AMORTIZED ANALYSIS OF ALGORITHMS FOR SET UNION WITH BACKTRACKING*

JEFFERY WESTBROOK† AND ROBERT E. TARJAN‡

Abstract. Mannila and Ukkonen [*Lecture Notes in Computer Science* 225, Springer-Verlag, New York, 1986, pp. 236-243] have studied a variant of the classical disjoint set union (equivalence) problem in which an extra operation, called de-union, can undo the most recently performed union operation not yet undone. They proposed a way to modify standard set union algorithms to handle de-union operations. In this paper several algorithms are analyzed based on their approach. The most efficient such algorithms have an amortized running time of $O(\log n/\log\log n)$ per operation, where n is the total number of elements in all the sets. These algorithms use $O(n \log n)$ space, but the space usage can be reduced to $O(n)$ by a simple change. The authors prove that any separable pointer-based algorithm for the problem requires $\Omega(\log n/\log\log n)$ time per operation, thus showing that our upper bound on amortized time is tight.

1. Introduction. The classical disjoint set union problem is that of maintaining a collection of disjoint sets whose union is $U=\{1, 2, \cdots, n\}$ subject to a sequence of m intermixed operations of the following two kinds:

find(x): Return the name of the set currently containing element x.

union(A, B): Combine the sets named A and B into a new set, named A.

The initial collection consists of n singleton sets, $\{1\}, \{2\}, \cdots, \{n\}$. The name of initial set $\{i\}$ is i. For simplicity in stating bounds we assume $m=\Omega(n)$. This assumption does not significantly affect any of the results, and it holds in most applications.

Several fast algorithms for this problem are known [10], [13]. They all combine a rooted tree set representation with some form of path compaction. The fastest such algorithms run in $O(\alpha(m, n))$ amortized time[1] per operation, where α is a functional inverse of Ackermann's function [10], [13]. No better bound is possible for any pointer-based algorithm that uses a separable set representation [11]. For the special case of the problem in which the subsequence of union operations is known in advance, the use of address arithmetic techniques leads to an algorithm with an amortized time bound of $O(1)$ per operation [2].

Mannila and Ukkonen [7] studied a generalization of the set union problem called *set union with backtracking*, in which the following third kind of operation is allowed:

de-union: Undo the most recently performed union operation that has not yet been undone.

This problem arises in Prolog interpreter memory management [6]. Mannila and Ukkonen showed how to extend path-compaction techniques to handle backtracking. They posed the question of determining the inherent complexity of the problem, and

[1] The *amortized time* is the time of an operation averaged over a worst-case sequence of operations. See Tarjan's survey paper [12].

they claimed an $O(\log \log n)$ amortized time bound per operation for one algorithm based on their approach. Unfortunately, their upper bound argument is faulty.

In this paper we derive upper and lower bounds on the amortized efficiency of algorithms for set union with backtracking. We show that several algorithms based on the approach of Mannila and Ukkonen run in $O(\log n/\log \log n)$ amortized time per operation. These algorithms use $O(n \log n)$ space, but the space can be reduced to $O(n)$ by a simple change. We also show that any pointer-based algorithm that uses a separable set representation requires $\Omega(\log n/\log \log n)$ amortized time per operation. All the algorithms we analyze are subject to this lower bound. Improving the upper bound of $O(\log n/\log \log n)$, if it is possible, will require the use of either a non-separable pointer-based data structure or of address arithmetic techniques.

The remainder of this paper consists of four sections. In § 2 we review six algorithms for set union without backtracking and discuss how to extend them to handle backtracking. In § 3 we derive upper bounds for the amortized running times of these algorithms. In § 4 we derive a lower bound on amortized time for all separable pointer-based algorithms for the problem. Section 5 contains concluding remarks and open problems.

2. Algorithms for set union with backtracking. The known efficient algorithms for set union without backtracking [10], [13] use a collection of disjoint rooted trees to represent the sets. The elements in each set are the nodes of a tree, whose root contains the set name. Each element contains a pointer to its parent. Associated with each set name is a pointer to the root of the tree representing the set. Each initial (singleton) set is represented by a one-node tree.

To perform union(A, B), we make the tree root containing B point to the root containing A, or alternatively make the root containing A point to the root containing B and swap the names A and B between their respective elements. (This not only moves the name A to the right place but also makes undoing the union easy, as we shall see below.) The choice between these two alternatives is governed by a *union rule*. To perform find(x), we follow the path of pointers from element x to the root of the tree containing x and return the set name stored there. In addition, we apply a *compaction rule*, which modifies pointers along the path from x to the root so that they point to nodes farther along the path.

We shall consider the following possibilities for the union and compaction rules:

Union Rules:

Union by weight: Store with each tree root the number of elements in its tree. When doing a union, make the root of the smaller tree point to the root of the larger, breaking a tie arbitrarily.

Union by rank: Store with each tree root a nonnegative integer called its *rank*. The rank of each initial tree root is zero. When doing a union, make the root of smaller rank point to the root of larger rank. In the case of a tie, make either root point to the other, and increase the rank of the root of the new tree by one.

Compaction Rules (see Fig. 1):

Compression: After a find, make every element along the find path point to the tree root.

Splitting: After a find, make every element along the find path point to its grandparent, if it has one.

Halving: After a find, make every other element along the find path (the first, third, etc.) point to its grandparent, if it has one.

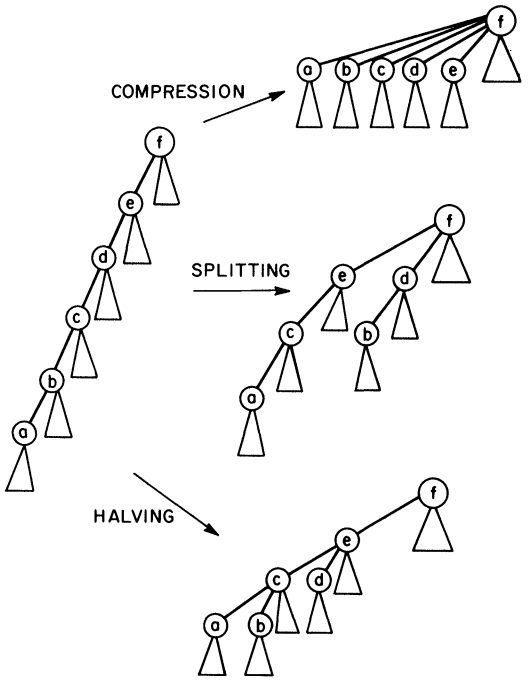

FIG. 1. *Path compression, path splitting, and path halving. The element found is "a."*

The two choices of a union rule and three choices of a compaction rule give six possible set union algorithms. Each of these has an amortized running time of $O(\alpha(m, n))$ per operation [13].

We shall describe two ways to extend these and similar algorithms to handle de-union operations. The first method is the one proposed by Mannila and Ukkonen; the second is a slight variant.

We call a union operation that has been done but not yet undone *live.* We denote a pointer from a node x to a node y by (x, y). Suppose that we perform finds without doing any compaction. Then performing de-unions is easy: to undo a set union we merely make null the pointer added to the data structure by the union. To facilitate this, we maintain a *union stack,* which contains the tree roots made nonroots by live unions. To perform a de-union, we pop the top element on the union stack and make the corresponding parent pointer null.

This method works with either of the two union rules. Some bookkeeping is needed to maintain set names and sizes or ranks. Each entry on the union stack must contain not only an element but also a bit that indicates whether the corresponding union operation swapped set names. If union by rank is used, each such entry must contain a second bit that indicates whether the union operation incremented the rank of the new tree root. The time to maintain set names and sizes or ranks is $O(1)$ per union or de-union; thus each union or de-union takes $O(1)$ time, worst-case. Either union rule guarantees a maximum tree depth of $O(\log n)$ [13]; thus the worst-case time per find is $O(\log n)$. The space needed by the data structure is $O(n)$.

Mannila and Ukkonen's goal was to reduce the time per find, possibly at the cost of increasing the time per union or de-union and increasing the space. They developed the following method for allowing compaction in the presence of de-unions. Let us call the forest maintained by the noncompacting algorithm described above the *reference*

forest. In the compacting method, each element x has an associated *pointer stack* $P(x)$, which contains the outgoing pointers that have been created during the course of the algorithm but have not yet been destroyed. The bottommost pointer on this stack is one created by a union. Such a pointer is called a *union pointer.* The other pointers on the stack are ones created by compaction. They are called *find pointers.* Each pointer (x, y) of either type is such that y is a proper ancestor of x in the reference forest.

Each pointer has an *associated union operation*, which is the one whose undoing would invalidate the pointer. To be more precise, for a pointer (x, y) the associated union operation is the one that created the pointer (z, y) such that z is a child of y and an ancestor of x in the reference forest. As a special case of this definition, if (x, y) is a union pointer, then $z = x$ and the associated union operation is the one that created (x, y). A pointer is *live* if its associated union is live.

Unions are performed as in the noncompacting method. Compactions are performed as in the set union algorithm without backtracking, except that each new pointer (x, y) is pushed onto $P(x)$ instead of replacing the old pointer, leaving x. When following a find path from an element x, the algorithm pops dead pointers from the top of $P(x)$ until $P(x)$ is empty or a live pointer is on top. In the former case, x is the root of its tree; in the latter case, the live pointer is followed.

This algorithm requires a way to determine whether a pointer is live or dead. For this purpose the algorithm assigns each union operation a distinct number as it is performed. Each entry on the union stack contains the number of the corresponding union. Each pointer on a pointer stack contains the number of the associated union and a pointer to the position on the union stack where the entry for this union was made. This information can be computed in $O(1)$ time for any pointer (x, y) when it is created. If (x, y) is a union pointer, the information is computed as part of the union. If (x, y) is a find pointer, then the last pointer on the find path from x to y when (x, y) was created has the same associated union as (x, y) and has stored with it the needed information. To test whether a pointer is live or dead, it is merely necessary to access the union stack entry whose position is recorded with the pointer and test first, if the entry is still on the stack, and second, whether its union number is the same as that stored with the pointer. If so, the pointer is live; if not, dead.

The implementation of de-union must be changed slightly, to preserve the invariant that in every pointer stack all the dead pointers are on top. To perform a de-union, the algorithm pops the top entry on the union stack. Let x be the element in this entry. The algorithm pops $P(x)$ until it contains only one pointer, which is the union pointer created by the union that is to be undone. The algorithm restores the set names and sizes or ranks as necessary, and pops the last pointer from $P(x)$. Because of the compaction, the state of the data structure after a de-union will not in general be the same as its state before the corresponding union.

We call this method the *lazy method* since it destroys dead pointers in a lazy fashion. Either of the union rules and any of the compaction rules can be used with the method. The total running time is proportional to m plus the total number of pointers created. (With any of the compaction rules, a compaction of a find path containing $k \geqq 2$ pointers results in the creation of $\Omega(k)$ pointers, $k-1$ in the case of compression or splitting and $\lfloor k/2 \rfloor$ in the case of halving.)

An alternative to the lazy method is the *eager method*, which pops pointers from pointer stacks as soon as they become dead. To make this popping possible, each union stack entry must contain a list of the pointers whose associated union is the one corresponding to the entry. When a union stack entry is popped, all the pointers on its list are popped from their respective pointer stacks as well. Each such pointer will

be on top of its stack when it is to be popped. To represent such a pointer, say (x, y), in a union stack entry, it suffices to store x. With this method, numbering the union operations is unnecessary, as is popping pointer stacks during finds.

The time required by the eager method for any sequence of operations is only a constant factor greater than that required by the lazy method, since both methods create the same pointers but the eager method destroys them earlier. With either union rule, the eager method uses $O(n \log n)$ space in the worst case, since the maximum tree depth is $O(\log n)$ and all pointers on any pointer stack point to distinct elements. (From bottom to top, the pointers on $P(x)$ point to shallower and shallower ancestors of x.)

The lazy method also has an $O(n \log n)$ space bound [3]. For any node x, consider the top pointer on $P(x)$, which is to a node, say y. Even if the pointer from x to y is currently dead, it must once have been live, and all pointers currently on $P(x)$ point to distinct nodes on the tree path from x to y as it existed when the pointer from x to y was live. Thus there can be only $O(\log n)$ such pointers. The total number of pointers therefore is $O(n \log n)$. The total number of numbers needed to distinguish relevant union operations is also $O(n \log n)$, which implies that the total space needed is $O(n \log n)$, as claimed.

The choice between the lazy and eager methods is not clear-cut. As we shall see at the end of § 3, a small change in the compaction rules reduces the space needed by either method to $O(n)$.

3. Upper bounds on amortized time. The analysis to follow applies to both the lazy method and the eager method. If we ignore the choice between lazy and eager pointer deletion, there are six versions of the algorithm, depending on the choice of a union rule and a compaction rule.

As a first step on the analysis, we note that compression with either union rule is no better in the amortized sense than doing no compaction at all, i.e., the amortized time per operation is $\Omega(\log n)$. The following class of examples shows this. For any k, form a tree of 2^k elements by doing unions on pairs of elements, then on pairs of pairs, and so on. This produces a tree called a *binomial tree* B_k, whose depth is k. (See Fig. 2.) Repeat the following three operations any number of times: do a find on the deepest element in B_k, undo the most recent union, and redo the union. Each find creates $k-1$ pointers, which are all immediately made dead by the subsequent de-union. Thus the amortized time per operation is $\Omega(k) = \Omega(\log n)$.

Both splitting and halving perform better; each has an $O(\log n / \log \log n)$ amortized bound per operation, in combination with either union rule. To prove this, we need a definition. For an element x, let size(x) be the number of descendants of x (including itself) in the reference forest. The *logarithmic size* of x, lgs(x), is $\lfloor \lg \text{size}(x) \rfloor$.[2]

We need the following lemma concerning logarithmic sizes when union by weight is used.

LEMMA 1 [10]. *Suppose union by weight is used. If node v is the parent of node w in the reference forest, then* $\text{lgs}(w) < \text{lgs}(v)$. *Any node has logarithmic size between* 0 *and* $\lg n$ *(inclusive).*

Proof. When a node v becomes the parent of another node w, $\text{size}(w) \leqq 2\,\text{size}(v)$ by the union by weight rule. Later unions can only increase size(v) and cannot increase size(w) (unless the union linking v and w is undone). The lemma follows. □

[2] For any x, $\lg x = \log_2 x$.

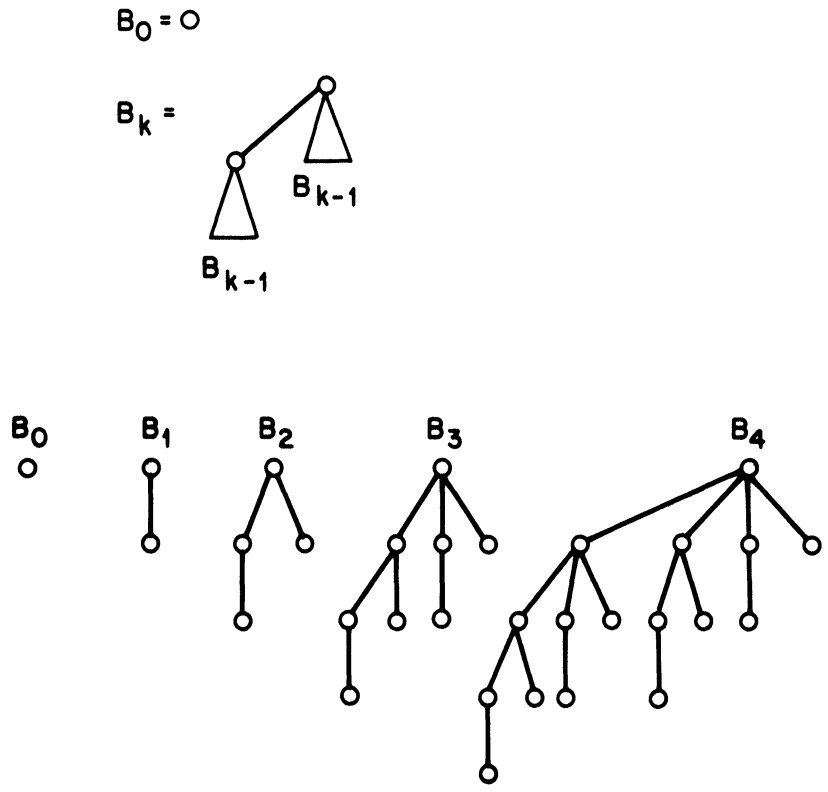

FIG. 2. *Binomial trees.*

THEOREM 1. *Union by weight in combination with either splitting or halving gives an algorithm for set union with backtracking running in* $O(\log n/\log\log n)$ *amortized time per operation.*

Proof. We shall charge the pointer creations during the algorithm to unions and finds in such a way that each operation is charged for $O(\log n/\log\log n)$ pointer creations. For an arbitrary positive constant $c<1$, we call a pointer (x, y) *short* if $\lg s(y)-\lg s(x)\leqq c\lg\lg n$ and *long* otherwise. (The logarithmic sizes in this definition are measured at the time (x, y) is created.) We charge the creation of a pointer (x, y) as follows:

(i) If y is a tree root, charge the operation (union or find) that created (x, y).
(ii) If y is not a tree root and (x, y) is long, charge the find that created (x, y).
(iii) If y is not a tree root and (x, y) is short, charge the union that most recently made y a nonroot.

A find with splitting creates two new paths of pointers, and a find with halving creates one new path of pointers. Thus $O(1)$ pointers are charged to each operation by (i). The number of long pointers along any path can be estimated as follows. For any long pointer (x, y), $\lg s(y)-\lg s(x)>c\lg\lg n$. Logarithmic sizes strictly increase along any path and are between 0 and $\lg n$ by Lemma 1. Thus if there are k long pointers on a path, $\lg n\geqq kc\lg\lg n$, which implies $k\leqq\lg n/(c\lg\lg n)$. Thus a find with either splitting or halving can create only $O(\log n/\log\log n)$ long pointers, which means that $O(\log n/\log\log n)$ pointers are charged to each find by (ii).

It remains for us to bound the number of pointers charged by (iii). Consider a union operation that makes an element x a child of another element y. Let I be the

time interval during which pointers are charged by (iii) to this union. During I, the sizes, and hence the logarithmic sizes, of all descendants of x remain constant. Interval I ends with the undoing of the union.

For each descendant w of x, at most one pointer (w, x) can be charged by (iii) to the union, since the creation of another such pointer charged by (iii) cannot occur at least until x again becomes a root and then becomes a nonroot, which can only happen after the end of I. Thus the number of pointers charged by (iii) to the union is at most one per descendant w of x such that $\text{lgs}(x) - \text{lgs}(w) \leqq c \lg \lg n$.

Since logarithmic sizes strictly increase along tree paths, any two elements u and v with $\text{lgs}(u) = \text{lgs}(v)$ must be unrelated, i.e., their sets of descendants are disjoint. This means that the number of descendants w of x with $\text{lgs}(w) = i$ is at most $\text{size}(x)/2^i \leqq 2^{\text{lgs}(x)+1-i}$, and the number of descendants w of x with $\text{lgs}(x) - \text{lgs}(w) \leqq c \lg \lg n$ is at most

$$\sum_{i=\text{lgs}(x)-\lfloor c \lg \lg n \rfloor}^{\text{lgs}(x)} 2^{\text{lgs}(x)+1-i} \leqq 2^{\lfloor c \lg \lg n \rfloor + 2} = O((\log n)^c) = O(\log n / \log \log n),$$

since $c < 1$. Thus there are $O(\log n / \log \log n)$ pointers charged to the union by (iii). □

The same result holds if union by rank is used instead of union by weight, but in this case the proof becomes a little more complicated because logarithmic sizes need not strictly increase along tree paths. We deal with this by slightly changing the definition of short and long pointers. We need the following lemma.

LEMMA 2 [13]. *Suppose union by rank is used. If node v is the parent of node w in the reference forest, then $0 \leqq \text{lgs}(w) \leqq \text{lgs}(v) \leqq \lg n$ and $0 \leqq \text{rank}(w) < \text{rank}(v) \leqq \lg n$.*

Proof. The first group of inequalities is immediate. The definition of union by rank implies $\text{rank}(w) < \text{rank}(v)$. A proof by induction on the rank of v shows that $\text{size}(v) \geqq 2^{\text{rank}(v)}$, which implies that $\text{rank}(v) \leqq \lg n$. □

THEOREM 2. *Union by rank in combination with either splitting or halving gives an algorithm for set union with backtracking running in $O(\log n / \log \log n)$ amortized time per operation.*

Proof. We define a pointer (x, y) to be *short* if $\max\{\text{lgs}(y) - \text{lgs}(x), \text{rank}(y) - \text{rank}(x)\} \leqq c \lg \lg n$ and *long* otherwise, where $c < 1$ is a positive constant. We charge the creation of pointers to unions and finds exactly as in the proof of Theorem 1 (rules (i), (ii), and (iii)). The number of pointers charged by rule (i) is $O(1)$ per union or find, exactly as in the proof of Theorem 1. A long pointer (x, y) satisfies at least one of the inequalities $\text{lgs}(x) - \text{lgs}(x) > c \lg \lg n$ and $\text{rank}(y) - \text{rank}(x) > c \lg \lg n$. Along any tree path only $O(\log n / \log \log n)$ long pointers can satisfy the former inequality and only $O(\log n / \log \log n)$ long pointers can satisfy the latter, by Lemma 2. It follows that only $O(\log n / \log \log n)$ pointers can be charged per find by rule (ii).

To count short pointers, we have one additional definition. For a nonroot element x, let $p(x)$ be the parent of x in the reference forest. A nonroot x is *good* if $\text{lgs}(x) < \text{lgs}(p(x))$ and *bad* otherwise, i.e., if $\text{lgs}(x) = \text{lgs}(p(x))$. The definition of lgs implies that any element can have at most one bad child. The bad elements thus form paths called *bad paths* of length $O(\log n)$; all elements on a bad path have the same logarithmic size. We call the element of largest rank on a bad path the *head* of the path. The head of a bad path is a bad element whose parent is either a good element or a tree root.

Consider a union operation that makes an element x a child of an element y. We count short pointers charged to this union as follows:

(1) *Short pointers leading from good elements.* If v and w are good elements such that $\text{lgs}(v) = \text{lgs}(w)$, then v and w are unrelated in the reference forest, i.e., they have

disjoint sets of descendants. The analysis that yielded the count of short pointers in the proof of Theorem 1 applies to the good elements here to yield a bound of $O((\log n)^c) = O(\log n/\log\log n)$ short pointers leading from good elements that are charged to the union by (iii).

(2) *Short pointers leading from bad elements.* Consider the number of bad paths from which short pointers can lead to x. The head of such a path is an element w such that $p(w)$ is either good or a tree root, and $\lg s(x) - \lg s(w) \leqq c \lg\lg n$. Heads of different bad paths have different parents. The analysis that counts short pointers in the proof of Theorem 1 yields an $O((\log n)^c)$ bound on the number of bad paths from which short pointers can lead to x. Along such a bad path, rank strictly increases, and the definition of shortness implies that only the $c \lg\lg n$ elements of largest rank along the path can have short pointers leading to x. The total number of short pointers leading from bad nodes that are charged to the union by (iii) is thus $O(c \log\log n\ (\log n)^c) = O(\log n/\log\log n)$. □

We conclude this section by discussing how to reduce the space bound for both the lazy method and the eager method to $O(n)$. This is accomplished by making the following simple changes in the compaction rules. If union by size is used, the compaction of a find path is begun at the first node along the path whose size is at least $\lg n$. If union by rank is used, the compaction of a find path is begun at the first node whose rank is at least $\lg\lg n$. With this modification, only $O(n/\log n)$ nodes have find pointers leaving them, and the total number of pointers in the data structure at any time is $O(n)$. The analysis in Theorems 1 and 2 remains valid, except that there is an additional time per find of $O(\log\log n)$ to account for the initial, noncompacted part of each find path.

4. A general lower bound on amortized time. We shall prove that the bound in Theorems 1 and 2 is best possible for a large class of algorithms for set union with backtracking. Our computational model is the *pointer machine* [4], [5], [9], [11] with an added assumption about the data structure called *separability.* Related results follow. Tarjan [11] derived an amortized bound in this model for the set union problem without backtracking. Blum [1] derived a worst-case-per-operation lower bound for the same problem. Mehlhorn, Näher, and Alt [8] derived an amortized lower bound for a related problem. Their result does not require separability.

The algorithms to which our lower bound applies are called *separable pointer algorithms.* Such an algorithm uses a linked data structure that can be regarded as a directed graph, with each pointer represented by an edge. The algorithm solves the set union with backtracking problem according to the following rules:

(i) The operations are presented on-line, i.e., each operation must be completed before the next one is known.

(ii) Each set element is a node of the data structure. There can be any number of additional nodes.

(iii) (Separability.) After any operation, the data structure can be partitioned into node-disjoint subgraphs, one corresponding to each currently existing set and containing all the elements in the set. The name of the set occurs in exactly one node in the subgraph. *No edge leads from one subgraph to another.*

(iv) The cost of an operation find(x) is the length (number of edges) of the shortest path from x to the node that holds the name of the set containing x. This length is measured at the beginning of the find, i.e., before the algorithm changes the structure as specified in (v).

(v) During any find, union, or de-union operation, the algorithm can add edges to the data structure at a cost of one per edge, delete edges at a cost of zero, and move,

add, or delete set names at a cost of zero. The only restriction is that separability must hold after each operation.

The eager method of § 2 obeys rules (i)-(v). This is also true of the lazy method, if we regard pointers as disappearing from the model data structure as soon as they become dead. This does not affect the performance of the algorithm in the model, since once a pointer becomes dead it is never followed.

THEOREM 3. *For any n, any $m = \Omega(n)$, and any separable pointer algorithm, there is a sequence of m find, union, and de-union operations whose cost is $\Omega(m \log n/\log\log n)$.*

Proof. We shall prove the theorem for n of the form 2^{2^k} for some $k \geqq 1$ and for $m \geqq 4n$. The result follows for all n and $m = \Omega(n)$ by padding the expensive problem instances constructed below with extra singleton sets on which no operations take place and with extra finds.

In estimating the cost of a sequence of operations, we shall charge the cost of adding an edge to the data structure to the deletion of the edge. Since this postpones the cost, it cannot increase the total cost of a sequence.

We construct an expensive sequence as follows. The first $n-1$ operations are unions that build a set of size n by combining singletons in pairs, pairs in pairs, and so on. The remaining operations occur in groups, each group containing between 1 and $2n-2$ operations. Each group begins and ends with all the elements in one set. We obtain a group of operations by applying the appropriate one of the following two cases (if both apply, either may be selected). Let $b = \lfloor \lg n/(2 \lg\lg n) \rfloor$.

(1) If some element in the (only) set is at distance at least b away from the set name, do a find on this element.

(2) If some sequence of ℓ de-unions will force the deletion of ℓb edges from the data structure (to maintain separability), do these de-unions. Then do the corresponding unions in the reverse order, restoring the initial set of size n.

We claim that if there is only one set, formed by repeated pairing, then case (1) or case (2) must apply. If this is true, we can obtain an expensive sequence of operations by generating successive groups of operations until more than $m-2n+2$ operations have occurred, and then padding the sequence with enough additional finds to make a total of m operations. The cost of such a sequence is at least $(m-3n+3)b = \Omega(m \log n/\log\log n)$.

It remains to prove the claim. Suppose case (2) does not apply. We shall show that case (1) does. Let $f = (\lg n)^2$. For $0 \leqq i \leqq \lg n/\lg f$ we define a partition P_i of the nodes of the data structure as follows:

$$P_i = \{X \mid X \text{ is the collection of nodes in the subgraph corresponding to one of the sets that would be formed by doing } f^i - 1 \text{ de-unions}\}.$$

Observe that $|P_i| = f^i$. Also $f^{\lg n/\lg f} = n$, so P_i is defined for $i \leqq \lg n/\lg f$. In particular P_b is defined, since $b = \lfloor \lg n/(2 \lg\lg n) \rfloor = \lfloor \lg n/\lg f \rfloor$.

For $0 \leqq i \leqq \lg n/\lg f$, we define the collection D_i of *deep sets* in P_i as follows:

$$D_i = \{X \in P_i \mid \text{all elements in } X \text{ are at distance at least } i \text{ from the name of the single set}\}.$$

Let $d_i = |D_i|$. We shall show that $d_b > 0$, which implies the existence of an element at distance at least b away from the name of the single set; hence case (1) applies.

Let ℓ_i be the number of edges leading from one set in P_i to another. We have $\ell_i \leqq bf^i$, since otherwise performance of $f^i - 1$ de-unions would force the deletion of bf^i edges from the data structure, and case (2) would apply.

Now we derive a recursive bound on d_i. We have $d_1 = f - 1$, since only one of the f sets in P_1 can contain the only set name. We claim that $d_{i+1} \geqq fd_i - \ell_i$. To verify the claim, let us consider D_i. Since $n = 2^{2^k}$ and the union structure of the only set forms

a binomial tree, each set X in D_i consists of f sets in P_{i+1}, all of whose elements are at distance at least i from the name of the only set. For an element $x \in X$ to be at distance exactly i from the set name, some edge must lead from x to a set in P_i other than X; otherwise X would not be in D_i. There are ℓ_i such edges. Each such edge can eliminate one set in P_{i+1} from being in D_{i+1}. But this leaves $fd_i - \ell_i$ sets in D_{i+1}, namely the fd_i sets into which the sets in D_i divide, minus at most ℓ_i eliminated by edges between different sets in P_i. That is, $d_{i+1} \geqq fd_i - \ell_i$, as claimed.

Applying the bound $\ell_i \leqq bf^i$ gives $d_{i+1} \geqq fd_i - bf^i$. Using $d_1 = f - 1$, a proof by induction shows that $d_i \geqq f^{i-1}(f-(i-1)b-1)$.

We wish to show that $d_b > 0$. This is true provided that $(f-(b-1)b-1) > 0$. But $f = (\lg n)^2$ and $b = \lfloor \lg n/(2\lg\lg n) \rfloor$, giving $(f-(b-1)b-1) = (f-b^2+b-1) \geqq \frac{3}{4}(\lg n)^2 > 0$, since we are assuming $n \geqq 4$, which implies $b^2 \leqq (\lg n)^2/4$ and $b \geqq 1$. Thus $d_b > 0$, which implies that some element is at distance at least b from the set name, i.e., case (1) applies. □

5. Remarks. Our bound of $\Theta(\log n/\log\log n)$ on the amortized time per operation in the set union problem with backtracking is the same as Blum's worst-case bound per operation in the set union problem without backtracking [1]. Perhaps this is not a coincidence. Our lower bound proof resembles his. Furthermore the data structure he uses to establish his upper bound can easily be extended to handle de-union operations; the worst-case bound per operation remains $O(\log n/\log\log n)$ and the space needed is $O(n)$.

The compaction methods have the advantage over Blum's method that as the ratio of finds to unions and de-unions increases, the amortized time per find decreases. The precise result is that if the ratio of finds to unions and de-unions in the operation sequence is γ and the amortized time per union and de-union is defined to be $\Theta(1)$, then the amortized time per find is $\Theta(\log n/(\max\{1, \log(\gamma \log n)\}))$. This bound is valid for any value of γ, and it holds for splitting or halving with either union rule, and it is the best bound possible for any separable pointer algorithm. This can be proved using straightforward extensions of the arguments in §§ 3 and 4. The space bound can be made $O(n)$ by an extension of the idea proposed at the end of § 3. If the de-union operations occur in bursts, the time per operation decreases further, but we have not attempted to analyze this situation.

Perhaps the most interesting open problem is whether the lower bound in § 4 can be extended to nonseparable pointer algorithms. (In place of separability, we require that the out-degree of every node in the data structure be constant.) We conjecture that the bound in Theorem 3 holds for such algorithms. The techniques of Mehlhorn, Näher, and Alt [8] suggest an approach to this question, which might yield at least an $\Omega(\log\log n)$ bound if not an $\Omega(\log n/\log\log n)$ bound on the amortized time.

THE BIT COMPLEXITY OF RANDOMIZED LEADER ELECTION ON A RING*

KARL ABRAHAMSON†, ANDREW ADLER‡, RACHEL GELBART†, LISA HIGHAM†, AND DAVID KIRKPATRICK†

Abstract. The inherent bit complexity of leader election on asynchronous unidirectional rings of processors is examined under various assumptions about global knowledge of the ring. If processors have unique identities with a maximum of m bits, then the expected number of communication bits sufficient to elect a leader with probability 1, on a ring of (unknown) size n is $O(nm)$. If the ring size is known to within a multiple of 2, then the expected number of communication bits sufficient to elect a leader with probability 1 is $O(n \log n)$.

These upper bounds are complemented by lower bounds on the communication complexity of a related problem called solitude verification that reduces to leader election in $O(n)$ bits. If processors have unique identities chosen from a sufficiently large universe of size s, then the average, overall choices of identities, of the communication complexity of verifying solitude is $\Omega(n \log s)$ bits. When the ring size is known only approximately, then $\Omega(n \log n)$ bits are required for solitude verification. The lower bounds address the complexity of certifying solitude. This is modelled by the best-case behaviour of nondeterministic solitude-verification algorithms.

1. Introduction.

Studies in the complexity of distributed computation typically ask two questions. (i) What is the complexity, under some chosen measure(s), of a chosen problem or family of problems, on distributed networks formalized in a chosen model? (The model might include both the network topology and assumptions about the processors and their interprocessor communication.) (ii) How is this complexity affected by changes in the model? This paper addresses these questions for the problem of electing a leader using randomized distributed algorithms running on asynchronous unidirectional rings of processors, where the measure of complexity is the expected number of bits transmitted.

Leader-election results in a unique processor, from among a specified subset of the processors, entering a distinguished final state. This problem is one of a small number of problems which are fundamental in that their solutions form the building blocks of many more involved distributed computations. Earlier work in the study of distributed computation has established the importance of the ring topology as a test-bed for the design and analysis of distributed algorithms. It is the chosen model here because it is a simple topology which exhibits many important attributes of distributed computations.

A unidirectional ring can be viewed as a sequence $P_1, \cdots, P_n$ of processors where each processor P_i sends messages to P_{i+1} and receives messages from P_{i-1} (subscripts are implicitly reduced in the obvious way). A number of variants of this basic model are distinguished by supplementary properties. Communication between processors is either synchronous or asynchronous. Processors may be indistinguishable or may have

distinct identifiers. Processors may or may not know the size of the ring at the start of computation. The complexity, measured by the number of communication messages, of leader election on models with various combinations of these properties has been well studied.

On an asynchronous unidirectional ring of processors with distinct identifiers, a leader can be elected by a deterministic algorithm which operates using pairwise comparisons of processor identifiers, using $O(n \log n)$ messages each of $O(m)$ bits [DKR], [Pe], where m is the number of bits in the largest processor identifier. If interprocessor communication is synchronous and identifiers are drawn from some known countable universe, then $O(n)$ messages suffice to elect a leader in the worst case [FL]. On the other hand, in the asynchronous case, if the universe of identifiers is unbounded, any deterministic leader-election algorithm must exchange $\Omega(n \log n)$ messages (of arbitrary length) in the worst case [B], [PKR] or average case [PKR], even if bidirectional communication is possible. Even if the ring size n is known to all processors and messages are transmitted synchronously, algorithms which are restricted to operate either on the basis of comparisons of processor identifiers or within a bounded number of rounds, must transmit $\Omega(n \log n)$ messages in the worst case [FL].

If processors are not endowed with distinct identifiers then, as was first observed by Angluin [A], deterministic algorithms are unable to elect leaders, even if n is known to all processors. Itai and Rodeh [IR] propose the use of randomized algorithms to skirt this limitation. They present a randomized algorithm that elects a leader in an asynchronous ring of known size n using $O(n \log n)$ expected messages of $O(\log n)$ bits each. The lower bound results of [Pa] show that even if processors have distinct identifiers drawn from some sufficiently large universe, the expected number of messages (of arbitrary length) communicated by a randomized leader election algorithm is $\Omega(n \log n)$. However, $O(n)$ expected messages suffice for randomized leader election on a synchronous ring without identifiers [IR], provided the ring size n is known to all processors.

In this paper, it is shown that with respect to bit complexity, the algorithms cited above for asynchronous rings are not optimal. The relationship between leader election and two subproblems, called attrition and solitude verification, is explored in § 2. Efficient reductions are established which motivate the development of procedures for these two subproblems (§ 3) and lower bounds for solitude verification (§ 4).

It follows from the results of § 3 that when each processor in a unidirectional ring of n processors has a distinct m-bit identifier, it is possible to elect a leader by a randomized algorithm using $O(mn)$ expected bits of communication. In addition, when the processors are indistinguishable but each knows the ring size n to within a factor of 2, then it is possible to elect a leader by a randomized algorithm using $O(n \log n)$ expected bits of communication.

These upper bounds are complemented by the lower bounds of § 4. It follows from the results of that section that when processors have unique identifiers drawn from a sufficiently large universe of size s then any algorithm must transmit $\Omega(n \log s)$ bits to elect a leader, even in the best case. If processors are indistinguishable but each knows the ring size only to within some interval of size Δ, then any algorithm must transmit $\Omega(n \log \Delta)$ bits to elect a leader, even in the best case.

The lower bounds are proved for successful computations of algorithms in a very general model. Algorithms may be nondeterministic and nonuniform and may deadlock. Moreover computations need only terminate in the weak nondistributive sense. An algorithm terminates distributively if whenever processors enter a decision state the

decision is irrevocable, that is, it will not change in light of subsequent messages received. The weaker nondistributive termination refers to the situation in which the cessation of message traffic is not necessarily detectable by individual processors and all decisions are predicated on this undetectable condition.

The upper and lower bounds are tight to within constant factors, except when the ring size is known to lie within some relatively small interval. This gap is reminiscent of earlier results concerning knowledge of ring size [FL]. The special case when the ring size is known exactly is the subject of a companion paper [AAHK2]. Another direction for investigation is uncertain leader election, that is, probabilistic leader election that terminates correctly with probability greater than $1-\varepsilon$ for some fixed $\varepsilon > 0$. A further companion paper [AAHK1] considers this problem on rings of indistinguishable processors. Pachl [Pa] studies the problem when processors have distinct identifiers. Some of these results together with an overview of the results of the present paper are briefly described in § 5.

2. Leader election, attrition, and solitude verification. This section sets out a general framework for the study of leader election on rings. Two fundamental problems are introduced and their relationship to leader election is established. This relationship motivates the algorithms and lower bound results of the next two sections.

Leader election requires that a single processor be chosen from among some nonempty subset of processors called *candidates*. Initially each candidate is a *contender*. Intuitively, a leader election algorithm must (i) eliminate all but one contender by converting some of the contenders to *noncontenders*, and (ii) confirm that only one contender remains. This separation was pointed out and exploited earlier by Itai and Rodeh [IR]. These subtasks are called attrition and solitude verification, respectively. More formally, a procedure solves the *attrition problem* if, when initiated by every candidate, it eventually takes all but exactly one of these candidates into a permanent state of noncontention. Typically an attrition procedure does not terminate but rather enters an infinite loop in which the remaining contender continues to send messages to itself. An algorithm solves the *solitude-verification problem* if, when initiated by a set of processors, it eventually terminates with an initiator in state "yes" if and only if it was the sole initiator. The more stringent *solitude-detection problem* requires, in addition, that all initiators be left in state "no" if there was more than one initiator.

Both attrition and solitude detection can be reduced to leader election with $O(n)$ bits of communication on rings of size n. For the attrition reduction, a leader is elected from among the attrition contenders. For the solitude-verification reduction, the processors wishing to detect their solitude first use $O(n)$ bits to alert the whole ring to contend for leadership.[1] Once a leader is elected, it is easy to see how to solve attrition (no additional communication) or to detect solitude (an additional $O(n)$ bits of communication). Hence, nonlinear lower bounds on the complexity of either attrition or solitude verification translate to lower bounds on the complexity of leader election. Conversely, attrition and solitude verification can be interleaved to solve leader election by annotating attrition messages with solitude-verification messages. Whenever a contender enters a state of noncontention, it forwards a solitude-verification restart message to alert remaining contenders that they were not previously alone. When attrition has reduced the set of contenders to one, solitude verification will proceed uninterrupted,

[1] The reduction outlined here is from solitude verification to a version of leader election in which all processors are candidates for leadership. In fact, this can be generalized to a reduction to an arbitrary set of candidates as is shown in § 4.2.

eventually verifying that only one contender, the "leader," remains. If the solitude-verification algorithm terminates distributively, so does the resulting leader-election algorithm.

The efficiency of the leader-election algorithm described above depends not only on the efficiency of the attrition and solitude verification procedures from which it is constructed, but also on the cost of interleaving. If solitude verification is *conservative* in the sense that every message is bounded in length by some fixed constant number of bits, then annotated attrition messages are at worst a constant factor longer than unannotated messages. So the cost of premature attempts to verify solitude is dominated by the cost of attrition. The only remaining cost attributable to interleaving involves the transmission of restart messages. In general this cost can also be subsumed by the cost of attrition. This is shown in the next section for the attrition procedure used in this paper. That section describes a randomized attrition procedure, two different conservative solitude-verification algorithms (each exploiting different possible properties of the ring of processors), and an interleaving strategy that combines the procedures to yield efficient leader-election algorithms.

3. Procedures for attrition and solitude verification. The previous section argues that leader election can be efficiently reduced to attrition and solitude verification. This section describes and analyses efficient procedures for these two subproblems. The attrition procedure is randomized but completely general in that it makes no assumptions about the host ring. Two solitude-verification algorithms are described which exploit different assumptions about the ring, specifically the existence of distinct identifiers or at least partial knowledge of the ring size. Both solitude-verification algorithms are deterministic and terminate distributively.

3.1. The attrition procedure.

3.1.1. Informal description. The attrition procedure is initiated by all candidates for leadership. The number of candidates is denoted by c. The candidates are the initial contenders; all other processors are noncontenders. The procedure uses coin tosses to eliminate some contenders while ensuring that it is not possible for all contenders to be eliminated. A noncontender never converts to a contender, but behaves entirely passively—simply forwarding any messages received. Contenders create messages which are propagated to the next contender. Since contenders (respectively, noncontenders) have active (respectively, passive) roles in the algorithm, they are referred to as *active* (*passive*) processors in the following description.

Like the randomized attrition procedure of [IR], the procedure here can be thought of as proceeding in *phases*. However, these phases are implicit only. They are not enforced by counters, but will be justified in the subsequent analysis of the procedure.

At the beginning of each phase, each active processor tosses an unbiased coin yielding h or t, sends the outcome to its successor, and waits to receive a message from its predecessor. Suppose an active processor P sends and receives the same coin toss. It is possible that this is true for every active processor, so no decision can be taken by P. P continues alternately to send and receive coin tosses, remaining in the same phase, until P receives a message different from what it most recently sent. Suppose P eventually sends t and receives h. Then some other active processor Q must have sent h and received t. If only one of P and Q becomes passive, the possibility of losing all active processors is avoided. The convention used is that sending t and receiving h changes an active processor to a passive processor in the next phase, while the opposite results in a processor remaining active in the next phase. Once any active processor has decided its stat. (active or passive) for the next phase, it sends a *

message to signal the end of its phase. Any undecided processor Q that receives a * message while waiting for a coin flip becomes passive in the next phase, since it is assured that there will remain at least one active processor. Q forwards the * message to announce that it has ended its phase. * messages continue to be forwarded until received by a decided processor (which has already propagated a * message).

These ideas are formalized in the transition diagram of Fig. 1. The notation "x/y" is read "receive x, then send y." λ is used where no reception or transmission is to occur. Each processor begins at START. The transition leaving state FLIP is chosen by an unbiased coin toss.

3.1.2. Formal description and correctness. This section establishes the following properties of the attrition algorithm of Fig. 1:

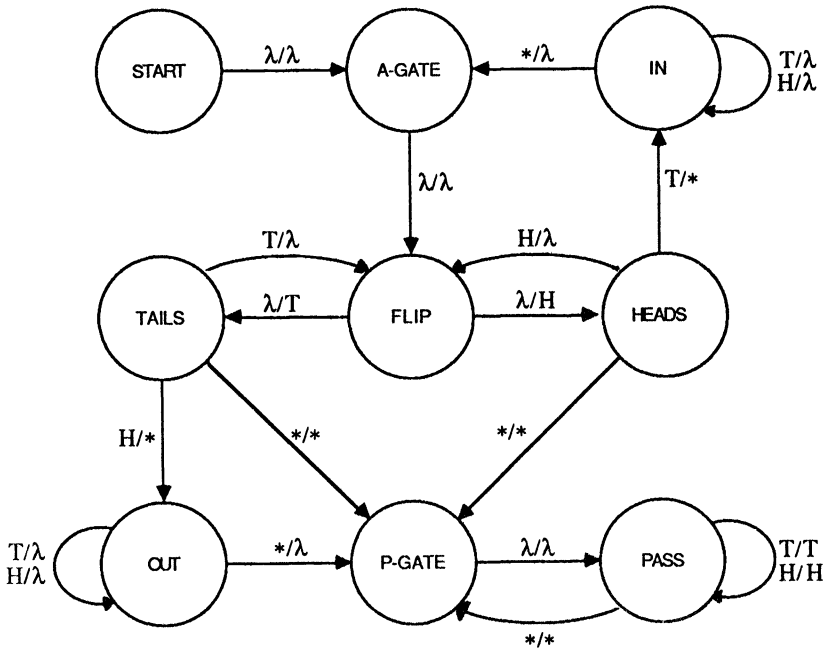

FIG. 1. *The attrition procedure.*

(1) There is always at least one active processor. (A processor is active if it is in any state other than *P*-GATE or PASS.)
(2) The attrition procedure cannot deadlock.
(3) The number of active processors never increases and eventually decreases to one.

Some definitions are introduced to facilitate the proofs. Let each processor P_x maintain an internal *phase counter*, ρ_x. ρ_x is initialized to 0 and incremented each time P_x enters a gate state. When $\rho_x = k$, P_x is in *phase k*. The following variables are defined relative to an arbitrary computation of the attrition process:

$s_{x,j}^{(k)}$ = the jth message sent by P_x while $\rho_x = k$.
$r_{x,j}^{(k)}$ = the jth message received by P_x while $\rho_x = k$.
$q_{x,j}^{(k)}$ = the state of P_x immediately after P_x sends its jth message of phase k.
$g_{x,j}^{(k)}$ = the state of P_x immediately before P_x receives its jth message of phase k.

If P_x does not receive (send) j messages in phase k, then $r_{x,j}^{(k)}$ and $g_{x,j}^{(k)}$ ($s_{x,j}^{(k)}$ and $q_{x,j}^{(k)}$) are undefined. Note that the state variables are parameterized by messages sent and received, not by transitions made. For example, if $q_{x,j}^{(k)} = \text{IN}$, then $q_{x,j-1}^{(k)} = \text{HEADS}$.

The following lemma establishes that * messages effectively delimit phase boundaries.

LEMMA 3.1. $s_{x,j}^{(k)} = r_{x+1,j}^{(k)}$.

Proof. Since messages sent by P_x are exactly those received by P_{x+1}, it suffices to show that P_x and P_{x+1} agree on phase boundaries. Notice from Fig. 1 that P_{x+1} enters a gate (a phase boundary) precisely when it receives a * message. But P_x, having sent the * message, cannot send any further message without first passing through a gate. Nor can P_x enter a gate without sending a * message. □

The following lemma is immediate from Fig. 1. It points out that within a phase, as long as a processor is undecided, its communication alternates between output and input messages.

LEMMA 3.2. *If P_x is active in phase k and $q_{x,j}^{(k)}$ is defined, then $q_{x,j}^{(k)} = g_{x,j}^{(k)}$.*

It follows from Lemma 3.1 that each phase can be considered in isolation. Consider an arbitrary phase k with $m > 1$ active processors. Since passive processors merely forward messages, they can be ignored for the following lemmas, and it can be assumed that the ring has only m processors, $P_0, \cdots, P_{m-1}$. In the remainder of this section, the superscript (k) is omitted, and variables are assumed to describe the kth phase.

The next lemma establishes that the processors cannot all become passive.

LEMMA 3.3. *If $q_{x,j} = \text{OUT}$, then there exists w and i such that $q_{w,i} = \text{IN}$.*

Proof. Choose the smallest i such that $s_{v,i} = *$, over all processors P_v. Let P_y be some processor for which i is minimized. Now either $q_{y,i} = \text{IN}$ or $q_{y,i} = \text{OUT}$. In the first case nothing remains to be proved. In the second case, it follows that $q_{y,i-1} = \text{TAILS}$, $s_{y,i-1} = t$, and $r_{y,i-1} = h$. Let C be the class of t-messages which were the $(i-1)$th messages sent by some processor. P_y sends a message of class C, but does not receive one, since $r_{y,i-1} = s_{y-1,i-1} = h$. Since there can be at most n messages in class C, and all are eventually delivered, some processor P_w must receive a class C message without sending one. The transition from OUT to OUT cannot correspond to the reception of a class C message, by the minimality of i. The transition from TAILS to FLIP pairs the absorption of one message in C with the production of one on the previous transition. The only remaining transitions compatible with receiving a t-message lead to state IN. Therefore P_w must be in state IN after receiving its ith message, and hence $q_{w,i} = \text{IN}$. □

The safety properties of the attrition procedure follow from Lemma 3.3 and the next lemma. At any point during the execution, let $N(*)$ be the number of * messages awaiting delivery. Let $N(\text{OUT})$ and $N(\text{IN})$ be the number of processors in states OUT and IN, respectively.

LEMMA 3.4. $N(*) = N(\text{IN}) + N(\text{OUT})$ *at every point during the execution.*

Proof. The equation holds initially and is preserved by every transition. □

COROLLARY 3.5. *If any processor reaches phase $k+1$, then some processor is active in phase $k+1$.*

Proof. In order for any processor to reach a gate, some processor must reach IN or OUT. By Lemma 3.3, some processor P_w reaches IN. As long as P_w remains at IN, there is an undelivered * message which must move around the ring, eventually reaching P_w and causing P_w to enter the active gate. □

COROLLARY 3.6. *The attrition procedure cannot deadlock.*

The next lemma leads to a bound on the number of phases in any computation of the attrition procedure.

LEMMA 3.7. *Suppose $q_{x,j} = \text{IN}$. Let y be the first number in the list $x-1, x-2, \cdots$ (counting modulo m), such that $q_{y,j} = \text{IN}$. (Such a y must exist since x occurs in the list.) Then there is a $w \in \{y+1, y+2, \cdots, x-1\}$ such that $q_{w,j} \in \{\text{OUT}, P\text{-GATE}\}$.*

Proof. If $q_{x,j} = \text{IN}$, then $r_{x,j-1} = s_{x-1,j-1} = t$. So $q_{x-1,j-1} = g_{x-1,j-1} = \text{TAILS}$. Suppose $r_{x-1,j-1} \neq t$. After receiving $r_{x-1,j-1}$, P_{x-1} moves from TAILS to either OUT or P-GATE, and $w = x-1$ satisfies the lemma.

Suppose, instead, that $r_{x-1,j-1} = t$. Then $q_{x-2,j-1} = \text{TAILS}$. Again, if $r_{x-2,j-1} \neq t$, then $w = x-2$ satisfies the lemma. Otherwise the search continues through $x-3$, $x-4, \cdots, y+1$ until a w is found such that $q_{w,j-1} = \text{TAILS}$ and $r_{w,j-1} \neq t$. Such a w must exist since

$$q_{y,j} = \text{IN} \Rightarrow q_{y,j-1} = \text{HEADS} \Rightarrow s_{y,j-1} = h \Rightarrow r_{y-1,j-1} = h$$

so some first non-t message $r_{w,j-1}$ must be encountered among $r_{x-1,j-1}$, $r_{x-2,j-1}, \cdots, r_{y+1,j-1}$. That w satisfies the lemma. □

COROLLARY 3.8. *At least half of the active processors at phase k are passive at phase $k+1$.*

Proof. Lemma 3.7 associates with each processor P_x which remains active, a distinct processor P_w which becomes passive. The same P_w is not associated with two different P_{x_1} and P_{x_2}, since $q_{w,j}, q_{w,j'} \in \{\text{OUT}, P\text{-GATE}\}$ implies $j = j'$. □

COROLLARY 3.9. *There are at most $\lfloor \log c \rfloor$ phases during which more than one processor is active, where c is the number of candidates for leadership.*

If there remain more than one active processor in phase k, then with probability 1, at least two of them will eventually produce opposite coin flips, thus resulting in a transition to phase $k+1$. This observation, together with Corollary 3.9 ensures that the final requirement for correctness is satisfied.

3.1.3. Complexity analysis. Recall that the last phase of the attrition procedure, when only one active processor remains, is an infinite loop broken by the intervention of the solitude-verification algorithm. Therefore the complexity of concern for the attrition procedure is the expected number of bits sent, up to but not including the last phase. Corollary 3.9 establishes that there can be at most $\lfloor \log c \rfloor + 1$ phases. It remains to bound the expected number of messages sent per phase.

The following random variables over computations are needed:

$$M_x^{(k)} = \begin{cases} 0 & \text{if only one processor is active in phase } k, \text{ or if phase } k \text{ is not reached,} \\ m & \text{if more than one processor is active in phase } k, \text{ and processor } P_x \\ & \text{sends } m \text{ messages during phase } k. \end{cases}$$

$M_x^{(k)}$ is defined for both active and passive processors x and for all integers $k \geqq 1$.

LEMMA 3.10. $\Pr(M_x^{(k)} \geqq m) \leqq 2^{2-m}$.

Proof. The lemma is trivial if k is greater than or equal to the number of the last phase. Therefore suppose that there are two or more active processors in phase k. It is sufficient to consider the active processors only, since each passive processor sends the same number of messages as its nearest active predecessor.

The lemma is proved by induction on m. The case $m = 2$ is trivial. If, in phase k, P_x reaches state FLIP s times, then P_x sends $s+1$ messages. But whenever P_x reaches FLIP, there is a probability of at least $\frac{1}{2}$ that it will not return to FLIP in the same phase, since its coin toss is random relative to that of its nearest active predecessor. The induction follows immediately. □

COROLLARY 3.11. $E(M_x^{(k)}) \leqq 3$.

COROLLARY 3.12. *The expected number of bits communicated by the attrition procedure up to the last phase is at most $6n\lfloor \log c \rfloor$.*

Proof. The total number of messages sent up to the last phase is given by $\sum_{x=0}^{n-1} \sum_{k \geqq 1} M_x^{(k)}$. By Corollaries 3.9 and 3.11 this has an expected value of at most

$3n\lfloor \log c \rfloor$. Since there are only three distinct messages used, each can be encoded in two bits yielding an expected bit complexity of at most $6n\lfloor \log c \rfloor$. □

3.1.4. Interleaving properties. The attrition procedure lends itself naturally to being interleaved with a solitude-verification algorithm. Attrition messages can simply be annotated with solitude-verification messages. The * messages which serve to delimit phase boundaries are interpreted as solitude-verification restart signals. The interleaved algorithm proceeds exactly like attrition until the last phase, at which point the absence of * messages allows solitude verification to run to completion. This is summarized by the following theorem.

THEOREM 3.13. *Any conservative solitude-verification algorithm of complexity $f(n)$ can be combined with the attrition procedure to yield a leader-election algorithm of complexity $O(n \log c + f(n))$.*

Note that under the right conditions, a nonconservative solitude-verification algorithm can be interleaved with attrition to achieve an efficient leader-election algorithm, but Theorem 3.13 suffices here.

3.2. Solitude verification algorithms. In the absence of any information about the ring, solitude verification with certainty is impossible. Therefore solitude-verification algorithms must use specific ring information to verify that there is a sole active processor. Two cases are considered here.

(1) Each processor P_x has a distinct identifier I_x, consisting of a string such that if $x \neq w$, then I_x is not a prefix of I_w.

(2) Each processor knows the size of the ring to within a factor of 2.

Individually, these assumptions are as weak as possible in the sense that if processors' identities can appear at most twice or the size of the ring is not known to within a factor of 2, solitude verification remains impossible. Though solitude verification is all that is required for leader election, the algorithms are, in fact, solitude-detection algorithms.

3.2.1. Solitude detection with distinct identifiers. Suppose each processor, P_x, has a distinct identifier, I_x, which is not the prefix of any other identifier in the ring. Processor P_x uses an internal string variable J_x, which is initialized to the empty string. Each initiator alternately sends the jth bit of its own identifier and receives the jth bit of its nearest active predecessor, which it appends to J_x. Thus P_x builds up in J_x the identifier of its nearest active predecessor. If I_x contains m bits then after receipt of at most m bits P_x can declare, by comparing J_x and I_x, whether or not it is alone. Because no identifier is a prefix of any other identifier, P_x can never falsely claim solitude.

THEOREM 3.14. *If processors have distinct m bit identifiers, then conservative and deterministic solitude detection can be achieved with distributive termination using at most $O(mn)$ bits.*

3.2.2. Solitude detection when the size of the ring is known approximately. Suppose that distinct identifiers are not available, but each processor knows the size n of the ring. In this case, a nonconservative algorithm for determining solitude has each initiator send a counter which is incremented and forwarded by each passive processor until it reaches an initiator, P_x. By comparing the received counter with n, P_x knows whether or not it is alone. This algorithm can be transformed into a conservative solitude-detection algorithm without any increase in bit-communication complexity.

Each processor P_x, whether active or passive, maintains a counter c_x, initialized to 0. Let $d_x > 0$ denote the distance from P_x to its nearest active predecessor. The algorithm maintains the invariant:

$$\text{if } P_x \text{ has received } j \text{ bits then } c_x = d_x \bmod 2^j.$$

Then if P_x reaches a state where $c_x = n$, there must be $n-1$ passive processors preceding P_x, so P_x can conclude that it is the sole initiator. It remains to describe the strategy necessary to maintain the invariant.

Initiators first send 0. Thereafter, all processors alternately send and receive bits. If P_x is passive, then P_x is required to send the jth low-order bit of d_x as its jth message. Initiators continue to send 0. Suppose a processor P_y has the lowest order j bits of d_y in c_y. A simple inductive argument shows that when P_y receives its $(j+1)$st message (by assumption the $(j+1)$st bit of $d_y - 1$), it can compute the first $(j+1)$ bits of d_y and thus can update the value of c_y to satisfy $c_y = d_y \bmod 2^j$.

In the previous algorithm, it was assumed that n is known exactly. Suppose instead, that each processor knows a quantity N, such that $N \leqq n \leqq 2N-1$. Then there can be at most one gap of length N or more between neighbouring active processors. Thus any gap of less than N confirms nonsolitude and any processor detecting a gap of N or more can determine solitude by initiating a single checking round. (For the purposes of leader election, it is sufficient for any active processor that detects a gap of N or more to declare itself the leader, since it has confidence that no other processor can do the same.) Thus, the algorithm can be used when n is known to within a factor of less than 2.

THEOREM 3.15. *If each processor knows a value N such that the ring size n satisfies $N \leqq n \leqq 2N-1$, then conservative and deterministic solitude detection can be achieved using at most $O(n \log n)$ bits.* □

3.3. Time complexity of the leader-election algorithm. The usual notion of the time complexity of an asynchronous algorithm becomes particularly simple for a unidirectional ring since message delays cannot influence computation sequences. The *time complexity* of a randomized algorithm on a unidirectional ring is the expected number of unit time intervals before the algorithm terminates, under the assumption that messages travel each communication link in at most unit time, and local processing is instantaneous.

The time complexity of [DKR] is $O(n)$. Our leader-election algorithm, as described, requires $O(n \log n)$ time steps even for just the final phase, when verification bits are sent and received one at a time by the sole remaining active processor. It therefore might appear that the algorithm achieves an improvement by a factor of $O(\log n)$ in bits, only at the expense of an additional factor of $O(\log n)$ in time over other leader-election algorithms. But a slight alteration in the attrition algorithm reduces the time complexity of the final phase from $O(n \log n)$ to almost linear. Suppose that the ith message of a phase of attrition contains a package of $f(i)$ annotated coin flips rather than a single coin flip as previously described. Let $f(1) = 1$ and $f(i) = 2^{f(i-1)}$ for $i > 1$. With this packaging, in the final phase of leader election, the remaining active processor will initiate only $O(\log^* n)$ messages which propagate around the ring. $O(n \log^* n)$ time steps are used to confirm solitude when ring size is known. Similar packaging yields $O(n \log^* m)$ timesteps when identifiers of length m are used to confirm solitude. Clearly this packaging does not alter the bit complexity of the solitude-verification stage of leader election, nor does it significantly affect the bit complexity of the earlier phases of attrition. The probability that a processor sends at least k packages of coin flips in a given phase is no more than $2^{-(f(1)+\cdots+f(k-1))}$. Hence

the expected number of coin-flip bits sent by an arbitrary processor in a given phase is no more than $\sum_{k=1}^{\infty} f(k)/2^{f(1)+\cdots+f(k-1)} = \sum_{k=1}^{\infty} 1/2^{f(1)+\cdots+f(k-2)} = O(1)$. So the expected number of annotated coin-flip bits sent by a processor in a phase is also constant as it was without the packaging.

It remains to analyse the expected time for attrition up to the last phase. Imagine that each initiator creates an envelope and sends its first message in it. Since the algorithm is message-driven, it can be thought to proceed as follows. Each processor waits to receive an envelope. Upon reception of an envelope, a processor examines its contents and either forwards the envelope (with a possibly new message) or destroys the envelope. The nature of the algorithm guarantees that at the beginning of each phase, the number of active processors is equal to the number of envelopes. Thus in order to bound the expected time for attrition, it is sufficient to bound the expected time until the number of envelopes is reduced to one. The analysis of the bit complexity of attrition implies that attrition has the following property *P*.

> *P*: If at some time there are ω envelopes on the ring, then the expected number of remaining messages exchanged until one envelope is left is at most $cn \log \omega$ for some constant c.

Let the random variable X_l be the number of envelopes at time nl. Then nX_{l+1} is no greater than the total number of messages from time nl until time $n(l+1)$. Given that there are ω envelopes at time nl, it follows from property *P* that this total has expected value at most $cn \log \omega + n$. Therefore $E(X_{l+1}|X_l = \omega) \leqq c \log \omega + 1$. Now

$$\begin{aligned} E(X_{l+1}) &= \sum_{\omega} E(X_{l+1}|X_l = \omega) \Pr(X_l = \omega) \\ &\leqq \sum_{\omega} (c \log \omega \Pr(X_l = \omega)) + 1 \\ &\leqq c \log \sum_{\omega} \omega \Pr(X_l = \omega) + 1 \quad \text{by the convexity of log,} \\ &= c \log E(X_l) + 1. \end{aligned}$$

Thus at time $n \log^* I$, where I is the number of initiators, the expected number of envelopes is reduced to a constant, say c'. Again by property *P*, given that $X_{\log^* I} = \omega$, the expected number of messages remaining to the completion of attrition following $n \log^* I$ timesteps is at most $cn \log \omega < cn\omega$. The expected remaining time, given $X_{\log^* I} = \omega$, is therefore also less than $cn\omega$. So the expected remaining time is less than $cn \sum_{\omega} \omega \Pr(X_{\log^* I} = \omega) = cnc'$. Thus the expected total time for attrition with I initiators is less than $n \log^* I + cnc'$. Combining these results for attrition and solitude verification yields the following theorem.

THEOREM 3.16. *The leader-election algorithm which results from combining the attrition procedure of* § 3.1 *and the solitude-verification algorithm of* § 3.2.1 (§ 3.2.2) *can be adapted to have time complexity* $O(n \log^* m)$ ($O(n \log^* n)$) *without any increase in the order of the communication complexity.*

4. Lower bounds for solitude verification. This section provides lower bounds on the number of bits of communication required for solitude verification. Two cases, paralleling those considered in § 3.2, are studied. In each case lower bounds are developed which show that the algorithms discussed earlier are essentially optimal.

The lower bounds apply even to nondeterministic distributed algorithms. In order to understand the generality of the lower bounds, a formal model of nondeterministic

algorithms and their computations are presented in § 4.1. In § 4.2, the solitude-verification and leader-election problems are defined in terms of the model. That section also contains an $O(n)$ reduction from solitude verification to leader election within the model, implying that even the general nondeterministic lower bounds for solitude verification translate to the same lower bounds for leader election. Techniques and tools common to the proofs are grouped together in § 4.3. Sections 4.4 and 4.5 study, respectively, the cases where processors have distinct identifiers, and processors know the approximate size of the ring.

4.1. Model of computation. In order to describe a computation, § 4.1.1 defines a process and states some useful properties of rings of processes. Section 4.1.2 clarifies the relationship between distributed algorithms and rings of processes.

4.1.1. Processes. The following description of a process incorporates two non-restrictive assumptions [PR], namely, that messages are self-delimiting, and that communication is message-driven with at most one message sent in response to receipt of a message.

A *message* is an element of $M = \{0, 1\}^* \cdot \square$. The symbol $\square$ is called the end-of-message marker. A *history* is a (possibly infinite) sequence of messages. If h is a finite history, then $\|h\|$ denotes the length of the binary encoding of h using some fixed encoding scheme to encode each symbol in $\{0, 1, \square\}$. Note that any history has a unique parse into a sequence of messages.

A *process* π is modelled as a pair of mappings which describe the next output message (possibly null) and the next state of π as a function of its current state and current input message. Notice that this models a deterministic process. A process' state encodes its entire history so far, and consequently the state set is not bounded. Process π is an *initiating process* if it produces an output message from its initial state (that is, before the arrival of the first message). Otherwise it is a *noninitiating process.*

Let $\pi_1, \cdots, \pi_n$ be a sequence of processes. We use $\pi_{1,n}$ to abbreviate $\pi_1, \cdots, \pi_n$. There is a sequence of histories, $C = h_1, \cdots, h_n$, called a *computation* associated with $\pi_{1,n}$ in the natural way. Each history h_i is composed of a sequence of messages $m_1^i \cdots m_{r_i}^i$. If π_i is an initiating process, then m_1^i is the message produced by π_i from its initial state. The computation is then determined inductively by applying the mappings defined by π_1 through π_n and letting successive non-null output messages of π_i be successive input messages of π_{i+1}. (Indices are reduced in the obvious way.) If the h_i are finite, then C is said to *terminate.* A terminating computation $C = h_1, \cdots, h_n$ has *complexity* equal to $\sum_{i=1}^{n} \|h_i\|$.

We distinguish a subset $M_a \subseteq M$ called *accepting* messages, and a subset $M_r \subseteq M$ called *rejecting* messages. A history is an *accepting* history (respectively, *rejecting* history) if and only if its *last* message is an accepting message (respectively, rejecting message). An accepting or rejecting history is a *decisive* history. All other histories are *indecisive* histories. If a computation $C = h_1, \cdots, h_n$ terminates, then each h_i has a last message and $f(h_i) \in \{\text{accepting, rejecting, indecisive}\}$ denotes its type. By extension, $f(C)$, the *final state* of C, abbreviates the sequence $f(h_1), \cdots, f(h_n)$.

Two types of termination for a distributed computation may be considered. A weak form of termination, *nondistributive termination*, allows processors to reach tentative conclusions which are firm only if all message traffic has terminated for the entire ring (possibly an undetectable condition.) This conclusion is open to revision upon receipt of additional messages. Under the usual, stronger type of termination called *distributive termination*, it is required that processors come to irrevocable

decisions and halt computation. Distributive termination is modelled by insisting that processes never output another message after sending a decisive message. Since the lower bounds for this paper hold even for nondistributively terminating algorithms, the model permits accepting and rejecting messages to occur throughout the histories of a computation.

4.1.2. Algorithms. A *labelled ring* is a unidirectional n-ring of processors $R = P_1, \cdots, P_n$ where each processor P_i has associated with it a *label* l_i from ID $\times$ {initiator, noninitiator} where ID denotes some fixed universe of identifiers. Depending upon the assumptions, a processor's identifier in ID may or may not be distinct. The second label field is used to distinguish processors that initiate a computation from those that only participate in response to other initiators. The ring R is said to be *labelled* by $\mathscr{L} = l_1, \cdots, l_n$.

A distributed algorithm can be viewed as an assignment of processes to processors. A *deterministic* algorithm for a labelled ring is a mapping from labels to (deterministic) processes where initiating (respectively, noninitiating) processes are assigned to initiators (respectively, noninitiators). A more general notion of an algorithm can be obtained by relaxing the constraint that the assignment be deterministic. Let $\mathscr{A}$ be the set of all processes as described in the preceding section. A (*distributed*) *algorithm* α is a mapping from labels to nonempty subsets of $\mathscr{A}$ such that sets of initiating processes are assigned to initiators and sets of noninitiating processes are assigned to noninitiators. The set $\alpha(l)$ is the collection of processes available to processors with label l. A sequence $\pi_{1,n} = \pi_1, \cdots, \pi_n$ with $\pi_i \in \alpha(l_i)$ corresponds to an arbitrary assignment of processes to processors on the n-ring labelled with the sequence $l_1, \cdots, l_n$. A *computation* of α on a ring labelled by $\mathscr{L} = l_1, \cdots, l_n$ is a computation induced by any process sequence $\pi_1, \cdots, \pi_n$ where $\pi_i \in \alpha(l_i)$.

The generalization from deterministic to arbitrary assignments gives algorithms a nondeterministic attribute. Like conventional nondeterministic algorithms, an algorithm is said to solve a problem efficiently on a ring labelled by $\mathscr{L} = l_1, \cdots, l_n$ is for *some* choice of process assignments consistent with $\mathscr{L}$, the resulting computation provides a solution and has low complexity.

Notice that the usual notion of a randomized algorithm is subsumed by this general definition of an algorithm. In the natural description of a randomized distributed algorithm, a process' next state and output message are determined by its current state, its last input message, and the result of a random experiment. Random choices occur throughout the run of the algorithm. But these random choices can be simulated as a single random choice by each processor at the beginning of the algorithm. A processor randomly chooses a function from internal state input message pairs to internal state output message pairs. (Essentially, the processor pre-selects all its random coin tosses.) Hence a randomized distributed algorithm can be modelled as a *random* assignment of deterministic processes to labels. This is further generalized by permitting an *arbitrary* assignment of processes to labels. Therefore lower bounds on the complexity of a problem under this model apply to lower bounds for randomized algorithms and in fact address the complexity of the *best-case* computation.

The following definition captures the notion of what it means for an algorithm to solve a given problem. Let T be a predicate defined over elements of $N \times F$, where N is the set of all label sequences in (ID $\times$ {initiator, noninitiator})^n, and F is the set of all final states in {accepting, rejecting, indecisive}^{n}. Let R be a ring labelled by $\mathscr{L} = l_1, \cdots, l_n$ and C be the computation of some process sequence $\pi_{1,n} = \pi_1, \cdots, \pi_n$, where $\pi_i \in \alpha(l_i)$. Then $\pi_{1,n}$ *respects* T *for label sequence* $\mathscr{L}$ if $T(\mathscr{L}, f(C))$. An algorithm

α computes T for label sequence $\mathscr{L}$ if every $\pi_{1,n}$, with $\pi_i \in \alpha(l_i)$, respects T for label sequence $\mathscr{L}$. An algorithm α *computes* T if it computes T for every element of N.

4.2. The problems. Although the algorithms of § 3 always solve leader election, the corresponding lower bounds even apply to a weak version of leader election which requires that at most one processor be left, at termination, in a distinguished final state. Formally, the *weak leader-election* predicate, LE, is defined over $N \times F$ by: $LE(\mathscr{L}, f(C)) =$ (if $\mathscr{L}$ contains at least one initiator then there exists at most one "accept" in $f(C)$). A weak version of solitude verification requires that if any initiator is left in an accepting final state at termination, then that initiator is the only initiator of the computation. Formally, the *weak solitude-verification* predicate, SV, is defined over $N \times F$ by: $SV(\mathscr{L}, f(C)) =$ (if there exists i such that $f(h_i)$ is "accept," then l_i is the only initiating label in $\mathscr{L}$).

Notice that an algorithm has to meet only a rather weak requirement in order that it be said to solve one of these problems. For example, deadlocking computations, leaving all processors undecided, are tolerated. This only serves to strengthen the lower-bound results that follow. Conclusions are drawn about the number of bits that must be transmitted in any computation of an algorithm which succeeds in verifying solitude (a *successful* computation), even if the algorithm solves the problem in only this weak sense. A *successful* solitude verification computation has exactly one initiating process π_i and its history h_i in $C = h_1, \cdots, h_n$ is an accepting history. A *successful* leader-election computation has exactly one of the initiators left in final state "accept." Nonsolitude can be ascertained with low expected communication complexity, but we wish to focus on the cost of verifying that there is only one initiator. Therefore the complexity of solitude verification is defined to be the expected complexity when solitude is asserted. Let α be an algorithm that computes SV. Say that α *has complexity* at least $f(n)$ on rings of size n if every successful computation of α has complexity at least $f(n)$.

Section 2 contains a description of how a randomized, distributively terminating algorithm for electing a leader from among all processors on the ring can be converted, using an additional $O(n)$ bits of communication, to an algorithm for solitude detection (and hence solitude verification). In fact this $O(n)$ reduction holds even for the nondeterministic, nondistributively terminating model, and for the weak versions of the two problems. Initiators, wishing to determine their solitude, alert the ring by propagating a wake-up message. All processors, having been alerted, nondeterministically choose whether or not to be candidates for leadership, and run the weak leader-election algorithm. A candidate remaining in contention guesses if and when the leader-election algorithm terminates with itself as leader. At this time the elected leader circulates a single message of constant length to determine whether one or more than one original initiator was present. A final round announces the result. Because the portion of this algorithm following leader election is deterministic, the reduction converts successful computations of leader election to correct computations of solitude detection. Unsuccessful leader election can happen if either no processor chose to be a candidate or if the weak leader election algorithm left all processors in a nonleader state. But in both of these cases the corresponding solitude-detection computation deadlocks, satisfying weak solitude verification. Finally, if a candidate guesses erroneously that it is the sole remaining contender before weak leader election has terminated (nondistributively), then eventually the leader-election algorithm must correct this error. So the resulting solitude-verification computation is also eventually alerted to the error, and correctly achieves nondistributive termination. Thus nonlinear

lower bounds for computations that verify solitude translate to lower bounds for computations that elect a leader even for this general model. Notice that nondeterminism allows this reduction to hold for the general version of leader election when a leader is elected from c candidates rather than from the fixed configuration of all processors on the ring. Thus the lower bounds for solitude verification imply lower bounds for a best-case configuration of candidates for leadership.

4.3. Tools. In the lower-bound results that follow, two techniques are used to convert low-complexity computations of an algorithm α on a ring R labelled by $\mathscr{L} = l_1, \cdots, l_n$ to new computations of α on a related ring R'. Let $C = h_1, \cdots, h_n$ be the computation of $\pi = \pi_1, \cdots, \pi_n$ where $\pi_i \in \alpha(l_i)$. Suppose $h_i = h_j$ and $h_{i+1}, \cdots, h_j$ contains no initiators. Consider the new sequence $C' = h_1, \cdots, h_i, h_{j+1}, \cdots, h_n$ formed by removing $h_{i+1}, \cdots, h_j$ from C. Then C' is a computation of $\pi_1, \cdots, \pi_i, \pi_{j+1}, \cdots, \pi_n$. Thus C' is a computation of α on the ring R' labelled by $\mathscr{L}' = l_1, \cdots, l_i, l_{j+1}, \cdots, l_n$. This process of forming C' on R' from C on R when $h_i = h_j$, while retaining all initiators, is referred to as *collapsing.*

Let $C_1 = h_1^1, \cdots, h_n^1$ and $C_2 = h_1^2, \cdots, h_m^2$ be computations of α on the two rings R_1 and R_2 labelled by $\mathscr{L}_1 = l_1^1, \cdots, l_n^1$ and $\mathscr{L}_2 = l_1^2, \cdots, l_m^2$. Suppose that $h_i^1 = h_j^2$ for some i and j. Consider the sequence $C' = h_1^1, \cdots, h_i^1, h_{j+1}^2, \cdots, h_m^2, h_1^2, \cdots, h_j^2, h_{i+1}^1, \cdots, h_n^1$ formed by combining C_1 and C_2. Then C' is a computation of α on R' labelled by $\mathscr{L}' = l_1^1, \cdots, l_i^1, l_{j+1}^2, \cdots, l_m^2, l_1^2, \cdots, l_j^2, l_{i+1}^1, \cdots, l_n^1$. This process of forming C' on R' by combining C_1 on R_1 and C_2 on R_2 is referred to as *splicing.* The special case of splicing a computation to itself is called *doubling.*

The following lemma takes advantage of the fact that any collection of k distinct binary strings contains at least $(k \log k)/2$ bits for $k > 3$.

LEMMA 4.1. *If $C = h_1, \cdots, h_n$ is a computation with complexity less than $cm \log m$, and $m \leqq n$, then there exist i and j, $0 < j - i < m^{4c}$ such that $h_i = h_j$.*

Proof. Let k be the maximum integer such that every subsequence of C containing k histories has each history distinct. The encoding of a subsequence of k distinct histories must contain a total of at least $(k \log k)/2$ bits. But C can be decomposed into $\lfloor n/k \rfloor \geqq \lceil n/(2k) \rceil$ disjoint subsequences each with at least k histories. Since the complexity of C is less than $cm \log m$, at least one of these subsequences must have less than $(cm \log m)/\lceil n/(2k) \rceil \leqq 2ck \log m$ bits. Hence, $(k \log k)/2 < 2ck \log m$. Thus $k < m^{4c}$. □

The lower-bound arguments both have similar structure. It is assumed that an algorithm α exists that solves solitude verification on a ring R with nondistributive termination and that α has a successful computation C with small communication complexity. It follows, by some combination of collapsing and splicing, that C can be transformed into a computation C' of α on a different ring R', in which more than one initiator terminates in state "accept." Thus α does not solve solitude verification on R'.

4.4. Distinct identifiers. The objective of this section is to characterize the complexity of algorithms that solve the solitude-verification problem on rings of processors with distinct identifiers chosen (otherwise arbitrarily) from a set ID of size s. Let α be any algorithm that solves weak solitude verification on all n-rings with distinct identifiers chosen from ID. There are $\binom{s}{n}$ possible identifier sets for such an n-ring. Suppose that for each of these sets, there is at least one permutation of the identifier set, such that for an n-ring labelled with this permutation and with exactly one initiator, α has some successful computation. α is then said to *nontrivially* compute solitude verification for n-rings with identifiers chosen from ID.

THEOREM 4.2. *Let α be any algorithm that nontrivially computes weak solitude verification on rings of between N and $2N$ processors with distinct identifiers chosen from a universe* ID *of size $s \geqq 2N$. Then for at least half of the $\binom{s}{N}$ identifier sets L of size N, the complexity of α on every ring labelled by some permutation of L is $\Omega(N \log (s/2N))$.*

Proof. Let L be any subset of ID of size N and let $C = h_1, \cdots, h_N$ be a successful computation of $\pi_{1,N} = \pi_1, \cdots, \pi_N$ where the identifiers associated with $\pi_{1,N}$ are distinct identifiers chosen from L. C is a *cheap computation* if it has complexity less than $N \log (s/2N)$. If a cheap C exists, the process sequence $\pi_{1,N}$ and the identifier set L are also said to be cheap. If C is cheap, then at least one of the histories $h_1, \cdots, h_N$ must have length less than $l = \log (s/2N)$. Choose any such history and call it the cheap history associated with C and indirectly associated with $\pi_{1,N}$ and L. Now suppose that α has the property that for at least one half of the $\binom{s}{N}$ possible choices for L, there exists a cheap successful computation of α and therefore an associated cheap history. Among all the partitions of ID into s/N subsets of size N, at least one such partition must have among its subsets at least $s/2N$ cheap identifier sets. Therefore there exist $s/2N$ disjoint, cheap labellings with corresponding cheap successful computations. But there are fewer than $2^l = s/2N$ distinct cheap histories in total. So some cheap history must be associated with successful computations of α on two process sequences with disjoint sets of identifiers. If these computations are spliced at their common history, the result is a decisive computation of α on a ring of size $2N$, whose processors all have distinct identifiers. However, this computation leaves two processors in the final state "accept" contradicting the correctness of α. □

COROLLARY 4.3. *Let α be an algorithm that meets the conditions of Theorem* 4.2. *If the size s of the universe* ID *is $\Omega(N^{1+\varepsilon})$ for some $\varepsilon > 0$, then for at least half of the identifier sets L of size N, the complexity of α on any ring labelled by some permutation of L is $\Omega(N \log s)$.*

4.5. Ring size known approximately. If ring size n is to be used to verify solitude, it must be known to within a factor of two. The objective of this subsection is to characterize the complexity of computations that verify solitude, as a function of processors' uncertainty of ring size within this limit.

THEOREM 4.4. *Let α be any nondistributively terminating algorithm that computes solitude verification on the class of all rings of size n, where $n \in [N, N+\Delta]$ for some N and $0 < \Delta < N$. Then the complexity of α on any ring in this class is $\Omega(N \log \Delta)$.*

Proof. Let $C = h_1, \cdots, h_n$ be any successful computation of α on a ring of size n, where $N \leqq n \leqq N + \Delta$. Then $f(h_i) =$ "accept" for some initiator π_i. Without loss of generality, suppose $i = 1$. Let $\varepsilon = \log \Delta / \log N$. Suppose that the communication complexity of C is less than $(N \log \Delta - 2N)/4 = (\varepsilon N \log N - 2N)/4$. By Lemma 4.1, there exist i and j such that $1 < j - i < N^{\varepsilon} = \Delta$ and $h_i = h_j$. Consider the new computation $h_1, \cdots, h_i, h_{j+1}, \cdots, h_n$ formed by removing $S = h_{i+1}, \cdots, h_j$ and apply repeated collapsing to each subsequence $H_1 = h_1, \cdots, h_i$ and $H_2 = h_{j+1}, \cdots, h_n$ separately until each of these subsequences is composed of distinct histories. Let the resulting computation be $C' = h'_1, \cdots, h'_l, h'_{l+1}, \cdots, h'_m$, where $h'_1 = h_1$, $h'_l = h_i$, and $h'_m = h_n$. Since $h'_1, \cdots, h'_l$ and $h'_{l+1}, \cdots, h'_m$ are sequences of distinct histories, their combined communication complexity is at least $l \log l/2 + (m-l) \log (m-l)/2$, which is at least $(m/2) \log (m/2)$. Thus their combined length m must not exceed $N/2$, since otherwise, the assumption on the complexity of C is violated. Therefore C' can be doubled to form a new computation, C'', of α on a ring of size $2m \leqq N$ processors. But since the subsequence S, which was originally removed, has length $s < \Delta$, there exists an integer $k \geqq 0$ such that $N \leqq 2m + ks \leqq N + \Delta$. Thus k copies of S can be spliced into C'', after

either history identical to h_i, forming a new computation of α on a ring of size $n' \in [N, N+\Delta]$ which contains two histories identical to h_1. Thus two processors conclude solitude, contradicting the correctness of α for rings of size $n \in [N, N+\Delta]$. □

It can be shown that Theorem 4.4 holds even if the algorithm α is required to work correctly only on the class of rings in which processors have identifiers, and no processor identifier appears more than twice. If all processor identifiers are known to be distinct then the results are different, as was shown in § 4.4.

5. Conclusions.

5.1. Technical results. The inherent communication complexity, measured in terms of the expected number of bits, of electing a leader in a ring of processors has been identified to within constant factors for two cases. When all processors know the ring size to be within some interval $[N_l, N_u]$ and all processors have distinct identifiers drawn from some set of size $s \geqq N_u^{1+\varepsilon}$, where $\varepsilon > 0$, then for all n satisfying $N_l \leqq n \leqq N_u/2$, the average, over all n-rings, of the expected bit complexity of randomized leader election is $\Theta(n \log s)$. On the other hand, if the ring size is known to be in some interval $[N_l, N_u]$ where $N_l + N_l^{\varepsilon} \leqq N_u < 2N_l$, for some $\varepsilon > 0$, and processor identifiers are not necessarily distinct then, for all n satisfying $N_l \leqq n \leqq N_u$, the expected bit complexity of randomized leader election is $\Theta(n \log n)$.

The results for leader election stem from bounds on the complexity of two more primitive processes called attrition and solitude verification. The identification of these subproblems and the clarification of their relationship to leader election is one of the important contributions of this paper. Efficient conservative solitude verification algorithms that exploit known properties of a ring can be combined with the randomized attrition procedure described in § 3.1 to provide new efficient leader-election algorithms. Solitude verification is of equal interest for its role in the proof of lower bounds for leader election. For all solitude-verification computations of concern there is only one initiator, which considerably simplifies the analysis. This is reflected in the strong lower bounds of § 4.

5.2. Related issues. In addition to the specific technical contributions cited above the results of this paper shed light on a number of important issues in distributed computing. These are summarized under three general headings below.

5.2.1. Global knowledge of ring. Suppose that all processors know that the ring size n lies in the interval $[N_l, N_u]$. If the processors are indistinguishable then deterministic leader election is impossible [A], even if $N_l = N_u$. Furthermore, if $N_u \geqq 2N_l$ then even randomized algorithms cannot elect a leader among indistinguishable processors with certainty. However, if $N_u < 2N_l$, then randomized leader election can be achieved in $O(n \log n)$ expected bits. If, in addition, $N_l + N_l^{\varepsilon} \leqq N_u$, for some $\varepsilon > 0$ (i.e., the interval is not too small), then $\Omega(n \log n)$ bits are required to elect a leader among indistinguishable processors.

On the other hand, even if $N_l = 1$ and $N_u = \infty$, if processors have distinct identities chosen from a universe S of size s (which need not be known explicitly) then a leader can be elected with $O(n \log s)$ expected bits. In fact, assuming $N_u \geqq 2N_l$ and $n \leqq s/2$, $\Omega(n \log (s/n))$ bits are required to elect a leader with distinct identities from S.

5.2.2. Type of algorithm. The leader-election algorithms described in this paper are all randomized. In fact, the solitude-verification process is deterministic. The algorithms cannot deadlock. They all terminate distributively with probability 1 and elect a leader (or detect solitude) with certainty. Finally, with the exception of those modifications described in § 3.3, the algorithms are all conservative.

In contrast to the above, the lower bounds on solitude verification (and hence leader election) are proved on a nondeterministic model of computation. The model admits algorithms that may deadlock. Furthermore algorithms may communicate nonconservatively, may terminate nondistributively, and may, in the case of solitude verification, tolerate errors when there is only one initiator. The lower bounds state a minimum bit complexity of any computation that provides a certificate of solitude.

The juxtaposition of the algorithms and model of computation highlight a remarkable insensitivity for the problems and complexity measure studied in this paper, to the details of the underlying model of computation. This insensitivity is not preserved when the focus shifts to certain closely related problems [AAHK1], [AAHK2].

5.2.3. Type of analysis. The solitude-verification algorithms are analysed with respect to the worst-case number of bits of communication. The lower bounds refer to the best-case number of bits communicated by computations of algorithms that certify solitude.

The bulk of earlier results on leader election are concerned with message complexity. The leader-election algorithms of this paper are competitive in this measure while improving upon earlier results by a factor of $\log n$ in the number of bits transmitted. While the obvious implementation of the leader-election algorithms of this paper on a synchronous model makes them somewhat unattractive in terms of communication time, implementations exist, as described in § 3.3, which for all practical purposes make the algorithms comparable with earlier algorithms in this measure as well.

5.3. Extensions. The results of the present paper can be extended in two natural directions. First, the case where the ring size n is known exactly—a situation where the upper and lower bounds of this paper do not agree—can be explored in more detail. The solitude-verification problem when n is known exactly is examined in [AAHK2]. In this case number-theoretic properties of n can be exploited to improve upon the $O(n \log n)$ algorithm contained in this paper. With exact knowledge of ring size, there is a distinction between the complexity of distributively and nondistributively terminating versions of solitude verification. $\Theta(n\sqrt{\log n})$ bits are necessary and sufficient to achieve solitude verification with distributive termination. This becomes $\Theta(n \log \log n)$ bits for nondistributive termination. The upper bounds in this case are achieved by nondeadlocking, deterministic algorithms, and the lower bounds apply on the same general models as used in this paper. The algorithms are nonconservative. (If conservative solitude verification is required then $\Theta(n \log n)$ bits are necessary and sufficient [H].)

This paper is concerned with leader-election and solitude-verification when enough information is available to achieve certainty. When processor information is insufficient to confirm solitude with certainty, it is still possible to solve these problems probabilistically. Reference [AAHK1] examines probabilistic solitude verification, that is, algorithms that are correct with probability at least $1-\varepsilon$. When there is no knowledge of ring size, the communication complexity of solitude verification with nondistributive termination is $\Theta(n \log 1/\varepsilon)$ bits. (Distributive termination with probability $1-\varepsilon$ of correctness is impossible.) When ring size is known to be less than a bound N, then distributive termination can be achieved with complexity $O(n\sqrt{\log (N/n)}+n \log 1/\varepsilon)$ bits. A matching lower bound is shown for rings of actual size no larger than $N/2$.

Finally, probabilistic solitude detection with exact knowledge of ring size combines the two extensions above. In this case number-theoretic properties of n and error tolerance can be simultaneously exploited to reduce the complexity of probabilistic

solitude detection still further. The results for this version of the problem are more elaborate than those quoted here. The reader is directed to [AAHK2] for details.

A FAST PARAMETRIC MAXIMUM FLOW ALGORITHM AND APPLICATIONS*

GIORGIO GALLO†, MICHAEL D. GRIGORIADIS‡, AND ROBERT E. TARJAN§

Abstract. The classical maximum flow problem sometimes occurs in settings in which the arc capacities are not fixed but are functions of a single parameter, and the goal is to find the value of the parameter such that the corresponding maximum flow or minimum cut satisfies some side condition. Finding the desired parameter value requires solving a sequence of related maximum flow problems. In this paper it is shown that the recent maximum flow algorithm of Goldberg and Tarjan can be extended to solve an important class of such parametric maximum flow problems, at the cost of only a constant factor in its worst-case time bound. Faster algorithms for a variety of combinatorial optimization problems follow from the result.

1. Introduction.

The well-known *maximum flow problem* calls for finding a maximum flow (or alternatively a minimum cut) in a capacitated network. This problem arises in a variety of situations in which the arc capacities are not fixed but are functions of a single parameter, and the goal is to find the value of the parameter such that the corresponding maximum flow (or minimum cut) meets some side condition. The usual approach to solving such problems is to use a maximum flow algorithm as a subroutine and to use either binary search, monotonic search, or some other technique, such as Megiddo's [29], to find the desired value of the parameter.

Existing methods take no advantage of the similarity of the successive maximum flow problems that must be solved. In this paper, we address the question of whether this similarity can lead to computational efficiencies. We show that the answer to this question is yes: an important class of parametric maximum flow problems can be solved by extending the new maximum flow algorithm devised by Goldberg and Tarjan [13]. This algorithm is the fastest among all such algorithms for real-valued data, uniformly for all graph densities. The resulting algorithm for the parametric problem has a worst-case time bound that is only a constant factor greater than the time bound to solve a nonparametric problem of the same size. The parametric problems we consider are those in which the capacities of the arcs leaving the source are nondecreasing functions of the parameter, those of arcs entering the sink are nonincreasing functions of the parameter, and those of all other arcs are constant. Our parametric maximum flow algorithm has a variety of applications in combinatorial optimization.

This paper consists of four sections in addition to the Introduction. In § 2 we extend the Goldberg-Tarjan algorithm to find maximum flows in an n-vertex, m-arc network for $O(n)$ ordered values of the parameter in $O(nm \log (n^2/m))$ time. In § 3 we use the algorithm of § 2 to compute information about the minimum cut capacity as a function of the parameter, assuming that each arc capacity is a linear function of the parameter. In this case, the minimum cut capacity is a piecewise linear concave function of the parameter. We describe successively more complicated algorithms for finding the smallest (or largest) breakpoint, finding a maximum, and finding all the breakpoints of this function. Each of these algorithms runs in $O(nm \log (n^2/m))$ time.

In § 4 we discuss applications of our parametric maximum flow algorithm to various combinatorial optimization problems. Depending on the application, our method is faster than the best previously known method by a factor of between $\log n$ and n. The applications include flow sharing problems [3], [18], [21], [22], [27], [28], zero-one fractional programming problems [4], [5], [11], [12], [24], [25], [30], [33]-[35], [39], and others [9], [43]. Section 5 contains a summary of our results and some final remarks.

2. Parametric maximum flows and the preflow algorithm. We begin in this section by reviewing the maximum flow algorithm of Goldberg and Tarjan [13], here called the *preflow algorithm.* Then we extend their method to the parametric maximum flow problem and we analyze three versions of the parametric preflow algorithm. We conclude with some remarks about the parametric problem and our algorithm for solving it.

2.1. Flow terminology. A *network* (see [10], [44]) is a directed graph $G=(V, E)$ with a finite vertex set V and arc set E, having a distinguished *source vertex* s, a distinguished *sink vertex* t, and a nonnegative *capacity* $c(v, w)$ for each arc (v, w). We denote the number of vertices by n and the number of arcs by m. We assume that for each vertex v, there is a path from s through v to t; this implies $n=O(m)$, since every vertex other than t has at least one exiting arc. We extend the capacity function to arbitrary vertex pairs by defining $c(v, w)=0$ if $(v, w) \notin E$. A *flow* f on G is a real-valued function on vertex pairs satisfying the following three constraints:

$$f(v, w) \leqq c(v, w) \quad \text{for } (v, w) \in V \times V \quad \text{(capacity)}, \tag{2.1}$$

$$f(v, w) = -f(w, v) \quad \text{for } (v, w) \in V \times V \quad \text{(antisymmetry)}, \tag{2.2}$$

$$\sum_{v \in V} f(u, v) = 0 \quad \text{for } v \in V - \{s, t\} \quad \text{(conservation)}. \tag{2.3}$$

The *value* of the flow f is $\sum_{v \in V} f(v, t)$. A *maximum flow* is a flow of maximum value.

If A and B are two disjoint vertex subsets, the *capacity* of the pair A, B is $c(A, B)=\sum_{v \in A, w \in B} c(v, w)$. A *cut* $(X, \bar{X})$ is a two-part vertex partition $(X \cup \bar{X}=V, X \cap \bar{X}=\emptyset)$ such that $s \in X$ and $t \in \bar{X}$. A *minimum cut* is a cut of minimum capacity. If f is a flow, the *flow across the cut* $(X, \bar{X})$ is $f(X, \bar{X})=\sum_{v \in X, w \in \bar{X}} f(v, w)$. The conservation constraint implies that the flow across any cut is equal to the flow value. The capacity constraint implies that for any flow f and any cut $(X, \bar{X})$, we have $f(X, \bar{X}) \leqq c(X, \bar{X})$, which in turn implies that the value of a maximum flow is no greater than the capacity of a minimum cut. The *max-flow min-cut theorem* of Ford and Fulkerson [10] states that these two quantities are equal.

2.2. The preflow algorithm. The preflow algorithm computes a maximum flow in a given network. To describe the algorithm we need two additional concepts, those of a *preflow* and a *valid labeling.*

A *preflow* f on G is a real-valued function on vertex pairs satisfying the capacity constraint (2.1), the antisymmetry constraint (2.2), and the following relaxation of the conservation constraint (2.3):

$$\sum_{u \in V} f(u, v) \geqq 0 \quad \text{for all } v \in V - \{s\} \quad \text{(nonnegativity)}. \tag{2.4}$$

For a given preflow, we define the *excess* $e(v)$ of a vertex v to be $\sum_{u \in V} f(u, v)$ if $v \neq s$, or infinity if $v = s$. The *value* of the preflow is $e(t)$. We call a vertex $v \notin \{s, t\}$ *active* if $e(v) > 0$. A preflow is a flow if and only if (2.4) is satisfied with equality for all $v \notin \{s, t\}$, i.e., $e(v) = 0$ for all $v \notin \{s, t\}$. A vertex pair (v, w) is a *residual arc* for f if $f(v, w) < c(v, w)$; the difference $c(v, w) - f(v, w)$ is the *residual capacity* of the arc. A pair (v, w) that is not a residual arc is *saturated*. A path of residual arcs is a *residual path*.

A *valid labeling* d for a preflow f is a function from the vertices to the nonnegative integers and infinity, such that $d(t) = 0$, $d(s) = n$, and $d(v) \leqq d(w) + 1$ for every residual arc (v, w). The *residual distance* $d_f(v, w)$ from a vertex v to a vertex w is the minimum number of arcs on a residual path from v to w, or infinity if there is no such path. A proof by induction shows that if d is a valid labeling, $d(v) \leqq \min \{d_f(v, t), d_f(v, s) + n\}$ for any vertex v.

The preflow algorithm maintains a preflow f, initially equal to the arc capacities on arcs leaving s and zero on arcs not incident to s. It improves f by pushing flow excess toward the sink along arcs estimated (by using d) to be on shortest residual paths. The value of f gradually becomes larger, and f eventually becomes a flow of maximum value. As a distance estimate, the algorithm uses a valid labeling d, initially defined by $d(s) = n$, $d(v) = 0$ for $v \neq s$. This labeling increases as flow excess is moved among vertices; such movement causes residual arcs to change.

To implement this approach, the algorithm uses an *incidence list* $I(v)$ for each vertex v. The elements of such a list, called *edges*, are the unordered pairs $\{v, w\}$ such that $(v, w) \in E$ or $(w, v) \in E$. Of the edges on $I(v)$, one, initially the first, is designated the *current edge* of v. The incidence lists $I(v)$ for all $v \in V$ can be generated from an arbitrarily ordered arc list E in $O(m)$ time.

The algorithm consists of repeating the following steps until there are no active vertices:

Push/Relabel. Select any active vertex v. Let $\{v, w\}$ be the current edge of v. Apply the appropriate one of the following three cases:

Push. If $d(v) > d(w)$ and $f(v, w) < c(v, w)$, send $\delta = \min \{e(v), c(v, w) - f(v, w)\}$ units of flow from v to w. This is done by increasing $f(v, w)$ and $e(w)$ by δ, and by decreasing $f(w, v)$ and $e(v)$ by δ. (The push is *saturating* if $\delta = c(v, w) - f(v, w)$ and *nonsaturating* otherwise.)

Get Next Edge. If $d(v) \leqq d(w)$ or $f(v, w) = c(v, w)$, and $\{v, w\}$ is not the last edge on $I(v)$, replace $\{v, w\}$ as the current edge of v by the next edge on $I(v)$.

Relabel. If $d(v) \leqq d(w)$ or $f(v, w) = c(v, w)$, and $\{v, w\}$ is the last edge on $I(v)$, replace $d(v)$ by $\min \{d(w) | \{v, w\} \in I(v) \text{ and } f(v, w) < c(v, w)\} + 1$ and make the first edge on $I(v)$ the current edge of v.

When the algorithm terminates, f is a maximum flow. A minimum cut can be computed as follows. For each vertex v, replace $d(v)$ by $\min \{d_f(v, s) + n, d_f(v, t)\}$ for each $v \in V$. (This replacement cannot decrease any distance label. The values $d_f(v, s)$ for all v and $d_f(v, t)$ for all v can be computed in $O(m)$ time by breadth-first searches backward

from s and t, respectively.) Then, the cut $(X, \bar{X})$ defined by $X = \{v \mid d(v) \geqq n\}$ is a minimum cut whose sink side $\bar{X}$ is of minimum size, a property that follows from Theorem 5.5 of Ford and Fulkerson [10]. If desired, a cut $(X', \bar{X}')$ of minimum-size source side can be computed as follows. For each $v \in V$ let $d'(v) = \min \{d_f(s, v), d_f(t, v) + n\}$, and let $X' = \{v \mid d'(v) < n\}$.

The efficiency of this "generic" form of the preflow algorithm depends on the order in which active vertices are selected for *push/relabel* steps. We shall consider this selection issue after we have extended the algorithm to the parametric problem. For the moment, we merely note the bounds derived by Goldberg and Tarjan for the generic algorithm (with any selection order).

LEMMA 2.1 [13]. *Any active vertex v has $d_f(v, s) < \infty$, which implies $d(v) \leqq 2n - 1$. The value of $d(v)$ never decreases during the running of the algorithm. The total number of relabel steps is thus $O(n^2)$; together they and all the get next edge steps take $O(nm)$ time.*

LEMMA 2.2 [13]. *The number of saturating push steps through any particular residual arc (v, w) is at most one per value of $d(v)$. The total number of saturating push steps is thus $O(nm)$; each such step takes $O(1)$ time.*

LEMMA 2.3 [13]. *The total number of nonsaturating push steps is $O(n^2 m)$; each such step takes $O(1)$ time.*

In all variants of the algorithm, the running time is $O(nm)$ plus $O(1)$ time per nonsaturating *push* step; making the algorithm more efficient requires reducing the number of such steps. This is also true in the parametric extension, as we shall see.

2.3. Extension to parametric networks. In a *parametric network*, the arc capacities are functions of a real-valued parameter λ. We denote the capacity function by c_λ and make the following assumptions:

(i) $c_\lambda(s, v)$ is a nondecreasing function of λ for all $v \neq t$.

(ii) $c_\lambda(v, t)$ is a nonincreasing function of λ for all $v \neq s$.

(iii) $c_\lambda(v, w)$ is constant for all $v \neq s$, $w \neq t$.

When speaking of a maximum flow or minimum cut in a parametric network, we mean maximum or minimum for some particular value of the parameter λ.

We shall address the problem of computing maximum flows (or minimum cuts) for each member of an increasing sequence of parameter values $\lambda_1 < \lambda_2 < \cdots < \lambda_l$. Successive values are given *on-line*; that is, λ_{i+1} need not be known until after the maximum flow for λ_i has been computed. In stating time bounds we shall assume that the capacity of an arc can be computed in constant time given the value of λ. (Such is the case if, for example, the arc capacities are linear functions of λ.) The algorithm we shall describe computes no more than $n - 1$ distinct minimum cuts, no matter how many values of λ are given. For all of our applications, $l = O(n)$.

We shall now extend the preflow algorithm to the parametric maximum flow problem. Suppose that for some value λ_i of the parameter we have computed a maximum flow f and a valid labeling d for f. What is the effect of changing the value of the parameter to λ_{i+1}? The capacity of each arc (s, v) may increase; that of each arc (v, t) may decrease. Suppose we modify f by replacing $f(v, t)$ by $\min \{c_{\lambda_{i+1}}(v, t), f(v, t)\}$ for each arc $(v, t) \in E$, and replacing $f(s, v)$ by $\max \{c_{\lambda_{i+1}}(s, v), f(s, v)\}$ for each arc $(s, v) \in E$ such that $d(v) < n$. The modified f is a preflow, since $e(v)$ for $v \notin \{s, t\}$ can only have increased. Furthermore, d is a valid labeling for the modified f, since the only new residual arcs are of the form (s, v) for $d(v) \geqq n$ and (v, s) for $d(v) < n$. This means that we can compute a maximum flow and a minimum cut for λ_{i+1} by applying the preflow algorithm beginning with the modified f and the current d.

This idea leads to the following *parametric preflow algorithm.* The algorithm finds a maximum flow f_i and a minimum cut $(X_i, \bar{X}_i)$ for each value λ_i of the parameter. It consists of initializing $f=0$, $d(s)=n$, $d(v)=0$ for $v \neq s$, and $i=0$, and repeating the following three steps l times:

Step 1. (Update preflow.) Replace i by $i+1$. For $(v, t) \in E$, replace $f(v, t)$ by $\min\{c_{\lambda_i}(v, t), f(v, t)\}$. For $(s, v) \in E$ with $d(v) < n$, replace $f(s, v)$ by $\max\{c_{\lambda_i}(s, v), f(s, v)\}$.

Step 2. (Find maximum flow.) Apply the preflow algorithm to the network with arc capacities corresponding to λ_i, beginning with the current f and d. Let f and d be the resulting flow and final valid labeling.

Step 3. (Find minimum cut.) Redefine $d(v) = \min\{d_f(v, s)+n, d_f(v, t)\}$ for each $v \in V$. The cut $(X_i, \bar{X}_i)$ is then given by $X_i = \{v \mid d(v) \geqq n\}$.

The minimum cuts produced by the algorithm have a *nesting property* that was previously observed in the context of various applications by Eisner and Severance [9], Stone [43], and perhaps others. Megiddo [27] has also noted a similar property in a related problem. Here, the result follows directly from our algorithm.

LEMMA 2.4. *For a given on-line sequence of parameter values* $\lambda_1 < \lambda_2 < \cdots < \lambda_l$, *the parametric preflow algorithm correctly computes maximum flows* $f_1, f_2, \cdots, f_l$ *and minimum cuts* $(X_1, \bar{X}_1), (X_2, \bar{X}_2), \cdots, (X_l, \bar{X}_l)$ *such that* $X_1 \subseteq X_2 \subseteq \cdots \subseteq X_l$.

Proof. The correctness of the algorithm is immediate. For any vertex v, the label $d(v)$ cannot decrease in Step 3, which implies that $d(v)$ never decreases during the running of the algorithm. This means that $X_1 \subseteq X_2 \subseteq \cdots \subseteq X_l$, which in turn implies that there can be at most $n-1$ distinct sets X_i. □

2.4. Analysis of the parametric preflow algorithm. In view of Lemma 2.4, Lemmas 2.1 and 2.2 hold without change for the parametric preflow algorithm. Furthermore, the time spent in Steps 1 and 3 is $O(m)$ per iteration, for a total of $O(lm)$ time. Thus the parametric preflow algorithm runs in $O((n+l)m)$ time plus $O(1)$ time per nonsaturating push.

The number of nonsaturating pushes depends on the order in which *push/relabel* steps are performed. We shall analyze three versions of the parametric preflow algorithm. For each, we show that the time bound for the nonparametric case extends to the parametric case with an increase of at most a constant factor. The proofs of the following three theorems are analogous to those given in [13].

We first analyze the generic version, in which *push/relabel* steps take place in any order.

THEOREM 2.5. *If the order of push/relabel steps is arbitrary, then the number of nonsaturating push steps is* $O(n^2(l+m))$. *The total running time of the parametric preflow algorithm is* $O((n^2(l+m))$, *or* $O(n^2m)$ *if* $l = O(n)$.

Proof. Let $\Phi = \sum\{d(v) \mid v \text{ is active}\}$ if some vertex is active, and $\Phi = 0$ otherwise. A nonsaturating *push* step decreases Φ by at least one. The function Φ is always in the range 0 to $2n^2$. Step 1 can increase Φ by at most $2n^2$, for a total over all iterations of Step 1 of $O(ln^2)$. A relabeling step increases Φ by the amount by which the label changes. Thus the total increase in Φ due to relabeling steps is $O(n^2)$. A saturating *push* step can increase Φ by at most $2n$. Thus the total increase in Φ due to such steps is $O(n^2m)$. These are the only ways in which Φ can increase. The total number of nonsaturating *push* steps is bounded by the total increase in Φ over the algorithm, which is $O(n^2m)$. □

Next we consider the *first-in first-out* (FIFO) version of the preflow algorithm, which solves the nonparametric problem in $O(n^3)$ time [13]. In this version, a queue

Q is used to select vertices for *push/relabel* steps. Initially Q is empty. At the beginning of Step 2 of the parametric preflow algorithm, every active vertex is appended to Q. The FIFO algorithm consists of repeating the following step until Q is empty:

Discharge. Remove the vertex v on the front of Q. Apply *push/relabel* steps to v until v is no longer active or v is relabeled. If a *push* from v to another vertex w makes w active, add w to the rear of Q.

THEOREM 2.6. *For the* FIFO *version of the parametric preflow algorithm, the number of nonsaturating push steps is* $O(n^3)$. *The total running time is* $O(n^3+ln^2)$, *or* $O(n^3)$ *if* $l=O(n)$.

Proof. We define *passes* over the queue Q as follows. The first pass during an iteration of Step 2 consists of the *discharge* steps applied to the vertices initially on Q. Each pass after the first in an iteration of Step 2 consists of the *discharge* steps applied to the vertices added to Q during the previous pass. There is at most one nonsaturating *push* step per vertex v per pass, since such a step reduces $e(v)$ to zero. We claim that the total number of passes is $O(n^2+ln)$, from which the theorem follows.

To establish the claim, we define $\Phi=\max\{d(v)\mid v\in Q\}$ if $Q\neq\emptyset$, and $\Phi=0$ if $Q=\emptyset$. Consider the effect on Φ of a pass over Q. If $v\in Q$ at the beginning of a pass and $d(v)=\Phi$, then $v\notin Q$ at the end of the pass unless a *relabel* step occurs during the pass. Thus, if Φ is the same at the end as at the beginning of the pass, some vertex label must have increased by at least one. If Φ increases over the pass, some $d(v)$ must increase by at least the amount of the increase in Φ. From the end of one iteration of Step 2 to the beginning of the next, Φ can increase by $O(n)$. Thus (i) the total number of passes in which Φ can increase or stay the same is $O(n^2+ln)$; (ii) the total number of passes in which Φ can decrease is at most the total increase in Φ between passes and during passes in which it increases, which is also $O(n^2+ln)$. We conclude that the total number of passes is at most $O(n^2+ln)$, verifying the claim and hence the theorem. □

A more elaborate version of the preflow algorithm [13] uses the dynamic tree data structure of Sleator and Tarjan [40], [41] to reduce the running time to $O(nm\log(n^2/m))$ if $l=O(n)$. The corresponding version of the parametric preflow algorithm also runs in $O(nm\log(n^2/m))$ time. It uses a queue Q for vertex selection, and it performs *discharge* steps exactly as does the FIFO algorithm, but in place of *push/relabel* steps it uses more complicated *tree-push/relabel* steps. A *tree-push/relabel step* can move an amount of flow excess through several arcs at once. Extending the analysis in [13] to the parametric case is straightforward. We shall merely summarize the results.

The dynamic tree algorithm uses a parameter k, the *maximum tree size*, which can be chosen freely in the range from 2 to n. An easy extension of the analysis in [13] shows that the parametric preflow algorithm runs in $O(nm\log k)$ time plus $O(\log k)$ time per addition of a vertex to Q. Furthermore, the number of additions of a vertex to Q is $O(nm)$ plus $O(n/k)$ per pass over Q, where passes are defined as in the proof of Theorem 2.6. The $O(n^2+ln)$ bound on the number of passes in the proof of Theorem 2.6 remains valid if the dynamic tree algorithm is used in place of the FIFO algorithm. Combining these estimates, we obtain an $O((nm+(n^3+ln^2)/k)\log k)$ bound on the total running time. Choosing $k=\max\{2, n^2/m\}$, we have the following theorem.

THEOREM 2.7. *The parametric preflow algorithm implemented using dynamic trees runs in* $O((n+l)m\log(n^2/m))$ *time. If* $l=O(n)$, *the time bound is* $O(nm\log(n^2/m))$.

2.5. Additional observations. We conclude this section with several observations about the parametric maximum flow problem and our algorithm for solving it. Our

first observation concerns variants of the parametric maximum flow problem. Our algorithm remains valid if the arc capacity functions are nonincreasing on arcs out of s and nondecreasing on arcs into t, and the values of the parameter λ are given in decreasing order. To see this, merely substitute $-\lambda$ for λ. The algorithm also applies if the arc capacity functions are nondecreasing on arcs out of s and nonincreasing on arcs into t, and the values of λ are given in decreasing order. In this case, reverse the directions of all the arcs, exchange the source and sink, and apply the original algorithm to this reversed network, which we shall denote by G^R. Each minimum cut $(\bar{X}, X)$ generated for G^R will correspond to a minimum cut $(X, \bar{X})$ in the original (nonreversed) network that will have the source side of minimum size instead of the sink side. Successively generated minimum cuts in G^R will correspond to cuts with successively smaller source sides in the original network.

If we are only interested in computing minimum cuts, there is a variant of the preflow algorithm that does less computation, although it has the same asymptotic time bound [13]. This variant, here called the *min-cut preflow algorithm*, computes a preflow of maximum value and a minimum cut, but not a maximum flow. It differs from the original algorithm in that a vertex v is considered to be active only if $e(v) > 0$ and $d(v) < n$. The algorithm terminates having computed a *maximum preflow*. (A preflow f is *maximum* if and only if for every vertex v, $v \neq t$ or $e(v) = 0$ or $d_f(v, t) < \infty$.) If this variant is used to compute minimum cuts, a maximum flow for a desired parameter value can be computed by beginning with the corresponding maximum preflow and converting it into a maximum flow using the original preflow algorithm. Most of the applications we shall consider only require the computation of a sequence of minimum cuts or even minimum cut values and not maximum flows. We shall refer to the variant of our parametric preflow algorithm that computes minimum cuts and maximum preflows as the *min-cut parametric algorithm.*

So far we have required all arc capacities to be nonnegative, but if we are only interested in computing minimum cuts, we can allow negative capacities on arcs out of s and on arcs into t. This is because there is a simple transformation that makes such arc capacities nonnegative without affecting minimum cuts [35]. For a given vertex v, suppose we add a constant $\Delta(v)$ to $c(s, v)$ and $c(v, t)$. Then the minimum cuts do not change since the capacity of every cut is increased by $\Delta(v)$.

By adding a suitably large $\Delta(v)$ to $c(s, v)$ and $c(v, t)$ for each v, we can make all the arc capacities positive. In the parametric problem, we can choose a new function Δ on the vertices of G for each new value λ_i of λ without affecting the $O((n+l)m \log (n^2/m))$ time bound for our algorithm. It suffices to choose

$$\Delta_{\lambda_1}(v) = \max \{0, -c_{\lambda_1}(s, v)\} + \max \{0, -c_{\lambda_1}(v, t)\},$$

$$\Delta_{\lambda_{i+1}}(v) = \Delta_{\lambda_i}(v) + c_{\lambda_i}(v, t) - c_{\lambda_{i+1}}(v, t) \quad \text{for } i \geqq 1.$$

With this choice, the transformed arc capacities are nondecreasing functions of λ on arcs leaving s and constant on arcs that enter t. Although the same effect could be obtained by adding a sufficiently large constant to the capacities of these arcs, the modification we have described has the additional advantage of keeping capacities as small as possible. In subsequent sections, when discussing minimum cut problems, we shall allow arbitrary capacities, positive or negative, on arcs leaving s and arcs entering t.

The minimum cuts corresponding to various parameter values have a *nesting property* that is a strengthening of Lemma 2.4. The following lemma is an extension of known results [10, pp. 13], [43] that we shall need in the next section. To prove the lemma, we shall use the min-cut preflow algorithm discussed above.

LEMMA 2.8. *Let* $(X, \bar{X})$ *be any minimum cut for* $\lambda = \lambda_1$, *and let* $(Y, \bar{Y})$ *be any minimum cut for* $\lambda = \lambda_2$ *such that* $\lambda_1 \leqq \lambda_2$. *Then,* $(X \cap Y, \bar{X} \cup \bar{Y})$ *is a minimum cut for* $\lambda = \lambda_1$ *and* $(X \cup Y, \bar{X} \cap \bar{Y})$ *is a minimum cut for* $\lambda = \lambda_2$.

Proof. Run the min-cut parametric algorithm for $\lambda = \lambda_1$, followed by $\lambda = \lambda_2$. At the beginning of the computation for $\lambda = \lambda_2$, all vertices $v \in X - \{s\}$ have $d(v) \geqq n$. Thus, after a maximum preflow is computed for $\lambda = \lambda_2$, all arcs (v, w) with $v \in X$, $w \in \bar{X}$ are saturated (their flow has not changed during the computation for $\lambda = \lambda_2$). Since $(Y, \bar{Y})$ is a minimum cut for $\lambda = \lambda_2$, all arcs (v, w) with $v \in Y$, $w \in \bar{Y}$ are saturated. Furthermore, if $v \in \bar{Y} - \{t\}$ then $e(v) = 0$, since the net flow across $(Y, \bar{Y})$ must be equal to the excess at t.

Now consider the cut $Z = (X \cup Y)$, $\bar{Z} = (\bar{X} \cap \bar{Y})$. Any arc (v, w) with $v \in Z$, $w \in \bar{Z}$ must be saturated. Since $v \in \bar{Z} - \{t\}$ implies $e(v) = 0$, the cut $(Z, \bar{Z})$ must have capacity $e(t)$, and hence it must be a minimum cut.

The proof for $(X \cap Y, \bar{X} \cup \bar{Y})$ is similar: proceed on G^R, and run the min-cut parametric algorithm for $\lambda = \lambda_2$, followed by $\lambda = \lambda_1$. □

A direct consequence of this lemma is the following corollary, which we shall need in the next section.

COROLLARY 2.9. *Let* $(X_1, \bar{X}_1)$ *be a minimum cut for* $\lambda = \lambda_1$, *let* $(X_2, \bar{X}_2)$ *be a minimum cut for* $\lambda = \lambda_2$ *such that* $X_1 \subseteq X_2$ *and* $\lambda_1 \leqq \lambda_2$, *and let* λ_3 *be such that* $\lambda_1 \leqq \lambda_3 \leqq \lambda_2$. *Then there is a cut* $(X_3, \bar{X}_3)$ *minimum for* λ_3 *such that* $X_1 \subseteq X_3 \subseteq X_2$.

Proof. Let $(X_3', \bar{X}_3')$ be any minimum cut for $\lambda = \lambda_3$. Take $X_3 = (X_3' \cup X_1) \cap X_2$, $\bar{X}_3 = V - X_3$, and apply Lemma 2.8 twice. □

Our last observation is that if the graph G is bipartite, the $O((n+l)m \log (n^2/m))$ time bound for computing parametric maximum flows can be improved slightly. Suppose $V = A \cup B$, $A \cap B \neq \emptyset$, and every arc in G has one vertex in A and one in B. Let $n_A = |A|$ and $n_B = |B|$ and suppose that $n_A \leqq n_B$. Then the time to compute maximum flows for l ordered values of λ can be reduced to $O(n_A m \log (n_A^2/m + 2))$ if $l = O(n_A)$. This requires modifying the preflow algorithm so that only vertices in A are active, and modifying the use of the dynamic tree data structure so that such a tree contains as many vertices in A as in B. The bound is slightly worse if $l = \omega(n_A)$. The details can be found in [42].

3. The min-cut capacity function of a parametric network. For a parametric network, we define the *min-cut capacity function* $\kappa(\lambda)$ to be the capacity of a minimum cut as a function of the parameter λ. We shall assume throughout this section that the arc capacities are *linear* functions of λ satisfying the conditions (i)-(iii) of § 2. It is well known [9], [43] and follows from the results of § 2 that under this assumption $\kappa(\lambda)$ is a piecewise-linear concave function with at most $n-2$ breakpoints. (By a *breakpoint* we mean a value of λ at which the slope of $\kappa(\lambda)$ changes.) The $n-1$ or fewer line segments forming the graph of $\kappa(\lambda)$ correspond to $n-1$ or fewer distinct cuts. We shall develop three algorithms for computing information about $\kappa(\lambda)$. The first computes the smallest (or equivalently the largest) breakpoint. The second computes a value of λ at which $\kappa(\lambda)$ is maximum. The third computes all the breakpoints. Each of these algorithms uses the algorithm of § 2 as a subroutine and runs in $O(nm \log (n^2/m))$ time. Although the algorithm for computing all breakpoints solves all three problems, we shall present all three algorithms since each is more complicated than the preceding one and since the resulting difference in constant factors may be important in practice.

We shall assume that the capacities $c_\lambda(s, v)$ and $c_\lambda(v, t)$ are given in the form $c_\lambda(s, v) = a_0(v) + \lambda a_1(v)$ and $c_\lambda(v, t) = b_0(v) - \lambda b_1(v)$, with arbitrary coefficients a_0, b_0 and nonnegative coefficients a_1, b_1. A minimum cut $(X_0, \bar{X}_0)$ for some

$\lambda = \lambda_0$ gives an equation for a line that contributes a line segment to the function $\kappa(\lambda)$ at $\lambda = \lambda_0$. This line is $L_{X_0}(\lambda) = \alpha_0 + \lambda\beta_0$, where $\alpha_0 = c_{\lambda_0}(X_0, \bar{X}_0) - \lambda_0\beta_0$ and $\beta_0 = \sum_{v \in \bar{X}_0} a_1(v) - \sum_{v \in X_0} b_1(v)$. (Recall from § 2 that $c_\lambda(X, \bar{X}) = \sum_{v \in X, w \in \bar{X}} c_\lambda(v, w)$. Also note that $a_1(v) = 0$ if $(s, v) \notin E$, and $b_1(v) = 0$ if $(v, t) \notin E$.)

3.1. Computing the smallest breakpoint of $\kappa(\lambda)$. To compute the smallest breakpoint of $\kappa(\lambda)$ we use an algorithm stated by Gusfield [18] for an application involving scheduling transmissions in a communication network, discussed in more detail in § 4.1.

The algorithm, an adaption of Newton's method, consists of the following two steps.

Step 0. Compute λ_1, λ_2 such that the smallest breakpoint λ_0 satisfies $\lambda_1 \leqq \lambda_0 \leqq \lambda_2$. Compute a cut $(X_1, \bar{X}_1)$ that is a minimum for λ_1. Go to Step 1.

Step 1. Compute a cut $(X_2, \bar{X}_2)$ that is a minimum for λ_2. If $L_{X_1}(\lambda_1) = L_{X_2}(\lambda_2)$, stop: λ_2 is the smallest breakpoint. Otherwise, replace λ_2 by the value of λ such that $L_{X_1}(\lambda) = L_{X_2}(\lambda)$ and repeat Step 1. (The appropriate value of λ is $(\alpha_2 - \alpha_1)/(\beta_1 - \beta_2)$.)

The values of λ_2 generated by this algorithm are strictly decreasing; thus the parametric preflow algorithm of § 2 applied to G^R performs all iterations of Step 1 in $O(nm \log (n^2/m))$ time, saving a factor of n over Gusfield's algorithm [18].

In Step 0, it suffices to select λ_1 sufficiently small so that for each vertex v such that (s, v) or (v, t) is of nonconstant capacity, $c_{\lambda_1}(s, v) + \sum_{u \in V - \{s,t\}} c(u, v) < c_{\lambda_1}(v, t)$. A simple computation shows that a suitable value of λ_1 is

$$\min_{v \in V - \{s,t\}} \left\{ \frac{b_0(v) - a_0(v) - \sum_{u \in V - \{s,t\}} c(u, v)}{a_1(v) + b_1(v)} \,\middle|\, a_1(v) + b_1(v) > 0 \right\} - 1. \tag{3.1}$$

Similarly, it suffices to select λ_2 sufficiently large so that for each vertex v such that (s, v) or (v, t) is of nonconstant capacity, $c_{\lambda_2}(v, t) + \sum_{w \in V - \{s,t\}} c(v, w) < c_{\lambda_2}(s, v)$. A suitable value of λ_2 is

$$\max_{v \in V - \{s,t\}} \left\{ \frac{b_0(v) - a_0(v) + \sum_{w \in V - \{s,t\}} c(v, w)}{a_1(v) + b_1(v)} \,\middle|\, a_1(v) + b_1(v) > 0 \right\} + 1. \tag{3.2}$$

Essentially the same algorithm can be used for computing the largest breakpoint; instead of successively decreasing λ_2 and using G^R, successively increase λ_1 and use G.

3.2. Finding a maximum of $\kappa(\lambda)$. Our algorithm for finding the value of λ that maximizes $\kappa(\lambda)$ is based on a simple method of iterative interval contraction for computing the maximum $f(\lambda^*)$ of a strictly concave and continuously differentiable function $f(\lambda)$ on a nonempty interval $[\lambda_1, \lambda_3]$ of the real line. The method is as follows. First, compute the function values and the tangents of $f(\lambda)$ at each end of the given interval. Second, compute the point $\lambda_2 \in [\lambda_1, \lambda_3]$ where the two tangent lines intersect, and also compute $f'(\lambda_2)$. Then, if $f'(\lambda_2) > 0$ replace λ_3 by λ_2 and repeat; if $f'(\lambda_2) > 0$ replace λ_1 by λ_2 and repeat; if $f'(\lambda_2) = 0$ accept λ_2 as the solution. Of course this algorithm need not terminate, but it will converge to the maximum.

The method is seldom used in this general setting because it is inferior to several other algorithms for one-dimensional maximization. But it can be specialized in the obvious way to handle the piecewise-linear concave function $\kappa(\lambda)$ efficiently. A maximum of $\kappa(\lambda)$ can be computed in as many function evaluations as there are linear segments that comprise $\kappa(\lambda)$, namely $n - 1$ or fewer. Using the notation introduced above, $\lambda_2 = (\alpha_3 - \alpha_1)/(\beta_1 - \beta_3)$ if the line segments of $\kappa(\lambda)$ at λ_1 and at λ_3 are distinct.

Otherwise, the search terminates with a line segment of zero slope and $\lambda^* = \lambda_1$ (or $\lambda^* = \lambda_3$). The algorithm will compute a maximum of $\kappa(\lambda)$ in $O(n^2 m \log(n^2/m))$ time since at most $n-1$ minimum cut problems must be solved.

The running time of this algorithm can be improved by partitioning the sequence of successive values of λ_2 into two subsequences, one increasing and the other decreasing. It is then possible to use two concurrent invocations of the parametric preflow algorithm: *invocation I* that starts with λ_1 and computes minimum cuts of G for an increasing sequence of λ values, and *invocation D* that starts with λ_3 and computes minimum cuts of G^R for a decreasing sequence of λ values. A new value λ_2 is a member of the increasing sequence if $\beta_2 > 0$, and a member of the decreasing sequence otherwise. The initial values of λ_1 and λ_3 must be such that all breakpoints lie in the interval $[\lambda_1, \lambda_3]$, a property that is assured by using (3.1) to give the initial value of λ_1 and (3.2) to give the initial value of λ_3.

The algorithm to compute a maximum of $\kappa(\lambda)$ consists of the following four steps.

Step 0. Compute the initial values λ_1 and λ_3 from (3.1) and (3.2). Start concurrent invocations (I and D) of the parametric preflow algorithm of §2: For $\lambda = \lambda_1$, invocation I computes a minimum cut $(X_1, \bar{X}_1)$ having $|X_1|$ maximum; for $\lambda = \lambda_3$, invocation D computes a minimum cut $(X_3, \bar{X}_3)$ having $|X_3|$ minimum.

Step 1. Compute $\lambda_2 = (\alpha_3 - \alpha_1)/(\beta_1 - \beta_3)$, pass λ_2 to both invocations I and D, and run them concurrently. If invocation I finds a minimum cut $(X_2^I, \bar{X}_2^I)$ first, suspend invocation D and go to Step 2 (the other case is symmetric). Compute $\beta_2 = \sum_{v \in \bar{X}_2} a_1(v) - \sum_{v \in X_2} b_1(v)$.

Step 2. If $\beta_2 = 0$, stop: $\lambda^* = \lambda_2$. Otherwise, if $\beta_2 > 0$, replace λ_1 by λ_2, back up invocation D to its state before it began processing λ_2, and go to Step 1. Otherwise, go to Step 3.

Step 3 ($\beta_2 < 0$). Finish running invocation D on λ_2. This produces a minimum cut $(X_2^D, \bar{X}_2^D)$, not necessarily the same as $(X_2^I, \bar{X}_2^I)$. If $\beta_2 \geqq 0$, stop: $\lambda^* = \lambda_2$. Otherwise, replace λ_3 by λ_2, back up invocation I to its state before processing λ_2, and go to Step 1.

Backing up invocation D or I as required in Steps 2 and 3 is merely a matter of restoring the appropriate flow and valid labeling, which takes $O(m)$ time. The total time spent during one iteration of Steps 1, 2, and 3 is proportional to the time spent in invocation I or D, whichever one is run to completion on λ_2 and not backed up. The total number of values of λ_2 processed is $O(n)$. Thus the total time is proportional to the time necessary to run the parametric preflow algorithm of § 2.3 twice, once on an increasing sequence of values and once on a decreasing sequence of values; i.e., $O(nm \log(n^2/m))$.

3.3. Finding all breakpoints of $\kappa(\lambda)$. In some applications it is necessary to produce all the line segments or breakpoints of $\kappa(\lambda)$, possibly along with the corresponding minimum cuts. To do this we extend the maximum-finding algorithm of the previous section. This algorithm uses iterative contraction of the interval $[\lambda_1, \lambda_3]$; it ignores breakpoints that lie in the discarded portion of the interval. We can find all the breakpoints by proceeding as in the algorithm of § 3.2 but using a divide-and-conquer strategy that recursively examines both of the subintervals $[\lambda_1, \lambda_2]$ and $[\lambda_2, \lambda_3]$ into which the current interval is split by the new value λ_2. This method was proposed by Eisner and Severance [9] for bipartite graphs in the context of a database record-segmentation problem (see § 4.4). Unfortunately, a straightforward implementation of this idea yields an $O(n^2 m \log(n^2/m))$-time algorithm. To obtain a better bound it is necessary to use two concurrent invocations of the parametric preflow algorithm, and

also use graph contraction so that recursive invocations of the method compute cuts on smaller and smaller graphs.

If G is a network and X is a set of vertices such that at most one of s and t is in X, we define $G(X)$, the *contraction of* G *by* X, to be the network formed by shrinking the vertices in X to a single vertex, eliminating loops, and combining multiple arcs by adding their capacities. The algorithm we present reports only the breakpoints of $\kappa(\lambda)$, although it computes cuts corresponding to the line segments of the graph of $\kappa(\lambda)$. If the actual cuts are needed, they can either be saved as the computation proceeds or computed in a postprocessing step using one application of the method in § 2.3.

Our algorithm uses a recursive procedure called *slice*. With each network G to which *slice* is applied, we associate four pieces of information: Two values of λ, denoted by λ_1 and λ_3, and two flows f_1 and f_3, such that f_1 is a maximum flow for λ_1, f_3 is a maximum flow for λ_3, the cut $(\{s\}, V-\{s\})$ is the unique minimum cut for λ_1, the cut $(V-\{t\}, \{t\})$ is the unique minimum cut for λ_3, and $\lambda_1 < \lambda_3$. The initial values for λ_1 and λ_3 are computed from (3.1) and (3.2) as before. The *breakpoint algorithm* consists of the following two steps.

Step 1. Compute λ_1 according to (3.1) and λ_3 according to (3.2). Compute a maximum flow f_1 and minimum cut $(X_1, \bar{X}_1)$ for λ_1 such that $|X_1|$ is maximum by applying the preflow algorithm to G. Compute a maximum flow f_3 and minimum cut $(X_3, \bar{X}_3)$ for λ_3 such that $|X_3|$ is minimum by applying the preflow algorithm to G^R. Form G' from G by shrinking the vertices in X_3 to a single vertex, shrinking the vertices in $\bar{X}_1$ to a single vertex, eliminating loops, and combining multiple arcs by adding their capacities. (Note that $X_3 \cap \bar{X}_1 = \emptyset$.)

Step 2. If G' contains at least three vertices, let f_1' and f_3' be the flows in G' corresponding to f_1 and f_3, respectively; perform *slice* $(G', \lambda_1, \lambda_3, f_1', f_3')$, where *slice* is defined as follows:

Procedure *slice* $(G, \lambda_1, \lambda_3, f_1, f_3)$.

Step S1. Let λ_2 be the value of λ such that $c_{\lambda_2}(\{s\}, V-\{s\}) = c_{\lambda_2}(V-\{t\}, \{t\})$. (This value will satisfy $\lambda_1 \leqq \lambda_2 \leqq \lambda_3$.)

Step S2. Run the preflow algorithm for the value λ_2 on G starting with the preflow f_1' formed by increasing f_1 on arcs (s, v) to saturate them and decreasing f_1 on arcs (v, t) to meet the capacity constraints. As an initial valid labeling, use $d(v) = \min\{d_{f_1'}(v, t), d_{f_1'}(v, s) + n\}$. Concurrently, run the preflow algorithm for the value λ_2 on G^R starting with the preflow f_3' formed by increasing f_3 on arcs (v, t) to saturate them and decreasing f_3 on arcs (s, v) to meet the capacity constraints. As an initial valid labeling, use $d(v) = \min\{d_{f_3'}(s, v), d_{f_3'}(t, v) + n\}$. Stop when one of the concurrent applications stops, having computed a maximum flow f_2. Suppose the preflow algorithm applied to G stops first. (The other case is symmetric.) Find the minimum cuts $(X_2, \bar{X}_2)$ and $(X_2', \bar{X}_2')$ for λ_2 such that $|X_2|$ is minimum and $|X_2'|$ is maximum. If $|X_2| > n/2$, complete the execution of the preflow algorithm on G^R and let f_2 be the resulting maximum flow.

Step S3. If $c_\lambda(X_2, \bar{X}_2) \neq c_\lambda(X_2', \bar{X}_2')$ for some λ, report λ_2 as a breakpoint.

Step S4. If $X_2 \neq \{s\}$, perform *slice* $(G(\bar{X}_2), \lambda_1, \lambda_2, f_1, f_2)$. If $\bar{X}_2' \neq \{t\}$, perform *slice* $(G(X_2'), \lambda_2, \lambda_3, f_2, f_3)$.

Remarks. Step 1 is an initialization step that guarantees that the graph G', on which *slice* is called, has unique minimum cuts $(\{s\}, V-\{s\})$ and $(V-\{t\}, \{t\})$ for λ_1

and λ_3, respectively. The flows f_1 and f_3 are needed as input parameters to *slice* to guarantee that the initial labeling is such that the time for a sequence of calls to *slice* is subject to the bound of § 2.

The correctness of this algorithm follows from Corollary 2.9. Note that the minimum cuts computed in Step S2 correspond to minimum cuts for λ_2 in the original network, with the correspondence obtained by expanding the contracted vertex sets. Since each vertex of G is in at most one of the two subproblems in Step S4, there are $O(n)$ invocations of *slice*.

3.4. Analysis of the breakpoint algorithm. Two ideas underlay the efficiency of the breakpoint algorithm. To explain them, we need to develop a framework for the analysis of the algorithm. We shall charge to an invocation of slice the time spent in the invocation, not including the time spent in nested invocations. The time charged to one invocation is then $O(m)$ plus the time spent running the preflow algorithm in Step S2. Summing $O(m)$ over all $O(n)$ invocations of *slice* gives a bound of $O(nm)$. It remains to estimate the time spent running the preflow algorithm.

In our analysis we shall denote by n_0 and m_0 the number of vertices and edges in the original (unshrunken) graph, and by n and m the number of vertices and edges in one of the shrunken graphs passed to *slice*. We use the dynamic tree version of the preflow algorithm, with the maximum tree size k chosen globally. Specifically, let $k_0 = \max\{2, n_0^2/m_0\}$. For an invocation of *slice* on a graph with n vertices and m edges, we let the maximum tree size for this subproblem be $k = \min\{n, k_0\}$. Then the running time of this invocation of the preflow algorithm is $O((nm + n^3/k)\log k) = O((nm + n^3/k_0)\log k_0)$.

The first idea contributing to the speed of the algorithm is that the results of § 2 allow us to bound the time of a sequence of preflow algorithm applications, not just a single one, by $O((nm + n^3/k_0)\log k_0)$. That is, if we charge this much time for an invocation of *slice*, we can regard certain of the nested invocations as being free. The second idea is that running the preflow algorithm concurrently on G and on G^R allows us to regard the larger of the nested invocations in Step S4 as being free, since the time spent on the larger subproblem invocation is no more than that spent on the smaller, which implies that the total time is at most twice the time spent on all the smaller subproblem invocations. This leads to a recurrence bounding the total running time for all nested invocations whose solution is $O((nm + n^3/k_0)\log k_0)$. This gives a total time bound for the breakpoint algorithm of $O(n_0 m_0 \log(n_0^2/m_0))$.

Consider an invocation of *slice* $G(\lambda_1, \lambda_3, f_1, f_3)$. Let $G_1 = G(\bar{X}_2)$ as computed in Step S4, and let $G_3 = G(X_2')$; let n_1, m_1 and n_2, m_2 be the numbers of vertices and arcs in G_1 and G_2, respectively. We regard this invocation of *slice* as being a continuation of the algorithm of § 2.3 applied to G, with λ_1 the most recently processed value of λ and f_1 the resulting maximum flow. Simultaneously, we regard the invocation as being a continuation of the algorithm of § 2 applied to G^R, with λ_3 the most recently processed value of λ and f_3 the resulting flow.

With this interpretation we can regard the preflow algorithm applications in Step S2 as being free, but if $|X_2| \leqq n/2$ we must account for new applications of the algorithm in § 2 on $G(\bar{X}_2)$ and $G^R(\bar{X}_2)$, and otherwise (i.e., $|\bar{X}_2'| \leqq n/2$) we must account for new applications of the algorithm in § 2 on $G(X_2')$ and $G^R(X_2')$. Thus we obtain the following bound on the time spent in invocations of the preflow algorithm. If G has n vertices and m arcs, the time spent in such invocations during the computation of $\kappa(\lambda)$ is at most $T(n, m) + O((nm + n^3/k_0)\log k_0)$, where $T(n, m)$ is defined recursively as follows:

$$T(n, m) = \begin{cases} 0 & \text{if } n \leqq 3, \\ \max \{T(n_1, m_1) + T(n_2, m_2) + O((n_1 m_1 + n_1^3/k_0) \log k_0): \\ \qquad n_1, n_2 \geqq 3;\ n_1 + n_2 \leqq n + 2; \\ \qquad n_1 \leqq n_2;\ m_1, m_2 \geqq 1;\ m_1 + m_2 \leqq m + 1\} & \text{if } n > 3. \end{cases}$$

Remark. In this analysis, the sequence of preflow algorithm invocations associated with a particular application of the algorithm of § 2.3 is on a sequence of successively smaller graphs, but the analysis in § 2.4 remains valid. In the definition of $T(n, m)$, the constraint $m_1 + m_2 \leqq m + 1$ allows for the existence of an arc (s, t), which will appear in both subproblems.

A straightforward proof by induction shows that $T(n, m) = O((nm + n^3/k_0) \log k_0)$. By setting $n = n_0$ and $m = m_0$, we obtain the following theorem.

THEOREM 3.1. *The breakpoint algorithm runs in $O(nm \log (n^2/m))$ time on a graph with n vertices and m edges.*

3.5. Additional observations. We conclude this section with two observations. First, as noted by Stone [43], a complete set of minimum cuts for all values of λ can be represented in $O(n)$ space: store with each vertex $v \notin \{s, t\}$ the breakpoint at which v moves from the sink side to the source side of a minimum cut, for a set of minimum cuts whose source sides are nested. The breakpoint algorithm can be augmented to compute this information without affecting its asymptotic time bound. Second, the time bound of the three algorithms in Sections 3.1–3.3 can be improved to $O(n_A m \log (n_A^2/m + 2))$ if G is bipartite and $\kappa(\lambda)$ has $O(n_A)$ breakpoints. Here n_A is the size of the smaller half of the bipartite partition of V. This bound follows using the bipartite variant of the preflow algorithm mentioned at the end of § 2.5.

4. Applications. In this section, we give a number of applications of the algorithms in §§ 2 and 3. For each application, we obtain an algorithm running in $O(nm \log (n^2/m))$ time, where n is the number of vertices and m is the number of arcs in the graph involved in the problem. For applications in which the graph is bipartite, the bound is $O(n_A m \log (n_A^2/m + 2))$, where n_A is the size of the smaller half of the bipartite partition of the vertex set. (When the latter bound is applicable, we shall state it within square brackets.) Depending on the application, our bound is a factor of from $\log n$ to n better than the best previously known bound. Our applications fall into four general categories: Flow-sharing problems, zero-one fractional programming problems, parametric zero-one polynomial programming problems, and miscellaneous applications.

4.1. Flow sharing. Consider a network with a set of sources $S = \{s_1, s_2, \cdots, s_k\}$ and a single sink t, in which we want to find a flow from the sources in S to t. We require flow conservation at vertices not in $S \cup \{t\}$. We can model this problem as an ordinary one-source, one-sink problem by adding a supersource s and an arc (s, s_i) of infinite capacity for each $i \in \{1, \cdots, k\}$. The resulting network can have many different maximum flows, with different utilizations of the various sources; we define the utilization u_i of source s_i to be the flow through the arc (s, s_i). The question arises of how to compare the quality of such flows. Suppose each source s_i has a positive weight w_i. Several figures of merit have been proposed, leading to the following optimization problems:

(i) *Perfect sharing.* Among flows with u_i/w_i equal for all $i \in \{1, \cdots, k\}$, find one that maximizes the flow value $e(t)$.

(ii) *Maximin sharing.* Among maximum flows, find one that maximizes the smallest u_i/w_i, $i \in \{1, \cdots, k\}$.

(iii) *Minimax sharing.* Among maximum flows, find one that minimizes the largest u_i/w_i, $i \in \{1, \cdots, k\}$.

(iv) *Optimal sharing.* Among maximum flows, find one that simultaneously maximizes the smallest u_i/w_i and minimizes the largest u_i/w_i, $i \in \{1, \cdots, k\}$.

(v) *Lexicographic sharing.* Among maximum flows, find one that lexicographically maximizes the k-component vector whose jth component is the jth smallest u_i/w_i, $i \in \{1, \cdots, k\}$.

Flow-sharing problems with one source and multiple sinks are completely analogous to the multiple-source case: merely exchange source and sinks and reverse the network. For the criteria (ii)-(v), we can even allow multiple sources and multiple sinks, and simultaneously optimize one criterion for the sources and a possibly different criterion for the sinks. This is because each of problems (ii)-(v) calls for a maximum flow, and a multiple-source, multiple-sink problem can be decomposed into a multiple-source, one-sink problem and a one-source, multiple-sink problem, by finding a minimum cut of all sources from all sinks, contracting all vertices on the sink side to give a one-sink problem, and separately contracting all vertices on the source side to give a one-source problem. This observation is due to Megiddo [27].

Perfect sharing arises in a network transmission problem studied by Itai and Rodeh [22] and Gusfield [18] and in a network vulnerability model proposed by Cunningham [5]. We discuss these models below. Brown studied maximin sharing [3], Ichimori, Ishii, and Nishida [21] formulated minimax and optimal sharing, and Megiddo [27], [28] studied lexicographic sharing. Motivation for these problems is provided by the following kind of example, which gives rise to a multiple-sink problem. During a famine, relief agencies supplying food to the stricken areas want to distribute their available food supplies so that each person receives a fair share. The weight associated with each sink (famine area) is the population in that area, possibly adjusted for differences in food needs between adults and children, and other factors. A perfect sharing solution gives every person in every famine area the same amount of food, but it may be too restrictive since it need not allocate all the available and transportable food supply. A better solution will be provided by solving one of the problems (ii)-(v). There are analogous industrial interpretations of this model.

We shall show that all five flow-sharing problems can be solved in $O(nm \log (n^2/m))$ time using the algorithms of §§ 2 and 3. The lexicographic sharing problem requires computing all the breakpoints of a min-cut capacity function by the algorithm of § 3.3. The other four problems are easier, and can be solved by the algorithm for finding the smallest (or largest) breakpoint given in § 3.1. Our tool for solving all five problems is the following parametric formulation: for each $s_i \in S$, let arc (s, s_i) have capacity $w_i\lambda$, where λ is a real-valued parameter. Since all arc capacities are nonnegative, the range of interest of λ is $[0, \infty)$. There are at most k breakpoints of the min-cut capacity function $\kappa(\lambda)$, one per source s_i.

Perfect sharing. Find the smallest breakpoint λ_s of $\kappa(\lambda)$. Any maximum flow for λ_s solves the perfect sharing problem. This was observed by Gusfield [18] in the context of the network transmission-scheduling problem described below. Another application will arise in § 4.2.

Scheduling transmissions. Itai and Rodeh state the following problem of scheduling transmissions in a "circuit-switched" communication network represented by a directed graph $G = (V, E)$ with fixed positive arc capacities. The capacity $c(v, w)$ is the effective transmission rate of the communication channel (v, w) in the direction from v to w,

say in bits per second. A central vertex (sink) $t \in V$ receives all traffic that originates at a subset of vertices $S \subseteq V - \{t\}$ called *emitters* (sources). Each emitter $s_i \in S$ has $w_i > 0$ bits of information that it wishes to send to t. We assume that G has paths from each $s_i \in S$ to t. The communication protocol allows the sharing of arc capacities by several paths, but it requires that at least one path from s_i to t be established before transmission from s_i can begin. Clearly, if transmissions are scheduled from each emitter, one at a time, the entire task can be completed in $T' = \sum_{s_i \in S} w_i / c(X_i, \bar{X}_i)$ seconds, where $(X_i, \bar{X}_i)$ is a minimum cut separating s_i and t. But since arc capacities can be shared, it may be possible to obtain a lower value for T. The objective is to minimize the time T within which all transmissions can be completed.

To see that the problem is a perfect sharing multiple-source problem, let $\lambda = 1/T$, where T is in seconds, and assign a capacity of $w_i \lambda$ bits per second to each arc (s, s_i) from the supersource s to an emitter $s_i \in S$. Once λ_s and the corresponding maximum flow have been computed by the algorithm above, the actual transmission schedule can be constructed from the flow in $O(m)$ time as described in [22]. Itai and Rodeh proposed two algorithms for this problem, with running times of $O(kn^2m)$ and $O(k^2nm \log n)$. These are modifications of known maximum-flow algorithms. In comparison, our algorithm runs in $O(nm \log (n^2/m))$ time.

Maximin sharing. Find the largest breakpoint λ_l of $\kappa(\lambda)$. Any maximum flow for λ_l solves the maximin sharing problem.

Minimax sharing. Find the smallest breakpoint λ_s of $\kappa(\lambda)$. Find a maximum flow for λ_s. Construct a residual network in which each arc (v, w) with $s \notin \{v, w\}$ has capacity $c(v, w) - f(v, w)$, each arc (s, s_i) has infinite capacity, and each arc (s_i, s) has zero capacity. Find a maximum flow f' in the residual network. The flow $f + f'$ is a minimax flow in the original network.

Optimal sharing. Find the smallest breakpoint λ_s and the largest breakpoint λ_l of $\kappa(\lambda)$. Find a maximum flow f for λ_s. Construct a residual network in which each arc (v, w) with $s \notin \{v, w\}$ has capacity $c(v, w) - f(v, w)$, each arc (s, s_i) has capacity $w_i(\lambda_l - \lambda_s)$, and each arc (s_i, s) has zero capacity. Find a maximum flow f' in the residual network. The flow $f + f'$ is an optimal flow in the original network.

Lexicographic sharing. Find all the breakpoints of $\kappa(\lambda)$. For each source s_i, let λ_i be the breakpoint at which s_i moves from the sink side to the source side of a minimum cut. For each arc (s, s_i) define its capacity to be $w_i \lambda_i$. Find a maximum flow f with these upper bounds on the capacities of the arcs out of s. Flow f is a lexicographic flow, and hence an optimal flow.

The correctness of the first four algorithms above is easy to verify. We shall prove the correctness of the algorithm for the lexicographic sharing problem. Renumber the sources if necessary so that $\lambda_1 \leqq \lambda_2 \leqq \cdots \lambda_k$, and let G_∞ denote the parametric network with $\lambda = \infty$.

THEOREM 4.1. *On G_∞ there is a maximum flow f such that $f(s, s_i) = w_i \lambda_i$ for all i. Such a flow is a lexicographic flow.*

Proof. Let $i_1, i_2, \cdots, i_{l-1}$ be the values of i such that $\lambda_{i_j} < \lambda_{i_j+1}$. Let $i_0 = 0$ and $i_l = k$. Then $\lambda_{i_1}, \lambda_{i_2}, \cdots, \lambda_{i_l}$ are the distinct breakpoints in increasing order. Let $\{s\} = X_0 \subset X_1 \subset X_2 \subset \cdots \subset X_l$ be the sets such that $(X_j, \bar{X}_j)$ for $1 \leqq j \leqq l$ is the minimum cut with the smallest sink side for $\lambda = \lambda_{i_j}$. Then $s_{i_{j-1}+1}, s_{i_{j-1}+2}, \cdots, s_{i_j} \in X_j - X_{j-1}$. For $1 \leqq j \leqq l$, the cut $(X_{j-1}, \bar{X}_{j-1})$ is a minimum cut for $\lambda = \lambda_{i_j}$ as well, specifically the one with the smallest source side. Thus, $c_{\lambda_{i_j}}(X_{j-1}, \bar{X}_{j-1}) = c_{\lambda_{i_j}}(X_j, \bar{X}_j)$. It follows by induction on j that for $1 \leqq j \leqq l$,

$$c_{\lambda_{i_j}}(X_j, \bar{X}_j) = \sum_{i=1}^{i_j} w_i \lambda_i + \sum_{i=i_j+1}^{k} w_i \lambda_{i_j}, \tag{4.1}$$

which implies that

$$c_\infty(X_j - \{s\}, \bar{X}_j) = \sum_{i=1}^{i_j} w_i \lambda_{i_j}. \tag{4.2}$$

Equation (4.2) implies that any flow for G_∞ such that $f(s, s_i) = w_i\lambda_i$ for all i must be a maximum flow (choose $j = l$ in (4.2)). It must also be a lexicographic flow, since for all j, any flow that has $f(s, s_i) \geqq w_i\lambda_i$ for $1 \leqq i \leqq i_{j-1}$ must either have $f(s, s_i) = w_i\lambda_i$ for $1 \leqq i \leqq i_j$ or have some $i \in \{i_{j-1}+1, \cdots, i_j\}$, such that $f(s, s_i) < w_i\lambda_i$.

It remains to show that G_∞ admits a flow f with $f(s, s_i) = w_i\lambda_i$. Consider running the min-cut parametric preflow algorithm presented in § 2.5 on the parametric network, for the successive λ values $\lambda_{i_1}, \lambda_{i_2}, \cdots, \lambda_{i_l}$. Let $f_1, f_2, \cdots, f_l$ be the successive maximum preflows generated by the algorithm. When the min-cut preflow algorithm is restarted with a new value λ_{i_j} of λ, the flow on each arc (s, s_i) with $i \in \{i_{j-1}+1, \cdots, k\}$ is first increased from $w_i\lambda_{i_{j-1}}$ to $w_i\lambda_{i_j}$. All of this new flow successfully reaches the sink t, because of (4.1) and the fact that $(X_j, \bar{X}_j)$ is a minimum cut for $\lambda = \lambda_{i_j}$. It follows by induction on j that f_j is a flow and that $f_j(s, s_i) = w_i\lambda_i$ for $1 \leqq i \leqq i_j$. In particular, f_l is the desired flow. □

4.2. Fractional programming applications. Another class of problems that can be solved by the parametric preflow algorithm of § 2.3 arises from various discrete and network optimization problems with fractional objectives. In general, the *fractional programming* problem is defined as

$$\lambda(x^*) = \max_{x \in S} \{\lambda(x) = f(x)/g(x)\}, \tag{4.3}$$

where $f(x)$ and $g(x)$ are real-valued functions on a subset S of R^n, and $g(x) > 0$ for all $x \in S$. Isbell and Marlow [23] proposed an elegant solution method for the important case of linear f and g, but their approach has been extended to nonlinear problems (see, e.g., Dinkelbach [7]), and more recently to several classes of combinatorial problems (see, e.g., Picard and Queyranne [33], [34], Padberg and Wolsey [31], and Cunningham [5]).

A problem that is intimately related to (4.3) is

$$z(x^*, \lambda) = \max_{x \in S} \{z(x, \lambda) = f(x) - \lambda g(x)\}, \tag{4.4}$$

where λ is a real-valued constant. These two problems are related in the sense that x^* solves (4.3) if and only if (x^*, λ^*) solves (4.4) for $\lambda = \lambda^* = \lambda(x^*)$ giving the value $z(x^*, \lambda^*) = 0$. Isbell and Marlow's algorithm generates a sequence of solutions until this condition is met. We state their algorithm below in a form useful for our purposes (see, e.g., Gondran and Minoux [14, pp. 636-641]):

ALGORITHM FP.

Step 0. Select some $x^0 \in S$. Compute $\lambda_0 = f(x^0)/g(x^0)$. Set $k = 0$.

Step 1. Compute x^{k+1}, solving the problem (4.4): $z(x^{k+1}, \lambda_k) = \max_{x \in S} z(x, \lambda_k) = f(x) - \lambda_k g(x)$.

Step 2. If $z(x^{k+1}, \lambda_k) = 0$, stop: $x^* = x^k$. Otherwise, let $\lambda_{k+1} = f(x^{k+1})/g(x^{k+1})$, replace k by $k+1$ and go to Step 1.

THEOREM 4.2. *Algorithm* FP *is correct. The sequence of values* $\{\lambda_k\}$ *generated by the algorithm is increasing.*

Proof. For any particular k, $z(x^{k+1}, \lambda_k)$ is nonnegative in Step 1, since $z(x^{k+1}, \lambda_k) \geqq z(x^k, \lambda_k) = 0$. If $z(x^{k+1}, \lambda_k) = 0$, the algorithm halts with x^k, which solves (4.4) for $\lambda = \lambda_k$, and hence solves (4.3). The algorithm continues only if $z(x^{k+1}, \lambda_k) > 0$; i.e., $f(x^{k+1}) - \lambda_k g(x^{k+1}) > 0$, which implies $\lambda_{k+1} = f(x^{k+1})/g(x^{k+1}) > \lambda_k$. □

If maximization is replaced by minimization in problem (4.3), it suffices to replace maximization by minimization in (4.4) and use the same algorithm. In this case all values of $z(x^{k+1}, \lambda_k)$, except the last one, are less than zero, and a decreasing sequence $\{\lambda_k\}$ is generated. Another important observation is that in Step 1 the maximization (4.4) can be taken over a larger set $S' \supset S$, provided that $z(x, \lambda_k) \leqq 0$ for all $x \in S' - S$. In the minimization problem, the corresponding requirement is $z(x, \lambda_k) \geqq 0$ for all $x \in S' - S$. Several of our applications make use of this extension.

The following lemma can be used to bound the number of iterations of Algorithm FP in some situations.

LEMMA 4.3. *$g(x^{k+1}) < g(x^k)$ for $k \geqq 1$.*

Proof. Consider iterations $k-1$ and k of Algorithm FP, and assume $\lambda(x^k) < \lambda(x^*)$. In iteration $k-1$ we have $z(x^k, \lambda_{k-1}) > 0$ and $\lambda_k = f(x^k)/g(x^k)$. In iteration k we have

$$\begin{aligned} 0 < z(x^{k+1}, \lambda_k) &= f(x^{k+1}) - \lambda_k g(x^{k+1}) \\ &= f(x^{k+1}) - \lambda_{k-1} g(x^{k+1}) + \lambda_{k-1} g(x^{k+1}) - \lambda_k g(x^{k+1}) \\ &\leqq f(x^k) - \lambda_{k-1} g(x^k) + \lambda_{k-1} g(x^{k+1}) - \lambda_k g(x^{k+1}) \\ &= \lambda_k g(x^k) - \lambda_{k-1} g(x^k) + \lambda_{k-1} g(x^{k+1}) - \lambda_k g(x^{k+1}) \\ &= (g(x^k) - g(x^{k+1}))(\lambda_k - \lambda_{k-1}), \end{aligned}$$

which implies that $g(x^k) > g(x^{k+1})$ since $\lambda_k > \lambda_{k-1}$. The inequality "$\leqq$" above follows from $z(x^{k+1}, \lambda_{k-1}) \leqq z(x^k, \lambda_{k-1})$ since x^k maximizes $z(x, \lambda_{k-1})$. □

The efficiency of Algorithm FP depends on the number of times problem (4.4) has to be solved, and on the time spent solving it. For continuous functions f and g defined on a nonempty compact set S, Schaible [38] has shown that the decreasing sequence $\{g(x^k)\}$ for $k \geqq 1$ approaches $g(x^*)$ linearly, and the increasing sequence $\{\lambda_k\}$ approaches λ^* superlinearly. Nevertheless, (4.4) may be as hard to solve as the original fractional problem unless some assumptions are made about f, g, and S. Fortunately, even the most restrictive assumptions find relevant applications in practice. For instance, if f and g are linear and S is polyhedral (the case in [23]), the algorithm consists of solving a finite number of linear programs (4.4) whose solution is implemented by *cost-parametric programming* on intervals $[\lambda_k, \lambda_{k+1}]$, for successive k. This can be specialized to network simplex parametric programming by using the primitives described by Grigoriadis [15]. If f is a negative semidefinite quadratic form and g is linear, the sequence of concave quadratic programs defined by (4.4) can be handled by the parametric algorithm of Grigoriadis and Ritter [16]. If f and g are negative- and positive-definite quadratic forms, respectively, Ritter's parametric quadratic programming method [37] can be used. Approaches for more general nonlinear problems are analyzed in [7] and [38].

If S is nonempty and finite, f is real-valued, and g is positive, integer-valued, and bounded above by some integer $p > 0$, Lemma 4.3 implies that Algorithm FP will terminate in $p+1$ or fewer iterations. This observation has been used in various applications where $g(x)$ is a set function, for which usually $p = O(n)$. Such is the case whether (4.3) is a maximization or a minimization problem.

We shall now describe a number of applications of the generic Algorithm FP. In each case the sequence of problems (4.4) that arises can be handled by our parametric preflow algorithm or its min-cut variant described in § 2.5.

Strength of a directed network. This is an application due to Cunningham [5, § 6]. Let $G = (V, E)$ be a given directed graph with n vertices, m arcs, nonnegative arc weights and nonnegative vertex weights, and a distinguished vertex $s \in V$. We assume that every $v \in V - \{s\}$ is reachable from s in G. The arc weight $c(v, w)$ represents the

cost required to "destroy" the arc $(v, w) \in E$. The node weight d_v is the "value" attributed to having v reachable from s. Destroying a set of edges $A \subseteq E$ (at a total cost of $f(A) = \sum_{(v,w)\in A} c(v, w)$) may cause some subset of vertices $V_A \subseteq V - \{s\}$ to become unreachable from s, resulting in a loss of $g(A) = \sum_{v\in V_A} d_v$ in total value. The ratio $f(A)/g(A)$ is the cost per unit reduction in value. Cunningham defines the *strength of the network* to be the minimum of this ratio taken over all subsets $A \subseteq E$ whose removal reduces the value of the network, i.e., such that $g(A) > 0$. This is a problem of the form (4.3):

$$\lambda(A^*) = \min_{A\subseteq E, g(A)>0} \{\lambda(A) = f(A)/g(A)\},$$

which leads to a sequence of problems (4.4) that Cunningham calls *attack problems*:

$$z(A^{k+1}, \lambda_k) = \max_{A\subseteq E} \{z(A, \lambda_k) = f(A) - \lambda_k g(A)\}.$$

Each such problem amounts to finding a minimum cut in an expanded network formed by adding to G a sink t and an arc (v, t) with capacity $\lambda_k d_v$ for each $v \in V - \{s\}$. If we solve the strength problem using Algorithm FP and use the algorithm of § 2.3 to compute minimum cuts for the generated parameter values, we obtain an algorithm running in $O(nm \log (n^2/m))$ time; as Cunningham notes, there can be only $O(n)$ iterations of Step 1. Alternatively, we can make use of his observation that (4.5) is zero if and only if there is flow in the expanded network such that $f(v, t) = \lambda_k d_v$ for each $v \in V$. Equivalently, $\lambda(A^*)$ is the largest value of λ for which the minimum cut is $(V, \{t\})$. That is, the strength problem is a perfect sharing problem, and it can be solved in $O(nm \log (n^2/m))$ time as described in § 4.1. Either method improves over Cunningham's method, which solves $O(n)$ minimum cut problems without making use of their similarity.

Zero-one fractional programming. An important subclass of (4.3) is the problem for which $f(x) \geqq 0$ and $g(x) > 0$ are given polynomials defined for all x in $S = \{0, 1\}^n - \{0\}^n$ as follows:

$$f(x) = \sum_{P\in A} a_P \prod_{i\in P} x_i + \sum_{i=1}^{n} a_i x_i, \tag{4.5}$$

$$g(x) = \sum_{Q\in B} b_Q \prod_{i\in Q} x_i + \sum_{i=1}^{n} b_i x_i. \tag{4.6}$$

The sets A and B are given collections of nonempty nonsingleton subsets of $\{1, \cdots, n\}$, $a_P \geqq 0$ for each $P \in A$, and $b_Q \leqq 0$ for each $Q \in B$. Since $f(x) \geqq 0$ and $g(x) > 0$ for all $x \in S$, we have $a_i \geqq 0$ and $b_i > 0$ for each $i \in \{1, \cdots, n\}$. This problem was studied by Picard and Queyranne [33]. For ease in stating time bounds we assume $n = O(|A| + |B|)$.

Algorithm FP leads to a sequence of problems of the form (4.4) for increasing values $\lambda_k \geqq 0$ of λ. Each such problem is an instance of the *selection* or *provisioning* problem, characterized by Rhys [36] and Balinski [2] as a minimum cut problem on a bipartite graph.

The entire sequence of these problems can be handled as a parametric minimum cut problem of the kind studied in § 2. We give two different formulations, one of which works for the special case of $B = \emptyset$ (i.e., $g(x)$ contains no nonlinear terms) and the other of which works for the general case. All the subsequent applications we consider fall into the case $B = \emptyset$.

If $B = \emptyset$, we define a bipartite network G whose vertex set contains one vertex for each set $P \in A$, one vertex for each $i \in \{1, \cdots, n\}$, and two additional vertices, a source s and a sink t. There is an arc (s, v) of capacity a_P for each vertex v corresponding

to a set $P \in A$, an arc (i, t) of capacity $\lambda b_i - a_i$ for every $i \in \{1, \cdots, n\}$, and an arc (v, i) of infinite capacity for every vertex corresponding to a set $P \in A$ that has i as one of its elements. Observe that the capacities of all arcs into t are nondecreasing functions of λ, and those of all other arcs are constant. The parametric preflow algorithm operates on G^R instead of G. For a given value of λ, a minimum cut $(X, \bar{X})$ in G corresponds to a solution x to (4.4) defined by $x_i = 1$ if $i \in X$, $x_i = 0$ if $i \in \bar{X}$.

In the general case ($B \neq \emptyset$), it is convenient to assume $f(x) > 0$ for some x (otherwise the solution to (4.3) is $\lambda(x) = 0$, attained for any x) and that Algorithm FP starts with an x^0 such that $\lambda_0 > 0$. Then, the entire sequence $\{\lambda_k\}$ is strictly positive. To solve (4.4) we rewrite it as follows:

$$z(x^*, \lambda) = \lambda \max_{x \in S} (f(x)/\lambda - g(x)).$$

We define the network G to have a vertex set consisting of one vertex for each set $P \in A$, one vertex for each set $Q \in B$, one vertex for each $i \in \{1, \cdots, n\}$, and a source s and a sink t. There is an arc (s, v) of capacity a_P/λ for each v corresponding to a set $P \in A$, an arc (s, v) of capacity $-b_Q$ for each v corresponding to a set $Q \in B$, an arc (v, i) of infinite capacity for each vertex v corresponding to a set $P \in A$ or $Q \in B$ that has i as one of its elements, and an arc (i, t) of capacity $b_i - a_i/\lambda$ for each $i \in \{1, \cdots, n\}$. The capacities of arcs out of s are nonincreasing functions of λ and those of arcs into t are nondecreasing functions of λ; the parametric preflow algorithm operates on G^R. Minimum cuts in G correspond to solutions exactly as described above.

Remark. This formulation differs from that in [33] because of the division by λ. The formulation of [33] gives a parametric minimum cut problem in which the capacities of arcs out of the source and of arcs into the sink are nondecreasing functions of λ, to which the results of § 2 do not apply.

The following analysis is valid for both of the above two cases. The nesting property of minimum cuts (Lemma 2.4) implies that the number of iterations of Step 1 of Algorithm FP is $O(n)$, a fact also observed by Picard and Queyranne [33]. To state time bounds, let us denote by n' and m' the number of vertices and edges, respectively, in G; $n' = n + |A| + |B| + 2$ and $m' = n + |A| + |B| + \sum_{P \in A} |P| + \sum_{Q \in B} |Q|$. Algorithm FP, in combination with the parametric preflow algorithm of § 2.3, yields a time bound of $O(n'm' \log (n'^2/m))$ [or $O(nm' \log (n^2/m' + 2))$], improving over the algorithms of Picard and Queyranne [33] and Gusfield, Martel, and Fernandez-Baca [20].

Maximum-ratio closure problem. This problem was considered by Picard and Queyranne [34] and independently by Lawler [25], who only considered acyclic graphs (see the next application). The problem can be solved by a straightforward application of Algorithm FP. Each problem in the sequence of problems (4.4) is a maximum-weight closure problem. The *maximum-weight closure problem* (Picard [32]) is the generalization to nonbipartite graphs of the selection or provisioning problem [2], [36] mentioned above.

These closure problems are defined formally as follows. Let $G = (V, E)$ be a directed graph with vertex weights a_v of arbitrary sign. A subset $U \subseteq V$ is a *closure* in G if for each arc $(v, w) \in E$ with $v \in U$ we also have $w \in U$. A closure $U^* \subseteq V$ is of *maximum weight* if the sum of its vertex weights is maximum among all closures in G. To compute a maximum-weight closure, construct the graph G^* from G as follows. Add a source s and a sink t to G. Create an arc (s, v) of capacity a_v and an arc (v, t) of zero capacity for each $v \in V$. Assign infinite capacity to all arcs in E. A minimum cut $(X, \bar{X})$ of G^* gives the desired closure $U^* = X - \{s\}$.

Now let $a_v \geqq 0$ and $b_v > 0$ be given weights on the vertices of $G = (V, E)$. The *maximum-ratio closure* problem is to find a closure U^* that maximizes the ratio $a(U)/b(U)$ over all nonempty closures $U \subseteq V$. To compute a maximum-ratio closure, Picard and Queyranne [34] suggest the use of Algorithm FP. This requires the solution of a sequence of $O(n)$ maximum-weight closure problems, each of which is a minimum-cut problem. Thus an $O(n^2 m \log (n^2/m))$-time algorithm results. Lawler's algorithm uses binary search and runs in $O(knm \log (n^2/m))$ time, where $k = \log (\max \{n, a_{\max}, b_{\max}\})$, assuming integer weights.

We can solve the entire sequence of these minimum-cut problems by the parametric preflow algorithm of § 2.3 as follows. Modify G^* so that for each vertex $v \in V$ there is an arc (s, v) of capacity $a_v - \lambda b_v$ and an arc (v, t) of capacity zero. All other arcs have infinite capacity. We start with $U^0 = V \cup \{s\}$; or, equivalently, with a sufficiently small value of λ so that the minimum cut is $(\{s\} \cup V, \{t\})$. Such a value is $\lambda_0 = \min_i a_i/b_i$. The capacities of arcs out of the source are nonincreasing functions of the parameter, and the parameter values are given on-line in increasing order. The parametric preflow algorithm operates on $(G^*)^R$ and runs in $O(nm \log (n^2/m))$ time, improving the bound of Picard and Queyranne by a factor of n and that of Lawler by a factor of k.

Remark. Negative arc capacities in the various minimum-cut problems can be made nonnegative using the transformation suggested in § 2.5. In the minimum-ratio closure problem, it suffices to assign a capacity of $\max \{0, a_v - \lambda b_v\}$ to each arc (s, v) and a capacity of $\max \{0, \lambda b_v - a_v\}$ to each arc (v, t).

A job-sequencing application. Lawler [25] applied his algorithm to a problem studied by Sidney [39] and others: there are n jobs to be scheduled for processing on a single machine subject to a partial order given as an acyclic graph $G = (V, E)$, where V is the set of jobs. Each job v has a processing time a_v and a "weight" $b_v > 0$ that describes its importance or some measure of profit. Let the completion time of job v as determined by a given feasible sequence be C_v. It is required to find a sequence that minimizes $\sum_{v \in V} b_v C_v$. This problem is NP-complete for an arbitrary partial order even when all $a_v = 1$ or all $b_v = 1$ [25]. Sidney offered the following decomposition procedure. First find a maximum-ratio closure U_1 such that $|U_1|$ is minimum. Remove the subgraph induced by U_1 from G, find a maximum-ratio closure U_2 of the reduced graph, and repeat this process until the entire vertex set is partitioned. Sidney and Lawler call closures *initial sets* of V. Once such a decomposition is found, an optimal schedule can be computed by finding an optimal schedule for each closure, for example, by a branch-and-bound method, and then concatenating the solutions. The algorithm described above can be used to find each closure. The overall time bound depends on the size of each closure. (Our algorithm will give closures of minimum cardinality, since the algorithm is applied to the graph $(G^*)^R$; see § 2.5.)

Maximum-density subgraph. A special case of the fractional programming problem (4.3) is that of finding a nonempty subgraph of maximum density in an undirected graph $G = (V, E)$ with n vertices and m edges. The *density* of a subgraph of G induced by a subset of vertices $V' \subseteq V$ is the number of its edges divided by the number of its vertices. For this application, (4.5) and (4.6) have the simpler forms $f(x) = \frac{1}{2} xAx$ and $g(x) = ex$, where e is the vector of all ones, A is the vertex-vertex incidence matrix of G, and $x_i = 1$ if vertex $i \in V'$, and $x_i = 0$ otherwise. Algorithm FP, which yields x^* and the maximum density λ^*, can be used to compute a maximum-density subgraph of G. It is not necessary to construct a bipartite network and solve minimum-cut problems on it. We can merely modify G by specializing the construction of [35]. Replace each edge of G by two oppositely directed arcs of unit capacity, add a source s and a sink t, and create an arc (s, v) of capacity $\delta_v - \lambda$ and an arc (v, t) of zero capacity for each

$v \in V$, where δ_v is one-half the degree of vertex v in G. We can also allow weights on the edges and vertices. The resulting algorithm runs in $O(nm \log (n^2/m))$ time. This bound is better than that of Picard and Queyranne [34] and of Goldberg [12] by a factor of $\log n$; Goldberg's bound is valid only for the unweighted version of the problem.

The integer $\lceil \lambda^* \rceil$ is known as the *pseudoarboricity* of G: the minimum number of edge-disjoint pseudoforests into which G can be decomposed. (A *pseudoforest* is a subgraph each of whose connected components is a tree or a tree plus an edge.) If in the above network the capacities of arcs (s, v) and (v, t) for each $v \in V$ are increased by m, the minimum cut and maximum flow for $\lambda = \lambda^*$ can be used to construct a decomposition of G into $\lceil \lambda^* \rceil$ pseudoforests by the procedure suggested in [33].

4.3. Parametric zero-one polynomial functions. We consider the problem of computing a minimum of the function

$$z(\lambda) = \max_{x \in S} \{f(x) - \lambda(dx - b)\}, \tag{4.7}$$

where $S = \{0, 1\}^n$, $f(x)$ is a polynomial in zero-one variables defined by (4.5), and $d_i > 0$, $i \in \{1, \cdots, n\}$, such that $\sum_i d_i > b > 0$.

The function $z(\lambda)$ differs from the corresponding function (4.4) that arises in the zero-one fractional programming application of § 4.2 because of the term λb in (4.7). The function $z(\lambda)$ is piecewise linear and convex, and it has at most $n-1$ linear segments and $n-2$ breakpoints. The network formulation of (4.7) is as defined for the zero-one fractional programming application. The breakpoints of $z(\lambda)$ coincide with those of the min-cut capacity function $\kappa(\lambda)$ for this network. In general, no minimum of $z(\lambda)$ coincides with a maximum of $\kappa(\lambda)$. To compute a minimum of $z(\lambda)$, we can use the algorithm of § 3.2 for finding a maximum of $\kappa(\lambda)$, modified to use the graph of $z(\lambda)$ instead of the graph of $\kappa(\lambda)$ to guide the search. We have $z(0) = \sum_{P \in A} a_P + \sum_{i=1}^{n} a_i > 0$ (for $x = e$). The slope of the leftmost line segment of $z(\lambda)$ is $b - de < 0$, and the slope of the rightmost line segment is $b > 0$. The algorithm consists of the following three steps and finds a minimum of $z(\lambda)$ in $O(n'm' \log (n'^2/m'))$ [or $O(nm' \log (n^2/m' + 2))$] time. A cut $(X, \bar{X})$ in this network defines a solution x by $x_i = 1$ if vertex $i \in X$, and $x_i = 0$ otherwise.

Step 0. Start with initial values $\lambda_1 = 0$, $x^1 = e$, $z(\lambda_1) = f(x^1)$, and $h_1 = b - dx^1$. Choose λ_3 sufficiently large so that $x^3 = 0$; let $z(\lambda_3) = \lambda_3 b$ and $\beta_3 = b$.

Step 1. Compute $\lambda_2 = (z(\lambda_3) - z(\lambda_1))/(\beta_1 - \beta_3)$, pass λ_2 to two invocations, I and D, of the parametric preflow algorithm, and run them concurrently. If invocation I finds a minimum cut $(X_2^I, \bar{X}_2^I)$ first, suspend invocation D and go to Step 2 (the other case is symmetric). Compute $\beta_2 = b - dx^2$, the slope of the line segment of $z(\lambda)$ derived from this cut.

Step 2. If $\beta_2 = 0$, stop: $\lambda^* = \lambda_2$. Otherwise, if $\beta_2 > 0$, replace λ_3 by λ_2, back up invocation D to its state before it began processing λ_2, and go to Step 1. Otherwise, go to Step 3.

Step 3 ($\beta_2 < 0$). Finish the invocation D for λ_2. This produces a minimum cut $(X_2^D, \bar{X}_2^D)$, not necessarily the same as $(X_2^I, \bar{X}_2^I)$. If $\beta_2 \geqq 0$, stop: $\lambda^* = \lambda_2$. Otherwise, replace λ_1 by λ_2, back up invocation I to its state before processing λ_2, and go to Step 1.

We now describe an application of this algorithm.

Knapsack-constrained provisioning problems. We consider the following provisioning problem with a knapsack constraint that limits the weight of the selected items:

$$z(x^*) = \max_{x \in \{0,1\}^n} \{f(x) \mid dx \leqq b\}, \tag{4.8}$$

where $f(x)$ is given by (4.5), d is a positive n-vector of item weights and b is a scalar, the knapsack size, such that $\sum_{i \in V} d_i > b > 0$, $V = \{1, \cdots, n\}$. Thus, in addition to the benefit a_i obtained for including an individual item $i \in V$ in the knapsack, the model allows the possibility of an additional reward of $a_P \geqq 0$ for including all of the items that comprise a given subset $P \in A$. The (linear) *knapsack problem* is a special case of (4.8) in which all subsets $P \in A$ are singletons.

This NP-complete problem was suggested by Lawler [24]. Because of its many practical applications there is interest in the fast computation of bounds on $z(x^*)$. To this end we consider the Lagrangian function for (4.8):

$$L(x, \lambda) = f(x) - \lambda(dx - b) \quad \text{for } \lambda \geqq 0,$$

which has a finite infimum over $x \in \{0, 1\}^n$. For each $\lambda \geqq 0$, we define the *dual function*:

$$\Phi(\lambda) = \max_{x \in \{0,1\}^n} L(x, \lambda).$$

$\Phi(\lambda)$ is a piecewise linear convex function of λ, having at most $n-1$ line segments and $n-2$ breakpoints. We wish to solve the following *Lagrangian dual problem*:

$$\Phi(\lambda^*) = \min_{\lambda \geqq 0} \Phi(\lambda).$$

This value is an upper bound on $z(x^*)$ and can be used to construct heuristics and search procedures for computing an approximate or exact solution to (4.8). It can be evaluated by the above algorithm in $O(n'm' \log (n'^2/m'))$ [or $O(nm' \log (n^2/m'+2))$] time.

A special case of considerable practical importance is the *quadratic knapsack* problem, for which $f(x) = xAx$, where $A = [a_{ij}]$ is a nonnegative real symmetric matrix having no null rows. For this case, Gallo, Hammer, and Simeone [11] proposed an $O(n^2 \log n)$-time algorithm for creating a class of "upper planes" bounding $z(x)$. Chaillou, Hansen, and Mahieu [4] showed that its Lagrangian dual can be solved as a sequence of $O(n)$ minimum-cut problems in $O(n^2 m \log (n^2/m))$ time.

The problem of evaluating $\Phi(\lambda)$ for a fixed λ can be formulated as a minimum-cut problem using a graph construction similar to that described earlier for the maximum-density subgraph problem, thereby avoiding the use of a bipartite graph. Let $G = (V, E)$ be a directed graph with vertex set $V = \{1, \cdots, n\}$, arc set $E = \{(v, w)\colon a_{vw} > 0,\ v, w \in V\}$, and arc weights $a(v, w) = a_{vw}$. We add to G a source s, a sink t, and an arc (s, v) of capacity $a_v - \lambda d_v$ and an arc (v, t) of zero capacity for each $v \in V$, where $a_v = \sum_{w \in V} a_{vw}$. Using this network formulation, the above algorithm computes the Lagrangian relaxation of a quadratic knapsack problem in $O(nm \log (n^2/m))$ time.

4.4. Miscellaneous applications. Our last two applications both use the algorithm developed in § 3.3 for computing the min-cut capacity function $\kappa(\lambda)$ of a parametric minimum-cut problem. The first application is to a problem of computing critical load factors for modules of a distributed program in a two-processor distributed system [43]. The second application is to a problem of record segmentation between primary and secondary memory in large shared databases [9].

Critical load factors in two-processor distributed systems. Stone [43] modeled this problem by a graph $G = (V, E)$ in which $V = \{1, \cdots, n\}$ is the set of program modules and E is the set of pairs of modules that need to communicate with each other. The capacity of an arc $(v, w) \in E$ specifies the communication cost between modules v and w (it is infinity if the modules must be coresident). The two processors, say A and B, are represented by the source s and the sink t, respectively, that are appended to the

network. There is an arc (s, v) of capacity $\lambda b_v > 0$, where b_v is the given cost of executing program module v on processor B. There is an arc (v, t) of capacity $(1-\lambda)a_v > 0$, where a_v is the given cost of executing program module v on processor A.

The parameter $\lambda \in [0, 1]$ is the fraction of the time processor A that delivers useful cycles, commonly known as the *load factor*. For a fixed value of λ, a minimum cut $(X, \bar{X})$ in this network gives an optimum assignment of modules to processors. For $\lambda = 0$, a minimum cut $(X, \bar{X})$ with $|X|$ minimum has $X = \{s\}$, i.e., all modules are assigned to B. For $\lambda = 1$ a minimum cut $(X, \bar{X})$ with $|X|$ maximum has $\bar{X} = \{t\}$, i.e., all modules are assigned to A. The objective is to find the best assignment of program modules to processors for various values of λ, or to generate these assignments for each breakpoint of the min-cut capacity function $\kappa(\lambda)$. Lemma 2.4 implies that, at each breakpoint, one or more modules shift from one side of the cut to the other. By listing, for each module, the breakpoint at which it shifts from one side of the minimum cut to the other, one can determine what Stone calls the *critical load factor* for each module. The operating system can then use this list of critical load factors to do dynamic assignment of modules to processors. The algorithm of § 3.3 will compute the critical load factors of the modules in $O(nm' \log((n+2)^2/m'))$ time, where $m' = m + 2n$. Stone does not actually propose an algorithm for this computation.

Record segmentation in large shared databases. Eisner and Severance [9] have stated a model for segmenting records in a large shared database between primary and secondary memory. Such a database consists of a set of data items $S = \{1, \cdots, N\}$ and serves a set of users $T = \{1, \cdots, n\}$. Each user $w \in T$ retrieves a nonempty subset $S_w \subseteq S$ of data items and receives a "value" (satisfaction) of $b_w > 0$ whenever all of the items in S_w reside in primary memory. The cost of transporting and storing a data item $v \in S$ in primary memory is $\lambda a_v > 0$, where $a_v > 0$. The scalar $\lambda > 0$ is a conversion factor such that λ units of transportation and storage costs equals one unit of user value. The objective is to find a segmentation that minimizes the total cost minus user satisfaction.

For a fixed value of λ the problem can be formulated as a selection or provisioning problem [2], [36] as follows. Construct a bipartite graph having the data items S as its source part and the users T as its sink part. Construct an arc (v, w), $v \in S$, $w \in T$ of infinite capacity if data item v belongs to the set of data items S_w retrieved by user w. Create a supersource s and a supersink t, and append an arc (s, v) of capacity λa_v for each $v \in S$ and an arc (w, t) of capacity b_w for each $w \in T$. A min-cut $(X, \bar{X})$ separating s and t in this network necessarily partitions S and T into $(S_X, \bar{S}_X)$ and $(T_X, \bar{T}_X)$, respectively. It is easy to see that

$$c(X, \bar{X}) = \min_{S_X \cup T_X, \bar{S}_X \cup \bar{T}_X} \left\{ \lambda \sum_{v \in \bar{S}_X} a_v + \sum_{w \in T_X} b_w \right\}.$$

The value of λ plays an important role in this linear performance measure, and it depends on the system load. In practice it is necessary to create a list of primary storage assignments for all critical values of λ. The database inquiry program can then select and implement the best assignment at appropriate times. This table consists of all the breakpoints of the min-cut capacity function $\kappa(\lambda)$ and, for each data item and user, the parameter value at which it moves from one side to the other of a minimum cut. This information can be computed by the breakpoint algorithm of § 3.3 in $O((n+N)m \log((n+N)^2/m))$ [or $O(\min\{n, N\}m \log((\min\{n, N\})^2/m+2))$] time. The algorithm proposed by Eisner and Severance [9] for solving the parametric problem requires the solution of $O(\min\{n, N\})$ minimum-cut problems. Our algorithm improves their method by a factor of $\min\{n, N\}$. They also consider a nonlinear performance measure,

for which an algorithm such as that in § 4.3 can be used to derive bounds on an optimum solution. This bounding method gives an approximate solution, and the method can be used in a branch-and-bound algorithm to give an exact solution.

5. Remarks. We have shown how to extend the maximum-flow algorithm of Goldberg and Tarjan to solve a sequence of $O(n)$ related maximum-flow problems at a cost of only a constant factor over the time to solve one problem. The problems must be instances of the same parametric maximum flow problem and the corresponding parameter values must either consistently increase or consistently decrease. We have further shown how to extend the algorithm to generate the entire min-cut capacity function of such a parametric problem, assuming that the arc capacities are linear functions of the parameter.

We have applied our algorithms to solve a variety of combinatorial optimization problems, deriving improved time bounds for each of the problems considered. Our list of applications is meant to be illustrative, not exhaustive. We expect that more applications will be discovered. Although we have only considered a special form of the parametric maximum-flow problem, most of the parametric maximum-flow problems we have encountered in the literature can be put into this special form.

We have discussed only sequential algorithms in this paper, but our ideas extend to the realm of parallel algorithms. Specifically, the preflow algorithm has a parallel version that runs in $O(n^2 \log n)$ time using n processors on a parallel random-access machine. This version extends to the parametric preflow algorithm in exactly the same way as the sequential algorithm. Thus we obtain $O(n^2 \log n)$-time, n-processor parallel algorithms for the problems considered in §§ 2 and 3 and for each of the applications in § 4, where n is the number of vertices in the network.

There are a number of remaining open problems. One is to find additional applications. Our methods might extend to parametric maximum-flow problems that do not have the structure considered in this paper. Such problems include computing the arboricity of a graph [30], [33], computing properties of activity-selection games [45], and computing processor assignment for a two-processor system in which the processor speeds vary independently [17]. (This last problem is a two-parameter generalization of Stone's model [43] discussed in § 4.4.) Gusfield [19] has recently found a new application, to a problem considered by Cunningham [5], of solving the sequence of attack problems involved in the computation of the strength of an undirected graph. (This problem is related to the strength problem considered in § 4.2 but is harder.)

Another area for research is investigating whether an arbitrary maximum-flow algorithm can be extended to the parametric problem at a cost of only a constant factor in running time. One algorithm that we have unsuccessfully tried to extend in this way is that of Ahuja and Orlin [1]. Working in this direction, Martel [26] has recently discovered how to modify an algorithm based on the approach of Dinic [6] so that it solves the parametric problem with only a constant factor increase in running time.

LOWER BOUNDS FOR ACCESSING BINARY SEARCH TREES WITH ROTATIONS*

ROBERT WILBER†

Abstract. Two methods are given for obtaining lower bounds on the cost of accessing a sequence of nodes in a symmetrically ordered binary search tree, in a model where rotations can be done on the tree and the entire sequence is known before accessing begins (but the accesses must be done in the order given). For example, it can be proven that the bit-reversal permutation requires $\Theta(n \log n)$ time to access in this model. It is also shown that the expected cost of accessing random sequences in this model is the same as it is for the case where the tree is static.

Key words. data structures, binary search tree, rotation, lower bound

AMS(MOS) subject classification. 68P

1. Introduction. A binary search tree is a binary tree whose nodes are distinct members of some totally ordered set and for which the nodes are in symmetric order, i.e., each node is greater than all nodes in its left subtree and less than all nodes in its right subtree. Binary search trees can efficiently support such operations as insert, find, delete, find minimum, find maximum, split, and join. A variety of algorithms for maintaining binary search trees have been proposed that provide some combination of these operations [1]-[3], [5]-[9]. Most of these algorithms use *rotations* to modify binary trees. If node u is the left child of node v, then u is rotated over v by making v the new right child of u; this makes the old right child of u (if there is one) the new left child of v, and the old parent of v (if there is one) the new parent of u. The mirror image operation applies if u is the right child of v. A rotation preserves the symmetric order of the tree.

Here we consider the following problem. Given an initial binary search tree T_0, and a sequence s of nodes in T_0, what is the minimum time required to access the nodes in s (in the order given) when we are allowed to do rotations on the tree? We assume that the entire sequence s is known before we start (i.e., the algorithm is "offline"). The cost of assessing a node at depth d (where the root is at depth zero) is $d+1$, and the cost of a rotation is 1. One easy observation is that by losing at most a factor of 2, we may assume that we always access a node by rotating it to the root in some way. For, given an arbitrary rotation algorithm, we may simulate as follows. Whenever the algorithm accesses a node at depth d (at cost $d+1$), we instead do d rotations to bring the node to the root, access it there (at cost 1), and then do the reverse sequence of d rotations to bring the node back to where it was, for a total cost of $2d+1$. So without loss of generality we will consider only those algorithms that access a node by rotating it to the root. Such an algorithm shall be called a *standard search algorithm.* We let $\chi(s, T_0)$ denote the minimum cost of accessing the nodes in sequence s, starting from tree T_0, by a standard search algorithm. We are concerned with finding lower bounds for $\chi(s, T_0)$.

This problem is motivated by a conjecture of Sleator and Tarjan concerning their *splay algorithm* [9]. The splay algorithm is an online algorithm for maintaining binary

search trees using rotations in a way that has provably good amortized behavior. Although any single operation on an n node tree can take $\Omega(n)$ time, Sleator and Tarjan were able to prove the following surprising fact.

THEOREM 0 (Sleator and Tarjan). *Let V be a set of n keys. Let s be a sequence of keys in V and let t be the minimum time required to access s on any static tree (i.e., a tree that is fixed for sequence s and cannot be modified as the sequence is accessed). Let T_0 be an arbitrary binary search tree whose nodes are the keys in V. Then the time required by the splay algorithm to access s starting from tree T_0 is $O(t+n)$.*

Thus the splay algorithm does essentially as well as the best static algorithm, even though the splay algorithm is an online algorithm. Sleator and Tarjan have conjectured that their splay algorithm does as well as the best offline dynamic binary tree algorithm (an algorithm that does rotations and is allowed to pick its initial tree after seeing the sequence). That is, for any sequence s and for any initial tree T_0 they conjecture that the time used by the splay algorithm to access sequence s is $O(\chi(s, T_0)+n)$.

This "dynamic optimality conjecture" implies that, for any initial n node tree, the splay algorithm is able to access the nodes of the tree in sorted order in $O(n)$ time. This corollary of the conjecture has been proved by Tarjan [11]. Even this very restricted case required a difficult proof.

In order to prove (or disprove) the dynamic optimality conjecture, it may be useful to have bounds on $\chi(s, T_0)$. Here two methods for getting lower bounds on $\chi(s, T_0)$ are described. The first method, described in the next section, requires the use of an auxiliary structure called a *lower bound tree.* The bound obtained is a function of the lower bound tree as well as of s and T_0. This method can achieve tight bounds for some particular sequences, such as a $\Theta(n \log n)$ bound for the bit reversal permutation, and can also be used to get tight expected time bounds for sequences generated at random. However, because of the somewhat artificial introduction of a lower bound tree, the method seems likely not to provide tight bounds in general.

Culik and Wood [4] showed that the number of rotations needed to convert one n node symmetrically ordered binary tree into another is at most $2n-2$. Sleator, Tarjan, and Thurston [10] proved that the bound is at most $2n-6$, and that this is tight for infinitely many n. Thus $\chi(s, T_0)$ does not have a strong dependence on T_0; the choice of initial tree cannot change the cost by more than $2n-6$. The second lower bound method, given in § 3, makes use of this—not only is there no dependence upon a lower bound tree, there is no dependence upon the initial tree T_0. The second lower bound method can also be used to get the $\Theta(n \log n)$ bound for accessing the bit reversal permutation (although with a worse constant factor than the first method yields). It seems more likely to give tight bounds for particular sequences than the first method, although it has not proven to be as suitable for analyzing the expected cost of accessing a random sequence.

2. The first lower bound. For a sequence of integers s and integer i we let $s+i$ denote the sequence obtained by adding i to each element of s. If s is an integer sequence and $x \leqq y$, then $s|_x^y$ denotes the subsequence of s consisting of the elements in the interval $[x, y]$.

We will assume without loss of generality that the nodes of search trees are consecutive integers. If u is a child of v the rotation of u over v is denoted by the pair (u, v). The action of a standard search algorithm on some particular access sequence and some particular initial search tree is completely described by the sequence of rotations generated by the algorithm. If R is a sequence of rotations and $x \leqq y$, then $R|_x^y$ denotes the subsequence of R consisting of the pairs in $[x, y]^2$.

Let T be a search tree whose nodes are the integers in $[j, k]$, for some $j \leqq k$. Then a *lower bound tree for* T is a symmetrically ordered binary tree with $2(k-j)+1$ nodes whose leaves are the integers $j, j+1, \cdots, k$ and whose internal nodes are the half-integers $j+\frac{1}{2}, j+\frac{3}{2}, \cdots, k-\frac{1}{2}$. We define an integer function $\Lambda_1(s, T_0, \Upsilon)$ such that for any search tree with consecutive integer nodes T_0, any sequence s of nodes in T_0, and any lower bound tree Υ for T_0, we have $\chi(s, T_0) \geqq \Lambda_1(s, T_0, \Upsilon)$. For fixed s and T_0 the function Λ_1 will have different values for different lower bound trees Υ; this lower bound method requires judgement in choosing a lower bound tree that will maximize the value of Λ_1.

We now describe how to compute $\Lambda_1(s, T_0, \Upsilon)$. Let m be the length of sequence s and let U be the set of internal nodes of Υ. For each node $u \in U$ we compute its *score*, $\lambda(u)$, as follows. Let l and r be the leftmost and rightmost leaf nodes, respectively, in the subtree of Υ with root u. Let $\sigma' = s|_l^r$ and let h be the length of σ'. Let v be the lowest common ancestor in T_0 of the nodes in $[l, r]$ (we always have $v \in [l, r]$). Let sequence $\sigma = \sigma_0, \sigma_1, \cdots, \sigma_h$, where $\sigma_0 = v$ and, for $i \in [1, h]$, $\sigma_i = \sigma'_i$. Say that an integer $i \in [1, h]$ is a *u-transition* if $\sigma_{i-1} < u$ and $\sigma_i > u$ or if $\sigma_{i-1} > u$ and $\sigma_i < u$. We define $\lambda(u) = |\{i \in [1, h]: i \text{ is a } u\text{-transition}\}|$. The function Λ_1 is computed as

$$\Lambda_1(s, T_0, \Upsilon) = m + \sum_{u \in U} \lambda(u).$$

THEOREM 1. *Let T_0 be a search tree with consecutive integer nodes, let Υ be a lower bound tree for T_0, and let s be a sequence of nodes in T_0. Then $\chi(s, T_0) \geqq \Lambda_1(s, T_0, \Upsilon)$.*

Before we can prove Theorem 1 we need to define a kind of generalized subtree operation. Let T be a search tree with integer nodes, and let V be the set of nodes in T. For any node $v \in V$, the *left inner path of* v is the path that starts at the left child of v and proceeds downward along the right child links until a node is reached that has no right child. If v has no left child its left inner path is the null path. Likewise, the *right inner path* of v is the path that starts at the right child of v and proceeds along the left links. Let $x \leqq y$. The *restriction of T to the interval* $[x, y]$, denoted $T|_x^y$, is defined as follows. The set of nodes of $T|_x^y$ is $V' = V \cap [x, y]$. Let $v \in V'$ and let P be v's left inner path in T. If P has no nodes in V' then v has no left child in $T|_x^y$. Otherwise the first node in P that is in V' is the left child of v in $T|_x^y$. The right child of v in $T|_x^y$ is defined similarly—it is the first node in V' along the right inner path of v in T, if such a node exists, and otherwise v has no right child in $T|_x^y$. Clearly $T|_x^y$ is a symmetrically ordered binary tree, and its root is the lowest common ancestor in T of the nodes in V'. Also, if u is a child of v in T and $u, v \in V'$, then u is a child of v in $T|_x^y$. More generally, if u is a descendent of v in T and $u, v \in V'$, then u is a descendent of v in $T|_x^y$.

LEMMA 2. *Let T_1 be a search tree with integer nodes, let node u be a child of node v in T, and let T_2 be the tree that results when u is rotated over v in T_1. Let $x \leqq y$. If either u or v is not in the interval $[x, y]$ then $T_1|_x^y = T_2|_x^y$. On the other hand, if u and v are both in $[x, y]$ then $T_2|_x^y$ is the tree obtained by rotating u over v in $T_1|_x^y$.*

Proof. Let $T'_1 = T_1|_x^y$ and $T'_2 = T_2|_x^y$. Consider the case where at least one of u or v is not in $[x, y]$. These are four subcases: u is the left child of v in T_1 and $u < x$, u is the left child of v and $v > y$, u is the right child of v and $u > y$, and u is the right child of v and $v < x$. The fourth case is the mirror image of the second case, the second case is the time reversal of the third case, and the third case is the mirror image of the first case, so we need consider only the first case, where u is the left child of v in T_1 and $u < x$. Let w be any node in $[x, y]$. We must show that the children of w in T'_1 are the same as in T'_2. Since $u < x$ and $w \geqq x$ node u cannot be in the right subtree of

w in T_1. Since v is the parent of u, v cannot be in the right subtree of w either. Thus the rotation of u over v has no effect on the right subtree of w, so the right child of w in T_2' is the same as the right child of w in T_1'. Let P be the left inner path of w. If $w \neq v$ and v is not in P then P is unaffected by the rotation, so the left child of w in T_1' is the same as it is in T_2'. If v is in P then the effect of the rotation is to insert u into P, and if $v = w$ the effect is to remove u from P, but since $u \notin [x, y]$ this does not change the left child of w in the restricted tree. Thus the rotation does not change the restricted tree.

The case where u and v are both in $[x, y]$ is just as easy and it is left to the reader. □

Proof of Theorem 1. Let m be the length of sequence s. After a node has been rotated to the root of the search tree the cost of accessing it is 1, so the access cost for sequence s, exclusive of the cost of all rotations, is m. Therefore it suffices to show that $\sum_{u \in U} \lambda(u)$, where U is the set of internal nodes of Υ, is a lower bound on the number of rotations that must be carried out by any standard search algorithm.

Let n be the number of nodes in the search tree. We use induction on n. If $n = 1$ then there is only one possible lower bound tree—the tree with a single leaf node and no internal nodes. In that case $\sum_{u \in U} \lambda(u) = 0$ and there is nothing to prove. So assume $n \geq 2$. Let R be the sequence of rotations generated by some standard search algorithm that accesses the sequence s starting from tree T_0. Let r be the length of R and, for an integer $t \in [1, r]$, let T_t be the tree that results from applying R_t to T_{t-1}. Let w be the root of Υ and let Υ^1 and Υ^2 be the left and right subtrees, respectively, of w. Let $R^1 = R|_{-\infty}^{w}$ and $R^2 = R|_{w}^{\infty}$. Let M be the subsequence of R obtained by deleting those rotations that are in R^1 or R^2. The sequences R^1, R^2, and M are disjoint, so we have $r = |R^1| + |R^2| + |M|$.

For $i = 1, 2$ let U^i be the set of internal nodes of Υ^i. Let $s^1 = s|_{-\infty}^{w}$ and let $s^2 = s|_{w}^{\infty}$. For $t \in [0, r]$, let $T_t^1 = T_t|_{-\infty}^{w}$ and let $T_t^2 = T_t|_{w}^{\infty}$. Let $T_0^{1\prime}, T_1^{1\prime}, \cdots, T_{r_1}^{1\prime}$ be the sequence of search trees obtained by deleting from the sequence $T_0^1, T_1^1, \cdots, T_r^1$ those trees T_t^1 such that $T_t^1 = T_{t-1}^1$. By Lemma 2, $T_t^{1\prime}$ can be derived from $T_{t-1}^{1\prime}$ by applying rotation R_t^1, for all $t \in [1, r_1]$. Also, for all $t \in [0, r]$ if the root v of T_t is less than w then v is also the root of T_t^1. Therefore R^1 is a sequence of rotations that, starting from T_0^1, brings to the root the successive nodes in s^1. Tree Υ^1 is a lower bound tree for T_0^1, and the scores assigned to its internal nodes are precisely the scores obtained in the computation of $\Lambda_1(s^1, T_0^1, \Upsilon^1)$. So by the induction hypothesis, $|R^1| \geq \sum_{u \in U^1} \lambda(u)$. Similarly, R^2 is a sequence of rotations that, starting from T_0^2, brings to the root the successive nodes in s^2, and Υ^2 is a lower bound tree for T_0^2. So $|R^2| \geq \sum_{u \in U^2} \lambda(u)$.

Let σ be the sequence obtained by concatenating the root of T_0 with s. Let integer i be a w-transition. Without loss of generality, we may assume that $\sigma_{i-1} < w$ and $\sigma_i > w$. After the $(i-1)$th access, σ_{i-1} is at the root of the search tree and after the ith access, σ_i is at the root. Thus between the $(i-1)$th and ith accesses there must be a time t such that the root of T_{t-1} is less than w and the root of T_t is greater than w. Let y be the root of T_{t-1} and z be the root of T_t. We must have $R_t = (z, y) \in M$. Thus there is at least one rotation in M for every w-transition so $|M| \geq \lambda(w)$.

Putting it all together, we have

$$r = |R^1| + |R^2| + |M| \geq \sum_{u \in U^1} \lambda(u) + \sum_{u \in U^2} \lambda(u) + \lambda(w) = \sum_{u \in U} \lambda(u). \qquad \square$$

As an application of Theorem 1, we show that the bit reversal permutation on n nodes requires $\Theta(n \log n)$ time to access. Let k be a nonnegative integer and let $i \in [0, 2^k - 1]$. If the k-binary representation of i is $b_{k-1} b_{k-2} \cdots b_1 b_0$ then the *k-bit reversal of i*, denoted by $\mathrm{br}_k(i)$, is the integer whose k-bit binary representation is

$b_0 b_1 \cdots b_{k-2} b_{k-1}$. The bit reversal permutation on $n = 2^k$ nodes is the sequence $B^k = \mathrm{br}_k(0), \mathrm{br}_k(1), \cdots, \mathrm{br}_k(n-1)$.

COROLLARY 3. *Let k be a nonnegative integer and let $n = 2^k$. Let T_0 be any search tree with nodes $0, 1, \cdots, n-1$. Then $\chi(B^k, T_0) \geq n \log n + 1$.*

(Note. All logarithms in this paper are base 2.)

PROOF. Let Υ be the balanced lower bound tree for T_0. That is, the root of Υ is $w = \frac{1}{2}n - \frac{1}{2}$ and in general at depth $d \in [0, k-1]$ the internal nodes are $(2i-1)2^{-(d+1)}n - \frac{1}{2}$, for $1 \leq i \leq 2^d$. Let U be the set of internal nodes of Υ and let $\lambda(u)$ be the score assigned to a node $u \in U$ for sequence B^k and initial tree T_0. By Theorem 1, we have $\chi(B^k, T_0) \geq \Lambda_1(B^k, T_0, \Upsilon) = n + \sum_{u \in U} \lambda(u)$. We show by induction that $\sum_{u \in U} \lambda(u) \geq n \log n - n + 1$.

If $k = 0$ then $n \log n - n + 1 = 0$ and there is nothing to prove. Suppose $k \geq 1$. Let Υ^1 and Υ^2 be the left and right subtree of Υ, respectively, and let U^1 and U^2 be the sets of their internal nodes. The elements of sequence B^k are alternatively less than w and greater than w. Thus, regardless of the choice of T_0, we have $\lambda(w) \geq n - 1$. We have $B^k|_{-\infty}^{w} = B^{k-1}$ and $B^k|_{w}^{\infty} = B^{k-1} + 2^{k-1}$. Also, Υ_1 and Υ_2 are balanced lower bound trees, so by induction $\sum_{u \in U^i} \lambda(u) \geq \frac{1}{2}n \log(\frac{1}{2}n) - \frac{1}{2}n + 1$, for $i = 1, 2$. Thus

$$\sum_{u \in U} \lambda(u) = \sum_{u \in U^1} \lambda(u) + \sum_{u \in U^2} \lambda(u) + \lambda(w) \geq n \log n - n + 1. \qquad \square$$

We now consider the expected cost of accessing a sequence generated at random. If x is a random variable we denote the expected value of x by $E(x)$. For $i \in [1, n]$ let $p_i \geq 0$ and let $\sum_{i=1}^{n} p_i = 1$. Suppose sequence s is generated by choosing m integers in $[1, n]$ independently and at random, where the probability that k is chosen is p_k. If we construct the optimum static tree for the given probabilities the expected cost of accessing s by an algorithm that does not change the tree is $\Theta(m(1 + \sum_{i=1}^{n} p_i \log(1/p_i)))$ [6]. We now show that the same expected cost applies to offline algorithms that do rotations.

THEOREM 4. *Let sequence s be generated in the manner described above. Then for any initial tree T_0 we have $E(\chi(s, T_0)) = \Theta(m(1 + \sum_{i=1}^{n} p \log(1/p_i)))$.*

Proof. The upper bound follows from the bound for the static case. For the lower bound it is convenient to assume that $p_i > 0$ for all i. If $p_k = 0$ for some k then that integer will never be selected and it does not contribute to the sum of the $p_i \log(1/p_i)$s, so it can be ignored. We use a lower bound tree Υ that is balanced with respect to probabilities. That is, for each internal node u of Υ we make the probability of accessing a leaf in the left subtree of u as close as possible to the probability of accessing a leaf in the right subtree of u. More precisely, a probability-balanced tree with leaves j through k is constructed recursively as follows (Υ is constructed by applying this procedure to leaves 1 through n). If $j = k$ then the tree has the single leaf node j and we are done. Otherwise, normalize the probabilities by setting $P = \sum_{i=j}^{k} p_i$ and, for $i \in [j, k]$, $p_i' = p_i / P$. Let c be the least integer such that $\sum_{i=j}^{c} p_i' \geq \frac{1}{2}$. If $\sum_{i=j}^{c-1} p_i' + \frac{1}{2}p_c' < \frac{1}{2}$, then set $b = c$, otherwise set $b = c - 1$. The root of the tree is $u = b + \frac{1}{2}$. The left subtree of u is the probability-balanced tree for leaves j through b, and the right subtree of u is the probability-balanced tree for leaves $b + 1$ through k. The assumption that $p_i > 0$ for all i ensures that the sets of leaves of the left and right subtrees of u are nonempty. The integer c is called the *center leaf* of u.

Let U be the set of internal nodes of Υ. We modify the accounting for the lower bound as follows. For $u \in U$, let $\alpha(u)$ be the number of times the center leaf of u occurs in sequence s. The *modified score* of u is $\lambda'(u) = \lambda(u) + \frac{1}{2}\alpha(u)$. Each leaf node is the center leaf of at most two internal nodes, so $\sum_{u \in U} \alpha(u) \leq 2m$. Thus $\Lambda_1(s, T_0, \Upsilon) = m + \sum_{u \in U} \lambda(u) \geq \sum_{u \in U} \lambda'(u)$.

Suppose we step through the successive elements of s, on the ith step computing the modified scores of the internal nodes on the basis of T_0 and the subsequence $s_1, s_2, \cdots, s_i$. For $u \in U$ let $\lambda_i'(u)$ be the increase in $\lambda'(u)$ due to step i. Let $\lambda_i(u)$ be the increase in $\lambda(u)$, and let $\alpha_i(u)$ be the increase in $\alpha(u)$. Let the leftmost leaf in the subtree with root u be l_u and let the rightmost leaf be r_u. Let $q_1 = \sum_{l_u \leqq j < u} p_j$ and let $q_2 = \sum_{u < j \leqq r_u} p_j$. Let $P = q_1 + q_2$ be the probability that s_i is a leaf of the subtree with root u. For $k = 1, 2$ let $q_k' = q_k / P$. We have $E(\lambda_i(u)) = P\tau$, where τ is the conditional probability that i is a u-transition, given that $s_i \in [l_u, r_u]$. If the last node accessed under u was in u's left subtree then $\tau = q_2'$, and if it was in u's right subtree then $\tau = q_1'$. (If there was no node previously accessed under u then τ is either q_2' or q_1', depending upon whether the lowest common ancestor of nodes l through r in T_0 is less than or greater than u.) In any case $\tau \geqq \min(q_1', q_2')$. Let c be the center leaf of u, and let $p_c' = p_c / P$ be the conditional probability that $s_i = c$, given that $s_i \in [l_u, r_u]$. We have $E(\alpha_i(u)) = Pp_c'$. Thus $E(\lambda_i'(u)) = E(\lambda_i(u)) + \frac{1}{2}E(\alpha_i(u)) \geqq P(\min(q_1', q_2') + \frac{1}{2}p_c')$.

By the construction of Υ, we always have $\min(q_1', q_2') + \frac{1}{2}p_c' \geqq \frac{1}{2}$. So $E(\lambda_i'(u)) \geqq \frac{1}{2}P$. Summing over all m elements of s, we have $E(\lambda'(u)) \geqq \frac{1}{2}mP$. Thus

$$E(\Lambda_1(s, T_0, \Upsilon)) \geqq \sum_{u \in U} E(\lambda'(u)) \geqq \frac{m}{2} \sum_{u \in U} \sum_{j=l_u}^{r_u} p_j = \frac{m}{2} \sum_{j=1}^{n} d_j p_j,$$

where d_j is the number of internal nodes along the path from the root of Υ to leaf j.

As is easily shown by induction, $\sum_{j=1}^{n} d_j p_j \geqq \sum_{j=1}^{n} p_j \log(1/p_j)$, for any binary tree with n leaves in which the internal path length of leaf j is d_j (see, for example, Knuth [6, p. 445]). So $E(\Lambda_1(s, T_0, \Upsilon)) \geqq \frac{1}{2}m \sum_{i=1}^{n} p_i \log(1/p_i)$. Also, we always have $\Lambda_1(s, T_0, \Upsilon) \geqq m$. So, by Theorem 1,

$$E(\chi(s, T_0)) \geqq E(\Lambda_1(s, T_0, \Upsilon)) \geqq \max\left(m, \frac{m}{2} \sum_{i=1}^{n} p_i \log(1/p_i)\right)$$

$$\geqq \frac{m}{3}\left(1 + \sum_{i=1}^{n} p_i \log(1/p_i)\right). \qquad \square$$

3. The second lower bound. One problem with the lower bound of the previous section is that it requires picking a good lower bound tree. For an initial tree with n nodes and an access sequence of length m the optimum lower bound tree (i.e., the one that gives the largest bound) can be found in time $O(mn^3)$ by dynamic programming, since if a lower bound tree with root w is optimal for sequence s its left subtree is optimal for sequence $s|_{-\infty}^{w}$ and its right subtree is optimal for sequence $s|_{w}^{\infty}$. However, if we hope to prove that an offline search algorithm is optimal by showing that the time it takes to access a sequence matches some known lower bound then the dynamic programming technique is not very helpful—it is very difficult to get a grip on how the lower bound that comes out relates to the access sequence. Also, there is good reason to believe that even the optimal lower bound tree does not in general give a good bound. For a long sequence may have an access pattern that varies widely from one section of the sequence to another, so that no single lower bound tree works very well.

In this section an alternative way of computing a lower bound for $\chi(s, T_0)$ is described. It does not depend upon a lower bound tree (or even upon T_0) and seems to be better able to handle shifting access patterns.

Let s be a sequence of length m. We describe below a procedure for computing, for each $i \in [1, m]$, a quantity $\kappa(i)$, called the *score* of access i. The new lower bound

is defined as

$$\Lambda_2(s) = m + \sum_{i=1}^{m} \kappa(i).$$

When $\kappa(i) > 0$ the procedure for computing $\kappa(i)$ also determines the *inside accesses of i*, $b_1, b_2, \cdots, b_{\kappa(i)}$, the *inside nodes of i*, $v_j = s_{b_j}$, for $j \in [1, \kappa(i)]$, the *crossing accesses of i*, $c_1, c_2, \cdots, c_{\kappa(i)+1}$, and the *crossing nodes of i*, $w_j = s_{c_j}$, for $j \in [1, \kappa(i)+1]$.

A formal procedure for computing the score of i, together with its inside and crossing accesses, is shown in Fig. 1. Here we give an informal description of the procedure. We find the inside and crossing accesses of i by working backward in time from access i. The first crossing access, c_1, is simply the access prior to access i, namely $i-1$. The corresponding crossing node is $w_1 = s_{c_1} = s_{i-1}$. The second crossing access, c_2, is found by going backward in time from c_1 until we reach an access to a node on the side of s_i opposite from w_1. That is, if $w_1 > s_i$ then c_2 is the latest access prior to c_1 to a node less than or equal to s_i, and if $w_1 < s_i$ it is the latest access prior to c_1 to a node greater than or equal to s_i. The corresponding crossing node is $w_2 = s_{c_2}$. Assume without loss of generality that $w_1 < s_i$ so that $w_2 \geqq s_i$. Once the second crossing access has been found we can determine the first inside node, v_1. It is the greatest node less than s_i accessed after c_2 but before (or at) access c_1. The first inside access, b_1, is the access to v_1 within this time interval (if v_1 has been accessed more than once within the interval b_1 is the latest such access). So we have at this point $c_2 < b_1 \leqq c_1 < i$ and $w_1 \leqq v_1 < s_i \leqq w_2$. If $w_2 = s_i$, we are done; otherwise we proceed with the computation of c_3. The third crossing access, c_3, is the latest access prior to c_2 to a node between

