{S}$, $h(S')\leqq h(\hat{S})\leqq hdpa$. □

Now we complete the proof of Case 2. Summarizing the information needed to apply (9), we get the following:

(a) $h_x\leqq hdpa-1$.

(b) Since *TMAX* is a unique maximal subtree of T and by Claim 3, for every $T^i\in F(x)$, $h_i\leqq hmax-1=hdpa$.

(c) $b_{v_{i-1}}\geqq b_x\geqq 1$.

Therefore, we can apply (9) and get $h(S')\leqq hdpa-1$, contradicting Theorem 4.4. □

6.2. A worse-case example. In § 6.1, we proved that $B\leqq 1.091$. Actually, for the tree of Fig. 1, $B=1.091$. For five registers or more, the optimal evaluation of this tree is PQ^6 of Fig. 2 with $c=11$, while $c(PQ_{root}[r])=12$ for $r\geqq 4$.

6.3. An ε-approximation scheme. Since $B\to 1$ as $n\to\infty$, we can develop an *ε-approximation algorithm*—given ε, design an algorithm that finds a schedule that is worse than the optimal by at most $B\leqq 1+\varepsilon$. The idea is straightforward: apply some exhaustive algorithm to find optimal schedule for trees with at most n_t vertices, and use DPA for larger trees. Formally, given ε, let n_ε be the solution of $n_\varepsilon=2^{n_\varepsilon\varepsilon/2}$. Since

$$B\leqq 1+2\log\frac{n_\varepsilon}{n_\varepsilon}$$

we get $B\leqq 1+\varepsilon$. For example, for $\varepsilon=0.1$, $n_\varepsilon=144$, and for $\varepsilon=0.01$, $n_\varepsilon=224$.

7. Extensions and open problems. Our results can be extended in a number of ways, but they also leave a few problems open for further research.

7.1. Larger arity. Every operation of our machine model has at most two operands, and therefore, only binary trees have been considered. Obviously, the machine model may be extended to allow larger arity of the expression trees. The DP scheme can be easily extended to nonbinary trees as suggested in [AJ76]. In the extended DP scheme at each internal vertex v all possible orders of computations of the subtrees rooted at the children of v should be considered and a minimal cost evaluation chosen. The complexity of this algorithm is still linear in n, but the amount of work performed at each vertex is exponential in the maximum allowed arity. The question is, how to extend the approximation techniques developed in this paper to nonbinary trees. It turns out that the generalization of our algorithm may yield schedules that are worse than the optimal by d time units even for trees with only $O(d)$ vertices.

7.2. Arbitrary execution times. We can relax our restriction that the execution time of memory access is equal to that of the arithmetic operations. Let τ_1 be the number of machine cycles required for memory access, and τ_2 be the elapsed time of every arithmetic operation. The P_r transformation of § 2.4 can be upgraded to accommodate unequal execution times of machine operations. Arbitrary execution times of operations affect the approximation results derived in § 6. If $\tau_2>\tau_1$ then all the results are valid, and it is even possible to decrease the worse-case ratio of the completion

times of the schedule generated by DPA and the shortest schedule. Moreover, for binary trees if $\tau_2 \geqq 2\tau_1$ then the algorithm becomes optimal since in this case optimal evaluations can always be found among normal form evaluations. By contrast, if $\tau_1 > \tau_2$ then it has an effect similar to that of larger arity (§ 7.1).

7.3. Store operations. Throughout the previous sections we have assumed that it is always possible to compute the given expression tree using R machine registers. Clearly, this assumption does not always holds.

DPA can be extended to a minimal store algorithm (MS) by producing store operations only when needed. Such a treatment of store operations is not general enough as in the dynamic programming algorithm of [AJ76]. It is quite similar to the approach proposed in [SU70] that leads to an optimal algorithm for a class of sequential machines.

In our case, the MS algorithm works fine when the cost of a store operation is significantly larger than the cost of the other operations. However, if a store operation takes about the same time as the other operations, then a new phenomenon arises. Sometimes it is preferable to perform a store operation even if it is not absolutely necessary so as to increase the parallelism between arithmetic and memory operations.

For example, consider the tree of Fig. 4. It can be computed using four registers. Since the minimal number of registers needed to compute T_2 without a store is four, T_2 must be computed first. Then, the cost is 16. But if T_1 is computed first and a store operation is used after the completion of T_1, the cost is reduced to 15. As a consequence of the last observation, more work concerning store operations is needed.

7.4. Different register allocation assumptions. Different classes of machines impose different restrictions on the use of registers. In our machine model, we only assumed that when an arithmetic operation is performed in parallel with a load, results of these

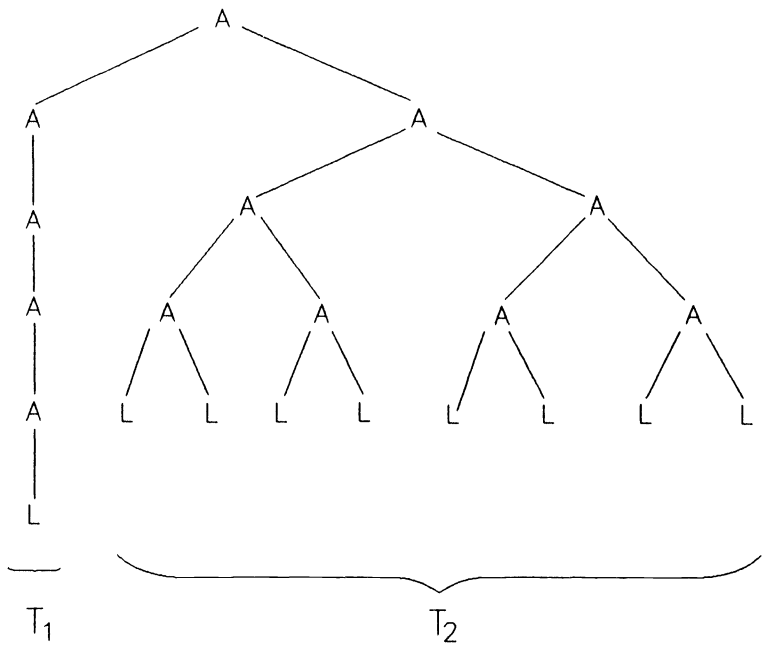

FIG. 4. *The tree demonstrating the store phenomenon.*

two parallel instructions are stored in different registers. Additional constraints on the structure of the machine registers may invalidate our results.

A simple refinement of our machine model is to assume that the register released by a binary arithmetic operation at time slot i cannot be used by a load operation performed in the same time slot. The earliest time that this register can be used again is time slot $i+1$. The main effect of this additional requirement is that an evaluation PQ of width ρ may use $\rho+1$ registers on such machine, i.e., one register more than previously. Still when we allow a number registers $r \geqq \rho(PQ)+1$, the completion time of PQ is the same on both machine models. It can be shown that when the optimal evaluation is bouncing, the number of registers needed by an optimal evaluation is greater than the minimal width of the best normal form evaluation. Therefore, the approximation results of § 6 remain valid.

7.5. ε-approximation algorithms. In § 6 we have shown how an ε-approximation algorithm can be obtained from DPA using the enumeration on the trees with $n \leqq n_\varepsilon$. Clearly, this approach is not practical since even to achieve $\varepsilon = 0.01$ the enumeration should be performed on the trees with $n = 2224$. Another ε-approximation scheme may be developed by keeping several candidates for each $PQ_v[r]$. Analyzing such a scheme is probably a nontrivial job.

7.6. The complexity of the optimal algorithm. This is the major question that remains open.

Appendix. Example for the DPA algorithm. The following example illustrates how DPA processes the vertices of the expression tree of Fig. 1. Let $R = 5$. We organize the results computed by DPA in Tables 1 and 2. The entry in the row v_i and in the column $PQ[j]$ of Table 1 is the $\langle c, h, t\rangle$ triple corresponding to $PQ_{vi}[j]$ where instead of $\langle\infty, \infty, \infty\rangle$ we use a single ∞. The entry in the row v_i and in the column $S[j]$ of Table 2 is the evaluation $S_{v_i}[j]$ that is compatible with $PQ_{vi}[j]$.

COMPUTING SIMPLE CIRCUITS FROM A SET OF LINE SEGMENTS IS NP-COMPLETE*

DAVID RAPPAPORT†

Abstract. Given a collection of line segments in the plane, the segments are connected by their endpoints to construct a simple circuit. (A simple circuit is the boundary of a simple polygon.) However, there are collections of line segments where this cannot be done. In this note it is proved that deciding whether a set of line segments admits a simple circuit is NP-complete. The NP-completeness proof relies on the fact that line segments may intersect at their endpoints. Deciding whether a set of horizontal line segments can be connected with horizontal and vertical line segments to construct an orthogonal simple circuit is also shown to be NP-complete.

Key words. NP-complete problem, Hamiltonian path, Euclidean travelling salesman problem, computational geometry, line segments

AMS(MOS) subject classifications. 68Q15, 68U05

1. Introduction. A natural generalization of the problem of finding simple circuits from a set of points is the problem of finding a simple circuit from a set of line segments. In general a set of line segments does not necessarily admit a simple circuit. An example of a set of line segments that does not admit a simple circuit is given in Fig. 1. An interesting question is when do a set of line segments admit a simple circuit?

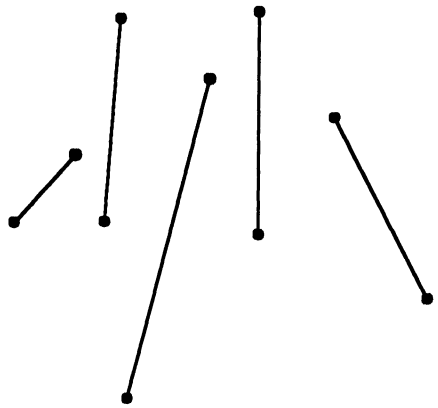

FIG. 1

The task of obtaining a simple circuit from a set of points is a recurring theme that appears in a variety of applications. In network routing problems the tour of shortest Euclidean distance that begins and ends at a common site and visits all other sites exactly once is a simple circuit. This is the Euclidean travelling salesman problem and is known to be NP-hard [3]-[5]. Simple circuits have also been used in the area

of pattern recognition for extracting perceptual information from sparse data [2], [7], [9], [16], [17]. Surprisingly, the problem of computing simple circuits from a set of line segments has not received much attention.

Given a collection of sites on a plane and the requirement that certain sites are visited in a prescribed order, the task of finding a shortest tour reduces to finding shortest tours from a set of line segments, or chains of line segments. If, in addition, edges in the tour that cross greatly increases the cost of the tour (because bridges or tunnels are required) then we are interested in finding a shortest tour with few crossings. In the extreme this reduces to deciding if a set of line segments, or chains of line segments, admits a simple circuit. In the context of pattern recognition, meaningful perceptual information may be obtained from a collection of line segments, or chains of line segments, by computing a minimal set of disjoint simple circuits. Again, in the extreme this problem reduces to deciding if a set of line segments admits one simple circuit.

In [13] it has been shown that, if the set of line segments are constrained so that every segment has at least one of its endpoints on the convex hull of the segments, an $O(n \log n)$ algorithm can be used to determine whether the set admits a simple circuit. Furthermore, we can deliver simple circuits, and optimize over the area and the perimeter of the polygons constructed, in the same time bound. Other special cases of the problem of obtaining a simple circuit from a set of line segments are discussed in [1], [12].

In this note it is shown that to determine whether a set of segments admits a simple circuit is NP-complete. After preliminary definitions a reduction is given to a variant of this problem. In this variant we are given a set of orthogonal line segments and are asked whether we can construct a simple circuit whose edges are orthogonal to the coordinate axes. After proving that the orthogonal simple circuit problem is NP-complete we show that the simple circuit problem is NP-complete. A detail in the proof requires that some of the segments intersect at their endpoints.

2. Preliminaries. A *simple circuit* is a sequence of edges, $e_0, e_1, \cdots, e_{k-1}$, such that for all $0 \leqq i < k$, e_i and $e_{(i+1) \bmod k}$ intersect at their endpoints, and no other intersections between edges occur. A simple circuit is the boundary of a simple polygon. Let S be a set of line segments in the plane. We require that the segments be properly disjoint, that is, no segments intersect in their interiors; however, we permit segments of S to intersect at their endpoints. If a set A can be found such that $S \cup A$ is a simple circuit of $|S|+|A|$ edges, then we say that S *admits* a simple circuit and A is a set of *augmenting segments.* To obtain a set of augmenting segments, we begin by considering a set of segments as *candidates.* We say that two points *see* each other, if the line segment between them does not intersect any segment. Since we are looking for crossing free circuits it is natural to choose as candidates connections of endpoints of segments that see each other.

An *orthogonal simple circuit* is a simple circuit whose edges are orthogonal to the coordinate axes. One can say two points *orthogonally see* each other, if they agree in one of their coordinates and they see each other.

It will be shown that the following problem is NP-complete.

SIMPLE CIRCUIT (SC).

Instance. A set of line segments S.

Question. Does S admit a simple circuit?

To simplify the presentation first it will be shown that the following more structured problem is NP-complete.

ORTHOGONAL SIMPLE CIRCUIT (OSC).

Instance. A set of line segments S orthogonal with respect to the coordinate axes.

Question. Does S admit an orthogonal simple circuit?

3. Orthogonal simple circuits is NP-complete. In this section it will be shown that the orthogonal simple circuit problem (OSC) is NP-complete. The following problem is known to be NP-complete [3].

HAMILTONIAN PATH IN PLANAR CUBIC GRAPHS (HPPCG).

Instance. A planar cubic (all vertices are of degree three) graph $G=(V, E)$.

Question. Is there a Hamiltonian path in G?

The idea behind the transformation of HPPCG to OSC is to build *modules* out of collections of line segments. Given a planar cubic graph G, the collection of modules $M(G)$ is constructed. Each module m_a will uniquely represent a vertex a of G. The edges of the graph will be simulated by a subset of the candidates of the collection of modules. The remainder of this section leads to the conclusion that a Hamiltonian path exists in a planar cubic graph, if and only if the set of corresponding modules admits an orthogonal simple circuit.

To construct modules corresponding to vertices we first compute a *rectilinear planar layout* of the graph. This layout maps vertices to horizontal line segments and maps edges to vertical line segments, such that all the endpoints of segments are at positive integer coordinates. Two horizontal segments are intersected by the endpoints of a vertical segment, if and only if the corresponding vertices are adjacent in the graph. Figure 2 shows a straight line drawing of a planar cubic graph with its rectilinear planar layout.

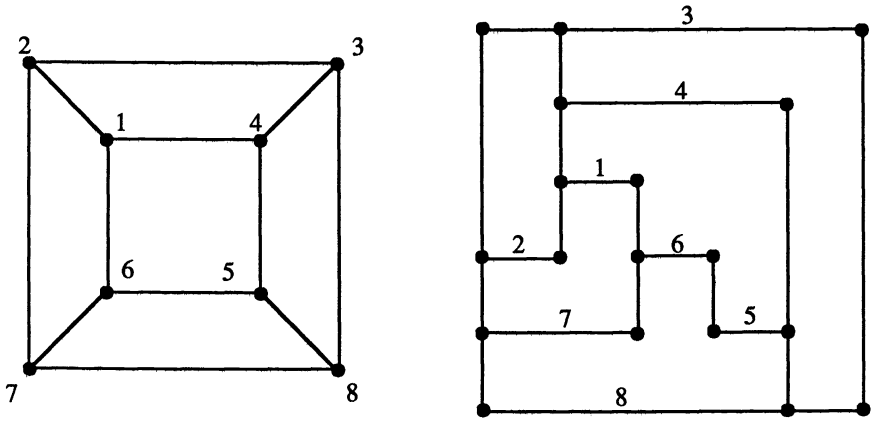

FIG. 2

In [14] it has been shown that a rectilinear planar layout can be computed for planar graphs with n vertices in $O(n)$ time. The height of the layout of this algorithm is guaranteed to be at most n, and the width at most F, where F is the number of faces in the graph. In cubic graphs $F=n/2+2$, by Euler's relation. For details regarding the algorithm used to obtain rectilinear planar layouts, refer to [14].

Given a planar cubic graph $G=(V, E)$, a configuration of modules can be constructed in polynomial time. In Fig. 3, we show a configuration of modules corresponding to the graph in Fig. 2. For completeness we give a procedure to construct such a configuration of modules.

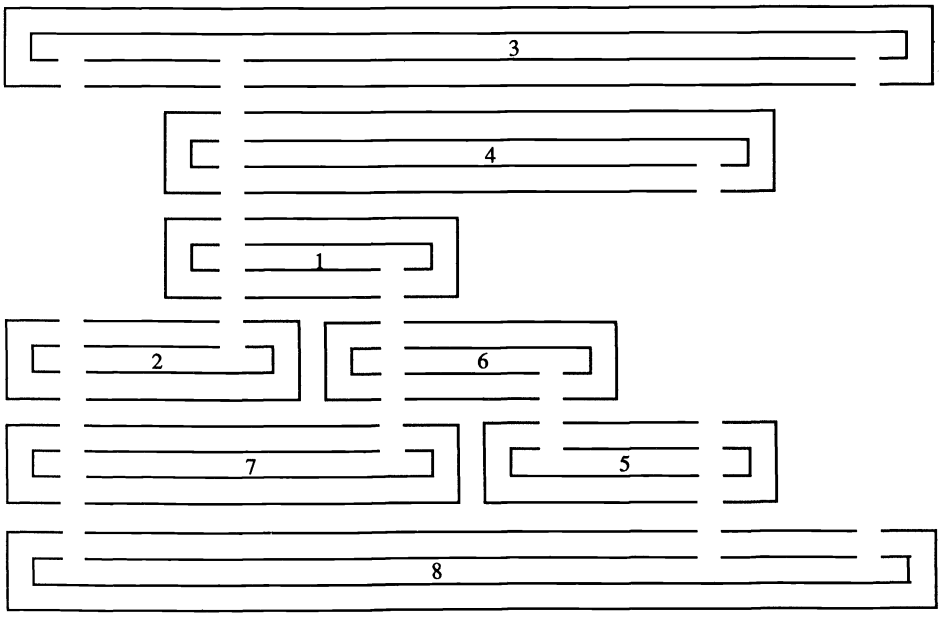

FIG. 3

PROCEDURE CONSTRUCT MODULES.

(1) Obtain a rectilinear planar layout of G.

(2) **for** each vertex v in G **do** steps 2.0, 2.1, and 2.2

(2.0) Let (x_l, y), (x_r, y) denote the coordinates of the horizontal line segment h that corresponds to v. Every vertex in G is of degree three. Therefore, there are three vertical segments intersecting h. Denote their intersection points as (x_1, y), (x_2, y), and (x_3, y).

if x_l is the top endpoint of its vertical line segment
then $top_i \leftarrow$ true **else** $top_i \leftarrow$ false.

(2.1) Construct an axis parallel outer rectangle with corners, $(6x_l, 4y)$, $(6(x_r+1)-1, 4y+3)$ and an axis parallel inner rectangle with corners, $(6x_l+1, 4y+1)$, $(6(x_r+1)-2, 4y+2)$.

(2.2) **for** $i \leftarrow 1$ **to** 3 **do**
if top_i is true **then**
Place a gap of width one at $(6x_i+2, 4y)$ of the outer rectangle and at $(6x_i+2, 4y+1)$ of the inner rectangle.
else
Place a gap of width one at $(6x_i+2, 4y+3)$ of the outer rectangle and at $(6x_i+2, 4y+2)$ of the inner rectangle. □

Denote the gaps found in the outer and inner frames of the modules as outer and inner *doors*, respectively. The endpoints at the extremes of these gaps will be referred to as left and right *doorjambs*. An inner and outer door pair will be referred to collectively as a DOOR. If the edge (a, b) is in G, then a door of module m_a faces a door of module m_b. We say that these doors are *neighbours*. By a logical extension, modules m_a and m_b are also termed as neighbours, if their doors are neighbours. Denote an alternating sequence of vertices and edges beginning and ending at a vertex, such that each edge

intersects its neighbouring edge at a vertex and no two edges intersect except at their endpoints, as a *polygonal chain.* Observe that the topology of every module is the same. Every module consists of three polygonal chains beginning and ending at outer doorjambs, and three polygonal chains beginning and ending at inner doorjambs.

Suppose there is a Hamiltonian path in the graph G. For notational simplicity assume that the sequence of vertices $1, 2, \cdots, n$ corresponds to the Hamiltonian path. For every edge, $(i, i+1)$, $i = 1, \cdots, n-1$, in the Hamiltonian path, we *link* the module m_i to module m_{i+1}. Since the vertices i and $i+1$ are neighbours in G, then m_i and m_{i+1} have neighbouring doors. We will use the following terminology to describe how modules are linked. We say a door is *augmented* if there are augmenting segments using both of its doorjambs. Denote a *gate* as an augmenting segment with endpoints on the left and right doorjambs of the same door. Denote an *egress* as a pair of augmenting segments linking the left and right outer doorjambs of neighbouring doors. Denote an *ingress* as a pair of augmenting segments linking the left and right doorjambs of an outer door to an inner door. See Fig. 4.

PROCEDURE LINK.

(1) Augment a DOOR of m_1 not a neighbour of m_2 with an ingress, and augment another DOOR of m_1 not a neighbour of m_2 with two gates. These choices can be made arbitrarily.

(2) **for** $i \leftarrow 2$ **to** n **do** steps 2.0, 2.1, and 2.2

(2.0) use an egress to augment the neighbouring outer doors of m_i and m_{i-1}.

(2.1) augment the corresponding inner doors of m_i and m_{i-1} with gates.

(2.2) **if** $i < n$ **then**

augment the DOOR of m_i not a neighbour of m_{i+1} or m_{i-1} with an ingress

else

augment a DOOR of m_n not a neighbour of m_{n-1} with an ingress.

(3) Augment the remaining unaugmented DOOR of m_n with two gates.

It should be clear that the procedure LINK has a linear worst-case running time. We now show that LINK produces an orthogonal simple circuit.

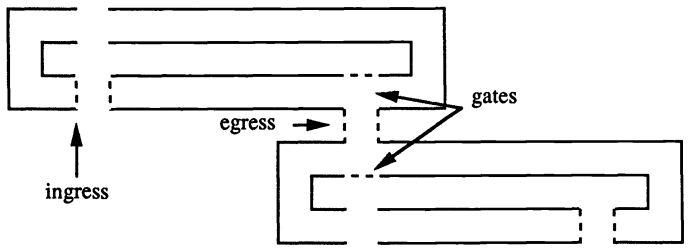

FIG. 4

LEMMA 1. *Given an ordering of the modules $M(G)$ corresponding to a Hamiltonian path in the graph G, procedure* LINK *produces an orthogonal simple circuit.*

Proof. Procedure LINK maintains the loop invariant that before and after every iteration of step (2) the modules m_1 to m_i and the added augmenting segments form

two disjoint polygonal chains. One chain begins at the inner right doorjamb and ends at the corresponding right outer doorjamb of a DOOR of module m_i. The other polygonal chain begins and ends at the left opposing inner and outer doorjambs of the same DOOR. See Fig. 5. After step (2) terminates (and $i = n$) we have two polygonal chains using all of the segments in $M(G)$. These chains are joined to complete the simple circuit in step (3). □

It remains to show that every orthogonal simple circuit in $M(G)$ can be used to obtain a Hamiltonian path in G in polynomial time. We denote a sequence of neighbouring modules, $m_1, m_2, \cdots, m_n$, augmented using procedure LINK as a *path of modules.* We will show that every orthogonal simple circuit that can be obtained from $M(G)$ is a path of modules.

Let us examine the ways in which a module can be linked to its neighbouring module with augmenting segments. A first step is to establish for each module a list of candidates, that is, line segments joining doorjambs that orthogonally see each other. In Fig. 6, a module is shown with its entire set of candidates drawn in dashed lines. The following lemma exhibits a crucial property of two neighbouring modules.

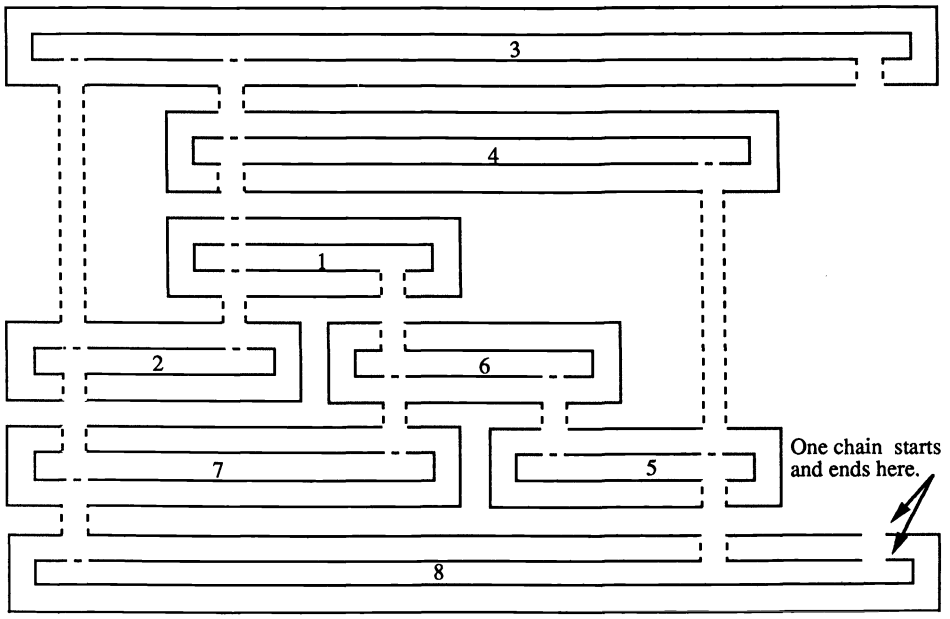

FIG. 5

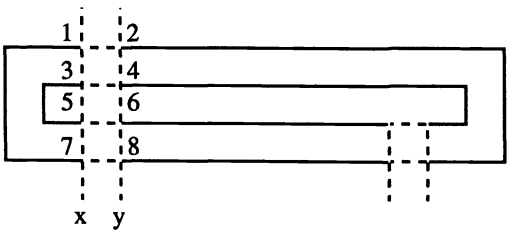

FIG. 6

LEMMA 2. *If two neighbouring modules are joined by a single augmenting segment, then an orthogonal simple circuit cannot be obtained in the collection of modules.*

Proof. First observe that all DOORS of modules have a similar structure. There are cases where there are two DOORS that are in the same vertical column. This is the case that will be argued. In the simpler case (for example, the unlabeled door in Fig. 6) a similar but simpler argument can be used. Referring to Fig. 6, assume we have the augmenting segment $(7, x)$. The edge $(8, 6)$ is forced, because we are assuming there is only one augmenting segment between modules. Now 5 can only be connected to 3, causing a disjoint circuit. This rules out the possibility of obtaining a single orthogonal simple circuit. Assume instead that we have augmenting segment $(8, y)$. This forces $(7, 5)$ and $(6, 4)$, which forces $(3, 1)$. But this causes a disjoint circuit. Therefore, neighbouring modules are joined with two augmenting segments, in every orthogonal simple circuit. □

We have established that at each door, modules are joined with two augmenting segments. Therefore, saying two modules are *connected*, refers to linking the modules with an egress. It should be clear that the corresponding inner doorjambs must also be joined with gates, because these doorjambs do not orthogonally see any alternate points. Another required fact is Lemma 3.

LEMMA 3. *A module can be connected to at most two of its neighbours.*

Proof. Assume that a module is connected to three of its neighbours. This leaves the inner frame disconnected from the rest of the segments of the module and isolated from all other modules. □

It should now be clear that the internal structure in each module forces each door to have two augmenting segments connecting each neighbour, and it forces each module to be connected to at most two of its neighbours. It is obvious that every module must be connected to at least one other module in every orthogonal simple circuit. Let the *circuit degree* of a module denote the number of neighbours a module is connected to in an orthogonal simple circuit. Clearly the circuit degree of a module can only be one or two.

LEMMA 4. *Every orthogonal simple circuit from a collection of modules is a path of modules.*

Proof. We cannot have an odd number of modules with circuit degree one. To see this, first obtain the total sum σ of all circuit degrees. If there is an odd number of modules of circuit degree one, then σ is odd. But σ must always be even, since σ counts each module connection twice.

Suppose there are four or more modules with circuit degree one. Since each module can have circuit degree at most two, σ is at most $2(n-4)+4$. As in graphs, if the sum of the degrees is less than $2n$ (less than n edges), then the graph must have disconnected components. Similarly, with σ less than $2n$ there must be some disconnected modules.

Suppose there are no modules of circuit degree one. Therefore, all modules are of circuit degree two. It has been shown that a path of modules is a simple circuit. If all modules are of circuit degree two, then we have the equivalent of a path of modules that is connected at its endpoints (module m_1 is connected to m_k) (or two or more such circuits of modules). This is topologically equivalent to taking a simple circuit, breaking it into two disjoint paths, and connecting each path to itself, thus creating two disjoint circuits.

We have exhausted the possibilities, therefore, every orthogonal simple circuit must be a path of modules. □

Finally, the preceding lemmas lead to the following conclusion.

THEOREM. OSC *is* NP-*complete.*

Proof. It is routine to show that OSC is in NP. If we are given a set of orthogonal segments with a set of augmenting segments, then the existence of a simple orthogonal circuit can be checked in linear time. We have shown that given a planar cubic graph G, we can construct a collection of modules $M(G)$, such that there is a Hamiltonian path in G, if and only if there is an orthogonal simple circuit in $M(G)$. Therefore OSC is NP-complete. □

In the reduction that has just been given there are segments that intersect at their endpoints. It is not hard to convert the collection of modules into a set of disjoint horizontal segments. Simply remove the vertical edges of each module and place each module on a row of its own. Modules with these changes are shown in Fig. 7. By examination we can see that all the vertical segments that were removed are now forced in the new layout of horizontal segments.

It is worth noting at this point that a remarkably similar problem has a polynomial time solution. Suppose we are given a set of orthogonal line segments and we wish to determine if the segments admit an *alternating orthogonal simple circuit.* This restricts the resulting orthogonal simple circuit to having edges that alternate between horizontal and vertical. An algorithm due to O'Rourke [8] used to decide whether there is an alternating orthogonal simple circuit in a set of points that can be applied in a straightforward manner. This algorithm returns an orthogonal simple circuit, if it exists, in $O(n \log n)$ time. Furthermore, it is shown that if an alternating orthogonal simple

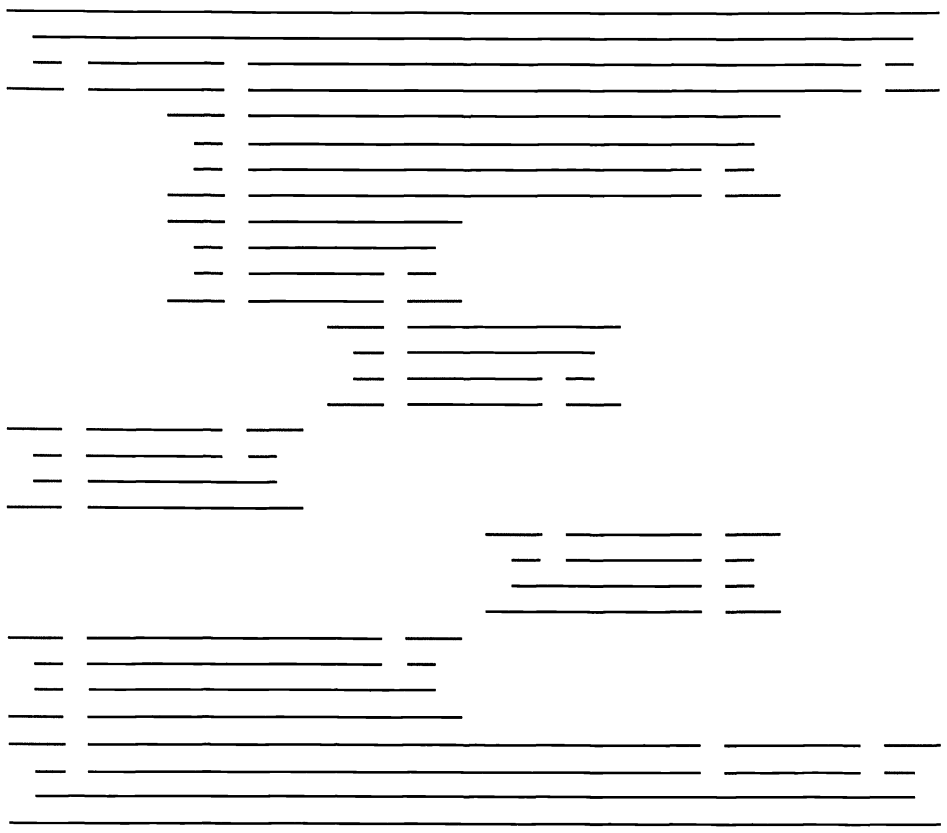

FIG. 7

circuit exists, then it is unique. Concerning (not necessarily alternating) orthogonal simple circuits of points, this problem has been shown to be NP-complete [11], [12].

4. Simple circuit is NP-complete. In this section it will be shown that the OSC problem, for a set of modules obtained from an instance of HPPCG, polynomially transforms to SC. Following the strategy taken in the previous section, we will build a collection of modules out of line segments. As a distinguishing feature we will denote the modules described in this section as SC modules, and those of the previous section as OSC modules.

SC modules are constructed in much the same way as OSC modules. Each module has an inner and outer rectangular frame with doors on the inner and outer frames. Shown in Fig. 8 is a collection of SC modules corresponding to OSC modules in Fig. 3, and ultimately to the graph in Fig. 2. In SC modules greater care must be taken to limit the visibility of the doorjambs. For this reason the doors are recessed. A possible solution is to let each door in an SC module be one unit wide, in a recessed three-unit enclosure that is two units deep. See Fig. 8. This limits the field of view of any doorjamb to a 45° angle. Let D be the distance between the top of the lowest module and the bottom of the highest module. If h is the total number of rows in the rectilinear planar layout (h is bounded by n, the number of vertices in G), and each module is w units wide (SC modules are constructed with a width of 10 units), with a one-unit space between rows of modules, then $D=(h-2)(w+1)+1$. DOORS are spaced so that the distance between them is at least D. The limited field of view ensures that a doorjamb can only see doorjambs of its neighbour. Another feature found in SC modules, and not in OSC modules, is the obstacle that runs the length of every module. These obstacles ensure that the visibility between inner and outer doorjambs remains local. The details concerning the construction of SC modules are omitted, as they are quite tedious, but given the above informal description it is a routine matter to construct the SC modules in $O(n)$ time.

A correspondence between the candidates of an OSC module and an SC module will be established. Since there are some candidates (endpoints that see each other) in SC modules that do not exist in OSC modules, it will be necessary to introduce the notion of a *useful candidate.* A candidate is useful if it can eventually appear as an augmenting segment. As will be shown, there are some candidates in SC modules that are not useful. However, all useful candidates in SC modules correspond exactly to the useful candidates of an OSC module.

Referring to Fig. 8, there are candidates in OSC modules that cross. For example the candidates $(5, 8)$ and $(6, 7)$. It will be shown that all these crossing candidates are not useful. Since the candidates found at every door of every module are equivalent, it is sufficient to examine a single door. Referring to Fig. 8, the inclusion of $(5, 8)$ forces $(6, 7)$, a crossing. Similarly $(6, 7)$ forces $(5, 8)$, a crossing. Therefore, $(6, 7)$ and $(5, 8)$ can never be augmenting segments. Including $(7, y)$ forces either $(8, x)$, $(8, 6)$, or $(8, 5)$. With $(8, x)$ we get a crossing, with $(8, 6)$ we isolate 5, and $(8, 5) = (5, 8)$ has been shown to be forbidden. As is the case for $(7, y)$, $(8, x)$ can never appear in a simple circuit. Therefore, $(5, 8)$, $(6, 7)$, $(7, y)$, and $(8, x)$ cannot be augmenting segments.

We can now conclude that the list of useful candidates in OSC modules is identical to those in SC modules. It is not hard to see that OSC modules are topologically equivalent to SC modules. Therefore we have the following theorem.

THEOREM. *There is an orthogonal simple circuit in* OSC *modules if and only if there is a simple circuit in the corresponding SC modules.*

The main result of the paper can now be proved.

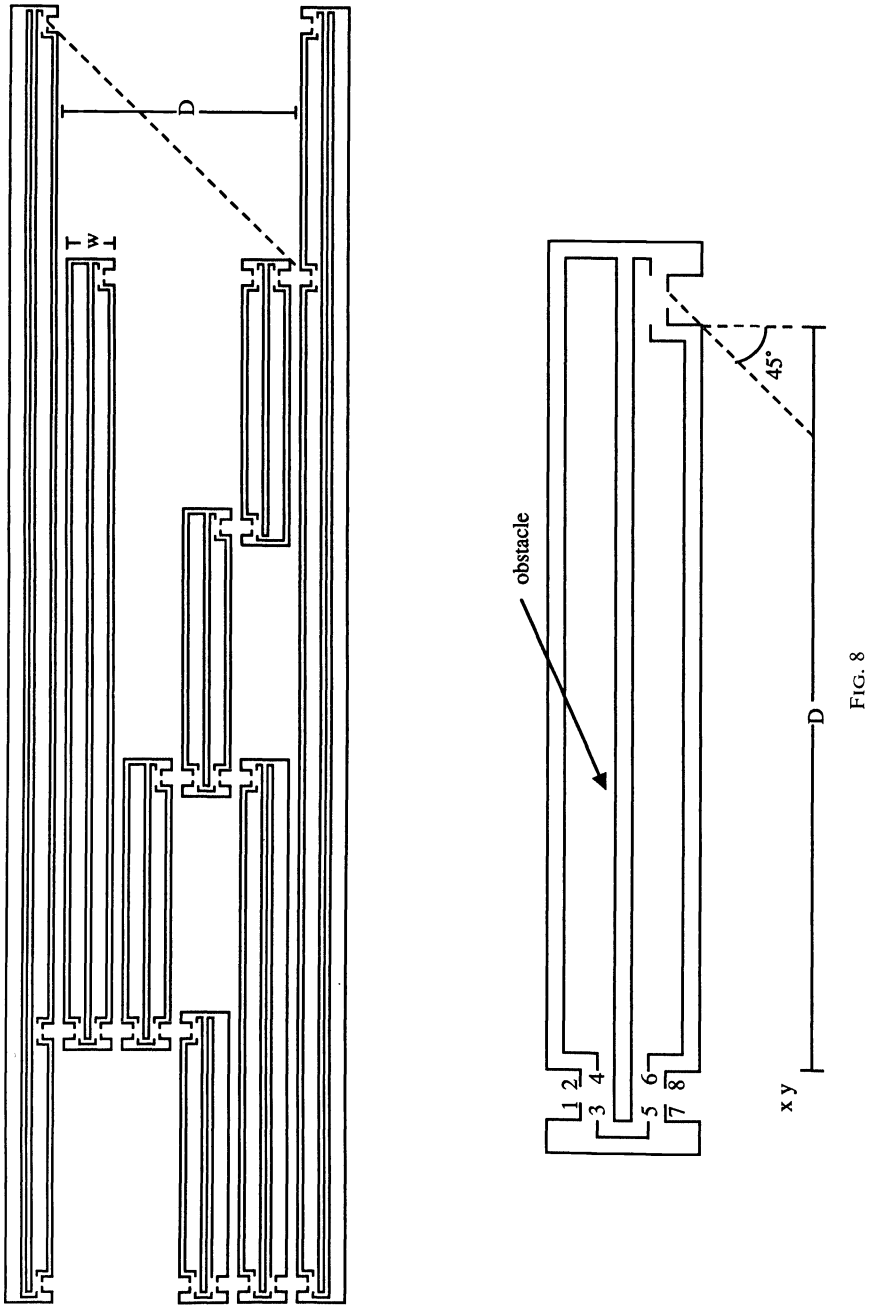

FIG. 8

THEOREM. SC *is* NP-*complete.*

Proof. It is routine to verify that SC is in NP. Given an instance of HPPCG, the graph G, we can construct a set of SC modules $M(G)$, so that there is a simple circuit from $M(G)$ if and only if there is a Hamiltonian path in G. Therefore SC is NP-complete. □

In the previous section it has been shown that OSC modules can be built from individual disjoint line segments. This does not appear to be the case for the SC modules described here. It remains an open problem to determine if SC is NP-complete even if we insist that the closed intervals of the segments are disjoint.

Observe that all the segments used in this reduction for SC are orthogonal. Therefore, SC is NP-complete for orthogonal segments.

5. Discussion. It has been shown that deciding whether a set of line segments admits a simple circuit is NP-complete. It is somewhat annoying that the result requires that some of the line segments must intersect at their boundaries. It would be more satisfying if this restriction could be removed. The reduction used in this paper is to a problem that is not far removed from a geometric setting. Using the rectilinear planar layout of planar cubic graphs is the major conceptual step of the result. Perhaps what is needed to prove a stronger result is a reduction to a more "primitive" NP-complete problem. A common approach used in other geometric NP-complete and NP-hard results has been to reduce the problem to the Planar 3-SAT problem [6], [10], [15]. It may be that this strategy would bear fruit in realizing an NP-completeness proof for disjoint segments. On the other hand, it may be (this appears to be the more exciting outcome) that the problem is not NP-complete at all and a polynomial solution exists!

Acknowledgments. I thank David Avis and Rafe Wenger for reading and commenting on earlier drafts of this paper.

THE TWO-PROCESSOR SCHEDULING PROBLEM IS IN RANDOM NC*

UMESH V. VAZIRANI† AND VIJAY V. VAZIRANI‡

Abstract. An efficient parallel algorithm (RNC^2) for the two-processor scheduling problem is presented. An interesting feature of this algorithm is that it finds a highest-level-first schedule: such a schedule defines a lexicographically first solution to this problem in a natural way. A key ingredient of the algorithm is a generalization of a theorem of Tutte which establishes a one-to-one correspondence between the bases of the Tutte matrix of a graph and the sets of matched nodes in maximum matchings in the graph.

Key words. scheduling, matching, parallel algorithms, randomized algorithms, basis of a matrix

1. Introduction. We present an efficient parallel RNC^2 algorithm for the following well-studied problem. Schedule n unit length jobs subject to given precedence constraints on two identical processors so as to minimize the finish time. Our algorithm uses $O(n^2M(n))$ processors, where $M(n)$ is the number of arithmetic operations required to multiply two $n \times n$ matrices.

There are close connections between two-processor scheduling and matching. The first polynomial time sequential algorithm for two processor scheduling relied on this connection [FKN], and in fact, techniques for finding matchings in parallel play an important role in the algorithm presented in this paper. The recent parallel matching algorithms [KUW], [MVV] are based on an algebraic connection established by a theorem of Tutte [Tu]. We present a generalization of this theorem, establishing a one-to-one correspondence between the bases of the Tutte matrix of a graph and the sets of matched nodes in maximum matchings in the graph. This yields an RNC^2 algorithm for computing the lexicographically largest such node-set. This subroutine is central to the parallel scheduling algorithm. The generalization is also of independent interest, and has been used in [MVV] to obtain an RNC^2 algorithm for maximum vertex-weighted matching.

The parallel scheduling algorithm finds a special type of schedule called a highest-level-first (HLF) schedule; a basic theorem of Gabow [Ga1], [Ga2] establishes the optimality of such a schedule. In § 5 we show that HLF schedules are "well behaved" by proving two new properties of such schedules. Using these properties, the task of computing an HLF schedule is shown to be reducible to parallel invocations of the lexicographically first node-set subroutine.

It is pointed out in § 4 that an HLF schedule is the lexicographically first schedule under a certain natural ordering on the jobs. In general, the parallel complexity of a problem is very sensitive to whether an arbitrary solution is acceptable or whether the lexicographically first solution is sought. Two important cases illustrate this point:

maximal independent set and depth-first search. The problems of finding the lexicographically first maximal independent set or the lexicographically first depth-first search tree are P-complete. Nevertheless, if an arbitrary solution is acceptable, in each case fast parallel algorithms exist. In the case of the maximum matching problem, fast parallel algorithms are known when an arbitrary solution suffices, but the parallel complexity of finding the lexicographically first maximum matching is still unresolved. Using the connection between two-processor scheduling and matching, the parallel algorithm presented in this paper can be interpreted as an algorithm for computing lexicographically first matchings for incomparability graphs under a certain natural ordering on the edges.

The algorithm presented here is randomized in the Las Vegas sense: it always produces the correct answer, but the guarantee on the running time is probabilistic. A preliminary report on this algorithm has appeared in [VV]. Subsequently, Helmboldt and Mayr [HM] have devised an algorithm that avoids the use of randomization. Their algorithm runs in $O(\log^2 n)$ time and uses $O(n^7 L^2)$ processors, where L is the length of the optimal schedule. Their algorithm shares some common features with ours; the proof of correctness of their algorithm relies on the "well-behavedness" properties of HLF schedules that are implicitly assumed in their paper, and explicitly proved here.

There is extensive literature on the two-processor scheduling problem (see [LR] for a general reference). We will use results from [FKN], [Ga1], and [Ga2].

2. Connection with matchings. We denote the set of jobs by V, and the precedence relations among the jobs by a directed acyclic graph $G(V, E)$.

DEFINITION. A *schedule* is a sequence of sets $S_1, \cdots, S_t$ that partition V, with $|S_i| \leqq 2$ and such that if x precedes y, $x \in S_i$, and $y \in S_j$ then $i < j$. The length of the schedule is t.

It is useful to associate a compatibility graph $H(V, E')$ with the given precedence graph $G(V, E)$. $H(V, E')$ is an undirected graph with an edge between a pair of vertices x and y if they are compatible, i.e., there is no directed path from x to y or y to x in G. The following theorem gives the fundamental relationship between matchings and schedules.

THEOREM 1 (Fujii, Kasami, and Ninomiya [FKN]). *For G and H as defined above, the paired jobs in any optimal schedule for G form a maximum matching in H. Moreover, any maximum matching in H can be transformed into an optimal schedule for G, leaving the set of unpaired jobs unchanged.*

Note that not all maximum matchings in H correspond to valid schedules for G; for a maximum matching to correspond to a valid schedule, it should be possible to linearly order the pairs so that all precedence constraints are satisfied. The content of the above theorem of [FKN] is a sequential procedure to transform any maximum matching into a valid schedule without changing the set of unpaired jobs.

The connection between matchings and schedules goes further. In § 5 we show that the lexicographically first maximum matching (under a natural ordering on the edges of H) always corresponds to an optimal schedule. The parallel algorithm presented in this paper finds an optimal schedule by constructing precisely such a lexicographically first matching.

3. The algebraic connection. The results of this section are of independent interest; in this section, we will let $G(V, E)$ denote an undirected graph, with $|V| = n$.

DEFINITION. The determinant of matrix A will be denoted by $\det(A)$, and its (i, j)th entry will be denoted by a_{ij}. The adjacency matrix D of graph $G(V, E)$ is given

by

$$d_{ij} = \begin{cases} 1 & \text{if } (v_i, v_j) \in E, \\ 0 & \text{otherwise.} \end{cases}$$

The Tutte matrix A of graph $G(V, E)$ is given by

$$a_{ij} = \begin{cases} x_{ij} & \text{if } (v_i, v_j) \in E \text{ and } i > j, \\ -x_{ij} & \text{if } (v_i, v_j) \in E \text{ and } i < j, \\ 0 & \text{otherwise.} \end{cases}$$

THEOREM 2 (Tutte [Tu]). *Let A be the Tutte matrix of a graph $G(V, E)$. Then, $\det(A) \not\equiv 0$ if and only if there exists a perfect matching in G.*

The following is a natural generalization of Tutte's theorem to maximum matchings.

THEOREM 3 (Lovász [LP]). *Let A be the Tutte matrix of a graph $G(V, E)$, and let m be the number of edges in a maximum matching in G. Then,* $\operatorname{rank}(A) = 2m$.

Rabin and Vazirani [RV] have given a simple proof of Theorem 3 using a theorem of Fröbenius [Ko, p. 144] stated below. We use their approach to give a further generalization below.

DEFINITION. The *node-set* of a maximum matching M is an n-dimensional 0/1 vector whose ith component is 1 if and only if vertex v_i is matched in M. Let n_G denote the lexicographically first such node-set.

Notation. We represent a basis of an $n \times n$ matrix A as an n-dimensional 0/1 vector, whose ith component is one if and only if the ith row of A is in the basis. Given n-dimensional vectors u, v, A_{uv} is the submatrix of A obtained by choosing rows corresponding to indices having 1's in u, and columns corresponding to indices having 1's in v. Similarly, G_u is the subgraph of G induced on vertices corresponding to indices having 1's in u. We will denote the number of 1's in u by $\#u$.

THEOREM 4 (Fröbenius [Ko, p. 144]). *Let B be an n by n skew-symmetric matrix. Let u, v be n-dimensional vectors such that $\#u = \#v = \operatorname{rank}(B)$. Then*

$$\det(B_{uu}) \cdot \det(B_{vv}) = (-1)^{\#u} \det(B_{uv})^2.$$

THEOREM 5. *Let A be the Tutte matrix of a graph $G(V, E)$. A vector $w \in \{0, 1\}^n$ is a basis of A if and only if w is the node-set of a maximum matching in G.*

Proof. Let w be the node set of a maximum matching in G. Since G_w has a perfect matching, by Tutte's theorem $\det(A_{ww}) \not\equiv 0$. Thus the rows of A indexed by w are linearly independent. Moreover, by Theorem 3 $\operatorname{rank}(A) = \#w$. Thus w is a basis of A.

Conversely, let w be a basis of A. Then, there is a vector $v \in \{0, 1\}^n$ such that $\#v = \#w$, and $\det(A_{wv}) \not\equiv 0$. Since $\operatorname{rank}(A) = \#w = \#v$, by Fröbenius' theorem $\det(A_{ww}) \not\equiv 0$. Now, by Tutte's theorem G_w has a perfect matching, and by Theorem 3 this matching is a maximum matching in G. Hence w is the node-set of a maximum matching in G. □

COROLLARY. *The lexicographically first basis of A is n_G.*

THEOREM 6. *There is an* RNC^2 *algorithm for finding n_G. It requires $(M(n) \log^2 n)$ processors.*

Proof. Choose a random substitution S: set of variables in $A \to [1, \cdots, 2n]$ to obtain the matrix A^S. Certainly, any basis of A^S is a basis of A. Let $w \in \{0, 1\}^n$ be the lexicographically first basis of A. Then, $\det(A_{ww}) \not\equiv 0$. This is a nonvanishing polynomial of degree at most n. Hence, by Schwartz's theorem [Sc], the probability that this

polynomial vanishes under the random substitution S is:

$$\Pr[\det(A_{ww}^S) = 0] \leqq \frac{\deg(\det(A_{ww}))}{2n} \leqq \frac{1}{2}.$$

Therefore, with probability at least $\frac{1}{2}$, A^S has the same lexicographically first basis as A. We now use the RNC^2 algorithm of Borodin, van zur Gathen, and Hopcroft [BGH] for finding the lexicographically first basis of A. For better processor efficiency, the computations can be done over a finite field (see [RV] for details). This requires $O(M(n)\log^2 n)$ processors, where $M(n)$ is the number of arithmetic operations required to multiply two $n \times n$ matrices.

4. Highest-level-first schedules. As before, let V be the set of jobs to be scheduled, and let $G(V, E)$ be a directed acyclic graph that represents the precedence constraints among the jobs.

DEFINITION. The *level* of a job is one plus the length of the longest directed path in G starting at the job.

Note that all constraints go from higher (numbered) levels to lower levels, and there are no constraints among jobs that are at the same level. Assume that the levels are numbered $L, L-1, \cdots, 1$.

DEFINITION. A schedule is a *level schedule* if for every level i, there is at most one job at level i paired with a job at a lower level, say j. Such a pair (if it exists) is called a *jump*, and the jump of level i is said to be j. If all jobs at level i are paired with jobs at level i or larger, then its jump is i, and if a job remains unpaired at level i, then its jump is 0.

THEOREM 7 (Gabow [Ga1]). *Any optimal schedule on a dag $G(V, E)$ can be transformed into a level schedule, without changing the set of unpaired jobs.*

DEFINITION. The *jump-sequence* of a level schedule is an L-tuple $(p_L, p_{L-1}, \cdots, p_1)$ where p_i is the jump of level i.

The lexicographic ordering on jump-sequences induces a partial ordering on level schedules.

DEFINITION. A level schedule is *highest-level-first* (HLF) if its jump sequence is lexicographically largest among all valid schedules for G.

Intuitively, such a schedule always jumps to the highest level possible. Moreover, within this level, it jumps to a job that allows subsequent jumps to be highest possible. The importance of such a schedule comes from the following theorem.

THEOREM 8 (Gabow [Ga1]). *Any highest-level-first schedule on a dag $G(V, E)$ is optimal.*

Remark. Let us assign to each edge in the compatibility graph the ordered pair (h, l) where h is the level of the higher endpoint of the edge and l is the level of the lower endpoint. Assign priorities to the edges by comparing the associated ordered pair; note that edges that run between the same levels have the same priority. Now matchings can be compared lexicographically in the obvious manner. It is easy to check that the paired jobs of any HLF schedule form a lexicographically highest matching in this sense.

5. Further connections between matchings and HLF schedules. In this section we prove two new properties of HLF schedules; these properties show that HLF schedules are "well behaved," and are essential to proving the correctness of the parallel algorithm. The first property (proved in Theorem 9) states that HLF schedules leave unpaired jobs at the lowest possible levels. The second (proved in Theorem 10) states that restricting an HLF schedule to jobs at levels i or greater yields an HLF schedule for the resulting dag.

DEFINITION. The coarse-jump-sequence of a level schedule S is an L-dimensional 0/1 vector $(s_L \cdots s_1)$ such that s_i is 0 if and only if S leaves a job unpaired on level i. Note that if S is a level schedule with jump sequence $(p_L, \cdots, p_1)$, its coarse-jump-sequence is given by $s_i = 0$ if and only if $p_i = 0$.

DEFINITION. The *level-set* of a maximum matching M in H is an L-dimensional 0/1 vector whose ith component is 0 if and only if there is an unmatched vertex at level i. Let l_H denote the lexicographically largest level-set. Recall that n_H is the lexicographically first node-set of a maximum matching in H.

THEOREM 9. *The coarse-jump-sequence of an* HLF *schedule is lexicographically greater than or equal to the coarse-jump-sequence of any level schedule on G.*

Proof. The proof is by contradiction. Suppose S is an HLF schedule on G with coarse-jump-sequence s, and T is a level schedule whose coarse-jump-sequence t is lexicographically larger than s. Let i be the highest level at which t and s differ; then S has an unpaired job at level i and T does not. Let k be the number of unpaired jobs in T at levels lower than i, and l the number of unpaired jobs in T at levels higher than i.

Obtain a new dag G' from G as follows. Add k new jobs at the first level; put in precedence constraints from each job at level i or higher to each new job. Let S' be an HLF schedule on G'. Note that any level schedule for G when restricted to levels i or higher (including jumps from these levels to lower levels) is valid for G', and vice versa. Since S and S' are HLF in G and G', respectively, their jump sequences must agree on level $\geqq i$. Therefore S' has at least $l+1$ unpaired jobs. On the other hand, T can be modified into a schedule for G' with only l unpaired jobs. This contradicts the optimality of S'.

LEMMA 1. *The* HLF *coarse-jump-sequence in G is the same as* l_H.

Proof. Let M be a maximum matching in H whose level-set is l_H. By Theorems 1 and 7 there is a level schedule for G having the same unpaired vertices as M, and therefore its coarse-jump-sequence is also l_H. The lemma now follows from Theorem 9.

Computing the HLF unpaired jobs in G has now been reduced to finding l_H. In Lemma 2 we will reduce this to finding n_G, for which an RNC^2 algorithm has been given in § 3. Note that if a maximum matching M achieves node-set n_H, then M leaves at most one vertex unmatched at each level. It is therefore straightforward to obtain the level-set of M.

LEMMA 2. *Pick any ordering* $>$ *on the vertices of H such that if* level (x) *is higher than* level (y) *then* $x > y$. *Under this ordering, the level-set of any maximum matching M achieving node-set* n_H *is* l_H.

Proof. Let M be a maximum matching achieving node-set n_H for this ordering, and let N be a maximum matching with level-set l_H. Since both matchings are maximum, the symmetric difference of M and N contains even cycles and even length paths. Each even length path must have its endpoints at the same level, otherwise we could improve either M or N. Hence M and N have their unmatched nodes at the same levels. □

DEFINITION. Let $G(V, E)$ be a dag, partitioned into L levels. For $1 \leqq i \leqq L$, define G_i to be the dag induced on vertices belonging to levels $L, L-1, \cdots, i$. For convenience, we number the levels of G_i as $L, L-1, \cdots, i$.

THEOREM 10. *Let the* HLF *jump-sequence for G be* $(p_L, p_{L-1}, \cdots, p_1)$. *Then, for* $1 \leqq i \leqq L$, *the* HLF *jump-sequence for* G_i *is* $(q_L, q_{L-1}, \cdots, q_i)$, *where*

$$q_j = \begin{cases} p_j & \text{if } p_j \geqq i, \\ 0 & \text{otherwise.} \end{cases}$$

We follow the method of Gabow for modifying schedules. First we introduce the relevant definitions and lemmas from [Ga1].

DEFINITION. A *k-schedule* is a level schedule for levels $L, \cdots, k$ and nodes in lower levels jumped from these levels. (A k-schedule is just a prefix of a complete schedule.)

DEFINITION. Let S be a k-schedule, with level $(x) >$ level (y). Say that y is *x-ready* in S if x does not precede y, and all predecessors of y below level (x) are jumped from above level (x).

Let M be an HLF k-schedule, and let O be a k-schedule that is HLF up to level $k+1$.

LEMMA 3 (Gabow [Ga1]). *If (x, y) is a jump in O with* level $(x) > k$, *then y is x-ready in M.*

DEFINITION. A *chain* consists of nodes x_i, $1 \leqq i \leqq c+1$, and y_i, $0 \leqq i \leqq c$ for $c \geqq 1$, where

(1) (x_i, y_i) is a jump in O, for $1 \leqq i \leqq c$.

(2) (y_i, x_{i+2}) is a jump in M, for $0 \leqq i \leqq c-1$.

(3) level (x_i) = level (y_{i-1}), for $1 \leqq i \leqq c+1$.

Adapting Theorem 2.1 of [Ga1] to our setting, we obtain Lemma 4.

LEMMA 4 (Gabow [Ga1]). *Let M and O be as above; consider a chain with* level (x_1) *as high as possible, and with c maximal with* level $(x_{c+1}) \geqq k$. *Let x_1 be paired with u in M and y_0 be paired with x_0 in O; clearly,* level (u) = level (y_0) = level (x_0) = level (x_1).

(1) *If there is no jump from x_{c+1} in O, then O can be modified into a valid k-schedule by replacing (x_i, y_i) by (y_{i-1}, x_{i+1}) for $i = 1$ to c, and by replacing (x_0, y_0) and (x_{c+1}, y_{c+1}) with (x_0, x_1) and (y_{c+1}, y_c).*

(2) *If there is no jump from y_c in M, then M can be modified into a valid k-schedule by replacing (y_{i-1}, x_{i+1}) with (x_i, y_i) for $i = 1$ to c, and by replacing (u, x_1) and (v, y_c) with (u, y_0) and (v, x_{c+1}).*

(3) level (x_{c+1}) = level $(y_c) = k$, *and (x_{c+1}, y_{c+1}) is a jump in O and (y_c, x_{c+2}) is a jump in M. Then O can be modified into a valid k-schedule, by replacing (x_i, y_i) with (y_{i-1}, x_{i+1}) for $i = 1$ to $c+1$, and by replacing (x_0, y_0) with (x_0, x_1).*

Proof of Theorem 10. Let S' be an HLF schedule for G_i, and let $(r_L, r_{L-1}, \cdots, r_i)$ be its jump-sequence. Assume for contradiction that $(r_L, r_{L-1}, \cdots, r_i)$ is larger than $(q_L, q_{L-1}, \cdots, q_i)$. Let k be the highest level where the two jump-sequences differ.

Choose k-schedules M and O for $G(V, E)$:

(1) M has jump sequence $(p_L, p_{L-1}, \cdots, p_k)$.

(2) O has jump sequence $(p_L, \cdots, p_{j+1}, r_j, \cdots, r_k)$.

(3) j is as small as possible.

(4) Among pairs of k-schedules satisfying (1), (2), and (3), M and O have the largest number of common jumps.

If $j = k$ then O has a larger jump-sequence than M, thus contradicting the fact that M is HLF. Otherwise, pick jumps (x_1, y_1) in O and (y_0, x_2) in M, with level (x_1) = level (y_0) as high as possible, and $(x_1, y_1) \neq (y_0, x_2)$. Let these jumps be the start of a chain as defined above with c maximal. We first prove that level $(x_c) \geqq j$. Assume for contradiction that level $(x_c) < j$. Let level $(x_d) > j >$ level $(x_{d+1}) \geqq k \geqq i$. Let x be the job that jumps from level j in M. By Lemma 3, x_{d+1} is y_{d+1}-ready in M, and therefore x-ready in M. Thus M can be modified by jumping x to y_{d-1}, thus contradicting the fact that M is HLF.

Now let M' and O' denote j-schedules corresponding to M and O, respectively. Then M' and O' satisfy the conditions of Lemma 4. Therefore either M' or O' can be

modified (according to which of the three cases applies to the chain defined above) to increase the number of common jumps or to make O' jump to level p_j from level j. The new pair of j-schedules can be extended to k-schedules, thus contradicting condition (3) or condition (4) above.

COROLLARY. $\max\{i : jth\ component\ of\ the\ \text{HLF}\ jump\text{-}sequence\ for\ G_i\ is\ nonzero\} = p_j$.

Say that a jump-sequence is *realizable* if there is a level schedule for G with this jump-sequence. Given a jump-sequence, we show how to construct a graph $K(V', E')$ which has a perfect matching if and only if the jump-sequence is realizable, and if so each perfect matching reveals the set of jumps of one such schedule.

$V' = V \cup V_1 \cup \cdots V_L$, where L is the number of levels in G, and the V_i's are disjoint from each other and from V.

Let $l(i)$ denote the number of vertices at level i;

Let $k(i)$ = number of levels that jump to level i;

If $0 < \text{jump}(i) < i$, then $|V_i| = l(i) - k(i) - 1$, and otherwise $|V_i| = l(i) - k(i)$.

$(x, y) \in E'$ if either

(1) $x, y \in V$, with level $(x) = i$ and level $(y) = j$, jump $(i) = j$, $0 < j < i$, and x is not a predecessor of y (these will be called the type 1 edges), or

(2) $x \in V$, with level $(x) = i$, and $y \in V_i$ (these will be called the type 2 edges).

LEMMA 5. *H has a perfect matching if and only if the given jump sequence is realizable. Moreover type* 1 *edges in the perfect matching are a valid realization of the jump sequence (with the exception of jumps to level* 0).

Proof. If the jump sequence is realizable, then H has the following perfect matching. Match a type 1 edge only if it is a jump. This leaves exactly the correct number of vertices at level i to be matched with vertices in V_i.

We prove that the type 1 edges in the perfect matching realize the jump sequence by induction on L. This is true for the Lth level by the choice of $|V_L|$. Removing V_L and the Lth level of V, we obtain a graph with $L-1$ partitions, and the proof follows by induction. □

6. The parallel algorithm. Procedure COARSE-JUMP-SEQUENCE below computes the coarse-jump-consequence of an HLF schedule for the given directed graph $G(V, E)$. Procedure JUMP-SEQUENCE computes the HLF jump-sequence for $G(V, E)$. Procedure JUMPS computes the jumps for some HLF schedule for $G(V, E)$. Once the jumps are known, it is an easy matter to pair up the remaining jobs to get an HLF schedule.

PROCEDURE COARSE-JUMP-SEQUENCE.

1. In parallel topologically sort G to assign levels.
2. Assign distinct numbers to the vertices of G, with $\#v > \#w$ if level $(v) >$ level (w).
3. Obtain the compatibility graph H.
4. In parallel compute n_H (under the above numbering).
5. Compute l_H from n_H and output it.

end.

PROCEDURE JUMP-SEQUENCE.

For $j = 1$ to L do in parallel:

Find the HLF coarse-jump-sequence for G_j.

end;

For $j = 1$ to L do in parallel:

jump $(j) = \max \{i : i \leqq j \wedge j$th component of the HLF coarse-jump-sequence for G_i is one$\}$.
output jump (j);
end;
end procedure;

PROCEDURE JUMPS $[G]$.
Compute the HLF jump-sequence for G;
Construct an undirected graph K for this jump sequence as in Lemma 6.
Find a perfect matching in H;
Output the type 1 edges in the perfect matching.
end procedure;

THEOREM 11. There is an RNC^2 algorithm that finds an optimal two-processor schedule (in particular, an HLF schedule) in a dag $G(V, E)$.

Proof. The correctness of procedure COARSE-JUMP-SEQUENCE follows from Theorem 9 and Lemmas 1 and 2; the correctness of procedure JUMP-SEQUENCE follows from the corollary to Theorem 10. The correctness of procedure JUMPS follows from Lemma 5. Procedure JUMPS determines the set of jumps of an HLF schedule (except the jumps to level 0). Now, if a level has an even number of jobs remaining, they can be paired off, and if it has an odd number of jobs remaining, one job will remain unpaired. The jobs can also be assigned appropriate time slots.

Each of the procedures can be implemented in RNC^2, yielding an RNC^2 algorithm overall. Two computations require the most number of processors: computing the ranks of n matrices in parallel, and finding a perfect matching. The second task dominates the first, since in the first task, the computations can be done modulo a prime, as elaborated in [RV] (see Theorem 6). The graph H in which a perfect matching is found has $O(n)$ vertices and $O(n^2)$ edges. This requires $O(n^2 M(N))$ processors using the matching algorithm of [MVV] that uses the matrix inversion algorithm of [Pa]. Here $M(n)$ denotes the number of arithmetic operations required to multiply two $n \times n$ matrices. The current best bound for $M(n)$ is $O(n^{2.376})$ [CW]. □

Using [FKN] and the RNC^2 algorithm of Karloff [Ka] for upper-bounding the size of maximum matching in a graph, we get an RNC^2 algorithm for upper-bounding the length of the optimal schedule. By running this algorithm and the scheduling algorithm in parallel, until they agree on the size of the optimal sequence, we get the following corollary.

COROLLARY. *There is a Las Vegas parallel algorithm that in expected time* $O(\log^2 n)$ *finds an optimal schedule in a dag* $G(V, E)$. *It runs on* $O(n^2 M(n))$ *processors.*

7. Discussion. An important issue left open in this paper is whether two-processor scheduling is in (deterministic) NC. Helmboldt and Mayr [HM] have resolved this question affirmatively. This result, together with the NC algorithm for transitively directing a comparability graph, yields a NC algorithm for constructing a maximum matching in an incomparability graph [KVV]. Both the parallel algorithm presented here as well as that due to Helmboldt and Mayr suffer from a large processor complexity—the parallel algorithm of this paper uses $O(n^{4.5})$ processors, and Helmboldt and Mayr's algorithm uses $O(n^7 L^2)$ processors. On the other hand, the problem can be solved sequentially in linear time [Ga2], [GT]. Improving the processor efficiency of the parallel algorithm remains an open problem.