        case
        w_l = s_i: begin κ(i) ← l − 1; quit end;
        w_l < s_i:
            begin
            Q ← {j ∈ [1, c_l): s_j ∈ [s_i, v_{l−1})};
            if Q = ∅ then begin κ(i) ← l − 1; quit end;
            c_{l+1} ← max Q;
            w_{l+1} ← s_{c_{l+1}};
            v_l ← max {s_j : j ∈ (c_{l+1}, c_l] and s_j < s_i};
            b_l ← max {j ∈ (c_{l+1}, c_l] : s_j = v_l};
            end
        w_l > s_i:
            begin
            Q ← {j ∈ [1, c_l) : s_j ∈ (v_{l−1}, s_i]};
            if Q = ∅ then begin κ(i) ← l − 1; quit end;
            c_{l+1} ← max Q;
            w_{l+1} ← s_{c_{l+1}};
            v_l ← min {s_j : j ∈ (c_{l+1}, c_l] and s_j > s_i};
            b_l ← max {j ∈ (c_{l+1}, c_l] : s_j = v_l};
            end
        endcase;
    endloop
```

FIG. 1. *Procedure for computing the score of an access.*

v_1 (exclusive) and s_i (inclusive), and the corresponding crossing node is $w_3 = s_{c_3}$. Then the second inside node, v_2, is computed as the smallest node greater than s_i that is accessed after c_3 but before (or at) c_2. The second inside access, b_2, is the latest access to v_2 within this time interval. At this point we have $c_3 < b_2 \leqq c_2 < b_1 \leqq c_1 < i$, and $w_1 \leqq v_1 < w_3 \leqq s_i < v_2 \leqq w_2$. If $w_3 = s_i$ we are done; otherwise c_4 is computed as the latest access prior to c_3 to a node between s_i (inclusive) and v_2 (exclusive), and w_4 is set to s_{c_4}. Then v_3 is computed as the greatest node smaller than s_i that is accessed after c_4 but before (or at) c_3. We continue in this way, with the crossing and inside nodes at alternate sides of s_i, getting closer to s_i as we go back in time. Eventually we reach the previous access of s_i (if there is one) or the beginning of the sequence (if there is not) at which point we stop. The score, $\kappa(i)$, is the number of inside accesses found.

It will help to go through an example. We distinguish between accesses and nodes by using boldface letters (ordered alphabetically), rather than integers, to denote nodes. Suppose the sequence s is **a, i, h, j, g, f, c, l, k, e, n, d, b, p, m, o, i**. This sequence is illustrated in Fig. 2. The nodes are in sorted order and the order of the access sequence is given by directed edges above the nodes. Suppose we wish to compute $\kappa(17)$, the score for the second access of node **i**. We start at access 17 and follow the access sequence backward in time. The previous access (16) is c_1, the first crossing access, so $w_1 = \mathbf{o}$. To find the second crossing access we go backward until we find an access to a node on the side of **i** opposite from **o**. The two accesses immediately prior to access 16 are to nodes **m** and **p**, which are on the same side of **i** as **o**. Access 13 is to node **b**, so $c_2 = 13$ and $w_2 = \mathbf{b}$. The first inside node is the closest node to **i** accessed after c_2 that is on the right side of **i**. This node is **m**, reached at access 15, so $b_1 = 15$ and $v_1 = \mathbf{m}$. To get the third crossing access we go backward from access c_2 until we reach an access to a node greater than or equal to **i** and less than $v_1 = \mathbf{m}$. The access before 13 is to node **d**, on the wrong side of **i**, the access before that is to **n**, on the wrong side of **m**, and the access before that is to **e**, on the wrong side of **i**. It is not until access 9, to **k**, that we find c_3. The second inside node is the closest node to **i** on its left side that is accessed after c_3 and before or at access c_2. This is node **e**, so $b_2 = 10$ and $v_2 = \mathbf{e}$. The fourth crossing access is obtained by going backward from c_3 until an access to a node between $v_2 = \mathbf{e}$ (exclusive) and **i** (inclusive) is reached. This is access 6, to node **f**. The third inside node is the closest node to **i** on its right side that is accessed after c_4 and before or at c_3. This is node **k**, the same as the third crossing node, so $b_3 = c_3 = 9$. The fifth crossing access is the first access before c_4 to a node

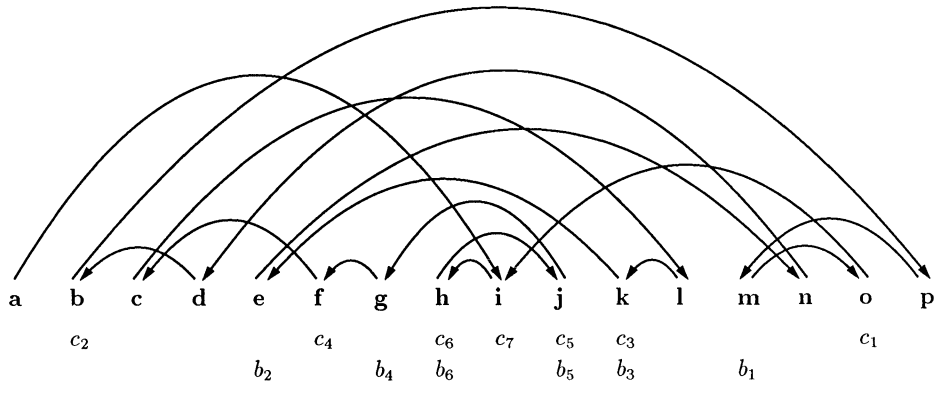

FIG. 2. *Computing the score for the second access of* **i** *in the sequence* **a, i, h, j, g, f, c, l, k, e, n, d, b, p, m, o, i.**

greater than or equal to **i** and less than $v_3 = \mathbf{k}$. This is access 4, to node $w_5 = \mathbf{j}$. The fourth inside node is the closest node to **i** on its left side that is accessed after c_5 and before or at c_4, and this is **g**, reached at access 5. Continuing in this way, we find $c_6 = 3$, $w_6 = \mathbf{h}$, and $b_5 = c_5 = 4$, $v_5 = w_5 = \mathbf{j}$. The seventh crossing access is 2, the previous access of **i**, and b_6 is determined to be equal to c_6. At this point the procedure terminates, with $\kappa(17) = 6$.

The crossing and inside accesses of i are all earlier than i and are equal to or later than the previous access of s_i (if there was one). Thus each of the crossing and inside nodes of i is above s_i at some time between the previous access of s_i and access i. Intuitively, after access $i-1$ we expect that the inside nodes of i will be on the path from the root to node s_i. Therefore for access i we expect that a standard search algorithm will have to rotate s_i over at least $\kappa(i)$ nodes, and then once s_i is at the root there will be a cost of 1 for accessing it. Of course, in general many other nodes will have been above s_i at some time since the previous access of s_i, but they can usually be kicked out of the way during the access of some inside node of i. Actually, you can always arrange to have as few inside nodes above s_i after access $i-1$ as you want, but for each inside node that is not above s_i either there will be some other node above s_i in its place or some extra cost will be imposed upon some access prior to the ith access.

The next two simple lemmas formally state properties that by now are probably quite clear.

LEMMA 5. *Let s be a sequence of integers of length m. Let $i \in [1, m]$, let $k = \kappa(i)$, and suppose $k \geqq 1$. Then the inside accesses of $i, b_1, \cdots, b_k$, the inside nodes of $i, v_1, \cdots, v_k$, the crossing accesses of $i, c_1, \cdots, c_{k+1}$, and the crossing nodes of $i, w_1, \cdots, w_{k+1}$, are all well defined. Also, the following relationships hold*:

$$c_{k+1} < b_k \leqq c_k < b_{k-1} \leqq c_{k-1} < \cdots < b_1 \leqq c_1 < i. \tag{1}$$

If $w_1 < s_i$ and k is odd then

$$w_1 \leqq v_1 < w_3 \leqq v_3 < \cdots < w_k \leqq v_k < s_i \leqq w_{k+1} < v_{k-1} \leqq w_{k-1} < \cdots < v_2 \leqq w_2, \tag{2a}$$

if $w_1 < s_i$ and k is even then

$$w_1 \leqq v_1 < w_3 \leqq v_3 < \cdots < w_{k-1} \leqq v_{k-1} < w_{k+1} \leqq s_i < v_k \leqq w_k < \cdots < v_2 \leqq w_2, \tag{2b}$$

if $w_1 > s_i$ and k is odd then

$$w_2 \leqq v_2 < w_4 \leqq v_4 < \cdots < w_{k-1} \leqq v_{k-1} < w_{k+1} \leqq s_i < v_k \leqq w_k < \cdots < v_1 \leqq w_1, \tag{2c}$$

and if $w_1 > s_i$ and k is even then

$$w_2 \leqq v_2 < w_4 \leqq v_4 < \cdots < w_k \leqq v_k < s_i \leqq w_{k+1} < v_{k-1} \leqq w_{k-1} < \cdots < v_1 \leqq w_1. \tag{2d}$$

Proof. Equations (2a)–(2d) are essentially the same, so assume without loss of generality that $w_1 < s_i$ and k is odd. Everything follows from an easy induction on l. Assume without loss of generality that $w_l < s_i$. If $l \leqq \kappa(i)$ then $\{j \in [1, c_l) : s_j \in [s_i, v_{l-1})\}$ is nonempty so c_{l+1} is well defined and is less than c_l. Also, $s_i \leqq w_{l+1} < v_{l-1}$, and the first branch of the **case** statement ensures that $w_{l+1} = s_i$ only if $l = \kappa(i)$. We have $w_l \in \{s_j : j \in (c_{l+1}, c_l]$ and $s_j < s_i\}$ so v_l is well defined and $v_l \geqq w_l$. The definition of v_l ensures that b_l is well defined and by definition of b_l we have $c_{l+1} < b_l \leqq c_l$. □

LEMMA 6. *Let s be a sequence of integers of length m and let $i \in [1, m]$ with $k = \kappa(i)$ positive. Let $c_1, \cdots, c_{k+1}$ be the crossing accesses of i, let $w_1, \cdots, w_{k+1}$ be the crossing nodes of i, and let $v_1, \cdots, v_k$ be the inside nodes of i. Let $l \in [1, k]$. Let interval I_l be*

either $(v_l, w_{l+1}]$ *or* $[w_{l+1}, v_l)$, *according to whether* $v_l < s_i$ *or* $v_l > s_i$. *Then* $i = \min\{j > c_{l+1} : s_j \in I_l\}$.

Proof. Assume without loss of generality that $v_l > s_i$. Let $Y = \{j > c_{l+1} : s_j \in (v_l, w_{l+1}]\}$. Let $h = \min Y$. Since $i \in Y$ we have $h \leqq i$. We show that the assumption that $h < i$ leads to a contradiction. Suppose $h < i$. Then $h \leqq i - 1 = c_1$. So, by (1), there is an $m \in [1, l]$ such that $h \in (c_{m+1}, c_m]$. We must have $w_m < s_i$ or $w_m > s_i$.

Suppose $w_m < s_i$. If $s_h < s_i$ then by definition of v_m we have $s_h \leqq v_m$. But $v_m \leqq v_l$ so $s_h \leqq v_l$, contradicting the definition of h. Thus the assumption that $w_m < s_i$ implies that $s_h \geqq s_i$. Since $s_{c_m} = w_m < s_i$ we must have $h < c_m$. Also, $w_{l+1} < v_{l-1} \leqq v_{m-1}$, so $s_h \in [s_i, v_{m-1})$. So by definition of c_{m+1} we have $c_{m+1} \geqq h$, a contradiction.

Therefore we must have $w_m > s_i$. Since $w_l < s_i$ we must have $m \neq l$, i.e., $m \leqq l - 1$. If $s_h > s_i$ then by definition of v_m we have $v_m \leqq s_h$. But $w_{l+1} \leqq w_{m+2} < v_m$, so $w_{l+1} < s_h$, contradicting the definition of h. So we must have $s_h \leqq s_i$ and since $v_{m-1} < v_l$ we have $s_h \in (v_{m-1}, s_i]$. Since $s_{c_m} = w_m > s_i$ we must have $h < c_m$. So by definition of c_{m+1} we have $c_{m+1} \geqq h$, a contradiction. □

THEOREM 7. *For any search tree* T_0 *and sequence* s *of nodes in* T_0 *we have* $\chi(s, T_0) \geqq \Lambda_2(s)$.

Proof. Let m be the length of s, and for each $i \in [1, m]$ define $\kappa(i)$ using the procedure `compute-kappa`(s, i). Once a node is at the root the cost of accessing it is 1, so it suffices to show that $\sum_{i=1}^{m} \kappa(i)$ is a lower bound on the number of rotations required by any standard search algorithm that accesses s.

We use an accounting argument. Let R be the sequence of rotations generated by some standard search algorithm acting on sequence s and initial tree T_0. Let r be the length of R. For $t \in [1, r]$, let T_t be the search tree obtained by applying rotation R_t to tree T_{t-1}. Let $\tau_0 = 0$ and, for $i \in [1, m]$, let τ_i be the smallest integer greater than or equal to τ_{i-1} such that s_i is at the root of T_{τ_i}.

For each time $t \in [1, r]$, we put a dollar on at most one node, determined as follows. Let $R_t = (u, v)$ (node u is rotated over node v). Let $I_{u,v} = (u, v]$ if $u < v$ and $I_{u,v} = [v, u)$ if $u > v$. Let j be the smallest integer such that $\tau_j \geqq t$ and $s_j \in I_{u,v}$, if such an integer exists. If j is undefined then no node gets a dollar at time t. Otherwise, a dollar is put on node s_j.

After rotation R_{τ_i} is carried out all the dollars on node s_i are thrown away. Since at most one dollar is put in the tree per rotation the number of dollars thrown away is a lower bound on the number of rotations used. Thus to get the desired bound it suffices to show that for each $i \in [1, m]$, after rotation R_{τ_i} has been carried out the number of dollars taken off node s_i is at least $\kappa(i)$.

Let $i \in [1, m]$ with $k = \kappa(i)$ positive. Let $b_1, \cdots, b_k$ be the inside accesses of i, let $v_1, \cdots, v_k$ be the inside nodes of i, let $c_1, \cdots, c_{k+1}$ be the crossing accesses of i, and let $w_1, \cdots, w_{k+1}$ be the crossing nodes of i. By setting $l = k$ in Lemma 6 we see that $i = \min\{j > c_{k+1} : s_j = s_i\}$, so no dollars are taken from s_i in the interval $(\tau_{c_{k+1}}, \tau_{c_1}]$. Therefore it suffices to show that for each $l \in [1, k]$ a dollar is placed on node s_i for some $t \in (\tau_{c_{l+1}}, \tau_{b_l}]$. (By Lemma 5 these k intervals are all disjoint.)

Let $l \in [1, k]$. Assume without loss of generality that $w_{l+1} \leqq s_i$. For all $t \in (\tau_{c_{l+1}}, \tau_{b_l}]$ let $a(t)$ be the lowest common ancestor of w_{l+1} and v_l in tree T_t. We have $a(\tau_{c_{l+1}}) = w_{l+1} \leqq s_i$ and $a(\tau_{b_l}) = v_l > s_i$. So there must be a $t \in (\tau_{c_{l+1}}, \tau_{b_l}]$ such that $a(t-1) \leqq s_i$ and $a(t) > s_i$. Let $R_t = (y, z)$. It is straightforward to verify that we must have $a(t-1) = z$ and $a(t) = y$, for otherwise the lowest common ancestor of w_{l+1} and v_l would not change with tth rotation. Also $w_{l+1} \leqq z$ and $y \leqq v_l$. Thus $s_i \in [z, y) \subseteq [w_{l+1}, v_l)$. Let h be the smallest integer such that $\tau_h \geqq t$. Since $t > \tau_{c_{l+1}}$ we have $h > c_{l+1}$. The node that gets the dollar for rotation t is s_j such that $j = \min\{g \geqq h : s_g \in [z, y)\}$ and by Lemma 6 that node is s_i. □

It is perhaps not immediately obvious that $\Lambda_2(s)$ ever gives a bound that is superlinear in the length of s. Here we show that $\Lambda_2(s)$ can be used to get the $\Theta(n \log n)$ bound for accessing the bit reversal permutation.

THEOREM 8. *Let B^k be the bit reversal permutation on $n = 2^k$ nodes. Then $\Lambda_2(B^k) \geqq \frac{1}{2} n \log n + 1$.*

Proof. It is convenient to index the sequence B^k from zero rather than 1, so that the ith access is to node $\mathrm{br}_k(i)$. By definition $\Lambda_2(s) = n + \sum_{i=0}^{n-1} \kappa(i)$, where $\kappa(i)$ is the number of inside accesses of i. We use induction on k to show that $\sum_{i=0}^{n-1} \kappa(i) \geqq \frac{1}{2} n \log n - n + 1$. When $k \leqq 1$ the claimed bound is zero so there is nothing to prove.

Suppose $k \geqq 2$. Clearly the sequence $\frac{1}{2}B_0^k, \frac{1}{2}B_1^k, \cdots, \frac{1}{2}B_{n/2-1}^k$ is precisely B^{k-1}. Let $i, j \in [0, n/2-1]$. Then j is an inside access of i for sequence B^k if and only if j is an inside access of i for sequence B^{k-1}. So by the induction hypothesis,

$$\sum_{i=0}^{n/2-1} \kappa(i) \geqq \frac{1}{2}\left(\frac{n}{2}\right) \log\left(\frac{n}{2}\right) - \frac{n}{2} + 1.$$

We also have $B^{k-1} = \frac{1}{2}(B_{n/2}^k - 1), \frac{1}{2}(B_{n/2+1}^k - 1), \cdots, \frac{1}{2}(B_{n-1}^k - 1)$. Let $i, j \in [n/2, n-1]$. Then j is a crossing access of i for sequence B^k if and only if $j - n/2$ is a crossing access of $i - n/2$ for sequence B^{k-1}. So each $i \in [n/2, n-1]$ has at least as many inside accesses in sequence B^k as $i - n/2$ has in sequence B^{k-1}. We will show that each $i \in [n/2, n-2]$ actually has at least one more inside access in B^k than $i - n/2$ has in B^{k-1}. When $i = n/2$ access $i - n/2$ has no crossing accesses and no inside accesses in B^{k-1}, but access i (to node 1) has two crossing accesses in B^k, namely, $i-1$ and 0, so it has one inside access. If $i \in [n/2+1, n-2]$ then $i - n/2$ has at least one crossing access in B^{k-1}, so it suffices to show that i has one more crossing access in B^k than $i - n/2$ has in B^{k-1}. Access i has a crossing access in $[n/2, n-1]$, namely $i-1$, so let c be the earliest crossing access of i that is greater than or equal to $n/2$. Let $u = B_i^k$. Suppose c is the lth crossing access of i. Assume without loss of generality that $B_c^k < u$. Let v be the $(l-1)$th inside node of i. (If $l = 1$ we may take v to be $+\infty$.) There is at least one even node in $[u, v)$ (namely $u+1$) and of these the one that is accessed latest is a crossing node of i, and its access is in $[0, n/2-1]$. So by the induction hypothesis,

$$\sum_{i=n/2}^{n-1} \kappa(i) \geqq \frac{1}{2}\left(\frac{n}{2}\right) \log\left(\frac{n}{2}\right) - \frac{n}{2} + 1 + \left(\frac{n}{2} - 1\right).$$

Therefore

$$\sum_{i=0}^{n-1} \kappa(i) \geqq \frac{1}{2} n \log n - n + 1. \qquad \square$$

Conclusions. Two methods for obtaining lower bounds on $\chi(s, T_0)$ have been described. The first is useful for getting bounds on the expected value of $\chi(s, T_0)$ when sequence s is chosen at random, whereas the second seems more likely to give tight bounds for specific sequences. The obvious unresolved problem is to obtain tight bounds for $\chi(s, T_0)$. That is, to find an efficient (polynomial-time) procedure for computing an upper bound on $\chi(s, T_0)$ that can be shown to match some known lower bound. Preferably the procedure would give an explicit method for optimally accessing sequence s offline. The function $\Lambda_2(s)$ may give a tight bound for the cost of accessing sequence s (up to a constant factor). However, I have been unable to find a binary search tree algorithm whose performance provably matches the $\Lambda_2(s)$ lower bound.

Of course, the ultimate goal is to find some simple online algorithm that always runs in time $O(\chi(s, T_0) + n)$. The splay algorithm may yet prove to be such an algorithm.

AN INCREMENTAL LINEAR-TIME ALGORITHM FOR RECOGNIZING INTERVAL GRAPHS*

NORBERT KORTE† AND ROLF H. MÖHRING‡

Abstract. The fastest-known algorithm for recognizing interval graphs [S. Booth and S. Lucker, *J. Comput. System Sci.*, 13 (1976), pp. 335–379] iteratively manipulates the system of all maximal cliques of the given graph in a rather complicated way in order to construct a consecutive arrangement (more precisely, a tree representation of all possible consecutive arrangements). This paper presents a much simpler algorithm using a related, but much more informative tree representation of interval graphs. This tree is constructed in an incremental fashion by adding vertices to the graph in a predefined order such that adding a vertex u takes $O(|\text{Adj}(u)|+1)$ amortized time.

Key words. interval graphs, incremental recognition, graph algorithm, perfect elimination scheme, modified *PQ*-tree, amortized time

AMS(MOS) subject classifications. 68C25, 68E10

1. Introduction. A graph (see [4] for all graph-theoretic notation not defined here) $G=(V, E)$ is called an *interval graph* if its vertices v can be represented by (not necessarily distinct) intervals I_v of the real line such that two vertices are adjacent if and only if the corresponding intervals intersect. Such a collection $(I_v)_{v\in V}$ is called an *interval representation* of G.

Interval graphs arise in many applications that deal with the arrangement of overlapping connected parts of a linear or sequential structure. Examples are seriation in archeology, consecutive retrieval in data base systems, scheduling problems, VLSI-layout problems, and many others (cf. [2], [4], [5], [8] for details and references). The main reason for these applications is the following characterization theorem due to [3], which relates the "sequential" structure of interval graphs to a consecutiveness property of their maximal cliques.

THEOREM 1.1 [3]. *A graph G is an interval graph if and only if the maximal cliques of G can be linearly ordered such that, for each vertex v, the maximal cliques containing v occur consecutively.*

We call such an arrangement of the maximal cliques a *consecutive arrangement.* Constructing such a consecutive arrangement is the basis of the fastest recognition algorithm for interval graphs presently available [1].

The **first phase** of this algorithm makes use of the fact that interval graphs are *triangulated* (cf. [4] for details) and thus have a *perfect vertex elimination scheme* (*perfect scheme* for short), i.e., an ordering $\delta=[v_1, v_2, \cdots, v_n]$ of the vertices of G such that each set $(\text{Adj}(v_i)\cup\{v_i\})\cap\{v_i, v_{i+1}, \cdots, v_n\}$ is a clique of G. (Here $\text{Adj}(v_i)$ denotes the set of vertices adjacent to v_i.) Testing whether such a scheme exists and constructing it can be done by lexicographic breadth-first search in $O(|V|+|E|)$ time (cf. [9], [11]). A perfect scheme $\delta=[v_1, \cdots, v_n]$ naturally induces a list of cliques $C(v_i)=\{v_j\in\text{Adj}(v_i)\,|\,j>i\}\cup\{v_i\}$ $(i=1, \cdots, n)$ which contains all maximal cliques.

* Received by the editors December 1, 1986; accepted for publication (in revised form) March 31, 1988. This work was done at the Institute of Operations Research, University of Bonn, Bonn, Federal Republic of Germany, and was supported by the Sonderforschungsbereich 303. A preliminary version of this paper was presented at the 12th Annual Workshop on Graphtheoretic Concepts in Computer Science, Munich, Federal Republic of Germany, 1986.

These maximal cliques are the input for the **second phase** of the algorithm, in which an attempt to construct a consecutive arrangement for the cliques is made. The data structure used in this phase is the *PQ-tree*. It was invented in [1] for the more general purpose of representing all permutations of a set M that are consistent with constraints of consecutiveness given by a system $\mathcal{M}$ of subsets of M with the convention that the elements of each $M' \in \mathcal{M}$ must occur consecutively in the permutation. In the interval graph case, M is the set of maximal cliques of G, and $\mathcal{M}$ consists of all $\mathcal{C}(v)$, $v \in V$, where $\mathcal{C}(v)$ denotes the set of all maximal cliques containing v.

A PQ-tree is a rooted tree T with two types of internal nodes: P and Q, which will be represented by circles and rectangles, respectively. The leaves of T are labeled 1-1 with the maximal cliques of the interval graph G (in general, with the elements of M).

The *frontier* of a PQ-tree T is the permutation of the maximal cliques obtained by the ordering of the leaves of T from left to right. PQ-trees T and T' are *equivalent*, if one can be obtained from the other by applying the following rules a finite number of times:

(1) Arbitrarily permute the successor nodes of a P-node.

(2) Reverse the order of the successor nodes of a Q-node.

For an example see Fig. 1, where the frontier of T is given by $[C_1, C_2, \cdots, C_6]$. An equivalent frontier is $[C_5, C_6, C_3, C_2, C_1, C_4]$.

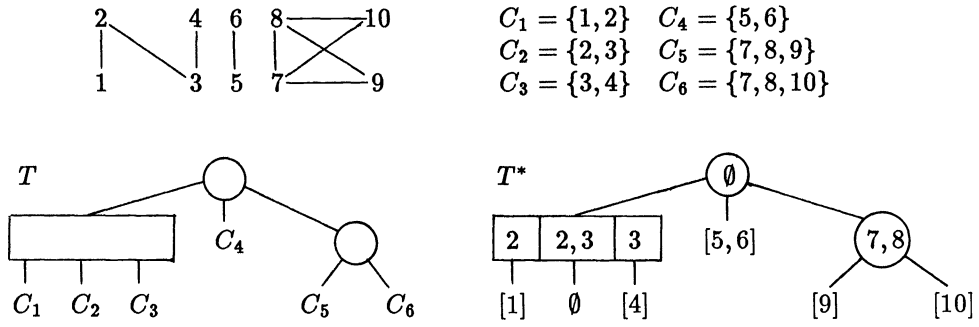

FIG. 1. *An interval graph G, its PQ-tree T, and its modified PQ-tree T*.*

In [1] it is shown that a graph G is an interval graph if and only if there is a PQ-tree T whose frontier represents a consecutive arrangement of the maximal cliques of G. They also develop an $O(|V|+|E|)$ algorithm that either constructs a PQ-tree for G (by successively making the maximal cliques from each $\mathcal{C}(v)$, $v \in V$, consecutive), or states that G is not an interval graph. If G is an interval graph, then all consecutive arrangements of the maximal cliques of G are obtained by taking equivalent PQ-trees.

The algorithm contains an update procedure that constructs, from a given PQ-tree T for a system $\mathcal{M} = \{\mathcal{C}(v_1), \cdots, \mathcal{C}(v_k)\}$, a PQ-tree T' representing $\mathcal{M}$ plus one additional constraint set $\mathcal{C}(v_{k+1})$. This is done in a bottom-up way along the tree T by comparing parts of the tree with a fixed number of *patterns* that induce certain local *replacements* in T. If none of the patterns applies, G is no interval graph. Otherwise, the algorithm returns T'. This update procedure is rather complicated, since many patterns must be considered, and large parts of the tree may be affected. Also the complexity analysis is rather intricate.

We develop a considerably simpler algorithm that follows a related approach (i.e., it uses a graph search method related to perfect schemes for constructing a consecutive arrangement), but differs essentially in the following points.

First, it uses a different data structure, the so-called *modified PQ-tree* introduced in [7]. Second, it is *incremental*, i.e., it grows the modified *PQ-tree* gradually by adding one vertex to the graph at a time (in a predefined order determined by lexicographic breadth-first search). The different data structure and the incremental growth result in a simple update scheme having three immediate advantages over that of Booth and Lueker: (a) fewer and simpler templates, (b) only a path of the tree must be modified when a vertex is added to the current graph (instead of a complete subtree), and (c) no need to be concerned with interior children of Q-nodes when exploring the path along which modifications occur (interior children of Q-nodes are a major headache for any PQ-tree implementation).

In addition, the modified PQ-tree contains much more information about the graph G than PQ-trees and is interesting in its own right. It is, for instance, used in [6], [7] to obtain fast algorithms for constructing an interval representation of G that respects given side constraints such as order relations among the intervals or their endpoints (*seriation with side constraints*; see also [8] for an overview).

Also, the incremental nature of the algorithm may be important for several applications. For instance, in gate matrix layout (a type of VLSI layout problem, see, e.g., [2]) we look for a large interval subgraph of an arbitrary graph representing conditions on the layout. One way to do this is to add as many vertices as we can while maintaining an interval graph. Hence data structures permitting incremental updating are very well suited to these applications.

The approach followed here has been extended in [6] to general *online algorithms* in which the graph is not known in advance, and vertices are added one at a time. This is, however, achieved at the cost of a higher worst-case complexity of $O(|V|^2)$ and a more complicated tree-updating scheme that must consider subtrees and interior sons of Q-nodes as does the algorithm of Booth and Lueker.

2. Modified *PQ*-trees. The *modified PQ-tree* (*MPQ*-tree) T^* assigns sets of vertices (possibly empty) to the nodes of a PQ-tree T representing an interval graph $G=(V, E)$. A P-node is assigned only one set, while a Q-node has a set for each of its sons (ordered from left to right according to the ordering of the sons).

For a P-node P, this set consists of those vertices of G contained in all maximal cliques represented by the subtree of P in T, but in no other cliques.

For a Q-node Q, the definition is more involved. Let $Q_1, \cdots, Q_m$ be the sons (in consecutive order) of Q, and let T_i be the subtree of T with root Q_i. (Note that $m \geqq 3$.) We then assign a set S_i (a so-called *section*) to Q for each Q_i. Section S_i contains all vertices that are contained in all maximal cliques of T_i *and* some other T_j, but *not* in any clique belonging to some other subtree of T that is not below Q. Since the maximal cliques containing a fixed vertex occur consecutively in T, it suffices to represent a vertex v belonging to several sections only in the leftmost and rightmost sections in which it appears. This convention assures that T^* represents G in $O(|V|)$ space, whereas PQ-trees require $O(|V|+|E|)$ space, since each maximal clique is stored separately. An example MPQ-tree is given in Fig. 1.

The following theorem from [7] summarizes some key properties of MPQ-trees:

THEOREM 2.1. [7]. *Let T be a PQ-tree for $G=(V, E)$ and let T^* be the associated MPQ-tree. Then we have the following*:

(a) *T^* can be obtained from T in $O(|V|+|E|)$ time and represents G in $O(|V|)$ space.*

(b) *Each maximal clique of G corresponds to a path in T^* from the root to a leaf, where each vertex $v \in V$ is as close as possible to the root.*

Property (b) states the essential property of *MPQ*-trees, which consists of distinguishing vertices of G with respect to their membership in maximal cliques while keeping the consecutiveness properties given by the underlying *PQ*-tree. In particular, the root of T^* contains all vertices belonging to all maximal cliques, while the leaves contain the *simplicial vertices* of G (vertices belonging only to one maximal clique).

As a consequence of this property, *MPQ*-trees may be viewed as *qbstract interval representations* of interval graphs that explicitly model the overlapping structure of the intervals while maintaining all degrees of freedom with respect to actual arrangements of the intervals by the *PQ*-tree operations. The higher a vertex u is located in the tree, the longer the respective interval I_u must be. *Standard* interval representations, in which the length of I_u is equal to the number of maximal cliques containing u, are given in Fig. 2 for the graphs and *MPQ*-trees from Figs. 1 and 3.

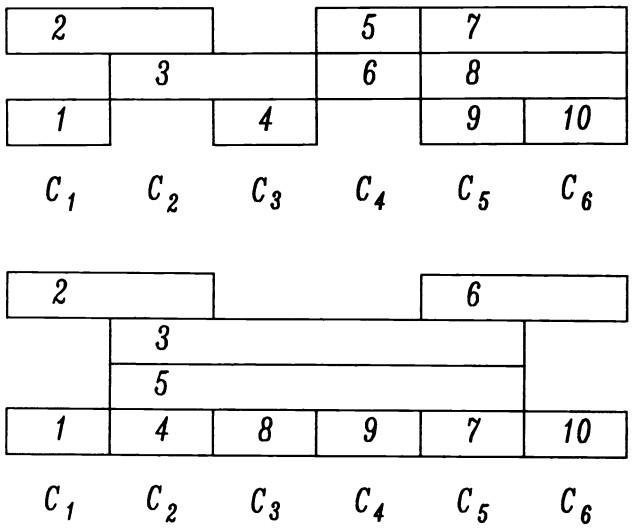

FIG. 2. *Standard interval representations for the graphs from Figs.* 1 *and* 3.

The following notation and statements concerning *MPQ*-trees will be used in the sequel. Given a node N of the tree T, we denote by V_N the associated vertex set if N is a P-node or a leaf. If N is a Q-node, we put $V_N := S_1 \cup \cdots \cup S_k$, i.e., the union of its sections. When no confusion is possible, we will sometimes identify a node N and its vertex set V_N.

LEMMA 2.2. *Let N be a Q-node. Let $S_1, \cdots, S_m$ (in this order) be the sections of N, and let V_i denote the set of vertices occurring below S_i in T $(i = 1, \cdots, m)$. Then we have the following*:

(a) $S_{i-1} \cap S_i \neq \emptyset$ *for* $i = 2, \cdots, m$.

(b) $S_1 \subseteq S_2$ *and* $S_{m-1} \supseteq S_m$.

(c) $V_1 \neq \emptyset$ *and* $V_m \neq \emptyset$.

(d) $(S_i \cap S_{i+1}) \setminus S_1 \neq \emptyset$ *and* $(S_{i-1} \cap S_i) \setminus S_m \neq \emptyset$ *for* $i = 2, \cdots, m-1$.

Proof. If $S_{i-1} \cap S_i = \emptyset$, then any two maximal cliques C_1, C_2 going through one of the sections $S_1, \cdots, S_{i-1}$ and $S_i, \cdots, S_m$, respectively, have only vertices in common that are above N in T. Hence, reversing the order of the maximal cliques going through

$S_i, \cdots, S_m$ and $S_1, \cdots, S_{i-1}$, respectively, gives another consecutive arrangement because of $m \geqq 3$. This contradicts the fact that only the reversal of the Q-node as a whole yields a consecutive arrangement. Hence (a) follows.

By definition of the sections, S_1 contains all the vertices that are in all the maximal cliques going through S_1 and some other S_j, but not those that occur in any other maximal clique. Since the S_j must also contain the respective vertices from S_1, this gives $S_1 = \bigcup_{j=2}^{m} (S_1 \cap S_j)$. The consecutiveness property implies $S_1 \cap S_j \subseteq S_1 \cap S_2$ for all $j \geqq 2$. Hence, $S_1 = S_1 \cap S_2$, which shows (b) for S_1. The proof for S_m is completely analogous.

Let C_1, C_2 be maximal cliques through S_1, S_2, respectively. Then $C_1 \backslash C_2 \neq \emptyset$ because of the maximality. All vertices above N in T belong to $C_1 \cap C_2$, and all vertices in $C_1 \cap V_N = S_1$ belong to $C_2 \cap V_N = S_2$ because of (b). So, $C_1 \backslash C_2 \subseteq V_1$, which gives $V_1 \neq \emptyset$, and also, by symmetry, $V_m \neq \emptyset$.

Assume that $(S_i \cap S_{i+1}) \backslash S_1 = \emptyset$, i.e., $S_i \cap S_{i+1} \subseteq S_1$. Then reversing the order of the maximal cliques going through $S_1, S_2, \cdots, S_i$ (there are at least two since $i \geqq 2$) gives another consecutive arrangement, since the overlapping condition with S_{i+1} is preserved. This contradicts the definition of a Q-node as in the proof of (a). □

3. Lexicographic breadth-first search. Lexicographic breadth-first search (LEXBFS for short) was introduced in [9] for the purpose of constructing perfect elimination schemes. LEXBFS is like the usual breadth-first search (BFS) with the additional rule that vertices with earlier visited neighbors are preferred.

More precisely, we say that $v, w \in V$ *disagree* on $u \in V$ is one of them is adjacent to u, but not both. Then LEXBFS produces an ordering $\lambda = [v_1, \cdots, v_n]$ of V with the property:

(3.1) If there is some v_i on which v_j, v_k with $i < j < k$ disagree, then the leftmost vertex on which they disagree is adjacent to v_j.

We will call this leftmost vertex that causes v_j to enter λ before v_k the *distinguisher* of v_j with respect to v_k.

THEOREM 3.1 [9]. *Let $G = (V, E)$ be a graph.*

(a) *A* LEXBFS*-ordering $\lambda = [v_1, \cdots, v_n]$ of G can be obtained in $O(|V|+|E|)$ time.*

(b) *G is triangulated if and only if $\delta = \lambda^R = [v_n, v_{n-1}, \cdots, v_1]$ is a perfect scheme. This can be tested for in $O(|V|+|E|)$ time.*

For implementation details (which are not too involved), we refer to [9], [4]. An example is given in Fig. 3.

We will show now that any LEXBFS traverses the *MPQ*-tree of a graph in a very special way. This feature will be exploited by our recognition algorithm.

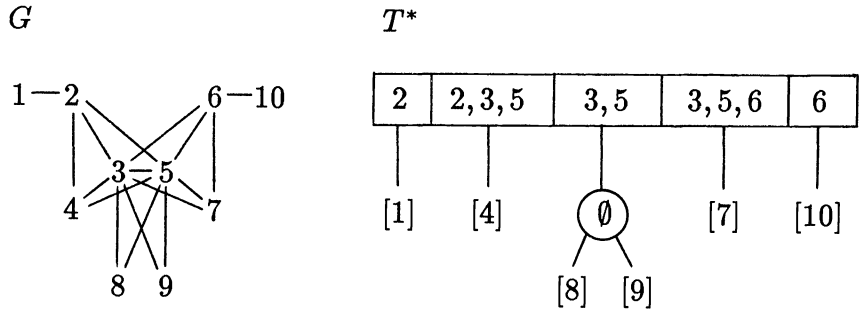

FIG 3. *A* LEXBFS*-ordering of an interval graph and the associated MPQ-tree.*

LEMMA 3.2. *Let $G=(V, E)$ be an interval graph, and let T be its associated MPQ-tree. Let N be a Q-node with sections $S_1, \cdots, S_m$ (in this order) and let V_i denote the set of vertices of G occurring below S_i in T.*

Then for any LEXBFS*-ordering λ, the rightmost vertex of $\bar{V} := S_1 \cup V_1 \cup \cdots \cup S_m \cup V_m$ with respect to λ is a member of V_1 or V_m.*

Proof. We will consider certain points or stages in the construction of λ. These stages occur when all vertices from $\bar{V} := \bigcup_{i=1}^{m} (S_i \cup V_i)$ that are forced by some earlier distinguisher have been visited, and the next distinguisher for vertices of $\bar{V}$ becomes active, i.e., determines the choice of the next vertices from $\bar{V}$ to be visited. We will show the following properties for each such stage:

(3.2) The already completely visited sets $S_i \cup V_i$ form a consecutive subsequence of $S_1 \cup V_1, \cdots, S_m \cup V_m$.

(3.3) If, at the current stage, $S_1 \cup V_1$ and $S_m \cup V_m$ are not completely visited, then at most one of them is completely visited at the next stage.

Obviously, (3.2) and (3.3) imply that the last vertex $v \in \bar{V}$ to be visited by λ belongs either to $S_1 \cup V_1$ or to $S_m \cup V_m$. Since $S_1 \subseteq S_2$ and $S_m \subseteq S_{m-1}$ (Lemma 2.2(b)), S_1 and S_m are then already completely visited. So $v \in V_1$ or $v \in V_m$, proving the lemma.

So it remains to show (3.2) and (3.3). We will do this by induction along the different stages. To start with, let u_1 be the first vertex in λ that disagrees on vertices from $\bar{V}$, i.e., u_1 is adjacent to some, but not to all vertices from $\bar{V}$. Since all vertices in an ancestor of node N are adjacent to all $v \in \bar{V}$, it follows that $u_1 \in \bar{V}$ and that u_1 is the first distinguisher for vertices from $\bar{V}$. So from $\bar{V}$, $\mathrm{Adj}(u_1)$ enters λ before any $v \in \bar{V} \backslash \mathrm{Adj}(u_1)$. If $u_1 \in \bar{S} := S_1 \cup \cdots \cup S_m$, then $\mathrm{Adj}(u_1) \cap \bar{V} = \bigcup_{u_1 \in S_i} (S_i \cup V_i)$, and these $S_i \cup V_i$ are consecutive. So (3.2) holds. Since u_1 is not adjacent to all $v \in \bar{V}$, we have $u_1 \notin S_1 \cap S_m$, which implies that V_1 or V_m still contains unvisited vertices after $\mathrm{Adj}(u_1)$ has been added to λ. This shows (3.3). If $u_1 \notin \bar{S}$, then u_1 is in some V_{i_0} (since all vertices above N are adjacent to every $v \in \bar{V}$). Then $\mathrm{Adj}(u_1) \cap \bar{V} \subseteq S_{i_0} \cup V_{i_0}$ and either no $S_i \cup V_i$ (if the inclusion is strict) or exactly $S_{i_0} \cup V_{i_0}$ has been completely visited after $\mathrm{Adj}(u_1)$ is added to λ. So (3.2) and (3.3) hold. Together, the cases $u_1 \in \bar{S}$ and $u_1 \notin \bar{S}$ yield the inductive base for the first stage.

So assume now that (3.2) and (3.3) were valid at the last stage, and that $u_1, \cdots, u_k$ are the previous distinguishers. Then, at the last stage, $\mathrm{Adj}(u_k) \cap \bar{V}$ was added to λ before any vertex $v \in \bar{V} \backslash \bigcup_{j=1}^{k} \mathrm{Adj}(u_j)$. Let $S_{i_0} \cup V_{i_0}, \cdots, S_{j_0} \cup V_{j_0}$ be the already completely visited sets after $\mathrm{Adj}(u_k)$ has been added to λ. We distinguish several cases.

Case 1. $i_0 = 1$, i.e., $S_1 \cup V_1$ is already completely visited. If $j_0 = m-1$, then only $S_m \cup V_m$ contains unvisited vertices and these are contained in V_m since $S_m \subseteq S_{m-1}$ and S_{m-1} is completely visited. So we may assume that $j_0 \leqq m-2$. Because of Lemma 2.2(a), $S_{j_0} \cap S_{j_0+1} \neq \emptyset$. For every $v \in S_{j_0} \cap S_{j_0+1}$, let $S_{r(v)}$ be the rightmost section containing v. We call $r(v)$ the *right range* of v. Let r be the minimum right range of a vertex $v \in S_{j_0} \cap S_{j_0+1}$. Any vertex $u \in S_{j_0}$ with $r(u) = r$ is said to have a *short right range.* By definition, $r > j_0$. Lemma 2.2(d) implies that $r < m$, i.e., every vertex u with short right range is not adjacent to any unvisited vertex from $(S_{r+1} \cup V_{r+1}) \cup \cdots \cup (S_m \cup V_m)$. Now consider two unvisited vertices $v_i \in S_i \cup V_i$ with $j_0 < i \leqq r$ and $v_j \in S_j \cup V_j$ with $j > r$. Then (3.2) and the definition of r imply that the only already visited vertices that disagree on v_i and v_j are vertices $u \in S_{j_0}$ with short range. So the first such u in λ is a distinguisher that forces all unvisited vertices from $\bigcup_{i=j_0+1}^{r} (S_i \cup V_i)$ to enter λ because of (3.1). This shows (3.2) and also (3.3) because of $r < m$.

Case 2. $j_0 = m$. This case is completely symmetric to the previous one.

Case 3. $i_0 = 2$ and $j_0 = m-1$. Then, only $S_1 \cup V_1$ and $S_m \cup V_m$ contain unvisited vertices from $\bar{V}$. Because of Lemma 2.2(a) these must belong to $V_1 \cup V_m$, which proves the lemma in this case.

Case 4. ($i_0 > 2$ and $j_0 \leqq m-1$) or ($i_0 \geqq 2$ and $i_0 < m-1$). Similar to Cases 1 and 2, we consider vertices $u \in S_{j_0} \cap S_{j_0+1}$ with short right range r and vertices $w \in S_{i_0-1} \cap S_{i_0}$ with short left range l. The assumptions on i_0 and j_0 guarantee that $l > 2$ or $r < m$. If $l > 2$ and $r < m-1$, then the first vertex in λ with short right or left range is the next distinguisher u_{k+1} that forces at least the sets $S_i \cup V_i$ in its short range to enter λ and possibly also on the other end if $l = l(u_{k+1})$ and $r = r(u_{k+1})$. So (3.2) and (3.3) hold. If $l > 2$ and $r = m-1$, then the first vertex with short left range or with neighbors in V_m but not in V_1 is the next distinguisher, and (3.2) and (3.3) follow. The final case $l = 2$ and $r < m-1$ is completely symmetric. □

In the example graph in Fig. 3, the stages are as follows. The first distinguisher is $u_1 = 1$, and it forces $S_1 \cup V_1 = \{1, 2\}$ into λ. Then $u_2 = 2$ is the first vertex with short right range $r = 2$. It forces $S_2 \cup V_2 = \{2, 3, 4, 5\}$ to enter λ. Then $u_3 = 3$, forcing $S_3 \cup V_3 \cup S_4 \cup V_4 = \{6, 7, 8, 9\}$ to enter λ. Finally, $u_4 = 6$, forcing $v = 10 \in V_m$ into λ.

Call a maximal clique C of G an *outer clique* if there is a consecutive arrangement of the maximal cliques of G with C as first (or last) clique. All maximal cliques that are not outer cliques are called *inner cliques*. If LEXBFS is viewed as traversing maximal cliques rather than vertices (a clique is traversed when its last vertex has been traversed), the maximal cliques for a vertex are not necessarily traversed consecutively (for example, vertex 6 of Fig. 3). But Lemma 3.2 implies that any such traversal ends with an outer clique. The following theorem gives a stronger version of this conclusion.

THEOREM 3.3. *Let $G = (V, E)$ be an arbitrary graph with associated* LEXBFS*-ordering $\lambda = [v_1, \cdots, v_n]$, and let G_i denote the subgraph of G induced by $V_i = \{v_1, \cdots, v_i\}$.*

Then G is an interval graph if and only if, for each $i = 1, \cdots, n-1$, G_i is an interval graph and $\mathrm{Adj}(v_{i+1}) \cap V_i$ *is contained in an outer clique of G_i. In this case, v_{i+1} is a simplicial vertex of G_{i+1}.*

Proof. If G is an interval graph then, by heredity, each G_i is an interval graph, and thus triangulated. Furthermore, $\lambda_{i+1} := [v_1, \cdots, v_{i+1}]$ is a LEXBFS-ordering for G_{i+1} and thus, by the results of [9], v_{i+1} is a simplicial vertex of G_{i+1}, i.e., it is contained in a unique maximal clique C of G_{i+1}. By Lemma 3.2, C is an outer clique of G_{i+1}. Since v_{i+1} is simplicial, $\mathrm{Adj}(v_{i+1}) \cap V_i \subseteq C$.

In the converse direction, suppose that G_i is an interval graph (which is trivial for $i = 1$) and $\mathrm{Adj}(v_{i+1}) \cap V_i$ is contained in an outer clique of G_i. Then there is a consecutive arrangement $C_1, \cdots, C_m$ of the maximal cliques of G_i with $C_0 := \mathrm{Adj}(v_{i+1}) \cap V_i \subseteq C_1$. Then either $C_1 \cup \{v_{i+1}\}, C_2, \cdots, C_m$ (if $C_0 = C_1$) or $C_0 \cup \{v_{i+1}\}, C_1, C_2, \cdots, C_m$ (if $C_0 \subset C_1$) is a consecutive arrangement of the maximal cliques of G_{i+1}. Thus, G_{i+1} is an interval graph with simplicial vertex v_{i+1}. The iterative application of this argument then yields that $G_n = G$ is an interval graph. □

Note that it is not necessary to know whether G is triangulated or not. Furthermore, Lemma 3.2 and the theorem do not hold for other graph-search orderings λ yielding perfect schemes (such as the simple maximal cardinality search considered in [11]). BFS together with lexicographical tie breaking are essential for these results.

4. The algorithm for growing the *MPQ*-tree. Theorem 3.3 is the basis for an incremental algorithm that traverses G in a LEXBFS-ordering and iteratively builds the *MPQ*-tree T_{i+1} representing G_{i+1} from the *MPQ*-tree T_i for G_i if G_{i+1} is an interval

graph (i.e., if v_{i+1} has only neighbors in some outer clique of G_i), or states that G_{i+1} (and thus $G = G_n$) is not an interval graph.

Each such *building step* consists of two phases, a *labeling phase*, and a *tree-updating phase.*

In the labeling phase, each node N (including Q-nodes) of the current tree T and each section S of a Q-node is labeled according to how the new vertex u is related to the vertices of N or S. The label is ∞, 1, or 0 if u is adjacent to all, some, or no vertex from N or S, respectively. Empty sets obtain the label 0. Labels 1 and ∞ are called *positive* labels. Note that a Q-node has a label for itself and for each of its sections. These labels will be used for testing the condition that u is adjacent only to vertices from an outer clique of the current graph.

LEMMA 4.1. *Let G be an interval graph, let T be its associated MPQ-tree, and let u be a vertex to be added to G. Then $G+u$ is an interval graph if and only if* (a) *and* (b) *hold*:

(a) *All nodes with a positive label are contained in a unique path of T.*

(b) *For each Q-node N with positive label, $\mathrm{Adj}(u) \cap V_N$ is contained in an outer section of Q.*

The proof follows immediately from Theorem 3.3. Note that (b) does not imply that only the outer section S has a positive label. There may be others, but all vertices in them that are adjacent to u are also contained in S. So, in particular, the sections with a positive label are consecutive and have label 1, except the outer section, which has label 1 or ∞.

If the labeling phase is affirmative (i.e., $G+u$ is an interval graph), then the new *MPQ*-tree $T(G+u)$ of $G+u$ is obtained by modifying $T(G)$ in the updating phase. This modification is *local* with respect to $T(G)$, as is shown by Lemma 4.2 below.

We use the following notation in the updating phase. G is the given graph, and $T(G)$ is its *MPQ*-tree. The vertex to be added is u, and $\mathrm{Adj}(u)$ is its set of adjacent vertices in G. We will omit the trivial case $\mathrm{Adj}(u) = \emptyset$, in which the tree updating can obviously be carried out in constant time (even the labeling phase can be omitted). Let P' denote the unique path of $T(G)$ containing all nodes with positive label, and let P be a path from the root to a leaf containing P'. There are several possible choices for P if P' does not contain a leaf of $T(G)$, but because of Lemma 4.1, P can be chosen such that it corresponds to a maximal outer clique C of G. Let N_* be the lowest node in P with label 1 or ∞. If P contains nonempty P-nodes or sections above N_* with label 0 or 1, let N^* be the highest such P-node or Q-node containing the section. Otherwise put $N_* = N^*$.

LEMMA 4.2. *In the above situation, exactly one of the two following cases applies*:

Case (a) *All nonempty P-nodes and sections on P have label ∞. Then in $G+u$, the maximal clique C of G is replaced by $C+u$. $T(G+u)$ is obtained from $T(G)$ by adding u to the leaf of P.*

Case (b) *There are nonempty P-nodes or sections or a leaf on P with label* 0 *or* 1. *Then in $G+u$, the maximal clique $\mathrm{Adj}(u) \cup \{u\}$ is added, and $T(G+u)$ is obtained from $T(G)$ by modifying only nodes between N_* and N^* on P (including N_*, N^*).*

Proof. Case (a) is obvious. Case (b) follows by observing that the set of cliques of $G+u$ differs from that of G only by adding the new maximal clique $C_0 := \mathrm{Adj}(u) \cup \{u\}$. This affects C and all maximal cliques of G that have a nonempty intersection with $\mathrm{Adj}(u) \subseteq C$. However, vertices belonging to nodes N not on P or below N_* or above N^* are either adjacent to no $v \in \mathrm{Adj}(u)$, or to all such v. So only vertices belonging to nodes between N_* and N^* must be reorganized. □

The construction of $T(G+u)$ in Case (a) is obvious. In Case (b), the modification is done by traversing the path P bottom-up from N_* to N^*.

In each step, the current node N (together with its associated sets and its label) is compared with a small number of patterns that trigger the appropriate modification of N. The combination of pattern recognition and modification is called a *template*. There are three groups of templates, depending on whether the current node N is a leaf, a P-node, or a Q-node. Each group has a template for up to three subcases, depending on whether or not $N = N_*$, $N_* \neq N^*$, etc. These groups of templates are displayed in Figs. 4–6. In all cases, $V_N = A \cup B$ denotes the partition of the vertex set V_N of the current node or section into the set A of vertices adjacent to u and the set B of vertices not adjacent to u. Furthermore, T_i and T_i' always denote subtrees of

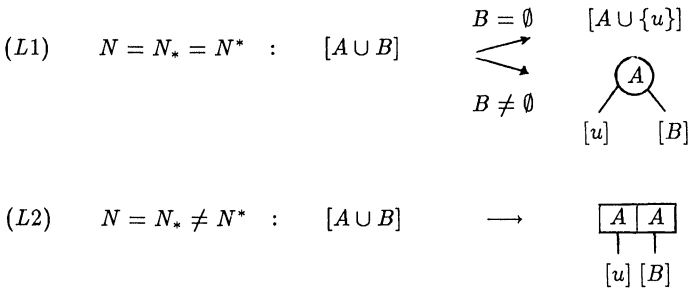

FIG. 4. *Templates for a leaf.*

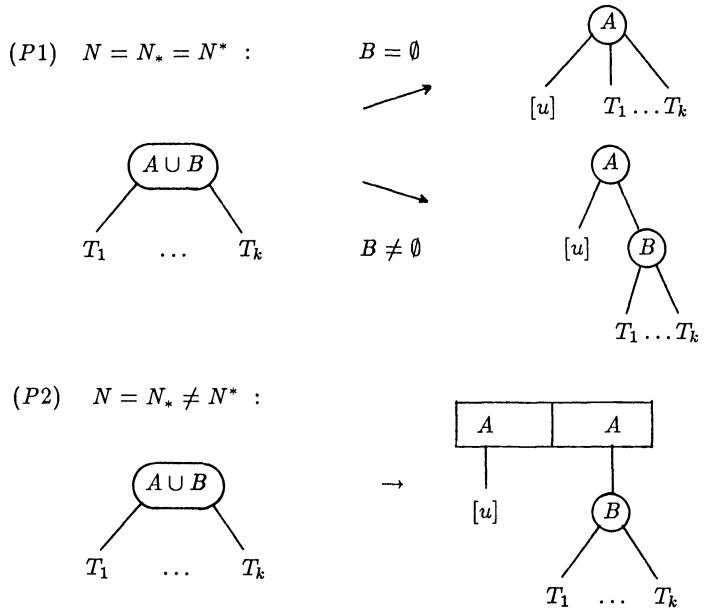

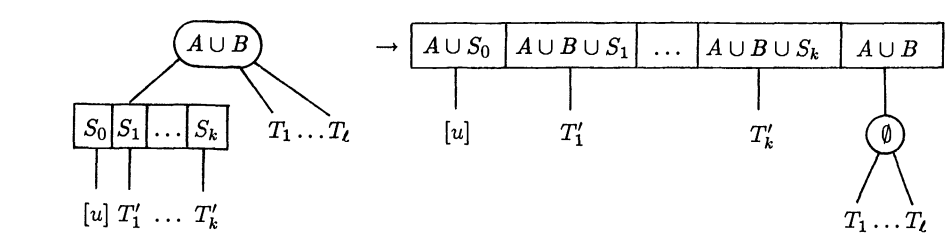

FIG. 5. *Templates for a P-node.*

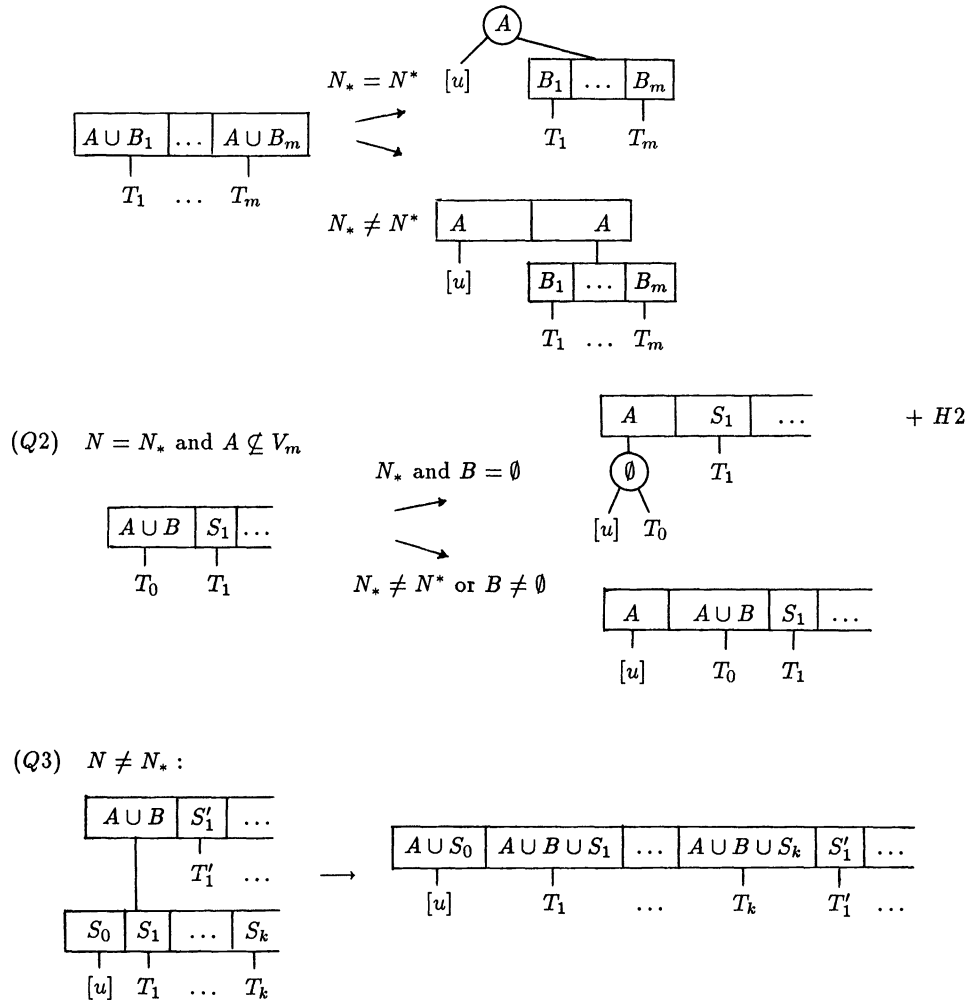

FIG 6. *Templates for a Q-node.*

$T(G)$ that contain only nodes with label 0. (This is an immediate consequence of Lemma 4.1.) $H1$ and $H2$ are help-templates that deal with special cases such as only one son, etc. They are displayed in Fig. 7. Note that template $(L1)$ is designed so as to also cover Case (a) in Lemma 4.2.

THEOREM 4.3. *The application of the templates along the path P from* N_* *to* N^* *correctly produces* $T(G+u)$.

Proof. It is easily seen that the templates cover all formally distinct cases. Also, all templates for the case $N_* = N^*$ and the help-templates $H1$ and $H2$ are easily shown to be correct.

Now consider the case $N_* \neq N^*$. Since N_* has the label 1 or ∞, the associated set A_* is nonempty. Similarly, the set B^* associated with N^* is nonempty. Let B^0 denote the set of vertices associated with nodes that are below N^* but not on P (which exist since N^* is not a leaf).

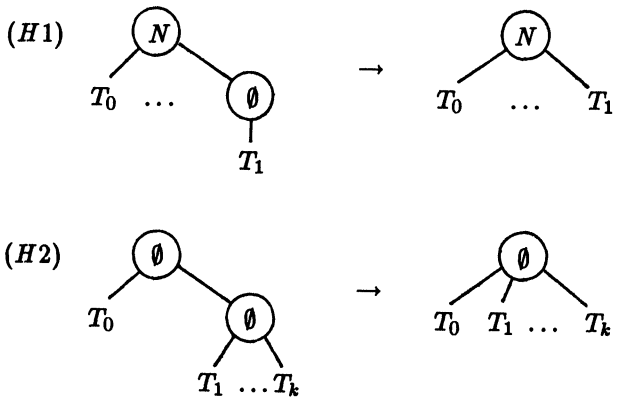

FIG. 7. *Help-templates* (H1) *and* (H2).

Let $\mathcal{C}_1$, $\mathcal{C}_2$, $\mathcal{C}_3$ denote the collections of maximal cliques of $G+u$ containing $A_* \cup \{u\}$, $A_* \cup B^*$, and $B^* \cup B^0$, respectively. Obviously, they must be represented by a Q-node in $T(G+u)$. Let $\bar{Q}$ be this Q-node. The first section of $\bar{Q}$ is the union of all sets A associated with the nodes or sections between N_* and N^*. Furthermore, $\bar{Q}$ contains an inner section S_N for each node N between N_* and N^* (including N_*, N^*), where S_N is the union of all sets A associated with nodes or sections between N and N^* on the path P. Other inner sections may occur by "gathering" sections from Q-nodes N between N_* and N^*. Finally, the last section has the associated vertex set $A^* \cup B^*$ of N^*.

The templates $L2$, $P2$, $Q1$ a) and $Q2$ a) (Figs. 4–6) construct the first part of this Q-node and return it as input for the next template. Inductively, the remaining templates on the path from N_* to N^* construct the complete Q-node. Although straightforward, the details are rather tedious, and therefore omitted. □

COROLLARY 4.4. *If $N_* \neq N^*$, then all nodes properly between N_* and N^* on the path P in $T(G)$ will become inner sections of a Q-node in $T(G+u)$.*

As an example, consider the interval graph in Fig. 3. Using the given LEXBFS, the following templates are applied (the notation is "added vertex: templates-added vertex," etc., the starting graph is the graph with vertex 1) 2: $L1$-3: $L1$-4: $L1$-5: $L1$-6: $L2$, $P3$, $H1$-7: $L1$-8: $Q2$-9: $P1$-10: $L2$, $P3$, $Q3$. This example also shows that while the Q-node $\bar{Q}$ of $T(G+u)$ is constructed, several sections may be equal or empty. This happens, e.g., when 10 is added and $P3$ is applied.

5. Implementation and complexity. In this section, we show that the above methods lead to an $O(|V|+|E|)$ algorithm for recognizing whether a given graph $G=(V, E)$ is an interval graph and for producing its associated MPQ-tree $T(G)$ if it is.

To achieve this complexity, we must use a good data structure for MPQ-trees. We assume that the children $N_1, \cdots, N_k$ of a P-node N are kept in a doubly linked circular list. Each N_i has a parent pointer to N, and N has a child pointer to one N_i. The sections $S_1, \cdots, S_m$ of a Q-node N have a pointer to their neighbor sections (so inner sections have two, while outer sections have only one). N has child pointers only to the outer sections S_1 and S_m, and only these have a parent pointer to N. Each section S_i has a pointer to its son. Each node has a parent pointer to its father (which is a P-node or a section of a Q-node). With each node or section, the associated set of vertices is given by a doubly linked circular list. Vertices contained in several sections

of a Q-node are included only in the lists belonging to the rightmost and the leftmost of these sections. Each vertex in a list has a pointer to the associated node or section. Vertex positions are given by an array with, for each vertex v, two vertex pointers pointing to the one or two list locations in which v occurs. Using this array, we have access to the node and/or sections containing a vertex v, the position of v in the associated list(s), and the type of the node in $O(1)$ time.

As was mentioned in § 3, a LEXBFS-ordering of G can be produced in $O(|V|+|E|)$ time. Consider now a labeling phase. For each $v \in \text{Adj}(u)$, we do the following:

A1. Find the associated node N (leaf, P-node or Q-node).
A2. If N is a Q-node, check whether one of the two sections pointed at is an outer section by looking at the neighbor pointers.
A3. Remove v from the element list associated with N or the outer section and insert it in a new list (that represents the set A).
A4. Put the node N or the outer section on a queue QU.

Altogether, this takes $O(|\text{Adj}(u)|)$ time. In particular, we have (in Step A2) already checked condition (b) of Lemma 4.1. If condition (b) is fulfilled we have two lists for each node or outer section with positive label: the new list representing the set A, and the modified old list representing the set B.

In order to check condition (a) of Lemma 4.1, we do the following until QU is empty:

B1. Delete N (a leaf, P-node or outer section) from the front of QU.
B2. If N is unmarked (initially all N on QU are unmarked), mark it and add its father (unmarked) at the rear of QU. Keep a pointer from the father to N.

When QU is empty, all nodes initially on QU and their ancestors have been marked and are kept (by the introduced pointers) in a rooted tree whose root is equal to the root of the MPQ-tree. Obviously, condition (a) of Lemma 4.1 is satisfied if and only if this rooted tree is a path, i.e., if and only if each node has at most one son. This can be checked by traversing it downward from the root in $O(1)$ time per node. Also in $O(1)$ time, we can check whether the associated set B is empty (i.e., the node/section has label ∞), and thus find N^*. Finally, N_* is the leaf of the rooted tree (if it is a path). Concerning the complexity, we have the following lemma.

LEMMA 5.1. *Testing whether condition* (b) *of Lemma* 4.1 *holds takes* $O(|\text{Adj}(u)|)$ *time. Testing whether condition* (a) *holds takes* $O(\#\ \text{nodes of}\ T) = O(|V|)$ *time if* (a) *is false, and* $O(n_0 + |\text{Adj}(u)|)$ *time if* (a) *is true, where* n_0 *denotes the number of nodes/sections with label* 0 *between* N_* *and* N^*.

Since the algorithm stops if (a) is false, the "bad" complexity of $O(|V|)$ occurs only once and thus does not destroy the overall complexity of $O(|V|+|E|)$ at which we aim. So in the sequel, we will assume that (a) and (b) always hold.

Our complexity analysis uses the notion of *amortized time* introduced in [10]. Its definition involves the assignment of a potential to the states that occur after certain steps of the algorithm. Here, a *step* is a joint labeling and updating phase. The *potential* after a step depends on the current MPQ-tree T and is defined as

$$\text{(5.1)}\quad \text{Pot}(T) := \#\ \text{nodes} + \#\ \text{outer sections} + \sum_{N \text{ is a leaf or a } P\text{ node}} 2 \cdot |V_N| + \sum_{S \text{ is an outer section}} |S|.$$

The *potential difference* $\Delta(s)$ of a step s is the difference of the potentials after the previous step and after s. Then the *amortized time* $AT(s)$ of step s is defined as $AT(s) = RT(s) + c \cdot \Delta(s)$, where $RT(s)$ is the *real time* required by step s and c is a

suitable positive constant (which will be specified later). In the beginning of the algorithm, the potential is 0; in the end it is nonnegative and equal to the sum of the $\Delta(s)$ over all steps. So summing up over all steps s, we obtain

$$\begin{aligned} \sum_s AT(s) &= \sum_s RT(s) + \sum_s \Delta(s) \\ &\geqq \sum_s RT(s) = \text{total real time.} \end{aligned} \tag{5.2}$$

Thus it suffices to consider only the amortized time per step s. Divide s into the labeling part s_1 and the updating part s_2. Then $RT(s_1) \leqq c_1 \cdot (n_0 + |\text{Adj}(u)|)$ with some constant c_1 because of Lemma 5.1, and $\Delta(s_1) = 0$ since the tree does not change in s_1. Now consider the updating part s_2 of step s.

The application of a template involves *recognition* of which template applies, *modification of the tree structure*, and an *update of the vertex sets* associated with tree nodes and sections.

The tree modification can obviously be carried out in $O(1)$ time per template.

Recognition requires knowing whether $N_* = N^*$, $N = N_*$, and, for $(Q1)$-$(Q3)$ whether or not $A \subseteq S_m$ and $B = \emptyset$. The first two tests can be done in constant real time per node N along the path, since N_* and N^* are known from the labeling phase. Testing whether $A \subseteq S_m$ can be done in $O(|A|)$ time by traversing the list representing A (which is available from the labeling phase) and using the array of vertices to check whether $u \in S_m$ for each $u \in A$. So for all sets A along the path in T, this takes real time proportional to $|\text{Adj}(u)|$. Finally, testing whether $B = \emptyset$ takes constant time per node, since B is available as list from the labeling phase.

Updating the vertex sets requires adjusting the vertex pointers from the vertices in $A \cup B$, and in cases in which a P-node is changed into a Q-node, making a copy of the sets A and B.

If possible, *adjustment of vertex pointers* is done in such a way that only vertices from A need to be considered (this is the case for $(L1)$, $(L2)$, $(P1)$, $(P2)$, and $(Q1)$). So in these cases, the real time for pointer adjustments is proportional to $|A|$, and thus to $|\text{Adj}(u)|$ along the path from N_* to N^*. In all other cases, the vertices from B are assigned to an inner section of the new Q-node. This reduces Pot (T) by $|B|$, since B was either contained in a leaf or P-node or in an outer section.

Similarly, copying all lists A along the path from N_* to N^* takes real time proportional to $|\text{Adj}(u)|$, while copying lists B also reduces the potential by $|B|$, since these vertices belong to inner sections of Q-nodes.

Altogether this shows that the real time per template can be subdivided into a constant amount c_1 plus an amount $c_2 \cdot |A|$ plus $c_3 \cdot |B|$. So along the path from N_* to N^*, this takes real time $c_2(n_0 + |\text{Adj}(u)|) + c_3 \cdot |\text{Adj}(u)| + c_4 \cdot |\bar{B}|$, where $\bar{B}$ is the union of all sets B for which vertex pointers must be adjusted or that must be copied. At the same time, the potential is reduced by $n_0 - 1 + |B|$, since all nodes properly between N_* and N^* become inner sections because of Corollary 4.4, and since the elements from B are moved from a P-node, leaf, or outer section into an inner section.

So choosing $c \geqq \max\{c_1 + c_2, c_3, c_4\}$, we obtain

$$\begin{aligned} AT(s) &= RT(s_1) + \Delta(s_1) + RT(s_2) + \Delta(s_2) \\ &\leqq (c_1 + c_2) \cdot (n_0 + |\text{Adj}(u)|) + c_3 \cdot |\text{Adj}(u)| + c_4 \cdot |\bar{B}| \\ &\quad - c \cdot (n_0 - 1) - c \cdot |\bar{B}| \\ &\leqq c \cdot (|\text{Adj}(u)| + 1). \end{aligned} \tag{5.3}$$

So altogether, we have the following.

THEOREM 5.2. *If $G+u$ is an interval graph, then constructing its MPQ-tree $T(G+u)$ from $T(G)$ takes $O(|\mathrm{Adj}\,(u)|+1)$ amortized time.*

COROLLARY 5.3. *Testing whether a given graph $G=(V, E)$ is an interval graph and constructing its MPQ-tree is possible in $O(|V|+|E|)$ time.*

Proof. The above complexity analysis gives Theorem 5.2. The total real time in the corollary is bounded by t_1+t_2, where t_1 is the time to recognize at some step that G is not an interval graph and where t_2 is the time required in the other steps. Lemma 5.1 yields $t_1=O(|V|)$, and (5.1), together with Theorem 5.2, yields

$$t_2 \leqq \sum_s AT(s) \leqq \sum_{u\in V} c\cdot(|\mathrm{Adj}\,(u)|+1)=O(|V|+|E|). \qquad \square$$

Concerning space requirement, the algorithm requires only $O(n)$ space if the current next vertex u in the LEXBFS-scheme and its adjacency set are given. We also note that LEXBFS requires only partial knowledge of the graph in the sense that unvisited parts may still change as the search continues. This implies that it is not necessary to know the whole graph in advance, but only portions "compatible" with LEXBFS.

Note that we can obtain an on-line, $O(n)$ space algorithm by allowing for more complicated templates. This is achieved in [6] at the cost of a higher time complexity of $O(n^2)$.

Acknowledgment. We thank the referees for pointing out several weaknesses in an earlier proof of Lemma 3.2 and for bringing the application to gate matrix layout problems to our attention.

MINIMUM DELAY CODES*

LAWRENCE L. LARMORE†

Abstract. Huffman's algorithm finds a prefix-free binary code on a weighted alphabet which minimizes the expected length of the code string for a single symbol. A definition is given for the *expected delay* for a prefix-free binary code on a weighted alphabet: it is the expected time between a request to transmit the symbol and the completion of that transmission, assuming a channel with fixed capacity, where requests are queued. An $O(n^5)$-time $O(n^3)$-space *convex hull* algorithm is given that finds a code of minimal expected delay, where n is the size of the alphabet. It is conjectured that the algorithm has substantially lower time and space complexities in the worst case, and still lower in the average case.

The heart of the proof of polynomial time complexity is the *convex hull theorem*, which states that under certain conditions a binary tree that minimizes one penalty measure can be changed to a binary tree that minimizes a second penalty measure in a carefully controlled sequence of changes called *elementary shifts*.

Key words. coding, binary tree, convex hull, dynamic programming

AMS(MOS) subject classifications. 68P20, 68P25

1. Introduction. *Motivation.* This paper is the response to a question originated by Gopinath [3], and treated by Flores [1] in his dissertation. The classic Huffman coding problem is to find a prefix-free binary code[1] for a weighted alphabet, which minimizes the expected time to transmit a symbol. If the goal is to maximize information transmitted over a channel, the expected length of one code string is the correct penalty measure that needs to be minimized. But suppose that what is desired is to minimize the expected waiting time between the request to transmit a symbol and the completion of that transmission. We call that quantity *delay*, and it is the sum of two components: the time the symbol waits on a queue if the channel is busy, and the actual time to transmit the code. The expected delay $\bar{d}$ is thus the sum of two quantities: one is the expected length of a code string, and the other depends on the distribution of arrival times of requests. (We assume that the channel transmits bits at the rate of one per unit time.) If arrivals are independent, the arrival times have a Poisson distribution, and standard queueing theory techniques show that

$$\bar{d} = \frac{\lambda \bar{l}^2}{2(1-\lambda \bar{l})} + \bar{l}$$

where λ is the expected number of requests per unit time, $\bar{l}$ is the expected length of a code string, and $\bar{l}^2$ is the expected value of the square of the length of a code string [1]. Huffman's classic algorithm [6] finds a code that minimizes $\bar{l}$ in $O(n \log n)$ time, actually linear time if the frequencies are presorted [8]. Finding a code that minimizes expected delay is much harder. In fact, up until now, no polynomial-time algorithm was known.

Preliminaries. We let n be the size of the source alphabet, and ϕ_i the frequency of its ith symbol. The alphabet can first be sorted by frequency; thus we can assume

* Received by the editors October 7, 1987; accepted for publication (in revised form) April 7, 1988.

† California State University, Dominguez Hills, California. Present address, Department of Information and Computer Science, University of California, Irvine, California 92717.

[1] A code is *prefix-free* if no code string is a proper prefix of any other. The advantage of a code being prefix-free is that a coded message can be uniquely decoded. For example, if $a \to 0$, $b \to 11$, and $c \to 10$, the string 0100011100 can be uniquely decoded as *acaabca*.

$\phi_i \geqq \phi_{i-1}$. A prefix-free binary code corresponds to a binary tree[2] of size n. If $T = (l_1, \cdots, l_n)$ is such a tree, define

$$\bar{l} = \bar{l}(T) = \sum_{i=1}^{n} \phi_i l_i, \qquad \bar{l}^2 = \bar{l}^2(T) = \sum_{i=1}^{n} \phi_i l_i^2,$$

$$\bar{d} = \bar{d}(T) = \frac{\lambda \bar{l}^2(T)}{2(1-\lambda \bar{l}(T))} + \bar{l}(T).$$

The *minimum delay problem* is then to find a binary tree T for which $\bar{d}(T)$ is minimized, subject to the condition that $\lambda \bar{l}(T) < 1$.

Plotting trees in a plane. Only trees for which $l_i \geqq l_{i-1}$ need be considered, since a tree that does not satisfy that monotonicity condition can always be replaced by a tree at least as good which does (see, for example, [1]). Abstractly, the minimum delay problem can be solved geometrically. Plot each T in the plane as the point $(\bar{l}(T), \bar{l}^2(T))$, and let $\mathcal{P}$ be the set of all those plotted points. It is possible for two distinct trees T and T' to be plotted to the same point: if so, we say that T and T' are *equivalent.* Let

$$f(x, y) = \frac{\lambda y}{2(1-\lambda x)} + x.$$

The minimum delay tree T^{opt} then is plotted as a point $P^{\text{opt}} \in \mathcal{P}$ in the region $0 < x < 1/\lambda$, $y > 0$, for which f is minimized. The level curves of f are parabolic, with negative first derivative and positive second derivative in that region. If a line is drawn through P^{opt} tangent to the level curve of f through that point, all other points of $\mathcal{P}$ will lie on or above the level curve, and hence above the tangent. (See Fig. 1.)

The convex hull. A set $C \subseteq \mathbf{R}^2$ is said to be *convex* if the line segment joining any two points of C lies entirely within C. If $S \subseteq \mathbf{R}^2$ is any set, $\mathrm{CH}(S)$, the *convex hull*

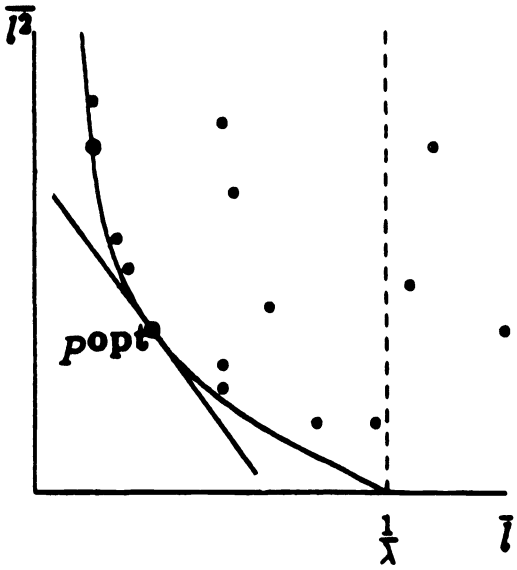

FIG. 1

[2] In this paper, a *binary tree* will be a full binary tree, i.e., each nonleaf node has exactly two children. Furthermore, a tree will be identified with the list consisting of the depths of its leaves, in left-to-right order.

of S, is defined to be the smallest convex set containing S. If S is finite, $\mathrm{CH}(S)$ is a polygon together with its interior.

Let $H = \mathrm{CH}(\mathcal{P})$. The boundary of H is a closed polygonal curve. One of the vertices of this boundary will be $P_{x\text{-min}}$, which we define to be the point of $\mathcal{P}$ for which x is minimized, and another is $P_{y\text{-min}}$, which we define to be the point of $\mathcal{P}$ for which y is minimized. (If there are two or more points of $\mathcal{P}$ for which x is minimized, the one with minimum y is taken to be $P_{x\text{-min}}$; this is similar for $P_{y\text{-min}}$.) Let B be the portion of the boundary of H that lies to the lower left of H, a polygonal arc joining $P_{x\text{-min}}$ and $P_{y\text{-min}}$. We call *extremal points* of $\mathcal{P}$ vertices of B, and one of them must be P^{opt}. (See Fig. 2.)

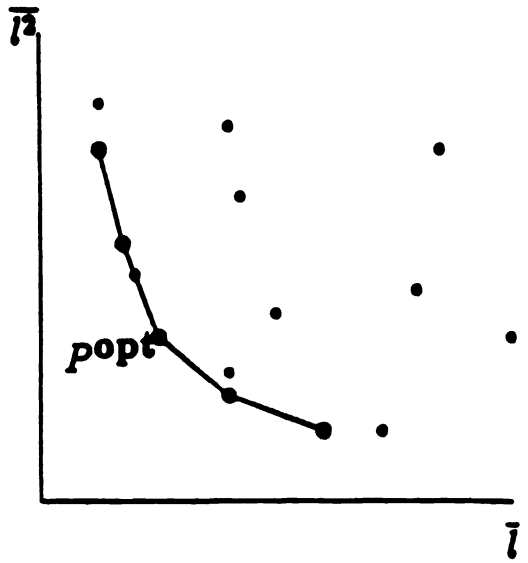

FIG. 2 *The polygonal path B.*

The convex hull algorithm finds all vertices of B and then simply determines which of them minimizes f by linear search. The time to find one vertex of B is $O(n^3)$, using a bottom-up approach similar to Garey's algorithm [2], and the number of vertices of B is $O(n^2)$ by the convex hull theorem given in § 5.

2. The convex hull algorithm. In this section, we give the details of the algorithm and the proof of correctness. Throughout, assume that a $\phi_1, \cdots, \phi_n$ are given, where ϕ_i is the frequency of the ith symbol of the source alphabet.

Outline of the method. The algorithm uses a subroutine we call *Find_Best*(α, β), which, for given $\alpha, \beta \geqq 0$, returns a tree T for which the quantity

$$\alpha \bar{l}(T) + \beta \bar{l}^2(T)$$

is minimized. If B has m vertices, all of those vertices may be found by executing *Find_Best* at most $4m+3$ times. Each call of *Find_Best* takes $O(n^3)$ time and uses $O(n^3)$ space, but the space can be reused for the next call.

The first step of the convex hull algorithm is to find a tree T_1 for which $\bar{l}(T)$ is minimized; either *Find_Best*$(1, 0)$ or Huffman's original algorithm can be used. The second step is to find a tree T_2 for which $\bar{l}^2(T)$ is minimized by calling *Find_Best*$(0, 1)$. The third step is a call to a recursive function *Span*, which produces a list of trees

whose plotted points in the graph include all vertices between two given points on the path B. Finally, linear search through those trees will locate T^{opt}. ("&" denotes concatenation of lists.)

THE CONVEX HULL ALGORITHM.
$T_1 \leftarrow$ *Find_Best*$(1, 0)$
$T_2 \leftarrow$ *Find_Best*$(0, 1)$
if T_1 and T_2 are equivalent **then**
    return T_1
else
    Candidate_List $\leftarrow (T_1)$ & *Span*(T_1, T_2) & (T_2)
    return some $T \in$ *Candidate_List* for which $\bar{d}(T)$ is minimized
end if

SPAN(T, T')
$\alpha = \bar{l}^2(T) - \bar{l}^2(T')$
$\beta = \bar{l}(T') - \bar{l}(T)$
$T'' \leftarrow$ *Find_Best*(α, β)
if $\alpha\bar{l}(T'') + \beta\bar{l}(T'') = \alpha\bar{l}(T) + \beta\bar{l}(T)$ **then**
    return *empty list*
else
    return *Span*(T, T'') & (T'') & *Span*(T, T'')
end if

Intuitively, *Span* works as follows. T is plotted above and to the left of T' in $\mathbf{R}^2$. Connect those two points by a line l, and find the lowest line l' parallel to l that meets $\mathcal{P}$. If $l' = l$, then T and T' both lie on B, and no vertices of B lie between them. Otherwise, some portion of B must meet l', and *Find_Best*(α, β) returns one point of B on l', although that point is not necessarily a vertex of B. (See Fig. 3.)

Correctness of the convex hull algorithm is guaranteed by the following lemma, whose proof we postpone to § 3:

LEMMA 2.1. (i) *Candidate_List contains all vertices of B.*

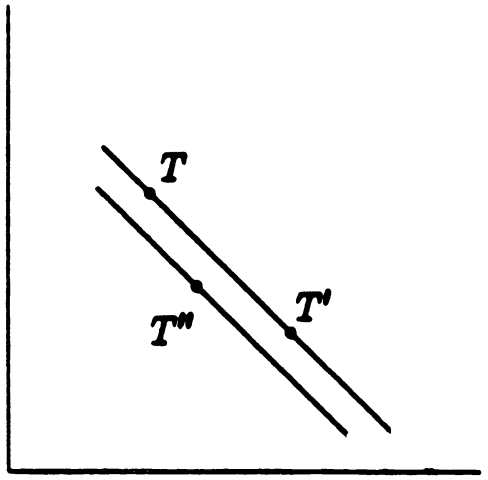

Fig. 3

(ii) *If m is the number of vertices of B, then the number of calls to Find_Best does not exceed $4m+3$.*

The following lemma is proved in § 5.

LEMMA 2.2. *If $\phi_i \leqq \phi_{i-1}$ for all i, the number of vertices of B does not exceed n^2.*

The time complexity of the convex hull algorithm is the time complexity of the subroutine *Find_Best*, multiplied by the number of calls of that subroutine. By Lemmas 2.1 and 2.2, the number of those calls is $O(n^2)$, if $\phi_i \leqq \phi_{i-1}$.

We now concentrate on the subroutine *Find_Best*(α, β). Let T be the tree that will be found by that subroutine, i.e., a tree for which α-β-*penalty*$(T) = \alpha \bar{l}(T) + \beta \bar{l}^2(T)$ is minimized.

The function g. For any pair i, j such that $1 \leqq i \leqq j \leqq n$, and for any $d \geqq 0$, we define $g(i, j, d)$ recursively, as follows:

$$g(i, i, d) = \alpha\phi_i d + \beta\phi_i d^2$$

$$\text{if } i < j, \text{ then } g(i, j, d) = \min\{g(i, k-1, d+1) + g(k, j, d+1) \mid i < k \leqq j\}.$$

If T has a subtree whose root is at depth d, and whose leaves are the ith through the jth leaves of T, then the contribution of that subtree to the α-β-penalty of T must be minimized, since T has minimum overall α-β-penalty. The recursive definition of g guarantees that $g(i, j, d)$ is that contribution. The α-β-penalty of T itself is $g(1, n, 0)$.

The values of $g(i, j, d)$ can then be computed dynamically, in order of increasing $j - i$. Since a subtree at depth d can have size at most $n - d$, g need only be computed for triples satisfying the condition $d \leqq n - j + i - 1$. There are $O(n^3)$ such triples, and (using linear search among all candidates for k) the time to compute $g(1, n, 0)$ is $O(n^4)$, and the space is $O(n^3)$.

Recovery of T. A system of pointers can be retained to recover the optimal tree T. If $i < j$, define $cut(i, j, d)$ to be that value of k for which the minimum is achieved in the recurrence portion of the definition of g. If there are multiple k's for which the minimum is achieved, $cut(i, j, d)$ is defined to be the smallest one. The values of *cut* are naturally computed during the dynamic algorithm, and if they are retained, the tree T can be recovered in $O(n)$ time.

The monotonicity lemma. Find_Best can actually be executed in $O(n^3)$ time by making use of the following lemma (similar to monotonicity lemmas used in [2] and [7], for example).

LEMMA 2.3 (Monotonicity Lemma). *If $j > i+1$, then*

$$cut(i, j-1, d) \leqq cut(i, j, d) \leqq cut(i+1, j, d).$$

We postpone the proof of the monotonicity lemma to § 4. The fact that the lemma reduces the computation time by an entire order of magnitude can be shown by an argument similar to that used by Knuth [7]. Let $N(i, j, d)$ be the number of candidates that need to be examined to determine $cut(i, j, d)$. The total time to execute *Find_Best* is dominated by the number of times such a candidate must be examined, which is

$$\sum_{i=1}^{n-1} \sum_{j=i+1}^{n} \sum_{d=0}^{n+j-i-1} N(i, j, d).$$

We have

$$N(i, i+1, d) = 1;$$

$$\text{if } j > i+1, \text{ then } N(i, j, d) = cut(i+1, j, d) - cut(i, j-1, d) + 1$$

by the monotonicity lemma. Substituting the values for $N(i, j, d)$ and canceling terms, we can see that the summation is $O(n^3)$.

Combining this result with Lemmas 2.1 and 2.2, we see that the convex hull algorithm has time complexity $O(n^5)$ if $\phi_i \leqq \phi_{i-1}$, since the search set for $cut(i, j, d)$ can be restricted to the range indicated by the monotonicity lemma.

3. Proof of Lemma 2.1. *Proof of Lemma* 2.1. We begin by making a claim, which we prove by induction.

CLAIM. *Suppose Span*(T, T') *is called and there are exactly* r *vertices of* B *that lie strictly between* T *and* T'. *Then Span*(T, T') *will find all those vertices, using at most* $4r+1$ *calls to Find_Best. Furthermore, at most* $4r-1$ *calls to Find_Best will be used if* $r>0$.

Proof of Claim. If $r=0$, one call to *Find_Best* will detect that there are no vertices of B strictly between T and T'. Now suppose $r>0$. Let T'' be the point returned by the top level call of *Find_Best* in the execution of *Span*(T, T'). Either T'' is itself a vertex of B, or lies in the interior of a line segment on B. Let r_0 be the number of vertices strictly between T and T'', and let r_1 be the number of vertices strictly between T'' and T'. We now consider the two cases. If T'' is a vertex of B, $r_0+r_1=r-1$. The number of calls already made is 1, the number of calls needed to find all vertices between T and T'' is at most $4r_0+1$, and the number of calls needed to find all vertices between T'' and T' is at most $4r_1+1$. Thus, the total number of calls does not exceed $4r-1$. On the other hand, suppose T'' lies in the interior of a line segment which is an edge of B. The endpoints of that edge must be vertices, both of which must be distinct from $\{T, T'\}$. It follows that $r_0>0$, $r_1>1$, and that $r=r_0+r_1$. The number of calls already made is 1, the number of calls needed to find all vertices between T and T'' is at most $4r_0-1$, and the number of calls needed to find all vertices between T'' and T' is at most $4r_1-1$. Thus, the total number of calls does not exceed $4r-1$.

The convex hull algorithm makes two initial calls to *Find_Best*. By the claim, no more than $4m+1$ additional calls are needed. This concludes the proof of Lemma 2.1.

4. The monotonicity lemma. Let g be the function introduced in § 2, with fixed choice of α and β. We first need a technical lemma.

LEMMA 4.1.

(i) $g(i, i, d+1)-g(i, i, d)=\phi_i(\alpha+(2d+1)\beta)$,

(ii) $g(i, j, d+1)-g(i, j, d)\geqq\phi_i(\alpha+(2d+1)\beta)$.

Proof. Equation (i) follows immediately from the basis of the definition of g. Equation (ii) is proved by induction on $j-i$, and the basis follows from (i). Now suppose that $j>i$. Let $k=cut(i, j, d+1)$. From the definitions of g and *cut*, we have

$$g(i, j, d+1)=g(i, k-1, d+2)+g(i, k-1, d+2), \tag{1}$$

$$g(i, j, d)\leqq g(i, k-1, d+1)+g(i, k-1, d+1), \tag{2}$$

while from the inductive hypothesis we have

$$g(i, k-1, d+2)-g(i, k-1, d+1)\geqq\phi_i(\alpha+(2d+3)\beta)\geqq\phi_i(\alpha+(2d+1)\beta), \tag{3}$$

$$g(k, j, d+2)-g(k, j, d+1)\geqq\phi_k(\alpha+(2d+3)\beta)\geqq 0. \tag{4}$$

Subtracting (2) from (1), then substituting (3) and (4), we conclude the proof of Lemma 4.1.

Next we need to show that the function g satisfies a "quadrangle condition," as defined by Yao [11].

LEMMA 4.2. *If* $i_0\leqq i_1\leqq j_0\leqq j_1$, *then*

$$g(i_0, j_0, d)+g(i_1, j_1, d)\leqq g(i_1, j_0, d)+g(i_0, j_1, d).$$

Proof. The proof is by induction on $j_0 - i_1$. We will consider the basis step last, since it is more complicated.

Suppose $i_1 < j_0$. Let $k_0 = cut(i_1, j_0, d)$ and let $k_1 = cut(i_0, j_1, d)$. By the symmetry of the problem, we can assume that $k_0 \leqq k_1$ without loss of generality. By the definitions of g and *cut*:

$$g(i_0, j_0, d) \leqq g(i_0, k_0 - 1, d+1) + g(k_0, j_0, d+1), \tag{1}$$

$$g(i_1, j_1, d) \leqq g(i_1, k_1 - 1, d+1) + g(k_1, j_1, d+1), \tag{2}$$

$$g(i_1, j_0, d) = g(i_1, k_0 - 1, d+1) + g(k_0, j_0, d+1), \tag{3}$$

$$g(i_0, j_1, d) = g(i_0, k_1 - 1, d+1) + g(k_1, j_1, d+1), \tag{4}$$

while by the inductive hypothesis:

$$g(i_0, k_0 - 1, d+1) + g(i_1, k_1 - 1, d+1) \leqq g(i_1, k_0 - 1, d+1) + g(i_0, k_1 - 1, d+1). \tag{5}$$

Add (1) and (2), add (3) and (4), and add the quantity $g(k_0, j_0, d+1) + g(k_1, j_1, d+1)$ to both sides of (5). The result follows by transitivity.

We now consider the basis case, namely $i_1 = j_0 = c$, which itself needs to be proved by induction on $j_1 - i_0$. The basis here, namely $i_0 = j_1$, is trivial. Otherwise, let $k = cut(i_0, j_1, d)$. By symmetry of the problem, we may assume, without loss of generality, that $k \leqq c$. By the definitions of g and of *cut*, we have

$$g(i_0, c, d) \leqq g(i_0, k - 1, d+1) + g(k, c, d+1), \tag{6}$$

$$g(i_0, j_1, d) = g(i_0, k - 1, d+1) + g(k, j_1, d+1), \tag{7}$$

while by Lemma 4.1

$$g(c, j_1, d+1) - g(c, j_1, d) \geqq g(c, c, d+1) - g(c, c, d). \tag{8}$$

By the inductive hypothesis

$$g(k, c, d+1) + g(c, j_1, d+1) \leqq g(c, c, d+1) + g(k, j_1, d+1). \tag{9}$$

Add $g(c, j_1, d)$ to both sides of (6). Subtract (8) from (9), add $g(i_0, k-1, d+1)$ to both sides, then substitute on the right side using (7). The result follows from transitivity.

5. The convex hull theorem. This section is devoted primarily to the statement and proof of the convex hull theorem, which is used to prove Lemma 2.2.

If f and g are weight functions that satisfy the hypotheses of the convex hull theorem, each tree can be plotted in a two-dimensional graph, using those two weight functions. The trees that lie along the lower left boundary of the convex hull of the graph of all trees are called (f, g)-*minimal.* The convex hull theorem states that consecutive trees along that boundary are obtained, one from the other, by a specific kind of change called an *elementary shift.* Under certain conditions that hold for the minimum delay problem, the theorem also limits the number of those trees. When we let the two weight functions be $\bar{l}^2$ and $\bar{l}$, the convex hull theorem yields an upper bound on the running time of the convex hull algorithm.

We begin by introducing a new representation of binary trees. Fix $n \geqq 1$ and $L \geqq 0$. We only consider trees $(l_1, \cdots, l_n)$ such that $l_i \leqq L$. We say that T is *monotone* if $l_i \geqq l_{i-1}$. If no depth restriction is desired, let $L = n - 1$.

Nodeset representation. Define a *node* to be an ordered pair (i, l) such that $i \in [1, n]$, which is called the *index* of the node, and $l \in [1, L]$, which is called the *level* of the node. Any set of nodes we call a *nodeset.* If T is a tree, define

$$nodeset(T) = \{(i, l) \mid 1 \leqq l \leqq l_i\}$$

where l_i is the depth of the ith leaf of T. For example, if T is the tree shown in Fig. 4(a), *nodeset*(T) is the set shown in Fig. 4(b).

Width and rank. If (i, l) is any node, define

$$width(i, l) = 2^{-l}, \qquad rank(i, l) = iL - l + 1.$$

If A is a nodeset, *width*(A) will be the sum of the widths of its constituent nodes.

Properties of nodesets. If A is any nodeset, we have the following:

(a) A is *monotone* if $(i, l) \in A$ implies $(i+1, l) \in A$;

(b) A is *proper* if $(i, l) \in A$ implies $(i, l-1) \in A$;

(c) A is a *virtual treeset* if $width(A) = n - 1$;

(d) A is a *treeset* if $A = nodeset(T)$ for some tree T.

The Kraft equality[3] implies that every treeset is a virtual treeset, and it can be shown (see, for example, [4]) that if A is a monotone proper virtual treeset, it is the treeset of some monotone tree.

Weight functions. We define a *weight function* to be any positive function

$$f: [1, n] \times [1, L] \to \Lambda$$

where Λ is any ordered integral domain.[4]

If A is any nodeset, define $f(A)$ (which we call the *f-weight* of A) to be the sum of the weights of the members of A, and if T is a tree, define $f(T) = f(nodeset(T))$. We have the following:

(a) f is *monotone* if $f(i+1, l) \leqq f(i, l)$;

(b) f is *proper* if $f(i, l-1) \leqq f(i, l)$;

(c) A is *f-minimal* if there is no nodeset of width equal to A of smaller f-weight.

To emphasize the fact that minimality is a relative term, we shall sometimes say, for clarity, that A is "f-minimal among nodesets of width w."

Example. Let $\Phi = (\phi_1, \cdots, \phi_n)$ be a frequency list. Define

$$\bar{l}_\Phi(i, l) = \phi_i, \qquad \bar{l}^2_\Phi(i, l) = \phi_i(2l - 1).$$

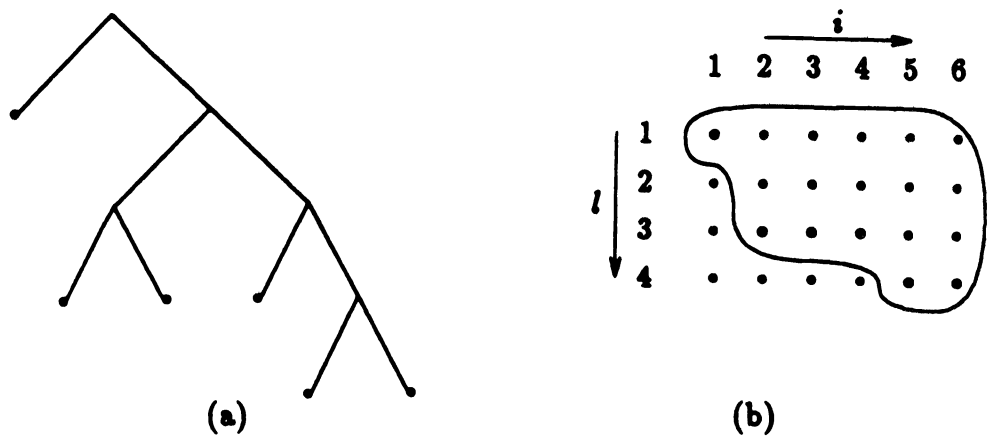

FIG. 4. (a) T. (b) *nodeset*(T).

[3] That is, $\sum_{i=1}^{n} 2^{-l_i} = 1$.

[4] That is, Λ has addition, subtraction, and multiplication; multiplicative identity; and satisfies the usual commutative, associative, and distributive laws. Furthermore, Λ is ordered, and $a < b$ implies $a + c < b + c$, also $ac < bc$ if $c > 0$. Two well-known examples are $\mathbf{R}$ = *reals* and $\mathbf{Z}$ = *integers*. See [10], for example, for a discussion of integral domains.

These weight functions are simply the expected path length and expected square path length defined in the Introduction. Furthermore, $\bar{l}_\Phi$ and $\bar{L}^2_\Phi$ are proper, and they are monotone if Φ is monotone (i.e., $\phi_i \leqq \phi_{i-1}$).

Pairs of weight functions. Suppose f and g are weight functions, taking values in the same ordered integral domain Λ. We say that a weight function h is a *positive linear combination* of f and g if there exist nonnegative $\alpha, \beta \in \Lambda$, not both zero, such that $h(i, l) = \alpha f(i, l) + \beta g(i, l)$ for all (i, l). We say that a nodeset is *(f, g)-minimal* if it is h-minimal for some h, which is a positive linear combination of f and g. For clarity, we shall sometimes say "A is (f, g)-minimal among nodesets of width w."

Flatness. We say that a weight function g is *flatter* than another weight function f provided $l' > l$ if the following inequality holds:

$$g(i, l)f(i', l') \leqq f(i, l)g(i', l').$$

For example, for any frequency list Φ, $\bar{l}^2_\Phi$ is flatter than $\bar{l}_\Phi$. (The word "flatter" is used because typically a tree that is g-minimal will have more equally deep leaves than a tree that is f-minimal.)

Elementary shifts. If A and A' are nodesets, we say that *A' is obtained from A by an elementary shift*, and write $A \Rightarrow A'$, if the following two conditions hold:

$$\mathit{width}(A') = \mathit{width}(A), \qquad A' - A \text{ consists of exactly one node.}$$

THEOREM 5.1 (convex hull theorem). *Let f, g be weight functions, taking values in a multiplicative ordered domain Λ, and let $0 \leqq w \leqq n(1-2^{-L})$ be an integer. Then there exists a sequence of nodesets $A_0, \cdots, A_K$, each of width w, such that we have the following*:

(1) $f(A_{k-1}) \leqq f(A_k)$;

(2) $g(A_{k-1}) \geqq g(A_k)$;

(3) *A_0 is f-minimal among nodesets of width w*;

(4) *A_K is g-minimal among nodesets of width w*;

(5) *A_k is (f, g)-minimal among nodesets of width w*;

(6) *If h is any positive linear combination of f and g, then there is some A_k that is h-minimal among nodesets of width w*;

(7) *Either $A_{k-1} \Rightarrow A_k$ or $A_k \Rightarrow A_{k-1}$.*

Furthermore, if f and g are both monotone and proper, then

(8) *A_k is monotone and proper.*

Furthermore, if g is flatter than f, then

(9) $A_{k-1} \Rightarrow A_k$;

(10) $K \leqq nL$.

We now prove Lemma 2.2. Let $\Lambda = \mathbf{R}$, $L = n-1$, $w = n-1$, $f = \bar{l}_\Phi$, and $g = \bar{l}^2_\Phi$. By (6), each tree whose plot is a vertex of B is equivalent to some tree whose nodeset is some A_k. Since $K \leqq n^2 - n$, we are done.

We will first prove the convex hull theorem under the additional hypothesis that the two weight functions satisfy a general position condition. Then we will reduce the general convex hull theorem to this special case by making use of infinitesimals.

General position. We say that a weight function f is in *general position* if no two nodesets have the same f-weight, and we say that f is in *almost general position* if no three nodesets have the same f-weight. If f and g are weight functions, we say that f and g are in *jointly general position* if f and g are each in general position and if each positive linear combination of f and g is in almost general position.

The concept of almost general position has a simple geometric interpretation. Graph each nodeset A to the point $(f(A), g(A))$. Then f and g are in jointly general position if no two nodesets are graphed to points in the same vertical or the same horizontal line, and no three nodesets are graphed to collinear points.

LEMMA 5.2. *If all the hypotheses of Theorem* 5.1 *are satisfied, and if f and g are in jointly general position, then the conclusions of Theorem* 5.1 *hold.*

We now begin the proof of Lemma 5.2. Let $A_0, \cdots, A_K$ be the set of all (f, g)-minimal nodesets, sorted in order of increasing f-weight. Then (1), (5), and (6) automatically hold. If $g(A_{k-1}) < g(A_k)$, then A_k could not be (f, g)-minimal, so (2) holds. Letting $\alpha = 1$ and $\beta = 0$, we obtain (3). Letting $\alpha = 0$ and $\beta = 1$, we obtain (4).

To prove (7), we need two lemmas.

LEMMA 5.3. *Let* $\alpha = g(A_{k-1}) - g(A_k)$, let $\beta = f(A_k) - f(A_{k-1})$, *and let* $h = \alpha f + \beta g$. *Then* A_{k-1} *and* A_k *are both h-minimal, and are the only two h-minimal nodesets.*

Proof. Since $h(A_{k-1}) = h(A_k)$, either both are h-minimal or neither is. Suppose neither is. Then there must exist an h-minimal nodeset. By (6), that h-minimal nodeset must be A_j for some j. By (5), A_k is h'-minimal for some positive linear combination $h' = \alpha' f + \beta' g$. We have three inequalities:

Inequality 1: $h(A_k) > h(A_j)$, since A_j is h-minimal and A_k is not;
Inequality 2: $h'(A_{k-1}) \geqq h'(A_k)$, since A_k is h'-minimal;
Inequality 3: $h'(A_j) \geqq h'(A_k)$, since A_k is h'-minimal.

The remainder of the proof is tedious but straightforward. First, multiply both sides of Inequality 1 by β', both sides of Inequality 2 by $f(A_j) - f(A_k)$, and both sides of Inequality 3 by β. Add the left sides and the right sides of the three resulting inequalities to obtain a single inequality, which will be strict, since Inequality 1 is strict. Replace each instance of α with $g(A_{k-1}) - g(A_k)$, and each instance of β with $f(A_k) - f(A_{k-1})$. There will be 12 terms on each side, all of which cancel. Thus we obtain $0 < 0$, a contradiction. The assumption that $j < k - 1$ leads to a similar contradiction. Finally, note that h must be in almost general position; thus A_{k-1} and A_k are the only h-minimal nodesets. This concludes the proof of Lemma 5.3.

LEMMA 5.4. *If A is any nodeset of width at least* 2^{-l}, *and if the level of every element of A is at least l, then there exists a nodeset* $B \subseteq A$ *such that* $width(B) = 2^{-1}$.

Proof. The proof is by backward induction on l. If $l = L$, every element of A has level L, and we can let B consist of just one of those elements. Otherwise, we consider two cases. The first case is that A contains a node of level l. Let B consist of just that node. In the second case, A has no node of level l, i.e., all of its elements have level at least $l+1$. By the inductive hypothesis, we can pick $B_1 \subseteq A$ and $B_2 \subseteq A - B_1$, each of width $2^{-(l+1)}$. Let $B = B_1 \cup B_2$. This completes the proof of Lemma 5.4.

We now prove (7). Let h be as in the statement of Lemma 5.3. Let $B = A_k - A_{k-1}$, and $B' = A_{k-1} - A_k$. If either B or B' consists of a single node, we are done by definition of elementary shift. Otherwise, let l be the smallest level of any node in either B or B', i.e., 2^{-l} is the greatest width of any node in B or B'. Note that $width(B) = width(B') > 2^{-l}$. By Lemma 5.4, we can pick nodesets $C \subseteq B$ and $C' \subseteq B'$ each of width 2^{-l}. Let $A = A_{k-1} \cup C - C'$, and let $A' = A_k \cup C' - C$. The combined h-weight of A and A' must be equal to the combined h-weight of A_{k-1} and A_k, because exactly the same nodes appear in the summations. On the other hand, it must be greater by Lemma 5.3, a contradiction. Thus (7) is established.

For the remainder of the proof of Lemma 5.2, assume that f and g are monotone and proper.

LEMMA 5.5. *If A is any nodeset of width* $q2^{-l} + r$, *where q is an integer and* $0 \leqq r < 2^{-l}$, *then there exists a nodeset* $B \subseteq A$ *such that* $width(B) = q2^{-l}$.

Proof. The proof is by induction on r, which is necessarily an integral multiple of 2^{-L}. If $r = 0$, let $B = A$. Otherwise, let $(i, l') \in A$ have the greatest level, i.e., smallest width. Then apply the inductive hypothesis to $A - \{(i, l')\}$, and Lemma 5.5 is proved.

Suppose that A_k is not monotone. Then there exists $(i, l) \in A_k$ such that $(i+1, l) \notin A_k$. Let $A = A_k \cup \{(i+1, l)\} - \{(i, l)\}$. By monotonicity and general position of f and g, A has smaller f-weight and also smaller g-weight than A_k. Thus, A_k cannot be (f, g)-minimal, which contradicts (5). Suppose that A_k is not proper. Then there exists $(i, l) \in A_k$ such that $(i, l-1) \notin A_k$. Let $A = A_k \cup \{(i, l-1)\} - \{(i, l)\}$. By Lemma 5.5, there exists a nodeset $B \subseteq A$ of width w. Since f and g are proper and in general position, B has smaller f-weight and smaller g-weight than A_k, so A_k cannot be (f, g)-minimal, which contradicts (5). Thus (8) holds.

For the remainder of the proof of Lemma 5.2, we assume that g is flatter than f.

By (7), either $A_{k-1} \Rightarrow A_k$ or $A_k \Rightarrow A_{k-1}$. If the former holds, we are done. If the latter holds, we will obtain a contradiction. Let (i, l) be the unique member of $A_{k-1} - A_k$. Let $B = A_k - A_{k-1}$. We first note that, for any $(i', l') \in B$, $l' \geqq l$, since B must have width 2^{-l}. Since A_{k-1} and A_k are monotone, $l' > l$.

By (1), we have

Inequality 1: $f(i, l) < \sum_{(i', l') \in B} f(i', l')$

while by (2), we have

Inequality 2: $g(i, l) > \sum_{(i', l') \in B} g(i', l')$.

Since g is flatter than f, $g(i, l) f(i', l') \leqq f(i, l) g(i', l')$ for all $(i', l') \in B$. Multiplying Inequality 1 by $g(i, l)$ and Inequality 2 by $f(i, l)$, we obtain a contradiction. Thus (9) is established.

Now, by (9), $A_k - A_{k-1}$ always consists of a single node, say (i, l). If $A_{k-1} - A_k$ consists of a single node, that would imply that $A_k \Rightarrow A_{k-1}$, which was shown to be impossible in the previous paragraph. Thus, A_{k-1} has greater cardinality than A_k, and $|A_0| \geqq |A_K| + K$. Since there are only nL nodes altogether, $|A_0| \leqq nL$. Inequality (10) follows immediately.

This concludes the proof of Lemma 5.2.

Proof in the general case. We now reduce the convex hull theorem to Lemma 5.2, i.e., to the special case where the weight functions are in relatively general position.

The polynomial domain. Let x and y be formal symbols, and let $\Lambda[x, y]$ be the polynomials with coefficients in Λ over x and y. We make $\Lambda[x, y]$ an ordered integral domain by the rules that y is infinitesimal, and x is infinitesimally smaller than y. That is, if p, q, r, s are nonnegative integers, and if λ, μ are positive elements of Λ, then $0 < \lambda x^p y^q < \mu x^r y^s$ if and only if one of the following holds: either $q > s$, or $q = s$ and $p > r$, or $q = s$ and $p = r$ and $\lambda < \mu$.

Degrees. If $\lambda \in \Lambda$, we say that the term $\lambda x^p y^q$ has *x_degree p* and *y_degree q*. Any nonzero $\alpha \in \Lambda[x, y]$ consists of the sum of unlike nonzero terms. We define the *x_y_degree* of α to be the maximum *x_degree* of a term of α of maximal *y_degree*. For example, *x_y_degree*$(x^5 + x^3 y^2 + x^4 y^2) = 4$. We note that, for nonzero $\alpha, \beta \in \Lambda[x, y]$:

$$x\_y\_degree(\alpha\beta) = x\_y\_degree(\alpha) + x\_y\_degree(\beta).$$

Proof of Theorem 5.1. We define weight functions $f^{[x]}$ and $g^{[y]}$, by taking values in $\Lambda[x, y]$, by

$$f^{[x]}(i, l) = f(i, l) + x^{n(L-l)+i}, \qquad g^{[y]}(i, l) = g(i, l) + y^{n(L-l)+i}.$$

Intuitively, $f^{[x]}$ and $g^{[y]}$ differ from f and g "infinitesimally." The differences are not enough to disturb relations among nodesets using f and g, but are used only to break enough ties to ensure general position.

We refer to the quantity $n(L-l)+i$ as the *degree* of the node (i, l). Each node has a distinct degree in the range $[1, nL]$.

LEMMA 5.6. *The weight functions $f^{[x]}$, $g^{[y]}$ are jointly in general position.*

Proof. Since no two nodes have the same degree both $f^{[x]}$ and $g^{[y]}$ are (individually) in general position. Now suppose that there are three distinct nodesets, A, B, and C of the same h-weight, where $h = \alpha f^{[x]} + \beta g^{[y]}$ and $\alpha, \beta \in \Lambda[x, y]$ are not both zero. Now let r be the highest degree that serves to distinguish between some two of those three nodesets, i.e., any node of degree higher than r lies in either all or none of the three sets A, B, and C, while the node of degree r lies in either one or two, but not in three, of those same sets.

Without loss of generality, A and B both contain the node of degree r while C does not, or C contains the node of degree r while A and B do not. Let $s < r$ be the highest degree of a node that lies in A but not in B, or in B but not in A. Since A and B have the same h-weight, we have

Equation 1: $\alpha(f^{[x]}(A) - f^{[x]}(B)) = \beta(g^{[y]}(B) - g^{[y]}(A))$,

while, since A and C have the same h-weight, we have

Equation 2: $\alpha(f^{[x]}(A) - f^{[x]}(C)) = \beta(g^{[y]}(C) - g^{[y]}(A))$.

Let $a = x\_y\_degree(\alpha)$ and $b = x\_y\_degree(\beta)$. From Equation 1, we have $a + s = b + 0$, while from Equation 2, we have $a + r = b + 0$, a contradiction. Thus, Lemma 5.6 is proved.

The difference between the f-weight of a node and the $f^{[x]}$-weight of that same node is infinitesimal in Λ, i.e., it cannot be made larger than any positive element of Λ by multiplication by any element of Λ. Thus, if a nodeset A is $f^{[x]}$-minimal it is also f-minimal. Similarly, if A is $g^{[y]}$-minimal it is also g-minimal, and if it is $(f^{[x]}, g^{[y]})$-minimal, it is also (f, g)-minimal. We also observe the following:

(a) If f is monotone, then $f^{[x]}$ is montone;
(b) If g is monotone, then $g^{[y]}$ is monotone;
(c) If f is proper, then $f^{[x]}$ is proper;
(d) If g is proper, then $g^{[y]}$ is proper;
(e) If g is flatter than f, then $g^{[y]}$ is flatter than $f^{[x]}$.

Thus, $f^{[x]}$ and $g^{[y]}$ satisfy the hypotheses of Lemma 5.2, and if $A_0, \cdots, A_K$ is a list of nodes which satisfies the conclusion of Lemma 5.2 for the inputs $f^{[x]}$ and $g^{[y]}$, it also satisfies the conclusion of Theorem 5.1 for the inputs f and g.

This concludes the proof of Theorem 5.1, the convex hull theorem.

6. Open questions. *Improvements.* When we use the methods of [8], the time to execute *Find_Best* should be reduced from $O(n^3)$ to roughly $O(n^{5/2} \log n)$. Such a result will be unimportant, though, if the conjectures given below hold.

CONJECTURE 1. The time for the convex hull algorithm can be reduced to $O(n^4 \log n)$ by dynamically computing, for all pairs (i, j), in order of increasing $j - i$, $g(i, j, 0)$ for all possible choices of α and β, and by making use of the monotonicity lemma, Lemma 2.3.

CONJECTURE 2. The number of vertices of B is $O(n^{1/2})$ in the average case.

Conjecture 2 is suggested by a statistical result by Renyi and Sulanke [9]. The Renyi–Sulanke result states that the number of points in the boundary of the convex hull of a randomly selected set of N points in the plane is expected to be $\Theta(\log^{1/2} N)$, if the points are placed according to a normal distribution. In our application, if N is the number of trees of size n, then $\log N = \Theta(n)$. We expect that it will be quite

difficult to show that Conjecture 2 holds, but simulations indicate just such a bound with random data.

The most optimistic conjecture, which combines the best features of Conjectures 1 and 2, follows.

CONJECTURE 3. The convex hull algorithm can be modified to run in $O(n^{5/2} \log n)$ time in the average case.

Again, simulations support Conjecture 3.

Alphabetic codes. We say that a prefix-free code is *alphabetic* if the source alphabet has a given order, and the lexical order of the code strings must correspond to that order. The example code given in the Introduction is not alphabetic, but the following code is:

$$a \to 0$$
$$b \to 10$$
$$c \to 11.$$

Hu and Tucker [5] present an algorithm that minimizes $\bar{l}$ for a prefix-free alphabetic code. The convex hull algorithm presented in this paper correctly finds an alphabetic code of minimal expected delay, since at no time was it necessary to assume that the ϕ_i are monotone during the proof of correctness. However, there is no guarantee that the algorithm will take polynomial time, since Lemma 2.2 strongly depends on monotonicity of the weights. The question of whether a polynomial-time algorithm exists for finding an alphabetic prefix-free code of minimal delay remains open.

Dynamic and parallel computation. The algorithm presented in this paper is sequential, and finds a minimum delay code for given (static) frequencies. Instead we could ask for a dynamic algorithm that changes the code as frequencies are updated during the transmission of a message. Either the static or the dynamic code could be computed using parallel processors; the question then would be to find an efficient tradeoff between the number of processors and time. We could also ask whether the problem of finding a minimum delay code is in class *NC*, the class of problems that can be solved in polylogarithmic time using polynomially many processors.

Acknowledgment. I wish to thank George Lueker for calling my attention to this problem.

THE BOOLEAN HIERARCHY II: APPLICATIONS*

JIN-YI CAI†, THOMAS GUNDERMANN‡, JURIS HARTMANIS§, LANE A. HEMACHANDRA¶, VIVIAN SEWELSON[1], KLAUS WAGNER[2], AND GERD WECHSUNG‡

Abstract. *The Boolean Hierarchy* I: *Structural Properties* [J. Cai et al., *SIAM J. Comput.*, 17 (1988), pp. 1232-1252] explores the structure of the boolean hierarchy, the closure of NP with respect to boolean operations. This paper uses the boolean hierarchy as a tool with which to extend and explain three important results in structural complexity theory.

(1) Hartmanis, Immerman, and Sewelson [*Proc. 15th Annual Symposium on the Theory of Computation*, 1983, pp. 382-391] showed that E = NE if and only if NP − P contains no sparse sets. In this paper it is shown that this reflects a behavior of the boolean hierarchy. When E = NE, sparse sets fall from alternate levels of the boolean hierarchy (Fig. 2(a)). Furthermore, it is shown that capturable sets (i.e., subsets of sparse NP sets) are banished from the boolean hierarchy when E = NE: E = NE implies that BH − P has no capturable sets.

(2) Counting classes are natural candidates as complete languages for the levels of the boolean hierarchy. The authors show that in relativized worlds counting classes are *not* complete for the levels of the boolean hierarchy. Relatedly, the work of Blass and Gurevich [*Inform. and Control*, 55 (1982), pp. 80-88] is extended and it is concluded that counting classes are weak in some relativized worlds.

(3) Karp and Lipton [*Proc. 12th Annual Symposium on the Theory of Computation*, 1980, pp. 302-309] showed that if NP has a sparse oracle (i.e., if there is a sparse set S so $NP \subseteq P^S$; equivalently, if NP has small circuits), then the polynomial hierarchy collapses to NP^{NP}. The authors demonstrate that this cannot be much improved. There is a relativized world in which NP has a sparse oracle, yet the boolean hierarchy is infinite. Thus no proof that relativizes can show: NP has a sparse oracle implies that the polynomial hierarchy equals the boolean hierarchy.

The results of this paper present new ideas and techniques, and put previous results about NP and D^P in a richer perspective. Throughout, the emphasis is on the structure of the boolean hierarchy and its relations with more common classes.

D^P, the closure of NP∪coNP under intersections, has recently been carefully studied [PY82], [PW85], [CM85]. A natural completion of such extensions of NP is the boolean hierarchy—the closure of NP under boolean operations. The boolean hierarchy (BH) has a clear "physical" interpretation. The sets in the boolean hierarchy are exactly those representable by *hardware over* NP. Each boolean hierarchy language is accepted by a hardware tree connecting NP machines (Fig. 1).

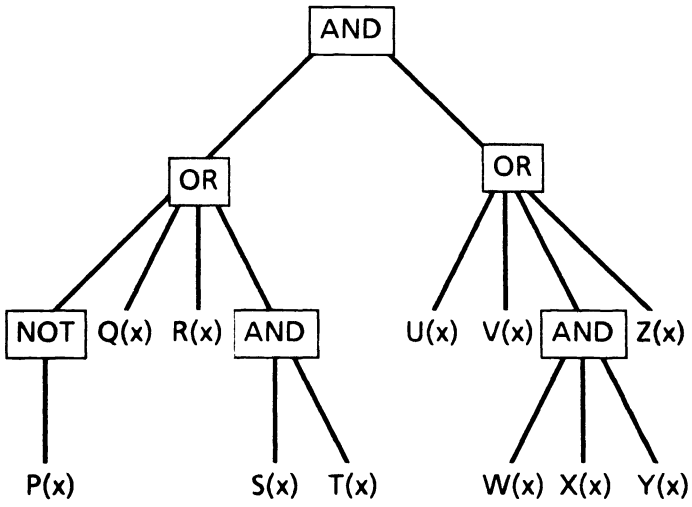

FIG. 1. *Hardware over* NP.

Each level of the boolean hierarchy consists of sets represented by a certain fixed structure of boolean operators on NP sets. Sets in the boolean hierarchy have normal forms. Each can be written as a finite union of D^P sets:

$$\mathrm{NP}(0) = \mathrm{P},$$
$$\mathrm{NP}(1) = \mathrm{NP},$$
$$\mathrm{NP}(2) = \mathrm{D}^{\mathrm{P}} = \{L_1 \cap \bar{L}_2 \mid L_1, L_2 \in \mathrm{NP}\},$$
$$\mathrm{NP}(3) = \{(L_1 \cap \bar{L}_2) \cup L_3 \mid L_1, L_2, L_3 \in \mathrm{NP}\},$$
$$\mathrm{NP}(4) = \{((L_1 \cap \bar{L}_2) \cup L_3) \cap \bar{L}_4 \mid L_1, L_2, L_3, L_4 \in \mathrm{NP}\},$$
$$\mathrm{BH} = \bigcup_{i>0} \mathrm{NP}(i),$$
$$\mathrm{coNP}(i) = \{S \mid \bar{S} \in \mathrm{NP}(i)\}.$$

LEMMA [CGI]. *The following are equivalent*:

(1) $T \in \mathrm{BH}$.

(2) *T is a finite union of* D^{P} *sets.*

(3) *T is a finite intersection of* $\mathrm{coD}^{\mathrm{P}}$ *sets.*

(4) *T is in the boolean closure of* NP.

(5) $T \leqq^{\mathrm{P}}_{btt} \mathrm{SAT}$.

1.2. Sparse sets in the boolean hierarchy and E = ?NE. Hartmanis, Immerman, and Sewelson [HIS83] linked the behavior of sparse sets in NP to the E = NE question. We show that E = NE forces sparse sets in odd levels of the boolean hierarchy down one level. This result is the best possible among results holding in all relativizations;

our "candy cane" relativization alternates stripes with and without sparse sets throughout the boolean hierarchy (Fig. 2b). Indeed, since this oracle leaves sparse sets in $\mathrm{coNP}(2k+1)-\mathrm{NP}(2k+1)$ but not in $\mathrm{NP}(2k+1)-\mathrm{coNP}(2k+1)$, we have an infinite set of structurally asymmetric complementary classes—the levels of the boolean hierarchy.

THEOREM. $\mathrm{E}=\mathrm{NE}$ *if and only if for all* k, $\mathrm{NP}(2k+1)-\mathrm{NP}(2k)$ *has no sparse sets.*

THEOREM (Candy Cane Relativization). *There exists a set* A *such that for all* $k \geq 0$, $\mathrm{NP}^A(2k+1)-\mathrm{NP}^A(2k)$ *has no sparse sets, yet* $\mathrm{NP}^A(2k+2)-\mathrm{NP}^A(2k+1)$ *has sparse sets.*

It follows easily that $\mathrm{E}=\mathrm{NE}$ forces all tally sets out of $\mathrm{BH}-\mathrm{P}$, but may leave sparse sets. Is there some natural class of sparse sets that is richer than the class of tally sets and can be forced from the boolean hierarchy? To answer this question, we define *capturability* of sets, a notion we feel to be of general interest.

DEFINITION. A set is **capturable** if it is a subset of some sparse set in NP.

THEOREM. *If* $\mathrm{E}=\mathrm{NE}$, *then all capturable sets in the boolean hierarchy are in* P.

1.3. Counting classes. Counting classes, such as the class US defined by Blass and Gurevich [BG82], seem promising sources of natural complete sets for the boolean hierarchy. Let S be a finite or cofinite set of natural numbers. We define its associated counting class, CP_S, as the set of languages accepted by a nondeterministic polynomial-time machine that has the following acceptance mechanism: an input x is accepted if and only if the number of accepting computation paths on input x is a member of S. These classes are all contained in Δ_2^{P}. In § 3 we discuss natural complete languages, containment relationships, and relativized separations among counting classes. Our relativizations, which are obtained by combinatorially exploiting the limited control of counting machines, reveal the weakness of counting classes; in appropriately relativized worlds, counting classes fail to even contain NP.

These classes have canonical complete languages of the form $\mathrm{SAT}_S=\{f \mid \text{the number of solutions to } f \text{ is a member of } S\}$. Further, many basic containments can be derived from the following theorem.

CONTAINMENT THEOREM. *For* $z \geq 1$, $c_l \geq 1$ $(1 \leq l \leq z)$, $k \geq 0$, *and* $j > i \geq \min_{1 \leq l \leq z}(k_l) \geq 1$:

$$\mathrm{CP}_{\{i,j\}} \subseteq \mathrm{CP}\left\{c_1\binom{i}{k_1}+c_2\binom{i}{k_2}+\cdots+c_z\binom{i}{k_z}+k,\ c_1\binom{j}{k_1}+c_2\binom{j}{k_2}+\cdots+c_z\binom{j}{k_z}+k\right\}.$$

We display a world where more counting is strictly more powerful. Nonetheless, the most interesting aspect of counting is that it can be made *weak*. Counting can be made too weak to capture NP or coNP. As a consequence, no amount of counting is hard for even low levels of the boolean hierarchy.

THEOREM. *There is a recursive set* A *so that* $\bigcup_{S \text{ finite}} \mathrm{CP}_S^A \not\supseteq \mathrm{NP}^A$ *and* $\bigcup_{S \text{ cofinite}} \mathrm{CP}_S^A \not\supseteq \mathrm{coNP}^A$.

COROLLARY. *There is a relativized world where no amount of counting is hard for* $\mathrm{D}^{\mathrm{P}}(A)$ *or* $\mathrm{coD}^{\mathrm{P}}(A)$ *(i.e., where no counting class contains either* $\mathrm{D}^{\mathrm{P}}(A)$ *or* $\mathrm{coD}^{\mathrm{P}}(A)$*).*

1.4. The boolean hierarchy and sparse oracles for NP. We study the relations between sparse oracles and the boolean hierarchy. We say NP has a *sparse oracle* if there is a sparse set S so that $\mathrm{NP} \subseteq \mathrm{P}^S$. Mahaney [M82] showed that if NP has a sparse many-one complete set then $\mathrm{P}=\mathrm{NP}$. Karp and Lipton [KL80] showed that if NP has a sparse Turing hard set or a sparse oracle, then $\Sigma_2^{\mathrm{P}}=\Pi_2^{\mathrm{P}}$. Does the existence of a sparse oracle for NP imply something stronger than $\Sigma_2^{\mathrm{P}}=\Pi_2^{\mathrm{P}}$?

By displaying a relativized world where NP has a sparse oracle but in which the boolean hierarchy is infinite, we show that the conclusion in [KL80] is nearly the

strongest possible among results that relativize. In terms of circuits, this result shows that (in relativized worlds) the existence of small circuits for NP does not imply that $P = NP$ or even that the boolean hierarchy is finite. Our result improves the work of Kurtz, Immerman, and Mahaney reported in [HIS83]. Similarly, by displaying a relativized world where PSPACE has a sparse oracle but where the boolean hierarchy is infinite, we show that the Karp-Lipton result on sparse oracles for PSPACE (i.e., if PSPACE has a sparse oracle then $\text{PSPACE} = \Sigma_2^P$) is also nearly as strong as possible. Indeed, we show the stronger result that $P^S = \text{PSPACE}^S$, S sparse, can be consistent with an infinite boolean hierarchy.

THEOREM. *There is a relativized world where the boolean hierarchy is infinite and* PSPACE *has sparse oracles (and, indeed, in which there is a sparse S so $P^S = \text{PSPACE}^S$).*

COROLLARY. *No proof that relativizes can show the following: if* NP *has a sparse oracle then the polynomial hierarchy equals the boolean hierarchy.*

2. Sparse sets in the boolean hierarchy and E = ?NE.

2.1. Basic results. In 1983, Hartmanis, Immerman, and Sewelson [HIS83] extending work of Book [B74], noted a connection between the density of sets in NP and the structure of exponential time classes. They proved the following theorem, in which $E = \bigcup_{c>0} \text{TIME}[2^{cn}]$ and $NE = \bigcup_{c>0} \text{NTIME}[2^{cn}]$.

THEOREM 2.1.1 [HIS83]. *The following are equivalent:*

(1) *There is a sparse set in* $NP - P$.

(2) *There is a tally set in* $NP - P$.

(3) $E \neq NE$.

COROLLARY 2.1.1 [HIS83]. *There is a recursive set A for which $E^A = NE^A$ and $\text{coNP}^A - P^A$ has sparse sets.*

This section considers the implications of the existence of sparse sets in the boolean hierarchy. We start by noting that there are tally sets in $BH - P$ if and only if $E \neq NE$. It follows that forcing tally sets from $NP - P$ banishes them from the entire boolean hierarchy; that is, $BH - P$ has tally sets if and only if $NP - P$ does.

THEOREM 2.1.2. *There are tally sets in* $BH - P$ if and only if $E \neq NE$.

Proof of Theorem 2.1.2. $\Rightarrow$: Assume $E = NE$. Let L be a tally set from the boolean hierarchy. In normal form, as the finite union of D^P sets, $L = (N_1 \cap A_1) \cup \cdots \cup (N_z \cap A_z)$, where the $N_i \in NP$ and $A_i \in \text{coNP}$. Since $L \subseteq 1^*$, $L = ((N_1 \cap 1^*) \cap (A_1 \cap 1^*)) \cup \cdots \cup ((N_z \cap 1^*) \cap (A_z \cap 1^*))$. When $E = NE$, all tally sets in $NP \cup \text{coNP}$ fall to P [HIS83], so L is the boolean combination of P sets. Thus L is in P.

$\Leftarrow$: If $E \neq NE$, there are even tally sets in $NP - P$, by an easy padding procedure. □

COROLLARY 2.1.2. *There are tally sets in* $NP - P$ *if and only if there are tally sets in* $BH - P$.

The behavior of sparse sets in the boolean hierarchy when $E = NE$ is unusual: sparse sets fall out of alternate levels. That is, $NP - P$, $NP(3) - DP$, $NP(5) - NP(4)$, $\cdots$ have no sparse sets when $E = NE$ (Fig. 2a). Also, $\text{coD}^P - \text{coNP}$, $\cdots$, $\text{coNP}(2k+2) - \text{coNP}(2k+1)$ have no sparse sets.

There is a relativized world where sparse sets do fall from alternate levels, yet they find sanctuary in the gaps, i.e., P, $D^P - NP$, $NP(4) - NP(3)$, $\cdots$. Since in this world the boolean hierarchy is striped with regions of sparseness and nonsparseness, we call this the candy cane relativization (Fig. 2(b)). Corollary 2.1.1 reflects the base case of this result.

THEOREM 2.1.3. (a) $E = NE \Leftrightarrow (\forall k)$ [$NP(2k+1) - NP(2k)$ *has no sparse sets*].[1]

[1] Recall that $NP(0) = P$.

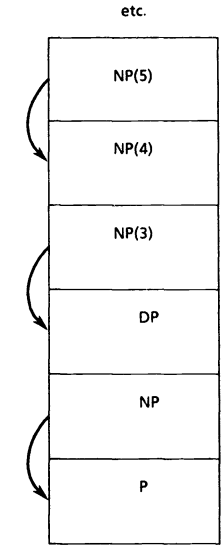

FIG. 2(a). *The arrows indicate the movement of sparse sets when* E = NE.

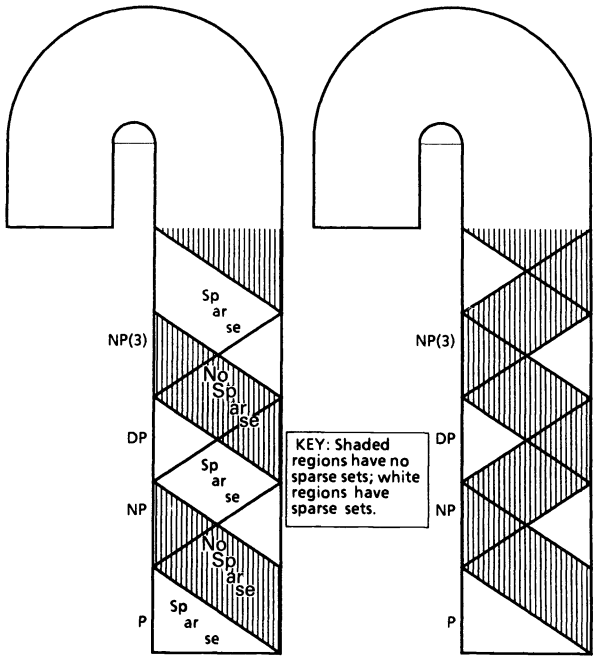

FIG. 2(b). *In our candy cane relativization, regions with and without sparse sets alternate. The left cane displays the world of Theorem* 2.1.4. *An easy modification of the oracle (noting Theorem* 2.1.3(b)) *gives the right cane.*

(b) $E = NE \Rightarrow (\forall k)\,[coNP(2k+2) - coNP(2k+1)$ *has no sparse sets*].

Proof of Theorem 2.1.3. (a) $\Leftarrow$: The proof is by Theorem 2.1.1.

(a) $\Rightarrow$: Let $E = NE$ and T be a sparse set in $NP(2k+1)$. T can, by the definition of $NP(2k+1)$, be written $N \cup V$, where N is in NP and V is in $NP(2k)$. Since T is sparse, N must be sparse. So N is a sparse set in NP and thus is in P, since $E = NE$. $NP(2k)$ is closed under intersection with P sets, so T is in $NP(2k)$.

(b) The proof of (b) is similar. □

THEOREM 2.1.4. *There is a recursive set A for which we have the following*:

(1) $E^A = NE^A$ (*thus* $NP^A - P^A$, $NP^A(3) - DP^A, \cdots, NP^A(2k+1) - NP^A(2k), \cdots$ *have no sparse sets*), *and*

(2) $(\forall k)\,[coNP^A(2k+1) - NP^A(2k+1)$ *has sparse sets*].

Proof. The proof is deferred to § 2.3.

Theorem 2.1.3(a) is a complete characterization, yet Theorem 2.1.3(b) is only an implication. Can Theorem 2.1.3(b) be made into an "if and only if" statement? In certain relativized worlds, the answer is *no*, as it is possible to construct an oracle for which $NP - P$ contains sparse sets (thus by [HIS83] $E \neq NE$) yet for which $coNP = NP$ (so $BH - coNP = \emptyset$).

2.2. Capturable sets in the boolean hierarchy. So far, we have noted that $E = NE$ forces all tally sets out of $BH - P$, but may leave sparse sets. Is there some natural class of sparse sets that is richer than the class of tally sets and can be forced from the boolean hierarchy?[2] To study this question, we define *capturability* of sets.

DEFINITION 2.2.1. A set is **capturable** if it is a subset of some sparse set in NP.

Immunity of sets has been intensely studied (see Russo [R85] and Schöning and Book [SB84]). A set is NP-immune if it contains no infinite NP subset. Our definition of uncapturability provides a complement to this notion; immunity means no NP set is inside a set and uncapturability means the set is inside no sparse NP set. A set T is uncapturable if every NP superset of T is nonsparse.

Capturable sets are a rich class. Nonetheless, capturable sets are sufficiently simple that we can answer the question that motivated this section. When $E = NE$, all capturable sets in the boolean hierarchy fall into P.

We first prove the following weaker result.

LEMMA 2.2.1. *If* $E = NE$, *then* $BH - coNP$ *has no capturable sets.*

Proof of Lemma 2.2.1. Assume $E = NE$ and let L be a capturable set from the boolean hierarchy. Write L in normal form as the finite union of D^P sets: $L = \bigcup_{i \leq k_L} (N_i \cap A_i)$, where $N_i \in NP$ and $A_i \in coNP$. Let S be the sparse NP set capturing L. Then $L = \bigcup_{i \leq k_L} ((N_i \cap S) \cap A_i)$. But since $E = NE$ each $N_i \cap S$ is in P, so L is the finite union of coNP sets and thus is itself in coNP. □

THEOREM 2.2.1. *If* $E = NE$, *then all capturable sets in the boolean hierarchy are in* P.

Proof of Theorem 2.2.1. Assume $E = NE$ and let S be a capturable set in the boolean hierarchy, captured by S': $S \subseteq S' \in NP$, S' and S are sparse. Let

$$L = \{n \# k \mid z_{n,k} \in S\}$$

where $z_{n,k}$ is the kth string (lexicographically) in $W_n = S' \cap (\Sigma + \varepsilon)^n$. Since $E = NE$, S' is P-printable by the results of Hartmanis and Yesha [HY84], and by the above lemma, $S \in coNP$. Thus $L \in coNE$, so $L \in E$.

---

[2] Certainly for the class "subsets of P-printable sets [HY84], [HH86a]" this property holds. We seek a far richer class.

Since $L \in \mathrm{E}$, the following program accepting S is in P:

{Let $n := |x|$;
P-print W_n;
If $x \notin W_n$ then {reject x}
else {suppose x is the kth string (lexicographically) in W_n;
accept x if and only if $n \# k \in L$.
}
}

□

2.3. The candy cane construction. Recall (§ 2.1) that the candy cane construction leaves sparse sets in patches throughout the boolean hierarchy (Fig. 2(b)). Though the construction is somewhat involved, the strategy is straightforward. While coding an NE complete set into E, we simultaneously perform diagonalizations in the boolean hierarchy to insure an infinite class of sets sanctuary at various levels of the hierarchy. The oracle places the "sawing" technique introduced in [CGI] within the framework developed in [HIS83, Thm. 12]. The "sawing" technique is described in detail in [CGI].

We achieve $\mathrm{E}^A = \mathrm{NE}^A$ by coding into our oracle an NE-complete language. Let N be a machine so that for all oracles A, $L(N^A)$ is complete for NE^A. Without loss of generality (i.e., by padding), N runs in time 2^{2^n}. We will code our oracle so $1 \# x \# 1^{2^{2^{|x|}}} \in A \Leftrightarrow x \in L(N^A)$.

Simultaneously, we wish to offer sanctuary to sparse sets in coNP, coNP(3), coNP(5), $\cdots$, coNP$(2k+1)$, $\cdots$. We define a family of languages $\{S_{2k+1}\}$, so that each S_{2k+1} is obviously in coNP$(2k+1)$. By careful diagonalization we show that, for each k, no NP$(2k+1)$ machine accepts S_{2k+1}. In addition, we poison the oracle to insure that each S_{2k+1} remains sparse.

To space out our diagonalizations so no two interfere with each other, we define widely spaced columns in which the diagonalizations are based. Let $C_k = \{m \mid (\exists i)[m = 2^{2^{\langle k,i \rangle}}]\}$, where $\langle \cdot, \cdot \rangle$ is a standard pairing function. Each diagonalization involving S_{2k+1} will use a diagonalizing string whose length is in C_{2k+1}.

Taking advantage of these columns as spacing mechanisms, define our sanctuary-finding sets as follows. Note that each S_{2k+1} is in coNP$(2k+1)$. The notation $(\forall w : C : S)$ means "for all w satisfying C, S holds."

$$S_1 = \{x \mid |x| \in C_1 \wedge (\forall y : |y| = |x| + 1 : 0xy \notin A)\},$$

$$S_3 = \{x \mid |x| \in C_3 \wedge [(\forall y : |y| = |x| + 1 : 0xy \notin A) \wedge [(\exists y : |y| = |x| + 2 : 0xy \in A) \vee (\forall y : |y| = |x| + 3 : 0xy \notin A)]]\}$$

$$S_{2k+1} = \{x \mid |x| \in C_{2k+1} \wedge [(\forall y : |y| = |x| + 1 : 0xy \notin A) \wedge [(\exists y : |y| = |x| + 2 : 0xy \in A) \vee [(\forall y : |y| = |x| + 3 : 0xy \notin A) \wedge [\cdots[(\exists y : |y| = |x| + 2k : 0xy \in A) \vee (\forall y : |y| = |x| + 2k + 1 : 0xy \notin A)]\cdots]]]]\}.$$

Now, for each k, we must assure that S_{2k+1} is accepted by no NP$(2k+1)$ machine. We model an NP$(2k+1)$ language H as a collection of $k+1$ NP machines N_i and k coNP machines A_i, so $H = N_1 \cup [A_2 \cap [N_2 \cup [\cdots \cup [A_{k+1} \cap N_{k+1}] \cdots]]]$. We use the machines and their languages synonymously. Without loss of generality, let the ith coNP$(2k+1)$ machine be composed of machines running each in time $n^i + i$.

Using the method of successive restrictions (the "sawing" technique) described in [CGI], we easily perform the needed diagonalizations.

CANDY CANE CONSTRUCTION.

Stage n, Part A. If $n \notin \bigcup_{l \geq 0} C_{2l+1}$ do nothing. Otherwise, suppose $n \in C_{2k+1}$. Let H be the first NP$(2k+1)$ machine that might still accept S_{2k+1}; let us say that H is the

lth NP $(2k+1)$ machine. If $l > \frac{1}{2}\log n$ then skip Part A, otherwise go on. We show that $L(H^A) \neq S^A_{2k+1}$.

Find an x_0, $|x_0| = n$, such that for all y with $n \leqq |y| \leqq n+2k+1$, $0x_0y$ is *unspecified* (i.e., a string that has been neither placed in nor barred from A).

Recall that

$$L(H) = L(N_1) \cup [L(A_2) \cap [L(N_2) \cup [\cdots \cup [L(A_{k+1}) \cap L(N_{k+1})]\cdots]]].$$

Case 1. There is some extension of A so $N_1(x_0)$ accepts. Thus $x_0 \in L(H^A)$ on this extension. Fix the oracle strings queried along some accepting path of $N_1^A(x_0)$ on this extension. To assure that $x_0 \notin S_{2k+1}$, find a y, $|y| = n+1$, so $0x_0y$ is unspecified and add it to the oracle.

Case 2. For every extension of A, $N_1^A(x_0)$ rejects and for some extension of A so that $(\forall y\colon |y| = n+1\colon 0x_0y \notin A)$, $A_2^A(x_0)$ rejects. Thus $x_0 \notin L(H^A)$ on this extension. Fix in A the elements along some rejecting path. Now assure $x_0 \in S_{2k+1}$ by adding an unspecified string $0x_0y$, $|y| = n+2$, to A.

Case $2j$ $(1 \leqq j \leqq k)$. Cases $1, 2, \cdots, 2j-1$ fail to hold and for some extension of A so that $(\forall y\colon n+1 \leqq |y| \leqq n+2j-1\colon 0x_0y \notin A)$, $A_{j+1}^A(x_0)$ rejects. Fixing a rejecting path assures $x_0 \notin L(H^A)$. Insure that $x_0 \in S_{2k+1}$ by choosing a $|y| = n+2j$ so $0x_0y$ is unspecified and add it to our oracle.

Case $2j+1$ $(0 \leqq j \leqq k)$. Cases $1, 2, \cdots, 2j$ fail to hold and for some extension of A so that $(\forall y\colon n+1 \leqq |y| \leqq n+2j\colon 0x_0y \notin A)$, $N_{j+1}^A(x_0)$ accepts. Fixing an accepting path puts x_0 in $L(H^A)$. Assure $x_0 \notin S_{2k+1}$ by choosing a y, $|y| = n+2j+1$, so $0x_0y$ is unspecified and add $0x_0y$ to our oracle.

Case $2k+2$. Cases $1, 2, \cdots, 2k+1$ fail to hold. So H rejects x_0 on any extension where $(\forall y\colon n+1 \leqq |y| \leqq n+2k+1\colon 0x_0y \notin A)$. Freeze all these strings out of A. Now $x_0 \in S_{2k+1}$, but $x_0 \notin L(H^A)$.

All cases. If any of the cases $1, 2, \cdots, 2k+2$ has occurred, we must act to maintain the sparseness of S_{2k+1}. For each $x \neq x_0$, find a y_x, $|y_x| = |x|+1$ so $0xy_x$ has not yet been specified and add that string to A. Thus S_{2k+1} has at most one string of length n.

Stage n, Part B. Recall that N is a machine so $L(N^A)$ is NE^A complete for all A. We will code so that $1\#x\#1^{2^{2|x|}} \in A \Leftrightarrow x \in L(N^A)$.

For each string x so that $\log^2 n \leqq |x| \leqq \log^2 (n+1)$, in order from the smallest such x to the largest, do the following. If there is an extension of A so that $N^A(x)$ accepts, fix the elements along that path and add $1\#x\#^{2^{2|x|}}$ to A. Otherwise, fix $1\#x\#1^{2^{2|x|}}$ as out of A.

End Construction

Notes on the construction.

(1) We can find an x_0 in Part A, as there are 2^n candidates and at most $2^{1+\log^2 n} 2^{2\log^2 n} = 2n^{3\log n}$ strings of length at least n have been fixed. All these have been fixed in Part B. Our Part A actions are spaced double exponentially far apart in length. Each Part A action cannot get near the strings involved in the next Part A diagonalization.

(2) Similarly, we can find the strings y_x with which we poison strings to maintain sparseness in Part A.

(3) In Part B, each coding string $1\#x\#1^{2^{2|x|}}$ will certainly be unspecified when we assign it. No Part B computation will have touched this string. Any Part A machine run at stage n cannot even reach things of length $n^{\log n}$, by our assumption that the ith NP $(2k+1)$ machine is composed of machines running in time at most $n^i + i$ and our choice of H. So no Part A machine has touched our coding strings.

3. Counting classes. Counting classes at first seems tempting as natural complete sets for the boolean hierarchy. In this section, we define the notion of a counting class, and display relativized worlds where counting classes are *not* complete for the levels of the boolean hierarchy.

NP is the class of sets accepted by nondeterministic polynomial-time Turing machines (NPTMs) that (by definition) accept when *at least one* computation path accepts. US is the class of sets accepted by NPTMs that accept when *exactly one* computation path accepts. Blass and Gurevich [BG82] showed that there are relativized worlds where UNIQUE-SAT, a natural complete set for US, is and is not complete for D^P.

We are interested in more generalized notions of machines that count accepting paths (see also [GW87]). Our machines accept an input if the number of accepting paths generated by that input is in a prescribed set. These counting classes have natural complete sets, i.e., formulas with specified numbers of satisfying assignments. By way of contrast, counting classes in which certain numbers of accepting paths are forbidden have no complete sets in appropriately relativized worlds (Hartmanis and Hemachandra [HH86b]).

Please note that throughout § 3, even when not explicitly mentioned, in every use of CP_S and SAT_S we tacitly assume that S is a subset of $\{1, 2, 3, \cdots\}$ and is either finite or cofinite.

DEFINITION 3.1. (a) SAT_S is the set of all formulas whose number of satisfying assignments is in S. For example, SAT is $SAT_{\{1,2,3,\cdots\}}$ and UNIQUE-SAT is $SAT_{\{1\}}$.

(b) CP_S is the class of sets accepted by NPTMs that accept, by definition, when they have a number of accepting computations in S. Mnemonically, CP stands for "counting polynomial time." Two examples are: NP is $CP_{\{1,2,3,\cdots\}}$ and US is $CP_{\{1\}}$.

LEMMA 3.1. (a) SAT_S *is many-one-complete for* CP_S.

(*b*) *For any S and any complexity class C closed downward under many-one polynomial-time reductions,*

$$SAT_S \textit{ is } A\textit{-hard}^3 \Leftrightarrow CP_S \supseteq A.$$

For example, SAT_S *is* NP-*hard* $\Leftrightarrow CP_S \supseteq NP$.

(c) *For S finite,* $SAT_S \supseteq coNP$. *For S cofinite,* $SAT_S \supseteq NP$.

Proof of Lemma 3.1. (a) Cook's reduction [C71], [GJ79] is parsimonious.

(b) The proof is immediate.

(c) Let S be finite. Let a_z be the largest element of S. Given a formula f, we can quickly either find a solution (so f is not in UNSAT) or find a_z nonsatisfying assignments. Thus f with these assignments ORed on has a_z more solutions than f, and is thus in SAT_S if and only if f is in UNSAT; thus SAT_S is coNP-hard. Thus we are done by part (b).

Similarly, for S cofinite, SAT_S is NP-hard because we can add j true assignments to a formula, $j = \max\{i \mid i \geq 0 \wedge i \notin S\}$. □

Clearly, counting of this sort can be done in hardware. For example, a set in CP_S, $|S| = z$, is the union of z D^P sets, and so is in $NP(2z)$. Similarly, for cofinite S, $CP_S \subseteq coNP(2y)$, when $|\bar{S}| = y$. The containment can easily be made an equality in relativized worlds. Is the containment always an equality?

We show that in appropriately relativized worlds counting is weak. For example, we display a world where for *no* choice of S is SAT_S complete for D^P or coD^P. Furthermore, in this world for no choice of finite S can SAT_S even be NP-hard and

[3] We always use "hard" in the many-one sense.

for no choice of cofinite S can SAT_S be coNP-hard (where we relativize satisfiability in the standard way—adding membership testing gates). Indeed, each counting class with S, S finite (cofinite), fails to contain NP (coNP) even when its run time is boosted from polynomial to certain *exponential* times.

Similarly, we separate many counting classes so strongly that large boosts in run time fail to give containment. All these relativized containments are obtained by combinatorially exploiting the limited control of counting machines. On the other hand, we note that a clear containment structure exists among counting classes.

3.1. A counting hierarchy. Suppose you have a party at which each guest may know the names of some of the other guests. The following combinatorial lemma states conditions under which your party will contain a large set of "strangers," i.e., a large set A such that each person in A knows the name of no person in A (except perhaps his own name). This lemma will be useful in proving our separations. S_i contains the names of party-goers known by party-goer i. In the proofs of the following relativizations (e.g., Theorem 3.1.1(b)), the S_w correspond to the strings queried by a certain counting machine when string w is added to the oracle. The combinatorial lemma lets us find strings w' and w'' so that adding both simultaneously causes the number of accepting paths to add.

COMBINATORIAL LEMMA.

$$(\forall S_1, \cdots, S_l \subseteq N) \quad \left[\sum |S_i| < \left\lceil \frac{l(l-1)}{k(k-1)} \right\rceil \Rightarrow (\exists T \subseteq \{1, 2, \cdots, l\}, |T| \geqq k)(\forall e \in T) \right.$$
$$\left. [S_e \cap (T - e) = \varnothing] \right].$$

Proof of Combinatorial Lemma. Indeed, we show there is a T of size exactly k. There are $\binom{l}{k}$ candidate k-tuples for T. Each element added to some set destroys the candidacy of at most $\binom{l-2}{k-2}$ new tuples. For example, adding $x \leqq l$ to set S_y eliminates tuples containing both x and y. Thus we need at least

$$\left\lceil \binom{l}{k} \Big/ \binom{l-2}{k-2} \right\rceil = \left\lceil \frac{l(l-1)}{k(k-1)} \right\rceil$$

elements to eliminate all tuples. □

Our first theorem shows that "the number of values accepted on" yields a hierarchy: *more counting is more powerful,* and strictly so in some worlds.

THEOREM 3.1.1.

(a) $\mathrm{CP}_{\{1\}} = \bigcup_{|S|=1} \mathrm{CP}_S \subseteq \bigcup_{|S|=2} \mathrm{CP}_S \subseteq \bigcup_{|S|=3} \mathrm{CP}_S \subseteq \cdots \subseteq \mathrm{BH} \subseteq \Delta_2^{\mathrm{P}}$.

(b) *There is a recursive oracle* A *so* $\bigcup_{|S|=1} \mathrm{CP}_S^A \subset \bigcup_{|S|=2} \mathrm{CP}_S^A \subset \bigcup_{|S|=3} \mathrm{CP}_S^A \subset \cdots$.

Proof of Theorem 3.1.1(a). Clearly counting is in BH. Indeed, CP_S sets can be represented as the union of $|S|$ D^{P} sets, and thus by the lemma cited in § 1.1 are in the boolean hierarchy. If $L \in \mathrm{CP}_{\{a_1, \cdots, a_z\}}$, there is a $\mathrm{CP}_{\{1, 2+a_1, 2+a_2, \cdots, 2+a_z\}}$ machine that simulates the $\mathrm{CP}_{\{a_1, \cdots, a_z\}}$ machine for L, and mindlessly adds two accepting paths. This new machine accepts L. Since this holds in general, $\bigcup_{|S|=1} \mathrm{CP}_S \subseteq \bigcup_{|S|=2} \mathrm{CP}_S \subseteq \bigcup_{|S|=3} \mathrm{CP}_S \subseteq \cdots$. Finally, $\mathrm{CP}_{\{j\}} = \mathrm{CP}_{\{1\}}$ from Theorem 3.2.1.1. □

Proof of Theorem 3.1.1(b). Because of space limitations, we just show a world in which $\bigcup_{|S|=1} \mathrm{CP}_S^A \subset \bigcup_{|S|=2} \mathrm{CP}_S^A$. By Theorem 3.1.1(a), it suffices to show a language L in $\mathrm{CP}_{\{1,2\}}^A$ that is not in $\mathrm{CP}_{\{1\}}^A$. We diagonalize over all $\mathrm{CP}_{\{1\}}$ machines to show that $L = \{0^i \mid 1 \leqq |\Sigma^i \cap A| \leqq 2\}$ is not in $\mathrm{CP}_{\{1\}}$. Since L is clearly in $\mathrm{CP}_{\{1,2\}}$ this suffices. Initially, set $A := \varnothing$.

Stage s. We will establish that the sth $\mathrm{CP}_{\{1\}}$ machine, call it C_i, does not accept L. Let $p(\cdot)$ be the polynomial bound on the length of each of C_i's computation paths

(and thus on the length of the strings it queries). Choose j so large that no string of length j or larger has yet been touched, and so large that $p(j) < (2^j - 1)/2$.

Case 1. $C_i^A(0^j)$ has accepting paths.

If it has one accepting path, freeze A for all strings of length up to $p(j)$; now $0^j \notin L$ but $0^j \in L(C_i^A)$.

If it has more than one accepting path, fix the elements along two paths, put some unfrozen length j string into A, and then freeze A for all strings of length up to $p(j)$; now $0^j \in L$ but $0^j \notin L(C_i^A)$.

Case 2. For some length j string y, $C_i^{A \cup y}(0^j)$ rejects.

Set $A := A \cup \{y\}$ and freeze A for all strings of length up to $p(j)$. Now $0^j \in L$, $0^j \notin L(C_i^A)$.

Case 3. For all length j strings, y: $C_i^{A \cup y}(0^j)$ accepts (i.e., it has a unique accepting path).

For each length j string w define a set

$$S_w = \{z \mid |z| = j \text{ and } C_i^{A \cup w}(0^j) \text{ queries } z \text{ along its accepting path}\}.$$

We use the Combinatorial Lemma from the start of this section with $k = 2$, $l = 2^j$, and using the 2^j sets S_w for $|w| = j$. The precondition of the lemma is met since by our conditions on the choice of j we have $2^j p(j) < 2^j((2^j - 1)/2)$. Thus there exist strings y', y'' so y' is not in $S_{y''}$ and y'' is not in $S_{y'}$. Thus if we add y' and y'' simultaneously to A we will get at least two accepting paths: the ones corresponding to $S_{y'}$ and $S_{y''}$. (Why are these two paths distinct? If $y'' \notin S_{y''}$ then we have an accepting path in $C_i^A(0^j)$, and this was treated in Case 1. Hence $S_{y''}$ and $S_{y'}$ differ on y''.) So $C_i^{A \cup y' \cup y''}(0^j)$ has at least two accepting paths and rejects. Setting $A := A \cup \{y', y''\}$ and fixing A up to length $p(j)$ we have insured that $0^j \in L$ but $0^j \notin L(C_i^A)$. □

More counting gives more power, as these theorems show. Indeed, we have an infinite hierarchy of counting power. Attempts to make the polynomial hierarchy infinite in some relativization took many years to succeed [Y85], [BS79].

Counting can also be made *weak*. Below, we show that counting may be too weak to even capture NP or coNP. As a consequence, we show that in certain relativized worlds no amount of counting is hard for even low levels of the boolean hierarchy.

THEOREM 3.1.2. *There is a recursive set A so that* $\bigcup_{S \text{ finite}} \mathrm{CP}_S^A \not\supseteq \mathrm{NP}^A$ *and* $\bigcup_{S \text{ cofinite}} \mathrm{CP}_S^A \not\supseteq \mathrm{coNP}^A$.

COROLLARY 3.1.1. *There is a relativized world where no amount of counting is hard for* $\mathrm{NP}^A(k)$ *or* $\mathrm{coNP}^A(k)$, $k > 1$ *(i.e., where no counting class contains either* $\mathrm{NP}^A(k)$ *or* $\mathrm{coNP}^A(k)$, $k > 1$*). In particular, no counting class contains* $\mathrm{D}^{\mathrm{P}}(A)$ *or* $\mathrm{coD}^{\mathrm{P}}(A)$.

Proof of Corollary 3.1.1. $\mathrm{NP}^A(k)$ and $\mathrm{coNP}^A(k)$ are each NP^A-hard and coNP^A-hard for every $k > 1$, yet the theorem above shows that the artificial and natural complete languages for counting classes fail to be hard for at least one of these. □

Proof of Theorem 3.1.2. Let $L_A = \{0^n \mid (\exists y)[|y| = n \wedge y \in A]\}$. Let $LL_A = \{0^n \mid (\forall y)[|y| = n \Rightarrow y \notin A]\}$. Clearly $L_A \in \mathrm{NP}^A$ and $LL_A \in \mathrm{coNP}^A$.

Stage $\langle\langle i, z, a_1, \cdots, a_z\rangle, 0\rangle$, $0 < a_1 < \cdots < a_z$. We show that the ith NP machine, viewed as a $\mathrm{CP}_{\{a_1, \cdots, a_z\}}^A$ machine, does not accept L_A. Without loss of generality NP_i runs in $\mathrm{NTIME}[n^i + i]$.

Choose m so large that nothing of length greater than m has yet been fixed, and so large that $2^m(m^i + i) < \lceil 2^m(2^m - 1)/a_z(a_z + 1) \rceil$. Let B be the current version of A. Run $N_i^B(0^m)$.

Case 1. $N_i^B(0^m)$ accepts. $L(N_i^B) \neq L_A$ and we are done.

Case 2a. $N_i^B(0^m)$ rejects and for one of the 2^m ways we can add a length m string, y, to B, $N_i^{B \cup y}(0^m)$ rejects. Set our current A to $B \cup y$ and again $L(N_i^A) \neq L_A$.

Case 2b. $N_i^B(0^m)$ rejects and for all the 2^m ways we can add a length m string, y, to B, $N_i^{B\cup y}(0^m)$ accepts. We apply the combinatorial lemma (from the start of this section) to get a contradiction.

That is, for each of the 2^m extensions, $B \cup y$, mark one accepting path of $N_i^{B\cup y}(0^m)$ and say the path is *named* by y. Let S_y denote the strings queried on the path named y. By our assumption that N_i runs in NTIME $[n^i+i]$, $\sum |S_y| \leqq 2^m(m^i+i)$. By our choice of m, the combinatorial lemma applies (with $l=2^m$, $k=a_z+1$) and chooses for us a set T of a_z+1 special marked paths, none of which queries the name of any of its a_z brethren. Furthermore, the a_z+1 paths are all distinct, since each one contains its own name and none of its brethren does. Each special path does indeed contain its name, otherwise it would have caused $N_i^B(0^m)$ to accept, but we supposed it did not. Thus $N_i^{B\cup T}(0^m)$ has at least a_z+1 accepting paths and, viewed as (i.e., with the acceptance mechanism of) a $\mathrm{CP}^A_{\{a_1,\cdots,a_z\}}$ machine, rejects. Yet $0^m \in L_A$. So setting our current A to $B \cup T$, $L(H_i^A) \neq L_A$ and we have diagonalized away another machine.

Stage $\langle\langle i, z, a_1, \cdots, a_z\rangle, b\rangle$, $0<a_1<\cdots<a_z<b$. We show that the ith NP machine, viewed as a $\mathrm{CP}^A_{\{a_1,\cdots,a_z,b,b+1,b+2,\cdots\}}$ machine, does not accept LL_A.

Choose m large. Denote by B the current version of A. Run $N_i^B(0^m)$. If it rejects, we are done. If it accepts, for each of the 2^m ways we can add a length m string, y, to B, run $N_i^{B\cup y}(0^m)$. If any of these 2^m ways accepts, we are done. Now if extension $B \cup y$ has no accepting paths or has some accepting paths but queries y on none of them, y must appear on some accepting path of $N_i^B(0^m)$. Thus all but at most $(b-1)m^i+i$ of our 2^m extensions cause "nice" rejections: rejections (with oracle $B \cup y$) where there is some accepting path that queries y.

From here, we are done by the argument of the previous part. In brief, for each "nice" extension mark a path that queries the extension's name; appeal to the combinatorial lemma to get a set T of b paths that do not contain each others' names; thus, $N_i^{B\cup T}(0^m)$ has b accepting paths and accepts, but $0^m \notin LL_A$, thus $L(N_i^A) \neq LL_A$. □

Indeed, counting is even weaker than these results suggest. By making full use of our combinatorial control arguments, we can show that even giving counting machines *exponential* run times does not allow them to subsume NP.

THEOREM 3.1.3. *For each k, there is a recursive oracle A for which* $\mathrm{NP}^A \not\subseteq \bigcup_{S\,\text{finite}} \mathrm{CTIME}_S^A[2^{kn}]$, *where* $\mathrm{CTIME}_S^A[f(n)]$ *is just like* CP_S^A, *except our time bound has been boosted from* P *to* $f(n)$.

Proof of Theorem 3.1.3. This is an improvement on our proof of Theorem 3.1.2, whose notation we adopt. We must make new versions of L_A and LL_A that depend on many strings. We let $L_A=\{0^n \mid (\exists y)[|y|=(k+1)n \wedge y \in A]\}$ and $LL_A=\{0^n \mid (\forall y)[|y|=(k+1)n \Rightarrow y \notin A]\}$. There are $2^{(k+1)^n}$ ways (the l for the Combinatorial Lemma) of adding strings. We choose m so large that

$$2^{(k+1)m}\left(c+\frac{2^{km}}{(a_z+1)^2}\right)<\frac{2^{(k+1)m}(2^{(k+1)m}-1)}{a_z(a_z+1)}. \qquad \square$$

Indeed, the same tricks apply within the counting hierarchy. For example, there is a world where

$$\bigcup_{c,|S|=z} \mathrm{CTIME}_S^A[2^{cn/\log n}] \not\supseteq \bigcup_{|S|=z+1} \mathrm{CP}_S^A.$$

3.2. Relations and natural containments among the CP classes.

3.2.1. Relations based on values. The previous section shows that "the number of values accepted on" gives a hierarchy. In this section, we fix the *number* of values, k,

our classes accept on and see what effects the actual *values* have. For $k = 1$, the number of paths makes no difference. We can multiply paths (to show $\mathrm{CP}_{\{1\}} \supseteq \mathrm{CP}_{\{k\}}$) and simulate k-tuples of paths (to show $\mathrm{CP}_{\{k\}} \supseteq \mathrm{CP}_{\{1\}}$) [see, for example, Theorem 3.2.2.1]. Hence we have the following theorem.

THEOREM 3.2.1.1. *For every j, k and A,* $\mathrm{CP}^A_{\{j\}} = \mathrm{CP}^A_{\{k\}}$.

The situation differs markedly when $k = 2$. Our classes here are $\mathrm{CP}_{\{a,b\}}$, $a < b$, and we will call a the *minor* subscript and b the *major* subscript. Here (with proper relativizations) a class never contains any class with a larger major subscript (Theorem 3.2.1.2). When the major subscripts are the same, we can usually relativize so the class with the larger minor subscript is not contained by the other. On the other hand, there is more than lexicographical ordering at work here. We can also relativize away from lexicographical ordering. Indeed, we can combine the relativizations to obtain a world A where, for example, $\mathrm{CP}^A_{\{1,73\}} \not\subseteq \mathrm{CP}^A_{\{40,73\}}$ and $\mathrm{CP}^A_{\{1,73\}} \not\supseteq \mathrm{CP}^A_{\{40,73\}}$.

THEOREM 3.2.1.2. (a) *There is a recursive oracle A so that for* $i < j < j'$, $\mathrm{CP}^A_{\{i,j\}} \subset \mathrm{CP}^A_{\{i,j'\}}$.

(b) *There is a recursive oracle A so that for all* $1 < j < k$, $\mathrm{CP}^A_{\{1,k\}} \not\subseteq \mathrm{CP}^A_{\{j,k\}}$.

(c) *There is a recursive set A so that for all i, j, k, l with* $i < k$, $j < k$, $jl \leqq k$, *and* $i + l > k$, $\mathrm{CP}^A_{\{i,k\}} \not\supseteq \mathrm{CP}^A_{\{j,k\}}$.

COROLLARY 3.2.1.1. *There is a world where no* $\mathrm{CP}^A_{\{i',j'\}}$ *contains* $\bigcup_{i,j} \mathrm{CP}^A_{\{i,j\}}$.

Our results extend naturally to $k = 3, 4, \cdots$, and by interlacing the relativizations, we can simultaneously obtain these results for all k.

3.2.2. Containments. As we have just seen, combinatorial manipulations allow us to construct many relativized separations. Nonetheless, there is a clear and ordered set of containments among counting classes. Figure 3 shows the containments implied by Corollary 3.2.2.1. Figure 4 shows further containments from Theorem 3.2.2.1.

THEOREM 3.2.2.1 (Containment Theorem). *For* $z \geqq 1$, $c_l \geqq 1$ $(1 \leqq l \leqq z)$, $k \geqq 0$, *and* $j > i \geqq \min_{1 \leqq l \leqq z}(k_l) \geqq 1$,

$$\mathrm{CP}_{\{i,j\}} \subseteq \mathrm{CP}\left\{ c_1\binom{i}{k_1} + c_2\binom{i}{k_2} + \cdots + c_z\binom{i}{k_z} + k,\ c_1\binom{j}{k_1} + c_2\binom{j}{k_2} + \cdots + c_z\binom{j}{k_z} + k \right\}.$$

COROLLARY 3.2.2.1. (a) $\mathrm{CP}_{\{i,j\}} \subseteq \mathrm{CP}_{\{i,j'\}}$ *when* $i < j < j'$.

(b) $\mathrm{CP}_{\{i,j\}} \subseteq \mathrm{CP}_{\{ki+l,kj+l\}}$ *for* $k \geqq 1$, $l \geqq 0$.

Proof of Theorem 3.2.2.1. Simulate the $\mathrm{CP}_{\{i,j\}}$ machine by simulating with c_l-fold replication each k_l-tuple of its paths (i.e., accepting and replicating the tuple if all k_l paths accept). Also, add k dummy accepting paths. If the $\mathrm{CP}_{\{i,j\}}$ machine has $i(j)$ accepting paths, we have $f(i)$ $(f(j))$ accepting paths, where $f(m) = \sum c_l\binom{m}{k_l} + k$. If the number of paths is neither i nor j, we will *not* get either $f(i)$ or $f(j)$ paths, as f is strictly increasing in the range $[\min(k_l) - 1, \infty)$. □

4. The boolean hierarchy and sparse oracles for NP. This section studies the relations between sparse oracles and the boolean hierarchy. We say NP has a *sparse oracle* if there is a sparse set S so that $\mathrm{NP} \subseteq \mathrm{P}^S$. Mahaney [M82] showed that if NP has a sparse many-one-complete set then P = NP. Karp and Lipton [KL80], [H82] showed that if NP has a sparse Turing-hard set or a sparse oracle, then $\Sigma^{\mathrm{P}}_2 = \Pi^{\mathrm{P}}_2$. Does the existence of a sparse oracle for NP imply something stronger than $\Sigma^{\mathrm{P}}_2 = \Pi^{\mathrm{P}}_2$?

By displaying a relativized world where NP has a sparse oracle but in which the boolean hierarchy is infinite, we show that the conclusion in [KL80] is near the strongest possible among proofs that relativize.[4] In terms of circuits, this result shows that (in

[4] Kadin has optimally strengthened the Karp–Lipton result for the special case of sparse Turing-complete sets for NP [K87a], [M82].

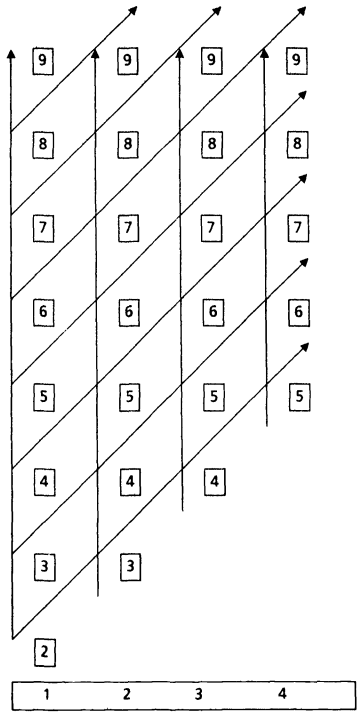

FIG 3. *Simple containments.*

relativized worlds) the existence of small circuits for NP does not imply that P = NP or even that the boolean hierarchy is finite, and improves the work of Kurtz, Immerman, and Mahaney reported in [HIS83]. Similarly, by displaying a relativized world where PSPACE has a sparse oracle but where the boolean hierarchy is infinite, we show that the Karp-Lipton result on sparse oracles for PSPACE (i.e., if PSPACE has a sparse oracle then PSPACE = Σ_2^P) is also nearly as strong as possible. Indeed, we show the stronger result that $P^S = PSPACE^S$, S sparse, can be consistent with an infinite boolean hierarchy.

Our proofs combine the methods of diagonalization and encoding of computations. By diagonalization, we win a block of space to use. We store the location of this space in the sparse oracle. We devote the space to encoding the computations of machines. Thus $NP^A \subseteq P^{A,S}$, because the sparse oracle S lets us find NP^A computations encoded in A. We carefully diagonalize to separate the boolean hierarchy. For simplicity, we prove the case of $D^P(A) \neq coD^P(A)$.

LEMMA 4.1. *There is a recursive set A and a sparse set S so* $NP^A \subseteq P^{A,S}$ *and* $D^P(A) \neq coD^P(A)$.

THEOREM 4.1. *There is a relativized world where the boolean hierarchy is infinite and* PSPACE *has sparse oracles (and, indeed, in which there is a sparse S so* $P^S = PSPACE^S$).

COROLLARY 4.1. *No proof that relativizes can show the following: if* NP *has a sparse oracle then the polynomial hierarchy equals the boolean hierarchy.*

Proof of Lemma 4.1. Let $\{N_i\}$ and $\{A_i\}$ be enumerations of standard clocked NP and coNP machines, respectively. Without loss of generality, N_i and A_i run at most $n^{\log^* i} + \log^* i$ steps on input of size n for $i > 20$, and one step for $i \leqq 20$. Define an

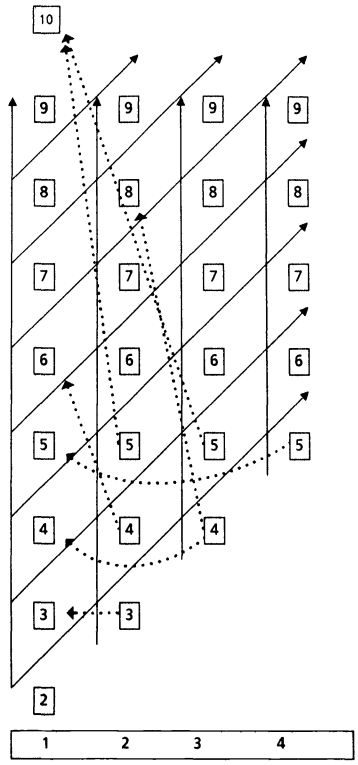

FIG. 4. *Additional containments.*

enumeration $\{H_i\}$ of standard clocked $\mathrm{coD^P}$ machines so $L(H_i) = L(N_j) \cup L(A_k)$, $i = \langle j, k \rangle$.

Let $U_A = \{N_i \# x \# 1^l \mid N_i^A(x)$ accepts in at most l steps$\}$. U_A encodes the computations of NP^A machines. We will code U_A into A and S so that $\mathrm{NP}^A \subseteq \mathrm{P}^{A,S}$.

Let $L_A = \{0^n \mid (\exists y)[|y| = 3n+1 \wedge y \in A]\} \cap \{0^n \mid (\forall y)[|y| = 3n+2 \Rightarrow y \notin A]\}$. Surely $L_A \in \mathrm{D^P}(A)$. We diagonalize over the H_i's to show that $L_A \notin \mathrm{coD^P}(A)$.

Stage q, encoding section. Choose an *address*, a_q, $|a_q| = q$, so no length $3q$ string starting with a_q has yet been fixed. The H_i's fix few enough strings that such an a_q can always be found. Now use the block of length $3q$ strings starting with a_q as a "treasure box," to encode the information of all length q strings of U_A: $[a_q y 0^q \in A \Leftrightarrow y \in U_A]$, for all $|y| = q$. Crucially, the computations being coded query strings of length at most q, and our length q strings have long since been settled.

Now we must code the precious address string, a_q, into S. For $j \leqq q$ put $1^{\langle q,j \rangle}$ in S if and only if bit j of a_q is 1. Now S codes a_q; with q calls to S we can recover a_q. Note that S will be sparse.

Stage q, diagonalizing section. Suppose H_i is the first $\mathrm{coD^P}$ machine that still might accept L_A. We will extend A so that $L(H_i^A) \neq L_A$.

Recall $L(H_i^A) = L(N_j^A) \cup L(A_k^A)$, $i = \langle j, k \rangle$. Run $N_j(0^q)$ with all possible extensions of A as its oracle.

Case 1. It accepts for some extension. Freeze all queried elements on some accepting path. Thus $L(H_i^A)$ accepts 0^q. Now, put an unfixed length $3q+2$ string into A, so $0^q \notin L_A$. H_i^A does not accept L_A.

Case 2. It rejects on all extensions. So $L(H_i^A) = L(A_k^A)$, and a coNP machine is left with the task of accepting a D^P set. Consider all extensions of A in which $(\forall z)\ [|z| = 3q+2 \Rightarrow z \notin A]$.

Case 2a. For some such extension, B, $A_i^B(0^q)$ rejects. Freeze in A the elements on a rejecting path and add to A an unfixed length $3q+1$ string. Thus $H_i^A(0^q)$ rejects but $0^q \in L_A$.

Case 2b. For all such extensions, A_i accepts. Then it accepts with A untouched, but $0^q \notin L_A$ so it should reject. □

Sketch of the proof of Theorem 4.1. The same method used above in the proof of the lemma can be used with the "sawing" diagonalization of [CGI], which allows an infinite separation of the levels. This combination creates a relativized world in which NP (or, as we note below, PSPACE) has a sparse oracle and the boolean hierarchy is infinite.

Note that once we win ourselves some coding space we can use the space to code the computations of *any* machine class that queries strings of length at most polynomial in its input's size. We just code the universal set of that class into our addressed treasure boxes. Thus the same proof works for PSPACE (part b), with the standard conventions [FSS81] about relativized PSPACE. Indeed, with a relativization we could even make the boolean hierarchy infinite while finding a sparse oracle for the badly nonrecursive class RE_{poly}, the class of sets accepted by machines that query strings of length at most polynomial in their input size. □

ALGORITHMS AND DATA STRUCTURES FOR AN EXPANDED FAMILY OF MATROID INTERSECTION PROBLEMS*

GREG N. FREDERICKSON† AND MANDAYAM A. SRINIVAS‡

Abstract. Consider a matroid of rank n in which each element has a real-valued cost and one of $d > 1$ colors. A class of matroid intersection problems is studied in which one of the matroids is a partition matroid that specifies that a base has q_j elements of color j, for $j = 1, 2, \cdots, d$. Relationships are characterized among the solutions to the family of problems generated when the vector $(q_1, q_2, \cdots, q_d)$ is allowed to range over all values that sum to n. A fast algorithm is given for solving such matroid intersection problems when d is small. A characterization is presented for how the solution changes when one element changes in cost. Data structures are given for updating the solution on-line each time the cost of an arbitrary matroid element is modified. Efficient update algorithms are given for maintaining a color-constrained minimum spanning tree in either a general or a planar graph. An application of the techniques to the problem of finding a minimum spanning tree with several degree-constrained vertices is described.

Key words. data structures, degree-constrained spanning tree, matroid intersection, minimum spanning tree, on-line updating, partition matroid

AMS(MOS)subject classification. 68Q

1. Introduction.

Matroids are discrete mathematical structures that appear in a variety of applications. They are structures for which the greedy algorithm gives an optimal solution, and when intersected characterize such problems as minimum-weight maximum-cardinality bipartite matching [L1]. In this paper we study a class of combinatorial problems from a matroid point of view. Consider a matroid in which each element has a real-valued cost, and one of d colors, for some constant $d > 1$. Given positive integers $q_1, q_2, \cdots, q_d$, we seek a base of the matroid that is of smallest cost subject to the constraint that the base must contain q_j elements of color j, for $j = 1, 2, \cdots, d$. For example, we can generalize the minimum spanning tree problem to a problem in which the edges have colors, and we desire a spanning tree of minimum cost subject to constraints on the number of edges of each color that are in the tree.

A *matroid* M consists of a set E of elements, and rules describing a property, called *independence*, of certain subsets of E. The rules satisfy axioms that may be found in [L1], [W]. A maximal independent subset of E is called a *base*. A *matroid optimization problem* is the problem of finding a minimum cost base in a matroid in which a cost is associated with each element. For example, finding a minimum spanning tree of a connected graph is a matroid optimization problem, where the matroid consists of the set of edges in the graph, and independence corresponds to acyclicity. As stated above, matroid optimization problems can be solved by the greedy algorithm.

A *matroid intersection* involves two matroids defined on the same set E of elements, but with different sets of rules determining the independence of subsets in each matroid. A *matroid intersection problem* is an optimization problem whose solution is a subset of E of maximum cardinality that is independent in both matroids simultaneously, and is of minimum cost among all such subsets of E. There are algorithms for solving

any given matroid intersection problem in polynomial time whenever independence of a set in the matroid can be tested in polynomial time [BCG1], [L2]. However the polynomial is large: at least $O(n^2m)$, where m is the number of elements, and n is the cardinality of the largest independent set. The special type of matroid intersection problem that we focus on in this paper is one in which each of the elements is labeled with one of d colors, and one of the matroids (a *partition* matroid) specifies that a certain number of elements of each color must be in the solution. For $d=2$ colors, very efficient special-purpose algorithms have been presented for a variety of problems in [GT], [G]. In this paper we explore the structure of d-color problems that allows for their efficient solution when $d>2$.

The solution techniques of [GT], [G] rely on finding a minimum cost solution from among only red elements and a minimum cost solution from among only green elements, and then pairing these red elements and green elements. However, for $d>2$ colors, the analogue of such a pairing does not seem to exist. We overcome this difficulty by generalizing other characterization results in [GT], [G]. We characterize the relationships among the solutions to a family of problems generated when the vector $(q_1, \cdots, q_d)$ is allowed to vary over all combinations that sum to n. The number of problems in this family is thus $(n+d-1)!/(n!(d-1)!)$, which is $\Theta(n^{d-1}/(d-1)!)$ for small d. The key relationship that we establish is the property of *dominance*, which allows us to search efficiently within the set of solutions to these problems. Dominance means that if one constrained minimum cost base dominates another with respect to the color constraints, then all elements of a certain color in the second base are in the first.

The dominance property makes possible a divide-and-conquer approach for finding a constrained minimum cost base that is efficient for small values of d. For a variety of matroids possessing certain desirable properties, the algorithm runs in time $O(dT_0(m, n)+(d!)^2T(n, 2))$, where $T_0(m, n)$ is the time to solve an uncolored version of the problem, and $T(n, 2)$ is the time to solve the 2-color version given a solution for each of the two colors. For graphic matroids, it has been shown in [FT], [GGST] that $T_0(m, n)$ is slightly larger than proportional to m, and in [GT] it has been shown that $T(n, 2)$ is $O(n \log n)$.[1] Our algorithm handles any d-color matroid intersection problem, such as scheduling unit-time jobs with integer release times and deadlines [GT], in essentially the same time bound. While the algorithm is factorial in d, it matches the bound in [GT] for $d=2$ and is significantly more efficient than the previously known algorithms when d is a small constant.

We also address the problem of updating a solution repeatedly, as the cost of elements changes one at a time. This on-line updating problem is a generalization of the 2-color update problem discussed in [FS]. We show how to use the dominance property to generate and maintain efficiently a sparse description of the $(n+d-1)!/(n!(d-1)!)$ solutions to all problems as the vector $(q_1, \cdots, q_d)$ ranges over all valid possibilities. We can update a d-color minimum spanning tree in $O(d^2m^{1/2}+d^{11/3}(d!)^2n^{1/3}\log n)$ time, and in $O(d^3(d!)^2(\log d)^{-1/2}2^{2(2\log(2d)\log n)^{1/2}}(\log n)^{3/2})$ time if the graph is planar. These match the update times in [FS] for the case when $d=2$.

Our d-color algorithm can be used to find a multiple-degree-constrained spanning tree of a communications network. Suppose the degrees of a number d of the nodes are prespecified, because of the number of ports that they have. When $d=1$, the problem is a special case of the 2-color minimum spanning tree problem [GT]. However, many interesting problem instances may require d degree-constrained nodes, where d

[1] All logarithms are to the base 2.

is a small constant greater than one. We reduce this problem to a set of $(d+1)$-color problems, one of which yields the solution. While the problem is NP-hard for general d [GJ, p. 206], our algorithm is efficient for small d. If the set of vertices for which there are degree constraints is an independent set, then finding a multiple-degree-constrained spanning tree is tractable, and an $O(n^3)$ algorithm exists [BCG2].

The remainder of the paper is organized as follows. In § 2 we introduce some terminology and new concepts that facilitate the later discussion. In § 3 we characterize the structure of d-color problem solutions, and establish the overall minimum cost, convexity, and dominance properties. In § 4 we apply these characterizations to develop an efficient divide-and-conquer algorithm for the static d-color problem, and illustrate its efficiency for graphic matroids. In §§ 5 and 6 we generalize the 2-color results of [FS] to d colors, and describe how to maintain a sparse description of certain arrangements of solutions to d-color problems to permit fast on-line update. In § 7 we discuss an application of our methods.

2. Definitions. We identify some additional matroid terminology; a more complete discussion can be found in [L1], [W]. The *rank* of a set $E' \subseteq E$, denoted as $rank(E')$, is the cardinality of a maximal independent subset of E'. Let B be a base, and f an element in $E-B$. The *circuit* $C(f, B)$ is the set consisting of every element that can be deleted from $B \cup \{f\}$ to restore independence. Let e be an element in B. The *cocircuit* $\bar{C}(e, B)$ is the set consisting of every element that restores rank to $B-\{e\}$. We will sometimes refer to an element in $C(f, B)-\{f\}$ as one *that f can replace in B*, and an element in $\bar{C}(e, B)-\{e\}$ as one *that can replace e in B*. Let M/E' denote the *contracted* matroid obtained from M by contracting the elements $E' \subset E$. The elements of M/E' are $E-E'$. Suppose E' is independent. Then the independent sets (bases) of M/E' are those sets $X \subset E-E'$ for which $X \cup E'$ is independent (a base) in M, and $rank(M/E') = rank(M) - rank(E')$.

For our problems on graphs, read *edge* for *element*, *spanning tree* for *base*, *cycle* for *circuit*, and *forest* for *independent set*. The *rank* is the number of edges in a spanning tree. Thus a minimum spanning tree is a minimum cost base of a graphic matroid. Similarly, for our unit-time job-scheduling problem, read *job* for *element*, a *set of jobs with a feasible schedule* for an *independent set*, a *maximal such set of jobs* for a *base*, and a *minimal infeasible set of jobs* for a *circuit*. Thus a maximum-profit set of jobs with a feasible schedule is a maximum-cost base of a job-scheduling matroid. Let $m = |E|$ and $n = rank(M)$.

We associate a *color* $j, j \in \{1, \cdots, d\}$ with each element in set E. For any set $E' \subset E$, let *colors* (E') be a d-tuple $(i_1, i_2, \cdots, i_d)$ giving the count of elements of each color in E'. Let $c_0(e)$ be the positive, real-valued cost of element e, and $c_0(E')$ the total cost of elements in a set E'. For a given cost function, we refer to a base B in such a matroid as *a constrained minimum cost base*, or a *minimum cost base for its vector colors*(B), if B is of minimum cost over all bases with the same *colors* vector. We assume that E has been augmented with elements of cost ∞ as necessary so that a base of each color $1, \cdots, d$ exists. Thus a *monochromatic minimum cost base* is a constrained minimum cost base whose *colors* vector has exactly one nonzero component.

Following [GT], we find it advantageous to extend the cost function so that each constrained minimum cost base B is unique for its vector *colors*(B). We make two different extensions, both similar to extensions given in [GT]. We assume that a unique index is associated with each element. Let $\alpha = \min(\{|c_0(E') - c_0(E'')|: E', E'' \text{ are sets of elements, } |E'| = |E''|, c_0(E') \neq c_0(E'')\} \cup \{c_0(e): e \text{ in } E\})$. We define $c(e) =$

$c_0(e)-\alpha/3^i$, where i is the index of e. By our choice of α, we note that for any two distinct bases B_1 and B_2, $c(B_1)\neq c(B_2)$, and for any three distinct bases B_1, B_2, and B_3, $2c(B_2)\neq c(B_1)+c(B_3)$.

The second extension $c_L(\cdot)$ of $c_0(\cdot)$ is based on lexicography. A real function $g(\cdot)$ is said to be *convex* if for any choice of values $x_1<x_2<x_3$, $(g(x_2)-g(x_1))/(x_2-x_1)\leqq(g(x_3)-g(x_2))/(x_3-x_2)$. Let $\bar{f}=(f_1(\cdot),f_2(\cdot),\cdots,f_d(\cdot))$ be a d-tuple of convex functions, and let π be any permutation on d-tuples. Let E' be a set of edges. We assume that $\bar{f}(colors(E'))$ yields d-tuple $(f_1(i_1),\cdots,f_d(i_d))$. Let *indices*$(E')$ be a sorted ordering of the indices of the elements in E'. Then we define $c_L(E')$ as the tuple $(c_0(E'),\ \pi(\bar{f}(colors(E'))),\ indices(E'))$. Comparisons between costs are resolved by lexicography on the tuples.

Note that for any two bases B_1 and B_2, $c_L(B_1)=c_L(B_2)$ implies that $B_1=B_2$. It is clear that for any two bases B_1 and B_2 with identical *colors* vectors, and any $\bar{f}$ and π, $c(B_1)<c(B_2)$ if and only if $c_L(B_1)<c_L(B_2)$. Thus a constrained minimum cost base under $c(\cdot)$ is a constrained minimum cost base under $c_L(\cdot)$. We find $c(\cdot)$ more convenient in proving several key properties about d-color matroids, and $c_L(\cdot)$ more appropriate to use when designing algorithms for d-color matroids. When the cost function ensures that there is a unique base of minimum cost over all bases with *colors* vector $\bar{i}$, we call this base $B_{\bar{i}}$.

We next define the notion of a uniform cost adjustment with respect to each of the extended cost functions. The notion of a uniform cost adjustment comes from [G], where it has been applied in handling 2-color matroids. A *uniform cost adjustment* with respect to $c(\cdot)$ consists of adding a constant δ_j to the cost of every element of color j in the matroid, for $j=1,2,\cdots,d$, and is specified by the d-tuple $\bar{\delta}$. A uniform cost adjustment with respect to $c_L(\cdot)$ consists of adjusting costs according to a d-tuple $\bar{\delta}$ and introducing a new d-tuple $\bar{f}$ of functions, along with permutation π. Since only differences in cost between elements of a particular color are significant in determining any constrained minimum cost base $B_{\bar{i}}$, the base $B_{\bar{i}}$ remains of minimum cost over the vector $\bar{i}$ after a uniform cost adjustment. Note that only differences in cost between various colors are significant in determining the relative costs of bases with different *colors* vectors. Furthermore, we can always assume without loss of generality that a uniform cost adjustment in a d-color matroid has at most $d-1$ nonzero components. The purpose of a uniform cost adjustment is to make some constrained minimum cost base $B_{\bar{i}}$ of overall minimum cost.

Let j_1 and $j_2\neq j_1$ be integers in $\{1,2,\cdots,d\}$. We say that a vector $\bar{i}'$ is a (j_1,j_2)-*neighbor* of $\bar{i}=(i_1,i_2,\cdots,i_d)$ if $i'_{j_1}=i_{j_1}-1$, $i'_{j_2}=i_{j_2}+1$, and $i'_j=i_j$ for all other j. Let the j_1-*negative neighbors* of $\bar{i}$ be the set of all (j_1,j_2)-neighbors of $\bar{i}$. Let the j_1-*positive neighbors* of $\bar{i}$ be the set of all (j_2,j_1)-neighbors of $\bar{i}$. When there is a unique minimum cost base for each vector $\bar{i}$, we extend the notion of neighbor from vectors to the bases that they index in the natural way. Let $\bar{i}$ and $\bar{i}'$ be the *colors* vectors of two bases. Suppose there is a *unique* color j for which $i_j>i'_j$. Then we say that $\bar{i}$ *dominates* $\bar{i}'$ *with respect to color* j, or that $\bar{i}$ j-*dominates* $\bar{i}'$.

Given a base B, a *swap* $s=(e,f)$ *available in* B is an ordered pair of elements, where $e\in B$, $f\notin B$, e and f are of different colors, and $C(f,B)$ contains e. Element f can be swapped in to replace element e, resulting in a base $B-\{e\}\cup\{f\}$ (denoted by $B\oplus s$ or $B-e+f$). Let S be a sequence of ordered element pairs $s_1,\cdots,s_r$, where each $s_i=(e_i,f_i)$. Given a base B, we say that S is *a swap sequence available in* B if s_1 is a swap available in B and if $r>1$ then $s_2,\cdots,s_r$ is a swap sequence available in $B\oplus s_1$. If S is a swap sequence available in B then $B\oplus S$ denotes the base obtained by applying S to B. Consider any cost function on E. Suppose swap sequence S is

available in a constrained minimum cost base B. Let $s_i = (e_i, f_i)$ for $i = 1, \cdots, r$. We say that the sequence S is *optimal* if bases $B \oplus s_1, \cdots, B \oplus s_1 \oplus \cdots \oplus s_r$ are all constrained minimum cost bases. The sequence S is *color-conserving* if $colors(f_i) = colors(e_{i+1})$ for $i = 1, \cdots, r-1$. The sequence S is *acyclic* if $colors(e_i) \neq colors(e_j)$ for $i, j \in \{1, \cdots, d\}$ and $i \neq j$. Finally, the sequence S is *regular* if it is optimal, acyclic, and color-conserving. Note that any subsequence of a regular swap sequence is regular. We refer to a regular swap sequence S with $colors(e_1) = j_1$ and $colors(f_r) = j_2$ as a *regular* (j_1, j_2) *sequence.*

Let D be a set of bases with distinct *colors* vectors. The set D is *tight* if, for every pair of bases B_1 and B_2 in D, B_1 and B_2 are neighbors. A tight set D with $|D| = k > 1$ is *negative* if colors $j_1, \cdots, j_k$ can be uniquely assigned to bases in D such that for any base B in D, if base B is assigned color j, then every base in $D - \{B\}$ is a j-negative neighbor of B. A *positive* tight set is defined analogously, using j-positive neighbors instead of j-negative neighbors. If $|D| = 1$, then we arbitrarily assign the single base in D the color 1, and call D negative. We say that $hue(B)$ is the color assigned to B, and for any subset D' of D, $hue(D') = \bigcup_{B \in D'} hue(B)$. Let D be a negative tight set, B a base in D with $colors(B) = \bar{i}$, and $r = \sum_{j \in hue(D)} i_j$. Let $hspan(D)$ be the set of bases with *colors* vectors $\bar{i}'$ such that $\sum_{j \in hue(D)} i'_j = r$, and $i'_j = i_j$ for $j \notin hue(D)$. A tight set D is *complete* if $|D| = d$. We denote the unique complete, negative, tight set associated with a base B and color j by $D(B, j)$. Note that if B, $B' \in D(B, j)$ and B' is B's (j, l) neighbor, then $D(B, j) = D(B', l)$.

Let D be a negative, tight set of bases. The *swap graph* G_D associated with D has vertex set D and contains an edge (B_1, B_2) if and only if bases B_1 and B_2 are related by a single swap. If every constrained minimum cost base is unique for its *colors* vector, then there is a close relationship between negative tight sets of minimum cost bases and regular swap sequences. If D is negative tight set of minimum cost bases and G_D is its swap graph, then every simple path in G_D corresponds to a regular swap sequence.

3. Characterization results. In this section we first give several properties of 2-color matroids identified in [GT], [G]. We then consider d-color matroids for $d > 2$ and establish the following important properties regarding constrained minimum cost bases and their neighbors which hold for the modified cost function $c(\cdot)$. First, there is a uniform cost adjustment that makes each constrained minimum cost base the overall (unconstrained) minimum cost base. Second, every pair of adjacent constrained minimum cost bases is related by a regular swap sequence of at most $d - 1$ swaps. Third, if the *colors* vector of one minimum cost base dominates that of another with respect to a certain color, then all elements of that color in the dominated base are contained in the dominating base. Finally, we characterize how a constrained minimum cost base changes when the cost of one element changes.

LEMMA 1 [GT, Thm. 3.1]. *Consider a matroid with elements of two colors, red and green. Consider any positive, real-valued cost function. Let B_i be a constrained minimum cost base with i red elements. Executing a lowest cost red-green swap available in B_i transforms B_i into a constrained minimum cost base B_{i+1} with $i+1$ red elements.* □

LEMMA 2 [GT, Cor. 3.3]. *Consider a matroid with elements of two colors, red and green. Consider any positive, real-valued cost function $c'(\cdot)$. Let B_{i-1}, B_i and B_{i+1} be constrained minimum cost bases with $i-1$, i and $i+1$ red elements, respectively. Then* $c'(B_i) - c'(B_{i-1}) \leqq c'(B_{i+1}) - c'(B_i)$. □

The following result is implicitly stated in [G]. We supply an explicit proof, using Lemma 2.

LEMMA 3. *Consider a matroid with elements of two colors, red and green. Consider any positive, real-valued cost function $c'(\cdot)$. Let B_i be a constrained minimum cost base*

with i red elements. There exists a uniform cost adjustment that makes the cost of B_i less than or equal to the cost of every other base.

Proof. Let l be the smallest index such that B_l exists, and u the largest index such that B_u exists. It is observed in [GT] that B_i exists for each i, $l \leqq i \leqq u$. Assume as boundary conditions that $c'(B_{l-1}) = 2c'(B_l) - c'(B_u)$ and $c'(B_{u+1}) = 2c'(B_u) - c'(B_l)$. Take $\delta_{\text{red}} = c'(B_{i-1}) - c'(B_i)$ and $\delta_{\text{green}} = 0$. It follows from Lemma 2 by induction that $c'(B_{i'}) \geqq c'(B_{i-1}) = c'(B_i) \leqq c'(B_{i''})$ for $l \leqq i' < i$ and $i < i'' \leqq u$. □

The following lemma, which is a variation of a lemma in [FS], establishes a fundamental property of bases in matroids.

LEMMA 4. *Let B be a base and e_1, e_2, f_1, f_2 be distinct matroid elements. Suppose $B - e_1 + f_1$ and $B - e_2 + f_2$ are bases, but $B - e_1 - e_2 + f_1 + f_2$ is not a base. Then both $B - e_1 + f_2$ and $B - e_2 + f_1$ are bases.*

Proof. The proof is similar to that of Lemma 3 of [FS]. □

We next present some lemmas that will be useful in the proof of the overall minimum cost and dominance theorems for matroids with elements of $d > 2$ colors. Lemma 5 establishes that if an overall minimum cost property holds for constrained minimum cost bases, then the convexity property holds. Lemma 6 shows that if an overall minimum cost property holds for a certain subset of constrained minimum cost bases centered on a negative tight set, then a stronger version of an overall minimum cost property holds. Lemma 7 establishes how the overall minimum cost property for a negative, tight set of constrained minimum cost bases impacts the connectedness of the corresponding swap graph. Finally, Lemma 8 uses the connectedness of the swap graph to establish the exact relationship between two neighboring constrained minimum cost bases for which the overall minimum cost property holds.

LEMMA 5. *Consider a matroid with elements of $d > 2$ colors. Let B_1, B_2, and B_3 be constrained minimum cost bases with respect to cost function $c(\cdot)$, such that B_2 is B_1's (j_1, j_2) neighbor and B_3 is B_2's (j_1, j_2) neighbor, for some j_1, j_2. Suppose each of B_1, B_2, and B_3 can be made an overall minimum cost base through some uniform cost adjustment. Then $c(B_2) - c(B_1) < c(B_3) - c(B_2)$.*

Proof. Suppose in contradiction that $c(B_2) - c(B_1) \geqq c(B_3) - c(B_2)$. Since B_1, B_2, and B_3 are distinct, this inequality must be strict, by definition of the modified cost function. Without loss of generality, suppose that B_1 is an overall minimum cost base. Let $\bar{\delta}$ be any cost adjustment vector that makes B_2 an overall minimum cost base. (By our initial assumption, $\bar{\delta}$ exists.) Make all the adjustments of $\bar{\delta}$, except those for colors j_1 and j_2. Note that the new costs $c'(B_1)$, $c'(B_2)$, and $c'(B_3)$ have the same relative values as $c(B_1)$, $c(B_2)$, and $c(B_3)$. Now make the adjustments for colors j_1 and j_2, yielding costs $c''(B_1)$, $c''(B_2)$, and $c''(B_3)$. Since B_2 becomes an overall minimum cost base, we must have $c'(B_2) - c'(B_1) \leqq \delta_{j_1} - \delta_{j_2}$. We also get $c''(B_3) - c''(B_2) = c'(B_3) - c'(B_2) - (\delta_{j_1} - \delta_{j_2})$, which by the preceding argument is less than $c'(B_2) - c'(B_1) - (\delta_{j_1} - \delta_{j_2})$, which is at most $\delta_{j_1} - \delta_{j_2} - (\delta_{j_1} - \delta_{j_2}) = 0$. Thus $c''(B_3) < c''(B_2)$, which contradicts our assumption that a suitable δ exists. □

Note that Lemma 5 will hold for any cost function $c'(\cdot)$ derived from $c(\cdot)$ by a uniform cost adjustment.

LEMMA 6. *Consider a matroid with elements of $d > 2$ colors. Let D be a negative, tight set of constrained minimum cost bases for cost function $c(\cdot)$. Suppose for each base B in hspan(D) there is a uniform cost adjustment that makes B an overall minimum cost base. Then there is a uniform cost adjustment that simultaneously makes every base in D of overall minimum cost and every base in hspan$(D) - D$ not of overall minimum cost.*

Proof. The proof is by induction on $p = |D|$. The basis case for $p = 1$ follows from our assumption that every base in *hspan*(D), and therefore every base in D, can

individually be made of overall minimum cost through a uniform cost adjustment. For the inductive step, with $p > 1$, assume that the lemma holds for any negative tight set D' of cardinality less than p. Let B_1 be a base in D, of hue j_1. Let B_2 be a second base in D, with hue $j_p \neq j_1$. Consider the negative, tight set of bases $D_1 = D - \{B_2\}$, which is of size $p-1$. Since $|D_1| < |D|$, by the induction hypothesis there is a uniform cost adjustment $\bar{\delta}$ that makes every base in D_1, but no other base in $hspan(D_1)$, of overall minimum cost. We next decrease the cost of color j_p so that the B_1 and B_2 are of the same cost, yielding uniform cost adjustment $\bar{\delta}'$ with respect to the original costs. This does not affect which bases in $hspan(D_1)$ are of minimum cost among those in $hspan(D_1)$, since all bases in $hspan(D_1)$ have the same number of elements of color j_p.

With respect to adjustment $\bar{\delta}'$, all bases in D have identical, though not necessarily overall minimum, cost. We claim that with respect to $\bar{\delta}'$, the bases in D are the *only* bases in $hspan(D)$ that are of minimum cost within $hspan(D)$. To prove the claim, we consider two cases. For $|D| = 2$, the claim follows directly from Lemma 5. For $|D| = p > 2$, consider the following. For any color k in $hue(D)$, let j_k be the minimum number of elements of color k in any base in D. (Note that the base of hue k in D will have $j_k + 1$ elements of color k, and all other bases in D will have j_k elements of color k.) Let c_m be the cost of each base in D.

Suppose there is some base B_3 in $hspan(D) - D$ with $c(B_3) \leqq c_m$. For some r in hue (D), B_3 has $j'_r < j_r$ elements of color r. Let D' be the set of all constrained minimum cost bases in D with exactly j_r elements of color r. We assert that with respect to adjustment $\bar{\delta}'$ all bases in $hspan(D') - D'$ have cost greater than c_m. We apply the inductive hypothesis to D' to prove the assertion. With respect to cost function $c(\cdot)$, there is a uniform cost adjustment $\bar{\delta}''$ that makes every base in D' of overall minimum cost, and every base in $hspan(D') - D'$ not of overall minimum cost. We argue that $\bar{\delta}'$ has the same effect as $\bar{\delta}''$ over the set of bases in $hspan(D')$. The adjustments in $\bar{\delta}''$ for colors not in hue (D') do not affect the relative costs of bases in $hspan(D')$ and can thus be equal to the corresponding values in $\bar{\delta}'$. Since bases in D' have identical cost under $\bar{\delta}'$, and also identical cost under $\bar{\delta}''$, then for any pair of colors k_1, k_2 in $hue(D')$, $\delta''_{k_1} - \delta'_{k_1} = \delta''_{k_2} - \delta'_{k_2}$. Subtracting $\delta''_{k_1} - \delta'_{k_1}$ from the adjustment δ''_k for each k in $hue(D')$ does not affect the relative costs of bases in $hspan(D')$, and gives $\bar{\delta}'$. Thus the adjustment $\bar{\delta}'$ has the same effect as $\bar{\delta}''$ over the set of bases in $hspan(D')$. We have proved the assertion that with respect to $\bar{\delta}'$, all bases in $hspan(D')$ have cost greater than c_m.

Now collapse all the hues in D *except* r to a new color s. Consider the set J of constrained minimum cost bases in this new matroid that have $1 + \sum_{k \in hue(D)} j_k$ elements of colors r and s combined. The base in J with j_r elements of color r has cost c_m, since the bases in $hspan(D') - D'$ have cost greater than c_m. The base in J with $j_r + 1$ elements of color r has cost at most c_m, since the base of hue r in D has cost c_m. By induction we can show that each base in J that has fewer than j_r elements of color r has cost greater than c_m, using Lemma 5. But the base in J with $j'_r < j_r$ elements of color r has cost at most c_m, since B_3 has cost at most c_m. Thus we achieve a contradiction, and prove the claim that with respect to $\bar{\delta}'$, the bases in D are the *only* bases in $hspan(D)$ that are of minimum cost within $hspan(D)$.

Finally, we make all colors in $hue(D)$ red, and the rest green. Note that one of the constrained minimum cost bases B_4 in this new problem is one of the bases of minimum cost in $hspan(D)$ under adjustment $\bar{\delta}'$. By Lemma 3, there is a uniform cost adjustment $(\gamma_{\text{red}}, \gamma_{\text{green}})$ that makes B_4 of overall minimum cost. We define the desired adjustment $\bar{\delta}'''$ from $\bar{\delta}'$ and $(\gamma_{\text{red}}, \gamma_{\text{green}})$ by adding γ_{red} to δ'_k for each k in $hue(D)$, and adding γ_{green} to δ'_k for each k not in $hue(D)$. The adjustment $\bar{\delta}'''$ will not alter the

relative costs of any bases in $hspan(D)$ under $\bar{\delta}'$, but will ensure that B_4, and thus all the bases in D, will be of overall minimum cost. □

LEMMA 7. *Consider a matroid M with elements of $d \geqq 2$ colors. Suppose that for any matroid M' with elements of $d' < d$ colors, and for any constrained minimum cost base B in M', there exists a uniform cost adjustment that makes B of overall minimum cost with respect to $c(\cdot)$ in M'. Let D be a complete negative tight set of constrained minimum cost bases with respect to $c(\cdot)$ in M. Let D_1 be a negative tight subset of D such that every base in $hspan(D_1)$ can be made of overall minimum cost through a uniform cost adjustment, and no base in $D - D_1$ can be made of overall minimum cost by a uniform cost adjustment. Then the swap graph G_{D_1} is connected.*

Proof. The proof is by induction on d. The basis is with $d = 2$. From Lemma 1, it is clear that the swap graph is connected. For the induction step, with $d > 2$, assume that for any matroid M' with elements of $d' < d$ colors, and sets D' and D_1' as specified, the swap graph $G_{D_1'}$ is connected. If $|D_1| = 1$, then G_{D_1} is connected. If $|D_1| > 1$, then consider a connected component D_2 in G_{D_1}.

We first argue that $|D_2| > 1$. Suppose $|D_2| = 1$. Let $B_1 \in D_2$, and without loss of generality assume that $hue(B_1) =$ green. Since $B_1 \in D_1$, we can adjust costs uniformly so that B_1 is a base of overall minimum cost. Temporarily change every color other than green to red, so that the resulting matroid has only red and green elements. Note that B_1 is the minimum cost base for its *colors* vector. By Lemma 1, B_1 is related by a swap to some constrained minimum cost base B_2 with one fewer green element than B_1. If we restore the original element colors, it is apparent that B_2 is in $D_1 - \{B_1\}$, since these are the only green-negative minimum cost neighbors of B_1. By the definition of swap graphs, D_2 should then include B_2, a contradiction. Thus $|D_2| > 1$

By Lemma 6, we can perform a uniform cost adjustment such that every base in D_2 is of overall minimum cost, and no other base in $hspan(D_2)$ is of overall minimum cost. We then change to green all colors in $hue(D_2)$. One of these bases, say B_1, will represent the component D_2 as a constrained minimum cost base in a matroid M' with $d - |D_2| + 1 < d$ colors. Clearly, $D' = D - D_2 \cup \{B_1\}$ is a complete negative tight set of bases M'. By assumption, for each constrained minimum cost base B in M', there exists a uniform cost adjustment that makes B of overall minimum cost with respect to $c(\cdot)$ in M'. Take $D_1' = D'$. Thus D_1' is a negative tight subset of D', and no base in $D' - D_1'$ can be made of overall minimum cost. Note that two bases in the same connected component of $G_{D_1'}$ will be in the same connected component of G_{D_1}. By the inductive hypothesis, $G_{D_1'}$ is connected. Since the bases in $D_1 - D_2 \cup \{B_1\}$ are in the same connected component of G_{D_1}, and the bases of D_2 are in the same connected component of G_{D_1}, G_{D_1} is connected. □

LEMMA 8. *Consider a matroid M with elements of $d \geqq 2$ colors. Suppose that for any matroid M' with elements of $d' < d$ colors, and any constrained minimum cost base B in M', there exists a uniform cost adjustment that makes B of overall minimum cost with respect to $c(\cdot)$ in M'. Let B_1 and B_2 be any two constrained minimum cost bases in M with respect to $c(\cdot)$ such that B_2 is B_1's j-negative neighbor, for some j. Let $B_2 \in D_1 \subseteq D(B_1, j)$. Suppose any base in $hspan(D_1)$ can individually be made of overall minimum cost through a uniform cost adjustment, and no base in $D(B_1, j) - D_1$ can be made of overall minimum cost by a uniform cost adjustment. Then B_1 and B_2 are connected by a regular swap sequence of length at most $d - 1$.*

Proof. Since $D_1 \subseteq D(B_1, j)$, the swap graph G_{D_1} has at most d vertices. By Lemma 7, G_{D_1} is connected. Thus there is a simple path p of length at most $d - 1$ between B_1 and B_2 in G_{D_1}. Let S be the corresponding swap sequence relating B_1 and B_2. Since p is acyclic and of length at most $d - 1$, so is S. Since D_1 is tight and negative, S is

color-conserving. Finally, since all bases in D_1 are constrained minimum cost bases, S is optimal. □

We now establish the overall minimum cost and dominance properties.

THEOREM 1 (Overall Minimum Cost). *Let M be a matroid with elements of d colors, $d > 1$. Let B be a constrained minimum cost base with respect to cost function $c(\cdot)$. There exists a uniform cost adjustment that makes B of overall minimum cost.*

Proof. The proof is by double induction, with the outer induction on d. The basis case, in which $d = 2$, follows from Lemma 3. For the inductive hypothesis, assume that the theorem is true for all matroids that have elements of at most $d-1$ colors. For the inductive step, consider a matroid of $d > 2$ colors. We prove the inductive step by induction on k, the number of elements of color 1. We will refer to color 1 as "*green.*"

For the inner basis, in which $k = 0$, we increase the cost of green elements by an amount sufficient to ensure that no constrained minimum cost base contains a green element. This is clearly equivalent to deleting every green element in the original matroid, obtaining a $(d-1)$-color matroid. The inner basis then follows from the outer inductive hypothesis. For the inner inductive hypothesis, assume that the theorem is true for all constrained minimum cost bases with at most $k-1$ green elements. For the inductive step, suppose $k > 0$.

Suppose the overall minimum cost property did not hold for some base B_1 with k green elements. We proceed to establish a contradiction. Consider the complete, negative, tight set $D(B_1, 1)$ and the negative, tight set $D_1 = D(B_1, 1) - \{B_1\}$. Every base in D_1 has $k-1$ green elements. By the inner inductive hypothesis, every base in $hspan(D_1)$ can be made of overall minimum cost. Thus by Lemma 6, we can adjust costs uniformly such that every base in D_1 is of identical, overall minimum cost in m, and no other base in $hspan(D_1)$ is of overall minimum cost. By temporarily changing every color other than green to red and applying Lemma 1, we conclude that for every base B in D_1 there is a base $mate(B)$ with k green elements such that B and $mate(B)$ are related by a swap. By Lemma 3, the cost of green elements can be uniformly adjusted, without disturbing the overall minimum cost property of any base in D_1, such that every base in $D_2 = \{mate(B) | B \in D_1\}$ is also of overall minimum cost. We have thus succeeded in uniformly adjusting costs such that every base in $D_1 \cup D_2$ is of identical, overall minimum cost. We now restore the original colors to the elements.

Now consider any base B_2 in D_1. Suppose B_2 is B_1's (green, red) neighbor, and $mate(B_2)$ is B_2's (blue, green) neighbor. (Since, by our assumption, B_1 cannot be made of overall minimum cost and $mate(B_2)$ can, $B_1 \neq mate(B_2)$ and therefore $mate(B_2)$ cannot be a (red, green) neighbor of B_2.) Let s_1 be the (blue, green) swap that transforms B_2 to $mate(B_2)$. Since B_2 and $mate(B_2)$ are of identical cost by our earlier cost adjustment, $c(s_1) = 0$.

We claim that swap s_1 is available in *any* base in D_1. In particular, s_1 is available in B_1's (green, blue) neighbor (and B_2's (red, blue) neighbor) B_3. This provides the desired contradiction: $B_3 \oplus s_1$ has the same color combination as B_1 and the same cost as B_3, which is of overall minimum cost. Thus $c(B_1) \leqq c(B_3)$, i.e., B_1 can be made of overall minimum cost through a uniform cost adjustment.

To prove the claim, we consider the regular (red, blue) swap sequence S_1 that, by Lemma 8, transforms B_2 into B_3. (The conditions of Lemma 8 apply by the inner and outer inductive hypotheses, and the assumption about B_1.) Let $|S_1| = p$. Note that every base in the sequence of bases induced by B_2 and S_1 is in D_1, and therefore every swap in S_1 is of zero cost. We establish by induction on p that s_1 remains available in a base B that is obtained from B_2 as a result of performing a sequence of p zero-cost swaps from a regular swap sequence.

The basis case for $p=0$ is trivial. For the inductive step, let $S_1 = S_2 s_2$, where S_2 is a regular (red, purple) swap sequence of length $p-1$ consisting of zero-cost swaps, and s_2 is a (purple, blue) zero-cost swap. By the inductive hypothesis, s_1 is available in $B_4 = B_2 \oplus S_2$, which is in D_1. Now suppose s_1 is not available in $B_3 = B_4 \oplus s_2$. Then, by Lemma 4, a (blue, blue) swap s_1' and a (purple, green) swap s_2' are available in B_4. Since $B_4 \in D_1$, it is of overall minimum cost. Therefore $c(s_1') \geqq 0$. Since $c(s_1') + c(s_2') = c(s_1) + c(s_2) = 0$, $c(s_2') \leqq 0$. Since $B_4 \oplus s_2'$ has the same color combination as B_1, it follows that $c(B_1) \leqq c(B_4 \oplus s_2') \leqq c(B_4)$, which is of overall minimum cost. By our assumption about B_1, this is impossible. Thus s_1 is available in B_3.

This completes the inductive step for k and the proof. □

THEOREM 2 (Dominance). *Let M be a matroid with elements of d colors, $d>1$. Let $B_{\bar{i}}$ and $B_{\bar{i}'}$ be constrained minimum cost bases with respect to $c(\cdot)$, such that $\bar{i}$ j-dominates $\bar{i}'$. Then every j-colored element in $B_{\bar{i}'}$ is in $B_{\bar{i}}$.*

Proof. If $d=2$, then the theorem follows from Lemma 1 and the fact that each constrained minimum cost base with respect to $c(\cdot)$ is unique for its *colors* index. If $d>2$, we can construct a sequence of $k = i_j - i_j' + 1$ constrained minimum cost bases $B_{\bar{i}}, \cdots, B_{\bar{i}'}$, such that each base in the sequence is a j-negative neighbor of its predecessor. Consider any two bases B_1 and B_2 that are consecutive in this sequence, with B_2 the j-negative neighbor of B_1. By Theorem 1, every constrained minimum cost base can be made of overall minimum cost by a uniform cost adjustment. By Lemma 7, B_1 and B_2 are connected by a regular swap sequence S. Since S is regular, it is acyclic, which implies that every element of color j in B_2 is in B_1. The theorem then follows by induction on k. □

To illustrate the properties of Theorems 1 and 2, we give an example of a graphic matroid. The edges of the graph will be of three different "colors," solid, dotted, and dashed. Figure 1 gives the graph in terms of the three subgraphs of each color. Each edge is labeled with its cost. In Fig. 2 we list the solutions to all possible subproblems, each labeled with its cost. For example, the solution with one solid, one dotted, and two dashed edges is the third solution in the fourth row, and is labeled with the cost

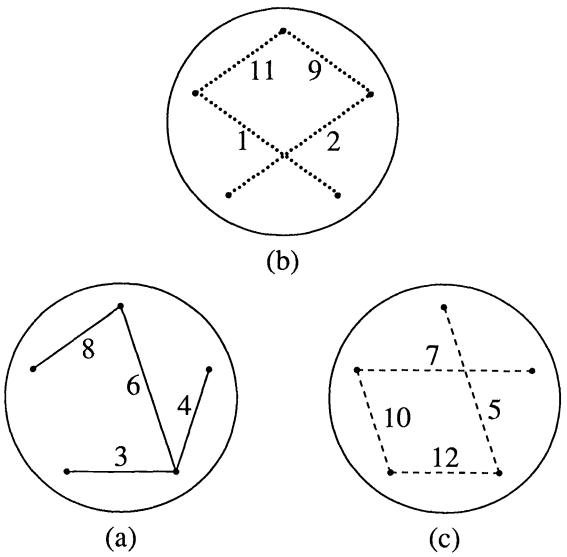

FIG. 1. *Subgraphs of a weighted graph with edges of three colors*: (a) *subgraph of solid edges*; (b) *subgraph of dotted edges*; (c) *subgraph of dashed edges.*

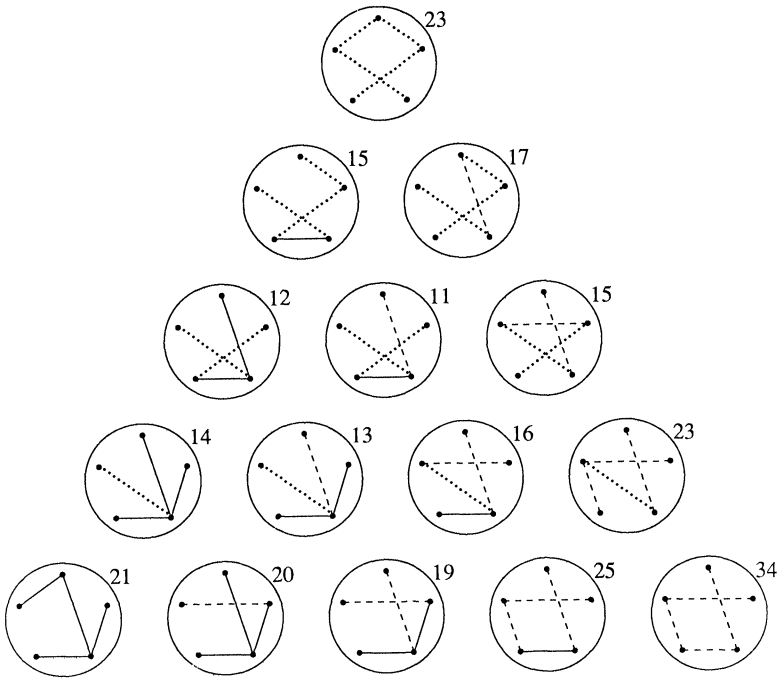

FIG. 2. *Solutions to all minimum spanning tree problems from Fig.* 1: *the tree with i solid edges, j dashed edges, and* $4-i-j$ *dotted edges is the* $(j+1)$*st tree in the* $(i+j+1)$*st row from the top.*

16. We illustrate the overall minimum cost property by making base $B_{\bar{i}}$ be the unconstrained minimum-cost base over all bases, where $\bar{i}$ is, for example, $(1, 1, 2)$. This can be done if we add 6 to the cost of every dotted element, and 4 to the cost of every solid element. To illustrate dominance, consider the solutions for $\bar{i} = (0, 1, 3)$ and $\bar{i}' = (1, 2, 1)$. (We assume that solid is color 1, dotted is color 2, and dashed is color 3.) Here $j_1 = 3$, i.e., there are fewer dashed elements in $B_{\bar{i}'}$ than in $B_{\bar{i}}$, and at least as many elements of every other color. Thus the one dashed edge (of cost 5) in $B_{\bar{i}'}$ is in $B_{\bar{i}}$.

Next we examine the impact of changing the cost of a single matroid element on a constrained minimum cost base. We begin as before with an earlier 2-color result, and proceed to generalize the result to $d > 2$ colors using the characterizations just developed.

LEMMA 9 [FS, Thm. 2]. *Let M be a matroid of red and green elements, with costs extended lexicographically to break ties. Let* B_{i-1}, B_i, *and* B_{i+1} *be the constrained minimum cost bases with* $i-1$, i *and* $i+1$ *red elements, respectively. If one element in M changes cost, then* B_i', *the new minimum cost base with i red elements, will result from either* B_{i-1}, B_i, *or* B_{i+1}, *with at most one element replaced in the appropriate base. Specifically, if a red element* r_t *increases in cost, then* B_i' *is the minimum cost base among the following three bases*:

(0) (*or* 3) B_i.

(1) $B_i - r_t + r_a$, *where* r_a *is the smallest cost red element that can replace* r_t *in* B_i.

(2) $B_{i+1} - r_t + g_a$, *where* g_a *is the smallest cost green element that can replace* r_t *in* B_{i+1}.

If a red element r_t *decreases in cost, then* B_i' *is the minimum cost base among the following three bases*:

(0) (*or* 3) B_i.

(1) *$B_i - r_a + r_t$, where r_a is the red element of greatest cost that r_t can replace in B_i.*

(2) *$B_{i-1} - g_a + r_t$, where g_a is the green element of greatest cost that r_t can replace in B_{i-1}.*

The cases for a green element changing in cost are analogous. □

We now give the generalization of the above result from two colors to d colors.

THEOREM 3. *Let M be a matroid with elements of d colors, $d > 1$. Let $B_{\bar{i}}$ be a constrained minimum cost base with respect to cost function $c(\cdot)$. If one element in M changes cost, then the new minimum-cost base $B'_{\bar{i}}$ will result from either $B_{\bar{i}}$ or one of its neighbors, with at most one element replaced in the appropriate base. Specifically, if a basic (respectively, nonbasic) element e (f) of color j_1 increases (decreases) in cost, then one of the following cases holds:*

(0) *The new base $B'_{\bar{i}} = B_{\bar{i}}$.*

(1) *$B'_{\bar{i}} = B_{\bar{i}} - e + f$, where e, f both have color j_1 and f (e) is the least (greatest) cost element of color j_1 that can replace e (be replaced by f) in $B_{\bar{i}}$.*

(2) *There is a color $j_2 \neq j_1$ such that $B'_{\bar{i}} = B_{\bar{i}'} - e + f$, where $\bar{i}'$ is a ($color(f)$, $color(e)$)-neighbor of $\bar{i}$ and f (e) is the least (greatest) cost element of color j_2 that can replace e (be replaced by f) in $B_{\bar{i}'}$.*

Proof. We first consider the case where a basic element e of color j_1 increases in cost. By Theorem 1 we can make $B_{\bar{i}}$ the unconstrained minimum-cost base, and therefore also the minimum-cost base over all bases with exactly i_{j_1} elements of color j_1, by uniformly adjusting the costs of all elements of colors $j \neq j_1$. Temporarily change the color of all j_1-colored elements to red and all other elements to green, so that $B_{\bar{i}}$ corresponds to red-green base $B_{i_{j_1}}$. We can then apply Lemma 9 with e in the role of r_t. If case (0) or (1) of Lemma 9 holds, then the corresponding case of our theorem holds. If case (2) of Lemma 9 holds, then there is a red-green base $B_{i_{j_1}+1}$ that differs from $B'_{i_{j_1}}$ by one element, g_a. Let f be the element corresponding to g_a in the original matroid, and let $j_2 = color(f)$. Since g_a is the least cost replacement element over all green elements, f is certainly the least cost replacement element of color j_2.

The symmetric case of a nonbasic element f decreasing in cost is handled similarly. □

Note that Theorems 1, 2, and 3 hold if cost function $c_L(\cdot)$ replaces cost function $c(\cdot)$ in the statement of the theorem. The use of $c_L(\cdot)$ has the advantage that arbitrarily many updates can be performed. This is not true for $c(\cdot)$, since changing the cost of one element can affect the value of α, which will alter the cost of every element.

4. Efficient solution of the static problem. We show how to find the constrained, lexicographically minimum cost base $B_{\bar{q}}$ consisting of q_j elements of color j, for $j = 1, 2, \cdots, d$, along with a uniform cost adjustment vector $\bar{\delta}$ that makes $B_{\bar{q}}$ of overall, unconstrained minimum cost. For matroids satisfying certain desirable properties, the time to do this will be $O(dT_0(m, n) + (d!)^2 T(n, 2))$, where $T_0(m, n)$ is the time to solve an uncolored, or monochromatic, problem, and $T(n, 2)$ is the time to solve a 2-color problem, given the constrained minimum cost bases for each color. Our algorithm DCOLOR first augments the set of elements with elements of large cost as necessary so that there is a base of each color, and finds monochromatic minimum cost bases for each color. This step accounts for the first term of the running time expression. Algorithm DCOLOR then calls a recursive routine DREC that is supplied with the d monochromatic bases and finds the desired base and associated vector $\bar{\delta}$. The call to DREC accounts for the second term in the running time expression.

Our presentation is organized as follows. We first review the 2-color algorithm of [GT], and explain how $\bar{\delta}$ can be computed in this case. We then augment the 2-color algorithm of [GT] with lexicographic cost comparisons to help handle calls from our

d-color recursive routine. We finally present our recursive routine DREC to find a d-color base.

The 2-color algorithm in [GT] is designed to find a minimum cost base constrained to have exactly s red elements, for some s. The algorithm calls a recursive routine to identify what is called a *restricted* swap sequence, which transforms a constrained minimum cost base of green elements to a constrained minimum cost base of red elements. The restricted swap sequence contains swaps in order of nondecreasing cost of the red element in each swap. The algorithm then sorts the swaps in order of nondecreasing cost of the swaps to yield an optimal swap sequence. The algorithm forms the desired base by taking the first portion of the swap sequence and applying it to the green constrained minimum cost base. Since the cost of a minimum cost base with i red elements is a convex function of i, the vector $\bar{\delta}$ can be readily determined by comparing the cost of swaps adjacent to the desired base.

We augment the algorithm to enforce a lexicographic tie-breaking scheme. In addition to its color, let each element have a unique index. Assign a *tag* to each element consisting of the pair (*j*, *index*), where j is the original color of the element. Ties in element costs are broken lexicographically using element tags. Ties in the costs of swaps are broken lexicographically as follows. Consider two swaps (e,f) and (e',f') of equal cost. Swap (e,f) will be lexicographically less than (e',f') if and only if either f or e' has the lexicographically smallest tag from among e, f, e', and f'. We can incorporate this lexicographic tie-breaking scheme into the 2-color algorithm of [GT] at constant cost for any comparison of two elements or two swaps.

We now describe our recursive routine DREC to find a d-color base. The input to this routine is a vector $\bar{q}$ and the set of dn elements that is the union of the d monochromatic bases. The routine uses a divide-and conquer approach, recursing first on fewer colors, and then again on fewer elements. The basis cases occur when either $d=2$ or $n<2d^2(d-1)$. If $d=2$ we use the augmented 2-color algorithm. We will discuss the other basis case later. If $d>2$ and $n\geqq 2d^2(d-1)$, we do the following. Order the colors so that $q_j \leqq q_{j+1}$, for $j=1, 2, \cdots, d-1$. Find the constrained minimum cost base $B_{\bar{i}}$, where $i_j = q_j + \lfloor (q_d + j - 1)/(d-1) \rfloor$ for $j=1, 2, \cdots, d-1$, and $i_d = 0$. This is a problem in $d-1$ colors, and is solved recursively by our routine. Note that $\bar{i}$ is defined so that for each color $j \neq d$, $B_{\bar{i}}$ has at least $\lfloor n/(d(d-1)) \rfloor$ more elements of color j than $B_{\bar{q}}$. Along with determining $B_{\bar{i}}$, the recursive call will supply the corresponding values $\delta(j)$, for $j=1, \cdots, d-2$ that make $B_{\bar{i}}$ of minimum cost among bases with no elements of color d.

Once $B_{\bar{i}}$ and $\bar{\delta}$ have been determined, temporarily add $\delta(j)$ to the cost of each element of color j in $B_{\bar{i}}$, for $j=1, \cdots, d-2$. Define $\bar{f}$ such that for any d-tuple $\bar{i}'$, $f_j(i'_j) = |i'_j - i_j|$, for $j=1, \cdots, d$. Note that by their definition the functions $f_j(\cdot)$ are convex. For any choice of π, $B_{\bar{i}}$ will be the minimum cost base among those with no elements of color d, with respect to the adjusted version of the cost function $c_L(\cdot)$, defined earlier.

Relabel the elements of base $B_{\bar{i}}$ with the color green, and label with the color red the elements in the constrained minimum cost base of color d. Now use the 2-color algorithm of [GT], augmented to use tags lexicographically to break ties in the costs of elements and swaps, to find the constrained minimum cost base B' that has $\lfloor q_d/(d-1) \rfloor - 1$ red elements and the rest green. Even though colors are reordered to satisfy $q_j \leqq q_{j+1}$, a permutation π can be chosen that undoes this reordering, and hence makes the use of the tags enforce $c_L(\cdot)$. Thus any base generated by the augmented 2-color algorithm will be a constrained minimum cost base with respect to $c_L(\cdot)$, and thus also $c(\cdot)$, in the original d-color matroid.

If we switch the elements in B' back to their original colors, we get a base $B_{\bar{k}}$ in which $k_d = \lfloor q_d/(d-1) \rfloor - 1$ and $k_j \geqq q_j + 1$ for $j = 1, 2, \cdots, d-1$. It is clear that the set of color vectors consisting of $\bar{q}$ and its immediate neighbors dominate $\bar{k}$ with respect to color d. By our dominance theorem, every element of color d in $B_{\bar{k}}$ is in $B_{\bar{q}}$, and also in every constrained minimum cost base that is an immediate neighbor of $B_{\bar{q}}$. Let D be the set of these elements of color d. Contract the matroid on set D, and decrease q_d by $|D|$. Since $q_d \geqq \lceil n/d \rceil$, the number of elements is reduced by at least $\lfloor \lceil n/d \rceil / (d-1) \rfloor - 1$, which is at least $\lceil n/d^2 \rceil$ if $n \geqq 2d^2(d-1)$. For $d > 2$ and $n \geqq 2d^2(d-1)$, note that the new value of q_d will be greater than 0. Solve the resulting smaller d-color problem recursively, yielding $\hat{B}$ and $\bar{\delta}$. Form $\hat{B} \cup D$, and return this set with $\bar{\delta}$ as the solution to the call on DREC.

We justify the contraction and union steps in the previous paragraph as follows. Let M/D be the contracted matroid. Note that $D \subset B_{\bar{q}}$, and $B_{\bar{q}} - d$ is a base in M/D. Let B be a base in M/D with the same index vector as $B_{\bar{q}} - D$ but not equal to $B_{\bar{q}} - D$. Now $c(B) > c(B_{\bar{q}} - D)$, since otherwise $B \cup D$ would be a base of M with index vector $\bar{q}$ but of smaller cost than $B_{\bar{q}}$, a contradiction to the definition of $B_{\bar{q}}$. We make use of the requirement that D be a subset of each neighbor of $B_{\bar{q}}$ in the following way. If $\hat{B}'$ is a neighbor of $B_{\bar{q}} - D$ in M/D, then $\hat{B}' \cup D$ will be the corresponding neighbor of $B_{\bar{q}}$ in M. This guarantees that the uniform cost adjustment $\bar{\delta}$ that makes $B_{\bar{q}} - D$ of overall minimum cost in M/D will also make $B_{\bar{q}}$ of overall minimum cost in M.

We now discuss the other basis case, when $n < 2d^2(d-1)$. Here we use the weighted matroid intersection algorithm [BCG1] to find $B_{\bar{q}}$ directly. We also need to determine the $\delta(j)$ values. This can be done by considering each of the elements not in $B_{\bar{q}}$. For each such element f, find the best swap in $B_{\bar{q}}$ for each color $j \neq color(f)$. We infer the values of $\delta(j)$ from the thresholds of these swaps as follows. Each best swap (e, f) yields a constraint $\delta(color(e)) - \delta(color(f)) \leqq c(f) - c(e)$. Choosing the $\delta(j)$'s then reduces to the following shortest path problem. Consider a graph with d vertices labeled from 1 to d. For each constraint $\delta(j_1) - \delta(j_2) \leqq c_{j_1 j_2}$ there is an edge from j_2 to j_1 of cost $c_{j_1 j_2}$. In the case of multiple edges, only the shortest edge is retained. Then choosing $\delta(j)$ to be the shortest distance from vertex d to vertex j, for all j, will give a consistent set of deltas. The shortest distances can be determined in $O(d^3)$ time using the Bellman-Ford algorithm in [L1]. This completes our presentation of the recursive routine DREC for the d-color algorithm.

LEMMA 10. *Let M' be a matroid of elements of $d > 2$ colors, that is comprised of the union of d monochromatic bases. Let $\bar{q}$ be a valid index for a base in M'. Routine* DREC *correctly computes a minimum cost base $B_{\bar{q}}$ and a uniform cost adjustment $\bar{\delta}$ that makes $B_{\bar{q}}$ of overall minimum cost in M'.*

Proof. Correctness can be established with a proof by induction. That the two basis cases are correct follows from the correctness of the algorithms in [GT], [BCG1] and the additional comments in the text. The correctness of the routine for the nonbasis case follows from the arguments that the set D of elements contracted is nonempty and is contained in $B_{\bar{q}}$ and each of its neighbors. Thus the solution $(\hat{B}, \bar{\delta})$ to the contracted problem can be augmented to $(\hat{B} \cup D, \bar{\delta})$, the solution to the given problem. □

We next discuss the running times of DREC and DCOLOR. The efficiency of DREC (and thus DCOLOR) depends on whether the matroid M under consideration possesses certain nice properties. Let $T(n, 2)$ be the time to solve the 2-color problem in M with elements recolored to just two colors, when the minimum-cost bases of each of the two colors are given. We identify the following properties as *desirable.*

(1) Independence testing in M is polynomial.

(2) The time to contract dn elements in m is $O(dT(n, 2))$.

(3) For $8/9 \leqq a < 1$ and $n \geqq 4/(1-a)$, $T(\lfloor an \rfloor, 2) \leqq aT(n, 2)$.

We note that the matroids handled in [GT], [G] possess the desirable properties. In particular, we discuss the motivation for assuming the bound of $dT(n, 2)$ on the time to contract $O(dn)$ elements in a matroid. By assigning color $d+1$ to each element to be contracted and solving d 2-color problems involving color $d+1$ and each original color, we can determine the elements in each monochromatic base in the contracted matroid. The correctness of this reduction follows from the definition of matroid contraction. It is also necessary to determine the new attributes of each element (e.g., endpoints of an edge in the case of a graphic matroid) in the contracted matroid. For all the matroids discussed in [GT], this can be done for each new base within time proportional to $T(n, 2)$.

THEOREM 4. *Let M be a matroid of rank n with m elements of $d > 2$ colors. Let $T_0(m, n)$ be the time to solve the uncolored (monochromatic) problem in M. Let $T(n, 2)$ be the time to solve the 2-color problem in M with elements recolored to just two colors, when the minimum-cost bases of each of the two colors are given. If M has the desirable properties, then the time to solve a d-color problem in M is $O(dT_0(m, n) + (d!)^2 T(n, 2))$. The space required is $O(d^3 n)$.*

Proof. Let $T(n, d)$ be the time to solve a d-color problem in a matroid of rank n, given that the monochromatic bases are provided. The intersection algorithm in [BCG1] uses $O(nm(n + I(m) + \log m))$ time, where $I(m)$ is the time to test independence. By assumption, $I(m) = m^k$ for some k. Since $m = nd$, this takes $O(d^4 n(d^3 + d^{4k}))$ time, which is $O(d^4(d^3 + d^{4k})T(n, 2))$, since $T(n, 2) \geqq n$. Finding the swaps to identify $\delta(j)$ values involves examining $O(d^4)$ elements f, at $O(d^3)$ time per element f, or $O(d^7)$ time altogether. For $n \geqq 2d^2(d-1)$, all work except for the recursive call on $d-1$ colors and the recursive call on fewer elements is $O(dT(n, 2))$. Thus for $d > 2$ we have the following recurrence:

$$T(n, d) \leqq c_1(d^7 + d^{4+4k})T(n, 2) \quad \text{for } n < 2d^2(d-1),$$

$$T(n, d) \leqq c_2 dT(n, 2) + T(n, d-1) + T(\lfloor n(1-1/d^2) \rfloor, d) \quad \text{for } n \geqq 2d^2(d-1)$$

where the c_i's are constants. We claim that

$$T(n, d) \leqq (c_3(d!)^2 - c_4 d)T(n, 2)$$

for $c_4 = 2c_2$ and $c_3 = (c_1 + c_2)c_5$, where c_5 is the maximum value of $(d^7 + d^{4+4k})/(d!)^2$ when d is chosen over the positive integers.

The proof is by double induction, with the outer induction on d, and the inner induction on n. For $d = 3$, we prove the claim by induction on n. For $n < 2d^2(d-1)$, $T(n, 3) \leqq c_1(3^7 + 3^{4+4k})T(n, 2) \leqq (c_3(3!)^2 - 3c_4)T(n, 2)$, for the choices of c_3 and c_4. For $n \geqq 2d^2(d-1)$,

$$T(n, 3) \leqq 3c_2 T(n, 2) + T(n, 2) + T(\lfloor 8n/9 \rfloor, 3)$$

which by the induction hypothesis is

$$\leqq (3c_2 + 1)T(n, 2) + (c_3(3!)^2 - 3c_4)T(\lfloor 8n/9 \rfloor, 2)$$

$$\leqq (3c_2 + 1)T(n, 2) + (36c_3 - 3c_4)(8/9)T(n, 2)$$

$$\leqq (36c_3 - 3c_4)T(n, 2)$$

for the choices of c_3 and c_4.

For $d > 3$, we assume as the outer induction hypothesis that the claim is true for all d', $3 \leqq d' < d$. We prove the claim by induction on n. For $n < 2d^2(d-1)$, $T(n, d) \leqq c_1(d^7 + d^{4+4k})T(n, 2) \leqq (c_3(d!)^2 - c_4 d)T(n, 2)$, for the choices of c_3 and c_4. For $n \geqq 2d^2(d-1)$, we assume as the inner induction hypothesis that the claim is true for all $n' < n$. We have

$$T(n, d) \leqq c_2 dT(n, 2) + T(n, d-1) + T(\lfloor n(1-1/d^2) \rfloor, d)$$

which by the inner and outer induction hypotheses is

$$\begin{aligned}
&\leqq c_2 dT(n, 2) + (c_3((d-1)!)^2 - c_4(d-1))T(n, 2) \\
&\quad + (c_3(d!)^2 - c_4 d)T(\lfloor n(1-1/d^2) \rfloor, 2) \\
&\leqq c_2 dT(n, 2) + (c_3(d!/d)^2 - c_4(d-1))T(n, 2) \\
&\quad + (c_3(d!)^2 - c_4 d)(1-1/d^2)T(n, 2) \\
&\leqq (c_3(d!)^2 - c_4 d + c_2 d + c_4 - c_4 d(1-1/d^2))T(n, 2) \\
&\leqq (c_3(d!)^2 - c_4 d)T(n, 2)
\end{aligned}$$

for the choice of c_4. This completes the inner induction, and then the outer induction.

As for the space required, either basis case will take $O(dn)$ space. For the nonbasis case, the space will satisfy the recurrence

$$S(n, d) \leqq \max\{n, d + S(n, d-1), dn + S(\lfloor n(1-1/d^2) \rfloor, d)\}.$$

The second term represents the space to store the color requirements for the base with $d-1$ colors and then to compute the base. The third term represents the space to represent the contracted matroid and then to compute a base in it. The solution to this recurrence is $O(d^3 n)$. □

Even though the running time involves factorials in terms of d, it is better than the running time for the weighted matroid intersection algorithm of [BCG1] whenever d is $o((\log n)/(\log \log n))$.

We suggest a modification to the algorithm that may yield a faster algorithm in practice. The 2-color algorithm in [GT] generates in succinct form the sequence of constrained minimum cost bases between the base of all one color and all the other color. Instead of specifying the number of elements of color d that we want in B', we take the swap sequence generated, switch back to original colors and find the furthest base $B_{\bar{k}}$ represented in the swap sequence such that $k_j \geqq q_j + 1$, for $j = 1, \cdots, d-1$. At least as many elements will be contracted as before.

Finally, as an illustration, we apply the above algorithm to graphic matroids. Here $T_0(m, n)$ is $O(m \log \beta(m, n))$ by the algorithm of [GGST], where $\beta(\cdot, \cdot)$ is a certain slowly growing function [FT]. $T(n, 2)$ is $O(n \log n)$ by the algorithm of [GT]. Independence is equivalent to acyclicity, and thus independence can be tested in $O(m)$ time. Contracting $O(dn)$ elements can be implemented in $O(dn)$ time. Therefore the time to find a constrained minimum cost spanning tree is $O(dm \log \beta(m, n) + (d!)^2 n \log n)$.

5. Basic on-line update strategy. In this section we give a basic description of our data structures for on-line updating of a constrained minimum cost base in a d-color matroid. This work is an extension of the updating approach in [FS] that handled 2-color problems. Let $B_{\bar{i}}^{(h)}$ represent the minimum cost base for *colors* vector $\bar{i}$ after h element cost updates have been performed. We first discuss data structures that allow us to find quickly base $B_{\bar{i}}^{(h+1)}$ given $B_{\bar{i}}^{(h)}$ and all of its neighbors after h updates. This operation, which relies on Theorem 3, is crucial to our on-line update technique. However, to compute $B_{\bar{i}}^{(h+2)}$ by this method, we need to have $B_{\bar{i}}^{(h+1)}$ and its neighboring

bases after $h+1$ updates, which in the worst case means we must have $B_{\bar{i}}^{(h)}$, its neighbors after h updates, and also the neighbors' neighbors after h updates. We therefore discuss how to maintain larger groups of neighboring bases, and introduce the notion of an *arrangement* of bases, generalizing the sequences employed in the 2-color algorithm. Since updating large groups of bases directly would be quite inefficient, we then discuss maintaining arrangements in an implicit form, which allows for efficient updating. Finally, we illustrate the technique with the example of a graphic matroid. Although our presentation of the d-color update technique is sufficiently detailed to be self-contained, familiarity with the 2-color update technique of [FS] will help greatly in understanding the details.

We recall from [FS] the definition of an *update structure* for a base in a matroid with uncolored elements. An update structure for a base B is a data structure that supports the following operations:

maxcirc(f, B): finds the maximum cost element in the circuit $C(f, B)$.
mincocirc(e, B): finds the minimum cost element in the cocircuit $\bar{C}(e, B)$.
swap(e, f, B): converts the update structure for B into an update structure for $B-e+f$ (assuming that $f \in \bar{B}$ and $e \in C(f, B)$).

Let $U(m, n)$ represent the maximum of the execution times of these three operations for a particular matroid. Thus a minimum cost base in a matroid with uncolored elements can be updated in time at most $2U(m, n)$ when the cost of a single matroid element is modified. Let $S(m, n)$ be the space required by the update structure.

In the case of a matroid with elements of d colors, the update structure is generalized to allow the color of the appropriate element to be specified. Thus for $j=1, 2, \cdots, d$, the operation *maxcirc*(j, f, B) finds the maximum cost element of color j in $C(f, B)$, and *mincocirc*(j, e, B) finds the minimum cost element of color j in $\bar{C}(e, B)$. The operation *swap*(e, f, B) is as before. The generalized update structure for d-colored matroids can be derived from the corresponding structure for uncolored matroids in a straightforward manner. For each field relating to costs in the uncolored update structure, maintain d fields in the new structure, with the jth field accessed for operations on color j. The values in the fields should be such that the cost of an element not of color j should be treated as $-\infty$ in handling a *maxcirc*$(j, \cdot, \cdot)$, and ∞ in handling a *mincocirc*$(j, \cdot, \cdot)$. The space requirement of the generalized update structure is then $O(dS(m, n))$.

Using Theorem 3, a generalized update structure can be used to find an updated base $B_{\bar{q}}^{(h+1)}$ from $B_{\bar{q}}^{(h)}$ and its neighbors after h updates. For instance, if a basic element e increases in cost, then $B_{\bar{q}}^{(h+1)}$ would be the least cost base in the set consisting of $B_{\bar{q}}^{(h)}$ and $B_{\bar{i}}^{(h)}-e+$ *mincocirc*$(j, e, B_{\bar{i}}^{(h)})$, where either the color of e is not j, and $B_{\bar{i}}$ is a neighbor of $B_{\bar{q}}$ containing one element fewer of color j, or j is the color of e, and $B_{\bar{i}}$ is $B_{\bar{q}}$. If a cobasic element f decreases in cost, then $B_{\bar{q}}^{(h+1)}$ would be the least cost base in the set consisting of $B_{\bar{q}}^{(h)}$ and $B_{\bar{i}}^{(h)}-$ *maxcirc*$(j, f, B_{\bar{i}}^{(h)})+f$, where either the color of f is not j, and $B_{\bar{i}}$ is a neighbor of $B_{\bar{q}}$ containing one more element of color j, or j is the color of f, and $B_{\bar{i}}$ is $B_{\bar{q}}$. The update is concluded by performing the appropriate *swap*.

As stated at the beginning of the section, maintaining just $B_{\bar{q}}^{(h)}$ and its neighbors after h updates is not enough, since there is not sufficient information to compute efficiently all neighbors of $B_{\bar{q}}^{(h+1)}$ after $h+1$ updates. For $l>0$, let $R_{\bar{i},l}$ be the set of bases $\{B_{\bar{i}'} | i_j' \leqq i_j+l-1, j=1, 2, \cdots, d\}$. We shall represent groups of bases in sets such as $R_{\bar{i},l}$, which we call *arrangements*. We say that arrangement $R_{\bar{i},l}$ is *centered on* $\bar{i}$ and has *radius* l. Our update procedure is periodic with period z. By this we mean that for

the hth element cost change the update procedure handles data in the same form (e.g., radius of arrangement) as the data during the $(h+z)$th element cost change, for any $h>0$. Here, z is a parameter that will be specified later, when we discuss the running time. Our update procedure consists of three parts. For clarity, we will uncover the parts one by one.

Consider h to be an integer in the range from 0 to z. Suppose after the hth update we keep an arrangement $A_0^{(h)} = R_{\bar{q},z-h}^{(h)}$. The superscript on R and on A_0 indicates how many element cost changes have been supplied, and will be omitted unless the context demands it. As long as $h<z$, there is sufficient information to generate $R_{\bar{q},z-h-1}^{(h+1)}$, no matter what type of element cost change occurs. Thus $z-1$ element cost changes can be successfully handled, but when the zth update occurs, $B_{\bar{q}}$ is lost. This follows, since $A_0^{(z-1)}$ is an arrangement consisting of one base $B_{\bar{q}}^{(z-1)}$, so there is insufficient information remaining in order to compute $B_{\bar{q}}^{(z)}$. We say that A_0 *decays* during this sequence of z updates. Of course, for large z, explicitly maintaining and updating the arrangement A_0 requires considerable time per cost change. In due course, we will show how to circumvent this problem by introducing an implicit representation for A_0.

When A_0 has completely decayed, we need to replace it with an arrangement containing many bases. But this means that certain work must be done in advance. We therefore discuss the second part of our solution. Thus we now consider unrestricted values of h. Whenever A_0 is initialized, i.e., $h \bmod z = 0$, we initiate a computation to solve a number of d-color problems on the current matroid, in order to generate a new arrangement of bases, given the minimum cost base after h updates containing only elements of color j, for $j=1,2,\cdots,d$. Note that any constrained base after h updates contains only elements from the union of these monochromatic bases. Let $P(n, d)$ be the time required to determine for a given d-color problem an arrangement of bases in an appropriate form. Assume that copies of the d monochromatic bases are maintained from one update to the next. Since just one of these monochromatic bases changes, a cost of $U(m, n)$ is charged to the update. Each static d-color problem will be solved during the time in which A_0 decays, by performing $O(P(n, d)/z)$ work over each of z update steps.

However, when all static d-color problems are completed, after $h=kz$ updates, we cannot just reconstitute A_0 with the appropriate bases. This is because each such base will be *out of date* by z element cost changes, since the element costs used in solving the static problems were extracted after $(k-1)z$ updates, and z further element cost updates have been applied to the matroid in the meantime. Thus we introduce the third part of our update strategy. We use a second arrangement A_1, centered at $B_{\bar{q}}$ and initially with $l=3z$, which is extracted from the out-of-date solution to the static d-color problems. Thus when A_1 is created after $h=kz$ updates have occurred, we have $A_1^{(h)} = R_{\bar{q},3z}^{(h-z)}$.

Since the bases in $A_1^{(kz)}$ will initially be out of date with respect to $A_0^{(kz)}$ by z element cost changes, we need to bring them up to date over the next z update steps of A_0, using the z element cost changes that have not yet been applied to A_1. These previous element cost changes can be saved in a queue as the static d-color problems are being solved. Thus, when $A_1^{(kz)}$ is created, the queue will contain element cost changes numbered $(k-1)z+1, (k-1)z+2, \cdots, kz$. Consider the hth update step, that transforms $A_1^{(h-1)}$ to $A_1^{(h)}$, Let $h=kz+r$, where $0<r\leqq z$. We first add the hth element cost change to the rear of the queue. We then delete the two element cost changes (namely, those numbered $h-z+r-1$ and $h-z+r$) for the front of the queue and apply them both to $A_1^{(h-1)}$, obtaining $A_1^{(h)}$. Thus $A_1^{(h)}$ will be the arrangement $R_{\bar{q},3z-2r}^{(h-z+r)}$. A_1 will then become up to date with respect to A_0, and also be of the correct radius,

precisely when A_0 has completely decayed. We then replace A_0 by the current arrangement A_1.

We can view our three-part update technique as three concurrent processes going on at once. Times at which $h > 0$ and $h \bmod z = 0$ are regarded as *renewal points* for A_0. At a renewal point, A_0 has completely decayed, A_1 has caught up with A_0 and can replace it, the static d-color problems have completed from which a new A_1 can be constituted, and new static problems can be initiated.

We now discuss how to avoid the expense of repeatedly updating each base in the arrangements A_0 and A_1. We do this by maintaining an implicit representation of each arrangement. An *extremal base of color j* of arrangement $R_{\bar{q},l}$ is a base $B_{\bar{i}}$, where $i_j = q_j - (d-1)(l-1)$ and $i_{j'} = q_{j'} + l - 1$ for $j' \neq j$. We denote this base as $B_{\bar{q},l,j}$. We also use the base $B_{\bar{q},l-1,j}$ and call this a *near-extremal base of color j*. For $g = 0$, 1 and $0 \leqq r < z$, let $a = g(z-r)$, and $b = z - r + g(2z-r)$. For each arrangement $A_g^{(h)}$ with $h = kz + r$, $0 \leqq r < z$ and $g = 0$, 1, except for when $g = 0$ and $r = z - 1$, we maintain for each color j, $B_{\bar{q},b,j}^{(h-a)}$ and its j-positive neighbors, and $B_{\bar{q},b-1,j}^{(h-a)}$ and its j-negative neighbors. For $d = 3$, this amounts to four bases near (and including) each of three extremal bases, for a total of twelve bases. For $d > 3$, there will be $2d$ bases near (and including) each of d extremal bases, for a total of $2d^2$ bases. We call the set of these bases the *extreme bases*. For each extreme base we maintain its update structure. Using the algorithm from the previous section, each of the $2d^2$ bases can be found in $T(n, d)$ time, and thus $P(n, d)$ is $O(d^2 T(n, d))$. (We provide a better bound on $P(n, d)$ in the proof of Theorem 5.) A symbolic representation of solutions to all problems for a matroid with $d = 3$ and $n = 24$ is given in Fig. 3. An arrangement centered at the base marked with an "X" and with radius $l = 4$ is shown in bold, with the extreme bases shown as the boldest. The extremal bases are the bases at the corners of the arrangement.

We now describe how the hth element cost change (involving an element of color j) is applied to the implicit representation of an arrangement $A_g^{(h-1)}$ to obtain the

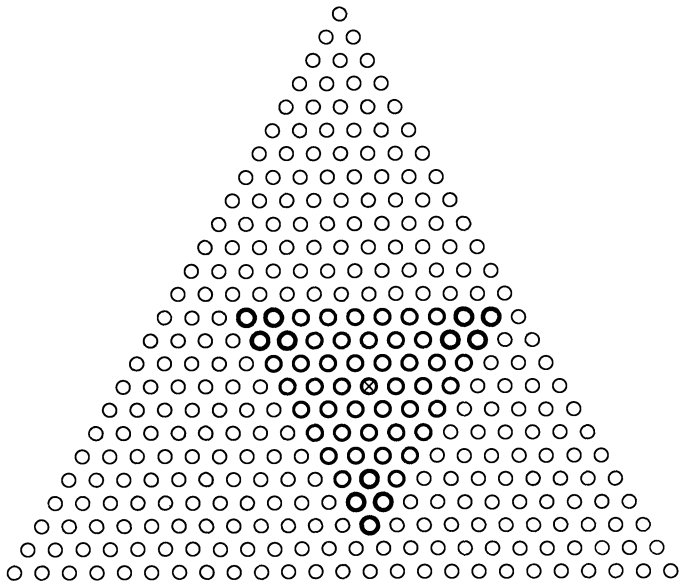

FIG. 3. *Symbolic representation of solutions to all problems in a matroid with three colors and rank* 24. *An arrangement centered at the base marked with an "X" and with radius* $l = 4$ *is in bold, and the extreme bases are the boldest of the bases.*

implicit representation of the updated arrangement $A_g^{(h)}$. We first update the monochromatic base of color j, and suitably modify the update structures of the extreme bases to reflect any change in this monochromatic base. We then compute new versions of a particular set of d extreme bases, one corresponding to each color, that we call the *cardinal bases* of the arrangement. We then compute a contracted matroid associated with the cardinal bases that is significantly smaller than the original matroid, but one that includes all the necessary elements. We finally extract and solve several static d-color problems in the contracted matroid; each static problem generates one extreme base in the implicit representation of the new arrangement.

The cardinal bases are chosen depending on the type of element cost change. For each color j, either the extremal base $B^{(h)}_{\bar{q},z-r,j}$ and its j-positive neighbors, or the near-extremal base $B^{(h)}_{\bar{q},z-r-1,j}$ and its j-negative neighbors are used to compute the cardinal bases. If the cost of a basic element of color j' increases, then the cardinal bases are generated using extremal bases and their j-positive neighbors. In this case the cardinal bases will be $B^{(h)}_{\bar{q},z-r,j'}$ and the (j',j)-neighbor of $B^{(h)}_{\bar{q},z-r,j}$ for all $j \neq j'$. We have previously discussed how $B^{(h)}_{\bar{q},z-r,j'}$ may be obtained from $B^{(h-1)}_{\bar{q},z-r,j'}$ and its j'-positive neighbors. When $j \neq j'$, let B denote $B_{\bar{q},z-r,j}$, and B' denote B's (j',j)-neighbor. Since the complete, positive, tight set consisting of B' and its j'-positive neighbors is identical to the complete, positive, tight set consisting of B and its j-positive neighbors, the sparse representation of the arrangement has sufficient information to generate the updated version of base B'. If the cost of a nonbasic element of color j' decreases, then the near-extremal bases and their j-negative neighbors are used. In this case the cardinal bases will be $B^{(h)}_{\bar{q},z-r-1,j'}$ and the (j,j')-neighbor of $B^{(h)}_{\bar{q},z-r-1,j}$ for all $j \neq j'$.

The details of how the cardinal bases and their associated contracted matroids are computed depends on the type of matroid. There are certain matroids (for instance, graphic matroids) for which update structures for bases in a contracted matroid can be maintained efficiently when elements are inserted into or deleted from its associated *contraction set* (the set of elements contracted). In such cases, we can save both space and time if we maintain a contracted matroid associated with the extremal bases of each arrangement. The contraction set consists of the union, over all colors j, of the j-colored elements in the extremal base of color j. Note that each element in the contraction set is common to all bases in the arrangement. In the contracted matroid associated with the cardinal bases, cardinal bases play the roles of extremal bases in the above definition. Once the cardinal bases are determined, the contracted matroid associated with the cardinal bases can be derived from the contracted matroid associated with the extremal bases by performing, for each color j, insertions and deletions corresponding to all elements of color j in the symmetric difference between the extremal and cardinal bases of color j. The time to compute these elements is charged to the cost of (subsequently) solving the static d-color problems. For matroids where efficient maintenance of contracted bases is not possible, we instead explicitly maintain the contraction set, and contract the elements each time the contracted matroid is required.

We discuss further the case in which the contracted matroid is explicitly maintained. If the update potentially involves a change in the contraction set, the contracted matroid associated with the extremal bases must be modified before computing the cardinal bases. Suppose an element e of color j in the contraction set increases in cost. If e remains in the monochromatic base of color j, then e should be deleted from the contraction set (yielding a contracted matroid of rank one greater), and the update structures for the extreme bases modified accordingly. If e is replaced by an element e' in the monochromatic base of color j, then e should be deleted from the

contraction set, and then replaced by e' in the contracted matroid, with the update structures for the extreme bases modified accordingly at each step. When an element e is removed from the contraction set, not only does e return to the contracted matroid, but also one element of each other color, which were deleted in various previous contractions. To facilitate identifying these other elements that should also return to the contracted matroid, we maintain for each color j' a base $\hat{B}_{j'}$. The base $\hat{B}_{j'}$ is the union of the contraction set with the elements of color j' in the contracted matroid. When element e of color j is removed from the contraction set, then for each $j' \neq j$ perform a *mincocirc*$(j', e, \hat{B}_{j'})$ to identify the element of color j' that should return to the contracted matroid.

Suppose an element f of color j decreases in cost. If f is in the monochromatic base of color j, but is in neither the contraction set nor the contracted matroid (such an element would have been deleted when some element in the contraction set was contracted), then there is some element e in the contraction set, which if deleted in the contraction set would cause f to be in the contracted matroid. The element e is found by performing a *maxcirc*$(j, f, \hat{B}_j)$, and is then deleted from the contraction set, with the update structures for the extreme bases modified accordingly. Finally, if f is not in the monochromatic base of color j and replaces an element f' in the monochromatic base of color j, then we handle f' as though it were an element that increases in cost and was replaced by f in the monochromatic base of color j. The cardinal bases can now be selected from the bases obtained by performing the appropriate update operations on the extreme bases, and the associated contracted matroid obtained as previously described.

Each extreme base in the new arrangement is then generated by extracting and solving a d-color problem in the contracted matroid associated with the cardinal bases. We also derive the contracted matroid associated with the extremal bases of the new arrangement from the contracted matroid associated with the cardinal bases of the old arrangement. As before, this is done by computing symmetric differences. The size of the contraction set associated with the extremal bases of an arrangement of radius l is $\sum_{j=1}^{d} (q_j - (d-1)(l-1)) = n - d(d-1)(l-1)$. Since the contracted elements are independent in the original matroid, the resulting contracted matroid will have rank $d(d-1)(l-1)$. We also note that since the original matroid has a monochromatic base of each color, so will the contracted matroid; thus the contracted matroid, like the original matroid, can be viewed as the union of d monochromatic bases. In what follows we will assume that, whenever appropriate, update structures are maintained for these smaller monochromatic bases in the contracted matroid.

To summarize, each update step h, where $h = kz + r$ and $0 \leqq r < z$, involves the following operations. The monochromatic minimum cost base is updated for the color of the element whose cost has changed. The arrangement $A_0^{(h-1)}$ is transformed to $A_0^{(h)}$ by applying the hth element cost change to it as follows. The cardinal bases are computed. Either the contracted matroid or the contraction set is updated, and in the latter case, the elements in the contraction set are contracted. Let the computation of the cardinal bases and the appropriate contraction structures be completed in $Q(n, d, z)$ time. A total of $2d^2+1$ static d-color problems of rank $n' = \Theta(d^2 z)$ are then extracted in the contracted matroid and each solved in $T(d^2 z, d)$ time, generating $B_{\bar{q}}^{(h)}$ and the extreme bases for the new arrangement $A_0^{(h)}$. For those matroids in which the update structures for the contracted matroid can be maintained efficiently under element insertion and deletion, the update structures for the extreme bases in $A_0^{(h-1)}$ are modified via swaps to yield update structures for these new bases, respectively. We then have the implicit representation for $A_0^{(h)}$ after the update step.

Finally, $A_1^{(h-1)}$ is transformed to $A_1^{(h)}$. The hth element cost change is added to the rear of the queue of element cost changes that we maintain for A_1. Two element cost changes from the front of the queue are then deleted and each is applied to $A_1^{(h-1)}$ in the same manner as the cost changes were applied to A_0, obtaining $A_1^{(h)}$.

THEOREM 5. *Let M be a matroid of rank n with m elements of d colors. Consider constrained minimum cost bases with respect to cost function $c_L(\cdot)$. The on-line update problem for such bases can be solved in $O(d^2U(m,n)+Q(n,d,z)+d^2T(d^2z,d)+dT(n,d)/z+d^2T(d^2z,d)/z)$ time and $O(dS(m,n)+d^3(d^2z+n))$ space.*

Proof. For each of the $O(d^2)$ extreme bases of each arrangement, an update operation will be performed. Then d cardinal bases in each arrangement are selected from these $O(d^2)$ updated bases. An updated arrangement $A_g^{(h)}$ is generated by solving $O(d^2)$ static d-color problems. This can be done by finding the new extreme bases of the arrangement for each color on a contracted matroid of rank $n'=O(d^2z)$. The space required for computing one of these bases is $O(d^3(d^2z))$, which is $O(d^5z)$ for computing all of them, since they are computed one at a time. The space required for storing the update structures for each of the extreme bases will be $O(d^3z)$, or $O(d^5z)$ overall. Solving the static d-color problems will take time $O(d^2T(d^2z,d))$. Thus each update step in A_0 or A_1 will take $O(d^2U(m,n)+Q(n,d,z)+d^2T(d^2z,d))$, time.

In addition, $O(d^2)$ static d-color problems of rank n must be solved over z updates in order to regenerate the arrangements. For each color j, compute the extremal bases of color j. Then contract the matroid to one of rank $n'=O(d^2z)$. The remaining extreme bases can be found in the contracted matroid. Thus the time spent per update step on solving these static d-color problems is $O((dT(n,d)+d^2T(d^2z,d))/z)$. The static d-color problems of rank n will be solved one at a time and thus require $O(d^3n)$ space overall. □

To illustrate the above technique, we describe the construction of update structures for graphic matroids and analyze their efficiency. The update structure for a minimum spanning tree uses dynamic tree data structures [ST] and two-dimensional topology trees [F]. The former allows us to perform the operations *maxcirc* and *swap* in time $O(\log n)$. The latter allows us to perform the operations *mincocirc* and *swap* in time $O(\sqrt{m})$. Thus for this update structure $U(m,n)=O(\sqrt{m})$. The space used by the structures is $O(m)$.

A contracted matroid is maintained in the form of a contracted graph. A topology tree [F] is used to maintain a heap of the edges incident on each vertex of the contracted graph. Each such vertex corresponds to a tree-structured connected component of contracted edges from the current constrained minimum spanning tree. Since topology trees of size d^2z support insert, delete, split, and merge operations in $O(\log(d^2z))$ time, updating the contracted graph can be implemented efficiently. Given the monochromatic bases, the time to solve a static d-color problem is $T(n,d)=O((d!)^2n\log n)$. We therefore have the following theorem.

THEOREM 6. *Let G be a graph with n vertices, and with m edges of d colors. Consider constrained minimum spanning trees with respect to cost function $c_L(\cdot)$. The on-line update problem for such spanning trees can be solved in $O(d^2\sqrt{m}+d^{5/2}(d!)^2\sqrt{n}\log n)$ time and $O(dm+d^3n)$ space.*

Proof. We have $U(m,n)=O(\sqrt{m})$, $T(n,d)=O((d!)^2n\log n)$ and $Q(n,d,z)$ will be $O(d^2U(d^2z,z)+d^2\log(d^2z))$, which is $O(d^3z^{1/2})$. Each update step in the arrangements will take $O(d^2\sqrt{m}+d^4(d!)^2z\log(d^2z))$ time. We must also replenish the second arrangement by solving a number of static problems of rank n, which will cost $O((d(d!)^2n\log n+d^4(d!)^2z\log(d^2z))/z)$ time per update. We choose $z=\Theta(n^{1/2}/d^{3/2})$. The space bound follows from our choice of z and $S(m,n)$. □

6. A recursive representation of arrangements. We can achieve better update times by using a more complex representation of arrangements. Consider the example in the last section involving graphic matroids. We can use a two-level approach for representing A_0 and A_1. Consider update step h, where $h = kz + r$ and $0 \leqq r < z$. Recall that $A_0^{(h)} = R_{\bar{q},z-h}^{(h)}$, where $R_{\bar{i},l}$ is the set of bases $\{B_{\bar{i}'} | i_j' \leqq i_j + l - 1, j = 1, 2, \cdots, d\}$. Arrangement A_0 was represented implicitly by the extreme bases, their associated data structures, and either the contracted matroid or the contraction set corresponding to the extremal bases. On an update step in A_0, d cardinal bases were determined, the contracted matroid (or contraction set) was updated using them, and $2d^2+1$ static problems of rank $n' = O(d^2 z)$ were solved to find the new extreme bases.

In our modified method, a base at each extreme is computed as before. However, instead of solving a number of static problems with respect to A_0 on each update step in A_0, we do the following. We maintain smaller arrangements A_{0j}, $j = 2, 3, \cdots, d+1$, centered near the extreme bases of A_0, and two smaller arrangements A_{00} and A_{01} centered at $B_{\bar{q}}$. We call these smaller arrangements *subarrangements.* Only when the subarrangements A_{0j}, $j = 2, 3, \cdots, d+1$, decay to single bases are a number of static problems solved with respect to A_0. A_{00} and A_{01} are maintained to be able to access $B_{\bar{q}}$ meanwhile.

Let l_{0j} be the radius of subarrangement A_{0j}, $j = 0, 1, \cdots, d+1$. For $j = 2, \cdots, d+1$, A_{0j} will be centered on $\bar{q}_j$, where $q_{jk} = q_k - (d-1)(l_0 - l_{0j})$ for $k = j$ and $q_{jk} = q_k + l_0 - l_{0j}$ for $k \neq j$. Let y be a parameter to be specified subsequently. At a renewal point for A_{0j}, $l_{0j} = y$ if $j = 0$, $l_{0j} = 3y$ if $j = 1$, and $l_{0j} = 2y$ if $j = 2, 3, \cdots, d+1$. Each subarrangement is represented implicitly by its $2d^2$ extreme bases, their associated data structures, and the contracted matroid (or contraction set). If the contracted matroid is maintained, the extreme bases are of rank $n' = \Theta(d^2 z)$; otherwise the bases are of rank n. After the A_{0j}, $j = 2, \cdots, d+1$, have decayed to radius 1, $2d^3$ static problems with $n' = d(d-1)(l - l_{0j})$ will be initiated to determine the extreme bases for the new A_{0j}, $j = 2, \cdots, d+1$.

At a renewal point for A_0, A_{00} will be up to date with respect to A_0, A_{0j}, $j = 1, 2, \cdots, d+1$, will be out of date with respect to A_{00} (and therefore A_0) by y element cost changes. Times at which $h \bmod z > 0$ and $h \bmod y = 0$ are regarded as renewal points for A_{0j}, $j = 0, 1, \cdots, d+1$. At a renewal point for A_{00}, A_{00} has completely decayed, A_{01} has caught up with A_{00} and can replace it, arrangements A_{0j}, $j = 2, \cdots, d+1$, have caught up with A_{00} but have decayed to single bases, the $(d+1)2d^2$ static problems have been completed which yield the extreme bases for the new arrangements A_{0j}, $j = 1, \cdots, d+1$, and a new set of static problems can be initiated using the single bases from the previous A_{0j}, $j = 2, \cdots, d+1$. As before, two update steps in an out-of-date arrangement will be performed for every update step in A_0. We will assume that $z \bmod y = 0$, so that A_{0j}, $j = 1, l, \cdots, d+1$, will catch up with A_0 precisely when A_0 reaches its next renewal point. Arrangement A_1 is represented in a similar fashion. Subarrangements A_{1j}, $j = 1, \cdots, d+1$, will initially be out of date with respect to A_1 by y element cost changes. Since A_1 is itself out of date with respect to A_0, four update steps will be performed in each of A_{1j}, $j = 1, \cdots, d+1$, for every update step in A_0.

We discuss how to perform an update in A_0. The update for A_1 is similar. For each of the extreme bases of A_0, an update operation is performed. Then the d cardinal bases are selected from those $O(d^2)$ updated bases. The contracted matroid (or contraction set) corresponding to the cardinal bases is computed. In addition, for all extreme bases of A_{0j} that are not extreme bases of A_0, an update operation is performed. For each group of d bases in this set, a cardinal base is computed. Then, for each

$j = 0, 1, \cdots, d+1$, the contracted matroid (or contraction set) corresponding to the cardinal bases of A_{0j} is computed. A total of $2d^2+1$ static d-color problems of rank $n' = \Theta(d^2 y)$ are solved for each of the $d+1$ subarrangements of A_0. From the extreme bases of the A_{0j} that correspond to extreme bases of A_0, swaps that transform the old extreme bases of A_0 into the new extreme bases can be inferred. The new contracted matroids (or contraction sets) for A_0 and its subarrangements can then be determined.

In addition, the following static problems must be solved over a sequence of updates. To generate the extreme bases for A_1, $O(d^2)$ static d-color problems of rank n must be solved over z updates. To generate the extreme bases for A_{gj}, $g = 0$, 1 and $j = 1, 2, \cdots, d+1$, $O(d^3)$ static d-color problems of rank $n' = \Theta(d^2 z)$ must be solved over y updates.

THEOREM 7. *Let G be a graph with n vertices, and with m edges of d colors. Consider constrained minimum spanning trees with respect to cost function $c_L(\cdot)$. The on-line update problem for such spanning trees can be solved in $O(d^2\sqrt{m} + d^{11/3}(d!)^2 n^{1/3} \log n)$ time and $O(dm + d^3 n)$ space.*

Proof. For each of the $O(d^2)$ extreme bases of arrangements A_0 and A_1, an update operation will be performed. Then d cardinal bases in each arrangement are selected from these $O(d^2)$ updated bases. The time required is $O(d^2 U(m, n))$. For each of the $O(d^3)$ extreme bases of subarrangements A_{0j} and A_{1j}, an update operation will be performed. Then d new extreme bases in each subarrangement are selected from its $O(d^2)$ updated bases. The total time required is $O(d^3 U(d^2 z, n))$. An updated arrangement A_{kj} is generated by solving $O(d^2)$ static d-color problems. This can be done by finding the extreme bases for each color on a contracted matroid of rank $n' = O(d^2 y)$. Thus solving the static d-color problems will take time $O(d^3 T(d^2 y, d))$. Thus each update step in the arrangements and subarrangements will take $O(d^2 U(m, n) + Q(n, d, z) + d^3 U(d^2 z, n) + d^3 T(d^2 y, d))$ time.

In addition, $O(d^2)$ static d-color problems of rank n must be solved over z updates. As in the proof of Theorem 5, this will take $O((dT(n, d) + d^2 T(d^2 z, d))/z)$ time per update step. Also, $O(d^3)$ static d-color problems of rank $\Theta(d^2 z)$ must be solved over y updates. The time spent per update step on solving these static d-color problems will be $O((d^3 T(d^2 z, d))/y)$. The time spent handling each element cost change is $O(d^2\sqrt{m} + d(d!)^2((n \log n)/z + d^4(z \log z)/y + d^4 y \log y))$. Choosing $z = \Theta(n^{2/3}/d^{8/3})$ and $y = \Theta(n^{1/3}/d^{4/3})$ yields the time claimed by the theorem.

For the space, proceeding in a fashion similar to that in the proof of Theorem 5, we obtain a bound of $O(dS(m, n) + d^3(n + d^3 z))$, which is $O(dm + d^3 n)$ for our choice of z and $S(m, n)$. □

For fixed d, the time for the above approach is limited by the $O(\sqrt{m})$ time to update a minimum spanning base in an uncolored graph. If the graph is planar however, then the update time in an uncolored graph has been shown to be $O(\log n)$ in [GS], and hence is not a limiting factor. We thus extend recursively the implicit representation of arrangements. The representations will be of two types, centered and uncentered. Let $a(d)$ be a value depending on d, which we shall specify subsequently. An arrangement, centered or uncentered, of radius at most $a(d)$, is the set of extreme bases, their associated data structures, and the contracted matroid (or contraction set) corresponding to the extremal bases. Let $f(\cdot)$ be a function to be defined subsequently. For an arrangement A_λ of radius l_λ initially equal to $z > a(d)$, *a centered representation* consists of the above items, in addition to the following:

(1) A centered representation of a subarrangement $A_{\lambda 0}$, which is centered on the same position as A_λ, with radius $l_{\lambda 0}$ initially equal to $f(z)$, and which is up to date with respect to A_λ.

(2) A centered representation of a subarrangement $A_{\lambda 1}$, which is centered on the same position as A_λ, with radius $l_{\lambda 1}$ initially equal to $3f(z)$, and which is out of date with respect to A_λ by $l_{\lambda 0}$ element cost changes.

(3) Uncentered representations of subarrangements $A_{\lambda j}$, $j=2, \cdots, d+1$, which are positioned at the extremes of A_λ, with radius $l_{\lambda j}$ initially equal to $2f(z)$, and which are out of date with respect to A_λ by $l_{\lambda 0}$ element cost changes.

(4) $2d^2$ static problems that have just been initiated. Of these, $2d$ will be of rank $n'=\Theta(d^2 z)$, and the remainder of rank $\Theta(d^2 f(z))$.

An *uncentered representation* consists of all items in a centered representation except items (1) and (2).

Let $f^{(0)}(x)=x$ and $f^{(i)}(x)=f(f^{(i-1)}(x))$, for $i>0$. Then we choose the function $f(\cdot)$ such that $f^{(i+1)}(n) \bmod f^{(i)}(n)=0$ for $i>0$. This can be done easily by forcing $f(\cdot)$ to be a power of 2. This choice of $f(\cdot)$ ensures that each $(i+1)$st level arrangement will have caught up with the appropriate ith level arrangement at an ith level renewal point.

Let $T_C(z)$ and $T_U(z)$ be the update times for centered and uncentered arrangements of radius z, respectively. The update times are described by the following recurrences:

$$T_U(z)=cd^3(d!)^2(z \log z)/f(z)+2dT_U(2f(z)),$$

$$T_C(z)=cd^3(d!)^2(z \log z)/f(z)+2dT_U(2f(z))+2T_C(3f(z))+T_C(f(z))$$

where c is a constant. The first term in each recurrence represents the time spent per update step on solving the static problems of rank $\Theta(d^2 z)$ and updating the data structures. The remaining terms represent the time for recursively updating subarrangements of radius $\Theta(f(z))$, and reflect the fact that two update steps are required for out-of-date subarrangements for each update step in the primary arrangement.

THEOREM 8. *Let G be a planar graph with n vertices, and edges of d colors. Consider constrained minimum spanning trees with respect to cost function $c_L(\cdot)$. The on-line update problem for such spanning trees can be solved in $O(d^3(d!)^2(\log d)^{-1/2} 2^{(2\log(2d)\log n)^{1/2}}(\log n)^{3/2})$ time and $O(d^3 n)$ space.*

Proof. We have $U(m, n)=O(\log n)$, $P(n)=O(n \log n)$ and $Q=0$. If we choose $f(x)=\Theta(x/2^{(2\log(2d)\log x)^{1/2}})$ and observe that

$$\sqrt{\log f(x)}=\sqrt{\log x-\sqrt{2\log(2d)\log x}}<\sqrt{\log x}-\sqrt{(\log(2d))/2},$$

then both $T_U(n)$ and $T_C(n)$ are $O(d^3(d!)^2(\log d)^{-1/2}2^{(2\log(2d)\log n)^{1/2}}(\log n)^{3/2})$, provided $a(d)$ is small enough, so that the basis of the recurrences satisfies these bounds.

For the space, the recursive representation has at most $(d+2)^i$ subarrangements, each using data structures of size $\Theta(f^{(i)}(n))$ at level i. With $d+2 \leqq 2d \leqq 2^{(2\log(2d)\log n)^{1/2}}$, the sizes of these structures sum to $O(n)$ over all levels.

Solving for n in the above inequality suggests the choice of $a(d)=\sqrt{2d}$. Since arrangements of radius at most $a(d)$ are represented explicitly, the space for representing arrangements is $O(n)$, aside from the space for the static problems being solved. At level i, there are $\Theta(d^{1+i})$ static d-color problems of rank $\Theta(f^{(i)}(n))$ and $\Theta(d^{2+i})$ static d-color problems of rank $\Theta(f^{(i+1)}(n))$ being solved. These static problems are solved one at a time, and the space requirement for computing and recording their solutions sums to $O(d^3 n)$ over all levels.

If the general matroid intersection algorithm is used for updating arrangements of radius at most $a(d)$ in the centered and uncentered representations, then the basis in the recurrences is polynomial in d. Thus the basis satisfies the claimed bounds on $T_U(n)$ and $T_C(n)$. □

7. An application. The techniques of § 4 can be used to solve the minimum spanning tree problem when d vertices have degree constraints. Assume that the vertices with degree constraints are indexed $v_1, v_2, \cdots, v_d$. Label each edge incident on two constrained vertices with color 0. Label each edge incident on exactly one constrained vertex v_i with color i. Label each edge incident on two unconstrained vertices with color $d+1$.

Since there are d constrained vertices, there are at most $d(d-1)/2$ edges of color 0. In turn we consider every subset of edges of color 0 that is a forest, such that the degree of each v_i in the forest does not exceed its degree requirement r_i. We generate a candidate solution for each such forest. The idea is to include all the forest edges in the solution and then choose remaining edges so as to satisfy the degree constraints in a minimum cost fashion. The minimum cost solution over all such forests is then the minimum spanning tree satisfying the degree constraints.

For each forest, we generate a reduced graph as follows. Make a copy of the graph, and initialize r_i' to be r_i for $i=1, 2, \cdots, d$. Delete from the graph all edges of color 0 that are not in the forest. For each edge (v_i, v_j) in the forest, decrease by 1 the degree requirements r_i' and r_j'. Then contract the remaining edges of color 0 in the graph. To get the candidate solution corresponding to this forest solve a $(d+1)$-color static problem on the reduced graph, where r_i' edges of color i are desired, for $i=1, 2, \cdots, d$, and the remaining edges are of color $d+1$.

THEOREM 9. *The time to solve a minimum spanning tree problem with degree constraints on d of the vertices is* $O(T_0(m, n)+((d+1)!)^2 d^{d-1} T(n, 2))$, *and the space is* $O(d^3 n)$.

Proof. For each forest, the set of edges of any color $j>0$ in the corresponding $(d+1)$-color problem is the same. The only monochromatic minimum spanning tree that cannot be inferred by definition is the one of color $d+1$. Thus the first term reflects the time to solve a minimum spanning tree problem on edges of color $d+1$.

We next derive a bound on the number of undirected labeled forests, and thus the number of $(d+1)$-color problems that must be solved. We first count directed labeled graphs in which each vertex has outdegree 1, with self-loops allowed. This quantity is an upper bound on the number of directed labeled forests, and is a loose bound since it allows directed cycles other than self-loops. The edge directed out of each vertex can be any one of d vertices. Hence at most d^d such graphs are possible. To obtain a slightly tighter bound for undirected labeled forests, observe that at least one vertex in a directed labeled forest is a root. In counting undirected labeled forests, it makes no difference which vertex this is. So in generating the above directed labeled graphs we arbitrarily choose vertex v_1 to be a root. Thus we choose from among d possible edges out of each of the remaining $d-1$ vertices, which means at most d^{d-1} undirected labeled forests are possible.

The space required is dominated by the space needed to find one $(d+1)$-color spanning tree. □

Acknowledgment. We thank the referee for a careful reading of the paper and for many helpful suggestions.

OPTIMAL BIN PACKING WITH ITEMS OF RANDOM SIZES II*

WANSOO T. RHEE† AND MICHEL TALAGRAND‡

Abstract. Consider a probability measure μ on $[0, 1]$ and independent random variables $X_1, \cdots, X_n$, distributed according to μ. Let $Q_n(X_1, \cdots, X_n)$ be the minimum number of unit-size bins needed to pack items of size $X_1, \cdots, X_n$. In this paper it is proven that $|E(Q_n(X_1, \cdots, X_n))/n - c(\mu)| \leqq K((\log n)/n)^{1/2}$, where K is a universal constant and $c(\mu)$ depends on μ, $c(\mu) = \lim_{n\to\infty} E(Q_n)/n$.

Key words. stochastic bin packing, asymptotic occupancy, size distribution, compactness, weak convergence

AMS(MOS) subject classifications. primary 90B05; secondary 05B99, 46A50, 28A33

1. Introduction. The bin-packing problem requires finding the minimum number of unit size bins needed to pack a given collection of items with sizes $X_1, \cdots, X_n$ in $[0, 1]$. This problem has many applications and has been shown to be NP-complete [3], [4]. Recently, a number of authors have been interested in analyzing stochastic models for bin packing. Coffman, Garey, and Johnson [1] gave an up-to-date survey of results on this question. Most authors have analyzed approximation algorithms under a model of elements drawn independently from the uniform distribution on $[0, 1]$. The main results of this paper are deterministic. They are however connected with a more general stochastic model. Consider a probability measure μ on $[0, 1]$. (No regularity assumption is made on μ.) Consider n items, and the sizes of these items $X_1, \cdots, X_n$ which are independent identically distributed random variables distributed according to μ. (For simplicity, we denote by X_k both item names and item sizes.) We let $Q_n = Q_n(X_1, \cdots, X_n)$ denote the minimum number of unit-size bins needed to pack $X_1, \cdots, X_n$. It is well known that Q_n is a subadditive process (see [5]). So we have $\lim_n Q_n/n = c(\mu)$ almost surely for some constant $c(\mu)$ depending on μ, and $E(Q_n)/n \geqq c(\mu)$ for each n. In [12], the authors have shown that Q_n is very concentrated around its expectation. More precisely, for all $t > 0$,

$$\Pr(|Q_n - E(Q_n)| \geqq t) \leqq 2\exp(-t^2/2n).$$

This however gives no information on the value of $E(Q_n)$. Among other results, we will find a sharp bound for the difference $E(Q_n) - nc(\mu)$ (see Theorem D below). In [11], Rhee has given a complete description of the distributions μ for which $c(\mu) = E(X_1)$. In order to state the full strength of our results, we need first to state an extension of Rhee's result. For $k \geqq 1$, let

$$R_k = \left\{(x_1, \cdots, x_k) \in R^k : 0 \leqq x_1 \leqq \cdots \leqq x_k, \sum_{i\leqq k} x_i \leqq 1\right\}.$$

For $x \in [0, 1]$, we denote by δ_x the probability measure concentrated at x, that is $\delta_x(G) = 1$ if x belongs to G and $\delta_x(G) = 0$ otherwise. For a compact metric space S, we denote by $M_1(S)$ the set of probability measures on S.

For $\nu \in M_1(R_k)$, we define $\mathcal{P}(\nu) \in M_1([0, 1])$ in the following way: for each Borel set G of $[0, 1]$,

$$\mathcal{P}(\nu)(G) = (1/k)\int_{R_k} \sum_{i\leqq k} \delta_{x_i}(G)\, d\nu(x_1, \cdots, x_k).$$

In short, this formula (and similar formulae) will be written

$$\mathcal{P}(\nu) = (1/k) \int_{R_k} \sum_{i \leqq k} \delta_{x_i} \, d\nu(x_1, \cdots, x_k).$$

The simple, but essential, idea is that if ν is the distribution of items $X_1, \cdots, X_k$, these items can always be packed in one bin and $\mathcal{P}(\nu)$ is the distribution of X_i, where $i \in \{1, \cdots, k\}$ is uniformly distributed independently of $X_1, \cdots, X_k$.

THEOREM A. *For μ in $M_1([0,1])$, there is a nonnegative sequence $(\alpha_k)_{k \geqq 0}$ with $\sum_{k \geqq 0} \alpha_k = 1$, and for each $k \geqq 1$, a ν_k in $M_1(R_k)$ such that*

$$\mu = \alpha_0 \delta_0 + \sum_{k \geqq 1} \alpha_k \mathcal{P}(\nu_k)$$

and that

$$c(\mu) \geqq \sum_{k \geqq 1} \alpha_k / k.$$

Here is the main result.

THEOREM B. *Consider a nonnegative sequence $(\alpha_k)_{k \geqq 0}$ with $\sum_{k \geqq 0} \alpha_k = 1$, and a sequence $\nu_k \in M_1(R_k)$. Consider the measure*

$$\mu = \alpha_0 \delta_0 + \sum_{k \geqq 1} \alpha_k \mathcal{P}(\nu_k). \tag{1.1}$$

For $l \geqq 1$, let $\beta_l = \sum_{k \geqq l} \alpha_k / k$. Consider a sequence $s_1, \cdots, s_n$ of items. Let

$$W = W(s_1, \cdots, s_n) = \operatorname*{Sup}_{0 \leqq t \leqq 1} \{\operatorname{card}\{i \leqq n;\ s_i \geqq t\} - n\mu([t,1])\}, \quad \text{and} \tag{1.2}$$

$$W+ = \operatorname{Sup}(W, 0).$$

Then

$$Q_n(s_1, \cdots, s_n) \leqq W^+ + n \sum_{k \geqq 1} (\alpha_k / k) + Kn^{1/2}\left(1 + \sum_{i \leqq n^{1/2}} (\beta_i / i)^{1/2}\right) \tag{1.3}$$

where K is a universal constant (independent of μ, n, and $s_1, \cdots, s_n$).

In particular,

$$Q_n(s_1, \cdots, s_n) \leqq W^+ + n \sum_{k \geqq 1} (\alpha_k / k) + K(n(1 + \log n))^{1/2}. \tag{1.3'}$$

Comments. (1) The packing procedure by which we obtain (1.3) is explicit and fairly simple. However it requires complete knowledge of the decomposition (1.1). We have not estimated its time complexity, since it is not clear what are realistic assumptions about the effort needed to compute the quantities related to (1.1) that we need.

(2) Our proof shows that (1.3) actually holds for $K = 8$, but we have used only simple estimates and have made no special efforts to find a small value for K; this would not be appropriate since we do not know what is the best possible order of the error term.

The following theorems are two consequences of Theorem B.

THEOREM C. *Let $s_1, \cdots, s_n \in [0,1]$. Let $\nu = \sum_{i \leqq n} \delta_{s_i} / n$. Then*

$$nc(\nu) \leqq Q_n(s_1, \cdots, s_n) \leqq nc(\nu) + K(n(1 + \log n))^{1/2}. \tag{1.4}$$

THEOREM D. *There is a universal constant K such that for any distribution μ,*

$$nc(\mu) \leqq E(Q_n(X_1, \cdots, X_n)) \leqq nc(\mu) + K(n(1 + \log n))^{1/2}. \tag{1.5}$$

If, moreover, the series $\sum_{i\geqq 1}(\beta_i/i)^{1/2}$ *converges (where* $\beta_i=\sum_{k\geqq i}\alpha_k/k$ *and* (α_k) *is as in Theorem* A), *we have*

$$nc(\mu)\leqq E(Q_n)\leqq nc(\mu)+K(\mu)n^{1/2} \tag{1.6}$$

where $K(\mu)$ *depends on* μ *only.*

When μ is the uniform distribution on $[0,1]$, (1.6) is due to Knödel [6] and Lueker [7]. In this context, it is of interest to note the following, related to a theorem of Lueker.

THEOREM E. *Let* μ *be a probability measure on* $[0,1]$. *Let* A *be a measurable subset of* $[0,1]$ *with* $\mu(A)=1$. *Let* $0<\theta\leqq 1$. *The following are equivalent*:

(a) $c(\mu)>\theta$.

(b) *There exists a nonnegative continuous function* f *on* $[0,1]$ *such that* $\int f\,d\mu>\theta$ *and* $f(0)=0$, *and that* f *satisfies the following condition*:

(*) *For any* $k\geqq 1$, *for each* $x_1,\cdots,x_k\in[0,1]$, $\sum_{i\leqq k}x_i\leqq 1\Rightarrow\sum_{i\leqq k}f(x_i)\leqq 1$.

(c) *There exists a Borel function* f *on* $[0,1]$ *such that* $\int f\,d\mu>\theta$ *and* $f(0)\leqq 0$, *and that* f *satisfies the following condition*:

(*) *For any* $k\geqq 1$, *for each* $x_1,\cdots,x_k\in A$, $\sum_{i\leqq k}x_i\leqq 1\Rightarrow\sum_{i\leqq k}f(x_i)\leqq 1$.

The paper is organized as follows: Section 2 contains all the proofs, except that of Theorem B; Section 3 prepares the proof of Theorem B, which is done in § 4.

2. Some simple facts. Let S be a compact metric space. We denote by $C(S)$ the class of continuous functions on S. Denote by $M_+(S)$ the set of all positive measures on S and by $M(S)$ the set of all bounded variation measures on S, so $M_1(S)\subset M_+(S)\subset M(S)$. The weak topology on $M(S)$ is the coarsest topology such that for every $f\in C(S)$, the map $\mu\to\int_S f\,d\mu$ is continuous. Provided with the weak topology, $M_1(S)$ is compact metric. Let $0\leqq\theta\leqq 1$. We define the set C_θ as the set of μ in $M_1([0,1])$, for which there exists a sequence $(\alpha_k)_{k\geqq 0}$ such that $\sum_{k\geqq 0}\alpha_k=1$ and $\sum_{k\geqq 1}\alpha_k/k\leqq\theta$, and a sequence $\nu_k\in R_k$, for $k\geqq 1$, such that

$$\mu=\alpha_0\delta_0+\sum_{k\geqq 1}\alpha_k\mathscr{P}(\nu_k).$$

PROPOSITION 1. C_θ *is convex. If a sequence* (θ_n) *converges to* θ *and* $\mu_n\in C_{\theta_n}$ *converges weakly to* μ, *then* $\mu\in C_\theta$. (*In particular* C_θ *is weakly closed.*)

Proof. The first assertion is obvious. The proof of the second needs only obvious modifications from the proof of Lemma 2 in [11], to which we refer the reader.

We now prove Theorem A. The proof is very similar to part of the proof of the main theorem of [11]. A well-known consequence of the Law of Large Numbers is that $(1/n)\sum_{i\leqq n}\delta_{X_i}\to\mu$ almost surely in the weak topology. Also, $(1/n)Q_n(X_1,\cdots,X_n)\to c(\mu)$ almost surely, so we can find a sequence (x_i) such that $\mu_n=(1/n)\sum_{i\leqq n}\delta_{x_i}$ converges weakly to μ and k_n/n converges to $c(\mu)$, where $k_n=Q_n(x_1,\cdots,x_n)$. (We denote item sizes and item names by lowercase letters to emphasize that they are not random.) We fix n and we consider a packing of items of size $x_1,\cdots,x_n$ in k_n bins. In the jth bin, $j\leqq k_n$, we have p_j items of size $y_{j,1},\cdots,y_{j,p_j}$ with $y_{j,1}\leqq\cdots\leqq y_{j,p_j}$. Let $\lambda_j=(1/p_j)(\sum_{l\leqq p_j}\delta_{y_{j,l}})$. We have

$$\mu_n=\sum_{j\leqq k_n}(p_j/n)\lambda_j. \tag{2.1}$$

We have $\sum_{j\leqq k_n}(p_j/n)/p_j=k_n/n$. It follows from (2.1) that $\mu_n\in C_{k_n/n}$, so $\mu\in C_{c(\mu)}$ by Proposition 1. This proves Theorem A.

We postpone the proof of (1.3) to §§ 3 and 4, and we deduce all the other results from it. Since $\beta_i = \sum_{k \geqq i} \alpha_k / k$, we have $\sum_{i \geqq 1} \beta_i = \sum_{k \geqq 1} \alpha_k \leqq 1$. From the Cauchy-Schwartz inequality,

$$\sum_{i \leqq n^{1/2}} (\beta_i / i)^{1/2} \leqq \left(\sum_{i \leqq n^{1/2}} \beta_i \right)^{1/2} \left(\sum_{i \leqq n^{1/2}} 1/i \right)^{1/2}.$$

Now $\sum_{i \leqq n^{1/2}} 1/i \leqq K_1(1+\log n)$ for some constant K_1. So, (1.3) implies (1.3′) (maybe with a different constant K).

Proof of Theorem C. We apply Theorem A to ν in order to get a decomposition of ν as in (1.1), where $\sum_{k \geqq 1} \alpha_k / k \leqq c(\nu)$. The right-hand side inequality of (1.4) then follows from (1.3′), since $W^+ = 0$. To prove the left-hand side inequality, if we draw items $X_1, \cdots, X_N$ distributed according to ν, for $i \leqq n$, let N_i be the number of items of size s_i and let $a_N = \operatorname{Sup}_{i \leqq n} N_i$. We partition the items into a_N collections, where each collection contains at most one item of each size and pack each collection optimally. We need at most $a_N Q_n(s_1, \cdots, s_n)$ bins. The Law of Large Numbers shows that $\lim_{N \to \infty} E(a_N)/N = 1/n$ and this implies the result, since

$$c(\nu) = \lim_{N \to \infty} E(Q_N(X_1, \cdots, X_N))/N$$

$$\leqq \lim_{N \to \infty} E(a_N Q_n(s_1, \cdots, s_n))/N = (1/n) Q_n(s_1, \cdots, s_n).$$

Proof of Theorem D. The left-hand side of (1.5) follows from subadditivity. For the right-hand side, if

$$W(X_1, \cdots, X_n) = \operatorname*{Sup}_{0 \leqq t \leqq 1} \{\operatorname{card}\{i \leqq n, X_i \geqq t\} - n\mu([t, 1])\},$$

the Kolmogorov-Smirnov theorem implies that $E(W^+) \leqq K n^{1/2}$ for some universal constant K. So Theorem D follows from Theorem B.

Remark. The argument also shows that for $\mu \in C_\theta$, we have $c(\mu) \leqq \theta$.

Proof of Theorem E. (a⇒b). Consider the set C of all measures γ in $M_+([0, 1])$ that can be written as a sum

$$\gamma = \alpha_0 \delta_0 + \sum_{k \geqq 1} \alpha_k \mathcal{P}(\nu_k)$$

where $\nu_k \in M_1(R_k)$, $\alpha_i \geqq 0$ for each $i \geqq 0$, and $\sum_{k \geqq 1} \alpha_k / k \leqq \theta$. It is clear that C is convex. Moreover, for γ in C, the probability $\gamma / \gamma([0, 1])$ belongs to $C_{\theta/\gamma([0,1])}$. We show now that μ does not belong to the weak closure of C. Otherwise, there is a sequence (γ_n) in C that converges weakly to μ. In particular, the sequence $a_n = 1/\gamma_n([0, 1])$ converges to 1, so the sequence $\gamma_n' = a_n \gamma_n$ converges weakly to μ. Moreover $\gamma_n' \in C_{a_n \theta}$, so Proposition 1 shows that $\mu \in C_\theta$. The remark before the proof shows that this is a contradiction.

We can now use the geometric form of the Hahn-Banach theorem (in the space $M(S)$ of all bounded variation measures provided with the weak topology) to get a continuous function g on $[0, 1]$ such that $\int g \, d\mu > \theta$ but $\int g \, d\nu \leqq \theta$ whenever $\nu \in C$. Since $\alpha \delta_0 \in C$ for all $\alpha \geqq 0$, we have $g(0) \leqq 0$. Now let $x_1, \cdots, x_k$ be in $[0, 1]$ with $\sum_{i \leqq k} x_i \leqq 1$. Since $\nu = \theta \sum_{i \leqq k} \delta_{x_i}$ belongs to C, we have $\int g \, d\nu = \theta \sum_{i \leqq k} g(x_i) \leqq \theta$. Now define $f = \operatorname{Max}(0, g)$, so f is continuous, and $\int f \, d\mu > \theta$. Given $x_1, \cdots, x_k \leqq 1$, let $J = \{i \leqq k; g(x_i) > 0\}$. Since $\sum_{i \in J} x_i \leqq 1$, we have $\sum_{i \in J} g(x_i) = \sum_{i \leqq k} f(x_i) \leqq 1$. This completes the proof.

(b⇒c). The proof is obvious.

(c⇒a). Suppose, if possible, that $c(\mu) \leqq \theta$. By Theorem A, we have $\mu \in C_\theta$. So there is a sequence α_k with $\sum_{k\geqq 0} \alpha_k \leqq 1$, $\sum \alpha_k/k \leqq \theta$ and $\nu_k \in M_1(R_k)$ such that $\mu = \alpha_0\delta_0 + \sum_{k\geqq 1} (\alpha_k/k)\mathcal{P}(\nu_k)$. In particular, for each Borel set G of $[0, 1]$, we have

$$\mu(G) = \alpha_0\delta_0(G) + \sum_{k\geqq 1} (\alpha_k/k) \int_{R_k} \sum_{i\leqq k} \delta_{x_i}(G)\, d\nu_k(x_1, \cdots, x_k).$$

Using this equality for $G = [0, 1]\backslash A$, we see that for each k such that $\alpha_k > 0$, each $i \leqq k$, we have $\delta_{x_i}(G) = 0$ for ν_k almost surely. In other words, $\delta_{x_i}(A) = 1$ ν_k almost surely. So ν_k is concentrated on

$$P_k = \{(x_1, \cdots, x_k);\ 0 \leqq x_1 \leqq \cdots \leqq x_k,\ x_1, \cdots, x_k \in A\}.$$

Now, we have

$$\int f d(\mathcal{P}(\nu_k)) = (1/k) \int_{R_k} \sum_{i\leqq k} f(x_i)\, d\nu_k(x_1, \cdots, x_k)$$

$$= (1/k) \int_{P_k} \sum_{i\leqq k} f(x_i)\, d\nu_k(x_1, \cdots, x_k).$$

It follows that

$$\int f d(\mathcal{P}(\nu_k)) \leqq \operatorname{Sup}\left\{(1/k) \sum_{i\leqq k} f(x_i);\ (x_i)_{i\leqq k} \in P_k\right\} \leqq 1.$$

We then have

$$\int f\, d\mu \leqq \alpha_0 f(0) + \sum_{k\geqq 1} \alpha_k/k \leqq \theta.$$

This contradiction concludes the proof.

3. Preparation.

LEMMA 1. (Well known; used and proved in [11] in the case $q = \operatorname{card} U$.) *Let $q \geqq 0$ and U be an index set. Consider two families $(a_i)_{i\leqq q}$, $(b_u)_{u\in U}$ and $0 \leqq a_i, b_u \leqq 1$. Let*

$$h = \sup_{0\leqq t\leqq 1} \{\operatorname{card}\{1 \leqq i \leqq q;\ a_i \geqq t\} - \operatorname{card}\{u \in U;\ b_u \geqq t\}\}. \tag{3.1}$$

Then there is a subset $H \subseteq \{1, \cdots, q\}$ with $\operatorname{card} H \geqq q - h$ and ϕ, a one-to-one map from H to U with $a_i \leqq b_{\phi(i)}$ for $i \in H$.

Note. We index the b's by an abstract index set U because we find it is more convenient to prove the next lemma.

LEMMA 2. *Let p, q, $n > 0$. Consider a family $(a_i)_{i\leqq q}$, $0 \leqq a_i \leqq 1$ and for $1 \leqq j \leqq p$, left-continuous nonincreasing functions $(f_j)_{j\leqq p}$ on $[0, 1]$. Set*

$$h = \sup_{0\leqq t\leqq 1} \left\{\operatorname{card}\{1 \leqq i \leqq q;\ a_i \geqq t\} - n \sum_{j\leqq p} f_j(t)\right\}.$$

Then there are disjoint subsets $(H_j)_{j\leqq p}$ of $\{1, \cdots, q\}$ with $\sum_{j\leqq p} \operatorname{card} H_j \geqq q - h - p$, and for each $j \leqq p$, for each $t \in [0, 1]$,

$$\operatorname{card}\{i \in H_j;\ a_i \geqq t\} \leqq nf_j(t). \tag{3.2}$$

Proof. The proof is easy, but very boring. For $x \in R$, let $[x]$ be the integer part of x. For $1 \leqq j \leqq p$, let $n_j = [nf_j(0)]$. For $1 \leqq l \leqq n_j$, let $b_{l,j} = \operatorname{Sup}\{t;\ 0 \leqq t \leqq 1,\ nf_j(t) \geqq l\}$. (Since $l \leqq n_j$, the set is not empty.) Since f_j is left-continuous, $nf_j(b_{l,j}) \geqq l$. Note also

that $b_{l,j}$ is nonincreasing in l, i.e., $b_{l+1,j} \leqq b_{l,j}$ for $1 \leqq l$, $l+1 \leqq n_j$. We first prove the following fact.

FACT. *For* $0 \leqq t \leqq 1$,

$$\text{card}\,\{1 \leqq l \leqq n_j;\ b_{l,j} \geqq t\} > nf_j(t) - 1. \tag{3.3}$$

Proof of the Fact. Let r be the largest integer with $r \leqq nf_j(t)$, so $r > nf_j(t) - 1$. By definition of $b_{l,j}$, $b_{l,j} \geqq t$ for $1 \leqq l \leqq r$. □

We return to the proof of Lemma 2. Consider the index set $U = \{(l,j);\ 1 \leqq j \leqq p,\ 1 \leqq l \leqq n_j\}$. For $u = (l,j) \in U$, let $b_u = b_{l,j}$. By summation of the inequalities (3.3), we get for each t,

$$\text{card}\,\{u \in U;\ b_u \geqq t\} > n \sum_{j \leqq p} f_j(t) - p.$$

So, by definition of h,

$$\sup_{0 \leqq t \leqq 1} \{\text{card}\,\{i \leqq q;\ a_i \geqq t\} - \text{card}\,\{u \in U;\ b_u \geqq t\}\} < h + p.$$

Using Lemma 1, we get $H \subseteq \{1, \cdots, q\}$ with card $H \geqq q - h - p$ and a one-to-one map ϕ from H to U such that $a_i \leqq b_{\phi(i)}$ for $i \in H$. For $j \leqq p$, define

$$H_j = \{i \in H;\ \phi(i) \text{ is of the form } (l,j) \text{ for some } l \leqq n_j\}.$$

Since $H = \bigcup_{j \leqq p} H_j$, we have $\sum_{j \leqq p} \text{card}\, H_j \geqq q - h - p$.

We now prove (3.2).

Fix $1 \leqq j \leqq p$ and $0 \leqq t \leqq 1$. Let r be the largest integer with $b_{r,j} \geqq t$. So $f_j(t) \geqq f_j(b_{r,j}) \geqq r/n$. Also, card $\{l \leqq n_j;\ b_{l,j} \geqq t\} = r \leqq nf_j(t)$. Since ϕ is one to one,

$$\begin{aligned} \text{card}\,\{i \in H_j;\ a_i \geqq t\} &\leqq \text{card}\,\{i \in H_j;\ b_{\phi(i)} \geqq t\} \\ &\leqq \text{card}\,\{l \leqq n_j;\ b_{l,j} \geqq t\} \leqq nf_j(t). \end{aligned}$$ □

Remark. The proof actually gives $\sum_{j \leqq p} \text{card}\, H_j \geqq q - m$, where m is the largest integer $< h + p$.

For two positive measures (not necessarily probabilities) η, ν on $[0,1]$, [11] shows the relevance of the relation $\eta \ll \nu$ given for each $t \in [0,1]$, $\eta([t,1]) \leqq \nu([t,1])$. Before we state Lemma 4, we explain its basic idea. There is a measure ν_i on $[0,1]$ with $\nu_i([t,1]) = f_i(t)$ (since f_i is nonnegative, nonincreasing, and left-continuous). Condition (3.2) reads

$$\text{for each } j \leqq p, \quad (1/n) \sum_{i \in H_j} \delta_{a_i} \ll \nu_j. \tag{3.4}$$

Also $H_j \subseteq \{1, \cdots, n_j\}$ and we have n_j bins. Bin number l, for $l \leqq n_j$, has occupancy level a_l. Then (3.4) also reads

$$(1/n_j) \sum_{l \in H_j} \delta_{a_l} \ll n\nu_j/n_j.$$

So, occupancy level of the bins is controlled by ν_j.

The basic idea of the construction is as follows: The decomposition of μ as in Theorem A contains (in an abstract way) directions on how to actually pack a given sequence of items (see [11]). We will try to follow these directions; the packing will be done in about $\sqrt{n}$ steps; after each step, we want to make sure (to make further steps possible) that the average level of bin occupancy is controlled (in the sense of (3.4)) by some suitable distribution.

The following lemma is purely technical, and will be needed in the proof of the basic Lemma 4.

LEMMA 3. *Let γ be a positive measure on $[0,1]^2$. Let $p>0$. Consider a sequence $(b_i)_{i\leqq p}$ such that $\sum_{i\leqq p} b_i = \|\gamma\|$. ($\|\cdot\|$ is the total variation norm. Since $\gamma \geqq 0$, $\|\gamma\| = \gamma(1) = \int d\gamma(x)$.) Then there is a sequence $0 = u_p \leqq u_{p-1} \leqq \cdots \leqq u_0 = 1$ and for $1 \leqq i \leqq p$ a positive measure γ_i such that*

$$\gamma = \sum_{i\leqq p} \gamma_i, \tag{3.5}$$

$$\gamma_i \text{ is supported by } [u_i, u_{i-1}]\times[0,1], \text{ and} \tag{3.6}$$

$$\|\gamma_i\| = b_i. \tag{3.7}$$

Proof. Define for $1 \leqq i \leqq p-1$,

$$u_i = \operatorname{Sup}\left\{0 \leqq t \leqq 1;\ \gamma([t,1]\times[0,1]) \geqq \sum_{j\leqq i} b_j\right\}.$$

Let $u_0 = 1$ and $u_p = 0$. We have for $1 \leqq i \leqq p-1$,

$$\gamma([u_i, 1]\times[0,1]) \geqq \sum_{j\leqq i} b_j. \tag{3.8}$$

If $u_i < 1$, then for $t > u_i$, we have

$$\gamma([t,1]\times[0,1]) \leqq \sum_{j\leqq i} b_j.$$

So,

$$\gamma(]u_i, 1]\times[0,1]) \leqq \sum_{j\leqq i} b_j. \tag{3.9}$$

This still holds if $u_i = 1$. We now construct γ_i by induction over i such that (3.6) and (3.7) hold, and also

$$\gamma - \sum_{j\leqq i} \gamma_j \text{ is supported by } [0, u_i]\times[0,1]. \tag{3.10}$$

We first construct γ_1. Let $b = \gamma([u_1,1]\times[0,1])$ and $a = \gamma(]u_1,1]\times[0,1])$. We have $a \leqq b_1 \leqq b$. Denote by ξ (respectively, η) the restriction of γ to $]u_1,1]\times[0,1]$ (respectively, $\{u_1\}\times[0,1]$). So $\|\xi\| = a$ and $\|\eta\| = b-a$. If $a = b$, we set $\gamma_1 = \eta$. Otherwise, we take $\gamma_1 = \xi + [(b_1 - a)/(b-a)]\eta$. We suppose now that γ_i has been constructed, for $i < p$, and we construct γ_{i+1}. Let $\gamma' = \gamma - \sum_{j\leqq i}\gamma_j$. By (3.10), γ' is supported by $[0, u_i]\times[0,1]$. By (3.5), (3.7), (3.8), and (3.9),

$$b = \gamma'([u_{i+1}, u_i]\times[0,1]) = \gamma'([u_{i+1},1]\times[0,1]) \geqq b_{i+1},$$

$$a = \gamma'(]u_{i+1}, u_i]\times[0,1]) = \gamma'(]u_{i+1},1]\times[0,1]) \leqq b_{i+1}$$

since $\gamma'(]u_i,1]\times[0,1]) = 0$. Denote by ξ (respectively, η) the restriction of γ' to $]u_{i+1}, u_i]\times[0,1]$ (respectively, $\{u_{i+1}\}\times[0,1]$), so $\|\xi\| = a$ and $\|\eta\| = b-a$. If $b = a$, we can take $\gamma_{i+1} = \xi$. Otherwise, we take

$$\gamma_{i+1} = \xi + \{(b_{i+1} - a)/(b-a)\}\eta.$$

The proof is complete.

The basic lemma is as follows.

LEMMA 4. *Let $1 \leqq m \leqq n$. Let γ be a positive measure on $[0,1]^2$. Assume $(m/n) \leqq \|\gamma\| \leqq (m+1)/n$. Consider the three positive measures, given by, for each Borel set U:*

$$\gamma'(U) = \gamma(U\times[0,1]),$$

$$\gamma''(U) = \gamma([0,1]\times U), \quad \text{and}$$

$$\eta(U) = \gamma(\{(x,y): x+y \in U\})$$

(in other words, γ' and γ'' are the marginals of γ, and η is the distribution of $x+y$).

Consider two sequences $(l_i)_{i\leqq m}$, $(y_i)_{i\leqq m}$ of numbers, $0\leqq l_i,\ y_i\leqq 1$. Assume that

$$\text{for each } t\in[0,1],\quad \operatorname{card}\{i\leqq m;\ l_i\geqq t\}\leqq n\gamma'([t,1]), \tag{3.11}$$

$$\text{for each } t\in[0,1],\quad \operatorname{card}\{i\leqq m;\ y_i\geqq t\}\leqq n\gamma''([t,1]). \tag{3.12}$$

Let $1\leqq k\leqq m/4$. Then there exist three subsets A, B, C of $\{1,\cdots,m\}$ such that $B\subseteq A$, $\operatorname{card} B=\operatorname{card} C$,

$$\operatorname{card} A\geqq m-\sqrt{m/k},\quad \text{and} \tag{3.13}$$

$$\operatorname{card} B\geqq m-7\sqrt{mk}, \tag{3.14}$$

and there exists a one-to-one and onto map ϕ from B to C such that if we set $z_i=l_i$ for $i\in A\backslash B$ and $z_i=l_i+y_{\phi(i)}$ for $i\in B$, then

$$\text{for each } t\geqq 0,\quad \operatorname{card}\{i\in A;\ z_i\geqq t\}\leqq n\eta([t,\infty[). \tag{3.15}$$

Interpretation. For simplicity, assume $\|\gamma\|=1$ and $m=n$. Consider a pair L, Y of random variables such that the pair (L, Y) has distribution γ. Then L is distributed according to γ', Y is distributed according to γ'', and $L+Y$ according to η. We are now given the items $L_1,\cdots,L_n$, $Y_1,\cdots,Y_n$, whose distributions of sizes are nicely controlled by γ' and γ'' as in (3.11) and (3.12). We try to pair the items by finding a one-to-one map ϕ: $\{1,\cdots,n\}\to\{1,\cdots,n\}$ such that the distribution of the sizes of the pairs is controlled by η, i.e.,

$$\text{for each } t\in[0,1],\quad \operatorname{card}\{i\leqq n;\ l_i+y_{\phi(i)}\geqq t\}\leqq n\eta([t,\infty[). \tag{3.16}$$

(Elements that are paired will go to the same bin.) This is not quite possible, so we have to settle for less, and dump some of the items. We will apply Lemma 4 to a situation where the items Y_i are of size $\leqq 1/k$, and the size of items L_i is of order 1. Since the items (Y_i) are smaller, we can afford to disregard more of them. We disregard the items Y_i for $i\notin B$, (at most $7\sqrt{mk}$ of them) and the items L_i for $i\notin A$ (at most $\sqrt{m/k}$ of them). If $i\in A\backslash B$, L_i will not be paired with any element (and will go alone to a bin). If $i\in A$, L_i will be paired with $Y_{\phi(i)}$. Formula (3.16) is then the appropriate substitute for (3.15).

Proof. Set $a=[\sqrt{m/k}]$. Since $m/k\geqq 4$, $\sqrt{m/k}\geqq 2$, so $a\geqq\sqrt{m/k}/2$. Let $p=[n\|\gamma\|/a]$. We have

$$p\leqq n\|\gamma\|/a\leqq 2\sqrt{k/m}\,n\|\gamma\|\leqq 2(m+1)\sqrt{k/m}\leqq 4\sqrt{mk}\quad(\text{since } m\geqq 1,\ m+1\leqq 2m).$$

For $i\leqq p$, let $b_i=a/n$. Let $b_{p+1}=\|\gamma\|-pa/n\leqq a/n$. We apply Lemma 3, to write $\gamma=\sum_{1\leqq i\leqq p+1}\gamma_i$, such that $\|\gamma_i\|=b_i$ and γ_i is supported by $[u_i,u_{i-1}]\times[0,1]$, where $0=u_{p+1}\leqq u_p\leqq\cdots\leqq u_1\leqq u_0=1$.

CLAIM. For $0\leqq t\leqq 1$, we have

$$\operatorname{card}\{1\leqq i\leqq p;\ u_i\geqq t\}\geqq(n/a)\gamma'([t,1])-1. \tag{3.17}$$

For $t=0$, this is equivalent to $p\geqq(n/a)\|\gamma\|-1$, which is true. Suppose now $t>0$, let r be the largest integer with $u_r\geqq t$, so $u_{r+1}<t$. We have

$$\gamma'([t,1])\leqq\gamma'(]u_{r+1},1])\leqq\|\gamma\|-\sum_{i>r+1}b_i\leqq(r+1)a/n.$$

On the other hand,

$$\operatorname{card}\{1\leqq i\leqq p;\ u_i\geqq t\}\geqq r$$

which proves the claim.

Let $W=\{(i,j);\ 1\leqq i\leqq p,\ 1\leqq j\leqq a\}$. For $w=(i,j)\in W$, set $v_w=u_i$. For $0\leqq t\leqq 1$, we have, by (3.17),

$$\begin{aligned}\operatorname{card}\{w\in W;\ v_w\geqq t\} &= a\ \operatorname{card}\{1\leqq i\leqq p;\ u_i\geqq t\}\\ &\geqq n\gamma'([t,1])-a.\end{aligned}$$

So,

$$\operatorname{card}\{i\leqq m;\ l_i\geqq t\}-\operatorname{card}\{w\in W;\ v_w\geqq t\}\leqq a.$$

It follows by Lemma 1 that there is a set $A\subseteq\{1,\cdots,m\}$ with $\operatorname{card} A\geqq m-a\geqq m-\sqrt{m/k}$, and a one-to-one map $\psi: A\to W$ such that $l_j\leqq v_{\psi(j)}$ for $j\in A$. For $i\leqq p$, let $K_i=\{j\in A;\ v_{\psi(j)}=u_i\}$. The sets K_i, $i\leqq p$ form a partition of A. So, $\sum_{1\leqq i\leqq p}\operatorname{card} K_i\geqq m-a$. Also $\operatorname{card} K_i\leqq a$. For $1\leqq i\leqq p+1$, define

$$f_i(t)=\gamma_i([0,1]\times[t,1]).$$

Since $\gamma=\sum_{1\leqq i\leqq p+1}\gamma_i$, we have for $0\leqq t\leqq 1$, $\gamma''([t,1])=\sum_{1\leqq i\leqq p+1}f_i(t)$. Since $|f_{p+1}(t)|\leqq b_{p+1}\leqq a/n$, we have $\sum_{1\leqq i\leqq p}f_i(t)\geqq\gamma''([t,1])-a/n$. It follows from (3.12) that

$$\operatorname*{Sup}_{0\leqq t\leqq 1}\left\{\operatorname{card}\{i\leqq m;\ y_i\geqq t\}-n\sum_{1\leqq i\leqq p}f_i(t)\right\}\leqq a.$$

From Lemma 2, there exist disjoint subsets $(H_i)_{1\leqq i\leqq p}$ of $\{1,\cdots,m\}$ such that $\sum_{1\leqq i\leqq p}\operatorname{card} H_i\geqq m-a-p$ and such that

(3.18) for each $i\leqq p$ and for each $t\in[0,1]$, $\operatorname{card}\{j\in H_i;\ y_j\geqq t\}\leqq nf_i(t)$.

For $1\leqq i\leqq p$, let M_i be a subset of K_i such that $\operatorname{card} M_i=\min\{\operatorname{card} K_i,\operatorname{card} H_i\}$. Let $B=\bigcup_{1\leqq i\leqq p}M_i$. For $1\leqq i\leqq p$, since $\operatorname{card} K_i\leqq a$, we have $\operatorname{card}(K_i\backslash M_i)\leqq a-\operatorname{card} H_i$. So,

$$\begin{aligned}\sum_{i\leqq p}\operatorname{card}(K_i\backslash M_i) &\leqq ap-\sum_{i\leqq p}\operatorname{card} H_i\\ &\leqq ap+a-m+p\leqq n\|\gamma\|-m+a+p\\ &\leqq a+p+1,\end{aligned}$$

since $n\|\gamma\|-m\leqq 1$ and $p=[n\|\gamma\|/a]$. So,

$$\operatorname{card} B=\sum_{i\leqq p}\operatorname{card} M_i=\sum_{i\leqq p}(\operatorname{card} K_i-\operatorname{card}(K_i\backslash M_i))\geqq m-2a-p-1\geqq m-7\sqrt{mk}.$$

Since $\operatorname{card} M_i\leqq\operatorname{card} H_i$, there is a one-to-one map ϕ_i from M_i into H_i. Consider the map ϕ from B to $\{1,\cdots,m\}$ given by $\phi(j)=\phi_i(j)$ for $j\in M_i$. We define $C=\phi(B)$. We set $z_j=l_j$ for $j\in A\backslash B$ and $z_j=l_j+y_{\phi(j)}$ for $j\in B$. For $j\in M_i$, $l_j\leqq v_{\psi(j)}=u_i$. We have for $1\leqq i\leqq p$,

$$\operatorname{card}\{j\in K_i;\ z_j\geqq u_i\}\leqq\operatorname{card} K_i\leqq a=n\|\gamma_i\|.$$

So, for $t\leqq u_i$, $\operatorname{card}\{j\in K_i;\ z_j\geqq t\}\leqq n\gamma_i([0,1]\times[t-u_i,\infty[)$. Now let $t>u_i$, $j\in K_i$, and $z_j\geqq t$. Since $z_j>u_i\geqq l_j$, we have $j\in M_i$ (otherwise $z_j=l_j$). Moreover, $z_j=l_j+y_{\phi(j)}\geqq t$, so $y_{\phi(j)}\geqq t-l_j\geqq t-u_i$. From (3.18), we have

$$\begin{aligned}\operatorname{card}\{j\in K_i;\ z_j\geqq t\} &\leqq\operatorname{card}\{l\in H_i;\ y_l\geqq t-u_i\}\\ &\leqq n\gamma_i([0,1]\times[t-u_i,\infty[).\end{aligned}$$

So for any t,

$$\operatorname{card}\{j\in K_i;\ z_j\geqq t\}\leqq n\gamma_i([0,1]\times[t-u_i,\infty[).$$

Since γ_i is supported by $[u_i, u_{i-1}]\times R$,

$$\begin{aligned}\operatorname{card}\{j\in A;\, z_j\geqq t\} &\leqq \sum_{i\leqq p} n\gamma_i([0,1]\times[t-u_i,\infty[)\\ &= \sum_{i\leqq p} n\gamma_i([u_i,u_{i-1}]\times[t-u_i,\infty[).\end{aligned}$$

Let η_i be the image of γ_i by the map $(x, y)\to(x+y)$, that is, for each $i\leqq p$

$$\begin{aligned}\eta_i([t,\infty[) &= \gamma_i(\{(x,y);\,(x+y)\geqq t\})\\ &\geqq \gamma_i([u_i,u_{i-1}]\times[t-u_i,\infty[).\end{aligned}$$

So,

$$\begin{aligned}n\eta([t,\infty[) &\geqq n\sum_{i\leqq p}\eta_i([t,\infty[) \geqq n\sum_{i\leqq p}\gamma_i([u_i,u_{i-1}]\times[t-u_i,\infty[)\\ &\geqq \operatorname{card}\{j\in A;\, z_j\geqq t\}.\end{aligned}$$

The proof is complete.

We finish the section with an obvious and well-known fact.

LEMMA 5. *A collection $(y_j)_{j\leqq m}$ of items of sizes $y_j\leqq\theta<1$ can be packed in at most $1+\sum_{j\leqq m} y_j/(1-\theta)$ bins.*

Proof. In an optimal packing, at most $(1-\theta)$ of each bin (except for the last one) is wasted.

4. Proof of Theorem B. We have the decomposition of μ:

$$\mu=\alpha_0\delta_0+\sum_{k\geqq 1}\alpha_k\mathcal{P}(\nu_k).$$

As was shown by the proof of Theorem A in [11], the natural interpretation is as follows: α_k is the proportion of items packed in bins that contain k elements, and ν_k is the distribution of sizes inside such bins. We need some distributions associated with μ. For $l\geqq 1$, consider the positive measure λ_l such that

$$\lambda_l=\sum_{k\geqq l}(\alpha_k/k)\int_{R_k}\delta_{x_{k-l+1}}\,d\nu_k(x_1,\cdots,x_k)$$

so $\|\lambda_l\|=\sum_{k\geqq l}\alpha_k/k=\beta_l$, and $\mu=\alpha_0\delta_0+\sum_{l\geqq 1}\lambda_l$. Since x_{k-l+1} is the lth largest element of $(x_1,\cdots,x_k)$, it is less than or equal to $1/l$, so λ_l is supported by $[0, 1/l]$. The natural interpretation is to say that (after normalization) λ_l is the distribution of the lth largest element in the bins that contain at least l elements. For $x\in R_k$, $k\geqq l$, let $u_{k,l}(x)=\sum_{k-l+1\leqq i\leqq k} x_i$. We note that $u_{k,l}(x)\leqq 1$. Consider the following two positive measures:

$$\eta_l=\sum_{k\geqq l}(\alpha_k/k)\int_{R_k}\delta_{u_{k,l}(x)}\,d\nu_k(x_1,\cdots,x_k),\quad\text{and}$$

$$\xi_l=\sum_{k\geqq l+1}(\alpha_k/k)\int_{R_k}\delta_{u_{k,l}(x)}\,d\nu_k(x_1,\cdots,x_k).$$

We note that $\eta_1=\lambda_1$, $\|\eta_l\|=\beta_l$, and $\|\xi_l\|=\beta_{l+1}$, and that η_l and ξ_l are supported by $[0, 1]$. The natural interpretation of η_l (respectively, ξ_l) is as follows. After normalization, η_l is the distribution of $\sum_{i\leqq l} X_i$ in bins that contain elements $X_1\geqq\cdots\geqq X_k$, $k\geqq l$ (respectively, $k\geqq l+1$).

We also need the distribution γ_l on $[0, 1]^2$ given by

$$\gamma_l=\sum_{k\geqq l+1}(\alpha_k/k)\int_{R_k}\delta_{v(x)}\,d\nu_k(x_1,\cdots,x_k)$$

where $v(x)=(u_{k,l}(x),\ x_{k-l})$. After normalization, γ_l expresses the joint distribution of $(u_{k,l}(x),\ x_{k-l})$ in bins that contain at least $l+1$ items. Note that $\|\gamma_l\|=\beta_{l+1}$. Using the fact that $u_{k,l}(x)+x_{k-l}=u_{k,l+1}(x)$, we have immediately the following lemma.

LEMMA 6. (a) *The first marginal of* γ_l *is* ξ_l, *the second is* λ_{l+1}.

(b) *The image of* γ_l *under the map* $(x, y)\to x+y$ *is* η_{l+1}.

We now set $q=[\sqrt{n}]$. For each i, let $f_i(t)=\lambda_i([t, 1])$, for $t>0$. So, $\sum_{i\geqq 1} f_i(t)=\mu([t, 1])$. For $t>1/i$, $f_i(t)=0$, so for $t\geqq 1/q$, we have $\sum_{i\leqq q} f_i(t)=\mu([t, 1])$. We note also that $f_i(0)=\beta_i$.

We now prove Theorem B. Consider a sequence $s_1, \cdots, s_n$ of items. Let $C_0=\{i\leqq n;\ s_i<1/q\}$. Let $\bar{C}=\{i\leqq n;\ s_i\geqq 1/q\}$. We have for each $1/q\leqq t\leqq 1$, card $\{i\in\bar{C};\ s_i\geqq t\}\leqq n\sum_{i\leqq q} f_i(t)+W^+$. We now use Lemma 2 (on the interval $[1/q, 1]$ instead of $[0, 1]$). Then we find disjoint subsets $(C_i)_{i\leqq q}$ of $\bar{C}$ with $\sum_{i\leqq q}$ card $C_i\geqq$ card $\bar{C}-q-W^+$ such that for each $i\leqq q$, for each $1/q\leqq t\leqq 1$, card $\{j\in C_i;\ s_j\geqq t\}\leqq nf_i(t)$. Now let $C'=\bar{C}\setminus\bigcup_{i\leqq q} C_i$, so card $C'\leqq q+W^+$. Since $s_j\geqq 1/q$ for $j\in\bar{C}$, we get for each $i\leqq q$, for each $t\in[0, 1]$,

$$\text{card}\,\{j\in C_i;\ s_j\geqq t\}\leqq nf_i(t). \tag{4.1}$$

We note that if we set $n_i=[n\beta_i]$, this implies card $C_i\leqq n_i$. We first pack the elements of C'. It can be done with card $C'\leqq q+W^+$ bins. To pack the elements of C_0, Lemma 5 shows that we need at most $1+(n/q)(1/(1-1/q))$ bins. For $n\geqq 4$, a simple computation shows that this number is less than or equal to $5\sqrt{n}/2$. If $1\leqq n\leqq 3$, we need at most n bins, and $n\leqq\sqrt{3n}$. Since $\sqrt{3n}\leqq 5\sqrt{n}/2$, we need at most $5\sqrt{n}/2$ bins for any n.

We now proceed to the main construction, the packing of the families $(C_l)_{l\leqq q}$. This is done in q steps. At step l, $l\leqq q$ we will pack the collection C_l. After the lth step is performed, we have two sets of bins. The first set D_l of bins is "dead." No elements will be added to these bins at further steps of the construction. The second set of bins (called live bins) has a cardinality $n_{l+1}=[n\beta_{l+1}]$, so for convenience we index it by $\{1, \cdots, n_{l+1}\}$, and denote these bins by $B_1, \cdots, B_{n_{l+1}}$. These bins already contain items. If L_i is the sum of the sizes of the items contained in bin B_i (i.e., level occupancy), we have the following condition (that allows us to continue the induction):

$$\text{for each } t \text{ in } [0, 1],\quad \text{card}\,\{i\leqq n_{l+1};\ L_i\geqq t\}\leqq n\xi_l([t, 1]). \tag{4.2}$$

Before we start the construction, we have no dead bins and a set of n_1 empty live bins. To pack C_1, we put each item in a different bin. Since $\eta_1=\lambda_1$, $\eta_1([t, 1])=f_1(t)$, (4.1) implies

$$\text{for each } t \text{ in } [0, 1],\quad \text{card}\,\{i\leqq n_1;\ L_i\geqq t\}\leqq n\eta_1([t, 1]).$$

We note that $\eta_1([t, 1])\leqq\xi_1([t, 1])+\alpha_1$. We use Lemma 2 (with $p=1$) to find a subset E_1 of $\{1, \cdots, n_1\}$ with card $E_1\geqq n_1-n\alpha_1-1$ such that

$$\text{for each } t \text{ in } [0, 1],\quad \text{card}\,\{i\in E_1,\ L_i\geqq t\}\leqq n\xi_1([t, 1]). \tag{4.3}$$

The bins of index which are in $\{1, \cdots, n_1\}\setminus E_1$ become "dead," so our collection D_1 of dead bins has now at most $n\alpha_1+1$ elements. From (4.3), since $\xi_1([0, 1])=\beta_2$, we have card $E_1\leqq n_2=[n\beta_2]$. By adding n_2-card E_1 bins to our collection of live bins, we can suppose that it has now n_2 elements and that (4.2) holds with $l=1$.

We suppose now that step l has been completed where $l<q$. So, the collections $C_1, \cdots, C_l$ are already packed and we pack C_{l+1}. We have n_{l+1} live bins $B_1, \cdots, B_{n_{l+1}}$, such that if L_i is the level of bin occupancy of B_i, (4.2) holds. Let us enumerate the

items of C_{l+1} as $Y_1, \cdots, Y_r$. From (4.1) we have

$$\text{for each } t \text{ in } [0,1], \quad \text{card}\{j \leqq r;\ Y_j \geqq t\} \leqq n f_{l+1}(t). \tag{4.4}$$

When we take $t=0$, this shows $r \leqq [nf_{l+1}(0)] = n_{l+1}$. By adding $n_{l+1}-r$ items of size zero to $Y_1, \cdots, Y_r$, we can assume that $r = n_{l+1}$ and that (4.4) still holds.

If $n_{l+1} \leqq 4(l+1)$, we can pack the n_{l+1} items into four new bins, since they are of size at most $1/(l+1)$. These bins become dead. (Each of the collections C_i, $i \geqq l+1$, can also be packed in four bins.) If $(l+1)4 \leqq n_{l+1}$, we can use Lemma 4 with $\gamma = \gamma_l$, $m = n_{l+1}$ and $k = l+1$; we note that $\gamma' = \xi_l$ and $\gamma'' = \lambda_{l+1}$, so (3.11) and (3.12) follow from (4.2) and (4.4), respectively. So, we can find three subsets A, B, and C of $\{1, \cdots, n_{l+1}\}$ such that $B \subseteq A$ with $\text{card}\, A \geqq n_{l+1} - \sqrt{n_{l+1}/(l+1)}$; $\text{card}\, C = \text{card}\, B \geqq n_{l+1} - 7\sqrt{n_{l+1}(l+1)}$, a one-to-one map ϕ from B to C such that if we set $Z_i = L_i$ for $i \in A \backslash B$ and $Z_i = L_i + Y_{\phi(i)}$ for $i \in B$, then for each $t \geqq 0$,

$$\text{card}\{i \in A;\ Z_i \geqq t\} \leqq n\eta_{l+1}([t, \infty[) = n\eta_{l+1}([t,1]). \tag{4.5}$$

If $i \notin A$, the bin B_i becomes dead. That creates at most $\sqrt{n_{l+1}/(l+1)}$ new dead bins. If $i \in A \backslash B$, the bin B_i stays alive but we add no new element to it. If $i \in B$, we put $Y_{\phi(i)}$ into B_i, and the bin B_i stays alive. At this point, the bins B_i, for i in A, are alive, and their level occupancy satisfies (4.5). We have packed all the $(Y_j)_{j \leqq n_{l+1}}$ except for $j \notin C$. This is at most $7\sqrt{n_{l+1}(l+1)}$ elements. Since these elements are of sizes $\leqq 1/(l+1)$, we can pack them into $7\sqrt{n_{l+1}/(l+1)}+1$ empty bins. These bins become dead. We now note that

$$\eta_{l+1}([t,1]) \leqq \xi_{l+1}([t,1]) + \alpha_{l+1}/(l+1).$$

Using (4.5) and Lemma 2 (with $p=1$) we can find $H \subseteq A$, with $\text{card}\,(A \backslash H) \leqq [n\alpha_{l+1}/(l+1)]+1$ such that

$$\text{for each } t \text{ in } [0,1], \quad \text{card}\{i \in H;\ Z_i \geqq t\} \leqq n\xi_{l+1}([t,1]). \tag{4.6}$$

The bins of $A \backslash H$ become dead. Taking into account the case $n_{l+1} \leqq 4(l+1)$, at this step, we have created at most $[n\alpha_{l+1}/(l+1)]+4+8\sqrt{n_{l+1}/(l+1)}$ dead bins. From (4.6), we have $\text{card}\, H \leqq [n\beta_{l+2}] = n_{l+2}$. The bins B_i, $i \in H$ stay alive, and we add to this collection $n_{l+2} - \text{card}\, H$ new empty bins. This gives us a collection of n_{l+2} live bins that we relabel $B_1, \cdots, B_{n_{l+2}}$. Obviously, their occupancy level that we call L_i again satisfies the following:

$$\text{for each } t \text{ in } [0,1], \quad \text{card}\{i \leqq n_{l+2};\ L_i \geqq t\} \leqq n\xi_{l+1}([t,1]).$$

This completes the induction. After the q steps are completed, we have created at most

$$\sum_{1 \leqq i \leqq q} n\alpha_i/i + \sum_{2 \leqq i \leqq q} 8\sqrt{n_i/i} + 4q$$

dead bins. From (4.2), our collection of live bins has at most $n\beta_{q+1}$ bins; since $n_i \leqq n\beta_i$ and $\beta_{q+1} = \sum_{i>q} \alpha_i/i$, we have succeeded in using $n\sum_{i \geqq 1} \alpha_i/i + 8\sqrt{n}(\sum_{2 \leqq i \leqq q} \sqrt{\beta_i/i}) + 4q$ bins to pack $C_1, \cdots, C_l$. To pack the whole family $\{s_1, \cdots, s_n\}$, we thus have used at most

$$W^+ + n\sum_{i \geqq 1} \alpha_i/i + 8\sqrt{n}\left(\sum_{2 \leqq i \leqq q} \sqrt{\beta_i/i}\right) + 15\sqrt{n}/2$$

bins. □

MINIMAL THRESHOLD SEPARATORS AND MEMORY REQUIREMENTS FOR SYNCHRONIZATION*

EDWARD T. ORDMAN†

Abstract. Suppose that in a system of asynchronous parallel processes, certain pairs of processes mutually exclude one another (must not be in their critical sections simultaneously). This situation is modeled by a graph in which each process is represented by a vertex and each mutually excluding pair is represented by an edge. Henderson and Zalcstein have observed that if this graph is a threshold graph, then mutual exclusion can be managed by simple entrance and exit protocols using **PV**-chunk operations on a single shared variable whose possible values range from zero to t, the minimal threshold separator number of the graph. A new expression is given for this separator t of a threshold graph in terms of the normal decomposition of the threshold graph given by Zalcstein and Henderson. It is shown that $t+1$ values would be needed in the shared variable even if the mutual exclusion were being managed by the Fischer-Lynch test-and-set operator, which is considerably less restrictive than **PV**-chunk.

1. Introduction.

Concurrent processing by several asynchronous processes presents control problems that have been widely studied [1], [2], [4]-[6], [9], [11], [14]. It may be, for instance, that due to a need to access shared resources, such as a printer or shared data, certain events must be prevented from happening simultaneously in two (or more) processes. One approach is to have a designated section of code in each process identified as a **critical section** and to have the processes execute a joint algorithm that controls access to the critical sections. This algorithm is typically represented within each process by two protocols: the **entry protocol**, which is a section of code executed by a process before it is admitted to its critical section (and in which it may loop for some time, if the shared resource is in use by other processes); and the **exit protocol**, which is executed when the process leaves its critical section and makes the shared resource available to other processes. See [2] for a more precise discussion.

The processes may communicate by sending and receiving messages or by manipulation of one or more **shared variables**. A large number of ways of accessing shared variables have been studied, such as elementary read and write operations [5], **P** and **V** operations [6], **PV**-chunk operations [9], and test-and-set operations [2], [14]. In this paper we will implicitly be using the model of critical sections and of test-and-set operations laid out in [2], which provided one of the principal motivations for this paper. One of our goals is to compare the **PV**-chunk and test-and-set operations in a certain context; we describe them further in § 4.

Many of the papers cited above study a form of the mutual exclusion problem in which only one process can be in a critical section at one time. In fact, there are problems of interest in which more than one process can be in a critical section at a time. An early example of such a problem in the literature is called the **dining philosophers problem** (see [10] and some earlier references cited therein); a very practical problem of this type is the **readers-and-writers problem** (see [17] and the references therein) in which several processes may be allowed to read a data item simultaneously, but a process may change the item (write it) only at a time when no other process is

accessing it. A set of processes, some of which may not enter critical sections simultaneously, is sometimes called a generalized dining philosophers problem; one study of such problems is given in [12]. A second principal motivation for this paper was the hope that the sort of analysis done in [2] could be extended to generalized dining philosophers problems. Only a small start is made on that here: we discuss memory requirements for mutual exclusion (although not lockout prevention, starvation avoidance, etc.) for a limited class of problems, which do include some forms of readers and writers problems. We find that, for this very limited goal, **PV**-chunk operations are as powerful as test-and-set operations, although they appear not to be as memory-efficient in some other cases.

Some generalized dining philosophers problems correspond in a natural way to graphs. Suppose each vertex of a graph represents a process, and two vertices are **adjacent** (connected by an edge) if and only if the two corresponding processes cannot be executing their critical sections simultaneously. In this way each finite undirected graph without self-loops (we describe this more formally below) corresponds to a generalized dining philosophers problem. On the other hand, not every generalized dining philosophers problem corresponds to a graph. Consider four processes, each of which requires two tape drives, in an environment where four tape drives are available. Clearly any two processes can (if all goes well) obtain two drives each and proceed, so the corresponding "graph" would have no edges. However, three processes can never acquire enough tape drives (and enter their critical sections) at once, so a hypergraph would be required to model this situation. For some further discussion of this analogy see [9], [13]. We will be considering mutual exclusion in systems of processes represented by a certain class of graphs, the threshold graphs. Graph theory background is given in the next section.

2. Graph theory preliminaries. By a **graph** $G = (V, E)$ we mean a finite set of vertices V together with a finite set of edges E, each of which is a different unordered pair of distinct vertices: that is, a finite undirected graph without self-loops or parallel edges. If a and b are vertices we say that they are **adjacent** if (a, b) (or equivalently (b, a)) is an edge of G; we also say that this edge **connects** a and b.

Threshold graphs were introduced in [3] and have been studied extensively [9], [11], [13], [15], [16]; we will rely very heavily on [9]. A graph $G = (V, E)$ is a **threshold graph** if there is an integer t called the **threshold** (or sometimes the **separator**), and with each vertex x in V is associated a nonnegative integer label $a(x)$ such that a subset S of N is **stable** (no two nodes in it are connected by an edge in E) if and only if the sum of the $a(s)$ for all s in S is less than or equal to t. (We will call such a labeling, including knowing t, a **threshold labeling**). A great many other characterizations of threshold graphs are known (see, for example, [3], [9], [13]); some that we need are recalled at the start of § 4.

A graph is a threshold graph if and only if it has a threshold labeling. The labeling, however, is not unique. In [16] Orlin has given an algorithm for determining the **minimal separator** t (and an associated labeling) that will work for a given threshold graph. In § 4 we use a slight modification of the **normal form** for a threshold graph (implied in Corollary 1B, [3, p. 151] described in detail and named in [9]) to give a more closed form for the minimal value of t, and to see that this minimal value of t is important in determining the minimum amount of shared memory to do mutual exclusion.

In § 5 we study a mutual exclusion problem (Example 5.2) for a generalized dining philosophers problem that corresponds, in the sense described in § 1, to a threshold

graph. The connection between threshold graphs and **PV**-chunk operations has already been discussed in [9]. We find that the minimal separator t is a measure of the amount of memory needed to enforce mutual exclusion (without lockout prevention) in a system of processes represented by a threshold graph, using **PV**-chunk operations; we further see that at least this much memory is required, even if test-and-set operations are used instead. We see that test-and-set is, in cases other than threshold graphs, less demanding of memory than **PV**-chunk. We also look at a simple application to concurrent accesses of data bases.

3. The minimal separator of a threshold graph. We review some graph theory terminology. If $G=(V, E)$ is a graph and V' is a subset of V, the **subgraph** of G **induced** by V' is the graph whose vertices are the vertices of V' and whose edges are all edges of E which connect points in V'. A graph is a **clique** if every two points in it are adjacent; a subgraph of another graph G is a clique if it is a clique considered as a graph by itself, and is a maximal clique in G if it is not contained in any larger subgraph of G which is a clique. The clique with n vertices is denoted K_n.

The **degree** of a vertex is the number of vertices adjacent to it. We call a vertex **isolated** if it has degree zero, and **nonisolated** otherwise. We will call a vertex **dominating** (this is *not* a standard notation) if it is adjacent to every nonisolated vertex. By the **neighborhood** $N(x)$ of a vertex x we mean the set of vertices adjacent to x, together with x itself.

By way of making these terms clearer, we restate a well-known fact [3] about threshold graphs: no threshold graph may have as an induced subgraph any of the graphs shown in Fig. 1. These are the path on four vertices, P_4; the cycle on four vertices, C_4; and the union of two disjoint edges, $2K_2$ (note that a single edge is a clique on two points, K_2).

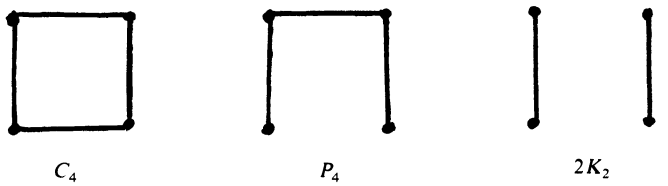

FIG. 1. *Graphs* C_4, P_4, *and* $2K_2$.

To prove that none of these graphs can be an induced subgraph of a threshold graph G, suppose that one of them is and label the four vertices w, x, y, and z. Suppose also that (w, z) and (x, y) are edges, but that (w, y) and (x, z) are not (e.g., label the vertices in each graph in Fig. 1 clockwise from upper left.) We will consider the labelings from a threshold labeling of G. Clearly, $a(w)+a(z)>t$ and $a(x)+a(y)>t$, since these pairs of vertices induce edges; clearly, $a(w)+a(y)\leqq t$ and $a(x)+a(z)\leqq t$, since these pairs do not. Adding the two pairs of inequalities produces a contradiction.

We also recall that an induced subgraph of a threshold graph must be a threshold graph; one simply restricts the threshold labeling to the subset of vertices and retains the same separator t.

Given a set of vertices V there may be various labelings $a(x)$ of the vertices and various separators t associated with them that lead to the same threshold graph G. For a given G, we want to determine the smallest possible t. This has been done in [16], which gives an algorithm to compute the smallest possible t; we approach the

problem slightly differently to get t in a more explicit form we can apply later in the paper. To this end, we need to recall and modify slightly the definition of "normal form" of a threshold graph given in [9].

LEMMA 3.1. *Let G be a threshold graph with an associated threshold labeling. Let x be a vertex with a label as large as any other label in G. Then x is a dominating vertex of G.*

Proof. Let z be any nonisolated node. Then it is connected to some node y and $a(z)+a(y)>t$. But $a(x)\geqq a(y)$, so $a(z)+a(x)>t$ and z is adjacent to x. □

In [3] threshold graphs are characterized by the fact that the three graphs of Fig. 1 cannot occur as induced subgraphs. We will need an additional characterization.

THEOREM 3.2. *For a graph G, the following are equivalent:*

(a) *G is a threshold graph.*

(b) *Every induced subgraph of G (including G itself) has a dominating node.*

(c) *G does not have as an induced subgraph the graphs P_4, $2K_2$, or C_4.*

Proof. Items (a) and (c) have been proved to be equivalent in [3]. Item (a) implies (b) by Lemma 3.1, since every induced subgraph of a threshold graph is threshold. Item (b) implies (c), since none of P_4, $2K_2$, or C_4 has a dominating vertex. □

The fact that (b) implies (a) is already implicit in [3]. That paper also contains the following Corollary 1B. A graph $G=(V, E)$ is threshold if and only if there is a partition of V into disjoint sets A, B, and an ordering $a_1, a_2, \cdots, a_k$ of A such that no two vertices in A are adjacent; every two vertices in B are adjacent; and if $j\leqq k$, then $N(a_j)\subseteq N(a_k)$. This fact is developed considerably in [9]; we will expand on it further here.

Given a threshold graph, we construct the normal form as follows. Choose all isolated vertices and put them in class D_0; take all dominating vertices and put them in class C_1. The subgraph of G induced by the remaining vertices we call G_1. For each consecutive subgraph G_k, place the isolated vertices in D_k, and the dominating vertices in C_{k+1}. Continue until G_{n+1} is empty.

Note the following:

(a) No vertex in any D_k is connected to any other vertex of any D_j (including $k=j$).

(b) Every vertex of every C_k is connected to every vertex of every C_j (including $k=j$).

(c) Every vertex of D_k is connected to every vertex of C_j for $j\leqq k$, but to no other vertices.

We may need to rearrange the last sets slightly to guarantee that both C_n and D_n are nonempty and that both C_{n+1} and D_{n+1} are empty. We distinguish, temporarily, two cases. If C_{n+1} is empty, D_n is nonempty (in fact it has at least two vertices, since if there were only one it would have been in C_n) and C_n is nonempty (else the construction would have stopped sooner). In the second case, C_{n+1} is nonempty. Then C_{n+1} must contain at least two vertices; otherwise the one vertex would have been in D_n. In this case we arbitrarily choose one vertex of C_{n+1}, move it to D_{n+1} (previously empty), and increase n by one. Thus we also have C_n and D_n both nonempty, and proceed with further analysis.

It is easy to see that all C_k and D_k are nonempty for $1\leqq k\leqq n$, since before each removal there are dominating vertices by Theorem 3.2 and their removal must leave some vertices isolated or else each dominating vertex of the newly reduced graph would have been already dominating prior to the reduction.

We call the resulting decomposition of G into $(D_0, D_1, \cdots, D_n, C_1, C_2, \cdots, C_n)$ the **normal form** of G. It is unique except perhaps for the choice of one node when we combined the two cases above; we tolerate that since it simplifies calculations below.

In Fig. 2 we illustrate the normal form, and the labeling that will be introduced below. On the left we show the graph G; the right shows the same graph with the vertex in C_1 labeled 11, that in C_2 labeled 8, those in D_1 labeled 1, and those in D_2 labeled 4. For this graph and labeling, $t = 11$. To convince ourselves that lower labels will not work, note that (once r, s, and u are labeled 1 and the separator is t) vertex x must have label at most $t-3$ since x, r, s, u induce no edges; now x and w induce an edge so w and similarly z must have label at least 4. Since r, s, u, z, and w induce no edges, t must be at least 11. The reader may find it helpful to delete vertex w from G and find the normal form and a labeling.

THEOREM 3.3. *Let G be a threshold graph and $(D_0, D_1, \cdots, D_n, C_1, C_2, \cdots, C_n)$ its normal form. Let d_k denote the number of vertices in D_k. Then the vertices can be labeled so as to give a threshold labeling with separator t satisfying*

$$t+1 = \prod (d_k+1), \qquad k = 1, \cdots, n.$$

Proof. Our labeling method is the same as that of [9] and [16]. For simplicity of formulas we define $g_i = \prod (d_j+1) - 1$, where the product is for $j = 1, \cdots, i$; by definition $g_0 = 0$. Assign each element of D_0 the label 0 (they lie on no edges). Assign each element of D_1 the label 1; the total of all the labels assigned so far is d_1, which is equal to g_1. Assign each element of D_2 the label d_1+1; the total of the labels in D_2 is $d_2(d_1+1)$ and the grand total so far is g_2. We show by induction that when we assign each element of D_k the label $g_{k-1}+1$, the labels in D_k will total $d_k(g_{k-1}+1)$ and the sum of the labels to this point will be g_k. The induction step is to observe that $g_k + d_{k+1}(g_k+1) = g_{k+1}$, that is,

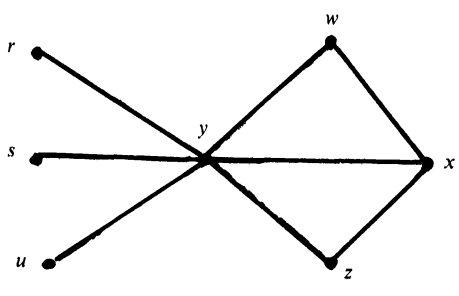
$$\begin{aligned} &\prod (d_j+1) - 1 + d_{k+1} \prod (d_j+1) && (j = 1, \cdots, k) \\ &\quad = (d_{k+1}+1) \prod (d_j+1) - 1 && (j = 1, \cdots, k) \\ &\quad = \prod (d_j+1) - 1, && (j = 1, \cdots, k+1) \end{aligned}$$

as desired.

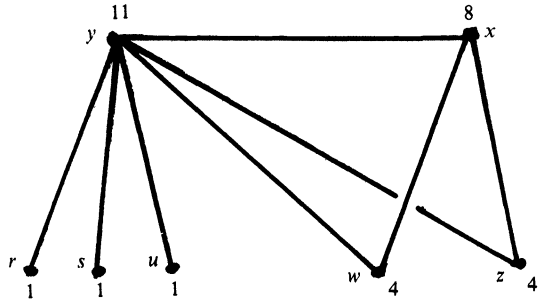
Now we let $t = g_n$, and for each k we assign each element of C_k the label $g_n - g_{k-1}$. We must show that this gives a threhold labeling of G. Note the following:

(a) No two vertices of any two D_k are connected, since the labels in all the D_k total g_n.

(b) Any two vertices in any C_k are connected, since each such point has label at least $g_n - g_{n-1}$. This must exceed half of g_n since $g_n = (g_{n-1}+1)(d_n+1) - 1$ and d_n is at least 1.



Graph G



Graph G with threshold labelling

FIG. 2.

(c) To test if a vertex in D_k is connected to a vertex in C_j, note that their labels total $(g_{k-1}+1)+(g_n-g_{j-i})$. This exceeds t exactly if k exceeds j, as required.

This completes the proof of Theorem 2.3. □

It can be shown that this is the same labeling as that in [16]. We could then rely on the proof there that the resulting t is minimal. However, a distinctly different proof of minimality will follow from the results of § 4 below.

4. Process synchronization. Now we turn to the problem of managing asychronous processes. We are motivated primarily by the considerations in [9] and in [2]; the reader is referred to [2] for a more complete background and terminology. Suppose we have a number of processes, some of which conflict with each other (e.g., they demand access to the same resources that cannot be shared simultaneously by all processes wanting them). We connect this to the considerations above by supposing that each vertex of the graph G represents a process, and that two processes conflict precisely if there is an edge connecting those vertices.

For example, suppose there is a record in a file consisting of two fields, a name (the key) and an address. Suppose there are five transactions in the system, each wanting to locate the same record, and then carry out the following tasks:

Process A: Read the name (that is, locate the record and confirm that it exists, no further use of it).
Processes B and C: Read the address.
Process D: Change the address in the existing record.
Process E: Change the name (key) and address.

This is a slight generalization of a conventional readers-and-writers problem. Processes A, B, and C are "readers" and all can access the record at once and still produce consistent results. Process D can proceed simultaneously with Process A but not with B or C; Process E cannot proceed at the same time as any of the others. Drawing a graph with vertices A through E and drawing the appropriate edges yields the graph of Fig. 3(a); this graph is, in fact, a threshold graph, with a threshold labeling as shown in Fig. 3(b). This example is further expanded in § 5.

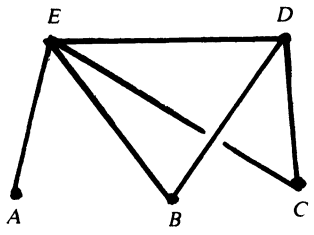


FIG. 3(a)

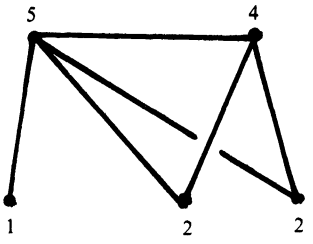

FIG. 3(b)

Suppose we are given a system of asynchronous processes and a set of pairs of these processes such that two processes in a pair cannot proceed simultaneously; i.e., members of each pair mutually exclude each other in the sense discussed in § 1 above and defined carefully in [2]. Each process has a piece of code called a "critical section"; we must provide entry and exit protocols for all processes in the system such that execution of these protocols will guarantee that two processes in a given pair will never be in their critical sections simultaneously. The graph G, with one vertex corresponding to each process and one edge for each mutually excluded pair of

processes, will be called the **exclusion graph** of the system. (For other work with this graph, see [15].)

Our treatment is much weaker than that in [2] in that we do not consider lockout prevention or any sort of fairness condition (e.g., bounded waiting). However, the treatment in [2] assumes that only one process out of the N processes in the system can be in its critical section at once: that is, the exclusion graph is a clique. Here we deal with an exclusion graph that is a threshold graph, and any set of processes corresponding to a stable set of vertices in the graph can be in their critical sections at the same time.

For communication between the processes, we will assume that there are one or more shared variables $V_1, \cdots, V_k$, each of which can be accessed by more than one process, perhaps by all the processes. One thing we are seeking is bounds on the storage necessary for these variables. We denote the size of the set of values assumable by V_k by $|V_k|$; thus if V_k can assume values from 0 to N, $|V_k| = N+1$.

The processes access these shared variables only by specified operations called synchronization primitives (see [1], [2], [5], [6], [9], [11], [14] for some guides to this rather extensive literature). In this paper we will have occasion to use two distinct synchronization primitives: **PV**-chunk [9] and test-and-set [2], [14].

The syntax of the test-and-set operator, given in more detail in [2], may be summarized as follows: a test-and-set operator allows a process to test a shared variable until it reaches a fixed (set of) values and then perform certain actions, including resetting the shared variable to a value, which may be determined by the process using its knowledge of the shared variable value. The statement may be written as follows:

test V until $V = x_1$ or x_2 or $\cdots$ or x_n
then $V :=$ function (V).

If V is not one of the indicated values then the statement is reexecuted from the beginning (busy waiting). As soon as V assumes one of the indicated values, function (V) is computed, V is set to the new value, and control passes to the next statement. (The computation and substitution is an atomic action; that is, if several processes are attempting to access V, only one at a time will actually change the value of V.) Note that $V :=$ function (V) is an acceptable form of the test-and-set statement, since by implication it tests V first and sees that it has any one of its finitely many possible values. In each case, the function in function (V) is an arbitrary programmable function; it may take significant computation time or space. It is this feature that makes the general test-and-set operator both extremely powerful and difficult to implement efficiently.

A **PV-chunk operator** [9] can be implemented as a special case of a test-and-set operator but, being much more restricted, is usually written rather differently. Essentially, it restricts the test to testing for a certain one-sided inequality and the function to incrementing or decrementing by a (freely user-chosen) constant. The syntax we will use is the following:

Test V until $V \geqq c_1$ then $V := V - c_1$.

Note that c_1 can vary from one occurrence of this statement to another. V is initialized to some positive integer at the start and will never become negative; it can be increased by any process by executing the statement with c_1 negative, in which case the test condition is met automatically.

Variations of both test-and-set and **PV**-chunk can be specified in which a "failure" message is returned if the condition is not met, instead of busy waiting until it is met.

An operation very much like **PV**-chunk is available as a system call "SEMOP" in UNIX System V. The operation there increments or decrements a variable (or even several variables) by varying amounts as an atomic operation, provided that the change does not carry the variable(s) below 0 or above $2^{15}-1$. Thus, there is real motivation for finding methods that coordinate large time-shared or networked systems using **PV**-chunk which require a limited range for the shared variable(s). In addition, hardware experimenters, such as those designing the New York University Ultra-computer, have been experimenting with parallel hardware designed to perform N changes on a variable in less than time proportional to N (e.g., time proportional to $\log N$). The operations proposed seem not inconsistent in complexity with **PV**-chunk, but are surely less complex than the general test-and-set. Test-and-set requires that an individual process receive a value from the shared memory, compute, and return a value to shared memory; **PV**-chunk allows a value to be sent to special hardware serving the shared memory, which can do the calculation internally and needs to pass very little back to the calling process (in the model given here, the calling process sleeps until V is large enough, then V is decremented and the process awakens; in an alternative model, a single-bit message "fails" or "succeeds" and may be returned to the caller by the special hardware.

A principal result of [9] is that given a collection of processes and conflicts forming a threshold graph, conflict avoidance (mutual exclusion) can be achieved by using **PV**-chunk operations on a single shared variable with range 0 to t; each process can enter its critical section if and only if it can decrement V by an amount given by the label of its node in the graph. Further, the threshold graphs are precisely the graphs for which **PV**-chunk operations on a single shared variable will achieve conflict avoidance.

The results in [2] assume that all processes in the system are deterministic and impose a technical requirement "No Memory": each process knows nothing about the state of the system other than what is in the shared variable(s). That is, each time a process enters or leaves its critical section when the shared variable(s) have a particular value, it makes the same change in the shared variable(s). We do require this in the proof of Theorem 4.2 below.

Our main result in this section is that managing mutual exclusion in a system where the exclusion graph is a threshold graph, both test-and-set and **PV**-chunk operations require the same amount of shared memory and that is the amount determined by Theorem 3.3.

THEOREM 4.1 [9]. *Let a system of processes have the exclusion graph $G=(V, E)$, which is a threshold graph with separator t. Then there are entry and exit protocols that achieve the desired mutual exclusion by using* **PV**-*chunk operations to access a single shared variable whose range includes the integers* 0 *to* t.

Proof [9]. It suffices to start the shared variable V with the value t. The entry protocol for a process whose corresponding vertex has label a is simply the following:

Test V until $V \geqq a$ then

$$V := V - a$$

and the exit protocol is simply

$$V := V + a$$

(as noted, the prefix "Test V until $V \geqq -a$" would add nothing). It is easy to see that a collection of processes can be in their critical sections at the same time if and only if their corresponding vertex labels total no more than t, i.e., if and only if there are no edges between their corresponding vertices. □

Clearly, the same theorem holds if the term **PV**-chunk is replaced by test-and-set, since **PV**-chunk is a special case of test-and-set. The main result of this section is that the range 0 to t in Theorem 4.1 is the best possible, even if we use several shared variables and the more general test-and-set operations.

THEOREM 4.2. *Let a system of processes have the exclusion graph $G=(V, E)$, which is a threshold graph with separator t as above. If there is a collection of entry and exit protocols that enforces the mutual exclusions in G, using test-and-set on a collection of shared variables $V_1, \cdots, V_k$ with $|V_j| = v_j$, then the number of different sets of values assumable by the V_j (and hence the product of the v_j) must be at least $t+1$.*

Proof. Suppose our synchronizing method stores adequate information in V_1 through V_k so that a process can determine from them if it can enter its critical section, and suppose the set of V_i assume no more than t values. We will obtain a contradiction.

Put G in normal form as in § 3, so that

$$t+1=\prod (d_k+1), \qquad (k=1, \cdots, n).$$

We will select $t+1$ distinct collections R_p of vertices from the union of the D_k, $k=1, \cdots, n$, and arrange them in order such that we have the following:

(a) Any two R_p and R_q differ, but their intersections with each D_k have one containing or equal to the other.

(b) R_p and R_{p+1} differ by only one vertex.

We do this by a process suggestive of Gray codes for numbers of mixed base. First, order each D_k. For each sequence of integers $(a_1, a_2, \cdots, a_n)$ with $0 \leqq a_k \leqq d_k$, select a set consisting of the first a_k elements of D_k for each k. This yields $\prod (d_k+1) = t+1$ sets meeting the conditions of (a). We must now order them to obey condition (b). We do this by starting with the set determined by $(0, \cdots, 0)$, then going to $(1, 0, \cdots, 0)$, $(2, 0, \cdots, 0), \cdots, (d_1, 0, \cdots, 0)$. On "filling" each position change the next position by one and then step "down" through the previous cases: $(d_1, 1, \cdots, 0)$, $(d_1-1, 1, 0, \cdots, 0), \cdots, (1, 1, 0, \cdots, 0)$, $(0, 1, 0, \cdots, 0)$, and then $(0, 2, 0, \cdots, 0)$ and so on. The resulting list includes all $t+1$ sets and consecutive sets differ in just one element.

Start the system G with all processes outside their critical sections. Clearly, the first element of D_1 can enter its critical section; let it do so. Now go through the sequence of starts and stops (entries and exits of critical sections) dictated by the sequence R_p above: each element of D_1 starts (enters its critical section), the first element of D_2 starts, each element of D_1 stops (exits its critical section), and so on. Each step involves one element of a D_i entering or exiting its critical section. At each stage some change may be made in one or more of the V_k. There are $t+1$ stages (starting with no processes in critical sections and going through all the R_p). By hypothesis, the collection of V_k can assume only t distinct values, so there are two stages, R_p and R_q, of the above process when the V_k are in identical states. We must now get from this to a contradiction.

Suppose the set R_p of processes in critical sections is represented by the n-tuple $(a_1, \cdots, a_n)$ and the set R_q by $(b_1, \cdots, b_n)$. These must differ; without loss of generality suppose $b_j < a_j$ and $b_i = a_i$ for $i > j$. Now, one at a time, stop each process (if any) represented by b_{j+1} through b_n and the corresponding process in a_{j+1} through a_n. Note that in each case we make the same process in each group leave its critical section, and the V_i have the same values afterward. Next we stop elements of D_j, one at a time, in both sets of processes (the same element in each) and do this b_j times so that one set has no elements of D_j left in its critical section and the other has one or more still in critical sections; the values of the V_i are still the same. But now we have our contradiction; i.e., a process from C_j can enter its critical section with the remnant of

the set R_q (where now no process in D_j or any later D_k is in its critical section) but cannot do so with the remnant of R_p, despite the fact that the V_k values are identical and no process in C_k can tell one situation from the other. This completes the proof of Theorem 4.2. □

Since this shows that $t+1$ values of shared variables are needed for a protocol using the test-and-set operation, it follows that at least $t+1$ values are needed using the more restrictive operation **PV**-chunk. From the fact that $\prod (d_k+1)$ values are needed we also obtain Corollary 4.3.

COROLLARY 4.3. *The value of t found in Theorem* 3.3 *is the smallest value of t allowing G to be labeled as a threshold graph.*

Proof. If the graph had a threshold labeling with a separator $s<t$, then by Theorem 4.1, mutual exclusion could be managed with a shared variable with $s+1$ distinct values. □

This is the minimality result of Orlin [16], proved in a quite different fashion. We also obtain a proof of a theorem on graph coverings [15].

COROLLARY 4.4. *Let G be a threshold graph and let* $G_1, G_2, \cdots, G_n$ *be subgraphs, which are threshold graphs and whose union covers G (i.e., includes all vertices and edges of G). Let G have separator t and let each* G_k *have separator* t_k. *Then* $\prod (t_k+1) \geqq t+1$.

Proof. The system of processes whose exclusion graph is G can have mutual exclusion enforced by enforcing it within each subgraph G_k. Each process will, in its entry protocol, attempt to decrement shared variables V_1 through V_n by the amount of its associated label in the respective G_k. While this approach is definitely lockout- and deadlock-prone, it does enforce the needed exclusions since every edge of G is in a G_k; hence the shared variables are capable of at least $t+1$ distinct values. (The tendency to deadlock can be overcome by having the set of **PV**-chunk operations be a single atomic action, as is the case in the UNIX System V implementation.)

We have now seen that for threshold graphs, $\prod (d_k+1) = t+1$ is a necessary and sufficient measure of the shared values needed to enforce mutual exclusion, both for **PV**-chunk and for test-and-set.

In the special case of a clique (all nodes connected), we have a threshold graph with (after adjustment for our normal form) one element in D_1, the rest in C_1, $t=1$, and a shared variable with two values is necessary and sufficient. This special case is Theorems 3.1 and 4.4 of [2].

5. Some examples. Section 4 shows that for processes whose conflict graph is a threshold graph, **PV**-chunk and test-and-set operations require similar storage to avoid conflicts. In Example 5.1 we show that when the conflict graph is not a threshold graph, test-and-set may require less storage.

Example 5.1. We consider a system **S** consisting of four processes A, B, C, and D (Fig. 4), such that each of A and C conflict with each of B and D. (This is the case $n=4$ of the famous dining philosophers problem. See, for instance, [10].) We can avoid conflict using test-and-set with one shared variable, values 0 through 3; to avoid

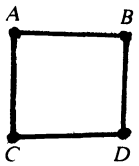

FIG. 4

conflict using **PV**-chunk requires at least two shared variables and four bits to store the shared variables.

We first give a solution for test-and-set. Let A and C each incorporate the entry protocol:

test V until $V=0$ or 1 then $V:=2*V+1$

(i.e., change 0 to 1 or change 1 to 3) and the following exit protocol:

$$V:=(V-1)/2.$$

Let B and D have the following entry protocol:

test V until $V=0$ or 2 then $V:=V/2+2$

(i.e., change 0 to 2 or change 2 to 3) and the following exit protocol:

$$V:=2*(V-2).$$

The effect is that V is 0 if no process is in its critical section (or entry or exit protocols), 1 if A or C is in its critical section, 2 if B or D is, and 3 if both A and C or both B and D are in critical sections. This shows that four possible shared values (one variable, occupying two bits of storage) enable test-and-set to enforce mutual exclusion in this system.

It is harder to show how many values are needed to control this system using **PV**-chunk. We use a method developed more fully in [15]. Suppose there are shared variables $V_1, \cdots, V_n$ which control the system **S**. Each of A, B, C, and D, while executing its entry protocol to enter its critical section, changes one or more of $V_1, \cdots, V_n$; it fails to enter its critical section if some V_k cannot be sufficiently decremented at this time. Denote by a_k through d_k the decrements that A through D, respectively, apply to each V_k and by t_k the maximum permissible value of each V_k. Now for each k, the labels a_k through d_k and maximum t_k induce a graph on the four vertices (possibly with no edges) showing the processes prevented from running at once by that V_k; in [9] it has been shown that each graph induced in this fashion is a threshold graph. The square denoting the system **S** is the union of these graphs. Since the square is not itself a threshold graph, there must be at least two V_k's: **PV**-chunk operations cannot control **S** with just one shared variable.

Here is a simple solution using two shared variables, both initialized to 2 before the processes begin execution. Note that it does enforce the necessary mutual exclusion, is deadlock-free, but is not lockout-free and does not have bounded waiting.

A's Entry Protocol:	Test V_1 until $V_1 \geqq 2$ then $V_1 := V_1 - 2$;
A's Exit Protocol:	$V_1 := V_1 + 2$;
B's Entry Protocol:	Test V_1 until $V_1 \geqq 1$ then $V_1 := V_1 - 1$;
	Test V_2 until $V_2 \geqq 1$ then $V_2 := V_2 - 1$;
B's Exit Protocol:	$V_1 := V_1 + 1$;
	$V_2 := V_2 + 1$;
C's Entry Protocol:	Test V_2 until $V_2 \geqq 2$ then $V_2 := V_2 - 2$;
C's Exit Protocol:	$V_2 := V_2 + 2$;
D's Protocols are the same as B's.	

In fact, the square can be a union of threshold graphs in very few ways: the threshold graphs that are subgraphs of the square are (i) the single edge, which we can take as having $t=1$ and each vertex labeled 1; and (ii) the union of two adjoining edges, which we can take as having the central vertex labeled 2, each end vertex 1,

and $t = 2$. Thus the minimal sets of V_i associated with the square, up to some reasonable notion of equivalence, must be one of (i) V_1 and V_2, each with values 0 to 2, each controlling two edges; (ii) V_1 to V_4, each with values 0 to 1, each controlling one edge; or (iii) one variable with values 0 to 2, controlling two edges, and two variables with values 0 to 1, each controlling one edge. Since a variable with values 0 through 2 requires two bits to store the shared variables, this means at least two shared variables and at least four bits of shared memory are needed to control this system. This completes Example 5.1. Some arguments very similar in philosophy to those in the latter part of this example have been given in [7] and [8].

Example 5.2. Here we illustrate a natural way in which threshold graphs arise in accessing data base management systems. The reader-writer problem is a well-known problem concerning synchronization of accesses to a data base; I was motivated to think about it in this context by [17], and other references may be found therein. This example is an expansion on this problem in the spirit of the example at the start of § 4. In the standard problem, there are in a system several transactions wishing to access the same record: some (readers) want to read data from it without changing it; others (writers) want to change the data (we oversimplify here by not distinguishing update or read-and-write transactions from simple writes). Any number of readers can proceed at once; a writer cannot proceed unless it has exclusive use of the record (a lock on the record), since simultaneous writes might produce nonsense and a read overlapped with a write might return, e.g., a partially changed, not internally consistent, record.

Suppose a database record contains keys with several parts. For example, the fields in a record might be

1: OFFICE# 2: SALESMAN# 3: ACCOUNT# 4: AMOUNT

where the first three are keys, that is, jointly they uniquely identify the customer's record so we can find the amount due from the customer; this amount is stored in field 4, "AMOUNT." It is possible that one or more of the keys, as well as the amount due, might change because of, e.g., the customer moving to a region served by a different office, the salesman being replaced, or two customer firms merging. Thus, for each of the four fields, we can image a transaction to read the record as far as that field, or to write the record from that field onward.

For example, a transaction of type 2R (read fields to 2) would answer a query of the form "Does salesman 3057 serve any accounts at office 103?" and a 3W (write from field 3) would serve a transaction of the form "Open account number 566 for salesman 3057 in office 103." Note that, in fact, these two transactions could proceed at the same time, if it is understood that the second will fail if there is no salesman 3057 in office 103. The second transaction could not proceed simultaneously with a 2W ("delete all records for salesman 3057 in office 103") or a 4R ("what is the balance due from account 566, office 103, salesman 3057?").

Interestingly, a set of transactions consisting of transactions of types 1R, 1W, $\cdots$, 4R, 4W (and similarly for longer sets of multiple keys) has an exclusion graph that is a threshold graph. The transactions of type 1W, $\cdots$, 4W correspond to vertices in the sets $C_1, \cdots, C_4$, respectively, and those of type 1R, $\cdots$, 4R correspond to vertices in the sets $D_1, \cdots, D_4$ in the normal form of a threshold graph. (All writes conflict with each other; no reads conflict with each other; jR conflicts with kW if $j \geqq k$.)

Thus, if we have an upper bound on the number of transactions of each type which might appear in the system at one time, we could manage record locking—including the indicated partial record locking—with **PV**-chunk operations on a single

shared variable. If we knew there would be at most four operations of each of the "read" types, the labels of the corresponding vertices would be 1 for 1R, 5 for 2R, 25 for 3R, 125 for 4R, and the separator would be $t = 624$. Mutual exclusion could be managed using a single shared variable capable of assuming 625 distinct values.

Interestingly, changing the number of writers—the transactions that appear to require the most extensive locks—does not change these numbers; to reduce t we must reduce the number of readers, not the number of writers. This is consistent in a broad sense with the observations in [17] where the added memory to avoid delays is determined by the number of potential readers (there, only one writer is considered). By contrast, changing reader transactions from one subtype to another does change t: if there were at most two transactions of types 1R and 2R, and at most six each of types 3R and 4R, then we would have

$$t = (2+1)(2+1)(6+1)(6+1) - 1 = 440.$$

6. Conclusions and additional problems. Earlier papers such as [2] present a careful analysis of the amount of shared memory required to solve the problem of mutual exclusion when all processes exclude all others. In real applications, it may be possible for some sets of processes, but not others, to enter critical sections simultaneously. A major step in this direction appears in [12], which bounds the delays occurring in the mutual exclusion algorithm by imposing a "locality" condition: particular processes are constrained to share resources only with a limited number of other "nearby" processes. It would be desirable to have efficient solutions, and bounds on possible solutions, for other more general cases. This paper considers systems of asynchronous parallel processes in which the desired mutual exclusions can be modeled by a threshold graph. These differ strongly from the cases concentrated on in [12], since threshold graphs always have a vertex that is adjacent to all other (nonisolated) vertices. In our limited case, simple mutual exclusion (without lockout prevention or other desirable features) can be managed by a single **PV**-chunk operation in the entry protocol preceding the critical section in each process, using a single shared variable with range from 0 to t, with t denoting the minimal separator of the corresponding threshold graph.

Establishing this requires giving a new algorithm for the minimal separator previously calculated by Orlin, and allowing the separator to be written as a product formula in terms of the numbers of vertices in certain classes in the graph (this could also be expressed in terms of vertex degrees or the size of maximal cliques; see also [15]).

For controlling mutual exclusion in this limited case, **PV**-chunk requires no more shared memory than the Lynch–Fischer test-and-set operation. An example suggests that for more general graphs, test-and-set will manage exclusion with fewer shared variables and fewer bits of shared variables than **PV**-chunk. A final example suggests that **PV**-chunk may, in fact, provide an efficient tool for certain kinds of partial-record locking and certain kinds of reader-writer management problems in data base systems.

This leaves a great many open problems. What are efficient ways of managing mutual exclusion situations modeled by more complex graphs than threshold graphs, or indeed, not modeled by graphs at all? (Surely the different form of graph models provided in [12] carry different information than the models here.) Can we find algorithms that incorporate lockout prevention or fairness as well as mutual exclusion, while still using **PV**-chunk operations or other operations that seem easier to implement in efficient hardware than the general test-and-set operation? Does test-and-set solve these other problems with significantly less memory, or significantly faster algorithms, than simpler synchronization primitives? A referee suggests that in some sense Theorem 4.2 does not appear to depend on the synchronization primitive used. The number

$t+1$ is in some sense a measure of the space needed to synchronize the processes represented in the graph, without regard to exact method. Can this be formalized? In Example 5.1, it appears that test-and-set needs less memory than **PV**-chunk; how can this be measured more systematically? Finally, is it connected to Lipton's concept of using one primitive to "simulate" another [11]?

Acknowledgments. The author had numerous helpful discussions with Y. Zalcstein. The referees suggested extensive revisions to improve clarity of the presentation; the remaining awkwardness is due to the author.

ALGORITHMS FOR PACKING SQUARES: A PROBABILISTIC ANALYSIS

E. G. COFFMAN, JR.† AND J. C. LAGARIAS†

Abstract. This paper gives a probabilistic performance analysis of simple algorithms for packing lists L_n of n squares into a strip or a set of bins. It is assumed that the square sizes are drawn independently from the uniform distribution on $[0, 1]$. The strip-packing problem is to pack the squares into a strip of width 1 so as to minimize the height of the packing. Let $\mathrm{OPT}(L_n)$ denote the height of an optimal strip packing for list L_n. A simple $O(n \log n)$ approximation algorithm, called Algorithm A, is described and it is proven that the height $A(L_n)$ of a packing of list L_n satisfies $A(L_n) - \mathrm{OPT}(L_n) \leqq \frac{1}{4}$ with probability $1 - O(e^{-c_0 n})$ for a positive constant c_0. It is also shown that $E[\mathrm{OPT}(L_n)] = 3n/8 + \Theta(n^{1/3})$.

The bin-packing problem is to pack the squares into square bins of size 1 so as to minimize the number of bins. Let $\mathrm{OPT}_B(L_n)$ denote the number of bins in an optimal packing of list L_n. The authors present another $O(n \log n)$ approximation algorithm and show that the number of bins it needs to pack a list L_n is precisely $\mathrm{OPT}_B(L_n)$ with probability $1 - O(e^{-c_1 n})$ for a positive constant c_1. Finally, it is shown that $E[\mathrm{OPT}_B(L_n)] = n/2 + \Theta(1)$. These bounds for packing squares into strips and bins are much tighter than those that have been obtained for packing rectangles.

Key words. packing squares, strip packing, two-dimensional bin packing, asymptotic probabilistic analysis

1. Introduction.

Probabilistic analysis of packing algorithms has yielded important and unexpected insights into a number of NP-complete packing problems. For example, it has often been shown that the average-case behavior of a simple approximation algorithm is extremely good, even though its worst-case behavior is relatively poor. In this paper, where the two-dimensional problem of packing square objects is considered, we find further instances of such algorithms. The results are distinguished by the fact that, in a strong probabilistic sense, our square-packing algorithms provably obtain packings much closer to optimal than algorithms previously considered for rectangle packing.

Two principal variations of square packing will be studied: *strip packing* and *bin packing* (in two dimensions). In the former, squares no larger than $w \times w$ are to be packed into a semi-infinite strip of width w so as to minimize the height or span of the packing, i.e., the maximum height reached by the top of any square in the packing. As illustrated in Fig. 1, the packing must be orthogonal, i.e., the sides of the squares must be parallel to the sides or the base of the strip, and the squares must not overlap each other or the strip boundaries. The squares are provided in a list $L_n = (X_1, \cdots, X_n)$, where $0 < X_i \leqq w$, $1 \leqq i \leqq n$ denotes the dimensions of the ith square. In what follows X_i refers to the name of the ith square as well as to its size.

We let $\mathrm{ALG}(L_n)$ denote the height of the packing of list L_n produced by algorithm ALG. $\mathrm{OPT}(L_n)$ denotes the height of an optimal packing of L_n.

We adopt the normalization $w = 1$ and consider the situation where $X_1, \cdots, X_n$ are independent uniform random draws from $[0, 1]$. In § 2 we devise an efficient $n \log n$-time algorithm, called Algorithm A, and prove that for n large, $A(L_n) - \mathrm{OPT}(L_n) \leqq \frac{1}{4}$ with very high probability, i.e., with a probability that approaches 1 as $1 - O(e^{-cn})$ for some constant $c > 0$. Our next result, in § 2, is a very strong characterization of the height of optimal packings, and hence of A-packings, viz.,

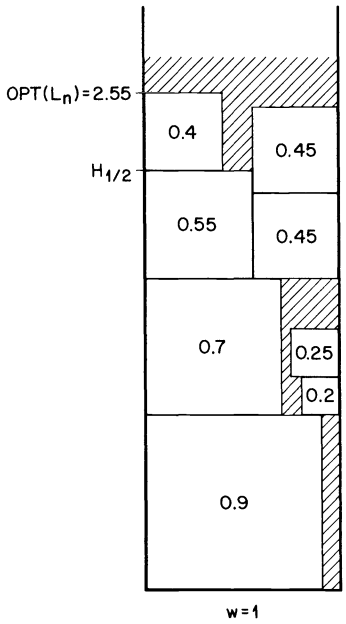

FIG. 1. *An optimal strip packing*; $L_n = (0.9, 0.7, 0.55, 0.45, 0.45, 0.4, 0.25, 0.2)$.

$\mathrm{OPT}(L_n) = 3n/8 + O(n^{1/3})$, and hence $A(L_n) = 3n/8 + O(n^{1/3})$, with very high probability. In addition, we prove the following average-case performance bounds:

$$E[A(L_n)] = E[\mathrm{OPT}(L_n)] + O(1),$$

$$E[\mathrm{OPT}(L_n)] = \frac{3n}{8} + \Theta(n^{1/3}).$$

Now consider the bin-packing version of square packing, and let OPT_B denote an optimal algorithm. Here, the strip of Fig. 1 is partitioned into unit squares called bins, $B_1, B_2, \cdots$, as shown in Fig. 2. Packings are as before but with the added requirement that squares must not overlap the boundaries between bins. The packing height is now measured as the index of the highest occupied bin, i.e., as the number of bins required by the packing of L_n. In § 3 we introduce an $n \log n$-time Algorithm B and prove that $B(L_n) = \mathrm{OPT}_B(L_n)$ with very high probability. In other words, with probability $1 - O(e^{-cn})$ for some $c > 0$, B is optimal. We also prove

$$E[\mathrm{OPT}_B(L_n)] = \frac{n}{2} + \Theta(1),$$

and similarly for $E[B(L_n)]$. Note that $n/2$ is the expected number of squares with sizes larger than $\frac{1}{2}$, and is therefore an obvious lower bound.

We conclude this section with a brief discussion of background results. Packing squares has long been a source of intriguing combinatorial problems. Numerous references to worst-case analysis can be found in [BCCL] and [CGJ]. However, we know of only two probabilistic studies, and these are briefly described below.

A probabilistic analysis of next-fit (NF) strip packing has been worked out by Hofri [Ho] for the general case of rectangles, where each dimension of each rectangle

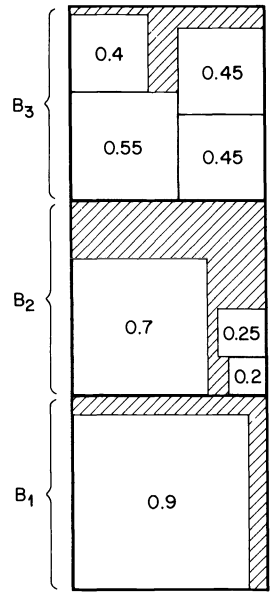

FIG. 2. *An optimal packing of L_n in three bins (see Fig. 1).*

is an independent uniform random draw from $[0, 1]$. According to NF, rectangles $X_1, X_2, \cdots$ are taken from L_n and placed left-justified along the bottom of the strip until a rectangle, say X_i, is encountered that will not fit in the remaining space. A baseline is then extended across the top of the tallest rectangle, and the process is repeated with rectangles from the list $(X_i, \cdots, X_n)$ placed along the new baseline. New baselines are created until all rectangles are packed.

An obvious shortcoming of NF is that a rectangle small enough to be packed on an earlier baseline is not so packed. For the special case of squares this leads to a performance substantially inferior to Algorithm A presented in § 2. Indeed, it is not difficult to show that $E[\mathrm{NF}(L_n)] - E[\mathrm{OPT}(L_n)]$ cannot be bounded by a constant independent of n (see [Ho]).

With the above model of rectangles, Karp, Luby, and Marchetti-Spaccamela [KLM] have devised an efficient algorithm for two-dimensional bin packing based on planar matching. Their results combined with recent results by Leighton and Shor [LS] show that this algorithm produces packings using $n/4 + \Theta(\sqrt{n}\log^{3/4} n)$ bins on the average. They also showed that *no* algorithm could pack L_n in fewer than $n/4 + \Omega(\sqrt{n})$ bins on the average.

2. The strip-packing problem. In this section we first derive a useful lower bound for optimal packings. Then we present Algorithm A and prove that, if the sizes of the squares in L_n satisfy a certain condition, then the height of the A-packing exceeds the lower bound by at most $\frac{1}{2}$. A probabilistic analysis then shows that with very high probability the above condition holds. Finally, we prove that the expected optimal packing height is $3n/8 + \Theta(n^{1/3})$.

In what follows we often simplify the presentation by ignoring the distinction between the notions of "square" and "square size." Thus, for example, when we say "a square in $[a, b]$" we mean the obvious "a square with a size in $[a, b]$."

The height of a packing cannot be less than the total area of the squares (since the strip width is 1), or less than the sum of the square sizes exceeding $\frac{1}{2}$:

$$H_{1/2} = H_{1/2}(L_n) = \sum_{X_i > 1/2} X_i.$$

The average total square area is

$$nEX_i^2 = n \int_0^1 x^2 \, dx = \frac{n}{3},$$

but $EH_{1/2} = n/2 \cdot 3/4 = 3n/8$. Thus,

$$\text{OPT}(L_n) \geqq H_{1/2} \tag{2.1}$$

is a better bound for our purposes.

Note that the above observations imply that no algorithm can waste less than $3n/8 - n/3 = n/24$ space on the average. In this sense, packings of squares drawn uniformly from [0, 1] are not particularly efficient. A more detailed explanation of this property is easy to find. Opposite each square X in $[1-a, 1]$, we can pack $\lfloor (1-a)/a \rfloor$ squares no larger than a without extending beyond the bottom or top of X. However, in our probabilistic model the expected numbers of squares in $[0, a]$ and in $[1-a, 1]$ are equal. Thus, for a moderately smaller than $\frac{1}{2}$ we can expect to have more space than we need for the efficient packing of squares in $[0, a]$, even when we allow for probable variations in the square sizes of L_n. Indeed, we prove later that if all squares in L_n with sizes in $[0, \frac{1}{3}]$ are removed, then with a probability that quickly approaches 1 as $n \to \infty$, the optimal packing height remains unchanged.

Thus, let us concentrate on squares in $(\frac{1}{3}, 1]$; because of their relatively large size it will be easier to characterize the packings of these squares. To obtain a more useful deterministic lower bound based only on the subset of squares in L_n with sizes in $(\frac{1}{3}, 1]$, it is helpful to define the following function. Let $\delta(y)$ denote the total height of squares in $[\frac{1}{2} - y, \frac{1}{2}]$ minus the total height of squares in $(\frac{1}{2}, \frac{1}{2} + y]$, i.e.,

$$\delta(y) = \sum_{1/2 - y \leqq X_i \leqq 1/2} X_i - \sum_{1/2 < X_i \leqq 1/2 + y} X_i, \qquad 0 < y \leqq \frac{1}{2}, \tag{2.2}$$

with $\delta(0) = 0$. We note immediately that if $\delta(y) > 0$ for any y in $(0, \frac{1}{6})$ then the packing of L_n must extend beyond the region occupied by squares in $(\frac{1}{2}, 1]$. This follows from the fact that at most one square in $(\frac{1}{3}, \frac{1}{2}]$ will fit abreast of a square in $(\frac{1}{2}, 1]$. We also note that the squares in $(\frac{1}{3}, \frac{1}{2}]$ not packed with squares in $(\frac{1}{2}, 1]$ can be packed at most two abreast.

To make use of these observations let

$$\Delta = \Delta(L_n) = \max_{0 \leqq y \leqq 1/2} \delta(y). \tag{2.3}$$

If $\Delta > 0$, then we let $X^* \leqq \frac{1}{2}$ denote a largest square size in L_n such that $\Delta = \delta(\frac{1}{2} - X^*)$, i.e.,

$$\Delta = \sum_{X^* \leqq X_i \leqq 1/2} X_i - \sum_{1/2 < X_i \leqq 1 - X^*} X_i; \tag{2.4}$$

but if $\Delta = 0$, then we define $X^* = \frac{1}{2}$, which may not be a square size in L_n.

We have the following deterministic bound.

THEOREM 1. *For any list L_n such that $X^* > \frac{1}{3}$, the optimal packing height satisfies*

$$\text{OPT}(L_n) \geqq H_{1/2} + \frac{\Delta}{2}. \tag{2.5}$$

Proof. If $\Delta = 0$ the result follows from (2.1), so suppose $\Delta > 0$. Consider an optimal strip packing of L_n. We may uniquely partition the packed strip into four disjoint collections R_1, R_2, R_3, R_4 of horizontal slices (or slabs) such that all squares hit by a horizontal cut in R_1 are in $[0, X^*)$; any horizontal cut in R_2 hits a square in $[X^*, \frac{1}{2}]$ but no square in $(\frac{1}{2}, 1]$; any horizontal cut in R_3 hits a square in $(\frac{1}{2}, 1-X^*]$; and any horizontal cut in R_4 hits a square in $(1-X^*, 1]$. We assign to each R_i the total vertical height, height(R_i), of the slices in its collection.

By definition,

$$\text{height}(R_3) + \text{height}(R_4) = H_{1/2} \tag{2.6}$$

and

$$\text{height}(R_3) = \sum_{1/2 < X_i \leqq 1-X^*} X_i. \tag{2.7}$$

It is also obvious from the definitions that the squares in $[X^*, \frac{1}{2}]$ can be packed only in the regions covered by R_2 and R_3. Since $X^* > \frac{1}{3}$, at most two such squares can fit side by side in R_2, and in R_3 a horizontal cut can hit at most 1. Thus,

$$2\,\text{height}(R_2) + \text{height}(R_3) \geqq \sum_{X^* \leqq X_i \leqq 1/2} X_i. \tag{2.8}$$

Subtracting (2.7) from (2.8), then using (2.4), yields

$$2\,\text{height}(R_2) \geqq \Delta.$$

Finally, this inequality and (2.6) yield

$$\begin{aligned} \text{OPT}(L_n) &\geqq \text{height}(R_2) + \text{height}(R_3) + \text{height}(R_4) \\ &\geqq H_{1/2} + \Delta/2. \end{aligned}$$

□

The development leading to Theorem 1 suggests the following algorithm. We say that a sequence of squares is packed *bottom-up* if, when each square is packed, it is placed at the lowest height where it will fit. It is convenient in describing and analyzing the algorithm to use the terms "big square" and "small square" when referring to squares greater than $\frac{1}{2}$ and less than or equal to $\frac{1}{2}$, respectively.

ALGORITHM A.

(1) Stack the big squares of L_n bottom-up in *decreasing* order of size along the left edge of the strip.
(2) Then pack the small squares bottom-up in *increasing* order of size along the right edge of the strip, placing each square as low as it will go, until all are packed. The algorithm then stops if at most one square extends above $H_{1/2}$; otherwise, step (3) is performed.
(3) Starting with the highest small square and working down, successively remove squares from the right edge of the strip and place them in a stack starting at $H_{1/2}$ along the left edge of the strip, until the heights of the two stacks agree to within the size of the top square in one of the two stacks.

Figure 3(a), (b) illustrates corresponding packings just after steps (2) and (3), respectively.

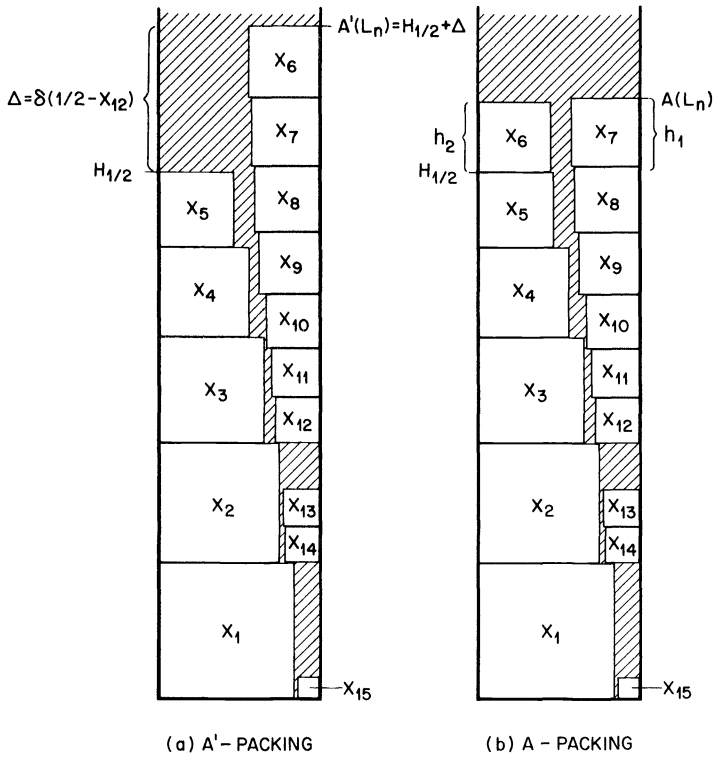

FIG. 3. *Examples for Theorem* 2.

The running time of Algorithm A is clearly dominated by the $O(n \log n)$ time required to sort the squares.

We let Algorithm A′ denote the first two steps of Algorithm A. It is clear that an A'-packing is never better and sometimes worse than an A-packing.

Our next result shows that Algorithm A is close to optimal when $X^* > \frac{1}{3}$.

THEOREM 2. *For all L_n we have*

$$A'(L_n) = H_{1/2} + \Delta \tag{2.9}$$

and

$$A(L_n) \leqq H_{1/2} + \frac{\Delta}{2} + \frac{1}{4}. \tag{2.10}$$

Remarks. (1) As illustrated in Fig. 3(a), the relation (2.9) gives a geometric interpretation of the quantity Δ.

(2) The bound (2.10) is tight. For example, consider any list L_n where n is odd and all squares are of size $\frac{1}{2}$. It is easy to see that $A(L_n) = \mathrm{OPT}(L_n) = (n+1)/4$. Also, $H_{1/2} = 0$ and $\Delta = n/2$, so $A(L_n) = \Delta/2 + \frac{1}{4} = (n+1)/4$. Similar examples for n even are obtained by adding a single big square to the above lists.

Proof. The main difficulty is (2.9); once (2.9) is proved, an easy analysis of step (3) of Algorithm A will then yield (2.10).

To prove (2.9) it is convenient to consider another algorithm, Algorithm A″, which packs the big squares as in step (1) and then packs the small squares in *decreasing* order, placing the largest small square along the right edge of the strip with its top

edge at height $H_{1/2}+\Delta$, and then successively placing each small square along the right edge of the strip with its top edge flush against the square above it (see Fig. 4, which corresponds to Fig. 3). We claim that Algorithm A″ actually produces a packing, i.e., that all of the small squares can be packed in this way without ever encountering a small square that does not fit. To establish the claim, we may suppose without loss of generality that the list L_n is in decreasing order:

$$X_1 \geqq X_2 \geqq \cdots \geqq X_k \geqq \tfrac{1}{2} > X_{k+1} \geqq X_{k+2} \geqq \cdots \geqq X_n.$$

When the small square X_{k+m} is to be packed, its bottom edge will be at height

$$h_m = H_{1/2}+\Delta-\sum_{j=1}^{m} X_{k+j}.$$

In order for X_{k+m} to fit, it is necessary and sufficient that the big square X_l placed opposite it during step (1) (the big square intersected by the line $y = h_m$) satisfy

$$X_l \leqq 1 - X_{k+m}.$$

Next, note that the set of big squares with sizes at most $1-X_{k+m}$ are placed by step (1) at vertical heights that occupy the interval $[h_m^*, H_{1/2}]$, where

$$h_m^* = H_{1/2} - \sum_{1/2 < X_i \leqq 1-X_{k+m}} X_i.$$

An equivalent necessary and sufficient condition for square X_{k+m} to fit is

$$h_m^* \leqq h_m. \tag{2.11}$$

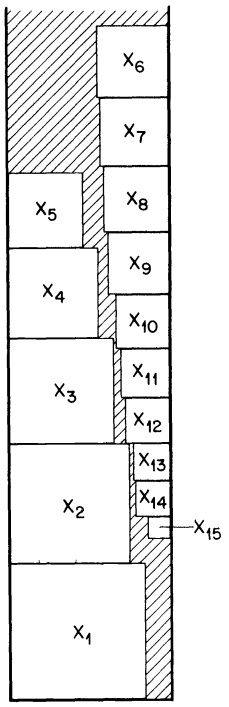

FIG. 4. *The A″-packing for Fig. 3.*

Now by definition of Δ we have

$$\begin{aligned}\Delta &\geqq \delta\left(\frac{1}{2}-X_{k+m}\right)\\ &= \sum_{X_{k+m}\leqq X_i\leqq 1/2} X_i - \sum_{1/2<X_i\leqq 1-X_{k+m}} X_i\\ &\geqq \sum_{j=1}^{m} X_{k+j} - \sum_{1/2<X_i\leqq 1-X_{k+m}} X_i\\ &= (H_{1/2}+\Delta-h_m)-(H_{1/2}-h_m^*)\\ &= h_m^*-h_m+\Delta.\end{aligned}$$

This inequality implies (2.11), which proves the claim.

It is clear that

$$A''(L_n) = H_{1/2}+\Delta.$$

The A'-packing is obtained by successively sliding the small squares packed along the right-hand side of the strip down as low as they will go, proceeding from the smallest to the largest (e.g., Fig. 3(a) is produced from Fig. 4). Hence

$$A'(L_n) \leqq H_{1/2}+\Delta.$$

To establish (2.9) it suffices to show that equality holds here. We do this by contradiction. Suppose equality did not hold; then the right side of the A''-packing in step (2) could be shifted down vertically by a positive amount α, and we would still have a packing. Then the lowest edge of each square X_{k+m} would be placed at height $\tilde{h}_m = h_m - \alpha$ in the new packing. However, by definition of Δ there is some value m_0 for which

$$\Delta = \delta\left(\frac{1}{2}-X_{k+m_0}\right).$$

Then we obtain, as in the proof above,

$$\begin{aligned}\Delta &= \delta(\tfrac{1}{2}-X_{k+m_0})\\ &= h_{m_0}^*-\tilde{h}_{m_0}+\Delta-\alpha,\end{aligned}$$

which shows that

$$\tilde{h}_{m_0} < h_{m_0}^*.$$

This violates (2.11), contradicting the assumption that we had a packing. So (2.9) is proved.

To prove (2.10), we first observe that if at most one square extends beyond $H_{1/2}$ in the A'-packing of L_n, then $A(L_n) = A'(L_n) = H_{1/2}+\Delta$ and $\Delta \leqq \frac{1}{2}$. But then

$$A(L_n) = H_{1/2}+\Delta \leqq H_{1/2}+\frac{\Delta}{2}+\frac{1}{4},$$

so it remains to consider cases where step (3) is performed. Let h_1 and h_2 be the heights of the higher and lower stacks, respectively, as measured from $H_{1/2}$ in the A-packing (see Fig. 3(b)). By (2.9) we have easily $h_1+h_2 = \Delta$, and by the definition of step (3), we have $h_1-h_2 \leqq \frac{1}{2}$. These two relations imply that $h_1 \leqq \Delta/2+\frac{1}{4}$, and hence that

$$A(L_n) = H_{1/2}+h_1 \leqq H_{1/2}+\frac{\Delta}{2}+\frac{1}{4}. \qquad \square$$

It is easy to verify that, if at most one square extends above $H_{1/2}$ in an A-packing, then $\mathrm{OPT}(L_n) = A(L_n) = A'(L_n) = H_{1/2}+\Delta$. A proof of optimality for this special case can be patterned after the proof of Theorem 1.

So far the analysis has been deterministic, with Theorems 1 and 2 combining to show that if $X^* > \frac{1}{3}$ then

$$\mathrm{OPT}(L_n) \leqq A(L_n) \leqq \mathrm{OPT}(L_n) + \tfrac{1}{4}.$$

We now begin a probabilistic analysis under the assumption that the squares are drawn independently from the uniform distribution on $[0, 1]$. Our objectives are estimates of the *probable* performance of the algorithms. As our first objective we prove Theorem 3.

THEOREM 3. *There is a constant $c > 0$ such that* $\Pr\{X^* \leqq 1/3\} = O(e^{-cn})$, *and consequently*

$$\Pr\{A(L_n) - \mathrm{OPT}(L_n) \leqq \tfrac{1}{4}\} = 1 - O(e^{-cn}).$$

Furthermore,

$$E[A(L_n)] = E[\mathrm{OPT}(L_n)] + O(1).$$

Our second objective is a proof of the following bound.

THEOREM 4. *There is a constant $c_1 > 0$ such that for all $x \geqq 1$,*

$$\Pr\{\Delta(L_n) > xn^{1/3}\} \leqq c_1 e^{-\sqrt{x}/3}.$$

Moreover,

$$E[\mathrm{OPT}(L_n)] = \frac{3n}{8} + \Theta(n^{1/3}).$$

Before getting into the proofs of these results we need a more detailed discussion of the function $\delta(y)$ and the tools needed for our probabilistic arguments.

We view $\delta(y)$ as a random process on $[0, \frac{1}{2}]$. To better understand this process, it is helpful to represent it as shown in Fig. 5. The points (square sizes) selected in

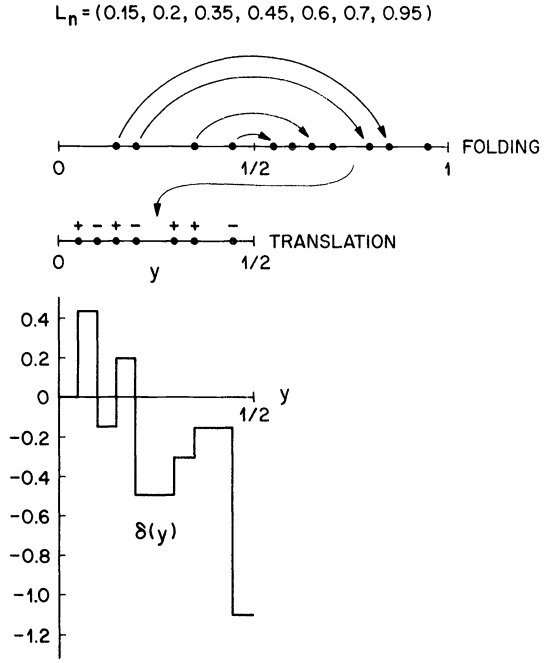

FIG. 5. *The function $\delta(y)$.*

$[0, \frac{1}{2})$ are reflected about the midpoint $\frac{1}{2}$ onto the interval $[\frac{1}{2}, 1]$. These "events" are labeled with a plus, while those falling originally in $(\frac{1}{2}, 1]$ are labeled minus. The pluses and minuses are then mapped by a simple translation onto $[0, \frac{1}{2}]$. Sample functions for $\{\delta(y), 0 < y \leqq \frac{1}{2}\}$ are step functions as illustrated in Fig. 5. A square $X \in [0, \frac{1}{2}]$ becomes a plus at $y = \frac{1}{2} - X$ and creates a positive step of size $X \leqq \frac{1}{2}$ in $\delta(y)$. A square $X \in (\frac{1}{2}, 1]$ becomes a minus at $y = X - \frac{1}{2}$ and creates a negative step of size $X \geqq \frac{1}{2}$ in $\delta(y)$. The event locations comprise n independent uniform random draws from the interval $0 \leqq y \leqq \frac{1}{2}$ in Fig. 5 (i.e., the mappings $y = \frac{1}{2} - X$ for $X \leqq \frac{1}{2}$ and $y = X - \frac{1}{2}$ for $X > \frac{1}{2}$ produce uniform random draws from $[0, \frac{1}{2}]$, since X is a uniform random draw from $[0, 1]$). The sign of each event is equally likely to be + or −, independent of its location.

In the analysis of $\delta(y)$ we need bounds on the tails of the distribution of a sum of bounded, independently and identically distributed random variables. We use the following bound of Bernstein (see [Be] for a proof).

LEMMA 1 (Bernstein). *Let S_n denote the sum of n independent samples of a bounded random variable X, and let $\sigma^2 = \operatorname{Var}[S_n] = n \operatorname{Var}[X]$ and $M = \max |X - E[X]|$. Then for any $t \geqq 0$*

$$\Pr\{S_n - E[S_n] > t\sigma\} < \exp\left\{ -t^2 \Big/ \left(2 + \frac{2}{3}\frac{Mt}{\sigma}\right)\right\}. \tag{2.12}$$

We will apply this lemma to several different random variables, each representing a weighted count of the independently and identically distributed random variables X_i on $[0, 1]$. For example, with y fixed, we define the random variable $N(y)$ counting the number of squares in $[\frac{1}{2} - y, \frac{1}{2} + y]$ by $N(y) = \sum_{i=1}^{n} Y_i$, where

$$Y_i = \begin{cases} 1 & \text{if } X_i \in [\frac{1}{2} - y, \frac{1}{2} + y], \\ 0 & \text{otherwise.} \end{cases}$$

Similarly, for a fixed y the process $\delta(y)$ is a random variable, which can be expressed as $\delta(y) = \sum_{i=1}^{n} Z_i$, where

$$Z_i = \begin{cases} X_i & \text{if } X_i \in [\frac{1}{2} - y, \frac{1}{2}], \\ -X_i & \text{if } X_i \in (\frac{1}{2}, \frac{1}{2} + y], \\ 0 & \text{otherwise.} \end{cases} \tag{2.13}$$

A routine calculation yields

$$E[Z_i] = -y^2, \qquad E[\delta(y)] = -y^2 n, \tag{2.14}$$

$$\operatorname{Var}[Z_i] = \frac{y}{2} + \frac{2}{3}y^3 - y^4, \qquad \operatorname{Var}[\delta(y)] = \left(\frac{y}{2} + \frac{2}{3}y^3 - y^4\right)n, \tag{2.15}$$

$$\max |Z_i - E[Z_i]| = \frac{1}{2} + y(1 - y) \leqq \frac{3}{4}. \tag{2.16}$$

As our last item of preparation we introduce a standard inequality to be used several times. In some probability space suppose the occurrence of event e implies that at least one of the events $e_1, \cdots, e_k$ must occur. Then by Boole's inequality,

$$\Pr\{e\} \leqq \sum_{i=1}^{k} \Pr\{e_i\}. \tag{2.17}$$

We are now in position to prove Theorems 3 and 4.

Proof of Theorem 3. To prove that $X^* > \frac{1}{3}$ with probability $1 - O(e^{-cn})$, for some $c > 0$, it is obviously sufficient to prove that $\delta(y) \leqq 0$ for all $\frac{1}{6} \leqq y \leqq \frac{1}{2}$, with probability $1 - O(e^{-cn})$. For this purpose we begin by considering those samples L_n that satisfy

$$\delta(\tfrac{1}{6}) < -\alpha n, \qquad N(\tfrac{1}{6}) \leqq \beta n \tag{2.18}$$

for any fixed choices of α, β satisfying $0 < \alpha < \frac{1}{36}$, $\frac{2}{3} < \beta < 1$. (We verify later that these inequalities hold jointly with very high probability.) For any such list we divide up the at least $n(1-\beta)$ events with $\frac{1}{6} \leqq y \leqq \frac{1}{2}$ into $[1/2\alpha]$ blocks containing either k or $k+1$ events, where

$$k = \left\lfloor \frac{n - N(\frac{1}{6})}{\lfloor 1/2\alpha \rfloor} \right\rfloor.$$

With no significant loss in generality, assume that $1/2\alpha$ is an integer and consider $n > 1/\alpha$. Then $0 \leqq N(\frac{1}{6}) \leqq \beta n$ implies that $2\alpha(1-\beta)n - 1 \leqq k \leqq 2\alpha n \leqq 3\alpha n - 1$.

Let δ_j denote the value of $\delta(y)$ just after the last event of block j, $1 \leqq j \leqq 1/2\alpha$, and let $\delta_0 = \delta(\frac{1}{6})$. The sizes of positive steps are at most $\frac{1}{3}$ and are decreasing as y varies from $\frac{1}{6}$ to $\frac{1}{2}$. Therefore, no block of at most $3\alpha n - 1$ events starting at $\delta_{j-1} < -\alpha n$ can include a zero crossing, where $\delta(y)$ would become positive. Thus, for $\delta(y)$ to become positive in $\frac{1}{6} \leqq y \leqq \frac{1}{2}$ there must be at least one $j \geqq 1$ such that $\delta_{j-1} < -\alpha n$ and $\delta_j \geqq -\alpha n$. But at any y in $[\frac{1}{6}, \frac{1}{2}]$ the magnitude $(\frac{1}{2}+y)$ of a negative jump is at least twice the magnitude $(\frac{1}{2}-y)$ of a positive jump. Hence for any $j \geqq 1$, the final value δ_j can be greater than the starting value δ_{j-1} only if the number of pluses, N_j^+, was greater than twice the number of minuses, N_j^-, in the jth block. Hence, if $\delta(\frac{1}{6}) < -\alpha n$ and $N_j^+ \leqq 2N_j^-$ for all $j \geqq 1$, then $\delta(y) \leqq 0$ for $\frac{1}{6} \leqq y \leqq \frac{1}{2}$.

If $p_{\alpha\beta}$ denotes the probability that an arbitrary L_n satisfies both inequalities in (2.18), then by the above argument and (2.17) we have

$$\begin{aligned} \Pr\{X^* \leqq \tfrac{1}{3}\} &\leqq \Pr\{\delta(y) \leqq 0, \tfrac{1}{6} \leqq y \leqq \tfrac{1}{2}\} \\ &\leqq (1 - p_{\alpha\beta}) + \sum_{j=1}^{1/2\alpha} \Pr\{N_j^+ > 2N_j^-\}, \end{aligned}$$

and

$$\Pr\left\{X^* \leqq \frac{1}{3}\right\} \leqq (1 - p_{\alpha\beta}) + \frac{1}{2\alpha} \max_j \Pr\{N_j^+ > 2N_j^-\}. \tag{2.19}$$

To bound the first term in (2.19) we use Lemma 1. Consider first the inequality $\delta(\frac{1}{6}) < -\alpha n$ in (2.18). Since $E[\delta(\frac{1}{6})] = -n/36$ (see (2.14)), we write

$$\Pr\left\{\delta\left(\frac{1}{6}\right) > -\alpha n\right\} = \Pr\left\{\delta\left(\frac{1}{6}\right) + \frac{n}{36} > \left(\frac{1}{36} - \alpha\right)n\right\},$$

so that, in the notation of Lemma 1 with $S_n = \delta(\frac{1}{6})$, we can put $t\sigma = (1/36 - \alpha)n$. Then by (2.15), t/σ is a positive constant and t^2 increases linearly with n for any $0 < \alpha < 1/36$. Since M is bounded as in (2.16), we conclude from Lemma 1 that for any $0 < \alpha < 1/36$, there exists a constant $c_1 > 0$ such that

$$\Pr\{\delta(\tfrac{1}{6}) > -\alpha n\} < e^{-c_1 n}. \tag{2.20}$$

For the second inequality in (2.18) the random variable $N(\frac{1}{6})$ is also governed by Lemma 1 with $E[N(\frac{1}{6})] = n/3$, $M \leqq 1$, and $\sigma^2 = \mathrm{Var}[N(\frac{1}{6})] = (2/9)n$. Thus, for any

$\frac{2}{3} < \beta < 1$, we have after substitution in (2.12)

$$\Pr\left\{N\left(\frac{1}{6}\right) > \beta n\right\} \leqq \Pr\left\{N\left(\frac{1}{6}\right) - \frac{n}{3} > \left(\beta - \frac{1}{3}\right)n\right\}$$
$$\leqq \Pr\left\{N\left(\frac{1}{6}\right) - \frac{n}{3} > \frac{n}{3}\right\}$$
$$\leqq e^{-n/6}.$$

It is easy to check that the c_1 in (2.20) must be less than $\frac{1}{6}$ for all $0 < \alpha < 1/36$. Consequently, for any α and β in $(0, 1/36)$ and $(\frac{2}{3}, 1)$, respectively, we have

$$1 - p_{\alpha\beta} = O(e^{-c_1 n}), \tag{2.21}$$

where $c_1 > 0$ is the constant determined by α in (2.20).

For the second term in (2.19), we observe that there will be more than twice as many pluses as minuses in a block if the number of pluses exceeds $\frac{2}{3}$ the total of k or $k+1$ signs. Our asymptotic results are independent of whether we choose k or $k+1$, so for simplicity we assume a total of exactly k signs. Then the distribution of the number of pluses is the binomial distribution for k tosses of a fair coin, i.e., $N_j^+ = \sum_{i=1}^{k} W_i$, where $W_i = 1$ if $X_i \geqq \frac{1}{2}$ and $W_i = 0$ otherwise. By Lemma 1 with $E[N_j^+] = k/2$, $M \leqq 1$, and $\sigma^2 = \mathrm{Var}[N_j^+] = k/4$, we have for all $j \geqq 1$

$$\Pr\{N_j^+ > 2N_j^-\} = \Pr\left\{N_j^+ - \frac{k}{2} > \frac{k}{6}\right\} \leqq e^{-k/22},$$

whereupon $k \geqq 2\alpha(1-\beta)n - 1$ implies that there exists a $c_2 > 0$ such that

$$\Pr\{N_j^+ > 2N_j^-\} \leqq e^{-c_2 n}, \qquad j \geqq 1. \tag{2.22}$$

Substituting (2.21) and (2.22) into (2.19), we obtain as desired

$$\Pr\{X^* \leqq \tfrac{1}{3}\} = O(e^{-cn}),$$

where $c = \min\{c_1, c_2\} > 0$.

The expected-height result is easy. We need only use the trivial bound $A(L_n) \leqq n$ in order to write

$$E[A(L_n) - \mathrm{OPT}(L_n)] \leqq \tfrac{1}{2}[1 - O(e^{-cn})] + O(n\, e^{-cn})$$
$$= O(1). \qquad \square$$

Proof of Theorem 4. To find an upper bound on $\Pr\{\Delta > xn^{1/3}\}$, we use an approach analogous to the proof of Theorem 3. For simplicity we assume that $n^{1/3}$ is an even integer; we leave to the interested reader the trivial modifications of the arguments below that account for values of n other than cubes of even integers. We partition the interval $0 \leqq y \leqq \frac{1}{2}$ in Fig. 5 into $\frac{1}{2}n^{1/3}$ subintervals of length $n^{-1/3}$. The initial value of $\delta(y)$ in the subinterval $[jn^{-1/3}, (j+1)n^{-1/3}]$, $0 \leqq j \leqq \frac{1}{2}n^{1/3} - 1$, is denoted by

$$\delta_j = \delta(jn^{-1/3}) = \sum_{1/2 - jn^{-1/3} \leqq X_i \leqq 1/2} X_i - \sum_{1/2 < X_i \leqq 1/2 + jn^{-1/3}} X_i,$$

and the maximum value is denoted by

$$\Delta_j = \max\{\delta(y); jn^{-1/3} \leqq y \leqq (j+1)n^{-1/3}\}.$$

Clearly,

$$\Delta = \max\{\delta(y); 0 \leqq y \leqq \tfrac{1}{2}\} = \max\{\Delta_j; 0 \leqq j \leqq \tfrac{1}{2}n^{1/3} - 1\},$$

so by (2.17) we can write

$$\Pr\{\Delta > xn^{1/3}\} \leqq \sum_{j=0}^{n^{1/3}/2-1} \Pr\{\Delta_j > xn^{1/3}\}. \tag{2.23}$$

Our next objective is an upper bound on $\Pr\{\Delta_j > xn^{1/3}\}$ for any $x \geqq 1$. First, we define $N_j(y)$ as the number of pluses in $[jn^{-1/3}, y]$ less the number of minuses in $[jn^{-1/3}, y]$, and let

$$\hat{N}_j = \max\{N_j(y); jn^{-1/3} \leqq y \leqq (j+1)n^{-1/3}\}.$$

Next we observe that, for any fixed constant z_j, the maximum value satisfies $\Delta_j > xn^{1/3}$ only if either the initial value satisfies $\delta_j > (x - z_j)n^{1/3}$ or the value of the function has a net increase exceeding $z_j n^{1/3}$ in some initial subinterval, i.e., $\delta(y) - \delta_j > z_j n^{1/3}$ for some $jn^{-1/3} \leqq y \leqq (j+1)n^{-1/3}$. Since the sizes of all positive jumps in δ are at most the size of any negative jump, the latter condition can occur only if in some initial subinterval $[jn^{-1/3}, y]$, the number of pluses exceeds the number of minuses by more than $z_j n^{1/3}$, i.e., only if $\hat{N}_j > z_j n^{1/3}$. Therefore, by (2.17),

$$\Pr\{\Delta_j > xn^{1/3}\} \leqq \Pr\{\delta_j > (x - z_j)n^{1/3}\} + \Pr\{\hat{N}_j > z_j n^{1/3}\}, \tag{2.24}$$

for $0 \leqq j \leqq \frac{1}{2}n^{1/3} - 1$. We will bound the right-hand side of this inequality, making the choice

$$z_j = \frac{x + j^2}{2}.$$

We start with the first of the probabilities on the right-hand side of (2.24). For $j = 0$ and any $x \geqq 0$ we have

$$\Pr\{\delta_0 > (x - z_0)n^{1/3}\} = \Pr\{\delta_0 > \tfrac{1}{2}xn^{1/3}\} = 0. \tag{2.25}$$

For the case $1 \leqq j \leqq \frac{1}{2}n^{1/3} - 1$, $x \geqq 1$, we now prove the bound

$$\Pr\{\delta_j > (x - z_j)n^{1/3}\} < e^{-(x+j^2)/3j}. \tag{2.26}$$

We obtain (2.26) from Lemma 1 using the definition of $\delta(y)$, with $y = jn^{-1/3}$, as a sum of independently and identically distributed random variables Z_i, $1 \leqq i \leqq n$. By (2.14), (2.15), and $j \leqq \frac{1}{2}n^{1/3} - 1$, we have

$$E[\delta_j] = -j^2 n^{1/3},$$

$$\operatorname{Var}[\delta_j] = \tfrac{1}{2}jn^{2/3} + j^3[\tfrac{2}{3} - jn^{-1/3}] < \tfrac{2}{3}jn^{2/3}.$$

We apply Lemma 1 with $t\sigma = z_j n^{1/3} = ((x + j^2)/2)n^{1/3}$, $\sigma^2 < \frac{2}{3}jn^{2/3}$, and $M \leqq \frac{3}{4}$ (by (2.16)) to conclude that

$$\begin{aligned} \Pr\{\delta_j > (x - z_j)n^{1/3}\} &= \Pr\{\delta_j + j^2 n^{1/3} > z_j n^{1/3}\} \\ &< \exp\left\{ -\frac{(t\sigma)^2}{2\sigma^2 + \frac{2}{3}Mt\sigma} \right\} \\ &< \exp\left\{ -\frac{z_j^2 n^{2/3}}{\frac{4}{3}jn^{2/3} + \frac{1}{2}z_j n^{1/3}} \right\}. \end{aligned} \tag{2.27}$$

Since $1 \leqq j \leqq \frac{1}{2}n^{1/3} - 1$ and $x \geqq 1$ imply that $z_j \geqq 1$ and $jn^{1/3} \geqq 4$, the magnitude of the exponent is bounded by

$$z_j^2 n^{2/3} \Big/ \left(\frac{4}{3}jn^{2/3} + \frac{z_j n^{1/3}}{2} \right) = \frac{z_j}{j}\left\{ 1 \Big/ \left(\frac{4}{3z_j} + \frac{1}{2jn^{1/3}} \right) \right\} \geqq \frac{2}{3}\frac{z_j}{j}.$$

Substituting this bound into (2.27) and then setting $z_j = (x + j^2)/2$ yields (2.26).

Next we turn to an estimate of the second probability on the right-hand side of (2.24). For given j and for $1 \leqq i \leqq n$ define the independently and identically distributed random variables

$$V_i = \begin{cases} +1 & \text{if } X_i \in [\tfrac{1}{2} - (j+1)n^{-1/3}, \tfrac{1}{2} - jn^{-1/3}], \\ -1 & \text{if } X_i \in [\tfrac{1}{2} + jn^{-1/3}, \tfrac{1}{2} + (j+1)n^{-1/3}], \\ 0 & \text{otherwise,} \end{cases} \tag{2.28}$$

and note that

$$N_j \equiv N_j((j+1)n^{-1/3}) = \sum_{i=1}^{n} V_i.$$

We claim that

$$\Pr\{\hat{N}_j > z_j n^{1/3}\} \leqq 2 \Pr\{N_j > z_j n^{1/3}\}. \tag{2.29}$$

To prove the claim we consider the conditional joint probability distribution of the V_i's given that exactly k of them are nonzero, i.e., $k = \sum_{i=1}^{n} |V_i|$. For each sample drawn from this conditional distribution, reorder the k nonzero V_i's in order of increasing value of the parameter

$$U_i = \begin{cases} \tfrac{1}{2} - X_i & \text{if } 0 < X_i \leqq \tfrac{1}{2}, \\ X_i - \tfrac{1}{2} & \text{if } \tfrac{1}{2} < X_i < 1, \end{cases}$$

to obtain an ordered sequence $\{W_l: 1 \leqq l \leqq k\}$ with each $W_l = \pm 1$. The joint probability distribution of the W_l's induced from that of the V_i's is easily seen to be that of a set of Bernoulli trials (coin flips). (Indeed the joint probability distribution of the X_i's is invariant under any subset of the reflections $X_i \to 1 - X_i$ for $1 \leqq i \leqq N$; each of these leaves all U_i unchanged but changes the sign of V_i, which shows that all sign patterns of $\{W_l: 1 \leqq l \leqq k\}$ are equally likely.) The quantities $\hat{N}_j$ and N_j are expressed in terms of the random variables W_l by

$$\hat{N}_j = \max_{1 \leqq i \leqq k} \sum_{l=1}^{i} W_l, \qquad N_j = \sum_{l=1}^{k} W_l.$$

A well-known result for Bernoulli trials [Fe1, Thm. 1, p. 88], proved using the reflection principle, is that for all w,

$$\Pr\left\{\max_{1 \leqq i \leqq k} \sum_{l=1}^{i} W_l > w\right\} \leqq 2 \Pr\left\{\sum_{l=1}^{k} W_l > w\right\}.$$

Choosing $w = z_j n^{1/3}$, this gives

$$\Pr\left\{\hat{N}_j > z_j n^{1/3} \,\middle|\, \sum_{i=1}^{n} |V_i| = k\right\} \leqq 2 \Pr\left\{N_j > z_j n^{1/3} \,\middle|\, \sum_{i=1}^{n} |V_i| = k\right\}.$$

Hence, removing the conditioning, we obtain (2.29) as claimed.

Now we bound $\Pr\{N_j > z_j n^{1/3}\}$ using Lemma 1 applied to the random variables V_i, $1 \leqq i \leqq n$. In this case $E[V_i] = 0$, $\sigma^2 = 2n^{2/3}$, and $M = 1$, so if we set $t\sigma = z_j n^{1/3}$ we obtain

$$\begin{aligned} \Pr\{N_j > z_j n^{1/3}\} &< \exp\left\{-\frac{(t\sigma)^2}{2\sigma^2 + \frac{2}{3}Mt\sigma}\right\} \\ &< \exp\left\{-\frac{z_j^2 n^{2/3}}{4n^{2/3} + \frac{2}{3}z_j n^{1/3}}\right\}. \end{aligned} \tag{2.30}$$

Since $0 \leqq j \leqq \frac{1}{2}n^{1/3} - 1$, $x \geqq 1$, and hence $z_j \geqq \frac{1}{2}$, the magnitude of the exponent in (2.30) is bounded by

$$\frac{z_j^2 n^{2/3}}{4n^{2/3} + \frac{2}{3}z_j n^{1/3}} = z_j \Big/ \left(\frac{4}{z_j} + \frac{2}{3n^{1/3}}\right) \geqq \frac{2}{17} z_j = \frac{x + j^2}{17}.$$

Thus, (2.30) implies the simpler bound

$$\Pr\{N_j > z_j n^{1/3}\} < e^{-(x+j^2)/17} \tag{2.31}$$

for $x \geqq 1$, $0 \leqq j \leqq \frac{1}{2}n^{1/3} - 1$. Combining (2.31) with (2.29), we obtain

$$\Pr\{\hat{N}_j > z_j n^{1/3}\} \leqq 2e^{-(x+j^2)/17}, \tag{2.32}$$

for $x \geqq 1$, $0 \leqq j \leqq \frac{1}{2}n^{1/3} - 1$.

Returning to (2.24), we substitute (2.25), (2.26), and (2.32) to obtain

$$\Pr\{\Delta_0 > xn^{1/3}\} \leqq 2e^{-x/17},$$

$$\Pr\{\Delta_j > xn^{1/3}\} \leqq 2e^{-(x+j^2)/17} + e^{-(x+j^2)/3j}, \qquad j \geqq 1,$$

and hence by (2.23)

$$\Pr\{\Delta > xn^{1/3}\} \leqq 2e^{-x/17} + \sum_{j=1}^{\infty} (2e^{-(x+j^2)/17} + e^{-(x+j^2)/3j}).$$

Clearly, $e^{-(x+j^2)/17} > e^{-(x+j^2)/3j}$ for $1 \leqq j \leqq 5$, whereas the opposite inequality holds for $j \geqq 6$. Hence,

$$\Pr\{\Delta > xn^{1/3}\} < 17e^{-x/17} + 3\sum_{j \geqq 6} e^{-(x+j^2)/3j}.$$

It is easy to verify that $(x+j^2)/3j$ is decreasing for $1 \leqq j \leqq \sqrt{x}$ and increasing for $j > \sqrt{x}$. Then using $(x+j^2)/3j \geqq 2\sqrt{x}/3$, $1 \leqq j \leqq \sqrt{x}$, and $(x+j^2)/3j \geqq j/3$, $j > \sqrt{x}$, we obtain

$$\begin{aligned}\Pr\{\Delta > xn^{1/3}\} &< 17e^{-x/17} + 3\sqrt{x}e^{-2\sqrt{x}/3} + 3\sum_{j > \sqrt{x}} e^{-j/3} \\ &< 17e^{-x/17} + 3\sqrt{x}e^{-2\sqrt{x}/3} + 11e^{-\sqrt{x}/3}.\end{aligned}$$

At this point it is easy to see that there exists a $c_1 > 0$ such that for all $x \geqq 1$,

$$\Pr\{\Delta > xn^{1/3}\} \leqq c_1 e^{-\sqrt{x}/3}. \tag{2.33}$$

It remains to prove the expected value result. Applying Theorems 1 and 2 and the fact that $\Pr\{X^* \leqq \frac{1}{3}\} = O(e^{-cn})$, we have

$$\frac{3n}{8} + \frac{1}{2}E[\Delta] \leqq E[\mathrm{OPT}(L_n)] \leqq \frac{3n}{8} + \frac{1}{2}E[\Delta] + O(1).$$

Hence, it suffices to prove

$$E[\Delta] = \Theta(n^{1/3}). \tag{2.34}$$

To prove the upper bound implied by (2.34) we write

$$E[\Delta] = n^{1/3} \int_0^{\infty} \Pr\{\Delta > xn^{1/3}\}\, dx.$$

Then $E[\Delta] = O(n^{1/3})$ follows directly from (2.33) and $\int_0^{\infty} e^{-\sqrt{x}/3}\, dx = O(1)$.

To prove the lower bound implied by (2.34) we show that there exists a constant $\gamma > 0$ such that

$$E[\Delta] \geqq \gamma n^{1/3} \tag{2.35}$$

for all n sufficiently large. Since $\Delta > \delta(y)$ for any fixed y, it suffices for each n to select a suitable value y_n and show that for all n sufficiently large,

$$\Pr\{\delta(y_n) > n^{1/3}\} > \gamma, \tag{2.36}$$

since (2.35) easily follows from this.

We choose $y_n = n^{-1/3}$, so that from (2.14) and (2.15)

$$E[\delta(y_n)] = -n^{1/3}, \qquad \operatorname{Var}[\delta(y_n)] = \frac{n^{2/3}}{2} + \frac{2}{3} - \frac{1}{n^{1/3}}.$$

The normalized sums

$$\hat{\delta}(y_n) = [\delta(y_n) - E[\delta(y_n)]]/\sqrt{\operatorname{Var}[\delta(y_n)]},$$

have mean zero and variance 1, and it is easy to see that for all $n \geqq 1$ if $\delta(y_n) \leqq n^{1/3}$ then $\hat{\delta}(y_n) \leqq 5$, and hence

$$\Pr\{\delta(y_n) > n^{1/3}\} \geqq \Pr\{\hat{\delta}(y_n) > 5\}. \tag{2.37}$$

Thus to prove (2.36) it suffices to show that

$$\Pr\{\hat{\delta}(y_n) \geqq 5\} \geqq \gamma$$

for a positive γ independent of n.

Now limit theorems on sums of independently and identically distributed random variables do not apply directly to $\{\hat{\delta}(y_n), n \geqq 1\}$. To get a corresponding limit theorem for this sequence we consider n as fixed and examine the random variables

$$\delta_m = \delta_{m,n} = \sum_{i=1}^{m} Z_i,$$

where

$$Z_i = \begin{cases} X_i & \text{if } X_i \in [\frac{1}{2} - n^{-1/3}, \frac{1}{2}], \\ -X_i & \text{if } X_i \in [\frac{1}{2}, \frac{1}{2} + n^{-1/3}], \\ 0 & \text{otherwise.} \end{cases} \tag{2.38}$$

The choice $m = n$ gives $\delta_{m,n} = \delta(y_n)$. There are classical limit theorems with error terms that apply to δ_m as m varies. One such result, the Berry-Esséen theorem [Fe2, p. 515], asserts that for any distribution of the Z_i's, which for some constant ρ satisfies

$$E[|Z_i - E[Z_i]|^3] < \rho, \qquad i \geqq 1,$$

we have for the normalized sums $\hat{\delta}_m = (\delta_m - E[\delta_m])/\sqrt{\operatorname{Var}[\delta_m]}$ that for all x and all m

$$|\Pr\{\hat{\delta}_m \leqq x\} - \Phi(x)| \leqq \frac{33}{4} \frac{\rho}{\sigma^3 \sqrt{m}}, \tag{2.39}$$

where $\Phi(x)$ is the normal distribution function with zero mean and unit variance, and where

$$\sigma^2 = \operatorname{Var}[Z_i - E[Z_i]] = \operatorname{Var}[Z_i].$$

For the random variables in (2.38) we have $E[Z_i] = n^{-2/3}$. Then $|Z_i - E[Z_i]| < \frac{1}{2} + n^{-1/3}$ when $Z_i = X_i$ or $Z_i = -X_i$, and $|Z_i - E[Z_i]| = n^{-2/3}$ when $Z_i = 0$. Hence,

$$\begin{aligned} E[|Z_i - E[Z_i]|^3] &\leqq [\tfrac{1}{2} + n^{-1/3}]^3 \cdot 2n^{-1/3} + n^{-2}[1 - 2n^{-1/3}] \\ &= O(n^{-1/3}). \end{aligned}$$

Using (2.15) we also obtain

$$\sigma^2 = \mathrm{Var}\,[Z_i - E[Z_i]] = \tfrac{1}{2}n^{-1/3} + O(n^{-1}).$$

Choosing $m = n$ in (2.39), we have

$$\hat{\delta}_{n,n} = \hat{\delta}(y_n) = \hat{\delta}(n^{-1/3}),$$

and

$$|\Pr\{\hat{\delta}(n^{-1/3}) \leqq x\} - \Phi(x)| = O\left(\frac{n^{-1/3}}{(n^{-1/3})^{3/2}n^{1/2}}\right)$$
$$= O(n^{-1/3}).$$

Thus,

$$\Pr\{\hat{\delta}(n^{-1/3}) > 5\} = 1 - \Phi(5) - O(n^{-1/3}),$$

so that for any $\gamma < 1 - \Phi(5)$, $\Pr\{\delta(n^{-1/3}) > n^{1/3}\} > \gamma$ for all n sufficiently large, and hence $E[\Delta] \geqq \gamma n^{1/3}$. □

3. Two-dimensional bin packing. The methods of the preceding section can be modified to prove similar results for packing squares into bins (unit squares). Since the analysis is rather simpler, we content ourselves here with stating the results obtained and briefly pointing out the basic observations used in their proofs. We use the subscript B to distinguish quantities in this section from the cognate quantities of § 2.

In the bin-packing problem it is the *number* of bins that is to be minimized. Consequently, the relevant quantities in the analysis turn out to be the numbers of squares within given ranges, rather than their cumulative heights. Specifically, the appropriate analogue $\delta_B(y)$ of the basic quantity $\delta(y)$, studied in § 2, is defined as

$$\delta_B(y) = \sum_{i=1}^{n} Y_i, \qquad 0 < y \leqq \frac{1}{2}, \tag{3.1}$$

where $Y_i = Y_i(y)$ is defined in terms of independently and identically distributed uniform random variables on $[0, 1]$ by

$$Y_i = \begin{cases} 1 & X_i \in [\frac{1}{2} - y, \frac{1}{2}], \\ -3 & X_i \in (\frac{1}{2}, \frac{1}{2} + y], \\ 0 & \text{otherwise.} \end{cases} \tag{3.2}$$

In other words, $\delta_B(y)$ counts the number of squares in $[\frac{1}{2} - y, \frac{1}{2}]$ minus three times the number in $(\frac{1}{2}, \frac{1}{2} + y]$. The factor of three comes from the fact that for all $0 \leqq y < \frac{1}{2}$ at least three squares of size $\frac{1}{2} - y$ can be packed into a bin along with a square of size $\frac{1}{2} + y$. As before, $\delta_B(0) = 0$, $\Delta_B = \max_{0 \leqq y \leqq 1/2} \delta_B(y)$, and X_B^* is a maximum square size such that $\Delta_B = \delta_B(\frac{1}{2} - X_B^*)$.

Our initial lower bound is now

$$\mathrm{OPT}_B(L_n) \geqq N_{1/2}, \tag{3.3}$$

where $N_{1/2}$ is the number of squares in L_n with sizes in $(\frac{1}{2}, 1]$, and has the expected value $EN_{1/2} = n/2$. The following more useful bound corresponds to Theorem 1 and is based on the simple observation that at most four of the squares in $(\frac{1}{3}, \frac{1}{2}]$ can be packed in a single bin.

THEOREM 5. *For any L_n such that $X_B^* > \frac{1}{3}$ there holds*

$$\mathrm{OPT}_B(L_n) \geqq N_{1/2} + \left\lceil \frac{\Delta_B}{4} \right\rceil.$$

Next, we define an algorithm similar to Algorithm A.

ALGORITHM B.

(1) Pack the squares $X_i \in (\frac{1}{2}, 1]$ bottom-up in *descending* order of size in bins $B_1, \cdots, B_{N_{1/2}}$, one per bin and against the left edge of the bin.

(2) Pack the remaining squares bottom-up in *ascending* order, placing each as far to the left as possible in the first (lowest indexed) bin where it will fit.

As in Theorem 2 it is easily verified that the squares in $[0, X_B^*)$ are all packed by Algorithm B in bins $B_1, \cdots, B_{N_{1/2}}$. Also, if $X_B^* > \frac{1}{3}$ then the squares in $[X_B^*, \frac{1}{2}]$ will be packed four per bin, except possibly for the last bin. We obtain Theorem 6.

THEOREM 6. *For any L_n there holds*

$$B(L_n) \leqq N_{1/2} + \left\lceil \frac{\Delta_B}{4} \right\rceil.$$

It follows from Theorems 5 and 6 that if $X_B^* > \frac{1}{3}$ then Algorithm B produces an optimal packing. The object of the probabilistic analysis is then to show that $X_B^* > \frac{1}{3}$ with very high probability. As before, this entails an analysis of $\delta_B(y)$, for which a calculation yields

$$E[\delta_B(y)] = -2yn, \tag{3.4}$$

$$\mathrm{Var}[\delta_B(y)] = (10y - 4y^2)n. \tag{3.5}$$

The following lemma applies a result in [Fe2, Example (c), p. 393] and provides the basis of the analysis.

LEMMA 2. *Let Z_i, $i = 1, 2, \cdots$ be independently and identically distributed random variables, each being $+1$ or -3 with equal probability. There exists a $C > 0$ such that*

$$\Pr\left\{ \max_{m \geqq 1} \sum_{i=1}^{m} Z_i > x \right\} \sim Ce^{-\alpha x} \quad \text{as } x \to \infty,$$

where $\alpha \approx 0.61$ is the unique root of $E[e^{\alpha Z_i}] = \frac{1}{2}[e^{\alpha} + e^{-3\alpha}] = 1$.

Let Z_i, $1 \leqq i \leqq n - N(\frac{1}{6})$, denote the jumps in $\delta_B(y)$ in the interval $\frac{1}{6} \leqq y \leqq \frac{1}{2}$, indexed in order of increasing y. Now $0 \leqq X_B^* \leqq \frac{1}{3}$ implies that $\delta_B(y) > 0$ for some $\frac{1}{6} < y \leqq \frac{1}{2}$, which in turn implies that either $\delta_B(\frac{1}{6}) > -n/6$ or

$$\max_{1 \leqq m \leqq n - N(1/6)} \sum_{i=1}^{m} Z_i > \frac{n}{6},$$

or both, whence

$$\Pr\left\{0 \leqq X_B^* \leqq \frac{1}{3}\right\} \leqq \Pr\left\{\delta\left(\frac{1}{6}\right) > -\frac{n}{6}\right\} + \Pr\left\{\max_{1 \leqq m \leqq n} \sum_{i=1}^{m} Z_i > \frac{n}{6}\right\}.$$

Using (3.4) and (3.5), we apply Lemma 1 to the first probability on the right, and then apply Lemma 2 to the second probability on the right to obtain Theorem 7.

THEOREM 7. *There is a constant $c > 0$ such that*

$$\Pr\{0 \leqq X_B^* \leqq \tfrac{1}{3}\} = O(e^{-cn}),$$

and hence

$$\Pr\{B(L_n) = \mathrm{OPT}_B(L_n)\} = 1 - O(e^{-cn}).$$

Finally, we can develop an analogue to Theorem 4 that describes the expected performance of an optimal algorithm. For this we again analyze the random variables $\delta_B(y)$ and Δ_B. In particular, let us consider a lower bound analysis such as that at the end of the proof of Theorem 4.

As before $E[\delta_B(y)] < 0$, and hence in order that $E[\Delta_B] > 0$ we must have for some y a positive probability of positive swings in $\delta_B(y)$ that are proportional to the absolute value of the mean. By the normal limit law, if the probability of such deviations is to remain bounded away from zero as $n \to \infty$, we need a standard deviation for each n that is proportional to the absolute value of the mean. In the strip-packing case this was obtained by the choice $y_n = n^{-1/3}$, where in absolute value the mean and standard deviation became $\Theta(n^{1/3})$ (see (2.14) and (2.15)). In the present case, an inspection of (3.4) and (3.5) shows that this requirement leads to $y_n = O(1/n)$. But for y_n proportional to $1/n$ the mean and standard deviation become constants. Thus, there is a constant $c > 0$ such that $E[\Delta_B] > c$ for all n sufficiently large.

Obtaining an upper bound is fairly easy. An application of Lemma 2 leads to an upper bound on the tails of Δ_B and shows that $E[\Delta_B]$ is bounded. The following result is obtained.

THEOREM 8. *For all n sufficiently large*

$$\Pr\{\Delta_B > x\} = O(e^{-\alpha x})$$

with α as defined in Lemma 2. Moreover,

$$E[\mathrm{OPT}_B(L_n)] = \frac{n}{2} + \Theta(1).$$

4. Final remarks. The performance of square-packing algorithms is sensitive to the probability distribution of the sizes of squares to be packed. How well Algorithms A and B perform for size distributions other than the uniform distribution on [0, 1] is an interesting question.

Roughly speaking, Algorithms A and B produce near optimum packings for any distribution that provides a sufficiently large number of squares greater than $\frac{1}{2}$, and allows us to effectively ignore small squares (e.g., squares smaller than $\frac{1}{3}$ in strip packing). As one example, Algorithms A and B perform well for distributions that are strictly positive on [0, 1] and symmetric about $\frac{1}{2}$. As a second example, consider a distribution uniform over $[0, \theta]$, for some θ. Here, we claim that, except for the adjustment of certain constants, our strip-packing analysis on a strip of width 1 applies to any θ large enough to ensure that the expected total height of squares greater than $\frac{1}{2}$ is greater than the expected total height of squares smaller than $\frac{1}{2}$. A simple calculation shows that this holds for $\theta > \sqrt{2}/2$ and that

$$E[H_{1/2}(L_n)] = \left(\frac{\theta^2 - \frac{1}{4}}{2\theta}\right) n$$

in this case. For the bin-packing case the corresponding requirement is that θ be large enough to ensure that the expected number of squares larger than $\frac{1}{2}$ is greater than one third the expected number of squares smaller than $\frac{1}{2}$, and a simple calculation shows that this holds for $\theta > \frac{2}{3}$. The analysis of previous sections can be adapted to cover such distributions.

The methods of this paper do not apply to probability distributions producing a preponderance of small squares. Indeed, in that situation the approximation algorithms analyzed in this paper will not perform well. It is an interesting problem to devise approximation algorithms that work well for such probability distributions.

Acknowledgments. We are indebted to George Lueker and Peter Shor for helpful comments and for many corrections to the original version of this paper.

THE KNOWLEDGE COMPLEXITY OF INTERACTIVE PROOF SYSTEMS*

SHAFI GOLDWASSER†, SILVIO MICALI†, AND CHARLES RACKOFF‡

Abstract. Usually, a proof of a theorem contains more knowledge than the mere fact that the theorem is true. For instance, to prove that a graph is Hamiltonian it suffices to exhibit a Hamiltonian tour in it; however, this seems to contain more knowledge than the single bit Hamiltonian/non-Hamiltonian.

In this paper a computational complexity theory of the "knowledge" contained in a proof is developed. Zero-knowledge proofs are defined as those proofs that convey no additional knowledge other than the correctness of the proposition in question. Examples of zero-knowledge proof systems are given for the languages of quadratic residuosity and quadratic nonresiduosity. These are the first examples of zero-knowledge proofs for languages not known to be efficiently recognizable.

1. Introduction. It is often regarded that saying a language L is in NP (that is, acceptable in nondeterministic polynomial time) is equivalent to saying that there is a polynomial time "proof system" for L. The proof system we have in mind is one where on input x, a "prover" creates a string α, and the "verifier" then computes on x and α in time polynomial in the length of the binary representation of x to check that x is indeed in L. It is reasonable to ask if there is a more general, and perhaps more natural, notion of a polynomial time proof system. This paper proposes one such notion.

We will still allow the verifier only polynomial time and the prover arbitrary computing power, but will now allow both parties to flip unbiased coins. The result is a probabilistic version of NP, where a small probability of error is allowed. However, to obtain what appears to be the full generality of this idea, we must also allow the prover and verifier to *interact* (i.e., to talk back and forth) and to *keep secret* their coin tosses. We call these proof systems "interactive proof systems." This notion is formally defined in § 2, where we also define what it means for a language to have an interactive proof system.

It is far from clear how to use this power of interaction. Languages with nondeterministic polynomial time algorithms or with probabilistic polynomial time algorithms have proof systems with little or no interaction. We would therefore like examples of languages that appear to have neither nondeterministic nor probabilistic polynomial time algorithms, and yet have interactive proof systems. Although we do not present any such examples here, there are now examples in the literature. Using ideas from an initial version of this paper [GMR] Goldreich, Micali, and Wigderson [GMW] have shown that the "graph nonisomorphism" language has an interactive

proof system. Independently of this paper, Babai and Szemeredi [BS] show that certain matrix group problems have what they call "Arthur-Merlin" proof systems, which immediately implies that they have interactive proof systems. In fact, the notion of an Arthur-Merlin proof system consists of a restricted interactive proof system in which the prover sees the coin flips of the verifier. Nevertheless, Goldwasser and Sipser [GS] have shown that a language has an interactive proof system if and only if it has an Arthur-Merlin proof system.

It appears, however, that our notion of interactive proof systems generalizes in the right way to attack a novel problem. The main purpose of this current paper, in fact, is to use interactive proof systems to investigate a natural question; how much knowledge is transmitted to the verifier in an interactive proof system for L? For example, consider SAT, the NP-complete language of satisfiable sentences of the propositional calculus. In the obvious proof system, to prove $F \in \text{SAT}$, the prover gives a satisfying assignment I for the formula F, which the verifier then checks in polynomial time. This assignment gives the verifier much more knowledge than merely the fact that $F \in \text{SAT}$; it also gives a satisfying assignment. At the other extreme, every language that can be accepted in probabilistic polynomial time has a proof system in which the prover does nothing, and hence gives no knowledge to the verifier.

We say an interactive proof system for L is *zero-knowledge* if for each $x \in L$, the prover tells the verifier essentially nothing, other than that $x \in L$; this should be the case even if the verifier chooses not to follow the proof system but instead tries (in polynomial time) to trick the prover into revealing something. The notion of zero-knowledge is formally defined in § 3. This definition is an important contribution of this paper.

The main technical contributions of this paper are the proofs in §§ 5 and 6 that the languages QR and QNR (defined below) both have zero-knowledge interactive proof systems. These are the first zero-knowledge protocols demonstrated for languages not known to be recognizable in probabilistic polynomial time. To understand the languages QR and QNR, it helps to read the (brief) number theory background given in § 4. However, for now, let x, y be integers, $0 < y < x$, such that $\gcd(x, y) = 1$; we say that y is a *quadratic residue* mod x if $y = z^2 \bmod x$ for some z; if not, we say that y is a *quadratic nonresidue* mod x. We define

$$\text{QR} = \{(x, y) | y \text{ is a quadratic residue mod } x\}, \quad \text{and}$$

$$\text{QNR} = \{(x, y) | y \text{ is a quadratic nonresidue mod } x\}.$$

(Actually, QNR will be defined slightly differently in § 4.) Both QR and QNR are in NP, and thus possess an elementary proof system. For instance, to prove membership in QNR, the prover just sends x's factorization. But looking ahead to zero-knowledge proof systems, let us discuss a more interesting example of a proof system for QNR.

Example 1. Let us call the prover A and the verifier B. Say that the input is (x, y). Let $n = |x|$, where $|x|$ is the length of the binary representation of x. We will now describe (omitting some details) an interactive proof system for QNR. B begins by flipping coins to obtain random bits $b_1, b_2, \cdots, b_n$. B then flips additional coins to obtain a string α, from which B computes $z_1, z_2, \cdots, z_n$ such that each z_i is a random z, $0 < z < x$, $\gcd(x, z) = 1$. B then computes $w_1, w_2, \cdots, w_n$ as follows: for each i, if $b_i = 0$ then $w_i = z_i^2 \bmod x$; if $b_i = 1$ then $w_i = (z_i^2 y) \bmod x$. B then sends $w_1, w_2, \cdots, w_n$ to A. For each i, A computes (somehow) whether or not w_i is a quadratic residue mod x, and sends B a sequence of bits $c_1, c_2, \cdots, c_n$, where $c_i = 0$ if and only if w_i is a quadratic residue mod x. B checks if $b_i = c_i$ for every i, and if so is "convinced" that $(x, y) \in \text{QNR}$.

It is not hard to see that if $(x, y) \in \text{QNR}$ and both parties follow the protocol, then B will become "convinced." On the other hand, if y is a quadratic residue mod x, then so is each w_i, and every value for w_i is equally likely; since A does not see the sequence $\{b_i\}$, the probability that every $c_i = b_i$ (and hence that B will be convinced) is 2^{-n}. So this is an interactive proof system for QNR. Let us now address the question of how much knowledge A may release.

It is an interesting question how zero-knowledge should be defined. If the prover is trying to prove to the verifier that y is a quadratic residue mod x, then certainly the verifier should not be able to trick the prover into revealing a square root of y mod x, or the factorization of x, or any information which would help the verifier to compute these things much faster than before. In fact, the prover should not reveal anything which would help the verifier compute *anything* much faster than before. The way to state this formally seems to be that what the verifier sees in the protocol (even if he cheats) should be something which the verifier could have computed for himself, merely from the fact that $(x, y) \in \text{QNR}$. Of course, what the verifier sees in the protocol is really a probability distribution. Thus, zero-knowledge means that one can compute in polynomial time, from $(x, y) \in \text{QNR}$, without a prover, the same (or almost the same) probability distribution that the verifier would see with the prover. This is defined formally in § 3. Here, let us informally discuss whether the above interactive proof system for QNR is zero-knowledge.

Consider a pair $(x, y) \in \text{QNR}$, and say that A follows the protocol. Can B obtain any additional knowledge? For the moment, assume that B follows the protocol. B "sees" $[\{b_i\}, \alpha, \{w_i\}, \{c_i\}]$ distributed according to a particular distribution. Without any help from a prover, we can quickly generate a random string according to this distribution: just choose $\{b_i\}$ and α randomly, and then compute $\{w_i\}$ from them; then compute $c_i = b_i$ for each i.

Now what if B were to cheat? B could begin by setting $w_1 = 42$, and then behave correctly. Consider now the induced distribution on $[\{b_i\}, \alpha, \{w_i\}, \{c_i\}]$; in order to compute a random member of it (without help from a prover), we must compute whether or not 42 is a quadratic residue x, given x and a quadratic nonresidue y. At this time it is not known how to compute this in polynomial time, so this proof system may not be zero-knowledge.

A zero-knowledge proof system for QNR is given in § 6. The ideas of this proof system partially come from the secret exchanging protocol of Luby, Micali, and Rackoff [LMR] and are useful there as well. They have also proved useful in the oblivious transfer protocol of Fischer, Micali, Rackoff, and Witenberg [FMRW] and for the identification scheme of Feige, Fiat, and Shamir [FFS]. These ideas have also helped Goldreich, Micali, and Wigderson [GMW] to show that the languages of "graph isomorphism" and "graph nonisomorphism" have zero-knowledge interactive proof systems.

Although we find the idea of a zero-knowledge interactive proof system fascinating in itself, the main motivation for it and the main applications of it are in the area of cryptographic protocols. For example, in the secret exchanging protocol in [LMR], one person wishes to exchange a secret with another without giving away any additional knowledge. Ideas similar to those here must be used to even define this concept.

More generally, however, it often arises at some point in a protocol that A wishes to convince B of some fact. Say that we know that the protocol would be secure if at this point an angel or someone B trusted were to tell B (truthfully) if A is telling the truth. We want the notion of zero-knowledge to be such that an appropriate zero-knowledge interactive proof system could be inserted at this point instead of the trusted

party, and the whole protocol would remain secure. (Of course, A would have to possess some additional information enabling her to implement the part of the prover efficiently.) In particular instances, we can prove that such substitution works, but a general framework for discussing protocols must exist before the general theorem can even be stated. However, based on intuition and experience, the authors (and many others who have studied these ideas since their initial appearance) believe that the definition of zero-knowledge proposed here has the required properties.

The most important development since these results first appeared is the proof by Goldreich, Micali, and Wigderson [GMW] that, subject to a common complexity theory assumption, every language in NP has a zero-knowledge interactive proof system. These proof systems for NP languages appear to have applications in just about every protocol problem. It is almost certain that these results will vastly simplify distributed cryptographic protocol design in the future, as demonstrated by the powerful results of [GMW2].

2. Interactive proof systems. Intuitively, what should we require from an efficient theorem-proving procedure?

(1) That it should be possible to "prove" a true theorem.
(2) That it should not be possible to "prove" a false theorem.
(3) That communicating the "proof" should be *efficient.* Namely, regardless of how much time it takes to come up with the proof, its correctness should be efficiently verified.

The NP formalization of the concept of an efficient proof system captures one way of communicating a proof. In this section, we will generalize the NP proof system to capture a more general way of communicating a proof. The verifier will be a probabilistic polynomial time (in the length of the common input) machine that is able to exchange messages (strings) with the prover.

At the same time that we introduce probability into the proof system, we relax the classical notion of a "proof." Our verifier may erroneously be convinced of the truth of a proposition with a very small probability of error (less than n^{-k} for each positive constant k and all sufficiently large input-sizes n).

We proceed to formally define the new system.

2.1. Interactive Turing machines and protocols.

DEFINITION. An *interactive Turing machine* (ITM) is a Turing machine equipped with a read-only input tape, a work tape, a random tape, one read-only communication tape, and one write-only communication tape. The random tape contains an infinite sequence of random bits, and can be scanned only from left to right. We say that an interactive machine *flips a coin,* meaning that it reads the next bit in its own random tape.

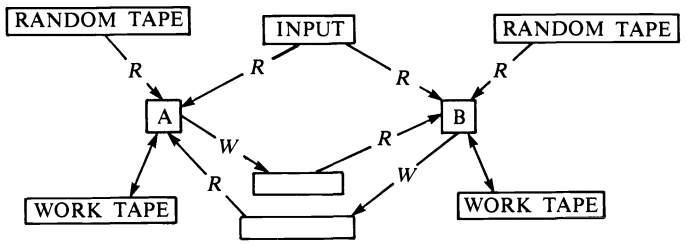

FIG. 1. *An interactive protocol. — denotes a read/write head, R a read-only head, W a write-only head.*

DEFINITION. An *interactive protocol* is an ordered pair of ITM's A and B such that A and B share the same input tape, B's write-only communication tape is A's read-only communication tape and vice versa. Machine A is not computationally bounded, while machine B's computation time is bounded by a polynomial in the length of the common input. The two machines take turns in being active, with B being active first. During an active stage machine $A(B)$ first performs some internal computation using its input tape, work tapes, communication tape and random tape; and, second, it writes a string (for $B(A)$) on its write-only communication tape. The ith message of $A(B)$ is the entire string that $A(B)$ writes on its communication tape during its ith active stage. As soon as machine $A(B)$ writes its message, it is deactivated and machine $B(A)$ becomes active, unless the protocol has been terminated. Either machine can terminate the computation of the protocol by not sending any message in an active stage. Machine B accepts (or rejects) the input by outputting *accept* (or *reject*) and terminating the protocol. The *computation time* of machine B is the sum of the B's computation time during its active stages, and it is this time that is bounded by a polynomial in the length of the input, denoted $|x|$.

2.2. Interactive proof systems.

DEFINITION. Let L be a language over $\{0, 1)^*$. Let (A, B) be an interactive protocol. We say that (A, B) is an *interactive proof system* for L if we have the following:

(1) For each k, for sufficiently large x in L given as input to (A, B), B halts and accepts with probability at least $1-|x|^{-k}$. (The probabilities here are taken over the coin tosses of A and B.)

(2) For each k, for sufficiently large x not in L, for any ITM A', on input x to (A', B), B accepts with probability at most $|x|^{-k}$. (The probabilities here are taken over the coin tosses of A' and B.)

Remark 1. The above probability of error can be decreased, say to smaller than $2^{-|x|}$, by the standard technique of repeating the protocol many times and choosing to accept by majority vote.

We now argue that this definition captures what we intuitively want from an efficient proof system. Condition (1) essentially says that, if $x \in L$, B will accept with overwhelming probability. Condition (2) says that, if x is not in L, there exists no strategy that succeeds with nonnegligible probability for convincing B to accept. In fact, B needs not to trust (or know the program of) the machine with which it is interacting. It is enough for B to trust the randomness of its own coin tosses.

Similar to the NP proof system, note that the definition of an interactive proof system for a language emphasizes the "yes-instances": when a string is in the language, B must be led to acceptance with high probability, but when a string is not in the language A is not required to convince B of the contrary.

A more general version of the above definition is where A is not a Turing machine, but an infinite state machine. However it has been shown by Feldman in [F] that this adds no extra power to the model. In fact, he shows that with respect to language recognition it is sufficient for A to be a deterministic PSPACE machine. The fact that A is probabilistic is of importance to the more subtle definition of zero-knowledge, which is given in the next section.

We define IP, *Interactive Polynomial time*, to be the class of languages for which there exists interactive proof systems.

The first examples of a language in IP but not known to be in NP have been exhibited by Babai and Szemeredi [BS]. Their examples are "matrix group nonmembership" and "matrix group order," where the matrix groups over finite fields are represented by a list of generator matrices. The other, more well-known example

of "graph nonisomorphism" is due to Goldreich, Micali, and Wigderson [GMW]. They have shown that the language of pairs of graphs that are nonisomorphic to each other is in IP.

2.3. Arthur–Merlin games. Babai independently conceived the notion of an "Arthur-Merlin Game," an interactive proof system in which Merlin plays the role of A and Arthur that of B. The interaction, though, is less "liberal" than in our model since Merlin sees all the coin tosses of Arthur. A message from Arthur to Merlin can only consist of a randomly selected string. In an interactive proof system, instead, the verifier is allowed, given a polynomial time computable function f, to secretly select a random string R and transmit only $f(R)$ to the prover (as in the interactive proof system for QNR of Example 1).

This restriction immediately implies that the languages recognized by an Arthur-Merlin game are a subset of those having an interactive proof system. Interestingly, Goldwasser and Sipser [GS] show that they are not a proper subset. However, there is value in having both definitions around. It is easier to design protocols using the interactive proof systems definition, and it is easier to prove complexity results using the Arthur-Merlin definition.

Though the ability to make secret random choices does not help us to recognize more languages, we believe that it is crucial for recognizing languages in zero-knowledge. We make precise this belief in the conjecture of § 3.7.

An Arthur-Merlin type of interactive proof system was already implicitly used in a paper by Blum [B1]. He showed an interactive protocol for recognizing the language of the Blum integers:

$$\mathrm{BL} = \{n \mid p^{\alpha} \text{ divides } n \text{ and } p^{\alpha+1} \text{ does not, where } p \equiv 3 \bmod 4 \text{ is prime and } \alpha \text{ is odd}\}.$$

The prover's goal was to demonstrate membership in BL without having to send n's prime factorization. In this proof system, the verifier talks only once and his message consists of sending the sequence of his coin tosses. Protocols of this type were also found by Goldwasser and Micali [GM1] to prove, without releasing the prime factorization membership in the languages:

$\mathrm{GM1} = \{n \mid n \text{ has exactly two distinct prime divisors}\}$ and

$\mathrm{GM2} = \{(x, n) \mid \gcd(x, \phi(n)) = 1\}$ where $\phi(n)$ is the number of positive integers smaller and relatively prime to n.

3. Zero-knowledge. Rather than giving the definition of zero-knowledge only for interactive proof systems, we will give a more general definition. We will define what it means for any interactive protocol (A, B) to be *zero-knowledge* for a language L, whether or not (A, B) is a proof system for L. Actually the definition will not depend on B at all; as we shall see, it says that for every polynomial time B', the distribution that B' "sees" on all its tapes, when interacting with A on input $x \in L$, is "indistinguishable" from a distribution that can be computed from x in polynomial time. We thus first focus on the notion of indistinguishability for random variables.

3.1. Indistinguishability of random variables. Throughout this paper, we will only consider families of random variables $U = \{U(x)\}$ where the parameter x is from a language L, a particular subset of $\{0, 1\}^*$, and all random variables take values in $\{0, 1\}^*$. Let $U = \{U(x)\}$ and $V = \{V(x)\}$ be two families of random variables. We want to express the fact that, when the length of x increases, $U(x)$ essentially becomes "replaceable" by $V(x)$. To do this, we consider the following framework.

A random sample is selected either from $U(x)$ or from $V(x)$ and it is handed to a "judge." After studying the sample, the judge will proclaim his verdict: 0 or 1. (We

may interpret 0 as the judge's decision that the sample came from $U(x)$; 1 as the decision that the sample came from $V(x)$.) It is then natural to say that $U(x)$ becomes "replaceable" by $V(x)$ for x long enough if, when x increases, the verdict of *any* judge becomes "meaningless," that is, essentially uncorrelated to the distribution from which the sample came.

There are two relevant parameters in this framework: the *size* of the sample and the amount of *time* the judge is given to produce his verdict. By bounding these two parameters in different ways we obtain different notions of indistinguishability for random variables. We focus on the three notions we believe to be the most important: equality, statistical indistinguishability, and computational indistinguishability. Roughly speaking, these notions correspond to the following restrictions on the relevant parameters. If the two families of random variables $\{U(x)\}$ and $\{V(x)\}$ are equal, then the judge's verdict will be meaningless even if he is given samples of arbitrary size and he can study them for an arbitrary amount of time. We will define the two families to be statistically indistinguishable if the judge's verdict becomes meaningless when he is given an infinite amount of time but only random, polynomial (in $|x|$) size samples to work on. We will define the two families to be computationally indistinguishable if the judge's verdict becomes meaningless when he is only given polynomial ($|x|$)-size samples and polynomial ($|x|$) time. Let us now proceed to formalize these notions.

DEFINITION (Statistical indistinguishability). Let $L \subset \{0,1\}^*$ be a language. Two families of random variables $\{U(x)\}$ and $\{V(x)\}$ are *statistically indistinguishable on* L if

$$\sum_{\alpha \in \{0,1\}^*} |\text{prob}\,(U(x)=\alpha) - \text{prob}\,(V(x)=\alpha)| < |x|^{-c}$$

for all constants $c>0$ and all sufficiently long $x \in L$.

Notice that, for U and V as above, if a "judge" is handed a polynomial (in $|x|$) size sample, having infinite computing power will not help him to decide whether it came from $U(x)$ or $V(x)$. His answer will be essentially useless, as he will say "1" with essentially the same probability in both cases.

Example 2. Let $U(x)$ assign equal probability to all strings of length $|x|$, and let $V(x)$ assign probability $2^{-|x|}$ to all strings of length $|x|$, except for $0^{|x|}$, which is given probability 0 and for $1^{-|x|}$, which is given probability $2^{-|x|+1}$. Then $\{U(x)\}$ and $\{V(x)\}$ are two families of random variables statistically indistinguishable on $\{0,1\}^*$.

To formalize the notion of computational indistinguishability we make use of nonuniformity (the reasons for this choice can be found in § 3.4). Thus, our "judge," rather than being a polynomial time Turing machine, will be a *poly-size family of circuits.* That is a family $C=\{C_x\}$ of Boolean circuits C_x with one Boolean output such that, for some constant $e>0$, all $C_x \in C$ have at most $|x|^e$ gates. In order to feed samples from our probability distributions to such circuits, we will consider only *poly-bounded* families of random variables, that is, families $U=\{U(x)\}$ such that, for some constant $d>0$, all random variable $U(x) \in U$ assigns positive probability only to strings whose lengths are exactly $|x|^d$. If $U=\{U(x)\}$ is a poly-bounded family of random variables and $C=\{C_x\}$ a poly-size family of circuits, we denote by $P(U, C, x)$ the probability that C_x outputs 1 on input a random string distributed according to $U(x)$. (Here we assume that strings assigned positive probability by $U(x)$ have lengths equal to the number of Boolean inputs of C_x.)

DEFINITION (Computational indistinguishability). Let $L \subset \{0,1\}^*$ be a language. Two poly-bounded families of random variables U and V are *computationally indistinguishable on* L if for all poly-size family of circuits C, for all constants $c>0$ and all

sufficiently long strings $x \in L$,

$$|P(U, C, x) - P(V, C, x)| < |x|^{-c}.$$

This notion of computational indistinguishability was already used by Goldwasser and Micali [GM] in the context of encryption and by Yao [Y] in the context of pseudorandom generation. It is trivial that if U and V are identical, then they are statistically indistinguishable. It is also not hard to see that if U and V are statistically indistinguishable, then they are computationally indistinguishable, as follows. Let C_x be a circuit and let S be the set of inputs on which C_x outputs 1. Since U and V are statistically indistinguishable, the value of $U(x)$ will be in S with almost exactly the same probability that the value of $V(x)$ will be. Hence $P(U, C, x)$ will be very close to $P(V, C, x)$.

Example 3. Consider a probabilistic encryption algorithm that is secure in the sense of Goldwasser and Micali [GM]; for n integer, let $U(1^n)$ and $V(1^n)$ be the random variables taking as values the possible encryptions of 0 and 1, respectively, on security parameter n. Then U and V are computationally indistinguishable on $L = \{1\}^*$.

We believe that the notion of computational indistinguishability for random variables achieves the right level of generality. Thus we will call *indistinguishable* any two families of random variables that are computationally indistinguishable.

Remark 2. Let us point out the robustness of the last definition. In this definition, we are handing our computationally bounded "judge" only samples of size 1. This, however, is not restrictive. We note that two families of random variables $\{U_x\}$ and $\{V_x\}$ are computationally indistinguishable (with respect to samples of size 1) if and only if when C_x is given a polynomial in $|x|$ number of input strings, each independently generated according to the distribution U_x, then the probability of accepting is close to the probability of accepting when V_x is used.

3.2. Approximability of random variables. We now formalize the notion that a random variable U is essentially easy to generate. That is, there exists an efficient algorithm that randomly outputs strings in a way that is indistinguishable from U.

DEFINITION. Let M be a probabilistic Turing machine that on input x halts with probability 1. We denote by $M(x)$ the random variable that, for each string α, takes on α with exactly the same probability that M on input x outputs α.

DEFINITION. Let $L \subset \{0, 1\}^*$ be a language and $U = \{U(x)\}$ a family of random variables. We say that U is *perfectly approximable on* L if there exists a probabilistic Turing machine M, running in expected polynomial time, such that for all $x \in L$, $M(x)$ is equal to $U(x)$. We say that U is *statistically* (*computationally*) *approximable on* L if there exists a probabilistic Turing machine M, running in expected polynomial time, such that the families of random variables $\{M(x)\}$ and $\{U(x)\}$ are statistically (computationally) indistinguishable on L.

In what follows, we will use *approximability* to mean computational approximability. We are now ready to define the notion of zero-knowledge.

3.3. Zero-knowledge protocols and proof systems. We first address the issue of a "cheating verifier," B', who is allowed not to follow the protocol.

DEFINITION. Let (A, B) be an interactive protocol. Let B' be an interactive Turing machine that has as input x and on an extra input tape H, where the length of H is bounded above by a polynomial in the length of x. (Figure 1 must be emended to allow B' this extra tape.) When B' interacts with A, A sees only x on its input tape, whereas B' sees (x, H). A good way to think of H is as some knowledge about x that

the cheating B' already possesses. Alternatively, H can be considered as the history of previous interactions that the cheating B' is trying to use to get knowledge from A; this is discussed in more detail in the next section. We assume that the total computation time of B' when interacting with A will be bounded above by a polynomial in the length of x.

For a run of the protocol on common input x and extra input H, we define the view of B' to be everything that B' sees. Namely, let σ (and ρ) be the strings contained in the random tapes of A (and B'). Say the computation of A and B', with these random choices, consist of n turns with B' going first, where a_i (and b_i) are the ith messages of A (and B'), respectively. Then, we say that $(\rho, b_1, a_1, \cdots, b_n, a_n)$ is the *view* of B' on inputs x and H, and let $\text{View}_{A,B'}(x, H)$ be the random variable whose value is this view. (Note that it would make no difference if we included in the view the material written by B' on its private tape, or excluded the strings that B' sends to A, since these bits can be efficiently computed from the other bits of the view.) For convenience, we consider each view to be a string from $\{0, 1\}^*$ of length exactly $|x|^c$ for some fixed $c > 0$.

DEFINITION. Let $L \subset \{0, 1\}^*$ be a language and (A, B) a protocol. Let B' be as above. We say that (A, B) is *perfectly* (*statistically*) (*computationally*) *zero-knowledge on L for* B' if the family of random variables $\text{View}_{A,B'}$ is perfectly (statistically) (computationally) approximable on

$$L' = \{(x, H) \mid x \in L \text{ and } |H| = |x|^c\}.$$

We say that (A, B) is *perfectly* (*statistically*) (*computationally*) *zero-knowledge on L* if it is perfectly (statistically) (computationally) zero-knowledge on L for all probabilistic polynomial time ITM B'.

Note that the definition of (A, B) being zero-knowledge (in some manner) for B' only depends on A and not at all on B. It might be less misleading to think of A as being zero-knowledge for B'. A similar issue arises in the definition of an interactive proof system in § 2.2. Part (2) of this definition depends only on B, and not at all on A.

Computational zero-knowledge is certainly the most general of the above notions, and we will refer to it simply as *zero-knowledge.* Zero-knowledge really captures any information, which could not have been obtained efficiently in polynomial time, about members of L. That is, if (A, B) is zero-knowledge, it is not possible, in probabilistic polynomial time, to extract any information about members of L by interacting with A, not even by "cheating."

DEFINITION. Let $L \subset \{0, 1\}^*$ be a language. We say that (A, B) is a *perfectly* (*statistically*) (*computationally*) *zero-knowledge proof system for L* if it is an interactive proof system for L and a perfectly (statistically) (computationally) zero-knowledge protocol on L.

We will refer to computationally zero-knowledge proof systems (the most general notion of the three) simply as *zero-knowledge proof systems.* This notion is totally adequate in the real world. That is, if (A, B) is a zero-knowledge proof system for L, it is not possible in polynomial time (not even for a "cheating" B') to interact with A and extract anything else besides proofs of membership in L.

3.4. Some remarks about the above definitions. First, let us stress that the coin tosses of B are an essential part of the notion of a view in the definition of zero-knowledge for B. Consider the language L of all composite integers and the following

protocol (A, B). On input an integer n, B randomly selects an integer x between 1 and n and relatively prime with n. It then sends A the number $a = x^2 \bmod n$. A responds by sending y, a randomly chosen square root of a mod n. Should the view consist only of the text of the interaction between A and B, then the above-mentioned protocol would be perfectly zero-knowledge on L. However, we define the view so as to contain also the coin tosses of B. Thus, if (x, a, y) is randomly selected in $\text{View}_{(A,B)}(n)$, then $\gcd(x+y, n)$ is not 1 or n with probability at least $\frac{1}{2}$. Thus, if factoring is not in probabilistic polynomial time, the above protocol is not zero-knowledge for B. (It should be noted, however, that in the definition of zero-knowledge (for *all* B'), it is *not* necessary to include the random bits of B' in the view; this is because we have included in the view the messages sent by B', and for every B' there is a B'', which is like B' except that it sends its random bits as part of its last message.)

Second, it should be explained why B' sees an additional string H. (The need for this was independently discovered by the authors of this paper, by Oren [O], and by Tompa and Woll [TW].) H may be thought about in a number of different ways; H may be some extra information that the verifier (cheating or not) happens to know. For example, a zero-knowledge protocol for graph isomorphism should remain zero-knowledge even if the verifier happens to know colorings for the graphs. It is also possible that the protocol will be inserted in the middle of another protocol, where the verifier has seen some history H. There is the fear that this H was generated perhaps by interacting with a machine of unlimited power; we want to rule out the possibility of the verifier then obtaining knowledge by using H when interacting with A. It is for a similar reason that the distinguishing circuits in the definition of computational indistinguishability are allowed to be nonuniform. We want to say that two families of random variables can be computationally distinguished if there are circuits that tell them apart, where the circuits may have wired in some information about x or some information obtained from the history of some protocol in which the protocol of interest is immersed. In other words, the view B' obtains on inputs (x, H) should look like the simulated distribution $M(x, H)$.

One test of a definition is that we should be able to prove those facts that intuition dictates *must* be true. One such fact is that the repetition of a zero-knowledge protocol a polynomial number of times is still zero-knowledge. We can prove this with our current definitions, but we cannot prove it if, for example, we do not give B' the extra string H. We can also prove that if B' wants to decide a special predicate $P(x)$ for $x \in L$, it does not help B' to engage in a zero-knowledge proof system for L. We can prove all the intuitively obvious "facts" we have tried to prove, but only time will tell if these definitions are the right ones, or if they need some further modifications. We feel (and hope) that these definitions capture exactly the intuitive ideas we have tried to capture.

Last, there is the peculiar fact that the machine M simulating the view is allowed to operate in *expected* polynomial time. This appears to be necessary for the zero-knowledge proof system for QNR given in § 6. To see why this is necessary in general, consider a pair (A, B), where B (on input of length n) sends n random bits α to A; if the predicate $P(\alpha)$ holds, then A sends a random β of length n such that $P(\beta)$ holds. Imagine that the predicate P is easily computable, but the number of strings of length n for which P holds is small—maybe a fraction n^{-10} or maybe n^{-20}—but we do not know exactly which; imagine that the only way we know to find a string for which P holds is to select random strings until one satisfying P is found. The only way we know how to simulate the view of B statistically closely (or even computationally indistinguishably) is to choose a random α; if $P(\alpha)$ holds, look through random n-bit

strings until a β is found such that $P(\beta)$ holds. This process is only expected polynomial time.

3.5. Examples of zero-knowledge languages. Trivially, all languages in BPP have perfect zero-knowledge proof systems. (A language is in BPP if there is a probabilistic, polynomial time machine which on each input computes membership in the language with small probability of error.)

The first nontrivial zero-knowledge proof systems (i.e., for recognizing languages not known to be in BPP) are the perfect zero-knowledge proof systems for the quadratic residuosity language QR given in § 5, and the statistically zero-knowledge proof system for QNR given in § 6.

Recently, Goldreich, Micali, and Wigderson have shown in [GMW] that the graph isomorphism language has a perfect zero-knowledge proof system, that the graph nonisomorphism language (though not known to belong to NP) has a statistically zero-knowledge proof system, and that all languages in NP possess computationally zero-knowledge proof systems if secure encryption schemes exist. In [BGGHKMR] it is proved that all languages in IP possess zero-knowledge proof systems.

Results by Boppana, Hastad, and Zachos [BHZ] and Fortnow [Fo] show that if an NP-complete language had a perfect or statistically zero-knowledge proof system, the polynomial time hierarchy would collapse. Thus it may not be surprising that the interactive proof systems in [GMW] for graph coloring were zero-knowledge only in a computational sense. A more immediate reason for their being computationally zero-knowledge is that they make use of probabilistic encryption [GM] (see Example 3). This may tempt us to interpret Fortnow's result as saying that encryption is crucial in any zero-knowledge proof system for NP-complete languages. (Further discussion on Fortnow's result can be found in § 7.)

3.6. A study of earlier proposals. Having reached the notion of a zero-knowledge proof system, let us now have a second look at the earlier, Arthur–Merlin type, proof systems of Blum [Bl] and Goldwasser and Micali [GM1] that we have already mentioned in § 2.3.

The Proof System for BL (defined in § 2.3). In his beautiful paper, assuming that integer factorization is computationally hard, Blum proposes a protocol for flipping a coin over the telephone. For "fairly" flipping a coin, Alice and Bob need an integer n whose prime factorization is known to Alice but not to Bob, and has a special property, namely, $n \in \mathrm{BL}$. Alice is sure that the coin flip is fair because she computes n by multiplying two randomly selected primes both congruent to 3 mod 4, and because she trusts that factoring is hard. Bob, after the coin has come up Head or Tail, checks that the flipping was fair by requesting n's factorization from Alice. Thus a different n should be selected for each coin flip. To make coin flipping more efficient, Blum proposed to test that $n \in \mathrm{BL}$, by means of a protocol that does not give away n's factorization in any obvious way. After slightly modifying it, Blum's protocol can be proved to be perfect zero-knowledge on BL. However, without this modification, it is not clear how much knowledge about n's factorization it releases.

The Proof Systems for GM1 *and* GM2 (defined in § 2.3). The cryptographic protocols of Goldwasser and Micali use the inefficient version of Blum's coin-flipping protocols, and thus assume that factoring integers is computationally difficult. Based on this assumption, they showed that their proof systems do not give away the prime factorization of an input n. That is, no cheating polynomial time verifier can, after participating in the protocol, compute n's factorization much faster than it could before.

More generally, their same protocols can actually be proved to be computationally zero-knowledge on, respectively, the languages GM1 and GM2. Thus, in particular, their protocols do not even give away whether or not, say, 3 is a quadratic residue mod n.

3.7. Interactive proof systems versus Arthur–Merlin games for zero-knowledge. We are now ready to formally express our belief that interactive proof systems are more appropriate than Arthur–Merlin games for recognizing languages in zero-knowledge.

CONJECTURE. There exist languages L that have perfect or statistical zero-knowledge proof systems, but do not have any Arthur–Merlin proof system that is perfect or zero-knowledge on L.

4. The quadratic residuosity problem. In this section we describe the necessary number-theoretic background and notation needed for the proofs in §§ 5 and 6.

Let $\mathbf{N}$ denote the natural numbers, $x \in \mathbf{N}$ and $\mathbf{Z}_x^* = \{y \mid 1 \leqq y < x, \gcd(x, y) = 1\}$. We can determine in time polynomial in $|x|$ and $|y|$ whether or not $y \in \mathbf{Z}_x^*$.

We say that y in $\mathbf{Z}_x^*$ is a *quadratic residue* mod x if there exists a w in $\mathbf{Z}_x^*$ such that $w^2 \equiv y \bmod x$. Otherwise, we call y in $\mathbf{Z}_x^*$ a *quadratic nonresidue* mod x.

FACT 1. Let $x \in \mathbf{N}$ and $y \in \mathbf{Z}_x^*$. Then, y is a quadratic residue mod x if and only if it is a quadratic residue mod all of the prime factors of x.

Define the quadratic residuosity predicate to be

$$Q_x(y) = \begin{cases} 0 & \text{if } y \text{ is a quadratic residue mod } x, \\ 1 & \text{otherwise.} \end{cases}$$

Then we have the following fact.

FACT 2. Let $x \in \mathbf{N}$ and $y \in \mathbf{Z}_x^*$. Given y and the prime factorization of x, $Q_x(y)$ can be computed in time polynomial in $|x|$.

Let $y \in \mathbf{Z}_x^*$ and the prime factorization of x be $\prod_{i=1}^{k} p_i^{\alpha_i}$. Then, the Jacobi symbol of y mod x is defined as

$$(y/x) = \prod_{i=1}^{k} (y/p_i)^{\alpha_i},$$

where $(y/p_i) = 1$ if y is a quadratic residue mod p_i, and -1 otherwise.

FACT 3. Given $x \in \mathbf{N}$ and $y \in \mathbf{Z}_x^*$, (y/x) can be computed in time polynomial in $|x|$.

The Jacobi symbol of y mod x gives some information about whether y is quadratic residue mod x or not. If $(y/x) = -1$, then y is a quadratic nonresidue mod x and $Q_x(y) = 1$. However, when $(y/x) = 1$, no efficient (probabilistic or deterministic polynomial time) solution is known for computing $Q_x(y)$ correctly with probability significantly better than $\frac{1}{2}$. This leads to the formulation of the quadratic residuosity problem.

DEFINITION. We define the *quadratic residuosity problem* as that of computing $Q_x(y)$ on inputs x and y, where y in Z_x^* and $(y/x) = 1$,

The current best algorithm for computing $Q_x(y)$, is to first factor x and then compute $Q_x(y)$. In fact, factoring integers and computing Q_x have been conjectured to be of the same time complexity. The difficulty of the quadratic residuosity problem has been used as a basis for the design of several cryptographic protocols [GM], [LMR], [Bl].

Define the following two languages:

$$\mathrm{QR} = \{(x, y) \mid x \in \mathbf{N}, y \in \mathbf{Z}_x^*, \text{ and } Q_x(y) = 0\},$$

$$\mathrm{QNR} = \{(x, y) \mid x \in \mathbf{N}, y \in \mathbf{Z}_x^*, (y/x) = 1, \text{ and } Q_x(y) = 1\},$$

where x and y are presented in binary.

Clearly, by Facts 1 and 2, both QR and QNR are in the intersection of CO-NP and NP. However, no probabilistic polynomial time algorithm is known that accepts these languages, and thus they are not trivially zero-knowledge. In § 5 we show a perfectly zero-knowledge proof system for QR, and in § 6 we show a statistically zero-knowledge proof system for QNR. The following facts will be useful in the zero-knowledge proofs of §§ 5 and 6.

FACT 4. Let $x \in \mathbf{N}$. Then, for all y such that $Q_x(y) = 0$, the number of solutions $w \in \mathbf{Z}_x^*$ to $w^2 \equiv y \bmod x$ is the same (independent of y).

FACT 5. Let $x \in \mathbf{N}$, $y, z \in \mathbf{Z}_x^*$. Then we have the following:

(a) If $Q_x(y) = Q_x(z) = 0$, then $Q_x(yz) = 0$.

(b) If $Q_x(y) \neq Q_x(z)$, then $Q_x(yz) = 1$.

FACT 6. Given x, y, the Euclidean gcd algorithm allows us to compute in polynomial time whether or not $y \in \mathbf{Z}_x^*$.

5. Zero-knowledge proofs of quadratic residuosity. Recall that $\mathrm{QR} = \{(x, y) \mid y$ is a quadratic residue mod $x\}$, where x and y are presented in binary.

We will first *informally* describe our zero-knowledge interactive proof system for QR, and then describe it with more rigor. Say that A and B are given (x, y), $|x| = m$; then the following is done m times:

- A sends B a random quadratic residue mod x, u.
- B sends A a random bit, *bit*.
- If $bit = 0$ then A sends B a random square root of u mod x, w; if $bit = 1$ then A sends B a random square root of (uy) mod x, w.
- B checks that either [$bit = 0$ and $w^2 \bmod x = u$] or [$bit = 1$ and $w^2 \bmod x = (uy) \bmod x$].

More formally, we assume, for convenience, that A starts the protocol.

A's PROTOCOL ON INPUT $(x, y) \in$ QR.

FOR $i = 1$ to m

Use random bits to generate u_i, a random quadratic residue mod x.

SEND u_i to B

GET a string β_i from B; let bit_i = the first bit of β_i (or 0 if β_i is empty). If $bit_i = 0$, use random bits and generate w_i, a random square root of u_i mod x; if $bit_i = 1$, use random bits and generate w_i, a random square root of $(u_i y)$ mod x.

SEND w_i to B

GET a string from B (this will merely indicate that B wishes to continue the protocol).

END FOR

SEND "terminate" (just a string to finish off the protocol) to B.

B's PROTOCOL ON INPUT (x, y).

See if $x \geqq 1$ and $y \in Z_x^*$; if not, halt.

FOR $i = 1$ to m

GET u_i from A. See if $u_i \in Z_x^*$; if not, halt.

Generate a random bit_i.

SEND bit_i to A.

GET w_i from A. See if $w_i \in Z_x^*$ and either [$bit_i = 0$ and $w_i^2 \bmod x = u_i$] or [$bit_i = 1$ and $w_i^2 \bmod x = (u_i y) \bmod x$]; if not, halt.

SEND "okay" (just a string to continue the protocol) to A.

END FOR

GET any string from A, and halt accepting.

This is clearly an interactive protocol.

CLAIM 1. *The above* (A, B) *protocol is an interactive proof system for* QR.

Proof. Say that B is interacting with an arbitrary A'. Say that $x \geqq 1$, $y \in Z_x^*$, and y is *not* a quadratic residue mod x. For each u_i that B receives from A' it cannot be the case that *both* u_i and $(u_i y)$ have square roots mod x. Since A' does not see any bit_i in advance, there is at most a $\frac{1}{2}$ probability that B will "okay" the ith pass. Hence, the probability that B will say "convinced" is at most $1/2^m$.

We will now show that the protocol is zero-knowledge for QR.

THEOREM 1. *The above* (A, B) *protocol is a perfectly zero-knowledge proof system for* QR.

Proof. Let B' be an arbitrary polynomial time ITM that interacts with A. Let $(x, y) \in \text{QR}$ be the common input to the pair (A, B'), $|x| = m$, and let H be the extra input to B'. For convenience we consider the view $\text{View}_{A,B'}((x, y), H)$ to consist of the random variables

$$R, U_1, \text{BIT}_1, W_1, U_2, \text{BIT}_2, W_2, \cdots, U_m, \text{BIT}_m, W_m,$$

where R is the string of random bits generated by B', U_i takes on the value u_i, BIT_i takes on the ith message of B', etc.

One way to describe the distribution of the view is as follows: R is assigned a random bit string r (of the appropriate length). Say that $R, U_1, \text{BIT}_1, W_1, \cdots, U_i, \text{BIT}_i, W_i$ is the random variable V_i. Assume that for some i, $1 \leqq i < m$, V_i has been given the value v_i; we will describe the experiment for giving values to $U_{i+1}, \text{BIT}_{i+1}, W_{i+1}$.

EXPERIMENT

Choose for U_{i+1} a random quadratic residue mod x, u_{i+1}. If B' were B, we would choose BIT_{i+1} to be the $(i+1)$st bit of r. However, all we can say is that BIT_{i+1} is assigned the value $bit_{i+1} = f(x, y, H, v_i, u_{i+1})$, where f is some $\{0, 1\}$-valued function computable in deterministic, polynomial time. If $bit_{i+1} = 0$, then W_{i+1} gets the value w_{i+1}, a random square root of $u_{i+1} \bmod x$; if $bit_{i+1} = 1$, then W_{i+1} gets the value w_{i+1}, a random square root mod x of $(u_{i+1} y) \bmod x$.

Having characterized the view with the above experiment, we will now describe a probabilistic Turing machine M that, given $(x, y) \in \text{QR}$ and a string H, runs in expected polynomial time, and such that its output distribution $M((x, y), H)$ is *exactly* the same as V_m above; that is, $M((x, y), H)$ is the same as $\text{View}_{A,B'}((x, y), H)$. M begins by choosing r equals a random bit string (of the appropriate length). Assume that v_i has been chosen for some i, $1 \leqq i < m$; M outputs $u_{i+1}, bit_{i+1}, w_{i+1}$ according to the following program:

```
DO FOREVER
    bit_{i+1} := a random member of {0, 1}
    w_{i+1} := a random member of Z_x^*
    IF bit_{i+1} = 0 THEN
        u_{i+1} := w_{i+1}^2 mod x
    ELSE
        u_{i+1} := (w_{i+1}^2 y^{-1}) mod x
    IF bit_{i+1} = f(x, y, H, v_i, u_{i+1}) THEN
        OUTPUT u_{i+1}, bit_{i+1}, w_{i+1} and HALT
END DO
```

Two things about M's program must be clarified. First, the way M chooses a random member of Z_x^* is by choosing random m-bit strings until one is found that is in $\mathbf{Z}_x^*$; this halts in expected polynomial time. Secondly, by "y^{-1}" we mean that unique member of Z_x^* which when multiplied by y mod x yields 1.

We now show that M halts in expected time polynomial in m, with exactly the right output distribution.

Let $R', \{U_i', \mathrm{BIT}_i', W_i'\}$ be the random variables corresponding to the output of M, and let V_i' be defined similarly to V_i. Certainly R' has exactly the same distribution as R. Let $1 \leqq i < m$ and assume that V_i' has exactly the same distribution as V_i, and assume that M gives a value to V_i' in expected time polynomial in m. Say that both V_i and V_i' have been given the value v_i; we wish to show that the above piece of program code halts in expected time polynomial in m, with the same output distribution as the above experiment, given that $V_i = V_i' = v_i$.

Consider the body of the DO loop up to but not including the last test. If $bit_{i+1} = 0$ at this point, then since every quadratic residue in Z_x^* has the same number of square roots (mod x), u_{i+1} is equally likely to be any quadratic residue, and w_{i+1} will be a random square root of u_{i+1}; if $bit_{i+1} = 1$ at this point, then u_{i+1} will also be a random quadratic residue in this case (since y is a quadratic residue), and w_{i+1} will be a random square root of $(u_{1+1}y)$ mod x. Therefore, the body of the DO loop has the following *effect* (even though the following code may not be efficiently executable):

EQUIVALENT DO BODY
$u_{i+1} :=$ a random quadratic residue mod x.
$bit_{i+1} :=$ a random bit
IF $bit_{i+1} = f(x, y, H, v_i, u_{i+1})$ THEN
IF $bit_{i+1} = 0$ THEN $w_{i+1} :=$ a random square root mod x of u_{i+1} FI
IF $bit_{i+1} = 1$ THEN $w_{i+1} :=$ a random square root mod x of $(u_{i+1}y)$ FI
HALT and output $(u_{i+1}, \mathrm{bit}_{i+1}, w_{i+1})$
FI

It is clear that the equivalent body halts (and outputs) with probability $\frac{1}{2}$, and therefore that the actual DO loop halts in expected polynomial time. Since for each value of u_{i+1} the equivalent body is equally likely to halt, U_{i+1}' gets assigned (by the DO loop) a random quadratic residue. BIT_{i+1}' will be assigned $f(x, y, H, v_i, u_{i+1})$. Lastly, we can see from the equivalent body that in the case where the DO loop halts, W_{i+1}' gets assigned a random square root of u_{i+1} or of $(u_{i+1}y)$, depending on bit_{i+1}, as required.

6. Zero-knowledge proofs of quadratic nonresiduousity. We define $\mathrm{QNR} = \{(x, y) \mid y \in \mathbf{Z}_n^*, (y/x) = 1, Q_x(y) = 1\}$, where x and y are presented in binary.

Let (A, B) be an interactive protocol given as input (x, y) such that $|x| = m$.

The basic idea of the protocol is that B generates at random elements w of two types: $w \equiv r^2$ mod x (type 1) and $w \equiv r^2 y$ mod x (type 2), and sends these elements to A. If $(x, y) \in \mathrm{QNR}$ then A can tell of which type w is by computing whether w is a quadratic residue (type 1) or not (type 2). If (x, y) is not a member of QNR, w is always a quadratic residue mod x and A cannot guess its type better than guessing at random. Thus, A will not be able to tell the types of the w's and B will not be convinced that $(x, y) \in \mathrm{QNR}$.

This idea is sufficient as a proof system but not as a zero-knowledge proof system. The danger is that B may not have followed the protocol and generated elements w in a manner differently than specified in the protocol. We get over this difficulty by complicating the protocol to force B to convince A that indeed B knows whether w

is of type 1 or type 2. He does this by convincing A that he knows either a square root of w or a square root of $wy^{-1} \bmod x$, without giving A any information (in the information-theoretic sense) of which one he really knows.

Our original protocol, which appeared in [GMR], was more complex to prove than the one presented here. The simplified protocol presented here was suggested by Cohen [Co].

As was done for the QR language, we will first informally describe an interactive protocol, which we claim is a statistical zero-knowledge interactive proof system for QNR, and then describe it with more rigor.

The following (A, B) protocol on input (x, y) should be repeated m times.

- B picks at random $r \in \mathbf{Z}_x^*$ and $bit \in \{0, 1\}$. If $bit = 0$, B sets $w = r^2 \bmod x$; otherwise B sets $w = r^2 y \bmod x$. B sends w to A.
  For $1 \leqq j \leqq m$, B picks random $r_{j1}, r_{j2} \in \mathbf{Z}_x^*$ and a random $bit_j \in \{0, 1\}$. B sets $a_j = r_{j1}^2 \bmod x$, and $b_j = y r_{j2}^2 \bmod x$. If $bit_j = 1$, B sends A the ordered pair, $\text{pair}_j = (a_j, b_j)$; else if $bit_j = 0$, B sends to A $\text{pair}_j = (b_j, a_j)$.
- A sends B an m-long random bit vector $i = i_1 i_2 \cdots i_m$.
- B sends A the sequence $v = v_1, v_2, \cdots, v_m$; if $i_j = 0$ then $v_j = (r_{j1}, r_{j2})$; if $i_j = 1$ then $v_j = r r_{j1} \bmod x$ (a square root of $wa_j \bmod x$) if $bit = 0$, and $v_j = y r r_{j2} \bmod x$ (a square root of $wb_j \bmod x$) if $bit = 1$.
  (The intuition behind this step is as follows: if $i_j = 0$, then B is convincing A that pair_j was chosen correctly; if $i_j = 1$, then B is convincing that *if* pair_j was chosen correctly, then w was chosen correctly.)
- A verifies that the sequence v was properly constructed. If not, A sends *terminate* to B and halts. Otherwise, A sets $answer = 0$ if w is a quadratic residue mod x and 1 otherwise. A sends *answer* to B.
- B checks whether $answer = bit$. If so B continues the protocol, otherwise B rejects and halts.

After m repetitions of this protocol, if B did not reject thus far, B accepts and halts.

More formally, we proceed to describe first the protocol for B and then the protocol for A. The protocol consists of B going through its first stage, followed by A's first stage, followed by B's second stage, followed by A's second stage, etc., until either A or B chooses to terminate the protocol.

Denote by $v = \{v; v_j\}$ the result of extending sequence v with element v_j.

B's PROTOCOL ON INPUT (x, y).
Check that $x \geqq 1$ and that $y \in \mathbf{Z}_x^*$ and that $(y/x) = 1$.
Set $m = |x|$.
Repeat Stages 1-3 m times.
Stage 1.[1]
    use random bits to pick $r \in \mathbf{Z}_x^*$ and $bit \in \{0, 1\}$.
    IF $bit = 0$ set $w \equiv r^2 \bmod x$, else set $w \equiv r^2 y \bmod x$ FI
    FOR $j = 1, 2, \cdots, m$
        choose random $r_{j1}, r_{j2} \in \mathbf{Z}_x^*$ and random $bit_j \in \{0, 1\}$.
        set $a_j \equiv r_{j1}^2 \bmod x$ and $b_j \equiv r_{j2}^2 y \bmod x$.

[1] The careful reader may observe that picking $r \in Z_x^*$ "exactly at random" can be done in expected polynomial time, while our B must by definition run in a fixed polynomial number of steps. Fortunately, B can pick $r \in Z_x^*$ "almost at random" in a fixed polynomial time. This will have a negligible effect on the result and we omit any further details on this point.

IF $bit_j = 0$ set $\text{pair}_j = (a_j, b_j)$ else set $\text{pair}_j = (b_j, a_j)$ FI
END FOR
SEND $(w, \text{pair}_j \text{ for } j = 1, \cdots, m)$ to A.

Stage 2.
GET from A and m-long bit vector $i = i_1 \cdots i_m$, where $i_j \in \{0, 1\}$.
Initialize the sequence v to the empty sequence.
FOR $j = 1, \cdots, m$
IF $i_j = 0$ then set $v_j = (r_{j1}, r_{j2})$ and set $v = \{v; v_j\}$ FI
IF $i_j = 1$ do one of the following:
IF $bit = 0$ then set $v_j = rr_{j1} \bmod x = \sqrt{wa_j} \bmod x$ and set $v = \{v; v_j\}$
otherwise set $v_j = yrr_{j2} \bmod x = \sqrt{wb_j} \bmod x$ and set $v = \{v; v_j\}$ FI
FI
END FOR
SEND v to A.

Stage 3.
GET $answer \in \{0, 1\}$ from A.
IF $answer \neq bit$ then reject and halt
otherwise go to stage 1 FI.

After m iterations of Stages 1-3, if the protocol has not halted by now, accept and halt.

A's PROTOCOL ON INPUT $(x, y) \in$ QNR.

Stage 1.
GET $(w, \text{pair}_j \text{ for } j = 1, \cdots, m)$ from B.
Pick at random $i = i_1 \cdots i_m$ where $i_j \in \{0, 1\}$.
SEND i to B.

Stage 2.
GET sequence v from B
for every $j = 1, \cdots, m$ check that, if $i_j = 0$, then v_j is a pair (s, t) such that $(s^2 \bmod x, t^2 y \bmod x)$ equals pair_j, possibly with the elements interchanged; and if $i_j = 1$, then $(v_j^2) w^{-1} \bmod x$ is a member of pair_j. If not, SEND *terminate* to B and halt.
(Assume that the above checks have succeeded.)
If w is a quadratic residue mod x, set $answer = 0$ and if w is a quadratic nonresidue mod x, set $answer = 1$.
SEND *answer* to B.
Go to Stage 1.

We first prove that (A, B) is an interactive proof system for QNR.

CLAIM 2. (A, B) *is an interactive proof system for* QNR.

Proof. Clearly (A, B) is an interactive protocol. If $(x, y) \in$ QNR and A and B follow the specification of the protocol, then for every execution of Stages 1-2 by B, w is a quadratic nonresidue mod x if and only if $bit = 1$. Thus, in A's Stage 2, A can always decide whether w is a quadratic residue mod x or not and send *answer* to B such that $answer = bit$ and B will always accept.

Suppose that (x, y) not in QNR (i.e., y is a quadratic residue mod x) and that B is interacting with an arbitrary prover A', in the kth iteration of Stages 1-3. Then we claim that even an A' with infinite computation power cannot distinguish an interaction with B where $bit = 0$ from an interaction with B where $bit = 1$. This is argued as follows. At Stage 1, A' gets the list $(w, \text{pair}_j \text{ for } j = 1, \cdots, m)$, where w is a *random* quadratic residue, and where pair_j simply consists of a pair of *random* quadratic residues. This gives absolutely no information about the value of *bit*.

Now consider Stage 2, where $i_j = 0$. A gets (r_{j1}, r_{j2}). Note that r_{j1} is just a random square root of a_j and r_{j2} is a random square root of $b_j/y \bmod x$. So all that A sees is the result of randomly choosing (or not) to reorder pair_j, and then taking a random square root of the first element and a random square root of the result of dividing the second element by y (all mod x, of course). This gives no information about *bit*.

Now consider the case where $i_j = 1$. If $bit = 0$ then A gets $rr_{j1} \bmod x$, which is a random square root of $wa_j \bmod x$. If $bit = 1$ then A gets $yrr_{j2} \bmod x$, which is a random square root of $wb_j \bmod x$. Since pair_j is a random reordering of (a_j, b_j), v_j is equally likely to be a random square root of w times the first element of pair_j as it is to be a random square root of w times the second element of pair_j, no matter what *bit* is.

Thus, from the information that A' receives in Stages 1 and 2, the value of *bit* is as likely to be 0 as it is to be 1 and the chance that A' predicts *bit* correctly is no greater than $\frac{1}{2}$. In m iterations through Stages 1-3, the probability that A' computed *answer* such that *answer* = *bit* is at most $1/2^m$. □

Proving that the (A, B) proof system is statistically zero-knowledge for QNR is much more complex.

THEOREM 2. *The above protocol* (A, B) *is a statistically zero-knowledge proof system for* QNR.

Proof. Let B' be an arbitrary probabilistic polynomial time interactive Turing machine interacting with A. Let $(x, y) \in \text{QNR}$ be input to (A, B'), let $m = |x|$, and let H be the extra input to B'.

For convenience, consider the random variable $\text{View}_{A,B'}((x, y), H)$ (B''s view of an iteration of the protocol) to consist of the random variables:

$$\text{RAN}, \quad \text{and}$$

$$\{W^k, \{\text{PAIR}_j^k : 1 \leqq j \leqq m\}, \{I_j^k : 1 \leqq j \leqq m\}, V^k, \text{ANSWER}^k \mid 1 \leqq k \leqq m\}.$$

RAN is the string of random bits generated by B'; W^k takes on the value of w in the kth iteration of the protocol; PAIR_j^k takes on the value of pair_j in the kth iteration of the protocol; I_j^k takes on the value of i_j in the kth iteration of the protocol; $V^k = \{V_j^k\}$ takes on the value of the sequence v in the kth iteration of the protocol; and ANSWER^k takes on the value of *answer* in the kth iteration of the protocol.

For simplicity (notational and otherwise) we concentrate on showing that a single iteration of the protocol is zero-knowledge. Doing the general case implies carrying along the view of the protocol so far as was done in the proof of Theorem 1. Thus, from here on we drop all superscripts and work with the random variables: RAN, W, $\{\text{PAIR}_j\}$, $\{I_j\}$, $V = \{V_j\}$, and ANSWER.

Note that in a good execution of the protocol (namely, if B's protocol is followed), we expect that $W = r^2 \bmod x$ or $W = r^2 y \bmod x$, where r is a substring of RAN; and that $\text{PAIR}_j = (r_{j1}^2 \bmod x, r_{j2}^2 y \bmod x)$ or $(r_{j2}^2 y \bmod x, r_{j1}^2 \bmod x)$, where r_{j1} and r_{j2} are substrings of RAN; and that for all $1 \leqq j \leqq m$, if $I_j = 0$ then V_j will equal (r_{j1}, r_{j2}); and if $I_j = 1$ then $V_j = rr_{j1} \bmod x$ or $yrr_{j2} \bmod x$.

However, since B' may not follow the protocol, all we can say about these random variables is that RAN is a random binary string; W (and PAIR_j) are assigned values w (and pair_j) computed by B' on inputs x, y, H and RAN; I is a random binary string of length m; and V_j is a value computed by B' on inputs x, y, H, RAN, I.

We will now describe a probabilistic Turing machine M that, given $(x, y) \in \text{QNR}$ and H, runs in expected polynomial time, and whose output distribution is statistically indistinguishable from $\text{View}_{A,B'}((x, y), H)$.

M starts by outputting a random string *ran* of the appropriate length and running B' on inputs (x, y, H), and random tape *ran* on it. B' goes through Stage 1 outputting w, pair_j, for $1 \leqq j \leqq m$.
Next, M chooses $i_1, \cdots, i_m$ at random in $\{0, 1\}$, sets $i = i_1 \cdots i_m$, and writes i on B'"s communication tape, activating B'"*s* Stage 2.
B' goes into Stage 2, writing on its communication tapes a sequence $v = \{v_j\}$. M outputs $w\{\text{pair}_j\}$, i, v.
Next M does the checking that A does in Stage 2.
If the check fails M outputs "*terminate*" and halts.

Let us assume that the check succeeds. Think of x, y, H, *ran* as being fixed, so that w and $\{\text{pair}_j\}$ are also fixed. The fact that the check succeeds means that A sending i to B' causes B' to send a v to A, which causes A to send a one-bit *answer* to B' (rather than *terminate*); let us call any such i' *special.* M has just computed that i is special, and now wants to compute the value of *answer* that A would send. This value is 0 if w is a quadratic residue mod x, and 1 otherwise. Since B' may not have computed w the way B would have, it is not obvious how to compute the quadratic residuosity of w, i.e., *answer.*

It turns out that finding one other special string $i' \neq i$ will allow M to determine if w is a quadratic residue, as follows:

> Say that $i_j = 0$ and $i'_j = 1$ and i, i' are special. Let v, v' be the sequences sent by B' after receiving i or i' (respectively); these can be computed in polynomial time by running B'. Since $i_j = 0$, $v_j = (s, t)$, where $(s^2 \bmod x, t^2 y \bmod x)$ equals pair_j, possibly with the elements reversed. Since $i'_j = 1$, $(v_j)^2 w^{-1} \bmod x \in \text{pair}_j$. If $(v_j)^2 w^{-1} \bmod x = s^2 \bmod x$, then w is a quadratic residue mod x; if $(v_j)^2 w^{-1} \bmod x = t^2 y \bmod x$ then w is a quadratic nonresidue mod x.

It therefore remains to find a special $i' \neq i \bmod x$. M uses the following algorithm.

ALGORITHM TO FIND A SPECIAL $i' \neq i$.

> Test 2^m random i' of length m (with replacement), halting when either a special $i' \neq i$ is found, or when 2^m strings have been tried. If no special $i' \neq i$ has been found, then test *all* m-bit strings (in order), looking for a special $i' \neq i$.

If a special $i' \neq i$ is found, then M calculates *answer* as explained above and outputs *answer.* If no such i' exists, then M outputs "?"; note that this will happen when i is the *only* special string.

In order to show that M operates in expected polynomial time, it is sufficient to show that M operates in expected polynomial time for each fixed value of (x, y, H, ran). Say that x, y, H, *ran* are fixed, and so w, pair are also fixed. Let k be the number of strings i that are special. If $k = 0$, then the ALGORITHM TO FIND A SPECIAL i' will not be invoked, and the running time is clearly polynomial in m. If $k = 1$, then with probability $(1/2^m)M$ will choose a special i; in that case the ALGORITHM will run for time $2^m m^c$ (for some c), so the expected running time is $(1/2^m)2^m m^c +$ a polynomial in m.

Assume that $k > 1$. M will choose a special i with probability $k/2^m$. To calculate an upper bound on the expected running time of the ALGORITHM, imagine that it was changed so that it tested random i', including i and with replacement, halting if and when a special $i' \neq i$ is found; the expected running time would be at least half that of the ALGORITHM. In effect, a coin is being tossed until "heads" comes up, where the probability of "heads" is exactly $(k-1)/2^m$. It is well known that the expected number of coin tosses is exactly $2^m/(k-1)$. Hence the expected time for the

ALGORITHM is $\leqq(2^m/(k-1))m^c$ (for some c). The total expected time is $\leqq(k/2^m)$-$(2^m/(k-1))m^c$ + a polynomial in m, which is polynomial in m.

Recall that $M((x, y), H)$ is the random variable denoting the distribution of M's output given x, y, H. It remains to show that M is statistically close to $\text{View}_{A,B'}$. Fix x, y, H. If *ran* is such that the number of special strings is not exactly 1, then any output string α beginning with *ran* is taken on by $\text{View}_{A,B'}((x, y), H)$ with exactly the same probability as by $M((x, y), H)$. Let S be the set of $\alpha = ran, w, \{\text{pair}_j\}, i, v, answer$, where i is the *unique* special string determined by *ran*. The probability that $\text{View}_{A,B'}((x, y), H)$ takes on a value in S is $\leqq 1/2^m$, since for each *ran* there is at most one i, which will be the unique special string. Similarly, the probability that $M((x, y), H)$ takes on a value in S is $\leqq 1/2^m$. Thus,

$$\sum_{\alpha} |\text{prob}\,(M((x, y), H) = \alpha) - \text{prob}\,(\text{View}_{A,B'}((x, y), H) = \alpha)|$$

$$= \sum_{\alpha \notin S} |\text{prob}\,(M((x, y), H) = \alpha) - \text{prob}\,(\text{View}_{A,B'}((x, y), H) = \alpha)|$$

$$+ \sum_{\alpha \in S} |\text{prob}\,(M((x, y), H) = \alpha) - \text{prob}\,(\text{View}_{A,B'}((x, y), H) = \alpha)|$$

$$\leqq 0 + \frac{1}{2^m} + \frac{1}{2^m} = \frac{2}{2^m}.$$

And for m iterations of the protocol, the difference is

$$\sum_{\alpha} |\text{prob}\,(M((x, y), H) = \alpha) - \text{prob}\,(\text{View}_{A,B'}((x, y), H) = \alpha)| \leqq \frac{2m}{2^m}.$$

This completes our proof. □

Remarks. In fact, the above protocol can be shown to be perfect zero-knowledge. We just have to change M so that when it discovers that i is the unique special string it *factors* x in time roughly 2^m, and then determines if w is a quadratic residue mod x in polynomial time. This does not change the expected running time by more than a polynomial factor, since when M decides to do this extra work, it has already spent time 2^m.

7. Related work.

7.1. Work related to interactive proof systems. In studying his Arthur-Merlin games, Babai [Ba] has focused on the number of *rounds*, i.e., the number of times the prover and the verifier alternate in sending messages. Babai denotes the set of all languages accepted by i *rounds* in an Arthur-Merlin proof system by AM[i], and AM[$f(n)$] denotes the set of languages accepted by an Arthur-Merlin proof system with $f(n)$ rounds. Here f is a nondecreasing function from natural numbers to natural numbers, and n the length of the input.

The elegant simplicity of Babai's definition allowed him to show that for every constant k, AM[k] collapses to AM[2]. This in turn is a subset of both Π_2^p and nonuniform NP.

We define IP[$f(n)$] as the class of languages having an interactive proof system with $f(n)$ rounds.

Goldwasser and Sipser [GS] show that, for all f, AM[$f(n)$] = IP[$f(n)$].

On the other hand, Aiello, Goldwasser, and Hastad [AGH] have shown that for any two nonconstant functions $g(n)$ and $f(n)$ such that $g(n) = o(f(n))$, there exists an oracle X such that (if we modify the definitions so that one is computing using the oracle X) IP[$g(n)$] is strictly contained in IP[$f(n)$]. This result is tight as Babai and Moran [BM] have shown that for all constants $c > 0$, IP[$f(n)$] = IP[$cf(n)$]. Namely, IP[$O(f(n))$] is well defined.

An interesting question is the following. Where does IP stand with respect to the polynomial time heirarchy? Boppana, Hastad, and Zachos [BHZ] have shown that if CO-NP has a constant-round interactive proof system, then the polynomial time hierarchy collapses. Thus, from the results of [GMW], [GS], and [BHZ], it follows that graph isomorphism is not NP-complete unless the polynomial time hierarchy collapses.

Other works related to the study of randomized and nondeterministic complexity classes appear in [P] and [ZF]. In Papadimitriou's *Games Against Nature*, the verifier is also a probabilistic polynomial time machine that flips coins and presents them to a prover capable of optimal moves. This is different from our model in that L is said to be accepted by a game against nature if $x \in L$ implies that the probability of the prover to win the game is greater than a $\frac{1}{2}$ rather than bounded away from a $\frac{1}{2}$.

Zachos and Furer [ZF], in a work investigating the robustness of probabilistic complexity classes, introduce a framework of probabilistic existential and universal quantifiers and prove several combinatorial lemmas about them. The AM and thus IP complexity classes can be formulated in terms of these special quantifiers.

7.2. Work related to knowledge complexity. Prior to our work, the theory of knowledge had received much attention in a model-theoretic framework (see [FHV] and [HM] for discussion). There are several essential differences between this framework and ours. In the latter, knowledge is defined with respect to a specific computational model with specific computational resources. In the former framework, there are no limitations on the computational power of the participants, i.e., they "know" all logical consequences of the information they possess. (For discussion of this aspect see, *Belief, Awareness, and Limited Reasoning* [FH].) As for another difference, in our model knowledge is defined with respect to an available public input and is gained by computing on this input. In their model-theoretic framework knowledge is gained by being told (or witnessing) that a certain event is true (e.g., the outcome of a coin flip is heads), rather than by computing.

Galil, Haber, and Yung [GHY] proposed the following extension of the concept of a zero-knowledge interactive proof systems. A language L is said to have a result-indistinguishable zero-knowledge proof system if there exists an interactive protocol (A, B) such that for every string $x \in \{0, 1\}^*$, A can convince B that $x \in L$ or x is not in L (whichever is the case) with high probability, such that no passive observer C can get any information of which is the case. They give a result-indistinguishable proof system for QR.

As previously mentioned, Goldreich, Micali, and Wigderson [GMW] have shown, subject to the existence of secure encryption schemes, that all languages in NP have computationally zero-knowledge proof systems. Subsequently, related notions of proof systems and zero knowledge were given by Brassard and Crepeau [BC] and Chaum [Ch]. They found that for any language L in NP, there is an interactive protocol that

(1) is zero-knowledge, and
(2) proves membership in L correctly (i.e., with probability approaching 1) only if factoring is computationally difficult and the prover is polynomial time.

Let us explicitly contrast their protocols with the ones in [GMW]. The latter ones

(1) correctly prove membership in L, and
(2) are zero-knowledge only if secure encryption schemes exist (which is true if factoring is difficult).

Finally, let us mention the recent result of Fortnow.

THEOREM [Fo]. *Assume a language L has an interactive proof system (A, B) that is statistically zero-knowledge with respect to B. Then L's complement has a constant-round interactive proof system.*

As a corollary, if SAT had statistically zero-knowledge proof systems, the polynomial time hierarchy would collapse.

Note that the hypothesis of Fortnow's theorem is much weaker than saying that (A, B) is a statistically zero-knowledge proof system on L, which would mean that, for all verifiers B', A is zero-knowledge on L for B'. Usually, it is defeating this latter quantifier "for all" that makes it hard to find a perfect or statistically zero-knowledge proof system. Thus Fortnow's result has the potential to be widely applicable.

Acknowledgments. We thank Mike Sipser, Steve Cook, and Mike Fischer who helped us focus on this research from its beginning. Without their enthusiastic encouragement we might not have completed this work.

Oded Goldreich and Ron Rivest, as usual, have been generous with comments and ideas. Thanks also go to Leonid Levin, Zvi Galil, and Dan Simon for having helped us in various ways.

Special thanks to Josh Cohen for simplifying our original zero-knowledge protocol for proving quadratic nonresiduosity. Thanks are also due to Manuel Blum for sharing with us so many beautiful ideas about cryptographic protocols.

Finally, we thank the anonymous referees, whose comments greatly improved this paper.

A LOWER BOUND ON THE COMPLEXITY OF DIVISION IN FINITE EXTENSION FIELDS AND INVERSION IN QUADRATIC ALTERNATIVE ALGEBRAS*

THOMAS LICKTEIG†

Abstract. Let k be a field. The author continues the work of Lickteig [*SIAM J. Comput.*, 16 (1987), pp. 278-311] and extends it in two directions: (1) A lower bound on the Ostrowski complexity of division in a finite extension field $A \supset k$: $L_{\mathrm{DIV}} \geqq 3[A:k] + \log_2[B:k] - 2$, where $B \subset A$ is some simple extension of k of maximal degree. The proof combines the technique of adjoining intermediate results to the ground field [T. Lickteig, *op. cit.*] and lower bound criteria for approximative complexity recently obtained by Griesser [*Theoret. Comput. Sci.*, 46 (1986), pp. 329-338].

(2) An optimal lower bound for the complexity of inversion in a quadratic alternative algebra A of dimension greater than or equal to 2, $A \neq k \times k$: $L_{\mathrm{INV}} = 2 \dim A -$ index of the norm.

Key words. arithmetic in finite extension fields, Ostrowski complexity, substitution method, adjunction of intermediate results to the groundfield and approximative complexity

AMS(MOS) subject classifications. 68C20, 68C25

Throughout this paper k is assumed to be an infinite field. We use the same notation as in [8, § 2].

1. Finite extension fields. Let $A \supset k$ be a finite extension, $m = [A:k]$. Division in A is a k-rational mapping:

$$A \times A \to A, \qquad (x, y) \mapsto x^{-1}y,$$

with A being viewed as m-dimensional k-vector space. When we fix a k-basis $\omega_1, \cdots, \omega_m$ of A and use the basis $(\omega_1, 0), \cdots, (0, \omega_m)$ of $A \times A$, division is given by rational functions $q_1, \cdots, q_m \in k(X_1, \cdots, X_m, Y_1, \cdots, Y_m)$ such that $x^{-1}y = \sum_{i \leqq m} q_i(\boldsymbol{\alpha}, \boldsymbol{\beta})\omega_i$ if $x = \sum_{i \leqq m} \alpha_i \omega_i$, $y = \sum_{i \leqq m} \beta_i \omega_i$ with $\alpha_i, \beta_i \in k$. The complexity of division L_{DIV} is defined as the Ostrowski complexity $L(q_1, \cdots, q_m)$ (cf. [2]). As is easily verified, L_{DIV} does not depend on the choice of the bases, so it is well defined.

As k is assumed to be infinite, we may equivalently view $k(\mathbf{X}, \mathbf{Y})$ as functions on $A \times A$. Accordingly, in the sequel we allow ourselves to change to the function interpretation if it is more convenient. In this sense $X_1, \cdots, Y_m$ is the dual basis to $(\omega_1, 0), \cdots, (0, \omega_m)$ in $(A \times A)^*$.

We note that division always has a reduction to multiplication; also in the more general case of arbitrary associative algebras A: for a unit $\zeta \in A^x$ and $\eta \in A$, we have the expansion

$$(\zeta - \zeta x)^{-1} \cdot (\eta + \zeta(y - x\zeta^{-1}\eta)) = \zeta^{-1}\eta + \zeta^{-1}x\eta + y + xy + (\text{higher-order terms}).$$

Now, choosing (ζ, η) appropriately and applying Strassen's idea of computing the quadratic terms [9], we obtain for the left division $L_{\mathrm{LDIV}} \geqq L_{\mathrm{MULT}}$. Similarly for the right division in A, we obtain $L_{\mathrm{RDIV}} \geqq L_{\mathrm{MULT}}$. Both coincide if A possesses an anti-automorphism. So in case of finite field extensions $L_{\mathrm{DIV}} \geqq 2m - 1$ by Fiduccia and

Zalcstein [4], Winograd [10], and Alder and Strassen [1]; and for simple extensions this lower bound is the best we can get in this way.

To obtain a more explicit representation for the q_i, we recall the norm function $N_k^A: A \to k$, $N_k^A(x)$ being defined as the determinant of the regular representation R_x of $x \in A$ (e.g., [7]). Let S denote the maximal separable extension, $k \subset S \subset A$. By the transitivity of the norm $N_k^A = N_k^S \circ N_S^A$, where $N_S^A: x \mapsto x^\nu$, $\nu = [A:k]_i = [A:S]$. Let $\mu = \min\{\nu: \forall x \in A, x^\nu \in S\}$. By the theorem on primitive elements, we have

$$\begin{aligned} \mu &= \max\{[B:k]_i: B \subset A, B \supset k \text{ simple}\} \\ &= \max\{[B:k]/[S:k]: B \subset A, B \supset k \text{ simple}\}. \end{aligned} \tag{1}$$

The *principal norm* $N: A \to k$ is defined by $N(x) = N_k^S(x^\mu)$ for $x \in A$. Let $n: A \times A \to k$ be the composition $N \circ \pi_1$ of N with the first projection; so $n \in k[\mathbf{X}]$, and by (1) $\deg n = \max\{[B:k]: B \subset A, B \supset k \text{ simple}\}$. Let k^a denote an algebraic closure of k, and $\mathcal{J}$ the set of all embeddings $\iota: A \hookrightarrow k^a (|\mathcal{J}| = [A:k]_s)$. In $k^a[\mathbf{X}] (= k^a \otimes_k k[\mathbf{X}])$, n has the linear factorization

$$n = \prod_{\iota \in \mathcal{J}} \left(\sum_{j=1}^{m} \iota\omega_j X_j \right)^\mu, \tag{2}$$

while n is irreducible in $k[\mathbf{X}]$ (as $n(\alpha_1 X - \beta_1, \cdots, \alpha_m X - \beta_m) = \operatorname{Irr}(\iota\omega, k, X)$ if $1 = \sum \alpha_i \omega_i$ and $\omega = \sum \beta_i \omega_i$ has maximal degree over k ($\alpha_i, \beta_i \in k$, $\iota \in \mathcal{J}$)). It follows that the q_i can be written in a reduced quotient representation as

$$q_i = \frac{1}{n} \sum_{j=1}^{m} a_{ij} Y_j \qquad (i \leqq m), \tag{3}$$

with $a_{ij} \in k[\mathbf{X}]$, $\deg a_{ij} = \deg n - 1$.

For later purpose we remark that every nonzero $f \in A^*$ induces an isomorphy of A with A^*:

$$A \cong A^* \quad \text{by } \theta \mapsto R_\theta^*(f) = f \circ R_\theta \quad (f \in A^* - \{0\}) \tag{4}$$

($\theta \neq 0 \Rightarrow f(\theta A) = f(A) \neq 0$ implies injectivity).

As in [8] we now follow de Groote's line (initiated in [6]) of first finding the symmetries of the computation problem. The affine group $\operatorname{Aff}(A \times A, k)$ operates in the natural way on $k(\mathbf{X}, \mathbf{Y})$, and thus also on $k^a(\mathbf{X}, \mathbf{Y}) = (k^a \otimes_k k(\mathbf{X}, \mathbf{Y}))$. The symmetry group Γ of the division is defined as follows:

$$\Gamma = \{\alpha \in \operatorname{Aff}(A \times A, k): L(q_1, \cdots, q_m \bmod q_1^\alpha, \cdots, q_m^\alpha) = 0\}.$$

This means

$$kq_1 + \cdots + kq_m + \Lambda = kq_1^\alpha + \cdots + kq_m^\alpha + \Lambda, \tag{5}$$

where $\Lambda = kX_1 + \cdots + kY_m + k$. We have an embedding $\Delta(2, A) \hookrightarrow \Gamma$ of the group $\Delta(2, A)$ of triangular 2×2 matrices over A into Γ via $\left(\begin{smallmatrix} \zeta & \eta \\ 0 & \theta \end{smallmatrix}\right) \mapsto ((x, y) \mapsto (x\zeta, x\eta + y\theta))$ as the following diagram

$$\begin{array}{ccc} A^x \times A & \longrightarrow & A \\ {\scriptstyle \left(\begin{smallmatrix} \zeta & \eta \\ 0 & \theta \end{smallmatrix}\right)} \downarrow & & \downarrow {\scriptstyle R_{\zeta^{-1}\theta + \zeta^{-1}\eta}} \\ A^x \times A & \longrightarrow & A \end{array} \tag{6}$$

commutes; here the horizontal mappings indicate division.

Similarly, we have an embedding $\operatorname{Aut}(A/k) \hookrightarrow \Gamma$, $\alpha \mapsto (\alpha, \alpha)$ of the Galois group $\operatorname{Aut}(A/k)$ into Γ, for (6) with the vertical mappings replaced by (α, α) and α commutes.

THEOREM 1. *Let $A \supset k$ be a finite field extension. The symmetry group of division in A over k is*

$$\Gamma = \Delta(2, A) \cdot \mathrm{Aut}\,(A/k).$$

Proof. As $\Delta(2, A)$ and $\mathrm{Aut}\,(A/k)$ commute, their product is a subgroup of Γ. To prove the nontrivial inclusion, let $\alpha \in \Gamma$ be given. Let $X = \sum \omega_j X_j$, $Y = \sum \omega_j Y_j \in A(\mathbf{X}, \mathbf{Y})(= A \otimes_k k(\mathbf{X}, \mathbf{Y}))$. (As functions on $A \times A$, $X = \pi_1$ and $Y = \pi_2$.) Comparing denominators in (5), we get $n = \lambda n^\alpha$ with some $\lambda \in k^\times$ because n is irreducible in $k[\mathbf{X}]$. Extending the $\iota \in \mathcal{J}$ canonically, $\iota : A(\mathbf{X}) \hookrightarrow k^a(\mathbf{X})$, we get in $k^a[\mathbf{X}]$

$$\left(\prod_{\iota \in \mathcal{J}} \iota X\right)^\mu = \lambda \left(\prod_{\iota \in \mathcal{J}} \iota X^\alpha\right)^\mu,$$

by $(\iota X)^\alpha = \iota X^\alpha$. Thus there are ι, $\iota' \in \mathcal{J}$, $\theta' \in (k^a)^\times$ such that $\iota X = \theta'(\iota' X^\alpha)$. Using function interpretation on $A \times A$ and evaluating both sides at $(\alpha 1, 0)$, it follows that $\theta' \in \iota A$, say $\theta' = \iota\theta$. Thus, $\iota' X^\alpha = \iota(\theta^{-1} X) = \iota X^{\left(\begin{smallmatrix} \theta & 0 \\ 0 & 1 \end{smallmatrix}\right)}$, and hence we may assume without loss of generality $\iota' X^\alpha = \iota X$, by the action of $\Delta(2, A)$. But then $\iota A \subset \iota' A$; thus $\iota A = \iota' A$. So $\iota^{-1}\iota' \in \mathrm{Aut}\,(A/k)$. Thus, by the action of (the embedded copy of) $\mathrm{Aut}\,(A/k) \subset \Gamma$, we may change α such that $X^\alpha = X$. It suffices to prove $Y^\alpha \in AX + AY$, for then $\alpha \in \Delta(2, A)$. Equivalently we show $AY^\alpha + AX = AY + AX$. This is obtained by extending the ground field in (5) to A, multiplying (5) by $X = X^\alpha$, and intersecting with $A\Lambda$. To see this, it suffices to verify that

$$AY = (AXq_1 + \cdots + AXq_m) \cap A\Lambda;$$

the corresponding identity then also holds for Y^α. Let $\sum \xi_i X q_i \in A\Lambda$ with $\xi_i \in A$, $1 = \sum \alpha_i \omega_i$ with $\alpha_i \in k$. Substituting $Y_i \mapsto \alpha_i$ we obtain $\sum \xi_i X q_i(\mathbf{X}, \boldsymbol{\alpha}) \in A$, as the q_i are linear in $\mathbf{Y}$ (cf. (3)). Since the image of inversion is $A^\times$, $q_1(\mathbf{X}, \boldsymbol{\alpha}), \cdots, q_m(\mathbf{X}, \boldsymbol{\alpha}) \in k(\mathbf{X})$ are k-linearly independent, and, as A and $k(\mathbf{X})$ are linearly disjoint over k, they are also A-linearly independent. It follows that $\xi_1 = \xi\omega_1, \cdots, \xi_m = \xi\omega_m$ for some $\xi \in A$. Thus $\sum \xi_i X q_i = \xi Y$.

THEOREM 2. *Let $A \supset k$ be a finite extension field, and let $B \subset A$ be a simple extension of k of maximal degree. Then*

$$L_{\mathrm{DIV}} \geqq 3[A : k] + \log_2 [B : k] - 2.$$

Remark. For quadratic extensions the bound is 5, so the result of [8] $L_{\mathrm{DIV}} = 6$, which requires much more involved considerations, is not within reach of this bound.

Proof. The proof is done in three steps. For convenience we assume without loss of generality that $\omega_1 = 1$.

(i) $L(q_1) \leqq L(q_1, \cdots, q_m) - (m-1)$. To see this, we observe that any nontrivial linear combination of $q_1, \cdots, q_m$ can be written as $q_1^{\left(\begin{smallmatrix} 1 & 0 \\ 0 & \theta \end{smallmatrix}\right)}$ for some $\theta \in A^\times$ (use (4) and (6)). On the other hand, if $(p_1, \cdots, p_r)$ is a computation sequence for $\{q_1, \cdots, q_m\}$, an elimination shows that $(p_1, \cdots, p_{r-m+1})$ is a computation sequence for some nontrivial linear combination of them. Now use the fact that complexity is constant on Γ-orbits.

(ii) There exists $f \in k(\mathbf{X})$ such that $L((a_{11}/n) Y_1 + f) \leqq L(q_1) - (m-1)$: First we remark that for every $\xi = \sum \alpha_i \omega_i \in A^\times$, a_{11}/n is in the Γ-orbit of $q_1(\mathbf{X}, \boldsymbol{\alpha})$ (by $\left(\begin{smallmatrix} \zeta^{-1} & 0 \\ 0 & 1 \end{smallmatrix}\right) \in \Delta(2, A)$). There exists $q^{(m)} = q_1, q^{(m-1)}, \cdots, q^{(1)}$ with $L(q^{(s-1)}) < L(q^{(s)})$ of the form

$$q^{(s)} = \sum_{i \in I} \frac{1}{n} \left(a_{1i} + \sum_{j \notin I} \alpha_{ij} a_{1j}\right) Y_i + f,$$

where $I \subset \{1, \cdots, m\}, |I| = s, \alpha_{ij} \in k, f \in k(\mathbf{X})$. As follows from the remark, the coefficient of each Y_i is not contained in k, so $L(q^{(s)}) \neq 0$. Thus there exists a substitution of one of the Y_i of the kind

$$Y_i \mapsto \sum_{j \in I - \{i\}} \alpha_j Y_j + \tilde{f}$$

with $\alpha_j \in k$, $\tilde{f} \in k(\mathbf{X})$, reducing the complexity of $q^{(s)}$. This defines $q^{(s-1)}$ given $q^{(s)}$. By the remark, $q^{(1)}$ can be assumed to be of the form $(a_{11}/n) Y_1 + f$.

(iii) For all $f \in k(\mathbf{X})$ $L((a_{11}/n) Y_1 + f) \geqq m + \log \deg n$. The first member p not in $k(\mathbf{X})$ in an optimal computation sequence for $(a_{11}/n) Y_1 + f$ can be written as $p = (\cdots)^*/(Y_1 - h)$, or as $p = (Y_i - h)/g$ with $g, h \in k(\mathbf{X})$. Here we use the stronger technique from [8] of adjoining a certain intermediate result to the ground field and deleting an operation of arity zero. In our case we adjoin $t = (Y_1 - h)/g$ to k ($g = 1$ in the first case) and delete Y_1 in order to reduce the complexity, obtaining

$$\left(\frac{a_{11}}{n} g\right) t + \left(\frac{a_{11}}{n} h + f\right).$$

After multiplying the above by t^{-1}, it becomes degenerable into $a_{11} n^{-1} g$ (by $t^{-1} \mapsto 0$). So the complexity $L((a_{11}/n) Y_1 + f)$ is greater than the approximative complexity $\mathbf{L}(a_{11} n^{-1} g)$ (cf. Griesser [5], Bini [2], or the definition below). If n does not divide the reduced numerator of g, the subsequent lemma yields the desired result. Otherwise we apply the lemma to the intermediate result g, and use $L((a_{11}/n) Y_1 + f) > L(g)$.

Steps (i), (ii), and (iii) imply the assertion.

Let ε be a further indeterminate over k, $k_\varepsilon = k(\varepsilon)$, and let $\mathcal{O}_\varepsilon \subset k_\varepsilon(X_1, \cdots, X_m)$ be the domain of $\varepsilon \mapsto 0$ (a discrete valuation ring). The *approximative complexity* $\mathbf{L}(f_1, \cdots, f_s)$ of $f_1, \cdots, f_s \in k(\mathbf{X})$ is defined as the minimum $k_\varepsilon(\mathbf{X})$-complexity of some $F_1, \cdots, F_s \in \mathcal{O}_\varepsilon$ such that $F_{i(\varepsilon=0)} = f_i$ for $i \leqq s$ (cf. Griesser [5] and Bini [2]).

LEMMA 1. *Let $f = r/s$ with $r, s \in k[\mathbf{X}]$ be nonzero and reduced. Then $\mathbf{L}(f) \geqq m - 1 + \log \deg n$ if $n \mid r$, and $\mathbf{L}(f) \geqq m - 1 + \log (\deg n + 1)$ if $n \mid s$.*

For the proof we recall a result in [5]. There Griesser extends the substitution method to the approximative model. In terms of adjunction of intermediate results to the ground field [5], formulation and proof of his result become more transparent. Let us call $f \in k(\mathbf{X})$ K-linear if $f \in KX_1 + \cdots + KX_m + K$, $K \subset k(\mathbf{X})$ a subfield. We shall need Griesser's result in the following form.

THEOREM 3 [5]. *Let $f_1, \cdots, f_s \in k(\mathbf{X})$, not all k-linear.*

(i) *There exist a k-linear $l \in k(\mathbf{X})$ such that adjunction of l to k and deletion of some X_j reduces $\mathbf{L}(f_1, \cdots, f_s)$.*

(ii) *$r := \mathbf{L}(f_1, \cdots, f_s) \leqq m$ implies the existence of a tower of purely transcendental extensions $k = K_0 \subset K_1 \subset \cdots \subset K_r \subset k(\mathbf{X})$ such that*

$$\forall 1 \leqq i \leqq r \quad K_i = K_{i-1}(l_i), \qquad l_i \quad K_{i-1}\text{-linear},$$

$$f_1, \cdots, f_s \quad K_r\text{-linear}.$$

Proof. (i) The first member p in an optimal approximative computation sequence for $f_1, \cdots, f_s$ can be written as $p = (\cdots)^*/(\sum_1^m \beta_i X_i + \beta_0)$ with $\beta_i \in k_\varepsilon$. Without loss of generality $\nu_\varepsilon(\sum_1^m \beta_i X_i) = 0$, where ν_ε denotes the valuation associated with $\mathcal{O}_\varepsilon$ (shift a power of ε to the first operand). We use an idea from [3, p. 488] to make $\tilde{l} = \sum_1^m \beta_i X_i$ k-linear by means of a linear transform according to some $M \in k_\varepsilon^{m \times m}$ with $\nu_\varepsilon(M) \geqq 0$ and $M_{(\varepsilon=0)} = 1$ as follows. If $\nu_\varepsilon(\beta_j) = 0$, then

$$\tilde{l} = \beta_j X_j + \sum_{\substack{\nu_\varepsilon(\beta_i) = 0 \\ i \neq j}} \beta_i X_i + \sum_{\nu_\varepsilon(\beta_i) > 0} \beta_i X_i$$

is transformed to

$$l = \beta_j\left(\frac{\beta_j(0)}{\beta_j} X_j - \sum_{\nu_\varepsilon(\beta_i)>0} \frac{\beta_i}{\beta_j} X_i\right) + \sum_{\substack{\nu_\varepsilon(\beta_i)=0 \\ i\neq j}} \beta_i\left(\frac{\beta_i(0)}{\beta_i} X_i\right) + \sum_{\nu_\varepsilon(\beta_i)>0} \beta_i X_i = \tilde{l}_{(\varepsilon=0)}.$$

It is now clear that $\mathbf{L}(f_1, \cdots, f_s)$ decreases if we adjoin l to k and delete X_j.

(ii) Is proved by induction using (i).

Proof of Lemma 1. By Theorem 3(i) there is some $l = X_j + \sum_{i\neq j} \alpha_i X_i (\alpha_i \in k)$ such that adjunction of l to k and deletion of X_j reduces $\mathbf{L}(f)$. We consider the effect on n more closely. When we substitute X_j, the linear factors become $\sum_{i\neq j} (\iota\omega_i - \alpha_i \iota\omega_j) X_i + \iota\omega_j l \notin k^a(l)$. So, as n as element of $k[\mathbf{X}] = k[l][X_1, \cdots, X_{j-1}, X_{j+1}, \cdots, X_m]$ is irreducible, n as element of $k(l)[X_1, \ldots, X_{j-1}, X_{j+1}, \ldots, X_m]$ is irreducible (by the Gauss lemma) and has the same degree. $m-1$ repetitions of this argument and a final application of the degree bound [5] yield the desired statements.

For inversion in a finite extension field we get the following corollary.

COROLLARY. *Let $A \supset k$ be a finite extension field, $B \subset A$ simple of maximal degree over k. Then*

$$L_{\mathrm{INV}} \geqq 2[A:k] + \log_2([B:k]+1) - 2.$$

Proof. Without loss of generality $\omega_1 = 1$. There is a nontrivial linear combination f of $a_{11}/n, \cdots, a_{m1}/n$ such that $L(a_{11}/n, \cdots, a_{m1}/n) \geqq L(f) + m - 1$. Now apply Lemma 1.

Remarks. (1) As we shall see in the next section (Example (6)), this lower bound is sharp for quadratic A ($\deg n = 2$).

(2) It is not clear whether the complexity of inversion (respectively, division) also has a linear upper bound. In certain cases, however, this is true. Assume there exists a tower $k = A_0 \subset A_1 \subset \cdots \subset A_s = A$ of subfields, with $A_i \supset k$ simple and the degrees $[A_i : A_{i-1}]$ bounded by some constant. Then, via computing the inverses of the norms $N_{A_{i-1}}^{A_i}$, we get a recurrence for inversion in A_i (over k) as

$$L_{\mathrm{INV}}(A_i) \leqq L_{\mathrm{INV}}(A_{i-1}) + C \cdot L_{\mathrm{MULT}}(A_{i-1})$$

for some constant C. Since multiplication in A_{i-1} (over k) has a linear upper bound [4], [10], this leads to a linear upper bound for the complexity of inversion in A (over k).

2. Quadratic alternative algebras. Let A be a finite-dimensional alternative algebra over k with identity element 1, i.e., we have the following weak associativity laws $x^2 y = x(xy)$ and $yx^2 = (yx)x$ for all $x, y \in A$. A is called *quadratic* if 1, x, x^2 are linearly dependent for all $x \in A$. In these algebras trace and norm t, $n : A \to k$ can be introduced such that for all $x \in A$

$$x^2 - t(x) + n(x) = 0;$$

t is linear, and n is a quadratic form (cf. [1, p. 37]). With the involution $x \mapsto \bar{x} = t(x) - x$, $t(x) = x + \bar{x}$, and $n(x) = x\bar{x}$. As is easily seen, $x \in A$ has a right inverse if and only if x has a left inverse if and only if right multiplication with x is regular if and only if left multiplication with x is regular if and only if $n(x) \neq 0$. Thus *the* inverse $x^{-1} = \bar{x}/n(x)$ is well defined if $n(x) \neq 0$. Let us define the index of n as $\mathrm{ind}(n) = \max\{\dim L : L \subset A$ a linear subspace, $n(L) = 0\}$. (For nondegenerate quadratic forms in char $k \neq 2$ this is the Witt index.) A has zero divisors if and only if $\mathrm{ind}(n) > 0$.

THEOREM 4. *Let A be a quadratic alternative algebra with identity element of dimension $\geqq 2$, $A \neq k \times k$. Then*

$$L_{\mathrm{INV}} = 2 \dim A - \mathrm{ind}\,(n).$$

Proof. Let $X_1, \cdots, X_m$ be indeterminates over k, $m = \dim A$. Via the choice of a basis we view n as an element of $k[\mathbf{X}]$. We have

$$L_{\mathrm{INV}} = L(X_1/n, \cdots, X_m/n),$$

as $x \mapsto \bar{x}$ is involutional, and therefore regular. Thus $L_{\mathrm{INV}} \leqq m + L(n) = 2m - \mathrm{ind}\,(n)$, by Strassen [9, § 4, Anwendung 7]. For the lower bound first we consider the case where n is reducible, $\mathrm{ind}\,(n) = m-1$. If $m=2$, then $A = k[T]/(T^2)$, and a direct calculation shows $L(X_2/X_1^2, 1/X_1^2) = 3$ ($n = X_1^2$, say). If $m \geqq 3$ and n is a square, say $n = X_1^2$, then two linearly independent linear combinations of the X_i/n have complexity $\leqq L_{\mathrm{INV}} - (m-3)$, and the assertion follows from $L(X_2/X_1^2, X_3/X_1^2) \geqq L(X_2/X_1^2, 1/X_1^2) = 3$ (replace X_3 by a multiple of X_1 in order to get this inequality). If n is not a square, say $n = X_1X_2$, then three linearly independent linear combinations of the X_i/n have complexity less than or equal to $L_{\mathrm{INV}} - (m-4)$. Here the result is obtained from $L(X_3/X_1X_2,\ X_4/X_1X_2,\ X_5/X_1X_2) \geqq L(X_3/X_1X_2,\ X_4/X_1X_2,\ 1/X_2 + \alpha/X_1) \geqq L(X_3/X_1X_2,\ 1/X_1,\ 1/X_2) > L(X_3/X_1^2,\ 1/X_1^2) = 3$, $\alpha \in k$ (here replace successively X_5, X_4, X_2 by multiples of $X_1 + \alpha X_2$, X_2, X_1, respectively, in order to get these inequalities). If $\mathrm{ind}\,(n) \leqq m-2$, a nontrivial linear combination f of the X_i/n has complexity less than or equal to $L_{\mathrm{INV}} - (m-1)$. Now, $m - \mathrm{ind}\,(n) - 2$ successive complexity decreasing adjunctions of linear forms to the ground field, and a final application of Lemma 3.2(ii) of [8] give $L_{\mathrm{INV}} - (m-1) \geqq L(f) \geqq m - \mathrm{ind}\,(n) - 2 + 3$, as desired.

Examples. (1) Null algebras $A = k[X_1, \cdots, X_{s-1}]/(\cdots, X_iX_j, \cdots)$, $L_{\mathrm{INV}} = s+1$.

(2) Quadratic extension fields A of k, $L_{\mathrm{INV}} = 4$.

(3) Quaternions $A = Q(\mu, \beta)$ (cf. [11, p. 30]). If A has no zero divisors, then n is anisotropic, so $L_{\mathrm{INV}} = 8$ (e.g., real quaternions $Q(-5/4, -1)$).

(4) 2×2 matrices $A = k^{2\times 2}$ ($= Q(0,1)$). As $\mathrm{ind}\,(\det) = 2$, $L_{\mathrm{INV}} = 6$. ($L_{\mathrm{INV}} = 5$ for the subalgebra of triangular matrices.)

(5) Cayley numbers $A = C(\mu, \beta, \gamma)$ [11]. $L_{\mathrm{INV}} = 16$ if A has no zero divisors (e.g., real Cayley numbers $C(-5/4, -1, -1)$).

(6) Char $k = 2$, a purely inseparable extension $A = k(\xi_1^{1/2}, \cdots, \xi_s^{1/2})$ with $[A:k] = 2^s$. Here $L_{\mathrm{INV}} = 2^{s+1}$.

Acknowledgment. This paper was written while the author visited Professor Volker Strassen's working group, University of Zurich. The inspiring and stimulating atmosphere is gratefully acknowledged.

ADAPTIVE BITONIC SORTING: AN OPTIMAL PARALLEL ALGORITHM FOR SHARED-MEMORY MACHINES*

GIANFRANCO BILARDI† AND ALEXANDRU NICOLAU‡

Abstract. A parallel algorithm, called *adaptive bitonic sorting*, that runs on a PRAC (parallel random access computer), a shared-memory multiprocessor where fetch and store conflicts are disallowed, is proposed. On a P processors PRAC, the algorithm presented here achieves optimal performance $TP = O(N \log N)$, for any computation time T in the range $\Omega(\log^2 N) \leqq T \leqq O(N \log N)$. Adaptive bitonic sorting also has a small constant factor, since it performs less than $2N \log N$ comparisons, and only a handful of operations per comparison.

Key words. sorting, parallel computation, shared-memory machines, bitonic sequence, time × processors optimality

1. Introduction.

Bitonic sorting [Ba68] is an interesting parallel algorithm based on a merge-sort scheme and an ingenious merging technique known as bitonic merging. Orginally proposed for a network of comparators, bitonic sorting has been considered for implementation on a variety of architectures such as the shuffle-exchange [St71], the binary cube [Pe77], the mesh [TK77], [NS79], the cube-connected cycles [PV81] and its pleated version [BP84], and on array processors [St78]. Various properties of bitonic networks have been investigated (e.g., [Kn73], [HS82], [Pr83], [Bl85], [Bl88]).

On an input of N elements, the bitonic merger performs $\Theta(N \log N)$ operations (comparisons and exchanges), coming to within a constant factor of a lower bound for merging networks of comparators that is due to Floyd [Kn73, p. 230]. However, in other models of parallel computation merging can be done with $O(N)$ operations [BH85], and therefore the bitonic algorithm is not optimal in these models.

In this paper we present procedures for merging and sorting which we propose to call *adaptive bitonic algorithms*. Our algorithms are based on bitonic sequences, as are Batcher's, but unlike Batcher's they perform a set of comparisons that is a function of the input values. As a result, our approach cannot be used in the context of a network of comparators, but will be shown to be more efficient than Batcher's, in terms of the number of operations performed, on a general purpose shared-memory machine. When necessary to avoid confusion, we shall refer to Batcher's algorithm as the nonadaptive or the network algorithm.

Adaptive bitonic merging [sorting] can be implemented on a PRAC (parallel random access computer) of P processors in time $T = O(N/P)[T = O((N \log N)/P)]$, for $1 \leqq P \leqq N/2^{\lfloor \log \log N \rfloor}$. The PRAC [LPV81] is a shared-memory multiprocessor of the EREW-PRAM variety [Sn85], where simultaneous access of the same memory location is disallowed. The product TP is optimal for both merging and sorting.

The merging algorithm also achieves the $T = \Omega(\log N)$ lower bound established in [Sn85] for merging on a PRAC. To our knowledge, ours is the first algorithm that attains the minimum time $T = O(\log N)$ with an optimal number of processors $P = O(N/\log N)$, on the PRAC model. An algorithm recently proposed in [AS85] achieves an optimal TP product, but for $T = \Omega(\log^2 N)$.

As for sorting on the PRAC, the question of asymptotic complexity was settled by the network of [AKS83], which is logspace uniform [L85], and therefore yields a PRAC algorithm with $TP = O(N \log N)$ for $T = \Omega(\log N)$. Very recently, the same asymptotic performance has been achieved by an adaptive algorithm proposed in [C86], building on the previous work of [P78] and [Kr83]. Our algorithm also achieves an optimal rate of growth for the TP measure, for $T = \Omega(\log^2 N)$, with a much smaller constant factor than in the AKS network, and probably smaller than the algorithm in [C86]: the latter algorithm performs less than $5N \log N$ comparisons ($2.5N \log N$ if concurrent reads are allowed). Furthermore, the number of other operations performed by that algorithm is significant [C87] and has not been precisely analyzed.

Adaptive bitonic sorting performs only about twice as many operations as the fastest sequential sorting algorithms, even for time $T = O(\log^2 N)$. It can obviously be implemented, with the same performance, on other shared-memory models with less restrictive memory access mechanisms. For results on the complexity of merging and sorting on some of these models see, for example, [BH85], [HH81], [Kr83], [SV81], [V75].

In the bitonic merging network, both the number of comparisons and the number of exchanges are $O(N \log N)$. Adaptive bitonic merging achieves a reduction of both numbers to $O(N)$, based on two properties established in the paper. First, there exists a subset of less than $2N$ of the comparisons performed by the network sufficient to determine the result of all the others. Second, there is a regularity in the pattern of exchanges that can be exploited by using a data structure, which we call *the bitonic tree*, whereby many element exchanges can be accomplished by a small number of subtree (i.e., pointers) exchanges. The properties of bitonic sequences exploited by our algorithm are discussed in § 2. The adaptive bitonic-merging algorithm is developed in § 3, where a sequential model is adopted for simplicity.

Parallel versions of merging and sorting are described in § 4. Here the main difficulty consists in avoiding a loss in time performance with respect to the network algorithm. In fact, in the PRAC implementation, adaptive bitonic merging emulates the kth stage of comparisons of the merging network in time $O(\log N - k)$, for $k = 0, 1, \cdots, \log N - 1$. If the stages are executed in sequence, the resulting time is $O(\log^2 N)$. However, a careful analysis of data-dependencies shows that $O(\log N)$ time can be achieved by a suitable overlapping of the stages.

The adaptive algorithms of §§ 3 and 4, as well as the network algorithms of [Ba68], assume that the length of the input sequence N is a power of two. The obvious strategy of padding the input sequence so that its length becomes a power of two leads to an increase of the complexity by a constant factor. In § 5 we show how this increase can be avoided by developing a variant of the algorithm that works for arbitrary N.

Besides attaining an optimal rate of growth, the performance of the algorithms presented here also exhibits very small constant factors. Adaptive bitonic sorting performs less than $2N \log N$ comparisons, independently of the number of processors, and appears to be attractive for practical implementation. Some indication of the practical behaviour is given in § 6.

2. Properties of bitonic sequences. Let $\mathbf{x} = (x_0, \cdots, x_{N-1})$ be a sequence of N (hereafter N is assumed even) elements from a totally ordered set. We introduce the

following operators on $\mathbf{x}$:

$$S_j\mathbf{x} \triangleq (x_{j \bmod N}, x_{(j+1) \bmod N}, \cdots, x_{(j+N-1) \bmod N}), \tag{1}$$

$$L\mathbf{x} \triangleq (\min\{x_0, x_{N/2}\}, \cdots, \min\{x_{N/2-1}, x_{N-1}\}), \tag{2}$$

$$U\mathbf{x} \triangleq (\max\{x_0, x_{N/2}\}, \cdots, \max\{x_{N/2-1}, x_{N-1}\}). \tag{3}$$

A sequence $\mathbf{x}$ is *bitonic* if, for some j, the sequence $S_j\mathbf{x} = (y_0, \cdots, y_{N-1})$ consists of a nondecreasing portion followed by a nonincreasing one. Bitonic merging is based on the fact that, if $\mathbf{x}$ is bitonic,

$$\text{sort}(\mathbf{x}) = (\text{sort}(L\mathbf{x}), \text{sort}(U\mathbf{x})). \tag{4}$$

This relation, due to [Ba68], leads to a recursive algorithm whose complexity is determined by that of computing $L\mathbf{x}$ and $U\mathbf{x}$. Theorem 1 below states four properties of L and U on bitonic operands. Property (P1) is a lemma for the others. Properties (P2) and (P3), obtained by Batcher, imply (4) above. Relation (P4) is crucial here since it provides the basis for a method to compute $L\mathbf{x}$ and $U\mathbf{x}$ that is more efficient than the direct application of definitions (2) and (3) above, which are used in the bitonic algorithm in [Ba68].

THEOREM 1. *If $\mathbf{x}$ is a bitonic sequence (of even length), then the following properties hold:*

(P1) *There is a shifted version $S_q\mathbf{x} = (z_0, \cdots, z_{N-1})$ of $\mathbf{x}$ such that*

$$L\mathbf{x} = S_{(-q \bmod N/2)}(z_0, \cdots, z_{N/2-1}), \tag{5}$$

$$U\mathbf{x} = S_{(-q \bmod N/2)}(z_{N/2}, \cdots, z_{N-1}). \tag{6}$$

(P2) *Each element of $U\mathbf{x}$ is no smaller than each element of $L\mathbf{x}$.*

(P3) *Sequences $L\mathbf{x}$ and $U\mathbf{x}$ are bitonic.*

(P4) *Let q be as in* (P1) *and let $t = q \bmod N/2$. Let $\mathbf{x} = (\mathbf{x}', \mathbf{x}'', \mathbf{x}''', \mathbf{x}'''')$ with $\mathbf{x}'$ and $\mathbf{x}'''$ of length t, and $\mathbf{x}''$ and $\mathbf{x}''''$ of length $N/2 - t$. If $q < N/2$ $(t = q)$, then*

$$(L\mathbf{x}, U\mathbf{x}) = (\mathbf{x}''', \mathbf{x}'', \mathbf{x}', \mathbf{x}''''). \tag{7}$$

If $q \geqq N/2$ $(t = q - N/2)$, then

$$(L\mathbf{x}, U\mathbf{x}) = (\mathbf{x}', \mathbf{x}'''', \mathbf{x}''', \mathbf{x}''). \tag{8}$$

Before proving Theorem 1, we show two relations among the operators L, U, and S_j.

LEMMA 1. *For any $\mathbf{x}$ and j,*

$$L\mathbf{x} = S_{(-j \bmod N/2)}LS_j\mathbf{x} \tag{9}$$

$$U\mathbf{x} = S_{(-j \bmod N/2)}US_j\mathbf{x}. \tag{10}$$

Proof. We prove only (9), the argument for (10) being similar. For $j = N/2$, (9) becomes $L\mathbf{x} = LS_{N/2}\mathbf{x}$, which can be trivially verified. Thus, index j in (9) can always be taken modulo $N/2$ and it is sufficient to consider $j < N/2$. In this case we have $-j \bmod N/2 = N/2 - j$, and

$$LS_j\mathbf{x} = (\min\{x_j, x_{j+N/2}\}, \cdots, \min\{x_{N/2-1}, x_{N-1}\}, \min\{x_0, x_{N/2}\}, \cdots, \min\{x_{j-1}, x_{j-1+N/2}\}),$$

or, in compact form, $LS_j\mathbf{x} = S_jL\mathbf{x}$, from which (9) follows by applying $S_{-j \bmod N/2}$ to both sides. □

Proof of Theorem 1. Let the *median* of a sequence $\mathbf{x} = (x_0, \cdots, x_{N-1})$ be defined as the minimum value m such that less than $N/2$ elements of $\mathbf{x}$ are greater than m. Let $\mathbf{x}$ be bitonic, and let $\mathbf{y} = S_j\mathbf{x} = (y_0, \cdots, y_{N-1})$ consist of a nondecreasing sequence followed by a nonincreasing sequence. In general, $\mathbf{y}$ is the concatenation of five (possibly empty) subsequences, respectively, containing N_1 elements smaller than m, N_2 elements equal to m, N_3 elements larger than m, N_4 elements equal to m, and N_5 elements smaller than m.

Obviously, $N_1 + \cdots + N_5 = N$. Also, by the definition of m, $N_3 < N/2$ and $N_2 + N_3 + N_4 \geqq N/2$. By simple arithmetic, $N_1 \leqq N/2 - N_5$ and there exists a k, with $N_1 \leqq k \leqq N/2 - N_5$, such that the sequence $(y_k, y_{k+1}, \cdots, y_{k+N/2-1})$ contains all the elements larger than m and none of those smaller than m.

We now consider the sequence $\mathbf{z} = S_{k+N/2}\mathbf{y} = S_q\mathbf{x}$, where $q = (j + k + N/2) \bmod N$. If we write $\mathbf{z} = (\mathbf{z}', \mathbf{z}'')$, with $\mathbf{z}'$ and $\mathbf{z}''$ sequences of $N/2$ elements, it is easy to see that $\mathbf{z}'' = (y_k, \cdots, y_{k+N/2-1})$.

Thus all the elements of $\mathbf{z}''$ are no smaller than the elements of $\mathbf{z}'$, which implies that $(L\mathbf{z}, U\mathbf{z}) = \mathbf{z}$. Lemma 1 applied to the latter relation yields $L\mathbf{x} = S_{(-q \bmod N/2)}\mathbf{z}'$ and $U\mathbf{x} = S_{(-q \bmod N/2)}\mathbf{z}''$, which are equivalent to (5) and (6) and establish (P1).

Property (P2) follows from (5), (6), and the fact that $\max\{z_0, \cdots, z_{N/2-1}\} \leqq \min\{z_{N/2}, \cdots, z_{N-1}\}$.

Sequences $\mathbf{z}'$ and $\mathbf{z}''$ are bitonic since they are subsequences of $\mathbf{z}$, which is bitonic. Then from (5) and (6), $L\mathbf{x}$ and $U\mathbf{x}$ are shifts of bitonic sequences, and (P3) is proved.

If $q < N/2$ and $\mathbf{x} = (\mathbf{x}', \mathbf{x}'', \mathbf{x}''', \mathbf{x}'''')$, as defined in (P4), then $S_q\mathbf{x} = (\mathbf{x}'', \mathbf{x}''', \mathbf{x}'''', \mathbf{x}')$. From (6) and (7), cyclically shifting each half of $S_q\mathbf{x}$ q positions to the right, we obtain $L\mathbf{x} = (\mathbf{x}''', \mathbf{x}'')$ and $U\mathbf{x} = (\mathbf{x}', \mathbf{x}'''')$. This proves (7). A similar argument yields (8), completing the proof of (P4). □

3. Adaptive bitonic merging with $O(N)$ comparisons. In this section we present a linear-time version of bitonic merging. For simplicity, we describe the algorithm in a sequential setting and we assume that N, the sum of the lengths of the sequences being merged, is a power of two. Parallelism and arbitrary input size are discussed in subsequent sections.

3.1. Analysis of comparisons. Let $\mathbf{x}$ be the bitonic sequence obtained by concatenating, in opposite order, two sorted sequences to be merged. The classical bitonic merging consists of the following steps:

(1) Compute $L\mathbf{x}$ and $U\mathbf{x}$ by $N/2$ (parallel) comparisons (according to definitions (2) and (3)).

(2) Recursively sort $L\mathbf{x}$ and $U\mathbf{x}$, in parallel.

The comparisons performed by the above algorithm are data-independent and hence can be hardwired in a network of comparator-exchangers, *the bitonic merger.* In the terminology of [Kn73], the bitonic merger has N (a power of two) lines numbered $0, 1, \cdots, N-1$ and $\log N$ stages each of $N/2$ comparator-exchangers. In the kth stage ($k = 0, 1, \cdots, \log N - 1$) lines i and j are connected by a comparator-exchanger if and only if the binary spellings of i and j differ exactly in the $(\log N - k)$th rightmost bit. Comparators output the smaller of the two inputs on the line with lower number.

Since, as is well known, N comparisons are sufficient to merge two sequences, the set C of the $(N \log N)/2$ comparisons executed by the bitonic merger obviously contains some redundancy. Less obviously, this redundancy can be almost eliminated by executing only a suitable subset of C, as shown in the next theorem. As it will become clear from the proof, this subset is a function of the input sequence $\mathbf{x}$.

THEOREM 2. *Let C be the set of the $(N \log N)/2$ comparisons executed by Batcher's merging network. Then, there is a subset $C' \subset C$ of size $|C'| = 2N - \log N - 2$ such that the results of the comparisons in C are uniquely determined by the results of the comparisons in C', as long as the input elements are distinct.*

Proof. Due to property (P4) established in Theorem 1, there is a decomposition $(\mathbf{x}', \mathbf{x}'', \mathbf{x}''', \mathbf{x}'''')$ of $\mathbf{x}$ such that $(L\mathbf{x}, U\mathbf{x})$ is obtained either by exchanging $\mathbf{x}'$ and $\mathbf{x}'''$ (7) or by exchanging $\mathbf{x}''$ and $\mathbf{x}''''$ (8). Due to (P2), if $x_{N/2-1} < x_{N-1}$ then (7) holds, else $(x_{N/2-1} > x_{N-1})$ (8) holds.

When (7) holds, $\mathbf{x}''$ contains x_i if and only if $x_i < x_{N/2+i}$. Thus the leftmost element of $\mathbf{x}''$ can be found by a binary search driven by comparisons of pairs of the form $(x_i, x_{N/2+i})$. Index i is first set to $N/4-1$, and then decremented if $x_i < x_{N/2+i}$ and incremented otherwise. The increment is initialized to $N/8$, and halved at each step. The search terminates after $\log N - 1$ steps, when the increment is zero. Therefore $\mathbf{x}''$, and thus $(L\mathbf{x}, U\mathbf{x})$, is determined by $\log N$ of the $N/2$ comparisons implicit in definitions (2) and (3). The case when (8) holds is completely symmetric.

Let C' be the set of comparisons resulting from recursively applying the above method to $L\mathbf{x}$ and $U\mathbf{x}$. Considering that at the kth level of recursion $(k = 0, 1, \cdots, \log N - 1)$ there are 2^k sequences each requiring $\log N - k$ comparisons, we can evaluate the cardinality of C' as follows:

$$M(N) \triangleq |C'| = \sum_{k=0}^{\log N - 1} 2^k (\log N - k) = 2N - \log N - 2. \qquad (11)$$

□

The assumption of distinct input elements is essential in Theorem 2. An arbitrary strategy for resolving ties may lead to incorrect behaviour. As an example, consider the bitonic sequences $\mathbf{u} = (0, 0, -1, 0, 0, 0, 0, 0)$ and $\mathbf{v} = (0, 0, 1, 0, 0, 0, 0, 0)$. It can be easily seen that if the case $x_i = x_{N/2+i}$ is treated as $x_i < x_{N/2+i}$, then $\mathbf{u}$ will be sorted properly, but $\mathbf{v}$ will not. The opposite will happen if the case $x_i = x_{N/2+i}$ is treated as $x_i > x_{N/2+i}$.

A simple and correct strategy consists of breaking ties (when comparing equal elements) according to the original position of the elements in the input sequence, which amounts to enforcing distinctness. The resulting algorithm clearly will be stable. In the remainder of the paper, distinct elements will be assumed.

3.2. The data structure. Although Theorem 2 gives a way to obtain all the information needed to merge two sequences with a linear number of comparisons, the problem remains of how to efficiently achieve the data rearrangement that in Batcher's network requires $\Omega(N \log N)$ exchanges in the worst case. We solve this problem with the adoption of a suitable data structure, which we call a bitonic tree.

A *bitonic tree* (see Fig. 1) is a binary tree where each node contains an element from a totally ordered set, and the sequence of elements encountered in the inorder traversal of the tree is bitonic. The bitonic tree is a simple generalization of the binary search-tree. In fact, an inorder traversal of the latter yields a monotonic (sorted) sequence.

Given a bitonic sequence of length N (a power of two), we adopt a representation in which the first $N-1$ elements are stored in a fully balanced bitonic tree of $\log N$ levels, and the last element is kept in a spare node. In this representation, the decomposition $\mathbf{x} = (\mathbf{x}', \mathbf{x}'', \mathbf{x}''', \mathbf{x}'''')$ considered in Theorem 1 corresponds to a decomposition of the bitonic tree into four forests (see Fig. 1). The roots of the trees in these forests form two parallel paths in the main subtrees of the bitonic tree. The exchange

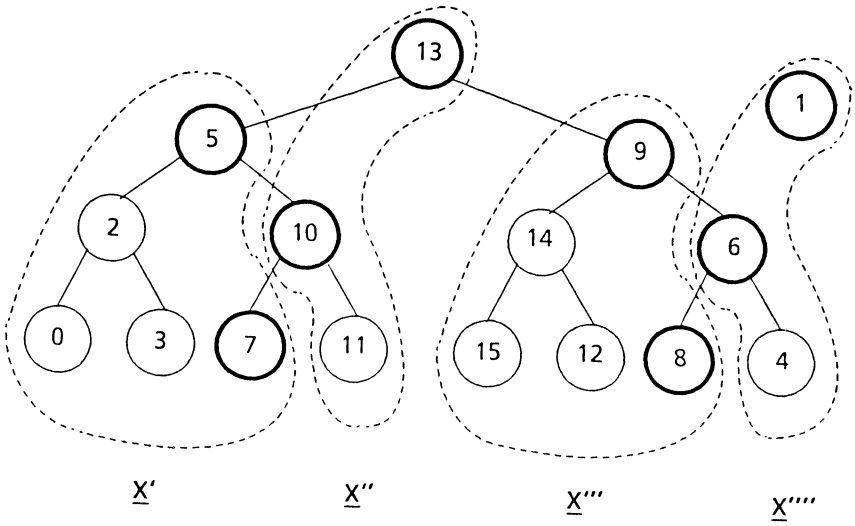

FIG. 1. *Bitonic tree. Bitonic tree for the sequence* $\mathbf{x} = (0, 2, 3, 5, 7, 10, 11, 13, 15, 14, 12, 9, 8, 6, 4, 1)$ *and the decomposition* $(\mathbf{x}, \mathbf{x}'', \mathbf{x}''', \mathbf{x}'''')$ *for the computation of* $(L\mathbf{x}, U\mathbf{x}) = (\mathbf{x}', \mathbf{x}'''', \mathbf{x}''', \mathbf{x}'')$. *Solid nodes are the ones examined by the binary search.*

of $\mathbf{x}'$ and $\mathbf{x}'''$ [$\mathbf{x}''$ and $\mathbf{x}''''$] required by (7) [(8)] to compute $(L\mathbf{x}, U\mathbf{x})$ can be accomplished with $O(\log N)$ exchanges of values and pointers in the bitonic tree.

The relation between the bitonic tree and the bitonic network can be viewed as a one-to-one correspondence between nodes and lines, the ith line being associated with the ith node encountered in the inorder traversal of the tree. However, a node and the corresponding line are guaranteed to hold the same value only at the beginning of merging and immediately after the completion of the computation of the sequences $(L\mathbf{x}, U\mathbf{x})$ at each level of the recursion.

3.3. The algorithm. Based on the preceding observations we give below a procedure bimerge(root, spare, dir) that sorts $\mathbf{x}$ by transforming the bitonic tree into a binary search-tree. Parameters root and spare are pointers to the root of the tree and to the spare node, respectively. Parameter dir is Boolean and represents the direction in which the sequence is to be sorted (dir = false for ascending, dir = true for descending).

Each node of the tree has three fields, value, left, and right, respectively storing an element of the sequence (or a pointer to it) and pointers to the left and right subtrees. The procedure bimerge given in Fig. 2 is written in pseudo-Pascal. The identifiers not explicitly defined are self-explanatory.

We now briefly comment on procedure bimerge. At the beginning, the root contains $x_{N/2-1}$ and the spare node contains x_{N-1}. After statement 1. of Fig. 2, rightexchange is false when (7) holds (i.e., $\mathbf{x}'$ and $\mathbf{x}'''$ are exchanged), and true when (8) holds (i.e., $\mathbf{x}''$ and $\mathbf{x}''''$ are exchanged). In the latter case, $x_{N/2-1}$ and x_{N-1} are exchanged (by statement 2.). After statement 3., *pl* and *pr* point to the nodes that contain $x_{N/4-1}$ and $x_{3N/4-1}$, respectively.

The binary search for the boundary between $\mathbf{x}'$ and $\mathbf{x}''$ (as well as between $\mathbf{x}''$ and $\mathbf{x}''''$) is performed by the while-loop (statements 4. ÷ 19.). At the end of the loop, an inorder traversal of the tree would yield $(L\mathbf{x}, U\mathbf{x})$. Sequences $L\mathbf{x}$ and $U\mathbf{x}$ are recursively

```
    procedure bimerge (root, spare, dir);
    begin
 1. rightexchange := (root↑value > spare↑value) XOR dir;
 2. if rightexchange then swap-value(root, spare);
 3. pl := root↑left; pr := root↑right;
 4. while (pl ≠ nil) do begin
 5.   elementexchange := (pl↑value > pr↑value) XOR dir;
 6.   if rightexchange then              /* X'' and X'''' exchange          */
 7.     if elementexchange then begin    /* swap values and right subtrees;
                                           search path goes left           */
 8.       swap-value(pl, pr);
 9.       swap-right(pl, pr);
10.       pl := pl↑left; pr := pr↑left
          end
11.     else begin                       /* search path goes right          */
12.       pl := pl↑right; pr := pr↑right
          end
13.   else                               /* X' and X''' exchange            */
14.     if elementexchange then begin    /* swap values and left subtrees;
                                           search path goes right          */
15.       swap-value(pl, pr);
16.       swap-left(pl, pr);
17.       pl := pl↑right; pr := pr↑right
          end
18.     else begin                       /* search path goes left           */
19.       pl := pl↑left; pr := pr↑left
          end
    end; /* while */
20. if (root↑left ≠ nil) then begin
21.   bimerge(root↑left, root, dir);
22.   bimerge(root↑right, spare, dir)
      end
    end; /* bimerge*/
```

FIG. 2. *Procedure Bimerge.*

sorted by the recursive calls in statements 21. and 22. We observe that $L\mathbf{x}$ and $U\mathbf{x}$ are represented, as is $\mathbf{x}$, by a bitonic tree and a spare node: $L\mathbf{x}$ by the left subtree and the root, $U\mathbf{x}$ by the right subtree and the original spare node. In general, the recursive calls of depth k (the first call being of depth zero) operate on sequences of length $N/2^k$. These sequences are represented by a subtree with root at level k (the root of the entire tree being at level zero) and a spare node. The spare node belongs to some level less than k or is the spare node of the original tree. More precisely, the ith subtree at level k, from left to right, is paired with the ith node encountered in the inorder traversal of the first k levels of the tree.

A simple analysis of bimerge shows that the total number of operations is of the same order as the number of comparisons. Thus, the algorithm runs in linear-time.

4. Parallel algorithms. In this section we present a parallel version of adaptive bitonic merging and a parallel sorting algorithm based on it. As a model of computation, we choose the PRAC of [LPV81]. The PRAC is a shared-memory multiprocessor machine. Any processor can access any common-memory location in constant time. However, simultaneous access (either read or write) of the same location is illegal and leads to termination error. For more details on the PRAC see [LPV81].

4.1. Merging. We call stage (k) of the merge $(k = 0, 1, \cdots, \log N - 1)$ the set of recursive calls of bimerge of depth k. There are 2^k such calls, each processing a different subsequence of $N/2^k$ elements. As already observed, this subsequence occupies a subtree with root at level k and a spare node in some level less than k. All the calls in stage (k) can be executed in parallel.

We call phase (0) of bimerge the execution of statements 1., 2., and 3. of Fig. 2. We call phase (i) the execution of the ith iteration of the while-loop. For a call in stage (k), i ranges from 1 to $\log N - k - 1$. A phase includes one comparison and a handful of tests and assignment statements. It can be executed in $O(1)$ time.

Since calls of depth k consist of $\log N - k$ phases, stage (k) takes $\log N - k$ parallel phases. The total time for executing stage $(0), \cdots,$ stage $(\log N - 1)$ in sequence is $O(\sum_{k=0}^{\log N - 1} (\log N - k)) = O(\log^2 N)$. We note a loss in performance with respect to the $O(\log N)$ time of Batcher's network. The loss is due to the difference in the computation of $(L\mathbf{x}, U\mathbf{x})$. For $\mathbf{x}$ of length N the $N/2$ comparisons of Batcher's network are data-independent and take only one time step, while the $\log N$ comparisons of our binary-search method are inherently sequential and take $\log N$ steps.

Little can be done to speed up the execution of a single stage without increasing the number of comparisons. However, a careful analysis of the data dependencies between comparisons of the various stages reveals that the execution of different stages can be partially overlapped, with considerable savings in running time.

We observe that, in stage (k), phase (0) operates on levels $0, 1, \cdots, k$ of the bitonic tree, and phase (i) operates on level $k + i$ $(i = 1, \cdots, \log N - k - 1)$. Thus, phase (0) of stage (k) can begin as soon as stage $(0), \cdots,$ stage $(k - 1)$ have processed the first k levels of the tree. In general, phase (i) of stage (k) can begin as soon as stage $(0), \cdots,$ stage (k) have processed the first $k + i$ levels of the tree. This condition is satisfied if a new stage is scheduled to begin every other phase step. The entire sequence of $\log N$ stages is completed in $2 \log N - 1$ phase steps, that is in $O(\log N)$ time. An example of the schedule of the phases of different stages is given in Table 1, for $N = 16$.

TABLE 1
Schedule for the overlapped execution of the stages of bimerge for $N = 16$.

Phase step	Stage (0)		Stage (1)		Stage (2)		Stage (3)	
	Phase	Tree levels	Phase	Tree levels	Phase	Tree levels	Phase	Tree levels
0	0	0	-	-	-	-	-	-
1	1	1	-	-	-	-	-	-
2	2	2	0	0, 1	-	-	-	-
3	3	3	1	2	-	-	-	-
4	-	-	2	3	0	0, 1, 2	-	-
5	-	-	-	-	1	3	-	-
6	-	-	-	-	-	-	0	0, 1, 2, 3

In the above schedule, the maximum number of calls simultaneously active is $N/2$, and hence $N/2$ processors are sufficient. We now consider a slightly different schedule that leads to a reduction of the number of processors without substantial degradation in time performance.

Let us assume a number of processors $P = 2^p$, with $P > 1$ and consider the following strategy:

(1) Stage $(0), \cdots,$ stage $(p-1)$ are scheduled to begin one every other step. The total number of calls in these stages is $P-1$ so that a different processor is available for each call. Stage (0) takes $\log N$ phase steps, after which a new stage terminates at each phase step. Thus, the first p stages take $t_1 = \log N + p - 1$ phase steps.
(2) For the remaining stages, one processor is assigned to each of the P subtrees corresponding to subsequences of length N/P. This will take $t_2 = 2N/P - \log(N/P) - 2$ phase steps (see (11)).

The total number of phase steps is $t = t_1 + t_2 = 2N/P - 2p - 3$.

If we choose $P = N/2^{\lfloor \log \log N \rfloor} \approx N/\log N$, we obtain $t = 2 \log N - 2 * 2^{\lfloor \log \log N \rfloor} - 2\lfloor \log \log N \rfloor - 2 < 4 \log N$. In conclusion, $T = O(t) = O(\log N)$, with $P = O(N/\log N)$ processors. The product TP is optimal, since N operations are necessary to merge. A similar result is obtained for $1 \leqq P \leqq N/2^{\lfloor \log \log N \rfloor}$, as summarized in the following theorem.

THEOREM 3. *Adaptive bitonic merge can be executed on a* PRAC *of P processors in time* $T = O(N/P)$, *for* $1 \leqq P \leqq N/2^{\lfloor \log \log N \rfloor}$.

It is of interest to estimate the overhead incurred to distribute the algorithm among P processors. Two aspects contribute to such overhead: (a) according to the schedule outlined above not all the processors are active all the time; and (b) some time will be spent in synchronizing the activities of different processors. Let us analyze each aspect in turn.

We can rewrite the expression for the number of phase steps t as $tP < 2N + 2pP$. Since $2N$ is essentially the number of phase steps for the sequential algorithm, the overhead due to idle processors is given by the term $2pP$, which for $P = N/2^{\lfloor \log \log N \rfloor}$ is about $2N$, and is smaller for smaller P's.

In the parallel version of bimerge, the parameters root, spare, and dir are computed by a processor different from the one that actually executes the call. Thus, the processor that computes the parameters must write them in the shared memory from which the processor assigned to the call will read them. A simple analysis shows that the total number of memory accesses for interprocessor communication is $O(P)$, so that the synchronization overhead contributes a lower-order term to the total number of operations of the merging algorithm.

4.2. Sorting. Essentially, using the classical sort-by-merge scheme (see Fig. 3) and standard manipulations, Theorem 2 leads to the following result.