A long-standing open problem in scheduling theory is to resolve the complexity of the k-processor scheduling problem, for fixed k, $k \geqq 3$. We conjecture that in contrast to the $k = 2$ case, for $k \geqq 3$, this problem is log-space hard for P.

Finally, the problem of finding an HLF schedule may be stated as the problem of finding the lexicographically largest maximum matching in an incomparability graph, with a partial ordering on the edges given by the level numbers of their endpoints (see the remark in § 4). The general problem of finding the lexicographically first maximum matching is open. Can some of the techniques of this paper be generalized to handle this larger problem?

Acknowledgments. The algorithm presented here benefited greatly from work done with Dexter Kozen on computing the interval representation of interval graphs in parallel. We wish to thank Dexter for his generous help throughout the evolution of this paper. We are also thankful to Ashok Chandra and Michael Rabin for several inspiring discussions.

APPROXIMATING THE PERMANENT*

MARK JERRUM† AND ALISTAIR SINCLAIR†

Abstract. A randomised approximation scheme for the permanent of a 0–1 matrix is presented. The task of estimating a permanent is reduced to that of almost uniformly generating perfect matchings in a graph; the latter is accomplished by simulating a Markov chain whose states are the matchings in the graph. For a wide class of 0–1 matrices the approximation scheme is fully-polynomial, i.e., runs in time polynomial in the size of the matrix and a parameter that controls the accuracy of the output. This class includes all dense matrices (those that contain sufficiently many 1's) and almost all sparse matrices in some reasonable probabilistic model for 0–1 matrices of given density.

For the approach sketched above to be computationally efficient, the Markov chain must be rapidly mixing: informally, it must converge in a short time to its stationary distribution. A major portion of the paper is devoted to demonstrating that the matchings chain is rapidly mixing, apparently the first such result for a Markov chain with genuinely complex structure. The techniques used seem to have general applicability, and are applied again in the paper to validate a fully-polynomial randomised approximation scheme for the partition function of an arbitrary monomer-dimer system.

1. Summary.

The *permanent* of an $n \times n$ matrix A with 0–1 entries a_{ij} is defined by

$$\operatorname{per}(A) = \sum_{\sigma} \prod_{i=0}^{n-1} a_{i\sigma(i)},$$

where the sum is over all permutations σ of $[n] = \{0, \cdots, n-1\}$. Evaluating $\operatorname{per}(A)$ is equivalent to counting perfect matchings (1-factors) in the bipartite graph $G = (U, V, E)$, where $U = V = [n]$ and $(i, j) \in E$ if and only if $a_{ij} = 1$. The permanent function arises naturally in a number of fields, including algebra, combinatorial enumeration, and the physical sciences, and has been an object of study by mathematicians since first appearing in 1812 in the work of Cauchy and Binet (see [26] for background). Despite considerable effort, and in contrast with the syntactically very similar determinant, no efficient procedure for computing this function is known.

Convincing evidence for the inherent intractability of the permanent was provided in the late 1970s by Valiant [32], who demonstrated that it is complete for the class #P of enumeration problems, and thus as hard as counting *any* NP structures. Interest has therefore recently turned to finding computationally feasible approximation algorithms for this and other hard enumeration problems [18], [30]. To date, the best approximation algorithm known for the permanent is due to Karmarkar et al. [17] and has a runtime that grows exponentially with the input size.

The notion of approximation we will use in this paper is as follows. Let f be a function from input strings to natural numbers. A *fully-polynomial randomised approximation scheme* (fpras) for f is a probabilistic algorithm that, when presented with a string x and a real number $\varepsilon > 0$, runs in time polynomial in $|x|$ and $1/\varepsilon$ and outputs

* Received by the editors October 6, 1988; accepted for publication January 10, 1989. A preliminary version of this paper appeared in the Proceedings of the 20th ACM Symposium on Theory of Computing, Chicago, May 1988, under the title "Conductance and the Rapid Mixing Property for Markov Chains: The Approximation of the Permanent Resolved."

† Department of Computer Science, University of Edinburgh, The King's Buildings, Edinburgh EH9 3JZ, United Kingdom.

a number that with high probability approximates $f(x)$ within ratio $1+\varepsilon$.[1] For definiteness we take the phrase "with high probability" to mean with probability at least $\frac{3}{4}$. This may be boosted to $1-\delta$ for any desired $\delta > 0$ by running the algorithm $O(\lg \delta^{-1})$ times and taking the median of the results [16, Lemma 6.1]. An fpras therefore embodies a strong notion of effective approximation.

A promising approach to finding an fpras for the permanent was recently proposed by Broder [8], who reduces the problem of approximately counting perfect matchings in a graph to that of generating them randomly from an almost uniform distribution. The latter problem is then amenable to the following dynamic stochastic technique. Given a graph G, construct a Markov chain whose states correspond to perfect and "near-perfect" matchings in G and which converges to a stationary distribution that is uniform over the states. Transitions in the chain correspond to simple local perturbations of the structures. Then, provided convergence is fast enough, we can generate matchings almost uniformly by simulating the chain for a small number of steps and outputting the structure corresponding to the final state.

When applying this technique, we are faced with the thorny problem of proving that a given Markov chain is *rapidly mixing*, i.e., that after a short period of evolution the distribution of the final state is essentially independent of the initial state. "Short" here means bounded by a polynomial in the input size. Since the state space itself may be exponentially large, rapid mixing is a strong property: the chain must typically be close to stationarity after visiting only a very small fraction of the space.

Recent work on the rate of convergence of Markov chains has focused on stochastic concepts such as coupling [1] and stopping times [3]. While these methods are intuitively appealing and yield tight bounds for simple chains, the analysis involved becomes extremely complicated for more interesting processes that lack a high degree of symmetry. Using a complex coupling argument, Broder [8] claimed that the perfect matchings chain above is rapidly mixing provided the bipartite graph is *dense*, i.e., has minimum vertex degree at least $n/2$. This immediately implies the existence of an fpras for the dense permanent. However, the coupling proof is hard to penetrate; more seriously, as was first observed by Mihail [25], it contains a fundamental error that is apparently not correctable. As a result Broder has withdrawn his proof (see the erratum to [8]).

In this paper we propose a completely different approach to analysing the rate of convergence of Markov chains that is based on a structural property of the underlying weighted graph. Under fairly general conditions, a finite ergodic Markov chain is rapidly mixing if and only if the *conductance* of its underlying graph is not too small. This characterisation, discussed in detail in a companion paper [29], is related to recent work by Alon [4] and Alon and Milman [5] on eigenvalues and expander graphs.

While similar characterisations of rapid mixing have been noted by other authors (see, e.g., [2], [22]), they have been of little practical value because independent estimates of the conductance have proved elusive for nontrivial chains. Using a novel method of analysis, we are able to derive a lower bound on the conductance of Broder's perfect matchings chain under the same density assumption, thus verifying that it is indeed rapidly mixing. This is the first rapid mixing result we know of for a Markov chain with nontrivial structure. The existence of an fpras for the dense permanent is therefore established.

Reductions from approximate counting to almost uniform generation similar to that mentioned above for perfect matchings also hold for the large class of combinatorial

[1] For nonnegative real numbers a, $\tilde{a}$, ε, we say that $\tilde{a}$ *approximates* a *within ratio* $1+\varepsilon$ if $a(1+\varepsilon)^{-1} \leqq \tilde{a} \leqq a(1+\varepsilon)$.

structures that are *self-reducible* [16], [29]. Consequently, the Markov chain approach is potentially a powerful general method for obtaining approximation algorithms for hard combinatorial enumeration problems.

In fact, Markov chain simulation is a rather useful algorithmic tool with a variety of computational applications. Perhaps the most familiar of these are to be found in the field of statistical physics, where a physical system is typically modelled by a set of combinatorial structures, or *configurations*, each of which has an associated weight depending on its energy. Most interesting properties of the model can be computed from the *partition function*, which is just the sum of the weights of the configurations. An fpras for this function may usually be obtained with the aid of a generator that selects configurations with probabilities roughly proportional to their weights. This suggests looking for a Markov chain on configurations with the appropriate (nonuniform) stationary distribution. Such chains are in fact the basis of the ubiquitous Monte Carlo method of Metropolis et al. [6] that is extensively used among other things to estimate the expectation of certain operators on configurations under the weighted distribution.

In such applications efficiency again depends crucially on the rate of convergence of the Markov chain. Significantly, our proof technique for rapid mixing seems to generalise easily to other interesting chains. We substantiate this claim here by considering a Metropolis-style process for *monomer-dimer systems* [14], which are a model of physical systems involving diatomic molecules. In this case configurations correspond to matchings (independent sets of edges of any size) in a given weighted graph, and the weight of a configuration is the product of its edge weights. Using our earlier method of analysis, we are able to show that this Markov chain is rapidly mixing under very general conditions. As a result we deduce the existence of an fpras for the monomer-dimer partition function. This includes as a special case an fpras for the #P-complete problem of counting all matchings in an arbitrary graph.

The monomer-dimer chain also provides valuable new insight into our original problem of approximating the permanent. Most notably, by appending suitably chosen weights to the edges of the input graph we can use the chain to obtain a more elegant approximation scheme for counting perfect matchings. The scheme is immediately seen to be fully-polynomial if and only if the number of "near-perfect" matchings in the graph does not exceed the number of perfect matchings by more than a polynomial factor. This turns out to be rather a weak condition: it is satisfied not only by all dense graphs but also, in a sense that we will make precise later, by almost every bipartite graph that contains a perfect matching. Moreover, we present an efficient randomised algorithm for testing the condition for an arbitrary graph, allowing pathological examples to be recognised reliably.

A further byproduct of our work on the monomer-dimer process is the following. Consider the problem of finding a maximum cardinality matching in a given graph. The Markov chain above may be viewed as an application of the search heuristic known as *simulated annealing* [21] to this optimisation problem. Suppose the maximum cardinality of a matching is m and let $\varepsilon > 0$ be fixed. Then our results readily imply that, with a suitable choice of edge weights (or equivalently, "temperature"), the search finds a matching of size at least $(1-\varepsilon)m$ in polynomial time with high probability. This represents a considerable simplification of a recent result of Sasaki and Hajek [27].

The remainder of the paper is structured as follows. In § 2 we state our characterisation of rapid mixing in terms of conductance for a broad class of Markov chains, and illustrate by means of a simple example our technique for obtaining lower bounds on the conductance. Section 3 is devoted to a proof that Broder's method does indeed yield an fpras for the dense permanent. In § 4 we discuss the Markov chain for

monomer-dimer systems and derive an fpras for the partition function. Other applications of this chain, including the improved algorithm for the permanent, appear in § 5. Section 6 deals with the approximation of the permanent of a randomly selected 0-1 matrix of given density. Finally, in § 7 we list a few open problems.

2. Markov chains and rapid mixing. In this section we establish some general machinery for reasoning about the nonasymptotic behavior of Markov chains which will play a central role throughout the paper. We assume a nodding acquaintance with the elementary theory of finite Markov chains in discrete time. (For more information the reader is referred to [20].)

Let $(X_t)_{t=0}^{\infty}$ be a time-homogeneous Markov chain with finite state space $\mathcal{N}$ and transition matrix $P=(p_{ij})_{i,j\in\mathcal{N}}$. (All chains in this paper are assumed to be of this form.) If the chain is ergodic we let $\boldsymbol{\pi}=(\pi_i)_{i\in\mathcal{N}}$ denote its stationary distribution, the unique vector satisfying $\boldsymbol{\pi}P=\boldsymbol{\pi}$ and $\sum_i \pi_i = 1$. In this case, if the chain is allowed to evolve for t steps from any initial state the distribution of its final state approaches $\boldsymbol{\pi}$ as $t\to\infty$. Necessary and sufficient conditions for ergodicity are that the chain is (a) *irreducible*, i.e., any state can be reached from any other in some number of steps; and (b) *aperiodic*, i.e., $\gcd\{s : i \text{ is reachable from } j \text{ in } s \text{ steps}\} = 1$ for all $i, j \in \mathcal{N}$.

As explained in the previous section, our intention is to use simulation of an ergodic chain as a means of sampling elements of the state space $\mathcal{N}$ from a distribution close to $\boldsymbol{\pi}$. We shall always assume that individual transitions can be simulated at low cost. From the point of view of efficiency, our major concern is therefore the rate at which the chain approaches stationarity. As a time-dependent measure of deviation from the limit, we define the *relative pointwise distance* (r.p.d.) after t steps by

$$\Delta(t) = \max_{i,j\in\mathcal{N}} \frac{|p_{ij}^{(t)} - \pi_j|}{\pi_j},$$

where $p_{ij}^{(t)}$ is the t-step transition probability from state i to state j. Thus $\Delta(t)$ gives the largest relative difference between the distribution of the state at time t and $\boldsymbol{\pi}$, maximised over initial states i. Our aim is to establish conditions under which the chain is *rapidly mixing*, in the sense that $\Delta(t)$ tends to zero fast as a function of t.

An ergodic Markov chain is said to be *time-reversible* if it satisfies the detailed balance condition

$$p_{ij}\pi_i = p_{ji}\pi_j \quad \forall i, j \in \mathcal{N}. \tag{1}$$

Analysis of time-reversible Markov chains is simplified by the following observation.

LEMMA 2.1. *Suppose (X_t) is an ergodic Markov chain with finite state space $\mathcal{N}$ and transition matrix P. Let $\boldsymbol{\pi}=(\pi_i)_{i\in\mathcal{N}}$ be any vector satisfying the detailed balance condition* (1) *and the normalisation condition $\sum_i \pi_i = 1$. Then the Markov chain (X_t) is time-reversible and $\boldsymbol{\pi}$ is its (unique) stationary distribution.* □

We may naturally identify a time-reversible chain with an underlying weighted graph as follows. The vertices of the graph are the states of the chain, and for each (not necessarily distinct) pair $i, j \in \mathcal{N}$ with $p_{ij} > 0$ there is an edge (i, j) of weight $w_{ij} = p_{ij}\pi_i = p_{ji}\pi_j$. For convenience we set $w_{ij} = 0$ for all pairs of states i, j between which no transition is possible. Note that this graph uniquely specifies the Markov chain.

As in [29], we define the *conductance* of a time-reversible chain with underlying graph H by

$$\Phi(H) = \min \frac{\sum_{i\in S, j\notin S} w_{ij}}{\sum_{i\in S} \pi_i} \tag{2}$$

where the minimisation is over all subsets S of states with $0<\sum_{i\in S}\pi_i\leqq\frac{1}{2}$. Note that the quotient in (2) is just the conditional probability that the stationary process escapes from S in a single step, given that it is initially in S. The conductance in some sense measures the rate at which the process can flow around the state space, so we might expect it to be connected with the rate of convergence of the chain. In fact, by relating $\Phi(H)$ to the second eigenvalue of the transition matrix that governs the transient behaviour of the chain, it is possible to obtain the following result. A proof can be found in [29].

THEOREM 2.2. *Let H be the underlying graph of a time-reversible ergodic Markov chain in which* $\min_i p_{ii}\geqq\frac{1}{2}$, *and let* $\pi_{\min}=\min_i \pi_i$ *be the minimum stationary state probability. Then the* r.p.d. *of the chain is bounded by*

$$\Delta(t)\leqq\frac{(1-\Phi(H)^2/2)^t}{\pi_{\min}}.$$ □

The following immediate corollary is useful. Define the function $\tau:\mathbb{R}^+\to\mathbb{N}$ by

$$\tau(\varepsilon)=\min\{t\in\mathbb{N}:\Delta(t')\leqq\varepsilon \text{ for all } t'\geqq t\}.$$

COROLLARY 2.3. *With the notation of Theorem* 2.2, *we have*

$$\tau(\varepsilon)\leqq\frac{2}{\Phi(H)^2}(\ln\pi_{\min}^{-1}+\ln\varepsilon^{-1}).$$ □

Theorem 2.2 allows us to investigate the rate of convergence of a time-reversible chain by examining the structure of its underlying graph: convergence will usually be rapid if the conductance is not too small. In our applications we will always be dealing with *families* of Markov chains $\mathcal{MC}(x)$ indexed by problem instances x. (Thus x might be a graph and $\mathcal{MC}(x)$ some Markov chain on the set of matchings in the graph.) Let $\tau^{(x)}$ denote the function τ above for the chain $\mathcal{MC}(x)$. Then the rapid mixing property referred to informally earlier requires that $\tau^{(x)}(\varepsilon)$ should be bounded above by a polynomial in the input size $|x|$ and $\lg\varepsilon^{-1}$. This means that the number of steps required to achieve some specified sampling accuracy increases only polynomially with the problem size. As is clear from Corollary 2.3, rapid mixing will usually follow from a lower bound of the form $1/\text{poly}(|x|)$ on the conductance Φ. In this and subsequent sections, we show how to derive such bounds for several interesting chains. Other examples are given in [29].

Remarks. (a) The condition $\min_i p_{ii}\geqq\frac{1}{2}$ is a technical device that simplifies the statement of the theorem by damping oscillatory or "near-periodic" behaviour [29]. Note that an arbitrary Markov chain can be modified to make the condition hold simply by replacing P by $\frac{1}{2}(I+P)$, where I is the $|\mathcal{N}|\times|\mathcal{N}|$ identity matrix. This operation leaves the stationary distribution unchanged and merely reduces the conductance by a factor of $\frac{1}{2}$. (In fact, we have just added a self-loop probability of $\frac{1}{2}$ to each state; for the purposes of practical implementation the waiting time at each state may be simulated more efficiently by a separate random process.)

(b) Theorem 2.2 has a converse stating that, under the same assumptions, $\Delta(t)\geqq(1-2\Phi(H))^t$ [28]. Hence we effectively have a *characterisation* of rapid mixing for a large class of time-reversible chains in terms of the graph-theoretic quantity Φ.

(c) Similar relationships between subdominant eigenvalues of graphs and their structural properties have appeared in the work of Alon [4] and Alon and Milman [5]. The significance of Alon's result as a sufficient condition for rapid mixing for certain Markov chains has been noted by several authors; in particular, Aldous [2] states a restricted version of Theorem 2.2 for random walks on regular graphs. Our

conductance Φ is a weighted edge analogue of the *magnification* studied in [4], [2] and gives a cleaner and more natural formulation of this connection. Very recently, Lawler and Sokal [22] have independently discovered a characterisation similar to ours but in a rather more general context. □

As it stands, the rapid mixing criterion of Theorem 2.2 is essentially only of theoretical interest. To turn it into a useful practical tool, we need to develop some technology for estimating the conductance of the underlying graphs of natural Markov chains. This we now do with the aid of a simple example.

For a positive integer n, let $B(n)=\{0,1\}^n$ denote the set of bit vectors of length n. Consider the family of Markov chains $\mathscr{MC}(n)$ with state space $B(n)$ and transitions as follows. In any state $v=(v_0,\cdots,v_{n-1})$, select $i\in\{0,\cdots,n-1\}$ uniformly at random and flip the value of the bit v_i. To eliminate periodicity, remain at v with probability $\frac{1}{2}$.

$\mathscr{MC}(n)$ is obviously irreducible and aperiodic, and hence ergodic. Using Lemma 2.1, it is easily verified that $\mathscr{MC}(n)$ is time-reversible and that its stationary distribution is uniform over $B(n)$. The conditions of Theorem 2.2 are satisfied, so the rate of convergence of $\mathscr{MC}(n)$ depends on the conductance of its underlying graph $H(n)$. In $H(n)$, two states are adjacent if and only if they differ in at most one bit. Thus $H(n)$ is just the n-dimensional hypercube, each nonloop edge having weight $(2nN)^{-1}$, where $N=|B(n)|$ is the number of states.

PROPOSITION 2.4. *The conductance of* $H(n)$ *satisfies* $\Phi(H(n))\geqq 1/2n$.

Before presenting the proof of Proposition 2.4, which is the main point of this example, let us note that it implies rapid mixing for the family of chains $\mathscr{MC}(n)$. By Corollary 2.3 the number of simulation steps required to achieve an r.p.d. of ε is $O(n^2(n+\ln\varepsilon^{-1}))$, which is polynomially bounded in n and $\lg\varepsilon^{-1}$. Thus an algorithm that simulates $\mathscr{MC}(n)$ from some arbitrary initial state constitutes an efficient almost uniform sampling procedure for bit strings of length n. (Of course, there are more direct ways of doing this!)

Proof of Proposition 2.4. From the definition (2) we may write

$$\Phi(H(n))=\frac{1}{2n}\min_{0<|S|\leqq N/2}\frac{|\mathrm{cut}(S)|}{|S|} \tag{3}$$

where for each $S\subseteq B(n)$, $\mathrm{cut}(S)$ denotes the set of cut edges in $H(n)$ defined by S. Our argument hinges on the following observation. Suppose it is possible to specify a canonical simple path in $H(n)$ between each ordered pair of distinct states in such a way that no oriented edge of $H(n)$ is contained in more than bN of the paths. If S is any subset of states with $0<|S|\leqq N/2$, then the number of paths which cross the cut from S to its complement is clearly

$$|S|(N-|S|)\geqq|S|N/2.$$

Thus for any such S the number of cut edges must be at least $|S|N/2bN=|S|/2b$, and so from (3) we have

$$\Phi(H(n))\geqq\frac{1}{4nb}. \tag{4}$$

To get a lower bound on $\Phi(H(n))$ it therefore suffices to define a collection of canonical paths in $H(n)$ that are "sufficiently edge disjoint," as measured by the parameter b.

We now proceed to define a suitable set of paths. Let $u=(u_i)_{i=0}^{n-1}$ and $v=(v_i)_{i=0}^{n-1}$ be distinct elements of $B(n)$, and $i_1<\cdots<i_l$ be the positions in which u and v differ.

Then for $1 \leqq j \leqq l$, the jth edge of the canonical path from u to v corresponds to a transition in which the i_jth bit is flipped from u_{i_j} to v_{i_j}.

Consider now an arbitrary transition t of $\mathcal{MC}(n)$ (or, equivalently, an oriented edge of $H(n)$); our aim is to bound the number of paths that contain t. Suppose that t takes state $w = (w_i)$ to state $w' = (w'_i)$ by flipping the value of w_k, and let $P(t)$ denote the set of paths containing t, viewed as ordered pairs of states. Rather than counting elements of $P(t)$ directly, we will set up an *injective* mapping from $P(t)$ into the state space $B(n)$; this will yield an upper bound on the ratio b appearing in (4).

The mapping $\sigma_t: P(t) \to B(n)$ is defined as follows. Given an ordered pair $\langle u, v \rangle \in P(t)$, set $\sigma_t(u, v) = (s_i)$, where

$$s_i = \begin{cases} u_i, & 0 \leqq i \leqq k, \\ v_i, & k < i < n. \end{cases}$$

Thus $\sigma_t(u, v)$ agrees with u on the first $k+1$ bits and with v on the remainder. Note that we can express this definition more succinctly as $\sigma_t(u, v) = u \oplus v \oplus w'$, where $\oplus$ denotes bitwise exclusive-or.

We claim that $\sigma_t(u, v)$ is an unambiguous *encoding* of the endpoints u and v, so that σ_t is indeed injective. To see this, simply note that

$$u_i = \begin{cases} s_i, & 0 \leqq i \leqq k, \\ w_i, & k < i < n, \end{cases} \qquad v_i = \begin{cases} w'_i, & 0 \leqq i \leqq k, \\ s_i, & k < i < n. \end{cases}$$

Hence u and v may be recovered from knowledge of t and $\sigma_t(u, v)$, so σ_t is injective. It follows immediately that $|P(t)| \leqq N$; in fact, since all vectors (s_i) in the range of σ_t satisfy $s_k = w_k$, we have the slightly stronger result that $|P(t)| \leqq N/2$. Since t was chosen arbitrarily, the number of paths traversing *any* oriented edge cannot exceed $N/2$. Thus we may set $b = \frac{1}{2}$ in inequality (4) and deduce the desired bound on the conductance $\Phi(H(n))$. □

Remark. The bound of Proposition 2.4 is tight. To see this, let S be the subset of $B(n)$ consisting of all vectors with first bit 0 and note that $|\text{cut}(S)|/|S| = 1$. Hence $\Phi(H(n)) = 1/2n$. □

Some observations on the above proof are in order here. The idea of path counting is quite general and has been used before in the literature to investigate the connectivity properties of various graphs in other contexts (see e.g., [31], in which the hypercube is also studied). The novelty of our proof lies in the use of the injective mapping technique to bound the number of paths which traverse an edge. This is not actually necessary in this simple example as the paths could have been counted explicitly. The point is that in more complex cases the states of the chain will be less trivial structures, such as matchings in a graph, and we will have no useful information about their number—indeed, this is what we will ultimately be trying to compute. It is then crucial to be able to bound the maximum number of paths through any edge in terms of the number of states *without* explicit knowledge of these quantities. This is precisely what the injective mapping technique achieves. As we will see presently, it turns out to be rather generally applicable.

Other simple Markov chains may be analysed in a similar fashion [28]. Examples of rapidly mixing families include random walks on n-dimensional cubes of side d and a host of "card-shuffling" processes whose state space is the set of permutations of n objects and whose transitions correspond to some natural shuffling scheme. These and similar processes have been extensively studied using other methods such as

coupling, stopping times, and group representation theory (see [1], [3], [10] for a variety of examples). The time bounds obtained by these methods are generally rather tighter than ours and can often be shown to be optimal. However, the full power of our approach will become apparent in the sequel where it will permit the analysis of highly irregular chains with only a little additional effort. Most significantly, such chains have seemingly not proved amenable to analysis by any of the other established methods.

3. Approximating the permanent. In this section we consider Broder's method for approximating the permanent of a square 0-1 matrix, as sketched in § 1. Our main result is that the method yields an fpras for a large class of matrices, including all those that are sufficiently dense. Thus Broder's principal claim in [8] turns out to be true despite the fallacious coupling argument given there.

We will work with the perfect matching formulation of the permanent as described in § 1. Let $G=(U, V, E)$ be a bipartite graph with $U=V=\{0, \cdots, n-1\}$, and for $k \in \mathbb{N}$ let $M_k(G)$ denote the set of matchings of size k in G. Thus $M_n(G)$ is the set of perfect matchings in G and its cardinality is equal to the permanent of the $n \times n$ 0-1 matrix associated with G. We assume throughout this section that $M_n(G)$ is nonempty: it is well known that this property can be tested in polynomial time [11].

The method is based on the observation that an fpras for $|M_n(G)|$ can be constructed easily given an efficient procedure for sampling perfect and "near-perfect" matchings in G almost uniformly at random. First we must say more precisely what we mean by such a procedure. Let $\mathcal{N}$ be the set $M_n(G) \cup M_{n-1}(G)$. An *almost uniform generator* for $\mathcal{N}$ is a probabilistic algorithm that, when presented with G and a positive real *bias* ε, outputs an element of $\mathcal{N}$ such that the probability of each element appearing approximates $|\mathcal{N}|^{-1}$ within ratio $1+\varepsilon$. The generator is *fully polynomial* (f.p.) if it runs in time bounded by a polynomial in n and $\lg \varepsilon^{-1}$. (Generators for combinatorial structures are discussed in a more general framework in [16], [28], [29].) Actually, since all the generators we construct in this paper are based on rapidly mixing Markov chains, it should be clear that they embody effective procedures for sampling structures from a given distribution under *any* reasonable definition.

We call the bipartite graph G *dense* if its minimum vertex degree is at least $n/2$. It is shown in [8] that the problem of counting perfect matchings in dense graphs is no easier than counting them in general graphs, and hence is #P-complete. The following result is also proved in [8], and formalises the reduction from approximate counting to almost uniform generation in the case of dense graphs.

THEOREM 3.1 (Broder). *Suppose that, for all dense bipartite graphs G, there exists an f.p. almost uniform generator for $M_n(G) \cup M_{n-1}(G)$. Then there exists an fpras for $|M_n(G)|$ for all such graphs G.* □

Broder investigates the generation problem using a family of ergodic Markov chains $\mathcal{MC}_{\mathrm{pm}}(G)$ with state space $\mathcal{N}=M_n(G) \cup M_{n-1}(G)$ and uniform stationary distribution, in which transitions are made by adding and/or deleting edges locally. We now give a slightly modified definition of $\mathcal{MC}_{\mathrm{pm}}(G)$. View E as a subset of $U \times V$ and matchings in G as subsets of E. If $A, B \subseteq E$ and $e \in E$ then $A \oplus B$ denotes the symmetric difference of A and B, while $A+e$ and $A-e$ denote the sets $A \cup \{e\}$, $A \backslash \{e\}$, respectively. Transitions in $\mathcal{MC}_{\mathrm{pm}}(G)$ are specified as follows. In any state $M \in \mathcal{N}$, choose an edge $e=(u, v) \in E$ uniformly at random and then

(i) If $M \in M_n(G)$ and $e \in M$, move to state $M'=M-e$ (*Type* 1 *transition*);

(ii) If $M \in M_{n-1}(G)$ and u, v are unmatched in M, move to $M'=M+e$ (*Type* 2 *transition*);

(iii) If $M \in M_{n-1}(G)$, u is matched to w in M and v is unmatched in M, move to $M' = (M+e)-(u, w)$; symmetrically, if v is matched to w and u is unmatched, move to $M' = (M+e)-(w, v)$ (*Type 0 transition*);

(iv) In all other cases, do nothing.

We again eliminate periodicity by introducing an additional self-loop probability of $\frac{1}{2}$ for each state, i.e., with probability $\frac{1}{2}$ the process does not select a random edge as above but simply remains at M.

Using Lemma 2.1, it is a simple matter to check that $\mathcal{MC}_{\text{pm}}(G)$ is ergodic and time-reversible with uniform stationary distribution. What is not at all obvious is that the family of chains is rapidly mixing. This surprising fact is a consequence of the following theorem.

THEOREM 3.2. *Let G be dense and H be the underlying graph of the Markov chain $\mathcal{MC}_{\text{pm}}(G)$. Then $\Phi(H) \geqq 1/12n^6$.*

We shall prove the theorem in a moment after examining its implications.

COROLLARY 3.3. *There exists an f.p. almost uniform generator for $M_n(G) \cup M_{n-1}(G)$ in all dense bipartite graphs G.*

Proof. On input $\langle G, \varepsilon \rangle$, the generator deterministically constructs an initial state of $\mathcal{MC}_{\text{pm}}(G)$ and then simulates the chain for some number $T \geqq \tau(\varepsilon/2)$ of steps, outputting the final state. (Assuming as we may that $\varepsilon \leqq 1$, an r.p.d. of $\varepsilon/2$ guarantees a bias of at most ε.) To see that the generator is f.p., note that for any G individual steps of $\mathcal{MC}_{\text{pm}}(G)$ can be simulated, and a perfect matching to serve as initial state found, in polynomial time. Moreover, since $\pi_{\min}^{-1} = |\mathcal{N}|$ is certainly bounded above by 2^{n^2}, Theorem 3.2 and Corollary 2.3 imply that $\tau(\varepsilon/2) \leqq \text{poly}(n, \lg \varepsilon^{-1})$, so T need only be this large. Hence the overall runtime is bounded as required. □

Combining this with Theorem 3.1 immediately yields the following Corollary.

COROLLARY 3.4. *There exists an fpras for $|M_n(G)|$ in all dense bipartite graphs G, and hence for the permanent of all dense square 0-1 matrices.* □

We return now to the proof of the key result above.

Proof of Theorem 3.2. As in (3) the conductance is given by

$$\Phi(H) = \frac{1}{2|E|} \min_{0<|S| \leqq |\mathcal{N}|/2} \frac{|\text{cut}(S)|}{|S|} \tag{5}$$

where again cut (S) denotes the set of cut edges in H defined by S. We will proceed as in the proof of Proposition 2.4 by defining a set of canonical paths in H. If no transition occurs in more than $b|\mathcal{N}|$ of these, by analogy with (4) we will have the bound

$$\Phi(H) \geqq \frac{1}{4b|E|} \geqq \frac{1}{4bn^2}. \tag{6}$$

We begin by specifying, for each $M \in \mathcal{N}$, canonical paths to and from a unique "closest" perfect matching $\bar{M} \in M_n(G)$ as follows, where $u \in U$ and $v \in V$ denote the unmatched vertices (if any) of M:

(i) If $M \in M_n(G)$ then $\bar{M} = M$ and the path is empty;

(ii) If $M \in M_{n-1}(G)$ and $(u, v) \in E$, then $\bar{M} = M + e$ and the path consists of a single Type 2 transition;

(iii) If $M \in M_{n-1}(G)$ and $(u, v) \notin E$, fix some $(u', v') \in M$ such that $(u, v'), (u', v) \in E$: note that at least one such edge must exist by the density assumption on G. Then $\bar{M} = (M-(u', v'))+(u, v')+(u', v)$, and we specify one of the two possible paths of length two from M to $\bar{M}$, involving a Type 0 transition followed by a Type 2 transition.

The canonical path from $\bar{M}$ to M consists of the same edges of H traversed in the opposite direction.

For future reference, we observe that no perfect matching is involved in too many canonical paths of the above form: for $M \in M_n(G)$ define the set

$$\mathcal{K}(M) = \{M' \in \mathcal{N} : \bar{M}' = M\}.$$

Then, since each matching in $\mathcal{K}(M)$ has at least $n-2$ edges in common with M, it is easy to see that $|\mathcal{K}(M)| \leq n^2$. Note that the sets $\mathcal{K}(M)$ partition $\mathcal{N}$, implying that $|\mathcal{N}| \leq n^2 |M_n(G)|$. It is also worth noting that this is the only point in the proof at which the bipartite structure of G is used: we will have more to say about this later (see remark (d) below).

Next we define a canonical path in H between an ordered pair I, F of *perfect* matchings (refer to Fig. 1(a)). To do this, we first assume a fixed ordering of all even cycles of G, and distinguish in each cycle a *start vertex* in U. Now consider the symmetric difference $I \oplus F$; we may write this as a sequence $C_1, \cdots, C_r$ of disjoint even cycles, each of length at least four, where the indices respect the above ordering. The path from I to F involves *unwinding* each of the cycles $C_1, \cdots, C_r$ in turn in the following way. Suppose the cycle C_i has start vertex u_0 and consists of the sequence of distinct vertices $(u_0, v_0, u_1, v_1, \cdots, u_l, v_l)$, where $(u_j, v_j) \in I$ for $0 \leq j \leq l$ and the remaining edges are in F. Then the first step in the unwinding of C_i is a Type 1 transition that removes the edge (u_0, v_0). This is followed by a sequence of l Type 0 transitions, the jth of which replaces the edge (u_j, v_j) by (u_j, v_{j-1}). The unwinding is completed by a Type 2 transition that adds the edge (u_0, v_l).

Finally, the canonical path between any pair of matchings $I, F \in \mathcal{N}$ is defined as the concatenation of three segments as follows:

initial segment: follow the canonical path from I to $\bar{I}$,
main segment: follow the canonical path from $\bar{I}$ to $\bar{F}$,
final segment: follow the canonical path from $\bar{F}$ to F.

Now consider an arbitrary oriented edge of H, corresponding to a transition t in the Markov chain. We aim to establish an upper bound of the form $b|\mathcal{N}|$ on the number of canonical paths that contain this transition. Suppose first that t occurs in the *initial* segment of a path from I to F, where $I, F \in \mathcal{N}$. Then it is clear from the definition of initial segment that the perfect matching $\bar{I}$ is uniquely determined by t. But we have already seen that $|\mathcal{K}(\bar{I})| \leq n^2$. Since $I \in \mathcal{K}(\bar{I})$, the number of paths that contain t in their initial segment is thus at most $n^2|\mathcal{N}|$. A symmetrical argument shows that the number of paths containing t in their final segment is similarly bounded.

To handle the main segments of the paths, we make use of the injective mapping technique seen in the proof of Proposition 2.4. This will obviate the need for any explicit counting of structures in $\mathcal{N}$, which is crucial here (cf. the discussion following the proof of Proposition 2.4). Let t be a transition from M to M', where $M, M' \in \mathcal{N}$ are distinct, and denote by $P(t)$ the set of ordered pairs $\langle I, F \rangle$ of *perfect* matchings such that t is contained in the canonical path from I to F. We proceed to define, for each pair $\langle I, F \rangle \in P(t)$, an encoding $\sigma_t(I, F) \in \mathcal{N}$ from which I and F can be uniquely reconstructed. The intention is that, if $C_1, \cdots, C_r$ is the ordered sequence of cycles in $I \oplus F$, and t is traversed during the unwinding of C_i, then the encoding should agree with I on $C_1, \cdots, C_{i-1}$ and on that portion of C_i that has already been unwound, and with F elsewhere.

With this in mind, consider the set $S = I \oplus F \oplus (M \cup M')$. Since $I \cap F \subseteq M \cup M' \subseteq I \cup F$ and $|I| = |F| = |M \cup M'| = n$, elementary set theory tells us that $|S| = n$. Furthermore, suppose that some vertex u is adjacent to two edges in S. Then both these edges necessarily lie in $I \oplus F$, which in turn implies that neither edge lies in $M \cup M'$. Hence

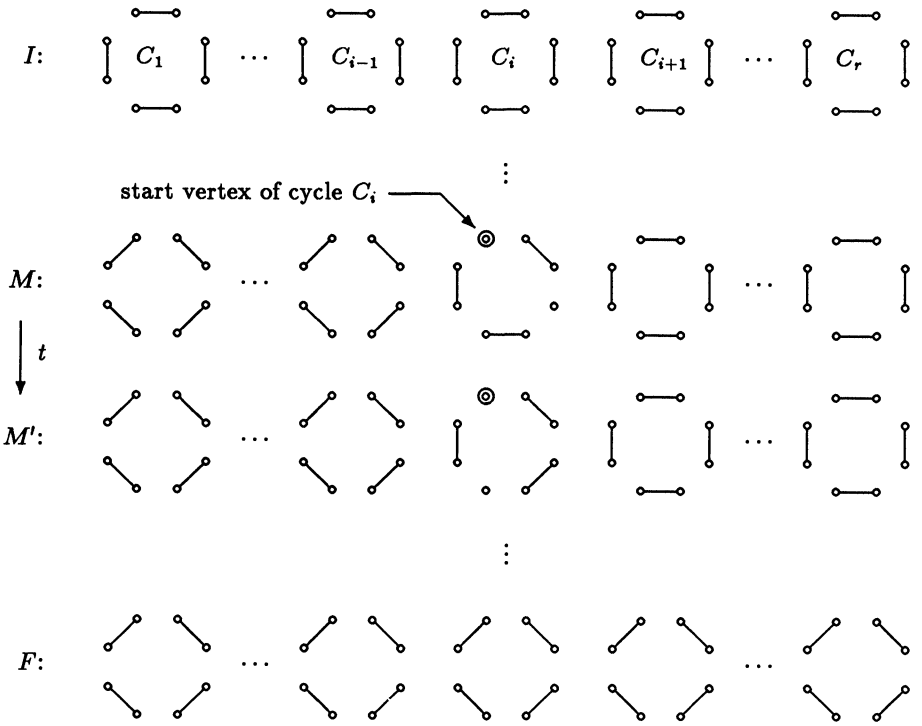

FIG. 1(a). *A transition t on the canonical path from I to F.*

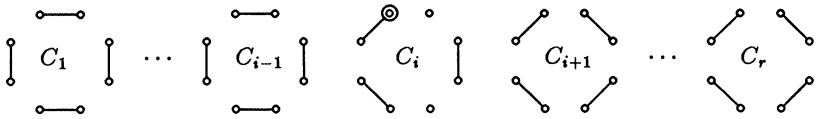

FIG. 1(b). *The corresponding encoding* $\sigma_t(I, F)$.

the vertex u must be unmatched in $M \cup M'$. From the form of the transitions, however, it is clear that $M \cup M'$ contains at most one such vertex $u = u_t$; moreover, this is the case if and only if t is a Type 0 transition, and u_t must then be the start vertex of the cycle currently being unwound. In this case, we denote by $e_{I,t}$ the edge of I incident with u_t.

We are now in a position to define the encoding:

$$\sigma_t(I, F) = \begin{cases} (I \oplus F \oplus (M \cup M')) - e_{I,t} & \text{if } t \text{ is Type 0,} \\ I \oplus F \oplus (M \cup M') & \text{otherwise.} \end{cases}$$

Figure 1(b) illustrates this definition for a Type 0 transition. In view of the above discussion, $\sigma_t(I, F)$ is always a matching of cardinality at least $n-1$, and hence an element of $\mathcal{N}$. It remains for us to show that I and F can be recovered from it.

First observe that $I \oplus F$ can be recovered immediately using the relation

$$I \oplus F = \begin{cases} (\sigma_t(I, F) \oplus (M \cup M')) + e_{I,t} & \text{if } t \text{ is Type 0,} \\ \sigma_t(I, F) \oplus (M \cup M') & \text{otherwise.} \end{cases}$$

(Note that $e_{I,t}$ is the unique edge that must be added to $\sigma_t(I, F) \oplus (M \cup M')$ to ensure that $I \oplus F$ is a union of disjoint cycles.) Thus we may infer the ordered sequence

$C_1, \cdots, C_r$ of cycles to be unwound on the path from I to F. The cycle C_i that is currently being unwound, together with its parity with respect to I and F, is then determined by the transition t. The parity of all remaining cycles may be deduced from M and the cycle ordering. Finally, the remaining portions of I and F may be recovered using the fact that $I \cap F = M \setminus (I \oplus F)$. Hence $\sigma_t(I, F)$ uniquely determines the pair $\langle I, F \rangle$, so σ_t is an injective mapping from $P(t)$ to $\mathcal{N}$.

The existence of σ_t ensures that $|P(t)| \leqq |\mathcal{N}|$ for any transition t. Since also $|\mathcal{K}(M)| \leqq n^2$ for any perfect matching M, we see that t is contained in the main segment of at most $n^4|\mathcal{N}|$ paths. Combining this with the results for initial and final segments derived earlier, we deduce that the maximum total number of paths that contain t is bounded by

$$(n^2 + n^2 + n^4)|\mathcal{N}| \leqq 3n^4|\mathcal{N}|.$$

To complete the proof we set $b = 3n^4$ in (6). □

Remarks. (a) In his original paper [8], Broder claimed that the above rapid mixing property holds under the same density assumption. However, as indicated in § 1, his proof based on coupling ideas is both complex and fundamentally flawed. The problem is that the "coupling" defined in [8] is not, in fact, a coupling because one of the two processes involved is not a faithful copy of $\mathcal{MC}_{\text{pm}}(G)$: this is explained in detail by Mihail [25]. As a result Broder has withdrawn his proof (see the erratum to [8]). We feel that this is compelling evidence of the unsuitability of coupling and related methods for the analysis of Markov chains that lack a high degree of symmetry.

(b) A chain with larger conductance is obtained by modifying $\mathcal{MC}_{\text{pm}}(G)$ slightly so that transitions are effected by selecting a random vertex in V rather than a random edge. This increases the transition probability in (5) from $1/2|E|$ to $1/2n$, saving a factor of n in the conductance bound.

(c) The f.p. almost uniform generator for $M_n(G) \cup M_{n-1}(G)$ may be adapted to one for *perfect* matchings in dense graphs G, by repeatedly generating elements of $M_n(G) \cup M_{n-1}(G)$ and outputting the first perfect matching which occurs. Since $|M_n(G)| \geqq n^{-2}|\mathcal{N}|$ we should not have to wait too long, but if so some arbitrary perfect matching may be output without affecting the bias too much. Among other things, with appropriate choice of G this provides a way of generating certain natural restricted classes of permutations that satisfy the density condition, such as displacements or ménage arrangements.

(d) So far we have concentrated exclusively on bipartite graphs because of their connection with the permanent. The Markov chain $\mathcal{MC}_{\text{pm}}(G)$ can be applied without essential modification to arbitrary graphs G. In fact, the only point at which we have relied on the bipartite structure of G is in the definition of the sets $\mathcal{K}(M)$ in the proof of Theorem 3.2 and the bound on their size. Let $G = (V, E)$ be an arbitrary graph with $|V| = 2n$. As before, we assume that G contains a perfect matching. Call G *dense* if its minimum vertex degree is at least n. This ensures that $\mathcal{K}(M)$ for $M \in M_n(G)$ is still well defined, and that $|\mathcal{K}(M)| \leqq 2n^2$. The rest of the proof carries through as before, yielding $b = 8n^4$ and consequently $\Phi(H) \geqq 1/64n^6$. (This can again be improved if transitions are implemented by random vertex selection.) Since a construction analogous to that of Theorem 3.1 holds for general dense graphs, we have:

COROLLARY 3.5. *There exists an fpras for $|M_n(G)|$ in arbitrary dense graphs.* □

We conclude this section by examining the role played in our results by the density assumption. In the proof of Theorem 3.2 it was used to show that each element of $M_{n-1}(G)$ is "close to" a perfect matching, so that near-perfect matchings could effectively be ignored in the conductance argument. In fact, it is enough to know that

the total *number* of near-perfect matchings is not too large. More specifically, the above results hold under the considerably weaker assumption that

$$|M_{n-1}(G)|/|M_n(G)| \leqq q(n) \tag{7}$$

for some fixed polynomial q. (Recall that we are assuming $|M_n(G)| > 0$.) This condition will arise more naturally in the context of the improved algorithm of § 5. Accordingly, we only sketch the proof modifications necessary to extend the method of this section. A fuller account can be found in [28].

First, it is not hard to see that the reduction of Theorem 3.1 still holds for graphs G satisfying the weaker condition (7). (This fact relies on Theorem 5.1 of § 5.) It is therefore enough to generate elements of $\mathcal{N} = M_n(G) \cup M_{n-1}(G)$ using the Markov chain $\mathcal{MC}_{\text{pm}}(G)$: the only thing we have to check is that its conductance remains bounded below by an inverse polynomial function of n. This is a consequence of the following generalised version of Theorem 3.2.

THEOREM 3.6. *For any graph $G = (V, E)$ with $|V| = 2n$ and $|M_n(G)| > 0$, the conductance of the underlying graph of $\mathcal{MC}_{\text{pm}}(G)$ is bounded below by*

$$\frac{1}{16|E|}\left(\frac{|M_n(G)|}{|M_{n-1}(G)|}\right)^2.$$

Sketch of proof. Let H be the underlying graph of $\mathcal{MC}_{\text{pm}}(G)$. The proof differs from that of Theorem 3.2 in one or two details. First, we use a variant of the canonical path counting argument in which only paths from perfect to near-perfect matchings are considered. If these can be defined in such a way that no edge of H carries more than $b|\mathcal{N}|$ of them, then a little algebra yields (cf. (6))

$$\Phi(H) \geqq \frac{1}{16b|E|}\left(\frac{|M_n(G)|}{|M_{n-1}(G)|}\right). \tag{8}$$

The paths themselves are similar to those between perfect matchings in the proof of Theorem 3.2: if $I \in M_n(G)$ and $F \in M_{n-1}(G)$, the symmetric difference $I \oplus F$ consists of a sequence $C_1, \cdots, C_r$ of disjoint cycles as before, together with a single open path O that is unwound in the obvious way *after* all the C_i.

Let t be an arbitrary transition. The injective mapping technique can again be used to bound the cardinality of the set $P(t)$ of paths of the above kind that involve t. For $\langle I, F\rangle \in P(t)$ the encoding $\sigma_t(I, F)$ is defined exactly as before, and σ_t is again injective. Now, however, we find that $\sigma_t(I, F) \in M_{n-1}(G) \cup M_{n-2}(G)$, as we get an additional pair of unmatched vertices arising from the open path O. (Note that this time the encoding takes us outside the state space.) Since σ_t is injective we have

$$|P(t)| \leqq |M_{n-1}(G)| + |M_{n-2}(G)| \leqq \left(\frac{|M_{n-1}(G)|}{|M_n(G)|}\right)|\mathcal{N}|,$$

where the second inequality again appeals to Theorem 5.1. Thus we may take $b = |M_{n-1}(G)|/|M_n(G)|$ in (8), completing the proof of the theorem. □

COROLLARY 3.7. *Let q be any fixed polynomial. There exists an fpras for $|M_n(G)|$ in all $2n$-vertex graphs G that satisfy $|M_{n-1}(G)|/|M_n(G)| \leqq q(n)$.* □

Our earlier results for dense graphs can be derived as a special case of Corollary 3.7 with $q(n) = O(n^2)$. Note that the density bound quoted is tight in the sense that it is possible to construct, for any fixed $\delta > 0$, a sequence of (bipartite) graphs (G_n) with $2n$ vertices and minimum vertex degree at least $n/(2+\delta)$ such that the ratio $|M_{n-1}(G_n)|/|M_n(G_n)|$ is exponentially large.

Remark. Dagum et al. [9] have shown that the reduction from counting to generation of Theorem 3.1 may be replaced by the following mechanism, with a small increase in efficiency. In analogous fashion to $\mathcal{MC}_{\text{pm}}(G)$, we may define for $1 \leqq k \leqq n$ a Markov chain $\mathcal{MC}_k(G)$ whose states are k- and $(k-1)$-matchings in G. (Thus $\mathcal{MC}_n(G)$ is just $\mathcal{MC}_{\text{pm}}(G)$.) By a simple extension of the proof of Theorem 3.6, whereby multiple rather than unique canonical paths between states are counted, it can be shown that each of the chains $\mathcal{MC}_k(G)$ is rapidly mixing under the same condition (7) on G. This allows the ratios $|M_k(G)|/|M_{k-1}(G)|$ to be estimated directly for each k in turn. We do not dwell on this point here as we will present a more natural algorithm in § 5. □

This concludes our discussion of perfect matchings for now. An alternative view of all these results will emerge as a by-product of our work on a different problem in the next section.

4. Monomer–dimer systems. This section is concerned with counting and generating at random all matchings (independent sets of edges) in a graph. Apart from their inherent interest, these problems arise in the theory of statistical physics, a rich source of combinatorial counting and generation problems.

A *monomer–dimer system* consists of a graph $G=(V, E)$, which is usually some form of regular lattice, together with a positive weight on each edge. The vertices of G represent physical sites, adjacent pairs of which may be occupied by diatomic molecules or *dimers*. Configurations of the system correspond to arrangements of dimers on the lattice in which no two dimers overlap, i.e., to matchings in G. In a configuration consisting of fewer than $|V|/2$ dimers, unoccupied sites are referred to as *monomers*. Monomer–dimer systems have been extensively studied as models of physical systems involving diatomic molecules. In the two-dimensional case they model the adsorption of dimers on the surface of a crystal. Three-dimensional systems occur in the theory of mixtures of molecules of different sizes and in the cell-cluster theory of the liquid state. For further information, see [14] and the references given there.

For each edge e of G, the weight $c(e)$ represents the relative probability of occupation by a dimer. This will depend on the contribution of such a dimer to the global energy of the system. Most thermodynamic properties of the system can be deduced from knowledge of the *partition function*

$$Z(G) = \sum_{M \in M_*(G)} W(G, M) \tag{9}$$

where $M_*(G)$ is the set of configurations (matchings in G) and $W(G, M) = \prod_{e \in M} c(e)$ is the *weight* of the configuration M. Counting matchings, i.e., computing (9) in the special case where all edge weights are unity, is a #P-complete problem even when restricted to planar graphs [15], [33]. The main result of this section is that the more general sum (9) can in fact be *approximated* efficiently for any weighted graph G.

We will proceed as in the previous section via a related random generation problem for configurations. Since the sum in (9) is weighted, however, configurations should be generated not uniformly but with probabilities proportional to their weights. In fact, this problem is of interest in its own right as a means of estimating the expectation of various physical operators on configurations by the so-called Monte Carlo method [6].

The notion of an almost uniform generator can be generalised to the weighted case in the obvious way. We will call a probabilistic algorithm an *almost W-generator* for matchings if, given a graph G with positive edge weights and a positive real bias $\varepsilon > 0$, it outputs a matching M in G with probability that approximates

$W(G, M)/Z(G)$ within ratio $1+\varepsilon$. As usual, the generator is f.p. if its runtime is bounded by a polynomial in the size of the input G and in $\lg \varepsilon^{-1}$.

The problem of approximating the partition function (9) is reduced to the weighted generation problem as follows. Let $e=(u, v)$ be any edge of the weighted graph $G=(V, E)$, G^- the graph obtained by removing e from G, and G^+ the graph obtained by removing the vertices u and v together with all their incident edges. By partitioning matchings in G into two sets according to whether they do or do not contain e, it is readily seen that

(i) There is a (1-1)-correspondence between $M_*(G)$ and the disjoint union of $M_*(G^+)$ and $M_*(G^-)$;

(ii) $Z(G)=c(e)Z(G^+)+Z(G^-)$.

This suggests the following recursive procedure for estimating $Z(G)$:

(1) Using an almost W-generator, construct an independent sample of elements of $M_*(G)$ as detailed below.

(2) For some edge e of G, let z^+, z^- denote the proportions of elements in the sample that do and do not contain e, respectively. Note that these quantities estimate $c(e)Z(G^+)/Z(G)$ and $Z(G^-)/Z(G)$, respectively.

(3) If $z^+ \geqq z^-$, recursively estimate $Z(G^+)$ and multiply the result by $c(e)/z^+$; otherwise, recursively estimate $Z(G^-)$ and multiply by $1/z^-$.

The procedure terminates when the input graph contains no edges. Note that the choice of the larger ratio in step (3) maximises the accuracy of the method.

Some elementary but tedious statistics (see [16, Thm. 6.4]) confirms that, if the bias in the generator is set to $\varepsilon/\alpha|E|$ for some constant α, the sample size required in step (1) to ensure that the final answer approximates $Z(G)$ within ratio $1+\varepsilon$ with probability at least $\frac{3}{4}$ is only $O(|E|^3\varepsilon^{-2})$. We therefore have the following theorem.

THEOREM 4.1. *Suppose there exists an f.p. almost W-generator for matchings. Then there exists an fpras for the partition function of monomer-dimer systems.* □

Remark. The foregoing is an example of a more general reduction from approximate counting to random generation, justified in detail in [16], [28], that applies to all structures that are *self-reducible*. Informally, this means that the set of structures corresponding to any problem instance is in (1-1)-correspondence with the disjoint union of sets corresponding to a few smaller problem instances (subproblems). In the case of matchings this property is expressed in condition (i) above. Since we are dealing here with *weighted* combinatorial sums, we need to supplement the definition of self-reducibility by demanding that any sum can be computed easily given the sums for its subproblems: condition (ii) states this for the monomer-dimer partition function. This implies that the Markov chain approach to random generation studied in this paper is potentially a powerful *general* method for approximating hard combinatorial counting problems. (Note that in the previous section it was necessary to resort to the specialised reduction provided by Theorem 3.1. The reason is that, while perfect matchings are easily seen to be self-reducible in general, this property is apparently destroyed when restrictions are placed on the input graph as in § 3.) □

Theorem 4.1 says that we will get an fpras for the monomer-dimer partition function provided we can efficiently generate matchings with probabilities roughly proportional to their weights. This we achieve by simulating a Markov chain in the style of Metropolis et al. [6]. Given a graph $G=(V, E)$ with positive edge weights $\{c(e): e \in E\}$, we consider the chain $\mathcal{MC}_{\mathrm{md}}(G)$ with state space $\mathcal{N}=M_*(G)$ and transitions as follows. In any state $M \in \mathcal{N}$, choose an edge $e=(u, v) \in E$ uniformly at random and then

(i) If $e \in M$, move to $M-e$ with probability $1/(1+c(e))$ (*Type* 1 *transition*);

(ii) If u and v are both unmatched in M, move to $M+e$ with probability $c(e)/(1+c(e))$ (*Type 2 transition*);

(iii) If $e'=(u, w)\in M$ for some w, and v is unmatched in M, move to $(M+e)-e'$ with probability $c(e)/(c(e)+c(e'))$ (*Type 0 transition*);

(iv) In all other cases, do nothing.

As always, we simplify matters by adding a self-loop probability of $\frac{1}{2}$ to each state. It is then readily checked that $\mathscr{MC}_{\mathrm{md}}(G)$ is irreducible and aperiodic, and hence ergodic. The stationary probability π_M of $M\in M_*(G)$ is easily seen, by Lemma 2.1, to be proportional to its weight $W(G, M)=\prod_{e\in M} c(e)$, so simulation of the chain will yield an f.p. almost W-generator for matchings provided the family $\mathscr{MC}_{\mathrm{md}}(G)$ is rapidly mixing. Now $\mathscr{MC}_{\mathrm{md}}(G)$ is clearly time-reversible by virtue of the detailed balance condition (1), so we may again apply Theorem 2.2. The crucial fact is the following.

THEOREM 4.2. *For a graph $G=(V, E)$ with positive edge weights $\{c(e): e\in E\}$, the conductance of the underlying graph of the Markov chain $\mathscr{MC}_{\mathrm{md}}(G)$ is bounded below by $1/(8|E|c_{\max}^2)$, where $c_{\max}=\max\{1, \max_{e\in E} c(e)\}$.*

Proof. Let H be the underlying graph of $\mathscr{MC}_{\mathrm{md}}(G)$. The first step is to establish a weighted version of the path counting argument that led to the bound (4). Suppose that between each ordered pair $\langle I, F\rangle$ of distinct states we have a canonical path in H, and let us associate with the path a weight $\pi_I\pi_F$. Also, for any subset S of states define

$$C_S=\sum_{M\in S}\pi_M \quad \text{the } \textit{capacity} \text{ of } S,$$

$$F_S=\sum_{M\in S, M'\notin S}\pi_M p_{MM'} \quad \text{the } \textit{ergodic flow} \text{ out of } S.$$

($p_{MM'}$ is the transition probability from M to M'.) Note that the conductance $\Phi(H)$ is just the minimum value of the ratio F_S/C_S over subsets S with $0<C_S\leqq\frac{1}{2}$. For any such S, the aggregated *weight* of all paths crossing the cut from S to its complement $\bar{S}$ in $\mathscr{N}$ is

$$\sum_{I\in S, F\in\bar{S}}\pi_I\pi_F=C_S C_{\bar{S}}\geqq\frac{C_S}{2}. \tag{10}$$

Now let t be a transition from a state M to a state $M'\neq M$, and denote by $P(t)$ the set of all ordered pairs $\langle I, F\rangle$ whose canonical path contains t. Suppose it is known that, for any such transition t, the aggregated weight of paths containing t satisfies

$$\sum_{\langle I,F\rangle\in P(t)}\pi_I\pi_F\leqq b w_t \tag{11}$$

where $w_t=\pi_M p_{MM'}=\pi_{M'}p_{M'M}$ is the weight of the edge in H corresponding to t. Taking (10) and (11) together, we have the following bound on the ergodic flow out of S, where $\mathrm{cut}(S)$ denotes the set of transitions crossing the cut from S to $\bar{S}$:

$$\begin{aligned} F_S=\sum_{t\in\mathrm{cut}(S)} w_t &\geqq b^{-1}\sum_{t\in\mathrm{cut}(S)}\sum_{\langle I,F\rangle\in P(t)}\pi_I\pi_F \\ &\geqq b^{-1}\sum_{I\in S, F\in\bar{S}}\pi_I\pi_F \\ &\geqq\frac{C_S}{2b}. \end{aligned}$$

By definition, the conductance of H therefore satisfies

$$\Phi(H)\geqq\frac{1}{2b}. \tag{12}$$

Our aim is thus to define a set of paths obeying a suitable bound b in (11).

To do this we generalise the proof of Theorem 3.2. Suppose there is an underlying order on all simple paths in G and designate in each of them a start vertex, which must

be an endpoint if the path is not a cycle but is arbitrary otherwise. For distinct $I, F \in \mathcal{N}$, we can write the symmetric difference $I \oplus F$ as a sequence $Q_1, \cdots, Q_r$ of disjoint paths that respects the ordering. The canonical path from I to F involves unwinding each of the Q_i in turn as follows. There are two cases to consider:

Case i. *Q_i is not a cycle.* Let Q_i consist of the sequence $(v_0, v_1, \cdots, v_l)$ of vertices, with v_0 the start vertex. If $(v_0, v_1) \in F$, perform a sequence of Type 0 transitions replacing (v_{2j+1}, v_{2j+2}) by (v_{2j}, v_{2j+1}) for $j = 0, 1, \cdots$, and finish with a single Type 2 transition if l is odd. If on the other hand $(v_0, v_1) \in I$, begin with a Type 1 transition removing (v_0, v_1) and proceed as before for the reduced path $(v_1, \cdots, v_l)$.

Case ii. *Q_i is a cycle.* Let Q_i consist of the sequence $(v_0, v_1, \cdots, v_{2l+1})$ of vertices, where v_0 is the start vertex, $l \geqq 1$ and $(v_{2j}, v_{2j+1}) \in I$ for $0 \leqq j \leqq l$, the remaining edges belonging to F. Then the unwinding begins with a Type 1 transition to remove (v_0, v_1). We are left with an open path O with endpoints v_0, v_1, one of which must be the start vertex of O. Suppose v_k, $k \in \{0, 1\}$, is *not* the start vertex. Then we unwind O as in Case (i) above but treating v_k as the start vertex. This trick serves to distinguish cycles from open paths, as will prove convenient shortly.

Now let t be a transition from M to $M' \neq M$. The next step is to define our injective mapping $\sigma_t : P(t) \to \mathcal{N}$. As in the proof of Theorem 3.2, we set $\sigma_t(I, F)$ equal to $I \oplus F \oplus (M \cup M')$, and remove the edge $e_{I,t}$ of I adjacent to the start vertex of the path currently being unwound if necessary: this is so if and only if the path is a cycle and t is Type 0. It is now easily seen that $\sigma_t(I, F)$ consists of independent edges, and so is an element of $\mathcal{N}$. The difference $I \oplus F$ can be recovered from $\sigma_t(I, F)$ using the relation

$$I \oplus F = \begin{cases} (\sigma_t(I, F) \oplus (M \cup M')) + e_{I,t} & \text{if } t \text{ is Type 0 and the current path is a cycle;} \\ \sigma_t(I, F) \oplus (M \cup M') & \text{otherwise.} \end{cases}$$

Note that we can tell whether the current path is a cycle from the sense of unwinding. Recovery of I and F themselves now follows as before from the path ordering. Hence σ_t is injective.

Moreover, it should be clear that $\sigma_t(I, F)$ is very nearly the complement of M in the union of I and F viewed as a multiset, so that the product $\pi_I \pi_F$ is approximately equal to $\pi_M \pi_{\sigma_t(I,F)}$, giving us a handle on b in (11). We now make this precise.

CLAIM. *For any $\langle I, F \rangle \in P(t)$, we have*

$$\pi_I \pi_F \leqq 4|E| c_{\max}^2 w_t \pi_{\sigma_t(I,F)}. \tag{13}$$

The claim will be proved in a moment. First note that it immediately yields the desired bound b in (11), since for any transition t we have

$$\sum_{\langle I,F \rangle \in P(t)} \pi_I \pi_F \leqq 4|E| c_{\max}^2 w_t \sum_{\langle I,F \rangle \in P(t)} \pi_{\sigma_t(I,F)} \leqq 4|E| c_{\max}^2 w_t$$

where the second inequality follows from the fact that σ_t is injective. We may therefore take $b = 4|E| c_{\max}^2$, which in light of (12) gives the conductance bound stated in the theorem.

It remains only for us to prove the claim. We distinguish three cases:

Case i. *t is a Type 1 transition.* Suppose $M' = M - e$. Then $\sigma_t(I, F) = I \oplus F \oplus M$, so, viewed as multisets, $M \cup \sigma_t(I, F)$ and $I \cup F$ are equal. Hence we have

$$\begin{aligned} \pi_I \pi_F &= \pi_M \pi_{\sigma_t(I,F)} \\ &= (w_t / p_{MM'}) \pi_{\sigma_t(I,F)} \\ &= 2|E|(1 + c(e)) w_t \pi_{\sigma_t(I,F)}, \end{aligned}$$

from which (13) follows.

Case ii. *t is a Type* 2 *transition.* This is handled by a symmetrical argument to Case (i) above, with M replaced by M'.

Case iii. *t is a Type* 0 *transition.* Suppose $M' = (M + e) - e'$, and consider the multiset $\sigma_t(I, F) \cup M$. This is equal to the multiset $I \cup F$ except that the edge e, and possibly also the edge $e_{I,t}$ are absent from it. Assuming $e_{I,t}$ is absent, which happens precisely when the current path is a cycle, we have

$$\begin{aligned}\pi_I \pi_F &= c(e_{I,t})c(e)\pi_M \pi_{\sigma_t(I,F)} \\ &= c(e_{I,t})c(e)(w_t/p_{MM'})\pi_{\sigma_t(I,F)} \\ &= 2|E|c(e_{I,t})(c(e)+c(e'))w_t \pi_{\sigma_t(I,F)},\end{aligned}$$

again satisfying (13). If $e_{I,t}$ is not absent, the argument is identical with the factor $c(e_{I,t})$ omitted.

This concludes the proof of the claim and the theorem. □

COROLLARY 4.3. *There exists an f.p. almost W-generator for matchings in arbitrary weighted graphs provided the edge weights are positive and presented in unary.*

Proof. Define $c_{\min} = \min\{1, \min_{e \in E} c(e)\}$. Then the minimum stationary state probability in $\mathcal{MC}_{\mathrm{md}}(G)$ is at least $c_{\min}^n 2^{-|E|} c_{\max}^{-n}$, where $n = |V|$. The logarithm of this quantity is at least $-p(|G|)$, where $|G|$ is the size of the description of G and p is a polynomial. Hence by Theorems 2.2 and 4.2, the Markov chains are rapidly mixing. Simulation of $\mathcal{MC}_{\mathrm{md}}(G)$ is a simple matter, starting from the empty matching. □

In view of Theorem 4.1, we may now state the main result of this section.

COROLLARY 4.4. *There exists an fpras for the monomer-dimer partition function of arbitrary weighted graphs with edge weights presented in unary.* □

COROLLARY 4.5. *There exists an fpras for the number of matchings in arbitrary graphs.* □

5. Some applications: The permanent revisited. As we have already mentioned, our analysis of the monomer-dimer Markov chain $\mathcal{MC}_{\mathrm{md}}(G)$ sheds new light on the results of § 3. In this section we will demonstrate that it yields a more natural approximation algorithm for counting perfect matchings in $2n$-vertex graphs G for which the ratio $|M_{n-1}(G)|/|M_n(G)|$ is polynomially bounded, and in addition allows this condition to be probabilistically tested for an arbitrary graph in polynomial time. We will also discuss an application of the chain to finding a maximum matching in a graph by simulated annealing. The key to all these algorithms is the introduction of carefully chosen edge weights.

The results of this section (and indeed Corollary 3.7 of § 3) depend crucially on the following property of matchings. As usual, let $M_k(G)$ denote the set of k-matchings in a graph G.

THEOREM 5.1. *For any graph G, the sequence* $\{|M_k(G)|: k \in \mathbb{N}\}$ *is log-concave, i.e.,*

$$|M_{k+1}(G)|\,|M_{k-1}(G)| \leqq |M_k(G)|^2 \quad \forall k \in \mathbb{N}^+.$$

Proof. A proof that relies on machinery from complex analysis can be found in Theorem 7.1 of [14] (see also [23, Exercise 8.5.10]). We present an elementary combinatorial proof that uses ideas seen elsewhere in this paper. Since log-concavity results in combinatorics tend to be rather hard to come by, we believe the simpler proof to be of independent interest.

Let $k \in \mathbb{N}^+$. We may assume that $|M_{k+1}(G)| > 0$, since the inequality is trivially true otherwise. Define the sets $A = M_{k+1}(G) \times M_{k-1}(G)$ and $B = M_k(G) \times M_k(G)$. Our aim is to show that $|A| \leqq |B|$.

As in the proof of Theorem 4.2, the symmetric difference $M \oplus M'$ of any two matchings M, M' in G consists of a set of disjoint simple paths (possibly closed) in G. Let us call such a path an *M-path* if it contains one more edge of M than of M'; an M'-path is defined similarly. Clearly, all other paths in $M \oplus M'$ contain equal numbers of edges from M and M'. Now for any pair $\langle M, M' \rangle \in A$, the number of M-paths in $M \oplus M'$ must exceed the number of M'-paths by precisely two. We may therefore partition A into disjoint classes $\{A_r : 0 < r \leqq k\}$, where

$$A_r = \{\langle M, M' \rangle \in A : M \oplus M' \text{ contains } r+1 \ M\text{-paths and } r-1 \ M'\text{-paths}\}.$$

Similarly, the sets $\{B_r : 0 \leqq r \leqq k\}$ with

$$B_r = \{\langle M, M' \rangle \in B : M \oplus M' \text{ contains } r \ M\text{-paths and } r \ M'\text{-paths}\}$$

partition B. The lemma will follow from the fact that $|A_r| \leqq |B_r|$ for each $r > 0$.

Let us call a pair $\langle L, L' \rangle \in B_r$ *reachable* from $\langle M, M' \rangle \in A_r$ if and only if $L \oplus L' = M \oplus M'$ and L is obtained from M by taking some M-path of $M \oplus M'$ and flipping the parity of all its edges with respect to M and M'. (This is analogous to *unwinding* the path in the proof of Theorem 4.2.) Clearly, the number of elements of B_r reachable from a given $\langle M, M' \rangle \in A_r$ is just the number of M-paths in $M \oplus M'$, namely $r+1$. Conversely, any given element of B_r is reachable from precisely r elements of A_r. Hence if $|A_r| > 0$ we have

$$\frac{|B_r|}{|A_r|} = \frac{r+1}{r} > 1,$$

completing the proof of the lemma. □

Remark. In [14] the tight inequality

$$|M_k(G)|^2 \geqq \frac{(k+1)(m-k+1)}{k(m-k)} |M_{k+1}(G)| \, |M_{k-1}(G)|$$

is proved, where $m = \lceil n/2 \rceil$ and n is the number of vertices in G. The bound in our proof can also be improved, but we will not labour this point here as simple log-concavity is quite adequate for our purposes. □

Note that Theorem 5.1 immediately implies the following:

COROLLARY 5.2. *For a $2n$-vertex graph $G = (V, E)$ with $|M_n(G)| > 0$, the ratio $|M_{k-1}(G)|/|M_k(G)|$ increases monotonically with k in the range $0 < k \leqq n$; the maximum value of the ratio is $|M_{n-1}(G)|/|M_n(G)|$ and the minimum value is $|E|^{-1}$.* □

Armed with log-concavity, let us sketch how an algorithm that generates matchings from the weighted distribution of § 4 may be used to estimate the number of perfect matchings in a given *unweighted* $2n$-vertex graph $G = (V, E)$. Write m_k in place of $|M_k(G)|$, and assume that $m_n > 0$. The idea is to estimate the ratios m_{k+1}/m_k in turn in a sequence of n stages for $k = 0, \cdots, n-1$. Since $m_0 = 1$, an approximation to m_n is then obtained as the product of the estimated ratios.

In stage k we could in principle estimate m_{k+1}/m_k using an algorithm that generates matchings in G *uniformly*: just observe the relative numbers of $(k+1)$- and k-matchings in an independent sample produced by the generator. However, a very large sample may be necessary since these matchings might constitute only a tiny fraction of all matchings in G. This difficulty can be overcome by adding to every edge of G a weight c_k that is chosen so as to make the aggregated weight $m_k c_k^k$ of k-matchings maximal,

i.e., at least as large as that of matchings of any other size. That such a weight exists is a direct consequence of the log-concavity of the m_i. To see this, take $c_k = m_{k-1}/m_k$ and let $G(c_k)$ denote the graph G augmented with weight c_k on every edge. (We will not have available the exact value of m_{k-1}/m_k, but it will suffice to substitute the *estimate* of this quantity obtained in the previous stage.) Then if p_i is the probability of being at an i-matching in the stationary distribution of the Markov chain $\mathcal{MC}_{\mathrm{md}}(G(c_k))$, we have for $i \geqq k$

$$\frac{p_k}{p_i} = \frac{m_k c_k^k}{m_i c_k^i} = c_k^{k-i} \prod_{j=k}^{i-1} \frac{m_j}{m_{j+1}} \geqq \left(\frac{m_{k-1}}{m_k}\right)^{k-i} \left(\frac{m_{k-1}}{m_k}\right)^{i-k} = 1 \tag{14}$$

where the inequality comes from Corollary 5.2. An identical bound holds for $i < k$. Since $\sum p_i = 1$, we conclude that $p_k \geqq (n+1)^{-1}$. Moreover, the probability of being at a $(k+1)$-matching satisfies

$$p_{k+1} = \left(\frac{m_{k+1} c_k}{m_k}\right) p_k = \left(\frac{m_{k+1}}{m_k}\right)\left(\frac{m_{k-1}}{m_k}\right) p_k \geqq \frac{1}{|E|}\left(\frac{m_n}{m_{n-1}}\right) p_k. \tag{15}$$

Hence a lower bound of the form $1/\mathrm{poly}(n)$ holds for p_{k+1} also, provided the ratio m_{n-1}/m_n is polynomially bounded. These observations allow the ratio m_{k+1}/m_k to be estimated efficiently by sampling from the *weighted* distribution.

For the sampling itself we appeal to the Markov chain technique of § 4. (The algorithm is robust enough to cope with a small bias.) In view of Corollary 4.3, the generator will be efficient provided the various edge weights used in the algorithm are polynomially bounded. But each weight will be close to m_{k-1}/m_k for some k that by Corollary 5.2 lies in the range $[|E|^{-1}, m_{n-1}/m_n]$. This ensures rapid convergence of the Markov chain at all stages, provided again that m_{n-1}/m_n is polynomially bounded.

Notice how a polynomial bound on the ratio m_{n-1}/m_n plays a central role in the efficient operation of this algorithm. For an arbitrary function q of the natural number n, let us call a $2n$-vertex graph G *q-amenable* if either

(i) $|M_n(G)| = 0$, or

(ii) $|M_n(G)| > 0$ and $|M_{n-1}(G)|/|M_n(G)| \leqq q(n)$.

From the above discussion, we might expect to get an fpras for counting perfect matchings in q-amenable graphs for any fixed polynomial q.

The new approximation scheme for counting perfect matchings in q-amenable graphs G is spelled out in detail in Fig. 2. In line (4), $\mathcal{G}$ denotes the almost W-generator for matchings described in § 4, i.e., the call $\mathcal{G}(G(c), \cdot)$ invokes a simulation of the Markov chain $\mathcal{MC}_{\mathrm{md}}(G(c))$. The values of the sample size T and bias ξ will depend on n and the accuracy $0 < \varepsilon \leqq 1$ specified for the final estimate, as described below. The test in line (1) for the existence of a perfect matching may be implemented using any standard polynomial time algorithm.

THEOREM 5.3. *For an arbitrary polynomial q, the algorithm of Fig. 2 is an fpras for $|M_n(G)|$ in all q-amenable $2n$-vertex graphs G.*

Proof. In view of line (1), we need only consider graphs for which $m_n > 0$. Line (2) and the iterations of the **for**-loop correspond to the n stages of the computation mentioned above. Let c_{k+1} be the value of the weight parameter c at the end of stage k. We claim that, by making T a polynomial function of n and ε^{-1} and setting $\xi = \varepsilon/\alpha n$ for a suitable constant $\alpha > 1$, the following may be guaranteed:

$$\forall k \quad \Pr\left(c_{k+1} \text{ approximates } m_k/m_{k+1} \text{ within ratio } 1+\frac{\varepsilon}{2n}\right) \geqq \left(1-\frac{1}{4n^2}\right)^k. \tag{16}$$

```
(1)  if |M_n(G)| = 0 then halt with output 0
     else begin
(2)    c := |E|^{-1}; Π := |E|;
       for k := 1 to n − 1 do begin
(3)      if c > 2q(n) or c < (2|E|)^{-1} then halt with output 0
         else begin
(4)        make T calls of the form 𝒢(G(c), ξ)
             and let Y be the set of outputs;
(5)        p̃_k := T^{-1}|Y ∩ M_k(G)|; p̃_{k+1} := T^{-1}|Y ∩ M_{k+1}(G)|;
(6)        if p̃_k = 0 or p̃_{k+1} = 0 then halt with output 0
(7)        else begin c := cp̃_k/p̃_{k+1}; Π := Π/c end
         end
       end;
(8)    halt with output Π
     end
```

FIG. 2. *Approximation scheme for counting perfect matchings.*

This will imply that the product Π output in line (8) approximates m_n within ratio $(1+\varepsilon/2n)^n \leqq 1+\varepsilon$ with probability $(1-1/4n^2)^{n^2} \geqq 3/4$, as required. Moreover, the runtime of the procedure is bounded by a polynomial in n and ε^{-1}. (Note in particular that, by Corollary 4.3, the bounds on edge weights in line (3) ensure that each call to $\mathscr{G}$ is bounded in this way.) Hence the procedure is indeed an fpras.

The proof of (16) is a straightforward induction on k, the technical details of which are left to the reader. The important points to note are the following, assuming that c_k is a good estimate of m_{k-1}/m_k:

(i) In line (3), c will not violate the prescribed bounds because m_{k-1}/m_k lies in the range $[|E|^{-1}, q(n)]$.

(ii) From (14) and (15), the probabilities p_k, p_{k+1} of being at a k- and $(k+1)$-matching in the stationary distribution of the Markov chain $\mathscr{MC}_{\mathrm{md}}(G(c_k))$ used in stage $k+1$ are bounded below by a function of the form $1/\mathrm{poly}(n)$. Hence the modest sample size T in line (4) is enough to make the estimates $\tilde{p}_k$, $\tilde{p}_{k+1}$ of these quantities in line (5) good with high probability. (Note that the pathological cases of line (6) are therefore very unlikely to occur.)

The assignment to c in line (7) therefore makes c_{k+1} a good estimate of m_k/m_{k+1} with high probability. □

The algorithm of Theorem 5.3 is preferable to those described in § 3 in several respects. For a given input graph G, it makes use of a single Markov chain structure, the only manipulations being simple scaling of transition probabilities. It avoids any discussion of ad hoc processes with state space $M_k(G) \cup M_{k-1}(G)$, whose transition structure is not uniform over states. Moreover, the condition that the ratio $|M_{n-1}(G)|/|M_n(G)|$ should be polynomially bounded (if $|M_n(G)| > 0$) is seen to arise directly from the log-concavity of the matching sequence.

Indeed, this condition seems to be a true characterisation of those graphs that can be handled by the algorithm, or equivalently of those matrices whose permanent we can efficiently approximate by this method. Since the condition is rather unfamiliar, it deserves further investigation. One worthwhile activity is to come up with simpler deterministic criteria that guarantee the condition holds. We have already seen one such criterion in § 3, namely that the graph is dense. Another criterion, due to Dagum et al. [9], is that the graph is bipartite and contains an αn-regular subgraph for some real $\alpha > 0$. However, as we will see in the next section, it turns out that the condition is a rather weak one and is, in fact, satisfied by almost all (bipartite) graphs. In other

words, there exists a fixed polynomial q such that almost every graph is q-amenable. Thus of more practical interest is the problem of testing efficiently for any given graph whether the condition holds. Such a test would enable us not only to approximate the permanent in almost all cases, but also to reliably identify difficult instances.

We now present an efficient randomised algorithm that tests the condition in the following strong probabilistic sense. Let q be a polynomial. When given as input a $2n$-vertex graph G containing a perfect matching and a positive real $\delta > 0$, the algorithm

(i) Accepts with probability at least $1-\delta$ if $|M_{n-1}(G)|/|M_n(G)| \leqq q(n)$;

(ii) Rejects with probability at least $1-\delta$ if $|M_{n-1}(G)|/|M_n(G)| > 6q(n)$.

For intermediate values of the ratio, we do not care whether the algorithm accepts or rejects. (The value 6 here is used for illustrative purposes only and may be replaced by any fixed constant greater than 1.) Furthermore, the runtime of the algorithm will be bounded by a polynomial in n and $\lg \delta^{-1}$.

Before presenting the algorithm we make precise its implications for counting perfect matchings. Consider the following combined procedure, whose input is an *arbitrary* $2n$-vertex graph G:

(1) Using a standard polynomial time algorithm, test whether G contains a perfect matching. If not, output 0 and halt.

(2) Apply the above randomised test for the condition $|M_{n-1}(G)|/|M_n(G)| \leqq q(n)$, having set an error probability $\delta = 2^{-n}$. If the algorithm rejects, output "Graph is not q-amenable" and halt.

(3) Using the approximation scheme of Fig. 2 with $q(n)$ replaced by $6q(n)$ (and the test of line (1) omitted), estimate $|M_n(G)|$ and output the result.

This procedure will run in polynomial time for any desired polynomial q. There are two ways in which it may produce a misleading result. With probability at most δ it may falsely claim that the input graph G is not q-amenable. Or, again with probability at most δ, it may output an unreliable approximation to $|M_n(G)|$ obtained under the false assumption that $|M_{n-1}(G)|/|M_n(G)| \leqq 6q(n)$. Since δ decreases exponentially with n, the procedure will, with very high probability, produce a result that is *not* misleading. This will either be a statement that G is not q-amenable, or a reliable approximation of $|M_n(G)|$.

We now show how to construct the testing algorithm advertised above. It again makes use of the weighted Markov chain generator $\mathcal{G}$ for matchings and is extremely simple to describe:

(1) Make T calls of the form $\mathcal{G}(G(2q(n)), 1/16)$, and let $\tilde{p}$ be the proportion of perfect matchings among the outputs. (T will depend on the input δ as specified below.)

(2) If $\tilde{p} \geqq 3/8$ accept, otherwise reject.

To see that this algorithm works, consider the stationary distribution of the Markov chain $\mathcal{MC}_{\mathrm{md}}(G(2q(n)))$, and let p denote the probability of being at a perfect matching. Writing as usual m_k in place of $|M_k(G)|$, Corollary 5.2 implies that

$$\frac{m_k}{m_n} = \prod_{i=k}^{n-1} \frac{m_i}{m_{i+1}} \leqq \left(\frac{m_{n-1}}{m_n}\right)^{n-k}$$

for $0 \leqq k \leqq n$. Hence in the case that $m_{n-1}/m_n \leqq q(n)$ we have

$$p = \frac{m_n(2q(n))^n}{\sum_{k=0}^{n} m_k(2q(n))^k} \geqq \frac{2^n}{\sum_{k=0}^{n} 2^k} > \frac{1}{2}. \tag{17}$$

On the other hand, if $m_{n-1}/m_n > 6q(n)$ we have

$$p \leqq \frac{m_n(2q(n))^n}{m_n(2q(n))^n + m_{n-1}(2q(n))^{n-1}} < \frac{m_n}{m_n + 3m_n} = \frac{1}{4}.$$

An elementary statistical argument now shows that, by taking $T = \alpha \lg \delta^{-1}$ for a suitable constant α, we can arrange for

$$\Pr(\tilde{p} \geqq \tfrac{3}{8}) \begin{cases} \geqq 1-\delta & \text{if } m_{n-1}/m_n \leqq q(n), \\ \leqq \delta & \text{if } m_{n-1}/m_n > 6q(n). \end{cases}$$

The runtime of the algorithm is therefore bounded as required.

Remark. It is often desirable to be able to count matchings of any specified cardinality in a given graph. In the context of the monomer-dimer systems of the previous section, these correspond to configurations with a given number of dimers. Obviously, the procedure of Fig. 2 may be modified so as to yield an fpras for $|M_k(G)|$ in graphs G for which the ratio $|M_{k-1}(G)|/|M_k(G)|$ is polynomially bounded. Such graphs may again be identified efficiently using a minor variant of the above randomised test. Note also that, under the same condition on G, we can easily adapt the algorithm of Fig. 2 to produce an f.p. almost uniform generator for $M_k(G)$ for any desired k. □

We close this section with a slight digression. In recent years, a stochastic search heuristic for combinatorial optimisation known as *simulated annealing* [21] has received much attention. The basic idea is that a Markov chain explores a space of configurations (feasible solutions), each of which has an associated cost or "energy." In the stationary distribution of the chain, low cost solutions have large weight so the chain tends to favour them asymptotically. By progressively reducing a "temperature" parameter, the weights are scaled so as to accentuate the depths of the energy wells. (Thus the process is not in general time-homogeneous.) While such a process is known to converge asymptotically under fairly general conditions (see, e.g., [13], [24]), virtually nothing useful is known about its *rate* of convergence when applied to nontrivial problems.

Consider the problem of finding a maximum cardinality matching in a graph G, which is nontrivial in the sense that all known polynomial time algorithms for solving it are far from simple. For any $c \geqq 1$ we may take the Markov chain $\mathcal{MC}_{\mathrm{md}}(G(c))$ as the basis for a simulated annealing algorithm for this problem: maximum cardinality matchings will certainly have maximum weight, and "temperature" may be reduced by increasing the edge weight c.

In [27], Sasaki and Hajek study the performance of algorithms of this kind. In particular, they prove a positive result of the following form.

THEOREM 5.4. *Let $\varepsilon > 0$ be any constant, $G = (V, E)$ be an input graph, and k_0 the maximum cardinality of a matching in G. Then a simulated annealing algorithm of the above type, operated at a fixed temperature (which depends on G and ε), finds a matching in G of cardinality at least $(1-\varepsilon)k_0$ with high probability in polynomial time.*

(In the same paper they also prove a strong negative result that says that no simulated annealing algorithm in this or a fairly large related class can be relied on to find a maximum cardinality matching in polynomial time with high probability.)

Sasaki and Hajek's proof is lengthy and complex. In contrast, we offer the following argument which rests directly on our earlier results.

Proof. Define $c_\varepsilon = 2|E|^{(1-\varepsilon)/\varepsilon}$. We claim that, in the stationary distribution of the Markov chain $\mathcal{MC}_{\mathrm{md}}(G(c_\varepsilon))$, the probability of being at a matching of size $k = \lceil (1-\varepsilon)k_0 \rceil$ or more is greater than $\frac{1}{2}$. Note that the theorem then follows at once: by

Corollary 4.3 a polynomially bounded simulation of $\mathscr{MC}_{\mathrm{md}}(G(c_\varepsilon))$ suffices to ensure that we visit a matching of size k or more with probability at least (say) $\frac{1}{4}$. This can be boosted to $1-\delta$ by repeating the entire experiment $O(\lg \delta^{-1})$ times. (However, in common with [27], our time bound increases exponentially with ε^{-1}.)

To justify the claim, note from Corollary 5.2 that

$$m_{k-1} = m_{k_0} \prod_{j=k}^{k_0} \frac{m_{j-1}}{m_j} \geqq \left(\frac{m_{k-1}}{m_k}\right)^{k_0-k+1}. \tag{18}$$

(Here we are using the fact that $m_{k_0} \geqq 1$.) But since j-matchings in G are subsets of E of size j, there is also the crude upper bound $m_{k-1} \leqq |E|^{k-1}$. Hence from (18) we conclude that

$$\frac{m_{k-1}}{m_k} \leqq |E|^{(1-\varepsilon)/\varepsilon} = \frac{c_\varepsilon}{2}. \tag{19}$$

A further application of Corollary 5.2 now shows that $m_i/m_k \leqq (c_\varepsilon/2)^{k-i}$ for $0 \leqq i \leqq k$, so the aggregated weight of matchings of size less than k is

$$\sum_{i=0}^{k-1} m_i c_\varepsilon^i \leqq \left(\sum_{i=0}^{k-1} 2^{i-k}\right) m_k c_\varepsilon^k < m_k c_\varepsilon^k.$$

It is now immediate that the probability of being at a matching of size k or more is at least $\frac{1}{2}$, completing the proof. □

Remark. Inequality (19) provides a polynomial upper bound on the ratio m_{k-1}/m_k, so from our earlier observations we are able to count and generate matchings of any cardinality up to $(1-\varepsilon)k_0$ in *arbitrary* graphs which contain a k_0-matching. □

6. Random permanents. For any polynomial q, the algorithm presented in Fig. 2 of the previous section is an fpras for the number of perfect matchings in a q-amenable graph G. For a bipartite graph G with $2n$ vertices, and $q(n) = n^2$, we have observed a sufficient condition for q-amenability, namely that the minimum vertex degree of G should be at least $n/2$. We have also observed that this result is the best possible, in the sense that, for any $\delta > 0$, there exists a family of graphs of minimum vertex degree at least $n/(2+\delta)$ for which $|M_{n-1}(G)|/|M_n(G)| = \exp\{\Omega(n)\}$.

The aim of this section is to demonstrate that these counterexamples are pathological, and that a randomly selected bipartite graph with given edge density—even when that density is small—will almost surely be q-amenable for some suitably chosen (fixed) polynomial q.

Let n be a positive integer, and p a real number in the interval $(0, 1)$. We will work with the probability space of bipartite graphs $G_{n,p}$ constructed according to the following random graph model. The vertex set of $G_{n,p}$ is $U+V$ where $U = V = \{0, \cdots, n-1\}$, and each potential edge (i.e., element of $U \times V$) is included in the edge set of $G_{n,p}$ independently and with probability p. (In the sequel, $G_{n,p}$ will always denote a graph randomly selected according to this model.) We say that an event A in this model occurs *with overwhelming probability* if $1 - \Pr(A) = O(n^{-k})$ for all integer k. (The O-expression here is a function of n only, and is independent of p.)

The main result of the section (Theorem 6.4) is that for most values of p, and for a suitably chosen (fixed) polynomial q, the graph $G_{n,p}$ is q-amenable with overwhelming probability. Thus, in probabilistic terms, the approximation scheme of Fig. 2 has very

wide applicability. Recall also that the rare examples that the scheme cannot handle reliably may be identified using the randomised test of the previous section. We approach Theorem 6.4 via a sequence of three technical lemmas, the proofs of which are deferred.

LEMMA 6.1. *Let $\varepsilon > 0$ be a fixed constant, and let $p \leqq (1-\varepsilon)n^{-1} \ln n$. Then, with overwhelming probability, $G_{n,p}$ has no perfect matching.*

Call a graph (k, m)-*expanding* [7, p. 327] if every k-subset of U is adjacent to at least m vertices of V, and vice versa.

LEMMA 6.2. *Let $\varepsilon > 0$ be a fixed constant, $p \geqq (1+\varepsilon)n^{-1} \ln n$, and $\alpha = pn/\ln \ln n$. Then, with overwhelming probability, $G_{n,p}$ is $(k, m+1)$-expanding for all integers k and m that satisfy the inequalities $k \geqq \ln n/\ln pn$, $m \leqq \alpha k$, and $m \leqq n/2$.*

LEMMA 6.3. *Let $p \geqq n^{-1} \ln n$. Then, with overwhelming probability, the maximum vertex degree of $G_{n,p}$ does not exceed $pn \ln n$.*

THEOREM 6.4. *Let $\varepsilon > 0$ be a fixed constant, and let p lie outside the interval*

$$((1-\varepsilon)n^{-1} \ln n, (1+\varepsilon)n^{-1} \ln n).$$

Then, with overwhelming probability, the graph $G_{n,p}$ is q-amenable for $q(n) = n^{10}$.

Proof. Let A_1 denote the event $|M_n(G_{n,p})| = 0$, and A_2 the event

$$|M_n(G_{n,p})| > 0 \quad \text{and} \quad |M_{n-1}(G_{n,p})|/|M_n(G_{n,p})| \leqq n^{10}.$$

The event that the graph $G_{n,p}$ is q-amenable is the disjunction of the events A_1 and A_2. If $p \leqq (1-\varepsilon)n^{-1} \ln n$ then, by Lemma 6.1, event A_1 occurs with overwhelming probability. So from now on we assume that $p \geqq (1+\varepsilon)n^{-1} \ln n$.

Let B be the event that $G_{n,p}$ is $(k, m+1)$-expanding for all k, m in the ranges allowed in the statement of Lemma 6.2; let C be the event that the maximum degree of $G_{n,p}$ does not exceed $pn \ln n$. Suppose, as we will prove, that the event A_2 is a logical consequence of the events B, C, and $\bar{A}_1$ (the complement of A_1), that is to say, $A_2 \supseteq B \cap C \cap \bar{A}_1$. Then, by elementary set theory, $A_1 \cup A_2 \supseteq A_1 \cup (B \cap C \cap \bar{A}_1) \supseteq (B \cap C)$. Thus, $\Pr(A_1 \cup A_2) \geqq \Pr(B \cap C) \geqq 1 - \Pr(\bar{B}) - \Pr(\bar{C})$. The theorem follows from the estimates for $\Pr(\bar{B})$ and $\Pr(\bar{C})$ provided by Lemmas 6.2 and 6.3.

To complete the proof, we need to show that any graph $G = G_{n,p}$ that satisfies B, C, and $\bar{A}_1$ must also satisfy A_2. Our strategy is to demonstrate that every $(n-1)$-matching M in G can be extended to a perfect matching of G by augmentation along a *short* alternating path. (An *alternating path* is a path in G whose edges lie alternately inside and outside the matching M.) Since every $(n-1)$-matching is "close to" some perfect matching, the ratio of $(n-1)$-matchings to perfect matchings cannot be very large. (A similar technique was used in the proof of Theorem 3.2.)

So let M be any $(n-1)$-matching in G. For $s \in U+V$, $T \subset U+V$ and i a positive integer, denote by $\Gamma^i_{\text{alt}}(s, T)$ the set of vertices in T that can be reached from vertex s by an alternating path of length at most i. Set $L = (1+\varepsilon_1(n)) \ln n/\ln pn$, where ε_1 is a positive real function that tends to zero (and that will be defined implicitly later in the proof). We will prove that M can be extended to a perfect matching via a path of length at most $8L$.

Let $u \in U$, $v \in V$ be the vertices of G that are left uncovered by M. Consider the set $\Gamma^{2L-1}_{\text{alt}}(u, V)$. If $v \in \Gamma^{2L-1}_{\text{alt}}(u, V)$ then we are done, so assume the contrary. For any i in the range $1 \leqq i < L$, we have the inequality $|\Gamma^{2i}_{\text{alt}}(u, U)| > |\Gamma^{2i-1}_{\text{alt}}(u, V)|$. To see this, note that $|\Gamma^{2i-1}_{\text{alt}}(u, V)|$ vertices in U can be reached from vertices in $\Gamma^{2i-1}_{\text{alt}}(u, V)$ via a single edge in M, and that these vertices do not include u, which can be reached by the null alternating path. Moreover, $|\Gamma^{2i+1}_{\text{alt}}(u, V)| \geqq |\Gamma^{2i}_{\text{alt}}(u, U)|$ since G is assumed to contain a perfect matching. (This is the trivial direction of Hall's Theorem.) Putting

the inequalities together we obtain $|\Gamma_{\text{alt}}^{2i+1}(u, V)| > |\Gamma_{\text{alt}}^{2i-1}(u, V)|$, and, by iteration, $|\Gamma_{\text{alt}}^{2L-1}(u, V)| \geqq L$.

We continue the process of computing lower bounds on $|\Gamma_{\text{alt}}^{i}(u, V)|$ for increasing i, but now using the improved expansion factor provided by Lemma 6.2. (Note that $k = |\Gamma_{\text{alt}}^{2L-1}(u, V)| \geqq L > \ln n / \ln pn$, the threshold stipulated in the lemma.) For $i \geqq L$ we have $|\Gamma_{\text{alt}}^{2i+1}(u, V)| \geqq \min\{\alpha |\Gamma_{\text{alt}}^{2i-1}(u, V)|, \lceil n/2 \rceil\}$, where $\alpha = pn/\ln\ln n$. Thus, $|\Gamma_{\text{alt}}^{4L-1}(u, V)| \geqq \min\{|\Gamma_{\text{alt}}^{2L-1}(u, V)|\alpha^L, \lceil n/2 \rceil\}$. Since

$$\alpha^L = \exp\left\{(1+\varepsilon_1(n))\frac{\ln n}{\ln pn}(\ln pn - \ln\ln\ln n)\right\} \geqq n$$

for suitably chosen $\varepsilon_1(n) \to 0$, we deduce that $|\Gamma_{\text{alt}}^{4L-1}(u, V)| \geqq \lceil n/2 \rceil$. A symmetrical argument gives $|\Gamma_{\text{alt}}^{4L-1}(v, U)| \geqq \lceil n/2 \rceil$. Since some pair of vertices in $\Gamma_{\text{alt}}^{4L-1}(u, V)$ and $\Gamma_{\text{alt}}^{4L-1}(v, U)$ must be connected by an edge of M, there must exist an augmenting path for M of length not greater than $8L-1$.

Finally, associate with each $(n-1)$-matching M of G a perfect matching $\bar{M}$ that is reachable from M via an augmenting path of length at most $8L-1$. For each perfect matching $P \in M_n(G)$, let $\mathcal{K}(P) = \{M \in M_{n-1}(G): \bar{M} = P\}$ be the set of $(n-1)$-matchings associated with P; clearly, $\{\mathcal{K}(P): P \in M_n(G)\}$ is a partition of the set $M_{n-1}(G)$. To complete the proof, it is sufficient to show that the cardinality of $\mathcal{K}(P)$ is bounded above by n^{10}, for sufficiently large n.

Let M be an element of $\mathcal{K}(P)$. By definition, M can be reached from P by unwinding an alternating path of length less than $8L$. We can view the construction of such an alternating path as a sequence of choices. First select one of the n vertices of U as a starting point. Then, at each of at most $4L$ points during the tracing of the path, namely, each time the path visits a vertex v in V, select one of at most $pn \ln n$ possible next moves: either terminate the path at v, or extend it along one of the $pn \ln n - 1$ free edges incident at v. (Recall that G has maximum degree $pn \ln n$, and note that moves from U to V are forced.) Thus the number of possible augmenting paths, and hence the cardinality of $\mathcal{K}(P)$, is bounded above by

$$n(pn \ln n)^{4L} = n \exp\{4L(\ln pn + \ln\ln n)\} \leqq n \exp\{8L \ln pn\} = n^{1+8(1+\varepsilon_1(n))}.$$

Since $\varepsilon_1(n) \to 0$ as $n \to \infty$, the cardinality of $\mathcal{K}(P)$ is bounded by n^{10} for sufficiently large n. □

Remark. Neither event A_1 nor A_2 need, in isolation, occur with overwhelming probability, only their disjunction. This can be demonstrated by setting $p = \beta n^{-1} \ln n$, where β is any constant greater than 1. □

The condition on p in Theorem 6.4 is an unfortunate blemish. Alan Frieze [34] has indicated that the condition can be dropped at the expense of a slight weakening of the conclusion: q-amenability would now hold with probability tending to 1 as n tends to infinity, rather than with overwhelming probability.

We close the section by providing proofs of the three technical lemmas, using standard techniques from the theory of random graphs.

Proof of Lemma 6.1. The probability that $G_{n,p}$ has a perfect matching is certainly less than the probability that no vertex in U is isolated (has degree zero) so it is enough to bound the latter probability. Our calculations will make free use of the inequalities $1 - t \geqq \exp(-t - t^2)$ and $1 - t \leqq \exp(-t)$, the first of which is valid for $0 \leqq t < 0.69$, and the second valid unconditionally [7, p. 5]. First consider the probability that a *particular*

vertex $u \in U$ is isolated:

$$\begin{aligned}\Pr(u \text{ is isolated}) &= (1-p)^n \\ &\geqq \exp\{n(-p-p^2)\} \\ &\geqq \exp\{-(1-\varepsilon)\ln n - n^{-1}\ln^2 n\} \\ &= n^{-(1-\varepsilon)} + o(n^{-1}).\end{aligned}$$

Thus, the probability that *no* vertex in U is isolated is $\{1-(1-p)^n\}^n \leqq \exp\{-n(1-p)^n\} \leqq \exp\{-n^{\varepsilon} + o(1)\}$. □

Proof of Lemma 6.2. Denote by A_{km} the event that $G_{n,p}$ is $(k, m+1)$-expanding. It is clearly enough to show that, for *arbitrary* k, m satisfying the given inequalities, the event A_{km} occurs with overwhelming probability. Furthermore, since $\Pr(A_{km})$ increases monotonically with k, it is sufficient to show that the event A_{km} occurs with overwhelming probability for k and m satisfying $\ln n/\ln pn \leqq k \leqq \lceil n/2\alpha \rceil$, and $m \leqq \alpha k$.

Let U' be an arbitrary k-subset of U. The set of vertices in V which are adjacent to U' in $G_{n,p}$ may be modelled as a sequence of n Bernoulli trials with success probability $q = 1-(1-p)^k$. Thus the probability that U' is adjacent to at most m vertices in V is

$$\sum_{t=0}^{m} \binom{n}{t} q^t (1-q)^{n-t},$$

and the probability $\Pr(\bar{A}_{km})$ that $G_{n,p}$ *fails* to be $(k, m+1)$-expanding is bounded above by

$$2\binom{n}{k} \sum_{t=0}^{m} \binom{n}{t} q^t (1-q)^{n-t}. \tag{20}$$

By Chernoff's bound [12, p. 18] and using the inequality

$$\binom{n}{k} \leqq \frac{1}{\sqrt{2\pi k}} \left(\frac{en}{k}\right)^k \leqq \frac{1}{2}\left(\frac{en}{k}\right)^k$$

the failure probability (20) may be bounded as follows:

$$\Pr(\bar{A}_{km}) \leqq \exp\left\{(n-m)\ln\frac{(1-q)n}{n-m} + m\ln\frac{qn}{m} + k\ln\frac{en}{k}\right\}. \tag{21}$$

Since $q = 1-(1-p)^k$, we have the relations $1-q \leqq \exp(-pk)$ and $q \leqq pk$; employing these in inequality (21), we obtain

$$\Pr(\bar{A}_{km}) \leqq \exp\left\{-pk(n-m) + (n-m)\ln\frac{n}{n-m} + m\ln\frac{pkn}{m} + k\ln\frac{en}{k}\right\}.$$

Further simplification, using the fact that $\ln(n/(n-m)) \leqq m/(n-m)$, yields

$$\Pr(\bar{A}_{km}) \leqq f(p, k, m) = \exp\left\{-pk(n-m) + m\left(1 + \ln\frac{pkn}{m}\right) + k\ln\frac{en}{k}\right\}. \tag{22}$$

Our goal is to bound $\Pr(\bar{A}_{km})$ by maximising $f(p, k, m)$ (viewed as a function of three real variables) over the ranges $p \geqq (1+\varepsilon)n^{-1}\ln n$, $\ln n/\ln pn \leqq k \leqq \lceil n/2\alpha \rceil$, and $m \leqq \alpha k$.

By differentiating (22) with respect to m we discover that, with p, k fixed and n sufficiently large, $f(p, k, m)$ is an increasing function of m. (Indeed it is sufficient for n to be greater than 15, guaranteeing $m \leqq pkn/\ln\ln n < pkn$.) Thus, in attempting to bound $f(p, k, m)$, it is enough to consider those triples (p, k, m) for which the inequality

that governs m, namely $m \leqq \alpha k$, is actually an equality. Substituting $k = m/\alpha = m \ln\ln n/pn$ in (22), our task is now to bound

$$f_1(p, m) = \exp\left\{-m \ln\ln n\left(1-\frac{m}{n}\right) + m(\ln\ln\ln n + 1) + \frac{m \ln\ln n}{pn} \ln \frac{epn^2}{m \ln\ln n}\right\}$$

over feasible p, m. Now, for fixed m, the function f_1 decreases with p. (For this we need the inequality $m \leqq pkn/\ln\ln n$.) So making the substitution $p = (1+\varepsilon)n^{-1} \ln n$ we are further reduced to bounding the function

$$f_2(m) = \exp\left\{-m \ln\ln n\left(1-\frac{m}{n}\right) + m(\ln\ln\ln n + 1) + \frac{m \ln\ln n}{(1+\varepsilon) \ln n} \ln \frac{e(1+\varepsilon)n \ln n}{m \ln\ln n}\right\}$$

over feasible m. The argument to the exponential is a convex function of m, so we can bound $f_2(m)$ by considering its values at the extremes of m's range. A lower bound for m is given by the chain of inequalities

$$m = \alpha k = \frac{pkn}{\ln\ln n} \geqq \frac{pn \ln n}{\ln\ln n \ln pn} \geqq \left(\frac{\ln n}{\ln\ln n}\right)^2 = m_{\min},$$

and an upper bound by

$$m = \alpha k \leqq \alpha\left\lceil \frac{n}{2\alpha} \right\rceil \leqq \frac{3n}{4} = m_{\max}$$

where we have used the known bounds on k and p, and assumed n sufficiently large. Substituting these extreme values in the expression for $f_2(m)$, we obtain

$$f_2(m_{\min}) = \exp\left\{-\left(\frac{\varepsilon}{1+\varepsilon} - o(1)\right)\frac{\ln^2 n}{\ln\ln n}\right\},$$

$$f_2(m_{\max}) = \exp\left\{-\left(\frac{3}{16} - o(1)\right) n \ln\ln n\right\}.$$

The former bound is the weaker and hence is the one that determines the overall bound on $f(p, k, m)$. □

Proof of Lemma 6.3. It is clearly enough to show that, with overwhelming probability, the degree of an arbitrary vertex $u \in U$ is bounded by $pn \ln n$. The set of vertices adjacent to u may be modelled as a sequence of n Bernoulli trials with success probability p. The probability that $\delta(u)$, the degree of u, exceeds m can be estimated from Chernoff's bound, using manipulations similar to those in the proof of Lemma 6.2:

$$\begin{aligned}\Pr(\delta(u) > m) &\leqq \exp\left\{(n-m) \ln \frac{(1-p)n}{n-m} + m \ln \frac{pn}{m}\right\} \\ &\leqq \exp\left\{-p(n-m) + m + m \ln \frac{pn}{m}\right\} \\ &\leqq \exp\left\{-m\left(\ln \frac{m}{pn} - 1\right)\right\}.\end{aligned}$$

(Clearly we may assume $m < n$.) Now, substituting $pn \ln n$ for m and noting $p \geqq n^{-1} \ln n$, we obtain

$$\Pr(\delta(u) > pn \ln n) \leqq \exp\{-(1-o(1)) \ln^2 n \ln\ln n\},$$

which decays faster than the reciprocal of any polynomial in n. □

7. Miscellaneous remarks and open problems. (i) The existence of an fpras for the unrestricted permanent remains an intriguing open question. Whereas the requirement that the ratio $|M_{n-1}(G)|/|M_n(G)|$ be polynomially bounded arises very naturally from our methods, there seems to be no a priori reason to suspect that graphs that violate this condition are particularly hard to handle. Perhaps an fpras of a different kind can be found for graphs in which the ratio is large. Alternatively, it is conceivable that counting perfect matchings approximately in general graphs is hard, in the sense that the existence of an fpras for this problem would imply that NP = RP. (Hardness results of this kind for other structures appear in [16], [28].)

(ii) It would be interesting to know whether the ratio $|M_{n-1}(G)|/|M_n(G)|$ is polynomially bounded for other natural classes of graphs, immediately yielding an fpras for the number of perfect matchings. For example, this question is pertinent for families of regular lattices encountered in statistical physics. Much effort has been expended on counting perfect matchings in such graphs, and an elegant exact solution obtained for planar lattices (or indeed arbitrary planar graphs [19]). The three-dimensional case, however, remains open even in approximate form.

(iii) From a practical point of view, it would be interesting to know whether the conductance bounds we have derived can be significantly improved. We make no claim of optimality here, preferring to concentrate on giving a clear exposition of the rapid mixing property. The practical utility of our algorithms, however, is likely to depend on rather tighter bounds being available.

Similar considerations apply to our methods for estimating the expectation of a 0-1 random variable under the stationary distribution of a Markov chain. We have chosen to view the chain as a generator of independent samples, partly to simplify the statistical concepts involved and partly because the random generation problems are of interest in their own right. In contrast, Aldous [2] considers estimates derived by observing a Markov chain continuously and formulates the definition of rapid mixing directly in terms of the variance of such an estimate. This approach may lead to increased efficiency.

(iv) A wider issue is the extent to which the techniques of this paper can be applied to the analysis of natural Markov chains whose states are combinatorial structures other than matchings. Since these chains are usually time-reversible, the conductance characterisation of rapid mixing presented in § 2 can in principle be applied. We conjecture that this is possible in practice for other interesting chains, and that the path counting technique developed in this paper is a promising general approach for obtaining positive results. It is to be hoped that this will yield efficient random generation and approximate counting procedures for further structures. Moreover, it may lead to rigorous performance guarantees for Monte Carlo experiments in statistical physics, and a demystification of currently fashionable stochastic optimisation techniques such as simulated annealing.

Acknowledgment. The authors thank Leslie Valiant for bringing reference [25] to their attention.

A CORRECTION NETWORK FOR N-SORTERS*

MANFRED SCHIMMLER† AND CHRISTOPH STARKE†

Abstract. A correction network C is introduced that can be added to an arbitrary N-input sorting net in order to achieve single-fault tolerance. Multiple (k) fault robustness is attained by adding C^k. For single-fault correction, C is proved to be asymptotically optimal.

Key words. sorting networks, comparators, fault tolerance, reliability, Hamming distance

AMS(MOS) subject classifications. 68C05, 68C25, 68E05

1. Introduction. The high integration density in VLSI technology has created an increasing probability of fabrication faults. Therefore, although it is cheap to produce large quantities of a single chip or wafer, only a small fraction of them can be expected to function correctly. One way of increasing the yield is by designing fault-tolerant algorithms.

Another aspect of fault tolerance is to increase the reliability of a chip. A useful technique is to introduce redundant components in order to keep the whole system reliable, even in the presence of several operating faults.

In this paper we present a method for adding a fault-correcting network to an arbitrary sorting net. It is very simple and needs little in the way of additional hardware and additional delay time. Furthermore, we will show that the number of additional comparators and the number of additional delay stages is asymptotically optimal for single-fault correction of arbitrary sorting nets.

The problem has already been investigated in [5]. The authors found a correction mechanism for k faults in an N-network, consisting of only $k(2N-3)$ additional comparators. Unfortunately, the number of additional delay stages is $k(2N-3)$, too. Therefore, even a single-fault tolerant N-sorter has time complexity $\Theta(N)$.

In [4] a multiple half-fault tolerant N-sorter is presented. For $N=2^n$ it consists of one block of the "balanced sorting network" [2], consisting of $\log N$ stages of $N/2$ comparators. The output of this block is recirculated back as input. If the block is fault free, sorting requires $\log N$ passes through the network. If it is not fault free, the number of necessary passes increases with the number of faulty comparators, but the network can still sort. There are n pairs of "critical" comparators. The network fails only if both comparators of such a pair are faulty.

2. Definitions. Let R denote the set of real numbers. An *N-comparator* (or comparator, if N is understood) is a pair $[i:j]$, with $0 \leqq i, j \leqq N-1$, $i \neq j$. Associate with the N-comparator $[i:j]$ the mapping from R^N to R^N defined by

$$\langle x_0, x_1, \cdots, x_{N-1}\rangle[i:j] := \langle x'_0, x'_1, \cdots, x'_{N-1}\rangle,$$

where $x'_p = x_p$ if $p \notin \{i, j\}$, $x'_i = \min(x_i, x_j)$ and $x'_j = \max(x_i, x_j)$. We call $[i:j]$ a *standard comparator* if $i < j$.

An *N-comparator stage* (or comparator stage if N is understood) s is a set of r N-comparators $\{[i_0:j_0], [i_1:j_1], \cdots, [i_{r-1}:j_{r-1}]\}$, where $i_0, j_0, i_1, j_1, \cdots, i_{r-1}, j_{r-1}$ are

* Received by the editors on September 28, 1987; accepted for publication (in revised form) January 30, 1989.

† Institut für Informatik und Praktische Mathematik, Christian-Albrechts-Universität Kiel, Olshausenstrasse 40, D-2300 Kiel 1, Federal Republic of Germany.

pairwise distinct. The N-comparator stage s defines a mapping from R^N to R^N which is the arbitrary sequential composition of the mappings associated with $[i_0:j_0], [i_1:j_1], \cdots, [i_{r-1}:j_{r-1}]$.

An *N-network* A is a sequence of N-comparator stages $s_1, s_2, \cdots, s_p$. The N-network A defines the mapping from R^N to R^N by successively applying the mappings induced by $s_1, s_2, \cdots, s_p$. A *standard N-network* is an N-network consisting of standard comparators only.

A vector $x = \langle x_0, x_1, \cdots, x_{N-1} \rangle \in \mathbf{R}^N$ is *sorted*, if and only if $x_{i-1} \leqq x_i$ for $1 \leqq i \leqq N-1$. An *N-sorter* A is an N-network that satisfies the following condition:

$$\forall x \in \mathbf{R}^N: xA = x' \Rightarrow x' \text{ is sorted.}$$

What follows is a very useful tool in the studies of sorting networks.

ZERO ONE PRINCIPLE. *Let A be an N-network. If xA is sorted for every* $x \in \{0, 1\}^N$, *then A is an N-sorter.*

Proof. See [3, 5.3.4, Thm. Z].

Using the Zero One Principle we can restrict our studies of sorting networks to input vectors $x \in \{0, 1\}^N$.

For $x \in \{0, 1\}^N$ the sorted version x_s denotes the nondecreasing sequence consisting of the same number of 0's and 1's as x:

$$x_s := xA \text{ for an arbitrary } N\text{-sorter } A.$$

Figure 1 shows, for example, the 4-sorter $\{[0:1], [3:2]\}, \{[0:2], [1:3]\}, \{[0, 1], [2:3]\}$, drawn as defined in [3, p. 222]: Comparators are drawn as vertical arrows between horizontal data lines. Elements to be sorted travel through the network from left to right, and whenever they meet a comparator they are compared and possibly interchanged such that the larger element appears at the line of the arrow head and the smaller one at the line of the arrow tail after passing the comparator. They arrive at the right end of the network in nondecreasing order.

3. Fault model. A correct comparator performs a comparison-exchange as depicted in Fig. 2a. We shall consider three different types of functional faults: Fig. 2b shows the *full-fault*, a comparator producing the maximum of its inputs instead of the minimum and vice versa. The *half-fault* comparator (Fig. 2c) leaves the inputs unchanged, and the *x-fault* (Fig. 2d) comparator exchanges the inputs independent of their values. Each of these faults is assumed to be static, i.e., the comparator always behaves in the same faulty way.

Of course, there are many other possible faults, as for example, dynamic faults, stuck-at faults, technology-dependent faults such as stuck-open faults in CMOS, etc. We do not want to discuss each of these fault types, but we are able to apply our correction method to arbitrary faults, if the considered sorter enables us to bypass faulty comparators.

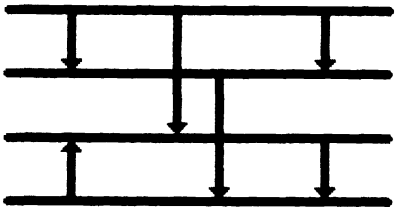

FIG. 1. *The bitonic 4-sorter* [1].

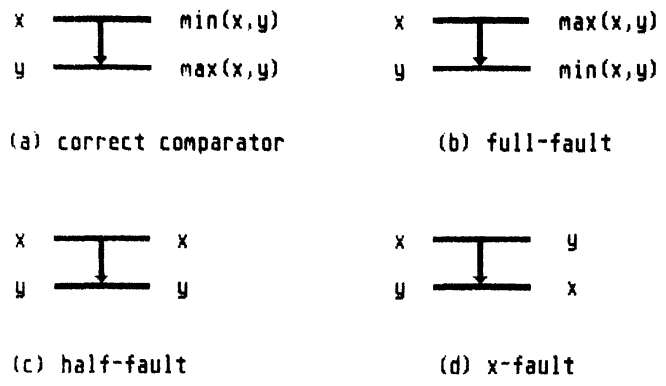

FIG. 2

Our aim is to find a solution for the half-fault correction problem. The reason for choosing this specific fault type is the fact that the mapping of a half-fault comparator is the identity (and thus it behaves like a simple storage cell). If we can locate the faults in a given sorting network, we can apply the following technique: we can bypass all of the faulty comparators by cutting out the comparator's logic and by connecting the input and the output lines, and we shall get a network that behaves exactly like the original sorting net, where every fault (of arbitrary type) is replaced by a half-fault. If we can add some half-fault correcting network (correcting an appropriate number of half-faults), the result is a fault-free sorter.

Of course, this construction is particularly useful, especially if the additional correction net is also allowed to contain faulty comparators, which can be bypassed if necessary. The same construction is not possible with full-faults or x-faults instead of half-faults, because the last stage of the resulting network could be faulty. In this case, a full-fault as well as an x-fault produces unsorted output sequences, which means that the network is not a correct sorter. In the remainder of the paper, a *k-fault N-sorter* denotes a network obtained from an N-sorter by replacing k comparators with half-fault comparators.

4. Lower bounds. Let C be an N-network that corrects any 1-fault N-sorter A', i.e.,

$$xA'C = x_s \quad \text{for every } x \in \{0,1\}^N.$$

In this section we will prove two lower bounds for C.

LEMMA 1. *The number of comparators of C is $\Omega(N)$.*

LEMMA 2. *The number of comparator stages of C is $\Omega(\log N)$.*

The proofs follow.

PROPOSITION 1. *For any i, j, $0 \leqq i < j \leqq N-1$ there is a 1-fault N-sorter A'_{ij} satisfying the following conditions for every $x \in \{0,1\}^N$:*

$$(x_s)_p = (xA'_{ij})_p \quad \text{for } p \notin \{i, j\},$$
$$(x_s)_i = (xA'_{ij})_j,$$
$$(x_s)_j = (xA'_{ij})_i.$$

In other words, A'_{ij} sorts every x except the items on positions i and j, which are exchanged.

Proof of Proposition 1. Take an arbitrary N-sorter S. If $i<j$, we define $A_{ij} = S$, $\{[j:i]\}, \{[i:j]\}$. A_{ij} is an N-sorter. Let A'_{ij} be A_{ij} with a half fault in the last comparator $[i:j]$. Obviously, A'_{ij} satisfies the conditions of Proposition 1. □

Proof of Lemma 1. From Proposition 1 we know the N-network A'_{0j} for every j, $1 \leqq j \leqq N-1$. An N-network C correcting an arbitrary A'_{0j} must be able to move the wrong item from position 0 to any position between 1 and $N-1$. Therefore, every position must appear at least once in a comparator of C. Hence, C consists of at least $N/2$ comparators. □

Proof of Lemma 2. Again we consider the N-networks A'_{0j} for $1 \leqq j \leqq N-1$. The correcting N-network C must be able to move the wrong item from position 0 to any position between 1 and $N-1$. Since every comparator connects only two lines, at least $\log N$ comparator stages are needed to obtain a path from position 0 to any other position. □

In § 6, the N-network C is presented, correcting every 1-fault N-sorter. C meets the lower bounds in the number of comparators and the number of comparator stages.

5. Symmetric networks. To simplify the proof of the Theorem in § 7 we need some more notations and a few lemmata.

For $x = \langle x_0, x_1, \cdots, x_{N-1}\rangle \in \{0,1\}^N$ we define the *complement*

$$\bar{x} := \langle \bar{x}_0, \bar{x}_1, \cdots, \bar{x}_{N-1}\rangle, \qquad \bar{x}_i := 1 - x_{N-1-i}, \qquad i \in \{0, 1, \cdots, N-1\}.$$

For a comparator $[i:j]$ the complement is defined by

$$\overline{[i:j]} = [N-1-j : N-1-i].$$

The complement $\bar{s}$ of a comparator stage $s = \{[i_0:j_0], [i_1:j_1], \cdots, [i_{r-1}:j_{r-1}]\}$ is defined by $\bar{s} := \{\overline{[i_0:j_0]}, \overline{[i_1:j_1]}, \cdots, \overline{[i_{r-1}:j_{r-1}]}\}$ and the complement of an N-network $A = s_1, s_2, \cdots, s_p$ is $\bar{A} = \bar{s}_1, \bar{s}_2, \cdots, \bar{s}_p$.

An N-network A is called *symmetric* if and only if $\bar{A} = A$.

LEMMA 3. *For* $x \in \{0,1\}^N$ *and* $0 \leqq i, j \leqq N-1$ *the following equations hold*:

(i) $\bar{\bar{x}} = x$,

(ii) $\overline{\overline{[i:j]}} = [i:j]$,

(iii) $\overline{x[i:j]} = \bar{x}[i:j]$.

Proof. (i) and (ii) are obvious.

(iii) Consider the pth component of $\overline{\bar{x}[i:j]}$:

$$(\overline{\bar{x}[i:j]})_p = (\overline{\bar{x}[N-1-j:N-1-i]})_p = 1 - \bar{x}[N-1-j:N-1-i]_{N-1-p}.$$

If $p \neq i$ and $p \neq j$, we have

$$1 - \bar{x}[N-1-j:N-1-i]_{N-1-p} = 1 - \bar{x}_{N-1-p} = x_p = x[i:j]_p.$$

If $p = i$, we have

$$\begin{aligned} 1 - \bar{x}[N-1-j:N-1-i]_{N-1-p} &= 1 - \max(\bar{x}_{N-1-j}, \bar{x}_{N-1-i}) \\ &= \min(1-\bar{x}_{N-1-j}, 1-\bar{x}_{N-1-i}) = \min(x_j, x_i) = x[i:j]_p. \end{aligned}$$

If $p = j$, we have

$$\begin{aligned} 1 - \bar{x}[N-1-j:N-1-i]_{N-1-p} &= 1 - \min(\bar{x}_{N-1-j}, \bar{x}_{N-1-i}) \\ &= \max(1-\bar{x}_{N-1-j}, 1-\bar{x}_{N-1-i}) = \max(x_j, x_i) = x[i:j]_p. \end{aligned}$$

Therefore, we know for every p, $0 \leqq p \leqq N-1$,

$$(\overline{\bar{x}[i:j]})_p = x[i:j]_p, \text{ which means } \overline{\bar{x}[i:j]} = x[i:j]. \qquad \square$$

LEMMA 4. *For every* N*-network* A *and every* $x \in \{0,1\}^N$: $\overline{\bar{x}A} = xA$.

Proof. Induction on the total number m of comparators in A:

$m = 0$: $\bar{x}\bar{A} = \bar{\bar{x}} = x = xA$;

$m > 0$: Assume Lemma 4 to be true for every N-network consisting of no more than $m-1$ comparators.

Let A consist of the comparators $[i_1:j_1]$, $[i_2:j_2]$, $\cdots$, $[i_m:j_m]$. Without loss of generality, $[i_m:j_m]$ is the last stage of A. Define G to be the N-network obtained by removing $[i_m:j_m]$ from A. Then

$$\overline{\bar{x}\bar{A}} = \overline{\overline{\bar{x}\bar{G}[i_m:j_m]}} = \overline{\overline{\bar{x}\bar{G}}[i_m:j_m]} = \overline{\bar{x}\bar{G}}[i_m:j_m] = xG[i_m:j_m] = xA. \qquad \square$$

SYMMETRIC NETWORK LEMMA. *For every symmetric N-network A and every* $x \in \{0,1\}^N$, $\overline{\bar{x}A} = xA$.

Proof. Definition of symmetric networks and Lemma 4. $\square$

6. The correction network. Let n be an integer greater than 1 and let $N = 2^n$. In this section we shall define the N-network C that can be used for single half-fault correction. We show that C consists of $2\log N - 1$ comparator stages, and of $3.5N - 2\log N - 5$ comparators.

DEFINITION. Let $N = 2^n$. The *correcting N-network* C is defined by

$$C := s_1, s_2, \cdots, s_{2n-1} \quad \text{with}$$

$$s_1 := \{[2i:2i+1] \mid 0 \leqq i \leqq 2^{n-1}-1\}$$

$$s_j := \{[2^j i : 2^j i + 2^{j-1}] \mid 0 \leqq i \leqq 2^{n-j}-1\} \cup$$

$$\{[N-1-(2^j i + 2^{j-1}) : N-1-2^j i] \mid 0 \leqq i \leqq 2^{n-j}-1\}$$

$$\text{for } 2 \leqq j \leqq n-1$$

$$s_j := \{[2^{2n-j-1} i - 2^{2n-j-2} : 2^{2n-j-1} i] \mid 1 \leqq i \leqq 2^{j-n+1}-1\} \cup$$

$$\{[N-1-2^{2n-j-1} i : N-1-(2^{2n-j-1} i - 2^{2n-j-2})] \mid 1 \leqq i \leqq 2^{j-n+1}-1\}$$

$$\text{for } n \leqq j \leqq 2n-3$$

$$s_{2n-2} := \{[2i-1:2i] \mid 1 \leqq i \leqq 2^{n-1}-1\}$$

$$s_{2n-1} := \{[2i:2i+1] \mid 0 \leqq i \leqq 2^{n-1}-1\}$$

As an example, Fig. 3 shows the network C for $N = 32$ $(n = 5)$.

To assure that C is well defined, we need to prove the following proposition.

PROPOSITION 2. *For every* $r \in \{1, 2, \cdots, 2n-1\}$ *and for all comparators* $[i_0:j_0]$ *and* $[i_1:j_1]$ *occurring in* s_r, i_0, i_1, j_0, j_1 *are pairwise distinct.*

Proof. For stages 1, $2n-2$, and $2n-1$ the proposition is obviously true. For $2 \leqq p \leqq n-1$ the comparators of the pth comparator stage are of the form

(*) $\quad [(2i)2^{p-1} : (2i+1)2^{p-1}]$ or

(*) $\quad [N-1-(2i+1)2^{p-1} : N-1-(2i)2^{p-1}]$ for $0 \leqq i \leqq 2^{n-p}-1$.

For two different comparators of the form (*) the proposition is true. The same holds for two comparators of the form (**). Now let $[i_0:j_0]$ be a (*) type comparator and $[i_1:j_1]$ a (**) type one. We have $i_0 \neq j_0$ as well as $i_1 \neq j_1$. Since i_0 and j_0 are even, whereas i_1 and j_1 are odd, they must be pairwise distinct. The same argument holds for the pth comparator stage where $n \leqq p \leqq 2n-2$, which completes the proof. $\square$

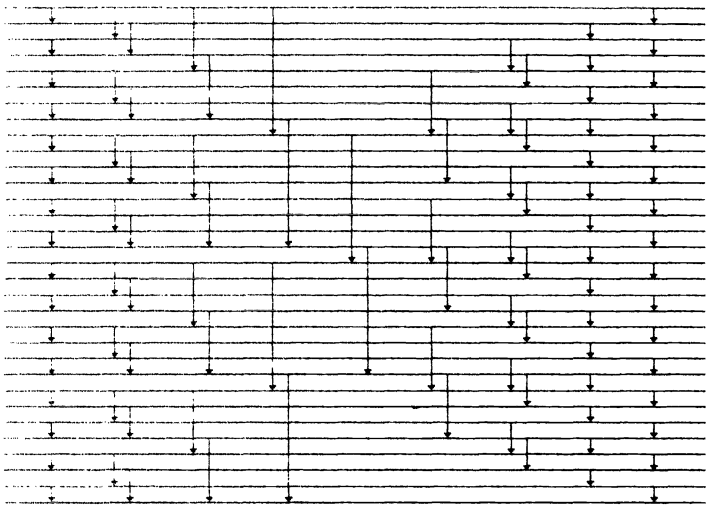

FIG. 3. *The correction* N-network C *for* $N = 32$.

Now we count the total number of comparators in C. The first stage consists of 2^{n-1} comparators. For $2 \leqq p \leqq n-1$ comparator stage p has $2 * 2^{n-p}$ comparators. For $n \leqq p \leqq 2n-3$ stage p consists of $2 * (2^{p-n+1}-1)$ comparators. Stages $2n-2$ and $2n-1$ have $2^{n-1}-1$ and 2^{n-1} comparators, respectively. Therefore, the total number of comparators in C is

$$m = 2^{n-1} + 2\sum_{p=2}^{n-1} 2^{n-p} + 2\sum_{p=n}^{2n-3} (2^{p-n+1}-1) + 2^{n-1} - 1 + 2^{n-1} = 3.5 * 2^n - 2n - 5.$$

Observe that C is a symmetric standard network. In particular each comparator stage s_j of C is symmetric and so is every subnetwork $s_1, s_2, \cdots, s_j$, for $1 \leqq j \leqq 2n-1$.

7. Correction property of C. The *Hamming distance* of two N bit vectors x and y is the number of bits in which they differ: $D(x, y) = \sum_{i=1}^{N-1} |x_i - y_i|$.

LEMMA 5. *Let* $x \in \{0,1\}^N$ *and let* $[i:j]$ *be a standard comparator in an* N*-network. Then* $D(x[i:j], x_s) \leqq D(x, x_s)$.

Proof. See [5, Lem. 2].

LEMMA 6. *Let* A' *be a* k*-fault* N*-sorter. Then for any* $x \in \{0,1\}^N$, $D(xA', x_s) \leqq 2k$.

Proof. See [5, Lem. 4].

THEOREM. *Let* $x \in \{0,1\}^N$, *with* $D(x, x_s) > 0$. *For the correcting* N*-network* $C = (s_1, s_2, \cdots, s_{2n-1})$ *the following relation holds*: $D(xC, x_s) \leqq D(x, x_s) - 2$.

Proof. Let b be the number of 0's in x, i.e., $x_s = 0^b 1^{N-b}$. Since $D(x, x_s) > 0$, b must be greater than 0 and smaller than N. We call the set of positions $\{0, 1, \cdots, b-1\}$ the *zero area*, and the set $\{b, b+1, \cdots, N-1\}$ the *one area*. A *wrong* 1 is a 1 positioned in the zero area and a *wrong* 0 a 0 in the one area.

If there is any comparator in C that compares a wrong 1 with a wrong 0, these two elements change their positions and the Hamming distance to the sorted sequence is reduced by two. Since the Hamming distance cannot be enlarged again by standard comparators (Lemma 5), after passing the network C we would have $D(xC, x_s) \leqq D(x, x_s) - 2$.

Therefore, it is sufficient to construct a contradiction to the following assumption:

(*) There is no wrong 1 compared with a wrong 0 in C.

Let P_0 be the position of the first wrong 0 in x, i.e.,

$$P_0 = \min\{p \in \{b, b+1, \cdots, N-1\} \mid x_p = 0\}.$$

We want to construct the sequence of positions $P_0, P_1, \cdots, P_{2n-2}$, which we shall show to be the path of this 0 through the network C:

Let $p_{n-1}p_{n-2}\cdots p_0$ be the binary representation of P_0, i.e.,

$$P_0 = \sum_{i=0}^{n-1} p_i 2^i.$$

Since $P_0 \geqq b$, we can define the constant K:

$$K := \max\left\{ j \;\middle|\; 0 \leqq j \leqq n-1 \quad \text{and} \quad \sum_{i=j}^{n-1} p_i 2^i \geqq b \right\}.$$

Now we define the sequence of positions P_j:

$$\text{for } 0 \leqq j \leqq K, \quad P_j := \sum_{i=j}^{n-1} p_i 2^i;$$

$$\text{for } K+1 \leqq j \leqq 2n-K-2, \quad P_j := P_K;$$

$$\text{for } 2n-K-1 \leqq j \leqq 2n-2, \quad d_j := \max\{i \in \{0,1\} \mid P_{j-1} - i * 2^{2n-2-j} \geqq b\},$$

$$P_j := P_{j-1} - d_j * 2^{2n-2-j}.$$

d_j is well defined because $P_{j-1} \geqq b$.

We need some observations concerning the P_j:

(1) For $0 \leqq j \leqq K$, P_j is a multiple of 2^j.

(2) For $0 \leqq j \leqq K$, $P_j = P_{j-1} - p_{j-1}2^{j-1}$.

The definition of K implies

$$P_K = \sum_{i=K}^{n-1} p_i 2^i \geqq b > \sum_{i=K+1}^{n-1} p_i 2^i.$$

Therefore, $0 \leqq P_K - b < p_K * 2^K$, which implies $p_K = 1$ and

(3) $$0 \leqq P_K - b < 2^K.$$

For $j = 2n-K-2$ we have $P_j = P_K$. From (1) we know that P_j is a multiple of 2^{2n-2-j}. For $2n-K-1 \leqq j \leqq 2n-2$ we have

$$\begin{aligned} P_j &= P_K - \sum_{i=2n-K-1}^{j} d_i 2^{2n-2-i} \\ &= 2^K \sum_{i=K}^{n-1} p_i 2^{i-K} - 2^{2n-2-i} * \sum_{i=2n-K-1}^{j} d_i 2^{j-i} \\ &= 2^{2n-2-j} * \left(2^{K-2n+2+j} * \sum_{i=K}^{n-1} p_i 2^{i-K} - \sum_{i=2n-K-1}^{j} d_i 2^{j-i} \right). \end{aligned}$$

Therefore, we know

(4) $$\forall j, \quad 2n-K-2 \leqq j \leqq 2n-2 \quad \exists \text{ integer } m_j : P_j = m_j * 2^{2n-2-j},$$
$$\text{where } 1 \leqq m_j \leqq 2^{j-n+2}, \quad \text{because } 0 < P_j = m_j * 2^{2n-2-j} < 2^n.$$

Now we want to prove that the sequence of positions P_j is the path of the first wrong 0 through the network:

$$\forall j,\quad 0 \leqq j \leqq 2n-2\colon x(s_1, s_2, \cdots, s_j)_{P_j} = 0. \tag{5}$$

Proof of (5) *by induction on j.*

$j=0$: By definition of P_0 we have $x_{P_0}=0$.

$j>0$: Assume $x(s_1, s_2, \cdots, s_{j-1})_{P_{j-1}}=0$. We have to consider three cases:

Case 1. $1 \leqq j \leqq K$; s_j contains the comparator $[P_j : P_j + 2^{j-1}]$, because P_j is a multiple of 2^j (see (1)). Since $P_j = P_{j-1} - P_{j-1} * 2^{j-1}$ (see (2)) and since $x(s_1, s_2, \cdots, s_{j-1})_{P_{j-1}}=0$, at least one input into the comparator is 0. Therefore, $x(s_1, s_2, \cdots, s_j)_{P_j}=0$.