```
    procedure bisort(root, spare, dir);
    begin
1.    if (root↑left = nil) then
          test-and-swap (root, spare, dir)   /* down at leaves */
2.    else begin
3.       bisort(root↑left, root, dir);
4.       bisort(root↑right, spare, ~dir);
5.       bimerge(root, spare, dir)
6.       end
    end;
```

FIG. 3. *Procedure Bisort.*

THEOREM 4. *Let S be the set of the $N \log N(\log N+1)/2$ comparisons executed by Batcher's sorting network. Then, there exists a subset $S' \subset S$ of size*

$$S(N) \triangleq |S'| = 2N \log N - 4N + \log N + 4 \tag{12}$$

such that the results of the comparisons in S are uniquely determined by the results of the comparisons in S'.

An efficient parallel version is provided by the following schedule. First, each processor sequentially sorts N/P elements, in $2(N/P)\log(N/P)$ phases. Then, for each $j = 1, 2, \cdots, \log P$, there will be a merging step where the P processors are partitioned in $P/2^j$ groups of size 2^j, with each group merging two sequences into one of length $(N/P)2^j$. The jth merging runs in less than $2(N/P)+2j$ phases. Thus, the total number of phases, t, for the entire sorting process is:

$$t < 2\left(\frac{N}{P}\right)\log\left(\frac{N}{P}\right) + \sum_{j=1}^{\log P}\left(2\left(\frac{N}{P}\right)+2j\right) = 2\left(\frac{N}{P}\right)\log N + (\log P+1)\log P.$$

Therefore,

$$tP < 2N \log N + P(\log P+1)\log P,$$

and we obtain the following result.

THEOREM 5. *Adaptive bitonic sorting can be implemented on a* PRAC *of P processors in time $T = O((N \log N)/P)$, for $1 \leqq P \leqq N/2^{\lfloor \log \log N \rfloor}$.*

We observe that $|S'|$ is within a factor of two of $\lceil \log N! \rceil$, which is a lower bound on the number of comparisons needed to sort N elements [Kn73]. It is remarkable that sorting can be done in $O(\log^2 N)$ time with so little redundance. An analysis similar to the one developed for merging shows that the total number of memory accesses for interprocessor communication (synchronization) is $O(P \log N)$, contributing a lower-order term to the total number of operations of our algorithm. The overhead due to idle processors is about $P \log^2 P$, which for $P = N/2^{\lfloor \log \log N \rfloor}$ is about $N \log N$, i.e., 50 percent of the sequential work. For smaller values of P, the overhead is obviously smaller.

5. Input sequence of arbitrary length. In the previous sections, it has been assumed that N, the number of elements to be sorted, is a power of two. The algorithms so derived can be used for any input sequence after adding enough dummy elements to it so that the length becomes a power of two. However, this strategy leads to a constant factor increase in time complexity, which is undesirable in practical applications.

In this section we modify our algorithm to handle arbitrary values of N, with a negligible increase in complexity with respect to the case where N is a power of two. The basic idea consists in simulating the actions that the power-of-two version of the algorithm would perform on the input sequence padded with dummies, while avoiding representing and processing most of the dummies.

5.1. Padding the input sequence. Let $n \triangleq \lceil \log N \rceil$, that is, let 2^n be the minimum power of two no less than N. Given a sequence $\mathbf{x} = (x_0, \cdots, x_{N-1})$ to be sorted, we augment it to obtain a sequence $\mathbf{z} = (d, \cdots, d, x_0, \cdots, x_{N-1})$ of length 2^n by inserting, at the beginning of $\mathbf{x}$, $D \triangleq 2^n - N$ dummy elements of value $d < x_i$, for all x_i's.

If $\mathbf{z}$ is stored in a tree according to the inorder traversal, the dummy elements occupy a left subforest of the tree. More precisely, let $D = \sum_{i=0}^{n-1} D_i 2^i$, with $D_i \in \{0, 1\}$. Let π be the path in the tree that starts at the root and whose ith edge goes left when $D_{n-i} = 0$, and goes right when $D_{n-i} = 1$, for $i = 1, 2, \cdots, n$. Then, the D dummy elements

occupy the nodes of π that are followed by a right edge and the left subtrees of such nodes. In other words, for each $D_i = 1$, there is a dummy subtree of height i, whose root is at level $n-i$ and is the left son of a node on π, also containing a dummy.

We now analyze the behaviour of our algorithm on a padded sequence $\mathbf{z}$ focusing in particular on the dummy subtrees.

For a given call to procedure bimerge, consider the "parallel" paths p' and p'' traced in the bitonic tree by the search for the boundary between $\mathbf{x}'$ and $\mathbf{x}''$ (see § 3.1). A given subtree T' can be modified by the call only if it is traversed by any of the two paths.

If p' and p'' originate at the root v' of T' or at a descendent of it, then only elements inside T' will be rearranged. In particular, if T' was originally a tree of dummies, it will remain such.

If p' and p'' originate at an ancestor of v', then only one path, say p', can traverse T', and v' is the first node of T' to be visited. During the traversal, v' will be compared with some node v'', root of a subtree T''. Paths p' and p'' continue in T' and T'', respectively. If T' is a tree of dummies, its elements form a consecutive run in the sorted output. Thus, the comparison of any node of p' with the corresponding node of p'' gives the same result as the comparisons of v' and v''. Therefore, subtrees T' and T'' will either be exchanged completely, or left in their positions.

5.2. Pruning the tree. The above discussion shows that dummy subtrees are left intact throughout the algorithm, and that they can be processed by examining only their root. This suggests a modification to the bitonic tree whereby a dummy subtree is represented by a single node (its root) with left and right pointers set to *nil*. We refer to the resulting data structure as the *pruned bitonic tree.*

The procedures bisort and bimerge have to be modified to work correctly on the pruned version of the tree. The necessary changes are simple, and are outlined below:

(1) The call bisort(root, spare, dir) is not executed whenever root is a node with dummy value and nil pointers.
(2) The call bimerge(root, spare, dir) is not executed whenever root is a node with dummy value and nil pointers.
(3) Whenever a node v', with dummy value and nil pointers is compared with another node v'', and v' and v'' are exchanged, their left and right pointers are also exchanged. In any case, the current call to bimerge is terminated after the comparison.

5.3. Analysis. Let us consider a dummy subtree of height i ($i \leqq n-2$). The savings in comparisons coming from each of the modifications to the algorithm described above are as follows:

(1) $(S(2^i)-1)$ for replacing a call to bisort with a single comparison between the root of the subtree and a spare node.
(2) $(M(2^i)-1)(n-i)$ for replacing each of the $(n-i)$ calls to bimerge with a single comparison between root and spare node.
(3) $(i-1)v_i$ for not traversing the $(i-1)$ levels below the root v' for each of the v_i times in which the dummy subtree should be traversed by a path originating above v'. In general, v_i is a function of the input sequence, but always satisfies the simple bound $v_i \leqq (n-i)(n-i+1)/2$, the latter being the number of calls to bimerge with an ancestor of v' as the root.

We can now estimate the total number of comparisons performed by the pruned-tree

sorting algorithm as

$$S(N) = S(2^n) - \text{savings} = S(2^n) - \sum_{i=0}^{n-2} d_i[S(2^i) - 1 + (M(2^i) - 1)(n-i) + (i-1)v_i]$$

and thus

$$S(N) \leqq 2N\lceil \log N \rceil - 4N + \text{lower order terms.} \tag{13}$$

To obtain the last expression we have (i) neglected the (negative) contribution of the term $(i-1)v_i$; (ii) used expressions (11) and (12) for $M(2^i)$ and $S(2^i)$, respectively; and (iii) applied some simple algebraic manipulation. The sublinear terms turn out to be of $O(\log^3 N)$. Comparing (13) with (12), we see that the complexity of the sorting algorithm for arbitrary N differs from the complexity for N a power of two only in sublinear terms. Summarizing the above discussion, we have Theorem 6.

THEOREM 6. *The pruned-tree version of adaptive bitonic sorting executes a number of comparisons*:

$$S(N) = 2N\lceil \log N \rceil - 4N + O(\log^3 N). \tag{14}$$

6. Conclusions. We have presented a parallel sorting algorithm with optimal $TP = O(N \log N)$ complexity for $\Omega(\log^2 N) \leqq T \leqq O(N \log N)$. To explore the practical potential of our algorithm we must examine the constant factors. The small comparison count ($<2N \log N$) is encouraging, but we need to consider the total number of operations. To this end, we observe that, when running on P processors, adaptive bitonic sorting executes all the operations that it would execute on one processor plus a small number ($O(P \log N)$) of memory references due to interprocessor communication. Therefore, an accurate estimate of the operation count can be obtained by considering the performance of uniprocessor implementations. In general, the operation count is a lower bound of the PT measure on the PRAC, which is met only if processors actually perform useful operations at each timestep. This is nearly the case for adaptive bitonic sorting since, even for $T = O(\log^2 N)$, on average a processor is idle for less than one third of the total running time.

We have coded the sequential pruned-tree version of our sorting algorithm in C under Berkeley Unix 4.2 on a VAX 780, and a Gould 9080. The only optimization we have performed is the straightforward removal of recursion. As a term of comparison, we have chosen "quicker-sort," the Unix system sort, which is a carefully tuned version of quicksort. On sequences of length up to 2^{19}, the running time of our algorithm has consistently been below 2.5 times the running time of quicker-sort. This performance is remarkable for an algorithm that, with a small synchronization overhead and high processor utilization, can run in $O(\log^2 N)$ parallel time.

The combination of relative simplicity, optimal operation count, and small overhead makes adaptive bitonic sorting appealing for practical implementation.

Acknowledgment. We are grateful to the referees for their careful reading of the paper and for their constructive comments.

THE TOKEN DISTRIBUTION PROBLEM*

DAVID PELEG† AND ELI UPFAL†

Abstract. A solution to the following fundamental communication problem is presented. Suppose that n tokens are arbitrarily distributed among n processors with no processor having more than K tokens. The problem is to specify a bounded-degree network topology and an algorithm that can distribute the tokens uniformly among the processors.

The first result is a tight $\Theta(K+\log n)$ bound on the complexity of this problem. It is also shown that an approximate version of this problem can be solved deterministically in $O(K+\log n)$ on any expander graph with sufficiently large expansion factor.

In the second part of this work, it is shown how to extend the solution for the approximate distribution problem to an optimal probabilistic algorithm for the exact distribution problem on a similar class of expander graphs. Note that communication through an expander graph is a necessary condition for an $O(K+\log n)$ solution of the problem.

These results have direct applications to the efficient implementation of many-to-one and one-to-many communication requests, as well as to the solution of load-balancing problems in distributed systems.

1. Introduction. Information exchange between processors is essential for any efficient parallel computation. In most applications, data transfer between individual processors has to be done through a relatively sparse communication network. Thus, the problem of routing simultaneously many packets on bounded-degree interconnection networks is fundamental to the theory of parallel and distributed computation.

The problem of packet routing is best formulated in terms of communication requests. An (m, K_1, K_2)-*communication request* is a set of up to m pairs. Each pair specifies a source and a destination for one packet in the network, and no processor appears as a source (respectively, destination) of more than K_1 (respectively, K_2) packets. The (m, K_1, K_2)-*routing problem* is the problem of routing simultaneously an (m, K_1, K_2)-communication request.

Most previous research has focused on the problem of routing a permutation or an $(n, 1, 1)$-communication request (one-to-one communication) on an n-vertex graph. An $O(\log n)$ deterministic solution for this problem is known for certain bounded-degree networks enabling sorting in $O(\log n)$ steps (henceforth, *S-networks*), based on the AKS sorting network [AKS], [L1]. $O(\log n)$ probabilistic algorithms have been analyzed for more practical networks like the butterfly [U] and the d-way shuffle [Ale]. These results match the $\Omega(\log n)$ lower bound for the implementation of an $(n, 1, 1)$-communication request on any n-vertex bounded-degree network.

However, permutation routing is a very restrictive form of communication, and the assumption that individual processors can coordinate their activity in a distributed computation so that only one message is addressed to each processor at any given time can rarely be justified. Furthermore, the algorithms developed for $(n, 1, 1)$-routing

† Computer Science Department K53, IBM Almaden Research Center, San Jose, California 95120. Present address, Department of Applied Mathematics, The Weizmann Institute of Science, Rehovot 76100, Israel.

do not "scale up" to give an optimal solution for communication requests with higher parameters. (A naive iterative application of a permutation algorithm for an (n, K, K)-communication request takes $O(K \log n)$ steps.) Thus, a new approach is needed for the more general problem.

In the first part of this work we give an optimal solution for the general communication problem on bounded-degree networks.

THEOREM 1. *Any solution of the (n, K_1, K_2)-routing problem on an n-processor bounded-degree network requires $\Omega(K_1 + K_2 + \log n)$ parallel steps.*

THEOREM 2. *There exist an (explicitly constructible) n-processor bounded-degree network and a deterministic algorithm that solves any (n, K_1, K_2)-communication request on this network in $O(K_1 + K_2 + \log n)$ parallel steps.*

The core of our solution is an optimal algorithm for the (n, K)-*token distribution problem*, which is stated as follows: n tokens are initially distributed among n processors, with no more than K at each site. Redistribute the tokens through a bounded-degree network so that each processor will have exactly one token.

This problem is thus very similar to the $(n, K, 1)$-routing problem, except that the destinations of the tokens are immaterial and not fixed in advance. It is trivial to see that any algorithm for the (n, K)-distribution problem, combined with any permutation-routing algorithm, implies also an algorithm for the $(n, K, 1)$-routing problem, with the same time complexity (up to an additive factor of $O(\log n)$). It is slightly harder to show that the same applies to the $(n, 1, K)$-, and hence also to the (n, K, K)-, routing problems.

This problem was studied to some extent on networks of unbounded degree. Leighton [L2] has derived an $O(K + \log n)$ algorithm for (n, K)-token distribution on an n-processor hypercube. The best lower bound known for this problem on the hypercube is $\Omega(K/\log K)$[K]. In this paper we give an optimal solution for the problem on bounded-degree networks.

THEOREM 3. *The complexity of the (n, K)-token distribution problem on bounded-degree communication networks is $\Omega(K + \log n)$.*

THEOREM 4. *There exist an (explicitly constructible) n-processor bounded-degree network and a deterministic algorithm that solves the (n, K)-token distribution problem on this network in $O(K + \log n)$ steps.*

In addition to its importance in the context of communication, the token distribution problem has direct applications to the problem of load balancing in distributed systems. Consider each token as an independent process waiting for execution. Then a token distribution algorithm provides an efficient distributed method for balancing the queue lengths of the individual processors. This and other applications motivate the study of a more general distribution problem, in which the number of tokens is larger than the number of processors in the system and the goal is to uniformly distribute the tokens among the processors. Our method is extended to give an optimal solution for this problem as well [PU].

The token distribution algorithm works in two phases. First an *approximate* token distribution problem is solved deterministically in $O(K + \log n)$ steps, leaving no more than $O(1)$ tokens in each processor. Then, an *exact* distribution is achieved using an $O(\log n)$ routing or sorting algorithm.

It is easy to verify that both these problems can be solved in $O(K + \log n)$ time only on expander graphs. (An (α, β)-*expander* is a graph with the property that for every set U subject to $|U| \leqq \beta n$, $|\Gamma(U) - U| \geqq \alpha |U|$, where $\Gamma(U)$ denotes the set of neighbors of nodes in U.) The rapid progress in the explicit construction of strong, low-degree expander graphs [LPS] suggests that expanders are very likely to become

a feasible pattern for future communication networks. These new construction methods should motivate more research on algorithms that exploit the special properties of expander graphs.

Since these problems appear in a variety of applications, our goal is to provide an optimal solution for a large class of communication networks, preferably for all networks for which such a solution exists. Indeed, the solution to the approximate token distribution problem differs from other known algorithms for network routing in that it is not tailored for one particular network; rather, it solves the problem on any d-regular expander graph with a sufficient expansion factor (which is still small enough so that there exist such explicitly constructed networks).

The solution to the approximate problem involves solving a subproblem which is of general interest by itself. This is the problem of constructing a directed subgraph in a network (e.g., a spanning tree), based on some local property P, such that the subgraph is centered around the nodes enjoying P, and the other nodes appear only in the periphery (i.e., as leaves). This can be done distributedly, when initially every node knows only whether he/she itself has P.

In the second part of this work (§ 5) we attempt to achieve a similarly wide result for the *exact* K token distribution problem. We do not know of any deterministic algorithm that can sort or route n elements in $O(\log n)$ steps on every expander. However, we present a probabilistic algorithm that solves the $(n, 1, 1)$-routing problem, i.e., executes any $(n, 1, 1)$-communication request in $O(\log n)$ steps on any d-regular expander. The algorithm is a variant of Valiant's two-phase routing algorithm [V]. Note that the routing algorithms mentioned above were devised for special networks, and their analyses depended strongly on the network topology. Our analysis of the new algorithm uses a completely different approach. Since we analyze the algorithm for a whole class of graphs, characterized by some abstract properties, the analysis can make use only of these properties of the graphs rather than their particular design. In our case we use information about the eigenvalues of the adjacency matrix of an expander graph to analyze the convergence of a Markov chain, which is the core of the algorithm.

THEOREM 5. *Let G be an n-vertex d-regular graph, and let $\lambda(G)$ denote the second largest eigenvalue in absolute value of its adjacency matrix. If $d - \lambda(G)$ is bounded away from zero, then the probabilistic routing algorithm implements any $(n, 1, 1)$-communication request on G in $O(\log n)$ parallel steps.*

A recent result of Alon [Al1], [Al2] guarantees that the above condition on $\lambda(G)$ holds for any d regular expander graph. Thus we prove Theorem 6.

THEOREM 6. *Exact (n, K)-token distribution can be achieved by a probabilistic algorithm in $O(K + \log n)$ steps on any sufficiently strong regular expander graph.*

Theorem 4 has further implications, beyond the context of the token distribution problem. To mention a few, using Leighton's sorting algorithm [L1] we get Corollary 7.

COROLLARY 7. *There exists a probabilistic algorithm for sorting n elements on any n-processor regular expander graph in $O(\log^2 n)$ steps.*

And in general, using a recent result of Alt et al. [AHMP].

COROLLARY 8. *There exists a probabilistic algorithm that can simulate the execution of any n-processor T-step* PRAM (*parallel random access machine*) *program in $O(T \log^2 n)$ steps on any n-vertex regular expander.*

Finally, in § 6 we study the token distribution problem on general given networks. We first give a specific lower bound for any network and any initial distribution. This bound can be as bad as $\Omega(n)$ for some particular graphs and distributions. We then

give a general deterministic algorithm that works on any network and for every initial distribution in $O(n)$ steps.

2. Notation. We first define precisely the underlying model. Throughout, our communication network is modeled by an undirected graph $G=(V, E)$, where $|V|=n$ and the maximal degree is d. The system is assumed to be synchronous, and we use the number of rounds (clock ticks) as our time measure. A node can send at most one message along any adjacent edge in one timestep, where by *message* we mean either a token (i.e., a packet) or a string of $O(\log n)$ bits. Thus a node may send up to d messages in any time unit. (This does not affect the time complexity of our problem, since we consider only graphs of bounded degree.) We assume that the processors can perform an unlimited amount of computation in every timestep. However, in our upper bounds local computations are minimal (i.e., logarithmic in n).

For every node $v \in V$ we denote the number of tokens in v in any given moment by $t(v)$, where $\sum_v t(v)=n$. We assume that the tokens are numbered. However, this is not necessary, as the tokens can be numbered initially in $O(\log n)$ time.

3. Reducing routing to distribution. In this section we sketch how an $O(K+\log n)$ algorithm for token distribution (to be described in the rest of the paper) implies an $O(K_1+K_2+\log n)$ solution for the (n, K_1, K_2)-routing problem on an n-vertex network.

For every processor v_i, let x_i denote the number of tokens whose destination is $v_i (x_i \leqq K_2)$.

A central component of the simulation is a step in which we count the number of tokens to be sent to each processor. For this step we assume that we have preconstructed on the graph a tree of bounded degree and depth $O(\log n)$ whose leaves are precisely all the nodes of the graph (so each node appears once as a leaf and possibly several more times as an internal node). It is easy to prove that such a tree exists for any bounded-degree graph whose diameter is $O(\log n)$, and hence in particular for any expander. The tree has to be constructed once, and be known to all the processors. We also assume, for the purposes of the simulation, that the nodes of the graph are numbered in an order corresponding to some depth-first traversal of the tree.

The routing problem is solved in six steps:

(1) Run the token distribution algorithm.
/* At the end of this step each processor stores exactly one token. */

(2) Sort the tokens according to their destinations.
/* At this point, the x_1 tokens with destinations v_1 are located in processors $v_1, \cdots, v_{x_1}$, the x_2 tokens with destinations v_2 are located in processors $v_{x_1+1}, \cdots, v_{x_1+x_2}$, and so on. */

(3) Count for each processor v_i the number x_i of tokens to be sent to it. This can easily done by the following three substeps:

(3.1) Perform the actual counting, using the tree structure described earlier, by shipping upwards partial counting information. (See [Ul].)
/* At the end, the numbers x_i are held at different nodes in various levels of the tree, with at most d numbers in any "virtual" tree node, and hence at most $O(d \log n)$ numbers in each "real" graph node. */

(3.2) Distribute the numbers in the graph, using the token distribution algorithm.

(3.3) Permute these values, sending x_i to v_i.
/* At the end of this step, each processor v_i knows the number of tokens it should expect. */

(4) Each processor v_i produces x_i dummy tokens and supplies them with the labels "(i, j)," $1 \leqq j \leqq x_i$.
(5) Run the token distribution algorithm on the dummy tokens and then sort them lexicographically according to their labels (with i being more significant than j). During this step the paths used by the tokens are recorded by the intermediate processors. (That is, in every time unit, every processor records the label and entry/exit edge of each token going through it.)
/* After this step every node has two tokens: a real one, destined for some node v_i, and a corresponding dummy one that originated at v_i. */
(6) Send the real tokens to their destinations, each traversing the path "marked" by its corresponding dummy token, in reverse order.

Analysis. The sorting and permutation of steps (2), (3.3), and (5) require the network to be an S-network and take time $O(\log n)$. Step (3.1) can be done in time $O(\log n)$ also; step (4) takes time $O(1)$; and step (6) takes the same amount of time as step (5). Assuming that we have an $O(K+\log n)$ token distribution algorithm, step (1) takes time $O(K_1+\log n)$; steps (5), (6) take time $O(K_2+\log n)$; and step (3.2) takes time $O(\log n)$ (since it starts with $K = O(\log n)$), so overall, the above reduction implies Theorem 3.1.

THEOREM 3.1. *There exist an (explicitly constructible) n-processor bounded-degree network and a (deterministic) algorithm that solves any (n, K_1, K_2)-communication request in $O(K_1+K_2+\log n)$ parallel steps on that network.*

To achieve this run-time we need a network that satisfies the requirements of the token distribution algorithm and is also an S-network.

4. The token distribution problem. In this section we give the lower bound for token distribution, and then describe a deterministic algorithm for the approximate problem on a wide class of expander networks. We then extend this algorithm to an algorithm for the exact problem.

THEOREM 4.1. *The approximate and exact (n, K)-token distribution problems require $\Omega(K+\log n)$ steps on any bounded-degree network. Further, $O(K+\log n)$ run time is achievable only on expander graphs.*

Proof. Since the degree of the graph is bounded, $\Omega(K)$ steps are needed in order to take K tokens out of a processor. Also, to send rs tokens out of any set of size s in $O(r)$ steps the set needs to have $O(s)$ edges connecting them to the rest of the network. Thus, the graph must be an expander.

To prove the $\Omega(\log n)$ bound, observe that in any bounded-degree network there are three vertices that are at least $\delta \log n$ apart from each other for some $\delta = \delta(d) \geqq 0$. Let u_1, u_2, and v be three such vertices. Fix an initial distribution of tokens as follows. Give one token to each processor in the graph other than u_1, u_2, and v. Give two tokens to v and the remaining one to either u_1 or u_2. Let $N(u_1, \frac{1}{2}\delta \log n)$ be the set of vertices that are within distance $\frac{1}{2}\delta \log n$ or less from u_1 and let $F(u_1, \frac{1}{2}\delta \log n)$ be the set of vertices that are in distance $\frac{1}{2}\delta \log n$ or more from u_1. At the termination of the algorithm, the total flow from the set $F(u_1, \frac{1}{2}\delta \log n) - N(u_1, \frac{1}{2}\delta \log n)$ to the set $N(u_1, \frac{1}{2}\delta \log n) - F(u_1, \frac{1}{2}\delta \log n)$ is one if u_1 did not get a token initially and zero otherwise. The set $N(u_1, \frac{1}{2}\delta \log n) \cap F(u_1, \frac{1}{2}\delta \log n)$ cannot get information on the initial number of tokens in u_1 in less than $\frac{1}{2}\delta \log n$ steps; thus the algorithm execution must take $\Omega(\log n)$ steps. □

4.1. Approximate token distribution. Our algorithm employs parallelism on two levels. The algorithm consists of $O(\log K)$ phases, each of which reduces the maximum number of tokens at any site in the network by a constant factor. In the execution of

each phase, parallelism is employed in the n processors in the usual sense. However, executing the $O(\log K)$ iterations successively does not yield the desired run-time. To speed up the algorithm we introduce a second level of parallelism by executing all of the phases in parallel. We manage to do so despite the fact that the input of one phase is the output of the previous one.

Our solution works on graphs of the following type. A *sqrt expander* is an expander with the additional property that there exists $0 \leqq i \leqq d$ subject to $\alpha > (d+i^2)/(i+1)$. For such expanders we define $l = \min\{i \mid \alpha > (d+i^2)/(i+1)\}$ as the *spanning factor* of the *sqrt* expander. Note that this requirement holds approximately when $\alpha > 2\sqrt{d}$, and it is possible to explicitly construct *sqrt* expanders with the above property and with relatively low degree. For instance, the construction in [LPS] yields expanders with second eigenvalue $\lambda_2 \leqq 2\sqrt{d-1}$, and using Tanner's equation [T, Thm. 2.1] we get $\alpha > d/4$ for sufficiently small β.

We first describe the algorithm assuming the phases are carried out sequentially. Our goal is to reach a situation in which $t(v) \leqq c$ for every v, for some fixed constant c (independent of n and K). In particular, for a *sqrt* (α, β)-expander we choose $c = \lceil 2/\beta \rceil$. In the beginning of phase j ($j = 0, 1, \cdots$) the current maximum is no larger than K_j. The *convergence property* relating the phases is $K_j = \gamma^j K$, or alternatively $K_{j+1} = \gamma K_j$, where $\gamma = (2l+1)/(2l+2)(0 < \gamma < 1)$ and l is the spanning factor of the underlying expander.

As the phases are identical, we shall describe one phase j in general. Consider a set U_j of "heavily loaded" nodes (i.e., all nodes with more tokens than a certain threshold). During the phase the nodes first distributedly construct a directed acyclic graph in which *all* of the heavy nodes participate as internal nodes, and the leaves are taken from among the lightly loaded nodes. Then, the internal nodes ship tokens to their children in the dag for a prescribed number of steps. The construction of the dag guarantees that the heavy nodes keep losing tokens in every shipping step (it is most convenient to visualize the particular case of a binary forest). More precisely, let $U_j = \{v \mid t(v) \geqq K_j/2\}$. The phase j consists of two parts.

Part (1) *Dag construction.* Distributedly construct a *dag* $G' = (V', E')$ with the following properties:

(1) $U_j \subseteq V' \subseteq V$.

(2) $E' \subseteq E$ (looking at the underlying undirected edges).

(3) For every $v \in V'$, indegree $(v) \leqq l$.

(4) For every $v \in U_j$, outdegree $(v) = l+1$.

(Again l is the spanning factor of the expander. Note that when $l = 1$ indeed we get a binary forest.)

Part (2) *Token flow.* Perform $K_j/2(l+1)$ "flow" steps, in which on every edge $(u, v) \in E'$, u sends a token to v.

Before going into the details of the construction, let us note that the above properties of the dag guarantee the promised convergence property.

LEMMA 4.2. *Upon completion of phase j, for every v,* $t(v) \leqq K_{j+1} (= \gamma K_j)$.

Proof. Clearly we only need to consider nodes in V'. If $v \in U_j$ then in every flow step it receives at most l tokens and sends $l+1$, so it loses a token per step, and hence the new bound. If $v \in V' - U_j$ then it begins with less than $K_j/2$ tokens, and gets at most l in every flow step, so it will also end with no more than γK_j tokens. □

Construction of the dag. The dag is constructed "bottom up" while keeping the nodes of U_j that did not choose children yet in a set W. Throughout, each node knows whether or not it is in W. Initially $W = U_j$ and in every following step some of the

nodes in W choose children and leave W, and are ready to be chosen as children of other members of W. Each step of the construction of the dag is of the following form:

(1) Every node $v \in W$ informs all its neighbors that it belongs to W.
(2) A node $v \notin W$ that received such messages from at most l neighbors returns to these neighbors the message "ready" (meaning intuitively: "I'm ready to be chosen as a child and consequently to receive tokens").
(3) A node $v \in W$ that has received "ready" messages from at least $l+1$ neighbors, chooses exactly $l+1$ of them as children and so informs them. (The edge set E' will contain directed edges from v to these nodes.) For the rest of the construction, v removes itself from W.
These steps are repeated as long as $W \neq \emptyset$.

It is easy to see that nodes participating in the dag obey the degree requirements in the definition. Specifically, we have the following lemma.

LEMMA 4.3. *For every* $v \in V'$, indegree $(v) \leqq l$, *and if* $v \in U_j$ *then also* outdegree $(v) = l+1$.

Proof. A node v receives parents in the dag only if and when $v \notin W$. Consider the first iteration i during which a node $v \notin W_i$ sends "ready" messages to (some of) its neighbors. This happens if there are at most l neighbors of v in W_i. The set W shrinks with every iteration, so clearly all possible parents of v come from among its (at most l) possible parents in W_i.

The second condition holds trivially. □

For the analysis, denote the sequence of sets W in the successive iterations by $U_j = W_0 \supseteq W_1 \supseteq \cdots \supseteq W_m$. We have to prove that the construction process stops with $W_m = \emptyset$ and further, that $m \in O(\log |U_j|)$. The proof can be sketched along the following lines.

For a set $U \subseteq V$ we denote by $\Gamma(U)$ the set of neighbors of nodes in U. Let $\Gamma_i = \Gamma(W_i) - W_i$, $X_i = \{v \mid v \in \Gamma_i, v \text{ has at most } l \text{ neighbors in } W_i\}$, $Y_i = \{v \mid v \in W_i, v \text{ has at least } l+1 \text{ neighbors in } X_i\}$, and $\delta = 1 - ((l+1)\alpha - d - l^2)/l(d-l)$.

LEMMA 4.4. $0 < \delta < 1$.

Proof. It suffices to show that $0 < ((l+1)\alpha - d - l^2)/l(d-l) < 1$, and this follows from the choice of the expander to satisfy $(d+l^2)/(l+1) < \alpha < d$. □

LEMMA 4.5. $|\Gamma_i| \geqq \alpha |W_i|$, *where* α *is the expansion constant of the graph.*

Proof. The definition of U_j implies $|U_j| \leqq 2n/K$. $W_i \subseteq U_j$, and $K > c = \lceil 2/\beta \rceil$. Put together, $|W_i| \leqq |U_j| \leqq 2n/\lceil 2/\beta \rceil \leqq \beta n$, so the expansion requirement holds for W_i. □

LEMMA 4.6. $|X_i| \geqq (((l+1)\alpha - d)/l)|W_i|$.

Proof. Denote by e the number of edges between W_i and Γ_i. Clearly $e \leqq d|W_i|$. On the other hand, from every node in X_i there is at least one edge to W_i, and from every node in $\Gamma_i - X_i$ there are at least $l+1$ such edges. Hence,

$$1 \cdot |X_i| + (l+1)|\Gamma_i - X_i| \leqq e.$$

Combining the two inequalities we get $(l+1)|\Gamma_i| - l|X_i| \leqq d|W_i|$. Together with the previous lemma we have $l|X_i| \geqq (l+1)\alpha|W_i| - d|W_i|$. □

LEMMA 4.7. $|Y_i| \geqq (1-\delta)|W_i|$.

Proof. Every node in Y_i has at most d neighbors in X_i, and every node in $W_i - Y_i$ has at most l neighbors in X_i. Therefore

$$l|W_i - Y_i| + d|Y_i| \geqq |X_i|,$$

and the result follows from the previous lemma. □

COROLLARY 4.8. $|W_{i+1}| \leqq \delta |W_i|$.

Proof. The proof follows from the fact that $W_{i+1} = W_i - Y_i$, together with the previous lemma. □

COROLLARY 4.9. *The dag can be constructed correctly in* $O(\log n)$ *steps.* □

Summarizing, the algorithm requires $O(\log K)$ phases, where phase j takes time $O(K_j + \log n)$ and $K_j = \gamma^j K$. Therefore, the K_j components sum up to $O(K)$, and the entire time is in $O(K + \log n \log K)$, which, for $K \leqq n$, is contained in $O(K + \log n \log\log n)$. To reach optimality it remains to eliminate the consecutive execution of the phases.

Parallelization of the phases. It is clear that as long as $K_j \geqq O(\log n)$, the cost of a single phase is dominated by the "token flow" steps. The cost of the dag construction becomes significant only from that point on. Therefore we may execute the first few phases sequentially, and parallelize only when $K_j < 2(l+1)\log n$.

The idea for parallelizing the phases is based on the observation that we can "separate" the phases, i.e., construct all the dags first and perform all the token transitions afterwards. Furthermore, the communication required for the construction of the dags is only $O(1)$ bits per step, while the model allows us to use $O(\log n)$ bit messages. We also observe that to begin building the dag for the $j+1$st phase it is not necessary to have completed the jth dag, but merely to know U_{j+1}. This leads to the idea of trying to find a fast way of identifying the sets U_j in advance, and then constructing the dags in parallel. An obvious obstacle to this idea is the fact that the exact composition of U_{j+1} is determined only upon completion of the construction of the jth dag. However, it is possible to maintain approximations $\hat{t}(v)$ for the number of tokens in every node, upper bounding the real number $t(v)$, and to identify a larger set $\hat{U}_{j+1}$ that is guaranteed to contain U_{j+1} and that can be constructed in $O(\log\log n)$ steps (from knowing $\hat{U}_j$).

It should be clear that when using $\hat{U}_j$ instead of U_j we will still have $K_j = \gamma^j K$ as the bounds on the number of tokens at the beginning of phase j. The worst that might happen is that nodes in $\hat{U}_j - U_j$ will discover this fact during the actual flow steps, and may cease sending tokens if they do not have any, which can only result in some nodes having fewer tokens than expected.

The sets $\hat{U}_j$ are constructed *serially* as follows. For $j = 0$, $\hat{U}_0 = U_0 = \{v \mid t(v) \geqq K/2\}$. For $j \geqq 0$, we start phase j from $\hat{U}_j$ and apply the dag construction for $m = 2\log_{1/\delta}\log n$ iterations. The remaining set of candidates (nodes from $\hat{U}_j$ who still need to choose children) was denoted earlier by W_m. Let $\hat{W}_j = W_m$ and $Z_j = \hat{W}_j \cup \Gamma(\hat{W}_j)$. Denote by T_j the set of all nodes $v \notin Z_j$ that entered the dag during the jth iteration (as parents, children, or both). At this point each node v in the graph is required to determine its value of $\hat{t}(v)$ at the end of the jth phase. For nodes $v \notin (Z_j \cup T_j)$ this value cannot possibly change during this phase. Nodes in T_j ask their parents in the dag for the number of tokens they should expect to receive during the flow steps of phase j (note that, unlike the situation in the serial execution, a parent may send its sons fewer than $K_j/2(l+1)$ tokens during phase j). Since the dag is of depth $m = -2\log_\delta \log n$, this information can be collected in $O(\log\log n)$ steps using $O(\log\log n)$-bit messages, and then the new value of $\hat{t}(v)$ can be computed directly, for every $v \in T_j$. Finally, nodes in Z_j *cannot* yet estimate the number of tokens they will have at the end of the phase. Therefore they exaggerate and take this number to be the maximum possible, K_{j+1}. This can be viewed as a commitment on behalf of these nodes to produce "dummy" tokens and distribute them if they do not have enough. (This assumption serves to simplify the analysis, but the commitments clearly do not have to be honored

during the actual flow steps, which accounts for the difference between $t(v)$ and $\hat{t}(v)$.) Now we take $\hat{U}_{j+1} = \{v \mid \hat{t}(v) \geqq K_{j+1}/2\}$.

This process can be repeated as long as $\hat{U}_j \leqq \beta n$. Clearly $U_j \subseteq \hat{U}_j$. The crux of the analysis is in showing that the sets $\hat{U}_j$ do not grow too fast. This requires us to bound the number of dummy tokens added along the process.

LEMMA 4.10. *The number of phases is* $O(\log \log n)$.

Proof. Since $\hat{U}_j \geqq U_j$, the number of phases is bounded above by the number of phases in the serial algorithm. □

LEMMA 4.11. *In every phase* j, $|Z_j| \leqq (d+1)n/\log^2 n$.

Proof. Recall that $\hat{W}_j$ is the set W_m obtained after m iterations of the dag construction in phase j. Hence $|\hat{W}_j| \leqq \delta^m |W_0| \leqq \delta^{-2 \log_\delta \log n} n = n/\log^2 n$, and $|Z_j| \leqq |\hat{W}_j| + |\Gamma(\hat{W}_j)| \leqq (d+1)n/\log^2 n$. □

LEMMA 4.12. *In every phase* j, $\sum_v \hat{t}(v) \leqq 2n$.

Proof. The number of dummy tokens added by nodes in Z_j in any single phase is bounded by $|Z_j| K_j \leqq (d+1)n/\log n$. Hence by Lemma 4.10, the total number of tokens added to the system is in $o(n)$. □

LEMMA 4.13. $|\hat{U}_j| \leqq 4n/K\gamma^j$.

Proof. By the definition of $\hat{U}_j$ and by Lemma 4.12,

$$2n \geqq \sum_{v \in \hat{U}_j} \hat{t}(v) \geqq |\hat{U}_j| \frac{K\gamma^j}{2},$$

and the result follows immediately. □

As noted before, the sets $\hat{U}_j$ are usable as long as they are no larger than βn. By the last lemma this holds while $4n/K\gamma^j \leqq \beta n$, or in other words while

$$j \leqq J = \left\lfloor \log\left(\frac{4}{\beta K}\right) \Big/ \log \gamma \right\rfloor.$$

This number of phases lowers K down to $K' \leqq \lceil 4/\beta \rceil$, which is still constant, although twice as large as that achieved in the serial construction. Therefore the general process proceeds as follows.

(1) For each of the first $J+1$ phases ($0 \leqq j \leqq J$), start from the set $\hat{U}_j$, perform the first m steps of the dag construction, identify the sets $\hat{W}_j$ and Z_j, and determine the new value of $\hat{t}(v)$ for every v and $\hat{U}_{j+1}$. These phases are executed serially, in time $O((\log \log n)^2)$.

(2) Complete the construction of all the dags of the first $J+1$ phases *in parallel*, based on the sets $\hat{W}_j$, in time $O(\log n)$.

(3) Perform the actual flow of tokens on the constructed dags, phase by phase (for J phases).
The total cost is therefore $O(K + \log n)$.

THEOREM 4.14. *The approximate* $V(n, K)$*-token distribution problem can be solved deterministically in time* $O(K + \log n)$ *on sqrt expanders.* □

4.2. Exact token distribution. Our algorithm for the exact (n, K)-token distribution problem starts with solving the approximate problem. Assuming that the tokens are numbered, the remaining problem can be viewed as an $(n, c, 1)$-routing problem, where c is a constant independent of n and K. In this section we will show that the $(n, c, 1)$-routing problem can be solved deterministically, in $O(\log n)$ steps on any n-vertex S-network. More significantly, the result of the next section shows that the same run-time can be achieved probabilistically on any regular $(\alpha, \frac{1}{2})$-expander graph ($\alpha > 0$). Thus, we have the following theorem.

THEOREM 4.15. *Exact (n, K)-token distribution can be achieved in time $O(K + \log n)$:*

(1) *Deterministically on any network combined of a sqrt-expander + an S-network.*
(2) *Probabilistically on any network combined of a sqrt-expander + a regular $(\alpha, \frac{1}{2})$-expander $(\alpha > 0)$.* □

THE $O(\log n)$ DETERMINISTIC $(n, c, 1)$-ROUTING ALGORITHM. Initially all the tokens are labeled *I*. When a token reaches its final location its label is changed to *F*.

Repeat the following six steps for c times:

(1) A processor that stores some tokens with label I changes the label of one of these tokens to R. A processor that does not store such tokens generates a dummy token with label R and value $-\infty$.
(2) Sort the n tokens with label R according to their values.
(3) Discard the dummy tokens.
(4) A processor that stores a token with label F generates a dummy token with label R and value $-\infty$. A processor that does not store a token with label F or R generates a dummy token with label R and value $+\infty$.
(5) Sort the n tokens with label R.
(6) Discard the dummy tokens and change all the labels R to F.

Analysis. Since initially there are no more than c tokens in each processor, after c iterations of the algorithm all the tokens are *processed*, i.e., given label R, moved to a new location and given label F. Note that each token moves during exactly one iteration, and does not move afterward.

Assume that x tokens have been processed during the first $i-1$ iterations, and assume also that at the beginning of the ith step these tokens are stored in processors $1, \cdots, x$, one in each processor. (These inductive assumptions certainly hold for $i = 1$ and $x = 0$.) Let y be the number of tokens processed during the ith iteration. After the first sorting phase (step (2)), these y tokens are stored in processors $n-y+1, \cdots, n$, one in each processor. Clearly, $n - y \geqq x$ and the second sorting phase (step (5)) involves x dummy tokens with value $-\infty$ and $n-y-x$ dummy tokens with value $+\infty$. This implies that the y "real" tokens processed in the ith iteration end up in places $x+1, \cdots, x+y$. Thus at the end of the last iteration all the tokens are evenly distributed among the processors.

Each iteration involves two sorting phases; thus the total run-time is $O(c \log n)$, which is $O(\log n)$ when c is a constant.

5. Routing on regular expanders. In this section we give a probabilistic algorithm that solves the (qn, q, q)-routing problem on any d-regular n-vertex $(\alpha, \frac{1}{2})$-expander graph in $O(q \log n)$ parallel steps. As mentioned in § 4, augmenting this result with the approximate distribution algorithm we get a probabilistic algorithm that solves the (n, K)-distribution problem in optimal time on any graph that is both a *sqrt*-expander and an $(\alpha, \frac{1}{2})$-expander for some $\alpha > 0$.

The communication protocol we use is a variant of the protocol used in [U] for the butterfly network, based on Valiant's two-phase randomized routing scheme [V]. The process of routing a packet to its destination has two phases. Each phase consists of L ($L = O(q \log n)$) transitions. In the first phase every packet X performs L random transitions. If X is in processor u and e is an edge going out of u, then X chooses e for its next transition with probability $1/d$.

The first phase defines the following sets of probabilities for every pair of vertices $\{u, v\}$ and for every $1 \leqq j \leqq L$. $P^j_{u,v}$ is the probability that a packet initially located at

u enters processor v in its jth random transition, and $P^j_{u,v}(e)$ is the probability that a packet initially located at u enters v in its jth random transition through edge e. Note that these probabilities do not depend on the destination of the packet.

In the second phase every packet is sent from its current location to its final destination in L transitions. Its route is defined as follows: If a packet is on its way to processor u, and is located in processor v after executing $L-j$ transitions of this phase, then it chooses an edge e for its next transition with probability $P^j_{u,v}(e)/P^j_{u,v}$. We show in the analysis that for every pair (u, v), $P^L_{u,v}>0$. Thus, the routes are properly defined and on the Lth transition a packet always reaches its destination. Note that these probabilities must be computed only once, when the network is constructed, and this computation can be done very efficiently.

We still have to specify the queue policy of processors. In each step every packet has a *priority* associated with it, which is the number of transitions the packet has already performed. In the first phase the priority numbers are $1, \cdots, L$ and in the second phase $L+1, \cdots, 2L$. The packet with the smallest priority number is the first to be transmitted. Thus, priorities are used to speed up slower packets at the expense of faster ones.

THEOREM 5.1. *There are constants $S=S(d)$ and $R=R(d)$ such that the routing algorithm executes any (qn, q, q)-communication request on any d-regular $(\alpha, \frac{1}{2})$-expander in $Sq \log n$ steps with probability $1-e^{-R \log n}$.*

Proof. Let G be a d-regular $(\alpha, \frac{1}{2})$-expander and let $A=(a_{i,j})$ be its adjacency matrix. A random walk of a packet on the graph defines a Markov process in which a state of a packet at a given time is its location in the graph. Let $B=(b_{i,j})$ be its stochastic transition matrix. An estimate of the convergence rate of this process to its stationary state is the crux of the analysis. Since G is d-regular, $B=A/d$. To analyze the Markov process we need bounds on the eigenvalues of B, which we obtain from the following algebraic characterization of expanders.

For any matrix M we denote its eigenvalues by $\lambda_1(M) \geqq \lambda_2(M) \geqq \cdots$.

THEOREM 5.2 (Alon [Al1]). *Let G be a d-regular $(\alpha, \frac{1}{2})$-expander with an adjacency matrix A. Then $d-\lambda_2(A)$ is bounded away from zero.* □

By observing that the proof of Theorem 5.2 holds even if G is a multigraph we can slightly extend the result of the theorem. Let G^2 be the graph defined by the matrix A^2. Since G is an expander, so is G^2. Thus, $\lambda_2(A^2)$ is bounded away from d^2. However, $\lambda_2(A^2)=\max_{i \neq 1} \lambda_i(A)$; thus $\max_{i \neq 1} |\lambda(A)|$ is bounded away from d.

COROLLARY 5.3. *Let G be a d-regular $(\alpha, \frac{1}{2})$-expander with an adjacency matrix A. Then $d-|\lambda_i(A)|$ is bounded away from zero for any $i \neq 1$.*

Let $Q^j_{u,v}$ be the probability that a packet located at u will reach v in exactly j random transitions.

LEMMA 5.4. *There is a constant $\gamma<1$ such that for every pair (u, v), $Q^j_{u,v} \leqq 1/n+\gamma^j$.*

Proof. The matrix B is real and symmetric and thus has real nonnegative eigenvalues $\lambda_1(B), \cdots, \lambda_n(B)$ with corresponding orthogonal eigenvectors $\bar{a}_1, \cdots, \bar{a}_n$. Since $B=A/d$, $\lambda_i(B)=\lambda_i(A)/d$. It is easy to check that $\lambda_1(A)=d$, and from Corollary 5.3 we get that $\lambda_2(A)$ is bounded away from d; thus $\lambda_1(B)=1$ and $\lambda_2(B)$ is bounded away from 1. It is also easy to check that a possible choice for $\bar{a}_1$ is the vector I/n, where I is the unit vector.

To compute $Q^j_{u,v}$ we start with a vector $\bar{b}$ having 1 in the entry corresponding to the processor u and zero elsewhere and look at the entry corresponding to v in the vector $\bar{b}B^j$. Let $\sum_{i=1}^n \eta_i \bar{a}_i$ be the orthogonal representation of $\bar{b}$. Then $\bar{b}B^j=\sum_{i=1}^n (\lambda_i(B))^j \eta_i \bar{a}_i$. It is easy to verify that η_1 must be 1 since $\sum_{i=2}^n (\lambda_i(B))^j \eta_i \bar{a}_i$ converges to zero. Therefore, we get $Q^j_{u,v} \leqq 1/n+(\lambda_2(B))^j$. □

LEMMA 5.5. *Let* $L = 3(\log 1/\gamma)^{-1} \log n$. *Then for every pair* u, v, $1/n - 1/n^2 \leqq Q^L_{u,v} \leqq 1/n + 1/n^3$.

Proof. From Lemma 5.4 we immediately get the second inequality, since $Q^L_{u,v} \leqq 1/n + \gamma^L = 1/n + 1/n^3$. Now fix a pair of nodes u and v. Clearly $\sum_{w \in V} Q^L_{u,w} = 1$, and by the second inequality, $\sum_{w \neq v} Q^L_{u,w} \leqq (n-1)(1/n + 1/n^3)$. Put together, we get $Q^L_{u,v} \geqq 1/n - 1/n^2$. □

LEMMA 5.6 *For any* d-*regular* $(\alpha, \frac{1}{2})$-*expander* G *there exists a bounded-degree* d'-*regular* $(\alpha', \frac{1}{2})$-*expander* G' *for some* $\alpha' > 0$, (*obtained by a suitable iterative construction*) *with an adjacency matrix* A' *such that* $\lambda_2(A'/d') < \frac{1}{2}$ *and a communication step on* G' *can be simulated by* $O(1)$ *communication steps on* G.

Proof. Define A and B as above with respect to G and let k be the minimum integer such that $\lambda(B)^k < \frac{1}{2}$. Define G' as follows: G' has the same vertex set as G, u and v are connected by an edge in G' if and only if their distance in G is k. Clearly G' is a d^k-regular (multi-)graph, and if A' is the adjacency matrix of G' then $\lambda_2(A') = (\lambda_2(A))^k$. Thus, $\lambda_2(A'/d^k) = (\lambda_2(A)/d)^k = (\lambda(B))^k < \frac{1}{2}$, and clearly a step on G' can be simulated by kd^k steps of G. □

Due to Lemma 5.6 we can assume without loss of generality that $\gamma = \lambda_2(B) < \frac{1}{2}$.

LEMMA 5.7. *There are positive constants* S' *and* R' *such that the execution of the first phase terminates in* $S'q \log n$ *steps with probability* $1 - e^{-R'q \log n}$.

Proof. For the purposes of the proof we consider the following modified algorithm. No processor ever transmits a message of priority i before it has transmitted all messages of priority less than i that it will ever transmit. Such an execution clearly takes at least as long as an execution of the original algorithm.

The analysis is based on the familiar technique of *critical delay sequences* [U]. This technique has so far been applied only to highly structured networks such as the butterfly [P], [RV]. In contrast, expanders are of much more general, unspecified and seemingly irregular structure, which makes the task harder. A *delay sequence* is a sequence of processors $v_0, \cdots, v_L$, such that for any $i < L$ either $v_i = v_{i+1}$ or v_i is one of the d processors connected to v_{i+1}. A delay sequence is *critical* if v_L was one of the last processors to transmit a message in the execution of the algorithm, and for each $0 \leqq i < L$, v_i was one of the last processors to transmit messages with priority i from among the d processors connected to v_{i+1} and v_{i+1} itself.

For a given critical delay sequence D, define two random variables:

f^D_i is the number of messages with priority i leaving v_i, and

t^D_i is the time when all messages of priority j leaving v_i, for $j \leqq i$, have been transmitted.

It follows from the construction of the critical delay sequence that if the algorithm terminates after t steps, then $t \leqq t^D_L$. Moreover, at time t^D_i, v_i has finished transmitting all messages with priority less than or equal to i that pass through it and v_{i+1} has received all messages that it should transmit with priority $i+1$. Thus, at time t^D_i each of the f^D_{i+1} messages that v_{i+1} should transmit is either in its queue or has already been transmitted. Therefore, the time required to transmit the f^D_{i+1} messages from the head of v_{i+1}'s queue is an upper bound for $t^D_{i+1} - t^D_i$. Hence $t^D_{i+1} - t^D_i \leqq f^D_{i+1}$.

Denoting $F^D = \sum_{0 \leqq i \leqq L} f^D_i$ and fixing $t^D_0 = 0$, we get $t \leqq \sum_{1 \leqq i \leqq L} (t^D_i - t^D_{i-1}) \leqq \sum_{0 \leqq i \leqq L} f^D_i = F^D$.

Hence we are interested in bounding the probability of an execution that has a critical delay sequence D of length $F^D \geqq cq \log n$ for some $c > 0$.

In order to perform this analysis, we present each f^D_i as the sum of two random variables g^D_i and h^D_i.

g_i^D is the number of messages in f_i^D not appearing in $\cup_{0\leq j\leq i-1} f_j^D$, and h_i^D is $f_i^D - g_i^D$.

Let $F_1^D = \sum_i g_i^D$ and $F_2^D = \sum_i h_i^D$. Then $F^D = F_1^D + F_2^D$.

It is easy to estimate F_1^D. $E(g_i^D) \leq q$ and F_1^D is bounded by the number of successes in qnL independent Poisson trials. Thus, by Hoeffding theorem [H], $Pr\{F_1^D \geq \eta\} \leq B(\eta, qnL, 1/n)$, and using Chernoff [C] bound, we prove that $Pr\{F_1^D \geq s_1' q \log n\} \leq e^{-r_1' q \log n}$ [U].

The tricky part is to bound F_2^D, the estimate for the number of transitions the $F_1^D (= O(q \log n))$ packets performed inside the delay sequence, since a packet might return for an *unpredictable* number of times to the sequence after leaving it (as opposed to the situation on the butterfly). Here we rely again on the expansion properties of the graph. Let Q be the probability that a packet, currently in processor v_i in the delay sequence, will ever return to the sequence. Then, by Lemma 5.4,

$$Q = \sum_{j=1}^{L} Q^j_{v_i, v_{i+j}} \leq \sum_{j=1}^{L} \left(\frac{1}{n} + \gamma^j\right) < 1 \qquad \left(\text{recall } \gamma < \frac{1}{2}\right).$$

Thus, the number of transitions a packet performs on the delay sequence is bounded by a geometrically distributed random variable. The routes of distinct packets are probabilistically independent. Thus, using Chernoff bound again we prove that

$$Pr\{F_2^D \geq s_2' q \log n\} \leq e^{-r_2' q \log n}.$$

Letting $S' = s_1' + s_2'$ and $R' = \min\{r_1', r_2'\}$, we get the required result. □

It remains to analyze the run-time of the second phase.

LEMMA 5.8. *There are constants S'' and R'' such that the second phase is executed in $2S''q \log n$ steps with probability $1 - e^{-R''q \log n}$.*

Proof. The proof is based on the near symmetry between the first and the second phases. The two phases are not entirely symmetric since the endpoint of a packet in the first phase is not uniformly distributed. The bias, however, is bounded by $1/n^2$ (Lemma 5.5), which enables us to prove that the number of packets traversing an edge e with priority i in the execution of an $(2qn, 2q, 2q)$-communication request stochastically bounds the number of packets traversing e with priority $2L - i$ in the execution of a (qn, q, q)-communication request.

Let τ be a path of length L from processor v to processor w, and let $\bar{\tau}$ be the path τ in a reverse order. Let P_τ be the probability that a packet going from v to w in the first phase of the algorithm will use the path τ. Let $A_1(2q)$ be the execution of the first phase of the algorithm on a $(2qn, 2q, 2q)$-communication request and let $A_2(q)$ be the execution of the second phase of the algorithm on a (qn, q, q)-communication request.

From Lemma 5.5 we know that the number of packets going from v to w in $A_1(2q)$ is stochastically lower bounded by the binomial distribution with parameters $B(2qn, 1/n - 1/n^2)$. Thus, the number of packets taking the route τ in $A_1(2q)$ is lower bounded by $B(2qn, (1/n - 1/n^2)P_\tau)$. On the other hand, the number of packets going from w to v in $A_2(q)$ is stochastically upper-bounded by $B(qn, 1/n + 1/n^3)$ and by the definition of the second phase of the algorithm the number of packets taking the route $\bar{\tau}$ is upper-bounded by $B(qn, (1/n + 1/n^3)P_\tau)$. Thus, the number of packets taking the route τ in $A_1(2q)$ is stochastically larger than the number of packets taking the route $\bar{\tau}$ in $A_2(q)$. Fixing an edge e and summing over all routes of length L that contain the edge e as the ith edge of the route, we get that the number of packets traversing e with priority $L - i$ in $A_2(q)$ is stochastically bounded by the number of packets traversing

e with priority i in $A_1(2q)$. Let $T[A_1(2q)]$ (respectively, $T[A_2(q)]$) be the run-time of $A_1(2q)$ (respectively, $A_2(q)$). Then by Lemma 5.6

$$Pr\{T[A_2(q)] \geqq S'2q \log n\} \leqq Pr\{T[A_1(2q)] \geqq S'2q \log n\} \leqq e^{-R'2q \log n}. \quad \square$$

6. Token distribution on general networks. In this section we return to token distribution and look at a generalized version of the problem. The application of token distribution as a tool for load balancing in distributed systems may require solving the problem on an arbitrary given network which might not have good expansion properties. This general problem is much harder. We first give a combinatorial characterization of a lower bound for any particular graph, depending on its specific properties. For each set of vertices $U \subseteq V$, denote by $\gamma(U)$ the number of edges leaving U, and let $t(U)$ denote the total number of tokens initially in U. Let

$$\mathcal{K} = \max\left\{\frac{t(U)-|U|}{\gamma(U)} \mid U \subseteq V, |U| \leqq \frac{n}{2}\right\}.$$

THEOREM 6.1. *The general (n, n)-token distribution problem requires $\Omega(\mathcal{K} + \text{diameter}(G))$ parallel steps on any network G.* $\square$

COROLLARY 6.2. *There exist bounded-degree networks for which the (n, K)-token distribution problem requires $\Omega(n)$ steps, even for $K = 2$.*

Proof. Consider a straight line graph of n nodes (i.e., in which node i is connected to $i+1$ and $i-1$, except the endpoints). Assume the initial distribution is such that

$$t(i) = \begin{cases} 2 & \text{if } i \leqq n/2, \\ 0 & \text{otherwise.} \end{cases}$$

$\square$

For the upper bound we make the assumption that a directed spanning tree was preconstructed on the graph, and is known to every node in the graph. The algorithm we give consists of two steps. In the first, the tokens are sent upwards to the root. In the second, the root sends the tokens downwards according to their destinations—the token labeled i is sent to node i.

It is clear that the algorithm works correctly, and it remains to analyze its running time. Clearly the second step runs in $O(n)$ time. In order to analyze the first phase, let us add the requirement that whenever a node has more than one token, it first sends the token numbered least.

Denote by $h(i)$ the initial distance of token i from the root, and let $\tau(i)$ be the time it took token i to reach the root.

LEMMA 6.3. $\tau(i) \leqq \max\{h(i), \tau(1)+1, \cdots, \tau(i-1)+1\}$.

Proof. If token i was not delayed on its way to the root by other tokens, then $\tau(i) = h(i)$ and we are done. Now assume i was delayed, and let j be the last token delaying i. It is clear that $j < i$, and also that $\tau(i) = \tau(j)+1$, since i was not delayed afterwards, and it followed the same path as j to the root. $\square$

LEMMA 6.4. $\tau(i) \leqq n + i - 1$.

Proof. The proof is by induction on i. For $i = 1$, $\tau(1) = h(1) \leqq n$. Now assume the claim for $1, \cdots, i-1$. By the previous lemma $\tau(i) \leqq \max\{h(i), \tau(1)+1, \cdots, \tau(i-1)+1\}$. By the inductive hypothesis $\tau(i) \leqq \max\{n, n+1, \cdots, (n+(i-1)-1)+1\} = n+i-1$. $\square$

COROLLARY 6.5. *For every token i, $\tau(i) \leqq 2n$.* $\square$

THEOREM 6.6. *The exact (n, K)-token distribution problem can be solved deterministically on any graph in $O(n)$ parallel steps.* $\square$

7. Some open problems. (1) Our algorithm works only for relatively strong expanders. Can it be extended to every expander?

(2) Can the exact token distribution algorithm be made deterministic?

(3) The optimal $O(K+\log n)$ run-time is achievable only on expander graphs. What is the complexity of this problem on other families of graphs? (The lower bound given in the previous section may well be nonoptimal.)

(4) Find a distributed algorithm that solves the problem on any graph in a time that matches its specific lower bound.

Acknowledgment. We thank Nick Pippenger for many stimulating discussions and helpful ideas.

SCHEDULING PRECEDENCE GRAPHS IN SYSTEMS WITH INTERPROCESSOR COMMUNICATION TIMES*

JING-JANG HWANG†, YUAN-CHIEH CHOW‡, FRANK D. ANGER§, AND CHUNG-YEE LEE‡

Abstract. The problem of nonpreemptively scheduling a set of m partially ordered tasks on n identical processors subject to interprocessor communication delays is studied in an effort to minimize the makespan. A new heuristic, called Earliest Task First (ETF), is designed and analyzed. It is shown that the makespan ω_{ETF} generated by ETF always satisfies $\omega_{\text{ETF}} \leqq (2-1/n)\omega_{\text{opt}}^{(i)} + C$, where $\omega_{\text{opt}}^{(i)}$ is the optimal makespan without considering communication delays and C is the communication requirements over some immediate predecessor-immediate successor pairs along one chain. An algorithm is also provided to calculate C. The time complexity of Algorithm ETF is $O(nm^2)$.

Key words. multiprocessor scheduling, worst-case analysis, communication delays

1. Introduction. An extensively studied problem in deterministic scheduling theory is that of scheduling a set of partially ordered tasks on a nonpreemptive multiprocessor system of identical processors in an effort to minimize the overall finishing time, or "makespan." So much literature has been produced in the related area that a number of review articles have been published, including excellent summaries by Coffman [1], Graham et al. [3], and Lawler, Lenstra, and Rinnooy Kan [6]. The underlying computing system of this classical problem is thought to have no interprocessor overhead such as processor communication or memory contention. Such an assumption is a reasonable approximation to some real multiprocessor systems; therefore, applications can be found for the derived theory [5]. The assumption, however, is no longer valid for message-passing multiprocessors or computer networks, since interprocessor communication overhead is clearly an important aspect in such systems and is not negligible.

In this paper, interprocessor communication overhead is made part of the problem formulation and corresponding solutions are derived. The augmented multiprocessing model starts with a given set $\Gamma = \{T_1, T_2, \cdots, T_m\}$ of m tasks, each with processing time $\mu(T_i)$, and a system of n identical processors. The tasks form a directed acyclic graph (DAG) in which each edge represents the temporal relationship between two tasks and is associated with a positive integer $\eta(T, T')$, the number of messages sent from an immediate predecessor T to an immediate successor T' upon the termination of the immediate predecessor. The task model is called an "enhanced directed acyclic graph (EDAG)" and is denoted as a quadruple $G = G(\Gamma, \rightarrow, \mu, \eta)$.

To characterize the underlying system, a parameter $\tau(P, P')$ is introduced to represent the time to transfer a message unit from processor P to P'. The system is then denoted as $S = S(n, \tau)$, where n is the number of identical processors. By varying the values of $\tau(P, P')$, the system model can be used to model several types of systems such as a fully connected system, a local area network, or a hypercube. To accommodate the deterministic scheduling approach, we further assume that the communication subsystem is contention free. Mathematically speaking, the time to take $\eta(T, T')$ units of messages from P to P' is $\tau(P, P') \times \eta(T, T')$, a deterministic value. Figure 1 shows an example of the computing model and a feasible schedule.

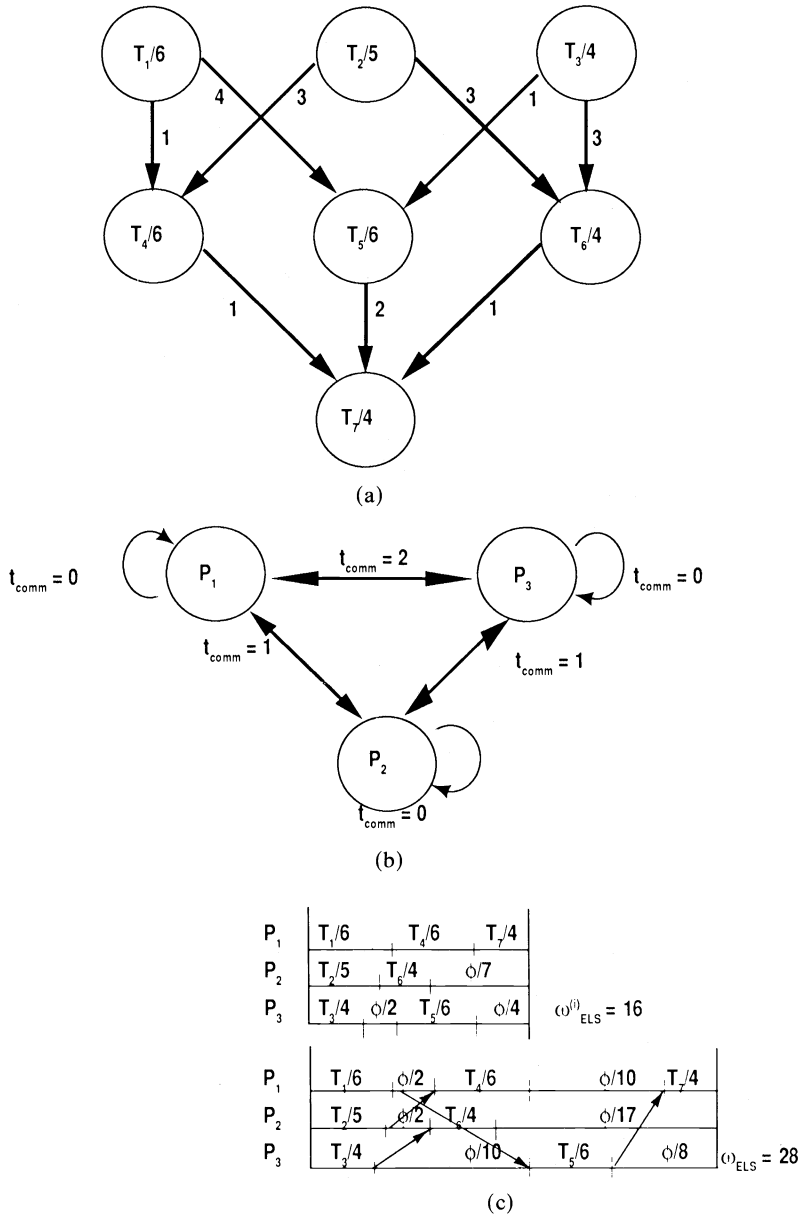

FIG. 1. *An example.* (a) *The* EDAG *model*; (b) *the system model*; (c) *schedules with and without communication delays.*

The computing model described above is an extension of Rayward-Smith's earlier model [7], which was confined to unit communication times (UCT) and unit execution times (UET). He shows that the problem of finding the minimum makespan is NP-complete and also presents a heuristic. The heuristic, called "generalized list scheduling," adopts the same greedy strategy as Graham's list scheduling [2]: No processor remains idle if there is some task available that it could process. For UET and UCT models, a task T can be processed on the processor P_i at time t if T has no immediate

predecessors, or each immediate predecessor of T has been scheduled (to start) on processor P_i at time $\leqq t-1$ or on processor $P_j \neq P_i$ at time $\leqq t-2$. A schedule using Rayward-Smith's heuristic always satisfies

$$\omega_g^c \leqq \left(3-\frac{2}{n}\right) \times \omega_{\text{opt}}^c - \left(1-\frac{1}{n}\right), \tag{1.1}$$

where ω_g^c is the length of the greedy schedule and ω_{opt}^c is the length of the optimal schedule.

This work generalizes Rayward and Smith's assumptions on communication times and execution times. The main result offers a new heuristic and its performance bound. The method is named "Earliest Task First (ETF)" and was first presented in Hwang's dissertation [4]. This paper simplifies the presentation, reduces its time complexity, and improves the performance bound. The main result indicates that the length of an ETF schedule is bounded by the sum of Graham's bound for list scheduling and the "communication requirement" over some immediate predecessor-immediate successor pairs along one chain that can be calculated using Algorithm C of § 3. In notation this is expressed as follows:

$$\omega_{\text{ETF}} \leqq \left(2-\frac{1}{n}\right)\omega_{\text{opt}}^{(i)} + C. \tag{1.2}$$

In (1.2), $\omega_{\text{opt}}^{(i)}$ denotes the optimal schedule length obtained by ignoring the interprocessor communication and is different from ω_{opt}^c in (1.1). The term $(2-1/n)\omega_{\text{opt}}^{(i)}$ is the Graham bound for list scheduling [2].

When ETF is applied to a problem with UET and UCT assumptions, its schedule length satisfies

$$\omega_{\text{ETF}} \leqq \left(3-\frac{1}{n}\right) \times \omega_{\text{opt}}^{(i)} - 1 \tag{1.3}$$

since $C \leqq \omega_{\text{opt}}^{(i)} - 1$. Both bounds ((1.1) and (1.3)) are close since 3 is the dominant factor in both expressions; but we should note that the bound on ETF uses $\omega_{\text{opt}}^{(i)}$, which is smaller than ω_{opt}^c in (1.1), as the base multiplier.

2. ETF—A new heuristic. Section 2.1 presents a simple approach, named ELS, for solving the scheduling problem formulated in § 1. ELS (extended list scheduling) is a straightforward extension of Graham's LS (list scheduling) method. The unsatisfactory performance of ELS motivates the development of ETF.

2.1. ELS—a simple solution. The ELS method adopts a two-phase strategy. First, it allocates tasks to processors by applying LS as if the underlying system were free of communication overhead. Second, it adds necessary communication delays to the schedule obtained in the first phase.

Graham's worst-case bound of LS as stated in (2.1) [2] provides a basis for deriving a similar bound for ELS:

$$\omega_{\text{LS}}^{(i)} \leqq \left(2-\frac{1}{n}\right)\omega_{\text{opt}}^{(i)}. \tag{2.1}$$

It is obvious that the difference between an ELS and an LS schedule, using the same task list L, is bounded by the total maximum communication requirement:

$$\omega_{\text{ELS}}(L) - \omega_{\text{LS}}^{(i)}(L) \leqq \tau_{\max} \times \sum_{T \in \Gamma, T' \in S_T} \eta(T, T'), \tag{2.2}$$

where $\tau_{\max} = \max\{\tau(P, P')\}$ is used to calculate the maximum communication requirements, and S_T denotes the set of immediate successors of T. We shall also use D_T to denote the set of immediate predecessors of T in later sections. Combining (2.1) and (2.2), we obtain (2.3):

$$\omega_{\mathrm{ELS}} \leqq \left(2 - \frac{1}{n}\right)\omega_{\mathrm{opt}}^{(i)} + \tau_{\max} \times \sum_{T \in \Gamma, T' \in S_T} \eta(T, T'). \tag{2.3}$$

The question raised here is whether the bound shown in (2.3) is the best possible. It is not hard to show that all maximum communication requirements may actually produce communication delays. However, to show that the bound stated in (2.3) is tight, it is necessary to produce an ELS schedule in which the schedule of computational tasks is the worst and, at the same time, almost no communications can be overlapped with the computations in the same schedule. This is not obvious since, in general, a longer schedule will allow more overlapping between computation and communication. Nevertheless, the example in Fig. 2 shows that the bound stated in (2.3) is asymptotically achievable as ε and δ approach zero. We summarize the result in Theorem 2.1.

THEOREM 2.1. *Any* ELS *schedule is bounded by the sum of Graham's bound and the total communication requirement* ((2.3)). *Furthermore, this bound is the best possible.*

FIG. 2—continued

2.2. ETF—a new heuristic. The performance of ELS is unsatisfactory when dealing with communication delays, as indicated by Theorem 2.1. ETF, the core of this paper, has a much better performance bound. ETF adopts a simple greedy strategy: the earliest schedulable task is scheduled first. The algorithm is event-driven and is to be described in detail in the following paragraphs.

A task is called *available* when all its predecessors have been scheduled. Let A and I be the sets of available tasks and free processors, respectively, with $A = \{T: D_T = \varnothing\}$ and $I = \{P_1, \cdots, P_n\}$ initially. The starting time of T is denoted as $s(T)$; the finishing time is $f(T)$; the processor to which T is assigned is $p(T)$. These three values for all tasks are the output of the scheduling algorithm.

The starting time of an available task is determined by several factors: when its preceding tasks are finished, how long the communication delays take, and where the

task and its predecessors are allocated. Let $r(T, P)$ denote the time the last message for T arrives at processor P; mathematically,

$$r(T, P) = \begin{cases} 0 & \text{if } T \text{ has no predecessors,} \\ \max\limits_{T' \in D_T} \{f(T') + \eta(T', T) \times \tau(p(T'), P)\}. \end{cases} \tag{2.4}$$

Then the earliest starting time of an available task T can be calculated by

$$e_s(T) = \max \{CM, \min_{P \in I} \{r(T, P)\}\} \tag{2.5}$$

where CM, called "current moment," denotes the curent time of the event clock. By definition, I is the set of free processors at time = CM. Now, the earliest starting time among all available tasks, $e_s^\wedge$, is calculated as follows:

$$e_s^\wedge = \min_{T \in A} \{e_s(T)\}. \tag{2.6}$$

The greedy strategy of ETF wants to find $\hat{T} \in A$ and $\hat{P} \in I$ such that $e_s^\wedge = e_s(\hat{T}) = \max \{\text{CM}, r(\hat{T}, \hat{P})\}$.

Since we assume arbitrary communication delays in our model, a newly available task after the event clock is advanced may have an earlier starting time than that of the select task $\hat{T}$. To overcome such a difficulty, a second time variable, called "next moment" and abbreviated as NM, is introduced to keep track of the scheduling process. NM denotes the earliest time after CM at which one or more currently busy processors become free. NM is set to ∞ if all processors are free after CM. It is clear that the scheduler will not generate any available task that can be started earlier than $e_s^\wedge$ if $\text{NM} \geqq e_s^\wedge$. The scheduling decision will be made in this case; otherwise the event clock is advanced and the decision is postponed.

Conflicts may occur during the scheduling process when two available tasks have the same starting time. To resolve the conflicts, we adopt a priority task list L as we did in LS and ELS methods. Such a strategy is called ETF/LS. If the priority list L is obtained through the critical-path analysis, then the method is called ETF/CP. Algorithm ETF below is a simple ETF implementation in which conflicts are resolved arbitrarily.

Example. Consider the same EDAG task graph and the same three-processor system as given in Fig. 1. The ETF schedule is presented in Fig. 3. Table 1 shows the detail of the scheduling process. In Table 1, i denotes ith execution of the inner loop of executing Algorithm ETF when it is applied to the given problem. The values of CM and NM at the beginning of ith execution of the inner loop are denoted as $\text{cm}(i)$ and $\text{nm}(i)$, respectively. $\hat{T}$ is the available task selected when $\text{CM} = \text{cm}(i)$ and $\text{NM} = \text{nm}(i)$; $\hat{T} = \text{NONE}$ means no task available at the current moment. The scheduling

decision of $\hat{T}$ is made if $e_s^{\wedge} \leqq \text{nm}(i)$ and postponed otherwise.

ALGORITHM ETF.

(0) Initialize: $I \leftarrow \{P_1, \cdots, P_n\}$, $A \leftarrow \{T: D_T = \varnothing\}$, $Q \leftarrow \varnothing$, CM $\leftarrow 0$, and NM $\leftarrow \infty$, $r(T, P) \leftarrow 0$ for each $T \in A$ and each $P \in I$.

(1) While $|Q| < m$ Do

begin

(1.1) While $I \neq \varnothing$ and A $\neq \varnothing$ Do

begin

(1.1.1) Find $\hat{T} \in A$ and $\hat{P} \in I$ such that
$\min_{T \in A} \min_{P \in I} r(T, P) = r(\hat{T}, \hat{P}) = \text{temp}$, let $e_s^{\wedge} = \max\{\text{CM}, \text{temp}\}$.

(1.1.2) If $e_s^{\wedge} \leqq$ NM
then
Assign $\hat{T}$ to run on $\hat{P}$: $p(\hat{T}) \leftarrow \hat{P}$; $s(\hat{T}) \leftarrow e_s^{\wedge}$; $f(\hat{T}) \leftarrow s(\hat{T}) + \mu(\hat{T})$,
$A \leftarrow A - \{\hat{T}\}$, $I \leftarrow I - \{\hat{P}\}$, append $\hat{T}$ to Q,
if $f(\hat{T}) \leqq$ NM then NM $\leftarrow f(\hat{T})$
else exit the inner loop.

end

(1.2) Proceed: CM $\leftarrow$ NM, find new NM.

(1.3) Repeat for each T, P such that T just finished on P:
$I \leftarrow I + \{P\}$, repeat for each $T' \in S_T$:
$d_{T'} = d_{T'} - 1$; if $d_{T'} = 0$ then T' is newly available

(1.4) For each newly available task T' do
$A \leftarrow A + \{A'\}$,
for each processor P, $r(T', P) = \max_{T \in D_{T'}} \{f(T) + \eta(T, T') \times \tau(p(T), P)\}$

end.

3. Analysis of ETF. Some properties of ETF are to be established in this section. The time complexity is analyzed first, followed by the three lemmas that help to explain the way ETF works. The establishment of a performance bound concludes this section.

THEOREM 3.1. *The time complexity of* ETF *is* $O(\text{nm}^2)$, *where n and m are the number of processors and the number of tasks, respectively.*

Proof. The ETF algorithm consists of a main loop containing an inner loop. It is obvious that the main loop repeats at most m times since some task "finishes" in step 1.2 each time. The running time depends on the number of repetitions of the inner

loop. We observe that there are two mutually exclusive possibilities after executing an iteration of the inner loop: (1) When $e_s^{\wedge} \leqq \mathrm{NM}$, the selected available task $\hat{T}$ was scheduled. (2) When $e_s^{\wedge} > \mathrm{NM}$ or $I = \varnothing$ or $A = \varnothing$, the inner loop was exited. For the latter case, the CM was moved forward to NM (by executing step 1.2, which follows the inner loop) and at least one task was finished at the new CM. Consequently, the inner loop repeats at most $2m$ times (since the algorithm either schedules a task or finishes at least one task for each iteration of the inner loop).

Each task becomes newly available once during the scheduling process; therefore, the total running time of step 1.4 is $O(\mathrm{nm}^2)$. The most time-consuming step is generally step 1.1.1, which takes $O(\mathrm{nm})$ for each execution and $O(\mathrm{nm}^2)$ for at most $2m$ executions. □

We introduce some conventions here. Let z be the number of iterations of statement 1.1, and let i be an index of a particular iteration, $i \leqq z$. By an execution of statement 1.1, we mean the execution of the whole inner loop. When $I = \varnothing$ or $A = \varnothing$, the statement 1.1 is also considered being executed once, though the substatements 1.1.1 and 1.1.2 are skipped. Let the sequences $\mathrm{cm}(1), \mathrm{cm}(2), \cdots, \mathrm{cm}(z)$ and $\mathrm{nm}(1), \mathrm{nm}(2), \cdots, \mathrm{nm}(z)$ denote values carried by variables CM and NM, respectively, at the beginning of each execution of statement 1.1. If the scheduling decision of a task T is made during the ith execution of statement 1.1, then i is called the *decision order* of T and denoted as $\mathrm{do}(T)$, and $\mathrm{cm}(i)$ is called the *decision time* of T and denoted as $\mathrm{dt}(T)$. Note that not every integer i, $1 \leqq i \leqq z$, is a decision order of some task. We define $e_s(i)$ as the earliest starting time among all available tasks while CM carries the value $\mathrm{cm}(i)$; $e_s(T, i)$ is similarly defined for each available task T and is calculated by (2.5).

LEMMA 1. *For any task* T, $\mathrm{dt}(T) \leqq s(T)$ *holds and there exists no task* T' *such that* $\mathrm{dt}(T) < f(T') < s(T)$ *or* $\mathrm{dt}(T) < \mathrm{dt}(T') < s(T)$.

Proof. The first part is obvious since each task was scheduled to start at a time no less than the value of the current moment at which the decision is made (see statements 1.1.1 and 1.1.2 of Algorithm ETF).

Suppose that T' is a task such that $\mathrm{dt}(T) < f(T') < s(T)$. Let $\mathrm{do}(T) = i$ and $\mathrm{do}(T') = j$. We have four cases:

(1) T was scheduled after $T'(i > j)$. We get $\mathrm{nm}(i) \leqq f(T')$ by definition and thus, $\mathrm{nm}(i) \leqq f(T') < s(T)$ follows. According to the decision principle (statement (1.1.2)), T should not be scheduled at the ith execution of statement 1.1. This contradicts $\mathrm{do}(T) = i$.

(2) T was scheduled before $T'(i < j)$ and T' has no predecessors. T' became available from the first execution of statement 1.1. Thus, $e_s(T, i) = s(T) > f(T') > s(T') = e_s(T', j) \geqq e_s(T', i)$. (The last inequality is due to the fact that the earliest starting time of a task is nondecreasing after it becomes available, since CM is nondecreasing (see (2.25)). The result $e_s(T, i) > e_s(T', i)$ implies that T' instead of T should have been selected in the ith execution of statement 1.1. This leads to a contradiction.

(3) T was scheduled before T' and $f(T^*) \leqq \mathrm{cm}(i)$, where T^* is a last finished predecessor of T'. The assumption $f(T^*) \leqq \mathrm{cm}(i)$ implies T' became available before the ith execution of statement 1.1. Thus, the same argument for case (2) leads to a contradiction.

(4) T was scheduled before T' and $f(T^*) > \mathrm{cm}(i)$, where T^* is a last finished predecessor of T'. For this case, we have $\mathrm{dt}(T) < f(T^*) < s(T)$. We replace T' by T^*, find the last predecessor of the new T', called T^* again, and repeat the same argument. One of the four cases may happen. If one of cases (1), (2), and (3) occurs, then we are done; otherwise the process is continued. Since a new task T^* with earlier finish

time is obtained in each cycle, we will reach the case $f(T^*) \leqq \text{cm}(i)$ in a finite number of cycles if case (4) occurs repeatedly. This concludes the proof of the second part.

Suppose now that $\text{dt}(T) < \text{dt}(T') < s(T)$. We can find a task T^* such that $f(T^*) = \text{dt}(T')$ since a decision is made only at some cm at which a task is finished. This contradicts the second part of this lemma. □

LEMMA 2. *If* $s(T) < s(T')$, *then* $\text{do}(T) < \text{do}(T')$ *and* $\text{dt}(T) \leqq \text{dt}(T')$.

Proof. Suppose $s(T) < s(T')$, $\text{do}(T) = i$, $\text{do}(T') = j$, $i > j$. Since the current-moment sequence is nondecreasing, two possibilities can be discussed: (1) $\text{dt}(T) > \text{dt}(T')$, or (2) $\text{dt}(T) = \text{dt}(T')$. For (1), we apply the first part of Lemma 1 and get $\text{dt}(T') < \text{dt}(T) \leqq s(T) < s(T')$. This contradicts the second part of Lemma 1. For (2) T and T' are available at $\text{cm}(i) = \text{cm}(j)$, and $e_s(T', j) = s(T') > s(T) = e_s(T, i) \geqq e_s(T, j)$. During the jth execution of statement 1.1, T should have been selected instead of T. This is a contradiction. □

LEMMA 3. *Let* T *and* T' *be two tasks satisfying* $f(T) < \text{dt}(T')$. *Then there exists an integer* i *such that* $\text{cm}(i) = f(T)$. *In other words, the current-moment sequence cannot skip any time point at which a task is finished until all tasks have been scheduled.*

Proof. Let $\text{do}(T') = j$. Then $0 = \text{cm}(1) \leqq f(T) < \text{cm}(j)$. Since the current-moment sequence is nondecreasing, an index k can be found such that $\text{cm}(k) \leqq f(T) < \text{cm}(k+1)$. If $\text{cm}(k) = f(T)$, then we are done. If $\text{cm}(k) < f(T) < \text{cm}(k+1)$ and T is not a task scheduled when $\text{CM} = \text{cm}(k)$, then T is a task whose scheduling decision was made earlier. Then $f(T) < \text{cm}(k+1) = \text{nm}(k)$ contradicts $\text{nm}(k) \leqq f(T)$. If $\text{cm}(k) < f(T) < \text{cm}(k+1)$ and T is a task scheduled at $cm(k)$, then NM should have been moved backward to $f(T)$, and thus $\text{cm}(k+1) = \text{nm}(k) = f(T)$ after the scheduling of T. This is also a contradiction. □

THEOREM 3.2. *For any* EDAG *task model* $G = G(\Gamma, \rightarrow, \mu, \eta)$ *to be scheduled on a system* $S = S(n, \tau)$, *the schedule length,* ω_{ETF}, *obtained by* ETF *always satisfies*

$$\omega_{\text{ETF}} \leqq \left(2 - \frac{1}{n}\right) \times \omega_{\text{opt}}^{(i)} + C_{\max} \tag{3.1}$$

where $C_{\max}$ *is the maximum communication requirement along all chains in* Γ. *That is,*

$$C_{\max} = \max\left\{\tau_{\max} \times \sum_{i=1}^{l-1} \eta(T_{c_i}, T_{c_{i+1}}) : (T_{c_1}, \cdots, T_{c_l}) \text{ is a chain in } \Gamma\right\}. \tag{3.2}$$

Proof. The set of all points of time in $(0, \omega_{\text{ETF}})$ can be partitioned into two subsets A and B. A is defined to be the set of all points for which all processors are executing some tasks. B is defined to be the set of all points of time for which at least one processor is idle (maybe all processors are idle due to simultaneous communication delays). If B is empty, then all processors complete their last assignment at ω_{ETF} and no idle interval can be found with $(0, \omega_{\text{ETF}})$. The ETF schedule is indeed optimal and thus the theorem holds obviously. We thus assume B is nonempty. In the interest of mathematical rigor, we suppose B is the disjoint union of q open intervals (b_{l_i}, b_{r_i}) as below:

$$B = (b_{l_1}, b_{r_1}) \cup \cdots \cup (b_{l_q}, b_{r_q})$$

where $b_{l_1} < b_{r_1} < b_{l_2} < b_{r_2} < \cdots < b_{l_q} < b_{r_q}$.

We claim that we can find a chain of tasks,

$$X : T_{J_l} \rightarrow T_{j_{l-1}} \rightarrow \cdots \rightarrow T_{j_1},$$

such that

$$\sum_{i=1}^{q} (b_{r_i} - b_{l_i}) \leqq \sum_{k=1}^{l} \mu(T_{j_k}) + \sum_{k=1}^{l-1} \tau_{\max} \times \eta(T_{j_{k+1}}, T_{j_k}). \tag{3.3}$$

In other words, the total length of B is no longer than the sum of all computational times and all pessimistic communication requirements along the chain X. We say that the chain X covers the set B.

Let T_{j_1} denote a task that finishes in the ETF schedule at time ω_{ETF}. Let $s(T_{j_1})$ denote the time at which T_{j_1} is started as scheduled by ETF. There are three possibilities regarding the starting time of T_{j_1}:

(1) $s(T_{j_1}) \leqq b_{l_1}$.

(2) $s(T_{j_1}) \in B$, i.e., there exists an integer h, $h \leqq q$, such that

$$b_{l_k} < s(T_{j_1}) < b_{r_h}. \tag{3.4}$$

(3) $s(T_{j_1}) \in A$ but $s(T_{j_1}) > b_{l_1}$, i.e., there exists an integer h, $h \leqq q-1$, such that

$$b_{r_k} \leqq s(T_{j_1}) \leqq b_{l_{k+1}} \quad \text{or} \quad b_{r_q} \leqq s(T_{j_1}). \tag{3.5}$$

If the first possibility occurs, then the task T_{j_1} by itself constitutes a chain that satisfies our claim. We shall show for the second and the third possibilities, respectively, that we can always add one or more tasks to the chain to extend the covered part of B to the left. To say a set of points is covered by a chain means that the length of the set is less than or equal to the sum of computation times and communication requirements along the chain, where communication requirements are estimated pessimistically (using $\tau_{\max}$).

Let us first consider the second possibility. Let h be the index satsifying (3.4). Then T_{j_1} alone has covered part of B from its right end to somewhere in between b_{l_k} and b_{r_k}. The mission here is to add the second task, T_{j_2}, to the chain. By the definition of B there is some processor P_α that was idle during $(s(T_{j_1})-\varepsilon, s(T_{j_1}))$ for some $\varepsilon > 0$. We consider three cases separately:

Case 1. T_{j_1} did not become available until $s(T_{j1})$.

Case 2. T_{j_1} became available at a time earlier than $s(T_{j_1})$ but later than time zero.

Case 3. T_{j_1} became available at time zero.

For Case 1, we simply take the last finished predecessor of T_{j_1} as T_{j_2}.

For Case 2, let T^* be the last finished immediate predecessor of T_{j_1}. Then $f(T^*) < s(T_{j_1})$. We further consider three subcases: (i) There exists no task T assigned to run P_α with $s(T) > s(T_{j_1}) - \varepsilon$. (ii) There exists at least one task T assigned to run on P_α with $s(T) > s(T_{j_1})$, but there exists no task T assigned on P_α with $s(T) = s(T_{j_1})$. (iii) There exists a task T assigned to run on P_α with $s(T) = s(T_{j_1})$.

For the first subcase (of Case 2), since no task is blocking T_{j_1} from starting earlier on P_α, it must be that $r(T_{j_1}, P_\alpha) \geqq s(T_{j_1})$. Let T_{j_2} be an immediate predecessor of T_{j_1} whose message to T_{j_1} arrives at P_α at time $r(T_{j_1}, P_\alpha)$. Let $p(T_{j_2}) = P_\beta$. Then $\tau(P_\beta, P_\alpha) \times \eta(T_{j_2}, T_{j_1}) = r(T_{j_1}, P_\alpha) - f(T_{j_2}) \geqq s(T_{j_1}) - f(T_{j_2})$. This result indicates that the communication requirement from T_{j_2} to T_{j_1} covers the interval $(f(T_{j_2}), s(T_{j_1}))$, and hence the covered part of B is shifted further left from $s(T_{j_1})$ after T_{j_2} is added to the chain. Furthermore, the parameter $\tau(P_\beta, P_\alpha)$ can be replaced by $\tau_{\max}$. This completes the first subcase.

For the second subcase (of Case 2), we let T_α be the first task allocated on P_α after $s(T_{j_1})$. By Lemma 2, do $(T_{j_1}) <$ do (T_α). The allocation of T_α on P_α cannot be a reason to block the possibility of T_{j_1} utilizing P_α at an earlier time. The reason T_{j_1} did not take such an advantage is again due to $r(T_{j_1}, P_\alpha) \geqq s(T_{j_1})$. T_{j_2} can therefore be found in the same way as in the first subcase.

We assume a task T_α satisfying $p(T_\alpha) = P_\alpha$ and $s(T_\alpha) = s(T_{j_1})$ in the last subcase. Now both do $(T_\alpha) >$ do (T_{j_1}) and do $(T_\alpha) <$ do (T_{j_1}) are possible. If do $(T_\alpha) >$ do (T_{j_1}), then T_α was scheduled later than T_{j_1}; hence, the same argument used in the previous subcase prevails. We need to argue why $r(T_{j_1}, P_\alpha) \geqq s(T_{j_1})$ when do $(T_\alpha) <$ do (T_{j_1}). Let

us assume do $(T_\alpha) = k$ and consider two situations separately: (1) dt $(T_\alpha) < s(T_\alpha)$, and (2) dt $(T_\alpha) = s(t_\alpha)$. For (1), at the beginning of the kth execution of the inner loop, both T_α and T_{j_1} were available. (T_{j_1} was available since $f(T^*) \leqq$ dt (T_α) guaranteed by Lemma 1.) If $r(T_{j_1}, P_\alpha) < s(T_\alpha)$, then T_{j_1}, and not T_α, should have been selected in the kth execution of the inner loop. For (2), we let cm be the largest value in the current-moment sequence satisfying $f(T^*) \leqq \text{cm} > s(T_\alpha)$. (The existence of such cm is guaranteed by Lemma 3.) At CM = cm, T_α was unscheduled and T_{j_1} was available. T_α could not block T_{j_1} from occupying P_α at a time earlier than $s(T_\alpha)$. If $r(T_{j_1}, P_\alpha) < s(T_{j_1})$, then T_{j_1} should have been allocated on P_α and started at an earlier time when CM carried the value cm. This contradiction implies that $r(T_{j_1}, P_\alpha) \geqq s(T_{j_1})$. Based on this result, the same technique as before can be applied to add a second task T_{j_2} to the chain finishing all subcases of Case 2.

Case 3 is indeed impossible. We can obtain $r(T_{j_1}, P_\alpha) \geqq s(T_{j_1})$ as we did above for Case 2; on the other hand, we have a contradictory fact that $r(T_{j_1}, P_\alpha) = 0$ due to $D_T = \varnothing$.

We have completed our discussion of the second possibility. Let us summarize the results obtained so far. Suppose $T_{j_1} < b_{r_h}$ for some $h \leqq q$. We constructed a second task T_{j_2} such that T_{j_2} precedes T_{j_1} and

$$\mu(T_{j_1}) + \mu(T_{j_2}) + \tau_{\max} \times \eta(T_{j_2}, T_{j_1}) \geqq (b_{r_q} - b_{l_q}) + \cdots + (b_{r_{h+1}} - b_{l_{h+1}}) + (b_{r_h} - s(T_{j_1})) + s((T_{j_1}) - s(T_{j_2})).$$

Since $s(T_{j_1})$ is an interior point of (b_{l_h}, b_{t_h}), at least some new portion (maybe all) of (b_{l_h}, b_{r_h}) has been covered now.

The location of $s(T_{j_2})$, once again, has three possibilities:

(1) $s(T_{j_2}) \leqq b_{l_1}$.

(2) $s(T_{j_2}) \in B$.

(3) $s(T_{j_2}) \in A$ but $s(T_{j_2}) > b_{l_1}$.

If the first possibility happens, then we are done. If not, we repeat our arguments to construct a third task or more tasks. (The third possibility may lead to adding more than one task in one cycle.) The cycle can be repeated until the starting time of the last added task satisfies the first possibility.

Now, it remains to show how to add tasks to the chain in the case of the third possibility (3.5). Suppose that h is the integer such that $b_{r_h} \leqq s(T_{j_1}) \leqq b_{l_{h+1}}$ or $h = q$ when $b_{r_q} \leqq s(T_{j_1})$. Let $\hat{\Gamma} = \{T\colon T$ is a predecessor of T_{j_1} satisfying $s(T) \geqq b_{r_h}$ or $T = T_{j_1}\}$. Clearly, $\hat{\Gamma} \neq \phi$. Let $T^\# \in \hat{\Gamma}$ such that $s(T) < b_{r_h}$ for any immediate predecessor T of $T^\#$. Then $T^\#$ is either a predecessor of T_{j_1} or T_{j_1} itself. In either case, we can always construct a sequence of tasks:

$$T^\# = T_{j_{d-1}} \to T_{j_{d-2}} \to \cdots \to T_{j_2} \to T_{j_1}.$$

Although these tasks are not scheduled during B, the last added task, $T^\#$, is closer to uncovered points of B. The task $T^\#$ will play the same role as T_{j_1} did in the discussion about the second possibility. The mission again is to add a task T_d to the chain. There are three cases:

Case 1. $T^\#$ did not become available until b_{r_h}.

Case 2. $T^\#$ became available at a time earlier than b_{r_h} but later than time zero.

Case 3. $T^\#$ became available at time zero.

We finish Case 1 by setting T_{j_d} to be the last finished predecessor of $T^\#$. Case 3 is impossible by the same argument for Case 3 of the second possibility.

For Case 2, let T^* be the last finished predecessor of $T^\#$. Then $f(T^*) < b_{r_h} \leqq s(T^\#)$. By the definition of B there is some processor P_α that was idle during the time $(b_{r_h} - \varepsilon, b_{r_h})$ for some $\varepsilon > 0$. We ask the same question as before. Why had $T^\#$ not

been allocated on P_α while it was available and P_α was idle? Let T_α be the task assigned to run on P_α at b_{r_h}. Then $f(T^*) \leqq \mathrm{dt}(T_\alpha) \leqq s(T_\alpha)$ by Lemma 1. As in the last subcase of Case 2 for the second possibility, (1) $\mathrm{do}(T_\alpha) > \mathrm{do}(T^\#)$ and (2) $\mathrm{do}(T_\alpha) < \mathrm{do}(T^\#)$ are distinguished. Two situations for (2) are further discussed separately: (1) $\mathrm{dt}(T_\alpha) < s(T_\alpha)$, and (2) $\mathrm{dt}(T_\alpha) = s(T_\alpha)$. The same techniques can be applied to conclude that $r(T^\#, P_\alpha) \geqq b_{r_h}$. Let T_{j_d} be the immediate predecessor whose message reaches P_α at $r(T^\#, P_\alpha)$ assuming $\hat{T}$ be allocated on P_α. This task is exactly what we want.

After T_{j_d} together with $T_{j_{d-1}}, \cdots, T_{j_2}$ is added to the chain, the enlarged chain clearly covers all of B from some point on, and this is a greater part of B than the initial one. We repeat the whole process by considering three possibilities regarding the position of $s(T_{j_d})$. The process is repeated until $s(T_{j_l}) \leqq b_{l_1}$ is satisfied by the added task in the chain. Finally, a chain satisfying our claim (see (3.3)) is constructed.

The important thing to note about this claim is

$$\sum_{\phi_i \in \Phi} \mu(\phi_i) \leqq (n-1) \times \sum_{k=1}^{l} \mu(T_{j_k}) + n \times \tau_{\max} \times \sum_{k=1}^{l-1} \eta(T_{j_{k+1}}, T_{j_k})$$

where the left-hand sum is over all empty tasks. (A processor is said to be executing an empty task when it is idle.) But the fact that $T_{j_l}, \cdots, T_{j_1}$ is a chain implies that it takes at least $\sum_{k=1}^{l} \mu(T_{j_k})$ to finish all tasks in Γ in any schedule, even on an ideal system, i.e.,

$$\omega_{\mathrm{opt}}^{(i)} \geqq \sum_{k=1}^{l} \mu(T_{j_k}).$$

The following inequality is obvious:

$$\sum_{T \in \Gamma} \mu(T) \leqq n \times \omega_{\mathrm{opt}}^{(i)}.$$

Consequently,

$$\begin{aligned}
\omega_{\mathrm{ETF}} &= \frac{1}{n}\left(\sum_{T_k \in \Gamma} \mu(T_k) + \sum_{\phi_i \in \Phi} \mu(\phi_i) \right) \\
&\leqq \frac{1}{n}\left(n\omega_{\mathrm{opt}}^{(i)} + (n-1)\omega_{\mathrm{opt}}^{(i)} + n \times \tau_{\max} \times \sum_{k=1}^{l-1} \eta(T_{j_{k+1}}, T_{j_k}) \right) \\
&= \left(2 - \frac{1}{n}\right)\omega_{\mathrm{opt}}^{(i)} + \tau_{\max} \times \sum_{k=1}^{l-1} \eta(T_{j_{k+1}}, T_{j_k}).
\end{aligned}$$

The theorem follows immediately by replacing the communication requirements along a particular chain by $C_{\max}$. □

The bound stated in Theorem 3.2 can be reduced by giving an algorithm to construct the task chain and the corresponding communication requirements used to cover idle times. The proof of Theorem 3.2 actually finds a chain X: $T_{j_l}, \cdots, T_{j_1}$ such that $|B| \leqq \sum_{k=1}^{l} \mu(T_{j_k}) + \textit{certain communication times.}$ The last term, called C in the following discussion, corresponds to the sum of just enough terms of the form $\tau(p(T_{j_{k+1}}), P_\alpha) \times \eta(T_{j_{k+1}}, T_{j_k})$ to "cover" the times at which (1) no task in the constructed chain is running, and (2) at least one processor is idle. Since it can frequently happen that all processors are busy while communication is taking place, much of the time $C_{\max}$ is "hidden" by being overlapped with computation of other tasks. We are therefore led to a better bound for ω_{ETF} that even coincides with Graham's bound if all communication is hidden. The algorithm assumes that all processors were idle for

$t<0$, and each task was scheduled to run during a closed time interval $[t_1, t_2]$. It calculates an upper bound C for the "unhidden" communication of the constructed chain.

ALGORITHM C
Input: An ETF Schedule
Output: C
(0) $C \leftarrow 0$, find a task T that was scheduled to finish last.
(1) Let $u = \text{l.u.b.}^1 \{t: t \leqq s(T)$ and at least one processor is idle at $t\}$.
(2) If $u = 0$ then output C and stop.
(3) If $u < s(T)$ then find a task T' such that T' is either a predecessor of T with $s(T') \geqq u$ or T itself but $s(T^*) < u$ for any immediate predecessor T^* of T'. Replace T by T'.
(4) Let T' be the last finished predecessor of T. If $f(T') = u$ then replace T by T' and go to (1).
(5) Find a processor P_α that was idle during $(u-\varepsilon, u)$ for some $\varepsilon > 0$, find a task $T' \in D_T$ such that $f(T') + \tau(p(T'), P_\alpha) \times \eta(T', T) = r(T, P_\alpha)$, $C \leftarrow C + \tau(p(T'), P_\alpha) \times \eta(T', T)$, replace T by T', go to step 1.

In general, C is much smaller than $C_{\max}$ depending on the case. It serves, however, to replace $C_{\max}$ in the performance bound of Theorem 3.2, and this is stated in the corollary below.

COROLLARY. *An* ETF *schedule is bounded from above by the sum of the Graham's bound and the output of Algorithm* C. *Mathematically,*

$$\omega_{\text{ETF}} \leqq \left(2 - \frac{1}{n}\right)\omega_{\text{opt}}^{(i)} + C. \tag{3.6}$$

4. Conclusion and discussion. An essential result of multiprocessor scheduling theory is the introduction of the list-scheduling method and the establishment of its performance guarantee. In this paper, we first extend the LS method to address the issue of communication delays. Theorem 2.1 indicates that the extended method, named ELS, fails to shorten communication delays, at least in worst cases. The new heuristic presented in this paper effectively reduces communication delays and also maintains the strength of the classical list scheduling.

It should be noted that the performance bound of ETF is made possible by the assumption of no communication contention; however, it is clear that the contention-free attribute alone does not guarantee the same bound.

Assume no communication contention is indispensable for maintaining the deterministic approach; but, strictly speaking, this assumption is only valid in fully connected systems or systems with contention-free protocols. For the later case, the protocol overhead should be included in the estimation of the communication parameters.

To expand the application domain of this theoretic work, we would rather consider the deterministic scheduling as a planning tool for task allocation suitable for most highly connected systems. Though each task is scheduled to start at some specific time, it will be started whenever enabled in the actual execution. In the case the actual start time of a task is later than its scheduled start time due to the queueing delay caused by communication contention, the succeeding tasks may become incapable of starting their execution at their scheduled times. This "postponement" may propagate. In the extreme case the postponement may propagate down to the critical execution path

[1] Least upper bound.

and then lengthen the total scheduled time of the graph. However, to some extent, queueing delay can be absorbed in noncritical paths. Only the portion of queueing delay that cannot be absorbed will lengthen the total graph's execution time. For this reason, the sensitivity of the no-communication contention assumption can be relaxed in real applications.

Acknowledgments. The authors are grateful to Drs. R. L. Graham and S. R. Kosaraju for their careful review and suggestions to the ETF algorithm. They are also indebted to the University of Florida and National Chiao Tung University. Without their support of the e-mail facility, the revision of the paper that required much communication across half the globe would have been very difficult.

FINDING AN APPROXIMATE MAXIMUM*

N. ALON†‡ AND Y. AZAR†

Abstract. Suppose that there are n elements from a totally ordered domain. The objective is to find, in a minimum possible number of rounds, an element that belongs to the biggest $n/2$, where in each round one is allowed to ask n binary comparisons. It is shown that $\log^* n + \Theta(1)$ rounds are both necessary and sufficient in the best algorithm for this problem.

Key words. searching, approximate maximum, parallel comparison algorithms

AMS(MOS) subject classification. 68E05

1. Introduction. Parallel comparison algorithms have received much attention during the last decade. The problems that have been considered include sorting [AA87], [AA88], [AAV86], [Ak85], [AKS83], [Al85], [AV87], [BT83], [BHe85], [HH81], [HH82], [Kn73], [Kr83], [Le84], [Pi86]; merging [BHo82], [HH82], [Kr83], [SV81]; selecting [AA88], [AKSS86a], [AP89], [Pi87], [Va75]; and approximate sorting [AA88], [AAV86], [AKSS86b], [BB87], [BR82]. The common model of computation considered is the parallel comparison model, introduced by Valiant [Va75], where only comparisons are counted. In this model, during each time unit (called a *round*) a set of binary comparisons is performed. The actual set of comparisons asked is chosen according to the results of the comparisons done in previous rounds. The objective is to solve the problem at hand, trying to minimize the number of comparison rounds as well as the total number of comparisons performed. Note that this model ignores the time corresponding to deducing consequences from comparisons performed, as well as communication and memory addressing time. However, in some situations this seems to be the relevant model. Moreover, any lower bound here applies to any comparison-based algorithm. There is an obvious, useful correspondence that associates each round of any comparison algorithm in the above parallel model with a graph whose vertices form the set of elements we have. The (undirected) edges of this graph are just the pairs compared during the round. The answer to each comparison corresponds to orienting the corresponding edge from the larger element to the smaller. Thus in each round we get an acyclic orientation of the corresponding graph, and the transitive closure of the union of the r oriented graphs obtained until round r represents the set of all pairs of elements whose relative order is known at the end of round r.

In many of the problems discussed so far in the parallel comparison model, the most interesting case is the one where the number n of elements is equal to the number of comparisons performed in each round. It is well known that in this case $\Theta(\log n)$ rounds are both necessary and sufficient for sorting. The lower bound follows trivially from the serial lower bound, and the upper bound follows from, e.g., the AKS sorting networks [AKS83]. As proved by Valiant, $\Theta(\log \log n)$ rounds are both necessary and sufficient for finding the maximum. The results of [AKSS86a] and [BHo82] show that the same $\Theta(\log \log n)$ bound holds for selecting and merging, respectively.

In the present paper we consider, motivated by the research on approximate sorting, another problem called the *approximate maximum* problem. This is the problem of finding, among n elements, an element whose rank belongs to the top $n/2$ ranks.

‡ The research of this author was supported in part by an Allon Fellowship and by a grant from the United States-Israel Binational Science Foundation.

It is easy to show that in the serial comparison model this problem requires $n/2$ comparisons: only a constant factor better than the problem of finding the maximum. It is therefore rather surprising that with n comparisons in each round this problem can be solved much faster than that of finding the exact maximum in the same conditions. As it turns out, $\log^* n + \Theta(1)$ rounds are both necessary and sufficient for finding an approximate maximum among n elements, using n comparisons in each round. Moreover, the gap between the upper and lower bounds we obtain is only six rounds! The precise formulation of our result is the following. For $a \geq 1$, $k \geq 0$ define $a^{(k)}$ by $a^{(0)} = 1$ and $a^{(k)} = a^{a^{(k-1)}}$ for $k \geq 1$. Also define, as usual, $\log^* n = \min\{k : 2^{(k)} \geq n\}$. Let $r(n)$ denote the worst-case number of rounds of the best deterministic algorithm that finds an approximate maximum among n elements using n comparisons in each round. Our result is the following theorem.

THEOREM 1.1. *For every* $n \geq 2$,

$$\log^* n - 4 \leq r(n) \leq \log^* n + 2.$$

The upper bound here is not by explicit algorithm, as our algorithm uses certain random graphs. However, the known results about expanders easily supply (as in, e.g., [Al85], [Al86], [Pi87]) an explicit version of the algorithm, which will take about $\log^* n + 12$ rounds.

We note that our methods can be extended to the case where we have p comparisons in each round, as well as to the problem of finding an element whose rank is in the top εn ranks for all $p \geq 1$ and $1/n \leq \varepsilon \leq \frac{1}{2}$. With some additional work we can also obtain the corresponding results for approximate sorting. However, for the sake of simplicity we present here, in §§ 2 and 3, only the proof of Theorem 1.1 and only state the more general results (the detailed proofs of which will appear elsewhere) in the final § 4.

2. The upper bound. In this section we prove the upper bound, i.e., that using n processors we can find an element whose rank belongs to the top half of the ranks of the n elements in $\log^* n + 2$ rounds. Our algorithm uses some known results. The first is the algorithm of Valiant for finding the exact maximum. The others deal with properties of some random graphs (or explicit expanders). First we state a theorem from [Va75] and two lemmas from [Pi87].

THEOREM 2.1 [Va75]. *The maximum of* $n > 4$ *elements can be bound using* n *processors in* $\lceil \log \log n \rceil$ *rounds.* □

LEMMA 2.2 [Pi87]. *For every* m *and* a, *there is a graph with* m *vertices and* $2m^2 \log m/a$ *edges in which any two disjoint sets of* $a+1$ *vertices are joined by an edge.* □

LEMMA 2.3 [Pi87]. *If* m *elements are compared according to the edges of a graph in which any two disjoint sets of* $a+1$ *vertices are joined by an edge, then for every rank all but at most* $6a \log m$ *elements will be known to be too small or too large to have that rank.* □

For our algorithm we use Theorem 2.1 and a corollary of the last two lemmas. Note that Lemma 2.2 does not give an explicit construction of a graph with the specified properties; therefore, the algorithm seems to be nonexplicit. However, we can use some of the known results about explicit expanders (as in [Pi87], [Al85], [Al86]) to obtain an explicit version of our algorithm (with a slightly bigger additive constant). As the treatment for this case is analogous, we discuss here only the algorithm that uses Lemma 2.2.

PROPOSITION 2.4. *Assume we have* m *elements and* $p = 2m^2 \log m/a$. *Then, we can find in one round (using* p *comparisons) an element whose rank belongs to the top* $7a \log m$ *ranks of elements.*

Proof. Compare the elements according to the edges of the graph supplied by Lemma 2.2. By Lemma 2.3, all but at most $6a \log m$ elements will be known to be too small or too large to have rank $m - 7a \log m$. Therefore, at least $(7-6)a \log m$ elements will be known to belong to the top $7a \log m$ elements. □

For the description of our algorithm, we define the following function: $f(x) = 2^{x^{1/4}} \cdot x$, $x \geq 1$. f is a monotone increasing function and therefore $f^{-1}(y)$ exists (for $y \geq 2$) and is also a monotone (increasing) function. Define the following two sequences:

$b_0 = 2^{16}$ $b_{i+1} = f(b_i)$, $i \geq 0$ (We can easily check that all the $b_i's$ are integers),

$a_0 = n$, $a_{i+1} = f^{-1}(a_i)$, $i \geq 0$.

Define $k(n)$ by

$$k(n) = \min\{k : b_k \geq n\}. \tag{2.1}$$

By trivial induction using the monotonicity of f^{-1}, we get

$$a_i \leq b_{k-i} \quad \text{for } 0 \leq i < k(n). \tag{2.2}$$

Our algorithm is based on the following lemma, which is a consequence of the previous proposition.

LEMMA 2.5. *Assume we have $n \geq 2^{32}$ elements, partitioned into $m = \lceil n/f^{-1}(n) \rceil$ pairwise disjoint set, the ith having $t_i \leq \lceil f^{-1}(n) \rceil$ elements. Suppose that in each set we have an element that is smaller than at most εt_i elements in this set. Then we can find in one round using n processors an element smaller than at most $(\varepsilon + c/\sqrt{f^{-1}(n)})n$ elements among the n elements, where $c = 32$.*

Proof. Choose $a = \lceil 4m/\log^3 m \rceil$. Note that $m \geq 2^{16}$, $a \geq 4m/\log^3 m \geq 2^6$. Clearly, $(2m^2 \log m)/a \leq (m \log^4 m)/2 \leq n$, because by the definition of f: $\log^4 (n/f^{-1}(n)) = f^{-1}(n)$.

Thus we can use Proposition 2.4 for the m special elements with the n processors and find an element that belongs to the top $7a \log m$ elements out of the m elements. But

$$7a \log m = 7\left\lceil \frac{4m}{\log^3 m} \right\rceil \log m \leq 7\left(\frac{4m}{\log^3 m} + 1\right) \log m \leq 7 \frac{65}{64} \cdot \frac{4m}{\log^2 m} \leq \frac{30m}{\log^2 m}.$$

Therefore, the number of elements greater than this element is at most

$$\varepsilon n + \lceil f^{-1}(n) \rceil \frac{30m}{\log^2 m} \leq \varepsilon n + \left(1 + \frac{1}{2^{16}}\right) f^{-1}(n) \cdot \frac{30(1 + 1/2^{16}) n/f^{-1}(n)}{\log^2 (n/f^{-1}(n))}$$

$$\leq n\left(\varepsilon + \frac{32}{\log^2 (n/f^{-1}(n))}\right).$$

(In the last inequalities we used the facts that $f^{-1}(n)$, $m \geq 2^{16}$.)

Now $\log^2 (n/f^{-1}(n)) = \log^2 (2^{f^{-1}(n)^{1/4}}) = \sqrt{f^{-1}(n)}$. Hence we can find an element that is smaller than at most $(\varepsilon + (c/\sqrt{f^{-1}(n)}))n$, where $c = 32$. □

Now we can describe our algorithm and prove that it works.

THEOREM 2.6. *We can find an element the rank of which belongs to the top half of the ranks of $n \geq 2$ elements in $\log^* n + 2$ rounds using n processors.*

To obtain the last theorem, we prove by induction a more exact lemma.

LEMMA 2.7. *Let n be the number of elements and the number of processors. Then we can find in $k(n)+4$ rounds (where $k(n)$ is the number defined in (2.1)) an element that is smaller than at most $cn \sum_{i=0}^{k-2} 1/\sqrt{b_i}$ elements.*

Proof. We apply induction on n. The basic case is $n \leqq b_1$. In this case, we find the exact maximum using Theorem 2.1. Here $k \leqq 1$ so $cn \sum_{i=0}^{k-2} 1/\sqrt{b_i} = 0$, and we really find the exact maximum. To calculate the number of rounds we consider three cases. If $n \leqq 4$, four rounds are more than what is needed. If $n \leqq b_0$, then by Theorem 2.1 $\lceil \log\log n \rceil \leqq \lceil \log\log b_0 \rceil = \lceil \log\log 2^{16} \rceil = 4 = k(n)+4$. Otherwise $b_0 < n \leqq b_1$, $k(n) = 1$, and $\lceil \log\log n \rceil \leqq \lceil \log\log b_1 \rceil = \lceil \log\log 2^{32} \rceil = 5 = 1+4 = k(n)+4$. Assuming that the lemma is true for every $n' < n$, we prove it for n $(n > b_1 = 2^{32},\ k(n) \geqq 2)$. Split the n elements into $m = \lceil n/f^{-1}(n) \rceil$ pairwise disjoint sets, where the jth set has size $n_j \leqq \lceil f^{-1}(n) \rceil$. Assign to each set a number of processors equal to the size of the set. Now we can use the inductive assumption for each of the new sets, and find in $k'+4 \leqq k(\lceil f^{-1}(n) \rceil)+4$ rounds an element in each set, where the one in the jth set is smaller than at most $cn_j \sum_{i=0}^{k'-2} 1/\sqrt{b_i}$ elements in his set. By the definition of k, $n \leqq b_k$ so $f^{-1}(n) \leqq f^{-1}(b_k) = b_{k-1}$ and because the right-hand side is an integer $n_j \leqq \lceil f^{-1}(n) \rceil \leqq b_{k-1}$. Hence $k' \leqq k-1$; therefore we are allowed to have one more round to find the right element (among the m special elements). For that we use Lemma 2.5 and find an element smaller than at most

$$\left(\varepsilon + \frac{c}{\sqrt{f^{-1}(n)}}\right) n \leqq \left(\sum_{i=0}^{k-3} \frac{1}{\sqrt{b_i}} + \frac{1}{\sqrt{f^{-1}(n)}}\right) \cdot cn$$

other elements. Note that $b_{k-1} < n$ so $b_{k-2} \leqq f^{-1}(n)$, and hence the last expression is at most

$$cn\left(\sum_{i=0}^{k-3} \frac{1}{\sqrt{b_i}} + \frac{1}{\sqrt{b_{k-2}}}\right) = cn \sum_{i=0}^{k-2} \frac{1}{\sqrt{b_i}}.$$

Hence, we can find an element smaller than at most $cn \sum_{i=0}^{k-2} 1/\sqrt{b_i}$ elements among all the n elements in $k(n)+4$ rounds. This completes the proof of Lemma 2.7. □

To complete the proof of the main theorem, we just have to check the following two simple facts:

$$cn \sum_{i=0}^{\infty} \frac{1}{\sqrt{b_i}} \leqq \frac{1}{4} n \left(< \frac{1}{2} n \right), \tag{2.3}$$

$$k(n)+4 \leqq \log^* n + 2. \tag{2.4}$$

Inequality (2.3) is trivial, since $b_{i+1} = 2^{(b_i)^{1/4}} \cdot b_i \geqq 2^2 b_i$ or $1/\sqrt{b_{i+1}} \leqq \frac{1}{2}/\sqrt{b_i}$. Thus

$$c \sum_{i=0}^{\infty} \frac{1}{\sqrt{b_i}} \leqq \frac{2c}{\sqrt{b_0}} = \frac{64}{2^8} = \frac{1}{4}.$$

To prove (2.4) we need the following simple lemma:

LEMMA 2.8. *$b_i \geqq 2^8(2^{(i+2)})^4$ for every $i \geqq 0$.*

Proof. The proof is by induction on i. For $i = 0$, $b_0 = 2^{16} = 2^8(2^2)^4 = 2^8 \cdot (2^{(2)})^4$. Assuming the inequality holds for i, we prove it for $i+1$. Indeed, $b_{i+1} = 2^{(b_i)^{1/4}} \cdot b_i \geqq 2^{(2^8)^{1/4} \cdot 2^{(i+2)}} \cdot 2^8(2^{(i+2)})^4$ by the definition of b_{i+1} and by the inductive assumption. But the right-hand side is $\geqq 2^8 \cdot 2^{4 \cdot 2^{(i+2)}} = 2^8(2^{(i+3)})^4$, which completes the proof. □

Taking $i = \log^* n - 2$, we get that $b_i \geqq n$ and, therefore, $k(n) \leqq \log^* n - 2$. Thus, we have the complexity of the algorithm, which is $k(n)+4 \leqq \log^* n + 2$. This completes the proof of Theorem 2.6. □

3. The lower bound. It is convenient to establish our lower bound by considering the following (full information) game, called the *orientation game*, and played by two

players, the *graphs player* and the *order player*. Let V be a fixed set of n vertices. The game consists of *rounds*. In the first round the graphs player presents an undirected graph G_1 on V with at most n edges, and the order player chooses an acyclic orientation H_1 of G_1 and shows it to the graphs player, thus ending the first round. In the second round the graphs player chooses again, an undirected graph G_2 with at most n edges on V, and the order player gives it an acyclic orientation H_2, consistent with H_1 (i.e., the union of H_1 and H_2 is also acyclic), which he presents to the graphs player. The game continues in the same manner; in round i the graphs player chooses an undirected graph G_i with at most n edges on V, and the order player gives it an acyclic orientation H_i, such that the union $H_1 \cup \cdots \cup H_i$ is also acyclic. The game ends when, after, say, round r, there is a vertex v in V whose outdegree in the *transitive closure* of $H_1 \cup \cdots \cup H_r$ is at least $n/2$. The objective of the graphs player is to end the game as early as possible, and that of the order player is to end it as late as possible. The following fact states the (obvious) connection between the orientation game and the approximate maximum problem.

PROPOSITION 3.1. *The graphs player can end the orientation game in r rounds if and only if there is a comparison algorithm that finds an approximate maximum among n elements, using n comparisons in each round in r rounds.* □

In view of the last proposition and the results of the previous section, the graphs player can always end the orientation game in at most $\log^* n + O(1)$ rounds. A proof of existence of a strategy for the order player that enables him to avoid ending the orientation game in r rounds implies that $r+1$ is a lower bound for the time complexity of the approximate maximum problem. The next proposition is our main tool for establishing the existence of such a strategy for $r = \log^* n - 5$.

PROPOSITION 3.2. *There exists a strategy for the order player to maintain, for every $d \geqq 1$, the following property $P(d)$ of the directed acyclic graph constructed during the game.*

Property $P(d)$. Let $H(d) = H_1 \cup \cdots \cup H_d$ be the union of the oriented graphs constructed in the first d rounds. Then there is a subset $V_0 \subseteq V$ of size at most $|V_0| \leqq n/8 + n/16 + \cdots + n/2^{d+2}$ and a proper $D = 2000^{(d)}$-vertex-coloring of the induced subgraph of $H(d)$ on $V - V_0$ with color classes $V_1, V_2, \cdots, V_D$ (some of which may be empty), such that for each $i > j \geqq 1$ and each $v \in V_i$, v has at most 2^{i-j-2} neighbors in V_j. Furthermore, for every $i > j \geqq 0$ any edge of $H(d)$ that joins a member of V_i to a member of V_j is directed from V_i to V_j.

Proof. We apply induction on d. For $d = 1$, the graph $G_1 = (V, E_1)$ constructed by the graphs player has at most n edges. Let V_{00} be the set of all vertices in V whose degree is at least 32. Clearly,

$$|V_{00}| \leqq n/16. \tag{3.1}$$

Put $U = V - V_{00}$ and let K be the induced subgraph of G_1 on U. As the maximum degree in K is at most 31, K has, by a standard, easy result from extremal graph theory (see, e.g., [Bo78, p. 222]) a proper vertex-coloring by 32 colors and hence, certainly, a proper vertex coloring by 2000 colors. Let $U_1, U_2, \cdots, U_{2000}$ be the color classes. For every vertex u of K, let $N(u)$ denote the set of all its neighbors in K. For a permutation π of $1, 2, \cdots, 2000$ and any vertex n of K, define the π-degree $d(\pi, u)$ of u as follows. Let i satisfy $u \in U_{\pi(i)}$; then $d(\pi, u) = \sum_{j=1}^{i-1} |N(u) \cap U_{\pi(j)}|/2^{i-j}$. We claim that the expected value of $d(\pi, u)$ over all permutations π of $\{1, \cdots, 2000\}$, is at most $31/2000$. Indeed, for a random permutation π the probability that a fixed neighbor v of u contributes $1/2^r$ to $d(\pi, u)$ is at most $1/2000$ for every fixed $r > 0$. Hence, each neighbor contributes to this expected value at most $1/2000 \sum_{r>0} 1/2^r = 1/2000$ and the desired result follows, since $|N(u)| \leqq 31$.

Now consider the sum $\sum_{u\in U} d(\pi, u)$. The expected value of this sum (over all π's) is at most $31/2000|U|$, by the preceding paragraph. Hence, there is a fixed permutation σ such that $\sum_{u\in U} d(\sigma, u) \leqq 31/2000|U|$. Put $V_{01} = \{u \in U | d(\sigma, u) > \frac{1}{4}\}$. Clearly,

$$|V_{01}| \leqq \frac{4 \cdot 31}{2000}|U| \leqq \frac{|U|}{16} \leqq \frac{n}{16}.$$

Define $V_0 = V_{00} \cup V_{01}$, $W = U - V_{01} = V - V_0$. The last inequality together with (3.1) gives

$$|V_0| \leqq n/8.$$

Let F be the induced subgraph of G_1 on W and define $V_i = U_{\sigma(i)} \cap W$ $(1 \leqq i \leqq 2000)$. The V_i's clearly form a proper vertex coloring of F. Also, for every i, $1 \leqq i \leqq 2000$ and every $v \in V_i$

$$\sum_{j=1}^{i-1} \frac{|N(v) \cap V_j|}{2^{i-j}} < \frac{1}{4}$$

and hence v has at most 2^{i-j-2} neighbors in V_j for each j, $1 \leqq j < i$. Let H_1 be any acyclic orientation of G_1 in which all the edges that join a member of V_i to a member of V_j, where $i > j \geqq 0$, are directed from V_i to V_j (the edges inside V_0 can be directed in an arbitrary acyclic manner). Clearly $H(1) = H_1$ satisfies the property $P(1)$. Thus, the order player can orient G_1 according to H_1. This completes the proof of the case $d = 1$. □

Continuing the induction, we now assume that $H(r)$ has property $P(r)$ for all $r < d$, and prove that the order player can always guarantee that $H(d)$ will have property $P(d)$. We start by proving the following simple lemma.

LEMMA 3.3. *Let F be a directed acyclic graph with a proper g-vertex coloring with color classes $W_1, W_2, \cdots, W_g$. Suppose that for each $g \geqq i > j \geqq 1$ and each $v \in W_i$, v has at most 2^{i-j-2} neighbors in W_j, and that every edge of F whose ends are in W_i and W_j for some $i > j$ is directed from W_i to W_j. Then the outdegree of every vertex of F in the transitive closure of F is smaller than 4^g.*

Proof. Let v be an arbitrary vertex of F. The outdegree of v in the transitive closure of F is obviously smaller than or equal to the total number of directed paths in F that start from v. Suppose $v \in W_i$. Each such directed path must be of the form $v, v_{i_2}, v_{i_3}, \cdots, v_{i_r}$, where $i > i_2 > i_3 > \cdots i_r \geqq 1$, $v_{i_2} \in W_{i_2}, \cdots, v_{i_r} \in W_{i_r}$. There are 2^{i-1} possibilities for choosing $i_2, i_3, \cdots, i_r$. Also, as each vertex of the path is a neighbor of the previous one, there are at most 2^{i-i_2-2} possible choices for v_{i_2}, $2^{i_2-i_3-2}$ possible choices for v_{i_3} (for each fixed choice of v_{i_2}), etc. Hence, the total number of paths is at most $2^{i-1} \cdot 2^{i-i_2-2} \cdot 2^{i_2-i_3-2} \bullet \cdots \bullet 2^{i_{r-1}-i_r-2} < 2^g \cdot 2^{i-i_r} < 4^g$. This completes the proof of the lemma. □

Returning to the proof of Proposition 3.2, recall that $d \geqq 2$ and that by the induction hypothesis $H(d-1)$ has property $P(d-1)$. Thus, there is a subset $V_0 \subseteq V$ satisfying

$$|V_0| \leqq \frac{n}{8} + \frac{n}{16} + \cdots + \frac{n}{2^{d+1}} \tag{3.2}$$

and a proper $D = 2000^{(d-1)}$-vertex-coloring of the induced subgraph of $H(d-1)$ on $V - V_0$ with color classes $V_1, V_2, \cdots, V_D$ satisfying the conditions of property $P(d-1)$. Put $U = V - V_0$, let F be the induced subgraph of $H(d-1)$ on U, and let $T = (U, E(T))$ be the transitive closure of F. Let $G_d = (V, E_d)$ be the graph constructed by the graphs

player in round number d. Let $\bar{V}_{00}$ be the set of all vertices in U whose degree in G_d is at least $2^{d+4} \cdot 4^D$ and define

$$V_{00} = \bar{V}_{00} \cup \{u \in U : \exists v \in \bar{V}_{00} \text{ with } (v, u) \in E(T)\}.$$

Since G_d has at most n edges, $|\bar{V}_{00}| \leqq n/(2^{d+3} \cdot 4^D)$. Also, by Lemma 3.3, the outdegree of each $v \in \bar{V}_{00}$ in T is at most $4^D - 1$. Hence

$$|V_{00}| \leqq n/2^{d+3}. \tag{3.3}$$

Let $\bar{G}$ be the induced subgraph of G_d on $U - V_{00}$. Then the maximum degree in $\bar{G}$ is smaller than $2^{d+4} \cdot 4^D$. For each i, $1 \leqq i \leqq D$, let $\bar{G}^i$ denote the induced subgraph of $\bar{G}$ on $(U - V_{00}) \cap V_i$. As each $\bar{G}^i$ is a subgraph of $\bar{G}$, it has a proper vertex coloring with $2^{d+4} \cdot 4^D$ colors. For each i, $1 \leqq i \leqq D$, fix a proper n_i-vertex-coloring of $\bar{G}^i$ with color classes $U_{N_i+1}, U_{N_i+2}, \cdots, U_{N_i+n_i}$ (some of which may be empty), where $N_i = \sum_{j=1}^{i-1} n_j$ and

$$n_i \geqq 100 \cdot 2^{2d+7} \cdot 16^D \quad \text{for each } 1 \leqq i \leqq D \text{ and } \sum_{i=1}^{D} n_i = 2000^D. \tag{3.4}$$

(Note that since $D = 2000^{(d-1)}$, $d \geqq 2$, there is such a choice for the n_i's.) For every vertex u of $\bar{G}$, let $N(u)$ denote the set of all its neighbors in $\bar{G}$. Let us call a permutation π of $1, 2, 3, \cdots, \sum_{i=1}^{D} n_i$ *legal* if it maps each set of the form $\{N_i + 1, \cdots, N_i + n_i\}$ into itself (and only permute the elements inside these sets among themselves). For any vertex u of $\bar{G}$ and any legal permutation π, define the π-degree $d(\pi, u)$ as follows; let k satisfy $u \in U_{\pi(k)}$, then

$$d(\pi, u) = \sum_{j=1}^{k-1} |N(u) \cap U_{\pi(j)}|/2^{k-j}.$$

We claim that the expected value of $d(\pi, u)$, over all $\prod_{i=1}^{D} n_i!$ legal permutations, is at most $|N(u)|/\min_{1 \leqq i \leqq D} n_i \leqq 1/(100 \cdot 2^{d+3} \cdot 4^D)$. Indeed, consider a fixed neighbor v of u. If v belongs, as does u, to the same graph $\bar{G}^k$, then the probability that for a random legal permutation π, v will contribute $1/2^r$ to $d(\pi, u)$ is at most $1/n_k$, for each fixed $r > 0$. Otherwise, it is easy to check that this probability is even smaller. Hence, each neighbor contributes to this expected value at most $1/n_k \sum_{r>0} 1/2^r = 1/n_k$, and the claim follows.

Consider now the sum $\sum d(\pi, u)$, where u ranges over all vertices of $\bar{G}$. The expected value of this sum (over all legal permutations π) is at most $|V(\bar{G})|/(100 \cdot 2^{d+3} \cdot 4^D) \leqq n/(100 \cdot 2^{d+3} \cdot 4^D)$. Hence, there is a fixed legal permutation σ such that $\sum_{u \in V(\bar{G})} d(\sigma, u) \leqq n/(100 \cdot 2^{d+3} \cdot 4^D)$. Define $\bar{V}_{01} = \{u \in V(\bar{G}) : d(\sigma, u) > 1/100\}$ and $V_{01} = \bar{V}_{01} \cup \{u \in V(\bar{G}) : \exists v \in \bar{V}_{01} \text{ with } (v, u) \in E(T)\}$. Clearly, $|\bar{V}_{01}| \leqq n/(2^{d+3} 4^D)$ and, hence, by Lemma 3.3,

$$|V_{01}| \leqq n/2^{d+3}. \tag{3.5}$$

Put $V_0' = V_0 \cup V_{00} \cup V_{01}$, $W = V - V_0$. By (3.2), (3.3), and (3.5)

$$|V_0'| \leqq \frac{n}{8} + \frac{n}{16} + \cdots + \frac{n}{2^{d+2}}.$$

Let $\tilde{G}$ be the induced subgraph of $\bar{G}$ on W, and define $V_i' = U_{\sigma(i)} \cap W$ $(1 \leqq i \leqq 2000^D = 2000^{(d)})$. The sets V_i' clearly form a proper vertex coloring of $\tilde{G}$. Moreover, as each U_k is an independent set in $H(d-1)$, the sets V_i' actually form a proper vertex coloring of $H(d-1)$, as well. Moreover, for every i, $1 \leqq i \leqq 2000^{(d)}$, every $v \in V_i'$ satisfies

$$\sum_{j=1}^{i-1} \frac{|N(v) \cap V_j'|}{2^{i-j}} \leqq \frac{1}{100},$$

where $N(v)$ is the set of all neighbors of v in $\bar{G}$. Thus, for each fixed j, $1 \leqq j < i$, v has

at most $2^{i-j}/100$ neighbors in V'_j. Let H_d be any acyclic orientation of the edges of G_d obtained by orienting all the edges that join a member of V'_i and a member of V'_j, where $i>j\geq 0$, from V'_i to V'_j. The edges inside V'_0 are oriented in an arbitrary acyclic order consistent with the order given on $H(d-1)$. Notice that all the edges of $H(d-1)$ that do not lie inside V'_0 are also oriented from V'_i to V'_j with $i>j\geq 0$. In order to show that $H(d)=H(d-1)\cup H_d$ has the property $P(d)$, it remains to check that for every $i>j\geq 1$, every $v\in V'_i$ has at most 2^{i-j-2} neighbors in V'_j. By the construction, v has at most $2^{i-j}/100$ neighbors in V'_j in the new graph H_d. Recall that each V'_i is a subset of one of the sets V_k corresponding to the graph $H(d-1)$. Suppose $V'_i\subseteq V_k$, $V'_j\subseteq V_l$. Then $k\geq l$. If $l=k$ or $l=k-1$, then, since v has at most $[2^{k-l-2}]=0$ neighbors in V_l in the graph $H(d-1)$, it follows that in $H(d)$ v has at most $2^{i-j}/100\leq 2^{i-j-2}$ neighbors in V'_j, as needed. If $l\leq k-2$, observe that our construction implies that

$$(i-j)\geq(k-l-1)\min_{1\leq i\leq D} n_i\geq(k-l-1)\cdot 100\cdot 2^{2d+7}\cdot 16^D>(k-l)\cdot 100\geq 200.$$

Thus, in this case, the total number of neighbors of v in V'_j is at most $2^{i-j}/100+2^{k-l-2}\leq 2^{i-j}/100+2^{(i-j)/100}\leq 2^{i-j-2}$.

We conclude that the order player can orient G_d according to H_d, and maintain the property $P(d)$ of the graph $H(d)=H(d-1)\cup H_d$. This completes the induction and the proof of Proposition 3.2. □

The main result of this section, stated in Theorem 3.5 below, is an easy consequence of Proposition 3.2 and the following simple lemma.

LEMMA 3.4. *For every* $d\geq 1$, $2^{(d+3)}\geq 32\cdot 2000^{(d)}$.

Proof. We apply induction on d. For $d=1$ the inequality is trivial, as $2^{(4)}=2^{16}>64{,}000=32\cdot 2000^{(1)}$. Assuming it holds for $d-1$, we prove it for $d\geq 2$. By assumption $2^{(d+2)}\geq 32\cdot 2000^{(d-1)}$. Hence $2^{(d+3)}=2^{2^{(d+2)}}\geq 2^{32\cdot 2000^{(d-1)}}=(2^{32})^{2000^{(d-1)}}\geq(2^{21}\cdot 2000)^{2000^{(d-1)}}=(2^{21})^{2000^{(d-1)}}\cdot(2000)^{2000^{(d-1)}}>32\cdot(2000)^{(d)}$. □

THEOREM 3.5. *The order player can avoid ending the orientation game during the first* $\log^* n-5$ *rounds. Hence, by Proposition* 3.1, *the time required for finding an approximate maximum among n elements using n comparisons in each round is at least* $\log^* n-4$.

Proof. Clearly, we may assume that $\log^* n-5\geq 0$. By Proposition 3.2, the order player can maintain the property $P(d)$ for each of the graphs $H(d)$ constructed during the algorithm. Notice that by Lemma 3.3, the outdegree of every vertex in the transitive closure of a graph that satisfies $P(d)$ is at most $4^D+n/8+n/16+\cdots+n/2^{d+2}<4^D+n/4$, where $D=2000^{(d)}$. Thus, it follows that if $4^{2000^{(r)}}\leq n/4$, then the graphs player can keep playing for at least $r+1$ rounds. Therefore, by Lemma 3.4, the assertion of the theorem will follow if for $r=\log^* n-5$ the inequality $4^{2^{(r+3)}/32}\leq n/4$ holds. Since for $r>0$ $4\cdot 4^{2^{(r+3)}/32}<2^{(r+4)}$, this follows immediately from the definition of $\log^* n$. □

4. Extensions and related results. In this section we merely state, without proof, several extensions of the results of this paper and several related results. The proofs of these results combine the methods used here with some new ideas, somewhat similar to ones used in [AV87], [AAV86], [AP89]. The detailed proofs are somewhat complicated and will appear somewhere else.

For integers $n\geq 2$ and p, $1\leq p\leq\binom{n}{2}$, and for a real number ε, $1/n\leq\varepsilon\leq\frac{1}{2}$, let $r(n,p,\varepsilon)$ denote the time complexity of the best deterministic comparison algorithm that finds, among n elements, an element whose rank belongs to the top εn ranks, using p comparisons in each round. Clearly $r(n,n,\frac{1}{2})$ is just the function $r(n)$ discussed in this paper. For $\varepsilon=1/n$, the problem is that of finding the exact maximum, and the case $p=1$ corresponds to serial algorithms. We can prove the following theorem.

THEOREM 4.1. *For all admissible* n, p, ε,

$$r(n, p, \varepsilon) = \Theta\left(\frac{n}{p} + \log \frac{\log (1/\varepsilon)}{\log (2 + p/n)} + \log^* n - \log^* \left(1 + \frac{p}{n}\right)\right).$$

Thus for all n, $p \leqq 2n$, ε

$$r(n, p, \varepsilon) = \Theta\left(\frac{n}{p} + \log \log \frac{1}{\varepsilon} + \log^* n\right)$$

and for all n, $p \geqq 2n$, ε

$$r(n, p, \varepsilon) = \Theta\left(\log \frac{\log 1/\varepsilon}{\log (p/n)} + \log^* n - \log^* \left(\frac{p}{n}\right)\right).$$

For $\varepsilon = 1/n$ this theorem reduces to Valiant's result about finding the maximum. For $\varepsilon = \frac{1}{2}$, $p = n$ this reduces to our Theorem 1.1 (with a somewhat cruder estimate).

Next we consider approximate sorting. For $n \geqq 2$, $1 \leqq p \leqq \binom{n}{2}$, and $2/n^2 \leqq \varepsilon \leqq \frac{1}{2}$, let $a(n, p, \varepsilon)$ denote the time complexity of the best deterministic comparison algorithm that uses p comparisons in each round and finds, given n elements, all the order relations between pairs but at most $\varepsilon\binom{n}{2}$. The results of [BR82], [AA88], [AKSS86b], [BB87] deal with the minimum p for which $a(n, p, \varepsilon) = 1$ for some $\varepsilon = o(1)$. Notice that a precise determination of $a(n, p, \varepsilon)$ contains all the known results about deterministic comparison sorting or approximate sorting algorithms. We can prove the following result, determining $a(n, p, \varepsilon)$, up to a constant factor, for all possible n, p, and ε.

THEOREM 4.2. *For all admissible* n, p, ε

$$a(n, p, \varepsilon) = \Theta\left(\frac{\log 1/\varepsilon}{\log (1 + p/n)} + \log^* n - \log^*\left(1 + \frac{p}{n}\right)\right).$$

Thus, for $p \leqq 2n$, $a(n, p, \varepsilon) = \Theta(n \log (1/\varepsilon)/p + \log^* n)$ *and for* $p \geqq 2n$, $a(n, p, \varepsilon) = \Theta(\log (1/\varepsilon)/\log (p/n) + \log^* n - \log^* (p/n))$.

For $\varepsilon = 2/n^2$ this theorem corresponds to sorting and gives the known $\Theta(\log n/\log(1 + p/n))$ bound (which is $\Theta(n \log n/p)$ for $p \leqq 2n$ and is $\Theta(\log n/\log (p/n))$ for $p \geqq 2n$), (see [AV87], [AAV86]). Notice that for $p = n$ and for any $\varepsilon > 1/2^{\log^* n}$, $a(n, n, \varepsilon) = \Theta(\log^* n)$. As shown in § 3, $\Omega(\log^* n)$ rounds are required (with $p = n$), even if we wish to find one element known to be greater than $n/2$ others. By the last equality, $O(\log^* n)$ rounds are already sufficient to get almost all the order relations between pairs.

Finally, we consider the problem of approximate merging. In this case the results and the methods are simpler and similar to the methods of [Va75], [BHo82]. For n, $1 \leqq p \leqq n^2$ and $1/2n^2 \leqq \varepsilon \leqq \frac{1}{2}$, let $m(n, p, \varepsilon)$ denote the time complexity of the best comparison merging algorithm that uses p comparisons in each round and finds, given two sorted lists, each of size n, all the order relation between pairs but at most εn^2.

The results of [Va75], [BHo82] deal with full merging, i.e., the case $\varepsilon < 1/n^2$. We can prove the following theorem that determines $m(n, p, \varepsilon)$, up to a constant factor, for all admissible n, p, ε.

THEOREM 4.3. *For all admissible* n, p *and* $1/n \leqq \varepsilon \leqq \frac{1}{2}$,

$$m(n, p, \varepsilon) = \Theta\left(\frac{1}{\varepsilon p} + \log \frac{\log 1/\varepsilon}{\log (2 + \varepsilon p)}\right).$$

Thus for $p \leqq 2/\varepsilon$ $m(n, p, \varepsilon) = \Theta(1/(\varepsilon p) + \log \log 1/\varepsilon)$ and for $p \geqq 2/\varepsilon$ $m(n, p, \varepsilon) = \Theta(\log (\log 1/\varepsilon/\log \varepsilon p))$. For the case $\varepsilon \leqq 1/n$, the bounds are the same as for $\varepsilon = 1/n$

(up to a constant factor), which are the same bounds as for exact merging: $\Theta(n/p + \log(\log n/\log(2+p/n)))$.

Acknowledgment. We thank N. Pippenger, who brought the problem of finding an approximate maximum to our attention.

BOUNDS ON UNIVERSAL SEQUENCES*

AMOTZ BAR-NOY†‡, ALLAN BORODIN†§¶, MAURICIO KARCHMER†§, NATHAN LINIAL†, AND MICHAEL WERMAN†

Abstract. Universal sequences for graphs, a concept introduced by Aleliunas [M.Sc. thesis, University of Toronto, Toronto, Ontario, Canada, January 1978] and Aleliunas et al. [*Proc. 20th Annual Symposium on Foundation of Computer Science*, 1979, pp. 218-223] are studied. By letting $U(d, n)$ denote the minimum length of a universal sequence for d-regular undirected graphs with n nodes, the latter paper has proved the upper bound $U(d, n) = O(d^2 n^3 \log n)$ using a probabilistic argument. Here a lower bound of $U(2, n) = \Omega(n \log n)$ is proved from which $U(d, n) = \Omega(n \log n)$ for all d is deduced. Also, for complete graphs $U(n-1, n) = \Omega(n \log^2 n / \log \log n)$. An explicit construction of universal sequences for cycles ($d = 2$) of length $n^{O(\log n)}$ is given.

Key words. universal sequences, graph connectivity, complexity theory

AMS(MOS) subject classifications. 05C40, 68R10, 68Q15

1. Introduction. In addition to their obvious computational interest, graph connectivity problems play a central role in complexity theory. Let STCON (respectively, USTCON) denote the problem of determining if a directed (respectively, undirected) graph has a path from a given source node s to a given goal node t. As usual, let NSPACE(S) (respectively, DSPACE (S) and RSPACE (S)) denote those sets accepted in nondeterministic (respectively, deterministic and random) space S. Savitch's [7] fundamental result that NSPACE (S) $\subseteq$ DSPACE (S^2) is based on the fact that STCON is complete for NSPACE ($\log n$) with respect to log-space reducibility. (In fact, it is complete with respect to log-depth $= NC^1$ reducibility.) Similarly, Lewis and Papadimitriou [6] show that USTCON is complete for symmetric log-space bounded computation.

It is easy to see that STCON $\subseteq NC^2 \subseteq$ DSPACE ($\log^2 n$). However, despite considerable attention to this problem, there has been no improvement to this upper bound. In one of the few significant attempts to give evidence that STCON is not contained in DSPACE ($\log n$), Cook and Rackoff [4] introduce the JAG (Jumping Automata for Graphs) model and show that within this restricted model STCON requires space $\Omega(\log^2 n / \log \log n)$.

Although USTCON appears to be a computationally easier problem (and indeed Cook and Rackoff [4] cannot prove such a strong result for JAGs operating on undirected graphs), the best known deterministic algorithms for USTCON also apply to STCON. However, when we consider random space bounded computations, the situation seems to be different, since Aleliunas et al. [2] show that USTCON is in RSPACE ($\log n$).

Motivated by the Cook and Rackoff [4] paper, Aleliunas [1] (for the special case of degree two) and then Aleliunas et al. [2] introduce the concept of a "universal sequence" for graphs. Let $G(d, n)$ denote the class of all connected d-regular graphs with n nodes and with labeled edges. Think of every edge as a pair of directed edges.

¶ This research was performed while this author was a Lady Davis Visiting Professor at the Hebrew University, Jerusalem 91904, Israel.

Every directed edge is labeled with a label from $\{0, \cdots, d-1\}$ in such a way that edges going out from the same vertex are labeled differently. (It is easy to verify that for $2 \leqq d \leqq n-1$, $G(d, n)$ is not empty if and only if dn is even, see Lovász [5, Ex. 5.2.] A sequence $s = s_1 s_2 \cdots s_r$ in $\{0, \cdots, d-1\}^*$ is interpreted as a sequence of edge traversal commands. Thus a sequence s and a node u_0 on a graph G in $G(d, n)$ define a unique sequence of nodes $u_0, u_1, \cdots, u_r$ in G with (u_{i-1}, u_i) labeled by s_i for $i = 1, \cdots, r$. We say that s *visits* the set of nodes $\{u_0, \cdots, u_r\}$. A sequence s *covers* a graph G in $G(d, n)$ if the sequence visits every node in G independent of the starting node. A sequence s is *universal* for $G(d, n)$ if s covers every G in $G(d, n)$. Finally, we let $U(d, n)$ denote the minimal length of a universal sequence for $G(d, n)$. We will see in § 5 that the restriction to regular graphs serves some aesthetic purposes.

Aleliunas et al. [2] show that the expected time for a random walk to visit all nodes of $G = (V, E)$ is at most $2|E||V|$. (No such result holds for directed graphs.) Hence the result that USTCON is in RSPACE $(\log n)$. They then use this result to assert the existence of a (nonuniform) universal sequence $s(d, n)$ for $G(d, n)$. The length of $s(d, n)$ is asymptotically bounded by

$$dn^2 \log (|G(d, n)|) = O(d^2 n^3 \log n).$$

In fact, they argue that most sequences of this length must be universal. Clearly, such universal sequences give a nonuniform method to test connectivity (using only two pebbles in the JAG model) within $O(\log n)$ space.

There are a number of reasons to study $U(d, n)$ further. If we could obtain a "sufficiently" explicit construction of polynomial length, then USTCON would be in DSPACE $(\log n)$. (We need to be able to generate any element of the sequence in DSPACE $(\log n)$.) In order to beat the previously mentioned $\log^2 n$ deterministic space bound, it suffices to show, by an explicit construction, that $U(3, n) = n^{o(\log n)}$. In this regard, we should also note that at present there is no deterministic sublinear space algorithm that runs in polynomial time. Second, for the purpose of time-space tradeoffs, it is important to determine the asymptotic behavior of $U(d, n)$ by any type of construction since lower bound techniques tend to apply to nonuniform models. In this regard an $U(d, n) = O(dn)$ or even $O(n^2)$ lower bound would have serious implications for any attempt at time-space lower bounds. In addition to complexity theory, universal sequences may play a role in the study of distributed systems (e.g., anonymous rings). And finally, of course, we think that the study of $U(d, n)$ raises a number of interesting combinatorial problems.

In §§ 2 and 3 we consider the special case of $d = 2$, the subject of Aleliunas [1]. First we give an explicit construction of length $n^{O(\log n)}$. Then we prove a nonlinear lower bound, $U(2, n) = \Omega(n \log n)$. Section 4 considers the other extreme, namely the case of complete graphs $(d = n-1)$. Here we observe that the probabilistic bound yields an upper bound of $n^3 \log^2 n$. We are able to prove that $U(n-1, n) = \Omega(n \log^2 n / \log \log n)$. In order to establish this lower bound, we view the problem as a game consisting of a graph generator (perhaps thought of as a taxi driver) versus a very powerful sequence generator (thought of as a passenger) where the passenger wants to see all n sites in as little time as possible and the driver would like to prolong the tour as long as possible. In § 5 we discuss the implication of the previous results for arbitrary d.

2. An explicit construction for the case of $d = 2$. There is only one regular connected graph of degree two, namely a cycle. In order to study $U(2, n)$, there is an equivalent way to formulate the problem as first discussed by Aleliunas in [1]. Instead of considering different labelings of the n-cycle, we consider the infinite line and label

each integer coordinate (= node) with a "0" or "1" with the interpretation that at a node labeled "b" the edge to the right is labeled "b" and the edge to the left is labeled "$1-b$." We now interpret $U(2, n)$ as the smallest length of a sequence that is guaranteed to visit at least n nodes on any labeled line.

From the probabilistic constructions of Aleliunas [1] and Aleliunas et al. [2] we know that $U(2, n) = O(n^3)$. In fact, Aleliunas [1] conjectured $U(2, n)$ to be exactly $\binom{n}{2}$. Exhaustive tests confirm $U(2, n) = \binom{n}{2}$ for $n < 8$ but we are aware of at least one claim (again by testing) that $U(2, n) < \binom{n}{2}$ for $n = 9$.

To gain insight for both a lower bound and an explicit construction, we first consider a special class of labeled lines. Let ODD denote the class of labeled lines of the form $\cdots 0^{i_1}1^{i_2}0^{i_3}1^{i_4}\cdots$, where all i_j are odd. Let $L(n)$ be the class of all sequences that cover at least n nodes on any line in ODD and let $U(n)$ denote the minimal length of any sequence in $L(n)$. Without loss of generality, we shall assume that n is even in order to avoid ceilings and floors. Let $n' = n+1$ so that n' is odd.

LEMMA 1. *The sequence* $w_n = (0^{n'}1^{n'})^{(n/2+1)}$ *has the following properties*:

(A) *If begun on the leftmost node of a block labeled with zeros (respectively, on the rightmost node of a block labeled with ones)* w_n *will move right (respectively, left) until encountering the first block of nodes with an even number of zeros or ones wherein it will terminate on the leftmost zero or rightmost one of this block. If no such block is encountered within the first n nodes visited, the sequence will be exhausted having visited at least n nodes.*

(B) *If not started on a leftmost zero or rightmost one the directional behavior of* w_n *on the line will depend on the parity of the initial location within the block on which the sequence is started. In any case the sequence will either visit n nodes or will terminate on the leftmost zero or rightmost one of some block of even length. In particular,* $w_n \in L(n)$ *and* $U(n) \leqq (n+1)^2$.

LEMMA 2. *The sequence* v_n *defined recursively by* $v_1 = 01$ *and* $v_n = v_{n/2}(0^{n'}1^{n'})v_{n/2}$ *is in* $L(n)$ *so that* $U(n) = O(n \log n)$.

We leave it to the reader to verify both lemmas. Let us remark that Theorem 2 of the next section shows that Lemma 2 is asymptotically optimal. We use the w_n sequences repeatedly to explicitly construct a universal sequence of length $n^{O(\log n)}$. We chose to use the w_n sequences for ODD rather than the shorter $O(n \log n)$ sequences v_n since its properties are easier to state and since the shorter length v_n would not significantly change the length of the universal sequence of Theorem 1.

THEOREM 1. *There is a recursively defined sequence* $s(n)$ *that is universal for* $G(2, n)$ *with length* $|s(n)| = n^{O(\log n)}$. *Furthermore, any bit of* $s(n)$ *can be computed in time bounded by a polynomial in n.*

Proof. By induction on n we construct $s(n)$. The basis of the induction is immediate. Let w_n be as in Lemma 1 and let $s(n/2) = s_1 s_2 \cdots s_t$. Then, $s(n) = w_n s_1 w_n s_2 \cdots w_n s_t w_n$. Consider any labeled line and mark the leftmost zero and rightmost one in every even-length block. Note that in a segment of length n at most $n/2$ nodes have been marked. Now after the first w_n, $s(n)$ has either visited n nodes or has positioned itself on a marked node. Once on a marked node, a sequence symbol s_i of $s(n/2)$ will move either left or right so that the next w_n (by Lemma 1) will continue to move in that direction until it is stopped at the next marked node. In this way we are guaranteed to visit at least n nodes with some w_n or at least $n/2$ marked nodes and all the nodes within the blocks containing those marked nodes. In either case, at least n nodes have been visited.

To bound the length we see that $|s(n)| \leqq (n+1)^2 |s(n/2)|$ from which the length bound easily follows. It is also easy to see how to compute any particular bit of $s(n)$ in polynomial time. □

3. A lower bound for the case of $d=2$. The aim of this section is to prove an $\Omega(n \log n)$ lower bound for $U(2, n)$. We shall pick a small subset of ODD and show that, just to traverse this subset, a sequence must be "long."

We begin by introducing some notation. Let S be the set of infinite lines of the form: $\cdots 0^a 1^a 0^a 1^a \cdots$, a odd. Let S_n be the set of segments of length n of lines in S with starting point a leftmost zero. We show that a sequence that traverses every line in S_n must be $\Omega(n \log n)$ long. We say that a sequence α is *good* for a segment w if, when started at the left of w, α eventually reaches the right of w. For a string $w \in \{0, 1\}^*$ and $x \in \{0, 1\}$ let $\#_x w$ be the number of occurrences of x in w.

We illustrate the idea of our proof by considering some very simple sequences. So let α cover every line in S_n where α is of the form $0^{r_1}1^{r_1}\cdots 0^{r_k}1^{r_k}$ with all r_i odd. Assume, moreover, that α covers at least $n/2$ locations to the right of the starting point.

FACT 1. $0^{r_i}1^{r_i}$ is good for 0^a1^a if and only if $r_i \geqq a$ and r_i is odd.

Define a_j to be the biggest odd number less than or equal to $n/(2j)$. Fact 1 implies that at least j r_i's must be bigger than a_j so that

$$|\alpha| \geqq \sum_{j=1}^{n/2} a_j \leqq \sum_{j=1}^{n/2} \left(\frac{n}{2j} - 2\right) = \Omega(n \log n).$$

We now give a lower bound for arbitrary α's. Consider the runs of a sequence α and the sequence 1α on a line from S. Since we start from a leftmost zero, these runs are symmetric with respect to the starting point. For a sequence β, let R_β (L_β) be the set of indices j such that β covers at least $n/2$ nodes to the right (left) of the starting point when run on the line $\cdots 0^{a_j}1^{a_j}0^{a_j}1^{a_j}\cdots$. Either $\sum_{j\in R_\alpha} a_j = \Omega(n \log n)$ or $\sum_{j\in L_\alpha} a_j = \Omega(n \log n)$. Since $R_\alpha = L_{1\alpha}$ and the lengths of α and 1α differ only by one we assume, without loss of generality, that $\sum_{j\in R_\alpha} a_j = \Omega(n \log n)$. We deal only with the runs of α on lines $\cdots 0^{a_j}1^{a_j}0^{a_j}1^{a_j}\cdots$, where $j \in R_\alpha$.

Fact 1 motivates the following lemma.

LEMMA 3. *Let α' be good for 0^a1^a, then $\alpha' = u_1\beta_a^0 u_2 \beta_a^1 u_3$, where*

(C1) $\#_0\beta_a^0 - \#_1\beta_a^0 = a$, *and* $\#_1\beta_a^1 - \#_0\beta_a^1 = a$;

(C2) *Every nonempty prefix and suffix of $\beta_a^0(\beta_a^1)$ has more zeros (ones) than ones (zeros).*

Proof. (C1) is necessary in order to pass the block of zeros or ones. (C2) can be obtained by extending u_1 to the right and u_2 to the left so as to make β_a^0 minimal, and extending u_2 to the right and u_3 to the left to make β_a^1 minimal. Note that $\#_0 u_2 = \#_1 u_2$. □

We denote $\beta_a^0 u_2 \beta_a^1$ by β_a and call it an a-block. β_a^0 and β_a^1 are called half blocks.

LEMMA 4. *Let α' be good for $(0^a1^a)^m$; then α' contains m disjoint a-blocks.* □

We say that two half blocks have a *trivial intersection* if they are either disjoint or one is contained in the other.

LEMMA 5. *Let β_{a_i}, β_{a_j} be an a_i-block and a_j-block respectively; then $\beta_{a_i}^0$ and $\beta_{a_j}^1$ have a trivial intersection.*

Proof. Follows by the prefix and suffix properties of $\beta_{a_i}^0$ and $\beta_{a_j}^1$. □

We say that a sequence $\{\beta_{a_j}^{x_j}\}_{j=1,\cdots,r}$; $x_j \in \{0, 1\}$, of half blocks is *nested* if we have the following.

(i) Every two half blocks have a trivial intersection;

(ii) $\beta_{a_j}^x \subseteq \beta_{a_k}^x$ implies that there exists an $l \neq j, k$ such that $\beta_{a_j}^x \subseteq \beta_{a_l}^{\bar{x}} \subseteq \beta_{a_k}^x$, $\bar{x}$ being the complement of x.

LEMMA 6. *Let α cover every line in S_n. Then α contains a nested sequence $\{\beta_{a_i}^{x_i}\}$, $i = 1, \cdots, n/2$ of half blocks where, again, a_j is the biggest odd number less than or equal to $n/(2j)$.*

Proof. The proof is by induction on i. Let B_{a_i} be a set of disjoint a_i-blocks in α. By Lemma 4 and the fact that $ia_i \leqq n$, $|B_{a_i}| \geqq i$. When $i=1$, pick any half block of any β_{a_1}. Assume the lemma is true for $i-1$. Let $B=\{\beta_{a_j}^{x_j}\}_{j=1,\cdots,i-1}$ be the nested sequence constructed up to step $i-1$. We will show how to find a half block of B_{a_i} that preserves the *nestedness* of B.

For each $\beta_{a_i} \in B_{a_i}$ define

$$In(\beta_{a_i})=\{j \mid \beta_{a_i}^{x_j} \cap \beta_{a_j}^{x_j} \neq \varnothing \wedge \beta_{a_i}^{\bar{x}_j} \not\subseteq B_{a_j}^{x_j}\}.$$

Intuitively, $In(\beta_{a_i})$ is the set of half blocks that prevent β_{a_i} from being properly nested.

CLAIM 1. $\{In(\beta_{a_i})\}$, $\beta_{a_i} \in B_{a_i}$, are pairwise disjoint. To see this, suppose that $j \in In(\beta_{a_i}) \cap In(\tilde{\beta}_{a_i})$ for some β_{a_i} and $\tilde{\beta}_{a_i}$ and without loss of generality assume that β_{a_i} appears in α to the left of $\tilde{\beta}_{a_i}$. Furthermore, assume that $\beta_{a_j}^{x_j}$ is of type 0, i.e., $x_j=0$. Then, either $\beta_{a_j}^0 \cap \beta_{a_i}=\varnothing$ or if $\beta_{a_j}^0 \cap \beta_{a_i} \neq \varnothing$, then $\beta_{a_i}^1 \subseteq \beta_{a_j}^0$ (because of suffix and prefix properties of the blocks). In either case, we get $j \notin In(\beta_{a_i})$. If $x_j=1$, a similar argument shows that $j \notin In(\tilde{\beta}_{a_i})$.

CLAIM 2. There exists a β_{a_i} such that $In(\beta_{a_i})=\varnothing$. This is true by Claim 1 and the fact that there are i a_i-blocks in B_{a_i}.

Choose a β_{a_i} as in Claim 2 and consider a minimal (in the inclusion sense) $\beta_{a_j}^{x_j}$ such that $\beta_{a_j}^{x_j} \cap \beta_{a_i} \neq \varnothing$. If no such $\beta_{a_j}^{x_j}$ exists then β_{a_i} is disjoint to every $\beta_{a_j}^{x_j}$ so that we can pick any half block of it. Otherwise, $\beta_{a_i}^{\bar{x}_j} \subseteq \beta_{a_j}^{x_j}$ and letting $x_i=\bar{x}_j$ we have that $\{\beta_{a_j}^{x_j}\}_{j=1,\cdots,i-1} \cup \{\beta_{a_i}^{x_i}\}$ is properly nested. □

LEMMA 7. *Let $B=\{\beta_{a_j}^{x_j}\}_{j=1,\cdots,i}$ be a nested sequence. Then*

$$\left|\bigcup_{j=1}^{i} \beta_{a_j}^{x_j}\right| \geqq \sum_{j=1}^{i} a_j.$$

Proof. Without loss of generality, assume that the half blocks in B are ordered so that $\beta_{a_i}^{x_i}$ is not contained in $\beta_{a_j}^{x_j}$ for $j=1,\cdots,i-1$. We proceed by induction on i. The case $i=1$ is obvious. Assume the lemma is true for $i-1$ so that $|\bigcup_{j=1}^{i-1} \beta_{a_j}^{x_j}| \geqq \sum_{j=1}^{i-1} a_j$.

By (ii) in the definition of nested sequences, we have that the maximal $\beta_{a_j}^{\bar{x}_j} \subseteq \beta_{a_i}^{x_i}$ are of opposite type, i.e., $x_i=\bar{x}_j$. Let β be the union of the $\beta_{a_j}^{\bar{x}_j}$, which are maximal half blocks contained in $\beta_{a_i}^{x_i}$. For $\beta_{a_i}^{x_i}$ to have (C1) we need $|\beta_{a_i}^{x_i} - \bigcup_{j=1}^{i-1} \beta_{a_j}^{x_j}| \geqq a_i$ so that $|\bigcup_{j=1}^{i} \beta_{a_j}^{x_j}| \geqq \sum_{j=1}^{i} a_j$. □

THEOREM 2. *A universal sequence α for S_n satisfies $|\alpha|=\Omega(n \log n)$.*

Proof. The proof follows immediately from Lemmas 6 and 7. □

4. The complete graph. There is only one graph in $G(n-1, n)$, namely K_n. While connectivity is no longer an issue, the question of $U(n-1, n)$ is still surprisingly difficult and interesting.

The probabilistic construction of Aleliunas et al. [2] shows that $U(n-1, n)=O(n^5 \log n)$ as the upper bound for any d. In fact, a more specific probabilistic analysis of random walks in K_n shows that the expected length to visit all nodes is $O(n \log n)$. From this follows $U(n-1, n)=O(n^3 \log^2 n)$.

For the lower bound, we consider the following two-player game, played between D (the driver) and P (the passenger). There is a fixed integer n and the game is with a taxi moving on a graph in $G(d, n)$. The game starts at any node of the graph. At each step, P can either direct the taxi along a directed edge that has already been traversed before, or he/she may let D choose any untraversed edge. In particular, if the present node is being visited for the first time, then D moves. The game ends at the first time when all nodes of the graph have been visited. P pays D the number of steps the game took.

We denote by $DP(d, n)$ the value of this game. Our result is Theorem 3.

THEOREM 3.

$$n^2-3n+3 \geqq DP(n-1, n) \geqq \Omega\left(\frac{n \log^2 n}{\log \log n}\right).$$

COROLLARY 1.

$$U(n-1, n) \geqq \Omega\left(\frac{n \log^2 n}{\log \log n}\right). \qquad \square$$

Proof of Theorem 3. The upper bound is obvious. P plays a strategy according to which he lets D play all the time. This insures that no edge is traversed twice in the same direction, so when $(n-1)(n-2)+1$ steps elapse all nodes must be visited.

To prove the lower bound, we consider a strategy for D that is defined inductively. At any time T in the game there is a digraph B_T on $V(K_n)$ consisting of all directed edges traversed thus far. The induction hypothesis follows:

(*) D has a strategy that causes the game to last at least $T(n) = (n \log^2 n)/(30 \log \log n)$ steps in such a way that all indegrees in B_T do not exceed $\log^2 n$.

We proceed to show how the strategy is carried over from n to $2n$. In the first stage D applies (*) to the first n nodes, thus he stays there at least $T(n) = (n \log^2 n)/(30 \log \log n)$ steps, with no indegree exceeding $\log^2 n$. At the first time after $T(n)$ at which D gets the right to move, he moves to node $n+1$. Now for another $T(n)$ steps he stays at nodes $\{n+1, \cdots, 2n\}$ according to (*). After these two stages, which take more than $2T(n)$ steps, no indegree exceeds $\log^2 n$ and node $2n+1$ is still isolated. Now begins a merging stage. To carry out the induction we show that for $(n \log n)/(5 \log \log n)$ steps D can proceed in the game with no indegree exceeding $\log^2 (2n)$. Since $T(2n)-2T(n) \leqq (n \log n)/(5 \log \log n)$ the induction hypothesis is maintained. We claim the following easy lemma.

LEMMA 8. *Let G be a digraph, $S \subseteq V(G)$, and let $d \geqq 3$ be the largest indegree in G. Then there are at least $|V|/2$ nodes u for which all paths from u to S have length at least* $(\log |V| - \log |S| - 1)/\log d$.

Now let us consider the set S of all nodes of largest outdegree. Whenever D is given the move, he chooses to go to a node whose indegree is strictly less than $\log^2 (2n)$ and whose distance in B_T from S is as large as possible. Note that the average indegree is at most $T(2n)/(2n) = (\log^2 (2n))/(30 \log \log (2n))$ so that all but $2n/(30 \log \log (2n)) = o(n)$ nodes have indegree strictly less than $\log^2 (2n)$. Thus during the whole process there are always many nodes with small indegree. In our case, all indegrees are at most $\log^2 (2n)$ and it follows by Lemma 8 that for every node u and for at least half of the nodes v, the distance from v to u is at least $\log n/(5 \log \log n)$. Therefore, if $|S| = 1$ then with this strategy the game proceeds at least $\log n/(5 \log \log n)$ steps more before the maximum outdegree increases. Ignoring momentarily the possibility that $|S|$ is larger, no degree reaches $2n$ before $(n \log n)/(5 \log \log n)$ steps. As long as the maximum outdegree is less then $2n$ the missing node will not be reached and the induction hypothesis is established since $T(2n)-2T(n) \leqq (n \log n)/(5 \log \log n)$.

To complete the proof for arbitrary $|S| \geqq 1$, consider the number of steps needed to increase the outdegree by two. We investigate a segment of the game during which the largest outdegree in B_T increases from m to $m+2$. Let us concentrate on that step where for the first time some outdegree reaches $m+2$ and let us say that at this point the number of nodes of degree $m+1$ is k. If $k \geqq (2 \log n)/(5 \log \log n)$ then our claim about the number of steps remains valid since the increase of the outdegree of any

node requires at least one move (of D). On the other hand, if $k < (2 \log n)/(5 \log \log n)$ then by Lemma 8 at the beginning of the stage there is a node whose distance from all k nodes of outdegree $m+1$ is at least $\log (n/k)/\log (\log^2 n) > (2 \log n)/(5 \log \log n)$ and, all of our previous arguments carry through. Thus $DP(n) \geqq T(n) = (n \log^2 n)/(30 \log \log n)$ and the proof is complete. □

5. Bounds for arbitrary graphs. Given the $U(2, n) = \Omega(n \log n)$ result, it is a little tedious but not difficult to derive the same (or improved as a function of n) lower bounds for all degrees. We again note that $G(d, n)$ is nonempty for $2 \leqq d \leqq n-1$ if and only if dn is even, so that we always assume that dn is even.

Aleliunas [1] has shown that $U(2, n) \leqq U(d, (d-1)n)$. We modify his construction to obtain Lemma 9.

LEMMA 9. $U(2, n) \leqq (2/d) U(d, (d-1)n)$.

Proof. We show how to derive a universal sequence s' for $G(2, n)$ from a universal sequence s for $G(d, (d-1)n)$. For any $a, b \in \{0, 1, \cdots, d-1\}$ let $s(a, b)$ be the sequence obtained from s by replacing each a by 0, each b by 1 and deleting all other symbols. Now let a, b be the least frequently occurring symbols in s and define $s' = s(a, b)$ so that $|s'| \leqq (2/d)|s|$. We will show that s' is universal for $G(2, n)$.

Let C be any labeled n-cycle. We want to construct a labeled graph G_C in $G(d, (d-1)n)$ whose traversal by s will guarantee that s' covers C. Let $K^i_{d-1} = (V^i, E^i)$ for $0 \leqq i \leqq n-1$ be n copies of the complete graph K_{d-1}. Say $V^i = \{v^i_1, \cdots, v^i_{d-1}\}$. Then $G_C = \langle \cup_i V^i, \cup_i E^i \cup D \rangle$, where

$$D = \{(v^i_j, v^{(i+1)(\mathrm{mod}\ n)}_j) | 0 \leqq i \leqq n-1, 1 \leqq j \leqq d-1\}.$$

Intuitively, the K^i_{d-1} correspond to nodes in C while the edges in D correspond to the edges in C. We label the edges in E^i by any labeling from $\{0, 1, \cdots, d-1\} \backslash \{a, b\}$. We label the edges in D in a way which corresponds exactly to the labeling in C. That is, if $\langle i, i+1 \rangle$ has label "0" (respectively, "1") in C then for all j, $\langle v^i_j, v^{i+1}_j \rangle$ has label a (respectively, b) and $\langle v^i_j, v^{i-1}_j \rangle$ has label b (respectively, a). Clearly G_C is in $G(d, (d-1)n)$. Now it should be clear that as s traverses the graph G_C, it is precisely the labels $\{a, b\}$ that cause a traversal between neighboring (in the cycle) copies of K_{d-1}. Thus s covers G_c implies s' covers C. □

LEMMA 10. $U(d_1, n) \leqq (d_1/d_2) U(d_2, (d_2 - d_1 + 1)n)$ *for all* $d_1 \leqq d_2$.

Proof. This is an immediate generalization of the construction in Lemma 9. □

LEMMA 11. $U(d, n) = \Omega(n \log n - n \log d)$.

Proof. If n was divisible by $d-1$, this lemma would follow immediately from Lemma 9 and Theorem 2. For arbitrary sufficiently large $n = q(d-1) + r$ we proceed as follows. If $r = 0$ then we would follow the construction of Lemma 9 and form a "cycle" with $q = n/(d-1)$ copies of K_{d-1}. If $r > 0$ we form $q-3$ copies of $K^i_{d-1} = (V^i, E^i)$ and a set of nodes W with $|W| = n - (q-3)(d-1) = 3(d-1) + r$. As before, each copy K^i_{d-1} will play the role of a node in a cycle as will W. We only have to describe how to fit W into a cyclic structure.

Suppose we want W to have K^1_{d-1} and K^{q-3}_{d-1} as its cyclic neighbors. Since dn is even, it follows that $d|W|$ is even and $|W| \geqq d+1$. Thus we can form a d-regular graph (W, E) and remove $d-1$ node-disjoint edges, say (u_j, w_j). We connect W to K^1_{d-1} and K^{q-3}_{d-1} by edges $\{(u_j, v^1_j)\}$ and $\{(w_j, v^{q-3}_j)\}$ for $1 \leqq j \leqq d-1$. We connect K^i_{d-1} to K^{i+1}_{d-1} $(1 \leqq i \leqq q-3)$ as in Lemma 9. In this way we are able to construct a d-regular graph G_C on n nodes. And again, as in Lemma 9, for any universal sequence s for $G(d, n)$ we construct $s' = s(a, b)$, where a and b are the least frequently occurring symbols in s. By labeling the "cycle" in G_C to mimic the labeling in C we can argue that if s is started on some node in $K^{\lceil (q-3)/2 \rceil}_{d-1}$, then s' would cover at least $\lceil (q-3)/2 \rceil$ nodes in

C. Since C is an arbitrary member of $G(2, n)$, this insures that s' covers at least $\lceil (q-3)/2 \rceil$ nodes in any infinite labeled line. Therefore $U(2, n/(3d)) \leqq U(2, (q-3)/2) \leqq (2/d)\, U(d, n)$ for any sufficiently large n which together with Theorem 2 yields Lemma 11. □

Lemma 11 shows that for small d (say $d \leqq n^{\varepsilon}$, $\varepsilon < 1$), we have $U(d, n) = \Omega(n \log n)$. For large d, there is a simple way to achieve the same bound using the driver-passenger game introduced in § 4.

LEMMA 12. $U(d, n) \geqq DP(d, n) = \Omega(n \log d)$.

Proof. The driver's strategy is simply first to form a directed cycle on n nodes with the first n labels. Then whenever the driver has a free choice he chooses to direct the new edge to the nearest nonadjacent node on the cycle. This continues until some node has degree d. On the ith tour of the cycle, the driver takes at least $\lfloor n/i \rfloor$ steps and the game continues for at least d tours. Thus,

$$DP(d, n) \geqq \sum_{i=1}^{d} \left\lfloor \frac{n}{i} \right\rfloor = \Omega(n \log d). \qquad \square$$

In terms of n, the largest known lower bound is obtained for $d = n/2 - 1$ by another simple driver-passenger game.

LEMMA 13. *For* $d \leqq n/2 - 1$, $U(d, n) \geqq DP(d, n) \geqq d(n-d)$.

Proof. The game will construct $G = (V, E)$ in $G(d, n)$ with $V = V_1 \cup V_2$, $|V_1| = n - d - 1$, $|V_2| = d + 1$. G is constructed so that a given universal sequence will visit only nodes in V_1 within the first $d(n-d-1)$ steps. This is simply achieved by thinking of the driver generating a d-regular graph on V_1 minus an edge. We complete the construction of G by choosing any complete graph on V_2 minus an edge with an arbitrary labeling. Now if (u_1, w_1) (respectively, (u_2, w_2)) is missing from V_1 (respectively, V_2), then G is the union of these graphs on V_1 and V_2 joined by the two edges (u_1, u_2) and (v_1, v_2). The driver forces the sequence (passenger) to stay on V_1 until $d(n-d-1)$ steps have expired and then trivially forces another d steps to cover the nodes of V_2. □

THEOREM 4. *For all* $d \leqq (n/2 - 1)$,

$$U(d, n) = \Omega((n \log n) + d(n-d)).$$

Proof. The proof is immediate from Lemmas 11, 12, and 13. □

Our final result emphasizes the importance of the case $d = 3$. Theorem 5 below is based on Theorem 4.13 of Cook and Rackoff [4]. Let $G'(d, n)$ denote the class of all graphs with n nodes and all degrees less than or equal to d labeled by $\{0, 1, \cdots, d-1\}$. In this case a sequence s in $\{0, 1, \cdots, d-1\}^*$ and a node u_0 in a graph G in $G'(d, n)$ uniquely defines a sequence of nodes $u_0, u_1, \cdots, u_{|s|}$ in G with (u_{i-1}, u_i) labeled s_i if u_{i-1} has an out edge so labeled and $u_i = u_{i-1}$ if u_{i-1} does not have an out edge labeled by s_i. And now, as before, let $U'(d, n)$ denote the minimal length of a universal sequence for $G'(d, n)$.

The following is a direct consequence of Theorem 4.13 in Cook and Rackoff [4].

LEMMA 14. *There is a finite state transducer computing a function*

$$f: \{0, 1, 2\}^* \to \{0, 1, \cdots, d-1\}^*$$

with the property that if s is universal for $G'(3, (2d-1)n)$ then $f(s)$ is universal for $G'(d, n)$. Furthermore, $|f(s)| \leqq (1/\log d)\, |s|$ so that

$$U'(d, n) \leqq \frac{1}{\log d}\, U'(3, (2d-1)n).$$

In order to place this result within the context of regular graphs we need to justify our introductory comment that regularity is not a significant restriction.

LEMMA 15. *$U'(d, n) \leqq U(d, d'n)$, where $d' = d$ if d is even and $d' = d+1$ if d is odd.*

Proof. For any G' in $G'(d, n)$ we construct a G in $G(d, d'n)$ by taking d' copies of G'. If x has degree $\delta < d$ in G' we connect all d' copies of x by a graph in $G(d-\delta, d')$ (a perfect matching if $\delta = d-1$). The new edges are labeled by the labels missing at x in G'. It is easily verified that a sequence that covers G covers G' as well. If all the degrees in G' are d and $d-1$ a slight modification is needed, which we omit. □

THEOREM 5.

$$U(d, n) \leqq \frac{1}{\log d} U(3, 2(2d-1)n).$$

Furthermore, there is a finite state transducer computing a function

$$f: \{0, 1, 2\}^* \to \{0, 1, \cdots, d-1\}^*$$

such that if s is universal for $G(3, 2(2d-1)n)$ then $f(s)$ is universal for $G(d, n)$.

Proof. The Cook and Rackoff construction on which Lemma 14 is based produces graphs where every node has degree two or three. In this case, we can take $d' = d-1 = 2$ in the construction of Lemma 15. The theorem then follows immediately from Lemmas 14 and 15. □

6. Conclusion. Perhaps the main technical result of this paper is the proof of a nonlinear lower bound for $d = 2$, thus answering a specific challenge in Aleliunas et. al. [2]. However it is clear that even for this restricted case we are far from understanding the true nature of $U(2, n)$. We know that the crucial aspect of labeled lines is the parity of the blocks. (We claim that, within a factor of n, we can assume that every block has length 1 or 2.) It seems feasible to us that some of the ideas developed here will lead to an explicit polynomial length universal sequence for $G(2, n)$. We also expect to be able to narrow the gap between the lower and upper bounds for $U(2, n)$.

For the complete graph, many obvious questions remain. It seems reasonable to be able to explicitly construct a "good" universal sequence. At present, we only know the brute force approach that gives $n^{n^2} \approx |G(n-1, n)|$. It is not difficult to see that a sequence universal for $G(n-1, n)$ will traverse at least n nodes when applied to members of $G(n, n+1)$. But we cannot see how to use this fact to construct such sequences. It also seems reasonable that we can narrow the gap for $\mathrm{DP}(n-1, n)$.

Theorem 5 emphasizes the importance of $U(3, n)$. In particular, any explicit universal sequence beyond brute force for $G(3, n)$ would be of interest. It will also be of interest if we could find for $d \geqq 3$ a simple d-ary infinite graph that would play the role that the infinite line played for $d = 2$.

Finally, there are many alternative universal sequence formulations that could be used for determining graph connectivity. One formulation we find particularly interesting is to number the nodes $V = \{1, \cdots, n\}$ and consider sequences in $\{1, \cdots, n\}^*$. Now, a sequence command i causes a move to node i if there is an edge from the currently scanned node to node i. Otherwise, it remains in the current node. Random walk arguments again show the existence of polynomial length universal sequences.

Note added in proof. Bridgland [*J. Algorithms*, 8 (1987), pp. 395-404] has given another construction for a universal sequence of length $n^{O(\log n)}$. His construction differs from ours. We were informed also of a construction by Barrington [private communication] for the same problem. Since the completion of this research in June

1986 there has been much activity in this area, and some of our results have been improved. Istrail [*Proc. 20th Annual ACM Symposium on Theory of Computing*, 1988, pp. 491-503] presents an explicit construction of a sequence of polynomial length that is universal for $d = 2$. The ideas required go beyond the ones presented here. Karloff, Paturi, and Simon [unpublished manuscript] have given an explicit construction of a sequence universal for complete graphs whose length is $n^{O(\log n)}$. The construction of a polynomial length sequence even for complete graphs remains open. Alon and Ravid [*Discrete Appl. Math.*, to appear] have improved our lower bound for $U(n-1, n)$ to $n^2/\log n$. Their bound does not apply to our driver-passenger game. Also in the closely related area of random walks on graphs there has been considerable progress. A special issue of the *Journal of Theoretical Probability*, D. Aldous, ed., will be dedicated to the subject. A paper by Kahn, Linial, Nisan, and Saks that will appear therein shows that the expected cover time for regular graphs is only $O(n^2)$. This yields an improvement on the upper bound for $U(d, n)$ over the one in [2].

WORST-CASE GROWTH RATES OF SOME CLASSICAL PROBLEMS OF COMBINATORIAL OPTIMIZATION*

J. MICHAEL STEELE† AND TIMOTHY LAW SNYDER‡

Abstract. A method is presented for determining the asymptotic worst-case behavior of quantities like the length of the minimal spanning tree or the length of an optimal traveling salesman tour of n points in the unit d-cube. In each of these classical problems, the worst-case lengths are proved to have the exact asymptotic growth rate of $\beta_n^{(d-1)/d}$ as $n \to \infty$, where β is a positive constant depending on the problem and the dimension. These results complement known results on the growth rates for the analogous quantities under probabilistic assumptions on the points, but the results given here are free of any probabilistic hypotheses.

Key words. asymptotics, traveling salesman problem, minimal spanning tree, Beardwood-Halton-Hammersley theorem

1. Introduction.

The purpose of this paper is to illustrate a general method for determining the asymptotic behavior of some classical quantities of operations research and combinatorial optimization. For specificity, we focus on the traveling salesman problem and on the minimal spanning tree of n points in the unit d-cube, but the general applicability of our method to a number of other problems will be made evident.

To set our problem precisely, we first note that a Euclidean minimal spanning tree or a traveling salesman tour can be represented by a graph $G = (V_n, E)$, where V_n denotes a set of n points in $[0, 1]^d$, where $d \geqq 2$, and E denotes a subset of the edges of the complete graph on the points of V_n. The length of an edge $e = \{x_i, x_j\}$ is taken to be the usual Euclidean distance, and we write $|e| = |x_i - x_j|$ for that length. For a collection E of edges we will often use $L(E)$ to denote the sum of the lengths of the edges in E, i.e., we define $L(E) = \sum_{e \in E} |e|$. Still, when V is a finite set there will be no ambiguity in using $|V|$ to denote the cardinality of V.

The objects of principal interest here are the sequences $\rho_{\mathrm{MST}}(n)$ and $\rho_{\mathrm{TSP}}(n)$, defined by

$$\rho_{\mathrm{MST}}(n) = \max_{\substack{V_n \subset [0,1]^d \\ |V_n| = n}} \left\{ \min_T \sum_{e \in T} |e| \colon T \text{ is a spanning tree of } V_n \right\}$$

and

$$\rho_{\mathrm{TSP}}(n) = \max_{\substack{V_n \subset [0,1]^d \\ |V_n| = n}} \left\{ \min_T \sum_{e \in T} |e| \colon T \text{ is a tour of } V_n \right\}.$$

In other words, $\rho_{\mathrm{MST}}(n)$ is equal to the largest possible length of any minimal spanning tree formed from n points in $[0, 1]^d$. Similarly, $\rho_{\mathrm{TSP}}(n)$ is the largest possible length of any optimal traveling salesman tour through n points in $[0, 1]^d$. The use of max instead of sup in the definitions of $\rho_{\mathrm{MST}}(n)$ and $\rho_{\mathrm{TSP}}(n)$ is justified by the fact that the expressions in braces can be viewed as continuous functions on the compact set obtained by forming the product of n copies of $[0, 1]^d$, i.e., $\prod_{1 \leqq i \leqq n} [0, 1]^d$.

One should note that the functions ρ_{MST} and ρ_{TSP} depend on the dimension d. This fact also applies to all of the other functions and constants that are used here. Since $d \geqq 2$ is fixed, we will suppress the dependence of ρ_{MST}, ρ_{TSP}, and other functions on d, but the reader should be mindful of this dependence, especially in the main result.

THEOREM. *There are constants β_{MST} and β_{TSP} depending on the dimension $d \geqq 2$ such that*

$$\rho_{MST}(n) \sim \beta_{MST} n^{(d-1)/d} \tag{1.1}$$

and

$$\rho_{TSP}(n) \sim \beta_{TSP} n^{(d-1)/d} \tag{1.2}$$

as $n \to \infty$, with $\beta_{TSP} \geqq \beta_{MST} \geqq 1$.

This result provides the determination of the exact asymptotic order of the functions ρ_{MST} and ρ_{TSP} in any dimension $d \geqq 2$. Considerable earlier effort focused on bounds for $\rho_{MST}(n)$ and $\rho_{TSP}(n)$, but none of the inequalities provided by that work is tight enough to determine that $\rho_{MST}(n)$ or $\rho_{TSP}(n)$ are actually asymptotic to a constant times $n^{(d-1)/d}$. Some earlier results of particular interest are the bound of Verblunsky (1951), which says that in $d = 2$ one has $\rho_{TSP}(n) \leqq (2.8n)^{1/2} + 3.15$, and the bounds of Fejes-Tóth (1940), which say that $\rho_{TSP}(n)$ and $\rho_{MST}(n)$ are both at least as large as $(1-\varepsilon)(4/3)^{1/4} n^{1/2}$ for all $n \geqq N(\varepsilon)$. Few (1955) improved the upper bound of Verblunsky (1951) to $\rho_{TSP}(n) \leqq (2n)^{1/2} + 1.75$ in $d = 2$ and obtained $\rho_{TSP}(n) \leqq d\{2(d-1)\}^{(1-d)/2d} n^{(d-1)/d} + 0(n^{1-2/d})$ for general $d \geqq 2$.

Recent results have improved these bounds. Few's bound on $\rho_{TSP}(n)$ in dimension two is sharpened in Supowit, Reingold, and Plaisted (1983), to show that $\rho_{TSP}(n) \geqq (4/3)^{1/4} n^{1/2}$, for all $n \geqq 1$. Moran (1984) used inequalities on sphere packing to obtain essential improvements on the upper bounds of Few for large values of d. Goldstein and Reingold (1988) carefully analyze Few's heuristic algorithm to improve the upper bounds in dimensions $3 \leqq d \leqq 7$. They also improve lower bounds, using the exact densities of sphere packings for $2 \leqq d \leqq 8$. Goldstein (personal communication) has further improved the upper bounds in dimensions three and four.

The $(2n)^{1/2}$ barrier on $\rho_{TSP}(n)$ in dimension two is broken by bounds of Karloff (1987) that show $\rho_{TSP}(n) < 0.984(2n)^{1/2} + 11$. Also, for low dimensions $d \geqq 3$, Goddyn (1988) improves all known upper bounds on $\rho_{TSP}(n)$ by considering an infinite number of translations of quantizers other than cubical cylinders.

Some other early work focused on the probabilistic circumstances under which one can provide bounds for the lengths of the minimal spanning tree or optimal traveling salesman tour. For example, Ghosh (1949) sharpened earlier results of Mahalanobis (1940) and Jessen (1942) to establish that the expected length of an optimal traveling salesman tour of n points chosen at random from the unit square was at most $1.27n^{1/2} + 0(1)$. The bound of Marks (1948) complements the upper bound of Ghosh (1949) by providing a lower bound of $(n^{1/2} - 1/n^{1/2})/2$ on the expected length of an optimal traveling salesman tour in $d = 2$.

The culminating result on the length of an optimal traveling salesman tour under probabilistic assumptions was provided by Beardwood, Halton, and Hammersley (1959). That work showed that if T_n denotes the length of an optimal traveling salesman tour of X_i, where $1 \leqq i \leqq n$ and the X_i are bounded independent identically distributed random vectors in $\mathbb{R}^d$, then with probability one we have the asymptotic relation

$$T_n \sim c_d n^{(d-1)/d} \int_{\mathbb{R}^d} f(x)^{(d-1)/d}\, dx. \tag{1.3}$$

Here, f denotes the density of the absolutely continuous part of the distribution of the X_i, and c_d is a constant depending only on the dimension.

In addition to providing improved upper and lower bounds on the constant c_d, Beardwood, Halton, and Hammersley (1959) also indicated that a result analogous to (1.3) holds for the minimal spanning tree. A review of the probability theory which has grown out of the Beardwood, Halton, and Hammersley theorem is given in Steele (1987), and a review oriented toward algorithmic applications is given in Karp and Steele (1985).

The focus of the present work is on the growth rates of the *worst-case* lengths of the traveling salesman tour and minimal spanning tree. There are no probabilistic assumptions used here, and it is perhaps remarkable that one obtains asymptotics that are so close in form to the probabilistic results. Another intriguing aspect of these limit theorems is that the same method applies both to a computationally difficult problem (the TSP) and to one which is computationally easy (the MST).

The proof of the main theorem is given in three sections. The first of these sections provides a general lemma that isolates inequalities that are sufficient to determine the asymptotic behavior of ρ_{MST} and ρ_{TSP}. The following section focuses on minimal spanning trees, and, in particular, it provides an approximate recursion relation for ρ_{MST}. The construction used to study ρ_{TSP} in § 4 is much like that used for ρ_{MST}; so the analysis required for the optimal traveling salesman tour is quite brief.

The final section points out some limitations of this method and comments on some open problems.

2. Asymptotics from an approximate recursion. One principle underlying our asymptotic analysis is that both $\rho_{\mathrm{MST}}(n)$ and $\rho_{\mathrm{TSP}}(n)$ satisfy inequalities which bound their rates of growth and express an approximate recursiveness. The following lemma shows that a slow incremental rate of growth (as expressed by (2.1(i))) and an approximate recursiveness (as expressed by (2.1(ii))) are together sufficient to determine the exact asymptotic behavior of a sequence. Even though the lemma appears technical, we will later see that the two required conditions are quite natural to the objects under study.

LEMMA 2.1. *If* $\rho(1)=0$ *and there is a constant* $c_1 \geqq 0$ *such that for all* $m \geqq 1$ *and* $k \geqq 1$

$$\text{(i)}\quad \rho(n+1) \leqq \rho(n) + c_1 n^{-1/d}$$

(2.1) *and*

$$\text{(ii)}\quad m^{d-1}\rho(k) - m^{d-1}k^{(d-1)/d}r(k) \leqq \rho(m^d k),$$

where $r(k) \to 0$ *as* $k \to \infty$, *then as* $n \to \infty$

$$\rho(n) \sim \beta n^{(d-1)/d}$$

for a constant β.

Proof. From the hypothesis (2.1(i)) and the fact that $\rho(1)=0$ we first note that for $1 \leqq i < j < \infty$ we have

$$\begin{aligned} \rho(j) - \rho(i) &= \sum_{k=i}^{j-1} \{\rho(k+1) - \rho(k)\} \\ &\leqq c_1 \int_{i-1}^{j-1} x^{-1/d}\, dx \leqq 5c_1(j^{(d-1)/d} - i^{(d-1)/d}). \end{aligned} \tag{2.2}$$

Letting $i=1$ and $j=n$ in (2.2) shows that $\rho(n) \leqq 5c_1 n^{(d-1)/d}$, so if we define $\psi(k) = \rho(k)/k^{(d-1)/d}$, then we see that $\psi(k) < 5c_1$ for all k. We can then introduce a candidate

for our limit by

$$\gamma = \limsup_{k\to\infty} \psi(k) < \infty. \tag{2.3}$$

Inequality (2.1(ii)) tells us that for all k and m,

$$\psi(k) - r(k) \leqq \psi(m^d k), \tag{2.4}$$

so, given any fixed $\varepsilon > 0$, we can choose a k_ε such that $\gamma - \varepsilon \leqq \psi(k_\varepsilon)$ and $r(k_\varepsilon) \leqq \varepsilon$, thus obtaining from (2.4) that

$$\gamma - 2\varepsilon \leqq \psi(m^d k_\varepsilon) \tag{2.5}$$

for all $m \geqq 1$.

Next define $j_m = m^d k_\varepsilon$ and consider n such that $j_m \leqq n \leqq j_{m+1}$. To bound the absolute difference $|\psi(n) - \psi(j_m)|$, we use (2.2):

$$\begin{aligned} \sup_{j_m \leqq n \leqq j_{m+1}} |\rho(n) - \rho(j_m)| &\leqq 5c_1 (j_{m+1}^{(d-1)/d} - j_m^{(d-1)/d}) \\ &= 5c_1 k_\varepsilon^{(d-1)/d} m^{d-1} [(1+1/m)^{d-1} - 1], \end{aligned} \tag{2.6}$$

or, in terms of ψ, the binomial expansion gives

$$\sup_{j_m \leqq n \leqq j_{m+1}} |\psi(n) - \psi(j_m)| \leqq 5c_1 \{(1+1/m)^{d-1} - 1\} < 5c_1 m^{-1} 2^{d-1}. \tag{2.7}$$

From (2.7) and (2.5) we find for $j_m \leqq n \leqq j_{m+1}$ that

$$\gamma - 2\varepsilon - 5c_1 m^{-1} 2^{d-1} \leqq \psi(n),$$

and, hence, $\gamma - 2\varepsilon \leqq \liminf_{n\to\infty} \psi(n)$. By the arbitrariness of $\varepsilon > 0$, we have proved

$$\limsup_{n\to\infty} \psi(n) \leqq \liminf_{n\to\infty} \psi(n)$$

and the lemma is complete.

3. Minimal spanning trees. We will now show that ρ_{MST} satisfies the hypotheses of the preceding lemma. The key issue is the derivation of an inequality like (2.1(ii)). This will be done by a recursive construction of a point set for which a minimal spanning tree has near maximal length.

We first divide the d-cube $Q = [0,1]^d$ into m^d *cells* Q_i, where $1 \leqq i \leqq m^d$ and each cell has side length $1/m$. The boundaries ∂Q_i of the cells Q_i create a natural *grating* in the unit d-cube which we denote by H, i.e., we set $H = \bigcup_{i=1}^{m^d} \partial Q_i$. For $0 < \alpha < 1/m$, let H^α denote the set of points of $[0,1]^d$ which are within $\alpha/2$ of H, thus H^α is the grating H fattened to a width of α. Similarly, we define *subcells* Q_i^α of Q_i by $Q_i^\alpha = Q_i - H^\alpha$.

Inside each of the Q_i^α we now place a set S_i of k points for which the length of the minimal spanning tree is $(m^{-1} - \alpha)\rho_{\mathrm{MST}}(k)$, i.e., inside each subcell we place a copy of a set of k points that attains the worst-case bound on the length of a minimal spanning tree of k points. The factor of $(m^{-1} - \alpha)$ equals the side length of Q_i^α, and it reflects the scaling of $\rho_{\mathrm{MST}}(k)$ down to the smaller cube. Next, we let T be a minimal spanning tree of the set of $m^d k$ points $\bigcup_{i=1}^{m^d} S_i$, and we let T_i denote a minimal spanning tree of S_i. We will now develop a relationship between $L(T)$ and $L(\bigcup_{i=1}^{m^d} T_i)$ that moves us toward an inequality like (2.1(ii)) for ρ_{MST}.

First consider the forest that is obtained from T by deleting from T all the edges that have length as great as α. We let $\lambda(\alpha)$ denote the number of edges deleted from T, i.e., we set

$$\lambda(\alpha) = |\{e \in T: |e| \geqq \alpha\}|.$$

Since T was connected, the graph that remains following the deletion of $\lambda(\alpha)$ edges has at most $\lambda(\alpha)+1$ connected components. Moreover, each of these connected components is contained entirely in some subcell Q_i^{α}.

Next, if two or more connected components of T coexist in the same subcell Q_i^{α}, then we join them together to make a tree on the point set S_i. Since, within any given cell, we can rejoin any two components at a cost not exceeding $d^{1/2}m^{-1}$, the total cost of rejoining all the within-cell components is bounded by $d^{1/2}m^{-1}\lambda(\alpha)$.

So far we have constructed a spanning tree for each S_i, where $1 \leqq i \leqq m^d$. Since the length of each of these trees must be at least as great as the length of the minimal spanning tree T_i of the point set S_i, we have the bound

$$\sum_{i=1}^{m^d} L(T_i) \leqq L(T) + d^{1/2}m^{-1}\lambda(\alpha).$$

But we know $L(T_i) = (m^{-1} - \alpha)\rho_{\mathrm{MST}}(k)$ and $L(T) \leqq \rho_{\mathrm{MST}}(m^d k)$, so we can rewrite this bound to provide

$$m^d(m^{-1} - \alpha)\rho_{\mathrm{MST}}(k) - d^{1/2}m^{-1}\lambda(\alpha) \leqq \rho_{\mathrm{MST}}(m^d k). \tag{3.1}$$

In order to extract an equality like (2.1(ii)) for ρ_{MST} from (3.1), we need some elementary facts about sets of points in $[0,1]^d$ and their associated minimal spanning trees. We begin by recalling an easy pigeonhole argument, which says that from any set of n points in $[0,1]^d$, one can always find a pair that are close together.

LEMMA 3.1. *There exists a constant c_2 such that for any $\{x_1, x_2, \cdots, x_n\} \subset [0,1]^d$, where $n \geqq 2$, one has*

$$|x_i - x_j| \leqq c_2 n^{-1/d}$$

for some x_i and x_j, $1 \leqq i < j \leqq n$.

Proof. Cover each x_i with a ball of radius r centered at x_i, and note that such a ball has volume $\omega_d r^d$, where ω_d is the volume of the unit d-ball. If all of the balls constructed in this way were non-intersecting, then each would cover at least $2^{-d-1}\omega_d r^d$ of $[0,1]^d$, even if we generously assume that each of the balls were centered exactly in a corner of the hypercube. In total, the n balls would cover at least a volume of $2^{-d-1}\omega_d r^d n$, and since $[0,1]^d$ has unit volume, we have $2^{-d-1}\omega_d r^d n \leqq 1$. The lemma is therefore established with $c_2 = 2^{(2d+1)/d}\omega_d^{-1/d}$.

One can easily improve the constant c_2, but this simply derived constant is sufficient for our purposes. It is now easy to give a bound on ρ_{MST} that shows the validity of the first hypothesis of Lemma 2.1.

LEMMA 3.2. *There exists a constant c_3 such that for all $n \geqq 1$, one has the bound*

$$\rho_{\mathrm{MST}}(n+1) \leqq \rho_{\mathrm{MST}}(n) + c_3 n^{-1/d}. \tag{3.2}$$

Proof. Let $S = \{x_1, x_2, \cdots, x_{n+1}\}$ denote a set of $n+1$ points in $[0,1]^d$ for which the length of a minimal spanning tree is $\rho_{\mathrm{MST}}(n+1)$. By Lemma 3.1, there exist x_i and x_j in S such that $|x_i - x_j| \leqq c_2(n+1)^{-1/d} \leqq c_2 n^{-1/d}$. We form a minimal spanning tree T of $\{x_1, x_2, \cdots, x_{i-1}, x_{i+1}, \cdots, x_{n+1}\}$ and then augment the tree by adding to it the edge

$\{x_i, x_j\}$. This construction provides a spanning tree of S at a cost of no more than $L(T)+c_2 n^{-1/d}$. Therefore, we have

$$\rho_{\mathrm{MST}}(n+1) \leqq L(T)+c_2 n^{-1/d} \leqq \rho_{\mathrm{MST}}(n)+c_2 n^{-1/d},$$

which proves our lemma with $c_3 = c_2$.

Naturally we can sum inequality (3.2) to provide a bound on $\rho_{\mathrm{MST}}(n)$.

COROLLARY. *There is a constant c_4 such that for all $n \geqq 1$, one has the bound*

$$\rho_{\mathrm{MST}}(n) \leqq c_4 n^{(d-1)/d}. \tag{3.3}$$

Here we note that $c_4 = 2c_3$ is a sufficient choice for the constant c_4.

The next lemma provides a tool for understanding how a minimal spanning tree changes as edges are added or deleted. While the result is reasonably intuitive and can be established by modification of Kruskal's algorithm (see, e.g., Aho, Hopcroft, and Ullman (1974)), the rigorous justification of the modified Kruskal algorithm does not seem to be as easy as the characterization-based proof used here.

LEMMA 3.3. *Let E be a subset of a minimal spanning tree of $S = \{x_1, x_2, \cdots, x_n\} \subset [0,1]^d$, and let S' be the set of points incident with the edges of E. Then, there exists a minimal spanning tree of S' that contains E.*

Proof. The graph corresponding to the set E consists of k connected components $(S_1, T_1), (S_2, T_2), \cdots, (S_k, T_k)$, where $1 \leqq k \leqq |E|$. We first show that for all $1 \leqq i \leqq k$, T_i is a minimal spanning tree of S_i. To see this, consider a minimal spanning tree T. If we form a forest of two trees by removing an edge from T, then it is trivial to note that each resulting tree is a minimal spanning tree of the respective set of points incident with it. Now let T be a minimal spanning tree of S, and recursively apply this fact by removing from the tree T all the edges of $T-E$. As each edge $e \in T-E$ is removed, the minimal spanning tree to which e belongs becomes two minimal spanning trees. After removing all the edges of $T-E$, the result is the edge set E, which is a forest of minimal spanning trees.

We first recall a well-known fundamental property of minimal spanning trees. If $\{(V_1, E_1), (V_2, E_2), \cdots, (V_k, E_k)\}$, where $k > 1$, is a forest spanning the point set S, and $e = \{x_i, x_j\}$ is an edge of minimum length such that e has exactly one endpoint in V_1, then there exists a tree T^* spanning S and including $\bigcup_{i=1}^{k} E_i \cup \{e\}$ such that $L(T^*) = \min\{L(T)\colon T \text{ is a tree spanning } S \text{ and } \bigcup_{i=1}^{k} E_i \subset T\}$. We use this easily proved fact (see Aho, Hopcroft, and Ullman (1974), or Papadimitriou and Steiglitz (1982)) to construct from the edge set E a minimal spanning tree of S'.

Begin with the edges of E, which constitute a forest of minimal spanning trees, and iteratively add to T_1 an edge of minimal length over all those edges having exactly one endpoint in S_1. Merging components this way, we obtain a tree T that spans S'. Moreover, T is a minimum-cost tree over all trees that span S' and contain E. Hence, the only way we could lessen the cost of T would be lessen the cost of a tree T_i, where $1 \leqq i \leqq k$. But, since T_i is a minimal spanning tree, this is impossible, and we conclude that T is a minimal spanning tree of S'. Since T contains E, the proof is complete.

We now use Lemma 3.3 and the corollary to Lemma 3.2 to bound the total length of any k edges of a minimal spanning tree.

LEMMA 3.4. *There is a constant c_5 such that if E is any subset of the edges of a minimal spanning tree of $\{x_1, x_2, \cdots, x_n\} \subset [0,1]^d$, then*

$$L(E) \leqq c_5 |E|^{(d-1)/d}.$$

Proof. Let S be the set of endpoints of the edges of E and note $|S| \leqq 2|E|$. By Lemma 3.3, there exists a minimal spanning tree of S that contains E. By inequality

(3.3) we have therefore that

$$\sum_{e \in E} |e| \leqq c_4 |S|^{(d-1)/d},$$

so the lemma is proved with $c_5 = 2^{(d-1)/d} c_4$.

We require one more general inequality in order to bound $\lambda(\alpha)$ in our key relation (3.1). Formally, we let $\nu_{\mathrm{MST}}(x)$ denote the maximal value k such that there exists a minimal spanning tree of some $V_n = \{x_1, x_2, \cdots, x_n\} \subset [0,1]^d$ with k edges greater than or equal to x in length.

LEMMA 3.5. *There is a constant c_6 such that for all $x > 0$, one has*

$$\nu_{\mathrm{MST}}(x) \leqq c_6 x^{-d}. \tag{3.4}$$

Proof. Let T be a minimal spanning tree of $\{x_1, x_2, \cdots, x_n\}$, and set $\phi_T(x) = |\{e \in T: |e| \geqq x\}|$. By Lemma 3.4 any set of $\phi_T(x)$ edges of T must have length bounded by $c_5 \phi_T(x)^{(d-1)/d}$, so

$$x\phi_T(x) \leqq \sum_{\substack{|e| \geqq x \\ e \in T}} |e| \leqq c_5 \phi_T(x)^{(d-1)/d}. \tag{3.5}$$

Clearing ϕ_T to the left side gives

$$\phi_T(x) \leqq c_5^d x^{-d},$$

and, since this bound holds for all minimal spanning trees T, the lemma is proved with $c_6 = c_5^d$.

Returning to our basic recurrence relation (3.1), we can write it in a form closer to the hypothesis of Lemma 2.1 as follows:

$$m^{d-1}\rho_{\mathrm{MST}}(k) - \{m^d \alpha \rho_{\mathrm{MST}}(k) + d^{1/2} m^{-1} \lambda(\alpha)\} \leqq \rho_{\mathrm{MST}}(m^d k). \tag{3.6}$$

By Lemma 3.2 and its corollary $\rho_{\mathrm{MST}}(k) \leqq c_4 k^{(d-1)/d}$, and by Lemma 3.5 $\lambda(\alpha) \leqq c_6 \alpha^{-d}$, so the bracketed expression of inequality (3.6) is majorized by

$$c_4 \alpha m^d k^{(d-1)/d} + c_6 d^{1/2} m^{-1} \alpha^{-d}.$$

This quantity is approximately minimized by choosing $\alpha = m^{-1} k^{(1-d)/d(d+1)}$, and making that choice proves that there is a constant c_7 such that the inequality

$$m^{d-1}\rho_{\mathrm{MST}}(k) - c_7 m^{d-1} k^{(d-1)/(d+1)} \leqq \rho_{\mathrm{MST}}(m^d k) \tag{3.7}$$

holds for all $m \geqq 1$ and $k \geqq 1$. This last inequality shows that the main hypothesis of Lemma 2.1 is valid with $r(k) = c_7 k^{(1-d)/d(d+1)}$. Since we already know that $\rho_{\mathrm{MST}}(n+1) \leqq \rho_{\mathrm{MST}}(n) + c_3 n^{-1/d}$, we have verified all of the hypotheses of Lemma 2.1. We have therefore proved that $\rho_{\mathrm{MST}}(n) \sim \beta_{\mathrm{MST}} n^{(d-1)/d}$ as $n \to \infty$ for all $d \geqq 2$.

To see that $\beta_{\mathrm{MST}} \geqq 1$, we just note that one can place n points in the unit d-cube in such a way that no two are closer together than $n^{-1/d}$. This proves that $\beta_{\mathrm{MST}} \geqq 1$, since any connected tree has $n-1$ edges.

4. The traveling salesman problem. Just as in the treatment of minimal spanning trees, the central task is to prove the validity of (2.1(ii)). For the traveling salesman problem the task actually turns out to be easier than it was for minimal spanning trees.

As before, we partition $[0,1]^d$ into m^d cells Q_i of edge length m^{-1}. We then obtain a fattened grating H^α of width α, where $0 < \alpha < m^{-1}$, and define corresponding subcells Q_i^α with edge length $m^{-1} - \alpha$. Into each subcell Q_i^α we insert a set S_i of k points having an optimal traveling salesman tour with length $\rho_{\mathrm{TSP}}(k)(m^{-1} - \alpha)$, i.e., the set S_i attains the maximal length of any set of k points in a cube of edge length $m^{-1} - \alpha$.

Now, for each $1 \leqq i \leqq m^d$, we let T_i denote an optimal traveling salesman tour of S_i, and we further let T be an optimal traveling salesman tour of the $m^d k$ points of $\bigcup_{i=1}^{m^d} S_i$. We need to establish a relationship between the total lengths of the two sets of edges T and $\bigcup_{i=1}^{m^d} T_i$.

To build a heuristic tour T_i' through S_i, we start by taking the set T_i' to be E_i, the set of all of the edges of T that are completely contained in Q_i^α. If this set of edges forms a graph $G_i = (S_i, E_i)$ with k_i connected components, then there is a set C_i of at least k_i vertices that are in different components of G_i and have degree one or zero. The case of degree zero occurs exactly for those components consisting of a single vertex.

Since C_i has cardinality at least k_i, we can apply Lemma 3.1 to find a pair of vertices in C_i that are separated by a distance of at most $c_2 k_i^{-1/d}(m^{-1} - \alpha)$. We now add the edge determined by this pair of vertices to T_i'. Repeating this construction, we can add a total of $k_i - 1$ edges to E_i and obtain a path T_i' through all of the vertices in S_i. The ends of this path can now be joined by one final edge in order to complete the heuristic tour T_i'.

This process shows that the length of T_i' is bounded by

$$L(T_i') \leqq L(E_i) + c_2 \sum_{j=1}^{k_i} j^{-1/d} m^{-1}. \tag{4.1}$$

Now, since $\rho_{\mathrm{TSP}}(k)(m^{-1} - \alpha) \leqq L(T_i')$ and $\sum_{i=1}^{m^d} L(E_i) \leqq L(T) \leqq \rho_{\mathrm{TSP}}(m^d k)$, we can sum (4.1) over $1 \leqq i \leqq m^d$ and obtain

$$m^d \rho_{\mathrm{TSP}}(k)(m^{-1} - \alpha) \leqq \rho_{\mathrm{TSP}}(m^d k) + c_2 m^{-1} \sum_{i=1}^{m^d} \sum_{j=1}^{k_i} j^{-1/d}. \tag{4.2}$$

Next, let $\lambda(\alpha)$ denote the number of edges of T that intersect H^α. The number of connected components of $\bigcup_{i=1}^{m^d} G_i$ equals $\sum_{i=1}^{m^d} k_i \leqq \lambda(\alpha)$; so, estimating the inner sum of (4.2) by $\sum_{j=1}^{k_i} j^{-1/d} \leqq 1 + \int_1^{k_i} x^{-1/d}\, dx \leqq 2k_i^{(d-1)/d}$ and then applying Hölders inequality, we have

$$\begin{aligned} m^d \rho_{\mathrm{TSP}}(k)(m^{-1} - \alpha) &\leqq \rho_{\mathrm{TSP}}(m^d k) + 2c_2 m^{-1} \sum_{i=1}^{m^d} k_i^{(d-1)/d} \\ &\leqq \rho_{\mathrm{TSP}}(m^d k) + 2c_2 m^{-1} \left(\sum_{i=1}^{m^d} 1 \right)^{1/d} \left(\sum_{i=1}^{m^d} k_i \right)^{(d-1)/d} \\ &\leqq \rho_{\mathrm{TSP}}(m^d k) + 2c_2 \lambda(\alpha)^{(d-1)/d}. \end{aligned} \tag{4.3}$$

This inequality will now be put in the form needed to verify (2.1(ii)). The only real issue which remains is that of bounding $\lambda(\alpha)$, but some intermediate facts are required. First, we note that we can show

$$\rho_{\mathrm{TSP}}(n+1) \leqq \rho_{\mathrm{TSP}}(n) + c_8 n^{-1/d} \tag{4.4}$$

by taking $n+1$ points S such that $\rho_{\mathrm{TSP}}(n+1)$ is the length of the shortest tour through S and then using Lemma 3.1 to exhibit a heuristic tour through S with cost bounded by $\rho_{\mathrm{TSP}}(n) + 2c_2 n^{-1/d}$, so we have inequality (4.4) with $c_8 = 2c_2$. (For examples of this type of argument, where more attention is given to obtaining good values for the associated constants, one can consult Moran (1984). For an easier, but less quantitative, version one can consult Few (1955).)

One immediate consequence of (4.4) is that by summing over $1 \leqq i \leqq n$, we have

$$\rho_{\mathrm{TSP}}(n) \leqq c_9 n^{(d-1)/d}, \tag{4.5}$$

where $c_9 = 2c_8$.

Now, for an edge of T to intersect H^{α}, it must have endpoints in two different Q_i^{α} and therefore have length at least α. This gives the bound

$$\alpha\lambda(\alpha) \leqq \sum_{\substack{|e| \geqq \alpha \\ e \in T}} |e| \leqq \rho_{\mathrm{TSP}}(m^d k) \leqq c_9 m^{d-1} k^{(d-1)/d}. \tag{4.6}$$

When we apply (4.5) and (4.6) to (4.3) we have

$$m^{d-1}\rho_{\mathrm{TSP}}(k) \leqq \rho_{\mathrm{TSP}}(m^d k) + \alpha m^d c_9 k^{(d-1)/d} + c_{10}\alpha^{-(d-1)/d} m^{(d-1)^2/d} k^{(d-1)^2/d^2}, \tag{4.7}$$

where $c_{10} = 2c_2 c_9^{(d-1)/d}$. If we now choose $\alpha = m^{-1}k^{(1-d)/d(2d-1)} < m^{-1}$, we see that (4.7) simplifies to give

$$m^{d-1}\rho_{\mathrm{TSP}}(k) \leqq \rho_{\mathrm{TSP}}(m^d k) + c_{11} m^{d-1} k^{2(d-1)^2/d(2d-1)}, \tag{4.8}$$

for a constant c_{11}.

From inequality (4.8) we see that the main hypothesis of Lemma 2.1 is justified with $r(k) = c_{11}k^{(1-d)/d(2d-1)}$. Since (4.4) verifies the first hypothesis of Lemma 2.1, we have completed the proof that $\rho_{\mathrm{TSP}}(n) \sim \beta_{\mathrm{TSP}} n^{(d-1)/d}$ as $n \to \infty$. Naturally, since the minimal spanning tree problem is a relaxation of the traveling salesman problem, we have $\beta_{\mathrm{MST}} \leqq \beta_{\mathrm{TSP}}$.

5. Summary and concluding remarks. The two classical examples that were studied here follow a general pattern that can be used for other problems. One pursues the following recipe: (1) divide the unit d-cube into m^d subcells of equal size that are separated by a fattened grating; (2) fill the ith subcell with S_i, a set of k points on which the geometric object being analyzed attains its worst-case length in the subcell; (3) construct a graph G that is associated with the points $\bigcup_{i=1}^{m^d} S_i \subset [0, 1]^d$; (4) delete all edges of G that are long enough to span the fattened grating; (5) in each subcell, add edges to what remains following the deletion to form a heuristic graph G_i on S_i; (6) derive from this construction a recursion involving the length of a worst-case edge set; and (7) show that the recursion justifies (2.1(ii)) of Lemma 2.1. Of course, we must also show that the worst-case length satisfies (2.1(i)) of Lemma 2.1 to guarantee the result, although proving that the second recursion of Lemma 2.1 is satisfied is usually the task of greater difficulty.

This recipe would be unacceptably vague in the absence of explicit examples, but, be referring to the detailed treatment of the MST and TSP, the application of this technique to other problems should be reasonably straightforward.

The fact that the traveling salesman problem is computationally difficult and the minimal spanning tree problem is computationally easy serves to show that computational complexity is not at the heart of the technique used here. This intriguing circumstance provided one of our motivations for illustrating our technique with these particular problems. A second motivation came from the heuristic algorithms developed by Held and Karp (1970), (1971) which are driven by the observation that the minimal spanning tree problem is a relaxation of the traveling salesman problem.

Limit results like those given here seem to provoke two inevitable questions. The first question concerns the determination of the constants β_{MST} and β_{TSP} (for each $d \geqq 2$), and the second concerns the possibility of providing convergence rates more precise than $\rho(n) = \beta n^{(d-1)/d} + o(n^{(d-1)/d})$. The experience of trying to deal with the analogous questions under probabilistic assumptions leaves us with little hope for progress on these points. In particular, one should note that to sharpen the results of Moran (1984) to give the exact value of β_{TSP} would seem to require new geometric insights into the traveling salesman problem as well as improvements on the best

available results on sphere packing. These steps would be major advances in their own right. Perhaps the problem of improving the error term in our limit theorem to something sharper than $o(n^{(d-1)/d})$ would be easier than determining β; but, still, one would have to develop a technique that would be completely different than that given here.

OPTIMAL PARALLEL 5-COLOURING OF PLANAR GRAPHS*

TORBEN HAGERUP†, MAREK CHROBAK‡, AND KRZYSZTOF DIKS‡

Abstract. We show that a 5-colouring of the vertices of an n-vertex planar graph may be computed in $O(\log n \log^* n)$ time by an exclusive-read exclusive-write parallel RAM with $O(n/(\log n \log^* n))$ processors. Our algorithm, while faster than all previously known methods, is at the same time the first parallel 5-colouring algorithm to exhibit an optimal speedup. Optimality is achieved through a method based on the accelerating cascades technique and of independent interest. It should be emphasized that although input to the algorithm is a planar graph, we do not require a planar embedding to be given as part of the input.

Other results concern the colouring of graphs of bounded genus and the construction of search structures for triangular planar subdivisions.

1. Introduction. The problem of colouring the vertices of a graph using few colours has given rise to one of the most intensively studied areas of graph theory. It is also important in practical terms because of its many applications in such fields as scheduling, resource allocation, and the construction and testing of VLSI circuits. A frequently encountered special case is that in which the graph to be coloured is planar. Computing a colouring that uses the smallest possible number of colours is known to be an NP-complete problem, even when restricted to the class of planar graphs [15] (more precisely, it is an NP-complete problem to decide in general whether a given planar graph is 3-colourable). Hence algorithms that colour planar graphs using a fixed and small number of colours are of interest.

Although every planar graph is 4-colourable, this is the famous "4-colour conjecture" whose lengthy proof [2], [3] seems so far to have put it somewhat out of the reach of efficient algorithm design. The situation changes if one allows five colours. A simple proof which establishes that every planar graph may be coloured using five colours also directly yields a sequential $O(n^2)$-time algorithm for doing so (n is the number of vertices in the graph). The algorithm first disassembles the graph by repeatedly removing a vertex of degree 5 or less. The vertices are then added back to an initially empty graph in the reverse order of their removal while a 5-colouring of the partially constructed graph is maintained. At each step it may be necessary to search and recolour almost the entire graph, which accounts for the quadratic running time. Lipton and Miller [19] reduced the running time to $O(n \log n)$ by a "batching" method in which a large number of vertices are removed from (and later added to) the graph in each step without increasing the time needed per step for searching and

recolouring beyond linear. Since then a number of optimal $O(n)$-time algorithms have appeared [7], [20], [14], [22], [8]; even a sequential simulation of the algorithm presented in this paper could be added to the list. In general terms, most of these algorithms revert to the idea of removing vertices one by one but introduce small changes to the remaining graph in order to make it possible to later reinsert each vertex at constant cost.

The parallel version of the problem did not attract much attention until fairly recently. Bauernöppel and Jung [4] described a colouring method that may be used for several classes of graphs. When applied to planar graphs and run on a CRCW PRAM with $\Theta(n^4)$ processors, it yields an 8-colouring in $O(\log n)$ time. Pushing further in the same direction and concentrating on planar graphs, Diks [12] reduced the number of colours used to six. These algorithms were parallel "by birth," i.e., not derived from sequential algorithms. Parallel 5-colouring algorithms based on various sequential methods were subsequently discovered, for the most part independently, at least five times [21], [6], [17], [8], [16]. Our algorithm, while using the batching idea of [19], is largely a parallel implementation of the linear-time sequential 5-colouring algorithm by Chiba, Nishizeki, and Saito [7], with ideas of [10] used crucially in the parallelization. By generalizing a theorem due to Cole and Vishkin and based on the accelerating cascades technique [10], we achieve a running time of $O(\log n \log^* n)$ on an EREW PRAM with $O(n/(\log n \log^* n))$ processors. This result is optimal in the sense of having a linear product of time and number of processors and represents a considerable improvement on previous work: The earlier algorithms mentioned above have time bounds between $O((\log n)^2)$ and $O((\log n)^5)$ and miss optimality by a factor of at least $\Theta((\log n)^2)$. Two of the algorithms show a better performance on graphs that have already been embedded in the plane; however, here we do not consider a planar embedding to be available for free.

2. Notation and definitions. We assume familiarity with basic notions concerning directed and undirected graphs. Throughout, graphs are finite and without multiple edges, and undirected graphs are without loops.

In the following, let $G = (V, E)$ be a graph. If G is undirected, two vertices $u, v \in V$ are called *neighbours* in G if $(u, v) \in E$. If G is directed, we call u and v neighbours in G if either $(u, v) \in E$ or $(v, u) \in E$. A set $S \subseteq V$ is said to be *independent* in G if it does not contain two vertices that are neighbours in G. S is *maximal* independent in G if S is independent in G and there is no independent vertex set S' in G with $S \subset S'$. For $w \in V$, the graph obtained from G by removing w together with all edges incident on w is denoted by $G - \{w\}$. In general, whenever vertices are removed from a graph, the intended meaning is that edges incident on such vertices are removed as well.

From now on, let G be undirected. For $u \in V$, we use $N(u)$ to denote the set of neighbours of u and $\deg(u)$ to denote the degree of u, i.e., $\deg(u) = |N(u)|$.

A (vertex) *colouring* of G is an assignment of colours to the vertices of G such that adjacent vertices receive distinct colours, i.e., a function g defined on V with the property that $g(u) \neq g(v)$ for all $(u, v) \in E$. g uses $|g(V)|$ colours, and for $k \geq 1$, G is said to be *k-colourable* if there is a colouring of G that uses at most k colours.

For $u, v \in V$ with $(u, v) \notin E$, the *identification* of u and v is an operation which replaces u and v and their incident edges by a new vertex z, adjacent to exactly those vertices in $V \setminus \{u, v\}$ that were adjacent to either u or v (or both) in the original graph. Identification of more than two pairwise nonadjacent vertices is defined analogously or may be thought of as repeated identification of two vertices. When C is an independent vertex set, we denote the identification of all vertices in C by $\langle C \rangle$.

A *planar embedding* of G is a function $\mathscr{E}$ that maps the vertices of G to distinct points in $\mathbb{R}^2$ and each edge $e=(u, v)\in E$ to a Jordan curve in $\mathbb{R}^2$ from $\mathscr{E}(u)$ to $\mathscr{E}(v)$ such that for all $e=(u, v)\in E$, $\mathscr{E}(e)\cap(\mathscr{E}(V)\cup\mathscr{E}(E\backslash\{e\}))\subseteq\{\mathscr{E}(u), \mathscr{E}(v)\}$ (i.e., edges do not cross). G is *planar* if there exists a planar embedding of G. Euler's formula [13] implies that if $G=(V, E)$ is planar, then $|E|\leqq 3|V|$. We occasionally do not distinguish between a vertex and its image under a given planar embedding.

Given a planar embedding $\mathscr{E}$ of G and a vertex $w\in V$ with $N(w)=\{u_1, \cdots, u_l\}$, the curves $\mathscr{E}((w, u_1)), \cdots, \mathscr{E}((w, u_l))$ occur in a particular cyclic order around $\mathscr{E}(w)$, namely the order in which they are encountered in a counterclockwise scan around $\mathscr{E}(w)$. If this cyclic order is $\mathscr{E}((w, u_1)), \cdots, \mathscr{E}((w, u_l))$, we also say that the neighbours of w occur in the cyclic order $u_1, \cdots, u_l$ around w in the planar embedding $\mathscr{E}$. The *faces* of $\mathscr{E}$ are the connected regions of $\mathbb{R}^2-\mathscr{E}(V\cup E)$. All graphs introduced in following sections, unless otherwise qualified, will be undirected.

A PRAM (parallel random access machine) consists of a finite number p of processors (RAMs) operating synchronously on common, shared memory cells numbered $0, 1, \cdots$. We assume that the processors are numbered $1, \cdots, p$ and that each processor is able to read its own number. All processors execute the same program. We use the unit-cost model in which each memory cell can hold integers of size polynomial in the size of the input, and each processor is able to carry out usual arithmetic operations including multiplication and integer division on such numbers in constant time. In addition, we assume the existence of (constant-time) instructions for bitwise logical operations on integers, which are then considered as represented in the binary number system (e.g., 2's complement), as well as for conversion from the unary to the binary number system.

One distinguishes between various types of PRAMs. EREW (exclusive-read exclusive-write) PRAMs allow no memory cell to be accessed simultaneously by more than one processor. In contrast, CRCW (concurrent-read concurrent-write) PRAMs allow simultaneous reading as well as simultaneous writing of each cell by arbitrary sets of processors, with some rule defining the exact semantics of simultaneous writing. CREW (concurrent-read exclusive-write) PRAMs allow simultaneous reading, but not simultaneous writing.

For $k\geqq 0$, $\log^{(k)}$ denotes the k-fold iterated logarithm function, i.e., $\log^{(0)} n=n$ and $\log^{(i)} n=\log\log^{(i-1)} n$, for $i\geqq 1$. For $n\geqq 1$, $\log^* n=\min\{i\geqq 1|\log^{(i)} n\leqq 1\}$. All logarithms in the paper are to base 2.

3. 5-colouring using a linear number of processors. Before we explain the technical details of the algorithm, we provide the following sketch of the main ideas involved. Note that the description assumes the availability of n processors. A later refinement reduces the number of processors needed to $O(n/(\log n \log^* n))$.

Starting from the given planar graph $G_0=G$, the algorithm produces in successive stages a sequence $G_0, G_1, G_2, \cdots$ of planar graphs. The size of each G_i is at most c times that of its predecessor, for some constant $c<1$. Hence after $O(\log n)$ stages there remains a graph which is trivial to colour.

For $i\geqq 0$, G_{i+1} is derived from G_i by applying a number of *reductions* to vertices of G_i. A reduction at a vertex w consists of the removal of w together with the possible identification of certain neighbours of w.

Suppose that w is a vertex in a graph G. If we derive a graph G' from G by identifying sufficiently many neighbours of w to reduce the degree of w to at most 4, then it is easy to extend any 5-colouring of $G'-\{w\}$ to a 5-colouring of G. First undo the identifications of neighbours of w, letting each new vertex created in the process

inherit the colour of the vertex from which it is derived (note that vertices that are identified are always nonadjacent). Then stick w back in place. By the colouring convention just mentioned, the neighbours of w will be coloured with at most four colours; hence the fifth colour may be used to colour w.

The above procedure cannot be applied indiscriminately. In order to be able to even guarantee that $G'-\{w\}$ is 5-colourable, one must ensure that it is planar. It turns out that there is a possible reduction preserving planarity at every vertex of degree at most 6; while such reductions are not always easy to determine, we identify a sufficiently large set of vertices for which they can be found in constant time.

The reductions that produce G_{i+1} from G_i are all executed in parallel. The set W of vertices at which reductions take place must be chosen with some care. First of all it must satisfy the constraints imposed by the need to preserve planarity. Secondly, the vertices in W must possess certain independence properties, both with respect to the current planar graph G_i and with respect to its representation. And lastly, W should contain a constant fraction of all vertices. The computation of a suitable set W is made difficult by the presence of vertices of high degree. Therefore, we show that such vertices are sufficiently rare that one may refrain from attempting certain types of reductions in their vicinity. After the exclusion of such reductions, the problem may be cast as one of finding a sufficiently large independent vertex set in a graph of bounded degree. Using a technique first employed by Cole and Vishkin, we show how to solve the latter problem in time $O(\log^* n)$.

Our choice of W is such that the reductions at vertices in W can be carried out in constant time. Hence each stage takes $O(\log^* n)$ time, and the running time of the entire algorithm is $O(\log n \log^* n)$.

Given a graph G, we formally define a *reduction* in G to be a set $r=\{w, C_1, \cdots, C_s\}$, where w is a vertex in G and $C_1, \cdots, C_s$ are pairwise disjoint independent subsets of $N(w)$. w is called the *center* of r. To *execute* the reduction r means to remove w and to apply the identifications $\langle C_1\rangle, \cdots, \langle C_s\rangle$ to the resulting graph (in any order).

Now fix a constant $K \geqq 12$. We call a vertex *small* if it has at most K neighbours, *large* otherwise.

DEFINITION. A vertex w in a graph G is called *reducible* if one of the following holds:

(1) $\deg(w) \leqq 4$.

(2) $\deg(w)=5$, and w has at most one large neighbour.

(3) $\deg(w)=6$, all neighbours of w are small, and the subgraph spanned by $N(w)$ is Hamiltonian.

The last part of condition (3) states that G contains a simple cycle whose vertices are exactly the neighbours of w.

DEFINITION. A reduction r centered at a reducible vertex w is called *safe* if one of the following holds:

(1) $\deg(w) \leqq 4$, and $r=\{w\}$.

(2) $\deg(w)=5$, and $r=\{w, \{x, y\}\}$ for some pair $\{x, y\}$ of distinct, small neighbours of w.

(3) $\deg(w)=6$, and either

(a) $r=\{w, C\}$ for some $C \subseteq N(w)$ with $|C|=3$, or

(b) $r=\{w, \{x_1, y_1\}, \{x_2, y_2\}\}$ for some pairwise distinct vertices $x_1, y_1, x_2, y_2 \in N(w)$ that occur in the cyclic order x_1, y_1, x_2, y_2 on a Hamilton cycle of the graph spanned by $N(w)$.

Note that by the definition of a reduction, the vertices to be identified in (2) and (3) must be pairwise nonadjacent.

The algorithm works by executing safe reductions centered at reducible vertices. It is based on six lemmas given below. Lemma 1 considers the problem locally and shows that there is a safe reduction centered at every reducible vertex. Lemma 2 guarantees that safe reductions preserve planarity. Lemmas 3 and 4, technical in nature, demonstrate that the number of reducible vertices is not too small, and Lemma 5 shows that a large independent vertex set in an n-vertex graph of bounded degree can be found in $O(\log^* n)$ time. Lemma 6, building on the previous lemma, finally states that reductions centered at a constant fraction of the reducible vertices can be carried out in $O(\log^* n)$ time.

LEMMA 1. *Given a reducible vertex w in a planar graph G, there is a safe reduction centered at w which can be determined in constant time by one processor from the adjacency lists of w and its small neighbours.*

Proof. If $\deg(w) \leqq 4$, there is nothing to show. If $\deg(w) = 5$, then we simply have to find and identify two small nonadjacent neighbours of w. These necessarily exist by Kuratowski's theorem [13] since otherwise G would contain a complete subgraph on five vertices, namely w and four of its small neighbours.

Suppose now that w has exactly six neighbours $u_1, \cdots, u_6$, and let their cyclic order on a Hamilton cycle of the graph spanned by $N(w)$ be $u_1, \cdots, u_6$. Note that this must also (up to reversal) be the cyclic order in which $u_1, \cdots, u_6$ occur around w in any planar embedding of G.

If $N(w)$ contains an independent set of three vertices, then we can identify these. Otherwise we may assume (after a cyclic renaming) that G contains the edge (u_1, u_3). Then G cannot also contain the edge (u_1, u_5), since in that case $\{u_2, u_4, u_6\}$ would form an independent set, cf. Fig. 1. Hence $\{w, \{u_1, u_5\}, \{u_2, u_4\}\}$ is a safe reduction centered at w. □

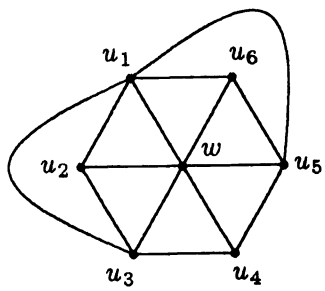

FIG. 1. *If u_1 is adjacent to both u_3 and u_5, then $\{u_2, u_4, u_6\}$ is an independent set.*

LEMMA 2. *The graph G' obtained from a planar graph G by the execution of a safe reduction is again planar.*

Proof. Consider first the case of a safe reduction of the form $\{w, \{x_1, y_1\}, \{x_2, y_2\}\}$. Note as above that x_1 and y_1 as well as x_2 and y_2 are adjacent in the cyclic order of x_1, y_1, x_2, and y_2 around w in any planar embedding of G. The planarity of G' is now evident from geometric considerations (see Fig. 2). The remaining cases are easy.

LEMMA 3. *Let $G = (V, E)$ be a planar graph with n vertices and m edges, and let*

$$Z = \{w \in V \mid \deg(w) \geqq 3 \text{ and the subgraph spanned by } N(w) \text{ is not Hamiltonian}\}.$$

Then $m \leqq 3n - \frac{1}{4}|Z|$.

Proof. Take any planar embedding of G and observe that each vertex in Z lies on the boundary of a face whose boundary contains at least four distinct vertices. Now for each such face F, add to G a new vertex u_F and edges joining u_F to all vertices

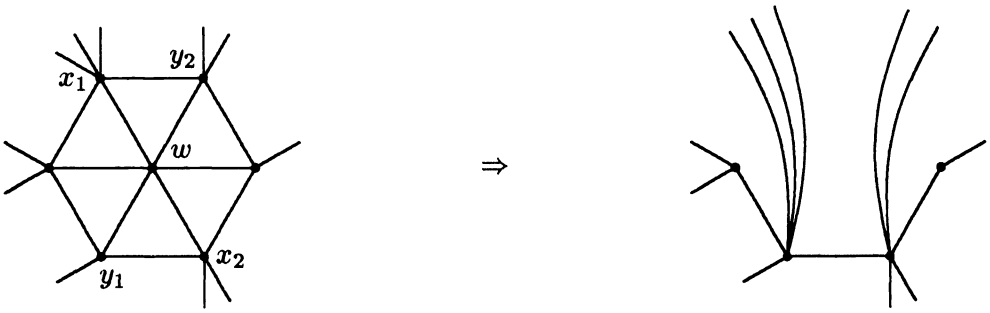

FIG. 2. *Execution of the safe reduction* $\{w, \{x_1, y_1\}, \{x_2, y_2\}\}$.

on the boundary of F (if a vertex occurs more than once on the boundary, join it to u_F by just one edge). The resulting graph is obviously planar. Let n' and m' be the total number of vertices and edges added, respectively. Clearly $m' \geqq 4n'$ and $m' \geqq |Z|$, and Euler's formula applied to the augmented graph gives

$$(m+m') \leqq 3(n+n')$$

or

$$m \leqq 3n+3n'-m' \leqq 3n-\tfrac{1}{4}m' \leqq 3n-\tfrac{1}{4}|Z|. \qquad \square$$

LEMMA 4. *Let A be the set of reducible vertices in a planar graph G on n vertices. Then $|A| \geqq n/196$.*

Proof. For $j = 0, 1, \cdots$, let n_j be the number of vertices in G of degree j, and let $\hat{n}_5$ be the number of reducible vertices of degree 5, $\bar{n}_6$ the number of reducible vertices of degree 6, and $\hat{n}_6$ the number of vertices of degree 6 all of whose neighbours are small. Then

$$|A| = \sum_{j=0}^{4} n_j + \hat{n}_5 + \bar{n}_6.$$

We first informally sketch why one has $|A| = \Omega(n)$. Let $n' = n_0 + \cdots + n_4 + \hat{n}_5 + \hat{n}_6$. As was shown in [8] and in [17], $n' = \Omega(n)$. Now, if $\hat{n}_6 - \bar{n}_6$ is small, then $|A|$ is close to n' and hence $|A| = \Omega(n)$. On the other hand, if $\hat{n}_6 - \bar{n}_6$ is large, then we may conclude from Lemma 3 that G is very sparse, i.e., contains considerably fewer than $3n$ edges. It then follows immediately from Euler's formula that G contains many vertices of degree at most 5. With some care, one may even show that $n_0 + \cdots + n_4 + \hat{n}_5 = \Omega(n)$. The details follow.

Let m be the number of edges in G and put $\varepsilon = 6 - 2m/n$. $\varepsilon \geqq 0$ by Euler's formula, and

$$2m = (6-\varepsilon)n$$

or

$$\sum_{j=0}^{\infty} jn_j = (6-\varepsilon) \sum_{j=0}^{\infty} n_j.$$

Isolating the terms containing n_5 gives

$$(1-\varepsilon)n_5 = \sum_{j=0}^{4} (j-6+\varepsilon)n_j + \sum_{j=6}^{\infty} (j-6+\varepsilon)n_j$$

and hence

$$n_5 \geqq \sum_{j=6}^{\infty} (j-6+\varepsilon)n_j - 6 \sum_{j=0}^{4} n_j. \tag{1}$$

Let m' be the number of edges in G that have at least one large endpoint. By the definition of $\hat{n}_5$ and $\hat{n}_6$,

$$m' \geqq 2(n_5 - \hat{n}_5) + (n_6 - \hat{n}_6).$$

On the other hand,

$$m' \leqq \sum_{j=K+1}^{\infty} jn_j,$$

and therefore

$$2(n_5 - \hat{n}_5) + (n_6 - \hat{n}_6) \leqq \sum_{j=K+1}^{\infty} jn_j$$

or

$$2\hat{n}_5 + \hat{n}_6 \geqq 2n_5 + n_6 - \sum_{j=K+1}^{\infty} jn_j. \tag{2}$$

Next add $\alpha = \frac{15}{8}$ times inequality (1) to the above inequality (2). The result is

$$\begin{aligned} 2\hat{n}_5 + \hat{n}_6 &\geqq (2-\alpha)n_5 + n_6 - \sum_{j=K+1}^{\infty} jn_j + \alpha \sum_{j=6}^{\infty} (j-6+\varepsilon)n_j - 6\alpha \sum_{j=0}^{4} n_j \\ &= \frac{n_5}{8} + n_6 + \alpha \sum_{j=6}^{K} (j-6+\varepsilon)n_j + \sum_{j=K+1}^{\infty} ((\alpha-1)j - 6\alpha + \alpha\varepsilon)n_j - 6\alpha \sum_{j=0}^{4} n_j \\ &\geqq \frac{n_5}{8} + n_6(1+\alpha\varepsilon) + \alpha \sum_{j=7}^{K} n_j + \sum_{j=K+1}^{\infty} ((\alpha-1)(K+1) - 6\alpha)n_j - 6\alpha \sum_{j=0}^{4} n_j. \end{aligned}$$

Since $(\alpha-1)(K+1) - 6\alpha \geqq \frac{1}{8}$, we finally get

$$6\alpha \sum_{j=0}^{4} n_j + 2\hat{n}_5 + \hat{n}_6 \geqq \frac{n_5}{8} + n_6(1+\alpha\varepsilon) + \frac{1}{8} \sum_{j=7}^{\infty} n_j. \tag{3}$$

Now consider two cases:

Case 1. $\varepsilon \geqq \frac{1}{32}$. Since $n_6 \geqq \hat{n}_6$,

$$6\alpha \sum_{j=0}^{4} n_j + 2\hat{n}_5 \geqq \frac{n_5}{8} + \frac{\alpha n_6}{32} + \frac{1}{8} \sum_{j=7}^{\infty} n_j$$

and, after multiplication by $32/\alpha > 8$ and addition of $\sum_{j=0}^{4} n_j$,

$$193|A| \geqq (6 \cdot 32 + 1) \sum_{j=0}^{4} n_j + \frac{64}{\alpha} \hat{n}_5 \geqq \sum_{j=0}^{4} n_j + n_5 + n_6 + \sum_{j=7}^{\infty} n_j = n,$$

from which the desired conclusion follows.

Case 2. $\varepsilon < \frac{1}{32}$. Since $m = 3n - (\varepsilon n/2)$, Lemma 3 implies that $\hat{n}_6 - \bar{n}_6 \leqq 2\varepsilon n$. Hence from (3),

$$6\alpha \sum_{j=0}^{4} n_j + 2\hat{n}_5 + \bar{n}_6 \geqq \frac{n_5}{8} + n_6 + \frac{1}{8} \sum_{j=7}^{\infty} n_j - 2\varepsilon n$$

and

$$(6\alpha+1)|A| \geqq (6\alpha+1) \sum_{j=0}^{4} n_j + 2\hat{n}_5 + \bar{n}_6 \geqq \left(\frac{1}{8} - 2\varepsilon\right) n \geqq \frac{n}{16}.$$

The desired conclusion again follows since $16(6\alpha+1) = 196$. □

We use a standard representation of undirected graphs. Vertices are represented by integers, and the graph itself is represented by a set of doubly linked adjacency lists. The adjacency list of each vertex u contains exactly one entry for each neighbour v of u in the graph. This entry contains, in addition to an identification of v, a pointer to u's entry in the adjacency list of v. Pointers of the latter type are called *cross links.*

Each vertex has an associated processor with constant-time access to the adjacency list of the vertex. Note that the presence of cross links enables conflict-free communication between processors associated with adjacent vertices.

We shall say that a graph is represented with *vertex number bound q* if each integer representing a vertex in the graph lies in the range $0, \cdots, q-1$, and if q and $\log^* q$ are known to each processor associated with a vertex. Our model of computation is the EREW PRAM.

LEMMA 5. *Let a graph $G=(V, E)$ with n vertices and maximum vertex degree bounded by a constant d be represented with vertex number bound q. Then an independent vertex set in G containing at least $n/6^d$ vertices may be computed by n processors in $O(\log^* q)$ time.*

Remark. A highly elegant algorithm computing a *maximal* independent vertex set within the stated resource bounds was found recently by Goldberg, Plotkin, and Shannon [16]. In terms of constant factors, their algorithm is far superior to the one given here.

Proof. Consider G as a directed graph by treating each undirected edge (u, v) as two directed edges (u, v) and (v, u). Each processor associated with some $u \in V$ with, say, l outgoing edges labels these $1, \cdots, l$ in some arbitrary order. For $j=1, \cdots, d$, let E_j be the set of edges labeled j. For $j=1, \cdots, d$, we eliminate "conflicts" caused by edges in E_j. More precisely, execute the following:

$V_0 := V$;
for $j := 1$ **to** d
do $V_j :=$ an independent vertex set in the graph $(V_{j-1}, E_j \cap (V_{j-1} \times V_{j-1}))$
with $|V_j| \geqq |V_{j-1}|/6$;

Then V_d will be an independent set in G containing at least $n/6^d$ vertices. It hence remains only to show that in any subgraph of G with t vertices and maximum out-degree 1, an independent vertex set containing at least $t/6$ vertices may be found in $O(\log^* q)$ steps.

Consider such a subgraph and remove each vertex with in-degree $\geqq 2$. This leaves a collection H of vertex-disjoint simple paths and simple cycles. Note that H contains at least $t/2$ vertices. A trivial extension of a result in [10], which considers the case of a *single* simple path or simple cycle, shows that a maximal independent vertex set in H can be found in $O(\log^* q)$ time. This concludes the proof since a maximal independent vertex set in H necessarily contains at least one third of the vertices in H, i.e., at least $t/6$ vertices. □

LEMMA 6. *There is a constant $\gamma > 0$ with the following property: Let A be a set of reducible vertices in an n-vertex graph $G=(V, E)$ represented with vertex number bound q and, for each $u \in A$, let r_u be a safe reduction centered at u. Then at least $\gamma|A|$ of the reductions in the set $\{r_u | u \in A\}$ may be executed by n processors in $O(\log^* q)$ time.*

Proof. Consider first the execution of a single safe reduction. The identification of vertices $x_1, \cdots, x_l$ is carried out by choosing a representative, x_1, say, renaming all adjacency list entries for $x_2, \cdots, x_l$ to be entries for x_1, concatenating the adjacency lists of $x_1, \cdots, x_l$ to obtain the new adjacency list for x_1, and removing $x_2, \cdots, x_l$ as well as duplicate entries of edges incident on x_1. Since the total number of vertices and edges involved is bounded by a constant, the computation can be done in constant time by a single processor. This also applies to the removal of w together with its at most six incident edges.

We now introduce an undirected auxiliary graph H on the vertex set A and with edges (u, v) intended to mean that the reductions r_u and r_v should not both be executed.

For all $u, v \in A$ with $u \neq v$, H contains an edge (u, v) exactly if one of the following holds:

(1) There is a path in G from u to v of length at most 4 and containing no large vertices.

(2) There are small vertices x and y, $x \in \{u\} \cup N(u)$, $y \in \{v\} \cup N(v)$, such that x and y have a common neighbour in whose adjacency list the entries for x and y are consecutive.

The maximum vertex degree of H is clearly bounded by a constant, and it is not difficult to see that H can be constructed in constant time, even in our chosen EREW PRAM model. By Lemma 5, there is a constant $\gamma > 0$ such that an independent set W in H of size at least $\gamma|A|$ can be computed in $O(\log^* q)$ time. We finish by letting the processor associated with w execute the reduction r_w, simultaneously for all $w \in W$, as described above. The well-definedness of this, as well as the fact that the computation can be carried out in constant time and yields the same graph as would have been obtained by sequentially executing the reductions one by one in any order, follow from the observation that processors executing reductions centered at distinct vertices in W operate on (read and write) disjoint sets of memory cells (let us say that they operate without *contention*). To see this, note first that if two such processors P_1 and P_2 operate on the same adjacency list L, then by (1) above, L is necessarily the adjacency list of a large vertex, the operations of P_1 and P_2 on L are limited to updating or deleting certain sets of single list entries, and no entry in L is updated or deleted by both P_1 and P_2; therefore updates cause no contention. And by (2), L does not even contain two consecutive entries such that P_1 deletes one, and P_2 the other. Hence deletion, which involves resetting pointers in successor and predecessor entries, causes no contention either. □

THEOREM 1. *Given a planar graph G on n vertices, a 5-colouring of the vertices of G may be computed in $O(\log n \log^* n)$ time by an* EREW PRAM *with n processors using $O(n)$ space.*

Proof. We use the following algorithm, γ being the constant from Lemma 6 and β another constant:

```
(01)  G_0 = (V_0, E_0) := G;
(02)  k := β⌈log n⌉;
(03)  for i := 0 to k − 1
(04)  do begin
(05)       A_i := the set of reducible vertices in G_i;
(06)       For all u ∈ A_i, compute a safe reduction r_u centered at u;
(07)       Let G_{i+1} = (V_{i+1}, E_{i+1}) be a graph obtained from G_i
               by executing at least γ|A_i| of the reductions in
               {r_u | u ∈ A_i};
(08)     end;
(09)  Colour G_k;
(10)  for i := k − 1 downto 0
(11)  do begin
(12)       Reconstruct G_i from G_{i+1};
(13)       Extend the colouring of G_{i+1} to a 5-colouring of G_i;
(14)     end;
```

We assume, as is standard, that G is presented to the algorithm in the form of a set of adjacency lists, and that vertices are represented by integers of size $O(n)$. An internal representation of G with vertex number bound $O(n)$ may then be constructed in

$O(\log n)$ time. In particular, cross links are computed by means of a sorting of the (undirected) edges [1], [9].

Lines (05) and (06) take constant time, whereas line (07) can be executed in time $O(\log^* n)$ by Lemma 6. Since $|V_{i+1}| \leqq |V_i| - \gamma|A_i| \leqq (1-\gamma/196)|V_i|$ for $i = 0, 1, \cdots$, a suitable choice of the constant β ensures that $|V_k| \leqq 1$, making the colouring of G_k trivial (strictly speaking, if $|V_i| = 0$, G_i is no longer a graph). Hence lines (01)-(09) take $O(\log n \log^* n)$ time. By running the process backwards, the reconstruction in lines (10)-(14) may be done within the same time bound. The procedure for extending a colouring of G_{i+1} to a colouring of G_i was already sketched: Whenever a vertex z is split into two vertices x and y, x and y inherit the colour of z, and whenever a vertex w is reinserted, it is coloured by a colour different from all of the at most 4 colours with which its neighbours are coloured. This is easy except that in order to avoid read conflicts, one must associate with each edge the colours of its endpoints. □

4. The optimal algorithm.

THEOREM 2. *Given a planar graph G on n vertices, a 5-colouring of the vertices of G may be computed in $O(\log n \log^* n)$ time by an* EREW PRAM *with $O(n/(\log n \log^* n))$ processors using $O(n^2)$ space.*

Proof. An internal representation of G with vertex number bound $O(n)$ may be constructed in $O(\log n \log^* n)$ time. In particular, since it is no longer feasible to sort the edges of G, cross links are established by the following simple method which uses $\Theta(n^2)$ space: Each processor which initially discovers in the input the entry of a vertex v in the adjacency list of a vertex u places a pointer to this entry in a cell $\Gamma_{u,v}$ associated with (the ordered pair) (u, v) and proceeds, if desired, to copy the pointer to a cell found using the information in $\Gamma_{v,u}$.

The remaining analysis is in fact identical to the proof of Theorem 5.1 in [10]. It applies to any algorithm that has an n-processor implementation consisting of $O(\log n)$ stages with the following characteristics:

(1) Each stage consists of some constant-time computation plus a constant number of computations of maximal independent vertex sets in simple cycles or simple paths by the Cole/Vishkin [10] method.

(2) For $i = 1, 2, \cdots$, the number of active processors in the ith stage is at most $2^{1-i}n$. Once a processor has become inactive, it remains so.

To see how the algorithm of Theorem 1 fits into this more general setting, note that the number of active processors decreases geometrically (in the first loop of the algorithm; the second loop may of course be treated analogously) because the number of vertices does. If a sufficiently large but constant number of stages is considered as a unit, each such unit will decrease the number of active processors by a factor of at least 2.

Let us deal with the general case and use the word *task* for the computation carried out by a single processor in the n-processor implementation. A task is said to be *active* when its associated processor is active. Our method will be a stage-by-stage simulation of the n-processor implementation using the available $p = O(n/(\log n \log^* n))$ processors, with each processor being responsible for (i.e., executing the instructions of) several tasks. Define the *maximum load* at a particular point during the simulation to be the maximum number of tasks for which a single processor is responsible. We need two preliminary results, both of which are proved in detail in Cole/Vishkin [10].

LEMMA 7. *Suppose that a set of m "items" is distributed among the p processors with each processor holding at most h items. Then the set of items may be evenly distributed*

among the processors (i.e., *such that each processor has either* $\lfloor m/p \rfloor$ *or* $\lceil m/p \rceil$ *items*) *in time* $O(\log p + h) = O(\log n + h)$.

LEMMA 8. *Let G be a simple cycle or a simple path on t vertices represented with vertex number bound $O(n)$. Then a maximal independent vertex set in G may be found in $O(\log n)$ time by $O(t/\log n)$ processors.*

We denote by REDISTRIBUTE the algorithm implied by Lemma 7. It is a simple application of the standard "parallel prefix computation." The redistributed items will be task descriptions or, equivalently, processor numbers of the processors associated with the given tasks in the n-processor implementation. After a call of REDISTRIBUTE, executed when the number of active tasks is m, the maximum load will be $O(m/p)$.

The algorithm guaranteed by Lemma 8 is much slower than the one used as a subroutine in the algorithm of Lemma 5, but it possesses an optimal time-processor product. A stage in which this algorithm is used instead of its faster counterpart will be called an *optimal* stage. We may substitute at will optimal stages for usual stages.

Let $k \geqq 0$ be the integer such that $\log^{(k+1)} n < \log^* n \leqq \log^{(k)} n$. Note that $k \leqq \log^* n$. We execute the following algorithm:

```
(01)  Distribute the n tasks evenly among the p processors;
(02)  for i := 1 to ⌈2 log^(k+1) n⌉
(03)  do begin
(04)       Execute one optimal stage;
(05)       REDISTRIBUTE;
(06)     end;
(07)  for j := k − 1 downto 1
(08)  do begin
(09)       Execute ⌈2 log^(j+1) n⌉ (usual) stages;
(10)       REDISTRIBUTE;
(11)     end;
(12)  Execute the remaining O(log n) (usual) stages;
```

It remains only to show that the execution time of the algorithm, using p processors, is $O(n/p)$.

Line (01) clearly takes constant time. For $i = 1, \cdots, \lceil 2 \log^{(k+1)} n \rceil$, the maximum load immediately before the ith execution of lines (04)-(05) is $O(n/(2^{i-1}p))$. Hence by Lemmas 7 and 8, the time needed for the ith execution of lines (04)-(05) is $O(n/(2^{i-1}p) + \log n)$, and the execution of the entire loop in lines (02)-(06) takes time

$$O\left(\sum_{i=1}^{\lceil 2 \log^{(k+1)} n \rceil} \left(\frac{n}{p}\frac{1}{2^{i-1}} + \log n\right)\right) = O(n/p).$$

The execution of lines (01)-(06) reduces the maximum load to $O(n/(p(\log^{(k)} n)^2)) = O(\log n)$. Hence by Lemma 7, each execution of line (10) takes $O(\log n)$ time. Furthermore, the maximum load immediately before the $(k-j)$th execution of line (09), for $j = k-1, \cdots, 1$, is $O(n/(p(\log^{(j+1)} n)^2))$. Hence the time required for the $(k-j)$th execution of line (09) is

$$O\left(\frac{n}{p}\frac{\log^{(j+1)} n \log^* n}{(\log^{(j+1)} n)^2}\right),$$

giving a total execution time for the loop in lines (07)-(11) of

$$O\left(\sum_{j=1}^{k-1} \left(\frac{n}{p}\frac{\log^* n}{\log^{(j+1)} n} + \log n\right)\right) = O(n/p).$$

Finally, when line (12) is reached, the maximum load has been reduced to 1. Hence the remaining stages may be executed as in the n-processor implementation in time $O(\log n \log^* n) = O(n/p)$. □

5. Further results. Techniques used in this paper may also be applied to the following problems:

Computation of maximal independent sets in planar graphs. The 5-colouring produced by our algorithm easily yields a maximal independent vertex set S of the input graph. Let $S = \varnothing$ initially, and then step sequentially through the set of colours, for each colour simultaneously adding to S all vertices of that colour that have no neighbours in S. The test of whether given vertices have neighbours in S, although not trivial in the EREW PRAM model, can nevertheless be carried out optimally in logarithmic time.

Colouring graphs of bounded genus. One consequence of Euler's formula [5] for graphs with n vertices, m edges, and genus g reads $m \leqq 3n + 6(g-1)$, implying that the number of vertices of degree at most 6 is at least $(n - 12g + 12)/7$. Hence as long as n is larger than some number depending only on g, there are at least $n/8$ vertices of degree at most 6. As in the proof of Lemma 6, one may construct a conflict graph H of bounded degree on the set of these vertices, find a large independent set, and carry out reductions centered at the vertices in the independent set, thereby in $O(\log^* n)$ time reducing the size of the graph by a constant factor. If seven colours are allowed, there is never any need to identify vertices. Hence the genus does not increase, and the process may be repeated until the proportion of vertices of degree at most 6 drops below $\frac{1}{8}$. Assuming that g is bounded by a constant, the remaining graph may be coloured optimally in constant time.

We conclude that an n-vertex graph G of bounded genus can be coloured with at most $\max\{\chi(G), 7\}$ colours in $O(\log n \log^* n)$ time by $O(n/(\log n \log^* n))$ processors. Here $\chi(G)$ is the chromatic number of G, i.e., the smallest k such that G is k-colourable. Note that for all $g \geqq 1$, there are graphs of genus g that cannot be coloured with fewer than seven colours. Hence the above procedure is in a certain sense optimal with respect to the number of colours used.

Construction of search structures for triangular planar subdivisions. We are here given a planar embedding $\mathscr{E}$ of an n-vertex graph all of whose faces are triangles (i.e., the boundary of each face consists of three line segments), and the problem is to construct a data structure that will allow a single processor to determine in $O(\log n)$ time the face of $\mathscr{E}$ containing a given query point. Our solution is a straightforward parallel implementation of the sequential algorithm of [18]. As above, it has the same resource requirements as the 5-colouring algorithm, $O(\log n \log^* n)$ time with an optimal number of processors. Essentially the same algorithm was discovered independently by Dadoun and Kirkpatrick [11].

Acknowledgments. We would like to thank K. Mehlhorn, L. Banachowski, T. Radzik, and M. Yung for their encouragement and for many useful suggestions.

NONBLOCKING MULTIRATE NETWORKS*

RICCARDO MELEN† AND JONATHAN S. TURNER‡

Abstract. An extension of the classical theory of connection networks is defined and studied. This extension models systems in which multiple connections of differing data rates share the links within a network. Conditions under which the Clos and Cantor networks are strictly nonblocking for multirate traffic are determined. The authors also determine conditions under which the Beneš network and variants of the Cantor and Clos networks are rearrangeable. It is found that strictly nonblocking operation can be obtained for multirate traffic with essentially the same complexity as in the classical context.

Key words. nonblocking networks, rearrangeable networks, multirate networks, fast packet networks

AMS(MOS) subject classification. 94A99

1. Introduction. In this paper we introduce a generalization of the classical theory of nonblocking switching networks to model communication systems designed to carry connections with a multiplicity of data rates. The theory of nonblocking networks was motivated by the problem of designing telephone switching systems capable of connecting any pair of idle terminals, under arbitrary traffic conditions. From the start, it was recognized that crossbar switches with N terminals and N^2 crosspoints could achieve nonblocking behavior, only at a prohibitive cost in large systems. In 1953, Clos [6] published a seminal paper giving constructions for a class of nonblocking networks with far fewer crosspoints, providing much of the initial impetus for the theory that has since been developed by Beneš [2], [3], Pippenger [16] and many others [1], [5], [8], [11], [12], [13], [14].

The original theory was developed to model electromechanical switching systems in which both the external links connecting switches and the internal links within them were at any one time dedicated to a single telephone conversation. During the 1960s and 1970s technological advances led to digital switching systems in which information was carried in a multiplexed format, with many conversations time-sharing a single link. While this was a major technological change, its impact on the theory of nonblocking networks was slight because the new systems could be readily cast in the existing model. The primary impact was that the traditional complexity measure of crosspoint count had a less direct relation to cost than in the older technology.

During the last 10 years, there has been a growing interest in communication systems that are capable of serving applications with widely varying characteristics. In particular, such systems are being designed to support connections with arbitrary data rates, over a range from a few bits per second to hundreds of megabits per second [7], [10], [19]. These systems also carry information in multiplexed format but, in contrast to earlier systems, each connection can consume an arbitrary fraction of the bandwidth of the link carrying it. Typically, the information is carried in the form of independent blocks, called *packets*, which contain control information identifying to which of many connections sharing a given link the packet belongs. One way to operate

such systems is to select for each connection a path through the switching system to be used by all packets belonging to that connection. When selecting a path it is important to ensure that the available bandwidth on all selected links is sufficient to carry the connection. This leads to a natural generalization of the classical theory of nonblocking networks, which we explore in this paper. Note that such networks can also be operated with packets from a given connection taking different paths; reference [20] analyzes the worst-case loading in networks operated in this fashion. The drawback of this approach is that it makes it possible for packets in a given connection to pass one another, causing them to arrive at their destination out of sequence.

In § 2, we define our model of nonblocking multirate networks in detail. Section 3 contains results on strictly nonblocking networks, in particular showing the conditions that must be placed on the networks of Clos and Cantor in order to obtain nonblocking operation in the presence of multirate traffic. We also describe two variants on the Clos and Cantor network that are wise-sense nonblocking in the general environment. Section 4 gives results on rearrangeably nonblocking networks, in particular, deriving conditions for which the networks of Beneš and Cantor are rearrangeable.

2. Preliminaries. We start with some definitions. We define a network as a directed graph $G=(V, E)$ with a set of distinguished input nodes I and output nodes O, where each input node has one outgoing edge and no incoming edge, and each output node has one incoming edge and no outgoing edge. We consider only networks that can be divided into a sequence of *stages*. We say that the input nodes are in stage 0 and for $i>0$, a node v is in stage i if for all edges (u, v), u is in stage $i-1$. An edge (u, v) is said to be in stage i if u is in stage i. In the networks that we consider, all output nodes are in the same stage, and no other nodes are in this stage. When we refer to a k-stage network, we generally neglect the stages containing the input and output nodes. We refer to a network with n input nodes and m output nodes as an (n, m)-network. We let $X_{n,m}$ denote the network consisting of n input nodes, m output nodes, and a single internal node. In this network model, nodes correspond to the hardware devices that perform the actual switching functions and the edges to the interconnecting data paths. This differs from the graph model traditionally used in the theory of switching networks, which can be viewed as a dual to our model.

When describing particular networks we will find it convenient to use a product operation. We denote the product of two networks Y_1 and Y_2 by $Y_1 \times Y_2$. The product operation yields a new network consisting of one or more copies of Y_1 connected to one or more copies of Y_2, with an edge joining each pair of subnetworks. More precisely, if Y_1 has n_1 outputs and Y_2 has n_2 inputs, then $Y_1 \times Y_2$ is formed by taking n_2 copies of Y_1 numbered from 0 to n_2-1, followed by n_1 copies of Y_2 numbered from 0 to n_1-1. Then, for $0 \leqq i \leqq n_1-1$, $0 \leqq j \leqq n_2-1$, we join $Y_1(i)$ to $Y_2(j)$ using an edge connecting output port j of $Y_1(i)$ to input port i of $Y_2(j)$. Next, we remove the former input and output nodes that are now internal, identifying the edges incident to them, and finally, we renumber the input and output nodes of the network as follows: if u was input port i of $Y_1(j)$, it becomes input jn_1+i in the new network; similarly if v was output port i of $Y_2(j)$, it becomes output jn_2+i. We also allow the product of more than two networks, which we denote with the symbol $\bowtie$; the product $Y_1 \bowtie Y_2 \bowtie Y_3$ is obtained by letting $Z_1 = Y_1 \times Y_2$ and $Z_2 = Y_2 \times Y_3$, then identifying the copies of Y_2 in Z_1 and Z_2. This requires of course that the number of copies of Y_2 generated by the two initial products be the same.

A *connection* in a network is a triple (x, y, ω), where $x \in I$, $y \in 0$, and $0 \leqq \omega \leqq 1$. We refer to ω as the *weight* of the connection and it represents the bandwidth required by the connection. A *route* is a path joining an input node to an output node, with

intermediate nodes in $V-(I \cup O)$, together with a weight. A route r *realizes* a connection (x, y, ω) if x and y are the input and output nodes joined by r, and the weight of r equals ω.

A set of connections is said to be *compatible* if for all nodes $x \in I \cup O$, the sum of the weights of all connections involving x is $\leqq 1$. A *configuration* for a network G is a set of routes. The weight on an edge in a particular configuration is just the sum of the weights of all routes including that edge. A configuration is compatible if for all edges $(u, v) \in E$, the weight on (u, v) is $\leqq 1$. A set of connections is said to be *realizable* if there is a compatible configuration that realizes that set of connections. If we are attempting to add a connection (x, y, ω) to an existing configuration, we say that a node u is *accessible* from x if there is a path from x to u, all of whose edges have a weight of no more than $1-\omega$.

A network is said to be *rearrangeably nonblocking* (or simply *rearrangeable*) if for every set C of compatible connections, there exists a compatible configuration that realizes C. A network is *strictly nonblocking* if for every compatible configuration R realizing a set of connections C, and every connection c compatible with C, there exists a route r that realizes c and is compatible with R. For strictly nonblocking networks, one can choose routes arbitrarily and always be guaranteed that any new connections can be satisfied without rearrangements. We say that a network is *wide-sense nonblocking* if there exists a routing algorithm for which the network never blocks; that is, for an arbitrary sequence of connection and disconnection requests, we can avoid blocking if routes are selected using the appropriate routing algorithm, and disconnection requests are performed by simply deleting the route.

Sometimes, improved performance can be obtained by placing constraints on the traffic imposed on a network. We will consider two such constraints. First, we restrict the weights of connections to the interval $[b, B]$. We also limit the sum of the weights of connections involving a node x in $I \cup O$ to β. Note that $0 \leqq b \leqq B \leqq \beta \leqq 1$. We say a network is strictly nonblocking for particular values of b, B, and β if for all sets of connections for which the connection weights are in $[b, B]$ and the total port weight is β, the network cannot block. The definitions of rearrangeably nonblocking and wide-sense nonblocking networks are extended similarly. The practical effect of a restriction on β is to require that a network's internal data paths operate at a higher speed than the external transmission facilities connecting switching systems, a common technique in the design of high-speed systems. The reciprocal of β is commonly referred to as the *speed advantage* for a system.

Two particular choices of parameters are of special interest. We refer to the traffic condition characterized by $B=\beta$, $b=0$ as unrestricted packet switching (UPS), and the condition $B=b=\beta=1$ as pure circuit switching (CS). Since the CS case is a special case of the multirate case, we can expect solutions to the general problem to be at least as costly as the CS case and that theorems for the general case should include known results for the CS case.

3. Strictly nonblocking networks. A three-stage Clos [6] network with N input and output nodes is denoted by $C_{N,k,m}$, where k and m are parameters, and is defined as: $C_{N,k,m} = X_{k,m} \bowtie X_{N/k,N/k} \bowtie X_{m,k}$. A Clos network is depicted in Fig. 1. The standard reasoning to determine the nonblocking condition (see [6]) can be extended in a straightforward manner, yielding the following theorem.

THEOREM 3.1. *The Clos network $C_{N,k,m}$ is strictly nonblocking if*

$$m > 2 \max_{b \leqq \omega \leqq B} \left\lfloor \frac{\beta k - \omega}{s(\omega)} \right\rfloor,$$

where $s(\omega) = \max\{1-\omega, b\}$.

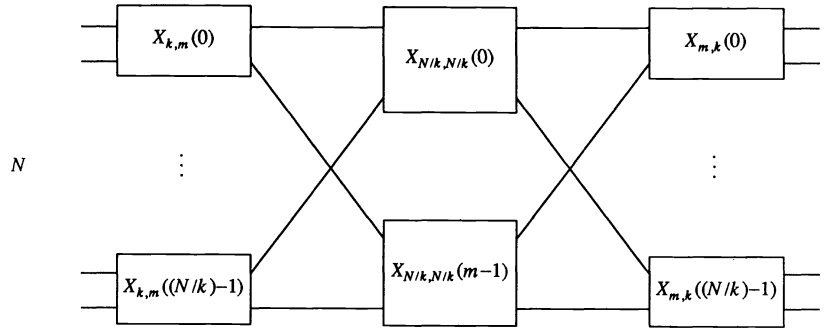

FIG. 1. *Clos network.*

Proof. Suppose we wish to add a connection (x, y, γ) to an arbitrary configuration C. Let u be the stage-1 node adjacent to x and note that the sum of the weights on all edges out of u is at most $\beta(k-1)+(\beta-\gamma)=\beta k-\gamma$. Consequently, the number of edges out of u that carry a weight of more than $(1-\gamma)$ is $\leqq \lfloor(\beta k-\gamma)/s(\gamma)\rfloor$, and hence the number of inaccessible middle stage nodes is

$$\leqq \left\lfloor \frac{\beta k-\gamma}{s(\gamma)} \right\rfloor \leqq \max_{b\leqq\omega\leqq B} \left\lfloor \frac{\beta k-\omega}{s(\omega)} \right\rfloor < m/2.$$

That is, less than half the middle stage nodes are inaccessible from x. By a similar argument, less than half the middle stage nodes are inaccessible from y, implying that there is at least one middle stage node accessible to both. □

Let us examine some special cases of interest. If we let $b=B=\beta=1$, the effect is to operate the network in CS mode. The theorem states that we get nonblocking operation when $m\geqq 2k-1$, as is well known. In the UPS case, the condition on m becomes $m>2(\beta/(1-\beta))(k-1)$. So $m=2k-1$ is sufficient here also if $\beta=\frac{1}{2}$.

Using Theorem 3.1, we can construct a wide-sense nonblocking network for unrestricted traffic by placing two Clos networks in parallel and segregating connections in the two networks based on weight. In particular if we let $m=4k-1$, the network $X_{1,2}\bowtie C_{N,k,m}\bowtie X_{2,1}$ is wide-sense nonblocking if all connections with weight $\leqq\frac{1}{2}$ are routed through one of the Clos subnetworks, and all the connections with weight $>\frac{1}{2}$ are routed through the other.

A k-ary Beneš network [2], built from $k\times k$ switching elements (where $\log_k N$ is an integer), can be defined recursively as follows: $B_{k,k}=X_{k,k}$ and $B_{N,k}=X_{k,k}\bowtie B_{N/k,k}\bowtie X_{k,k}$ (see Fig. 2). A k-ary Cantor network of multiplicity m is defined

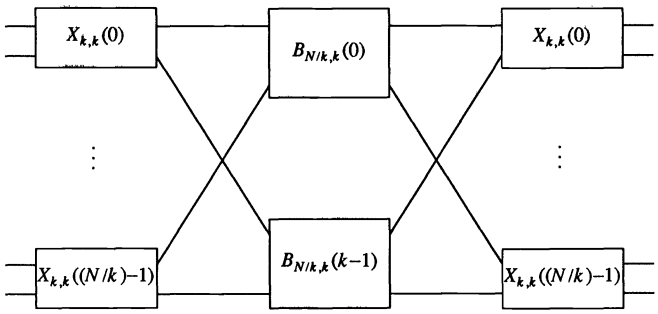

FIG. 2. *Beneš network* $(B_{N,k})$.

as $K_{N,k,m} = X_{1,m} \bowtie B_{N,k} \bowtie X_{m,1}$. Note that this definition is expressed differently from those given in [5], [13], but we find it preferable as it shows clearly the close relationship between these two structures. Figure 3 depicts a binary Cantor network of multiplicity three with one of its Beneš subnetworks highlighted. The next theorem captures the condition on m required to make the Cantor network strictly nonblocking.

THEOREM 3.2. *The Cantor network $K_{N,k,m}$ is strictly nonblocking if*

$$m \geqq \frac{2\beta}{ks(B)}(1+(k-1)\log_k (N/k)).$$

Proof. Suppose we wish to add a connection (x, y, ω) to an arbitrary configuration. Note that there are mN/k nodes in the middle stage of the network. We will show that more than half of these nodes are accessible from x if m satisfies the inequality in the statement of the theorem.

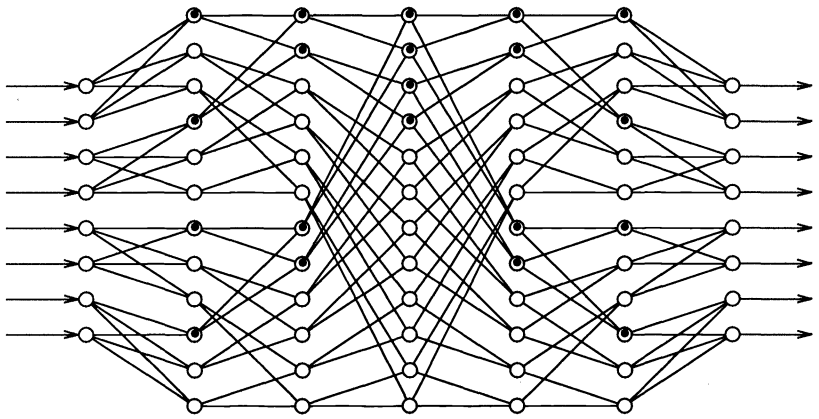

FIG. 3. *Cantor network.*

Define W_i to be the set of all edges (u, v) in stage i, for which u is accessible from x, but v is not. Define λ_i to be the sum of the weights on all edges in W_i, and note that $\lambda_i \geqq |W_i| s(\omega)$. If we let $h = \log_k N$, then the number of middle stage nodes (stage $h+1$) that are not accessible from x is given by

$$\sum_{i=2}^{h} k^{h-i}|W_i| \leqq \frac{1}{s(\omega)} \sum_{i=2}^{h} k^{h-i}\lambda_i.$$

It is easily verified that

$$\sum_{i=2}^{h} k^{h-i}\lambda_i \leqq (\beta-\omega)k^{h-2} + \sum_{i=2}^{h} k^{h-i}(k^{i-1}-k^{i-2})\beta.$$

To see this, note that each term in the summation on the left gives the weight used for blocking at stage i weighted by k^{h-i}. The terms in the summation on the right give an upper bound on the total weight of the traffic that could possibly block connections from x at stage i, similarly weighted by k^{h-i}. The initial term on the right corresponds to the weight from input port x that is available for blocking. The right side of the above inequality equals

$$\left(\frac{\beta-\omega}{k}\right)\left(\frac{N}{k}\right) + \beta\left(\frac{k-1}{k}\right)\left(\frac{N}{k}\right)\log_k(N/k) < \frac{\beta N}{k^2}(1+(k-1)\log_k (N/k)).$$

Combining this with the first inequality above, the number of inaccessible middle stage nodes is strictly less than

$$\frac{\beta N}{s(B)k^2}(1+(k-1)\log_k(N/k)) \leqq (mN/2k).$$

That is, fewer than half the middle stage nodes are inaccessible from x. By a similar argument, fewer than half of the middle stage nodes are inaccessible from y, meaning that there exists an available route from x to y. □

COROLLARY 3.1. *The Beneš network $B_{N,k}$ is strictly nonblocking if*

$$\beta \leqq \left[\frac{2}{ks(B)}(1+(k-1)\log_k(N/k))\right]^{-1}.$$

Proof. Substitute 1 for m in the statement of the theorem and solve for β. □

When we apply the theorem to the CS case for $k=2$, we find that the condition on m reduces to $m \geqq \log_2 N$, as is well known. For the UPS case with $k=2$, we have $m \geqq (\beta/(1-\beta))\log_2 N$; that is, we again need a speed advantage of two to match the value of m needed in the CS case.

We can construct wide-sense nonblocking networks for $\beta = 1$ by increasing m. We divide the connections into two subsets, with all connections of weight $\leqq \frac{1}{2}$ segregated from those with weight $>\frac{1}{2}$. Applying Theorem 3.2 we find that $m \geqq 4((k-1)/k)\log_k N$ is sufficient to carry each portion of the traffic, giving a total of $8((k-1)/k)\log_k N$ subnetworks.

4. Rearrangeably nonblocking networks. As mentioned earlier, a k-ary Beneš network [2], can be defined recursively as follows: $B_{k,k} = X_{k,k}$ and $B_{N,k} = X_{k,k} \bowtie B_{N/k,k} \bowtie X_{k,k}$. The Beneš network is rearrangeable in the CS case [2], and efficient algorithms exist to reconfigure it [12], [14]. In this section, we show that under certain conditions, the Beneš network can be rearrangeable for multirate traffic as well. We start by reviewing a proof of rearrangeability for the CS case, as we will be extending the technique for this case to the general environment.

Consider a set of connections $C = \{c_1, \cdots, c_r\}$ for $B_{N,k}$, where $c_i = \{x_i, y_i, 1\}$. There is at most one connection for each input and output port. The recursive structure of the network allows us to decompose the routing problem into a set of subproblems, corresponding to each of the stages in the recursion. The top level problem consists of selecting, for each connection, one of the k subnetworks $B_{N/k,k}$ through which to route. Given a solution to the top level problem, we can solve the routing problems for the k subnetworks independently. We can solve the top level problem most readily by reformulating it as a graph coloring problem. To do this, we define the connection graph $G_C = (V_C, E_C)$ for C as follows:

$$V_C = \{u_j, v_j | 0 \leqq j < N/k\},$$

$$E_C = \{\{u_{\lfloor x_i/k \rfloor}, v_{\lfloor y_i/k \rfloor}\} | 1 \leqq i \leqq r\}.$$

To solve the top level routing problem, we color the edges of G_C with colors $\{0, \cdots, k-1\}$ so that no two edges with a common endpoint share the same color. The colors assigned to the edges correspond to the subnetwork through which the connection must be routed. Because G_C is a bipartite multigraph with maximum vertex degree k, it is always possible to find an appropriate coloring [4], [9]. In brief, given a partial coloring of G_C, we can color an uncolored edge $\{u, v\}$ as follows. If there is a color $i \in \{0, \cdots, k-1\}$ that is not already in use at both u and v, we use it. Otherwise, we let i be any unused color at u and j be any unused color at v. We then find a maximal

alternating path from v, that is, a longest path with edges colored i or j, which has v as one of its endpoints. Because the graph is bipartite, the alternating path must end at some vertex other than u or v. Then, we interchange the colors i and j for all edges on the path and use i to color the edge $\{u, v\}$.

To prove results for rearrangeability in the presence of multirate traffic, we must generalize the graph coloring methods used in the CS case. We define a connection graph G_C for a set of connections C as previously, with the addition that each edge is assigned a weight equal to that of the corresponding connection. We say that a connection graph is (β, k)-*permissible* if the edges incident to each vertex can be partitioned into k groups whose weights sum to no more than β. A *legal* (β, m)-*coloring* of a connection graph is an assignment of colors in $\{0, \cdots, m-1\}$ to each edge so that at each vertex u, the sum of the weights of the edges of any given color is no more than β.

Now, suppose we let $Y = Y_1 \bowtie Y_2 \bowtie Y_3$, where Y_1 is a (k, m)-network, Y_2 is an $(N/k, N/k)$-network, and Y_3 is an (m, k)-network, and also let $0 \leqq \beta_1 \leqq \beta_2 \leqq 1$. Then, if Y_1, Y_2, Y_3 are rearrangeable for connection sets with $\beta \leqq \beta_2$, and every (β_1, k)-permissible connection graph for Y has a legal (β_2, m) coloring, then Y is rearrangeable for connection sets with $\beta \leqq \beta_1$.

Our first use of the coloring method is in the analysis of $B_{N,k}$. We apply it in a recursive fashion. At each stage of the recursion, the value of β may be slightly larger than at the preceding stage. The key to limiting the growth of β is the algorithm used for coloring the edges of the connection graph at each stage. We describe that algorithm next.

Let $G_C = (V_C, E_C)$ be an arbitrary connection graph. For each vertex u, let C_u be the set of edges involving u. Next, number the edges in C_u from zero, in nonincreasing order of their weight, and let $C_u^i \subseteq C_u$ comprise the edges with indices in the range $\{ik, \cdots, (i+1)k-1\}$ for $i \geqq 0$. Our coloring algorithm assigns unique colors to edges in each subset C_u^i. In particular, given a partial coloring of G_C, we color an uncolored edge $\{u, v\}$ belonging to C_u^i and C_v^j as follows. If there is a color $a \in \{0, \cdots, k-1\}$ that is not already in use within C_u^i and C_v^j, we use it. Otherwise, we let a_1 be any used color within C_u^i and a_2 be any unused color within C_v^j. We then find a maximal *constrained alternating path* from v, that is, a longest path with edges colored a_1 or a_2 with v as one of its endpoints and such that for every interior vertex w on the path, the path edges incident to w belong to a common set C_w^h. Because the graph is bipartite, the last edge cannot be a member of either C_u^i or C_v^j. Given the path, we interchange the colors a_1 and a_2 for all edges on the path, and use a_1 to color the edge $\{u, v\}$. We refer to this as the CAP (constrained alternating path) algorithm. We can route a set of connections through $B_{N,k}$ by applying CAP recursively. Our first theorem gives conditions under which this routing is guaranteed not to exceed the capacity of any edge in the network.

THEOREM 4.1. *The* CAP *algorithm successfully routes all sets of connections for* $B_{N,k}$ *for which*

$$\beta \leqq \left[1 + \frac{k-1}{k}(B/\beta)\log_k (N/k)\right]^{-1}.$$

Proof. Let G_C be any (β_1, k)-permissible connection graph with maximum edge weight B, and $\beta_1 \leqq 1 - B(k-1)/k$. We start by showing that the CAP algorithm produces a legal (β_2, k)-coloring for some $\beta_2 \leqq \beta_1 + B(k-1)/k$.

Let u be any vertex in G_C. Since each color is used at most once for each subset C_u^i of the edges at u, the largest weight that can be associated with any one color at

u is bounded by the sum of the weights of the heaviest edges in C_u^i for all i. Because the edges were assigned to the C_u^i in nonincreasing order of weight, the total weight of like-colored edges at u is at most $B+(k\beta_1-B)/k=\beta_1-B(k-1)/k$.

Given this, if we route a set of connections through $B_{N,k}$ by recursive application of the CAP algorithm, we will succeed if

$$\beta+\left(\frac{k-1}{k}\right)B\log_k(N/k)\leqq 1,$$

or equivalently, $\beta\leqq[1+((k-1)/k)(B/\beta)\log_k(N/k)]^{-1}$. □

As an example, if $N=2^{16}$, $k=4$, and $B=\beta$, it suffices to have $\beta\leqq 0.16$. We can improve on this result by modifying the CAP algorithm. Because the basic algorithm treats each stage in the recursion completely independently, it can in the worst-case concentrate traffic unnecessarily. The algorithm we consider next attempts to balance the traffic between subnetworks when constructing a coloring. We describe the algorithm only for the case of $k=2$, although extension to higher values is possible.

Let G_C be a connection graph for $B_{N,2}$. G_C comprises vertices $u_0,\cdots,u_{(N/2)-1}$ corresponding to nodes in stage one of $B_{N,2}$ and vertices $v_0,\cdots,v_{(N/2)-1}$ corresponding to nodes in stage $2(\log_2 N-1)$. We have an edge from u_1 to v_j corresponding to each connection to be routed between the corresponding nodes of $B_{N,2}$. We note that for $0\leqq i<N/4$, the nodes corresponding to u_{2i} and u_{2i+1} have the same successors in stage two of $B_{N,2}$. Similarly, the nodes in $B_{N,2}$ corresponding to v_{2i} and v_{2i+1} have common predecessors. We say such vertex pairs are *related.*

Let a and b be any pair of related vertices in G_C. The idea behind the modified coloring algorithm is to balance the coloring at a and b so that the total weight associated with each color is more balanced, thus limiting the concentration of traffic in one subnetwork. The technique used to balance the coloring is to constrain it so that when appropriate, the edges of largest weight at a and b are assigned different colors; hence the corresponding connections are routed through distinct subnetworks. For any vertex v in G_C, let $\omega_0(v)\geqq\omega_1(v)\geqq\cdots$ be the weights of the edges defined at v, let $W_0(v)=\sum_{i\geqq 0}\omega_{2i}$, $W_1(v)=\sum_{i\geqq 0}\omega_{2i+1}$, and $W(v)=W_0(v)$. Also, let $x(v)=W_0(v)-W_1(v)$.

The *modified* CAP *algorithm* proceeds as follows. For each pair of related vertices a and b in G_C, if $x(a)+x(b)>B$, add a dummy node z to G_C with edges of weight two connecting it to a and b. We then color this modified graph as in the original CAP algorithm, and on completion we simply ignore the added nodes and edges. The effect of adding the dummy node is to constrain the coloring at a and b so that the edges of maximum weight are assigned distinct colors. We apply this procedure recursively except that in the last step of the recursion we use the original CAP algorithm.

THEOREM 4.2. *The modified* CAP *algorithm successfully routes all sets of connections for* $B_{N,2}$ *for which*

$$\beta\leqq[1+\tfrac{1}{4}(B/\beta)\log_2 N]^{-1}.$$

Proof. Let a and b be related vertices with $\omega_0(a)\geqq\omega_0(b)$. Let $z_1=\max\{W(a),W(b)\}$ and let z_2 be the total weight on edges colored 0 at a and b. If $x(a)+x(b)\leqq B$, no dummy vertex is added and we have that

$$z_2\leqq W_0(a)+W_0(b)\leqq(z_1+x(a))/2+(z_1+x(b))/2\leqq z_1+B/2.$$

Similarly, if $x(a)+x(b)\geqq B$, a dummy vertex is added and we have that

$$z_2\leqq\omega_0(a)+W_1(a)+W_1(b)\leqq\omega_0(a)+(z_1-x(a))/2+(z_1-x(b))/2\leqq z_1+B/2.$$

Thus, the total weight on a node in stage i is at most $2\beta+(i-1)B/2$. In particular, this holds for $i=\log_2 N-1$. Also note that for a link (u, v) in stage $j\leqq\log_2 N-2$, the maximum weight is at most B plus half the weight on u. For a link (u, v) in stage $\log_2 N-1$, the weight is at most $B/2$ plus the maximum weight at u, since in this last step the original CAP algorithm was used. Consequently, no link carries a weight greater than $\beta+(B/4)\log_2 N$. □

Theorem 4.2 implies for example that if $\beta=B=0.2$, a binary Beneš network with 2^{16} input and output nodes is rearrangeable. Theorem 4.1, on the other hand gives rearrangeability in this case only if β is limited to about 0.118. It turns out that we can obtain a still stronger result by exploiting some additional properties of the original CAP algorithm.

THEOREM 4.3. *The* CAP *algorithm successfully routes all sets of connections for* $B_{N,k}$ *for which*

$$\beta\leqq[\max\{2, \lambda-\ln\lfloor\beta/B\rfloor\}]^{-1},$$

where $\lambda=2+\ln\log_k(N/k)$.

So, for example, if $k=4$, $N=2^{16}$, and $\beta/B=2$, we can have $\beta=0.3$. The proof of Theorem 4.3 requires the following lemmas.

LEMMA 4.1. *Let* r *be any positive integer. If a set of connections for* $B_{N,k}$ *is routed by repeated applications of the* CAP *algorithm, no link will carry more than* r *connections of weight* $>\beta/(r+1)$.

Proof. (By induction.) The condition is true by definition for the external links. If the assertion holds at a given level of recursion, the connection graph for the next stage will have at most rk edges of weight greater than $\beta/(r+1)$ at any given node u. These edges are all contained in $C_u^0\cup\cdots\cup C_u^{r-1}$, implying that the CAP algorithm will use a single color for at most r of them. □

If l is a link in $B_{N,k}$, we define S_l^j to be the set of links l' in stage j for which there is a path from l' to l. If a given set of connections uses a link l, we refer to one connection of maximum weight as the *primary connection* on l and all others as *secondary connections.* We note that if the CAP algorithm is used to route a set of connections through $B_{N,k}$, then if there are $r+1$ connections of weight $\geqq\omega$ on a link $l=(u, v)$, there are at least $1+kr$ connections of weight $\geqq\omega$ on the links entering u.

LEMMA 4.2. Let $0\leqq i\leqq\log_k(N/k)$, *let* l *be a stage* i *link in* $B_{N,k}$ *carrying connections routed by the* CAP *algorithm, and let the connection weights be* $\omega_0\geqq\omega_1\geqq\cdots\geqq\omega_h$. *For* $0\leqq t\leqq h$ *and* $0\leqq s\leqq\min\{i, t\}$, *there are at least* $(t-s+1)k^s+sk^{s-1}$ *connections of weight* $\geqq\omega_t$ *on the links in* S_l^{i-s}.

Proof. The proof is by induction on s. When $s=0$, the lemma asserts that there are $t+1$ connections of weight $\geqq\omega_t$ which is trivially true. Assume then that the lemma holds for $s-1$; that is, there exist $(t-s+2)k^{s-1}+(s-1)k^{s-2}$ connections of weight $\geqq\omega_t$ on the links in S_l^{i-s+1}. Because $|S_l^{i-s+1}|=k^{s-1}$, by the pigeon-hole principle, at least $(t-s+1)k^{s-1}+(s-1)k^{s-2}$ of these are secondary connections. This implies that there at least

$$k^{s-1}+k[(t-s+1)k^{s-1}+(s-1)k^{s-2}]=(t-s+1)k^s+sk^{s-1}$$

connections of weight $\geqq\omega_t$ in S_l^{i-s}. □

Proof of Theorem 4.3. Consider an arbitrary set of connections for $B_{N,k}$ satisying the bound on β given in the theorem, and assume that the CAP algorithm is used to route the connections. Let l be any link in stage i, where $i\leqq\log_k(N/k)$, and let the weights of the connections on l be $\omega_0\geqq\cdots\geqq\omega_h$. Let r be the positive integer defined by $\beta/(r+1)<B\leqq\beta/r$ (equivalently, $r=\lfloor\beta/B\rfloor$). By Lemma 4.2, S_l^0 carries connections

with a total weight of at least

$$\omega_0 + k\omega_1 + k^2\omega_2 + \cdots + k^{i-1}\omega_{i-1} + k^i(\omega_i + \cdots + \omega_h).$$

Since the total weight on S_l^0 is at most βk^i, we have

$$\beta k^i \geqq \sum_{j=0}^{i-1} k^j \omega_j + k^i \sum_{j=i}^{h} \omega_j.$$

From this and Lemma 4.1, we have that

$$\sum_{j=0}^{r-1} \omega_j + \sum_{j=r}^{i-1} \omega_j + \sum_{j=i}^{h} \omega_j \leqq Br + \beta \sum_{j=r}^{i-1} \frac{1}{j+1} + \beta \leqq 2\beta + \beta \sum_{j=r+1}^{\log_k (N/k)} \frac{1}{j}.$$

If $\lfloor \beta/B \rfloor \geqq \log_k (N/k)$, the summation vanishes and we have that the weight on l is $\leqq 2\beta$. Otherwise, the weight is bounded by

$$\leqq \beta(2 + \ln \log_k (N/k)/r) = \beta(\lambda - \ln \lfloor \beta/B \rfloor).$$

So, if β satisfies the bound in the statement of the theorem, the weight on l is no more than one. By a similar argument, the weight on any link in stage j for $j \geqq \log_k N$ is at most one. □

We now turn our attention to the Cantor network and give conditions for rearrangeability in that case.

THEOREM 4.4. *Let $\varepsilon > 0$ and $\lfloor \beta/B \rfloor \leqq \log_k (N/k)$. $K_{N,k,m}$ is rearrangeable if*

$$m \geqq \lceil (1+\varepsilon)(\lambda - \ln \lfloor \beta/B \rfloor) \rceil + 2(2 + \log_2 \lambda + \log_2 (B/c)),$$

where $\lambda = 2 + \ln \log_k (N/k)$ and $c = 1 - \beta\lambda/(1+\varepsilon)(\lambda - \ln \lfloor \beta/B \rfloor)$.

The proof of Theorem 4.4 requires several lemmas.

LEMMA 4.3. *Let α, r be $\geqq 1$ with r and αr integers. $B_{N,k}$ is rearrangeable for sets of connections with weights ω that satisfy $\beta/(\alpha r + 1) < \omega \leqq \beta/r$ and $\alpha \leqq e^{(1/\beta)-1}$.*

Proof. By Lemma 4.2, if $B_{N,k}$ is routed using the CAP algorithm, no link contains more than αr connections. The sum of the weights of the connections on any given link is

$$\leqq r\left(\frac{\beta}{r}\right) + \frac{\beta}{r+1} + \cdots + \frac{\beta}{\alpha r} = \beta + \beta \sum_{i=r+1}^{\alpha r} 1/i \leqq \beta(1 + \ln \alpha) \leqq 1. \qquad \square$$

LEMMA 4.4. *Let α, r be $\geqq 1$ with r and αr integers. $K_{N,k,m}$ is rearrangeable for sets of connections with weights ω that satisfy*

$$\beta/(\alpha r + 1) < \omega \leqq \beta/r \quad \text{and} \quad \alpha \leqq \exp\left[\frac{rm}{\beta(r+m-1)} - 1\right].$$

Proof. The connections can be distributed among the m Beneš subnetworks using the CAP algorithm; the resulting maximum port weight on the subnetworks is

$$\beta' \leqq \frac{\beta}{m} + \frac{(m-1)\beta}{mr} = \frac{\beta(r+m-1)}{mr}.$$

By Lemma 4.3, each subnetwork can be successfully routed if

$$\alpha \leqq \exp\left[\frac{rm}{\beta(r+m-1)} - 1\right] \leqq e^{(1/\beta')-1}. \qquad \square$$

LEMMA 4.5. *$K_{N,k,m}$ is rearrangeable if $m \geqq 2(2 + \log_2 (B/b))$.*

Proof. Define h, i by letting

$$\frac{\beta}{2^{h+1}} < B \leqq \frac{\beta}{2^h} \quad \text{and} \quad \frac{\beta}{2^{i+1}} < b \leqq \frac{\beta}{2^i}.$$

By Lemma 4.4, two of the Beneš subnetworks are sufficient to route connections with weights in the interval $(2^{-(j+1)}\beta, 2^{-j}\beta]$ for any $j \geqq 0$. For $h \leqq j \leqq i$ then, we devote two subnetworks for the connections with weights in $(2^{-(j+1)}\beta, 2^{-j}\beta]$. The total number of subnetworks required is at most

$$2(i-h+1) \leqq 2(2+\log_2(B/b)) \leqq m. \qquad \square$$

LEMMA 4.6. *$K_{N,k,m}$ is rearrangeable if*

$$\frac{(\beta - B)\lambda}{1 - B\lambda} \leqq m \leqq \frac{\beta}{B},$$

where $\lambda = 2 + \ln \log_k (N/k)$.

Proof. We distribute the traffic among the m Beneš subnetworks using the CAP algorithm. The resulting maximum port weight is β', where

$$\beta' \leqq \frac{\beta}{m} + \frac{m-1}{m} B = B + \frac{\beta - B}{m}.$$

By Theorem 4.3, the maximum weight on any link is at most

$$\beta'(\lambda - \ln \lfloor \beta'/B \rfloor) \leqq B\lambda + \frac{(\beta - B)\lambda}{m} \leqq 1. \qquad \square$$

Proof of Theorem 4.4. Let $B' = c/\lambda$. By Lemma 4.5, all the traffic with weight $> B'$ can be handled using

$$2(2 + \log_2 \lambda + \log_2 B/c)$$

of the Beneš subnetworks. By Lemma 4.6, the remaining traffic can be carried using

$$\frac{(\beta - B')\lambda}{1 - B'\lambda} = \frac{\beta\lambda - c}{1 - c} \leqq \lceil (1+\varepsilon)(\lambda - \ln \lfloor \beta/B \rfloor) \rceil$$

subnetworks. $\square$

Theorem 4.4 holds when $\lfloor \beta/B \rfloor \leqq \log_k (N/k)$. When this condition does not hold, $K_{N,k,m}$ is rearrangeable with m between one and three, depending on the value of β. In particular, if $\beta \leqq \frac{1}{2}$, $m = 1$ is sufficient using Theorem 4.1. If $(\frac{1}{2}) < \beta \leqq 1 - 1(2 \log_k (N/k))$, $m = 2$ is sufficient since in this case the traffic can be split among the two subnetworks so that each experience a maximum port weight of at most $\frac{1}{2}$.

The graph coloring methods used to route connections for $B_{N,k}$ can also be applied to networks that "expand" at each level of recursion. Let $C^*_{k,k,m} = X_{k,k}$ and for $N = k^i$, $i > 1$, let $C^*_{N,k,m} = X_{k,m} \bowtie C^*_{N/k,N/k} \bowtie X_{m,k}$. The following theorem gives conditions under which $C^*_{N,k,m}$ is rearrangeable.

THEOREM 4.5. *$C^*_{N,k,m}$ is rearrangeable if*

$$\beta \leqq \left[1/\gamma^c + \frac{m-1}{m} \frac{B}{\beta} \frac{1 - 1/\gamma^c}{1 - 1/\gamma} \right]^{-1},$$

where $\gamma = m/k$ *and* $c = \log_k (N/k)$.

Proof. We use the CAP algorithm to route the connections. If we let β_i be the largest resulting weight on a link in stage i for $1 \leqq i \leqq \log_k (N/k)$, we have

$$\beta_i \leqq B + \frac{k\beta_{i-1} - B}{m} = (\beta_{i-1}/\gamma) + \frac{m-1}{m} B \leqq (\beta_0/\gamma^i) + \frac{m-1}{m} B \frac{1-(1/\gamma)^i}{1-1/\gamma} \leqq 1. \qquad \square$$

So, for example, $C^*_{N,k,2k-1}$ is rearrangeable, if $B \leqq \frac{1}{2}$.

5. Closing remarks. In recent years, there has been a growing interest in switching systems capable of carrying general multirate traffic, in order to be able to support a wide range of applications including voice, data, and video. A variety of research teams have constructed high-speed switching systems of moderate size [7], [10], [19], [21], but little consideration has yet been given to the problem of constructing very large switching systems using such modules as building blocks. The theory we have developed here is a first step to understanding the blocking behavior of such systems.

In this paper, we have introduced what we feel is an important research topic and have given some fundamental results. There are several directions in which our work may be extended. While we have good constructions for strictly nonblocking networks, we expect that our results for rearrangeably nonblocking networks can be improved. In particular, we suspect that the Beneš network can be operated in a rearrangeable fashion with just a constant speed advantage. Another interesting topic is nonblocking networks for multipoint connections. While this has been considered for space-division networks [1], [8], [11], [17], it has not been studied for networks supporting multirate traffic. Another area to consider is determination of blocking probability for multirate networks. We expect this to be highly dependent on the particular choice of routing algorithm.

MINIMIZING SCHEDULE LENGTH SUBJECT TO MINIMUM FLOW TIME*

JOSEPH Y-T. LEUNG† AND GILBERT H. YOUNG†

Abstract. The problem of scheduling n independent tasks on $m \geqq 1$ identical processors, with the objective of minimizing the schedule length under the constraint that it must have minimum flow time, is considered. For nonpreemptive scheduling, it is known that the problem is NP-hard. This paper shows that the problem is a lot easier for preemptive scheduling. Specifically, an $O(n \log n)$ time algorithm to find an optimal preemptive schedule is given. This algorithm generates schedules with at most $m-1$ preemptions. It is also shown that an optimal nonpreemptive schedule can be almost twice as long as an optimal preemptive schedule. The results suggest that preemption is extremely beneficial in simultaneously minimizing the flow time and the schedule length.

Key words. schedule length, flow time, nonpreemptive scheduling, preemptive scheduling, NP-hard

1. Introduction. In deterministic scheduling theory, schedule length and flow time are two commonly studied performance measures. Minimizing the schedule length has the effect of increasing the processor utilization, while minimizing the flow time tends to decrease the average number of unfinished tasks in the system. To obtain good overall performance, a system should aim at optimizing both performance measures. Unfortunately, the two criteria seem to conflict with each other. Scheduling algorithms that do well with respect to one measure tend to do poorly for the other. For example, the LPT rule [9] is known to produce schedules that are reasonably short, yet the schedules produced tend to have large flow time. On the other hand, the SPT rule [5] is known to be an optimal algorithm for minimizing the flow time, but it is usually outperformed by the LPT rule in producing short schedules. With the exception of [4], [7], [8], most of the scheduling algorithms studied in the literature have concentrated on just one of the two criteria. In this paper, we continue the work of [4], [7], [8] by studying the scheduling problem of optimizing both performance measures simultaneously.

Formally, our problem can be stated as follows: We are given a set $TS = \{T_1, T_2, \cdots, T_n\}$ of n independent tasks with execution times $\{p_1, p_2, \cdots, p_n\}$ to be scheduled on $m \geqq 1$ identical processors. If S is a schedule of TS on the m processors, then $f_i(S)$ denotes the finishing time of T_i in S. The schedule length of S, denoted by $SL(S)$, is defined to be $SL(S) = \max_{i=1}^{n} \{f_i(S)\}$, and the flow time of S, denoted by $FT(S)$, is defined to be $FT(S) = \sum_{i=1}^{n} f_i(S)$. A minimum length schedule, S^+, is one such that $SL(S^+) \leqq SL(S)$ for all schedules S, and a minimum flow-time schedule, S^-, is one such that $FT(S^-) \leqq FT(S)$ for all schedules S. Our goal is to find a schedule, S^*, that has the minimum schedule length among all minimum flow-time schedules. That is, S^* is one such that $FT(S^*) = FT(S^-)$ and $SL(S^*) \leqq SL(S^-)$ for all schedules S^-.

The set of tasks can be scheduled nonpreemptively or preemptively on the processors. In nonpreemptive scheduling, a task, once execution has begun, must proceed to completion. In contrast, preemptive scheduling allows a task to be preempted; execution is later resumed, sometimes on a different processor. It is assumed, however, that there is no time loss in preemption. We shall use the symbols S_{NP}^+ and S_P^+ to denote a minimum-length nonpreemptive schedule and a minimum-length preemptive

schedule, respectively. Similarly, S_{NP}^{-}, S_{P}^{-}, S_{NP}^{*}, and S_{P}^{*} are defined analogously. It is known that finding a S_{NP}^{+} is strongly NP-hard [6]. This problem, known in the literature as the multiprocessor scheduling problem or the makespan minimization problem, has been studied by many researchers [2], [3], [9], [10], [12], [13], [15]. Due to the intractability of the problem, most research efforts have been directed towards designing and analyzing fast approximation algorithms [2], [9], [10], [12], or studying special cases of the problem which admit polynomial-time solutions [3], [13], [15]. Finding a S_{P}^{+} is a lot easier [14]; it can be done in $O(n)$ time. In fact, the schedule length of S_{P}^{+} is simply given by $SL(S_{P}^{+}) = \max\{\max_{i=1}^{n}\{p_i\}, (1/m)\sum_{i=1}^{n} p_i\}$. Recently, it has been shown [11] that for any given set of independent tasks to be scheduled on $m \geqq 1$ identical processors, we have $SL(S_{NP}^{+})/SL(S_{P}^{+}) \leqq 2m/(m+1)$. Furthermore, the bound is achievable for every $m \geqq 1$. Thus, when m gets large, a minimum-length non-preemptive schedule can be almost twice as long as a minimum-length preemptive schedule. Hence, preemption can reduce the length of a schedule by a significant proportion.

Finding a S_{NP}^{-} can be done in $O(n \log n)$ time. The well-known SPT rule [5] always constructs a S_{NP}^{-} and it works as follows: Add enough zero-execution-time tasks so that n becomes an integer multiple of m. Sort the tasks in nondecreasing order of their execution times. Divide the tasks into $r = n/m$ ranks, with tasks $T_{(j-1)m+1}$, $T_{(j-1)m+2}, \cdots, T_{(j-1)m+m}$ in rank j, $1 \leqq j \leqq r$. Assign the tasks to the processors rank by rank, in order of increasing rank, each task in a given rank being assigned to a different processor. A schedule constructed by the SPT rule will be called an SPT schedule. Since there are $m!$ ways of assigning the tasks in any given rank, there are $(m!)^r$ SPT schedules for a set of rm tasks to be scheduled on m processors. Figure 1 shows two SPT schedules for a particular set of tasks. Observe that all SPT schedules give the same minimum flow time, $FT(S_{NP}^{-}) = \sum_{j=1}^{r}(r-j+1)\sum_{k=1}^{m} p_{(j-1)m+k}$. It has been shown [14] that preemption cannot reduce the minimum flow time. Thus, $FT(S_{P}^{-}) = FT(S_{NP}^{-}) = \sum_{j=1}^{r}(r-j+1)\sum_{k=1}^{m} p_{(j-1)m+k}$.

The problem of finding an S_{NP}^{*} has been shown to be NP-hard [1]. In [4], several fast approximation algorithms have been proposed and their worst-case performance bounds analyzed. In this paper, we give an $O(n \log n)$ time algorithm to find an S_{P}^{*}. Our algorithm generates schedules with at most $m-1$ preemptions. The set of tasks given in Fig. 2 shows that $SL(S_{NP}^{*})/SL(S_{P}^{*}) = 2m/(m+1)$. From the result in [11], $2m/(m+1)$ is also an upper bound of $SL(S_{NP}^{*})/SL(S_{P}^{*})$ for any given set of tasks. Thus, preemption can be very beneficial in reducing the schedule length of a minimum flow-time schedule.

Gonzalez [7] has given an $O(n \log n + nm)$-time algorithm to find a preemptive schedule with the minimum flow time subject to the constraint that the length of the schedule is no more than a given parameter β. It is tempting to suggest that Gonzalez's algorithm can be used to find an S_{P}^{*} by repeatedly calling his algorithm with the parameter β, where β is the schedule length obtained in a binary search on an interval in which the minimum schedule length lies. However, the binary search may not terminate in a finite amount of time because the schedule length of S_{P}^{*} may be a real number even when the execution times of the tasks are integers. Moreover, even if the number of iterations in the binary search can be bounded by a polynomial function of the size of the input, the overall running time of the algorithm will be substantially higher than that of our algorithm.

As will be seen in the next section, our algorithm employs a subroutine to preemptively schedule a subset of tasks to meet a certain deadline. This subroutine is actually a slight modification of Sahni's algorithm [16], which has been shown to solve

T_i	T_1	T_2	T_3	T_4	T_5	T_6
p_i	2	5	6	6	8	10

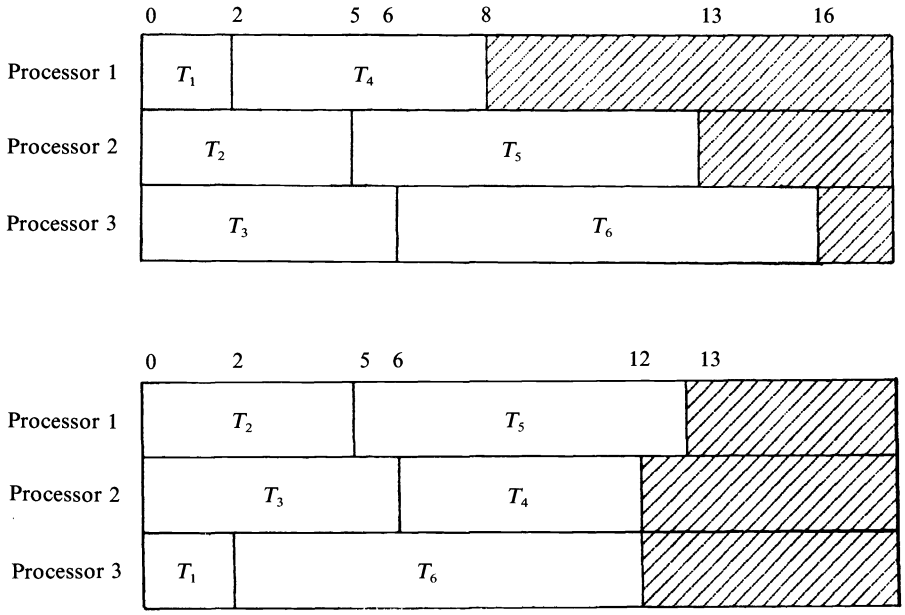

FIG. 1. *Two* SPT *schedules for a set of tasks.*

the Deadline Scheduling problem. In the Deadline Scheduling problem, we are given $m \geqq 1$ identical processors and a set of n independent tasks $TS = \{T_1, T_2, \cdots, T_n\}$ with execution times $\{p_1, p_2, \cdots, p_n\}$ and deadlines $\{d_1, d_2, \cdots, d_n\}$. The problem is to determine if there is a preemptive schedule of TS on the m processors such that all deadlines are met. Such a schedule is called a feasible schedule. The idea of Sahni's algorithm is to schedule the tasks in nondecreasing order of their deadlines. Assume the tasks have been indexed such that $d_1 \leqq d_2 \leqq \cdots \leqq d_n$, and consider the scheduling of task T_i. Let $F(k)$, $1 \leqq k \leqq m$, denote the finishing time of processor k after T_{i-1} has been scheduled. (Initially, $F(k) = 0$ for all $1 \leqq k \leqq m$.) Let $k_1, k_2, \cdots, k_{x_i}$ be the indexes of the processors such that $F(k_1) \leqq F(k_2) \leqq \cdots \leqq F(k_{x_i}) < d_i$. The scheduling of T_i is done by one of the following four cases: (1) If $p_i > d_i - F(k_1)$, then output "infeasible" (i.e., there are no feasible schedules for TS on m processors). (2) If $p_i \leqq d_i - F(k_{x_i})$, then schedule T_i completely on processor k_{x_i} and set $F(k_{x_i})$ to be $F(k_{x_i}) + p_i$. (3) If $p_i = d_i - F(k_l)$ for some $1 \leqq l < x_i$, then schedule T_i completely on processor k_l and set $F(k_l)$ to be d_i. (4) If none of the above three cases apply, let processor k_l be such that $d_i - F(k_{l+1}) < p_i < d_i - F(k_l)$. Schedule $d_i - F(k_{l+1})$ of T_i on processor k_{l+1} and the remainder of T_i on processor k_l. Set $F(k_{l+1})$ to be d_i and $F(k_l)$ to be $F(k_l) + (p_i - (d_i - F(k_{l+1})))$. The tasks are scheduled iteratively by the above procedure until

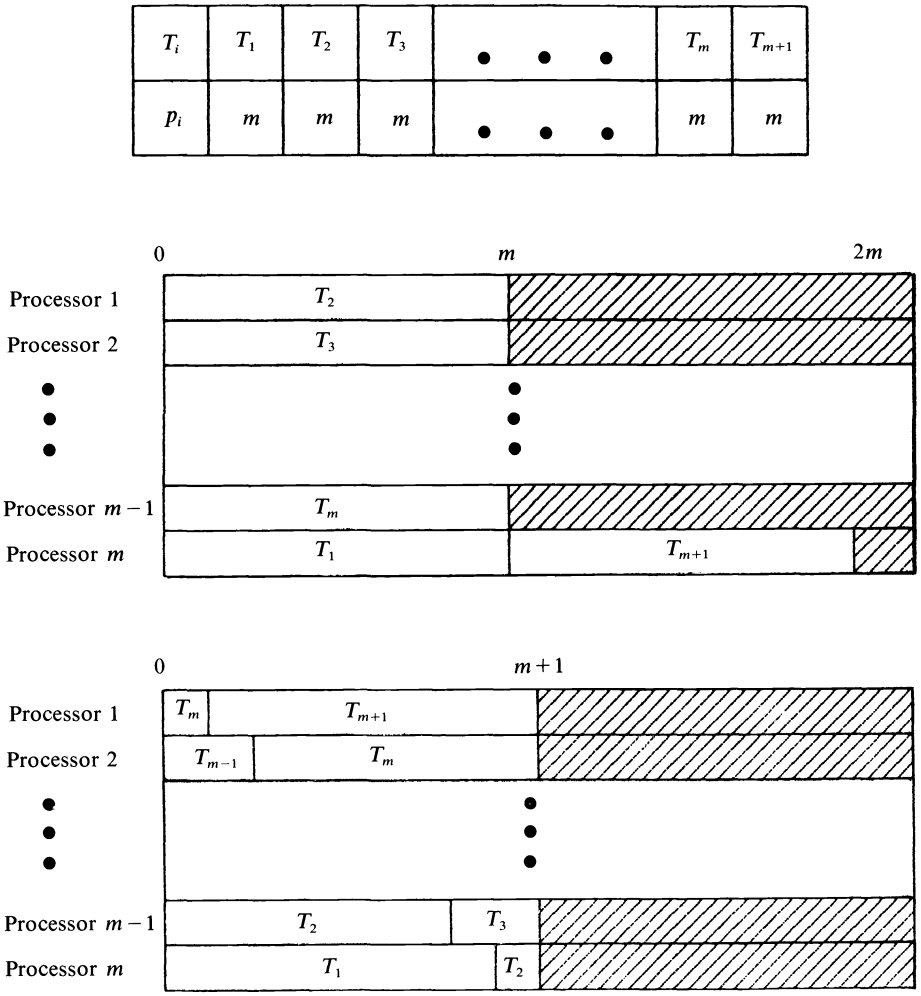

FIG. 2. *A task set such that* $SL(S^*_{NP})/SL(S^*_P) = 2m/(m+1)$.

it outputs "infeasible," or all tasks have been scheduled. In the latter case, the schedule constructed by the algorithm is a feasible schedule.

We now define some conventions and notations that will be used consistently throughout the remainder of this paper. For a given set of n tasks $TS = \{T_1, T_2, \cdots, T_n\}$, to be scheduled on m processors, we always assume that the tasks have been indexed such that $p_1 \leqq p_2 \leqq \cdots \leqq p_n$, and that $n = rm$ for some integer $r \geqq 1$. For each $1 \leqq j \leqq r$, we call the tasks $T_{(j-1)m+1}$, $T_{(j-1)m+2}, \cdots, T_{(j-1)m+m}$ the rank j tasks. Furthermore, we say that rank $(T_i) = j$ if T_i is a rank j task. We define a particular SPT schedule, denoted by $SPT^{\#}$, as follows: For each $1 \leqq k \leqq m$, assign the tasks $T_k, T_{m+k}, \cdots, T_{(r-1)m+k}$ to processor k. It is easy to see that $SPT^{\#}$ has the longest schedule length among all SPT schedules for any given set of tasks. Furthermore, if $F(k)$ denotes the finishing time of processor k in the $SPT^{\#}$ schedule, then we have $F(k) = \sum_{j=1}^{r} p_{(j-1)m+k}$ for each $1 \leqq k \leqq m$. Clearly, we have $F(k) \leqq F(k+1)$ for each $1 \leqq k < m$. Finally, an optimal schedule always means an S^*_P.

The organization of the paper is as follows. In § 2, we describe our algorithm and analyze its running time. In § 3, we prove that our algorithm always constructs an

optimal schedule for any given set of tasks. Finally, we draw some concluding remarks in the last section.

2. The algorithm. In this section, we shall describe our algorithm and analyze its running time. Given a set of n tasks, $TS=\{T_1, T_2, \cdots, T_n\}$, to be scheduled on m processors, our algorithm constructs a schedule as follows. First, we construct the $SPT^{\#}$ schedule for the tasks in the first $r-1$ ranks. Next, we compute the optimal schedule length, denoted by OSL, using the finishing times of the processors in the $SPT^{\#}$ schedule and the execution times of the rank r tasks. As will be shown later, $OSL=\max_{k=1}^{m}\{\sum_{l=1}^{k}(\mathrm{F}(l)+p_{n-l+1})/k\}$, where $\mathrm{F}(l)$, $1\leqq l\leqq m$, denotes the finishing time of processor l in the $SPT^{\#}$ schedule. Finally, we preemptively schedule the rank r tasks into the $SPT^{\#}$ schedule such that (1) no two rank r tasks finish on the same processor, (2) no processors have idle times before their finishing times, and (3) no tasks finish later than OSL. Note that the first two conditions are to ensure that the schedule has the minimum flow time. The last step of our algorithm is done by a subroutine that is a modification of Sahni's algorithm. The rank r tasks are preemptively scheduled to meet the deadline OSL in the same manner as Sahni's procedure, with the following three exceptions. First, Case 1 of Sahni's procedure no longer applies, since all tasks can meet the deadline OSL. Second, if a task T_i is scheduled on processor k_{x_i} by Case 2 of Sahni's procedure, then processor k_{x_i} will no longer be used to execute any subsequent tasks. This is to ensure that no two rank r tasks finish on the same processor. Finally, the tasks are scheduled in nonincreasing order of their execution times. A full description of our algorithm, to be called Algorithm B, is given below. A schedule produced by Algorithm B will be called a B-schedule.

ALGORITHM B

Input: A set $TS=\{T_1, T_2, \cdots, T_n\}$ of n tasks to be scheduled on $m\geqq 1$ identical processors.

Output: An optimal schedule of TS on the m processors.

Method:

1. Construct the $SPT^{\#}$ schedule for the tasks $T_1, T_2, \cdots, T_{(r-1)m}$.
2. $\mathrm{F}(k)\leftarrow\sum_{j=1}^{r-1}p_{(j-1)m+k}$ for each $1\leqq k\leqq m$.
3. $OSL\leftarrow\max_{k=1}^{m}\{\sum_{l=1}^{k}(\mathrm{F}(l)+p_{n-l+1})/k\}$.
4. Initialize the set of available processors to be processors $1, 2, \cdots, m$. Schedule the tasks $T_n, T_{n-1}, \cdots, T_{n-m+1}$ in that order. Suppose we are scheduling task T_i. Let $k_1, k_2, \cdots, k_{x_i}$ be the indexes of the available processors such that $\mathrm{F}(k_1)\leqq\mathrm{F}(k_2)\leqq\cdots\leqq\mathrm{F}(k_{x_i})<OSL$. T_i will be scheduled by one of the following three rules: (1) If $p_i\leqq OSL-\mathrm{F}(k_{x_i})$, then schedule T_i completely on processor k_{x_i}. $\mathrm{F}(k_{x_i})\leftarrow\mathrm{F}(k_{x_i})+p_i$. Delete processor k_{x_i} from the set of available processors. (2) If $p_i=OSL-\mathrm{F}(k_l)$ for some $1\leqq l<x_i$, then schedule T_i completely on processor k_l. $\mathrm{F}(k_l)\leftarrow OSL$. Delete processor k_l from the set of available processors. (3) If the above two cases do not apply, then let l be such that $OSL-\mathrm{F}(k_{l+1})<p_i<OSL-\mathrm{F}(k_l)$. Schedule $OSL-\mathrm{F}(k_{l+1})$ of T_i on processor k_{l+1} and the remainder of T_i on processor k_l. $\mathrm{F}(k_l)\leftarrow\mathrm{F}(k_l)+(p_i-(OSL-\mathrm{F}(k_{l+1})))$. $\mathrm{F}(k_{l+1})\leftarrow OSL$. Delete processor k_{l+1} from the set of available processors. □

Shown in Fig. 3 is a set of 12 tasks to be scheduled on four processors. Figure 3(b) shows the $SPT^{\#}$ schedule constructed in step 1 of the algorithm. The finishing times of processors 1, 2, 3, and 4 are 7, 9, 12, and 14, respectively. Step 3 of the algorithm gives $OSL=\max\{(7+16)/1, (7+16+9+16)/2, (7+16+9+16+12+10)/3, (7+16+9+16+12+10+14+10)/4\}=24$. In step 4, T_{12} is scheduled by rule (3) on

T_i	T_1	T_2	T_3	T_4	T_5	T_6	T_7	T_8	T_9	T_{10}	T_{11}	T_{12}
p_i	2	3	4	5	5	6	8	9	10	10	16	16

FIG. 3. *An example showing Algorithm B.*

processors 1 and 2. Then, processor 2 is deleted from the available set of processors. T_{11} is scheduled by rule (2) on processor 1, which is then deleted from the available set of processors. Finally, T_{10} and T_9 are both scheduled by rule (1) on processors 4 and 3, respectively.

The running time of Algorithm B is determined as follows. Steps 1 and 2 take $O(n)$ time. Step 3 takes $O(m)$ time. Step 4 can be implemented to run in $O(m \log m)$ time. Thus, the overall running time of Algorithm B is $O(n+m \log m)$ time. If we include the time needed to sort the tasks into nondecreasing order of their execution times, then the overall running time of the algorithm is $O(n \log n)$ time, since n is assumed to be larger than m. It is easy to see that a B-schedule has at most $m-1$ preemptions.

3. Algorithm correctness. In this section, we shall show that Algorithm B always constructs an optimal schedule. We first show that a B-schedule always gives the minimum flow time. Observe that in step 4 of Algorithm B, the rank r tasks are scheduled

in such a way that no two tasks finish on the same processor. This follows from the observation that if a task is scheduled by rules (1) or (2), then the processor to which it is assigned will not be used to schedule any subsequent tasks. If a task is scheduled by rule (3), then it finishes on processor k_{l+1} but not on processor k_l. Furthermore, processor k_{l+1} will not be used to schedule any subsequent tasks. Since a task is scheduled by one of the three rules, no two tasks can finish on the same processor. With this observation in mind, it is readily verified that the flow time of a B-schedule is $\sum_{j=1}^{r}(r-j+1)\sum_{k=1}^{m} p_{(j-1)m+k}$, which is the minimum as stated in § 1. For the remainder of this section, we shall concentrate on showing that a B-schedule has the minimum schedule length among all minimum flow-time schedules.

Let S be a schedule of $TS=\{T_1, T_2, \cdots, T_n\}$ on m processors. With respect to S, we can define an ordering of the tasks $\rho(S)=(T_{i_1}, T_{i_2}, \cdots, T_{i_n})$ such that $f_{i_1}(S) \leqq f_{i_2}(S) \leqq \cdots \leqq f_{i_n}(S)$. We call this ordering the finishing-time ordering of the tasks with respect to S. Furthermore, we call the tasks $T_{i_{(j-1)m+1}}, T_{i_{(j-1)m+2}}, \cdots, T_{i_{(j-1)m+m}}$ the rank j tasks, $1 \leqq j \leqq r$, with respect to $\rho(S)$. A schedule S is said to be in canonical form if for each $1 \leqq k \leqq m$, the tasks $T_{i_k}, T_{i_{m+k}}, \cdots, T_{i_{(r-1)m+k}}$ finish on processor k, where T_{i_l}, $1 \leqq l \leqq n$, is the lth task in $\rho(S)$. The following theorem shows that every preemptive schedule can be converted into one in canonical form with no change in schedule length and flow time.

THEOREM 1. *For every preemptive schedule S of TS on m processors, there is another schedule S' in canonical form such that $FT(S')=FT(S)$ and $SL(S')=SL(S)$.*

Proof. Let $\rho(S)=(T_{i_1}, T_{i_2}, \cdots, T_{i_n})$ be the finishing-time ordering of the tasks with respect to S. We construct a new schedule S' as follows. Suppose T_{i_1} finishes on processor $k \neq 1$ in S. We interchange a small segment, δ, of T_{i_1} executed in the time interval $[f_{i_1}(S)-\delta, f_{i_1}(S)]$ with the task executed in the same interval on processor 1. The new schedule is a valid schedule with no change in the finishing times of the tasks. Repeating this operation for $T_{i_2}, T_{i_3}, \cdots, T_{i_n}$ gives a new schedule S' such that $FT(S')=FT(S)$ and $SL(S')=SL(S)$. □

Let S be a preemptive schedule in canonical form and let $\rho(S)=(T_{i_1}, T_{i_2}, \cdots, T_{i_n})$ be the finishing-time ordering of the tasks with respect to S. We divide S into r segments $E_1, E_2, \cdots, E_r$ as follows. Segment E_1 consists of all the time intervals from time 0 until a rank 1 task (with respect to $\rho(S)$) finishes. That is, E_1 consists of the time intervals $[0, f_{i_1}(S)]$ on processor 1, $[0, f_{i_2}(S)]$ on processor 2, $\cdots$, $[0, f_{i_m}(S)]$ on processor m. For each $2 \leqq j \leqq r$, E_j consists of the time intervals $[f_{i_{(j-2)m+1}}(S), f_{i_{(j-1)m+1}}(S)]$ on processor 1, $[f_{i_{(j-2)m+2}}(S), f_{i_{(j-1)m+2}}(S)]$ on processor 2, $\cdots$, $[f_{i_{(j-2)m+m}}(S), f_{i_{(j-1)m+m}}(S)]$ on processor m. We use ES_j to denote the total length of all time intervals in segment E_j. Thus, $ES_1=\sum_{k=1}^{m} f_{i_k}(S)$, and for each $2 \leqq j \leqq r$, $ES_j=\sum_{k=1}^{m}(f_{i_{(j-1)m+k}}(S)-f_{i_{(j-2)m+k}}(S))$. With these definitions in mind, we can prove the following theorem, which characterizes the structure of a minimum flow-time preemptive schedule.

THEOREM 2. *Let S be a minimum flow-time preemptive schedule in canonical form, and let $\rho(S)=(T_{i_1}, T_{i_2}, \cdots, T_{i_n})$ be the finishing-time ordering of the tasks with respect to S. For each segment E_j, $1 \leqq j \leqq r$, we have: (1) there are no idle processor times in E_j, and (2) the tasks that are executed in E_j are rank j tasks (with respect to $\rho(S)$) only. Furthermore, every rank j task (with respect to $\rho(S)$) has execution time no larger than any rank $j+1$ task, $1 \leqq j < r$.*

Proof. Let S, $\rho(S)$, and E_j be as stated in the theorem. Let ES_j denote the total length of all time intervals in E_j, and let R_j denote the total execution time of all tasks in rank j (with respect to $\rho(S)$), $1 \leqq j \leqq r$. It is easy to see that $FT(S)=\sum_{j=1}^{r}(r-j+1)*ES_j$. Since S has the minimum flow time, we also have $FT(S)=$

$\sum_{j=1}^{r}(r-j+1)\sum_{k=1}^{m}p_{(j-1)m+k}$. Thus, we have

$$\sum_{j=1}^{r}(r-j+1)ES_j=\sum_{j=1}^{r}(r-j+1)\sum_{k=1}^{m}p_{(j-1)m+k}. \tag{1}$$

For each $1\leqq j\leqq r$, let $X_{i,j}$ denote the total execution time of all rank i tasks (with respect to $\rho(S)$) executed in E_j, $i>j$, and let ϕ_j denote the total idle processor time in E_j. Clearly, we have

$$ES_j=R_j+\phi_j+\sum_{i>j}X_{i,j}-\sum_{j>i}X_{j,i},$$

and hence

$$\sum_{j=1}^{r}(r-j+1)ES_j=\sum_{j=1}^{r}(r-j+1)R_j+\sum_{j=1}^{r}(r-j+1)\left(\phi_j+\sum_{i>j}X_{i,j}-\sum_{j>i}X_{j,i}\right). \tag{2}$$

Since $\sum_{j=1}^{r}R_j=\sum_{i=1}^{n}p_i$, we have

$$\sum_{j=1}^{r}(r-j+1)R_j\geqq\sum_{j=1}^{r}(r-j+1)\sum_{k=1}^{m}p_{(j-1)m+k}. \tag{3}$$

From (1), (2), and (3), we have

$$\sum_{j=1}^{r}(r-j+1)\left(\phi_j+\sum_{i>j}X_{i,j}-\sum_{j>i}X_{j,i}\right)\leqq 0.$$

Observing that $\phi_j\geqq 0$ for each $1\leqq j\leqq r$, and

$$\sum_{j=1}^{r}(r-j+1)\left(\sum_{i>j}X_{i,j}-\sum_{j>i}X_{j,i}\right)=\sum_{j=1}^{r-1}\sum_{i>j}(i-j)X_{i,j}\geqq 0,$$

we have $\phi_j=0$ and $X_{i,j}=0$, $i>j$, for each $1\leqq j\leqq r$. Therefore, each segment E_j can only have rank j tasks (with respect to $\rho(S)$) executing in it, and it cannot have any idle processor time. Finally, from (1) and (2), we have

$$\sum_{j=1}^{r}(r-j+1)R_j=\sum_{j=1}^{r}(r-j+1)\sum_{k=1}^{m}p_{(j-1)m+k}. \tag{4}$$

From (4), we observe that no rank j tasks (with respect to $\rho(S)$) can have execution time larger than any rank $j+1$ tasks; otherwise, (4) cannot hold. □

From Theorem 2, we see that a minimum flow-time preemptive schedule, S, in canonical form is actually very similar to a B-schedule. The rank j tasks with respect to $\rho(S)$ are the same as the rank j tasks of the task system, $1\leqq j\leqq r$. The tasks are executed rank by rank in S, and there are no idle processor times before the finishing time of a processor. If S is a schedule, we let $P(S)$ denote the partial schedule obtained from S by deleting all rank r tasks.

LEMMA 1. *Let S be a minimum flow-time preemptive schedule in canonical form and let S' be a B-schedule. Let* $\mathrm{F}(k, S)$ *and* $\mathrm{F}(k, S')$ *denote the finishing time of processor k in $P(S)$ and $P(S')$, respectively, $1\leqq k\leqq m$. Then, we have* $\sum_{k=l}^{m}(\mathrm{F}(k, S')-\mathrm{F}(k, S))\geqq 0$ *for all $1\leqq l\leqq m$.*

Proof. Both $P(S)$ and $P(S')$ consist of the same set of tasks and both schedule tasks rank by rank. The lemma will be proved if we can show that $\sum_{k=1}^{l}(\mathrm{F}(k, S')-\mathrm{F}(k, S))\geqq 0$ for all $1\leqq l\leqq m$. But this follows immediately from the observation that $P(S')$ is an $SPT^{\#}$ schedule. □

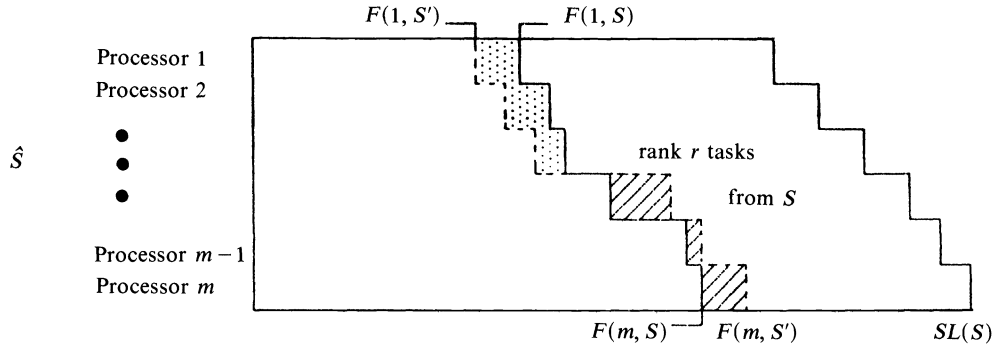
THEOREM 3. *Let S be a minimum flow-time preemptive schedule in canonical form and let S' be a B-schedule. Then, there is another schedule $\hat{S}$ such that $FT(\hat{S}) = FT(S)$, $SL(\hat{S}) = SL(S)$, and $\mathrm{F}(k, \hat{S}) = \mathrm{F}(k, S')$, $1 \leqq k \leqq m$, where $\mathrm{F}(k, \hat{S})$ and $\mathrm{F}(k, S')$ denote the finishing time of processor k in $P(\hat{S})$ and $P(S')$, respectively.*

Proof. Let S be a minimum flow-time preemptive schedule in canonical form and let S' be a B-schedule. We construct $\hat{S}$ using the following three steps: (1) Copy the rank r tasks from S to $\hat{S}$. As shown in Fig. 4(a), the solid lines enclose the rank r tasks. The solid staircase on the left is given by $\mathrm{F}(k, S)$, $1 \leqq k \leqq m$, where $\mathrm{F}(k, S)$ denotes the finishing time of processor k in $P(S)$. The dotted staircase is given by $\mathrm{F}(k, S')$, $1 \leqq k \leqq m$. Processor k is said to be a cross-hatched processor if $\mathrm{F}(k, S') > \mathrm{F}(k, S)$; the time interval $[\mathrm{F}(k, S), \mathrm{F}(k, S')]$ is said to be a cross-hatched interval. Processor k is said to be a dotted processor if $\mathrm{F}(k, S) > \mathrm{F}(k, S')$; the time interval $[\mathrm{F}(k, S'), \mathrm{F}(k, S)]$ is said to be a dotted interval. As shown in Fig. 4(a), processor 1 is a dotted processor, whereas processor m is a cross-hatched processor. (2) Move all portions of the rank r tasks executed in a cross-hatched interval on a cross-hatched processor to a dotted interval on a dotted processor. The moving is done systematically by starting from the highest indexed cross-hatched (dotted) processor to the lowest indexed cross-hatched (dotted) processor. From Lemma 1, we know that for any $1 \leqq l \leqq m$, the total length of all cross-hatched intervals is no less than the total length of all dotted intervals on processors l to m. Therefore, we will always be moving from a higher indexed processor to a lower indexed processor. We need to show that this transformation gives a valid schedule with no change in the finishing times of the rank r tasks. Since each rank r task has execution time larger than $\mathrm{F}(m, S') - \mathrm{F}(1, S')$, no rank r task can finish by $\mathrm{F}(m, S')$ in S. Thus, the transformation will not change the finishing times of rank r tasks. When we move portions of a rank r task, say T_i, executed in a cross-hatched interval $[t_1, t_2]$ to a dotted interval $[t_1', t_2']$, we need to ensure that T_i is not executed in $[t_1', t_2']$ on some other processor. This can be done by swapping tasks among processors in $[t_1, t_2]$ before the move to avoid possible conflicts. Since we are always moving from a higher indexed processor to a lower indexed processor, we can always swap tasks among processors in $[t_1, t_2]$ to avoid conflicts. Thus, the schedule after the transformation is still a valid schedule. Figure 4(b) shows the schedule of the rank r tasks after the transformation. (3) Construct the SPT^* schedule for the tasks in the first $r-1$ ranks. Figure 4(c) shows the completed schedule $\hat{S}$.

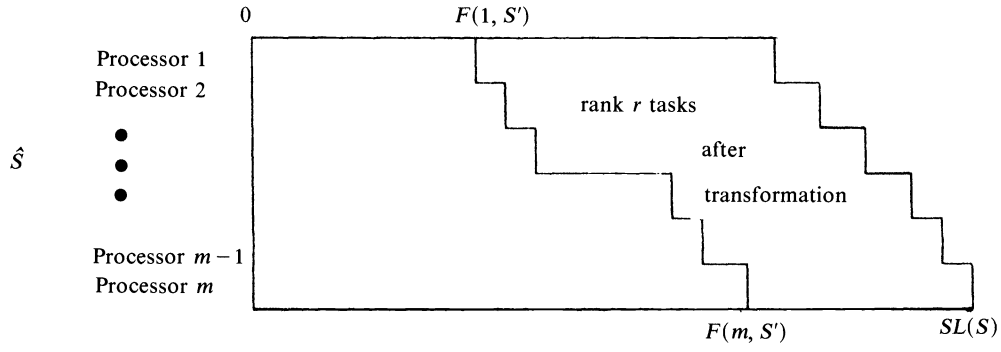
From the construction, it is easy to see that $FT(\hat{S}) = FT(S') = FT(S)$, $SL(\hat{S}) = SL(S)$, and $\mathrm{F}(k, \hat{S}) = \mathrm{F}(k, S')$ for each $1 \leqq k \leqq m$. □

By Theorems 1 and 3, an optimal schedule can always be found such that the tasks in the first $r-1$ ranks are scheduled in the same manner that they are scheduled by Algorithm B. Thus, to show that a B-schedule has the minimum schedule length among all minimum flow-time schedules, all we need to show is that Algorithm B schedules the rank r tasks in such a way that the resulting schedule length is minimum. In the following, we shall show that: (I) An optimal schedule must schedule the rank r tasks such that the resulting schedule length is at least *OSL*, which is computed in step 3 of Algorithm B and (II) Algorithm B can always schedule the rank r tasks such that no rank r tasks finish later than *OSL*.

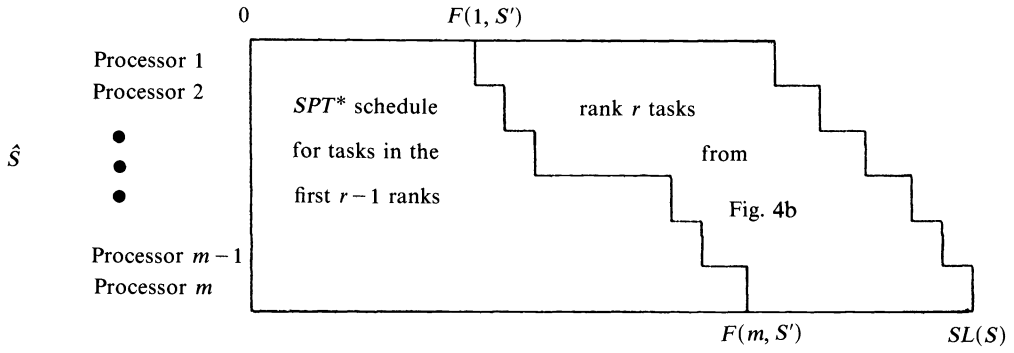
Before we show the above, we need to introduce the following notations. Let $\mathrm{F}(k)$, $1 \leqq k \leqq m$, denote the finishing time of processor k of a partial schedule S such that $\mathrm{F}(1) \leqq \mathrm{F}(2) \leqq \cdots \leqq \mathrm{F}(m)$. The m-tuple $\mathrm{PF} = (\mathrm{F}(1), \mathrm{F}(2), \cdots, \mathrm{F}(m))$ is called the processor profile of S. For a given $D > \mathrm{F}(m)$, the ordered pair (PF, D) is called a block and it consists of the time intervals $[\mathrm{F}(1), D]$ on processor 1, $[\mathrm{F}(2), D]$ on processor 2, $\cdots$, $[\mathrm{F}(m), D]$ on processor m.



(a) *Step 1 in the construction.*



(b) *Step 2 in the construction.*



(c) *Step 3 in the construction.*

FIG. 4. *Illustrating the proof of Lemma* 3.

THEOREM 4. *Let* $\mathrm{PF} = (\mathrm{F}(1), \mathrm{F}(2), \cdots, \mathrm{F}(m))$ *be the processor profile of a partial schedule S, and let* $TS' = \{T'_1, T'_2, \cdots, T'_m\}$ *be a set of m tasks such that* $p'_1 \geqq p'_2 \geqq \cdots \geqq p'_m$. *Then, TS' can be preemptively scheduled into the block* (PF, D) *only if* $D \geqq \max_{k=1}^{m} \{\sum_{l=1}^{k} (\mathrm{F}(l) + p'_l)/k\}$.

Proof. Let j be such that $\sum_{l=1}^{j}(\mathrm{F}(l)+p'_l)/j = \max_{k=1}^{m}\{\sum_{l=1}^{k}(\mathrm{F}(l)+p'_l)/k\}$. Since $D-\mathrm{F}(1)\geqq D-\mathrm{F}(2)\geqq\cdots\geqq D-\mathrm{F}(m)$, the processors are in nonincreasing order of processing capacity. Therefore, if TS' can be scheduled into the block (PF, D), then we must be able to schedule $T'_1, T'_2, \cdots, T'_j$ completely on processors $1, 2, \cdots, j$ of the block. Thus, $D\geqq\sum_{l=1}^{j}(\mathrm{F}(l)+p'_l)/j = \max_{k=1}^{m}\{\sum_{l=1}^{k}(\mathrm{F}(l)+p'_l)/k\}$. □

Theorem 4 shows that *OSL* computed in step 3 of Algorithm B is a lower bound of the schedule length of an optimal schedule. We shall show in Theorem 5 that step 4 of Algorithm B can always schedule the rank r tasks into the block (PF, *OSL*), where PF is the processor profile of the SPT^{*} schedule constructed in step 1 of Algorithm B. Note that the rank r tasks are scheduled in nonincreasing order of their execution times. Task T_{n-l+1} is scheduled at the lth iteration of step 4 of Algorithm B, $1\leqq l\leqq m$. The next three lemmas are instrumental in proving Theorem 5.

LEMMA 2. *In step* 4 *of Algorithm B, the number of available processors remaining after the* lth *iteration is* $m-l$, $1\leqq l\leqq m$.

Proof. The lemma follows from the observations that we start out with m processors, and that each iteration removes one processor from the set of available processors. □

LEMMA 3. *Let* $\mathrm{F}(k, l)$, $1\leqq k\leqq m$, $1\leqq l\leqq m$, *denote the finishing time of processor* k *before the* lth *iteration in step* 4 *of Algorithm B. Let processors* $k_1<k_2<\cdots<k_{m-l+1}$ *be the available processors before the* lth *iteration. Then, we have* $\mathrm{F}(k_1, l)\leqq\mathrm{F}(k_2, l)\leqq\cdots\leqq\mathrm{F}(k_{m-l+1}, l)$.

Proof. We shall prove the lemma by induction on l. The lemma is clearly true for $l=1$, since $\mathrm{F}(1, 1)\leqq\mathrm{F}(2, 1)\leqq\cdots\leqq\mathrm{F}(m, 1)$. Assume the lemma is true for $l=j$, we shall prove it is also true for $l=j+1$. In the jth iteration, task T_{n-j+1} is being scheduled. Let $k_1<k_2<\cdots<k_{m-j+1}$ be the indexes of the available processors before the jth iteration. By the inductive hypothesis, we have $\mathrm{F}(k_1, j)\leqq\mathrm{F}(k_2, j)\leqq\cdots\leqq\mathrm{F}(k_{m-j+1}, j)$. If T_{n-j+1} is scheduled by rules (1) or (2) in step 4 of Algorithm B, then the lemma is clearly true for $l=j+1$. Thus, we assume that T_{n-j+1} is scheduled by rule (3) of step 4. Let processors k_c and k_{c+1} be used in the scheduling of T_{n-j+1}. Then, we have $\mathrm{F}(k_c, j+1)\leqq\mathrm{F}(k_{c+1}, j)\leqq\mathrm{F}(k_{c+2}, j)$, and $\mathrm{F}(k_i, j+1)=\mathrm{F}(k_i, j)$ for $i\neq c$ and $c+1$. Thus, we have $\mathrm{F}(k_1, j+1)\leqq\mathrm{F}(k_2, j+1)\leqq\cdots\leqq\mathrm{F}(k_c, j+1)\leqq\mathrm{F}(k_{c+2}, j+1)\leqq\cdots\leqq\mathrm{F}(k_{m-j+1}, j+1)$. Hence, the lemma is also true for $l=j+1$. □

LEMMA 4. *Let processors* $k_1<k_2<\cdots<k_{m-l+1}$ *be the available processors before the* lth *iteration in step* 4 *of Algorithm B. If task* T_{n-l+1} *is scheduled by rules* (1) *or* (2) *in the* lth *iteration on processor* k_c, *or if* T_{n-l+1} *is scheduled by rule* (3) *on processors* k_c *and* k_{c+1}, *then after* T_{n-l+1} *is scheduled there are at least* $c-1$ *available processors that have processing capacity at least* p_{n-l+1}.

Proof. Let $\mathrm{F}(k, l)$ denote the finishing time of processor k before the lth iteration, and let $k_1<k_2<\cdots<k_{m-l+1}$ be the indexes of the available processors. If T_{n-l+1} is scheduled by rule (1) or rule (2) on processor k_c, or if T_{n-l+1} is scheduled by rule (3) on processors k_c and k_{c+1}, then we must have $OSL-\mathrm{F}(k_c, l)\geqq p_{n-l+1}$. Since $OSL-\mathrm{F}(k_i, l)\geqq OSL-\mathrm{F}(k_c, l)$ and $\mathrm{F}(k_i, l+1)=\mathrm{F}(k_i, l)$ for each $1\leqq i<c$, we have $OSL-\mathrm{F}(k_i, l+1)\geqq p_{n-l+1}$ for each $1\leqq i<c$. Thus, we have at least $c-1$ processors that have processing capacity no smaller than p_{n-l+1}. □

THEOREM 5. *Step* 4 *of Algorithm B can always schedule the tasks* $T_n, T_{n-1}, \cdots, T_{n-m+1}$ *into the block* (PF, *OSL*), *where* PF *is the processor profile of the* SPT^{*} *schedule constructed in step* 1 *and OSL is computed in step* 3 *of Algorithm B.*

Proof. We prove the theorem by contradiction and assume that at the lth iteration T_{n-l+1} is the first task that cannot be scheduled into the block. We first observe that none of the tasks $T_n, T_{n-1}, \cdots, T_{n-l+2}$ were scheduled by rule (1) of step 4 of Algorithm

B. For otherwise, since the tasks are in nonincreasing order of their execution times, all tasks can be scheduled into the block. Let $F(k, l)$, $1 \leqq k \leqq m$, denote the finishing time of processor k at the time T_{n-l+1} is scheduled, and let processors $k_1 < k_2 < \cdots < k_{m-l+1}$ be the available processors. By Lemma 3, we have $F(k_1, l) \leqq F(k_2, l) \leqq \cdots \leqq F(k_{m-l+1}, l)$, and hence $OSL - F(k_1, l) \geqq OSL - F(k_2, l) \geqq \cdots \geqq OSL - F(k_{m-l+1}, l)$. Since T_{n-l+1} cannot be scheduled, we have $p_{n-l+1} > OSL - F(k_1, l)$.

By Lemma 2, $k_1 \leqq l$. We want to show that $k_2 > l$. If $k_2 \leqq l$, then, by Lemma 2, there is a processor $x > l$ that has been deleted as a result of scheduling some task T_{n-y+1}, $y < l$. By Lemmas 4 and 2, there are at least $(x-2)-(y-1) = x-y-1 \geqq l-y$ available processors among processors $1, 2, \cdots, l$ with processing capacity no smaller than p_{n-y+1}. Since the tasks are in nonincreasing order of their execution times, we must be able to schedule the tasks $T_{n-y+2}, T_{n-y+3}, \cdots, T_{n-l+1}$ into one of these processors. But this contradicts our assumption that T_{n-l+1} cannot be scheduled. Thus, $k_2 > l$.

From the above discussions, there is only one available processor among processors $1, 2, \cdots, l$ at the time T_{n-l+1} is scheduled. Since $T_n, T_{n-1}, \cdots, T_{n-l+2}$ were all scheduled by rules (2) and (3) of step 4 of Algorithm B, and since T_{n-l+1} cannot be scheduled, we must have $\sum_{k=1}^{l} (F(k) + p_{n-k+1})/l > OSL$, where $F(k)$ is the finishing time of processor k in the $SPT^{\#}$ schedule. But this contradicts the definition of OSL. □

From the above theorems, we have the main result of this paper, which is stated in the following theorem.

THEOREM 6. *Algorithm B always generates an optimal schedule.*

4. Concluding remarks. In this paper, we have given an $O(n \log n)$-time algorithm to find a minimum-length preemptive schedule subject to the constraint that it must have the minimum flow time. As a generalization of our problem, it will be interesting to find a minimum-length preemptive schedule subject to the constraint that the flow time is not larger than a given parameter α. One can also generalize this problem to the case of uniform processors. We note that, for the case of uniform processors, Gonzalez [8] has given an $O(nm)$-time algorithm to find a minimum flow-time preemptive schedule subject to the constraint that the schedule length is not larger than a given parameter β.

FAST PARALLEL ALGORITHMS FOR CHORDAL GRAPHS*

JOSEPH NAOR†, MONI NAOR‡, AND ALEJANDRO A. SCHÄFFER§

Abstract. Techniques for parallel algorithms on chordal graphs are developed. An NC algorithm for recognizing chordal graphs is developed, as are NC algorithms for finding the following objects in chordal graphs: all maximal cliques, an intersection graph representation, an optimal coloring, a perfect elimination scheme, a weighted maximum independent set, and a minimum clique cover. The recognition algorithm presented in this paper is simpler than previous algorithms given by Edenbrandt and by Chandrasekharan and Iyengar; the other problems were apparently open. The known polynomial-time algorithms for these problems seem highly sequential, and therefore a different approach to find parallel algorithms is used.

Key words. parallel algorithms, chordal graphs, perfect elimination scheme, perfect graphs, maximum independent set, chromatic number

1. Introduction.

An undirected graph is *chordal* if every cycle of length at least four contains a chord, that is, an edge between two vertices that are not consecutive in the cycle. Chordal graphs arise in the study of sparse matrices [Ro70], [Ro72] and in the study of acyclic relational database schemes [Be83]. Many NP-complete problems can be solved in polynomial time if the input graph is chordal, but the standard algorithms seem highly sequential [Jo85]. We give fast parallel algorithms for several problems on chordal graphs.

Chordal graphs comprise an important subclass of perfect graphs. Perfect graphs are characterized by either of two min-max identities:

1) the chromatic number equals the maximum clique size for every induced subgraph

2) the maximum independent set and the minimum clique cover are of the same size for every induced subgraph.

These two characterizations were developed somewhat independently, but Lovász [Lo72] showed that they describe precisely the same graphs.

The problem of recognizing perfect graphs is open, but chordal graphs can be recognized in polynomial time. Rose, Tarjan, and Lueker [Ro76] and Tarjan and Yannakakis [Ta84] gave linear-time sequential algorithms for this problem based on an alternative characterization of chordal graphs. To understand this characterization, we need some definitions: a vertex, v, is *simplicial* if the graph induced by v and its neighbors is a clique. We use the term *clique* to mean a completely connected subgraph; we use the term *maximal clique* to mean a clique such that no vertex outside the clique is adjacent to every vertex in the clique. An ordering of the vertices $v_1, v_2, \cdots, v_n$

with v_i simplicial in the graph induced by $\{v_i, v_{i+1}, \cdots, v_n\}$ for all i is called a *perfect elimination scheme* or PES, for short. A graph is chordal if and only if it has a perfect elimination scheme [Fu65], [Go80].

Interval graphs, which arise in a variety of scheduling and resource-allocation problems [Go80], form an important subclass of chordal graphs. An *interval graph* is the intersection graph of intervals on the real line. There is a bijection between the vertex set of the graph and a set of intervals such that two vertices are adjacent if and only if the corresponding intervals overlap.

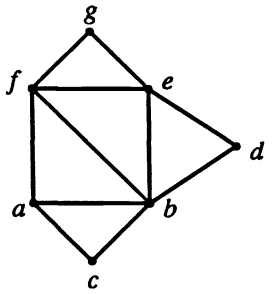

FIG. 1. *A chordal graph; one perfect elimination scheme is cadbefg.*

Our parallel algorithms use an intersection graph characterization of chordal graphs due to Buneman [Bu74] and Gavril [Ga74]. A graph G is chordal if and only if it is the intersection graph of a family of subtrees of a tree. That is to say, there is an undirected tree T, a family of subtrees $\mathcal{S} = \langle S_1, S_2, \cdots, S_{|V|} \rangle$, and a bijection from $V(G)$ to the multiset $\mathcal{S}$ with the property that two vertices in G are adjacent if and only if the corresponding subtrees share a node in T. We use the convention that an element of $V(G)$ is called a *vertex*, and if T is fixed, an element of $V(T)$ is called a *node* or a *tree node*. Buneman [Bu74] and Gavril [Ga74] gave different polynomial-time algorithms for building a tree-and-subtrees representation of a chordal graph.

A PES can be used to give polynomial-time algorithms on chordal graphs for many graph problems that are NP-complete on general inputs [Jo85]. Algorithms to build a PES and use it, appear hard to parallelize because they choose one vertex to process at a time based on previous choices. Algorithms that build and use the tree representation appear hard to parallelize because the tree may have long paths.

Our main results are:

THEOREM 1.1. *Chordal graphs can be recognized in polylogarithmic time on a* PRAM (*parallel random access machine*) *having polynomially many processors. Given a chordal graph, it is possible to find the following objects in polylogarithmic time on a* PRAM *having polynomially many processors*:

— *all maximal cliques and the chromatic number* (§ 3),
— *a tree-and-subtrees representation* (§ 4),
— *an explicit optimal coloring* (§ 4),
— *a perfect elimination scheme* (§ 5),
— *unweighted and weighted maximum independent sets* (§ 5), *and*
— *a minimum clique cover* (§ 5).

Next to each item is the section in which we give its algorithm.

Sequential algorithms for all these problems, except building a tree representation, follow directly from the PES, and to build a tree, the most important step is to find

all maximal cliques from the PES. Our parallel algorithms that recognize chordal graphs and find all maximal cliques use neither a tree-and-subtrees representation nor a PES. The maximal cliques are used to build the tree and to find a coloring; we use the tree to find a PES and a maximum independent set. The coloring algorithm uses only the existence of the tree to guide the recursion, but does not require an explicit tree or a PES. We present algorithms for both the unweighted and weighted independent set problems because the algorithm for the unweighted case runs faster and uses fewer processors in the worst case. In a longer technical report [Na87], we extend our results to obtain simple parallel algorithms for three sample problems related to chordal graphs: computing the chromatic polynomial of a chordal graph, deciding whether a database scheme is acyclic [Be83], and finding a largest k-colorable subgraph of a chordal graph [Ya87].

We take our processors to be Concurrent-Read Exclusive-Write (CREW) PRAMs, and all our algorithms run within the bounds required for the complexity class commonly known as NC, which means they use polynomially many processors, and their runtime is polylogarithmic. All our algorithms except those for weighted independent set and maximum k-colorable subgraph run in $O(\log^2 n)$ time, where n is the number of vertices.

Edenbrandt [Ed85], [Ed87] and Chandrasekharan and Iyengar [Ch86] gave NC algorithms to recognize chordal graphs. Our recognition algorithm uses fewer processors on sparse graphs, but its main advantage over the previous algorithms is that its correctness proof is much simpler. The other seven problems appear to have been open. Coincidentally with the preparation of this paper and independent from it, Dahlhaus and Karpinski [Da86] discovered NC algorithms very different from ours for finding a PES, all maximal cliques, and a tree representation; their algorithms are sketched in [Da86]. They present their algorithms as polynomial-time algorithms on a LOGSPACE-bounded alternating Turing machine. To make the algorithms deterministic and suitable for a PRAM, they rely on the simulation of Ruzzo [Ru80]. The resulting deterministic algorithms require at least $\Omega(n^9)$ processors [Da87] and run in $O(\log^2 n)$ time, while our algorithms for all the problems we solve, except weighted independent set and maximum k-colorable subgraph, use at most $O(n^5)$ processors to run in $O(\log^2 n)$ time or $O(n^4)$ processors to run in $O(\log^3 n)$ time.

After the publication of [Na87], Dahlhaus and Karpinski found a new maximal cliques algorithm that simultaneously achieves $O(\log^2 n)$ time and $O(n^4)$ processors [DK87]. Klein has announced more efficient NC algorithms for all the problems mentioned in Theorem 1.1, except maximum weight independent set. His algorithms run in $O(\log^2 n)$ time using $O(m+n)$ processors on the more powerful Concurrent-Read Concurrent-Write (CRCW)PRAM model [Kl88].

Finding a perfect elimination scheme in NC is explicitly left open in [Ed85], [Ed87], and [Ch86]. The problems of finding maximal cliques and a maximum independent set are mentioned in [Ch86].

Our algorithms for finding a PES and maximum independent set use a new recursion technique on trees: at every stage we process and prune all terminal branches of the tree that represents the chordal graph. A terminal branch is a path containing only nodes of degree two and a leaf. A variety of parallel algorithms for graph problems, expression evaluation, and language recognition use bottom-up recursion on rooted trees [Mi85]. However, these algorithms change the edge structure of the tree during the computation, so as to shorten long paths. Our algorithms, which process terminal branches, do the computations without changing the tree structure (except for deleting vertices already processed).

To build the tree representation and to give an optimal coloring, we use recursion around a centroid. This method has been used to give parallel algorithms for other tree problems where the tree structure is completely known [Me83]. However, we use recursion around a centroid to build the tree when we know only its nodes (and what they represent in the graph), but not its edges.

2. Recognizing chordal graphs. We first consider the problem of recognizing a chordal graph. The fastest sequential solutions rely on the existence of a PES [Ro76], [Ta84].

Edenbrandt gives an NC-recognition algorithm that searches for certain types of clique separators [Ed85], [Ed87]. Chandrasekharan and Iyengar give a recognition algorithm similar to Edenbrandt's [Ch86]. The main advantage of our algorithm is that its correctness follows easily from the definition of chordal graphs as graphs that contain no induced chordless cycles of length greater than 3. A secondary advantage is that on sparse graphs it uses asymptotically fewer processors.

Let $N(v)$ denote the set of vertices adjacent to a vertex v. Let $G\backslash v$ be the graph induced by $V(G)\backslash\{v\}$; if W is a subset of $V(G)$, let $G\backslash W$ be the graph induced by $V(G)\backslash W$. The following lemma suggests a recognition algorithm.

LEMMA 2.1. *The graph G is not chordal if and only if it contains a vertex v with the property that a connected component of $(G\backslash v)\backslash N(v)$ is adjacent to two vertices v_i, $v_j \in N(v)$, and the vertices v_i and v_j are not adjacent.*

Proof. If such a vertex v exists, then G has a chordless cycle including v_1, v, v_j, and vertices in the connected component of $(G\backslash v)\backslash N(v)$ adjacent to v_i and v_j. To prove the converse, suppose that $v_1 - v_2 - \cdots - v_p - v_1$ with $p \geqq 4$ is a shortest chordless cycle of length at least 4 in G. In $(G\backslash v_1)\backslash N(v_1)$, vertices $v_3, \cdots, v_{p-1}$ are in the same connected component, which is adjacent to both v_2 and v_p in G. Letting $v = v_1$, $v_i = v_2$, and $v_j = v_p$ satisfies the conditions of the Lemma. □

ALGORITHM TO RECOGNIZE A CHORDAL GRAPH
Input: A simple undirected graph $G = (V, E)$.
Output: Is G chordal?

1. For every vertex $v \in V$ *in parallel*: Find all connected components of $(G\backslash v)\backslash N(v)$ and number them.
2. For every vertex $V \in V$ *in parallel*: Compute the set of pairs $\langle v_i, v_j \rangle$, such that v_i and v_j are distinct neighbors of v, but v_i and v_j are not adjacent.
3. For every vertex $v \in V$ *in parallel*: For every neighbor v_i of v, compute a sorted list of the connected components in $(G\backslash v)\backslash N(v)$ to which v_i is adjacent.
4. For every vertex $v \in V$ *in parallel*: Test if there exist vertices v_i and v_j in $N(v)$ such that v_i and v_j are not adjacent to each other, but there exists a connected component A in $(G\backslash v)\backslash N(v)$, such that both v_i and v_j are adjacent to A.
5. If the test in step 4 is not satisfied for every vertex $v \in V$, then G is chordal; if the test is satisfied for some vertex, then G is not chordal.

Correctness of the algorithm follows immediately from Lemma 2.1.

LEMMA 2.2. *The above recognition algorithm can be implemented to run in $O(\log^2 n)$ time using $O(mn^2)$ processors, where m is the number of edges.*

Proof. In step 1 we can use the connected-components algorithm of Hirschberg, Chandra, and Sarwate [Hi79], which requires $O(\log^2 n)$ time and $O(n^2)$ processors. We do n connected components computations in parallel, so we need $O(n^3)$ processors for step 1.

Steps 2 and 3 can be implemented $O(\log n)$ and $O(\log^2 n)$ time, respectively, both using $O(mn)$ processors.

Step 4 can be implemented with $O(mn^2)$ processors in $O(\log n)$ time. To every triple $\langle v, v_i, v_j\rangle$ such that v is adjacent to v_i, v is adjacent to v_j, v_i and v_j are not adjacent, and $v_i < v_j$, assign one processor for every component on the list of components which we computed for the pair $\langle v, v_i\rangle$ in step 3. The total length of the component lists for all pairs $\langle v, v_i\rangle$ is $O(mn)$. To each entry on such a list assign at most $n-2$ processors, one for each choice of v_j. The total number of processors is $O(mn^2)$. A processor corresponding to entry C for the triple $\{v, v_i, v_j\}$ does a binary search for C on the component list of $\langle v, v_j\rangle$ and records the result (1 if it finds C, 0 otherwise). For each fixed value of v, all processors corresponding to triples with v as the first component do a boolean OR of their results. This leaves n boolean values for step 5.

Step 5 can be implemented with $O(n)$ processors in $O(\log n)$ time by doing a boolean OR of the n values computed in step 4. □

3. Maximal cliques. We now develop an algorithm to compute all maximal cliques in a chordal graph. A chordal graph can have at most n maximal cliques [Go80]. Define a graph G to be a *bi-clique* if its vertex set can be divided into two disjoint sets P and Q such that the induced graphs G_P and G_Q are cliques. We reduce computing all maximal cliques in any chordal graph to computing all maximal cliques in a chordal bi-clique using divide and conquer.

ALGORITHM TO COMPUTE ALL MAXIMAL CLIQUES (SUMMARY)
Input: A chordal graph G.
Output: A list containing each maximal clique of G exactly once.

1. Divide the vertex set of G arbitrarily into two disjoint sets A and B of equal size. (If n is odd, then $|A|-|B|=1$.)
2. Recursively compute all maximal cliques in the induced graphs G_A and G_B.
3. For every pair of maximal cliques $P \subset A$ and $Q \subset B$, compute all maximal cliques of $A \cup B$ in the induced subgraph $G_{P\cup Q}$, which is a bi-clique.
4. Eliminate duplicates occurring in more than one bi-clique.

LEMMA 3.1. *The above algorithm to compute all maximal cliques in a chordal graph G is correct.*

Proof. Every maximal clique of G not contained entirely in either G_A or G_B is contained in the union of two maximal cliques—one from A and the other from B. □

We now show how to compute all maximal cliques in a bi-clique. Let the vertex set of the chordal bi-clique be $CA \cup CB$, where $CA \subset A$, $CB \subset B$, and CA and CB induce cliques. If $v \in CA$ and $w \in CB$, then let $N_{CB}(v)$ be the set of neighbors of v in CB, and let $N_{CA}(w)$ be the set of neighbors of w in CA.

LEMMA 3.2. *The $|CA|$ sets $\{N_{CB}(v) \mid v \in CA\}$ are ordered by inclusion. Similarly, the $|CB|$ sets $\{N_{CA}(x) \mid x \in CB\}$ are ordered by inclusion.*

Proof. Suppose that there were four vertices $v', v'' \in CA$ and $w', w'' \in CB$ such that $w' \in N_{CB}(v')$ and $w'' \in N_{CB}(v'')$ but, $w' \notin N_{CB}(v'')$ and $w'' \notin N_{CB}(v')$. In this case, there would be a chordless cycle $v' - w' - w'' - v'' - v'$. □

LEMMA 3.3. *Let $Q = QA \cup QB$ be any maximal clique of the chordal bi-clique $G_{CA\cup CB}$. Suppose that $QA \subset CA$, $QB \subset CB$, and both are nonempty. Then QA is the smallest set in the set of sets $\{N_{CA}(x) \mid x \in QB\}$, and QB is the smallest set in $\{N_{CB}(v) \mid v \in QA\}$.*

Proof. By Lemma 3.2, the sets $\{N_{CA}(x) \mid x \in QB\}$ are ordered by inclusion. If one of these sets were a proper subset of QA, then Q would not be a clique. (There would be a vertex in QA that is not adjacent to our vertex in QB.) If QA were not one of the sets in $\{N_{CA}(x) \mid x \in QB\}$, then Q would not be maximal. □

ALGORITHM TO GENERATE ALL MAXIMAL CLIQUES OF G OCCURRING IN A BI-CLIQUE
Input: Vertex sets CA, CB, and $G_{A\cup B}$.
Output: A list of cliques that occur in $G_{CA\cup CB}$ and are maximal cliques in $G_{A\cup B}$.

1. Compute $N_{CB}(v)$ for every $v \in CA$. Sort these sets by inclusion and sort the vertices of CA so that vertices with larger neighborhoods in CB are higher. Do the analogous computation for every $v \in CB$. We treat CA and CB as both sets and ordered lists.
2. Find those vertices in the list for CA such that the successor (and therefore every vertex lower in the list) has a strictly smaller neighborhood in CB.
3. Each vertex v chosen in step 2 yields a different maximal clique $Q(v) = QA(v) \cup QB(v)$. $QA(v)$ consists of v and every vertex in CA with the same or a larger neighbor set in CB. Given $QA(v)$, $QB(v)$ is defined by Lemma 3.3. We may also need to include the cliques CA and CB.
4. Decide which maximal cliques of the bi-clique $G_{CA\cup CB}$ are maximal in $G_{A\cup B}$. See the expanded version of this step below.

If $G_{CA\cup CB}$ is a bi-clique having Q as a maximal clique, Q need not be a maximal clique in the graph $G_{A\cup B}$. There may be a vertex $v \notin CA \cup CB$ adjacent to all the vertices of Q but not to all the vertices of CA or CB. To eliminate these nonmaximal cliques, in step 4 of the bi-clique subroutine, we use the following algorithm.

ALGORITHM TO ELIMINATE LOCALLY MAXIMAL CLIQUES THAT ARE NOT GLOBALLY MAXIMAL
Input: A bi-clique $G_{CA\cup CB}$, a list of the maximal cliques in $G_{CA\cup CB}$.
Output: A list of the cliques that are maximal in both $G_{CA\cup CB}$ and $G = G_{A\cup B}$.

4a. For each vertex $v \notin CA \cup CB$, find its neighbors in $G_{CA\cup CB}$.
4b. Try to find the highest vertex $u(CA, v)$ in the sorted list CA such that $N_{CB}(u(CA, v)) \subset N_{CB}(v)$; there may be no vertex in CA with this subset property, in which case $u(CA, v)$ does not exist. Similarly try to find $u(CB, v)$.
4c. For every clique Q that is maximal in $G_{CA\cup CB}$ and has a nonempty intersection with both CA and CB, test if for every $v \notin CA \cup CB$, Q contains at most one of $u(CA, v)$ or $u(CB, v)$. If either $u(CA, v)$ or $u(CB, v)$ does not exist, then v automatically passes the test.
4d. Put every clique Q that passes the test in step 4c on the output list.
4e. If either CA or CB is an input clique, test it for maximality directly. That is, test if any vertex not in the clique is adjacent to all the clique's members. If no vertex can be added, then copy the clique (CA or CB) to the output.

LEMMA 3.4. *The bi-clique algorithm correctly identifies every maximal clique in $G_{CA\cup CB}$ that is also maximal in G.*

Proof. By Lemma 3.3 each maximal clique of $G_{CA\cup CB}$ consists of a (possibly empty) prefix of the sorted list CA and a (possibly empty) prefix of the sorted list CB. One maximal clique contains the entire set CA, and one maximal clique contains the entire set CB. A prefix $P \neq CA$ of CA generates a maximal clique (i.e., is the intersection of a maximal clique with CA) if and only if no vertex of $CA \setminus P$ has as neighborhood in CB the intersection

$$\bigcap_{v \in P} N_{CB}(v).$$

This intersection is precisely the neighborhood in CB of the lowest vertex in P. Moreover, the neighborhood in CB of the first vertex below P contains the neighborhood in CB of all vertices below P. Thus, P generates a maximal clique if and only

if the neighborhood in CB of the lowest vertex in P is different from the neighborhood in CB of the highest vertex not in P. This is the test we implement in steps 1, 2, and 3.

It remains to show that in step 4 we properly eliminate cliques that are not maximal in $G_{A\cup B}$. The test in step 4e for the cliques CA and CB is the standard maximality test. For the other cliques, we use a different test for the sake of efficiency.

Let Q be a maximal clique in $G_{CA\cup CB}$ that has a nonempty intersection with both CA and CB. Let x be the last vertex in the sorted list CA that belongs to Q, and let y be the last vertex in the sorted list CB that belongs to Q. The clique Q is not maximal in $G_{A\cup B}$ if and only if there exists $v\notin CA\cup CB$ such that $Q\subset N(v)$. Since CA and CB are sorted by their neighborhoods, an equivalent rule is that Q is *not* maximal if and only if there exists $v\notin CA\cup CB$ such that

$$N_{CA}(y)\cup N_{CB}(x)=Q\subset N_{CA}(v)\cup N_{CB}(v)\subset N(v).$$

This is equivalent to the condition that

$$N_{CA}(y)\subset N_{CA}(v) \text{ and } N_{CB}(x)\subset N_{CB}(v).$$

Taking the contrapositive, Q is maximal in $G_{A\cup B}$ if and only if for every $v\notin CA\cup CB$,

$$N_{CA}(y)\not\subset N_{CA}(v) \text{ or } N_{CB}(x)\not\subset N_{CB}(v).$$

The condition $N_{CA}(y)\notin N_{CA}(v)$ is satisfied if and only if $u(CB, v)$ does not exist, or $u(CB, v)$ occurs strictly lower than y in the sorted list CB. Similarly, the condition $N_{CB}(x)\notin N_{CB}(v)$ is satisfied if and only if $u(CA, v)$ does not exist, or $u(CA, v)$ occurs strictly lower than y in the sorted list CA. If $u(CB, v)$ occurs strictly lower than y, then Q does not contain $u(CB, v)$; symmetric conditions hold for $u(CA, v)$. Thus Q is maximal in $G_{A\cup B}$ if and only if for every $v\notin CA\cup CB$, one of $u(CA, v)$ and $u(CB, v)$ does not exist or they both exist, but Q contains at most one. This is precisely the test that we implement in step 4c. □

LEMMA 3.5. *The bi-clique algorithm can be implemented to run in $O(\log n)$ time using $O(n^2)$ processors.*

Proof. Step 1 takes $O(\log n)$ time and step 2 takes constant time. Both use $O(n^2)$ processors.

In each clique $Q(v)$ obtained in step 3, $QA(v)$ is a prefix of CA. The size of $QA(v)$ is the rank of v in CA. The set $QB(v)$ is the same as $N_{CB}(v)$. Thus for each clique $Q(v)$, we can compute its size in $O(\log n)$ time with one processor. For each member of $Q(v)$, we can then assign one processor responsible for listing that member in the output. It follows from the existence of a PES that the sum of the sizes of all maximal cliques in a chordal graph with m edges and n vertices is at most $m+n$ [Go80]. Therefore $O(m+n)$ processors suffice for step 3.

Step 4a can be implemented in $O(\log n)$ time using $O(n^2)$ processors by assigning one processor to each pair $\langle v, w\rangle$ such that $v\notin CA\cup CB$ and $w\in CA\cup CB$. Step 4b (for finding $u(CA, v)$) can be implemented as follows. If $N_{CB}(v)=CB$, then $u(CA, v)$ is the first vertex of CA. Otherwise, let $h(CB, v)$ be the highest vertex in CB that is not adjacent to v. If every vertex in CA is adjacent to $h(CB, v)$, then $u(CA, v)$ does not exist. If there is a vertex in CA that is not adjacent to $h(CB, v)$, then $u(CA, v)$ is the highest such vertex in the sorted list CA. The computation of $u(CB, v)$ is analogous. Testing if h and u exist can be done with $O(n)$ processors in $O(\log n)$ time. Finding their values can be done in $O(\log n)$ time with one binary search for each. Since there are $O(n)$ choices for v, the total processor requirement for step 4b is $O(n^2)$. Steps 4c and 4d require $O(\log n)$ time and $O(n)$ processors for each choice of Q; there are at

most n choices of Q. Step 4e requires $O(\log n)$ time and $O(n)$ processors for each vertex not in $CA \cup CB$; there are at most n such vertices. □

Each of the $O(n^2)$ parallel subroutine calls may produce $O(n)$ maximal cliques, although there can be at most n distinct maximal cliques. One way to eliminate duplicates is to sort the clique copies lexicographically. However, this may take $\Omega(\log^2 n)$ time, increasing the total running time to $O(\log^3 n)$. We can eliminate duplicates in $O(\log n)$ time using the following algorithm.

ALGORITHM TO ELIMINATE DUPLICATE MAXIMAL CLIQUES

Input: G, A, B, all maximal cliques in A and B without duplicates, all maximal cliques in G with duplicates.

Output: A list of all maximal cliques of G with no duplicates.

Definitions/Assumptions: Let the maximal cliques in A be numbered $CA_1, CA_2, \cdots, CA_s$. Let the maximal cliques in B be numbered $CB_1, CB_2, \cdots, CB_t$. Assume that each entry on the list of maximal cliques in G comes with a pair of indices indicating which bi-clique generated it. Every step is done in parallel for every (copy of a) maximal clique Q in G.

0. Assume that Q was generated from the bi-clique induced by $CA_i \cup CB_j$.
1. For each $k < i$ test if $Q \cap CA_k$ is a subset of CA_i.
2. For each $l < j$ test if $Q \cap CB_l$ is a subset of CB_j.
3. If no successful k is found in step 1, and no successful l is found in step 2, then output Q.

LEMMA 3.6. *The above algorithm to eliminate duplicate maximal cliques is correct.*

Proof. For each maximal clique R in G, the algorithm implicitly finds the lexicographically smallest pair $\langle k, l \rangle$ such that R is contained in the bi-clique induced by $CA_k \cup CB_l$. If $R \cap A$ is contained in both CA_i and CA_k, then R is generated by the bi-clique induced by $CA_i \cup CB_l$ as well as by the bi-clique induced by $CA_k \cup CB_l$. Thus we can eliminate copies generated by bi-cliques with first part CA_i, for $i > k$; this is the test in step 1. Similarly, if $R \cap B$ is contained in both CB_j and CB_l, then R is generated by the bi-clique induced by $CA_k \cup CB_j$ as well as by the bi-clique induced by $CA_k \cup CB_l$. We eliminate copies generated by bi-cliques with second part CB_j, for $j > l$ in step 2. □

LEMMA 3.7. *It is possible to eliminate duplicate maximal cliques in $O(\log^2 n)$ time using $O(n^4)$ processors or in $O(\log n)$ time using $O(n^5)$ processors.*

Proof. The first pair of resource bounds can be obtained by sorting the cliques lexicographically [Co86] and eliminating any clique that is identical to its predecessor. The second pair of resource bounds come from the algorithm given above. There are at most $O(n^3)$ copies of maximal cliques in the input. Both A and B induce chordal graphs and therefore have at most n (distinct) maximal cliques. Thus in each of steps 1 and 2, we compute at most n set intersections and subset tests for each input clique. Each intersection and subset test can be done in $O(\log n)$ time using n processors. This yields the bounds of $O(\log n)$ time and $O(n^5)$ processors. □

If we allowed our processors to write concurrently, then a subset test could be done with $O(n)$ processors in constant time, and we could eliminate duplicates in $O(\log n)$ time using only $O(n^4)$ processors as follows. If there are more than $2n$ total copies of cliques to consider, partition the cliques into sets of size between $2n$ and $4n$. Within each set, compare all cliques against each other, and within any identical pair, eliminate the copy with the higher number. As there are at most n distinct maximal cliques, these comparisons eliminate at least half of the $O(n^3)$ candidates with which we started. At most $O(\log n)$ rounds of partitioning and comparing leave fewer than

$4n$ candidates that might be distinct. Each of these can then be compared against all the others to eliminate the remaining duplicates.

LEMMA 3.8. *The algorithm to compute all maximal cliques of a chordal graph can be implemented to run in* $O(\log^3 n)$ *time using* $O(n^4)$ *processors or* $O(\log^2 n)$ *time using* $O(n^5)$ *processors. The bounds* $O(\log^2 n)$ *and* $O(n^4)$ *can be achieved simultaneously if the processors are allowed to write concurrently.*

Proof. There are at most $O(\log n)$ levels of recursive calls. At each fixed level, no vertex occurs in the input graph G in more than one call. All the calls together at any level produce at most n cliques, and generate at most $O(n^2)$ calls to the bi-clique subroutine. By Lemma 3.5, all these calls (at step 3) taken together can be implemented to run in $O(\log n)$ time using $O(n^2)$ processors per call, for a total of $O(n^4)$ processors. By Lemma 3.7, duplicate cliques can be eliminated in $O(\log^2 n)$ time using $O(n^4)$ processors or in $O(\log n)$ time using $O(n^5)$ processors. As noted after Lemma 3.7, the bounds $O(\log n)$ time and $O(n^4)$ processors can be achieved simultaneously if processors can write concurrently. Multiplying these time bounds, for a single recursion level, by $\log n$ yields the desired results. □

Since chordal graphs are perfect, the size of the largest clique is the chromatic number.

4. Optimal coloring and representing chordal graphs by trees. Although we just showed how to compute the chromatic number of a chordal graph, obtaining an explicit coloring in NC seems to be nontrivial. In order to do that, we represent a chordal graph as an intersection graph of a family of subtrees. A graph G is the intersection graph of a family $\mathcal{S} = \langle S_1, S_2, \cdots, S_{|V(G)|} \rangle$ of subtrees in a tree T if:

(i) there is a one-to-one correspondence between the subtrees $\mathcal{S}$ and the vertices in G.

(ii) two vertices in G are adjacent if and only if their corresponding subtrees share a node in T.

The choice of T and $\mathcal{S}$ is not unique in general. Two members of $\mathcal{S}$ may be identical.

THEOREM 4.1 ([Go80], [Ga74], [Bu74]). *The following statements are equivalent*:

(i) G is a chordal graph.

(ii) G is the intersection graph of a family of subtrees of a tree.

(iii) There exists a tree $T = (K, E)$ whose vertex set K is the set of maximal cliques of G such that for each $v \in V$ the subgraph induced in T by the set K_v (consisting of all maximal cliques that contain v) is connected, and hence, a subtree.

From now on, we assume that G is connected; otherwise, each component can be processed separately.

Two members of $\mathcal{S}$ corresponding to vertices v and w will be precisely the same when v and w are in exactly the same maximal cliques in G. Even with the three restrictions given in the theorem, the tree T may not be unique. We adopt the convention

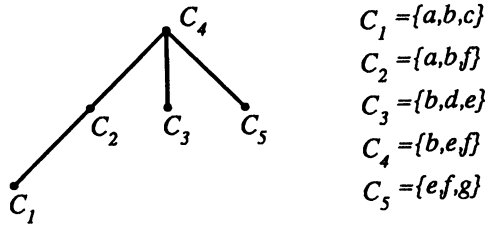

FIG. 2. *One tree representation for the graph of Fig.* 1.

that if a tree node is denoted by a lowercase letter, then its corresponding maximal clique is denoted by the corresponding upper case letter.

The sequential algorithms in [Bu74], [Ga74] that compute a tree representation extend it node by node, but we use a different approach. Mark Novick recently pointed out that a paper by Bernstein and Goodman [Be81] implicitly contains a different algorithm to build a clique tree representation (given all the maximal cliques) that is parallelizable. One advantage of our algorithm is that from it we can easily derive a coloring algorithm.

Our tree-construction algorithm is based on the following idea. Deleting an internal node of a tree makes the tree into a forest with trees of various sizes. A node whose deletion results in a forest where the size of the *largest* component is *minimized* (over all possible choices of one node to delete) is called a *centroid.* Removing a centroid disconnects a tree into components, each including at most half of the nodes [Jo69]. Using properties of G, we decide if a node can be a centroid *without* knowing the exact structure of the tree. We compute a tree representation using a divide-and-conquer method that in each recursive call, finds a centroid of the tree we eventually construct for the induced subgraph of G passed to that call. In each recursion step, a connected input graph is divided into components such that in each component, the number of maximal cliques decreases to at most a constant fraction of the number of maximal cliques in the input. The recursion is based on the following lemmas and observation regarding a tree T representing a chordal graph G.

LEMMA 4.2. *Let C, C_1, and C_2 be maximal cliques of the graph G with corresponding nodes c, c_1, and c_2 in the tree T. If the nodes c_1 and c_2 are in different connected components of $T\backslash c$, and the cliques C_1 and C_2 share a vertex v, then $v \in C$.*

Proof. The subtree corresponding to v consists of all tree nodes that correspond to cliques containing v. Since T is a tree, there is a unique path between nodes c_1 and c_2, and it passes through c. □

LEMMA 4.3. *The removal of any maximal clique C that does not correspond to a leaf in T disconnects the remainder of G.*

Proof. The proof is by contradiction. The removal of the node c disconnects the tree T. Let $T_1, T_2, \cdots, T_l$ denote the connected components (trees) of $T\backslash c$. For each j such that $1 \leqq j \leqq l$, let W_j be the set of vertices of G occurring in a maximal clique represented by a node of T_j. Let $X_j = W_j \backslash C$.

Suppose there were an edge $v - w$ with $v \in X_j$, $w \in X_k$, and $j \neq k$. The edge $v - w$ must belong to some maximal clique. Thus there is an i such that $v, w \in X_i$. If $i = j$, then by Lemma 4.2, w must belong to C, contradicting the choice of w. Similarly if $i = k$, then v must belong to C, contradicting the choice of v. If $i \notin \{j, k\}$, then both v and w must belong to C, a contradiction. This shows that no two of the sets $X_1, X_2, \cdots, X_l$ have adjacent vertices. Since c is an internal node with degree at least 2, $l \geqq 2$, and G must be disconnected. □

Observation 4.4. If removing the maximal clique Q from G leaves $G\backslash Q$ with components $C_1, C_2, \cdots, C_l$, then it is possible to build a tree T so that for each i, with $1 \leqq i \leqq l$, the maximal cliques in $C_i \cup Q$ correspond to the nodes in one component of the forest $T\backslash q$ plus one node for the clique Q.

Our recursion divides the problem into subproblems, each of which includes, at most, half of the maximal cliques (plus one) of the original problem, by finding a centroid node in the tree. At the bottom level we have a graph with exactly two overlapping maximal cliques whose tree is simply two adjacent nodes. We compute a centroid c as follows: for every maximal clique Q, count in parallel how many maximal cliques are in each connected component of $G\backslash Q$ with a copy of Q added to each

component. Let $p(Q)$ be the maximum number of maximal cliques in any of these components. We choose c to be that q such that $p(Q)$ is minimized over all choices of maximal clique Q.

To bound the depth of the recursion, we need to observe that every maximal clique in each connected component of $G \backslash Q$ is either a maximal clique of G or is contained in a maximal clique of G. Thus the number of maximal cliques in each connected component is cut by at least half not counting the centroid clique.

ALGORITHM TO COMPUTE A TREE-AND-SUBTREES REPRESENTATION (SUMMARY)
Input: A connected chordal graph G and the list of maximal cliques of G.
Output: A tree representation for G.

1. If G has more than two maximal cliques, then find a maximal clique that corresponds to a centroid c as explained above.
2. Let the connected components of $G \backslash C$ be $C_1, C_2, \cdots, C_l$. Compute recursively the tree representation of $C_i \cup C$ for every i.
3. Let $T_1, T_2, \cdots, T_l$ be the trees that result from the recursion. $T = \cup_{i=1}^{l} T_i$, where the T_i are disjoint except for c. The subtree corresponding to each vertex is defined in Theorem 4.1(iii).

In the base case of the recursion, we have two maximal cliques whose intersection is not empty. Their corresponding tree consists of two adjacent nodes. The correctness of the algorithm follows from Lemmas 4.2 and 4.3 and Observation 4.4.

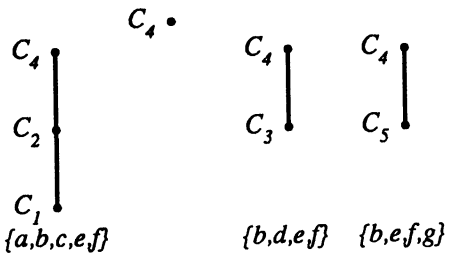

FIG. 3. *Building the tree of Fig. 2 by using C_4 as the centroid clique.*

To keep the running time and number of processors down, we do not recompute the maximal cliques and connected components from scratch in every recursive call. Before making the recursive call in step 2, we compute the maximal cliques in each graph of the form $C_i \cup C$ with the following algorithm.

ALGORITHM TO UPDATE LISTS OF MAXIMAL CLIQUES
DEFINITIONS. Let G_j be the graph considered in the current call. Let c be the centroid we chose in step 1 above. Let the connected components of $G_j \backslash C$ be $C_1, C_2, \cdots, C_l$.
Input: G_j, C, $C_1, C_2, \cdots, C_l$, a list of maximal cliques in G_j.
Output: For each component C_i a list of maximal cliques in $C \cup C_i$.

1. Put C on each output list.
2. For each maximal clique $Q \neq C$ of G_j *in parallel*: find a vertex $v(Q)$ that does not belong to C.
3. For each maximal clique Q, let $C_i(Q)$ be the unique connected component among $C_1, C_2, \cdots, C_l$ that contains $v(Q)$.
4. For each maximal clique $Q \neq C$ of G_j *in parallel*: put Q on the list for $C_i(Q)$ (and on no other list).

LEMMA 4.5. *The algorithm to update the lists of maximal cliques is correct.*

Proof. Let $Q \neq C$ be a maximal clique in G_j. Because C separates G_j, the vertices in Q/C must belong to exactly one connected component in $G_j \backslash C$. That component, $C_i(Q)$, is identified in step 3, and Q must be a clique in $C_i(Q) \cup C$.

If there were a vertex $w \in (C_i(Q) \cup C) \backslash Q$ adjacent to every vertex of Q, then Q would not be maximal in G_j. This shows that Q must be maximal in $C_i(Q) \cup C$. Since Q is arbitrary, every maximal clique output is legitimate. We now show that no maximal clique is omitted. Suppose, seeking to establish a contradiction, that there is a maximal clique $R \neq C$ in some $C_k \cup C$ such that R is *not* maximal in G_j. Since R is not maximal in G_j, there must be a vertex $x \notin C_k \cup C$ such that every vertex is R is adjacent to x. Since $R \neq C$, the graph induced by $R \cap C_k$ is nonempty. The previous two assertions contradict the assumption that C_k is an entire connected component of $G_j \backslash C$. □

In step 1 of the main algorithm, we compute for each clique Q the connected components of $G \backslash Q$. In the first call, we use the algorithm in [Hi79]. In subsequent calls, we compute the connected components more efficiently by reusing previous computations.

ALGORITHM TO UPDATE CONNECTED COMPONENTS IN STEP 1.

Definitions/Assumptions. Let G_j be the current input graph. Let G_{j-1}, a supergraph of G_j, be the input graph for the recursive call that preceded this one. Let C_{j-1} be the centroid clique that we chose for G_{j-1}. Each component can be represented as a sorted subset of the vertices of v. For each graph G_j, it is also useful to have a table showing to which component each vertex belongs.

Input: The graphs G_j and G_{j-1}; for each maximal clique Q in G_{j-1}, a list of connected components of $G_{j-1} \backslash Q$ (this was computed in the previous recursive call); a list of maximal cliques in G_j, and the centroid clique C for G_{j-1}.

Output: For each maximal clique $R \neq C$ in G_j, a list of connected components of $G_j \backslash R$.

1. For each maximal clique $R \neq C$ in G_j, let $L_{j-1}(R)$ be the list of components of $G_{j-1} \backslash R$.
2. For each R in parallel; let $w(R)$ be a vertex in $C \backslash R$.
3. For each R *in parallel*: let $H_{j-1}(R)$ be the component in $L_{j-1}(R)$ that contains $w(R)$.
4. For each R *in parallel*: put every component on the list $L_{j-1}(R)$ except $H_{j-1}(R)$ on the output list for R.
5. For each R *in parallel*: compute $H_{j-1}(R) \cap G_j$ and add it to the output list for R.

LEMMA 4.6. *The algorithm to update connected components is correct.*

Proof. Let T be a tree for G_{j-1} satisfying the conditions of Observation 4.4. Remove a node c from T and reconnect c to each tree in the resulting forest. This yields a forest of trees $T_1, T_2, \cdots$ that are disjoint except for the common node c. Using Observation 4.4, define a bijection ϕ_c from the set of trees in the forest $T \backslash c$ to the set of connected components $G_{j-1} \backslash C$. Let T_i be one of the trees, and let W_i be the union of maximal cliques whose corresponding nodes lie in W_i. Then $\phi_c(T_i) := W_i \backslash C$ is a connected component of $G_{j-1} \backslash C$.

Let c be the centroid we chose for G_{j-1}. Let a maximal clique $R \neq C$ in G_j be given. Assume, without loss of generality, that the node r lies in tree T_1 defined above. Let $d(r)$ be the degree of node r in T; r has the same degree in T_1. Thus removing r from either T or T_1 would leave a forest of $d(r)$ trees. Moreover, the only difference between these two forests is in the tree containing c. Thus the bijection ϕ_r, which defines the connected components of $G_{j-1} \backslash R$, also yields $d(r) - 1$ of the connected components of $G_j \backslash R$. In each graph, there is one component left over. The one

component that changes is found in step 3; the components that remain the same are reported in step 4.

The component that changes in going from $G_{j-1}\backslash R$ to $G_j\backslash R$ is the one containing $C\backslash R$. In going from T to T_1, we deleted all nodes representing cliques that did not intersect $G_j\backslash C$. Thus the component in $G_{j-1}\backslash R$ that included $C\backslash R$, loses all vertices not in G_j when converting to G_j and keeps the rest. This is what we compute in step 5.

Since $R \neq C$ was an arbitrary maximal clique of G_j, the algorithm works correctly for each candidate separating clique in G_j. □

LEMMA 4.7. *The algorithm to build a tree representation can be implemented to run in time* $O(\log^2 n)$ *using* $O(n^3)$ *processors (assuming that all the maximal cliques are part of the input).*

Proof. To update the maximal cliques, we use at most one processor per vertex occurring in a clique. As remarked in the proof of Lemma 3.5, the sum of all the maximal clique sizes is bounded by $m+n$. Each step of the maximal clique updating algorithm takes $O(\log n)$ time.

The algorithm to update connected components can be analyzed as follows. Step 1 can be done in constant time by table lookup. In step 2, we may need as many as $m+n$ processors to find all the values $w(R)$ in $O(\log n)$ time. Step 3 can be done in constant time by table lookup. In step 4, we just copy part of the input to the output. The size of the output may be $O(n)$ for each R, so we need $O(n^2)$ processors and $O(\log n)$ time. In step 5 we compute the intersection of two sets (represented by sorted lists or bitmaps) of size at most n. This can be done in $O(\log n)$ time using n processors for each R, for a total of $O(n^2)$ processors.

Finally, we analyze the main algorithm. The first time we do the connected components computations in step 1, we use the algorithm in [Hi79]. Since we do at most n such computations in parallel, $O(n^3)$ processors suffice.

The maximum depth of recursion is $O(\log n)$. Assume that the recursive calls are synchronized by level in the sense that for any level i, all calls at level i are started simultaneously, and no call at level i is resumed (after its recursive calls) until all calls one level deeper are complete. We show that for any recursion level i, $O(\log n)$ time and $O(n^3)$ processors suffice for all the calls at level i together. Each input graph at level i that has more than two maximal cliques includes a maximal clique that belongs to no other input graph at level i. Since a chordal graph can have at most n maximal cliques, the number of calls at level i in which the input graph has three or more maximal cliques is bounded by n. Each call in which the input contains exactly two maximal cliques corresponds to a *distinct* edge in the final; thus, there can be at most $n-1$ such calls on any level. In all, there can be at most $2n-1$ parallel calls at any recursion level.

We showed above that updating the maximal cliques and connected components can be done in $O(\log n)$ time and $O(n^2)$ processors per call. Thus the total cost per level of these subroutines is $O(\log n)$ time and $O(n^3)$ processors. The only remaining steps to analyze are the selection of the centroid and the union of the trees.

Once a maximal clique has been chosen as a centroid, it cannot be chosen again because its removal cannot disconnect graphs deeper in the recursion. Thus for any level i, the sets of candidate centroids in any two calls at that level are disjoint. Since there are at most n maximal cliques, there are at most n candidate centroids among all calls at any recursion level. For each candidate centroid q and each maximal clique $R \neq Q$, we have to decide which component of $G\backslash Q$ contains $R\backslash Q$. This can be done in $O(\log n)$ time with $O(n)$ processors by finding one vertex of $R\backslash Q$ and then finding out which component of $G\backslash Q$ contains it. Altogether, at level i of recursion, there are

at most n candidate centroids and at most n cliques per candidate. Thus we need $O(n^3)$ processors to find out which clique belongs to which component. In order to sum the results and find the minima, we again need $O(n^3)$ processors.

To combine the trees, we identify the copy of c in each tree and append the adjacency lists for copies of c together. The adjacency lists for the tree nodes need not be sorted, so the copying and appending can be done in $O(\log n)$ time using $O(n)$ processors. □

The coloring algorithm proceeds using exactly the same structure of recursive calls as the tree-construction algorithm. For coloring, the tree is primarily a conceptual tool used to design the algorithm, and there is no need to actually build a tree. The coloring algorithm uses the same subroutines to update maximal cliques and connected components as the tree-construction algorithm.

SUMMARY OF ALGORITHM TO COMPUTE AN OPTIMAL COLORING

1. Find a maximal clique Q that has the centroid property.
2. Let the connected components of $G \setminus Q$ be $C_1, C_2, \cdots, C_l$. Compute recursively an optimal coloring for $C_i \cup Q$ for every i.
3. Merge the colorings so that each copy of Q is colored consistently. Since Q is a clique, each of its vertices must have a different color, and we need only to rename the color classes relative to one of $C_i \cup Q$.

The base case of the recursion is the same as in constructing the tree. We color one clique first and then the other.

LEMMA 4.8. *The coloring algorithm is correct.*

Proof. Assume as inductive hypothesis that the colorings of $C_1 \cup Q$, $C_2 \cup Q, \cdots, C_l \cup Q$ are legal and optimal. By Lemma 4.3, the only edges in both $C_i \cup Q$ and $C_j \cup Q$, for $i \neq j$ have an endpoint in Q. Therefore Q can always be colored the same way, and the combined coloring is legal and optimal. □

LEMMA 4.9. *The coloring algorithm can be implemented in $O(\log^2 n)$ time using $O(n^3)$ processors if the maximal cliques are included as part of the input.*

Proof. The analysis of the subroutines and steps 1 and 2 is identical to that in the proof of Lemma 4.7 analyzing the tree-construction algorithm.

We can implement step 3 as follows. Suppose that the graphs $C_i \cup Q$ are numbered in such a way that $C_1 \cup Q$ has the largest chromatic number. Take the coloring of $C_1 \cup Q$ to be fixed. For each other $C_i \cup Q$, compute a mapping Γ_i, represented as a table, from colors to colors. Every vertex of Q must get a different color from all the other vertices of Q. If $v \in Q$ has color a_1 in $C_1 \cup Q$ and color a_2 in $C_i \cup Q$, then in the table for $C_i \cup Q$, set $\Gamma_i(a_2) := a_1$; any vertex that used to be colored a_2 will be colored a_1. Let A_i be the set of colors used in $C_i \cup Q$ that are not used to color vertices of Q. Define Γ_i on A_i so that it maps A_i injectively to (arbitrary colors in) A_1. A satisfactory mapping Γ_i can be constructed in $O(\log n)$ time with $O(n)$ processors for each graph $C_i \cup Q$. Finally, recolor each vertex in $C_i \cup Q$ by applying the mapping Γ_i. Recoloring can be done in constant time using at most $O(n)$ processors per graph. Since there are at most $O(n)$ parallel calls at any given level of recursion, the total processor requirement for step 3 is $O(n^2)$. □

5. Perfect elimination scheme, independent set, clique cover. We use the tree-and-subtrees representation constructed in § 4 to give NC algorithms for finding a perfect elimination scheme, a maximum unweighted or weighted independent set, and a minimum clique cover in a chordal graph. The clique cover follows directly from the PES and the unweighted independent set. The basic idea for the PES and the independent sets is to process the tree in stages: in each stage, we first process and then delete

all terminal branches of the tree in parallel. A *terminal branch* is any path consisting of tree nodes of degree two or less and containing a leaf. After deleting the terminal branches, the new tree has at most half as many leaves as the old tree; therefore, there are at most $O(\log n)$ stages.

To process the terminal branches, we first need to identify them and number the nodes on them. On each terminal branch we number the nodes 1, 2, $\cdots$ starting at one leaf. Terminal branches can be identified and numbered with several applications of path doubling. Details are given in the technical report [Na87].

LEMMA 5.1 [Na87]. *The terminal branches can be identified and numbered in* $O(\log n)$ *time using* $O(n^2)$ *processors.*

To process one terminal branch in polylogarithmic time, we use the following observation.

Observation 5.2 [Gi64], [Go80]. If a chordal graph G has a tree-and-subtrees representation T, $\mathcal{S}$ in which every tree node corresponds to a maximal clique, every subtree in $\mathcal{S}$ corresponds to the set of maximal cliques containing a particular vertex, and T is a *path*, then G is an interval graph. In an interval graph the vertex corresponding to the interval with the leftmost right endpoint is simplicial.

Thus the cliques represented by nodes on any particular terminal branch induce an interval graph. Kozen, Vazirani, and Vazirani explain how to build an interval model for an interval graph [Ko85]. However, we want to build the models in such a way that the partial perfect elimination schemes for each of the interval graphs induced by the terminal branches fit together in a PES for the entire graph. The PES algorithm implicitly relies on the fact (proved below) that the following algorithm yields a representation of the interval graph corresponding to a terminal branch.

ALGORITHM TO CONSTRUCT AN INTERVAL MODEL FOR THE VERTICES ON A TERMINAL BRANCH

Input: A chordal graph G, a tree representation T, a terminal branch B of T, the set $\mathcal{C}(B)$ of maximal cliques corresponding to nodes on B.

Definition: Let $V(B)$ be the set of vertices of G occurring in some member of $\mathcal{C}(B)$.

Output: An interval model for the interval graph $G_{V(B)}$.

1. Let the size of $\mathcal{C}(B)$ be p_B. Index the members of $\mathcal{C}(B)$, by 1, 2, $\cdots$, p_B in the order in which the corresponding nodes appear on B starting at a leaf clique.
2. For each $v \in V(B)$, let $J(v)$ be the interval corresponding to v. Let the left endpoint of $J(v)$ be the lowest index of a maximal clique containing v. If v appears in a maximal clique of G that is not in $\mathcal{C}(B)$, then let the right endpoint of $J(v)$ be $p_B + 1$. Otherwise, let the right endpoint of $J(v)$ be the highest index of a maximal clique containing v.

LEMMA 5.3. *The algorithm to construct an interval model for* $G_V(B)$ *is correct.*

Proof. By Theorem 4.1, the nodes of B corresponding to maximal cliques containing a given vertex v induce a path. Therefore the interval $J(v)$ contains the index of a maximal clique $K \in \mathcal{C}(B)$ if and only if $v \in K$. Let distinct vertices v and $w \in V(B)$ be given. If v is adjacent to w, then they must both occur in some maximal clique $K \in \mathcal{C}(B)$. The index of K must be in both $J(v)$ and $J(w)$, so the intervals overlap. If v and w are not adjacent, they do not occur together in any maximal cliques, and the intervals $J(v)$ and $J(w)$ are disjoint. □

By Observation 5.2, the set $V(B)$ sorted according to the right endpoints of the intervals $J(v)$ is a PES for $G_{V(B)}$. For any terminal branch B, let $U(B)$ be the set of vertices that are in no maximal cliques represented by tree nodes outside B.

Observation 5.4. A vertex in $U(B_i)$ can never be adjacent to a vertex in $U(B_j)$ if B_i and B_j are different terminal branches. □

Since the vertices in $U(B)$ occur in no cliques corresponding to tree nodes outside B, a vertex in $U(B)$ is simplicial in G if and only if it is simplicial in $G_V(B)$. The PES defined by sorting the intervals produced by the algorithm above puts all vertices of $U(B)$ first. Thus there must be a PES for all of G that puts $U(B)$ first.

PERFECT ELIMINATION SCHEME ALGORITHM

Input: A chordal graph G, the maximal cliques of G, a tree representation T in which every node corresponds to a maximal clique.

Assumption: The cliques are represented by a vertex versus a maximal clique incidence matrix.

Output: A PES for $V(G)$.

1. In parallel, find all the terminal branches and number them arbitrarily, B_1, $B_2, \cdots, B_k$.
2. In each B_i, index the nodes (maximal cliques) 1, 2, $\cdots$ starting at a leaf.
3. For each B_i *in parallel*: Find the set $U(B_i)$.
4. For each B_i *in parallel*: Sort the vertices in $U(B_i)$ according to the highest index of a maximal clique in which they occur. Vertices whose highest indexed clique is lower come first. This sorted order is a PES for $G_{U(B_i)}$.
5. Append the vertices in the perfect elimination schemes for $U(B_1)$, $U(B_2), \cdots, U(B_k)$.
6. Delete every node in a terminal branch from T to get a new tree T'. Delete every vertex in every $U(B_i)$ to get a new graph G'. If T' is not empty, compute recursively a PES for the remaining nodes and append it to the partial elimination scheme computed so far.

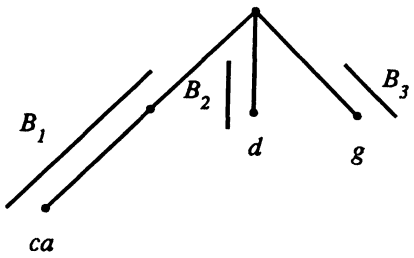

FIG. 4. *Terminal branches B_1, B_2, B_3 for the tree of Fig. 2 and their perfect elimination schemes.*

LEMMA 5.5. *The perfect elimination scheme algorithm is correct.*

Proof. As remarked after Observation 5.4 the sorted order on $U(B_i)$ produced in step 4 is not only a PES for $G_{U(B_i)}$, but it is also the beginning of a PES for all of G. From Observation 5.4, it follows that the perfect elimination schemes for the different branches can be put together in any order. The tree obtained by deleting all tree nodes in $B_1, B_2, \cdots, B_k$ is a tree representation having the desired clique properties for the graph induced by the vertices $V(G)\backslash(U(B_1) \cup U(B_2) \cup \cdots \cup U(B_K))$. □

Each ordering of the branches $B_1, B_2, \cdots, B_k$ gives a different PES. For example in Fig. 4, the perfect elimination schemes for the three branches are *ca*, *d*, and *g*. When the branches are numbered as shown, the complete PES is *cadgbef*. A different order of branches would result in a different, equally correct scheme.

LEMMA 5.6. *The perfect elimination scheme algorithm can be implemented to run in* $O(\log^2 n)$ *time using* $O(n^2)$ *processors (given all the maximal cliques and a tree representation).*

Proof. Steps 1 and 2 can be implemented in $O(\log n)$ time using $O(n^2)$ processors by Lemma 5.1.

If the entire tree consists of one branch B, then $U(B) = V(G)$. Otherwise, step 3 can be implemented in $O(\log n)$ time using $O(m)$ processors by assigning one processor to every pair $\langle v, Q\rangle$, where v is in the maximal clique Q, and the node q is on a terminal branch (B_i). The processor tests whether v also occurs in the maximal clique whose node is one further away from the leaf. If v does not occcur in that clique, then it is part of $U(B_i)$.

If v is put in $U(B_i)$ by the processor assigned to $\langle v, Q\rangle$ in step 3, then Q is the highest indexed clique in which it occurs. The clique indices can be sorted in step 4 in $O(\log n)$ time using $O(n)$ processors [Co86].

For step 5, we need to compute prefix sums of the sizes of $U(B_i)$ in order to decide where the PES for each branch starts in the final output sequence. This can be done in $O(\log n)$ time using $O(n)$ processors.

Step 6 requires copying every part of T and G and every maximal clique that remains for the recursive call. To copy T, assign one processor to each entry on an adjacency list for T. Keep the entry if and only if it is not a node on a terminal branch. Ignore all adjacency lists for nodes on terminal branches. The surviving part of the graph G can be copied similarly. If we represent G by an adjacency matrix, this operation requires $O(n^2)$ processors. The maximal cliques that survive are precisely those represented by nodes that are not on terminal branches.

As remarked at the beginning of § 5 an algorithm that in each stage prunes all terminal branches in a tree with at most n nodes is guaranteed to terminate after $O(\log n)$ stages. Therefore the PES algorithm requires $O(\log^2 n)$ time and $O(n^2)$ processors. □

Next we turn to maximum independent sets. To find an unweighted maximum independent set, we rely on the result of Gavril [Ga72] that the lexicographically first maximal independent set, using the vertex numbering given by a PES, is a maximum independent set. Our parallel algorithm computes a lexicographically first maximal independent set with respect to the PES computed by the previous algorithm.

The special case of maximum independent sets in interval graphs, even if the nodes have weights, can be solved by an algorithm of Helmbold and Mayr [He86] (or a similar algorithm of Bertossi and Bonuccelli [Be87]), which we discuss in more detail after showing how to use it for the unweighted independent set. In the unweighted case, the algorithms in [He86], [Be87] find the lexicographically first maximal independent set, which will be exactly what we need to make the independent set for the entire chordal graph lexicographically maximal, that is, maximum by Gavril's result.

If I is an independent set in G, and B is a branch of T, let $R(B, I)$ be $U(B)\backslash\{v \in V(G) \mid v \in N(I)\}$, where $N(I)$ is the set of neighbors of vertices in I.

UNWEIGHTED MAXIMUM INDEPENDENT SET ALGORITHM

Input: A chordal graph G, the set of maximal cliques of G, a tree representation T for G.

Output: An unweighted maximum independent set for G.

1. Set $I := \varnothing$.
2. In parallel, find all the terminal branches and number them arbitrarily, B_1, $B_2, \cdots, B_k$.

3. In each B_i, index the nodes (maximal cliques) 1, 2, $\cdots$ starting at a leaf.
4. For each B_i *in parallel*: Find the set $U(B_i)$.
5. For each B_i *in parallel*: Find the set $R(B_i, I)$.
6. For each branch B_i, use the algorithm in [He86] to compute a lexicographically first maximal independent set on $R(B_i, I)$ with respect to the lexicographic ordering given by the PES on $U(B_i)$.
7. Add the independent sets computed in step 6 to I.
8. Delete every node in a terminal branch from T to get a new tree T'. Delete every vertex in every $U(B_i)$ to get a new graph G'. Set $T := T'$. Do not overwrite the input copy of G, since we need it to compute the sets $R(B_i, I)$ in step 5.
9. If the new T is empty, return I; otherwise, go back to step 2 with the new values of T and I.

LEMMA 5.7. *The unweighted maximum independent set algorithm is correct.*

Proof. Let $v_1, v_2, \cdots, v_n$ be the PES we would get ordering the terminal branches the same way throughout both the PES and independent set algorithms. Partition $V(G)$ into sets $U_1, U_2, \cdots, U_l$ of vertices that occur consecutively in the PES so that each set U_j consists of precisely the vertices coming from one terminal branch. That is, $U_1 = U(B_1)$, $U_2 = U(B_2)$, and so on.

We prove by induction on j that the unweighted maximum independent set algorithm chooses a lexicographically first maximal independent set among the vertices in $U_1 \cup U_2 \cup \cdots \cup U_j \cup \cdots \cup U_l$. It then follows from Gavril's [Ga72] observation mentioned above that the algorithm computes a maximum independent set.

For the base case, consider $U_1 = U(B_1)$. The algorithm in [He86] yields a lexicographically first maximal independent set on the interval graph G_{U_1}. Let $I_j := I \cap (U_1 \cup U_2 \cup \cdots \cup U_j)$. Assume as the inductive hypothesis that I_{j-1} is the lexicographically first maximal independent set for the vertices in $U_1 \cup U_2 \cup \cdots \cup U_{j-1}$. Any vertex $v \in U(B_j)$ that is adjacent to a vertex w in I_{j-1} should not occur in the output. By Observation 5.4, any such vertex w must be in some $U(B_k)$, where B_k is a terminal branch that is processed before B_j and *not* in parallel with B_j. Thus the set $R(B_j, I)$ computed in step 5 contains precisely the vertices in $U(B_j)$ that are not adjacent to any vertex in I_{j-1}. The Helmbold and Mayr algorithm computes a lexicographically first maximal independent set for $R(B_j, I)$. Adding this set to I_{j-1} to obtain I_j ensures that I_j is indeed the lexicographically maximal independent set for $U_1 \cup U_2 \cup \cdots \cup U_j$. It follows by induction on j that the final independent set $I_l = I$ is the lexicographically first maximal independent set for the entire graph G. □

Before analyzing the resource requirements of our unweighted independent set algorithm, we describe the Helmbold and Mayr algorithm in more detail for both the unweighted and weighted cases. Let H be an interval graph with vertices $u_1, u_2, \cdots, u_p$ ordered by the left to right order of the right endpoints of the corresponding intervals, $i_1, i_2, \cdots, i_p$. Construct a directed graph $D(H)$ on the same vertex set as follows. Put in the arc $u_j \to u_k$ if $j < k$ and the right endpoint of i_j comes before the left endpoint of i_k, so that the intervals i_j and i_k do not overlap. The edge set of $D(H)$ is a partial order, often called the *interval order*, associated with $\{i_1, i_2, \cdots, i_p\}$ [Go80].

Helmbold and Mayr observed that the lexicographically first maximal unweighted independent set of H contains exactly the vertices on the lexicographically first maximal path in $D(H)$. At most one outgoing arc from each vertex can possibly occur in the maximal path, namely the arc to the vertex with the lowest index (subscript). Thus the computation can be restricted to a subgraph $D'(H)$ of $D(H)$ where every vertex has outdegree at most 1; the *outdegree* of a vertex is the number of outgoing arcs

incident to it. The lexicographically first maximal paths of $D'(H)$ and of $D(H)$ coincide. The subgraph $D'(H)$ can be computed in $O(\log n)$ time using $O(V(D(H))^2)$ processors. Since each vertex of $D'(H)$ has outdegree 1, one can find the lexicographically first maximal path by path doubling in $O(\log n)$ time using a linear number of processors.

In the weighted independent set algorithm, we will need to allow H to be weighted, and to find the heaviest independent set containing only vertices in $\{u_1, u_2, \cdots u_r\}$ for different values of $r \leqq p$. We build $D(H)$ as before with two minor differences. First, we add a source vertex u_0 and an arc $u_0 \to u_j$ for each j, $1 \leqq j \leqq p$, having as its weight the weight of u_j in H. Second, we give arc $u_j \to u_k$ the weight that u_k has in H.

A maximum weight independent set in H corresponds to a maximum weight path in $D(H)$. Helmbold and Mayr do the computation by applying a *max-plus closure* to the weighted adjacency matrix for $D(H)$. Max-plus closure produces a $(p+1) \times (p+1)$ matrix, and is algebraically analogous to multiplying p copies of the weighted adjacency matrix for $D(H)$ together, except that the usual operations of addition and multiplication are replaced by max and addition, respectively. The weight of a heaviest path will be the largest number in the final result. The weight of the heaviest path using only vertices in $\{u_0, u_1, \cdots, u_r\}$ for some $r < p$, is given by the maximum among the entries in the submatrix of the final result induced by rows $0, 1, \cdots, r$ and columns $0, 1, \cdots, r$.

LEMMA 5.8. *The unweighted independent set algorithm for chordal graphs can be implemented to run in $O(\log^2 n)$ time using $O(n^2)$ processors (if the maximal cliques and a tree representation are included in the input).*

Proof. Step 1 can be implemented in constant time using $O(n)$ processors. Steps 2, 3, and 4 are identical to steps 1, 2, and 3 of the PES algorithm. In step 5, we compute $R(B_i, I)$. This can be done by checking all the neighbors of each vertex in $U(B_i)$, assigning one processor per edge. If $v \in U(B_i)$ has a neighbor w that is already in I, then v should not be in $R(B_i, I)$. This computation takes $O(\log n)$ time and $O(m)$ processors. In the unweighted case, the Helmbold and Mayr algorithm used in step 6 takes $O(\log n)$ time and use $O(m)$ processors. The augmentation of I in step 7 can be done in constant time using $O(n)$ processors. Step 8 is identical to step 6 of the PES algorithm, except that in this case we do not overwrite the original copy of G.

In each iteration of the loop in steps 2 through 9, we process and delete all terminal branches. Thus, there are $O(\log n)$ iterations, and the total running time is $O(\log^2 n)$. □

Our algorithm for maximum weighted independent sets in a chordal graph is a parallelization of the following sequential algorithm of Frank [Fr75] (see also [Lo85]). Let $w(v)$ be the weight of vertex v.

SEQUENTIAL MAXIMUM WEIGHTED INDEPENDENT SET ALGORITHM
Input: A chordal graph G with vertex weights and numbered as in a PES.
Output: A maximum weight independent set for G.

1. Let v be the first vertex in the PES.
2. Delete all vertices $u \in N(v)$ such that $w(u) \leqq w(v)$.
3. For all remaining vertices $u \in N(v)$, set $w(u) := w(u) - w(v)$.
4. Recursively find a maximum weight independent set in the remaining graph with the updated weights.
5. If no vertex in $N(v)$ is in the set computed in step 4, then add v to the weighted independent set.

To implement this algorithm in parallel, we again process all terminal branches of the tree in parallel, but the computation for each branch is more complicated than

in the unweighted case.

SKETCH OF A PARALLELIZATION OF FRANK'S WEIGHTED INDEPENDENT SET ALGORITHM

Input: G, all maximal cliques, a tree representation, a weight function w on $V(G)$.
Output: The maximum weight independent set that Frank's sequential algorithm would compute, assuming the vertices are numbered according to the PES that our parallel algorithm would compute.

1. If the tree is a path, use the algorithm of Helmbold and Mayr to compute a maximum weighted independent set on the interval graph G. Otherwise, proceed to the following steps.
2. Identify and number the terminal branches $B_1, B_2, \cdots, B_k$.
3. Index the nodes on each terminal branch as in the previous algorithms.
4. For each branch B_i *in parallel*: Compute the set $U(B_i)$.
5. For each $U(B_i)$ *in parallel*: Find its subset $S_2(B_i)$ of vertices that would survive step 2 of the sequential algorithm if it were to process the vertices in $U(B_i)$ in the same order as in the PES. Ignore any vertices of weight less than or equal to zero.
6. Update the weights of all vertices, as in step 3 of the sequential algorithm.
7. Delete the terminal branches and recursively compute the maximum weight independent set of what remains.
8. For each $S_2(B_i)$ computed in step 5, decide which vertices can be added to the independent set, as in step 5 of the sequential algorithm.

We now elaborate a bit on steps 5, 6, and 8 that are especially sketchy. Suppose $U(B_i)$ contains the vertices $v_{i_1}, v_{i_2}, \cdots, v_{i_s}$, which are consecutive in the PES we construct. We need to decide for each of those vertices whether it would get deleted in step 2 of Frank's sequential algorithm. To do this, we use the weighted version of the Helmbold and Mayr algorithm. Recall that we mentioned that the Helmbold and Mayr algorithm also allows us to determine the maximum weight independent set of any of the subgraphs H_j induced by $\{v_{i_1}, v_{i_2}, \cdots, v_{i_j}\}$ for each j, $1 \leqq j \leqq s$. The vertex v_{i_j} is eliminated in step 2 of Frank's algorithm if and only if there is a maximum weight independent set in H_j that does not contain v_{i_j}. This can be determined by comparing the maximum weight for H_{j-1} and for H_j. An analogous computation works for all terminal branches.

In step 6, we update the weights of all the vertices as in step 4 of Frank's algorithm. For each B_i and each vertex $v \in S_2(B_i)$, the fact that v survives step 5 forces us to update the weights of its neighbors not yet processed. If u is one of its neighbors, we want to change the "current" weight of u by the following assignment: $w(u) := w(u) - w(v)$. Each assignment is an arithmetic expression using one subtraction and no additions, divisions, or multiplications. We can compute all the assignments symbolically and order them as we would have done them in the sequential algorithm. All the assignments required by vertices in $S_2(B_i)$ are listed before those for $S_2(B_{i+1})$. The list of assignments is a straight-line program for the weights involving no multiplications or divisions. By evaluating this program, we can compute the weight of each vertex after all vertices in $U(B_1), U(B_2), \cdots, U(B_k)$ have been processed as far as step 7. The program can be evaluated using the methods of Miller and Reif [Mi85]. In their framework, our straight-line program becomes an expression tree. One subtlety is that we may need $O(n)$ processors at each of the $O(n)$ nodes in the expression tree because each time we consider one vertex, we may change the weight of any of its neighbors.

To do step 8 for $S_2(B_i)$, we first delete any vertex in $S_2(B_i)$ adjacent to any vertex in the maximum weight independent set returned by the next deepest recursive call.

What remains is a subset of $S_2(B_i)$ that again induces an interval graph. We number the vertices in the reverse order to that in which they were processed. This order corresponds to the fact that in the sequential algorithm the vertices are chosen in the PES order at step 1, and considered in reverse PES order at step 5. Once we have the remaining vertices in reverse order, we run the unweighted version of the Helmbold and Mayr algorithm to find the lexicographically maximal independent set among them. This set contains precisely those vertices that would be chosen in step 5 of the sequential algorithm.

Summarizing the above discussion, gives us Lemma 5.9.

LEMMA 5.9. *The parallel algorithm to compute a maximum weight independent set is correct.*

Proof. We process the vertices in the order of a PES as is done in Frank's sequential algorithm. Vertices that come from two different terminal branches that are processed in parallel have no effect on each other in the sequential algorithm. The fact that step 5 of the parallel algorithm correctly simulates the test in step 2 of the sequential algorithm follows from the correctness of the algorithm in [He86]. In step 6, we do the same weight updates as in step 3 of the sequential algorithm. In step 8, we consider adding vertices in reverse order exactly as in the sequential algorithm. The correctness of our implementation of step 8 follows from correctness of the algorithm in [He86]. □

LEMMA 5.10. *The maximum weight independent set algorithm can be implemented to run in $O(\log^3 n)$ time using $O(n^4)$ processors (given the maximal cliques and a tree representation).*

Proof. Step 1 can be implemented in $O(\log^2 n)$ time using $O(n^3)$ processors which are the bounds for computing the necessary max-plus closure. Steps 2, 3, and 4 are identical to steps 2, 3, and 4 in the unweighted case. In step 5, we instantiate one copy of the Helmbold and Mayr algorithm for each vertex in $U(B_i)$, where B_i is some terminal branch that we are processing. This takes $O(\log^2 n)$ time and $O(n^3)$ processors per instance. The total processor requirement is $O(n^4)$ for all the instances that we run in parallel.

In step 6, we evaluate the straight-line program containing the weight updates. The program can be evaluated in $O(\log n)$ time with $O(n^2)$ processors using the methods of Miller and Reif [Mi85]. Step 7 is similar to step 8 in the unweighted independent set algorithm. In step 8, we instantiate one copy of the unweighted version of the Helmbold and Mayr algorithm for each terminal branch. No vertex occurs in more than one of the parallel instances, so they can be implemented in $O(\log n)$ time using $O(n^2)$ processors altogether.

Multiplying the time requirements for each step by $O(\log n)$ to account for the recursion depth yields the desired results. □

To conclude this section we explain how to compute a minimum clique cover for a chordal graph.

LEMMA 5.11. *Given a perfect elimination scheme for a chordal graph G and the corresponding lexicographically first maximal independent set, it is possible to compute a minimum clique cover for G in $O(\log n)$ time using $O(m)$ processors.*

Proof. Given a perfect elimination scheme $v_1, v_2, \cdots, v_n$, and any vertex $v \in V(G)$, let $X(v)$ be the neighbors of v that are listed after v in the scheme. Gavril [Ga72] observed that if $\{w_1, w_2, \cdots, w_k\}$ is the lexicographically first maximal independent set corresponding to the given elimination scheme, then the sets $\{w_1\} \cup X(w_1)$, $\{w_2\} \cup X(w_2), \cdots, \{w_k\} \cup X(w_k)$ form a minimum clique cover for G.

These k cliques can be computed in parallel by assigning one processor to every

edge $v-w$. If v comes before w in the PES, then $w \in X(v)$; otherwise $v \in X(w)$. □

This concludes the proof of Theorem 1.1. Combining Lemmas 2.2, 3.8, 4.7, 4.9, 5.6, 5.8, 5.10, and 5.11 yields:

COROLLARY 5.12. *All the objects listed in Theorem* 1.1, *except a maximum weighted independent set, can be computed in* $O(\log^2 n)$ *time using* $O(n^5)$ *processors. All the objects can be found in* $O(\log^3 n)$ *time using* $O(n^4)$ *processors.* □

Acknowledgments. Danny Soroker suggested the current formulation of Lemma 3.2 which led us to find a simplification for the bi-clique subroutine. Professor Richard Anderson, Dr. Ronald Fagin, Professor Richard Karp, Professor Ernst Mayr, Professor Christos Papadimitriou, Dr. David Peleg, and Dr. Larry Stockmeyer, and two referees made helpful comments on various earlier drafts. Professor D. Shier told us about the work in [Ch86]. Mark Novick told us about the tree-construction algorithm in [Be81]. Professors Elias Dahlhaus, Marek Karpinski, and Ernst Mayr helped us understand the algorithms of Dahlhaus and Karpinski sketched in [Da86].

ON THE WORST-CASE ARITHMETIC COMPLEXITY OF APPROXIMATING ZEROS OF SYSTEMS OF POLYNOMIALS*

JAMES RENEGAR†

Abstract. Let $d_1, \cdots, d_n$ be positive integers. Let $\mathcal{P}$ denote the set of systems of polynomials $f: \mathbb{C}^n \to \mathbb{C}^n$ that have only finitely many zeros, including those "at infinity," and that satisfy degree $(f_i) = d_i$ for all i. Let $0 < \varepsilon \leqq R$. It is shown for fixed $d_1, \cdots, d_n$, that with respect to a certain model of computation, the worst-case computational complexity of obtaining ε-approximations to at least those zeros ξ satisfying $|\xi| \leqq R$ for arbitrary $f \in \mathcal{P}$, is $\Theta(\log\log(R/\varepsilon))$; that is to say, both upper and lower bounds are proved. An algorithm for proving the upper bound is introduced. The number of operations required by this algorithm is

$$O\left[n\mathcal{D}^4(\log \mathcal{D})(\log\log(R/\varepsilon)) + n^2\mathcal{D}^4\binom{1+\sum d_i}{n}^4\right], \quad \text{where } \mathcal{D} = \prod_{i=1}^{n} d_i.$$

1. Introduction. Let $P_d(R)$ denote the set of degree-d univariate complex polynomials with all zeros ξ satisfying $|\xi| \leqq R$. It was shown in [10], for fixed $d \geqq 2$, that with respect to a certain model of computation, the worst-case arithmetic complexity of obtaining ε-approximations to either one, or to each, zero of arbitrary $f \in P_d(R)$ is $\Theta(\log\log(R/\varepsilon))$. More specifically, in terms of d as well, a lower bound of $\Omega(\log\log(R/\varepsilon)) - O(\log d)$ operations was proven, and a new algorithm, requiring $O(d^2(\log d)(\log\log(R/\varepsilon)) + d^3 \log d)$ operations, was introduced for the problem of obtaining ε-approximations to all of the zeros. We refer the reader to Renegar [10] for the general model of "computation tree" used to prove the lower bound, but we remark that it encompasses algebraic RAMs (random access machines) whose operations are $+, -, \times, \div$, complex conjugation, and inequality comparison. (See Borodin and Munro [1] as a reference.) Arithmetic operations are assumed to be performed with infinite precision over the complex numbers. The coefficients of the polynomials are *not* assumed to be rationals; therefore, in terms of the "length" of the coefficients, simplifying properties such as lower bounds on the distance between distinct zeros cannot be used. For rational coefficients of fixed length, a uniform $\log\log(R/\varepsilon)$ upper bound is fairly straightforward to prove, but for arbitrary complex coefficients it is not.

The purpose of this paper is to present appropriate generalizations of the above results to the several-variable setting.

Of course, systems of polynomials are not nearly as simple as univariate polynomials. For example, univariate polynomials have finitely many zeros but polynomial systems $f: \mathbb{C}^n \to \mathbb{C}^n$ can have infinitely many zeros, so we cannot hope to approximate all of the zeros unless we restrict attention to "nice" systems. The nice systems to which we restrict our attention in this paper are those systems having only finitely many zeros, including the zeros "at infinity." Formally, if $F: \mathbb{C}^{n+1} \to \mathbb{C}^n$ is the

homogenization of f (i.e., if degree $(f_i) = d_i$, then the terms of F_i are obtained by multiplying the terms of f_i by the appropriate powers of z_{n+1} so as all to become a degree d_i), then f is said to have finitely many zeros, including those at infinity, if the zero set of F is the union of finitely many complex lines through the origin in $\mathbb{C}^{n+1}$. We refer to these lines as the "zero lines" of F; in the literature they are often referred to as the "solution rays" of F. The zero lines of F that are in $\mathbb{C}^n \times \{0\}$ correspond to the zeros of f at infinity. There is an obvious correspondence between the other zero lines of F and the zeros of f in $\mathbb{C}^n$.

Let $d_1, \cdots, d_n$ be positive integers. Let $\mathscr{P}$ denote the set of systems $f = (f_1, \cdots, f_n): \mathbb{C}^n \to \mathbb{C}^n$ with only finitely many zeros, including those at infinity, and satisfying degree $(f_i) = d_i$ for all i. (Of course $\mathscr{P}$ depends on the specific values of $d_1, \cdots, d_n$.)

We consider the following problem. Let $R \geqq \varepsilon > 0$ and assume $f: \mathbb{C}^n \to \mathbb{C}^n$ is a polynomial system satisfying degree $(f_i) = d_i$ for all i. First determine if $f \in \mathscr{P}$. If so, determine ε-approximations to a subset of the zeros of f containing at least all zeros ξ satisfying $|\xi| \leqq R$. (An ε-approximation of a zero is a point within Euclidean distance ε of the zero.) More specifically, determine points $\mathbb{X}^{(1)}, \cdots, \mathbb{X}^{(m)} \in \mathbb{C}^n$ for which there exist zeros $\xi^{(1)}, \cdots, \xi^{(m)}$ of f with $\|\mathbb{X}^{(i)} - \xi^{(i)}\| \leqq \varepsilon$, where each zero ξ of f satisfying $|\xi| \leqq R$ is listed among the $\xi^{(i)}$ a number of times exactly equal to its multiplicity, and where no zero of f is listed among the $\xi^{(i)}$ a greater number of times than its multiplicity. (Thus, if each zero ξ of f satisfies $|\xi| \leqq R$, then each zero can be considered as being approximated by several points $\mathbb{X}^{(i)}$, the number of such points being equal to its multiplicity.)

We refer to the above approximation problem as "the (ε, R)-approximation problem for f."

We present a test involving

$$O\left[n\mathscr{D}^2 \binom{1+\sum d_i}{n}^4 \right] \quad \text{operations,} \quad \text{where } D = \prod_{i=1}^{n} d_i$$

for determining if $f \in \mathscr{P}$. The validity of this test follows straightforwardly from well-known facts regarding resultants. (Resultants are discussed in § 2.) For those f's that pass this test, that is, for $f \in \mathscr{P}$, we also present an algorithm for solving the (ε, R)-approximation problem for f. The operation count for this algorithm is

$$O\left[n\mathscr{D}^4(\log \mathscr{D})(\log\log(R/\varepsilon)) + n^2\mathscr{D}^4 \binom{I+\sum d_i}{n}^4 \right].$$

Note that coefficient "sizes" do not enter into this bound in any way.

A significant fact about the bound is how it depends on ε and R, that is, the $\log\log(R/\varepsilon)$ term. The lower bound in Renegar [10] showed that in the univariate setting this is the best possible dependence on R and ε that can be obtained. However, that lower bound implies the same lower bound for the several-variable setting. Assume that one of the $d_i \geqq 2$, say, $d_1 \geqq 2$. If $g \in P_{d_1}(R)$ (i.e., a degree-d_1 univariate polynomial with all zeros ξ satisfying $|\xi| \leqq R$), then $f: \mathbb{C}^n \to \mathbb{C}^n$ defined by $f_1(z) = g(z_1)$, $f_2(z) = z_2^{d_2}, \cdots, f_n(z) = z_n^{d_n}$ satisfies $f \in \mathscr{P}$. Any ε-approximation to a zero of f easily gives an ε-approximation to a zero of g. Hence, the (ε, R)-approximation problem for arbitrary $f \in \mathscr{P}$ is at least as hard as the ε-approximation problem for arbitrary $g \in P_{d_1}(R)$, and thus, in the worst case, requires $\Omega(\log\log(R/\varepsilon)) - O(n + \log d_1)$ operations. (The "n" occurs to account for the cost of conversion to the several-variable problem.)

Together, our upper and lower bounds give the main theorem.

MAIN THEOREM. *Fix* $d_1, \cdots, d_n$ *and assume* $\mathscr{D} = \prod_{i=1}^n d_i \geqq 2$. *Let* $0 < \varepsilon \leqq R$. *The arithmetic complexity of obtaining* ε*-approximations to at least those zeros* ξ *of arbitrary* $f \in \mathscr{P}$ *satisfying* $|\xi| \leqq R$ *is* $\Theta(\log\log(R/\varepsilon))$.

Another noteworthy fact about the upper bound is that it is not doubly exponential in n, in contrast to bounds for classical approaches using elimination theory (e.g., see the sections on elimination theory that appear in Van der Waerden [11]—these sections do not appear in newer editions of the book).

The algorithm for obtaining approximations to the zeros of $f \in \mathscr{P}$ is actually an algorithm for obtaining approximations to all of the zero lines of the homogenization $F: \mathbb{C}^{n+1} \to \mathbb{C}^n$ of f, along with a few operations to transform the approximations for F to those for f. By "ε-approximations to all of the zero lines of F" we mean nonzero vectors $\mathbb{X}^{(i)} \in \mathbb{C}^{n+1}$, $i = 1, \cdots, \mathscr{D}$, for which there exists a one-to-one correspondence with nonzero vectors $\xi^{(i)} \in \mathbb{C}^{n+1}$, $i = 1, \cdots, \mathscr{D}$ (say, $\mathbb{X}^{(i)}$ corresponds to $\xi^{(i)}$), where the zero lines of F are precisely the lines $\{\lambda\xi^{(i)};\ \lambda \in \mathbb{C}\}$, $i = 1, \cdots, \mathscr{D}$, each occurring according to its multiplicity, and where

$$\left\| \frac{\mathbb{X}^{(i)}}{\|\mathbb{X}^{(i)}\|} - \frac{\xi^{(i)}}{\|\xi^{(i)}\|} \right\| \leqq \varepsilon.$$

$\| \ \|$ denoting the Euclidean norm on $\mathbb{C}^{n+1}$. (The fact that F has $\mathscr{D}$ zero lines, counting multiplicities, is immediate from Theorem 2.3.)

Assuming $\varepsilon \leqq R$, in the appendix we show that if $\mathbb{X}^{(i)}$, $i = 1, \cdots, \mathscr{D}$, are $\varepsilon/4(R+1)^2$-approximations to all of the zero lines of F, then the set of vectors

$$\left\{ \left(\frac{\mathbb{X}_1^{(i)}}{\mathbb{X}_{n+1}^{(i)}}, \cdots, \frac{\mathbb{X}_n^{(i)}}{\mathbb{X}_{n+1}^{(i)}} \right);\ |\mathbb{X}_{n+1}^{(i)}| / \|\mathbb{X}^{(i)}\| \geqq \frac{3}{4}(R+1) \right\} \tag{1.1}$$

is a solution for the (ε, R)-approximation problem for f.

Let $d_1, \cdots, d_n$ be positive integers. Let $\mathscr{H}$ denote the set of systems of homogeneous polynomials $F: \mathbb{C}^{n+1} \to \mathbb{C}^n$ that have only finitely many zero lines and that satisfy degree $(F_i) = d_i$ for all i.

Henceforth, we focus on the following problem. Given a system of homogeneous polynomials $F: \mathbb{C}^{n+1} \to \mathbb{C}^n$, where degree $(F_i) = d_i$ for all i, is $F \in \mathscr{H}$? If so, determine ε-approximations to all of the zero lines of F.

We present a test involving $O\left[n\mathscr{D}^2\binom{1+\sum d_i}{n}\right]$ operations for determining if $F \in \mathscr{H}$, where $\mathscr{D} = \prod_{i=1}^n d_i$. For $F \in \mathscr{H}$, we present an algorithm for obtaining ε-approximations to all of the zero lines of F. The operation count for this algorithm is

$$O\left[n\mathscr{D}^4(\log \mathscr{D})(\log\log(1/\varepsilon)) + n^2\mathscr{D}^4\binom{1+\sum d_i}{n}^4 \right]. \tag{1.2}$$

From these bounds and (1.1), follow the upper bounds stated earlier to determine if $f \in \mathscr{P}$ and to solve the (ε, R)-approximation problem for arbitrary $f \in \mathscr{P}$.

Using the lower bound of Renegar [10], one can prove that as regards ε, the term $\log\log(1/\varepsilon)$ occurring in (1.2) is the best possible.

Our algorithm is similar in spirit to the algorithm of Lazard [6]; both algorithms work by factoring the "u-resultant." Lazard only sketches a complexity analysis, avoiding degenerate situations and implicitly assuming that the zeros of a single-variable polynomial can be calculated exactly. It is not very difficult to determine "reasonable" complexity bounds for his algorithm if one is only concerned with rational coefficients and is satisfied with a bound on the number of arithmetic operations that grows with the coefficient "lengths." However, his algorithm and analysis are far from providing a uniform bound on arithmetic operations that is independent of the coefficients.

It should be mentioned that Lazard does not restrict attention to the field of complex numbers. Chistov and Grigor'ev [3], [4] extended Lazard's analysis to the problem of approximating a point in each component of the zero set of an arbitrary system of polynomials $f:\mathbb{C}^n \to \mathbb{C}^m$ with rational coefficients. Their bound on the required number of arithmetic operations has the maximal coefficient length as a factor. Similarly, this length appears as a factor in the arithmetic operation bound for the recent algorithm of Canny [2]. Canny's algorithm approximates zeros of systems $f:\mathbb{C}^n \to \mathbb{C}^n$ also via the u-resultant.

Of related interest is Grigor'ev and Vorobjov [5], where the problem of constructing approximate solutions to systems of real polynomial inequalities with rational coefficients is considered. Their arithmetic operation bound has the maximal coefficient length as a factor.

It is certainly not the case that our upper bound can be obtained by rounding coefficients to rationals (where the rounding is a function of R and ε) and then applying the results mentioned above. Because those results have arithmetic operation bounds (not just bit operation bounds) with the maximal coefficient bit length as a fundamental factor, proving our $\log\log(R/\varepsilon)$ result in this manner would require showing that every polynomial system can be perturbed to one with rational coefficients of length bounded by $\log(R/\varepsilon)$, where each zero ξ, $\|\xi\| \leqq R$ of the original system is approximated within distance ε by a zero of the perturbed system. For example, assuming $R=1$ and $\varepsilon=(1/2)^L$, in the univariate case of degree d one would at least need each point in the unit disk in $\mathbb{C}$ to be within distance $(1/2)^L$ of a root of one of the $[O(L)]^{2(d+1)}$ polynomials $\sum_{i=0}^{d} a_i z^i$ with a_i complex rationals of bit length $O(L)$. Of course this is not possible for L large compared to d.

In Renegar [9], a probabilistic analysis of an algorithm for approximating all of the zeros of systems of polynomials is given. The bounds are polynomial in n, $\mathscr{D}$, and L, where L is the number of nonzero coefficients in the considered systems. Hence, by focusing on "sparse" systems, a probabilistic bound independent of $\binom{1+\sum d_i}{n}$ can be obtained. (Note that $\binom{1+\sum d_i}{n}$ grows like $\mathscr{D}^n$ when, for example, all polynomials except one are linear.)

Our algorithm relies on the univariate algorithm of Renegar [10]. The reliance on that particular algorithm is not crucial. What is needed is an algorithm for approximating all zeros of arbitrary $f \in P_d(R)$ with worst-case operation count growing only like $\log\log(R/\varepsilon)$ with respect to ε and R.

2. A few facts about resultants. Let $\mathscr{H}^n_{d_1,\cdots,d_n}$ denote the set of all homogeneous polynomial systems $G:\mathbb{C}^n \to \mathbb{C}^n$ satisfying degree $(G_i) = d_i$. The resultant R for systems in $\mathscr{H}^n_{d_1,\cdots,d_n}$ is a homogeneous polynomial in the coefficients of these systems. It has the property that $R(G)=0$ if and only if G has a nontrivial zero, i.e., $G(x)=0$ for some $x \neq 0$. In this section we state a few facts regarding the resultant that are crucial for our algorithm.

Let $\bar{d} = 1 - n + \sum_i d_i$ and consider $\mathscr{H}^n_{\bar{d}}$, the vector space consisting of all homogeneous polynomials $g:\mathbb{C}^n \to \mathbb{C}$ of degree $\bar{d}$, along with the zero map. A basis for this space is easily seen to be given by the set of terms

$$B = \left\{ z_1^{i_1} z_2^{i_2} \cdots z_n^{i_n}, \qquad \sum_j i_j = \bar{d}, \text{ each } i_j \text{ is a nonnegative integer} \right\}.$$

It is easily shown by the definition of $\bar{d}$ that each of the terms in B satisfies $i_j \geqq d_j$ for at least one j. Partition B into the disjoint union $\cup_{j=1}^{n} B_j$, where B_j contains all terms $z_1^{i_1} \cdots z_n^{i_n}$ satisfying $i_1 < d_1, \cdots, i_{j-1} < d_{j-1}, i_j \geqq d_j$.

To each system $G \in \mathscr{H}^n_{d_1,\cdots,d_n}$ we can associate a linear map from $\mathscr{H}^n_{\bar{d}}$ to itself, defined for the basis terms in B_j by

$$z_1^{i_1} \cdots z_n^{i_n} \mapsto z_1^{i_1} \cdots z_j^{i_j - d_j} \cdots z_n^{i_n} \cdot G_j(z_1, \cdots, z_n).$$

Let $a_j(i_1, \cdots, i_n)$ denote the coefficient in G_j of the term $z_1^{i_1} \cdots z_n^{i_n}$. In terms of the basis B, the matrix corresponding to the above linear map is simply the following: the entry in the intersection of the column and row corresponding to $z_1^{i_1} \cdots z_n^{i_n} \in B_j$ and $z_1^{k_1} \cdots z_n^{k_n}$, respectively, is $a_j(k_1 - i_1, \cdots, k_j - i_j + d_j, \cdots, k_n - i_n)$ if $i_1 \leqq k_1, \cdots, i_j \leqq k_j + d_j, \cdots, i_n \leqq k_n$, and equals zero otherwise. Let $D(G)$ denote the determinant of this matrix. Then $D(G)$ is a homogeneous polynomial in the coefficients of $G \in \mathscr{H}^n_{d_1,\cdots,d_n}$. In fact, it is homogeneous in the coefficients of G_i and has degree, in those coefficients, equal to the number of terms in B_i. Its total degree equals the number of terms in B, that is, $\binom{\bar{d}+n-1}{n-1} = \binom{\sum d_i}{n-1}$.

Assume that the linear map associated with $G \in \mathscr{H}^n_{d_1,\cdots,d_n}$ is nonsingular, so that for each $i = 1, \cdots, n$ some polynomial in $\mathscr{H}^n_{\bar{d}}$ is mapped to the term $z_i^{\bar{d}}$. Hence, for each i,

$$z_i^{\bar{d}} = \sum_{j=1}^{n} p_j(z_1, \cdots, z_n) G_j(z_1, \cdots, z_n)$$

for some polynomials $p_1, \cdots, p_n$ (dependent on i). It easily follows that $G(x) \neq 0$ if $x \neq 0$. Thus $D(G) = 0$ is a necessary condition for these to exist a nontrivial zero for G. However, it is not a sufficient condition, but we do have the following remarkable theorem.

THEOREM 2.1 (Macaulay, 1902, Theorem 6). *Let $M(G)$ denote the determinant of the submatrix (of the matrix corresponding to the linear map induced by G) consisting of entries for which both the row and column correspond to terms in B of the form $z_1^{i_1} \cdots z_n^{i_n}$, with at least two i_j and i_k satisfying $i_j \geqq d_j$, $i_k \geqq d_k$. Then $M(G)$, a polynomial in the coefficients of $G \in \mathscr{H}^n_{d_1,\cdots,d_n}$, is a factor of the polynomial $D(G)$. Moreover, letting $R(G)$ be the polynomial satisfying $D(G) = M(G)R(G)$, then having $R(G) = 0$ is a necessary and sufficient condition for G to have a nontrivial zero.* □

Remark. Macaulay's Theorem 6 actually does not state the last conclusion of Theorem 2.1. This was well known to him, and is stated in the introduction to his paper. A proof of the last conclusion is given in Van der Waerden [11], § 82. (Beware that in some editions of Van der Waerden's book this section on elimination theory has been eliminated!)

The polynomial $R(G)$ is the "resultant." Both it and $M(G)$ are homogeneous in the coefficients of each G_i. The degree of $R(G)$ in the coefficients of G_i is $\prod_{j \neq i} d_j$. Also, $M(G)$ is independent of the coefficients of G_n.

We now turn our attention to systems of homogeneous polynomials $F: \mathbb{C}^{n+1} \to \mathbb{C}^n$ satisfying degree $(F_i) = d_i$. Let $\mathscr{H}^{n+1}_{d_1,\cdots,d_n}$ denote the set of these systems. Here we are concerned with the question, "Does $F \in \mathscr{H}^{n+1}_{d_1,\cdots,d_n}$ have only finitely many zero lines?"

Let $u_1, \cdots, u_{n+1}$ denote variables. For specified values of these variables, consider the system $z \mapsto (F(z), u \cdot z)$, where $u \cdot z = \sum_i u_i z_i$. This is a system in $\mathscr{H}^{n+1}_{d_1,\cdots,d_n,1}$. Let $R(F, u)$ denote the resultant of this system. For D and M as in Theorem 2.1, define $D(F, u)$ and $M(F, u)$ analogously. These are polynomials in the coefficients of $F \in \mathscr{H}^{n+1}_{d_1,\cdots,d_n}$ and the variables u. In the literature, $R(F, u)$ is sometimes referred to as "the u-resultant of F."

We remark, for future reference, that the determinant $M(F, u)$ is independent of the variables u. Also, $D(F, u)$ is the determinant of a $\binom{1+\sum d_i}{n} \times \binom{1+\sum d_i}{n}$ matrix, and $M(F, u)$ is the determinant of a smaller matrix.

PROPOSITION 2.2. *Fix* $F \in \mathscr{H}^{n+1}_{d_1,\cdots,d_n}$. *Then* $R(F, u) = 0$ *for all* u *if and only if* F *has infinitely many zero lines.*

Proof. This is well known. Here is a short proof.

Assume that F has finitely many solution lines. For each of these lines, choose a nonzero vector on that line. Assume $\alpha^{(1)}, \cdots, \alpha^{(m)}$ are the chosen vectors. There exists $x \in \mathbb{C}^{n+1}$ such that $x \cdot \alpha^{(i)} \neq 0$ for all i. Then the system $z \mapsto (F(z), x \cdot z)$ has no nontrivial zero and hence $R(F, x) \neq 0$.

Now assume that F has infinitely many solution lines. Choose nonzero vectors $\alpha^{(1)}, \alpha^{(2)}, \cdots$, on each line in an infinite, but countable, subset of the zero lines. Fix $x \in \mathbb{C}^{n+1}$ satisfying $x \notin \bigcup_i \{y;\ \alpha^{(i)} \cdot y = 0\}$. There exists a complex line L containing x that has infinitely many intersection points with $\bigcup_i \{y;\ \alpha^{(i)} \cdot y = 0\}$. However, for each of these intersection points y, the map $z \mapsto (F(z), y \cdot z)$ has a nontrivial solution so that $R(F, y) = 0$. Hence, the univariate polynomial obtained by restricting $R(F, u)$ to $u \in L$ has infinitely many zeros, and thus must be the zero polynomial. Consequently, $R(F, x) = 0$. Finally, if $x \in \bigcup_i \{y;\ \alpha^{(i)} \cdot y = 0\}$ then it is easy to prove that $R(F, x) = 0$. □

The following theorem is the cornerstone for our algorithm.

THEOREM 2.3. *Assume that* $F \in \mathscr{H}^{n+1}_{d_1,\cdots,d_n}$ *has only finitely many zero lines. For* $u \in \mathbb{C}^{n+1}$, *let* $R(u) = R(F, u)$. *Then* $R(u)$ *has factorization*

$$R(u) = \prod_{l=1}^{\mathscr{D}} (\xi^{(l)} \cdot u),$$

where $\xi^{(l)} \cdot u = \sum_i \xi_i^{(l)} u_i$, $\mathscr{D} = \prod_{i=1}^n d_i$, *and each* $\xi^{(l)}$ *is a nontrivial zero of* F. *Moreover, for each zero line of* F, *the number of the* $\xi^{(l)}$ *that are contained in that zero line equals the multiplicity of that zero line.*

Proof. A proof can be found in § 83 of Van der Waerden [11]. (Again, be careful to choose an edition of Van der Waerden's book containing the section on elimination theory.) □

3. Computing $R(u)$. Using the notation of the previous section, assume that $F \in \mathscr{H}^{n+1}_{d_1,\cdots,d_n}$ has only finitely many solution lines and let $R(u) \doteq R(F, u)$, where $R(F, u)$ is the u-resultant of F. Our algorithm depends on being able to compute $R(u)$ and some of its derivatives along certain complex lines. In this section we discuss procedures for doing this.

Let $\alpha, \beta \in \mathbb{C}^{n+1}$, where $\alpha \neq 0$. We first discuss a procedure for obtaining an expansion of the single-variable polynomial $\lambda \mapsto R(\lambda\alpha + \beta)$.

Referring again to the notation of the previous section, begin by computing the determinant $M(F, u)$—this determinant is independent of the variables u, depending only on the fixed coefficients of F. It can be computed with $O\left[\binom{\bar{d}+n}{n}^3\right]$ operations, where $\bar{d} = 1 - n + \sum_i d_i$.

If $M(F, u) \neq 0$, then by Theorem 2.1, $R(u) = D(F, u)/M(F, u)$. Noting that $D(\lambda\alpha + \beta) \doteq D(F, \lambda\alpha + \beta)$ is defined as the determinant of a certain $\binom{1+\sum d_i}{n} \times \binom{1+\sum d_i}{n}$ matrix, and is of degree $\mathscr{D}$ in the variable λ, compute the coefficients of the polynomial $D(\lambda\alpha + \beta)$ by evaluating this determinant at $\mathscr{D}+1$ distinct values of λ, and then interpolating. Thus, assuming $M(F, u) \neq 0$, we can obtain the coefficients of a nonzero multiple of $R(\lambda\alpha + \beta)$ with $O\left[\mathscr{D}\binom{1+\sum d_i}{n}^3\right]$ operations (using $\mathscr{D} < \binom{1+\sum d_i}{n}$).

Now assume $M(F, u) = 0$. For $t \in \mathbb{R}$, let $F_i^t(z) = tz_i^{d_i} + (1-t)F_i(z)$ for $i = 1, \cdots, n$. Then $M(F^t, u)$ is a polynomial in t alone, and is of degree not exceeding $\binom{1+\sum d_i}{n}$. It is nonconstant since $M(F^0, u) = 0$ and $M(F^1, u) = 1$. Determine the coefficients of $M(F^t, u)$ by evaluating the corresponding determinant for $\binom{1+\sum d_i}{n} + 1$ distinct values of t, and then interpolating.

Determine *the least* integer $0 \leqq k \leqq \binom{1+\sum d_i}{n}$ such that

$$\left.\frac{d^k}{dt^k} M(F^t, u)\right|_{t=0} \neq 0.$$

Then, using Theorem 2.1 and the product rule for differentiation,

$$\left.\frac{d^k D(F^t, u)}{dt^k}\right|_{t=0} = R(F, u) \cdot \left.\frac{d^k M(F^t, u)}{dt^k}\right|_{t=0}$$

as polynomials in u. Hence, $R(\lambda\alpha+\beta)$ equals

$$\left.\frac{d^k D(F^t, \lambda\alpha+\beta)}{dt^k}\right|_{t=0}$$

divided by the already computed nonzero constant

$$\left.\frac{d^k M(F^t, u)}{dt^k}\right|_{t=0}.$$

Finally, we examine the computation of

$$\left.\frac{d^k D(F^t, \lambda\alpha+\beta)}{dt^k}\right|_{t=0}.$$

Since $D(F^t, \lambda\alpha+\beta)$ is a polynomial in the variables λ and t, of degree not exceeding $\mathscr{D}$ in λ and of degree not exceeding $\binom{1+\sum d_i}{n}$ in t, $D(F^t, \lambda\alpha+\beta)$ can be expanded as follows:

$$D(F^t, \lambda\alpha+\beta) = \sum_{i=1}^{\binom{1+\sum d_i}{n}} \left(\sum_{j=0}^{\mathscr{D}} a_{ij}\lambda^j \right) t^i.$$

We wish to determine $\sum_{j=0}^{\mathscr{D}} a_{kj}\lambda^j$ for k, as defined earlier.

Choose $\mathscr{D}+1$ distinct values $\lambda_l \in \mathbb{C}$ and $\binom{1+\sum d_i}{n}+1$ distinct values t_m. For fixed λ_l, evaluate the determinant $D(F^{t_m}, \lambda_l\alpha+\beta)$ for all pairs $\{(\lambda_l, t_m)\}_m$. Interpolate in t to determine the expansion of the single-variable polynomial $D(F^t, \lambda_l\alpha+\beta)$, thereby obtaining the value $\sum_{j=0}^{\mathscr{D}} a_{kj}\lambda_l^j$. Do this for each λ_l. Then interpolate in λ to obtain the expansion $\sum_{j=0}^{\mathscr{D}} a_{kj}\lambda^j$.

Thus, we have a method for computing the coefficients of $R(\lambda\alpha+\beta)$. The total operation count is dominated by the operation required to compute the $[\mathscr{D}+1]\left[\binom{1+\sum d_i}{n}+1\right]$ determinants $D(F^{t_m}, \lambda_l\alpha+\beta)$. Hence, the total operation count is $O\left[\mathscr{D}\binom{1+\sum d_i}{n}^4\right]$.

Besides an expansion for $R(\lambda\alpha+\beta)$, we will also need expansions for the multivariable polynomials $R(\lambda\alpha+\rho_1 e_i+\rho_2 e_j+\beta)$, where ρ_1 and ρ_2 are variables over $\mathbb{C}$ and where e_i and e_j are ith and jth unit vectors. Defining F^t as before, and writing

$$D(F^t, \lambda\alpha+\rho_1 e_i+\rho_2 e_j+\beta) = \sum_{m_1=1}^{\binom{1+\sum d_i}{n}} \left(\sum_{m_2=0}^{\mathscr{D}} \left(\sum_{m_3=0}^{\mathscr{D}} \left(\sum_{m_4=0}^{\mathscr{D}} a_{m_1 m_2 m_3 m_4} \rho_2^{m_4} \right) \rho_1^{m_3} \right) \lambda^{m_2} \right) t^{m_1},$$

we wish to obtain the triple summation which is a multiple of t^k, where k is the smallest integer such that $d^k M(F^t, u)/dt^k|_{t=0} \neq 0$. Dividing that triple summation by the constant $d^k M(F^t, u)/dt^k|_{t=0}$ gives $R(\lambda\alpha+\rho_1 e_i+\rho_2 e_j+\beta)$. However, to obtain the triple summation we can use the generalization of the procedure we used for computing $d^k D(F^t, \lambda\alpha+\beta)/dt^k|_{t=0}$. First, interpolate in t to obtain

$$\sum_{m_2=0}^{\mathscr{D}} \left(\sum_{m_3=0}^{\mathscr{D}} \left(\sum_{m_4=0}^{\mathscr{D}} a_{m_1 m_2 m_3 k} \rho_2^{m_4} \right) \rho_1^{m_3} \right) \lambda^{m_2}$$

for *fixed* values of the parameters ρ_1, ρ_2, and λ. Then interpolate in λ to obtain

$$\sum_{m_3=0}^{\mathscr{D}} \left(\sum_{m_4=0}^{\mathscr{D}} a_{m_1 m_2 m_3 k} \rho_2^{m_4} \right) \rho_1^{m_3}, \qquad m_2 = 1, \cdots, \mathscr{D}$$

for fixed values of the parameters ρ_1 and ρ_2. For each m_2, interpolate in ρ_1 to obtain

$$\sum_{m_4}^{\mathscr{D}} a_{m_1 m_2 m_3 k} \rho_2^{m_4} \qquad m_2, m_3 = 1, \cdots, \mathscr{D}$$

for fixed values of the parameter ρ_2. Finally, for each pair (m_2, m_3), interpolate in ρ_1 to obtain all of the coefficients $a_{m_1 m_2 m_3 k}$. Altogether, $O\left[\mathscr{D}^3 \binom{1+\sum d_i}{n}^4\right]$ operations suffice.

4. The algorithm. In this section we present the algorithm which, given $F \in \mathscr{H}^{n+1}_{d_1, \cdots, d_n}$, determines if F has only finitely many solution lines and, if so, obtains ε-approximations to all of them.

The idea underlying the algorithm is rather simple, although the technicalities that must be dealt with are not. Here is the idea. Assume that F has only finitely many solution lines and, for simplicity, assume that each of these are of multiplicity 1. By Theorem 2.1,

$$R(u) = \prod_{l=1}^{\mathscr{D}} (\xi^{(l)} \cdot u), \tag{4.1}$$

where the $\xi^{(l)}$ are vectors on the solution lines. Let

$$H^{(l)} = \{x \in \mathbb{C}^{n+1};\ \xi^{(l)} \cdot x = 0\}. \tag{4.2}$$

Assume that $\alpha', \beta' \in \mathbb{C}^{n+1}$, $\alpha' \neq 0$, and assume that the complex line $\{\lambda\alpha' + \beta';\ \lambda \in \mathbb{C}\}$ intersects each of the hyperplanes $H^{(l)}$, but does not intersect $H^{(l)} \cap H^{(m)}$ if $l \neq m$. Compute the zeros λ' of the degree $\mathscr{D}$ single-variable polynomial $R(\lambda\alpha' + \beta')$—for the moment we assume that these can be calculated exactly. There is a one-to-one correspondence between the λ' and the l defined by the relation $\lambda'\alpha' + \beta' \in H^{(l)}$. For λ' corresponding to l, the vector

$$\left(\frac{\partial}{\partial u_1} R(u) \Big|_{u=\lambda'\alpha+\beta}, \cdots, \frac{\partial}{\partial u_{n+1}} R(u) \Big|_{u=\lambda'\alpha+\beta} \right)$$

is a nonzero scalar multiple of $\xi^{(l)}$ and hence is on the zero line $\{\lambda\xi^{(l)};\ \lambda \in \mathbb{C}\}$. This is the main idea behind the algorithm.

Of course the algorithm must be able to work without relying on the above simplifying assumptions.

We present the steps of the algorithm and state propositions regarding the steps simultaneously in hopes that this will better motivate what the steps are designed to accomplish. Proofs are relegated to § 5. Some of the propositions rely on $O(\ )$ notation for upper bounds and $\Omega(\ )$ notation for lower bounds. The constants are independent of $n, d_1, \cdots, d_n$ and hence independent of F. Specific constants can be obtained with more lengthy proofs.

For nonzero $X, Y \in \mathbb{C}^{n+1}$, define

$$\operatorname{dis}(X, Y) = \min \left\{ \left\| \frac{w_1 X}{\|w_1 X\|} - \frac{w_2 Y}{\|w_2 Y\|} \right\|;\ w_1, w_2 \in \mathbb{C} \setminus \{0\} \right\}.$$

Using the homogeneity of F, it is easily shown that $\mathbb{X}^{(i)}$, $i = 1, \cdots, \mathscr{D}$ are ε-approximations to the zero lines of F if and only if $\operatorname{dis}(\mathbb{X}^{(i)}, \xi^{(i)}) \leqq \varepsilon$ for all i, where the $\xi^{(i)}$ are as in (4.1).

For $x \in \mathbb{C}$, define

$$\mu(x) = (1, x, x^2, \cdots, x^n).$$

We use λ to denote a complex variable.

Step 1. Compute $R(\alpha)$ for all $\alpha \in \{\mu(j); j = 0, 1, \cdots, n\mathscr{D}\}$.

From the results in § 3, Step 1 can be accomplished with $O\left[n\mathscr{D}^2\binom{1+\sum d_i}{n}^4\right]$ operations.

PROPOSITION 4.1. *All numbers computed in Step* 1 *are zero if and only if* F *has infinitely many zero lines.*

Proof. Since for any distinct integers $j_1, \cdots, j_{n+1}$ the $(n+1) \times (n+1)$ matrix with ith row $\mu(j_i)$ is invertible, there are at most $n\mathscr{D}$ integer values j such that $\mu(j) \in \bigcup_l \{u; \zeta^{(l)} \cdot u = 0\}$. □

Hereafter, we assume that F has only finitely many zero lines.

The purpose of the next two steps is to determine a vector α' for which the "angle of incidence" of α' with any of the complex hyperplanes $H^{(l)}$ can be bounded away from zero. This property of α' will be relied on in the analysis in two ways. First, it will provide a bound on the absolute value of the zeros of any univariate polynomial $\lambda \mapsto R(\lambda\alpha' + \beta)$. We will need this bound when we call on the univariate algorithm of Renegar [10]. Second, the property of α' will guarantee that for any β, if dis $(\xi^{(l)}, \xi^{(m)})$ is small, then so is $|\lambda^{(l)} - \lambda^{(m)}|$ where $\lambda^{(l)}\alpha' + \beta \in H^{(l)}$, $\lambda^{(m)}\alpha' + \beta \in H^{(m)}$. This will be important for proving the correctness of the procedure for determining the number of lines in a "clustered" set of zero lines.

More specifically, for α' as determined by Steps 2 and 3, we have the following.

PROPOSITION 4.2. *For any* $\beta \in \mathbb{C}^{n+1}$, *all zeros* λ' *of* $R(\lambda\alpha' + \beta)$ *satisfy*

$$|\lambda'| = O(\|\beta\|[n\mathscr{D}]^{2n\mathscr{D}}).$$

Moreover, if $\lambda^{(l)}\alpha' + \beta \in H^{(l)}$, $\lambda^{(m)}\alpha' + \beta \in H^{(m)}$, *then*

$$|\lambda^{(l)} - \lambda^{(m)}| = O(\|\beta\|[n\mathscr{D}]^{5n\mathscr{D}} \text{ dis } (\xi^{(l)}, \xi^{(m)})).$$

Proof. Proposition 5.4. □

If we are only concerned with polynomial systems with rational coefficients, an analogue of Proposition 4.2 with bounds depending on the bit lengths of the coefficients is easily proven. Bounds, such as ours, which hold for all polynomial systems require more detailed arguments.

Step 2. For each $j = 0, 1, \cdots, n\mathscr{D}$ and each $i = 1, \cdots, n+1$, compute the coefficients $a_k(i, j)$ of $R(\lambda\alpha + e_i) = \sum_{k=1}^{\mathscr{D}} a_k(i, j)\lambda^k$, where $\alpha = \mu(j)$.

From the results in § 3, Step 2 can be accomplished with $O\left[n^2\mathscr{D}^2\binom{1+\sum d_i}{n}^4\right]$ operations.

Note that $a_{\mathscr{D}}(i, j) = R(\mu(j))$.

Step 3. Let $J \subseteq \{0, 1, \cdots, n\mathscr{D}\}$ denote the subset $J = \{j; R(\mu(j)) \neq 0\}$. By Proposition 4.1, $J \neq \varnothing$. Determine $j' \in J$ satisfying

$$\max_{\substack{i \\ k < \mathscr{D}}} \left| \frac{a_k(i, j')}{R(\mu(j'))} \right|^2 = \min_{j \in J} \max_{\substack{i \\ k < \mathscr{D}}} \left| \frac{a_k(i, j)}{R(\mu(j))} \right|^2.$$

Let $\alpha' = \mu(j)$.

The reduction to the univariate case occurs in the next step. However, rather than a reduction to a single univariate polynomial, we are forced to consider $n\mathscr{D}(\mathscr{D} - 1)/2 + 1$ univariate polynomials, approximating the zeros for each of these for the following reason. Recall the "idea" behind the algorithm as discussed at the beginning of this section. Assume β' is such that the complex line $\{\lambda\alpha' + \beta'; \lambda \in \mathbb{C}\}$ intersects $H^{(l)}$ and

$H^{(m)}$ at nearly the same point, yet dis $(\xi^{(l)}, \xi^{(m)})$ is large. Then even if $\gamma^{(l)}$ is a close approximation to the point $\lambda^{(l)}$, for which $\lambda^{(l)}\alpha'+\beta' \in H^{(l)}$, it is not likely that dis $(X^{(l)}, \xi^{(l)})$ is small where

$$X^{(l)} = \left(\frac{\partial}{\partial u_1} R(u) \Big|_{u=\gamma^{(l)}\alpha'+\beta'}, \cdots, \frac{\partial}{\partial u_{n+1}} R(u) \Big|_{u=\gamma^{(l)}\alpha'+\beta'} \right).$$

To guarantee good approximations, we need $\{\lambda\alpha'+\beta'; \lambda \in \mathscr{C}\}$ to intersect $H^{(l)}$ and $H^{(m)}$ at nearly the same point only if dis $(\xi^{(l)}, \xi^{(m)})$ is small. (Furthermore, in that case, we need to define $X^{(l)}$ by appropriate higher-order derivatives.) As will be proven, at least one of the β's considered in Step 4 has this property; the large amount of computation required in Steps 4, 5, and 6 is to determine which one. (What these steps are designed to accomplish can be achieved easily if we restrict ourselves to rational coefficients and are only concerned with bounding the number of required arithmetic operations in the algorithm by a polynomial in the bit length of the coefficients.)

Step 4 involves a new parameter, $\varepsilon' > 0$.

Step 4. For each $k = 0, 1, \cdots, n\mathscr{D}(\mathscr{D}-1)/2$ apply the algorithm in Renegar [10] (or any other algorithm with an $O(\log\log(R/\varepsilon))$ bound) to obtain ε'-approximations $\gamma_1(k), \cdots, \gamma_{\mathscr{D}}(k)$ for all of the zeros $\lambda_1(k), \cdots, \lambda_{\mathscr{D}}(k)$ (counting multiplicities) of $R(\lambda\alpha'+\beta)$, where $\beta = \mu(k)$.

We will later show that any value $\varepsilon' = O(\varepsilon^{n\mathscr{D}^4+1}/[n\mathscr{D}]^{10n^2\mathscr{D}^5+3n+3})$ suffices for our purposes.

The algorithm in Renegar [10] requires an a priori bound on the $|\lambda_i(k)|$. However, since $\|\mu(k)\| < [n\mathscr{D}]^{2n}$, such a bound can be obtained from Proposition 4.2. Using this and the $O(d^2(\log d)(\log\log(R/\varepsilon)) + d^3 \log d)$ bound for the algorithm in Renegar [10], we find that Step 4 can be accomplished with $O(n\mathscr{D}^4(\log \mathscr{D})(\log\log(1/\varepsilon')) + n\mathscr{D}^5 \log \mathscr{D})$ operations.

In the next step we partition the approximations $\gamma_1(k), \cdots, \gamma_{\mathscr{D}}(k)$ into clusters for each k. Roughly, a cluster of the approximations is a subset of the approximations that is contained in a disk and for which none of the other approximations is contained in a much larger concentric disk. The radius ε'' of the smaller disk and the magnitude δ of the quotient of the radius of the larger disk to that of the smaller disk will be crucial in our analysis.

In Step 6 we will single out a k for which Step 5 has produced the largest number of clusters. As we will prove, this k has the property that $\{\lambda\alpha'+\mu(k); \lambda \in \mathbb{C}\}$ intersects $H^{(l)}$ and $H^{(m)}$ at nearly the same point only if dis $(\xi^{(l)}, \xi^{(m)})$ is small.

Step 5 requires the cluster parameter δ mentioned above. As will be proven, all $\delta = \Omega([n\mathscr{D}]^{10n\mathscr{D}}/\varepsilon)$ will suffice for our purposes.

Step 5. Initially, let $\varepsilon'' = \varepsilon'$, where ε' is as in Step 4.

Step 5.1. Determine if there exists i, j, k such that

$$(\varepsilon'')^2 < |\gamma_i(k) - \gamma_j(k)|^2 \leqq (\delta\varepsilon'')^2.$$

If so, let $\delta\varepsilon'' \to \varepsilon''$ and repeat Step 5.1.

Step 5.2. For each k, partition the approximations into disjoint subsets $P^{[h]}(k)$, $h = 1, \cdots, h(k)$, where $\gamma_i(k)$ and $\gamma_j(k)$ are in the same subset if and only if $|\gamma_i(k) - \gamma_j(k)| \leqq \varepsilon''$. (To establish the existence of this partition, we need the property that $|\gamma_i(k) - \gamma_j(k)| \leqq \varepsilon''$ and $|\gamma_j(k) - \gamma_m(k)| \leqq \varepsilon''$ together imply $|\gamma_i(k) - \gamma_m(k)| \leqq \varepsilon''$.) But this is trivial, assuming $\delta \geqq 2$, since Step 5.1 has been passed through.

It is easily seen that Step 5.1 will be passed through after at most $O(n\mathscr{D}^4)$ iterations, and hence the final value of ε'' satisfies $\varepsilon'' \leqq \delta^{n\mathscr{D}^4}\varepsilon'$. Since each iteration of 5.1 involves $O(n\mathscr{D}^4)$ operations, as does Step 5.2, the operation count for Step 5 is $O(n^2\mathscr{D}^8)$.

Step 6. Determine k' satisfying $h(k') = \max_k h(k)$, i.e., a k with the largest number of clusters. Let $\beta' = \mu(k')$. For each h fix a $\gamma^{[h]} \in P^{[h]}(k')$. Let $x^{[h]} = \gamma^{[h]}\alpha' + \beta'$. (If $h(k') = 1$, we define $x[h] = 0$ to simplify the analysis later.)

To ease the exposition, we now alter our notation slightly. There is a one-to-one correspondence between the points $\lambda_i(k')$, k' as in Step 6, and the complex hyperplanes $H^{(l)}$, where $\lambda_i(k')$ corresponds to $H^{(l)}$ only if $\lambda_i(k')\alpha' + \beta' \in H^{(l)}$. Re-indexing the hyperplanes if necessary, we may write $\lambda^{(l)}$ for the $\lambda_i(k')$ corresponding to $H^{(l)}$, and $\gamma^{(l)}$ for the approximation $\gamma_i(k')$ of that $\lambda_i(k')$. Also, we replace $P^{[h]}(k')$ by $P^{[h]}$.

The goals of all preceding steps are summarized in the following proposition.

PROPOSITION 4.3. *For any* $\delta = \Omega([n\mathscr{D}]^{10n\mathscr{D}})$ *and for* ε'' *as given at the end of Step* 5.1,

$$\gamma^{(l)} \in P^{[h]} \Rightarrow |\xi^{(l)} \cdot x^{[h]}| = O(\varepsilon''[n\mathscr{D}]^{n+1}\|\xi^{(l)}\|). \tag{4.3}$$

$$\gamma^{(l)} \notin P^{[h]} \Rightarrow |\xi^{(l)} \cdot x^{[h]}| = \Omega(\delta\varepsilon''\|\xi^{(l)}\|/[n\mathscr{D}]^{2n\mathscr{D}}), \tag{4.4}$$

$$\gamma^{(l)}, \gamma^{(m)} \in P^{[h]} \Rightarrow \operatorname{dis}(\xi^{(l)}, \xi^{(m)}) = O(\varepsilon''[n\mathscr{D}]^{3n+2}). \tag{4.5}$$

Proof. Proposition 5.6. □

Combining Proposition 4.3 with the following two propositions will motivate the final step of the algorithm. The first of these two propositions covers a "trivial" case.

PROPOSITION 4.4. *Assume that for all* $l, m \in \{1, \cdots, \mathscr{D}\}$ *we have that* $\operatorname{dis}(\xi^{(l)}, \xi^{(m)}) \leqq \varepsilon'''$. *For all* $\varepsilon''' = O(1/\sqrt{n})$, *the following is then true. Let* i' *be an index satisfying*

$$\left|\frac{\partial^{\mathscr{D}} R(u)}{\partial u_{i'}^{\mathscr{D}}}\right|_{u=0}\Bigg| = \max_i \left|\frac{\partial^{\mathscr{D}} R(u)}{\partial u_i^{\mathscr{D}}}\right|_{u=0}\Bigg|$$

and let $\mathbb{X} \in \mathbb{C}^{n+1}$ *be the vector*

$$\mathbb{X}_i = \left.\frac{\partial^{\mathscr{D}} R(u)}{\partial u_{i'}^{\mathscr{D}-1}\partial u_i}\right|_{u=0} \qquad i = 1, \cdots, n+1.$$

Then $\operatorname{dis}(\mathbb{X}, \xi^{(l)}) = O(n\varepsilon''')$ *for all* l.

Proof. Proposition 5.8. □

PROPOSITION 4.5. *Let* $S \subset \{1, \cdots, \mathscr{D}\}$ *contain* N *elements, where* $0 < N < \mathscr{D}$. *Assume that for all* $l, m \in S$, *we have* $\operatorname{dis}(\xi^{(l)}, \xi^{(m)}) \leqq \varepsilon'''$. *Let* $x \in \mathbb{C}^{n+1}$, $x \neq 0$. *Assume that if* $l \notin S$, *then* $|\xi^{(l)} \cdot x| \leqq \rho_1\|\xi^{(l)}\|\,\|x\|$, *and assume that if* $l \notin S$, *then* $|\xi^{(l)} \cdot x| \geqq \rho_2\|\xi^{(l)}\|\,\|x\|$, *where* $\rho_2 > 0$. *Then for all* $\varepsilon''' = O(1/\sqrt{n})$ *and for all* $\rho_1/\rho_2 = O(\varepsilon'''/\mathscr{D}!n)$, *the following is true. Let* i' *be an index satisfying*

$$\left|\frac{\partial^N R(u)}{\partial u_{i'}^N}\right|_{u=x}\Bigg| = \max_i \left|\frac{\partial^N R(u)}{\partial u_i^N}\right|_{u=x}\Bigg|,$$

and let $\mathbb{X} \in \mathbb{C}^{n+1}$ *be the vector*

$$\mathbb{X}_i = \left.\frac{\partial^N R(u)}{\partial u_{i'}^{N-1}\partial u_i}\right|_{u=x} \qquad i = 1, \cdots, n+1.$$

Then $\operatorname{dis}(\mathbb{X}, \xi^{(l)}) = O(n\mathscr{D}\varepsilon''')$ *for all* $l \in S$.

Proof. Proposition 5.9. □

Now we combine the last three propositions to motivate and prove the correctness of the final step of the algorithm.

Assume that $0 < C \leqq 1$ is sufficiently small so that for all n, $\mathscr{D}$ and $0 < \varepsilon \leqq 1$,

$$\varepsilon''' \doteq \frac{C\varepsilon}{n\mathscr{D}} \tag{4.6}$$

satisfies the conditions required for Propositions 4.4 and 4.5.

For $h = 1, \cdots, h(k')$, let

$$S^{[h]} = \{l;\ \gamma^{(l)} \in P^{[h]}\},$$

i.e., the "indices" of the approximations in $P^{[h]}$. We now show that for all

$$\delta = \Omega\left(\frac{[n\mathscr{D}]^{10n\mathscr{D}}}{\varepsilon}\right), \tag{4.7}$$

and for all

$$\varepsilon' = O(\varepsilon/\delta^{n\mathscr{D}^4}[n\mathscr{D}]^{3n+3}) \tag{4.8}$$

the conditions required for Proposition 4.4 (if $h(k') = 1$) or the conditions required for Proposition 4.5 (if $h(k') > 1$) are satisfied by $S = S^{[h]}$, $x = x^{[h]}$ for ε''' as defined by (4.6).

First note that combining the bound $\varepsilon'' \leqq \delta^{n\mathscr{D}^4}\varepsilon'$ (as discussed after Step 5) with (4.5) gives

$$l, m \in S^{[h]} \Rightarrow \operatorname{dis}(\xi^{(l)}, \xi^{(m)}) \leqq O(\delta^{n\mathscr{D}^4}[n\mathscr{D}]^{3n+2}\varepsilon'). \tag{4.9}$$

Assume $h(k') = 1$. Then assuming δ is of the form (4.7) (to meet the requirement of Proposition 4.3) by choosing ε' of the form (4.8), we have from (4.9) that $\operatorname{dis}(\xi^{(l)}, \xi^{(m)}) \leqq \varepsilon'''$ for all l, m, where ε''' is as in (4.6). Hence the conditions required for Proposition 4.4 are then satisfied.

Now assume $h(k') > 1$ and fix $h \in \{1, \cdots, h(k')\}$. Define

$$\begin{aligned} \rho_1 &= \max\{|\xi^{(l)} \cdot x^{[h]}|/\|\xi^{(l)}\|\ \|x^{[h]}\|;\ l \in S^{[h]}\}, \\ \rho_2 &= \min\{|\xi^{(l)} \cdot x^{[h]}|/\|\xi^{(l)}\|\ \|x^{[h]}\|;\ l \notin S^{[h]}\}. \end{aligned} \tag{4.10}$$

By (4.3) and (4.4),

$$\frac{\rho_1}{\rho_2} = O([n\mathscr{D}]^{2n\mathscr{D}+n+1}/\delta),$$

and hence, assuming (4.7), we find that ρ_1/ρ_2 is sufficiently small as required by Proposition 4.5 for ε''' as in (4.6). Also, assuming δ fixed and of the form (4.7), by choosing ε' of the form (4.8) we have from (4.9) that

$$l, m \in S^{[h]} \Rightarrow \operatorname{dis}(\xi^{(l)}, \xi^{(m)}) \leqq \varepsilon''',$$

for ε''' as in (4.6). Finally, we note that $x^{[h]} \neq 0$ since otherwise we would contradict (4.4) for $l \notin S^{[h]}$. We have thus established the conditions required for Proposition 4.5 in the case that $h(k') > 1$ and for Proposition 4.4 in the case that $h(k') = 1$.

Step 7. If $h(k') = 1$, then determine the index i' satisfying

$$\left|\frac{\partial^{\mathscr{D}} R(u)}{\partial u_{i'}^{\mathscr{D}}}\bigg|_{u=0}\right|^2 = \max_i \left|\frac{\partial^{\mathscr{D}} R(u)}{\partial u_i^{\mathscr{D}}}\bigg|_{u=0}\right|^2,$$

and let $\mathbb{X}^{[1]} \in \mathbb{C}^{n+1}$ be the vector

$$\mathbb{X}_i^{[1]} = \frac{\partial^{\mathscr{D}} R(u)}{\partial u_{i'}^{\mathscr{D}-1}\partial u_i}\bigg|_{u=0} \qquad i = 1, \cdots, n+1.$$

If $h(k') > 1$, then perform the following for each $h \in \{1, \cdots, h(k')\}$. Let $N = N_h$, where N_h is the number of indices in $S^{[h]}$. Determine the index i' satisfying

$$\left|\frac{\partial^N R(u)}{\partial u_{i'}^N}\bigg|_{u=x^{[h]}}\right|^2 = \max_i \left|\frac{\partial^N R(u)}{\partial u_i^N}\bigg|_{u=x^{[h]}}\right|^2,$$

and let $\mathbb{X}^{[h]}$ be the vector

$$\mathbb{X}_i^{[h]} = \frac{\partial^N R(u)}{\partial u_{i'}^{N-1} \partial u_i}\bigg|_{u=x^{[h]}} \qquad i = 1, \cdots, n+1.$$

Letting $\mathbb{X}^{(i)}$, $i = 1, \cdots, \mathscr{D}$ be the vectors $\mathbb{X}^{[h]}$, $h = 1, \cdots, h(k')$, where $\mathbb{X}^{[h]}$ occurs N_h times, we find from the conclusions of Proposition 4.4 and 4.5 that if C in (4.6) is sufficiently small, then $\mathbb{X}^{(i)}$, $i = 1, \cdots, \mathscr{D}$ give ε-approximations to the zero lines of F, accounting for their multiplicities.

We assume the computations in Step 7 are carried out as follows. (If $h(k') = 1$, redefine $\alpha' = \beta' = x^{[1]} = 0$.) First compute the coefficients for the three variable polynomials $R(\lambda\alpha' + \rho_1 e_i + \rho_2 e_j + \beta')$, $i, j = 1, \cdots, n+1$, using the method of § 3. This requires $O\left[n^2\mathscr{D}^3\binom{1+\sum d_i}{n}^4\right]$ operations. From these compute the required derivatives. In all, Step 7 requires $O\left[n^2\mathscr{D}^3\binom{1+\sum d_i}{n}^4\right]$ operations.

Relying on (4.7), (4.8) and the operation counts already given for each of the steps, the total operation count for the algorithm is

$$O\left[n\mathscr{D}^4(\log \mathscr{D})(\log\log(1/\varepsilon)) + n^2\mathscr{D}^8 + n^2\mathscr{D}^3\binom{1+\sum d_i}{n}^4\right].$$

5. Proofs. In this section we prove the propositions that we relied on in the previous section. In the course of doing this we will need to prove several lemmas.

In our calculations we sometimes implicitly use the assumption $\mathscr{D} \geqq 2$. For example, under this assumption we may write $n\mathscr{D} + n + 1 \leqq 2n\mathscr{D}$. The following lemma will also occasionally be used implicitly in the analysis.

We retain the notation $\xi^{(l)}$ and $H^{(l)}$ as in (4.1) and (4.2).

LEMMA 5.1. *Assume $R(u) \not\equiv 0$ (i.e., is not identically the zero polynomial). Let $\alpha \in \mathbb{C}^{n+1}$. Then $\alpha \in \bigcup_l H^{(l)}$ implies $R(\lambda\alpha + \beta)$ is of degree less than $\mathscr{D}$ for all $\beta \in \mathbb{C}^{n+1}$, and $\alpha \notin \bigcup_l H^{(l)}$ implies $R(\lambda\alpha + \beta)$ is of degree exactly $\mathscr{D}$ for all $\beta \in \mathbb{C}^{n+1}$.*

Proof. Follows immediately from the identity

$$R(\lambda\alpha + \beta) = \prod_l \xi^{(l)} \cdot (\lambda\alpha + \beta). \qquad \square$$

Recall that $\mu(x) = (1, x, x^2, \cdots, x^n)$.

LEMMA 5.2. *Let $\mathscr{M}$ be any set of complex hyperplanes M in $\mathbb{C}^{n+1}$. Let N denote the number of hyperplanes in $\mathscr{M}$. For at least one $j'' \in \{0, 1, \cdots, nN\}$, $\mu(j'')$ satisfies*

$$\|\mu(j'') - x\| \geqq 1/(1+nN)^{n+1} \quad \text{for all } x \in M \in \mathscr{M}.$$

Proof. For each $j \in \{0, 1, \cdots, nN\}$, let $v(j)$ be a vector of smallest length such that $\mu(j) + v(j)$ lies in a hyperplane in $\mathscr{M}$. Note that for some distinct $j_1, \cdots, j_{n+1}$, each of the $\mu(j_i) + v(j_i)$ must lie in the same hyperplane. Thus, letting A, respectively, B, be the matrix with ith row $\mu(j_i)$, respectively, $v(j_i)$, we have that $A + B$ is singular. Hence,

$$\min_{\|w\|=1} \|Aw\| \leqq \max_{\|w\|=1} \|Bw\| \leqq \sqrt{n+1} \max_{j_i} \|v(j_i)\|.$$

Letting $j'' \in \{j_1, \cdots, j_{n+1}\}$ denote an index satisfying $\|v(j'')\| = \max_{j_i} \|v(j_i)\|$, we thus have

$$\|\mu(j'') - x\| \geqq \frac{1}{\sqrt{n+1}} \min_{\|w\|=1} \|Aw\|, \quad \text{for all } x \in M \in \mathscr{M}. \tag{5.1}$$

Note that for any $w \neq 0$, Aw has coordinates equal to the values taken on by the nonzero polynomial of degree at most n, $z \mapsto \sum_{i=0}^{n} w_{i+1} z^i$, at the $n+1$ distinct integers j_i. Since this polynomial can have at most n zeros, $Aw \neq 0$ and hence A is invertible.

Finally we note that for each i, $A^{-1}e_i$ gives the coefficients of the degree-n polynomial p satisfying $p(j_i)=1$, $p(j_k)=0$ if $k\neq i$, that is, the coefficients of $p(z)=\prod_{k\neq i}(z-j_k)/\prod_{k\neq i}(j_i-j_k)$. Writing $p(z)=\sum a_i z^i$ and noting $|\prod_{k\neq i} j_i-j_k|\geqq 1$, we thus have

$$\|A^{-1}e_i\|\leqq\sum|a_i|\leqq\sum_{j=0}^{n}\binom{n}{j}(nN)^j=(1+nN)^n.$$

Hence

$$\min_{\|w\|=1}\|Aw\|=\frac{1}{\max_{\|w\|=1}\|A^{-1}w\|}\geqq\frac{1}{\sqrt{n+1}\max_i\|A^{-1}e_i\|}\geqq\frac{1}{\sqrt{n+1}(1+nN)^n}.$$

Together with (5.1) this gives the lemma. □

LEMMA 5.3. *Assume $R(u)\not\equiv 0$. For at least one $j''\in\{0,1,\cdots,n\mathscr{D}\}$, $\alpha''=\mu(j'')$ has the property that for all i, $R(\lambda\alpha''+e_1)$ is a degree-$\mathscr{D}$ polynomial with all zeros λ'' satisfying $|\lambda''|\leqq(1+n\mathscr{D})^{n+1}$.*

Proof. Let $\mathscr{M}=\{H^{(l)};\ l=1,\cdots,\mathscr{D}\}$ and let $j''\in\{0,1,\cdots,n\mathscr{D}\}$ denote an integer such that $\alpha''=\mu(j'')$ satisfies the conclusion of Lemma 5.2. Then $\alpha''\notin\bigcup_l H^{(l)}$ and hence, by Lemma 5.1, $R(\lambda\alpha''+e_i)$ is of degree $\mathscr{D}$ for all i. Moreover, for all i and l,

$$\frac{|\xi^{(l)}\cdot\alpha''|}{\|\xi^{(l)}\|}=\min\{\|x-\alpha''\|;\ x\in H^{(l)}\}\geqq 1/(1+n\mathscr{D})^{n+1}.$$

Hence, if $\lambda''\alpha''+e_i\in H^{(l)}$, so that $\xi^{(l)}\cdot(\lambda''\alpha''+e_i)=0$, then

$$|\lambda''|=\frac{|\xi^{(l)}\cdot e_i|}{|\xi^{(l)}\cdot\alpha''|}\leqq(1+n\mathscr{D})^{n+1}.$$ □

PROPOSITION 5.4. *Assume $R(u)\not\equiv 0$. Let α' be as chosen in Step 3 of the algorithm. Then for all l,*

$$|\xi^{(l)}\cdot\alpha'|=\Omega(\|\xi^{(l)}\|/[n\mathscr{D}]^{2n\mathscr{D}}). \tag{5.2}$$

Moreover, for any $\beta\in\mathbb{C}^{n+1}$, letting $\lambda^{(l)},\lambda^{(m)}\in\mathbb{C}$ satisfy $\lambda^{(l)}\alpha'+\beta\in H^{(l)}$, $\lambda^{(m)}\alpha'+\beta\in H^{(m)}$, we have

$$|\lambda^{(l)}|=O(\|\beta\|[n\mathscr{D}]^{2n\mathscr{D}}), \tag{5.3}$$

$$|\lambda^{(l)}-\lambda^{(m)}|=O(\|\beta\|[n\mathscr{D}]^{5n\mathscr{D}}\operatorname{dis}(\xi^{(l)},\xi^{(m)})). \tag{5.4}$$

Proof. For any polynomial $\sum_{k=0}^{d}a_k\lambda^k$, $a_d\neq 0$, with zeros $\lambda_1,\cdots,\lambda_d$ we of course have $|a_k/a_d|=|\sum\lambda_{i_1}\cdots\lambda_{i_k}|$, where the summation is over all tuples $i_1<i_2<\cdots<i_k$. Hence if $|\lambda_i|\leqq R$ for all i, then $|a_k/a_d|\leqq\binom{d}{k}R^k$. In particular, letting j'' be as in Lemma 5.3, then for j' as in Step 3 of the algorithm

$$\max_{i,k}\left|\frac{a_k(i,j')}{a_{\mathscr{D}}(i,j')}\right|\leqq\max_{i,k}\left|\frac{a_k(i,j'')}{a_{\mathscr{D}}(i,j'')}\right|\leqq(1+n\mathscr{D})^{(n+1)\mathscr{D}}. \tag{5.5}$$

For each zero λ' of a polynomial $\sum_{k=0}^{d}a_k\lambda^k$, $a_d\neq 0$, one has the property that $|\lambda'|\leqq 1+\max\{|a_k/a_d|;\ 0\leqq k<d\}$ (cf. Marden [7, Thm. 27.2]). In particular, using (5.5), we find that for each i, every zero λ' of $R(\lambda\alpha'+e_1)$ satisfies

$$|\lambda'|=O([n\mathscr{D}]^{(n+1)\mathscr{D}}). \tag{5.6}$$

Fix l and assume that $|\xi_i^{(l)}| \geq \|\xi^{(l)}\|/\sqrt{n+1}$ (this is certainly true for some i). Assume $\lambda^{(l)}\alpha' + e_i \in H^{(l)}$. Then $|\lambda^{(l)}||\xi^{(l)} \cdot \alpha'| = |\xi^l \cdot e_i| \geq \|\xi^{(l)}\|/\sqrt{n+1}$. Thus, using (5.6),

$$|\xi^{(l)} \cdot \alpha'| = \Omega(\|\xi^{(l)}\|\sqrt{n}[n\mathscr{D}]^{(n+1)\mathscr{D}}),$$

from which (5.2) is immediate.

Since $R(\lambda\alpha' + e_i)$ is of degree exactly $\mathscr{D}$ (for any i) by choice of α', Lemma 5.1 implies $R(\lambda\alpha' + \beta)$ is of degree exactly $\mathscr{D}$ for any $\beta \in \mathbb{C}^{n+1}$. Fix β and assume $\lambda^{(l)}\alpha' + \beta \in H^{(l)}$. Then

$$|\lambda^{(l)}|\,|\xi^{(l)} \cdot \alpha'| = |\xi^{(l)} \cdot \beta| \leq \|\xi^{(l)}\|\,\|\beta\|.$$

Substituting (5.2) into this inequality gives (5.3).

Finally, let $\mathscr{Z}^{(l)} = w_1\xi^{(l)}$, $\mathscr{Z}^{(m)} = w_2\xi^{(m)}$ ($w_1, w_2 \in \mathbb{C}$) be such that $|\mathscr{Z}^{(l)}| = |\mathscr{Z}^{(m)}| = 1$ and $\|\mathscr{Z}^{(l)} - \mathscr{Z}^{(m)}\| = \operatorname{dis}(\xi^{(l)}, \xi^{(m)})$. Then

$$\begin{aligned} 0 &= \mathscr{Z}^{(l)} \cdot (\lambda^{(l)}\alpha' + \beta) \\ &= (\mathscr{Z}^{(m)} + [\mathscr{Z}^{(l)} - \mathscr{Z}^{(m)}]) \cdot ([\lambda^{(m)}\alpha' + \beta] + [\lambda^{(l)} - \lambda^{(m)}]\alpha') \\ &= [(\mathscr{Z}^{(l)} - \mathscr{Z}^{(m)})] \cdot [(\lambda^{(m)}\alpha' + \beta)] + [(\lambda^{(l)} - \lambda^{(m)})]\mathscr{Z}^{(l)} \cdot \alpha'. \end{aligned}$$

However, using (5.3) and $\|\alpha'\| < (n\mathscr{D})^{n+1}$, we have

$$|[(\mathscr{Z}^{(l)} - \mathscr{Z}^{(m)})] \cdot [(\lambda^{(m)}\alpha' + \beta)]| = O([n\mathscr{D}]^{3n\mathscr{D}}\|\beta\| \cdot \operatorname{dis}(\xi^{(l)}, \xi^{(m)})),$$

and by (5.2),

$$|\lambda^{(l)} - \lambda^{(m)}|\,|\mathscr{Z}^{(l)} \cdot \alpha'| = \Omega(|\lambda^{(l)} - \lambda^{(m)}|/[n\mathscr{D}]^{2n\mathscr{D}}).$$

Now (5.4) follows. □

The next lemma will be used in proving Proposition 4.3.

LEMMA 5.5. *Assume $R(u) \not\equiv 0$. Let α' be as in Step 3 of the algorithm. For some $k'' \in \{0, 1, \cdots, n\mathscr{D}(\mathscr{D}-1)/2\}$, $\beta'' = \mu(k'')$ has the property that for all l and m, if $\lambda^{(l)}\alpha' + \beta'' \in H^{(l)}$, $\lambda^{(m)}\alpha' + \beta'' \in H^{(m)}$, then*

$$\operatorname{dis}(\xi^{(l)}, \xi^{(m)}) = O([n\mathscr{D}]^{3n+2}|\lambda^{(l)} - \lambda^{(m)}|).$$

Proof. For all pairs $l < m$, $l, m \in \{1, \cdots, \mathscr{D}\}$ such that $H^{(l)} \neq H^{(m)}$, let

$$M^{(l,m)} = \{\lambda\alpha' + y; \qquad \lambda \in \mathbb{C}, y \in H^{(l)} \cap H^{(m)}\}.$$

Let $\mathscr{M} = \{M^{(l,m)}\}$. Let $k'' \in \{0, 1, \cdots, n\mathscr{D}(\mathscr{D}-1)/2\}$ denote an integer such that $\mu(k'')$ satisfies the conclusion of Lemma 5.2 with this choice of $\mathscr{M}$. Let $\beta'' = \mu(k'')$.

If $H^{(l)} = H^{(m)}$, then the bound on $|\lambda^{(l)} - \lambda^{(m)}|$ provided by the lemma is trivial. So assume $H^{(l)} \neq H^{(m)}$. By a change of coordinates $x \mapsto Qx$, where Q is a complex unitary matrix (to preserve distances), and by replacement of $\xi^{(l)}$ (respectively, $\xi^{(m)}$, α', β'') with $Q^{-1}\xi^{(l)}$ (respectively, $Q^{-1}\xi^{(m)}$, $Q\alpha'$, $Q\beta''$) we may assume without loss of generality that $\xi_3^{(l)} = 0, \cdots, \xi_{n+1}^{(l)} = 0$, $\xi_3^{(m)} = 0, \cdots, \xi_{n+1}^{(m)} = 0$ and

$$H^{(l)} \cap H^{(m)} = \{x \in \mathbb{C}^{n+1};\ x_1 = x_2 = 0\}.$$

Let $x = \lambda^{(l)}\alpha' + \beta'' \in H^{(l)}$. Then by the definition of $M^{(l,m)}$ and the choice of β'' (satisfying the conclusion of Lemma 5.2), we must have the distance from x to $H^{(l)} \cap H^{(m)}$ bounded below by $1/(1+n\mathscr{D}^2)^{n+1}$, that is,

$$(|x_1|^2 + |x_2|^2)^{1/2} \geq 1/(1+n\mathscr{D}^2)^{n+1}. \tag{5.7}$$

Let $\mathscr{Z}^{(l)} = w_1\xi^{(l)}$, $\mathscr{Z}^{(m)} = w_2\xi^{(m)}$ be such that $\|\mathscr{Z}^{(l)}\| = \|\mathscr{Z}^{(m)}\| = 1$ and dis $(\xi^{(l)}, \xi^{(m)}) = \|\mathscr{Z}^{(l)} - \mathscr{Z}^{(m)}\|$. Since $\mathscr{Z}^{(l)} \cdot x = 0$, $\mathscr{Z}^{(m)} \cdot [x + (\lambda^{(m)} - \lambda^{(l)})\alpha'] = 0$ and the last $n-1$ coordinates of both $\mathscr{Z}^{(l)}$ and $\mathscr{Z}^{(m)}$ are zero, we have

$$\begin{bmatrix} \mathscr{Z}_1^{(l)} & \mathscr{Z}_2^{(l)} \\ \mathscr{Z}_1^{(m)} & \mathscr{Z}_2^{(m)} \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} = (\lambda^{(l)} - \lambda^{(m)})(\mathscr{Z}^{(m)} \cdot \alpha') \begin{bmatrix} 0 \\ 1 \end{bmatrix}.$$

solving for x via Cramer's rule and then using (5.7) gives

$$\frac{|\lambda^{(l)} - \lambda^{(m)}|\,|\mathscr{Z}^{(m)} \cdot \alpha'|}{|\mathscr{Z}_1^{(l)}\mathscr{Z}_2^{(m)} - \mathscr{Z}_2^{(l)}\mathscr{Z}_1^{(m)}|} \geqq \frac{1}{(1 + n\mathscr{D}^2)^{n+1}}. \tag{5.8}$$

Noting that $\{\omega(-\bar{\mathscr{Z}}_2^{(m)}, \bar{\mathscr{Z}}_1^{(m)});\ \omega \in \mathbb{C}\}$ is the orthogonal complement of $\{\omega(\mathscr{Z}_1^{(m)}, \mathscr{Z}_2^{(m)});\ \omega \in \mathbb{C}\}$ when considered as subspaces of $\mathbb{R}^4$, we have

$$(\mathscr{Z}_1^{(l)}, \mathscr{Z}_2^{(l)}) = v(\mathscr{Z}_1^{(m)}, \mathscr{Z}_2^{(m)}) + w(-\bar{\mathscr{Z}}_2^{(m)}, \bar{\mathscr{Z}}_1^{(m)}),$$

where $v \geqq 0$, $w \in \mathbb{C}$ and $v^2 + |w|^2 = 1$. (In stating $v \geqq 0$ we are using the fact that $\|\mathscr{Z}^{(l)} - \mathscr{Z}^{(m)}\| = \text{dis}\,(\mathscr{Z}^{(l)}, \mathscr{Z}^{(m)})$.) Substituting for $\mathscr{Z}^{(l)}$ in the denominator of (5.8) gives

$$\frac{|\lambda^{(l)} - \lambda^{(m)}|\,|\mathscr{Z}^{(m)} \cdot \alpha'|}{|w|} \geqq \frac{1}{(1 + n\mathscr{D}^2)^{n+1}}. \tag{5.9}$$

Observe that

$$\text{dis}^2\,(\xi^{(l)}, \xi^{(m)}) = \|\mathscr{Z}^{(l)} - \mathscr{Z}^{(m)}\|^2 = (1 - v)^2 + |w|^2 \leqq 2|w|^2,$$

where the inequality follows from $v^2 + |w|^2 = 1$ and $v \geqq 0$. Substituting for $|w|$ in (5.9) and using $|\mathscr{Z}^{(m)} \cdot \alpha'| \leqq \|\alpha'\| \leqq \sqrt{n+1}(n\mathscr{D})^n$ gives the proposition. □

We can now give the proof of Proposition 4.3, which relies on the notation introduced just prior to that proposition. For the reader's convenience, we restate the proposition as

PROPOSITION 5.6. *For all* $\delta = \Omega([n\mathscr{D}]^{10n\mathscr{D}})$ *and for* ε'' *as given at the end of Step* 5,

$$\gamma^{(l)} \in P^{[h]} \Rightarrow |\xi^{(l)} \cdot x^{[h]}| = O(\varepsilon''[n\mathscr{D}]^{n+1}\|\xi^{(l)}\|), \tag{5.10}$$

$$\gamma^{(l)} \notin P^{[h]} \Rightarrow |\xi^{(l)} \cdot x^{[h]}| = \Omega(\delta\varepsilon''\|\xi^{(l)}\|/[n\mathscr{D}]^{2n\mathscr{D}}), \tag{5.11}$$

$$\gamma^{(l)}, \gamma^{(m)} \in P^{[h]} \Rightarrow \text{dis}\,(\xi^{(l)}, \xi^{(m)}) = O(\varepsilon''[n\mathscr{D}]^{3n+2}). \tag{5.12}$$

Proof. We begin by recalling that for each $k = 0, 1, \cdots, \mathscr{D}(\mathscr{D}-1)/2$, Step 5 partitions the approximations $\gamma_i(k)$ into "clusters" $P^{[h]}(k)$, $h = 1, \cdots, h(k)$, where

$$\gamma_i(k), \gamma_j(k) \in P^{[h]}(k) \Rightarrow |\gamma_i(k) - \gamma_j(k)| \leqq \varepsilon'', \tag{5.13}$$

$$\gamma_i(k) \in P^{[h]}(k),\ \gamma_j(k) \notin P^{[h]}(k) \Rightarrow |\gamma_i(k) - \gamma_j(k)| > \delta\varepsilon''. \tag{5.14}$$

To prove (5.10), note that since $x^{[h]} = \gamma^{(m)}\alpha' + \beta'$ for some $\gamma^{(m)} \in P^{[h]}$, where $\gamma^{(m)}$ approximates $\lambda^{(l)}$ within distance ε', we have

$$\begin{aligned} |\xi^{(l)} \cdot x^{[h]}| &\leqq |\xi^{(l)} \cdot (\gamma^{(m)} - \gamma^{(l)})\alpha'| + |\xi^{(l)} \cdot (\gamma^{(l)} - \lambda^{(l)})\alpha'| + |\xi^{(l)} \cdot (\lambda^{(l)}\alpha' + \beta')| \\ &\leqq (\varepsilon'' + \varepsilon')\|\xi^{(l)}\|\,\|\alpha'\| + 0 \quad \text{(using (5.13))}. \end{aligned}$$

Since $\varepsilon' \leqq \varepsilon''$ by the construction of Step 5 and $\|\alpha'\| < (n\mathscr{D})^{n+1}$, (5.10) follows.

Now we prove (5.11). Again assume $x^{[h]} = \gamma^{(m)}\alpha' + \beta'$, but now assume $\gamma^{(l)} \notin P^{[h]}$. Then $|\gamma^{(m)} - \gamma^{(l)}| > \delta\varepsilon''$ by (5.14). Using this and (5.2) along with $|\gamma^{(l)} - \lambda^{(l)}| \leqq \varepsilon'$ and

$\|\alpha'\| < (n\mathscr{D})^{n+1}$, we have

$$\begin{aligned}|\xi^{(l)} \cdot x^{[h]}| &= |\xi^{(l)} \cdot x^{[h]}| + |\xi^{(l)} \cdot (\lambda^{(l)}\alpha' + \beta')| \\ &= |\xi^{(l)} \cdot (\gamma^{(m)} - \lambda^{(l)})\alpha'| \\ &\geqq |\xi^{(l)} \cdot (\gamma^{(m)} - \gamma^{(l)})\alpha'| - |\xi^{(l)} \cdot (\gamma^{(l)} - \lambda^{(l)})\alpha'| \\ &= \Omega(\delta\varepsilon''\|\xi^{(l)}\|/[n\mathscr{D}]^{2n\mathscr{D}}) - O(\varepsilon'\|\xi^{(l)}\|(n\mathscr{D})^{n+1}).\end{aligned}$$

Assuming $\delta = \Omega([n\mathscr{D}]^{3n\mathscr{D}})$ and using $\varepsilon'' \geqq \varepsilon'$, (5.11) follows.

Now we turn to proving (5.12). Let β'' be as in Lemma 5.5. Let $P^{[j]}(k''), j = 1, \cdots, h(k'')$ be the sets determined for β'' at the end of Step 5. Assuming $\lambda^{(l)}(k'') \in \mathbb{C}$ satisfies $\lambda^{(l)}(k'')\alpha' + \beta'' \in H^{(l)}$, let $\gamma^{(l)}(k'')$ denote the ε'-approximation to $\lambda^{(l)}(k'')$ obtained in Step 4. We will show that if $\gamma^{(l)}(k''), \gamma^{(m)}(k'') \in P^{[j]}(k'')$ for some j, then $\gamma^{(l)}, \gamma^{(m)} \in P^{[h]}$ for some h. However, since the union $\cup_j P^{[j]}(k'')$ contains the same number of elements as the disjoint union $\cup_h P^{[h]}$, and since $h(k') \geqq h(k'')$ by choice of β'', it follows that the converse is also true: that is, if $\gamma^{(l)}, \gamma^{(m)} \in P^{[h]}$ for some h, then $\gamma^{(l)}(k''), \gamma^{(m)}(k'') \in P^{[j]}(k'')$ for some j. Then $|\gamma^{(l)}(k'') - \gamma^{(m)}(k'')| \leqq \varepsilon''$ by (5.13) and hence $|\lambda^{(l)}(k'') - \lambda^{(m)}(k'')| \leqq 2\varepsilon' + \varepsilon''$. Thus, since β'' satisfies the conclusion of Lemma 5.5,

$$\operatorname{dis}(\xi^{(l)}, \xi^{(m)}) = O(\varepsilon''[n\mathscr{D}]^{3n+2}),$$

establishing (5.12).

Finally, we prove that if $\gamma^{(l)}(k''), \gamma^{(m)}(k'') \in P^{[j]}(k'')$ for some j, then $\gamma^{(l)}, \gamma^{(m)} \in P^{[h]}$ for some h. Assume otherwise. Then $|\gamma^{(l)} - \gamma^{(m)}| > \delta\varepsilon''$ by (5.14) and hence $|\lambda^{(l)} - \lambda^{(m)}| > \delta\varepsilon'' - 2\varepsilon'$. Assuming $\delta \geqq 3$ and thus $\delta\varepsilon'' - 2\varepsilon' \geqq \delta\varepsilon''/3$, and using $\|\beta''\| < (n\mathscr{D}^2)^n$, we conclude from (5.4) that

$$\operatorname{dis}(\xi^{(l)}, \xi^{(m)}) = \Omega(\delta\varepsilon''/[n\mathscr{D}]^{7n\mathscr{D}}). \tag{5.15}$$

However, since $\gamma^{(l)}(k''), \gamma^{(m)}(k'') \in P^{[j]}(k'')$, we have that $|\lambda^{(l)}(k'') - \lambda^{(m)}(k'')| \leqq 2\varepsilon' + \varepsilon''$, and hence, since the conclusion of Lemma 5.5 holds for β'',

$$\operatorname{dis}(\xi^{(l)}, \xi^{(m)}) = O(\varepsilon''[n\mathscr{D}]^{3n+2}). \tag{5.16}$$

But for $\delta = \Omega([n\mathscr{D}]^{10n\mathscr{D}})$, (5.15) and (5.16) contradict one another, concluding the proof of the proposition. □

Finally, we turn to proving Propositions 4.4 and 4.5. We begin with a lemma.

LEMMA 5.7. *Fix* $\xi^{(m)}$ *and assume* $\xi_i^{(m)} \neq 0$. *If* $\operatorname{dis}(\xi^{(l)}, \xi^{(m)}) \leqq |\xi_i^{(m)}|/2\|\xi^{(m)}\|$, *then*

$$\frac{|\xi_i^{(l)}|}{\|\xi^{(l)}\|} \geqq \frac{|\xi_i^{(m)}|}{2\|\xi^{(m)}\|}, \tag{5.17}$$

$$\left\| \frac{\xi^{(l)}}{\xi_i^{(l)}} - \frac{\xi^{(m)}}{\xi_i^{(m)}} \right\| \leqq \frac{4\|\xi^{(m)}\|^2 \cdot \operatorname{dis}(\xi^{(l)}, \xi^{(m)})}{|\xi_i^{(m)}|^2}. \tag{5.18}$$

Proof. Assume $\mathscr{X}^{(l)} = w_1\xi^{(l)}$, $\mathscr{X}^{(m)} = w_2\xi^{(m)}$ satisfy $\|\mathscr{X}^{(l)}\| = \|\mathscr{X}^{(m)}\| = 1$, and $\operatorname{dis}(\xi^{(l)}, \xi^{(m)}) = \|\mathscr{X}^{(l)} - \mathscr{X}^{(m)}\|$. Since $\operatorname{dis}(\xi^{(l)}, \xi^{(m)}) \leqq |\mathscr{X}_i^{(m)}|/2$, it is easily shown that $|\mathscr{X}_i^{(l)}| \geqq |\mathscr{X}_i^{(m)}|/2$, and hence (5.17).

Note that

$$\begin{aligned}\left\| \frac{\xi^{(l)}}{\xi_i^{(l)}} - \frac{\xi^{(m)}}{\xi_i^{(m)}} \right\| &= \left\| \frac{\mathscr{X}^{(l)}}{\mathscr{X}_i^{(l)}} - \frac{\mathscr{X}^{(m)}}{\mathscr{X}_i^{(m)}} \right\| \\ &= \left\| \frac{\mathscr{X}^{(l)}}{\mathscr{X}_i^{(l)}} - \frac{\mathscr{X}^{(m)}}{\mathscr{X}_i^{(l)}} + \left(\frac{\mathscr{X}_i^{(m)} - \mathscr{X}_i^{(l)}}{\mathscr{X}_i^{(l)}\mathscr{X}_i^{(m)}} \right) \mathscr{X}^{(m)} \right\| \\ &\leqq \frac{1}{|\mathscr{X}_i^{(l)}|} \left[\operatorname{dis}(\xi^{(l)}, \xi^{(m)}) + \left(\frac{\operatorname{dis}(\xi^{(l)}, \xi^{(m)})}{|\mathscr{X}_i^{(m)}|} \right) \right].\end{aligned}$$

However, $2|\mathscr{X}_i^{(l)}| \geqq |\mathscr{X}_i^{(m)}| = |\xi_i^{(m)}|/\|\xi^{(m)}\|$. Now (5.18) follows. □

Here is Proposition 4.4 restated as Proposition 5.8.

PROPOSITION 5.8. *Assume that for all* $l, m \in \{1, \cdots, \mathscr{D}\}$ *we have that* $\operatorname{dis}(\xi^{(l)}, \xi^{(m)}) \leqq \varepsilon'''$. *For all* $\varepsilon''' = O(1/\sqrt{n})$, *the following is then true. Let* i' *be an index satisfying*

$$\left|\frac{\partial^{\mathscr{D}} R(u)}{\partial u_{i'}^{\mathscr{D}}}\bigg|_{u=0}\right| = \max_i \left|\frac{\partial^{\mathscr{D}} R(u)}{\partial u_i^{\mathscr{D}}}\bigg|_{u=0}\right|$$

and let $\mathbb{X} \in \mathbb{C}^{n+1}$ *be the vector*

$$\mathbb{X}_i = \frac{\partial^{\mathscr{D}} R(u)}{\partial u_{i'}^{\mathscr{D}-1} \partial u_i}\bigg|_{u=0} \qquad i = 1, \cdots, n+1.$$

Then $\operatorname{dis}(\mathbb{X}, \xi^{(l)}) = O(n\varepsilon''')$ *for all* l.

Proof. Fix $m \in \{1, \cdots, \mathscr{D}\}$ and let i'' denote an index satisfying $|\xi_{i''}^{(m)}| \geqq \|\xi^{(m)}\|/\sqrt{n+1}$. Then, by (5.17), assuming $\varepsilon''' \leqq 1/2\sqrt{n+1}$, we have that $|\xi_{i''}^{(l)}| \geqq \|\xi^{(l)}\|/2\sqrt{n+1}$ for all $l \in \{1, \cdots, \mathscr{D}\}$.

Next, note that by definition of i' and using $R(u) = \prod_l (\xi^{(l)} \cdot u)$,

$$\mathscr{D}! \left|\prod_l \xi_{i'}^{(l)}\right| = \left|\frac{\partial^{\mathscr{D}} R(u)}{\partial u_{i'}^{\mathscr{D}}}\bigg|_{u=0}\right| \geqq \left|\frac{\partial^{\mathscr{D}} R(u)}{\partial u_{i''}^{\mathscr{D}}}\bigg|_{u=0}\right| = \mathscr{D}! \left|\prod_l \xi_{i''}^{(l)}\right|.$$

Hence, for at least one $k \in \{1, \cdots, \mathscr{D}\}$, we have that $|\xi_{i'}^{(k)}| \geqq |\xi_{i''}^{(k)}|$. Since $|\xi_{i''}^{(k)}| \geqq \|\xi^{(k)}\|/2\sqrt{n+1}$, we thus have $|\xi_{i'}^{(k)}| \geqq \|\xi^{(k)}\|/2\sqrt{n+1}$. It thus follows from (5.17) that if $\varepsilon''' \leqq 1/4\sqrt{n+1}$, then

$$|\xi_{i'}^{(l)}| \geqq \|\xi^{(l)}\|/4\sqrt{n+1} \quad \text{for all } l. \tag{5.19}$$

Consider the identity

$$\frac{\partial^{\mathscr{D}} R(u)}{\partial u_{i'}^{\mathscr{D}-1} \partial u_i}\bigg|_{u=0} = (\mathscr{D}-1)! \sum_l \left(\xi_i^{(l)} \prod_{m \neq l} \xi_{i'}^{(m)}\right).$$

Defining $\mathbb{X}$ as in the statement of the proposition, we thus have

$$\frac{\mathbb{X}}{\prod_l \xi_{i'}^{(l)}} = (\mathscr{D}-1)! \sum_l \frac{\xi^{(l)}}{\xi_{i'}^{(l)}}. \tag{5.20}$$

However, using (5.18) and (5.19), if $\varepsilon''' \leqq 1/8\sqrt{n+1}$ we have that for any m,

$$\left\| \mathscr{D} \frac{\xi^{(m)}}{\xi_{i'}^{(m)}} - \sum_l \frac{\xi^{(l)}}{\xi_{i'}^{(l)}} \right\| \leqq 64(\mathscr{D}-1)(n+1)\varepsilon'''.$$

Hence, for any m, (5.20) gives

$$\left\| \frac{\mathbb{X}}{\prod_l \xi_{i'}^{(l)}} - \mathscr{D}! \frac{\xi^{(m)}}{\xi_{i'}^{(m)}} \right\| \leqq 64(\mathscr{D}!)(n+1)\varepsilon'''.$$

Since $\|\xi^{(m)}\|/|\xi_{i'}^{(m)}| \geqq 1$, it follows that $\operatorname{dis}(\mathbb{X}, \xi^{(m)}) = O(n\varepsilon''')$. □

Finally, we prove Proposition 4.5 restated as Proposition 5.9.

PROPOSITION 5.9. *Let* $S \subset \{1, \cdots, \mathscr{D}\}$ *contain* N *elements, where* $0 < N < \mathscr{D}$. *Assume that for all* $l, m \in S$, *we have* $\operatorname{dis}(\xi^{(l)}, \xi^{(m)}) \leqq \varepsilon'''$. *Let* $x \in \mathbb{C}^{n+1}$, $x \neq 0$. *Assume*

that if $l \in S$, *then* $|\xi^{(l)} \cdot x| \leqq \rho_1 \|\xi^{(l)}\| \, \|x\|$, *and assume that if* $l \notin S$, *then* $|\xi^{(l)} \cdot x| \geqq \rho_2 \|\xi^{(l)}\| \, \|x\|$, *where* $\rho_2 > 0$. *Then for all* $\varepsilon''' = O(1/\sqrt{n})$ *and for all* $\rho_1/\rho_2 = O(\varepsilon'''/\mathscr{D}!n)$, *the following is true. Let* i' *be an index satisfying*

$$\left| \frac{\partial^N R(u)}{\partial u_{i'}^N}\bigg|_{u=x} \right| = \max_i \left| \frac{\partial^N R(u)}{\partial u_i^N}\bigg|_{u=x} \right|,$$

and let $\mathbb{X} \in \mathbb{C}^{n+1}$ *be the vector*

$$\mathbb{X}_i = \frac{\partial^N R(u)}{\partial u_{i'}^{N-1} \partial u_i}\bigg|_{u=x} \qquad i = 1, \cdots, n+1.$$

Then $\operatorname{dis}(\mathbb{X}, \xi^{(l)}) = O(n\mathscr{D}\varepsilon''')$ *for all* $l \in S$.

Proof. The proof is analogous to, but much more complicated than, the proof of Proposition 5.8.

We begin by showing that if ε'' and ρ_1/ρ_2 are as small as certain prescribed quantities, then $|\xi_{i'}^{(l)}| \geqq \|\xi^{(l)}\|/8\sqrt{n+1}$ for all $l \in S$.

Fix $m \in S$ and let i'' denote an index satisfying $|\xi_{i''}^{(m)}| \geqq \|\xi^{(m)}\|/\sqrt{n+1}$. Then, by (5.17), if $\varepsilon''' \leqq 1/2\sqrt{n+1}$ we have that

$$|\xi_{i''}^{(l)}| \geqq \|\xi^{(l)}\|/2\sqrt{n+1} \quad \text{for all } l \in S.$$

Consider the identity

$$\frac{\partial^N R}{\partial u_{i''}^N}\bigg|_{u=x} = \sum \left(\prod_{l \in L} \xi_{i''}^{(l)} \right) \left(\prod_{l \notin L} \xi^{(l)} \cdot x \right) \tag{5.21}$$

where the summation is over all ordered N-tuples $(l_1, \cdots, l_N)$ of distinct indices from $\{1, \cdots, \mathscr{D}\}$, and where $l \in L$ is used to denote $l \in \{l_1, \cdots, l_N\}$. Let $\sum^*$ denote summation over the $N!$ N-tuples with $l_1, \cdots, l_N \in S$, and let $\sum^{**}$ denote summation over the remaining tuples. Then from (5.21)

$$\frac{1}{(\prod_{l \in S} \xi_{i''}^{(l)})(\prod_{l \notin S} \xi^{(l)} \cdot x)} \cdot \frac{\partial^N R}{\partial u_{i''}^N}\bigg|_{u=x} = N! + \sum^{**} \left(\prod_{l \in S \setminus L} \frac{\xi^{(l)} \cdot x}{\xi_{i''}^{(l)}} \right) \left(\prod_{l \in L \setminus S} \frac{\xi_{i''}^{(l)}}{\xi^{(l)} \cdot x} \right). \tag{5.22}$$

Note that (i) $|\xi^{(l)} \cdot x / \xi_{i''}^{(l)}| \leqq 2\rho_1\sqrt{n+1}\|x\|$ for all $l \in S$ since $|\xi_{i''}^{(l)}| \geqq \|\xi^{(l)}\|/2\sqrt{n+1}$ for all $l \in S$; (ii) $|\xi_{i''}^{(l)}/\xi^{(l)} \cdot x| \leqq 1/\rho_2\|x\|$ for all $l \notin S$; (iii) $L \setminus S$ and $S \setminus L$ have the same number of elements; (iv) at least one $l \in S$ satisfies $l \notin L$ for each of the tuples defining $\sum^{**}$; (v) $\sum^{**}$ is a summand over fewer than $\mathscr{D}!$ N-tuples; and (vi)

$$\left| \frac{\partial^N R}{\partial u_{i'}^N}\bigg|_{u=x} \right| \geqq \left| \frac{\partial^N R}{\partial u_{i''}^N}\bigg|_{u=x} \right|$$

by choice of i'. Assuming $\rho_1 \leqq \rho_2/8\sqrt{n+1}\mathscr{D}!$, it follows from (5.22) that

$$\left| \frac{1}{(\prod_{l \in S} \xi_{i''}^{(l)})(\prod_{l \notin S} \xi^{(l)} \cdot x)} \cdot \frac{\partial^N R}{\partial u_{i'}^N}\bigg|_{u=x} \right| \geqq N! - \frac{1}{4}.$$

Relying on the identity (5.21) with i' replacing i'', this becomes

$$\left| \sum^* \left(\prod_{l \in S} \frac{\xi_{i'}^{(l)}}{\xi_{i''}^{(l)}} \right) + \sum^{**} \left(\prod_{l \in S \cap L} \frac{\xi_{i'}^{(l)}}{\xi_{i''}^{(l)}} \right) \left(\prod_{l \in S \setminus L} \frac{\xi^{(l)} \cdot x}{\xi_{i''}^{(l)}} \right) \left(\prod_{l \in L \setminus S} \frac{\xi_{i'}^{(l)}}{\xi^{(l)} \cdot x} \right) \right| \geqq N! - \frac{1}{4}. \tag{5.23}$$

Making use of the above observations (i)-(v) with i' replacing i'' in (ii), as well as $|\xi_{i'}^{(l)}/\xi_{i''}^{(l)}| \leqq 2\sqrt{n+1}$ for all $l \in S$ (since $|\xi_{i''}^{(l)}| \geqq \|\xi^{(l)}\|/2\sqrt{n+1}$ for all $l \in S$), and assuming that $\rho_1 \leqq \rho_2/4(2\sqrt{n+1})^N \mathscr{D}!$, it follows from (5.23) that

$$N!\left|\prod_{l\in S}\frac{\xi_{i'}^{(l)}}{\xi_{i''}^{(l)}}\right| \geqq N! - \frac{1}{2}.$$

Hence, for at least one $m \in S$ we must have $|\xi_{i'}^{(m)}| \geqq |\xi_{i''}^{(m)}|/2$. Since $|\xi_{i''}^{(m)}| \geqq \|\xi^{(m)}\|/2\sqrt{n+1}$, it now follows from (5.17) that if $\varepsilon''' < 1/8\sqrt{n+1}$, then

$$|\xi_{i'}^{(l)}| \geqq \|\xi^{(l)}\|/8\sqrt{n+1} \quad \text{for all } l \in S. \tag{5.24}$$

Consider the identity, for any i,

$$\begin{aligned}&\frac{1}{(\prod_{l\in S}\xi_{i'}^{(l)})(\prod_{l\notin S}\xi^{(l)}\cdot x)}\frac{\partial^N R}{\partial u_{i'}^{N-1}\,du_i}\bigg|_{u=x}\\ &\quad = (N-1)!\sum_{l\in S}\frac{\xi_i^{(l)}}{\xi_{i'}^{(l)}} + \sum{}^{**}\left(\prod_{l\in S\setminus L}\frac{\xi^{(l)}\cdot x}{\xi_{i'}^{(l)}}\right)\left(\prod_{l\in L^{\square}\setminus S}\frac{\xi_{i'}^{(l)}}{\xi^{(l)}\cdot x}\right)\cdot g(x, l_N),\end{aligned} \tag{5.25}$$

where $L^{\square} = \{l_1, \cdots, l_{N-1}\}$ and

$$g(x, l_N) = \begin{cases} \xi_i^{(l_N)}/\xi_{i'}^{(l_N)} & \text{if } l_N \in S \\ \xi_i^{(l_N)}/\xi^{(l_N)}\cdot x & \text{if } l_N \notin S. \end{cases}$$

Making use of the above observations (iii)-(v) and (5.23), we find from (5.25) that if $\rho_1/\rho_2 \leqq \varepsilon'''/8\sqrt{n+1}$, then for $\mathbb{X}$ as defined in the statement of the proposition, we have

$$\left\|\frac{\mathbb{X}}{(\prod_{l\in S}\xi_{i'}^{(l)})(\prod_{l\notin S}\xi^{(l)}\cdot x)} - (N-1)!\sum_{l\in S}\frac{\xi^{(l)}}{\xi_{i'}^{(l)}}\right\| \leqq \varepsilon'''. \tag{5.26}$$

However, using (5.18) and (5.24), if $\varepsilon''' \leqq 1/16\sqrt{n+1}$ we have that for any $m \in S$,

$$\left\|\frac{N}{\xi_{i'}^{(m)}}\xi^{(m)} - \sum_{l\in S}\frac{\xi^{(l)}}{\xi_{i'}^{(l)}}\right\| \leqq 256(N-1)(n+1)\varepsilon'''.$$

Hence, for any $m \in S$, (5.26) gives

$$\left\|\frac{\mathbb{X}}{(\prod_{l\in S}\xi_{i'}^{(l)})(\prod_{l\notin S}\xi^{(l)}\cdot x)} - \frac{N!\,\xi^{(m)}}{\xi_{i'}^{(m)}}\right\| \leqq \varepsilon''' + 16(N-1)(n+1)\varepsilon'''.$$

Since $\|\xi^{(m)}\|/|\xi_{i'}^{(m)}| \geqq 1$, the proposition follows. □

6. Appendix. Here we prove the claim (1.1). Let $\varepsilon' = \varepsilon/4(R+1)^2$, $0 < \varepsilon \leqq R$, and assume that $\mathbb{X}^{(i)}$, $i = 1, \cdots, \mathscr{D}$ are ε'-approximations to all of the zero lines of F. In the notation of § 1, $\|\mathbb{X}^{(i)}/\|\mathbb{X}^{(i)}\| - \xi^{(i)}/\|\xi^{(i)}\|\| \leqq \varepsilon'$ where the zero lines of F are precisely the lines $\{\lambda\xi^{(i)};\ \lambda \in \mathbb{C}\}$.

For each $\xi^{(i)}$ such that $\xi_{n+1}^{(i)} \neq 0$, let

$$\tilde{\xi}^{(i)} = \left(\frac{\xi_1^{(i)}}{\xi_{n+1}^{(i)}}, \cdots, \frac{\xi_n^{(i)}}{\xi_{n+1}^{(i)}}\right).$$

Then $\tilde{\xi}^{(i)}$ is the zero of f corresponding to the solution line $\{\lambda\xi^{(i)};\ \lambda \in \mathbb{C}\}$ of F. Define $\tilde{\mathbb{X}}^{(i)}$ analogously.

We show that

$$\|\tilde{\xi}^{(i)}\| \leqq R \Rightarrow \frac{|\mathbb{X}_{n+1}^{(i)}|}{\|\mathbb{X}^{(i)}\|} \geqq \frac{3}{4(R+1)}, \tag{6.1}$$

and

$$\frac{|\mathbb{X}_{n+1}^{(i)}|}{\|\mathbb{X}^{(i)}\|} \geqq \frac{3}{4(R+1)} \Rightarrow \|\tilde{\mathbb{X}}^{(i)} - \tilde{\xi}^{(i)}\| \leqq \varepsilon. \tag{6.2}$$

Together, (6.1) and (6.2) imply that the points $\{\tilde{\mathbb{X}}^{(i)}; |\mathbb{X}_{n+1}^{(i)}|/\|\mathbb{X}^{(i)}\| \geqq 3/4(R+1)\}$ are a solution for the (ε, R)-approximation problem for f.

To prove (6.1), first note that $\|\tilde{\xi}^{(i)}\| \leqq R$ if and only if $\|\xi^{(i)}\|^2 \leqq (R^2+1)|\xi_{n+1}^{(i)}|^2$. Thus, if $\|\tilde{\xi}^{(i)}\| \leqq R$, then

$$\frac{|\mathbb{X}_{n+1}^{(i)}|}{\|\mathbb{X}^{(i)}\|} \geqq \frac{|\xi_{n+1}^{(i)}|}{\|\xi^{(i)}\|} - \varepsilon' \geqq \left(1 - \frac{\varepsilon}{4(R+1)}\right)\frac{1}{R+1} \geqq \frac{3}{4(R+1)}.$$

In proving (6.2), let $\hat{\mathbb{X}}^{(i)} = \mathbb{X}^{(i)}/\|\mathbb{X}^{(i)}\|$ and $\hat{\xi}^{(i)} = \xi^{(i)}/\|\xi^{(i)}\|$. Then assuming that $\hat{\mathbb{X}}_{n+1}^{(i)} \geqq 3/4(R+1)$, we have

$$\begin{aligned}
\|\tilde{\mathbb{X}}^{(i)} - \tilde{\xi}^{(i)}\| &= \left\| \frac{\hat{\mathbb{X}}^{(i)}}{\hat{\mathbb{X}}_{n+1}^{(i)}} - \frac{\hat{\xi}^{(i)}}{\hat{\xi}_{n+1}^{(i)}} \right\| = \frac{1}{|\hat{\mathbb{X}}_{n+1}^{(i)}|} \left\| \hat{\mathbb{X}}^{(i)} - \frac{\hat{\mathbb{X}}_{n+1}^{(i)}}{\hat{\xi}_{n+1}^{(i)}} \hat{\xi}^{(i)} \right\| \\
&\leqq \frac{1}{|\hat{\mathbb{X}}_{n+1}^{(i)}|} \left[\|\hat{\mathbb{X}}^{(i)} - \hat{\xi}^{(i)}\| + \frac{|\hat{\mathbb{X}}_{n+1}^{(i)} - \hat{\xi}_{n+1}^{(i)}|}{|\hat{\xi}_{n+1}^{(i)}|} \right] \\
&\leqq \frac{4}{3}(R+1)\left[\varepsilon' + \frac{\varepsilon'}{\frac{3}{4(R+1)} - \varepsilon'} \right] \\
&\leqq \frac{4}{3}(R+1)[\varepsilon' + 2(R+1)\varepsilon'] \quad \text{(by substituting } \varepsilon' = \varepsilon/4(R+1)^2 < 1/4(R+1) \text{ in the denominator)} \\
&< 4(R+1)^2\varepsilon' = \varepsilon.
\end{aligned}$$

Hence, (6.2) is proven.

PARTITIONING SPACE FOR RANGE QUERIES*

F. FRANCES YAO†, DAVID P. DOBKIN‡, HERBERT EDELSBRUNNER§, AND MICHAEL S. PATERSON¶

Abstract. It is shown that, given a set S of n points in R^3, one can always find three planes that form an *eight-partition* of S, that is, a partition where at most $n/8$ points of S lie in each of the eight open regions. This theorem is used to define a data structure, called an *octant tree*, for representing any point set in R^3. An octant tree for n points occupies $O(n)$ space and can be constructed in polynomial time. With this data structure and its refinements, efficient solutions to various range query problems in two and three dimensions can be obtained, including (1) half-space queries: find all points of S that lie to one side of any given plane; (2) polyhedron queries: find all points that lie inside (outside) any given polyhedron; and (3) circle queries in R^2: for a planar set S, find all points that lie inside (outside) any given circle. The retrieval time for all these queries is $T(n) = O(n^\alpha + m)$, where $\alpha = 0.8988$ (or 0.8471 in case (3)), and m is the size of the output. This performance is the best currently known for linear-space data structures that can be deterministically constructed in polynomial time.

1. Introduction.

Consider a database that contains a collection of records with multidimensional keys. Given a *range query*, which is specified by certain constraints on the value of the multidimensional key, the database is expected to return the set of all records (or some function of the set of all records) whose keys satisfy those constraints. Efficient solutions to range queries are important both in themselves and also as subroutines for solving other multidimensional search problems. In this paper we will consider solutions to range queries that use only linear space for data structure storage.

There is an extensive literature on efficient algorithms for handling *orthogonal queries*, that is, queries with constraints of the form $a_1 \leqq k_1 \leqq b_1, \cdots, a_d \leqq k_d \leqq b_d$, where the key is $(k_1, \cdots, k_d)$. Relatively little is known about solving queries of more general types, such as *half-space queries*, where the constraints are linear inequalities $a_1k_1 + \cdots + a_dk_d \leqq c$. Willard [W] was the first to consider half-space queries for $d = 2$, and gave a solution with linear space and sublinear query time $O(n^\alpha)$, where $\alpha \approx 0.774$. Edelsbrunner and Welzl [EW] improved α to $\log_2(\sqrt{5}+1)/2 \approx 0.695$. Both of these results are based on the fact that a set of n points in R^2 can be partitioned by two lines so that each open quadrant contains at most $n/4$ points.

For $d = 3$, the first nontrivial time bound was $O(n^\alpha)$ for $\alpha \approx 0.98$ by Yao [Y]. The data structure is based on a partition of any point set by three planes into eight regions with the property that no seven regions together contain more than 23/24 of the points. Such a partition was obtained by making use of the concept of a *centerpoint* of a set (see [YB]).

In this paper, we prove a stronger result on partitions in R^3 by using the *Borsuk-Ulam theorem* of topology. It is shown that, given a set S of n points in R^3, one can

always find three planes that form an *eight-partition* of S, that is, a partition where at most $n/8$ points of S lie in each of the eight open regions. This theorem is used to define a data structure, called an *octant tree*, for representing any point set in R^3. Efficient solutions to various range query problems in R^2 and R^3 can be obtained by using this data structure and its refinements. For example, one can solve in time $O(n^{0.8988}+m)$, where m is the size of the output,

1) half-space queries: find all points that lie to one side of a query plane;
2) polyhedron queries: find all points that lie inside (outside) a query polyhedron; and
3) circle queries in R^2: given a planar set, find all points that lie inside (outside) a query circle.

An octant tree for n points occupies $O(n)$ space and can be constructed in $O(n^6 \log n)$ preprocessing time.

The paper contains five sections. In § 2 we define the concepts necessary for discussing space partitions in both the continuous case and the discrete case. Section 3 contains the proof of the main theorem of the paper. In § 4 we present and analyze several data structures based on the main theorem for representing point sets. Finally we comment on open problems and related results in § 5.

2. Preliminaries. We use S^{d-1} to denote the unit sphere $\{(x_1, x_2, \cdots, x_d) | x_1^2+x_2^2+\cdots+x_d^2=1\}$ in R^d. An *oriented hyperplane* (or *hyperplane* for short) h in R^d with *normal vector* $\mathbf{v}=(v_1, v_2, \cdots, v_d) \in S^{d-1}$ is defined by an equation $\sum v_i x_i = t$. If v has length 1, then the real number t is the *distance* of h from the origin; it is the unique scalar for which the point $t \cdot \mathbf{v}$ lies on h. The hyperplane h separates R^d into a *positive half-space* h^+ defined by $\sum v_i x_i > t$ and a *negative half-space* h^- defined by $\sum v_i x_i < t$. When we consider continuous functions defined on the collection of hyperplanes in R^d, we assume that the latter is endowed with the topology of $S^{d-1} \times R$ through the representation of h by $(\mathbf{v}, t)$. Corresponding to $h=(\mathbf{v}, t)$ we let $-h$ denote the hyperplane $(-\mathbf{v}, -t)$; thus, $-h$ is a hyperplane defined by the same equation as h but with the opposite orientation.

We shall limit our discussions to R^d with $d \leqq 3$ in this paper. A hyperplane in R^3 will simply be called a *plane*. For a set S of n points in R^3, we are interested in finding three planes h_1, h_2, h_3 so that at most $n/8$ points lie in each of the eight open regions defined by the three planes. Such a triple (h_1, h_2, h_3) is termed an *eight-partition* of S. We shall prove the existence of an eight-partition for any finite point set by first transforming the problem to a continuous framework. Thus, let A be a positive density function defined on some bounded, connected region in R^3, and let an *eight-partition* of A be a triple of planes (h_1, h_2, h_3) that partitions A into eight parts of equal mass.

LEMMA 2.1. *If every positive density function over a bounded connected region in R^3 has an eight-partition, then every finite point set in R^3 has an eight-partition.*

Proof. We replace a set S of n points with a density function A by placing at each point $p \in S$ a small ball $b(p)$ of uniform mass $(1-\delta)/n$ with radius ε and center p. We choose ε to be small enough so that a set of balls can intersect a common plane only if their centers are coplanar. Let C be a large sphere of volume $\|C\|$ which contains all the balls, and place additional density $\delta/\|C\|$ uniformly inside C. Thus the total mass over C is 1, and the mass outside of the union of the balls is less than δ, which is chosen to be less than $1/2n$. Suppose we find an eight-partition for A with planes (h_1, h_2, h_3). Then we can find $(\bar{h}_1, \bar{h}_2, \bar{h}_3)$ with the property that (1) $p \in \bar{h}_\ell$ if $b(p)$ intersects h_ℓ, and (2) $p \in \bar{h}_\ell^+ \cup \bar{h}_\ell$ (or $\bar{h}_\ell^- \cup \bar{h}_\ell$) if $b(p)$ lies in h_ℓ^+ (or h_ℓ^-). This is possible by the choice of ε. The partition $(\bar{h}_1, \bar{h}_2, \bar{h}_3)$ has the property that there are at most $n/8$ points in each of the eight open regions of the partition. □

Because of Lemma 2.1, it suffices to prove the existence of eight-partitions in the continuous setting. Let A be a density function as described in the lemma. Any triple of planes (h_1, h_2, h_3) partitions A into the eight proportions denoted by $a_{xyz}(h_1, h_2, h_3)$ for $x, y, z \in \{0, 1\}$, where the ℓth subscript is 0 or 1 depending on whether the region lies in h_ℓ^+ or h_ℓ^-. We shall abbreviate $a_{xyz}(h_1, h_2, h_3)$ as a_{xyz} whenever possible. Thus, a_{010} denotes the mass contained in $h_1^+ \cap h_2^- \cap h_3^+$, and a_{111} denotes the mass contained in $h_1^- \cap h_2^- \cap h_3^-$. (See Fig. 1, where $\mathbf{v}_i$ is the normal vector to h_i.) The a_{xyz}'s are continuous functions of h_1, h_2, and h_3. We use $*$ as a subscript to indicate a summation of the a_{xyz}'s where that subscript can assume both 0 and 1. For example, we write a_{xy*} for $\sum_z a_{xyz} = a_{xy0} + a_{xy1}$, and a_{*y*} for $\sum_{x,z} a_{xyz} = a_{0y0} + a_{0y1} + a_{1y0} + a_{1y1}$, etc.

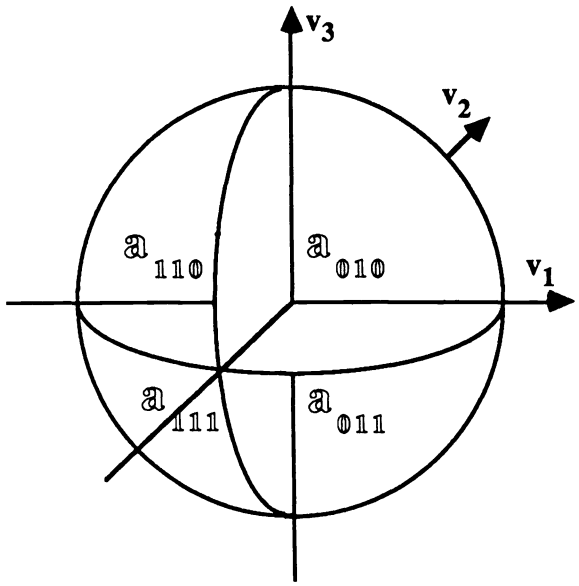

FIG. 1

DEFINITIONS. Let A be a positive density function on R^3, and consider the a_{xyz}'s defined by three planes (h_1, h_2, h_3). We say that

1) h_1 is a *bisector* of A if $a_{x**} = \frac{1}{2}$ for $x \in \{0, 1\}$;
2) the pair (h_1, h_2) forms a *four-partition* of A if $a_{xy*} = \frac{1}{4}$ for all $x, y \in \{0, 1\}$;
3) the triple (h_1, h_2, h_3) forms an *eight-partition* of A if $a_{xyz} = \frac{1}{8}$ for all $x, y, z \in \{0, 1\}$.

In order to achieve $a_{xyz} = \frac{1}{8}$ for all x, y, z, it is convenient to form eight linear combinations of the a_{xyz}'s as follows. Let $f_{ijk} = \sum_{xyz} \varepsilon_{ijk}^{xyz} a_{xyz}$, where $\varepsilon_{ijk}^{xyz} = (-1)^b$ with $b = (i, j, k) \cdot (x, y, z) = ix + jy + kz$. For example, $f_{000} = a_{***} \equiv 1$, $f_{100} = a_{0**} - a_{1**}$, and

$$f_{110} = a_{00*} - a_{01*} - a_{10*} + a_{11*}.$$

The f_{ijk}'s, like the a_{xyz}'s, are continuous functions of h_1, h_2, and h_3. Note that f_{110} is symmetric in the first and the second arguments: $f_{110}(h_1, h_2, h_3) = f_{110}(h_2, h_1, h_3)$. Also, when we flip the sign of an argument h_ℓ, the function f_{xyz} either changes sign or not depending on whether the corresponding subscript in f_{xyz} is 1 or 0. For example, for $\ell = 1$, $f_{110}(-h_1, h_2, h_3) = -f_{110}(h_1, h_2, h_3)$; while for $\ell = 3$, $f_{110}(h_1, h_2, -h_3) = f_{110}(h_1, h_2, h_3)$. We state these symmetry properties in the next lemma.

LEMMA 2.2.

1) $f_{ijk}(h_1, h_2, h_3) = f_{jik}(h_2, h_1, h_3)$.

2) $f_{ijk}(-h_1, h_2, h_3) = (-1)^i f_{ijk}(h_1, h_2, h_3)$.

Proof. Immediate from the definition of f_{ijk}. □

In seeking an eight-partition for A, we shall make use of the following characterization in terms of the f_{ijk}'s.

LEMMA 2.3.

1) *h_1 is a bisector of A if and only if $f_{100} = 0$.*

2) *the pair (h_1, h_2) forms a four-partition of A if and only if $f_{100} = f_{010} = f_{110} = 0$.*

3) *The triple (h_1, h_2, h_3) forms an eight-partition of A if and only if $f_{ijk} = 0$ for all $(i, j, k) \neq (0, 0, 0)$.*

Proof. 1) $a_{0**} = a_{1**} = \frac{1}{2}$ if and only if $a_{0**} - a_{1**} = f_{100} = 0$ since $a_{0**} + a_{1**} = f_{000} \equiv 1$.

2) Note that

$$\begin{pmatrix} f_{100} \\ f_{010} \\ f_{110} \\ f_{000} \end{pmatrix} = \begin{pmatrix} 1 & 1 & -1 & -1 \\ 1 & -1 & 1 & -1 \\ 1 & -1 & -1 & 1 \\ 1 & 1 & 1 & 1 \end{pmatrix} \begin{pmatrix} a_{00*} \\ a_{01*} \\ a_{10*} \\ a_{11*} \end{pmatrix}$$

If $a_{00*} = a_{01*} = a_{10*} = a_{11*} = \frac{1}{4}$, then $f_{100} = f_{010} = f_{110} = 0$ and $f_{000} \equiv 1$. Since the 4×4 matrix is nonsingular, indeed orthogonal, the converse is also true.

3) We show that the matrix of the coefficients $\{\varepsilon_{ijk}^{xyz}\}$ is orthogonal, and so nonsingular. Since

$$\sum_{xyz} \varepsilon_{ijk}^{xyz} \varepsilon_{i'j'k'}^{xyz} = \sum_{xyz} (-1)^{(x,y,z)(i+i', j+j', k+k')}$$

$$= 0 \text{ unless } i = i',\ j = j',\ \text{and } k = k',$$

the inner product of any two distinct rows of the matrix is zero. □

3. Eight-partition in R^3. It is well known that a four-partition can always be found for a positive density function over a bounded connected region in R^2. (See, e.g., [Me].) We first show this as a lemma and then prove a slightly stronger version in R^3 for later use.

LEMMA 3.1 (Four-Partition). *Let A_0 and A_1 be two positive density functions on the plane whose domains are bounded, connected, and separable by a line L. There is a unique (unoriented) line L' that bisects A_0 and A_1 simultaneously.*

Proof. For any point p on L, let ℓ_p and r_p be the (unique) lines that go through p and bisect A_0 and A_1, respectively. We can assume that L is vertical and that A_1 is to the right of L. As p moves up L from bottom to top, the slope of r_p decreases continuously and monotonically from ∞ to $-\infty$, while that of ℓ_p increases continuously and monotonically from $-\infty$ to ∞. Hence there is a unique p for which ℓ_p and r_p coincide, giving the desired L'. □

We next consider four-partitions in R^3.

LEMMA 3.2. *Let A_0 and A_1 be two positive density functions in R^3 whose domains are bounded, connected, and separable by a plane h. Let $S_h \cong S^1$ denote the set of unit vectors in R^3 that are parallel to h. Then,*

1) *for any $u \in S_h$ there is a unique plane $p(u)$ parallel to u which bisects A_0 and A_1 simultaneously and has an orientation induced by u;*

2) *the mapping $f: S_h \mapsto S^2$ which maps $u \in S_h$ to the normal vector of $p(u)$ gives a continuous antipodal mapping of S_h into S^2, i.e., $f(-u) = -f(u)$ for all $u \in S_h$.*

Proof. For any $u \in S_h$, a plane $p(u)$ parallel to u bisects A_0 and A_1 simultaneously if and only if the projection of $p(u)$ along the direction u (onto a plane normal to u) gives a line that bisects the projections of A_0 and A_1 simultaneously. The intersection of h and $p(u)$ is a line parallel to u. The orientation of u gives it a natural orientation which can be used to define the left and right half-planes of h with respect to this line. The orientation of $p(u)$ is chosen so that these lie respectively in the positive and negative half-spaces determined by $p(u)$. By Lemma 3.1, $p(u)$ is unique.

It is easy to see that the function f defined in (2) is continuous and antipodal. □

We shall make use of the $d=2$ case of the following topological theorem in proving that every density function A in R^3 can be eight-partitioned.

THEOREM (Bursuk-Ulam). *Let $f: S^d \mapsto R^d$ be a continuous, antipodal map, i.e., $f(-p) = -f(p)$ for $p \in S^d$. Then there is a point $p \in S^d$ such that $f(p) = 0$.*

A proof of the Borsuk-Ulam theorem can be found in textbooks on algebraic topology such as Munkres [Mu]. The theorem does not extend in general to mappings defined on direct products of spheres. However, we can establish the following extension for mappings defined on the torus $S^1 \times S^1$ which satisfy certain additional symmetry properties. This lemma is sufficient, as we shall see, for establishing the existence of eight-partitions in R^3.

LEMMA 3.3. *Let $f: S^1 \times S^1 \mapsto R^2$ be a continuous map such that*

1) *f is symmetric,* i.e., $f(u, v) = f(v, u)$,

2) *f is antipodal in each argument,* i.e., $f(u, -v) = f(-u, v) = -f(u, v)$, *and*

3) *f is constant on the diagonal $\{(u, u) | u \in S^1\}$.*

Then there is a point $p \in S^1 \times S^1$ such that $f(p) = 0$.

Proof. We can represent $S^1 \times S^1$ by the square $\mathcal{Q} = [0, 2\pi] \times [0, 2\pi]$ with opposite sides identified. Consider the rectangle $\mathcal{P} = \{(u, v) | \pi \leqq u + v \leqq 3\pi,\ u \leqq v \leqq u + \pi\}$ contained in $\mathcal{Q}$ with vertices $A = (\pi/2, \pi/2)$, $B = (0, \pi)$, $C = (3\pi/2, 3\pi/2)$, and $D = (\pi, 2\pi)$ (Fig. 2). Note that f is constant on side AC by property (3), constant on side BD since $f(u, u+\pi) = -f(u, u)$ by (2), and defined identically on AB and CD since $f(u, v) = f(u+\pi, v+\pi)$. The involution $(u, v) \leftrightarrow (v, u+\pi)$ maps square $ABFE$ to $FECD$ and vice versa, while $f(v, u+\pi) = -f(v, u) = -f(u, v)$. Consider any map $\alpha: \mathcal{P} \mapsto S^2$ which identifies sides AB and CD, contracts BD and AC to points, and maps every pair of points of the form (u, v) and $(v, u+\pi)$ in $\mathcal{P}$ to a pair of antipodal

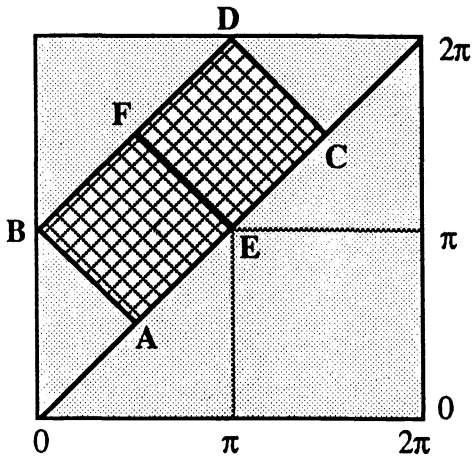

FIG. 2.

points $(p, -p)$ on S^2. Such an α yields an induced continuous function f': $S^2 \mapsto R^2$ where $f'(\alpha(p)) = f(p)$ for $p \in \mathcal{P}$. Since f' is an antipodal map, it follows from the Borsuk–Ulam theorem that f', and hence f, must map some point onto the origin of R^2. □

MAIN THEOREM. *Let A be a positive density function over a bounded connected region in R^3, and let $w_0 \in S^2$ be given. Then there exists a triple of planes (h_1, h_2, h_3) which forms an eight-partition for A, and where the normal vector of h_3 is w_0.*

Proof. By Lemma 2.3, this is equivalent to finding h_1, h_2, h_3 such that $f_{ijk}(h_1, h_2, h_3) = 0$ for all $(i, j, k) \neq (0, 0, 0)$. Since h_1, h_2, and h_3 must be bisectors for A, and for any $u \in S^2$ there is a unique bisector h_u for A with normal vector u, we can define functions g_{ijk}: $S^2 \times S^2 \times S^2 \mapsto R$ by

$$g_{ijk}(u, v, w) = f_{ijk}(h_u, h_v, h_w). \tag{1}$$

the g_{ijk}'s are obviously continuous. It suffices to find u_0 and v_0 such that $g_{110} = g_{101} = g_{011} = g_{111} = 0$ at (u_0, v_0, w_0). We can limit the choice of u_0 (or v_0) to the set $\{u\}$ (or $\{v\}$) for which (h_u, h_{w_0}) (respectively, (h_v, h_{w_0})) forms a four-partition, i.e.,

$$g_{101}(u, v, w_0) = 0 \quad \text{and} \quad g_{011}(u, v, w_0) = 0. \tag{2}$$

By Lemma 3.2, the set of (u, v) that satisfies (2) is homeomorphic to $S^1 \times S^1$. Our goal is thus to find a point $(u_0, v_0) \in S^1 \times S^1$ where both of the functions

$$G_0(u, v) \overset{\text{def}}{=} g_{110}(u, v, w_0) \text{ and } G_1(u, v) \overset{\text{def}}{=} g_{111}(u, v, w_0)$$

are zero. Let $G \overset{\text{def}}{=} (G_0, G_1)$: $S^1 \times S^1 \mapsto R^2$. Note that G is symmetric in its two arguments and antipodal on each S^1 by Lemma 2.2 and (1):

$$G(u, v) = G(v, u),$$

$$G(u, -v) = -G(u, v).$$

Furthermore it is easy to verify that on the diagonal we have

$$G(u, u) = (1, 0).$$

It follows from Lemma 3.3 that there exists $(u_0, v_0) \in S^1 \times S^1$ such that $G(u_0, v_0) = (0, 0)$. We conclude that $(h_{u_0}, h_{v_0}, h_{w_0})$ yields the desired eight-partition. □

LEMMA 3.4. *Consider a partition of R^3 into eight open regions by three mutually intersecting planes. Any plane h in R^3 can intersect at most seven of these eight regions.*

Proof. Define the origin O to be the point where the three planes meet, and axes X, Y, and Z to be the lines where pairs of planes intersect. Then O divides each axis into two half-axes $\{X^+, X^-\}$, $\{Y^+, Y^-\}$, and $\{Z^+, Z^-\}$. Without loss of generality, assume that h intersects the half-axes X^+, Y^+, and Z^+. Then h does not intersect the open region bounded by X^-, Y^-, and Z^-. □

The Borsuk–Ulam theorem also leads to the following well-known corollary (see, e.g., [E]), which we shall employ in defining a data structure in § 4.2. We state it in the discrete version for convenience.

THEOREM (Ham-Sandwich Cut). *Let $S_1, S_2, \cdots, S_d$ be d finite point sets in R^d. There exists a hyperplane which simultaneously bisects $S_1, S_2, \cdots, S_d$.*

4. Data structures and algorithms. Let S be a finite set of points in R^3. We will describe several tree structures for representing S, based on partitions of S by planes. These partitions are obtained by recursive applications of the theorems proved in the last section, and the resulting tree structures are suitable for the purpose of half-space retrieval and related searches on S.

We first present a recursive partition scheme based on the main theorem, giving a data structure termed an *octant tree.* Two variations of this basic scheme are derived by applying recursion in more intricate ways. The retrieval time is analyzed for each scheme, with the last variant achieving a retrieval time of $(n^{0.8988})$ for half-space query.

4.1. Octant tree. An octant tree is a recursively defined structure for storing a finite set S of points in R^3. If S is empty the octant tree is the special node NIL, otherwise the root of the octant tree contains a plane h, and its left, middle, and right children represent the subsets $S \cap h^-$, $S \cap h$, and $S \cap h^+$, respectively. More precisely, the middle child points to a two-dimensional data structure for $S \cap h$ (such as a polygon tree [W] or a conjugation tree [EW]), while the left and right children point to the root nodes of octant trees for $S \cap h^-$ and $S \cap h^+$, respectively. We define the *domain* of any node v, denoted by dom (v), to be the intersection of the "regions" on the path from the root to v. That is, the domain of the root is the whole space, and if v is a child of w, and h is the plane stored at w, then dom (v) is the intersection of dom (w) with h^-, h, or h^+, depending on whether v is the left, middle, or right child of w. The *set stored at* v, denoted by $S(v)$, is $S \cap$ dom (v).

The plane h at each node v of the octant tree is chosen so that both $|S(v) \cap h^-|$ and $|S(v) \cap h^+|$ are at most $|S(v)|/2$. There is no difficulty in finding planes with this property, but, without further conditions, such a data structure would have poor worst-case performance for half-space retrieval. (For example, k-d trees [B] require $O(n)$ time in the worst case.) In the schemes to be described, we achieve better performance by appropriately grouping the tree nodes so that all nodes within a group can share a common plane. For this purpose, we build octant trees recursively from small *primitive trees* and define the grouping among the nodes of a primitive tree. The data structures pointed to by middle children represent the corresponding two-dimensional sets efficiently for a retrieval time of $O(t^\delta)$ for a set of size t, where $\delta \approx 0.695$ [EW]. These substructures are ignored in the recursive structures described below and contribute just $O(n^\delta)$ terms to the recurrence relations given.

OCTANT TREE A. In this basic scheme, the primitive tree is of height 3 and all nodes on the same level share the same plane (see Fig. 3). The existence of such primitive trees is implied by the Main Theorem. The octant tree is obtained by applying recursion at the leaves of the primitive tree. In the figure solid nodes represent the roots of primitive trees.

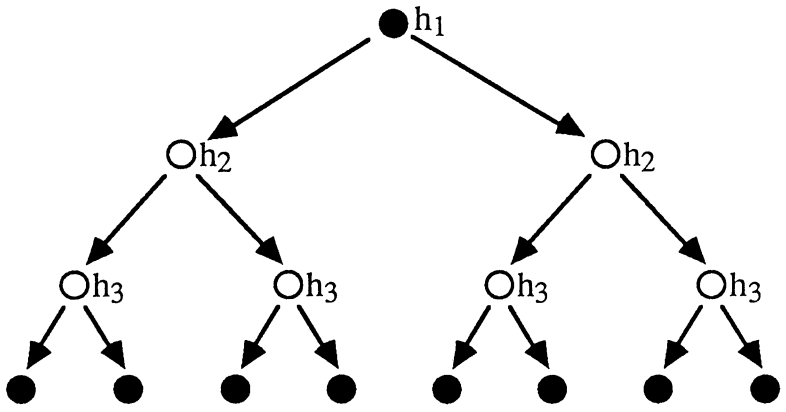

FIG. 3.

A search algorithm for the octant tree can be derived recursively from a search algorithm for the corresponding primitive tree. The general search strategy for primitive trees, with respect to a query plane q, is to identify those leaves in the primitive tree which need not be searched further. More precisely, a leaf v can be excluded from future search if dom (v) lies completely in a half-space of q, since the entire set $S(v)$ can be either reported or discarded. A leaf satisfying this condition is said to be *free* with respect to q.

By Lemma 3.4, the primitive tree has at least one free leaf with respect to any query q. Furthermore, the time required to identify the free leaves is bounded by a constant. Thus the search time for the derived octant tree is proportional to the total number of nodes visited. The recurrences below yield upper bounds for the search time. The reporting time, which is always linear in the size of the result, is not included here. Let $f(n)$ denote the maximum number of nodes visited in an octant tree for a set of n points. The constant δ arising from the two-dimensional subtrees has value at most 0.695.

LEMMA 4.1. *$f(n)$ satisfies the recurrence relation*

$$f(n) \leqq 7 + 7f(n/8) + O(n^{\delta}),$$

which gives a search time of $O(f(n)) = O(n^{\alpha})$ for $\alpha = \log_8 7 \approx 0.9358$.

Proof. In Fig. 3, the seven upper nodes of the primitive tree are visited, followed by visits to the seven substructures of size at most $n/8$ corresponding to the non-free leaves. The total number of nodes visited from middle children is at most $O(n^{\delta})$. The linear recurrence relation is solved by standard techniques (see, e.g., Knuth [K]). □

4.2. Refined octant trees.

OCTANT TREE B. In this variant of the basic scheme, we apply recursion to the four sets at level 2, while requiring that the same h_3 be used as the first plane for all four sets. The primitive tree is of depth 2 (see Fig. 4). Here we take advantage of the strength of the Main Theorem, which allows one of the three partitioning planes to be an arbitrary bisector.

To estimate the search time for scheme B, let $f(n)$ (and $g(n)$) denote the maximum number of nodes searched for any query, when the search starts at a root-level (and, respectively, second-level) node v of the primitive tree with $S(v) = n$.

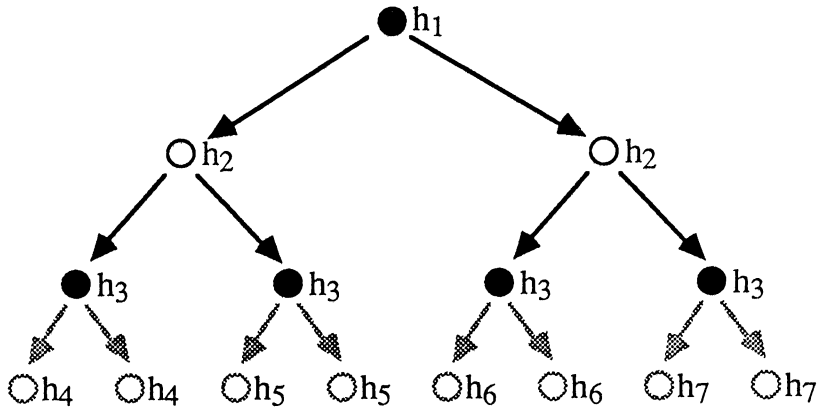

FIG. 4.

LEMMA 4.2. *$f(n)$ and $g(n)$ satisfy the recurrence relations*

$$f(n) \leqq 4+3f(n/4)+g(n/8)+O(n^{\delta}),$$

$$g(n) \leqq 1+2f(n/2)+O(n^{\delta}),$$

which give a search time under scheme B *of $O(f(n)) = O(n^{\beta})$, where $\beta \approx 0.9163$.*

Proof. Suppose without loss of generality that the rightmost of the eight lowest nodes, r, is free. The algorithm visits the three upper nodes and the parent of r, then recurses from the root level in the three left subtrees. In the fourth subtree, since r is free the search can begin at the second-level node which is r's sibling. This yields the first inequality. For the second, a search begun at second-level node searches that node and recurses on its children, which are root-level nodes. Substituting the second inequality into the first, we have

$$f(n) \leqq 5+3f(n/4)+2f(n/16)+O(n^{\delta}).$$

The recurrence yields $f(n) = O(n^{\beta})$, where $\beta \approx 0.9163$. □

OCTANT TREE C. This is a hybrid of schemes A and B with some further refinements. The primitive tree has six leaves on level 3 and one leaf on level 2. (See Fig. 5.) The six leaves on level 3 are divided into two triplets, where each triplet is to share a common first plane in the recursion. This is possible since, by the Ham-Sandwich theorem, any three point sets in R^3 can be bisected by a single plane. We choose each triplet to consist of three octants that do not share any common faces; indeed the six octants can be divided into two such triplets as shown in Fig. 6, where the octants are represented as the vertices of a cube.

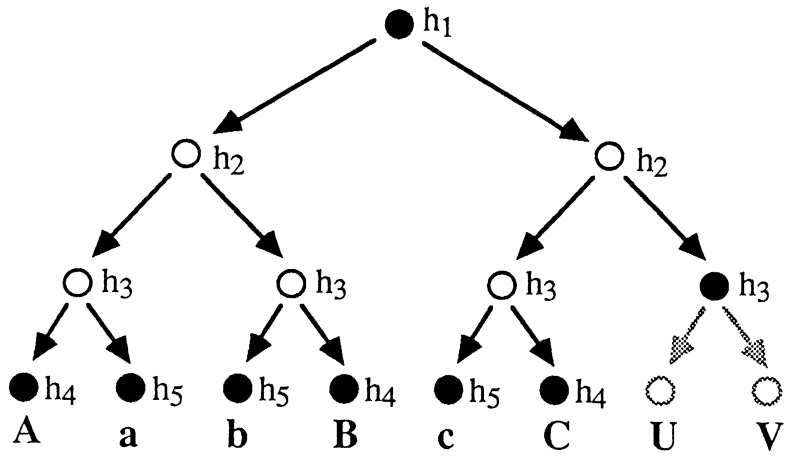

FIG. 5.

Again, define $f(n)$ and $g(n)$ as in the analysis of scheme B. We have the following bound for $f(n)$.

LEMMA 4.3. *Under scheme C, $f(n)$ satisfies the recurrence relation*

$$f(n) \leqq 10+f(n/4)+4f(n/8)+4f(n/64)+O(n^{\delta}),$$

which gives a search time of $O(f(n)) = O(n^{\gamma})$ for $\gamma \approx 0.8988$.

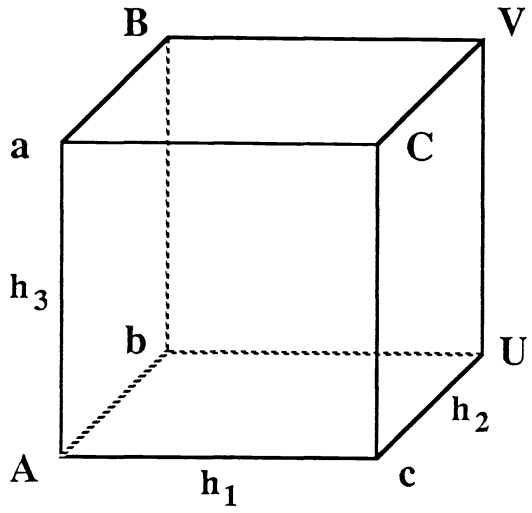

FIG. 6.

Proof. There are a number of cases to consider depending on which of the eight nodes is free.

If A is free then the intersection of the query plane q with the other domains will be similar to Fig. 7. The domains A, B, and C are bisected by h_4, while h_5 bisects a, b, and c. In the worst case, q will intersect both halves of B and C but, by our choice of the triplets, q cannot intersect both halves of a, b, and c. (In Fig. 7, the intersections of q with a, b, and c form three regions which cannot be simultaneously intersected by the line representing the intersection of q and h_5.) For the case detailed in Fig. 7, our algorithm is to search the six non-leaf nodes of the primitive tree; recursively

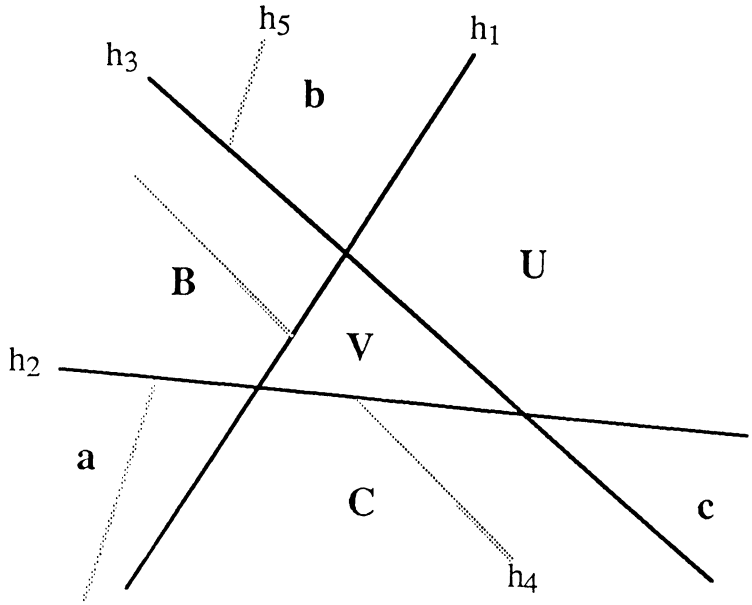

FIG. 7.

search from the parent of U and V; recursively search a, b, B, and C; search the node labelled c; and search from the second-level node corresponding to the child of c which is intersected by q. This yields the inequality

$$f(n) \leqq 7 + f(n/4) + 4f(n/8) + g(n/16) + O(n^{\delta}). \tag{3}$$

If U is free the intersection with q is similar to Fig. 8. Here at most two of A, B, and C and two of a, b, and c can have both of their halves (with regard to h_4 and h_5, respectively) intersected by q. For the case detailed in Fig. 8, our algorithm is to search the upper seven nodes; search the nodes labelled B and b; recursively search a, c, A, and C; recursively search the single children of B and b which are intersected by q; and recursively search V. The corresponding inequality is

$$f(n) \leqq 9 + 4f(n/8) + 2g(n/16) + g(n/8) + O(n^{\delta}). \tag{4}$$

We also have two inequalities for $g(n)$, depending on whether the second-level node where the search starts is the left child or the right child of a root node.

$$g(n) \leqq 3 + 4f(n/4) + O(n^{\delta}), \tag{5}$$

$$g(n) \leqq 2 + 2f(n/4) + f(n/2) + O(n^{\delta}). \tag{6}$$

The worst case is obtained by substituting (5) into (3), resulting in

$$f(n) \leqq 10 + f(n/4) + 4f(n/8) + 4f(n/64) + O(n^{\delta}).$$

This yields $f(n) = O(n^{\gamma})$, where $\gamma \approx 0.8988$. □

4.3. Preprocessing cost. We look at the time it takes to construct an octant tree for a set S of n points. First consider the computation of an eight-partition (h_1, h_2, h_3) for S. The first bisector h_1 can be found in $O(n)$ time by a median-finding algorithm.

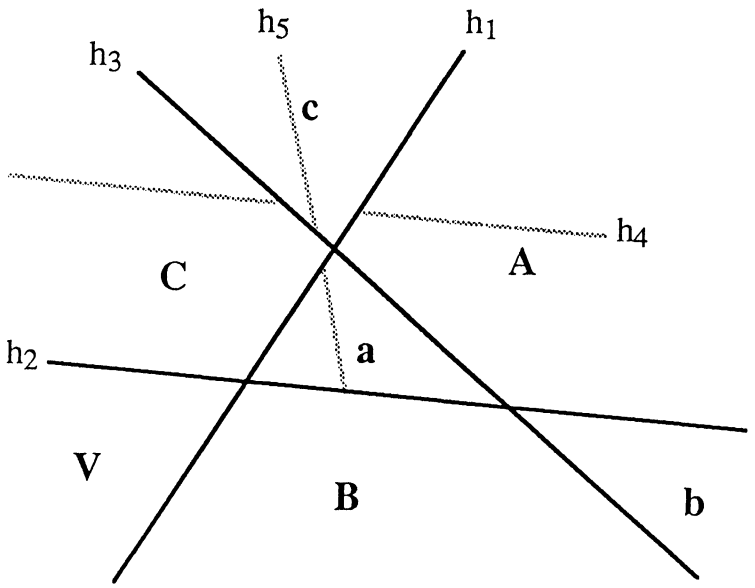

FIG. 8.

We may assume that h_2 and h_3 are each determined by three points of S. For each of the $O(n^6)$ possible choices of (h_2, h_3), we decide in $O(n)$ time whether it forms an eight-partition together with h_1 by explicitly counting the number of points in each octant. This amounts to a total time of $O(n^7)$ with linear space. The time can be reduced to $O(n^6)$ by lowering the cost due to counting as follows. For any two fixed points a, b, of S, order the remaining points as $c_1, c_2, \cdots$ by projecting the points of S onto a plane perpendicular to $\overline{ab}$ and sorting them radially. Coplanar sets of more than three points introduce some complication but no significant difficulty. With such orderings imposed on h_3 during the search, the task of counting associated with each pair (h_2, h_3) becomes that of doing simple updates, with constant cost per pair on average. The total cost for finding an eight-partition, with sorting included, is thus $O(n^6)$ time using $O(n^3)$ storage. The storage could be made $O(n)$ by repeating the sorting operations whenever needed, but at a cost of $O(n^6 \log n)$ time.

The octant trees of schemes A and B can be constructed by applying the above procedure recursively, in total time $O(n^6 \log^n)$ for n points with linear space. The same bounds hold for scheme C since a "ham-sandwich cut" can be computed in $O(n^3 \log n)$ time.

4.4. Circle queries. The problem of finding all points (x, y) in a planar set S which lie inside a query circle C with center (a, b) and radius r can be transformed to a three-dimensional half-space problem in the following way. Since

$$(x, y) \text{ lies inside } C \Leftrightarrow (x-a)^2+(y-b)^2 < r^2$$

$$\Leftrightarrow -2ax-2by+(x^2+y^2) < r^2-a^2-b^2,$$

if we represent each point $(x, y) \in S$ as a three-vector $\mathbf{v} = (x, y, x^2+y^2)$ then the query with respect to circle C can be expressed by the half-space query:

$$(-2a, -2b, 1) \cdot \mathbf{v} < (r^2-a^2-b^2).$$

A geometrical interpretation of this is that, when the xy-plane is projected upwards onto the paraboloid $z = x^2+y^2$, the image of any circle in the plane is the intersection of the paraboloid with a suitable plane. The same technique is applicable to other "algebraic" queries, but the dimension required is the number of degrees of freedom of the defining polynomial.

Rather than transform the circle query problem to three dimensions, we can also recast our three-dimensional results in two dimensions. An eight-partition of the n points on the paraboloid can be projected down to the xy-plane yielding a partition by three circles. Our main theorem implies the following.

COROLLARY 4.4. *For any finite point set and any bisecting circle in the plane, there are two circles such that each open region defined by the three circles contains at most one eighth of the set.*

Any query circle intersects at most six of the eight regions since it meets the three circles in at most six points. Using (the two-dimensional projection of) octant tree A we therefore get $O(f(n))$ query time, where

$$f(n) \leqq 7+6f(n/8)+O(\log n) = O(n^\alpha),$$

for $\alpha = \log_8 6 \approx 0.8617$. Here the $O(\log n)$ term takes care of the one-dimensional queries needed for points lying on the partitioning circles.

We get the same worst-case time using scheme C, but using octant tree B yields a slight improvement. The query time is $O(f(n))$, where

$$f(n) \leqq 7 + 2f(n/4) + 4f(n/16) + O(\log n),$$

which solves to $f(n) = O(n^{\beta})$, with $\beta = (\log_2 \sqrt{5} + 1)/2 \approx 0.8471$.

4.5. Polyhedron queries. Based on our half-space query schemes, we may derive a generalization to queries for convex polyhedra defined by the intersection of r hyperplanes. For fixed r, the query time will be of the same order as for half-space queries, but the constant increases with r. Since every (not necessarily convex) polyhedron can be decomposed into (possibly unbounded) tetrahedra (see, e.g., [Ch1]), it would suffice to consider at most tetrahedral queries, i.e., $r \leqq 4$.

Let $f_r(n)$ be the number of nodes of the data structure for n points which may be searched in a query with a polyhedron C which is the intersection of r half-spaces, where we already have by our scheme C above that $f_1(n) = O(n^{\gamma})$ for some $\gamma \leqq 0.8988$. We prove by induction on r that $f_r(n) = O(n^{\gamma})$ for all r.

Suppose $f_{r-1}(n) = O(n^{\gamma})$ and consider a query with respect to the intersection of r half-spaces. In the case that some level-three node is free with respect to all r planes, the recurrence relations considered above hold for f_r. In the alternative case, there are two level-three nodes, each free with respect to some plane or planes. Now the recurrence terms in f_r are diminished and so correspond to some exponent $\gamma' < \gamma$, while the remaining terms are of size $O(f_{r-1}(n)) = O(n^{\gamma})$. The result is that $f_r(n) = O(n^{\gamma})$ and the induction is complete.

Of course the same general argument is valid for any similar scheme in any finite dimension.

5. Conclusion and related results. We showed that an eight-partition with three planes exists for any finite point set in R^3. It was brought to the authors' attention that a continuous version of this theorem was proved earlier by Hadwiger with a more complicated argument [H]. As far as generalization to higher dimensions is concerned, Avis [A] showed that 2^d-partitions are not always possible in dimensions $d \geqq 5$. A different and simpler proof is as follows (stated here for $d = 5$ but adaptable to any larger d). Take thirteen small balls of equal mass and place them in general position so that no hyperplane in R^5 can intersect more than five of the balls. Now, in any 2^5-partition, each ball must be cut by at least two hyperplanes, otherwise some orthant will contain at least one half of a ball, with at least $1/26$ of the total mass, which is larger than the $1/32$ required. Therefore, for all thirteen balls, at least 26 instances of hyperplane-ball intersections are needed. Since the balls are in general position, five hyperplanes can provide at most 25 such instances and we have a contradiction.

The case of $d = 4$ still remains an intriguing open question, that is, given any finite point set in R^4, whether one can always partition it with four hyperplanes such that each orthant contains at most $1/16$ of the points. Our proof for $d = 3$ makes use of the Borsuk–Ulam theorem of algebraic topology; the case of $d = 4$ is likely to draw further upon classical mathematics for its resolution.

Generalizations of eight-partition to higher dimensions have also been studied along a different line, by relaxing the number of hyperplanes used in the partition (see Cole [Co] and Yao and Yao [YY]). Deterministic partition schemes in three dimensions that are different from those described in this paper can be found in [EH]. Their main construction is based on the existence of a six-partition for every planar point set, that

is, a partition by three concurrent lines so that every wedge contains at most one sixth of the points. The best such scheme achieves $O(n^{\alpha})$ query time, where $\alpha \approx 0.9089$.

Haussler and Welzl [HW] used random sampling to demonstrate the existence of partitions in R^d which afford the best query time currently known. In particular, for $d = 3$ their scheme gives query time $O(n^{\alpha})$ for $\alpha \approx 0.857$. As their algorithms are probabilistic, it is an interesting open question to find deterministic algorithms for constructing partitions to realize similar or even better query time in R^d.

Chazelle [Ch2] established a lower bound under a rather general model for range search in d dimensions. His bound in three dimensions assuming $O(n)$ space is $\Omega(n^{2/3} \log n)$ query time.

CNF SATISFIABILITY TEST BY COUNTING AND POLYNOMIAL AVERAGE TIME*

KAZUO IWAMA†

Abstract. The average-case performance of an algorithm for CNF SAT, recently introduced by the author, is discussed. It is shown that the algorithm takes polynomial average time for a class of CNF equations satisfying the condition that for a constant c, $p^2 v \geqq \ln t - c$, where v is the number of variables, t is the number of clauses, and p is the probability that a given literal appears in a clause. It was known that backtracking plus the pure literal rule, a common way of solving CNF SAT, takes polynomial average time if $p \geqq \varepsilon$ (any small constant) or $p \leqq c\,(\ln v/v)^{3/2}$, but no algorithms were known to take polynomial average time (for all t) in the range $c\,(\ln v/v)^{3/2} < p < \varepsilon$. For reasonable t ($t \leqq v^{\alpha}$ for some constant $\alpha > 0$) the new algorithm runs in polynomial average time for $p > (\alpha \ln v/v)^{1/2}$, so the unfavorable region is reduced to $c(\ln v/v)^{3/2} < p < (\alpha \ln v/v)^{1/2}$.

Key words. CNF SAT, average time, independent sets, backtracking

AMS(MOS) subject classifications. 68Q20, 68Q25, 68R05

1. Introduction. A number of approaches to attack hard (typically NP-hard) combinatorial problems are known, most of which are claimed to be "realistic" in the sense that they work well in most average cases. However, if, as is widely believed, there are no good algorithms which work efficiently for *all* instances, those approaches should have some weak points. This seems to be true. For example, when trying to solve CNF Boolean equations (or their satisfiability, SAT) by backtracking [3], [4], [5], [9], [10], [11], [12], [13], it is known that the number of literals in each clause plays an important role. The more literals, the less efficiently backtracking works, which is clearly due to the fundamental structure of the approach. Probabilistic approaches to the Hamiltonian circuit problem [2], [7] also depend on the average degree of given graphs. (For example, [7] shows that there is a polynomial-time algorithm which almost surely finds a Hamilton circuit for the graphs whose average degree is greater than $\ln n$.) They seldom work for the graphs such that Hamiltonian circuits exist, but the average degree is small.

Knowing some specific weak point of one approach, it is quite natural to look for another approach which will compensate for that weak point. It is a little surprising, however, that there have been very few articles focusing on this complementary nature of algorithms for hard combinatorial problems. (Trivial ones like sequential searches in opposite directions usually do not help in the case of hard problems.) In solving CNF SAT, most efforts have been made to improve backtracking by means of heuristics or to analyze the efficiency of backtracking, which has not changed the approach's fundamental weak points.

Recently the author introduced a completely new approach, called IS, to solve CNF SAT [6]. In [6], it was shown that (i) IS is complementary to backtracking in that it becomes faster as the number of literals in each clause increases, and (ii) there is evidence that IS is actually faster than backtracking in a certain class of instances. In this paper, we look into the IS approach from a slightly different angle. It is shown that IS takes polynomial average time for CNF equations satisfying the condition that

* Received by the editors September 14, 1987; accepted for publication (in revised form) July 21, 1988. This work was supported by the Science Foundation Grant of the Ministry of Education, Science and Culture of Japan.

† Department of Computer Sciences, Kyoto Sangyo University, Kyoto 603, Japan.

for a constant c

$$p^2 v \geqq \ln t - c$$

where v is the number of variables, t is the number of clauses, and p is the probability that a given literal appears in a clause (the same for all literals).

Among others, Purdom and Brown have investigated extensively the performance of backtracking for CNF SAT [3], [5], [9], [10], [11], [12], [13], [14]. In [13], [14] it is shown that backtracking (with the pure literal rule) takes polynomial average time when any of the following conditions is satisfied: (1) $t \leqq c \ln v$, (2) $t \geqq \exp(\varepsilon v)$, (3) $p \geqq \varepsilon$, and (4) $p \leqq c(\ln v/v)^{3/2}$, where c is any large constant and ε any small constant (see [13], [14] for the t dependence of bound (4)). In discussing a practical class of instances, it is common to introduce the assumption $t = v^{\alpha}$ for some positive constant α [3], [12]. Then the above (1) and (2) do not apply because neither c nor ε can be constant. (3) and (4) leave the range

$$c(\ln v/v)^{3/2} < p < \varepsilon$$

where there are no known algorithms which take polynomial average time. Our present result makes this unfavorable gap smaller, i.e.,

$$c_1(\ln v/v)^{3/2} < p < c_2(\ln v/v)^{1/2}.$$

It should be noted that this gap is the worst case (when $t = (2 \ln 2)v/\ln v$). For example, when $t = v$ it becomes

$$c_1/v < p < c_2(\ln v/v)^{1/2}.$$

The algorithm, as well as some preliminaries, are described in the next section. In § 3 we analyze the performance of IS and prove our main result. In § 4 we present a preprocessor to reduce the number of clauses and discuss its advantages. Analysis of several heuristics other than this preprocessor (see [6]) will be given in future reports.

2. Algorithm IS. The following small example will clarify the basic idea of the algorithm. Let

$$f_0 = (x_1 + x_2)(x_3 + x_4)(\bar{x}_2 + \bar{x}_4)(\bar{x}_1 + \bar{x}_2)(\bar{x}_1 + x_3 + \bar{x}_4)(\bar{x}_1 + x_2 + \bar{x}_3)$$

and remember the Karnaugh map [8] used to minimize logic functions. Note that the first clause $(x_1 + x_2)$ of f_0 covers four *maxterms* (or *cells* of the map), $(x_1 + x_2 + x_3 + x_4)$, $(x_1 + x_2 + \bar{x}_3 + x_4)$, $(x_1 + x_2 + x_3 + \bar{x}_4)$ and $(x_1 + x_2 + \bar{x}_3 + \bar{x}_4)$. The second clause also covers four cells and so on. Note that cell $(x_1 + x_2 + x_3 + x_4)$ is covered by both the first and the second clauses. It is a fundamental fact that f_0 is satisfiable if and only if the number of cells covered by at least one clause is less than 2^4 (4 is the number of variables). In f_0, the first and second clauses overlap on one cell, as do the second and fourth clauses, the third and fifth clauses, the fourth and fifth clauses, and the third, fourth, and fifth clauses; the third and fourth clauses overlap on two cells. Therefore by the inclusion-exclusion principle we can calculate that

$$4+4+4+4+2+2-(1+1+2+1+1)+1 = 15$$

cells are covered, which means that f_0 is satisfiable since $15 < 2^4$. In fact, one can verify that no clauses cover cell $(x_1 + \bar{x}_2 + \bar{x}_3 + x_4)$. That means that $(x_1, x_2, x_3, x_4) = (0, 1, 1, 0)$ makes the whole f_0 logical 1 (true). The efficiency of this approach clearly depends on the number of overlaps, which can be exponentially large in general.

With the predicate f_0, we can associate the graph $G(f_0)$ of Fig. 1, where the nodes n_1 through n_6 correspond to the clauses s_1 through s_6 ($s_1 = (x_1 + x_2)$, $s_2 = (x_3 + x_4)$ and so on). Edges between two nodes show that the corresponding two clauses do not overlap. Hence two or more clauses that overlap are represented on the graph by two or more nodes that construct an independent set (IS stands for independent sets).

More formally, a (CNF) *predicate* is a product (logical and) of *clauses*, each of which is a sum (logical or) of *literals* (variables x or their negation $\bar{x}$). For the problem set, we assume, as in [5], [11], [13], a set of random predicates with parameters v (the number of variables), t (the number of clauses) and p (the probability that each literal appears in a clause). A random clause is formed by independently selecting each of the $2v$ literals with probability p. A random predicate is formed by independently selecting t random clauses. Thus the clause may consist of no literals (*false*) or may include both x and $\bar{x}$ for some variable x (*tautological*).

For a clause s and a set S of clauses, we define

$$\mathrm{LIT}(s) = \{z | s \text{ includes literal } z\},$$

$$\mathrm{LIT}(S) = \bigcup_{s \text{ in } S} \mathrm{LIT}(s).$$

A set $S(|S| \geqq 1)$ of clauses are said to be *independent* if there is no variable x such that both x and $\bar{x}$ are in $\mathrm{LIT}(S)$. Thus, if S is not independent then no two clauses in S overlap on the Karnaugh map and if S contains a tautological clause then it is not independent even if $|S| = 1$. For an independent set S of clauses of predicate f with v variables, we define

$$\mathrm{SIZE}_f(S) = 2^{v - |\mathrm{LIT}(S)|}.$$

For an integer i, $\mathrm{IND}_f(i)$ is defined as

$$\mathrm{IND}_f(i) = \{S | S \text{ is an independent set of } i \text{ clauses}\}.$$

SIZE_f and IND_f can be written as SIZE and IND, respectively, if predicate f is clear.

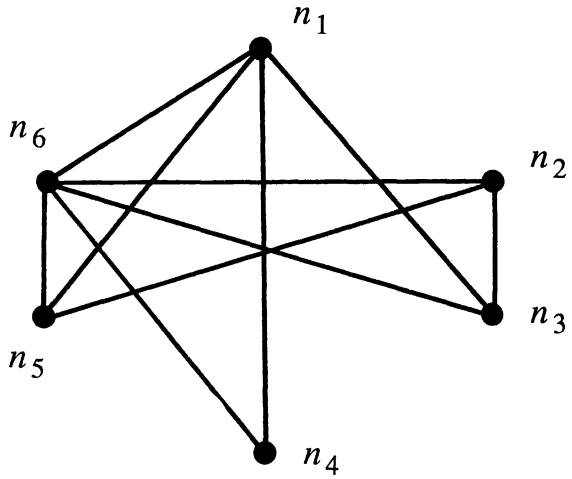

FIG. 1. *Graph* $G(f_0)$.

For the predicate f_0 above,

$$\text{IND}(2) = \{\{s_1, s_2\}, \{s_2, s_4\}, \{s_3, s_4\}, \{s_3, s_5\}, \{s_4, s_5\}\},$$
$$\text{LIT}(\{s_3, s_4\}) = \{\bar{x}_1, \bar{x}_2, \bar{x}_4\},$$
$$\text{SIZE}(\{s_3, s_4\}) = 2^{4-3} = 2.$$

Now here is the algorithm:

procedure IS
begin
  sum := 0; i := 1;
  repeat
    compute IND (i);
    sum := sum + $\sum_{S \text{ in IND}(i)} (-1)^{i-1}$ SIZE (S);
    $i := i+1$
  until IND (i) = ϕ;
  if sum = 2^v **then** answer "unsatisfiable" **else** answer "satisfiable"
end.

Note that SIZE (S) is the total number of the cells on the Karnaugh map that are covered by all the clauses in S. Then it is not hard to see that the algorithm is correct, namely, it counts the number of cells covered by at least one clause of the given predicate f in the repeat loop. There seem to be several methods to compute IND (i) efficiently. For example, the following way, although elementary, does not recompute the same element more than once. Suppose that f consists of t clauses $s_1, s_2, \cdots, s_t$ and that $S = \{s_{j_1}, s_{j_2}, \cdots, s_{j_{i-1}}\}, j_1 < j_2 < \cdots < j_{i-1}$, is in IND ($i-1$). Then check for each s_h, $h > j_{i-1}$, whether $S \cup \{s_h\}$ is independent. If so, we put $S \cup \{s_h\}$ into IND (i). Clearly IND (1) = $\{\{s\} | s$ is any clause but a tautological one$\}$.

Now let us take a look at the number of steps IS needs. For a single member S of IND ($i-1$), we have to check for $O(t)$ clauses s_h whether or not $S \cup \{s_h\}$ is independent. To check if $S \cup \{s_h\}$ is independent, $O(|s_h|)$ steps are enough by computing in advance LIT (S) for all S in IND ($i-1$) and LIT (s_h) for all clauses of f. Thus it takes $O(t \cdot |\text{IND}(i-1)|)$ steps to compute IND (i) if we consider $|s_h|$ a constant. (That is a usual and reasonable assumption since the real size parameter for given predicates is their length, but instead we now take the number of clauses as the size parameter.) To compute *sum*, $O(t \cdot |\text{IND}(i)|)$ steps are obviously enough. Therefore IS takes

$$O(t \cdot N_f)$$

steps where N_f is the number of all independent sets or

$$N_f = |\text{IND}(1)| + |\text{IND}(2)| + |\cdots.$$

The above method of computing IND (i) is simple and easy to implement but requires a lot of memory to hold the whole IND (i) and IND ($i-1$). Note that we can use a standard technique (recursive tree search) to save memory while increasing the number of steps only by a constant factor (see, e.g., pp. 64–69 of [1] for a general idea of this technique).

3. Polynomial average time. In this section, we obtain the expected number N_f of all independent sets of clauses for the predicate f such that the number of variables is v, the number of clauses is t, and the probability that a literal appears in a clause is p. Let $P(k)$ be the probability that k clauses are independent. One can see that the k clauses are independent if, for all variables x, x appears in none of the k clauses or

$\bar{x}$ appears in none of the k clauses. The probability that x appears in none of the k clauses is $(1-p)^k$ and the same for $\bar{x}$. The probability that neither x nor $\bar{x}$ appears is $[(1-p)(1-p)]^k$. Hence

$$
\begin{aligned}
P(k) &= \{(-p)^k + (1-p)^k - [(1-p)(1-p)]^k\}^v \\
&= \{(1-p)^k(2-(1-p)^k)\}^v \\
&= \{(1-p)^k(1+kp-\binom{k}{2}p^2+\cdots)\}^v \\
&\leqq \{(1-p)^k(1+kp)\}^v.
\end{aligned} \tag{1}
$$

Let $\bar{P}(k) = \{(1-p)^k(1+kp)\}^v$. (Note that $\bar{P}(k) < 1$ for $0 < p \leqq 1$ and $k \geqq 1$.)

The value N_f we want can be written as $N_f = \sum_k \binom{t}{k} P(k)$. Let

$$
\bar{N}_f = \sum_k \binom{t}{k} \bar{P}(k) \tag{2}
$$

and

$$
\bar{N}(k) = \binom{t}{k} \bar{P}(k).
$$

Then it is not hard to observe that, as k increases, $\bar{N}(k)$ first increases, becomes maximum at some point $k = k_0$ and then decreases. To obtain k_0 we compute

$$
\begin{aligned}
\frac{\bar{N}(k+1)}{\bar{N}(k)} &= \frac{\dfrac{t(t-1)\cdots(t-k+1)(t-k)}{(k+1)k\cdots 1}[(1-p)^{k+1}(1+(k+1)p)]^v}{\dfrac{t(t-1)\cdots(t-k+1)}{k(k-1)\cdots 1}[(1-p)^k(1+kp)]^v} \\
&= \frac{t-k}{k+1}(1-p)^v\left(1+\frac{p}{1+kp}\right)^v \qquad (3) \\
&\leqq \frac{t-k}{k+1}(1-p)^v(1+p)^v \\
&= \frac{t-k}{k+1}(1-p^2)^v.
\end{aligned}
$$

One can see that k_0 is the least integer that satisfies $\bar{N}(k_0+1)/\bar{N}(k_0) \leqq 1$. Hence $k_1 \geqq k_0$ if k_1 satisfies

$$
\frac{t-k_1}{k_1+1}(1-p^2)^v \leqq 1 \tag{4}
$$

or

$$
\frac{t(1-p^2)^v - 1}{1+(1-p^2)^v} \leqq k_1. \tag{5}
$$

The sum in (2) is less than t times the biggest term, so $\bar{N}_f \leqq t^c$ for some constant c if $k_1 = c-1$. The condition can be rewritten by (5) as

$$
\frac{t(1-p^2)^v - 1}{1+(1-p^2)^v} \leqq c-1. \tag{6}
$$

Clearly $1+(1-p^2)^v \geqq 1$ and therefore (6) holds if

$$t(1-p^2)^v \leqq c \tag{7}$$

or

$$p^2 v \geqq \ln t - \ln c, \tag{8}$$

since $\ln(1-p^2) \leqq -p^2$. Condition (8) guarantees that $N_f \leqq t^c$. We have already shown that it takes IS $O(t \cdot N_f)$ steps in Section 2; hence, the following theorem follows.

THEOREM 1. IS *takes* $O(t^{c+1})$ *steps on average for the class of predicates satisfying the condition that* $p^2 v \geqq \ln t - \ln c$ *for the constant* c.

4. Clause reduction. Consider the following predicate f_1

$$f_1 = (x_1 + \bar{x}_4)(x_1 + \bar{x}_2)(\bar{x}_1 + x_2 + x_3)(x_3 + \bar{x}_4)(x_1 + x_2 + \bar{x}_3)(x_2 + x_4).$$

Note that the first clause of f_1, $(x_1 + \bar{x}_4)$, can be removed without changing f_1's satisfiability since the four cells covered by $(x_1 + \bar{x}_4)$ are also covered by the conjunction of the second, fourth, and fifth clauses

$$(x_1 + \bar{x}_2)(x_3 + \bar{x}_4)(x_1 + x_2 + \bar{x}_3).$$

We can prove this through another satisfiability test, i.e., by showing that predicate

$$F(f_1, (x_1 + \bar{x}_4)) = \bar{x}_2 \cdot x_3 \cdot (x_2 + \bar{x}_3)$$

is not satisfiable. $F(f_1, (x_1 + \bar{x}_4))$ is obtained by (i) picking clauses s out of f_1 such that s and $(x_1 + \bar{x}_4)$ are independent and (ii) deleting the literals x_1 and $\bar{x}_4$ (of $(x_1 + \bar{x}_4)$) appearing in those clauses.

Since removing such clauses clearly makes the given predicate simpler, it is worth trying, if testing of $F(f, s)$'s satisfiability for each clause s of f is much easier than to test the whole f's satisfiability. (The test need not be done for all clauses but for some chosen by a certain heuristic.) Clause reduction may lead to a large saving, and the author believes that it should be investigated further.

5. Concluding remarks. Our main result clearly indicates the complementary nature between backtracking and IS: Backtracking works well for small p and IS for large p. However, there still remains the gap, $c_1(\ln v/v)^{3/2} < p < c_2(\ln v/v)^{1/2}$, where no polynomial-time algorithms are known. Just as the lower bound of this gap has long been raised by improvements of backtracking itself and its performance analysis, the upper bound also will possibly be lowered by future research on IS. Some candidates are (i) to include the close reduction (in § 4) in the algorithm systematically and (ii) to take into account in the analysis another heuristic [6] that makes it possible to stop the main loop before IND(i) becomes empty.

Acknowledgments. The author thanks Y. Okabe for his help in computing N_f in Section 3 and P. Purdom for pointing out an inappropriate approximation in an early version of this paper.

RELATIVIZED POLYNOMIAL TIME HIERARCHIES HAVING EXACTLY K LEVELS*

KER-I KO†

Abstract. It is proved that for every integer $k \geq 0$, there is an oracle A_k relative to which the polynomial time hierarchy collapses so that it has exactly k levels. Furthermore, sets B_k and C_k may be constructed so that, relative to B_k, the polynomial time hierarchy has exactly k levels and the class PSPACE coincides with the polynomial time hierarchy, and, relative to C_k, the polynomial time hierarchy has exactly k levels and the class PSPACE is different from the polynomial time hierarchy.

Key words. polynomial time hierarchy, relativization, oracle

AMS(MOS) subject classification. 68C25

1. Introduction. One of the main goals in complexity theory is to develop proof techniques to separate complexity classes. While it is well recognized that most separation results are beyond today's proof techniques, interesting progress has been made recently on separation results for relativized complexity classes. Baker, Gill, and Solovay [2] showed that the relativized P = ?NP question may be answered in both ways depending on the oracles; i.e., there exist sets X and Y such that $\mathrm{P}(X) = \mathrm{NP}(X)$ and $\mathrm{P}(Y) \neq \mathrm{NP}(Y)$. Baker and Selman [3] extended it to the second level of the polynomial time hierarchy showing that there exists a set Z such that $\Sigma_2^P(Z) \neq \Sigma_3^P(Z)$. The proof technique of Baker and Selman's result is a complicated counting argument which, however, does not seem powerful enough to be applicable to separating the third level of the relativized polynomial time hierarchy.

More recently, Furst, Saxe, and Sipser [4] and Sipser [9] proposed the idea of applying probabilistic arguments to this problem. They reduced the problem of separating the relativized polynomial time hierarchy to the problem of proving lower bounds on the size of constant depth circuits. The major breakthrough in this direction is due to Yao [12] who, based on Furst, Saxe, and Sipser's idea, showed an exponential lower bound on the size of constant depth parity circuits and hence exhibited an oracle A which separates the class PSPACE (A) from PH (A). Hastad [5], [6] simplified Yao's proof and gave a proof for the claim made in [12] that there exists an oracle B such that for all $k > 0$, $\mathrm{PH}(B) \neq \Sigma_k^P(B)$. We summarize the known results about the relativized polynomial time hierarchies as follows:

(1) $\forall A \forall k > 0 [\Sigma_k^P(A) = \Pi_k^P(A) \Rightarrow \mathrm{PH}(A) = \Sigma_k^P(A)]$ (Stockmeyer [10]).

(2) $\exists B\ \mathrm{PSPACE}(B) = \mathrm{P}(B)$ (Baker, Gill, and Solovay [2]).

(3) $\exists C \forall k > 0\ \mathrm{PSPACE}(C) \neq \mathrm{PH}(C) \neq \Sigma_k^P(C)$ (Yao [12] and Hastad [5], [6]).

(4) $\forall k = 1, 2, \exists D_k\ \mathrm{PH}(D_k) = \Sigma_k^P(D_k) \neq \Sigma_{k-1}^P(D_k)$ (Baker, Gill, and Solovay [2], Heller [7]).

From the above results, the relativized polynomial time hierarchies may have quite different structures depending on the oracles. However, these results have not exhausted all possible structures of the relativized polynomial time hierarchies. For example, the following question remains open: does there exist a set D_k for each $k \geq 3$ such that

* Received by editors June 30, 1987; accepted for publication July 21, 1988. This research was supported in part by National Science Foundation grant CCR-8696135; a preliminary version of this paper has appeared in the 20th ACM Symposium on Theory of Computing (1988), pp. 245-253.

† Department of Computer Science, State University of New York at Stony Brook, Stony Brook, New York 11794.

(4) above holds? Furthermore, if such sets D_k exist, can we construct them to also separate PSPACE (D_k) from PH (D_k)? In this paper, we show that the probabilistic arguments developed by Yao [12] and Hastad [5], [6] are powerful enough to construct oracles D_k with the above required properties. More precisely, we prove the following results.

(5) $\forall k \geqq 1 \exists E_k$ PSPACE $(E_k) = \Sigma_k^P(E_k) \neq \Sigma_{k-1}^P(E_k)$.

(6) $\exists F_0$ PSPACE $(F_0) \neq$ NP $(F_0) = P(F_0)$.

(7) $\forall k \geqq 1 \exists F_k$ PSPACE $(F_k) \neq$ PH $(F_k) = \Sigma_k^P(F_k) \neq \Sigma_{k-1}^P(F_k)$.

The proof techniques for these results are the combination of the encoding scheme of Baker, Gill, and Solovay [2] and the probabilistic arguments of Yao [12] and Hastad [5]. The main complication comes from the possible interference between the two constructions, which can be handled by using slightly different formulations of Yao and Hastad's basic lemmas.

2. Preliminaries.

2.1. Basic notation. In this paper, all sets A are sets of strings over the alphabet $\Sigma = \{0, 1\}$. For each string x, let $|x|$ denote its *length*. Let Σ^n be the set of all strings of length n. We assume that there is a one-to-one *pairing function* $\langle , \cdots , \rangle$ that encodes an arbitrary number of strings $x_1, \cdots, x_n$ into a single string $\langle x_1, \cdots, x_n \rangle$. We assume that $|\langle x_1, \cdots, x_n \rangle| \geqq \Sigma_{i=1}^n |x_i|$. For each set A, let χ_A be its characteristic function; i.e., for each x, $\chi_A(x) = 1$ if $x \in A$, and $\chi_A(x) = 0$ if $x \notin A$.

2.2. Complexity classes. We assume that the reader is familiar with Turing machines (TMs), nondeterministic TMs, oracle TMs, nondeterministic oracle TMs, and their time and space complexity (see, for example, [8]). Let $\mathscr{C}$ be a class of sets. We let P $(\mathscr{C})$ (NP $(\mathscr{C})$) denote the class of sets that are computable in polynomial time by a deterministic (nondeterministic, respectively) oracle TM using some set $A \in \mathscr{C}$ as an oracle. If $\mathscr{C} = \{A\}$ then we write P (A), NP (A) for P $(\{A\})$, NP $(\{A\})$, respectively. Also, if $A = \varnothing$ then we write P, NP for P $(\varnothing)$, NP $(\varnothing)$, respectively. Let PSPACE $(\mathscr{C})$ denote the class of sets that are computable in polynomial space by a deterministic oracle TM using some set $A \in \mathscr{C}$ as an oracle. The *relativized polynomial time hierarchy* is defined as follows. For any class $\mathscr{C}$, let *co-*$\mathscr{C}$ be the class of sets whose complements are in $\mathscr{C}$.

$$\Sigma_0^P(\mathscr{C}) = \Pi_0^P(\mathscr{C}) = \Delta_0^P(\mathscr{C}) = \mathrm{P}(\mathscr{C});$$

$$\Sigma_{k+1}^P(\mathscr{C}) = \mathrm{NP}(\Sigma_k^P(\mathscr{C}));$$

$$\Pi_{k+1}^P(\mathscr{C}) = co\text{-}\Sigma_{k+1}^P(\mathscr{C});$$

$$\Delta_{k+1}^P(\mathscr{C}) = \mathrm{P}(\Sigma_k^P(\mathscr{C})).$$

Let PH $(\mathscr{C})$ be the union of all of the above classes. When $\mathscr{C} = \{A\}$ or $\mathscr{C} = \{\varnothing\}$, we also use simpler notation $\Sigma_k^P(A)$ or Σ_k^P, respectively, for $\Sigma_k^P(\mathscr{C})$, etc.

The relativized polynomial time hierarchy PH $(\mathscr{C})$ can be characterized by alternating quantifiers. Let $R(A; x)$ be a predicate over a set variable A and a string variable x. We say that $R(A; x)$ is a P^1-*predicate* if R is computable in polynomial time by a deterministic oracle machine that uses set A as the oracle and takes string x as the input. (The superscript 1 indicates that the predicate is on a type-1 object.) Let $k \geqq 1$. We say $\sigma(A; x)$ is a $\Sigma_k^{P,1}$-*predicate* if there exist a P^1-predicate $R(A; x, y_1, \cdots, y_k)$ over a set variable and $k+1$ string variables and a polynomial q, such that for all sets A and all x with $|x| = n$, $\sigma(A; x)$ is true if and only if

$$(\exists y_1, |y_1| \leqq q(n))(\forall y_2, |y_2| \leqq q(n)) \cdots (Q_k y_k, |y_k| \leqq q(n)) R(A; x, y_1, \cdots, y_k),$$

where $Q_k = \exists$ if k is odd, and $Q_k = \forall$ if k is even. It is well known that a set B is in $\Sigma_k^P(\mathscr{C})$ if and only if there exist a $\Sigma_k^{P,1}$-predicate σ and a set $A \in \mathscr{C}$ such that for all x, $[x \in B \Leftrightarrow \sigma(A; x)]$ [10], [11].

2.3. Enumerations of machines. We will assume a fixed enumeration $\{p_i\}$ of polynomials, a fixed enumeration $\{M_i\}$ for all polynomial time oracle TMs, a fixed enumeration $\{N_i\}$ of all polynomial time nondeterministic oracle TMs, and, for each $k \geqq 1$, a fixed enumeration $\{\sigma_i^k\}$ of all $\Sigma_k^{P,1}$-predicates. We assume that the ith machine M_i or N_i has its runtime bounded by the ith polynomial p_i. Without loss of generality, we may assume that $p_i(n) \leqq n^i$ for sufficiently large n. Let $k > 1$. We assume that the ith $\Sigma_k^{P,1}$-predicate $\sigma_i^k(A; x) \equiv (\exists y_1, |y_1| \leqq q(n))(\forall y_2, |y_2| \leqq q(n)) \cdots (Q_k y_k, |y_k| \leqq q(n))$ $R(A; x, y_1, \cdots, y_k)$ has the property that both the length-bonding polynomial q and the runtime of the deterministic oracle TM that computes the predicate R are bounded by the ith polynomial p_i. We say that the computation of σ_i^k on input x queries about the string z if the computation of the corresponding P^1-predicate $R(A; x, y_1, \cdots, y_k)$ queries about the string z for some $y_1, \cdots, y_k$ of length $\leqq p_i(n)$ and for some oracle A.

2.4. Complete sets. For any of the above defined class $\mathscr{D}$, a set $A \in \mathscr{D}$ is $(\leqq_m^P)$-*complete* for $\mathscr{D}$ if for every set $B \in \mathscr{D}$ there exists a polynomial time computable function f such that for all x, $x \in B$ if and only if $f(x) \in A$. We will use some specific complete sets for these classes. Define, for each set A, the set $K(A)$ to be $\{\langle i, z, 1^j\rangle |$ the nondeterministic oracle TM N_i accepts z in j moves when A is used as the oracle$\}$. Then, it is obvious that $K(A)$ is complete for NP(A). Furthermore, for any string x, the question of whether $x \in K(A)$ depends only on the set $\{y \in A \mid |y| < |x|\}$, because $x = \langle i, z, 1^j\rangle$ implies $j < |x|$. (In other words, if B agrees with A on strings of length $< |x|$, then $x \in K(A)$ if and only if $x \in K(B)$.) We can extend this to $\Sigma_k^P(A)$-complete sets for $k > 1$. Let $K^1(A) = K(A)$ and $K^k(A) = K(K^{k-1}(A))$ for $k > 1$. Then, for each $k \geqq 1$ and each set A, $K^k(A)$ is complete for $\Sigma_k^{P,A}$, and the question of whether $x \in K^k(A)$ depends only on the set $\{y \in A \mid |y| < |x|\}$ (this can be proved by induction).

Define, for each set A, the set $Q(A)$ to be $\{\langle i, x, 1^j\rangle |$ the ith oracle machine M_i accepts x using at most j cells$\}$. Then $Q(A)$ is complete for the class PSPACE(A) and the question of whether $x \in Q(A)$ depends only on the set $\{y \in A \mid |y| < |x|\}$.

2.5. Circuits. We will deal with *circuits* of unbounded fanin which have only AND and OR gates and which have variables or its negations as inputs. We formally define a circuit as a tree. Each interior node of the tree is attached with an AND gate or an OR gate, and has an unlimited number of child nodes. Unless otherwise specified, it is assumed that the gates alternate so that all children of an OR (or AND) gate are AND (or OR, respectively) gates. Each leaf is attached with a constant 0, a constant 1, a variable v, or a negated variable $\bar{v}$. In this paper, we will relate circuits to oracle TMs. So, each variable in C is represented by a string $z \in \Sigma^*$. We write v_z to denote the variable, which will eventually be given the value $\chi_A(z)$ for some set A, and write $\overline{v_z}$ to denote its negation, which will eventually be given the value $1 - \chi_A(z)$. Each circuit computes a boolean function on its variables. The *depth* of a circuit is the length of the longest path in the tree. The *size* of a circuit is the number of gates (or, the number of interior nodes) in the tree. The *fanin* of a gate is the number of children of the node. The *bottom fanin* of a circuit is the maximum fanin of a gate of the lowest level in the tree.

Each circuit C has a dual circuit $\tilde{C}$ which has the same tree structure as C but computes the negation of the function computed by C. Formally, the dual circuit of a single variable v is its negation $\bar{v}$. The dual circuit $\tilde{C}$ of a circuit C of depth $\geqq 1$ and

with a top OR (AND) gate is the circuit with a top AND (OR, respectively) gate and its children being the dual circuits of the children of the top gate of C.

Let V be the set of variables which occur in a circuit C. Then a *restriction* ρ of C is a mapping from V to $\{0, 1, *\}$. For each restriction ρ of C, $C\lceil_\rho$ denotes the circuit C' obtained from C by replacing each variable v_x with $\rho(v_x)=0$ by 0 and each v_y with $\rho(v_y)=1$ by 1 (and each v_z with $\rho(v_z)=*$ remaning a variable). Assume that ρ' is a restriction of $C\lceil_\rho$. We write $C\lceil_{\rho\rho'}$ to denote $(C\lceil_\rho)\lceil_{\rho'}$. We also write $\rho\rho'$ to denote the combined restriction on C with values $\rho\rho'(v_x)=\rho(v_x)$ if $\rho(v_x)\neq *$ and with values $\rho\rho'(v_x)=\rho'(v_x)$ if $\rho(v_x)=*$. If a restriction ρ of C maps no variable to $*$, then we say ρ is an *assignment* of C. Let ρ be a restriction of C, we say that ρ *completely determines* C if $C\lceil_\rho$ computes a constant function 0 or 1. An assignment ρ of C always completely determines the circuit C.

There are some specific circuits that are useful in our proofs. A particularly interesting class of circuits has been used by Sipser [9], and later adopted by Hastad [5], to define the functions f_k^m. Our definition of function f_k^m is a little different from those defined in [5] and [9]. Let C_k^m be a depth-k circuit having the following properties:

(a) the top gate of C_k^m is an OR gate with fanin $\sqrt{m}$,

(b) the fanin of all bottom gates of C_k^m is $\sqrt{m}$,

(c) the fanin of all other gates is m, and

(d) there are m^{k-1} variables each of which occurs exactly once in a leaf in the positive form.

Let the function computed by C_k^m be f_k^m.

2.6. Circuits and relativized complexity classes. The following relation between the relativized polynomial time hierarchy and constant depth circuits is due to Furst, Saxe, and Sipser [4].

LEMMA 2.1 [4]. *Let $k\geqq 1$ and $q(n)$ and $r(n)$ be two polynomial functions. Let $\sigma(A; x)=(\exists y_1, |y_1|\leqq q(n))(\forall y_2, |y_2|\leqq q(n))\cdots(Q_k y_k, |y_k|\leqq q(n))R(A; x, y_1, \cdots, y_k)$ be a $\Sigma_k^{P,1}$-predicate, where $n=|x|$ and $R(A; x, y_1, \cdots, y_k)$ is computable in time $r(n)$ by a deterministic oracle* TM *M using oracle A. Then, for each string x, there exists a circuit C having the following properties*:

(a) *the depth of C is $k+1$,*

(b) *the fanin of each gate in C is $\leqq 2^{q(n)+r(n)}$,*

(c) *the bottom fanin of C is $\leqq r(n)$,*

(d) *the variables of C are represented by strings queried by M on input $(x, y_1, \cdots, y_k)$ for some $y_1, \cdots, y_k$ of length $\leqq q(n)$ and some oracle A, and*

(e) *for each set A, if we use $\chi_A(z)$ as the input value for each variable v_z in C then C outputs 1 if and only if $\sigma(A; x)$ is true.*

Sketch of Proof. The proof is done by induction on k. For the case $k=1$, let $\sigma(A; x)=(\exists y, |y|\leqq q(n))R(A; x, y)$, where R is computable by a deterministic oracle TM M in time $r(n)$. Then, for each y of length $\leqq q(n)$, consider the computation tree T of $M(x, y)$. Each path of T corresponds to a sequence of answers to queries made by M. For each accepting path in T, let U_1 be the set of strings answered positively by the oracle and U_0 the set of strings answered negatively by the oracle. Define an AND gate with $|U_0\cup U_1|$ many children, each attached with a variable v_z, with $z\in U_1$, or the negation $\overline{v_z}$ of a variable v_z, with $z\in U_0$. Then, the OR of all these AND gates is a circuit G_y (depending only on x and y) which computes $R(A; x, y)$ when each variable v_z in G_y is given the value $\chi_A(z)$. Note that each AND gate of the circuit G_y has $\leqq r(n)$ children. Now consider the circuit C which is the OR of all G_y's for y of length $\leqq q(n)$. We know that C computes $\sigma(A; x)$ when each variable v_z in C is given

value $\chi_A(z)$. Furthermore, combining all OR gates of G_y's into one, C can be written as a depth-2 circuit with top fanin $\leqq 2^{q(n)+r(n)}$ and bottom fanin $\leqq r(n)$.

For the inductive step, assume that

$$\sigma(A; x) = (\exists y_1, |y_1| \leqq q(n))(\forall y_2, |y_2| \leqq q(n)) \cdots (Q_k y_k, |y_k| \leqq q(n)) R(A; x, y_1, \cdots, y_k).$$

Then, for each y_1 of length $\leqq q(n)$ there is a depth-k circuit C_{y_1} satisfying the conditions (a)-(e) with respect to predicate

$$\tau(A; x, y_1) = (\exists y_2, |y_2| \leqq q(n)) \cdots (Q_{k-1} y_k, |y_k| \leqq q(n))[\text{not } R(A; x, y_1, \cdots, y_k)].$$

Take the dual circuits $\tilde{C}_{y_1}$ of C_{y_1} and let C be the OR of all these circuits. Then, C is the circuit we need. □

Another interesting relation between circuits and sets in relativized polynomial time hierarchies is about complete sets $K^k(A)$. The following lemma will not be used in § 3. The reader may wish to skip it until § 4.

LEMMA 2.2. *Let $k \geqq 1$. For every x of the form $\langle i, y, 1^j \rangle$, there is a circuit C such that*

(a) *the depth of C is $\leqq 2k$,*

(b) *the fanin of each gate is C is $\leqq 2^{|x|}$,*

(c) *the bottom fanin of C is $\leqq |x|$,*

(d) *the variables of C are v_z's over strings z of length $\leqq |x|$, and*

(e) *for each set A, if we use $\chi_A(z)$ as the input value for each variable v_z in C then C outputs 1 if and only if $x \in K^k(A)$.*

Proof. We prove the lemma by induction on k. First, let $k = 1$. Then, $x = \langle i, y, 1^j \rangle \in K(A)$ if and only if the machine N_i accepts y in $\leqq j$ moves using A as an oracle. That is, $x \in K(A)$ if and only if $(\exists w, |w| \leqq j) R(A; y, w)$ for some P^1-predicate R which is computable in time $\leqq j - |w|$ (without loss of generality, we may assume that N_i is a specific machine which first uses $|w|$ moves to generate the witness string w and then uses $\leqq j - |w|$ moves to compute R). By Lemma 2.1, there is a depth-2 circuit C such that its top gate has fanin $\leqq 2^j \leqq 2^{|x|}$, its bottom fanin is $\leqq j \leqq |x|$, the variables in C are represented by strings of length $\leqq j \leqq |x|$, and for each set A, if we use $\chi_A(z)$ as the input value for each variable v_z in C then C outputs 1 if and only if $x \in K(A)$.

Assume that $k > 1$. Let $x = \langle i, y, 1^j \rangle$ be given. Then, $x \in K^k(A)$ if and only if the machine N_i accepts y in $\leqq j$ moves using $K^{k-1}(A)$ as an oracle. As in the case $k = 1$, there is a depth-2 circuit C_1 such that its top gate has fanin $\leqq 2^j \leqq 2^{|x|}$, its bottom fanin is $\leqq j \leqq |x|$, its variables are represented by strings of length $\leqq |x|$, and for each set A, if we use $\chi_{K^{k-1}(A)}(z)$ as the input value for each variable v_z in C_1 then C_1 outputs 1 if and only if $x \in K^k(A)$.

Now, by the inductive hypothesis, for each string z of the form $\langle i_1, u, 1^{j_1} \rangle$ such that variable v_z occurs in C_1, there is a circuit C_z of depth $2(k-1)$ such that

(a) the fanin of each gate of C_z is $\leqq 2^{|z|}$,

(b) the bottom fanin of C_z is $\leqq |z|$,

(c) the variables in C_z are represented by strings of length $\leqq |z|$, and

(d) for any set A, if we use $\chi_A(w)$ as the input value for each variable v_w in C_z, then C_z outputs 1 if and only if $z \in K^{k-1}(A)$.

For each variable v_z in C_1 such that z is not of such a form, let C_z be the constant 0 (because $z \notin K^{k-1}(A)$). Replace each variable v_z in C_1 by the circuit C_z (i.e., each leaf with the variable v_z is replaced by the tree C_z, and each leaf with the negated variable $\overline{v_z}$ is replaced by the dual circuit $\tilde{C}_z$ of C_z). Since strings z corresponding to variables v_z in C_1 have length $|z| \leqq |x|$, we obtain a circuit C of depth $2k$ such that the fanin of each gate of C is $\leqq 2^{|x|}$, the bottom fanin of C is $\leqq |x|$, and the variables in C are

represented by strings of length $\leqq|x|$. (It should be pointed out that in circuit C, a child of an AND gate is not necessarily an OR gate. If we combine all adjacent AND gates and OR gates, then the resulting circuit may have fanin $\leqq|x|\cdot 2^{|x|}$.)

Finally, for any set A, if we use $\chi_A(w)$ as the input value for each variable v_w in C, then for each variable v_z in C_1, the circuit C_z outputs 1 if and only if $z\in K^{k-1}(A)$; therefore, the circuit C outputs 1 if and only if $x\in K^k(A)$. This completes the proof. □

3. Relativized hierarchy having exactly k levels. In this section we prove that for each $k\geqq 1$, there exists an oracle A such that $\Sigma_k^P(A)=\Pi_k^P(A)\neq\Sigma_{k-1}^P(A)$. We need a lower bound result on constant depth circuits. Hastad [5] has proved that there exists a function f_k^m computable by a polynomial-size depth-k circuit but not by any depth-k circuit with small bottom fanin. The following lemma is a stronger form of this result. It states that no depth-k circuit with small bottom fanin can compute any of an exponential number of f_k^m functions. The main idea of the proof is the same as that of Hastad's proof. We give the formal proof in the Appendix.

Recall that C_k^m is a circuit defining the function f_k^m. Let $\mathrm{CIR}(k, t)$ be the class of depth-k circuits which have size $\leqq 2^t$ and bottom fanin $\leqq t$.

LEMMA 3.1. *For every $k\geqq 2$ there exists a constant n_k such that the following holds for all $n>n_k$. Let $t=n^{\log n}$, $m<2^t$, and $C_0, C_1, \cdots, C_m$ be $m+1$ circuits each defining a $f_k^{2^n}$ function, with their variables pairwisely disjoint. Let C be a circuit in $\mathrm{CIR}(k, t)$. Then, there exists a restriction ρ on C such that ρ completely determines C but it does not completely determine any C_i, $0\leqq i\leqq m$.*

THEOREM 3.2. *For each $k\geqq 1$, there exists a set A such that $\Sigma_k^P(A)=\Pi_k^P(A)\neq\Sigma_{k-1}^P(A)$.*

Proof. The case $k=1$ has been proven by Baker, Gill, and Solovay [2]. We assume that $k\geqq 2$. (Actually, the case $k=2$ has been proven by Baker and Selman [3] and Heller [7].)

Recall that $\{p_i\}$ is an enumeration of polynomial functions, $\{M_i\}$ is an enumeration of all polynomial time deterministic oracle TMs, and $\{\sigma_i^{k-1}\}$ is an enumeration of all $\Sigma_{k-1}^{P,1}$-predicates which are of the form

$$\sigma_i^{k-1}(A; x)=(\exists y_1, |y_1|\leqq q(n))(\forall y_2, |y_2|\leqq q(n))\cdots (Q_{k-1}y_{k-1}, |y_{k-1}|\leqq q(n))R(A; x, y_1, \cdots, y_{k-1}),$$

where $n=|x|$, $q(n)\leqq p_i(n)$, and $R(A; x, y_1, \cdots, y_{k-1})$ is computable in time $p_i(n)$ by some deterministic oracle machine M. Also recall that $K^k(A)$ is a complete set for $\Sigma_k^P(A)$ which has the property that the question of whether $x\in K^k(A)$ depends only on the set $\{y\in A\,|\,|y|<|x|\}$. Let

$$L_k(A)=\{1^n\,|\,(\exists z_1, |z_1|=n)(\forall z_2, |z_2|=n)\cdots(Q_kz_k, |z_k|=n)1^nz_1z_2\cdots z_k\in A\}.$$

Note that $L_k(A)$ is in $\Sigma_k^P(A)$.

The construction of the oracle A will be done by stages. At each stage $\alpha=(k+1)n+1$, we will satisfy the requirement

$R_{0,n}$: for all strings u of length n, $u\notin K^k(A)$
$\Leftrightarrow(\exists z_1, |z_1|=n)(\forall z_2, |z_2|=n)\cdots(Q_kz_k, |z_k|=n)0uz_1z_2\cdots z_k\in A.$

At stage $\alpha=(k+1)n$, we will try to satisfy the following requirement $R_{1,i}$ with the least integer i for which $R_{1,i}$ is not yet satisfied:

$R_{1,i}$: there exists an n_i such that $1^{n_i}\in L_k(A)$ if and only if $\sigma_i^{k-1}(A; 1^{n_i})$ is false.

The requirement $R_0=\Lambda_{n=1}^{\infty}R_{0,n}$ states that $K^k(A)$ is in $\Pi_k^P(A)$, and hence $\Sigma_k^P(A)=$

$\Pi_k^P(A)$. The requirement $R_1 = \Lambda_{i=1}^{\infty} R_{1,i}$ states that $L_k(A)$ is not in $\Sigma_{k-1}^P(A)$. Therefore a set A satisfying all requirements has the property $\Sigma_k^P(A) = \Pi_k^P(A) \neq \Sigma_{k-1}^P(A)$.

The main difficulty of the construction is that when we try to satisfy requirement $R_{1,i}$ in stage $\alpha = (k+1)n$, we may have to simulate some oracle machine M which may query about strings of length longer than α. We cannot arbitrarily assign answers to the queries made by M because such an assignment may conflict with requirement $R_{0,m}$ for some $m > n$. What we need is an assignment of answers to queries which does not conflict with future constructions at stage $\alpha' > \alpha$. The existence of such an assignment will be proved by using Lemma 3.1.

In each stage α, we will determine an initial segment of set A by putting some strings into set A and some into $\bar{A}$. We let $A(\alpha)$ denote the set of strings reserved for A by stage α and $A'(\alpha)$ denote the set of strings reserved for $\bar{A}$ by stage α. Sets $A(\alpha)$ and $A'(\alpha)$ are defined so that $A(\alpha)$ is always an extension of $A(\alpha-1)$, $A'(\alpha)$ is always an extension of $A'(\alpha-1)$, and $A(\alpha) \cap A'(\alpha) = \emptyset$. Also, in stage α we do not add any string of length $< \alpha$ to $A(\alpha)$ or $A'(\alpha)$. Eventually, we will define set A to be the union of all $A(\alpha)$. That is, a string x is in $\bar{A}$ either if it is put in $A'(\alpha)$ at some stage α or if it has never been touched in the construction.

In the construction, we keep track of all integers i for which the corresponding requirement $R_{1,i}$ has been satisfied. We let all integers i for which $R_{1,i}$ is not yet satisfied be *uncancelled.* If the requirement $R_{1,i}$ is satisfied in stage α, then we *cancel* this integer i at this stage. To avoid the potential interference between requirements $R_{1,i}$ and $R_{1,j}$ for $i \neq j$, we set a pointer β_α in each stage α. The integer β_α is defined to be an upper bound of the maximum length of strings added to $A(m)$ or $A'(m)$ in stages $m \leqq \alpha$. When $\alpha > \beta_{\alpha-1}$, the construction in stage α can be done without interfering with the constructions made in earlier stages.

Prior to stage 1, assume that $A(0) = A'(0) = \emptyset$, and let $\beta_0 = 1$. Let all integers i be uncancelled.

Stage α, where α does not have the form $\alpha = (k+1)n+1$ or $\alpha = (k+1)n$. Do nothing. Let $A(\alpha) := A(\alpha-1)$, $A'(\alpha) := A'(\alpha-1)$ and $\beta_\alpha := \beta_{\alpha-1}$.

Stage $\alpha = (k+1)n$. Let i be the least integer that is not yet cancelled. If $\alpha \leqq \beta_{\alpha-1}$ or $n \leqq n_k$ (n_k is the constant defined in Lemma 3.1) or $2kp_i(n) \geqq t = n^{\log n}$, then do nothing. Let $A(\alpha) := A(\alpha-1)$, $A'(\alpha) := A'(\alpha-1)$, and $\beta_\alpha := \beta_{\alpha-1}$.

If $\alpha > \beta_{\alpha-1}$ and $n > n_k$ and $2kp_i(n) < t = n^{\log n}$, then consider the following circuits:

(1) For each u of length $n \leqq |u| \leqq p_i(n)$, the circuit C_u of depth k is defined as follows:

(a) the top gate of C_u is an OR gate,

(b) the fanin of each gate of C_u is $2^{|u|}$,

(c) the variables of C_u are exactly those in $\{v_y \mid y \in 0u\Sigma^{k|u|}\}$; each occurred positively in exactly one leaf of C_u in the increasing order (under the lexicographic order on y).

There are totally $\leqq 2^{p_i(n)} < 2^t$ many such circuits C_u. Note that each circuit C_u has the property that for all sets A, if we use $\chi_A(y)$ as the input value for each variable v_y then C_u outputs 1 if and only if

$$(\exists z_1, |z_1| = |u|)(\forall z_2, |z_2| = |u|) \cdots (Q_k z_k, |z_k| = |u|) 0u z_1 z_2 \cdots z_k \in A.$$

Also note that each circuit C_u contains a subcircuit computing a function $f_k^{2^n}$.

(2) The circuit C_0 has the same tree structure as the circuit C_u defined above, with $|u| = n$, except that the variables of C_0 are those in $\{v_y \mid y \in 1^n\Sigma^{kn}\}$. Note that if we use $\chi_A(y)$ as the input value for each variable v_y then C_0 outputs 1 if and only if $1^n \in L_k(A)$.

(3) The circuit C is the circuit associated with the $\Sigma_{k-1}^{P,1}$-predicate $\sigma_i^{k-1}(A; 1^n)$ as defined in Lemma 2.1, with the restriction that each variable v_y with $|y| < \alpha = (k+1)n$ is replaced by the constant value $\chi_{A(\alpha-1)}(y)$. In particular, C has depth k, has size $\leqq 2^{2kp_i(n)}$, and has the bottom fanin $\leqq p_i(n)$. The variables in C are represented by strings of length $\leqq p_i(n)$. For each set A which agrees with $A(\alpha-1)$ on strings of length $<\alpha$, if we use $\chi_A(y)$ as the input value for each variable v_y then C outputs 1 if and only if $\sigma_i^{k-1}(A; 1^n)$ is true.

It is easy to see that each circuit C_u or C_0 contains a subcircuit C'_u or C'_0, respectively, which defines a $f_k^{2^n}$ function. Choose a restriction ρ such that for each u, $C'_u = C_u\lceil_\rho$ computes exactly a $f_k^{2^n}$ function and $C'_0 = C_0\lceil_\rho$ computes exactly a $f_k^{2^n}$ function. We observe that by the choice of n such that $2kp_i(n) < t = n^{\log n}$, $C \in \mathrm{CIR}(k, t)$. So, $C' = C\lceil_\rho$ is also in $\mathrm{CIR}(k, t)$. Furthermore, the number of circuits C'_u is $<2^t$. Thus, we can apply Lemma 3.1 to the circuits C'_0 and C'_u, $n \leqq |u| \leqq p_i(n)$, and the circuit C' to obtain a restriction ρ' of C' such that ρ' completely determines the circuit C' but not circuit C'_0 nor any circuit C'_u, $n \leqq |u| \leqq p_i(n)$. Finally, we find an assignment ρ'' of variables of $C'_0\lceil_{\rho'}$ such that $C'_0\lceil_{\rho'\rho''}$ computes a constant function 1 if and only if $C'\lceil_{\rho'}$ computes a constant function 0. Note that ρ'' only assigns values to variables corresponding to strings in $1^n\Sigma^{kn}$, and so none of $C'_u\lceil_{\rho'}$ is completely determined by ρ''.

Define $A(\alpha) := A(\alpha-1) \cup \{y \mid \rho\rho'\rho''(v_y) = 1\}$ and $A'(\alpha) := A'(\alpha-1) \cup \{y \mid \rho\rho'\rho''(v_y) = 0\}$. Let $\beta_\alpha = \max\{\alpha, p_i(n)+1\}$ and cancel i. This completes stage $\alpha = (k+1)n$.

Stage $\alpha = (k+1)n+1$. For each u of length n, we determine whether $u \in K^k(A(\alpha-1))$. Then, we find a subset $B \subseteq \{y \in 0u\Sigma^{kn} \mid y \notin A(\alpha-1) \cup A'(\alpha-1)\}$ such that $u \notin K^k(A(\alpha-1)) \Leftrightarrow (\exists z_1, |z_1| = n)(\forall z_2, |z_2| = n) \cdots (Q_k z_k, |z_k| = n) 0uz_1z_2 \cdots z_k \in A(\alpha-1) \cup B$. (We will show that such a set B always exists.) Let $A(\alpha) = A(\alpha-1) \cup B$ and $A'(\alpha) = A'(\alpha-1)$. Let $\beta_\alpha = \max\{\alpha, \beta_{\alpha-1}\}$. Stage $\alpha = (k+1)n+1$ is complete when we finish the above construction for each u of length n.

Let $A = \bigcup_{\alpha=1}^{\infty} A(\alpha)$. First, we claim that in each stage $\alpha = (k+1)n+1$; for each u of length n, the set B can be found.

Proof of claim. If none of strings in $0u\Sigma^{kn}$ has been assigned to $A(\alpha-1)$ or $A'(\alpha-1)$, then certainly such a set B exists. Assume that some strings in $0u\Sigma^{kn}$ have been assigned to $A(\alpha-1)$ or $A'(\alpha-1)$. Then, by the choice of β_α, there is at most one stage $\alpha' = (k+1)m < \alpha$ in which these assignments are made.

In that stage, the assignments are made such that the corresponding circuit C_u, after applying the restriction $\rho\rho'\rho''$, is not completely determined. Note that the circuit C_u and the predicate

$$\tau(A; u) = (\exists z_1, |z_1| = n)(\forall z_2, |z_2| = n) \cdots (Q_k z_k, |z_k| = n) 0uz_1z_2 \cdots z_k \in A$$

has the relation that when assigning value $\chi_A(y)$ to each variable v_y, circuit C_u outputs 1 if and only if the predicate $\tau(A; u)$ is true. The fact that the restriction $\rho\rho'\rho''$ does not completely determine C_u implies that there exist assignments ρ_0 and ρ_1 such that $C_u\lceil_{\rho\rho'\rho''\rho_0}$ outputs 0 and $C_u\lceil_{\rho\rho'\rho''\rho_1}$ outputs 1. Let $B_0 = \{y \in 0u\Sigma^{kn} \mid \rho\rho'\rho''(v_y) = *,\ \rho_0(v_y) = 1\}$ and $B_1 = \{y \in 0u\Sigma^{kn} \mid \rho\rho'\rho''(v_y) = *,\ \rho_1(v_y) = 1\}$. Then, B_0 and B_1 are disjoint from $A(\alpha-1)$ and $A'(\alpha-1)$ and $\tau(A(\alpha-1) \cup B_0; 1^n) = 0$ and $\tau(A(\alpha-1) \cup B_1; 1^n) = 1$. This proves the claim. □

Next we observe that after stage α, we never add any string of length $\leqq \alpha$ to $A(\alpha)$ or $A'(\alpha)$. From this observation and the fact that the question of $x \in K^k(A)$ does not depend on the strings of length $\geqq |x|$, we see that each stage $\alpha = (k+1)n+1$ satisfies requirement $R_{0,n}$.

Finally, for each i, we observe that eventually we will cancel it in some stage $\alpha=(k+1)n$, since the inequality $2kp_i(n)<t=n^{\log n}$ holds for almost all n. In that stage, we add strings to $A(\alpha)$ or $A'(\alpha)$ (by $\rho\rho'\rho''$) so that when we use $\chi_A(y)$ as the input value for each variable v_y, the circuits C and C_0 are completely determined and circuit C outputs 1 if and only if circuit C_0 outputs 0. By the relation between circuit C and predicate $\sigma_i^{k-1}(A;1^n)$ and the relation between circuit C_0 and the predicate $1^n\in L_k(A)$, we know that $\sigma_i^{k-1}(A;1^n)$ is true if and only if $1^n\notin L_k(A)$. This shows that the requirement $R_{1,i}$ is satisfied by A and $n_i=n$. This completes the proof of Theorem 3.2. □

The above proof can easily be modified to construct an oracle A such that $\mathrm{PSPACE}(A)=\Sigma_k^P(A)\neq\Sigma_{k-1}^P(A)$.

COROLLARY 3.3. *For each $k\geqq 1$, there exists a set A such that* $\mathrm{PSPACE}(A)=\Sigma_k^P(A)\neq\Sigma_{k-1}^P(A)$.

Proof. First consider the cases when $k>1$. The proof is similar to that of Theorem 3.2. All we need to do is to replace the set $K^k(A)$ by the set $Q(A)$, which is $\leqq_m^P$-complete for $\mathrm{PSPACE}(A)$. Furthermore, note that $Q(A)$ has the same property as $K^k(A)$: for any x, the question of whether $x\in Q(A)$ depends only on the set $\{y\in A\,||y|<|x|\}$.

The case $k=1$ can be similarly proved. Baker, Gill, and Solovay [2] have shown that there exists a set A such that $\mathrm{NP}(A)=co\text{-}\mathrm{NP}(A)\neq\mathrm{P}(A)$. To extend it to $\mathrm{PSPACE}(A)=\mathrm{NP}(A)\neq\mathrm{P}(A)$, all we need to do is to replace the set $K(A)$ used in that proof by $Q(A)$. We omit the details. □

4. Relativized hierarchies and PSPACE. In this section, we show that for each $k\geqq 1$, there exists an oracle A such that $\Sigma_k^P(A)=\Pi_k^P(A)\neq\Sigma_{k-1}^P(A)$ and also $\mathrm{PSPACE}(A)\neq\mathrm{PH}(A)$. The proof also uses the lower-bound results on constant depth circuits developed by Yao [12] and Hastad [5]. The following lemma is from [5]. We say a circuit C *computes the parity* of n inputs if C has n variables and for all inputs to those varibables, C outputs 1 if and only if the number of 1's in the input is odd.

LEMMA 4.1 [5]. *There exist an integer n_0' and a real number $\varepsilon>0$ such that for any $k>0$ and any $n>(n_0')^k$, no depth-k circuit C of $\leqq 2^{\varepsilon n^{1/(k-1)}}$ gates can compute the parity of n inputs.*

COROLLARY 4.2. *For any constant c, there is an n_c' such that for all $n>n_c'$, no depth-k, $k=c\log\log n$, circuit C of $\leqq 2^{\varepsilon n^{1/(k-1)}}$ gates can compute the parity of n inputs.*

Proof. Let n_c' be the smallest integer m such that $m>(n_0')^{c\log\log m}$, where n_0' is the absolute constant of Lemma 4.1. □

We first consider the simplest case that the relativized polynomial time hierarchy collapses to the class $\mathrm{P}(A)$.

THEOREM 4.3. *There exists a set A such that* $\mathrm{PSPACE}(A)\neq\mathrm{NP}(A)=\mathrm{P}(A)$.

Proof. Recall that $\{N_i\}$ is an enumeration of all polynomial time nondeterministic oracle TMs, and the machine N_i has its runtime bounded by polynomial p_i. Without loss of generality, we assume that $p_i(n)\leqq n^i$. Recall that $K(A)$ is a set $\leqq_m^P$-complete for $\mathrm{NP}(A)$ such that the question of $x\in K(A)$ depends only on the set $\{y\in A\,||y|\leqq|x|\}$. Let $L_{\mathrm{odd}}(A)=\{1^n\,|$ the number of strings of length n which are in A is odd$\}$. Note that $L_{\mathrm{odd}}(A)$ is in $\mathrm{PSPACE}(A)$.

The construction of A is done by stages. At stage $n=2t$, we want to satisfy the requirement

$R_{0,t}$: for each u of length t, $u\in K(A)$ if and only if $0'u\in A$.

At stage $n=2t+1$, we will try to satisfy the following requirement $R_{1,i}$ with the least integer i for which $R_{1,i}$ is not yet satisfied:

$R_{1,i}$: there exists an m_i such that $1^{m_i}\in L_{\mathrm{odd}}(A)$ if and only if N_i rejects 1^{m_i}.

The requirement $R_0 = \bigwedge_{t=1}^{\infty} R_{0,t}$ states that $K(A)$ is in $\mathrm{P}(A)$, and hence $\mathrm{NP}(A) = \mathrm{P}(A)$. The requirement $R_1 = \bigwedge_{i=1}^{\infty} R_{1,i}$ states that $L_{\mathrm{odd}}(A)$ is not in $\mathrm{NP}(A)$. Therefore a set A satisfying all requirements has the property $\mathrm{PSPACE}(A) \neq \mathrm{NP}(A) = \mathrm{P}(A)$.

In each stage n, we will define, in terms similar to the ones used in the proof of Theorem 3.2, two sets $A(n)$ and $A'(n)$ and an integer β_n. Sets $A(n)$ and $A'(n)$ contain strings reserved by stage n for sets A and $\bar{A}$, respectively. The integer β_n is defined to be an upper bound of the maximum length of the strings added to $A(m)$ or $A'(m)$ in stages $m \leqq n$.

Prior to stage 1, assume that $A(0) = A'(0) = \emptyset$, and let $\beta_0 = 2$. Let all integers i be uncancelled.

Stage $n = 2t$, $t > 0$. We will satisfy requirement $R_{0,t}$. For each string u of length t, we determine whether $u \in K(A(n-1))$. Then, we let $A(n) = A(n-1) \cup \{0^t u\}$ and $A'(n) = A'(n-1)$ if $u \in K(A(n-1))$; and $A(n) = A(n-1)$ and $A'(n) = A'(n-1) \cup \{0^t u\}$ if $u \notin K(A(n-1))$. After this is done for all u of length t, let $\beta_n = \max\{n, \beta_{n-1}\}$.

Stage $n = 2t+1$. Let i be the least integer which has not been cancelled. Let $m = 2i \log n$. If $n \leqq \beta_{n-1}$ or $2^n \leqq n'_{2i}$ or $\varepsilon 2^{n/(m-1)} \leqq 2(m+1)p_i(n)$ (where n'_{2i} is the constant defined in Corollary 4.2), then do nothing. Let $A(n) = A(n-1)$, $A'(n) = A'(n-1)$, and $\beta_n = \beta_{n-1}$.

If $n > \beta_{n-1}$ and $2^n > n'_{2i}$ and $\varepsilon 2^{n/(m-1)} > 2(m+1)p_i(n)$, then consider the machine N_i on input 1^n. From Lemma 2.1, we know that for machine N_i and input 1^n, there is a circuit C of depth 2 such that

(a) the top gate of C is an OR gate with fanin $\leqq 2^{2p_i(n)}$,

(b) the bottom fanin of C is $\leqq p_i(n)$,

(c) the variables in C are those corresponding to strings queried by N_i on input x under some oracle A, and

(d) for each set A, if we use $\chi_A(y)$ as the input value for each variable v_y then C outputs 1 if and only if N_i^A accepts 1^n.

We are going to modify this circuit to a new circuit C' having the following properties. During the modification of C to C', we also define a set B.

(a′) C' has depth $\leqq m = 2i \log n$.

(b′) The number of gates in C' is $\leqq 2^{2(m+1)p_i(n)}$.

(c′) The variables of C' are represented by strings of length n.

(Circuit C' and set B also have nice properties related to the computation of $N_i(1^n)$ and set $L_{\mathrm{odd}}(A)$. We will prove them later.)

Recall that $m = 2i \log n$. The modification of the circuit C is done in $m/2$ steps. Let $C_1 = C$. In each step $j \leqq m/2 - 1$, assume that a circuit C_j is given. For each variable v_y in C_j such that $|y| > n$ and $y = 0^{|u|}u$ for some u, we do the following.

By Lemma 2.2, there is a depth-2 circuit C'_y such that

(a″) the top fanin of C'_y is $\leqq 2^{|u|}$,

(b″) the bottom fanin of C'_y is $\leqq |u|$,

(c″) the variables in C'_y are represented by strings of length $\leqq |u|$, and

(d″) for any set A, if we use $\chi_A(z)$ as the input value for each variable v_z in C'_y then C'_y outputs 1 if and only if $u \in K(A)$.

Replace v_y by the circuit C'_y. (That is, the leaf node of C_j with variable v_y is replaced by the tree C'_y, and the leaf node with the negation $\overline{v_y}$ of variable v_y is replaced by the tree of the dual circuit $\tilde{C}'_y$ of C'_y.) Let C_{j+1} be the new circuit with all such variables v_y in C_j replaced by circuit C'_y.

Assume that a variable v_y is C_j with $y = 0^{|u|}u$ is replaced by C'_y. Then, by Lemma 2.2, each variable v_w in circuit C'_y corresponds to a string w of length $|w| \leqq |u| = |y|/2$.

Note that all strings y such that $v_y \in C_1 = C$ have length $\leqq p_i(n) \leqq n^i$. So, after $\log(p_i(n)) - 1 \leqq i \log n - 1 = m/2 - 1$ steps, none of the variables v_y in $C_{m/2}$ corresponds to a string y of length $|y| > n$ and of the form $0^{|u|}u$ for some u.

In step $m/2$, we replace each variable v_y in $C_{m/2}$ such that $|y| < n$ by the constant $\chi_{A(n-1)}(y)$, and replace each variable v_y in $C_{m/2}$ such that $|y| > n$ by a constant 0 (note that none of these y such that $|y| > n$ is of the form $0^{|u|}u$). Also, each $\overline{v_y}$ is replaced by the opposite value. Let C' be the resulting circuit, and let $B = \{y \,|\, |y| > n, v_y \text{ occurs in } C_{m/2}\}$.

We verify that the final circuit C' satisfies the properties (a')-(c') listed above. First, in each step $j \leqq m/2 - 1$, we replaced some variables in C_j by depth-2 circuits. So, C_{j+1} has depth 2 plus the depth of C_j. Thus, $C_{m/2}$ has depth at most m. Since we only replaced variables in $C_{m/2}$ by constants, the final circuit C' also has depth at most m.

Next, to check (b') we note that every gate in C has fanin $\leqq 2^{2p_i(n)}$. Furthermore, by Lemma 2.2, every gate in circuit C'_y has the same bound for its fanin. Therefore, without combining adjacent gates of the same type, each gate of C' has fanin $\leqq 2^{2p_i(n)}$. That is, the total number of gates in C' is at most $(2^{2p_i(n)})^{m+1} = 2^{2(m+1)p_i(n)}$.

For condition (c'), we note that all variables v_y such that $|y| \neq n$ are replaced by constants or other circuits. So, the only variables left in C' are those v_y with $|y| = n$.

Now from the inequality $\varepsilon 2^{n/(m-1)} > 2(m+1)p_i(n)$, we can apply Corollary 4.2 to circuit C' and conclude that C' does not compute the parity of the 2^n variables v_x, with $x \in \Sigma^n$. So, we can find a set $D \subseteq \Sigma^n$ such that $1^n \in L_{\text{odd}}(D)$ if and only if C' outputs 0 when variables v_z are given values $\chi_D(z)$.

Define $A(n) = A(n-1) \cup D$, $A'(n) = A'(n-1) \cup B$, $\beta_n = \max\{n, p_i(n)+1\}$, and cancel i. Stage $n = 2t+1$ is complete.

Let $A = \bigcup_{n=1}^{\infty} A(n)$. We need to verify that A satisfies every requirement $R_{0,t}$, $t > 0$, and $R_{1,i}$, $i > 0$. For requirement $R_{0,t}$, $t > 0$, we note that in Stage $n = 2t$, we have assigned all strings $0^t u$, $|u| = t$, to $A(n)$ or $A'(n)$ such that $u \in K(A(n-1)) \Leftrightarrow 0^t u \in A(n)$. Since A agrees with $A(n-1)$ on strings of length $< n$, we have $u \in K(A(n-1)) \Leftrightarrow u \in K(A)$. Furthermore, once a string $0^t u$ is added to $A(n)$ or $A'(n)$, its membership in A is never changed in later stages. So, $0^t u \in A(n) \Leftrightarrow 0^t u \in A$. The only thing left to check is that in earlier stages $n' < n$, no string of the form $0^t u$, with $|u| = t$, has been put in $A(n')$ or $A'(n')$. This is true because in an even stage $n' = 2t'$ we never add any string of length longer than n' to $A(n')$ or $A'(n')$, and in an odd stage $n' = 2t'+1$ we only add strings of length n', or strings which are not of the form $0^{|u|}u$ to $A(n')$ or $A'(n')$ (note that none of the strings in B is of the form $0^{|u|}u$).

To verify requirement $R_{1,i}$, we note that the inequality $\varepsilon 2^{n/(m-1)} > 2(m+1)p_i(n)$ is satisfied by almost all integers n. Therefore, each integer i will eventually be cancelled. Assume that i is cancelled in stage $n = 2t+1$. We want to show that $1^n \in L_{\text{odd}}(A)$ if and only if N_i^A rejects 1^n. To show this, we claim that circuit C' constructed in stage n satisfies the following property.

(d') When we use $\chi_A(w)$ as the input value for each variable v_w in C', C' outputs 1 if and only if N_i^A accepts 1^n. (Note that the set A here is the fixed set defined by $A = \bigcup_{n=0}^{\infty} A(n)$ which satisfies requirements $R_{0,t}$ for all $t > 0$.)

In fact, property (d') is satisfied by all circuits C_j, $1 \leqq j \leqq m/2$, constructed in Stage n. We prove it by induction. First, for $j = 1$, we observe that this claim is exactly the property (d) of circuit C.

Now, assume that property (d') is satisfied by C_j, for some $j \leqq m/2 - 1$. To obtain C_{j+1}, assume that some circuit C'_y has replaced a variable v_y in C_j with $y = 0^{|u|}u$. Then, by Lemma 2.2, if we use $\chi_A(z)$ as input value for each variable v_z in C'_y, then C'_y

outputs 1 if and only if $u \in K(A)$. Since A satisfies the property $R_{0,|u|}$ that $u \in K(A)$ if and only if $0^{|u|}u \in A$, C'_y outputs exactly the value $\chi_A(y)$. This means that C_{j+1} outputs the same value as C_j. So, the induction proof is complete.

Finally, in step $m/2$, we replaced all variables v_y by 1 if $y \in A(n-1)$, all variables v_y by 0 if $[|y| \leqq n-1$ and $y \notin A(n-1)]$ or $y \in B$. Since A agrees with these assignments, circuit C' outputs the same value as $C_{m/2}$. This completes the proof of property (d').

Now, observe that, in stage n, the set D is chosen such that $1^n \in L_{\text{odd}}(D)$ if and only if C' outputs 0 when each variable v_z is given the input value $\chi_D(z)$. Since we have added set D to A, the following holds when each variable v_z in C' is given the input value $\chi_A(z)$:

$$1^n \in L_{\text{odd}}(A) \Leftrightarrow 1^n \in L_{\text{odd}}(D) \Leftrightarrow C' \text{ outputs } 0 \Leftrightarrow N_i^A \text{ rejects } 1^n.$$

Thus requirement $R_{1,i}$ is satisfied when i is cancelled. This completes the proof of Theorem 4.3. □

Now we extend Theorem 4.3 to more general cases.

THEOREM 4.4. *For each $k > 0$, there exists a set A such that* PSPACE $(A) \neq \Sigma_k^P(A) = \Pi_k^P(A) \neq \Sigma_{k-1}^P(A)$.

Proof. First, assume that $k > 1$. The proof is a combination of the constructions in the proofs of Theorems 3.2 and 4.3. We only give an outline of the proof. We will construct a set A to satisfy three sets of requirements:

$R_{0,n}$: for all strings u of length n, $u \notin K^k(A) \Leftrightarrow (\exists z_1, |z_1| = n)$

$$(\forall z_2, |z_2| = n) \cdots (Q_k z_k, |z_k| = n) 0 u z_1 z_2 \cdots z_k \in A.$$

$R_{1,i}$: there exists an n_i such that $1^{n_i} \in L_k(A)$ if and only if the ith $\Sigma_{k-1}^{P,1}$-predicate $\sigma_i^{k-1}(A; 1^{n_i})$ is false.

$R_{2,j}$: there exists an m_j such that $1^{m_j} \in L_{\text{odd}}(A)$ if and only if the jth $\Sigma_k^{P,1}$-predicate $\sigma_j^k(A; 1^{m_j})$ is false.

As we argued before, the requirement $R_0 = \bigwedge_{n=1}^{\infty} R_{0,n}$ implies $\Sigma_k^P(A) = \Pi_k^P(A)$ and the requirement $R_1 = \bigwedge_{i=1}^{\infty} R_{1,i}$ implies that $\Sigma_k^P(A) \neq \Sigma_{k-1}^P(A)$. Furthermore, the requirement $R_2 = \bigwedge_{j=1}^{\infty} R_{2,j}$ implies that $L_{\text{odd}}(A) \notin \Sigma_k^P(A)$ and hence PSPACE $(A) \neq \Sigma_k^P(A)$.

In each stage α, we will define, in terms similar to the ones used in the proof of Theorem 3.2, two sets $A(\alpha)$ and $A'(\alpha)$ and an integer β_α. Sets $A(\alpha)$ and $A'(\alpha)$ contain strings reserved by stage α for sets A and $\bar{A}$, respectively. The integer β_α is defined to be an upper bound of the maximum length of the strings added to $A(m)$ or $A'(m)$ in stages $m \leqq \alpha$.

In our construction, we will consider three types of stages. At stage $\alpha = (k+1)n$, we try to satisfy requirement $R_{1,i}$ for the integer i such that $2i$ is the least uncancelled integer. (If the least uncancelled integer is an odd integer, then do nothing.) Assume that $2i$ is the least uncancelled integer and α is sufficiently large (so that $\alpha > \beta_{\alpha-1}$, $n > n_k$, and $2kp_i(n) < n^{\log n}$). Then, we satisfy $R_{1,i}$, with $n_i = n$, by doing almost the same thing as in stage α of the construction in the proof of Theorem 3.2; the only difference is that at the end of the stage we turn on a flag: $F =$ **true**, and cancel the integer $2i$ (instead of i).

At stage $\alpha = (k+1)n+2$, we try to satisfy requirement $R_{2,j}$ for the integer j such that $2j+1$ is the least uncancelled integer. The action in this stage is similar to the construction in an odd stage of the proof of Theorem 4.3.

More precisely, when α is sufficiently large (so that $\alpha > \beta_{\alpha-1}$, $2^\alpha > n'_{2kj}$ and $\varepsilon 2^{\alpha/(m-1)} > 2(m+1)p_j(\alpha)$, where $m = 2k \log p_j(\alpha)$), we consider the jth $\Sigma_k^{P,1}$-predicate $\sigma_j^k(A; 1^\alpha)$. By Lemma 2.1, there is a circuit C associated with $\sigma_j^k(A; 1^\alpha)$ having the following properties:

(a) the depth of C is $\leqq k+1$,

(b) each gate of C has fanin $\leqq 2^{2p_j(\alpha)}$,

(c) the bottom fanin of C is $\leqq p_j(\alpha)$,

(d) the variables in C are represented by strings of length $\leqq p_j(\alpha)$, and

(e) for every set A, if every variable v_y in C is given the value $\chi_A(y)$, then C outputs 1 if and only if $\sigma_j^k(A; 1^\alpha)$ is true.

Using a method similar to the construction in Theorem 4.3, we modify circuit C into C' and define set B to satisfy the following properties:

(a') the depth of C' is $\leqq m = 2k \log p_j(\alpha)$,

(b') the number of gates in C' is $\leqq 2^{2(m+1)p_j(\alpha)}$, and

(c') all variables in C' are represented by strings of length α.

The modification of C into C' is similar to the modification in an odd stage of the construction in Theorem 4.3. The main idea is to replace each variable v_y having $|y| > \alpha$ and $y = 0uz$, for some u and z with $|z| = k|u|$, by the dual circuit $\tilde{C}'_y$ of the circuit C'_y, where C'_y is a depth-$2k$ circuit satisfying conditions of Lemma 2.2 (with respect to the string u). (The reason for using the dual circuit $\tilde{C}'_y$ of C'_y instead of C'_y itself is that we want to get the relation $u \notin K^k(A) \Leftrightarrow y \in A$.) Note that for each y of the form $0uz$, with $|z| = k|u|$, the variables in circuit C'_y correspond to strings of length $\leqq |u| \leqq |y|/(k+1) \leqq |y|/2$. Thus, as argued in the proof of Theorem 4.3, the circuit C will be expanded into a new circuit with depth $\leqq 2k \log p_j(\alpha)$ such that no variable v_y in it is represented by a string y of length $> \alpha$ and of the form $y = 0uz$, $|v| = k|u|$. By replacing all other variables v_w such that $|w| > \alpha$ by constant 0 (and form the set B') and all other variables v_w such that $|w| < \alpha$ by value $\chi_{A(\alpha-1)}(z)$, we obtain a new circuit C' satisfying the above conditions (a')-(c'). Choose a set $D \subseteq \Sigma^\alpha$ such that $1^n \in L_{\text{odd}}(D)$ if and only if C' outputs 0 when each variable v_z is given value $\chi_D(z)$. Let $A(\alpha) = A(\alpha-1) \cup D$, $A'(\alpha) = A'(\alpha-1) \cup B'$, and $\beta_\alpha = \max\{\alpha, p_j(\alpha)+1\}$. Finally, we cancel integer $2j+1$ and turn off the flag: $F =$ **false**.

We can prove, as we did in the proof of Theorem 4.3, that circuit C' satisfies the following property:

(d') Assume that A is an extension of $A(\alpha)$ and $A \cap A'(\alpha) = \varnothing$. Also assume that for all u of length $n < |u| \leqq p_j(\alpha)/(k+1)$, $(\forall z, |z| = k|u|)[u \notin K^k(A) \Leftrightarrow 0uz \in A]$. Then, if we give $\chi_A(w)$ as input value for each variable v_w in C', then C' outputs 1 if and only if $\sigma_j^k(A; 1^\alpha)$ is true.

At stage $\alpha = (k+1)n+1$, we satisfy requirement $R_{0,n}$. For each u of length n, we determine whether $u \in K^k(A(\alpha-1))$, and try to find a set $B \subseteq 0u\Sigma^{kn}$ such that

$$(*) \quad u \notin K^k(A(\alpha-1)) \Leftrightarrow (\exists z_1, |z_1| = n) \cdots (Q_k z_k, |z_k| = n) 0uz_1 \cdots z_k \in A(\alpha-1) \cup B.$$

This set B will be determined as follows: if the flag F is true, then search for a set B satisfying both $(*)$ and $B \cap (A(\alpha-1) \cup A'(\alpha-1)) = \varnothing$; if the flag is false, then let $B = \varnothing$ when $u \in K^k(A(\alpha-1))$ and $B = 0u\Sigma^{kn}$ when $u \notin K^k(A(\alpha-1))$. Finally, let $A(\alpha) = A(\alpha-1) \cup B$ and $A'(\alpha) = A'(\alpha-1)$.

Note that the flag F is turned *on* whenever an even integer $2i$ is cancelled. When $2i$ is cancelled in stage α', some strings of the form $0uz$, $|u| = n$ and $|z| = kn$, may have been added to set $A(\alpha')$ or $A'(\alpha')$. However, later in stage $\alpha = (k+1)n+1$, before the flag F is turned off, a set B satisfying both $(*)$ and $B \cap (A(\alpha-1) \cup A'(\alpha-1)) = \varnothing$ can always be found, as proved by Lemma 3.1. (Note that by setting $\beta_{\alpha'}$ to be an upper bound of the maximum length of strings added to $A(\alpha')$ or $A'(\alpha')$, we know that the flag F will not be turned off until in some stage $\alpha > \beta_{\alpha'}$.)

The flag F will be turned *off* when we cancel an odd integer $2j+1$. Suppose we cancel $2j+1$ at stage α'', then we must have $\alpha'' > \beta_{\alpha''-1}$, and hence no string of length

$\geqq \alpha''$ is in set $A(\alpha''-1)$ or in set $A'(\alpha''-1)$. Thus, in a later stage $\alpha=(k+1)n+1$, before the flag is turned on, we have $0u\Sigma^{kn} \cap (A(\alpha-1) \cup A'(\alpha-1))=\varnothing$ for all u of length n. So, in stage α, the choice of the set B can be made free from interference of earlier stages.

This completes the construction of set A. Note that by setting β_α be an upper bound of the maximum length of the strings added to $A(m)$ or $A'(m)$ for all $m \leqq \alpha$, we prevent the possible interference between stages $(k+1)n$ and stages $(k+1)n+2$. By the discussions in the construction, set A satisfies requirements $R_{0,n}$ for all n and $R_{1,i}$ for all i. The only thing left to check for requirement $R_{2,j}$ is that after we cancel $2j+1$ in stage $\alpha=(k+1)n+2$, we construct A in later stages such that, for all u of length $n<|u| \leqq p_j(\alpha)/(k+1)$, $(\forall z, |z|=k|u|)[u \notin K^k(A) \Leftrightarrow 0uz \in A]$. This is stronger than the requirement $R_{0,|u|}$. However, we note that by the definition of β_α the flag F is off at stage $\alpha'=(k+1)|u|+1$. Therefore, in stage α', we satisfy the requirement $R_{0,|u|}$ by letting $0u\Sigma^{k|u|} \subseteq A$ if $u \notin K^k(A)$ and $0u\Sigma^{k|u|} \cap A=\varnothing$ if $u \in K^k(A)$. This shows that the assumption, and hence the conclusion, of property (d′) of stage α is satisfied by A. As a consequence, requirement $R_{2,j}$ is satisfied when $2j+1$ is cancelled. This completes the proof of the cases $k>1$.

The proof of the case $k=1$ is almost identical to the general case $k>1$, except that the requirement $R_{1,i}$ is actually easier to satisfy. We may simply use Baker, Gill, and Solovay's [2] original proof for the result $(\exists A)[\mathrm{NP}(A)=co\text{-}\mathrm{NP}(A) \neq \mathrm{P}(A)]$. We omit the details. □

5. Open questions. In the last two sections, we have constructed oracles which collapse the polynomial time hierarchy to exactly the kth level. Furthermore, relative to different oracles, the class PSPACE may either collapse to the kth level of the polynomial time hierarchy or may be different from the polynomial time hierarchy. Several questions about the relativized polynomial time hierarchy, however, remain open. First, note that the set $L_{\mathrm{odd}}(A)$ is actually in the class $D\#\mathrm{P}(A)$ (see, for definition, Angluin [1]). Thus, our results together with Yao's [12] result actually showed that relative to some oracles, the class $D\#\mathrm{P}$ may be separated from the polynomial time hierarchy while the hierarchy may have either finite or infinite levels. An interesting question here is to find an oracle to separate the class PSPACE from $D\#\mathrm{P}$.

Heller [7] has constructed oracles X and Y such that $\Sigma_2^P(X)=\Pi_2^P(X) \neq \Delta_2^P(X)$ and $\Sigma_2^P(Y)=\Delta_2^P(Y) \neq \Sigma_1^P(Y)$. It would be interesting to see whether these results could be extended to the kth level of the polynomial time hierarchy.

Appendix. In this appendix, we give a proof for Lemma 3.1. The proof will be done by induction on k. The induction proof is easier on the following stronger form of Lemma 3.1.

LEMMA 3.1 (stronger form). *For every $k \geqq 2$ there exists a constant n_k such that the following holds for all $n>n_k$. Let $t=n^{\log n}$, $m<2^t$, and $C_0, C_1, \cdots, C_m$ be $m+1$ circuits each defining a $f_k^{2^n}$ function, with their variables pairwisely disjoint. Let C be a depth-k circuit such that the bottom fanin is $\leqq t$ and the number of gates in C of distance at least 2 from the leaves is $\leqq 2^t$. Then, there exists a restriction ρ on C such that ρ completely determines C but it does not completely determine any C_i, $0 \leqq i \leqq m$.*

First we need some definitions from Hastad [5]. Let V be a set of variables, and $\mathcal{B}=\{B_j\}_{j=1}^r$ a partition of V. Let q be a real number, $0<q<1$. Define $R_{q,\mathcal{B}}^+$ to be the probability space of restrictions which take values as follows. To define a random restriction ρ in $R_{q,\mathcal{B}}^+$, first, for each B_j, $1 \leqq j \leqq r$, let $s_j=*$ with probability q and $s_j=0$ with probability $1-q$; and then, independently, for each variable $x \in B_j$, let $\rho(x)=s_j$ with probability q and $\rho(x)=1$ with probability $1-q$. Similarly, a $R_{q,\mathcal{B}}^-$ probability

space of restrictions is defined by interchanging the roles played by 0 and 1. Furthermore, define for each $\rho \in R^+_{q,\mathcal{B}}$ a restriction $g(\rho)$: for all B_j with $s_j = *$, let V_j be the set of all variables in B_j which are given value $*$ by ρ; $g(\rho)$ selects one variable y in V_j and gives value $*$ to y and value 1 to all others in V_j. For $\rho \in R^-_{q,\mathcal{B}}$, $g(\rho)$ is similarly defined by interchanging the roles of 0 and 1.

Now, for given circuits C_i, $0 \leqq i \leqq m$, let $\mathcal{B} = \{B_j\}$ be the partition of all variables that occurred in C_i, $0 \leqq i \leqq m$, such that each B_j is the set of all variables leading to a bottom gate in some C_i, $0 \leqq i \leqq m$ (when k is even, the bottom gates of C_i's are AND gates). Also let $t = n^{\log n}$ and $q = 1/(24t)$. We will prove two lemmas which state that with a high probability, a random restriction ρ from $R^+_{q,\mathcal{B}}$ (or, from $R^-_{q,\mathcal{B}}$) has the properties that $C\lceil_{\rho g(\rho)}$ is equivalent to a depth-$(k-1)$ circuit with bottom fanin $\leqq t$ and that each $C_i\lceil_{\rho g(\rho)}$, $0 \leqq i \leqq m$, contains a subcircuit computing a $f^{2^n}_{k-1}$ function. Thus an induction can be used.

In the following, the first lemma is exactly Lemma 6.3 of Hastad [5], and the second lemma is a stronger form of Lemma 6.8 of [5]. The main difference is that we use a smaller bound t for the bottom fanin, and hence a bigger probability q of assigning $*$ to variables, so that the probability of a circuit $C_i\lceil_{\rho g(\rho)}$ having a subcircuit computing a $f^{2^n}_{k-1}$ function is bigger.

LEMMA A.1. *Let s, t be integers and q a real number, $0 < q < 1$. Let G be an* AND *of* ORs *with bottom fanin $\leqq t$, and $\mathcal{B} = \{B_j\}$ be a partition of variables in G. Then, for a random restriction ρ from $R^+_{q,\mathcal{B}}$, the probability that $G\lceil_{\rho g(\rho)}$ is not equivalent to a circuit of* OR *of* ANDs *with bottom fanin $\leqq s$ is bounded by α^s, where $\alpha < 6qt$.*

Lemma A.1 also holds with $R^+_{q,\mathcal{B}}$ replaced by $R^-_{q,\mathcal{B}}$, or with G being an OR of ANDs to be converted to a circuit of an AND of ORs.

Proof. See Hastad [5]. □

LEMMA A.2. *For each $k > 2$, there exists an integer n_k such that the following holds for all $n > n_k$. If k is even and ρ is a random restriction from $R^+_{q,\mathcal{B}}$, then the probability that every circuit $C_i\lceil_{\rho g(\rho)}$, $0 \leqq i \leqq m$, contains a subcircuit computing an $f^{2^n}_{k-1}$ function is $\geqq \frac{2}{3}$. If k is odd, then the same probability holds for a random restriction ρ from $R^-_{q,\mathcal{B}}$.*

Proof. Assume k is even and ρ is a random restriction from $R^+_{q,\mathcal{B}}$. Note that the subcircuits of the two lower levels of a $C^{2^n}_k$ circuit are ORs of ANDs with bottom fanin exactly $2^{n/2}$. There are $2^{(k-5/2)n}$ such depth-2 subcircuits in $C^{2^n}_k$.

(i) We first show that with a high probability all bottom AND gates $H_j\lceil_{\rho g(\rho)}$ (corresponding to block B_j) of all circuits $C_i\lceil_{\rho g(\rho)}$, $0 \leqq i \leqq m$, take the value s_j (the value assigned to block B_j by ρ). Note that each $H_j\lceil_{\rho g(\rho)}$ has $2^{n/2}$ inputs. Also note that $H_j\lceil_{\rho g(\rho)}$ has value $\neq s_j$ if and only if all inputs to $H_j\lceil_{\rho g(\rho)}$ are 1. Therefore, we have

$$\begin{aligned}\Pr[H_j\lceil_{\rho g(\rho)} \text{ has value} \neq s_j] &= \Pr[\text{all inputs to } H_j\lceil_{\rho g(\rho)} \text{ are } 1] \\ &= (1-q)^{2^{n/2}} = \left(\left(1 - \frac{1}{24n^{\log n}}\right)^{24n^{\log n}}\right)^{2^{n/2}/(24n^{\log n})} \\ &< e^{-2[(n/2-5(\log n)^2]} < 2^{-2^{n/4}},\end{aligned}$$

if $n > 20(\log n)^2$. In the above, the first inequality comes from the observation that $(1-1/n)^n < e^{-1}$ for all n.

Note that there are exactly $m+1$ many circuits C_i, and each has exactly $2^{(k-3/2)n}$ many bottom AND gates. So the probability that all bottom AND gates $H_j\lceil_{\rho g(\rho)}$ of all circuits $C_i\lceil_{\rho g(\rho)}$, $0 \leqq i \leqq m$, take the value s_j is

$$\geqq 1 - 2^{-2^{n/4}} \cdot 2^{(k-3/2)n} \cdot (m+1) > 1 - 2^{-2^{n/8}} > \tfrac{5}{6},$$

if $2^{n/8} > n^{\log n} + kn$ and $n \geqq 16$.

(ii) Next we show that with a high probability all OR gates at level 2 of circuits $C_i\lceil_{\rho g(\rho)}$, $0 \leqq i \leqq m$, have at least $2^{n/2}$ many child nodes $H_j\lceil_{\rho g(\rho)}$ of AND gates having values $s_j = *$. Let G be an OR gate at level 2 of some C_i, $0 \leqq i \leqq m$. Note that $G\lceil_{\rho g(\rho)}$ has 2^n many children $H_j\lceil_{\rho g(\rho)}$, each having probability q of having the value $s_j = *$. Let p_l be the probability that $G\lceil_{\rho g(\rho)}$ has exactly l many AND gates $H_j\lceil_{\rho g(\rho)}$ having values $s_j = *$. Then,

$$p_l = \binom{2^n}{l} q^l (1-q)^{2^n - l}.$$

Note that when $l \leqq 2^{n/2+1}$, we have $p_l \leqq \frac{1}{2}$ and

$$\frac{p_l}{p_{l-1}} = \frac{2^n - l + 1}{l} \cdot \frac{q}{1-q} \geqq (2^{n/2-1} - 1)q \geqq 2,$$

if $2^{n/4} > 10n^{\log n}$. So, we have

$$\sum_{l=0}^{2^{n/2}} p_l \leqq p_{2^{n/2}} \cdot \sum_{l=0}^{2^{n/2}} 2^{-l} \leqq 2 \cdot p_{2^{n/2}} \leqq 2 \cdot 2^{-2^{n/2}} \cdot p_{2^{n/2+1}} \leqq 2^{-2^{n/2}}.$$

Thus the probability that all OR gates at level 2 of circuits $C_i\lceil_{\rho g(\rho)}$, $0 \leqq i \leqq m$, have at least $2^{n/2}$ many child nodes H_j of AND gates having value $s_j = *$ is

$$\geqq 1 - 2^{-2^{n/2}} \cdot 2^{(k-5/2)n} \cdot (m+1) > 1 - 2^{-2^{n/4}} > \frac{5}{6},$$

if $2^{n/4} > n^{\log n} + kn$ and $n \geqq 8$.

Combining results (i) and (ii) and letting n_k be the smallest integer which satisfies all the inequalities of the "if" clauses above, we have proved Lemma A.2 for even k. The case for odd k is symmetric. □

Now we are ready to prove the stronger form of Lemma 3.1. Note that the integer n_k chosen in Lemma A.2 is so large that $2^{n/4} > n^{\log n} + kn$. First let $k = 2$. Assume that C is an OR of ANDs which does not compute a constant function 0. Then we define a restriction ρ that maps all variables which are children of the first AND gate of C to 1, and maps all variables whose negations are the children of the first AND gate of C to 0, and all other variables to $*$. This makes C computing a constant function 1. However, this restriction ρ only assigns $\leqq t = n^{\log n}$ many variables to 0 or 1. Since each circuit C_i, $0 \leqq i \leqq m$, has both the bottom fanin and the top fanin $2^{n/2} > t$, it has the following properties:

(a) For each AND gate of C_i, there is at least one variable assigned $*$ by ρ.

(b) There is at least one AND gate of C_i having all variables assigned $*$ by ρ.

From these two properties, we know that $C_i\lceil_{\rho g(\rho)}$, $0 \leqq i \leqq m$, does not compute a constant function.

The argument for a depth-2 circuit C which is an AND of ORs is similar.

For the inductive step, let $k > 2$. Recall that $q = 1/(24t)$. Assume, without loss of generality, that the bottom gates of C are OR gates. Then, by Lemma A.1, for any random restriction ρ from $R^+_{q,\mathcal{B}}$ or from $R^-_{q,\mathcal{B}}$, the probability that any single subcircuit G of the two lower levels of $C\lceil_{\rho g(\rho)}$ is not equivalent to an OR of ANDs with bottom fanin $\leqq t$ is at most α^t. Since there are at most 2^t such subcircuits, the probability that at least one such subcircuit is not equivalent to an OR of ANDs with bottom fanin $\leqq t$ is at most $(2\alpha)^t < (12qt)^t = 2^{-t}$. Thus, with probability at least $\frac{2}{3}$, the circuit $C\lceil_{\rho g(\rho)}$ can be written as a depth-$(k-1)$ circuit with the bottom fanin $\leqq t$. Furthermore, the number of gates in $C\lceil_{\rho g(\rho)}$ of distance at least 2 from the leaves is exactly the number of gates in C of distance at least 3 from the leaves and is $\leqq 2^t$.

Assume that k is even, then we choose a restriction ρ from $R^{+}_{q,\mathcal{B}}$ such that (a) $C\lceil_{\rho g(\rho)}$ is equivalent to a depth-$(k-1)$ circuit with the bottom fanin $\leqq t$ and with $\leqq 2^{t}$ gates of distance $\geqq 2$ from leaves, and (b) every $C_i\lceil_{\rho g(\rho)}$, $0 \leqq i \leqq m$, has a subcircuit computing an $f^{2^n}_{k-1}$ function. (By Lemma A.2 and the above argument, there are at least $\frac{1}{3}$ of restrictions from $R^{+}_{q,\mathcal{B}}$ having these properties.) Similarly, if k is odd, we can choose a restriction ρ from $R^{-}_{q,\mathcal{B}}$ which has these properties. By the inductive hypothesis, we can find a restriction ρ' such that ρ' completely determines the circuit $C\lceil_{\rho g(\rho)}$ but none of $C_i\lceil_{\rho g(\rho)}$, $0 \leqq i \leqq m$. The combined restriction $\rho g(\rho)\rho'$ satisfies our requirement, and Lemma 3.1 is proven. □

EXPONENTIAL AVERAGE TIME FOR THE PURE LITERAL RULE*

KHALED M. BUGRARA†, YOUFANG PAN‡, AND PAUL WALTON PURDOM, JR. §

Abstract. This paper gives exponential lower bounds for the average time of an algorithm based on a simplified version of the pure literal rule from the Davis–Putnam procedure. It is shown that this algorithm requires an average time that is exponential in v, the number of variables, when p, the probability that a literal is in a clause, is proportional to $1/v$ and t, the number of clauses in the predicate, is at least a linear function of v. The time is greater than any polynomial in v over a somewhat larger range of parameters. For the two cases $t = \Theta(\ln v)$ and $p = O(\ln v/v^{3/2})$, the results of this lower-bound analysis are the same (to within a constant factor) as the upper-bound results in [SIAM J. Comput., 14 (1985), pp. 943–953]. The results of this and other papers show that the fastest analyzed algorithm for random satisfiability problems depends on the parameters of the distribution. Backtracking, the pure literal rule, and the new algorithm of Iwama [Report KSU/ICS 88-01, Institute of Computer Science, Kayoto Sangyo University, Kyoto, Japan, 1988] each have a large region of parameter setting where it is exponentially faster than the other two.

AMS(MOS) subject classifications. 68P10, 68Q20, 68Q25, 68T15

1. Introduction.

Many of the ideas that are used in practice for solving satisfiability problems are related to the Davis–Putnam procedure: the problem instance is solved directly if it has no clauses (in which case the problem is satisfiable) or if it has a clause of length zero (in which case it is unsatisfiable). Otherwise, a variable is selected and two subproblems are generated: one with the variable set to *true* and one with it set to *false*. The original problem has no solutions if and only if both subproblems have no solutions. The subproblems are simplified by removing all clauses with true literals (because they are satisfied with the present partial assignment of values to variables) and by removing all false literals from clauses (because a false literal cannot contribute to making the clause true). The subproblems are solved by recursive use of the algorithm.

The Davis–Putnam procedure uses four additional techniques that often speed up the algorithm: 1) the unit clause rule, 2) the pure literal rule, 3) subsumption, and 4) a dynamic order of assigning values to variables. The unit clause rule says that a variable that appears in a clause with only one literal must be set so as to make that literal true. The pure literal rule says that a variable that appears only in positive literals or only in negative literals needs to be set only in the way that makes its literal true. The pure literal rule does not find all the solutions to a problem, but it does find a solution if one exists. Subsumption removes each clause whose literals are a superset of the literals of some other clause. The search order is dynamic because whenever possible the Davis–Putnam procedure sets a variable that generates only one subinstance (a variable associated with a unit clause or a pure literal).

For several models of random satisfiability (SAT) problems, it is well known that the Davis–Putnam procedure can solve some random sets of SAT problems in polyno-

mial average time. The first result was that of Goldberg [4]. He showed that a variant of the Davis–Putnam procedure that uses only the pure literal rule and splitting requires polynomial average time for one probability distribution. His *Pure Literal Rule Algorithm* uses a fixed order for assigning values to variables. The main feature of the algorithm is that only one subproblem is generated when the splitting variable is a pure literal.

Goldberg's analysis was later extended in [5]. Additional analysis of the Pure Literal Rule Algorithm was done in [9], where it was shown that the algorithm could solve a much larger class of problems in polynomial average time. This behavior is a direct result of two factors: the ability of the pure literal rule to recognize variables that are relevant to the solution, and the large (exponential) number of solutions associated with these problem sets. The previous upper-bound studies show that the pure literal rule plus splitting is more efficient than backtracking [8], [11] for some random sets of problems. (The version of backtracking that was analyzed was required to find all solutions.) The lower-bound results in [2] showed that there are some random sets of problems where backtracking is more efficient. The lower-bound results of this paper show that there is a large region in parameter space where the pure literal rule is known to be slower than backtracking, and they show that there is a large region where neither the pure literal rule nor backtracking runs in polynomial average time.

So far it has been too difficult to analyze the complete Davis–Putnam procedure. Instead, investigators have simplified the algorithm in various ways that reduce its performance. When the simplified algorithm is fast, the original one is also fast. When the simplified algorithm is slow, the complete one may or may not be slow. One might suspect, however, that the Davis–Putnam procedure is slow in that region where neither backtracking nor the pure literal rule is fast.

Figure 1 is a diagram of the parameter space (p, the probability that a literal is in a clause, and t, the number of clauses, as functions of v, the number of variables) that shows where both backtracking and the Pure Literal Rule Algorithms take large amounts of time to solve random conjunctive normal form SAT problems. The only points that are significant are those where lines intersect. The axes are labeled with various functions of v. The ϵ on the diagram is a positive constant that can be as small as one wishes. (In the text, the results that use ϵ are expressed with the more formal o and ω notations.) Constants have been suppressed in these functions (except for $\ln 2/v$ on the p axis, and v on the t axis). For example, the points marked with $p = (\ln v)^2/(\epsilon v^{3/2})$ and $t = v/\ln v$ have a much larger constant associated with the formula for t than has the point marked with $p = (1/\epsilon)[(\ln v)/v]^{3/2}$. Problems in the lower right region (small p and large t) can be solved in polynomial average time by backtracking [11]. For these problems the average number of solutions per problem is exponentially small. Problems in the lower left region (small p and small t), in the left region (small t), and in the upper region (large p) can be solved in polynomial average time by the Pure Literal Rule Algorithm [9]. The analyses for the superpolynomial region (the region where the average running time grows faster than any polynomial in v) and the exponential region are from this paper. The left boundary of the exponential region ($t = \epsilon v$) is definite; problem sets to the left of it require superpolynomial, but nonexponential average time. The upper boundary is not definite. Problem sets below the boundary require exponential time, while those above the boundary definitely require superpolynomial average time and might require exponential average time. In the two regions marked with question marks it is

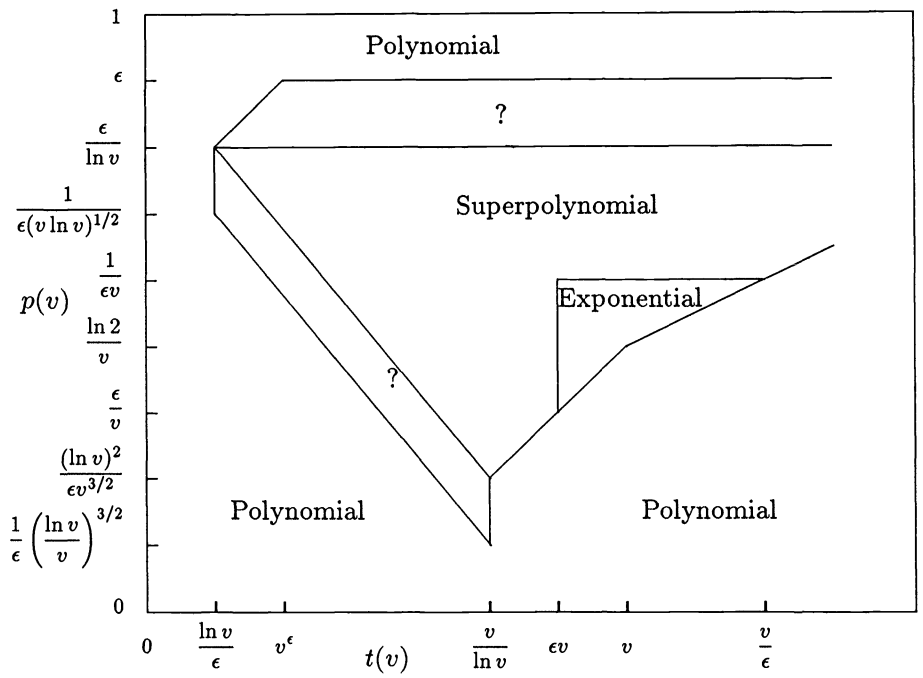

FIG. 1. *The regions where both backtracking and the pure literal rule need polynomial, superpolynomial, and exponential time are shown.*

not known whether the time for the pure literal rule is polynomial or superpolynomial. Backtracking takes exponential average time in all of the regions marked exponential, superpolynomial, or unknown. In most of these regions it is also the case that the average number of solutions per problem is exponentially large [9], but there is a region to the right of the $t = v$ line where the average number of solutions per problem is exponentially small (see the diagram in [9]).

Recently, Iwama [6] analyzed a SAT algorithm that is based on counting solutions. The average time of his algorithm is polynomial when $p > \sqrt{(\ln t)/v}$. Thus, Iwama's algorithm is better than the pure literal rule and backtracking when p is not small. The pure literal rule is better than (the upper limit analysis of) Iwama's algorithm when p is small, and it is better than backtracking when t is not too large. Finally, backtracking is better when t is large and p is small. In practice, these three techniques should be combined into a single algorithm, which would be fast where any one of the three is fast.

2. Random problems. We compute the average time required to find solutions to a predicate with v variables, t clauses, and with probability p that a literal is in a clause. The predicates are in *conjunctive normal form.* A random clause is formed by including each literal with probability p. A predicate consists of t independently selected random clauses. Since there are $2v$ literals altogether, and since each literal is included with probability p, the expected clause size is equal to $2vp$. The expected clause size is linear in v whenever p is fixed; it is fixed when p varies inversely with v, i.e., $p = \Theta(v^{-1})$. (The asymptotic notations Θ, O, Ω, o, and ω are given in [7].)

The Pure Literal Rule Algorithm generates a search tree, giving values to the variables in a fixed order. At each step it is working with a simplified predicate where

each clause with a *true* literal is eliminated and each *false* literal has been removed from all of its clauses. The simplified predicate contains only those literals whose variables do not yet have a value. If the simplified predicate contains the current variable in both positive and negative literals, then two subproblems are generated, one with the variable set to *true* and one with it set to *false*. If the variable only occurs positively, then only the subproblem with the variable set to *true* is generated; if the variable only occurs negatively, then only the subproblem with the variable set to *false* is generated. If the variable does not occur at all, then one subproblem identical to the current predicate is generated.

The average time for the Pure Literal Rule Algorithm is given by [4], [5]:

$$(1) \quad A(t,v) = tv + (1-p)^{2t}A(t,v-1) + 2\sum_{j\geqq 1}\binom{t}{j}p^j(1-p)^{t-j}A(t-j,v-1)$$

with boundary conditions $A(0,v) = A(t,0) = 0$. This implies that $A(1,v) \geqq v$ for $v \geqq 1$ and $A(t,1) = t$ for $t \geqq 1$. The first term in the recurrence corresponds to the time of one step of the recursion; the second term corresponds to the case where the selected variable does not occur in any clause of the predicate; the sum is the weighted sum of those cases where a literal that corresponds to the selected variable occurs j times in the predicate. Although there is no obvious way to solve the full history recurrence, the behavior of the solution can be determined from upper- and lower-bound methods.

3. Lower bound. Since the algorithm considers variables in fixed order, adding a clause to the predicate can only increase the size of the pure literal rule search tree (or leave it unchanged). Notice that the algorithm only looks for pure literals. If a predicate includes the pair of clauses $x \wedge \bar{x}$, then x will not be selected because x is not a pure literal. Thus, $A(t,v)$ is an increasing function of t. Also, it is an increasing function of v [9]. Therefore,

$$A(t,v) \geqq \max\{t,v\} \quad \text{for } t \geqq 1,\ v \geqq 1.$$

Since each term in the right-hand side of (1) is positive, we obtain a lower bound by taking selected terms (the tv term is dropped, and only the first n terms of the sum are retained):

$$A(t,v) \geqq (1-p)^{2t}A(t,v-1) + 2\sum_{1\leqq j\leqq n}\binom{t}{j}p^j(1-p)^{t-j}A(t-j,v-1).$$

This equation is still too complex to solve.

Since $A(t,v)$ is an increasing function of t, we replace $A(t-j,v)$ by $A(t-n,v)$ to obtain an equation that is easier to solve. This gives the lower bound

$$A(t,v) \quge A_n(t,v) \quad \text{for } t \geqq t_0,\ v \geqq v_0,$$

where

$$(2) \quad A_n(t,v) = \left[(1-p)^{2t} + 2\sum_{1\leqq j\leqq n}\binom{t}{j}p^j(1-p)^{t-j}\right]A_n(t-n,v-1),$$

and with boundary conditions such that

$$A_n(t_0, v) \leqq A(t, v) \quad \text{for } t \geqq t_0 \quad \text{and} \quad A_n(t, v_0) \leqq A(t, v) \quad \text{for } v \geqq v_0.$$

This equation is first-order linear in A_n. Let a be some number such that $a \leqq \min\{v-1, (t-1)/n\}$ (a is the depth of the recursion). Choose $t_0 = t - an$, $v_0 = v - a$, and $A_n(t_0, v) = A_n(t, v_0) = 1$. By iterating for a steps, the solution

$$A_n(t, v) = \prod_{0 \leqq k < a} \left[(1-p)^{2(t-nk)} + 2 \sum_{1 \leqq j \leqq n} \binom{t-nk}{j} p^j (1-p)^{t-nk-j} \right] \tag{3}$$

is obtained (see [10]). The function $A_n(t, v)$ depends on a as well as on n, t, and v, but we do not show the dependence on a because we intend to set a to obtain a large value for $A_n(t, v)$.

4. Asymptotic analysis. This section gives derivations of the asymptotic behavior of the bound given by (3), determining conditions where the average time is a rapidly increasing function of v. We consider p and t to be functions of v, but to avoid notational clutter, we call the functions p and t rather than $p(v)$ and $t(v)$. We determine conditions for which $A(t, v)$ is superpolynomial, i.e., greater than v^n for large but fixed n, and conditions for which $A(t, v)$ is exponential, i.e., greater than $(1+\epsilon)^v$ for small positive ϵ. Since $A(t, v)$ is polynomial if p is a fixed constant as v goes to infinity [9], we restrict the analysis to the case where p approaches zero.

4.1. Approximations. We will show that when pt is small enough, setting $n = 2$ includes enough terms to obtain an exponential lower bound (setting $n = 1$ does not lead to an exponential lower bound). When n is equal to 2, a lower bound is given by

$$A_2(t, v) = \prod_{0 \leqq k < a} \Big[(1-p)^{2(t-2k)} + 2(t-2k)p(1-p)^{t-2k-1} + (t-2k)(t-2k-1)p^2(1-p)^{t-2k-2} \Big], \tag{4}$$

where $a \leqq \min\{v-1, (t-1)/2\}$.

We show that $A_2(t, v)$ is large for some small pt by first showing that the factor in brackets is larger than 1 plus a small quantity, $f(v)$, over a range of k, $0 \leqq k \leqq g(v)$. The functions f and g must be in the ranges $0 \leqq f(v) \leqq 1$ and $0 \leqq g(v) < v$. That is, for the various values of $g(v)$ and $f(v)$, we want to show that

$$A_2(t, v) \geqq [1 + f(v)]^{g(v)} = v^{\Theta(f(v)g(v)/\ln v)},$$

so the bound is exponential [$(1+\epsilon)^v$ for some $\epsilon > 0$] if and only if

$$f(v) = \Theta(1) \quad \text{and} \quad g(v) = \Theta(v). \tag{5}$$

The function $A_2(t, v)$ is polynomial if $f(v)g(v) = O(\ln v)$. This can occur over a range of functions. For $g(v) = \Theta(v)$ [the largest value for $g(v)$], polynomial time results if and only if $f(v) = O([\ln v]/v)$. For $f(v) = \Theta(1)$ [the largest value for $f(v)$] polynomial time results if and only if $g(v) = O(\ln v)$. In what follows, let $N(v)$ be an increasing function that goes to infinity very slowly. So, $N(v) = \omega(1) = 1/o(1)$, but it is not too large. If

$$f(v)g(v) = N(v) \ln v, \tag{6}$$

then the bound is superpolynomial (larger than any polynomial).

We now find the conditions on p and t that lead to large running times. First concentrate on the size of the factor in square brackets from (4): replacing $t - 2k$ by τ gives

$$(1-p)^{2\tau} + 2p\tau(1-p)^{\tau-1} + p^2\tau(\tau-1)(1-p)^{\tau-2}. \tag{7}$$

Each term in (7) can now be expanded with the binomial theorem. Assume that there is an upper-bound on $p\tau$ and that τ goes to infinity as v goes to infinity. Then the terms with a power of p larger than the power of τ go to zero, and the following expansions are obtained:

$$\begin{aligned}(1-p)^{2\tau} &= 1 - 2p\tau + 2p^2\tau^2 - \frac{4}{3}p^3\tau^3 + \Theta(p^4\tau^4),\\ 2p\tau(1-p)^{\tau-1} &= 2p\tau - 2p^2\tau^2 + p^3\tau^3 - \Theta(p^4\tau^4),\\ p^2\tau(\tau-1)(1-p)^{\tau-2} &= p^2\tau^2 - p^3\tau^3 + \Theta(p^4\tau^4).\end{aligned}$$

Adding the terms gives

$$(1-p)^{2\tau} + 2p\tau(1-p)^{\tau-1} + p^2\tau(\tau-1)(1-p)^{\tau-2} = 1 + p^2\tau^2 - \Theta(p^3\tau^3).$$

Therefore, the factor in square brackets from (4) is larger than $1 + f(v)$ when

$$p^2\tau^2 - \Theta(p^3\tau^3) > f(v).$$

If C is the larger constant implied by the Θ so that $\Theta(p^3\tau^3) \leqq Cp^3\tau^3$, then this equation has a solution for $\sqrt{(2f(v))} < p\tau < 1/(2C)$. In particular, for $f(v) < 1/(128C^2)$ there exist solutions for a range of $p\tau$ where the upper-bound is at least four times the lower bound. So, if $f(v)$ is below the appropriate constant, we can find the lower bound on $p\tau$ by factoring out the $p^2\tau^2$ term from the left-hand side and taking the square root to obtain

$$p\tau > \sqrt{f(v)}[1 - Cp\tau]^{-1/2}.$$

Taylor's theorem with a remainder gives $(1-x)^{-1/2} = 1 + \frac{1}{2}x(1-c)^{-3/2}$ for some c in the range $0 < c < x$. For $0 < x < \frac{1}{2}$, this gives $(1-x)^{-1/2} < 1 + \sqrt{2}x$. Thus, for $p\tau < 1/(2C)$,

$$p\tau > \sqrt{f(v)}[1 + \sqrt{2}Cp\tau].$$

If we require $p\tau$ to be less than or equal to $N\sqrt{f(v)}$ for some constant N, then the rightmost term, $\sqrt{2}Cp\tau$, is no more than $\sqrt{2}CNf(v)$. So, a lower bound on $p\tau$ is

$$p\tau > \sqrt{f(v)}[1 + \Theta(\sqrt{f(v)})]. \tag{8}$$

For $f(v) < 1/(128C^2)$, the upper bound on $p\tau$ is at least four times larger than the lower bound.

Since p approaches zero, requiring (7) to be larger than $1 + \epsilon$ is equivalent to

$$\begin{aligned}(1-p)^{2\tau} + 2p\tau(1-p)^{\tau-1} + p^2\tau(\tau-1)(1-p)^{\tau-2} =&\\ (e^{-2p\tau} + 2p\tau e^{-p\tau} + p^2\tau^2 e^{-p\tau})[1 + O(p)] > 1 + \epsilon.&\end{aligned}$$

Solving this numerically gives a solution for all $p\tau$ such that

$$0 < p\tau < 2.304602987. \tag{9}$$

Equations (8) and (9) say that in order for $A_2(t,v)$ to be superpolynomial or exponential, $p\tau$ must be bounded from above and below.

4.2. Results and comparisons. Since $A(t,v)$ is an increasing function of t, the critical question is, for each p, how small can t be and still have $A(t,v)$ be large? If $A(t_0,v)$ is large, then $A(t,v)$ is at least as large for $t > t_0$. Since $\tau = t-2k$, $0 \leqq k \leqq a$, and τ must be greater than zero, we would like a to be as small as possible, but we cannot make it too small because then we would not have enough factors that would lead to a large bound. From (8), if $(t-2a)p$ is small (below $N\sqrt{f(v)}$ for some N) and slightly greater than $\sqrt{f(v)}$, and if pt is also small (below $N\sqrt{f(v)}$ for some N), then the term in square brackets from (4) is larger than $1+f(v)$ for $t-2a < t-2k \leqq t$. All these conditions are satisfied by setting

$$pt = 2\sqrt{f(v)} + 2ap \tag{10}$$

and requiring that $t \geqq 4a$ and that $f(v)$ be small (below $1/(128C^2)$). The lower bound on t ensures that pt and $p(t-2a)$ are about the same size ($pt \geqq p(t-2a) \geqq pt/2$). To keep the formulas simple, the number 2 is used in all places where a constant factor bigger than 1 is needed; slightly better results could be obtained by using smaller constants. Setting $a = g(v)$ in (4) gives us $g(v)$ terms, where each term is larger than $1+f(v)$.

Recall that (6) says that the bound is superpolynomial for $f(v)g(v) = N(v)\ln v$, so we set $g(v) = (N(v)\ln v)/f(v)$, giving superpolynomial time when

$$pt = 2\sqrt{f(v)} + \frac{2pN(v)\ln v}{f(v)} \tag{11}$$

for $t \geqq 4g(v)$. The right side of (11) is as small as possible when $f(v)$ is chosen so that

$$f(v) = [pN(v)\ln v]^{2/3}. \tag{12}$$

Applying (12) to (11) gives superpolynomial time for

$$t = 4[N(v)\ln v]^{1/3}p^{-2/3},$$

provided $pN(v)\ln v$ is bounded by a small constant (because $f(v)$ must be small) and provided that $[N(v)\ln v]^{1/3}p^{-2/3} < v$ (because $g(v)$ must be smaller than v).

The time for the algorithm is an increasing function of t, thus we have superpolynomial time whenever

$$t \geqq 4[N(v)\ln v]^{1/3}p^{-2/3}, \tag{13}$$

and

$$N(v)^{1/2}v^{-3/2}(\ln v)^{1/2} \leqq p \leqq \frac{1}{N(v)\ln v}. \tag{14}$$

Since $N(v) = \omega(1)$, (13) and (14) give superpolynomial time whenever

$$t = \omega((\ln v)^{1/3}p^{-2/3}), \qquad p = o(1/\ln v), \qquad \text{and} \qquad p = \omega(v^{-3/2}(\ln v)^{1/2}). \tag{15}$$

Equation (13) corresponds to the line in Fig. 1 that separates superpolynomial average time from the lower left unknown region, and (14) leads to the boundary that separates polynomial average time from the upper unknown region.

The small t upper-bound result of [9, Eq. (19)] shows that for any p the time for the Pure Literal Rule Algorithm is polynomial if $t = O(\ln v)$. This is essentially the same as the lower-bound result of (15) when p is just below $\Omega(1/\ln v)$. Thus, we conclude that for p of this form the time for the Pure Literal Rule Algorithm is polynomial if

$$t = O(\ln v),$$

and superpolynomial if

$$t = \omega(\ln v).$$

When p is below the lower bound of (14), the best results come from the case when $g(v) = v - 1$ and $f(v) = [N(v) \ln v]/v$, which gives

$$pt = 2\sqrt{\frac{N(v) \ln v}{v}} + 2pv - 2p. \tag{16}$$

The first term on the right side dominates for $p = O(v^{-3/2}(\ln v)^{1/2})$. The small pt upper bound of [9, Eq. (28)] is the same, except for the $N(v)$ factor, as the lower bound results of (16) for $p = O(v^{-3/2}(\ln v)^{1/2})$. Thus, for $p = O(v^{-3/2}(\ln v)^{1/2})$ the time for the Pure Literal Rule Algorithm is polynomial if

$$t = O\left(\frac{1}{p}\sqrt{\frac{\ln v}{v}}\right),$$

and it is superpolynomial if

$$t = \omega\left(\frac{1}{p}\sqrt{\frac{\ln v}{v}}\right).$$

There is no boundary line for (16) in Fig. 1, because it applies to a region where backtracking uses polynomial average time.

To show exponential time we need $a = g(v) = \alpha v$ and $f(v) = \epsilon$ (see (5)). Applying this to (10), we have exponential time when

$$pt = \epsilon^{1/2} + 2\alpha pv.$$

This equation has no solution unless $t > 2\alpha v$. Therefore, for $t = \beta v$ with $\beta > 2\alpha$, the bound is exponential whenever

$$p \leqq \frac{\epsilon^{1/2}}{(\beta - 2\alpha)v}.$$

If (19) and (28) of [9] are modified to obtain an exponential bound rather than a polynomial bound, then the same equation is obtained (within a constant factor). Thus, for $p = O(1/v)$ the time for the Pure Literal Rule Algorithm is exponential if

$$t = \Omega\left(\frac{1}{p}\right) \tag{17}$$

and subexponential if

$$t = o\left(\frac{1}{p}\right). \tag{18}$$

Equations (17) and (18) define the left boundary of the exponential average-time region, as shown in Fig. 1.

Our lower-bound analysis does not give a lower bound to match the large p upper bound of [9, Eq. (24)]. These results and the results from previous analyses of satisfiability algorithms are shown in schematic form in Fig. 1.

Numerical calculations similar to those used to derive (9) show that for the case when n is equal to 3 the lower bound is exponential whenever

$$0 < pt < 3.536962614.$$

This shows the tendency to extend the range of pt for which we have an exponential lower bound as n increases. (Since we must have $t - na \geqq 1$, increasing n decreases the range of t over which the resulting lower bound is exponential.) If this result is used in the previous analysis only the size of some constants change.

Finally, one should note that when pt is large, it is possible to use the technique of [1] to approximate the sum in (2). If n is slightly larger than pt the sum is near 2, whereas if n is slightly smaller than pt then the sum is near zero. Unfortunately, this approach does not lead to smaller bounds on t for large p [i.e., $p = \Omega(1/\ln v)$]. That is because $t - ng(v)$ must be larger than 1. If $n = pt$, this implies that $pg(v)$ is smaller than 1. Therefore, this approach does not produce interesting results for $p = \Omega(1/\ln v)$, since the smallest value for $g(v)$ that leads to superpolynomial time is $\omega(\ln v)$.

5. Conclusion. For the random clause model of generating random predicates, where there are v variables, t clauses, and probability p, each literal is in a clause; the average time of the Pure Literal Rule Algorithm is exponential in v when the average clause size is constant ($p = \Theta(1/v)$) and the average number of clauses per literal is constant or growing ($t = \Omega(1/p)$) (see Fig. 1). The average time grows faster than any polynomial function of v over a much larger region. For $p = O(1/\ln v)$ the results of the upper- and lower-bound analyses are the same except for the region between $p = o(1/\ln v)$ and $p = \omega((\ln v)/v^{3/2})$, and they are close in this region. More work is needed on the upper and lower bounds for $p = \omega(1/\ln v)$.

This work, combined with the analyses of backtracking algorithms [8], [11], show that the region where the average clause size is constant ($p = \Theta(1/v)$) and the average number of clauses is proportional to the number of variables ($t = \Theta(v)$), is the most difficult region for a satisfiability algorithm to handle. Backtracking algorithms can handle a portion of this region efficiently. The design of satisfiability algorithms should concentrate on algorithms that can handle more of this region efficiently.

A NEW PARALLEL ALGORITHM FOR THE MAXIMAL INDEPENDENT SET PROBLEM*

MARK GOLDBERG†‡ AND THOMAS SPENCER†§

Abstract. A new parallel algorithm for the maximal independent set problem is constructed. It runs in $O(\log^4 n)$ time when implemented on a linear number of EREW-processors. This is the first deterministic algorithm for the maximal independent set problem (MIS) whose running time is polylogarithmic and whose processor-time product is optimal up to a polylogarithmic factor.

Key words. parallel computation, $\mathcal{NC}$, efficient, deterministic, maximal independent set, matching

AMS (MOS) subject classification. 68R10

1. Introduction.

When researchers investigate the parallel complexity of a problem, one of the main questions they ask is whether a polylogarithmic running time is achievable on a PRAM containing a polynomial number of processors. If the answer is positive, then the problem and the corresponding algorithm are said to belong to class $\mathcal{NC}$ introduced in [22] (see also [8], [25]). Having constructed an $\mathcal{NC}$-algorithm for a given problem, it is natural to try to improve its computational complexity. The complexity of a parallel algorithm is characterized by the pair (T, P), where $T = T(N)$ is the worst-case running time, $P = P(N)$ is the number of processors used, and N is the size of the input. It has been traditional to consider the product $W = T(N)P(N)$ as a unified measure for different parallel algorithms solving the same problem. W represents the total amount of work that the parallel algorithm does; it is also the running time of the sequential algorithm into which the algorithm can be converted.

Let a sequential algorithm A_s with running time T_s and a parallel algorithm A_p solve the same problem. The *relative efficiency* $E(A_p, A_s)$ of A_p with respect to A_s measures the amount of extra work that A_p does, and it is given by $E = T_s/W_p$. The value of $E(A_p) = E(A_p, A_s)$, where A_s is the fastest known sequential algorithm for the problem, characterizes the efficiency of A_p. Thus, in general, this characteristic of a parallel algorithm depends on the progress in designing a sequential algorithm, but for the problems with a linear sequential algorithm, $E(A_p)$ is absolute. Clearly, the optimal algorithms introduced by Galil in [9] have the maximum relative efficiency of $O(1)$. We should expect that for many problems, achieving the speedup from a polynomial to a polylogarithmic running time is only possible if the efficiency $E(A_p)$ is a function that tends to 0 when $N \to \infty$. Consequently, the algorithms whose relative efficiency is large enough may be called *efficient*. In particular, we call an $\mathcal{NC}$-algorithm *efficient* if it has relative (to the fastest sequential algorithm) efficiency at least $\Omega(1/\log^l N)$, where l is a constant.

In this paper, we present an *efficient deterministic* parallel algorithm for the *Maximal Independent Set* problem (MIS). Recall that a subset I of the vertices of a graph G is *independent* if there are no edges between any two vertices in I. An

independent set I is *maximal* if it is not a proper subset of any other independent set. MIS is the problem of constructing a maximal independent set of a given graph.

Karp and Widgerson were the first to prove that MIS is in $\mathcal{NC}$. On graphs with n vertices and m edges, their algorithm [17] runs in $O(\log^4 n)$ time and uses $O(n^3/\log^3 n)$ processors. In [19] Luby constructed a probabilistic algorithm that runs in $O(\log n)$ time when implemented on a linear number of processors under the CRCW PRAM model of computation. In the EREW PRAM model, it runs in $O(\log^2 n)$ time. The deterministic version of the algorithm uses $O(n^2 m)$ processors. A still different probabilistic algorithm for MIS was described by Alon, Babai, and Itai in [4].

Since there is a trivial sequential algorithm that runs in linear time, every efficient algorithm for MIS must use at most a linear number of processors (up to a polylogarithmic factor). A deterministic algorithm that uses a linear number of processors was proposed by Goldberg in [12]; its running time is $O(n^\alpha)$, where $\alpha > \frac{1}{2}$ is arbitrary. Using the *deterministic coin-flipping technique* introduced by Cole and Vishkin in [6], Goldberg, Plotkin, and Shannon [11] developed algorithms for MIS as well as for the vertex-coloring problem, VC, which run in $O(\log^* n)$ time[1] on graphs with bounded maximum degree. Unfortunately, when the degree is allowed to grow, the algorithms become inefficient.

The algorithm we present in this paper runs in $O(\log^4 n)$ time on an EREW PRAM consisting of $O(m+n)$ synchronous processors that share a common memory [8], [22], [25], [26]. Each processor is a standard random access machine [2] capable of doing elementary operations on words of length $O(\log(n+m))$.

We follow the usual graph-theoretic terminology [7]. Our graphs are without loops or parallel edges. The vertices of a graph on n vertices are represented by integers $0, 1, \cdots, n-1$; the edges are given by a list of pairs $\{(i,j)\}$, where $0 \le i < j \le n-1$. Given a set T of vertices of a graph $G = (V, E)$, the neighborhood $N(T)$ is defined as the set of all vertices in V that are adjacent to at least one vertex in T. Thus, a set I is independent if $I \cap N(I) = \emptyset$. A subgraph of a graph G induced on a set A of vertices is denoted by $G[A]$. A matching is a collection of disjoint edges.

A partial coloring ϕ of a graph G is given by a collection of disjoint independent subsets $(C_1, \cdots, C_p)$ of G. We say that the vertices in C_i have color i $(1 \le i \le p)$; thus, the colors are always positive integers. If $V(G) = \cup_{i=1}^{p} C_i$, then ϕ is called complete. A trivial partial coloring is that for which $p = |V(G)|$; hence, for a trivial partial coloring, every vertex is its own color class. Given a partial coloring $\phi = (C_1, \cdots, C_p)$, we define matrix $D(\phi) = (d_{ij})$ and function $Q(\phi)$ by

$$d_{ij} = |N(C_i) \cap C_j|, \qquad (i, j = 1, \cdots, p);$$

$$Q(\phi) = \max_{1 \le i \le p} (|C_i| + |N(C_i)|).$$

For $h > 0$, we define a graph $B(\phi, h)$, on p vertices, by setting vertices i and j adjacent if and only if both $d_{ij} \ge h$ and $d_{ji} \ge h$ $(0 \le i, j \le p-1)$.

If L is a list of items sorted according to a key function f, then a maximal sublist of L with identical values of the key is called an interval of L. Every sorted list L can be viewed as the concatenation of its intervals.

A pair (r, s) is lexicographically smaller than another pair (r', s') if and only if either $r < r'$, or $r = r'$ and $s < s'$.

---

[1] We write $log\, n$ for $log_2 n$ and $log^*\, n$ for the minimum i such that the ith iteration of log function applied to n is < 2.

2. The algorithm. All parallel algorithms for MIS mentioned above as well as our algorithm have the same top-level description as the very first algorithm developed by Karp and Widgerson in [17].