Case 2. $K+1 \leqq j \leqq 2N-K-2$; by the definition of C, for every comparator $[r:s]$ in stage s_j we know $s-r>2^K$. On the other hand, we know from (3) that $2^K > P_K - b$. Since $P_K = P_{j-1} = P_j$, this implies that a comparator of the form $[r : P_{j-1}]$ in s_j compares an element from the zero area with a wrong 0 in position P_{j-1} in the one area. Assumption (*) forces this element to be a 0, which implies $x(s_1, s_2, \cdots, s_j)_{P_j}=0$. If there is a comparator of the form $[P_{j-1} : s]$ in s_j, then the 0 remains in P_j and again we have $x(s_1, s_2, \cdots, s_j)_{P_j}=0$.

Case 3. $2n-K-1 \leqq j \leqq 2n-2$; if $d_j=0$, then $P_j = P_{j-1}$ and $P_{j-1} - 2^{n-2-j} < b$. If there is a comparator $[r : P_{j-1}]$ in s_j, then $r<b$ and $x(s_1, s_2, \cdots, s_{j-1})_r$ must be 0, due to assumption (*). Therefore, $x(s_1, s_2, \cdots, s_j)_{P_j}=0$. If $d_j=1$, then $P_j = P_{j-1} - 2^{2n-2-j}$. By (4), there is an integer m_{j-1}, $1 \leqq m_{j-1} \leqq 2^{j-n+1}$, with $P_{j-1} = m_{j-1} * 2^{2n-j-1}$. Therefore, in stage s_j there is a comparator $[P_j : P_{j-1}]$, which implies that $x(s_1, s_2, \cdots, s_j)_{P_j}=0$.

For $2n-K-2 \leqq j \leqq 2n-2$ we need an additional statement concerning the distance of P_j from the zero area:

$$\forall j,\quad 2n-K-2 \leqq j \leqq 2n-2\colon 0 \leqq P_j - b < 2^{2n-2-j}. \tag{6}$$

Proof of (6) *by induction on j.*

$j=2n-K-2$: from (3) we know $0 \leqq P_K - b < 2^K = 2^{2n-2-j}$.

$j>2n-K-2$: assume (6) to be true for $j-1$. $P_j = P_{j-1} - d_j * 2^{2n-2-j} \geqq b$. If $d_j=0$, then $P_j = P_{j-1}$ and $P_{j-1} - 2^{2n-2-j} < b$. Thus we have $0 \leqq P_j - b \leqq 2^{2n-2-j}$.

If $d_j=1$, then we know by induction hypothesis

$$P_j = P_{j-1} - 2^{2n-j-2} < b + 2^{2n-1-j} - 2^{2n-2-j} = b + 2^{2n-2-j}.$$

This implies $0 \leqq P_j - b \leqq 2^{2n-2-j}$.

Equation (6), in particular, implies that for $j=2n-2$ holds $0 \leqq P_{2n-2} - b < 1$, or in other terms $P_{2n-2}=b$. From (5) we know $x(s_1, s_2, \cdots, s_{2n-2})_{P_{2n-2}}=0$, and thus we get

$$x(s_1, s_2, \cdots, s_{2n-2})_b = 0. \tag{7}$$

Since the complement $\bar{x}$ consists of $N-b$ 0's and b 1's, we get from equation (7)

$$\bar{x}(s_1, s_2, \cdots, s_{2n-2})_{N-b}=0, \quad \text{and therefore,} \quad \overline{\bar{x}(s_1, s_2, \cdots, s_{2n-2})}_{N-1-(N-b)}=1.$$

Because of the Symmetric Network Lemma, this is equivalent to

$$x(s_1, s_2, \cdots, s_{2n-2})_{b-1}=1, \tag{8}$$

since $s_1, s_2, \cdots, s_{2n-2}$ is a symmetric network.

Now (7) and (8) show that there is a 0 in position b and a 1 in position $b-1$ after $2n-2$ stages. Since in stage $2n-2$ there are the comparators $[2i-1 : 2i]$, they would have been interchanged if b is even. Hence b must be odd. But then in stage

s_{2n-1}, there is a comparator $[b-1:b]$. This comparator compares a wrong 1 with a wrong 0, a contradiction to (*). □

COROLLARY. *An N-sorter S is given. If in the network SC^k at most k comparators are replaced by half-fault comparators, then the resulting network is still an N-sorter.*

Proof. Let r be the number of comparators replaced in S. Then at most $k-r$ copies of C are faulty and at least r copies of C are fault free. Lemma 6 ensures that for the network S' obtained from S by replacing the r comparators the following condition holds: $D(xS', x_s) \leqq 2r$.

By the theorem, each of the fault-free copies of C reduces the Hamming distance by at least 2. Therefore, after passing the r fault-free copies, the sequence is sorted. □

8. Conclusions. We have introduced an efficient way to achieve fault tolerance in sorting networks. We have shown the asymptotic optimality of our method for single half-fault correction. It is certainly of further interest to find lower bounds for multiple half-fault correction and correction networks that meet these bounds.

9. Acknowledgments. We would like to thank the referees for helpful suggestions and remarks.

SOLUTION OF A DIVIDE-AND-CONQUER MAXIMIN RECURRENCE*

ZHIYUAN LI†‡ AND EDWARD M. REINGOLD†

Abstract. The solution of the divide-and-conquer recurrence

$$M(n) = \max_{1 \leq k < n} (M(k) + M(n-k) + \min(f(k), f(n-k)))$$

is found for a variety of functions f. Asymptotic bounds on $M(n)$ are found for arbitrary nondecreasing f, and the exact form of $M(n)$ is determined for f nondecreasing and weakly concave. As a corollary to the asymptotic bounds, it is shown that $M(n)$ remains linear even when f is almost linear. Among the exact forms determined: For $f(x) = \lfloor \lg x \rfloor$, the solution is $M(n) = (M(1)+1)n - \lfloor \lg n \rfloor - \nu(n)$ where $\nu(n)$ is the number of 1-bits in the binary representation of n. For $f(x) = \lceil \lg x \rceil$, the solution is $M(n) = (M(1)+1)n - \lceil \lg n \rceil - 1$, while for $f(x) = \lceil \lg (x+1) \rceil$, the solution is $M(n) = (M(1)+2)n - \lfloor \lg n \rfloor - \nu(n) - 1$.

1. Introduction.

Let $M(n)$ be defined by the recurrence

$$M(n) = \max_{1 \leq k < n} (M(k) + M(n-k) + \min(f(k), f(n-k))), \tag{1}$$

with $M(1)$ given. Divide-and-conquer recurrence relations of this type, for various functions f, occur in a variety of problems in the analysis of algorithms. For instance, the number of element interchanges in the worst case of quicksort (see, for example, [15] or [16]) is given by $M(n)$ when $f(x) = x$ and $M(1) = 0$; this $M(n)$ counts the worst-case number of interchanges used by quicksort in sorting $n-1$ elements, provided we make the simplifying assumption that the element used for partitioning is *always* interchanged to put it between the left and right parts of the array. The identical recurrence relation describes the worst-case behavior of a certain permutation algorithm (see [8]) and a merging process (see [14]).

The case $f(x) = \Theta(\log x)$ is well known. The recurrence (1) occurs, with such an f, in the construction of binary search trees [6], [15], [16], in the finding of common ancestors [10], and several computational-geometric problems [3], [5], [7], [9], [12], [21]. $M(n)$ is $\Theta(n)$ by an inductive argument [15], but the behavior of $M(n)$ in this case has not been investigated more precisely.

There is even a version of the recurrence (1) over trees. In this version, which occurs in the analysis of a certain tree-drawing algorithm, the function f is the height of the tree. See [18] or [22] for details.

Our purpose in this paper is to obtain precise solutions to the recurrence (1) under a number of choices of f. These solutions will be instructive for several reasons. First, the order-of-magnitude approximations conceal the precise behavior of the algorithms being analyzed. Second, and most important, by giving a more precise analysis of (1), we will discover that $f(x) = \Theta(\log x)$ is a *much* stronger condition than is necessary to guarantee that $M(n)$ is linear—any $f(x) = O(x/(\log x)^{1+\varepsilon})$, $\varepsilon > 0$, will do. This

means that the "merge steps" in the divide-and-conquer algorithms with this behavior can use almost linear time without sacrificing the overall linearity of the algorithm. Third, there is the challenge of explicitly solving a hard recurrence relation.

The published literature of exact solutions to (1) is scant—only the case $f(x)=x$, $M(1)=0$ has come under scrutiny. This case arises in the algorithmic problems outlined above, and also in at least one combinatorial setting [11]. The solution turns out to be

$$M(n)=\sum_{i=1}^{n-1}\nu(i)$$

where $\nu(i)$ is the number of 1-bits in the binary representation of i. This $M(n)$ has been well studied; see [14] for a detailed discussion and [4] for an extensive analysis of its asymptotic behavior.

Our analysis is aided considerably by the work of [2] on subadditive inequalities. In this paper (and in [1]), the determination of the value of k giving the maximum in (1) is given for some general classes of f. In particular, [2] considers the cases of f decreasing, f increasing and concave, and f increasing and convex. These cases, while of obvious interest, do not help in determining the exact behavior of $M(n)$ when f is a step function. Of course, step functions such as $\lfloor \lg x \rfloor$, $\lceil \lg (x+1) \rceil$, or $\lfloor x/2 \rfloor$ occur often as the cost of the merge step in divide-and-conquer algorithms, but the results of [2] do not apply to such functions. We will show how to handle many such cases.

To begin, we note that [2] observed that when f is nonincreasing, a simple induction on n verifies that $M(n)=nM(1)+(n-1)f(1)$. In the next section we treat the case in which f is nondecreasing and satisfies a certain concavity condition that is weak enough to encompass many step functions of interest. Similarly, in § 3 of this paper, we cover the case in which f is nondecreasing and satisfies a certain weak convexity condition that is less restrictive than general convexity. In these two sections, the main theorems are reformulated versions of results in [2], rewritten with emphasis on the less restrictive concavity/convexity condition. The corollaries show how these results apply to various step functions of interest. Section 4 develops some general bounds for arbitrary nondecreasing f. Finally, we summarize these results and give some unresolved questions in § 5.

2. The concave case.

DEFINITION. A real-valued function $f(n)$ is *concave* if $\Delta^2 f(n)\leqq 0$ for all $n\geqq 0$, that is, if

$$f(n+2)-f(n+1)\leqq f(n+1)-f(n) \quad \text{for all } n\geqq 0.$$

THEOREM 1. *Let $M(n)$ be defined by the recurrence* (1), *where $M(1)$ is given and f is nondecreasing and satisfies the inequality*

$$f(2^{m-1}+j)-f(2^{m-1})\leqq f(i)-f(i-j), \qquad 1\leqq j\leqq i/2\leqq 2^{m-1}. \tag{2}$$

Then $M(n)$ satisfies

$$M(2^m+i)=M(2^m)+M(i)+f(i), \qquad 1\leqq i\leqq 2^m, \quad m\geqq 0. \tag{3}$$

Proof. The proof is by induction on $n=2^m+i$. First, observe that since f is nondecreasing, the original recurrence simplifies to

$$M(n)=\max_{1\leqq k\leqq \lfloor n/2\rfloor}(M(k)+M(n-k)+f(k)). \tag{4}$$

Direct computation gives

$$M(2) = M(1) + M(1) + f(1), \qquad M(3) = M(1) + M(2) + f(1),$$
$$\begin{aligned} M(4) &= \max\,(M(1) + M(3) + f(1),\, M(2) + M(2) + f(2)) \\ &= \max\,(4M(1) + 3f(1),\, 4M(1) + 2f(1) + f(2)) \\ &= 4M(1) + 2f(1) + \max\,(f(1), f(2)) \\ &= 4M(1) + 2f(1) + f(2) \\ &= M(2) + M(2) + f(2). \end{aligned}$$

This establishes the theorem for $n \leqq 4$.

Suppose, by induction, that the theorem is true for values less than n; we will show that (3) holds for $n = 2^m + i$ as well. In particular, we will show that for $m \geqq 2$, $1 \leqq i \leqq 2^m$, (that is, $n \geqq 5$),

$$M(2^m) + M(i) + f(i) \geqq M(k) + M(2^m + i - k) + f(k), \qquad 1 \leqq k \leqq 2^{m-1} + i/2.$$

Since equality occurs at $k = i$, it follows that

$$\begin{aligned} M(2^m) + M(i) + f(i) &= \max_{1 \leqq k \leqq \lfloor (2^m + i)/2 \rfloor} (M(k) + M(2^m + i - k) + f(k)) \\ &= M(2^m + i). \end{aligned}$$

The range $1 \leqq k \leqq 2^{m-1} + i/2$ is broken into four subranges that are handled in separate cases.

Case 1. $1 \leqq k < i$. This is the simplest case; we have

$$\begin{aligned} M(k) + M(2^m + i - k) + f(k) &= M(k) + (M(2^m) + M(i - k) + f(i - k)) + f(k) \\ &\qquad \text{(by induction)} \\ &= M(2^m) + (M(k) + M(i - k) + \min\,(f(k), f(i - k))) \\ &\quad + \max\,(f(k), f(i - k)) \\ &\leqq M(2^m) + M(i) + \max\,(f(k), f(i - k)) \\ &\qquad \text{(by the definition of } M) \\ &\leqq M(2^m) + M(i) + f(i), \end{aligned}$$

since f is nondecreasing.

Case 2. $i + 1 \leqq k < 2^{m-2} + i/2$.

$$\begin{aligned} M(k) + M(2^m + i - k) + f(k) &= M(k) + M(2^{m-1} + 2^{m-1} + i - k) + f(k) \\ &= M(k) + (M(2^{m-1}) + M(2^{m-1} + i - k) \\ &\quad + f(2^{m-1} + i - k)) + f(k) \qquad \text{(by induction)} \\ &= M(2^{m-1}) + (M(k) + M(2^{m-1} + i - k) + f(k)) \\ &\quad + f(2^{m-1} + i - k) \\ &\leqq M(2^{m-1}) + M(2^{m-1} + i) + f(2^{m-1} + i - k) \\ &\qquad \text{(by the definition of } M) \\ &= M(2^{m-1}) + (M(2^{m-1}) + M(i) + f(i)) + f(2^{m-1} + i - k) \\ &\qquad \text{(by induction)} \\ &\leqq (M(2^{m-1}) + M(2^{m-1}) + f(2^{m-1})) + M(i) + f(i), \end{aligned}$$

because $i < k$ and f is nondecreasing.

$$= M(2^m) + M(i) + f(i) \quad \text{(by induction).}$$

Case 3. $2^{m-2} + i/2 \leqq k \leqq 2^{m-1}$.

$$\begin{aligned} M(k) + M(2^m + i - k) + f(k) &= M(k) + M(2^{m-1} + 2^{m-1} + i - k) + f(k) \\ &= M(k) + (M(2^{m-1}) + M(2^{m-1} + i - k) + f(2^{m-1} + i - k)) \\ &\quad + f(k), \end{aligned}$$

by induction, since $i < k$.

$$\begin{aligned} &= M(2^{m-1}) + (M(k) + M(2^{m-1} + i - k) + f(2^{m-1} + i - k)) \\ &\quad + f(k) \\ &\leqq M(2^{m-1}) + M(2^{m-1} + i) + f(k), \end{aligned}$$

by the definition of M, since $k \geqq 2^{m-1} + i - k$.

$$\begin{aligned} &= M(2^{m-1}) + (M(2^{m-1}) + M(i) + f(i)) + f(k) \\ &\qquad\qquad \text{(by induction)} \\ &= (M(2^{m-1}) + M(2^{m-1})) + M(i) + f(i) + f(k) \\ &= M(2^m) - f(2^{m-1}) + M(i) + f(i) + f(k) \quad \text{(by induction)} \\ &= M(2^m) + M(i) + f(i) + (f(k) - f(2^{m-1})) \\ &\leqq M(2^m) + M(i) + f(i), \end{aligned}$$

since $k \leqq 2^{m-1}$ and f is nondecreasing.

Case 4. $2^{m-1} < k \leqq 2^{m-1} + i/2$. Let $k = 2^{m-1} + j$, $1 \leqq j \leqq i/2 \leqq 2^{m-1}$; if $i - j > 2^{m-1}$ then $i - (k - 2^{m-1}) > 2^{m-1}$, so that $i > k$ and we have Case 1. Hence we may assume that $i - j \leqq 2^{m-1}$ and we have

$$\begin{aligned} M(k) + M(2^m + i - k) + f(k) &= M(2^{m-1} + j) + M(2^{m-1} + i - j) + f(2^{m-1} + j) \\ &= (M(2^{m-1}) + M(j) + f(j)) + (M(2^{m-1}) + M(i - j) \\ &\quad + f(i - j)) + f(2^{m-1} + j), \end{aligned}$$

by induction, since $j \leqq 2^{m-1}$ and $i - j \leqq 2^{m-1}$.

$$\begin{aligned} &= (M(2^{m-1}) + M(2^{m-1})) + (M(j) + M(i - j) + f(j)) \\ &\quad + f(i - j) + f(2^{m-1} + j) \\ &\leqq (M(2^m) - f(2^{m-1})) + M(i) + f(i - j) + f(2^{m-1} + j), \end{aligned}$$

by induction and the definition of M.

$$\begin{aligned} &= M(2^m) + M(i) + f(i) + ((f(2^{m-1} + j) - f(2^{m-1})) \\ &\quad - (f(i) - f(i - j))) \\ &\leqq M(2^m) + M(i) + f(i), \end{aligned}$$

because for $1 \leqq j \leqq i/2 \leqq 2^{m-1}$ the bracketed term is negative by hypothesis. □

A detailed examination of [2] reveals that Batty and Rogers actually proved Theorem 1. However, all they state is the following corollary.

COROLLARY 1 [2]. *Let $M(n)$ be defined by the recurrence* (1), *where $M(1)$ is given and f is nondecreasing and concave. Then $M(n)$ satisfies*

$$M(2^m+i)=M(2^m)+M(i)+f(i), \qquad 1\leqq i\leqq 2^m, \quad m\geqq 0.$$

Proof. The concavity of f guarantees that it satisfies the inequality (2) in the hypothesis of Theorem 1. □

We can use Theorem 1 to obtain an explicit solution to recurrence (1) for nondecreasing functions f that satisfy inequality (2). First, we get the solution for powers of two, then we extend it to arbitrary n.

COROLLARY 2. *Let $M(n)$ be defined by the recurrence* (1), *where $M(1)$ is given and f is nondecreasing and satisfies inequality* (2). *Then*

$$M(2^k)=2^kM(1)+2^{k-1}\sum_{i=0}^{k-1}\frac{f(2^i)}{2^i}.$$

Proof. The proof is by repeated application of (3). □

COROLLARY 3. *Let $M(n)$ be defined by the recurrence* (1), *where $M(1)$ is given and f is nondecreasing and satisfies inequality* (2). *Let* $n=2^{k_1}+2^{k_2}+\cdots+2^{k_l}$, $0\leqq k_1<k_2<\cdots<k_l$, $l=\nu(n)\geqq 1$; *then*

$$M(n)=nM(1)+\sum_{j=1}^{l}2^{k_j-1}\sum_{i=0}^{k_j-1}\frac{f(2^i)}{2^i}+\sum_{j=1}^{l-1}f\left(\sum_{i=1}^{j}2^{k_i}\right) \tag{5}$$

$$=nM(1)+\sum_{j=1}^{\infty}\left\lfloor\frac{n}{2^j}\right\rfloor f(2^{j-1})+\sum_{j=1}^{l-1}f\left(\sum_{i=1}^{j}2^{k_i}\right). \tag{6}$$

Proof. Equation (5) follows from repeated application of (3), together with Corollary 2. Equation (6) follows from (5) by observing that the coefficient of $f(2^{t-1})$ in (5) is $\sum_{1\leqq j\leqq l,\,k_j\geqq t}2^{k_j-t}=\lfloor n/2^t\rfloor$. □

Corollary 3 can be applied to a variety of step functions f, including $f(x)=\lceil\lg(x+1)\rceil$, $f(x)=\lfloor x/2\rfloor$, and so on. The evaluations of $M(n)$ in such cases are straightforward algebraic calculations. We give one example of such a calculation in the next corollary. We chose to give this example, $f(x)=\lfloor\lg n\rfloor$, because this particular choice of f is what initiated our investigation [16].

COROLLARY 4. *Let $M(n)$ be defined by the recurrence* (1) *with $f(x)=\lfloor\lg x\rfloor$. Then* $M(n)=(M(1)+1)n-\lfloor\lg n\rfloor-\nu(n)$.

Proof. Since $\lfloor\lg x\rfloor$ is nondecreasing and satisfies (2), Theorem 1 and its corollaries apply. Equation (5) in Corollary 3 tells us that

$$\begin{aligned}M(n)&=M(1)n+\sum_{j=1}^{l}2^{k_j-1}\sum_{i=0}^{k_j-1}\frac{i}{2^i}+\sum_{j=1}^{l-1}k_j\\&=M(1)n+\sum_{j=1}^{l}\sum_{i=0}^{k_j-1}i2^{k_j-1-i}+\sum_{j=1}^{l}k_j-\lfloor\lg n\rfloor,\end{aligned}$$

since $k_l=\lfloor\lg n\rfloor$. It remains to show that

$$\sum_{j=1}^{l}\sum_{i=0}^{k_j-1}i2^{k_j-1-i}+\sum_{j=1}^{l}k_j=n-\nu(n).$$

We have

$$\sum_{j=1}^{l}\sum_{i=0}^{k_j-1}i2^{k_j-1-i}+\sum_{j=1}^{l}k_j=\sum_{j=1}^{l}(2^{k_j}-k_j-1)+\sum_{j=1}^{l}k_j=\sum_{j=1}^{l}2^{k_j}-\sum_{j=1}^{l}1=n-\nu(n),$$

since $\sum_{i=0}^{t}i2^{t-i}=2^{t+1}-t-2$. □

The most famous instance of (1) is with $f(x)=x$ and $M(1)=0$ [4], [8], [11], [14]. We have Corollary 5.

COROLLARY 5 [8], [11], [14]. *Let $M(n)$ be defined by the recurrence* (1), *with $f(x)=x$ and $M(1)=0$. Then $M(n)=\sum_{k=0}^{n-1}\nu(k)$.*

Proof. Since $f(x)=x$ satisfies inequality (2), we apply Corollary 3 and find that

$$M(n)=\sum_{j=1}^{\infty}\left\lfloor\frac{n}{2^j}\right\rfloor 2^{j-1}+\sum_{j=1}^{l-1}\sum_{i=1}^{j}2^{k_i}$$

from equation (6). Now, imagine the binary representations of $0, 1, 2, \cdots, n-1$ written in an array, one above the other with the columns aligned. The number of 1-bits can be counted row by row to give $\sum_{k=0}^{n-1}\nu(k)$. Alternatively, the number of 1-bits can be counted column by column as follows. In the jth column from the right there will be $\lfloor n/2^j\rfloor$ complete groups of 2^{j-1} 1-bits, for a total of $\lfloor n/2^j\rfloor 2^{j-1}$ 1-bits in those complete groups; summing this value from one to infinity counts the 1-bits in complete groups, column by column. Now we count the fragmentary groups of 1-bits column by column as follows. If the jth column of n is a 1-bit (that is, if 2^{j-1} appears in the binary representation of n), there will be a fragmentary group of 1-bits in column j. The fragmentary group in column j will have a number of 1-bits equal to the value of the binary number formed by the bits of n to the right of the jth column, that is, $\sum_{i=1}^{j}2^{k_i}$ 1-bits. Summing this for all the 1-bits in n (except the first which can have no fragmentary group), we obtain precisely $\sum_{j=1}^{l-1}\sum_{i=1}^{j}2^{k_i}$. □

3. The convex case. The case of nondecreasing, convex f is not nearly as interesting as the concave case. As in the concave case, we state and prove a result that holds for a relatively weak form of convexity, and then state as a corollary the result for usual convexity. Also as in the concave case, Batty and Rogers [2] proved a more general result than they state.

DEFINITION. A real-valued function $f(n)$ is *convex* if $\Delta^2 f(n)\geqq 0$ for all $n\geqq 0$, that is, if

$$f(n+2)-f(n+1)\geqq f(n+1)-f(n) \quad \text{for all } n\geqq 0.$$

THEOREM 2. *Let $M(n)$ be defined by the recurrence* (1), *where $M(1)$ is given and f is nondecreasing and satisfies*

$$f(\lfloor(p+q)/2\rfloor)-f(\lfloor q/2\rfloor)\geqq f(p)-f(\lceil p/2\rceil) \tag{7}$$

for all integers p and q, $0\leqq p\leqq q$. Then $M(n)$ satisfies

$$M(n)=M(\lfloor n/2\rfloor)+M(\lceil n/2\rceil)+f(\lfloor n/2\rfloor). \tag{8}$$

Proof. The proof is by induction on n. As in the proof of Theorem 1, the original recurrence simplifies to

$$M(n)=\max_{1\leqq k\leqq\lfloor n/2\rfloor}(M(k)+M(n-k)+f(k))$$

and direct computation gives

$$M(2)=M(1)+M(1)+f(1),$$

so the theorem holds for $n\leqq 2$. Suppose it holds for all values less than n; we will show that (8) holds for n as well. In particular, we will show that for all p, q, $0<p\leqq q$, $p+q=n$,

$$M(\lfloor n/2\rfloor)+M(\lceil n/2\rceil)+f(\lfloor n/2\rfloor)\geqq M(p)+M(q)+f(p).$$

Since equality occurs for $p = \lfloor n/2 \rfloor$, $q = \lceil n/2 \rceil$, it follows that

$$M(\lfloor n/2 \rfloor) + M(\lceil n/2 \rceil) + f(\lfloor n/2 \rfloor) = \max_{1 \leqq k \leqq \lfloor n/2 \rfloor} (M(k) + M(n-k) + f(k)).$$

If p is odd and q is even, we have $\lfloor p/2 \rfloor + \lceil q/2 \rceil = \lfloor (p+q)/2 \rfloor$ and $\lceil p/2 \rceil + \lfloor q/2 \rfloor = \lceil (p+q)/2 \rceil$. Since $p+q=n$ we have

$$\begin{aligned}
M(p)+M(q)+f(p) &= M(\lfloor p/2 \rfloor)+M(\lceil p/2 \rceil)+f(\lfloor p/2 \rfloor)+M(\lfloor q/2 \rfloor)+M(\lceil q/2 \rceil) \\
&\quad +f(\lfloor q/2 \rfloor)+f(p) \quad \text{(by induction)} \\
&= (M(\lfloor p/2 \rfloor)+M(\lceil q/2 \rceil)+f(\lfloor p/2 \rfloor))+(M(\lceil p/2 \rceil) \\
&\quad +M(\lfloor q/2 \rfloor)+f(\lceil p/2 \rceil))+f(\lfloor q/2 \rfloor)-f(\lceil p/2 \rceil)+f(p) \\
&\leqq M(\lfloor n/2 \rfloor)+M(\lceil n/2 \rceil)+f(\lfloor q/2 \rfloor) \\
&\quad -f(\lceil p/2 \rceil)+f(p) \quad \text{(by the definition of } M) \\
&= M(\lfloor n/2 \rfloor)+M(\lceil n/2 \rceil)+f(\lfloor n/2 \rfloor) \\
&\quad -((f(\lfloor (p+q)/2 \rfloor)-f(\lfloor q/2 \rfloor))-(f(p)-f(\lceil p/2 \rceil))) \\
&\leqq M(\lfloor n/2 \rfloor)+M(\lceil n/2 \rceil)+f(\lfloor n/2 \rfloor),
\end{aligned}$$

because f satisfies inequality (7). On the other hand, if either p is even and q is odd, or if both p and q have the same parity, we have $\lfloor p/2 \rfloor + \lceil q/2 \rceil = \lceil (p+q)/2 \rceil$ and $\lceil p/2 \rceil + \lfloor q/2 \rfloor = \lfloor (p+q)/2 \rfloor$ and the proof continues exactly as above. □

COROLLARY 6 [2]. *Let $M(n)$ be defined by the recurrence* (1), *where $M(1)$ is given and f is nondecreasing and convex. Then $M(n)$ satisfies*

$$M(n) = M(\lfloor n/2 \rfloor) + M(\lceil n/2 \rceil) + f(\lfloor n/2 \rfloor).$$

Proof. Since

$$\lfloor (p+q)/2 \rfloor - \lfloor q/2 \rfloor \geqq p - \lceil p/2 \rceil$$

for all nonnegative integers p, q, it follows that inequality (7) holds by the convexity of f. □

COROLLARY 7. *Let $M(n)$ be defined by the recurrence* (1), *where $M(1)$ is given and f is nondecreasing and satisfies inequality* (7); *we have*

$$M(2^k) = 2^k M(1) + 2^{k-1} \sum_{i=0}^{k-1} \frac{f(2^i)}{2^i}.$$

Proof. The proof is by repeated application of equation (8). □

COROLLARY 8 [8], [14]. *Let $M(n)$ be defined by the recurrence* (1), *with $f(x) = x$; then $M(n) = M(\lfloor n/2 \rfloor) + M(\lceil n/2 \rceil) + \lfloor n/2 \rfloor$.* □

4. The general case. Corollaries 2 and 7 suggest that the general asymptotic character of $M(n)$ does not depend on the particular shape of f, only on it being nondecreasing. In this section we verify this observation and derive bounds on $M(n)$ for arbitrary nondecreasing f.

In studying the function $M(n)$ as defined by recurrence (1) for arbitrary nondecreasing f, it will be convenient to use binary trees to represent the recursive evaluation of (1) for a given n. We define a *partition tree of n* as a rooted binary tree T containing $n-1$ internal nodes and n external nodes (see, for example, [16]) in which every node

x in T is labeled with a natural number: the root is labeled with n, every internal node is labeled with the sum of the labels of its two children, and every external node is labeled with one. Furthermore, the label of a left child must never be larger than the label of its sibling. When no confusion results, we will refer to a node by its label. We denote by $\mathcal{T}(n)$ the set of all partition trees of n.

We will want to consider partition trees in which parts of the tree have been pruned away. Given a particular partition tree T in $\mathcal{T}(n)$, we define the sequence of truncated partition trees $T_0 = T$, T_1, T_2, $\cdots$ as follows. T_t, $t \geqq 0$, is the tree that results when all nodes $x < 2^t$ in T are delected.

Finally, we define the function $F(T)$, for a truncated partition tree T, to be

$$F(T) = \sum_{\text{left children } x \text{ in } T} f(x).$$

The formation rule for partition trees and the nondecreasing property of f make the relationship between the recurrence (1) and partition trees

$$M(n) = nM(1) + \max_{T \text{ in } \mathcal{T}(n)} F(T).$$

We will, therefore, be able to bound $M(n)$ by bounding $F(T)$. Specifically, we will show below (in the proof of Theorem 3) that

$$F(T) \leqq \sum_{i=1}^{k-1} (\lfloor n/2^i \rfloor + b_{i-1}) f(2^i) \quad \text{for all } T \text{ in } \mathcal{T}(n)$$

where $k-1 = \lfloor \lg n \rfloor$ and $n = (\cdots b_3 b_2 b_1 b_0)_2$. First, however, we need a preliminary result.

Given a partition tree T, let $L(T)$ denote the number of left children in T. Then, we define

$$L_t(n) = \max_{T \text{ in } \mathcal{T}(n)} L(T_t);$$

that is, $L_t(n)$ denotes the largest number of left children remaining in any partition tree of n that has been pruned of all nodes with labels less than 2^t. Obviously, $L_t(1) = 0$ and $L_t(n)$ can be defined recursively by

$$L_t(n) = \max_{1 \leqq k \leqq \lfloor n/2 \rfloor} (L_t(k) + L_t(n-k) + g(k)) \tag{9}$$

where

$$g(x) = \begin{cases} 0 & \text{if } x < 2^t, \\ 1 & \text{otherwise;} \end{cases}$$

the $g(k)$ term in the recurrence counts the root of the left subtree.

LEMMA.

$$L_t(n) = \begin{cases} \lfloor n/2^t \rfloor - 1 & \text{if } n \geqq 2^t, \\ 0 & \text{otherwise.} \end{cases}$$

Proof. Recurrence (9) is an instance of recurrence (4) and the function g is nondecreasing and satisfies inequality (2), so that Theorem 1 and its corollaries apply.

Corollary 3 tells us that

$$L_t(n) = nL_t(1) + \sum_{\substack{1 \le j \le l \\ k_j > t}} 2^{k_j - 1} \sum_{i=t}^{k_j - 1} 2^{-i} + \sum_{j=1}^{l-1} \begin{cases} 1 & \text{if } k_j \ge t, \\ 0 & \text{otherwise} \end{cases}$$

$$= \sum_{\substack{1 \le j \le l \\ k_j > t}} (2^{k_j - t} - 1) + \begin{cases} \nu(\lfloor n/2^t \rfloor) - 1 & \text{if } n \ge 2^t, \\ 0 & \text{otherwise} \end{cases}$$

$$= \lfloor n/2^t \rfloor - \nu(\lfloor n/2^t \rfloor) + \begin{cases} \nu(\lfloor n/2^t \rfloor) - 1 & \text{if } n \ge 2^t, \\ 0 & \text{otherwise} \end{cases}$$

$$= \begin{cases} \lfloor n/2^t \rfloor - 1 & \text{if } n \ge 2^t, \\ 0 & \text{otherwise.} \end{cases}$$

□

THEOREM 3. *Let $M(n)$ be defined by the recurrence* (1), *where $M(1)$ is given and f is nondecreasing. Then $M(n)$ satisfies*

$$M(n) \le nM(1) + \sum_{i=0}^{\lfloor \lg n \rfloor} (\lfloor n/2^i \rfloor + b_{i-1}) f(2^i)$$

where $n = (\cdots b_3 b_2 b_1 b_0)_2$.

Proof. Let $2^{k-1} \le n < 2^k$ so that $k - 1 = \lfloor \lg n \rfloor$. The theorem will follow from the lemma and the inequality

$$F(T) \le \sum_{i=1}^{k-1} [L_{k-(i+1)}(n) - L_{k-i}(n)] f(2^{k-i}) \quad \text{for all } T \text{ in } \mathcal{T}(n),$$

because

$$M(n) = nM(1) + \max_{T \text{ in } \mathcal{T}(n)} F(T).$$

In fact, for any given partition tree T in $\mathcal{T}(n)$ we will establish, by induction on t, the more general inequality

$$F(T_{k-t}) \le \left[\sum_{i=1}^{t-1} (L_{k-(i+1)}(n) - L_{k-i}(n)) f(2^{k-i}) \right] - (L_{k-t}(n) - L(T_{k-t})) f(2^{k-t+1}), \tag{10}$$

for $1 \le t \le k$.

We need to establish the basis. Because $k - 1 = \lfloor \lg n \rfloor$, there is no left child $x \ge 2^{k-1}$ in any T in $\mathcal{T}(n)$; thus $F(T_{k-1}) = 0$, for all T in $\mathcal{T}(n)$. Similarly, $L_{k-1}(n) = L(T_{k-1}) = 0$, so (10) holds for $t = 1$.

Suppose (10) holds and $t < k$; we will show that it holds for $t + 1$ as well. We have

$$F(T_{k-(t+1)}) = F(T_{k-t}) + \sum_{\substack{2^{k-(t+1)} \le x < 2^{k-t} \\ x \text{ is a left child in } T}} f(x)$$

$$\le F(T_{k-t}) + \sum_{\substack{2^{k-(t+1)} \le x < 2^{k-t} \\ x \text{ is a left child in } T}} f(2^{k-t})$$

because f is nondecreasing.

$$= F(T_{k-t}) + \begin{pmatrix} \text{the number of left children} \\ x \text{ in } T \text{ such that } 2^{k-(t+1)} \le x < 2^{k-t} \end{pmatrix} f(2^{k-t})$$

$$= F(T_{k-t}) + (L(T_{k-(t+1)}) - L(T_{k-t})) f(2^{k-t}).$$

Using (10), we have

$$\leqq \left[\sum_{i=1}^{t-1} (L_{k-(i+1)}(n) - L_{k-i}(n)) f(2^{k-i})\right] - (L_{k-t}(n) - L(T_{k-t})) f(2^{k-t+1})$$
$$+ (L(T_{k-(t+1)}) - L(T_{k-t})) f(2^{k-t})$$
$$\leqq \left[\sum_{i=1}^{t-1} (L_{k-(i+1)}(n) - L_{k-i}(n)) f(2^{k-i})\right] - (L_{k-t}(n) - L(T_{k-t})) f(2^{k-t})$$
$$+ (L(T_{k-(t+1)}) - L(T_{k-t})) f(2^{k-t}),$$

since f is nondecreasing.

$$= \left[\sum_{i=1}^{t-1} (L_{k-(i+1)}(n) - L_{k-i}(n)) f(2^{k-i})\right] - (L_{k-t}(n) - L(T_{k-(t+1)})) f(2^{k-t})$$
$$= \left[\sum_{i=1}^{t} (L_{k-(i+1)}(n) - L_{k-i}(n)) f(2^{k-i})\right] - (L_{k-(t+1)}(n) - L(T_{k-(t+1)})) f(2^{k-t}),$$

completing the induction.

Now, $T = T_0$, so

$$M(n) = nM(1) + \max_{T \text{ in } \mathcal{T}(n)} F(T_0),$$

and then

$$M(n) \leqq nM(1) + \sum_{i=1}^{k-1} (L_{k-(i+1)}(n) - L_{k-i}(n)) f(2^{k-i}), \tag{11}$$

by (10) with $t = k$ since $L_0(n) = L(T_0) = n - 1$.

The lemma tells us that

$$L_{k-(i+1)}(n) - L_{k-i}(n) = \begin{cases} \lfloor n/2^{k-(i+1)} \rfloor - 1 - (\lfloor n/2^{k-i} \rfloor - 1), & n \geqq 2^{k-i}, \\ \lfloor n/2^{k-(i+1)} \rfloor - 1 - 0, & 2^{k-(i+1)} \leqq n < 2^{k-i}, \\ 0 - 0 & n < 2^{k-(i+1)}, \end{cases}$$
$$= \begin{cases} \lfloor n/2^{k-(i+1)} \rfloor - \lfloor n/2^{k-i} \rfloor, & n \geqq 2^{k-i}, \\ \lfloor n/2^{k-(i+1)} \rfloor - 1, & 2^{k-(i+1)} \leqq n < 2^{k-i}, \\ 0, & n < 2^{k-(i+1)}, \end{cases}$$
$$= \begin{cases} \lfloor n/2^{k-i} \rfloor + b_{k-(i+1)}, & n \geqq 2^{k-i}, \\ 0, & \text{otherwise}, \end{cases}$$

because $\lfloor n/2^m \rfloor = 2\lfloor n/2^{m+1} \rfloor + b_m$. Inequality (11) thus becomes

$$M(n) \leqq nM(1) + \sum_{i=1}^{k-1} (\lfloor n/2^{k-i} \rfloor + b_{k-(i+1)}) f(2^{k-i})$$
$$= nM(1) + \sum_{i=1}^{k-1} (\lfloor n/2^{i} \rfloor + b_{i-1}) f(2^{i}),$$

as desired. □

COROLLARY 9. *Let $M(n)$ be defined by the recurrence* (1), *where $M(1)$ is given and f is nondecreasing. Then $M(n)$ satisfies*

$$(12)\quad nM(1)+\sum_{j=1}^{\lceil \lg n\rceil}\lfloor n/2^j\rfloor f(2^{j-1})+\sum_{j=1}^{l-1} f\left(\sum_{i=1}^{j}2^{k_i}\right)\leqq$$

$$M(n)\leqq nM(1)+\sum_{j=1}^{\lfloor \lg n\rfloor}\lfloor n/2^j\rfloor f(2^j)+\sum_{j=1}^{l-1} f(2^{k_j+1}),$$

where $n=2^{k_1}+2^{k_2}+\cdots+2^{k_l}$, $0\leqq k_1<k_2<\cdots<k_l$, and $l=\nu(n)\geqq 1$.

Proof. The upper bound follows directly from Theorem 3. The lower bound follows from equation (6) in Corollary 3, interpreted as the evaluation of $F(T(n))$, where $T(n)$ in $\mathscr{T}(n)$ is defined recursively as follows: $T(1)$ is a single leaf labeled one. If $n=2^m+i$, $1\leqq i\leqq 2^m$, then $T(n)$ has the label n at the root, $T(i)$ as its left subtree, and $T(2^m)$ as its right subtree. □

5. Conclusions and open problems. The most striking conclusion we can make is that divide-and-conquer algorithms whose time requirements are given by (1) can use far more than logarithmic time for their merge step, without losing overall linear-time behavior: Inequality (12) guarantees that $M(n)=O(n)$, even for $f(x)$ as large as $O(x/(\log x)^{1+\varepsilon})$, $\varepsilon>0$, that is, even when f is almost linear! This observation should make possible the use of more sophisticated merge steps in the divide-and-conquer algorithms.

Table 1 gives some examples of the comparative growth rates of $M(n)$ versus f, based on inequality (12). All of the entries in Table 1 are straightforward to verify, except those for

$$f(x)=\Theta\left(x\Big/\prod_{1\leqq i<\log_b^* n}\log_b^{(i)}x\right);$$

TABLE 1

Relative growth rates of f versus $M(n)$, based on inequality (12). *For any particular base, $\log^{(k)}x$ is the kth iterated logarithm defined by $\log^{(0)}x=x$, $\log^{(k+1)}x=\log(\log^{(k)}x)$ and $\log^* x$ is the least k such that $\log^{(k)}\leqq 1$. Unless otherwise indicated, the base of the logarithms is arbitrary.*

$f(x)$	$M(n)$
$O(x/(\log x)^{1+\varepsilon})$, $\varepsilon>0$	$\Theta(n)$
$\Theta\left(x\Big/\prod_{1\leqq i<\log_b^* x}\log_b^{(i)}x\right)$, $b<e$	$\Theta(n)$
$\Theta\left(x\Big/\prod_{1\leqq i<\ln^* x}\ln^{(i)}x\right)$	$\Theta(n\ln^* n)$
$\Theta\left(x\Big/\prod_{1\leqq i<\log_b^* x}\log_b^{(i)}x\right)$, $b>e$	$\Theta(n(\ln b)^{\log_b^* n})$
$\Theta\left(x\Big/\prod_{1\leqq i\leqq k}\log^{(i)}x\right)$, $k\geqq 0$	$\Theta(n\log^{(k+1)}n)$
$\Theta(x/\log\log x)$	$\Theta((n\log n)/\log\log n)$
$\Theta(x(\log x)^k)$, $k\geqq 0$	$\Theta(n(\log n)^{k+1})$
$\Theta(x^{1+\varepsilon}(\log x)^k)$, $\varepsilon>0$, $k\geqq 0$	$\Theta(n^{1+\varepsilon}(\log n)^k)$

those interesting entries follow from the proof of Lemma B.1 in [13] (see also [19]). We may also ask for what function f will $M(n) = n\alpha(n)$, where $\alpha(n)$ is a functional inverse of Ackermann's function (see [20]); the answer, which is fairly complex, can be found in [17].

The specific case of $f(x) = \lceil \lg x \rceil$ is very strange. Inequality (2) in Theorem 1 fails (with, for example, $m = i = 4$ and $j = 1$), as does inequality (7) in Theorem 2 (with $p = 31$ and $q = 34$, for instance). However, the *conclusions* of both theorems hold! That is, the solution to recurrence (1) in this case is $M(n) = (M(1)+1)n - \lceil \lg n \rceil - 1$ which satisfies both equations (3) and (8) as is easily shown by induction on n. This anomaly suggests that both Theorems 1 and 2 can be proved under weaker assumptions than we have used. The seemingly insignificant change of f from $f(x) = \lceil \lg x \rceil$ to $f(x) = \lceil \lg (x+1) \rceil$, which does satisfy inequality (2), yields the solution $M(n) = (M(1)+2)n - \lfloor \lg n \rfloor - \nu(n) - 1$. When $M(1) = 0$, this is roughly twice as large as when $f(x) = \lceil \lg x \rceil$, demonstrating a somewhat unstable dependence of $M(n)$ on f.

The bound in Theorem 3, and hence the upper bound in Corollary 9, is fairly tight when f is a constant, but becomes progressively looser as the rate of growth of f increases. For $f(x) = \Theta(x^w)$, $w \geqq 0$, for example, the upper bound is approximately 2^w times the lower bound. We believe that the lower bound is more nearly correct, but an improved upper bound has eluded us.

We should mention that the solution to the minimax form of the recurrence (1), namely,

$$M(n) = \min_{1 \leqq k < n} (M(k) + M(n-k) + \max(f(k), f(n-k))),$$

is precisely parallel to the maximin form that we have considered. In the minimax form, the roles of nondecreasing and nonincreasing are interchanged, as are the roles of concavity and convexity. It is the minimax form that was studied in [2].

Finally, there are two natural generalizations of recurrence (1) that can also be studied:

$$M(n) = \max_{k_1 + k_2 + \cdots + k_t = n} \left(\sum_{i=1}^{t} M(k_i) + \min_{1 \leqq i \leqq t} f(k_i) \right),$$

and the identical definition with "min" replaced by "sum-of-all-but-the-max." Little is known about either generalized form. The generalization with "min" has been considered in [1], while the generalization with "sum-of-all-but-the-max" occurs in [22] and [23].

Acknowledgments. We thank Herbert Edelsbrunner for asking us about the behavior of the recurrence for f other than $\Theta(\log n)$, for pointing out references [3], [5], [7], [9], [12], and [23], and for his helpful comments. We thank Ronald Rivest for pointing out reference [19].

GEOMETRY HELPS IN MATCHING*

PRAVIN M. VAIDYA†

Abstract. A set of $2n$ points on the plane induces a complete weighted undirected graph as follows. The points are the vertices of the graph, and the weight of an edge between any two points is the distance between the points under some metric. The problem of finding a minimum weight complete matching (MWCM) in such a graph is studied. An $O(n^{2.5}(\log n)^4)$ algorithm is given for finding an MWCM in such a graph, for the L_1 (*manhattan*), the L_2 (*Euclidean*), and the L_∞ metrics. The bipartite version of the problem is also studied, where half the points are painted with one color and the other half with another color, and the restriction is that a point of one color may be matched only to a point of another color. An $O(n^{2.5} \log n)$ algorithm for the bipartite version, for the L_1, L_2, and L_∞ metrics, is presented. The running time for the bipartite version can be further improved to $O(n^2(\log n)^3)$ for the L_1 and L_∞ metrics.

1. Introduction.

Given a complete weighted undirected graph on a set of $2n$ vertices, a complete matching is a set of n edges such that each vertex has exactly one edge incident on it. The weight of a set of edges is the sum of the weights of the edges in the set, and a minimum weight complete matching (MWCM) is a complete matching that has the least weight among all the complete matchings.

We study the problem of finding an MWCM in the complete graph induced by a set of $2n$ points on the plane. The points are the vertices of the graph, and the weight of an edge between any two points is the distance between the points under some metric. We shall investigate two common metrics: the L_1 (*manhattan*) metric, and the L_2 (*Euclidean*) metric. (We note that the L_∞ metric can be converted to the L_1 metric by rotating the coordinate system by 45°, and so any algorithm for the L_1 metric can be trivially modified to work for the L_∞ metric.) The input consists of $2n$ points that specify the locations of the vertices on the plane. Each point p is given as an ordered pair (p_x, p_y), where p_x and p_y denote the x and y coordinates of p, respectively. The L_r distance between two points p and q is given by $(|p_x - q_x|^r + |p_y - q_y|^r)^{1/r}$. (Note that the L_1 distance between p and q is given by $|p_x - q_x| + |p_y - q_y|$.) We shall assume that the metric defining the edge weights is fixed.

We also study the bipartite version of the MWCM problem for points on the plane. In the bipartite version, half the points are painted with one color and the other half another color, and the restriction is that a point of one color can be matched only to a point of the other color.

The complete graph induced by a set of $2n$ points on the plane is entirely specified by the locations of the vertices. So the problem of finding an MWCM in such a graph differs from the problem of finding an MWCM in a general complete graph in that the size of the input is $O(n)$ rather than $\Omega(n^2)$. The input is sparse since the edge weights are implicitly defined by the underlying geometry. It is interesting to investigate if the geometric nature of the MWCM problem for points on the plane can be exploited

to obtain an algorithm for its solution that is faster than the $\Theta(n^3)$ algorithm [6], [11] for general graphs. At this point we note that several heuristics for finding a good complete matching (not necessarily of minimum weight) on points on the plane have been developed [2], [9], [17], but the only known way to find an MWCM on $2n$ points on the plane is to run the MWCM algorithm for general graphs that requires $\Theta(n^3)$ time. In this paper we show that geometry does help to obtain a faster algorithm. We give an $O(n^{2.5}(\log n)^4)$ algorithm for finding an MWCM in the complete graph induced by a set of $2n$ points on the plane, for the L_1 and L_2 metrics. For the bipartite version of the MWCM problem for $2n$ points on the plane, we give an $O(n^{2.5} \log n)$ algorithm for the L_1 and L_2 metrics. For the bipartite case, the running time of the MWCM algorithm can be further improved to $O(n^2(\log n)^3)$ for the L_1 metric. The space requirement of all the algorithms is $O(n \log n)$ in the case of L_2 metric and $O(n(\log n)^2)$ in the case of L_1 metric.

The algorithms described in this paper will be essentially the well-studied primal-dual algorithms for weighted matching, namely, the Hungarian method [10], [11], [14] for bipartite matching, and Edmond's algorithm [4], [11], [14] for general matching. The primal-dual algorithms for weighted matching associate a dual variable with each vertex of the given graph, and the *slack* associated with an edge is the weight of the edge minus the sum of the dual variables associated with the end vertices of the edge. The algorithms can be substantially speeded up for points in the plane by the application of two key ideas. First, associating a weight with each vertex (point) that is suitably related to the dual variable corresponding to the vertex and that changes much less frequently than the dual variable, and implicity maintaining the dual variable using the weight. Second, reducing the computation of the minimum slack for certain subsets of edges to geometric query problems that involve the weights associated with the vertices and that can be efficiently solved using known data structures in computational geometry.

In § 2 we shall discuss some geometric query problems that arise naturally in the implementation of the primal-dual weighted matching algorithm for points on the plane, and see how known data structures in computational geometry can be used to solve them efficiently. In § 3 we shall give the algorithm for the bipartite version of the MWCM problem for points in the plane. The bipartite case is easier, and serves to illustrate the main ideas that are used in developing the algorithm for the general case. In § 4 we describe the algorithm for finding an MWCM in the complete graph induced by a set of points on the plane.

We shall assume a real RAM model of computation [15] standard in computational geometry, so arithmetic operations (i.e., addition, subtraction, multiplication, division), memory access operations, and comparison operations, on real numbers require constant time. (Actually, it is not necessary to assume that division requires constant time; the restricted assumption that division by two takes constant time is adequate.) For the case of the L_2 metric, we must make the additional assumption that either square roots can be computed in constant time (so that edge weights can be obtained in constant time) or that the edge weights have been precomputed and are available at the start of the algorithm.

Next, we introduce some notation and definitions.

A *priority queue* [1] is an abstract data structure consisting of a collection of elements, each element being associated with a real-valued *priority*. A priority queue supports the three operations—insert an element with some priority, delete an element, and find an element with the minimum priority—in time proportional to the logarithm of the number of elements in the priority queue.

We let $d(p, q)$ denote the distance between points p and q. (The metric under consideration will be clear from the context.) Let $H_x(a, b)$ denote the set of all points p on the plane such that $a \leqq p_x \leqq b$. Similarly, let $H_y(a, b)$ denote the set of all points p on the plane such that $a \leqq p_y \leqq b$. For a pair of real numbers a and b, $[a, b)$ denotes the set of all real numbers c such that $a \leqq c < b$. With respect to an ordered sequence $a_1 < a_2 < \cdots < a_m$, $[a_i, a_j)$ denotes the set of all a_k such that $i \leqq k < j$.

With respect to a set of points P such that there is a weight $w(p)$ associated with each point p in P, we define the following terms. For subsets P_1, P_2 of P, *shortest*$[P_1, P_2]$ denotes an edge (p_1^*, p_2^*), $p_1^* \in P_1$, $p_2^* \in P_2$, such that

$$d(p_1^*, p_2^*) - w(p_1^*) - w(p_2^*) = \min_{p_1 \in P_1,\, p_2 \in P_2} \{d(p_1, p_2) - w(p_1) - w(p_2)\}.$$

For a point q, *nearest*$[q, P]$ denotes a point $p^* \in P$ such that

$$d(q, p^*) - w(p^*) = \min_{p \in P} \{d(q, p) - w(p)\},$$

and *shortest*$[q, P]$ denotes the edge $(q,$ *nearest*$[q, P])$.

Finally, we shall use the term *vertex* when referring to a graph, and the term *node* when referring to a data structure.

2. Geometric query problems arising in matching on the plane. The primal-dual algorithms for weighted matching associate a dual variable with each vertex of the given graph, and the slack associated with an edge is the weight of the edge minus the sum of the dual variables associated with the end vertices of the edge. During the execution of the matching algorithm, we are repeatedly required to compute the minimum slack for certain subsets of edges. To perform this computation efficiently we shall need a good solution to the following query problems.

PROBLEM 1. Given a set of points P and a weight $w(p)$ for each point p in P, preprocess P so that for a given query point q, *nearest*$[q, [p_i, p_j)]$ can be found quickly.

PROBLEM 2. Given a set of points P, an ordering $p_1 < p_2 < \cdots < p_{|P|}$ of the points in P, and a weight $w(p)$ associated with each point p in P, preprocess P, so that given a query point q, and an interval $[p_i, p_j)$ such that $1 \leqq i < j \leqq |P| + 1$, *nearest*$[q, [p_i, p_j)]$ can be computed quickly.

In Problems 1 and 2 the set P is static. We shall also require a solution to the *semidynamic* version of Problems 1 and 2. In the semidynamic version, a new point can be added to P but a point can never be deleted from P. Furthermore, P is totally ordered by the following rule. For a pair of points $p, p' \in P$, $p < p'$ if and only if p was added to P before p'.

Problem 1 comes up in the bipartite case as well as the general case, and its solution enables us to quickly compute the minimum slack for various subsets of edges. Problem 2 and the semidynamic versions of the two problems arise because of certain subsets of vertices of odd cardinality, called blossoms, in Edmond's algorithm for general weighted matching. One type of blossom corresponds to intervals in some ordering on the set of vertices (points), and given a vertex q and a blossom B of this type, we are required to compute the minimum slack over all edges between q and vertices in B. This leads to Problem 2. The semidynamic versions arise because of blossoms merging to form bigger blossoms.

In §§ 2.1 and 2.2 we describe solutions to Problems 1 and 2, respectively. In § 2.3 we shall describe how to suitably modify the data structures for Problems 1 and 2 to handle the semidynamic case where new points may be inserted into P but no point

may be deleted from P. The solutions use segment trees [15], a data structure common in computational geometry. So we shall first briefly discuss segment trees. The segment tree for the interval $[i, j)$ is a rooted binary tree defined as follows:

(1) $j > i+1$. The interval $[i, j)$ is associated with the root of the segment tree. The left subtree at the root is the segment tree for $[i, \lceil (i+j)/2 \rceil)$ and the right subtree at the root is the segment tree for $[\lceil (i+j)/2 \rceil, j)$.

(2) $j = i+1$. With the root is associated the interval $[i, i+1)$, and the left and right subtrees are both empty.

(3) $j \leqq i$. The segment tree is empty.

The segment tree has $O(\log(|j-i|))$ levels, and the disjoint union of all the intervals at a specific level in the tree is the interval $[i, j)$. Any subinterval of $[i, j)$ with integer endpoints can be expressed as the disjoint union of $O(\log(|j-i|))$ intervals in the segment tree. The segment tree data structure extends naturally to an ordered sequence $a_1 < a_2 < \cdots < a_m$ via the correspondence between the interval $[i, j)$ and the interval $[a_i, a_j)$.

2.1. Problem 1. For the case of the Euclidean (L_2) metric the weighted Voronoi diagram (WVD) [5], [16] of the points in P provides an adequate solution to Problem 1. Such a Voronoi diagram divides the plane into $|P|$ regions (some possibly empty), there being a region $Vor(p)$ for each point $p \in P$. $Vor(p)$ is the region given by

$$Vor(p) = \{p'': \forall p' \in P,\ d(p'', p) - w(p) \leqq d(p'', p') - w(p')\}.$$

The WVD of P can be constructed in $O(|P| \log(|P|))$ time [5]. Furthermore, in $O(|P| \log(|P|))$ additional time it can be preprocessed, so that given a query point q, in $O(\log(|P|))$ time we can find a point $\bar{p}$ in P such that $q \in Vor(\bar{p})$ [3], [12]. So once the WVD of P is available, $nearest[q, P]$ can be obtained in $O(\log(|P|))$ time for any point q.

For the case of the L_1 metric we shall use the Willard–Lueker modification of the two-dimensional range tree [15] to provide a suitable solution to Problem 1. The range tree (RT) for P is as follows. At the top level is a segment tree for the nondecreasing sequence of x-coordinates of the points in P. At a segment tree node ψ associated with the interval $[a, b)$ of the x-axis is stored an ordered list of points in $P \cap H_x(a, b)$, with the points being ordered by y-coordinate. The segment tree also contains extra pointers from each internal node to its two children for efficient searching. The entire RT for P can be constructed in $O(|P| \log(|P|))$ time. To facilitate the search for $nearest[q, P]$ we shall store some additional information at each node. Let ψ be a node in the top level segment tree, and let $[a, b)$ be the interval associated with ψ. Let $p \in H_x(a, b) \cap P$. In addition to storing p in the ordered list at ψ, we store along with p the following points:

(1) $nearest[(a, p_y), P \cap H_x(a, b) \cap H_y(p_y, \infty)]$.

(2) $nearest[(a, p_y), P \cap H_x(a, b) \cap H_y(-\infty, p_y)]$.

(3) $nearest[(b, p_y), P \cap H_x(a, b) \cap H_y(p_y, \infty)]$.

(4) $nearest[(b, p_y), P \cap H_x(a, b) \cap H_y(-\infty, p_y)]$.

For a vertical strip $H_x(a, b)$ these additional points may be computed in $O(|P \cap H_x(a, b)|)$ time leading to a total of $O(|P| \log(|P|))$ for all the nodes in the tree. Suppose p, p' are adjacent points in the ordered list of points in $P \cap H_x(a, b)$ stored at node ψ. Also suppose that the query point q is such that $p_y \geqq q_y \geqq p'_y$. Then q satisfies the following two conditions:

(1) If $q_x \leqq a$ then one of the two points $nearest[(a, p_y), P \cap H_x(a, b) \cap H_y(p_y, \infty)]$, and $nearest[(a, p'_y), P \cap H_x(a, b) \cap H_y(-\infty, p'_y)]$, is $nearest[q, P \cap H_x(a, b)]$.

(2) If $q_x \geqq b$ then one of the two points *nearest*$[(b, p_y), P \cap H_x(a, b) \cap H_y(p_y, \infty)]$, and *nearest*$[(b, p'_y), P \cap H_x(a, b) \cap H_y(-\infty, p'_y)]$ is *nearest*$[q, P \cap H_x(a, b)]$.
So given a query point q, we visit the $O(\log(|P|))$ nodes in the segment tree corresponding to the decomposition of the two segments $[-\infty, q_x)$, and $[q_x, \infty)$, locate q in the ordered lists at these nodes, and compute *nearest*$[q, P]$ in $O(\log(|P|))$ time.

LEMMA 1. *Given a set of points P on the plane, and a weight $w(p)$ associated with each point p in P, P can be preprocessed in $O(|P| \log(|P|))$ time, so that given a query point q, nearest$[q, P]$ and shortest$[q, P]$ can be found in $O(\log(|P|))$ time.* □

2.2. Problem 2. The data structure for Problem 2 has two levels. At the top level is a segment tree for the ordered sequence $p_1 < p_2 < \cdots < p_{|P|}$ of the points in P. At a segment tree node associated with the interval $[p_k, p_l)$ is stored the WVD for the set $[p_k, p_l)$ in the case of L_2 metric, and the RT for the set $[p_k, p_l)$ in the case of L_1 metric. Given an interval $[p_i, p_j)$, we visit the $O(\log(|P|))$ nodes in the segment tree corresponding to the decomposition of $[p_i, p_j)$, and search the WVD/RT at each of these nodes, and thereby compute *nearest*$[q, [p_i, p_j)]$ in $O((\log(|P|))^2)$ time. The data structure may be easily constructed in $O(|P|(\log(|P|))^2)$ time.

LEMMA 2. *Let $P = \{p_1 < p_2 < \cdots < p_{|P|}\}$ be an ordered set of points on the plane, and let there be a weight $w(p)$ associated with each point p in P. P can be preprocessed in $O(|P|(\log(|P|))^2)$ time, so that given a query point q and an interval $[p_i, p_j)$ such that $1 \leqq i < j \leqq |P|+1$, nearest$[q, [p_i, p_j)]$ and shortest$[q, [p_i, p_j)]$ can be found in $O((\log(|P|))^2)$ time.* □

2.3. Dynamizing the data structures for insertion. In this section we shall describe how to dynamize the data structures for Problems 1 and 2 (described in §§ 2.1 and 2.2, respectively) to handle the semidynamic case where new points may be inserted into P, but no points may be deleted from P. P is totally ordered by the following rule. For a pair of points p, p' in P, $p < p'$ if and only if p was added to P before p'.

There are standard techniques [13] for dynamizing a static data structure to support insertion, and we shall briefly describe how to apply one of them to the weighted Voronoi diagram and the range tree.

Let

$$|P| = \sum_{0 \leqq i \leqq \log_2(|P|)} a_i 2^i, \qquad a_i \in \{0, 1\},$$

be the binary representation of $|P|$. Let $P_1, P_2, \cdots$ be a partition of P such that:

(1) $|P_i| = a_i 2^i$, $0 \leqq i \leqq \log_2(|P|)$.

(2) If $i > j$ then each point in P_i was inserted into P before any of the points in P_j.

The *semidynamic* WVD (RT) is just a collection of WVDs (RTs), one for each nonempty P_i in the partition of P. Using the semidyanmic WVD (RT), given a query point q, *nearest*$[q, P]$ may be obtained $O((\log(|P|))^2)$ time. Furthermore, if we start with $P = \phi$ and there are a total of m insertions into P, then the total cost of maintaining the semidynamic WVD (RT) for P is $O(m(\log m)^2)$ operations [13].

The static data structure for Problem 2 described in § 2.2 may be dynamized to allow insertions into P in a similar manner. The dynamization increases the query time and the total time for all the insertions by a factor of at most $2 \log_2(|P|)$ [13].

LEMMA 3. *Let P be a set of points such that new points may be added to P, but no point may be deleted from P. With each point $p \in P$ is associated a weight $w(p)$. Suppose in the beginning $P = \phi$, and in the end P contains m points.*

(1) *We can maintain a semidynamic* WVD/RT *for P such that:*
  (1.1) *The total time for all the m insertions and thereby the total time for maintaining for the semidynamic* WVD/RT *is* $O(m(\log m)^2)$.
  (1.2) *Given a query point q, nearest*$[q, P]$ (*and shortest*$[q, P]$) *can be found in* $O((\log m)^2)$ *time.*

(2) *Suppose P is totally ordered by the following rule. For a pair of points p, p' in P,* $p < p'$ *if and only if p was added to P before p'. Also, let* $p_1 < p_2 < \cdots < p_{|P|}$ *be the ordered sequence of the points in P. Then we can maintain a semidynamic data structure for P such that:*
  (2.1) *The total time for inserting all the m points and thereby the total time for maintaining the semidynamic data structure is* $O(m(\log m)^3)$.
  (2.2) *Given a query point q, and an interval* $[p_i, p_j)$ *such that* $1 \leqq i < j \leqq |P|+1$, *nearest*$[q, [p_i, p_j)]$ (*and shortest*$[q, [p_i, p_j)]$) *can be found in* $O((\log m)^3)$ *time.* □

3. Weighted bipartite matching on the plane. We are given two sets U and V each consisting of n points on the plane. U and V induce a complete bipartite graph whose vertices are the points in U and V, and the weight of an edge (u_i, v_j), $u_i \in U$, $v_j \in V$, is the distance between u_i and v_j under some metric. We consider two metrics, the L_1 metric and the L_2 metric. The problem is to find a minimum weight complete matching in the complete bipartite graph on U and V.

Let $u_1, \cdots, u_n$ be an enumeration of the vertices in U, and let $v_1, \cdots, v_n$ be an enumeration of the vertices in V. A linear programming formulation [11] of the above bipartite weighted matching problem is:

$$\min \sum_{i,j} d(u_i, v_j) x_{ij}$$

$$\text{subject to} \quad \sum_j x_{ij} = 1, \qquad i = 1, \cdots, n,$$

$$\sum_i x_{ij} = 1, \qquad j = 1, \cdots, n,$$

$$x_{ij} \geqq 0$$

with the understanding that (u_i, v_j) is in the matching X if and only if $x_{ij} = 1$. The dual linear program is

$$\max \sum_i \alpha_i + \sum_j \beta_j$$

$$\text{subject to} \quad \alpha_i + \beta_j \leqq d(u_i, v_j), \qquad 1 \leqq i \leqq n, \quad 1 \leqq j \leqq n,$$

$$\alpha_i, \beta_j, \quad \text{unconstrained}$$

α_i and β_j are the dual variables associated with u_i and v_j, respectively. Orthogonality conditions that are necessary and sufficient for optimality of primal and dual solutions are:

$$x_{ij} > 0 \Rightarrow \alpha_i + \beta_j = d(u_i, v_j) \tag{3.1}$$

$$\alpha_i \neq 0 \Rightarrow \sum_j x_{ij} = 1, \qquad i = 1, \cdots, n, \tag{3.2}$$

$$\beta_j \neq 0 \Rightarrow \sum_i x_{ij} = 1, \qquad j = 1, \cdots, n. \tag{3.3}$$

We will use the version of the Hungarian method [10] for weighted bipartite matching given in [11]. The Hungarian method maintains dual feasibility at all times, and in addition maintains satisfaction of all orthogonality conditions except (3.3). Initially, we start with the empty matching $X = \phi$, and a feasible dual solution $\beta_j = \min_i \{d(u_i, v_j)\}$, $\alpha_i = 0$. The method proceeds in phases, and during each phase the matching X is augmented by an edge. Thus during each phase the number of violations of (3.3) is decreased by one.

During each phase we focus on those edges (u_i, v_j) such that $\alpha_i + \beta_j = d(u_i, v_j)$. These are the *admissible* edges. The *exposed* vertices are those that are not matched by the current matching X. An alternating path is one that alternately traverses an edge in the matching X, and an edge not in the matching X. An augmenting path is one that is between two exposed vertices. A phase consists of searching for an augmenting path among the admissible edges.

For each exposed vertex in V, we grow an alternating tree rooted at the vertex. Each vertex in $U \cup V$ that is in an alternating tree is reachable from the root of the tree via an alternating path that uses only admissible edges. Each vertex in an alternating tree is *labelled*, and each vertex that is not in any of the alternating trees is *free*. The root of an alternating tree is given an s-label of the form $[s, root]$. A matched vertex $v_j \in V$ in an alternating tree is given an s-label of the form $[s, u_k]$ where u_k is the vertex to which v_j is matched. A vertex $u_i \in U$ in an alternating tree is given a t-label of the form $[t, v_j]$, where v_j is the vertex from which u_i was labelled. An s-vertex (t-vertex) is a vertex with an s-label (t-label). Furthermore, an s-vertex (t-vertex) is reachable from an exposed vertex in V by an even (odd) length alternating path that uses only admissible edges.

Let $S(T)$ denote the set of all the s-vertices (t-vertices), and let F denote the set of all the free vertices in U. (Thus $F = U - T$.) Initially all the vertices are free, and to start with each exposed vertex in V is given an s-label. Thus at the beginning of a phase, S consists of the exposed vertices in V and $F = U$. Let δ be defined as

$$\delta = \min_{u_i \in F, v_j \in S} \{d(u_i, v_j) - \alpha_i - \beta_j\}.$$

We use a variable Δ to keep track of the sum of dual changes δ, and associate a weight $w(v)(w(u))$ with each vertex v in V (u in U). The weights are used to implement a phase efficiently. At the beginning of a phase $\Delta = 0$; for each $u_i \in U$, $w(u_i) = \alpha_i$; and for each $v_j \in V$, $w(v_j) = \beta_j$. Depending on whether δ equals zero or exceeds zero, the alternating trees are grown or there is a dual variable change.

Case 1. $\delta = 0$ (add to alternating trees or augment). Let (u_i, v_j), $u_i \in F$, $v_j \in S$ be an admissible edge, i.e., $d(u_i, v_j) - \alpha_i - \beta_j = 0$.

If u_i is exposed, then we have discovered an augmenting path among the admissible edges, and we can construct such a path by backtracking from v_j to the root of the alternating tree containing v_j using the labels on the vertices in the tree.

If u_i is matched to v_k, then give u_i the t-label $[t, v_j]$, and give v_k the s-label $[s, u_i]$,

$$F := F - \{u_i\}, \quad T := T \cup \{u_i\}, \quad S := S \cup \{v_k\},$$

$$w(u_i) := \alpha_i + \Delta, \qquad w(v_k) := \beta_k - \Delta. \qquad \square$$

Case 2. $\delta > 0$ (dual variable change). $\Delta := \Delta + \delta$;

For each vertex $u_i \in T$, $\alpha_i := \alpha_i - \delta$;
For each vertex $v_j \in S$, $\beta_j := \beta_j + \delta$. □

We note that for each s-vertex v_j, β_j equals $w(v_j)+\Delta$, and for each t-vertex u_i, α_i equals $w(u_i)-\Delta$. So during a phase, it suffices to maintain Δ and the weights associated with all the vertices, and there is no need to explicitly update the dual variables α_i, β_j, every time δ exceeds zero. At the end of a phase the correct values of the dual variables may be computed using Δ and the weights. A useful property of the weights is that the weight of a vertex changes only when it is labelled, and once it has been labelled its weight does not change during the remainder of the phase. Thus we may write

$$\delta = \min_{u \in F, v \in S} \{d(u, v) - w(u) - w(v)\} - \Delta.$$

We will use the data structures used in the solution of Problem 1 in § 2, namely, the weighted Voronoi diagram (WVD) and the range tree (RT), to efficiently compute δ, and an edge (u, v), $u \in F$, $v \in S$, such that $d(u, v) - w(u) - w(v) = \delta + \Delta$. Throughout a phase, S is partitioned into S_1 and S_2 such that $|S_2| \leqq \sqrt{n}$. Also, F is partitioned into $F_1, F_2, \cdots, F_{\lceil n^{0.5} \rceil}$, (some of the F_i's possibly empty) such that $|F_i| \leqq \lceil n^{0.5} \rceil$, $1 \leqq i \leqq \lceil n^{0.5} \rceil$. We maintain following data structures:

(1) A priority queue containing the edge *shortest*$[u, S_1]$ for each $u \in F$. The priority of an edge (u, v) in this queue is $d(u, v) - w(u) - w(v)$.

(2) A priority queue containing the edges *shortest*$[v, F_i]$, $1 \leqq i \leqq \lceil n^{0.5} \rceil$, for each vertex v in S_2. The priority of an edge (u, v) in this queue is also $d(u, v) - w(u) - w(v)$.

(3) The WVD/RT for each of the sets $F_1, F_2, \cdots, F_{\lceil n^{0.5} \rceil}$.

δ and an edge for which δ is achieved can be obtained in $O(\log n)$ time by examining an edge with minimum priority in (1) and (2) above. A new vertex added to S always gets inserted into S_2. In order to maintain the condition that $|S_2| \leqq \sqrt{n}$, whenever the size of S_2 reaches the threshold of $\sqrt{n}$ we add all the vertices in S_2 to S_1 and reset S_2 to the null set. Then *shortest*$[u, S_1]$ must be recomputed for every $u \in F$. From Lemma 1 in § 2, this recomputation may be done in $O(n \log n)$ time using a WVD/RT for S_1, leading to total of $O(n^{1.5} \log n)$ operations for the recomputation for the entire phase. Next we shall see that an insertion into S_2, and a deletion from F, each cost $O(n^{0.5} \log n)$ operations. As there are $O(n)$ such insertions and deletions in a phase, this leads to a total of $O(n^{1.5} \log n)$ operations per phase.

(i) Suppose a vertex v is inserted into S_2. Then we must compute *shortest*$[v, F_i]$, and insert it into the priority queue in (2) above, for $i = 1, \cdots, \lceil n^{0.5} \rceil$. Using the maintained WVD/RT for F_i, *shortest*$[v, F_i]$ can be found in $O(\log n)$ time. Hence an insertion costs $O(n^{0.5} \log n)$ operations.

(ii) Suppose a vertex u is deleted from F, and suppose $u \in F_i$. Then recomputing the WVD/RT for F_i requires $O(n^{0.5} \log n)$ time, and recomputing *shortest*$[v, F_i]$ for all the vertices v in S_2 and maintaining the priority queue also requires $O(n^{0.5} \log n)$ time. Thus a deletion costs $O(n^{0.5} \log n)$ operations.

Finally, since a phase takes $O(n^{1.5} \log n)$ time, and as there are at most n phases, the total running time of the weighted bipartite matching algorithm for points in the plane is $O(n^{2.5} \log n)$. In § 3.1 we shall see how to further improve the running time of the bipartite matching algorithm to $O(n^2(\log n)^3)$ for the case of L_1 metric.

3.1. Improving the complexity for the L_1 metric. In this section we shall show that for the case of the L_1 metric, the running time of the weighted bipartite matching algorithm for points on the plane can be further improved to $O(n^2(\log n)^3)$. Since we shall be dealing with the L_1 metric only in this section, $d(p, q)$ will denote the L_1

distance between p and q throughout this section. Note that maintaining the dual variables can be accomplished in $O(n)$ time per phase. To efficiently compute δ, we shall maintain a data structure containing all the points in $F \cup S$ such that:

(1) *shortest*(F, S) can be obtained in $O(1)$ time.

(2) A point in S can be inserted (or deleted) in $O((\log n)^3)$ time, and a point in F can be deleted (or inserted) in $O((\log n)^3)$ time.

Suppose that *shortest*$(F, S) = (u, v)$. Depending on whether $d(u, v) - w(u) - w(v) - \Delta$ equals or exceeds zero there is a dual variable change, and then (u, v) becomes admissible. If u is exposed then there is an augmentation and the phase ends. Otherwise, both u and the vertex to which u is matched get labelled and enter an alternating tree. u is deleted from F and the vertex to which u is matched is inserted into S. Correspondingly, there is a deletion from and an insertion into the above-mentioned data structure. Thus, using the above data structure it takes $O((\log n)^3)$ operations to increase the number of labelled vertices by 2, thereby leading to $O(n(\log n)^3)$ operations per phase. This leads to a running time of $O(n^2(\log n)^3)$ for the L_1 case.

Next, we describe a data structure for maintaining *shortest*$[F', S']$ for the special case when F' and S' are separated by a vertical line. Then using the data structure for this special case we shall show how to implement the above-mentioned data structure for maintaining *shortest*$[F, S]$. Let U' and V' be fixed subsets of U and V, respectively, such that all the points in U' lie on one side of the vertical line $x = a$, and all the points in V' line on the other side of the line $x = a$. (Points in U' and V' could lie on the line $x = a$.) Let $F' = F \cap U'$, and let $S' = S \cap V'$. Let $m = |U' \cup V'|$. Let $b_1 \leqq b_2 \leqq \cdots \leqq b_m$ be the nondecreasing sequence of the y-coordinates of the points in $U' \cup V'$. The data structure consists of a segment tree for this sequence of y-coordinates together with extra information stored at each node in the segment tree. Consider a node ψ in the segment tree associated with the interval $[b_i, b_j)$ of the y-axis. Let $k = \lceil (i+j)/2 \rceil$. At node ψ we store the following:

(i) Four priority queues, one for each of the four sets $F' \cap H_y(b_i, b_k)$, $F' \cap H_y(b_k, b_j)$, $S' \cap H_y(b_i, b_k)$, and $S' \cap H_y(b_k, b_j)$. The priority of a point p in any of the four queues is given by $d(p, (a, b_k)) - w(p)$.

(ii) The edge *shortest*$[F' \cap H_y(b_i, b_j), S' \cap H_y(b_i, b_j)]$.

Next, we shall see that once the two edges *shortest*$[F' \cap H_y(b_i, b_k), S' \cap H_y(b_i, b_k)]$ and *shortest*$[F' \cap H_y(b_k, b_j), S' \cap H_y(b_k, b_j)]$ are available, using the priority queues stored at node ψ, *shortest*$[F' \cap H_y(b_i, b_j), S' \cap H_y(b_i, b_j)]$ may be computed in $O(\log m)$ time. This is seen as follows. First, note that for a pair of points u and v, $u \in F' \cap H_y(b_i, b_k)$, and $v \in S' \cap H_y(b_k, b_j)$,

$$d(u, v) = d(u, (a, b_k)) + d(v, (a, b_k)),$$

and hence

$$d(u, v) - w(u) - w(v) = d(u, (a, b_k)) - w(u) + d(v, (a, b_k)) - w(v).$$

Thus

$$\min_{u \in F' \cap H_y(b_i, b_k),\, v \in S' \cap H_y(b_k, b_j)} \{d(u, v) - w(u) - w(v)\}$$

$$= \min_{u \in F' \cap H_y(b_i, b_k)} \{d(u, (a, b_k)) - w(u)\} + \min_{v \in S' \cap H_y(b_k, b_j)} \{d(v, (a, b_k)) - w(v)\}.$$

The same relationship holds for $u \in F' \cap H_y(b_k, b_j)$ and $v \in S' \cap H_y(b_i, b_k)$. Thus

shortest$[F' \cap H_y(b_i, b_k),\ S' \cap H_y(b_k, b_j)]$ and *shortest*$[F' \cap H_y(b_k, b_j),\ S' \cap H_y(b_i, b_k)]$ may be computed by examining the four points with minimum priority in the four priority queues described in (i) above. This requires $O(\log m)$ time. And once, *shortest*$[F' \cap H_y(b_i, b_k),\ S' \cap H_y(b_i, b_k)]$, *shortest*$[F' \cap H_y(b_k, b_j),\ S' \cap H_y(b_k, b_j)]$, *shortest*$[F' \cap H_y(b_i, b_k),\ S' \cap H_y(b_k, b_j)]$, and *shortest*$[F' \cap H_y(b_k, b_j),\ S' \cap H_y(b_i, b_k)]$, are available, *shortest*$[F' \cap H_y(b_i, b_j),\ S' \cap H_y(b_i, b_j)]$ is computable in constant time.

We now show that a point may be inserted into or deleted from the data structure for maintaining *shortest*$[F', S']$ in $O((\log m)^2)$ time. When a point p is added to S' (or F'), it is inserted into the priority queues at the nodes in the segment tree that lie on the path from the root to the leaf corresponding to the point p. So there are $O(\log m)$ insertions, each costing $O(\log m)$ operations. We then start from the leaf corresponding to the inserted point p and work our way up toward the root, updating in sequence the edge (as specified by (ii) above) that is stored at each of the $O(\log m)$ nodes on the path from the leaf to the root. Let ψ be a node on this path. Once the updates at nodes on the subpath from the leaf to ψ have been performed, the update at node ψ may be performed in $O(\log m)$ time using the priority queues stored at ψ. Thus, whenever there is an insertion, *shortest*$[F', S']$ is updated in $O((\log m)^2)$ operations. The same bound holds when a point is deleted from F' (or S').

The data structure for maintaining *shortest*$[F, S]$ is a two level data structure. At the top level is a segment tree for the nondecreasing sequence $a_1 \leqq a_2 \leqq \cdots \leqq a_{2n}$ of the x-coordinates of the points in $U \cup V$, and at each node is a data structure for the special case mentioned above. Specifically, let ψ be a node in the top level segment tree and let $[a_i, a_j)$ be the interval of the x-axis associated with ψ. Let $k = \lceil (i+j)/2 \rceil$. At node ψ we store the following:

(I). A data structure as described above for maintaining each of the two edges *shortest*$[F \cap H_x(a_i, a_k),\ S \cap H_x(a_k, a_j)]$ and *shortest*$[F \cap H_x(a_k, a_j),\ S \cap H_x(a_i, a_k)]$. This is the secondary data structure stored at ψ.

(II). The edge *shortest*$[F \cap H_x(a_i, a_j),\ S \cap H_x(a_i, a_j)]$.

We note that the edge stored at the root (as specified by (II) above) is *shortest*$[F, S]$. When a point is inserted, we start at the leaf in the top level segment tree corresponding to the inserted point, and perform updates in sequence at the nodes on the path from this leaf to the root. Suppose ψ is a node on this path. Once the updates at nodes on the subpath from the leaf to ψ have been performed, the edges *shortest*$[F \cap H_x(a_i, a_k),\ S \cap H_x(a_i, a_k)]$ and *shortest*$[F \cap H_x(a_k, a_j),\ S \cap H_x(a_k, a_j)]$, are available. The updates in the secondary data structure at ψ are performed in $O((\log n)^2)$ time, and then *shortest*$[F \cap H_x(a_i, a_k),\ S \cap H_x(a_k, a_j)]$, and *shortest*$[F \cap H_x(a_k, a_j),\ S \cap H_x(a_i, a_k)]$, are also available. Then *shortest*$[F \cap H_x(a_i, a_j),\ S \cap H_x(a_i, a_j)]$ is computable in constant time. Since there are $O(\log n)$ nodes on the path from a leaf in the top level segment tree to the root, the total cost of an insertion is $O((\log n)^3)$ operations. The same bound holds for deleting a point.

4. Weighted general matching on points in the plane. We are given a set V of $2n$ points in the plane. The set of points V induces a complete graph whose vertices are the points in V, and the weight of an edge between two points is the distance between the points under some metric. We shall consider two cases, one where the weight of an edge is given by the Euclidean (L_2) distance between the two endpoints of the edge, and the other where the weight of an edge is given by the L_1 distance between the endpoints of the edge. We let $v_1, v_2, \cdots, v_{2n}$ denote the $2n$ vertices (points) in V. Let O denote the set of all those subsets of V having cardinality that is odd and greater than one.

The MWCM problem in the complete graph on V is formulated as a linear program [4], [11], [14]:

$$\min \sum_{1 \leqq i < j \leqq 2n} d(v_i, v_j) x_{ij},$$

$$\text{subject to} \quad \sum_{1 \leqq j \leqq 2n, j \neq i} x_{ij} = 1, \qquad i = 1, \cdots, 2n$$

$$\forall B \in O, \quad \sum_{v_i, v_j \in B} x_{ij} \leqq \frac{|B| - 1}{2},$$

$$x_{ij} \geqq 0, \qquad 1 \leqq i < j \leqq 2n$$

with the understanding that $x_{ij} = 1$ if and only if (v_i, v_j) is in the matching X.

The dual linear program is given by

$$\max \sum_{i=1}^{2n} \alpha_i + \sum_{B \in O} z(B)$$

$$\text{subject to} \quad \alpha_i + \alpha_j + \sum_{v_i, v_j \in B, B \in O} z(B) \leqq d(v_i, v_j), \qquad 1 \leqq i < j \leqq 2n$$

$$\forall B \in O, \quad z(B) \leqq 0.$$

α_i is the dual variable associated with vertex v_i, and $z(B)$ is the dual variable associated with the odd set B. Orthogonality conditions that are necessary and sufficient for optimality of primal and dual solutions are:

$$x_{ij} > 0 \Rightarrow \alpha_i + \alpha_j + \sum_{v_i, v_j \in B, B \in O} z(B) = d(v_i, v_j), \tag{4.1}$$

$$\alpha_i \neq 0 \Rightarrow \sum_{1 \leqq j \leqq 2n, j \neq i} x_{ij} = 1, \tag{4.2}$$

$$z(B) < 0 \Rightarrow \sum_{v_i, v_j \in B} x_{ij} = \frac{|B| - 1}{2}. \tag{4.3}$$

Edmond's algorithm [4], [11], [14] for finding a minimum weight complete matching maintains dual feasibility at all times, and in addition maintains the satisfaction of all orthogonality conditions, except conditions (4.2). The algorithm starts with the empty matching $X = \phi$, and a feasible dual solution given by $\alpha_i = \frac{1}{2} \min_{v_j \in V - \{v_i\}} d(v_i, v_j)$, $i = 1, \cdots, 2n$, and $z(B) = 0$, for all $B \in O$. The algorithm proceeds in phases. During each phase the cardinality of the matching X increases by one thereby decreasing the number of violations of (4.2) by one.

An $O(nm \log n)$ implementation of Edmond's algorithm for finding a minimum weight complete matching in a graph with n vertices and m edges is given in [8]. We shall utilize the underlying geometry together with some of the ideas in [8] to obtain an $O(n^{2.5}(\log n)^4)$ algorithm for finding an MWCM on $2n$ points on the plane. First, we shall sketch Edmond's algorithm, and then show how to efficiently implement it for points in the plane.

4.1. Blossoms and their representation. As the algorithm proceeds, it discovers certain subsets of V (of odd size) called *blossoms*. It is convenient to consider the vertices of V as (trivial) blossoms of size one. For a pair of blossoms B, B', either $B \cap B' = \phi$, $B \subseteq B'$, or $B' \subseteq B$, and a blossom that is not a subset of any other blossom is a *maximal* blossom. The algorithm has $z(B) < 0$ only for those $B \in O$ that are nontrivial blossoms. Consequently, the number of nonzero $z(B)$'s is $O(n)$.

The discussion below about blossoms follows [8]. The representation that we use for blossoms is identical to the one in [8] but we shall describe it here for completeness.

An edge (v_i, v_j) is *admissible* if and only if

$$\alpha_i + \alpha_j + \sum_{v_i, v_j \in B, B \in O} z(B) = d(v_i, v_j).$$

An *alternating path* from v_0 to v_r is a sequence of edges $\{e_i = (v_{i-1}, v_i)\}_{i=1}^{r}$ such that for $i = 1, \cdots, r-1$, $e_i \in X$ if and only if $e_{i+1} \notin X$. An *alternating path* from a maximal blossom B_0 to a maximal blossom B_r (possibly $B_0 = B_r$) is a sequence of edges $\{e_i = (u_{i-1}, v_i)\}_{i=1}^{r}$ such that for $i = 0, \cdots, r$, $u_i, v_i \in B_i$, where $B_0, \cdots, B_r$ are distinct maximal blossoms, and for $i = 1, \cdots, r-1$, $e_i \in X$ if and only if $e_{i+1} \notin X$. When the algorithm discovers an odd length alternating path, that uses only admissible edges, from a maximal blossom B_0 to itself (i.e., $B_0 = B_r$, $e_1, e_r \notin X$), a new blossom B is formed. $B_1, \cdots, B_r$ are the subblossoms of the new blossom B. (Note: A blossom that is a proper subset of B_i, for some i, $1 \leqq i \leqq r$, is not a subblossom of B.) Each blossom has a *base* vertex. The base of a trivial blossom is the unique vertex in it. The base of the blossom B defined above is the base of B_0 $(= B_r)$.

A nontrivial blossom B is represented by the cyclic double-linked list $\{(B_i, e_i)\}_{i=1}^{r}$, and by its base. (From an entry (B_i, e_i) in the list there are bidirectional links to (B_l, e_l) where $l = (i \bmod r) + 1$.) B_i, $i = 1, \cdots, r$ are the subblossoms of B, and B_r is the distinguished subblossom that contains the base of B. For each i, $1 \leqq i \leqq r-1$, $(e_1, e_2, \cdots, e_i)$ and $(e_r, e_{r-1}, \cdots, e_{i+1})$ are alternating paths that use admissible edges only from B_r to B_i. The one of even length is the one whose last edge is in X.

A blossom B of size $2k+1$ has the following two properties. First, there are exactly k matched edges (i.e., edges in X) both of whose endpoints are in B, and the base of B is that vertex in B not an endpoint of one of these k edges. Second, there is an even length alternating path, which uses only admissible edges, from the base of B to every vertex in B. As a consequence an alternating path, which uses admissible edges only, from a maximal blossom B to a maximal blossom B' can be expanded into an alternating path, which uses admissible edges only, from the base of B to the base of B'.

The structure of a maximal blossom B can be represented by a tree. In this tree the sons of a blossom B are its subblossoms $B_1, \cdots, B_r$, and the leaves are the vertices of B. This tree will be denoted as the *structure tree* of B. The structure tree of B is implicitly represented by the cyclic double-linked lists $\{(B_i, e_i)\}_{i=1}^{r}$ corresponding to B, its subblossoms, the subblossoms of its subblossoms, and so on. The tree implies a total order on the vertices in B: $v_i < v_j$ if and only if v_i is to the left of v_j in the tree. The base of B is largest vertex in this ordering. Furthermore, a blossom B' that is a subset of B corresponds to an interval in this ordering. Also note that the base of a blossom changes only when the matching X is augmented, and so during a phase of the algorithm the ordering of the vertices in an existing blossom does not change.

During the course of the matching algorithm, given a vertex v_j we shall need to know the identity of the maximal blossom containing v_j. To be able to obtain this identity efficiently, we also represent the maximal blossoms as ordered sets of vertices. These ordered sets are implemented as *concatenable queues* [1]. Such queues support the operations of find, split, and concatenate [1] in time proportional to the logarithm of the number of items in the queue. So given a vertex v_j, the base of the maximal blossom containing v_j and thereby the identity of the maximal blossom containing v_j can be computed in $O(\log n)$ time. When a blossom B splits into r subblossoms, the splitting of the concatenable queue for B into the concatenable queues for the subblossoms of B may be carried out in $O(r \log n)$ time. Similarly, when a new blossom

B is formed from r blossoms, the concatenation of the r concatenable queues of the subblossoms of B to obtain the concatenable queue for B may also be carried out in $O(r \log n)$ time.

4.2. A phase of the algorithm. An edge in the matching X is said to be matched, and an edge not in X is said to be unmatched. A vertex is *matched* if there is an edge in X incident to it. A vertex is *exposed* if there is no edge in X incident to it. A blossom is exposed (matched) if and only if its base is exposed (matched). An *augmenting path* is an alternating path between two distinct exposed maximal blossoms or between two distinct exposed vertices. A phase consists of looking for an augmenting path, that uses admissible edges only, between two exposed maximal blossoms.

We grow an alternating tree rooted at each exposed maximal blossom. The nodes in an alternating tree are themselves maximal blossoms. Each node in an alternating tree is reachable from the root by an alternating path that uses only admissible edges. Each maximal blossom that is a node in an alternating tree is *labelled*, and each maximal blossom that is not in any of the alternating trees is *free*. (Note that only a maximal blossom can be labelled or free.) A node in an alternating tree that is reachable by an even (odd) length alternating path from the root is given an s-label (t-label). An s-label (t-label) given to a node B is of the form $[s, (v_i, v_j)]([t, (v_i, v_j)])$ where $v_j \in B$ and v_i is the first vertex (point) on the alternating path from B to the root of the alternating tree containing B. A node with an s-label (t-label) is called an s-blossom (t-blossom). A vertex in an s-blossom (t-blossom) is referred to as an s-vertex (t-vertex). A vertex in a free blossom is called a free vertex. We let $S(T)$ denote the set of all the s-vertices (t-vertices), and let F denote the set of free vertices. (Note that $V = S \cup T \cup F$.)

At the start of a phase each maximal exposed blossom is given an s-label, and each maximal matched blossom is free. (So initially, $T = \phi$.) A phase consists of several steps and at each step one of following four things must happen. Either there is an admissible edge between two s-vertices not in the same s-blossom or there is an admissible edge between an s-vertex and a free vertex or the dual variable corresponding to a t-blossom is zero or there is a dual variable change. In the first case an alternating tree can be grown, in the second case an augmenting path is found or a new blossom is discovered, in the third case a t-blossom expands, and an occurrence of the fourth case is always followed by an occurrence of one the first three cases in the next step. Let

$$\delta_1 = \min_{v_i \in S, v_j \in F} \{d(v_i, v_j) - \alpha_i - \alpha_j\},$$

$$\delta_2 = \min_{v_i, v_j \in S, v_i, v_j \text{ not in the same } s\text{-blossom}} \left\{\frac{d(v_i, v_j) - \alpha_i - \alpha_j}{2}\right\},$$

$$\delta_3 = \min_{B \text{ a } t\text{-blossom}} \left\{\frac{-z(B)}{2}\right\},$$

and

$$\delta = \min\{\delta_1, \delta_2, \delta_3\}.$$

A detailed description of the four cases that can occur at a step during a phase is given below. Δ accumulates the dual variable changes δ during a phase, and at the start of a phase $\Delta = 0$.

Case 1. $\delta_1 = 0$ (grow an alternating tree). In this case there is an admissible edge between an s-vertex and a free vertex. Let (v_i, v_j) be such an edge where v_i is an

s-vertex and v_j is in a free blossom B. Let b be the base of B and let (b, v_k) be the matched edge incident on b. Then v_k is also a free vertex, and is in some free blossom B'. B gets the label $[t, (v_i, v_j)]$, and B' gets the label $[s, (b, v_k)]$.

By using the representations of the blossoms as ordered sets (i.e., the concatenable queues), the maximal blossoms containing v_i, v_j, and v_k, may be found in $O(\log n)$ time, and so once the edge (v_i, v_j) is available the labelling takes $O(\log n)$ time. □

Case 2. $\delta_2 = 0$ (discover a new blossom or augment). In this case there is an admissible edge between two s-vertices not in the same s-blossom. Let (v_i, v_j) be such an edge, and let v_i, v_j, be in distinct s-blossoms B, B', respectively. Using the labels on blossoms, we backtrack along the alternating path from B to the root of the alternating tree containing B. Simultaneously, we also backtrack along the alternating path from B' to the root of the alternating tree containing B'. We make a careful backtrack by backtracking one blossom on both paths each time, marking blossoms along the way. Either we discover a new blossom or find an augmenting path.

(i) A new blossom is found. Suppose the new blossom has r subblossoms. Then we will visit at most $2r$ blossoms before finding the first common blossom C on both paths. We use the parts of the paths from C to B and from C to B' to generate the cyclic double-linked list $\{(B_i, e_i)\}_{i=1}^{r}$ for the new blossom, where $B_r = C$ and e_i are taken from the labels on the two paths. The base of the new blossom is the base of C. The new blossom gets an s-label, and the subblossoms of the new blossom get unlabelled and stop being s-blossoms/t-blossoms (since they are no longer maximal blossoms). The dual variable associated with the new blossom is initialized to zero. Using the concatenable queues and the labels, finding the common blossom C and constructing the new cyclic double-linked list requires $O(r \log n)$ operations. The concatenable queue for the new blossom is obtained by concatenating together the concatenable queues for the r subblossoms in $O(r \log n)$ time.

(ii) An augmenting path is discovered between two exposed blossoms. If we discover an augmenting path π between two exposed blossoms, then we construct an augmenting path between the base vertices of the two exposed blossoms as follows. For each blossom on the path π, we recursively find an even length alternating path between the base of the blossom and the vertex by which the path π leaves the blossom. Once the even length alternating paths within all the blossoms that lie on the path π are available, we connect up these paths using the edges on π to give an augmenting path between the base vertices of the two exposed blossoms. The resulting augmenting path uses admissible edges only. We switch the status of the edges on the resulting augmenting path from matched to unmatched and vice versa. This augments the matching X and the current phase ends. We note that for each blossom through which the augmenting path passes, the base vertex changes and the ordering of the vertices in the blossom that is implied by the structure tree also changes. □

Case 3. $\delta_3 = 0$ (expand a t-blossom). Let B be a t-blossom such that the dual variable $z(B)$ associated with B is zero, and let B be labelled $[t, (v_j, v_i)]$. Suppose that $v_i \in B_i$ where $B_1, \cdots, B_r$ are the subblossoms of B and B_r contains the base of B. The blossom B expands, the blossoms on the odd length alternating path from B_i to B_r become free, and the blossoms on the even length alternating path from B_i to B_r get alternating labels starting and ending with a t-label. The labels are generated using the edges e_i in the cyclic double-linked list for B. The concatenable queues for the subblossoms of B are obtained by splitting for $i = 1, \cdots, r-1$ each B_i from B according to its base, which is its largest element.

Using the cyclic double-linked lists and the concatenable queues, the expansion of a t-blossom B with r subblossoms can be carried out in $O(r \log n)$ time. □

Case 4. $\delta > 0$ (dual variable change). In this case the dual variables are changed as follows:

For every s-vertex v_i, $\alpha_i := \alpha_i + \delta$;
For every t-vertex v_j, $\alpha_j := \alpha_j - \delta$;
For every s-blossom B, $z(B) := z(B) - 2\delta$;
For every t-blossom B', $z(B') := z(B') + 2\delta$;
$\Delta := \Delta + \delta$. □

At the end of a phase we construct the augmenting path, and augment the matching X by switching the status of the edges on the augmenting path from matched to unmatched and vice versa. We then change the base of each blossom through which the augmenting path passes, and rebuild the concatenable queues for all the maximal blossoms through which the augmenting path passes, since changing the base changes the ordering of the vertices in the blossom. Finally, we expand all maximal blossoms B such that $z(B) = 0$. (This ensures that at the start of the next phase the dual variable associated with each maximal blossom has nonzero value.)

We have the following useful lemma concerning the behavior of blossoms in a phase, which follows directly from Cases 1–4 described above.

LEMMA 4. (a) *Each blossom that gets an s-label some time during the phase, corresponds to a unique node in the structure tree of some maximal blossom at the end of the phase. Each blossom that gets a t-label or becomes free some time during the phase, corresponds to a unique node in the structure tree of some maximal blossom at the beginning of the phase.*

(b) *A free blossom is either free from the beginning of the phase or becomes free because it is the subblossom of some t-blossom that expands. Once a blossom receives a t-label, either it stays as a t-blossom until the phase ends, it expands, or it loses its label because it becomes the subblossom of a new s-blossom, in which case it stays unlabelled until the phase ends. Once a blossom receives an s-label, it either remains an s-blossom, until the phase ends, or it loses its label because it becomes the subblossom a new s-blossom, in which case it stays unlabelled until the phase ends.*

(c) *The total number of free blossoms plus s-blossoms plus t-blossoms in a phase is* $O(n)$. □

The remainder of § 4 will be devoted to the efficient implementation of a phase. We shall assign a weight $w(v_i)$, suitably related to the dual variable α_i, to each vertex v_i in V, a weight $w(B)$ to each s-blossom/t-blossom B, and also an offset $\mu(B)$ to each blossom B, which measures the change in the value of the dual variable of a vertex in B. In § 4.3 we shall describe how to compute these weights and offsets, and show how to efficiently maintain the dual variables using these weights and offsets. In §§ 4.4 and 4.5 these weights and offsets will be used along with the underlying geometry to construct a scheme for efficiently maintaining δ_1 and δ_2, respectively. The running time per phase may be broken down as follows:

(1) The computation at the end of a phase (i.e., constructing the augmenting path, etc.) requires $O(n \log n)$ time.

(2) In § 4.3 it is shown that the time for computing the weights and the offsets and for maintaining the dual variables using the weights and the offsets is $O(n^{1.5})$ per phase.

(3) In § 4.4 we show that the time required for maintaining δ_1, and an appropriate edge between an s-vertex and a free vertex for which δ_1 is achieved, is $O(n^{1.5}(\log n)^2)$ per phase. Furthermore, since Case 1 can occur $O(n)$ times during one phase, $O(n \log n)$ extra time is spent in Case 1 per phase in addition to the time required for maintaining δ_1. So the total time spent in Case 1 is $O(n^{1.5}(\log n)^2)$ per phase.

(4) In § 4.5 we show that the time required to maintain δ_2, and an appropriate edge between two s-vertices not in the same s-blossom for which δ_2 is achieved, is $O(n^{1.5}(\log n)^4)$ per phase. From Lemma 4 above it follows that $O(n \log n)$ extra time is spent in Case 2 per phase in addition to the time required for maintaining δ_2. So the total time spent in Case 2 is $O(n^{1.5}(\log n)^4)$ per phase.

(5) To maintain δ_3 the t-blossoms are kept in a priority queue, and the priority of a t-blossom B in this queue is given by $-w(B)$. Each t-blossom B satisfies the condition $z(B) = w(B) + 2\Delta$, and so the t-blossom with the largest weight is also the t-blossom with largest value for the dual variable $z(B)$. Then from Lemma 4 above it follows that $O(n \log n)$ time is spent in Case 3 per phase in addition to the time for computing the weights $w(B)$ of blossoms.

Thus the time required by the algorithm per phase is $O(n^{1.5}(\log n)^4)$. Since the number of phases is at most n, the total running time is $O(n^{2.5}(\log n)^4)$.

4.3. Weights, offsets, and dual variables. It is too time consuming to explicitly update the dual variables whenever there is a dual variable change (i.e., whenever Case 4 in § 4.2 occurs), so they are implicitly maintained by associating weights w with the vertices and the blossoms, and offsets μ with the blossoms. Similar ideas are also used in [8] to implicitly maintain the dual variables. Let $w(v_i)$ denote the weight associated with vertex v_i, and let $\mu(B)$ denote the offset associated with blossom B. We divide blossoms into *large* and *small* blossoms according to their size: a large blossom is one that contains at least $\sqrt{n}$ vertices, and a small blossom is one that contains less than $\sqrt{n}$ vertices. As mentioned in § 4.2, Δ denotes the sum of the dual variable changes δ since the beginning of the phase. The weights associated with vertices and the offsets associated with blossoms are updated so that after each step of a phase (that consists of executing one of the four cases in § 4.2) the following four relationships are maintained:

(1) For each s-vertex v_i, $\alpha_i = w(v_i) + \Delta$.

(2) For each vertex v_j in a t-blossom B, $\alpha_j = w(v_j) + \mu(B) - \Delta$.

(3) For each vertex v_k in a large free blossom B', $\alpha_k = w(v_k) + \mu(B')$.

(4) For each vertex v_l in a small free blossom B'', $\alpha_l = w(v_l)$.

At any time during a phase, to compute the value of the dual variable associated with a t-vertex or a free vertex we find the maximal blossom containing the vertex and then use the above relations. So at any time during the phase, the value of the dual variable associated with a vertex is computable in $O(\log n)$ time. At the end of a phase the values of the dual variables associated with all the vertices are explicitly computed.

At the beginning of a phase the weights and offsets are initialized as follows.

For each $v_i \in V$, $w(v_i) := \alpha_i$;

For each blossom B, $\mu(B) := 0$.

Note that $\Delta = 0$ at the beginning of a phase.

Next we shall describe how to update the weights and offsets during each of the four cases that occur at a step during a phase. (These cases were described in § 4.2.)

Case 1. $\delta_1 = 0$. In this case a free blossom B gets a t-label, and a free blossom B', such that a matched edge joins the base of B to a vertex in B', gets an s-label. The weights and offsets are updated as follows.

If newly labelled t-blossom B is a large blossom

then $\mu(B) := \mu(B) + \Delta$

else $\mu(B) := \Delta$;

For each vertex v_i in newly labelled s-blossom B',

If B' is a large blossom

then $w(v_i) := w(v_i) + \mu(B') - \Delta$
else $w(v_i) := w(v_i) - \Delta$. □

Case 2. $\delta_2 = 0$. The weights and offsets need to be updated only in the case when a new blossom is discovered in Case 2. Let B be the new blossom that is discovered. Note that B gets an s-label, and all the vertices in each subblossom of B, which had a t-label, switch status from t-vertices to s-vertices.

For each subblossom B' of B which had a t-label,
For each vertex v_i in B', $w(v_i) := w(v_i) + \mu(B') - 2\Delta$. □

Case 3. $\delta_3 = 0$. In this case a t-blossom B expands, and each of its subblossoms either becomes free or gets an s- or a t-label. We perform the following updates:

For each subblossom B' of B,
If B' gets a t-label then $\mu(B') := \mu(B)$;
If B' gets an s-label then
For each vertex v_i in B', $w(v_i) := w(v_i) + \mu(B) - 2\Delta$;
If B' is a large blossom and B' becomes free then $\mu(B') := \mu(B) - \Delta$;
If B' is a small blossom and B' becomes free then
For each vertex v_i in B', $w(v_i) := w(v_i) + \mu(B) - \Delta$. □

Case 4. $\delta > 0$. $\Delta := \Delta + \delta$. □

It is easily verified that the updates to the weights and the offsets maintain the above-mentioned four relationships between the weights, the offsets, and the dual variables. A blossom switches status whenever one of three things happens: (1) it is free and gets labelled; (2) it is labelled and gets unlabelled because it becomes the subblossom of a new blossom; or (3) it becomes free or labelled because it is the subblossom of some blossom that expands. From Lemma 4 in § 4.2, the total number status switches of blossoms is $O(n)$ per phase. So the total number of updates to the offsets μ is $O(n)$, since $\mu(B)$ is updated only when B switches status. The weight of a vertex is updated when it switches status from t-vertex/free vertex to s vertex, and whenever it becomes free and is in a small free blossom. Since a vertex switches status to s-vertex at most once during a phase, since the total number of status switches of blossoms is $O(n)$ per phase, and since a small blossom contains at most $\sqrt{n}$ vertices, we get that the total number of updates to weights w of vertices is $O(n^{1.5})$ per phase. So maintaining the weights of all the vertices and the offsets of all the blossoms requires $O(n^{1.5})$ time per phase.

The values of the dual variables associated with s-blossoms and t-blossoms are also implicitly maintained by weights associated with these blossoms. Let $w(B)$ denote the weight associated with blossom B. When a blossom B receives a t-label we initialize its weight as

$$w(B) := z(B) - 2\Delta.$$

As long as B remains a t-blossom the value of $z(B)$ is implicitly given by the relation

$$z(B) = w(B) + 2\Delta.$$

When B stops being a t-blossom (by becoming a subblossom of a new blossom and thereby getting unlabelled) we explicitly compute the value of the dual variable $z(B)$. When a blossom B' receives an s-label we initialize its weight as

$$w(B') := z(B') + 2\Delta,$$

and for the duration of the period for which B' is an s-blossom the value of $z(B')$ is implicitly given by

$$z(B') = w(B') - 2\Delta.$$

When B' stops being an s-blossom (by becoming a subblossom of a new blossom and thereby getting unlabelled) we explicitly compute the value of the dual variable $z(B')$. Since the total number of times blossoms are labelled is $O(n)$ per phase, the weights of the blossoms can be maintained in $O(n)$ time per phase.

4.4. Maintaining δ_1 during a phase. In this section we shall describe how to maintain δ_1, and an edge between an s-vertex and a free vertex such that δ_1 is achieved for that edge. The slack associated with an edge (v_i, v_j) is given by the quantity $d(v_i, v_j) - \alpha_i - \alpha_j$, and denoted by $slack[(v_i, v_j)]$. Let

$$\delta_{11} = \min_{v_i \in S, v_j \text{ in a large free blossom}} \{slack[(v_i, v_j)]\},$$

and

$$\delta_{12} = \min_{v_i \in S, v_j \text{ in a small free blossom}} \{slack[(v_i, v_j)]\}.$$

Then clearly,

$$\delta_1 = \min\{\delta_{11}, \delta_{12}\}.$$

In §§ 4.4.1 and 4.4.2 we shall describe how to maintain δ_{11} and δ_{12} in $O(n^{1.5}(\log n)^2)$ and $O(n^{1.5} \log n)$ time per phase, respectively.

4.4.1. Maintaining δ_{11}. During the computation of δ_{11}, we will be required to quickly find $shortest[v_j, B]$ for an s-vertex v_j and a large free blossom B. A data structure for doing this is obtained as follows. From Lemma 4 (§ 4.2), a free blossom B is a blossom that existed at the beginning of the phase. Consider the maximal blossom B' that contained B at the start of the phase, and the ordering imposed on the vertices of B' by the structure tree of B'. The free blossom B corresponds to an interval in this ordering, in other words if $v_i, v_l \in B$ and $v_i < v_l$ then each vertex v_k in B' such that $v_i < v_k < v_l$ is also in B. So the problem is to preprocess each maximal blossom B' at the start of a phase, so that later on in the phase, given a vertex v_j and a blossom B that is a subset of B' (and therefore corresponds to an interval in the ordering on B'), $shortest[v_j, B]$ may be found quickly. This is precisely Problem 2 given in § 2. So, by Lemma 2 (§ 2.2) we can preprocess all the maximal blossoms B' that exist at the start of a phase in $O(n(\log n)^2)$ time, so that given a free blossom B later in the phase together with a vertex v_j, $shortest[v_j, B]$ can be found in $O((\log n)^2)$ time.

As in the bipartite case, the set of s-vertices S is partitioned into S_1, S_2, such that $|S_2| \leqq \sqrt{n}$. We maintain the following edges:

(1) For each large free blossom B, the edge $shortest[B, S_1]$. All these edges are in a priority queue, with the priority of an edge (v_i, v_j) being given by $slack[(v_i, v_j)]$.

(2) For each large blossom B' that is either a subset of a t-blossom or a subset of a free blossom, the edge $shortest[B', S_1]$.

(3) For each pair v_j, B, where $v_j \in S_2$ and B is a large free blossom, the edge $shortest[v_j, B]$. All these edges are also in a priority queue, with the priority of an edge being given by its slack.

We note that for each vertex v_i in a large free blossom B, $\alpha_i = w(v_i) + \mu(B)$ where $\mu(B)$ is the offset associated with B, and that for each s-vertex v_j, $\alpha_j = w(v_j) + \Delta$. Thus if B is a large free blossom and $S' \subseteq S$, then

$$slack[shortest[B, S']] = \min_{v_i \in B, v_j \in S'} \{slack[(v_i, v_j)]\}.$$

So, δ_{11} is achieved either for the edge in (1) above with minimum priority or for the edge in (3) above with minimum priority, and may be computed in $O(\log n)$ time by examining these two edges.

At the beginning of a phase, S_1 consists of the vertices in exposed blossoms and S_2 is empty. Note that a vertex is never deleted from S. A new s-vertex is always inserted into S_2. Whenever the size of S_2 reaches the threshold of $\lceil n^{0.5} \rceil$, we add all the vertices in S_2 to S_1 and reset S_2 to the empty set. When vertices are moved from S_2 to S_1 the edges in (1) and (2) above must be recomputed, and this may be accomplished in $O(n \log n)$ time as follows. We utilize the data structures for Problem 1 described in § 2.1. We construct the weighted Voronoi diagram/range tree (WVD/RT) for the points in S_1, and for each vertex v_i that is a free vertex or a t-vertex, we compute $shortest[v_i, S_1]$ by querying the WVD/RT for S_1. This requires $O(n \log n)$ time by Lemma 1 in § 2.1. Then using the structure trees of the t-blossoms and the free blossoms, the edges in (1) and (2) above can be computed in $O(n)$ extra time. As the recomputation is done at most $\sqrt{n}$ times per phase, the time for the recomputation is $O(n^{1.5} \log n)$ for the entire phase.

Note that for each vertex v_i in a large t-blossom or in a large free blossom, the weight $w(v_i)$ equals the value of dual variable α_i at the beginning of the phase, and so the edges in (1) and (2) above need to be recomputed only when S_1 changes.

Next, we show that the time required for updating the edges in (1), (2), and (3) above whenever a large blossom becomes free or a large free blossom gets labelled or a vertex is inserted into S_2 is $O(\sqrt{n}(\log n)^2)$.

(a) Suppose a t-blossom expands and one of its subblossoms, say B, becomes free. Also, suppose B is a large blossom. Then the edge $shortest[B, S_1]$, which is one of the edges in (2) above, is inserted into the priority queue in (1) above. For each vertex $v_j \in S_2$, the edge $shortest[v_j, B]$ is computed in $O((\log n)^2)$ time using the data structure described at the start of the section and is inserted into the priority queue in (3) above. This leads to a cost of $O\sqrt{n}(\log n)^2)$ operations when a large blossom becomes free.

(b) Suppose a large free blossom gets a t-label/s-label. Then the $O(\sqrt{n})$ edges that are incident to vertices in B are deleted from the priority queues in (1) and (3) above.

(c) Suppose a vertex v_j is inserted into S_2. Then for each large free blossom B, we find $shortest[v_j, B]$ in $O((\log n)^2)$ time, and insert it into the priority queue in (3) above. Since at most $\sqrt{n}$ large free blossoms can be present at any given time, an insertion into S_2 costs $O(\sqrt{n}(\log n)^2)$ operations.

From Lemma 4 (§ 4.2), it follows that the number of times blossoms become free or get labelled is $O(n)$, and the number of insertions into S_2 is also $O(n)$. So from (a)-(c) and the bound on the time for recomputing the edges in (1) and (2) above, we may conclude that the time for maintaining δ_{11} is $O(n^{1.5}(\log n)^2)$ per phase.

4.4.2. Maintaining δ_{12}. In this case too S is partitioned into S_1 and S_2 such that $|S_2| \leqq \sqrt{n}$. The free vertices in the small free blossoms are partitioned into $F_1, F_2, \cdots, F_{\lceil n^{0.5} \rceil}$ (some of the F_i's could be empty) such that for each small free blossom B

$$F_i \cap B \neq \phi \Rightarrow B \subseteq F_i, \qquad i = 1, \cdots, \lceil n^{0.5} \rceil,$$

and

$$|F_i| \leqq 2(\sqrt{n}+1), \qquad i = 1, \cdots, \lceil n^{0.5} \rceil.$$

We maintain the following edges and data structures:

(1) For each vertex v_k that is in a small free blossom, the edge $shortest[v_k, S_1]$. All these edges are in a priority queue with the priority of an edge being given by its slack.

(2) For each vertex $v_j \in S_2$, the edges $shortest[v_j, F_i]$, $1 \leqq i \leqq \lceil n^{0.5} \rceil$. All these edges are also in a priority queue with the priority of an edge being given by its slack.

(3) The weighted Voronoi diagram/range tree (WVD/RT) for S_1 and for each F_i, $1 \leqq i \leqq \sqrt{n}$. For each vertex v_k in a small free blossom, $\alpha_k = w(v_k)$, and for each vertex $v_j \in S$, $\alpha_j = w(v_j) + \Delta$. Thus if F' is a subset of the set of vertices in small free blossoms and $S' \subseteq S$, then

$$slack[shortest[F', S']] = \min_{v_k \in F', v_j \in S'} \{slack[(v_k, v_j)]\}.$$

Hence δ_{12} is achieved either for the edge in (1) above with minimum priority or for the edge in (2) above with minimum priority, and can be computed in $O(\log n)$ time by examining these edges.

A new s-vertex is always inserted into S_2. Whenever the size of S_2 reaches the threshold of $\sqrt{n}$, all the vertices in S_2 are added to S_1 and S_2 is reset to the null set, and the edges in (1) above are recomputed. By Lemma 1 (§ 2.1) the recomputation may be done in $O(n \log n)$ time using the WVD/RT for S_1. So the time for recomputation is $O(n^{1.5} \log n)$ per phase.

Next, we show that the time for updating the edges in (1) and (2) above when a small blossom becomes free or a small free blossom gets labelled or a vertex is inserted in S_2 is $O(\sqrt{n} \log n)$.

(a) Suppose a small blossom B becomes free. Let F_i be such that $|F_i| \leqq \sqrt{n}$. (By the pigeonhole principle, there always exists such an F_i.) All the vertices in B are added to F_i, the WVD/RT for F_i is recomputed, and then for each $v_j \in S_2$, $shortest[v_j, F_i]$ is recomputed in $O(\log n)$ time by querying the WVD/RT for F_i. For each vertex $v_k \in B$, the edge $shortest[v_k, S_1]$ is found in $O(\log n)$ time by querying the WVD/RT for S_1. So when a small blossom B becomes free it costs $O((\sqrt{n} + |B|) \log n) = O(\sqrt{n} \log n)$ operations.

(b) Suppose a small free blossom B gets a t-label/s-label. First, the $O(\sqrt{n})$ edges in the above priority queues that are incident to vertices in B are deleted. Let $B \subseteq F_i$. All the vertices in B get deleted from F_i, the WVD/RT for F_i is recomputed, and then for each $v_j \in S_2$, $shortest[v_j, F_i]$ is recomputed by querying the WVD/RT for F_i. So when a small free blossom gets labelled it costs $O(\sqrt{n} \log n)$ operations.

(c) Suppose a vertex v_j is inserted into S_2. Then we have to compute $shortest[v_j, F_i]$, $1 \leqq i \leqq \lceil n^{0.5} \rceil$. So the cost in this case is also $O(\sqrt{n} \log n)$ operations.

From Lemma 4 (§ 4.2) it follows that the number of times blossoms become free or get labelled is $O(n)$, and the number of insertions into S_2 is also $O(n)$. From (a)-(c), and the time bound for recomputing the edges in (1) above, we may then conclude that the time for maintaining δ_{12} is $O(n^{1.5} \log n)$.

4.5. Maintaining δ_2 during a phase. In this section we will describe how to maintain δ_2, and an associated edge (v_i, v_j) for which δ_2 is achieved, where v_i, v_j, are s-vertices in distinct s-blossoms. As before, the slack associated with an edge (v_i, v_j), is given by the quantity $d(v_i, v_j) - \alpha_i - \alpha_j$, and denoted by $slack[(v_i, v_j)]$. Note that for each $v_i \in S$, $\alpha_i = w(v_i) + \Delta$. Thus if $S' \subseteq S$ and $S'' \subseteq S$, then

$$slack[shortest[S', S'']] = \min_{v_i \in S', v_j \in S''} \{slack[(v_i, v_j)]\}.$$

So we can use the weights rather the dual variables in maintaining δ_2. Let

$$\delta_{21} = \min_{v_i, v_j \text{ are in distinct large } s\text{-blossoms}} \{slack[(v_i, v_j)]\},$$

$$\delta_{22} = \min_{\substack{v_i \text{ is in a small } s\text{-blossom} \\ v_j \text{ is in a large } s\text{-blossom}}} \{slack[(v_i, v_j)]\},$$

and

$$\delta_{23} = \min_{v_i, v_j \text{ are in distinct small } s\text{-blossoms}} \{slack[(v_i, v_j)]\}.$$

Clearly,

$$\delta_2 = \tfrac{1}{2} \min \{\delta_{21}, \delta_{22}, \delta_{23}\}.$$

In §§ 4.5.1–4.5.3, we describe how to maintain δ_{21}, δ_{22}, and δ_{23}, in $O(n^{1.5}(\log n)^2)$, $O(n^{1.5} \log n)$, and $O(n^{1.5}(\log n)^4)$, time per phase, respectively.

Consider a specific phase. Let B be a blossom that has an s-label sometime during the phase. An s-subblossom (t-subblossom) of B is a subblossom of B that has an s-label (t-label), sometime during the phase, prior to B getting its s-label. We require the following easily proven lemma.

LEMMA 5. *Consider the s-blossoms that are present at the end of a particular phase. With each such s-blossom $\hat{B}$ is associated a tree whose root is $\hat{B}$ itself, and the leaves are all the vertices in $\hat{B}$. Each nonleaf node in this tree is a blossom that had an s-label sometime during the phase. The sons of a nonleaf node (blossom) B are as follows. Each son of B that is not a leaf is an s-subblossom of B. Each son of B that is a leaf is a vertex in B that has switched status from free vertex/t-vertex to s-vertex as a result of B getting an s-label. Let τ denote the forest of such trees associated with the s-blossoms at the end of the phase. Note that for a blossom (node) B in forest τ, the number of vertices in B (i.e., $|B|$) equals the number of leaves in the subtree rooted at B.*

For each node B in the forest τ, define $\sigma(B)$ as follows:

(1) *For a leaf B, let $\sigma(B) = 1$.*

(2) *Let B be a nonleaf node. Consider vertices to be trivial blossoms of size 1. Let B' be a son of B such that B' contains the largest number of vertices among all the sons of B. We let $\sigma(B) = |B| - |B'|$.*

Then

$$\sum_{B \text{ a node in forest } \tau} \sigma(B) = O(n \log n). \qquad \square$$

4.5.1. Maintaining δ_{21}. For each pair $B, \hat{B}$, where B and $\hat{B}$ are distinct large s-blossoms, we maintain the edge $shortest[B, \hat{B}]$. The edges are in a priority queue, with the priority of an edge (v_i, v_j) being $slack[(v_i, v_j)]$. δ_{21} is achieved for an edge with the minimum priority in this priority queue. We also maintain a semidynamic weighted Voronoi diagram/range tree (WVD/RT) described in § 2.3 for each large s-blossom. Note that once the semidynamic WVD/RT for a blossom B is available, $shortest[v_i, B]$ is computable in $O(\log n)^2)$ time for any vertex v_i. The shortest edges between large s-blossoms are updated as follows:

(1) Suppose a large blossom B gets an s-label in Case 1 or Case 3 in § 4.2. Then each vertex in B switches status to s-vertex. For each large s-blossom $\hat{B}$ (other than B), we compute the edge $shortest[v_i, \hat{B}]$ for all vertices v_i in B by querying the WVD/RT for $\hat{B}$, and use these edges to find $shortest[B, \hat{B}]$. We also build the semidynamic WVD/RT for B. As the number of large s-blossoms present at any time is $O(\sqrt{n})$, we spend $O(|B|\sqrt{n}(\log n)^2)$ time when B gets an s-label.

(2) Suppose a new large s-blossom B is created in Case 2 in § 4.2. Let C be the set of all vertices v in B such that v is either in a t-subblossom of B or in a

small s-subblossom of B. Note that each subblossom of B is either a t-subblossom or an s-subblossom, and that each vertex in each t-subblossom of B switches status to s-vertex when B receives an s-label.

(2.1) For each large s-subblossom B' of B, we delete from the above priority queue the $O(\sqrt{n})$ edges which are incident to vertices in B'.

(2.2) Let $\hat{B}$ be a large s-blossom other than B. For each vertex v_i in C, the edge *shortest*$[v_i, \hat{B}]$ is found by querying the semidynamic WVD/RT for $\hat{B}$. Using these edges together with the edges *shortest*$[B', \hat{B}]$, where B' are the large s-subblossoms of B, *shortest*$[B, \hat{B}]$ is obtained, and inserted into the above priority queue. Since at most $O(\sqrt{n})$ large s-blossoms may be simultaneously present and since the number of subblossoms of B is $O(|C|)$, the time to compute *shortest*$[B, \hat{B}]$ for all large s-blossoms $\hat{B}$ is $O(|C|\sqrt{n}(\log n)^2)$.

(2.3) Let B' be an s-subblossom of B such that B' has the greatest size among all the s-subblossoms of B.

(2.3.1) If B' is a small blossom, then $B = C$ and the semidynamic WVD/RT for B is constructed in $O(|C|(\log n)^2)$ time.

(2.3.2) If B' is a large blossom, then the semidynamic WVD/RT for B is obtained by inserting all the vertices in $B - B'$ into the semidynamic WVD/RT for B'. So there are $\sigma(B)$ insertions into a semidynamic WVD/RT where $\sigma(B)$ is as defined in Lemma 5.

A upper bound of $O(n^{1.5}(\log n)^2)$ on the time per phase for the computations in (1), (2.1), and (2.2) follows from the following observations. First, the total number of status switches of vertices to s-vertices is $O(n)$ per phase. Second, the number of blossoms labelled during a phase is $O(n)$, and so the number of s-subblossoms generated during a phase is $O(n)$. Third, for each vertex v, the condition that v is in a small s-subblossom of a large s-blossom can occur at most once during a phase. From these observations it also follows that the time spent in (2.3.1) is $O(n(\log n)^2)$ per phase. By Lemma 5, the total number of insertions into semidynamic WVD/RT's in (2.3.2) is $O(n \log n)$ per phase, and so the total time per phase spent in (2.3.2) is $O(n(\log n)^3)$ at the average rate of at most $O((\log n)^2)$ per insertion. Thus the time for maintaining δ_{21} is $O(n^{1.5}(\log n)^2)$ per phase.

4.5.2. Maintaining δ_{22}. The procedure for maintaining δ_{22} is similar to the one for maintaining the minimum slack δ in the bipartite case discussed in § 3. Let S_L denote the set of those vertices in S that are in large s-blossoms, and let S_M denote the set of those vertices in S that are in small s-blossoms. S_L is partitioned into S_{L1}, S_{L2}, such that $|S_{L2}| \leqq \sqrt{n}$. S_M is partitioned into $S_{M1}, S_{M2}, \cdots, S_{Mr}$, $r = \lceil n^{0.5} \rceil$, such that $|S_{Mi}| \leqq 2(\lceil n^{0.5} \rceil + 1)$, $1 \leqq i \leqq \lceil n^{0.5} \rceil$. (Some of the S_{M_i}'s could possibly be empty.) The following information is maintained:

(i) For each $v_i \in S_M$, the edge *shortest*$[v_i, S_{L1}]$. These edges are in a priority queue, with the priority of an edge being its slack.

(ii) For each $v_j \in S_{L2}$, the edges *shortest*$[v_j, S_{Mi}]$, $1 \leqq i \leqq \lceil n^{0.5} \rceil$. These edges too are in a priority queue with the priority of an edge being given by its slack.

(iii) The WVD/RT for S_{L1} and for each S_{Mi}, $1 \leqq i \leqq \lceil n^{0.5} \rceil$.

Clearly, δ_{22} is achieved for either the edge in (i) with minimum priority or the edge in (ii) with minimum priority.

Initially, S_{L1} contains all the vertices in the large exposed blossoms, and $S_{L2} = \phi$. When a new vertex is added to S_L, it is always inserted into S_{L2}. When the size of S_{L2} reaches the threshold of $\lceil n^{0.5} \rceil$, all the vertices in S_{L2} are moved over to S_{L1}, and the

edges in (i) are recomputed. By Lemma 1 (§ 2.1), using the WVD/RT for S_{L1} the recomputation may be performed in $O(n \log n)$ time, leading to a time of $O(n^{1.5} \log n)$ per phase for the recomputation.

Suppose there is an insertion into S_M, say v_i is inserted into S_{M_i}. Then the WVD/RT for S_{Mi} and the edges *shortest*$[v_j, S_{Mi}]$ for the vertices v_j in S_{L2} must be recomputed, and *shortest*$[v_i, S_{L1}]$ must be computed and inserted into the priority queue in (i). So an insertion into S_M costs $O(n^{0.5} \log n)$ time. Similarly, a deletion from S_M costs $O(n^{0.5} \log n)$ time. Insertion of a vertex v_j into S_{L2} also costs $O(n^{0.5} \log n)$ time, as the edges *shortest*$[v_j, S_{Mi}]$, $1 \leqq i \leqq \lceil n^{0.5} \rceil$ have to be computed. (Note that there are no deletions from S_L.) The number of insertions into S_L and S_M is $O(n)$ per phase. So the time for all the insertions into S_{L2}, and all the insertions into and deletions from S_M, is $O(n^{1.5} \log n)$ per phase.

Thus the time for maintaining δ_{22} is $O(n^{1.5} \log n)$ per phase.

4.5.3. Maintaining δ_{23}. Next, we show how to maintain δ_{23}. Let the vertices in S be ordered by the following rule. For $v_i, v_j \in S$, $v_i < v_j$ if and only if v_i was added to S before v_j. Note that for an s-blossom B, the ordering on the vertices in S induces a partition of $S - B$ into at most $|B|+1$ intervals. Let $u_1 < u_2 < \cdots < u_{|S|}$ denote the ordered sequence of the vertices in S. By Lemma 3 (§ 2.3), we can maintain a semidynamic data structure for S (that is a dynamized version of the data structure for Problem 2 in § 2) such that:

(I) The total cost of inserting all the points in S, and thus the total time for maintaining the data structure for an entire phase is $O(n(\log n)^3)$.

(II) Given an interval $[u_i, u_j)$, $1 \leqq i < j \leqq |S|+1$, and a vertex v_k, *shortest*$[v_k, [u_i, u_j)]$ may be computed in $O((\log n)^3)$ time.

For each small s-blossom B the following edges incident on the vertices in B are maintained. Let $|B| = r$, and let $u_{i_1} < u_{i_2} < \cdots < u_{i_r}$ be the ordered sequence of the vertices in the small s-blossom B. Then $S - B$ can be expressed as the disjoint union of the intervals $[u_1, u_{i_1})$, $[u_{i_1+1}, u_{i_2}), \cdots, [u_{i_{r-1}+1}, u_{i_r})$, $[u_{i_r+1}, u_{|S|+1})$. (Some of the intervals could possibly be empty.) We shall maintain the edge *shortest*$[B, [u_1, u_{i_1})]$, and the edges *shortest*$[B, [u_{i_k+1}, u_{i_{k+1}})]$, $1 \leqq k < |B|$. (Note that *shortest*$[B, [u_{i_r+1}, u_{|S|+1})]$ is not included.)

All these edges corresponding to the small s-blossoms are placed in a priority queue, with the priority of an edge given by its slack. It is easily seen that if (u_i, u_j) is an edge in this priority queue with the minimum priority then *slack*$[(u_i, u_j)] \leqq \delta_{23}$.

The computations required to maintain the above edges associated with small s-blossoms are broken down into two cases:

(a) An existing small blossom B gets an s-label. This happens in Case 1 and Case 3 in § 4.2, and the vertices in the newly labelled blossom B switch status from free vertices/t-vertices to s-vertices. All the vertices in B get added to S and so B corresponds to a single interval in the ordering on S. Moreover, $S - B$ is also an interval. For each vertex $u_{i_k} \in B$, *shortest*$[u_{i_k}, S - B]$ is found in $O((\log n)^3)$ time by querying the data structure for S, and using these edges *shortest*$[B, S - B]$ is obtained in $O(|B|)$ extra time. So the time spent is $O(|B|(\log n)^3)$.

(b) A new small blossom B is discovered and gets an s-label. This happens in Case 2 in § 4.2. Let B' be an s-subblossom of B such that B' has the largest size among all the s-subblossoms of B. Let $|B| = r$, and let $|B'| = m$. Let $u_{i_1} < u_{i_2} < \cdots < u_{i_r}$ be the vertices in B, and let $u_{j_1} < u_{j_2} < \cdots < u_{j_m}$ be the vertices in B'. Let J be the set of intervals defined by

$$J = \{[u_1, u_{i_1}), [u_{i_1+1}, u_{i_2}), \cdots, [u_{i_{r-1}+1}, u_{i_r})\},$$

and J' be the set of intervals defined by

$$J' = \{[u_1, u_{j_1}), [u_{j_1+1}, u_{j_2}), \cdots, [u_{j_{m-1}+1}, u_{j_m})\}.$$

Note that $(V-B) \cap [u_1, u_{i_r})$ can be expressed as the disjoint union of all the intervals in J, and that $(V-B') \cap [u_1, u_{j_m})$ can be expressed as the disjoint union of all the intervals in J'. Furthermore, $|J \cap J'| \geqq |B'| - (|B| - |B'|)$ and so $|J - J'| \leqq 2(|B| - |B'|)$. The edges *shortest*$[B, I]$ for all the intervals I in J may be obtained in $O(|B|(|B| - |B'|) \times (\log n)^3)$ time as follows. For each interval I' in $J - J'$, we compute *shortest*$[u', I']$ for all vertices u' in B'. For each interval I in J, we compute *shortest*$[u, I]$ for all vertices u in $B - B'$. Each edge is obtained by querying the data structure for S (described in § 2.3) in $O((\log n)^3)$ time, and all these edges may be obtained in $O(|B|(|B| - |B'|) \times (\log n)^3)$ time. Then as the edges *shortest*$[B', I']$, $I' \in J \cap J'$, are already available, the edges *shortest*$[B, I]$, $I \in J$, can be found in $O(|B|(|B| - |B'|) \log n)$ additional time. The time per phase for the computations in (a) above is $O(n(\log n)^3)$, since all the blossoms labelled by an s-label in Case 1 and Case 3 in § 4.2 are disjoint. As the size of a small s-blossom is at most $\sqrt{n}$, $O((|B| - |B'|)\sqrt{n}(\log n)^3)$ time is spent in (b) per each new blossom B, where B' is an s-subblossom of B that contains the largest number of vertices among all the s-subblossoms of B. In other words, $O(\sigma(B)\sqrt{n}(\log n)^3)$ time is spent in (b) above per each new s-blossom B, where $\sigma(B)$ is as defined in Lemma 5. Then we may apply Lemma 5 and conclude that the time per phase spent in performing the computations in (b) above is $O(n^{1.5}(\log n)^4)$. Thus the time per phase for maintaining δ_{23} is $O(n^{1.5}(\log n)^4)$.

5. Conclusion. We have shown that the underlying geometry can be exploited to speed up algorithms for weighted matching when the vertices of the graph are points on the plane, and the weight of an edge between two points is the distance between the points under some metric. The techniques described in the paper can be used to speed up algorithms for related problems such as bottleneck matching [11] for points on the plane, and the transportation problem [11], [14] where the sources and the sinks are located on the plane and the cost of transporting from a source to a sink is proportional to the distance between the source and the sink. The techniques in the paper can also be utilized to speed up scaling algorithms [7], [18] for matching and related problems by a factor of about $\sqrt{n}$ for points on the plane. Finally, we note that for the L_1 and the L_∞ metrics the algorithms in the paper easily extend to the case where the vertices of the graph are points in d-dimensional space (d fixed) rather than points on the plane. For points in d-dimensional space we use d-dimensional range trees instead of two-dimensional range trees [15], and this increases the running time of the matching algorithms by at most $O(\log n)^d$.

Acknowledgments. The author thanks F. P. Preparata for suggesting the problem of matching on the plane, P. Shor, S. Fortune, and H. Edelsbrunner for helpful discussions, and M. R. Garey and D. S. Johnson for useful comments and suggestions concerning the presentation of this paper.