```
begin
    I := ∅;      A := V(G);
    (* I is an independent set *)
    while A ≠ ∅ do
        begin
        C := FINDSET(A);
        I := I ∪ C;
        A := A − (C ∪ N(C))
    end;
end;
```

It is not hard to prove that an algorithm with such a structure will have a polylogarithmic running time if every application of FINDSET runs in polylogarithmic time and produces independent set C such that $|C \cup N(C)| = \Omega(|A|/\log^s |A|)$ for some fixed $s \geq 0$. Later, we will see that for our version of FINDSET, $s = 1$.

Informally, FINDSET works as follows. Starting with a trivial partial coloring ϕ_0 of graph $H = G[A]$, it constructs a sequence of partial colorings ϕ_j $(j \geq 0)$. For each $j \geq 0$, the procedure checks whether

$$(*) \qquad Q(\phi_j) > \frac{c_0 k}{\log k}$$

where $k = |A|$. If $(*)$ holds, FINDSET outputs the color class C' for which $|C'| + |N(C')| > c_0 k/\log k$; otherwise, it constructs a new partial coloring by decoloring some of the vertices and uniting some of the color classes. The construction is done by the procedure REDUCE. The input to REDUCE is a partial coloring ϕ and a matching M in the complement $\bar{B}$ of graph $B(\phi, h)$ (the selection of $h > 0$ is specified later). The matching M supplies a collection of pairs of color classes of ϕ. For each pair (C, C'), either the set $C \cap N(C')$ or the set $N(C) \cap C'$ (whichever is smaller) is decolored and the remaining vertices in $C \cup C'$ are declared to be a new color class. The new color classes obtained in this way, and the old color classes that were not changed, comprise the set of color classes of the new partial coloring.

A procedure MATCH finds a matching in $\bar{B}(\phi, h)$. It will be seen that the running time of the whole algorithm depends on the size of the matching delivered by this procedure as well as on its running time. In the context of our algorithm, each graph B to which MATCH is applied is such that its complement $\bar{B}$ contains a quadratic number $\Theta(|V(B)|^2)$ of edges even if the original graph G is sparse. This is our reason for not using any of the known algorithms for constructing a maximal matching (see [1], [10], [14], [15], [16], [18], [19], [20]). The subroutine MATCH runs in $O(\log n)$ time on an EREW PRAM with $O(n+m)$ processors. For graphs with a dense complement, MATCH constructs a matching of size $\Omega(|V(B)|)$, which is maximum up to a constant. On the other hand, it is not necessarily maximal.

Our algorithm uses $O(n + m)$ processors; every vertex and every edge of a graph has a processor associated with it; abusing the language, we identify a vertex or an edge with the corresponding processor. Each edge has, for each of its endpoints, a pointer to a record that stores the color of that vertex. If $\Delta(v)$ is the degree of a vertex v, then there are $\Delta(v)$ records containing the information related to v. Thus,

each edge can access its endpoints independently. An uncolored vertex has its color set to 0; a vertex that has been deleted by an earlier iteration of the top-level loop has its color set to -1.

A Pascal-like description of FINDSET is as follows:

```
function FINDSET(A);
begin
    k := |A|;      H := G[A];
    φ := trivial coloring of H;
    while Q(φ) < c0 k/log k do
        begin
            p:= the number of colors of φ_i;
            h := c1 k/(p log k);
            B := BUILD(φ, h);
            M := MATCH(B);
            φ := REDUCE(φ, h, M)
        end;
    C := a color class with Q(C) ≥ c0 k/log k;
    FINDSET := C
end;
```

In the description of FINDSET and MATCH we use two constants, c_0 and c_1; their values, which guarantee the necessary performance behavior, are defined in §3.

The function BUILD accepts a partial coloring ϕ and a number $h > 0$ and constructs the auxiliary graph $B(\phi, h)$. It does this by computing the values of the d_{ij} that are nonzero, and then finding out which d_{ij} and d_{ji} are both greater than h.

To calculate the d_{ij}, BUILD first creates a list of records containing, for each edge, its endpoints and their colors written in increasing order. Next, BUILD sorts this list lexicographically by color. Each interval of the resulting list consists of the edges with the endpoints colored by the same pair of colors. Let L_{ij} be the interval containing the edges whose endpoints are colored i and j. To calculate d_{ij}, BUILD sorts L_{ij} by the vertex colored j; the number of intervals of this list is the value of d_{ij}. Similarly, d_{ji} is the number of intervals that result when L_{ij} is sorted by the vertex colored i.

To find the intervals of a sorted list, every member of the list compares itself with the element on its right and the element on its left. This indicates the elements that are the ends of the intervals. Then, every other member assigns itself to the corresponding interval. This can be done in $O(\log n)$ time using the path-doubling technique of Wyllie [27].

```
function BUILD(φ, h);
begin
    L := a list of the edges with the colors of their endpoints
            listed in increasing order;
    sort L lexicographically by the colors of the endpoints;
    determine the set of intervals of L;
    for each interval L_ij in parallel do
        (* the subscripts i, j are the corresponding colors *)
        begin
            sort L_ij in increasing order of the endpoint colored by j;
            set d_ij to be the number of intervals of L_ij;
```

```
            sort L_ij in order of the endpoint colored by i;
            set d_ji to be the number of intervals of L_ij;
            if d_ij > h and d_ji > h then
                include (i, j) in E(B(φ, h));
        end;
end;
```

All sorts are done using Cole's algorithm [5]; thus, BUILD runs in $O(\log n)$ time on an EREW PRAM with a linear number of processors.

The idea of the procedure MATCH is as follows. Let the vertices of B be numbered by $0, 1, \cdots, p-1$, where $p = |V(B)|$, let K_p be the complete graph on $V(B)$, and let $\chi = p$ if p is odd, and $\chi = p-1$ if p is even. It is well known that there is a partition of the edges of K_p into χ matchings $P_0, P_1, \cdots, P_{\chi-1}$, each of size exactly $\lfloor p/2 \rfloor$. We give an explicit construction of such a partition in terms of the function "index" defined below, where the edge (i, j) is assigned to the matching $P_{\text{index}(i,j)}$. If the total number of edges of $\bar{B}$ is quadratic, the set $\bar{M}_t$ of the maximum size contains $\Omega(p)$ edges. For the same t, the size of M_t is a minimum. When such a t is found, we can check every of $\lfloor p/2 \rfloor$ pairs of $\bar{P}_t$ to compute $\bar{M}_t$.

```
function index(i, j, p);
begin
    if p is odd then
        index := (i + j) mod p
    else
        if j = p − 1 then
            index := 2i mod (p − 1)
        else
            index := index(i, j, p − 1)
        end;

function MATCH(B);
begin
    M := ∅; p := |V(B)|;
    if p is even then χ := p − 1 else χ := p;
    for each edge (i, j) of B in parallel
        compute index(i, j, p);
    for l := 0 to χ − 1 in parallel compute g(l)
        the number of edges (i, j) with index(i, j, p) = l;
    find t such that g(t) is minimized;
    compute M := P_t ∩ B̄;
    remove all but ⌈p(c_1 − c_0)/(2c_1)⌉ edges from M;
end;
```

Computing the number of the edges with a given index is done by sorting the edges of B according to their indices and then determining the lengths of all intervals. Finding a t for which the corresponding color class P_t contains the fewest number of edges can be done using Valiant's algorithm [24]. To determine $P_t \cap \bar{B}$, MATCH appends a list of edges in $P_t \cap B$ to the list of the edges in P_t. Then, the list is sorted lexicographically to bring the duplicates next to each other. If a pair (a, b) occurs in the list twice, then both occurrences are removed. The remaining pairs are a list of the edges in $\bar{B} \cap P_t$.

It turns out that the analysis is simpler if the matching returned by MATCH has a known size. We will show in §3 that, for our choice of c_0 and c_1, the size of $\bar{B} \cap P_t$ is at least $p(c_1 - c_0)/(2c_1)$. Thus, after removing a few edges from $\bar{B} \cap P_t$, MATCH returns a matching with exactly $\lceil p(c_1 - c_0)/(2c_1) \rceil$ edges. It is easy to see that every application of MATCH is executed on a linear number of processors in $O(\log n)$ time.

The matching M calculated by MATCH is used by REDUCE to construct a new partial coloring with a smaller number of color classes. In particular, REDUCE does the following three things:

(1) Decides which vertices are to be decolored;
(2) Merges the appropriate color classes; and
(3) Renumbers the color classes.

It is easy to implement REDUCE so that it runs in $O(\log n)$ time on a CRCW PRAM with a linear number of processors, which also yields an implementation on an EREW PRAM running in $O(\log^2 n)$ time. A more elaborate technique is needed to implement REDUCE so that it runs in $O(\log n)$ time on an EREW PRAM.

Intuitively, each vertex of color l needs to know which color, if any, is matched to l by M. We use a routine called BROADCAST to deliver this information. Specifically, BROADCAST is given a list L of ordered pairs of the form (l_i, m_i), where l_i is a color, m_i is a "message," and each color appears on the list at most once. The task of BROADCAST is to label each vertex of color l_i with the message m_i. For this purpose, BROADCAST first creates a new list L' with one record for each colored vertex. Each record is of the form (l_v, v), where l_v is the color of vertex v. Then, it sorts the concatenation of L' and L by color, that is by first coordinate; if two pairs from L and L', respectively, have the color, the pair from L is declared to be smaller. Next, BROADCAST uses the standard path-doubling technique to give m_i to each element of the list with color l_i. Finally, each element from L' that received a message labels its vertex with the message. Clearly, BROADCAST runs in $O(\log n)$ time and uses $O(n + m)$ processors.

In the context of REDUCE, the procedure BROADCAST is used to decide, for each edge $(i, j) \in M$, whether to decolor vertices with color i or with color j. Recall that the vertices of color j are decolored if and only if $d_{ij} \leq d_{ji}$. Both values d_{ij} and d_{ji} can either be obtained from BUILD, or REDUCE can calculate them itself. Having obtained these values, REDUCE orients each edge (i, j) of M so that $d_{ij} \leq d_{ji}$; hence the color of the vertices to be decolored is listed second. Then, REDUCE calls BROADCAST(M) to tell which vertices need to change color. If a vertex v receives a color l as a message, it checks to see if it has a neighbor of color l. If it does, it decolors itself; otherwise it changes its color to l.

Finally, REDUCE renumbers the surviving color classes by consecutive integers, starting with zero. This is necessary for the next application of MATCH to be done correctly. To do this, it sorts all the vertices by color and removes duplicates. The result is a list of all the colors in use. This list is then numbered, and the position of each color in the list is broadcast. Each colored vertex then changes its color to the color it receives.

A Pascal-like description of REDUCE is as follows:

```
function REDUCE(φ, h, M);
begin
    orient each edge (i, j) of M so that d_ij ≤ d_ji;
    BROADCAST(M);
    for each vertex v that received a color, l(v), in parallel do
```

```
            if v is adjacent to a vertex of color l(v)
                then decolor v
              else change the color of v to l(v);
        sort the vertices by their (new) colors;
        number the colors in use;
        make L, a list (l, n(l)), where n(l) is the number of l;
        BROADCAST(L);
        each colored vertex changes its color to the message it received;
    end;
```

3. Analysis. Our goal is to show that using $O(n+m)$ processors and in $O(\log^2 n)$ time FINDSET constructs an independent set C such that $|C \cup N(C)| > c_0 k/\log k$, where $|A| = k$ and c_0 is a constant. Once this is established, it is easy to see that FINDSET is called $O(\log^2 n)$ times and that the running time of the algorithm is $O(\log^4 n)$.

First, let us estimate the size of the set that MATCH returns. Recall that FINDSET calls MATCH on the graph $B(\phi, h)$. Let ϕ_i be the value of ϕ at the beginning of the ith iteration of the body of the *while* loop in FINDSET, and let p_i be the number of color classes in ϕ_i. If the body of the loop is executed then

$$Q(\phi_i) < \frac{c_0 k}{\log k}.$$

Let Δ_i be the maximum degree of a vertex in $B(\phi_i, h_i)$, where $h_i = c_1 k/(p_i \log k)$. If the degree, in B, of a vertex corresponding to a color class C is Δ_i, then $N(C)$ must contain at least $\Delta_i h_i$ vertices. On the other hand, $|N(C)| < c_0 k/\log k$. Therefore,

$$\Delta_i \frac{c_1 k}{p_i \log k} < \frac{c_0 k}{\log k}, \qquad \text{and} \qquad \Delta_i < \frac{c_0}{c_1} p_i.$$

This implies that the degree of every vertex of $\bar{B}(\phi_i, h_i)$, is at least $p_i(c_1 - c_0)/c_1$, yielding

$$|E(\bar{B}(\phi_i, h_i))| \geq \frac{c_1 - c_0}{2c_1} p_i^2.$$

Recall that MATCH divides the edges of $\bar{B}(\phi_i, h_i)$ into at most p classes and finds $P_t \cap \bar{B}$, the class with the most edges. Thus,

$$|P_t \cap \bar{B}| \geq \frac{c_1 - c_0}{2c_1} p_i,$$

and MATCH can discard edges from this set to return a matching M_i with

$$|M_i| = \frac{c_1 - c_0}{2c_1} p_i.$$

When REDUCE creates ϕ_{i+1}, it decolors at most

$$|M_i| \frac{c_1 k}{p_i \log k} = \frac{(c_1 - c_0)k}{2 \log k}$$

vertices and reduces the number of color classes to ap_i, where $a = (c_1 + c_0)/(2c_1)$. The initial partial coloring ϕ_0 has k color classes with a total of k vertices. Thus the

while loop in FINDSET will be executed at most $-\log k/\log a$ times. If none of the partial colorings ϕ_i with more than one color class satisfies

$$Q(\phi_i) \geq \frac{c_0 k}{\log k},$$

then FINDSET decolors at most

$$\frac{\log k}{-\log a}\frac{(c_1 - c_0)k}{2\log k}$$

vertices while reducing the number of color classes to one. Thus, the size of the only color class of the last coloring is at least

$$Q_0 = k - \frac{c_1 - c_0}{2}\frac{k}{\log k}\frac{\log k}{(-\log a)} = k - \frac{c_1 - c_0}{2}\frac{k}{(-\log a)}.$$

If we choose c_0 and c_1 such that

$$-\log a = \log\left(\frac{2c_1}{c_1 + c_0}\right) > (1+\epsilon)\frac{c_1 - c_0}{2c_1(1 - c_0)},$$

for some fixed $\epsilon > 0$, then

$$Q_0 > \frac{\epsilon}{1+\epsilon}k > \frac{c_0 k}{\log k},$$

for sufficiently large k. The criterion will be satisfied, for example, if $c_1 = 1$ and $c_0 = 1/3$.

Since every application of the *while* loop is executed in $O(\log n)$ time and the number of times the loop is iterated is $O(\log n)$, we have that the running time of FINDSET is $O(\log^2 n)$. It implies that the running time of the whole algorithm is $O(\log^4 n)$.

4. Open problems. This work addresses several interesting unresolved questions, including the following:

(1) The processor-time product for our algorithm is $O((n+m)\log^4 n)$. We would like to reduce the total amount of work that our algorithm does by reducing the number of processors it requires while not increasing its running time. We note that the technique developed by Miller and Reif in [20] does not seem to apply to this algorithm.

(2) There is a trivial sequential algorithm that colors a given graph G in at most $\Delta + 1$ colors, where Δ is the maximal degree of a vertex in G. Using the standard reduction of VC to MIS, we get an $\mathcal{NC}$-algorithm for $\Delta + 1$-coloring which is run on $O(n\Delta^2 + m\Delta)$ processors. However, no efficient $\mathcal{NC}$-algorithm for $\Delta + 1$-coloring is known.

(3) In [23] Túran proved that every graph with n vertices and m edges contains an independent set of size $\geq n^2/(2m+n)$. Such a set can be constructed by a linear sequential algorithm [13]. Can it be constructed by an $\mathcal{NC}$-algorithm using a linear number of processors? So far, the best approximation is achieved by an algorithm COLOR from [12]. It produces a coloring such that the size of at least one color class is $n/2$ if $m \leq n/4$, and $n^2/(32m)$ otherwise. The algorithm uses a linear number of processors and runs in $O(\log^3 n)$ time.

Acknowledgment. We are grateful to both referees for their helpful comments on the first version of this paper.

A DESIGN THEORY FOR SOLVING THE ANOMALIES PROBLEM*

EDWARD P. F. CHAN†

Abstract. A theory is proposed for designing database schemes that are free of update anomalies. Unlike previous approaches, insertion and deletion anomalies are investigated in the context of a relation scheme, while replacement anomalies are studied in the context of a database scheme. Two simple models are developed for analyzing when a relation scheme is free of insertion and deletion anomalies. Techniques are also proposed for obtaining desirable decompositions that are free of insertion and deletion anomalies. A class of database schemes that is free of replacement anomalies is also proposed. This class of schemes is highly desirable with respect to constraint enforcement when attribute values of some tuple are being changed. By making different assumptions on the modifiable attributes, several important classes of database schemes that are free of replacement anomalies are characterized. Throughout, we assume update operations are performed on relation schemes at the conceptual level.

Key words. schema design, update anomalies, relational database, functional dependencies

AMS(MOS) subject classification. H21

1. Introduction.

Database design theory began with the pioneering work of Codd [Cod1], [Cod2]. Codd observed that in the presence of functional dependencies, updating a relation at the conceptual level may result in certain problems that are widely known as *update anomalies* [Cod2]. Codd argued that the cause of such problems is due to several independent facts being stored in the same relation, causing the relation to be semantically overloaded. He proposed normalization as a way of separating independent facts into different relations and reducing logical data duplication. Since then, normalization has generated a great deal of interest among researchers as well as practitioners [Da], [Ma], [TL], [U]. Various normal forms and other desirable properties related to normalization have been proposed [ABU], [B], [BDB], [Cod1], [Cod2], [Cod3], [F1], [F2], [Z]. To illustrate the problem of update anomalies, let us consider the following example from Codd [Cod2].

Example 1. Let us consider $R(Emp, Dept, Manager, Contract\text{-}type)$, and let the functional dependencies imposed on R be $\{Emp \rightarrow Dept,\ Dept \rightarrow Manager\ Contract\text{-}type\}$. With this set of functional dependencies, the primary key of R is *Emp*. In this relation, Codd assumed the following facts or relationships are being stored: The *Emp_Dept* relationship, which tells the department for whom an employee is working; the *Dept_Manager* relationship, which gives the manager of each department; and the *Dept_Contract-type* relationship, which indicates the type of contracts a department is handling. For semantic reasons, Codd further assumed that each inserted tuple cannot be null on the primary key of the relation [Cod2]. Hence under Codd's assumptions, partial tuples are allowed in a relation, but the tuples cannot be null on the primary key. With these assumptions, certain problems arise when the relation is being updated.

When a new department is set up to handle a particular contract type, the data cannot be entered into R unless an employee has been hired for the new department. The cause of this problem is the assumption that tuples in a relation cannot be null on the primary key. This phenomenon may be considered an anomaly because setting

† Department of Computer Sciences, University of Alberta, Edmonton, Alberta, Canada T6G 2E9. Present address, Department of Computer Science, University of Waterloo, Waterloo, Ontario, Canada, N2L 3G1.

up a new department should not imply that some employee has been hired for the department. On the other hand, when the last employee working in a department is fired, the tuple representing the employee is deleted. Consequently, the associated department information will cease to exist. This event may again be considered an anomaly since department information should be independent of employee information. The inability to insert data into a relation and the unexpected deletion of data are widely known as *insertion anomalies* and *deletion anomalies*, respectively.

Now consider that the manager of a department is being replaced. Such a change necessitates a series of modifications to the manager for each employee working in that department. This event may again be considered an anomaly, since modifying an attribute value of a tuple results in an unpredictable number of tuples being updated. This phenomenon is called a *replacement anomaly* in the literature [BG], [LP]. □

Codd argued that the cause of updated anomalies is due to several independent facts being stored in the same relation. Normalization is an attempt to separate independent facts into different relations and to reduce logical data duplication using constraint information, such as functional dependencies. Until Bernstein and Goodman [BG] questioned the benefit of normalization, it was widely held that normalization eliminates update anomalies. In fact, normalization has *never* proven to solve the anomalies problem [BG], [LP]. The following example shows that a relation scheme R in BCNF does not necessarily mean that R is free of insertion and deletion anomalies.

Example 2. Let $R(Course, Student\_name, Grade)$ and $F = \{Course\ Student\_name \rightarrow Grade\}$. R clearly is in BCNF. If we assume that *Student_name* information can be recorded independently, then R has insertion and deletion anomalies since *Student_name* information cannot be inserted and deleted independently of $\{Course, Student\_name, Grade\}$. □

The above example illustrates that basic facts or relationships stored in a relation may not be completely determined by constraints like functional dependencies. To capture a portion of database semantics that is not captured by functional dependencies, Sciore [Sc] introduced *objects* to define basic facts in a relation. Maier and Ullman [MU] argued that not all objects can be related, and they suggested *maximal objects* to limit the scope of connections among objects. Maier and Warren [MW] went a step further by proposing a semantically richer model called the association-object data model. *Associations* are basic facts recorded in a database and are nondecomposable. *Objects* are decomposable relationships defined from associations. Various semantically motivated considerations have been discussed to constrain how objects and associations can be syntactically related. Desai, Goyal, and Sadri [DGS1], [DGS2] studied the problem of insertion and deletion anomalies, nevertheless, with assumptions that are different from Codd's. They introduced the *primary fact structure* of a relation as a semantic structure describing nondecomposable information represented by a relation. Primary fact structures are essentially associations in the association-object data model. Having introduced primary fact structures, Desai et al. investigated how to insert and delete facts from a relation without any "side effects." An important difference between Codd's assumptions and the aforementioned authors' assumptions is that Codd assumed each relation has a primary key, while the concept of key is not inherent in other approaches. Since our work is primarily based on Codd's assumptions, the problem as well as results obtained here are different from those mentioned above.

In this paper, we present an alternative to the update anomalies problem. In the same way as Bernstein and Goodman [BG], we view insertion and deletion anomalies as a problem that is different from replacement anomalies. For instance, if we assume in Example 1 that tuples are only inserted and deleted, but not modified, then the

insertion and deletion anomalies still exist but the replacement anomalies as conceived by Codd will disappear. Similarly to Codd [Cod2], we regard insertion and deletion anomalies as a problem of the ability of a relation scheme to record independent facts, whereas replacement anomalies are considered as a problem of independent modification of tuple values in relations. As we will show later, the replacement anomaly problem is closely related to the constraint enforcement problem. Because of this difference, insertion and deletion anomalies will mainly be analyzed in the context of a single relation scheme. On the other hand, it is not meaningful to discuss replacement anomalies with respect to a relation scheme; instead, we have to study the problem in the context of a database scheme.

In § 2, we define the necessary notation needed throughout this paper. In § 3, we investigate insertion and deletion anomalies. Depending on the assumption of whether null values are allowed in an inserted tuple, two simple models are developed for analyzing when a relation scheme is free of insertion and deletion anomalies. Techniques are also proposed for constructing desirable decompositions that are free of insertion and deletion anomalies. In § 4, we study replacement anomalies and show that this problem closely relates to the constraint enforcement problem. In view of the desirability of replacement-anomaly-freedom, we characterize several important classes of database schemes that are free of replacement anomalies. Finally, we give our conclusion in § 5.

2. Definitions and notation.

2.1. Basics. Following standard notation [Ma], [U], we fix a finite set of attributes $U = \{A_1, \cdots, A_n\}$ and call it the *universe*. We use $Z, Y, X, \cdots$ to denote sets of attributes in U and $A, B, C, \cdots$ to denote attributes in U. A *relation scheme* R is a subset of U. A *database scheme* $\mathbf{R} = \{R_1, \cdots, R_k\}$ is a collection of relation schemes such that the union of the R_i's is U.

Associated with each attribute $A_i \in U$ is a set of constants called the *domain* of A_i or dom (A_i). A *tuple* t over $R_i = \{A_1, \cdots, A_m\}$ is an element of dom $(A_1) \times \cdots \times$ dom (A_m). A *relation* r_i over R_i is a set of tuples over R_i. A *database state* for a database scheme $\mathbf{R}$ is a function r that maps every relation scheme R_i in $\mathbf{R}$ to a relation on R_i; we write $r = \langle r_1, \cdots, r_k \rangle = \langle r(R_1), \cdots, r(R_k) \rangle$.

If t is a tuple over R_i and X is a subset of R_i, $t[X]$ is the *restriction* of t to the attributes X. If r_i is a relation over R_i, the *projection* of r_i onto X is

$$\pi_X(r_i) = \{t[X] \mid t \in r_i\}.$$

Given a relation I defined on U and a database scheme $\mathbf{R} = \{R_1, \cdots, R_k\}$, $\pi_{\mathbf{R}}(I) = \langle \pi_{R_1}(I), \cdots, \pi_{R_k}(I) \rangle$.

2.2. Tableaux. Tableaux were originally proposed by Aho, Sagiv, and Ullman to represent relational expressions [ASU]. A *tableau* consists of a *body* and a possibly empty *summary row*. The body of a tableau is a relation over $U' = U \cup \{TAG\}$. Each tuple in the body is simply called a *row*. The tableau domain of $A_i \in U$, tdom (A_i), is the disjoint union of dom (A_i), the set $\{a_i\}$, where a_i is called the *distinguished variable* (dv) for A_i, and a countable set Ndv (A_i) of *nondistinguished variable* (ndv's) for A_i. The tag domain tdom $(TAG) = \mathbf{R} \cup \{\mathbf{U}\}$. The elements of tdom (A_i), for all $A_i \in U$, are ordered by a partial order $\ll$ such that we have the following:

- all elements of dom (A_i) are pairwise incomparable.
- $c \ll v$, for $c \in$ dom (A_i), $v \in$ tdom $(A_i) -$ dom (A_i).
- $a \ll b$, for a the dv for A_i, $b \in$ Ndv (A_i).
- Ndv (A_i) is a linear order set under $\ll$.

The summary row of a tableau is a tuple over a subset of U called the *target relation scheme.* Where it is defined, the summary row may contain only dv's and constants that appear in the body of the tableau. Let $\mathbf{R}=\{R_1, \cdots, R_k\}$. The tableau for $\mathbf{R}$, denoted by $T_{\mathbf{R}}$, is a tableau of k rows $t_1, \cdots, t_k$ such that $t_i[A]$ is a dv exactly when $A \in R_i$ and distinct ndv otherwise, for all $1 \leqq i \leqq k$. The summary row of $T_{\mathbf{R}}$ is a tuple of all dv's $\langle a_1, \cdots, a_n \rangle$.

Given a database state $r=\langle r_1, \cdots, r_k \rangle$, we define a tableau T_r on $U \cup \{TAG\}$ and call it *the tableau for database state r.* For each relation $r_i \in r$, and for each tuple $t \in r_i$, there is a row u in T_r corresponding to it. The tuple u is said to *originate* from r_i or R_i and is defined as follows:

- $u[R_i]=t$.
- $u[A]=b_{ij}$, b_{ij} is an ndv that appears nowhere else in T_r, $A \in U-R_i$.
- $u[TAG]=R_i$.

The summary of T_r is empty.

2.3. Dependencies and chasing. The kinds of constraints considered are functional dependencies (fd's) and join dependencies (jd's). Associated with each fd or jd is an F-rule or J-rule, respectively. Given a tableau T and a set of fd's and jd's Σ, we can use the J-rules to infer additional tuples that must be in T if it is to satisfy Σ, and the F-rules to infer equalities among symbols of T for the same reason. These transformation rules are defined as follows and their properties are described in [MMS].

F-rule: For each fd $X \to A$, there is an F-rule corresponding to it. Suppose a tableau T has rows t_1, t_2 that agree in all X-columns. Let v_1, v_2 be the values in the A-column of t_1, t_2, respectively. Furthermore, $v_1 \neq v_2$. Applying the F-rule corresponding to $X \to A$ to rows t_1, t_2 of T yields a transformed tableau S. S is the same as T except v_1, v_2 are replaced as follows. If one of v_1 or v_2 is a constant (or a dv) and the other is not, then replace all occurrences of the other by the constant (or the dv, respectively). If both are ndv's, then replace all occurrences of the variable with the higher subscript by the variable with the lower subscript. If both are distinct constants, the result of applying the rule is usually defined to be the empty tableau and an *inconsistency* is said to be found.

J-rule: Let $\mathbf{S}=\{S_1, \cdots, S_k\}$, with the union of S_i's yielding U. Rows $t_1, \cdots, t_k$ of T (not necessarily distinct) are joinable on $\mathbf{S}$ if there exists a row w not in T that agrees with t_i on S_i, $1 \leqq i \leqq k$. Row w is the result of joining t_i's. An application of the J-rule corresponding to the jd $\|\times\|\mathbf{S}$ allows us to take rows $t_1, \cdots, t_k$ of T that are joinable on $\mathbf{S}$ and to add their result w to T. The added tuple is assumed to have $\mathbf{U}$ as its tag.

Suppose Σ is a set of fd's and/or jd's. $CHASE_{\Sigma}(T)$ is the tableau obtained by applying the F-rules and/or J-rules corresponding to the members of Σ exhaustively to T.

Given a set of dependencies Σ, there are additional dependencies implied by this set in the sense that any relation that satisfies this set must also satisfy the additional dependencies. The set of dependencies that is logically implied by Σ is the *closure* of Σ, denoted by Σ^+. Σ is said to be *equivalent* to a set of dependencies Ψ if $\Sigma^+=\Psi^+$. A set G of fd's is a *cover* of F if G is equivalent to F. Given a set of attributes X, the *closure* of X with respect to Σ, denoted by X_{Σ}^+, is the set of attributes $\{A \mid X \to A \in \Sigma^+\}$. We shall use X^+, instead of X_{Σ}^+ if Σ is understood. Let Σ be a set of fd's F. If $A \in X^+$, then there is a sequence of fd's $Y_1 \to A_1, \cdots, Y_n \to A_n = A$ such that $Y_i \to A_i \in F$, for all i.

Let Σ be a set of dependencies defined on a relation scheme R. An fd $X \to A \in \Sigma^+$ is *nontrivial* if $A \notin X$. A set of fd's is *nontrivial* if each of its members is. An fd $X \to A \in \Sigma^+$ is *left-reduced* if $X \to A$ is nontrivial and there is no proper subset Z of X with $Z \to A \in \Sigma^+$. A set of fd's is said to be *left-reduced* if each of its elements is. $K \subseteq R$ is a *candidate key* of R if $K \to R \in \Sigma^+$ and there is no proper subset of K that has this property. $X \subseteq R$ is a *superkey* of R if X contains a candidate key of R. A relation scheme R is said to be in BCNF with respect to Σ if whenever $X \to A \in \Sigma^+$ is nontrivial implies X is a superkey of R. A relation scheme R is *single-key* with respect to Σ if X and Y are candidate keys of R implies $X = Y$.

Let Σ be a set of dependencies on the universe U and let $\mathbf{R} = \{R_1, \cdots, R_k\}$ be a database scheme on U. $\Sigma^+ | R_i$ denotes the set of dependencies in Σ^+ that is defined on R_i, for some $R_i \in \mathbf{R}$. $\Sigma^+ | R_i$ is the set of *projected* dependencies onto R_i. $\mathbf{R}$ is said to be *single-key* with respect to Σ if each of its relation schemes R_i is single-key with respect to $\Sigma^+ | R_i$. $\mathbf{R}$ is in BCNF with respect to Σ if each $R_i \in \mathbf{R}$ is in BCNF with respect to $\Sigma^+ | R_i$. $\mathbf{R}$ is said to be *cover embedding with respect to a set* fd's F if there is a cover G of F such that every $g \in G$ is embedded in some relation scheme in $\mathbf{R}$. G is said to be an *embedded cover* of $\mathbf{R}$. $\mathbf{R}$ is said to be *lossless* with respect to Σ if $CHASE_\Sigma(T_\mathbf{R})$ has a row of dv's. $\mathbf{R}$ is said to be *dependency preserving* or to *preserve a set of* fd's F if for any relation I on U, I satisfies F implies $\pi_{R_1}(I) \| \times \| \cdots \| \times \| \pi_{R_k}(I)$ also satisfies F [BMSU]. It has been proved that $\mathbf{R}$ is cover embedding implies $\mathbf{R}$ is dependency preserving [BMSU].

2.4. Consistency of data in a database. Let r be a state for a database scheme $\mathbf{R} = \{R_1, \cdots, R_k\}$. Let I be an instance defined on U. Then I is a *weak instance* for r with respect to a set of dependencies Σ if

- $\pi_{R_i}(I) \supseteq r_i$, for each $1 \leqq i \leqq k$.
- I satisfies Σ.

Under the *weak instance model*, a database state r is said to be *consistent* with a set of dependencies Σ if a weak instance exists for the state with respect to Σ [GMV], [H], [V]. Otherwise r is *inconsistent* with respect to Σ. It has been shown that $CHASE_\Sigma(T_r)$ is nonempty if and only if r is a consistent state [GMV]. $CHASE_\Sigma(T_r)$ is called *the representative instance for state r.*

3. Insertion and deletion anomalies. In the Introduction, we have argued that whether a relation exhibits insertion and deletion anomalies depends on the types of partial tuples allowed in the relation. Following other authors [BMSU], [DGS1], [DGS2], [LP], [MW], [MU], [Sc], we need an additional concept to capture the idea of "basic facts" in a relation. We shall borrow the concept of *insertion sets* [LP] to denote basic facts we want to store in a relation. Insertion sets are similar to update sets in [BMSU], except that insertion sets are basic units of insertion and deletion, but not of update. So insertion sets are primarily associations or primary fact structures referenced elsewhere in the literature [DGS1], [DGS2], [MW]. We also assume each tuple in a relation represents an identifiable object in the real world. Codd suggested that an identifiable object in a relation is represented by a primary key value. Consequently Codd's assumptions on relational systems are as follows [Cod2], [Cod4]. A relation scheme R is assumed to have a candidate key designated as the primary key of R. A relational system is assumed to allow users to insert partial tuples into a relation with the restriction that the primary key cannot contain any null value. On the other hand, when a tuple is deleted, the whole tuple will be removed.

Most existing relational systems, for instance SQL-lookalike systems, support Codd's assumptions. However, several researchers [LP], [M] have felt the assumption

that a partial tuple inserted into a relation must have non-null values on the primary key is too restrictive. Instead, they proposed that this assumption should be relaxed by requiring inserted tuples to be non-null on a candidate key only.

These two different sets of assumptions lead to two different models for analyzing insertion and deletion anomalies and they are presented, respectively, in the following two sections. In both cases, a definition of anomalies-freedom is first given. We then address the question of how to obtain a desirable anomalies-free decomposition from an anomalous relation scheme.

Since insertion and deletion anomalies deal with the problem of whether some facts could be inserted and deleted independently in a relation, we shall consider this problem within the context of a relation scheme in the remainder of this section.

3.1. The case of non-null primary key values. In this section, we study the case that when a partial tuple is inserted into a relation R, it must be non-null on the primary key of R. We first define when a relation scheme is free of insertion and deletion anomalies. We then investigate how to find a decomposition that is free of insertion and deletion anomalies from a relation scheme.

3.1.1. A definition of anomalies-free schemes. In this section, we first define when a relation scheme is free of insertion and deletion anomalies under our assumptions. We then compare our approach with classical normalization theory by showing the condition under which normalization guarantees the resulting decomposition is free of insertion and deletion anomalies.

We have shown in the Introduction that independent facts cannot always be represented by constraints such as functional dependencies. To solve the problem of insertion and deletion anomalies formally, we need to define explicitly the meaning of independent facts. Let X be a subset of a relation scheme R. We call X an *insertion set* (on R) if X denotes a nondecomposable relationship by which data may be recorded. Several authors have studied the problem of how to find insertion sets [DGS1], [DGS2], [MW], [Sc], while others have addressed the question of how to convert a decomposable fact into a collection of insertion sets [B], [BDB]. In this paper, we assume insertion sets have been identified and we shall concentrate on how to find desirable decompositions that are free of the anomalies problem.

Informally, a relation scheme R is free of insertion anomalies if tuples on any insertion set on R can be inserted independently into R. R is free of deletion anomalies if no fact on an insertion set on R is "unexpectedly" deleted. Following LeDoux and Parker [LP], we capture these ideas formally as follows. A relation scheme R is *anomalies-free* if every insertion set on R contains the primary key of R. First we want to argue that R is anomalies-free exactly when R does not exhibit insertion and deletion anomalies illustrated in Example 1.

From this definition, R is anomalies-free if and only if R is free of insertion anomalies. To show that R is anomalies-free exactly when it is free of deletion anomalies, let us consider the following. If R is anomalies-free, then deleting a tuple from R will delete facts that contain the same primary key value. Under the assumption of this model, a primary key value of a tuple represents an object and the nonprimary attribute values are properties of the object. Therefore deleting a tuple results in deleting an object and its associated properties from the database. Hence no fact on an insertion set on R is "unexpectedly" deleted. On the other hand, if R is not anomalies-free, then R has an insertion set I defined on it which does not contain the primary key of R. Since the primary keys of the relation schemes represent objects in the real world, I is an insertion set which is different from any insertion set on R containing the

primary key. As a result, deleting a tuple on R will result in deleting a fact on I that is supposed to have independent existence from any insertion sets containing the primary key of R. So some fact on I is deleted "unexpectedly" when the last tuple containing the fact is deleted from R. Therefore in the sense of Codd [Cod2], R is not free of deletion anomalies. Hence R is anomalies-free exactly when R is free of deletion anomalies. This shows that our definition captures the essence of insertion and deletion anomalies. A database scheme or a decomposition **R** is *anomalies-free* if each of its relation schemes R_i is anomalies-free.

In this model, determining if a relation scheme R exhibits insertion and deletion anomalies is simple once the primary key and the insertion sets are identified. Although constraints such as fd's do not play an explicit role in this model, it is often the case that fd's convey some information about insertion sets, and this is assumed in the older literature [BMSU], [B], [Cod2]. So it would be interesting to see how this relates to our work. Under this model, the following result characterizes when a relation scheme is anomalies-free if every nontrivial fd is assumed to be an insertion set on a relation scheme.

THEOREM 1. *Let R and Σ be a relation scheme and a set of constraints on R, respectively. Suppose every nontrivial* fd *represents an insertion set on R. R is anomalies-free if and only if for every nontrivial* fd $X \to A \in \Sigma^+$, *X does not contain the primary key implies $XA = R$.*

Proof. This theorem is proved by showing that every nontrivial fd embeds the primary key of R if and only if for every nontrivial fd $X \to A \in \Sigma^+$ such that X does not contain the primary key implies $XA = R$.

"If." The proof is trivial.

"Only if." Assume there exists some nontrivial fd $X \to A \in \Sigma^+$ such that X does not contain the primary key and $R - XA \neq \emptyset$. If XA does not contain the primary key, what we want to prove follows trivially. If XA embeds the primary key, then A is a primary key attribute since X does not contain the primary key. Since $R - XA \neq \emptyset$, let $B \in R - XA$. Since XA contains the primary key, $X \to B \in \Sigma^+$. By assumption, X does not embed the primary key and A is an attribute of the primary key, $X \to B \in \Sigma^+$ is a nontrivial fd that does not contain the primary key. Therefore in all cases, there is a nontrivial fd that does not embed the primary key of R. □

In many cases, an fd in a nontrivial cover denotes an insertion set [BMSU]: the following result characterizes when R is anomalies-free under such an assumption.

THEOREM 2. *Let R and F be a relation scheme and a set of nontrivial* fd's *on R, respectively. If every* fd $X \to A \in F$ *represents an insertion set on R, then R is anomalies-free if and only if for every $X \to A \in F$, XA embeds the primary key of R.*

Proof. The proof is trivial. □

From Theorems 1 and 2, if we assume nontrivial fd's denote insertion sets on a relation scheme, then the classes of anomalies-free relation schemes are subclasses of BCNF relation schemes.

3.1.2. Synthesizing anomalies-free decompositions by grouping. From § 3.1.1, there is a simple test to determine if a relation scheme is anomalies-free once the primary key and its insertion sets are identified. In this section, we consider the problem of constructing an anomalies-free decomposition from a relation scheme R using the insertion sets. We implicitly assume that candidate keys of insertion sets are given and we are free to choose any candidate key to be the primary key in the design of anomalies-free decompositions. The technique proposed here is to group together insertion sets with a common candidate key.

Given a relation scheme R and associated insertion sets D, then clearly D forms an anomalies-free decomposition of R. However, there are cases where such a design is poor. For example, suppose we have insertion sets AB and ABC, both with key A. Then all we really need is a relation over ABC. Similarly, if we have insertion sets AB and AC both with key A, it makes sense to combine them into a single relation ABC. Thus our goal is to decompose an anomalous relation scheme R into a *minimal* collection of anomalies-free schemes.

Minimality and anomalies-freedom are important criteria for a decomposition, as is the property of preserving insertion sets. An insertion set I is *preserved* in a decomposition if I is defined on some relation scheme. However, if I is defined on more than one relation scheme, then whenever tuples on I are inserted into the database, more than one relation is updated. Storing duplicate data at the conceptual level is not desirable in general; hence each insertion set should be defined on exactly one relation scheme in the decomposition.

D is an *insertion-set-preserving* decomposition of R if every insertion set on R is defined on exactly one element in **D**. A decomposition **D** of R is *minimal-insertion-set-preserving* if for all decompositions **E** of R with anomalies-free and insertion-set-preserving properties, $|\mathbf{D}| \leqq |\mathbf{E}|$. It is worth mentioning that the cardinality of a minimal-insertion-set-preserving decomposition of R is one if and only if R is anomalies-free.

In view of the desirability of minimal-insertion-set-preserving decompositions, it is interesting to know if a minimal-insertion-set-preserving decomposition **D** of R can be found efficiently. A straightforward solution is to identify all subsets S of candidate keys of the insertion sets such that every insertion set has at least one candidate key in the subset S. The candidate keys in such subset S partition the insertion sets into groups such that insertion sets in each group share a common candidate key. The union of elements in each group forms a relation scheme in an anomalies-free decomposition with the common candidate key designated as the primary key of the relation scheme. Each insertion set is defined on the relation scheme corresponding to the partition in which it is included. It is easy to verify that a decomposition formed this way is anomalies-free and insertion-set-preserving. We call this technique of finding minimal-insertion-set-preserving decompositions the *grouping* technique. Having found all such subsets, we select a subset S with minimal cardinality and the decomposition resulting from S is a minimal-insertion-set-preserving decomposition of R.

Example 3. Let $R(A, B, C, D)$ and the insertion sets be AB, AC, BC, and BD. Suppose every attribute functionally determines the others and therefore each attribute is a candidate key. Then a minimal subset of candidate keys such that the subset contains at least one candidate key from each insertion set is $S = \{B, C\}$. A partition induced by S is $\{AB, BD\}$ and $\{AC, BC\}$. Note that the partition induced is not unique. For instance, $\{AB, BD, BC\}$ and $\{AC\}$ is another partition induced by S. The resulting anomalies-free relation schemes from the former partition are ABD and ABC, with B and C as the primary keys of the relation schemes, respectively. The sets of insertion sets $\{AB, BD\}$ and $\{AC, BC\}$ are assumed to be defined on ABD and ABC, respectively. It is easy to see that $\{ABD, ABC\}$ is a minimal-insertion-set-preserving decomposition of R. If the partition $\{AB, BD, BC\}$ and $\{AC\}$ is used instead, the resulting minimal-insertion-set-preserving decomposition would be $\{ABCD, AC\}$. □

The above method of finding minimal-insertion-set-preserving decompositions requires exhaustively considering all subsets of candidate keys of the insertion sets; hence it may take exponential time. Unfortunately, there does not seem to be a polynomial-time algorithm for finding a minimal-insertion-set-preserving decomposi-

tion in general even if we assume the set of candidate keys can be found for each insertion set efficiently. This fact follows from the following theorem.

THEOREM 3. *Given a database scheme* $\mathbf{D} = \{\langle R_i, K_i\rangle \mid R_i$ *is a relation scheme and* K_i *is the set of candidate keys of* $R_i\}$. *Then the problem "Does there exist a subset* S *of* $\bigcup_i K_i$ *with size* n *such that for each* K_i, S *contains at least one element from* K_i?" *is* NP-*complete.*

Proof. The problem is obviously in NP, since we have only to select nondeterministically a subset S of size n from $\bigcup_i K_i$ and verify that S contains at least one element from each K_i. Clearly, the verification process can be done efficiently. We now present a polynomial-time reduction of a known NP-complete problem called the hitting set to our problem. The hitting set problem is formulated as follows. Given a family $\{V_1, \cdots, V_q\}$ subsets of $T = \{t_1, \cdots, t_p\}$, we must decide if there exists a subset W of T of size n such that for each V_i, W contains at least one element from V_i. Such a set is called a *hitting set of size n.* This problem can be found in [GJ] and was proved to be NP-complete in [K]. We now construct a polynomial-time algorithm that maps each instance of the hitting set problem to a corresponding instance of our problem.

Let T be the universe. For each i, $R_i = V_i$ and $K_i = V_i$. In other words, every attribute in a relation scheme is a candidate key of the relation scheme. This can easily be constructed by assuming each attribute in T functionally determines all other attributes. We want to show that $\mathbf{D}$ has a subset S of $\bigcup_i K_i$ with size n such that for each K_i, S contains at least one element from K_i if and only if T contains a hitting set of size n.

"If." Let W be a hitting set of size n. Let $S = W$. We want to show that S contains at least one element from each K_i. Since W is a hitting set, for each V_i, W contains at least one element from V_i. Since $V_i = K_i$, S contains at least one element from each K_i.

"Only if." Assuming that there is a subset S of $\bigcup_i K_i$ of size n such that for each K_i, S contains at least one element from K_i. Let $W = S$. Since $K_i = V_i$, W contains at least one element from each V_i. So W is a hitting set of size n. □

So given a set of insertion sets on R, even if we can find the candidate keys of each insertion set efficiently, it is highly unlikely that there is an efficient algorithm for finding a minimal-insertion-set-preserving decomposition of R. This is because solving this problem efficiently necessarily implies the problem in Theorem 3 can be solved efficiently. It is worth noting that the key-finding problem has also been proved to be NP-hard [BB]. In fact, we do not even know if the problem of finding a minimal-insertion-set-preserving decomposition is in NP.

COROLLARY 1. *Let* $\mathbf{S} = \{\langle S_i, K_i\rangle \mid S_i$ *is an insertion set and* K_i *is the set of candidate keys of* $S_i\}$ *be the set of insertion sets for a relation scheme* R. *Then given* $\mathbf{S}$, *the problem of finding a minimal-insertion-set-preserving decomposition of* R *is* NP-*hard.*

Proof. The proof follows directly from the above argument. □

Up to now, we only require an anomalies-free decomposition of R to be minimal. There are some other properties we may want a decomposition to have. For example, if we assume it is meaningful to have a tuple defined on the original relation scheme R, we may want the minimal-insertion-set-preserving decomposition to be lossless [ABU]. In view of existence of nonunique minimal-insertion-set-preserving decompositions, it is interesting to know if every such decomposition is equally desirable with respect to the losslessness criterion of the original scheme R. It should be clear that it is not always possible to construct a lossless decomposition from the insertion sets. For example, if the constraints are fd's and the insertion sets on R are disjoint, then

any insertion-set-preserving decomposition is lossy. So the question is: under what condition(s) do we have a lossless decomposition of R. It turns out there is a simple answer if the decomposition is anomalies-free and insertion-set-preserving.

THEOREM 4. *Let* **S** *be a set of insertion sets on a relation scheme* R, *and let* **D** *be any insertion-set-preserving and anomalies-free decomposition of* R. *Let* Σ *be the set of constraints on* R. **D** *is lossless with respect to* Σ *if and only if* **S** *is lossless with respect to* Σ.

Proof. First observe that since **D** is anomalies-free and insertion-set-preserving, every element D_i in **D** is a union of elements in **S** that share a common candidate key. So we can chase the tableau $T_{\mathbf{S}}$ to give an intermediate tableau that is equivalent to $T_{\mathbf{D}}$. It follows that $\Sigma \models \|\times\|\mathbf{R}$ if and only if $\Sigma \models \|\times\|\mathbf{S}$. □

Theorem 4 says that whether an insertion-set-preserving and anomalies-free decomposition is lossless depends solely on the given insertion sets. So any insertion-set-preserving and anomalies-free decomposition is equally desirable with respect to the losslessness criterion of R.

3.2. The case of non-null values on a candidate key. In § 3.1, an inserted tuple is assumed to have nonnull values on the primary key of the relation scheme. This basically is the assumption made by Codd on relational systems [Cod2], [Cod4]. Some authors [LP], [M] have felt that this assumption on an inserted tuple is too restrictive and they proposed an inserted tuple should be non-null on a candidate key only. This less restrictive assumption still allows tuples in a relation to be uniquely identified by a candidate key and yet this is more flexible than Codd's assumption with respect to tuple insertions. We study the insertion and deletion anomalies problem under this assumption in this section. We first give a definition of anomalies-free schemes. We then characterize when a relation scheme is anomalies-free if every functional relationship is assumed to be an insertion set on a relation scheme. Then, we investigate how a minimal-insertion-set-preserving decomposition is obtained from a relation scheme.

3.2.1. A definition of anomalies-free schemes. Since we now assume every tuple inserted into a relation must be non-null on a candidate key, we implicitly assume that candidate keys in a relation scheme are semantically equivalent and that they all represent the same object the relation is supposed to model. For example, assume the attributes *SIN* and *Emp-no* are both candidate keys in the EMP relation. Then, either *SIN* or *Emp-no* could be used to represent an employee in the company. Therefore, as long as an inserted tuple on EMP is nonnull on one of these two attributes, it is legal to insert it into the relation.

Using an analysis similar to the one given in § 3.1.1, the following definition captures the essence of anomalies-freedom. A relation scheme R is *anomalies-free* if every insertion set on R contains a candidate key of R. With this definition, the following result characterizes when a relation scheme is anomalies-free if every functional relationship on a relation scheme is assumed to be an insertion set.

THEOREM 5. *Let* R *and* Σ *be a relation scheme and a set of dependencies on* R, *respectively. Suppose every nontrivial* fd *on* R *represents an insertion set on* R. *Then* R *is anomalies-free if and only if* R *is in* BCNF *with respect to* Σ.

Proof. R is anomalies-free if and only if every nontrivial fd $X \to A \in \Sigma^+$ embeds a candidate key of R. Every nontrivial fd $X \to A \in \Sigma^+$ embeds a candidate key of R if and only if every nontrivial fd $X \to A \in \Sigma^+$ implies X contains a candidate key of R, and hence is a superkey of R. □

If every fd in a nontrivial cover F is assumed to represent an insertion set, the following characterizes when R is anomalies-free.

THEOREM 6. *Let R and F be a relation scheme and a set of nontrivial* fd*'s on R, respectively. Suppose every $X \to A \in F$ represents an insertion set on R. Then R is anomalies-free if and only if R is* BCNF *with respect to F.*

Proof. This follows from the fact that R is BCNF with respect to F exactly when every fd $X \to A \in F$ embeds a superkey of R. □

It is interesting to note that under a different model, Bernstein and Goodman [BG] have shown that BCNF relation schemes are exactly the class of anomalies-free schemes when fd's are given as constraints.

3.2.2. Synthesizing anomalies-free decompositions by merging. Suppose after the set of insertion sets on a relation scheme R is identified, R exhibits insertion and deletion anomalies. Then, as was argued in § 3.1.2, we would like to find a minimal-insertion-set-preserving decomposition for R. Notice that the definition of minimal-insertion-set-preserving decomposition is the same as the one given in § 3.1.2, except that the definition of anomalies-freedom is the one given in § 3.2.1. Because the definition of anomalies-frredom in § 3.1.1 implies the definition of anomalies-freedom in this section (but not vice versa), any insertion-set-preserving and anomalies-free decomposition under the previous model is an insertion-set-preserving and anomalies-free decomposition in this model. However, the converse does not hold.

Example 4. Let $R(A, B, C, D)$ and let the insertion sets be AB, ABC, CD with fd's $\{A \to BC, C \to AD\}$. The attributes A and C are the candidate keys of the insertion sets. Under the previous model, AB and ABC could be grouped together and a minimal-insertion-set-preserving decomposition is $\{ABC, CD\}$ with A and C as the primary keys in the corresponding relation schemes. Under the current model, $\{ABC, CD\}$ is an anomalies-free and insertion-set-preserving decomposition. The minimal-insertion-set-preserving decomposition is R, which clearly is not anomalies-free under the previous model. □

Example 5. Let $R(A, B, C, D)$, $F = \{A \to B, B \to C, C \to BD\}$ and the insertion sets be AB, BC, and CD. The only candidate key of R is A and since BC and CD do not contain A, R has the insertion and deletion anomalies problem. The decomposition that consists of AB (with candidate key A) and BCD (with candidate keys B and C) is a minimal-insertion-set-preserving decomposition of R. The sets of insertion sets $\{AB\}$ and $\{BC, CD\}$ are assumed to be defined on AB and BCD, respectively. □

It turns out that a minimal-insertion-set-preserving decomposition in this model can be found easily if the closure of a set of attributes with respect to Σ can be computed efficiently. The following algorithm is a method for obtaining such a decomposition and it is obtained by merging insertion sets.

ALGORITHM Merge.
Input: R, Σ and the insertion sets $I = \{I_1, \cdots, I_k\}$ on R.
Output: A minimal-insertion-set-preserving decomposition of R.
Method:
(1) Compute I_j^+ with respect to Σ, for all $1 \leqq j \leqq k$.
(2) Define a binary relation $\approx$ on I as follows. $I_i \approx I_j$ if $I_i^+ = I_j^+$, for all I_i and I_j in I. Clearly the relation $\approx$ is an equivalence relation. Let $[I_i]$ be the equivalence class of I_i with respect to $\approx$. Then $\cup [I_i]$ is a relation scheme in the decomposition. The insertion set I_i is assumed to be defined on $\cup [I_j]$.
(3) Output $\mathbf{D} = \{\cup [I_j] \mid I_j \in I\}$.

By step (2), the decomposition **D** output preserves insertion sets and is anomalies-free. **D** is insertion-set-preserving since the equivalence partitions I. **D** is anomalies-free

since each insertion set embeds a candidate key of the relation scheme on which it is defined. Let $\mathbf{S} = \{S_1, \cdots, S_m\}$ be a minimal-insertion-set-preserving decomposition for R. We want to show $\mathbf{D} = \mathbf{S}$. Let S_{j_1} and S_{j_2} be two insertion sets on S_j, for some $1 \leqq j \leqq m$. By the definition of anomalies-freedom, $S_{j_1}^+ = S_{j_2}^+$. Since $\mathbf{S}$ preserves insertion sets, let $I_i \in I$ be defined on S_j, for some $1 \leqq j \leqq m$. Then, elements in $[I_i]$ are defined on S_j, otherwise $\mathbf{S}$ is not minimal. By the definition of $[I_i]$ and the fact that $S_{j_1}^+ = S_{j_2}^+$, for all insertion sets S_{j_1} and S_{j_2} defined on S_j, it follows that $[I_i]$ is exactly the set of insertion sets defined on S_j. This shows that $\mathbf{D} = \mathbf{S}$. Therefore the minimal-insertion-set-preserving decomposition is unique. Once the insertion sets on a relation scheme are identified, whether the minimal-insertion-set-preserving decomposition can be obtained efficiently depends on the time complexity for computing the closure of a set of attributes with respect to Σ.

THEOREM 7. *The algorithm Merge correctly obtains a minimal-insertion-set-preserving decomposition for R and the decomposition is unique for R given the input.*

Proof. The proof follows directly from the above analysis. □

It is worth noting that relation schemes in a decomposition produced by Bernstein's synthesizing algorithm are anomalies-free if each embedded key dependency of a relation scheme denotes an insertion set on the relation scheme. Hence the synthesizing algorithm could be used in converting an anomalous relation scheme into an anomalies-free decomposition.

4. Replacement anomalies. Example 1 illustrated replacement anomalies, as conceived by Codd [Cod2]. In that example, a relation exhibits replacement anomalies if modification of a tuple on some attribute causes some constraints to be violated. Whether or not a relation exhibits replacement anomalies depends on its constraints as well as the set of attributes allowed to be modified in the relation. An attribute in a relation scheme that is allowed to be modified is said to be *updatable.*

We first give a definition that captures the essence of the replacement anomaly problem as illustrated in Example 1. Then we argue that unlike insertion and deletion anomalies, it is not meaningful to discuss replacement anomalies in the context of a single relation. Instead, this problem should be addressed in the context of a database scheme. As we will show later, the replacement anomaly problem is closely related to the constraint enforcement problem. We then give a more intuitively correct definition of replacement-anomaly-frredom. By varying the assumptions on the updatable attributes, several important classes of replacement-anomaly-free database schemes are characterized.

4.1. A definition of replacement-anomaly-free schemes. From Example 1, a relation scheme R that exhibits replacement anomalies implies that when some value of a tuple on R is changed, other tuples in the relation may be modified on the updated attribute. Consequently, an update on a tuple results in an unpredictable number of tuples being retrieved and changed. The following definition captures the essence of replacement-anomaly-freedom when a relation is considered. A relation scheme R is *replacement-anomaly-free* with respect to Σ if the resulting relation from a modification of a tuple in a satisfying relation is also satisfying with respect to Σ.

However, just requiring each relation to satisfy its projected or local dependencies is inadequate.

Example 6. Let $\mathbf{R} = \{R_1(\textit{Supplier}, \textit{City}), R_2(\textit{Supplier}, \textit{Status})\}$, and $F = \{\textit{Supplier} \rightarrow \textit{City}, \textit{City} \rightarrow \textit{Status}\}$. The *Supplier* attribute is the primary key of both relations. Suppose the only updatable attributes for R_1 and R_2 are *City* and *Status*, respectively. Because of the updatable attributes and since each relation is in BCNF, each relation scheme

is replacement-anomaly-free with respect to its projected fd's. Let us consider the following state:

Supplier	City	Supplier	Status
s_1	c	s_1	t_1
s_2	c	s_2	t_1

The given state is consistent with respect to the given fd's [GMV], [H]. Suppose now we change the status of supplier "s_1" located in city "c" from "t_1" to "t_2." To maintain the consistency of the state, all "t_1" values in r_2 should be changed to "t_2." Since more than one tuple is retrieved and updated, this database scheme is not free of replacement anomalies. □

Intuitively, a database scheme **R** is replacement-anomaly-free with respect to Σ if every update on a consistent state is legal and the database system is not required to retrieve any tuple from the state as a result of the update. In view of this, we now give a more appropriate definition that captures the intuition on replacement-anomaly-freedom.

A database scheme **R** is *replacement-anomaly-free* with respect to Σ if for every consistent state r, whenever a tuple t_i on some $R_i \in \mathbf{R}$ is modified on some updatable attribute A, the resulting state is also consistent with respect to Σ. So if a scheme is replacement-anomaly-free, then nothing needs to be done by the system with respect to consistency whenever an update is performed on a consistent state. In the remainder of this section, we first study some properties of replacement-anomaly-free schemes, we then characterize several important classes of replacement-anomaly-free database schemes.

4.2. Properties and characterizations of replacement-anomaly-free schemes.

4.2.1. Some necessary conditions and properties for replacement-anomaly-free schemes. In this section, we first identify some necessary conditions for a database scheme to be replacement-anomaly-free when a set of dependencies is given. In view of the importance of fd's and the full jd $\|\times\|\mathbf{R}$ [FMU], we then describe a condition under which the augmentation of fd's with the full jd $\|\times\|\mathbf{R}$ does not change the characterization of replacement-anomaly-free schemes.

A database scheme **R** is said to satisfy the *nondetermining and key-determined* condition with respect to Σ if for every $R_i \in \mathbf{R}$, and for every left-reduced fd $X \to A \in \Sigma^+ \mid R_i$, $B \in XA$ is updatable implies $A = B$, X is a candidate key of R_i and there is no other R_j that embeds XA, $i \neq j$. The following two examples illustrate why the above condition is necessary for replacement-anomaly-freedom.

Example 7. Let $\mathbf{R} = \{S(Project, Part, Cost)\}$ and $F = \{Part \to Cost\}$. The relation scheme S tells us what parts are used in which projects and at what prices. Suppose the updatable attribute is *Part*, we claim that **R** is not replacement-anomaly-free with respect to F. Consider the following consistent state $r = \langle s = \{t_1 = \langle pj_1, p_1, c_1\rangle, t_2 = \langle pj_2, p_2, c_2\rangle\}\rangle$. Suppose we change $t_1[Part]$ from p_1 to p_2, then the update gives rise to a violation of the fd $Part \to Cost$. On the other hand, if *Cost* is the only updatable attribute in **R**, then **R** still has replacement anomalies. Let us consider the following consistent state $r = \langle s = \{t_1 = \langle pj_1, p_1, c_1\rangle, t_2 = \langle pj_2, p_1, c_1\rangle\}\rangle$. If $t_1[Cost]$ is changed from c_1 to c_2, then the update maps r into an inconsistent state. This example illustrates that if **R** is replacement-anomaly-free, then for every nontrivial fd $X \to A \in \Sigma^+ \mid R_i$, $B \in XA$ and B is updatable necessarily implies $B = A$ and X is a candidate key of R_i. □

Example 8. Let $\mathbf{R} = \{S(Project, Part, Cost), T(Part, Cost)\}$ and $F = \{Part \rightarrow Cost\}$. Let us assume *Cost* in T is the only updatable attribute. Note that the attribute *Cost* is the right-hand side of the fd $Part \rightarrow Cost$ and *Part* is a candidate key of T. However, $\mathbf{R}$ is not replacement-anomaly-free since the relationship *Part_Cost* is also embedded in S and therefore we can easily construct a consistent state on $\mathbf{R}$ such that changing the *Cost*-component of some tuple in T will map the state into a state that violates the fd $Part \rightarrow Cost$. □

The following theorem proves that the nondetermining and key-determined condition is necessary for replacement-anomaly-freedom.

THEOREM 8. *Let* Σ *be a set of dependencies on* $\mathbf{R}$. *If* $\mathbf{R}$ *does not satisfy the nondetermining and key-determined condition with respect to* Σ, *then* $\mathbf{R}$ *is not replacement-anomaly-free with respect to* Σ.

Proof. If $\mathbf{R}$ violates the condition, then there is a $R_i \in \mathbf{R}$ that embeds a left-reduced fd $X \rightarrow A \in \Sigma^+$ and $B \in XA$ is updatable but $A \neq B$, or X is not a candidate key of R_i, or XA is embedded in some other relation scheme R_j. There are three possible cases to be considered.

Case 1. $A \neq B$. That is, there is some updatable attribute $B \in X$ in R_i. Let $I = \{t_1, t_2\}$ be such that t_1 and t_2 agree exactly on $\{X - \{B\}\}^+$ and distinct constants otherwise. Then chase I with respect to Σ to obtain $CHASE_\Sigma(I)$. By considering $CHASE_\Sigma(I)$ as an instance, $CHASE_\Sigma(I)$ is a satisfying relation with respect to Σ [BV], [MMS]. Since Σ does not imply the fd $(X - \{B\}) \rightarrow A$, t_1 and t_2 in $CHASE_\Sigma(I)$ disagree on A and B but agree on $(X - \{B\})$. Let $r = \pi_{\mathbf{R}}(CHASE_\Sigma(I))$. The state r is consistent with respect to Σ since $CHASE_\Sigma(I)$ is a weak instance for r. Note that $t_1[R_i]$ and $t_2[R_i]$ are two tuples in $r_i \in r$ and they agree on $(X - \{B\})$ but disagree on A and B. Since by assumption B is updatable in R_i, we change the B-component of $t_1[R_i]$ to the B-component of $t_2[R_i]$. Hence the tuples $t_1[R_i]$ and $t_2[R_i]$ in r_i violate the fd $X \rightarrow A \in \Sigma^+ \mid R_i$. This shows that $\mathbf{R}$ is not replacement-anomaly-free with respect to Σ.

Case 2. $A = B$ and X is not a candidate key of R_i. Let $I = \{t_1, t_2\}$ be such that t_1 and t_2 agree exactly on X^+ and distinct constants otherwise. As in Case 1, we first obtain $CHASE_\Sigma(I)$. By considering $CHASE_\Sigma(I)$ as a satisfying instance, let $r = \pi_{\mathbf{R}}(CHASE_\Sigma(I))$ and r is a consistent state with respect to Σ. By assumption, X is not a candidate key of R_i. This implies $t_1[R_i]$ and $t_2[R_i]$ are two distinct tuples in $r_i \in r$. By the construction of $CHASE_\Sigma(I)$, $t_1[R_i]$ and $t_2[R_i]$ agree on X. Since A is updatable in R_i, change the A-component of $t_1[R_i]$ to a constant that appears nowhere else. The resulting relation violates $X \rightarrow A \in \Sigma^+ \mid R_i$ and therefore the updated state is inconsistent with respect to Σ. Hence $\mathbf{R}$ is not replacement-anomaly-free with respect to Σ.

Case 3. $A = B$ and XA is embedded in some other relation scheme R_j. Let r be the consistent state constructed in Case 2. Since XA is embedded in both R_i and R_j, $t_1[R_i]$ and $t_1[R_j]$ are tuples in r_i and r_j, respectively, and they agree on XA. Since A is updatable in R_i, change the A-component of $t_1[R_i]$ to a constant that appears nowhere else. Clearly the state is inconsistent with respect to Σ. Hence $\mathbf{R}$ is not replacement-anomaly-free with respect to Σ. □

The following example illustrates another necessary condition for replacement-anomaly-freedom.

Example 9. Let $\mathbf{R} = \{R_1(Patient, Hospital), R_2(Patient, Doctor), R_3(Doctor, Hospital)\}$, and $F = \{Patient \rightarrow Hospital\ Doctor,\ Doctor \rightarrow Hospital\}$. R_1 records the registration information, and each patient registers in a unique hospital. R_2 stores the in-charge-of relationship, and each patient is assigned to a unique doctor. R_3 tells the

affiliation information, and each doctor is assumed to be associated with at most one hospital.

First observe that R_2^+ with respect to $\{Doctor \rightarrow Hospital\}$ contains R_1, and hence there are two different derivations of the functional relationship between *Patient* and *Hospital*. Let $r = \langle r_1 = \{\langle p, h\rangle\}, r_2 = \{\langle p, d\rangle\}, r_3 = \{\langle d, h\rangle\}\rangle$ be a consistent state on $\mathbf{R}$. If the attribute *Hospital* in R_1 is updatable, then the state r can be transformed into an inconsistent state by changing the *Hospital*-component of the tuple in r_1 to some other constant. This shows that $\mathbf{R}$ is not replacement-anomaly-free with respect to F. □

The following theorem formally states a necessary condition for replacement-anomaly-freedom illustrated in the example above.

THEOREM 9. *Let F be a set of* fd's. *Let $Z_1 \rightarrow A_1, \cdots, Z_n \rightarrow A_n$ be a sequence of* fd's *used in computing (partially or totally) the closure of $R_i \in \mathbf{R}$ such that each $Z_j \rightarrow A_j \in F^+$ and is embedded in some $R_{i_j} \in \mathbf{R}$. Suppose $R_i \cup Z_1A_1 \cup \cdots \cup Z_nA_n$ contains XB, where $X \rightarrow B \in F^+$ is a left-reduced* fd *embedded in some $R_p \in \mathbf{R}$, $p \neq i$. Moreover, for all $1 \leqq j \leqq n$, Z_jA_j embedded in $R_{i_j} = R_p$ implies Z_j is not a superkey of R_p. If some attribute of XB in R_p is updatable, then $\mathbf{R}$ is not replacement-anomaly-free with respect to F.*

Proof. By assumption that $X \rightarrow B$ is left-reduced, if X is not a candidate key of R_p or B is not the only updatable attribute of XB in R_p, then by Theorem 8, $\mathbf{R}$ is not replacement-anomaly-free with respect to F. In the remainder of this proof, we assume X is a candidate key of R_p and B is the only updatable attribute of XB in R_p.

We first construct a tagged satisfying universal relation T with $t_0, \cdots, t_{n+1}$ as its rows as follows: t_0 has zero exactly in R_i^+ with tag R_i. For each $Z_j \rightarrow A_j$, $1 \leqq j \leqq n$, there is exactly one row t_j in T with tag R_{i_j}. The tuple t_j has the constant zero exactly in Z_j^+ and distinct constants that otherwise appear nowhere else. The tuple t_{n+1} with tag R_p has zero exactly in X^+ and distinct constants that appear nowhere else otherwise. It can be shown that $\pi_U(T)$ is a satisfying relation with respect to F [GY].

Let us construct a consistent state r from T as follows. For each $R_k \in \mathbf{R}$, $r_k = \{t[R_k] \mid t \in T \text{ and } t[Tag] = R_k\}$. Since $\pi_U(T)$ is a satisfying relation, and hence a weak instance for r, r is consistent with respect to F. Next we want to show that r can be mapped into an inconsistent state with a modification on a tuple. First observe that by assumption on Z_jA_j, $t_{n+1}[R_p] \neq t_j[R_p]$, for any Z_jA_j embedded in R_p. By construction of r, $t_{n+1}[R_p] \in r_p$. Since B is updatable in R_p, change the B-component of $t_{n+1}[R_p]$ from zero to a constant w that appears nowhere else. Let s be the updated state. By assumption, $Z_1 \rightarrow A_1, \cdots, Z_n \rightarrow A_n$ is a sequence of fd's used in computing the closure of R_i and the closure contains XB, it is easy to see that during the chase process the tuple in the state tableau corresponding to $t_0[R_i]$ in s has the constants zero and w simultaneously assigned to $t_0[B]$. Hence s is not consistent with respect to F. Therefore $\mathbf{R}$ is not replacement-anomaly-free with respect to F. □

The following theorem describes a condition under which the augmentation of fd's with the full jd does not change the characterization of replacement-anomaly-free schemes. We need a result from [CM] before we give the theorem.

THEOREM 10. *Let $\mathbf{R}$ be dependency preserving with respect to F and $\Sigma = F \cup \{\|\times\|\mathbf{R}\}$. Let r be a state on $\mathbf{R}$. Then r is consistent with respect to F if and only if r is consistent with respect to Σ.*

Proof. See [CM] for the proof. □

THEOREM 11. *Let $\mathbf{R}$ be dependency preserving with respect to F and $\Sigma = F \cup \{\|\times\|\mathbf{R}\}$. Let Z_i be the set of updatable attributes in R_i, for all $R_i \in \mathbf{R}$. Then $\mathbf{R}$ is replacement-anomaly-free with respect to F if and only if $\mathbf{R}$ is replacement-anomaly-free with respect to Σ.*

Proof. "If." Let r be a consistent state with respect to F. By Theorem 10, r is consistent with respect to Σ. Suppose s is the state after a tuple in r has been updated

on some updatable attribute $A \in Z_i$, for some $R_i \in \mathbf{R}$. Since $\mathbf{R}$ is replacement-anomaly-free with respect to Σ, the updated state s is consistent with respect to Σ. By Theorem 10, s is consistent with respect to F. Hence $\mathbf{R}$ is replacement-anomaly-free with respect to F.

"Only if." Using an argument similar to the "if" part, it is easy to show that this implication also holds. □

4.2.2. Independent and γ-acyclic cover embedding BCNF schemes. In this section, we characterize two important classes of replacement-anomaly-free schemes. We show this result by proving that the nondetermining and key-determined condition is also sufficient for replacement-anomaly-freedom when the class of independent schemes and the class of γ-acyclic cover embedding BCNF schemes are considered.

Constraint enforcement is an important function in any database system. A class of database schemes known as independent schemes was proposed to allow efficient enforcement of constraints imposed on a database. Independent schemes were proposed independently by several researchers [GY], [IIK], [S1], [S3] and have been shown to be desirable with respect to query answering [AC], [IIK], [S3]. Let $\Sigma = F \cup \{\|\times\|\mathbf{R}\}$, where F is a set of fd's. A database scheme $\mathbf{R}$ is *independent with respect to* Σ if ensuring every relation $r_i \in r$ satisfies $\Sigma^+ | R_i$ guarantees that the state r is globally consistent with respect to Σ. It has been shown that $\Sigma^+ | R_i$ is a set of fd's embedded in R_i, for every $R_i \in \mathbf{R}$ [GY]. The following theorem shows that the nondetermining and key-determined condition characterizes replacement-anomaly-frredom when independence is assumed.

THEOREM 12. *Let* $\mathbf{R}$ *be independent with respect to* $\Sigma = F \cup \{\|\times\|\mathbf{R}\}$. $\mathbf{R}$ *is replacement-anomaly-free with respect to* Σ *if and only if* $\mathbf{R}$ *satisfies the nondetermining and key-determined condition with respect to* Σ.

Proof. "Only if." The "only if" part follows directly from Theorem 8.

"If." Let r be a consistent state with respect to Σ. Let $\Sigma^+ | R_i = F_i$ be the set of fd's embedded in R_i. Without loss of generality, we assume F_i is left-reduced. Suppose some tuple in $r_i \in r$ is updated on A and the updated relation violates some left-reduced fd $Y \to B \in F_i$. Clearly $A \in YB$. Since $\mathbf{R}$ is nondetermining and key-determined with respect to Σ, Y is a candidate key of R_i and $A = B$. Since the Y-column of r_i is not changed by the update, no two tuples in the updated relation agree on Y. We can conclude that the updated relation cannot violate the fd $Y \to B$. Hence after each update on some r_i, the resulting relation satisfies F_i. Since $\mathbf{R}$ is independent with respect to Σ, updates preserve the consistency of data in a database. Therefore $\mathbf{R}$ is replacement-anomaly-free with respect to Σ. □

Recently, the class of γ-acyclic cover embedding BCNF database schemes has been shown to be highly desirable with respect to query processing and constraint enforcement [CH]. With this class of schemes, Algorithm Enforce, shown in Fig. 1, is an incremental algorithm used to enforce satisfaction of fd's efficiently.

Let $\mathbf{R}$ be a γ-acyclic cover embedding BCNF database scheme with respect to F and let r be a consistent state of $\mathbf{R}$. Let r_p be a relation that is being changed by an insertion of a tuple t, where $r_p \in r$. Let $\{K_{p_1}, \cdots, K_{p_m}\}$ be the set of nontrivial candidate keys of R_p. A candidate key K of R is *nontrivial* if there is a nontrivial fd $K \to A$ embedded in R. It was proved in [CH] that Algorithm Enforce correctly determines if an updated state is consistent with respect to F.

Given this class of database schemes, the nondetermining and key-determined condition again characterizes the class of replacement-anomaly-free schemes with respect to $\Sigma = F \cup \{\|\times\|\mathbf{R}\}$.

Input: A consistent state r of a γ-acyclic cover embedding BCNF database scheme $\mathbf{R}$ with respect to F.
A tuple t to be inserted in $r_p \in r$, $R_p \in \mathbf{R}$.
Output: *No*, if $r \cup \{t\}$ is not consistent with respect to F; *yes* otherwise.
Notation: $\{K_{p_1}, \cdots, K_{p_m}\}$ is the set of nontrivial candidate keys of R_p.