ON RELAXED SQUASHED EMBEDDING OF GRAPHS INTO A HYPERCUBE*

MING-SYAN CHEN† AND KANG G. SHIN‡

Abstract. Task allocation in an n-dimensional hypercube (or an n-cube) multicomputer consists of two sequential steps: (i) determination of the size of the cube required to accommodate an incoming task composed of a set of interacting modules, and (ii) allocation of the task to a cube of the dimension determined from (i). Step (i) is usually done manually by the users, which is often difficult and leads to the underutilization of processors in an n-cube system. The main objective here is to automate step (i). Step (ii) has already been addressed in [*IEEE Trans. Comput.*, 36 (1987), pp. 1396–1407].

Each incoming task is represented by a graph in which each node denotes a module of the task and each link represents the need of intermodule communication. Each module must be assigned to a subcube in such a way that node adjacencies in the associated task graph are preserved. This assignment problem is called the *relaxed squashed* (RS) *embedding* of a graph, and the minimal dimension of a cube required for a given graph is termed the *weak cubical dimension* of the graph. Some mathematical properties of the RS embedding are derived first. In light of these mathematical properties, fast algorithms are developed to RS embed task graphs. A heuristic function for the A^* search algorithm is also derived to determine the weak cubical dimension of a graph.

Key words. n-cube, loop switching addressing scheme, squashed embedding, weak cubical dimension, heuristic search

1. Introduction.

Recently, hypercube multicomputers are beginning to spread widely in the research and development community as well as in commercial markets [Cor85], [Sei85], [Val82], [Wil87]. To execute a task in an n-dimensional hypercube (or n-cube) multicomputer, the task is usually decomposed into a set of interacting modules that are then assigned to a subcube. Thus, task allocation in an n-cube multicomputer system consists of two sequential steps: (i) determination of the dimension of the subcube required to accommodate all the modules of each incoming task, and (ii) allocation of each task to a subcube of the dimension determined from (i) in the hypercube multicomputer. As an efficient solution to (ii), we propose a first-fit linear search for required subcubes whose addresses are represented by the binary reflected Gray code [ChS87]. Conventionally, (i) is determined manually by the users, which is often very difficult and results in the underutilization of processors and degradation of system performance. The automation of step (i) is thus very important and will be the focus of this paper.

Each incoming task is described by a graph (called *task graph*), in which each node denotes a module of the task and each link represents the need of intermodule communication. We want to determine a subcube in the n-cube system that can accommodate the incoming task subject to some constraints. Note that different computing systems and user environments may require different criteria to be used for

the determination of the subcube size required for each task. Several important results in various types of embedding have been reported [Fir65], [GaG75], [GrP72], [Har86], [Har80], [HaM72]. Basically, *isomorphic embedding* is a node-to-node adjacency-preserving mapping [GaG75], [HaM72], whereas *isometric embedding* is a node-to-node distance-preserving mapping [Fir65]. In *homeomorphic embedding*, additional nodes are allowed to be inserted into edges so as to make the graph isomorphically embeddable into a cube [Har86]. *Squashed embedding* is a node-to-subcube distance-preserving mapping [GrP72].

In this paper, we propose and investigate a new type of embedding, called *relaxed squashed* (RS) *embedding*, a node-to-subcube adjacency-preserving mapping. In other words, adjacent modules in the task graph are assigned to adjacent subcubes. The dimension of the minimal cube required for the RS embedding of a given graph will henceforth be called the *weak cubical dimension* of the graph. Clearly, the problem of determining the weak cubical dimension of a task graph is similar to the squashed embedding problem [BGK72], [GrP71], [GrP72], [Yao78], [Win83] in the sense that each node in the source graph is mapped into a subcube. But, it differs from the squashed embedding problem in that only adjacency, rather than internode distance, must be preserved under the mapping. For example, the embedding from a path P_4 into a Q_2 in Fig. 1 preserves adjacency, but not distance.

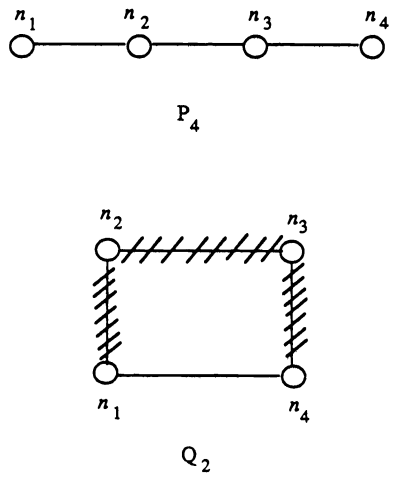

FIG. 1. *A mapping that preserves adjacency but not distance.*

From the result of the squashed embedding problem [Win83], we know that every graph has its weak cubical dimension, although the cubical dimension is defined only for cubical graphs [Har69]. Similarly to the determination of the cubical dimension of cubical graphs [KVC85] [CKV87], we shall prove that the problem of determining the existence of an RS embedding from a graph to a cube of a given dimension is NP-complete. This proof justifies the need of our heuristic approaches to the RS embedding problem. Some mathematical properties for the RS embedding problem will be derived first. Then, using these results, we shall develop (a) fast algorithms for the RS embedding of a given task graph and (b) a heuristic function for the A^* search algorithm to determine if a graph can be RS embedded into a cube of a given dimension.

By applying this search algorithm for different dimensions repeatedly, we can determine the weak cubical dimension of a graph.

This paper is organized as follows. The definitions and notation necessary for our discussion are given in § 2 where related topics and results are also reviewed. Section 3 deals with the mathematical properties of the RS embedding. Using these properties, fast algorithms for the RS embedding are then developed in § 4. A heuristic search algorithm to determine if a graph can be RS embedded into a cube of a given dimension is proposed. Illustrative examples are presented in § 5, and the paper concludes with § 6.

2. Preliminaries.

2.1. Notation and definitions. Denote an undirected graph by $G_A = (V_A, E_A)$, where V_A and E_A are the set of nodes and the set of links in G_A, respectively, and use $\bar{G}$ to denote the *complement* of a graph G [Har69]. For two graphs $G_A = (V_A, E_A)$ and $G_B = (V_B, E_B)$, G_B is a *subgraph* of G_A if $V_B \subseteq V_A$ and $E_B \subseteq E_A$. An *induced subgraph* of G_A with a node set $V_S \subseteq V_A$ is the maximal subgraph of G_A with the node set V_S.

An edge in a connected graph is called a *bridge* if its removal disconnects the graph. Clearly, the removal of an edge from a tree will result in two trees, called the *attached trees* of the edge. The number of nodes in the larger[1] of the two attached trees of an edge is called the *weight* of the edge. The *centroid edge* of a tree is defined as the edge with the minimal weight. Besides, the graph operations, $\times$ (product), $\cup$ (union) and $+$ (join) [Har69] will be used to facilitate our presentation. Note that while the union operation may be applied on two graphs that are not disjoint, the join operation is applied only on two disjoint graphs. An illustrative example of the above operations is given in Fig. 2. An n-cube can now be defined as $Q_n = K_2 \times Q_{n-1}$, for all $n \geqq 1$, where K_2 is the complete graph with two nodes and Q_0 is a trivial graph with one node.

Let Σ be the ternary symbol set $\{0, 1, *\}$, where $*$ is the *don't care* symbol. Then, every subcube of an n-cube can be uniquely represented by a sequence of ternary symbols, called the *address* of the subcube. Also, let $|q|$ denote the dimension of the subcube q. The distance between two subcubes is then defined as follows.

DEFINITION 1. The Hamming distance, $H: \sum^n \times \sum^n \to I^+$, between two subcubes with addresses $\alpha = a_n a_{n-1} \cdots a_1$ and $\beta = b_n b_{n-1} \cdots b_1$ in a Q_n is defined as $H(\alpha, \beta) = \sum_{i=1}^{n} h(a_i, b_i)$, where

$$h(a, b) = \begin{cases} 1 & \text{if } [a = 0 \text{ and } b = 1] \text{ or } [a = 1 \text{ and } b = 0], \\ 0 & \text{otherwise.} \end{cases}$$

A subcube $\alpha = a_n a_{n-1} \cdots a_1$ is said to *contain* another subcube $\beta = b_n b_{n-1} \cdots b_1$, denoted by $\beta \subseteq \alpha$, if and only if all the nodes in β belong to α. The notation $\beta \subset \alpha$ is used to denote the case when $\beta \subseteq \alpha$ and $\beta \neq \alpha$. The *minimal upper subcube* of two subcubes α and β, denoted by $\text{lcm}(\alpha, \beta)$, is then defined as the smallest subcube among all those subcubes which contain both α and β. Similarly, the *maximal lower subcube* of two subcubes α and β, denoted by $\gcd(\alpha, \beta)$, is the largest subcube among all those subcubes contained in both α and β. For notational convenience, we let $\gcd(\alpha, \beta) = \varnothing$ if $H(\alpha, \beta) \geqq 1$. For example, $H(00*1*, 1000*) = 2$, $\text{lcm}(*100, 0110) = *1*0$, and $\gcd(01**, *10*) = 010*$. Also, let $D(n_i)$ denote the address of the subcube assigned to module n_i and $B(n_i)$ denote the set of nodes adjacent to n_i in the graph. For the graph of Fig. 3, we get $B(n_1) = \{n_2, n_3, n_4, n_6\}$.

[1] One tree is said to be *larger* than the other if it contains more nodes.

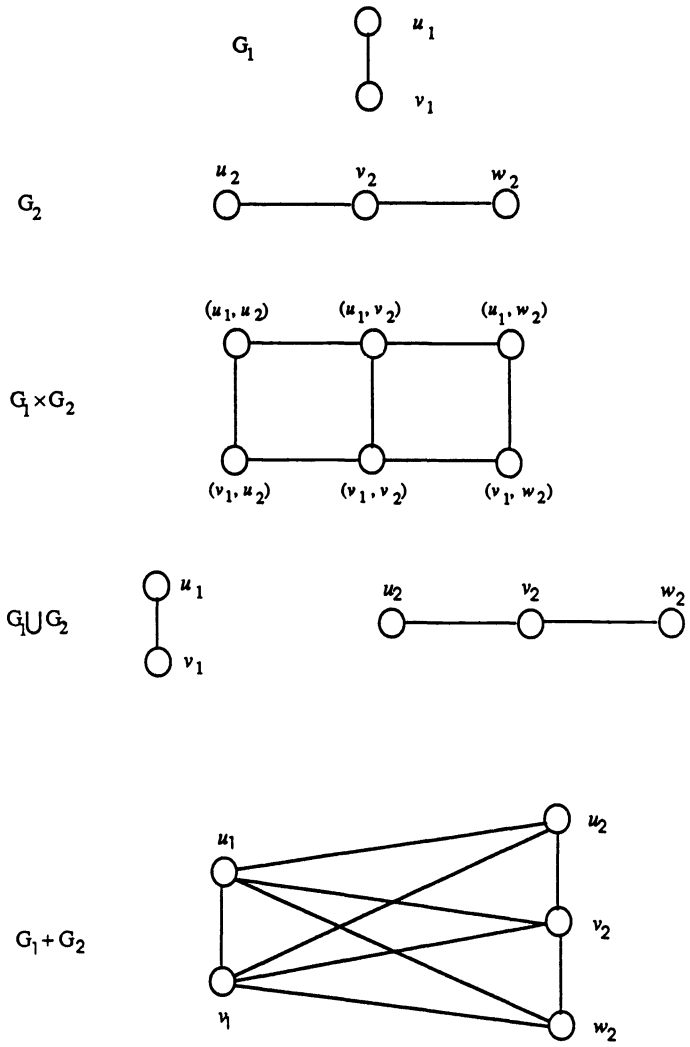

FIG. 2. *The product, union, and join operations on graphs.*

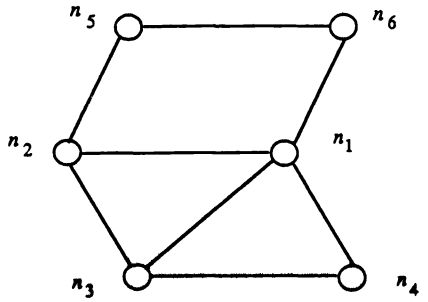

FIG. 3. *An example task graph.*

2.2. Previous related results. In [GrP71], an interesting addressing scheme for loop switching networks [Pie72] has been proposed. In this scheme, a loop switching network is represented by a graph in which nodes and links represent the loops and the contact points between loops, respectively. The problem is to find an addressing scheme in which each node is assigned a sequence of ternary symbols to correctly represent distances between nodes in the graph. More formally, this problem can be stated as follows. Given a connected graph G with n nodes, find the least integer $N(G)$ with which it is possible to assign each node v in G an address $D(v) \in \Sigma^{N(G)}$ such that $d_G(v_1, v_2) = H(D(v_1), D(v_2))$, for all $v_1, v_2 \in V_G$, where $d_G(v_1, v_2)$ is the distance between v_1 and v_2 in G, and V_G is the set of nodes in G. Naturally, the following two questions arise. (1) Does there always exist such an addressing scheme for an arbitrary network G with n nodes? (2) If the answer to (1) is yes, what is the least number $N(G)$ of ternary symbols that suffices to implement the addressing scheme for G? This problem was studied for more than a decade [BGK72], [GrP71], [GrP72], [Yao78] until an important conjecture $N(G) \leqq n-1$ was proved in [Win83]. Thus, questions (1) and (2) have been answered.

As pointed out in [GrP72], this problem is equivalent to the *squashed embedding* problem. Embed a task graph into a cube in such a way that each node of the graph is assigned to a subcube while preserving internode distances. Fig. 4 shows an example of the squashed embedding, where $D(v_1) = *11$, $D(v_2) = 110$, $D(v_3) = 010$, and $D(v_4) = 000$.

When task allocation in a hypercube multicomputer is considered, it is more important to preserve node adjacencies than internode distances, since node adjacencies are directly related to intermodule communication delays. Based on this observation, we shall consider the problem of embedding a given task graph into a hypercube in such a way that each task module must be assigned to a subcube while preserving task module adjacencies. This problem can be viewed as a relaxed version of the squashed

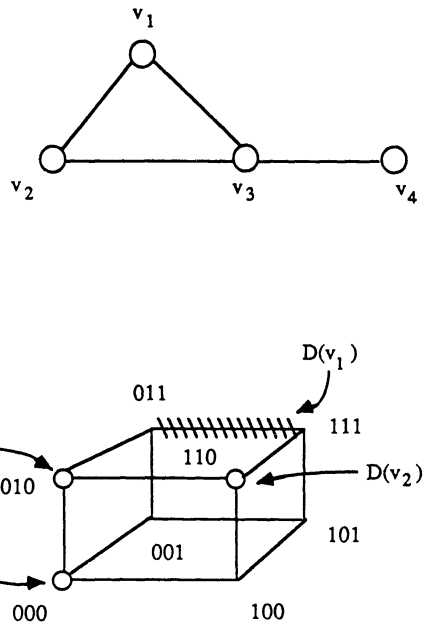

FIG. 4. *An example of squashed embedding.*

embedding problem since it preserves node adjacencies instead of internode distances. (Henceforth it will be called the *relaxed squashed* (RS) *embedding.*) Obviously, a graph can be RS embedded in any cube of size greater than or equal to its weak cubical dimension. Insofar as system utilization is concerned, however, we want to find a minimal cube for the RS embedding of each task graph. Several important properties of the RS embedding problem will be derived in the following section. We shall prove first that the problem of determining the existence of an RS-embedding for a given task graph is NP-complete, and then derive some mathematical properties of the RS embedding. These properties will be applied to develop our heuristic solutions.

3. Mathematical properties of RS-embedding.

THEOREM 1. *The problem of determining if a graph can be* RS *embedded into a cube of a given dimension is* NP*-complete.*

Proof. Suppose k is the dimension of the cube into which a source graph is to be RS embedded. Consider the instance that the source graph contains 2^k nodes. Clearly, the source graph can be RS embedded into a Q_k if and only if it can be isomorphically embedded into a Q_k. However, the problem of determining whether a graph of 2^k nodes can be isomorphically embedded into a Q_k has already been proved to be NP-complete in [CKV87], meaning that the problem of determining whether a graph of 2^k nodes can be RS embedded into a Q_k is also NP-complete. This theorem is thus proved by restriction [GaJ79]. □

Theorem 1 justifies the need of heuristic solution approaches to the RS embedding problem. It is necessary to develop some mathematical properties of the RS embedding problem, on which these heuristic approaches will be based. The following theorem about the squashed embedding has been proved in [GrP72].

THEOREM 2 [GrP72]. $N(K_n) = n-1$, *where* K_n *is a complete graph with n nodes.*

Note that when the graph to be embedded is a complete graph, the requirement of preserving distance is the same as the adjacency requirement. This fact is described by the following corollary.

COROLLARY 2.1. *Let wd* (G) *be the weak cubical dimension of G. Then, wd* $(K_n) = n-1$.

Consider the case when G_1 is a subgraph of G_2. Clearly, we have less restirction in the RS embedding of G_1 than that of G_2. This leads to the following proposition.

PROPOSITION 1. *If* G_1 *is a subgraph of* G_2, *then* $\mathrm{wd}(G_1) \leqq \mathrm{wd}(G_2)$.

Since the number of nodes in the n-cube must be greater than or equal to that of the task graph to be embedded, we have the following corollary.

COROLLARY 2.2. *Let G be a graph with n nodes. Then,* $\lceil \log_2 n \rceil \leqq \mathrm{wd}(G) \leqq n-1$.

Note that Corollary 2.2 provides loose bounds for the weak cubical dimension of a graph with n nodes.

THEOREM 3. *Let* $G=(V, E)$ *be a connected graph and let* $G_S=(V_S, E_S)$ *be a subgraph of G. Suppose the induced subgraph of G with the node set* V_S, *denoted by* $\mathrm{ind}_G(V_S)$, *can be* RS *embedded into a* Q_m, *and the removal of all edges in* E_S *from G results in* $|V_S|$ *disjoint graphs,* $G_i=(V_i, E_i)$, $1 \leqq i \leqq |V_S|$. *Then,* $\mathrm{wd}(G) \leqq \max_{1 \leqq i \leqq |V_S|} \{\mathrm{wd}(G_i)\} + m$.

Proof. Let u_i, $1 \leqq i \leqq |V_S| = k$, be the nodes in $G_S \cap G_i$. Since $\mathrm{ind}_G(V_S)$ can be RS embedded into a Q_m and $G_S \subseteq \mathrm{ind}_G(V_S)$, there exists an addressing scheme for the RS embedding of G_S into the Q_m. Let $D_{G_S}(u_i)$ denote the address of $u_i \in V_S \cap V_i$ in the addressing scheme.

Partition V into k disjoint node sets V_i, $1 \leqq i \leqq k$. For $1 \leqq i \leqq k$, let $D_{G_i}(v)$ denote the address of $v \in V_i$ for the RS embedding of G_i into a $Q_{\mathrm{wd}(G_i)}$ and let $D^k_{G_i}(v)$ denote

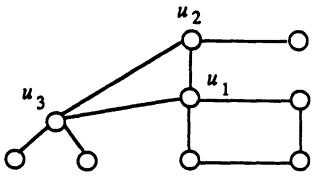
the kth bit of $D_{G_i}(v)$. Without loss of generality, we can assume $r_1 = \max_{1 \leq i \leq k} \{r_i = \text{wd}(G_i)\}$. Address each node w in G with $D_G(w)$ according to the following rules:

(1) For all $w \in V_i$, encode the first m bits of $D_G(w)$ with $D_{G_S}(u_i)$.

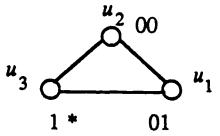
(2) For all $w \in V_i$, $m+1 \leq k \leq r_i + m$, **if** $D^k_{G_i}(u_i) = 1$ **then** $D^k_G(w) = D^{k-m}_{G_i}(w)$ **else** $D^k_G(w) = D^{k-m}_{G_i}(w)$. And, let $D^k_G(w) = *$ for $r_i + m + 1 \leq k \leq r_1 + m$.

This theorem follows from the existence of the above addressing scheme for G, whose length is $\max_{1 \leq i \leq |V_S|} \{\text{wd}(G_i)\} + m$. □

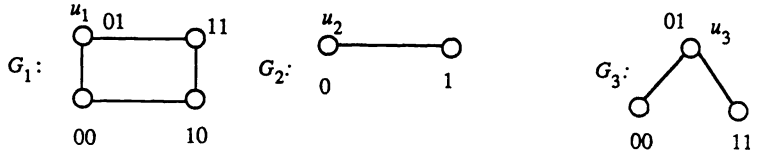
For an illustrative purpose, consider the example graph in Fig. 5(a). The induced subgraph of the node set $\{u_1, u_2, u_3\}$ is G_S in Fig. 5(b) and can be RS embedded into a Q_2. G_1, G_2, and G_3 in Fig. 5(c) are the resulting graphs after removing the edges of G_S from G. We have $\max_{1 \leq i \leq 3} \{\text{wd}(G_i)\} = 2$. By encoding the last two bits of $D_G(u_i)$, $1 \leq i \leq 3$, with 0's and *'s only, inverting some corresponding bits in the address $D_{G_i}(w)$ to preserve the adjacency in G_i, and using $D_{G_S}(u_i)$ as the leading portion of the address of $w \in V_i$, we get the address of each node in G as shown in Fig. 5(d).



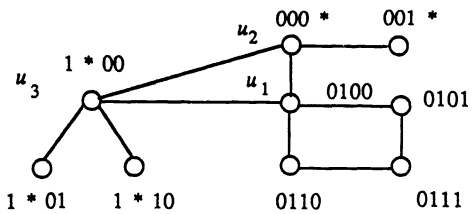
(a) An example graph G.



(b) The encoding of G_S.



(c) The encoding of G_1, G_2 and G_3.



(d) The encoding of G.

FIG. 5. *An illustrative example for Theorem* 3.

It is important to note that there does not exist any bound tighter than the upper bound provided in Theorem 3. This can be proved by showing the existence of some graphs for which the equality relation in Theorem 3 holds. For example, if $G_i = Q_p$ for $1 \leqq i \leqq |V_S|$ and some nonnegative integer p and $G_S = Q_m$, then $\text{wd}(G) = \text{wd}(G_i) + m$. Furthermore, the above theorem and Proposition 1 lead to the following corollary.

COROLLARY 3.1. *Let G_i, $1 \leqq i \leqq k$, be disjoint graphs and $G = \cup_{i=1}^{k} G_i$. Then,* $\text{wd}(G) \leqq \max_{1 \leqq i \leqq k} \{\text{wd}(G_i)\} + \lceil \log_2 k \rceil$.

Since every edge in a tree is a bridge, the following corollary, an immediate result of Theorem 3, can be used to determine a tighter upper bound for the weak cubical dimension of a tree.

COROLLARY 3.2. *Let $c_1(T)$ and $c_2(T)$ denote the two attached trees of the centroid edge of a tree T. Then,* $\text{wd}(T) \leqq \max\{\text{wd}(c_1(T)), \text{wd}(c_2(T))\} + 1$.

As it will be shown in § 4, Corollary 3.2 can be applied to implement a fast algorithm for the RS embedding of a given tree. In addition, the effects of join and product operations on the weak cubical dimension of graphs can be described below by Theorems 4 and 5.

THEOREM 4. $\text{wd}(G_1 + G_2) \leqq \text{wd}(G_1) + \text{wd}(G_2) + 1$.

Proof. Let $D_{G_j}(w)$ denote the address of $w \in G_j$, $j = 1, 2$, before a join operation. Address each node w in $G = G_1 + G_2$ according to the following rules:

(1) If $w \in V_1$, then $D_G(w) = 0* \cdots * D_{G_1}(w)$, which contains $\text{wd}(G_2)$ consecutive $*$'s before $D_{G_1}(w)$.

(2) If $w \in V_2$, then $D_G(w) = 1 D_{G_2}(w) * \cdots *$, which contains $\text{wd}(G_1)$ consecutive $*$'s after $D_{G_2}(w)$.

Clearly, the above addressing scheme, having length $\text{wd}(G_1) + \text{wd}(G_2) + 1$, not only preserves the original adjacency in G_1 and G_2, but also joins every pair of nodes (u_1, u_2), $u_1 \in V_1$, $u_2 \in V_2$. □

Note that Theorem 4 provides the best upper bound, since there exist some graphs for which the equality relation in Theorem 4 holds, e.g., $\text{wd}(Q_1 + Q_2) = \text{wd}(Q_1) + \text{wd}(Q_2) + 1$.

COROLLARY 4.1. *Let $\{V_1, V_2\}$ be a partition of the node set of a graph G_A, i.e., $V_1 \cap V_2 = \varnothing$ and $V_1 \cup V_2 = V_A$. Let the induced subgraphs of G_A with the node sets V_1 and V_2 be G_{I_1} and G_{I_2}, respectively. Then,* $\text{wd}(G_A) \leqq \text{wd}(G_{I_1}) + \text{wd}(G_{I_2}) + 1$.

Proof. Since $G_A \subseteq G_{I_1} + G_{I_2}$, the inequality $\text{wd}(G_A) \leqq \text{wd}(G_{I_1} + G_{I_2}) \leqq \text{wd}(G_{I_1}) + \text{wd}(G_{I_2}) + 1$ follows from Proposition 1 and Theorem 4. □

Let $G_{I_{A-S}}$ denote the induced subgraph of G_A with the node set $V_A - V_S$ where $V_S \subseteq V_A$. Then, we have the following corollary.

COROLLARY 4.2. $\text{wd}(G_A) \leqq \text{wd}(G_{I_{A-S}}) + |V_S|$.

Proof. Let G_{I_S} be the induced subgraph of G_A with V_S. From Corollary 4.1, $\text{wd}(G_A) \leqq \text{wd}(G_{I_S}) + \text{wd}(G_{I_{A-S}}) + 1$. In addition, we get $\text{wd}(G_{I_S}) \leqq |V_S| - 1$ from Corollary 2.2, and thus, this corollary follows. □

Using Corollaries 4.1 and 4.2, in § 4 we shall propose two fast algorithms for the RS embedding of a given graph. The relationship between the weak cubical dimensions of several graphs and that of their union can be described by the following corollary.

COROLLARY 4.3. *Let $G = \cup_{i=1}^{m} G_i$. Then,* $\text{wd}(G) \leqq \sum_{i=1}^{m} \text{wd}(G_i) + m - 1$.

Proof. First, prove the inequality $\text{wd}(G_1 \cup G_2) \leqq \text{wd}(G_1) + \text{wd}(G_2) + 1$. Let G_{I^*} be the induced subgraph of G_2 with the node set $V_2 - V_1$. Clearly, $G_1 \cup G_2 \subseteq G_1 + G_{I^*}$. Then, the inequality, $\text{wd}(G_1 \cup G_2) \leqq \text{wd}(G_1) + \text{wd}(G_{I^*}) + 1 \leqq \text{wd}(G_1) + \text{wd}(G_2) + 1$, follows from Theorem 4 and Proposition 1. The corollary follows by applying this inequality repeatedly. □

It is interesting to compare Corollary 4.3 with Corollary 3.1 that is applicable to disjoint graphs only. This result agrees with our intuition, since there are fewer restrictions in the RS embedding of disjoint graphs. Moreover, we have the following corollary for the complement of a graph.

COROLLARY 4.4. *Let G be a graph with n nodes. Then,* $\text{wd}(G)+\text{wd}(\bar{G}) \geqq n-2$.

Proof. Since $K_n = G \cup \bar{G}$, we get $n-1 = \text{wd}(K_n) = \text{wd}(G \cup \bar{G}) \leqq \text{wd}(G) + \text{wd}(\bar{G})+1$. □

Corollary 4.4 can sometimes be used to determine tighter bounds of the weak cubical dimension of a graph. For example, Corollary 2.2 offers a loose lower bound (6) of wd $(\overline{Q_6})$, whereas Corollary 4.4 gives a much tighter lower bound (56) of wd $(\overline{Q_6})$.

COROLLARY 4.5. *Let T be a tree with n nodes. Then,* $\text{wd}(T) \leqq 2\lceil \log_2 n \rceil$.

Proof. Since every tree is a bigraph, there exists an integer m such that T is a subgraph of $K_{n-m,m}$, where $K_{p,q}$ is a complete bigraph [Har69]. Without loss of generality, we can let $m \leqq n/2$. Clearly, $\lceil \log_2 m \rceil \leqq \lceil \log_2 n/2 \rceil = \lceil \log_2 n \rceil - 1$, and $\lceil \log_2 (n-m) \rceil \leqq \lceil \log_2 n \rceil$. Then, we have $\text{wd}(T) \leqq \text{wd}(K_{n-m,m}) \leqq \lceil \log_2 (n-m) \rceil + \lceil \log_2 m \rceil + 1 \leqq \lceil \log_2 n \rceil + \lceil \log_2 n \rceil - 1 + 1 = 2\lceil \log_2 n \rceil$. □

This corollary offers a tighter upper bound of the weak cubical dimension of a tree. Using Corollary 4.5, a fast RS embedding algorithm for a given tree will be developed in § 4.

THEOREM 5. $\text{wd}(G_1 \times G_2) \leqq \text{wd}(G_1) + \text{wd}(G_2)$.

Proof. For all $u_1 \in V_1$, $u_2 \in V_2$, let $D_{G_1}(u_1)$ and $D_{G_2}(u_2)$ be the addresses of u_1 and u_2 before the product operation. Encode the address of a node (u_1, u_2) in $G_1 \times G_2$ with the concatenation of their original addresses, $D_{G_1}(u_1)D_{G_2}(u_2)$, whose length is $\text{wd}(G_1) + \text{wd}(G_2)$. Obviously, the adjacency requirement in $G_1 \times G_2$ is preserved under the above addressing scheme, and thus the theorem follows. □

Note that Theorem 5 also provides the best upper bound. For example, $\text{wd}(Q_r \times Q_s) = \text{wd}(Q_r) + \text{wd}(Q_s)$ for positive integers r and s. It can also be verified that the above addressing schemes are valid for the squashed embedding problem, i.e., $N(G_1 \times G_2) \leqq N(G_1) + N(G_2)$. In addition, from the topology of a hypercube, we have the theorem below.

THEOREM 6. *Let q be an m-dimensional subcube of a Q_n, where $n \geqq m$. Then, q is adjacent to at most $(n-m)2^m$ subcubes within the Q_n.*

Proof. Without loss of generality, we can let the address of q be $00\cdots0*\cdots*$, in which there are $n-m$ consecutive 0's followed by m consecutive *'s. Note that the address of every Q_0 adjacent to q must have one 1 and $(n-m-1)$ 0's in its left $n-m$ bits. Among all Q_0's adjacent to q, there are 2^m different Q_0's with the kth bit equal to 1 for $m+1 \leqq k \leqq n$. Thus, q is adjacent to exactly $(n-m)2^m Q_0$'s. □

In what follows, the number $(n-m)2^m$ will be referred to as the *adjacency number* of q, where q is an m-dimensional subcube of a Q_n.

COROLLARY 6.1. *Let $\{d_i\}$ be the degree sequence of a graph G_A. If wd $(G_A) \leqq m$, then $\sum_{i=1}^{|V_A|} 2^{b_i} \leqq 2^m$, where for each $1 \leqq i \leqq |V_A|$, b_i is the least nonnegative integer such that the adjacency number of $Q_{b_i} \geqq d_i$.*

Proof. From Theorem 6, the dimension of the subcube assigned to a task node n_i with degree d_i cannot be less than b_i. This corollary follows from the fact that the total number of nodes in a Q_m assigned to G_A must be less than or equal to the total number of its nodes, 2^m. □

Since $b_i \geqq 0$, $1 \leqq i \leqq |V_A|$, we have $\sum_{i=1}^{|V_A|} 2^{b_i} \geqq |V_A|$, meaning that using the knowledge of degree sequence provides a tighter lower bound than Corollary 2.2. Moreover, the relationship between the number of edges in a graph and its weak cubical dimension can be described by the following theorem.

THEOREM 7. *Let* $m = \mathrm{wd}(G_A)$ *and* $k = \lfloor \log_2 (2m/|V_A|) \rfloor$. *Then,*

$$|E_A| \leqq \tfrac{1}{2}[(2^{m-k} - |V_A|) \min\{(m-k-1)2^{k+1}, |V_A|-1\} + (2|V_A| - 2^{m-k}) \min\{(m-k)2^k, |V_A|-1\}].$$

Note that Theorem 7 provides a necessary condition for a task graph with a given number of edges to be RS embedded into a cube. This condition provides information useful for the decomposition of a task into (interacting) modules in such a way that the resulting task graph can be embedded into a cube of a given dimension. In order to simplify the proof of Theorem 7, first it is necessary to introduce the following two lemmas.

LEMMA 1. *The maximal adjacency number of a subcube in a* Q_n *is* 2^{n-1}, *which is attained by a subcube of dimension* $n-1$ *or* $n-2$.

Proof. Let $F(k) = (n-k)2^k$. Since $dF(k)/dk = 2^k[(n-k)\log_e 2 - 1] > 0$ for $0 \leqq k \leqq n-2$, and $F(n-1) = F(n-2) = 2^{n-1} > F(n) = 0$, this lemma follows. □

LEMMA 2. *Let* a_i, $1 \leqq i \leqq r$, *be nonnegative integers and* $\sum_{i=1}^{r} 2^{a_i} \leqq 2^m$. *Then,* $f(a_1, a_2, \cdots, a_r) = \sum_{i=1}^{r} (m-a_i)2^{a_i} \leqq 2^{m-k} - r)(m-k-1)2^{k+1} + (2r - 2^{m-k})(m-k)2^k$, *where* $k = \lfloor \log_2 (2^m/r) \rfloor$.

Proof. Let $(a_1^*, a_2^*, \cdots, a_r^*)$ be the vector that maximizes $f(a_1, a_2, \cdots, a_r)$, i.e., $f^* = f(a_1^*, \cdots, a_r^*)$. From the proof of Lemma 1, we know that $g(a_i) = (m-a_i)2^{a_i}$ is a monotonically increasing function in the integer variables a_i, where $1 \leqq a_i \leqq m-1$. Let $a_p^* = \min_{1 \leqq i \leqq r}\{a_i^*\}$ and suppose $2^m - \sum_{i=1}^{r} 2^{a_i^*} > 0$. Then, $2^m - \sum_{i=1}^{r} 2^{a_i^*}$ must be an integral multiple of $2^{a_p^*}$. This is impossible, since the a_p^* in the function f can be replaced with $a_p^* + 1$, resulting in a larger f-value than f^*. Thus, $\sum_{i=1}^{r} 2^{a_i^*} = 2^m$, implying that there exist a_p^* and a_x^*, $p \neq x$, such that $a_p^* = a_x^* = \min_{1 \leqq i \leqq r}\{a_i^*\}$. We claim that $\max_{1 \leqq i \leqq r}\{a_i^*\} - \min_{1 \leqq i \leqq r}\{a_i^*\} \leqq 1$, and then this lemma follows from the fact that $2^{m-k} - r$ variables among a_i^*'s are $k+1$ and $2r - 2^{m-k}$ variables among a_i^*'s are k.

Let $a_y^* = \max_{1 \leqq i \leqq r}\{a_i^*\}$, $a_p^* = a_x^* = \min_{1 \leqq i \leqq r}\{a_i^*\}$ and suppose $a_y^* - a_p^* \geqq 2$. Then, we have $2^{a_y^*} + 2^{a_p^*} + 2^{a_x^*} = 2^{a_y^*-1} + 2^{a_y^*-1} + 2^{a_p^*+1}$ and $(m-a_y^*)2^{a_y^*} + (m-a_p^*)2^{a_p^*} + (m-a_x^*)2^{a_x^*} \leqq (m-a_y^*+1)2^{a_y^*-1} + (m-a_y^*+1)2^{a_y^*-1} + (m-a_p^*-1)2^{a_p^*+1}$. This leads to a contradiction, because a_y^*, a_p^*, and a_x^* in the function f can be replaced by $a_y^* - 1$, $a_y^* - 1$, and $a_p^* + 1$, respectively, yielding a larger f-value than f^*. Therefore, the claim $\max_{1 \leqq i \leqq r}\{a_i^*\} - \min_{1 \leqq i \leqq r}\{a_i^*\} \leqq 1$ is proved and, thus, this lemma follows. □

Proof of Theorem 7. Let a_i be the dimension of the subcube assigned to a task node n_i in G_A, $1 \leqq i \leqq |V_A| = r$. Then, $\sum_{i=1}^{r} 2^{a_i} \leqq 2^m$ follows from the capacity constraint of a Q_m. Note that the adjacency number of the subcube assigned to n_i is $(m-a_i)2^{a_i}$ and the degree of any node in $G_A \leqq |V_A| - 1$. This theorem follows from Lemma 2 and the fact that $\sum_{i=1}^{r} d_i = 2|E_A|$. □

When a graph belongs to some regular families, its weak cubical dimension can be determined by the theorem below.

THEOREM 8. *The weak cubical dimensions of a cycle* C_m, *a path* P_m, *and a star* S_m *can be determined by the following formulas*:

(i) $\mathrm{wd}(C_m) = \lceil \log_2 m \rceil$;

(ii) $\mathrm{wd}(P_m) = \lceil \log_2 m \rceil$;

(iii) $\mathrm{wd}(S_m) = \lceil \log_2 (m-1) \rceil + 1$.

Proof. Consider (i) first. Clearly, $\mathrm{wd}(C_m) \geqq \lceil \log_2 m \rceil \equiv k$. From the existence of Hamiltonian cycles in a Q_k, we know that a C_m can be RS embedded into a Q_k by embedding $2^k - m$ nodes of the C_m into Q_1's and $2m - 2^k$ nodes of the C_m into Q_0's, and thus (i) is proved. Part (ii) follows from (i) immediately.

Consider (iii). Let δ_k be a trivial graph with k nodes and no edges. Note that $S_m = \delta_{m-1} + \delta_1$ and $\mathrm{wd}(\delta_k) = \lceil \log_2 k \rceil$. Then, we have $\mathrm{wd}(S_m) \leqq \lceil \log_2 (m-1) \rceil + 1$ by

Theorem 4. From Lemma 1, we know that the maximal adjacency number of a subcube in a $Q_{\lceil \log_2(m-1) \rceil}$ is $2^{\lceil \log_2(m-1) \rceil - 1} < m-1$. Thus, $\text{wd}(S_m) > \lceil \log_2(m-1) \rceil$ and (iii) follows. □

COROLLARY 8.1. *Let $m_{c\times d}$ denote a $(c\times d)$-dimensional mesh. Then,* $\text{wd}(m_{c\times d}) \leqq \lceil \log_2 c \rceil + \lceil \log_2 d \rceil$.

Proof. Since a $(c\times d)$-dimensional mesh is $P_c \times P_d$, this corollary follows from Theorem 5 and (ii) of Theorem 8. □

Due to its nature of NP-completeness, the weak cubical dimension of a graph is in general very difficult to characterize. However, as we shall show in the following section, the mathematical properties derived in this section can play a significant role in designing efficient algorithms for the RS embedding of a given graph.

4. Algorithms for relaxed squashed embedding. The mathematical properties derived in § 3 are applied to the design of algorithms for the RS embedding. Fast algorithms of polynomial time complexity that are efficient but may not provide the minimal cube required for a given task graph are presented first. Then, a heuristic search algorithm is developed to determine the weak cubical dimension of a graph.

4.1. Fast algorithms for RS-embedding. Since every tree is a bigraph, we have an efficient addressing scheme for a tree with n nodes as described below.

ALGORITHM $A_1(T)$/*. This algorithm uses the property that every tree T is a bigraph and determines an efficient addressing scheme for T.*/

Step (1). Choose an arbitrary node in T. Label it with a symbol +.

Step (2). Label with −'s all the nodes adjacent to each node labeled with +. **If** every node in T has been labeled with + or − **then** goto Step (4).

Step (3). Label with +'s all the nodes adjacent to each node labeled with −. **If** every node in T has been labeled with + or − **then** goto Step (4) **else** goto Step (2).

Step (4). Suppose there are j nodes with + and k nodes labeled with −. Then, encode all the nodes labeled with + with $0*\cdots*B^{(+)}(i)$, $0 \leqq i \leqq j-1$, where $B^{(+)}(i)$ is a binary representation of the number i with $\lceil \log_2 j \rceil$ bits, which follows $\lceil \log_2 k \rceil$ *'s. Also, encode all the nodes labeled with − with $1B^{(-)}(i)*\cdots*$, $0 \leqq i \leqq k-1$, where $B^{(-)}$(i) is a binary representation of the number i with $\lceil \log_2 k \rceil$ bits, followed by $\lceil \log_2 j \rceil$ *'s.

By Corollary 4.5, the length of the above addressing scheme must be less than or equal to $2\lceil \log_2 n \rceil$. (This, in general, is significantly less than $n-1$ for a large n.) Although the required length of the addressing scheme used in A_1 may be larger than the weak cubical dimension of the tree, A_1 is favorable in some cases due to its *linear* complexity.

Corollary 3.2 suggests the following algorithm that also determines a cube required to accommodate a tree.

ALGORITHM $A_2(T)$/*. This algorithm determines the dimension of a cube to accommodate a task tree T.*/

Step (1). **If** T is a star or a path **then** determine $\text{wd}(T)$ by Theorem 8 and return $\text{wd}(T)$ **else** compute the weight of each edge and determine the centroid edge of the tree.

Step (2). Let T_1 and T_2 be the two attached trees of the centroid edge of T. Return $\max\{A_2(T_1), A_2(T_2)\}+1$.

A_2 is recursive and uses the divide-and-conquer technique. We decompose a tree by removing its centroid edge first, and then continue to decompose the remaining

trees in the same way until only stars or paths are left, whose weak cubical dimension can be determined by Theorem 8. An illustrative example for this algorithm can be found in § 5. Note that the complexity of A_2 depends on the degree of sophistication in the way of determining the centroid edge. Nevertheless, it is easy to verify that A_2 requires only polynomial time.

Consider the case when the task graph is an *arbitrary* graph. Clearly, using Corollary 2.1, we can derive a straightforward algorithm for the RS embedding of each graph: address any first two nodes with $0\cdots0$ and $0\cdots01$, respectively, each of which consists of $n-1$ bits, and then the kth node, $3 \leqq k \leqq n$, with $0\cdots01*\cdots*$ that consists of $n-k$ consecutive 0's and $k-2$ consecutive $*$'s. However, despite its linear complexity, this naive algorithm is not used for a better system utilization. Instead, we present Algorithm A_3 below that is derived from Corollary 4.2.

ALGORITHM $A_3(G)$/*. Using the technique of node-removing, this is a fast algorithm to determine the size of the cube required for a given task graph.*/

Step (1). Let n^* be the node with the largest degree among all the nodes in G. **If** $d(n^*) \leqq 2$ **then** goto Step (2) **else** goto Step (3).

Step (2). Determine all the cycles in G, denoted by $C^1, C^2, \cdots, C^m$, and the least integer p such that $2^p \geqq \sum_{i=1}^{m} 2^{\lceil \log_2 |C^i| \rceil} + 2^{\lceil \log_2 (|V| - \sum_{i=1}^{m} |C^i|) \rceil}$, where $|C^i|$ is the number of nodes in the cycle C^i. Return p.

Step (3). Let $G_1 := G - n^*$ and return $A_3(G_1)+1$.

Using A_3, a graph is reduced by removing the node with the largest degree from the graph. The reduction steps are performed repeatedly until the graph is reduced to the extent that it contains only disjoint cycles and paths. By Corollary 4.2, the size determined in Step (2) plus the total number of nodes removed will be the dimension of a cube required to accommodate the original task graph. Note that in A_2 and A_3, it is required to determine if a graph belongs to some families of graph such as paths, stars, and cycles. For this purpose, an adjacency matrix [Har69] can be used to represent each task graph, since these families of graph can be easily identified if they are represented with adjacency matrices. Moreover, by Corollary 4.1 we can modify Step (3) of A_3 as follows and get a generalized version of A_3, called Algorithm A_4.

Step (3′). Partition V into V_1 and V_2. Let G_{I_1} and G_{I_2} be, respectively, the induced subgraphs of G with the node sets V_1 and V_2. Return $A_4(G_{I_1}) + A_4(G_{I_2}) + 1$.

Several heuristic approaches can be employed in determining how to partition the node set V into V_1 and V_2 in Step (3′) of A_4. Clearly, a more sophisticated method will lead to an addressing scheme with a shorter length at the cost of higher computational costs of A_4.

Although the above proposed algorithms are efficient in determining the required cube for a given graph, the resulting cube may not be minimal. As far as the system utilization is concerned, we want to find the minimal subcube required for a given task graph. This is explored in § 4.2.

4.2. An algorithm for determining the weak cubical dimension. To determine the weak cubical dimension of a task graph, first we present an algorithm that determines whether or not there is an RS embedding from a given task graph into a cube. Then, the algorithm is applied to determine the weak cubical dimension of the graph. To facilitate our discussion, we label the task graph as follows. Label the node with the largest degree with n_1 and let $X := \{n_1\}$ and $i := 2$. Then, among all the nodes that are adjacent to any node in X and are not in X, choose a node with the largest degree

and label this node with n_i. Then, let $X := X \cup \{n_i\}$ and $i := i+1$. Repeat the same procedure until all nodes are labeled.

Now, we want to assign a subcube within the n-cube to each node in a task graph, node by node, subject to the adjacency requirement in the RS embedding. Clearly, this problem is a graph matching problem and can be solved by a state-space search similar to the one in [ShT85]. In what follows, we shall formulate a heuristic function, and the A^* search algorithm [Nil80] will then be used to determine the existence of an RS embedding from a given graph into a cube. The following definitions are necessary to facilitate our presentation.

DEFINITION 2. The *merge* operation, denoted by $\odot$, of two sets of subcubes, U_1 and U_2, is defined as

$$U_1 \odot U_2 = \{\tau \mid \tau = \text{lcm}(\alpha, \beta) \text{ for } \alpha \in U_1 \text{ and } \beta \in U_2\}.$$

The merge operation among $k \geqq 2$ sets of subcubes is written as $\odot_{1 \leqq i \leqq k} U_i$.

DEFINITION 3. The *exclusion* operation of two sets of subcubes, U_1 and U_2, is defined as

$$U_1 - U_2 = \{r \mid r \in U_1 \text{ and } \gcd(t, r) = \varnothing, \forall t \in U_2\}.$$

DEFINITION 4. The *reduced set* of a set of subcubes U is defined as

$$\text{Rd}(U) = U - \{r \mid r \in U \text{ and } t \subset r \text{ for some } t \in U\}.$$

For example, let $U_1 = \{0{**}, 0{*}0, 01{*}, 001\}$, $U_2 = \{00{*}, 10{*}\}$, and $U_3 = \{001\}$. Then, $\text{Rd}(U_1) = \{0{*}0, 01{*}, 001\}$, $U_1 - U_2 = \{01{*}\}$, and $U_2 \odot U_3 = \{00{*}, {*}0{*}\}$. Recall that $B(n_i)$ is the set of all nodes adjacent to n_i in the task graph G_T. Let M^i denote the partial mapping for the task node n_j, $1 \leqq j \leqq i$. Let $A_{n_j}^{(i)}$ be the set of unoccupied Q_0's that are adjacent to $D(n_j)$ under the partial mapping M^i. Also, define the set of *essential subcubes* of n_j under the partial mapping M^i, denoted by $E_{n_j}^{(i)}$, as the reduced set of unoccupied subcubes that are adjacent to the subcubes assigned to all $n_k \in B(n_j)$, $1 \leqq k \leqq i$. For example, suppose that in the graph of Fig. 3, we have $D(n_1) = 00{*}$, $D(n_2) = 010$. Then, $A_{n_1}^{(2)} = \{011, 100, 101\}$, $A_{n_2}^{(2)} = \{110, 011\}$, and $E_{n_3}^{(2)} = \{011, 1{*}0\}$. That is, the subcube to be assigned to n_3 should contain either 011 or $1{*}0$ to satisfy the adjacency requirement. Then, the $E_{n_k}^{(i)}$ generated under M^i can be expressed as follows:

$$E_{n_k}^{(i)} = Rd\left(\bigodot_{\substack{n_j \in B(n_k) \\ 1 \leqq j \leqq i}} A_{n_j}^{(i)} \right) - \bigcup_{j=1}^{i} D(n_j) \quad \forall k > i. \tag{1}$$

From this formula, we can determine the sets of all essential subcubes of unassigned task nodes. Note that $E_{n_k}^{(i)}$ is determined by $A_{n_j}^{(i)}$, for all $n_j \in B(n_k)$, and the adjacency requirement, and the term $\cup_{j=1}^{i} D(n_j)$ in equation (1) is necessary to exclude the possibility of allocating the already occupied subcubes. Given a partial mapping M^i, the set of all possible subcubes that can be assigned to the task node n_{i+1} is represented by

$$\text{Sp}(E_{n_{i+1}}^{(i)}) = \left\{ q \;\middle|\; \text{there exists } t \in E_{n_{i+1}}^{(i)},\ t \subseteq q \text{ and } \sum_{j=1}^{i} |D(n_j)| + |q| < 2^n - (|V_T| - i - 1) \right\} - \bigcup_{j=1}^{i} D(n_j). \tag{2}$$

The inequality in equation (2) is to ensure that after the allocation of q to n_{i+1}, there is a sufficient number of nodes in the Q_n to be assigned to the remaining task nodes. From equation (2), it is easy to see that *both* (i) more subcubes in $E_{n_{i+1}}^{(i)}$ *and* (ii) subcubes of smaller dimensions in $E_{n_{i+1}}^{(i)}$ will allow for more freedom in allocating

a required subcube to n_{i+1}. This in turn implies that the sets of essential subcubes of unassigned nodes can be used in determining the heuristic value of the node in the search tree associated with the partial mapping made thus far.

Suppose that a node p in the search tree corresponds to the allocation of a subcube q to the task node n_i. Then, $A_{n_i}^{(i)}$ can be determined by the method introduced in the proof of Theorem 6, and the sets $A_{n_k}^{(i)}$, $1 \leqq k < i$, can be updated from their predecessors by equation (3) below. They are in turn used to determine $E_{n_k}^{(i)}$, $k > i$, by using equation (1).

$$A_{n_k}^{(i)} = A_{n_k}^{(i-1)} - \{q\}, \qquad 1 \leqq k < i. \tag{3}$$

Combining all the results and findings discussed thus far, a heuristic function for each node p in the search tree can be contructed as follows:

$$\begin{aligned} &f(p) = g(p) + h(p) \text{ where } g(p) = i2^n, \\ &h(p) = \sum_{i+1}^{|V_s|} V(E_{n_k}^{(i)}), \quad \text{and} \quad V(E_{n_k}^{(i)}) = \sum_{t \in E_{n_k}^{(i)}} \frac{1}{2^{|t|}}. \end{aligned} \tag{4}$$

Note that the heuristic value (or h-value) of a node p is defined so that *both* more subcubes in $E_{n_k}^{(i)}$ *and* subcubes of smaller dimensions in $E_{n_k}^{(i)}$, $k > i$, will result in a larger h-value of p. Applying the above heuristic function to the A^* search algorithm, we propose the following RS-embedding algorithm.

ALGORITHM RS-embedding $(G_T, k)/*$. This algorithm determines the existence of an RS embedding from a task graph G_T into a Q_k.*/

Step (1). Without loss of generality, let the list OPEN be $\{00\cdots0, 0\cdots0*, \cdots, 0*\cdots*\}$ consisting of k strings of length $k-1$ each. Check the validity of these nodes by using Theorem 6. Compute equations (1), (3), and (4) for nodes in the list OPEN.

Step (2). If OPEN $= \varnothing$, report *false* and exit. Determine the node p with the maximal f-value from the list OPEN. Remove it from OPEN and put it into the list CLOSE. If node p is associated with the allocation of the last node, report *true* and exit.

Step (3). Determine the successors of p by equation (2). Check the validity of successors by using Theorem 6, evaluate equations (1), (3), and (4) for valid nodes, and put these nodes in the list OPEN.

Step (4). Go to Step 2.

According to the formulation of the heuristic function, the h-value of any node in the search tree must be less than 2^n. This means that our heuristic function satisfies the monotone restriction [Nil80]. In other words, the goal nodes whose distances from the root node are $|V_T|$ have the maximal f-value. Thus, if there exist goal nodes in the search tree, then one of them should be reached in a finite number of steps. Note that there may be more than one goal node in the search tree. However, we are concerned only with the existence of such nodes, rather than the number of such nodes in the search tree.

Using the RS embedding algorithm, we can determine the existence of an RS embedding of a given graph into a cube. For some graphs whose weak cubical dimensions are in a narrow range, a linear search algorithm is suggested as follows. Since an unsuccessful search usually involves more computational costs than a successful one, the linear search algorithm is designed to perform a top-down search for the weak cubical dimension of a graph. Let *ub* and *lb* be, respectively, the upper and lower bounds of the weak cubical dimension of the graph determined by the mathematical properties in § 3. Using a linear search, the expected number of times to execute

the RS embedding algorithm is $(ub - lb + 1)/2$, containing $(ub - lb - 1)/2$ successful searches and one unsuccessful search.

On the other hand, the bounds for the weak cubical dimension of some other graphs may be quite loose, making any linear search algorithm inefficient. For those graphs, a binary search algorithm is suggested. Then, the expected number of times used to execute the RS embedding algorithm becomes $\lceil \log_2 (ub - lb + 1) \rceil$, in which successful and unsuccessful searches have the same likelihood of occurrence.

5. Examples. In this section, examples are presented to illustrate the application of the results developed in § 3 and the execution of the algorithms proposed in § 4.

Example 1. Consider the example graph G shown in Fig. 6. From Corollary 2.2, we have $\lceil \log_2 6 \rceil = 3 \leqq \text{wd}(G) \leqq 6 - 1 = 5$. Moreover, from Corollary 6.1 we get $\text{wd}(G) \neq 3$. Let $V_1 = \{n_1, n_2, n_5, n_6\}$ and $V_2 = \{n_3, n_4\}$. Denote the induced subgraph with the node in V_j by $G_{I_j}, j = 1, 2$. Clearly, $G_{I_1} = C_4$ and $G_{I_2} = P_2$. Thus, from Corollary 4.1 we obtain $\text{wd}(G) \leqq \text{wd}(C_4) + \text{wd}(P_2) + 1 = 2 + 1 + 1$. From the above results, we get $\text{wd}(G) = 4$.

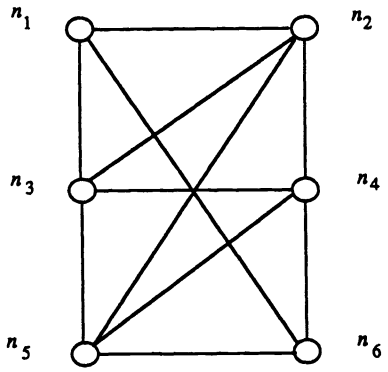


FIG. 6. *An example graph G.*

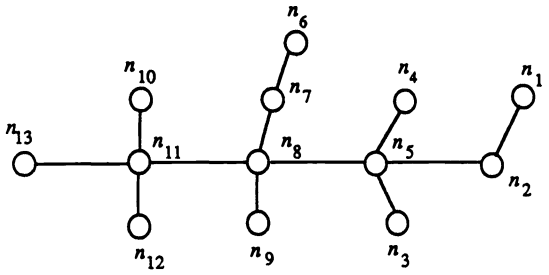
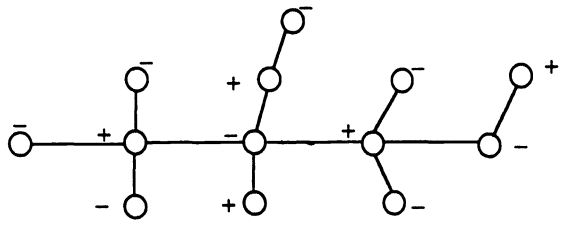
Example 2. Consider the task tree shown in Fig. 7(a). Using A_1, we obtained a labeled tree as shown in Fig. 7(b), and then derived an addressing scheme with the length $\lceil \log_2 5 \rceil + \lceil \log_2 8 \rceil + 1 = 7$. For example, under this addressing scheme the assigned address of n_5, the second node labeled with +, is 0010*** and that of n_8, the fourth node labeled with −, is 1***100.

The application of A_2 to the tree in Fig. 7(a) can be described by Fig. 8. The tree with the weight of each edge specified is given in Fig. 8(a), and the operations of A_2 are illustrated by the binary tree in Fig. 8(b). Each internal node in Fig. 8(b) has two children that are the disjoint trees resulting from the removal of its centroid edge. For example, T_1 and T_2 are the two attached trees of the edge (n_5, n_8), while n_8 is in T_1 and n_5 in T_2. Using A_2, we get $A_2(T_3) = 3$, $A_2(T_4) = 2$, $A_2(T_5) = 2$, $A_2(T_6) = 1$, $A_2(T_1) = 4$, $A_2(T_2) = 3$, and $A_2(T) = 5$.

Example 3. Consider the example graph $G = (V, E)$ of Fig. 3. Again, we have $\text{wd}(G) \geqq \lceil \log_2 |V| \rceil = 3$ from Corollary 2.2. In addition, the induced subgraph of G with the node set $\{n_2, n_3, n_4, n_5, n_6\}$ is P_5 whose weak cubical dimension is 3. From Corollary 4.2, we get $3 \leqq \text{wd}(G) \leqq 4$. To determine $\text{wd}(G)$, we must apply the RS embedding algorithm.



(a) An example tree T.



(b) The labeling of the tree T.

FIG. 7. *An example of labeling a tree.*

Figure 9 shows the state-space search tree for a Q_3 to accommodate the task graph. Let L denote the list of occupied subcubes. By using the heuristic search algorithm in § 4.2, initially we get OPEN = {000, 00*, 0**}. Note that the allocation $(n_1 \leftarrow 000)$ and $(n_1 \leftarrow 0**)$ will be eliminated by Theorem 6 and equation (2), respectively. Thus, node A is the only node to be expanded. According to equations (1), (3), and (4), we have the following:

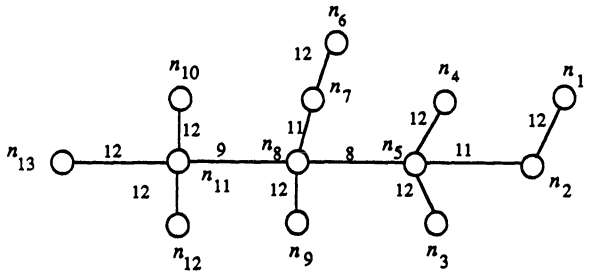
(1) Node $A(n_1 \leftarrow 00*)$: $A^{(1)}_{n_1} = E^{(1)}_{n_2} = E^{(1)}_{n_3} = E^{(1)}_{n_4} = E^{(1)}_{n_6} = \{010, 011, 100, 101\}$, $E^{(1)}_{n_5} = \{010, 011, 100, 101, 110, 111\}$, and $L = \{00*\}$. $g(A) = 2^3$, $h(A) = 4+4+4+4+6$, and $f(A) = 30$.

Under the allocation $M^1 = (n_1 \leftarrow 00*)$, we get $\mathrm{Sp}(E^{(1)}_{n_2}) = \{010, 011, 101, 100, 01*, 10*, *10, *11, 1*0, 1*1\}$ from equation (2). Due to the symmetry, only the computation for the nodes B, C, and D is shown below.

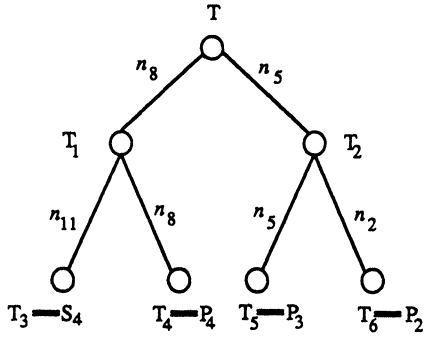
(2) Node B $(n_2 \leftarrow 010)$: $A^{(2)}_{n_1} = \{011, 100, 101\}$, $A^{(2)}_{n_2} = \{011, 110\}$, $E^{(2)}_{n_3} = \mathrm{Rd}(A^{(2)}_{n_1} \odot A^{(2)}_{n_2}) = \{011, 1*0\}$, $E^{(2)}_{n_4} = E^{(2)}_{n_6} = \{011, 100, 101\}$, $E^{(2)}_{n_5} = \{011, 110\}$, and $L = \{00*, 010\}$. $g(B) = 2^3 2 = 16$, $h(B) = 1\frac{1}{2}+3+2+3$, and $f(B) = 25\frac{1}{2}$.

(3) Node C $(n_2 \leftarrow 01*)$: $A^{(2)}_{n_1} = \{100, 101\}$, $A^{(2)}_{n_2} = \{110, 111\}$, $E^{(2)}_{n_3} = \mathrm{Rd}(A^{(2)}_{n_1} \odot A^{(2)}_{n_2}) = \{1*0, 1*1\}$, $E^{(2)}_{n_4} = E^{(2)}_{n_6} = \{100, 101\}$, $E^{(2)}_{n_5} = \{110, 111\}$, and $L = \{00*, 01*\}$. $g(C) = 2^3 2 = 16$, $h(C) = \frac{1}{2}+\frac{1}{2}+2+2+2$, and $f(C) = 23$.

(4) Node D $(n_2 \leftarrow *10)$: $A^{(2)}_{n_1} = \{011, 100, 101\}$, $A^{(2)}_{n_2} = \{100, 011, 111\}$, $E^{(2)}_{n_3} = \{011, 100, 1*1\}$, $E^{(2)}_{n_4} = E^{(2)}_{n_6} = \{101, 100, 011\}$, $E^{(2)}_{n_5} = \{100, 011, 111\}$, and $L = \{00*, *10\}$. $g(D) = 2^3 2 = 16$, $h(D) = 2\frac{1}{2}+3+3+3$, and $f(D) = 27\frac{1}{2}$.



(a) A tree with the weight of each edge specified.



(b) The determination of the subcube required for a tree using divide and conquer.

FIG. 8. *An application example for Corollary* 3.2.

Since node D has the maximal f-value among the three nodes, D is now the next node to be expanded. Note that under the partial mapping $M^2 = (n_1 \leftarrow 00*, n_2 \leftarrow *10)$, $\mathrm{Sp}(E^{(2)}_{n_3}) = \{011, 100\}$. Then, using the same procedure, the remaining computation for the heuristic search algorithm is given below.

(5) Node E $(n_3 \leftarrow 011)$: $g(E) = 2^3 3 = 24$, $h(E) = \frac{1}{2} + 2 + 2$ and $f(E) = 28\frac{1}{2}$.

(6) Node F $(n_3 \leftarrow 100)$: $g(F) = 2^3 3 = 24$, $h(F) = 1 + 2 + 2$ and $f(F) = 29$.

Node F is now the next node to be expanded. Using the same procedure, it is easy to verify that all the children of nodes F and E can be pruned, and node B becomes the next node to be expanded, since $f(B) > f(C)$. Thus, $M^2 = (n_1 \leftarrow 00*, n_2 \leftarrow 010)$, leading to the following results: $f(G) = 27\frac{1}{2}$, $f(H) = 28\frac{1}{2}$, and $f(I) = 28\frac{1}{2}$.

Now, node H is to be expanded. Continuing the same procedure, we obtain the following results: $f(J) = 34$, $f(K) = 41$, and $f(L) = 48$.

Since the node L is associated with the allocation of the last node, *true* will be reported, meaning that an RS embedding of G into Q_3 has been found and $\mathrm{wd}(G) = 3$. It is easy to see that the proposed heuristic function plays an important role in guiding and, thus, speeding up the state-space search. Use of the f-value of a node as an indication of the likelihood for the node to lead to a successful mapping results in a significant improvement over a blind search. However, as the size of the task graph increases, large amounts of computation will be required for the node expansion of the heuristic search, and the necessity of applying this state search algorithm to every graph calls for an optimization in some sense. For example, depending on the system's objective function, one can strike a compromise between the system utilization and the computational cost.

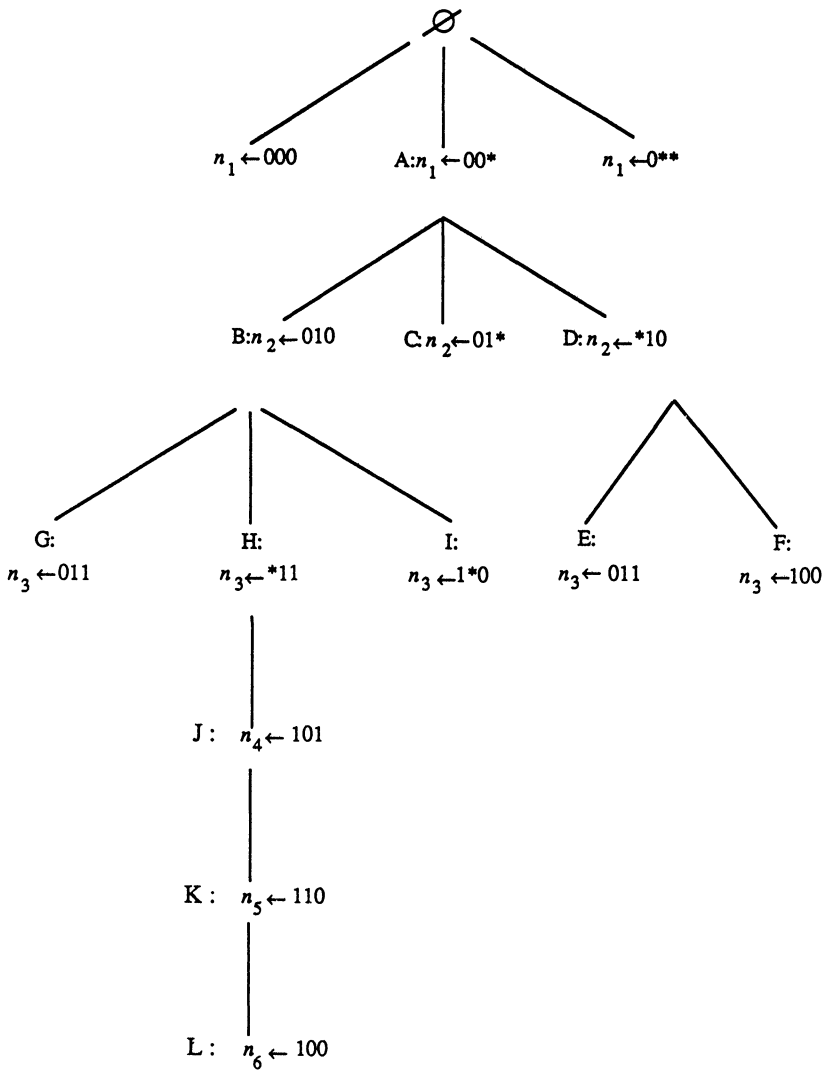


FIG. 9. *Part of the search tree.*

6. Discussion and conclusion. We have proposed and investigated a new type of embedding, called the RS embedding, that was motivated by the problem of allocating tasks in a hypercube multicomputer. Several mathematical properties for the weak cubical dimension have been derived that are not only applied to develop fast algorithms for the RS embedding, but also used to guide the heuristic search for an RS embedding.