```
(1) for each K_{p_i} do begin
(2)     for each A ∈ R_p − K_{p_i} do begin

FIG. 1. *Algorithm Enforce.*

THEOREM 13. *Let* $\mathbf{R}$ *be cover embedding* BCNF *with respect to* F *and is* γ*-acyclic.* $\mathbf{R}$ *is replacement-anomaly-free with respect to* F *if and only if* $\mathbf{R}$ *satisfies the nondetermining and key-determined condition with respect to* F.

Proof. "Only if." Follows from Theorem 8.

"If." Suppose we update a tuple of r_p in a consistent state on an attribute A. We can consider the update as a deletion followed by an insertion. Since under our assumption deletion does not map a consistent state to an inconsistent one, let us consider the insertion. If after the insertion some nontrivial key dependency $K_{p_i} \to B \in F^+ \mid R_p$ is violated, then by the nondetermining and key-determined condition, $A = B$. Hence the update did not change any value of K_{p_i} in r_p. By statement (4) in Algorithm Enforce (see Fig. 1), the updated relation r_p cannot violate $K_{p_i} \to B$. Hence after the insertion, the updated relation r_p satisfies the set of nontrivial key dependencies. Again by the nondetermining and key-determined condition, $K_{p_i} \to A$ is embedded in no other relation scheme. This implies the updated state is consistent with respect to F. Hence $\mathbf{R}$ is replacement-anomaly-free with respect to F. □

COROLLARY 2. *Let* $\mathbf{R}$ *be cover embedding* BCNF *with respect to* F *and be* γ*-acyclic. Let* $\Sigma = F \cup \{\|\times\|\mathbf{R}\}$. $\mathbf{R}$ *is replacement-anomaly-free with respect to* Σ *if and only if* $\mathbf{R}$ *satisfies the nondetermining and key-determined condition with respect to* F.

Proof. The proof follows directly from Theorems 11 and 13. □

4.2.3. A natural case. In § 4.2.1 and 4.2.2, no assumption is made on the updatable attributes. In many cases, a candidate key of a relation scheme is designated as the primary key of the relation scheme. The primary key of a relation scheme is used to represent an object or entity in the real world. Hence the primary key values cannot be modified by an application program [Cod4], [TL]. In this case, we assume every attribute in $R_i - P_i$ is updatable, where P_i is the primary key of R_i, for all $R_i \in \mathbf{R}$. In this section, we want to characterize when a cover embedding database scheme $\mathbf{R}$ is replacement-anomaly-free with respect to F. By Theorem 11, the characterization is also applicable when $F \cup \{\|\times\|\mathbf{R}\}$ is considered. We need the following results before we prove the characterization.

THEOREM 14. *Let* Σ *be a set of dependencies. Assume further that* $R_i - P_i$ *is the set of updatable attributes in* R_i, *where* P_i *is a candidate key of* R_i, *for all* $R_i \in \mathbf{R}$. *If* $\mathbf{R}$ *is replacement-anomaly-free with respect to* Σ, *then* $\mathbf{R}$ *is single-key with respect to* Σ.

Proof. Suppose there is $R_i \in \mathbf{R}$ such that R_i embeds two candidate keys. Let the candidate keys be X and Y. Without loss of generality, let X be P_i. Since X and Y

are two distinct candidate keys, there is an $A \in X - Y$. Since Y is a candidate key, $Y \to A$ is a nontrivial fd embedded in R_i. This implies there is a subset Z of Y such that $Z \to A$ is left-reduced. Since X cannot embed a nontrivial fd and $A \in X$, there is an attribute $B \in Z - X$. By assumption, B is updatable. Since $Z \to A$ is left-reduced, B is updatable and $A \neq B$, **R** violates the nondetermining and key-determined condition. By Theorem 8, **R** is not replacement-anomaly-free with respect to Σ. □

THEOREM 15. *Let Σ be a set of dependencies. Assume further that $R_i - P_i$ is the set of updatable attributes in R_i, where P_i is a candidate key of R_i, for all $R_i \in \mathbf{R}$. If* **R** *is replacement-anomaly-free with respect to Σ, then* **R** *is* BCNF *with respect to Σ.*

Proof. Suppose there is $R_i \in \mathbf{R}$, which is not in BCNF with respect to $\Sigma^+ | R_i$. That is, there is some nontrivial fd $X \to A \in \Sigma^+$ embedded in R_i but X is not a superkey, and hence is not a candidate key of R_i. Without loss of generality, we assume $X \to A$ is left-reduced. By assumption on the updatable attributes and the fact that the candidate key P_i cannot contain a nontrivial fd, some attribute $B \in XA$ is updatable. This implies **R** does not satisfy the nondetermining and key-determined condition. By Theorem 8, **R** is not replacement-anomaly-free with respect to Σ. □

For the class of cover embedding BCNF database schemes with respect to F, Sagiv has shown that independence is characterized by a condition known as the *uniqueness* condition [S1], [S2]. A database scheme **R** is said to satisfy the *uniqueness* condition if there is no R_i and R_j in **R**, $i \neq j$, such that $(R_i)^+_{F-F_j}$ embeds a nontrivial fd $K_j \to A \in F_j$, where F_j is the set of projected fd's on R_j. The following shows that under certain assumptions, independence is necessary for replacement-anomaly-freedom.

THEOREM 16. *Let* **R** *be cover embedding with respect to F. Assume further that $R_i - P_i$ is the set of updatable attributes in R_i, where P_i is a candidate key of R_i, for all $R_i \in \mathbf{R}$. If* **R** *is single-key* BCNF *and replacement-anomaly-free with respect to F, then* **R** *is independent with respect to F.*

Proof. Suppose **R** is not independent with respect to F. Since **R** is cover embedding BCNF and nonindependent with respect to F, **R** violates the uniqueness condition. That is, there are R_i and R_j, $i \neq j$, such that $(R_i)^+_{F-F_j}$ embeds a nontrivial fd $K_j \to A \in F_j = F^+ | R_j$, where K_j is a superkey of R_j. Since **R** is single-key with respect to Σ, A is updatable in R_j. Let $X_1 \to A_1, \cdots, X_p \to A_p$ be a sequence of fd's in F used in computing $(R_i)^+_{F-F_j}$. By the cover embedding property, we can assume each $X_q \to A_q$ embedded in some S_q, where $S_q \neq R_j$, for all $1 \leqq q \leqq p$. By Theorem 9, **R** is not replacement-anomaly-free with respect to F. □

THEOREM 17. *Let* **R** *be cover embedding with respect to F. Assume further that $R_i - P_i$ is the set of updatable attributes in R_i, where P_i is a candidate key of R_i, for all $R_i \in \mathbf{R}$.* **R** *is replacement-anomaly-free with respect to F if and only if* **R** *is single-key,* BCNF *and independent with respect to F.*

Proof. "If." Let t_i be a tuple of R_i in some consistent state that is being modified on some updatable attribute A. Since A is updatable, $A \in R_i - P_i$. Since **R** is single-key BCNF and independent with respect to F, the modified state is consistent with respect to F. Hence **R** is replacement-anomaly-free with respect to F.

"Only if." By Theorems 14 and 15, **R** is single-key and BCNF with respect to F. By Theorem 16, **R** is independent with respect to F. □

THEOREM 18. *Let* **R** *be cover embedding with respect to F and $\Sigma = F \cup \{\| \times \| \mathbf{R}\}$. Assume further that $R_i - P_i$ is the set of updatable attributes in R_i, for all $R_i \in \mathbf{R}$.* **R** *is replacement-anomaly-free with respect to Σ if and only if* **R** *is single-key,* BCNF *and independent with respect to F.*

Proof. First observe that the sets of fd's implied by F and Σ are identical [GY]. Then the theorem follows directly from Theorems 11 and 17. □

5. Conclusion. We have argued that normalization does not necessarily solve the problem of update anomalies. In view of this, we have studied this problem and proposed a theory for designing database schemes that are free of update anomalies.

Unlike Codd, LeDoux, and Parker [Cod2], [Cod3], [LP], we have viewed insertion and deletion anomalies as a problem that is different from replacement anomalies. Unlike Bernstein and Goodman [BG], we have regarded insertion and deletion anomalies as a problem of recording data in a relation, and replacement anomalies as a problem of independent modification of attribute values of a tuple in a consistent state. Because of the nature of these problems, we have studied insertion and deletion anomalies in the context of a single relation scheme. We have proposed two simple models for analyzing and designing desirable database schemes that are free of insertion and deletion anomalies. With the assumption that every embedded nontrivial fd represents a basic relationship in a database, we have shown that BCNF is a necessary condition for a relation scheme to be free of insertion and deletion anomalies. For replacement anomalies, it is closely related to the constraint enforcement problem and therefore it was analyzed in the context of a database scheme. Assuming any attribute is updatable, we have given some necessary conditions for a database scheme to be free of replacement anomalies. We also have characterized when an independent scheme or a γ-acyclic BCNF scheme is replacement-anomaly-free. In many cases, a candidate key of a relation scheme is assumed to be nonupdatable. Under this assumption, we proved that single-key, BCNF and independence characterize replacement-anomaly-freedom when the constraints considered are a set of embedded fd's. This characterization is also applicable when an embedded cover is augmented with the full jd $\|\times\|\mathbf{R}$.

Acknowledgments. The author is grateful to Héctor Hernández for his helpful comments on an initial draft of this paper. The author also thanks an anonymous referee, D. Wood, and J. D. Ullman for their constructive comments that greatly enhanced the readability of this paper.

ON TALLY RELATIVIZATIONS OF *BP*-COMPLEXITY CLASSES*

SHOUWEN TANG† AND OSAMU WATANABE‡

Abstract. It is known that $AM = BP \cdot NP$. Babai [Proc. 17th Annual ACM Symposium Theory of Computing, 1985, pp. 421-429] and Goldwasser and Sipser [Proc. 18th Annual ACM Symposium on Theory of Computing, 1986, pp. 59-68] asked whether $BP \cdot NP$ is equal to $\{A \mid$ for almost every set B, $A \in NP(B)\}$. This question is still open. In this paper it is shown that (1) for every $k \geqq 0$ and every set A, $A \in BP \cdot \Sigma_k^P$ if and only if for almost every tally set T, $A \in \Sigma_k^P(T)$, and (2) for every $k \geqq 0$ and almost every tally set T, $BP \cdot \Sigma_k^P(T) = \Sigma_k^P(T)$. From them are obtained some properties of the "*BP*-polynomial-time hierarchy" studied by Schöning [Proc. 2nd Annual Conference on Structure in Complexity Theory, 1987, pp. 2-8]. That is, the *BP*-polynomial-time hierarchy has the properties that are precisely parallel to those of the polynomial-time hierarchy. The proofs of these results provide examples of the use of properties of complexity classes specified by relativizations to obtain properties of unrelativized complexity classes.

Key words. probabilistic complexity classes, tally relativizations, random oracle sets

AMS(MOS) subject classifications. 68Q15, 68Q30, 03D15

1. Introduction. Baker, Gill, and Solovay [BGS75] have proved that there exists an oracle set A separating P and $NP: P(A) \neq NP(A)$. It is natural to ask about the number of oracle sets with this separating property. One way to measure the size of this class of sets has been used by Bennett and Gill [BG81]. The characteristic function of a language is an infinite string. Every language can be identified with a real number in the unit interval $[0, 1]$, and a class of languages is identified with a subset of the unit interval. The Lebesgue measure ν of that subset provides a natural way to measure the size of the corresponding class of languages. This measure corresponds to the Bernoulli independent testing sequence: a random language (infinite string) is the sequence that results from tossing an unbiased coin infinitely often. Bennett and Gill have shown that $\nu(\{B \mid P(B) \neq NP(B)\}) = 1$ and $\nu(\{C \mid P(C) = BPP(C)\}) = 1$; this can be described as that for a random oracle set B (or for "almost every" oracle set B), $P(B) \neq NP(B)$, and for a random oracle set C (or for "almost every" oracle set C), $P(C) = BPP(C)$. Following Yao's proof [Ya85] of the existence of an oracle set D such that $PH(D) \neq \text{PSPACE}(D)$, Cai [Ca86] and Babai [Ba87] have shown that for a random oracle set D, $PH(D) \neq \text{PSPACE}(D)$.

When studying probabilistic complexity classes and lowness properties, Schöning [Sc87] introduced the notion of the "*BP*-operator" and developed some properties of the "*BP*-polynomial-time hierarchy," that is, the variation of the polynomial-time hierarchy obtained by applying the "*BP*" operator to classes in that hierarchy. Babai [Ba85] introduced the class AM and, in addition, claimed that $BPP = \{A \mid$ for almost every set B, $A \in P(B)\}$. Ambos-Spies [Am86] showed that (i) $A \in P$ if and only if $A \leqq_m^P B$ for almost every B; (ii) $A \in BPP$ if and only if $A \leqq_T^P B$ for almost every B; and (iii) for almost every pair (B_1, B_2), $BPP = P(B_1) \cap P(B_2)$. (Kurtz [Ku87] also proved (ii) and (iii).) Babai [Ba85] and Goldwasser and Sipser [GS86] proposed the

following open problem: While $AM = BP \cdot NP$, is it the case that $AM = \{A \mid \text{for almost every set } B,\ A \in NP(B)\}$?

Consider the following two questions.

QUESTION 1. Can $BP \cdot \Sigma_k^P$ be characterized by means of oracles? That is, is it true that $A \in BP \cdot \Sigma_k^P$ if and only if for almost every oracle B, $A \in \Sigma_k^P(B)$?

QUESTION 2. What is the relation between relativizations of $BP \cdot \Sigma_k^P$ and Σ_k^P? Specifically, is it true that for almost every oracle B, $BP \cdot \Sigma_k^P(B) = \Sigma_k^P(B)$?

For Question 1, case $k = 0$ was solved by Ambos-Spies [Am86] and case $k \geqq 1$ is still open.[1] For Question 2, case $k = 0$ was solved by Bennett and Gill [BG81] and case $k \geqq 1$ was solved by Tang [Ta87].

In this paper, we introduce the concept of random tally sets and both Question 1 and Question 2 are solved for the tally oracle case (see Theorems 5.2 and 5.4). That is, we establish the following results.

(1) $A \in BP \cdot \Sigma_k^P$ if and only if for almost every tally oracle T, $A \in \Sigma_k^P(T)$;

(2) For almost every tally oracle T, $BP \cdot \Sigma_k^P(T) = \Sigma_k^P(T)$.

Note that in many cases the results for random *tally* oracle sets are independent from those for random oracle sets. For example, the above statement (2) with $k = 0$ is not a direct consequence of the result by Bennett and Gill [BG81] that $BPP(B) = P(B)$ for almost every oracle B. Also the statement (1) with $k = 1$ is not a complete answer to the original question of Babai and of Goldwasser and Sipser.

Compared with general relativizations, relativization with respect to a tally oracle set is "much closer" to the corresponding unrelativized case. For example, $P \neq NP$ if and only if there is a tally set T such that $P(T) \neq NP(T)$ [LS86]: thus, the existence of even one tally oracle that separates NP from P is not known, whereas $NP(B) \neq P(B)$ for almost every oracle B [BG81]. Similarly PH collapses if and only if there is a tally set T such that $PH(T)$ collapses; and $PH = \text{PSPACE}$ if and only if there is a tally set T such that $PH(T) = \text{PSPACE}(T)$ [BBS86], [LS86]. This suggests that the tally oracle is of special significance for the unrelativized case and the role of random tally sets as oracle sets should be investigated. Indeed, using the above two statements, we show that the BP-polynomial-time hierarchy has properties faithfully reflecting those of the polynomial-time hierarchy (see Theorems 5.6–5.9). That is, the properties established by relativization yield results for unrelativized cases.

The characterization of $BP \cdot \Sigma_k^P$ by statement (1) explicitly tells the difference between $\Sigma_k^P/poly$ and $BP \cdot \Sigma_k^P$. Take $k = 0$ as an example. A set L has polynomial-size circuits (belongs to $P/poly$: see, e.g., [BH77]) if and only if there is one tally set T such that L is in $P(T)$. On the other hand, a set L is in BPP if and only if for almost every tally set T, L is in $P(T)$. (Kämper [Kä87] also has observed this in his framework.)

This paper is organized as follows: In § 2 preliminaries are given. In § 3 the concept of random tally sets is introduced so that we can use the phrase "for almost every tally set." In § 4 we solve Questions 1 and 2 in a general setting. As a consequence of § 4, we get the desired results on BP-polynomial-time hierarchy in § 5.

2. Preliminaries. Let $\Sigma = \{0, 1\}$ so that Σ^* denotes the set of all finite strings over $\{0, 1\}$, with the empty word being denoted by ε. Let Σ^ω denote the set of all infinite sequences over $\{0, 1\}$. All languages will be assumed to be taken over Σ. The length of a string w is denoted by $|w|$. The cardinality of a set S is denoted by $\|S\|$. A *tally* set is a set of strings over $\{0\}^*$. We denote the class of all tally sets by $TALLY$. In this paper, let T with or without subscript always denote a tally set, and let $\mathcal{T}$ denote a

[1] Recently Nisan and Wigderson [NW88] solved this problem.

class of tally sets. If A is a language over Σ, then $\bar{A}$ denotes $\Sigma^* - A$, but if T is a tally set, then $\bar{T}$ denotes $\{0\}^* - T$. For a class $\mathscr{A}$ of languages over Σ and a class $\mathscr{T}$ of tally languages, we denote $\{\bar{A} \mid A \in \mathscr{A}\}$ by $\mathrm{co}-\mathscr{A}$ and $\{\bar{T} \mid T \in \mathscr{T}\}$ by $\mathrm{co}-\mathscr{T}$. In addition, $\mathscr{A}^c$ denotes $\{A \mid A \text{ is not in } \mathscr{A}\}$ and $\mathscr{T}^c$ denotes $\{T \in TALLY \mid T \text{ is not in } \mathscr{T}\}$.

Some fixed pairing function computable in polynomial time is assumed and is denoted by $\langle\ ,\ \rangle$. Furthermore, it is assumed that $\langle\ ,\ \rangle$ restricted to $\{0\}^* \times \{0\}^*$ takes values in $\{0\}^*$.

For an oracle machine M and a set A, M^A is the language accepted relative to A by M. For any set A, the class of functions that can be computed relative to A by polynomial time-bounded deterministic oracle transducers is denoted by $PF(A)$, and PF denotes the class $PF(\varnothing)$. Frequently, we will say "$f \in PF(-)$" to mean that f denotes a polynomial time-bounded oracle transducer. If $f \in PF(-)$, then for any set A, $f^A \in PF(A)$ denotes the function computed relative to A by the polynomial time-bounded transducer f. We will say "$f \in PF$" to mean that f denotes a polynomial time-bounded transducer or the function computed by such a transducer.

Classes in the polynomial-time hierarchy are denoted in the usual way: $\Sigma_0^P = \Delta_1^P = \Pi_0^P = P$, $\Sigma_{k+1}^P = NP(\Sigma_k^P)$, $\Delta_{k+1}^P = P(\Sigma_k^P)$, $\Pi_k^P = \mathrm{co}-\Sigma_k^P$, and $PH = \bigcup_{n \geqq 0} \Sigma_n^P$ [St77], [Wr77].

If $\mathscr{C}$ is a class of languages on Σ and $\leqq_R$ is a reducibility, we say that $\mathscr{C}$ is *closed under* $\leqq_R$ if $A \leqq_R B$ and $B \in \mathscr{C}$ imply $A \in \mathscr{C}$. There are two specific reducibilities that are of interest here.

(a) For sets A and B, define $A \leqq_{\mathrm{pos}}^P B$ (also written $A \in P_{\mathrm{pos}}(B)$) if $A \in P(B)$ is witnessed by a polynomial time-bounded oracle machine M with the property that $X \subseteq Y$ implies $M^X \subseteq M^Y$.

(b) For sets A and B, define $A \leqq_{\mathrm{maj}}^P B$ if there exists a function $f \in PF$ such that if $f(x) = y_1 \# y_2 \# \cdots \# y_t$, then $x \in A$ if and only if the majority of y_i's are in B.

It is easy to see that for any set A, all of $\Sigma_k^P(A)$, $\Pi_k^P(A)$, $\Delta_k^P(A)$, $PH(A)$, and PSPACE (A) are closed under $\leqq_{\mathrm{pos}}^P$. Note that $A \leqq_{\mathrm{maj}}^P B$ implies $A \leqq_{\mathrm{pos}}^P B$. If a class $\mathscr{C}$ is closed under $\leqq_{\mathrm{pos}}^P$, then $\mathscr{C}$ is also closed under $\leqq_{\mathrm{maj}}^P$. Thus, we see that for any set A, all of $\Sigma_k^P(A)$, $\Pi_k^P(A)$, $\Delta_k^P(A)$, $PH(A)$, and PSPACE (A) are closed under $\leqq_{\mathrm{maj}}^P$. Also, if $\mathscr{C}$ is closed under $\leqq_{\mathrm{maj}}^P$, then $\mathscr{C}$ is closed under $\leqq_m^P$.

In this paper, we first develop our results in general framework; then using this machinery, the classes in the polynomial-time hierarchy are observed. In order to discuss relativized complexity classes in general setting, we introduce the following notion and notation.

For language A, if $x \in A$, then $A(x) = 1$, else $A(x) = 0$. For language A and total function f, $A \circ f$ is a language B such that for all x, $B(x) = A \circ f(x)$: i.e., $B = A \circ f$ means $B \leqq_m A$ via f, or equivalently, $B = f^{-1}(A)$. So, for sets D and A, and oracle transducer f, $D \circ f^A$ is the language $\{x \mid D \circ f^A(x) = 1\}$.

DEFINITION 2.1. For language class $\mathscr{C}$ and class $\mathscr{F}$ of total functions, $\mathscr{C} \circ \mathscr{F}$ is the language class $\{A \circ f \mid A \in \mathscr{C}, f \in \mathscr{F}\}$.

It is clear from the definitions that the following hold:

(a) $\mathscr{C}$ is closed under $\leqq_m^P$ if and only if $\mathscr{C} \circ PF = \mathscr{C}$.

(b) $(\mathrm{co}-\mathscr{C}) \circ \mathscr{F} = \mathrm{co}-(\mathscr{C} \circ \mathscr{F})$.

(c) $(\mathscr{C} \circ \mathscr{F}_1) \circ \mathscr{F}_2 = \mathscr{C} \circ (\mathscr{F}_1 \circ \mathscr{F}_2)$.

For any set A and language class $\mathscr{C}$, we regard $\mathscr{C} \circ PF(A)$ as the relativized class of $\mathscr{C}$ with respect to A. Let us take $NP \circ PF(A)$ as an example. The decision problem in $NP \circ PF(A)$ can be done as follows: For a word x, first run a polynomial-time transducer f on x relative to A to get the output $y = f^A(x)$; then run an NP-machine M on y (without oracle); $x \in L$ if and only if M accepts y. Hence, $NP \circ PF(A) \subseteq NP(A)$.

However, the question of whether $NP \circ PF(A) = NP(A)$ is still open. In general we have that $\Sigma_k^P \circ PF(A) \subseteq \Sigma_k^P(A)$, but the equality problem is open. Nevertheless, $\Sigma_k^P \circ PF(T) = \Sigma_k^P(T)$ for every tally set T (see Lemma 5.1); hence, when considering tally oracles, the above notion is a reasonable abstraction for relativized complexity classes.

For any class $\mathscr{C}$ of languages, define $\mathscr{C}/poly$ to be the class of languages A such that for some $C \in \mathscr{C}$, some polynomial length-bounded function $h: \{0\}^* \to \Sigma^*$, and all x, $x \in A$ if and only if $\langle x, h(0^{|x|})\rangle \in C$.

The following relation is a generalization of a characterization of $P/poly$, and the proof is essentially the same as the one for $P/poly$ (see, e.g., [BH77]).

LEMMA 2.2. *If $\mathscr{C}$ is closed under $\leqq_m^P$, then $\mathscr{C}/poly = \mathscr{C} \circ PF(TALLY)$.*

Proof. Suppose that $A \in C/poly$. Then there exist $C \in \mathscr{C}$ and a polynomial length-bounded function h such that $A(x) = C(\langle x, h(0^{|x|})\rangle)$ for all x.

Let $T_h = \{\langle 0^n, 0^i, 0^b\rangle | b = 0 \text{ or } 1, \text{ the } i\text{th bit of } h(0^n) \text{ is } b\}$, and let $f^{T_h}(x) = \langle x, h(0^{|x|})\rangle$. Then $A = C \circ f^{T_h} \in \mathscr{C} \circ PF(TALLY)$.

Suppose that $A \in \mathscr{C} \circ PF(TALLY)$. Then there exists $C \in \mathscr{C}$, tally set T, and $f \in PF(-)$ such that $A \in C \circ f^T$. Let $p(n)$ be a polynomial that bounds the running time of f. Let $h(0^n) = T(\varepsilon)T(0)T(0^2) \cdots T(0^{p(n)})$. For any $z \in \Sigma^*$, let T_z denote the tally language with characteristic sequence $z0^\omega$. Let $g(\langle x, y\rangle) = f^{T_y}(x)$. Then $g \in PF$, h is polynomial length-bounded, and $f^T(x) = g(\langle x, h(0^{|x|})\rangle)$. Thus, $A(x) = C \circ f^T(x) = C \circ g(\langle x, h(0^{|x|})\rangle)$. Let $D = C \circ g$. Then $D \in \mathscr{C} \circ PF = \mathscr{C}$. Hence, $A(x) = D(\langle x, h(0^{|x|})\rangle)$ for all x, i.e., $A \in \mathscr{C}/poly$. □

For predicate P and natural number m, $\Pr_m[y: P(y)]$ is the conditional probability $\Pr[P/\Sigma^M] = 2^{-m} \times \|\{y \mid P(y) \text{ and } |y| = m\}\|$.

In this paper we focus on the operator "BP" defined by Schöning [Sc87] as follows: For language class $\mathscr{C}$, $BP \cdot \mathscr{C}$ is the class of languages A such that for some $C \in \mathscr{C}$, and polynomial $p(n)$, and all $x \in \Sigma^*$,

$$\Pr_{p(|x|)}[y: A(x) = C(\langle x, y\rangle)] > \tfrac{3}{4}.$$

It is clear that $BP \cdot P = BPP$ and $BP \cdot NP = AM$ (see [Sc87], [Ba85] for discussion about AM). However, we had better clarify the relativized case. Recall that for any sets A and L, $L \in BPP(A)$ if and only if there exists a nondeterministic oracle machine M that runs in polynomial time, has fan-out two, and has the following properties:

(i) $x \in L \Rightarrow$ more than $\frac{3}{4}$ of M's computations on x relative to A are accepting.

(ii) $x \notin L \Rightarrow$ less than $\frac{1}{4}$ of M's computations on x relative to A are accepting.

On the other hand, for a set A, $BP \cdot P(A)$ is the class of sets L such that there exist $D \in P(A)$ and polynomial $p(n)$ such that for all x

$$Pr_{p(|x|)}[y: L(x) = D(\langle x, y\rangle)] > \tfrac{3}{4}.$$

It is easy to prove that for every set A, $BPP(A) = BP \cdot P(A)$.

The following facts are immediate from the definitions:

(a) $BP \cdot \text{co}-\mathscr{C} = \text{co}-(BP \cdot \mathscr{C})$.

(b) $\mathscr{C} \subseteq \mathscr{D}$ implies $BP \cdot \mathscr{C} \subseteq BP \cdot \mathscr{D}$.

(c) If $\mathscr{C}$ is closed under padding (i.e., $A \in \mathscr{C}$ implies $\langle A, \Sigma^*\rangle \in \mathscr{C}$), then $\mathscr{C} \subseteq BP \cdot \mathscr{C}$.

Thus, we see that if $\mathscr{C}$ is closed under $\leqq_m^P$, i.e., $\mathscr{C} \circ PF = \mathscr{C}$, then $\mathscr{C} \subseteq BP \cdot \mathscr{C}$. From the above remarks, we see that if $\mathscr{C}$ is closed under $\leqq_{\text{pos}}^P$, then $\mathscr{C} \subseteq BP \cdot \mathscr{C}$.

Now we have the Amplification Lemma. While Schöning proved this under the hypothesis that $\mathscr{C}$ is closed under $\leqq_{\text{pos}}^P$, we state the result in terms of $\mathscr{C}$ being closed under $\leqq_{\text{maj}}^P$. The proof is essentially the same as that of Schöning and so is omitted.

LEMMA 2.3 (Amplification). *If $\mathscr{C}$ is closed under $\leqq^P_{\text{maj}}$, then for all $A \in BP \cdot \mathscr{C}$ and all polynomials $q(n)$, there is a set $B \in \mathscr{C}$ and a polynomial $p(n)$ such that for all $n \geqq 0$*

$$\Pr_{p(n)}[y: \forall x_{|x| \leqq n}(A(x) = B(\langle x, y\rangle))] > 1 - 2^{-q(n)}.$$

PROPOSITION 2.4. *If $\mathscr{C}$ is closed under $\leqq^P_{\text{maj}}$, then $BP \cdot \mathscr{C} \subseteq \mathscr{C}/poly$; thus $BP \cdot \mathscr{C} \subseteq \mathscr{C} \circ PF(TALLY)$.*

Proof. The proof is immediate from Lemmas 2.2 and 2.3. □

The following facts will be used or re-proved in later sections.

PROPOSITION 2.5 [Sc87].

(a) $\forall k \geqq 1$, $BP \cdot \Sigma^P_k \subseteq \Pi^P_{k+1}$.

(b) $\forall k \geqq 1$, $\Pi^P_k \subseteq BP \cdot \Sigma^P_k$ *implies* $PH = \Sigma^P_{k+1}$.

(c) $\forall k \geqq 0$, $\Sigma^P_2(BP \cdot \Sigma^P_k) = \Sigma^P_{k+2}$.

(d) $\forall k \geqq 1$, $\Sigma^P_2(BP \cdot \Sigma^P_k \cap BP \cdot \Pi^P_k) = \Sigma^P_{k+1}$.

(e) $PH = \bigcup_{k \geqq 0} BP \cdot \Sigma^P_k$.

Relationships between some of the above-mentioned classes are described in Fig. 1.

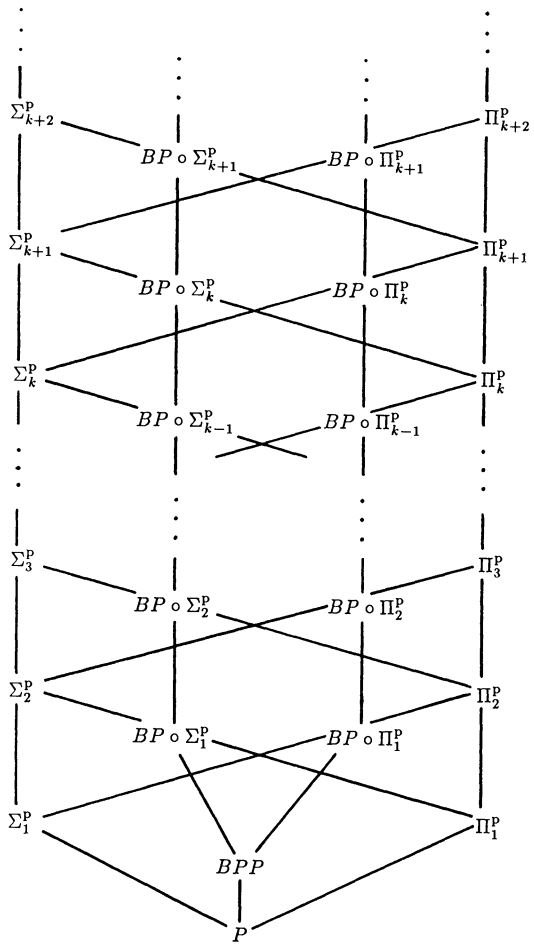

FIG. 1. *Polynomial hierarchy.*

PROPOSITION 2.6 [Ko82].
(a) $BPP(BPP) = BPP$.
(b) $NP \subseteq BPP$ *implies* $PH = BPP$.
PROPOSITION 2.7 [Za86], [ZF87].
(a) $\Sigma_1^P(BPP) \subseteq BP \cdot \Sigma_1^P \subseteq BPP(\Sigma_1^P)$.
(b) $BP \cdot \Sigma_1^P(BPP)\ (= AM(BPP)) = BP \cdot \Sigma_1^P$.

3. Random tally sets. One of the important tools in this paper is the notion of "random" tally sets. For every tally language $T \subseteq \{0\}^*$, let $\tau_T = b_0 b_1 b_2 b_3 \cdots \in \Sigma^\omega$ denote the characteristic sequence of T: $b_i = 1$ if and only if $0^i \in T$. Dually, for every $\alpha \in \Sigma^\omega$, let T_α denote the tally language with characteristic sequence α. For $z \in \Sigma^*$, T_z denotes T_α, where $\alpha = z0^\omega$. For $z \in \Sigma^*$ and $\alpha \in \Sigma^\omega$, $z \otimes \alpha$ denotes $z\beta$, where $\alpha = x\beta$ and $|x| = |z|$.

In the following, we will identify a tally language and its characteristic sequence: the power set of $\{0\}^*$ is identified with Σ^ω, and then any subset of Σ^ω is identified with a class of tally languages. Thus, $z \otimes T$ is well defined for word z and tally language T. For word z, let $\mathcal{R}_z = \{z\alpha \mid \alpha \in \Sigma^\omega\}$; thus, $\mathcal{R}_z$ is a "rectangular" infinite product in Σ^ω: $\mathcal{R}_z = \{z\}\Sigma^\omega = \{T \mid \tau_T = z\alpha \text{ for some } \alpha \in \Sigma^\omega\}$. Such an infinite product will be referred to as a *basic rectangle.*

In Σ, we define $\mu(\{0\}) = \mu(\{1\}) = \frac{1}{2}$. By taking the completion of the infinite product of this discrete measure (probabilistic) space, we have the measure of probability μ in Σ^ω. By identifying elements in Σ^ω and real numbers in the unit interval, μ can be interpreted as the Lebesgue measure in the unit interval. This means that for any fixed n, 0^n belongs to a random tally set T with probability $\frac{1}{2}$: $\mu(\{T \mid 0^n \in T\}) = \frac{1}{2}$. That is, we produce a random tally set T by an independent series of tosses of an unbiased coin: if the result of the nth tossing is "heads," then put 0^{n-1} into T; otherwise, do not put 0^{n-1} into T.

Since we identify a tally set and its characteristic sequence, we have $\mu(\mathcal{T}) = \mu(\{\alpha \in \Sigma^\omega \mid T_\alpha \in \mathcal{T}\})$ for a class $\mathcal{T}$ of tally sets. We will freely use either or both of these formulations in any given context.

For any string z of length n, $\mu(\mathcal{R}_z) = \frac{1}{2^n}$. For every n and m, $n \neq m$,

$$\begin{aligned}\mu(\{T \mid 0^n \in T, 0^m \in T\}) &= \mu(\{T \mid 0^n \in T, 0^m \notin T\}) \\ &= \mu(\{T \mid 0^n \notin T, 0^m \in T\}) \\ &= \mu(\{T \mid 0^n \notin T, 0^m \notin T\}) = \tfrac{1}{4},\end{aligned}$$

and for fixed T_0,

$$\mu(\{T \mid T_0 \subseteq T\}) = \mu(\{T \mid T_0 \cap T = \varnothing\}) = \begin{cases} 1/2^n & \text{when } \|T_0\| = n, \\ 0 & \text{when } \|T_0\| = \infty. \end{cases}$$

Recalling the notation for conditional probability, we have the following fact.

PROPOSITION 3.1. *For every integer* $m > 0$ *and predicate* P, $\Pr_m[y : P(y)] = \mu(\{y\alpha \mid |y| = m, \alpha \in \Sigma^\omega, \text{ and } P(y)\})$.

Recall that a class $\mathcal{C}$ of languages is closed under finite variation if for any $C \in \mathcal{C}$ and any finite set F, both $C \cup F$ and $C - F$ are in $\mathcal{C}$. Bennett and Gill [BG81] have claimed the following useful fact. (The following two facts are well known and can be found in any standard textbook on measure theory, e.g., [Ha50].)

PROPOSITION 3.2 (0-1 Law). *If* $\mathcal{T}$ *is a measurable class of tally sets that is closed under finite variation, then* $\mu(\mathcal{T}) = 0$ *or* $\mu(\mathcal{T}) = 1$.

Proof. Because $\mathcal{T}$ is closed under finite variation, we see that if $|y| = |z|$, then $\forall \alpha[y\alpha \in \mathcal{T} \Leftrightarrow z\alpha \in \mathcal{T}]$. Hence, $\mu(\mathcal{T} \cap \mathcal{R}_y) = \mu(\mathcal{T} \cap \mathcal{R}_z)$ if $|y| = |z|$; and so, $\mu(\mathcal{T} \cap \mathcal{R}_z) = \mu(\mathcal{T})\mu(\mathcal{R}_z)$ for all z. Thus, if $\mathcal{S}$ is a countable union of basic rectangles, then

$\mu(\mathcal{T}\cap\mathcal{S})=\mu(\mathcal{T})\mu(\mathcal{S})$. Since $\mathcal{T}$ is measurable, there exists a sequence $\mathcal{S}_1,\mathcal{S}_2,\cdots$ of countable unions of basic rectangles such that $\mathcal{S}_1\supseteq\mathcal{S}_2\supseteq\cdots\supseteq\mathcal{T}$ and $\mu(\mathcal{S}_n)\to\mu(\mathcal{T})$ as $n\to\infty$. Now, $\mu(\mathcal{T})=\mu(\mathcal{T}\cap\mathcal{S}_n)=\mu(\mathcal{T})\mu(\mathcal{S}_n)\to\mu(\mathcal{T})\mu(\mathcal{T})$ as $n\to\infty$. Thus, $\mu(\mathcal{T})=\mu(\mathcal{T})^2$. Therefore, $\mu(\mathcal{T})=0$ or $\mu(\mathcal{T})=1$. □

We will also use the following fact.

PROPOSITION 3.3. *If $\mathcal{T}$ is a class of tally sets such that $\mu(\mathcal{T})>0$, then there is a basic rectangle $\mathcal{R}_z$ such that $\mu(\mathcal{T}\cap\mathcal{R}_z)>(\frac{3}{4})\mu(\mathcal{R}_z)$.*

Proof. (Suppose that for all z, $\mu(\mathcal{T}\cap\mathcal{R}_z)\leqq(\frac{3}{4})\mu(\mathcal{R}_z)$. If $\mathcal{S}$ is a countable union of basic rectangles, then we have $\mu(\mathcal{T}\cap\mathcal{S})\leqq(\frac{3}{4})\mu(\mathcal{S})$. As in the proof of Proposition 3.2, $\mu(\mathcal{T})=\mu(\mathcal{T}\cap\mathcal{S}_n)\leqq(\frac{3}{4})\mu(\mathcal{S}_n)\to(\frac{3}{4})\mu(\mathcal{T})$ as $n\to\infty$. Hence, $\mu(\mathcal{T})\leqq(\frac{3}{4})\mu(\mathcal{T})$. Therefore $\mu(\mathcal{T})=0$, contradicting the hypothesis. □

Let $\mathcal{T}$ be a class of tally sets, or equivalently, a property for tally sets. If $\mu(\mathcal{T})=1$, we say that property $\mathcal{T}$ holds *for almost every tally set T.*

4. $BP\cdot\mathcal{C}$. In this section we investigate properties of classes of the form $BP\cdot\mathcal{C}$. Our first main result, Theorem 4.2, characterizes the assertion "$A\in BP\cdot\mathcal{C}$." Next, in Theorem 4.9, we show that $BP\cdot(\mathcal{C}\circ PF(T))=\mathcal{C}\circ PF(T)$ for almost every tally set T.

In the next section we apply these results to the situation where the class $\mathcal{C}$ is one of the well-studied complexity classes: P, NP, Σ_k^P, Δ_k^P, Π_k^P, PH, and PSPACE. Since we prove the results in this section with very few restrictions on the class $\mathcal{C}$, the results in the next section follow as simple corollaries with little or no additional proof needed.

As noted in § 2, we identify a tally set and its characteristic sequence so that we have $\mu(\mathcal{T})=\mu(\{\alpha\in\Sigma^\omega\mid T_\alpha\in\mathcal{T}\})$.

LEMMA 4.1. *Let $\mathcal{B}$ and $\mathcal{C}$ be countably infinite classes. For any set A, both of the classes $\{T\mid A\in\mathcal{C}\circ PF(T)\}$ and $\{T\mid\mathcal{B}\subseteq\mathcal{C}\cdot PF(T)\}$ are measurable and are closed under finite variation.*

Proof. It is easy to see that both of the classes are closed under finite variation. There are countably many sets in $\mathcal{C}$ and countably many oracle transducers so that it is sufficient to prove that for every $D\in\mathcal{D}$ and every $f\in PF(-)$, $\mathcal{T}=\{T\mid A=D\circ f^T\}$ is measurable.

Let $\mathcal{T}_n=\{\mathcal{T}\mid\forall x_{|x|\leqq n}[A(x)=D\circ f^T(x)]\}$. Then $\mathcal{T}_n$ is a finite union of basic rectangles since for all x with $|x|\leqq n$, $D\circ f^T(x)$ depends on only a finite prefix of T. Thus, $\mathcal{T}_n$ is measurable for all n. Note that $\mathcal{T}=\bigcap_{n\geqq0}\mathcal{T}_n$. Hence, $\mathcal{T}$ is measurable as desired.

That $\{\mathcal{T}\mid\mathcal{B}\subseteq\mathcal{C}\circ PF(T)\}$ is measurable follows from the fact that it is a countable intersection of classes $\{T\mid A\in\mathcal{C}\circ PF(T)\}$ for all $A\in\mathcal{B}$, and, as shown in the last paragraph, each such class is measurable. □

THEOREM 4.2. *If $\mathcal{C}$ is a countably infinite class that is closed under $\leqq^P_{\text{maj}}$, then $A\in BP\cdot\mathcal{C}$ if and only if $\mu(\{T\mid A\in\mathcal{C}\circ PF(T)\})=1$, that is, $A\in BP\cdot\mathcal{C}$ if and only if for almost every tally set T, $A\in\mathcal{C}\circ PF(T)$.*

Proof. Only if. Since $A\in BP\cdot\mathcal{C}$ and $\mathcal{C}$ is closed under $\leqq^P_{\text{maj}}$, the amplification lemma (Lemma 2.3) shows that there exist a polynomial $p(n)$ and a set $\mathcal{D}\in\mathcal{C}$ such that $\Pr_{p(n)}\{y\mid\forall x_{|x|=n}[A(x)=D(\langle x,y\rangle)]\}>1-2^{-(n+2)}$. Without loss of generality, we may assume that $p(n)\leqq p(n+1)$ and that if $|y|=p(|x|)$, then for all z, $D(\langle x,y\rangle)=D(\langle x,yz\rangle)$. Let $\mathcal{T}_n=\{\mathcal{T}_{y\alpha}\mid|y|=p(n),\quad\alpha\in\Sigma^\omega,\quad\forall x_{|x|=n}[A(x)=D(\langle x,y\rangle)]\}$. By Proposition 2.3,

$$\mu(\mathcal{T}_n)=\Pr_{p(n)}[y\mid\forall x_{|x|=n}[A(x)=D(\langle x,y\rangle)]]>1-2^{-(n+2)}.$$

Letting $\mathcal{T}=\bigcap_{n\geqq0}\mathcal{T}_n$, we have

$$\mathcal{T}=\bigcap_{n\geqq0}\mathcal{T}_n$$

$$= \{T_\alpha \mid \alpha \in \Sigma^\omega \text{ and } \forall x[A(x)$$
$$= D(\langle x, y\rangle)], \text{ where } y \text{ is the prefix of } \alpha \text{ of length } p(|x|)\}$$
$$= \{T \mid \forall x[A(x) = D(\langle x, T(\varepsilon)T(0)T(0^2)\cdots T(0^m)\rangle)], \text{ where } m = p(|x|)-1\}.$$

Then we have $\mu(\mathscr{T}^c) = \mu(\bigcup_{n\geq 0}\mathscr{T}_n^c) \leqq \sum_{n\geq 0}\mu(\mathscr{T}_n^c) < \sum_{n\geq 0}2^{-(n+2)} = \frac{1}{2}$. (Recall that $\mathscr{T}^c$ denotes $\{T \in TALLY \mid T \text{ is not in } \mathscr{T}\}$.) Thus, $\mu(\mathscr{T}) \geqq \frac{1}{2}$.

Let f be a polynomial time-bounded oracle transducer that has value $f^T(x) = \langle x, T(\varepsilon)T(0)T(0^2)\cdots T(0^m)\rangle$, where $m = p(|x|)-1$, i.e., $y = T(\varepsilon)T(0)T(0^2)\cdots T(0^m)$ is the prefix of length $m+1 = p(|x|)$ of τ_T. If $T \in \mathscr{T}$, then $\forall x[A(x) = D \circ f^T(x)]$; i.e., $A = D \circ f^T$. Hence, $\mu(\{T \mid A \in \mathscr{C} \circ PF(T)\}) \geqq \mu(\{T \mid A = D \circ f^T\}) \geqq \mu(\mathscr{T}) \geqq \frac{1}{2}$. By the 0-1 Law, this means that $\mu(\{T \mid A \in \mathscr{C} \circ PF(T)\}) = 1$.

If. Suppose that $\mu(\{T \mid A \in \mathscr{C} \circ PF(T)\}) = 1$. Then there exist a $D \in \mathscr{C}$ and a polynomial time-bounded oracle transducer f such that $\mu(\{T \mid A = D \circ f^T\}) > 0$.

Let $\mathscr{T} = \{T \mid A = D \circ f^T\}$. By Proposition 3.3, there is a basic rectangle $\mathscr{R}_z$ such that $\mu(\mathscr{T} \cap \mathscr{R}_z) > (\frac{3}{4})\mu(\mathscr{R}_z)$. Without loss of generality, we may assume that $\mu(\mathscr{T}) > \frac{3}{4}$ (for, consider transducer f' defined by $f'^T(x) = f^{z\otimes T}(x)$). Suppose that the running time of f is bounded above by the polynomial $p(n)$.

Let $C(\langle x, y\rangle) = D \circ f^{T_y}(x)$. Then $C \in \mathscr{C}$ because if g is defined by $g(\langle x\, y\rangle) = f^{T_y}(x)$, then $g \in PF$ and $C = D \circ g \in \mathscr{C} \circ PF = \mathscr{C}$. Thus, for all $x \in \Sigma^*$,

$$\begin{aligned}
&\Pr_{p(|x|)}[y \mid A(x) = C(\langle x, y\rangle)] \\
&\quad = \mu(\{T_{y\alpha} \mid |y| = p(|x|),\ \alpha \in \Sigma^\omega,\ A(x) = D \circ f^{T_y}(x) = D \circ f^{T_{y\alpha}}(x)\}) \\
&\quad = \mu(\{T_\beta \mid A(x) = D \circ f^{T_\beta}(x)\}) \geqq \mu(\{T_\beta \mid A = D \circ f^{T_\beta}\}) \\
&\quad = \mu(\{T \mid A = D \circ f^T\}) = \mu(\mathscr{T}) > \tfrac{3}{4}.
\end{aligned}$$

Hence, $A \in BP\cdot\mathscr{C}$. □

Recall that $A \in \mathscr{C}/\text{poly}$ if and only if $A \in \mathscr{C} \circ PF(T)$ for some tally set T (Lemma 2.2) and that $BP\cdot\mathscr{C} \subseteq \mathscr{C}/\text{poly}$ (Lemma 2.4). Comparing this fact with the above theorem, we see the difference between $BP\cdot\mathscr{C}$ and $\mathscr{C}/\text{poly}$.

COROLLARY 4.3. *If $\mathscr{C}$ is a countably infinite class and closed under $\leqq^P_{\text{maj}}$, then each of the following hold*:

(a) *$A \in BP\cdot\mathscr{C}$ if and only if $\mu(\{T \mid A \in \mathscr{C} \circ PF(T)\}) = 1$ if and only if $\mu(\{T \mid A \in \mathscr{C} \circ PF(T)\}) > 0$. That is, $A \in BP\cdot\mathscr{C}$ if and only if for almost every tally set T, $A \in \mathscr{C} \circ PF(T)$, and $A \notin BP\cdot\mathscr{C}$ if and only if for almost every tally set T, $A \notin \mathscr{C} \circ PF(T)$.*

(b) *$A \in PB\cdot\mathscr{C}$ if and only if there exists $C \in \mathscr{C}$ and $f \in PF(-)$ such that $\mu(\{T \mid A = C \circ f^T\}) > 0$.*

(c) *For any class $\mathscr{D}$, $\mathscr{D} \subseteq BP\cdot\mathscr{C}$ if and only if $\mu(\{T \mid \mathscr{D} \subseteq \mathscr{C} \circ PF(T)\}) = 1$ if and only if $\mu(\{T \mid \mathscr{D} \subseteq \mathscr{C} \circ PF(T)\}) > 0$; that is, $\mathscr{D} \subseteq BP\cdot\mathscr{C}$ if and only if for almost every tally set T, $\mathscr{D} \subseteq \mathscr{C} \circ PF(T)$.*

COROLLARY 4.4. *If $\mathscr{C}$ is a countably infinite class that is closed under $\leqq^P_{\text{maj}}$ and $\mathscr{D}$ is a countably infinite class, then $BP\cdot\mathscr{C} \subseteq \mathscr{D}$ implies $\mu(\{T \mid BP\cdot\mathscr{C} = \mathscr{D} \cap \mathscr{C} \circ PF(T)\}) = 1$.*

Proof. Let X denote the class $\mathscr{D} - BP \circ \mathscr{C}$. Since $BP\cdot\mathscr{C} \subseteq \mathscr{D}$, we have

$$\begin{aligned}
\{T \mid BP\cdot\mathscr{C} = \mathscr{D} \cap \mathscr{C} \circ PF(T)\} &= \bigcap_{A\in X}\{T \mid A \notin \mathscr{C} \circ PF(T) \text{ and } BP\cdot C \subseteq C \circ PF(T)\} \\
&= \bigcap_{A\in X}\{T \mid A \notin \mathscr{C} \circ PF(T)\} \cap \{T \mid BP\cdot\mathscr{C} \subseteq \mathscr{C} \circ PF(T)\}.
\end{aligned}$$

It follows from Corollary 4.3(a) and (c) that $\mu(\{T \mid A \notin \mathscr{C} \circ PF(T)\}) = 1$ for every $A \notin BP\cdot\mathscr{C}$ and that $\mu(\{T \mid BP\cdot\mathscr{C} \subseteq \mathscr{C} \circ PF(T)\}) = 1$. That is, the above class is a countable intersection of classes of measure one; hence, it has measure one. □

COROLLARY 4.5. *If $\mathscr{C}$ is countably infinite and closed under $\leqq^P_{\text{maj}}$, then* $(\mu \times \mu) \times (\{(T_1, T_2) \mid BP \cdot \mathscr{C} = \mathscr{C} \circ PF(T_1) \cap \mathscr{C} \circ PF(T_2)\}) = 1$.

Proof. From Corollary 4.3(c), $\mu(\{T_1 \mid BP \cdot \mathscr{C} \subseteq \mathscr{C} \circ PF(T_1)\}) = 1$; and from Corollary 4.4, for any T_1 such that $BP \cdot \mathscr{C} \subseteq \mathscr{C} \circ PF(T_1)$, $\mu(\{T_2 \mid BP \cdot \mathscr{C} = \mathscr{C} \circ PF(T_1) \cap C \circ PF(T_2)\}) = 1$. Then by Fubini's theorem [Ha50], $(\mu \times \mu) \times (\{T_1, T_2) \mid BP \cdot \mathscr{C} = \mathscr{C} \circ PF(T_1) \cap C \circ PF(T_2)\}) = 1$. □

Now we move to the next main theorem. In the proof of this theorem, we make use of the following technical lemma.

LEMMA 4.6. *For any T, let $L(T) \subseteq \Sigma^*$ denote a set determined by T. Let C and f be a set and a function in $PF(-)$, respectively. If for every T, $L(T) \leqq^P_{\text{maj}} C \circ f^T$ via some fixed $g \in PF$, then $L(T) = D \circ k^T$ for some $k \in PF(-)$ and $D \leqq^P_{\text{maj}} C$.*

Proof. Note that $L(T) \leqq^P_{\text{maj}} C \circ f^T$ via g means that if $g(x) = y_1 \# y_2 \# \cdots \# y_t$, then $x \in L(T)$ if and only if the majority of $f^T(y_1), f^T(y_2), \cdots, f^T(y_t)$ are in C.

Suppose that $q(n)$ and $r(n)$ are polynomials that bound the running times of f and g, respectively. Let $p(n) = q(r(n))$, so for each i and each T, $|f^T(y_i)| \leqq q(r(|x|)) = p(|x|)$. Let h be defined by $h(\langle x, z\rangle) = f^{T_z}(y_1) \# f^{T_z}(y_2) \# \cdots \# f^{T_z}(y_t)$, where $g(x) = y_1 \# y_2 \# \cdots \# y_t$. Then, $h \in PF$.

Let k be a polynomial time-bounded oracle transducer that on input x relative to oracle set T computes $\langle x, T(\varepsilon)T(0)T(0^2) \cdots T(0^m)\rangle$, where $m = p(|x|)$. Let $D = \{\langle x, z\rangle \mid$ the majority of the words in $h(\langle x, z\rangle)$ are in $C\} = \{\langle x, z\rangle \mid$ the majority of $f^{T_z}(y_1), \cdots, f^{T_z}(y_t)$ are in $C\}$. Then $D \leqq^P_{\text{maj}} C$ via h.

It is not difficult to show that for all T, $L(T) = D \circ k^T$: if $g(x) = y_1 \# y_2 \# \cdots \# y_t$, then $x \in D \circ k^T \Leftrightarrow k^T(x) \in D \Leftrightarrow \langle x, z\rangle = \langle x, T(\varepsilon)T(0)T(0^2) \cdots T(0^m)\rangle \in D$ (where $m = p(|x|)) \Leftrightarrow$ majority of $f^{T_z}(y_1) = f^T(y_1), \cdots, f^{T_z}(y_t) = f^T(y_t)$ are in $C \Leftrightarrow$ majority of $y_1, \cdots, y_t$ are in $C \circ f^T \Leftrightarrow x \in L(T)$. □

It is worth mentioning here that this lemma also proves that the closure property under $\leqq^P_{\text{maj}}$ of $\mathscr{C}$ is inherited by $\mathscr{C} \circ PF(T)$ and $BP \cdot \mathscr{C}$.

COROLLARY 4.7. *If $\mathscr{C}$ is closed under $\leqq^P_{\text{maj}}$, then so is $\mathscr{C} \circ PF(T)$ for every tally set T.*

Proof. Suppose that $A \leqq^P_{\text{maj}} C \circ f^T \in \mathscr{C} \circ PF(T)$ via $g \in PF$. For every tally set T_1, let $L(T_1) = \{x \mid$ the majority of words in $g(x)$ are in $C \circ f^{T_1}\}$. Hence, $A = L(T)$. By Lemma 4.6, there exist D and $k \in PF(-)$ such that $D \leqq^P_{\text{maj}} C$; hence $D \in \mathscr{C}$, and for every T_1, $L(T_1) = D \circ k^{T_1}$. Thus, $A = L(T) = D \circ k^T \in \mathscr{C} \circ PF(T)$, i.e., $\mathscr{C} \circ PF(T)$ is closed under $\leqq^P_{\text{maj}}$. □

COROLLARY 4.8. *If $\mathscr{C}$ is a countably infinite class that is closed under $\leqq^P_{\text{maj}}$, then so is $BP \cdot \mathscr{C}$.*

Proof. Suppose that $A \leqq^P_{\text{maj}} B$ for some $B \in BP \cdot \mathscr{C}$. Then it follows from Theorem 4.2 that $B \in \mathscr{C} \circ PF(T)$ for almost every tally set T. Since $A \leqq^P_{\text{maj}} B$ and $\mathscr{C} \circ PF(T)$ is closed under $\leqq^P_{\text{maj}}$, $A \in \mathscr{C} \circ PF(T)$ for almost every tally set T; again from Theorem 4.2, $A \in BP \cdot \mathscr{C}$. □

Now we have Theorem 4.9, our next main result of this section concerning the power of the BP-operator in tally relativizations. It is shown that the BP-operator does not increase the complexity of $\mathscr{C} \circ PF(T)$ for almost every tally set T. In other words, for almost every tally set T, $\mathscr{C} \circ PF(T)$ is a "fixed point" of the BP-operator.

THEOREM 4.9. *If $\mathscr{C}$ is countably infinite and closed under $\leqq^P_{\text{maj}}$, then $\mu(\{T \mid BP \cdot (\mathscr{C} \circ PF(T)) = \mathscr{C} \circ PF(T)\}) = 1$; that is, for almost every tally set T, $BP \cdot (\mathscr{C} \circ PF(T)) = \mathscr{C} \circ PF(T)$.*

Proof. By Corollary 4.7, we have that $\mathscr{C} \circ PF(T)$ is closed under $\leqq^P_{\text{maj}}$, for every tally set T; so, it is closed under padding. Thus, it follows from the fact concerning the BP-operator (see § 2) that $\mathscr{C} \circ PF(T) \subseteq BP \cdot (\mathscr{C} \circ PF(T))$.

In order to prove the reverse containment, let us first give some notation. For any set A and any polynomial $p(n)$, define $L_{\mathrm{maj}}(A, p(n))$ and $e(x, A, p(n))$ by

$$L_{\mathrm{maj}}(A, p(n)) = \{x \mid \Pr_{p(|x|)}[y: \langle x, y\rangle \in A] \geqq \tfrac{1}{2}\},$$
$$e(x, A, p(n)) = \min\{\Pr_{p(|x|)}[y: \langle x, y\rangle \in A], 1 - \Pr_{p(|x|)}[y: \langle x, y\rangle \in A]\}.$$

We call $e(x, A, p(n))$ the *error probability*. Note that for any tally set T,

$$BP\cdot(\mathscr{C} \circ PF(T)) = \bigcup_{p:\mathrm{poly}} \{L_{\mathrm{maj}}(C \circ f^T, p(n)) \mid C \in \mathscr{C}, f \in PF(-), \text{ and } \forall x[e(x, C \circ f^T, p(n)) < \tfrac{1}{4}]\}.$$

What we must prove is that for any $C \in \mathscr{C}$, any $f \in PF(-)$, and any polynomial $p(n)$,

$$\mu(\{T \mid \forall x[e(x, C \circ f^T, p(n)) < \tfrac{1}{4}] \Rightarrow [L_{\mathrm{maj}}(C \circ f^T, p(n)) \in \mathscr{C} \circ PF(T)]\}) = 1.$$

In the following, we shall see that this class is measurable.

For any choice of $C \in \mathscr{C}$, $f \in PF(-)$, and polynomial $p(n)$, we have the following fact.

CLAIM 1. For any integer $c > 0$, there exist $D \in \mathscr{C}$ and $g \in PF(-)$ such that for all x,

$$\mu(\{T \mid [e(x, C \circ f^T, p(n)) < \tfrac{1}{4}] \Rightarrow [x \in L_{\mathrm{maj}}(C \circ f^T, p(n)) \Leftrightarrow x \in D \circ g^T]\}) > 1 - 2^{-(c+2|x|)}.$$

Proof of Claim 1. Let $L(T) = \{\langle x, y_1, y_2, \cdots, y_t\rangle \mid t = 5(c+2|x|), \forall i_{1 \leqq i \leqq t} |y_i| = p(|x|),$ and the majority of the $\langle x, y_i\rangle$ are in $C \circ f^T\}$.

Obviously, $L(T) \leqq^P_{\mathrm{maj}} C \circ f^T$ via a fixed function in PF. By Lemma 4.6, there exist $D \in \mathscr{C}$ and $k \in PF(-)$ such that $L(T) = D \circ k^T$ for all T. It is easy to prove that for all x and T,

$$e(x, C \circ f^T, p(n)) < \tfrac{1}{4} \Rightarrow e(x, D \circ k^T, 5(c+2n)p(n)) < 2^{-(c+2|x|)}.$$

Let $q(n) = 5(c+2n)p(n)$. Suppose that $r(n)$ is a polynomial large enough such that we have the following:

(i) For all x and y, if $|x| = n$ and $|y| = q(n)$, then $k^T(\langle x, y\rangle)$ never queries the oracle about words of length greater than $r(n)$,

(ii) For all x and y, if $|x| = n$ and $|y| = p(n)$, then $f^T(\langle x, y\rangle)$ never queries the oracle about words of length greater than $r(n)$.

Let $h \in PF(-)$ behave as follows:

$$h^T(x) = \langle x, T(0^{(n)+1})T(0^{r(n)+2}) \cdots T(0^{r(n)+q(n)})\rangle \quad \text{where } n = |x|.$$

Let $g^T = k^T \circ h^T$. So $g \in PF(-)$.

We shall prove that D and g meet the requirement of Claim 1.

Note that $D \circ g^T(x) = D \circ k^T(\langle x, z\rangle)$ where $z = T(0^{r(n)+1})T(0^{r(n)+2}) \cdots T(0^{r(n)+q(n)})$, $n = |x|$.

Because $r(n)$ is large enough, we see that $e(x, C \circ f^T, p(n))$ and $e(x, D \circ k^T, q(n))$ depend only on $T^{\leqq r(|x|)}$. Thus, for any x, if we let $\mathscr{T} = \{T \mid [e(x, C \circ f^T, p(n)) < \tfrac{1}{4}] \Rightarrow [x \in L_{\mathrm{maj}}(C \circ f^T, p(n)) \Leftrightarrow x \in D \circ g^T]\}$, then we see that $\mathscr{T}$ is a finite union of basic rectangles. Since for any x and any T, $e(x, C \circ f^T, p(n)) < \tfrac{1}{4} \Rightarrow e(x, D \circ k^T, q(n)) < 2^{-(c+2|x|)}$, it follows that if $T^{\leqq r(|x|)}$ does not satisfy $e(x, C \circ f^T, (n)) < \tfrac{1}{4}$, then $T \in \mathscr{T}$. Furthermore, if $T^{\leqq r(|x|)}$ does satisfy $e(x, C \circ f^T, p(n)) < \tfrac{1}{4}$, then the next $q(|x|)$ bits in τ_T will determine whether $L_{\mathrm{maj}}(C \circ f^T, p(n))$ and $D \circ g^T$ agree on x. Only those situations that have the error probability $e(x, D \circ k^T, q(n))$ cause disagreement. Because $e(x, D \circ k^T, q(n)) < 2^{-(c+2|x|)}$, the ratio of the number of T's that agree (i.e., belong to $\mathscr{T}$) to the total number is greater than $1 - 2^{-(c+2|x|)}$.

Hence, $\mu(\mathscr{T}) > 1 - 2^{-(c+2|x|)}$. This concludes the proof of Claim 1.

CLAIM 2. For any integer $c > 0$, there exist $D \in C$ and $g \in PF(-)$ such that

$$\mu(\{T \mid \forall x[e(x, C \circ f^T, p(n)) < \tfrac{1}{4}] \Rightarrow [L_{\mathrm{maj}}(C \circ f^T, p(n)) = D \circ g^T]\}) > 1 - 2^{-c}.$$

Proof of Claim 2. The set $\{T \mid \forall x[e(x, C \circ f^T, p(n)) < \frac{1}{4}] \Rightarrow [L_{\text{maj}}(C \circ f^T, p(n)) = D \circ g^T]\}$ contains the intersection over all x of all of the classes studied in Claim 1. Thus, we have Claim 2.

To complete the proof of the theorem, note that for any integer $c > 0$,

$$\mu(\{T \mid \forall x[e(x, C \circ f^T, p(n)) < \tfrac{1}{4}] \Rightarrow [L_{\text{maj}}(C \circ f^T, p(n)) \in \mathscr{C} \circ PF(T)]\}) > 1 - 2^{-c}.$$

Since c is chosen arbitrarily, we have

$$\mu(\{T \mid \forall x[e(x, C \circ f^T, p(n)) < \tfrac{1}{4}] \Rightarrow [L_{\text{maj}}(C \circ f^T, p(n)) \in \mathscr{C} \circ PF(T)]\}) = 1. \qquad \square$$

COROLLARY 4.10. *If $\mathscr{C}$ is countably infinite and closed under $\leqq^P_{\text{maj}}$, then for almost every tally set T, $(BP \cdot \mathscr{C}) \circ PF(T) = BP \cdot (\mathscr{C} \circ PF(T))$.*

Proof. First, $(BP \cdot \mathscr{C}) \circ PF(T) \subseteq (\mathscr{C} \circ PF(T_1)) \circ PF(T)$ for every tally set T and almost every tally set T_1, since $BP \cdot \mathscr{C} \subseteq \mathscr{C} \circ PF(T_1)$ for almost every tally set T_1.

Second, $(\mathscr{C} \circ PF(T_1)) \circ PF(T) = (\mathscr{C} \circ PF(T)) \circ PF(T_1)$ for every tally set T_1 and T, since $PF(T_1) \circ PF(T_2) = PF(T_1 \oplus T_2)$ for every tally set T_1 and T_2.

By Corollary 4.3(c), we have $(BP \cdot \mathscr{C}) \circ PF(T) \subseteq BP \cdot (\mathscr{C} \circ PF(T))$ for every tally set T. Thus, $\mathscr{C} \circ PF(T) \subseteq (BP \cdot \mathscr{C}) \circ PF(T) \subseteq BP \cdot (\mathscr{C} \circ PF(T))$ for every tally set T. By Theorem 4.9, for almost every tally set T, $\mathscr{C} \circ PF(T) = BP \circ (\mathscr{C} \circ PF(T))$. $\square$

Although we have the equality $(BP \cdot \mathscr{C}) \circ PF(T) = BP \cdot (\mathscr{C} \circ PF(T))$ for almost every tally set T, it is left open whether this equality holds for all tally sets.

5. Polynomial complexity classes. In this section we have the main results on classes such as Σ^P_k, Π^P_k, Δ^P_k, *PH*, and PSPACE. To a large extent the results follow from Theorem 5.2 below, and the proof of that result is immediate from the corollaries of Theorems 4.2 and 4.9 and Lemma 5.1. The proof of Lemma 5.1 is immediate from the definition of the $\mathscr{C} \circ \mathscr{F}$ and the fact that every tally set is "self-P-printable," i.e., for every tally set T, there is a polynomial time-bounded oracle transducer that on input 0^n, $n \geqq 0$, will compute relative to T the list of all strings in T of length at most n.

LEMMA 5.1. *Let T be a tally set and let $\mathscr{C}$ be any of the classes Σ^P_k, Π^P_k, Δ^P_k, PH, or* PSPACE, *$k \geqq 0$. For any set L, $L \in \mathscr{C}(T)$ if and only if there exists $f \in PF(T)$ and $D \in \mathscr{C}$ such that $(\forall x)[x \in L \Leftrightarrow f(x) \in D]$. That is, for every tally set T, $\mathscr{C}(T) = \mathscr{C} \circ PF(T)$.*

Because each of the classes Σ^P_k, Π^P_k, Δ^P_k, *PH*, and PSPACE is countable and closed under $\leqq^P_{\text{pos}}$, and hence is closed under $\leqq^P_{\text{maj}}$; all of the results in § 4 can be applied to these classes. Thus, we can focus our attention on the interpretation of the results developed in § 4 in the context of these classes. The main result is the next two theorems.

THEOREM 5.2. *For every integer $k \geqq 0$, each of the following hold*:

(a) *For every set A, $A \in BP \cdot \Sigma^P_k$ if and only if for almost every tally set T, $A \in \Sigma^P_k(T)$.*

(b) *For any countable class $\mathscr{D}$, $\mathscr{D} \subseteq BP \cdot \Sigma^P_k$ if and only if for almost every tally set T, $\mathscr{D} \subseteq \Sigma^P_k(T)$.*

(c) *For almost every pair (T_1, T_2) of tally sets, $BP \cdot \Sigma^P_k = \Sigma^P_k(T_1) \cap \Sigma^P_k(T_2)$.*

(d) *For any countable class $\mathscr{D}$ such that $BP \cdot \Sigma^P_k \subseteq \mathscr{D}$, $BP \cdot \Sigma^P_k = \mathscr{D} \cap \Sigma^P_k(T)$ for almost every tally set.*

Proof. In each case the proof follows from Lemma 5.1 and the corresponding part of Corollary 4.3. $\square$

The above statements characterize the class $BP \cdot \Sigma^P_k$ from several points of view. Parts (a) and (b) of this theorem are basic characterizations and are used in the following discussion. Part (c) concerns the problem of finding a minimal pair [Ro67] in the context of complexity theory. Ambos-Spies [Am86] and Kurtz [Ku87] have shown the existence of a minimal pair for the class *BPP* (with respect to Turing reductions). Part (c) states the existence of a *tally* minimal pair for each $BP \cdot \Sigma^P_k$ with respect to Σ^P_k-reductions.

For example, by letting $k=0$ or 1 in this theorem, we have the following characterizations of BPP $(=BP\cdot P)$ and AM $(=BP\cdot NP)$.

COROLLARY 5.3. (a) *For every set A, $A\in BPP$ if and only if for almost every tally set T, $A\in P(T)$.*

(b) *For almost every pair (T_1, T_2) of tally sets, $BPP=P(T_1)\cap P(T_2)$, so (T_1, T_2) is a $\leqq_T^P$-minimal pair for BPP.*

(c) *For any countable class $\mathscr{D}$ such that $BPP\subseteq\mathscr{D}$, $BPP=\mathscr{D}\cap P(T)$ for almost every tally set.*

(d) *For every set A, $A\in AM$ if and only if for almost every tally set T, $A\in NP(T)$.*

(e) *For almost every pair (T_1, T_2) of tally sets, $AM=NP(T_1)\cap NP(T_2)$, so (T_1, T_2) is a $\leqq_T^{NP}$-minimal pair for AM.*

(f) *For any countable class $\mathscr{D}$ such that $AM\subseteq\mathscr{D}$, $AM=\mathscr{D}\cap NP(T)$ for almost every tally set.*

THEOREM 5.4. *Let k be any nonnegative integer. For almost every tally set T, $BP\cdot\Sigma_k^P(T)=\Sigma_k^P(T)$.*

Proof. The proof is immediate from Lemma 5.1 and Theorem 4.9. □

COROLLARY 5.5. (a) *For almost every tally set T, $BPP(T)=P(T)$.*

(b) *For almost every tally set T, $AM(T)=NP(T)$.*

In Theorems 5.2 and 5.4, we can uniformly replace Σ_k^P by Π_k^P or by Δ_k^P, and all of the resulting statements will be true.

What follows is applications of the above two theorems. Here we improve or generalize the known facts (see Propositions 2.5–2.7 for the summary of previous works).

It is known that $BPP(BPP)=BPP$ [Ko82] and that $BP\cdot NP(BPP)=BP\cdot NP$, i.e., $AM(BPP)=AM$[ZF87]. Theorems 5.2 and 5.4 yield the following generalization.

THEOREM 5.6. *For all $k, j\geqq 0$, the following hold*:

(a) $BP\cdot\Sigma_k^P(BP\cdot\Sigma_j^P)=BP\cdot\Sigma_{k+j}^P$.

(b) $BP\cdot\Sigma_k^P(BP\cdot\Delta_{j+1}^P)=BP\cdot\Sigma_{k+j}^P$.

(c) $BP\cdot\Delta_{k+1}^P(BP\cdot\Delta_{j+1}^P)=BP\cdot\Delta_{k+j+1}^P$.

Proof. First we prove (a). By Theorem 5.2(b), $BP\cdot\Sigma_j^P\subseteq\Sigma_j^P(T)$ for almost every T. Hence $BP\cdot\Sigma_k^P(BP\cdot\Sigma_j^P)\subseteq BP\cdot\Sigma_k^P(\Sigma_j^P(T))=BP\cdot\Sigma_{k+j}^P(T)$ for almost every T. By Theorem 5.4, $BP\cdot\Sigma_{k+j}^P(T)=\Sigma_{k+j}^P(T)$ for almost every T. Therefore, we have

$$BP\cdot\Sigma_k^P(BP\cdot\Sigma_j^P)\subseteq\Sigma_{k+j}^P(T) \quad \text{for almost every } T.$$

So $BP\cdot\Sigma_k^P(BP\cdot\Sigma_j^P)\subseteq BP\cdot\Sigma_{k+j}^P$ by Theorem 5.2(b). On the other hand,

$$BP\cdot\Sigma_{k+j}^P=BP\cdot\Sigma_k^P(\Sigma_j^P)\subseteq BP\cdot\Sigma_k^P(BP\cdot\Sigma_j^P).$$

This completes the proof of (a).

The proofs of (b) and (c) are similar. □

Schöning has proved that $\Sigma_2^P(BP\cdot\Sigma_k^P)=\Sigma_{k+2}^P$. Here we have something a little stronger. Theorem 5.6 yields $BP\cdot NP(BP\cdot\Sigma_k^P)=BP\cdot\Sigma_{k+1}^P$ so that $NP(BP\cdot\Sigma_k^P)\subseteq BP\cdot\Sigma_{k+1}^P$.

THEOREM 5.7. *For every $k\geqq 0$, the following hold*:

(a) $BP\cdot\Sigma_{k+1}^P\subseteq BP\cdot\Sigma_k^P$ *implies* $PH=BP\cdot\Sigma_k^P$.

(b) $BP\cdot\Sigma_{k+1}^P\subseteq BP\cdot\Delta_{k+1}^P$ *implies* $PH=BP\cdot\Delta_{k+1}^P$.

Proof. (a) $BP\cdot\Sigma_{k+2}^P=BP\cdot\Sigma_1^P(BP\cdot\Sigma_{k+1}^P)\subseteq BP\cdot\Sigma_1^P(BP\cdot\Sigma_k^P)=BP\cdot\Sigma_{k+1}^P\subseteq BP\cdot\Sigma_k^P$. By induction on i, we can prove $BP\cdot\Sigma_{k+1}^P\subseteq BP\cdot\Sigma_i^P$.

(b) the proof of (b) is similar to that of (a). □

In Theorem 5.7, Σ_k^P can be uniformly replaced by Π_k^P, and the resulting statements will still hold. Note that Theorem 5.7(a) is a generalization of Proposition 2.6(b): $NP\subseteq BPP$ implies $BP\cdot NP\subseteq BPP$, and taking $k=0$ in Theorem 5.7(a), we have $BP\cdot NP\subseteq BPP$ implies $PH=BPP$.

Schöning has proved that $\Sigma_2^P(BP\cdot\Sigma_k^P\cap BP\cdot\Pi_k^P)=\Sigma_{k+1}^P$. We improve this in the following way.

THEOREM 5.8. *For $k\geqq 1$, $BP\cdot NP(BP\cdot\Sigma_k^P\cap BP\cdot\Pi_k^P)=BP\cdot\Sigma_k^P$.*

Proof. From Theorem 5.2(b), we see that for almost every tally set T, $BP\cdot\Sigma_k^P\cap BP\cdot\Pi_k^P\subseteq\Sigma_k^P(T)\cap\Pi_k^P(T)$. Since for every tally set T, $NP(\Sigma_k^P(T)\cap\Pi_k^P(T))=\Sigma_k^P(T)$, we have $NP(BP\cdot\Sigma_k^P\cap BP\cdot\Pi_k^P)\subseteq NP(\Sigma_k^P(T)\cap\Pi_k^P(T))=\Sigma_k^P(T)$ for almost every tally set T. Thus, $NP(BP\cdot\Sigma_k^P\cap BP\cdot\Pi_k^P)\subseteq BP\cdot\Sigma_k^P$. So $BP\cdot NP(BP\cdot\Sigma_k^P\cap BP\cdot\Pi_k^P)\subseteq BP\cdot\Sigma_k^P$. On the other hand, $BP\cdot NP(BP\cdot\Sigma_k^P\cap BP\cdot\Pi_k^P)\supseteq BP\cdot NP(\Sigma_k^P\cap\Pi_k^P)=BP\cdot\Sigma_k^P$. □

Using this theorem, we can strengthen Theorem 5.7 in the case where $k\geqq 1$.

THEOREM 5.9. *For every $k\geqq 1$,*

(a) *$BP\cdot\Pi_k^P\subseteq BP\cdot\Sigma_k^P$ implies $PH=BP\cdot\Sigma_k^P$;*

(b) *$BP\cdot\Sigma_k^P\subseteq BP\cdot\Pi_k^P$ implies $PH=BP\cdot\Pi_k^P$.*

Proof. Because $BP\cdot\Pi_k^P\subseteq BP\cdot\Sigma_k^P\Leftrightarrow BP\cdot\Pi_k^P=BP\cdot\Sigma_k^P\Leftrightarrow BP\cdot\Sigma_k^P\subseteq BP\cdot\Pi_k^P$, it is enough to prove (a).

By Theorem 5.6(a), we have $BP\cdot\Sigma_{k+1}^P=BP\cdot NP(BP\cdot\Sigma_k^P)$. By assumption and Theorem 5.8, $BP\cdot NP(BP\cdot\Sigma_k^P)=BP\cdot NP(BP\cdot\Sigma_k^P\cap BP\cdot\Pi_k^P)=BP\cdot\Sigma_k^P$. Hence, $BP\cdot\Sigma_{k+1}^P=BP\cdot\Sigma_k^P$. By Theorem 5.7(a), we have $PH=BP\cdot\Sigma_k^P$. □

Note that $BP\cdot\Pi_k^P\subseteq BP\cdot\Sigma_k^P\Leftrightarrow\Pi_k^P\subseteq BP\cdot\Sigma_k^P$. Theorem 5.9 is stronger than the corresponding result of Schöning, i.e., Proposition 2.5(c), since it forces PH to collapse to $BP\cdot\Sigma_k^P$ instead of Σ_{k+1}^P.

Note $BP\cdot\Pi_k^P\subseteq BP\cdot\Sigma_k^P$ if and only if for almost every T, $\Pi_k^P\subseteq\Sigma_k^P(T)$. Yap [Yap83] has proved that if there is a tally set T such that $\Pi_k^P\subseteq\Sigma_k^P(T)$, then $PH=\Sigma_{k+2}^P$. The above theorem says that if there are "lots of" such T's, then $PH=BP\cdot\Sigma_k^P$, i.e., PH collapses to a lower level.

All of the results above relativize to arbitrary oracle sets, that is, the results hold for classes such as $\Sigma_k^P(A)$, $\Pi_k^P(A)$, $\Delta_k^P(A)$, and $PH(A)$ for arbitrary A. All that is needed is that Lemma 5.1 remain valid for these classes.

Reviewing the consequences of Theorems 5.2 and 5.4, i.e., Theorems 5.6–5.9, we may note the similarity between the polynomial-time hierarchy and its probabilistic version, i.e., $\{BP\cdot\Sigma_k^P\}_{k\geqq 0}$. For example, since $BP\cdot PH=BP\cdot(\bigcup_{k\geqq 0}\Sigma_k^P)=\bigcup_{k\geqq 0}(BP\cdot\Sigma_k^P)=PH$, the following well-known facts [St77] are faithfully reflected in the corresponding statements of those theorems.

PROPOSITION 5.10. *For every $k,j\geqq 0$ and $l\geqq 1$, the following hold:*

(a) *$\Sigma_k^P(\Sigma_j^P)=\Sigma_{k+j}^P$.*

(b) *$\Sigma_{k+1}^P\subseteq\Sigma_k^P$ implies $PH=\Sigma_k^P$.*

(c) *$NP(\Sigma_l^P\cap\Pi_l^P)=\Sigma_l^P$.*

(d) *$\Pi_l^P\subseteq\Sigma_l^P$ implies $PH=\Sigma_l^P$.*

Our technique for proving the above theorems is also interesting. Note that Theorems 5.6–5.9 state the relationships in unrelativized settings. Nevertheless, the properties established for relativized complexity classes, i.e., Theorems 5.2 and 5.4, yield simple proofs for those theorems.

As a final remark of this section, we show the application of Theorem 4.2 to higher complexity classes.

THEOREM 5.11. *For every set A, the following hold:*

(a) *$A\in PH$ if and only if for almost every tally set T, $A\in PH(T)$ if and only if for all tally sets T, $A\in PH(T)$.*

(b) *For almost every pair (T_1,T_2) of tally sets, $PH=PH(T_1)\cap PH(T_2)$.*

(c) *For any countable class $\mathscr{D}$ such that $PH\subseteq\mathscr{D}$, $PH=\mathscr{D}\cap PH(T)$ for almost every tally set.*

Remark. The same results hold by replacing PH by PSPACE.

Acknowledgments. The authors are grateful to Professor Ronald Book for his support and encouragement. Comments from and discussions with Professors Book, Ker-I Ko, and Christopher Wilson have been very helpful. The ideas in this paper are deeply affected by the work of Ambos-Spies [Am86] and Bennett and Gill [BG81]. DYNAMIC PROGRAMMING BY EXCHANGEABILITY*

SHUO-YEN ROBERT LI†

Abstract. This article introduces the concept of *exchangeable stopping time* and a technique of dynamic programming based upon this concept for fast computation of the expected value of a payoff function upon stopping. One instance of an exchangeable stopping time is when a stopping time is defined by a threshold on the sequential sum of the process. Another instance is when a stopping time is defined by the occurrence of given patterns in observed values of the process. This new computation technique has applications in bin packing, casino blackjack, and random drawing for patterns.

Key words. bin packing, casino blackjack, dynamic programming, exchangeability, fast computation, permutation groups

1. Introduction. Let $\mathbf{X}_1, \mathbf{X}_2, \mathbf{X}_3, \cdots$ be a discrete stochastic process with a stopping time N. Let p be a function defined over all finite integer sequences, called the *payoff* function. We want to compute $E[p(\mathbf{X}_1, \mathbf{X}_2, \cdots, \mathbf{X}_N)]$, i.e., the average payoff upon stopping. Assuming $N, \mathbf{X}_1, \mathbf{X}_2, \mathbf{X}_3, \cdots$ are uniformly bounded, the computation can always be done by exhaustive search. This would require the computation of the probability of every sample path of the stopping process and the evaluation of the payoff function at the end of each path.

Computation of this type often can be simplified by techniques derived from fundamental structures in probability theory such as Markov chains, martingales, independently and identically distributed random variables, etc. When the stochastic process, the stopping time, and the payoff function do not meet requirements for invoking such fundamental techniques, we still hope to do the computation more efficiently than exhaustive search. This motivates the exploration of new concepts that give rise to efficient computation techniques but not necessarily close-form solutions. This article introduces one such concept called the *exchangeable stopping time* and the technique of *dynamic exchangeable programming.* Over a process of exchangeable random variables, the expected value of a symmetric payoff function upon an exchangeable stopping time can be computed by this new technique, which is exponentially faster than exhaustive search. Examples of applications of this fast computation technique are found in bin packing, casino blackjack, and random drawing for patterns.

2. Exchangeability and computation.

2.1. Taking advantage of symmetry in computation. Throughout the article, a process means a *finite or infinite* stochastic process and a stopping time is always *nonrandomized* (in the sense of Wald [8]). Let Σ denote a fixed finite set of nonnegative integers. Unless otherwise specified, a stochastic process always means a sequence of Σ-valued random variables. A finite sequence of elements from the set Σ will be called a *tuple.* In particular, the null tuple means the null sequence. Following DeFinetti [3], we define a process to be *exchangeable,* if rearrangements of random variables do not change the process. In other words, a stochastic process is exchangeable if the probability of any tuple is independent of the ordering among entries in the tuple.

Consider a process $\mathbf{X}_1, \mathbf{X}_2, \mathbf{X}_3, \cdots$ with a stopping time N. A tuple $(x_1, x_2, \cdots, x_n)$ is said to be N-attainable if

$$P\{\mathbf{X}_1 = x_1, \mathbf{X}_2 = x_2, \cdots, \mathbf{X}_n = x_n, \text{ and } n \leqq N\} > 0. \tag{2.1}$$

Given a payoff function defined over tuples, we want to compute the expected payoff upon stopping but avoid repetitive computation on symmetric tuples. This, of course, would require the property that *the ordering of the random variables in the process is immaterial.* What does this property precisely mean and how does a computation algorithm take advantage of it? It should mean the "exchangeability" of the random variables in three regards. First, the random variables are exchangeable with regard to chain probabilities, i.e., they form an exchangeable process. Second, they are exchangeable with regard to the payoff function, i.e., the payoff function is symmetric. Finally, they are exchangeable with regard to the stopping time.

The meaning of this third exchangeability needs clarification. One possible interpretation could be that all symmetric tuples are either N-attainable together or non-N-attainable together. This interpretation is too strict to be useful because it essentially implies that the stopping time N is independent of the stochastic process. Another possible interpretation could be that, when two symmetric tuples are both known to be N-attainable, the stochastic process stops at both of them or at neither of them. Note that, for a given tuple, the prefix of a permutation of the tuple is not necessarily a permutation of a prefix. Therefore the latter interpretation of an exchangeable stopping time would be weak in linking the N-attainability among symmetric tuples. However, we shall use this interpretation of an exchangeable stopping time as the principal condition in the definition and compensate its weakness by side conditions.

2.2. Exchangeable stopping time. Let S_n denote the group of permutations on the numbers $1, 2, \cdots, n$. For $0 \leqq m < n$, we regard S_m as a subgroup of S_n. The product of two permutations a and b is denoted as $a \times b$. As a composite function over the numbers $1, 2, \cdots, n$, this product is interpreted as the function a followed by the function b. (It could be interpreted as b followed by a instead, as long as the interpretation is consistent throughout all definitions pertaining to products of permutations in this article.)

Consider a process $\mathbf{X}_1, \mathbf{X}_2, \mathbf{X}_3, \cdots$ with a stopping time N. For every tuple $(x_1, x_2, \cdots, x_n)$, write

$$A(x_1, x_2, \cdots, x_n) = \{\sigma \in S_n \mid (x_{\sigma(1)}, x_{\sigma(2)}, \cdots, x_{\sigma(n)}) \text{ is } N\text{-attainable}\}. \tag{2.2}$$

We say that N is an *exchangeable* stopping time if the following two properties hold:

(A) When two symmetric tuples are both N-attainable, the stochastic process stops at both of them or at neither of them.

(B) For any nondecreasing tuple $(x_1, x_2, \cdots, x_n)$, if $A(x_1, x_2, \cdots, x_n)$ is nonempty, then so is $A(x_1, x_2, \cdots, x_{n-1})$.

The property (B) has been stated with respect to the natural ordering among integers in the set Σ. But, since elements of Σ can be relabeled, the property can actually be stated with respect to any other ordering as well. It has turned out that this technical condition is usually easy to meet.

The goal of introducing the concept of exchangeable stopping times is to derive a computation algorithm that avoids repetitive computation on symmetric tuples. Naturally, the algorithm will require some mechanism to quantify the symmetry among N-attainable tuples. Since our definition of the exchangeability of a stopping time is very weak in linking the N-attainability among symmetric tuples, the application of the algorithm would require more than just the exchangeability. The required extra

property of the stopping time can be a reasonably computable $|A(x_1, \cdots, x_n)|$ for certain tuples $(x_1, \cdots, x_n)$. It turns out that the reasonable computability of the following quantity would also suffice: Write

$$a(x_1, \cdots, x_n) = \frac{|A(x_1, \cdots, x_n)|}{|A(x_1, \cdots, x_{n-1})|}, \tag{2.3}$$

whenever the denominator is nonzero, where $|\ |$ is the usual notation for cardinality. Instances of exchangeable stopping times with easily computable $a(x_1, \cdots, x_n)$ are presented in § 3.

2.3. The computation algorithm. A fast computation algorithm based upon exchangeability will be given in § 2.3.2. First, § 2.3.1 describes the computation by exhaustive search so that the new algorithm can be described in parallel terms for easy contrast.

2.3.1. Dynamic programming. Let $\mathbf{X}_1, \mathbf{X}_2, \mathbf{X}_3, \cdots$ be a process with a stopping time N and p a function defined over tuples. Define another function over tuples as follows:

$$D(x_1, \cdots, x_n) = E[p(\mathbf{X}_1, \cdots, \mathbf{X}_N) | \mathbf{X}_1 = x_1, \cdots, \mathbf{X}_n = x_n]. \tag{2.4}$$

In particular, the expected value of p upon stopping is $D(\ )$, i.e., the function D evaluated at the null tuple, which can be calculated from "backward induction" as follows. If $n = N$ for the tuple $(x_1, \cdots, x_n)$, then

$$D(x_1, \cdots, x_n) = p(x_1, \cdots, x_n). \tag{2.5}$$

If $N > n-1$ for the tuple $(x_1, \cdots, x_{n-1})$, then

$$D(x_1, \cdots, x_{n-1}) = \sum_{x_n} P\{\mathbf{X}_n = x_n | \mathbf{X}_1 = x_1, \cdots, \mathbf{X}_{n-1} = x_{n-1}\} D(x_1, \cdots, x_n). \tag{2.6}$$

The computation based upon this recursion is equivalent to the exhaustive search through a tree where each node is a tuple and an ancestor of a node means a prefix. This computation algorithm will be referred to as *dynamic programming.*

2.3.2. Dynamic exchangeable programming. Assume that $\mathbf{X}_1, \mathbf{X}_2, \mathbf{X}_3, \cdots$ is an exchangeable process with an exchangeable stopping time N and that p is a symmetric function defined over tuples. Define the *stabilizer group* of a nondecreasing tuple $(x_1, x_2, \cdots, x_n)$ as follows:

$$G(x_1, \cdots, x_n) = \{\sigma \in S_n | (x_{\sigma(1)}, \cdots, x_{\sigma(n)}) = (x_1, \cdots, x_n)\}. \tag{2.7}$$

This group measures repetition of values in the tuple. Define the function

$$g(x_1, \cdots, x_n) = \frac{|G(x_1, \cdots, x_n)|}{|G(x_1, \cdots, x_{n-1})|} \tag{2.8}$$

over *nondecreasing* tuples of any nonzero length. Then g satisfies the following easy recursion:

$$g(x_1, \cdots, x_n) = 1 \qquad \text{if } n = 1 \text{ or } x_n > x_{n-1}, \tag{2.9}$$

$$g(x_1, \cdots, x_n) = g(x_1, \cdots, x_{n-1}) + 1 \quad \text{if } n \geqq 2 \text{ and } x_n = x_{n-1}. \tag{2.10}$$

Let a tuple be called a *stus-tuple* if it is symmetric to an upon-stopping tuple. Our goal is to compute the expected value of the function p upon stopping. Without loss of generality, hereafter throughout this section, we shall assume the following:

(C) p can have nonzero values only at stus-tuples.

We want to construct an algorithm that is similar to the exhaustive tree search in the above-described dynamic programming but avoids repetitive computation on symmetric tuples. Thus, consider all *nondecreasing* tuples that are symmetric to N-attainable tuples. We organize these tuples into a tree structure by linking each of them to its prefix with one less element, i.e., linking $(x_1, \cdots, x_n)$ to $(x_1, \cdots, x_{n-1})$. The requirement (B) of the exchangeability of N guarantees the connectivity of this tree structure.

All *external nodes* (also called *leaves*) of this tree and possibly some *internal nodes* are stus-tuples; we shall call them *stus-nodes*. To compute the expected value of p upon stopping, we need only to evaluate p at stus-nodes and enumerate the number of upon-stopping tuples symmetric to it. From the requirement (A) of the exchangeability of N, the number of upon-stopping tuples symmetric to a stus-node is the same as the number of N-attainable tuples symmetric to it. Note that $|A(x_1, \cdots, x_n)|/|G(x_1, \cdots, x_n)|$ is the number of *distinct* N-attainable tuples that are symmetric to $(x_1, \cdots, x_n)$. Therefore, by the assumption (C), we have

$$E[p(\mathbf{X}_1, \cdots, \mathbf{X}_N)] = \sum_{x_1 \leqq \cdots \leqq x_n} \frac{|A(x_1, \cdots, x_n)|}{|G(x_1, \cdots, x_n)|} P\{(\mathbf{X}_1, \cdots, \mathbf{X}_n) = (x_1, \cdots, x_n)\} p(x_1, \cdots, x_n). \tag{2.11}$$

This formula can be computed by tree search according to the following recursion. If $(x_1, \cdots, x_n)$ is an external node of the tree, let

$$F(x_1, \cdots, x_n) = p(x_1, \cdots, x_n)|A(x_1, \cdots, x_n)|. \tag{2.12}$$

If $(x_1, \cdots, x_{n-1})$ is an internal node of the tree, then let

$$\begin{aligned} F(x_1, \cdots, x_{n-1}) &= p(x_1, \cdots, x_{n-1})|A(x_1, \cdots, x_{n-1})| \\ &\quad + \sum_{x_n \geqq x_{n-1}} \frac{F(x_1, \cdots, x_n)}{g(x_1, \cdots, x_n)} P\{\mathbf{X}_n = x_n | \mathbf{X}_1 = x_1, \cdots, \mathbf{X}_{n-1} = x_{n-1}\}. \end{aligned} \tag{2.13}$$

We can then recursively compute $F(\ )$, which equals the expected value of p upon stopping. This algorithm involves the computation of $|A(x_1, \cdots, x_n)|$ on every stus-node $(x_1, \cdots, x_n)$.

Recall the definition (2.3) of $a(x_1, \cdots, x_n)$. If $|A(x_1, \cdots, x_n)|$ is computable, then, of course, $a(x_1, \cdots, x_n)$ can be computed with little extra effort. But the converse is not always true. Also, even when $|A(x_1, \cdots, x_n)|$ is computable, $a(x_1, \cdots, x_n)$ is often a much simpler number to compute. For these reasons, we prefer to compute the expected value of p upon stopping by the following recursion instead of (2.12) and (2.13): If $(x_1, \cdots, x_n)$ is an external node of the tree, let

$$M(x_1, \cdots, x_n) = p(x_1, \cdots, x_n). \tag{2.14}$$

If $(x_1, \cdots, x_{n-1})$ is an internal node of the tree, let

$$\begin{aligned} M(x_1, \cdots, x_{n-1}) &= p(x_1, \cdots, x_{n-1}) \\ &\quad + \sum_{x_n \geqq x_{n-1}} \frac{a(x_1, \cdots, x_n)}{g(x_1, \cdots, x_n)} P\{\mathbf{X}_n = x_n | \mathbf{X}_1 = x_1, \cdots, \mathbf{X}_{n-1} = \mathbf{X}_{n-1}\} M(x_1, \cdots, x_n). \end{aligned} \tag{2.15}$$

Then the expected value of p upon stopping equals $M(\ )$. This computation algorithm will be referred to as *dynamic exchangeable programming*.

2.3.3. Comparison of computational efficiency. Dynamic exchangeable programming applies only under the exchangeability assumptions, but, when applicable, its computation can be significantly faster than dynamic programming. Dynamic programming invokes its recursive formula (2.6) for every tuple before stopping, and evaluates the payoff at every tuple upon stopping. Dynamic exchangeable programming invokes its recursive formula (2.15) only for nondecreasing rearrangements of tuples before stopping, and evaluates the payoff only at nondecreasing rearrangements of tuples upon stopping. Except for the extra effort in the computation of $a(x_1, \cdots, x_n)$, the speedup factor of dynamic exchangeable programming over dynamic programming is roughly the ratio between the number of upon-stopping tuples and the number of nondecreasing upon-stopping tuples. Thus the speedup factor may be estimated as follows. For a fixed length n, there are $|\Sigma|^n$ tuples, while there are only $(n+|\Sigma|)!/n!|\Sigma|!$ nondecreasing tuples; in terms of the order in the parameter n, the ratio between these two numbers is $|\Sigma|^n$. In view of the convexity of the exponential function, we then estimate the speedup factor to be of the order of $|\Sigma|^{E[N]}$.

The computational complexity of $a(x_1, \cdots, x_n)$ is very much up to the individual instance of the exchangeable stopping time N. For example, if the exchangeability of N is due to Theorem 3.1 below, then the computational complexity depends solely upon the structure of the monotonic function f in the theorem. In particular, if N is as in Corollary 3.2, this computation would be a very minor effort incurred by the algorithm.

An alternative implementation of dynamic programming is to tabulate values of the payoff function at nondecreasing tuples and then look up the table whenever the function needs to be evaluated. This would save one aspect of the repetitive computation, i.e., the evaluation of the function at symmetric tuples. However, the implementation requires an algorithm for the translation of a tuple into the proper table address. A desirable algorithm should take only a reasonable amount of time and space. Conceivably, the number of tuples can be quite large in applications and there may not exist any natural way of storing nondecreasing tuples in a compact linear fashion. Hence, the desired translation algorithm is often unavailable in applications.

3. Quantification of symmetry. Dynamic exchangeable programming requires the computation of $a(x_1, \cdots, x_n)$ for nondecreasing tuples $(x_1, \cdots, x_n)$. In this section, we investigate structures of exchangeable stopping times that lead to natural ways of computing $a(x_1, \cdots, x_n)$. Then we present examples of applications of dynamic exchangeable programming.

3.1. Computation of $a(x_1, \cdots, x_n)$. For any two sets A and B of permutations, let $A \times B$ denote the set of permutations of the type $a \times b$, where a, b are elements of A, B, respectively. For $n \geqq 1$, let $\mathbf{F}_n$ be an n-element subset of S_n such that

$$S_n = S_{n-1} \times \mathbf{F}_n. \tag{3.1}$$

In other words, $\mathbf{F}_n$ is a complete set of representatives of right *cosets* of S_n over the subgroup S_{n-1}.

Our property of the stopping time that enhances the computability of $a(x_1, \cdots, x_n)$ is a natural expression of the set $A(x_1, \cdots, x_n)$ in the form of a "direct product" of the set $A(x_1, \cdots, x_{n-1})$ with another subset of S_n. A special form of this property is that, for every nondecreasing tuple $(x_1, \cdots, x_n)$, there exists a subset $H(x_1, \cdots, x_n)$ of $\mathbf{F}_n$ satisfying the equation

$$A(x_1, \cdots, x_n) = A(x_1, \cdots, x_{n-1}) \times H(x_1, \cdots, x_n), \tag{3.2}$$

because, then, $a(x_1, \cdots, x_n)$ is simply the cardinality of $H(x_1, \cdots, x_n)$. When a stopping time is exchangeable and possesses this property, we shall say that the stopping time is exchangeable with respect to the sequence $\mathbf{F}_1, \mathbf{F}_2, \mathbf{F}_3, \cdots$. The simplest example of the set $\mathbf{F}_n$ consists of *transpositions*:

$$\mathbf{F}_n = \{(1\ \ n), (2\ \ n), \cdots, (n\ \ n)\}. \tag{3.3}$$

When a stopping time is exchangeable with respect to the particular sequence $\mathbf{F}_n$ defined by (3.3), we say that it is *exchangeable with respect to transpositions.*

Let a function f over tuples be called *monotonic* if

$$f(x_1, \cdots, x_n) \leqq f(y_1, \cdots, y_n) \leqq f(y_1, \cdots, y_n, y_{n+1}) \tag{3.4}$$

whenever $x_1 \leqq y_1$, $x_2 \leqq y_2, \cdots, x_n \leqq y_n$, and $n \geqq 0$.

THEOREM 3.1. *Let f be a symmetric monotonic function on tuples and K a constant. Define the stopping time N on the process $\mathbf{X}_1, \mathbf{X}_2, \mathbf{X}_3, \cdots$, as the smallest number n such that*

$$f(\mathbf{X}_1, \mathbf{X}_2, \cdots, \mathbf{X}_n) \geqq K. \tag{3.5}$$

Then N is exchangeable with respect to transpositions.

Proof. Given a nondecreasing tuple $(x_1, x_2, \cdots, x_n)$, we need to verify the condition (3.2) with a properly chosen subset $H(x_1, x_2, \cdots, x_n)$ of the set $\mathbf{F}_n$ in (3.3). If $f(x_1, x_2, \cdots, x_{n-1}) \geqq K$, then $A(x_1, x_2, \cdots, x_n)$ is null due to the monotonicity and the symmetry of f. We may therefore assume that $f(x_1, x_2, \cdots, x_{n-1}) < K$. Then the symmetry of f implies that $A(x_1, x_2, \cdots, x_{n-1}) = S_{n-1}$. Define m as the smallest index such that

$$f(x_1, x_2, \cdots, \hat{x}_m, \cdots, x_n) < K. \tag{3.6}$$

Here $\hat{}$ is the usual notation for deleting an item from an array. An element σ of S_n belongs to $A(x_1, x_2, \cdots, x_n)$ if and only if

$$f(x_{\sigma(1)}, x_{\sigma(2)}, \cdots, x_{\sigma(n-1)}) < K, \tag{3.7}$$

which is equivalent to that $\sigma(n) \geqq m$. This means that

$$A(x_1, x_2, \cdots, x_n) = S_{n-1} \times \{(m\ \ n), (m+1\ \ n), \cdots, (n\ \ n)\}. \tag{3.8}$$

The condition (3.2) is verified by choosing $H(x_1, x_2, \cdots, x_n)$ to be the set $\{(m\ \ n), (m+1\ \ n), \cdots, (n\ \ n)\}$, and the theorem is proved.

For the stopping time in the theorem, we have $a(x_1, \cdots, x_n) = n - m + 1$, where m is defined by (3.6). In other words, the computation of $a(x_1, \cdots, x_n)$ is equivalent to the computation of m, which directly relates to the structure of the symmetric monotonic function f. One simple and useful case of a symmetric monotonic function is as follows.

COROLLARY 3.2. *Given a constant K and a nonnegative nondecreasing function f on the set Σ, define the stopping time N as the smallest index n such that*

$$f(\mathbf{X}_1) + \cdots + f(\mathbf{X}_n) \geqq K. \tag{3.9}$$

Then N is exchangeable with respect to transpositions.

Proof. Expand the domain of the function f from Σ to tuples by

$$f(x_1, \cdots, x_m) = f(x_1) + \cdots + f(x_m). \tag{3.10}$$

Then f is a symmetric monotonic function on tuples.

3.2. Application to bin packing. A collection of items of various sizes are to be packed into bins. The number of items of each size is predetermined. All items are

mixed in a random order and revealed one at a time. A bin collects items one by one according to the order of arrival until the accumulative load reaches a predetermined threshold. Then a second bin starts to be loaded by subsequent items in the same manner, and so on. In other words, a new bin is started *after* overflow occurs. This differs from the usual bin packing, where a new bin is started *before* overflow occurs (see Coffman, Garey, and Johnson [2] for a comprehensive survey and Rhee [6] for a recent reference on bin packing).

To demonstrate the application of dynamic exchangeable programming, we shall compute the variance and the covariance of bin loads. When there are enough items to guarantee the filling of a fixed number, say k, of bins, then the loads of these k bins are identically distributed (and, in fact, form an exchangeable process). We want to compute the average load of the first bin, the average square of the load of the first bin, and the average product of the first two loads.

Thus, let $\mathbf{X}_i$ represent the size of the ith item. This defines an exchangeable process. Define the stopping time N as the smallest n such that $\mathbf{X}_1+\cdots+\mathbf{X}_n$ reaches the given threshold of bin load. Note that this is the special case of Corollary 3.2 with the function f being the identity function. Therefore the quantity $a(x_1, \cdots, x_n)$ is easily computable. To compute the average load of the first bin and the average square, the payoff functions are, respectively,

$$p_1(x_1, \cdots, x_n) = x_1+\cdots+x_n \tag{3.11}$$

and

$$p_2(x_1, \cdots, x_n) = (x_1+\cdots+x_n)^2. \tag{3.12}$$

To compute the average product of the first two loads, we use the same stopping time N and the payoff function:

$$p_3(x_1, \cdots, x_n) = E[\text{product of two loads} \mid \mathbf{X}_1 = x_1, \cdots, \mathbf{X}_n = x_n]. \tag{3.13}$$

At an upon-stopping tuple $(x_1, \cdots, x_n)$ the evaluation of $p_3(x_1, \cdots, x_n)$ can be done by exhaustive search through all possible values of $\mathbf{X}_{n+1}$, $\mathbf{X}_{n+2}, \cdots$ given that $\mathbf{X}_1 = x_1, \cdots, \mathbf{X}_n = x_n$. Alternatively, this evaluation can be done through a recursive application of dynamic exchangeable programming, since the conditional process of $\mathbf{X}_{n+1}$, $\mathbf{X}_{n+2}, \cdots$ given that $\mathbf{X}_1 = x_1, \cdots, \mathbf{X}_n = x_n$ can be regarded as the initial process in the bin-packing problem where those items corresponding to $x_1, \cdots, x_n$ are deducted from the initial collection.

3.3. Computation of casino blackjack. Since the pioneering work of Thorp [7], there have been numerous publications analyzing and simulating strategies for casino blackjack. A partial list of these studies is the bibliography of Humble and Cooper [4]. These studies, except for relatively simple ones, have all been based upon statistical simulations and estimations instead of full-confidence computation. One reason for avoiding computation is the immense computational complexity. In principle, for any version of the game rules, any shuffle practices of the house, and any strategy of the gambler, the exact expected return at any situation can be exhaustively computed. However, the complexity of blackjack computation often overwhelms the processing power of modern-day computers.

Consider the computation of the expected payoff of the *exhaustively optimal* strategy for playing *one* game *head-on* against the house. The net payoff depends on minor variations of game rules from house to house and can sometimes be extremely close to zero. There are many situations that one option for the gambler (such as *hit*,

stand, *split*, and *double-down*) may be better than another option by a margin so tiny that only the exact computation can make the right decision. This makes the simulation of the exhaustively optimal strategy difficult.

Dynamic exchangeable programming offers an alternative to exhaustive computation or simulations. The random variables in the exchangeable process are cards received by the gambler. Given the value of dealer's *up-card*, let K and KS be the minimum *hard* and *soft* points, respectively, that are not known to be sure hits. For example, when a game starts with a fresh deck, KS is 19 against an up-card 9 or 10 and is 18 against all others. The exchangeable process stops when either the hard total is at least K or the soft total is at least KS. (For the consideration of special stopping due to double-down, split, or *natural*, the readers are referred to Li [5].) The payoff function, at a standing hand, is defined as the average receipt to be credited to the hand, which is averaged over all possibilities of dealer's remaining cards. The payoff function, at any tuple upon stopping (not necessarily a standing hand yet), is the average receipt to be credited to the hand, assuming that the gambler plays optimally from that point on.

This would have set up the problem as a typical application of Corollary 3.2 except for the ambiguity of an ace being counted as either 1 or 11, and hence also the ambiguity in the meaning of a nondecreasing tuple. We classify tuples upon stopping into the following types:

(A) All cards are non-aces.

(B) There is exactly one ace and one non-ace.

(C) There is exactly one ace. The total points of non-aces are greater than or equal to K.

(D) There is exactly one ace and at least two non-aces. The total points of non-aces are less than K.

(E) There are at least two aces and at least one non-ace.

Assign point values to aces as follows. The ace in a type (B), (C), or (D) hand is counted as 11 points, and each ace in a type (E) hand is counted as one point. Figure 1 is a *finite-state diagram* that depicts the growth from the null tuple to the nondecreasing permutation of a tuple upon stopping. Note that $2 \leqq y_1 \leqq y_2 \leqq \cdots \leqq 10$ and $1 \leqq z_1 \leqq z_2 \leqq \cdots \leqq 10$ in Fig. 1. Application of dynamic exchangeable programming to this stopping process can be done in the same fashion as Corollary 3.2, because the stopping times for exiting both loops in Fig. 1 are defined by thresholds on the sequential sum.

3.4. Random drawing for patterns. Let the process $\mathbf{X}_1, \mathbf{X}_2, \mathbf{X}_3, \cdots$ represent *Polya's urn scheme* (see, for example, Chung [1]), where the "urn" contains a collection of numbers with repetitions allowed. A specific instance of this process would be drawing cards from a deck (full or partial) without replacement. Consider the type of stopping times that are defined by the occurrence of certain "patterns of combinations." For example, define the stopping time N as when any number appears for a third time or when there are two repeated numbers. A stopping time of this type is clearly exchangeable. It is usually not difficult to compute the function $a(x_1, \cdots, x_n)$ for such a stopping time and thereby apply dynamic exchangeable programming to the averaging of any symmetric payoff function upon stopping. Below, we compute the function $a(x_1, \cdots, x_n)$ for the particular stopping time N.

Recall the function g over nondecreasing tuples in (2.9) and (2.10). Write

$$b(x_1, \cdots, x_n) = \prod_{i=1}^{n} g(x_1, \cdots, x_i). \tag{3.14}$$

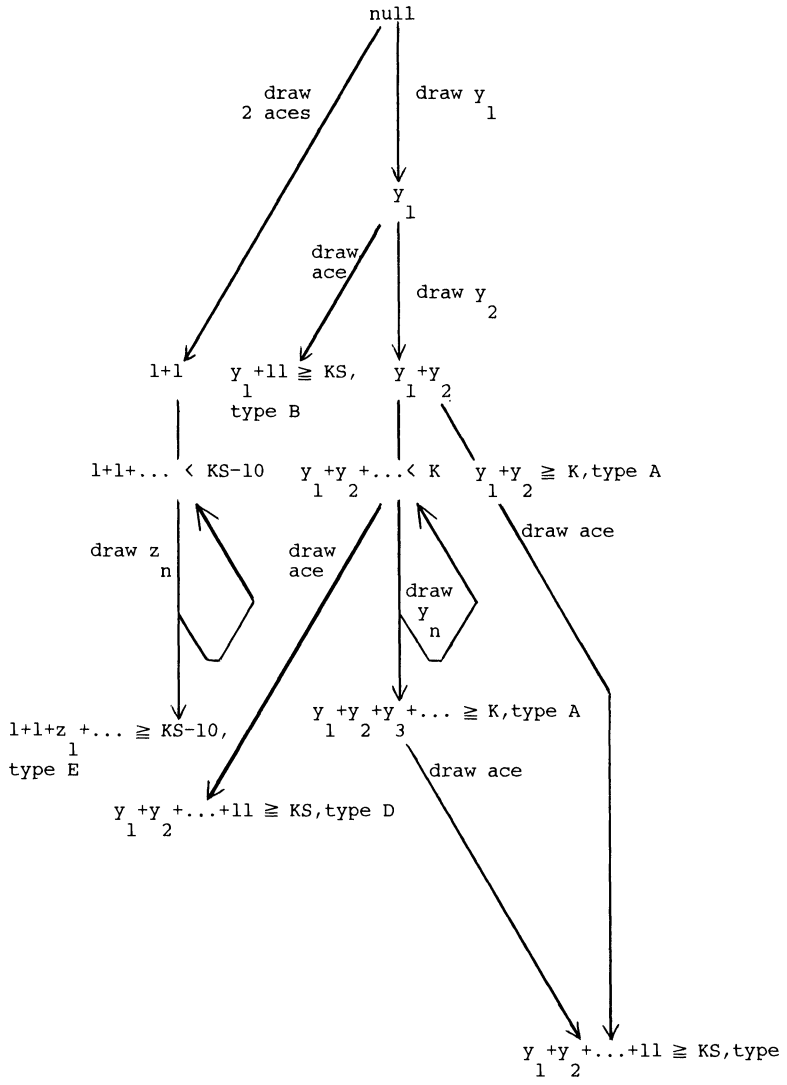

FIG. 1

Since the function g can be computed by an easy recursion, so can the function b. The function a relates to the function b as follows:

$$
\begin{aligned}
a(x_1, \cdots, x_n) = n \quad & \text{if } b(x_1, \cdots, x_n) \leqq 2, \\
4 \quad & \text{if } b(x_1, \cdots, x_{n-1}) = 2 \text{ and } b(x_1, \cdots, x_n) = 4 \\
3 \quad & \text{if } b(x_1, \cdots, x_{n-1}) = 2 \text{ and } b(x_1, \cdots, x_n) = 6, \\
n-1 \quad & \text{if } 4 \leqq b(x_1, \cdots, x_{n-1}) = b(x_1, \cdots, x_n) \leqq 6, \\
0 \quad & \text{if } b(x_1, \cdots, x_n) \geqq 8.
\end{aligned} \tag{3.15}
$$

The proof of (3.15) is relatively elementary, and hence is omitted.

OPTIMAL BIN PACKING WITH ITEMS OF RANDOM SIZES III *

WANSOO T. RHEE† AND MICHEL TALAGRAND‡

Abstract. Consider a probability measure μ on $[0, 1]$ and independent random variables $X_1, \cdots, X_n$ distributed according to μ. Let $Q_n = Q_n(X_1, \cdots, X_n)$ be the minimum number of unit-size bins needed to pack items of size $X_1, \cdots, X_n$. Let $c(\mu) = \lim_{n\to\infty} E(Q_n)/n$. In this paper it is proved that the random variable $(Q_n - nc(\mu))/\sqrt{n}$ converges in distribution. The limit is identified as a distribution of the supremum of a certain Gaussian process canonically attached to μ.

Key words. optimal stochastic bin packing, weak convergence

AMS(MOS) subject classifications. 90B99, 60K30

1. Introduction. The bin-packing problem requires finding the minimum number of unit-size bins needed to pack a given collection of items with sizes $X_1, \cdots, X_n$ in $[0, 1]$. This problem has many applications and has been shown to be NP-complete [Kar]. Consider a probability measure μ on $[0, 1]$. (No regularity assumption is made on μ.) Consider n items with sizes $X_1, \cdots, X_n$ which are independent identically distributed random variables distributed according to μ. (For simplicity, we denote by X_k both item names and item sizes.) We let $Q_n = Q_n(X_1, \cdots, X_n)$ denote the minimum number of unit-size bins needed to pack $X_1, \cdots, X_n$. It is well known that Q_n is a subadditive process (see [Kin]). So we have $\lim_n Q_n/n = c(\mu)$ almost surely for some constant $c(\mu)$ depending on μ, and $E(Q_n)/n \geqq c(\mu)$ for each n. In [Rhe3], the authors have shown that Q_n is very concentrated around its expectation. More precisely, for all $t > 0$,

$$P(|Q_n - E(Q_n)| \geqq t) \leqq 2 \exp(-t^2/2n).$$

This however gives no information on the value of $E(Q_n)$. In [Rhe2], the authors have shown that for some universal constant K, we have

$$0 \leqq E(Q_n) - nc(\mu) \leqq K(n(1+\log n))^{1/2}. \tag{1.1}$$

(Throughout the paper, a universal constant means a number independent of all the data of the problem. We will always denote by K a universal constant, not necessarily the same at each line.)

The present paper will go one step further in the description of Q_n. We will describe a random variable T_n, whose distribution is independent of n, and for which $E(|(Q_n - nc(\mu))/\sqrt{n} - T_n|) = o(1)$. This implies in particular that $(Q_n - nc(\mu))/\sqrt{n}$ converges in distribution. Some deterministic estimates were essential in the proof of (1.1); a sharpening of these results (Theorem A below) will be essential here. We now proceed to a precise description of our results. The ideas and concepts developed in our earlier paper [Rhe2] will be essential.

For $k \geqq 1$, let

$$R_k = \left\{ (x_1, \cdots, x_k) \in R^k : 0 \leqq x_1 \leqq \cdots \leqq x_k, \sum_{i \leqq k} x_i \leqq 1 \right\}.$$

For $x \in [0,1]$, we denote by δ_x the probability measure concentrated at x, that is for a Borel set G we have $\delta_x(G)=1$ if x belongs to G and $\delta_x(G)=0$ otherwise. For a compact metric space S, we denote by $M_1(S)$ the set of probability measures on S.

The following improves on [Rhe2], Theorem B.

THEOREM A. *Consider a nonnegative sequence* $(\alpha_k)_{k\geqq 0}$ *with* $\sum_{k\geqq 0}\alpha_k = 1$, *and a sequence* $\nu_k \in M_1(R_k)$. *Consider the measure*

$$\mu = \alpha_0\delta_0 + \sum_{k\geqq 1}(\alpha_k/k)\int_{R_k}\sum_{i\leqq k}\delta_{x_i}\,d\nu_k(x_1,\cdots,x_k).$$

For $l \geqq 1$, *let* $\beta_l = \sum_{k\geqq l}\alpha_k/k$. *Consider a sequence* $s_1,\cdots,s_n$ *of items. Let*

$$D = D(s_1,\cdots,s_n) = \operatorname*{Sup}_{0\leqq t\leqq 1}\{\operatorname{card}\{i\leqq n;\ s_i \geqq t\} - n\mu([t,1])\},$$

so $D \geqq 0$. *Then for all* $1 \leqq q \leqq n$, *we have*

$$Q_n(s_1,\cdots,s_n) \leqq D + n\sum_{k\geqq 1}(\alpha_k/k) + n/q^2 + 3q + 4 + K(\log n)^{1/2}\left(\sum_{1\leqq l\leqq q}\operatorname{Max}((n\beta_l/l)^{1/3},(n\beta_l)^{1/4})\right) \tag{1.2}$$

where K *is a universal constant* (i.e., *independent of* μ, n, *and* $s_1,\cdots,s_n$). *In particular,*

$$Q_n(s_1,\cdots,s_n) \leqq D + n\sum_{k\geqq 1}(\alpha_k/k) + Kn^{5/11}(1+\log n)^{1/2}. \tag{1.3}$$

Comments. It is sufficient (but essential) for our present purposes to have an error term in (1.3) that is of order $< n^{1/2}$. We do not know however what would be the best possible order of this error term. Since we see no reason why the present bound should be optimal, we have not conducted our computations in order to attempt to get a small value for K and we have always used crude but simple estimates.

PROPOSITION B. (a) *Let* $s_1,\cdots,s_n$ *be in* $[0,1]$. *Let* $\nu = (1/n)\sum_{i\leqq n}\delta_{s_i}$. *Then we have*

$$nc(\nu) \leqq Q_n(s_1,\cdots,s_n) \leqq nc(\nu) + Kn^{5/11}(1+\log n)^{1/2}. \tag{1.4}$$

(b) *For each distribution* μ,

$$nc(\mu) \leqq E(Q_n(X_1,\cdots,X_n)) \leqq nc(\mu) + Kn^{1/2}.$$

For a probability measure γ on $[0,1]$, we set $F_\gamma^-(t) = \gamma([0,t))$, $F_\gamma(t) = \gamma([0,t])$. We denote by $W_t = B_t - tB_1$ the Brownian bridge, where B_t is the standard Brownian motion (see [Bre]). For the simplicity of notation, we set

$$W_{\mu,t} = W_{\mu([0,t])},\quad W_{\mu,t}^- = W_{\mu([0,t))}.$$

Consider the set $\mathscr{C}$ of nondecreasing functions f from $[0,1]$ to $[0,1]$ that satisfy $f(0)=0$ and $f(a)+f(b) \leqq f(a+b)$ whenever $a, b \in [0,1]$. $a+b \leqq 1$.

To each f in $\mathscr{C}$, we associate f^- given by $f^-(0)=0$, and for $x>0$ by $f^-(x) = \lim_{y\to x, y<x} f(y)$, so $f^- \leqq f$, and it is easily seen that $f^- \in \mathscr{C}$. There is a unique positive measure γ_f on $[0,1]$ such that $\gamma_f(\{1\})=0$ and that $F_{\gamma_f}^-(t) = f^-(t)$ for each $0 \leqq t \leqq 1$, and γ_f has mass $f^-(1) \leqq 1$. We now fix μ in $M_1([0,1])$. We denote by $(z_i)_{i\in J}$ an enumeration of the points $z \in [0,1]$ such that $\mu(\{z\}) > 0$, where J is either empty, finite or countable infinite.

THEOREM C. *The set*

$$\mathscr{C}_\mu = \left\{ f \in \mathscr{C};\ \int f\,d\mu = c(\mu) \right\}$$

is nonempty. Consider the random variable

$$T = \operatorname*{Sup}_{f \in \mathscr{C}_\mu} \left[-\int_0^1 W_{\mu,t}\, d\gamma_f(t) + \sum_{i \in J} (f(z_i) - f^-(z_i))(W_{\mu,z_i} - W^-_{\mu,z_i}) \right]. \tag{1.5}$$

Then, for each n, one can find a random variable T_n distributed as T, and such that

$$\lim_{n\to\infty} E(|(Q_n(X_1, \cdots, X_n) - nc(\mu))/\sqrt{n} - T_n|) = 0.$$

Remarks. (1) The proof actually shows that for some $\alpha > 0$, we have

$$\lim_{n\to\infty} E(\exp(\alpha|(Q_n(X_1, \cdots, X_n) - nc(\mu))/\sqrt{n} - T_n|)) = 1.$$

(2) T is the supremum of a Gaussian process indexed by $\mathscr{C}_\mu$.

(3) The reason for the unintuitive formula (1.5) is explained in the heuristic proof of Theorem C given at the beginning of § 3.

COROLLARY D. *We have*

$$\lim_{n\to\infty} E((Q_n(X_1, \cdots, X_n) - nc(\mu))/\sqrt{n}) = 0$$

if and only if for any two functions f_1 and f_2 of $\mathscr{C}_\mu$, then $f_1 - f_2 = 0$ on the support of μ, except maybe on a countable set of μ-measure zero (that may depend on f_1 and f_2). (We recall that the support of a probability measure is the smallest closed set A for which $\mu(A) = 1$.)

Comments. While it is somehow surprising that results as accurate as Theorem C can be proved, it must be pointed out that the structure of the set $\mathscr{C}$ is very complicated and seems to contain a lot of the difficulty that is inherent to bin packing. In particular, we do not know how to describe the probability measures that satisfy the conditions of Corollary D.

The paper is organized as follows. Some simple facts are collected in § 2. Theorem C is deduced from Theorem A in § 3. In § 4, we prove the sharpened matching lemma that is basic for the proof of Theorem A, and Theorem A is proved in the final § 5.

2. Some basis facts. The *pointwise convergence topology* on the set of all functions on $[0, 1]$ is the coarsest topology such that all the maps $f \to f(t)$ are continuous for all $0 \leqq t \leqq 1$. *Helly's compact* H is the set of all nondecreasing functions from $[0, 1]$ to $[0, 1]$ provided with the pointwise convergence topology [Eng], and $\mathscr{C}$ is a closed subset of Helly's compact. It should be noted that $\mathscr{H}$ is not metrizable. For each probability measure γ on $[0, 1]$, the map $f \to \int f\,d\gamma$ is pointwise continuous on $\mathscr{H}$, and hence on $\mathscr{C}$ (see [Eng], 3.2.E). (This is an elementary exercise.) The following will be essential.

LEMMA 1. *For each probability measure γ on $[0, 1]$, we have*

$$c(\gamma) = \operatorname*{Sup}_{f \in \mathscr{C}} \int f\,d\gamma. \tag{2.1}$$

Proof. Let $\theta < c(\gamma)$. Then, according to Theorem E, b, of [Rhe2], there exists a nonnegative continuous function g on $[0, 1]$ such that $\int g\,d\gamma > \theta$, $g(0) = 0$, and that $\sum_{i \leqq k} g(x_i) \leqq 1$ whenever $\sum_{i \leqq k} x_i \leqq 1$, $0 \leqq x_i \leqq 1$. This shows that if we define

$$f(x) = \operatorname{Sup} \left\{ \sum_{i \leqq k} g(x_i);\ k \geqq 1,\ \sum_{i \leqq k} x_i \leqq x,\ 0 \leqq x_i \leqq 1 \right\}$$

then $f \leqq 1$. It is routine to check that $f \in \mathscr{C}$; and since $f \geqq g$, we have $\int f\,d\gamma \geqq \int g\,d\gamma$. So, we have shown that

$$c(\gamma) \leqq \operatorname*{Sup}_{f \in \mathscr{C}} \int f\,d\gamma.$$

To prove the reverse inequality, we note that if $f \in \mathscr{C}$, then if $0 \leqq x_i \leqq 1$ and $\sum_{i \leqq k} x_i \leqq 1$, we have $\sum_{i \leqq k} f(x_i) \leqq f(\sum_{i \leqq k} x_i) \leqq 1$, so the inequality $\int f\,d\gamma \leqq c(\gamma)$ follows from [Rhe2], Theorem E, c.

Since $f \to \int f\,d\mu$ is pointwise continuous, this Lemma implies that $\mathscr{C}_\mu$ is not empty, and that $c(\gamma) = \max_{f \in \mathscr{C}} \int f\,d\gamma$.

LEMMA 2. *For each n, we can find independent identically distributed random variables $X_1, \cdots, X_n$ distributed according to μ and processes $W_{n,\mu,t}$, $W^-_{n,\mu,t}$ jointly distributed as $W_{\mu,t}$, $W^-_{\mu,t}$ such that*

$$E(S_n) \leqq K(\log n)/\sqrt{n}, \qquad E(S_n^-) \leqq K(\log n)/\sqrt{n} \tag{2.2}$$

where

$$S_n = \operatorname*{Sup}_{0 \leqq t \leqq 1} |(\operatorname{card}\{i \leqq n;\ X_i \leqq t\} - nF_\mu(t))/\sqrt{n} - W_{n,\mu,t}| \tag{2.3}$$

$$S_n^- = \operatorname*{Sup}_{0 \leqq t \leqq 1} |(\operatorname{card}\{i \leqq n;\ X_i < t\} - nF_\mu^-(t))/\sqrt{n} - W^-_{n,\mu,t}|. \tag{2.4}$$

Proof. It is proved in [Kom] that one can find independent identically distributed random variables $Y_1, \cdots, Y_n$ uniformly distributed on $[0, 1]$ and a process $W_{n,t}$ distributed as W_t such that if

$$S_n' = \operatorname*{Sup}_{0 \leqq t \leqq 1} |(\operatorname{card}\{i \leqq n;\ Y_i \leqq t\} - nt)/\sqrt{n} - W_{n,t}|,$$

then $E(S_n') \leqq Kn^{-1/2} \log n$ (and actually $E(\exp(\alpha n^{1/2}(\log n)^{-1} S_n')) < K$ for some $\alpha > 0$). Consider the function H given by $H(u) = \inf\{t \geqq 0;\ \mu([0, t]) \geqq u\}$. Then (as well known), if $X_i = H(Y_i)$, the sequence $(X_i)_{i \leqq n}$ is independent identically distributed and distributed according to μ; and it is easy to see that the result follows by setting $W_{n,\mu,t} = W_{n,F_\mu(t)}$, $W^-_{n,\mu,t} = W^-_{n,F_\mu^-(t)}$ (note that $H(u) \leqq a \Leftrightarrow u \leqq F_\mu(a)$ and $H(u) < a \Leftrightarrow u < F_\mu^-(a)$).

LEMMA 3. (*Integration by parts*; *well known.*) *Let $f \in \mathscr{H}$ and ν be a probability measure on $[0, 1]$, and let $(u_i)_{i \in J}$ be an enumeration of the points t for which $\nu(\{t\}) > 0$. Then*

$$\int f\,d\nu = f^-(1) - \int F_\nu\,d\gamma_f + \sum_{i \in J} (f(u_i) - f^-(u_i))\nu(\{u_i\}).$$

Proof. We have $\int f\,d\nu = \int f^-\,d\nu + \sum_{i \in J} (f(u_i) - f^-(u_i))\nu(\{u_i\})$, since $f = f^-$ except on a set which is at most countable. It remains to show that $\int F^-_{\gamma_f}\,d\nu + \int F_\nu\,d\gamma_f = f^-(1)$. But the first integral is the measure of the set $\{(t, u);\ 0 \leqq t < u \leqq 1\}$ for the product measure $\gamma_f \times \nu$ while the second integral is the measure of $\{(t, u);\ 0 \leqq u \leqq t \leqq 1\}$.

LEMMA 4. *For a continuous function g on $[0, 1]$, and f in $\mathscr{H}$, consider*

$$\phi(f, g) = -\int g \circ F_\mu(t)\,d\gamma_f(t) + \sum_{i \in J} (f(z_i) - f^-(z_i))(g(F_\mu(z_i)) - g(F_\mu^-(z_i))).$$

Then for each g such that $g(0) = g(1) = 0$, the map $f \to \phi(f, g)$ is pointwise continuous on $\mathscr{H}$.

Comment. The purpose of the functional ϕ is to give a rigorous meaning to the expression $\int f\,d(g \circ F_\mu)$.

Proof. We consider first the case where g is piecewise affine. In that case, we can write $g = g_1 - g_2$, where g_1 and g_2 are nondecreasing, $g_1(0) = g_2(0) = 0$, $g_1(1) = g_2(1)$. There is no loss of generality to assume that $g_1(1) = g_2(1) = 1$. In that case, for $l = 1, 2$, $g_l \circ F_\mu$ is right continuous, so it is of the type F_{ν_l} for some probability measure ν_l on $[0, 1]$. Only the points $(z_i)_{i \in J}$ can be atoms of ν_l, and $\nu_l(\{z_i\}) = g_l(F_\mu(z_i)) - g_l(F_\mu^-(z_i))$. Lemma 3 then shows that

$$\phi(f, g_l) = -f^-(1) + \int f \, d\nu_l,$$

so that

$$\phi(f, g) = \int f \, d\nu_1 - \int f \, d\nu_2$$

is pointwise continuous as mentioned above.

We note that for each f in $\mathscr{H}$, we have

$$\sum f(t) - f^-(t) \leqq 1, \tag{2.5}$$

where the summation is taken over all the t for which $f(t) - f^-(t) > 0$. (This fact will be used repeatedly in the sequel.)

It follows easily that for each f in $\mathscr{H}$, we have

$$|\phi(f, g)| \leqq 3 \operatorname{Sup} |g|. \tag{2.6}$$

To conclude the proof, we note that any continuous function which is zero at 0 and 1 can be approximated arbitrarily well in the supremum norm by a piecewise affine function which is zero at 0 and 1.

Remark. If W denotes the function $t \to W_t$, we see from (1.5) that

$$T = \operatorname*{Sup}_{f \in \mathscr{C}_\mu} \phi(f, W).$$

3. Proof of Theorem C. The idea is very simple. Let $\nu = (1/n) \sum_{i \leqq n} \delta_{X_i}$. According to (1.4), and since $n^{-1/2}(n^{5/11}(\log n)^{1/2}) = o(1)$, it is enough to show that $E(|n^{1/2}(c(\nu) - c(\mu)) - T_n|) = o(1)$. The heuristic proof goes as follows. We have, by (2.1)

$$c(\nu) - c(\mu) = \operatorname*{Sup}_{f \in \mathscr{C}} \left(\int f \, d\nu - c(\mu) \right). \tag{3.1}$$

By (2.3), we have

$$F_\nu(t) = F_\mu(t) + n^{-1/2} W_{n, F_\mu(t)} + o(n^{-1/2}), \tag{3.2}$$

so we can hope that

$$d\nu = d\mu + n^{-1/2} \, d(W_{n, F_\mu}) + o(n^{-1/2})$$

and hence

$$\begin{aligned} \int f \, d\nu &= \int f \, d\mu + n^{-1/2} \int f \, d(W_{n, F_\mu}) + o(n^{-1/2}) \\ &= \int f \, d\mu + n^{-1/2} \phi(f, W_{n,\cdot}) + o(n^{-1/2}), \end{aligned}$$

(where $W_{n,\cdot}$ is the function $t \to W_{n,t}$). So we have

$$\begin{aligned} c(\nu) - c(\mu) &= \operatorname*{Sup}_{f \in \mathscr{C}} \left(\int f \, d\mu - c(\mu) + n^{-1/2} \phi(f, W_{n,\cdot}) \right) + o(n^{-1/2}) \\ &= n^{-1/2} \Delta + o(n^{-1/2}), \end{aligned} \tag{3.3}$$

where Δ is the right derivative at zero of the function $a \to \mathrm{Sup}_{f\in\mathscr{C}}(\int f\,d\mu - c(\mu) + a\phi(f, W_{n,\cdot}))$, that turns out to be $\mathrm{Sup}_{f\in\mathscr{C}_\mu}\phi(f, W_{n,\cdot}) = T_n$. This completes the heuristic proof.

We start the rigorous proof, and we first collect a few easy facts.

LEMMA 5. *With probability one, we have for all f in $\mathscr{H}$,*

$$\left|\int f\,d\nu - f^-(1) + \int F_\nu\,d\gamma_f - \sum_{i\in J}(f(z_i)-f^-(z_i))\nu(\{z_i\})\right| \leqq 1/n.$$

Proof. The points $X_1, \cdots, X_n$ are not distinct in general. However, with probability 1, if two points X_i, X_j are equal, they are equal to one z_i. Let $u_1, \cdots, u_m$ $(m \leqq n)$ be the points u for which $\nu(\{u\}) > 0$; that is $u_1, \cdots, u_m$ is the set of different values taken by $X_1, \cdots, X_n$. According to Lemma 3, we have

$$\int f\,d\nu = f^-(1) - \int F_\nu\,d\gamma_f + \sum_{i\leqq m}(f(u_i)-f^-(u_i))\nu(\{u_i\}). \tag{3.4}$$

Now (with probability 1) if u_j is not one of the points z_i, then $\nu(\{u_j\}) \leqq 1/n$. The result then follows from (2.5).

For f in $\mathscr{C}$, we denote by $T_{n,f}$ (respectively, T_f) the random variable given by

$$T_{n,f} = \phi(f, W_{n,\cdot}) = -\int W_{n,\mu,t}\,d\gamma_f(t) + \sum_{i\in J}(f(z_i)-f^-(z_i))(W_{n,\mu,z_i} - W^-_{n,\mu,z_i})$$

$$\left(\text{respectively,}\quad T_f = \phi(f, W_\cdot) = -\int W_{\mu,t}\,d\gamma_f(t) + \sum_{i\in J}(f(z_i)-f^-(z_i))(W_{\mu,z_i} - W^-_{\mu,z_i})\right)$$

so that $T = \mathrm{Sup}_{f\in\mathscr{C}_\mu} T_f$. We set $T_n = \mathrm{Sup}_{f\in\mathscr{C}_\mu} T_{n,f}$, so that T_n is distributed as T.

LEMMA 6. *With probability* 1, *for all f in $\mathscr{H}$, we have*

$$\left|\int f\,d\nu - \int f\,d\mu - n^{-1/2}T_{n,f}\right| \leqq 1/n + (2S_n + S_n^-)n^{-1/2}. \tag{3.5}$$

Proof. From Lemmas 3 and 5, with probability 1 we have for all f in $\mathscr{H}$,

$$\left|\int f\,d\nu - \int f\,d\mu + \int (F_\nu - F_\mu)\,d\gamma_f - \sum_{i\in J}(f(z_i)-f^-(z_i))(\nu(\{z_i\}) - \mu(\{z_i\}))\right| \leqq 1/n.$$

From (2.3), we have, for all $0 \leqq t \leqq 1$,

$$|F_\nu(t) - F_\mu(t) - n^{-1/2}W_{n,\mu,t}| \leqq S_n n^{-1/2}.$$

For all $i \in J$, we have

$$\nu(\{z_i\}) - \mu(\{z_i\}) = F_\nu(z_i) - F_\mu(z_i) - (F^-_\nu(z_i) - F^-_\mu(z_i)),$$

so from (2.3) and (2.4), we have

$$|\nu(\{z_i\}) - \mu(\{z_i\}) - n^{-1/2}(W_{n,\mu,z_i} - W^-_{n,\mu,z_i})| \leqq (S_n + S_n^-)n^{-1/2}.$$

Hence

$$\left|\int f\,d\nu - \int f\,d\mu - n^{-1/2}T_{n,f}\right| \leqq 1/n + S_n n^{-1/2} + \sum_{i\in J}(f(z_i)-f^-(z_i))(S_n + S_n^-)n^{-1/2}.$$

This concludes the proof.

The basic lemma is as follows.

LEMMA 7. *Consider the function*

$$\psi(a) = \operatorname{Sup}_{f \in \mathscr{C}} \left(\int f \, d\mu + a T_f - c(\mu) \right). \tag{3.6}$$

Then $\psi(0) = 0$, ψ is convex, and its right derivative at zero is equal to T.

Proof. It is obvious that $\psi(0) = 0$ (since $c(\mu) = \operatorname{Sup}_{f \in \mathscr{C}} \int f \, d\mu$) and that ψ is convex. Denote by Δ its right derivative at zero, i.e., $\Delta = \lim_{a \to 0, a > 0} \psi(a)/a$. Since ψ is convex, we have $\psi(a) \geqq a\Delta$ for $a > 0$. Obviously, we have $\psi(a) \geqq aT$, so $\Delta \geqq T$. Since $\psi(k^{-1}) \geqq k^{-1}\Delta$ for each k, we can find $f_k \in \mathscr{C}$ such that

$$\int f_k \, d\mu + k^{-1} T_{f_k} - c(\mu) \geqq k^{-1}\Delta - k^{-2}.$$

Since $T_{f_k} = \phi(f_k, W_\cdot)$ satisfies $|T_{f_k}| \leqq 3 \operatorname{Sup}_t |W_t|$ for all k by (2.6), we see that $\liminf_{k \to \infty} \int f_k \, d\mu \geqq c(\mu)$. Hence all cluster points of the sequence (f_k) (for the pointwise topology) belong to $\mathscr{C}_\mu$. Let f be such a cluster point. We have

$$k^{-1}\Delta - k^{-2} \leqq \int f_k \, d\mu + k^{-1} T_{f_k} - c(\mu) \leqq k^{-1} T_{f_k},$$

so $\Delta - k^{-1} \leqq T_{f_k}$ for each k. Since, by Lemma 4, the map $h \to T_h$ is pointwise continuous on $\mathscr{H}$, we see that $\Delta \leqq T_f$, and $T_f \leqq T$ since $f \in \mathscr{C}_\mu$. So $\Delta \leqq T$, and this concludes the proof.

We now prove Theorem C. From Lemma 1, we have $c(\nu) = \operatorname{Sup}_{f \in \mathscr{C}} \int f \, d\nu$, so $c(\nu) - c(\mu) = \operatorname{Sup}_{f \in \mathscr{C}} \int f \, d\nu - c(\mu)$. From (3.5), we have

$$\left| c(\nu) - c(\mu) - \operatorname{Sup}_{f \in \mathscr{C}} \left(\int f \, d\mu + n^{-1/2} T_{n,f} - c(\mu) \right) \right| \leqq (2S_n + S_n^-) n^{-1/2} + 1/n,$$

so if ψ_n denotes the function defined as ψ but using $T_{n,f}$ instead of T_f, we have

$$|n^{1/2}(c(\nu) - c(\mu)) - n^{1/2}\psi_n(n^{-1/2})| \leqq 2S_n + S_n^- + n^{-1/2}.$$

So we have

$$E(|n^{1/2}(c(\nu) - c(\mu)) - n^{1/2}\psi_n(n^{-1/2})|) \leqq K n^{-1/2} \log n$$

for some universal constant K. Now the random variable $n^{1/2}\psi_n(n^{-1/2}) - T_n$ is distributed as $n^{1/2}\psi(n^{-1/2}) - T$. By Lemma 7, we have $T \leqq n^{1/2}\psi(n^{-1/2}) \leqq \psi(1)$, and $\lim_{n \to \infty} n^{1/2}\psi(n^{-1/2}) = T$. Since $E(|\psi(1)|) < \infty$, by dominated convergence we see that $\lim_{n \to \infty} E(|n^{1/2}\psi(n^{-1/2}) - T|) = 0$, so $\lim_{n \to \infty} E(|n^{1/2}\psi_n(n^{-1/2}) - T_n|) = 0$. This concludes the proof.

Proof of Corollary D. From Theorem C, we see that

$$\lim_{n \to \infty} E((Q_n(X_1, \cdots, X_n) - nc(\mu))/\sqrt{n}) = 0$$

if and only if $E(T) = 0$. Now T is the supremum of a collection of centered Gaussian random variables, so it can have zero expectation only if whenever $f_1, f_2 \in \mathscr{C}_\mu$, we have $T_{f_1} = T_{f_2}$ almost surely, i.e. $T_{f_1} - T_{f_2} = 0$ almost surely. It is a well-known fact that for a continuous linear functional Z on $C([0, 1])$, the random variable $Z(W_t)$ is almost surely zero if and only if $Z(g) = 0$ for all g in $C([0, 1])$ for which $g(0) = g(1) = 0$. We have (with the notation of Lemma 4) $T_{f_1} - T_{f_2} = \phi(f_1, W_t) - \phi(f_2, W_t)$. So, the necessary and sufficient condition is that $\phi(f_1, g) = \phi(f_2, g)$ for all g in $C([0, 1])$ such that $g(0) = g(1) = 0$.

FACT. *We have $f_1 = f_2$ on the support A of μ, except on a countable set of μ measure zero if and only if $\int f_1\, d\nu = \int f_2\, d\nu$ for each probability measure ν such that $F_\nu = h \circ F_\mu$ for a continuous nondecreasing function h.*

Proof. It is routine to check that ν has the property that $F_\nu = h \circ F_\mu$ for a continuous nondecreasing function h if and only if $\nu(A) = 1$ and $\nu(\{t\}) = 0$ whenever $\mu(\{t\}) = 0$. This makes the necessity obvious. Conversely, if $\int f_1\, d\nu = \int f_2\, d\nu$ for each such probability ν, then $f_1 = f_2$ at each point t for which $\mu(\{t\}) > 0$, as well as at each point t of A at which f_1 and f_2 are continuous. Since f_1 and f_2 each have at most a countable number of discontinuities, this concludes the proof.

We go back to the proof of Corollary D.

Proof of Necessity. We define the function ι by $\iota(t) = t$. Whenever h is continuous nondecreasing, $h(0) = 0$ and $h(1) = 1$, we must have $\phi(f_1, h - \iota) = \phi(f_2, h - \iota)$. Using Lemma 3, we see that for $i = 1, 2$, we have $\phi(f_i, \iota) = \int f_i\, d\mu - f_i^-(1) = c(\mu) - f_i^-(1)$. Let ν be the probability measure such that $F_\nu = h \circ F_\mu$. Then Lemma 3 shows that $\phi(f_i, h) = \int f_i\, d\nu - f_i^-(1)$ for $i = 1, 2$, so $\phi(f_i, h - \iota) = \int f_i\, d\nu - c(\mu)$, so we must have $\int (f_1 - f_2)\, d\nu = 0$ whenever $F_\nu = h \circ F_\mu$ for a continuous function h such that $h(0) = 0$, $h(1) = 1$. The conclusion then follows from the Fact.

Proof of Sufficiency. The fact shows that $\int f_1\, d\nu = \int f_2\, d\nu$ whenever $F_\nu = h \circ F_\mu$ for some continuous nondecreasing function h with $h(0) = 0$, $h(1) = 1$, and hence that $\phi(f_1, h - \iota) = \phi(f_2, h - \iota)$ by the same computation as above. It follows that for each continuous nondecreasing function h which is zero at the origin, we have $\phi(f_1, h - h(1)\iota) = \phi(f_2, h - h(1)\iota)$. Any g in $C([0, 1])$ with $g(0) = g(1) = 0$ can be approximated in the uniform norm by a difference $h_1 - h_2$, where h_1 and h_2 are nondecreasing and $h_1(0) = h_2(0) = 0$, $h_1(1) = h_2(1)$. Since $h_1 - h_2 = h_1 - h_1(1)\iota - (h_2 - h_2(1)\iota)$, we see that $\phi(f_1, g) = \phi(f_2, g)$ and this completes the proof.

4. Tighter bounds for packing. The proof closely follows that of Theorem B of [Rhe2]. The crucial point of that proof was a matching Lemma (Lemma 4 of [Rhe2]). Our gain in accuracy will be obtained by an improvement of that lemma. While the proof of Lemma 4 of [Rhe2] was purely deterministic, the method we will use here is partly probabilistic. It will make use of the following lemma. Lemma 8 could be sharpened and generalized, but we will give only the simplest version that is suitable for our needs.

LEMMA 8. *Let $m \geqq 16$. Consider independent random variable $(Z_i)_{i \leqq m}$, numbers a, b, and numbers $(a_i)_{i \leqq m}$, $(b_i)_{i \leqq m}$ such that $a \leqq a_i \leqq Z_i \leqq b_i \leqq b$ for each i. Assume that for some $r \geqq \sqrt{\log m}$ and for any t, we have*

$$\operatorname{card}\{i \leqq m;\ a_i \leqq t \leqq b_i,\ a_i \neq b_i\} \leqq r.$$

Then we have

$$P\left(\sup_{a \leqq t \leqq b} \left| \operatorname{card}\{i \leqq m;\ Z_i \geqq t\} - \sum_{i \leqq m} P(Z_i \geqq t) \right| \leqq 1 + 3\sqrt{r \log m} \right) \geqq \frac{3}{4}.$$

Proof. Let $F(t) = \sum_{i \leqq m} P(Z_i \geqq t)$, so F is left continuous and nonincreasing. Let $t_0 = b$ and by induction over $l \geqq 1$, define

$$t_l = \operatorname{Sup}\{t;\ a \leqq t \leqq b,\ F(t) > F(t_{l-1}) + 1\},$$

so that $F(t_l) \geqq F(t_{l-1}) + 1$, and hence $F(t_l) \geqq l$. The construction continues until we construct t_q, for which $F(a) = m \leqq F(t_q) + 1$. Set $t_{q+1} = a$. Since $F(t_q) \leqq m$, we have $q \leqq m$. For $0 \leqq l \leqq q + 1$, $i \leqq m$, define

$$X_{i,l} = P(Z_i \geqq t_l) - 1_{\{Z_i \geqq t_l\}}, \qquad Y_{i,l} = P(Z_i > t_l) - 1_{\{Z_i > t_l\}},$$

and set

$$X_l = \sum_{1 \leqq i \leqq m} X_{i,l}, \qquad Y_l = \sum_{1 \leqq i \leqq m} Y_{i,l}.$$

We note that $E(X_{i,l}) = E(Y_{i,l}) = 0$.

Fix t in $[a, b[$ and let l be the smallest integer $\leqq q+1$ such that $t_l \leqq t$, so $t < t_{l-1}$. Assume that $t_l < t$. By definition of t_l, we have $F(u) \leqq F(t_{l-1}) + 1$ for $u > t_l$. Also $F(t_{l-1}) \leqq F(t)$. We have

$$\sum_{i \leqq m} P(Z_i > t_l) = \lim_{u \to t_l, u > t_l} F(u) \leqq F(t_{l-1}) + 1 \leqq F(t) + 1,$$

and hence

$$-F(t) + \operatorname{card}\{i \leqq m;\ Z_i \geqq t\} \leqq -\sum_{i \leqq m} P(Z_i > t_l) + \operatorname{card}\{i \leqq m;\ Z_i > t_l\} + 1 = 1 - Y_l.$$

We also have

$$F(t) - \operatorname{card}\{i \leqq m;\ Z_i \geqq t\} \leqq F(t_{l-1}) - \operatorname{card}\{i \leqq m;\ Z_i \geqq t_{l-1}\} + 1 = 1 + X_{l-1}.$$

This shows that

$$\operatorname*{Sup}_{t \in [a,b]} |F(t) - \operatorname{card}\{i \leqq m;\ Z_i \geqq t\}| \leqq 1 + \operatorname*{Sup}_{0 \leqq l \leqq q+1} (|X_l|, |Y_l|).$$

For any given l, by hypothesis at most r of the variables $X_{l,i}$ are not constant. Also $-1 \leqq X_{l,i} \leqq 1$ and $\operatorname{Var}(X_{l,i}) \leqq 1$. It then follows from Bernstein's inequality, as in [Hoe], that for $u > 0$,

$$P\left(\left|\sum_{i \leqq m} X_{l,i}\right| > u\right) \leqq 2 \exp(-u^2/(2r + 2u/3)).$$

Taking $u = 3\sqrt{r \log m}$, we have $u \leqq 3r$, so

$$P\left(\left|\sum_{i \leqq m} X_{l,i}\right| > 3\sqrt{r \log m}\right) \leqq 2 \exp(-(\tfrac{9}{4}) \log m) = 2m^{-9/4}$$

and a similar inequality holds for $Y_{l,i}$. So for $m \geqq 16$,

$$P(\text{for each } l, |X_l| \leqq 3\sqrt{r \log m}, |Y_l| \leqq 3\sqrt{r \log m}) \geqq 1 - 2(m+2)m^{-9/4} \geqq 1 - 4/m \geqq \tfrac{3}{4}.$$

The following lemma is purely technical. Its proof is entirely similar to that of Lemma 3 of [Rhe2].

LEMMA 9. *Let γ be a positive measure on a compact metric space S. Consider $p \geqq 1$. Consider a sequence $(b_i)_{i \leqq p}$ such that $\sum_{1 \leqq i \leqq p} b_i = \|\gamma\|$, and a continuous function f on S. Then there is $u_p \leqq u_{p-1} \leqq \cdots \leqq u_0$ and for $1 \leqq i \leqq p$ there is a positive measure γ_i on S such that the following hold*

$$\gamma = \sum_{i \leqq p} \gamma_i \tag{4.1}$$

$$\gamma_i \text{ is supported by } f^{-1}([u_i, u_{i-1}]) \tag{4.2}$$

$$\|\gamma_i\| = b_i. \tag{4.3}$$

LEMMA 10. *Let $16 \leqq m \leqq n$. Let γ be a positive measure on $[0,1]^2$. Assume that $(m/n) \leqq \|\gamma\| < (m+1)/n$. Consider the three positive measures given by, for each Borel set U,*

$$\gamma'(U) = \gamma(U \times [0,1])$$
$$\gamma''(U) = \gamma([0,1] \times U)$$
$$\eta(U) = \gamma(\{(x,y);\ x + y \in U\}).$$

(In other words, γ' and γ'' are the marginals of γ, and η is the distribution of $x+y$, so η is supported by $[0,2]$.)

Consider two sequences $(l_i)_{i\le m}$, $(y_i)_{i\le m}$ of numbers, $0\le l_i,\ y_i\le 1$. Assume that

$$\text{for each } t\in[0,1],\quad \text{card}\{i\le m;\ l_i\ge t\}\le n\gamma'([t,1]), \tag{4.4}$$

$$\text{for each } t\in[0,1],\quad \text{card}\{i\le m;\ y_i\ge t\}\le n\gamma''([t,1]). \tag{4.5}$$

Let $1\le k\le m^{1/4}$. There exist two subsets A and B of $\{1,\cdots,m\}$ such that $B\subset A$, and that

$$\text{card } A\ge m-K\sqrt{\log m}\,(m/k)^{1/3}, \tag{4.6}$$

$$\text{card } B\ge m-K\sqrt{\log m}\,(mk^2)^{1/3}, \tag{4.7}$$

and there exists a one-to-one map ϕ from B to $\{1,\cdots,m\}$ such that if we set $z_i=l_i$ for $i\in A\setminus B$ and $z_i=l_i+y_{\phi(i)}$ for $i\in B$, then

$$\text{for each } t\in[0,2],\quad \text{card}\{i\in A;\ z_i\ge t\}\le n\eta([t,2]). \tag{4.8}$$

Remark. In the case $k=\lfloor m^{1/4}\rfloor$, this means that there is a subset B of $\{1,\cdots,m\}$ with card $B\ge m-Km^{1/4}\sqrt{\log m}$ and a one-to-one map ϕ from B to $\{1,\cdots,m\}$ such that

$$\text{for each } t\in[0,2],\ \text{card}\{i\in B;\ l_i+y_{\phi(i)}\ge t\}\le n\eta([t,2]). \tag{4.9}$$

Proof of Lemma 10. Let $q=\lfloor m^{1/3}k^{-4/3}\rfloor$, $p=\lfloor\sqrt{m/q}\rfloor$. We note that $q\le m^{1/3}$, so $p\ge\lfloor m^{1/3}\rfloor\ge q$ and $p\ge 2$. We note that $(p+1)^2q\ge m$, so $(p+3)pq\ge m+1$. Also $p^2q\le m\le n\|\gamma\|$. Hence, if $p'=\lceil n\|\gamma\|/pq\rceil$, we have $q\le p\le p'\le p+3$.

Step 1. Using Lemma 9, we can find numbers $u_{p'}\le\cdots\le u_0$ and for $1\le i\le p'$ a positive measure γ_i on $[0,1]^2$ that is supported by the set

$$\{(x,y)\in[0,1]^2;\ u_i\le x+y\le u_{i-1}\},$$

such that $\gamma=\sum_{1\le i\le p'}\gamma_i$, and that

$$\|\gamma_i\|=pq/n\quad\text{for } 1\le i<p',$$

$$\|\gamma_{p'}\|=(n\|\gamma\|-(p'-1)pq)/n\le pq/n.$$

Step 2. For each $1\le i\le p'-1$, let $q'(i)=q$. Define $q'(p')$ as the smallest integer $\ge\|\gamma_{p'}\|n/p$, so $q'(p')\le q$. Using Lemma 9 for each $1\le i\le p'$, we can find numbers $u_{i,q'(i)}\le\cdots\le u_{i,0}$, and for $1\le i\le q'(i)$ a positive measure $\gamma_{i,j}$ on $[0,1]^2$, that is supported by the set

$$\{(x,y)\in[0,1]^2;\ u_i\le x+y\le u_{i-1},\ u_{i,j}\le y\le u_{i,j-1}\},$$

such that $\gamma_i=\sum_{1\le j\le q(i)}\gamma_{i,j}$ and that

$$\|\gamma_{i,j}\|=p/n\quad\text{for } i<p'\ \text{ or }\ j<q'(p)$$

and

$$\|\gamma_{p',q'(p')}\|\le p/n.$$

Step 3. For each $1\le i\le p'$, and each $1\le j\le q'(i)$, we denote by $r(i,j)$ the smallest integer $\ge n\|\gamma_{i,j}\|$, so $r(i,j)=p$ unless $i=p'$, $j=q'(p')$, in which case $r(p',q'(p'))\le p$. Using Lemma 9 for each $1\le i\le p'$, $1\le j\le q'(i)$, we can find numbers $u_{i,j,r(i,j)}\le\cdots\le u_{i,j,0}$ and for $1\le l\le r(i,j)$ a positive measure $\gamma_{i,j,l}$ on $[0,1]^2$, that is supported by the set

$$A_{i,j,l}=\{(x,y)\in[0,1]^2;\ u_i\le x+y\le u_{i-1},\ u_{i,j}\le y\le u_{i,j-1}$$
$$u_{i,j,l}\le x\le u_{i,j,l-1}\}$$

and such that $\gamma_{i,j} = \sum_{1 \leqq l \leqq r(i,j)} \gamma_{i,j,l}$ and $\|\gamma_{i,j,l}\| = 1/n$ except for $i = p'$, $j = q'(p')$, $l = r(p', q'(p'))$ in which case $\|\gamma_{i,j,l}\| \leqq 1/n$.

For the sake of simplicity, we set

$$S = \{(i, j, l);\ 1 \leqq i \leqq p';\ 1 \leqq j \leqq q'(i);$$

$$1 \leqq l \leqq r(i, j);\ (i, j, l) \neq (p', q'(p'), r(p', q'(p')))\}$$

so that card $S = m$ and $\|\gamma_{i,j,l}\| = 1/n$ for (i, j, l) in S.

Step 4. We prove the following assertions: for all t,

$$\text{card}\{s \in S;\ \text{there exists } (x, y) \in A_s,\ x + y = t,\ \text{there exists } (x', y') \in A_s,\ x' + y' \neq t\} \leqq 2pq, \tag{4.10}$$

$$\text{card}\{s \in S;\ \text{there exists } (x, y) \in A_s,\ y = t,\ \text{there exists } (x', y') \in A_s,\ y' \neq t\} \leqq 2p'p, \tag{4.11}$$

$$\text{card}\{s \in S;\ \text{there exists } (x, y) \in A_s,\ x = t,\ \text{there exists } (x', y') \in A_s,\ x' \neq t\} \leqq 2p'q. \tag{4.12}$$

To prove (4.10), we fix t and we denote by i' the smallest index for which $u_{i'} < t$, and by i'' the largest index for which $t < u_{i''-1}$. (The case where one of these indices cannot be defined is simpler and is left to the reader.) If, for some $s = (i, j, l) \in S$, there exists $(x, y) \in A_s$ with $x + y = t$, then necessarily $i'' \leqq i \leqq i'$. If we have $i'' < i < i'$, then, by definition of i' and i'', we have $u_i \geqq t$, $u_{i-1} \leqq t$. Since $u_{i-1} \geqq u_i$, we have $t = u_i = u_{i-1}$, and there exists no (x', y') in A_s with $x' + y' \neq t$. So, we have shown that if there is (x, y) in A_s with $x + y = t$, and there is (x', y') in A_s with $x' + y' \neq t$, then $i = i'$ or $i = i''$. So there are only two possibilities for i and at most p possibilities for j, q possibilities for l, which proves (4.10).

To prove (4.11) (respectively, (4.12)), we fix t and we prove in a similar way, that for any $1 \leqq i \leqq p'$ (respectively $1 \leqq i \leqq p'$, $1 \leqq j \leqq q'(i)$) there are at most two possibilities for j (respectively, l).

Step 5. For each s in S, we consider a random variable (U_s, V_s) distributed according to $n\gamma_s$. We set

$$F'(t) = \sum_{s \in S} P(U_s \geqq t), \quad F''(t) = \sum_{s \in S} P(V_s \geqq t), \quad F(t) = \sum_{s \in S} P(U_s + V_s \geqq t).$$

Since $\|\gamma - \sum_{s \in S} \gamma_s\| \leqq 1/n$, we have

$$\sup_{0 \leqq t \leqq 1} |F'(t) - n\gamma'([t, 1])| \leqq 1, \qquad \sup_{0 \leqq t \leqq 1} |F''(t) - n\gamma''([t, 1])| \leqq 1,$$

$$\sup_{0 \leqq t \leqq 2} |F(t) - n\gamma([t, 2])| \leqq 1.$$

It is easily seen that, since $m \geqq 16$, we have $pq \geqq \sqrt{\log m}$, so that $p'p \geqq p^2 \geqq pq \geqq \sqrt{\log m}$. We can then use Step 4 and Lemma 8 to see that

$$P\left(\sup_{0 \leqq t \leqq 1} |\text{card}\{s \in S;\ U_s \geqq t\} - n\gamma'([t, 1])| \leqq 2 + 3\sqrt{2p'q \log m}\right) \geqq \frac{3}{4},$$

$$P\left(\sup_{0 \leqq t \leqq 1} |\text{card}\{s \in S;\ V_s \geqq t\} - n\gamma''([t, 1])| \leqq 2 + 3\sqrt{2p'p \log m}\right) \geqq \frac{3}{4},$$

$$P\left(\sup_{0 \leqq t \leqq 2} |\text{card}\{s \in S;\ U_s + V_s \geqq t\} - n\eta([t, 2])| \leqq 2 + 3\sqrt{2pq \log m}\right) \geqq \frac{3}{4}.$$

So, we can find points $(u_s, v_s)_{s\in S}$ such that for $0\leqq t\leqq 1$,

$$\text{card}\,\{s\in S;\ u_s\geqq t\}\geqq n\gamma'([t,1])-2-3\sqrt{2p'q\log m}\,,$$

$$\text{card}\,\{s\in S;\ v_s\geqq t\}\geqq n\gamma''([t,1])-2-3\sqrt{2p'p\log m}\,,$$

and for $0\leqq t\leqq 2$,

$$\text{card}\,\{s\in S;\ u_s+v_s\geqq t\}\leqq n\eta([t,2])+2+3\sqrt{2pq\log m}\,.$$

Step 6. It follows from [Rhe2], Lemma 2 (in which we take $p=1$) that there is $S'\subset S$ with $\text{card}\,(S\backslash S')\leqq 3+3\sqrt{2pq\log m}$, and such that for $0\leqq t\leqq 2$,

$$\text{card}\,\{s\in S';\ u_s+v_s\geqq t\}\leqq n\eta([t,2]). \tag{4.13}$$

So we have, for $0\leqq t\leqq 1$,

$$\text{card}\,\{s\in S';\ u_s\geqq t\}\geqq n\gamma'([t,1])-5-6\sqrt{2p'q\log m}\,,$$

$$\text{card}\,\{s\in S';\ v_s\geqq t\}\geqq n\gamma''([t,1])-5-6\sqrt{2p'p\log m}\,.$$

In the last inequality, we have used the fact that $q\leqq p\leqq p'$. It then follows from (4.4) and (4.5) that for $0\leqq t\leqq 1$,

$$\text{card}\,\{i\leqq m;\ l_i\geqq t\}\leqq \text{card}\,\{s\in S';\ u_s\geqq t\}+5+6\sqrt{2p'q\log m}\,,$$

$$\text{card}\,\{i\leqq m;\ y_i\geqq t\}\leqq \text{card}\,\{s\in S';\ v_s\geqq t\}+5+6\sqrt{2p'p\log m}\,.$$

It follows from [Rhe2] Lemma 1, that there is a subset A of $\{1,\cdots,m\}$ such that

$$\text{card}\,A\geqq m-5-6\sqrt{2p'q\log m}\,, \tag{4.14}$$

and a one-to-one map ϕ_1 from A to S' such that $l_i\leqq u_{\phi_1(i)}$ for i in A. The same lemma implies that there is a subset C of $\{1,\cdots,m\}$ such that

$$\text{card}\,C\geqq m-5-6\sqrt{2p'p\log m}\,,$$

and a one-to-one map ϕ_2 from C to S' such that $y_i\leqq v_{\phi_2(i)}$ if $i\in C$. We consider the subset B of A where $\phi=\phi_2^{-1}\circ\phi_1$ is defined; so

$$\text{card}\,B\geqq m-10-12\sqrt{2p'p\log m}\,. \tag{4.15}$$

For i in A, we have $l_i\leqq u_{\phi_1(i)}\leqq u_{\phi_1(i)}+v_{\phi_1(i)}$. For i in B, we have

$$l_i\leqq u_{\phi_1(i)},\ y_{\phi(i)}\leqq v_{\phi_2\phi(i)}=v_{\phi_1(i)},\quad \text{so } l_i+y_{\phi(i)}\leqq u_{\phi_1(i)}+v_{\phi_1(i)}.$$

This and (4.13) easily imply (4.8) while (4.14) and (4.15) imply (4.6) and (4.7).

5. Proof of Theorem A. For $l\geqq 1$, consider the positive measure λ_l on $[0,1]$ given by

$$\lambda_l=\sum_{k\geqq l}(\alpha_k/k)\int_{R_k}\delta_{x_{k-l+1}}\,d\nu_k(x_1,\cdots,x_k),$$

so that $\|\lambda_l\|=\sum_{k\geqq l}\alpha_k/k=\beta_l$. After normalization, λ_l is the distribution of the size of the lth largest item in bins that contain at least l items.

We now fix q and we prove Theorem A. Consider the positive measure

$$\mu'=\sum_{k\geqq q+1}(\alpha_k/k)\int_{R_k}\sum_{1\leqq i\leqq k-q}\delta_{x_i}\,d\nu_k(x_1,\cdots,x_k), \tag{5.1}$$

so, since $x_i\leqq x_{k-q}\leqq 1/(q+1)$, μ' is supported by $[0,1/(q+1)]$. After normalization, μ' is the distribution of the sizes of the items which are not among the q largest in

the bin that contains them. We note that $\mu = \sum_{l \leqq q} \lambda_l + \mu'$. For $1 \leqq l \leqq q$, let $f_l(t) = \lambda_l([t, 1])$ for $0 \leqq t \leqq 1$. Let

$$f_{q+1}(t) = \mu'([t, 1]), \quad \text{so} \sum_{l \leqq q+1} f_l(t) = \mu([t, 1]).$$

Consider the sequence $s_1, \cdots, s_n$ of items. For each t,

$$\text{card}\,\{i \leqq n;\ s_i \geqq t\} \leqq n \sum_{l \leqq q+1} f_l(t) + D.$$

We now use Lemma 2 of [Rhe2] to find disjoint subsets $(C_l)_{l \leqq q+1}$ of $\{1, 2, \cdots, n\}$ with $\sum_{i \leqq q+1} \text{card}\, C_i \geqq n - q - D - 1$ such that for each $l \leqq q+1$, we have

$$\text{card}\,\{i \in C_l;\ s_i \geqq t\} \leqq n f_l(t)$$

for all $0 \leqq t \leqq 1$.

Let $C' = \{1, \cdots, n\} \backslash \cup_{l \leqq q+1} C_l$, so card $C' \leqq q + D + 1$, and hence C' can be packed in $q + D + 1$ bins.

We now pack the families $(C_l)_{l \leqq q}$. This is done exactly as in [Rhe2], except that now at step l, we can use the improved matching Lemma 10 (with $m = \lfloor n\beta_l \rfloor$, $k = \text{Min}\,(\lfloor n\beta_l \rfloor^{1/4}, l)$) instead of the Lemma 4 of [Rhe2]. This replaces terms $(n/\beta_l)^{1/2}$ by $K(\log m)^{1/2}\,\text{Max}\,((n\beta_l/l)^{1/3}, (n\beta_l)^{1/4})$. Denote by ξ_q the positive measure given by

$$\xi_q = \sum_{k \geqq q+1} (\alpha_k/k) \int_{R_k} \delta_{u_k(x)}\, d\nu_k(x_1, \cdots, x_k), \tag{5.2}$$

where $u_k(x) = \sum_{k-q+1 \leqq i \leqq k} x_i$. After normalization, ξ_q is the distribution of the sum of the sizes of the q largest item in bins that contain at least $q+1$ items. We have $\|\xi_q\| = \beta_{q+1}$. Let $n_{n+1} = \lfloor n\beta_{q+1} \rfloor$. The proof of [Rhe2] shows that the families $C_1, \cdots, C_q$ can be packed in two sets of bins the first of which ("dead bins") have at most

$$n \sum_{l \leqq q} \alpha_l/l + 2q + K(\log n)^{1/2} \sum_{l \leqq q} \text{Max}\,((n\beta_l/l)^{1/3}, (n\beta_l)^{1/4})$$

elements. The second set of bins ("live bins") contains n_{q+1} bins $B_1, \cdots, B_{n_{q+1}}$. If we denote by L_i the sum of the sizes of the items packed in bin B_i, we have the following relation:

$$\text{for all } t \text{ in } [0, 1],\ \text{card}\,\{i \leqq n_{q+1};\ L_i \geqq t\} \leqq n\xi_q([t, 1]).$$

We have

$$\begin{aligned} \sum_{i \leqq n_{q+1}} L_i &= \int_0^1 \text{card}\,\{i \leqq n_{q+1};\ L_i \geqq t\}\, dt \\ &\leqq n \int_0^1 \xi_q([t, 1])\, dt = n \int x\, d\xi_q(x) \\ &= n \sum_{k \geqq q+1} (\alpha_k/k) \int_{R_k} \sum_{k-q+1 \leqq i \leqq k} x_i\, d\nu_k(x_1, \cdots, x_k), \end{aligned} \tag{5.3}$$

where the last equality follows from (5.2). Since $n_{q+1} \geqq n\beta_{q+1} - 1$, we see that the available empty space S in the bins B_i, $i \leqq n_{q+1}$, satisfies

$$\begin{aligned} S &= n_{q+1} - \sum_{i \leqq n_{q+1}} L_i \\ &\geqq -1 + n \sum_{k \geqq q+1} (\alpha_k/k) \int_{R_k} \left(1 - \sum_{k-q+1 \leqq i \leqq k} x_i\right) d\nu_k(x_1, \cdots, x_k) \\ &\geqq -1 + n \sum_{k \geqq q+1} (\alpha_k/k) \int_{R_k} \sum_{1 \leqq i < k-q} x_i\, d\nu_k(x_1, \cdots, x_k) \end{aligned}$$

since $\sum_{1\le i\le k} x_i \le 1$ for $(x_1, \cdots, x_k) \in R_k$. The sum $\sum$ of the elements of C_{q+1} is equal to

$$\int_0^1 \text{card}\,\{i \le C_{q+1};\ s_i \ge t\}\,dt \le \int_0^1 n\mu'([t,1])\,dt = n\int_0^1 x\,d\mu'(x)$$

$$= n\sum_{k\ge q+1}(\alpha_k/k)\int_{R_k}\sum_{1\le i<k-q} x_i\,d\nu_k(x_1,\cdots,x_k).$$

This shows that $\sum \le S+1$. We now pack as many as possible of the elements of C_{q+1} in the available space in the bins $(B_i)_{i\le n_{q+1}}$. Since each element of C_{q+1} has size $\le 1/(q+1)$, if we cannot pack all of C_{q+1}, there is at most $1/(q+1)$ wasted space in each bin B_i, so a total amount of wasted space at most $n_{q+1}/(q+1) \le n\beta_{q+1}/(q+1) \le n/(q+1)^2$. Since $\sum \le S+1$, the sum of the sizes of the items of C_{q+1}, which we have not packed, is at most $n/(q+1)^2+1$, and then, according to [Rhe2], Lemma 5, they can be packed in at most $1+(1+n/(q+1)^2)/(1-1/(q+1)) \le 3+n/q^2$ bins. Thus, we have succeeded in packing the families $(C_l)_{l\le q+1}$ in at most

$$3+n/q^2+2q+n\sum_{l\ge 1}\alpha_l/l+K(\log n)^{1/2}\sum_{l\le q}\text{Max}\,((n\beta_l/l)^{1/3},(n\beta_l)^{1/4})$$

for some universal constant K. This proves (1.2). To prove (1.3), we note that by Hölder's inequality,

$$\sum_{l\le q}(n\beta_l)^{1/4} \le n^{1/4}q^{3/4}\left(\sum_{l\le q}\beta_l\right)^{1/4} \le n^{1/4}q^{3/4}$$

and

$$\sum_{l\le q}(n\beta_l/l)^{1/3} \le n^{1/3}\left(\sum_{l\le q}\beta_l\right)^{1/3}\left(\sum_{1\le l\le q}1/l^{1/2}\right)^{2/3} \le Kn^{1/3}q^{1/3}.$$

Taking $q = \lfloor n^{3/11}\rfloor$ gives (1.3). This completes the proof.

OPTIMAL BIN COVERING WITH ITEMS OF RANDOM SIZE*

WANSOO T. RHEE† AND MICHEL TALAGRAND‡

Abstract. Consider a probability measure μ on $[0, 1]$ and independent random variables $X_1, \cdots, X_n$ distributed according to μ. Let $Q_n = Q_n(X_1, \cdots, X_n)$ be the largest number of unit-size bins that can be covered by items of size $X_1, \cdots, X_n$. The properties of Q_n are investigated in the spirit of our work on optimal bin packing with items of random sizes. While the covering problem has many similarities with the packing problem, it turns out to be significantly harder.

Key words. stochastic bin packing, size distribution, compactness, weak convergence

AMS(MOS) subject classifications. 90B99, 60K30

1. Introduction and results. The bin-packing problem requires finding the minimum number of unit-size bins needed to pack a given collection of items with sizes $x_1, \cdots, x_n$, subject to the constraint that the sum of the sizes of the items placed in any given bin must not exceed one. This problem has many applications and has been shown to be *NP*-complete. The *bin-covering problem* requires finding the maximum number $Q_n(x_1, \cdots, x_n)$ of unit-size bins that can be covered by a given collection of items with sizes $x_1, \cdots, x_n$, subject to the constraint that the sum of the sizes of the items attributed to any given bin must be greater than or equal to one. This paper is mostly concerned with the bin-covering problem. This problem is closely related to the bin-packing problem.

The bin-covering problem is *NP*-complete. The purpose of this paper is to make a stochastic analysis of the problem. In our model, we consider a probability measure μ on $[0, 1]$. (No regularity assumption is made on μ.) Consider n items with sizes $X_1, \cdots, X_n$, which are independent identically distributed (i.i.d.) according to μ. (For simplicity, we denote by X_k both item names and item sizes.) It is transparent that $Q_n = Q_n(X_1, \cdots, X_n)$ is a superadditive process, and hence $\lim_{n\to\infty} Q_n/n = d(\mu)$ almost surely (a.s.) for a constant $d(\mu)$, depending only on μ. Also $E(Q_n)/n \leqq d(\mu)$. Among the main results of this paper are the description of $d(\mu)$ in function of the structure of μ and (under mild conditions on μ) the convergence in distribution of the process $n^{-1/2}(Q_n - nd(\mu))$. It should also be noted that one of our most difficult results is purely deterministic (Theorem 2). Our study is in the spirit of our previous work on stochastic bin packing ([3], [4], [5]). Actually, at first glance, our present results look like rather automatic modifications of our bin-packing results (by just "inversing inequalities"). It is true indeed that the bin-packing and bin-covering problems have many similarities, and we do not dwell in great detail on the arguments that are mere transpositions of arguments used for the bin-packing problem (and that are contained in § 2). The whole point of the present paper is that a crucial deterministic estimate (3) is not as sharp as for the bin-packing problem (the reason for this is explained in the comment near the end of the paper). This makes the proof of the convergence in distribution of $n^{-1/2}(Q_n - nd(\mu))$ considerably harder than in the bin-packing case (§ 3). We now explain our basic notations and describe our results.

For $k \geqq 1$, we set

$$S_k = \left\{ (x_1, \cdots, x_k) \in \mathbf{R}^k; 0 \leqq x_k \leqq \cdots \leqq x_1 \leqq 1, 1 \leqq \sum_{i \leqq k} x_i \leqq 3 \right\}$$

so S_k is compact metric. For a compact space S, we denote by $M_1(S)$ the set of probability measures on S. For $x \in S$, we denote by δ_x the probability measure concentrated at x, that is, for a Borel set G, we have $\delta_x(G) = 1$ if x belongs to G, and $\delta_x(G) = 0$ otherwise. To each $\nu \in M_1(S_k)$, we associate $\mathscr{P}_k(\nu) \in M_1([0, 1])$, such that for each Borel set G of $[0, 1]$, we have

$$\mathscr{P}_k(\nu)(G) = \frac{1}{k} \int_{S_k} \sum_{i \leqq k} \delta_{x_i}(G)\, d\nu(x_1, \cdots, x_k).$$

In short, we will write this formula as

$$\mathscr{P}_k(\nu) = \frac{1}{k} \int_{S_k} \sum_{i \leqq k} \delta_{x_i}\, d\nu(x_1, \cdots, x_k)$$

and we will use a similar convention for similar expressions.

THEOREM 1. *For $\mu \in M_1([0, 1])$, there exists a nonnegative sequence $(\alpha_k)_{k \geqq 0}$ with $\sum_{k \geqq 0} \alpha_k = 1$ and for each $k \geqq 1$, a $\nu_k \in M_1(S_k)$ such that*

$$\mu = \alpha_0 \delta_0 + \sum_{k \geqq 1} \alpha_k \mathscr{P}_k(\nu_k), \tag{1}$$

and that $d(\mu) = \sum_{k \geqq 1} \alpha_k / k$.

In the converse direction, we have the following theorem.

THEOREM 2. *Consider a nonnegative sequence $(\alpha_k)_{k \geqq 0}$ such that $\sum_{k \geqq 0} \alpha_k = 1$, and a sequence ν_k in $M_1(R_k)$. Consider the measure μ given by (1). For $k \geqq 1$, let $\beta_k = \sum_{l \geqq k} \alpha_l / l$. Consider a sequence $s_1, \cdots, s_n$ of items. Let*

$$D = D(s_1, \cdots, s_n) = \sup_{0 \leqq t \leqq 1} n\mu([t, 1]) - \operatorname{card}\{i \leqq n; s_i \geqq t\}.$$

Then, for each $q \geqq 1$, we have

$$Q_n(s_1, \cdots, s_n) \geqq n \sum_{k \geqq 1} \alpha_k / k - (D + 3q + n\beta_q + Kn^{1/3} \sum_{1 \leqq i < q} (\beta_i)^{1/3} (\log n)^{1/2}), \tag{2}$$

where K is a universal constant (independent of μ, n, $s_1, \cdots, s_n$). In particular, we have

$$Q_n(s_1, \cdots, s_n) \geqq n \sum_{k \geqq 1} \alpha_k / k - Kn^{3/5} (\log n)^{3/10} - D. \tag{3}$$

It is to be noted that the error term $n^{3/5}(\log n)^{3/10}$ that we obtain here is of a larger order than the error term $n^{1/3}(\log n)^{1/2}$ that we obtained for the corresponding result in the bin-packing probem ([4]). While we do not know what the best possible error term in (3) is, either for the bin-packing or the bin-covering problems, there are reasons to believe that the bin-covering problem does require a bigger error term. These reasons will be explained in the course of the proof of Theorem 2.

COROLLARY 3. *Under the assumptions of Theorem 2, assume moreover that $\beta_k = o(k^{-3/2}(\log k)^{-3/4})$. Then we have*

$$Q_n(s_1, \cdots, s_n) \geqq n \sum_{k \geqq 1} \alpha_k / k - D - n^{1/2} \varepsilon_n, \tag{4}$$

where ε_n is a quantity depending only on μ and n and that satisfies $\lim_{n \to \infty} \varepsilon_n = 0$.

COROLLARY 4. *Let $s_1, \cdots, s_n \in [0, 1]$. Let $\nu = 1/n \sum_{i \leqq n} \delta_{s_i}$. Then*

$$nd(\nu) \geqq Q_n(s_1, \cdots, s_n) \geqq nd(\nu) - Kn^{3/5} (\log n)^{3/10}. \tag{5}$$

COROLLARY 5. *For each distribution* μ, *we have*

$$nd(\mu) \geqq EQ_n(X_1, \cdots, X_n) \geqq nd(\mu) - Kn^{3/5}(\log n)^{3/10}.$$

COROLLARY 6. *If* μ *is as in* (1), *then* $d(\mu) \geqq \sum_{k \geqq 1} \alpha_k / k$.

Another corollary deserves special notice. It is clear that we always have $d(\mu) \leqq \int x\, d\mu$ for μ in $M_1([0, 1])$. It is said that a distribution μ allows *perfect packing* when the asymptotic level of bin occupancy in optimal bin-packing of a random sequence of items is 1. (See [6] for a more formal definition.) Let us say that μ allows *perfect covering* if this occurs for optimal *bin-covering* packing, or equivalently when $d(\mu) = \int x\, d\mu$. Then we have the following theorem.

THEOREM 7. *A distribution* μ *on* $[0, 1]$ *allows perfect covering if and only if it allows perfect packing.*

This statement surely supports the fact that the bin-packing problem and the bin-covering problem are closely related. (It should however be noted that, for $\varepsilon > 0$, when packing items of constant size $1 - \varepsilon$ (respectively, $\frac{1}{2} + \varepsilon$), there is a proportion of wasted bin space of ε (respectively, $\frac{1}{2} - \varepsilon$) in bin packing, and of $1 - 2\varepsilon$ (respectively, 2ε) in bin covering.

We denote by $\mathscr{C}$ the class of nondecreasing functions f from $[0, 1]$ to $[0, 1]$ that satisfy $f(1) = 1$ and $f(x + y) \leqq f(x) + f(y)$ whenever $x, y, x + y \in [0, 1]$.

THEOREM 8. *For any distribution* μ *on* $[0, 1]$, *we have*

$$d(\mu) = \inf_{f \in \mathscr{C}} \int f\, d\mu.$$

For a positive measure γ on $[0, 1]$, we set $F_\gamma^-(t) = \gamma([0, t))$, $F_\gamma(t) = \gamma([0, t])$. We denote by B_t the standard Brownian motion, and by $W_t = B_t - tB_1$ the Brownian bridge (see [1]). For the simplicity of notations, we set $W_{\mu,t} = W_{\mu([0,t])}$, $W_{\mu,t}^- = W_{\mu([0,t))}$. To each f in $\mathscr{C}$, we associate f^- given by $f^-(x) = \lim_{y \to x, y < x} f(y)$, so that $f^- \leqq f$. Since f^- is left continuous, there is a unique positive measure γ_f on $[0, 1]$ such that $F_{\gamma_f}^-(t) = f^-(t)$ for each $0 \leqq t \leqq 1$ and γ_f has mass $f^-(1) \leqq 1$. Fixing μ in $M([0, 1])$, we denote by $(z_i)_{i \in J}$ an enumeration of the points z in $[0, 1]$ such that $\mu(\{z\}) > 0$, where J is either empty, finite, or countably infinite.

THEOREM 9. *Assume that we can write* $\mu = \alpha_0 \delta_0 + \sum_{k \geqq 1} \alpha_k \mathscr{P}_k(\nu_k)$, *where* $\alpha_k \geqq 0$, $\sum_{k \geqq 0} a_k = 1$, $\sum_{k \geqq 1} \alpha_k / k = d(\mu)$, $\nu_k \in M_1(S_k)$, *and* $\beta_k = o(k^{-3/2}(\log k)^{-3/4})$, *where* $\beta_k = \sum_{l \geqq k} \alpha_l / l$. *Then the set*

$$\mathscr{C}_\mu = \left\{ f \in \mathscr{C};\ \int f\, d\mu = d(\mu) \right\}$$

is nonempty. Consider the random variable

$$T = \inf_{f \in \mathscr{C}_\mu} \left\{ -\int_0^1 W_{\mu,t}\, d\gamma_f(t) + \sum_{i \in J} (f(z_i) - f^-(z_i))(W_{\mu,z_i} - W_{\mu,z_i}^-) \right\}.$$

Then for each n, one can find a random variable T_n *distributed like T and such that*

$$\lim_{n \to \infty} E|(Q_n(X_1, \cdots, X_n) - nd(\mu))/\sqrt{n} - T_n| = 0.$$

The paper is organized as follows. All the proofs are contained in § 2, with the exception of the proof of Theorems 2 and 9. Theorem 9 is deduced from Theorem 2 in § 3, and Theorem 2 itself is proved in the final § 4.

2. Easiest proofs. We recall that for a compact metric space S, the weak topology on $M_1(S)$ is the topology such that a sequence (μ_n) converges weakly to μ whenever

$\int f d\mu_n$ converges to $\int f d\mu$ for all f in $C(S)$, the space of continuous functions of S. For that topology, $M_1(S)$ is compact metric.

Proof of Theorem 1. The proof is very similar to the proof of Theorem A of [4]. Let $D_0 = \{\delta_0\}$, and for $k \geqq 1$, consider the set D_k of probability measures on $[0, 1]$ that are of the type $\mathcal{P}_k(\nu)$ for $\nu \in M_1(S_k)$. Since the map $\nu \to \mathcal{P}_k(\nu)$ is weakly continuous, D_k is convex and weakly compact. We now observe that, if $\mu \in D_k$, $k \geqq 1$, we have $\int x\, d\mu(x) \leqq 3/k$. Indeed, if $\mu = \mathcal{P}_k(\nu)$, $\nu \in M_1(S_k)$, we have

$$\int x\, d\mu(x) = \frac{1}{k} \int_{S_k} \sum_{i \leqq k} x_i\, d\nu(x_1, \cdots, x_k) \leqq 3/k$$

since $\sum_{i \leqq k} x_i \leqq 3$ for $(x_1, \cdots, x_k) \in S_k$. It follows that if we have a sequence (μ_n) in $D_{i(n)}$, where $i(n) \geqq n$, that converge weakly to μ, we must have $\mu = \delta_0$, since $\int x\, d\mu = \lim_{n \to \infty} \int x\, d\mu_n = 0$. It follows that the sequence $(D_i)_{i \geqq 0}$ satisfies the hypothesis of Proposition 2.2 of [4].

It is a well-known consequence of the law of large numbers that $(1/n) \sum_{i \leqq n} \delta_{X_i} \to \mu$ almost surely in the weak topology. Also, $(1/n) Q_n(X_1, \cdots, X_n) \to d(\mu)$ almost surely, so we can find a sequence (x_i) such that $\mu_n = (1/n) \sum_{i \leqq n} \delta_{x_i}$ converges weakly to μ, and that k_n/n converges to $d(\mu)$, where $k_n = Q_n(x_1, \cdots, x_n)$. (We denote item sizes by lowercase letters to emphasize the fact that they are not random.) For each n, we can cover k_n bins with items of size $x_1, \cdots, x_n$. The jth bin, $j \leqq k_n$, is covered by p_j items of size $y_{j,1}, \cdots, y_{j,p_j}$, $y_{j,1} \geqq \cdots \geqq y_{j,p_j}$. Obviously, we have $1 \leqq \sum_{1 \leqq i \leqq p_j} y_{j,i} \leqq 3$ (otherwise one more bin could be covered) and if we set $\vec{y}_j = (y_{j,1}, \cdots, y_{j,p_j})$, we have $\vec{y}_j \in S_{p_j}$. Let $\nu_j = \delta_{\vec{y}_j} \in M_1(S_{p_j})$. If we set $\eta_j = \mathcal{P}_{p_j}(\nu_j)$, we have $\eta_j = (1/p_j)(\sum_{1 \leqq i \leqq p_j} \delta_{y_{j,i}})$. We have $\mu_n = \sum_{j \leqq k_n} (p_j/n) \eta_j$, where $\sum_{j \leqq k_n} p_j/n = 1$, $\sum_{j \leqq k_n} (p_j/n)/p_j = k_n/n$, and $\eta_j \in D_{p_j}$. Theorem 1 then follows from Proposition 2.2 of [4].

Proof of Corollary 3. If we denote by $\lfloor t \rfloor$ the integer part of $t \in \mathbf{R}$, equation (4) is a consequence of (2), by taking $q = \lfloor n^{1/3} (\log n)^{-1/2} \rfloor$ and by elementary computations.

Proof of Corollary 4. According to Theorem 1, ν has a representation as in (1) with $d(\nu) = \sum_{k \geqq 1} \alpha_k/k$. If we apply (3) with $\mu = \nu$, we get the right-hand side of (5), since $D = 0$. To prove the left-hand side inequality, let us draw a random number N of items independent and distributed according to ν, and for $i \leqq n$, let us denote by N_i the number of items of size s_i. Let $a_N = \inf_{i \leqq n} N_i$. Among our items, we can find a_N collections that contain exactly one item of each size. Each of these collections allows us to cover $Q_n(s_1, \cdots, s_n)$ bins, so we can cover at least $a_N Q_n(s_1, \cdots, s_n)$ bins. The law of large numbers shows that $\lim_{N \to \infty} E(a_N)/N = 1/n$. Since

$$\begin{aligned} d(\nu) = \lim_{N \to \infty} E(Q_N(X_1, \cdots, X_n))/N &\geqq \lim_{N \to \infty} E(a_N Q_n(s_1, \cdots, s_n))/N \\ &= Q_n(s_1, \cdots, s_n)/n, \end{aligned}$$

this implies the result.

Proof of Corollary 5. This is an immediate consequence of (3), and of the fact that $ED = O(n^{1/2})$, as follows from the well-known properties of the Kolmogorov–Smirnov statistics.

Proof of Corollary 6. Obvious from Corollary 5.

Proof of Theorem 7. Suppose first that μ allows perfect covering. Then, from Theorem 1, we can find a sequence $\alpha_k \geqq 0$ with $\sum_{k \leqq 0} \alpha_k = 1$, $\sum_{k \geqq 1} \alpha_k/k = d(\mu) = \int x\, d\mu(x)$, and ν_k in $M_1(S_k)$, such that $\mu = \alpha_0 \delta_0 + \sum_{k \geqq 1} \alpha_k \mathcal{P}_k(\nu_k)$. We have

$$\int x\, d\mathcal{P}_k(\nu_k)(x) = \frac{1}{k} \int_{S_k} \sum_{i \leqq k} x_i\, d\nu_k(x_1, \cdots, x_k) \geqq 1/k \tag{6}$$

since $\sum_{i\leqq k} x_i \geqq 1$ for $(x_1, \cdots, x_k)$ in S_k. So we have

$$\int x\, d\mu(x) = \sum_{k\geqq 1} \alpha_k \int x\, d\mathscr{P}_k(\nu_k)(x)$$

$$\geqq \sum_{k\geqq 1} \alpha_k/k = d(\mu) = \int x\, d\mu(x).$$

This shows that we have $\int x\, d\mathscr{P}_k(\nu_k)(x) = 1/k$ whenever $\alpha_k \neq 0$. But (6) shows that this implies $\sum_{i\leqq k} x_i = 1\, \nu_k$ almost surely. If we set

$$R_k = \left\{(x_1, \cdots, x_k) \in \mathbf{R}^k;\ x_1, \cdots, x_k \geqq 0,\ \sum_{i\leqq k} x_i = 1\right\},$$

we then have $\nu_k(R_k) = 1$ whenever $\alpha_k \neq 0$. Since when $\alpha_k = 0$, the value of ν_k is irrelevent, we can assume that $\nu_k(R_k) = 1$ for $k \geqq 1$, so that $\nu_k \in M_1(R_k)$. It then follows from [3] that μ allows perfect packing.

Conversely, assume that μ allows perfect packing. Then, by the results of [3], we can write $\mu = \alpha_0\delta_0 + \sum_{k\geqq 1} \alpha_k \mathscr{P}_k(\nu_k)$, where $\sum_{k\geqq 0} \alpha_k = 1$ and $\nu_k \in M_1(R_k)$. Since $\nu_k \in M_1(R_k)$, we have, for $k \geqq 1$,

$$\int x\, d\mathscr{P}_k(\nu_k)(x) = \frac{1}{k} \int_{S_k} \sum_{i\leqq k} x_i\, d\nu_k\,(x_1, \cdots, x_k) = 1/k$$

so we have $\int x\, d\mu = \sum_{k\geqq 1} \alpha_k/k$. By Corollary 6, we have $d(\mu) \geqq \sum_{k\geqq 1} \alpha_k/k = \int x\, d\mu$. Since the reverse inequality is obvious, we have shown that $d(\mu) = \int x\, d\mu$, so μ allows perfect covering. □

Proof of Theorem 8. Let us fix f in $\mathscr{C}$. We first note that (as easily seen) for $k \geqq 1$, $x_1, \cdots, x_k$ in $[0, 1]$ with $\sum_{i\leqq k} x_i \geqq 1$, we have $\sum f(x_i) \geqq 1$. For ν in $M_1(S_k)$, we then have

$$\int f\, d\mathscr{P}_k(\nu) = \frac{1}{k} \int_{S_k} \sum_{i\leqq k} f(x_i)\, d\nu(x_1, \cdots, x_k) \geqq 1/k$$

since $\sum_{i\leqq k} x_i \geqq 1$ for $(x_1, \cdots, x_k) \in S_k$. So, when we have a representation of μ as in (1), we have $\int f\, d\mu \geqq \sum_{k\geqq 1} \alpha_k/k$. Since, by Theorem 1, we can find such a representation with $d(\mu) = \sum_{k\geqq 1} \alpha_k/k$, we have shown that $d(\mu) \leqq \inf_{f\in\mathscr{C}} \int f\, d\mu$.

To prove the converse inequality, let $\theta > d(\mu)$. Consider the set C_θ of probability measures η on $[0, 1]$ that can be written as $\eta = \sum_{k\geqq 0} \alpha_k \eta_k$, where $\alpha_k \geqq 0$, $\sum_{k\geqq 0} \alpha_k = 1$, $\sum_{k\geqq 1} \alpha_k/k \geqq \theta$, and $\mu_k \in D_k$ (where D_k is defined in the proof of Theorem 1). Then, by Corollary 8, we have $\mu \notin C_\theta$. It then follows from the Proposition 2.5 of [4] that there is a continuous function g on $[0, 1]$, such that $\int g\, d\mu < \theta$ and $\int g\, d\eta \geqq 1/k$ whenever $\eta \in D_k$, $k \geqq 1$. So we have $g(0) \geqq 0$, and since for $k \geqq 1$, we have $1/k \sum_{i\leqq k} \delta_{x_i} \in D_k$ whenever $0 \leqq x_i \leqq 1$, $1 \leqq \sum_{i\leqq k} x_i \leqq 3$, we also have $\sum_{i\leqq k} g(x_i) \geqq 1$. For $0 < x \leqq 1$, if m is the smallest integer for which $mx \geqq 1$, we have $mx \leqq 2$, so we have $mg(x) \geqq 1$, and $g(x) \geqq 0$. It follows that $g \geqq 0$. Define

$$h(t) = \inf\left\{\sum_{i\leqq k} g(x_i);\ k \geqq 1, \forall i,\ 1 \leqq i \leqq k,\ 0 \leqq x_i \leqq 1,\ t \leqq \sum_{i\leqq k} x_i \leqq 3\right\}.$$

Since $g \geqq 0$, it is easily seen that

$$h(t) = \inf\left\{\sum_{i\leqq k} g(x_i);\ k \geqq 1, \forall i,\ 1 \leqq i \leqq k,\ 0 \leqq x_i \leqq 1,\ t \leqq \sum_{i\leqq k} x_i \leqq 1 + t\right\}.$$

This implies that when $t, u \leqq 1$, and $t + u \leqq 1$, we have $h(t+u) \leqq h(t) + h(u)$. Also, we have $h \leqq g$, so we have $\int h\, d\mu < \theta$. Clearly, we have $h(1) \geqq 1$. Let now $f = \min(h, 1)$,

so we have $\int f\,d\mu < \theta$, and it is clear that $f \in \mathscr{C}$. So we have shown that $\inf_{f\in\mathscr{C}} \int f\,d\mu < \theta$. Since θ is arbitrary, the proof is complete.

3. Proof of Theorem 9. The proof will use many of the ideas of the proof of Theorem C of [5]. It is, however, made harder by the fact that in (5) the error term is of order $> n^{1/2}$; hence, it is not possible proving Theorem 9 to replace $Q_n(X_1, \cdots, X_n)$ by $d(\nu)$, where $\nu = 1/n \sum_{i\leqq n} \delta_{X_i}$ (as is done in [5] for bin packing). As in [5], we see that $\mathscr{C}_\mu$ is not empty (the point being that the map $f \to \int f\,d\mu$ is continuous for a certain compact topology on $\mathscr{C}$). We first recall some lemmas.

LEMMA 1 ([5]). *For some universal constant K, for each n, we can find independently and identically distributed random variables $X_1, \cdots, X_n$ distributed according to μ, and processes $W_{n,\mu,t}$, $W^-_{n,\mu,t}$ jointly distributed like $W_{\mu,t}$, $W^-_{\mu,t}$, such that*

$$ES_n \leqq K(\log n)^2 n^{-1/2};\ ES_n^- \leqq K(\log n)^2 n^{-1/2} \tag{7}$$

where

$$S_n = \sup_{0\leqq t\leqq 1} |(\operatorname{card}\{i \leqq n;\ X_i \leqq t\} - nF_\mu(t))/\sqrt{n} - W_{n,\mu,t}| \tag{8}$$

$$S_n^- = \sup_{0\leqq t\leqq 1} |(\operatorname{card}\{i \leqq n;\ X_i < t\} - nF_\mu^-(t))/\sqrt{n} - W^-_{n,\mu,t}|. \tag{9}$$

For f in $\mathscr{C}$, we consider the random variables defined by

$$T_{n,f} = -\int W_{n,\mu,t}\,d\gamma_f(t) + \sum_{i\in J} (f(z_i) - f(z_i)^-)(W_{n,\mu,z_i} - W^-_{n,\mu,z_i})$$

$$T_f = -\int W_{\mu,t}\,d\gamma_f(t) + \sum_{i\in J} (f(z_i) - f(z_i)^-)(W_{\mu,z_i} - W^-_{\mu,z_i})$$

so that

$$T = \inf_{f\in\mathscr{C}_\mu} T_f.$$

We set

$$T_n = \inf_{f\in\mathscr{C}_\mu} T_{n,f}.$$

LEMMA 2 ([5]). *For f in $\mathscr{C}$, and a probability measure η on $[0, 1]$ such that $(u_i)_{i\in J}$ is an enumeration of the points t for which $\eta(\{t\}) > 0$, we have*

$$\int f\,d\eta = f^-(1) - \int F_\eta\,d\gamma_f + \sum_{i\in J} (f(u_i) - f^-(u_i))\eta(\{u_i\}).$$

LEMMA 3 ([5]). *With probability one, we have for all f in $\mathscr{C}$ that*

$$\left| \int f\,d\nu - \int f\,d\mu - n^{-1/2} T_{n,f} \right| \leqq 1/n + 2S_n + S_n^-$$

where $\nu = 1/n \sum_{i\leqq n} \delta_{X_i}$.

The following is proved exactly as Lemma 6 of [5].

LEMMA 4. *Consider the function*

$$\psi(x) = \inf_{f\in\mathscr{C}} \left(\int f\,d\mu + xT_f - d(\mu) \right).$$

Then $\psi(0) = 0$, ψ is concave, and its right derivative at zero is equal to T.

The next lemma is similar to Lemma 2 of [4].

LEMMA 5. *Let $p, q, n > 0$. Consider a family $(a_i)_{i \leqq q}$, $0 \leqq a_i \leqq 1$, and for $1 \leqq j \leqq p$, consider left continuous nonincreasing functions $(f_j)_{j \leqq p}$ on $[0, 1]$. Set*

$$h = \sup_{0 \leqq t \leqq 1} \left\{ n \sum_{j \leqq p} f_j(t) - \operatorname{card} \{1 \leqq i \leqq q;\ a_i \geqq t\} \right\}.$$

Then there are disjoint subsets $(H_j)_{j \leqq p}$ of $\{1, \cdots, q\}$ with $\operatorname{card} H_j \leqq nf_j(0)$ and integers $(h_j)_{j \leqq p}$ such that $\sum_{j \leqq p} h_j \leqq h + p$ and that for each $j \leqq p$, each t in $[0, 1]$, we have

$$\operatorname{card} \{i \in H_j;\ a_i \geqq t\} \geqq nf_j(t) - h_j. \tag{10}$$

Proof. For $1 \leqq j \leqq p$, let $n_j = \lfloor nf(0) \rfloor$. *For* $l \leqq n_j$, define

$$b_{l,j} = \sup \{t;\ 0 \leqq t \leqq 1,\ nf_j(t) \geqq l\}.$$

Since f_j is left continuous, we have $nf_j(b_{l,j}) \geqq l$. Note also that $(b_{l,j})$ is nonincreasing in l, i.e., $b_{l+1,p} \leqq b_{l,j}$ for $1 \leqq l, l+1 \leqq n_j$.

FACT. For $0 \leqq t \leqq 1$, we have

$$nf_j(t) - 1 < \operatorname{card} \{l \leqq n_j;\ b_{l,j} \geqq t\} \leqq nf_j(t). \tag{11}$$

Proof of Fact. Let r be the largest integer with $r \leqq nf_j(t)$, so $r > nf_j(t) - 1$. By definition of $b_{l,j}$, we have $b_{l,j} \geqq t$ if and only if $1 \leqq l \leqq r$. □

We return to the proof of Lemma 2. Consider the index set

$$U = \{(l, j);\ 1 \leqq j \leqq p,\ 1 \leqq l \leqq n_j\}.$$

For $u = (l, j) \in U$, let $b_u = b_{l,j}$. By summation of the inequalities (11), we get for each t,

$$n \sum_{j \leqq p} f_j(t) \geqq \operatorname{card} \{u \in U;\ b_u \geqq t\}$$

so, by the definition of h,

$$\sup_{0 \leqq t \leqq 1} \{\operatorname{card} \{u \in U;\ b_u \geqq t\} - \operatorname{card} \{i \leqq q;\ a_i \geqq t\}\} \leqq h.$$

Using [4], Lemma 1, we get a subset H of U, with $\operatorname{card} H \geqq \operatorname{card} U - h$, and a one-to-one map ϕ from H to $\{1, \cdots, q\}$ such that $b_u \leqq a_{\phi(u)}$ for u in H. Consider the set H_j of those elements of $\{1, \cdots, q\}$ of the form $\phi((l, j))$, $l \leqq n_j$, $(l, j) \in H$, and let $m_j = n_j - \operatorname{card} H_j$. for each t, we have

$$\begin{aligned} nf_j(t) &< 1 + \operatorname{card} \{l \leqq n_j;\ b_{l,j} \geqq t\} \\ &< 1 + \operatorname{card} \{l \leqq n_j;\ (l, j) \in H;\ b_{l,j} \geqq t\} + m_j \\ &\leqq 1 + m_j + \operatorname{card} \{i \in H_j;\ a_j \geqq t\} \end{aligned}$$

so (10) holds with $h_j = 1 + m_j$. We have $\sum_{j \leqq p} h_j = p + \operatorname{card} U - \operatorname{card} H \leqq p + h$. This concludes the proof.

We now start to prove Theorem 9. By Corollary 4 and Theorem 8, we have, for all $f \in \mathscr{C}$,

$$Q_n(X_1, \cdots, X_n) \leqq n\, d(\nu) \leqq n \int f\, d\nu.$$

By Lemma 3, we have

$$Q_n(X_1, \cdots, X_n) \leqq n \int f\, d\mu + n^{1/2} T_{n,f} + n^{-1/2} + n^{1/2}(2S_n + S_n^-).$$

So, if $f \in \mathscr{C}_\mu$, we have

$$Q_n(X_1, \cdots, X_n) - n\, d(\mu) \leqq n^{1/2} T_{n,f} + n^{-1/2} + n^{1/2}(2S_n + S_n^-)$$

and hence

$$n^{-1/2}(Q_n(X_1, \cdots, X_n) - n\, d(\mu)) - T_n \leqq 2S_n + S_n^- + n^{-1}. \tag{12}$$

It will be much harder to get an inequality in the reverse direction. We set $m = \lfloor n^{2/3} \rfloor$, $\varepsilon = n^{1/2}/m$. Consider, for $0 \leqq t \leqq 1$,

$$G_n(t) = \max\,(0, \min_{u \leqq t}\,(\mu([u, 1]) + \varepsilon W^-_{n,\mu,u})). \tag{13}$$

This is a nonnegative nonincreasing function, and it is easily checked to be left-continuous. Also $G_n(0) = 1$. So there exists a probability measure θ on $[0, 1]$ such that for all t, we have $\theta([t, 1]) = G_n(t)$. We have $\theta(\{t\}) > 0$ only if $\mu(\{t\}) > 0$. It follows from (9) that

$$\begin{aligned}
\nu([t, 1]) &= 1 - F_\nu^-(t) \geqq 1 - F_\mu^-(t) + n^{-1/2} W^-_{n,\mu,t} - n^{-1/2} S_n^- \\
&= \mu([t, 1]) + n^{-1/2} W^-_{n,\mu,t} - n^{-1/2} S_n^- \\
&= (1 - (m/n))\mu([t, 1]) + (m/n)(\mu([t, 1]) + \varepsilon W_{n,\mu,t}) - n^{-1/2} S_n^-.
\end{aligned}$$

This means that, for $0 \leqq t \leqq 1$,

$$\text{card}\,\{i \leqq n;\, X_i \geqq t\} \geqq (n - m)\mu([t, 1]) + m\theta([t, 1]) - n^{1/2} S_n^-.$$

We apply Lemma 5 with $q = n$, $p = 2$, and we find two disjoint sets $H_1, H_2 \subset \{1, \cdots, n\}$ and with card $H_1 \leqq n - m$, card $H_2 \leqq m$, and h_1, h_2 with $h_1 + h_2 \leqq n^{1/2} S_n^{-1} + 2$ such that for each t in $[0, 1]$,

$$\text{card}\,\{i \in H_1;\, X_1 \geqq t\} \geqq (n - m)\mu([t, 1]) - h_1, \tag{14}$$

$$\text{card}\,\{i \in H_2;\, X_2 \geqq t\} \geqq m\theta([t, 1]) - h_2. \tag{15}$$

Let $q_1 = \text{card}\, H_1$, $q_2 = \text{card}\, H_2$, so $q_1 \leqq n - m$, $q_2 \leqq m$, and making $t = 0$ in (14) and (15), we have $q_1 \geqq n - m - h_1$, $q_2 \geqq m - h_2$. We have, for $0 \leqq t \leqq 1$,

$$\text{card}\,\{i \in H_1;\, X_i \geqq t\} \geqq q_1 \mu([t, 1]) - h_1, \tag{16}$$

$$\text{card}\,\{i \in H_2;\, X_i \geqq t\} \geqq q_2 \theta([t, 1]) - h_2. \tag{17}$$

We now use (4) with $n = q_1$ to see that the number Q_1 of bins that can be covered by the items X_i, $i \in H_1$ is such that

$$Q_1 \geqq q_1\, d(\mu) - h_1 - n^{1/2}\varepsilon_{q_1} \geqq (n - m)\, d(\mu) - 2h_1 - n^{1/2}\varepsilon_n'',$$

where ε_n'' is a nonrandom quantity with $\lim_{n \to \infty} \varepsilon_n'' = 0$. We now use (3) with $n = q_2$ and $\mu = \theta$ to see that the number Q_2 of bins that can be covered by the items X_i, $i \in H_2$ satisfies

$$\begin{aligned}
Q_2 &\geqq q_2\, d(\theta) - h_2 - Km^{3/5}(\log m)^{3/10} \\
&\geqq m\, d(\theta) - 2h_2 - Km^{3/5}(\log m)^{3/2}.
\end{aligned}$$

We have shown that

$$Q_n(X_1, \cdots, X_n) \geqq (n - m)\, d(\mu) + m\, d(\theta) - 2n^{1/2} S_n - n^{1/2}\varepsilon_n'$$

where ε_n' is a nonrandom quantity with $\lim_{n \to \infty} \varepsilon_n' = 0$. So we have

$$Q_n(X_1, \cdots, X_n) \geqq n\, d(\mu) + m(d(\theta) - d(\mu)) - 2n^{1/2} S_n - n^{1/2}\varepsilon_n'. \tag{18}$$

We will now estimate $d(\theta)$ using Theorem 8. For this we need to estimate F_θ. This is the purpose of the next lemma.

LEMMA 6. *Let* $S'_n = \sup_{0\leqq t\leqq 1} |F_\theta(t) - F_\mu(t) - \varepsilon W_{n,\mu,t}|$. *Then* $E(S'_n) = o(\varepsilon) = o(n^{-1/6})$.

Proof. Let $G'_n(t) = \mu([t,1]) + \varepsilon W^-_{n,\mu,t}$. We note that

$$F_\theta(t) = 1 - \lim_{u>t, u\to t} \theta([u,1])$$

$$F_\mu(t) - \varepsilon W_{n,\mu,t} = 1 - \lim_{u>t, u\to t} (\mu([u,1]) + \varepsilon W^-_{n,\mu,u})$$

so that

$$S'_n = \sup_{0\leqq t\leqq 1} |G'_n(t) - G_n(t)|.$$

Let $M_n = \sup_{0\leqq t\leqq 1} |W_{n,t}|$. We first note the obvious fact that $S'_n \leqq 2\varepsilon M_n$. Since $E(M_n)$ is finite and the distribution of M_n is independent of n, it suffices to show that given $\gamma > 0$, for n large enough, we have $S'_n < \gamma\varepsilon$ with probability $> 1-\gamma$. There exists a real $\delta > 0$ and $M > 0$ independent of n such that with probability $\geqq 1-\gamma$, we have $M_n \leqq M$ and $|W_{n,t} - W_{n,u}| \leqq \gamma$ whenever $|t-u| \leqq \delta$. Let n be large enough that $\varepsilon \leqq \delta/2M$. If for $u < t$, we have $\mu([u,1]) \geqq \mu([t,1]) + \delta$, since $\varepsilon|W^-_{n,\mu,u}| + \varepsilon|W_{n,\mu,t}| \leqq \delta$, we have

$$\mu([u,1]) + \varepsilon W^-_{n,\mu,u} \geqq \mu([t,1]) + \varepsilon W^-_{n,\mu,t}.$$

If $\mu([u,1]) \leqq \mu([t,1]) + \delta$, then $|F^-_\mu(u) - F^-_\mu(t)| \leqq \delta$, so we have $|W^-_{n,\mu,u} - W^-_{n,\mu,t}| \leqq \gamma$, and hence

$$\mu([u,1]) + \varepsilon W^-_{n,\mu,u} \geqq \mu([t,1]) + \varepsilon W^-_{n,\mu,t} - \varepsilon\gamma.$$

This shows that, with probability $\geqq 1-\gamma$, for all t, we have $G_n(t) \geqq G'_n(t) - \varepsilon\gamma$. The same argument with $t = 1$ shows that $G'_n(t) \geqq -\varepsilon\gamma$ for all t, so that $G_n(t) \leqq \max(0, G'_n(t)) \leqq G'_n(t) + \varepsilon\gamma$. This concludes the proof.

For f in $\mathscr{C}$, we have, by Lemma 2, that

$$\int f\,d\theta = f^-(1) - \int F_\theta\,d\gamma_f + \sum_{i\in J} (f(z_i) - f(z_i)^-)\theta(\{z_i\}).$$

Since $\theta(\{z_i\}) = F_\theta(z_i) - F^-_\theta(z_i)$, and since $\sum_{i\in J} |f(z_i) - f(z_i)^-| \leqq 1$ for f in $\mathscr{C}$, we see from the definition of S'_n that

$$\left| \int f\,d\theta - (f^-(1) - \int F_\mu\,d\gamma_f - \varepsilon \int W_{n,\mu,t}\,d\gamma_f \right.$$

$$\left. + \sum_{i\in J} (f(z_i) - f(z_i)^-)(\mu(\{z_i\}) + \varepsilon W_{n,\mu,z_i} - \varepsilon W^-_{n,\mu,z_i})) \right| \leqq 3S'_n.$$

Using Lemma 2 again, we see that

$$\left| \int f\,d\theta - \int f\,d\mu - \varepsilon T_{n,f} \right| \leqq 3S'_n.$$

So, since $d(\theta) = \inf_{f\in\mathscr{C}} \int f\,d\theta$, we have

$$\left| d(\theta) - d(\mu) - \inf_{f\in\mathscr{C}} \left(\int f\,d\mu + \varepsilon T_{n,f} - d(\mu) \right) \right| \leqq 3S'_n$$

i.e., $|d(\theta) - d(\mu) - \psi_n(\varepsilon)| \leqq 3S'_n$, where ψ_n is defined as ψ but using $T_{n,f}$ instead of T_n. From (18), we then have

$$Q_n(X_1, \cdots, X_n) \geqq n\,d(\mu) + m\psi_n(\varepsilon) - 2n^{1/2}S_n - n^{1/2}\varepsilon'_n - 3mS'_n$$

so, since $\varepsilon = n^{1/2}/m$,

$$(19)\quad (Q_n(X_1, \cdots, X_n) - nd(\mu))n^{-1/2} - T_n \geqq (\psi_n(\varepsilon)/\varepsilon - T_n) - 2S_n - \varepsilon'_n - 3n^{1/6}S'_n.$$

The random variable $U_n = \psi_n(\varepsilon)/\varepsilon - T_n$ is distributed like $\psi(\varepsilon)/\varepsilon - T$. By Lemma 5 and dominated convergence, we have that $\lim_{n\to\infty} E|U_n| \to \infty$. By Lemma 6, $\lim_{n\to\infty} n^{1/6} E(S_n') = 0$. It then follows that the expectation of the absolute value of the right-hand side of (19) goes to zero. Together with (12), this concludes the proof.

4. Proof of Theorem 2. The proof will be similar, but somewhat simpler than the proof of theorem of [5]. The proof is simpler because the strategy is less sophisticated (and, of course, the error term obtained is of a larger order). We have not been able to get an error term as small as in [4], and with our approach, bin covering seems genuinely harder than bin packing. Our proof will make essential use of the following lemma, which proof is entirely similar to that of Lemma 10 of [4].

LEMMA 7. *Let γ be a positive measure on $[0,3]^2$. Let $m \leqq n$. Assume that $m/n \leqq \|\gamma\| \leqq (m+1)/n$. Consider the three positive measures given by, for a Borel set U,*

$$\gamma'(U) = \gamma(U \times [0,3]), \qquad \gamma''(U) = \gamma([0,3] \times U)$$

$$\eta(U) = \gamma(\{(x,y);\ x+y \in U\}).$$

In other words, γ' and γ'' are the marginals of γ, and η is the distribution of $x+y$.

Consider two sequences $(l_i)_{i\leqq m}$, $(y_i)_{i\leqq m}$ of numbers, $0 \leqq l_i, y_i \leqq 1$ and $a, b > 0$. Assume that for each t in $[0,3]$,

$$\text{card}\,\{i \leqq m;\ l_i \geqq t\} \geqq n\gamma'([t,3]) - a, \tag{20}$$

$$\text{card}\,\{i \leqq m;\ y_i \geqq t\} \geqq n\gamma''([t,3]) - b. \tag{21}$$

Then there exists a one to one and onto map ϕ from $\{1, \cdots, m\}$ to $\{1, \cdots, m\}$ such that for each $t \geqq 0$,

$$\text{card}\,\{i \leqq m;\ l_i + y_{\phi(i)} \geqq t\} \geqq n\eta([t,\infty)) - a - b - Km^{1/3}(\log n)^{1/2}, \tag{22}$$

where K is a universal constant.

Remark. It is likely that it is possible with some extra effort to remove the factor $(\log n)^{1/2}$ in (22), which would remove the term $(\log n)^{3/10}$ in (3). There is, however, little motivation to do that, since we see no reason why the exponent $\frac{1}{3}$ in (22) should be sharp.

We will need some distributions associated with μ. For $l \geqq 1$, consider the positive measure λ_l on $[0,1]$ such that

$$\lambda_l = \sum_{k\geqq l} (\alpha_k/k) \int_{S_k} \delta_{x_l}\, d\nu_k(x_1, \cdots, x_k)$$

so $\|\lambda_l\| = \sum_{k\geqq l} \alpha_k/k = \beta_l$ and $\mu = \alpha_0\delta_0 + \sum_{l\geqq 1} \lambda_l$. For x in R_k, $k \geqq l$, let $u_{k,l}(x) = \sum_{1\leqq i\leqq l} x_i$. Consider the following three positive measures on $[0,3]$,

$$\theta_l = (\alpha_l/l) \int_{S_l} \delta_{u_{l,l}(x)}\, d\nu_l(x_1, \cdots, x_l)$$

$$n_l = \sum_{k\geqq l} (\alpha_k/k) \int_{S_k} \delta_{u_{k,l}(x)}\, d\nu_k(x_1, \cdots, x_k)$$

$$\xi_l = \sum_{k\geqq l+1} (\alpha_k/k) \int_{S_k} \delta_{u_{k,l}(x)}\, d\nu_k(x_1, \cdots, x_k)$$

$$= \eta_l - \theta_l.$$

We note that $\eta_1 = \lambda_1$, $\|\eta_l\| = \beta_l$, and $\|\xi_l\| = \beta_{l+1}$. After normalization, θ_l, η_l, ξ_l can be interpreted as follows. θ_l is the distributions of the level of bins that are covered by l

elements. η_l (respectively, ξ_l) is the distribution of the sum of the l largest items in bins that are covered by at least l (respectively, at least $l+1$) elements. We also need the distribution γ_l on $[0,3]^2$ given by

$$\gamma_l = \sum_{k \geqq l+1} (\alpha_k / k) \int_{S_k} \delta_{v(x)}\, d\nu_k(x_1, \cdots, x_k),$$

where $v(x) = (u_{k,l}(x), x_{l+1})$. Note that $\|\gamma_l\| = \beta_{l+1}$. Using the fact that $u_{k,l}(x) + x_{l+1} = u_{k,l+1}(x)$, we see that the first marginal of γ_l is ξ_l, the second is λ_{l+1}, and the distribution of $x+y$ is η_{l+1}.

For each i, let $f_i(t) = \lambda_i([t,3])$, so $\sum_{i \geqq 1} f_i(t) = \mu([t,1])$. We set $n_i = \lfloor n f_i(0) \rfloor = \lfloor n\beta_i \rfloor$. We now prove Theorem 2. We have for each $0 \leqq t \leqq 3$,

$$\sum_{i \leqq q} n f_i(t) - \text{card}\,\{i \leqq n;\ s_i \geqq t\} \leqq D. \tag{23}$$

By Lemma 5, (used with $q = n$, and q instead of p), we can find disjoint subsets $(H_j)_{j \leqq q}$ of $\{1, \cdots, n\}$ with card $H_j \leqq \lfloor n f_j(0) \rfloor = n_j$ and integers $(h_j)_{j \leqq q}$ such that $\sum_{j \leqq q} h_j \leqq D + q$ and that for $j \leqq q$, for each t in $[0,3]$,

$$\text{card}\,\{i \in H_j;\ s_i \geqq t\} \geqq n f_j(t) - h_j. \tag{24}$$

By adding some zero size elements, we can actually assume that card $H_j = n_j$. The core of the proof is to show, by induction over $r \leqq q$, that the items s_i for $i \in \bigcup_{j \leqq r} H_j$ can be packed in a collection of bins whose occupancy levels $(L_u)_{u \in U}$ satisfy for each t in $[0,3]$,

$$\text{card}\,\{u \in U;\ L_u \geqq t\} \geqq n\left(\sum_{1 \leqq j \leqq r} \theta_j + \xi_r\right)([t,3]) - \sum_{1 \leqq j \leqq r} h_j - \sum_{1 \leqq j < r} K n_j^{1/3} (\log n)^{1/2} - 2(r-1). \tag{25}$$

(We index the bins by an arbitrary set U since their number is irrelevant at that stage.) We note that $\lambda_1 = \theta_1 + \xi_1$, so for $r = 1$, there is nothing to prove, since (25) follows from (24) when $j = 1$.

We now perform the induction step from r to $r+1$. For simplicity, we let $a = \sum_{1 \leqq j \leqq r} h_j - \sum_{1 \leqq j < r} K n_j^{1/3} (\log n)^{1/2} - 2(r-1)$ and $\theta = \sum_{1 \leqq j \leqq r} \theta_j$, so (25) becomes for all t in $[0,3]$,

$$n(\theta + \xi_r)([t,3]) - \text{card}\,\{u \in U;\ L_\mu \geqq t\} \leqq a.$$

It follows from Lemma 2 (used on $[0,3)$ instead of $[0,1)$), that we can find two disjoint subsets U_1, U_2 of U with card $U_1 \leqq n\|\xi_r\|$, card $U_2 \leqq n\|\theta\|$, and a_1, a_2 with $a_1 + a_2 \leqq a + 2$ such that for $0 \leqq t \leqq 3$, we have

$$\text{card}\,\{u \in U_1;\ L_u \geqq t\} \geqq n\xi_r([t,3]) - a_1 \tag{26}$$

$$\text{card}\,\{u \in U_2;\ L_u \geqq t\} \geqq n\theta([t,3]) - a_2. \tag{27}$$

By adding some new empty bins, we can assume that card $U = \lfloor n\|\xi_r\| \rfloor$. We are now in position to use Lemma 7, with $m = \lfloor n\|\xi_r\| \rfloor = n_{r+1}$, $\gamma = \gamma_r$, $\gamma' = \xi_r$, $\gamma'' = \lambda_{r+1}$, $\eta = \eta_{r+1}$, to find a one-to-one and onto map ϕ from H_{r+1} to U such that for any $t \geqq 0$, we have

$$\text{card}\,\{i \in H_{r+1};\ L_{\phi(i)} + s_i \geqq t\} \geqq n\eta_{r+1}([t,3]) - a_1 - h_{r+1} - K n_{r+1}^{1/3} (\log n)^{1/2}. \tag{28}$$

We now attribute the element s_i to bin $\phi(i)$. Combining (28) with (27) finishes the induction hypothesis, since $\eta_{r+1} = \theta_{r+1} + \xi_{r+1}$.

Comment. When considering the same problem for bin packing ([3], [4]) in pairing the bin occupancy level L_i with the elements s_i controlled by λ_{r+1}, we took advantage of the fact that these elements s_i are $\leqq 1/(r+1)$, and hence that it is possible to disregard a rather large number of them in the pairing procedure since these elements can be efficiently packed in any case. We do not see how to take advantage of a similar feature in the case of bin covering.

If we use (25) for $r=q$, $t=1$, we see that

$$\operatorname{card}\{u\in U;\ L_u\geqq 1\}\geqq n\left(\sum_{1\leqq j<q}\alpha_j/j\right)-D-3q-\sum_{1\leqq j<q}Kn_j^{1/3}(\log n)^{1/2}$$

and this proves (2).

To prove (3), we note that $\sum_{k\geqq 1}\beta_k=\sum_{k\geqq 1}\alpha_k\leqq 1$, so by Holder's inequality, we have $\sum_{j\leqq q}\beta_j^{1/3}\leqq q^{2/3}$. Also $\beta_q\leqq 1/q$. Then (3) follows from (2) by taking $q=\lfloor n^{2/5}(\log n)^{-3/10}\rfloor$.

CASCADING DIVIDE-AND-CONQUER: A TECHNIQUE FOR DESIGNING PARALLEL ALGORITHMS*

MIKHAIL J. ATALLAH†, RICHARD COLE‡, AND MICHAEL T. GOODRICH§

Abstract. Techniques for parallel divide-and-conquer are presented, resulting in improved parallel algorithms for a number of problems. The problems for which improved algorithms are given include segment intersection detection, trapezoidal decomposition, and planar point location. Efficient parallel algorithms are algo given for fractional cascading, three-dimensional maxima, two-set dominance counting, and visibility from a point. All of the algorithms presented run in $O(\log n)$ time with either a linear or a sublinear number of processors in the CREW PRAM model.

Key words. parallel algorithms, parallel data structures, divide-and-conquer, computational geometry, fractional cascading, visibility, planar point location, trapezoidal decomposition, dominance, intersection detection

1. Introduction.

This paper presents a number of general techniques for parallel divide-and-conquer. These techniques are based on nontrivial generalizations of Cole's recent parallel merge sort result [13] and enable us to achieve improved complexity bounds for a large number of problems. In particular, our techniques can be applied to any problem solvable by a divide-and-conquer method such that the subproblem merging step can be implemented using a restricted, but powerful, set of operations, which include (i) merging sorted lists, (ii) computing the values of labeling functions on elements stored in sorted lists, and (iii) changing the identity of elements in a sorted list monotonically. The elements stored in such sorted lists need not belong to a total order, so long as the computation can be specified so that we will never try to compare two incomparable elements. We demonstrate the power of these techniques by using them to design efficient parallel algorithms for solving a number of fundamental problems from computational geometry.

The general framework is one in which we want to design efficient parallel algorithms for the CREW PRAM or EREW PRAM models. Recall that the CREW PRAM model is the synchronous shared memory model in which processors may simultaneously read from any memory location but simultaneous writes are not allowed. The EREW PRAM model does not allow for any simultaneous access to a memory cell. Our goal is to find algorithms that run as fast as possible and are efficient in the following sense: if $p(n)$ is the processor complexity, $t(n)$ the parallel time complexity, and $seq(n)$ the time complexity of the best-known sequential algorithm for the problem

under consideration, then $t(n) * p(n) = O(seq(n))$. If the product $t(n) * p(n)$ achieves the sequential lower bound for the problem, then we say the algorithm is *optimal.* When specifying the processor complexity, we omit the "big oh," e.g., we say "n processors" rather than "$O(n)$ processors"; this is justified because we can always save a constant factor in the number of processors at a cost of the same constant factor in the running time. In all of the problems listed below, we achieve $t(n) = O(\log n)$ and, simultaneously (except for planar point location), an optimal $t(n) * p(n)$.

Previous work on parallel divide-and-conquer has produced relatively few algorithms that are optimal in the above sense. Exceptions to this include some of the previous algorithms for the convex hull problem [1], [4], [6], [18], [27] and the problem of circumscribing a convex polygon with a minimum-area triangle [1]. Unfortunately, each of these approaches was very problem-specific. Thus, there is a need for techniques of wider scope.