The problem studied in this paper can be generalized by considering both the computation load of each module and the communication load between modules in a task graph. The task graph can then be represented by a labeled graph. The number assigned to a node of the graph denotes the dimension of a subcube required for the corresponding module to perform the computation load of the module. The number assigned to an edge of the task graph represents the required number of communication links between the two subcubes assigned to the two task nodes incident to this edge to provide enough communication capacity between them. Note that two adjacent

subcubes could have different numbers of connecting links. For example, *10* and 00*0 are connected by a link (0100, 0000), and 010* and 00** are connected by two links, (0100, 0000) and (0101, 0001). Thus, the constraint treated in this paper is a special case of the generalized version, since one is assigned to every node and every edge of the task graph.

Clearly, the inclusion of computation and communication loads of modules increases the number of constraints to meet, and thus, makes the RS embedding more realistic but complicated.

SIMPLE FAST ALGORITHMS FOR THE EDITING DISTANCE BETWEEN TREES AND RELATED PROBLEMS*

KAIZHONG ZHANG† AND DENNIS SHASHA‡

Abstract. Ordered labeled trees are trees in which the left-to-right order among siblings is significant. The distance between two ordered trees is considered to be the weighted number of edit operations (insert, delete, and modify) to transform one tree to another. The problem of approximate tree matching is also considered. Specifically, algorithms are designed to answer the following kinds of questions:

1. What is the distance between two trees?

2. What is the minimum distance between T_1 and T_2 when zero or more subtrees can be removed from T_2?

3. Let the pruning of a tree at node n mean removing all the descendants of node n. The analogous question for prunings as for subtrees is answered.

A dynamic programming algorithm is presented to solve the three questions in sequential time $O(|T_1| \times |T_2| \times \min(depth(T_1), leaves(T_1)) \times \min(depth(T_2), leaves(T_2)))$ and space $O(|T_1| \times |T_2|)$ compared with $O(|T_1| \times |T_2| \times (depth(T_1))^2 \times (depth(T_2))^2)$ for the best previous published algorithm due to Tai [*J. Assoc. Comput. Mach.*, 26 (1979), pp. 422-433]. Further, the algorithm presented here can be parallelized to give time $O(|T_1| + |T_2|)$.

1. Motivation.

1.1. Applications. Ordered labeled trees are trees whose nodes are labeled and in which the left-to-right order among siblings is significant. As such they can represent grammar parses, image descriptions, and many other phenomena. Comparing such trees is a way to compare scenes, parses, and so on.

As an example, consider the secondary structure comparison problem for RNA. Because RNA is a single strand of nucleotides, it folds back onto itself into a shape that is topologically a tree (called its secondary structure). Each node of this tree contains several nucleotides. Nodes have colorful labels such as "bulge" and "hairpin." Various researchers [ALKBO], [BSSBWD], [DD] have observed that the secondary structure influences translation rates (from RNA to proteins). Because different sequences can produce similar secondary structures [DA], [SK], comparisons among secondary structures are necessary to understanding the comparative functionality of different RNAs. Previous methods for comparing multiple secondary structures of RNA molecules represent the tree structures as parenthesized strings [S88]. These have been recently converted to using our tree distance algorithms.

Currently we are implementing a package containing algorithms described in this paper and some other related algorithms. A preliminary version of the package is being used at the National Cancer Institute for the RNA comparison problem.

1.2. Algorithmic approach. The tree distance problem is harder than the string distance problem. Intuitively, here is why. In the string case, if $S_1[i] = S_2[j]$, then the

distance between $S_1[1..i-1]$ and $S_2[1..j-1]$ is the same as between $S_1[1..i]$ and $S_2[1..j]$. The main difficulty in the tree case is that preserving ancestor relationships in the mapping between trees prevents the analogous implication from holding.

By introducing the distance between ordered forests and careful elimination of certain subtree-to-subtree distance calculations we are able to improve the time and space of best previous published algorithm [T]. Note that the improvement of space for this problem is extremely important in practical applications.

Besides improving on the time and space of the best previous algorithm [T], our algorithm is far simpler to understand and to implement. In style, it resembles algorithms for computing the distance between strings. In fact, the string distance algorithm is a special case of our algorithm when the input is a string.

2. Definitions.

2.1. Edit operations and editing distance between trees. Let us consider three kinds of operations. Changing node n means changing the label on n. Deleting a node n means making the children of n become the children of the parent of n and then removing n. Inserting is the complement of delete. This means that inserting n as the child of n' will make n the parent of a consecutive subsequence of the current children of n'. Figs. 1-3 illustrate these editing operations.

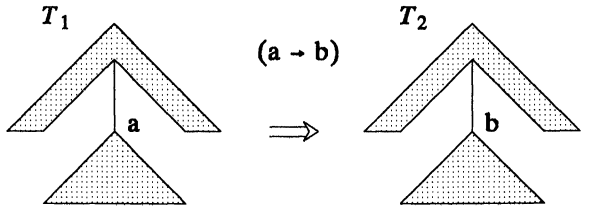

FIG. 1

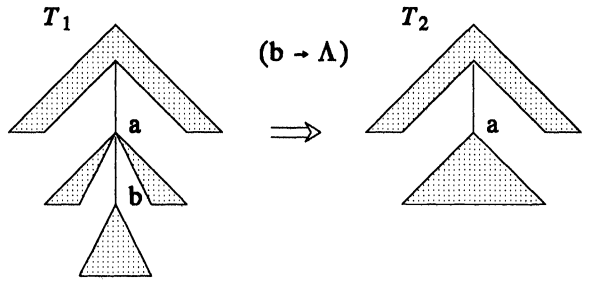

FIG. 2

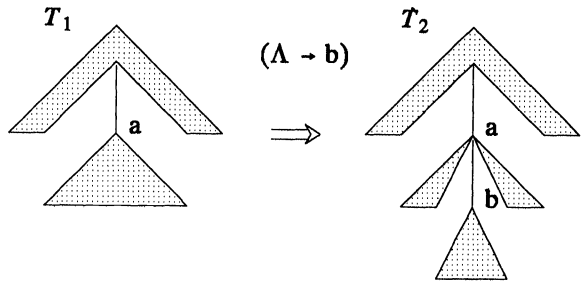

FIG. 3

(1) Change. To change one node label to another.

(2) Delete. To delete a node. (All children of the deleted node b become children of the parent a.)

(3) Insert. To insert a node. (A consecutive sequence of siblings among the children of a become the children of b.)

Following [WF] and [T], we represent an edit operation as a pair $(a, b) \neq (\Lambda, \Lambda)$, sometimes written as $a \to b$, where a is either Λ or a label of a node in tree T_1 and b is either Λ or a label of a node in tree T_2. We call $a \to b$ a change operation if $a \neq \Lambda$ and $b \neq \Lambda$; a delete operation if $b = \Lambda$; and an insert operation if $a = \Lambda$. Since many nodes may have the same label, this notation is potentially ambiguous. It could be made precise by identifying the nodes as well as their labels. However, in this paper, which node is meant will always be clear from the context.

Let S be a sequence $s_1, \cdots, s_k$ of edit operations. An S-derivation from A to B is a sequence of trees $A_0, \cdots, A_k$ such that $A = A_0$, $B = A_k$, and $A_{i-1} \to A_i$ via s_i for $1 \leqq i \leqq k$.

Let γ be a cost function that assigns to each edit operation $a \to b$ a nonnegative real number $\gamma(a \to b)$. This cost can be different for different nodes, so it can be used to give greater weights to, for example, the higher nodes in a tree than to lower nodes.

We constrain γ to be a distance metric. That is,

(i) $\gamma(a \to b) \geqq 0$; $\gamma(a \to a) = 0$

(ii) $\gamma(a \to b) = \gamma(b \to a)$; and

(iii) $\gamma(a \to c) \leqq \gamma(a \to b) + \gamma(b \to c)$.

We extend γ to the sequence S by letting $\gamma(S) = \sum_{i=1}^{i=|S|} \gamma(s_i)$. Formally the distance between T_1 and T_2 is defined as follows:

$$\delta(T_1, T_2) = \min \{\gamma(S) \mid S \text{ is an edit operation sequence taking } T_1 \text{ to } T_2\}.$$

The definition of γ makes δ a distance metric also.

2.2. Mapping. Let T_1 and T_2 be two trees with N_1 and N_2 nodes, respectively. Suppose that we have an ordering for each tree, then $T[i]$ means the ith node of tree T in the given ordering.

The edit operations give rise to a mapping that is a graphical specification of what edit operations apply to each node in the two trees (or two ordered forests). The mapping in Fig. 4 shows a way to transform T_1 to T_2. It corresponds to the sequence (delete (node with label c), insert (node with label c)).

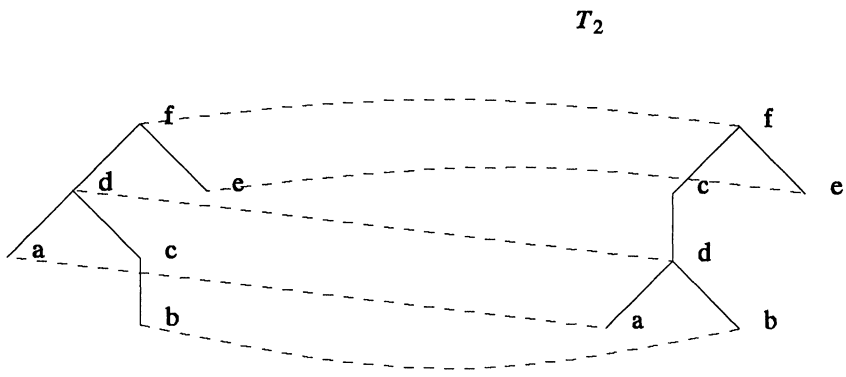

FIG. 4

Consider the diagram of a mapping in Fig. 4. A dotted line from $T_1[i]$ to $T_2[j]$ indicates that $T_1[i]$ should be changed to $T_2[j]$ if $T_1[i] \neq T_2[j]$, or that $T_1[i]$ remains unchanged if $T_1[i] = T_2[j]$. The nodes of T_1 not touched by a dotted line are to be deleted and the nodes of T_2 not touched are to be inserted. The mapping shows a way to transform T_1 to T_2.

Formally we define a triple (M, T_1, T_2) to be a mapping from T_1 to T_2, where M is any set of pair of integers (i, j) satisfying:[1]

(1) $1 \leqq i \leqq N_1, 1 \leqq j \leqq N_2$;

(2) For any pair of (i_1, j_1) and (i_2, j_2) in M,

(a) $i_1 = i_2$ if and only if $j_1 = j_2$ (one-to-one),

(b) $T_1[i_1]$ is to the left of $T_1[i_2]$ if and only if $T_2[j_1]$ is to the left of $T_2[j_2]$ (sibling order preserved),

(c) $T_1[i_1]$ is an ancestor of $T_1[i_2]$ if and only if $T_2[j_1]$ is an ancestor of $T_2[j_2]$ (ancestor order preserved).

We will use M instead of (M, T_1, T_2) if there is no confusion. Let M be a mapping from T_1 to T_2. Let I and J be the sets of nodes in T_1 and T_2, respectively, not touched by any line in M. Then we can define the cost of M:

$$\gamma(M) = \sum_{(i,j) \in M} \gamma(T_1[i] \to T_2[j]) + \sum_{i \in I} \gamma(T_1[i] \to \Lambda) + \sum_{j \in J} \gamma(\Lambda \to T_2[j]).$$

Mappings can be composed. Let M_1 be a mapping from T_1 to T_2 and let M_2 be a mapping from T_2 to T_3. Define

$$M_1 \circ M_2 = \{(i, j) \mid \exists k \text{ s.t. } (i, k) \in M_1 \text{ and } (k, j) \in M_2\}.$$

LEMMA 1. (1) *$M_1 \circ M_2$ is a mapping.*

(2) $\gamma(M_1 \circ M_2) \leqq \gamma(M_1) + \gamma(M_2)$.

Proof. Case (1) follows from the definition of mapping.

(2) Let M_1 be the mapping from T_1 to T_2. Let M_2 be the mapping from T_2 to T_3. Let $M_1 \circ M_2$ be the composed mapping from T_1 to T_3 and let I and J be the corresponding deletion and insertion sets. Three general situations occur. $(i, j) \in M_1 \circ M_2$, $i \in I$, or $j \in J$. In each case this corresponds to an editing operation $\gamma(x \to y)$ where x and y may be nodes or may be Λ. In all such cases, the triangle inequality on the distance metric γ ensures that $\gamma(x \to y) \leqq \gamma(x \to z) + \gamma(z \to y)$. □

The relation between a mapping and a sequence of edit operation is as follows.

LEMMA 2. *Given S, a sequence $s_1, \cdots, s_k$ of edit operations from T_1 to T_2, there exists a mapping M from T_1 to T_2 such that $\gamma(M) \leqq \gamma(S)$. Conversely, for any mapping M, there exists a sequence of editing operations such that $\gamma(S) = \gamma(M)$.*

Proof. The first part can be proved by induction on k. The base case is $k = 1$. This case holds, because any single editing operation preserves the ancestor and sibling relationships in the mapping. In the general case, let S_1 be the sequence $s_1, \cdots, s_{k-1}$ of edit operations. There exist a mapping M_1 such that $\gamma(M_1) \leqq \gamma(S_1)$. Let M_2 be the mapping for s_k. From Lemma 1, we have that

$$\gamma(M_1 \circ M_2) \leqq \gamma(M_1) + \gamma(M_2) \leqq \gamma(S).$$

To construct the sequence of editing operations, simply perform all the deletes indicated by the mapping (i.e., all nodes in T_1 having no lines attached to them are deleted), then all relabellings, then all inserts. □

[1] Note that our definition of mapping is different from the definition in [T]. We believe that our definition is more natural because it does not depend on any traversal ordering of the tree.

Hence, $\delta(T_1, T_2) = \min\{\gamma(M) | M$ is a mapping from T_1 to $T_2\}$.

There has been previous work on this problem. Tai [T] gave the best published algorithm for the problem. [Z83] is an improvement of [T], giving better sequential time and space than [T]. Our new algorithm is much simpler than [T] and [Z83], gives better time and space than both of them, and extends to related problems. The algorithm of Lu [L] does not solve this problem for trees of more than two levels.

3. A simple new algorithm. This algorithm, unlike [T], [L], and [Z83], will, in its intermediate steps, consider the distance between two ordered forests. At first sight one may think that this will complicate the work, but it will in fact make matters easier.

We use a postorder numbering of the nodes in the trees. In the postordering, $T_1[1..i]$ and $T_2[1..j]$ will generally be forests as in Fig. 5. (The edges are those in the subgraph of the tree induced by the vertices.) Fortunately, the definition of mapping for ordered forests is the same as for trees.

3.1. Notation. Let $T[i]$ be the ith node in the tree according to the left-to-right postorder numbering. $l(i)$ is the number of the leftmost leaf descendant of the subtree rooted at $T[i]$. When $T[i]$ is a leaf, $l(i) = i$. The parent of $T[i]$ is denoted $p(i)$. We define $p^0(i) = i, p^1(i) = p(i), p^2(i) = p(p^1(i))$, and so on. Let $anc(i) = \{p^k(i) | 0 \leqq k \leqq depth(i)\}$.

$T[i..j]$ is the ordered subforest of T induced by the nodes numbered i to j inclusive (Fig. 5). If $i > j$, then $T[i..j] = \varnothing$. $T[1..i]$ will be referred to as $forest(i)$, when the tree T referred to is clear. $T[l(i)..i]$ will be referred to as $tree(i)$. $Size(i)$ is the number of nodes in $tree(i)$.

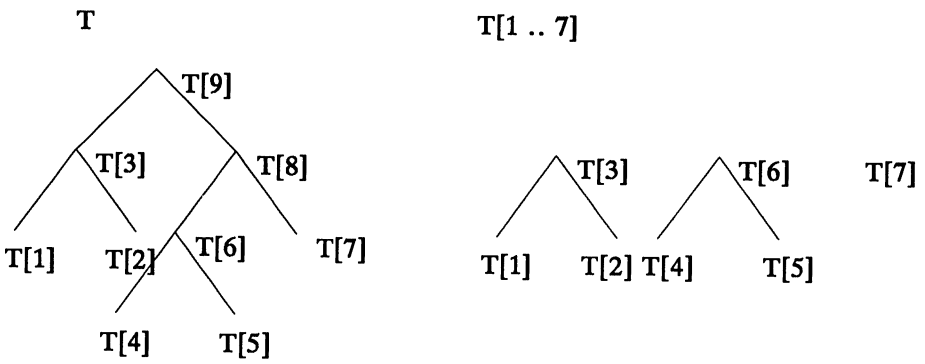

FIG. 5

The distance between $T_1[i'..i]$ and $T_2[j'..j]$ is denoted $forestdist(T_1[i'..i], T_2[j'..j])$ or $forestdist(i'..i, j'..j)$ if the context is clear. We use a more abbreviated notation for certain special cases. The distance between $T_1[1..i]$ and $T_2[1..j]$ is sometimes denoted $forestdist(i, j)$. The distance between the subtree rooted at i and the subtree rooted at j is sometimes denoted $treedist(i, j)$.

3.2. New algorithm. We first present three lemmas and then give our new algorithm. Recall that $anc(i) = \{p^k(i) | 0 \leqq k \leqq depth(i)\}$.

LEMMA 3. (i) $forestdist(\varnothing, \varnothing) = 0$.

(ii) $forestdist(T_1[l(i_1)..i], \varnothing) = forestdist(T_1[l(i_1)..i-1], \varnothing) + \gamma(T_1[i] \to \Lambda)$.

(iii) $forestdist(\varnothing, T_2[l(j_1)..j]) = forestdist(\varnothing, T_2[l(j_1)..j-1]) + \gamma(\Lambda \to T_2[j])$

where $i_1 \in anc(i)$ *and* $j_1 \in anc(j)$.

Proof. Case (i) requires no edit operation. In (ii) and (iii), the distances correspond to the cost of deleting or inserting the nodes in $T_1[l(i_1)..i]$ and $T_2[l(j_1)..j]$), respectively. □

LEMMA 4. *Let* $i_1 \in anc(i)$ *and* $j_1 \in anc(j)$. *Then*

$$forestdist(l(i_1)..i, l(j_1)..j) = \min\begin{cases} forestdist(l(i_1)..i-1, l(j_1)..j) + \gamma(T_1[i] \to \Lambda), \\ forestdist(l(i_1)..i, l(j_1)..j-1) + \gamma(\Lambda \to T_2[j]), \\ forestdist(l(i_1)..l(i)-1, l(j_1)..l(j)-1) \\ \quad + forestdist(l(i)..i-1, l(j)..j-1) \\ \quad + \gamma(T_1[i] \to T_2[j]). \end{cases}$$

Proof. We compute $forestdist(l(i_1)..i, l(j_1)..j)$ for $l(i_1) \leqq i \leqq i_1$ and $l(j_1) \leqq j \leqq j_1$. We are trying to find a minimum-cost map M between $forest(l(i_1)..i)$ and $forest(l(j_1)..j)$. The map can be extended to $T_1[i]$ and $T_2[j]$ in three ways.

(1) $T_1[i]$ is not touched by a line in M. Then $(i, \Lambda) \in M$. So, $forestdist(l(i_1)..i, l(j_1)..j) = forestdist(l(i_1)..i-1, l(j_1)..j) + \gamma(T_1[i] \to \Lambda)$.

(2) $T_2[j]$ is not touched by a line in M. Then $(\Lambda, j) \in M$. So, $forestdist(l(i_1)..i, l(j_1)..j) = forestdist(l(i_1)..i, l(j_1)..j-1) + \gamma(\Lambda \to T_2[j])$.

(3) $T_1[i]$ and $T_2[j]$ are both touched by lines in M. Then $(i, j) \in M$. Here is why. Suppose (i, k) and (h, j) are in M. If $l(i_1) \leqq h \leqq l(i)-1$, then i is to the right of h so k must be to the right of j by the sibling condition on mappings. This is impossible in $forest(l(j_1)..j)$. Similarly, if i is a proper ancestor of h, then k must be a proper ancestor of j by the ancestor condition on mappings. This too is impossible. So, $h = i$. By symmetry, $k = j$ and $(i, j) \in M$.

Now, by the ancestor condition on mapping, any node in the subtree rooted at $T_1[i]$ can only be touched by a node in the subtree rooted at $T_2[j]$. Hence,

$$forestdist(l(i_1)..i, l(j_1)..j) = forestdist(l(i_1)..l(i)-1, l(j_1)..l(j)-1) + forestdist(l(i)..i-1, l(j)..j-1) + \gamma(T_1[i] \to T_2[j]).$$

Figure 6 shows the situation.

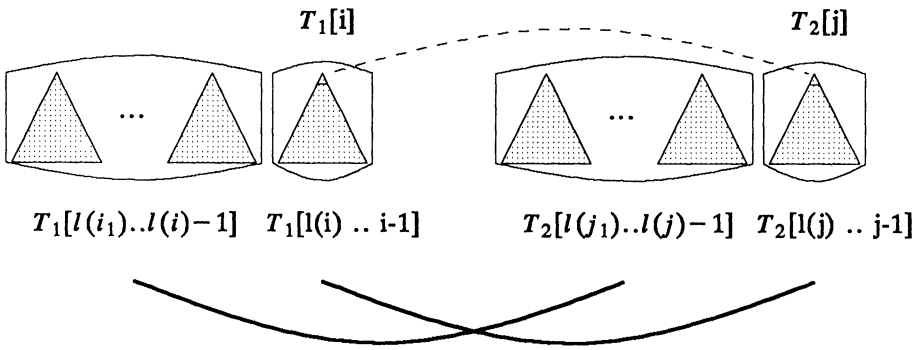

FIG. 6. *Case* (3) *of Lemma* 4.

Since these three cases express all the possible mappings yielding *forestdist*$(l(i_1)..i, l(j_1)..j)$, we take the minimum of these three costs. Thus,

$$forestdist(l(i_1)..i, l(j_1)..j) = \min \begin{cases} forestdist(l(i_1)..i-1, l(j_1)..j) + \gamma(T_1[i] \to \Lambda) \\ forestdist(l(i_1)..i, l(j_1)..j-1) + \gamma(\Lambda \to T_2[j]) \\ forestdist(l(i_1)..l(i)-1, l(j_1)..l(j)-1) \\ \quad + forestdist(l(i)..i-1, l(j)..j-1) \\ \quad + \gamma(T_1[i] \to T_2[j]). \end{cases}$$

□

LEMMA 5. *Let* $i_1 \in anc(i)$ *and* $j_1 \in anc(j)$. *Then*

(1) *If* $l(i) = l(i_1)$ *and* $l(j) = l(j_1)$

$$forestdist(l(i_1)..i, l(j_1)..j) = \min \begin{cases} forestdist(l(i_1)..i-1, l(j_1)..j) + \gamma(T_1[i] \to \Lambda), \\ forestdist(l(i_1)..i, l(j_1)..j-1) + \gamma(\Lambda \to T_2[j]), \\ forestdist(l(i_1)..i-1, l(j_1)..j-1) + \gamma(T_1[i] \to T_2[j]). \end{cases}$$

(2) *If* $l(i) \neq l(i_1)$ *or* $l(j) \neq l(j_1)$ (i.e., *otherwise*)

$$forestdist(l(i_1)..i, l(j_1)..j) = \min \begin{cases} forestdist(l(i_1)..i-1, l(j_1)..j) + \gamma(T_1[i] \to \Lambda), \\ forestdist(l(i_1)..i, l(j_1)..j-1) + \gamma(\Lambda \to T_2[j]), \\ forestdist(l(i_1)..l(i)-1, l(j_1)..l(j)-1) \\ \quad + treedist(i, j). \end{cases}$$

Proof. By Lemma 4, if $l(i) = (i_1)$ and $l(j) = l(j_1)$ then, since *forestdist*$(l(i_1)..l(i) - 1, l(j_1)..l(j)-1) = forestdist(\emptyset, \emptyset) = 0$, (1) follows immediately.

Because the distance is the cost of a minimal cost mapping, we know *forestdist*$(l(i_1)..i, l(j_1)..j) \leqq forestdist(l(i_1)..l(i)-1, l(j_1)..l(j)-1) + treedist(i, j)$ since the latter formula represents a particular (and therefore possibly suboptimal) mapping of *forest*$(l(i_1)..i)$ to *forest*$(l(j_1)..j)$. For the same reason, *treedist*$(i, j) \leqq$ *forestdist*$(l(i)..i-1, l(j)..j-1) + \gamma(T_1[i] \to T_2[j])$. Lemma 4 and these two inequalities imply that the substituting of *treedist*(i, j) for *forestdist*$(l(i)..i-1, l(j)..j-1) + \gamma(T_1[i] \to T_2[j])$ in (2) is correct. (See Fig. 7.) □

Lemma 5 has three important implications:

First, the formulas it yields suggest that we can use a dynamic programming style algorithm to solve the tree distance problem.

Second, from (2) of Lemma 5 we observe that to compute *treedist*(i_1, j_1) we need in advance almost all values of *treedist*(i, j) where i_1 is the root of a subtree containing i and j_1 is the root of a subtree containing j. This suggests a bottom-up procedure for computing all subtree pairs.

Third, from (1) in Lemma 5 we can observe that when i is in the path from $l(i_1)$ to i_1 and j is in the path from $l(j_1)$ to j_1, we do not need to compute *treedist*(i, j) separately. These subtree distances can be obtained as a byproduct of computing *treedist*(i_1, j_1).

These implications lead to the following definition and then our new algorithm. Let us define the set *LR_keyroots* of tree T as follows:

$$LR\_keyroots(T) = \{k \mid \text{there exists no } k' > k \text{ such that } l(k) = l(k')\}.$$

That is, if k is in *LR_keyroots*(T) then either k is the root of T or $l(k) \neq l(p(k))$, i.e., k has a left sibling. Intuitively, this set will be the roots of all the subtrees of tree T that need separate computations.

Consider trees T_1 and T_2 in Fig. 4. From the above definition we can see that *LR_keyroots*$(T_1) = \{3, 5, 6\}$ and *LR_keyroots*$(T_2) = \{2, 5, 6\}$.

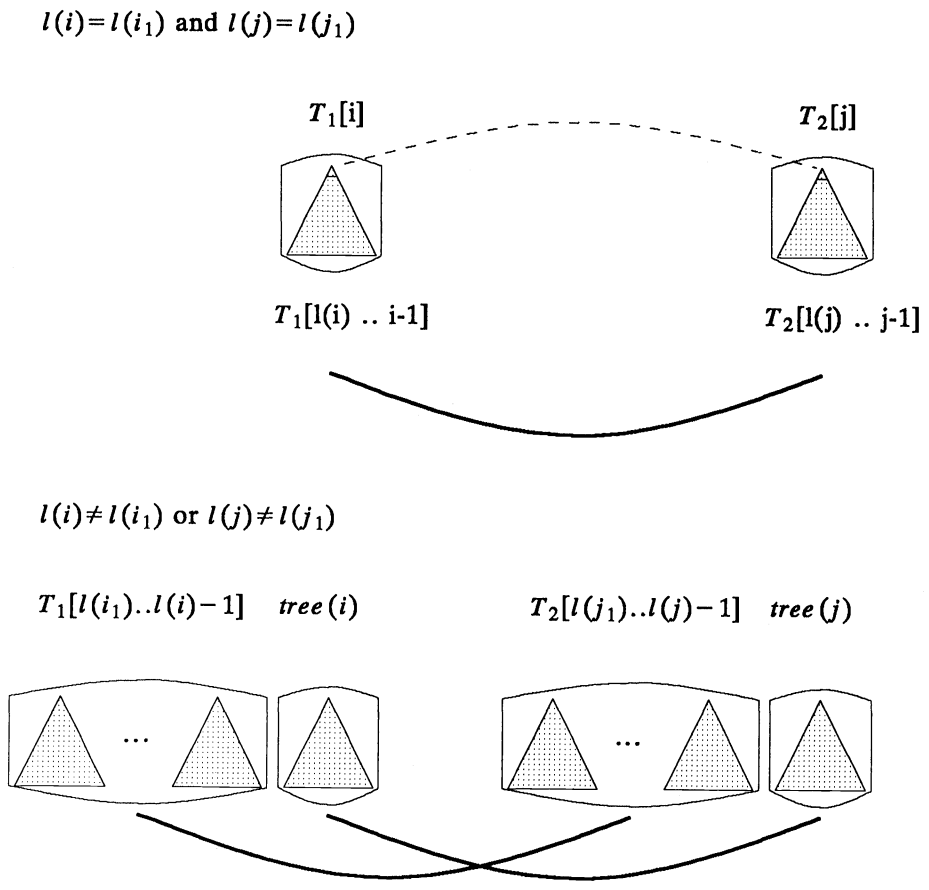

FIG. 7. *The two situations of Lemma* 5.

It is easy to see that there is a linear time algorithm to compute the function $l(\ )$ and the set *LR_keyroots*. We can also assume that the result is in array l and *LR_keyroots*. Furthermore, in array *LR_keyroots* the order of the elements is in increasing order.

We are now ready to give our new simple algorithm.

Input: Tree T_1 and T_2.
Output: *Tree_dist*(i, j), where $1 \leqq i \leqq |T_1|$ and $1 \leqq j \leqq |T_2|$.
Preprocessing
(To compute $l(\ )$, *LR_keyroots*1 and *LR_keyroots*2)
Main loop
  for $i' := 1$ to $|LR\_keyroots(T_1)|$
    for $j' := 1$ to $|LR\_keyroots(T_2)|$
      $i = LR\_keyroots1[i']$;
      $j = LR\_keyroots2[j']$;
      Compute *treedist*(i, j);

We use dynamic programming to compute *treedist*(i, j). The forestdist values computed and used here are put in a temporary array that is freed once the corresponding treedist is computed. The treedist values are put in the permanent treedist array.

The computation of *treedist*(i, j).

```
forestdist(∅, ∅) = 0;
for i1 := l(i) to i
  forestdist(T1[l(i)..i1], ∅) = forestdist(T1[l(i)..i1 − 1], ∅) + γ(T1[i1] → Λ)
for j1 := l(j) to j
  forestdist(∅, T2[l(j)..j1]) = forestdist(∅, T2[l(j)..j1 − 1]) + γ(Λ → T2[j1])
for i1 := l(i) to i
  for j1 := l(j) to j
    if l(i1) = l(i) and l(j1) = l(j) then
      forestdist(T1[l(i)..i1], T2[l(j)..j1)] = min {
        forestdist(T1[l(i)..i1 − 1], T2[l(j)..j1]) + γ(T1[i1] → Λ),
        forestdist(T1[l(i)..i1], T2[l(j)..j1 − 1]) + γ(Λ → T2[j1]),
        forestdist(T1[l(i)..i1 − 1], T2[l(j)..j1 − 1]) + γ(T1[i1] → T2[j1])}
      treedist(i1, j1) = forestdist(T1[l(i)..i1], T2[l(j)..j1])/* put in permanent
        array */
    else
      forestdist(T1[l(i)..i1], T2[l(j)..j1]) = min {
        forestdist(T1[l(i)..i1 − 1], T2[l(j)..j1]) + γ(T1[i1] → Λ),
        forestdist(T1[l(i)..i1], T2[l(j)..j1 − 1]) + γ(Λ → T2[j1]),
        forestdist(T1[l(i)..l(i1) − 1], T2[l(j)..l(j1) − 1]) + treedist(i1, j1)}
```

THEOREM 1. *The basic algorithm is correct.*

Proof. We will prove that for any pair (i, j) such that $i \in LR\_keyroots(T_1)$ and $j \in LR\_keyroots(T_2)$, the following invariants holds.

FIG. 8. *The result of computation for T_1 and T_2 in Fig. 4.*

(1) Immediately before the computation of $treedist(i, j)$, all distances $treedist(i_1, j_1)$, where $l(i) \leqq i_1 \leqq i$ and $l(j) \leqq j_1 \leqq j$ and either $l(i) \neq l(i_1)$ or $l(j) \neq l(j_1)$, are available. In other words, $treedist(i_1, j_1)$ is available if i_1 is in the subtree of $tree(i)$ but not in the path from $l(i)$ to i and j_1 is in the subtree of $tree(j)$ but not in the path from $l(j)$ to j.

(2) Immediately after the computation of $treedist(i, j)$, all distances $treedist(i_1, j_1)$, where $l(i) \leqq i_1 \leqq i$ and $l(j) \leqq j_1 \leqq j$ are available.

We first show that if (1) is true then (2) is true. From Lemma 5 we know that all required subtree-to-subtree distances are available. (We need all $treedist(i_1, j_1)$ such that $l(i) \leqq i_1 \leqq i$ and $l(j) \leqq j_1 \leqq j$ and either $l(i) \neq l(i_1)$ or $l(j) \neq l(j)$, and by (1) all these distances are available.) We compute each $treedist(i_1, j_1)$, where $l(i_1) = l(i)$ and $l(j_1) = l(j)$ in the if part and add it to the permanent treedist array. So, (2) holds.

Let us show that (1) always holds. Suppose $l(i_1) \neq l(i)$. Let i_1' be the lowest ancestor of i_1 such that $i_1' \in LR\_keyroots(T_1)$. Since $l(i_1') = l(i_1) \neq l(i)$, $i_1' \neq i$. Since $i \in LR\_keyroots(T_1)$, $i_1' \leqq i$. So $i_1' < i$. Let j_1' be the lowest ancestor of j_1 such that $j_1' \in LR\_keyroots(T_2)$. Since $j \in LR\_keyroots(T_2)$, $j_1' \leqq j$. Hence $i_1' + j_1' < i + j$. This means that $treedist(i_1', j_1')$ will have already been computed before $treedist(i, j)$ because in the main loop $LR\_keyroots1$ and $LR\_keyroots2$ are in increasing order. Hence $treedist(i_1, j_1)$ is available after the computation of $treedist(i_1', j_1')$. □

As an example, consider tree T_1 and T_2 in Fig. 4. For simplicity, assume that all insert, delete, and change (of labels) operations will cost one. Figure 8 shows the result of applying our new algorithm to T_1 and T_2. The matrix below $tree\_dist(i, j)$ is the result of temporary array produced by the computation of $tree\_dist(i, j)$. (Out of 36 possible *tree_dist* arrays, only nine—those corresponding to pairs of keyroots—are explicitly computed.) The matrix below *tree_dist* is the final result. The value in the lower right corner (2) is the distance between T_1 and T_2.

4. Some aspects of our algorithm.

4.1. Complexity.

LEMMA 6. $|LR\_keyroots(T)| \leqq |leaves(T)|$.

Proof. We will prove that for any $i, j \in LR\_keyroots(T)$, $l(i) \neq l(j)$.

Let $i, j \in LR\_keyroots(T)$ and $i < j$. If $l(i) = l(j)$ from $i < j$ we know that i is in the path from $l(j)$ to j. By the definition of $l(j)$, i has no *left_sibling*. This contradicts the assertion that $i \in LR\_keyroots(T)$. Hence each leaf is the leftmost descendant of at most one member of $LR\_keyroots(T)$. So, $|LR\_keyroots(T)| \leqq |leaves(T)|$. □

Because not all subtree-to-subtree distances need be computed, the number of such calculation a node participates in is less than its depth. Instead, it is the node's *collapsed depth*:

$$LR\_colldepth(i) = |anc(i) \cap LR\_keyroots(T)|.$$

We define the collapsed depth of tree T as follows:

$$LR\_colldepth(T) = \max LR\_colldepth(i).$$

By the definition and Lemma 6 we can see that $LR\_colldepth(i) \leqq \min(depth(T), leaves(T))$ for $1 \leqq i \leqq |T|$. Hence $LR\_colldepth(T) \leqq \min(depth(T), leaves(T))$.

LEMMA 7.

$$\sum_{i=1}^{i=|LR\_keyroots(T)|} Size(i) = \sum_{j=1}^{j=N_1} |LR\_colldepth(j)|.$$

Proof. Consider when node j is counted in the first summation: in the subtrees corresponding to each of its ancestors that is in $LR\_keyroots(T)$. By the definition of $LR\_colldepth(\ )$, j is counted $LR\_colldepth(j)$ times.

THEOREM 2. *The time complexity is* $O(|T_1| \times |T_2| \times \min(depth(T_1), leaves(T_1)) \times \min(depth(T_2), leaves(T_2)))$. *The space complexity is* $O(|T_1| \times |T_2|)$.

Proof. Let us consider the space complexity first. We use a permanent array for *treedist* and a temporary array for *forestdist.* Each of these two arrays requires space $O(|T_1| \times |T_2|)$.

Consider the time complexity of our algorithm. The preprocessing takes linear time. The subtree distance dynamic programming algorithm takes $Size(i) \times Size(j)$ for the subtree rooted at $T_1[i]$ and the subtree rooted at $T_2[j]$. We have a main loop that calls this subroutine several times. So the time is:

$$\sum_{i=1}^{i=|LR\_keyroots(T_1)|} \sum_{j=1}^{j=|LR\_keyroots(T_2)|} Size(i) \times Size(j)$$

$$= \sum_{i=1}^{i=|LR\_keyroots(T_1)|} Size(i) \times \sum_{j=1}^{j=|LR\_keyroots(T_2)|} Size(j).$$

By Lemma 6, the above equals

$$\sum_{i=1}^{i=N_1} LR\_colldepth(i) \times \sum_{j=1}^{j=N_2} LR\_colldepth(j).$$

This is less than

$$|T_1| \times |T_2| \times LR\_colldepth(T_1) \times LR\_colldepth(T_2).$$

By the definition of $LR\_colldepth$, we have that the time complexity is

$$O(|T_1| \times |T_2| \times \min(depth(T_1), leaves(T_1)) \times \min(depth(T_2), leaves(T_2))). \quad \square$$

These time and space complexities are an improvement over the $O(|T_1| \times |T_2| \times depth(T_1)^2 \times depth(T_2)^2)$ time and space complexity of [T].

Note. If we use a right-to-left postorder numbering for tree nodes and define similar functions $r(i)$, $RL\_keyroots(T)$ and $RL\_colldepth(i)$, we can have the same result as above. The complexity will be $\sum_{i=1}^{i=N_1} RL\_colldepth(i) \times \sum_{j=1}^{j=N_2} RL\_colldepth(j)$.

Clearly, using the left-to-right or right-to-left postorder numberings give the same worst-case time complexity. However, in practice it may be beneficial to choose the ordering that gives the lower of the following two products: $\sum_{i=1}^{i=N_1} LR\_colldepth(i) \times \sum_{j=1}^{j=N_2} LR\_colldepth(j)$ and $\sum_{i=1}^{i=N_1} RL\_colldepth(i) \times \sum_{j=1}^{j=N_2} RL\_colldepth(j)$.

4.2. Mapping. It is natural to ask for a mapping that yields the distance computed. Also given two trees, we may ask, what is the largest common substructure of these two trees? This is analogous to the longest common substring problem for strings. We can find the mapping in the same time and space complexity as finding the distance, although we do not give the details here. The mapping is produced by our toolkit.

4.3. Parallel implementation. A straightforward transformation of our algorithm to a parallel one yields an algorithm with time complexity $O(N_1 + N_2)$ whereas [T] and [Z83] have time complexity $O((N_1 + N_2) \times (depth(T_1) + depth(T_2)))$. Our algorithm uses $O(\min(|T_1|, |T_2|) \times leaves(T_1) \times leaves(T_2))$ processors.[2]

[2] Actually, by controlling the starting point of each *treedist* computation more carefully, we can reduce the processor bound to $O(\min(|T_1|, |T_2|) \times \min(depth(T_1), leaves(T_1)) \times \min(depth(T_2), leaves(T_2))$. The algorithm is more complicated however.

The algorithm computes in "waves" for all subtree pairs $tree(i)$ and $tree(j)$, where $i \in LR\_keyroots(T_1)$ and $j \in LR\_keyroots(T_2)$, simultaneously. We start at wave 0. At wave k, for each such subtree pair $tree(i)$ and $tree(j)$, compute $forestdist(l(i)..i_1, l(j)..j_1)$, where $(i_1 - l(i)) + (j_1 - l(j)) = k$.

We now present the parallel algorithm in detail. (When the PARBEGIN-PAREND construct surrounds one or more for loops, it means that every setting of the iterators in the enclosed for loops can be executed in parallel. The semantics are those of the sequential program ignoring this construct.)

In the algorithm $dist[i, j]$ is the array for the computation of $treedist(i, j)$. Therefore $dist[i, j][p, q]$ is the distance $forestdist(l(i)..p, l(j)..q)$ and is the p, qth member of the array computing $treedist(i, j)$.

        j := LR_keyroots2[j']
        dist[i,j][l(i)-1, l(j)+k]
          := dist[i,j][l(i)-1, l(j)+k-1] + γ(Λ → T1[l[j]+k])
  PAREND
for k := 0 to N+M-2
  PARBEGIN
    for i' := 1 to |LR_keyroots(T1)|
      for j' := 1 to |LR_keyroots(T2)|
        i := LR_keyroots1[i']
        j := LR_keyroots2[j']
        for i1, j1 satisfying i1 - l(i) + j1 - l(j) = k and l(i) ≦ i1 ≦ i, l(j) ≦ j1 ≦ j
          if l(i) = l(i1) and l(j) = l(j1) then
            dist[i,j][i1, j1] := min {
              dist[i,j][i1-1, j1] + γ(T1[i1] → Λ)
```

```
            dist[i, j][i1, j1 − 1] + γ(Λ → T2[j1])
            dist[i, j][i1 − 1, j1 − 1] + γ(T1[i1] → T2[j1])
          }
          treedist(i1, j1) := dist[i, j][i1, j1]
        else
          dist[i, j][i1, j1] := min {
            dist[i, j][i1 − 1, j1] + γ(T1[i1] → Λ)
            dist[i, j][i1, j1 − 1] + γ(Λ → T2[j1])
            dist[i, j][l(i1) − 1, l(j1) − 1] + treedist[i1, j1]
          }
end
```

It is easy to see that in the above algorithm all the terms, except $treedist[i_1, j_1]$, are available whenever needed. We now show that $treedist[i_1, j_1]$ is available whenever we use it. Our argument is similar to the one we used in the sequential case.

Note that we compute all terms such that $(i_1 - l(i)) + (j_1 - l(j)) = k$ together. During that computation, all terms such that $(i_1 - l(i)) + (j_1 - l(j)) < k$ are available. So, when we need item $treedist[i_1, j_1]$, either $l(i_1) > l(i)$ or $l(j_1) > l(j)$. Let i_2 be the lowest ancestor of i_1 such that $i_2 \in LR\_keyroots(T_1)$. Let j_2 be the lowest ancestor of j_1 such that $j_2 \in LR\_keyroots(T_2)$. Since $l(i_1) = l(i_2)$ and $l(j_1) = l(j_2)$ we know either $l(i_2) > l(i)$ or $l(j_2) > l(j)$. Therefore, $(i_1 - l(i_2)) + (j_1 - l(j_2)) < (i_1 - l(i)) + (j_1 - l(j)) = k$. Hence $treedist[i_1, j_1]$ was already computed in the computation of $dist[i_2, j_2][i_1, j_1]$ and put into the permanent tree distance array. This settles correctness.

THEOREM 3. *The Parallel Distance Algorithm has time complexity* $O(|T_1| + |T_2|)$.

Proof. By simple analysis of the for loop. □

4.4. From trees to strings. Strings are an important special case of trees. This algorithm is a generalization of the natural dynamic programming algorithms on strings in two senses: time complexity and algorithmic style.

First, we consider the time complexity. Since a string has only one leaf, applying our algorithms to strings yields a time complexity of $O(|T_1| \times |T_2|)$. This is the same as that of the best available algorithm for the general problem of string distance.

Second, we consider the algorithm itself. For a string S, $LR\_keyroots(S) = \{root\}$. So the main loop will only have one iteration. In the dynamic programming subroutine, since $l(i) = 1$, we will never come to the case $l(i) \neq l(i_1)$ or $l(j) \neq l(j_1)$. So if we change i to $|T_1|$, j to $|T_2|$, $l(i)$ to one, $l(j)$ to one, delete the main loop and delete the case where $l(i) \neq l(i_1)$ or $l(j) \neq l(j_1)$, we will have exactly the string distance algorithm.

5. The general technique applied to approximate tree matching. Many problems in strings can be solved with dynamic programming. Similarly, our algorithm not only applies to tree distance but also provides a way to do dynamic programming for a variety of tree problems with the same time complexity. In this section we show how to apply this general paradigm to approximate tree matching.

5.1. Algorithm template. Here is the general form of the algorithm (assuming a left-to-right postorder traversal):

```
preprocessing
main loop
  for i' := 1 to |LR_keyroots(T1)|
    for j' := 1 to |LR_keyroots(T2)|
      i = LR_keyroots1[i'];
      j = LR_keyroots2[j'];
```

```
        compute Tree_D(i, j);
subroutine for Tree_D(i, j)
  empty_initialization
  for i1 := l(i) to i
    left_initialization
  for j1 := l(j) to j
    right_initialization
  for i1 := l(i) to i
    for j1 := l(j) to j

5.2. Approximate tree matching. We first consider approximate string matching [S80], [U83], [U85], [LV]. We will then give two natural generalizations of approximate string matching to approximate tree matching. This will also be a generalization of the exact tree matching algorithm as found in Hoffmann and O'Donnell [HO].

The approximate string matching problem is the following. Given two strings *STEXT* and *SPAT*, the problem is to compute, for each i, $SD[i, SPAT] = \min_j \{D(STEXT[j..i], SPAT)\}$, where $1 \leqq j \leqq i+1$ and D is the string distance metric. In other words, the problem is to compute, for each i, the minimum number of editing operations between the "pattern" string $SPAT[1..|PAT|]$ and the "text string" $STEXT[1..i]$ where any prefix can be removed from $STEXT[1..i]$. (Intuitively, the algorithm finds the "occurrence" in *TEXT* that most closely matches *PAT*.)

To extend this problem to trees, we must generalize the notion of removing a prefix. For us, a prefix will mean a collection of subtrees.

We first define two operations at a node.

Removing at node $T[i]$ means removing the subtree rooted at $T[i]$. In other words, delete $T[l(i)..i]$. (See Fig. 9.)

Pruning at node $T[i]$ means removing all the descendants of $T[i]$. In other words, delete $T[l(i)..i-1]$. (Thus, a pruning never eliminates the entire tree.) (See Fig. 10.)

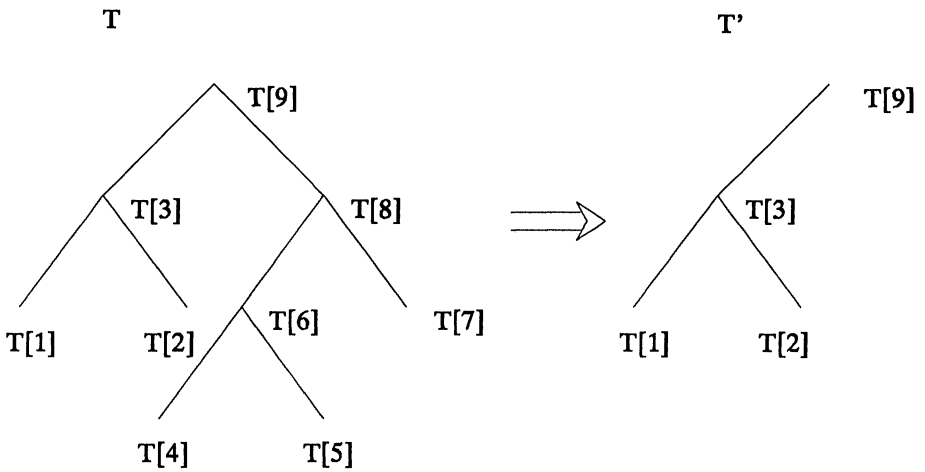

FIG. 9. Remove subtree rooted at T[8].

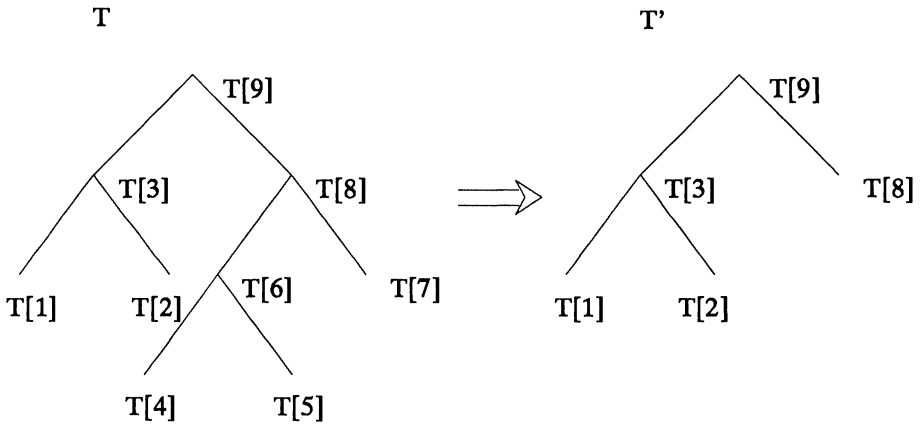

FIG. 10. *Pruning at T[8]—remove all its proper descendants.*

Assume an ordering for tree T. Define a subtree set $S(T)$ as follows: $S(T)$ is a set of numbers satisfying

(1) $i \in S(T)$ implies that $1 \leqq i \leqq |T|$

(2) $i, j \in S(T)$ implies that neither is an ancestor of the other.

Define $R(T, S(T))$ to be the tree T with removing at all nodes in $S(T)$.
Define $P(T, S(T))$ to be the tree T with pruning at all nodes in $S(T)$.

Now we can give the definition of approximate tree matching. Given tree T and PAT, for each i, we want to calculate

$$DR(T[l(i)..i, PAT) = \min_S \{treedist(R(T[l(i)..i], S(T[l(i)..i])), PAT)\}.$$

$$DP(T[l(i)..i, PAT) = \min_S \{treedist(P(T[l(i)..i], S(T[l(i)..i])), PAT)\}.$$

The minimum here is over all possible subtree sets $S(T[l(i)..i])$. We consider each generalization in turn.

5.2.1. Remove any number of subtrees from *TEXT* tree. The problem is as follows. Given trees T_1 and T_2, we want to know what is the minimum distance between $T_1[l(i)..i]$ and T_2 when zero or more subtrees can be removed from $T_1[l(i)..i]$.

Let $F\_DR(T_1[l(i)..i_1], T_2[l(j)..j_1])$ denote the minimum distance between forest $T_1[l(i)..i_1]$ and $T_2[l(j)..j_1]$ with zero or more subtrees removed from $T_1[l(i)..i_1]$. Let $T\_DR(i, j)$ denote the minimum distance between tree $T_1[l(i)..i]$ and $T_2[l(j)..j]$ with zero or more subtrees removed from $T_1[l(i)..i]$. We write the algorithm in the form suggested by the algorithm template.

ALGORITHM SUBTREE REMOVAL.
empty_initialization:
$F\_DR(\varnothing, \varnothing) = 0$
left_initialization:
$F\_DR(T_1[l(i)..i_1], \varnothing) = 0$
right_initialization:
$F\_DR(\varnothing, T_2[l(j)..j_1]) = F\_DR(\varnothing, T_2[l(j)..j_1 - 1]) + \gamma(\Lambda \to T_2[j_1])$
general_if_computation
/* applies if $l(i_1) = l(i)$ and $l(j_1) = l(j)$*/
$F\_DR(T_1[l(i)..i_1], T_2[l(j)..j_1]) = \min\{$

$F\_DR(\varnothing, T_2[l(j)..j_1])$,
$F\_DR(T_1[l(i)..i_1-1], T_2[l(j)..j_1]) + \gamma(T_1[i_1] \to \Lambda)$,
$F\_DR(T_1[l(i)..i_1], T_2[l(j)..j_1-1]) + \gamma(\Lambda \to T_2[j_1])$,
$F\_DR(T_1[l(i)..i_1-1], T_2[l(j)..j_1-1]) + \gamma(T_1[i_1] \to T_2[j_1])\}$
/* put the derived *treedist* in the permanent array, as specified by template */
general_else_computation
$F\_DR(T_1[l(i)..i_1], T_2[l(j)..j_1]) = \min\{$
$F\_DR(T_1[l(i)..l(i_1)-1], T_2[l(j)..j_1])$,
$F\_DR(T_1[l(i)..i_1-1], T_2[l(j)..j_1]) + \gamma(T_1[i_1] \to \Lambda)$,
$F\_DR(T_1[l(i)..i_1], T_2[l(j)..j_1-1]) + \gamma(\Lambda \to T_2[j_1])$,
$F\_DR(T_1[l(i)..l(i_1)-1], T_2[l(j)..l(j_1)-1]) + T\_DR(i_1, j_1)\}$

LEMMA 8. *Algorithm Subtree Removal is correct.*

Proof. First we show that the initialization is correct. The empty_initialization and the right_initialization are the same as in the tree distance algorithm. The left_initialization $F\_DR(T_1[l(i)..i_1], \varnothing) = 0$ is correct, because we can remove all of $T_1[l(i)..i_1]$.

For the general term $F\_DR(T_1[l(i)..i_1], T_2[l(j)..j_1])$, we ask first whether or not the subtree $T_1[l(i_1)..i_1]$ is removed. If it is removed, then the distance should be $F\_DR(T_1[l(i)..l(i_1)-1], T_2[l(j)..j_1])$. Otherwise, consider the mapping between $T_1[l(i)..i_1]$ and $T_2[l(j)..j_1]$ after we perform an optimal removal of subtrees of $T_1[l(i)..i_1]$. Now we have the same three cases as in Lemma 4. Hence the general expression should be the minimum of these four terms:

$F\_DR(T_1[l(i)..i_1], T_2[l(j)..j_1]) = \min\{$
$F\_DR(T_1[l(i)..l(i_1)-1], T_2[l(j)..j_1])$,
$F\_DR(T_1[l(i)..i_1-1], T_2[l(j)..j_1]) + \gamma(T_1[i_1] \to \Lambda)$,
$F\_DR(T_1[l(i)..i_1], T_2[l(j)..j_1-1]) + \gamma(\Lambda \to T_2[j_1])$,
$F\_DR(T_1[l(i)..l(i_1)-1], T_2[l(j)..l(j_1)-1])$
$+ F\_DR(T_1[l(i_1)..i_1-1], T_2[l(j_1)..j_1-1]) + \gamma(T_1[i_1] \to T_2[j_1])\}$

As in Lemma 5, this specializes to the general_if_computation and the general_else_computation given in the algorithm. □

5.2.2. Prune at any number of nodes from the *TEXT* tree. Given trees T_1 and T_2, we want to know what is the minimum distance between $T_1[l(i)..i]$ and T_2 when there have been zero or more prunings at nodes of $T_1[l(i)..i]$.

Let $F\_DP(T_1[l(i)..i_1], T_2[l(j)..j_1])$ denote the minimum distance between *forest* $T_1[l(i)..i_1]$ and $T_2[l(j)..j_1]$ with zero or more pruning from $T_1[l(i)..i_1]$. Let $T\_DP(i, j)$ denote the minimum distance between *tree* $T_1[l(i)..i]$ and $T_2[l(j)..j]$ with zero or more prunings from $T_1[l(i)..i]$. The following initialization and general term computation steps will give us an algorithm to solve our problem.

ALGORITHM PRUNINGS.
empty_initialization:
$F\_DP(\varnothing, \varnothing) = 0$
left_initialization:
$F\_DP(T_1[l(i)..i_1], \varnothing = F\_DP(T_1[l(i)..l(i_1)-1], \varnothing) + \gamma(T_1[i_1] \to \Lambda)$
right_initialization:
$F\_DP(\varnothing, T_2[l(j)..j_1]) = F\_DP(\varnothing, T_2[l(j)..j_1-1]) + \gamma(\Lambda \to T_2[j_1])$
general_if_computation
/* applies if $l(i_1) = l(i)$ and $l(j_1) = l(j)$*/
$F\_DP(T_1[l(i)..i_1], T_2[l(j)..j_1]) = \min\{$

$F\_DP(\varnothing, T_2[l(j)..j_1-1]) + \gamma(T_1[i_1] \to T_2[j_1]),$
$F\_DP(T_1[l(i)..i_1-1], T_2[l(j)..j_1]) + \gamma(T_1[i_1] \to \Lambda),$
$F\_DP(T_1[l(i)..i_1], T_2[l(j)..j_1-1]) + \gamma(\Lambda \to T_2[j_1]),$
$F\_DP(T_1[l(i)..i_1-1], T_2[l(j)..j_1-1]) + \gamma(T_1[i_1] \to T_2[j_1])\}$

/* put the derived *treedist* in the permanent array, as specified by template */

general_else_computation

$F\_DP(T_1[l(i)..i_1], T_2[l(j)..j_1]) = \min\{$
$F\_DP(T_1[l(i)..l(i_1)-1], T_2[l(j)..j_1]) + \gamma(T_1[i_1] \to \Lambda),$
$F\_DP(T_1[l(i)..i_1-1], T_2[l(j)..j_1]) + \gamma(T_1[i_1] \to \Lambda),$
$F\_DP(T_1[l(i)..i_1], T_2[l(j)..j_1-1]) + \gamma(\Lambda \to T_2[j_1]),$
$F\_DP(T_1[l(i)..l(i_1)-1], T_2[l(j)..l(j_1)-1]) + T\_DP(i_1, j_1)\}$

LEMMA 9. *Algorithm Prunings is correct.*

Proof. First we show that the initialization is correct. The empty_initialization and the right_initialization are the same as in the tree distance algorithm. For left_initialization, the best we can do for tree $T_1[l(i_1)..i_1]$ is to prune at $T_1[i_1]$. Therefore $F\_DP(T_1[l(i)..i_1], \varnothing) = F\_DP(T_1[l(i)..l(i_1)-1], \varnothing) + \gamma(T_1[i_1] \to \Lambda)$. Hence the left_initialization is correct.

For the general term $F\_DP(T_1[l(i)..i_1], T_2[l(j)..j_1])$, we have the following similar three cases.

(1) $T_1[i_1]$ is not touched by a line of M.
  (1a) (without pruning) $F\_DP(T_1[l(i)..i_1-1], T_2[l(j)..j_1]) + \gamma(T_1[i_1] \to \Lambda)$
  (1b) (with pruning) $F\_DP(T_1[l(i)..l(i_1)-1], T_2[l(j)..j_1]) + \gamma(T_1[i_1] \to \Lambda)$

(2) $T_2[j_1]$ is not touched by a line of M. Since we only prune from T_1, there is only one case here:

$$F\_DP(T_1[l(i)..i_1], T_2[l(j)..j_1-1]) + \gamma(\Lambda \to T_1[i_1])$$

(3) both $T_1[i_1]$ and $T_2[j_1]$ are touched by lines of M.
  (3a) (without pruning)

$$F\_DP(T_1[l(i)..l(i_1)-1], T_2[l(j)..l(j_1)-1]) + F\_DP(T_1[l(i_1)..i_1-1], T_2[l(j_1)..j_1-1]) + \gamma(T_1[i_1] \to T_2[j_1])$$

  (3b) (with pruning)

$$F\_DP(T_1[l(i)..l(i_1)-1], T_2[l(j)..l(j_1)-1]) + F\_DP(\varnothing, T_2[l(j_1)..j_1-1]) + \gamma(T_1[i_1] \to T_2[j_1])$$

If $l(i) = l(i_1)$ and $l(j) = l(j_1)$, consider cases (1b) and (3b.) Case (1b) becomes $F\_DP(\varnothing, T_2[l(j)..j_1]) + \gamma(T_1[i_1] \to \Lambda)$. Case (3b) becomes $F\_DP(\varnothing, T_2[l(j)..j_1-1]) + \gamma(T_1[i_1] \to T_2[j_1])$. Now from the right_initialization we know that

$$\begin{aligned} &F\_DP(\varnothing, T_2[l(j)..j_1]) + \gamma(T_1[i_1] \to \Lambda) \\ &\quad \geqq F\_DP(\varnothing, T_2[l(j)..j_1-1]) + \gamma(\Lambda \to T_2[j_1]) + \gamma(T_1[i_1] \to \Lambda) \\ &\quad \geqq F\_DP(\varnothing, T_2[l(j)..j_1-1]) + \gamma(T_1[i_1] \to T_2[j_1]). \end{aligned}$$

So the distance given by case (1b) $\geqq$ the distance from (3b). The proposed general_if_computation is therefore correct where the first term handles two cases.

If $l(i) \neq l(i_1)$ or $l(j) \neq l(j_1)$, consider case (3). As in Lemma 6, cases (3a) and (3b) can be replaced by $F\_DP(T_1[l(i)..l(i_1)-1], T_2[l(j)..l(j_1)-1]) + T\_DP(i_1, j_1)$. The proposed general_else_computation is therefore correct. Hence algorithm pruning is correct. □

6. Conclusion. We present a simple dynamic programming algorithm for finding the editing distance between ordered labelled trees.[3] Our algorithm

(1) Has better time and space complexity than any in the literature;

(2) Is efficiently parallelizable; and

(3) Is generalizable with the same time complexity to approximate tree matching problems.

We have implemented these algorithms as a toolkit that has already been used at the National Cancer Institute.

Acknowledgments. We thank Bob Hummel for helpful discussions and the referees for valuable comments.

RELATING THE TYPE OF AMBIGUITY OF FINITE AUTOMATA TO THE SUCCINCTNESS OF THEIR REPRESENTATION*

BALA RAVIKUMAR† AND OSCAR H. IBARRA‡

Abstract. This paper considers the problem of how the size of a nondeterministic finite automaton (nfa) representing a regular language depends on the type of ambiguity of the nfa. Primarily, the relationship between the ambiguity and the size in five types of nfa's with increasing degrees of nondeterminism is studied: DFA (deterministic), UNA (unambiguous), FNA (finitely ambiguous), PNA (polynomially ambiguous), and ENA (exponentially ambiguous) nfa's. The goal is to show "separation" among these classes, where a class A is said to be "separated" from B (written (A, B)) if for infinitely many n, there are machines of type B with n states whose minimal equivalent type A machine has more than $p(n)$ states for any polynomial p. Two classes are "polynomially equivalent" (written $A = B$) if machines of type A can be converted to machines of type B with only a polynomial increase in the number of states, and vice versa. For a class X, let $X(b)$ denote the restricted class of machines of type X with the restriction that the language accepted is bounded. The first main result compares the bounded restrictions of the five classes mentioned above. Specifically, the following is shown: $(\mathrm{DFA}(b), \mathrm{UNA}(b))$, $(\mathrm{UNA}(b), \mathrm{FNA}(b))$, $\mathrm{FNA}(b) = \mathrm{PNA}(b)$ and $\mathrm{PNA}(b) = \mathrm{ENA}(b)$, providing a complete picture of how the type of ambiguity affects the size complexity for unary and bounded languages. For unbounded languages it is conjectured that each of the five types of nondeterminism is separate from its higher types. But a proof does not exist at this time for two of the separations, the other two carrying over directly from the unary case. Candidates are offered that may be useful in proving the (other two) conjectured separations, and also a weaker form of separation in one case is shown. The notion of "concurrent conciseness" introduced by Kintala and Wotschke is studied. A class C is said to be concurrently concise over two classes A and B if (A, B) and (B, C) can be proved using the same collection of witness languages. One of the main results of this paper shows that, for unrestricted inputs, PNA is concurrently concise over DFA and UNA. This answers an open problem of Stearns and Hunt. The succinctness problem is also studied through (regularity preserving) closure properties, an approach initiated by Sakoda and Sipser, and some interesting contrasts between various classes of nfa's are shown.

Key words. nondeterministic finite automaton, ambiguity, succinctness of representation

AMS(MOS) subject classifications. 68O, 68Q

1. Introduction.

Ever since Rabin and Scott [RABI59] introduced the concept of a nondeterministic finite automaton (nfa), problems concerning the complexity of representation (size complexity) of regular languages have been studied extensively. Since regular languages have a plethora of different characterizations, the study of concise representations of regular languages seems to offer an endless stream of problems. In light of recent developments relating the randomness of strings to the size complexity of machines generating them (this is the idea of Kolmogorov complexity, see e.g., [PAUL79]), there is a renewed interest in the study of succinctness of representations. We begin with a brief summary of some earlier results in this area.

Meyer and Fischer [MEYE71] have considered the blow-up in the number of states when converting an nfa to a deterministic finite automaton (dfa) and have shown that, in the worst case, the number of states in a minimum dfa equivalent to an nfa of n states is 2^n. The same problem has also been considered when the underlying alphabet is unary. In this case the blow-up, although smaller than 2^n, is still exponential. An exact expression for the blow-up has hitherto remained elusive. Moore [MOOR71],

Mandl [MAND73], and recently Denes, Kim, and Rouch [DENE85] have obtained a near-optimal bound of $\Theta(e^{(n \log n)^{1/2}})$ for this problem. (In the above expression, e stands for the base of the natural logarithm, and $\log n$ denotes $\log_2 n$, as do all the logarithms in the rest of the paper.)

Schmidt [SCHM78] has compared the relative succinctness offered by several pairs of devices that include, apart from finite-state devices, pushdown machines. Kintala and Wotschke [KINT80] have defined the "amount of nondeterminism" as the minimum number of nondeterministic moves on any accepted input and established a hierarchy of succinctness based on the amount of nondeterminism. They [KINT86] also have introduced a concept called concurrent conciseness and compared the concurrent conciseness of degree automata [WOTC77], probabilistic automata [RABI63], and nfa's. Ehrenfeucht and Zeiger [EHRE76] have obtained several results comparing the relative succinctness of finite automata and regular expressions. Additional results comparing the expressive power of various control features (such as "goto") in regular expressions have been presented by Abrahamson [ABRA87].

An important classification of nfa's is based on the notion of ambiguity, i.e., the number of accepting derivations of an input string x. (An accepting derivation of a string is defined as a sequence of states visited on input x leading to acceptance.) This notion was first introduced and studied by Mandel and Simon [MAND77], Jacob [JACO77], and Reutenauer [REUT77]. It has been further investigated by Chan and Ibarra [CHAN83], Stearns and Hunt [STEA85], Ibarra and Ravikumar [IBAR86], and Weber and Seidl [WEBE86]. An nfa is said to be k-ambiguous if, for each string accepted, there are at most k accepting computations. An nfa is said to be finitely ambiguous if it is k-ambiguous for some k. An nfa is said to be polynomially ambiguous if there is a polynomial $p(.)$ such that the number of accepting computations for any string of length n is at most $p(n)$. An nfa that is polynomially ambiguous, but not finitely ambiguous is called strictly polynomially ambiguous. The same way, an nfa is said to be strictly exponentially ambiguous if it is not polynomially ambiguous. (Note that the number of derivations of a string in *any* nfa is at most a single exponential in the length of the string, hence the term exponentially ambiguous would hold for any nfa.) It has been shown by Mandel and Simon [MAND77] and Reutenauer [REUT77] (and independently by others) that there is an algorithm to decide if a given nfa is finitely, strictly polynomially or strictly exponentially ambiguous. Weber and Seidl [WEBE86] have shown that there is a polynomial time algorithm for the above classification. The present study is motivated by the following question regarding the above classification. How is the succinctness of representation related to the degree of ambiguity?