This is in fact the motivation for our work, for we give a number of general techniques for efficiently solving problems in parallel by divide-and-conquer. We model the divide-and-conquer paradigm as a binary tree whose nodes contain sorted lists of some kind. The computation involves computing on this tree in a recursively defined bottom-up fashion using lists of items and labeling functions defined for each node in the tree. In Cole's scheme [13], the list at a node was defined to be the sorted merge of the two lists stored at its children. In our scheme, however, the lists at a node of the tree can depend on the lists of its children in more complex ways. For example, in our solution to the *segment intersection detection* problem, the lists at a node depend on computing, in addition to merges, set difference operations that are not directly solvable by the "cascading" method used by Cole [13]. Such operations arise here because the lists at a node contain segments ordered by their intersections with a vertical line (the so-called "above" relationship), which is obviously not a total order. One may be tempted to try to solve this problem by delaying the performance of these set difference operations until the end of the computation. Unfortunately, this is not feasible for many reasons, not the least of which is that this approach could lead to a situation in which a processor tries to compare two incomparable items. Nor does it seem possible to explicitly perform the set difference operations on-line without sacrificing the time-efficiency of the cascading method. Our solution avoids both of these problems by using an on-line "identity-changing" technique.

Another significant contribution of this paper is an optimal parallel construction of the "fractional cascading" data structure of Chazelle and Guibas [12]. This too is based on a generalization of Cole's method [13] in the sense that instead of having the computation proceeding up and down a tree, it now moves around a directed graph (possibly with cycles). Our solution to fractional cascading is quite different from the sequential method of Chazelle and Guibas (their method relies on an amortization scheme to achieve a linear running time).

The following is a list of the problems for which our techniques result in improved complexity bounds. Unless otherwise specified, each performance bound is expressed as a pair $(t(n), p(n))$, where $t(n)$ and $p(n)$ are the time and processor complexities, respectively, in the CREW PRAM model.

Fractional cascading. Given a directed graph $G = (V, E)$, such that every node v contains a sorted list $C(v)$, construct a data structure that, given a walk $(v_1, v_2, \cdots, v_m)$ in G and an arbitrary element x, enables a single processor to locate x quickly in each $C(v_i)$, where $n = |V| + |E| + \sum_{v \in V} |C(v)|$. In [12] Chazelle and Guibas gave an elegant $O(n)$ time, $O(n)$ space, sequential construction, where $n = \sum_{v \in V} |C(v)|$. We give a $(\log n, n/\log n)$ construction.

Trapezoidal decomposition. Given a set S of n line segments in the plane, determine for each segment endpoint p the first segment "stabbed" by the vertical ray emanating upward (and downward) from p. A $(\log^2 n, n)$ solution to this problem was given by Aggarwal et al. in [1], later improved to $(\log n \log\log n, n)$ by Atallah and Goodrich in [5]. We improve this to $(\log n, n)$.

Planar point location. Given a subdivision of the plane into (possibly unbounded) polygons, construct, in parallel, a data structure that, once built, enables one processor to determine for any query point p the polygonal face containing p. Let $Q(n)$ denote the time for performing such a query, where n is the number of edge segments in the subdivision. A $(\log^2 n, n)$, $Q(n) = O(\log^2 n)$ solution was given by Aggarwal et al. in [1], later improved to $(\log n \log\log n, n)$, $Q(n) = O(\log n)$ by Atallah and Goodrich in [5]. In [14] Dadoun and Kirkpatrick further improved this to $(\log n \log^* n, n)$, $Q(n) = O(\log n)$. We give a $(\log n, n)$, $Q(n) = O(\log n)$ solution.

Segment intersection detection. Given a set S of n line segments in the plane, determine if any two segments in S intersect. A $(\log^2 n, n)$ solution was given in [1], later improved to $(\log n \log\log n, n)$ in [5]. We improve this to $(\log n, n)$.

Three-dimensional maxima. Given a set S of n points in three-dimensional space, determine which points are maxima. A *maximum* in S is any point p such that no other point of S has x, y, and z coordinates that simultaneously exceed the corresponding coordinates of p. A $(\log n \log\log n, n)$ solution was given in [5]. We improve this to $(\log n, n)$.

Two-set dominance counting. Given a set $A = \{q_1, q_2, \cdots, q_l\}$ and a set $B = \{r_1, r_2, \cdots, r_m\}$ of points in the plane, determine for each point r_i in B the number of points in A whose x and y coordinates are both less than the corresponding coordinates of r_i. The problem size is $n = l + m$. A $(\log n \log\log n, n)$ solution was given in [5]. We improve this to $(\log n, n)$.

Visibility from a point. Given n line segments such that no two intersect (except possibly at endpoints) and a point p, determine that part of the plane visible from p if all the segments are opaque. A $(\log n \log\log n, n)$ solution was given in [5]. We improve this to $(\log n, n)$.

We recently learned that Reif and Sen [24] solved planar point location, trapezoidal decomposition, segment intersection and visibility in randomized $O(\log n)$ time using $O(n)$ processors in the CREW PRAM model. All of our algorithms are deterministic.

This paper is organized as follows. In § 2 we present a generalized version of the cascading merge procedure and in § 3 we give our method for doing fractional cascading in parallel. In § 4 we show how to apply the fractional cascading technique to a data structure we call the *plane sweep tree*, showing how to solve the trapezoidal decomposition and point location problems. In § 5 we show how to extend the cascading merge technique to allow for cascading in the "above" partial order of line segments, giving solutions to the problems of building the plane sweep tree and solving the intersection detection problem. In § 6 we use the cascading divide-and-conquer technique to compute labeling functions and show how to use this approach to solve three-dimensional maxima, two-set dominance counting, and visibility from a point. Finally, in § 7, we briefly describe how most of our algorithms can be implemented in the EREW PRAM model with the same time and processor bounds as our CREW PRAM algorithms, and we conclude in § 8.

2. A generalized cascading merge procedure. In this section we present a technique for a generalized version of the merge sorting problem. Suppose we are given a binary tree T (not necessarily complete) with items, taken from some total order, placed at

the leaves of T, so that each leaf contains at most one item. For simplicity, we assume that the items are distinct. We wish to compute for each internal node $v \in T$ the sorted list $U(v)$ that consists of all the items stored in descendant nodes of v. (See Fig. 1.) In this section we show how to constrict $U(v)$ for every node in the tree in $O(height\ (T))$ time using $|T|$ processors, where $|T|$ denotes the number of nodes in T. This is a generalization of the problem studied by Cole [13], because in his version the tree T is complete. Without loss of generality, we assume that every internal node v of T has two children. For if v has only one child then we can add a child to v (a leaf node) that does not store any items from the total order. Such an augmentation will at most double the size of T and does not change its height.

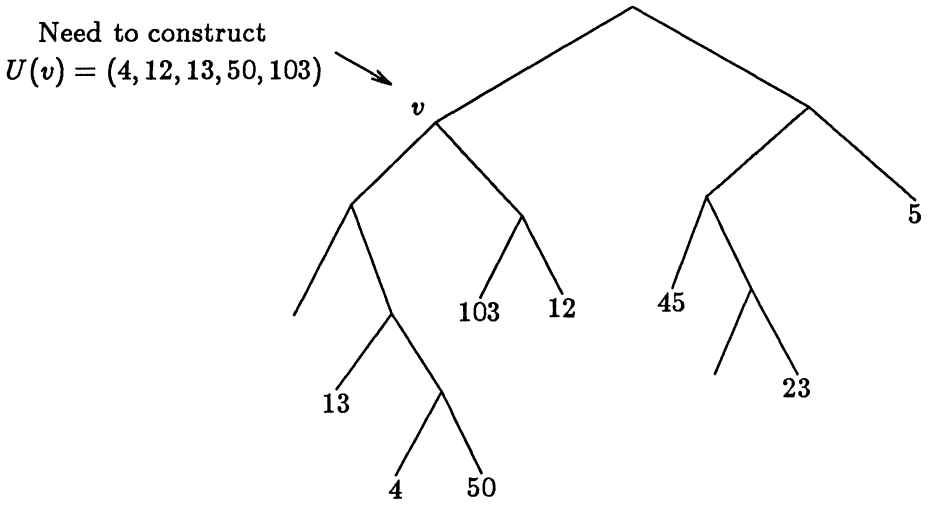

FIG. 1. *An example of the generalized merge problem.*

Let a, b, and c be three items, with $a \leqq b$. We say c is *between* a and b if $a < c \leqq b$. Let two sorted (nondecreasing) lists $A = (a_1, a_2, \cdots, a_n)$ and $B = (b_1, b_2, \cdots, b_m)$ be given. Given an element a, we define the *predecessor* of a in B to be the greatest element in B that is less than or equal to a. If $a < b_1$, then we say that the predecessor of a is $-\infty$. We define the *rank* of a in B to be the rank of the predecessor of a in B ($-\infty$ has rank zero). We say that A is *ranked* in B if for every element in A we know its rank in B. We say that A and B are *cross-ranked* if A is ranked in B and B is ranked in A. We define two operations on sorted lists. We define $A \cup B$ to be the sorted *merged* list of all elements in A or B. If B is a subset of A, then we define $A - B$ to be the sorted list of the elemented in A that are not in B.

Let T be a binary tree. For any node v in T we let $parent(v)$, $sibling(v)$, $lchild\ (v)$, $rchild\ (v)$, and $depth(v)$ denote the parent of v, the sibling of v, the left child of v, the right child of v, and the depth of v (the root is at depth zero), respectively. We also let $root(T)$ and $height(T)$ denote the root node of T and the height of T, respectively. The *altitude*, denoted $alt(v)$, is defined $alt(v) = height(T) - depth(v)$. $Desc(v)$ denotes the set of descendant nodes of v (including v itself).

Let a sorted list L and a sorted list J be given. Using the terminology of Cole [13], we say that L is a *c-cover* of J if between each two adjacent items in $(-\infty, L, \infty)$ there are at most c items from J (where $(-\infty, L, \infty)$ denotes the list consisting of $-\infty$, followed by the elements of L, followed by ∞). We let $SAMP_c(L)$ denote the sorted

list consisting of every cth element of L, and call this list the *c-sample* of L. That is, $SAMP_c(L)$ consists of the cth element of L followed by the $(2c)$th element of L, and so on.

The algorithm for constructing $U(v)$ for each $v \in T$ proceeds in stages. Intuitively, in each stage we will be performing a portion of the merge of $U(lchild\ (v))$ and $U(rchild\ (v))$ to give the list $U(v)$. After performing a portion of this merge we will gain some insight into how to perform the merge at v's parent. Consequently, we will pass some of the elements formed in the merge at v to v's parent, so we can begin performing the merge at v's parent.

Specifically, we denote the list stored at a node v in T at stage s by $U_s(v)$. Initially, $U_0(v)$ is empty for every node except the leaf nodes of T, in which case $U_0(v)$ contains the item stored at the leaf node v (if there is such an item). We say that an internal node v is *active at stage s* if $\lfloor s/3 \rfloor \leqq alt(v) \leqq s$, and we say v is *full at stage s* if $alt(v) = \lfloor s/3 \rfloor$. As will become apparent below, if a node v is full, then $U_s(v) = U(v)$. For each active node $v \in T$ we define the list $U'_{s+1}(v)$ as follows:

$$U'_{s+1}(v) = \begin{cases} SAMP_4(U_s(v)) & \text{if } alt(v) \geqq s/3, \\ SAMP_2(U_s(v)) & \text{if } alt(v) = (s-1)/3, \\ SAMP_1(U_s(v)) & \text{if } alt(v) = (s-2)/3. \end{cases}$$

At stage $s+1$ we perform the following computation at each internal node v that is currently active.

Per-stage computation $(v, s+1)$. Form the two lists $U'_{s+1}(lchild\ (v))$ and $U'_{s+1}(rchild\ (v))$, and compute the new list

$$U_{s+1}(v) := U'_{s+1}(lchild\ (v)) \cup U'_{s+1}(rchild\ (v)).$$

This formalizes the notion that we pass information from the merges performed at the children of v in stage s to the merge being performed at v in stage $s+1$. Note that until v becomes full, $U'_{s+1}(v)$ will be the list consisting of every fourth element of $U_s(v)$. This continues to be true about $U'_{s+1}(v)$ up to the point that v becomes full. If s_v is the stage at which v becomes full (and $U_s(v) = U(v)$), then at stage s_v+1, $U'_{s+1}(v)$ is the two-sample of $U_s(v)$, and, at stage s_v+2, $U'_{s+1}(v) = U_s(v)$ $(= U(v))$. Thus, at stage s_v+3, $parent(v)$ is full. Therefore, after $3 * height(T)$ stages every node has become full and the algorithm terminates. We have yet to show how to perform each stage in $O(1)$ time using n processors.

We begin by showing that the number of items in $U_{s+1}(v)$ can be only a little more than twice the number of items in $U_s(v)$, a property that is essential to the construction.

LEMMA 2.1. *For any stage* $s \geqq 0$ *and any node* $v \in T$, $|U_{s+1}(v)| \leqq 2|U_s(v)| + 4$.

Proof. The proof is by induction on s.

Basis $(s = 0)$. The claim is clearly true for $s = 0$.

Induction step $(s > 0)$. Assume the claim is true for stage $s-1$. If v is full (i.e., $alt(v) = \lfloor s/3 \rfloor$), then the claim is obviously true, since $U_{s+1}(v) = U_s(v) = U(v)$. Consider the case where either the children of v were not full at stage s or had just become full at stage s. We know that $U_{s+1}(v) = U'_{s+1}(x) \cup U'_{s+1}(y)$, where $x = lchild(v)$ and

$y = rchild\ (v)$. In addition, we have the following:

$$
\begin{aligned}
|U_{s+1}(v)| &= \left\lfloor \frac{|U_s(x)|}{4} \right\rfloor + \left\lfloor \frac{|U_s(y)|}{4} \right\rfloor \quad \text{(from definitions)} \\
&\leqq \left\lfloor \frac{2|U_{s-1}(x)|+4}{4} \right\rfloor + \left\lfloor \frac{2|U_{s-1}(y)|+4}{4} \right\rfloor \quad \text{(by induction hypothesis)} \\
&\leqq 2\left(\left\lfloor \frac{|U_{s-1}(x)|}{4} \right\rfloor + \left\lfloor \frac{|U_{s-1}(y)|}{4} \right\rfloor \right) + 4 \\
&= 2|U_s(v)| + 4.
\end{aligned}
$$

The case when the children of v are full at stage $s-1$ is similar (except that one divides by 2 or 1 instead of 4). Actually, it is simpler, since in this case the children of v were full in stage $s-1$; hence, the step using the induction hypothesis can be replaced by a simple algebraic substitution step. □

In the next lemma we show that the way in which the $U_s(v)$'s grow is "well behaved."

LEMMA 2.2. *Let* $[a, b]$ *be an interval with* $a, b \in (-\infty, U'_s(v), \infty)$. *If* $[a, b]$ *intersects* $k+1$ *items in* $(-\infty, U'_s(v), \infty)$, *then it intersects at most* $8k+8$ *items in* $U_s(v)$ *for all* $k \geqq 1$ *and* $s \geqq 1$.

Proof. The proof is by induction on s. The claim is initially true (for $s = 1$). Actually, for any stage s, if $U'_s(v)$ is empty, then $U_{s-1}(v)$ contains at most three items, hence, $U_s(v)$ contains at most ten elements, by the previous lemma. Also, if $U'_s(v)$ contains one item, then $U_{s-1}(v)$ contains at most seven items, hence, $U_s(v)$ contains at most 18 items, by the previous lemma. At most 15 of these items can be between any two adjacent items in $(-\infty, U'_s(v), \infty)$, since the item in $U'_s(v)$ was the fourth item in $U_{s-1}(v)$ by definition.

Inductive step (assume true for stage s). Let $[a, b]$ be an interval with a, b both in the list $(-\infty, U'_{s+1}(v), \infty)$, and suppose $[a, b]$ intersects $k+1$ items in $(-\infty, U'_{s+1}(v), \infty)$. The lemma is immediately true if v was full stage s, since the smallest sample we take is a four-sample. So, next, suppose that either the children of v are not full or have just become full in stage s. Let g be the number of items in $(-\infty, U_s(v), \infty)$ intersected by $[a, b]$. Recall that $U_s(v) = U'_s(lchild\ (v)) \cup U'_s(rchild\ (v))$. Let $[a_1, b_1]$ (respectively, $[a_2, b_2]$) be the smallest interval containing $[a, b]$ such that $a_1, b_1 \in (-\infty, U'_s(lchild\ (v)), \infty)$ (respectively, $a_2, b_2 \in (-\infty, U'_s(rchild\ (v)), \infty)$). Suppose the interval $[a_1, b_1]$ intersects $h+1$ items in the list $(-\infty, U'_s(lchild\ (v)), \infty)$ and $[a_2, b_2]$ intersects $j+1$ items in $(-\infty, U'_s(rchild\ (v)), \infty)$. Note that $h+j = g$. By the induction hypothesis, $[a_1, b_1]$ intersects at most $8h+8$ items in $U_s(lchild\ (v))$, and hence at most $(8h+8)/4 = 2h+2$ items in $U'_{s+1}(lchild\ (v))$. Likewise, $[a_2, b_2]$ intersects at most $2j+2$ items in $U'_{s+1}(rchild\ (v))$. The definition of $U'_{s+1}(v)$ implies that $g \leqq 4k+1$. Therefore, since $U_{s+1}(v) = U'_{s+1}(lchild\ (v)) \cup U'_{s+1}(rchild\ (v))$, $[a, b]$ intersects at most $(2h+2)+(2j+2)$ items in $U_{s+1}(v)$, where $(2h+2)+(2j+2) \leqq (2h+2)+(2(4k-h+1)+2) \leqq 8k+8$.

The proof for the case when the children of v were full in stage $s-1$ is similar. Actually, it is simpler, since the induction steps can be replaced by algebraic substitution steps in this case. □

COROLLARY 2.3. *The list* $(-\infty, U'_s(v), \infty)$ *is a four-cover for* $U'_{s+1}(v)$, *for all* $s \geqq 0$. □

This corollary is used in showing that we can perform each stage of the merge procedure in $O(1)$ time. In addition to this corollary, we also need to maintain the following rank information at the start of each stage s:

(1) For each item in $U'_s(v)$: its rank in $U'_s(sibling(v))$.

(2) For each item in $U'_s(v)$: its rank in $U_s(v)$ (and hence, implicitly, its rank in $U'_{s+1}(v)$).

The lemma that follows shows that the above information is sufficient to allow us to merge $U'_{s+1}(lchild\ (v))$ and $U'_{s+1}(rchild\ (v))$ into the list $U_{s+1}(v)$ in $O(1)$ time using $|U_{s+1}(v)|$ processors.

LEMMA 2.4 (THE MERGE LEMMA) [13]. *Suppose we are given sorted lists A_s, A'_{s+1}, B'_s, B'_{s+1}, C'_s, and C'_{s+1}, where the following (input) conditions are true*:

(1) $A_s = B'_s \cup C'_s$;

(2) A'_{s+1} *is a subset of* A_s;

(3) B'_s *is a* c_1*-cover for* B'_{s+1};

(4) C'_s *is a* c_2*-cover for* C'_{s+1};

(5) B'_s *is ranked in* B'_{s+1};

(6) C'_s *is ranked in* C'_{s+1};

(7) B'_s *and* C'_s *are cross-ranked.*

Then in $O(1)$ time using $|B'_{s+1}|+|C'_{s+1}|$ processors in the CREW PRAM *model, we can compute the following (output computations)*:

(1) *the sorted list* $A_{s+1} = B'_{s+1} \cup C'_{s+1}$;

(2) *the ranking of* A'_{s+1} *in* A_{s+1};

(3) *the cross-ranking of* B'_{s+1} *and* C'_{s+1}. □

We apply this lemma by setting $A_s = U_s(v)$, $A'_{s+1} = U'_{s+1}(v)$, $A_{s+1} = U_{s+1}(v)$, $B'_s = U'_s(x)$, $B'_{s+1} = U'_{s+1}(x)$, $C'_s = U'_s(y)$, and $C'_{s+1} = U'_{s+1}(y)$, where $x = lchild\ (v)$ and $y = rchild\ (v)$. Note that assigning the lists of Lemma 2.4 in this way satisfies input conditions (1)–(4) from the definitions. The ranking information we maintain from stage to stage satisfies input conditions (5)–(7). Thus, in each stage s, we can construct the list $U_{s+1}(v)$ in $O(1)$ time using $|U_{s+1}(v)|$ processors. Also, the new ranking information (of output computations (2) and (3)) gives us the input conditions (5)–(7) for the next stage. By Corollary 2.3 we have that the constants c_1 and c_2 (of input conditions (3) and (4)) are both equal to four. Note that in stage s it is only necessary to store the lists for $s-1$; we can discard any lists for stages previous to that.

The method for performing all these merges with a total of $|T|$ processors is basically to start out with $O(1)$ virtual processors assigned to each leaf node, and each time we pass k elements from a node v to the parent of v (to perform the merge at the parent), we also pass $O(k)$ virtual processors to perform the merge. When v's parent becomes full, then we no longer "store" any processors at v. (See [17] for details.) There can be at most $O(n)$ elements present in active nodes of T for any stage s (where n is the number of leaves of T), since there are n elements present on the full level, at most $n/2$ on the level above that, $n/8$ on the level above that, and so on. Thus, we can perform the entire generalized cascading procedure using $O(n)$ virtual processors, or n actual processors (by a simple simulation argument). This also implies that we need only $O(n)$ storage for this computation, in addition to that used for the output, since once a node v becomes full we can consider the space used for $U(v)$ to be part of the output. Equivalently, if we are using the generalized merging procedure in an algorithm that does not need a $U(v)$ list once v's parent becomes full, then we can implement that algorithm in $O(n)$ space by deallocating the space for a $U(v)$ list once it is no longer needed (this is in fact what we will be doing in § 6).

It will often be more convenient to relax the condition that there be at most one item stored at each leaf. So, suppose there is an unsorted set $A(v)$ (which may be empty) stored at each leaf. In this case we can construct a tree T' from T by replacing each leaf v of T with a complete binary tree with $|A(v)|$ leaves, and associating each item in $A(v)$ with one of these leaves. T' would now satisfy the conditions of the method outlined above. We incorporate this observation in the following theorem, which summarizes the discussion of this section.

THEOREM 2.5. *Suppose we are given a binary tree T such that there is an unsorted set $A(v)$ (which may be empty) stored at each leaf. Then we can compute, for each node $v \in T$, the list $U(v)$, which is the union of all items stored at descendents of v, sorted in an array. This computation can be implemented in $O(\text{height}(T) + \log(\max_v |A(v)|))$ time using a total of $n + N$ processors in the* CREW PRAM *computational model, where n is the number of leaves of T and N is the total number of items stored in T.*

Proof. The complexity bounds follow from the fact that the tree T' described above would have height at most $O(\text{height}(T) + \log(\max_v |A(v)|))$ and $|T'|$ is $O(|T| + N)$. □

The above method comprises one of the main building blocks of the algorithms presented in this paper. We present another important building block in the following section.

3. Fractional cascading in parallel. Given a directed graph $G = (V, E)$, such that every node v contains a sorted list $C(v)$, the fractional cascading problem is to construct an $O(n)$ space data structure that, given a walk $(v_1, v_2, \cdots, v_m)$ in G and an arbitrary element x, enables a single processor to locate x quickly in each $C(v_i)$, where $n = |V| + |E| + \sum_{v \in V} |C(v)|$. Fractional cascading problems arise naturally from a number of computational geometry problems. As a simple example of a fractional cascading problem, suppose we have five different English dictionaries and would like to build a data structure that would allow us to look up a word w in all the dictionaries. Chazelle and Guibas [12] give an elegant $O(n)$ time sequential method for constructing a fractional cascading data structure from any graph G, as described above, achieving a search time of $O(\log n + m \log d(G))$, where $d(G)$ is the maximum degree of any node in G. However, their approach does not appear to be "parallelizable."

In this section we show how to construct a data structure achieving the same performance as that of Chazelle and Guibas in $O(\log n)$ time using $\lceil n/\log n \rceil$ processors. Our method begins with a preprocessing step similar to one used by Chazelle and Guibas where we "expand" each node of G into two binary trees—one for its in-edges and one for its out-edges—so that each node in our graph has in-degree and out-degree at most 2. We then perform a cascading merge procedure in stages on this graph. Each catalogue $C(v)$ is "fed into" the node v in samples that double in size with each stage and these lists are in turn sampled and merged along the edges of G. Lists continue to be sampled and "pushed" across the edges of G (even in cycles) for a logarithmic number of stages, at which time we stop the computation and add some links between elements in adjacent lists. We conclude this section by showing that this gives us a fractional cascading data structure, and that the computation can be implemented in $O(\log n)$ time and $O(n)$ space using $\lceil n/\log n \rceil$ processors.

We show below how to perform the computations in $O(\log n)$ time and $O(n)$ space using n processors. We will show later how to get the number of processors down to $\lceil n/\log n \rceil$ by a careful application of Brent's theorem [11].

Define $In(v, G)$ (respectively, $Out(v, G)$) to be the set of all nodes w in V such that $(w, v) \in E$ (respectively, $(v, w) \in E$). The *degree* of a vertex v, denoted $d(v)$, is

defined as $d(v) = \max\{|In(v, G)|, |Out(v, G)|\}$. The *degree* of G, denoted $d(G)$, is defined as $d(G) = \max_{v \in V}\{d(v)\}$. A sequence $(v_1, v_2, \cdots, v_m)$ of vertices is a *walk* if $(v_i, v_{i+1}) \in E$ for all $i \in \{1, 2, \cdots, m-1\}$.

As mentioned above, we begin the construction by preprocessing the directed graph G to convert it into a directed graph $\hat{G} = (\hat{V}, \hat{E})$ such that $d(\hat{G}) \leqq 2$ and such that an edge (v, w) in G corresponds to a path in $\hat{G}$ of length at most $O(\log d(G))$. Specifically, for each node $v \in V$ we construct two complete binary trees T_v^{in} and T_v^{out}. Each leaf in T_v^{in} (respectively, T_v^{out}) corresponds to an edge coming into v (respectively, going out of v). So there are $|In(v, G)|$ leaves in T_v^{in} and $|Out(v, G)|$ leaves in T_v^{out}. (See Fig. 2.) We call T_v^{in} the *fan-in tree* for v and T_v^{out} the *fan-out tree* for v. An edge $e = (v, w)$ in G corresponds to a node e in $\hat{G}$ such that e is a leaf of the fan-out tree for v and e is also a leaf of the fan-in tree for w. The edges in T_v^{in} are all directed up towards the root of T_v^{in}, and the edges in T_v^{out} are all directed down towards the leaves of T_v^{out}. For each $v \in V$ we create a new node v' and add a directed edge from v' to v, a directed edge from the root of T_v^{in} to v', and an edge from v' to the root of T_v^{out}. We call v' the *gateway* for v. (See Fig. 2). Note that $d(\hat{G}) = 2$. We assume that for each node v we have access to the nodes in $In(v, \hat{G})$ as well as those in $Out(v, \hat{G})$. We structure fan-out trees so that a processor needing to go from v to w in $\hat{G}$, with $(v, w) \in E$, can correctly determine the path down T_v^{out} to the leaf corresponding to (v, w). More specifically, the leaves of each fan-out tree are ordered so that they are listed from left to right by increasing destination name, i.e., if the leaf in T_v^{out} for $e = (v, u)$ is to the left of the leaf for $f = (v, w)$, then $u < w$. (The leaves of T_v^{in} need not be sorted, since all edges are directed towards the root of that tree.) If we are not given the $Out(v, G)$ sets in sorted order, then we must perform a sort as a part of the T_v^{out} construction, which can be done in $O(\log d(G))$ time using n processors using Cole's merge sorting algorithm [13]. We also store in each internal node z of T_v^{out} the leaf node u that has the smallest name of all the descendants of z.

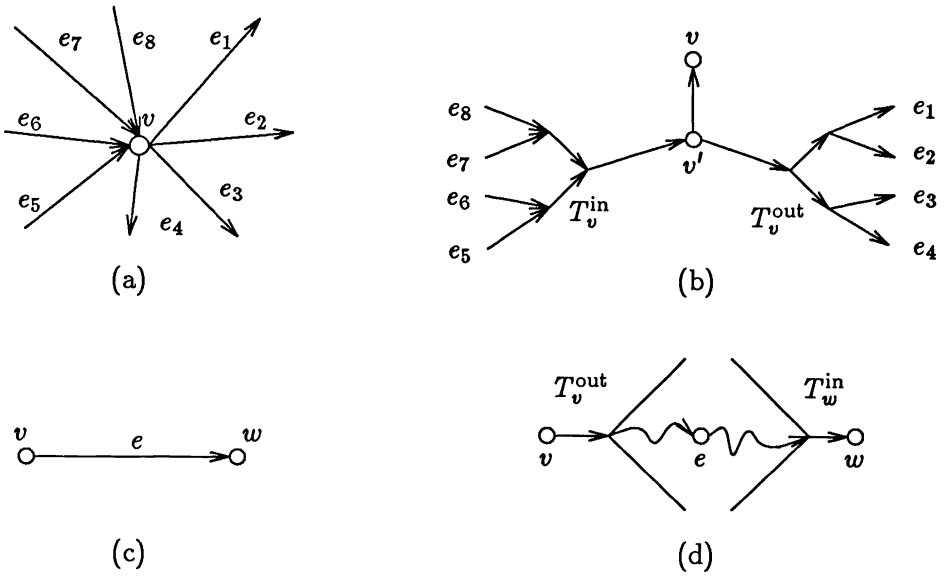

FIG. 2. *Converting G into a bounded degree graph $\hat{G}$. A node v in G* (a) *corresponds into a node v adjacent to its gateway v', which is connected to the fan-in tree and the fan-out tree for v* (b). *An edge e in G* (c) *is converted into a node in $\hat{G}$ which corresponds to a leaf node of two trees* (d).

The above preprocessing step is similar to a preprocessing step used in the sequential fractional cascading algorithm of Chazelle and Guibas [12]. This is where the resemblance to the sequential algorithm ends, however.

The goal for the rest of the computation is to construct a special sorted list $B(v)$, which we call the *bridge list*, for every node $v \in \hat{V}$. We shall define these bridge lists so that $B(v) = C(v)$ if v is in V; if v is in $\hat{V}$ but not in V, then for every $(v, w) \in \hat{E}$, if a single processor knows the position of a search item x in $B(v)$, it can find the position of x in $B(w)$ in $O(1)$ time.

The construction of the $B(v)$'s proceeds in stages. Let $B_s(v)$ denote the bridge list stored at node $v \in \hat{V}$ at the end of stage s. Initially, $B_0(v) = \varnothing$ for all v in $\hat{V}$. Intuitively, the per-stage computation is designed so that if v came from the original graph G (i.e., $v \in V$), then v will be "feeding" $B_s(v)$ with samples of the catalogue $C(v)$ that double in size with each stage. These samples are then cascaded back into the gateway v' for v and from there back through the fan-in tree for v. We will also be merging any samples "passed back" from the fan-out tree for v with $B_s(v')$, and cascading these values back through the fan-in tree for v as well. We iterate the per-stage computation for $\lceil \log N \rceil$ stages, where N is the size of the largest catalogue in G. We will show that after we have completed the last stage, and updated some ranking pointers, $\hat{G}$ will be a fractional cascading data structure for G. The details follow.

Recall that $B_0(v) = \varnothing$ for all $v \in \hat{V}$. For stage $s \geqq 0$, we define $B'_{s+1}(v)$ and $B_{s+1}(v)$ as follows:

$$B'_{s+1}(v) = \begin{cases} SAMP_4(B_s(v)) & \text{if } v \in \hat{V} - V, \\ SAMP_{c(s)}(C(v)) & \text{if } v \in V, \end{cases}$$

$$B_{s+1}(v) = \begin{cases} B'_{s+1}(w_1) \cup B'_{s+1}(w_2) & \text{if } Out(v, \hat{G}) = \{w_1, w_2\}, \\ B'_{s+1}(w) & \text{if } Out(v, \hat{G}) = \{w\}, \\ \varnothing & \text{if } Out(v, \hat{G}) = \varnothing, \end{cases}$$

where $c(s) = 2^{\lceil \log N \rceil - s}$ and N is the size of the largest catalogue. The per-stage computation, then, is as follows.

Per-stage computation $(v, s+1)$. Using the above definitions, construct $B_{s+1}(v)$ for all $v \in \hat{V}$ in parallel (using $|B_{s+1}(v)|$ processors for each v).

The function $c(s)$ is defined so that if $v \in V$, then as the computation proceeds the list $B'_{s+1}(v)$ will be empty for a while. Then at some stage $s+1$, it will consist of a single element of $C(v)$ (the $(2^{\lceil \log N \rceil - s})$th element), in stage $s+2$ at most three elements (evenly sampled), in stage $s+3$ at most five elements, in stage $s+4$ at most nine elements, and so on. This continues until the final stage (stage $\lceil \log N \rceil$), when $B'_{s+1}(v) = C(v)$. Intuitively, the $c(s)$ function is a mechanism for synchronizing the processes of "feeding" the $C(v)$ lists into the nodes of $\hat{G}$ so that all the processes complete at the same time. We show below that each stage can be performed in $O(1)$ time, resulting in a running time of the cascading computations that is $O(\log N)$ (plus the time it takes time to compute the value of N, namely, $O(\log n)$). The following important lemma is similar to Lemma 2.1 in that it guarantees that the bridge lists do not grow "too much" from one stage to another.

LEMMA 3.1. *For any stage* $s \geqq 0$ *and any node* $v \in T$, $|B_{s+1}(v)| \leqq 2|B_s(v)| + 4$.

Proof. The proof is by induction on s.

Basis $(s = 0)$. The claim is clearly true for $s = 0$.

Induction step $(s > 0)$. Assume the claim is true for stage $s-1$. If $v \in V$, then the claim follows immediately from the definition of $c(s)$, since in this case $B_{s+1}(v)$ and

$B_s(v)$ are both samples of $C(v)$ with $B_{s+1}(v)$ being twice as fine as $B_s(v)$, i.e., $|B_{s+1}(v)| \leqq 2|B_s(v)|+1$.

Consider the case when $v \in \hat{V} - V$, and $Out(v, \hat{G}) = \{w_1, w_2\}$. We know in this case $B_{s+1}(v) = B'_{s+1}(w_1) \cup B'_{s+1}(w_2)$. Thus, we have the following:

$$
\begin{aligned}
|B_{s+1}(v)| &= \left\lfloor \frac{|B_s(w_1)|}{4} \right\rfloor + \left\lfloor \frac{|B_s(w_2)|}{4} \right\rfloor \quad \text{(from definitions)} \\
&\leqq \left\lfloor \frac{2|B_{s-1}(w_1)|+4}{4} \right\rfloor + \left\lfloor \frac{2|B_{s-1}(w_2)|+4}{4} \right\rfloor \quad \text{(by induction hypothesis)} \\
&\leqq 2\left(\left\lfloor \frac{|B_{s-1}(w_1)}{4} \right\rfloor + \left\lfloor \frac{|B_{s-1}(w_2)|}{4} \right\rfloor \right) + 4 \\
&= 2|B_s(v)|+4.
\end{aligned}
$$

For the case when $v \in \hat{V} - V$ and $Out(v, \hat{G})$ contains only one node, w, the argument is similar and, in fact, simpler. We simply repeat the above argument, replacing w_1 with w and eliminating those terms that contain w_2. □

In the next lemma we show that the way in which the $B_s(v)$'s grow is "well behaved," much as we did in Lemma 2.2.

LEMMA 3.2. *Let* $[a, b]$ *be an interval with* $a, b \in (-\infty, B'_s(v), \infty)$. *If* $[a, b]$ *intersects* $k+1$ *items in* $(-\infty, B'_s(v), \infty)$, *then it intersects at most* $8k+8$ *items in* $B_s(v)$ *for all* $k \geqq 1$ *and* $s \geqq 1$.

Proof. The proof is structurally the same as that of Lemma 2.2, since that lemma was based on a merge definition similar to that for $B_{s+1}(v)$. □

COROLLARY 3.3. *The list* $(-\infty, B'_s(v), \infty)$ *is a four-cover for* $B'_{s+1}(v)$, *for* $s \geqq 0$.

COROLLARY 3.4. *The list* $(-\infty, B_s(v), \infty)$ *is a* 16*-cover for* $B_s(w)$, *for* $s \geqq 0$ *and* $(v, w) \in \hat{E}$.

The first of these two corollaries implies that we can satisfy all the c-cover input conditions for the Merge Lemma (Lemma 2.4) for performing the merge operations for the computation at stage s in $O(1)$ time using n_s processors, where $n_s = \sum_{v \in \hat{V}} |B_s(v)|$. We use the second corollary to show that when the computation is completed we will have a fractional cascading data structure (after adding the appropriate rank pointers). We maintain the following rank information at the start of each stage s.

(1) For each item in $B'_s(v)$: its rank in $B'_s(w)$ if $In(v, \hat{G}) \cap In(w, \hat{G})$ is nonempty, i.e., if there is a vertex u such that $(u, v) \in \hat{E}$ and $(u, w) \in \hat{E}$.

(2) For each item in $B'_s(v)$: its rank in $B_s(v)$ (and thus, implicitly, its rank in $B'_{s+1}(v)$).

By having this rank information available at the start of each stage s, we satisfy all the ranking input conditions of the Merge Lemma. Thus, we can perform each stage in $O(1)$ time using n_s processors. Moreover, the output computations of the Merge Lemma allow us to maintain all the necessary rank information into the next stage. Note that in stage s it is only necessary to store the lists for $s-1$; we can discard any lists for stages previous to that, as in the generalized cascading merge.

Recall that we perform the computation for $\lceil \log N \rceil$ stages, where N is the size of the largest catalogue. When the computation completes, we take $B(v) = B_s(v)$ for all $v \in \hat{V}$, and for each $(v, w) \in \hat{E}$ we rank $B(v)$ in $B(w)$. We can perform this ranking step by the following method. Assign a processor to each element b in $B(v)$ for all $v \in \hat{V}$ in parallel. The processor for b can find the rank of b in each $B'_s(w)$ such that $w \in Out(v, \hat{G})$ in $O(1)$ time because $B_s(v)$ contains $B'_s(w)$ as a proper subset ($B'_s(w)$ was one of the lists merged to make $B_s(v)$). This processor can then determine the

rank of b in $B(w) = B_s(w)$ for each $w \in Out(v, \hat{G})$ in $O(1)$ time by using the ranking information we maintained (from $B'_s(w)$ to $B_s(w)$) for stage s (rank condition (2) above).

Given a walk $W = (v_1, \cdots, v_m)$, and an arbitrary element x, the query that asks for locating x in every $C(v_i)$ is called the *multilocation* of x in $(v_1, \cdots, v_m)$. To perform a multilocation of x in a walk $(v_1, \cdots, v_m)$, we extend the walk W in G to its corresponding walk $\hat{W} = (\hat{v}_1, \cdots, \hat{v}'_m)$ in $\hat{G}$ and perform the corresponding multilocation in $\hat{G}$, similar to the method given by Chazelle and Guibas [12] for performing multilocations in their data structure. The multilocation begins with the location of x in $B(\hat{v}_1) = B(v'_1)$, the gateway bridge list for v_1, by binary search. For each other vertex in this walk we can locate the position of x in $B(\hat{v}_i)$ given its position in $B(\hat{v}_{i-1})$ in $O(1)$ time. The method is to follow the pointer from x's predecessor in $B(\hat{v}_{i-1})$ to the predecessor of that element in $B(\hat{v}_i)$ and then locate x in $B(\hat{v}_i)$ by a linear search from that position (which will require at most 15 comparisons by Corollary 3.4). In addition, if $\hat{v}_i$ corresponds to a gateway v', then we can locate x in $C(v)$ in $O(1)$ time given its position in $B(v')$ by a similar argument. (See Fig. 3.) Since each edge in the walk W corresponds to a path in $\hat{W}$ of length at most $O(\log d(G))$, this implies that we can perform the multilocation of x in $(v_1, \cdots, v_m)$ in $O(\log |B(v'_1)| + m \log d(G))$ time. In other words, $\hat{G}$ is a fractional cascading data structure. We show that $\hat{G}$ uses $O(n)$ space in the following lemma.

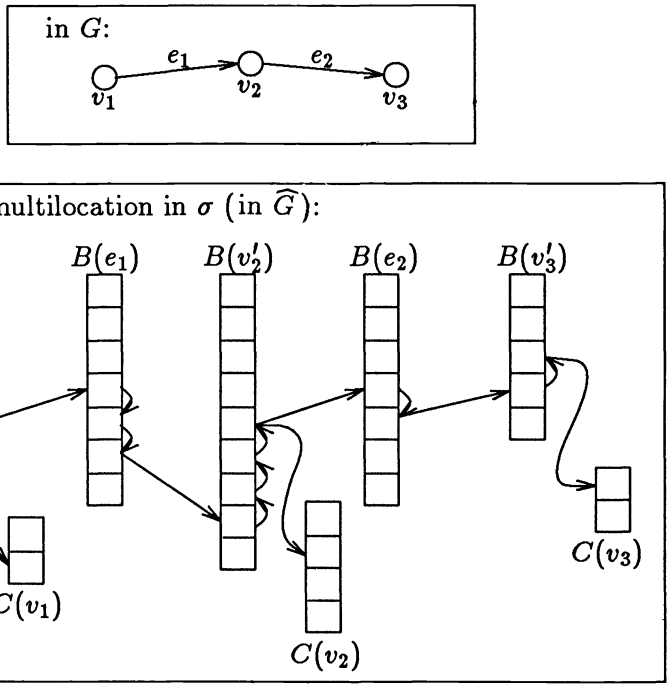

FIG. 3. *Multilocating an element x in* (v_1, v_2, v_3).

LEMMA 3.5. *Let* n_v *denote the amount of space that is added to* $\hat{G}$ *because of the presence of a particular catalogue* $C(v)$, $v \in V$. *Then* $n_v \leqq 2|C(v)|$.

Proof. Recall that while constructing the bridge lists in $\hat{G}$ we copy one-fourth of the elements in each bridge list to at most two of its neighbors. Thus, we have the

following:

$$n_v \leqq |C(v)| + 2\lfloor |C(v)|/4 \rfloor + 2^2 \lfloor |C(v)|/4^2 \rfloor + 2^3 \lfloor |C(v)|/4^3 \rfloor + \cdots$$
$$\leqq 2|C(v)|.$$

(This is obviously an overestimate, but it is good enough for the purposes of the analysis.) □

COROLLARY 3.6. *The total amount of space used by the fractional cascading data structure is* $O(n)$, *where* $n = |V| + |E| + \sum_{v \in V} |C(v)|$.

Proof. The total amount of space used by the fractional cascading data structure is $O(|\hat{V}| + |\hat{E}| + \sum_{v \in \hat{V}} |B(v)|)$. Since all the bridge lists start out empty, $\sum_{v \in \hat{V}} |B(v)| = \sum_{v \in V} n_v$. The previous lemma implies that $\sum_{v \in V} n_v \leqq \sum_{v \in V} 2|C(v)|$. Therefore, since $|\hat{V}| + |\hat{E}|$ is $O(|V| + |E|)$ by the definition of $\hat{G}$, the total amount of space used by the fractional cascading data structure is $O(n)$. □

Note that the upper bound on the space of the fractional cascading data structure holds even if $\hat{G}$ contains cycles. This corollary, then, implies that we can construct a fractional cascading data structure $\hat{G}$ from any catalogue graph G in $O(\log n)$ time and $O(n)$ space using n processors, even if G contains cycles. We have not shown, however, how to assign these n processors to their respective jobs.

The method for performing the processor allocation is as follows. Initially, we assign $2|C(v)|$ virtual processors to each node $v \in V$ and no processors to each node $v \in \hat{V} - V$. This requires at most $2n$ virtual processors; hence, can be easily simulated with n actual processors. Each time we pass k elements from a node v to a node w (in performing the merge at node w) we also pass along (exactly) k virtual processors to go with them. When we say that we are passing a virtual processor from some node v to some node w, all we are actually changing is the node to which that processor is assigned. Since, by Lemma 3.5, $n_v \leqq 2|C(v)|$, we know that there are enough virtual processors assigned to $v \in V$ to do this. To see that this also suffices for $v \in \hat{V} - V$ note that at the beginning of stage s node v has $|B_{s-1}(v)|$ elements (and processors). We "give away" at most $2\lfloor |B_{s-1}(v)|/4 \rfloor$ elements (and processors) from $B_{s-1}(v)$ in stage s and receive $|B_s(v)|$ elements (and processors). Consequently, there are enough processors to perform the merge to construct $B_s(v)$ and repeat the give-away procedure for the next stage. In addition, since we pass a processor for each item we pass to another node, each processor p_i can maintain not only which node it is assigned but p_i can also maintain m_v, the number of other processors that are assigned to that node, as well as maintaining a unique integer identification for itself in the range $[1, m_v]$. Thus, we have the following lemma.

LEMMA 3.7. *Given any catalogue graph* G, *we can construct a fractional cascading data structure for* G *in* $O(\log n)$ *time and* $O(n)$ *space using* n *processors in the* CREW PRAM *model.* □

Thus, we can solve the fractional cascading problem in $O(\log n)$ time using n processors. For the applications we study in this paper, however, we can do even better. The following lemma enumerates two important situations where the method just described can be improved.

LEMMA 3.8. *Given any catalogue graph* G, *if* $d(G)$ *is* $O(1)$ *or if we are given* $Out(v, G)$ *in sorted order for each* $v \in V$, *then the total number of operations performed by the fractional cascading algorithm is* $O(n)$.

Proof. If $d(G)$ is $O(1)$ or we are given $Out(v, G)$ in sorted order, then the construction of the graph $\hat{G}$ (without any bridge lists) requires only $O(n)$ operations, since we do not have to perform any sorting. Let us account for the total work performed

by computing the total number of other operations that are performed because of the fact that the catalogue for each node v contains $|C(v)|$ elements (we will only charge vertices in V). Let s_v be the first stage that $B_s(v')$ becomes nonempty. In this stage $B_s(v')$ receives one element of $C(v)$ from v, and hence we charge one operation in stage s_v for the node v. In stage s_v+1 we will then perform at most 3 operations, at most 7 in stage s_v+2, at most 15 in stage s_v+3, and so on. As soon as $B_s(v')$ contains at least four elements from v (as early as stage s_v+2), then we will perform one more operation, passing one element to the fan-in tree for v. In the next stage, s_v+3, we will perform at most two additional operations, then at most four additional operations in stage s_v+4, and so on. This pattern will "ripple" back through the fan-in tree for v and on through the graph $\hat{G}$ for as long as the computation proceeds. Specifically, the number of operations charged to a node $v \in V$ is, at most, the sum of the following $k_v = \lceil \log_4 |C(v)| \rceil$ rows:

$$
\begin{array}{ccccccccc}
1 & 3 & 7 & 15 & 31 & 63 & 127 & \cdots & |C(v)| \\
 & & 2*1 & 2*3 & 2*7 & 2*15 & 2*31 & \cdots & 2\lfloor |C(v)|/4 \rfloor \\
 & & & & 2^2*1 & 2^2*3 & 2^2*7 & \cdots & 2^2\lfloor |C(v)|/4^2 \rfloor \\
 & & & & & & \vdots & & \vdots \\
 & & & & & & & & 2^{k_v}*1
\end{array}
$$

where the number in row i and column j corresponds to the maximum number of operations performed in stage s_v+j-1 at nodes at distance i from v because of the fact that the catalogue at node v contains $|C(v)|$ elements. (This is actually an overestimate, since not all nodes in $\hat{G}$ have out-degree 2). Summing the number of operations for each row, and then summing the rows, we get that the number of operations charged to $v \in V$ is at most $2(|C(v)|+2\lfloor |C(v)|/4 \rfloor + 2^2\lfloor |C(v)|/4^2 \rfloor + \cdots + 2^{k_v})$, which is at most $4|C(v)|$. Thus, the total number of operations performed by the fractional cascading algorithm is $O(n)$. □

This lemma immediately suggests that we may be able to apply Brent's theorem to the fractional cascading algorithm so that it runs in $O(\log n)$ time using $\lceil n/\log n \rceil$ processors.

THEOREM 3.9 ([11]). *Any synchronous parallel algorithm taking time T that consists of a total of N operations can be simulated by P processors in $O(\lfloor N/P \rfloor + T)$ time.*

Proof of Brent's theorem. Let N_i be the number of operations performed at step i in the parallel algorithm. The P processors can simulate step i of the algorithm in $O(\lceil N_i/P \rceil)$ time. Thus, the total running time is $O(\lfloor N/P \rfloor + T)$:

$$\sum_{i=1}^{T} \lceil N_i/P \rceil \leqq \sum_{i=1}^{T} (\lfloor N_i/P \rfloor + 1) \leqq \lfloor N/P \rfloor + T. \qquad \square$$

There are two qualifications we must make to Brent's theorem before we can apply it in the PRAM model, however. The first is that we must be able to compute N_i at the beginning of step i in $O(\lceil N_i/P \rceil)$ time using P processors. And, second, we must know how to assign each processor to its job. Thus, in order to apply Brent's theorem to our problem of doing fractional cascading, we must deal with these processor allocation problems.

Let $\Gamma = \{p_1, p_2, \cdots, p_m\}$ be the set of virtual processors used in the fractional cascading algorithm (with $m \leqq 2n$), and let $\Gamma' = \{p'_1, p'_2, \cdots, p'_{\lceil n/\log n \rceil}\}$ be the set of processors we will be using to simulate the fractional cascading algorithm. Assuming that $d(G)$ is constant or we are given the list of vertices in $Out(v, G)$ in sorted order, we can compute the graph $\hat{G}$ and the initial assignment of processors from Γ, so that

we assign $2|C(v)|$ virtual processors to each node $v \in V$, in $O(\log n)$ time using the processors in Γ' by a parallel prefix computation. (Recall that the problem of computing all prefix sums $c_k = \sum_{i=1}^{k} a_i$ of a sequence of integers $(a_1, a_2, \cdots, a_n)$ can be done in $O(\log n)$ time using $\lceil n/\log n \rceil$ processors [21], [22].) Let $v(p_i)$ denote the vertex in $\hat{G}$ to which $p_i \in \Gamma$ is assigned. Recall that we will be "passing" the processor p_i around $\hat{G}$ during the computation, so the value of $v(p_i)$ can change from one stage to the next. Once a processor p_i becomes active, it stays active for the remainder of the computation. So, the only thing left to show is how to compute the number of processors active in stage s, and to assign the processors in Γ' to their respective tasks of simulating the processors in Γ. We do this by sorting the set of processors in Γ by the stage in which they become active. It is easy to compute the stage in which a processor p_i becomes active in $O(1)$ time, because this depends only on the initial value of $v(p_i)$ and the size of $C(v(p_i))$ relative to N (the size of the largest catalogue). We can sort the processors in Γ by the stage in which they become active in $O(\log n)$ time using the $\lceil n/\log n \rceil$ processors in Γ', by using an algorithm from Reif [23] (since the stage numbers fall in the range $[1, \lceil \log N \rceil]$). Thus, by performing a parallel prefix computation on this ordered list of processors, we can determine the number of processors active in each stage s, and also know how to assign the processors in Γ' so that they optimally simulate the activities of the processors in Γ during stage s. We thus have established the following theorem.

THEOREM 3.10. *Given a catalogue graph $G = (V, E)$, such that $d(G)$ is $O(1)$ or given each Out(v, G) set in sorted order, we can build a fractional cascading data structure for G in $O(\log n)$ time and $O(n)$ space using $\lceil n/\log n \rceil$ processors in the* CREW PRAM *model, where $n = |V| + |E| + \sum_{v \in V} |C(v)|$. This bound is optimal.* □

4. The plane-sweep tree data structure. In this section we define a data structure, which we call the plane-sweep tree, and show how to use it and the fractional cascading procedure of the previous section to solve the trapezoidal decomposition problem and the planar-point location problem in $O(\log n)$ time using n processors. Since the construction of this data structure is quite involved, we merely define the data structure now, and show how to construct it in these same bounds in § 5.

Let $S = \{s_1, s_2, \cdots, s_n\}$ be a set of nonintersecting line segments in the plane, and let $X(S) = (\alpha_1, \alpha_2, \cdots, \alpha_{2n})$ be the (nondecreasing) sorted list of the x-coordinates of the endpoints of the segments in S. To simplify the exposition, we assume that no two endpoints in S have the same x-coordinate, i.e., $\alpha_i < \alpha_{i+1}$. Let $X' = (x_1, x_2, \cdots, x_m)$ be some subsequence of $X(S)$ and let T be the complete binary tree whose $m+1$ leaves, in left to right order, correspond to the intervals $(-\infty, x_1]$, $[x_1, x_2]$, $[x_2, x_3]$, $\cdots$, $[x_{m-1}, x_m]$, $[x_m, +\infty)$, respectively. Associated with each internal node $v \in T$ is the interval I_v which is the union of the intervals associated with the descendants of v. Let Π_v denote the vertical strip $I_v \times (-\infty, +\infty)$. We say a segment s_i *covers a node* $v \in T$ if it spans Π_v but not $\Pi_{parent(v)}$. No segment covers more than two nodes of any level of T; hence, every segment covers at most $O(\log m)$ nodes of T. For each node $v \in T$ we let $Cover(v)$ denote the set of all segments in S that cover v.

The idea of using a tree data structure such as this to parallelize plane-sweeping is due to Aggarwal et al. [1] and is itself based on the "segment tree" of Bentley and Wood [8]. The data structure of Aggarwal et al. consists of the tree T described above with $X' = X(S)$ (i.e., it has $2n+1$ leaves). Aggarwal et al. store the list $Cover(v)$ at each node v sorted by the "above" relation for line segments. They construct these lists by first collecting the segments in each $Cover(v)$ and then sorting all the $Cover(v)$'s in parallel, an operation that requires $\Theta(\log^2 n)$ time using n processors [13], since

there are a total $\Theta(n \log n)$ items to sort. Once these lists are constructed the data structure can then be used to solve various problems by performing certain searches on the nodes of T. These searches are of the following nature: given a set of $O(n)$ input points, for each point p locate the segment in $Cover(v)$ that is directly above (or below) p, for all $v \in T$ such that $p \in \Pi_v$. Notice that for the leaf-to-root walk starting with the leaf v such that $p \in \Pi_v$, this search can be solved by the multilocation of p in that walk. Aggarwal et al. [1] perform all $O(n)$ multilocations in $O(\log^2 n)$ time using n processors by assigning a processor to each point p and doing a binary search for p in all the $Cover(v)$ lists such that $p \in \Pi_v$ (there are $O(\log n)$ such lists for each p).

Although based on the structure of Aggarwal et al., the plane-sweep tree differs from it in some important ways. One such difference is that the plane-sweep tree allows us to perform $O(n)$ multilocations in $O(\log n)$ time using n processors, after a preprocessing step that takes $O(\log n)$ time using n processors. Also, instead of taking X' to be the entire $X(S)$ list, we define X' to be the list consisting of every $\lceil \log n \rceil$th element of $X(S)$, i.e., $X' = SAMP_{\lceil \log n \rceil}(X(S))$. Thus, each vertical strip Π_v associated with a leaf of T in our construction contains $O(\log n)$ segment endpoints. Like Aggarwal et al., we also store each $Cover(v)$ list sorted by the "above" relation. In addition, for every node v of T we define the set $End(v)$ as follows:

$$End(v) = \{s_i | s_i \in S, \text{ has an endpoint in } \Pi_v, \text{ and does not span } \Pi_v\}.$$

Although $End(v)$ is defined for each node of T we only construct a copy of $End(v)$ if v is a leaf node. We do not store the elements of any $End(v)$ in any particular order. This is due to the fact that $End(v)$ contains $O(\log n)$ segments for any leaf node; hence a single processor can search the entire list in $O(\log n)$ time.

Note that all the segments in the $Cover(v)$'s of any root-to-leaf path in T are comparable by the "above" relation. Thus, if we direct all the edges in T so that each edge goes from a child to its parent, then the elements stored in any directed walk in T are all comparable by the "above" relationship. Therefore, we can apply the fractional cascading technique of the previous section to T (with each $Cover(v)$ playing the role of the catalogue $C(v)$). Since T has bounded degree and has $O(n \log n)$ space, we can, by Theorem 3.10, construct a fractional cascading data structure $\hat{T}$ for T in $O(\log n)$ time and $O(n \log n)$ space using n processors. This data structure allows us to perform the multilocation of any point p (in a leaf-to-root walk) in $O(\log n)$ time ($O(\log n)$ for the binary search at the leaf, and an additional $O(1)$ for each internal node on the path to the root). We also store the set $End(v)$ in each leaf v of $\hat{T}$. The plane-sweep tree data structure, then, consists of the tree $\hat{T}$ constructed from T by fractional cascading, where T is defined with $X' = SAMP_{\lceil \log n \rceil}(X(S))$, has $Cover(v)$ stored in sorted order for every node $v \in T$, and the set $End(v)$ stored (unsorted) for each leaf node $v \in T$ (see Fig. 4).

In § 5 we show how to construct this data structure efficiently in parallel. Since the construction is rather involved, before giving the details of the construction, we give two applications of this data structure. We begin with the trapezoidal decomposition problem.

4.1. The trapezoidal decomposition problem. Let $S = \{s_1, s_2, \cdots, s_n\}$ be a set of nonintersecting line segments in the plane. For any endpoint p of a segment in S a *trapezoidal segment* for p is a segment of S that is directly above or below p such that the vertical line segment from p to this edge is not intersected by any other segment in S. The trapezoidal decomposition problem is to find the trapezoidal segment(s) for each endpoint of the segments in S. Even in the parallel setting, this problem is often

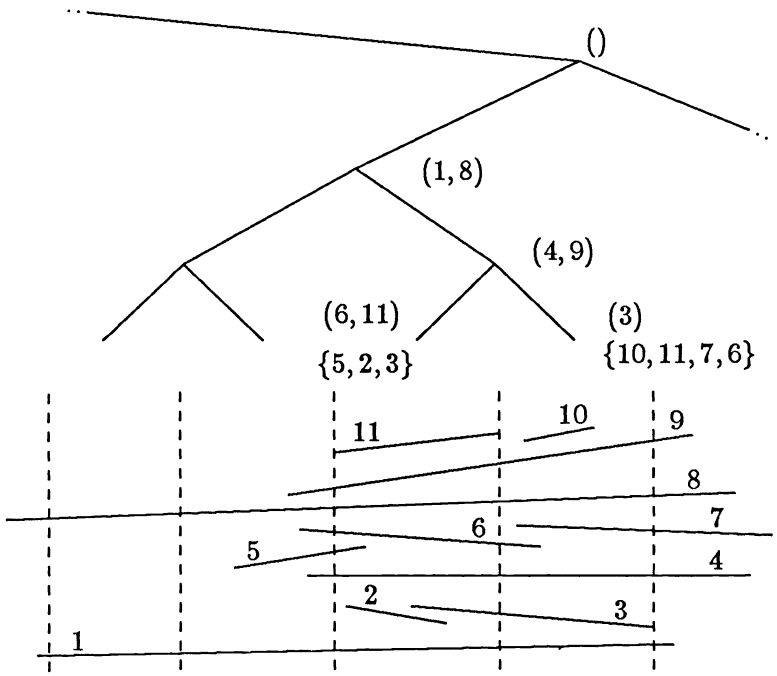

FIG. 4. *A portion of a plane-sweep tree. The segments are numbered in this example by embedding the "above" relation of* § 2 *in the total order* $1, 2, \cdots, 11$. *For simplicity we denote the list* $Cover(v)$ *by parentheses and the set* $End(v)$ *by set braces.*

used as a building block to solve other problems, such as polygon triangulation [1], [19], [28] or shortest paths in a polygon [16].

THEOREM 4.1. *A trapezoidal decomposition of a set* S *of* n *nonintersecting segments in the plane can be constructed in* $O(\log n)$ *time using* n *processors in the* CREW PRAM *model, and this is optimal.*

Proof. Construct the plane-sweep tree data structure T for S. Theorem 5.2 (to be given later, in § 5) shows that this structure can be constructed in $O(\log n)$ time using n processors. And we already know that T can be made into a fractional cascading data structure $\hat{T}$ in these same bounds. We assign a single processor to every segment endpoint (there are $2n$ such points). Let us concentrate on computing the trapezoidal segment below a single segment endpoint p. Let $(v, \cdots, root(T))$ be the leaf-to-root path in $\hat{T}$ that starts with the leaf v such that $p \in \Pi_v$. We first search through $End(v)$ to see if there are any segments in this set that are below p, and take the one that is closest to p (recall that $End(v)$ contains $O(\log n)$ segments). We then perform the multilocation of p in the leaf-to-root walk starting at v, giving us for each w such that $p \in \Pi_w$ the segment in $Cover(w)$ directly below p. We choose among these $\lceil \log n \rceil$ segments the segment that is closest to p. Comparing this segment to the one (possibly) found in $End(v)$, we get the segment in S, if there is one, that is directly below p. Since the length of the walk from v to $root(T)$ is at most $\lceil \log n \rceil$, by the method outlined at the end of § 3 [12], this computation can be done in $O(\log n)$ time using n processors. Since the two-dimensional maxima problem can be reduced to trapezoidal decomposition in $O(1)$ time using n processors [17], and the two-dimensional maxima problem has a sequential lower bound of $\Omega(n \log n)$ in the algebraic computation tree model [7], [20], we cannot do better than $O(\log n)$ time using n processors. □

Solving the trapezoidal decomposition problem efficiently in parallel has proven to be an important step in triangulating a polygon efficiently in parallel [1], [2], [5], [17], [28]. In fact, Theorem 4.1 is used in the algorithms of Goodrich [19] and Yap [28] to achieve an $O(\log n)$ time solution to polygon triangulation using only n processors. We next point out that the plane-sweep tree can also be used to solve the planar point location problem.

4.2. The planar point location problem. The planar point location problem is the following: Given a planar subdivision S consisting of n edges, construct a data structure that, once constructed, enables one processor to determine for a query point p the face in S containing p. This problem has applications in several other parallel computational geometry problems, such as Voronoi diagram construction.

THEOREM 4.2. *Given a planar subdivision S consisting of n edges, we can construct a data structure that can be used to determine for any query point p the face in S containing p in $O(\log n)$ serial time. This construction takes $O(\log n)$ time using n processors in the* CREW PRAM *model.*

Proof. The solution to this problem is to build the plane-sweep tree data structure for S (with fractional cascading) and associate with each edge s_i the name of the face above s_i. As already mentioned, Theorem 5.2 (to be given later, in § 5) shows that the tree T can be constructed in $O(\log n)$ time using n processors. Also recall that T can be made a fractional cascading data structure $\hat{T}$ in these bounds. Let a query point p be given. A planar point location query for p can be solved in $O(\log n)$ serial time by performing a multilocation like that used in the proof of Theorem 4.1 to find the segment in S directly below p. After we have determined the segment s_i in S that is directly below p, we then can read off the face of S containing p by looking up which face is directly above s_i. □

Incidentally, Theorem 4.2 immediately implies that the running time of the Voronoi diagram algorithm of Aggarwal et al. [1] can be improved from $O(\log^3 n)$ to $O(\log^2 n)$, still using only n processors. (We have recently learned that in the final version of their paper [2], they reduce the time bound of their algorithm to $O(\log^2 n)$ using a substantially different technique.)

The results of §§ 4.1 and 4.2 are conditional: they hold if we can construct the plane-sweep tree data structure efficiently in parallel. We next show how to construct the plane-sweep tree in $O(\log n)$ time using only n processors.

5. Cascading with line segment partial orders. In this section we show how to modify the cascading divide-and-conquer technique of § 2 to solve some geometric problems in which the elements being merged belong to the partial order defined by a set of nonintersecting line segments. Recall that in this partial order a segment s_1 is "above" a segment s_2 if there is a vertical line that intersects both segments, and its intersection with s_1 is above its intersection with s_2. We apply this technique to the problems of constructing the plane-sweep tree data structure and of detecting if any two of n segments in the plane intersect.

We now give a brief overview of the problems encountered and our solutions to them. The essential computation is as follows: we have a binary tree with lists stored in its leaves, and we wish to combine them in pairs (up the tree) to construct lists at internal nodes. The main difficulty is that the list stored at some node v is not defined as a simple merge of the lists stored at the children of v. Instead, its definition involves deleting elements from lists stored at children nodes before performing a merge. These deletions are quite troublesome, because if we try to perform these deletions while cascading, then the rank information will become corrupted, and the cascade will fail.

On the other hand, if we try to postpone the deletions to some postprocessing step, then there will be nondeleted elements that are not comparable to others at the same node; hence, there will be instances when processors try to compare two elements that are not comparable, and the cascade will fail. The main idea of our method for getting around these problems is to embed partial orders in total orders "on the fly" while we are cascading up the tree. That is, we change the identity of segments as they are being passed up the tree, so that the segments in any list are always linearly ordered. To be able to do this, however, we must do some preprocessing that involves simultaneously performing a number of cascading merges in parallel. We complete the computation by performing a purging postprocessing step to remove the segments that "changed identity" (as an alternative to being deleted).

For the intersection detection problem, we need to dovetail the detection of intersections with the cascading. That is, we cascade the results of intersection checks along with the segments being passed up the tree. The complication here is that if we should ever detect an intersection on the way up the tree we cannot stop and answer "yes" as this would require $O(\log n)$ time (to "fan-in" all the possible answers). Thus we are forced to proceed with the merging until we reach the root, even though in the case of an intersection the segments being merged no longer even belong to a partial order. We show that in this case we can replace the segment with a special place holder symbol so that the cascades can proceed. After the cascading merge completes we perform some postprocessing to then check if any intersections are present.

The next two subsections give the details.

5.1. Plane-sweep tree construction. In this subsection we describe how to construct the $Cover(v)$ lists for each node v in the plane-sweep tree T. We begin by making a few definitions and observations. We let left (Π_v) (respectively, right (Π_v)) denote the left (right) vertical boundary line for Π_v. We define the *dominator node* of a segment s_i, denoted $dom(s_i)$, to be the deepest node v (i.e., farthest from the root) in T such that s_i is completely contained in Π_v. That is, the dominator of s_i is the node v such that s_i does not intersect left (Π_v) or right (Π_v), but s_i does intersect the vertical boundary separating $\Pi_{lchild(v)}$ and $\Pi_{rchild(v)}$. In addition, we define the following sets for each node $v \in T$:

$$L(v) = \{s_i | s_i \in End(v) \text{ and } s_i \cap \text{left } (\Pi_v) \neq \emptyset\},$$

$$R(v) = \{s_i | s_i \in End(v) \text{ and } s_i \cap \text{right } (\Pi_v) \neq \emptyset\},$$

$$l(v, d) = \{s_i | s_i \in L(v) \text{ and } d = depth(dom(s_i))\},$$

$$r(v, d) = \{s_i | s_i \in R(v) \text{ and } d = depth(dom(s_i))\}.$$

Note that $l(v, d)$ and $r(v, d)$ are only defined for $0 \leqq d < depth(v)$. Any time we construct one of these sets it will be ordered by the "above" relation, so for the remainder of this section we represent these sets as sorted lists. In the following lemma we make some observations concerning the relationships between the various lists defined above.

LEMMA 5.1. *Let v be a node in T with left child x and right child y. Then we have the following (see Fig. 5):*

(1) $l(v, d) = l(x, d) \cup l(y, d)$ *for* $d < depth(v)$,
(2) $r(v, d) = r(x, d) \cup r(y, d)$ *for* $d < depth(v)$,
(3) $L(v) = l(v, 0) \cup l(v, 1) \cup \cdots \cup l(v, depth(v) - 1)$,
(4) $R(v) = r(v, 0) \cup r(v, 1) \cup \cdots \cup r(v, depth(v) - 1)$,
(5) $L(v) = L(x) \cup (L(y) - l(y, depth(v)))$,

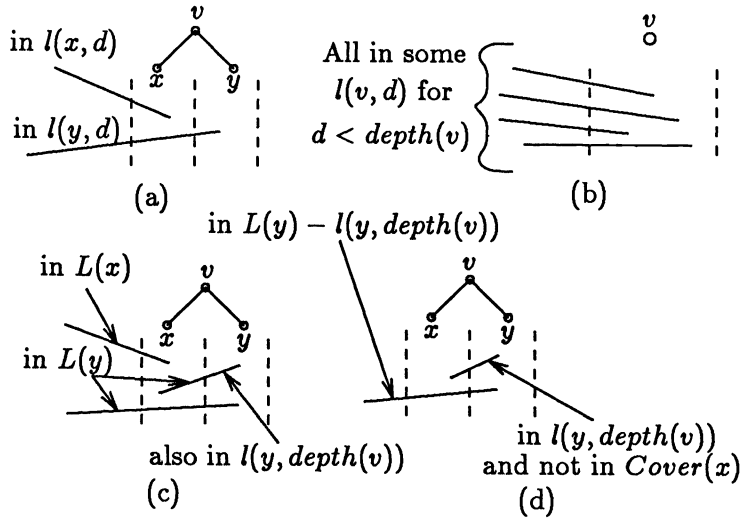

FIG. 5. *The plane-sweep tree equations.* (a) $l(v,d) = l(x,d) \cup l(y,d)$; (b) $L(v) = l(v,0) \cup l(v, depth(v)-1)$; (c) $L(v) = L(x) \cup (L(y) - l(y, depth(v)))$; (d) $Cover(x) = L(y) - l(y, depth(v))$.

(6) $R(v) = (R(x) - r(x, depth(v))) \cup R(y)$,

(7) $Cover(x) = L(y) - l(y, depth(v))$,

(8) $Cover(y) = R(x) - r(x, depth(v))$.

Proof. The proof follows from the definitions. □

Lemma 5.1 essentially states that the lists l, r, L, R, and *Cover* for the nodes on a particular level of T can be defined in terms of lists for nodes on the next lower level of T. We could use this lemma and the parallel merge technique of Valiant [26], as implemented by Borodin and Hopcroft [10], to construct a sorted copy of each $Cover(v)$ list in $O(\log n \log\log n)$ time using n processors, improving on the previous bound of $O(\log^2 n)$ time using the same number of processors, due to Aggarwal et al. [1]. We can do even better, however, by exploiting the structure of the L and R lists. We describe how to do this below, in order to achieve a running time of $O(\log n)$ still using n processors. Before going into the details of the plane-sweep tree construction, we give a brief overview of the algorithm.

HIGH-LEVEL DESCRIPTION OF PLANE-SWEEP TREE CONSTRUCTION.

The construction consists of the following four steps:

Step 1. Construct $l(v,d)$ and $r(v,d)$ for every $v \in T$. To implement this step, we perform $\lceil \log n \rceil$ generalized cascading merges in parallel (one for each d) based on (1) and (2) of Lemma 5.1 (starting with the leaf nodes of T). We implement this step in $O(\log n)$ time using n processors in total for all the merges.

Step 2. Let $d_v = depth(parent(v))$. Compute for each segment in $l(v,d_v)$ (respectively, $r(v,d_v)$) its predecessor segment in $L(v) - l(v,d_v)$ (respectively, $R(v) - r(v,d_v)$) based on (3) and (4). We do this, for each $v \in T$, by making d_v copies of $l(v,d_v)$ and $r(v,d_v)$, and merging $l(v,d_v)$ (respectively, $r(v,d_v)$) with all the $l(v,d)$ (respectively, $r(v,d)$) such that $d < d_v$. Note: we perform this step without actually constructing $L(v)$ or $R(v)$.

Step 3. Construct $L(v)$ and $R(v)$ for every $v \in T$. To implement this step we perform a generalized cascading merge procedure based on (5) and (6) and the information computed in Step 2 (starting with the leaf nodes of T). We never actually perform the set difference operations of (5) and (6), however. Instead, at the point in the merge that a segment in, say, $l(v,d_v)$, should be deleted we "change the identity"

of that segment to its predecessor in $L(v) - l(v, d_v)$ (which we know from Step 2). That is, from this point on in the cascading merge this segment is indistinguishable from its predecessor in $L(v) - l(v, d_v)$. We show below that (i) the cascading merge will not be corrupted by doing this, (ii) the lists never contain too many duplicate entries (that would require us to use more than n processors), and (iii) after the merge completes, we can construct $L(v)$ and $R(v)$ for each node by removing duplicate segments in $O(\log n)$ time using n processors.

Step 4. Construct $Cover(v)$ for every $v \in T$ using (7) and (8) and the lists constructed in Step 3. The implementation of this step amounts to compressing each $L(v)$ (respectively, $R(v)$) so as to delete all the segments in $l(v, d_v)$ (respectively, $r(v, d_v)$), and then copying the list of segments so computed to the sibling node in T.

END OF HIGH-LEVEL DESCRIPTION.

We now describe how to perform each of these high-level steps.

5.2. Step 1: Constructing $l(v, d)$ and $r(v, d)$. We construct the $l(v, d)$ and $r(v, d)$ lists as follows. We make $\lceil \log n \rceil$ copies of T, and let $T(d)$ denote tree number d. Note that by our definition of T the space needed to store the "skeleton" of each $T(d)$ is $O(n/\log n)$. This of course results in a total of $O(n)$ space for all the $T(d)$'s. For each node v of $T(d)$ such that $depth(v) > d$ we wish to construct the lists $l(v, d)$ and $r(v, d)$, as given by (1) and (2) of Lemma 5.1. This implies that if we store $l(v, d)$ (respectively, $r(v, d)$) in every leaf node v of $T(d)$, then for any node $v \in T(d)$, $l(v, d)$ is precisely the sorted merge of the lists stored in the descendants of v. We start with the elements belonging to $l(v, d)$ (respectively, $r(v, d)$) stored (unsorted) in a list $A(v)$ for each leaf v in $T(d)$, and construct each $l(v, d)$ and $r(v, d)$ by the generalized cascading merge technique of Theorem 2.5 (using the $A(v)$'s as in the theorem). Note: since $l(v, d)$ and $r(v, d)$ are only defined for $d < depth(v)$, we only proceed up any tree $T(d)$ as far as nodes at depth $d+1$, terminating the cascading merge at that point. We allocate $\lceil n/\log n \rceil + N_d$ processors to each tree $T(d)$, where N_d denotes the number of segments stored initially in the leaves of $T(d)$. Thus, since $\sum_{d=1}^{\lceil \log n \rceil} N_d = n$, we have shown how to construct all the $l(v, d)$ and $r(v, d)$ lists in $O(\log n)$ time and $O(n \log n)$ space using n processors.

5.3. Step 2: Computing predecessors. In Step 2 we wish to compute for each segment in the list $l(v, d_v)$ (respectively, $r(v, d_v)$) its predecessor segment in $L(v) - l(v, d_v)$ (respectively, $R(v) - r(v, d_v)$), where $d_v = depth(parent(v))$. Without loss of generality, we restrict our attention to the segments in $l(v, d_v)$ (the treatment for the segments in $r(v, d_v)$ is similar). Recall that (3) and (4) state that $L(v) = l(v, 0) \cup l(v, 1) \cup \cdots \cup l(v, d_v)$ and that $R(v) = r(v, 0) \cup r(v, 1) \cup \cdots \cup r(v, d_v)$. We make d_v copies of $l(v, d_v)$ and, using the merging procedure of Shiloach and Vishkin [25] or that of Bilardi and Nicolau [9], we merge a copy of $l(v, d_v)$ with each of $l(v, 0), \cdots, l(v, d_v - 1)$. This takes $O(\log n)$ time using $\lceil |L(v)|/\log n \rceil + \lceil d_v |l(v, d_v)|/\log n \rceil$ processors for each $v \in T$. Since (i) there are $O(n/\log n)$ nodes in each $T(d)$; (ii) each segment appears exactly once in some $l(v, d_v)$; and (iii) $\sum_{v \in T} |L(v)|$ is $O(n \log n)$, we can implement all these merges in parallel using n processors. Once we have completed all the merges, we assign a single processor to each segment s_i and compare the predecessors of s_i in $l(v, 0), \cdots, l(v, d_v - 1)$ so as to find the predecessor of s_i in $L(v) - l(v, d_v)$ $(= l(v, 0) \cup \cdots \cup l(v, d_v - 1))$. This amounts to $O(\log n)$ additional work for each s_i; thus Step 2 can be implemented in $O(\log n)$ time using n processors.

5.4. Step 3: Constructing $L(v)$ and $R(v)$. In this step we perform another cascading merge on T; this time to construct $L(v)$ and $R(v)$ for each $v \in T$ based on (5) and (6)

of Lemma 5.1. Initially, we have $L(v)$ and $R(v)$ constructed only for the leaves. We then merge these lists up the tree based on (5) and (6) as in Theorem 2.5. The computation for this step differs from the cascading merge of Step 2, however, in that we need to be performing set-difference operations as well as list merges as we are cascading up the tree. Unfortunately, it is not clear how to perform these difference operations on-line any faster than $O(\log n)$ time per level, which would result in a running time that is $O(\log^2 n)$. We get around this problem by never actually performing the difference operations. That is, we do not actually delete segments from any lists. Instead, we change the identity of a segment s_i in say, $l(y, d_y)$, to its predecessor in $L(y) - l(y, d_y)$ when we are performing the merge as node v, where $y = rchild\ (v)$ (see Fig. 6). We do this instead of simply marking s_i as "deleted" in $L(v)$, because segments in $l(y, d_y)$ may not be comparable to segments in $L(x)$ (the list with which we wish to merge $L(y) - l(y, d_y)$). Simply marking a segment as being "deleted" could thus result in a processor attempting to compare two incomparable segments.

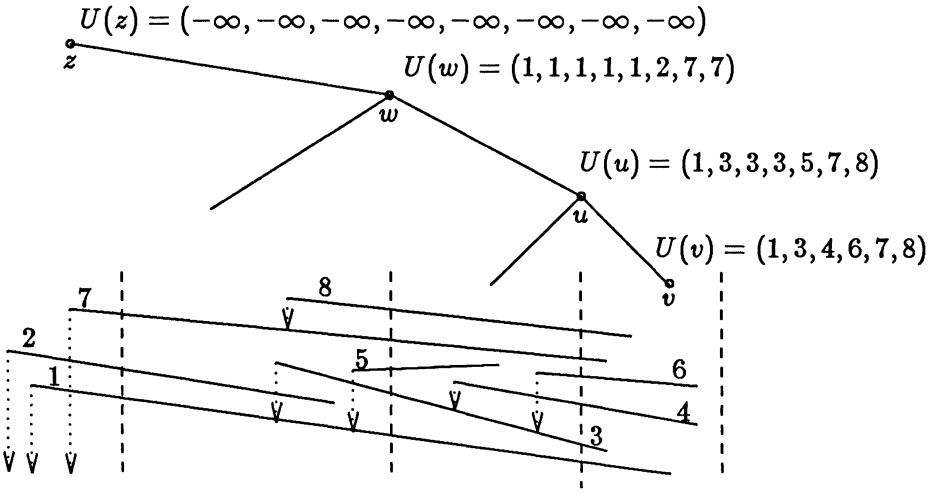

FIG. 6. *Segment identity changing during the cascading merge. We illustrate the way segment names change identity to that of their predecessor as we are performing the cascading merge. In this case we are constructing the $L(v)$'s. We denote the predecessor of each segment by a dotted arrow.*

Clearly, the fact that we change the identity of a segment in $l(y, d_y)$ to its predecessor in $L(y) - l(y, d_y)$ means that there will be multiple copies of some segments. This will not corrupt the cascading merge, however, because one of the properties of the "above" relation for segments is that all duplicate copies of a segment will be contiguous. Moreover, they will remain contiguous as the cascading merge proceeds up the tree. In addition, even though we will have multiple copies of segments in lists as they are merging up the tree, we can still implement this step with a total of n processors, because there will never be more items present in any $L(v)$ than the total number of items stored in the (leaf) descendants of v. At the end of this step we assign $\lceil |L(v)|/\log n \rceil$ processors to each v and compress out the duplicate entries in $L(v)$ in $O(\log n)$ time. Thus, we can construct $L(v)$ and $R(v)$ (compressed and sorted) for each $v \in T$ in $O(\log n)$ time using n processors.

5.5. Step 4: Constructing *Cover*(*v*). In this step we construct $Cover(v)$ for every v in T, based on (7) and (8) of Lemma 5.1. We implement this step by first compressing each $L(v)$ (respectively, $R(v)$) so as to delete all the segments in $l(v, d_v)$ (respectively,

$r(v, d_v)$), and then by copying the list of segments so computed to the sibling of v in T. This can all be done in $O(\log n)$ time using n processors.

Thus, summarizing the entire previous section, we have the following theorem.

THEOREM 5.2. *Given a set S of nonintersecting line segments in the plane, we can construct the plane-sweep tree T for S in $O(\log n)$ time using n processors in the* CREW PRAM *model, and this is optimal.*

Proof. We have already established the correctness and complexity bounds. To see that our construction is optimal, note that the plane-sweep tree requires $\Omega(n \log n)$ space. □

In the previous sections we assumed that segments did not intersect. Indeed, T is defined only if they do not intersect. We show in the next section that we can detect an intersection, if there is one, by constructing T while simultaneously checking for intersections.

5.6. The segment intersection detection problem. The problem we solve in this section is the following: given a set S of n line segments in the plane, determine if any two segments in S intersect. We begin by stating the conditions that we use to test for an intersection.

LEMMA 5.3 [1]. *The segments in S are nonintersecting if and only if we have the following for the plane-sweep tree T of S:*

(1) *For every $v \in T$ all the segments in $Cover(v)$ intersect* left (Π_v) *in the same order as they intersect* right (Π_v).

(2) *For every $v \in T$ no segment in $End(v)$ intersects any segment in $Cover(v)$.* □

Aggarwal et al. [1] used this lemma and their data structure to solve the intersection detection problem in $O(\log^2 n)$ time using n processors. Their method consisted of constructing the $Cover(v)$ lists independently of one another, basing comparisons on segment intersections with left (Π_v), and then testing for condition (1) by checking if each list $Cover(v)$ would be in the same order if they based comparisons on segment intersections with right (Π_v). If no intersection was detected by this step, then they tested for condition (2) by performing $O(n)$ multilocations of segment endpoints. This entire process took $O(\log^2 n)$ time using n processors.

We use this lemma by testing for condition (1) while we are constructing the plane-sweep tree for S (instead of waiting until after it has been built) and in so doing we achieve an $O(\log n)$ time bound for this test (since our construction takes only $O(\log n)$ time). We test condition (2) in the same fashion as Aggarwal et al., that is, by doing $O(n)$ multilocations after the plane-sweep tree has been built. Since with our data structure the multiplications can all be performed in $O(\log n)$ time, the entire intersection-detection process takes $O(\log n)$ time using n processors.

Since we do not construct the $Cover(v)$ lists independently of one another, but instead construct them by performing several cascading merges, we must be very careful in how we base segment comparisons, and in how we test for condition (1). For if two segments intersect, then determining which segment is above the other depends on the vertical line upon which we base the comparison.

We consider each step of the construction in turn, beginning with Step 1. Recall that in Step 1 we construct all the $l(v, d)$ and $r(v, d)$ lists for each $v \in T$. In the following lemma we show that if we base segment comparisons on appropriate vertical lines, Step 1 can be performed just as before.

LEMMA 5.4. *Let $v \in T$ and $0 \leq d < depth(v)$ be given, and let s_1 and s_2 be two segments such that $s_1 \in l(w, d)$ and $s_2 \in l(z, d)$ (or $s_1 \in r(w, d)$ and $s_2 \in r(z, d)$), where $w, z \in Desc(v)$. Then $dom(s_1) = dom(s_2)$.*

Proof. Let $v \in T$ and $0 \leqq d \leqq \lceil \log n \rceil$ be given. Recall that $l(v, d)$ (respectively, $r(v, d)$) is defined to be the list of all segments in $L(v)$ ($R(v)$) that have a dominator node at depth d in T. Note that the dominator node for any segment s_i in $l(w, d)$, $r(w, d)$, $l(z, d)$, or $r(z, d)$, where $w, z \in Desc(v)$, must be an ancestor of v, since $d < depth(v)$ and, by definition, $s_i \in End(v)$ and $s_i \in End(dom(s_i))$. There is only one node that is an ancestor of v and is at depth d in T. □

Thus, we can perform the merges based on (1) and (2) of Lemma 5.1 (e.g., $l(v, d) = l(x, d) \cup l(y, d)$) by basing all segment comparisons on the intersection of the segments with the vertical boundary separating the two children of their dominator node. That is, if s_1 and s_2 are two segments to be compared in Step 1, then we say that s_1 is "above" s_2 if and only if the intersection of s_1 with L is above the intersection of s_2 with L, where L is the vertical boundary line separating the two children of $dom(s_1)$ $(= dom(s_2))$.

In Step 2 we computed for each segment in $l(v, d_v)$ (respectively, $r(v, d_v)$) its predecessor segment in $L(v) - l(v, d_v)$ (respectively, $R(v) - r(v, d_v)$), where $d_v = depth(parent(v))$. Recall that we did this by merging $l(v, d_v)$ with each of $l(v, 0), \cdots, l(v, d_v - 1)$. A similar computation was done for $r(v, d_v)$; without loss of generality, we concentrate on the computation involving $l(v, d_v)$. Also recall that all the segments in $l(v, 0), \cdots, l(v, d_v)$ belong to $L(v)$; hence they intersect left (Π_v). After Step 1 finishes, each list $l(v, d)$ will be sorted based on segment intersections with the vertical boundary line separating the two children of the ancestor of v at depth d (the dominator of all the segments in $l(v, d)$). In $O(\log n)$ time we can check if this order is preserved in each of $l(v, 0), \cdots, l(v, d_v)$ if we base segment intersections on left (Π_v), instead. If the order changed in any $l(v, d)$, then we have detected an intersection, and we are done. Otherwise, we proceed with Step 2 just as before, basing comparisons on segment intersections with left (Π_v).

In Step 3 we performed a cascading merge up the tree T, constructing $L(v)$ and $R(v)$ for every node $v \in T$. Recall that this cascading merge was based on (5) and (6) of Lemma 5.1 (e.g., $L(v) = L(x) \cup (L(y) - l(y, depth(v)))$). Let us concentrate on the testing procedure for the $L(v)$'s, since the method for the $R(v)$'s is similar. Initially, let us start with each $L(v)$ constructed at the leaves of T sorted by segment intersections with left (Π_v). Thus, before we perform the merge based on the equation $L(v) = L(x) \cup (L(y) - l(y, depth(v)))$, we must first check to see if the segments in the sample of $L(y) - l(y, depth(v))$ (to be merged with the sample of $L(x)$) have the same order independent of whether comparisons are based on segment intersections with left (Π_y) or left (Π_v). Unfortunately, to do this completely would require $O(\log n)$ time at every level of the tree, resulting in an $O(\log^2 n)$ time algorithm. So, instead of broadcasting at each level whether an intersection has occurred or not, we cascade that information up along with the merges. More precisely, before doing the merge at a node v, we test if every consecutive pair of items in the sample of $L(y) - l(y, depth(v))$ would remain in the same order independent of whether comparisons were based on segment intersections with left (Π_y) or with left (Π_v). If we detect that an intersection has occurred, then we will have two elements that are out of order. If this should occur, we replace both items by the distinguished symbol \$. Then, as the merges continue up the tree, any time we compare an item with \$, we replace that item with \$ and proceed just as before. This keeps the merging process consistent, and after the cascading merge completes we can then in $O(\log n)$ time test if any of the items in any $L(v)$ or $R(v)$ contain a \$ symbol, by assigning $\lceil |L(v)|/\log n \rceil$ processors to each $v \in T$.

In Step 4 we constructed $Cover(v)$ for each $v \in T$. Recall that we did this by simply performing compressing and copying operations on lists constructed in Step 3. Thus,

assuming that no intersection was detected in Step 3, we can perform Step 4 just as before. After Step 4 completes we can assign $\lceil |Cover(v)|/\log n \rceil$ processors to each $v \in T$ and test condition (1) directly in $O(\log n)$ time, checking if the items in $Cover(v)$ would be in the same order independent of whether comparisons were based on left (Π_v) or on right (Π_v).

If we have not discovered an intersection after Step 4, then the only computation left is to perform fractional cascading on the plane-sweep tree T, constructing a fractional cascading data structure $\hat{T}$. In directing all the edges in T to the root, and performing the fractional cascading preprocessing on T to construct $\hat{T}$, we associate a vertical strip with each node in $\hat{T}$. Since T is a tree then $\hat{T}$ is also a tree (recall the preprocessing step of the fractional cascading algorithm). For each node v in $\hat{T}$ if v is also in T, then we take Π_v for v in $\hat{T}$ to be the same as Π_v for v in T. Then, for any v that is in $\hat{T}$ but not in T (i.e., v is a gateway or a node in a fan-in or fan-out tree), we take Π_v to be the union of all the vertical strips that are descendents of v. Every time we perform the per-stage merge computation we compare adjacent entries in each bridge list $B(v)$ to see if they would be in the same order independent of whether we base comparisons on segment intersections with left (Π_v) or right (Π_v). If we detect that two adjacent segments intersect, then we replace both with the special symbol \$. Then, as before, any time we compare a segment with \$ we replace that segment by \$. Finally, when we complete the computation for Step 5, we assign $\lceil |B(v)|/\log n \rceil$ processors to each node v and check if there are any \$ symbols present in any $B(v)$ list.

If there are no intersections detected during the fractional cascading, then we perform $O(n)$ multilocations of all the segment endpoints as in [1] to test condition (2). Let p be an endpoint of some segment s_i. We perform the multilocation of p in the plane-sweep tree for S, and check if s_i intersects the segment directly above p or the segment directly below p in each $Cover(v)$ list such that $p \in \Pi_v$. This test is sufficient, since if s_i intersects any segment in $Cover(v)$, it must intersect the segment directly above p in $Cover(v)$ or the segment directly below p in $Cover(v)$. Thus, by performing a multilocation for p, we can test for condition (2) in $O(\log n)$ time using n processors. We summarize this discussion in the following theorem.

THEOREM 5.5. *Given a set of n line segments in the plane, we can detect if any two intersect in* $O(\log n)$ *time using n processors in the* CREW PRAM *model.* □

So far in this paper we have restricted ourselves to applications involving line segments. In the next section we show how to apply the cascading divide-and-conquer technique to other geometric problems as well.

6. Cascading with labeling functions. In this section we show how to solve several different geometric problems by combining the merging procedure of § 2 with divide-and-conquer strategies based on merging lists with labels defined on their elements. For most of these problems our divide-and-conquer approach gives an efficient sequential alternative to the known sequential algorithms (which use the plane-sweeping paradigm) and gives rise to efficient parallel algorithms as well. We begin with the three-dimensional maxima problem.

6.1. The three-dimensional maxima problem. Let $V = \{p_1, p_2, \cdots, p_n\}$ be a set of points in $\Re^3$. For simplicity, we assume that no two input points have the same x (respectively, y, z) coordinate. We denote the x, y, and z coordinates of a point p by $x(p)$, $y(p)$, and $z(p)$, respectively. We say that a point p_i *one-dominates* another point p_j if $x(p_i) > (p_j)$, *two-dominates* p_j *if* $x(p_i) > x(p_j)$ and $y(p_i) > y(p_j)$, and *three-dominates*

p_j if $x(p_i) > x(p_j)$, $y(p_i) > y(p_j)$, and $z(p_i) > z(p_j)$. A point $p_i \in V$ is said to be a *maximum* if it is not three-dominated by any other point in V. The three-dimensional maxima problem, then, is to compute the set, M, of maxima in V. We show how to solve the three-dimensional maxima problem efficiently in parallel in the following algorithm.

Our method is based on cascading a divide-and-conquer strategy in which the subproblem merging step involves the computation of two labeling functions for each point. The labels we use are motivated by the optimal sequential plane-sweeping algorithm of Kung, Luccio, and Preparata [20]. Specifically, for each point p_i we compute the maximum z-coordinate from among all points that one-dominate p_i and use that label to also compute the maximum z-coordinate from among all points that two-dominate p_i. We can then test if p_i is a maximum point by comparing $z(p_i)$ to this latter label. The details follow.

Without loss of generality, we assume the input points are given sorted by increasing y-coordinates, i.e., $y(p_i) < y(p_{i+1})$, since if they are not given in this order we can sort them in $O(\log n)$ time using n processors [13]. Let T be a complete binary tree with leaf nodes $v_1, v_2, \cdots, v_n$ (in this order). In each leaf node v_i we store the list $B(v_i) = (-\infty, p_i)$, where $-\infty$ is a special symbol such that $x(-\infty) < x(p_j)$ and $y(-\infty) < y(p_j)$ for all points p_j in V. Initializing T in this way can be done in $O(\log n)$ time using n processors. We then perform a generalized cascading merge from the leaves of T as in Theorem 2.5, basing comparisons on increasing x-coordinates of the points (not their y-coordinates). Using the notation of § 2, we let $U(v)$ denote the sorted array of the points stored in the descendants of $v \in T$ sorted by increasing x-coordinates. For each point p_i in $U(v)$ we store two labels: $zod(p_i, v)$ and $ztd(p_i, v)$, where $zod(p_i, v)$ is the largest z-coordinate of the points in $U(v)$ that one-dominate p_i, and $ztd(p_i, v)$ is the largest z-coordinate of the points in $U(v)$ that two-dominate p_i. Initially, *zod* and *ztd* labels are only defined for the leaf nodes of T. That is, $zod(p_i, v_i) = ztd(p_i, v_i) = -\infty$ and $zod(-\infty, v_i) = ztd(-\infty, v_i) = z(p_i)$ for all leaf nodes v_i in T (where $U(v_i) = (-\infty, p_i)$). In order to be more explicit in how we refer to various ranks, we let $\text{pred}(p_i, v)$ denote the predecessor of p_i in $U(v)$ (which would be $-\infty$ if the x-coordinates of the points in $U(v)$ are all larger than $x(p_i)$) (see Fig. 7). As we are performing the cascading merge, we update the labels *zod* and *ztd* based on the equations in the following lemma.

LEMMA 6.1. *Let p_i be an element of $U(v)$ and let $u = lchild(v)$ and $w = rchild(v)$. Then we have the following*:

$$zod(p_i, v) = \begin{cases} \max\{zod(p_i, u), zod(\text{pred}(p_i, w), w)\} & \text{if } p_i \in U(u), \\ \max\{zod(\text{pred}(p_i, u), u), zod(p_i, w)\} & \text{if } p_i \in U(w), \end{cases} \tag{9}$$

$$ztd(p_i, v) = \begin{cases} \max\{ztd(p_i, u), zod(\text{pred}(p_i, w), w)\} & \text{if } p_i \in U(u), \\ ztd(p_i, w) & \text{if } p_i \in U(w). \end{cases} \tag{10}$$

Proof. Consider (9). If $p_i \in U(u)$, then every point that one-dominates p_i's predecessor in $U(w)$ also one-dominates p_i, since p_i's predecessor in $U(w)$ is the point with largest x-coordinate less than $x(p_i)$ (or $-\infty$ if every point in $U(w)$ has larger x-coordinate than p_i). Thus $zod(p_i, v)$ is the maximum of $zod(p_i, u)$ and $zod(\text{pred}(p_i, w), w)$ in this case. The case when $p_i \in U(w)$ is similar. Next, consider (10). We know that every point in $U(w)$ has y-coordinate greater than every point in $U(u)$, by our construction of T. Therefore, if $p_i \in U(u)$, then every point in $U(w)$ that one-dominates p_i's predecessor in $U(w)$ must two-dominate p_i. Thus, $ztd(p_i, v)$ is the

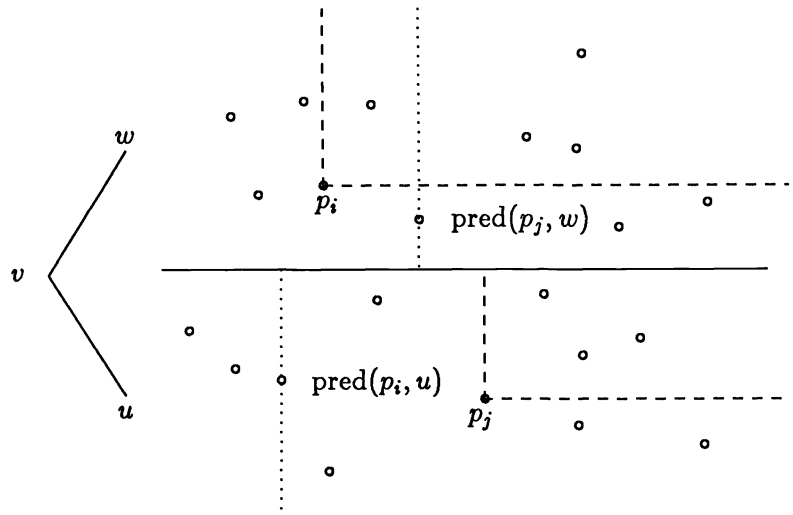

FIG. 7. *The combining step for three-dimensional maxima. Points to the right of the dotted line one-dominate* p_i (*respectively,* p_j), *and points enclosed in the dashed lines two-dominate* p_i(p_j).

maximum of $ztd(p_i, u)$ and $zod(\text{pred}(p_i, w), w)$. On the other hand, if $p_i \in U(w)$ then no point in $U(u)$ can two-dominate p_i; thus, $ztd(p_i, v) = ztd(p_i, w)$. □

We use these equations during the cascading merge to maintain the labels for each point. By Lemma 6.1, when v becomes full (and we have $U(u)$, $U(w)$, and $U(u) \cup U(w)$ available), we can determine the labels for all the points in $U(v)$ in $O(1)$ additional time using $|U(v)|$ processors. Thus, the running time of the cascading merge algorithm, even with these additional label computations, is still $O(\log n)$ using n processors. Moreover, after v's parent becomes full we no longer need $U(v)$, and can deallocate the space it occupies, resulting in an $O(n)$ space algorithm, as outlined in § 2. After we complete the merge, and have computed $U(root(T))$, along with all the labels for the points in $U(root(T))$, note that a point $p_i \in U(root(T))$ is a maximum if and only if $ztd(p_i, root(T)) \leqq z(p_i)$ (there is no point that two-dominates p_i and has z-coordinate greater than $z(p_i)$). Thus, after completing the cascading merge we can construct the set of maxima by compressing all the maximum points into one contiguous list using a simple parallel prefix computation. We summarize in the following theorem.

THEOREM 6.2. *Given a set* V *of* n *points in* $\Re^3$, *we can construct the set* M *of maxima points in* V *in* $O(\log n)$ *time and* $O(n)$ *space using* n *processors in the* CREW PRAM *model, and this is optimal.*

Proof. We have established the correctness and complexity bounds for parallel three-dimensional maxima finding in the discussion above. Kung, Luccio, and Preparata [20] have shown that this problem has an $\Omega(n \log n)$ sequential lower bound (in the comparison model). Thus, we can do no better than $O(\log n)$ time using n processors. □

It is worth noting that we can use roughly the same method as that above as the basis step of a recursive procedure for solving the general k-dimensional maxima problem. The resulting time and space complexities are given in the following theorem. We state the theorem for $k \geqq 3$ (since the two-dimensional maxima problem can easily be solved in $O(\log n)$ time and $O(n)$ space by a sorting step followed by a parallel prefix step).

THEOREM 6.3. *For $k \geqq 3$ the k-dimensional maxima problem can be solved in $O((\log n)^{k-2})$ time using n processors in the* CREW PRAM *model.*

Proof. The method is a straightforward parallelization of the algorithm by Kung, Luccio, and Preparata [20], using a procedure very similar to that described above as the basis for the recursion. We leave the details to the reader. □

Next, we address the two-set dominance counting problem. We also show how the multiple range-counting problem and the rectilinear segment intersection counting problem can be reduced to two-set dominance problems efficiently in parallel.

6.2. The two-set dominance counting problem. In the two-set dominance counting problem we are given a set $A = \{q_1, q_2, \cdots, q_m\}$ and a set $B = \{r_1, r_2, \cdots, r_l\}$ of points in the plane, and wish to know for each point r_i in B the number of points in A that are two-dominated by r_i. For simplicity, we assume that the points have distinct x (respectively, y) coordinates. Our approach to this problem is similar to that of the previous subsection, in that we will be performing a cascading merge procedure while maintaining two labeling functions for each point. In this case the labels maintain for each point p_i(from A or B) how many points of A are one-dominated by p_i and also how many points of A are two-dominated by p_i. As in the previous solution, the first label is used to maintain the second. The details follow.

Let $Y = \{p_1, p_2, \cdots, p_{l+m}\}$ be the union of A and B with the points listed by increasing y-coordinate, i.e., $y(p_i) < y(p_{i+1})$. We can construct Y in $O(\log n)$ time using n processors [13], where $n = l + m$. Our method for solving the two-set dominance counting problem is similar to the method used in the previous subsection. As before, we let T be a complete binary tree with leaf nodes $v_1, v_2, \cdots, v_n$, in this order, and in each leaf node v_i we store the list $U(v_i) = (-\infty, p_i)$ ($-\infty$ still being a special symbol such that $x(-\infty) < x(p_i)$ and $y(-\infty) < y(p_i)$ for all points p_i in Y). We then perform a generalized cascading merge from the leaves of T as in Theorem 2.5, basing comparisons on increasing x-coordinates of the points (not their y-coordinates). We let $U(v)$ denote the sorted array of the points stored in the descendants of $v \in T$ sorted by increasing x-coordinate. For each point p_i in $U(v)$ we store two labels: $nod(p_i, v)$ and $ntd(p_i, v)$. The label $nod(p_i, v)$ is the number of points in $U(v)$ that are in A and are one-dominated by p_i, and the label $ntd(p_i, v)$ is the number of points in $U(v)$ that are in A and are two-dominated by p_i. Initially, the *nod* and *ntd* labels are only defined for the leaf nodes of T. That is, $nod(p_i, v_i) = nod(-\infty, v_i) = ntd(p_i, v_i) = ntd(-\infty, v_i) = 0$. For each $p_i \in Y$ we define the function $\chi_A(p_i)$ as follows: $\chi_A(p_i) = 1$ if $p_i \in A$, and $\chi_A(p_i) = 0$ otherwise. (We also use pred (p_i, v) to denote the predecessor of p in $U(v)$. As we are performing the cascading merge, we update the labels *nod* and *ntd* based on the equations in the following lemma (see Fig. 8).

LEMMA 6.4. *Let p_i be an element of $U(v)$ and let $u = lchild\ (v)$ and $w = rchild\ (v)$. Then we have the following:*

$$(11)\quad nod(p_i, v) = \begin{cases} nod(p_i, u) + nod(\text{pred}(p_i, w), w) + \chi_A(\text{pred}(p_i, w)) & \text{if } p_i \in U(u), \\ nod(\text{pred}(p_i, u), u) + nod(p_i, w) + \chi_A(\text{pred}(p_i, u)) & \text{if } p_i \in U(w), \end{cases}$$

$$(12)\quad ntd(p_i, v) = \begin{cases} ntd(p_i, u) & \text{if } p_i \in U(u), \\ nod(\text{pred}(p_i, u), u) + ntd(p_i, w) + \chi_A(\text{pred}(p_i, u)) & \text{if } p_i \in U(w). \end{cases}$$

Proof. Consider (11). For any point $p_i \in U(u)$ the number of points one-dominated by p_i is equal to the number of points in $U(u)$ that are in A and one-dominated by

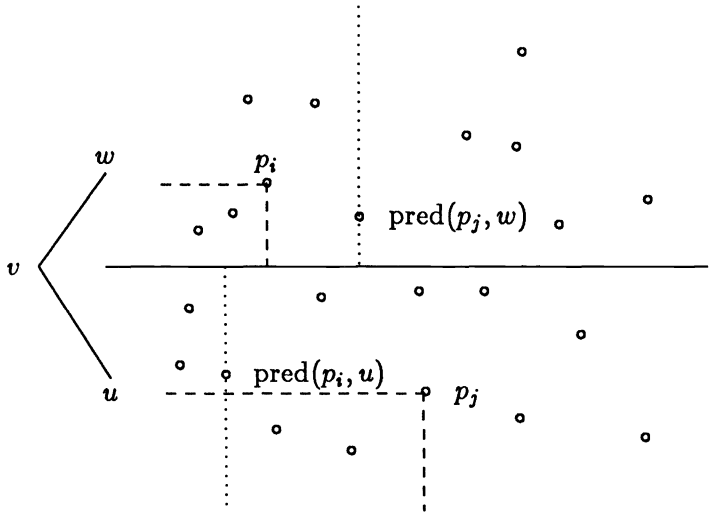

FIG. 8. *The combining step for dominance counting. Points to the left of the dotted line are one-dominated by p_i (respectively, p_j), and points enclosed in dashed lines are two-dominated by p_i (p_j).*

p_i, plus the number of points in $U(w)$ that are in A and one-dominated by pred(p_i, w), plus one if pred(p_i, w) is in A (since the predecessor of p_i is one-dominated by p_i). Thus, we have the equation for the case when $p_i \in U(u)$. The case when $p_i \in U(w)$ is similar. Next, consider (12). By our construction, every point in $U(u)$ has y-coordinate less than the y-coordinate of every point in $U(w)$. So if $p_i \in U(u)$, then the number of points in $U(v)$ that are in A and are two-dominated by p_i is precisely $ntd(p_i, u)$, since p_i cannot two-dominate any points in $U(w)$. If $p_i \in U(w)$, on the other hand, then the number of points in $U(v)$ that are in A and two-dominated by p_i is the number of points in $U(u)$ that are in A and one-dominated by pred(p_i, u), plus the number of points in $U(w)$ that are in A and two-dominated by p_i, plus one if pred(p_i, u) is in A. This is exactly (12) in this case. □

By Lemma 6.4, when v becomes full (and we have $U(u)$, $U(w)$, and $U(v) = U(u) \cup U(w)$ available), we can determine the labels for all the points in $U(v)$ in $O(1)$ additional time using $|U(v)|$ processors. Thus, the running time of the cascading merge algorithm, even with these additional label computations, is still $O(\log n)$ using n processors. After we complete the merge, and have computed $U(\text{root}(T))$, along with all the labels for the points in $U(\text{root}(T))$, then we are done. We summarize in the following theorem.

THEOREM 6.5. *Given a set A of l points in the plane and a set B of m points in the plane, we can compute for each point p in B the number of points in A two-dominated by p in $O(\log n)$ time and $O(n)$ space using n processors in the* CREW PRAM *model, where $n = l + m$, and this is optimal.*

Proof. The correctness and complexity bounds should be apparent from the discussion above. To prove the lower bound note that the two-dimensional maxima problem can be reduced to dominance counting in $O(1)$ time using n processors (see [17]). Since the maxima problem has an $\Omega(n \log n)$ lower bound [20] in the comparison model, we conclude that we can do no better than $O(\log n)$ time using n processors in the CREW PRAM model. □

There are a number of other problems that can be reduced to two-set dominance counting. We mention two here, the first being the multiple range-counting problem:

given a set V of l points in the plane and a set R of m isothetic rectangles (ranges) the multiple range-counting problem is to compute the number of points interior to each rectangle.

COROLLARY 6.6. *Given a set V of l points in the plane and a set R of m isothetic rectangles, we can solve the multiple range-counting problem for V and R in $O(\log n)$ time and $O(n)$ space using n processors, where $n = l + m$.*

Proof. Let $d(p)$ be the number of points in V two-dominated by a point p. Edelsbrunner and Overmars [15] have shown that counting the number of points interior to a rectangle can be reduced to dominance counting. That is, given a rectangle $r = (p_1, p_2, p_3, p_4)$ (where vertices are listed in counterclockwise order starting with the upper right-hand corner), the number of points in V interior to r is $d(p_1) - d(p_2) + d(p_3) - d(p_4)$. Therefore, it suffices to solve the two-set dominance counting problem. □

Another problem that reduces to two-set dominance counting is rectilinear segment intersection counting: given a set S of n rectilinear line segments in the plane, determine for each segment the number of other segments in S that intersect it.

COROLLARY 6.7. *Given a set S of n rectilinear line segments in the plane, we can determine for each segment the number of other segments in S that intersect it in $O(\log n)$ time and $O(n)$ space using n processors in the* CREW PRAM *model.*

Proof. Let U_1 (U_2) be the set of left (right) endpoints of horizontal segments, and let $d_1(p)$ ($d_2(p)$) denote the number of points in U_1 (U_2) two-dominated by p. For any vertical segment s, with upper endpoint p and lower endpoint q, the number of horizontal segments that intersect s is $d_1(p) - d_1(q) + d_2(q) - d_2(p)$. This is because $d_1(p) - d_1(q)$ (respectively, $d_2(p) - d_2(q)$) counts the number of horizontal segments with a left (right) endpoint to the left of s and y-coordinate in the interval $[y(q), y(p)]$. Thus, $d_1(p) - d_1(q) - (d_2(p) - d_2(q))$ counts the number of horizontal segments with left endpoint to the left of s, right endpoint to the right of s, and y-coordinate in the interval $[y(q), y(p)]$ (i.e., the set of horizontal segments that intersect s). □

The final problem we address at is visibility from a point.

6.3. The visibility from a point problem. Given a set of line segments $S = \{s_1, s_2, \cdots, s_n\}$ in the plane that do not intersect, except possibly at endpoints, and a point p, the visibility from a point problem is to determine the part of the plane that is visible from p assuming every s_i is opaque. Intuitively, we can think of the point p as a specular light source, the segments as walls, and the problem to determine all the parts of the plane that are illuminated. We can use the cascading divide-and-conquer technique to solve this problem in $O(\log n)$ time and $O(n)$ space using n processors. Without loss of generality, we assume that the point p is at negative infinity below all the segments. The algorithm is essentially the same if p is a finite point, except that the notion of segment endpoints being ordered by x-coordinate is replaced by the notion that they are ordered radially around p. In other words, it suffices to compute the *lower envelope* of the n segments to give a method for computing the visibility from a point. For simplicity of expression, we also assume that the x-coordinates of the endpoints are distinct.

In the previous two subsections the set of objects consisted of points, but in the visibility problem we are dealing with line segments. The method is slightly different in this case. In this case, we store the segments in the leaves of a binary tree and perform a cascading merge of the x-coordinates of intervals of the x-axis determined by segment endpoints. We maintain a single label for each interval which represents the segment which is visible from $-\infty$ on that interval. The details follow.

Let T be a complete binary tree with leaf nodes $v_1, v_2, \cdots, v_n$ ordered from left to right. We associate the segment s_i with the leaf v_i and at v_i store the list $U(v_i) = (-\infty, p_1, p_2)$, where p_1 and p_2 are the two endpoints of s_i, with $x(p_1) < x(p_2)$, and $-\infty$ is defined such that $x(-\infty) < x(p)$ and $y(-\infty) < y(p)$ for all points p. We then perform a generalized cascading merge from the leaves of T as in Theorm 2.5, basing comparisons on increasing x-coordinates of the points. For each internal node v we let $U(v)$ denote an array of the points stored in the descendants of $v \in T$ sorted by increasing x-coordinates. For each point p_i in $U(v)$ we store a label $vis(p_i, v)$ which stores the segment with endpoints in $U(v)$ that is visible in the interval $(x(p_i), x(succ(p_i, v)))$, where $succ(p_i, v)$ denotes the successor of p_i in $U(v)$ (based on x-coordinates). Initially, the *vis* labels are only defined for the leaf nodes of T. That is, if $U(v) = (-\infty, p_1, p_2)$, where $s_i = p_1 p_2$, then $vis(-\infty) = +\infty$, $vis(p_1) = s_i$, and $vis(p_2) = +\infty$. We use pred (p_i, v) to denote the predecessor of p_i in $U(v)$. As we are performing the cascading merge, we update the *vis* labels based on the equation in the following lemma (see Fig. 9).

LEMMA 6.8. *Let p_i be an element of $U(v)$ and let $u = lchild\ (v)$ and $w = rchild\ (v)$. Then we have the following (if two segments s_i and s_j are comparable by the "above"*

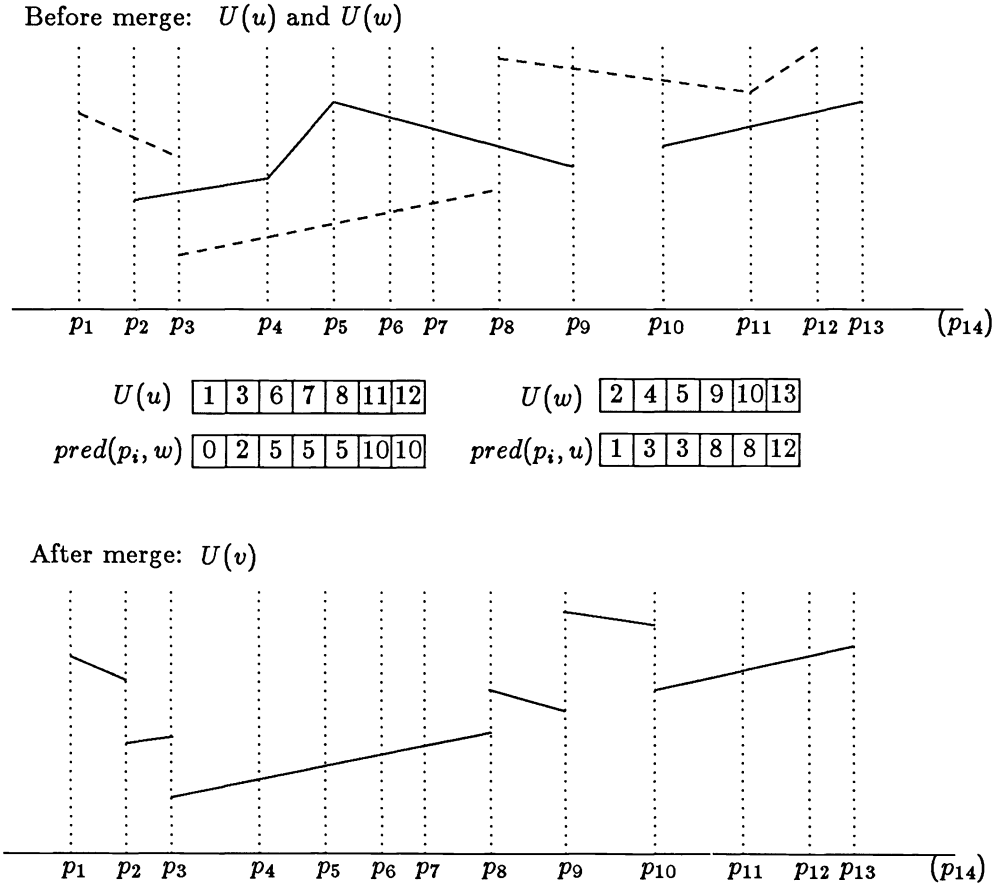

FIG. 9. *An example of visibility merging. The dashed segments correspond to the visible region for $X(u)$ and the solid segments correspond to the visible region for $X(w)$. For simplicity, we store the pointers* pred (p_i, u) *and* pred (p_i, w) *in arrays and denote each point p_i by its index i. Note that points are never removed, even if the same segment defines the visible region for many consecutive intervals (e.g., p_3 through p_7).*

relation, then we let $\min\{s_i, s_j\}$ *denote the lower of the two*):

$$vis(p_i, v) = \begin{cases} \min\{vis(p_i, u), vis(\text{pred}(p_i, w), w)\} & \text{if } p_i \in U(u), \\ \min\{vis(\text{pred}(p_i, u), u), vis(p_i, w)\} & \text{if } p_i \in U(w). \end{cases}$$

Proof. If we restrict our attention to the segments with an endpoint in $U(n)$, then for any point $p_i \in U(u)$ the segment visible (from $-\infty$) on the interval $(x(p_i), x(succ(p_i, v)))$ is the minimum of the segment visible on the interval $(x(p_i), x(succ(p_i, u)))$ and the segment that is visible on the interval $(x(\text{pred}(p_i, w)), x(succ(\text{pred}(p_i, w), w)))$. This is because the interval $(x(p_i), x(succ(p_i, v)))$ is exactly the intersection of the interval $(x(p_i), x(succ(p_i, u)))$ and the interval $(x(\text{pred}(p_i, w)), x(succ(\text{pred}(p_i, w), w)))$, and there is no segment in $U(v)$ with an endpoint interior to the interval $(x(p_i), x(succ(p_i, v)))$. Thus, $vis(p_i, v)$ is equal to minimum of $vis(p_i, u)$ and $vis(\text{pred}(p_i, w), w)$. The case when $p_i \in U(v)$ is similar. □

By Lemma 6.8, after merging the lists $U(u)$ and $U(w)$, we can determine the labels for all the points in $U(v)$ in $O(1)$ additional time using $|U(v)|$ processors. Thus, the running time of this generalized cascading merge algorithm is still $O(\log n)$ using n processors. After we complete the merge and have computed $U(root(T))$, along with all the *vis* labels for the points in $U(root(T))$, then we can compress out duplicate entries in the list $(vis(p_1, root(T)), vis(p_2, root(T)), \cdots, vis(p_{2n}, root(T)))$ using a parallel prefix computation to construct a compact representation of the visible portion of the plane. We summarize in the following theorem.

THEOREM 6.9. *Given a set S of n nonintersecting segments in the plane, we can find the lower envelope of S in* $O(\log n)$ *time and* $O(n)$ *space using n processors in the* CREW PRAM *model, and this is optimal.*

Proof. The correctness and complexity bounds follow from the discussion above. Since we require that the points in the description of the lower envelope be given by increasing x-coordinates, we can reduce sorting to this problem, and thus can do no better than $O(\log n)$ time using n processors. □

7. EREW PRAM implementations. In this section we briefly note that the same techniques as employed by Cole in [13] to implement his merging procedure in the EREW PRAM model (no simultaneous reads) can be applied to our algorithms for generalized merging, fractional cascading, constructing the plane-sweep tree, three-dimensional maxima, two-set dominance counting, and visibility from a point, resulting in EREW PRAM algorithms for these problems. Apparently, we cannot apply his techniques to our algorithms for trapezoidal decomposition and segment intersection detection, however, since our algorithms for these problems explicitly use concurrent reads (in the multilocation steps).

Applying his techniques to our algorithms results in EREW PRAM algorithms with the same asymptotic bounds as the ones presented in this paper, except that the space bounds for the problems addressed in § 6 all become $O(n \log n)$. The reason that his techniques increase the space complexity of these problems is because of our use of labeling functions. Specifically, it is not clear how to perform the merges on-line and still update the labels in $O(1)$ time after a node becomes full. This is because a label whose value changes on level l may have to be broadcasted to many elements in level $l-1$ to update their labels, which would require $\Omega(\log n)$ time in this model if there were $O(n)$ such elements.

We can get around the problem arising from the labeling functions, however. For the three-dimensional maxima problem and the two-set dominance counting problem,

we separate the computation of the $U(v)$ lists and computation of the labeling functions into two separate steps, rather than "dovetailing" the two computations as before. Each of the labeling functions we used for these two problems can be redefined so as to be EREW-computable. Specifically, the label for an element p in $U(v)$, on level l, can be expressed in terms of a label $pref(p, v)$ and a label $up(p, v)$, where $pref(p, v)$ can be computed by performing a parallel prefix computation [21], [22] in $U(v)$ and $up(p, v)$ can be defined in terms of $pref(pred(p, lchild(v)), lchild(v))$, $pref(pred(p, rchild(v)), rchild(v))$, and the up label p had on level $l+1$ (say, in $U(rchild(v))$ if $p \in U(rchild(v))$). In particular, for the three-dimensional maxima problem $pref(p, v) = zod(p, v)$ and $up(p, v) = ztd(p, v)$, and for the two-set dominance counting problem $pref(p, v) = nod(p, v)$ and $up(p, v) = ntd(p, v)$. We can compute all the $pref(p, v)$ labels in $O(\log n)$ time using n processors by assigning $\lceil |U(v)|/\log n \rceil$ processors to each node v [21]. We can then broadcast each $pref(p, v)$ label to the successor of v in $sibling(v)$, which takes $O(\log n)$ time using n processors by assigning $\lceil |U(v)|/\log n \rceil$ processors to each node v. Finally, we can compute all the $up(p, v)$ labels in $O(\log n)$ additional time by assigning a single processor to each point p and tracing the path in the tree from the leaf node that contains p up to the root. This is an EREW operation because computing all the $up(p, v)$ labels only depends upon accessing memory locations associated with the point p.

The EREW solution to the visibility from a point problem requires $O(n \log n)$ space for a different reason, namely, because we can solve it by constructing the plane-sweep tree for the segments (we need not have the $Cover(v)$'s in sorted order, however), computing the lowest segment in each $Cover(v)$, and then performing a top-down parallel *min*-finding computation to find the segment visible on each interval (p_i, p_{i+1}). Since these are all straightforward computations, given the discussion presented earlier in this paper, we leave the details to the reader.

8. Conclusion. In this paper we gave several general techniques for solving problems efficiently using parallel divide-and-conquer. Our techniques are based on nontrivial generalizations of the merge-sorting approach of Cole [13]. It is interesting to note that Cole's algorithm improved the previous results by a constant factor, whereas our algorithms improve the previous results asymptotically.

Two of our techniques involved methods for performing fractional cascading and a generalized version of the merge-sorting problem optimally in parallel. Our method for doing fractional cascading runs in $O(\log n)$ time using $\lceil n/\log n \rceil$ processors, and, if implemented as a sequential algorithm, results in a sequential alternative to the method of Chazelle and Guibas [12] for fractional cascading.

We also showed how to apply the generalized merging procedure and fractional cascading to efficiently solve several problems by "cascading" the divide-and-conquer paradigm. For three of the problems—trapezoidal decomposition, planar point location, and segment intersection detection—the method involved merging in the line segment partial order, and required considerable care to avoid situations in which the algorithm would halt because it attempted to compare two incomparable segments. All three of these algorithms ran in $O(\log n)$ time using n processors, which is optimal for all but the point location problem. In addition, since our algorithm for doing planar point location results in a query time of $O(\log n)$, our result immediately implies an $O(\log^2 n)$ time, n processor solution to the problem of constructing the Voronoi diagram of n planar points, using the algorithm of Aggarwal et al. [1].

We showed how to apply the cascading divide-and-conquer technique to problems that can be solved by merging with labeling functions. We used this approach to solve

the three-dimensional maxima problem, the two-set dominance counting problem, the rectilinear segment intersection counting problem, and the visibility from a point problem. Our algorithms for these problems all ran in $O(\log n)$ time using n processors, which is optimal.

A NEW PEBBLE GAME THAT CHARACTERIZES PARALLEL COMPLEXITY CLASSES*

H. VENKATESWARAN† AND MARTIN TOMPA‡

Abstract. A new two-person pebble game that models parallel computations is defined. This game extends the two-person pebble game defined by Dymond and Tompa [*J. Comput. System Sci.*, 30 (1985), pp. 149-161] and is used to characterize two natural parallel complexity classes, namely LOGCFL and AC^1. The characterizations show a fundamental way in which the computations in these two classes differ. This game model also unifies the proofs of some well-known results of complexity theory.

Key words. pebbling, alternation, parallel complexity, LOGCFL, AC^k

1. Introduction. Games have provided a useful framework for studying computational models. The game abstraction helps us to focus on the fundamental aspects of computation in the models of interest by stripping away some of the inessential details. The view of computations by an alternating Turing machine as a two-person game is one of the most noted examples of such use. The one-person pebble game (see the survey by Pippenger [Pi80]) that models deterministic and nondeterministic evaluation of straight-line programs is another game that has found wide applications in computer science.

This paper defines and studies a new two-person pebble game that models certain synchronous parallel computations. This game extends the two-person pebble game defined by Dymond and Tompa [DT85] in two ways: (a) the game is played on a Boolean circuit taking into consideration the types of the gates, rather than on an uninterpreted graph, and (b) the two players' roles are made completely symmetric.

Although the original game defined by Dymond and Tompa [DT85] modeled some essential features of alternating Turing machine computations, the extension proposed here more accurately models general alternating computations. As an indication of this improved accuracy, the new game is used to characterize two natural parallel complexity classes. Previous versions of pebble games apparently could not be used to characterize standard complexity classes, since they were played on uninterpreted graphs. The classes characterized in this paper are LOGCFL and AC^1. LOGCFL is the class of languages log space reducible to context-free languages. AC^1 is the class of languages accepted by (1) a concurrent-read, concurrent-write parallel random access machine (CRCW PRAM) in polynomial hardware and $O(\log n)$ time or, equivalently, (2) an alternating Turing machine in space $O(\log n)$ and alternation depth $O(\log n)$ or, equivalently, (3) a uniform family of unbounded fan-in circuits of polynomial size and $O(\log n)$ depth [SV84].

As another application, this game is shown to unify in a single framework the proofs of the following three well-known results of complexity theory: (1) Savitch's

theorem that nondeterministic space S is contained in deterministic space S^2 [Sa70]; (2) Ruzzo's NC algorithm for context-free language recognition [Ru80]; and (3) Borodin and Ruzzo's simulation of simultaneous space and alternation bounded alternating Turing machines by simultaneous space and time bounded alternating Turing machines [CKS81], [Ru81]. More generally, the new game provides a simple understanding of the combinatorial structure of parallel computations. This makes it a useful device for discovering new parallel algorithms.

In order to motivate the new pebble game, it is helpful to question why it has certain characteristics:

(1) *Why does the game use two players, rather than one as in the standard pebble game*? The two competing players model, respectively, the existential and universal moves of an alternating Turing machine, just as the single player in the "black" or "black and white" pebble games [Pi80] models the moves of a sequential machine. The close relationship between alternating Turing machines and other models of parallel computation such as Boolean circuits and PRAMs [Ru81], [SV84] makes the two-person game a good model of parallel computation.

(2) *Why should the gate type* (AND, OR) *enter into the rules of the game*? It is often the case that a circuit has a more efficient pebbling when the interpretation of gates is exploited than it does in the uninterpreted game defined by Dymond and Tompa [DT85]. This translates into more efficient parallel algorithms. The Cocke-Kasami-Younger algorithm for context-free language recognition [HU69] is an example of a circuit for a natural problem for which such a speedup can be demonstrated [Ve86].

(3) *Why are the roles of the two players made symmetric*? Without this symmetry, the game captures those alternating computations of the form "existentially guess and universally verify" [Sa70], [Ru80]. By giving the universal player a more active role than merely verifying the guesses of the existential player, the game captures the symmetry between existential and universal moves found in more general alternating computations. In fact, it will be seen that the new computations thus captured are exactly those in $AC^1 - LOGCFL$.

As noted earlier, the game defined in this paper provides a setting for examining the relationship between the two parallel complexity classes LOGCFL and AC^1. It is known that $LOGCFL \subseteq AC^1$ [Ru80]. Showing that the inclusion is proper is likely to be difficult, as it would imply that $\mathcal{P}$ is not equal to $DSPACE(\log n)$, settling this celebrated open problem in complexity theory. This is because of the following relationship among these complexity classes [Co85]:

$$DSPACE(\log n) \subseteq LOGCFL \subseteq AC^1 \subseteq NC^2 \subseteq NC \subseteq \mathcal{P}.$$

For many problems in LOGCFL the algorithms that show their membership in that class also show their membership in AC^1. However, these algorithms do not use the full power of AC^1 computations. The two-person game defined in this paper provides a model of computation in which this perceived difference can be quantified. This is done by characterizing the two classes using the same measures of resources in the game model. The results so obtained not only illustrate the striking similarity between these two classes, but also isolate the fundamental way in which they differ: the recognition of languages in LOGCFL does not utilize the symmetry between the two players, whereas the recognition of languages in AC^1 does. Thus, the results indicate why these two classes may not be equal.

Both LOGCFL and AC^1 have been characterized using different models of computation [Co85]. These characterizations fall into three categories: models on which characterizations of both LOGCFL and AC^1 are known, models on which only

characterizations of LOGCFL are known, and models on which only characterizations of AC^1 are known. Among the characterizations of the first category, the only result that characterized both of them using the same type of resources on a model of computation is that of Immerman [Im82]. This result used the size and number of variables needed to express properties in first-order logic as resources in the model, and showed that LOGCFL is the class of properties expressible in $O(1)$ variables and $O(\log n)$ size when the universal quantifiers are restricted to being Boolean, and that AC^1 is the class of properties expressible using $O(1)$ variables and $O(\log n)$ size when the universal quantifiers are unrestricted. Considering the arity of universal quantification as a resource, this showed how the languages in the two classes differed in a fundamental way. The characterizations in this paper are in the same spirit and show another fundamental way in which these classes differ.

As a final note, the new game suggests a new complexity measure, called "role switches," for Boolean circuits and alternating machines. This measure captures a higher-level notion of alternation than the standard measure of alternations between existential and universal moves. The characterizations of LOGCFL and AC^1 demonstrate that these two classes differ in how much of the role-switch resource is used: languages in LOGCFL use no role switches and those in AC^1 use $O(\log n)$ role switches. This resource thus can be used to define a natural hierarchy of parallel complexity classes between LOGCFL and AC^1.

Section 2 contains some basic definitions. In § 3, the original two-person pebble game defined by Dymond and Tompa [DT85] is presented. In § 4, the new game is defined. In § 5, the classes LOGCFL and AC^1 are characterized using this game. In § 6, the game is used to unify the three results mentioned in a previous paragraph. Section 7 contains some concluding remarks and open problems.

2. Preliminaries. A *Boolean circuit* G_n with n inputs is a finite acyclic directed graph with vertices having indegree zero or two and labeled as follows. Vertices of indegree zero are labeled from the set $\{0, 1, x_1, x_2, \cdots, x_n, \bar{x}_1, \bar{x}_2, \cdots, \bar{x}_n\}$. All vertices with indegree two (also called *gates*) are labeled either AND or OR. Vertices with outdegree zero are called *outputs*. The evaluation of G_n on inputs of length n is defined in the standard way. Typically, only circuits with one output vertex will be considered. This makes it convenient to consider circuits as language acceptors.

A *family* of circuits is a sequence $\{G_n | n = 0, 1, 2, \cdots\}$, where the nth circuit G_n has n inputs.

The *size* $C(G_n)$ of a circuit G_n is the number of gates in G_n. The *depth* of a vertex v in a circuit is the length of a longest path from any input to v. The depth of a circuit is the depth of its output vertex.

Not including negation gates in the definition of a Boolean circuit is done with no loss of generality as there is a well-known technique to simulate, with a doubling of size and no increase in depth, a Boolean circuit with negations by a Boolean circuit in which the negations appear only at the inputs. (See, for example, [Go77].)

A family $\{G_n\}$ of circuits is said to be *uniform* if, on input 1^n, a reasonable encoding of G_n can be generated by a deterministic Turing machine using space $O(\log C(G_n))$. This uniformity condition is sometimes referred to as log-space uniformity in the literature. This uniformity condition suffices for the purposes of this paper. See the paper by Ruzzo [Ru81] for a more detailed treatment of uniformity conditions for circuits.

For the rest of the paper, $\{G_n\}$ will denote a *uniform* family of *polynomial-size* Boolean circuits, where G_n has n inputs and one output. L will denote the language accepted by this family.

In a directed acyclic graph or Boolean circuit, u is an *immediate predecessor* of v if and only if (u, v) is a directed edge, and u is a *predecessor* of v if and only if there is a directed path from u to v. The predecessor relation is an irreflexive and transitive relation.

The notion of an accepting subtree can be defined for Boolean circuits by analogy to the notion of accepting subtrees for alternating Turing machines [Ru80]. Consider the tree-equivalent $T(G_n)$ of the circuit G_n. (The tree-equivalent of a graph is obtained by replicating vertices whose outdegree is greater than one until the resulting graph is a tree.) Let $x \in L$ be of length n. An *accepting subtree* H of a circuit G_n on input x is a subtree of $T(G_n)$:

- That includes the output vertex;
- That includes both the immediate predecessors of any AND vertex included in H;
- That includes exactly one immediate predecessor of any OR vertex included in H; and
- In which any included vertex of indegree zero has value 1 as determined by the input x.

The following fact is easy to verify.

FACT. G_n evaluates to 1 on input x if and only if there exists an accepting subtree of G_n on input x.

3. The uninterpreted game. The two-person pebble game defined by Dymond and Tompa [DT85] is played on the vertices of a directed acyclic graph by two players called the *Challenger* and the *Pebbler*.

Rules. The Challenger begins the game by challenging any vertex v. The game now proceeds in rounds with each round consisting of a *pebbling* move followed by a *challenging* move. In a pebbling move, the Pebbler picks up zero or more pebbles from vertices already pebbled and places pebbles on any nonempty set of vertices. In a challenging move, the Challenger either rechallenges the currently challenged vertex v, or challenges one of the vertices that acquired a pebble in the current round.

The Challenger loses the game at a vertex v if, immediately following the Challenger's move, v is the current challenged vertex and all immediate predecessors of v have pebbles on them.

This two-person game will be referred to as the *uninterpreted game* in the rest of the paper.

If G is thought of as a circuit computing some function, then a play of this two-person game corresponds to an alternating implementation of that circuit, in the following sense. A pebble placed on a vertex v by the Pebbler corresponds to existentially guessing the value computed at v. A move of the Challenger corresponds to universally verifying each of those guesses, plus the fact that those guesses lead to the correct value computed at the current challenged vertex.

Resources. There are three resources of interest in a play of this game: *space*, *time*, and *rounds*. The space used is the maximum number of pebbles on the graph at any point in the game, the time is the number of pebble placements, and the rounds is the number of rounds in the play.

The game on a graph with n inputs is said to take space $p(n)$ (time $t(n)$, rounds $r(n)$), if and only if there is a winning strategy for the Pebbler such that, for all plays by the Challenger, the Pebbler uses at most space $p(n)$ (time $t(n)$, rounds $r(n)$, respectively).

Illustrations of the game on a simple path with N vertices and a tree with N

vertices are presented below. These two results will be useful later.

LEMMA 1. *The uninterpreted game on a path of N vertices can be played with two pebbles and $O(\log N)$ time.*

Proof. A simple divide-and-conquer strategy is used to prove this lemma. □

The game on a binary tree uses the following tree-cutting lemma. This tree-cutting lemma is a classical result that was first used by Lewis, Stearns, and Hartmanis [LSH65] to show that context-free languages are in DSPACE($\log^2 n$).

LEMMA 2. *Let T be a tree with N vertices, each of which has at most two children. Then there is a vertex s of T such that the subtree rooted at s has p vertices, where $N/3 \leqq p < 2N/3+1$.*

(See the paper by Lewis, Stearns, and Hartmanis [LSH65] or the book by Hopcroft and Ullman [HU69] for a proof.)

Ruzzo [Ru80] discovered an efficient parallel algorithm for context-free language recognition, based on Lemma 2. The essence of his algorithm is captured in the following lemma.

LEMMA 3. *Let T be a tree with N vertices, each of which has at most two children. Then the uninterpreted game on T can be played using $O(1)$ pebbles and $O(\log N)$ time.*

Proof. Let r be the root of T with the initial challenge. Let s be an internal vertex of T as in Lemma 2. Let T_2 be the subtree rooted at s and T_1 be the subtree rooted at r with all vertices except s of T_2 deleted from it. Suppose the Pebbler pebbles s. If the Challenge is moved to s, the game is confined to T_2. If the Challenge is retained at r, the game is confined to T_1. In either case, the size is decreased by a constant factor. Therefore, in $O(\log N)$ steps the game will be over.

The problem with this strategy is that the number of pebbled vertices is $\Omega(\log N)$, as no pebbles are picked up. To keep the number of pebbled vertices constant, a two-phase strategy is adopted. Let r_1, the current challenged vertex, be the root of a subtree T_1 with three pebbled leaves. Given three distinguished leaves of a binary tree, there is an internal vertex v that is an ancestor of exactly two of them. The Pebbler pebbles v. This divides the tree T_1 into two subtrees T_{12}, the subtree with v as the root, and T_{11}, the subtree rooted at r_1 with all vertices except v of T_{12} deleted from T_1. Whether the Challenge is moved or retained, the subtrees involved have only two pebbled leaves, so two pebbles can be picked up. It is possible that v may not induce a balanced split of T_1. This is taken care of in the next round, when the Pebbler chooses a vertex that causes a balanced split as guaranteed by Lemma 2. Therefore, the size of the subtree to which the game is confined decreases by a constant factor every two rounds.

This strategy uses four pebbles and $O(\log N)$ time. It is possible to reduce the number of pebbles used to two with $O(\log N)$ time by a slightly more involved pebbling strategy. The details are left to the interested reader. □

3.1. Motivation for extensions. This section examines the two-person pebble game played on the graph underlying a Boolean circuit. A play of this game on a circuit can be viewed as a parallel evaluation of the circuit on some input. The Pebbler in the game is like a prover asserting values for the gates on which it places pebbles and the Challenger is like a verifier who verifies these assertions in parallel. Given an input x in the language accepted by a circuit G_n, the time to play the game on G_n corresponds to the time to discover a "proof" that the circuit evaluates to 1 on input x. This suggests a correspondence between the resources of the game and the resources of circuits that accept the language. In fact, the following result by Dymond and Tompa [DT85] formalizes such a relationship.

THEOREM. *Let G be a Boolean circuit that accepts a finite language L. If the uninterpreted game can be played on G in time t, then L is accepted by a Boolean circuit H of depth $O(t)$.*

This motivates the discovery of efficient pebbling strategies on Boolean circuits. One way of achieving efficiency is to exploit some of the properties of Boolean circuits. Two such properties are discussed below.

Consider the n input Boolean circuit G_n that is a complete binary tree. The uninterpreted game on the graph underlying this circuit can be played in $\log n$ time and two pebbles, by always pebbling the immediate predecessors of the challenged vertex. It can be shown that $\Omega(\log n)$ time is required to play the uninterpreted game on G_n using any number of pebbles. Suppose now that all gates of G_n are OR gates. Then a "proof" that the circuit evaluates to 1 on some input x is a path of $\log n$ vertices from some input with value 1 to the output. By Lemma 1, the game can be played on this path in $\log \log n$ time and two pebbles. There are circuits of other natural problems, such as Boolean matrix multiplication and context-free language recognition, for which similar speedups are made possible by exploiting the types of the gates in the circuit.

Consider the following natural circuit G_n for computing the inner product of two Boolean vectors of length m each. G_n consists of one output and $n = 2m$ inputs. The output is the root of a balanced binary tree of OR gates whose m leaves are AND gates with two inputs each. The argument given above for playing the game on a tree of OR gates applies to this circuit also. That is, without taking into consideration the gate types, any pebbling of this circuit with only a constant number of pebbles takes $\Omega(\log n)$ time. If the gate types are taken into account a suitably modified game can be played with two pebbles and $O(\log \log n)$ time.

For context-free language recognition, consider the Cocke-Kasami-Younger algorithm. It can be shown that the game takes $\Omega(n)$ time on this circuit if the gate types are not taken into account, but can be played on this circuit with two pebbles and $O(\log n)$ time if they are [Ve86].

This motivates extending the uninterpreted game to take into consideration the types of the gates of the circuit on which the game is played.

Suppose now that all the gates of the binary tree circuit G_n are AND gates. In this case, a proof that the circuit evaluates to 0 on some input x is a path of $\log n$ vertices from some input with value 0 to the output. By Lemma 1, the game can be played on this path in $\log \log n$ time with two pebbles. A proof that G_n evaluates to 1 will be simply the failure to demonstrate such a path in $\log \log n$ time with two pebbles. In other words, a proof that a circuit G_n evaluates to 1 on x can consist of showing that it does not evaluate to 0 on x. Intuitively, we would like to take advantage if the complement of the problem is easier. In general, when the circuit consists of both OR and AND gates, sometimes it will be more efficient to demonstrate that a given gate evaluates to 1, and sometimes 0.

This motivates the second extension of the uninterpreted game to incorporate duality between the two players.

4. The dual game. The new game obtained by extending the uninterpreted game will be referred to as the *dual interpreted two-person pebble game* (or *dual game*, for short). This game is played by two players called *Player* 0 and *Player* 1 on the vertices of a Boolean circuit G_n together with its input x. The objective of Player 0 (Player 1) is to establish that the output of the circuit evaluates to 0 (1). Thus, a pebble placement or challenge on a gate v by Player 0 (Player 1) corresponds to asserting that v evaluates

to 0 (1). At any point, one of the players takes on the role of the Challenger and the other that of the Pebbler. The role of a player is automatically determined as part of the circuit information as follows. The gates in G_n are partitioned into two sets, those of "challenge type" 0 and those of "challenge type" 1. A challenge placed on a gate of challenge type 0 (challenge type 1) causes Player 0 (Player 1) to be the Challenger in the next round. For the remainder of this paper, all circuits will be assumed to contain this additional bit per vertex. A Boolean circuit augmented with this role information for each of its gates will be referred to as an *augmented* circuit. For augmented uniform circuits, it will be assumed that this role information is available from the log space uniformity machine.

A challenge by Player 0 (Player 1) will be referred to as a 0-challenge (1-challenge). Similarly, a pebble placed by Player 0 (Player 1) will be referred to as a 0-pebble (1-pebble).

Rules. The initial challenge is on the output gate. The game proceeds in rounds with a round consisting of the following three parts: (a) If the game is not over at the currently challenged vertex u according to the conditions below, then Player 0 is the Challenger for this round if u is of challenge type 0 and the Pebbler otherwise. (b) In the *pebbling move*, the Pebbler picks up zero or more of its own pebbles from vertices already pebbled and places pebbles on any nonempty set of vertices. (c) In the *challenging move*, the Challenger either rechallenges the currently challenged vertex, or challenges one of the vertices that acquired a pebble in the current round.

Winning/losing conditions. Player 1 wins the game if, immediately following the Challenger's move, the current challenged vertex is an input with value 1, or an OR gate at least one of whose immediate predecessors is 1-pebbled, or an AND gate both of whose immediate predecessors are 1-pebbled. Player 0 wins if, immediately following the Challenger's move, the current challenged vertex is an input with value 0, or an OR gate both of whose immediate predecessors are 0-pebbled, or an AND gate at least one of whose immediate predecessors is 0-pebbled. It is also possible to have a winner in an infinite play of the game, namely that player (if either) who is the Pebbler in only finitely many rounds. (The purpose of this last rule is to force the eventual loser to make progress as the Pebbler.)

Resources. There are four resources of interest in a play of this game: *space*, *time*, *rounds*, and *role switches*.

The game on an augmented circuit G_n with input $x \in L$ of length n is said to use space $p(n)$ (time $t(n)$, rounds $r(n)$, role switches $s(n)$, respectively) if and only if there is a strategy for Player 1 such that, for all plays by Player 0, Player 1 wins using at most $p(n)$ 1-pebbles ($t(n)$ 1-pebble placements, $r(n)$ rounds in which Player 1 is the Pebbler, $s(n)$ role switches between pebbling and challenging roles, respectively). Resources when $x \notin L$ are defined by interchanging Player 0 and Player 1. The augmented circuit G_n is said to be *pebbleable* in space $p(n)$ (time $t(n)$, rounds $r(n)$, role switches $s(n)$, respectively) if and only if, for all x of length n, the game on G_n with input x uses at most space $p(n)$ (time $t(n)$, rounds $r(n)$, role switches $s(n)$, respectively). Note that the loser's space, time, and rounds are not even counted.

These notions should all be defined more precisely. This is done by considering the game tree associated with the game. The reader willing to proceed on an intuitive level may skip the remainder of this section.

The game tree is defined in terms of configurations and moves of the game. Fix an augmented circuit G_n and its input x.

A *configuration* of the game is a tuple $(t, P_1, P_0, R_1, R_0, v)$ where:

$t \in \{P, C\}$ indicates whether it is the Pebbler's or the Challenger's turn to move;

P_1 is the set of vertices with 1-pebbles on them from previous rounds;
P_0 is the set of vertices with 0-pebbles on them from previous rounds;
R_1 is the set of vertices 1-pebbled in the current round;
R_0 is the set of vertices 0-pebbled in the current round; and
v is the current challenged vertex.

The initial configuration of the game is $(P, \varnothing, \varnothing, \varnothing, \varnothing, s)$, where s is the output of the circuit.

A configuration $(P, P_1, P_0, \varnothing, \varnothing, v)$ is *terminal* if v is an input, or an OR (AND) gate with some (both) of its immediate predecessors in P_1 or both (some) of its immediate predecessors in P_0.

A *move* in the game is made in accordance with a binary relation $\vdash$ on configurations defined as follows (where P_0, P_1, S_0, and S_1 are arbitrary sets of vertices, and R_0 and R_1 are arbitrary nonempty sets of vertices):

$(P, P_1, P_0, \varnothing, \varnothing, v) \vdash (C, P_1 - S_1, P_0, R_1, \varnothing, v)$, for all configurations $(P, P_1, P_0, \varnothing, \varnothing, v)$ that are not terminal and where v is of challenge type 0;

$(P, P_1, P_0, \varnothing, \varnothing, v) \vdash (C, P_1, P_0 - S_0, \varnothing, R_0, v)$, for all configurations $(P, P_1, P_0, \varnothing, \varnothing, v)$ that are not terminal and where v is of challenge type 1;

$(C, P_1, P_0, R_1, \varnothing, v) \vdash (P, P_1 \cup R_1, P_0, \varnothing, \varnothing, u_1)$, for all $u_1 \in R_1 \cup \{v\}$;

$(C, P_1, P_0, \varnothing, R_0, v) \vdash (P, P_1, P_0 \cup R_0, \varnothing, \varnothing, u_0)$, for all $u_0 \in R_0 \cup \{v\}$.

The *game tree* T is a maximal rooted tree whose nodes are labeled by configurations of the game, and whose root is labeled by the initial configuration, and whose edge relation is given by $\vdash$. Note that the leaves of the tree are labeled by terminal configurations.

A *finite play* of the game is a finite path in the game tree from the root to some leaf labeled by the configuration $(P, P_1, P_0, \varnothing, \varnothing, v)$. It is a *winning finite play for Player* 1 if v is an input with value 1, or if v is an OR gate at least one of whose immediate predecessors is in P_1, or if v is an AND gate both of whose immediate predecessors are in P_1; otherwise it is a *winning finite play for Player* 0. An infinite path Π in the game tree is a *winning infinite play* for the player (if either) that is the Pebbler in only finitely many configurations on Π.

A *winning strategy for Player* 1 (if it exists) is a subtree W of T such that:

(1) W contains the root of T;

(2) W contains exactly one child of every nonterminal node in W that is labeled by a configuration in which it is Player 1's turn to move;

(3) W contains all children of every nonterminal node in W that is labeled by a configuration in which it is Player 0's turn to move; and

(4) All paths in W are winning (finite or infinite) plays for Player 1.

A *winning strategy for Player* 0 is defined dually.

It is not hard to show that, for all augmented circuits G_n, and for all inputs x, exactly one of Player 0 and Player 1 has a winning strategy. In particular, Player 1 has a winning strategy if and only if G_n evaluates to 1 on input x.

Let $\{G_n\}$ accept the language L, where each member G_n of the family is an augmented circuit. The game on G_n with input $x \in L$ can be *played in space* $p(n)$ if and only if there is a winning strategy for Player 1 in which every pebbling configuration $(P, P_1, P_0, \varnothing, \varnothing, v)$ along every path satisfies $|P_1| \leqq p(n)$. It can be *played in time* $t(n)$ if and only if there is a winning strategy for Player 1 for which every path Π satisfies $\sum |R_1^i| \leqq t(n)$, where the sum is over all challenging configurations $(C, P_1^i, P_0^i, R_1^i, R_0^i, v^i)$ on Π. It can be *played in* $r(n)$ *rounds* if and only if there is a winning strategy for Player 1 for which every path has at most $r(n)$ pebbling configurations $(P, P_1, P_0, \varnothing, \varnothing, v)$ with v of challenge type 0. It can be *played in* $s(n)$ *role*

switches if and only if there is a winning strategy for Player 1 in which, on any path, there are at most $s(n)$ edges $(C, P_1, P_0, R_1, R_0, v) \vdash (P, P_1', P_0', \varnothing, \varnothing, u)$ having the challenge types of v and u unequal.

Resources on inputs $x \notin L$ are defined dually, considering winning strategies for Player 0 in place of those for Player 1.

Finally, G_n is *pebbleable* in space $p(n)$ (time $t(n)$, rounds $r(n)$, role switches $s(n)$, respectively) if and only if, for all x of length n, the game on G_n can be played in space $p(n)$ (time $t(n)$, rounds $r(n)$, role switches $s(n)$, respectively). Note again that only the resources used by the winning player are counted.

It is important to note the similarity between the definition of a winning strategy and the definition of an accepting subtree of an alternating Turing machine. This relationship between the two structures is critical in the correctness proof of Theorem 11.

4.1. Example. An example is presented here to illustrate how role switches can help in reducing the time to play the game on some Boolean circuits.

Consider a two-layered binary tree circuit G_n defined as follows. The top layer F_m is a complete binary tree of OR gates with m leaves $y_1, y_2, \cdots, y_m$. Each of these m leaves is the root of a complete binary tree of AND gates with m leaves. (See Fig. 1.) Thus, G_n has $n = m^2$ inputs.

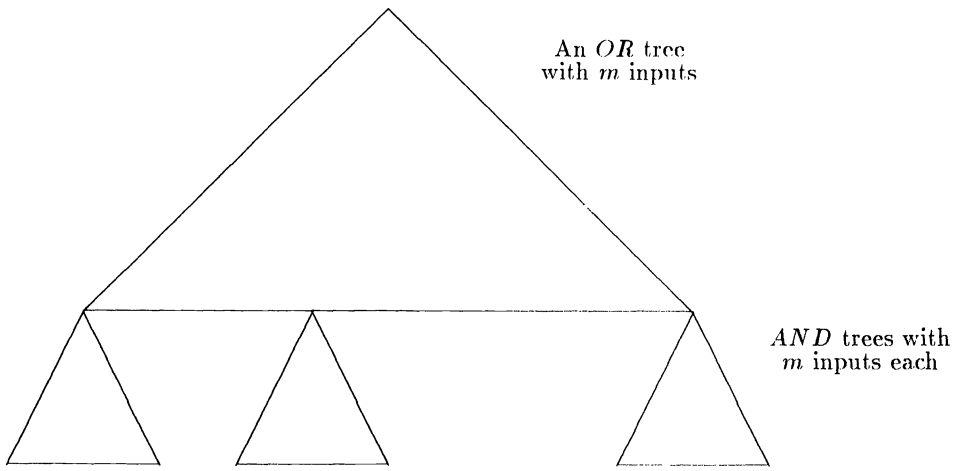

FIG. 1. *Two-layered binary tree circuit.*

Suppose all gates of G_n are designated as of the same challenge type, say, challenge type 0. Then, given an input x the game on G_n will take $\Omega(\log m)$ time no matter how many pebbles are available. Consider now allowing one role switch by designating all OR gates as gates of challenge type 0 and all AND gates as gates of challenge type 1. Then G_n is pebbleable in $O(\log \log m)$ time and two pebbles as follows.

Let x be an input on which G_n evaluates to 1. Thus, the goal is a winning strategy for Player 1 that does not exceed the stated bounds. Let $G_{n,x}$ be an accepting subtree of G_n. The output of G_n is of challenge type 0 and therefore Player 1 begins the game as the Pebbler. The subtree $G_{n,x}$ starts off as a path of OR gates. Let u be the first AND gate on this path. Player 1 pebbles u. If Player 0 retains its challenge on the output, then Player 1 can win the game on the path using two pebbles, $\log \log m$ time, and no role switches, as in Lemma 1. Suppose Player 0 moves its challenge to u. Then a role switch occurs, so that Player 0 is the pebbler for the next round. If Player 0

never pebbles a gate in the subtree of $G_{n,x}$ rooted at u, Player 1 retains its challenge on u and wins using no additional resources. Suppose Player 0 pebbles a gate in this subtree. Consider the first such move. Let w be such a gate of minimum depth among the gates that are pebbled. Player 1 moves its challenge to w. The depth of the challenged gate decreases without Player 1 using any additional resources. Therefore, in a finite number of rounds Player 1 wins without expending any additional resources.

Suppose now that x is an input on which G_n evaluates to 0, and a winning strategy for Player 0 must be described. If Player 1 never pebbles a predecessor of the challenged gate that evaluates to 0, Player 0 retains its challenge and wins using no resources. Whenever Player 1 pebbles one or more predecessors of the challenged gate that evaluate to 0, Player 0 moves its challenge to one such gate of minimum depth. In this manner, the challenge eventually reaches an AND gate v that evaluates to 0, without expending any of Player 0's resources. At this point Player 0 becomes the Pebbler, and can win the game using two pebbles and log log m time by pebbling the path from some input with value 0 to v.

This pebbling strategy forms the basis of the proof of Theorem 10.

5. Characterizations of LOGCFL and AC^k. This section contains the main results of the paper, namely the characterizations of the classes LOGCFL and AC^1.

Let PEBBLE, TIME, SWITCHES($p(n)$, $t(n)$, $s(n)$) be the class of languages L accepted by a uniform family $\{G_n\}$ of polynomial-size augmented circuits such that Player 1 begins the game as the Pebbler, and such that G_n is pebbleable in $p(n)$ pebbles, $t(n)$ time, and $s(n)$ role switches.

In §§ 5.1–5.3, the following characterizations are demonstrated.

THEOREM 4. LOGCFL = PEBBLE, TIME, SWITCHES($O(1)$, $O(\log n)$, 0).

Proof. This follows from Theorem 8 and Corollary 12 below. □

AC^k is defined as the class of languages recognized by alternating Turing machines using space $O(\log n)$ and alternation depth $O(\log^k n)$ [Co85].

THEOREM 5. *For any* $k \geq 1$,

$$AC^k = \text{PEBBLE, TIME, SWITCHES}(O(1), O(\log^k n), O(\log^k n)).$$

Proof. This follows from Theorems 10 and 11 below. □

In Theorem 5 note that, given the time bound, the number of role switches is as great as possible. Such a class will be denoted simply as PEBBLE, TIME($p(n)$, $t(n)$).

As a consequence of Theorem 5, the class NC can also be characterized in terms of the pebble game. This is because $NC = \bigcup_{k \geq 0} AC^k$ [Co85].

THEOREM 6. $NC = \text{PEBBLE, TIME}(O(1), (\log n)^{O(1)})$.

It is interesting to note that the class $\mathcal{P}$ also can be defined in this model by bounding only the space used, i.e., $\mathcal{P} = \text{PEBBLE}(O(1))$, where PEBBLE($p(n)$) denotes the class of languages L accepted by a uniform family $\{G_n\}$ of polynomial-size augmented circuits such that G_n is pebbleable in space $p(n)$. The characterization so obtained in § 5.4 is similar to the one by Immerman [Im82], where it is shown that $\mathcal{P}$ is the class of properties expressible in first-order logic using $O(1)$ variables and polynomial size.

5.1. Game on a LOGCFL circuit. The notion of tree-size for Boolean circuits defined below is analogous to the notion of tree-size for alternating Turing machines [Ru80], and is useful in obtaining a circuit characterization of LOGCFL.

DEFINITION. Let x be a length n input on which G_n evaluates to 1. G_n is said to use tree-size $Z(n)$ on input x if and only if there is an accepting subtree of G_n of size at most $Z(n)$. If for every $x \in L$, G_n uses tree-size $Z(n)$ on input x, then G_n is said to have *tree-size* $Z(n)$.

The following lemma is the circuit analogue of the alternating Turing machine characterization of LOGCFL [Ru80].

LEMMA 7. *If $L \in$ LOGCFL, then there exists a uniform family of polynomial-size Boolean circuits $\{G_n\}$ accepting L such that $\{G_n\}$ has polynomial tree-size.*

Proof. Let $L \in$ LOGCFL. Then, by the characterization of LOGCFL by Ruzzo [Ru80], there is an alternating Turing machine M that accepts L within space $O(\log n)$ and $n^{O(1)}$ tree-size. Such an alternating Turing machine can be simulated by a uniform family of Boolean circuits with polynomial size and polynomial tree-size by using the method of Ruzzo [Ru81]. (Actually, this simulation requires that the simulated alternating Turing machine be in a normal form such that only one input symbol is read along any path of the machine's computation tree. This is accomplished as follows. If a read is encountered in the middle of a path, M existentially guesses the value to be read and universally does two things: verifies that the read value is correct and, in parallel, continues with the successor of the original read configuration as though the guess is correct. This does not increase the tree-size by more than a constant factor.) □

The converse of Lemma 7 can also be proved by adapting Ruzzo's proofs [Ru80], [Ru81].

THEOREM 8. LOGCFL $\subseteq$ PEBBLE, TIME, SWITCHES($O(1)$, $O(\log n)$, 0).

Proof. Let $L \in$ LOGCFL. By Lemma 7, there is a uniform family $\{G_n\}$ of polynomial-size Boolean circuits that have polynomial tree-size and accept L. All the gates of G_n are designated as gates of challenge type 0.

If the input x is not in L, then Player 0 has a winning strategy identical to that of Player 0 in the subgraph F_m in § 4.1. This strategy uses no resources, since all vertices are of challenge type 0. If $x \in L$, let H be a polynomial-size accepting subtree of G_n. By Lemma 3, H can be pebbled in the uninterpreted game of § 3 using $O(1)$ pebbles and $O(\log n)$ time. Player 1 simulates this strategy on G_n by pebbling a gate whenever any of its copies in H is pebbled, and removing the pebble from a gate whenever all of its copies in H become pebble-free. That Player 1 wins on G_n in the same round as the Pebbler would win on H follows from the definition of accepting subtree and the rules of the games as follows. If the Challenger loses at an input of H, then the corresponding input in G_n must have value 1, so Player 1 wins. If the Challenger loses at an OR gate v of H, then the gate in G_n corresponding to the child of v in H is also 1-pebbled, so Player 1 wins. Finally, if the Challenger loses at an AND gate v of H, then both inputs of the corresponding AND gate in G_n are 1-pebbled, so Player 1 wins. □

5.2. Game on an AC^k circuit. The notion of alternation can be defined naturally for Boolean circuits analogously to the notion of alternation in alternating Turing machines. This definition is used in Lemma 9 below to obtain a circuit characterization of AC^k.

DEFINITION. A language L is said to be accepted by a family $\{G_n\}$ of Boolean circuits within *alternation* bound $A(n)$ if and only if, for all paths p in G_n from some input of G_n to the output gate, the number of edges on p connecting an AND gate to an OR gate or vice versa is at most $A(n)$.

LEMMA 9. *For any $k \geq 1$, if $L \in AC^k$, then there exists a uniform family of polynomial-size Boolean circuits $\{G_n\}$ accepting L such that G_n has $O(\log^k n)$ alternations.*

Proof. The proof is similar to that of Lemma 7. However, the method used there of putting the simulated alternating Turing machine M in normal form will not do here, as it introduces at least one alternation for every input symbol read. Instead, M is simulated as in Borodin and Ruzzo's theorem [Ru81] (see also Corollary 17) by an

alternating Turing machine in normal form that uses $O(S)$ space and $O(A+S)$ alternations, where $S = O(\log n)$ and $A = O(\log^k n)$ are the space and alternations, respectively, used by M. □

The converse of Lemma 9 can also be proved using the alternating Turing machine simulation of circuits by Ruzzo [Ru81].

THEOREM 10. *For any* $k \geq 1$,

$$\mathrm{AC}^k \subseteq \mathrm{PEBBLE, TIME, SWITCHES}(O(1), O(\log^k n), O(\log^k n)).$$

Proof. Let $\{G_n\}$ accept L using $O(\log^k n)$ alternations. All OR gates are designated as gates of challenge type 0 and all AND gates are designated as gates of challenge type 1. Let x be an input to G_n.

Case 1. Suppose G_n evaluates to 1 on input x. Then there exists an accepting subtree H of G_n. The proof that Player 1 can win the game on G_n within the stated bounds follows from the claim below.

CLAIM. If v is the current challenged gate in H, no predecessor of v is 0-pebbled, and there are A alternations in the subtree of H rooted at v, then Player 1 can win the game with two pebbles, at most $A+t$ steps, and at most A role switches, where t is the number of steps required to play the uninterpreted game on the longest path of OR gates in H. (By Lemma 1, $t = O(\log n)$.)

Proof of the Claim. The claim is proved by induction on A.

Basis ($A = 0$). Suppose all gates are OR gates. Then Player 1 is the Pebbler. The subtree of H rooted at v is a simple path of OR gates and the result follows immediately.

Suppose all gates are AND gates. Then Player 1 has a winning strategy using no resources, since Player 1 is never the Pebbler.

Induction ($A > 0$). Assume that the claim is true if the number of alternations is less than A. Let the subgraph rooted at v have A alternations.

Let v be an OR gate. Then Player 1 is the Pebbler. The subtree of H rooted at v starts off as a simple path of OR gates. Let u be the first AND gate on this path. Player 1 removes all 1-pebbles from the graph and pebbles u. If Player 0 retains its challenge on v, then Player 1 can win the game on the path using two pebbles, t steps, and no role switches. Suppose Player 0 moves its challenge to u. Then a role switch occurs, so that Player 0 is the Pebbler for the next round. The subtree rooted at u has $A-1$ alternations and no 0-pebbles. Therefore, by the induction hypothesis, Player 1 can win the game on the subtree rooted at u using two pebbles, at most $(A-1)+t$ steps and at most $A-1$ role switches. It took one pebble placement and one role switch to get the game to u, so the total number of steps is at most $A+t$ and the total number of role switches is at most A.

Let v be an AND gate. Then Player 1 is the Challenger. If Player 0 never pebbles a predecessor of v that evaluates to 1, Player 1 retains its challenge on v and wins using no resources. Suppose Player 0 pebbles a predecessor of v that evaluates to 1. Consider the first such move. Let u be such a predecessor of minimum depth among the gates that are pebbled. Player 1 moves its challenge to u. Note that no predecessor of u is 0-pebbled. If u is an input, Player 1 wins immediately. If u is an OR gate, the number of alternations decreases at least by one at the cost of one role switch, and the result follows by induction. If u is an AND gate, Player 0 is the Pebbler again. The depth of the challenged gate is decreased without Player 1 using any resources. Therefore in a finite number of rounds the game reaches one of the two cases above without Player 1 expending any resources. This proves the claim.

Case 2. Suppose G_n evaluates to 0 on x. The proof that Player 0 can win the game on G_n within the claimed bounds is dual to the proof above. □

5.3. An alternating Turing machine simulation of the game.

THEOREM 11. *For $r \geqq \log n$, if L is accepted by a uniform family $\{G_n\}$ of polynomial-size augmented circuits that is pebbleable in p pebbles, t time, and r rounds in the dual game, then L is accepted by an alternating Turing machine within space $O(p \log n)$, time $O(t \log n)$, and alternations $O(r)$. If, in addition, Player 1 is always the Pebbler, then L is accepted within space $O(p \log n)$ and tree-size $p^{O(r)}$.*

Proof. Without loss of generality, assume that the players each have $2p$ pebbles, and they remove them p at a time. This does not affect the other resources.

An alternating Turing machine M simulates the game using existential (universal) configurations for the moves of Player 1 (Player 0). M begins by guessing the values of p, t, and r.

M keeps track of the time used by each player by initializing two counters T_0 and T_1 to t, and decrementing the appropriate one for each pebble placement. Likewise, M keeps track of the rounds charged to each player by initializing counters R_0 and R_1 to r, and decrementing the appropriate one for each round. M also uses four tapes to record the names of gates: (1) previously 1-pebbled, (2) previously 0-pebbled, (3) pebbled in the current round, and (4) challenged. Each round of the game is simulated as follows.

M first existentially guesses whether Player 1 has won according to the basis rules. If the guess is *yes*, M verifies this using the uniformity machine. M accepts if this is the case, and rejects otherwise. If M guessed that Player 1 has not yet won, M universally does the following: (a) It checks whether Player 0 has won the game, using the uniformity machine. M rejects if this is the case, and accepts otherwise. (b) M existentially determines who should be the current Challenger and universally does two things: verifies with the uniformity machine that the guess is correct and, in parallel, continues with the simulation as though the guess is correct. (See Fig. 2.)

Suppose Player 1 (Player 0) is the Pebbler. M existentially (universally) decides whether or not p pebbles are to be removed in this round. If so, M existentially (universally) deletes p gate names from the "1-pebbled" ("0-pebbled") tape, using a temporary tape for copying.

M then existentially (universally) records one or more gate names on the "recently pebbled" tape, up to a total not exceeding $2p$ on both tapes. If t' new names are recorded, then T_1 (T_0) is decremented by t' and R_1 (R_0) is decremented by 1. If $T_1 < 0$ ($T_0 < 0$) or $R_1 < 0$ ($R_0 < 0$), then M rejects (accepts).

Next M universally (existentially) chooses v as the new challenged gate, where v is chosen from among the gates on the "challenged" and "recently pebbled" tapes. v is written on the "challenged" tape, and the "recently pebbled" tape is appended to the "1-pebbled" ("0-pebbled") tape and erased.

M continues these steps until the basis conditions are reached, or one of the players runs out of time or rounds.

Correctness. Suppose G_n evaluates to 1 on x. The fact that the alternating Turing machine M accepts x is shown by arguing that there is an accepting subtree of the alternating Turing machine's computation tree on x.

Since G_n evaluates to 1 on x, there is a winning strategy S_1 for Player 1 in which Player 1 uses at most $2p$ pebbles, t steps, and r rounds. By construction, there is a corresponding subtree A of M's computation tree that contains the initial configuration, and in which one successor of each existential configuration and all successors of each universal configuration are retained. The major difference between S_1 and A is that some plays (in particular, all infinite plays) in S_1 are cut off in A due to the conditions $T_0 < 0$ and $R_0 < 0$. (Neither $T_1 < 0$ nor $R_1 < 0$ ever occurs, since Player 1's strategy uses

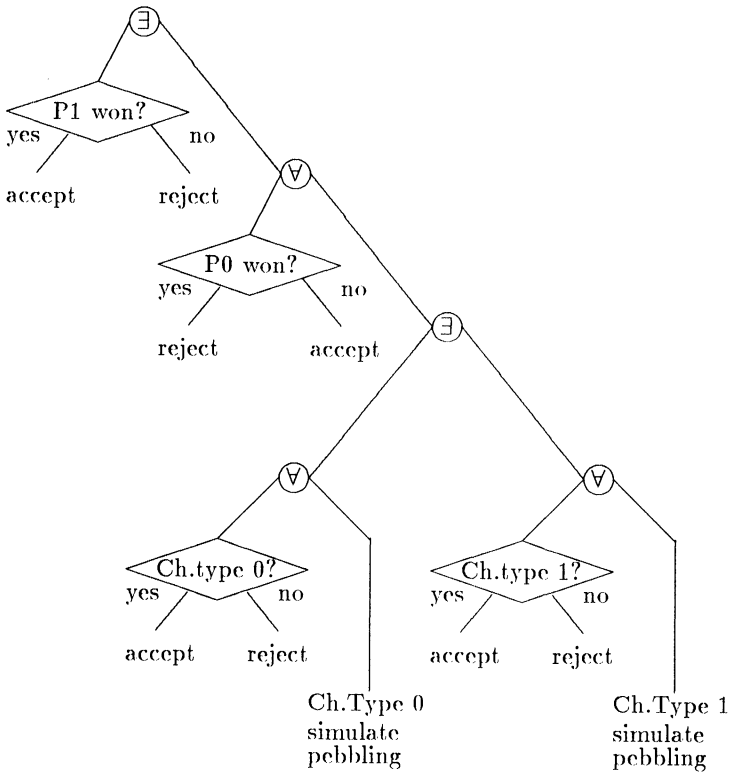

FIG. 2. *Beginning of a round.*

time at most t and rounds at most r.) All leaves of A that correspond to leaves of S_1 will be accepting, since Player 1 wins at all leaves of S_1. Furthermore, all leaves of A that do not correspond to leaves of S_1 are accepting by construction, since they arise from the cutoff due to $T_0 < 0$ or $R_0 < 0$. Thus, M accepts.

The proof that there is a rejecting subtree of M's computation tree for the case when G_n evaluates to 0 on input x is analogous.

Analysis. For the purposes of the analysis here, the uniformity machine will be assumed to be an alternating Turing machine with the simultaneous resource bounds of space $O(\log n)$, time $O(\log^2 n)$, alternations $O(\log n)$ and tree-size $O(n^{O(1)})$. This is possible since an $O(\log n)$ space deterministic Turing machine can be simulated by an alternating Turing machine with these resource bounds [CKS81]. Note that the uniformity machine is consulted at most once on any path of the computation tree. Hence, the resources required by the uniformity machine can be accommodated within the stated bounds, since $t \geqq r \geqq \log n$.

The counters T_0, T_1, R_0, and R_1 take space $O(\log t)$. Since t is at most the size of the circuit G_n, this space is $O(\log n)$. Since only $O(p)$ gate names each requiring $O(\log n)$ space are recorded on the tapes, the total space used by M is $O(p \log n)$.

There are at most six alternations per round of the game and therefore M makes $O(r)$ alternations.

The overall time for pebble placements, and hence for updating the tapes at the ends of the rounds, is $O(t \log n)$. Because pebbles are removed p at a time, the $O(p \log n)$ cost of updating the tapes to reflect removals is only incurred every p placements. Hence, the overall time due to removals is also $O(t \log n)$.

If Player 1 is the Pebbler throughout the game, then the following argument shows that the tree-size of M is $p^{O(r)}$. Consider the actions of the machine corresponding to a round of the game. For the Pebbler's move M existentially guesses at most $2p$ gates to pebble, and for the Challenger's moves it universally chooses a gate from the "challenged" and "recently pebbled" tapes. This universal move results in at most $2p+1$ configurations that correspond to the start of the next round. Thus, each round of the game increases the tree-size by at most a factor of $2p+1$. Over all the r rounds simulated by M, its tree-size is bounded by $p^{O(r)}$. More formally, let $z(k)$ be the tree-size required to demonstrate acceptance from a configuration reachable after k rounds from the initial configuration. Then,

$$z(k) \leqq \begin{cases} (2p+1)z(k+1)+n^{O(1)}, & k<r, \\ n^{O(1)}, & k=r. \end{cases}$$

So, $z(0)=(2p+1)^{O(r)}$. □

COROLLARY 12. *If L is accepted by a uniform family $\{G_n\}$ of polynomial-size augmented circuits that is pebbleable in the dual game in $t=O(\log n)$ steps and $p=O(1)$ pebbles, then L is in* AC^1. *If, in addition, Player* 1 *is always the Pebbler, then L is in* LOGCFL.

Proof. The proof is a direct application of the theorem along with Ruzzo's characterization of LOGCFL [Ru80]. □

5.4. Characterization of $\mathscr{P}$.

THEOREM 13. $\mathscr{P}=\mathrm{PEBBLE}(O(1))$.

Proof. If $L\in\mathscr{P}$, then it is known that there is a uniform family $\{G_n\}$ of polynomial-size Boolean circuits accepting L [La75]. All the gates in G_n are designated as gates of challenge type 0. Suppose G_n evaluates to 1 on x. A winning strategy for Player 1 is to pebble those immediate predecessors of the challenged gate that evaluate to 1. This strategy uses two pebbles. Suppose G_n evaluates to 0 on x. Then Player 0 has a winning strategy that uses no resources, since Player 0 is never the Pebbler.

Conversely, suppose $\{G_n\}$ is a uniform family of polynomial-size augmented circuits accepting L such that G_n is pebbleable with a constant number of pebbles. Then the result follows from Theorem 11 and the fact that $\mathrm{ASPACE}(\log n)=\mathscr{P}$ [CKS81]. □

6. Unifying framework. The dual game defined in § 4 can be played on computation graphs of certain models of computation that have properties similar to Boolean circuits. In this section the dual game is played on the computation graphs of alternating Turing machines. This is used to show that the following three important results in complexity theory are described naturally as pebbling results: (a) Savitch's theorem showing that $\mathrm{NSPACE}(S)\subseteq\mathrm{DSPACE}(S^2)$ [Sa70]; (b) Ruzzo's simulation of an alternating Turing machine with simultaneous space and tree-size bound by an alternating Turing machine with simultaneous space and time bound [Ru80]; and (c) Borodin and Ruzzo's simulation of an alternating Turing machine with simultaneous space and alternation bound by an alternating Turing machine with simultaneous space and time bound [Ru81]. The latter two results generalized Savitch's theorem in two different ways. These three theorems are derived as corollaries of a theorem on the resource requirements for pebbling alternating Turing machine computation graphs.

Let M be an $S(n)\geqq\log n$ space bounded alternating Turing machine that accepts L. Given an input x of length n in L, let $G(M,x)$ be the *computation graph* of M on x; that is, the vertices of $G(M,x)$ correspond to the configurations of the machine M on input x, and there is a directed edge from a vertex u to a vertex v if and only if there is a transition of M from the configuration corresponding to v to the configuration

corresponding to u. It will be assumed that $G(M, x)$ does not have any cycles. This can be arranged by using an extra tape as a "clock" that is incremented each step.

For defining the dual game on $G(M, x)$, the vertices in this graph are partitioned into two sets, those of challenge type 0 and those of challenge type 1. A computation graph is said to be an *augmented* computation graph if this role information is also available for each of its vertices. It will be assumed that for all $x \in L$, there is an alternating Turing machine that can determine this role information for each vertex in $G(M, x)$ in time $O(S(n))$.

The dual game on $G(M, x)$ is defined similarly to the definition in § 4 of the game on Boolean circuits. Its description will be omitted here.

Let ASPACE, TIME $(S(n), T(n))$ denote the class of languages accepted by alternating Turing machines within space $O(S(n))$ and time $O(T(n))$ simultaneously. The classes ASPACE, ALTERNATIONS$(S(n), A(n))$ and ASPACE, TREESIZE$(S(n), Z(n))$ are defined similarly.

THEOREM 14. *Fix any $x \in L$ and an augmented computation graph $G(M, x)$ of a space $S(n)$ bounded alternating Turing machine M on input x. If the dual game on $G(M, x)$ can be played in space $p(n)$ and time $t(n)$, then*

$$L \in \text{ASPACE, TIME}(p(n)S(n), t(n)S(n)).$$

Sketch of Proof. The proof of this theorem is similar to the proof of Theorem 11. □

COROLLARY 15 (Savitch's theorem). *For $S(n) \geqq \log n$,*

$$\text{NSPACE}(S(n)) \subseteq \text{ASPACE, TIME}(S(n), S^2(n)).$$

Proof. Let M in Theorem 14 be a nondeterministic Turing machine. All vertices of $G(M, x)$ are designated to be of challenge type 0. $G(M, x)$ can be pebbled with $O(1)$ pebbles and $O(S(n))$ time, as in Lemma 1. □

COROLLARY 16 (Ruzzo's theorem). *For $S(n) \geqq \log n$,*

$$\text{ASPACE, TREESIZE}(S(n), Z(n)) \subseteq \text{ASPACE, TIME}(S(n), S(n) \log Z(n)).$$

Proof. All vertices of $G(M, x)$ are designated to be of challenge type 0. $G(M, x)$ can be pebbled with $O(1)$ pebbles and $O(\log Z(n))$ time, as in Theorem 8. □

COROLLARY 17 (Borodin and Ruzzo's theorem). *For $S(n) \geqq \log n$,*

$$\text{ASPACE, ALTERNATIONS}(S(n), A(n)) \subseteq \text{ASPACE, TIME}(S(n), S(n)(S(n)+A(n))).$$

Proof. All existential configurations are designated as of challenge type 0 and all universal configurations are designated as of challenge type 1. $G(M, x)$ can be pebbled with $O(1)$ pebbles and $O(S(n)+A(n))$ time, as in Theorem 10. □

7. Conclusion and open problems. A new combinatorial game that abstracts certain synchronous parallel computations has been defined and this game has been used to study the relationship between the complexity classes LOGCFL and AC^1.

Although the dual interpreted two-person pebble game has been defined in § 4 in terms of Boolean circuits, the game is easily extended to computation graphs of other models of computation. An alternating Turing machine is an example of such a model and this was exploited in § 6 to provide a unifying framework for some well-known simulation results involving alternating Turing machines.

The basic difference in the way Player 0 contributes to the computations in LOGCFL and AC^1 has motivated the discovery of new characterizations of LOGCFL on models such as bounded fan-in Boolean circuits, unbounded fan-in Boolean circuits, and alternating Turing machines [Ve86]. These characterizations are in terms of the same resources used to characterize AC^1 on these models.

There are many possible approaches used to compare two complexity classes. The approach taken in this paper is to obtain characterizations of the classes using the same measures of resources on a model of computation, namely the game model. This approach seems general enough to be applicable in the study of problems of this type: given two complexity classes A and B with $A \subseteq B$, is A properly contained in B?

This study raises several open questions. Some of them are listed below.

The ultimate justification for this game would be to use Theorem 11 to discover new efficient parallel algorithms for natural problems. In retrospect, we could imagine Ruzzo's parallel context-free language recognition algorithm [Ru80] being discovered this way. It would be particularly appealing if new algorithms exploited the symmetry available between the two players.

The uninterpreted game is used by Dymond and Tompa [DT85] to provide an alternative proof of the result of Paterson and Valiant [PV76] that $\mathrm{SIZE}(T) \subseteq \mathrm{DEPTH}(O(T/\log T))$ for (nonuniform) Boolean circuits. Is it possible to improve this result using the dual game? What circuits are hard to pebble?

There are natural circuits such as the Cocke-Kasami-Younger circuits on which the dual game without role switches is exponentially faster than the uninterpreted game. A simple example where one role switch provided such a speedup has been seen in § 4.1. It would be interesting to show similar speedups for circuits for natural problems. A related question is to prove that there are AC^1 circuits for natural problems that require $\Omega(\log n)$ role switches if the time is $O(\log n)$.

Acknowledgments. We are indebted to Larry Ruzzo and Richard Ladner for very useful discussions.

SUCCINCT CERTIFICATES FOR ALMOST ALL SUBSET SUM PROBLEMS*

MERRICK L. FURST† AND RAVI KANNAN†

Abstract. Given n natural numbers $a_1, \cdots, a_n$ and a target integer b, the *SubsetSum* problem is to determine whether some subset of the a_i sums to b. That is, to recognize members of the following set:

$$\text{SubsetSum} = \{\langle a_1, \cdots, a_n; b\rangle \mid a_i \in \mathbf{N}, b \in \mathbf{Z}, \text{ and } \exists x \in \{0,1\}^n \text{ such that } a \cdot x = b\}.$$

For a given vector $a = (a_1, \cdots, a_n)$ and integer b, if a subset of the a_i sums to b, then listing which subset provides a short proof that $\langle a; b\rangle \in$ SubsetSum. However, in general there are no short (polynomial-length) proofs of nonmembership unless NP equals coNP.

The main result in this paper provides a proof system that contains polynomial-length nonmembership proofs for a vast majority of the problem instances that do not belong to SubsetSum.

1. Introduction.

A *SubsetSum* problem instance is of a set of n positive integer *coefficients* $a_1, \cdots, a_n$ together with a *target* (or right-hand side) integer b. The "answer" to a SubsetSum problem is *yes* if some subset of the coefficients sum to the target and *no* otherwise. For positive integers n, M, let

$$G_n(M) = \{(a_1, a_2, \cdots, a_n) \mid a_i \text{ an integer in the range } \{1 \cdots M\}\}.$$

Let FEA be the set of feasible SubsetSum problems and let INF be the set of infeasible SubsetSum problems, i.e.,

$$\text{FEA} = \{\langle (a_1, \cdots, a_n); b\rangle \mid \text{a subset of the } a_i \text{ sums to } b\},$$

$$\text{INF} = \{\langle (a_1, \cdots, a_n); b\rangle \mid \text{no subset of the } a_i \text{ sums to } b\}.$$

The set FEA is NP-complete, therefore, the set INF is coNP-complete.

Let T be a nondeterministic Turing machine accepting the set INF. The collection of valid computations of Turing machine T may be thought of, in the sense of Cook and Reckhow [8], as a *formal proof system* $\mathcal{F}$ for demonstrating the infeasibility of SubsetSum problems. Define a *generic SubsetSum problem* to be an n-tuple $a = (a_1, a_2, \cdots, a_n)$, with no sum b specified. Then define

$$\text{INF}(a) = \{b \in N \mid b \leqq \sum a_i \text{ and } \langle a; b\rangle \in \text{INF}\}.$$

The *proof complexity* of the generic instance a with respect to $\mathcal{F}$ is the maximum length, over all $b \in \text{INF}(a)$, of proofs of infeasibility using $\mathcal{F}$ of the SubsetSum instance $\langle a; b\rangle$. Let $f(n, \mathcal{F})$ be the maximum proof complexity (using $\mathcal{F}$) taken over all instances a requiring n or fewer bits as input. Since INF is coNP-complete, if $N \neq \text{coNP}$ then $f(n, \mathcal{F})$ grows more rapidly than any polynomial function of n. The main result asserts that, despite this fact, we can isolate a large, interesting class of generic instances a that has small proof complexity.

The main result of this paper is the following.

THEOREM 1. *Let* $M \geqq 2^{3/2n \log n + 5n}$. *There is a proof system* $\mathcal{F}$ *and a polynomial* p *such that*

$$\left(1 - \frac{1}{2^n}\right) \cdot |G_n(M)|$$

of the generic subset sum problems a *in* $G_n(M)$ *have proof complexity bounded above by* $p(n)$.

We also show the following theorem.

THEOREM 2. *There is a deterministic algorithm* A *that solves the SubsetSum problem correctly in all instances and moreover, there exists a polynomial* $p(\cdot)$ *such that, for any* $M \geqq 2^{n^2/2+2n} \cdot n^{3n/2}$, *some subset* S *of* $G_n(M)$ *has the following property*:

- $|S| \geqq (1 - 1/2^n)|G_n(M)|$, *and*
- *For each vector* $a = (a_1, \cdots, a_n) \in S$, *and any* b, A *runs in* $p(|\langle a; b\rangle|)$*-time on* $\langle a; b\rangle$.

This theorem is a strengthening of a result of Lagarias and Odlyzko [22]. They exhibit a deterministic polynomial-time algorithm B that accomplishes the following. Pick any constant c, and let $M \geqq 2^{cn^2}$. For all but $(1 - 1/2^n)$ of the vectors $a = (a_1, \cdots, a_n)$ in $G_n(M)$, if integer b *is* the sum of a subset of the a_i, then their Algorithm B finds which a_i sum to b. Frieze [11] simplifies and sharpens their argument. Aside from the constants in the lower bound on M, the algorithm of our Theorem 2 improves on these results in that it solves instances that have a negative answer as well as those that have a positive answer.

1.1. Comparison with previous results. There are several results known to lead to proof systems for nonmembership for portions of other NP-complete languages. The proof systems so obtained share a similar structure. Typically, a simple polynomial-time property Q is given. This property is chosen so as to imply nonmembership, i.e., if property Q is true of an instance I then I is not in the NP-complete set. Property Q is then shown to hold for almost all instances within a restricted class. In this way, since Q is polynomial time and holds for almost all instances, simply testing for Q becomes a way of giving short proofs of nonmembership. A more detailed background can be found in § 4.

Our proof system differs from these in two respects. The property Q we identify is not known to be polynomial-time computable. The power of nondeterminism seems to be needed to prove that Q holds. As well, the set of instances we consider is comprehensive and not very restrictive. It contains all SubsetSum problems with coefficients $O(n \log n)$-bits long.

It is an interesting open problem to find a general proof system for other NP-complete sets such as three-CNF satisfiability, vertex cover, and clique. There are indications that the techniques we describe could be used for such problems.

2. Main theorem. The algorithms implicit in both our theorems use techniques from the geometry of numbers. Good general references for this subject are Cassels [5] and Lekkerkerker [25]. For a recent survey, see [19]. We begin with a definition and some lattice terminology. A *lattice* in $\Re^n$ (Euclidean n space) is the set of all *integer* linear combinations of some linearly independent vectors $b_1, b_2, \cdots, b_m$ in $\Re^n$. The set of vectors $b_1, b_2, \cdots, b_m$ is a *basis* and the lattice it generates is denoted $L(b_1, b_2, \cdots, b_m)$. A lattice has many bases; the cardinality is always the same and is called the *dimension.*

Suppose $a = (a_1, a_2, \cdots, a_n)$ is a vector in $\mathbf{Z}^n$. Consider the set of vectors

$$L_a = \{x \mid x \in \mathbf{Z}^n \text{ and } a \cdot x = 0\}.$$

This collection of vectors, L_a, is a lattice and moreover, given the vector a, a basis for L_a can be found in polynomial time by using the algorithms of Kannan and Bachem [17].

Our approach to the SubsetSum problem follows. Wishing to determine whether there is a 0-1 vector x such that $a \cdot x = b$, we start by computing some particular integral solution x^0 to $a \cdot x = b$. An integer solution exists if and only if the greatest common divisor of all the components of a divides b. This criterion can be checked in polynomial time using the Euclidean algorithm.

Any 0-1 vector x such that $a \cdot x = b$ must be of the form $x^0 - y$, where y is a vector belonging to L_a. Since $x^0 - y$ is a 0-1 vector its length is at most $\sqrt{n}$. Thus, for a 0-1 solution to exist, there must be a point y in the lattice L_a that is at a distance at most $\sqrt{n}$ from x^0. Having found x^0 and a basis for L_a, we determine whether there is a vector y in L_a which is this close to x^0. It turns out that finding whether such a y exists is not hard if the shortest nonzero element of L_a is longer than $2n^{3/2}$. It also turns out that most a in $G_n(M)$, for large enough M, give rise to lattices L_a whose shortest nonzero vectors are longer than $2n^{3/2}$.

Let L be a lattice. The length of the shortest nonzero vector in L is denoted

$$\lambda_1(L) = \min \{|x|: x \in L \text{ and } x \neq 0\}$$

where $|\cdot|$ is Euclidean length.

LEMMA 1. *Recall that* $G_n(M) = \{(a_1, \cdots, a_n) \mid a_i \in \{1, \cdots, M\}\}$. *For any* k, *the length of the shortest vector in* L_a, $\lambda_1(L_a)$, *is greater than* k *for all but* $M^{n-1}(2k+1)^n$ *of the nonzero vectors* a *in* $G_n(M)$.

Proof. Consider a nonzero vector $v = (v_1, \cdots, v_n) \in \mathbf{Z}$ such that $|v_i| \leqq k$. Without loss of generality, assume $v_n \neq 0$. Suppose Suppose $a \in G_n(M)$ and $a \cdot v = 0$. Then

$$a_n v_n = -\sum_{i=1}^{n-1} a_i v_i,$$

and, hence,

$$a_n = \frac{-\sum_{i=1}^{n-1} a_i v_i}{v_n}.$$

Thus, the number of nonzero a's in $G_n(M)$ such that $a \cdot v = 0$ is at most M^{n-1}.

The number of vectors v in $\mathbf{Z}^n$ with components bounded in magnitude by k is $(2k+1)^n$. Therefore, at most $M^{n-1}(2k+1)^n$ of the elements a of $G_n(M)$ are such that $\lambda_1(L_a) \leqq k$. □

Remark 1. In the other direction, it is easy to argue using the pigeon-hole principle that every a in $G_n(M)$ has $\lambda_1(L_a) \leqq \sqrt{n} \cdot \lceil 1 + (Mn)^{1/(n-1)} \rceil$. Fix an a in $G_n(M)$. Let $k = [(Mn)^{1/(n-1)} + 1]$. The dot product of each v in $G_n(k)$ with a is an integer between 0 and Mnk. If any v in $G_n(k)$ makes a dot product 0 with a, then we will know that $\lambda_1(L_a) \leqq |v| \leqq k\sqrt{n}$ as desired. So assume this does not happen. Since $|G_n(k)| = k^n > Mnk$ (via a simple calculation), there must exist two distinct elements u, v in $G_n(k)$ such that $u \cdot a = v \cdot a$, whence $(v-u) \cdot a = 0$. Furthermore, $|u - v| \leqq \sqrt{n}k$, which proves the claim. A better bound can be obtained by observing that the determinant of L_a equals $|a|$, provided the gcd of $a_1, \cdots, a_n$ is 1. Thus, by Minkowski's convex body theorem [25, § 5], it follows that $\lambda_1(L_a) \leqq \sqrt{n} \cdot |a|^{1/n}$.

COROLLARY 1. *For* $M \geqq (20)^n n^{3n/2}$ *in the above lemma, the fraction of vectors* a *in* $G_n(M)$ *for which* $\lambda_1(L_a) \leqq 2n^{3/2}$ *is at most* $1/2^n$.

Proof. The number of vectors a in $G_n(M)$ is M^n. From the lemma we know that the number of a's with $\lambda_1(L_a) \leqq 2n^{3/2}$ is at most

$$M^{n-1}(4n^{3/2}+1)^n.$$

Thus, the fraction of such a's is at most

$$\frac{(4n^{3/2}+1)^n}{M} \leqq \frac{1}{2^n}.$$

□

We need some notation now. Suppose $b_1, b_2, \cdots, b_m$ is a basis of a lattice L_a (so $m = n-1$). Using the Gram-Schmidt orthonormalization process we may obtain from these b_i mutually orthogonal vectors $b_1^*, b_2^*, \cdots, b_m^*$ as follows:

$$b_1^* = b_1$$

and

$$b_{i+1}^* = b_{i+1} - \sum_{j=1}^{i} \mu_{i+1,j} b_j^* \quad \text{for } i = 1, \cdots, m-1$$

where

$$\mu_{kl} = \frac{b_k \cdot b_l^*}{b_l^* \cdot b_l^*} \quad \text{for } 1 \leqq l < k \leqq m.$$

These b_i^* are generally useful.

LEMMA 2. *Suppose $a = (a_1, \cdots, a_n) \in \mathbf{Z}^n$ and $\lambda_1(L_a) > 2n^{3/2}$. There exists a basis $b_1, \cdots, b_{n-1}$ of L_a such that we have the following:*

- $|b_i^*| > 2\sqrt{n}$, *for* $1 \leqq i \leqq n-1$, *and*
- *The vectors $b_1, \cdots, b_{n-1}$ can be expressed in polynomially many bits.*

Proof. Lagarias, Lenstra, and Schnorr [23, Thm. 5.1] show that for any m-dimensional lattice L, there is a basis $b_1, \cdots, b_m$ such that $|b_i^*| \geqq \lambda_1(L)/m$, and the b_i can be expressed in polynomially many bits. From this, Lemma 2 follows readily. □

A basis $b_1, \cdots, b_m$ of a lattice is *proper* if the μ_{ij} defined in the Gram-Schmidt process all satisfy $|\mu_{ij}| \leqq \frac{1}{2}$.

PROPOSITION 1. *Suppose L is an m-dimensional lattice given by a basis $b_1, \cdots, b_m$ satisfying*

$$|b_i^*| > 2k.$$

Let x be any given point in span (L). *There is at most one lattice point $v \in L$ such that $|x - v| \leqq k$. We can determine whether such a lattice point exists and if so, we can find it in polynomial time.*

Proof. First we show uniqueness. If v and v' are two *distinct* elements of L such that $|x - v|$ and $|x - v'|$ are less than or equal to k, then $|v - v'| \leqq 2k$ and $v - v' \neq 0$. Let $v - v' = \sum_{i=1}^{s} \alpha_i b_i$, $s \leqq m$, $\alpha_i \in \mathbf{Z}$, and $\alpha_s \neq 0$. Then $v - v'$ has a component $\alpha_s b_s^*$ along b_s^* of length $|\alpha_s||b_s^*| > 2k$, giving the needed contradiction.

Now we show how to compute the coordinates of a lattice vector $v \in L$ which is within a ball of radius k about x, if one exists. Suppose there is a lattice vector $v \in L$ such that $|x - v| \leqq k$. Write

$$v = \sum_{i=1}^{m} \alpha_i b_i$$

with $\alpha_i \in \mathbf{Z}$. Let

$$x = \sum_{i=1}^{m} \beta_i b_i^*$$

with $\beta_i \in \mathfrak{R}$. The projection of $x - v$ in the direction of b_m^* is of length $|\beta_m - \alpha_m||b_m^*|$. Thus,

$$|x - v| \leqq k$$

implies

$$|\beta_m - \alpha_m||b_m^*| \leqq k,$$

which means

$$|\beta_b - \alpha_m| \leqq \frac{k}{|b_m^*|} < \frac{k}{2k} = \frac{1}{2}.$$

Therefore, there is at most one possible integer value for α_m, namely $[\beta_m]$, the integer closest to β_m. Having found α_m, the coordinates $\alpha_{m-1}, \cdots, \alpha_1$ can be calculated in like fashion. □

2.1. Short proofs of infeasibility. Let $a = (a_1, \cdots, a_n)$ be an instance of a generic SubsetSum problem such that $\lambda_1(L_a) \geqq n^{3/2}$. Suppose B is an integer. If a subset of the a_i sums to B, a list of the coefficients that sum to B gives a short proof of that fact. Suppose no subset of the a_i sums to B. We describe how to write a short proof.

Begin the proof by exhibiting a *nice* basis $b_1, \cdots, b_m$ such that we have the following:

- $b_1, \cdots, b_m$ is a basis of L_a, and
- The inequalities $b_i^* > 2\sqrt{n}$ are satisfied.

(Such a nice basis of L_a is guaranteed to exist by Lemma 2.)

Then verify that $b_1, \cdots, b_m$ is a basis of L_a by doing the following:

(1) Checking that each b_i belongs to L_a; and also

(2) Checking that the determinant of the lattice spanned by the b_i equals the determinant of the lattice spanned by a basis of L_a found using the Hermite normal form algorithm of [17].

Next we write down any solution x^0 of x in $a \cdot x = b$; $x \in \mathbf{Z}^n$. It goes without saying that it is easy to check that a particular x^0 works. Observe that x^0 is not a 0-1 vector since we are assuming this SubsetSum problem has no 0-1 solution.

Following the deterministic algorithm given in the proof of Proposition 1, we find a unique $v \in L_a$, which is a candidate for satisfying $|v - x^0| \leqq \sqrt{n}$. If the original problem is infeasible, either the candidate v fails to satisfy this inequality or $v - x^0$ is not a 0-1 vector. This gives a polynomial-length proof in either case.

We now prove Theorem 1. By Corollary 1, if $M \geqq 2^{3/2 \log n + 5n}$, then at least $(1 - 1/2^N)|G_n(M)|$ such A have $\lambda_1(L_a) > n^{3/2}$. Then we can find the short proofs constructed above.

To summarize, with the *nice* basis on hand there is at most one easily identified v in L_a with $|x^0 - v|$ bounded above by $\sqrt{n}$. We determine whether such a v exists and if it does we check whether $x^0 - v$ has each component equal to 0 or 1. There is a solution to the subset sum problem if and only if this happens. This provides polynomial-length proofs of infeasibility and proves Theorem 1.

It is important to observe that this is not a polynomial-time *algorithm* for feasibility or infeasibility. Since the first step involves guessing a nice basis we have only given a proof that there are short proofs.

An algorithm. Under what conditions can the above proofs, or nondeterministic procedures, be made into deterministic polynomial-time algorithms? Examining Lagarias, Lenstra, and Schnorr's theorem [23] observe that they obtain a nice basis as follows. Start with a basis of the polar (dual) lattice and reduce it so that it is a "Korkine-Zolotarev-reduced" basis. The dual to this new basis is a nice basis of the original lattice. The best-known algorithm for finding such a "Korkine-Zolotarev-reduced" basis runs in exponential time, [18]. Furthermore, if a polynomial-time algorithm could be found for this problem, then the shortest vector problem for lattices could be solved in polynomial time. The latter question is open. It is perhaps the most important open question in the area of lattice algorithms.

In this way we obtain one more indication of the significance of the shortest vector problem (SVP). If SVP can be solved in polynomial time, then all the instances of the SubsetSum problem for which our theorems give a proof system would be determinisitic polynomial-time solvable.

In their famous paper, Lenstra, Lenstra, and Lovász [24] show how to approximate the length of the shortest vector in a lattice within a factor of $2^{n/2}$. That result can be used to obtain a deterministic algorithm for generic SubsetSum problems when the parameter M, which determines the number of bits in each coefficient, is large enough.

THEOREM 3. *Let $M \geqq (2^{n^2/2+2n})(n^{3n/2})$, i.e., $|M| = O(n^2)$. There is a deterministic algorithm A, and a polynomial p such that A solves all instances of the SubsetSum problem correctly and, for $(1-1/2^n)|G_n(M)|$ of the generic SubsetSum problems in $G_n(M)$, A runs in time bounded above by polynomial $p(n)$.*

Proof. Following the proof of Lemma 1, for most generic SubsetSum problems a in $G_n(M)$, the associated lattice L_a satisfies

$$\lambda_1(L_a) \geqq 2\sqrt{n}2^{(n-1)/2}.$$

If the Lenstra, Lenstra, and Lovász basis reduction algorithm is run on such a lattice L_a, a reduced basis $b_1, \cdots, b_{n-1}$ is produced. The vectors b_i in this representation of L_a satisfy

$$|b_i^*| \geqq 2\sqrt{n} \quad \text{for each } i.$$

Following the argument for our main theorem, the computed reduced basis can be used to solve SubsetSum problems derived from the generic problem a. Since the reduced basis may be computed in polynomial time, the whole algorithm is polynomial-time bounded. □

This provides a rigorous analysis of Brickell's algorithm [2].

3. Small circuits. The question of whether the proof system we have described contains short proofs of infeasibility for a given set of integer weights $a_1, \cdots, a_n$ and target b, depends only on the coefficients a_i. It is not difficult to show that for those $(a_1, \cdots, a_n)$'s that admit small proofs, there is also a polynomial-sized Boolean circuit $C(a_1, \cdots, a_n)$ that accepts precisely those b's that equal the sum of some subset of the a_i's. To see this, encode into the circuit $C(a_1, \cdots, a_n)$ the basis of the lattice L_a used in the proof of Theorem 2. The rest of the procedure inherent in the proofs are deterministic polynomial-time computable, so they can be simulated by the polynomial-sized circuit. The details are omitted.

THEOREM 4. *Suppose $M \geqq 2^{3/2n \log n+5n}$. There is a subset S of $G_n(M)$ of cardinality at least $(1-1/2^n)|G_n(M)|$ such that, for each $a \in S$, there is a polynomial-sized circuit that accepts precisely those b's that are the sum of a subset of the a_i.*

The reason this result is interesting is the following. We know that the SubsetSum problem is NP-complete. So, if M is any polynomial-time bounded nondeterministic

Turing machine, there is a many-one reduction f of $L(M)$ to the SubsetSum problem. For any string x, $f(x)$ has two parts: the SubsetSum coefficients $a_1, \cdots, a_n$ and the right-hand side integer b. It can be shown that the number n and the coefficients a_i depend only on the machine M and the length of x. The input x only specifies the target b. Getting a small circuit C is thus equivalent to finding a small circuit for another language in NP. We do not, at present, know of other natural languages in NP for which this works.

4. Previous results. A survey of results related to solving almost all instances of NP-complete problems is found in Johnson's NP-completeness column [16]. Here we discuss several of them.

4.1. Hamilton cycles. A considerable study has been made on the subject of Hamiltonicity in random graphs [30], [21], [1]. The culmination of which is an expected polynomial-time algorithm for the Hamilton cycle problem in random graphs having enough edges [3]. The elegant paper of Bollobás, Fenner, and Frieze demonstrates an expected polynomial-time bound on the run-time of a straightforward Hamiltonicity algorithm.

Prior to their work it was known that random graphs with many edges almost surely contain Hamilton cycles. What Bollobás, Fenner, and Frieze show is that a fairly simple algorithm actually finds Hamilton cycles almost all the time. However, for each graph that is non-Hamiltonian, the algorithm takes exponential time before it can positively conclude non-Hamiltonicity. It is useful in practice. However, it never provides nontrivial proofs of non-Hamiltonicity.

4.2. Satisfiability. There has been some work on algorithms for solving random instances of the satisfiability problem. Suppose $G(n, m, p)$ denotes the class of CNF-formulae with n random clauses and m variables generated as follows. For each variable v_i, $1 \leqq i \leqq m$, a random clause contains the literal v_i, or the literal $\bar{v}_i$, or neither with probabilities p, p, $1-2p$, respectively. (Obviously, $0 \leqq p \leqq \frac{1}{2}$.) The choices are made independently for each variable and the clauses are generated independently. Goldberg, Purdom, and Brown [12] show that a version of the Davis–Putnam procedure [9] runs in expected polynomial time on such problems. The expected time is polynomially bounded in n, m but it is exponential in $1/p$.

Following the analysis of Franco and Paull [10], it is possible to show that there are constants c, $d > 0$ depending only on p such that if n, the number of clauses, is at most 2^{cm} (m was the number of variables), then for almost all CNF-formulae, the number of truth assignments that make the formula false is at most $2^{(1-d)m}$. Almost any truth assignment renders the formula true in this case; thus, the Davis–Putnam procedure does not yield proofs of nonsatisfiability for very many instances. In the other case, when $n > 2^{cm}$, the value 2^m is polynomially bounded in n. Therefore, the satisfiability of the formula can be checked in polynomial time by enumerating all the 2^m truth assignments. It is only in this case, once again by doing enumeration, that proofs of unsatisfiability are seen.

4.3. Vertex coloring. The problem of three-coloring (in general k-coloring for any fixed k) a random graph has been considered by Wilf [32]. If each edge of a graph is put in with probability $p > 0$, then for a large enough number of vertices, with high probability, there will be a clique of size four in the graph. Thus, most "random" graphs contain four-cliques and cannot be colored with three colors. Unlike the other problems discussed, in this case nonmembership in the NP-complete language can be proved for most instances. However, nonmembership is for an absolutely local reason.

4.4 Minimum bisection width. Determining the minimum number of edges that must be removed from a graph in order to separate the vertices into two equal-sized sets is NP-complete. Bui et al. [4] suggest an algorithm for minimum bisection width that is based on min-cut max-flow methods. Their algorithm always runs in polynomial time. For almost all regular, degree d graphs that have minimum bisection width bounded above by $o(n^{1-1/\lfloor (d+2)/2 \rfloor})$, their algorithm calculates the correct bisection width. However, the class of graphs the algorithm works for is a vanishing fraction of the class of all graphs on n vertices. Moreover, membership in the class is itself NP-hard. Thus, their algorithm is providing proofs of nonmembership for a large fraction of a noncomprehensive set.

TWO APPLICATIONS OF INDUCTIVE COUNTING FOR COMPLEMENTATION PROBLEMS*

ALLAN BORODIN†, STEPHEN A. COOK†, PATRICK W. DYMOND‡, WALTER L. RUZZO§, AND MARTIN TOMPA¶

Abstract. Following the recent independent proofs of Immerman [*SIAM J. Comput.*, 17 (1988), pp. 935-938] and Szelepcsényi [*Bull. European Assoc. Theoret. Comput. Sci.*, 33 (1987), pp. 96-100] that nondeterministic space-bounded complexity classes are closed under complementation, two further applications of the inductive counting technique are developed. First, an errorless probabilistic algorithm for the undirected graph s-t connectivity problem that runs in $O(\log n)$ space and polynomial expected time is given. Then it is shown that the class *LOGCFL* is closed under complementation. The latter is a special case of a general result that shows closure under complementation of classes defined by semi-unbounded fan-in circuits (or, equivalently, nondeterministic auxiliary pushdown automata or tree-size bounded alternating Turing machines). As one consequence, it is shown that small numbers of "role switches" in two-person pebbling can be eliminated.

Key words. complementation, inductive counting, connectivity, symmetric computation, probabilistic algorithm, random walk, *LOGCFL*, *NC*, semi-unboundedness, pebbling, hierarchy

1. Introduction.

Let *NL* denote the class of languages accepted by nondeterministic Turing machines running in $O(\log n)$ space. Let

$$STCON = \{(G, s, t) \mid G \text{ is a directed graph containing a directed path from vertex } s \text{ to vertex } t\}.$$

Using any reasonable encoding of graphs, it is well known that *STCON* is in *NL* and, moreover, is complete for *NL* with respect to deterministic log space reductions (Savitch [29]). In a surprising development, Immerman [17] and Szelepcsényi [33] have shown independently that $\overline{STCON}$, the complement of *STCON*, is also in *NL*; that is, *NL* is closed under complementation.

Their proofs rely on an inductive counting technique similar to counting techniques used in related results, for instance, Mahaney [24], Lange, Jenner, and Kirsig [22], Hemachandra [15], Toda [34], Buss, Cook, Dymond, and Hay [4], and Schöning and Wagner [30]. (For additional background and references see Hartmanis [14].) It seems inevitable that this technique should have further application and in this paper we develop two such applications.

For our first application, we consider reachability in undirected graphs, a problem

not known to be complete for *NL*. Indeed, Aleliunas et al. [2] have shown that

$$USTCON = \{(G, s, t) \mid G \text{ is an undirected graph containing a path from vertex } s \text{ to vertex } t\}$$

is in *RLP*, the class of languages accepted by probabilistic Turing machines running in $O(\log n)$ space and polynomial time. In this model, the machine never reaches an accepting state on any input not in *USTCON*, and has probability at least $\frac{1}{2}$ of reaching an accepting state on any input in *USTCON*. *USTCON* is a complete problem for *SL*, the class of languages accepted by symmetric Turing machines (Lewis and Papadimitriou [23]) running in $O(\log n)$ space. It follows that $SL \subseteq RLP \subseteq NL$.

It is tempting to believe that Immerman's and Szelepcsényi's proofs extend to show that *SL* is closed under complementation. However, a direct translation of their technique fails to establish this result, as explained in § 2.2. In that section we prove the somewhat weaker result that $\overline{USTCON}$ is in *RLP* or, equivalently, that *USTCON* is in *ZPLP*, the class of languages accepted by errorless probabilistic Turing machines running in $O(\log n)$ space and polynomial expected time. (The equivalence is due to the fact that $RLP \cap \text{co}RLP = ZPLP$.) This answers a problem raised by Aleliunas et al. [2]. In § 2.3 we extend this result to show that Reif's symmetric log space complementation hierarchy [26] is also contained in *ZPLP*.

In our second application we show the closure under complementation of a number of complexity classes that are (seemingly) more powerful than *NL*. The classes we consider may be characterized in terms of several different models. The most intuitively appealing model is perhaps the semi-unbounded fan-in circuit model (see Venkateswaran [37]). In this model, we allow OR gates with arbitrary fan-in, whereas all AND gates have bounded fan-in. Input variables and their negations are supplied, but negations are prohibited elsewhere.

For simplicity we will restrict the discussion to polynomial-size circuits, although the results can be generalized. Of particular interest is the class SAC^k of languages accepted by polynomial-size, $O(\log^k n)$ depth, uniform semi-unbounded fan-in circuits. (See Cook [7] for an appropriate definition of uniformity.) SAC^1 is the most often studied of these classes. SAC^1 is equal to the class *LOGCFL* of languages log space reducible to context-free languages [32], [37]. It is known that $NC^1 \subseteq NL \subseteq SAC^1 \subseteq AC^1$ where, as is customary, we let NC^k and AC^k denote the classes analogous to SAC^k for bounded fan-in and (respectively) unbounded fan-in uniform circuits. More generally, $NC^k \subseteq SAC^k \subseteq AC^k \subseteq NC^{k+1}$.

Both NC^k and AC^k are easily seen to be closed under complementation by application of De Morgan's laws. However, SAC^k does not yield to the same technique, since it would produce circuits with unbounded fan-in AND gates. In fact, it is known that there is a language accepted by polynomial size, constant depth, uniform semi-unbounded fan-in circuits, but whose complement is not accepted by semi-unbounded fan-in circuits of depth $o(\log n)$ and arbitrary size, even nonuniformly (Venkateswaran [36], [37]). The main result of § 3.1 is to show that polynomial-size semi-unbounded circuit classes *are* closed under complementation for all depths that are $\Omega(\log n)$. Closure under complementation of classes defined by auxiliary pushdown automata, tree-size bounded alternating Turing machines, and simple first-order formulae then follows by known equivalences (see § 3.1).

In § 3.2, we examine some consequences of the closure of semi-unbounded circuit classes under complementation. In the same way that the alternating and oracle hierarchies based on *NL* [5], [28] collapse because of Immerman's and Szelepcsényi's result, hierarchies based on semi-unbounded circuit classes also collapse. As a con-

sequence, the "role switch" resource in the pebble game introduced by Venkateswaran and Tompa [38] is shown to be much weaker than previously seemed plausible. For instance, we demonstrate that any fixed number of role switches can be eliminated.

2. Errorless algorithms related to undirected reachability.

2.1. Probabilistic complexity classes. An explanation of our taxonomy for probabilistic complexity classes is in order. Table 1 illustrates the sense in which the names *RLP* and *ZPLP* encountered in § 1 are consistent with the notation *ZPP*, *BPP*, and *PP* of Gill [12], *RP* of Welsh [40], and *BPL* and *PL* of Ruzzo, Simon, and Tompa [28].

TABLE 1
Taxonomy for probabilistic complexity classes.

Type of error	Polynomial expected time	$O(\log n)$ space	$O(\log n)$ space and polynomial expected time
Zero-sided	*ZPP*	*ZPL*	*ZPLP*
One-sided	*RP*	*RL*	*RLP*
Bounded two-sided	*BPP*	*BPL*	*BPLP*
Unbounded two-sided	*PP*	*PL*	*PLP*

Since this section concentrates on the classes *RLP* and *ZPLP*, we give them careful definitions here. We say that a language A is in *RLP* if and only if there is a probabilistic Turing machine M such that

(1) For all inputs, M runs in space $O(\log n)$ and expected time $n^{O(1)}$,

(2) If $w \in A$, $\Pr[M \text{ reaches an accepting state on input } w] \geqq \frac{1}{2}$, and

(3) If $w \notin A$, $\Pr[M \text{ reaches an accepting state on input } w] = 0$.

ZPLP is the class obtained by replacing condition 2 by 2′:

(2′) If $w \in A$, $\Pr[M \text{ reaches an accepting state on input } w] = 1$.

The class *RLP* remains unchanged if we require polynomial time rather than just polynomial expected time. Results of Gill [12], Immerman [17], and Szelepcsényi [33] show that, when the polynomial time bound is removed, the corresponding one-sided (*RL*) and zero-sided (*ZPL*) classes are equal to *NL*. Ruzzo, Simon, and Tompa [28] and Simon [31] have shown that *PL* and *BPL* are closed under complementation. Jung [20] has shown that $PL = PLP$. These relations and others (including those proved in this paper) are summarized in Fig. 1. (Those complexity classes whose complements are not explicitly shown in Fig. 1 are closed under complementation. *DL* denotes $DSPACE(\log n)$. *DET* is the set of languages reducible to computing integer matrix determinants [7]. $\bigcup_k C\sum_k^{SL}$ is the symmetric log space hierarchy, discussed in § 2.3.)

2.2. An errorless algorithm for undirected reachability. Immerman's and Szelepcsényi's proofs that $\overline{STCON} \in NL$ rely on computing

$$N_k = \#\{v \mid v \text{ is within distance } k \text{ of } s\}$$

by induction on k. As mentioned in § 1, it is tempting to believe that the same method can be used to show that *SL* is closed under complementation. Perhaps the easiest way to see the difficulty (and importance) of such a result is to observe that Immerman's and Szelepcsényi's algorithm also computes the length of a shortest path from s to t. By a known reduction (Ladner (personal communication)), *STCON* is log space reducible to the problem of determining if the length of a shortest path from s to t in an undirected graph is $n-1$. Hence a direct translation of Immerman's and Szelepcsényi's proof to *SL* would also solve this problem, thus implying $SL = RLP = NL$.

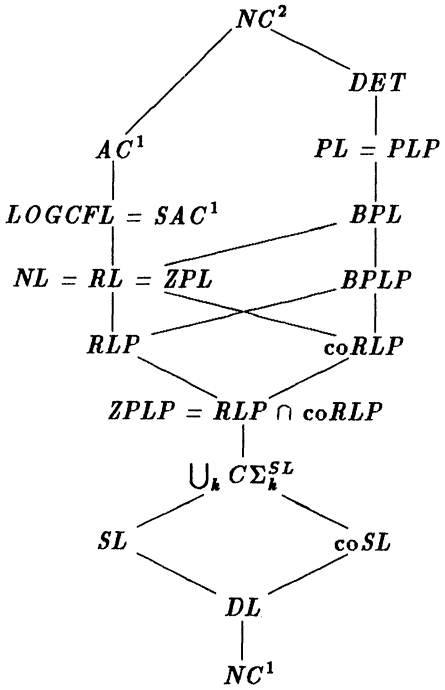

FIG. 1. *Inclusion relations among* $O(\log n)$ *space bounded complexity classes.*

The specific obstacle in applying Immerman's and Szelepcsényi's proof technique to *SL* is that a symmetric computation cannot "nondeterministically count," which seems to be the key feature in their method. (This was also noted in [16].) In particular, suppose that, for any value of *count*, there is a configuration (*R*, *count*) from which the computation can proceed nondeterministically on either of the following paths:

(1) $(R, count) \vdash^* (R', count)$.

(2) $(R, count) \vdash^* (R', count+1)$.

Since all moves in a symmetric machine are reversible, the machine can realize the computation sequence $(R, count) \vdash^* (R', count+1)\ {}^*\!\dashv (R, count+1)$. Hence the *count* can be increased (or decreased) arbitrarily.

The main result of this section is Theorem 1.

THEOREM 1. *USTCON* $\in$ *ZPLP* (*or, equivalently,* $SL \subseteq ZPLP$).

This theorem will follow immediately from Lemma 6.

In proving Theorem 1 we no longer face the handicap of symmetric computations discussed above, but we do face another difficulty: the random walk approach of Aleliunas et al. [2] does not seem to provide any useful information on the distance between vertices. To circumvent our inability to compute undirected distances with an *RLP* computation, we use the following idea, which is basic to the algorithms of Kleene [21], Floyd [9], and Warshall [39]. Let $u \to_k^* v$ denote the existence of a path between u and v that does not pass through any intermediate vertices l with $l > k$. Let

$$P_k = \{(u, v) \mid u \to_k^* v\}.$$

The *ZPLP* algorithm for *USTCON* is outlined in the remainder of this paragraph, and described fully thereafter. It proceeds similarly to Immerman's and Szelepcsényi's algorithm, by iteratively computing $\# P_k$, the cardinality of P_k. Having computed $\# P_n$,

we alternately attempt to verify that $(G, s, t) \in USTCON$ via a random walk, or that $(G, s, t) \in \overline{USTCON}$ by verifying that there are $\# P_n$ pairs $(u, v) \neq (s, t)$ that are in P_n. We compute $\# P_k$ from $\# P_{k-1}$ by determining, for each pair (u, v), whether or not it is in P_k. We note that $(u, v) \in P_k$ if and only if either $(u, v) \in P_{k-1}$, or both $(u, k) \in P_{k-1}$ and $(k, v) \in P_{k-1}$. Again, $\# P_{k-1}$ is used to insure that the algorithm never makes a mistake when claiming some (g, h) is or is not in P_{k-1}.

The following lemma is obvious.

LEMMA 2. *$(u, v) \in P_k$ if and only if u and v are in the same connected component of the subgraph $G(k, u, v)$ of G induced by vertices $\{1, 2, 3, \cdots, k, u, v\}$.*

The basis for our algorithm is the random walk technique as used in Aleliunas et al. [2]. It is modified slightly for our purposes in the following algorithm.

ALGORITHM *WALK*(k, u, v).
comment: *WALK*(k, u, v) simulates a random walk on the subgraph $G(k, u, v)$ starting at u, returns *FOUND* if v is encountered, and *NOT FOUND* otherwise;
begin
  if $u = v$ **then return** *FOUND*;
  $n \leftarrow \# V$;
  $x \leftarrow u$;
  repeat $2n^3 \log_2 (2n^2)$ **times**
    begin
      choose y randomly and uniformly from among the neighbors of x in $G(k, u, v)$;
      if $y = v$ **then return** *FOUND* **else** $x \leftarrow y$
    end;
  return *NOT FOUND*
end.

LEMMA 3. (1) *If* $(u, v) \in P_k$, $\Pr[WALK(k, u, v) = FOUND] \geqq 1 - 1/2n^2$.
(2) *If* $(u, v) \notin P_k$, $\Pr[WALK(k, u, v) = FOUND] = 0$.
(3) *WALK*(k, u, v) *uses space* $O(\log n)$.
(4) *WALK*(k, u, v) *uses expected time* $O(n^5 \log n)$ *(on a probabilistic Turing machine).*

Proof. The main result of Aleliunas et al. [2] is that the expected number of edge traversals a random walk requires to visit all vertices of a connected undirected graph, beginning at any vertex, is at most n^3. By Markov's inequality [3] and Lemma 2, the probability is at most $\frac{1}{2}$ that *WALK*(k, u, v) does not encounter v within any specified $2n^3$ iterations of the **repeat** loop, given that $(u, v) \in P_k$. The correctness assertions follow from this.

For the time complexity, we assume that G is presented as an $n \times n$ adjacency matrix. Locating the row of this matrix corresponding to x, computing the degree in $G(k, u, v)$ of x, and selecting a neighbor y can be done in $O(n^2)$ time. There is a technical detail if we assume $\{0, 1\}$ valued probabilistic choices when the degree need not be a power of 2. Suppose $2^r \leqq \text{degree}(x) < 2^{r+1}$. We then choose $r+1$ random bits to compute a random integer $i \in [0, 2^{r+1} - 1]$. If $i > \text{degree}(x)$ we discard i and try again. The expected number of random integers i that need be generated (to obtain $i \leqq \text{degree}(x)$) is at most 2. Thus *WALK*(k, u, v) uses expected time $O(n^2 n^3 \log n) = O(n^5 \log n)$. □

If $\# P_k$ is known exactly, we need an errorless probabilistic algorithm that determines whether or not (u, v) is in P_k.

ALGORITHM *PATH*(k, cpk, u, v).
comment: *PATH*$(k, \#P_k, u, v)$ returns *TRUE* iff $(u, v) \in P_k$;
repeat forever
begin
if *WALK*$(k, u, v) = FOUND$ **then return** *TRUE*;
$c \leftarrow 0$;
for all $(g, h) \neq (u, v)$ **do**
if *WALK*$(k, g, h) = FOUND$ **then** $c \leftarrow c + 1$;
if $c = cpk$ **then return** *FALSE*
end.

LEMMA 4. (1) *If PATH*$(k, \#P_k, u, v)$ *returns TRUE, then* $(u, v) \in P_k$.
(2) *If PATH*$(k, \#P_k, u, v)$ *returns FALSE, then* $(u, v) \notin P_k$.
(3) *PATH*$(k, \#P_k, u, v)$ *uses space* $O(\log n)$.
(4) *PATH*$(k, \#P_k, u, v)$ *uses expected time* $O(n^7 \log n)$.

Proof. The correctness and space complexity of *PATH* are immediate from Lemma 3. For the expected time, note that each iteration of *PATH's* **repeat** loop uses at most n^2 calls to *WALK*, that is, expected time $O(n^7 \log n)$. The probability that a given iteration of *PATH* fails to return a value is equal to the probability that an incorrect answer is given by one or more of its invocations to *WALK*, which is at most $n^2/2n^2 = \frac{1}{2}$, by Lemma 3. Hence, the expected number of iterations is at most 2. □

We now show how to extend $\#P_{k-1}$ to $\#P_k$.

ALGORITHM *COUNT*$(k, cpkm1)$.
comment: *COUNT*$(k, \#P_{k-1})$ returns the correct value for $\#P_k$;
begin
$cpk \leftarrow 0$;
for all (u, v) **do**
if *PATH*$(k-1, cpkm1, u, v)$
or (*PATH*$(k-1, cpkm1, u, k)$ **and** *PATH*$(k-1, cpkm1, k, v)$)
then $cpk \leftarrow cpk + 1$;
return *cpk*
end.

LEMMA 5. (1) *COUNT*$(k, \#P_{k-1})$ *returns* $\#P_k$.
(2) *COUNT*$(k, \#P_{k-1})$ *uses space* $O(\log n)$.
(3) *COUNT*$(k, \#P_{k-1})$ *uses expected time* $O(n^9 \log n)$.

Proof. By Lemma 4, the calls to *PATH* correctly determine whether or not $(u, v), (u, k), (k, v)$ are in P_{k-1}. Correctness follows since $(u, v) \in P_k$ if and only if $(u, v) \in P_{k-1}$ or $((u, k) \in P_{k-1}$ and $(k, v) \in P_{k-1})$. For the time complexity, there are $O(n^2)$ invocations of *PATH*, each of which runs in expected time $O(n^7 \log n)$, by Lemma 4. □

It only remains to state the main routine.

ALGORITHM *USTCON*(G, s, t).
begin
comment: Initialize $\#P_0$: $P_0 = \{(u, u)\} \cup \{(u, v) | \{u, v\} \in E\}$;
$cpk \leftarrow \#V + 2\#E$;
for k **from** 1 **to** $\#V$ **do** $cpk \leftarrow$ *COUNT*(k, cpk);
comment: *cpk* is now set to $\#P_n$;
return *PATH*$(\#V, cpk, s, t)$
end.

LEMMA 6. (1) *USTCON*(G, s, t) returns *TRUE* if and only if $(G, s, t) \in$ *USTCON*.

(2) *USTCON* uses space $O(\log n)$.

(3) *USTCON* uses expected time $O(n^{10} \log n)$.

Proof. This follows immediately from Lemmas 4 and 5. □

It is interesting to compare the running time of the errorless algorithm (Lemma 6) to that of the version with one-sided error (Lemma 3).

2.3. An errorless algorithm for symmetric space hierarchies. As previously mentioned, *USTCON* is a complete problem for *SL*, the class of languages accepted by nondeterministic $O(\log n)$ space machines whose next move relation is symmetric. Reif [26] defined an "alternating" hierarchy based on *SL* in a manner analogous to the alternating hierarchy based on *NL* defined by Chandra, Kozen, and Stockmeyer [5]. While Immerman and Szelepcsényi's result shows that the *NL*-based hierarchy collapses to *NL*, the *SL* hierarchy may be infinite. For example, "bounded degree planarity" is in the hierarchy but is not known to be in *SL* [26]. The main result of this section is Theorem 9, which extends Theorem 1 by showing that the entire *SL* hierarchy is in *ZPLP*.

For technical reasons related to the problem of nondeterministic counting discussed in § 2.2, Reif's hierarchy is defined in terms of Turing machines with complementing moves, rather than existential and universal states as is standard for alternating machines. In Reif's complementing machines, a configuration p_0 is "accepting" if and only if there is a finite computation sequence $p_0 \vdash p_1 \vdash p_2 \cdots \vdash p_j, j \geqq 0$, with no complementing moves such that either

(1) p_j is in an accepting state, or

(2) there is at least one complementing move from p_j and for all complementing moves (p_j, p'), p' is not "accepting."

In a symmetric complementing machine, all noncomplementing moves must be symmetric. The kth level of the symmetric complementation hierarchy is

$$C\Sigma_k^{SL} = \{B \mid B \text{ is accepted by an } O(\log n) \text{ space-bounded symmetric complementing machine making at most } k-1 \text{ complement moves on any computation sequence}\}.$$

The following result is an easy modification of Theorem 5 in Ruzzo, Simon, and Tompa [28]. (See that reference for a discussion of space-bounded oracle machines.)

LEMMA 7. $\bigcup_k C\Sigma_k^{SL} \subseteq DL^{SL}$.

Proof. Consider a $C\Sigma_k^{SL}$ computation. Let $E(p)$ be the set of configurations q reachable from p using only noncomplementing moves. Note that an *SL* oracle can decide if $q \in E(p)$, since all noncomplementing moves are symmetric. Let $ACC(p, k) =$ *TRUE* if and only if there is a $p_j \in E(p)$ such that either

(1) p_j is an accepting state, or

(2) $k \geqq 1$, and there is a complementing move from p_j, and $\neg ACC(p', k-1)$ for all complementing moves (p_j, p').

If p_0 is the initial configuration, then the $C\Sigma_k^{SL}$ computation accepts if and only if $ACC(p_0, k-1) =$ *TRUE*. We determine the existence of p_j by deterministically enumerating all configurations and calling the appropriate *SL* oracle. The recursive calls on *ACC* are tested by maintaining a stack of k configurations. □

Ruzzo, Simon, and Tompa [28] use the notation $A^{\langle B \rangle}$ to denote a restricted form of relativization in which the query tape is subject to the relativized machine's space

bound, but the oracle receives that machine's input together with each query. This restriction is required to ensure the space bound in the following simulation.

LEMMA 8. $ZPLP^{\langle ZPLP\rangle} = ZPLP$.

Proof. Consider a relativized *ZPLP* machine M_1 that uses an oracle A accepted by a *ZPLP* machine M_2. Let w be the input to M_1. $M_1^{\langle A\rangle}$ is simulated by a *ZPLP* machine M_3. M_3 operates as if it were M_1 until M_1 invokes the oracle with some query x. M_3 then simulates M_2 on input $w\$x$. Whenever M_2 decides its output, M_3 is able to continue its simulation of M_1. If $M_1(M_2)$ runs in expected time p_1 (respectively, p_2) then the expected time of M_3 is $O(p_1(n)p_2(n+O(\log n))) = n^{O(1)}$. □

THEOREM 9. $\bigcup_k C\Sigma_k^{SL} \subseteq ZPLP$.

Proof. By Theorem 1 and Lemmas 7 and 8,

$$\bigcup_k C\Sigma_k^{SL} \subseteq DL^{SL} \subseteq DL^{ZPLP} \subseteq ZPLP^{\langle ZPLP\rangle} = ZPLP.$$

The third inclusion follows from the fact that the deterministic oracle machine can be assumed to write short queries, namely its configuration as it is about to write a long query. (See [28, Lemma 7] for more details.) □

This improves Reif's result that $\bigcup_k C\Sigma_k^{SL} \subseteq BPLP$ (defined in § 2.1).

Reif also considered the implications of his result for probabilistic parallel models. Simulation of *DL* by $O(\log n)$ time parallel models such as concurrent-read, exclusive-write, parallel random access machines (CREW-PRAMs) [10] and hardware modification machines [8] was well known. It has been observed (see, for example, Reif [25], [26]) that these simulations extend to the simulation of *RLP* and *BPLP* by one-sided and (respectively) bounded two-sided error probabilistic parallel machines. Reif noted that, as a corollary, any language in $\bigcup_k C\Sigma_k^{SL}$ can be recognized by such a probabilistic parallel machine with bounded two-sided error in $O(\log n)$ time.

Theorem 9 improves this result also, since any language in *ZPLP* can be accepted by an errorless probabilistic hardware modification machine (and thus by an errorless probabilistic CREW-PRAM) in expected time $O(\log n)$ using polynomially many processors. The simulation of an expected time $p(n)$ *ZPLP* algorithm proceeds as follows. Simulate $2p(n)$ steps of the *ZPLP* algorithm in time at most $c \log n$ using at most $(p(n))^c$ processors (for some constant c) as in Reif [25], [26]. If the simulated algorithm has not halted within that time, restart the simulation, using independently chosen random moves. The expected number of repetitions of this procedure is at most two.

Finally, an oracle hierarchy based on *SL* could be defined in the same manner as the $O\Sigma_k^L$ hierarchy of Ruzzo, Simon, and Tompa [28]. If we are careful about the definition of a symmetric oracle machine (see [16] for one possible definition), we would expect to find that, for all oracles A, $SL^{\langle A\rangle} \subseteq ZPLP^{\langle A\rangle}$ and thus by induction that $\bigcup_k O\Sigma_k^{SL} \subseteq ZPLP$. However, we have not pursued this question.

3. Semi-unbounded circuits, LOGCFL, and pebbling.

3.1. Complementation of semi-unbounded fan-in circuits. In this section we show closure under complementation of the class of languages accepted by semi-unbounded fan-in circuits.

The class of languages recognizable by size- and depth-bounded semi-unbounded fan-in circuits has been characterized in terms of several other models. The oldest is the nondeterministic auxiliary pushdown automaton of Cook [6]. Ruzzo has related space and time on such machines to space and *tree-size* of alternating Turing machines, where tree-size is the number of nodes in the smallest accepting subtree of the computation tree [27]. Venkateswaran has related them to space and alternations on

semi-unbounded alternating Turing machines—ones where there are no two consecutive universal configurations on any path in the computation [37]. The relation to semi-unbounded fan-in circuits follows from this. Immerman has shown relations to uniform families of short first-order formulae with a fixed number of variables and Boolean universal quantifiers—a property analogus to the semi-unbounded fan-in restriction [18]. These equivalences are summarized in the propositions below. They also generalize to larger space bounds.

PROPOSITION 10 [18], [27], [37]. *For* $T(n) = \Omega(\log n)$, *the following* (*uniform*) *complexity classes are identical.*

(1) NauxPDA Space, Time $(O(\log n), 2^{O(T(n))})$.

(2) ATM Space, Tree-size $(O(\log n), 2^{O(T(n))})$.

(3) Semi-Unbounded ATM Space, Alternations $(O(\log n), O(T(n)))$.

(4) Uniform Semi-Unbounded Fan-in Circuit Size, Depth $(2^{O(\log n)}, O(T(n)))$.

(5) Uniform Var&Sz $(B\forall)[O(1), O(T(n))]$.

PROPOSITION 11. *The equivalences in Proposition* 10 *also hold among the nonuniform versions of the models.*

In all these models, closure under complementation seems surprising. In nondeterministic auxiliary pushdown automata we face the usual problems of nondeterminism, in addition to the difficulties introduced by large stacks, and perhaps by super-polynomial running times. Although alternating Turing machine space and/or time classes are easily seen to be closed under complementation, the same proof (basically De Morgan's laws) converts a computation of small tree-size into one of large tree-size. Similar issues thwart the De Morgan approach to complementing circuits with bounded fan-in AND gates and formulate with Boolean universal variables—they become bounded fan-in OR gates and Boolean existentials instead. Nevertheless, closure under complementation follows for all these models from the theorem below.

THEOREM 12. *There is a constant* $\bar{c}$ *such that, for any n-input semi-unbounded fan-in circuit* α_n *of size* (*number of gates plus inputs*) Z *and depth* D, *there is a semi-unbounded fan-in circuit* $\overline{\alpha_n}$ *of size at most* $\bar{c}DZ^2 \log Z$ *and depth at most* $\bar{c}(D + \log Z)$ *that computes the complement of the function computed by* α_n. *The same result holds uniformly for uniform families of circuits* $\{\alpha_n\}$.

Proof. The key idea in the proof is again the use of inductive counting to verify "negative" information. In this case we are interested in counting the number of gates at a given depth that evaluate to 1.

Suppose we are given a circuit α_n of size Z and depth D. It is convenient to first convert it to a circuit β_n of size $2DZ + 2n$ and depth $2D$ that is:

(1) Synchronous—i.e., vertices can be assigned to levels so that input variables and their negations are on level 0, any gate on level i receives all its inputs from vertices on level $i-1$, and all output gates are on level $2D$;

(2) Fixed width—i.e., each level $i \geqq 1$ contains exactly Z gates;

(3) Strictly alternating—i.e., for all $i \geqq 0$, all gates on level $2i+1$ are OR gates and all gates on level $2i+2$ are AND gates; and

(4) Equivalent—i.e., it computes the same function as α_n.

This normal form is easily achieved. For example, for each level of β_n except the 0th, make a replica of each vertex of α_n. The replica on level i of an input vertex g is a trivial gate (of the appropriate type) whose only input is the replica of g on level $i-1$. Similarly, the replica of an AND gate g on an OR level i is a trivial OR gate whose only input is the replica of g on level $i-1$. A replica of an AND gate g on an AND level i has as inputs the replicas on level $i-1$ of g's inputs. OR gates are handled similarly, but with nontrivial replicas only on OR levels. Level 0 contains only the $2n$

vertices representing the input literals. Level 1 replicas of gates whose inputs are not all input literals are arbitrarily connected to literals. We can show by induction that all vertices of depth at most i in α_n will be correctly computed by their replicas on levels greater than or equal to $2i$ in β_n.

The "counting" we need in the construction is easily accomplished by threshold functions. Thus, rather than producing the circuit advertised by the theorem directly, it is easier to first produce a circuit γ_n containing THRESHOLD gates. (A c-THRESHOLD gates has unbounded fan-in, and outputs 1 if and only if at least c of its inputs have value 1.) This circuit will have the following properties:

(1) It has bounded fan-in AND gates and unbounded fan-in OR gates, i.e., it has semi-unbounded fan-in.

(2) It contains arbitrary THRESHOLD gates.

(3) No path from output to input contains more than two THRESHOLD gates.

(4) It has size $4D(Z+1)^2+2DZ+2n-1=O(DZ^2)$.

(5) It has depth at most $2D+3$.

(6) It computes the complement of the function computed by β_n.

The theorem will then follow by replacing the THRESHOLD gates by monotone SAC^1 threshold circuits. (Monotonicity is needed to preserve the semi-unbounded fan-in property. By property (3) above, the depth of the threshold subcircuits will increase the overall depth only additively.)

For $0 \leqq k \leqq D$, let

$$P_k = \{g \mid g \text{ is a vertex of } \beta_n \text{ on level } 2k \text{ having value } 1\}.$$

The main quantities we will be interested in counting are $\# P_k$, the cardinalities of the sets P_k.

Our main construction, of γ_n from β_n, follows. It is sketched in Fig. 2.

Construction Step 1. The entire circuit β_n is a subcircuit of γ_n. The gates in this subcircuit will be referred to as "original" gates. (Note that this means original to β_n, not to α_n.)

Construction Step 2. For $1 \leqq k \leqq D$, each original gate g on level $2k-1$ or $2k$, and each $0 \leqq c \leqq Z$, there is a "contingent complement" gate $\text{CC}(g \mid c)$ whose value will be the complement of the value of g *if* $c = \# P_{k-1}$; if $c \neq \# P_{k-1}$, then the value of $\text{CC}(g \mid c)$ is irrelevant. We compute $\text{CC}(g \mid c)$ as follows:

(1) If g is an AND gate, say $\text{AND}(a, b)$, then $\text{CC}(g \mid c)$ is the OR of $\text{CC}(a \mid c)$ and $\text{C}(b \mid c)$. (Fan-in greater than two is handled similarly.)

(2) If g is an OR gate (on level $2k-1$), then $\text{CC}(g \mid c)$ is a c-THRESHOLD gate whose inputs are all original gates on level $2k-2$ that are *not* inputs to g.

We now argue the correctness of this part of the construction.

LEMMA 13. *For* $k \geqq 1$, *and all original gates* g *on level* $2k-1$ *or* $2k$,

$$\text{CC}(g \mid \# P_{k-1}) \equiv \neg g.$$

Proof.

Case 1. g is an OR gate on level $2k-1$, $k \geqq 1$. Then g evaluates to 0 if and only if all g's inputs evaluate to 0, if and only if all $\# P_{k-1}$ original gates on level $2(k-1)$ that evaluate to 1 are *not* inputs to g, if and only if the THRESHOLD gate $\text{CC}(g \mid \# P_{k-1})$ evaluates to 1.

Case 2. g is an AND gate on level $2k$, $k \geqq 1$. Its inputs a and b are OR gates on level $2k-1$. From Case 1 we know that $\text{CC}(a \mid \# P_{k-1}) \equiv \neg a$ and $\text{C}(b \mid \# P_{k-1}) \equiv \neg b$, so

$$\neg g \equiv \neg(a \wedge b) \equiv \neg a \vee \neg b \equiv \text{CC}(a \mid \# P_{k-1}) \vee \text{CC}(b \mid \# P_{k-1}) \equiv \text{CC}(g \mid \# P_{k-1}).$$

The proof for fan-in greater than two is analogous. □

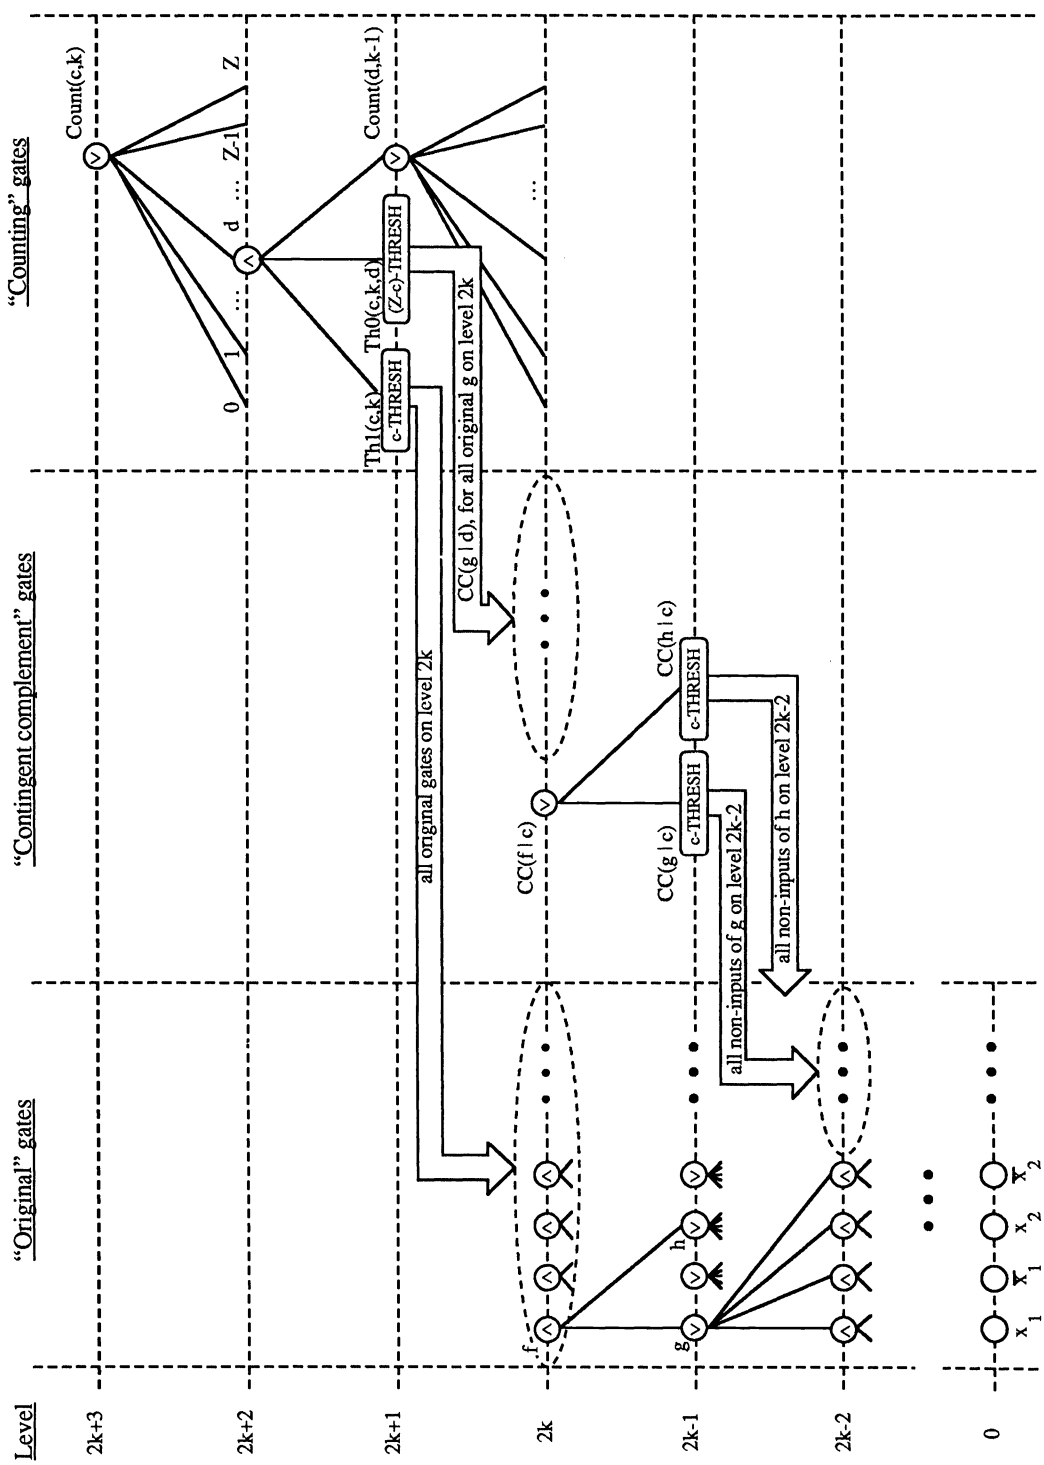

FIG. 2. *Construction of* γ_n.

Construction Step 3. Continuing the construction, there is a "counting" gate COUNT(c, k), for all $0 \leqq c \leqq Z$ and $0 \leqq k \leqq D-1$, whose value will be 1 if and only if $\# P_k = c$. This is computed as follows:

$$\text{COUNT}(c,k) = \begin{cases} 1 \Leftrightarrow (c = n) & \text{if } k = 0, \\ \bigvee_{d=0}^{Z} \text{AND}(\text{COUNT}(d, k-1), \text{TH1}(c,k), \text{TH0}(c,k,d)) & \text{if } k \geqq 1, \end{cases}$$

where

TH1(c, k) is the c-THRESHOLD of all original gates on level $2k$, and
TH0(c, k, d) is the $(Z-c)$-THRESHOLD of the contingent complement gates CC$(g \mid d)$, where g ranges over all original gates on level $2k$.

LEMMA 14. COUNT$(c, k) = 1$ *if and only if* $\# P_k = c$.

Proof. The proof proceeds by induction on k.

Basis $(k = 0)$. There are exactly $2n$ vertices on level 0, namely the n inputs and their complements. Exactly n of them evaluate to 1.

Induction $(k > 0)$. By induction, COUNT$(d, k-1)$ evaluates to 1 for exactly one value of d, namely $d = \# P_{k-1}$. Thus the only term in the disjunction $\bigvee_{d=0}^{Z} \cdots$ that could possibly evaluate to 1 is $d = \# P_{k-1}$. For this term, each contingent complement gate CC$(g \mid d)$ counted by TH0(c, k, d) computes $\neg g$ by Lemma 13. Thus, TH1$(c, k) \wedge$ TH0(c, k, d) evaluates to 1 if and only if, on level $2k$, there are at least c original gates with value 1 and at least $(Z-c)$ original gates with value 0, and hence exactly c with value 1. Thus, COUNT(c, k) evaluates to 1 if and only if $c = \# P_k$. □

Construction Step 4. We complete the construction by defining the outputs of γ_n. For all original gates g that are outputs of β_n (hence on level $2D$), γ_n contains a gate COMP(g) that evaluates to 1 if and only if g evaluates to 0. COMP(g) is computed as follows:

$$\text{COMP}(g) = \bigvee_{c=0}^{Z} \text{AND}(\text{COUNT}(c, D-1), \text{CC}(g \mid c)).$$

Correctness is easily shown. By Lemma 14, COUNT$(c, D-1)$ evaluates to 1 if and only if $\# P_{D-1} = c$, and by Lemma 13, CC$(g \mid \# P_{D-1}) \equiv (\neg g)$. Hence COMP$(g) \equiv (\neg g)$.

Thus γ_n correctly computes the complement of the function computed by α_n.

Analysis. Next we will analyze the size and depth of γ_n.

Define the THRESHOLD-*depth* of a gate g of γ_n to be the maximum number of THRESHOLD gates, including g, along any path from g to an input vertex.

For each original gate g on level k, g is also at depth k in γ_n, and has THRESHOLD-depth 0. For all $0 \leqq c \leqq Z$, gate CC$(g \mid c)$ also has depth k, and THRESHOLD-depth 1, since the THRESHOLD gates among CC$(g \mid c)$ depend *only* on original gates, not on other contingent complement gates.

The gates TH1(c, k) have depth $2k+1$ and THRESHOLD-depth 1. The gates TH0(c, k, d) have depth $2k+1$ and THRESHOLD-depth 2.

The gates COUNT(c, k) have THRESHOLD-depth 2 and depth d_k, where

$$d_k = \begin{cases} 0 & \text{if } k = 0, \\ 2 + \max(d_{k-1}, 2k+1) & \text{if } k \geqq 1. \end{cases}$$

Thus $d_k \leqq 2k+3$.

Finally, the output gates COMP(g) have THRESHOLD-depth 2 and depth $2+\max(d_{D-1}, 2D) \leqq 2D+3$.

The size of the circuit is easily seen to be polynomial in Z and D. The dominant contributions are from the contingent complement subcircuits, which contain $O(DZ^2)$ OR and THRESHOLD gates, and from the COUNT subcircuits, which contain $O(DZ^2)$ AND and THRESHOLD gates. A careful analysis gives the exact bound of $4D(Z+1)^2+2DZ+2n-1$ claimed above.

To complete the proof of Theorem 12, we need to replace the THRESHOLD gates in γ_n by monotone SAC^1 threshold circuits, and analyze the size and depth of the resulting Boolean circuit $\overline{\alpha_n}$.

The existence of monotone SAC^1 threshold circuits is easily established. A simple divide-and-conquer technique gives n input monotone SAC^1 circuits of size $O(n^2)$ and depth at most $2\lceil \log_2 n \rceil$: the k-THRESHOLD of n bits can be computed as the OR over $0 \leqq j \leqq k$ of the AND of the j-THRESHOLD of the first half of the bits and the $(k-j)$-THRESHOLD of the last half of the bits:

$$k\text{-THRESHOLD}(x_1, \cdots, x_n)$$

$$= \bigvee_{j=0}^{k} \text{AND}(j\text{-THRESHOLD}(x_1, \cdots, x_{\lfloor n/2 \rfloor}),$$

$$(k-j)\text{-THRESHOLD}(x_{\lfloor n/2 \rfloor+1}, \cdots, x_{2n})).$$

Asymptotically, the smallest known monotone SAC^1 threshold circuits are actually NC^1 circuits: the $O(n \log n)$ size "AKS" sorting networks of Ajtai, Komlós, and Szemerédi [1]. Replacing each THRESHOLD gate in γ_n by one of these subcircuits, and noting that each THRESHOLD gate has at most Z inputs, would give an overall size for the Boolean circuit $\overline{\alpha_n}$ of $O(DZ^3 \log Z)$.

One observation reduces this substantially. Namely, a *single* n-input AKS network computes the c-threshold of its inputs for *all* $1 \leqq c \leqq n$. Thus, although an OR gate g gives rise to Z THRESHOLD gates CC$(g \mid c)$, $1 \leqq c \leqq Z$, all of these values can be computed by one AKS network. Similar combination is possible among the TH0$(c, -, -)$ and TH1$(c, -)$ gates, $1 \leqq c \leqq Z$. This reduces the size of $\overline{\alpha_n}$ to $O(DZ^2 \log Z)$, as claimed.

The depth of $\overline{\alpha_n}$ is the depth of γ_n plus twice the depth of the AKS network (since γ_n has THRESHOLD-depth 2), which is $O(D+\log Z)$, as claimed.

For the uniform case of the theorem, we observe that the transformation from α_n to $\overline{\alpha_n}$ is quite simple and regular. We leave it to the reader to verify that this transformation preserves uniformity. (The AKS networks are known to be uniform.) □

COROLLARY 15. *For all $k \geqq 1$, SAC^k and nonuniform SAC^k are closed under complementation.*

Cook [7] defined *CFL** as the set of functions each computable by a uniform family $\{\alpha_n\}$ of circuits, where α_n has n inputs, bounded fan-in AND, OR, and NOT gates, unbounded fan-in oracle gates for some context-free language, and $O(\log n)$ depth. An oracle gate with fan-in f is defined to contribute $\lceil \log_2 f \rceil$ to the depth of any path containing it.

COROLLARY 16. *Any function in CFL* can be computed by a uniform family of polynomial size, $O(\log n)$ depth, semi-unbounded fan-in circuits.*

Proof. Let α_n be a *CFL** circuit with oracle gates for some context-free language L. With a doubling of size and no increase in depth, α_n can be simulated by a *CFL**

circuit β_n whose NOT gates appear only at the inputs, provided β_n is allowed oracle gates for both L and $\bar{L}$. (See, for example, [13].) The result now follows from the fact that LOGCFL $= SAC^1$ [37], together with Corollary 15. □

Similarly, it is true that any 0-1 valued function in NL^* (see Cook [7]) is also in NL. This follows from Immerman's [17] and Szelepcsényi's theorems [33], and was noted independently by S. Buss (personal communication).

3.2. The weakness of role switches in pebbling. There are a number of ways in which we might define a "*LOGCFL* hierarchy." One consequence of Corollary 15 is that, for many reasonable ways of doing so, the resulting hierarchy collapses to *LOGCFL*. In this section we consider one such hierarchy that collapses. As a consequence, the "role switch" resource [38] in pebbling is shown to be much weaker than previously seemed plausible.

(In contrast, following a preliminary version of the present paper, Jenner and Kirsig [19] considered an alternative formulation of a hierarchy based on *LOGCFL*, showing that it coincides with the polynomial hierarchy and hence presumably does *not* collapse.)

We begin by presenting the hierarchy. Define a (z, d, k, f)-*circuit* as an unbounded fan-in circuit of size z and depth d, where negations appear only at the inputs, and the vertices can be partitioned into k "layers" that alternately have AND fan-in at most f and OR fan-in at most f. More precisely, the vertices can be partitioned into blocks $B_k, B_{k-1}, \cdots, B_1$ (B_1 containing the outputs) such that:

(1) Any wire (u, v) with $u \in B_i$ and $v \in B_j$ satisfies $i \geqq j$;

(2) All AND gates of odd-numbered blocks have fan-in at most f; and

(3) All OR gates of even-numbered blocks have fan-in at most f.

For any fixed k, let

$$\Sigma_k^{CFL} = \{L \mid L \text{ can be recognized by a (nonuniform) family of } (n^{O(1)}, O(\log n), k, O(1))\text{-circuits}\}.$$

For instance, Σ_1^{CFL} is nonuniform SAC^1. Corollary 18 demonstrates that this hierarchy collapses.

THEOREM 17. *Let $\{\alpha_n\}$ be a family of $(z, d, k, O(1))$-circuits, where z, d, and k may be functions of n. Then there is a family $\{\beta_n\}$ of $(O(dz^2 \log z), O(d + k \log z), 1, O(1))$-circuits such that β_n computes both the outputs of α_n and their negations.*

Proof. This is proved by induction on k, using Theorem 12 and De Morgan's laws in a straightforward way. □

COROLLARY 18. *For any fixed $k \geqq 1$, $\Sigma_k^{CFL} = \Sigma_1^{CFL}$.*

Proof. This follows from Theorem 17 by substituting $z = n^{O(1)}$ and $d = O(\log n)$. □

To see how much more general Theorem 17 is than Corollary 18, consider the case $z = n^{O(1)}$ and $d = O(\log^i n)$, for any $i \geqq 1$, which might be called the "SAC^i hierarchy." Not only does $k = \Theta(1)$ fail to add power to nonuniform SAC^i, but $k = \Theta(\log^{i-1} n)$ does as well.

The purpose of this section is to apply this result to a pebble game introduced by Venkateswaran and Tompa [38]. They defined a new resource called "role switches." It will follow from Theorems 19 and 20 that Σ_k^{CFL} is the set of languages recognized by polynomial-size circuits pebbleable with $O(1)$ pebbles, $O(\log n)$ rounds, and $k-1$ role switches. Hence, by Corollary 18, any such circuit can be simulated by one pebbleable with $O(1)$ pebbles, $O(\log n)$ rounds, and zero role switches. Similarly, any

polynomial-size circuit pebbleable with $O(1)$ pebbles, $O(\log^i n)$ rounds, and $O(\log^{i-1} n)$ role switches can be simulated by one pebbleable with $O(1)$ pebbles, $O(\log^i n)$ rounds, and zero role switches.

The pebble game introduced by Venkateswaran and Tompa is referred to as the *dual interpreted two-person pebble game.* This game is played by two players, called Player 0 and Player 1, on a circuit α_n together with values for its n inputs and their negations (referred to collectively as *literals*). There are two minor differences between Venkateswaran and Tompa's game and the one used in this section: for convenience, we assume that α_n is *nonuniform* and has *unbounded* fan-in. The latter condition does not affect the resources considered, provided the depth of α_n is $\Omega(\log n)$.

At any point, one of the players takes on the role of the Challenger and the other that of the Pebbler. The Challenger is responsible for selecting the "currently challenged vertex"; the Pebbler has a collection of pebbles that it can place on or remove from the vertices of α_n. The role of a player is automatically determined as part of the circuit information as follows. The vertices in α_n are partitioned into two sets, those of "challenge type" 0 and those of "challenge type" 1. If the currently challenged vertex is of challenge type 0 (challenge type 1), then Player 0 (Player 1) is the Challenger in the next round. A Boolean circuit augmented with this role information for each of its vertices will be referred to as an *augmented* circuit. For convenience, it is assumed that the output vertex has challenge type 0.

The objective of Player 0 (Player 1) is to establish that the output of the circuit evaluates to 0 (1). A pebble placement or challenge on a vertex v by Player 0 (Player 1) corresponds to asserting that v evaluates to 0 (1). A pebble placed by Player 0 (Player 1) will be referred to as a 0-pebble (1-pebble).