In this study, we compare the following families of devices: DFA (the collection of deterministic finite automata), UNA (the collection of unambiguous nfa, i.e., one-ambiguous nfa's), FNA (the collection of finitely ambiguous nfa's), PNA (the collection of polynomially ambiguous nfa's), and ENA (the collection of exponentially ambiguous nfa's). For a collection X of devices (such as $X = \text{UNA}$, etc.), let $X(b)$ denote the subset of X with the property that each device in this subset accepts a bounded language (i.e., a language whose strings are of the form $a_1^{i_1} a_2^{i_2} \cdots a_k^{i_k}$, where a_i's are symbols of the alphabet). Also, for two classes of devices A and B, let (A, B) denote the fact that B *can be* exponentially more succinct than A (i.e., there exists a collection of languages $\{L_n\}$ such that L_n can be accepted by an n state device of type B, but any device of type A accepting L_n must have more than $p(n)$ states for any polynomial p) and let $A = B$ denote the fact that each device in A can be converted to an *equivalent* device in B with a polynomial blow-up and vice versa. We present

results comparing DFA(b), UNA(b), FNA(b), PNA(b), and ENA(b). Specifically, we show that (DFA(b), UNA(b)), (UNA(b), FNA(b)), FNA(b) = PNA(b), and PNA(b) = ENA(b) hold, i.e., for bounded inputs, fna's can be exponentially more succinct than una's and una's can be exponentially more succinct than dfa's; however, ena's and pna's are convertible to fna's at only a polynomial increase in the number of states. Note that the above claims immediately imply, for unrestricted inputs, the following relations: (DFA, UNA) and (UNA, FNA). The other relationships seem hard to prove. We conjecture that (FNA, PNA) and (PNA, ENA), and offer candidates for proving the claim. We also provide an evidence for the later conjecture by proving a special case of it.

Concurrent conciseness of a family A of devices over two families B and C has been defined in [KINT86] as a simultaneous succinctness of A over B and C. By "simultaneous" we mean that the same collection of languages bears witness to the succinctness of A over B, as also of B over C. The question of whether ENA is concurrently concise over UNA and DFA has been raised by Stearns and Hunt [STEA85]. We prove the stronger claim that PNA is concurrently concise over UNA and DFA, resolving the question of Stearns and Hunt in the affirmative.

We also study the succinctness problem through "closure properties," an approach initiated by Sakoda and Sipser [SAKO78]. We define the closure (with respect to an operation $\bullet$) for a class A of finite-state devices as follows. Let $\bullet$ be a regularity preserving operation, and let $M_1, M_2 \in A$. Then $L(M_1) \bullet L(M_2)$ is regular, and assuming that A is universal in the sense that it can accept the class of all regular languages, there is an $M \in A$ such that $L(M) = L(M_1) \bullet L(M_2)$. The question is: "What is the size of the smallest such M, as a function f of the numbers of states of M_1 and M_2?" If f is bounded by a polynomial, then we say that A is polynomially closed under $\bullet$. Closure properties show an interesting contrast between different subclasses of nfa's. For example, the class DFA is not polynomially closed under concatenation or Kleene star but ENA is, under these operations. Apart from the fact that many results regarding succinctness can be sharpened or presented in a different perspective through the closure properties, we feel that this study is of interest in its own right. We prove some closure and nonclosure properties for the various classes of devices mentioned above.

The main results are presented in §§ 3–5 following some definitions and background material in § 2.

2. Preliminaries. We begin with some basic definitions and notation. Define a dfa M to be a 5-tuple $M = \langle Q, \Sigma, \delta, q_0, F\rangle$, where Q is a finite set of states, Σ is a finite alphabet, $q_0 \in Q$ is the start state, $F \subseteq Q$ is the set of accepting states, and δ is defined as $\delta : Q \times \Sigma \to Q$. An nfa is defined as a five-tuple $\langle Q, \Sigma, \delta, q_0, F\rangle$, where all the components are exactly as above except δ that is defined as a map $\delta : Q \times \Sigma \to 2^Q$. We do not allow ε-moves in an nfa. We further assume that the fa's are reduced, i.e., they do not have useless states (thus, all the states are reachable from the start state on some input, and from each state an accepting state can be reached on some input). Note that none of the results presented in this paper require these assumptions; rather these are made for stylistic simplicity and avoidance of inessential details. $|M|$ denotes the number of states in M. This will be used as the *size complexity* of a machine. We use $a_M(n)$ to denote the "ambiguity function" of an nfa, defined as the maximum number of *accepting* computations (i.e., sequences of states ending in an accepting state) for any input string w such that $|w| = n$ and $w \in L(M)$, the language accepted by M. An nfa is said to be k-ambiguous (for a fixed k) if $a_M(n) \leqq k$, for all n. One-ambiguous nfa's are called unambiguous. An nfa is polynomially ambiguous if

there exists a polynomial $p(.)$ such that $a_M(n) \leqq p(n)$ for all n. The unrestricted nfa is called exponentially ambiguous since the number of derivations for a string of length n is bounded by c^n (where c is the number of states of the machine).

Let Γ be an arbitrary collection of symbols. We use DFA to denote the collection of dfa's whose input alphabet is a finite subset Σ of Γ. In the same way, the collections of unambiguous, finitely, polynomially, and exponentially ambiguous nfa's are denoted by UNA, FNA, PNA, and ENA, respectively. Clearly DFA $\subseteq$ UNA $\subseteq$ FNA $\subseteq$ PNA $\subseteq$ ENA. To make a more definite reference to the type of ambiguity of an nfa, we use the following definition. An nfa of a given type X (in the above sequence of inclusions) is said to be *strictly* of type X if it is of type X, but not of any preceding type. For example, a polynomially ambiguous nfa is strictly polynomially ambiguous if it is polynomially ambiguous but not finitely ambiguous. We will also be interested in the following subsets of these classes of collections. When the input of any fixed device in any of these collections is restricted to a unary alphabet, we obtain the families DFA(u), UNA(u), etc. When the underlying languages accepted by these collections are bounded (i.e., subsets of $a_1^* a_2^* \cdots a_r^*$, where $a_i \in \Sigma$), we obtain the collections DFA(b), UNA(b), etc. We denote the collections of two-way dfa's (whose head can move on either directions on the input tape) by 2-DFA and those of sweeping dfa's (that are 2-dfa's whose head can reverse only on the endmarkers) by SDFA. Their restrictions to unary and bounded languages will be denoted by 2-DFA(u), 2-DFA(b), etc. To denote a typical or generic device of a specific type, we use the name of the collection in small letters, e.g., "Let M be an fna," etc.

The following definition of f-conciseness was adopted from [KINT86] with a minor modification:

DEFINITION. A class of automata B is f-concise over another class A if and only if there is an infinite sequence of languages $\{L_n\}$ such that

(i) For all n, there exists an n-state automaton M_n in B accepting L_n.

(ii) For infinitely many n, every M in A accepting L_n must have at least $f(n)$ states.

We write $B - f(n) \to A$ to denote the fact that B is f-concise over A. Since we are mainly interested in contrasting polynomial growths and superpolynomial growths, we also need the following coarser definition. We denote by (A, B) the fact that B is f-concise over A for some f that cannot be upper-bounded by a polynomial. If (A, B) is not true, then we write $B \leqq A$. Thus, if $B \leqq A$, then any $M \in B$ can be converted to an equivalent M' in A with at most a polynomial increase in the number of states. We write $A = B$ to denote the fact that $A \leqq B$ and $B \leqq A$. If $B \leqq A$ and if it is not true that $A \leqq B$, then we write $B < A$. Observe that it is possible that (A, B) and (B, A) are both true. In this case, we write $A <\ > B$. (A and B are *incomparable.*)

3. Succinctness problem for unary and bounded languages. In this section, we study the succinctness versus size relation when the input is restricted to bounded languages. First we consider unary languages and prove that DFA(u) $<$ UNA(u), UNA(u) $<$ FNA(u), and FNA(u) = PNA(u) = ENA(u). We then extend these results to bounded languages. We also present results comparing 2-DFA(u) with some of the classes stated above. Obviously the inequalities stated above among DFA, UNA, and FNA carry over to the unbounded languages. At present we can claim much less about the relative succinctness of FNA, PNA, and ENA. We conjecture that PNA $<$ FNA and ENA $<$ PNA, i.e., all the five types of nfa's form a hierarchy. We offer candidates that might enable us to prove the conjectured separations. In the latter case, we also provide an evidence in defense of the conjecture by proving a weaker form of it.

We need the following preliminary results. Our first lemma is from [STEA85].

LEMMA 1. *Let* $M=\langle Q, \Sigma, \delta, q_0, F\rangle$ *be an unambiguous* nfa *with* m *states. The shortest word not accepted by* M *is no longer than* m.

Our next result is from [IBAR86] and [WEBE86]. This result provides a characterization of polynomial and exponential ambiguities of nfa's. Before we state the result, we need the following notation. For an nfa $M=\langle Q, \Sigma, \delta, q_0, F\rangle$, where $p, q \in Q$, and $w \in \Sigma^*$, define $N(p, w, q)$ to be the number of ways in which w can be derived starting from p, ending in q.

LEMMA 2. *Let* $M=\langle Q, \Sigma, \delta, q_0, F\rangle$ *be an* nfa.

(i) [IBAR86] *A necessary and sufficient condition for* M *to be strictly exponentially ambiguous is that there exists a* $q \in Q$ *and a string* $w \neq \varepsilon$ *such that* $N(q, w, q) \geqq 2$.

(ii) [WEBE86] *A necessary and sufficient condition for* M *to be strictly polynomially ambiguous is that* M *is not exponentially ambiguous and there exist different states* p, q *and a word* $w \neq \varepsilon$ *such that* $p \in \delta(p, w)$, $q \in \delta(p, w)$, *and* $q \in \delta(q, w)$.

Figures 1 and 2 show examples of strictly polynomially and exponentially ambiguous nfa's.

The following definition and lemma are from [CHRO86].

DEFINITION. An nfa $M=\langle Q, \Sigma, \delta, q_0, F\rangle$ where $\Sigma=\{a\}$ is in *normal form* if it has the following properties:

(a) $Q=\{q_0, \cdots, q_m\} \cup C_1 \cup \cdots C_k$, where $C_i=\{p_{i,0}, \cdots, p_{i,y_i-1}\}$, $i=1, 2, \cdots, k$,

(b) δ can be described as follows: $q_{i+1} \in \delta(q_i, a)$, $i=1, \cdots, m-1$, $p_{i,j+1} \in \delta(p_{i,j}, a)$, $i=1, \cdots, k$, and $j=0, \cdots, y_i-1$, $p_{i,0} \in \delta(q_m, a)$, $i=1, \cdots, k$.

(The addition $j+1$ above is mod y_i.)

We now state the next lemma.

LEMMA 3 [CHRO86]. *For each* nfa A *(over a unary alphabet) with* n *states there is an equivalent* nfa A' *in normal form with at most a total of* $O(n^2)$ *states, and at most* n *states that are not in a loop.*

Proof. For the proof see Lemma 4.3 of [CHRO86]. □

In fact, [CHRO86] presents a simple algorithm to construct A' from A.

We now prove the result comparing UNA(u), FNA(u), PNA(u), and ENA(u).

THEOREM 1. DFA(u) < UNA(u), UNA(u) < FNA(u), and FNA(u) = PNA(u) = ENA(u).

Proof of DFA(u) < UNA(u). It is sufficient to show (DFA(u), UNA(u)). We construct a collection $\{L_n\}$, $n=1, 2, \cdots$ of regular languages such that for all sufficiently

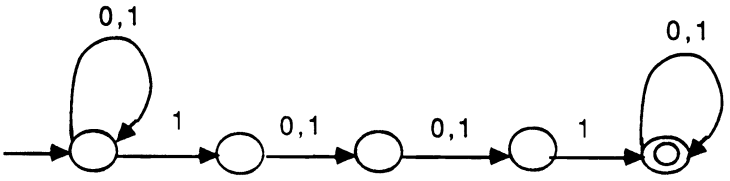

FIG. 1. *Example of a strictly polynomially ambiguous* nfa.

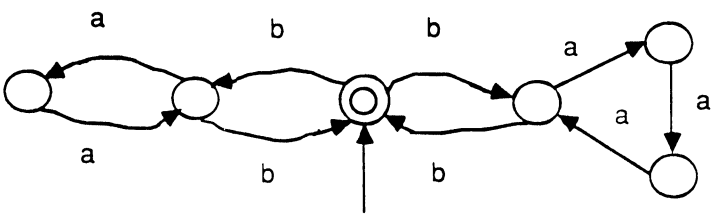

FIG. 2. *Example of a strictly exponentially ambiguous* nfa.

large n, the following holds: (i) L_n can be accepted by an unambiguous nfa with m_n+1 states, and (ii) for any dfa N accepting L_n, the number of states M_n of N must be at least $m^{(\log m_n)^{1/2}/8}$. We first show how to construct $\{L_n\}$, $n=1,2,\cdots$, and prove claims (i) and (ii) about them.

Let p_i denote the ith prime number. In order to define $\{L_n\}$, it is convenient to construct a square matrix A_n of order $n\times n$: the diagonal entries of A_n are * (space-filler), A_n is symmetric so we only need to describe the upper triangular portion of A_n. The upper triangular portion of A_n (consisting of $n(n-1)/2$ entries) is simply the sequence $p_n, p_{n+1}, \cdots, p_{n-1+n(n-1)/2}$ placed in the row-major order. Figure 3 shows A_n. A specific example is shown in Fig. 4.

Now define the sets $\{S_i^n\}$, $i=1,\cdots,n$ as follows: S_i^n is the collection of elements of the ith column in A_n (excluding *). Also let $T_n=\cup_{i=1}^{n} S_i^n$. We can now define the languages $\{L_j^n\}$, $j=1,2,\cdots,n$ as follows: $L_j^n=\{a^i \mid i\equiv j \pmod m\}$ for all $m\in S_j^n\}$. Finally, let $L_n=\cup_{j=1}^{n} L_j^n$. Also let $m_n=\prod_{p\in S_1^n} p+\prod_{p\in S_2^n} p+\cdots+\prod_{p\in S_n^n} p$, and $M_n=\prod_{p\in T_n} p$.

To simplify the notation we use m and M instead of m_n, M_n, respectively. The same way, we will drop n from all the symbols keeping in mind the fact that we are

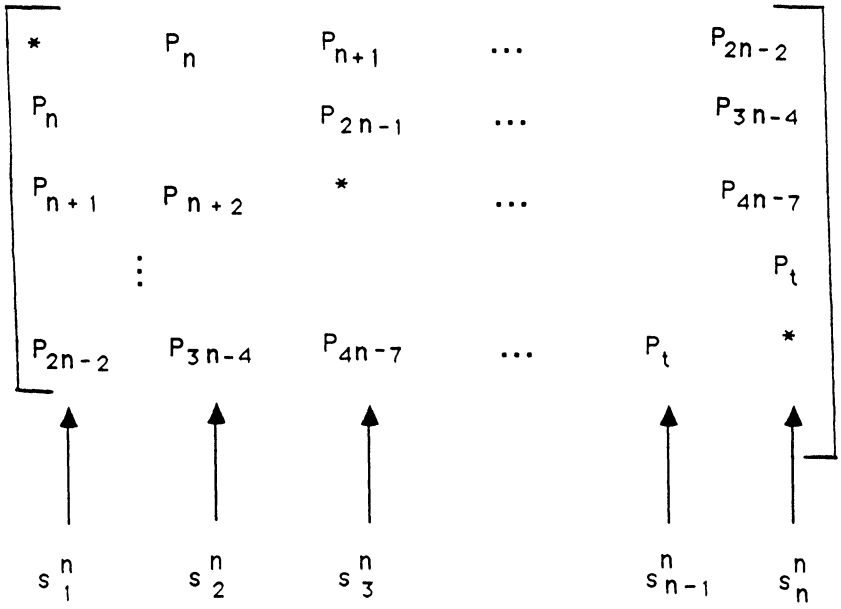

FIG. 3. *The matrix* A_n $(t=n-1+n(n-1)/2)$.

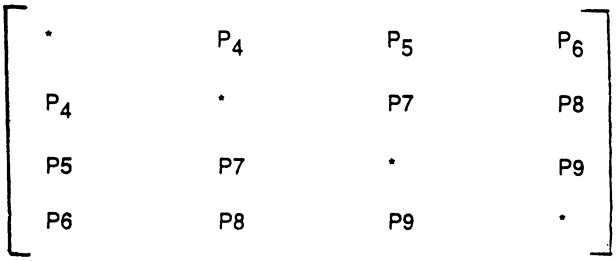

FIG. 4. *Matrix* A_4.

proving the result for a generic n. Thus, for example, we will use S_i, T, L_j, and L in the place of S_i^n, T_n, L_j^n, and L_n, respectively.

CLAIM 1. For all sufficiently large n, $M \geqq m^{(\log m)^{1/2}/8}$.

Proof. Recall from the prime number formula [APOS76] and [ROSS62] that there exist integers c_1, c_2 such that for all r, $c_1 r \log r \leqq p_r \leqq c_2 r \log r$. Now for any $p \in T$, $p \leqq p_{n^2}$. Thus $\prod_{p \in S_i} p \leqq (p_{n^2})^{n-1}$. Therefore

$$\begin{aligned} m &= \prod_{p \in S_1} p + \prod_{p \in S_2} p + \cdots + \prod_{p \in S_n} p \\ &\leqq n \cdot (p_{n^2})^{n-1} \\ &\leqq n \cdot (2c_2 n^2 \log n)^{n-1} \\ &\leqq (c_2 n \log n)^{2n} \end{aligned} \tag{1}$$

for all sufficiently large n. Thus, for all large n,

$$m \leqq (c_2 n \log n)^{2n}.$$

Next,

$$\begin{aligned} M &= \prod_{p \in T} p \\ &\geqq p_n^{|T|} \text{ (since } p_n \text{ is the smallest element in } T) \\ &= p_n^{n(n-1)/2} \\ &\geqq (c_1 n \log n)^{n(n-1)/2} \\ &\geqq (c_2 n \log n)^{n^2/4} \text{ for all sufficiently large } n, \\ &\geqq m^{n/8} \text{ from inequality (1).} \end{aligned}$$

Thus,

$$M \geqq m^{n/8}. \tag{2}$$

Also from the inequality (1), $m \leqq (c_2 n \log n)^{2n}$ so $\log m \leqq 2n \log (c_2 n \log n) < n^2$ for large n. Thus, $n \geqq (\log m)^{1/2}$. Combining this with (2) we have the desired inequality. □

CLAIM 2. There exists an unambiguous nfa with $m+1$ states that accepts L.

Proof. It is easy to see that there exists a dfa M_i with $\prod_{p \in S_i} p$ states accepting L_i. Now construct an nfa M with $1 + \sum_{i=1}^{n} |M_i| = 1 + m$ states as shown in Fig. 5. The machine M has ε-moves, but they can be removed without increasing the number of states.

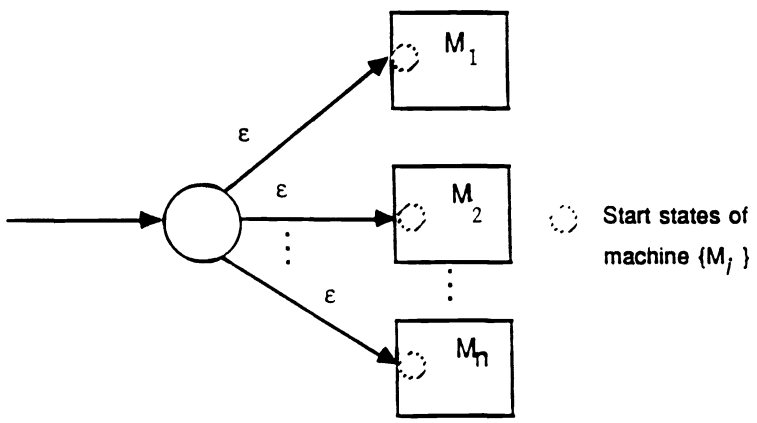

FIG. 5. nfa M.

Clearly M accepts L and has $m+1$ states as claimed. It only remains to show that M is unambiguous. We show this by proving that $L_i \cap L_j = \emptyset$ for $i \neq j$.

SUBCLAIM. For $i \neq j$, $L_i \cap L_j = \emptyset$.

Proof. Assume the contrary. (Without loss of generality we assume that $i > j$.) Then there exists k such that $a^k \in L_i \cap L_j$. We then have $k \equiv i \pmod{p}$ for all $p \in S_i$, and $k \equiv j \pmod{p}$ for all $p \in S_j$.

This means that $k = \alpha \cdot (\prod_{p \in S_i} p) + i$ for some integer α, and $k = \beta \cdot (\prod_{p \in S_j} p) + j$ for some integer β. Thus

$$(**) \qquad -\alpha \cdot \left(\prod_{p \in S_i} p \right) + \beta \cdot \left(\prod_{p \in S_j} p \right) = i - j.$$

Note that there is (exactly) one $t \in S_i \cap S_j$. Clearly, t divides $-\alpha \cdot (\prod_{p \in S_i} p) + \beta \cdot (\prod_{p \in S_j} p)$. Thus, from (**) it follows that t divides $i-j$. Note that $1 \leqq j < i \leqq n$, so $i - j < n$. However $t \geqq p_n \geqq c_1 n \log n > n$. Therefore t cannot divide $i-j$ since t is larger than $i-j$. This is a contradiction. Hence M is unambiguous. □

We now prove our final claim.

CLAIM 3. For any dfa N accepting L, the number of states in N must be at least M.

Proof. Assume the contrary, i.e., there is a dfa $N = \langle Q, \Sigma, \delta, q_0, F \rangle$ with fewer than M states accepting L. Then there exist integers i, j $(0 \leqq j < i < M)$ such that $\delta(q_0, a^i) = \delta(q_0, a_j)$. Let the modular representation of i and j be $\bar{i} = (i_1, i_2, \cdots, i_t)$ and $\bar{j} = (j_1, j_2, \cdots, j_t)$, respectively, where $t = |T|$. (This means that i_m is the remainder when i is divided by the mth element s_m in some fixed ordering $s_1, s_2, \cdots, s_t$ of T.) Clearly, $\bar{i} \neq \bar{j}$, so for some r, $1 \leqq r \leqq t$, $i_r \neq j_r$. We will now describe a procedure to find an integer k such that $a^{i+k} \in L$, but $a^{j+k} \notin L$. The procedure is given below.

First note that there is a unique pair of sets (S_p, S_q) where $p < q$ such that $S_p \cap S_q = \{s_r\}$. The basic idea is to choose k such that

(i) $a^{j+k} \notin L_i$ for any $i \neq q$, and

(ii) $a^{i+k} \in L_q$.

We would then argue that a^{j+k} is in L_q. We carry out the construction using the matrix A_n. First delete the qth row and the qth column of A_n to obtain A'_n. In A'_n choose the elements in the diagonal immediately above the main diagonal. Let these elements be $r_2, r_3, \cdots, r_{q-1}, r_{q+1}, \cdots, r_{n-1}$. (Note that the sets to which these elements belong are $S_2, S_3, \cdots, S_{q-1}, S_{q+1}, \cdots, S_{n-1}$, respectively.) Finally pick r_1 from the set $S_1 - \{r_2, r_3, \cdots, r_{n-1}\}$.

Let the remainders when j is divided by $r_1, r_2, \cdots, r_{n-1}$ be $e_1, \cdots, e_{n-1}$, respectively. (Note that $e_1, e_2, \cdots$, etc. are components of the vector $\bar{j}$.) Also let the elements of S_q be $\{u_1, \cdots, u_{n-1}\}$ and the remainders when i is divided by $u_1, \cdots, u_{n-1}$ be $f_1, f_2, \cdots, f_{n-1}$, respectively. (As above, note that $f_1, f_2, \cdots$, etc. are components of vector $\bar{i}$.) Now k (a positive integer) can be chosen to satisfy the following set of congruences:

$$\left\{ \begin{array}{l} k \equiv -e_1 + 1 + 1 \pmod{r_1} \\ k \equiv -e_2 + 2 + 1 \pmod{r_2} \\ \qquad \cdots \\ k \equiv -e_{n-1} + n - 1 + 1 \pmod{r_{n-1}} \end{array} \right\} \quad \text{(set 1)}$$

$$\left\{ \begin{array}{l} k \equiv -f_1 + q \pmod{u_1} \\ k \equiv -f_2 + q \pmod{u_2} \\ \qquad \cdots \\ k \equiv -f_{n-1} + q \pmod{u_{n-1}} \end{array} \right\} \quad \text{(set 2)}$$

Note that, by the Chinese Remainder Theorem [NIVE60], such a positive integer k exists. It is easy to see that $a^{j+k} \notin L_i$ for any $i \neq q$, and $a^{i+k} \in L_q$. Let c be such that $u_c = s_r$. Clearly $i+k \equiv q \pmod{u_c}$, but $i \not\equiv j \pmod{u_c}$. (Recall that $i \equiv i_r \pmod{u_c}$, $j \equiv j_r \pmod{u_c}$ and $i_r \neq j_r$.) Thus $j+k \not\equiv q \pmod{u_c}$ so $a^{j+k} \notin L_q$. Thus $a^{j+k} \notin L$. This is a contradiction since $\delta(q_0, a^i) = \delta(q_0, a^j)$. This completes the proof of Claim 3. Thus $\mathrm{DFA}(u) < \mathrm{UNA}(u)$.

Proof of $\mathrm{UNA}(u) < \mathrm{FNA}(u)$. Since $\mathrm{UNA}(u) \leqq \mathrm{FNA}(u)$, it is enough to show that $(\mathrm{UNA}(u), \mathrm{FNA}(u))$. Define a collection of languages as follows. Let p_i denote the ith prime number and L_k be defined as

$$L_k = \{a^n \mid n \not\equiv 0 \pmod{p_j} \text{ for some } j \leqq k\}.$$

It is easy to see that L_k can be accepted by an fna with $\sum_{i=1}^{k} p_i$ states. Such an fna for $k=3$ is shown in Fig. 6. By the prime number theorem [APOS76], $p_i = O(i \log i)$, so $\sum_{i=1}^{k} p_i = O(\sum_{i=1}^{k} i \log i) = O(k^2 \log k)$.

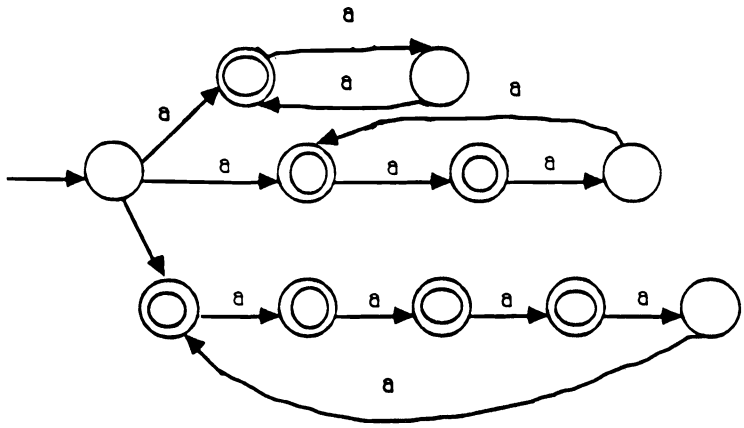

FIG. 6. *An* fna *accepting* L_3.

We next show that any una accepting L_k requires at least $\prod_{i=1}^{k} p_i - 1$ states. To show this, let M be any una accepting L_k. We see that the shortest string not accepted by L_k is $a^{p_1 p_2 \cdots p_k}$. Thus, by Lemma 1, the size of M must be at least $\prod_{i=1}^{k} p_i - 1 \geqq 2^k - 1$. This proves that $(\mathrm{UNA}(u), \mathrm{FNA}(u))$. Using the f-conciseness notation of [KINT86] (see § 2), the above result can be stated in a sharper form as $\mathrm{FNA}(u) - (2^{(2n/\log n)^{1/2}} - 1) \to \mathrm{UNA}(u)$.

Proof of $\mathrm{FNA}(u) = \mathrm{PNA}(u) = \mathrm{ENA}(u)$. This immediately follows from Lemma 3 via the following observations: (i) A' in Lemma 3 is finitely ambiguous and (ii) $|A'| \leqq O(|A|^2)$. □

We next show how to extend Theorem 1 to bounded languages.

THEOREM 2. $\mathrm{DFA}(b) < \mathrm{UNA}(b)$, $\mathrm{UNA}(b) < \mathrm{FNA}(b)$, *and* $\mathrm{FNA}(b) = \mathrm{PNA}(b) = \mathrm{ENA}(b)$.

Proof. The facts that $\mathrm{DFA}(b) < \mathrm{UNA}(b)$ and $\mathrm{UNA}(b) < \mathrm{FNA}(b)$ immediately follow from Theorem 1. In the rest of the proof we show that $\mathrm{FNA}(b) = \mathrm{ENA}(b)$. For simplicitly we consider bounded languages L such that $L \subseteq a^*b^*$. It is easy to generalize the result. Let $L \subseteq a^*b^*$ be accepted by an ena and let $|M| = n$. We further simplify the discussion by assuming that $L \cap a^* = \varnothing$. (Otherwise, we can let $L = L_1 \cup L_2$ where $L_1 \cap a^* = \varnothing$ and $L_2 \subseteq a^*$ and apply the following procedure for the language L_1. It is

straightforward to construct a machine for L_2 from M. Finally one can construct a machine for $L_1 \cup L_2$.) We show that L can be accepted by a fna with at most $p(n)$ states for some polynomial $p(.)$. The intuitive idea behind the proof is simple, and we illustrate it with an example. Intuitively the states of an nfa accepting $L \subseteq a^*b^*$ can be partitioned into two sets A and B as follows: for some state q, if all the arcs incident into q are labeled a, then q is in A else it is in B. For the nfa in Fig. 7, the partition is as shown in Fig. 8.

Clearly if p, q are in A (in B) and if $q \in \delta(p, t)$, then $t = a$ ($t = b$). As a next step, we introduce additional states in A and B so that in the resulting machine there are only ε-arcs from A to B. This requires the introduction of the following states: for each q in B such that for some $p \in A$, $q \in \delta(p, a)$, introduce a state q' in A and replace the arc $\langle p, q\rangle$ labeled a by two arcs: $\langle p, q'\rangle$ labeled a and $\langle q', q\rangle$ labeled ε. For each q in B such that for some $p \in A$, $q \in \delta(p, b)$, introduce a state q'' in B and replace the arc $\langle p, q\rangle$ labeled a by two arcs: $\langle p, q''\rangle$ labeled ε and $\langle q', q\rangle$ labeled b. This construction applied on Fig. 8 results in Fig. 9.

Let M_1 and M_2 be the machines in Fig. 9, whose transition graphs are induced by the set of states A and B, respectively. For any pair (p, q), where p and q are states in M_i ($i = 1$ or 2), let $M_i(p, q)$ denote the machine obtained by keeping the transitions of M_i, but renaming the start state as p, and the accepting state as q. Convert each $M_i(p, q)$ to a finitely ambiguous machine using Lemma 3. (Call the resulting machine again as $M_i(p, q)$.) Also assume that the states of $M_i(p, q)$ have been distinctly named. Finally, construct a new machine M' as follows. M' uses the following machines: (1) For each q with an ε-arc leaving q, the machine $M_1(p_0, q)$ where p_0 is the start state of M, (2) for each p with an ε-arc entering into p, and for each accepting state q of

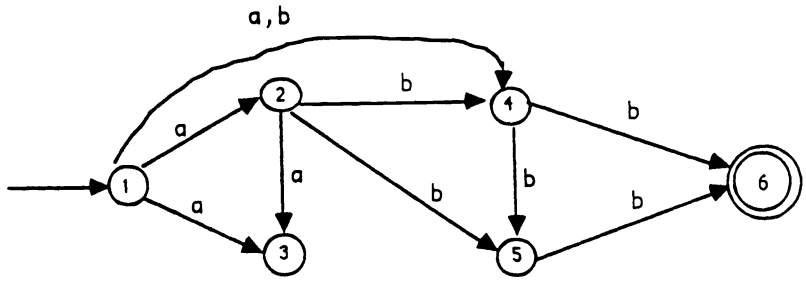

FIG. 7

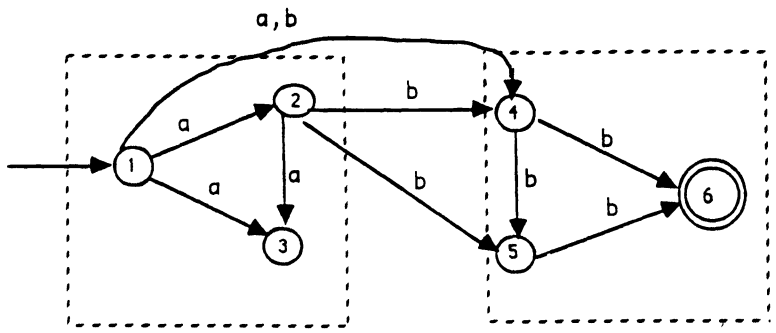

FIG. 8

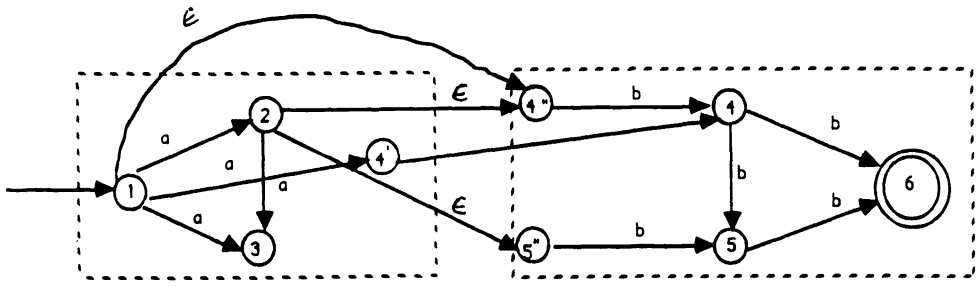

FIG. 9

M, the machine $M_2(p, q)$. Also introduce a new start state p_0' and introduce an ε-arc from p_0' to the start state p_0 in each machine $M_1(p_0, r)$ for each r. Also for each ε-arc $\langle p, q\rangle$ in Fig. 9, connect an ε-arc from the state p of the machine $M_1(p_0, p)$ to the state q of the machine $M_2(q, t)$ for each t. Finally, the set of accepting states of M' is $\{t | M_2(q, t)$ is used in $M'\}$. The machine M' derived from Fig. 9 is shown in Fig. 10.

It is easy to prove the correctness of the above construction. □

We conclude this section with a brief discussion of the relative conciseness of the collections 2-DFA(u) and NFA(u). The problem of 2-DFA versus NFA was considered in [SAKO78] and [SIPS79]. In [SAKO78] it has been shown that (ENA, 2-DFA) and conjectured that ENA $<>$ 2-DFA, but this claim is (to the best of our knowledge) still open. In [SIPS79] it has been proved that (SDFA, ENA), a weaker claim. Berman [BERM79] and Sipser [SIPS79] have shown that (SDFA, 2-DFA). In contrast to the above claims, we prove the following result.

THEOREM 3. (i) ENA(u) $<$ 2-DFA(u), (ii) 2-DFA(u) $=$ SDFA(u).

Proof of (i). To prove the desired claim, we must show two results: ENA(u) $\leqq$ 2-DFA(u) and (ENA(u), 2-DFA(u)). We first outline a proof of the former result. This result was also obtained independently by Chrobak [CHRO86]. We must show that any given nfa M over a unary alphabet can be converted to a 2-dfa with a polynomial blowup in the number of states. Using Lemma 3, convert M to a fna M' in the normal form. M' can be viewed as a finite union of dfa's. Now construct a 2-dfa

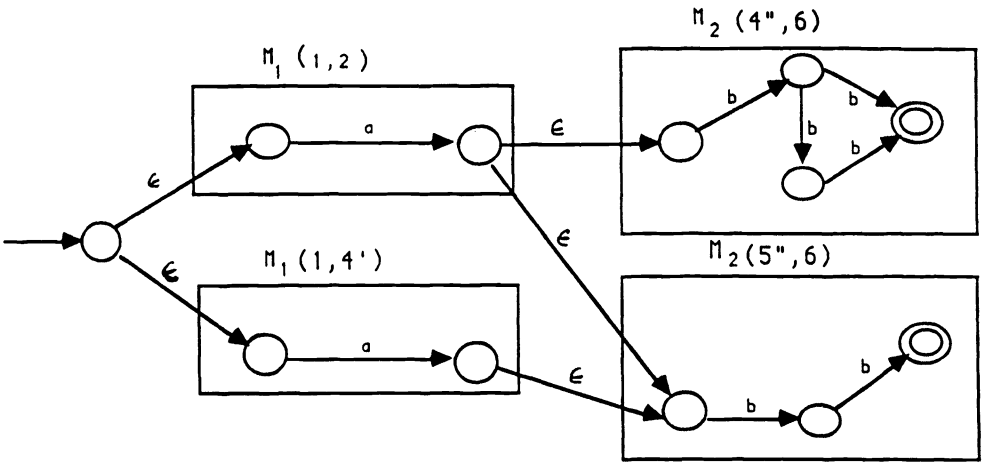

FIG. 10

that simulates this fna by simulating a dfa during each sweep. This result was independently obtained by Chrobak [CHRO86]. We next prove that (ENA(u), 2-DFA(u)). Consider the collection F_k of languages defined as follows: $F_k = \{a^n | n$ is divisible by p_j for *all* $j \leqq k\}$. It is easy to show that F_k can be accepted by a $\sum_{j=1}^{k} p_j$ state 2-dfa, and any nfa accepting F_k requires at least $\prod_{j=1}^{k} p_j$ states. This completes the proof of (i).

Proof of (ii). The proof is analogous to Theorem 2 presented in [IBAR88]. We omit the details. □

We conclude this section with some remarks regarding the succinctness problem for unbounded languages. The result (DFA, UNA) has been proved by Meyer and Fischer [MEYE71] using the following candidate: $L_m = L(r_m)$ where $r_m = (0+1+\varepsilon)^m 1(0+1)^{m-1}$. L_m can be accepted by a ufa with $2m+1$ states and any dfa that accepts L_m has at least 2^m states. Note that Theorem 1 shows that the claim holds even over a one-letter alphabet. The same way, as shown in Theorem 1, (UNA, FNA) also holds even for unary alphabet languages. We have not been able to prove either of the following claims: (1) PNA $<$ ENA (2) FNA $<$ PNA. We conjecture that both these results are true and offer the following candidate languages.

For (FNA, PNA): Let $L_k = L(r_k)$ where $r_k = (0+1)^*1(0+1)^k1(0+1)^*$. Figure 11 shows a pna with $k+3$ states accepting L_k. We conjecture that there is no polynomial $p(.)$ such that for a collection $\{M_k\}$ of fna's accepting L_k, $|M_k| \leqq p(k)$ for all k.

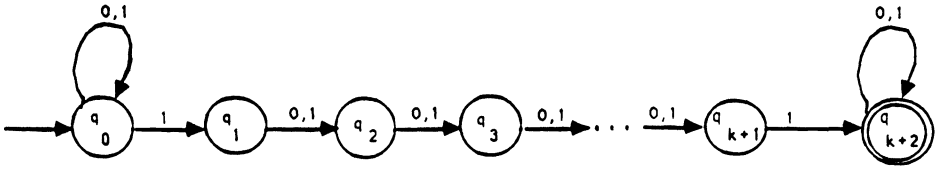

FIG. 11. *A* pna *for* L_k.

For (PNA, ENA): Let $L_k = \{a^n | n \not\equiv 0 \pmod{p_j}$ for some $j \leqq k$ and $n \geqq 1\}$, where p_j is the jth prime number. (Recall that this collection of languages was used in Theorem 1.) Now let $A_k = (\# L_k \#)^*$. (A_k is the "marked Kleene closure" of L_k in the automata theoretic parlance.) It is easy to see that there exists an ena of size $O(\sum_{i=1}^{k} p_i) = O(k^2 \log k)$ states accepting A_k.

We conjecture that the number of states in any pna accepting A_k is not bounded by a polynomial in k. Although we do not have a proof of this result, we provide an evidence by showing that among a restricted class of pna's none with fewer than $2^{k/2}$ states can accept A_k. This restricted class of machines is defined as follows. For any machine M in this class, there is only one state q in Q, the set of states of M, such that for any q', q'' in Q, if $q'' \in \delta(q', \#)$, then $q'' = q$. Informally it means that there is only one state in M with arcs labeled "#" entering into it. We now prove the following claim regarding restricted pna's.

CLAIM. Let M be a restricted pna accepting A_k. Then $|M| \geqq 2^{k/2}$.

Proof. Let $M = \langle Q, \Sigma, \delta, q_0, \{f\}\rangle$. Clearly, f is the only state such that for some $q \in Q$, $f \in \delta(q, \#)$. Define $Q_1 = \{q | f \in \delta(q, \#)\}$ and $Q_2 = \{q | q \in \delta(f, \#)\} = \{f\}$. For any $q \in Q_1$, define M'_q as $M'_q = \langle Q, \Sigma, \delta, f, \{q\}\rangle$. Next define M_q from M'_q as follows: (i) Remove all the edges labeled # from M'_q; and (ii) reduce the resulting nfa, i.e., remove the useless states.

First observe that $Q_1 \cap Q_2 = \varnothing$, for if $q \in Q_1 \cap Q_2$, then for some string $w \in A_k$, $f \in \delta(q_0, w)$, and hence $f \in \delta(q_0, w\#\#)$ implying that $w\#\# \in A_k$, a contradiction, since

ε is not in A_k. We claim that M_q is a ufa for all $q \in Q_2$, as seen from the following argument. Suppose M_q is ambiguous. Then there is a word $w \neq \varepsilon$ such that $N(p, w, q) \geqq 2$. In this case, for the original machine M, $N(f, \# w \#, f) \geqq 2$. Thus by Lemma 2, M is exponentially ambiguous, a contradiction. Furthermore, using the same argument, we observe that $L(M_r) \cap L(M_s) \neq \varnothing$ for $r \neq s$. Now it is easy to construct a ufa M' with the following properties: (i) $|M'| \leqq \sum_q |M_q| + 1$; and (ii) $L(M') = L_k$. The construction of M' is by simply introducing a new start state and having ε-transitions to the start states of all M_q's and then removing the ε-transitions. Hence, M' is unambiguous. We now show that $L(M') = L_k$. Since it is obvious that $L(M') \subseteq L_k$, we need only to show that $L_k \subseteq L(M')$. Let $\# w \# \in L_k$. Then, $\# w \# \# w \#$ is in A_k. Since M is a restricted machine, any computation (i.e., any sequence of states) on the input $\# w \#$ will terminate in f, and hence $f \in \delta(f, \# w \#)$. Thus $w \in L(M_q)$ for some q, so $w \in L(M')$. This completes the proof that $L_k = L(M')$. The bound on the number of states in M' is obvious. Thus, if $|M| = t$, then $|M'| \leqq t^2 + 1$. From Lemma 1, we see that $t^2 + 1 \geqq |M'| \geqq \prod_i p_i > 2^k$, and thus $t \geqq 2^{k/2}$ (for $k \geqq 2$). This proves the desired claim. □

Table 1 summarizes the results on succinctness for unary and bounded languages.

4. Concurrent conciseness of representations. Concurrent conciseness was introduced in [KINT86] as an important generalization of "usual" conciseness for the following reasons:

> Assume that we have three classes of automata C_1, C_2, and C_3. One is often able to prove the conciseness of C_2 over C_1 using a sequence of languages $\{A_n\}$, and the conciseness of C_3 over C_2 using another sequence of languages $\{B_n\}$. The problem is that $\{A_n\}$ and $\{B_n\}$ have often very little in common since $\{A_n\}$ exploits the advantages of C_2 over C_1 and $\{B_n\}$ exploits the advantages of C_3 over C_2. Concurrent conciseness addresses the question whether there is *one* sequence of languages which concurrently establishes the conciseness of C_2 over C_1 and that of C_3 over C_2.

Following [KINT86], we quantify the concurrent conciseness as follows.

DEFINITION. Say that C_1 is *f,g-concurrently concise* over C_2 and C_3 denoted by $C_1 - f(n) \to C_2 - g(n) \to C_3$ for some $f(n)$ and $g(n)$ if C_1 is f-concise over C_2 and C_2 is g-concise over C_3 for the same sequence of languages.

TABLE 1
Succinctness results for unary and bounded inputs.

	UNA	FNA	PNA	ENA	2-DFA

UNA		<	<	<	<
FNA			=	=	<
PNA				=	<
ENA					<

Since our primary concern in this paper has been to contrast the polynomial growth and the superpolynomial growth, we need the following coarser definition. We write (A, B, C) to denote the fact that $C - f(n) \to B - g(n) \to A$, where f and g are both superpolynomials. Thus (A, B, C) means that, in a strong sense, A, B, and C form a hierarchy with respect to concise representations. Our next result is to show that (DFA, UNA, PNA). This result settles an open problem mentioned by Stearns and Hunt [STEA85].

THEOREM 4. PNA-$2^{\sqrt{n}/(4\sqrt{2})} \to$ UNA-$(n/16)^{(\log n - 4)} \to$ DFA.

Proof. Consider the collection $\{J_k\}$ of languages defined as follows:

$J_k = \{x1y1 | x, y \in \{0, 1\}^*, |y| = k^2$ and x has a substring of the form $1z1$ where $|z| = k\}$.

We show the following.

CLAIM 1. J_k can be accepted by a k^2+k+4 state pna.

Proof. We describe informally a pna accepting J_k. M_k uses $k+3$ states to verify the existence of the substring $1z1$, and counts k^2 characters following a 1 to accept strings in J_k. It is easy to see that M_k satisfies our requirements. □

CLAIM 2. Any dfa accepting J_k requires at least 2^{k^2+1} states.

Proof. Let M be a dfa accepting J_k. For any strings $x, y \in 1^{k+3}\Sigma^{k^2+1}$, $x \neq y$ implies $\delta(q_0, x) \neq \delta(q_0, y)$. Thus M must have 2^{k^2+1} states. □

CLAIM 3. There exists a $(2^{k+3}+k^2+1)$-state una accepting J_k.

Proof. We first construct a dfa M'_k with 2^{k+3} states to accept the language $\{x1y1 | x, y \in \{0, 1\}^*, |y| = k\}$. M'_k has as its states q_σ where σ in $\{0, 1\}^*$ with $|\sigma| \leqq k+2$. q_λ is the start state. The δ-function of M'_k is constructed in such a way that $\delta(q_\lambda, w) = q_w$ if $|w| \leqq k+2$, else $\delta(q_\lambda, w) = q_{w'}$ where w' is a suffix of w of length $k+2$. The accepting states of M'_k are $F = \{q_w | w = 1w'1$ for some w' of length $k\}$. We modify M'_k to M_k as follows:

(A) Introduce new states $p_0, p_1, \cdots, p_{k^2}$, and introduce the following transitions:

$$\delta(p_i, 0) = \delta(p_i, 1) = \{p_{i+1}\} \text{ if } i < k^2,$$

(B) Remove the transitions from all the states of F in M'_k and add the following transitions:

$$\delta(p, 0) = \{p\}, \delta(p, 1) = \{p, p_0\} \text{ for all } p \text{ in } F.$$

(C) The only accepting state of M_k is the state p_{k^2}.

Figure 12 shows the construction of M_k from M'_k:

Clearly, M_k is an una such that $L(M_k) = J_k$. □

The final step in the proof is the following claim:

CLAIM 4. Any una accepting the language J_k has at least $2^{k/4}$ states.

Proof. The basic machinery used in this proof is an argument based on linear independence that was originally proposed by Schmidt [SCHM78] (Theorem 3.9). This technique was also used in [SIPS79].

Let M be a ufa accepting J_k. We want to show that $|M| \geqq 2^{k/4}$. In the rest of the proof, we follow the notation used in Theorem 3.9 of [SCHM78].

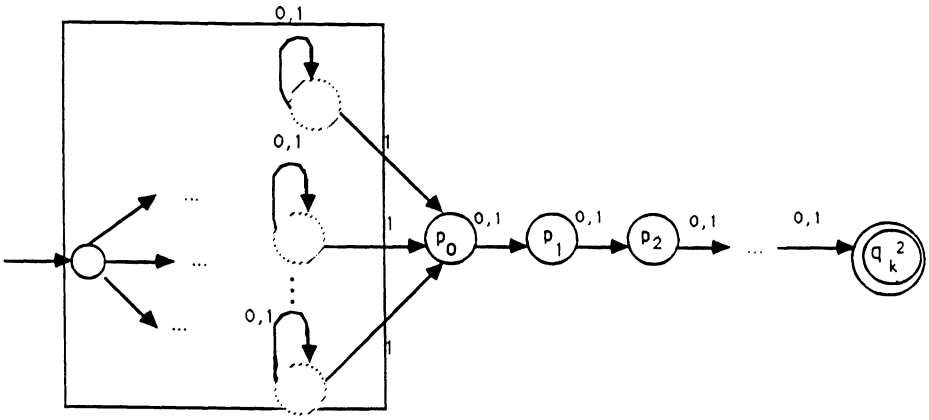

FIG. 12. M_k *constructed from* M'_k.

Let $x \in \{0,1\}^{k+1}$, and assume that $K_x = \{q_1, q_2, \cdots, q_{f(x)}\}$ is the set of states reachable from q_0 via x. Define for each i, $(1 \leqq i \leqq f(x))$, the set $A_i^x = \{y \text{ in } \{0,1\}^{k+1} |$ there exists a $q \in F \cap \delta(q_i, y10^{k^2})\}$. Thus A_i^x is the set of words of length $k+1$ that lead from the state q_i (in K_x) to acceptance. Define $A = \{\{A_i^x\} | i = 1, 2, \cdots, f(x), x \in \{0,1\}^{k+1}\}$. Let $B_1, B_2, \cdots, B_m$ be a listing of the members of A without repetitions. Let $K = \{q | q \in \delta(q_0, x)$ for some x in $\{0,1\}^{k+1}\}$. For any $q \in K$, associate the set $B_j = \{y$ in $\{0,1\}^{k+1} |$ there exists a q in $F \cap \delta(q, y10^{k^2})\}$. Since this mapping is surjective (onto), $m \leqq |K|$. Also since $|K| \leqq |M|$, we have $m \leqq |M|$. We complete the proof of Claim 4 by showing that $m \geqq 2^{k/4}$.

To do this, we interpret the subsets of $\{0,1\}^{k+1}$ as elements of the 2^n-dimensional vector-space over the field Z_2. Let x_i, $0 \leqq i \leqq 2^{k+1} - 1$, be the binary representation of i with a padding of zeros (at the left) to make $|x_i| = k+1$. With each $C \subseteq \{0,1\}^{k+1}$, we associate the vector $\bar{C} = (c_0, c_1, \cdots, c_{2^{k+1}-2}, c_{2^{k+1}-1})$, where $c_j = 1$ if $x_j \in C$ and $C_j = 0$ otherwise. For simplicity, assume that k is odd. The proof can be easily modified to handle the case when k is even.

Now let $T \subseteq \{0,1\}^{k+1}$ be defined as: $T = \{w |$ number of 0's in w is $(k+1)/2\}$. For any $x \in T$, consider the set $A_x = \bigcup_{i=1}^{f(x)} A_x^i$ defined as above. A_x thus consists of y's such that $xy10^{k^2} \in J_k$. Since M is unambiguous, the sets $A_x^1, \cdots, A_x^{f(x)}$ are mutually disjoint and furthermore, all the A_x^i's occur among the B_i's, the vector $\overline{A_x}$ can be written as a linear combination of vectors $\{\overline{B_i}\}$, $i = 1, 2, \cdots, m$, i.e., there exist $t_1, t_2, \cdots, t_m \in \{0,1\}$ such that

$$\overline{A_x} = \sum_{j=1}^{m} t_j \overline{B_j}. \tag{3}$$

Consider the set of vectors $V = \{\overline{A_y} | y \in T\}$. We shall show that V is linearly independent, as follows. Let $y_1, y_2, \cdots, y_r$ (r, the number of elements in $T = \binom{k+1}{(k+1)/2}$) be an arbitrary but fixed ordering of T. We define a Boolean matrix U of order $r \times 2^k$ as follows:

$$U = \begin{bmatrix} \overline{A_{y_1}} \\ \overline{A_{y_2}} \\ \overline{A_{y_3}} \\ \cdots \\ \overline{A_{y_r}} \end{bmatrix}.$$

Thus the rows of U are the vectors $\overline{A_{y_1}}, \overline{A_{y_2}}, \cdots, \overline{A_{y_r}}$. Proving that V is linearly independent is equivalent to proving that the rank of U is r. We prove the latter by showing that there exists a submatrix $\bar{U}$ (of U) of order $r \times r$ that can be derived by permuting the columns of the complement of the permutation matrix $\overline{I_r}$ given by

$$\overline{I_r} = \begin{bmatrix} 011 & \cdots & 1 \\ 101 & \cdots & 1 \\ \cdots & \cdots & \cdots \\ 111 & \cdots & 0 \end{bmatrix}.$$

For any i, $1 \leqq i \leqq r$, define $g(i)$ as the integer obtained by complementing the bits in the string $y_i = x_{g(i)}$. Now the submatrix $\bar{U}$ is defined by the set of columns $\{g(i)\}$, $i = 1, 2, \cdots, r$ of U. We claim that, in the column $g(i)$ of U, the only 0 entry is $U_{i,g(i)}$. For a string x, let $\bar{x}$ denote the string obtained by interchanging the 0's and 1's in x. Clearly, the string $y_i \overline{y_i} 10^{k^2} \notin J_k$ since for any pair of positions $(t, \bar{t})$ separated by k in $y_i \overline{y_i}$, the tth and $\bar{t}$th letters are complementary. Thus, $\overline{y_i} \notin A_{y_1}$ implying $U_{i,g(i)} = 0$. Next

observe that $y_j\overline{y_1}10^{k^2}$ is in J_k as seen from the following argument. Since $y_j \neq y_i$, there exists a t, $1 \leqq t \leqq k$, such that the tth letter of y_j is the same as the tth letter of $\overline{y_i}$. Thus, $y_j\overline{y_i}10k^2 \in J_k$. This implies $\overline{y_i} \in A_{y_j}$ implying $U_{j,g(i)} = 1$ for any $j \neq i$. Thus the rank of $\bar{U}$ and U is r and hence V is linearly independent. From (1) it follows that V is a subset of the vector space generated by $\overline{B_1}, \overline{B_2}, \cdots, \overline{B_m}$. Therefore $m \geqq r = \binom{k+1}{(k+1)/2} \geqq 2^{k/4}$. □

The claim made in Theorem 4 follows from the proof of Claims 1-4. □

Since both $2^{\sqrt{n}/(4\sqrt{2})}$ and $(n/16)^{\log n - 4}$ are superpolynomials, we obtain the following corollary.

COROLLARY 1. (DFA, UNA, PNA).

This corollary settles the question raised in [STEA85] of whether it is possible to have simultaneous nonpolynomial blowups among the three collections, DFA, UNA, and ENA. In fact, our result proves a stronger claim.

It appears that the same candidate languages $\{J_k\}$ can be used to prove (DFA, FNA, PNA). This can be done by showing a claim stronger than Claim 4 of Theorem 4, namely, any fna accepting J_k requires $f(k)$ states for some superpolynomial $f(.)$.

5. Closure properties of classes of finite-state devices. In this section, we consider the closure properties of various classes of finite-state devices. Let A be a class of finite state devices that is universal in the sense that every regular language can be accepted by some machine in A. (Note that all the classes of finite state devices considered in this paper are universal.) We ask the following question. "If L_1 and L_2 are accepted by machines M_1 and M_2 of type A, is it true that $L_1 \bullet L_2$ can also be accepted by a machine of type A, whose size is bounded by a polynomial in the sizes of M_1 and M_2, where $\bullet$ is a regularity preserving operation?" If the answer is yes, then we say that A is *polynomially closed* under $\bullet$. Many of the succinctness claims made earlier can be sharpened by studying the polynomial closure of various classes of devices under some fundamental regularity preserving operations such as concatenation and complementation.

The following definition is essentially due to Sakoda and Sipser [SAKO78].

DEFINITION. Let A be a collection of devices, and let $\bullet$ be a regularity preserving operation. A is said to be closed under $\bullet$ if there exists a polynomial $p(.)$ such that the following holds: For any $M_1, M_2 \in A$, there is an $M \in A$ such that $L(M) = L(M_1) \bullet L(M_2)$ and $|M| \leqq p(\max\{|M_1|, |M_2|\})$.

We study the closure of the collections DFA, UNA, FNA, PNA, ENA, and 2-DFA under the following fundamental regularity preserving operations: union, intersection, complementation, concatenation, Kleene star, and reversal. Table 2 contains a summary of results. A Y denotes that the closure property holds and an N denotes that it does not. A question mark indicates that the problem is open. A number next to a Y or N (such as $Y(3)$, etc.) denotes its location in the proof of Theorem 5. (Trivial proofs of closure are omitted.)

THEOREM 5. *The closure properties as indicated in Table 2 hold.*

Proof. (1) Let L_1 and $L_2 \subseteq \{0, 1\}^*$ be defined by the following regular expressions $r_1 = (0+1)^*1$ and $r_2 = (0+1)^{n-1}$. There exist dfa with 2 and n states, respectively, accepting L_1 and L_2. It is also easy to see that $L_1 . L_2$ cannot be accepted by a dfa with less than 2^n states.

(2) To prove this result, we first define a large alphabet, similar to the alphabet used in [SAKO78] to obtain a "hardest language" for the problem of conversion from 1-nfa to 2-dfa.

Let B_n be the set of bipartite graphs with $2n$ vertices, whose vertex partition has

TABLE 2
Closure properties.

	DFA	UNA	FNA	PNA	ENA	2-DFA
Union	*Y*	*Y*	*Y*	*Y*	*Y*	*Y*
Intersection	*Y*	*Y*	*Y*	*Y*	*Y*	*Y*
Complement	*Y*	?	*N*(7)	*N*(7)	*N*(7)	*Y*(3)
Reversal	*N*(4)	*Y*(4)	*Y*(4)	*Y*(4)	*Y*(4)	*Y*
Concatenation	*N*(1)	*N*(5)	?	*Y*	*Y*	?
Kleene star	*N*(2)	*N*(6)	?	?	*Y*	?

n vertices each. Pictorially, the graphs are represented as in Fig. 13, with the vertices occurring in two columns (left and right). The directed edges are from left to right and each vertex has outdegree and indegree at most 1. Figure 13 shows two members of the alphabet B_4.

For two graphs G_1 and G_2, the product $G_1 \otimes G_2$ is defined as a graph obtained by superposing the right boundary of G_1 with the left boundary of G_2. Figure 14 shows the graph $G_1 \otimes G_2$ for G_1 and G_2 of Fig. 13.

The notion of product can be extended in an obvious way to several graphs. In a product graph, the start vertex is the vertex in the first row of the leftmost boundary, and the terminal vertex is the last row of the rightmost boundary (u and v, respectively, in Fig. 14).

Now we define a collection of languages L_k as follows: $L_k = \{G_1 \cdots G_r | G_i \in B_k$ for all i, and $G_1 \otimes G_2 \otimes \cdots \otimes G_r$ has a directed path from start to terminal vertex$\}$. It is easy to see that L_k can be recognized by a dfa with k states. We show that any dfa M recognizing L_k^* has a least 2^{k-1} states. For any string $G_1 \cdots G_r$, define $\sigma(G_1 \cdots G_r) \subseteq \{2, 3, \cdots, k\}$ as follows. In the product graph $G_1 \otimes \cdots \otimes G_r$, add new edges from the last row to the first row on all columns except the first and last columns.

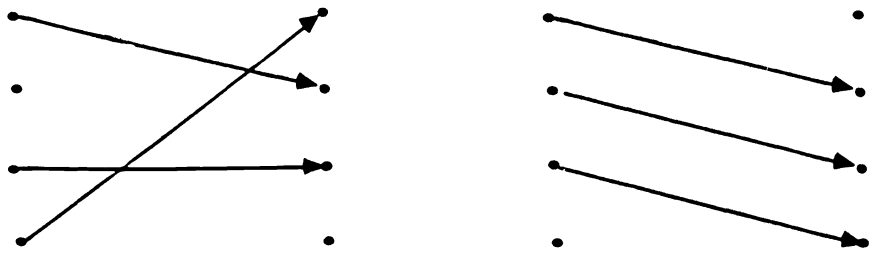

FIG. 13. *Two members of* B_4.

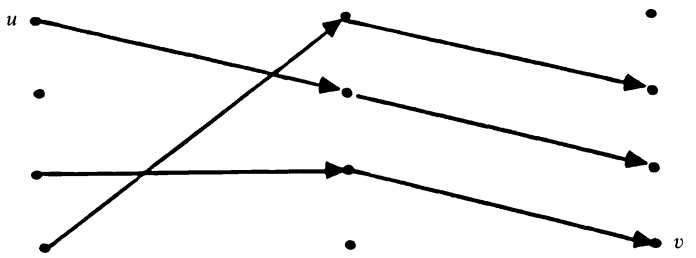

FIG. 14. *The graph of* $G_1 \otimes G_2$.

An integer i, $2 \leqq i \leqq k$, is in $\sigma(G_1 \cdots G_r)$ if in the resulting graph, there is a path from the start vertex to the vertex on the ith row of the last column. Let M be a dfa that accepts L_k^*, and let δ be its transition function. It is easy to see that if $\delta(q_0, G_1 \cdots G_m) = q_i$, and $\delta(q_0, G_1' \cdots G_n') = q_j$, and if $\sigma(G_1 \cdots G_m) \neq \sigma(G_1' \cdots G_n')$, then q_i and q_j are different. Thus, there are at least 2^{k-1} states in M. Finally note that B_k can be mapped to $\{0, 1\}$ and the lower bound claim still holds.

(3) This result has been proved by Sipser [SIPS80] as an application of a general result that any deterministic off-line TM using bounded space can be made halting.

(4) For DFA, the nonclosure follows from the collection of languages $L_n = (0+1)^{n-1}1(0+1)^*$. The closure for the other families follows from the fact that the standard procedure for constructing a machine to accept the reverse of a language (viz, reversing the direction of the arrows, etc.) preserves the type of ambiguity.

(5) To prove that ufa's are not closed under concatenation, we need a result of [SCHM78]. Let $C_k = \{x \# y \| x| = |y| = k, \text{ and } x \neq y\}$. It has been shown in [SCHM78] that any una accepting C_k requires at least 2^k states. We define the languages

$$L_1 = \{x \| x| \leqq k\},$$

$$L_2 = \{ay \# x_1 b x_2 | a, b \in \{0, 1\}, a \neq b, |y| \leqq k-1, |y| = |x_2|, |x_1| + |x_2| = k-1\},$$

$$L_3 = \{x \# y \| x| = |y| = k\}.$$

It is easy to see that L_1 and L_3 can be accepted by una's with $O(k)$ states, and L_2 can be accepted by a una with $O(k^2)$ states. Also note that $L_1 \,.\, L_2 \cap L_3 = C_k$. Since una's are closed under intersection, the desired claim follows from Schmidt's result.

(6) The nonclosure of ufa's under Kleene star follows from the fact that $C_k = (L_1 \cup L_2)^* \cap L_3$.

(7) We show the stronger claim that FNA(u) is not closed under complement. Let p_i be the ith prime number. Consider $L_k = \{a^n | n \not\equiv 0 \pmod{p_i} \text{ for some } 1 \leqq i \leqq k, n \geqq 1\}$. We have noted in Theorem 1 that there exists a finitely ambiguous nfa with $\sum_{i=1}^{k} p_i = O(k^2 \log k)$ states to accept L_k. We shall now show that any nfa M accepting $\overline{L_k}$ requires at least $\prod_{i=1}^{k} p_i > 2^k$ (for $k \geqq 2$) states. First observe that the two shortest strings in $\overline{L_k}$ are of length 0 and $t = \prod_{i=1}^{k} p_i$. Consider a sequence of states in M leading to acceptance on input a^t. (Such a sequence exists since a^t is in $\overline{L_k}$.) Let this sequence be $q_0, \cdots, q_t$. If M has fewer than t states, there exist integers i and j $(1 \leqq i < j \leqq t)$ such that $q_i = q_j$. This implies that a^{t-j+i} is in $\overline{L_k}$, a contradiction since $0 < t-j+i < t$. This completes the proof. □

6. Concluding remarks. In this paper, we have compared the relative succinctness of nondeterministic finite automata of various types of ambiguities and have established that the machines with "higher ambiguity" tend to be more succinct. These results are refinements and/or improvements over the earlier results of similar kind such as presented in [MEYE71] and [SCHM78]. We have presented a result on the concurrent conciseness of NFA over UFA and DFA, solving an open problem due to Stearns and Hunt. We also have studied the succinctness of various classes of finite-state devices through regularity preserving transformations.

Among the problems that remain open, we mention the following:

(1) Prove that (FNA, PNA).

(2) Prove that (PNA, ENA).

(3) Prove that FNA is not polynomially closed under concatenation.

It appears that the same candidate languages $D_k \subseteq \{0, 1\}^*$ are suitable for problems (1) and (3). The collection D_k is: $D_k = \{w | w = x1y1z, x, y, z \text{ in } \{0, 1\}^*, |y| = k\}$. It is easy to see that D_k can be accepted by a pna with $O(k)$ states. It remains to be shown that any fna accepting D_k requires at least $\Omega(\tau^k)$ for some $\tau > 0$. In addition to solving

open problems (1) and (3), this claim would also settle an unproven conjecture stated in § 4, namely, (DFA, FNA, PNA).

Acknowledgment. The authors are grateful to an anonymous referee for a remarkably thorough reading of an earlier version of this paper that led to many corrections and improvements.

ERRATUM: TWO APPLICATIONS OF INDUCTIVE COUNTING FOR COMPLEMENTATION PROBLEMS*

ALLAN BORODIN†, STEPHEN A. COOK†, PATRICK W. DYMOND‡, WALTER L. RUZZO§, AND MARTIN TOMPA¶

Jun Tarui has pointed out a technical error in the last row of Table 1: expected time is not the correct measure for defining the classes *PP* and *PLP*. Gill [2, Prop. 3.1], for instance, shows that any recursively enumerable set can be accepted in *constant* expected time by a probabilistic machine with unbounded two-sided error. Similarly, Jung's result [3] that $PL = PLP$ would have a straightforward proof if expected time were used in the definition of *PLP*. In both cases, the definition should be in terms of worst case time. This error has no effect on the results in the remainder of the paper.
